Malanowski [18]. For the important but more difficult case of pointwise state constraints in the control of ordinary differential equations, we refer to Malanowski [19] and to the references therein.

At present, the control of distributed parameter systems with pointwise state constraints is a very active field of research. Although the majority of papers are still devoted to convex problems with linear equations, the important case of nonlinear state equations is attracting more interest. Here, second-order conditions are needed. However, when pointwise state constraints are imposed, the situation is more complicated, since the Lagrange multipliers associated with them are measures. In contrast to the theory for ordinary differential equations, this causes severe restrictions on the dimension of the spatial domains of the equations and reduces the regularity of the adjoint state.

To our best knowledge, there exist only two contributions to the theory of second-order sufficient conditions for distributed problems with pointwise state constraints. The elliptic case was discussed in [12], while parabolic problems were investigated in [22]. The method of these papers was inspired by the splitting technique used in [11]. When applied to pointwise state constraints, the cones of critical directions established by this technique are too large so that the second-order sufficient conditions are based on slightly too strong assumptions. Moreover, the method was fairly complicated.

For other contributions to second-order optimality conditions for distributed parameter systems, we mention, for instance, the work by Bonnans [3] and the exposition in the monography by Bonnans and Shapiro [4] on elliptic problems with control constraints. We also refer to [9], where second-order necessary optimality conditions were first treated for elliptic problems, [10] for an abstract framework with applications to elliptic and parabolic problems, and [7], where elliptic problems with control constraints and state constraints of integral type were considered Moreover, we refer to the references therein.

In this paper, the sufficiency of second-order conditions is proven by a method that is close to the theory of nonlinear optimization in finite-dimensional spaces. We establish a cone of critical directions that is sharp; i.e., it is the one closest to the cone for establishing second-order necessary conditions.

We present a detailed proof for the case of distributed elliptic problems in domains of spatial dimension $n \leq 3$. Moreover, we briefly sketch the extension of this result to elliptic boundary control problems for $n \leq 2$ and to the parabolic distributed case for $n = 1$.

2. Problem statement. Let Ω be an open and bounded domain in $\mathbb{R}^n$, $n \leq 3$, with a Lipschitz boundary Γ. In this domain we consider the following state equation:

$$\begin{cases} Ay + f(x,y) = u & \text{in } \Omega, \\ y = 0 & \text{on } \Gamma, \end{cases} \tag{2.1}$$

where $f : \Omega \times \mathbb{R} \longrightarrow \mathbb{R}$ is a Carathéodory function and A denotes a second-order elliptic operator of the form

$$Ay(x) = -\sum_{i,j=1}^{n} \partial_{x_j}(a_{ij}(x)\partial_{x_i} y(x));$$

the coefficients $a_{ij} \in L^\infty(\Omega)$ satisfy

$$\lambda_A \|\xi\|^2 \leq \sum_{i,j=1}^{n} a_{ij}(x)\xi_i\xi_j \quad \forall \xi \in \mathbb{R}^n \text{ for a.e. } x \in \Omega$$

for some $\lambda_A > 0$. In (2.1), the function u denotes the control, and y_u is the solution associated to the control u. We will state later the conditions leading to the existence and uniqueness of a solution of (2.1) in $C(\bar\Omega) \cap H^1(\Omega)$.

In this paper, we study the following optimal control problem:

$$(\mathrm{P}) \begin{cases} \min J(u) = \displaystyle\int_\Omega L(x, y_u(x), u(x))\, dx \\ \text{subject to } \ (y_u, u) \in (C(\bar\Omega) \cap H^1(\Omega)) \times L^\infty(\Omega), \\ \alpha(x) \le u(x) \le \beta(x) \quad \text{for a.e. } \ x \in \Omega, \\ g(x, y_u(x)) \le 0 \ \ \forall x \in K, \end{cases}$$

where $\alpha(x) < \beta(x)$ for almost all $x \in \Omega$, $\alpha, \beta \in L^\infty(\Omega)$, and $K \subset \bar\Omega$ is a compact set. Let us state the assumptions on the functions L, f, and g.

(A1) f is of class C^2 with respect to the second variable:

$$f(\cdot, 0) \in L^2(\Omega), \qquad \frac{\partial f}{\partial y}(x, y) \ge 0 \quad \text{for a.e. } x \in \Omega,$$

and for all $M > 0$ there exists a constant $C_{f,M} > 0$ such that

$$\left|\frac{\partial f}{\partial y}(x, y)\right| + \left|\frac{\partial^2 f}{\partial y^2}(x, y)\right| \le C_{f,M} \text{ for a.e. } x \in \Omega \text{ and } |y| \le M,$$

$$\left|\frac{\partial^2 f}{\partial y^2}(x, y_2) - \frac{\partial^2 f}{\partial y^2}(x, y_1)\right| \le C_{f,M}|y_2 - y_1| \ \text{ for } |y_1|, |y_2| \le M \text{ and for a.e. } x \in \Omega.$$

(A2) $L : \Omega \times (\mathbb{R} \times \mathbb{R}) \longrightarrow \mathbb{R}$ is a Carathéodory function of class C^2 with respect to the second and third variables, $L(\cdot, 0, 0) \in L^1(\Omega)$, and for all $M > 0$ there is a constant $C_{L,M} > 0$ and a function $\psi_M \in L^2(\Omega)$ such that

$$\left|\frac{\partial L}{\partial u}(x, y, u)\right| + \left|\frac{\partial L}{\partial y}(x, y, u)\right| \le \psi_M(x), \quad \|D^2_{(y,u)} L(x, y, u)\| \le C_{L,M},$$

$$\|D^2_{(y,u)} L(x, y_2, u_2) - D^2_{(y,u)} L(x, y_1, u_1)\| \le C_{L,M}(|y_2 - y_1| + |u_2 - u_1|)$$

for a.e. $x \in \Omega$ and $|y|, |y_i|, |u|, |u_i| \le M$, $i = 1, 2$, where $D^2_{(y,u)} L$ denotes the second derivative of L with respect to (y, u).

(A3) The function $g : K \times \mathbb{R} \longrightarrow \mathbb{R}$ is continuous, of class C^2 with respect to the second variable and $\partial_y g$, and $\partial^2_y g$ are also continuous functions in $K \times \mathbb{R}$. Moreover we will assume that $g(x, 0) < 0$ is satisfied for every $x \in K \cap \Gamma$.

The following result on the existence of a solution holds true for (2.1) as well as for the problem (P).

THEOREM 2.1. *Suppose that* (A1) *holds. Then, for every $u \in L^2(\Omega)$, the state equation* (2.1) *has a unique solution $y_u \in C(\bar\Omega) \cap H^1_0(\Omega)$. Furthermore, if $u_k \rightharpoonup u$ weakly in $L^2(\Omega)$, then $y_{u_k} \to y_u$ strongly in $C(\bar\Omega) \cap H^1_0(\Omega)$.*

The existence of a unique solution of (2.1) in $H^1(\Omega) \cap L^\infty(\Omega)$ is classical. It is a consequence of the monotonicity of f with respect to the second component. The continuity of y_u is also a well-known result; see, for instance, [15]. The continuity property is a consequence of the compactness of the inclusion $L^2(\Omega) \subset W^{-1,p}(\Omega)$ for any $p < 6$ and the fact that data $u \in W^{-1,p}(\Omega)$, with $6/5 < p < 6$, provide solutions in $C(\bar\Omega) \cap H^1_0(\Omega)$, the mapping $u \to y_u$ being continuous between these spaces.

THEOREM 2.2. *Let the function L be convex with respect to the third component and the set of feasible controls be nonempty. Then, under assumptions* (A1)–(A3)*, the control problem* (P) *has at least one solution.*

The proof of this theorem can be obtained by standard arguments.

Remark 2.3. We should remark that the differentiability of the functions f, L, and g is not necessary to prove the previous theorems. In fact, the only properties we need are the continuity of g and f with respect to the second variable, the continuity of L with respect to the second and third variables, the monotonicity of f with respect to y, the convexity of L with respect to u, and, for every $M > 0$, the existence of two functions $\phi_{f,M} \in L^2(\Omega)$ and $\phi_{L,M} \in L^1(\Omega)$ such that

$$|f(x,y)| \le \phi_{f,M}(x) \quad \text{and} \quad |L(x,y,u)| \le \phi_{L,M}(x) \text{ for a.e. } x \in \Omega \text{ and } |y|, |u| \le M.$$

These properties are an immediate consequence of the assumptions (A1)–(A3).

We finish this section by recalling some results about the differentiability of the nonlinear mappings involved in the control problem. For the detailed proofs, the reader is referred to Casas and Mateos [7].

THEOREM 2.4. *If* (A1) *holds, then the mapping $G : L^2(\Omega) \longrightarrow C(\bar{\Omega}) \cap H_0^1(\Omega)$, defined by $G(u) = y_u$, is of class C^2. Moreover, for all $v, u \in L^2(\Omega)$, $z_v = G'(u)v$ is defined as the solution of*

$$\begin{cases} Az_v + \dfrac{\partial f}{\partial y}(x, y_u) z_v = v \ \text{ in } \Omega, \\ z_v = 0 \ \text{ on } \Gamma. \end{cases} \tag{2.2}$$

Finally, for every $v_1, v_2 \in L^2(\Omega)$, $z_{v_1 v_2} = G''(u)v_1 v_2$ is the solution of

$$\begin{cases} Az_{v_1v_2} + \dfrac{\partial f}{\partial y}(x, y_u) z_{v_1v_2} + \dfrac{\partial^2 f}{\partial y^2}(x, y_u) z_{v_1} z_{v_2} = 0 \text{ in } \Omega, \\ z_{v_1v_2} = 0 \text{ on } \Gamma, \end{cases} \tag{2.3}$$

where $z_{v_i} = G'(u)v_i$, $i = 1, 2$.

Remark 2.5. This theorem shows why we assume $n \le 3$: To prove Theorem 4.1 on second-order sufficient conditions, we need the operator G to be differentiable from $L^2(\Omega)$ to $C(\bar{\Omega})$. This result holds true only for $n \le 3$.

The proof can be obtained by the implicit function theorem; see, for instance, [7, Thm. 2.5] for the proof in the case of a Neumann problem, which can be translated straightforwardly to the Dirichlet case.

THEOREM 2.6. *Suppose that* (A1) *and* (A2) *hold. Then $J : L^\infty(\Omega) \to \mathbb{R}$ is a functional of class C^2. Moreover, for every $u, v, v_1, v_2 \in L^\infty(\Omega)$,*

$$J'(u)v = \int_\Omega \left(\frac{\partial L}{\partial u}(x, y_u, u) + \varphi_{0u} \right) v \, dx \tag{2.4}$$

and

$$\begin{aligned} J''(u)v_1v_2 = \int_\Omega \Bigg[& \frac{\partial^2 L}{\partial y^2}(x, y_u, u) z_{v_1} z_{v_2} + \frac{\partial^2 L}{\partial y \partial u}(x, y_u, u)(z_{v_1} v_2 + z_{v_2} v_1) \\ & + \frac{\partial^2 L}{\partial u^2}(x, y_u, u) v_1 v_2 - \varphi_{0u} \frac{\partial^2 f}{\partial y^2}(x, y_u) z_{v_1} z_{v_2} \Bigg] \, dx, \end{aligned} \tag{2.5}$$

where $y_u = G(u)$ *and* $\varphi_{0u} \in W^{2,p}(\Omega)$ *is the unique solution of the problem*

$$\begin{cases} A^*\varphi + \dfrac{\partial f}{\partial y}(x, y_u)\varphi = \dfrac{\partial L}{\partial y}(x, y_u, u) \quad \text{in } \Omega, \\ \varphi = 0 \quad \text{on } \Gamma, \end{cases} \tag{2.6}$$

A^* *being the adjoint operator of* A *and* $z_{v_i} = G'(u)v_i$, $i = 1, 2$.

Let us remark that the linear and quadratic functionals $J'(u)$ and $J''(u)$ can be extended from $L^\infty(\Omega)$ to $L^2(\Omega)$ by the formulas (2.4) and (2.5). To check this point it is enough to use the assumptions (A1) and (A2). This extension will be used in the rest of the paper.

The previous theorem and the next one follow easily from Theorem 2.4 and the chain rule.

THEOREM 2.7. *Suppose that* (A1) *and* (A3) *hold. Then the mapping* $F : L^2(\Omega) \to C(K)$, *defined by* $F(u) = g(\cdot, y_u(\cdot))$, *is of class* C^2. *Moreover, for every* $u, v, v_1, v_2 \in L^2(\Omega)$,

$$F'(u)v = \frac{\partial g}{\partial y}(\cdot, y_u(\cdot))z_v(\cdot) \tag{2.7}$$

and

$$F''(u)v_1v_2 = \frac{\partial^2 g}{\partial y^2}(\cdot, y_u(\cdot))z_{v_1}(\cdot)z_{v_2}(\cdot) + \frac{\partial g}{\partial y}(\cdot, y_u(\cdot))z_{v_1v_2}(\cdot), \tag{2.8}$$

where $z_{v_i} = G'(u)v_i$, $i = 1, 2$, *and* $z_{v_1v_2} = G''(u)v_1v_2$.

Remark 2.8. A functional L that is very frequently appearing in the applications is given by

$$L(x, y, u) = L_0(x, y) + \frac{N}{2}u^2.$$

In this case, the functional J is twice differentiable not only in $L^\infty(\Omega)$ but also in $L^2(\Omega)$. Indeed, $J : L^2(\Omega) \longrightarrow \mathbb{R}$ is of class C^2, and the derivatives are given by the expressions

$$J'(u)v = \int_\Omega (Nu(x) + \varphi_{0u})\, v\, dx \tag{2.9}$$

and

$$J''(u)v_1v_2 = \int_\Omega \left[\frac{\partial^2 L_0}{\partial y^2}(x, y_u)z_{v_1}z_{v_2} + Nv_1v_2 - \varphi_{0u}\frac{\partial^2 f}{\partial y^2}(x, y_u)z_{v_1}z_{v_2} \right] dx. \tag{2.10}$$

Remark 2.9. The adjoint state φ_{0u} allows us to get a simple expression of $J'(u)$, but it is not the complete adjoint state of the control problem because the adjoint state equation (2.6) does not include the Lagrange multiplier associated to the state constraint; see (3.2) below for the full definition.

3. First-order optimality conditions. We define the Hamiltonian associated with problem (P), $H^\lambda : \Omega \times \mathbb{R}^3 \longrightarrow \mathbb{R}$, by

$$H^\lambda(x, y, u, \varphi) = \lambda \cdot L(x, y, u) + \varphi\,[u - f(x, y)].$$

We denote by $M(K)$ the Banach space of all real and regular Borel measures in K, which is identified with the dual space of $C(K)$.

In the rest of the paper, a local minimum of (P) is assumed to be a local solution in the sense of the topology of $L^\infty(\Omega)$. More precisely, we will say that $\bar u$ is a local minimum or a local solution of (P) in the sense of $L^q(\Omega)$, $1 \le q \le \infty$, if it is an admissible control of (P) and there exists $\varepsilon_{\bar u} > 0$ such that the minimum of J in the admissible set of (P) intersected with the ball $\bar B_{\varepsilon_{\bar u}}(\bar u) \subset L^q(\Omega)$ is achieved at $\bar u$.

The following result concerning Pontryagin's principle for problem (P) is well known; look into [8] and [17] as well as in the references therein for the proof.

THEOREM 3.1. *Let $\bar u$ be a local solution of* (P)*, and suppose that the assumptions* (A1)–(A3) *hold. Then there exist a real number $\bar\lambda \ge 0$, a measure $\bar\mu \in M(K)$, and a function $\bar\varphi \in W_0^{1,s}(\Omega)$, for all $1 \le s < n/(n-1)$, such that*

$$\bar\lambda + \|\bar\mu\| > 0 \tag{3.1}$$

$$\begin{cases} A^*\bar\varphi + \dfrac{\partial f}{\partial y}(x,\bar y(x))\bar\varphi = \bar\lambda\, \dfrac{\partial L}{\partial y}(x,\bar y,\bar u) + \dfrac{\partial g}{\partial y}(x,\bar y(x))\bar\mu \ \text{ in } \Omega, \\ \bar\varphi = 0 \ \text{ on } \Gamma, \end{cases} \tag{3.2}$$

$$\int_K (z(x) - g(x,\bar y(x)))\,d\bar\mu(x) \le 0 \quad \forall z \in C(K) \text{ such that } z(x) \le 0\ \forall x \in K, \tag{3.3}$$

$$H^{\bar\lambda}(x,\bar y(x),\bar u(x),\bar\varphi(x)) = \min_{t\in[\alpha_{\varepsilon_{\bar u}}(x),\beta_{\varepsilon_{\bar u}}(x)]} H^{\bar\lambda}(x,\bar y(x),t,\bar\varphi(x)) \ \text{ for a.e. } x \in \Omega, \tag{3.4}$$

where

$$\alpha_{\varepsilon_{\bar u}}(x) = \max\{\alpha(x), \bar u(x) - \varepsilon_{\bar u}\} \ \text{ and } \ \beta_{\varepsilon_{\bar u}}(x) = \min\{\beta(x), \bar u(x) + \varepsilon_{\bar u}\},$$

assuming that $\bar u$ is a minimum of (P) *in the ball $\bar B_{\varepsilon_{\bar u}}(\bar u) \subset L^\infty(\Omega)$. Moreover, if the following linearized Slater condition holds:*

$$\begin{aligned} &\exists u_0 \in L^\infty(\Omega), \text{with } \alpha(x) \le u_0(x) \le \beta(x) \ \text{ for a.e. } x \in \Omega, \text{such that} \\ &g(x,\bar y(x)) + \frac{\partial g}{\partial y}(x,\bar y(x)) z_{u_0-\bar u}(x) < 0 \quad \forall x \in K, \end{aligned} \tag{3.5}$$

where $\bar y$ is the state associated to $\bar u$ and $z_{u_0-\bar u} = G'(\bar u)(u_0 - \bar u)$, then the choice $\bar\lambda = 1$ can be made.

From now on, we take $\bar\lambda = 1$ and denote the Hamilton function by $H := H^1$.

Remark 3.2. Together with the inequality $g(x,\bar y(x)) \le 0$, relation (3.3) is equivalent to the well-known complementarity conditions

$$g(x,\bar y(x)) \le 0\ \forall x \in K, \quad \bar\mu \ge 0 \text{ in } M(K), \ \text{ and } \int_K g(x,\bar y(x))\,d\bar\mu(x) = 0.$$

It is also well known that (3.3) implies that $\bar\mu$ is a positive measure concentrated on the set of points

$$K_0 = \{x \in K : g(x,\bar y(x)) = 0\};$$

see, for instance, the references given before the statement of the previous theorem. From this property and assumption (A3), we deduce that $\bar\mu(K \cap \Gamma) = 0$.

Remark 3.3. By using elementary calculus, we obtain from (3.4) that

$$\frac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))(k-\bar u(x))\ge 0\quad\forall k\in[\alpha(x),\beta(x)] \tag{3.6}$$

and

$$\frac{\partial^2 H}{\partial u^2}(x,\bar y(x),\bar u(x),\bar\varphi(x))\ge 0\ \text{ if }\ \frac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))=0 \tag{3.7}$$

for a.e. $x\in\Omega$. On the other hand, notice that

$$\frac{\partial^2 L}{\partial u^2}(x,y,u)=\frac{\partial^2 H}{\partial u^2}(x,y,u,\varphi). \tag{3.8}$$

The inequality (3.6) implies that

$$\begin{cases}\dfrac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))\ge 0 & \text{if }\ \bar u(x)=\alpha(x),\\[2mm] \dfrac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))\le 0 & \text{if }\ \bar u(x)=\beta(x),\\[2mm] \dfrac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))=0 & \text{if }\ \alpha(x)<\bar u(x)<\beta(x).\end{cases} \tag{3.9}$$

Reciprocally we also deduce from (3.6) that

$$\begin{cases}\bar u(x)=\alpha(x) & \text{if }\ \dfrac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))>0,\\[2mm] \bar u(x)=\beta(x) & \text{if }\ \dfrac{\partial H}{\partial u}(x,\bar y(x),\bar u(x),\bar\varphi(x))<0.\end{cases} \tag{3.10}$$

The properties given by (3.8) and (3.9) are satisfied almost everywhere in Ω.

Remark 3.4. If we consider $\bar u$ in Theorem 3.1 to be a local minimum of (P) in the sense of $L^q(\Omega)$, $1\le q<+\infty$, then (3.4) can be written in the form (see [8])

$$H^{\bar\lambda}(x,\bar y(x),\bar u(x),\bar\varphi(x))=\min_{t\in[\alpha(x),\beta(x)]}H^{\bar\lambda}(x,\bar y(x),t,\bar\varphi(x))\ \text{ for a.e. } x\in\Omega.$$

Let us formulate the Lagrangian version of the optimality conditions (3.2)–(3.4). The Lagrange function $\mathcal{L}:L^\infty(\Omega)\times M(K)\longrightarrow\mathbb{R}$ associated to problem (P) is defined by

$$\mathcal{L}(u,\mu)=J(u)+\int_K g(x,y_u(x))\,d\mu(x)=\int_\Omega L(x,y_u(x),u(x))\,dx+\int_K g(x,y_u(x))\,d\mu(x).$$

By using (2.4) we find that

$$\frac{\partial\mathcal{L}}{\partial u}(u,\mu)v=\int_\Omega\left(\frac{\partial L}{\partial u}(x,y_u(x),u(x))+\varphi_u(x)\right)v(x)\,dx=\int_\Omega H_u(x)v(x)\ dx, \tag{3.11}$$

where

$$H_u(x)=\frac{\partial H}{\partial u}(x,y_u(x),u(x),\varphi(x)) \tag{3.12}$$

and $\varphi_u \in W_0^{1,s}(\Omega)$, for all $1 \le s < n/(n-1)$, is the solution of the Dirichlet problem

$$\begin{cases} A^*\varphi + \dfrac{\partial f}{\partial y}(x, y_u)\varphi = \dfrac{\partial L}{\partial y}(x, y_u, u) + \dfrac{\partial g}{\partial y}(x, y_u(x))\mu \ \text{ in } \Omega, \\ \varphi = 0 \ \text{ on } \Gamma. \end{cases} \tag{3.13}$$

Notice that the subscript u in y_u and H_u has a different meaning. While y_u is used to indicate that y is the state associated with u, H_u denotes the partial derivative of H with respect to u. This short notation for partial derivatives is frequently used in the following and will not cause confusion. Later, we also write H_{uu}, H_{yu}, or H_{yu} for $\partial^2 H/\partial u^2$, $\partial^2 H/\partial y \partial u$, etc.

If we insert $(\bar y(x), \bar u(x), \bar\varphi(x))$ into expression (3.12), then we denote $H_u(x)$ by $\bar H_u(x)$.

Now the inequality (3.6) along with (3.11) leads to

$$\frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)(u - \bar u) \ge 0 \ \text{ if } \alpha(x) \le u(x) \le \beta(x) \text{ for a.e. } x \in \Omega \tag{3.14}$$

for any local solution $\bar u$, where $\bar y$ is the associated state and $\bar\varphi$ is the adjoint state given by (3.2), provided that (3.5) holds.

Before finishing this section we provide the expression of the second derivative of the Lagrangian with respect to the control, which will be used in the next section. From (2.8) we get

$$\frac{\partial^2 \mathcal{L}}{\partial u^2}(u, \mu)v_1 v_2 = J''(u)v_1 v_2 + \int_K \left[\frac{\partial^2 g}{\partial y^2}(x, y_u(x))z_{v_1}(x)z_{v_2}(x) + \frac{\partial g}{\partial y}(x, y_u(x))z_{v_1 v_2}(x)\right] d\mu(x).$$

By (2.5), this is equivalent to

$$\begin{aligned} \frac{\partial^2 \mathcal{L}}{\partial u^2}(u, \mu)v_1 v_2 = \int_\Omega \Bigg[& \frac{\partial^2 L}{\partial y^2}(x, y_u, u)z_{v_1} z_{v_2} + \frac{\partial^2 L}{\partial y \partial u}(x, y_u, u)(z_{v_1} v_2 + z_{v_2} v_1) \\ & + \frac{\partial^2 L}{\partial u^2}(x, y_u, u)v_1 v_2 - \varphi_u \frac{\partial^2 f}{\partial y^2}(x, y_u)z_{v_1} z_{v_2}\Bigg] dx \\ & + \int_K \frac{\partial^2 g}{\partial y^2}(x, y_u(x))z_{v_1}(x)z_{v_2}(x)\, d\mu(x), \end{aligned} \tag{3.15}$$

where φ_u is the solution of (3.13).

4. Second-order optimality conditions. Let $\bar u$ be a feasible control of problem (P) and $\bar y$ be the associated state. We assume that there exist $\bar\mu \in M(K)$ and $\bar\varphi \in W_0^{1,s}(\Omega)$, $1 \le s < n/(n-1)$, such that (3.2)–(3.4) are satisfied. As in the previous section, we use the notation

$$\bar H_u(x) := \frac{\partial H}{\partial u}(x, \bar y(x), \bar u(x), \bar\varphi(x)).$$

The partial derivative of H with respect to y at $(x, \bar y(x), \bar u(x), \bar\varphi(x))$ is denoted analogously by $\bar H_y(x)$.

Associated with $\bar{u}$, we define the cone of critical directions by

$$C_{\bar{u}} = \{h \in L^2(\Omega) : h \text{ satisfies (4.1), (4.2), and (4.3)}\},$$

$$h(x) = \begin{cases} \geq 0 \text{ if } \bar{u}(x) = \alpha(x), \\ \leq 0 \text{ if } \bar{u}(x) = \beta(x), \\ = 0 \text{ if } \bar{H}_u(x) \neq 0, \end{cases} \tag{4.1}$$

$$\frac{\partial g}{\partial y}(x, \bar{y}(x)) z_h(x) \leq 0 \quad \text{if} \quad g(x, \bar{y}(x)) = 0, \tag{4.2}$$

$$\int_K \frac{\partial g}{\partial y}(x, \bar{y}(x)) z_h(x)\, d\bar{\mu}(x) = 0. \tag{4.3}$$

If we think in terms of the finite-dimensional case, inequality (4.2) says that the derivative of the state constraint in the direction h is nonpositive if the constraint is active, and (4.3) states that this derivative is zero whenever the corresponding Lagrange multiplier is strictly positive. The relations (4.2)–(4.3) provide a convenient extension of the usual conditions in the finite-dimensional case.

We should mention that (4.3) is new in the context of infinite-dimensional optimization problems. In earlier papers on this subject, other extensions to the infinite-dimensional case were suggested. For instance, Maurer and Zowe [21] used first-order sufficient conditions to consider strict positivity of Lagrange multipliers. Inspired by their approach, in [12] an application to state-constrained elliptic boundary control was suggested. In terms of our problem, (4.3) was relaxed by

$$\int_K \frac{\partial g}{\partial y}(x, \bar{y}(x)) z_h(x)\, d\bar{\mu}(x) \geq -\varepsilon \int_{\Omega \setminus \Omega^\tau} |h(x)|\, dx$$

for some $\varepsilon > 0$; cf. [12, ineq. (5.15)]. Here $\Omega^\tau \subset \Omega$ is the set of points where $|\bar{H}_u(x)| \geq \tau$ holds true. We will prove that this relaxation is not necessary, which leads to a smaller cone of critical directions that seems to be optimal.

The sufficient second-order optimality conditions are given by the expressions (4.4) and (4.5) in the next theorem.

THEOREM 4.1. *Let $\bar{u}$ a feasible control of problem* (P)*, $\bar{y}$ be the associated state, and $(\bar{\varphi}, \bar{\mu}) \in W_0^{1,s}(\Omega) \times M(K)$, for all $1 \leq s < n/(n-1)$, satisfying* (3.2)–(3.4)*. Assume further that there exist two constants $\omega > 0$ and $\tau > 0$ such that*

$$\frac{\partial^2 L}{\partial u^2}(x, \bar{y}(x), \bar{u}(x)) \geq \omega \quad \textit{if} \quad |\bar{H}_u(x)| \leq \tau \quad \textit{for a.e. } x \in \Omega, \tag{4.4}$$

$$\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu}) h^2 > 0 \quad \forall h \in C_{\bar{u}} \setminus \{0\}. \tag{4.5}$$

Then there exist $\varepsilon > 0$ and $\delta > 0$ such that for every admissible control u of problem (P) *the following inequality holds:*

$$J(\bar{u}) + \frac{\delta}{2} \|u - \bar{u}\|^2_{L^2(\Omega)} \leq J(u) \quad \textit{if} \quad \|u - \bar{u}\|_{L^\infty(\Omega)} < \varepsilon. \tag{4.6}$$

Remark 4.2. Thanks to (3.8), we can compare the second-order necessary condition (3.7) with the sufficient one given by (4.4). We do not require only the strict positivity on the second derivative of the Hamiltonian with respect to the control at the points where the first derivative vanishes, as in the finite-dimensional case. We

also impose the second derivative to be strictly positive whenever the first derivative is "small." This is the usual case when we pass from finite to infinite dimension. For an instructive example the reader is referred to [14].

Inequality (4.4) is satisfied if the second derivative of L with respect to u is strictly positive for any $(y,u,\varphi)\in\mathbb{R}^3$ and almost all $x\in\Omega$. This assumption implies that L is strictly convex with respect to u. We recall that the convexity of L with respect to u was necessary to prove the existence of an optimal control. Under this strict convexity assumption, the sufficient second-order optimality conditions are reduced to (4.5). This is the case when $L(x,y,u)=L_0(x,y)+Nu^2/2$ if $N>0$.

The condition (4.5) seems to be natural. In fact, under some regularity assumption, we can expect the inequality

$$\frac{\partial^2\mathcal{L}}{\partial u^2}(\bar u,\bar\mu)h^2\ge 0\quad\forall h\in C_{\bar u}$$

to be a necessary condition for local optimality. At least this is the case when the state constraints are of integral type (see [7]) or when K is a finite set of points (see [6]).

Proof of Theorem 4.1. We argue by contradiction. Suppose that $\bar u$ does not satisfy the quadratic growth condition (4.6). Then there exists a sequence $\{u_k\}_{k=1}^\infty\subset L^2(\Omega)$ of feasible controls of (P) such that $u_k\to\bar u$ in $L^\infty(\Omega)$ and

$$J(\bar u)+\frac{1}{k}\|u_k-\bar u\|^2_{L^2(\Omega)}>J(u_k)\quad\forall k. \tag{4.7}$$

Let us take

$$\rho_k=\|u_k-\bar u\|_{L^2(\Omega)}\quad\text{and}\quad h_k=\frac{1}{\rho_k}(u_k-\bar u).$$

Since $\|h_k\|_{L^2(\Omega)}=1$, we can extract a subsequence, denoted in the same way, such that $h_k\rightharpoonup h$ weakly in $L^2(\Omega)$. Now we split the proof into several steps.

Step 1: $\frac{\partial\mathcal{L}}{\partial u}(\bar u,\bar\mu)h=0$. In the following, we write $y_k=y_{u_k}$. Since u_k is feasible, it holds that $g(x,y_k(x))\le 0$ for every $x\in K$. By using (3.3) and (4.7) we obtain

$$J(\bar u)+\frac{1}{k}\|u_k-\bar u\|^2_{L^2(\Omega)}=\mathcal{L}(\bar u,\bar\mu)+\frac{1}{k}\|u_k-\bar u\|^2_{L^2(\Omega)}>J(u_k)\ge\mathcal{L}(u_k,\bar\mu). \tag{4.8}$$

From the mean value theorem we know that

$$\mathcal{L}(u_k,\bar\mu)=\mathcal{L}(\bar u,\bar\mu)+\rho_k\frac{\partial\mathcal{L}}{\partial u}(v_k,\bar\mu)h_k,$$

with v_k a point between $\bar u$ and u_k. This identity and (4.8) imply that

$$\frac{\partial\mathcal{L}}{\partial u}(v_k,\bar\mu)h_k<\frac{1}{k\rho_k}\|u_k-\bar u\|^2_{L^2(\Omega)}=\frac{1}{k}\|u_k-\bar u\|_{L^2(\Omega)}.$$

Since $h_k\rightharpoonup h$ weakly in $L^2(\Omega)$, $v_k\to\bar u$ in $L^\infty(\Omega)$, $y_{v_k}\to\bar y$ in $C(\bar\Omega)\cap H^1_0(\Omega)$, and $\varphi_{v_k}\to\bar\varphi$ in $W^{1,s}_0(\Omega)\subset L^2(\Omega)$ for s close to $n/(n-1)$, we deduce from the above inequality and the expression of the derivative of the Lagrangian given by (3.11) that

$$\frac{\partial\mathcal{L}}{\partial u}(\bar u,\bar\mu)h=\lim_{k\to\infty}\frac{\partial\mathcal{L}}{\partial u}(v_k,\bar\mu)h_k\le 0. \tag{4.9}$$

On the other hand, since $\alpha(x) \le u_k(x) \le \beta(x)$ holds for almost all $x \in \Omega$, we deduce from the variational inequality (3.14) that

$$\frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)h_k = \rho_k \frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)(u_k - \bar u) \ge 0,$$

which implies that

$$\frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)h = \lim_{k\to\infty} \frac{\partial \mathcal{L}}{\partial u}(v_k, \bar\mu)h_k \ge 0.$$

This inequality, along with (4.9), leads to

$$\frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)h = 0. \tag{4.10}$$

Step 2: $h \in C_{\bar u}$. We have to confirm (4.1)–(4.3). The set of functions of $L^2(\Omega)$ that are nonnegative if $\bar u(x) = \alpha(x)$ and nonpositive if $\bar u(x) = \beta(x)$, almost everywhere, is convex and closed. Therefore, it is weakly closed. Moreover $u_k - \bar u$ obviously belongs to this set, and thus every h_k also does. Consequently, h belongs to the same set. Then (3.10), together with (3.12), implies that

$$\int_\Omega |\bar H_u(x)h(x)|\,dx = \int_\Omega \bar H_u(x)h(x)\,dx = \frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)h = 0,$$

and hence $h(x) = 0$ if $\bar H_u(x) \ne 0$, which concludes the proof of (4.1).

Let us prove (4.2). From Theorem 2.4 we have

$$z_h = G'(\bar u)h = \lim_{k\to\infty} \frac{(y_{\bar u+\rho_k h_k} - \bar y)}{\rho_k} \quad \text{in } C(\bar\Omega) \cap H_0^1(\Omega),$$

which implies for every $x \in K$ such that $g(x, \bar y(x)) = 0$ that

$$\frac{\partial g}{\partial y}(x, \bar y(x))z_h(x) = \lim_{k\to\infty} \frac{[g(x, y_{\bar u+\rho_k h_k}(x)) - g(x, \bar y(x))]}{\rho_k} \le 0. \tag{4.11}$$

The last inequality follows from the fact that u_k is feasible, $\bar u + \rho_k h_k = u_k$, and consequently $g(x, y_{\bar u+\rho_k h_k}(x)) = g(x, y_{u_k}(x)) \le 0$ for every $x \in K$.

Finally, we prove (4.3). By taking $z = g(\cdot, y_{u_k}(\cdot))$ in (3.3), we get

$$\begin{aligned}\int_K \frac{\partial g}{\partial y}(x, \bar y(x))z_h(x)\,d\bar\mu(x) &= \lim_{k\to\infty} \frac{1}{\rho_k} \int_K [g(x, y_{\bar u+\rho_k h_k}(x)) - g(x, \bar y(x))]\,d\bar\mu(x) \\ &= \lim_{k\to\infty} \frac{1}{\rho_k} \int_K [g(x, y_{u_k}(x)) - g(x, \bar y(x))]\,d\bar\mu(x) \le 0. \end{aligned} \tag{4.12}$$

On the other hand, from (4.7) we find

$$J'(\bar u)h = \lim_{k\to\infty} \frac{J(\bar u + \rho_k h_k) - J(\bar u)}{\rho_k} = \lim_{k\to\infty} \frac{J(u_k) - J(\bar u)}{\rho_k} \le \lim_{k\to\infty} \frac{\rho_k}{k} = 0. \tag{4.13}$$

Then (4.10), (4.12), (4.13), and the fact that

$$\frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu)h = J'(\bar u)h + \int_K \frac{\partial g}{\partial y}(x, \bar y(x))z_h(x)\,d\bar\mu(x)$$

imply that

$$J'(\bar{u})h = \int_K \frac{\partial g}{\partial y}(x, \bar{y}(x)) z_h(x)\, d\bar{\mu}(x) = 0.$$

Thus (4.3) holds, and we know that $h \in C_{\bar{u}}$.

Step 3: $h = 0$. By taking into account (4.5), it is enough to prove that

$$\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu})h \le 0. \tag{4.14}$$

For this purpose, we evaluate the Lagrangian. By a second-order Taylor expansion, we derive

$$\mathcal{L}(u_k, \bar{\mu}) = \mathcal{L}(\bar{u}, \bar{\mu}) + \rho_k \frac{\partial \mathcal{L}}{\partial u}(\bar{u}, \bar{\mu})h_k + \frac{\rho_k^2}{2}\frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k, \bar{\mu})h_k^2, \tag{4.15}$$

w_k being an intermediate point between $\bar{u}$ and u_k. From here we get

$$\begin{aligned} &\rho_k \frac{\partial \mathcal{L}}{\partial u}(\bar{u}, \bar{\mu})h_k + \frac{\rho_k^2}{2}\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu})h_k^2 \\ &= \mathcal{L}(u_k, \bar{\mu}) - \mathcal{L}(\bar{u}, \bar{\mu}) + \frac{\rho_k^2}{2}\left[\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu}) - \frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k, \bar{\mu})\right] h_k^2. \end{aligned} \tag{4.16}$$

Now (4.8) can be written

$$\mathcal{L}(u_k, \bar{\mu}) - \mathcal{L}(\bar{u}, \bar{\mu}) \le \frac{\rho_k^2}{k}. \tag{4.17}$$

On the other hand, by taking into account the expression (3.15) of the second derivative of the Lagrangian, assumptions (A1)–(A3) and Theorems 2.1 and 2.4, and the fact that $u_k \to \bar{u}$ in $L^\infty(\Omega)$ and $\|h_k\|_{L^2(\Omega)} = 1$, we obtain

$$\begin{aligned} \left|\left[\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu}) - \frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k, \bar{\mu})\right] h_k^2\right| &\le \left\|\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu}) - \frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k, \bar{\mu})\right\|_{B(L^2(\Omega))} \|h_k\|^2_{L^2(\Omega)} \\ &= \left\|\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u}, \bar{\mu}) - \frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k, \bar{\mu})\right\|_{B(L^2(\Omega))} \to 0 \quad \text{when} \quad k \to \infty, \end{aligned} \tag{4.18}$$

where $B(L^2(\Omega))$ is the space of quadratic forms in $L^2(\Omega)$.

Let us define

$$\Omega^\tau = \{x \in \Omega : |\bar{H}_u(x)| > \tau\}.$$

From (3.10) and the definition of h_k we know that $\bar{H}_u(x)h_k(x) \ge 0$ in Ω; therefore

$$\frac{\partial \mathcal{L}}{\partial u}(\bar{u}, \bar{\mu})h_k = \int_\Omega \bar{H}_u(x)h_k(x)\, dx \ge \int_{\Omega^\tau} |\bar{H}_u(x)||h_k(x)|\, dx \ge \tau \int_{\Omega^\tau} |h_k(x)|\, dx. \tag{4.19}$$

For any $\varepsilon > 0$ we can take k_ε such that

$$\|\rho_k h_k\|_{L^\infty(\Omega)} = \|\bar{u} - u_k\|_{L^\infty(\Omega)} < \varepsilon \quad \forall k \ge k_\varepsilon \quad \text{for a.e. } x \in \Omega,$$

and therefore

$$\frac{\rho_k^2 h_k^2(x)}{\varepsilon} \le \rho_k |h_k(x)| \quad \forall k \ge k_\varepsilon \quad \text{for a.e. } x \in \Omega.$$

From this inequality and (4.19) it follows that

$$\rho_k \frac{\partial \mathcal{L}}{\partial u}(\bar u, \bar\mu) h_k \ge \rho_k \tau \int_{\Omega^\tau} |h_k(x)|\, dx \ge \frac{\rho_k^2 \tau}{\varepsilon} \int_{\Omega^\tau} h_k^2(x)\, dx. \tag{4.20}$$

By collecting (4.16)–(4.18) and (4.20) and dividing by $\rho_k^2/2$, we obtain for any $k \ge k_\varepsilon$

$$\frac{2\tau}{\varepsilon} \int_{\Omega^\tau} h_k^2(x)\, dx + \frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar u, \bar\mu) h_k^2 \le \frac{2}{k} + \left\| \frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar u, \bar\mu) - \frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k, \bar\mu) \right\|_{B(L^2(\Omega))}. \tag{4.21}$$

Next, we study the left-hand side of this inequality. First of all let us notice that from (3.15) we obtain for any $v \in L^2(\Omega)$

$$\begin{aligned} \frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar u, \bar\mu) v^2 = &\int_\Omega \left[\bar H_{uu}(x) v^2(x) + 2 \bar H_{uy}(x) z_v(x) v(x) + \bar H_{yy}(x) z_v^2(x) \right] dx \\ &+ \int_K \frac{\partial^2 g}{\partial y^2}(x, \bar y(x)) z_v^2(x)\, d\bar\mu(x), \end{aligned}$$

where

$$\bar H_{uu}(x) = \frac{\partial^2 H}{\partial u^2}(x, \bar y(x), \bar u(x), \bar\varphi(x))$$

and $\bar H_{uy}$ and $\bar H_{yy}$ are defined analogously. We also recall that

$$\bar H_{uu}(x) = \frac{\partial^2 L}{\partial u^2}(x, \bar y(x), \bar u(x)). \tag{4.22}$$

Then we have

$$\begin{aligned} &\frac{2\tau}{\varepsilon} \int_{\Omega^\tau} h_k^2(x)\, dx + \frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar u, \bar\mu) h_k^2 \\ &\quad = \int_{\Omega^\tau} \left(\frac{2\tau}{\varepsilon} + \bar H_{uu}(x) \right) h_k^2(x)\, dx + \int_{\Omega \setminus \Omega^\tau} \bar H_{uu}(x) h_k^2(x)\, dx \\ &\qquad + \int_\Omega \left[2 \bar H_{uy}(x) z_{h_k}(x) h_k(x) + \bar H_{yy}(x) z_{h_k}^2(x) \right] dx \\ &\qquad + \int_K \frac{\partial^2 g}{\partial y^2}(x, \bar y(x)) z_{h_k}^2(x)\, d\bar\mu(x). \end{aligned} \tag{4.23}$$

From assumptions (A1)–(A3) we deduce the existence of $C > 0$ such that $|\bar H_{uu}(x)| \le C$ for a.e. $x \in \Omega$. Therefore we can take $\varepsilon > 0$ small enough so that the following inequality holds:

$$\frac{2\tau}{\varepsilon} + \bar H_{uu}(x) \ge \frac{2\tau}{\varepsilon} - C > 0 \quad \text{for a.e. } x \in \Omega^\tau.$$

Thus

$$\liminf_{k \to \infty} \int_{\Omega^\tau} \left(\frac{2\tau}{\varepsilon} + \bar H_{uu}(x) \right) h_k^2(x)\, dx \ge \int_{\Omega^\tau} \left(\frac{2\tau}{\varepsilon} + \bar H_{uu}(x) \right) h^2(x)\, dx. \tag{4.24}$$

Moreover from (4.4) we have $\bar{H}_{uu}(x) \geq \omega > 0$ in $\Omega \setminus \Omega^\tau$, and therefore we also get

$$\liminf_{k\to\infty} \int_{\Omega\setminus\Omega^\tau} \bar{H}_{uu}(x)h_k^2(x)\,dx \geq \int_{\Omega\setminus\Omega^\tau} \bar{H}_{uu}(x)h^2(x)\,dx. \tag{4.25}$$

Finally, by taking into account that $z_{h_k} \to z_h$ strongly in $C(\bar{\Omega}) \cap H_0^1(\Omega)$, we deduce from (4.21)–(4.24) and (4.18) that

$$\begin{aligned}&\int_{\Omega^\tau} \left(\frac{2\tau}{\varepsilon} + \bar{H}_{uu}(x)\right) h^2(x)\,dx + \int_{\Omega\setminus\Omega^\tau} \bar{H}_{uu}(x)h^2(x)\,dx\\ &+ \int_\Omega [2\bar{H}_{uy}(x)h(x)z_h(x) + \bar{H}_{yy}(x)z_h^2(x)]dx + \int_K \frac{\partial^2 g}{\partial y^2}(x,\bar{y}(x))z_h^2(x)\,d\bar{\mu}(x) \leq 0.\end{aligned} \tag{4.26}$$

This expression can be written as follows:

$$\frac{2\tau}{\varepsilon}\int_{\Omega^\tau} h^2(x)\,dx + \frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u},\bar{\mu})h^2 \leq 0,$$

which along with (4.5) and the fact that $h \in C_{\bar{u}}$ implies that $h = 0$.

Step 4: $h_k \to 0$ strongly in $L^2(\Omega)$. We have already proved that $h_k \rightharpoonup 0$ weakly in $L^2(\Omega)$; therefore $z_{h_k} \to 0$ strongly in $C(\bar{\Omega}) \cap H_0^1(\Omega)$. By using (4.21) and (4.23) and the fact that $\|h_k\|_{L^2(\Omega)} = 1$, we conclude that

$$\begin{aligned}0 &< \min\left\{\omega, \frac{2\tau}{\varepsilon} - C\right\} = \min\left\{\omega, \frac{2\tau}{\varepsilon} - C\right\} \limsup_{k\to\infty} \int_\Omega h_k^2(x)\,dx\\ &\leq \limsup_{k\to\infty} \left\{\int_{\Omega^\tau} \left(\frac{2\tau}{\varepsilon} + \bar{H}_{uu}(x)\right) h_k^2(x)\,dx + \int_{\Omega\setminus\Omega^\tau} \bar{H}_{uu}(x)h_k^2(x)\,dx\right\}\\ &\leq \limsup_{k\to\infty} \left\{\frac{2}{k} + \left\|\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar{u},\bar{\mu}) - \frac{\partial^2 \mathcal{L}}{\partial u^2}(w_k,\bar{\mu})\right\|_{B(L^2(\Omega))}\right.\\ &\left. - \int_K \frac{\partial^2 g}{\partial y^2}(x,\bar{y}(x))z_{h_k}^2(x)\,d\bar{\mu}(x) - \int_\Omega \left[2\bar{H}_{uy}(x)z_{h_k}(x)h_k(x) + \bar{H}_{yy}(x)z_{h_k}^2(x)\right]dx\right\} = 0.\end{aligned}$$

Thus we have the contradiction. □

There is a very interesting particular case of (P) where Theorem 4.1 has a stronger formulation.

THEOREM 4.3. *Assume that $L(x,y,u) = L_0(x,y) + Nu^2/2$, with $N > 0$. If $\bar{u}$ is a feasible control of problem* (P)*, $\bar{y}$ is the associated state, $(\bar{\varphi},\bar{\mu}) \in W_0^{1,s}(\Omega) \times M(K)$, for all $1 \leq s < n/(n-1)$, and $(\bar{y},\bar{u},\bar{\varphi},\bar{\mu})$ satisfies* (3.2)–(3.4) *and* (4.5)*, then there exist $\varepsilon > 0$ and $\delta > 0$ such that for every admissible control u of problem* (P) *the following inequality holds:*

$$J(\bar{u}) + \frac{\delta}{2}\|u-\bar{u}\|_{L^2(\Omega)}^2 \leq J(u) \quad \text{if} \quad \|u-\bar{u}\|_{L^2(\Omega)} < \varepsilon. \tag{4.27}$$

We have already mentioned in Remark 4.2 that the first-order optimality conditions along with (4.5) are sufficient for optimality when $L(x,y,u) = L_0(x,y) + Nu^2/2$, with $N > 0$. But the above theorem includes more very important information. Relation (4.27) says that $\bar{u}$ is a strict local minimum of (P) in $L^2(\Omega)$. The fact that the control appears linearly in the state equation and quadratically in the cost functional allows us to get sufficient optimality conditions for a local minimum not only in $L^\infty(\Omega)$ but also in $L^2(\Omega)$. This fact is very important in the analysis of stability and convergence of numerical algorithms to solve (P). The proof of Theorem 4.3 follows the same arguments and steps as those given in the proof of Theorem 4.1. The essential fact is that the functional J is of class C^2 in $L^2(\Omega)$; see Remark 2.8.

5. Bilateral state constraints. In this section we will consider the extension of the control problem to the case of bilateral state constraints. More precisely we formulate the control problem as follows:

$$(\mathrm{P})\quad \begin{cases} \min J(u) = \displaystyle\int_\Omega L(x, y_u(x), u(x))\,dx \\ \text{subject to } \ (y_u, u) \in (C(\bar\Omega) \cap H^1(\Omega)) \times L^\infty(\Omega), \\ \alpha(x) \le u(x) \le \beta(x) \quad \text{for a.e. } \ x \in \Omega, \\ g_a(x) \le g(x, y_u(x)) \le g_b(x) \ \ \forall x \in K, \end{cases}$$

where $g_a, g_b : K \mapsto \mathbb{R}$ are continuous functions and $g_a(x) < g_b(x)$ for every $x \in K$. We assume the same hypotheses as in the previous sections. All of the previous theorems remain valid with some obvious modifications that we are going to mention. The Slater assumption required in Theorem 3.5 is now formulated as follows:

$$\begin{aligned} &\exists u_0 \in L^\infty(\Omega), \text{with } \alpha(x) \le u_0(x) \le \beta(x) \text{ for a.e. } x \in \Omega, \text{ such that} \\ &g_a(x) < g(x, \bar y(x)) + \frac{\partial g}{\partial y}(x, \bar y(x)) z_{u_0 - \bar u}(x) < g_b(x) \quad \forall x \in K. \end{aligned} \tag{5.1}$$

Under this assumption, Theorem 3.1 remains valid except for (3.3), which is written now in the following way:

$$\int_K (z(x)) - g(x, \bar y(x))\, d\bar\mu(x) \le 0 \ \forall z \in C(K), \text{ with } g_a(x) \le z(x) \le g_b(x) \ \forall x \in K. \tag{5.2}$$

From (5.2) we deduce that $\bar\mu$ is concentrated at the set of points K_0 where the state constraint is active:

$$K_0 = K_- \cup K_+ = \{x \in K : g(x, \bar y(x)) = g_a(x)\} \cup \{x \in K : g(x, \bar y(x)) = g_b(x)\}.$$

Now the Lagrange multiplier $\bar\mu$ is not necessarily a positive measure. However, its Jordan decomposition into nonnegative measures $\bar\mu^+$, $\bar\mu^-$ is as follows:

$$\bar\mu = \bar\mu^+ - \bar\mu^-, \ \text{ with } \operatorname{supp}(\bar\mu^+) \subset K_+ \text{ and } \operatorname{supp}(\bar\mu^-) \subset K_-.$$

The cone of critical directions $C_{\bar u}$ is formed by the functions $h \in L^2(\Omega)$ satisfying (4.1) and

$$\frac{\partial g}{\partial y}(x, \bar y(x)) z_h(x) \le 0 \ \text{ if } \ g(x, \bar y(x)) = g_b(x), \tag{5.3}$$

$$\frac{\partial g}{\partial y}(x, \bar y(x)) z_h(x) \ge 0 \ \text{ if } \ g(x, \bar y(x)) = g_a(x), \tag{5.4}$$

$$\int_K \left| \frac{\partial g}{\partial y}(x, \bar y(x)) z_h(x) \right| d|\bar\mu|(x) = 0, \tag{5.5}$$

where $|\bar\mu| = \bar\mu^+ + \bar\mu^-$. Then Theorem 4.1 is still true, and the only changes of the proof appear in Steps 1 and 2. In particular, (4.8) can be rewritten with the help

of (3.3) in the following way:

$$\mathcal{L}(\bar u,\bar\mu)+\frac{1}{k}\|u_k-\bar u\|^2_{L^2(\Omega)}-\int_K g(x,\bar y(x))\,d\bar\mu(x)=J(\bar u)+\frac{1}{k}\|u_k-\bar u\|^2_{L^2(\Omega)}$$
$$>J(u_k)\ge\mathcal{L}(u_k,\bar\mu)-\int_K g(x,\bar y(x))\,d\bar\mu(x)\ge\mathcal{L}(u_k,\bar\mu),$$

and the proof can continue as in Theorem 4.1.

On the other hand, relation (4.11) in Step 2 must be replaced by

$$\frac{\partial g}{\partial y}(x,\bar y(x))z_h(x)=\begin{cases}\le 0 & \forall x\in K_+,\\ \ge 0 & \forall x\in K_-.\end{cases}\tag{5.6}$$

Relations (4.12) and (4.13) remain valid. Finally, by using (4.10) and (5.6) we deduce the identity (5.5) as follows:

$$\int_K\left|\frac{\partial g}{\partial y}(x,\bar y(x))z_h(x)\right|\,d|\bar\mu|(x)=-\int_K\frac{\partial g}{\partial y}(x,\bar y(x))z_h(x)\,d\bar\mu(x)=J'(\bar u)h=0.$$

6. Elliptic boundary control.

6.1. Problem statement. The method of the preceding sections can be extended to other types of equations in a straightforward way. Here we discuss the case of boundary control, while the next section is devoted to a one-dimensional distributed parabolic control problem. Instead of (2.1), we consider now

$$\begin{cases} Ay+f(x,y)=0 & \text{in }\Omega,\\ \partial_\nu y+\gamma\,y=u & \text{on }\Gamma,\end{cases}\tag{6.1}$$

where ∂_ν denotes the conormal-derivative associated with A and $\gamma\in L^\infty(\Gamma)$ is nonnegative with $\gamma\not\equiv 0$. In contrast to section 1, we assume here that $n=2$. We need this stronger assumption, since now the control-to-state mapping G must be twice continuously differentiable from $L^2(\Gamma)$ to $C(\bar\Omega)$; cf. Remark 2.5. The differential operator A is defined as in section 1.

We consider the optimal boundary control problem

$$(\mathrm{PB})\begin{cases}\min J(u)=\displaystyle\int_\Omega L(x,y_u(x))\,dx+\int_\Gamma \ell(x,y_u(x),u(x))\,ds(x)\\ \text{subject to}\quad (y_u,u)\in(C(\bar\Omega)\cap H^1(\Omega))\times L^\infty(\Gamma),\\ \alpha(x)\le u(x)\le\beta(x)\quad\text{for a.e. } x\in\Gamma,\\ g(x,y_u(x))\le 0\ \ \forall x\in K.\end{cases}\tag{6.2}$$

Here α and β are now functions from $L^\infty(\Gamma)$, with $\alpha(x)\le\beta(x)$ for a.a. $x\in\Gamma$, ds denotes the surface measure on Γ, y_u is the solution of (6.1) associated with $u\in L^2(\Gamma)$, and $K\subset\bar\Omega$ is again a compact set.

The following assumptions are imposed on the data: We assume (A1)–(A3) on f, L, and g (where, of course, the dependence of L on u in (A2) is redundant). Moreover, we require the following.

(A4) The function $\ell:\Gamma\times(\mathbb{R}\times\mathbb{R})\longrightarrow\mathbb{R}$ satisfies assumption (A2) with ℓ substituted for L and Γ substituted for Ω.

Remark 6.1. We confine ourselves to a linear boundary condition. An extension to a nonlinear condition of the type $\partial_\nu y + b(x,y) = u$ is possible under associated assumptions on b. On the other hand, the assumption $\gamma \not\equiv 0$, that allows us to deduce the existence of a unique solution of (6.1), can be replaced by

$$\frac{\partial f}{\partial y}(x,t) > 0 \quad \text{for all } x \in E \text{ and } t \in \mathbb{R},$$

where E is a measurable subset of Ω with a strictly positive measure.

The proof of the next theorems is completely analogous to that of Theorems 2.2 and 2.4; see Alibert and Raymond [1].

THEOREM 6.2. *Suppose that* (A1) *holds. Then, for every* $u \in L^2(\Gamma)$*, the state equation* (6.1) *has a unique solution* $y_u \in C(\bar\Omega) \cap H^1(\Omega)$*. Furthermore, if* $u_k \rightharpoonup u$ *weakly in* $L^2(\Gamma)$*, then* $y_{u_k} \to y_u$ *strongly in* $C(\bar\Omega) \cap H^1(\Omega)$*.*

Notice that controls of $L^2(\Gamma)$ are transformed continuously to states in the Hölder space $C^{0,\kappa}(\Omega)$, with some $0 < \kappa < 1$; cf. Stampacchia [23, Thm. 14.2]. The second part of the statement is an immediate conclusion.

THEOREM 6.3. *Assume that* (A1)–(A4) *are fulfilled, the function* ℓ *is convex with respect to the third component, and the set of feasible controls is nonempty. Then the control problem* (PB) *has at least one solution.*

The proof can be performed by standard methods.

6.2. Necessary optimality conditions. We first state results on the first- and second-order derivatives of the control-to-state mapping $G(u) = y_u$ and of the reduced objective functional J. The results are analogous to Theorems 2.6–2.7 so that we only collect them without proof, since the associated modifications are obvious. Under assumptions (A1)–(A4), all mappings listed below are of class C^2 from $L^\infty(\Gamma)$ to their respective image spaces. The associated derivatives can be obtained as follows.

We define, for $v \in L^2(\Gamma)$, the function z_v as the unique solution to

$$\begin{cases} Az_v + \dfrac{\partial f}{\partial y}(x,y_u)z_v = 0 \ \text{ in } \Omega, \\ \partial_\nu z_v + \gamma z_v = v \ \text{ on } \Gamma. \end{cases} \tag{6.3}$$

Then G' is given by $G'(u)v = z_v$. Moreover, for v_1, $v_2 \in L^2(\Gamma)$, we introduce $z_{v_i} = G'(u)v_i$, $i = 1, 2$, and obtain $G''(u)v_1v_2 = z_{v_1v_2}$, where $z_{v_1v_2}$ is the solution to

$$\begin{cases} Az_{v_1v_2} + \dfrac{\partial f}{\partial y}(x,y_u)z_{v_1v_2} + \dfrac{\partial^2 f}{\partial y^2}(x,y_u)z_{v_1}z_{v_2} = 0 \text{ in } \Omega, \\ \partial_\nu z_{v_1v_2} + \gamma\, z_{v_1v_2} = 0 \text{ on } \Gamma. \end{cases} \tag{6.4}$$

The adjoint state $\varphi_{0u} \in H_0^1(\Omega)$ associated with u and J is introduced as the unique solution to

$$\begin{cases} A^*\varphi + \dfrac{\partial f}{\partial y}(x,y_u)\varphi = \dfrac{\partial L}{\partial y}(x,y_u) \ \text{ in } \Omega, \\ \partial_\nu \varphi + \gamma\, \varphi = \dfrac{\partial \ell}{\partial y}(x,y_u,u) \ \text{ on } \Gamma. \end{cases} \tag{6.5}$$

It holds that

$$J'(u)v = \int_\Gamma \left(\frac{\partial \ell}{\partial u}(x, y_u, u) + \varphi_{0u} \right) v \, ds, \tag{6.6}$$

$$\begin{aligned} J''(u)v_1v_2 = &\int_\Omega \left[\frac{\partial^2 L}{\partial y^2}(x, y_u, u) z_{v_1} z_{v_2} - \varphi_{0u} \frac{\partial^2 f}{\partial y^2}(x, y_u) z_{v_1} z_{v_2} \right] dx \\ &+ \int_\Gamma \left[\frac{\partial^2 \ell}{\partial y^2}(x, y_u, u) z_{v_1} z_{v_2} + \frac{\partial^2 \ell}{\partial y \partial u}(x, y_u, u)(z_{v_1} v_2 + z_{v_2} v_1) \right. \\ &\left. + \frac{\partial^2 \ell}{\partial u^2}(x, y_u, u) v_1 v_2 \right] ds. \end{aligned} \tag{6.7}$$

Under (A1) and (A3), the mapping $F : L^2(\Gamma) \to C(K)$, defined by $F(u) = g(\cdot, y_u(\cdot))$, is of class C^2. For every $u, v, v_1, v_2 \in L^2(\Gamma)$, its first- and second-order derivatives are given again by (2.7) and (2.8), respectively.

Now we introduce the Hamiltonian H by

$$H(x, y, u, \varphi) = \ell(x, y, u) + \varphi \, [u - \gamma \, y].$$

The first-order necessary conditions admit the following form.

THEOREM 6.4. *Let $\bar u$ be a local solution of* (PB). *Suppose that assumptions* (A1)–(A4) *hold, and assume the linearized Slater condition* (3.5) *with some $u_0 \in L^\infty(\Gamma)$, $\alpha(x) \le u_0(x) \le \beta(x)$ for a.e. $x \in \Gamma$. Then there exist a measure $\bar\mu \in M(K)$ and a function $\bar\varphi \in W^{1,s}(\Omega)$ for all $1 \le s < n/(n-1)$ such that*

$$\begin{cases} A^* \bar\varphi + \dfrac{\partial f}{\partial y}(x, \bar y(x)) \bar\varphi = \dfrac{\partial L}{\partial y}(x, \bar y, \bar u) + \dfrac{\partial g}{\partial y}(x, \bar y(x)) \bar\mu_{|\Omega} \ \text{ in } \Omega, \\ \partial_\nu \bar\varphi + \gamma \, \bar\varphi = \dfrac{\partial g}{\partial y}(x, \bar y(x)) \bar\mu_{|\Gamma} \ \text{ on } \Gamma, \end{cases} \tag{6.8}$$

$$\int_K (z(x) - g(x, \bar y(x))) d\bar\mu(x) \le 0 \quad \forall z \in C(K) \text{ such that } z(x) \le 0 \ \forall x \in K, \tag{6.9}$$

$$H(x, \bar y(x), \bar u(x), \bar\varphi(x)) = \min_{t \in [\alpha_{\varepsilon \bar u}(x), \beta_{\varepsilon \bar u}(x)]} H(x, \bar y(x), t, \bar\varphi(x)) \quad \text{for a.e. } x \in \Gamma, \tag{6.10}$$

where $\alpha_{\varepsilon_{\bar u}}$ and $\beta_{\varepsilon_{\bar u}}$ are defined similarly as in Theorem 3.1 *and $\bar\mu_{|\Omega}$ and $\bar\mu_{|\Gamma}$ denote the restrictions of μ to Ω and Γ, respectively.*

At the optimal point, the derivatives of H fulfill the relations (3.6)–(3.10) with an obvious modification: We have to substitute $x \in \Gamma$ for $x \in \Omega$. Moreover, we have to replace (3.8) by

$$\frac{\partial^2 \ell}{\partial u^2}(x, y, u) = \frac{\partial^2 H}{\partial u^2}(x, y, u, \varphi). \tag{6.11}$$

The Lagrangian function $\mathcal{L} : L^\infty(\Gamma) \times M(K) \longrightarrow \mathbb{R}$ associated to problem (PB) is defined by

$$\mathcal{L}(u, \mu) = \int_\Omega L(x, y_u(x)) \, dx + \int_\Gamma \ell(x, y_u(x), u(x)) \, ds + \int_K g(x, y_u(x)) \, d\mu(x).$$

By using (6.6) we deduce that

$$\frac{\partial \mathcal{L}}{\partial u}(u,\mu)v = \int_\Gamma H_u(x)v(x)\,ds, \tag{6.12}$$

where

$$H_u(x) = \frac{\partial H}{\partial u}(x, y(x), u(x), \varphi_u(x)) \tag{6.13}$$

and φ_u is obtained from the adjoint equation (6.8), where y_u is substituted for $\bar y$, u for $\bar u$, and μ for $\bar\mu$, respectively. We finally indicate the expression for the second-order derivative of $\mathcal{L}$:

$$\begin{aligned}\frac{\partial^2 \mathcal{L}}{\partial u^2}(u,\mu)v_1v_2 = &\int_\Omega \left[\frac{\partial^2 L}{\partial y^2}(x,y_u)z_{v_1}z_{v_2} - \varphi_u \frac{\partial^2 f}{\partial y^2}(x,y_u)z_{v_1}z_{v_2}\right] dx\\ &+ \int_\Gamma \left[\frac{\partial^2 \ell}{\partial y^2}(x,y_u,u)z_{v_1}z_{v_2} + \frac{\partial^2 \ell}{\partial y \partial u}(x,y_u,u)(z_{v_1}v_2 + z_{v_2}v_1)\right.\\ &\left. + \frac{\partial^2 \ell}{\partial u^2}(x,y_u,u)v_1v_2\right] ds\\ &+ \int_K \frac{\partial^2 g}{\partial y^2}(x,y_u(x))z_{v_1}(x)z_{v_2}(x)\,d\mu(x),\end{aligned} \tag{6.14}$$

where φ_u is defined as after (6.13).

6.3. Second-order sufficient optimality conditions. Let $\bar u$ be a feasible control of problem (PB) and $\bar y$ be the associated state. We assume that there exist $\bar\mu \in M(K)$ and $\bar\varphi \in W_0^{1,s}(\Omega)$, $1 \le s < n/(n-1)$, such that the first-order necessary conditions (6.8)–(6.10) are satisfied. Associated with $\bar u$, we introduce the function

$$\bar H_u(x) = \frac{\partial H}{\partial u}(x, \bar y(x), \bar u(x), \bar\varphi(x))$$

and define the cone of critical directions by

$$C_{\bar u} = \{h \in L^2(\Gamma) : h \text{ satisfies (4.1)–(4.3) with } x \in \Gamma\}. \tag{6.15}$$

Notice that this cone is only formally the same as in (4.1)–(4.3), since x varies here through Γ. The second-order sufficient condition admits now the following form.

THEOREM 6.5. *Assume that $n = 2$, and let $\bar u$ be a feasible control of problem* (PB)*, $\bar y$ the associated state, and $(\bar\varphi, \bar\mu) \in W^{1,s}(\Omega) \times M(K)$, for all $1 \le s < n/(n-1)$, satisfying* (6.8)–(6.10)*. Let there exist two constants $\omega > 0$ and $\tau > 0$ such that*

$$\frac{\partial^2 \ell}{\partial u^2}(x, \bar y(x), \bar u(x)) \ge \omega \quad \text{if} \quad |\bar H_u(x)| \le \tau \quad \text{for a.e. } x \in \Gamma, \tag{6.16}$$

$$\frac{\partial^2 \mathcal{L}}{\partial u^2}(\bar u, \bar\mu)h^2 > 0 \quad \forall h \in C_{\bar u} \setminus \{0\}, \tag{6.17}$$

where $C_{\bar u}$ is defined in (6.15) *and $\partial^2\mathcal{L}/\partial u^2$ is taken from* (6.14)*, with $u := \bar u$ and $\mu := \bar\mu$.*

Then there exist $\varepsilon > 0$ and $\delta > 0$ such that, for every admissible control u of problem (PB)*, the following inequality holds:*

$$J(\bar u) + \frac{\delta}{2}\|u - \bar u\|^2_{L^2(\Gamma)} \le J(u) \quad \text{if} \quad \|u - \bar u\|_{L^\infty(\Gamma)} < \varepsilon. \tag{6.18}$$

Proof. The proof is almost identical with the one of Theorem 4.1. Therefore, we mention only where essential changes occur.

Throughout the proof, we have to perform the obvious modification that $L^2(\Gamma)$, $L^\infty(\Gamma)$, and $H^1(\Omega)$ must be substituted for $L^2(\Omega)$, $L^\infty(\Omega)$, and $H_0^1(\Omega)$, respectively. Moreover, in some integrals, Ω must obviously be replaced by Γ. Then Steps 1 and 2 can be adopted without further changes.

Step 3: The arguments up to (4.18) do not need changes. Next, we modify Ω^τ by

$$\Gamma^\tau = \{x \in \Gamma \,:\, |\bar H_u(x)| > \tau\}.$$

Hereafter, Ω and Ω^τ are replaced by Γ and Γ^τ, respectively. In (4.22), ℓ must be substituted for L, and in (4.23) we add the integral over $\partial^2 L/\partial u^2$ to arrive at

$$\begin{aligned}
&\frac{2\tau}{\varepsilon}\int_{\Gamma^\tau} h_k^2(x)\,ds + \frac{\partial^2\mathcal{L}}{\partial u^2}(\bar u,\bar\mu)h_k^2 \\
&\quad= \int_{\Gamma^\tau}\left(\frac{2\tau}{\varepsilon} + \bar H_{uu}(x)\right) h_k^2(x)\,ds + \int_{\Gamma\setminus\Gamma^\tau} \bar H_{uu}(x)h_k^2(x)\,ds \\
&\qquad+ \int_\Gamma \left[2\bar H_{uy}(x)z_{h_k}(x)h_k(x) + \bar H_{yy}(x)z_{h_k}^2(x)\right] ds \\
&\qquad+ \int_K \frac{\partial^2 g}{\partial y^2}(x,\bar y(x))z_{h_k}^2(x)\,d\bar\mu(x) + \int_\Omega \frac{\partial^2 L}{\partial y^2}(x,\bar y(x))z_{h_k}^2(x)\,dx. \qquad (6.19)
\end{aligned}$$

Analogously, this term must be added to the left-hand side of (4.26).

Step 4: First, we conclude from $h_k \rightharpoonup 0$ in $L^2(\Gamma)$ that $z_{h_k} \to 0$ strongly in $C(\bar\Omega)$. Proceeding as in the former Step 4, we finally conclude with

$$\begin{aligned}
0 < \limsup_{k\to\infty}\Bigg\{ &\frac{2}{k} + \left\|\frac{\partial^2\mathcal{L}}{\partial u^2}(\bar u,\bar\mu) - \frac{\partial^2\mathcal{L}}{\partial u^2}(w_k,\bar\mu)\right\|_{B(L^2(\Gamma))} \\
&- \int_K \frac{\partial^2 g}{\partial y^2}(x,\bar y(x))z_{h_k}^2(x)\,d\bar\mu(x) - \int_\Omega \frac{\partial^2 L}{\partial y^2}(x,\bar y(x))z_{h_k}^2(x)\,dx \\
&- \int_\Omega \left[2\bar H_{uy}(x)z_{h_k}(x)h_k(x) + \bar H_{yy}(x)z_{h_k}^2(x)\right] dx\Bigg\} = 0. \qquad \square
\end{aligned}$$

7. The parabolic case.

7.1. Problem statement. Finally we prove that our method can also be extended to one-dimensional parabolic problems with distributed control. This extension is addressed here. To define the parabolic problem, we consider the one-dimensional domain $\Omega = (a,b)$ and the time interval $[0,T]$ for given $T > 0$. We fix an initial value $y_0 \in C[a,b]$ and introduce the set $Q = (a,b)\times(0,T)$. Moreover, we introduce the space $W(0,T) = \{y \in L^2(0,T;H^1(\Omega)) \,:\, \frac{dy}{dt} \in L^2(0,T;H^1(\Omega)')\}$.

Remark 7.1. Again, the restriction on the dimension of Ω comes from the requirement that the control-to-state mapping is of class C^2 from $L^2(Q)$ to $C(\bar Q)$. This holds true only for $n = 1$. We should mention here that boundary controls cannot be handled by our approach. Neumann boundary data from $L^2(0,T)$ are not, in general, transformed into continuous states.

The parabolic equation is defined by

$$\text{(7.1)}\qquad \begin{cases} \dfrac{dy}{dt} + Ay + f(x,t,y) = u & \text{in } (a,b)\times(0,T),\\ -\partial_x y(a,t) = 0 & \text{in } (0,T),\\ \partial_x y(b,t) = 0 & \text{in } (0,T),\\ y(\cdot,0) = y_0 & \text{in } (a,b), \end{cases}$$

where ∂_x denotes the partial derivative with respect to x. The associated optimal control problem is

$$\text{(7.2)}\quad \text{(PP)}\quad \begin{cases} \min J(u) = \displaystyle\int_0^T \int_a^b L(x,t,y_u(x,t),u(x,t))\,dxdt + \int_a^b r(x,y(x,T))\,dx \\ \qquad\qquad + \displaystyle\int_0^T \ell_a(t,y_u(a,t))\,dt + \int_0^T \ell_b(t,y_u(b,t))\,dt \\ \text{subject to } \ (y_u,u)\in (C(\bar{Q})\cap W(0,T))\times L^\infty(Q), \\ \alpha(x,t)\le u(x,t)\le \beta(x,t) \quad \text{for a.e. } \ (x,t)\in Q, \\ g(x,t,y_u(x,t))\le 0 \ \ \forall (x,t)\in K. \end{cases}$$

Here α and β are functions from $L^\infty(Q)$, with $\alpha(x,t)\le\beta(x,t)$ for a.a. $(x,t)\in Q$, y_u is the solution of (7.1) associated with $u\in L^2(Q)$, and $K\subset\bar{Q}$ is a compact set.

The following assumptions are required.

(A5) The function $f: Q\times\mathbb{R}\longrightarrow\mathbb{R}$ satisfies the modification of assumption (A1) that is obtained by substituting Q for Ω and (x,t) for x, respectively.

(A6) The function $L: Q\times(\mathbb{R}\times\mathbb{R})\longrightarrow\mathbb{R}$ satisfies the modified assumption (A2) obtained by substituting Q for Ω and (x,t) for x, respectively.

(A7) The function $g: K\times\mathbb{R}\longrightarrow\mathbb{R}$ is continuous and is of class C^2 with respect to the second variable, and $\partial_y g$ and $\partial_y^2 g$ are also continuous functions in $K\times\mathbb{R}$. Moreover, the strict inequality

$$\text{(7.3)}\qquad g(x,0,y_0(x))<0$$

holds for every $x\in K\cap\bar{\Omega}$.

(A8) The functions $\ell_k:[0,T]\times\mathbb{R}\longrightarrow\mathbb{R}$, $k\in\{a,b\}$, are Carathéodory functions of class C^2 with respect to the second variable with $\ell_k(\cdot,0)\in L^1(0,T)$. For all $M>0$, there exist a constant $C_M>0$ and a function $\psi_M\in L^2(0,T)$ such that

$$\left|\frac{\partial\ell_k}{\partial u}(t,y)\right|\le\psi_M(x), \quad \left|\frac{\partial^2\ell_k}{\partial y^2}(t,y)\right|\le C_M,$$
$$\left|\frac{\partial^2\ell_k}{\partial y^2}(t,y_2)-\frac{\partial^2\ell_k}{\partial y^2}(t,y_1)\right|\le C_M\,|y_2-y_1|$$

holds for $k\in\{a,b\}$ for a.e. $t\in[0,T]$ and $|y|,|y_i|\le M$, $i=1,2$.

Analogously, $r:[a,b]\times\mathbb{R}\longrightarrow\mathbb{R}$ is a Carathéodory function of class C^2 with respect to the second variable with $r(\cdot,0)\in L^1(a,b)$. It satisfies the assumptions on ℓ_k above with ℓ_k replaced by r, (a,b) substituted for $(0,T)$, and x substituted for t.

For the parabolic equation, the following result on existence and regularity holds true.

THEOREM 7.2. *Suppose that* (A5) *is satisfied. Then, for every* $u \in L^2(Q)$*, the state equation* (7.1) *has a unique solution* $y_u \in C(\bar{Q}) \cap W(0,T)$*. If* $u_k \rightharpoonup u$ *weakly in* $L^2(Q)$*, then* $y_{u_k} \to y_u$ *strongly in* $C(\bar{Q})$*.*

The proof of the theorem is postponed to section 7.4.

THEOREM 7.3. *Assume that* (A5)–(A8) *are fulfilled, the function* L *is convex with respect to the third component, and the set of feasible controls is nonempty. Then the control problem* (PP) *has at least one solution.*

This theorem is a standard consequence of Theorem 7.2.

7.2. Necessary optimality conditions. Also here, the control-to-state mapping $G(u) = y_u$, $G : L^2(Q) \to C(\bar{Q}) \cap W(0,T)$, and the reduced objective functional J are of class C^2 from $L^\infty(Q)$ to their image spaces, provided that assumptions (A5)–(A8) are satisfied. Since this is known (see [5]) we state the associated derivatives for convenience below.

We define, for $v \in L^2(Q)$, the function z_v as the unique solution to

$$
\left\{
\begin{aligned}
\frac{dz_v}{dt} + Az_v + \frac{\partial f}{\partial y}(x,t,y_u)z_v &= v \quad \text{in } Q,\\
-\partial_x z_v(a,t) &= 0 \quad \text{in } (0,T),\\
\partial_x z_v(b,t) &= 0 \quad \text{in } (0,T),\\
y(x,0) &= 0 \quad \text{in } (a,b).
\end{aligned}
\right. \tag{7.4}
$$

Then $G'(u)$, $G : L^2(Q) \to C(\bar{Q}) \cap W(0,T)$, is given by $G'(u)v = z_v$. Moreover, for v_1, $v_2 \in L^2(Q)$, we introduce $z_{v_i} = G'(u)v_i$, $i = 1, 2$, and obtain $G''(u)v_1v_2 = z_{v_1v_2}$, where $z_{v_1v_2}$ is the solution to

$$
\left\{
\begin{aligned}
\frac{dz_{v_1v_2}}{dt} + Az_{v_1v_2} + \frac{\partial f}{\partial y}(x,t,y_u)z_{v_1v_2} + \frac{\partial^2 f}{\partial y^2}(x,t,y_u)z_{v_1}z_{v_2} &= 0 \quad \text{in } Q,\\
-\partial_x z_{v_1v_2}(a,t) &= 0 \quad \text{in } (0,T),\\
\partial_x z_{v_1v_2}(b,t) &= 0 \quad \text{in } (0,T),\\
z_{v_1v_2}(x,0) &= 0 \quad \text{in } (a,b).
\end{aligned}
\right. \tag{7.5}
$$

The adjoint state $\varphi_{0u} \in W(0,T)$ associated with u and J is introduced as the unique solution to

$$
\left\{
\begin{aligned}
-\frac{d\varphi}{dt} + A^*\varphi + \frac{\partial f}{\partial y}(x,t,y_u)\varphi &= \frac{\partial L}{\partial y}(x,t,y_u,u) \quad \text{in } Q,\\
-\partial_x\varphi(a,t) &= \frac{\partial \ell_a}{\partial y}(t,y_u(a,t)) \quad \text{in } (0,T),\\
\partial_x\varphi(b,t) &= \frac{\partial \ell_b}{\partial y}(t,y_u(b,t)) \quad \text{in } (0,T),\\
\varphi(x,T) &= \frac{\partial r}{\partial y}(x,y_u(x,T)) \quad \text{in } (a,b).
\end{aligned}
\right. \tag{7.6}
$$

We have

$$J'(u)v = \int_Q \left(\frac{\partial L}{\partial u}(x,t,y_u,u) + \varphi_{0u} \right) v \, dxdt, \tag{7.7}$$

$$\begin{aligned} J''(u)v_1v_2 = \int_Q \Bigg[& \frac{\partial^2 L}{\partial y^2}(x,t,y_u,u) z_{v_1} z_{v_2} + \frac{\partial^2 L}{\partial y \partial u}(x,t,y_u,u)(z_{v_1}v_2 + z_{v_2}v_1) \\ & + \frac{\partial^2 L}{\partial u^2}(x,t,y_u,u)v_1v_2 - \varphi_{0u} \frac{\partial^2 f}{\partial y^2}(x,t,y_u) z_{v_1} z_{v_2} \Bigg] dxdt \\ & + \int_0^T \frac{\partial^2 \ell_a}{\partial y^2}(t, y_u(a,t)) z_{v_1}(a,t) z_{v_2}(a,t) \, dt \\ & + \int_0^T \frac{\partial^2 \ell_b}{\partial y^2}(t, y_u(b,t)) z_{v_1}(b,t) z_{v_2}(b,t) \, dt \\ & + \int_\Omega \frac{\partial^2 r}{\partial y^2}(x, y_u(x,T)) z_{v_1}(x,T) z_{v_2}(x,T) \, dx. \end{aligned} \tag{7.8}$$

We require the following linearized Slater condition: There exists $u_0 \in L^\infty(Q)$ with $\alpha(x,t) \le u_0(x,t) \le \beta(x,t)$ for a.e. $(x,t) \in Q$ such that

$$g(x,t,\bar y(x,t)) + \frac{\partial g}{\partial y}(x,t,\bar y(x,t)) z_{u_0-\bar u}(x,t) < 0 \quad \forall (x,t) \in K. \tag{7.9}$$

Notice that we have assumed (7.3), since this is needed to satisfy (7.9). The Hamiltonian H is defined by

$$H(x,t,y,u,\varphi) = L(x,t,y,u) + \varphi\,[u - f(x,t,y)],$$

and the first-order necessary conditions admit the following form (see Casas [5]).

THEOREM 7.4. *Let $\bar u$ be a local solution of* (PP). *Suppose that assumptions* (A5)–(A8) *hold, and assume the Slater condition* (7.9) *with some $u_0 \in L^\infty(Q)$, $\alpha(x,t) \le u_0(x,t) \le \beta(x,t)$ for a.e. $(x,t) \in Q$. Then there exist a measure $\bar\mu \in M(K)$ and a function $\bar\varphi \in L^\tau(0,T;W^{1,\sigma}(\Omega))$, for all τ, $\sigma \in [1,2)$, with $\frac{1}{\tau} + \frac{1}{\sigma} > \frac{3}{2}$, such that*

$$\begin{cases} -\dfrac{d\bar\varphi}{dt} + A^*\varphi + \dfrac{\partial f}{\partial y}(x,t,\bar y)\,\bar\varphi = \dfrac{\partial L}{\partial y}(x,t,\bar y,\bar u) + \dfrac{\partial g}{\partial y}(x,t,\bar y)\bar\mu_{|_Q}, \\ -\partial_x\bar\varphi(a,t) = \dfrac{\partial \ell_a}{\partial y}(t,y_u(a,t)) + \dfrac{\partial g}{\partial y}(a,t,\bar y(a,t))\bar\mu_{|_{\{a\}\times(0,T)}}, \\ \partial_x\bar\varphi(b,t) = \dfrac{\partial \ell_b}{\partial y}(t,\bar y(b,t)) + \dfrac{\partial g}{\partial y}(b,t,\bar y(b,t))\bar\mu_{|_{\{b\}\times(0,T)}}, \\ \bar\varphi(x,T) = \dfrac{\partial r}{\partial y}(x,\bar y(x,T)) + \dfrac{\partial g}{\partial y}(x,T,\bar y(x,T))\bar\mu_{|_{\Omega\times\{T\}}} \end{cases} \tag{7.10}$$

for a.a. $x \in (a,b)$, $t \in (0,T)$, where $\bar\mu_{|_Q}$, $\bar\mu_{|_{\{a\}\times(0,T)}}$, $\bar\mu_{|_{\{b\}\times(0,T)}}$, and $\bar\mu_{|_{\Omega\times\{T\}}}$ denote the restrictions of μ to Q, $\{a\}\times(0,T)$, $\{b\}\times(0,T)$, and $\Omega\times\{T\}$, respectively,

$$\int_K (z(x,t) - g(x,t,\bar y(x,t)))d\bar\mu(x,t) \le 0 \ \forall z \in C(K), \ \text{with } z(x,t) \le 0 \ \forall (x,t) \in K, \tag{7.11}$$

and, for almost all $(x,t) \in Q$,

$$H(x,t,\bar y(x,t),\bar u(x,t),\bar\varphi(x,t)) = \min_{s\in[\alpha_{\varepsilon\bar u}(x,t),\beta_{\varepsilon\bar u}(x,t)]} H(x,t,\bar y(x,t),s,\bar\varphi(x,t)), \tag{7.12}$$

where $\alpha_{\varepsilon\bar u}$ and $\beta_{\varepsilon\bar u}$ are defined along the lines of Theorem 3.1.

The Lagrange function is defined in a standard way by

$$\mathcal{L}(u,\mu) = \int_Q L(x,t,y_u(x,t),u(x,t))\,dxdt + \int_0^T \ell_a(t,y_u(a,t))\,dt + \int_0^T \ell_b(t,y_u(b,t))\,dt + \int_K g(x,t,y_u(x,t))\,d\mu(x,t).$$

For convenience, we establish only the second-order derivative of $\mathcal{L}$:

(7.13)
$$\begin{aligned}&\frac{\partial^2\mathcal{L}}{\partial u^2}(u,\mu)v_1v_2\\ &= \int_Q \left[\frac{\partial^2 L}{\partial y^2}(x,t,y_u,u)z_{v_1}z_{v_2} + \frac{\partial^2 L}{\partial y\partial u}(x,t,y_u,u)(z_{v_1}v_2+z_{v_2}v_1) + \frac{\partial^2 L}{\partial u^2}(x,t,y_u,u)v_1v_2\right.\\ &\quad \left. - \varphi_u\frac{\partial^2 f}{\partial y^2}(x,t,y_u)z_{v_1}z_{v_2}\right]dxdt + \int_\Omega \frac{\partial^2 r}{\partial y^2}(x,y_u(x,T))z_{v_1}(x,T)z_{v_2}(x,T)\,dx\\ &\quad + \int_0^T \left[\frac{\partial^2\ell_a}{\partial y^2}(t,y_u(a,t))z_{v_1}(a,t)z_{v_2}(a,t) + \frac{\partial^2\ell_b}{\partial y^2}(t,y_u(b,t))z_{v_1}(b,t)z_{v_2}(b,t)\right]dt\\ &\quad + \int_K \frac{\partial^2 g}{\partial y^2}(x,t,y_u(x,t))z_{v_1}(x)z_{v_2}(x)\,d\bar\mu(x,t),\end{aligned}$$

where φ_u is the solution of (7.10), where u is taken for $\bar u$, y_u instead of $\bar y$, and μ for $\bar\mu$.

7.3. Second-order sufficient optimality conditions. With the prerequisites of the preceding section at hand, the extension of the second-order sufficient optimality conditions to the parabolic case is straightforward. We define the cone of critical directions associated with $\bar u$ by

$$C_{\bar u} = \{h \in L^2(Q) : h \text{ satisfies (7.14), (7.15), and (7.16) below}\},$$

$$h(x,t) = \begin{cases} \geq 0 \text{ if } \bar u(x,t) = \alpha(x,t),\\ \leq 0 \text{ if } \bar u(x,t) = \beta(x,t),\\ = 0 \text{ if } \bar H_u(x,t) \neq 0,\end{cases} \tag{7.14}$$

$$\frac{\partial g}{\partial y}(x,t,\bar y(x,t))z_h(x,t) \leq 0 \quad \text{if} \quad g(x,t,\bar y(x,t)) = 0, \tag{7.15}$$

$$\int_K \frac{\partial g}{\partial y}(x,t,\bar y(x,t))z_h(x,t)\,d\bar\mu(x,t) = 0. \tag{7.16}$$

The sufficient second-order optimality conditions for $\bar u$ are stated in the following result.

THEOREM 7.5. *Let $\bar u$ be a feasible control of problem* (PP) *that satisfies, together with the associated state $\bar y$ and $(\bar\varphi, \bar\mu) \in L^\tau(0,T;W^{1,\sigma}(\Omega))\times M(K)$ for all τ, $\sigma \in [1,2)$, with $\frac{1}{\tau}+\frac{1}{\sigma} > \frac{3}{2}$, the first-order conditions* (7.10)–(7.12). *Assume in addition that there exist two constants $\omega > 0$ and $\tau > 0$ such that*

$$\frac{\partial^2 L}{\partial u^2}(x,t,\bar y(x,t),\bar u(x,t)) \geq \omega \quad \text{if} \quad |\bar H_u(x,t)| \leq \tau \quad \text{for a.e. } (x,t) \in Q, \tag{7.17}$$

$$\frac{\partial^2\mathcal{L}}{\partial u^2}(\bar u,\bar\mu)h^2 > 0 \quad \forall h \in C_{\bar u}\setminus\{0\}. \tag{7.18}$$

Then there exist $\varepsilon > 0$ and $\delta > 0$ such that, for every admissible control u of problem (PP)*, the following inequality holds:*

$$J(\bar u) + \frac{\delta}{2}\|u - \bar u\|^2_{L^2(Q)} \le J(u) \quad \text{if} \quad \|u - \bar u\|_{L^\infty(Q)} < \varepsilon. \tag{7.19}$$

The proof is analogous to the one of Theorem 4.1. We have to perform obvious modifications that are along the line of the ones explained in the proof of Theorem 6.5. Therefore, we skip these details.

7.4. Proof of Theorem 7.2. To prepare the proof of Theorem 7.2, we first state some results on maximal parabolic regularity of the elliptic differential operator A. In the one-dimensional case we study here, A admits the form

$$A = \frac{\partial}{\partial x}\left[a_{11}(\cdot)\frac{\partial}{\partial x}\right].$$

Let us consider A on its natural domain

$$D := D(A) = \left\{ w \in H^2(\Omega) \,:\, \frac{\partial w}{\partial x}(a) = \frac{\partial w}{\partial x}(b) = 0 \right\} \tag{7.20}$$

that is dense in $L^2(\Omega)$. It is known that, for all $\tau \in (0,1)$,

$$D(A^\tau) = \begin{cases} H^{2\tau}(\Omega) \cap \left\{ w \,:\, \dfrac{\partial w}{\partial x}(a) = \dfrac{\partial w}{\partial x}(b) = 0 \right\} & \text{if } \tau > \frac{3}{4}, \\ H^{2\tau}(\Omega), & \text{if } \tau < \frac{3}{4}; \end{cases}$$

cf. [24]. In particular, we have $D(A^{\frac12}) = H^1(\Omega)$. To shorten the notation, we write below $S := (0,T)$ with closure $\bar S$. Moreover, for a Banach space $X \subset L^1(\Omega)$ and $1 < p < \infty$, we introduce the space

$$W^{1,p}(S,X) = \left\{ y \in L^p(S,X) \,:\, \frac{\partial y}{\partial t} \in L^p(S,X) \right\}.$$

It is known that, for all $1 < p < \infty$, A exhibits maximal parabolic $L^p(S,L^p(\Omega))$-regularity. This means that, for all $f \in L^p(S,L^p(\Omega))$, there is a unique solution $y \in W^{1,p}(S,L^p(\Omega)) \cap L^p(S,D(A))$ of

$$\frac{\partial y}{\partial t} + A\,y = f \text{ in } S, \quad y(0) = 0, \tag{7.21}$$

where the differential equation is to be understood in the distributional sense; cf. [13]. Here the definition of $D(A)$ must be adapted by replacing $W^{2,p}(\Omega)$ for $H^2(\Omega)$ in (7.20). In all that follows, we apply this result with $p = 2$ for $X = H := L^2(\Omega)$. Therefore, for all $f \in L^2(S,H) \cong L^2(Q)$, there is a unique solution $y \in W^{1,2}(S,H) \cap L^2(S,D)$ of (7.21). The mapping $f \mapsto y$ is surjective and hence continuous.

Our proof relies on the following result.

LEMMA 7.6. *For all $0 < \tau < \eta < 1$ and $\kappa = \frac{\eta-\tau}{2\eta}$, there holds the continuous injection $W^{1,2}(S,H) \cap L^2(S,D) \hookrightarrow C^\kappa(S,H^\tau(\Omega))$.*

Proof. We show first that $W^{1,2}(S,H) \hookrightarrow C^{\frac12}(S,H)$. To this aim, let $y \in W^{1,2}(S,H)$ and $t,s \in \bar S$ be given. Then

$$\begin{aligned} \|y(t) - y(s)\|_H &= \left\| \int_s^t y'(\rho)\,d\rho \right\|_H \le \int_s^t \|y'(\rho)\|_H\,d\rho \\ &\le \left(\int_s^t \|y'(\rho)\|_H^2\,d\rho \right)^{\frac12} \left(\int_s^t d\rho \right)^{\frac12} \le \|y\|_{W^{1,2}(S,H)}\,|t-s|^{\frac12} \end{aligned}$$

verifies the injection claimed above. Next, we prove the statement of the lemma. We denote by $[\cdot,\cdot]_\theta$ the complex interpolation functor; see Triebel [24]. It follows from [2, Chap. III, Thm. 4.10.2] and [24, Chap. 1.8] that the continuous injection

$$W^{1,2}(S,H)\cap L^2(S,D)\hookrightarrow C(\bar S,[H,D]_{1/2})=C(\bar S,H^1(\Omega)) \tag{7.22}$$

takes place. The interpolation identity $[H,D]_{1/2}=H^1(\Omega)$ is well known and can be found, for instance, in [24].

We fix now τ and η by $0<\tau<\eta<1/2$ and put $\lambda=\tau/\eta$. Then we obtain with a generic constant c that

$$\begin{aligned}\frac{\|y(t)-y(s)\|_{[H,D]_\tau}}{|t-s|^{\frac12(1-\lambda)}} &\le c\,\frac{\|y(t)-y(s)\|_{[H,[H,D]_\eta]_\lambda}}{|t-s|^{\frac12(1-\lambda)}} \qquad (7.23)\\ &\le c\,\frac{\|y(t)-y(s)\|_H^{1-\lambda}}{|t-s|^{\frac12(1-\lambda)}}\,\|y(t)-y(s)\|^\lambda_{[H,D]_\eta}\\ &\le c\left(\frac{\|y(t)-y(s)\|_H}{|t-s|^{\frac12}}\right)^{1-\lambda}\|y(t)-y(s)\|^\lambda_{[H,D]_\eta}, \qquad (7.24)\end{aligned}$$

where we have applied the complex reiteration theorem, [24, Chap. 1.9.3]. In the last estimate, the first factor is bounded, since $W^{1,2}(S,H)\hookrightarrow C^{\frac12}(S,H)$. In view of the injection (7.22) and $[H,D]_\eta=H^{2\eta}(\Omega)$, with $0<2\eta<1$, the second factor can be estimated by

$$\begin{aligned}\|y(t)-y(s)\|^\lambda_{[H,D]_\eta}\le c\,\|y(t)-y(s)\|^\lambda_{H^{2\eta}(\Omega)} &\le \Big(2c\,\|y\|_{C(\bar S,H^{2\eta}(\Omega))}\Big)^\lambda\\ &\le \Big(c\,\|y\|_{C(\bar S,H^1(\Omega))}\Big)^\lambda\le c\,\|y\|^\lambda_{W^{1,2}(S,H)\cap L^2(S,D)}.\end{aligned}$$

In the last estimate, we have used the embedding (7.22). Moreover, we took advantage of the equivalence of the norms of $[H,D]_\eta$ and $H^{2\eta}(\Omega)$. Therefore, the second factor in (7.24) is bounded, too. The statement of the lemma follows now from (7.24) after inserting $\tau:=2\tau$, $\eta:=2\eta$, $[H,D]_\tau=H^{2\tau}(\Omega)$, and $\kappa=\frac12(1-\lambda)$ into (7.23). □

Proof of Theorem 7.2. The existence result of Theorem 7.2 is well known; we refer to Casas [5]. Therefore, we show only that weakly converging sequences of controls are transformed to strongly converging sequences of states.

Let a sequence (u_k) be given that converges weakly in $L^2(Q)$ to u. Consider the equation for y_k and u_k:

$$\begin{aligned}\frac{\partial y_k}{\partial t}+Ay_k+f(x,y_k)&=u_k \quad \text{in } Q,\\ \frac{\partial y_k}{\partial x}(a,t)&=0 \quad \text{in } S,\\ \frac{\partial y_k}{\partial x}(b,t)&=0 \quad \text{in } S,\\ y_k(0)&=y_0 \quad \text{in } \Omega.\end{aligned}$$

Standard arguments show that $y_k\rightharpoonup y$ in $W(0,T)\cap C(\bar Q)$, where $y=y_u$. The functions y_k are uniformly bounded in $C(\bar Q)$, hence the sequence $\big(d(\cdot,y_k)\big)$ is bounded in $L^2(Q)$, and we can select a weakly converging subsequence indexed by k_l. We write $f_k=u_k-d(\cdot,y_k)$ and split $y_k=v+w_k$, where w_k solves

$$\frac{\partial w_k}{\partial t}+Aw_k=f_k$$

with homogeneous inital and boundary conditions, while v solves

$$\frac{\partial v}{\partial t} + Av = 0$$

with inhomogeneous initial condition $v(0) = y_0$ and homogeneous boundary conditions. Thanks to Lemma 7.6, the sequence (w_{k_l}) converges weakly in $C^\kappa(S, H^\tau(\Omega))$, where $\kappa > 0$ and $\tau > 1/2$ can be chosen. Therefore, the functions w_{k_l} belong to a space $C^\sigma(\bar{Q})$ with some positive σ so that, by compact embedding into $C(\bar{Q})$, the sequence converges strongly in $C(\bar{Q})$. Consequently, $y_{k_l} = v + w_{k_l}$ converges strongly in $C(\bar{Q})$ towards y. Moreover, it follows by standard arguments that $y = y_u$. Since this holds for all subsequences with the same limit y, the whole sequence (y_k) converges uniformly to y_u. □

Acknowledgment. The authors are grateful to J. Rehberg (Weierstrass Institute Berlin (WIAS)) for pointing out the proof of Lemma 7.6.

ON STABLE FEASIBLE SETS IN GENERALIZED SEMI-INFINITE PROGRAMMING*

HARALD GÜNZEL†, HUBERTUS TH. JONGEN†, AND JAN-J. RÜCKMANN‡

Abstract. We consider the feasible set of a generalized semi-infinite programming problem with a one-dimensional index set of inequality constraints depending on the state variable. The latter dependence on the state variable gives rise to a complicated structure of the feasible set. Under appropriate transversality conditions we partially present the local description of feasible sets in new coordinates by means of the finitely many basic functions.

Key words. generalized semi-infinite programming, feasible set, transversal zero-point, transversality, normal form

DOI. 10.1137/070694259

1. Introduction.

We consider the feasible set M of a generalized semi-infinite programming (GSIP) problem, which is defined as

$$M := \{x \in \mathbb{R}^n \mid v_0(x,y) \geq 0,\ y \in Y(x)\}$$

with the index set

$$Y(x) := \{y \in \mathbb{R} \mid v_i(x,y) \geq 0,\ i \in I = \{1,\dots,p\}\}.$$

For $x \in \mathbb{R}^n$ define the corresponding set of active constraints as

$$Y_0(x) := \{y \in Y(x) \mid v_0(x,y) = 0\}.$$

In GSIP the index set $Y(x)$ may depend on the state variable x. This is in contrast to standard semi-infinite programming (SIP) where the corresponding index set is fixed. GSIP became in recent years a substantial research area in mathematical programming. There exists a wide range of applications, we refer, e.g., to design-centering problems, reverse Chebyshev approximation, robust optimization, time-minimal control problems, and others. For a more detailed study see, e.g., the recent book [11] and the compilations [2], [10].

Throughout the paper we make the following two assumptions.

(A1) The set-valued mapping $x \in \mathbb{R}^n \mapsto Y(x) \subset \mathbb{R}$ is upper-semicontinuous in the sense of Berge [1], and $Y(x)$ is compact.

(A2) $v_i \in C^\infty(\mathbb{R}^n \times \mathbb{R}, \mathbb{R}),\ i = 0,\dots,p.$

Assumption (A1) is an usual assumption in GSIP. If $\bar{x} \in M$ and $Y_0(\bar{x}) = \emptyset$, then (A1) implies that $\bar{x} \in \operatorname{int} M$. We assume (A2) in order to avoid unnecessary technicalities. Note that (A2) is a mild differentiability assumption since the C^∞-functions are C^l_s-dense in the space of C^l-functions (here, C^l_s denotes the strong (Whitney) C^l-topology [5]).

The feasible set M in GSIP may exhibit some topological properties which do not appear in standard SIP, e.g.,

- M need not be closed;
- M may have a disjunctive structure (for details see [3], [6], [7], and [11]).

If $\bar{x} \in M$, then each $\bar{y} \in Y_0(\bar{x})$ is a global minimizer of the function $v_0(\bar{x}, .)$ subject to $y \in Y(\bar{x})$. By using the corresponding optimal value function, M can be described as

$$M = \{x \in \mathbb{R}^n \mid \min_{y \in Y(x)} v_0(x, y) \geq 0\}.$$

In the case where $Y(\bar{x}) = \emptyset$, the minimum in the latter description of M is defined to be ∞; in particular, in that case $\bar{x}$ belongs to M. If for $\bar{x} \in M$ each $y \in Y_0(\bar{x})$ is a nondegenerate minimizer of $v_0(\bar{x}, .)$ restricted to $Y(\bar{x})$, then the so-called reduction approach is available and in a neighborhood of $\bar{x}$ the set M can be described by finitely many differentiable functions (e.g., [4], [9]). Unfortunately, one cannot avoid degenerate minimizers $y \in Y_0(x)$ for some $x \in M$. Moreover, some of these degeneracies also remain stable under small perturbations.

The goal of this paper is to describe the local structure of M around $\bar{x} \in \partial M$ (the boundary of M) in new coordinates by means of the finitely many basic functions. If $\bar{x} \in \operatorname{int} M$, then the local structure of M is trivial since an open neighborhood of $\bar{x}$ belongs completely to M. The knowledge of the local structure of M gives insight into the complicated structure of this type of optimization problem, and might be useful for the design of corresponding solution methods.

DEFINITION 1. *Let $v \in C^\infty(\mathbb{R}^n \times \mathbb{R}, \mathbb{R})$. For $k \geq 1$, a point $\bar{y} \in \mathbb{R}$ is called a* zero-point *for $v(\bar{x}, .)$* of an order *k, if the following holds at $(\bar{x}, \bar{y})$:*

$$\left(\frac{\partial}{\partial y}\right)^i v = 0, \ i = 0, \ldots, k-1, \quad \left(\frac{\partial}{\partial y}\right)^k v \neq 0. \tag{1}$$

Moreover, the zero-point $\bar{y}$ for $v(\bar{x}, .)$ of an order k is called transversal*, if in addition to* (1)*, the Jacobian matrix with respect to (x, y) of the system of the equations $(\frac{\partial}{\partial y})^i v = 0$, $i = 0, \ldots, k-1$, has rank k at $(\bar{x}, \bar{y})$.*

The local description of M around $\bar{x} \in \partial M$ may become extremely complicated if the functions $v_i(\bar{x}, .)$, $i = 0, \ldots, p$, have the zero-points of arbitrary order. Therefore, we restrict our forthcoming analysis to the four most simple cases, where $\bar{x} \in \partial M$ and $\bar{y} \in Y(\bar{x})$ (note: If $Y(\bar{x}) = \emptyset$, then $\bar{x} \in M$ with $Y_0(\bar{x}) = \emptyset$, and, hence $\bar{x} \in \operatorname{int} M$). In the following we present a first characterization of these four cases; their complete definitions will be given in section 3.

Case A. $\bar{y}$ is a transversal zero-point for $v_0(\bar{x}, .)$ of an order k, $k \geq 2$, and $v_i(\bar{x}, \bar{y}) > 0$, $i \in I$.

Case B. $\bar{y}$ is a transversal zero-point for $v_0(\bar{x}, .)$ of an order k, $k \geq 2$, there exists an index $i_0 \in I$ such that $\bar{y}$ is a transversal zero-point for $v_{i_0}(\bar{x}, .)$ of an order one, and $v_i(\bar{x}, \bar{y}) > 0$, $i \in I \setminus \{i_0\}$.

Case C. $\bar{y}$ is a transversal zero-point for $v_i(\bar{x}, .)$ of an order one for each $i \in \{0\} \cup I$ with $v_i(\bar{x}, \bar{y}) = 0$.

Case D. The set $\{i \in I \mid v_i(\bar{x}, \bar{y}) = 0\}$ is a singleton, say $\{1\}$, and

- either $v_0(\bar{x}, \bar{y}) \neq 0$ and $\bar{y}$ is a transversal zero-point for $v_1(\bar{x}, .)$ of an order two,
- or $v_0(\bar{x}, \bar{y}) = 0$ and with $\{i_1, i_2\} = \{0, 1\}$, $\bar{y}$ is a transversal zero-point for $v_{i_1}(\bar{x}, .)$ of an order two and a transversal zero-point for $v_{i_2}(\bar{x}, .)$ of an order one or two.

Remark 2. The local analysis of these four cases will describe the existence of the above-mentioned phenomena (nonclosedness and the disjunctive structure of M) while a further analysis which includes the zero-points of higher order would only illustrate that the local fine structure of M becomes more complicated. This can already be seen by comparing the analysis of Cases A, B, and C with that of Case D. In this sense, the choice of these four cases can be considered as complete.

The results of this paper can be extended to the more general case, where M is described by finitely many equality constraints and finitely many inequality constraints of the type $v_0(x,y) \geq 0$, $y \in Y(x)$.

This paper is organized as follows. Section 2 contains some basic results, and section 3 presents the discussion of the four cases and a decomposition theorem in which the feasible set M around $\bar{x} \in \partial M$ is locally described in new coordinates by means of the finitely many basic functions. Since this decomposition theorem mainly uses a transversality condition, the description of M remains stable under sufficiently small smooth perturbations of the defining functions.

2. Basic results. We start with a definition and a lemma that is a consequence of [8], Lemma 1.

DEFINITION 3. *A local C^∞-coordinate transformation on $\mathbb{R}^n \times \mathbb{R}$, mapping $(x,y) \mapsto (u,w)$, is called* admissible*, if it can be written in the form*

$$\begin{aligned} u &= \xi^1(x), \\ w &= \xi^2(x,y). \end{aligned}$$

LEMMA 4. *Let $v \in C^\infty(\mathbb{R}^n \times \mathbb{R}, \mathbb{R})$, $\bar{x} \in \mathbb{R}^n$, and let $\bar{y} \in \mathbb{R}$ be a transversal zero-point for $v(\bar{x},.)$ of an order k, $k \geq 2$. Let $\varepsilon := \operatorname{sign}(\frac{\partial}{\partial y})^k v(\bar{x},\bar{y})$. Then, there exists an admissible C^∞-coordinate transformation sending $(\bar{x},\bar{y})$ to $(0,0)$ such that v has in new coordinates the form*

$$\varepsilon y^k + \sum_{i=1}^{k-1} x_i y^{k-1-i}, \tag{2}$$

where the new coordinates are again denoted by x and y. Let the associated set of vectors $S(\bar{y})$ be defined as

$$S(\bar{y}) := \left\{ \left(\frac{\partial}{\partial y} \right)^i v_x(\bar{x},\bar{y}),\ i = 0, \ldots, k-2 \right\}$$

(v_x denotes the partial derivative of v with respect to x). Then, the vectors in $S(\bar{y})$ are linearly independent.

Remark 5. Let $\varepsilon = 1$, and k be even. Then, the local optimal value function $\min_y v(x,y)$, takes in new coordinates the form

$$x \mapsto \eta^{k-1}(x_1, \ldots, x_{k-1}) = \min_{y \in [-1,1]} y^k + \sum_{i=1}^{k-1} x_i y^{k-1-i}. \tag{3}$$

In particular, if $k = 2$, we have $\eta^1(x_1) = x_1$.

Remark 6. The associated set $S(\bar{y})$ is related to a fundamental part of the Jacobian matrix $D\xi^1(\bar{x})$. Moreover, $\frac{\partial}{\partial y}\xi^2(\bar{x},\bar{y}) > 0$. See [8] for details.

As done in the lemma, we will always denote the resulting coordinates after an admissible coordinate transformation for (x,y) by (x,y).

Now, we consider the following special situation, which will be related later to case D. Let $\bar{x} \in \mathbb{R}^n$, and let $\bar{y} \in \mathbb{R}$ be a zero-point for $v_0(\bar{x}, .)$ of an order two and a zero-point for $v_1(\bar{x}, .)$ of an order two such that $v_i(\bar{x}, \bar{y}) > 0$ for $i = 2, \ldots, p$. Furthermore, assume that the Jacobian matrix of the system

$$v_0 = 0, \quad v_1 = 0, \quad v_{0,y} = 0, \quad v_{1,y} = 0$$

has rank four at $(\bar{x}, \bar{y})$ (by $v_{0,x}$, $v_{0,y}$, $v_{0,xx}$, $v_{0,xy} \ldots$ we denote the corresponding partial derivatives of v_0). Omitting all arguments $(\bar{x}, \bar{y})$ the latter Jacobian is the first entry in (4), and since the following matrices in (4)–(5) are the results of simple row manipulations, the matrix in (5) also has rank four:

$$\begin{pmatrix} v_{0,x} & 0 \\ v_{1,x} & 0 \\ v_{0,yx} & v_{0,yy} \\ v_{1,yx} & v_{1,yy} \end{pmatrix} \qquad \begin{pmatrix} v_{0,x} & 0 \\ v_{1,x} & 0 \\ v_{0,yx}(v_{0,yy})^{-1} & 1 \\ v_{1,yx}(v_{1,yy})^{-1} & 1 \end{pmatrix} \tag{4}$$

$$\left(\begin{array}{l|l} v_{0,x} & 0 \\ v_{1,x} & 0 \\ v_{0,yx}(v_{0,yy})^{-1} - v_{1,yx}(v_{1,yy})^{-1} & 0 \\ \hline v_{1,yx}(v_{1,yy})^{-1} & 1 \end{array}\right). \tag{5}$$

The rows of the upper-left submatrix, marked in (5), must therefore be linearly independent. They form the associated set of vectors

$$S(\bar{y}) := \left\{ v_{0,x},\ v_{1,x},\ v_{0,yx}(v_{0,yy})^{-1} - v_{1,yx}(v_{1,yy})^{-1} \right\}.$$

Let $y_i(x)$ denote the locally unique solution of the system $v_{i,y}(x, .) = 0$, $i = 0, 1$ for x close to $\bar{x}$. Applying the chain rule, one obtains

$$Dy_i(x) = -v_{i,yx}(v_{i,yy})^{-1}\big|_{y=y_i(x)}, \quad i = 0, 1.$$

Hence, $S(\bar{y})$ is linearly independent if and only if the Jacobian at $x = \bar{x}$ of the mapping $x \mapsto (v_0(x, y_0(x)),\ v_1(x, y_1(x)),\ y_1(x) - y_0(x))$ has rank three. The latter mapping is related to the coordinate transformation in the following lemma.

LEMMA 7. *Let the assumptions of the above special situation be satisfied. Then, there exists an admissible local C^∞-coordinate transformation sending $(\bar{x}, \bar{y})$ to $(0, 0)$ such that in the new coordinates the functions v_0, v_1 take the form:*

$$\begin{aligned} v_0(x, y) &= \pm y^2 \mp x_1, \\ v_1(x, y) &= \alpha(x, y)(y - x_2)^2 + x_3, \end{aligned}$$

where $\alpha \in C^\infty(\mathbb{R}^n \times \mathbb{R}, \mathbb{R})$ with $\alpha(0, 0) \neq 0$.

Proof. First we show that there exists a local representation of v_i with smooth functions γ_i, $\gamma_i(\bar{x}, \bar{y}) \neq 0$, $i = 0, 1$ such that

$$v_i(x, y) = \gamma_i(x, y)(y - y_i(x))^2 + v_i(x, y_i(x)). \tag{6}$$

The formula (6) can be derived as follows (omitting the index i):

$$\begin{aligned} v(x, y) &= v(x, y) - v(x, y(x)) + v(x, y(x)) \\ v(x, y) - v(x, y(x)) &= \int_0^1 \frac{d}{dt} v(x, ty + (1 - t)y(x))dt \\ &= \int_0^1 v_y(x, ty + (1 - t)y(x))(y - y(x))dt \\ &= (y - y(x))h(x, y), \end{aligned} \tag{7}$$

where $h(x,y)$ stands for the part separated by $y - y(x)$. Noting $h(x,y(x)) = 0$, we can use the same integral representation for $h(x,y)$, obtaining (with $\gamma(x,y)$ denoting the analogous part separated by $y - y(x)$)

$$h(x,y) = (y - y(x))\gamma(x,y). \tag{8}$$

Substituting (8) in (7), we get (6).

Now we take $(y - y_0(x))\sqrt{|\gamma_0(x,y)|}$ as a new y-coordinate and $v_0(x, y_0(x))$ as new x-coordinate, say, x_1 if $\gamma_0(\bar{x},\bar{y}) < 0$ (or $-x_1$ if $\gamma_0(\bar{x},\bar{y}) > 0$). Let $\tilde{v}_1$ denote the function v_1 in the new coordinates, and let $\tilde{y}_1(x)$ be the corresponding solution of $\tilde{v}_{1,y}(x,.) = 0$ for x near $\bar{x}$. In an analogous way as in (6) we can write $\tilde{v}_1$ as follows:

$$\tilde{v}_1(x,y) = \tilde{\gamma}_1(x,y)(y - \tilde{y}_1(x))^2 + \tilde{v}_1(x, \tilde{y}_1(x)).$$

Finally, we take $\tilde{y}_1(x)$ and $\tilde{v}_1(x,\tilde{y}_1(x))$ as new coordinates, say, x_2 and x_3 (without affecting x_1 and y). Then, the linear independence of the vectors in $S(\bar{y})$ guarantees that the above procedure results in an admissible local C^∞-coordinate transformation, indeed. This completes the proof. □

3. Main results.

3.1. The four cases. In this subsection we will discuss the cases A, B, C, and D mentioned in section 1. Throughout this subsection we assume that $\bar{x} \in \partial M$, $\bar{y} \in Y(\bar{x})$ (hence $v_i(\bar{x},\bar{y}) \geq 0$, $i \in I$), and that the set

$$I^* := \{i \in \{0\} \cup I \mid v_i(\bar{x},\bar{y}) = 0\}$$

is nonempty. Note that $\bar{x}$ need not be feasible since M is not necessarily closed. If $\bar{y}$ is a transversal zero-point for $v_i(\bar{x},.)$ of an order k for some $i \in I^*$, then let $y_i(x)$ denote the locally unique solution of $(\frac{\partial}{\partial y})^{k-1} v_i(x,.) = 0$ (with $y_i(\bar{x}) = \bar{y}$). Furthermore, if the functions v_i, $i \in \{0\} \cup I$, or their derivatives are evaluated at $(\bar{x},\bar{y})$, then we omit the argument $(\bar{x},\bar{y})$ in the remainder of this paper. Moreover, all considered coordinate transformations in this subsection will be admissible.

In what follows we will define certain sets M^k, $k = 1,\ldots,11$. These sets partially describe the feasible set M. In fact, they define local normal forms, say, basic sets. Finally, the feasible set will be the intersection of such basic sets (see section 3.2).

Case A. $I^* = \{0\}$ and $\bar{y}$ is a transversal zero-point for $v_0(\bar{x},.)$ of an order k, $k \geq 2$.

Then, the associated set of vectors $S(\bar{y})$ is

$$S(\bar{y}) = \left\{ \left(\frac{\partial}{\partial y}\right)^i v_{0,x},\ i = 0,\ldots,k-2 \right\},$$

and its cardinality $|S(\bar{y})|$ is called the *rank of* $\bar{y}$, i.e., we have $\operatorname{rank}(\bar{y}) = k - 1$. Since $\bar{x} \in \partial M$, $\bar{y}$ is a transversal zero-point for $v_0(\bar{x},.)$ of an even order with $\varepsilon = 1$ (recall that, $\varepsilon := \operatorname{sign}(\frac{\partial}{\partial y})^k v_0$) and, by Lemma 4, there exists an admissible local coordinate transformation sending $(\bar{x},\bar{y})$ to $(0,0)$ such that the local optimal value function takes the form $\eta^{k-1}(x_1,\ldots,x_{k-1})$ (in (3)).

We say that $\bar{y}$ is of *Type* 1 and define the set

$$M^1(x_1,\ldots,x_{k-1}) := \left\{x \in U \mid \eta^{k-1}(x_1,\ldots,x_{k-1}) \geq 0\right\}$$

for an appropriate neighborhood U of $0 \in \mathbb{R}^n$. In particular, if $k = 4$, then the set M^1 is the upper part of the so-called swallow tail (see [8], where a picture is also included).

Case B. $\bar{y}$ is a transversal zero-point for $v_0(\bar{x}, .)$ of an order k, $k \geq 2$; there exists an index $i_0 \in I$ (say $i_0 = 1$) such that $I^* = \{0, 1\}$, and $\bar{y}$ is a transversal zero-point for $v_1(\bar{x}, .)$ of an order one. Furthermore, the Jacobian matrix of the system

$$\left(\frac{\partial}{\partial y}\right)^i v_0 = 0, \quad i = 0, \ldots, k-1, \quad v_1 = 0$$

has rank $k + 1$.

The associated set of vectors $S(\bar{y})$ is

$$S(\bar{y}) = \left\{ \left(\frac{\partial}{\partial y}\right)^{k-1} v_{0,x} \left[\left(\frac{\partial}{\partial y}\right)^k v_0\right]^{-1} - v_{1,x}(v_{1,y})^{-1}, \ \left(\frac{\partial}{\partial y}\right)^i v_{0,x}, \ i = 0, \ldots, k-2 \right\},$$

and we have $\operatorname{rank}(\bar{y}) = k$.

The linear independence of the vectors in $S(\bar{y})$ implies that the following C^∞-coordinate transformation is admissible. First, by Lemma 4, in new coordinates, v_0 takes the form

$$\varepsilon y^k + \sum_{i=1}^{k-1} x_i y^{k-i-1},$$

and we obtain $y_0(x) = 0$ for x near $\bar{x}$. Then, we take $y_1(x)$ $(= y_1(x) - y_0(x))$ as a new x-coordinate, say, x_k.

Note that $\operatorname{sign} v_{1,y}$ is invariant under the former admissible coordinate transformation, since $\frac{\partial}{\partial y}\xi^2(\bar{x}, \bar{y}) > 0$. If $v_{1,y} > 0$, then we say that $\bar{y}$ is of *Type* 2 and define the set

$$M^2(x_1, \ldots, x_k) := \left\{ x \in U \mid \min_{y \in [x_k, 1]} y^k + \sum_{i=1}^{k-1} x_i y^{k-i-1} \geq 0 \right\},$$

where, without loss of generality, we have taken (and will also take in the following cases) the same neighborhood U of $0 \in \mathbb{R}^n$ as for M^1 (see [8] for a picture of M^2). Note that in the latter case we have $\varepsilon = 1$.

If $v_{1,y} < 0$, then we say the $\bar{y}$ is of *Type* 3 and define the set

$$M^3(x_1, \ldots, x_k) := \left\{ x \in U \mid \min_{y \in [-1, x_k]} (-1)^k y^k + \sum_{i=1}^{k-1} x_i y^{k-i-1} \geq 0 \right\}.$$

In the latter case there exist the following two options: Either k is even and $\varepsilon = 1$, or k is odd and $\varepsilon = -1$.

Remark 8. In [8], the index y belongs to a fixed interval Y. In our context, the boundary points of $Y(x)$ may vary as a function of the state variable x. This is the reason why, in the definitions of the sets M^2, M^3, the variable boundary x_k appears.

Case C. $\bar{y}$ is a transversal zero-point for $v_i(\bar{x}, .)$ of an order one, $i \in I^*$, and the Jacobian matrix of the system

$$v_i = 0, \quad i \in I^*$$

has rank $|I^*|$.

We define the sets $I_0 := I^* \cap I$, $I_0^+ := \{i \in I_0 \mid v_{i,y} > 0\}$, and $I_0^- := I_0 \setminus I_0^+$ and consider the following two subcases.

Subcase C1. $0 \notin I^*$.

If $v_0 > 0$, then $v_0(x, y) > 0$ for all x near $\bar{x}$ and all $y \in Y(x)$ locally around $\bar{y}$.

Now, let $v_0 < 0$. If $I_0^+ = \emptyset$ or $I_0^- = \emptyset$, then $\bar{x} \in \text{int } \complement M$, where $\complement M := \mathbb{R}^n \setminus M$. Next, let I_0^+ and I_0^- both be nonempty. Furthermore, let $I_0 =: \{1, \ldots, k\}$, $k \in I_0^+$ and define the associated set of vectors $S(\bar{y})$ as

$$S(\bar{y}) := \left\{ v_{k,x}(v_{k,y})^{-1} - v_{i,x}(v_{i,y})^{-1} \mid i = 1, \ldots, k-1 \right\}.$$

The vectors in $S(\bar{y})$ are linearly independent, and we put $\text{rank}(\bar{y}) = k - 1$. Note that $\bar{x} \notin M$ (since $\bar{y} \in Y(\bar{x})$ and $v_0 < 0$)!

Obviously, if $\bar{x} \in \partial M$, then there exist indices $i \in I_0^-$ and $j \in I_0^+$ with $y_i(x) < y_j(x)$ for some x near $\bar{x}$. After choosing $y_i(x) - y_k(x)$ as new x-coordinates x_i, $i = 1, \ldots, k-1$, we say that $\bar{y}$ is of *Type* 4 and define the set:

$$M^4(x_1, \ldots, x_{k-1}) := \bigcup_{i \in I_0^-} \{x \in U \mid x_i < 0\} \cup \left\{ x \in U \mid \exists\, i \in I_0^-, j \in I_0^+ \setminus \{k\} :\ x_i < x_j \right\}.$$

Note that M^4 (as well as some further sets M^i, $i \geq 5$ to be defined) are related to both of the topological features of M mentioned in section 1: It has a disjunctive structure, and its constraints do not describe a closed set.

Subcase C2. $0 \in I^*$.

If $I_0 = \emptyset$, then we have $\bar{x} \in \text{int } \complement M$. Now, let $I_0 =: \{1, \ldots, k\}$ with $k \geq 1$, define

$$S(\bar{y}) := \left\{ v_{0,x}(v_{0,y})^{-1} - v_{i,x}(v_{i,y})^{-1} \mid i = 1, \ldots, k \right\},$$

and hence, $\text{rank}(\bar{y}) = k$.

First, let $v_{0,y} > 0$ and define the new x-coordinates $x_i := y_i(x) - y_0(x)$, $i = 1, \ldots, k$. Assume for the moment that $I_0^+ \neq \emptyset$ and $I_0^- \neq \emptyset$. Then, locally around $\bar{y}$, the set $Y(\bar{x})$ reduces to the singleton $\{\bar{y}\}$. If there exist indices $i \in I_0^-$ and $j \in I_0^+$ with $x_i < x_j$, then $Y(x)$ becomes empty locally around $\bar{y}$. If $Y(x)$ is not empty around $\bar{y}$, we must have $x_i \geq x_j$ for all $i \in I_0^-$ and $j \in I_0^+$. In the latter case, it is necessary for the feasibility of x to have $\max\{x_j \mid j \in I_0^+\} \geq 0$. Now, we define the set:

$$\begin{aligned} M^5(x_1, \ldots, x_k) := {} & \textstyle\bigcup_{i \in I_0^-,\ j \in I_0^+} \{x \in U \mid x_i < x_j\} \\ & \cup \left\{ x \in U \mid x_j \leq x_i,\ i \in I_0^-,\ j \in I_0^+,\ \max\{x_j \mid j \in I_0^+\} \geq 0 \right\}. \end{aligned}$$

If $I_0^+ = I_0$, the latter set reduces to

$$M^5(x_1, \ldots, x_k) = \left\{ x \in U \mid \max\{x_j \mid j \in I_0^+\} \geq 0 \right\}.$$

The case $I_0^- = I_0$ is not possible, since it would imply $\bar{x} \in \text{int}\, \complement M$. Altogether, if $v_{0,y} > 0$, we say that $\bar{y}$ is of *Type* 5, and we have $\text{rank}(\bar{y}) = k$.

Now, let $v_{0,y} < 0$ and define the new x-coordinates $x_i := y_i(x) - y_0(x)$, $i = 1, \ldots, k$. If $I_0^+ \neq \emptyset$ and $I_0^- \neq \emptyset$, then, by analogous arguments, we define the set:

$$\begin{aligned} M^6(x_1, \ldots, x_k) \quad := \quad & \textstyle\bigcup_{i \in I_0^-,\ j \in I_0^+} \{x \in U \mid x_i < x_j\} \\ & \cup \left\{ x \in U \mid x_j \leq x_i,\ i \in I_0^-,\ j \in I_0^+,\ \min\{x_i \mid i \in I_0^-\} \leq 0 \right\}. \end{aligned}$$

For $I_0^- = I_0$, the latter set reduces to

$$M^6(x_1, \ldots, x_k) = \left\{ x \in U \mid \min\{x_i \mid i \in I_0^-\} \leq 0 \right\}.$$

If $v_{o,y} < 0$, we say that $\bar{y}$ is of *Type* 6, and we have $\text{rank}(\bar{y}) = k$.

Case D. The set I_0 is a singleton, say, $I_0 = \{1\}$, and

- either $I^* = \{1\}$, and $\bar{y}$ is a transversal zero-point for $v_1(\bar{x}, .)$ of an order two;
- or $I^* = \{0, 1\}$, and there exist indices $i_1, i_2 \in I^*$ such that $\bar{y}$ is a transversal zero-point for $v_{i_1}(\bar{x}, .)$ of order two, and a transversal zero-point for $v_{i_2}(\bar{x}, .)$ of an order one or two.

Furthermore, a corresponding rank condition for the Jacobian matrix is satisfied (to be specified).

We consider four subcases.

Subcase D1. $I^* = \{1\}$.

If $v_0 > 0$, then $v_0(x, y) > 0$ for all x near $\bar{x}$ and all $y \in Y(x)$ locally around $\bar{y}$. Now, let $v_0 < 0$ and $v_{1,yy} < 0$ ($v_{1,yy} > 0$ implies $\bar{x} \in \operatorname{int} \complement M$). Note that $\bar{x} \notin M$. We have $S(\bar{y}) = \{v_{1,x}\}$ and, by Lemma 4, in new coordinates the function v_1 takes the form $-y^2 + x_1$. We define the set:

$$M^7(x_1) := \{x \in U \mid x_1 < 0\}.$$

We say that $\bar{y}$ is of *Type* 7, and we have $\operatorname{rank}(\bar{y}) = 1$.

Subcase D2. $I^* = \{0, 1\}$, and $\bar{y}$ is a transversal zero-point for $v_0(\bar{x}, .)$ of an order one, and a transversal zero-point for $v_1(\bar{x}, .)$ of an order two. Furthermore, the Jacobian matrix of the system

$$v_0 = 0, \quad v_1 = 0, \quad v_{1,y} = 0$$

has rank 3.

Then, define

$$S(\bar{y}) := \left\{v_{1,yx}(v_{1,yy})^{-1} - v_{0,x}(v_{0,y})^{-1},\ v_{1,x}\right\}.$$

We have $v_{1,yy} < 0$ ($v_{1,yy} > 0$ would imply $\bar{x} \in \operatorname{int} \complement M$) and, by Lemma 4, in new coordinates, v_1 takes the form $-y^2 + x_1$ (here, $v_1(x, y_1(x))$ is the new coordinate x_1). First, let $v_{0,y} > 0$. We take $y_0(x)$ ($= y_0(x) - y_1(x)$) as a new x-coordinate, say, x_2. Now, if $x_1 < 0$, then $Y(x)$ becomes empty locally around $\bar{y}$. If $x_1 \geq 0$, then for the feasibility of x one needs that $x_2 \leq -\sqrt{x_1}$. Therefore, we define the set:

$$M^8(x_1, x_2) := \{x \in U \mid x_1 < 0\} \cup \{x \in U \mid x_1 \geq 0,\ x_2 \leq -\sqrt{x_1}\}.$$

If $v_{0,y} < 0$, then take $-y_0(x)$ ($= -y_0(x) + y_1(x)$) as the new coordinate x_2, and we obtain the same description M^8. We say that $\bar{y}$ is of *Type* 8, and we have $\operatorname{rank}(\bar{y}) = 2$.

Subcase D3. $I^* = \{0, 1\}$, and $\bar{y}$ is a transversal zero-point for $v_0(\bar{x}, .)$ of an order two, and a transversal zero-point for $v_1(\bar{x}, .)$ of an order one. Furthermore, the Jacobian matrix of the system

$$v_0 = 0, \quad v_{0,y} = 0, \quad v_1 = 0$$

has rank 3. This case is already included in Case B (for $k = 2$).

Subcase D4. $I^* = \{0, 1\}$, and $\bar{y}$ is a transversal zero-point for $v_i(\bar{x}, .)$ of an order two, $i = 0, 1$. The Jacobian matrix of the system

$$v_0 = 0, \quad v_{0,y} = 0, \quad v_1 = 0, \quad v_{1,y} = 0$$

has rank 4.

Then, we define the set:

$$S(\bar{y}) := \left\{v_{0,x},\ v_{1,x},\ v_{0,yx}(v_{0,yy})^{-1} - v_{1,yx}(v_{1,yy})^{-1}\right\}.$$

By Lemma 7, in new coordinates, the functions v_0, v_1 take the form:

$$\begin{aligned} v_0(x,y) &= \pm y^2 \mp x_1, \\ v_1(x,y) &= \alpha(x,y)(y-x_2)^2 + x_3, \end{aligned}$$

where $\alpha \in C^\infty(\mathbb{R}^n \times \mathbb{R}, \mathbb{R})$ with $\alpha(0,0) \neq 0$.

First, let $v_{0,yy} > 0$ and $v_{1,yy} > 0$. For $x_1 \leq 0$ we obtain locally $v_0(x,y) \geq 0$. If $x_1 > 0$, then for the feasibility of x one needs $v_1(x, \sqrt{x_1}) \leq 0$ and $v_1(x, -\sqrt{x_1}) \leq 0$. Then, define

$$\begin{aligned} M^9(x_1,x_2,x_3) := \{x \in U \mid x_1 \leq 0\} \cup \\ \cup \left\{ x \in U \;\middle|\; \begin{array}{r} x_1 > 0,\ \alpha(x,\sqrt{x_1})(\sqrt{x_1}-x_2)^2 + x_3 \leq 0 \\ \alpha(x,-\sqrt{x_1})(-\sqrt{x_1}-x_2)^2 + x_3 \leq 0 \end{array} \right\}. \end{aligned}$$

We say that $\bar{y}$ is of *Type* 9, and we have $\operatorname{rank}(\bar{y}) = 3$.

Now let $v_{0,yy} > 0$ and $v_{1,yy} < 0$. As in the latter case, locally we obtain $v_0(x,y) \geq 0$ for $x_1 \leq 0$. If $x_3 < 0$, then $Y(x)$ is empty locally around $\bar{y}$. If $x_1 > 0$ and $x_3 \geq 0$, then for the feasibility of x one needs

$$\begin{aligned} v_1(x,\sqrt{x_1}) \leq 0 \qquad &\text{and} \quad v_{1,y}(x,\sqrt{x_1}) \geq 0 \quad \text{or} \\ v_1(x,-\sqrt{x_1}) \leq 0 \qquad &\text{and} \quad v_{1,y}(x,-\sqrt{x_1}) \leq 0. \end{aligned}$$

Therefore, define

$$\begin{aligned} M^{10}(x_1,x_2,x_3) := \{x \in U \mid x_1 \leq 0\} \cup \{x \in U \mid x_3 < 0\} \\ \cup \left\{ x \in U \;\middle|\; \begin{array}{l} x_1 > 0,\ x_3 \geq 0,\ \alpha(x,\sqrt{x_1})(\sqrt{x_1}-x_2)^2 + x_3 \leq 0 \\ \dfrac{\partial}{\partial y}\left(\alpha(x,y)(y-x_2)^2 + x_3\right)|_{y=\sqrt{x_1}} \geq 0 \end{array} \right\} \\ \cup \left\{ x \in U \;\middle|\; \begin{array}{l} x_1 > 0,\ x_3 \geq 0,\ \alpha(x,-\sqrt{x_1})(-\sqrt{x_1}-x_2)^2 + x_3 \leq 0 \\ \dfrac{\partial}{\partial y}\left(\alpha(x,y)(y-x_2)^2 + x_3\right)|_{y=-\sqrt{x_1}} \leq 0 \end{array} \right\}. \end{aligned}$$

We say that $\bar{y}$ is of *Type* 10, and we have $\operatorname{rank}(\bar{y}) = 3$.

Now let $v_{0,yy} < 0$ and $v_{1,yy} < 0$. Again, $x_3 < 0$ implies that $Y(x)$ is empty locally around $\bar{y}$. If $x_3 \geq 0$, then for the feasibility of x one needs $x_1 \geq 0$ as well as $v_1(x,\sqrt{x_1}) \leq 0$, $v_{1,y}(x,\sqrt{x_1}) \leq 0$, $v_1(x,-\sqrt{x_1}) \leq 0$, and $v_{1,y}(x,-\sqrt{x_1}) \geq 0$. Define

$$\begin{aligned} M^{11}(x_1,x_2,x_3) := \{x \in U \mid x_3 < 0\} \\ \cup \left\{ x \in U \;\middle|\; \begin{array}{l} x_1 \geq 0,\ x_3 \geq 0,\ \alpha(x,\sqrt{x_1})(\sqrt{x_1}-x_2)^2 + x_3 \leq 0 \\ \alpha(x,-\sqrt{x_1})(-\sqrt{x_1}-x_2)^2 + x_3 \leq 0 \\ \dfrac{\partial}{\partial y}\left(\alpha(x,y)(y-x_2)^2 + x_3\right)|_{y=\sqrt{x_1}} \leq 0 \\ \dfrac{\partial}{\partial y}\left(\alpha(x,y)(y-x_2)^2 + x_3\right)|_{y=-\sqrt{x_1}} \geq 0 \end{array} \right\}. \end{aligned}$$

We say that $\bar{y}$ is of *Type* 11, and we have $\operatorname{rank}(\bar{y}) = 3$.

If $v_{0,yy} < 0$ and $v_{1,yy} > 0$, then $\bar{x} \in \operatorname{int} \complement M$.

Note that the sets M^i, $i = 1, .., 8$ are of cylindric type. They depend only on a subset of the coordinates $x_1, \ldots, x_n$. However, the sets M^9, M^{10}, and M^{11} depend

on the whole vector $x \in \mathbb{R}^n$, since the functions α depend on all coordinates $x_1, ., , x_n$. This completes the analysis of the four cases.

Remark 9. As already mentioned in section 1, there exist some topological phenomena of the feasible set M of a GSIP (nonclosedness, disjunctive structure), which do not appear in standard SIP. The reason for the existence of these phenomena and for the much more complicated analysis of the local structure of M is that the index set $Y(x)$ depends on the state variable x. In standard SIP we have the constant index set $Y(x) = Y$, and a local description of the feasible set takes into account only the zero-points of v_0 (see [8] for a complete discussion of the standard SIP case).

Remark 10. In the discussion of Cases A and B we already referred to the pictures in [8], which are related to the sets M^1 and M^2. In the following we illustrate for some of the subcases of the Cases C and D, where the above-mentioned topological phenomena (nonclosedness, disjunctive structure) of M appear.

Consider Subcase C1 with $I_0 = \{1, 2, 3\}$, $I_0^- = \{1, 2\}$, and $I_0^+ = \{3\}$. Then, the set

$$M^4(x_1, x_2) := \{x \in U \mid x_1 < 0\} \cup \{x \in U \mid x_2 < 0\}$$

is not closed and has a disjunctive structure.

Consider Subcase C2 with $I_0 = I_0^+$ and $v_{0,y} > 0$. Then, the set

$$M^5(x_1, \ldots, x_k) := \{x \in U \mid \max\{x_1, \ldots, x_k\} \geq 0\}$$

has a disjunctive structure (an analogous result holds for M^6).

Consider Subcase D1. Then, the set

$$M^7(x_1) := \{x \in U \mid x_1 < 0\}$$

is not closed.

Consider Subcase D2. Then, the set

$$M^8(x_1, x_2) := \{x \in U \mid x_1 < 0\} \cup \{x \in U \mid x_1 \geq 0,\ x_2 \leq -\sqrt{x_1}\}$$

is not closed.

The sets in Subcase D4 depend on the function $\alpha(x, y)$.

3.2. The decomposition theorem. Throughout this subsection let $\bar{x} \in \partial M$ and assume the following conditions:

(A3) The set $Y_0(\bar{x}) \cup \{y \in Y(\bar{x}) \mid v_0(\bar{x}, y) < 0,\ \exists\, i \in I :\ v_i(\bar{x}, y) = 0\}$ is finite—say $\{y^1, \ldots, y^q\}$—and each y^i, $i \in Q := \{1, \ldots, q\}$ is of one of the Types j, $j = 1, \ldots, 11$.

(A4) For $i \in Q$ let $\operatorname{rank}(y^i) =: r_i$, and let y^i be of Type m_i. For the sets $S(y^i)$ of linearly independent vectors let

$$\dim \operatorname{span} \bigcup_{i \in Q} S(y^i) = \sum_{i \in Q} r_i. \tag{9}$$

We note that (9) is a multitransversality condition; it guarantees the stability of the local description of the feasible set under sufficiently small smooth perturbations of the functions $v_i, i = 0, \ldots, p$. In fact, the conditions describing the Types 1–11 remain fulfilled under small perturbations up to the corresponding order of the zero-point $\bar{y}$ for $v_i(\bar{x}, .)$, $i \in I^*$.

THEOREM 11. *Assume* (A3) *and* (A4). *Let* t_i, $i = 0, \ldots, q$, *recursively be defined as follows:* $t_0 := 0$, $t_i := t_{i-1} + r_i$, $i \in Q$. *Then, there exist an open neighborhood* V

of $\bar{x}$, an open neighborhood U of $0 \in \mathbb{R}^n$, and a local C^∞-coordinate transformation $\phi : V \to U$, sending $\bar{x}$ to $0 \in \mathbb{R}^n$ such that

$$\phi(M \cap V) = \bigcap_{i \in Q} M^{m_i}(x_{t_{i-1}+1}, \ldots, x_{t_i}). \tag{10}$$

Proof. Choose for each $\bar{y} \in Y(\bar{x}) \setminus \{y^i \mid i \in Q\}$ the open neighborhoods $U_{\bar{y}}$ of $\bar{y}$ and $U_{\bar{y}}(\bar{x})$ of $\bar{x}$ such that $v_0(x, y) > 0$ for all $x \in U_{\bar{y}}(\bar{x})$ and all $y \in U_{\bar{y}} \cap Y(x)$. For y^i, $i \in Q$, choose the open neighborhoods U_{y^i} of y^i and $U_{y^i}(\bar{x})$ of $\bar{x}$ such that locally around $(\bar{x}, y^i)$ the local C^∞-coordinate transformation for the Type m_i can be applied for all $(x, y) \in U_{y^i}(\bar{x}) \times U_{y^i}$. Then, select a finite covering of $Y(\bar{x})$ from $\{U_y,\ y \in Y(\bar{x})\}$ which, by (A3), also covers $Y(x)$ for x sufficiently near $\bar{x}$. We obtain a neighborhood V of $\bar{x}$ as the intersection of the finitely many neighborhoods of $\bar{x}$, which appear in this covering. Recall that the sets $S(y^i)$ are closely related to the Jacobian $D_x\xi^1$ of the corresponding local admissible coordinates (ξ^1, ξ^2). Therefore, the multitransversality condition (9) allows the choice of new coordinates $x_1, \ldots, x_{r_1=t_1}, x_{t_1+1}, \ldots, x_{t_2}, x_{t_2+1}, \ldots, x_{t_q}$ simultaneously. After that, the functions α appearing in the sets of Types 9, 10, and 11 take their final form, and we obtain (10). ∎

Acknowledgments. The authors would like to thank the referees for their careful reading of the manuscript and constructive comments. The improved version of the paper has benefited from their valuable suggestions and detailed remarks.

FURTHER RELAXATIONS OF THE SEMIDEFINITE PROGRAMMING APPROACH TO SENSOR NETWORK LOCALIZATION*

ZIZHUO WANG†, SONG ZHENG‡, YINYU YE§, AND STEPHEN BOYD¶

Abstract. Recently, a semidefinite programming (SDP) relaxation approach has been proposed to solve the sensor network localization problem. Although it achieves high accuracy in estimating the sensor locations, the speed of the SDP approach is not satisfactory for practical applications. In this paper we propose methods to further relax the SDP relaxation, more precisely, to relax the single semidefinite matrix cone into a set of small-size semidefinite submatrix cones, which we call a sub-SDP (SSDP) approach. We present two such relaxations. Although they are weaker than the original SDP relaxation, they retain the key theoretical property, and numerical experiments show that they are both efficient and accurate. The speed of the SSDP is even faster than that of other approaches based on weaker relaxations. The SSDP approach may also pave a way to efficiently solving general SDP problems without sacrificing the solution quality.

Key words. sensor network localization, semidefinite programming, second-order cone programming, principal submatrix, chordal graph

1. Introduction.

There has been an increase in the use of ad hoc wireless sensor networks for monitoring environmental information (e.g., temperature, sound levels, and light) across an entire physical space, where the sensor network localization problem has received considerable attention recently. Typical networks of this type consist of a large number of densely deployed sensor nodes which gather local data and communicate with other nearby nodes. The sensor data from these nodes are relevant only if we know to what location they refer. Therefore knowledge of the node positions becomes imperative. The use of a GPS system could be a very expensive or otherwise impossible approach to this requirement. This problem is also related to other practical distance geometry problems.

The mathematical model of the problem can be described as follows. There are n distinct sensor points in R^d, whose locations are to be determined, and m other fixed points (called the anchor points), whose locations $a_1, a_2, \ldots, a_m$ are known. The Euclidean distance d_{ij} between the ith and jth sensor points is known if $(i,j) \in N_x$, and the distance $\bar{d}_{ik}$ between the ith sensor and kth anchor points is known if $(i,k) \in N_a$. Usually, $N_x = \{(i,j) : \|x_i - x_j\| = d_{ij} \le r_d\}$ and $N_a = \{(i,k) : \|x_i - a_k\| = \bar{d}_{ik} \le r_d\}$, where r_d is a fixed parameter called the radio range. The sensor network

localization problem is to find $x_i \in R^d$, $i = 1, 2, \ldots, n$, for which

$$\begin{aligned} \|x_i - x_j\|^2 &= d_{ij}^2 \qquad \forall\ (i,j) \in N_x, \\ \|x_i - a_k\|^2 &= \bar{d}_{ik}^2 \qquad \forall\ (i,k) \in N_a. \end{aligned}$$

Unfortunately, this problem is hard to solve in general even for $d = 1$; see, e.g., [15, 35].

For simplicity, we restrict ourselves to $d = 2$ in this paper. Many relaxations have been developed to tackle this and other related problems; see, e.g., [1, 4, 3, 5, 23, 6, 7, 28, 29, 33, 25, 16, 21, 12, 18, 20, 22, 26, 2, 31, 30, 19]. Among them, the work of [1, 4, 3, 5, 23, 16, 20, 19] used a Euclidean distance matrix-based approach, where no anchor was needed or used to compute the unknown portions of the distance matrix [36]; [12, 22] developed a global optimization approach; [21, 30] constructed a second-order cone relaxation; [26, 18] adapted the sum-of-squares (SOS) approach; [33] modeled a problem similar to the dual of the distance completion problem; and [6, 27] considered bounds on the solution rank of a semidefinite programming (SDP) problem. Recently, an SDP relaxation (see, e.g., [7, 28, 29, 25, 2, 31]) which explicitly used the anchors' positions as the first-order information, was applied to solving a class of sensor network localization problems. Their relaxation model can be represented by a standard SDP model

$$\begin{aligned} &\text{minimize} && \mathbf{0} \bullet Z \\ &\text{subject to} && Z_{(1,2)} = I, \\ &&& (\mathbf{0}; e_i - e_j)(\mathbf{0}; e_i - e_j)^T \bullet Z = d_{ij}^2 \quad \forall\ (i,j) \in N_x, \\ &&& (-a_k; e_i)(-a_k; e_i)^T \bullet Z = \bar{d}_{ik}^2 \quad \forall\ (i,k) \in N_a, \\ &&& Z \succeq 0. \end{aligned} \tag{1.1}$$

Here I is the 2-dimensional identity matrix and $Z_{(1,2)}$ is the upper-left 2×2 principal submatrix of Z, $\mathbf{0}$ is a vector or matrix of all zeros, and e_i is the vector of all zeros, except for a one in the ith position. If a solution

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

to (1.1) is of rank 2, or, equivalently, $Y = X^T X$, then $X = [x_1, \ldots, x_n] \in R^{2 \times n}$ is a solution to the sensor network localization problem. Note that the SDP variable matrix has two parts: the first-order part X (positions) and the second-order part of Y (position inner products). Both parts give valuable information about the estimation and confidence measure of the final localization solution.

As the size of the SDP problem increases, the dimension of the matrix cone increases and the number of variables increases quadratically, no matter how sparse N_x and N_a might be. It is also known that the arithmetic operation complexity of the SDP is at least $O(n^3)$ to obtain an approximate solution. This complexity bound prevents solving large-size problems. Therefore, it would be very beneficial to further relax the full SDP problem by exploiting the sparsity of N_x and N_a at the relaxation modeling level.

Throughout the paper, R^d denotes d-dimensional Euclidean space, S^n denotes the space of $n \times n$ symmetric matrices, and $\mathrm{Rank}(A)$ denotes the rank of A. For $A \in S^n$, A_{ij} denotes the (i,j) entry of A, and $A_{(i_1,\ldots,i_k)}$ denotes the principal submatrix from the rows and columns indexed by $i_1, \ldots, i_k$. For $A, B \in S^n$, $A \succeq B$ means that $A - B$ is positive semidefinite, and $A \bullet B$ denotes the inner product, i.e., $A \bullet B = \mathrm{Tr}(AB)$.

2. Further relaxations of the SDP model. We will give two such relaxations. The first is a node-based relaxation, which we call the NSDP relaxation:

$$\begin{array}{ll} \text{minimize} & \mathbf{0} \bullet Z \\ \text{subject to} & Z_{(1,2)} = I, \\ & (\mathbf{0}; e_i - e_j)(\mathbf{0}; e_i - e_j)^T \bullet Z = d_{ij}^2 \quad \forall\ (i,j) \in N_x, \\ & (-a_k; e_i)(-a_k; e_i)^T \bullet Z = \bar{d}_{ik}^2 \quad \forall\ (i,k) \in N_a, \\ & Z^i = Z_{(1,2,i,N_i)} \succeq 0 \quad \forall i, \end{array} \tag{2.1}$$

where $N_i = \{j : \ (i,j) \in N_x\}$ is the sensor-i-connected point set. Here the single $(2+n)$-dimensional matrix cone is replaced by n smaller $3+|N_i|$-dimensional matrix cones, each of which is a principal submatrix of Z. We should mention that a similar idea was proposed in [24] for solving general SDP problems.

The second relaxation is an edge-based relaxation, which we call the ESDP relaxation:

$$\begin{array}{ll} \text{minimize} & \mathbf{0} \bullet Z \\ \text{subject to} & Z_{(1,2)} = I, \\ & (\mathbf{0}; e_i - e_j)(\mathbf{0}; e_i - e_j)^T \bullet Z = d_{ij}^2 \quad \forall\ (i,j) \in N_x, \\ & (-a_k; e_i)(-a_k; e_i)^T \bullet Z = \bar{d}_{ik}^2 \quad \forall\ (i,k) \in N_a, \\ & Z_{(1,2,i,j)} \succeq 0 \quad \forall (i,j) \in N_x. \end{array} \tag{2.2}$$

Here the single $(2+n)$-dimensional matrix cone is replaced by $|N_x|$ smaller 4-dimensional matrix cones, each of which is a principal submatrix of Z. If a solution

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

to (2.2) satisfies $\text{Rank}(Z_{(1,2,i,j)} = 2$ for all $(i,j) \in N_x$, then $X = [x_1, \ldots, x_n]$ is a localization for the localization problem. An edge-based decomposition was also used for the SOS approach to localization in [26].

In practice, the distances may be corrupted by random measurement errors. In this case the ESDP model can be adjusted by forming a suitable objective. For example, if there is a random Laplacian noise added to each d_{ij}^2 and $\bar{d}_{ik}^2$, then we solve

$$\begin{array}{ll} \text{minimize} & \displaystyle\sum_{(i,j)\in N_x} |(0, e_i - e_j)(0, e_i - e_j)^T \bullet Z - d_{ij}^2| \\ & \quad + \displaystyle\sum_{(i,k)\in N_a} |(-a_k, e_i)(-a_k, e_i)^T \bullet Z - \bar{d}_{ik}^2| \\ \text{subject to} & Z_{(1,2)} = I, \\ & Z_{(1,2,i,j)} \succeq 0 \quad \forall (i,j) \in N_x, \end{array}$$

which can be written as an SDP:

$$\begin{array}{ll} \text{minimize} & \displaystyle\sum_{(i,j)\in N_x} (u_{ij} + v_{ij}) + \sum_{(i,k)\in N_a} (u_{ik} + v_{ik}) \\ \text{subject to} & Z_{(1,2)} = I, \\ & (\mathbf{0}; e_i - e_j)(\mathbf{0}; e_i - e_j)^T \bullet Z - u_{ij} + v_{ij} = d_{ij}^2 \quad \forall\ (i,j) \in N_x, \\ & (-a_k; e_i)(-a_k; e_i)^T \bullet Z - u_{ik} + v_{ik} = \bar{d}_{ik}^2 \quad \forall\ (i,k) \in N_a, \\ & Z_{(1,2,i,j)} \succeq 0, \quad u_{ij}, v_{ij} \geq 0 \quad \forall (i,j) \in N_x, \\ & u_{ik}, v_{ik} \geq 0 \quad \forall (i,k) \in N_a. \end{array} \tag{2.3}$$

Similarly, NSDP can be reformulated as

$$
\begin{aligned}
\text{minimize} \quad & \sum_{(i,j)\in N_x} (u_{ij}+v_{ij}) + \sum_{(i,k)\in N_a} (u_{ik}+v_{ik}) \\
\text{subject to} \quad & Z_{(1,2)} = I, \\
& (\mathbf{0}; e_i - e_j)(\mathbf{0}; e_i - e_j)^T \bullet Z - u_{ij} + v_{ij} = d_{ij}^2 \quad \forall\ (i,j) \in N_x, \\
& (-a_k; e_i)(-a_k; e_i)^T \bullet Z - u_{ik} + v_{ik} = \bar{d}_{ik}^2 \quad \forall\ (i,k) \in N_a, \\
& Z^i = Z_{(1,2,i,N_i)} \succeq 0 \quad \forall i, \\
& u_{ij}, v_{ij} \geq 0 \quad \forall (i,j) \in N_x, \quad u_{ik}, v_{ik} \geq 0 \quad \forall (i,k) \in N_a.
\end{aligned} \tag{2.4}
$$

For simplicity, we focus on the feasibility models of (1.1), (2.1), and (2.2) in the rest of this paper.

Obviously, (2.1) is a relaxation of (1.1), and (2.2) is a relaxation of (2.1). The following proposition will formalize these relations.

PROPOSITION 2.1. *If*

$$Z_{SDP}^* = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

is a solution to (1.1)*, then* Z_{SDP}^**, after removing the unspecified variables, is a solution to relaxation* (2.1)*; if*

$$Z_{NSDP}^* = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

is a solution to (2.1)*, then* Z_{NSDP}^**, after removing the unspecified variables, is a solution to relaxation* (2.2)*. Hence*

$$F^{SDP} \subset F^{NSDP} \subset F^{ESDP},$$

where $F^{\cdot}$ *represents the solution set of the corresponding SDP relaxation.*

We notice that (1.1) has $(n+2)^2$ variables and $|N_x| + |N_a|$ equality constraints, (2.1) has at most $4+2n+\sum_i |N_i|^2$ variables and $|N_x|+|N_a|$ equality constraints, and (2.2) has $4+3n+|N_x|$ variables and also $|N_x| + |N_a|$ equality constraints. Usually, $4+3n+|N_x|$ is much smaller than $(n+2)^2$, so that (2.2) has a much smaller number of variables than (1.1); hence, the NSDP or ESDP relaxation has the potential to be solved much faster than (1.1). Our computational results will confirm this fact.

But how good is the NSDP or ESDP relaxation? How do these relaxations perform? In the rest of the paper, we will prove that, although they are weaker than the SDP relaxation, the NSDP and ESDP relaxations share some of the same desired theoretical properties possessed by the full SDP relaxation, including the trace criterion for accuracy. We develop a sufficient condition when NSDP coincides with SDP. We also show that the ESDP relaxation is stronger than the second-order cone programming (SOCP) relaxation. Furthermore, we will present computational results and compare our method with the full SDP, SOS, SOCP relaxation, and domain-decomposition methods. One will see that our method is among the fastest methods, and its localization quality is comparable or superior to that of other methods.

3. Theoretical analyses of NSDP. We make the following basic assumption: G, the undirected graph of a sensor network consisting of all sensors and anchors, with edge sets N_x and N_a, is connected and contains at least three anchors. Before

we present our results, we recall three basic concepts: the d-uniquely localizable graph, the chordal graph, and the partial positive semidefinite matrix.

The definition of a d-uniquely localizable graph is given by [2].

DEFINITION 3.1. *A sensor localization problem is d-uniquely localizable if there is a unique localization $\bar{X} \in R^{d\times n}$ and there is no $x_i \in R^h,\ i = 1,\dots,n$, where $h > d$, such that:*

$$\begin{aligned} &\|x_i - x_j\|^2 = d_{ij}^2 && \forall\ (i,j) \in N_x,\\ &\|(a_k;\mathbf{0}) - x_i\|^2 = \bar{d}_{ik}^2 && \forall\ (i,k) \in N_a,\\ &x_i \neq (\bar{x}_i;\mathbf{0}) && \text{for some } i \in \{1,\dots,n\}. \end{aligned}$$

The latter says that the problem cannot have a nontrivial localization in some higher-dimensional space R^h (i.e., a localization different from the one obtained by simply setting $x_i = (\bar{x}_i;\mathbf{0})$, where anchor points are augmented to $(a_k;\mathbf{0}) \in R^h$).

The condition of a d-unique localizability has been proved to be the necessary and sufficient condition for the SDP relaxation to compute a solution in R^d; see [2]. For the case of $d = 2$, if a graph is 2-uniquely localizable, then the SDP relaxation (1.1) produces a unique solution Z with rank 2, and $X = [x_1,\dots,x_n] \in R^{2\times n}$ of Z is the unique localization of a localization problem in R^2.

DEFINITION 3.2. *An undirected graph is a chordal graph if every cycle of length greater than three has a chord; see, e.g.,* [8].

The chordal graph has been used for solving sparse SDP problems or reducing the number of high-order variables in SOS relaxations; see, e.g., [24, 17, 18].

DEFINITION 3.3. *A square matrix, possibly containing some unspecified entries, is called partial symmetric if whenever the (i,j) entry of the matrix is specified, then so is the (j,i) entry, and the two are equal. A partial semidefinite matrix is a partial symmetric matrix for which every fully specified principal submatrix is positive semidefinite.*

The concept of a partial positive semidefinite matrix can be found, e.g., in [9, 13, 14].

The following result was proved in [9, 13].

LEMMA 3.4. *Every partial positive semidefinite matrix with undirected graph G has positive semidefinite completion if and only if G is chordal.*

Although the NSDP model is weaker than the SDP relaxation in general, the following theorem implies that they are equivalent under the chordal condition.

THEOREM 3.5. *Let the undirected graph of sensor nodes with edge set N_x be chordal. Then*

$$F^{SDP} = F^{NSDP}.$$

Proof. We need only to prove that any solution to (2.1) can be completed to a solution of (1.1). Let

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

be a solution to (2.1). Then all entries of Z are specified except those Y_{ij} such that $(i,j) \notin N_x$. The conic constraints of (2.1) indicate that every fully specified principal submatrix of Z is positive semidefinite, since it is a principal submatrix of Z^i in (2.1). Thus, Z is a partial semidefinite matrix.

We are also given that the undirected graph induced by Y in Z is chordal. We now prove that the undirected graph induced by Z is also chordal. Notice that the graph of Z has a total of $n+2$ nodes, and every specified entry represents an edge. Let

nodes D_1 and D_2 represent the first two rows (columns) of Z, respectively. Then each of the two nodes has edges to all other nodes in the graph. Now consider any cycle in the graph of Z. If the cycle contains D_1 or D_2 or both, then it must have a chord since each of D_1 and D_2 connect to every other node; if the cycle contains neither D_1 nor D_2, then it still contains a chord since the graph of Y is chordal. Therefore, Z has a positive semidefinite completion, say, $\bar{Z}$, from Lemma 3.4, and $\bar{Z}$ must be a solution to (1.1), since (2.1) and (1.1) share the same constraints involving only the specified entries. □

Under the condition of 2-unique localizability, we further have the following.

COROLLARY 3.6. *If a sensor network is 2-uniquely localizable and its undirected graph of sensor nodes with edge set N_x is chordal, then the solution of* (2.1) *is a unique localization for the sensor network.*

4. Theoretical analyses of ESDP. We now focus on our second relaxation, the ESDP relaxation of (2.2).

4.1. Relation between ESDP and SDP. In the SDP relaxation model, let

$$Z_{SDP} = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

be a solution to (1.1). Then it is shown that the individual traces or the diagonal entries of $Y - X^T X$ represent confidence measures in the accuracy of the corresponding sensor's location; see [7, 2]. We will show that the ESDP model retains this very desired property. More precisely, if

$$Z_{ESDP} = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

is a solution to (2.2), then the individual traces of $Y - X^T X$ also represent confidence measures in the accuracy of the corresponding sensor's location.

First, we introduce a lemma involving the rank of SDP solutions.

LEMMA 4.1. *Consider the following SDP:*

$$\begin{aligned} \text{minimize} \quad & \sum_i C_i \bullet X_i \\ \text{subject to} \quad & \sum_i A_{ij} \bullet X_i = b_j \quad \forall j, \\ & X_i \succeq 0 \quad \forall i. \end{aligned} \tag{4.1}$$

Then applying the path-following interior-point method will produce a max-rank (relative interior) solution for each X_i, i.e., if X^1 and X^2 are two different optimal solutions satisfying

$$\operatorname{Rank}(X^1_{\bar{i}}) < \operatorname{Rank}(X^2_{\bar{i}}) \quad \textit{for at least one } \bar{i}.$$

Then solving (4.1) *by applying the path-following interior-point method will not yield solution X^1.*

Proof. Problem (4.1) can be reformulated into

$$\begin{aligned} \text{minimize} \quad & \overline{C} \bullet X \\ \text{subject to} \quad & \overline{A}_j \bullet X = b_j \quad \forall j, \\ & X = \begin{pmatrix} X_1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & X_n \end{pmatrix} \succeq 0, \end{aligned}$$

where $\overline{C} = \mathrm{diag}(C_i)_{i=1}^n$ and $\overline{A}_j = \mathrm{diag}(A_{ij})_{i=1}^n$. This can also be written as

$$\begin{array}{ll} \text{minimize} & \overline{C} \bullet X \\ \text{subject to} & \overline{A_j} \bullet X = b_j \ \forall j, \\ & E_{ij} \bullet X = 0 \ \forall (i,j) \notin D, \\ & X \succeq 0, \end{array}$$

where D denotes those positions that do not belong to any diagonal block of X.

Thus, the path-following algorithm will return a max-rank solution to the problem; see, e.g., [10, 11]. In other words, if X^* is a solution calculated by the path-following method, then $\sum_{i=1}^n \mathrm{Rank}(X_i^*)$ is maximal among all solutions; hence, for every i, $\mathrm{Rank}(X_i^*)$ must be maximal among all solutions to (4.1). Thus, X^1 cannot be a solution generated by the interior-point method. □

By applying this lemma, we have the following result which provides a justification for using the individual traces to measure the accuracy of computed sensor locations.

THEOREM 4.2. *Let*

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

be a max-rank solution of (2.2). *If the diagonal entry or individual trace*

$$(Y - X^T X)_{\bar{i}\bar{i}} = 0, \tag{4.2}$$

then the $\bar{i}$th column of X, $x_{\bar{i}}$, must be the true location of the $\bar{i}$th sensor, and $x_{\bar{i}}$ is invariant over all solutions Z for (2.2).

Proof. Our proof is by contradiction. Without losing generality, we assume that $(Y - X^T X)_{jj} > 0$ for all $j \neq \bar{i}$.

Note that the constraints in (2.2) ensured that $Z_{(1,2,\bar{i},j)} \succeq 0$ for all $(\bar{i}, j) \in N_x$. Thus, $(Y - X^T X)_{\bar{i}\bar{i}} = 0$ implies that $(Y - X^T X)_{\bar{i}j} = 0$ for all $(\bar{i}, j) \in N_x$, i.e., $Z_{(1,2,\bar{i},j)}$ has rank 3 for all $(\bar{i}, j) \in N_x$. Moreover, from Lemma 4.1, the max-rank of $Z_{(1,2,\bar{i},j)}$ is at most 3 for all solutions to (2.2).

Denote by $\bar{Z}$ a true localization for (2.2), that is, $\bar{Z}_{(1,2,i,j)}$ has rank 2 for all $(i,j) \in N_x$, where

$$\bar{Z}_{(1,2,i,j)} = \begin{pmatrix} I & \bar{x}_i & \bar{x}_j \\ \bar{x}_i^T & \bar{Y}_{ii} & \bar{Y}_{ij} \\ \bar{x}_j^T & \bar{Y}_{ji} & \bar{Y}_{jj} \end{pmatrix} = \begin{pmatrix} I & \bar{x}_i & \bar{x}_j \\ \bar{x}_i^T & \|\bar{x}_i\|^2 & \bar{x}_i^T \bar{x}_j \\ \bar{x}_j^T & \bar{x}_j^T \bar{x}_i & \|\bar{x}_j\|^2 \end{pmatrix}.$$

Suppose that $\bar{x}_{\bar{i}} \neq x_{\bar{i}}$. Since the solution set is convex, then

$$Z^\alpha = \alpha \bar{Z} + (1 - \alpha) Z, \quad 0 \leq \alpha \leq 1,$$

is also a solution to (2.2). By taking α sufficiently small but strictly positive, we will get another solution Z^α which satisfies

$$\mathrm{Rank}(Z^\alpha_{(1,2,i,j)}) \geq \mathrm{Rank}(Z_{(1,2,i,j)}) \ \forall (i,j) \in N_x,$$

and the *strict inequality* holds for $i = \bar{i}$. This is because for $(\bar{i}, j) \in N_x$

$$\begin{aligned} & Y^\alpha_{(\bar{i},j)} - [x^\alpha_{\bar{i}}, x^\alpha_j]^T [x^\alpha_{\bar{i}}, x^\alpha_j] \\ &= \alpha \bar{Y}_{(\bar{i},j)} + (1-\alpha) Y_{(\bar{i},j)} - (\alpha[\bar{x}_{\bar{i}}, \bar{x}_j] + (1-\alpha)[x_{\bar{i}}, x_j])^T (\alpha[\bar{x}_{\bar{i}}, \bar{x}_j] + (1-\alpha)[x_{\bar{i}}, x_j]) \\ &= (1-\alpha)(Y_{(\bar{i},j)} - [x_{\bar{i}}, x_j]^T [x_{\bar{i}}, x_j]) + \alpha(1-\alpha)([x_{\bar{i}}, x_j] - [\bar{x}_{\bar{i}}, \bar{x}_j])^T ([x_{\bar{i}}, x_j] - [\bar{x}_{\bar{i}}, \bar{x}_j]). \end{aligned}$$

Since $(Y - X^T X)_{\bar{i}\bar{i}} = (Y - X^T X)_{\bar{i}j} = (Y - X^T X)_{j\bar{i}} = 0$,

$$Y_{(\bar{i},j)} - [x_{\bar{i}}, x_j]^T [x_{\bar{i}}, x_j] = \begin{pmatrix} 0 & 0 \\ 0 & \gamma \end{pmatrix}$$

for some $\gamma > 0$.

Also we are given that $\bar{x}_{\bar{i}} \neq x_{\bar{i}}$, so that $([x_{\bar{i}}, x_j] - [\bar{x}_{\bar{i}}, \bar{x}_j])^T([x_{\bar{i}}, x_j] - [\bar{x}_{\bar{i}}, \bar{x}_j])$ is a positive semidefinite matrix whose first element is positive, which implies that

$$\det\left[(1-\alpha)\begin{pmatrix} 0 & 0 \\ 0 & \gamma \end{pmatrix} + \alpha(1-\alpha)([x_{\bar{i}}, x_j] - [\bar{x}_{\bar{i}}, \bar{x}_j])^T([x_{\bar{i}}, x_j] - [\bar{x}_{\bar{i}}, \bar{x}_j])\right] > 0.$$

That is, $Z^{\alpha}_{(1,2,\bar{i},j)}$ is a solution to (2.2) with rank 4, which is a contradiction.

Therefore, we proved that $\bar{x}_{\bar{i}}$ must be the true location of the $\bar{i}$th sensor and $\bar{x}_{\bar{i}}$ is invariant over all solutions to (2.2). □

Theorem 4.2 is related to Proposition 2 of [30]. Moreover, the desired invariance property of $x_{\bar{i}}$ extends to the case with noises, which can also be seen from the proof in [30]. In summary, we have the following.

COROLLARY 4.3. *Let*

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

be a solution to (2.2) *and condition* (4.2) *hold for all* i. *Then the ESDP model* (2.2) *produces a unique solution for the sensor network in* R^2.

Next we enhance Proposition 2.1 by the following theorem.

THEOREM 4.4. *Let*

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

be a solution to (2.2), *and let*

$$\bar{Z} = \begin{pmatrix} I & \bar{X} \\ \bar{X}^T & \bar{Y} \end{pmatrix}$$

be any solution to (1.1); *both are calculated by the path-following method. If condition* (4.2) *holds for* Z, *so it does for* $\bar{Z}$.

Proof. Our proof is again by contradiction. If (4.2) holds for Z but not for $\bar{Z}$, e.g., $(\bar{Y} - \bar{X}^T \bar{X})_{ii} > 0$. Since, for $0 \leq \alpha \leq 1$,

$$Z_\alpha = (1-\alpha)Z + \alpha\bar{Z}$$

is always a solution to (2.2), by taking α sufficiently small, we will get a solution with a higher rank than Z, and this fact contradicts Lemma 4.1. □

Theorem 4.4 says that if the ESDP relaxation can accurately locate a certain sensor, so can the SDP relaxation. This implies that the ESDP relaxation is weaker than the SDP relaxation. We illustrate this by using an example.

Example 1. Consider the following graph with 3 sensors and 3 anchors. The 3 anchors are located at $(-0.4, 0)$, $(0.4, 0)$, and $(0, 0.4)$, and the 3 sensors are located at $(-0.05, 0.3)$, $(-0.08, 0.2)$, and $(0.2, 0.3)$, respectively. We set the radio range to be 0.50; see Figure 4.1.

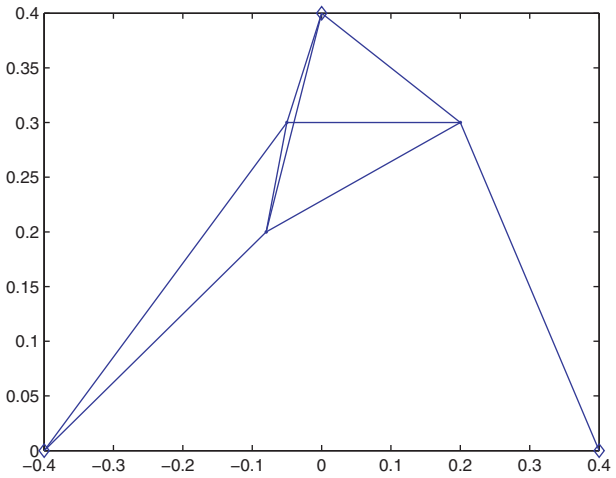

FIG. 4.1. *The locations of sensors, anchors, and connection edges in Example* 1.

In Figure 4.1 (and throughout this paper), we use diamonds to represent the anchor positions. We use a solid line to connect two points (sensors and/or anchors) when their Euclidean distance is smaller than the radio range, so that the length of the line segment is known.

First, we use full SDP relaxation (1.1) to solve this sensor localization problem, where the result is accurate (see Figure 4.2(a)). In Figure 4.2(a) (and throughout this paper), a circle denotes the true location of a sensor (they are not known to the SDP models), and a star denotes the location of a sensor computed by the SDP model. If we use the quantity of the root mean square deviance (RMSD) to measure the deviance of the computed result:

$$RMSD = \left(\frac{1}{n} \sum_{i=1}^{n} \|x_i - \bar{x}_i\|_2^2 \right)^{\frac{1}{2}}, \tag{4.3}$$

where x_i is the position vector of sensor i computed by the algorithm and $\bar{x}_i$ is its true position vector, then the RMSD of the full SDP localization is about $1e-7$. Note that the NSDP model (2.1) returns the exactly same localization of the full SDP from Theorem 3.5, since N_x is a chordal graph.

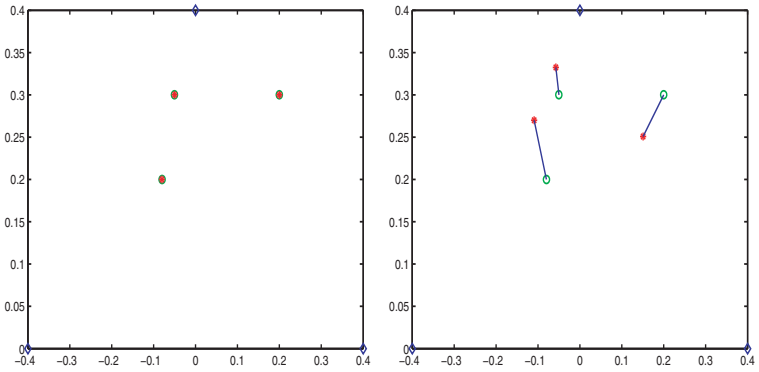
Next we use the ESDP model (2.2) to solve the problem, and this time the result is inaccurate with the RMSD at 0.048; see Figure 4.2(b), where every true sensor location and its computed corresponding position are connected by a solid line.

Now we illustrate why this error happened. In SDP model (1.1), the solution matrix Z^* is required to be positive semidefinite. If we write

$$Z^*_{SDP} = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix},$$

then the matrix $Y - X^T X$ is required to be positive semidefinite. But in model (2.2),

$$Z^*_{ESDP} = \begin{pmatrix} I & \bar{X} \\ \bar{X}^T & \bar{Y} \end{pmatrix},$$



(a) Graphical localization result of the SDP model

(b) Graphical localization result of the ESDP model

FIG. 4.2. *Comparision of graphical localization results generated by the SDP and ESDP in Example* 1.

where we just require that each 2×2 principal submatrix of $\bar{Y} - \bar{X}^T\bar{X}$ be positive semidefinite. This does not imply that the entire matrix is positive semidefinite. In fact, the solution calculated by the ESDP model (2.2) is

$$Z^*_{ESDP} = \begin{pmatrix} 1 & 0 & -0.07278 & -0.13467 & 0.14884 \\ 0 & 1 & 0.32778 & 0.25467 & 0.24884 \\ -0.07278 & 0.32778 & 0.11072 & 0.09498 & 0.06865 \\ -0.13467 & 0.25467 & 0.09498 & 0.09014 & 0.04540 \\ 0.14884 & 0.24884 & 0.06865 & 0.04540 & 0.08907 \end{pmatrix}.$$

It can be verified that Z^*_{ESDP} satisfies all constraints in (2.2) as well as in (1.1), and each 2×2 principal matrix of $\bar{Y} - \bar{X}^T\bar{X}$ is positive semidefinite. But the three eigenvalues of $\bar{Y} - \bar{X}^T\bar{X}$ are $(-0.00048, 0.0048, 0.0091)$, so that the entire matrix of $\bar{Y} - \bar{X}^T\bar{X}$ is indefinite, and this is the cause of the difference between the two relaxations.

4.2. Relation between ESDP and SOCP. A SOCP relaxation for the sensor network localization problem has been proposed (see, e.g., [21, 30]):

$$\begin{aligned} \text{minimize} \quad & \sum_{(i,j)\in N_x} (u_{ij} + v_{ij}) + \sum_{(i,k)\in N_a} (u_{ik} + v_{ik}) \\ \text{subject to} \quad & x_i - x_j - w_{ij} = 0 \quad \forall (i,j) \in N_x, \quad x_i - a_k - w_{ik} = 0 \quad \forall (i,k) \in N_a, \\ & y_{ij} - u_{ij} + v_{ij} = d_{ij}^2 \ \forall (i,j) \in N_x, y_{ik} - u_{ik} + v_{ik} = \bar{d}_{ik}^2 \ \forall (i,k) \in N_a, \\ & u_{ij} \geq 0, v_{ij} \geq 0, (y_{ij} + \tfrac{1}{4}, y_{ij} - \tfrac{1}{4}, w_{ij}) \in SOC \ \forall (i,j) \in N_x, \\ & u_{ik} \geq 0, v_{ik} \geq 0, (y_{ik} + \tfrac{1}{4}, y_{ik} - \tfrac{1}{4}, w_{ik}) \in SOC \ \forall (i,k) \in N_a. \end{aligned} \tag{4.4}$$

The SOCP relaxation can be also viewed as a further relaxation of the SDP relaxation, and it was proved to be faster than the SDP method and to serve as a useful preprocessor of the actual problem. In this section, we will show that the ESDP model is stronger than the SOCP relaxation. Our proof refers to Proposition 1 of [30].

THEOREM 4.5. *If*

$$Z = \begin{pmatrix} I & X \\ X^T & Y \end{pmatrix}$$

is an optimal solution to (2.3)*, then the ith column of* X*,* x_i*,* $i = 1, \ldots, n$*, and*

$$y_{ij} = \begin{cases} Y_{ii} + Y_{jj} - 2Y_{ij}, & (i,j) \in N_x, \\ \|a_k^2\| - 2a_k^T x_i + Y_{ii}, & (i,k) \in N_a \end{cases}$$

form a feasible solution for (4.4) *with the same objective value.*

Proof. Since Z is a feasible solution to (2.3), we have $Z_{(1,2,i,j),(1,2,i,j)} \succeq 0$ for all $(i,j) \in N_x$. So, for each $(i,j) \in N_x$, we have

$$\begin{pmatrix} Y_{ii} - \|x_i^2\| & Y_{ij} - x_i^T x_j \\ Y_{ij} - x_i^T x_j & Y_{jj} - \|x_j^2\| \end{pmatrix} \succeq 0.$$

This implies that $Y_{ii} - \|x_i^2\| \geq 0$, $Y_{jj} - \|x_j^2\| \geq 0$, and $(Y_{ii} - \|x_i^2\|)(Y_{jj} - \|x_j^2\|) \geq (Y_{ij} - x_i^T x_j)^2$.

Hence $(Y_{ii} - \|x_i^2\| + Y_{jj} - \|x_j^2\|)^2 \geq 4(Y_{ij} - x_i^T x_j)^2$, i.e.,

$$Y_{ii} + Y_{jj} - 2Y_{ij} \geq \|x_i^2\| + \|x_j^2\| - 2x_i^T x_j,$$

and the theorem follows. □

COROLLARY 4.6. *If* x_i *is invariant over all of the solutions of* (4.4)*, then it is also invariant over all of the ESDP solutions. That is, if SOCP relaxation can return the true location for a sensor, so can ESDP relaxation.*

The above theorem and corollary indicate that one can always derive the same SOCP relaxation solution from an ESDP relaxation solution; that is, the solution set of the ESDP relaxation is smaller than that of the SOCP relaxation. Thus, the ESDP relaxation is stronger than the SOCP relaxation. The following example shows that the reverse is not true.

Example 2. Consider the following problem with 3 anchors and 2 sensors. The true locations of 3 anchors are $a_1 = (-0.4, 0), a_2 = (0, 0.5)$, and $a_3 = (0.4, 0)$, and the true locations of the 2 sensors are $x_1 = (0, -0.3)$ and $x_2 = (0.4, 0.2)$ with radio range 0.7 (see Figure 4.3).

Since there are only two sensors, the ESDP relaxation is the same with the full SDP relaxation, and it is known that this graph is strongly localizable (see [2]), so we know that the ESDP relaxation will give the *unique* solution Z where X is the accurate positions of the sensors. However, for SOCP relaxation, since the graph is 2-realizable, its optimal value of (4.4) is 0 so that the optimal solution must satisfy $y_{ij} = d_{ij}^2$ and $y_{ik} = \bar{d}_{ik}^2$. Thus, any $(\bar{x}_1, \bar{x}_2)$ that satisfies

$$\begin{aligned} \|\bar{x}_1 - \bar{x}_2\|^2 &\leq 0.4^2 + 0.5^2 = 0.41, \\ \|\bar{x}_1 - a_1\|^2 &\leq 0.3^2 + 0.4^2 = 0.25, \\ \|\bar{x}_1 - a_3\|^2 &\leq 0.3^2 + 0.4^2 = 0.25, \\ \|\bar{x}_2 - a_2\|^2 &\leq 0.4^2 + 0.3^2 = 0.25, \\ \|\bar{x}_2 - a_3\|^2 &\leq 0^2 + 0.2^2 = 0.04 \end{aligned}$$

must be also optimal to (4.4).

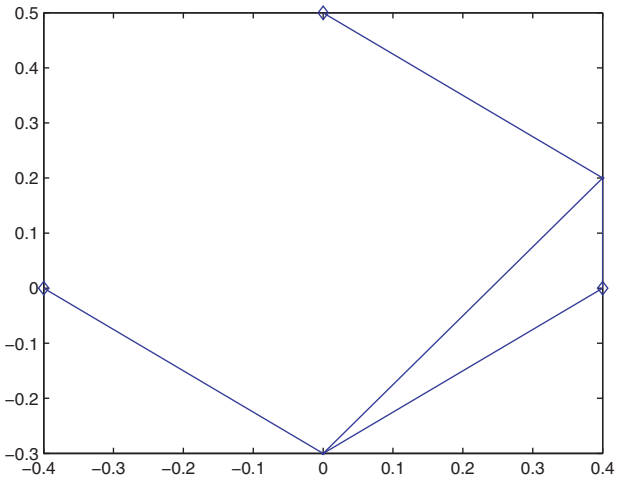


FIG. 4.3. *The locations of sensors, anchors, and connection edges in Example* 2.

Now let $\bar{x}_1 = (0, 0) \neq x_1$ and $\bar{x}_2 = (0.3, 0.15) \neq x_2$. Then it is easy to verify that the above inequalities hold, so that $(\bar{x}_1, \bar{x}_2)$ is also an optimal solution to (4.4). But we know that the interior-point method would always maximize the potential function (see [11, 10])

$$P(x, y) = \sum_{(i,j)\in N_x} \log\left(y_{ij} - \|x_i - x_j\|^2\right) + \sum_{(i,k)\in N_a} \log\left(y_{ik} - \|x_i - a_k\|^2\right)$$

in the optimal solution set; and it is obvious that $P(\bar{x}_1, \bar{x}_2) > P(x_1, x_2)$. Therefore the SOCP relaxation model (4.4) will not give the true solution x_1 and x_2, and, thereby, the ESDP relaxation is *strictly* stronger than the SOCP relaxation for this example.

4.3. The dual problem of ESDP. For a conic programming problem, it is important to consider its dual problem. In many cases, the dual problem can give much important information about the primal problem as well as many useful applications. Here we will present the dual problem of (2.2) and list some basic properties between the primal and dual.

Consider a general conic programming problem:

$$\begin{array}{ll} \text{minimize} & C \bullet X \\ \text{subject to} & A_j \bullet X = b_j \quad \forall j, \\ & X_{(N_i)} \succeq 0 \quad \forall i, \end{array} \tag{4.5}$$

where $X \in S^n$ and N_i is an index subset of $\{1, 2, \ldots, n\}$. Then the dual to the problem is

$$\begin{array}{ll} \text{maximize} & \displaystyle\sum_j b_j y_j \\ \text{subject to} & \displaystyle\sum_j y_j A_j + \sum_i S^i = C, \\ & S^i_{(N_i)} \succeq 0, \text{ and } S^i_{kj} = 0 \quad \forall k \notin N_i \text{ or } j \notin N_i; \quad \forall i. \end{array} \tag{4.6}$$

In other words, S^i is an S^n matrix, and its entries are zero outside the principal submatrix of S_{N_i,N_i}.

For the ESDP model (2.2), the dual problem is

$$
\begin{aligned}
\text{maximize} \quad & \sum_{(i,j)\in N_x} \omega_{ij} d_{ij}^2 + \sum_{(i,k)\in N_a} \omega_{ik} \bar{d}_{ik}^2 + u_{11} + 2u_{12} + u_{22} \\
\text{subject to} \quad & \sum_{(i,j)\in N_x} \omega_{ij} (\mathbf{0}; e_i - e_j)^T (\mathbf{0}; e_i - e_j) + \sum_{(i,k)\in N_a} \omega_{ik} (-a_k; e_i)^T (-a_k; e_i) \\
& + \begin{pmatrix} u_{11} + u_{12} & u_{12} & \mathbf{0} \\ u_{12} & u_{22} + u_{12} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{pmatrix} + \sum_{(i,j)\in N_x} S^{(i,j)} = \mathbf{0}, \\
& S^{(i,j)}_{(1,2,i,j)} \succeq 0, \text{ and } S^{(i,j)}_{kl} = 0 \ \forall k \notin \{i,j\} \text{ or } \ l \notin \{i,j\}, \ \forall (i,j) \in N_x.
\end{aligned} \tag{4.7}
$$

We have the following complementarity result.

PROPOSITION 4.7. *Let Z be a solution to* (2.2) *and $\{S^{(i,j)}\}$ be an optimal solution to the dual. Then*

$$S^{(i,j)}_{(1,2,i,j)} \bullet Z_{(1,2,i,j)} = 0 \ \forall (i,j) \in N_x.$$

In particular, if $\text{Rank}(S^{(i,j)}_{(1,2,i,j)})$ *is* 2 *for all* $(i,j) \in N_x$, *then* $\text{Rank}\left(Z_{(1,2,i,j)}\right)$ *is* 2 *for all* $(i,j) \in N_x$ *so that* (2.2) *produces a unique localization for the sensor network in* R^2.

By using duality we can solve the dual problem and simultaneously yield a primal solution from the complementarity proposition. We demonstrate in the next section that the solution speed of solving the dual is about twice as fast as solving the primal problem, which was originally observed in [34].

5. Computational results and comparison to other approaches. Now we address the question: Will the improvement in the speed of the ESDP relaxation compensate the loss in relaxation quality? In this section, we first present some computational results of the ESDP relaxation model. Then we compare the model with different kinds of approaches, including the full SDP approach (1.1) of [7], the SOCP approach [30], the SOS approach [26], and the domain-decomposition approach of [25, 29].

5.1. Computational results of the ESDP relaxation. In our numerical simulation, we follow [7]. We randomly generate the true positions of n points in a square of 1 by 1, then randomly select m points to be anchors, and compute every edge length $\bar{d}_{ij}$. We select only those edges whose edge length is less than the given radio range rd and add a multiplicative random noise to every selected edge length,

$$d_{ij} = \bar{d}_{ij}(1 + nf \cdot randn(1)),$$

as the distance input data to the SDP models. Here nf is a specified noisy factor, and $randn(1)$ is a standard Gaussian random variable. There may still be many points within the radio range for a sensor or anchor. Thus, in order to maintain the sparsity of the graph, we set a limit 7 on the number of selected edges connected to every sensor or anchor, and they are *randomly* chosen.

In our computational experiments we also implement the steepest-descent local search refinement proposed in [28, 29] for solving noisy problems. All test problems are solved by SeDuMi 1.05 [32] of Matlab7.0 on a DELL D420 laptop with 1.99 GB memory and 1.06 GHz CPU.

TABLE 5.1
Noisy test problems and the SDP solution time comparison.

(a) Graphic result of the full SDP model

(b) Graphic result of the dual ESDP model

FIG. 5.1. *Comparision of graphical localization results generated by the full SDP and dual ESDP on a* 10% *noisy problem.*

The first set of test problems has noisy factor $nf = 0.1$ throughout. Table 5.1 contains a computational comparison of ESDP to the full SDP relaxation [7]. Here three models, the full SDP model (up to 400 points), the ESDP model, and the dual of the ESDP model, are all solved by SeDuMi 1.05. In order to see the efficiency of the ESDP model itself, the solution time (in seconds) in Table 5.1 includes only the SeDuMi solver time; that is, the data input/preparation time is excluded.

As we can see, while the full SDP solution time increases cubically in size, the SDP solver times of both ESDP and dual ESDP increase little faster than *linearity*. While this speedup was remarkable, how about the localization quality? Figure 5.1 shows two graphical results generated by full SDP and dual ESDP on solving a smaller problem, where one can barely see much difference. Here diamonds represent the anchor positions, circles represent sensor's true positions, and stars represent the computed sensor positions. (The codes and a few test problems have been placed on the public site [37]. We welcome the reader to test them and draw their own conclusions.)

Next we compare our approach to the SOS approach, the SOCP approach, and the domain-decomposition approach. We will use the same examples presented in these papers.

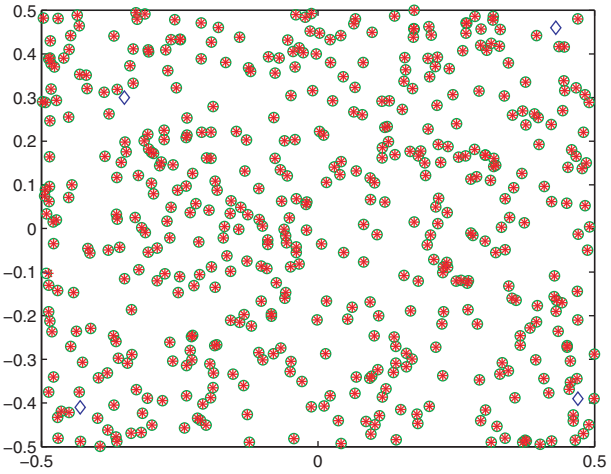

FIG. 5.2. *Graphical localization result of the ESDP model on the problem of Nie* [26]*, 500 sensors, 4 anchors,* $rd = 0.3$*,* $nf = 0$*, and RMSD* $= 1e-6$.

5.2. Computational comparison with the SOS method. The SOS method is an SDP relaxation which applies to solving the problem

$$\min \quad f(x) = \sum_{(i,j)\in N_x} (\|x_i - x_j\|_2^2 - d_{ij}^2)^2 + \sum_{(i,k)\in N_a} (\|x_i - a_k\|_2^2 - \bar{d}_{ik}^2)^2, \tag{5.1}$$

where the objective function is a polynomial.

Recent study [26] has shown that by exploiting the sparsity in SOS relaxation one can get faster computing speed than the SDP relaxation (1.1) and sometimes higher accuracy as well. The author demonstrated that this structure can help save computation time significantly. In [26], the author used the model of 500 sensors and 4 anchors with a radio range of 0.3 and no noises in distance measurements.

The author of [26] reported that it took totally about 1 hour and 25 minutes on a 0.98 GB RAM and 1.46 GHz CPU computer to get a result with RMSD$=2.9e-6$. However, with the same parameters, our approach needs only 30 seconds to get the result with RMSD$=1e-6$. Thus, the ESDP approach is much faster than the SOS approach in this case, and the solution quality is comparable to that of the SOS method; see Figure 5.2.

5.3. Computational comparison with the SOCP method. The SOCP model performs best with a large fraction of anchors and a low noise. Thus, we test (primal) ESDP on the same set of problems reported in [30], where $m = 0.1n$ (10% of points are anchors) and $nf \le 0.01$ (less than 1% noise), and the results are shown in Table 5.2. To solve the SOCP relaxation model, two methods are proposed in [30]: one directly uses Matlab SeDuMi, and the other uses a smoothing coordinate gradient descent (SCGD) method coded in FORTRAN 77. The latter is highly parallelizable, similar to the distributed methods of [25, 29].

From Table 5.2, we see that the ESDP approach is much faster than the SOCP approach when both use Matlab SeDuMi, and it is slower than the tailored and FORTRAN-coded SCGD method. On the other hand, the localization quality (see RMSD in Table 5.3) of ESDP is much better than that reported in [30] for both SeDuMi of SOCP and SCGD of SOCP. Figure 5.3 shows the graphical result of test

problem 2 (900 sensors, 100 anchors, $nf = 0.001$, and $rd = 0.06$), where the localization of ESDP is quite accurate compared with the graphical result on the same problem reported in [30].

In Table 5.2, "ESDP time" denotes the *total* solution running time, including Matlab data preparation and SeDuMi input setup time. By comparing Tables 5.1 and 5.2, one can see that, for ESDP, the Matlab data input and SeDuMi setup time is considerable. This is because Matlab is notoriously slow on matrix loops and data inputs. This problem should go away when the algorithm is coded in C or FORTRAN 77.

Table 5.3 contains more detailed statistical results on this test, where "SeDuMi SDP dim" represents problem dimensions solved by SeDuMi, "CPU time" denotes

the total ESDP solution time in seconds (including Matlab data preparation and SeDuMi input setup time), "obj" denotes the SDP objective value, and RMSD is the localization quality defined by (4.3).

5.4. Computational comparison with the decomposition method. There are other earlier approaches to speed up the SDP solution time. The domain-decomposition method of [29] and SpaceLoc of [25] are both based on breaking the localization problem into many geographically partitioned and smaller-sized localization problems, since each smaller SDP problem can be solved much faster and more accurately. Thus, they work quite well when many anchors are uniformly distributed in the region so that one is able to partition the network into many smaller domains; and, as a result, each of them contains enough anchors and forms its own independent localization problem. However, when the quantity of anchors is small or most of them are located on the boundary, such as the problems in Table 5.1, these approaches would fail at the beginning, simply because they are reduced to solving a nearly full-size SDP problem.

In contrast, our new approach does not depend on the quantity and location of anchors, since it is designed to improve the efficiency of solving a full-size SDP problem. In fact, any improvement on solving an individual SDP problem would complement the domain-decomposition approaches, since it would be possible to handle much larger-sized subproblems.

6. Future directions. From the computational results, we can see that the sub-SDP approaches indeed have a great potential to save computation time in solving sensor network localization problems, and the efficiency of the model is considerable. At the same time, they retain some of the most important theoretical features of the original SDP relaxation and achieve high localization quality.

There are many directions for future research. First, although our ESDP relaxation performs very well in localization quality, we still lack some powerful theorems to illustrate why the model works. This is a major issue that needs to be answered. Second, since, in our ESDP model, the decision matrix has its special structure, applying a tailored interior-point method (such as SCGD for the SOCP approach) may save more computational time. We also see that the NSDP relaxation has its own merit, both in theory and in practice. Therefore, further research about the NSDP model is also worth perusing. In fact, we have experimented with the NSDP model for solving the Max-Cut problem and will discuss its behavior and performance in another report. Finally, we plan to investigate the applicability of the SSDP relaxation idea for solving general SDP problems.

A SAMPLE APPROXIMATION APPROACH FOR OPTIMIZATION WITH PROBABILISTIC CONSTRAINTS*

JAMES LUEDTKE† AND SHABBIR AHMED†

Abstract. We study approximations of optimization problems with probabilistic constraints in which the original distribution of the underlying random vector is replaced with an empirical distribution obtained from a random sample. We show that such a sample approximation problem with a risk level larger than the required risk level will yield a lower bound to the true optimal value with probability approaching one exponentially fast. This leads to an a priori estimate of the sample size required to have high confidence that the sample approximation will yield a lower bound. We then provide conditions under which solving a sample approximation problem with a risk level smaller than the required risk level will yield feasible solutions to the original problem with high probability. Once again, we obtain a priori estimates on the sample size required to obtain high confidence that the sample approximation problem will yield a feasible solution to the original problem. Finally, we present numerical illustrations of how these results can be used to obtain feasible solutions and optimality bounds for optimization problems with probabilistic constraints.

Key words. probabilistic constraints, chance constraints, Monte Carlo, stochastic programming, large deviation

1. Introduction.

We consider optimization problems with probabilistic constraints (also known as chance constraints) of the form

$$\text{(PCP)} \qquad \min \{ f(x) : x \in X,\ \Pr \{ G(x, \xi) \leq \mathbf{0} \} \geq 1 - \epsilon \},$$

where $X \subset \mathbf{R}^n$ represents a deterministic feasible region, $f : \mathbf{R}^n \to \mathbf{R}$ represents the objective to be minimized, ξ is a random vector with suport $\Xi \subseteq \mathbf{R}^d$, $G : \mathbf{R}^n \times \mathbf{R}^d \to \mathbf{R}^m$ is a given constraint mapping, and ϵ is a risk parameter chosen by the decision maker, typically near zero, e.g., $\epsilon = 0.01$ or $\epsilon = 0.05$. Such problems are sometimes called probabilistic programs. In (PCP) a single probabilistic constraint is enforced over *all* rows in the constraints $G(x, \xi) \leq \mathbf{0}$ rather than requiring that each row independently be satisfied with high probability. Such a constraint is known as a *joint probabilistic constraint* and is appropriate in a context in which it is important to have all constraints satisfied simultaneously and there may be dependence between random variables in different rows.

Problems with joint probabilistic constraints have been extensively studied; see [25] for a background and an extensive list of references. Probabilistic constraints have been used in various applications including supply chain management [17], production planning [21], optimization of chemical processes [13, 14], and surface water quality management [30].

Unfortunately, probabilistic programs are still largely intractable except for a few special cases. There are two primary reasons for this intractability. First, in general, for a given $x \in X$, the quantity $\Pr\{G(x, \xi) \leq \mathbf{0}\}$ is hard to compute, as it requires

multidimensional integration, and hence just checking the feasibility of a solution is difficult. Second, the feasible region defined by a probabilistic constraint generally is not convex. In this paper, we study how the difficulty in checking feasibility can be addressed by solving a *sample approximation* problem based on a Monte Carlo sample of ξ. In particular, we study how this approximation can be used to generate feasible solutions and optimality bounds for general probabilistic programs.

The sample approximation that we study is a probabilistic program in which the original distribution of the random vector ξ is replaced with the empirical distribution obtained from the random sample. We show that such a sample approximation problem with a risk level larger than the nominal risk level ϵ will yield a lower bound to the true optimal value with probability approaching one exponentially fast. This leads to an a priori estimate of the sample size required to have high confidence that the sample approximation will yield a lower bound. We also discuss alternative means of generating lower bounds, which can be used regardless of the sample size used. We then provide conditions under which solving a sample approximation problem with a risk level smaller than ϵ will yield feasible solutions to the original problem with high probability. Once again, we obtain a priori estimates on the sample size required to obtain high confidence that the sample approximation problem will yield a feasible solution to the original problem.

Recently, a number of approaches have been proposed to find approximate solutions to probabilistic programs; the common theme among these is that they all seek "safe" or conservative approximations which can be solved efficiently. That is, they propose approximation problems which are convex and yield solutions which are feasible, or at least highly likely to be feasible, to the original probabilistic program. Approaches of this type include: the scenario approximation method studied by Calafiore and Campi [7, 8] and extended by Nemirovski and Shapiro [22]; the Bernstein approximation scheme of Nemirovski and Shapiro [23]; and robust optimization, e.g., [4, 6, 11]. The conservative approximations, when applicable, are attractive because they allow efficient generation of feasible solutions. In particular, they can yield feasible solutions when the probabilistic constraint is "hard," that is, with ϵ very small, such as $\epsilon = 10^{-6}$ or even $\epsilon = 10^{-12}$. However, in a context in which ϵ is not so small, such as $\epsilon = 0.05$ or $\epsilon = 0.01$, the probabilistic constraint is more likely to represent a "soft" constraint, one which the decision-maker would like to have satisfied but is willing to allow a nontrivial chance that it will be violated if doing so would sufficiently decrease the cost of the implemented solution. In this latter context, it would be desirable to obtain solutions which are feasible to the probabilistic constraint *along with* an assurance that the solutions are not much more costly than the lowest-cost solution attaining the same risk level. In this way, the decision-maker can be confident that they are choosing from solutions on the efficient frontier between the competing objectives of cost and risk. Unfortunately, the recently proposed conservative approximations say very little in terms of how conservative the solutions are. In particular, it is generally not possible to make a statement about how much worse the objective is relative to the optimal value at a fixed risk level ϵ.

The scenario approximation methods are most similar to the sample approach that we study in that they solve an approximation problem based on an independent Monte Carlo sample of the random vector. For example, the scenario approximation of [7, 8] takes a sample $\xi^1, \ldots, \xi^N$ and solves the problem

$$\min_{x \in X} \{ f(x) : G(x, \xi^i) \leq \mathbf{0}, \quad i = 1, \ldots, N \}. \tag{1}$$

That is, the scenario approximation enforces *all* of the constraints corresponding to the sample taken. When the nominal problem is convex (that is, $X \subseteq \mathbf{R}^n$ is a convex set, f is convex, and G is convex in x for each ξ), they show that the scenario approximation problem will yield a feasible solution to (PCP) with probability of at least $1 - \delta$ for

$$N \geq \frac{2}{\epsilon} \log\left(\frac{1}{\delta}\right) + 2n + \frac{2n}{\epsilon} \log\left(\frac{2}{\epsilon}\right). \tag{2}$$

In addition, under the stated convexity assumptions, the scenario approximation problem remains a convex program. An advantage of this approach relative to the approximations [4, 6, 11, 23] is that the only assumption that is made on the distribution of ξ is that it can be sampled from.

The key difference between the sample approximation that we study and scenario approximation is that we allow the risk level in the sample approximation problem to be positive; that is, we do not require that all sampled constraint sets be satisfied. Instead, the constraint sets which will be satisfied can be chosen optimally. The disadvantage of this scheme is that the sample approximation problem with a positive risk level has a nonconvex feasible region and hence may be difficult to solve despite having a simplified probabilistic structure. Specifically, if we allow k of the N sampled constraint sets to be violated, then we must choose a set of k constraint sets which will not be enforced, and there are $\binom{N}{k}$ possible sets from which to choose. Choosing the optimal set is an NP-hard problem even in a very special case [20]. However, in some special cases, such as when randomness appears only in the right-hand side of the constraints, the sample approximation problem may be relatively tractable to solve with integer programming techniques; see [20, 19]. In addition, for generating feasible solutions to (PCP), our analysis indicates that with appropriately chosen parameters *any* feasible solution to the sample approximation problem will be feasible to the original problem with high probability, so that it is sufficient to generate heuristic solutions. Similarly, to obtain a lower bound for (PCP), it is sufficient to obtain a lower bound for the appropriate sample approximation problem.

In the context of generating feasible solutions for (PCP), our sample approximation scheme includes as a special case the scenario approximation of [7, 8] in which the constraints corresponding to all sampled vectors ξ^i are enforced. In this special case, we obtain results very similar to those in [8] in terms of how many samples should be used to yield a solution feasible to (PCP) with high probability. However, our analysis is quite different from the analysis of [8] and, in particular, requires a significantly different set of assumptions. In some cases our assumptions are more stringent, but there are also a number of cases in which our assumptions apply and those of [8] do not, most notably if the feasible region X is not convex, as in the case of a mixed-integer program. Thus, our results complement those of [8] in two ways: First we show that sample approximations with positive risk levels can be used to yield feasible solutions to (PCP), and second we relax the convexity assumptions. Another closely related work is [9], in which the authors consider a sample approximation problem in which some of the sampled constraints are allowed to be violated. When the nominal problem is convex and a nondegeneracy assumption holds, they present an estimate on the sample size needed to obtain a feasible solution with high probability when a fixed number of sampled constraint sets are discarded optimally. Under these assumptions, their results for generating feasible solutions are very similar to the results that we present. The unique contributions of the present paper are (1) we use assumptions which are significantly different from the convexity and nondegeneracy assumptions

used in [9] (neither set of assumptions implies the other), (2) we analyze a method for generating *lower* bounds on the optimal value (which is useful for validating the quality of a given solution), (3) we prove that the sample approximation yields an *exact* optimal solution with high probability when X is finite (as in the case of an integer program), and (4) we conduct extensive numerical experiments on practical size problems indicating the potential of the approach.

The sample approximation problem that we study can be thought of as a variation of the well-studied *sample average approximation* (SAA) approach; see, e.g., [1, 10, 16, 29]. The difference is that the approximation that we study enforces a sample average constraint involving expectations of indicator functions, whereas the SAA approach typically optimizes a sample average objective. Shapiro [28] and Wang [32] have considered SAA approximation for expected value constraints. However, in these works, the function taken under expectation in the constraints is assumed to be continuous, and hence these results cannot be directly applied because of the discontinuity of indicator functions. In [2] a model with expected value constraints in which the function taken under expectation is not necessarily continuous is considered, and hence their analysis does apply to the case of probabilistic constraints. However, they consider only the case in which the feasible region is finite, and they discuss only the theoretical rate of convergence. In contrast, we begin with a similar analysis for the finite feasible region case but then extend the analysis to a number of significantly more general settings. In addition, we separate the analysis of when the sample approximation will be likely to yield a lower bound and when it will be likely to yield feasible solutions. This separate analysis allows for the development of methods which yield optimality statements which hold with high probability.

Finally, we mention the work of Vogel [31], which considers convergence properties of the sample approximation we use for probabilistic programs. When only the right-hand side is random with continuous distribution, it is shown that the probability that the distance between the sample feasible region and the true feasible region is larger than any positive threshold decreases exponentially fast with the size of the sample. However, the convergence rate has poor dependence on the dimension of the random vector, implying that the number of samples required to yield a reasonable approximation would have to grow exponentially in this dimension. Better convergence is demonstrated for the case of random right-hand side with discrete distribution. For the general case, linear convergence is demonstrated in the case of continuous distributions. Our analysis of the sample approximation problem extends these results by improving on the convergence rates and by analyzing what happens when the sample approximation problem is allowed to have a different risk level than the nominal risk level ϵ. This allows the sample approximation problem to be used to generate feasible solutions and optimality bounds.

The remainder of this paper is organized as follows. In section 2 we present and analyze the sample approximation scheme. We present results of a preliminary computational study of the use of the sample approximation scheme in section 3. We close with concluding remarks and directions for future research in section 4.

2. Analysis of sample approximation. We now study how Monte Carlo sampling can be used to generate probabilistically constrained problems with finite distribution which can be used to approximate problems with general distributions. Let us restate (PCP) as

$$(\mathrm{P}_\epsilon) \qquad z_\epsilon^* = \min\{f(x) : x \in X_\epsilon\},$$

where

$$X_\epsilon = \Big\{ x \in X : \Pr\{G(x,\xi) \leq \mathbf{0}\} \geq 1-\epsilon \Big\}.$$

We assume that z_ϵ^* exists and is finite. For example, if X is compact and $G(x,\xi)$ is affine in x for each $\xi \in \Xi$, then X_ϵ is closed [12] and hence compact, and so if $f(x)$ is continuous, then an optimal solution exists whenever $X_\epsilon \neq \emptyset$. Furthermore, we take as an assumption the measurability of any event S taken under probability, such as the event $\{G(x,\xi) \leq \mathbf{0}\}$ for each $x \in X$.

If X is a polyhedron, $f(x) = cx$, $G(x,\xi) = \xi - Tx$ $(d = m)$, then we obtain the probabilistically constrained linear program with random right-hand side

$$\min\Big\{ cx : x \in X, \Pr\{Tx \geq \xi\} \geq 1-\epsilon \Big\}.$$

We can also model a two-stage problem in which we make a decision x and wish to guarantee that with probability at least $1-\epsilon$ there is a feasible recourse decision y satisfying $Wy \geq H(x,\xi)$, where W is an m by l matrix and $H : \mathbf{R}^n \times \mathbf{R}^d \to \mathbf{R}^m$. This is accomplished by letting $G : \mathbf{R}^n \times \mathbf{R}^d \to \mathbf{R}$ be defined by

$$G(x,\xi) = \min_{\mu,y} \{\mu : Wy + \mu\mathbf{e} \geq H(x,\xi), \mu \geq -1\},$$

where $\mathbf{e} \in \mathbf{R}^m$ is a vector of all ones. Indeed, $G(x,\xi) \leq \mathbf{0}$ if and only if there exists $y \in \mathbf{R}^l$ and $\mu \leq 0$ such that $Wy + \mu\mathbf{e} \geq H(x,\xi)$, which occurs if and only if there exists $y \in \mathbf{R}^l$ such that $Wy \geq H(x,\xi)$.

Due to the general difficulty in calculating $\Pr\{G(x,\xi) \leq \mathbf{0}\}$ for a given $x \in X$, we seek to approximate (P_ϵ) by solving a sample approximation problem. We let $\xi^1, \ldots, \xi^N$ be an independent Monte Carlo sample of the random vector ξ. Then, for fixed $\alpha \in [0,1)$, the sample approximation problem is defined to be

$$(\mathrm{P}_\alpha^N) \qquad \hat{z}_\alpha^N = \min\big\{ f(x) : x \in X_\alpha^N \big\},$$

where

$$X_\alpha^N = \left\{ x \in X : \frac{1}{N} \sum_{i=1}^N \mathbb{I}\big(G(x,\xi^i) \leq \mathbf{0}\big) \geq 1-\alpha \right\},$$

where $\mathbb{I}(\cdot)$ is the indicator function which takes value one when $\cdot$ is true and zero otherwise. We adopt the convention that if $X_\alpha^N = \emptyset$, then $\hat{z}_\alpha^N = +\infty$, whereas if (P_α^N) is unbounded, we take $\hat{z}_\alpha^N = -\infty$. We assume that, except for these two cases, (P_α^N) has an optimal solution. This assumption is satisfied, for example, if X is compact, $f(x)$ is continuous, and $G(x,\xi)$ is continuous in x for each $\xi \in \Xi$, since then X_α^N is the union of finitely many compact sets (in this case $\hat{z}_\alpha^N = -\infty$ is also not possible). If $\alpha = 0$, the sample approximation problem (P_0^N) corresponds to the *scenario approximation* of probabilistic constraints, studied in [8, 22]. Our goal is to establish statistical relationships between problems (P_ϵ) and (P_α^N) for $\alpha \geq 0$. We first consider when (P_α^N) yields lower bounds for (P_ϵ) and then consider when (P_α^N) yields feasible solutions for (P_ϵ).

2.1. Lower bounds. We now establish a bound on the probability that (P_α^N) yields a lower bound for (P_ϵ). Let

$$\rho(\alpha, \epsilon, N) = \sum_{i=0}^{\lfloor \alpha N \rfloor} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}.$$

$\rho(\alpha, \epsilon, N)$ represents the probability of having at most $\lfloor \alpha N \rfloor$ "successes" in N independent trials, in which the probability of a success in each trial is ϵ.

LEMMA 1. *Assume that* (P_ϵ) *has an optimal solution. Then*

$$\Pr\left\{\hat{z}_\alpha^N \le z_\epsilon^*\right\} \ge \rho(\alpha, \epsilon, N).$$

Proof. Let $x^* \in X_\epsilon$ be an optimal solution to (P_ϵ). Then $\Pr\{G(x^*, \xi^i) \not\le \mathbf{0}\} \le \epsilon$ for each i. Hence, if we call the event $\{G(x^*, \xi^i) \not\le \mathbf{0}\}$ a success, then the probability of a success in trial i is $\bar{\phi}(x^*) := \Pr\{G(x^*, \xi^i) \not\le \mathbf{0}\} \le \epsilon$. By the definition of X_α^N, $x^* \in X_\alpha^N$ if and only if

$$\begin{aligned} \frac{1}{N}\sum_{i=1}^N \mathbb{I}\big(G(x^*, \xi^i) \le \mathbf{0}\big) \ge 1-\alpha \quad &\Leftrightarrow \quad \frac{1}{N}\sum_{i=1}^N \mathbb{I}\big(G(x^*, \xi^i) \not\le \mathbf{0}\big) \le \alpha \\ &\Leftrightarrow \quad \sum_{i=1}^N \mathbb{I}\big(G(x^*, \xi^i) \not\le \mathbf{0}\big) \le \lfloor \alpha N \rfloor. \end{aligned}$$

Hence, $\Pr\{x^* \in X_\alpha^N\}$ is the probability of having at most $\lfloor \alpha N \rfloor$ successes in N trials. Also, if $x^* \in X_\alpha^N$, then $\hat{z}_\alpha^N \le z_\epsilon^*$. Thus,

$$\Pr\left\{\hat{z}_\alpha^N \le z_\epsilon^*\right\} \ge \Pr\left\{x^* \in X_\alpha^N\right\} = \rho(\alpha, \bar{\phi}(x^*), N) \ge \rho(\alpha, \epsilon, N)$$

since $\rho(\alpha, \epsilon, N)$ is decreasing in ϵ. ∎

For example, if $\alpha = 0$ as in the previously studied scenario approximation [8, 22], then we obtain $\Pr\{\hat{z}_\alpha^N \le z_\epsilon^*\} \ge \rho(0, \epsilon, N) = (1-\epsilon)^N$. For this choice of α, it becomes very unlikely that the sample approximation (P_α^N) will yield a lower bound as N gets large. For $\alpha > \epsilon$ we see different behavior: the sample approximation yields a lower bound with probability approaching one exponentially fast as N increases. The proof is based on Hoeffding's inequality.

THEOREM 2 (Hoeffding's inequality [15]). *Let* $Y_1, \ldots, Y_N$ *be independent random variables, with* $\Pr\{Y_i \in [a_i, b_i]\} = 1$*, where* $a_i \le b_i$ *for* $i = 1, \ldots, N$*. Then if* $t > 0$*,*

$$\Pr\left\{\sum_{i=1}^N (Y_i - \mathbb{E}[Y_i]) \ge tN\right\} \le \exp\left\{-\frac{2N^2t^2}{\sum_{i=1}^N (b_i - a_i)^2}\right\}.$$

THEOREM 3. *Let* $\alpha > \epsilon$*, and assume that* (P_ϵ) *has an optimal solution. Then*

$$\Pr\left\{\hat{z}_\alpha^N \le z_\epsilon^*\right\} \ge 1 - \exp\big\{-2N(\alpha-\epsilon)^2\big\}.$$

Proof. Let x^* be an optimal solution to (P_ϵ). As in the proof of Lemma 1, if $x^* \in X_\alpha^N$, then $\hat{z}_\alpha^N \le z_\epsilon^*$. For $i = 1, \ldots, N$ let Y_i be a random variable taking value 1

if $G(x^*, \xi^i) \not\leq \mathbf{0}$ and 0 otherwise. Then $\Pr\{Y_i \in [0,1]\} = 1$ and $E[Y_i] \leq \epsilon$. Hence,

$$\begin{aligned}\Pr\left\{\hat{z}_\alpha^N > z_\epsilon^*\right\} \leq \Pr\left\{x^* \notin X_\alpha^N\right\} &= \Pr\left\{\frac{1}{N}\sum_{i=1}^N Y_i > \alpha\right\} \\ &\leq \Pr\left\{\frac{1}{N}\sum_{i=1}^N (Y_i - E[Y_i]) > \alpha - \epsilon\right\} \\ &\leq \exp\Big\{-\frac{2N^2(\alpha-\epsilon)^2}{N}\Big\} = \exp\big\{-2N(\alpha-\epsilon)^2\big\},\end{aligned}$$

where the first inequality follows since $E[Y_i] \leq \epsilon$ and the second inequality follows from Hoeffding's inequality. □

Theorem 3 states that, by taking a risk parameter $\alpha > \epsilon$ in our sample approximation problem, we will obtain a lower bound to the true optimal value with probability approaching one exponentially fast as N increases. Stated another way, suppose that we solve a sample approximation problem (P_α^N) with $\alpha = \epsilon$. Then for any $\gamma > 0$ such that $\gamma < \epsilon$, the optimal value of this problem, $\hat{z}_\epsilon^N$, will be a lower bound to the optimal value of $\mathrm{P}_{\epsilon-\gamma}$ with probability approaching one exponentially fast with N. If γ is small, this states that the optimal solution to the sample problem will have cost no worse than any solution that is "slightly less risky" than the nominal risk level ϵ.

Theorem 3 immediately yields a method for generating lower bounds with specified confidence $1-\delta$, where $\delta \in (0,1)$. If we select $\alpha > \epsilon$ and

$$N \geq \frac{1}{2(\alpha-\epsilon)^2}\log\Big(\frac{1}{\delta}\Big),$$

then Theorem 3 ensures that $\hat{z}_\alpha^N \leq z_\epsilon^*$ with probability of at least $1-\delta$. Indeed, with this choice of α and N, we have

$$\Pr\left\{\hat{z}_\alpha^N > z_\epsilon^*\right\} \leq \exp\big\{-2N(\alpha-\epsilon)^2\big\} \leq \exp\Big\{-\log\Big(\frac{1}{\delta}\Big)\Big\} = \delta.$$

Because $1/\delta$ is taken under logarithm, we can obtain a lower bound with high confidence, i.e., with δ very small, without significantly increasing the required sample size N. On the other hand, the required sample size grows quadratically with $1/(\alpha-\epsilon)$ and hence will be large for α very close to ϵ.

Lemma 1 can also be used to obtain lower bounds with specified confidence, by using the bounding procedure proposed by Nemirovski and Shapiro [23]. They restrict $\alpha = 0$ in the sample approximation, but the technique can be applied in exactly the same way when $\alpha > 0$, and it is likely that this can make the bounding technique significantly more powerful. The idea is as follows. Take M sets of N independent samples of ξ, given by $\xi^{i,j}$ for $j = 1, \ldots, M$ and $i = 1, \ldots, N$, and for each j solve the associated sample approximation problem

$$\hat{z}_{\alpha,j}^N = \min\big\{f(x) : x \in X_{\alpha,j}^N\big\},$$

where

$$X_{\alpha,j}^N = \left\{x \in X : \frac{1}{N}\sum_{i=1}^N \mathbb{I}\big(G(x,\xi^{i,j}) \leq \mathbf{0}\big) \geq 1-\alpha\right\}.$$

We then rearrange the values $\{\hat{z}^N_{\alpha,j}\}_{j=1}^M$ to obtain the *order statistics* $\hat{z}^N_{\alpha,[j]}$ for $j = 1,\ldots,M$ satisfying $\hat{z}^N_{\alpha,[1]} \le \cdots \le \hat{z}^N_{\alpha,[M]}$. Then a lower bound which is valid with specified confidence $1-\delta$ can be obtained as follows.

THEOREM 4. *Let $\delta \in (0,1)$, $\alpha \in [0,1)$, and N, L, and M be positive integers such that $L \le M$ and*

$$\sum_{i=0}^{L-1} \binom{M}{i} \rho(\alpha,\epsilon,N)^i \big(1-\rho(\alpha,\epsilon,N)\big)^{M-i} \le \delta. \tag{3}$$

Then

$$\Pr\left\{\hat{z}^N_{\alpha,[L]} \le z^*_\epsilon\right\} \ge 1-\delta.$$

Proof. We show that $\Pr\{\hat{z}^N_{\alpha,[L]} > z^*_\epsilon\} \le \delta$. Note that $\hat{z}^N_{\alpha,[L]} > z^*_\epsilon$ if and only if less than L of the values $\hat{z}^N_{\alpha,j}$ satisfy $\hat{z}^N_{\alpha,j} \le z^*_\epsilon$. Thus, calling the event $\{\hat{z}^N_{\alpha,j} \le z^*_\epsilon\}$ a success, the event $\hat{z}^N_{\alpha,[L]} > z^*_\epsilon$ occurs if and only if there are fewer than L successes in M trials, in which the probability of a success is $\eta := \Pr\{\hat{z}^N_{\alpha,j} \le z^*_\epsilon\}$. The result then follows since $\eta \ge \rho(\alpha,\epsilon,N)$ by Lemma 1 and so

$$\sum_{i=0}^{L-1} \binom{M}{i} \eta^i (1-\eta)^{M-i} \le \sum_{i=0}^{L-1} \binom{M}{i} \rho(\alpha,\epsilon,N)^i \big(1-\rho(\alpha,\epsilon,N)\big)^{M-i} \le \delta$$

by (3). □

An interesting special case of Theorem 4 is obtained by taking $L = 1$. In this case, we are taking as our lower bound the minimum of the optimal values obtained from solving the M sample approximation problems. To have confidence $1-\delta$ that the lower bound is truly a lower bound, we should choose M such that

$$\big(1-\rho(\alpha,\epsilon,N)\big)^M \le \delta. \tag{4}$$

With the choice of $L = 1$, let us consider how large M should be with $\alpha = 0$ and with $\alpha = \epsilon$. With $\alpha = 0$, we obtain $\rho(0,\epsilon,N) = (1-\epsilon)^N$. Hence, to have confidence $1-\delta$ to obtain a lower bound, we should take

$$M \ge \log\left(\frac{1}{\delta}\right) / \log\left(\frac{1}{1-(1-\epsilon)^N}\right). \tag{5}$$

By using the inequality $\log(1+x) \le x$ for $x > 0$, we have

$$\log\left(\frac{1}{1-(1-\epsilon)^N}\right) = \log\left(1 + \frac{(1-\epsilon)^N}{1-(1-\epsilon)^N}\right) \le \frac{(1-\epsilon)^N}{1-(1-\epsilon)^N}.$$

Hence, when $\alpha = 0$, we should take

$$M \ge \log\left(\frac{1}{\delta}\right) \frac{1-(1-\epsilon)^N}{(1-\epsilon)^N}.$$

Thus, for fixed $\epsilon \in (0,1)$, the required M grows exponentially in N. For example, by using (5), if $\delta = 0.001$ and $\epsilon = 0.01$, then for $N = 250$ we need $M \ge 82$, for $N = 500$ we need $M \ge 1048$, and for $N = 750$ we need $M \ge 12967$. If $\delta = 0.001$ and $\epsilon = 0.05$,

then for $N = 50$ we should take $M \geq 87$, for $N = 100$ we should take $M \geq 1160$, and for $N = 150$ we must already have $M \geq 15157$! Thus, to keep M reasonably small, we must keep N small, but this will weaken the lower bound obtained in each sample.

Now suppose that we take $L = 1$ and $\alpha = \epsilon$. Then, for N "large enough" (e.g., $N\epsilon \geq 10$), we have $\rho(\epsilon, \epsilon, N) \approx 1/2$. Indeed, $\rho(\epsilon, \epsilon, N)$ is the probability that a binomial random variable with success probability ϵ and N trials is at most $\lfloor \epsilon N \rfloor$. With N large enough relative to ϵ, this probability can be approximated by the probability that a random variable with normal distribution having mean ϵN does not exceed $\lfloor \epsilon N \rfloor$. Because the median of the normal distribution equals the mean, we obtain $\rho(\epsilon, \epsilon, N) \gtrsim 1/2$. Thus, with $L = 1$ and $\alpha = \epsilon$, we should choose M such that $(1/2)^M \leq \delta$ or

$$M \geq \log_2 \left(\frac{1}{\delta} \right).$$

Note that this bound is *independent of* N *and* ϵ. For example, for $\delta = 0.001$, we should take $M \geq 10$. The independence of N has the advantage that we can take N to be as large as is computationally tractable, which will tend to make each of the optimal values $\hat{z}^N_{\epsilon,j}$ closer to the true optimal z^*_ϵ and hence make the lower bound $\min_j \{\hat{z}^N_{\epsilon,j}\}$ tighter.

We close this section by commenting that, although our results have been stated in terms of the *exact* optimal solution $\hat{z}^N_\alpha$ of the sample approximation problem, it is not necessary to calculate this value exactly to use the results. All of the results about lower bounds for z^*_ϵ will be valid if $\hat{z}^N_\alpha$ is replaced with a lower bound of $\hat{z}^N_\alpha$, at the expense, of course, of weakening the lower bound.

2.2. Feasible solutions. We now consider conditions under which an optimal solution to (P^N_α), if one exists, is feasible to (P_ϵ). The idea is that if we take the risk parameter α in (P^N_α) to be smaller than ϵ, then for N large enough the feasible region of (P^N_α) will be a subset of the feasible region of (P_ϵ), so that any optimal solution to (P^N_α) must be feasible to (P_ϵ). Unlike the case for lower bounds, we will need to make additional assumptions to assure that (P^N_α) yields a feasible solution with high probability.

We begin by assuming that the feasible region X is finite. Note, however, that $|X|$ may be exponentially large; for example, X could be the feasible region of a bounded integer program. We then show how this assumption can be relaxed and replaced with some milder assumptions.

2.2.1. Finite X.

THEOREM 5. *Suppose that X is finite and $\alpha \in [0, \epsilon)$. Then*

$$\Pr\left\{X^N_\alpha \subseteq X_\epsilon\right\} \geq 1 - |X \setminus X_\epsilon| \exp\left\{-2N(\epsilon - \alpha)^2\right\}.$$

Proof. Consider any $x \in X \setminus X_\epsilon$, i.e., $x \in X$ with $\Pr\{G(x, \xi) \leq \mathbf{0}\} < 1 - \epsilon$. We want to estimate the probability that $x \in X^N_\alpha$. For $i = 1, \ldots, N$ define the random variable Y_i by $Y_i = 1$ if $G(x, \xi^i) \leq \mathbf{0}$ and $Y_i = 0$ otherwise. Then $E[Y_i] = \Pr\{G(x, \xi^i) \leq \mathbf{0}\} < 1 - \epsilon$ and $\Pr\{Y_i \in [0, 1]\} = 1$. By observing that $x \in X^N_\alpha$ if and only if $(1/N) \sum_{i=1}^N Y_i \geq 1 - \alpha$ and applying Hoeffding's inequality, we obtain

$$\begin{aligned}\Pr\left\{x \in X^N_\alpha\right\} = \Pr\left\{ \frac{1}{N} \sum_{i=1}^N Y_i \geq 1 - \alpha \right\} &\leq \Pr\left\{ \sum_{i=1}^N (Y_i - E[Y_i]) \geq N(\epsilon - \alpha) \right\} \\ &\leq \exp\left\{-2N(\epsilon - \alpha)^2\right\}.\end{aligned}$$

Then

$$\begin{aligned}\Pr\left\{X_\alpha^N \not\subseteq X_\epsilon\right\} &= \Pr\left\{\exists x \in X_\alpha^N \text{ such that } \Pr\left\{G(x,\xi) \leq \mathbf{0}\right\} < 1-\epsilon\right\} \\ &\leq \sum_{x \in X \setminus X_\epsilon} \Pr\left\{x \in X_\alpha^N\right\} \\ &\leq |X \setminus X_\epsilon| \exp\left\{-2N(\epsilon-\alpha)^2\right\}. \qquad \square\end{aligned}$$

For fixed $\alpha < \epsilon$ and $\delta \in (0,1)$, Theorem 5 shows that if we take

$$N \geq \frac{1}{2(\epsilon-\alpha)^2} \log\left(\frac{|X \setminus X_\epsilon|}{\delta}\right),$$

then, if (P_α^N) is feasible, it will yield a feasible solution to (P_ϵ) with probability at least $1-\delta$. If $|X| \leq U^n$, we can take

$$N \geq \frac{1}{2(\epsilon-\alpha)^2} \log\left(\frac{1}{\delta}\right) + \frac{n}{2(\epsilon-\alpha)^2} \log(U). \tag{6}$$

Note that N grows linearly with the dimension n of the feasible region and logarithmically with $1/\delta$, so that the confidence of generating a feasible solution can be made large without requiring N to be too large. However, the quadratic dependence on $\epsilon - \alpha$ implies that this a priori estimate of how large N should be will grow quite large for α near ϵ.

Theorem 5 states that for $\alpha < \epsilon$ *every* feasible solution to the sample approximation problem will be feasible to the original problem with risk level ϵ with high probability as N gets large. This is in contrast to the results of the scenario approximation method presented in [8] in which $\alpha = 0.0$ is required, and the result is that the *optimal* solution to the sample approximation problem will be feasible to the original problem with high probability. The advantage of our approach is that one need not solve the sample approximation problem to optimality to obtain a solution to the original problem. Simple heuristics which select which sampled constraints to be satisfied, e.g., greedily or by local search, can be used to yield feasible solutions for the approximation problem, which by virtue of Theorem 5 will have high probability of being feasible to the original problem. This comment also applies to subsequent feasibility results in which we relax the assumption that the feasible region X is finite.

In this case of finite X, we can combine Theorem 5 with Theorem 3 to demonstrate that solving a sample approximation with $\alpha = \epsilon$ will yield an exact optimal solution with probability approaching one exponentially fast with N. Let X_ϵ^* be the set of optimal solutions to (P_ϵ), and define $\underline{\alpha} = \max\{\Pr\{G(x,\xi) \not\leq \mathbf{0}\} : x \in X_\epsilon^*\}$. By definition, we have $z_{\underline{\alpha}}^* = z_\epsilon^*$. Next, let $\overline{\alpha} = \min\{\Pr\{G(x,\xi) \not\leq \mathbf{0}\} : x \in X \setminus X_\epsilon\}$. By definition, we have $\overline{\alpha} > \epsilon$. Finally, define $\kappa = \min\{\epsilon - \underline{\alpha}, \overline{\alpha} - \epsilon\}$.

COROLLARY 6. *Assume that* $\underline{\alpha} < \epsilon$. *Then*

$$\Pr\left\{\hat{z}_\epsilon^N = z_\epsilon^*\right\} \geq 1 - (|X|+1)\exp\left\{-2N\kappa^2\right\}.$$

Proof. First observe that $\kappa > 0$ when $\underline{\alpha} < \epsilon$. Next, we apply Theorem 3 with $\underline{\alpha}$ in place of ϵ and ϵ in place of α to obtain $\Pr\{\hat{z}_\epsilon^N \leq z_{\underline{\alpha}}^*\} \geq 1 - \exp\{-2N(\epsilon-\underline{\alpha})^2\}$. Because $z_{\underline{\alpha}}^* = z_\epsilon^*$, this implies that $\Pr\{\hat{z}_\epsilon^N > z_\epsilon^*\} \leq \exp\{-2N(\epsilon-\underline{\alpha})^2\}$.

We next observe that the proof of Theorem 5 can be modified to show the slightly stronger result that

$$\Pr\left\{X_\alpha^N \subseteq X_\epsilon'\right\} \geq 1 - |X \setminus X_\epsilon'| \exp\left\{-2N(\epsilon-\alpha)^2\right\},$$

where $X'_\epsilon = \{x \in X : \Pr\{G(x,\xi) \leq \mathbf{0}\} > 1-\epsilon\}$. (In the proof, we consider each $x \in X \setminus X'_\epsilon$ and observe that the defined random variable Y_i satisfies $E[Y_i] \leq 1-\epsilon$. The remainder of the proof is identical with X_ϵ replaced by X'_ϵ.) By applying this result, we obtain

$$\Pr\left\{X_\epsilon^N \subseteq X'_{\overline{\alpha}}\right\} \geq 1 - |X \setminus X'_{\overline{\alpha}}| \exp\left\{-2N(\overline{\alpha}-\epsilon)^2\right\}.$$

However, if $x \in X'_{\overline{\alpha}}$, then $\Pr\{G(x,\xi) \not\leq \mathbf{0}\} < \overline{\alpha}$, and by definition of $\overline{\alpha}$ this implies that $\Pr\{G(x,\xi) \not\leq \mathbf{0}\} \leq \epsilon$ and thus $X'_{\overline{\alpha}} \subseteq X_\epsilon$. It follows that

$$\Pr\left\{\hat{z}_\epsilon^N < z_\epsilon^*\right\} \leq \Pr\left\{X_\epsilon^N \not\subseteq X_\epsilon\right\} \leq |X| \exp\left\{-2N(\overline{\alpha}-\epsilon)^2\right\}.$$

Therefore,

$$\begin{aligned}\Pr\left\{\hat{z}_\epsilon^N \neq z_\epsilon^*\right\} &\leq \Pr\left\{\hat{z}_\epsilon^N > z_\epsilon^*\right\} + \Pr\left\{\hat{z}_\epsilon^N < z_\epsilon^*\right\} \\ &\leq \exp\left\{-2N(\epsilon-\underline{\alpha})^2\right\} + |X| \exp\left\{-2N(\overline{\alpha}-\epsilon)^2\right\} \\ &\leq (1+|X|)\exp\left\{-2N\kappa^2\right\}. \qquad \square\end{aligned}$$

The assumption that $\underline{\alpha} < \epsilon$ is mild since, because X is finite, there are only finitely many values of $\epsilon \in [0,1]$ for which it is possible to have $\epsilon = \underline{\alpha}$. Stated another way, if we add a random perturbation uniformly distributed in $(-\gamma,\gamma)$ to ϵ, where γ can be arbitrarily small, then the assumption will hold with probability one. On the other hand, the number of scenarios required to guarantee a reasonably high probability of obtaining the optimal solution will be at least proportional to $(\epsilon-\underline{\alpha})^{-2}$ and hence may be very large. Thus, Corollary 6 illustrates the *qualitative* behavior of the sample approximation with $\alpha = \epsilon$ in the finite feasible region case but may not be useful for estimating the required sample size.

If we take $\alpha = 0$ in Theorem 5, we obtain improved dependence of N on ϵ.

THEOREM 7. *Suppose that X is finite and $\alpha = 0$. Then*

$$\Pr\left\{X_0^N \subseteq X_\epsilon\right\} \geq 1 - |X \setminus X_\epsilon|(1-\epsilon)^N.$$

Proof. With $\alpha = 0$, if $x \in X$ satisfies $\Pr\{G(x,\xi) \leq \mathbf{0}\} < 1-\epsilon$, then $x \in X_0^N$ if and only if $G(x,\xi^i) \leq \mathbf{0}$ for each $i = 1,\ldots,N$, and hence $\Pr\{x \in X_0^N\} < (1-\epsilon)^N$. The claim then follows just as in the proof of Theorem 5. $\square$

When $\alpha = 0$, to obtain confidence $1-\delta$ that (P_α^N) will yield a feasible solution to (P_ϵ) whenever (P_α^N) is feasible, we should take

$$N \geq \log^{-1}\left(\frac{1}{1-\epsilon}\right) \log\left(\frac{|X \setminus X_\epsilon|}{\delta}\right).$$

If $|X| \leq U^n$, then it is sufficient to take

$$N \geq \frac{1}{\epsilon}\log\left(\frac{1}{\delta}\right) + \frac{n}{\epsilon}\log U, \tag{7}$$

where we have used the inequality $\log(1/(1-\epsilon)) \geq \epsilon$. Hence, with $\alpha = 0$, the required sample size again grows linearly in n but now also linearly with $1/\epsilon$. Note the similarity between the bound (7) and the bound of Campi and Calafiore [8]

$$N \geq \frac{2}{\epsilon}\log\left(\frac{1}{\delta}\right) + 2n + \frac{2n}{\epsilon}\log\left(\frac{2}{\epsilon}\right),$$

which also exhibits linear dependence in n and (nearly) linear dependence in $1/\epsilon$. This is interesting considering the significantly different assumptions used for the analysis. In [8] it is assumed that X is a convex set and $G(x,\xi)$ is a convex function of x for every possible value of ξ. In contrast, we make the strong assumption that X is finite but require no other assumptions on the form of the random constraint $G(x,\xi) \le \mathbf{0}$.

2.2.2. Random right-hand side. We now show how the assumption that X is finite can be relaxed when the probabilistic constraint involves randomness only in the right-hand side. Thus, in this section we assume that $G(x,\xi) = \xi - g(x)$, where $g : \mathbf{R}^n \to \mathbf{R}^m$, and $\Xi \subseteq \mathbf{R}^m$. Let the cumulative distribution function of ξ be $F(y) = \Pr\{\xi \le y\}$ for $y \in \mathbf{R}^m$. Then the feasible region of the probabilistically constrained problem with a random right-hand side is

$$\bar{X}_\epsilon = \Big\{ x \in X : F(g(x)) \ge 1 - \epsilon \Big\}.$$

The feasible region of the sample approximation problem for $\alpha \in [0,1)$ is

$$\bar{X}_\alpha^N = \left\{ x \in X : \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}\big(g(x) \ge \xi^i\big) \ge 1 - \alpha \right\}.$$

We first consider the case that ξ has a finite distribution, that is, $\Xi = \{\xi^1, \ldots, \xi^K\}$. Note that K may be very large, for example, $K = U^m$ for a positive integer U. Next, for $j = 1, \ldots, m$ define $\Xi_j = \{\xi_j^k : k = 1, \ldots, K\}$, and finally let $C = \prod_{j=1}^m \Xi_j$.

THEOREM 8. *Suppose that ξ has a finite distribution, and let $\alpha \in [0,\epsilon)$. Then*

$$\Pr\big\{\bar{X}_\alpha^N \subseteq \bar{X}_\epsilon\big\} \ge 1 - |C| \exp\big\{-2N(\epsilon-\alpha)^2\big\}.$$

Proof. Let $C_\epsilon = \{y \in C : F(y) \ge 1 - \epsilon\}$ and

$$C_\alpha^N = \left\{ y \in C : \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}\big(y \ge \xi^i\big) \ge 1 - \alpha \right\}.$$

Because C is a finite set, we can apply Theorem 5 to obtain

$$\Pr\big\{C_\alpha^N \subseteq C_\epsilon\big\} \ge 1 - |C| \exp\big\{-2N(\epsilon-\alpha)^2\big\}. \tag{8}$$

Now, let $x \in \bar{X}_\alpha^N$, so that $x \in X$ and $\sum_{i=1}^N \mathbb{I}(g(x) \ge \xi^i) \ge N(1-\alpha)$. Define $\bar{y} \in C$ by

$$\bar{y}_j = \max\{y_j \in \Xi_j : y_j \le g_j(x)\}, \qquad j = 1, \ldots, m,$$

so that by definition $\bar{y} \le g(x)$. Next, note that if $g(x) \ge \xi^i$ for some i, then also $\bar{y} \ge \xi^i$ since $\xi^i \in C$. Hence, $\sum_{i=1}^N \mathbb{I}(\bar{y} \ge \xi^i) \ge N(1-\alpha)$ and so $\bar{y} \in C_\alpha^N$. Hence, when $C_\alpha^N \subseteq C_\epsilon$, $F(\bar{y}) \ge 1 - \epsilon$, and, because $\bar{y} \le g(x)$, also $F(g(x)) \ge 1 - \epsilon$ and so $x \in \bar{X}_\epsilon$. Since $x \in \bar{X}_\alpha^N$ was arbitrary, this shows that, when $C_\alpha^N \subseteq C_\epsilon$, $\bar{X}_\alpha^N \subseteq \bar{X}_\epsilon$, and the result follows from (8). ∎

If, for example, $|\Xi_j| \le U$ for each j, then $|C| \le U^m$, so to obtain confidence $1 - \delta$ that $\bar{X}_\alpha^N \subseteq \bar{X}_\epsilon$ it is sufficient to take

$$N \ge \frac{1}{2(\epsilon-\alpha)^2} \log\left(\frac{1}{\delta}\right) + \frac{m}{2(\epsilon-\alpha)^2} \log U. \tag{9}$$

The difference between this bound and (6) is that (9) depends linearly on m, the dimension of ξ, whereas (6) depends linearly on n, the dimension of x.

Similarly to the case of finite feasible region X, when ξ has a finite distribution, it can be shown that the sample approximation problem with $\epsilon = \alpha$ will yield an exact optimal solution with probability approaching one as N increases. The statement and proof of this result are completely analogous to those of Corollary 6 and are omitted for the sake of brevity.

As in the case of Theorem 7, if we take $\alpha = 0$, we can obtain the stronger convergence result

$$\Pr\left\{\bar{X}_0^N \subseteq \bar{X}_\epsilon\right\} \geq 1 - |C|(1-\epsilon)^N.$$

The assumption in Theorem 8 that Ξ is finite can be relaxed if we assume that $\bar{X}_\epsilon \subseteq \bar{X}(l,u) := \{x \in X : l \leq g(x) \leq u\}$ for some $l, u \in \mathbf{R}^m$. This assumption is not very strict. Indeed, if we define $l \in \mathbf{R}^m$ by

$$l_j = \min\{l \in \mathbf{R} : F_j(l) \geq 1 - \epsilon\},$$

where F_j is the marginal distribution of ξ_j for $j = 1, \ldots, m$, then $g(x) \geq l$ for any $x \in \bar{X}_\epsilon$. This holds because if $g_j(x) < l_j$ for some j, then $\Pr\{g(x) \geq \xi\} \leq \Pr\{g_j(x) \geq \xi_j\} = F_j(g_j(x)) < 1 - \epsilon$ by the definition of l_j and hence $x \notin \bar{X}_\epsilon$. Furthermore, if X is compact and $g(x)$ is continuous in x, then if we define $u \in \mathbf{R}^m$ by

$$u_j = \max\{g_j(x) : x \in X\}, \qquad j = 1, \ldots, m,$$

each u_j is finite, and, by definition, $g(x) \leq u$ for any $x \in \bar{X}$. Under the assumption that $\bar{X}_\epsilon \subseteq \bar{X}(l,u)$ the assumption that Ξ is finite can be replaced by the assumption that $\Xi \cap \{y \in \mathbf{R}^m : l \leq y \leq u\}$ is finite, leading to a result similar to Theorem 8, with a nearly identical proof.

Alternatively, when $\bar{X}_\epsilon \subseteq \bar{X}(l,u)$, we can obtain a similar result if ξ has a Lipschitz continuous cumulative distribution function F on $[l,u] = \{y \in \mathbf{R}^m : l \leq y \leq u\}$. That is, we assume that there exists $L > 0$ such that

$$|F(y) - F(y')| \leq L\|y - y'\|_\infty \qquad \forall y, y' \in [l,u],$$

where $\|y\|_\infty = \max\{|y_j| : j = 1, \ldots, m\}$. Under the assumption that $\bar{X}_\epsilon \subseteq \bar{X}(l,u)$ we add the constraints $l \leq g(x) \leq u$ to the sample approximation problem to obtain

$$\bar{X}_\alpha^N(l,u) = \left\{ x \in \bar{X}(l,u) : \frac{1}{N}\sum_{i=1}^N \mathbb{I}\big(g(x) \geq \xi^i\big) \geq 1 - \alpha \right\}.$$

We define $D = \max\{u_j - l_j : j = 1, \ldots, m\}$. Then we have the following.

THEOREM 9. *Suppose that $\bar{X}_\epsilon \subseteq \bar{X}(l,u)$ and F is Lipschitz continuous with constant L. Let $\alpha \in [0, \epsilon)$ and $\beta \in (0, \epsilon - \alpha)$. Then*

$$\Pr\left\{\bar{X}_\alpha^N(l,u) \subseteq \bar{X}_\epsilon\right\} \geq 1 - \lceil DL/\beta \rceil^m \exp\left\{-2N(\epsilon - \alpha - \beta)^2\right\}.$$

Proof. Let $K = \lceil DL/\beta \rceil$, and define $Y_j = \{l_j + (u_j - l_j)i/K : i = 1, \ldots, K\}$ for $j = 1, \ldots, m$ and $Y = \prod_{j=1}^m Y_j$, so that $|Y| = K^m$ and that for any $y \in [l,u]$ there exists $y' \in Y$ such that $y' \geq y$ and $\|y - y'\|_\infty \leq \beta/L$. Indeed, for a given $y \in [l,u]$ such a y' can be obtained by letting

$$y'_j = \min\{w \in Y_j : w \geq y_j\}, \qquad j = 1, \ldots, m.$$

With this definition of y', we have $y' \geq y$ and

$$|y'_j - y_j| = y'_j - y_j \leq (u_j - l_j)/K \leq D/K \leq \beta/L, \qquad j = 1, \ldots, m.$$

Next, let $Y_{\epsilon-\beta} = \{y \in Y : F(y) \geq 1 - \epsilon + \beta\}$ and

$$Y_\alpha^N = \left\{ y \in Y : \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}\big(y \geq \xi^i\big) \geq 1 - \alpha \right\}. \tag{10}$$

Since Y is finite and $\alpha < \epsilon - \beta$, we can apply Theorem 5 to obtain

$$\Pr\left\{Y_\alpha^N \subseteq Y_{\epsilon-\beta}\right\} \geq 1 - |Y| \exp\left\{-2N(\epsilon - \alpha - \beta)^2\right\}.$$

Now, let $x \in \bar{X}_\alpha^N(l, u)$, and let $y' \in Y$ be such that $y' \geq g(x)$ and $\|y' - g(x)\|_\infty \leq \beta/L$. By Lipschitz continuity of F, this implies that

$$F(y') - F(g(x)) \leq L\|y' - g(x)\|_\infty \leq \beta. \tag{11}$$

Because x satisfies $\sum_{i=1}^N \mathbb{I}(g(x) \geq \xi^i) \geq N(1-\alpha)$ and $y' \geq g(x)$, we have $\sum_{i=1}^N \mathbb{I}(y' \geq \xi^i) \geq N(1-\alpha)$ and hence $y' \in Y_\alpha^N$. Thus, by using (11), when $Y_\alpha^N \subseteq Y_{\epsilon-\beta}$ occurs,

$$F(g(x)) \geq F(y') - \beta \geq (1 - \epsilon + \beta) - \beta = 1 - \epsilon.$$

Since $x \in \bar{X}_\alpha^N(l, u)$ was arbitrary, $Y_\alpha^N \subseteq Y_{\epsilon-\beta}$ implies that $\bar{X}_\alpha^N(l, u) \subseteq \bar{X}_\epsilon$, and the result follows from (10). □

To obtain a confidence of at least $1 - \delta$ that $\bar{X}_\alpha^N(l, u) \subseteq \bar{X}_\epsilon$, it is sufficient to take

$$N \geq \frac{1}{2(\epsilon - \alpha - \beta)^2} \log\left(\frac{1}{\delta}\right) + \frac{m}{2(\epsilon - \alpha - \beta)^2} \log\left\lceil \frac{DL}{\beta} \right\rceil.$$

Note that for fixed $\epsilon > 0$ and $\alpha \in [0, \epsilon)$, β is a free parameter which can be chosen in $(0, \epsilon - \alpha)$. If, for example, we take $\beta = (\epsilon - \alpha)/2$, we obtain

$$N \geq \frac{2}{(\epsilon - \alpha)^2} \log\left(\frac{1}{\delta}\right) + \frac{2m}{(\epsilon - \alpha)^2} \log\left\lceil \frac{2DL}{\epsilon - \alpha} \right\rceil.$$

Once again, if $\alpha = 0$, similar arguments can be used to conclude that if

$$N \geq \frac{2}{\epsilon} \log\left(\frac{1}{\delta}\right) + \frac{2m}{\epsilon} \log\left\lceil \frac{2DL}{\epsilon} \right\rceil,$$

then $\Pr\{\bar{X}_0^N(l, u) \subseteq \bar{X}_\epsilon\} \geq 1 - \delta$.

2.2.3. Lipschitz continuous *G*. We now turn to the problem of using a sample approximation problem to generate feasible solutions to (P_ϵ) when X is not necessarily finite and $G(x, \xi)$ does not necessarily have the form $G(x, \xi) = g(x) - \xi$. In this section, we assume for simplicity of exposition that G takes values in $\mathbf{R}$. This is without loss of generality, since if $\bar{G} : \mathbf{R}^n \times \mathbf{R}^d \to \mathbf{R}^m$, we can define $G : \mathbf{R}^n \times \mathbf{R}^d \to \mathbf{R}$ by $G(x, \xi) = \max\{\bar{G}_j(x, \xi) : j = 1, \ldots, m\}$ and the constraints $G(x, \xi) \leq 0$ and $\bar{G}(x, \xi) \leq \mathbf{0}$ are equivalent. In this section, we shall make the following Lipschitz continuity assumption on G.

Assumption 1. There exists $L > 0$ such that

$$|G(x, \xi) - G(x', \xi)| \leq L\|x - x'\|_\infty \qquad \forall x, x' \in X \text{ and } \forall \xi \in \Xi.$$

It is important that the Lipschitz constant L is independent of $\xi \in \Xi$, and this condition may make Assumption 1 appear rather stringent. There are, however, interesting cases in which the assumption does hold. For example, if Ξ is finite (with possibly huge cardinality) and $G(x,\xi)$ is Lipschitz continuous with Lipschitz constant $L(\xi)$ for each $\xi \in \Xi$, then Assumption 1 holds with $L = \max\{L(\xi) : \xi \in \Xi\}$. Alternatively, if Ξ is compact, $G(x,\xi) = \max\{T_j(\xi)x : j = 1,\dots,m\}$, and $T_j : \Xi \to \mathbf{R}^n$ is continuous in ξ for each j, then Assumption 1 holds with

$$L = \sup_{\xi\in\Xi}\big\{\max\{\|T_j(\xi)\|_\infty : j = 1,\dots,m\}\big\}.$$

To generate feasible solutions for this general case, we will also need to modify the sample approximation problem somewhat. In addition to taking a risk level α less than the nominal risk level ϵ, we will require that at least $(1-\alpha)N$ of the constraints be satisfied *strictly*. That is, for a fixed $\gamma > 0$, we define the sample approximation feasible region to be

$$X^N_{\alpha,\gamma} = \left\{ x \in X : \frac{1}{N}\sum_{i=1}^{N} \mathbb{I}\big(G(x,\xi) + \gamma \le 0\big) \ge 1 - \alpha \right\}.$$

Finally, we will assume that X is bounded and let $D = \sup\{\|x - x'\|_\infty : x, x' \in X\}$ be the diameter of X.

THEOREM 10. *Suppose that X is bounded with diameter D and Assumption 1 holds. Let $\alpha \in [0,\epsilon)$, $\beta \in (0, \epsilon-\alpha)$, and $\gamma > 0$. Then*

$$\Pr\big\{X^N_{\alpha,\gamma} \subseteq X_\epsilon\big\} \ge 1 - \lceil 1/\beta \rceil \lceil 2LD/\gamma \rceil^n \exp\big\{-2N(\epsilon - \alpha - \beta)^2\big\}.$$

Proof. For $x \in X$, let $\phi(x) = \Pr\{G(x,\xi) \le 0\}$. Let $J = \lceil 1/\beta \rceil$, for $j = 1,\dots,J-1$, define

$$X_j = \left\{ x \in X : \frac{j-1}{J} \le \phi(x) < \frac{j}{J} \right\},$$

and let $X_J = \{x \in X : (J-1)/J \le \phi(x) \le 1\}$. Next, we claim that for each j there exists a finite set $Z^\gamma_j \subseteq X_j$ such that $|Z^\gamma_j| \le \lceil 2LD/\gamma \rceil^n$ and for all $x \in X_j$ there exists $z \in Z^\gamma_j$ such that $\|x - z\|_\infty \le \gamma/L$. Indeed, because $X_j \subseteq X$ and X is bounded with diameter D, there exists a finite set $Y \subseteq \mathbf{R}^n$ with $|Y| \le \lceil 2LD/\gamma \rceil^n$ such that for all $x \in X$ there exists $y \in Y$ such that $\|x - y\|_\infty \le \gamma/2L$. For any $y \in \mathbf{R}^n$ and $\eta > 0$, define $B(y,\eta) = \{x \in \mathbf{R}^N : \|y - x\|_\infty \le \eta\}$. Now, let $Y'_j = \{y \in Y : X_j \cap B(y, \gamma/2L) \ne \emptyset\}$, and for $y \in Y'_j$ select an arbitrary $x_y \in X_j \cap B(y,\gamma/2L)$. Then let $Z^\gamma_j = \bigcup_{y\in Y'_j} x_y$. By definition, $Z^\gamma_j \subseteq X_j$ and $|Z^\gamma_j| \le \lceil 2LD/\gamma \rceil^n$. In addition, for any $x \in X_j$, there exists y such that $x \in B(y,\gamma/2L)$, and, because for this y, $X_j \cap B(y,\gamma/2L) \ne \emptyset$, there exists $x_y \in Z^\gamma_j$ such that $\|x_y - y\|_\infty \le \gamma/2L$. Hence,

$$\|x_y - x\|_\infty \le \|x_y - y\|_\infty + \|y - x\|_\infty \le \gamma/L.$$

Now define $Z^\gamma = \bigcup_{j=1}^J Z^\gamma_j$, and observe that $|Z^\gamma| \le J\lceil 2LD/\gamma \rceil^n$. Next, define $Z^\gamma_{\epsilon-\beta} = \big\{x \in Z^\gamma : \Pr\{G(x,\xi) \le 0\} \ge 1 - \epsilon + \beta\big\}$ and

$$Z^{\gamma,N}_\alpha = \left\{ x \in Z^\gamma : \frac{1}{N}\sum_{i=1}^{N} \mathbb{I}\big(G(x,\xi^i) \le 0\big) \right\}.$$

Since Z^γ is finite and $\alpha < \epsilon - \beta$, we can apply Theorem 5 to obtain

$$\Pr\left\{Z_\alpha^{\gamma,N} \subseteq Z_{\epsilon-\beta}^\gamma\right\} \geq 1 - \lceil 1/\beta \rceil \lceil 2LD/\gamma \rceil^n \exp\{-2N(\epsilon - \alpha - \beta)^2\}. \tag{12}$$

Now consider an arbitrary $x \in X_{\alpha,\gamma}^N$. Let $j \in \{1, \ldots, J\}$ be such that $x \in X_j$. By the definition of Z_j^γ there exists $z \in Z_j^\gamma$ such that $\|x - z\|_\infty \leq \gamma/L$. By the definition of X_j and because $Z_j^\gamma \subseteq X_j$, we have $|\phi(x) - \phi(z)| \leq \beta$. In addition, Assumption 1 implies that $|G(x, \xi^i) - G(z, \xi^i)| \leq \gamma$. Hence, if $G(x, \xi^i) + \gamma \leq 0$, then $G(z, \xi^i) \leq 0$, and, because x satisfies $\sum_{i=1}^N \mathbb{I}(G(x, \xi^i) + \gamma \leq 0) \geq N(1-\alpha)$, it follows that z satisfies $\sum_{i=1}^N \mathbb{I}(G(z, \xi^i) \leq 0) \geq N(1 - \alpha)$. Thus $z \in Z_\alpha^{\gamma,N}$, and so if $Z_\alpha^{\gamma,N} \subseteq Z_{\epsilon-\beta}^\gamma$, then $\phi(z) \geq 1 - \epsilon + \beta$. Thus, $\phi(x) \geq \phi(z) - \beta \geq 1 - \epsilon$ when $Z_\alpha^{\gamma,N} \subseteq Z_{\epsilon-\beta}^\gamma$. Since $x \in X_{\alpha,\gamma}^N$ was arbitrary, $Z_\alpha^{\gamma,N} \subseteq Z_{\epsilon-\beta}^\gamma$ implies that $X_{\alpha,\gamma}^N \subseteq X_\epsilon$, and the result follows from (12). □

Once again, for fixed ϵ and $\alpha < \epsilon$, β is a free parameter to be chosen in $(0, \epsilon - \alpha)$. If we choose, for example, $\beta = (\epsilon - \alpha)/2$, then we can assure that $X_{\alpha,\gamma}^N \subseteq X_\epsilon$ with confidence at least $1 - \delta$ by taking

$$N \geq \frac{2}{(\epsilon - \alpha)^2}\left[\log\left(\frac{1}{\delta}\right) + n \log\left\lceil \frac{2LD}{\gamma} \right\rceil + \log\left\lceil \frac{2}{\epsilon - \alpha} \right\rceil\right].$$

Additionally, if $\alpha = 0$, similar arguments show that $X_{0,\gamma}^N \subseteq X_\epsilon$ occurs with probability at least $1 - \delta$ if

$$N \geq \frac{2}{\epsilon}\left[\log\left(\frac{1}{\delta}\right) + n \log\left\lceil \frac{2LD}{\gamma} \right\rceil + \log\left\lceil \frac{2}{\epsilon} \right\rceil\right].$$

Regardless of whether $\alpha = 0$ or $\alpha > 0$, the term $1/\gamma$ is taken under log, and hence γ can be made very small without significantly increasing the required sample size, suggesting that modifying the sample approximation problem to require at least $(1 - \alpha)N$ of the sampled constraints to be satisfied with a slack of at least γ need not significantly alter the feasible region.

2.2.4. A posteriori feasibility checking. The results of sections 2.2.1–2.2.3 demonstrate that, with appropriately constructed sample approximation problems, the probability that the resulting feasible region will be a subset of the true feasible region X_ϵ approaches one exponentially fast. This gives strong theoretical support for using these sample approximations to yield solutions feasible to X_ϵ. These results yield *a priori* estimates on how large the sample size N should be to have high confidence that the sample approximation feasible region will be a subset of X_ϵ. However, these a priori estimates are likely to yield required sample sizes which are very large, and hence the sample approximation problems will still be impractical to solve. This is particularly true if $\alpha > 0$ and $\epsilon - \alpha$ is small. However, typically in sampling approximation results such as these, the a priori estimates of the required sample size are very conservative, and in fact much smaller sample sizes are sufficient. See [18] for a computational demonstration of this phenomenon for the case of SAA applied to two-stage stochastic linear programs. Thus, a natural alternative to using the sample size suggested by the a priori estimates is to solve a sample approximation problem with a smaller sample to yield a candidate solution $\hat{x} \in X$ and then conduct an *a posteriori* check to see whether $\Pr\{G(\hat{x}, \xi) \leq \mathbf{0}\} \geq 1 - \epsilon$. A simple method for conducting an a posteriori analysis of the risk of a candidate solution is to take a single

very large Monte Carlo sample $\xi^1, \ldots, \xi^{N'}$ and count how many times $G(\hat{x}, \xi^i) \leq \mathbf{0}$ holds. Bounds on the true risk $\Pr\{G(\hat{x}, \xi) \leq \mathbf{0}\}$ which hold with high confidence can then be constructed, and, if N' is very large, these bounds should be tight. This approach will not work well if the allowed risk ϵ is extremely small, but, on the other hand, we do not expect the sample approximation approach to be practical in this case anyway. Of course, if good estimates of $\Pr\{G(\hat{x}, \xi) \leq \mathbf{0}\}$ can be obtained efficiently by some other method, then this other method should be used for a posteriori feasibility checking. For example, if $G(x, \xi) = \xi - g(x)$ and the components of ξ are independent, then $\Pr\{g(x) \geq \xi\}$ can be calculated as $\prod_i \Pr\{g_i(x) \geq \xi_i\}$.

3. Numerical experiments. We conducted experiments to test the effectiveness of the sample approximation approach for yielding good feasible solutions and lower bounds. In particular, our aim is to determine whether using $\alpha > 0$ in the sample approximation can yield better solutions than when using $\alpha = 0$ as in the scenario approximation approach of [7, 22]. In addition, we test whether reasonable lower bounds which are valid with high probability can be obtained. We first conducted tests on a probabilistic version of the classical set covering problem, which has been studied recently in [5, 26, 27]. This problem has both a finite feasible region and finite distribution (although both are exponentially large) so that, for generating feasible solutions, the stronger Theorems 5 and 8 apply. These results are given in section 3.1. We also conducted tests on a probabilistic version of the transportation problem. For this problem, the feasible region is continuous, and we also use a joint normal distribution for the right-hand side vector, so that Theorem 9 applies. These results are presented in section 3.2.

Note that, although Theorem 3 provides support for using the sample approximation scheme to generate lower bounds, we will use Theorem 4 to actually obtain lower bounds which are valid with high confidence, because it can be used regardless of how large the sample size N is (with the possible drawback that using smaller N will yield weaker lower bounds). Similarly, Theorems 5, 8, and 9 support the use of sample approximation to yield feasible solutions, but we do not use these theorems to guide our choice of α and N. Indeed, the bounds implied by these theorems would suggest using N which is far too large to be able to solve the approximation problem. Instead, we experiment with different values of α and N and perform an a posteriori test on each solution generated to determine whether it is feasible (with high confidence).

3.1. Probabilistic set cover problem. The probabilistic set cover problem is given by

$$\text{(PSC)} \qquad \min\bigl\{cx : \Pr\{Ax \geq \xi\} \geq 1 - \epsilon, x \in \{0,1\}^n\bigr\},$$

where $c \in \mathbf{R}^n$ is the cost vector, A is an $m \times n$ zero-one matrix, and ξ is a random vector taking values in $\{0,1\}^m$. We conducted tests on a single instance of (PSC), with two values of ϵ: 0.05 and 0.1.

3.1.1. Test instance. Following [5], we based our tests on a deterministic set-covering instance, scp41, of the OR library [3], which has $m = 200$ rows and $n = 1000$ columns. Also following [5], the random vector ξ is assumed to consist of 20 independent subvectors, with each subvector having size $k = 10$ following the *circular* distribution. The circular distribution is defined by parameters $\lambda_j \in [0,1]$ for $j = 1, \ldots, k$. First, Bernoulli random variables Y_j for $j = 1, \ldots, k$ are generated independently, with $\Pr\{Y_j = 1\} = \lambda_i$. Then the random subvector is defined by $\xi_j = \max\{Y_j, Y_{j+1}\}$

for $j < k$ and by $\xi_k = \max\{Y_1, Y_k\}$. Because of the simple form of this distribution, given a solution x, it is possible to calculate exactly $\Pr\{Ax \geq \xi\}$. Thus, when a solution is obtained from a sample approximation problem, we test a posteriori whether it is feasible at a given risk level by exactly calculating $\Pr\{Ax \geq \xi\}$. To illustrate this calculation, we show how to calculate the probability for a single subvector, that is, $\Pr\{\xi_j \leq y_j,\ j = 1, \ldots, k\}$. Then, with $y = Ax$, the overall probability $\Pr\{Ax \geq \xi\}$ is calculated as the product of the probabilities for each subvector. Let $J = \{1 \leq j \leq k : y_j = 0\}$. Then

$$\Pr\{\xi_j \leq y_j,\ j = 1, \ldots, k\} = \Pr\{\xi_j = 0, j \in J\} = \Pr\left\{Y_j = 0, j \in J^+\right\} = \prod_{j \in J^+} (1 - \lambda_j),$$

where $J^+ = \cup_{j \in J}\{j, (j+1) \mod k\}$. Although in this test calculation of the distribution function is easy, we stress that this is not a necessary condition to use the sample approximation; it is necessary only that sampling from the distribution can be done efficiently.

3.1.2. Solving the sample approximation. To solve the sample approximation of problem (PSC), we used a mixed-integer program (MIP) formulation which is equivalent to an extended formulation studied in [20] (see also [19]). The formulation is not exactly the same, since, because the random right-hand side can take on only two values, it can be simplified somewhat. Let the scenarios obtained in the sample of size N be denoted by ξ^i for $i = 1, \ldots, N$, where each $\xi^i \in \{0,1\}^m$. Then the formulation we use is

$$\begin{aligned}
\min \quad & cx \\
\text{subject to } & Ax \geq y, \\
& y_j + z_i \geq 1 \qquad \forall i, j \text{ s.t. } \xi^i_j = 1, \qquad (13) \\
& \sum_{i=1}^{N} z_i \leq p, \qquad (14) \\
& x \in \{0,1\}^n,\ z \in \{0,1\}^N,\ y \in \{0,1\}^m,
\end{aligned}$$

where $p = \lfloor \alpha N \rfloor$. We could relax the intregrality restriction on the y variables, but we found that leaving this restriction and also placing a higher branching priority on these variables significantly improved performance when solving with CPLEX 9.0. The intuition behind this is that if we fix $y_j = 1$, then we are enforcing the constraint $A^j x \geq 1$, and, on the other hand, if we fix $y_j = 0$, then any scenario i for which $\xi^i_j = 1$ will be fixed to 1, and constraint (14) will quickly become binding. We also found that some simple preprocessing of the formulation significantly helped solution times. If, for a row j, $\sum_i \xi^i_j > p$, then we cannot have $y_j = 0$, and so we fixed $y_j = 1$, and the corresponding inequalities (13) for j were not included. After this preprocessing, for each j there will be at most p inequalities in (13), so that these inequalities add at most mp rows and $O(mp)$ nonzeros to the formulation. By using this formulation, we found that the sample approximation problems could be solved quickly, in all cases in less than ten seconds and usually much less. However, this may be due to the particular distribution used (and the simplicity of the underlying set cover instance), and thus this should not be taken as a study of the effectiveness of this formulation in general. Rather, we are interested here only in the properties of the solutions generated by the sample approximation problems.

3.1.3. Feasible solutions. We first tested the effectiveness of the sample approximation approach for generating feasible solutions. To do so, we varied the risk level of the approximation problem α and the sample size N. For each combination of α and N, we generated and solved 10 sample approximation problems. Table 1 gives statistics of the solutions generated for the (PSC) instance with $\epsilon = 0.05$, and Table 2 gives the same for the (PSC) instance with $\epsilon = 0.1$. For each combination of α and N, we report statistics on the risk of the generated solutions, where for a solution x the risk is $\Pr\{Ax \not\geq \xi\}$, as well as on the costs of the *feasible* solutions generated, i.e., those solutions which have risk less than 0.05 and 0.1, respectively. For the risk of the solutions, we report the average, minimum, maximum, and sample standard deviation over the 10 solutions. For the solution costs, we report first how many solutions were feasible, then report the average, minimum, maximum, and sample standard deviation of the cost taken over these solutions.

We first discuss results for the case of nominal risk level $\epsilon = 0.05$. When using $\alpha = 0$, the best results were obtained with N in the range of 100–150, and these are the results that we report. With $\alpha = 0$, as N increases, more constraints are being enforced, which leads to a smaller feasible region of the approximation and a higher likelihood that the optimal solution of the approximation is feasible at the nominal risk level. However, the smaller feasible region also causes the cost to increase, so that increasing N more would yield overly conservative solutions. We also conducted tests with $\alpha = 0.05$, and for this value of α we used significantly larger sample sizes.

TABLE 3
Lower bounds (LB) *for* (PSC) *sample problems with* $\alpha = \epsilon = 0.05$.

	LB with confidence at least:				Gap with confidence at least:			
N	0.999	0.989	0.945	0.828	0.999	0.989	0.945	0.828
1000	412	414	414	414	0.5%	0.0%	0.0%	0.0%
3000	412	414	414	414	0.5%	0.0%	0.0%	0.0%
5000	412	414	414	414	0.5%	0.0%	0.0%	0.0%
7500	414	414	414	414	0.0%	0.0%	0.0%	0.0%
10000	413	414	414	414	0.2%	0.0%	0.0%	0.0%

The best feasible solution found by using $\alpha = 0$ had cost 420, and the average cost of the feasible solutions found was significantly greater than this. When $\alpha = 0.05$, every sample size N yielded at least one feasible solution in the ten runs, and *every* feasible solution found had cost 414. Thus, using $\alpha = 0.05$ consistently yields solutions which are closer to the efficient frontier between the objectives of risk and cost.

For $\epsilon = 0.1$, we observed similar results. In this case, when using $\alpha = 0$, the best results were obtained with N in the range of 80–130. The best solution found by using $\alpha = 0$ had cost 419, whereas the best solution found by using $\alpha = 0.1$ was 400, which was obtained by one of the ten runs for *every* sample size N. In addition, observe from Table 1 that using $\alpha = 0.05$ yields solutions with a risk not exceeding 0.05 and a cost of 414, which is also less than the cost of the best solution found that had a risk not exceeding 0.1 when using $\alpha = 0$. Thus, by using $\alpha > 0$ we are able to get solutions with lower risk *and* lower cost as compared to those obtained when using $\alpha = 0$.

In terms of the variability of the risks and costs of the solutions generated, using $\alpha > 0$ and a much larger sample size yielded solutions with much lower variability than when using $\alpha = 0$ and small sample size. This is not surprising since using a larger sample size naturally should reduce variability. On the other hand, constraining the sample approximation to have $\alpha = 0$ prohibits the use of a larger sample size, as the solutions produced then become overly conservative.

3.1.4. Lower bounds. We next discuss the results for obtaining lower bounds for (PSC). We used the procedure of Theorem 4 with $\alpha = \epsilon$ and $M = 10$. We use the same 10 sample approximation problems as when generating feasible solutions. As argued after Theorem 4, with $\alpha = \epsilon$, we have $\rho(\alpha, \epsilon, N) = \rho(\epsilon, \epsilon, N) \gtrsim 1/2$. Then, if we take $L = 1$, the test of Theorem 4 yields a lower bound with confidence 0.999. Taking $L = 1$ corresponds to taking the minimum optimal value over all of the $M = 10$ runs (not just over the ones which yielded feasible solutions). More generally, we can take $L \in \{1, \ldots, 10\}$ yielding a lower bound with confidence at least

$$1 - \sum_{i=0}^{L-1} \binom{10}{i} \rho(\epsilon, \epsilon, N)^i \big(1 - \rho(\epsilon, \epsilon, N)\big)^{10-i} \gtrsim 1 - \sum_{i=0}^{L-1} \binom{10}{i} (1/2)^{10}$$

to obtain possibly "tighter" lower bounds of which we are less confident.

The results obtained by using varying values of N and $\epsilon = \alpha = 0.05$ are given in Table 3. The gaps reported are the percent by which the lower bound is below the best feasible solution (414, obtained with $\alpha = 0.05$ and any of the tested sample sizes N). Thus, for example, by solving 10 problems with sample size $N = 1000$, we obtained a feasible solution of cost 414 and a lower bound of 412, which is valid with probability at least 0.999. In addition, we obtain a lower bound of 414 which is valid

TABLE 4
Lower bounds for (PSC) *sample problems with* $\alpha = \epsilon = 0.1$.

	LB with confidence at least:				Gap with confidence at least:			
N	0.999	0.989	0.945	0.828	0.999	0.989	0.945	0.828
1000	397	397	398	398	0.8%	0.8%	0.5%	0.5%
3000	399	400	400	400	0.3%	0.0%	0.0%	0.0%
5000	400	400	400	400	0.0%	0.0%	0.0%	0.0%
7500	400	400	400	400	0.0%	0.0%	0.0%	0.0%
10000	400	400	400	400	0.0%	0.0%	0.0%	0.0%

with probability of at least 0.989. Thus, we have confidence at least 0.989 that 414 is the optimal value. Similar results were obtained with larger sample sizes.

Table 4 yields the lower bound results obtained with $\epsilon = \alpha = 0.1$ and varying sample size N. By solving 10 sample problems with $N = 1000$, we obtained a feasible solution of cost 400 and can say with confidence 0.999 that the optimal solution is at most 0.8% less costly than this solution. By using $N = 5000$ (or greater), we obtain a feasible solution of the same cost but a lower bound which states that with confidence at least 0.999 this feasible solution is optimal.

3.2. Probabilistic transportation problem. We next tested the sampling approach on a probabilistic version of the classical transportation problem, which we call the probabilistic transportation problem (PTP). In this problem, we have a set of suppliers I and a set of customers D, with $|D| = m$. The suppliers have limited capacity M_i for $i \in I$. There is a transportation cost c_{ij} for shipping a unit of product from supplier $i \in I$ to customer $j \in D$. The customer demands are random and are represented by a random vector $\tilde{d}$ taking values in $\mathbf{R}^m$. We assume that we must choose the shipment quantities before the customer demands are known. We enforce the probabilistic constraint

$$\Pr\left\{\sum_{i\in I} x_{ij} \geq \tilde{d}_j, j = 1, \ldots, m\right\} \geq 1 - \epsilon, \tag{15}$$

where $x_{ij} \geq 0$ is the amount shipped from supplier $i \in I$ to customer $j \in D$. The objective is to minimize distribution costs subject to (15) and the supply capacity constraints

$$\sum_{j\in D} x_{ij} \leq M_i \quad \forall i \in I.$$

3.2.1. Test instances. We conducted our tests on an instance with 40 suppliers and 50 customers. The supply capacities and cost coefficients were randomly generated by using normal and uniform distributions, respectively. The demand is assumed to have a joint normal distribution. The mean vector and covariance matrix were randomly generated. We considered two cases for the covariance matrix: a low variance and a high variance case. In the low variance case, the standard deviation of the one-dimensional marginal random demands is 10% of the mean on average. In the high variance case, the covariance matrix of the low variance case is multiplied by 25, yielding standard deviations of the one-dimensional marginal random demands being 50% of the mean on average. In both cases, we consider a single risk level $\epsilon = 0.05$.

We remark that, for this particular choice of distribution, the feasible region defined by the probabilistic constraint is convex [24]. However, the dimension of the

random vector $\tilde{d}$ is $m = 50$, and so evaluating $\Pr\{y \geq \tilde{d}\}$ for a single vector $y \in \mathbf{R}^m$ would present a computational challenge, whereas in our approach we merely need to generate random samples from the joint normal distribution, which is relatively easy. On the other hand, we have not conducted experiments using the convex programming approach, so we cannot comment on whether our approach works better than this. This would be an interesting future experiment. Our intention here is merely to test our approach on a problem with a continuous feasible region and distribution.

Once a sample approximation is solved yielding solution $\hat{x}$, we use a single very large sample ($N' = 250000$) to estimate $\Pr\{\hat{y} \geq \tilde{d}\}$, where $\hat{y} \in \mathbf{R}^m$ is the vector given by $\hat{y}_j = \sum_{i \in I} \hat{x}_{ij}$ for $j \in D$. Letting $d^1, \ldots, d^{N'}$ be the realizations of this large sample, we calculate $\sum_{i=1}^{N'} \mathbb{I}(\hat{y} \geq d^i)$ and use the normal approximation to the binomial distribution to construct an upper bound $\hat{\alpha}$ on the true solution risk $\Pr\{\hat{y} \geq \tilde{d}\}$, which is valid with confidence 0.999. Henceforth for this experiment, if we say a solution is feasible at risk level ϵ, we mean $\hat{\alpha} \leq \epsilon$, and so it is feasible at this risk level with confidence 0.999. We used such a large sample to get a good estimate of the true risk of the solutions generated, but we note that, because this sample was so large, generating this sample and calculating $\sum_{i=1}^{N'} \mathbb{I}(\hat{y} \geq d^i)$ often took longer than solving the sample approximation itself.

3.2.2. Solving the sample approximation. We solved the sample approximation problem by using an MIP formulation, augmented with a class of strong valid inequalities. We refer the reader to [20, 19] for details of this formulation and the valid inequalities, as well as detailed computational results for solving the sample approximation problems. However, we mention that, in contrast to the probabilistic set cover problem, solving the sample approximation problem with the largest sample size that we consider ($N = 10000$) and the largest α (0.05) takes a nontrivial amount of time, in some cases as long as 30 minutes. On the other hand, for $N = 5000$, the worst case was again $\alpha = 0.05$ and usually took less than 4 minutes to solve.

3.2.3. Low variance instance. We begin by presenting results for the instance in which the distribution of demand has relatively low variance. For generating feasible solutions, we tested $\alpha = 0$ with various sample sizes N and report the results for the sample sizes which yielded the best results. Once again, this means that we use a relatively small sample size for the case $\alpha = 0$, as compared to the cases with $\alpha > 0$. We tested several values of $\alpha > 0$ and varying sample size. In contrast to the (PSC) case, we found that taking $\alpha = \epsilon$ or even α close to ϵ did not yield feasible solutions, even with a large sample size. Thus, we report results for several different values of α in the range 0.03–0.036. The reason that we report results for this many different values of α is to illustrate that, within this range, the results are not extremely sensitive to the choice of α (results for more values of α can be found in [19]).

Table 5 gives the characteristics of the solutions generated for the different values of α and N. We observe that, as in the case of (PSC), the *average* cost of the feasible solutions obtained by using $\alpha > 0$ is always less than the *minimum* cost of the feasible solutions obtained with $\alpha = 0$. However, for this instance, the minimum cost solution obtained by using $\alpha = 0$ is not so significantly worse than the minimum cost solutions using different values of $\alpha > 0$, being between 0.40% and 0.58% more costly. As in the case of (PSC), using $\alpha > 0$ and large N significantly reduced the variability of the risk and cost of the solutions generated.

We next investigated the quality of the lower bounds that can be obtained for PTP by solving sample approximation problems. As in the case of (PSC), we obtained

lower bounds by generating and solving 10 sample approximation problems with $\alpha = \epsilon = 0.05$. By taking the lowest value of all of the optimal values, we obtain a lower bound valid with confidence 0.999, and taking the second smallest yields a lower bound which is valid with confidence 0.989, etc. The results for different values of N are given in Table 6. For reference, the percentage gap between these lower bounds and the best feasible solution found (with cost 2.0066) is also given. By using $N \geq 3000$ we obtain lower bounds that are valid with confidence 0.999 and are within one percent of the best feasible solution, indicating that, for this low variance instance, the lower bounding scheme yields good evidence that the solutions that we have found are good quality.

3.2.4. High variance instance. Table 7 gives the characteristics of the solutions generated for the high variance instance. In this case, the *maximum* cost of a feasible solution generated by using any combination of $\alpha > 0$ and N was less than the *minimum* cost of any feasible solution generated by using $\alpha = 0$. The minimum cost feasible solution generated with $\alpha = 0$ was between 0.87% and 1.6% more costly than the best feasible solution generated for the different combinations of $\alpha > 0$ and N. Thus, it appears that, for the high variance instance, using $\alpha > 0$ in a sample approximation is more important for generating good feasible solutions than for the low variance instance.

Table 8 gives the lower bounds for different confidence levels and sample sizes, as well as the gaps between these lower bounds and the best feasible solution found. In this case, solving 10 instances with sample size $N = 1000$ yields a lower bound that is not very tight, 5.11% from the best solution cost at confidence level 0.999. Increasing the sample size improves the lower bound, but even with $N = 10000$ the gap between

TABLE 7
Solution results for high variance PTP sample problems with $\epsilon = 0.05$.

the lower bound at confidence 0.999 and the best solution found is 1.83%. Thus, it appears that, for the high variance instance, the sample approximation scheme exhibits considerably slower convergence, in terms of the lower bounds, the feasible solutions generated, or both.

4. Concluding remarks. We have studied a sample approximation scheme for probabilistically constrained optimization problems and demonstrated how this scheme can be used to generate optimality bounds and feasible solutions for very general optimization problems with probabilistic constraints. We have also conducted a preliminary computational study of this approach. This study demonstrates that using sample approximation problems that allow a choice of which sampled constraints to satisfy can yield good quality feasible solutions. In addition, the sample approximation scheme can be used to obtain lower bounds which are valid with high confidence. We found that good lower bounds could be found in the case of a finite (but possibly exponential) feasible region and distribution and also in the case of a continuous feasible region and distribution, provided the distribution has a reasonably low variance. With a continuous feasible region and distribution, if the distribution has a high variance, the lower bounds were relatively weak. Future work in this area will include conducting more extensive computational tests and also extending the theory to allow generation of samples which are not necessarily independent and identically distributed. For example, the use of variance-reduction techniques such as Latin hypercube sampling or quasi-Monte Carlo sampling may yield significantly faster convergence. In addition, to apply the results of this paper to more general probabilistic programs, such as mixed-integer programming with a random constraint matrix, it will be necessary to study how to solve the nonconvex sample approximation problem in these cases.

OUTER SEMICONTINUITY OF POSITIVE HULL MAPPINGS WITH APPLICATION TO SEMI-INFINITE AND STOCHASTIC PROGRAMMING*

DINH THE LUC† AND ROGER J.-B. WETS‡

Abstract. Let W be an arbitrary subset of $\mathbb{R}^n$ and pos$W$ the positive hull of W. We are concerned with conditions under which one can guarantee continuity properties for pos$W$ as a function of W. The results are then applied in the context of semi-infinite linear programs and stochastic programs with recourse.

Key words. positive hull, set limits, horizon limits

AMS subject classifications. 49J53, 90C15, 90C34

1. Introduction. Let $\{W; W^\nu, \nu \in \mathbb{N}\}$ be a collection of nonempty subsets of $\mathbb{R}^m$ and $\{\text{pos}W; \text{pos}W^\nu, \nu \in \mathbb{N}\}$ the positive hulls generated by these sets, i.e.,

$$\text{pos}W = \left\{ t = \sum_{j=1}^{q} t^j x_j | t^j \in W, x_j \geq 0, \qquad \text{with} \quad q \quad \text{finite} \right\},$$

and posW^ν is defined similarly for each W^ν. Our overall concern is with the continuity of the positive hull mapping $W \mapsto \text{pos}W$, but, more specifically, we are interested in finding conditions under which

$$\limsup_{\nu \to \infty} \text{pos}W^\nu \subset \text{pos}W$$

when the W^ν "converge" to W; here and throughout, $\limsup_\nu C^\nu$ designates the *outer limit*, in the sense of Painlevé-Kuratowski, of the sets C^ν, that is, the set of all limits of subsequences $\lim_{\nu_i \to \infty} t^{\nu_i}$, with $t^{\nu_i} \in C^{\nu_i}$; cf. [11, Chapter 4].

One can view this work as an extension, in various directions, of a result of Walkup and Wets [12, Theorem 2] where the sets W and W^ν were of constant finite cardinality, or, more simply, they consist of the points identified by the columns of constant size matrices. Questions of this type occur in a variety of variational problems. For example, in the analysis of the stability of the solutions of linear programs, semi-infinite linear programs [3], linear complementarity problems [7], [8, section 4], equilibrium and quasi-equilibrium problems [9], generalized linear programs [5, Chapter 22], and stochastic programming problems [2, 10]. Two of these applications are further analyzed in the last two sections.

2. Outer semicontinuity. Our major objective is to obtain the inclusion $\limsup_\nu \text{pos}W^\nu \subset \text{pos}W$ that can be viewed as an outer-semicontinuity result. We

begin with a characterization of the outer limit of a sequence of sets that could be deduced from the results in [11, Chapter 4, section H] but isn't readily available in the literature. A (closed) ball centered at x and radius ρ is denoted by $\mathbb{B}(x,\rho)$ and the unit ball simply by $\mathbb{B}$, and so, for some positive scalar η, $\eta\mathbb{B} = \mathbb{B}(0,\eta)$.

PROPOSITION 2.1 (outer limit of sets). *A closed set $C \subset \mathbb{R}^m$ is the outer limit of a sequence of sets $\{C^\nu \subset \mathbb{R}^m,\ \nu \in \mathbb{N}\}$ if and only if given any $\epsilon > 0, \rho > 0$, there is $\nu_{\epsilon,\rho}$ such that*

$$\forall\, \nu \geq \nu_{\epsilon,\rho}: \quad C^\nu \cap \rho\mathbb{B} \subset C + \epsilon\mathbb{B}.$$

Proof. We rely on the criterion provided by [11, Proposition 4.5(b)], namely, that $C \supset \limsup_\nu C^\nu$ if and only if whenever $C \cap B = \emptyset$ for a compact set B, then also $C^\nu \cap B = \emptyset$ for ν large enough. The proof, in both directions, proceeds by contradiction.

When the asserted inclusion is not satisfied for some pair $\epsilon > 0, \rho > 0$, then for a countable collection of indexes, say, for $\nu \in N^\sharp$, there is a collection

$$\left\{x^\nu \in (C^\nu \cap \rho\mathbb{B}) \setminus (C + \epsilon\mathbb{B}),\ \nu \in N^\sharp\right\}$$

converging to some $\bar{x}$; all these points belong to the compact set $\rho\mathbb{B}$. Thus, $C \cap B = \emptyset$ for the compact set $B = \{\bar{x}; x^\nu,\ \nu \in \mathbb{N}\}$, whereas there is no ν_B arbitrarily large so that $C^\nu \cap B$ is empty for all $\nu \geq \nu_B$. Hence, C can't contain the outer limit of the C^ν.

On the other hand, if there is a compact set B such that $C \cap B = \emptyset$ but for some countable collection of indexes, say, $\nu \in N^\sharp$, $C^\nu \cap B$ fails to be empty, choose $\rho > 0$ such that $B \subset \rho\mathbb{B}$ and $\epsilon > 0$ such that $(C + \epsilon\mathbb{B}) \cap B = \emptyset$. Then, for all $\nu \in N^\sharp$, $C^\nu \cap \rho\mathbb{B} \not\subset C + \epsilon\mathbb{B}$; i.e., there is no $\nu_{\epsilon,\rho}$ such that the asserted inclusion holds for all $\nu \geq \nu_{\epsilon,\rho}$. ∎

3. The core cone. To obtain the outer semicontinuity of the positive hulls, our conditions will involve two limit cones associated with a collection of sets $\{C^\nu,\ \nu \in \mathbb{N}\}$. The first one, generated by the directions at the "horizon," is the *horizon outer limit* defined as

$$\limsup_\nu^\infty C^\nu = \{0\} \cup \left\{t = \lim_{\nu\in N} \lambda_\nu t^\nu,\ t^\nu \in C^\nu,\ \lambda_\nu \downarrow 0\right\},$$

where $N \subset \mathbb{N}$ indicates that the limit is conceivable with respect to a subsequence. This set is a closed cone whose properties are detailed in [11, Chapter 4, section F]. The notation

$$C^\infty = \{t | \exists\, t^\nu \in C,\ \lambda_\nu \downarrow 0,\ \text{with } \lambda_\nu t^\nu \to t\}$$

is reserved for the *horizon cone* associated with a set $C \neq \emptyset$ [11, Chapter 3, section B] (see also [1, Chapter 2]).

The second one, believed to be new, can be interpreted as the "inverse" of the horizon limit cone, as will be seen below. It's defined by

$$\limsup_\nu^o C^\nu = \left\{t = \lim_{\nu\in N} \lambda_\nu^{-1} t^\nu,\ t^\nu \in C^\nu,\ \lambda_\nu \downarrow 0\right\},$$

where, again, $N \subset \mathbb{N}$ suggests that the limit may involve only a subsequence of indexes. We refer to this limiting set as the *core outer limit* of the sequence of nonempty sets

$\{C^\nu, \nu \in \mathbb{N}\}$. So, rather than the direction points at the horizon, it identifies the "direction points" at the origin. It's immediate, from the definition, that this (core) limit set is also a *closed cone*. We recall that given a set C, the tangent cone of C at 0 is the cone $\limsup_{\lambda \downarrow 0} \lambda^{-1} C$. Here are some simple rules of calculus of the core outer limit.

PROPOSITION 3.1. *Let $\{C^\nu \subset \mathbb{R}^m, \nu \in \mathbb{N}\}$ and $\{D^\nu \subset \mathbb{R}^m, \nu \in \mathbb{N}\}$ be two collections of sets. Then*

(i) *the core outer limit of C^ν coincides with the intersection of the tangent cones $\limsup_{\lambda \downarrow 0} \lambda^{-1}(\cup_{\nu \geq k} C^\nu)$ for all $k \geq 1$. In particular, when the sets C^ν are constant, say, equal to C, the core outer limit is exactly the tangent cone of C at 0;*

(ii) $\limsup^o_\nu C^\nu \subseteq \limsup^o_\nu D^\nu$ *if* $C^\nu \subseteq D^\nu$ *for all* ν*;*

(iii) $\limsup^o_\nu C^\nu \cup D^\nu = \limsup^o_\nu C^\nu \cup \limsup^o_\nu D^\nu$*;*

(iv) $\limsup^o_\nu C^\nu \cap D^\nu \subseteq \limsup^o_\nu C^\nu \cap \limsup^o_\nu D^\nu$*;*

(v) $\limsup^o_\nu C^\nu + \limsup^o_\nu D^\nu \subseteq co \limsup^o_\nu (C^\nu + D^\nu)$ *provided that C^ν and D^ν contain the origin;*

(vi) $\limsup^o_\nu C^\nu + \limsup^o_\nu D^\nu \supseteq \limsup^o_\nu (C^\nu + D^\nu)$ *provided that the core outer limit of C^ν and that of $-D^\nu$ have only the zero vector in common.*

Proof. To prove the first assertion let $t = \lim_{\nu_i} \lambda^{-1}_{\nu_i} t^{\nu_i}$, with $t^{\nu_i} \in C^{\nu_i}$. Then, for each k, $t^{\nu_i} \in \cup_{\nu \geq k} C^\nu$ whenever $\nu_i \geq k$. Thus, t belongs to the tangent cone of $\cup_{\nu \geq k} C^\nu$ for every k. Conversely, let t be a vector such that, for every $k \geq 1$, there is a sequence of positive numbers $\lambda_{k,i}$ converging to 0 as i tends to ∞ and $t^{\nu_i}_k \in \cup_{\nu \geq k} C^\nu$ such that $t = \lim_i \lambda^{-1}_{k,i} t^{\nu_i}_k$. For each k, choose $i(k)$, with $\lambda_{k,i(k)} \leq \frac{1}{k}$, and $\nu(k) \geq k$, with $t^{\nu_{i(k)}}_k \in C^{\nu(k)}$. By taking a subsequence if necessary, one may assume that $\nu(k) > \nu(k-1)$ for every $k > 1$. Then t is the limit of $\lambda^{-1}_{k,i(k)} t^{\nu_{i(k)}}_k$, with $\lambda_{k,i(k)}$ tending to 0, and hence belongs to the core outer limit of C^ν.

The three assertions that follow are straightforward. The assertion (v) is obtained from (ii) and the fact that C^ν and D^ν are contained in the sum $C^\nu + D^\nu$. For the last assertion, let $v = \lim_{\lambda_i \downarrow 0} \lambda_i (t^{\nu_i} + s^{\nu_i})$, $v \neq 0$, with $t^{\nu_i} \in C^{\nu_i}$ and $s^{\nu_i} \in D^{\nu_i}$. Consider the sequences $\{\lambda_i t^{\nu_i}\}_i$ and $\{\lambda_i s^{\nu_i}\}_i$. They are both either bounded or unbounded. In the first case we may assume that they converge, respectively, to some vector v_1 of the core outer limit of C^ν and some v_2 of the core outer limit of D^ν, which yields $v = v_1 + v_2$. In the other case we divide the general terms of these sequences by $\|\lambda_i t^{\nu_i}\|$ and assume that the obtained sequences converge, respectively, to some vector u_1 of the core outer limit of C^ν and some u_2 of the core outer limit of D^ν. Then, $u_1 + u_2 = 0$, which contradicts the hypothesis. ∎

Example 3.2. The inclusion of (v) and the containment of (vi) may be strict, and, without appropriate assumptions, they may fail to hold.

Detail. In $\mathbb{R}^2$, set $C^\nu = \{(\frac{1}{\nu}, \frac{1}{\nu^2}), (0,0)\}$ and $D^\nu = \{(-\frac{1}{\nu}, \frac{1}{\nu^2}), (0,0)\}$. Then the core outer limit of C^ν consists of the vectors $(x, 0)$, with $x \geq 0$, and the core outer limit of D^ν consists of the vectors $(-x, 0)$, with $x \geq 0$. The core outer limit of the sum $C^\nu + D^\nu$ contains the above-mentioned vectors and the vectors $(0, y)$, with $y \geq 0$, as well. This shows that the inclusion of (v) is strict.

By setting $C^\nu_0 = \{(\frac{1}{\nu}, \frac{1}{\nu^2})\}$ and $D^\nu_0 = \{(-\frac{1}{\nu}, \frac{1}{\nu^2})\}$ we see that the hypothesis of (v) is violated for these families. The convex hull of the core outer limit of their sum is the half-space $\{(0, y) | y \geq 0\}$, which contains neither the core outer limit of C^ν_0 nor the core outer limit of D^ν_0.

For the families C^ν and D^ν above, the hypothesis of (vi) does not hold, and the containment is not true. For the families $A^\nu = \{(\frac{1}{\nu}, \frac{1}{\nu})\}$ and $B^\nu = \{(-\frac{1}{\nu}, \frac{1}{\nu})\}$, direct

calculation shows that the core outer limit of $A^\nu + B^\nu$ is the set of the vectors $(0, y)$, with $y \geq 0$, the core outer limit of A^ν is the ray (x, x), with $x \geq 0$, and the core outer limit of B^ν is the ray $(-x, x)$, with $x \geq 0$. Hence, the sum of the latter core outer limits contains the core outer limit of $A^\nu + B^\nu$ as a proper subset.

To see that the core outer limit set can be interpreted as an inverse of a horizon outer limit set, let's introduce the mapping

$$t \mapsto t^- = t/|t|^2 \qquad \text{for} \qquad t \in \mathbb{R}^m, t \neq 0,$$

with $0^- = 0$. For a set $C \subset \mathbb{R}^m$, by definition, $C^- = \{t^- | t \in C \subset \mathbb{R}^m\}$, and obviously $(C^-)^- = C$. The mapping $t \mapsto t^-$ has the following properties:

(a) It's a homeomorphism on $\mathbb{R}^m \setminus \{0\}$.
(b) C is bounded if and only if $\mathrm{cl}\,(C \setminus \{0\})^-$ does not contain the origin.
(c) With $C^o = \{0\} \cup \{t = \lim_\nu \lambda_\nu^{-1} t^\nu | t^\nu \in C,\ \lambda_\nu \downarrow 0\}$, the *core cone* associated with C, one has $C^o = (C^-)^\infty$ and $C^\infty = (C^-)^o$.
(d) If C is itself a cone, then $C^- = C$.

PROPOSITION 3.3. *For a sequence of nonempty sets* $\{C^\nu \subset \mathbb{R}^m,\ \nu \in \mathbb{N}\}$,

$$\limsup{}^o_\nu C^\nu = \limsup{}^\infty_\nu (C^\nu)^-$$

and

$$\limsup{}^\infty_\nu C^\nu = \limsup{}^o_\nu (C^\nu)^-.$$

Proof. Indeed, let $t \neq 0$ belong to the core outer limit. Without loss of generality, one can assume that $|t| = 1$ and is the limit of some sequence $\{t^\nu/|t^\nu|\}_{\nu=1}^\infty$, with $t^\nu \in C^\nu$ and $\lim_\nu t^\nu = 0$. Then $(t^\nu)^- = t^\nu/|t^\nu|^2 \in (C^\nu)^-$, with $|(t^\nu)^-| \to \infty$. Clearly, t is the limit of the sequence $(t^\nu)^-/|(t^\nu)^-|$, and hence t belongs to the horizon outer limit of the sets C^ν. The converse is obtained by the same argument. The second equality follows from the first one via the identity $(C^-)^- = C$. □

4. The outer semicontinuity of pos$W$. In addition to the limiting cones introduced in the previous section, our conditions also involve $\mathrm{lil}\, K$, the *lineality space* of a convex cone K; it's the maximal linear subspace contained in K.

THEOREM 4.1 (the outer semicontinuity of positive hulls). *The taking of positive hulls is outer semicontinuous, more precisely: Given* $\{W; W^\nu,\ \nu \in \mathbb{N}\}$, *a collection of nonempty subsets of* $\mathbb{R}^m$,

$$\limsup{}_\nu \mathrm{pos} W^\nu \subset \mathrm{pos} W$$

under the following hypotheses:

(a) W *includes the outer limit of the sets* W^ν,
(b) pos$W$ *includes the horizon outer limit of the sets* W^ν,
(c) pos$W$ *includes the core outer limit of the sets* W^ν,
(d) *when* $0 \neq t \in \mathrm{lil}(\mathrm{pos} W)$ *is a cluster point of a sequence* $\{t^\nu/|t^\nu|,\ \nu \in \mathbb{N}\}$, *where* $t^\nu \in \mathrm{pos} W^\nu \setminus \{0\}$, *then* $t^\nu \in \mathrm{lil}(\mathrm{pos} W^\nu)$ *for* ν *sufficiently large and* $\mathrm{lil}(\mathrm{pos} W) \supset \limsup_\nu \mathrm{lil}(\mathrm{pos} W^\nu)$.

Proof. Let $\{t^\nu \in \mathrm{pos} W^\nu\}_{\nu=1}^\infty$ converge to $t \in \mathbb{R}^m$. One needs to show that $t \in \mathrm{pos} W$. According to Carathéodory's theorem [11, Theorem 2.29], one can always express t^ν as

$$t^\nu = \sum_{i=1}^m \lambda_{\nu,i} w^{\nu,i}, \text{ with } \lambda_{\nu,i} \geq 0,\ w^{\nu,i} \in W^\nu,$$

i.e., as a nonnegative linear combination of no more than m vectors in W^ν. Fix an index $i \in \{1, \ldots, m\}$, and consider the sequence $\{\lambda_{\nu,i} w^{\nu,i}\}_{\nu=1}^{\infty}$.

CLAIM 1. *Any cluster point, say,* $\hat{t}^i$*, of* $\{\lambda_{\nu,i} w^{\nu,i},\ \nu \in \mathbb{N}\}$ *belongs to* pos$W$.

In all of the arguments that follow, it's taken for granted that one passes to a subsequence whenever that's required or appropriate. Certainly, if $\hat{t}^i = 0$, it belongs to pos$W$. When $\hat{t}^i \neq 0$, one has to consider three possibilities: (i) $\lim_\nu \lambda_{\nu,i} = 0$ (i.e., the limit of some subsequence is 0), (ii) $\lim_\nu \lambda_{\nu,i} = \lambda_i > 0$ is finite, or (iii) $\lim_\nu \lambda_{\nu,i} = \infty$. In case (i), the sequence $\{w^{\nu,i}\}$ must be unbounded, and all of its "cluster points" belong to the horizon outer limit $\limsup_\nu^\infty W^\nu$. From (b) it follows that they also belong to pos$W$. In case (ii), the (sub)sequence $\{w^{\nu,i},\ \nu \in \mathbb{N}\}$ must be bounded, and hence $\hat{t}^i = \lambda_i w^i$ for some $w^i \in \limsup_\nu W^\nu$. From (a), it then follows that every such cluster point $\hat{t}^i$ also belongs to pos$W$. In the third case (iii), i.e., $\lim_\nu \lambda_{\nu,i} = \infty$, $\hat{t}^i$ then belongs to the core outer limit of the sets W^ν, in which case $\hat{t}^i \in$ pos$W$ by (c). This completes the proof of the assertion.

Let i_0 be an index such that

$$|\lambda_{\nu,i_0} w^{\nu,i_0}| = \max_{i=1,\ldots,m} |\lambda_{\nu,i} w^{\nu,i}|,$$

and consider the sequence $\{\lambda_{\nu,i_0} w^{\nu,i_0}\}$; i_0 is assumed to be common for all ν, again passing to a subsequence if required. If it is bounded, then all of the sequences $\{\lambda_{\nu,i} w^{\nu,i}\}$, $i = 1, \ldots, m$, are bounded, and one can assume that, for each i, they converge to (cluster at) some $\hat{t}^i \in \mathbb{R}^m$. In view of the earlier claim, these limits belong to pos$W$. Thus, also $t = \hat{t}^1 + \cdots + \hat{t}^m$ belongs to pos$W$. There remains only to consider the case when the sequence $\{\lambda_{\nu,i_0} w^{\nu,i_0}\}$ is unbounded, say, $\lim_\nu |\lambda_{\nu,i_0} w^{\nu,i_0}| = \infty$. For all $i = 1, \ldots, m$, the sequences $\{\lambda_{\nu,i} w^{\nu,i} / |\lambda_{\nu,i_0} w^{\nu,i_0}|\}$ are bounded, and one can assume that, for each i, they converge to (equivalently, cluster at) some $u^1, \ldots, u^m$. By Claim 1, these u^i belong to pos$W$.

CLAIM 2. *These limit points* $u^1, \ldots, u^m$ *belong to* lil(pos$W$)*. Consequently, if* u^i *is nonzero, then, for* ν *sufficiently large,* $w^{\nu,i}$ *belong to* lilposW^ν.

Since $|\lambda_{\nu,i_0} w^{\nu,i_0}| \to \infty$, dividing t^ν by $|\lambda_{\nu,i_0} w^{\nu,i_0}|$ and passing to the limit when ν tends to ∞, one obtains $u^1 + \cdots + u^m = 0$. Since pos$W$ is a convex cone, we conclude that $u^1, \ldots, u^m$ must belong to the lineality space of pos$W$. The second part of the assertion now follows directly from condition (d), and thus Claim 2 is verified.

Let I_0 denote the set of all indexes i such that $u^i = 0$ and J_0 the set of remaining indexes. Note that i_0 belongs to J_0 since $|u^{i_0}| = 1$. According to Claim 2, if the index set I_0 is empty, then t^ν belongs to lilposW^ν for ν large enough and, consequently, so does $t \in$ pos$W$. Thus, one has only to consider the case when I_0 is nonempty. Let's write t^ν as the sum of two following terms:

$$t^\nu = z^\nu + y^\nu, \quad \text{where} \quad z^\nu = \sum_{j \in J_0} \lambda_{\nu,j} w^{\nu,j},\ y^\nu = \sum_{i \in I_0} \lambda_{\nu,i} w^{\nu,i}.$$

Now, consider the sequence $\{z^\nu\}_{\nu=1}^{\infty}$. It's bounded or not.

Bounded case: The sequence $\{z^\nu\}$ is bounded. Let z be a cluster point of this sequence that necessarily belongs to pos$W$. Then the corresponding (sub)sequence $\{y^\nu\}$ converges to $t - z$. There are two possibilities as far as this latter sequence is concerned. The first one is when all sequences $\{\lambda_{\nu,i} w^{\nu,i}\}$ are bounded; hence, one may assume that they converge to some w^i, with $i \in I_0$. In view of Claim 1, these limits w^i belong to pos$W$, the limit $t - z = \sum_{i \in I_0} w^i$ also belongs to pos$W$, and one may conclude that $t \in$ pos$W$. When all of the sequences $\{\lambda_{\nu,i} w^{\nu,i}\}$ are not necessarily

bounded, there is a sequence, again possibly passing to a subsequence, $\{\lambda_{\nu,i_1} w^{\nu,i_1}\}$ such that

$$|\lambda_{\nu,i_1} w^{\nu,i_1}| = \max_{i\in I_0} |\lambda_{\nu,i} w^{\nu,i}| \text{ and } \lim_{\nu} |\lambda_{\nu,i_1} w^{\nu,i_1}| = \infty.$$

One can appeal to the same argument as that used earlier for the sequence $\{\lambda_{\nu,i_0} w^{\nu,i_0},\ \nu \in \mathbb{N}\}$, and one can find subsets $I_1 \subset I_0$ and $J_1 = I_0 \setminus I_1$ such that

$$y^\nu = v^\nu + \sum_{i\in I_1} \lambda_{\nu,i} w^{\nu,i},$$

where $v^\nu = \sum_{j\in J_1} \lambda_{\nu,j} w^{\nu,j}$ belongs to lilposW^ν for ν sufficiently large. One can rewrite t^ν as follows:

$$t^\nu = (z^\nu + v^\nu) + \sum_{i\in I_1} \lambda_{\nu,i} w^{\nu,i}.$$

Note that the first term $(z^\nu + v^\nu)$ belongs to lilposW^ν for ν sufficiently large and that the index set I_1 has cardinality strictly smaller than that of I_0. One can proceed in this manner, one eventually exhausts all possible indexes, and one is led to conclude that $t \in \text{pos}W$.

Unbounded case: The sequence $\{z^\nu\}$ is unbounded, say, $\lim_\nu |z^\nu| = \infty$. Assume that $\lim_\nu z^\nu/|z^\nu| = v \in \text{pos}W, v \neq 0$, and

$$0 = \lim_{\nu} \frac{t^\nu}{|z^\nu|} = v + \lim \frac{y^\nu}{|z^\nu|}.$$

Set $\mu_{\nu,i} = \lambda_{\nu,i}/|z^\nu|$, and consider the sequences $\{\mu_{\nu,i} w^{\nu,i}\}_{\nu=1}^\infty$, with $i \in I_0$. By the same argument as in the "bounded case" for the sequences $\{\lambda_{\nu,i} w^{\nu,i}\}_{\nu=1}^\infty$, we come to the conclusion that either $w^{\nu,i}$ belong to lilposW^ν for ν sufficiently large and $i \in I_0$ or there is a nonempty subset $J_{1,ubdd}$ of I_0 such that

$$t^\nu = \sum_{j\in J_0\cup J_{1,ubdd}} \lambda_{\nu,j} w^{\nu,j} + \sum_{i\in I_{1,ubdd}} \lambda_{\nu,i} w^{\nu,i},$$

where the elements of the first sum belong to lilposW^ν for ν sufficiently large and $I_{1,ubdd} := I_0 \setminus J_{1,ubdd}$ is of cardinality strictly smaller than that of I_0. Continuing this procedure and remembering that the number of indexes is finite (m), we arrive at the final step in which either all terms t^ν belong to lilposW^ν for ν sufficiently large or t is a sum of the limit points that belong to pos$W$. In both cases, t is an element of pos$W$ because the latter set is a convex cone. This completes the proof of the theorem. ∎

Remark 4.2. Let's record the following observations about the hypotheses of this theorem:

- (a) When Theorem 4.1(a) holds, so does Theorem 4.1(c), trivially, when either of the following conditions is satisfied:
  - (a_1) The closure of W does not contain the origin;
  - (a_2) $[\limsup_\nu^o W^\nu] \setminus \{0\} \subset \text{int}(\text{pos}W)$.
- (b) If pos$W$ is pointed, then Theorem 4.1(d) is trivially satisfied.
- (c) In Theorem 4.1(d), the inclusion $\text{lil}(\text{pos}W) \supset \limsup_\nu \text{lil}(\text{pos}W^\nu)$ when
  - (c_1) $\text{pos}W \supset \liminf_\nu W^\nu$;
  - (c_2) $\dim \text{lil}(\text{pos}W^\nu) \leq \dim \text{lil}(\text{pos}W)$.

Clearly, condition 4.1(a) is essential. Next, we give three examples to show that each of the remaining conditions can't be neglected either.

Example 4.3 (necessity of condition 4.1(b)). Let $W = \{(0, y) \in \mathbb{R}^2 : y \geq 0\}$, and let $W^\nu = W \cup \{(\nu, \nu)\}$. Then $\text{pos}W = \{(0, y) \in \mathbb{R}^2 : y \geq 0\}$, while $\text{pos}W^\nu = \text{pos}W \cup \{(x, x) : x \geq 0\}$. All of the conditions of the theorem are fulfilled except for the second one.

Example 4.4 (necessity of condition 4.1(c)). Let $W = \{(0, y) : y \geq 0\}$, and let $W^\nu = W \cup \{(1/\nu, 1/\nu^2)\}$. Then $\text{pos}W$ coincides with W, but $\limsup_\nu \text{pos}W^\nu$ is the positive orthant of $\mathbb{R}^2$. In this example only the third condition is violated.

Example 4.5 (necessity of condition 4.1(d)). Let $W = \{(-1, 0), (1, 0)\}$, and let $W^\nu = \{(-1, 1/\nu), (1, 1/\nu)\}$. Then $\text{pos}W = \{(x, 0) : x \in \mathbb{R}\}$, while $\limsup_\nu \text{pos}W^\nu = \{(x, y) : y \geq 0\}$. In this example all of the conditions of the theorem are satisfied except for the fourth one.

When W^ν consists of the columns $a^{\nu,1}, \ldots, a^{\nu,k}$ of a constant size $m \times k$-matrix, Theorem 4.1 yields the following improvement of [12, Theorem 2].

COROLLARY 4.6 (positive hull of converging matrices). *Assume that the vectors $a^{\nu,1}, \ldots, a^{\nu,k}$ converge, respectively, to $a^i, i = 1 \ldots, k$. Set $W = \{a^1, \ldots, a^k\}$, and assume further that*

(a) *for all ν,* $\dim \text{lil}(\text{pos}W^\nu) = \dim \text{lil}(\text{pos}W)$*;*

(b) $\text{pos}W$ *includes all of the cluster points of* $\{a^{\nu,i}/|a^{\nu,i}|\}$ *when* $a^i = 0$*;*

(c) *if* $0 \neq a^i \in \text{lil}(\text{pos}W)$*, then* $a^{\nu,i} \in \text{lil}(\text{pos}W^\nu)$ *for all* ν*.*

Then $\limsup_\nu \text{pos}W^\nu \subset \text{pos}W$*.*

Proof. The proof combines the observations in Remark 4.2(c) with the assertion of Theorem 4.1. □

The condition (b) of [12, Theorem 2] requires that Corollary 4.6(c) holds even when $a^i = 0$. It is clear that this condition then implies both conditions 4.6(b) and 4.6(c), but the converse is not the case, as seen by the next example.

Example 4.7 (relaxed outer semicontinuity). Let $a^{\nu,1} = (0, 1)$ and $a^{\nu,2} = (\frac{1}{\nu}, \frac{1}{\sqrt{\nu}})$.

Detail. Then $a^1 = (0, 1)$ and $a^2 = (0, 0)$. The lineality spaces of $\text{pos}W^\nu$ and $\text{pos}W$ are the null space, and therefore conditions 4.6(a) and 4.6(c) clearly hold. Since $a^{\nu,2} \neq 0$, condition (b) of [12, Theorem 2] is not satisfied. However, one still has $\limsup_\nu \text{pos}W^\nu \subset \text{pos}W$ according to the previous corollary.

The outer semicontinuity of the positive hulls can also be characterized in terms of the inner limits of their positive polar cones. Given a nonempty subset W of $\mathbb{R}^m$ the polar cone of W consists of linear functions that are positive on W, that is,

$$W^* := \{u \in \mathbb{R}^m : \langle u, t\rangle \geq 0, t \in W\}.$$

The *inner limit* of a collection of sets $\{C^\nu, \nu \in \mathbb{N}\}$ is denoted by $\liminf_\nu C^\nu$, which consists of those vectors v for which there exist $v_\nu \in C^\nu$ for every ν such that v is the limit of the sequence $\{v_\nu\}_\nu$.

PROPOSITION 4.8 (limits under polarity). *Let $C \subset \mathbb{R}^n$ be a closed convex cone. Then the following conditions are equivalent:*

(a) $\limsup_\nu \text{pos}W^\nu \subset C$*,*

(b) $\liminf_\nu (\text{pos}W^\nu)^* \supset C^*$*.*

Hence, under the assumptions of Theorem 4.1*,*

$$\liminf_\nu (W^\nu)^* \supset W^*.$$

Proof. Observe that the outer limit of posW^ν coincides with the outer limit of their closures. Now, apply [11, Corollary 11.35] to the closed convex cones $\text{cl}\,\text{posW}^\nu$

to obtain the first assertion. The second assertion is deduced from (a) and Theorem 4.1. □

Let us close up this section by some remarks on lower semicontinuity and upper semicontinuity of the positive hull mappings. It is clear that the inclusion

$$\liminf_{\nu} \mathrm{pos}W^{\nu} \supset \mathrm{pos}W,$$

which characterizes the lower semicontinuity of the positive hull, is true under a quite standard assumption that $\liminf_{\nu} W^{\nu} \supset W$. The upper semicontinuity means that, for any open set A containing $\mathrm{pos}W$, one can find an index ν_0 such that A contains all $\mathrm{pos}W^{\nu}$ for $\nu > \nu_0$. Since $\mathrm{pos}W^{\nu}$ are cones, the above condition implies that $\mathrm{pos}W$ contains all of the cones $\mathrm{pos}W^{\nu}$ whenever $\nu \geq \nu_0$. This is the reason why we focus our attention to outer semicontinuity only.

5. Application: Semi-infinite programs. Consider the following semi-infinite linear program,

$$\text{(siLP)} \qquad \begin{aligned} &\min \langle c, x\rangle \\ &\text{so that} \quad \langle a_t, x\rangle + \beta_t \leq 0,\ t \in T, \end{aligned}$$

where $a_t \in \mathbb{R}^n, \beta_t \in \mathbb{R}$, and T is supposed to be a compact metric space. The system of constraints $\langle a_t, x\rangle + \beta_t \leq 0,\ t \in T$, is denoted by σ and its solution set (the feasible set of (siLP)) is denoted by S. Set

$$W = \{a_t | t \in T\} \qquad \text{and} \qquad \hat{W} = \{(a_t, \beta_t) | t \in T\}.$$

The convex cones generated by W and $\hat{W}$ are, respectively, called the first-moment and the second-moment cone of the system σ (see [6]). We recall also that a sequence $\{x^{\nu}\}_{\nu}$ of vectors in $\mathbb{R}^n$ is said to be an asymptotic solution of the system σ if for every $t \in T$ one has $\liminf_{\nu\to\infty}\langle a_t, x^{\nu}\rangle + \beta_t \leq 0$. It is clear that the system σ is consistent (that is, S is nonempty) if and only if it has a bounded asymptotic solution. A system that has no asymptotic solutions is called strongly inconsistent. Of course, an inconsistent system may have asymptotic solutions as well.

Now we consider a collection of perturbed problems of the same form: For $\nu \in \mathbb{N}$,

$$\text{(siLP}^{\nu}\text{)} \qquad \begin{aligned} &\min \langle c^{\nu}, x\rangle \\ &\text{so that} \quad \langle a_t^{\nu}, x\rangle + \beta_t^{\nu} \leq 0,\ t \in T^{\nu}. \end{aligned}$$

As functions of t, a_t, a_t^{ν}, β_t, and β_t^{ν} are continuous. When the spaces $C(T)$ and $C(T^{\nu})$ of the continuous functions on T and T^{ν} are equipped with the max-norm topology, their (topological) duals are the spaces of measures $M(T)$ and $M(T^{\nu})$, respectively. The cone of positive measures is denoted by $M_+(T^{\nu})$, and $M_+^F(T^{\nu})$ is the cone of positive measures with finite support. The system σ^{ν} and the sets S^{ν}, W^{ν}, and $\hat{W}^{\nu}$ are defined accordingly as σ, S, W, and $\hat{W}$ above.

The first result that can be derived from Theorem 4.1 is on the stability of consistency and strong inconsistency of the system of constraints of (siLP).

PROPOSITION 5.1. *Assume that the collection* $\{\hat{W}; \hat{W}^{\nu}, \nu \in \mathbb{N}\}$ *satisfies the hypotheses of Theorem* 4.1. *Then the following assertions hold:*

(a) *If the system σ is consistent, then, for ν sufficiently large, the systems σ^ν are consistent.*

(b) *If the systems σ^ν are strongly inconsistent, then the system σ is strongly inconsistent.*

Proof. According to the consistency tests (Theorem 4.4 of [6]) the system σ is consistent if and only if the cone $\operatorname{clpos}\hat{W}$ does not contain the vector $e := (0, \ldots, 0, 1)$ of the space $\mathbb{R}^{n+1}$. Since the outer limit of $\operatorname{pos}\hat{W}^\nu$ coincides with the outer limit of $\operatorname{clpos}\hat{W}^\nu$, in view of Theorem 4.1, when ν is sufficiently large, the cone $\operatorname{clpos}\hat{W}^\nu$ does not contain that vector either, and hence the system σ^ν is consistent.

Now, if the systems σ^ν are strongly inconsistent, then again, in view of the consistency tests, the cones $\operatorname{pos}\hat{W}^\nu$ contain the vector e. By Theorem 4.1, the vector e belongs to the cone $\operatorname{pos}\hat{W}$, and hence the strong inconsistency of the system σ follows. □

It is known that the horizon cone of the feasible set S (when it is nonempty) is the solution set to the homogeneous system $\langle a_t, x\rangle \leq 0, t \in T$. It is exactly the negative polar cone of the set W. We derive the outer and inner continuity of the horizon cone of S as follows.

PROPOSITION 5.2. *The following assertions hold:*

(a) *If the collection $\{W; W^\nu, \nu \in \mathbb{N}\}$ satisfies the hypotheses of Theorem* 4.1 *and if the problems* (siLP$^\nu$) *have feasible solutions, then*

$$S_\infty \subseteq \liminf_\nu S^\nu_\infty.$$

(b) *If $W \subseteq \liminf_\nu W^\nu$ and the problem* (siLP) *has feasible solutions, then*

$$S_\infty \supseteq \limsup_\nu S^\nu_\infty.$$

Proof. If S is empty, then the inclusion of (a) holds trivially. If S is not empty, as we have already mentioned, the horizon cone of S is the negative polar cone of the set W. Then (a) follows from Theorem 4.1 and Proposition 4.8. The second assertion is obtained from Proposition 4.8 and the remark at the end of section 4 on the inner semicontinuity of the positive hull mappings. □

An immediate consequence of the above proposition is on the boundedness of the feasible set.

COROLLARY 5.3. *If nonempty, the feasible set S of* (siLP) *is bounded provided that the hypotheses of Theorem* 4.1 *are satisfied and that the feasible sets S^ν are nonempty and bounded. For ν sufficiently large, if nonempty, the sets S^ν are bounded provided that S is nonempty and bounded and that $W \subseteq \liminf_\nu W^\nu$.*

Proof. It is known that, being nonempty, the set S is bounded if and only if its horizon cone is trivial. The corollary now follows from Proposition 5.2. □

We notice that the hypotheses of Theorem 4.1 do not guarantee that problem (siLP) has feasible solutions even if (siLP$^\nu$) have. Next we turn to the stability the of existence of optimal solutions for (siLP).

PROPOSITION 5.4 (existence of solutions). *Assume the following:*

(a) (siLP) *and* (siLP$^\nu$) *satisfy the Slater condition;*

(b) *the collection $\{W; W^\nu, \nu \in \mathbb{N}\}$ satisfies the hypotheses of Theorem* 4.1 *and $c^\nu \to c$;*

(c) *problems* (siLP$^\nu$) *have finite optimal values.*

Then the optimal value of (siLP) *is finite.*

Proof. Direct calculation, either via the Lagrangian function or conjugate calculus (see also [3]), yields the dual problem of (siLP$^\nu$):

$$(siD^\nu) \qquad \begin{aligned} &\max \int_{T^\nu} \beta_t^\nu \, d\mu(t) \\ &\text{so that} \quad \mu \in M_+(T^\nu), \\ &\qquad c^\nu + \int_{T^\nu} a_t^\nu d\mu(t) = 0. \end{aligned}$$

The *finite support dual*, whose (dual) variables are restricted to be measures with finite support, is

$$(\text{siFD}^\nu) \qquad \begin{aligned} &\max \sum_{t\in \text{supp}(\mu)} \beta_t^\nu \mu(t) \\ &\mu \in M_+^F(T^\nu), \\ &c^\nu + \sum_{t\in \text{supp}(\mu)} a_t^\nu \mu(t) = 0, \end{aligned}$$

where $\text{supp}(\mu)$ designates the (finite) support of the measure μ. With $v(\cdot)$ denoting the optimal value, one has the following weak duality inequalities [3]:

$$v(\text{siLP}^\nu) \geq v(\text{siD}^\nu) \geq v(\text{siFD}^\nu).$$

By assumption $v(\text{siLP}^\nu)$ is finite, and hence the set of feasible solutions of (siFD$^\nu$) is nonempty [3, Theorem 5.27], which means that

$$0 \in c^\nu + \text{pos} W^\nu.$$

Passing to the limit and applying Theorem 4.1, one obtains

$$0 \in c + \limsup_\nu \text{pos} W^\nu \subset c + \text{pos} W.$$

Hence, (siFD) is feasible, and in turn this implies that v(siLP) is finite. □

Remark 5.5 (convergence of the solutions). The propositions that we have established in this section are direct applications of Theorem 4.1. Some more convergence properties which are less direct from the above-said theorem can also be said about (siLP). For instance, the convergence of the feasible solutions is stated as follows.

(i) If $\hat{W} \subseteq \liminf_\nu \hat{W}^\nu$, then

$$S \supseteq \limsup_\nu S^\nu;$$

(ii) if the family $\hat{W}^\nu$ is relaxed upper semicontinuous in the sense that, for every $\epsilon > 0$, there is some integer ν_0 such that all $\hat{W}^\nu$, $\nu \geq \nu_0$, are within an ϵ-neighborhood of $\hat{W}$ in the product space $\mathbb{R}^m \times \mathbb{R}$, and if S admits a strong Slater point, that is, a point $\overline{x} \in S$, with $\langle a_t, \overline{x}\rangle + \beta_t \leq -\delta$ for all $t \in T$ and some $\delta > 0$, then

$$S \subseteq \liminf_\nu S^\nu.$$

The proof of these assertions presents no difficulty, so we omit it. The convergence of the optimal solutions and the optimal value of (siLP) can also be obtained by using the methods of [4, 6], in which a rather complete analysis of convergence of (siLP) has been exposed in the case when the index sets T^ν are common for all ν.

6. Application: Stochastic programs. Here, we consider an extension of the *"linear" stochastic program recourse model* [2, 10] to one where the recourse problem takes on the form of a generalized linear program. This brings us into the realm of problems with nonlinear recourse, and, for this particular class, we derive rather explicit expressions for the induced constraints as well as a lower semicontinuity result for the optimal value function. Let $\Im$ stand for the random components of the problem that takes its values, denoted by ξ, in $\Xi \subset \mathbb{R}^d$, the (closed) support of the associated probability measure P. The *recourse cost function* is

$$Q(\xi, x) = \inf\left\{\sum_{j=1}^{J} q_j y_j \,|\, y_j \geq 0, \text{ with } \xi - Tx = \sum_{j=1}^{J} t^j y_j, t^j \in W, j = 1, \ldots, J, \text{ and } J \in \mathbb{N}\right\},$$

where, for $j = 1, \ldots, J$,

$$\begin{pmatrix} q_j \\ t^j \end{pmatrix} \in C \subset \mathbb{R}^{m+1},$$

with C convex; it could be the epigraph of (nonlinear) convex functions, for example. The *expected recourse function* is

$$EQ(x) = E\{Q(\Im, x)\} = \int_{\Xi} Q(\xi, x)\, P(d\xi),$$

with the stochastic program

$$\begin{aligned} &\min f_0(x) + EQ(x) \\ \text{so that} \quad &Ax = b, x \geq 0, \end{aligned}$$

with $f_0 : \mathbb{R}^n \to \mathbb{R}$. Let

$$K_1 = \left\{x \in \mathbb{R}^n_+ \,|\, Ax = b\right\} \quad \text{and} \quad K_2 = \text{dom}EQ.$$

The problem is said to have *relatively complete recourse* when $K_1 \subset K_2$. That's a desirable property, but, unfortunately, this is not universally the case. When $E\{\Im\}$ is finite [13], as we now assume, for the set of *induced constraints*, one has

$$K_2 = \text{dom}EQ = \bigcap_{\xi \in \Xi} \text{dom}Q(\xi, \cdot) = \bigcap_{\xi \in \Xi} \{x \,|\, \xi - Tx \in \text{pos}W\}.$$

Our emphasis here will be on the dependence of the set K_2 on perturbations affecting T, W, and Ξ, in particular when the set of feasible solutions of the stochastic program is not necessarily bounded. Let's denote these perturbed versions by T^ν, W^ν, and Ξ^ν.

LEMMA 6.1 (outer semicontinuity of the induced constraints). *When*

(a) $\liminf_\nu \Xi^\nu \supset \Xi$ *and* $T^\nu \to T$,

(b) *the collection* $\{W; W^\nu, \nu \in \mathbb{N}\}$ *satisfies the hypotheses of Theorem* 4.1,

then $\limsup_\nu K_2^\nu \subset K_2$.

Proof. Let $\{x^\nu \in K_2^\nu\}_{\nu=1}^\infty$ converge to x and $\xi \in \Xi$. In view of (a), one can find $\xi^\nu \in \Xi^\nu$ such that $\lim_\nu \xi^\nu = \xi$. Then $\lim_\nu (\xi^\nu - T^\nu x^\nu) = \xi - Tx$ that belongs to pos$W$ according to Theorem 4.1. It follows that $x \in K_2$. ∎

Generally, the inclusion $\limsup_\nu D^\nu \subset D$ does not imply $\limsup_\nu^\infty D^\nu \subset D^\infty$. A remarkable exception is the case of induced constraints.

LEMMA 6.2 (the horizon outer limit of the induced constraints). *Under the hypothesis of Lemma* 6.1*, one has*

$$\limsup_\nu^\infty K_2^\nu \subset K_2^\infty.$$

Moreover, when $K_1 \cap K_2 \neq \emptyset$*, also* $\limsup_\nu^\infty (K_1 \cap K_2^\nu) \subset (K_1 \cap K_2)^\infty$.

Proof. Observe first that a vector x belongs to the horizon cone K_2^∞ if and only if $-Tx$ belongs to clpos$W$. Let $z \in \limsup_\nu^\infty K_2^\nu$, say, $z = \lim_k \lambda_k z^{\nu_k}$, where $z^{\nu_k} \in K_2^{\nu_k}$ and $\lambda_k \downarrow 0$. For $\xi \in \Xi$, in view of Lemma 6.1(a), one can find $\xi^k \in \Xi^{\nu_k}$ such that $\xi^k \to \xi$. Thus, $\xi^k - T^{\nu_k} z^{\nu_k} \in \text{pos}W^{\nu_k}$ and $\lambda_k \xi^k - T^{\nu_k}(\lambda_k z^{\nu_k}) \in \text{pos}W^{\nu_k}$, as well. Passing to the limit when k goes to ∞ yields $-Tz \in \text{pos}W$ via Lemma 6.1. Thus, $z \in K_2^\infty$. The second assertion is obtained from the first one by relying on [11, Proposition 3.9]. □

This leads us to a lower-semicontinuity result for the optimal value. Here, we also allow for perturbations f_0^ν of the objective function f_0 as well as for perturbations P^ν of the probability measure P. The expected recourse functions $E^\nu Q$ of the perturbed problems are then defined by

$$EQ^\nu(x) = \int_{\Xi^\nu} \left[\inf \left\{ \sum_{j=1}^J q_j y_j | y_j \geq 0 \text{ such that } \xi - T^\nu x = \sum_{j=1}^J t^j y_j, t^j \in W^\nu, \right. \right.$$
$$\left. \left. j = 1, \ldots, J, \text{with } J \text{ finite} \right\} \right] P^\nu(d\xi).$$

Let v and v^ν denote the optimal values of the given stochastic program and of its perturbations, respectively.

PROPOSITION 6.3 (lower semicontinuity of the optimal value). *When*

(a) $\liminf_\nu \Xi^\nu \supset \Xi$ *and* $T^\nu \to T$,

(b) *the collection* $\{W; W^\nu, \nu \in \mathbb{N}\}$ *satisfies the hypotheses of Theorem* 4.1,

(c) *given* (b), $E^\nu Q$ *epiconverges to* EQ,[1]

(d) *the functions* $f^\nu = f_0^\nu + E^\nu Q$ *are quasi-convex,*

(e) *the functions* f_0^ν *converge continuously to* f_0,

(f) *the set of solutions of our (given) stochastic program is nonempty and bounded, then* $\liminf_\nu v^\nu \geq v$.

Proof. A standard argument about the inf-projection and the summation, or integration, of convex functions yields the convexity of EQ and $E^\nu Q$. Assumptions (c) and (e) imply that the functions f^ν epiconverge to f [11, Theorem 7.46(b)]. We now proceed by contradiction. Suppose that one can find x^ν such that $\liminf_\nu f^\nu(x^\nu) < v$. Let $x^0 \in \text{argmin}_{K_1 \cap K_2} f$. If the sequence $\{x^\nu, \nu \in \mathbb{N}\}$ is bounded, in view of Lemma 6.1, one may assume that it converges to some $x \in K_1 \cap K_2$. This means, by epiconvergence, that $\liminf_\nu f^\nu(x^\nu) \geq f(x) \geq v$, and that's a contradiction. If the sequence $\{x^\nu\}$ is unbounded, we may assume that $\{x^\nu/|x^\nu|\}$ converges to some nonzero vector $z \in \limsup_\nu^\infty (K_1 \cap K_2^\nu)$. By Lemma 6.2, $z \in (K_1 \cap K_2)^\infty$; i.e., given $\lambda > 0$, one can find $\lambda_\nu > 0$ converging to 0 such that $x^0 + \lambda_\nu(x^\nu - x^0)$ converges to $x^0 + \lambda z$. Since the f^ν are quasi-convex, one must have

$$f^\nu(x^0 + \lambda_\nu(x^\nu - x^0)) \leq \max\{f^\nu(x^0), f^\nu(x^\nu)\} \leq \max\{f^\nu(x^0), v\}.$$

[1] This is not a very demanding condition, and it actually occurs under rather minimal assumptions; cf. [14, sections 6 and 8] for a brief survey.

This implies that

$$f(x^0 + \lambda z) \leq \max\{f(x^0), v\} = v.$$

Thus, for all $\lambda \geq 0$, $x^0 + \lambda z$ minimizes f on $K_1 \cap K_2$, in contradiction with assumption (f). □

Example 6.4 (without quasi-convexity). If the functions f^ν are not quasi-convex, then the inequality $\liminf_\nu v^\nu \geq v$ is no longer valid.

Detail. To see this, let us define the objective function $f_0 : \mathbb{R} \to \mathbb{R}_+$ by

$$f(x) = \begin{cases} -x - 1 & \text{if } x \leq 0, \\ x - 1 & \text{if } 0 < x < 3, \\ 2 & \text{if } x \geq 3 \end{cases}$$

and choose the constraints so that the feasible set $K_1 \cap K_2 = \mathbb{R}_+$. (The set W consists of one element 1, T is the matrix (-1), and the random variable Ξ takes the values $0, 1, 2, \ldots$.) The perturbed problems are given with the same feasibility set, and the objective functions are

$$f^\nu(x) = \begin{cases} f(x) & \text{if } x \leq \nu, \\ -x + \nu + 1 & \text{if } \nu < x < \nu + 3, \\ -f(x) & \text{if } x \geq \nu + 3. \end{cases}$$

Then all of the hypotheses of the proposition are fulfilled except for the quasi convexity of the f^ν. The optimal value v^ν is -2 while the optimal value $v = -1$.

Example 6.5 (without boundedness of $\operatorname{argmin} f$). The conclusion of Proposition 6.3 is no longer true if the set of minimizers of f on $K_1 \cap K_2$ is unbounded as demonstrated by the following example.

Detail. Again, let $K_1 \cap K_2 = \mathbb{R}_+$. The objective function is

$$f(x) = \begin{cases} -x - 1 & \text{if } x \leq 0. \\ -1 & \text{if } x > 0, \end{cases} \text{ and } f^\nu(x) = \begin{cases} f(x) & \text{if } x \leq \nu, \\ -x + \nu - 1 & \text{if } \nu < x < \nu + 1, \\ x - \nu - 3 & \text{if } x \geq \nu + 1. \end{cases}$$

Then the set of minimizers of f is unbounded, and the optimal value of the perturbed problems is $v^\nu = -2$ while $v = -1$.

Acknowledgment. The authors are thankful to a referee for bringing their attention to references [4] and [6].

FINDING BEST APPROXIMATION PAIRS RELATIVE TO A CONVEX AND PROX-REGULAR SET IN A HILBERT SPACE*

D. RUSSELL LUKE†

Abstract. We study the convergence of an iterative projection/reflection algorithm originally proposed for solving what are known as phase retrieval problems in optics. There are two features that frustrate any analysis of iterative methods for solving the phase retrieval problem: nonconvexity and infeasibility. The algorithm that we developed, called relaxed averaged alternating reflections (RAAR), was designed primarily to address infeasibility, though our strategy has advantages for nonconvex problems as well. In the present work we investigate the asymptotic behavior of the RAAR algorithm for the general problem of finding points that achieve the minimum distance between two closed convex sets in a Hilbert space with empty intersection, and for the problem of finding points that achieve a local minimum distance between one closed convex set and a closed *prox-regular set*, also possibly nonintersecting. The nonconvex theory includes and expands prior results limited to convex sets with nonempty intersection. To place the RAAR algorithm in context, we develop parallel statements about the standard alternating projections algorithm and gradient descent. All of the various algorithms are unified as instances of iterated averaged alternating proximal reflectors applied to a sum of regularized maximal monotone mappings.

Key words. best approximation pair, convex set, prox-regular, inconsistent feasibility problems, projection, relaxed averaged alternating reflections, fixed point, resolvent, maximal monotone mappings

1. Introduction.

Projection algorithms are simple yet powerful iterative techniques for finding the intersections of sets. Perhaps the most prevalent example of a projection algorithm is the alternating projections onto convex sets (POCS) dating back to von Neumann [54]. This and algorithms like it have been applied in image processing [19], medical imaging and economics [14], and optimal control [27] to name a few. For a review and historical background, see [4]. The theory for these algorithms is limited mainly to convex setting and to *consistent feasibility problems*, that is, problems where the set intersection is nonempty; if the intersection is empty, then the problem is referred to as an *inconsistent* feasibility problem; examples are abound of practitioners using these methods for nonconvex and/or inconsistent problems. We have in recent years been particularly interested in projection algorithms in crystallography and astronomy [6, 39], and more recently in inverse scattering [34, 33, 15, 12, 11]. Until now, we have been forced to rely on convex heuristics to justify certain strategies [7, 38] for want of an adequate nonconvex theory. In the absence of a nonconvex theory, practitioners resort to ad hoc stopping criteria and other strategies to get their algorithms to work according to user defined criteria. Depending on the algorithms, iterates tend to either stagnate at an undesirable point, or "blow up." We are particularly interested in those algorithms that appear to be unstable. Using convex heuristics we were able to provide plausible explanations [8] and remedies [38] for algorithmic instabilities; however, a general theory was not pursued.

Our goal in this paper is two-fold: first, to prove the convergence in the convex setting of an algorithm that we have proposed to solve inconsistent feasibility problems [38], and second, to modify the theory to accommodate nonconvexity. Our algorithm, called relaxed averaged alternating reflections (RAAR), can be viewed as a relaxation of a fixed point mapping used by Lions and Mercier to solve generalized equations involving the sum of maximal monotone mappings [37] and which is an extension of an implicit iterative algorithm by Douglas and Rachford [24] for solving linear partial differential equations.

In section 2 we analyze the RAAR algorithm in the convex setting. Our task here is to characterize the fixed point set of the mapping, as well as to verify the assumptions of classical theorems. Our main result for this section is Theorem 2.7 which establishes convergence of the RAAR algorithm with approximate evaluation of the fixed point operator and variable relaxation parameter. The novelty of our mapping is that it addresses the crucial instance of inconsistent feasibility problems. Inconsistency is a source of instability for more conventional strategies. To place our new algorithm in the context of better-known strategies, we show in Proposition 2.5 that RAAR, alternating projections, and gradient descent are all instances of iterated alternating averaged proximal reflectors—the Lions–Mercier algorithm—applied to the problem of minimizing the sum of two regularized maximal monotone mappings.

In section 3 we expand our convex results to accommodate nonconvexity. In addition to characterizing the fixed point set, we formulate local, nonconvex versions of convex theorems, in particular formulations where *prox-regularity* is central. Our main result in this section is Theorem 3.12 which establishes local convergence of nonconvex applications of the RAAR algorithm. While the nonconvex theory includes the convex case, we present both separately to highlight the places where nonconvexity requires extra care, and to make the nonconvex theory more transparent. The nature of nonconvexity requires focused attention to specific mappings; however, we generalize wherever possible. Failing that, we detail parallel statements about the more conventional alternating projection algorithm; this also allows comparison of our algorithm with gradient descent methods for solving nonlinear least squares problems.

Our analysis complements other results on the convergence of projection algorithms for consistent nonconvex problems [22, 36, 35]. In particular, we point out that the key assumption that we rely upon for convergence, namely a type of local nonexpansiveness of the fixed point mapping, does not appear to yield *rates* of convergence as are achieved in [36, 35] using notions of *regularity* of the intersection. On the other hand, regularity, in addition to assuming the intersection is nonempty, is a strong condition on the intersection that, in particular, is not satisfied for ill-posed inverse problems, our principal motivation.

To close this subsection, we would like to clarify the relationship of the present work to previous work on the phase retrieval problem in crystallography and astronomy that has been a major motivation for these investigations. The results developed in this work apply in principle to the finite-dimensional phase retrieval problem (that is, discrete bandlimited images), so long as certain regularity of the fixed point mapping, namely local firm nonexpansiveness, can be determined. Such an investigation is beyond the scope of this work. The infinite dimensional phase retrieval problem, on the other hand, as studied in [13] does *not* fall within the theory developed here because the sets generated by the magnitude constraints are not weakly closed [39, Property 4.1], hence they are not prox-regular.

1.1. Basic tools and results. We begin with the central tools and basic results that we will use in our analysis. Throughout this paper $\mathcal{H}$ is a real Hilbert space with inner product $\langle \cdot, \cdot \rangle$ and induced norm $\| \cdot \|$. For $A, B \subset \mathcal{H}$ closed, the underlying problem is to

$$\text{find } x \in A \cap B. \tag{1.1}$$

Note that it could happen that $A \cap B = \varnothing$, in which case one might naturally formulate the problem as a nonlinear least squares problem

$$\underset{x}{\text{minimize}}\, J(x) = \tfrac{1}{2}\left(\tfrac{1}{2}\operatorname{dist}_A^2(x) + \tfrac{1}{2}\operatorname{dist}_B^2(x)\right), \tag{1.2}$$

where $\operatorname{dist}_C(x)$ is the distance of the point x to a set C:

$$\operatorname{dist}_C(x) := \inf_{c \in C} |x - c|.$$

If x_* is a locally optimal point, then $0 \in \partial J(x_*)$, where ∂ denotes the subdifferential [17, 51, 18, 30, 31, 32, 43]. Another characterization of a locally optimal point x_* is to associate it with a *best approximation* pair (a, b) satisfying $b \in P_B x_* \subset P_B a$ and $a \in P_A x_* \subset P_A b$, where P_C is the projection defined by

$$P_C x := \operatorname{argmin}_{c \in C} |x - c| = \{ y \in C \subset \mathcal{H} \mid |x - y| = \operatorname{dist}_C(x) \}.$$

If C is convex, then the projection is single-valued. If in addition C is closed and nonempty, then $P_C x$ is characterized by [23, Theorem 4.1]

$$P_C x \in C \quad \text{and} \quad \langle c - P_C x, x - P_C x \rangle \leq 0 \quad \text{for all } c \in C. \tag{1.3}$$

If C is not convex, then the projection, if it exists, is a set. If the projection exists and is single-valued near all points in C, then C is said to be *prox-regular* [49]. The relationship between the subdifferential of the squared distance function to a prox-regular set C and the projection is shown in [49, Proposition 3.1] to be

$$\partial\left(\operatorname{dist}_C^2(x)\right) = 2(x - P_C x) \tag{1.4}$$

for x in a neighborhood of C. If C is convex, then this relationship holds globally. In particular, for A and B prox-regular and x in a proximal neighborhood of both sets, we have

$$\partial J(u) = \tfrac{1}{2}\left((x - P_A x) + (x - P_B x)\right).$$

Example 1.1 (gradient descent and averaged projections). Consider the steepest descent iteration with step length λ_n where P_A and P_B are single-valued:

$$\begin{aligned} x_{n+1} &= x_n - \lambda_n \partial J(x_n) \\ &= (1 - \lambda_n) x_n + \lambda_n \tfrac{1}{2}\left(P_A x_n + P_B x_n\right). \end{aligned} \tag{1.5}$$

In other words, gradient descent for least squares minimization is a *relaxed averaged projection algorithm*. We will come back to this particular algorithm later.

Projection algorithms seek to find an element in $A \cap B$, or best approximation thereof, by iterated projections, possibly with some relaxation strategy, onto A and

B separately. The example above interprets the steepest descent algorithm as a relaxed averaged projection algorithm. Another elementary projection algorithm is the well-known alternating projections algorithm: Given $x_0 \in \mathcal{H}$ generate the sequence $\{x_n\}_{n\in\mathbb{N}}$ by

$$x_n = (P_A P_B)\, x_{n-1}. \tag{1.6}$$

Example 1.2 (averaged projections and alternating projections). A standard formulation in the product space [46] identifies the averaged projections (and hence steepest descent) given by (1.5) with alternating projections. To see this, consider the product space $\mathcal{H}\times\mathcal{H}$ with inner product $\langle (x_1,x_2),\ (y_1,y_2)\rangle := \frac{1}{2}\left((x_1,y_1)+(x_2,y_2)\right)$. Let $C = \{(x,y)\in\mathcal{H}\times\mathcal{H} \mid x = y\}$ and $D = \{(x,y)\in\mathcal{H}\times\mathcal{H} \mid x\in A, y\in B\}$; then

$$P_C P_D(x,x) = \left(\tfrac{1}{2}(P_A+P_B)x, \tfrac{1}{2}(P_A+P_B)x\right).$$

Our focus in this paper is on the convergence of projection algorithms, but the above example serves to emphasize that convergence results about such algorithms can be very broadly applied.

When $A\cap B = \varnothing$ we say that the feasibility problem (1.1) is inconsistent. The distinction between inconsistent and consistent feasibility problems has profound implications for the stability and convergence of numerical algorithms. It is convenient to define *difference set* $B-A$. The *gap* between the sets A and B is the point in $B-A$ closest to the origin. Specifically,

$$G := \overline{B-A}, \qquad g := P_G 0, \qquad E := A\cap(B-g), \quad \text{and} \quad F := (A+g)\cap B, \tag{1.7}$$

where $\overline{B-A}$ denotes the closure of $B-A$. Note that these definitions only make sense when A and B are convex. We will generalize these sets in section 3. Basic characterizations are given in [3, 8]. We note that if $A\cap B\neq\varnothing$, then $E=F=A\cap B$. Even in the case where $A\cap B=\varnothing$, the gap vector g is unique and always well defined. A useful characterization of the gap vector g is via the *normal cone mapping of* G: for G convex $-g\in N_G(g)$, where $N_G(g)$ is defined by

$$N_G\colon g\mapsto \begin{cases} \{y\in\mathcal{H} \mid \langle c-g, y\rangle \le 0 \quad \text{for all } c\in G\} & \text{if } g\in G,\\ \varnothing & \text{otherwise.}\end{cases} \tag{1.8}$$

Example 1.3 (projections and normal cone mappings for convex sets). If C is convex, then the normal cone mapping is the subdifferential of the (infinite) indicator function, ι_C, of the set C:

$$\iota_C(x) := \begin{cases} 0 & \text{for } x\in C,\\ \infty & \text{else,}\end{cases} \tag{1.9}$$

$$\partial\iota_C(x) \;=\; N_C(x), \tag{1.10}$$

$$(I+\rho N_C)^{-1}x \;=\; P_C x \quad \text{for all } \rho>0. \tag{1.11}$$

The mapping $(I+N_C)^{-1}$ is called the *resolvent* of the normal cone mapping, or equivalently in this case, the resolvent of $\partial\iota_C$. Specializing to $C=A\cap B$, the indicator function of the intersection is the sum of the indicator functions of the individual sets

$$\iota_{A+B} = \iota_A + \iota_B$$

and, for A and B convex, the resolvent $(I + (N_A + N_B))^{-1}$ is the projection onto $A \cap B$ supposing this is nonempty. In other words, an element of $A \cap B$ is a zero of $\partial \iota_{A\cap B}$. The parameter ρ in (1.11) is interpreted as a *step size* consistent with backward-stepping descent algorithms (see [25]).

Throughout this work we compare the asymptotic properties of alternating projections to more recent projection strategies. A common framework in the convex setting that provides an elegant synthesis of these algorithms is through operator splitting strategies for solving

$$\underset{x\in\mathcal{H}}{\text{minimize}}\ f_1(x) + f_2(x), \tag{1.12}$$

where f_1 and f_2 are proper, lower semi-continuous (l.s.c.) convex functions from $\mathcal{H}$ to $\mathbb{R}\cup\{\infty\}$. The subdifferentials ∂f_j are then *maximal monotone* [44, Proposition 12.b.]; that is, $\operatorname{gph} \partial f_j$ cannot be enlarged in $\mathcal{H}\times\mathcal{H}$ without destroying the monotonicity of ∂f_j defined by

$$\langle v_2 - v_1, x_2 - x_1\rangle \geq 0 \quad \text{whenever} \quad v_1 \in \partial f_j(x_1),\ v_2 \in \partial f_j(x_2).$$

We then seek points that satisfy the inclusion for the sum of two maximal monotone mappings:

$$0 \in \partial f_1(x) + \partial f_2(x). \tag{1.13}$$

Iterative techniques for solving (1.13) are built on combinations of forward- and backward-stepping mappings of the forms $(I - \lambda\partial f_j)$ and $(I + \lambda\partial f_j)^{-1}$, respectively. For proper, l.s.c. convex functions f_j Moreau [44] showed the correspondence between the resolvent $(I + \lambda\partial f_j)^{-1}$ and the argmin of the regularized mapping f_j centered on x. In particular, define the Moreau envelope, $e_{\lambda f}$, and the proximal mapping, $\operatorname{prox}_{\lambda,f}$, of a function f by

$$e_{\lambda,f}x := \inf_w \left\{ f(w) + \frac{1}{2\lambda}|w - x|^2 \right\} \quad \text{and}$$

$$\operatorname{prox}_{\lambda,f} x := \operatorname{argmin}_w \left\{ f(w) + \frac{1}{2\lambda}|w - x|^2 \right\}.$$

Then by [44, Proposition 6.a] we have

$$\operatorname{prox}_{1,f_j} x = J_{\partial f_j}x := (x + \partial f_j(x))^{-1}, \tag{1.14}$$

where $J_{\partial f_j}$ is the resolvent of ∂f_j. The Moreau envelope at zero, $e_{\lambda,f}0$, is perhaps better known as Tikhonov regularization [53, 52].

Maximal monotonicity of ∂f_j is equivalent to *firm nonexpansiveness* of the resolvent $J_{\partial f_j}$, whose domain is all of $\mathcal{H}$ [42]. A mapping $T : \operatorname{dom} T = \mathbb{X} \to \mathbb{X}$ is *nonexpansive* on the closed convex subset $\mathbb{X} \subset \mathcal{H}$ if

$$|Tx - Ty| \leq |x - y| \quad \text{for all} \ \ x, y \in \mathbb{X}; \tag{1.15}$$

we say that T is firmly nonexpansive on $\mathbb{X}$ when

$$|Tx - Ty|^2 \leq \langle x - y, Tx - Ty\rangle \quad \text{for all} \ \ x, y \in \mathbb{X}. \tag{1.16}$$

Firmly nonexpansive mappings also satisfy the following convenient relation:

$$|Tx - Ty|^2 + |(I-T)x - (I-T)y|^2 \leq |x-y|^2 \quad \text{for all} \quad x, y \in \mathbb{X}. \tag{1.17}$$

For more background, see [28, Theorem 12.1] and [23, Theorem 5.5].

Example 1.4 (projections onto and reflections across convex sets). Let C be a nonempty closed convex set in $\mathcal{H}$. The projection onto C is firmly nonexpansive on $\mathcal{H}$ [23, Theorem 5.5], and the corresponding reflection, defined by $R_C := 2P_C - I$, is nonexpansive.

The following central result we build upon concerns the convergence of iterated nonexpansive mappings allowing for *approximate evaluation* of *dynamically relaxed* mappings with variable *step sizes*. Our formulation follows [20], which is a generalization of an analogous result in [25]. Both [25] and [20] synthesize previous work of Rockafellar [50] and Gol'stein and Tret'yakov [29], and are also related to work of Martinet [40, 41] and Brezis and Lions [10] concerning resolvents of maximally monotone mappings. The theorem is formulated for a common relaxation of the fixed point mapping T. For any arbitrary nonexpansive mapping T, the standard relaxation of the iteration $x_{n+1} = Tx_n$ is to a *Krasnoselski–Mann* iteration [9] given by

$$x_{n+1} = U(T, \lambda_n)x_n := \lambda_n T x_n + (1-\lambda_n)x_n, \quad 0 < \lambda_n < 2. \tag{1.18}$$

By Example 1.1, gradient descent for the squared distance objective (1.2) with step length λ_n is equivalent to a Krasnoselski–Mann relaxation of the averaged projection mapping $T := \frac{1}{2}(P_A + P_B)$. In general, the Krasnoselski–Mann relaxation does not change the set of *fixed points* of T denoted $\mathsf{Fix}\ T$.

LEMMA 1.5. *Let $T = (I+\rho S)^{-1}$ $(\rho > 0)$ be firmly nonexpansive with* $\operatorname{dom} T = \mathcal{H}$. *Then $\mathsf{Fix}\ T = \varnothing$ if and only if there is no solution to $0 \in Sx$.*

Proof. T with $\operatorname{dom} T = \mathcal{H}$ is *firmly nonexpansive* if and only if it is the resolvent of a maximally monotone mapping $F : \mathcal{H} \to 2^{\mathcal{H}}$ [42]. Direct calculation then shows that $\mathsf{Fix}\ T = \varnothing$ is equivalent to $\{x \in \mathcal{H} \mid Fx = 0\} = \varnothing$. ∎

THEOREM 1.6 (inexact evaluation of firmly nonexpansive mappings). *Let T be a firmly nonexpansive mapping on $\mathcal{H}$ with* $\operatorname{dom} T = \mathcal{H}$. *Given any $x_0 \in \mathcal{H}$, let the sequence $\{x_n\}_{n\in\mathbb{N}}$ be generated by*

$$x_{n+1} = (1-\lambda_n)x_n + \lambda_n\left(Tx_n + \epsilon_n\right) \quad \textit{for all } n \geq 0, \tag{1.19}$$

where $\{\lambda_n\}_{n\in\mathbb{N}} \subset]0, 2[$ and $\{\epsilon_n\}_{n\in\mathbb{N}} \subset \mathcal{H}$ are sequences with

$$\sum_{n=0}^{\infty} |\epsilon_n| < \infty, \quad \lambda_- = \inf_{n\geq 0} \lambda_n > 0, \quad \lambda_+ = \sup_{n\geq 0} \lambda_n < 2. \tag{1.20}$$

Then if T possesses a fixed point, x_n converges weakly to a fixed point of T. Convergence is strong if any one of the following holds:

- $\underline{\lim} \operatorname{dist}_{\mathsf{Fix}\ T}(x_n) = 0$.
- $\operatorname{int} \mathsf{Fix}\ T \neq \varnothing$.
- *T is* demicompact *at 0; that is, for every bounded sequence $\{x_n\}_{n\in\mathbb{N}}$ with $Tx_n - x_n$ converging strongly to y, the set of strong cluster points of $\{x_n\}_{n\in\mathbb{N}}$ is nonempty.*

If T is firmly nonexpansive with $\operatorname{dom} T = \mathcal{H}$ *and* $\mathsf{Fix}\ T = \varnothing$, *then $\{x_n\}_{n\in\mathbb{N}}$ is unbounded.*

Proof. All but the last statement is the content of Theorem 5.5 in [20]. To show that x_n is unbounded if T does not have a fixed point for T firmly nonexpansive with

dom $T = \mathcal{H}$, we note that by Lemma 1.5 $\mathsf{Fix}\, T = \varnothing$ if and only if there is no solution to $0 \in Fx$, where T is the resolvent of the maximally monotone mapping F. The result now follows from [25, Theorem 3]. □

For the remainder of this paper we will be concerned with applying the above results to particular instances of the mapping T for convex and nonconvex settings. Our principal task, therefore, is to characterize $\mathsf{Fix}\,(T)$ and to modify the above theory to accommodate nonconvexity. To account for realistic limitations in computing accuracy, we consider fixed point iterations where T is only approximately evaluated. With this in mind, and in the context of (1.12), we compare the following approximate algorithms.

ALGORITHM 1.7 (approximate alternating proximal mappings). *Choose* $x_0 \in \mathcal{H}$. *For* $n \in \mathbb{N}$ *set*

$$x_{n+1} = (1-\lambda_n)x_n + \lambda_n \left(\operatorname{prox}_{1,f_1}\left(\operatorname{prox}_{1,f_2} x_n\right) + \epsilon_n\right). \tag{1.21}$$

ALGORITHM 1.8 (approximate averaged alternating proximal reflections). *Choose* $x_0 \in \mathcal{H}$. *For* $n \in \mathbb{N}$ *set*

$$x_{n+1} = (1-\lambda_n)x_n + \frac{\lambda_n}{2}\left(R_{f_1}\left(R_{f_2}x_n + \epsilon_n\right) + \rho_n + x_n\right), \tag{1.22}$$

where $R_{f_j}x := 2\operatorname{prox}_{1,f_j} x - x$.

The parameter λ_n is the Krasnoselski–Mann relaxation parameter, and the terms ρ_n and ϵ_n account for the error made in the calculation of each of the resolvents separately.

The exact version of Algorithm 1.8 was proposed by Lions and Mercier [37] who adapted the Douglas–Rachford [24] algorithm to solving $0 \in F + G$ for general maximal monotone mappings F and G. Convergence results for the application of this algorithm hinge on the following assumption.

Assumption 1.9. There exist $x \in \mathcal{H}$, $a \in \partial f_1(x)$, and $b \in \partial f_2(x)$ such that $a + b = 0$.

The key result of Lions and Mercier adapted to our setting is that, if Assumption 1.9 holds, then the sequence of iterates $\{x_n\}_{n\in\mathbb{N}}$ generated by Algorithm 1.8 with $\epsilon_n = \rho_n = 0$ for all n converges weakly to $\overline{x} \in \mathcal{H}$ as $n \to \infty$ such that $x_* = J_{\partial f_2}\overline{x}$ solves (1.12) [37, Theorem 1].

Example 1.10 (specialization of (1.12) to convex feasibility). Let $f_1 = \iota_A$ and $f_2 = \iota_B$ in (1.12), where A and B are convex. Then, following Example 1.3 we have

$$\operatorname{prox}_{1,f_1}\operatorname{prox}_{1,f_2} = P_A P_B, \tag{1.23}$$

$$\tfrac{1}{2}(R_{f_1}R_{f_2} + I) = \tfrac{1}{2}(R_A R_B + I). \tag{1.24}$$

Specialization of Algorithm 1.7 to this setting yields the classical alternating projection algorithm. Convergence of the exact algorithm was obtained in [16, Theorem 4] under the assumption that either (a) one of A or B is compact, or (b) one of A or B is finite dimensional and the distance between the sets is attained. In other words, $A \cap B$ can be empty. *Rates* of convergence, however, appear to require a certain regularity of the intersection [35].

Specialization of Algorithm 1.8 yields the averaged alternating reflection (AAR) algorithm studied in [8]. It follows immediately from Example 1.4 that $\frac{1}{2}(R_A R_B + I)$ is firmly nonexpansive (see also [8, Proposition 3.1]). Assumption (1.9) reduces to $A \cap B \neq \varnothing$. If $A \cap B = \varnothing$, then by Theorem 1.6 we have $|\frac{1}{2}(R_A R_B + I)x_n| \to \infty$

as $n \to \infty$. Nevertheless, as long as there exist nearest points in B to A, then the sequences $\{P_B x_n\}_{n\in\mathbb{N}}$ and $\{P_A P_B x_n\}_{n\in\mathbb{N}}$ are bounded with weak cluster points belonging to the sets F and E defined by (1.7) [8, Theorem 3.13]. Indeed, regardless of whether or not $A \cap B = \varnothing$, the set $\mathsf{Fix}\,(T_{AAR} + g)$ is closed and convex and [8, Theorem 3.5]

$$F + N_G(g) \subset \mathsf{Fix}\,(T_{AAR} + g) \subset g + F + N_G(g). \tag{1.25}$$

In other words, if $A \cap B = \varnothing$, then T_{AAR} does not have fixed points, but rather has fixed *directions* or *velocities*. Examples 3.7 and 3.8 of [8] show that the upper and lower bounds on this fixed point set are tight, consistent with the case $A \cap B \neq \varnothing$. The salient point here is that convergence of this algorithm is contingent on the consistency of the feasibility problem.

Generalizations of Lions and Mercier's results to approximate evaluation of the resolvents of maximally monotone mappings have been investigated in [25, 20, 21]. The following theorem, adapted from [21], is a specialization of Theorem 1.6 to Algorithms 1.7 and 1.8.

COROLLARY 1.11 (specialization to Algorithms 1.7 and 1.8). *Let f_1 and f_2 be proper, l.s.c. convex functions from $\mathcal{H}$ to $\mathbb{R} \cup \{\infty\}$, let $\{\rho_n\}_{n\in\mathbb{N}}$ and $\{\epsilon_n\}_{n\in\mathbb{N}}$ be sequences in $\mathcal{H}$, and let $\{\lambda_n\}_{n\in\mathbb{N}}$ be a sequence in $]0,2[$.*

(i) *Let $E := \mathsf{Fix}\,\mathrm{prox}_{1,f_1}\mathrm{prox}_{1,f_2} \neq \varnothing$ and $\{\epsilon_n\}_{n\in\mathbb{N}}$ and $\{\lambda_n\}_{n\in\mathbb{N}}$ satisfy* (1.20). *Then every sequence $\{x_n\}_{n\in\mathbb{N}}$ of Algorithm* 1.7 *converges weakly to a point in E. If $\mathrm{int}\, E \neq \varnothing$, then convergence is strong.*

(ii) *If Assumption* 1.9 *holds and $\{\lambda_n\}_{n\in\mathbb{N}} \subset]0,2[$ with $\sum_{n\in\mathbb{N}} \lambda_n(2-\lambda_n) = \infty$ and $\sum_{n\in\mathbb{N}} \lambda_n\left(\|\rho_n\| + \|\epsilon_n\|\right) < \infty$, then the sequence $\{x_n\}_{n\in\mathbb{N}}$ generated by Algorithm* 1.8 *converges weakly to $\overline{x} \in \mathcal{H}$ as $n \to \infty$ such that $x_* = J_{\partial f_2}\overline{x}$ solves* (1.12). *If Assumption* 1.9 *does not hold, then the sequence $\{x_n\}_{n\in\mathbb{N}}$ generated by Algorithm* 1.8 *is unbounded.*

Proof. (i) is an immediate specialization of Theorem 1.6. For (ii), all but the last statement is [21, Corollary 5.2] with $\gamma = 1$. The last statement of (ii) follows from Theorem 1.6 since $\frac{1}{2}(R_{f_1}R_{f_2} + I)$ is firmly nonexpansive. ∎

2. Convex analysis. For this section we will assume that the sets A and B are closed and convex. Denote

$$T_{AP} := P_A P_B \quad \text{and} \quad T_{AAR} := \tfrac{1}{2}(R_A R_B + I) \tag{2.1}$$

discussed in Example 1.10. As discussed in Example 1.10, the existence of fixed points of T_{AP} is independent of whether or not the feasibility problem is consistent. Indeed, it is easy to see that $\mathsf{Fix}\, T_{AP} = E$ for E defined by (1.7). This is not the case for T_{AAR}. We will argue in the nonconvex setting that the fact that T_{AAR} has no fixed points if $A \cap B = \varnothing$ has tremendous algorithmic potential since it means that averaged alternating reflections will not get stuck in a local minimum. Other algorithms for solving feasibility problems do not suffer from such instabilities with inconsistent problems (alternating projections for instance), but for nonconvex problems, this stability is at the cost of getting caught in local minima. It is this resilience of the AAR algorithm in nonconvex applications that first attracted our attention and, we believe, warrants a closer look. In the next section we compare the behavior of these algorithms in the convex setting.

2.1. Relaxations/regularizations. In this subsection we consider relaxations of T_{AAR} whose associated mappings have fixed points independent of whether or not

$A \cap B = \varnothing$. The common relaxation that we have already discussed is of the form

$$U(T, \lambda) := \lambda T + (1 - \lambda)I, \quad 0 < \lambda < 2, \tag{2.2}$$

for the generic mapping T. If the mapping T is firmly nonexpansive (for instance T_{AP} or T_{AAR}), then this property is preserved under the relaxation $U(T, \beta)$ for $\beta \in]0, 1[$. Krasnoselski–Mann iterations have been extensively studied in Hilbert spaces and more general normed spaces [9] so there is ample theory to draw from for the study of the relaxation $U(T, \beta)$.

An advantage and disadvantage of this relaxation is that the fixed points of $U(T, \lambda)$ are the same as those of T. In particular, since T_{AAR} has a fixed point if and only if $A \cap B \neq \varnothing$, it follows immediately that the same holds for $U(T_{AAR}, \lambda)$: for inconsistent problems neither mapping has a fixed point. To remedy this we consider the following alternative relaxation:

$$V(T, \beta) := \beta T + (1 - \beta)P_B, \quad 0 < \beta < 1. \tag{2.3}$$

Like the Krasnoselski–Mann relaxation, for A and B convex and T firmly nonexpansive, $V(T, \beta)$ is also firmly nonexpansive since it is the convex combination of firmly nonexpansive mappings. Hence if $\mathsf{Fix}\, V(T_{AAR}, \beta)$ is nonempty, then the associated approximate fixed point iteration converges to the fixed point set according to Theorem 1.6. One of the principal advantages of this relaxation is that, as we show in Lemma 2.1, $\mathsf{Fix}\, V(T_{AAR}, \beta)$ is independent of whether or not the associated problem (1.1) is feasible. Moreover, the relaxation parameter β can be used to exert some control on the iterates (see subsection 2.2).

In characterizing the fixed points we note that the relaxation $V(T_{AAR}, \beta)$ is fundamentally different than the standard relaxation $U(T_{AAR}, \lambda)$ which has little qualitative effect on the set of fixed points. The two are independent and may be used together without any redundancy of effect. There can, however, be diminishing returns to the addition of parameters to algorithms of this sort. For our application we have found no significant advantage to employing relaxations of the form (2.2). Nevertheless, by Example 1.1, for cases where the relaxation is related to a step length in a gradient descent algorithm, the optimization of λ_n in (2.2) can clearly lead to improved performance. We therefore retain this relaxation and, for the sake of generality, consider nested relaxations of the form

$$\begin{gathered} U\left(V\left(U(T_{AAR}, \lambda_1), \beta\right), \lambda_2\right) = \lambda_2 V\left(U(T_{AAR}, \lambda_1), \beta\right) + (1 - \lambda_2)I, \\ \text{where } \lambda_2 \in]0, 2[\,. \end{gathered} \tag{2.4}$$

The next theorem is a generalization of [38, Theorem 2.2] where we determined the fixed points of the mapping $V(T_{AAR}, \beta)$ alone. The following analysis of the nested relaxations demonstrates the relative importance of the relaxation strategies. This is discussed in greater detail following the proof of the next observation.

LEMMA 2.1 (characterization of fixed points). *Let* $\beta \in]0, 1[$ *and* $\lambda_1, \lambda_2 \in]0, 2[$. *Then*

$$\mathsf{Fix}\, U\left(V\left(U(T_{AAR}, \lambda_1), \beta\right), \lambda_2\right) = F - \frac{\beta\lambda_1}{1 - \beta} g, \tag{2.5a}$$

where F *and* g *are defined by* (1.7). *Moreover,* $\mathsf{Fix}\, U\left(V\left(U(T_{AAR}, \lambda_1), \beta\right), \lambda_2\right)$ *is closed*

and convex and, for every $x \in \mathsf{Fix}\, U\left(V\left(U(T_{AAR}, \lambda_1), \beta\right), \lambda_2\right)$, *we have the following:*

$$x = P_B x - \frac{\beta\lambda_1}{1-\beta} g, \tag{2.5b}$$

$$P_B x - P_A R_B x = g, \tag{2.5c}$$

$$P_B x \in F, \quad \text{and} \quad P_A P_B x \in E. \tag{2.5d}$$

In the special case where $\beta = 1$, *we have*

$$F + N_G(g) \subset \mathsf{Fix}\,(U(T_{AAR}, \lambda) + \lambda g) \subset g + F + N_G(g). \tag{2.5e}$$

By comparison,

$$\mathsf{Fix}\, U(V(U(T_{AP}, \lambda_1), \beta), \lambda_2) = F - \beta g. \tag{2.6}$$

Proof. For all $\beta \in [0, 1[$, since $\mathsf{Fix}\,(\lambda T + (1-\lambda)I) = \mathsf{Fix}\, T$ for *any* mapping T, the fixed point set is invariant with respect to the outer relaxation $(\lambda_2 V(U(T, \lambda_1)) + (1 - \lambda_2)I)$, so without loss of generality we ignore this relaxation.

Equation (2.6) follows immediately from $\mathsf{Fix}\, T_{AP} = E$.

What remains, then, is to show (a) that $F - \frac{\beta\lambda_1}{(1-\beta)} g \subset \mathsf{Fix}\, V\left(U(T_{AAR}, \lambda_1), \beta\right)$ and, conversely, (b) that $\mathsf{Fix}\, V\left(U(T_{AAR}, \lambda_1), \beta\right) \subset F - \frac{\beta\lambda_1}{(1-\beta)} g$.

We first establish the inclusion $F - \frac{\beta\lambda_1}{1-\beta} g \subset \mathsf{Fix}\, V\left(U(T_{AAR}, \lambda_1), \beta\right)$. Pick $f \in F$, let $x = f - \frac{\beta\lambda_1}{1-\beta} g$, and define $e := f - g$. Now, since $f \in F$ and $g \in P_G 0$, $e \in E$, $-\gamma g \in N_B(f)$, and $\gamma g \in N_A(e)$ for all $\gamma > 0$. Hence $P_B x = f$ and $P_A(e + \gamma g) = e$; thus

$$R_B x = 2P_B x - x = f + \frac{\beta\lambda_1}{1-\beta} g,$$

and

$$P_A R_B x = P_A\left(f + \frac{\beta\lambda_1}{1-\beta} g\right) = P_A\left(e + \frac{1 + \beta(\lambda_1 - 1)}{1-\beta} g\right) = e = f - g.$$

Hence $P_B x - P_A R_B x = g$. This together with the observation that

$$x - T_{AAR} x = P_B x - P_A R_B x \quad \text{for all } x \in \mathcal{H} \tag{2.7}$$

implies $x - \beta U(T_{AAR}, \lambda_1) x - (1-\beta) P_B x = \beta\lambda_1 (x - T_{AAR} x) + (1-\beta)(x - P_B x) = \beta\lambda_1 g + (1-\beta)(x - f) = 0$. Thus, as previously claimed, $F - \frac{\beta\lambda_1}{1-\beta} g \subset \mathsf{Fix}\,(\beta U(T_{AAR}, \lambda_1) + (1-\beta) P_B)$.

We show next that $\mathsf{Fix}\,(\beta U(T_{AAR}, \lambda_1) + (1-\beta) P_B) \subset F - \frac{\beta\lambda_1}{1-\beta} g$. To see this, pick any $x \in \mathsf{Fix}\,(\beta U(T_{AAR}, \lambda_1) + (1-\beta) P_B)$. Let $f = P_B x$ and $y = x - f$. Recall that

$$P_A(2f - x) = P_A(2P_B x - x) = P_A R_B x. \tag{2.8}$$

This, together with the identity (2.7), yields

$$P_A(2f - x) = f + T_{AAR} x - x. \tag{2.9}$$

For our choice of x we have $\beta U(T_{AAR},\lambda_1)x+(1-\beta)P_Bx=\beta\lambda_1 T_{AAR}x+\beta x-\beta\lambda_1 x+(1-\beta)P_Bx=x$, which yields

$$T_{AAR}x-x=\frac{1-\beta}{\beta\lambda_1}(x-P_Bx). \tag{2.10}$$

Then (2.9) and (2.10) give

$$P_A(2f-x)=f+\frac{1-\beta}{\beta\lambda_1}(x-f)=f+\frac{1-\beta}{\beta\lambda_1}y. \tag{2.11}$$

Now, for any $a\in A$, since A is nonempty, closed, and convex, we have

$$\langle a-P_A(2f-u),(2f-u)-P_A(2f-u)\rangle\leq 0, \tag{2.12}$$

and hence

$$\begin{aligned}0&\geq\left\langle a-\left(f+\frac{1-\beta}{\beta\lambda_1}y\right),\ (2f-x)-\left(f+\frac{1-\beta}{\beta\lambda_1}y\right)\right\rangle\\&=\left\langle a-\left(f+\frac{1-\beta}{\beta\lambda_1}y\right),\ -y-\frac{1-\beta}{\beta\lambda_1}y\right\rangle\\&=\frac{\beta(\lambda_1-1)+1}{\beta\lambda_1}\langle -a+f,\ y\rangle+\frac{(1-\beta)(\beta(\lambda_1-1)+1)}{(\beta\lambda_1)^2}|y|^2. \qquad (2.13)\end{aligned}$$

Here we have used (2.12), (2.11), and the fact that $y=x-f$. On the other hand, for any $b\in B$, since B is a nonempty, closed convex set and $f=P_Bx$, we have

$$\langle b-P_Bx,x-f\rangle\leq 0, \tag{2.14}$$

which yields

$$\langle b-f,\ y\rangle=\langle b-f,\ x-f\rangle\leq 0. \tag{2.15}$$

Note that, for $\beta\in\,]0,1[$ and $\lambda_1\in\,]0,2[$, the numerator $\beta(\lambda_1-1)+1>0$; thus (2.13) and (2.15) yield

$$\langle b-a,\ y\rangle\leq-\frac{1-\beta}{\beta\lambda_1}|y|^2\leq 0. \tag{2.16}$$

Now take a sequence $\{a_n\}_{n\in\mathbb{N}}$ in A and a sequence $\{b_n\}_{n\in\mathbb{N}}$ in B such that $g_n=b_n-a_n\to g$. Then

$$\langle g_n,\ y\rangle\leq-\frac{1-\beta}{\beta\lambda_1}|y|^2\leq 0\quad\text{for all } n\in\mathbb{N}. \tag{2.17}$$

Taking the limit and using the Cauchy–Schwarz inequality yields

$$|y|\leq\frac{\beta\lambda_1}{1-\beta}|g|. \tag{2.18}$$

Conversely, $x-(\beta U(T_{AAR},\lambda_1)x+(1-\beta)P_Bx)=\beta\lambda_1\left(f-P_A(2f-x)\right)+(1-\beta)y=0$ gives

$$|y|=\frac{\beta\lambda_1}{1-\beta}\Big|f-P_A(2f-x)\Big|\geq\frac{\beta\lambda_1}{1-\beta}|g|. \tag{2.19}$$

Hence $|y| = \frac{\beta\lambda_1}{1-\beta}|g|$ and, taking the limit in (2.17), $y = -\frac{\beta\lambda_1}{1-\beta}g$, which confirms the identity (2.5b). From (2.8) and (2.11) with $y = -\frac{\beta\lambda_1}{1-\beta}g$ it follows that $f - P_A R_B x = g$, which proves (2.5c) and, by definition, implies that $P_B x = f \in F$ and $P_A P_B x \in E$. This yields identity (2.5d) and proves (2.5a). The closedness and convexity of the fixed point set then follows from the fact that F is closed and convex. (Generally, the fixed point set of any nonexpansive map defined everywhere in a Hilbert space is closed convex; see [28, Lemma 3.4].)

For the special case where $\beta = 1$, a straightforward calculation shows that $\mathsf{Fix}\,(T_{AAR} + g) = \mathsf{Fix}\,(U(T_{AAR}, \lambda) + \lambda g)$. Since, by [8, Theorem 3.5], we have

$$F + N_G(g) \subset \mathsf{Fix}\,(T_{AAR} + g) \subset g + F + N_G(g), \tag{2.20}$$

the result follows immediately, which completes the proof. □

Remark 2.2. Lemma 2.1 shows that the inner relaxation parameter λ_1 has only a marginal effect on the set of fixed points of T_{AAR} compared to the β relaxation, which, provided $g \neq 0$, is unbounded as $\beta \to 1$; it has no effect on the set of fixed points of T_{AP}. The outer relaxation parameter λ_2 has no effect on either mapping. In stark contrast to these, the relaxation parameter β in the relaxation $V(T, \beta)$ has a profound impact on the set of fixed points of T_{AAR} and marginal impact on the fixed points of T_{AP}. Indeed, from (2.20) and (2.5a) it is clear that, for all $0 < \beta < 1$, $\mathsf{Fix}\; V(T_{AAR}, \beta) \subset \mathsf{Fix}\,(T_{AAR} + g)$; thus, by definition, $x_\beta - T_{AAR} x_\beta = g$, where $x_\beta \in \mathsf{Fix}\; V(T_{AAR}, \beta)$. More interestingly, however, the fixed point set becomes vastly larger at $\beta = 1$. Similarly, at $\beta = 0$ the fixed point set becomes all of B.

Having characterized the fixed points of $V(T_{AAR}, \beta)$, we turn our attention to *inexact* Relaxed Averaged Alternating Reflections (RAAR) iterations.

ALGORITHM 2.3 (inexact RAAR algorithm). *Choose $x_0 \in \mathcal{H}$ and the sequence $\{\beta_n\}_{n\in\mathbb{N}} \subset]0, 1[$. For $n \in \mathbb{N}$ set*

$$x_{n+1} = \frac{\beta_n}{2}\left(R_A\left(R_B x_n + \epsilon_n\right) + \rho_n + x_n\right) + (1 - \beta_n)\left(P_B x_n + \frac{\epsilon_n}{2}\right). \tag{2.21}$$

The analogous algorithm to this for inexact alternating projections is the following.

ALGORITHM 2.4 (inexact alternating projection algorithm). *Choose $x_0 \in \mathcal{H}$ and the sequence $\{\eta_n\}_{n\in\mathbb{N}} \subset]0, 1[$. For $n \in \mathbb{N}$ set*

$$x_{n+1} = (1 - \eta_n)x_n + \eta_n\left(P_A\left(P_B x_n + \epsilon_n\right) + \rho_n\right). \tag{2.22}$$

For fixed relaxation parameter β, additional insight into the relaxation $V(T_{AAR}, \beta)$ and the Krasnoselski–Mann-relaxed alternating projection algorithm is gained by considering regularizations of iterated proximal mappings applied to (1.12).

PROPOSITION 2.5 (unification of algorithms).

(i) *Algorithm* 1.8 *applied to* (1.12) *with*

$$f_1(x) = \frac{\beta}{2(1-\beta)}\,\mathrm{dist}^{\,2}_A(x) \quad \text{and} \quad f_2(x) = \iota_B(x) \tag{2.23}$$

and $\lambda_n = 1$ for all n is equivalent to Algorithm 2.3 *with $\beta_n = \beta$ for all n.*

(ii) *Algorithm* 1.8 *applied to* (1.12) *with*

$$f_1(x) = \tfrac{1}{2}\,\mathrm{dist}^{\,2}_A(x) \quad \text{and} \quad f_2(x) = \tfrac{1}{2}\,\mathrm{dist}^{\,2}_B(x) \tag{2.24}$$

and relaxation parameter λ_n is equivalent to Algorithm 2.4 *with $\eta_n = \lambda_n/2$.*

(iii) *Algorithm* 1.8 *applied to* (1.12) *on the product space with* f_1 *and* f_2 *defined by*

$$f_1(x,y) = \tfrac{1}{2}\operatorname{dist}^2_C(x,y) \quad \text{and} \quad f_2(x,y) = \tfrac{1}{2}\operatorname{dist}^2_D(x,y) \tag{2.25}$$

for $C = \{(x,y) \in \mathcal{H} \times \mathcal{H} \mid x = y\}$, $D = \{(x,y) \in \mathcal{H} \times \mathcal{H} \mid x \in A, y \in B\}$, $\epsilon_n = \rho_n = 0$ *for all* n *and relaxation parameter* λ_n *is equivalent to gradient descent with step length* $\lambda_n/2$ *applied to the nonlinear least squares problem* (1.2).

Proof. (i) Let

$$f_1(x) = \frac{\beta}{2(1-\beta)}\operatorname{dist}^2_A(x) \quad \text{and} \quad f_2(x) = \iota_B(x);$$

then $\operatorname{prox}_{1,f_2}(x) = P_B x$ and a short calculation yields $\operatorname{prox}_{1,f_1}(x) = x + \beta(P_A x - x)$. The result then follows upon substituting these expressions into (1.22) with $\lambda_n = 1$ for all n and ρ_n of Algorithm 1.8 replaced by ρ_n of (2.21) scaled by β.

(ii) A similar calculation shows that when $f_1(x) = \frac{1-\beta}{2\beta}\operatorname{dist}^2_A(x)$ and $f_2(x) = \frac{\beta}{2(1-\beta)}\operatorname{dist}^2_B(x)$, the recursion (1.22) is equivalent to

$$\begin{aligned} x_{n+1} &= (1-\lambda_n)x_n \\ &\quad + \lambda_n\left((1-\beta)P_A y_n + \beta(2\beta-1)P_B x_n + 2(\beta-\beta^2)x_n + (\beta - \tfrac{1}{2})\epsilon_n + \tfrac{1}{2}\rho_n\right), \end{aligned} \tag{2.26}$$

where $y_n = (1-2\beta)x_n + 2\beta P_B x_n + \epsilon_n$. In particular, when $\beta = 1/2$ we have $x_{n+1} = (1 - \frac{\lambda_n}{2})x_n + \frac{\lambda_n}{2}(P_A(P_B x_n + \epsilon_n) + \rho_n)$, the Krasnoselski–Mann relaxation of approximate alternating projections given by (2.22) with relaxation parameter $\eta_n = \lambda_n/2$ for all n.

(iii) We use the product space formulation as in Example 1.2. By (ii) of this theorem, Algorithm 1.8, with relaxation parameter λ_n applied to (1.12), where f_1 and f_2 are defined by (2.25), is equivalent to alternating projections on the product space—Algorithm 2.4 with $x_{n+1} = (1-\lambda_n/2)x_n + \lambda_n/2 P_C P_D x_n$. But by Example 1.2 alternating projections is equivalent to Krasnoselski–Mann-relaxed averaged projections on the product space with relaxation parameter $\lambda_n/2$. To complete the proof we note that, by Example 1.1, Krasnoselski–Mann-relaxed averaged projections on the product space with relaxation parameter $\lambda_n/2$ is equivalent to gradient descent with step length $\lambda_n/2$ applied to the nonlinear least squares problem (1.2). ∎

In other words, $V(T_{AAR}, \beta)$ is not a relaxation of T_{AAR} but rather the exact instance of Algorithm 1.8 applied to (1.12) with f_1 and f_2 defined by (2.23). Similarly, alternating projections is also an instance of Algorithm 1.8, which, in turn, yields the equivalence of this algorithm to gradient descent.

Proposition 2.5 yields a proof of the next theorem by direct application of Corollary 1.11 with $\lambda_n = 1$ for all n.

THEOREM 2.6 (the inexact RAAR algorithm with fixed β). *Let* $\{\rho_n\}_{n\in\mathbb{N}}$ *and* $\{\epsilon_n\}_{n\in\mathbb{N}}$ *be sequences in* $\mathcal{H}$ *such that* $\sum_{n\in\mathbb{N}} \|\rho_n\| + \|\epsilon_n\| < \infty$, *and fix* $\beta \in]0,1[$, $x_0 \in \mathcal{H}$, *and* $\lambda_n = 1$ *for all* n. *If* F *defined by* (1.7) *is nonempty, then the sequence* $\{x_n\}_{n\in\mathbb{N}}$ *generated by Algorithm* 2.3 *with* $\beta_n = \beta$ *for all* n *converges weakly to* $\overline{x} \in \mathcal{H}$ *as* $n \to \infty$ *such that* $x_* = P_B\overline{x}$ *solves*

$$\operatorname*{minimize}_{x\in\mathcal{H}} \frac{\beta}{2(1-\beta)}\operatorname{dist}^2_A(x) + \iota_B(x). \tag{2.27}$$

If $F = \varnothing$, then the sequence $\{x_n\}_{n\in\mathbb{N}}$ generated by (2.21) is unbounded.

Proof. The result follows from Corollary 1.11(ii) once the equivalence of the condition $F \neq \varnothing$ to Assumption (1.9) is established. To see this, note that by Proposition 2.5 the recursion (2.21) is equivalent to (1.22) with $\lambda_n = 1$ for all n applied to (2.27). Moreover, for $f_1 = \frac{\beta}{2(1-\beta)} \operatorname{dist}^2_A(x)$ and $f_2 = \iota_B$, we have $\partial f_1(x) = \frac{\beta}{1-\beta}(x - P_A x)$ $\partial f_2(x) = N_B(x)$ (see (1.10) and (1.4)), so the existence of points $x \in F$ implies that $\frac{\beta}{1-\beta}(x - P_A x) = \frac{\beta}{1-\beta} g \in -N_B(x)$; hence Assumption 1.9 holds. Conversely, the existence of points $x \in \mathcal{H}$ and $a \in \partial f_1(x)$ and $b \in \partial f_2(x)$ such that $a + b = 0$ implies that, for such x, $\frac{\beta}{1-\beta}(x - P_A x) \in -N_B(x)$; hence $x \in F$, which completes the proof. ∎

While Theorem 2.6 takes advantage of regularizations to reinterpret the relaxation (2.3), it does not easily allow us to verify the effect of variable β. To account for variable β_n we take a different approach.

THEOREM 2.7 (the inexact RAAR algorithm with variable β). *Fix $\beta \in]0,1[$ and $x_0 \in \mathcal{H}$. Let $\{\beta_n\}_{n\in\mathbb{N}}$ be a sequence in $]0,1[$, and let $\{x_n\}_{n\in\mathbb{N}} \in \mathcal{H}$ be generated by Algorithm 2.3 with corresponding errors $\{\epsilon_n\}_{n\in\mathbb{N}}, \{\rho_n\}_{n\in\mathbb{N}} \subset \mathcal{H}$. Define*

$$\nu_n = 2|\beta_n - \beta|\,|(P_A - I)R_B x_n|\,. \tag{2.28}$$

If $F \neq \varnothing$ and

$$\sum_{n\in\mathbb{N}} |\epsilon_n| + |\rho_n| + \nu_n < +\infty, \tag{2.29}$$

then $\{x_n\}_{n\in\mathbb{N}}$ converges weakly to a point $x_* \in F - \beta g/(1-\beta)$.

Proof. The mapping $V(T_{AAR}, \beta) = \beta T_{AAR} + (1-\beta)P_B$. Then $V(T_{AAR}, \beta)$ is firmly nonexpansive as a convex combination of the two firmly nonexpansive mappings T_{AAR} and P_B. Accordingly, the mapping $R = 2V(T_{AAR}, \beta) - I$ is nonexpansive since $V(T_{AAR}, \beta)$ is firmly nonexpansive if and only if $2V(T_{AAR}, \beta) - I$ is nonexpansive [28, Theorem 12.1]. Moreover, it follows from Lemma 2.1 that $\mathsf{Fix}\, R = \mathsf{Fix}\, V(T_{AAR}, \beta) = F - \beta g/(1-\beta) \neq \varnothing$. Setting $r_n = 2x_{n+1} - x_n$, an elementary calculation shows that

$$\begin{aligned} |r_n - Rx_n| \leq \beta_n |R_A\left(R_B x_n + \epsilon_n\right) - R_A R_B x_n| + \beta_n|\rho_n| \\ + (1-\beta_n)|\epsilon_n| + 2|\beta_n - \beta|\,|(P_A - I)R_B x_n|\,. \end{aligned} \tag{2.30}$$

Now, since R_A is nonexpansive

$$|R_A\left(R_B x_n + \epsilon_n\right) - R_A R_B x_n| \leq |\epsilon_n|$$

and from (2.28)

$$|r_n - Rx_n| \leq |\rho_n| + |\epsilon_n| + \nu_n. \tag{2.31}$$

The recursion (2.21) can thus be rewritten as

$$x_0 \in \mathcal{H} \quad \text{and} \quad x_{n+1} = \tfrac{1}{2}x_n + \tfrac{1}{2}r_n \quad \text{for all } n \in \mathbb{N}, \tag{2.32}$$

where, from (2.29) and (2.31),

$$\sum_{n\in\mathbb{N}} |r_n - Rx_n| < +\infty. \tag{2.33}$$

It then follows from [20, Theorem 5.5(i)] that $\{x_n\}_{n\in\mathbb{N}}$ converges weakly to a fixed point of R, which proves the result. □

Analogous results for the important case of the RAAR algorithm with $\beta = 1$, that is, the AAR algorithm, have been treated extensively in [8]. Surprisingly, the proof techniques for these two cases are distinct, and it appears that a unification is not readily available.

A more detailed picture of the behavior of iterates of the exact RAAR algorithm can be obtained in the following restricted setting.

COROLLARY 2.8 (exact RAAR algorithm in Euclidean space). *Let $\mathcal{H}$ be a Euclidean space. Fix $\beta \in]0,1[$ and let*

$$x_0 \in \mathbb{R}^n \quad \text{and} \quad x_{n+1} = V(T_{AAR},\beta)x_n \quad \text{for all } n \in \mathbb{N}.$$

Suppose that $F \neq \varnothing$. Then $\{x_n\}_{n\in\mathbb{N}}$ converges to some point $x \in F - \beta g/(1-\beta)$ and, furthermore,

(i) $P_B x_n - P_A P_B x_n \to g$;
(ii) $P_B x_n \to P_B x$ *and* $P_A P_B x_n \to P_A P_B x$;
(iii) $P_B x - P_A P_B x = g$; *hence* $P_B x \in F$ *and* $P_A P_B x \in E$.

Proof. The convergence of $\{x_n\}_{n\in\mathbb{N}}$ follows from Theorem 2.7 (with $\epsilon_n = \rho_n = \nu_n := 0$); denote the limit by x. From (1.7) we can write $x \in F - \beta g/(1-\beta)$ as $x = f - \beta g/(1-\beta)$, where $f = P_B x \in F$ (see also [8, Proposition 2.4.(ii)]). Since the mappings P_A, P_B, R_A, R_B are continuous, (ii) follows. Next, using (2.5c), we have

$$P_B x_n - P_A R_B x_n \to P_B x - P_A R_B x = g. \tag{2.34}$$

Hence

$$|g| \leq |P_B x_n - P_A P_B x_n| \leq |P_B x_n - P_A R_B x_n| \to |g|, \tag{2.35}$$

and thus $|P_B x_n - P_A P_B x_n| \to |g|$. Now (i) follows from [8, Proposition 2.5]. Taking the limit in (i) yields (iii). □

We would like to note in closing this subsection that the duality theory for (1.12) with f_1 and f_2 given by (2.23) has been detailed in [2, section 2]. The connection between algorithms (1.8) and (1.7) and (2.3) allows for an attractive synthesis in the convex setting. However, at this time the nonconvex theory is much less developed than the convex theory. A notable exception is the recent work of Moudafi [45], who studies the convergence of the prox-gradient method in a prox-regular setting. Nevertheless, the view of the parameter β as a weight in a regularized objective does not, in our opinion, lead to a natural justification for dynamic β_n as does the interpretation of this parameter as a relaxation. This is discussed in greater detail in the next subsection.

2.2. Controlling the iterates. The implementation of the RAAR algorithm that we studied in [38] was motivated by the following observation that indicates that the relaxation parameter β might be used to *steer* the iterates.

PROPOSITION 2.9. *Let $x \in \mathcal{H}$ and suppose that $F \neq \varnothing$.*

(i) $\operatorname{dist}(x, \operatorname{Fix} V(T_{AP},\beta)) = \operatorname{dist}(x, F + \beta g)$ *for all* $\beta \in (0,1]$.
(ii) *If $A \cap B \neq \varnothing$, then* $\operatorname{dist}(x, \operatorname{Fix} V(T_{AAR},\beta)) = \operatorname{dist}(x, A \cap B)$ *for all* $\beta \in]0,1[$; *otherwise,* $\lim_{\beta\nearrow 1} \operatorname{dist}(x, \operatorname{Fix} V(T_{AAR},\beta)) = +\infty$.

Proof. The proof of (i) follows immediately from (2.6). To see (ii), note that if $A \cap B \neq \varnothing$, then $g = 0$ and $\operatorname{Fix} V(T_{AAR},\beta) = A \cap B$, which proves the first part of the statement. Now assume $A \cap B = \varnothing$ and fix $f_0 \in F$. Then $g \neq 0$ and F is contained in

the hyperplane $\{x \in \mathcal{H} \mid \langle x - f_0,\ g\rangle = 0\}$ [3, Lemma 2.2(v)]. Hence, it follows from Lemma 2.1 that

(2.36)
$$\mathsf{Fix}\ V(T_{AAR},\beta) = F - \frac{\beta}{1-\beta}g \subset \left\{x \in \mathcal{H} \;\middle|\; \left\langle x + \frac{\beta}{1-\beta}g - f_0,\ g\right\rangle = 0\right\} = H_\beta.$$

Accordingly,

$$\text{dist}\ \big(x, \mathsf{Fix}\ V(T_{AAR},\beta)\big) \geq \text{dist}\ (x, H_\beta) = \frac{\left|\left\langle x + \frac{\beta}{1-\beta}g - f_0,\ g\right\rangle\right|}{|g|} \geq \frac{\beta}{1-\beta}|g| - \frac{|\langle x - f_0,\ g\rangle|}{|g|}, \tag{2.37}$$

which proves the second assertion of part (ii). □

By Proposition 2.9, for any estimate x_n "close" to $\mathsf{Fix}\ V(T_{AAR},\beta_n)$, there is a β_{n+1} such that x_n is comparatively distant from $\mathsf{Fix}\ V(T_{AAR},\beta_{n+1})$. It will become clear in the next section that it is the proximity to the set F, rather than $\mathsf{Fix}\ V(T_{AAR},\beta_n)$, that is critical to the quality of an iterate x_n. We therefore use the relaxation parameter β_n to control the *step size* of an iterate toward the set F. By comparison, the relaxation parameter β has very little effect on the iterates x_n of the alternating projection algorithm. The next proposition shows that by varying β the step size can be regulated in the direction of the gap vector g.

PROPOSITION 2.10. *Let $x \in \mathcal{H}$ satisfy $|x - x_{\beta_1}| < \delta$, where $x_{\beta_1} \in \mathsf{Fix}\ V(T_{AAR},\beta_1)$, $\delta > 0$ and $\beta_1 \in\ ]0,1[$. Then, for all $\beta_2 \in\ ]0,1[$, we have*

$$\left|V(T_{AAR},\beta_2)x - \left(f_{\beta_1} - \frac{\beta_2}{1-\beta_1}g\right)\right| < \delta, \tag{2.38}$$

where $f_{\beta_1} = P_B x_{\beta_1} \in F$.

Proof. This proof was proved in [38, Proposition 2.3]. □

This ability to control the step lengths with the relaxation parameter stands out next to other relaxed projection algorithms. For this reason descent algorithms are often preferred since there is ample theory for determining optimal step sizes.

3. Nonconvex analysis.

3.1. Prox-regular sets. In this section A is still convex, but we allow the set B to be nonconvex. Such a situation is encountered in the numerical solution to the phase retrieval problem in inverse scattering [39, 6, 38], and is therefore of great practical interest. Indeed, our results form the basis for proving local convergence of some phase retrieval algorithms for inconsistent (noisy) problems which, to our knowledge, would be the first such results. The central notion for getting a handle on this situation is *prox-regularity* as developed by Poliquin and Rockafellar [48, 47]. Prox-regular sets were, to our knowledge, first introduced by Federer [26] though he called them sets of *positive reach*, and are characterized as those sets C for which the projection is locally single-valued and continuous from the strong topology in the domain to the weak topology in the range [49, Theorem 3.1]. The main difficulty for our analysis is that prox-regularity is a local property relative to elements of the set B while the fixed points of the mapping $V(T,\beta)$ lie somewhere in the normal cone to B

at the local best approximation points of this set. A localized normal cone mapping is obtained through the *truncated normal cone mapping*

$$N_C^r(x) := \begin{cases} N_C(x) \cap \operatorname{int} \mathbb{B}(0,r), & x \in C, \\ \varnothing, & x \notin C, \end{cases} \tag{3.1}$$

where $\mathbb{B}(0,r)$ is the closed ball of radius r centered on the origin. The principal result we draw from can be found in [49, Corollary 2.2 and Proposition 3.1].

LEMMA 3.1 (properties of prox-regular sets). *Let $C \subset \mathcal{H}$ be prox-regular at $\overline{x}$. Then for some $r > 0$ and a neighborhood of $\overline{x}$, denoted $\mathcal{N}(\overline{x})$, the truncated normal cone mapping N_C^r is hypomonotone on $\mathcal{N}(\overline{x})$; that is, there is a $\sigma > 0$ such that*

$$\langle y_1 - y_2,\ x_1 - x_2 \rangle \geq -\sigma |x_1 - x_2|^2 \quad \text{whenever } y_i \in N_C^r(x_i) \text{ and } x_i \in \mathcal{N}(\overline{x}).$$

As suggested by Proposition 2.9 we can control to some extent the location of the fixed points of $V(T,\beta)$ by adjusting the parameter β. In particular, note that for $\beta = 0$ we have $V(T,0) = P_B$; hence we can adjust β so that the fixed points remain in prox-neighborhoods of the best approximation points in B.

The next result is a prox-regular analogue of (1.3).

LEMMA 3.2. *For C prox-regular at $\overline{x}$ there exist $\epsilon > 0$ and $\sigma > 0$ such that whenever $x \in C$ and $v \in N_C(x)$ with $|x - \overline{x}| < \epsilon$ and $|v| < \epsilon$ one has*

$$\langle x' - x, v \rangle \leq \sigma |x' - x|^2 \quad \text{for all } x' \in C \quad \text{with } |x' - x| < \epsilon. \tag{3.2}$$

Proof. Since C is prox-regular at $\overline{x}$, by Lemma 3.1 the truncated normal cone mapping $N_C^r(x)$ is hypomonotone on a neighborhood $\mathcal{N}(\overline{x})$, that is, there are $\sigma > 0$ and $\epsilon > 0$ such that

$$\langle x' - x, v \rangle \leq \sigma |x' - x|^2,$$

whenever $v \in N_C(x)$, and $0 \in N_C(x')$ with $|v| < \epsilon$ and $|x' - x| < \epsilon$. ∎

A stronger version (with a different proof) of the above proposition can be found in [49, Proposition 1.2].

For this prox-regular setting we must define local versions of the sets G, E, and F defined in (1.7).

DEFINITION 3.3 (local best approximation points). *For A convex and B nonconvex, a point $f \in B$ is a* local best approximation point *if there exists a neighborhood $\mathcal{N}(f)$ on which $|f - P_A f| \leq |b - P_A b|$ for all $b \in B \cap \mathcal{N}(f)$. For such a point, we define*

$$G_{\mathcal{N}(f)} := \overline{(B \cap \mathcal{N}(f)) - A} \quad \text{and} \quad \text{for } g := f - P_A f \in P_{G_{\mathcal{N}(f)}} 0,$$

$$E_{\mathcal{N}(f)}(g) := A \cap ((B \cap \mathcal{N}(f)) - g), \quad F_{\mathcal{N}(f)}(g) := (A + g) \cap (B \cap \mathcal{N}(f)). \tag{3.3a}$$

If $|f - P_A f| \leq |b - P_A b|$ for all $b \in B$, then $f \in B$ is a global best approximation point*. Whether or not such a point exists, the following sets are well defined:*

$$G := \overline{B - A} \quad \text{and} \quad \text{for } g \in P_G 0,$$

$$E(g) := A \cap (B - g), \quad F(g) := (A + g) \cap B. \tag{3.3b}$$

From Definition 3.3 it is immediate that any global best approximation point is also a local best approximation point. Note that $P_{G_{\mathcal{N}(f)}} 0$ and $P_G 0$ are now possibly *sets*

of gap vectors since, for A convex and B prox-regular, $G = \overline{B - A}$ is not in general convex. For any $g_1, g_2 \in P_{G_{\mathcal{N}(f)}}0$, although it may happen that $g_1 \neq g_2$, it is still the case that $|g_1| = |g_2|$; hence the (local) gap between the sets A and B in the nonconvex setting is still well defined.

We will assume the following throughout the rest of this work.

Assumption 3.4 (prox-regularity of G). The set G is prox-regular at all $g \in P_G 0$, and, for every local best approximation point $f \in B$, the set $G_{\mathcal{N}(f)}$ is prox-regular at the corresponding point $g_f := f - P_A f \in P_{G_{\mathcal{N}(f)}}0$.

Example 3.5. Consider the example in $\mathbb{R}^2$ where $A = \{(0, x_2) \text{ for } x_2 \in [-2, \epsilon]\}$ for $\epsilon \geq 0$ and

$$B = \left\{ (x_1, x_2) \in \mathbb{R}^2 \;\middle|\; \begin{array}{cc} x_1 = \pm\sqrt{1 - x_2^2} & \text{for } x_2 \geq 0, \\ x_1 = -1 & \text{for } x_2 \in [0, -1], \\ x_1 = -\sqrt{1 - (x_2 + 1)^2} & \text{for } x_2 \in [-2, -1] \end{array} \right\}.$$

The corresponding set G is not prox-regular everywhere. In particular, if $\epsilon = 0$ it is not prox-regular at the point $(-\sqrt{3}/2, 1/2)$ since the projection onto G is multivalued along the line segment $(-\sqrt{3}/2, 1/2) + \tau(1, 0)$ for all $\tau \in [0, \sqrt{3}/2]$. For this example, however, this is the only point in G where prox-regularity fails. Since A and B intersect at the point $(0, -2)$, the global gap vector is $(0, 0)$, and $F = E = \{(0, -2)\}$. Each of the vectors in the set $\left\{(x_1, x_2) \in \mathbb{R}^2 \,\middle|\, x_1 = \pm\sqrt{1 - x_2^2} \quad \text{for } x_2 \geq 0, \right\}$, on the other hand, is a local gap vector relative to some neighborhood of points in B. At the point $f = (0, 1)$, for example, all of these vectors are local gap vectors of the set $G_{\mathcal{N}(f)}$, where $\mathcal{N}(f)$ is a disk of radius $\sqrt{2}$. The corresponding local best approximation points in B are $F_{\mathcal{N}(f)}(g) = \{g\}$, while the local best approximation points in A are $E_{\mathcal{N}(f)}(g) = \{(0, 0)\}$ for all $g \in \left\{(x_1, x_2) \in \mathbb{R}^2 \,\middle|\, x_1^2 + x_2^2 = 1 \text{ for } x_2 \geq 0\right\}$. We call this collection of best approximation points a *fan*, characterized by the nonuniqueness of the gap vector. We shall disallow such regions in what follows. Indeed, if in the definition of A we set $0 < \epsilon \ll 1$, then there is no such fan region and the unique best approximation point in B corresponding to $(0, \epsilon) \in A$ is $f = (0, 1)$ with corresponding unique gap vector $g = (0, 1 - \epsilon)$.

The next fact is an adjustment of [8, Proposition 2.5] for B prox-regular.

PROPOSITION 3.6. *Let A be closed convex and B prox-regular subsets of $\mathcal{H}$. Suppose that $\{a_n\}_{n\in\mathbb{N}}$ and $\{b_n\}_{n\in\mathbb{N}}$ are sequences in A and $B \cap \mathcal{N}(f)$, respectively, with f a local best approximation point, $\mathcal{N}(f)$ a suitable neighborhood and $b_n - a_n \to g = f - P_A f \in P_{G_{\mathcal{N}(f)}}0$. Then the following hold.*

(i) *$b_n - P_A b_n \to g$ while $P_B a_n - a_n \to \widetilde{G}_{\mathcal{N}(f)} \subset P_{G_{\mathcal{N}(f)}}0$.*

(ii) *The cluster points of $\{a_n\}_{n\in\mathbb{N}}$ and $\{P_A b_n\}_{n\in\mathbb{N}}$ belong to $E_{\mathcal{N}(f)}(g)$. The cluster points of $\{b_n\}_{n\in\mathbb{N}}$ belong to $F_{\mathcal{N}(f)}(g)$. Consequently, the cluster points of the sequences*

$$\left\{(a_n, b_n)\right\}_{n\in\mathbb{N}},\ \left\{(P_A b_n, b_n)\right\}_{n\in\mathbb{N}}$$

are local best approximation pairs relative to (A, B).

(iii) *If g is the unique gap vector on $\mathcal{N}(f)$, that is, if $P_{G_{\mathcal{N}(f)}}0 = g$, then*

$$b_n - a_n \to g \quad \Longleftrightarrow \quad |b_n - a_n| \to |g|.$$

Proof. Since

$$\begin{aligned}|b_n - a_n| &\geq \max\left\{|b_n - P_A b_n|, |P_B a_n - a_n|\right\}\\ &\geq \min\left\{|b_n - P_A b_n|, |P_B a_n - a_n|\right\}\\ &\geq |g|,\end{aligned}$$

we conclude that $\left\{|b_n - P_A b_n|\right\}_{n\in\mathbb{N}}$ and $\left\{|P_B a_n - a_n|\right\}_{n\in\mathbb{N}}$ both converge to $|\widetilde{g}|$ for any $\widetilde{g} \in P_{G_{\mathcal{N}(f)}}0$. Since A is convex, $P_A b_n$ is single-valued and continuous; hence $b_n - P_A b_n \to g$. Since B is prox-regular, P_B is possibly set-valued and $\lim_{n\to\infty} P_B a_n - a_n = \widetilde{G}_{\mathcal{N}(f)}$, a subset of $P_{G_{\mathcal{N}(f)}}0$. Hence (i) holds. Let $a \in A$ be a cluster point of $\{a_n\}_{n\in\mathbb{N}}$, say $a_{n_k} \to a$. Then $b_{n_k} \to g + a \in B \cap \mathcal{N}(f) \cap (g + A) = F_{\mathcal{N}(f)}(g)$, and hence $a \in A \cap (B \cap \mathcal{N}(f) - g) = E_{\mathcal{N}(f)}(g)$. The arguments for $\{b_n\}_{n\in\mathbb{N}}$ and $\{P_A b_n\}_{n\in\mathbb{N}}$ are similar. Finally, (iii) follows from (i) and the fact that g is the unique gap vector. ∎

Remark 3.7. Convergence of $|b_n - a_n| \to |g|$ does not, in general, imply that $b_n - a_n \to g$. To see this, consider B and A in Example 3.5 with $\epsilon = 0$. Construct the sequences $a_n := (0, -1/n)$ and $b_n := (-1, -1/n)$ for all n and let $g = (0, 1)$. Now, $a_n \to (0, 0)$, $b_n \to (-1, 0)$, and $b_n - a_n \to (-1, 0) = \widetilde{g} \neq g$, even though both belong to $P_{G_{\mathcal{N}(f)}}0$ and $|b_n - a_n| \to |g|$ when $f = (0, 1)$ and $\mathcal{N}(f)$ is a disk of radius $\sqrt{2}$. Note also that $P_B a_n \to (-1, 0)$ while $P_B a = \left\{(x_1, x_2) \in \mathbb{R}^2 \;\middle|\; x_1^2 + x_2^2 = 1 \text{ and } x_2 \geq 0\right\}$.

3.2. Relaxed averaged alternating reflections: Prox-regular sets. The difference between T_{AP} and T_{AAR} is in the control exerted on the fixed points of the respective mappings by the relaxation strategy $V(T, \beta)$. As shown in (2.6) in the case of T_{AP}, the relaxation $\beta \in (0, 1]$ simply shifts the set of fixed points from best approximation points in A to their corresponding points in B. In the nonconvex setting this shift property is restricted to local best approximation points. Hence, the relaxation parameter does not change in any significant way the set of fixed points and, in particular, it does not change the correspondence between the set of local best approximation points and the fixed points of $V(T_{AP}, \beta)$. For T_{AAR} with the relaxation parameter in (2.21) the nonconvex situation is quite different. Indeed, as we show in Lemma 3.8, the relaxation parameter β can be chosen to *limit* the set of local best approximation points that correspond to fixed points of $V(T_{AAR}, \beta)$, thus eliminating *bad* local best approximation points.

Before proceeding with the prox-regular versions of Theorem 2.7 and Corollary 2.8, we need to define what we mean by $V(T, \beta)x$ in the case when $P_B x$ is multivalued. We shall define this as

$$V(T_{AP}, \beta)x := \{v = \beta P_A b + (1 - \beta)b \quad | \quad b \in P_B x\}, \tag{3.4a}$$

$$V(T_{AAR}, \beta)x := \left\{v = \frac{\beta}{2}\left(R_A(2b - x) + x\right) + (1 - \beta)b \quad | \quad b \in P_B x\right\}. \tag{3.4b}$$

LEMMA 3.8 (characterization of fixed points). *For A closed and convex and B prox-regular, suppose that Assumption* 3.4 *holds, and define $V(T_{AAR}, \beta)$ by* (3.4b) *for $\beta \in]0, 1[$ fixed. Then*

$$\begin{aligned}&\mathsf{Fix}\, V(T_{AAR}, \beta)\\ &\quad\subset \left\{f - \frac{\beta}{1 - \beta}(f - P_A f) \mid f \in B \text{ is a local best approximation point}\right\}\end{aligned} \tag{3.5a}$$

and the two sets are equal for all $\beta \leq 1/2$. Moreover, for every $x \in \mathsf{Fix}\, V(T_{AAR}, \beta)$, there is a local best approximation point f and corresponding gap vector g_f with

$$x \in P_B x - \frac{\beta}{1-\beta} g_f, \tag{3.5b}$$

$$g_f \in P_B x - P_A R_B x. \tag{3.5c}$$

By comparison, for all $\beta \in]0,1[$ fixed,

$$\mathsf{Fix}\, V(T_{AP}, \beta) = \{ f - \beta(f - P_A f) \mid f \in B \text{ is a local best approximation point} \}. \tag{3.6}$$

Proof. The proof is almost identical to that of Lemma 2.1. We skip most of the details and point only to the main differences.

To prove (3.5a)–(3.5c) we must take account of two issues: first, that P_B might not be single-valued at all $x \in \mathsf{Fix}\, V(T_{AAR}, \beta)$ and second, that the relation (2.14) does not hold for B prox-regular. The possible multivaluedness of $P_B x$ is handled by choosing $f \in P_B x$ for a given $x \in \mathsf{Fix}\, V(T_{AAR}, \beta)$ and setting $y = x - f$. The corresponding gap vector is uniquely determined by $g_f = f - P_A(f)$. This changes (2.8) and (2.9) to *inclusions*

$$P_A(2f - x) \in P_A R_B x \quad \text{and} \quad P_A R_B x - P_B x = T_{AAR} x - x \tag{3.7}$$

by (2.7). The second equation is actually an expression of set equality. When T_{AAR} is restricted to the selection $f \in P_B x$, which we write as $T_{AAR}|_f$, this yields

$$P_A(2f - x) - f = T_{AAR}|_f x - x. \tag{3.8}$$

For $x \in \mathsf{Fix}\,(V(T_{AAR}, \beta))$, (3.7) and (3.8) give

$$(1-\beta)(x - f) = \beta(T_{AAR}|_f - x) = \beta(P_A(2f - x) - f); \tag{3.9}$$

hence, with $y = x - f$,

$$f + \frac{1-\beta}{\beta} y = P_A(2f - x). \tag{3.10}$$

This is the same result as (2.11) for the selection $f \in P_B x$. As with (2.13), using (2.12) and (3.10) we have, for any $a \in A$ nonempty, closed, and convex,

$$\frac{1}{\beta} \langle -a + f,\ y \rangle + \frac{1-\beta}{\beta^2} |y|^2 \leq 0. \tag{3.11}$$

On the other hand, since B is nonempty prox-regular and $f \in P_B x$, by Lemma 3.2 we have

$$\langle b - f, x - f \rangle \leq \sigma |f - b|^2, \tag{3.12}$$

where $x - f \in N_B(f)$, and $0 \in N_B(b)$ for b close enough to f. This yields (compare to (2.15))

$$\langle b - f,\ y \rangle = \langle b - f,\ x - f \rangle \leq \sigma |b - f|^2. \tag{3.13}$$

Now, (3.11) and (3.13) yield

$$\langle b-a,\ y\rangle \le \langle b-f,\ y\rangle - \frac{1-\beta}{\beta}|y|^2 \le \sigma\,|f-b|^2 - \frac{1-\beta}{\beta}|y|^2. \tag{3.14}$$

The right-hand side is nonpositive for all b close enough to f. The rest of the proof follows the proof of Lemma 2.1 with the caveat that the sequence $b_n \to f$ be chosen close enough to f that

$$\sigma\,|f-b_n|^2 - \frac{1-\beta}{\beta}|y|^2 \le 0 \quad \text{for all } n.$$

The identities (3.5b)–(3.5c) follow immediately since $f \in P_B x$ is a local best approximation point.

To prove that the set inequality in (3.5a) is not, in general, tight we show that, given a local best approximation point $f \in B$ and corresponding gap vector g_f,

$$f - \frac{\beta}{1-\beta}g_f \in \mathsf{Fix}\, V(T_{AAR},\beta) \quad \text{if and only if} \quad f \in P_B\left(f - \frac{\beta}{1-\beta}g_f\right). \tag{3.15}$$

The "easy" implication is that the left-hand side of (3.15) implies the right-hand side (expand $0 \in (I - V(T_{AAR},\beta))\,(f - \frac{\beta}{1-\beta}g_f)$ in terms of P_B and P_A and "solve" for $P_B(f - \frac{\beta}{1-\beta}g_f)$). The other implication follows exactly as in Lemma 2.1 with the generalization to inclusions since the projection onto B need not be single-valued.

Finally, to show that set equality holds in (3.5a) for all $\beta \le 1/2$ note that, for any local best approximation point $f \in B$ with B prox-regular, $f \in P_B(f - \frac{\beta}{1-\beta}g_f)$ for all $\beta \in [0,1/2]$, where g_f is the corresponding gap vector. The result then follows from (3.15).

For T_{AP}, since the parameter β simply shifts the fixed point within the gap of a local best approximation pair as β ranges from 0 to 1, the fixed points of $V(T_{AP},\beta)$ coincide precisely with the local best approximation points of A and B, whence (3.6). ∎

COROLLARY 3.9. *$\mathsf{Fix}\, V(T_{AAR},\beta) = \varnothing$ for all $\beta > 0$ if and only if B does not contain a local best approximation point.*

Proof. This follows immediately from (3.5). ∎

Remark 3.10. Note that, while in the case of T_{AAR} all local best approximation points correspond to fixed points of $V(T_{AAR},\beta)$ for $\beta \in [0,1/2]$, this is not the case for $\beta > 1/2$. Indeed, by (3.15) of Lemma 3.8, the fixed points of $V(T_{AAR},\beta)$ consist only of local best approximation points for which $f - \frac{\beta}{1-\beta}g_f$ is in a proximal neighborhood of B. This certainly will not hold for all $\beta \in [1/2,1[$. One might envision an algorithmic strategy for *filtering out* certain local best approximation points by choosing β large enough. Of course, how such a filtering might work in practice depends entirely on local proximal properties of the set B. The point is that, by simply increasing β, one can avoid local minima. This is a potentially powerful algorithmic tool for global projection algorithms for nonconvex problems.

We finish this section with nonconvex versions of Theorem 2.7 and Corollary 2.8. The convex results exploited the firm nonexpansiveness of the fixed point mapping, or equivalently maximal monotonicity. We show that, for the nonconvex problem, if this property holds locally, then local versions of the results of section 2.1 follow. This is not an empty assumption as Example 3.5 illustrates. Indeed, for the sets defined there with $\epsilon > 0$, an elementary calculation of $V(T_{AAR},1/2)x$ for points x on convex neighborhoods of $(0,\epsilon) \in \mathsf{Fix}\, V(T_{AAR},1/2)$ (not even very small neighborhoods)

shows that $2V(T_{AAR}, 1/2) - I$ is nonexpansive, and hence $V(T_{AAR}, 1/2)$ is locally firmly nonexpansive.

One consequence of such an assumption is the following.

PROPOSITION 3.11. *For either $T = T_{AAR}$ or $T = T_{AP}$, if $V(T, \beta)$ is firmly nonexpansive on a neighborhood $\mathcal{N}(x_0)$ of $x_0 \in \mathsf{Fix}\, V(T, \beta)$, then $g_0 = P_B x_0 - P_A P_B x_0$ is the unique gap vector on $\mathcal{N}(x_0)$; that is, for all $x \in \mathsf{Fix}\, V(T, \beta) \cap \mathcal{N}(x_0)$ one has $P_B x - P_A P_B x = P_B x_0 - P_A P_B x_0$. Moreover, P_B is single-valued on $\mathcal{N}(x_0)$.*

Proof. We prove the statement for $T = T_{AAR}$ as the proof for $T = T_{AP}$ is almost identical. Let x_1 be any fixed point on $\mathcal{N}(x_0)$ with corresponding gap vectors $g_1 \in P_B x_1 - P_A P_B x_1$, and let $b_j \in P_B x_j$, for $j = 0, 1$. Then by Lemma 3.8 $x_j = b_j - \frac{1-\beta}{\beta} g_j$, $j = 0, 1$. Since P_A is nonexpansive we have

$$|g_1 - g_0|^2 = |b_1 - b_0|^2 + |P_A b_1 - P_A b_0|^2 - 2\langle b_1 - b_0,\ P_A b_1 - P_A b_0\rangle \tag{3.16}$$
$$\leq |b_1 - b_0|^2 - |P_A b_1 - P_A b_0|^2$$

and

$$|P_A b_1 - P_A b_0| \leq |b_1 - b_0|. \tag{3.17}$$

If $|P_A b_1 - P_A b_0| = |b_1 - b_0|$, then by (3.16) $g_1 = g_0$. If, on the other hand, $|P_A b_1 - P_A b_0| < |b_1 - b_0|$, then $|y_1 - x_0| < |x_1 - x_0|$, where $y_1 := b_1 - \left(\frac{1-\beta}{\beta} + \epsilon\right) g_1$ for some $\epsilon > 0$ small enough. A straightforward calculation shows that

$$Ry_1 = b_1 - \left(\frac{1-\beta}{\beta} + (2\beta - 1)\epsilon\right) g_1 \quad \text{and} \quad Rx_0 = x_0,$$

where $R := 2V(T_{AAR}, \beta) - I$. So for $\beta < 1$, $|y_1 - x_0| < |Ry_1 - Rx_0|$, which contradicts the assumption that $V(T_{AAR}, \beta)$ is firmly nonexpansive. It must hold, then, that $|P_A b_1 - P_A b_0| = |b_1 - b_0|$; hence $g_1 = g_0$.

To see that the projection P_B is single-valued on $\mathcal{N}(x_0)$, consider any $x \in \mathcal{N}(x_0)$ and the corresponding vectors $y_1 = b_1 - x$ and $y_2 = b_2 - x$ with $b_j \in P_B x$ $(j = 1, 2)$. The same argument as above applies here with A replaced by $\{x\}$ to show that $y_1 = y_2$ since $V(T_{AAR}, \beta)$ is firmly nonexpansive; hence $b_1 = b_2$. Since x was arbitrarily chosen, this completes the proof. ∎

The inexact RAAR algorithm, Algorithm 2.3, is modified in the obvious way to inclusions for B prox-regular. For variable relaxation parameters, we then have the following generalization of Theorem 2.7.

THEOREM 3.12 (inexact prox-regular RAAR algorithm, variable β). *For A closed and convex and B prox-regular, suppose that Assumption 3.4 holds. Let $\beta \in]0, 1[$ be small enough that $\mathsf{Fix}\, V(T_{AAR}, \beta) \neq \varnothing$. Suppose that $V(T_{AAR}, \beta)$ is firmly nonexpansive on a convex neighborhood $\mathcal{N}(\overline{x})$ of $\overline{x} \in \mathsf{Fix}\, V(T_{AAR}, \beta)$ with $\operatorname{dom} V(T_{AAR}, \beta) = \mathcal{H}$. Choose $x_0 \in \mathcal{N}(\overline{x})$, let $\{\beta_n\}_{n\in\mathbb{N}}$ be a sequence in $]0, 1[$, and let $\{x_n\}_{n\in\mathbb{N}} \subset \mathcal{H}$ be generated by Algorithm 2.3 with corresponding errors $\{\epsilon_n\}_{n\in\mathbb{N}}, \{\rho_n\}_{n\in\mathbb{N}} \subset \mathcal{H}$. Define*

$$\nu_n = 2|\beta_n - \beta|\,|(P_A - I)R_B x_n| \tag{3.18}$$

and suppose that

$$\sum_{n\in\mathbb{N}} |\epsilon_n| + |\rho_n| + \nu_n = M \tag{3.19}$$

for $M \in \mathbb{R}$ small enough that $\{x_n\}_{n\in\mathbb{N}} \subset \mathcal{N}(\overline{x})$. Then $\{x_n\}_{n\in\mathbb{N}}$ converges weakly to a point in

$$\operatorname{Fix} V(T_{AAR},\beta) \cap \mathcal{N}(\overline{x}) \subset \left\{ f - \frac{\beta}{1-\beta}(f - P_A f) \;\middle|\; f \in F_{P_B\mathcal{N}(\overline{x})} \right\},$$

where $F_{P_B\mathcal{N}(\overline{x})}$ denotes the set of best approximation points in B corresponding to the projected neighborhood $P_B\mathcal{N}(\overline{x})$. Convergence is strong if any one of the following holds:

- $\underline{\lim} \operatorname{dist}_{\operatorname{Fix} V(T_{AAR},\beta)}(x_n) = 0$;
- $\operatorname{int} \operatorname{Fix} V(T_{AAR},\beta) \neq \varnothing$;
- $V(T_{AAR},\beta)$ *is* demicompact at 0.

Proof. Let $R = 2V(T_{AAR},\beta) - I$ and note that $\operatorname{Fix} R = \operatorname{Fix} V(T_{AAR},\beta)$, which, by assumption, is nonempty. Moreover, it follows from Lemma 3.8 that

$$\operatorname{Fix} R \cap \mathcal{N}(\overline{x}) = \operatorname{Fix} V(T_{AAR},\beta) \cap \mathcal{N}(\overline{x}) \subset \left\{ f - \frac{\beta}{1-\beta}(f - P_A f) \;\middle|\; f \in F_{P_B\mathcal{N}(\overline{x})} \right\}.$$

Following the proof of Theorem 2.7, let $r_n = 2x_{n+1} - x_n$ and rewrite the recursion (2.21) as

$$x_0 \in \mathcal{H} \quad \text{and} \quad x_{n+1} = \tfrac{1}{2}x_n + \tfrac{1}{2}r_n \quad \text{for all } n \in \mathbb{N}, \tag{3.20}$$

where, from (3.19) and

$$|r_n - Rx_n| \leq |\rho_n| + |\epsilon_n| + \nu_n, \tag{3.21}$$

it holds that

$$\sum_{n\in\mathbb{N}} |r_n - Rx_n| < M \tag{3.22}$$

for M small enough that $\{x_n\}_{n\in\mathbb{N}} \subset \mathcal{N}(\overline{x})$. Since $V(T_{AAR},\beta)$ is firmly nonexpansive on this neighborhood with $\operatorname{dom} V(T_{AAR},\beta) = \mathcal{H}$, it follows that R is nonexpansive on the same neighborhood with $\operatorname{dom} R = \mathcal{H}$. The result then follows from [20, Theorem 5.5]. ∎

A more detailed picture of the behavior of iterates of the exact RAAR algorithm can be obtained in the following restricted setting.

COROLLARY 3.13 (exact prox-regular RAAR algorithm in Euclidean space). *Let $\mathcal{H}$ be a Euclidean space. For the assumptions of Theorem* 3.12, *fix $\beta \in]0,1[$ small enough that $\operatorname{Fix} V(T_{AAR},\beta) \neq \varnothing$, and let*

$$x_0 \in \mathcal{N}(\overline{x}) \quad \textit{and} \quad x_{n+1} = V(T_{AAR},\beta)x_n \quad \textit{for all } n \in \mathbb{N},$$

where $\overline{x} \in \operatorname{Fix} V(T_{AAR},\beta)$ with corresponding local best approximation point $f = P_B\overline{x}$ and gap vector $g_f = f - P_A f$. Then $\{x_n\}_{n\in\mathbb{N}}$ converges to a point $x \in F_{\mathcal{N}(f)}(g_f) - \beta g_f/(1-\beta)$ and

(i) *$P_B x_n - P_A P_B x_n \to g_f$;*
(ii) *$P_B x_n \to P_B x$ and $P_A P_B x_n \to P_A P_B x$;*
(iii) *$P_B x - P_A P_B x = g_f$; hence $P_B x \in F_{\mathcal{N}(f)}(g_f)$ and $P_A P_B x \in E_{\mathcal{N}(f)}(g_f)$.*

Proof. The convergence of $\{x_n\}_{n\in\mathbb{N}}$ follows from Theorem 3.12 (with $\mu_n := \nu_n := 0$); denote the limit by x. From (3.3a) we can write $x \in F_{\mathcal{N}(f)}(g_f) - \beta g_f/(1-\beta)$ as $x = f - \beta g_f/(1-\beta)$, where $f = P_B x \in F_{\mathcal{N}(f)}(g_f)$ (see also [8, Proposition 2.4.(ii)]).

Since the mappings P_A, P_B, R_A, R_B are continuous, (ii) follows. Next, using (3.5c), we have

$$P_B x_n - P_A R_B x_n \to P_B x - P_A R_B x = g_f. \tag{3.23}$$

Hence

$$|g_f| \leq |P_B x_n - P_A P_B x_n| \leq |P_B x_n - P_A R_B x_n| \to |g_f|, \tag{3.24}$$

and thus $|P_B x_n - P_A P_B x_n| \to |g_f|$. Now (i) follows from Propositions 3.6 and 3.11. Taking the limit in (i) yields (iii). □

4. Conclusion and open problems. In this work we have laid some groundwork for a comprehensive theory of the asymptotic behavior of projection algorithms in prox-regular settings, with particular focus on the RAAR algorithm. The RAAR algorithm has many attractive features, namely that it is robust for consistent and inconsistent problems, the relaxation parameter can be interpreted as a *step length* and thus can be optimized, and, moreover, the relaxation parameter can be used to avoid "bad" local minima. In the convex setting the RAAR algorithm, together with the classical alternating projections and averaged projections algorithms, can be viewed as instances of the classical Lions–Mercier/Douglas–Rachford algorithm applied to the problem of minimizing the sum of two maximal monotone mappings; hence the analysis of the RAAR algorithm can be broadly applied. We conjecture that these correspondences carry over to the nonconvex setting; however, the details of this correspondence are beyond the scope of the present study.

The analytical tools that we use derive from analogues in convex theory. As one would expect from nonconvex problems, our most general results are local in nature. Our hope is that this analysis can serve as a guide to the analysis of similar algorithms. For the purpose of proving the convergence of the RAAR algorithm for the phase retrieval problem in crystallography, it remains to be shown that the fixed point mapping $V(T_{AAR}, \beta)$ is firmly nonexpansive on a neighborhood of a fixed point. This question would be quickly resolved by sufficient conditions under which firm nonexpansiveness holds in nonconvex settings. Less restrictive notions of firm nonexpansiveness, namely *quasi*-1/2-*averaged* mappings as studied in [5, 20], could also be quite fruitful here. Another key assumption for our results was the prox-regularity of the set $G_{\mathcal{N}(f)} = \overline{B \cap \mathcal{N}(f) - A}$ at local best approximation points f. We conjecture that this assumption as well as the assumption of local firm nonexpansiveness of the corresponding reflection can be removed on neighborhoods of local best approximation points. The assumption that one of the sets is convex, not just prox-regular, was useful for our proofs, but is probably not necessary in general. With the exception of what we called fan regions, local best approximation points will by definition be in the proximal neighborhood of the other set. We therefore conjecture that these results can be extended to two prox-regular sets. Finally, we note that our use of hypomonotonicity defined in Lemma 3.1 might be relaxed to approximate monotonicity of the closed set C at a point $\overline{x} \in C$ defined by

$$\langle y_1 - y_2,\ x_1 - x_2 \rangle \geq -\sigma |x_1 - x_2| \quad \text{whenever } y_i \in N_C^r(x_i) \text{ and } x_i \in \mathcal{N}(\overline{x})$$

for all $\sigma > 0$. By [35, Corollary 4.11] this is equivalent to the super-regularity of C [35, Definition 4.4], a weaker condition than prox-regularity. This generalization would immediately extend our results to sets with other types of regularity such as subsmooth sets [1].

Acknowledgments. The author would like to thank the anonymous reviewers for their thoughtful comments, particularly with regard to the interpretation of RAAR as a regularization rather than relaxation.

PITCHFORK BIFURCATIONS IN NONLINEAR LEAST SQUARES PROBLEMS–APPLICATIONS TO TOA GEOLOCATION*

LOUIS A. ROMERO† AND JEFF MASON‡

Abstract. We prove a general result concerning nonlinear least squares problems in the neighborhood of a singular Hessian. Assuming the Hessian has a one-dimensional null space, we show that in the neighborhood of such a point, there will be three solutions with small residuals. Counter to our intuition, assuming certain transversality conditions are satisfied, the solution with the largest residual is actually the most accurate solution. We illustrate this general theory by applying it to a time of arrival (TOA) geolocation problem.

Key words. bifurcations, nonlinear least squares, geolocation, TOA, TDOA, global positioning system

AMS subject classifications. 62L12, 65H10, 65F15

DOI. 10.1137/070697598

1. Introduction.

The results in this paper were motivated by phenomena observed while solving overdetermined systems of equations arising in time of arrival (TOA) geolocation as described in section 6 and [10, 7, 5]. TOA geolocation is used in a variety of settings including global positioning systems (GPS). As part of a program to make the relevant algorithms as robust as possible, we sought configurations of satellites where the algorithms were severely tested, in particular, where the Hessian (3.4) was singular or nearly singular. In the language of GPS, we were seeking out situations where the geometrical dilution of precision (GDOP) was very high. Here we observed a phenomena that seems counterintuitive, and that we have not seen reported elsewhere in the literature.

To describe this phenomena, we consider a system of equations

$$\mathbf{f}(\mathbf{z}, \mathbf{d}) = \mathbf{0}, \tag{1.1}$$

where $\mathbf{z}$ is a vector that we are trying to determine, $\mathbf{d}$ is a vector of data, and $\mathbf{f}$ is a nonlinear function of $\mathbf{z}$. Assuming we have more equations than unknowns, this gives us an overdetermined system of nonlinear equations that can be solved using least squares [4]. That is, we try to minimize

$$P(\mathbf{z}) = \frac{1}{2}\mathbf{f}^T(\mathbf{z})\mathbf{f}(\mathbf{z}). \tag{1.2}$$

Here it is assumed that the weighting has been absorbed into our equations.

In the absence of noise, we have data $\mathbf{d}_0$ such that there is a scripted solution $\mathbf{z}_0$ that exactly solves the overdetermined system

$$\mathbf{f}(\mathbf{z}_0, \mathbf{d}_0) = \mathbf{0}. \tag{1.3}$$

‡Radar and Signal Analysis Department, Sandia National Laboratories, MS 0519, P.O. Box 5800, Albuquerque, NM 87123-1320 (jjmason@sandia.gov).

We now add noise to our system, but for the sake of analysis, we do this in a deterministic way. That is, we suppose that the data is given by

$$\mathbf{d} = \mathbf{d}_0 + \epsilon \mathbf{n}, \tag{1.4}$$

where ϵ gives the level of the noise, and $\mathbf{n}$ is a unit vector that is random, but held fixed during our analysis. We are now ready to state the counterintuitive results that we have encountered.

When we put the satellites in a configuration where the Hessian evaluated at $\mathbf{z}_0$ is singular (with a one-dimensional null space), and then add noise to the data, we observe that typically there are three critical points of our least squares problem that are all close to $\mathbf{z}_0$. Two of these, which we will call $\mathbf{z}_+$ and $\mathbf{z}_-$, differ from $\mathbf{z}_0$ by an amount that is proportional to the square root of the noise.

$$\mathbf{z}_\pm = \mathbf{z}_0 + \nu_\pm \boldsymbol{\phi} + O(\epsilon), \quad \nu_\pm = \pm constant \times \sqrt{\epsilon}. \tag{1.5}$$

The third answer, which we call $\mathbf{z}_M$, differs from the scripted answer by an amount that is proportional to the noise.

$$\mathbf{z}_M = \mathbf{z}_0 + \epsilon \mathbf{q}_0 + \nu_M \boldsymbol{\phi} + O(\epsilon^2), \quad \nu_M = constant \times \epsilon. \tag{1.6}$$

In these equations $\boldsymbol{\phi}$ is the null vector of the Hessian in the absence of noise. For small noise levels, ϵ will be much smaller than $\sqrt{\epsilon}$; hence $\mathbf{z}_M$ is much more accurate than the solutions $\mathbf{z}_\pm$, and is clearly the answer that we would like to report. However, of the three candidates for the solution, we will show that $\mathbf{z}_M$ always gives the largest residual P (as defined in (1.2)).

$$P(\mathbf{z}_M, \mathbf{d}) > P(\mathbf{z}_\pm, \mathbf{d}). \tag{1.7}$$

This clearly violates our intuition since we feel as though the best solution should be the one with the minimum residual, which it is not.

At first sight it may seem impossible to know which solution to report (since in practice we do not know $\mathbf{z}_0$). However, it can be shown that $\mathbf{z}_M$ is much less sensitive to changes in the data. This sensitivity can be computed without knowing the scripted solution, and hence this offers a viable way of determining which solution to report. Alternatively, (1.5) and (1.6) show that if we average all three of these solutions we get a solution that differs from the scripted solution by $O(\epsilon)$. This suggests that if we see three solutions close to each other, the average may be an accurate estimate of the solution we seek.

In this paper we use techniques from bifurcation theory to show that this is in fact a general phenomenon that occurs when solving nonlinear least squares problems. In particular, we use what is known as the Liapanov–Schmidt reduction [2, 6, 3, 9] to effectively turn this into a one-dimensional problem. This reduction allows us to solve a one-dimensional equation for the determination of the constant ν in front of the eigenvector $\boldsymbol{\phi}$ in (1.5) and (1.6). We will see that to leading order, ν satisfies an equation

$$c_0 \epsilon^2 + 2a_1 \epsilon \nu + 4a_3 \nu^3 = 0, \tag{1.8}$$

where

$$a_3 > 0, \tag{1.9}$$

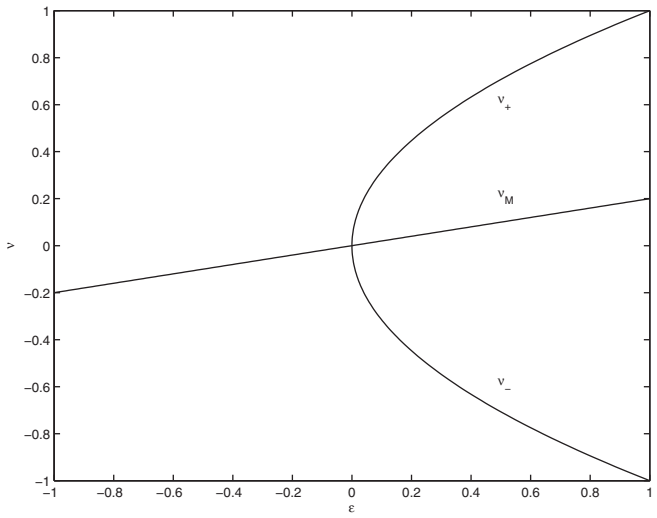

FIG. 1.1. *This is a schematic illustrating the pitchfork bifurcation described by* (1.8). *Note that this is not a symmetry breaking bifurcation. That is, it is not symmetrical except for asymptotically small values of* ϵ.

and the objective function can be written as

$$P(\nu, \epsilon) = a_0\epsilon^2 + a_1\epsilon\nu^2 + a_3\nu^4 + \text{Higher order terms.} \tag{1.10}$$

Note that (1.8) is missing the linear term in ϵ and both the linear and quadratic terms in ν. This is a general property of nonlinear least squares problems in the vicinity of a singularity. An analysis of (1.8) shows that it exhibits a pitchfork bifurcation, having three real solutions for one sign of ϵ, and one real solution for the opposite sign. The form in (1.10) for the residual P is noteworthy in that two of the constants appearing in it are the same as the constants in (1.8). This, along with the fact that $a_3 > 0$, will allow us to prove that the solutions $\mathbf{z}_\pm$ have lower residuals than $\mathbf{z}_M$ for small values of ϵ.

Figure 1.1 illustrates the pitchfork bifurcation described by (1.8). It should be noted that this is not a symmetry-breaking bifurcation. That is, the bifurcation is only symmetrical for asymptotically small values of ϵ.

A relevant question is: How likely are we to see such degenerate configurations? In order for such a configuration to exist, we will see that we must have a vector $\boldsymbol{\phi}$ such that $\mathbf{J}\boldsymbol{\phi} = 0$, where $\mathbf{J}$ is the Jacobian of $\mathbf{f}$. If we have $N+1$ equations in N unknowns, $\mathbf{J}$ will be an $(N+1)\times N$ matrix, and typically we cannot find a nontrivial vector $\boldsymbol{\phi}$ that satisfies $\mathbf{J}\boldsymbol{\phi} = 0$. However, such a solution is generic if we adjust two parameters. For example, in a GPS problem we have four unknowns: the three-dimensional vector giving the location of the receiver, and the clock bias. If we have five satellites this gives us five equations in four unknowns. If we fix the location of the receiver, then it is not likely that at some point in time the five satellites will pass through such a configuration. However, it is likely that at some point in time there is a point on a curve (such as the equator) that will see the satellites as being degenerate. On the other hand, if we have $N + 2$ equations in N unknowns, we will need to adjust three parameters.

We now describe the outline of this paper. In section 2 we give a review of the Liapanov–Schmidt reduction in bifurcation theory. In section 3 we apply this theory

to the case of nonlinear least squares problems, in section 4 we discuss the residuals of the solutions in the neighborhood of the singular point, and in section 5 we discuss a criterion for choosing the best solution. In section 6 we give examples of this phenomena occurring in geolocation problems, and in section 7 we give conclusions.

2. Review of the Liapanov–Schmidt reduction. We will carry out the bifurcation analysis using a standard technique in bifurcation theory known as the Liapanov–Schmidt reduction. Though this procedure can be found in many different sources [2, 6, 3, 9], we have chosen to review it here for the convenience of the reader, and to introduce the notation that we will be using. We limit our discussion of this procedure to systems that have a simple zero eigenvalue. This technique allows us to analyze an N-dimensional system near a bifurcation point by analyzing a one-dimensional equation that solves for the component ν of the solution in the direction of the critical eigenvector.

Suppose we have N nonlinear equations in N unknowns

$$\mathbf{G}(\mathbf{z}, \epsilon) = \mathbf{0}, \tag{2.1}$$

where ϵ is a parameter, $\mathbf{G}$ is an N-dimensional vector, and we are solving for the N-dimensional vector $\mathbf{z}$. We suppose that for $\epsilon = 0$ we have a solution $\mathbf{z}_0$, and that the Jacobian of this system is singular at $(\mathbf{z}, \epsilon) = (\mathbf{z}_0, 0)$, with a simple real eigenvector $\boldsymbol{\phi}$, and adjoint eigenvector $\boldsymbol{\psi}$. This is equivalent to making the following assumptions:

Assumptions 1 (assumptions for Liapanov–Schmidt reduction). *We assume that for* $(\mathbf{z}, \epsilon) = (\mathbf{z}_0, 0)$ *we have*

$$\mathbf{G}(\mathbf{z}_0, 0) = \mathbf{0}. \tag{2.2}$$

The Jacobian $\frac{\partial \mathbf{G}}{\partial \mathbf{z}}$ *has a simple zero eigenvector* $\boldsymbol{\phi}$

$$\frac{\partial \mathbf{G}}{\partial \mathbf{z}}(\mathbf{z}_0, 0)\boldsymbol{\phi} = \mathbf{0} \tag{2.3}$$

and a left eigenvector

$$\boldsymbol{\psi}^T \frac{\partial \mathbf{G}}{\partial \mathbf{z}}(\mathbf{z}_0, 0) = \mathbf{0}^T. \tag{2.4}$$

The simplicity requirement requires that

$$\boldsymbol{\psi}^T \boldsymbol{\phi} \neq 0. \tag{2.5}$$

For the problems we will be concerned with, the Jacobian will be symmetric, and we will have $\boldsymbol{\psi} = \boldsymbol{\phi}$. However, we will not make this assumption in this brief review.

Since our Jacobian is singular at $(\mathbf{z}_0, 0)$, we have a violation of the conditions of the implicit function theorem [1], and we are not guaranteed that we can uniquely solve for $\mathbf{z}(\epsilon)$ in the neighborhood of such a point. However, since we have a simple zero eigenvalue, it can be shown that we can solve for $N - 1$ of the components of $\mathbf{z}$ in terms of the component ν of $\mathbf{z}$ that is in the direction of the critical eigenvector $\boldsymbol{\phi}$. Once we have expressed the other components in terms of ν, we can reduce the N-dimensional problem to a one-dimensional problem.

To be precise we will write our solution as

$$\mathbf{z} = \mathbf{z}_0 + \mathbf{v} + \nu\boldsymbol{\phi} \tag{2.6}$$

and require that

$$\boldsymbol{\psi}^T \mathbf{v} = 0. \tag{2.7}$$

These equations express the fact that ν is the component of $\mathbf{z} - \mathbf{z}_0$ in the direction of $\boldsymbol{\phi}$, and that $\mathbf{v}$ gives the components in the other directions.

We would like to solve for $\mathbf{v}(\nu, \epsilon)$ in the neighborhood of $(\mathbf{z}_0, 0)$. To do that we will require that all of the components of the equation $\mathbf{G}(\mathbf{z}, \epsilon) = \mathbf{0}$ are satisfied, except for the component in the direction $\boldsymbol{\phi}$. We can do this by using the equation

$$\mathbf{G}(\mathbf{z}_0 + \mathbf{v} + \nu\boldsymbol{\phi}, \epsilon) = \kappa\boldsymbol{\phi}. \tag{2.8}$$

Here κ is a variable that we will solve for. By introducing κ, (2.8) does not require that $\mathbf{G}(\mathbf{z}, \epsilon) = 0$ in the direction of $\boldsymbol{\phi}$. Equations (2.7) and (2.8) give us $N + 1$ equations in the $N + 1$ unknowns $\mathbf{v}$ and κ, with ν and ϵ as parameters. These equations are satisfied by $\mathbf{v} = \kappa = 0$, when $\epsilon = \nu = 0$. Furthermore, when we linearize about this point, it can be shown that the Jacobian of this extended system is nonsingular with respect to the variables $\mathbf{v}$ and κ (we omit the details here). This implies that we can uniquely solve for $\mathbf{v}(\nu, \epsilon)$ and $\kappa(\nu, \epsilon)$.

LEMMA 2.1. *Under the assumptions* (1), (2.7) *and* (2.8) *have a unique solution* $\mathbf{v}(\nu, \epsilon)$, $\kappa(\nu, \epsilon)$ *for* (ν, ϵ) *in the neighborhood of* $(0, 0)$, *and* $\mathbf{v}$ *in the neighborhood of* $\mathbf{0}$.

For any values of ν and ϵ in the neighborhood of $(0, 0)$, we will have

$$\mathbf{q}^T \mathbf{G}(\mathbf{z}_0 + \mathbf{v}(\nu, \epsilon) + \nu\boldsymbol{\phi}, \epsilon) = 0; \text{ for } \mathbf{q}^T\boldsymbol{\phi} = 0. \tag{2.9}$$

This implies that $\mathbf{z} = \mathbf{z}_0 + \mathbf{v}(\nu, \epsilon) + \nu\boldsymbol{\phi}$ will satisfy the equation $\mathbf{G}(\mathbf{z}, \epsilon) = \mathbf{0}$ in all directions except for one, the direction of $\boldsymbol{\phi}$. In order to ensure that $\mathbf{z} = \mathbf{z}_0 + \mathbf{v}(\nu, \epsilon) + \nu\boldsymbol{\phi}$ is in fact a solution to $\mathbf{G}(\mathbf{z}, \epsilon) = 0$, we need only require that the equation is also satisfied in the direction $\boldsymbol{\phi}$. To do this we require that

$$g(\nu, \epsilon) = \boldsymbol{\psi}^T \mathbf{G}(\mathbf{z}_0 + \mathbf{v}(\nu, \epsilon) + \nu\boldsymbol{\phi}, \epsilon) = 0. \tag{2.10}$$

This last equation gives us a one-dimensional equation $g(\nu, \epsilon) = 0$ to solve. This is the end result of the Liapanov–Schmidt reduction. Our main goal is to determine the topology of the solution space in the neighborhood of $(\mathbf{z}_0, 0)$. That is, we would like to know how many solutions there are as a function of ϵ, and what the leading order behavior of these solutions is. Through our reduction, this is equivalent to determining the topology of the solutions to $g(\nu, \epsilon) = 0$ near $(\nu, \epsilon) = (0, 0)$. This can be determined if we know the leading order terms in the Taylor series expansion of $g(\nu, \epsilon)$, which can be found by taking derivatives of g. That is, the process we carry out in the next section for the case where $\mathbf{G}$ comes from a nonlinear least squares problem.

A general property of this Liapanov–Schmidt reduction is that $\frac{\partial \mathbf{v}}{\partial \nu}(0, 0) = 0$. This follows from taking the derivative of (2.7) and (2.8) with respect to ν. If we do this we get

$$\frac{\partial \mathbf{G}}{\partial \mathbf{z}} \left(\frac{\partial \mathbf{v}}{\partial \nu} + \boldsymbol{\phi} \right) = \frac{\partial \kappa}{\partial \nu} \boldsymbol{\phi}, \tag{2.11}$$

$$\boldsymbol{\psi}^T \frac{\partial \mathbf{v}}{\partial \nu} = 0. \tag{2.12}$$

If we evaluate these equations at $\nu = \epsilon = 0$, and use the fact that at that point $\frac{\partial \mathbf{G}}{\partial \mathbf{z}}\boldsymbol{\phi} = 0$, we get the equation

$$\frac{\partial \mathbf{G}}{\partial \mathbf{z}}\frac{\partial \mathbf{v}}{\partial \nu} = \frac{\partial \kappa}{\partial \nu}\boldsymbol{\phi}. \tag{2.13}$$

If we multiply both sides of this equation on the left by $\boldsymbol{\psi}^T$ and use (2.4) and (2.5), we see that $\frac{\partial \kappa}{\partial \nu} = 0$. It follows that $\frac{\partial \mathbf{G}}{\partial \mathbf{z}}\frac{\partial \mathbf{v}}{\partial \nu} = 0$ and hence $\frac{\partial \mathbf{v}}{\partial \nu}$ is proportional to $\boldsymbol{\phi}$, but (2.12) shows that the constant of proportionality must in fact be zero.

LEMMA 2.2. *Under the assumptions* (1)*, we have*

$$\frac{\partial \mathbf{v}}{\partial \nu} = 0 \quad \textit{for } \nu = \epsilon = 0. \tag{2.14}$$

Collecting all of this we get the following:

THEOREM 2.3 (Liapanov–Schmidt). *Under the assumptions* (1)*, as* $\epsilon \to 0$*, any solution* $\mathbf{z}(\epsilon)$ *(in the neighborhood of* $\mathbf{z}_0$*) to* $\mathbf{G}(\mathbf{z}, \epsilon) = 0$ *can be written as*

$$\mathbf{z}(\epsilon) = \mathbf{z}_0 + \mathbf{v}(\epsilon, 0) + \nu(\epsilon)\boldsymbol{\phi} + \ldots, \tag{2.15}$$

where $\nu(\epsilon)$ *is a solution to* $g(\nu, \epsilon) = 0$ *as defined in* (2.10)*. Similarly, any solution to* $g(\nu, \epsilon) = 0$ *gives a solution to* $\mathbf{G}(\mathbf{z}, \epsilon) = 0$*, whose leading order behavior is as in* (2.15)*.*

3. Bifurcation analysis. In this section we apply the Liapanov–Schmidt procedure to the specific case where the function $\mathbf{G}(\mathbf{z}, \epsilon)$ (as in the last section) comes from solving an overdetermined system of equations $\mathbf{f}(\mathbf{z}, \epsilon) = 0$ in a least squares sense. The analysis is applied to the case where the Jacobian of our system has a single null vector. In Lemma (3.2) we show that in this case the function $g(\nu, \epsilon)$ (as in (2.10)) is missing the order ϵ, ν, and ν^2 terms in the Taylor series about $(\nu, \epsilon) = (0, 0)$. This gives us the form as in (1.8). We will see that this implies that for small values of ϵ we have three solutions as in (1.5) and (1.6).

We assume we have a suitably differentiable function $\mathbf{f}(\mathbf{z}, \epsilon)$ where $\mathbf{z}$ is an N-dimensional vector, and $\mathbf{f}(\mathbf{z}, \epsilon)$ is an M-dimensional vector, with $M > N$. Here the parameter ϵ is meant to specify the level of noise in our system. We will solve this system of equations using nonlinear least squares. That is, we minimize the objective function

$$P(\mathbf{z}, \epsilon) = \frac{1}{2}\mathbf{f}^T(\mathbf{z}, \epsilon).\mathbf{f}(\mathbf{z}, \epsilon). \tag{3.1}$$

The equations for $\mathbf{z}$ come from setting the gradient of this to zero. This gives us the equations

$$\mathbf{G}(\mathbf{z}, \epsilon) = \mathbf{J}^T(\mathbf{z}, \epsilon)\mathbf{f}(\mathbf{z}, \epsilon) = \mathbf{0}, \tag{3.2}$$

where

$$\mathbf{J}(\mathbf{z}, \epsilon) = \frac{\partial \mathbf{f}(\mathbf{z}, \epsilon)}{\partial \mathbf{z}} \tag{3.3}$$

is the Jacobian of $\mathbf{f}$.

In general, the Hessian matrix is given by

$$\mathbf{H}(\mathbf{z}, \epsilon) = \frac{\partial \mathbf{J}^T}{\partial \mathbf{z}}\mathbf{f} + \mathbf{J}^T\mathbf{J}. \tag{3.4}$$

Here $\frac{\partial \mathbf{J}^T}{\partial \mathbf{z}}$ is a third rank tensor. Since we will always be using the Hessian when $\mathbf{f} = \mathbf{0}$, we do not need to further specify what we mean by this quantity.

We will assume that when there is no noise, there is a solution $\mathbf{z}_0$ that satisfies the equations exactly. That is, we have

$$\mathbf{f}(\mathbf{z}_0, 0) = \mathbf{0}. \tag{3.5}$$

Furthermore, we assume that we are at a point where the Hessian $\mathbf{H}$ is singular. Since $\mathbf{f} = \mathbf{0}$, this means that the Hessian is given by $\mathbf{H} = \mathbf{J}^T\mathbf{J}$. The only way this can be singular is if there is a vector $\boldsymbol{\phi}$ such that

$$\mathbf{J}(\mathbf{z}_0, 0)\boldsymbol{\phi} = \mathbf{0}. \tag{3.6}$$

We make the assumption that there is only one vector $\boldsymbol{\phi}$ in the null space of $\mathbf{J}$.

We now carry out the Liapanov–Schmidt reduction for equations of the form (3.2). In particular, we will show that the function $g(\nu, \epsilon)$ in the Liapanov–Schmidt reduction has no linear terms, and that it is missing the term ν^2. We will write the function $g(\nu, \epsilon)$ as

$$g(\nu, \epsilon) = \boldsymbol{\phi}^T \hat{\mathbf{J}}^T(\nu, \epsilon)\hat{\mathbf{f}}(\nu, \epsilon), \tag{3.7}$$

where

$$\hat{\mathbf{f}}(\nu, \epsilon) = \mathbf{f}(z_0 + \mathbf{v}(\nu, \epsilon) + \nu\boldsymbol{\phi}, \epsilon) \quad \text{and} \tag{3.8}$$

$$\hat{\mathbf{J}}(\nu, \epsilon) = \mathbf{J}(z_0 + \mathbf{v}(\nu, \epsilon) + \nu\boldsymbol{\phi}, \epsilon). \tag{3.9}$$

In our case (2.8) can be written as

$$\hat{\mathbf{J}}^T(\nu, \epsilon)\hat{\mathbf{f}}(\nu, \epsilon) = \kappa(\nu, \epsilon)\boldsymbol{\phi}. \tag{3.10}$$

The calculation of the low-order derivatives of $g(\nu, \epsilon)$ is simple due to the following lemma.

LEMMA 3.1. *At $\nu = \epsilon = 0$, we have $\hat{\mathbf{f}} = \mathbf{0}$, $\boldsymbol{\phi}^T\hat{\mathbf{J}}^T = \mathbf{0}^T$, and $\frac{\partial \hat{\mathbf{f}}}{\partial \nu} = \mathbf{0}$.*

Proof. The fact that $\hat{\mathbf{f}} = \mathbf{0}$ results from the fact that $\mathbf{v}(0, 0) = \mathbf{0}$, and $\mathbf{f}(\mathbf{z}_0, 0) = \mathbf{0}$. The fact that $\boldsymbol{\phi}^T\hat{\mathbf{J}}^T = \mathbf{0}^T$ follows from the fact that $\mathbf{J}\boldsymbol{\phi} = \mathbf{0}$ for $(\mathbf{z}, \epsilon) = (\mathbf{z}_0, 0)$. The last equality in the theorem arises from differentiating $\hat{\mathbf{f}}$ with respect to ν. If we do this, we get

$$\frac{\partial \hat{\mathbf{f}}}{\partial \nu} = \hat{\mathbf{J}}\left(\frac{\partial \mathbf{v}}{\partial \nu} + \boldsymbol{\phi}\right). \tag{3.11}$$

This equation is a direct consequence of the chain rule, and the fact that $\mathbf{J}$ is the gradient of $\mathbf{f}$. However, (2.14) shows that we have $\frac{\partial \mathbf{v}}{\partial \nu} = \mathbf{0}$ at $\nu = \epsilon = 0$. Using the fact that $\hat{\mathbf{J}}\boldsymbol{\phi} = \mathbf{0}$ at $\nu = \epsilon = 0$, we conclude that $\frac{\partial \hat{\mathbf{f}}}{\partial \nu}(0, 0) = \mathbf{0}$. ∎

The basic structure of the solutions near $\epsilon = 0$ results from the following lemma.

LEMMA 3.2. *At $\epsilon = \nu = 0$ we have $\frac{\partial g}{\partial \nu} = \frac{\partial g}{\partial \epsilon} = \frac{\partial^2 g}{\partial \nu^2} = 0$.*

Proof. To show that we are missing the linear terms in ν, we differentiate (3.7) with respect to ν to get

$$\frac{\partial g}{\partial \nu} = \boldsymbol{\phi}^T\hat{\mathbf{J}}^T\frac{d\hat{\mathbf{f}}}{d\nu} + \boldsymbol{\phi}^T\frac{d\hat{\mathbf{J}}^T}{d\nu}\hat{\mathbf{f}}. \tag{3.12}$$

When we evaluate this at $\nu = \epsilon = 0$, this clearly vanishes, since $\boldsymbol{\phi}^T \hat{\mathbf{J}}^T(0) = \mathbf{0}^T$, and $\hat{\mathbf{f}}(0,0) = \mathbf{0}$. Identical arguments hold for the vanishing of $\frac{\partial}{\partial \epsilon} g(0,0)$. To show that $\frac{\partial^2 g}{\partial \nu^2} = 0$ at $\nu = \epsilon = 0$, we differentiate (3.12) with respect to ν to get

$$\frac{\partial^2 g}{\partial \nu^2} = \boldsymbol{\phi}^T \left(\hat{\mathbf{J}}^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} + 2 \frac{\partial \hat{\mathbf{J}}}{\partial \nu}^T \frac{\partial \hat{\mathbf{f}}}{\partial \nu} + \frac{\partial^2 \hat{\mathbf{J}}}{\partial \nu^2}^T \hat{\mathbf{f}} \right). \tag{3.13}$$

The first term in this sum vanishes at $\nu = \epsilon = 0$ since $\boldsymbol{\phi}^T \hat{\mathbf{J}} = \mathbf{0}^T$. The second term vanishes since $\frac{\partial \hat{\mathbf{f}}}{\partial \nu} = \mathbf{0}$ (see Lemma 3.1), and the third term vanishes since $\hat{\mathbf{f}} = \mathbf{0}$. □

Lemma 3.2 shows that near $\nu = \epsilon = 0$, the equation $g(\nu, \epsilon) = 0$ is given by

$$g(\nu, \epsilon) = c_0 \epsilon^2 + c_1 \epsilon \nu + c_3 \nu^3 + \cdots \tag{3.14}$$

We now determine these constants. If we differentiate (3.7) twice with respect to ϵ, we get

$$\frac{\partial^2 g}{\partial \epsilon^2} = \boldsymbol{\phi}^T \left(\hat{\mathbf{J}}^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \epsilon^2} + 2 \frac{\partial \hat{\mathbf{J}}}{\partial \epsilon}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} + \frac{\partial^2 \hat{\mathbf{J}}}{\partial \epsilon^2} \hat{\mathbf{f}} \right). \tag{3.15}$$

If we evaluate this at $\epsilon = \nu = 0$, and use Lemma 3.1 we get

$$c_0 = \boldsymbol{\phi}^T \frac{\partial \hat{\mathbf{J}}^T}{\partial \epsilon} \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon}, \tag{3.16}$$

where the derivatives are all evaluated at $\epsilon = \nu = 0$. A similar calculation shows that

$$c_1 = \boldsymbol{\phi}^T \frac{\partial \hat{\mathbf{J}}}{\partial \nu}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} \tag{3.17}$$

and

$$c_3 = \frac{1}{2} \boldsymbol{\phi}^T \frac{\partial \hat{\mathbf{J}}}{\partial \nu}^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2}. \tag{3.18}$$

If we ignore the higher order terms in (3.14), and set $g(\nu, \epsilon) = 0$, we get a cubic equation for ν.

$$c_0 \epsilon^2 + c_1 \epsilon \nu + c_3 \nu^3 = 0. \tag{3.19}$$

THEOREM 3.3. *Assuming that none of c_0, c_1, and c_3 vanish, as $\epsilon \to 0$ the three roots of* (3.19) *are given by*

$$\nu_M = -\frac{c_0}{c_1} \epsilon + \cdots \tag{3.20}$$

$$\nu_\pm = \pm \sqrt{\frac{-\epsilon c_1}{c_3}} + \cdots \tag{3.21}$$

Proof. If $\nu(\epsilon)$ is a root of (3.19), then when we substitute it into that equation, we must have two of the terms be of the same order as $\epsilon \to 0$, and these terms must be

larger than the remaining term. This leaves us with three possibilities for the leading order behavior, either $c_0\epsilon^2 + c_1\epsilon\nu = 0$, $c_1\epsilon\nu + c_3\nu^3 = 0$, or $c_0\epsilon^2 + c_3\nu^3 = 0$. It is easily verified that the first two of these limits results in solutions where the ignored term is in fact smaller than the terms we kept. For example, if we assume that $c_0\epsilon^2 + c_1\epsilon\nu = 0$, then we will have $\nu = O(\epsilon)$, and the terms we kept are both order ϵ, but the term we did not keep is of order ϵ^3, which is in fact higher order than the terms we kept. Similar arguments hold for the equation $c_1\epsilon\nu + c_3\nu^3 = 0$. However, if we assume that $c_0\epsilon^2 + c_3\nu^3 = 0$, then $\nu = O(\epsilon^{2/3})$, but in such a solution the terms we kept are order ϵ^2, but the term we ignored is on the order of $\epsilon^{5/3}$, so this is not a valid solution. ∎

DEFINITION 3.4. *We will refer to* $\mathbf{z}_M(\epsilon)$ *as the solution associated with the root* ν_M *in Theorem* 3.3*, and* $\mathbf{z}_\pm(\epsilon)$ *as the roots associated with* $\nu_\pm$ *in Theorem* 3.3.

4. The objective function near the bifurcation point. In order to show that the residual is larger for $\mathbf{z}_M$ than for $\mathbf{z}_\pm$, we need to expand the objective function for $\epsilon \to 0$. In order to do this we introduce the function

$$\hat{P}(\nu, \epsilon) = \frac{1}{2}\hat{\mathbf{f}}^T(\nu, \epsilon)\hat{\mathbf{f}}(\nu, \epsilon). \tag{4.1}$$

If we have a solution $\nu(\epsilon)$ of (3.7), then the residual of the solution $\mathbf{z}(\epsilon)$ associated with this function will be $\hat{P}(\nu(\epsilon), \epsilon)$. Using the fact that $\hat{\mathbf{f}} = \frac{\partial \hat{\mathbf{f}}}{\partial \nu} = \mathbf{0}$, repeated differentiation shows that

$$\frac{\partial \hat{P}}{\partial \nu} = \frac{\partial \hat{P}}{\partial \epsilon} = \frac{\partial^2 \hat{P}}{\partial \nu^2} = \frac{\partial^2 \hat{P}}{\partial \nu \partial \epsilon} = \frac{\partial^3 \hat{P}}{\partial \nu^3} = 0 \quad \text{for } \nu = \epsilon = 0. \tag{4.2}$$

It follows that to leading order we have

$$\hat{P}(\nu, \epsilon) = a_0\epsilon^2 + a_1\epsilon\nu^2 + a_3\nu^4 + \cdots. \tag{4.3}$$

The constants a_0, a_1, and a_3 can be computed by computing the appropriate partial derivatives.

$$a_0 = \frac{1}{2}\frac{\partial \hat{\mathbf{f}}}{\partial \epsilon}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} \quad \text{for } \nu = \epsilon = 0, \tag{4.4}$$

$$a_1 = \frac{1}{2}\frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} \quad \text{for } \nu = \epsilon = 0, \tag{4.5}$$

$$a_3 = \frac{1}{8}\frac{\partial^2 \hat{\mathbf{f}}^T}{\partial \nu^2}\frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} \quad \text{for } \nu = \epsilon = 0. \tag{4.6}$$

In order to compare the residuals for $\mathbf{z}_M$ and $\mathbf{z}_\pm$ we need to express the coefficients c_1 and c_3 in (3.14) in terms of a_1 and a_3. The following lemma will help us do this.

LEMMA 4.1. *At* $\nu = \epsilon = 0$ *we have the identities*

$$\hat{\mathbf{J}}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} = \mathbf{0} \tag{4.7}$$

$$\hat{\mathbf{J}}^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} = \mathbf{0} \tag{4.8}$$

Proof. The first of these results is obtained from taking the derivative of (3.10) with respect to ϵ. If we do this and use the fact that $\hat{\mathbf{f}} = \mathbf{0}$ at $\nu = \epsilon = 0$, we get

$$\hat{\mathbf{J}}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} = \frac{\partial \kappa}{\partial \epsilon}\boldsymbol{\phi}. \tag{4.9}$$

If we multiply both sides of this equation by $\boldsymbol{\phi}^T$, we see that the left-hand side vanishes, and hence we get $\frac{\partial \kappa}{\partial \epsilon} = 0$. This implies (4.7). We can derive (4.8) using a similar argument. In particular, by taking the second derivative of (3.10) with respect to ν, using the fact that $\hat{\mathbf{f}} = \frac{\partial \hat{\mathbf{f}}}{\partial \nu} = \mathbf{0}$ (see Lemma 3.1) for $\nu = \epsilon = 0$, and multiplying through by $\boldsymbol{\phi}^T$ to see that $\frac{\partial^2 \kappa}{\partial \nu^2} = 0$, and (4.8) follows from this. ∎

LEMMA 4.2. *We have the identity*

$$\frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} = \hat{\mathbf{J}} \frac{\partial^2 \mathbf{v}}{\partial \nu^2} + \frac{\partial \hat{\mathbf{J}}}{\partial \nu} \boldsymbol{\phi} \qquad \text{for } \nu = \epsilon = 0. \tag{4.10}$$

Proof. If we take the second derivative of (3.8) with respect to ν, we get

$$\frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} = \frac{\partial \hat{\mathbf{J}}}{\partial \nu} \left(\frac{\partial \mathbf{v}}{\partial \nu} + \boldsymbol{\phi} \right) + \hat{\mathbf{J}} \frac{\partial^2 \mathbf{v}}{\partial \nu^2}. \tag{4.11}$$

If we evaluate this at $\nu = \epsilon = 0$, and use the fact that $\frac{\partial \mathbf{v}}{\partial \nu}$ vanishes at that point (Lemma 2.2), we prove the lemma. ∎

LEMMA 4.3. *With a_1 and a_3 defined as in* (4.5) *and* (4.6)*, and c_1 and c_3 defined as in* (3.17) *and* (3.18)*, we have*

$$a_1 = \frac{1}{2} c_1, \tag{4.12}$$

$$a_3 = \frac{1}{4} c_3. \tag{4.13}$$

Proof. Using the expression for $\frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2}$ from (4.10), and the fact that $\hat{\mathbf{J}}^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} = \mathbf{0}$ (from (4.8)) we can write (4.6) as

$$a_3 = \frac{1}{8} \left(\hat{\mathbf{J}} \frac{\partial^2 \mathbf{v}}{\partial \nu^2} + \frac{\partial \hat{\mathbf{J}}}{\partial \nu} \boldsymbol{\phi} \right)^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} = \frac{1}{8} \boldsymbol{\phi}^T \frac{\partial \hat{\mathbf{J}}}{\partial \nu}^T \frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2} = \frac{1}{4} c_3. \tag{4.14}$$

Here the last equality has used (3.18). Similarly, if we use the expression for $\frac{\partial^2 \hat{\mathbf{f}}}{\partial \nu^2}$ from (4.10) and the fact that $\hat{\mathbf{J}}^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} = \mathbf{0}$ from (4.7), we can write (4.5) as

$$a_1 = \frac{1}{2} \left(\hat{\mathbf{J}} \frac{\partial^2 \mathbf{v}}{\partial \nu^2} + \frac{\partial \hat{\mathbf{J}}}{\partial \nu} \right)^T \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} = \frac{1}{2} \frac{\partial \hat{\mathbf{J}}^T}{\partial \nu} \frac{\partial \hat{\mathbf{f}}}{\partial \epsilon} = \frac{1}{2} c_1 \tag{4.15}$$

The last equality follows from (3.17). ∎

We can now collect our results to prove the following theorem.

THEOREM 4.4. *To leading order, we have*

$$\hat{P}(\nu_M(\epsilon), \epsilon) = a_0 \epsilon^2, \tag{4.16}$$

$$\hat{P}(\nu_\pm(\epsilon), \epsilon) = a_0 \epsilon^2 + \nu^2 \left(a_1 \epsilon + a_3 \nu^2 \right) = a_0 \epsilon^2 - \nu_\pm^4 a_3, \tag{4.17}$$

and since $a_3 > 0$,

$$\hat{P}(\nu_M(\epsilon), \epsilon) > \hat{P}(\nu_\pm(\epsilon), \epsilon) \quad \text{as } \epsilon \to 0. \tag{4.18}$$

Proof. We compute the objective function using (4.3) with $\nu(\epsilon)$ substituted for ν. Using (3.20), (4.16) follows from the fact that the terms ν_M^4 and $\epsilon\nu_M^2$ are higher order than $a_0\epsilon^2$. Equation (3.21) and the fact that $c_1 = 2a_1$, and $c_3 = 4a_3$, implies that $a_1\epsilon\nu_\pm + 2a_3\nu_\pm^3 = 0$, and hence $a_1\epsilon\nu_\pm + a_3\nu_\pm^3 = -a_3\nu_\pm^3$, which gives us the last equation on the right of (4.17). When we compare (4.16) and (4.17), and use the fact that $a_3 > 0$ (which follows from (4.6)), the inequality in the lemma follows. ∎

In this last theorem we showed that for small values of ϵ we have $P(\nu_\pm, \epsilon) \approx a_0\epsilon^2 - \nu_\pm^4 a_3$. It is not immediately clear that this is a positive quantity (which it must be). This can be shown to be positive by noting that as in the proof of Theorem 4.4 we have $\nu_\pm^2 = -\frac{\epsilon a_1}{2a_3}$, and hence $P(\nu_\pm, \epsilon) \approx \epsilon^2(a_0 - \frac{a_1^2}{4a_3}) = \epsilon^2 a_3(a_0a_3 - \frac{1}{4}a_1^2) > 0$. The last inequality follows from using the expressions for a_0, a_1, and a_3 in (4.4), (4.5), and (4.6) along with the Cauchy–Schwarz inequality.

5. A criterion for choosing the best solution. In this section we address how we can detect which of the three solutions $\mathbf{z}_\pm$ and $\mathbf{z}_M$ in the neighborhood of the singularity is actually the best solution. In our analysis, we have assumed that in the absence of noise, the data is given by $\mathbf{d}_0$, and that we have added noise $\epsilon\mathbf{n}$ to this vector. We have considered the solutions to be functions of ϵ, but we could more generally consider them to be functions of $\mathbf{d} - \mathbf{d}_0$. In this case the gradient of the solutions in the direction of $\mathbf{n}$ will just be the derivatives of the solutions with respect to ϵ. The derivatives of $\mathbf{z}_\pm$ with respect to ϵ will be on the order of $1/\sqrt{\epsilon}$, while the derivative of $\mathbf{z}_M$ will be order one.

On the other hand, if we change the noise in a direction perpendicular to $\mathbf{n}$, then we will keep ϵ fixed, but change the constants in (3.14). The gradient of the solutions in directions perpendicular to $\mathbf{n}$ will not be large for any of the three solutions. It follows that if we compute the gradient of our solutions with respect to the data, and find the direction where this gradient is largest, then the solutions $\mathbf{z}_\pm$ will give a large gradient, whereas the solution $\mathbf{z}_M$ will not.

To quantify this reasoning we can write our least squares equations as

$$\mathbf{G}(\mathbf{z}, \mathbf{d}) = \mathbf{0}. \tag{5.1}$$

When we change $\mathbf{d}$ by an amount $\delta\mathbf{d}$, the change in the solution $\mathbf{z}$ satisfies

$$\frac{\partial \mathbf{G}}{\partial \mathbf{z}}\delta\mathbf{z} + \frac{\partial \mathbf{G}}{\partial \mathbf{d}}\delta\mathbf{d} = \mathbf{0}. \tag{5.2}$$

This shows us that

$$\delta\mathbf{z} = R\delta\mathbf{d} \tag{5.3}$$

where

$$R = -\left(\frac{\partial \mathbf{G}}{\partial \mathbf{z}}\right)^{-1}\frac{\partial \mathbf{G}}{\partial \mathbf{d}}. \tag{5.4}$$

We can write

$$\frac{(\delta\mathbf{z})^T(\delta\mathbf{z})}{(\delta\mathbf{d})^T(\delta\mathbf{d})} = \frac{(\delta\mathbf{d})^T R^T R(\delta\mathbf{d})}{(\delta\mathbf{d})^T(\delta\mathbf{d})}. \tag{5.5}$$

The direction $\delta\mathbf{d}$ that causes the greatest change in the solution is given by the eigenvector $\mathbf{q}$ associated with the largest eigenvalue of $R^T R$. This suggests that we define the sensitivity as

$$\textit{sensitivity} = \text{largest eigenvalue of } R^T R \tag{5.6}$$

It follows that we can determine the sensitivity of the solutions by looking at the largest eigenvalue of $R^T R$. Using this measure, the solutions $\mathbf{z}_\pm$ will have a large sensitivity, and the solution $\mathbf{z}_M$ will have an order one sensitivity.

6. Example from TOA geolocation. We will now describe the application where the bifurcation was observed. The location $\mathbf{x}$ of a radio frequency (RF) emitter can be determined by measuring time of arrival t_k of the RF signal at a geographically dispersed constellation of receivers with positions $\mathbf{s}_k$ using the relation

$$| \mathbf{x} - \mathbf{s}_k | = \tau_k - \tau \quad \text{for } k = 1, N, \tag{6.1}$$

where τ_k is the arrival time times the speed of light; i.e., $\tau_k = ct_k$ and τ is the similarly scaled signal transmission time, which is also a solution variable. There are four unknowns in this problem: the 3×1 vector $\mathbf{x}$ and τ. We will consider the case of five receivers giving five equations, which make an overdetermined system.

Equation (6.1) is also used for the navigation problem where an RF receiver wishes to locate its self using signals transmitted from a constellation of overhead transmitters, such as GPS. Here the transmit time of any section of the received signal can be determined from the modulation impressed on the signal. The GPS satellites carry accurate clocks so that we can assume the transmit time to be known exactly. The receiver, however, measures the signal arrival time with a clock that has an unknown bias. For this application τ_k in (6.1) is the receiver's estimate of the range to satellite k using its biased clock and τ is the clock bias, which must be solved for along with the receiver's position. Again we will consider the case of five satellites giving five equations in four unknowns, $\mathbf{x}$ and τ.

It is easier to treat these equations algebraically if we square both sides to get the equations

$$| \mathbf{x} - \mathbf{s}_k |^2 = (\tau_k - \tau)^2 \quad \text{for } k = 1, N. \tag{6.2}$$

This gives us N equations for the four unknowns $\mathbf{x}$ and τ. We will write this as a four-dimensional vector of unknowns

$$\mathbf{z}^T = (\mathbf{x}^T, \tau). \tag{6.3}$$

and keeping with the notation used throughout this paper, the overdetermined system of (6.2) is written as $\mathbf{f}(\mathbf{z}) = 0$. The Jacobian $\mathbf{J}(\mathbf{z})$ is obtained by linearizing $\mathbf{f}(\mathbf{z})$ about the vector $\mathbf{z}$.

$$\mathbf{J}\delta\mathbf{z} = \delta\mathbf{f} \tag{6.4}$$

If we use the notation $\delta\mathbf{z}^T = (\delta\mathbf{x}^T, \delta\tau)$, we have

$$2\left(\mathbf{x} - \mathbf{s}_k\right)^T \delta\mathbf{x} + 2\left(\tau_k - \tau\right)\delta\tau = kth \text{ component of } \mathbf{J}\delta\mathbf{z}. \tag{6.5}$$

If the system is singular, this implies that there is a vector $\boldsymbol{\phi}$ such that $\mathbf{J}\boldsymbol{\phi} = 0$. If we write

$$\boldsymbol{\phi} = \begin{pmatrix} \mathbf{p} \\ \alpha \end{pmatrix}, \tag{6.6}$$

this implies that we have

$$\left(\mathbf{s}_k - \mathbf{x}\right)^T \mathbf{p} = (\tau_k - \tau)\alpha. \tag{6.7}$$

This can be written as

$$\mathbf{e}_k^T \mathbf{p} = \alpha \quad \text{for } k = 1, N, \tag{6.8}$$

where

$$\mathbf{e}_k = \frac{\mathbf{s}_k - \mathbf{x}}{\tau_k - \tau} = \frac{\mathbf{s}_k - \mathbf{x}}{\mid \mathbf{x} - \mathbf{s}_k \mid}. \tag{6.9}$$

Geometrically, (6.8) implies that the satellites all lie on a cone whose vertex is at the receiver $\mathbf{x}$.

In GPS the sensitivity to location errors arising from errors in the data is typically defined using the GDOP. The GDOP is defined as $GDOP = \sqrt{tr(\mathbf{H}^{-1})}$. Clearly the GDOP becomes large when the Hessian $\mathbf{H} = \mathbf{J}^T\mathbf{J}$ becomes nearly singular. Hence, in the language of GPS, we are considering situations where the satellite configurations have extremely large GDOP.

In [8] we show that the least squares solution to these equations can be obtained by solving a ninth order eigenvalue problem. We also show that there is something quite degenerate about the situation in GPS problems where all of the satellites are equidistant from the center of the earth. This is a very common situation in GPS problems, but it is not the only situation of interest. In our singular cases, it turns out that when the satellites are at equal radius, the coefficient c_3 in (3.14) comes out to be extremely close to zero. This makes such situations even more degenerate than the case we have discussed in this paper. For this reason we chose examples from situations where not all of the satellites are at the same radius. In particular, we will have four satellites at the middle earth orbit (MEO) radius, and one of them at geosynchronous earth orbit (GEO) radius. This corresponds to a wide area augmentation system (WAAS) augmented GPS contellation of satellites. We use coordinates made dimensionless by the radius of the earth. In this case, four of our satellites have a radius of 4.16, and the fifth has a radius of $2^{2/3}$ times this. In the example we use, the satellites have the following positions:

$$\begin{pmatrix} \mathbf{s}_1^T \\ \mathbf{s}_2^T \\ \mathbf{s}_3^T \\ \mathbf{s}_4^T \\ \mathbf{s}_5^T \end{pmatrix} = \begin{pmatrix} (.87299, 1.87293, 6.27191) \\ (2.13601, 0.55425, 3.52644) \\ (2.39458, 0.13330, 3.39908) \\ (2.00895, 0.68732, 3.57732) \\ (2.22186, 0.44388, 3.48882) \end{pmatrix} \tag{6.10}$$

The particular noise vector we are using is

$$\mathbf{n} = \begin{pmatrix} 0.57112950 \\ 0.97354900 \\ 0.43808954 \\ 0.97092952 \\ 0.41250846 \end{pmatrix}. \tag{6.11}$$

Table 6.1 shows the residual, location error, and sensitivity for the three different solutions, and for different amounts of noise levels. In all cases, the solution $\mathbf{z}_M$ has the largest residual, but the smallest location error and sensitivity. Figure 6.1 shows a log-log plot of the error as a function of ϵ for the solutions $\mathbf{z}_M$ and $\mathbf{z}_+$. The plot shows that the error for $\mathbf{z}_M$ is varying linearly with ϵ, and that for $\mathbf{z}_+$ is varying like $\sqrt{\epsilon}$.

TABLE 6.1

This shows the residual, resid $= |\mathbf{f}(\mathbf{z})|$, the location error, e_{loc}, and the sensitivity (as defined in (5.6) for the three different solutions at noise levels of $\epsilon = 1.e-4$, $\epsilon = 1.e-5$, and $\epsilon = 1.e-6$. Note that in all cases, the residual for $\mathbf{z}_M$ is the largest, and the location error and sensitivity are the smallest.

Solution	ϵ	resid	e_{loc}	σ_{sens}
$\mathbf{z}_+$	$1.e-4$	$1.88e-4$	$1.85e-1$	$3.67e7$
$\mathbf{z}_-$	$1.e-4$	$2.07e-4$	$1.86e-1$	$6.16e7$
$\mathbf{z}_M$	$1.e-4$	$2.32e-4$	$1.72e-2$	$1.16e6$
$\mathbf{z}_+$	$1.e-5$	$1.94e-5$	$5.88e-2$	$4.32e8$
$\mathbf{z}_-$	$1.e-5$	$2.00e-5$	$5.89e-2$	$5.09e8$
$\mathbf{z}_M$	$1.e-5$	$2.31e-5$	$1.71e-3$	$1.10e6$
$\mathbf{z}_+$	$1.e-6$	$1.97e-6$	$1.86e-2$	$4.56e9$
$\mathbf{z}_-$	$1.e-6$	$1.98e-6$	$1.86e-2$	$4.79e9$
$\mathbf{z}_M$	$1.e-6$	$2.31e-6$	$2.28e-4$	$2.14e5$

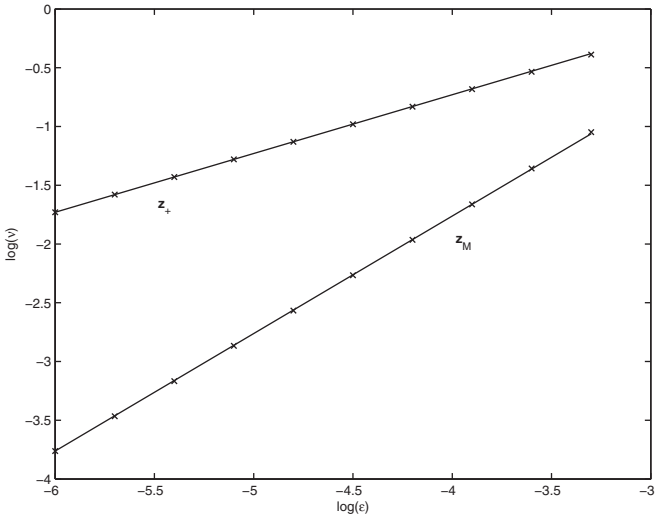

FIG. 6.1. *This gives a log-log plot of the errors of the low residual solution $\mathbf{z}_M$ and one of the larger residual solutions $\mathbf{z}_+$. The continuous lines have slopes of* 1 *and* .5*, and the numerical data are marked by crosses. The plot shows that the error for $\mathbf{z}_M$ is linear in ϵ, and the error for $\mathbf{z}_+$ varies as $\sqrt{\epsilon}$. A similar plot would show that the error in $\mathbf{z}_-$ varies like $\sqrt{\epsilon}$, but we have not shown it here since it would almost completely overlie the plot for $\mathbf{z}_+$.*

As mentioned in the introduction, if we have five satellites, the conditions in (6.8) are generic if we allow two parameters to vary. For example, if we specify the positions of the satellites, the equations (6.8) specifying that we have a degenerate configuration can be considered to be five equations for the three components of $\mathbf{p}/\alpha$. This gives five equations in three unknowns. This shows that generically we do not expect to have a degenerate configuration. However, if we allow the point $\mathbf{x}$ being located to move around on the surface of the earth, this gives us two more unknowns, and we get five equations in five unknowns. For a given configuration of satellites, we are not guaranteed that there will be a point $\mathbf{x}$ on the surface of the earth that gives a degenerate configuration, but it is generic for such a situation to occur. That is, if we arrange for such a situation, and then perturb the satellites, we can find a new point on earth that gives us a degenerate configuration.

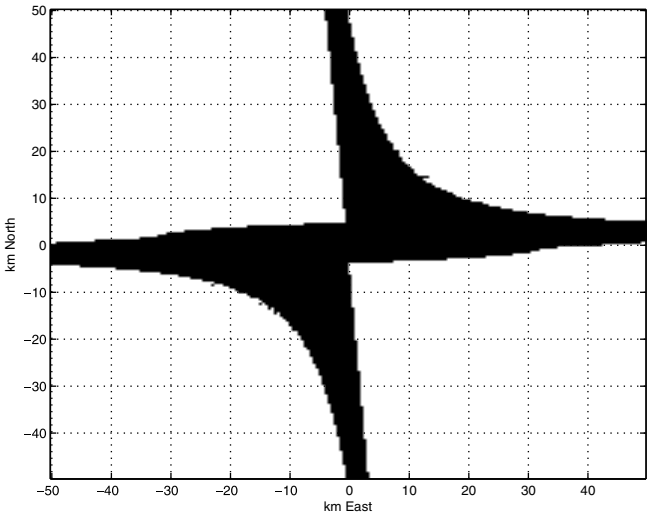

FIG. 6.2. *This shows a plot of the region surrounding a singularity where the most accurate solution does not have the smallest residual. In making this plot, the same noise was added to all of the locations. The noise had a magnitude of* 100 *nanoseconds, which is equivalent to an error of about* 30 *meters. The point where the system is exactly singular is in the middle of the figure.*

We have carried out simulations using true satellite trajectories. In these simulations we once again put four of the satellites at MEO radius, and one of the satellites at the GEO radius. However, rather than purposely putting the satellites in a degenerate configuration, we generated a million different configurations of satellites consistent with actual satellite trajectories. When the noise level was 0.001 earth radii (approximately 21 microseconds), we found that in about one out of every five thousand trials, we would get situations where the solution with the smallest residual was not the solution with the smallest error. When such a situation occurred, we found that we could adjust the position of the point being located (using Newton's method) so that we in fact had a degenerate situation where (6.8) was satisfied.

As another illustration, we once again used true satellite trajectories where one of the satellites was at GEO and the other four satellites were at MEO radius. This time we added 100 nanosecond noise to the data (equivalent to about a 30 meter error for a well-conditioned system). Out of a million trials we found four configurations where the smallest residual did not give the most accurate location. We took one of these solutions and determined the exact location of the nearby singularity. We then surrounded this point by a grid of points, and used the TOA equations with the same fixed satellite positions and fixed TOA noise vector to locate a receiver at each point on this grid. Figure 6.2 shows the region around the singularity where the most accurate solution is not the one with the smallest residual. We see that there is a central core around the singularity where this phenomenon occurs, but it spreads out in some narrow arms to quite large distances.

7. Conclusions. We have proven a general theorem concerning the solutions to nonlinear least squares problems in the neighborhood of a singularity of the equations. We have shown that in the neighborhood of a point where the Hessian has a one-dimensional null space, we will have three solutions $\mathbf{z}_\pm$ and $\mathbf{z}_M$. The general theory shows that the solution $\mathbf{z}_M$ will have the largest residual when evaluating the objective function, but it will have the smallest error when compared to the exact scripted

solution. We have shown that the solution $\mathbf{z}_M$ can be picked out of the three candidate solutions based on the fact that it is less sensitive to perturbations in the data.

A CHARACTERIZATION OF EFFICIENT AND WEAKLY EFFICIENT POINTS IN CONVEX VECTOR OPTIMIZATION*

KRISTIN WINKLER†

Abstract. We present efficiency criteria for multicriteria problems with $\mathcal{C}(T)$-valued maps via directional derivatives and subdifferentials. It turns out that the essential structure of similar results known for $\mathbb{R}^n$-valued optimization problems remains valid. As an improvement, our formulas allow us to distinguish between efficient and weakly efficient elements.

Key words. vector-valued optimization, efficiency criteria, convex optimization

DOI. 10.1137/060674363

1. Introduction.

We consider the vector-valued optimization problem

$$\mathfrak{f}(x) \to \min, \qquad x \in X \subset \mathfrak{X},$$

with $\mathfrak{f} : \mathfrak{X} \to \mathcal{C}(T)$. $\mathcal{C}(T)$ denotes the space of continuous real-valued functions on a compact separated Hausdorff space T. Further, let $\mathfrak{X}$ be a locally convex space, and let X be a nonempty subset of $\mathfrak{X}$. The aim of our paper is to study efficiency criteria for this problem via directional derivatives and subdifferentials known from convex analysis.

There are at least two good reasons for investigating mappings with values in $\mathcal{C}(T)$:

- Location problems frequently consist of identifying an optimal location $x \in \mathbb{R}^2$ for a new facility with respect to n reference facilities $a_1, \dots, a_n \in \mathbb{R}^2$ (for instance customers ...). Modeling them as a multicriteria problem, one gets a goal function $f : \mathbb{R}^2 \to \mathbb{R}^n$,

$$f(x) := \begin{pmatrix} d_1(x, a_1) \\ \vdots \\ d_n(x, a_n) \end{pmatrix},$$

  with distance functions $d_i : \mathbb{R}^2 \to \mathbb{R}$. If we consider a whole service area (for instance, a complete district of a town) instead of a finite number of service points a_i, this problem finds a natural extension in a multicriteria problem with goal function $g(x)(t) := d_t(x, a(t))$. Here, $t \in T$ represents a single point in the service area T. In the simpliest version, for instance, with $d_t(x, a(t)) := \|x - t\|$, g is a function with values in the space of continuous functions over the area T. So, at the end, one has to identify efficient elements in (a subset of) the space $\mathcal{C}(T)$.
- The space $\mathcal{C}(T)$ marks an important stage between the finite-dimensional Euclidean space $\mathbb{R}^n$ and general partially ordered vector spaces. $\mathcal{C}(T)$ with

its natural componentwise ordering $\mathcal{C}(T)^+$ is not order complete; the cone $\mathcal{C}(T)^+$ does not possess the Daniell property and is not nuclear. Therefore, the space $\mathcal{C}(T)$ lacks essential analytic and order theoretic properties. On the other hand, componentwise calculus—i.e., using realizations $y(t)$, $t \in T$ of functions $y \in \mathcal{C}(T)$, allows us to use definitions and ideas from $\mathbb{R}^n$.

In [22], we proved a characterization of weakly efficient points in $\mathcal{C}(T)$ based on subdifferentials for convex functions. [2] and [11] presented similar results for general distance functions on $\mathbb{R}^n$. But these papers contain only results concerning weak efficiency. Now we add formulas which distinguish efficient points from weak efficient points.

The extensions of the notion of subdifferential (and its applications) from the scalar to the vector-valued case have been investigated for more than 30 years. Early results go back, for instance, to [5, 12, 20, 21]. At a second stage, as the papers of [1, 8, 17, 18, 19] show, the properties of the partial ordering that guarantee existence of subgradients moved into the center of attention. Order completeness and/or Daniell property emerged as essential ingredients for a workable subdifferential theory—the reason why we can not use these results in $\mathcal{C}(T)$. Finally, [9, 14, 13] proposed efficiency criteria on the basis of subdifferentials for a different minimality notion.

This paper is divided as follows: In the next section we repeat some basic notions that we use in this paper, and sections 3–5 contain the main results.

2. Basic notions and preliminaries. Let $\mathfrak{X}$ be a locally convex space, denote by $\mathfrak{X}'$ its topological dual space. As usual, we denote by $\operatorname{int} M$ the topological interior of a subset $M \subseteq \mathfrak{X}$ and by $\operatorname{cl} M$ its closure. $M_1 + M_2$ denotes the pointwise sum of two subsets M_1, M_2 of a vector space, and we write shortly $M + m$ for $M + \{m\}$. Remember that the *algebraic interior* of a set $M \subset \mathfrak{X}$ is given by $\operatorname{core} M := \{x \in M : \forall\, y \in \mathfrak{X}\ \ \exists\, \lambda > 0,\ x + \lambda y \in M\}$.

Let $X \subset \mathfrak{X}$ be a nonempty convex set. The *normal cone* at X in $\bar{x}$ is given by

$$N(X; \bar{x}) = \{p \in \mathfrak{X}' :\ p(x - \bar{x}) \leq 0\ \ \forall\, x \in X\}.$$

Note that $N(X; \bar{x})$ is weak*-closed.

Let T be a compact space. The space $\mathcal{C}(T)$ of all real-valued continuous functions $y : T \to \mathbb{R}$ endowed with the maximum norm

$$\|y\| := \max_{t \in T} |y(t)|, \qquad y \in \mathcal{C}(T),$$

is a Banach space itself. Together with its order cone

$$\mathcal{C}(T)^+ := \{y \in \mathcal{C}(T) :\ y(t) \geq 0\ \ \forall\, t \in T\},$$

$\mathcal{C}(T)$ is a partially ordered vector lattice. It can be shown that

$$\operatorname{int} \mathcal{C}(T)^+ := \{y \in \mathcal{C}(T) :\ y(t) > 0\ \ \forall\, t \in T\}.$$

There exist bases for the cone $\mathcal{C}(T)^+$, but no bounded base. In general, the space $(\mathcal{C}(T), \mathcal{C}(T)^+)$ is not order-complete, does not satisfy the Daniell property, and is not nuclear (for further details on these properties compare, for instance, the monographs of [4] and [10]).

Let $X \subset \mathfrak{X}$ be a nonempty subset, and let $\mathfrak{f} : \mathfrak{X} \to \mathcal{C}(T)$. An element $\bar{x} \in X$ is called *efficient in X with respect to* $\mathfrak{f}$ if

$$\mathfrak{f}(X) \cap (\mathfrak{f}(\bar{x}) - \mathcal{C}(T)^+ \backslash \{0\}) = \emptyset.$$

$\bar{x} \in X$ is called *weakly efficient in X with respect to* $\mathfrak{f}$ if

$$\mathfrak{f}(X) \cap (\mathfrak{f}(\bar{x}) - \operatorname{int} \mathcal{C}(T)^+) = \emptyset.$$

The set of all (weakly) efficient elements in X with respect to $\mathfrak{f}$ is denoted by $\operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+)$, and $\operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+)$, respectively. Obviously $\operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+) \subseteq \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+)$.

A function $\mathfrak{f} : \mathfrak{X} \to \mathcal{C}(T)$ is said to be *convex* iff

$$\forall\ x, y \in \mathfrak{X},\ \forall\ \lambda \in [0,1], \quad \lambda \mathfrak{f}(x) + (1-\lambda)\mathfrak{f}(y) \in \mathfrak{f}(\lambda x + (1-\lambda)y) + \mathcal{C}(T)^+,$$

i.e., if the functions $x \mapsto \mathfrak{f}(x)(t)$ are convex for all $t \in T$. Note that the classical definitions of generalized derivatives for real-valued convex functions can be applied to such functions $x \mapsto \mathfrak{f}(x)(t)$: For $t \in T$ we denote by

$$\mathfrak{f}^\circ(\bar{x}; d)(t) := \lim_{\tau \downarrow 0} \frac{\mathfrak{f}(\bar{x} + \tau d)(t) - \mathfrak{f}(\bar{x})(t)}{\tau} \tag{2.1}$$

the *directional derivative* of the function $x \mapsto \mathfrak{f}(x)(t)$ in $\bar{x}$ and direction d. Further, we call

$$\partial \mathfrak{f}(\bar{x})(t) := \{p \in \mathfrak{X}' :\ p(x - \bar{x}) \le \mathfrak{f}(x)(t) - \mathfrak{f}(\bar{x})(t)\ \ \forall\ x \in X\} \tag{2.2}$$

the *subdifferential* (in the sense of convex analysis) of $x \mapsto \mathfrak{f}(x)(t)$ in $\bar{x}$. If $\mathfrak{X}$ is a Banach space and if the function $x \mapsto \mathfrak{f}(x)(t)$ is convex and Lipschitz near $\bar{x} \in \mathfrak{X}$, then we have

$$\mathfrak{f}^\circ(\bar{x}; d)(t) := \max\{p(d) :\ p \in \partial \mathfrak{f}(\bar{x})(t)\}, \qquad t \in T. \tag{2.3}$$

Note that $\mathfrak{f}^\circ(x; d)(.)$ may be not continuous. In this point, our concept of generalized derivatives for $\mathcal{C}(T)$-valued functions differs completely from those concepts for vector-valued functions known in literature.

3. Efficiency conditions via directional derivatives. We start with a necessary and sufficient condition for weakly efficient elements.

THEOREM 3.1. *Let $\mathfrak{X}$ be a locally convex space, $X \subset \mathfrak{X}$ a convex subset, and T a compact space. Let $\mathfrak{f} : \mathfrak{X} \to \mathcal{C}(T)$ be a convex map. Then we have for $\bar{x} \in X$*

$$\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) \ge 0\ \ \forall\ x \in X \quad \Longleftrightarrow \quad \bar{x} \in \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+). \tag{3.1}$$

Proof. From the definition of weak efficiency, the continuity of the functions $\mathfrak{f}(x)(.)$, and the compactness of T we deduce that

$$\begin{aligned} &\bar{x} \notin \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) \\ &\Longleftrightarrow \quad \exists\ x \in X,\ \exists\ M < 0 :\ \ \mathfrak{f}(x)(t) - \mathfrak{f}(\bar{x})(t) \le M\ \ \forall\ t \in T. \end{aligned} \tag{3.2}$$

With $\tau = 1$, assertion (3.2) can be written as

$$\begin{aligned} &\bar{x} \notin \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) \\ &\Longleftrightarrow \quad \exists\ x \in X,\ \exists\ M < 0 :\ \ \frac{\mathfrak{f}(\bar{x} + \tau(x - \bar{x}))(t) - \mathfrak{f}(\bar{x})(t)}{\tau} \le M\ \ \forall\ t \in T. \end{aligned}$$

The convexity of X yields $\bar{x} + \tau(x - \bar{x}) \in X$ for $0 < \tau \leq 1$. By convexity of $\mathfrak{f}(.)(t)$, the difference quotients are monotone-decreasing as a function of τ for $\tau \downarrow 0$, hence

$$\begin{aligned} & \bar{x} \notin \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) \\ \Longrightarrow \quad & \exists\, x \in X,\ \exists\, M < 0 : \quad \mathfrak{f}^\circ(\bar{x}, x - \bar{x})(t) \leq M \quad \forall\, t \in T \\ \Longrightarrow \quad & \exists\, x \in X : \quad \sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) < 0. \end{aligned}$$

The contraposition of this assertion yields

$$\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) \geq 0 \quad \forall\, x \in X \quad \Longrightarrow \quad \bar{x} \in \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+),$$

which completes the first part of the proof.

To verify sufficiency, assume $\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x}) < 0$ for some $x \in X$, i.e., $\mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) < 0$ for all $t \in T$. Therefore, for each $t \in T$, there exists some $\varepsilon(t) > 0$ such that

$$\mathfrak{f}(\bar{x} + \tau(x - \bar{x}))(t) < \mathfrak{f}(\bar{x})(t) \qquad \forall\, \tau,\ 0 < \tau < \varepsilon(t),\ \forall\, t \in T.$$

For each $\tau > 0$ with $\bar{x} + \tau(x - \bar{x}) \in X$, we consider the set

$$U_\tau := \{t \in T :\ \mathfrak{f}(\bar{x} + \tau(x - \bar{x}))(t) < \mathfrak{f}(\bar{x})(t)\}.$$

Due to the continuity of the functions, the sets U_τ are open in the relative topology. Further, by the convexity of the functions $\mathfrak{f}(.)(t)$, $t \in U_\tau$ implies that $t \in U_\alpha$ for all $0 < \alpha < \tau$. Therefore $\bigcup_{\{\tau > 0:\ \bar{x} + \tau(x - \bar{x}) \in X\}} U_\tau$ is an open cover of T. Since T is compact, there exist a finite number of $\tau_1, \ldots, \tau_n > 0$, $\bar{x} + \tau_i(x - \bar{x}) \in X$ such that $T = \bigcup_{i=1}^n U_{\tau_i}$. Let $\bar{\tau} := \min\{\tau_1, \ldots, \tau_n\}$. Then we have $\bar{x} + \bar{\tau}(x - \bar{x}) \in X$ and $\mathfrak{f}(\bar{x} + \bar{\tau}(x - \bar{x}))(t) < \mathfrak{f}(\bar{x})(t)$ for all $t \in T$. This yields $\bar{x} \notin \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+)$. ∎

The idea of the last part is taken from [11].

Since $\operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+) \subseteq \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+)$, equivalence (3.1) can be interpreted as a necessary condition for efficient points. In the next theorem, we add a sufficient condition.

THEOREM 3.2. *Under the assumptions of Theorem* 3.1*,*

$$\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) > 0 \quad \forall\, x \in X,\ \mathfrak{f}(x) \neq \mathfrak{f}(\bar{x})$$

is sufficient for $\bar{x} \in \operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+)$.

Proof. Using the definition of efficiency, we deduce that

$$\begin{aligned} & \bar{x} \notin \operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+) \\ \Longleftrightarrow \quad & \exists\, x \in X,\ \mathfrak{f}(x) \neq \mathfrak{f}(\bar{x}) : \quad \mathfrak{f}(x)(t) - \mathfrak{f}(\bar{x})(t) \leq 0 \quad \forall\, t \in T. \end{aligned} \tag{3.3}$$

We continue as in the first part of the proof of Theorem 3.1 and get

$$\begin{aligned} & \bar{x} \notin \operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+) \\ \Longrightarrow \quad & \exists\, x \in X,\ \mathfrak{f}(x) \neq \mathfrak{f}(\bar{x}) : \quad \mathfrak{f}^\circ(\bar{x}, x - \bar{x})(t) \leq 0 \quad \forall\, t \in T \\ \Longrightarrow \quad & \exists\, x \in X,\ \mathfrak{f}(x) \neq \mathfrak{f}(\bar{x}) : \quad \sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) \leq 0. \end{aligned}$$

So, if $\bar{x} \in X$ and if for all $x \in X$ either $\mathfrak{f}(x) = \mathfrak{f}(\bar{x})$ or $\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x}) > 0$ holds, then $\bar{x} \in \operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+)$. ∎

In comparison to Theorem 3.2, the condition for weak efficiency is necessary as well as sufficient. This agrees with corresponding results in real-valued optimization. The strict inequality in Theorem 3.2 is not necessary for efficiency: Consider the example $\mathfrak{f}(x)(t) = x^2$, $t \in T$, at $\bar{x} = 0$.

Example 3.1. We consider the function $\mathfrak{f} : [-1,1] \to \mathcal{C}([-1,1])$ defined by

$$\mathfrak{f}(x)(t) := \max\{x, t\}, \quad t \in T = [-1,1].$$

$\mathfrak{f}$ is $\mathcal{C}(T)^+$-convex, $\mathrm{Eff}\,(\mathfrak{f}([-1,1]), \mathcal{C}(T)^+) = \{-1\}$ and $\mathrm{Eff}_w(\mathfrak{f}([-1,1]), \mathcal{C}(T)^+) = [-1,1]$. The directional derivative in direction $x - \bar{x}$, $x \in [-1,1]$, $x \neq \bar{x}$, can be calculated as

$$\mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) = \begin{cases} x - \bar{x} & \text{for} \quad -1 \le t < \bar{x} \ \text{ or } \ t = \bar{x} < x, \\ 0 & \text{for} \quad \bar{x} < t \le 1 \ \text{ or } \ t = \bar{x} > x, \end{cases}$$

$$\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) = \begin{cases} 0 & \text{for} \quad -1 \le x < \bar{x}, \\ x - \bar{x} & \text{for} \quad \bar{x} < x \le 1. \end{cases}$$

We deduce that $\sup_{t \in T} \mathfrak{f}^\circ(\bar{x}; x - \bar{x})(t) \ge 0$ for all $\bar{x}, x \in [-1,1]$, but the sufficient condition for efficiency is fulfilled only for $\bar{x} = -1$.

4. Efficiency conditions via subdifferentials—absence of constraints. In a similar way as in the theorems above we can prove assertions based on convex subdifferentials. In the following, $\sigma(\mathfrak{X}', \mathfrak{X})$ represents the weak* topology on $\mathfrak{X}'$.

THEOREM 4.1. *Let $\mathfrak{X}$ be a real Banach space, $\bar{x} \in \mathfrak{X}$, and T a compact space. Let $\mathfrak{f} : \mathfrak{X} \to \mathcal{C}(T)$ be a convex mapping such that the functions $x \mapsto \mathfrak{f}(x)(t)$ are Lipschitz near $\bar{x}$. Then we have*

$$0 \in \mathrm{cl}_{\sigma(\mathfrak{X}', \mathfrak{X})} \mathrm{conv} \bigcup_{t \in T} \partial \mathfrak{f}(\bar{x})(t) \iff \bar{x} \in \mathrm{Eff}_w(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+),$$

$$0 \in \mathrm{core}\, \mathrm{cl}_{\sigma(\mathfrak{X}', \mathfrak{X})} \mathrm{conv} \bigcup_{t \in T} \partial \mathfrak{f}(\bar{x})(t) \implies \bar{x} \in \mathrm{Eff}\,(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+).$$

Proof. We claim that

$$\begin{aligned} &\bar{x} \notin \mathrm{Eff}_w(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+) \\ &\iff \quad \exists\, x \in \mathfrak{X},\ \exists\, M < 0,\ \forall\, p \in \bigcup_{t \in T} \partial \mathfrak{f}(\bar{x})(t) : \quad p(x - \bar{x}) \le M. \end{aligned} \tag{4.1}$$

Indeed, the definition of the subdifferential (2.2), together with the characterization (3.2), yields necessity; sufficiency can be deduced from (2.3) and (3.1). Due to the linearity and the continuity of the functionals $p \mapsto p(x - \bar{x})$, assertion (4.1) remains valid even if we consider all p in the $\sigma(\mathfrak{X}', \mathfrak{X})$-closure of the convex hull of $\bigcup_{t \in T} \partial \mathfrak{f}(\bar{x})(t)$. Hence

$$\begin{aligned} &\bar{x} \notin \mathrm{Eff}_w(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+) \\ &\iff \quad \exists\, x \in \mathfrak{X},\ \exists\, M < 0,\ \forall\, p \in \mathrm{cl}_{\sigma(\mathfrak{X}', \mathfrak{X})} \mathrm{conv} \bigcup_{t \in T} \partial \mathfrak{f}(\bar{x})(t) : \quad p(x - \bar{x}) \le M. \end{aligned}$$

Now we apply a separation theorem (e.g., [6], Theorem 3.18) for a point and a closed convex set in $\mathfrak{X}'$, equipped with the weak* topology $\sigma(\mathfrak{X}', \mathfrak{X})$, i.e., with dual space $\mathfrak{X}$, and get

$$\bar{x} \notin \mathrm{Eff}_w(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+) \iff 0 \notin \mathrm{cl}_{\sigma(\mathfrak{X}', \mathfrak{X})} \mathrm{conv} \bigcup_{t \in T} \partial \mathfrak{f}(\bar{x})(t).$$

Contraposition yields the wanted assertion for weakly efficient elements.

On the other hand, inserted in (3.3), the definition of the subdifferential (2.2) yields

$$\begin{aligned} &\bar{x} \notin \operatorname{Eff}(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+) \\ \Longrightarrow \quad &\exists\, x \in \mathfrak{X}\backslash\{\bar{x}\}: \quad p(x-\bar{x}) \le 0 \ \ \forall\, p \in \bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t). \end{aligned} \tag{4.2}$$

Again, due to the linearity and the continuity of the functionals $p \mapsto p(x-\bar{x})$, assertion (4.2) remains valid even if we consider all p in the weak*-closed convex hull of $\bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)$. A restriction to the algebraic interior of $\operatorname{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\operatorname{conv} \bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)$, if nonempty, allows us to strengthen the inequality to a strict inequality:

$$\begin{aligned} &\bar{x} \notin \operatorname{Eff}(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+) \\ \Longrightarrow \quad &\exists\, x \in \mathfrak{X}\backslash\{\bar{x}\}: \ p(x-\bar{x}) < 0 \ \ \forall\, p \in \operatorname{core}\operatorname{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\operatorname{conv} \bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t). \end{aligned}$$

Therefore 0 cannot be an element in the convex hull of the subdifferentials. Finally, contraposition yields that $0 \in \operatorname{core}\operatorname{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\operatorname{conv} \bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)$ is sufficient for $\bar{x} \in \operatorname{Eff}(\mathfrak{f}(\mathfrak{X}), \mathcal{C}(T)^+)$. □

Remark 4.1. By a result of [15], a convex function $f : \mathfrak{X} \to \mathbb{R}$ on a Banach space is Lipschitz near any point x of an open convex set $X \subset \mathfrak{X}$ if it is bounded above on a neighborhood of some point of X. So, boundedness can replace the Lipschitz assumption.

5. Efficiency conditions via subdifferentials—presence of constraints. Including constraints into the problem, we get the following characterization of (weak) efficient elements.

THEOREM 5.1. *Let $\mathfrak{X}$ be a Banach space, $X \subset \mathfrak{X}$ a closed convex set, $\bar{x} \in X$ and T a compact space. Assume $\mathfrak{f} : \mathfrak{X} \to \mathcal{C}(T)$ to be a convex mapping such that the functions $x \mapsto \mathfrak{f}(x)(t)$ are Lipschitz near $\bar{x}$. Then we have*

$$0 \in \operatorname{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\operatorname{conv}\left(\bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)\right) + N(X;\bar{x}) \Longleftrightarrow \bar{x} \in \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+),$$

$$0 \in \operatorname{core}\left(\operatorname{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\operatorname{conv}\left(\bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)\right) + N(X;\bar{x})\right) \Longrightarrow \bar{x} \in \operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+).$$

We need two technical results.

LEMMA 5.2. *Under the assumptions of Theorem* 5.1*, the set $\bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)$ is norm bounded in $\mathfrak{X}'$.*

Proof. For $h \in \mathfrak{X}$ we estimate that

$$\begin{aligned} \sup\{p(h): \ p \in \bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)\} &= \sup_{t\in T} \ \sup\{p(h): \ p \in \partial\mathfrak{f}(\bar{x})(t)\} \\ &\le \sup_{t\in T} \ (\mathfrak{f}(\bar{x}+h)(t) - \mathfrak{f}(\bar{x})(t)) \\ &= \max_{t\in T} \ (\mathfrak{f}(\bar{x}+h)(t) - \mathfrak{f}(\bar{x})(t)) \\ &< +\infty. \end{aligned}$$

Hence the set $\bigcup_{t\in T} \partial\mathfrak{f}(\bar{x})(t)$ is $\sigma(\mathfrak{X}',\mathfrak{X})$-bounded and finally (since $\mathfrak{X}'$ is a Banach space) norm bounded in $\mathfrak{X}'$. □

The idea of this proof is from a paper of [11].

LEMMA 5.3. *Let M_1 and M_2 be two subsets of the dual space $\mathfrak{X}'$ of a Banach space $\mathfrak{X}$, and let M_1 be norm bounded. Then we have*

$$\mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}(M_1 + M_2) = \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}M_1 + \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}M_2.$$

Proof. Norm boundedness of M_1 implies the $\sigma(\mathfrak{X}',\mathfrak{X})$-compactness of $\mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}M_1$. Further it is known that the sum of a compact set and an arbitrary closed set is closed (in the same topology as the compactness is valid in). Therefore, the assertion of the lemma above is a consequence of the formula

$$\mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}(M_1 + M_2) = \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\left(\mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}M_1 + \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}M_2\right),$$

which holds for every topological vector space. □

Proof. (Theorem 5.1). To show sufficiency we apply the proof of Theorem 4.1 to the extended real-valued functions

$$\hat{\mathfrak{f}}(x)(t) := \mathfrak{f}(x)(t) + \delta_X(x), \qquad t \in T$$

where $\delta_X(.)$ denotes the indicator function of the set X, $\delta_X(x) = 0$ if $x \in X$ and $\delta_X(x) = +\infty$ else. We have

$$\partial\hat{\mathfrak{f}}(\bar{x})(t) = \partial\mathfrak{f}(\bar{x})(t) + N(X;\bar{x}), \qquad t \in T$$

(compare [3], Proposition 2.3.3 together with Corollary 3 and Proposition 2.3.6). Using the same ideas as in the proof of Theorem 4.1 we can show the following:

$$\bar{x} \notin \mathrm{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) \Longrightarrow 0 \notin \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\left(\bigcup_{t\in T}\partial\hat{\mathfrak{f}}(\bar{x})(t)\right),$$

$$\bar{x} \notin \mathrm{Eff}\,(\mathfrak{f}(X), \mathcal{C}(T)^+) \Longrightarrow 0 \notin \mathrm{core}\,\mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\left(\bigcup_{t\in T}\partial\hat{\mathfrak{f}}(\bar{x})(t)\right).$$

Applying the two lemmata above we derive

$$\bar{x} \notin \mathrm{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) \Longrightarrow 0 \notin \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\left(\bigcup_{t\in T}\partial\mathfrak{f}(x)(t)\right) + N(X;x),$$

$$\bar{x} \notin \mathrm{Eff}\,(\mathfrak{f}(X), \mathcal{C}(T)^+) \Longrightarrow 0 \notin \mathrm{core}\left(\mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\left(\bigcup_{t\in T}\partial\mathfrak{f}(x)(t)\right) + N(X;x)\right).$$

The contraposition of this implications yields the claimed assertions.

To verify necessity, let $0 \notin \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\left(\bigcup_{t\in T}\partial\mathfrak{f}(x)(t)\right) + N(X;x)$. By the strong separation theorem there exist $d \in \mathfrak{X}$ and $M < 0$ such that

$$(p_1 + p_2)(d) \le M < 0 \quad \forall\, p_1 \in \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\bigcup_{t\in T}\partial\mathfrak{f}(x)(t),\ \forall\, p_2 \in N(X;\bar{x}).$$

Since $N(X;\bar{x})$ is a cone, we get

$$\begin{aligned} &p_2(d) \le 0 \qquad \forall\, p_2 \in N(X;\bar{x}),\\ &p_1(d) \le M < 0 \quad \forall\, p_1 \in \mathrm{cl}_{\sigma(\mathfrak{X}',\mathfrak{X})}\mathrm{conv}\bigcup_{t\in T}\partial\mathfrak{f}(x)(t). \end{aligned}$$

The convexity of X yields $d \in T(X;\bar{x}) = \operatorname{cl} \bigcup_{\tau>0} \tau(X-\bar{x})$. Due to Lemma 5.2, the set $\bigcup_{t\in T} \partial \mathfrak{f}(x)(t)$ is bounded; therefore there exist for each $\tilde{d} \in \mathfrak{X}$ some $\varepsilon > 0$ such that

$$p_1(d+\varepsilon\tilde{d}) \le M/2 < 0 \quad \forall\, p_1 \in \bigcup_{t\in T} \partial \mathfrak{f}(x)(t).$$

Further there exist $\bar{d} \in \bigcup_{\tau>0} \tau(X-\bar{x})$ such that $p_1(\bar{d}) \le M/2 < 0$ for all $p_1 \in \bigcup_{t\in T} \partial \mathfrak{f}(x)(t)$. We get $\mathfrak{f}^\circ(\bar{x};\bar{d})(t) \le M/2 < 0$ for all $t \in T$ and $\bar{x} + \tau\bar{d} \in X$ for sufficiently small $\tau > 0$. By Theorem 3.1 this is a contradiction to the weak efficiency of $\bar{x}$. The contraposition of this result yields the wanted assertion. □

Plastria and Carrizosa [11] proved for $\mathcal{C}(T)^+$-convex maps $\mathfrak{f}$ the efficiency criterium

$$\bar{x} \in \operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) \iff 0 \in \operatorname{cl}\operatorname{conv}\left(\bigcup_{t\in T} \partial \mathfrak{f}(x)(t)\right) + N(X;x).$$

They choose another idea for their proof: They scalarized the vector-valued optimization problem by the functional

$$F(x) := \sup_{t\in T} [\mathfrak{f}(x)(t) - \mathfrak{f}(\bar{x})(t)] = \max_{t\in T} [\mathfrak{f}(x)(t) - \mathfrak{f}(\bar{x})(t)]$$

($\bar{x} \in X \subset \mathbb{R}^n$ fixed) and proved that

$$\partial F(x) = \operatorname{conv} \bigcup_{t\in T} \partial \mathfrak{f}(x)(t).$$

This idea also influenced our studies. In comparison to [11], we work in a Banach space $\mathfrak{X}$ instead of $\mathbb{R}^n$. Nevertheless, we could have applied the results of [16]; there we found a formula for the subdifferential of the pointwise maxima of infinitely many convex functions. But by this way it is not possible to distinguish between efficient and weakly efficient points.

Finally, let us continue Example 3.1.

Example 5.1. We consider the function $\mathfrak{f} : \mathbb{R} \to \mathcal{C}([-1,1])$ defined by

$$\mathfrak{f}(x)(t) := \max\{x,t\}, \quad t \in T = [-1,1],$$

and add now the constraint set $X = [-1,1]$. Remember $\operatorname{Eff}(\mathfrak{f}(X), \mathcal{C}(T)^+) = \{-1\}$ and $\operatorname{Eff}_w(\mathfrak{f}(X), \mathcal{C}(T)^+) = [-1,1]$. Obviously,

$$N(X;\bar{x}) = \begin{cases} \mathbb{R}^- & \text{for} \quad \bar{x} = -1, \\ \{0\} & \text{for} \quad -1 < \bar{x} < 1, \\ \mathbb{R}^+ & \text{for} \quad \bar{x} = 1. \end{cases}$$

The subdifferentials of the functions $x \mapsto \mathfrak{f}(x)(t)$ for $\bar{x} \in X$ can be calculated as

$$\partial \mathfrak{f}(\bar{x})(t) = \begin{cases} \{1\} & \text{for} \quad t < \bar{x}, \\ [0,1] & \text{for} \quad t = \bar{x}, \\ \{0\} & \text{for} \quad \bar{x} < t, \end{cases}$$

$$\operatorname{cl}\operatorname{conv} \bigcup_{t\in T} \partial \mathfrak{f}(\bar{x})(t) = [0,1].$$

So we verify $0 \in \operatorname{cl}\operatorname{conv} \bigcup_{t\in T} \partial \mathfrak{f}(\bar{x})(t) + N(X;\bar{x})$ for all $\bar{x} \in X$, but 0 is contained in the algebraic interior of $\operatorname{cl}\operatorname{conv} \bigcup_{t\in T} \partial \mathfrak{f}(\bar{x})(t) + N(X;\bar{x})$ only for $\bar{x} = -1$.

6. Conclusions. In this paper, we proved geometrical characterizations of efficient and weakly efficient points based on directional derivatives and subdifferentials in the sense of convex (real-valued) optimization. These assertions extend known results that provide only weakly efficient points.

In this paper, we focused on convex maps. It is possible to prove similar assertions for Lipschitz maps using results of [7], concerning optimality criteria for maximum functions. For more details, compare [23].

Acknowledgments. We are indebted to Prof. C. Zălinescu, University Iaşi (Romania) and the anonymous referees for helpful comments on the presented results.

THE PROXIMAL AVERAGE: BASIC THEORY*

HEINZ H. BAUSCHKE†, RAFAL GOEBEL‡, YVES LUCET§, AND XIANFU WANG†

Abstract. The recently introduced proximal average of two convex functions is a convex function with many useful properties. In this paper, we introduce and systematically study the proximal average for finitely many convex functions. The basic properties of the proximal average with respect to the standard convex-analytical notions (domain, Fenchel conjugate, subdifferential, proximal mapping, epi-continuity, and others) are provided and illustrated by several examples.

Key words. arithmetic average, arithmetic mean, convex analysis, convex function, epi-convergence, epigraphical average, epi-topology, essential smoothness, essential strict convexity, Fenchel conjugate, harmonic mean, Legendre function, Moreau envelope, proximal average, proximal mapping, subdifferential operator

1. Overview.

Let f_1 and f_2 be two functions that are convex, lower semicontinuous, and proper, and let λ_1 and λ_2 be strictly positive real numbers adding up to 1. How can we average the two functions f_1 and f_2 with respect to the weights λ_1 and λ_2 in a useful way? Perhaps the first approach is to consider the *arithmetic average* $\lambda_1 f_1 + \lambda_2 f_2$. However, functions in convex analysis are allowed to take on the value $+\infty$, for example, to model constraints in optimization problems. Thus, the arithmetic average can turn out to be $+\infty$ everywhere and then carries little information about f_1 and f_2; this happens whenever f_1 and f_2 are nowhere both finite. How could we possibly average such functions? A second thought may suggest to construct the *epigraphical average* $\lambda_1 \star f_1 \mathbin{\blacksquare} \lambda_2 \star f_2$ obtained by forming a convex combination of the epigraphs of f_1 and f_2. Unfortunately, if the functions f_1 and f_2 lack coercivity, then the epigraphical average fails to be helpful: For instance, if f_1 and f_2 are two distinct linear functions, then their epigraphical average is identically equal to $-\infty$, and hence of little use. The *proximal average*, first introduced in [5] in the context of fixed point theory and recently studied in [3, 4, 6, 8, 13] from various viewpoints, avoids the mentioned difficulties and possesses numerous properties that are attractive to convex analysts.

The aim of this paper is to provide the basic theory of the proximal average. In addition, we extend it to more than two functions, and we allow for an additional positive parameter. For the reader's convenience and the sake of completeness, the

presentation of the theory is largely self-contained. It is shown that the proximal average has many desirable properties in terms of its domain, Fenchel conjugate, Moreau envelope, proximal mapping, subdifferential, epi-continuity, and other convex-analytical notions. Moreover, the arithmetic and epigraphical averages turn out to be limits of the proximal average as the parameter tends to 0 and $+\infty$, respectively. Various examples illustrate our results. An interesting topic for future research is the extension to series and integrals.

The rest of this paper is organized as follows. Section 2 collects the notation used throughout this paper, and section 3 collects and presents results that simplify later proofs. The proximal average is introduced in section 4, where its domain is also characterized. In section 5, we present one very useful result (Theorem 5.1), which states that the Fenchel conjugate of the proximal average is the proximal average of the Fenchel conjugates. An important consequence of this result is that the proximal average is convex, lower semicontinuous, and proper. In section 6 we consider the Moreau envelope and proximal mapping of the proximal average. In section 7 we consider its subdifferential operator as well as essential smoothness and essential strict convexity. In section 8 it is shown that the arithmetic and epigraphical averages are pointwise limits of the proximal average. Epi-convergence properties are discussed in section 9, where the arithmetic and epigraphical averages are shown to be limiting instances of the proximal average with respect to epi-convergence.

2. Standing assumptions and notation. Throughout this paper,

(1) X is a real Hilbert space with inner product $\langle \cdot, \cdot \rangle$ and corresponding norm $\| \cdot \|$.

Due to its repeated use, we abbreviate the quadratic energy function by

$$\mathfrak{q} = \tfrac{1}{2}\| \cdot \|^2. \tag{2}$$

We set

$$\Gamma(X) = \big\{ f \colon X \to \left]-\infty, +\infty\right] \mid f \text{ is convex, lower semicontinuous, and proper} \big\}. \tag{3}$$

We assume throughout that

$$n \in \{1, 2, 3, \dots\}, \tag{4}$$

that

$$f_1, \dots, f_n \text{ belong to } \Gamma(X), \tag{5}$$

that

$$\lambda_1, \dots, \lambda_n \text{ are nonnegative real numbers such that } \lambda_1 + \cdots + \lambda_n = 1, \tag{6}$$

and that

$$\mu \text{ is a strictly positive real number.} \tag{7}$$

The Fenchel conjugate of a function f is denoted by f^*. It will be convenient to set

$$\boldsymbol{f} = (f_1, \dots, f_n), \quad \boldsymbol{f}^* = (f_1^*, \dots, f_n^*), \quad \text{and} \quad \boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_n). \tag{8}$$

Other notation not explicitly defined here or later is standard in convex analysis and as in, e.g., [18, 19, 20]. Let f be a convex function, and let S be a set. Then we write $\operatorname{dom} f$, $\operatorname{epi} f$, ∂f, $\operatorname{cl} f$, $\inf f$, $\min f$, $\operatorname{argmin} f$, d_S, $\operatorname{conv} S$, $\operatorname{int} S$, ι_S, and N_S to denote the (effective) domain, epigraph, subdifferential operator, lower closure, infimum value, minimum value if the infimum value is attained, the set of minimizers, distance function, convex hull, interior, indicator function, and normal cone operator, respectively. The identity operator is represented by Id.

3. Auxiliary results. We start by reviewing the key notions of epi-multiplication and epi-addition, following the viewpoint taken in [19, section 1.H]. Let $\alpha \geq 0$, $f \in \Gamma(X)$, $g \in \Gamma(X)$, and $h \in \Gamma(X)$. Then

$$\alpha \star f = \begin{cases} \alpha f(\cdot/\alpha) & \text{if } \alpha > 0, \\ \iota_{\{0\}} & \text{if } \alpha = 0. \end{cases} \tag{9}$$

The term "epi-multiplication" stems from the fact that $\operatorname{epi}(\alpha \star f) = \alpha \operatorname{epi}(f)$ when $\alpha > 0$. Epi-addition, or infimal convolution, is defined by

$$f \operatorname{\blacktriangle} g \colon X \to [-\infty, +\infty] : x \mapsto \inf_{y+z=x} \big(f(y) + g(z)\big); \tag{10}$$

and the term "epi-addition" stems from the fact that the strict epigraph of $f \operatorname{\blacktriangle} g$ is the Minkowski sum of the strict epigraphs of f and g, i.e., $\big\{(x,r) \in X \times \mathbb{R} \mid (f \operatorname{\blacktriangle} g)(x) < r\big\} = \big\{(y,s) \in X \times \mathbb{R} \mid f(y) < s\big\} + \big\{(z,t) \in X \times \mathbb{R} \mid g(z) < t\big\}$. The epi-sum of finitely many functions is defined analogously.

To avoid excessive usage of parentheses, epi-multiplication and regular multiplication are given precedence over epi- and regular addition, i.e., $\alpha \star f + g = (\alpha \star f) + g$, $\alpha \star f \operatorname{\blacktriangle} g = (\alpha \star f) \operatorname{\blacktriangle} g$, $\alpha f + g = (\alpha f) + g$, and $\alpha f \operatorname{\blacktriangle} g = (\alpha f) \operatorname{\blacktriangle} g$. It will also be convenient to give epi-addition a higher precedence than regular addition or subtraction, i.e., $f \operatorname{\blacktriangle} g + h = (f \operatorname{\blacktriangle} g) + h$ and $f \operatorname{\blacktriangle} g - h = (f \operatorname{\blacktriangle} g) - h$.

The next three propositions are elementary. Proofs for the finite-dimensional case are in [19]; they extend without difficulty to the present Hilbert space setting.

PROPOSITION 3.1. *Let $f \in \Gamma(X)$, let $\alpha \geq 0$, and let $\beta \geq 0$. Then the following hold.*

(i) $\alpha > 0 \Rightarrow \operatorname{epi}(\alpha \star f) = \alpha(\operatorname{epi} f)$.
(ii) $\operatorname{dom}(\alpha \star f) = \alpha(\operatorname{dom} f)$.
(iii) $f \operatorname{\blacktriangle} \iota_{\{0\}} = f$.
(iv) $\operatorname{dom}(f_1 \operatorname{\blacktriangle} \cdots \operatorname{\blacktriangle} f_n) = (\operatorname{dom} f_1) + \cdots + (\operatorname{dom} f_n)$.
(v) $\alpha \star (f_1 \operatorname{\blacktriangle} \cdots \operatorname{\blacktriangle} f_n) = \alpha \star f_1 \operatorname{\blacktriangle} \cdots \operatorname{\blacktriangle} \alpha \star f_n$.
(vi) $\alpha(f_1 \operatorname{\blacktriangle} \cdots \operatorname{\blacktriangle} f_n) = \alpha f_1 \operatorname{\blacktriangle} \cdots \operatorname{\blacktriangle} \alpha f_n$.
(vii) $\alpha \star (\beta \star f) = (\alpha\beta) \star f$.
(viii) $(\alpha + \beta) \star f = \alpha \star f \operatorname{\blacktriangle} \beta \star f$.
(ix) $\alpha > 0 \Rightarrow \alpha(\beta \star (\alpha^{-1} f)) = \beta \star f$.

Proof. The conclusions all follow readily from the definitions; see also [19, Exercise 1.28(a)] for (i), [19, page 25] for (v) and (vii), and [19, Exercise 2.24(c)] for (viii). ∎

PROPOSITION 3.2. *Let $\alpha \geq 0$. Then the following hold.*

(i) $(\alpha f)^* = \alpha \star f^*$.
(ii) $(\alpha \star f)^* = \alpha f^*$.
(iii) $(f_1 \operatorname{\blacktriangle} \cdots \operatorname{\blacktriangle} f_n)^* = f_1^* + \cdots + f_n^*$.

Proof. The statements are simple consequences of the definitions; see also [19, page 475] for (i) and (ii), and [19, Theorem 11.23(a)] for (iii). ∎

PROPOSITION 3.3. *Let $f \in \Gamma(X)$, and let $\alpha \geq 0$. Then the following hold.*

(i) $\mathfrak{q}^* = \mathfrak{q}$; *in fact,* $\mathfrak{q}$ *is the only function equal to its Fenchel conjugate.*
(ii) $\alpha > 0 \Rightarrow \alpha^{-1} \mathbin{\star} \mathfrak{q} = \alpha\, \mathfrak{q}$.
(iii) $(\alpha \mathbin{\star} \mathfrak{q})^* = \alpha\, \mathfrak{q}$.
(iv) $(\alpha\, \mathfrak{q})^* = \alpha \mathbin{\star} \mathfrak{q}$.
(v) $(f \mathbin{\blacktriangleleft} \mathfrak{q}) + (f^* \mathbin{\blacktriangleleft} \mathfrak{q}) = \mathfrak{q}$.

Proof. (i): See, e.g., [19, Example 11.11]. (ii): An immediate consequence of the definition of $\mathfrak{q}$. (iii): Combine Proposition 3.2(ii) with (i). (iv): Combine Proposition 3.2(i) with (i). (v): See [16] or [19, Example 11.26]. □

The next result is deep and stated as a fact.

FACT 3.4. *The following hold.*

(i) *If* $\operatorname{int}\operatorname{dom} f_1 \cap \cdots \cap \operatorname{int}\operatorname{dom} f_{n-1} \cap \operatorname{dom} f_n \neq \varnothing$, *then* $(f_1 + \cdots + f_n)^* = f_1^* \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} f_n^*$ *and the epi-sum is exact, i.e., the infimum in the definition of the epi-sum is attained.*
(ii) *If* $\operatorname{int}\operatorname{dom} f_1^* \cap \cdots \cap \operatorname{int}\operatorname{dom} f_{n-1}^* \cap \operatorname{dom} f_n^* \neq \varnothing$, *then* $f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} f_n$ *is exact and* $\operatorname{epi}(f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} f_n) = (\operatorname{epi} f_1) + \cdots + (\operatorname{epi} f_n)$.

Proof. This is a consequence of [20, Theorem 2.8.7]. □

The following result on the conjugate of the difference will be useful.

FACT 3.5. *Let $g \in \Gamma(X)$, and let $h \in \Gamma(X)$ such that both h and h^* have full domain. Then*

$$(\forall x^* \in X) \quad (g - h)^*(x^*) = \sup_{y^* \in X} \big(g^*(y^*) - h^*(y^* - x^*)\big). \tag{11}$$

Proof. This is a consequence of [9, Theorem 2.2]. □

COROLLARY 3.6. *Let $g \in \Gamma(X)$. Then*

$$(g - \mu \mathbin{\star} \mathfrak{q})^* = \mu(\mathfrak{q} - \mu^{-1} g^*)^* - \mu^{-1} \mathbin{\star} \mathfrak{q}. \tag{12}$$

Proof. Set $h = \mu \mathbin{\star} \mathfrak{q}$. Then $h^* = \mu\, \mathfrak{q}$ by Proposition 3.3(iii), and hence both h and h^* have full domain. Using Fact 3.5, we deduce that for every $x^* \in X$

$$\begin{aligned}
(g - h)^*(x^*) &= \sup_{y^* \in X} \big(g^*(y^*) - \mu\, \mathfrak{q}(y^* - x^*)\big) \\
&= \sup_{y^* \in X} \big(g^*(y^*) - \mu\, \mathfrak{q}(y^*) - \mu\, \mathfrak{q}(x^*) + \mu \langle y^*, x^* \rangle\big) \\
&= -\mu\, \mathfrak{q}(x^*) + \sup_{y^* \in X} \big(\langle y^*, \mu x^* \rangle - \big(\mu\, \mathfrak{q}(y^*) - g^*(y^*)\big)\big) \\
&= -\mu\, \mathfrak{q}(x^*) + \mu \sup_{y^* \in X} \big(\langle y^*, x^* \rangle - \big(\mathfrak{q}(y^*) - \mu^{-1} g^*(y^*)\big)\big) \\
&= -(\mu^{-1} \mathbin{\star} \mathfrak{q})(x^*) + \mu(\mathfrak{q} - \mu^{-1} g^*)^*(x^*). \qquad (13)
\end{aligned}$$

The proof is complete. □

LEMMA 3.7. $\big(\lambda_1 \mathbin{\star} (f_1 + \mu \mathbin{\star} \mathfrak{q}) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \mathbin{\star} (f_n + \mu \mathbin{\star} \mathfrak{q})\big)^* = \lambda_1(f_1^* \mathbin{\blacktriangleleft} \mu\, \mathfrak{q}) + \cdots + \lambda_n(f_n^* \mathbin{\blacktriangleleft} \mu\, \mathfrak{q})$.

Proof. Using Proposition 3.2(iii), Proposition 3.2(ii), Fact 3.4(i), and Proposition 3.3(iii), we compute that

$$\begin{aligned}
&\big(\lambda_1 \mathbin{\star} (f_1 + \mu \mathbin{\star} \mathfrak{q}) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \mathbin{\star} (f_n + \mu \mathbin{\star} \mathfrak{q})\big)^* \\
&\quad = \big(\lambda_1 \mathbin{\star} (f_1 + \mu \mathbin{\star} \mathfrak{q})\big)^* + \cdots + \big(\lambda_n \mathbin{\star} (f_n + \mu \mathbin{\star} \mathfrak{q})\big)^* \\
&\quad = \lambda_1 (f_1 + \mu \mathbin{\star} \mathfrak{q})^* + \cdots + \lambda_n (f_n + \mu \mathbin{\star} \mathfrak{q})^* \\
&\quad = \lambda_1 \big(f_1^* \mathbin{\blacktriangleleft} (\mu \mathbin{\star} \mathfrak{q})^*\big) + \cdots + \lambda_n \big(f_n^* \mathbin{\blacktriangleleft} (\mu \mathbin{\star} \mathfrak{q})^*\big) \\
&\quad = \lambda_1 (f_1^* \mathbin{\blacktriangleleft} \mu\, \mathfrak{q}) + \cdots + \lambda_n (f_n^* \mathbin{\blacktriangleleft} \mu\, \mathfrak{q}). \qquad (14)
\end{aligned}$$

This completes the proof. □

FACT 3.8. *Let* $(\forall i)$ $x_i \in \operatorname{dom} f_i$, *and set* $x = x_1 + \cdots + x_n$. *Then the following implications hold.*

(i) $(f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} f_n)(x) = f_1(x_1) + \cdots + f_n(x_n) \Rightarrow \partial(f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} f_n)(x) = \partial f_1(x_1) \cap \cdots \cap \partial f_n(x_n)$.

(ii) $\partial f_1(x_1) \cap \cdots \cap \partial f_n(x_n) \neq \varnothing \Rightarrow (f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} f_n)(x) = f_1(x_1) + \cdots + f_n(x_n)$.

Proof. See [20, Corollary 2.4.7]. □

PROPOSITION 3.9. *Let* $f \in \Gamma(X)$, *and let* $\alpha > 0$. *Then* $\partial(0 \mathbin{\star} f) = N_{\{0\}}$ *and* $\partial(\alpha \mathbin{\star} f) = (\partial f) \circ (\alpha^{-1} \operatorname{Id})$.

Proof. Since $0 \mathbin{\star} f = \iota_{\{0\}}$, we deduce that $\partial(0 \mathbin{\star} f) = \partial \iota_{\{0\}} = N_{\{0\}}$. Also, $\partial(\alpha \mathbin{\star} f) = \partial(\alpha f \circ (\alpha^{-1} \operatorname{Id}))$; the formula thus follows from convex calculus (see, e.g., [20, Theorem 2.8.3]). □

4. Definition, reformulations, domain, and exactness. In section 1, we have seen that the idea of computing the averaged Minkowski sum is doomed in general, due to the potential lack of coercivity properties of the terms. The proximal average can be interpreted as a three-step remedy of this idea. First, each function is "coercified" by epi-adding $\mu \mathbin{\star} \mathfrak{q}$. Second, the epi-average of the coercified terms is computed. The third step removes $\mu \mathbin{\star} \mathfrak{q}$ through subtraction. We are now ready to describe the proximal average.

DEFINITION 4.1 (proximal average). *The* $\boldsymbol{\lambda}$-weighted proximal average of $\boldsymbol{f}$ with parameter μ *is*

$$p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \lambda_1 \mathbin{\star} (f_1 + \mu \mathbin{\star} \mathfrak{q}) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \mathbin{\star} (f_n + \mu \mathbin{\star} \mathfrak{q}) - \mu \mathbin{\star} \mathfrak{q}, \tag{15}$$

i.e., if $I = \big\{ i \in \{1, \ldots, n\} \mid \lambda_i > 0 \big\}$, *then*

$$(\forall x \in X) \quad p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = \frac{1}{\mu} \left(-\frac{1}{2}\|x\|^2 + \inf_{\sum_{i \in I} x_i = x} \sum_{i \in I} \lambda_i \left(\mu f_i(x_i/\lambda_i) + \frac{1}{2}\|x_i/\lambda_i\|^2 \right) \right). \tag{16}$$

We also write $p(\boldsymbol{f}, \boldsymbol{\lambda})$ *if* $\mu = 1$, $p_\mu(\boldsymbol{f})$ *if all* λ_i *coincide, and* $p(\boldsymbol{f})$ *if* $\mu = 1$ *and all* λ_i *coincide.*

Remark 4.2. Some immediate consequences of the definition are the following.

(i) $p_\mu(f_1, 1) = f_1$.

(ii) If $I = \big\{ i \in \{1, \ldots, n\} \mid \lambda_i > 0 \big\}$, $\widetilde{\boldsymbol{f}} = (f_i)_{i \in I}$ and $\widetilde{\boldsymbol{\lambda}} = (\lambda_i)_{i \in I}$, then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = p_\mu(\widetilde{\boldsymbol{f}}, \widetilde{\boldsymbol{\lambda}})$.

(iii) If π is a permutation of $I = \{1, \ldots, n\}$, $\widetilde{\boldsymbol{f}} = (f_{\pi(i)})_{i \in I}$ and $\widetilde{\boldsymbol{\lambda}} = (\lambda_{\pi(i)})_{i \in I}$, then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = p_\mu(\widetilde{\boldsymbol{f}}, \widetilde{\boldsymbol{\lambda}})$.

(iv) $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \mu^{-1} p_1(\mu \boldsymbol{f}, \boldsymbol{\lambda})$; equivalently, $p(\mu \boldsymbol{f}, \boldsymbol{\lambda}) = \mu p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$.

(v) If $\Lambda_{n-1} = \lambda_1 + \cdots + \lambda_{n-1} > 0$, then

$$\begin{aligned} p_1(\boldsymbol{f}, \boldsymbol{\lambda}) &= p_1\big((f_1, \ldots, f_n), (\lambda_1, \ldots, \lambda_n)\big) \\ &= p_1\Big(\Big(p_1\big((f_1, \ldots, f_{n-1}), \Lambda_{n-1}^{-1}(\lambda_1, \ldots, \lambda_{n-1})\big), f_n\Big), (\Lambda_{n-1}, \lambda_n)\Big). \end{aligned} \tag{17}$$

The identities in items (iv) and (v) may be useful if one wishes to develop the theory of results for a general $\mu > 0$ and a general $n \geq 2$ from the simpler case $\mu = 1$ and $n = 2$; however, the direct approach favored in this paper is not only self-contained, but it also yields proofs that we found much more readable. Nonetheless, (iv) and (v) may be convenient for the numerical computation of the proximal average—especially when the simpler case is already implemented [13].

PROPOSITION 4.3 (reformulations).

$$p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) = \big(\lambda_1(f_1^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}) + \cdots + \lambda_n(f_n^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q})\big)^* - \mu^{-1}\,\mathfrak{q} \tag{18}$$

$$= \big(\lambda_1(f_1 + \mu^{-1}\,\mathfrak{q})^* + \cdots + \lambda_n(f_n + \mu^{-1}\,\mathfrak{q})^*\big)^* - \mu^{-1}\,\mathfrak{q} \tag{19}$$

and

$$(\forall x \in X)\quad p_\mu(\boldsymbol{f},\boldsymbol{\lambda})(x) = \inf_{\sum \lambda_i y_i = x} \sum \lambda_i f_i(y_i) + \frac{1}{\mu}\bigg(\Big(\sum \lambda_i\,\mathfrak{q}(y_i)\Big) - \mathfrak{q}(x)\bigg). \tag{20}$$

Proof. By Proposition 3.1(iv), $(\forall i)$ $\operatorname{dom}(f_i^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}) = (\operatorname{dom} f_1^*) + (\operatorname{dom} \mu\,\mathfrak{q}) = X$. Fact 3.4(i), Proposition 3.2(i), Proposition 3.2(iii), and Proposition 3.3(iv) imply that

$$\begin{aligned}
\big(\lambda_1(f_1^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}) + \cdots + \lambda_n(f_n^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q})\big)^* &= (\lambda_1(f_1^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}))^* \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} (\lambda_n(f_n^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}))^* \\
&= \lambda_1 \star (f_1^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q})^* \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \star (f_n^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q})^* \\
&= \lambda_1 \star (f_1^{**} + (\mu\,\mathfrak{q})^*) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \star (f_n^{**} + (\mu\,\mathfrak{q})^*) \\
&= \lambda_1 \star (f_1 + \mu \star \mathfrak{q}) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \star (f_n + \mu \star \mathfrak{q}). \qquad (21)
\end{aligned}$$

This and Proposition 3.3(ii) yield (18). In turn, Fact 3.4(i) and Proposition 3.3(iv) imply (19). Changing variables, we see that (20) is equivalent to (16). □

Remark 4.4 (some history). In [5], the proximal average was considered for $n = 2$ and $\mu = 1$, and written equivalently as

$$\big(\lambda_1(f_1^* \mathbin{\blacktriangleleft} \mathfrak{q}) + \lambda_2(f_2^* \mathbin{\blacktriangleleft} \mathfrak{q})\big)^* - \mathfrak{q}; \tag{22}$$

see (18). The function (22) was utilized in [5] to explicitly illustrate Moreau's observation [16] that the set of proximal mappings is convex. More recently, the proximal average was considered in [3], again with $n = 2$ and $\mu = 1$, though it was written as (see (19))

$$\big(\lambda_1(f_1 + \mathfrak{q})^* + \lambda_2(f_2 + \mathfrak{q})^*\big)^* - \mathfrak{q}. \tag{23}$$

Example 4.5 (connection to means of numbers). Let $\alpha_1, \ldots, \alpha_n$ be strictly positive numbers and suppose that $(\forall i)$ $f_i = \alpha_i\,\mathfrak{q}$. Using (19), we see that

$$\begin{aligned}
p_{\mu^{-1}}(\boldsymbol{f},\boldsymbol{\lambda}) &= \left(\sum_{i=1}^n \lambda_i(\alpha_i\,\mathfrak{q} + \mu\,\mathfrak{q})^*\right)^* - \mu\,\mathfrak{q} \\
&= \left(\sum_{i=1}^n \frac{\lambda_i}{\alpha_i + \mu}\,\mathfrak{q}\right)^* - \mu\,\mathfrak{q} = \left(\sum_{i=1}^n \frac{\lambda_i}{\alpha_i + \mu}\right)^{-1} \mathfrak{q} - \mu\,\mathfrak{q}, \qquad (24)
\end{aligned}$$

and thus

$$p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) = \left(\left(\sum_{i=1}^n \frac{\lambda_i}{\alpha_i + \mu^{-1}}\right)^{-1} - \mu^{-1}\right)\mathfrak{q}. \tag{25}$$

Denote the coefficient of $\mathfrak{q}$ in (25) by δ. Since δ is the difference of the weighted harmonic mean of $\alpha_1 + \mu^{-1}, \ldots, \alpha_n + \mu^{-1}$ and μ^{-1}, the harmonic-arithmetic mean inequality implies that δ does not exceed the weighted arithmetic mean

$$\sum_{i=1}^n \lambda_i \alpha_i. \tag{26}$$

As $\mu \to +\infty$, we note that δ converges to the weighted harmonic mean

$$\left(\sum_{i=1}^{n} \frac{\lambda_i}{\alpha_i}\right)^{-1}, \tag{27}$$

while a calculus exercise shows that δ approaches, as $\mu \to 0^+$, the weighted arithmetic mean (26). In Remark 8.6, we revisit this example from a more general point of view.

The next result locates the domain of the proximal average exactly; moreover, it strengthens [3, Theorem 4.11], where equality was observed only for the closures and interiors.

THEOREM 4.6 (domain). $\operatorname{dom} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \lambda_1 \operatorname{dom} f_1 + \cdots + \lambda_n \operatorname{dom} f_n$.

Proof. Using Proposition 3.1(iv) and Proposition 3.1(ii), we obtain $\operatorname{dom} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \operatorname{dom}(\lambda_1 \star (f_1 + \mu \star \mathfrak{q})) + \cdots + \operatorname{dom}(\lambda_1 \star (f_1 + \mu \star \mathfrak{q})) = \lambda_1 \operatorname{dom}(f_1 + \mu \star \mathfrak{q}) + \cdots + \lambda_n \operatorname{dom}(f_n + \mu \star \mathfrak{q}) = \lambda_1 \operatorname{dom}(f_1) + \cdots + \lambda_n \operatorname{dom}(f_n)$. ∎

COROLLARY 4.7. *Suppose that at least one function f_i has full domain and that $\lambda_i > 0$. Then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ has full domain.*

Example 4.8. Assume each $\lambda_i > 0$ and each $f_i = \iota_{C_i}$ where C_i is a nonempty closed convex subset of X. In X^n, set $H = \{(z_i) \mid \sum \sqrt{\lambda_i} z_i = 0\}$ and $(\forall x \in X)\ D_x$ is the Cartesian product $\bigtimes \left(\sqrt{\lambda_i} C_i - \sqrt{\lambda_i} x\right)$. Then

$$p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})\colon X \to \left]-\infty, +\infty\right] : x \mapsto \tfrac{1}{2\mu} d^2_{H \cap D_x}(0). \tag{28}$$

Proof. Fix $x \in X$. Using (16), we obtain

$$\begin{aligned}
p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) &= \mu^{-1} \left(-\frac{1}{2}\|x\|^2 + \inf_{\sum_i x_i = x} \sum \lambda_i \left(\mu\, \iota_{C_i}(x_i/\lambda_i) + \frac{1}{2}\|x_i/\lambda_i\|^2 \right) \right) \\
&= \mu^{-1} \inf_{\substack{\text{each } c_i \in C_i \\ \sum \lambda_i c_i = x}} \sum \lambda_i \left(\frac{1}{2}\|c_i\|^2 - \frac{1}{2}\|x\|^2 \right) \\
&= \mu^{-1} \inf_{z=(z_i) \in H \cap D_x} \sum \lambda_i \left(\frac{1}{2}\left\|x + z_i/\sqrt{\lambda_i}\right\|^2 - \frac{1}{2}\|x\|^2 \right) \\
&= \mu^{-1} \inf_{z=(z_i) \in H \cap D_x} \sum \frac{1}{2}\|z_i\|^2, \qquad (29)
\end{aligned}$$

which completes the proof. ∎

Remark 4.9. Consider Example 4.8 with $n = 2$, $\mu = 1$, $\lambda_1 > 0$, and $\lambda_2 > 0$. Then (28) simplifies to

$$p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})\colon X \to \left]-\infty, +\infty\right] : x \mapsto \frac{1}{2\lambda_1\lambda_2} d^2_{(\lambda_1(C_1 - x)) \cap (\lambda_2(x - C_2))}(0), \tag{30}$$

which is a formula first observed in [5, Theorem 6.1].

THEOREM 4.10 (exactness). *For every $x \in \operatorname{dom} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ there exist $y_i \in \lambda_i \operatorname{dom} f_i$ such that $x = y_1 + \cdots + y_n$ and $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = (\lambda_1 \star (f_1 + \mu \star \mathfrak{q}))(y_1) + \cdots + (\lambda_n \star (f_n + \mu \star \mathfrak{q}))(y_n) - (\mu \star \mathfrak{q})(x)$.*

Proof. Set $(\forall i)\ g_i = \lambda_i \star (f_i + \mu \star \mathfrak{q})$. If $\lambda_i = 0$, then $g_i = \iota_{\{0\}}$, and hence $g_i^* = \iota_X$ has full domain. If $\lambda_i > 0$, then using Proposition 3.2(i), Fact 3.4(i), and Proposition 3.3(iv), we see that

$$g_i^* = \left(\lambda_i \star (f_i + \mu \star \mathfrak{q})\right)^* = \lambda_i (f_i + \mu \star \mathfrak{q})^* = \lambda_i (f_i^* \mathbin{\blacktriangleright} (\mu \star \mathfrak{q})^*) = \lambda_i (f_i^* \mathbin{\blacktriangleright} \mu\, \mathfrak{q}); \tag{31}$$

thus, g_i^* also has full domain. Therefore, by Fact 3.4(ii), the epi-sum

$$p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) + \mu \star \mathfrak{q} = g_1 \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} g_n \tag{32}$$

is *exact*. Since $\operatorname{dom} p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) = \lambda_1 \operatorname{dom} f_1 + \cdots + \lambda_n \operatorname{dom} f_n$ by Theorem 4.6, the existence of the y_i is now clear. □

5. Fenchel conjugate. In this section, we compute the Fenchel conjugate of the proximal average. The explicit form obtained has several interesting consequences. We begin with a reformulation of Lemma 3.7:

$$(p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) + \mu \star \mathfrak{q})^* = \lambda_1(f_1^* \mathbin{\blacklozenge} \mu\,\mathfrak{q}) + \cdots + \lambda_n(f_n^* \mathbin{\blacklozenge} \mu\,\mathfrak{q}). \tag{33}$$

We are now ready for a useful generalization of [5, Theorem 6.1] where $n = 2$ and $\mu = 1$.

THEOREM 5.1 (Fenchel conjugate). $\big(p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\big)^* = p_{\mu^{-1}}(\boldsymbol{f}^*,\boldsymbol{\lambda})$.

Proof. Set

$$g = p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) + \mu \star \mathfrak{q}. \tag{34}$$

By (33), we have

$$g^* = \lambda_1(f_1^* \mathbin{\blacklozenge} \mu\,\mathfrak{q}) + \cdots + \lambda_n(f_n^* \mathbin{\blacklozenge} \mu\,\mathfrak{q}). \tag{35}$$

In view of (6), (35), Proposition 3.1(vi), Proposition 3.3(v), and Proposition 3.2(i), we obtain that

$$\begin{aligned}
\mathfrak{q} - \mu^{-1}g^* &= \lambda_1\big(\mathfrak{q} - \mu^{-1}(f_1^* \mathbin{\blacklozenge} \mu\,\mathfrak{q})\big) + \cdots + \lambda_n\big(\mathfrak{q} - \mu^{-1}(f_1^* \mathbin{\blacklozenge} \mu\,\mathfrak{q})\big)\\
&= \lambda_1\big(\mathfrak{q} - (\mu^{-1}f_1^* \mathbin{\blacklozenge} \mathfrak{q})\big) + \cdots + \lambda_n\big(\mathfrak{q} - (\mu^{-1}f_1^* \mathbin{\blacklozenge} \mathfrak{q})\big)\\
&= \lambda_1\big((\mu^{-1}f_1^*)^* \mathbin{\blacklozenge} \mathfrak{q}\big) + \cdots + \lambda_n\big((\mu^{-1}f_n^*)^* \mathbin{\blacklozenge} \mathfrak{q}\big)\\
&= \lambda_1\big(\mu^{-1} \star f_1 \mathbin{\blacklozenge} \mathfrak{q}\big) + \cdots + \lambda_n\big(\mu^{-1} \star f_n \mathbin{\blacklozenge} \mathfrak{q}\big). \qquad (36)
\end{aligned}$$

Consequently, using Fact 3.4(i), Proposition 3.2(i), Proposition 3.2(iii), Proposition 3.2(ii), Proposition 3.3(i), we see that

$$\begin{aligned}
\big(\mathfrak{q} - \mu^{-1}g^*\big)^* &= \Big(\lambda_1\big(\mu^{-1} \star f_1 \mathbin{\blacklozenge} \mathfrak{q}\big) + \cdots + \lambda_n\big(\mu^{-1} \star f_n \mathbin{\blacklozenge} \mathfrak{q}\big)\Big)^*\\
&= \Big(\lambda_1\big(\mu^{-1} \star f_1 \mathbin{\blacklozenge} \mathfrak{q}\big)\Big)^* \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \Big(\lambda_n\big(\mu^{-1} \star f_n \mathbin{\blacklozenge} \mathfrak{q}\big)\Big)^*\\
&= \lambda_1 \star \big(\mu^{-1} \star f_1 \mathbin{\blacklozenge} \mathfrak{q}\big)^* \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \lambda_n \star \big(\mu^{-1} \star f_n \mathbin{\blacklozenge} \mathfrak{q}\big)^*\\
&= \lambda_1 \star \big((\mu^{-1} \star f_1)^* + \mathfrak{q}^*\big) \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \lambda_n \star \big((\mu^{-1} \star f_n)^* + \mathfrak{q}^*\big)\\
&= \lambda_1 \star \big(\mu^{-1}f_1^* + \mathfrak{q}\big) \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \lambda_n \star \big(\mu^{-1}f_n^* + \mathfrak{q}\big). \qquad (37)
\end{aligned}$$

Now Proposition 3.1(vi), Proposition 3.1(ix), and Proposition 3.3(ii) imply that

$$\begin{aligned}
\mu\big(\mathfrak{q} - \mu^{-1}g^*\big)^* &= \mu\Big(\lambda_1 \star \big(\mu^{-1}(f_1^* + \mu\,\mathfrak{q})\big) \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \lambda_n \star \big(\mu^{-1}(f_n^* + \mu\,\mathfrak{q})\big)\Big)\\
&= \mu\Big(\lambda_1 \star \big(\mu^{-1}(f_1^* + \mu\,\mathfrak{q})\big)\Big) \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \mu\Big(\lambda_n \star \big(\mu^{-1}(f_n^* + \mu\,\mathfrak{q})\big)\Big)\\
&= \lambda_1 \star (f_1^* + \mu\,\mathfrak{q}) \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \lambda_n \star (f_n^* + \mu\,\mathfrak{q})\\
&= \lambda_1 \star (f_1^* + \mu^{-1} \star \mathfrak{q}) \mathbin{\blacklozenge} \cdots \mathbin{\blacklozenge} \lambda_n \star (f_n^* + \mu^{-1} \star \mathfrak{q}). \qquad (38)
\end{aligned}$$

Combining (34), Corollary 3.6, and (38), we conclude that

$$\begin{aligned}\big(p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\big)^* &= (g-\mu\mathbin{\star}\mathfrak{q})^*\\ &= \mu(\,\mathfrak{q}-\mu^{-1}g^*)^*-\mu^{-1}\mathbin{\star}\mathfrak{q}\\ &= \lambda_1\mathbin{\star}(f_1^*+\mu^{-1}\mathbin{\star}\mathfrak{q})\mathbin{\blacktriangleleft}\cdots\mathbin{\blacktriangleleft}\lambda_n\mathbin{\star}(f_n^*+\mu^{-1}\mathbin{\star}\mathfrak{q})-\mu^{-1}\mathbin{\star}\mathfrak{q}\\ &= p_{\mu^{-1}}(\boldsymbol{f}^*,\boldsymbol{\lambda}),\end{aligned}\tag{39}$$

as claimed. □

COROLLARY 5.2 (lower semicontinuity). *$p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ is convex, lower semicontinuous, and proper.*

Proof. Applying Theorem 5.1 twice, we deduce that $(p_\mu(\boldsymbol{f},\boldsymbol{\lambda}))^{**}=(p_{\mu^{-1}}(\boldsymbol{f}^*,\boldsymbol{\lambda}))^*$ $=p_{(\mu^{-1})^{-1}}(\boldsymbol{f}^{**},\boldsymbol{\lambda})=p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$. □

The next result refines the corresponding two-function version [3, Proposition 4.8].

Example 5.3. $p(\boldsymbol{f},\boldsymbol{f}^*)=\mathfrak{q}$.

Proof. Theorem 5.1 readily implies that the $p(\boldsymbol{f},\boldsymbol{f}^*)$ is equal to its conjugate; consequently, it must be equal to $\mathfrak{q}$ by Proposition 3.3(i). □

THEOREM 5.4 (inequalities). $(\lambda_1f_1^*+\cdots+\lambda_nf_n^*)^*\le p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\le\lambda_1f_1+\cdots+\lambda_nf_n$.

Proof. The right inequality follows from (20) (by setting $y_i=x$). Applying the right inequality to $\boldsymbol{f}^*$ and μ^{-1}, we learn that

$$p_{\mu^{-1}}(\boldsymbol{f}^*,\boldsymbol{\lambda})\le\lambda_1f_1^*+\cdots+\lambda_nf_n^*.\tag{40}$$

Taking the Fenchel conjugate of (40) and utilizing Theorem 5.1, we deduce that $p_\mu(\boldsymbol{f},\boldsymbol{\lambda})=\big(p_{\mu^{-1}}(\boldsymbol{f}^*,\boldsymbol{\lambda})\big)^*\ge\big(\lambda_1f_1^*+\cdots+\lambda_nf_n^*\big)^*$. □

COROLLARY 5.5 (infimum value).

$$\lambda_1\inf f_1+\cdots+\lambda_n\inf f_n\le\inf p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\le\inf(\lambda_1f_1+\cdots+\lambda_nf_n).\tag{41}$$

COROLLARY 5.6 (common minimizers). *Suppose that $\bigcap_{i\colon\lambda_i>0}\operatorname{argmin}(f_i)\neq\varnothing$. Then*

$$\min p_\mu(\boldsymbol{f},\boldsymbol{\lambda})=\sum_{i\colon\lambda_i>0}\lambda_i\min f_i\quad\textit{and}\quad\operatorname{argmin}p_\mu(\boldsymbol{f},\boldsymbol{\lambda})=\bigcap_{i\colon\lambda_i>0}\operatorname{argmin}(f_i).\tag{42}$$

Proof. Combine Theorem 5.4 and Corollary 5.5. □

6. Moreau envelope and proximal mapping.

DEFINITION 6.1. *Let $f\in\Gamma(X)$. The* Moreau envelope *of f with parameter μ is* $e_\mu f=f\mathbin{\blacktriangleleft}\mu\mathbin{\star}\mathfrak{q}$.

Observe that

$$e_\mu f=(f^*+\mu\,\mathfrak{q})^*.\tag{43}$$

THEOREM 6.2 (Moreau envelope and its Fenchel conjugate).

(i) $e_\mu p_\mu(\boldsymbol{f},\boldsymbol{\lambda})=\lambda_1e_\mu f_1+\cdots+\lambda_ne_\mu f_n$.

(ii) $\big(e_\mu p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\big)^*=\lambda_1\mathbin{\star}(e_\mu f_1)^*\mathbin{\blacktriangleleft}\cdots\mathbin{\blacktriangleleft}\lambda_n\mathbin{\star}(e_\mu f_n)^*$.

Proof. Fix $y \in X$, and set $I = \big\{i \in \{1,\ldots,n\} \mid \lambda_i > 0\big\}$. Using (16), we obtain

$$\begin{aligned}
\big(e_\mu p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\big)(y) &= \inf_x p_\mu(\boldsymbol{f},\boldsymbol{\lambda})(x) + \frac{1}{2\mu}\|y-x\|^2 \\
&= \inf_x \inf_{\sum_{i\in I} x_i = x} \sum_{i\in I} \lambda_i\Big(f_i(x_i/\lambda_i) + \frac{1}{2\mu}\|x_i/\lambda_i\|^2\Big) \\
&\qquad + \frac{1}{2\mu}\|y\|^2 - \frac{1}{\mu}\langle x, y\rangle \\
&= \inf_x \inf_{\sum_{i\in I} x_i = x} \sum_{i\in I} \lambda_i\Big(f_i(x_i/\lambda_i) \\
&\qquad + \frac{1}{2\mu}\|x_i/\lambda_i\|^2 + \frac{1}{2\mu}\|y\|^2 - \frac{1}{\mu}\langle x_i/\lambda_i, y\rangle\Big) \\
&= \inf_x \inf_{\sum_{i\in I} x_i = x} \sum_{i\in I} \lambda_i\Big(f_i(x_i/\lambda_i) + \frac{1}{2\mu}\|y - x_i/\lambda_i\|^2\Big) \\
&= \inf_{x_i, i\in I} \sum_{i\in I} \lambda_i\Big(f_i(x_i/\lambda_i) + \frac{1}{2\mu}\|y - x_i/\lambda_i\|^2\Big) \\
&= \sum_{i\in I} \lambda_i \inf_{x_i}\Big(f_i(x_i/\lambda_i) + \frac{1}{2\mu}\|y - x_i/\lambda_i\|^2\Big) \\
&= \sum_{i\in I} \lambda_i \big(e_\mu f_i\big)(y). \qquad (44)
\end{aligned}$$

This implies (i), and (ii) follows by Fenchel conjugation. Alternatively, using Definition 6.1, Proposition 3.2(iii), Theorem 5.1, Proposition 3.3(iv), and Proposition 3.3(ii), one may prove (ii) via $\big(e_\mu p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\big)^* = \big(p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}\big)^* = \big(p_\mu(\boldsymbol{f},\boldsymbol{\lambda})\big)^* + \mu\,\mathfrak{q} = p_{\mu^{-1}}(\boldsymbol{f}^*,\boldsymbol{\lambda}) + \mu^{-1}\star\mathfrak{q} = \lambda_1\star(f_1^* + \mu^{-1}\star\mathfrak{q}) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n\star(f_n^* + \mu^{-1}\star\mathfrak{q}) = \lambda_1\star(f_1^* + \mu\,\mathfrak{q}) \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n\star(f_n^* + \mu\,\mathfrak{q}) = \lambda_1\star(e_\mu f_1)^* \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n\star(e_\mu f_n)^*$ and then deduces (i) by Fenchel conjugation. □

The following result is well known.

PROPOSITION 6.3. *Let $f \in \Gamma(X)$. Then* $\operatorname{argmin} e_\mu f = \operatorname{argmin} f$.

Proof. $\operatorname{argmin} e_\mu f = \partial(e_\mu f)^*(0) = \partial(f^* + \mu\,\mathfrak{q})(0) = (\partial f^* + \mu\,\mathrm{Id})(0) = \partial f^*(0) = \operatorname{argmin} f$. □

COROLLARY 6.4 (minimizers). $\operatorname{argmin} p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) = \operatorname{argmin}\big(\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n\big)$.

Proof. Combine Proposition 6.3 and Theorem 6.2(i). □

Example 6.5 (least-squares solutions). Let $C_1,\ldots,C_n$ be nonempty closed convex subsets of X, and suppose that $(\forall i)\ f_i = \iota_{C_i}$. Then $\operatorname{argmin} p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) = \operatorname{argmin}(\lambda_1 d_{C_1}^2 + \cdots + \lambda_n d_{C_n}^2)$.

Proof. This is a consequence of Corollary 6.4, since $(\forall i)\ e_\mu f_i = e_\mu \iota_{C_i} = \iota_{C_i} \mathbin{\blacktriangleleft} \mu\star\mathfrak{q} = \mu^{-1}\iota_{C_i} \mathbin{\blacktriangleleft} \mu^{-1}\,\mathfrak{q} = \mu^{-1}(\iota_{C_i} \mathbin{\blacktriangleleft} \mathfrak{q}) = \mu^{-1}\frac{1}{2}d_{C_i}^2$. □

DEFINITION 6.6. *Let $f \in \Gamma(X)$. The* proximal mapping *of f with parameter μ is* $P_\mu f = (\mathrm{Id} + \mu\partial f)^{-1}$.

Observe that

$$\mu^{-1}(P_\mu f)^{-1} = \partial f + \mu^{-1}\,\mathrm{Id}, \qquad (45)$$

that

$$P_\mu f = \big(\nabla(f + \mu^{-1}\,\mathfrak{q})^*\big) \circ (\mu^{-1}\,\mathrm{Id}), \qquad (46)$$

and that

$$(P_\mu f) \circ (\mu \operatorname{Id}) = \nabla(e_{\mu^{-1}}(f^*)). \tag{47}$$

We now show that the proximal mapping of the proximal average is simply the average of the individual proximal mappings. This result, which also explains how the proximal average got its name, was first proved in [5, Theorem 6.1] when $n = 2$ and $\mu = 1$.

THEOREM 6.7 (proximal mapping). $P_\mu\big(p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})\big) = \lambda_1 P_\mu f_1 + \cdots + \lambda_n P_\mu f_n$.

Proof. Theorem 5.1 and Theorem 6.2(i) (the latter applied to $\boldsymbol{f}^*$ and μ^{-1}) show that

$$e_{\mu^{-1}}\big((p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}))^*\big) = e_{\mu^{-1}}\big(p_{\mu^{-1}}(\boldsymbol{f}^*, \boldsymbol{\lambda})\big) = \lambda_1 e_{\mu^{-1}}(f_1^*) + \cdots + \lambda_n e_{\mu^{-1}}(f_n^*); \tag{48}$$

in turn, taking gradients yields

$$\nabla\big(e_{\mu^{-1}}\big((p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}))^*\big)\big) = \lambda_1 \nabla(e_{\mu^{-1}}(f_1^*)) + \cdots + \lambda_n \nabla\big(e_{\mu^{-1}}(f_n^*)\big). \tag{49}$$

Using (47), we see that this is equivalent to

$$\big(P_\mu\big(p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})\big)\big) \circ (\mu \operatorname{Id}) = \lambda_1 (P_\mu f_1) \circ (\mu \operatorname{Id}) + \cdots + \lambda_n (P_\mu f_n) \circ (\mu \operatorname{Id}). \tag{50}$$

The result follows. ∎

7. Subdifferential.

THEOREM 7.1 (subdifferential). *Let* $(\forall i)\ x_i \in \operatorname{dom} f_i$, *and set* $x = \lambda_1 x_1 + \cdots + \lambda_n x_n$. *Then the following hold.*

(i) *If* $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = (\lambda_1 \bigstar (f_1 + \mu \star \mathfrak{q}))(\lambda_1 x_1) + \cdots + (\lambda_n \bigstar (f_n + \mu \star \mathfrak{q}))(\lambda_n x_n) - (\mu \star \mathfrak{q})(x)$, *then*

$$\partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = -\mu^{-1} x + \bigcap_i \partial(\lambda_i \bigstar (f_i + \mu \star \mathfrak{q}))(\lambda_i x_i) \tag{51}$$

$$= -\mu^{-1} x + \bigcap_{i\colon \lambda_i > 0} \big(\partial f_i(x_i) + \mu^{-1} x_i\big) \tag{52}$$

$$= -\mu^{-1} x + \bigcap_{i\colon \lambda_i > 0} \big(\mu^{-1}(P_\mu f_i)^{-1}(x_i)\big). \tag{53}$$

(ii) *If* $\bigcap_{i\colon \lambda_i > 0} (P_\mu f_i)^{-1}(x_i) \neq \varnothing$, *then*

$$p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = (\lambda_1 \bigstar (f_1 + \mu \star \mathfrak{q}))(\lambda_1 x_1) + \cdots + (\lambda_n \bigstar (f_n + \mu \star j))(\lambda_n x_n) - (\mu \star \mathfrak{q})(x). \tag{54}$$

Proof. Set $(\forall i)\ g_i = \lambda_i \bigstar (f_i + \mu \star \mathfrak{q})$. Theorem 4.6, Theorem 4.10, and Proposition 3.3(ii) imply that

$$g_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} g_n = p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) + \mu \star \mathfrak{q} = p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) + \mu^{-1}\, \mathfrak{q} \tag{55}$$

is exact on $\operatorname{dom}(g_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} g_n) = \lambda_1 \operatorname{dom} f_1 + \cdots + \lambda_n \operatorname{dom} f_n = \operatorname{dom} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$. (i): (51), (52), and (53) follow from Fact 3.8(i), Proposition 3.9, and (45), respectively. (ii): Use Fact 3.8(ii). ∎

COROLLARY 7.2. $(\forall x \in X) \bigcap_{i\colon \lambda_i > 0} \partial f_i(x) \subseteq \partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x)$.

Proof. Take $x^* \in \bigcap_{i\colon \lambda_i > 0} \partial f_i(x)$. Then $(\forall i)\ \lambda_i > 0 \Rightarrow \mu x^* + x \in \mu \partial f_i(x) + x = (P_\mu f_i)^{-1}(x)$. By Theorem 7.1(ii), $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = (\lambda_1 \bigstar (f_1 + \mu \star \mathfrak{q}))(\lambda_1 x) + \cdots +$

$(\lambda_n \star (f_n + \mu \star j))(\lambda_n x) - (\mu \star \mathfrak{q})(x)$. Using Theorem 7.1(i), we deduce that $x^* = -\mu^{-1}x + \mu^{-1}(\mu x^* + x) \in \partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x)$. ☐

For the following results, it will be convenient to write $x = x_1 \oplus \cdots \oplus x_n$ if $x = x_1 + \cdots + x_n$ and $x_i \perp x_j$ for $i \neq j$. We also write $K_1 \oplus \cdots \oplus K_n = \big\{x_1 \oplus \cdots \oplus x_n \mid$ each $x_i \in K_i$ and $x_i \perp x_j$ for $i \neq j\big\}$.

COROLLARY 7.3. *Let $K_1, \ldots, K_n$ be nonempty closed convex cones, and set $(\forall i)$ $P_i = P_{K_i}$, the orthogonal projector onto K_i. Suppose that*

$$(\forall x = x_1 \oplus \cdots \oplus x_n \in K_1 \oplus \cdots \oplus K_n)(\forall i) \quad P_i x = x_i, \tag{56}$$

that

$$(\forall x \in X) \quad x = P_1 x \oplus \cdots \oplus P_n x, \tag{57}$$

and that $(\forall i)$ $f_i = \iota_{K_i}$ and $\lambda_i > 0$. Then

$$(\forall x \in X) \quad p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = \frac{1}{2\mu} \sum_i \frac{(1-\lambda_i)}{\lambda_i} \|P_i x\|^2. \tag{58}$$

Proof. Observe that $(\forall i)$ $P_\mu f_i = (\mathrm{Id} + \mu \partial \iota_{K_i})^{-1} = (\mathrm{Id} + \partial \iota_{K_i})^{-1} = P_i$. Take $x \in X$ and set

$$(\forall i) \quad x_i = \frac{1}{\lambda_i} P_i x = P_i\left(\frac{1}{\lambda_i} x\right). \tag{59}$$

Using (57), we obtain that

$$x = \lambda_1 x_1 \oplus \cdots \oplus \lambda_n x_n. \tag{60}$$

Now set

$$z = x_1 \oplus \cdots \oplus x_n. \tag{61}$$

By (56), we have $(\forall i)$ $P_i z = x_i$. Thus $z \in \bigcap_i (P_\mu f_i)^{-1}(x_i)$. Therefore, by (60) and Theorem 7.1(ii),

$$\begin{aligned} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) &= (\lambda_1 \star (f_1 + \mu \star \mathfrak{q}))(\lambda_1 x_1) + \cdots + (\lambda_n \star (f_n + \mu \star \mathfrak{q}))(\lambda_n x_n) - (\mu \star \mathfrak{q})(x) \\ &= \mu^{-1}\lambda_1\, \mathfrak{q}(x_1) + \cdots + \mu^{-1}\lambda_n\, \mathfrak{q}(x_n) - \mu^{-1}\, \mathfrak{q}(x) \\ &= \frac{1}{2\mu}\big(\lambda_1 \|x_1\|^2 + \cdots + \lambda_n \|x_n\|^2 - \|\lambda_1 x_1 + \cdots + \lambda_n x_n\|^2\big) \\ &= \frac{1}{2\mu} \sum_i \lambda_i (1-\lambda_i) \|x_i\|^2. \end{aligned} \tag{62}$$

The conclusion thus follows from (59). ☐

The following two examples are special cases of Corollary 7.3.

Example 7.4. Let $K_1, \ldots, K_n$ be closed subspaces that are pairwise orthogonal and such that $K_1 \oplus \cdots \oplus K_n = X$, and suppose that $f_i = \iota_{K_i}$. Then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \mu^{-1} \sum_i (\lambda_i^{-1} - 1)(\mathfrak{q} \circ P_{K_i})$.

Example 7.5 (See also [3, Example 4.9]). Let K be a nonempty closed convex cone in X, and let $\lambda \in]0,1[$. Then

$$(\forall x \in X) \quad p\big((\iota_K, \iota_{K^\ominus}), (1-\lambda, \lambda)\big)(x) = \frac{1}{2(1-\lambda)\lambda}\big(\lambda^2 \|P_K x\|^2 + (1-\lambda)^2 \|P_{K^\ominus} x\|^2\big), \tag{63}$$

where $K^\ominus$ is the polar cone of K.

Remark 7.6. We are now in a position to show that the inequalities in Theorem 5.4 can be strict. Suppose that $n = 2$, that $f_1 = \iota_K$, and that $f_2 = \iota_{K^\ominus}$ where K is a nonempty closed convex cone in X, and that $\lambda_2 = \lambda \in]0,1[$. Using Example 7.5, we see that Theorem 5.4 becomes

$$(\forall x \in X) \quad \iota_X(x) \leq \frac{1}{2(1-\lambda)\lambda}\big(\lambda^2\|P_K x\|^2 + (1-\lambda)^2\|P_{K^\ominus}x\|^2\big) \leq \iota_{\{0\}}(x). \tag{64}$$

The inequalities are strict for every $x \in X \smallsetminus \{0\}$.

Let $f \in \Gamma(X)$. Following [2, section 5], we say that f is *essentially smooth* if ∂f is at most single valued and $\operatorname{int}\operatorname{dom} f$ is nonempty, that f is *essentially strictly convex* if f^* is essentially smooth, and that f is *Legendre* if f is both essentially smooth and essentially strictly convex. These notions coincide in our (reflexive) Hilbert space setting with the well-known notions of the same name in Euclidean space (see [18, section 26]).

The next three results extend corresponding results in [3, section 6] considerably.

COROLLARY 7.7 (essential smoothness). *Suppose that at least one function f_i is essentially smooth, and that $\lambda_i > 0$. Then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ is essentially smooth.*

Proof. Since f_i is essentially smooth, the set $\operatorname{dom} f_i$ has a nonempty interior. Thus $\lambda_i \operatorname{dom} f_i$ and $\operatorname{dom} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \lambda_1 \operatorname{dom} f_1 + \cdots + \lambda_n \operatorname{dom} f_n$ (see Theorem 4.6) both have nonempty interiors as well. Now take $x \in \operatorname{dom} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$, and let $y_1, \ldots, y_n$ be as in Theorem 4.10, say, $(\forall i)$ $y_i = \lambda_i x_i$, where $x_i \in \operatorname{dom} f_i$. By Theorem 7.1(i), $\partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) \subseteq -\mu^{-1}x + \partial f_i(x_i) + \mu^{-1}x_i$. Because f_i is essentially smooth, the set $\partial f_i(x_i)$ is either empty or singleton. Thus $\partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x)$ is either empty or singleton. Altogether, $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ is essentially smooth. ∎

COROLLARY 7.8 (essential strict convexity). *Suppose that at least one function f_i is essentially strictly convex, and that $\lambda_i > 0$. Then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ is essentially strictly convex.*

Proof. Since f_i is essentially strictly convex, its conjugate f_i^* is essentially smooth. By Corollary 7.7, $p_{\mu^{-1}}(\boldsymbol{f}^*, \boldsymbol{\lambda})$ is essentially smooth. Hence $(p_{\mu^{-1}}(\boldsymbol{f}^*, \boldsymbol{\lambda}))^*$ is essentially strictly convex. This last function is equal to $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ (by Theorem 5.1), and the proof is thus complete. ∎

COROLLARY 7.9 (Legendre function). *Suppose that at least one function f_i is essentially smooth, and that $\lambda_i > 0$. Furthermore, suppose that at least one function f_j is essentially strictly convex, and that $\lambda_j > 0$. (It does not matter whether j and i are identical or distinct.) Then $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ is both essentially smooth and essentially strictly convex, i.e., Legendre.*

Proof. Combine Corollary 7.7 and Corollary 7.8. ∎

Before we formulate and prove the last result in this section, we briefly return to the Moreau envelope and the proximal mapping. Let $f \in \Gamma(X)$. Applying Proposition 3.3(v) to μf, we readily deduce that (see also [19, Example 11.26(b)])

$$\mu(e_\mu f) + \mu \star (e_{\mu^{-1}}(f^*)) = \mathfrak{q}. \tag{65}$$

Taking gradients and recalling (47) yields $\operatorname{Id} = P_\mu f + \mu(P_{\mu^{-1}}(f^*)) \circ (\mu^{-1}\operatorname{Id})$; equivalently, $\mu \operatorname{Id} = (P_\mu f) \circ (\mu \operatorname{Id}) + \mu P_{\mu^{-1}}(f^*)$, or

$$\operatorname{Id} = \mu^{-1}(P_\mu f) \circ (\mu \operatorname{Id}) + P_{\mu^{-1}}(f^*). \tag{66}$$

The following result generalizes [4, Theorem 4.22] where $n = 2$, $\lambda_1 = \lambda_2 = \frac{1}{2}$, and $\mu = 1$.

THEOREM 7.10. *Suppose that* $(a, a^*) \in X \times X$ *satisfies* $a^* \in \partial f_1(a) \cap \cdots \cap \partial f_n(a)$, *and that* $\{1, 2, \ldots, n\}$ *is the disjoint union of two sets of indices* I *and* J. *Set* $\lambda_J = \sum_{j\in J} \lambda_j$, *and suppose that* $\lambda_J > 0$. *Then for every* $z \in a + (\bigcap_{i\in I} N_{\operatorname{dom} f_i}(a) \cap \bigcap_{j\in J} N_{\operatorname{dom} f_j^*}(a^*))$, *we have*

$$a^* + \mu^{-1}(\lambda_J^{-1} - 1)(z - a) \in \partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(z). \tag{67}$$

Consequently, $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ *is differentiable on* $a + \operatorname{int}(\bigcap_{i\in I} N_{\operatorname{dom} f_i}(a) \cap \bigcap_{j\in J} N_{\operatorname{dom} f_j^*}(a^*))$, *with gradient* $z \mapsto a^* + \mu^{-1}(\lambda_J^{-1} - 1)(z - a)$.

Proof. Let z be as in the conclusion, and set $y = z - a$. Fix $i \in I$. Now $a^* \in \partial f_i(a)$ and $\lambda_J^{-1} y \in N_{\operatorname{dom} f_i}(a) = \partial \iota_{\operatorname{dom} f_i}(a) = \partial \iota_{\operatorname{dom} \mu f_i}(a)$. Hence $\mu a^* \in \mu \partial f_i(a) = \partial(\mu f_i)(a)$. Thus $\mu a^* + \lambda_J^{-1} y \in \partial(\mu f_i)(a) + \partial(\iota_{\operatorname{dom} \mu f_i})(a) \subseteq \partial(\mu f_i + \iota_{\operatorname{dom} \mu f_i})(a) = \partial(\mu f_i)(a)$. It follows that

$$(\forall i \in I) \quad a = (P_\mu f_i)(\mu a^* + \lambda_J^{-1} y + a). \tag{68}$$

Next, fix $j \in J$. Then $a + \lambda_J^{-1} y \in \partial f_j^*(a^*)$, and $\mu^{-1} a + \mu^{-1} \lambda_J^{-1} y \in \partial(\mu^{-1} f_j^*)(a^*)$. Using (66), we thus have $a^* = (P_{\mu^{-1}} f_j^*)(\mu^{-1} a + \mu^{-1} \lambda_J^{-1} y + a^*) = \mu^{-1} a + \mu^{-1} \lambda_J^{-1} y + a^* - \mu^{-1}(P_\mu f_j)(a + \lambda_J^{-1} y + \mu a^*)$. Hence

$$(\forall j \in J) \quad a + \lambda_J^{-1} y = (P_\mu f_j)(a + \lambda_J^{-1} y + \mu a^*). \tag{69}$$

Now (68), (69), and Theorem 6.7 imply that

$$a + y = (P_\mu p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}))(a + \lambda_J^{-1} y + \mu a^*), \tag{70}$$

equivalently,

$$a^* + \mu^{-1}(\lambda_J^{-1} - 1) y \in \partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(a + y). \tag{71}$$

This verifies (67). Denote the intersection of the n normal cones by N. On $a + \operatorname{int} N$, the mapping $z \mapsto a^* + \mu^{-1}(\lambda_J^{-1} - 1)(z - a)$ is thus a continuous selection of $\partial p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$; therefore, $\nabla p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(z) = a^* + \mu^{-1}(\lambda_J^{-1} - 1)(z - a)$ by [17, Proposition 2.8]. □

8. Pointwise limits of the proximal average.

PROPOSITION 8.1. *Let* $f \in \Gamma(X)$. *Then* $e_{\mu^{-1}}\big(f \circ (\mu \operatorname{Id})\big) = (e_\mu f) \circ (\mu \operatorname{Id})$.

Proof. For every $x \in X$, we have $e_{\mu^{-1}}\big(f \circ (\mu \operatorname{Id})\big)(x) = \inf_y \big(f(\mu y) + \mu\, \mathfrak{q}(x - y)\big) = \inf_y \big(f(\mu y) + \mu^{-1}\, \mathfrak{q}(\mu x - \mu y)\big) = \inf_z \big(f(z) + \mu^{-1}\, \mathfrak{q}(\mu x - z)\big) = e_\mu f(\mu x)$. □

PROPOSITION 8.2 ([19, Example 11.26(c)]). *Let* $f\colon X \to [-\infty, +\infty]$. *Then*

$$(f + \mu\, \mathfrak{q})^* = (\mu\, \mathfrak{q} - e_{\mu^{-1}} f) \circ (\mu^{-1} \operatorname{Id}). \tag{72}$$

Proof. For every $x^* \in X$, we obtain that

$$\begin{aligned}
(f + \mu\, \mathfrak{q})^*(x^*) &= \sup_x \big(\langle x, x^*\rangle - f(x) - \mu\, \mathfrak{q}(x)\big) \\
&= \sup_x \big(\langle x, x^*\rangle - f(x) - \mu\, \mathfrak{q}(x - \mu^{-1} x^*) + \mu^{-1}\, \mathfrak{q}(x^*) - \langle x, x^*\rangle\big) \\
&= \mu^{-1}\, \mathfrak{q}(x^*) + \sup_x \big(- f(x) - \mu\, \mathfrak{q}(x - \mu^{-1} x^*)\big) \\
&= \mu^{-1}\, \mathfrak{q}(x^*) - \inf_x \big(f(x) + \mu\, \mathfrak{q}(\mu^{-1} x^* - x)\big) \\
&= \mu^{-1}\, \mathfrak{q}(x^*) - (f \mathbin{\blacktriangledown} \mu\, \mathfrak{q})(\mu^{-1} x^*) \\
&= \mu\, \mathfrak{q}(\mu^{-1} x^*) - (f \mathbin{\blacktriangledown} \mu^{-1} \star \mathfrak{q})(\mu^{-1} x^*) \\
&= \big(\mu\, \mathfrak{q} - e_{\mu^{-1}} f\big)(\mu^{-1} x^*). \qquad (73)
\end{aligned}$$

The result follows. □

The following alternative expression of the proximal average was discovered by Hare for the case when $n = 2$ and $\mu = 1$.

THEOREM 8.3 (see [7]). $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = -e_\mu\big(-(\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n)\big)$.

Proof. Set $g = -(\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n)$. Taking the Fenchel conjugate on both sides of (33) leads to $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \big(\lambda_1(f_1^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q}) + \cdots + \lambda_n(f_n^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q})\big)^* - \mu \star \mathfrak{q}$. On the other hand, $(\forall i)$ $f_i^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q} = (f_i + \mu \star \mathfrak{q})^*$ by Fact 3.4(i) and Proposition 3.3(iii). Altogether,

$$p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \big(\lambda_1(f_1 + \mu \star \mathfrak{q})^* + \cdots + \lambda_n(f_n + \mu \star \mathfrak{q})^*\big)^* - \mu \star \mathfrak{q}. \tag{74}$$

Using (74), Proposition 3.3(ii), Proposition 8.2, and Proposition 8.1 we deduce that

$$\begin{aligned}
p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) &= \big(\lambda_1(f_1 + \mu \star \mathfrak{q})^* + \cdots + \lambda_n(f_n + \mu \star \mathfrak{q})^*\big)^* - \mu \star \mathfrak{q} \\
&= \big(\lambda_1(f_1 + \mu^{-1}\,\mathfrak{q})^* + \cdots + \lambda_n(f_n + \mu^{-1}\,\mathfrak{q})^*\big)^* - \mu \star \mathfrak{q}. \\
&= \big(\lambda_1(\mu^{-1}\,\mathfrak{q} - e_\mu f_1) \circ (\mu\,\mathrm{Id}) + \cdots + \lambda_n(\mu^{-1}\,\mathfrak{q} - e_\mu f_n) \circ (\mu\,\mathrm{Id})\big)^* - \mu \star \mathfrak{q} \\
&= \big(\mu\,\mathfrak{q} + g \circ (\mu\,\mathrm{Id})\big)^* - \mu \star \mathfrak{q} \\
&= \big(\mu\,\mathfrak{q} - e_{\mu^{-1}}(g \circ (\mu\,\mathrm{Id}))\big) \circ (\mu^{-1}\,\mathrm{Id}) - \mu \star \mathfrak{q} \\
&= \mu^{-1}\,\mathfrak{q} - \big(e_{\mu^{-1}}(g \circ (\mu\,\mathrm{Id}))\big) \circ (\mu^{-1}\,\mathrm{Id}) - \mu \star \mathfrak{q} \\
&= -\big((e_\mu g) \circ (\mu\,\mathrm{Id})\big) \circ (\mu^{-1}\,\mathrm{Id}) \\
&= -e_\mu g. \qquad (75)
\end{aligned}$$

This verifies the result. □

The *μ-proximal hull* of a function g is defined by $h_\mu g = -e_\mu(-e_\mu g)$; it satisfies $e_\mu g \le h_\mu g \le g$ and $e_\mu(h_\mu g) = e_\mu g$ (see [19, Example 1.44]). Theorem 8.3 shows that $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ can be interpreted as some sort of weighted proximal hull of the functions $f_1, \ldots, f_n$. We now turn to the proximal hull of $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$.

COROLLARY 8.4 (proximal hull). $h_\mu p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$.

Proof. By Theorem 6.2(i), $e_\mu p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) = \lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n$. Hence, using Theorem 8.3, $h_\mu(p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})) = -e_\mu(-e_\mu p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})) = -e_\mu(-\lambda_1 e_\mu f_1 - \cdots - \lambda_n e_\mu f_n) = p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$. Since $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) + \mu \star \mathfrak{q}$ is clearly convex and lower semicontinuous (by Corollary 5.2), the result follows alternatively from [19, Example 11.26(d)]. □

Let us now determine the pointwise behavior of $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$.

THEOREM 8.5 (pointwise limits). *Let $x \in X$. Then the function*

$$]0, +\infty[\to \,]-\infty, +\infty] : \mu \mapsto p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) \quad \textit{is decreasing.} \tag{76}$$

Consequently, $\lim_{\mu \to 0^+} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x)$ *and* $\lim_{\mu \to +\infty} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x)$ *exist. In fact,*

$$\lim_{\mu \to 0^+} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = \sup_{\mu > 0} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = \big(\lambda_1 f_1 + \cdots + \lambda_n f_n\big)(x) \tag{77}$$

and

$$\lim_{\mu \to +\infty} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = \inf_{\mu > 0} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) = \big(\lambda_1 \star f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \star f_n\big)(x). \tag{78}$$

Proof. The fact that $\mu \mapsto p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x)$ is decreasing follows from (20); consequently, the two limits exist and the supremum/infimum descriptions are clear. Now $e_\mu\big(-(\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n)\big) \le -(\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n)$. Thus, using Theorem 8.3,

we deduce that $\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n \leq -e_\mu\big(-(\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n)\big) = p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$. On the other hand, Theorem 5.4 implies that $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) \leq \lambda_1 f_1 + \cdots + \lambda_n f_n$. Altogether,

$$\lambda_1 e_\mu f_1 + \cdots + \lambda_n e_\mu f_n \leq p_\mu(\boldsymbol{f}, \boldsymbol{\lambda}) \leq \lambda_1 f_1 + \cdots + \lambda_n f_n. \tag{79}$$

It is well known that Moreau envelopes converge pointwise to the underlying function as the parameter approaches 0; see, e.g., [1, Theorem 2.64] or [19, Theorem 1.25 and Theorem 2.26]. Thus $(\forall i)\ \lim_{\mu\to 0^+} e_\mu f_i = f_i$ pointwise, and (77) follows from taking the pointwise limit in (79) at x as $\mu \to 0^+$. Using (20), we deduce that

$$\begin{aligned}
\lim_{\mu\to+\infty} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) &= \inf_{\mu>0} p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})(x) \\
&= \inf_{\mu>0} \inf_{\sum \lambda_i y_i = x} \sum \lambda_i f_i(y_i) + \frac{1}{\mu}\bigg(\Big(\sum \lambda_i\, \mathfrak{q}(y_i)\Big) - \mathfrak{q}(x)\bigg) \\
&= \inf_{\sum \lambda_i y_i = x} \inf_{\mu>0} \sum \lambda_i f_i(y_i) + \frac{1}{\mu}\bigg(\Big(\sum \lambda_i\, \mathfrak{q}(y_i)\Big) - \mathfrak{q}(x)\bigg) \\
&= \inf_{\sum \lambda_i y_i = x} \sum \lambda_i f_i(y_i) \\
&= \inf_{\sum' x_i = x} \sum{}' \lambda_i f_i(x_i/\lambda_i) \\
&= \inf_{\sum' x_i = x} \sum{}' (\lambda_i \mathbin{\triangleright} f_i)(x_i) \\
&= \big(\lambda_1 \mathbin{\triangleright} f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \mathbin{\triangleright} f_n\big)(x), \qquad (80)
\end{aligned}$$

where the indices in the $\sum'$ sums range over all i such that $\lambda_i > 0$. □

The following nice observation, which is based on the comments of an anonymous referee, builds a bridge to [15].

Remark 8.6 (parallel sums). Suppose that $X = \mathbb{R}^N$, let $A_1, \ldots, A_n$ be positive definite $N \times N$ matrices, and suppose that $(\forall i)\ f_i(x) = \frac{1}{2}\langle x, A_i x\rangle$, i.e., identify each A_i with its quadratic form. As $\mu \to 0^+$, $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ converges pointwise to $\lambda_1 f_1 + \cdots + \lambda_n f_n$, and as $\mu \to +\infty$, $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ converges pointwise to $\lambda_1 \mathbin{\triangleright} f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \mathbin{\triangleright} f_n$. Using [15] (see also [10, Example IV.2.3.8], [12], and [14]), the matrices corresponding to the quadratic forms $\lambda_1 f_1 + \cdots + \lambda_n f_n$, $\lambda_1 \mathbin{\triangleright} f_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} \lambda_n \mathbin{\triangleright} f_n$, and $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ are, respectively, the arithmetic average $\lambda_1 A_1 + \cdots + \lambda_n A_n$; the harmonic average $(\lambda_1 A_1^{-1} + \cdots + \lambda_n A_n^{-1})^{-1}$, i.e., the *parallel sum* of the matrices $\lambda_1^{-1} A_1, \ldots, \lambda_n^{-1} A_n$; and $(\lambda_1 (A_1 + \mu^{-1}\,\mathrm{Id})^{-1} + \cdots + \lambda_n (A_n + \mu^{-1}\,\mathrm{Id})^{-1})^{-1} - \mu^{-1}\,\mathrm{Id}$, i.e., a μ^{-1}-shifted version of the harmonic average (in accordance with the comment before Definition 4.1). Note that this provides another proof of Example 4.5, and that the theory for parallel sum extends to matrices that are only positive semidefinite.

9. Epi-continuity and epi-limits of the proximal average. We now discuss the convergence behavior of the proximal average with respect to the epi-topology. Analogously to [3, section 5], we assume throughout this section that

$$X \text{ is finite-dimensional.} \tag{81}$$

Definition 9.1 (epi-convergence and epi-topology). *(See* [19, *Chapter* 6]*.) Let* g *and* $(g_k)_{k\in\mathbb{N}}$ *be functions from* X *to* $]-\infty, +\infty]$. *Then* $(g_k)_{k\in\mathbb{N}}$ epi-converges *to* g, *in symbols* $g_k \xrightarrow{\mathrm{e}} g$, *if the following hold for every* $x \in X$.

(i) $\big(\forall\, (x_k)_{k\in\mathbb{N}}\big)\ x_k \to x \Rightarrow g(x) \leq \underline{\lim}\, g_k(x_k)$.

(ii) $\big(\exists\, (y_k)_{k\in\mathbb{N}}\big)\ y_k \to x$ *and* $\overline{\lim}\, g_k(y_k) \leq g(x)$.

The epi-topology *is the topology induced by epi-convergence.*

FACT 9.2. *Let g and $(g_k)_{k\in\mathbb{N}}$ be in $\Gamma(X)$ such that $g_k \xrightarrow{\text{e}} g$, and let h and $(h_k)_{k\in\mathbb{N}}$ be in $\Gamma(X)$ such that $h_k \xrightarrow{\text{e}} h$. Let ρ and $(\rho_k)_{k\in\mathbb{N}}$ be in $[0,+\infty[$ such that $\rho_k \to \rho$, and let $q\colon X \to \mathbb{R}$ be continuous. Then the following hold.*

(i) $g_k \pm q \xrightarrow{\text{e}} g \pm q$.
(ii) $\rho > 0 \Rightarrow \rho_k g_k \xrightarrow{\text{e}} \rho g$.
(iii) $\rho = 0$ *and* $\operatorname{dom} g = X \Rightarrow \rho_k g_k \xrightarrow{\text{e}} \rho g$.
(iv) $g_k^* \xrightarrow{\text{e}} g^*$.
(v) $0 \in \operatorname{int}(\operatorname{dom} g - \operatorname{dom} h) \Rightarrow g_k + h_k \xrightarrow{\text{e}} g + h$.

Proof. (i): See [19, Exercise 7.8(a)]. (ii): See [19, Exercise 7.8(d)]. (iii): See [3] or verify this directly. (iv): See [19, Theorem 11.34]. (v): See [19, Exercise 7.47(b)]. □

LEMMA 9.3. *Let $g_1,\ldots,g_n,h$ be in $\Gamma(X)$, and let $(g_{1,k})_{k\in\mathbb{N}},\ldots,(g_{n,k})_{k\in\mathbb{N}},(h_k)_{k\in\mathbb{N}}$ be sequences in $\Gamma(X)$ such that $(\forall i)$ $g_{i,k} \xrightarrow{\text{e}} g_i$ and $h_k \xrightarrow{\text{e}} h$. Let ρ and $(\rho_k)_{k\in\mathbb{N}}$ be in $[0,+\infty[$ such that $\rho_k \to \rho$. Suppose that $\operatorname{dom} g_1^* = \cdots = \operatorname{dom} g_{n-1}^* = \operatorname{dom} h^* = X$ and that $(\forall i \in \{1,\ldots,n-1\})(\forall k)$ $\operatorname{dom} g_{i,k}^* = X$. Then the following hold.*

(i) $g_{1,k} \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} g_{n,k} \xrightarrow{\text{e}} g_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} g_n$.
(ii) $\rho_k \star h_k \xrightarrow{\text{e}} \rho \star h$.

Proof. (i): Fact 9.2(iv)&(v) imply that $g_{1,k}^* + \cdots + g_{n,k}^* \xrightarrow{\text{e}} g_1^* + \cdots + g_n^*$. Using Fact 9.2(iv), we see that $(g_{1,k}^* + \cdots + g_{n,k}^*)^* \xrightarrow{\text{e}} (g_1^* + \cdots + g_n^*)^*$, which is equivalent to $g_{1,k} \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} g_{n,k} \xrightarrow{\text{e}} g_1 \mathbin{\blacktriangleleft} \cdots \mathbin{\blacktriangleleft} g_n$ by Fact 3.4(i). (ii): Fact 9.2(ii)–(iv) imply that $\rho_k h_k^* \xrightarrow{\text{e}} \rho h^*$. Using Fact 9.2(iv) once more, we deduce that $(\rho_k h_k^*)^* \xrightarrow{\text{e}} (\rho h^*)^*$, which is the same as the conclusion in view of Proposition 3.2(i). □

Remark 9.4. Using the horizon functions associated with $g_1,\ldots,g_n$ and [19, Proposition 7.56], one may obtain a stronger version of Lemma 9.3 where the assumption on the functions $g_{i,k}^*$ is less restrictive; however, this is not needed in the sequel.

The next result extends [3, Theorem 5.4].

THEOREM 9.5 (epi-continuity of the proximal average). *Let $(f_{i,k})_{k\in\mathbb{N}}$ be sequences in $\Gamma(X)$ such that $(\forall i)$ $f_{i,k} \xrightarrow{\text{e}} f_i$, let $(\lambda_{i,k})_{k\in\mathbb{N}}$ be sequences in $[0,1]$ such that $(\forall k)$ $\sum_i \lambda_{i,k} = 1$ and $(\forall i)$ $\lambda_{i,k} \to \lambda_i$, and let $(\mu_k)_{k\in\mathbb{N}}$ be a sequence in $]0,+\infty[$ such that $\mu_k \to \mu$. Then*

(82)
$$p_{\mu_k}\big((f_{1,k},\ldots,f_{n,k}),(\lambda_{1,k},\ldots,\lambda_{n,k})\big) \xrightarrow{\text{e}} p_\mu\big((f_1,\ldots,f_n),(\lambda_1,\ldots,\lambda_n)\big) = p_\mu(\boldsymbol{f},\boldsymbol{\lambda}).$$

Proof. By Theorem 9.3(ii),

$$\mu_k \star \mathfrak{q} \xrightarrow{\text{e}} \mu \star \mathfrak{q}. \tag{83}$$

Furthermore,

$$(\forall i) \quad f_{i,k} + \mu_k \star \mathfrak{q} \xrightarrow{\text{e}} f_i + \mu \star \mathfrak{q} \tag{84}$$

by Fact 9.2(v) because $(\mu \star \mathfrak{q})^* = \mu\,\mathfrak{q}$ has full domain. Using (84), Lemma 9.3(ii), and the fact that $(\forall i)$ $(f_i + \mu \star \mathfrak{q})^* = (f_i^* \mathbin{\blacktriangleleft} (\mu \star \mathfrak{q})^*)^{**} = (f_i^* \mathbin{\blacktriangleleft} \mu\,\mathfrak{q})^{**}$ has full domain (and similarly for $(f_{i,k} + \mu_k \star \mathfrak{q})^*$), we deduce that

$$(\forall i) \quad \lambda_{i,k} \star (f_{i,k} + \mu_k \star \mathfrak{q}) \xrightarrow{\text{e}} \lambda_i \star (f_i + \mu \star \mathfrak{q}). \tag{85}$$

Since $(\forall i)\ \big(\lambda_i \mathbin{\star}(f_i+\mu \mathbin{\star} \mathfrak{q})\big)^* = \lambda_i(f_i+\mu \mathbin{\star} \mathfrak{q})^* = \lambda_i(f_i^* \mathbin{\#} \mu \mathbin{\star} \mathfrak{q})$ has full domain (and similarly for $(\lambda_{i,k} \mathbin{\star}(f_{i,k}+\mu_k \mathbin{\star} \mathfrak{q}))^*$), (85) and Lemma 9.3(i) yield

(86)
$$\lambda_{1,k} \mathbin{\star}(f_{1,k}+\mu_k \mathbin{\star} \mathfrak{q}) \mathbin{\#} \cdots \mathbin{\#} \lambda_{n,k} \mathbin{\star}(f_{n,k}+\mu_k \mathbin{\star} \mathfrak{q}) \xrightarrow{\mathrm{e}} \lambda_1 \mathbin{\star}(f_1+\mu \mathbin{\star} \mathfrak{q}) \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star}(f_n+\mu \mathbin{\star} \mathfrak{q}).$$

In turn, (83), (86), and Fact 9.2(i) imply (82). □

We now describe the behavior of $p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ when μ approaches either 0 or $+\infty$ while $\boldsymbol{f}$ and $\boldsymbol{\lambda}$ are fixed.

COROLLARY 9.6. *$p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) \xrightarrow{\mathrm{e}} \lambda_1 f_1 + \cdots + \lambda_n f_n$ as $\mu \to 0^+$, and $p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) \xrightarrow{\mathrm{e}} \mathrm{cl}(\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n)$ as $\mu \to +\infty$.*

Proof. Theorem 8.5 shows that $\mu \mapsto p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ is pointwise increasing. In view of (77) and the lower semicontinuity of $p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ (see Corollary 5.2), an application of [19, Proposition 7.4(d)] yields that $p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) \xrightarrow{\mathrm{e}} \lambda_1 f_1 + \cdots + \lambda_n f_n$ as $\mu \to 0^+$. Combining (78) with [19, Proposition 7.4(e)], we deduce similarly that $p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) \xrightarrow{\mathrm{e}} \mathrm{cl}(\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n)$ as $\mu \to +\infty$. □

Corollary 9.6 and (77) show that, as $\mu \to 0^+$, the pointwise and epigraphical limits of $p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ coincide. When $\mu \to +\infty$, the pointwise and epigraphical limits of $p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ may differ as we illustrate next.

Example 9.7. Suppose that $X = \mathbb{R}^2$, that $n = 2$, that $\lambda_1 > 0$, that $\lambda_2 > 0$, that $f_1 = \iota_{C_1}$, and that $f_2 = \iota_{C_2}$ where C_1 and C_2 are nonempty closed convex subsets of X such that $\lambda_1 C_1 + \lambda_2 C_2$ is not closed. Concretely, we may let C_1 and C_2 be the epigraphs of $x \mapsto \exp(x)$ and $x \mapsto \exp(-x)$, respectively. Then the pointwise limit (see (78))

$$\lim_{\mu \to +\infty} p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) = \lambda_1 \mathbin{\star} f_1 \mathbin{\#} \lambda_2 \mathbin{\star} f_2 = \iota_{\lambda_1 C_1 + \lambda_2 C_2} \tag{87}$$

is not lower semicontinuous, and hence different from the epigraphical limit (see Corollary 9.6) $\mathrm{cl}(\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \lambda_2 \mathbin{\star} f_2)$, which is the indicator function of the closure of $\lambda_1 C_1 + \lambda_2 C_2$.

We now show that the limiting behavior as $\mu \to +\infty$ cannot be obtained by conjugation.

Example 9.8. Suppose that $X = \mathbb{R}^2$, that $n = 2$, that $f_1 \colon (x,y) \mapsto -x + \iota_{\{0\}}(y)$, that $f_2 \colon (x,y) \mapsto x + \iota_{\{0\}}(y)$, that $\lambda_1 > 0$, and that $\lambda_2 > 0$. Now fix $(x,y) \in \mathbb{R}^2$. Using (16) and some calculus, we calculate

$$p_\mu(\boldsymbol{f},\boldsymbol{\lambda})(x,y) = (\lambda_2-\lambda_1)x + \iota_{\{0\}}(y) - 2\mu\lambda_1\lambda_2 = (\lambda_1 f_1 + \lambda_2 f_2)(x,y) - 2\mu\lambda_1\lambda_2. \tag{88}$$

Letting $\mu \to 0^+$ in (88) and in accordance with (77), we observe that $p_\mu(\boldsymbol{f},\boldsymbol{\lambda}) \to \lambda_1 f_1 + \lambda_2 f_2$ pointwise. Recalling (78) and letting $\mu \to +\infty$ in (88), we see that

$$(\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \lambda_2 \mathbin{\star} f_2)(x,y) = \lim_{\mu \to +\infty} p_\mu(\boldsymbol{f},\boldsymbol{\lambda})(x,y) = \begin{cases} -\infty & \text{if } y = 0; \\ +\infty & \text{if } y \neq 0. \end{cases} \tag{89}$$

Since $f_1^*(x,y) = \iota_{\{-1\}}(x)$ and $f_2^*(x,y) = \iota_{\{1\}}(x)$, we have $\mathrm{dom}(f_1^*) \cap \mathrm{dom}(f_2^*) = \varnothing$, and thus $\lambda_1 f_1^* + \lambda_2 f_2^* \equiv +\infty$. Altogether,

$$\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \lambda_2 \mathbin{\star} f_2 \neq \big(\lambda_1 f_1^* + \lambda_2 f_2^*\big)^* \equiv -\infty. \tag{90}$$

Therefore, due to the absence of a constraint qualification on f_1^* and f_2^*, the epigraphical convergence of $p_\mu(\boldsymbol{f},\boldsymbol{\lambda})$ to the epigraphical average of f_1 and f_2 as $\mu \to$

$+\infty$ could not have been obtained by conjugating the epigraphical convergence of $p_{\mu^{-1}}(f_1^*, f_2^*, \lambda_1, \lambda_2)$ to $\lambda_1 f_1^* + \lambda_2 f_2^*$ as $\mu \to +\infty$.

In the presence of a constraint qualification, we can use the proximal average to construct a homotopic curve with very nice properties.

Remark 9.9 (epigraphical and arithmetic averages are homotopic). Suppose that $\operatorname{int}\operatorname{dom} f_1^* \cap \cdots \cap \operatorname{int}\operatorname{dom} f_{n-1}^* \cap \operatorname{dom} f_n^* \neq \varnothing$. By Fact 3.4(i) and Proposition 3.2(i), we have $(\lambda_1 f_1^* + \cdots + \lambda_n f_n^*)^* = \lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n$. Therefore,

$$\operatorname{cl}(\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n) = \lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n, \tag{91}$$

and hence the pointwise and epigraphical limits of $p_\mu(\boldsymbol{f}, \boldsymbol{\lambda})$ as either $\mu \to 0^+$ or $\mu \to +\infty$ coincide by Theorem 8.5 and Corollary 9.6. Now set

$$(\forall \rho \in [0,1]) \quad q_\rho \colon x \mapsto \begin{cases} (\lambda_1 f_1 + \cdots + \lambda_n f_n)(x) & \text{if } \rho = 0; \\ p_{\tan(\rho\pi/2)}(\boldsymbol{f}, \boldsymbol{\lambda})(x) & \text{if } 0 < \rho < 1; \\ (\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n)(x) & \text{if } \rho = 1. \end{cases} \tag{92}$$

Then Theorem 8.5, Corollary 9.5, and Corollary 9.6 show that $(q_\rho)_{\rho\in[0,1]}$ is a decreasing, pointwise convergent, homotopic (with respect to the epi-topology) curve between the arithmetic average $\lambda_1 f_1 + \cdots + \lambda_n f_n$ and the epigraphical average $\lambda_1 \mathbin{\star} f_1 \mathbin{\#} \cdots \mathbin{\#} \lambda_n \mathbin{\star} f_n$.

Acknowledgments. We wish to thank Prof. J.-B. Hiriart-Urruty for lending us his copy of [14], and two anonymous referees for their comments.

ON THE BEHAVIOR OF SUBGRADIENT PROJECTIONS METHODS FOR CONVEX FEASIBILITY PROBLEMS IN EUCLIDEAN SPACES*

DAN BUTNARIU†, YAIR CENSOR†, PINI GURFIL‡, AND ETHAN HADAR§

Abstract. We study some methods of subgradient projections for solving a convex feasibility problem with general (not necessarily hyperplanes or half-spaces) convex sets in the inconsistent case and propose a strategy that controls the relaxation parameters in a specific self-adapting manner. This strategy leaves enough user flexibility but gives a mathematical guarantee for the algorithm's behavior in the inconsistent case. We present the numerical results of computational experiments that illustrate the computational advantage of the new method.

DOI. 10.1137/070689127

1. Introduction.

In this paper we consider, in an Euclidean space framework, the method of simultaneous subgradient projections for solving a convex feasibility problem with general (not necessarily linear) convex sets in the consistent and inconsistent cases. To cope with this situation, we propose two algorithmic developments. One uses *steering parameters* instead of *relaxation parameters* in the simultaneous subgradient projection method, and the other is a strategy that controls the relaxation parameters in a specific self-adapting manner that leaves enough user flexibility while yielding some mathematical guarantees for the algorithm's behavior in the inconsistent case. For the algorithm that uses steering parameters there is currently no mathematical theory. We present the numerical results of computational experiments that show the computational advantage of the mathematically-founded algorithm implementing our specific relaxation strategy. In the remainder of this section we elaborate upon the meaning of the above-made statements.

Given m closed convex subsets $Q_1, Q_2, \ldots, Q_m \subseteq R^n$ of the n-dimensional Euclidean space, expressed as

$$Q_i = \{x \in R^n \mid f_i(x) \leq 0\}, \tag{1.1}$$

where $f_i : R^n \to R$ is a convex function, the *convex feasibility problem* (CFP) is

$$\text{find a point } x^* \in Q := \cap_{i=1}^m Q_i. \tag{1.2}$$

As is well known, if the sets are given in any other form, then they can be represented in the form (1.1) by choosing, for f_i, the squared Euclidean distance to the set. Thus, it is required to solve the system of convex inequalities

$$f_i(x) \leq 0, \quad i = 1, 2, \ldots, m. \tag{1.3}$$

A fundamental question is how to approach the CFP in the inconsistent case when $Q = \cap_{i=1}^{m} Q_i = \emptyset$. Logically, algorithms designed to solve the CFP by finding a point $x^* \in Q$ are bound to fail and should, therefore, not be employed. But this is not always the case. Projection methods that are commonly used for the CFP, particularly in some very large real-world applications (see details below), are applied to CFPs without prior knowledge whether or not the problem is consistent. In such circumstances it is imperative to know how would a method, that is originally known to converge for a consistent CFP, behave if consistency is not guaranteed.

We address this question for a particular type of projection methods. In general, sequential projection methods exhibit *cyclic convergence* in the inconsistent case. This means that the whole sequence of iterates does not converge, but it breaks up into m convergent subsequences (see Gubin, Polyak, and Raik [25, Theorem 2] and Bauschke, Borwein and Lewis [3]). In contrast, simultaneous projection methods generally converge, even in the inconsistent case, to a minimizer of a proximity function that "measures" the weighted sum of squared distances to all sets of the CFP provided such a minimizer exists (see Iusem and De Pierro [28] for a local convergence proof and Combettes [17] for a global one).

Therefore, there is an advantage in using simultaneous projection methods from the point of view of convergence. Additional advantages are that (i) they are inherently parallel already at the mathematical formulation level due to the simultaneous nature, and (ii) they allow the user to assign weights (of importance) to the sets of the CFP. However, a severe limitation, common to sequential as well as simultaneous projection methods, is the need to solve an inner-loop distance-minimization step for the calculation of the orthogonal projection onto each individual set of the CFP. This need is alleviated only for convex sets that are simple to project onto, such as hyperplanes or half-spaces.

A useful path to circumvent this limitation is to use subgradient projections that rely on the calculation of subgradients at the current (available) iteration points; see Censor and Lent [12] or [13, section 5.3]. Iusem and Moledo [32] studied the simultaneous projection method with subgradient projections but only for consistent CFPs. To the best of our knowledge, there does not exist a study of the simultaneous projection method with subgradient projections for the inconsistent case. Our present results are a contribution towards this goal.

The CFP is a fundamental problem in many areas of mathematics and the physical sciences; see, e.g., Combettes [16, 18] and references therein. It has been used to model significant real-world problems in image reconstruction from projections; see, e.g., Herman [26], in radiation therapy treatment planning; see Censor, Altschuler, and Powlis [11] and Censor [9], and in crystallography; see Marks, Sinkler and Landree [33], to name but a few, and has been used under additional names such as *set-theoretic estimation* or the *feasible set approach*. A common approach to such problems is to use projection algorithms; see, e.g., Bauschke and Borwein [2], which employ *orthogonal projections* (i.e., nearest-point mappings) onto the individual sets Q_i. The orthogonal projection $P_\Omega(z)$ of a point $z \in R^n$ onto a closed convex set $\Omega \subseteq R^n$ is defined by

$$P_\Omega(z) := \operatorname{argmin}\{\| z - x \| \mid x \in \Omega\}, \tag{1.4}$$

where, throughout this paper, $\|\cdot\|$ and $\langle\cdot,\cdot\rangle$ denote the Euclidean norm and inner product, respectively, in R^n. Frequently a *relaxation parameter* is introduced so that

$$P_{\Omega,\lambda}(z) := (1-\lambda)z + \lambda P_\Omega(z) \tag{1.5}$$

is the *relaxed projection* of z onto Ω with relaxation λ. Many iterative projection algorithms for the CFP were developed; see subsection 1.1 below.

1.1. Projection methods: Advantages and earlier work. The reason why the CFP is looked at from the viewpoint of projection methods can be appreciated by the following brief comments, that we made in earlier publications, regarding projection methods in general. Projections onto sets are used in a variety of methods in optimization theory, but not every method that uses projections really belongs to the class of projection methods. *Projection methods* are iterative algorithms which use projections onto sets. They rely on the general principle that projections onto the given individual sets are easier to perform than projections onto other sets derived from the given individual sets (intersections, image sets under some transformation, etc.).

A projection algorithm reaches its goal, related to the whole family of sets, by performing projections onto the individual sets. Projection algorithms employ projections onto convex sets in various ways. They may use different kinds of projections and, sometimes, even use different types of projections within the same algorithm. They serve to solve a variety of problems, which are of either the feasibility or of the optimization types. They have different algorithmic structures, of which some are particularly suitable for parallel computing, and they demonstrate nice convergence properties and/or good initial behavior patterns.

Apart from theoretical interest, the main advantage of projection methods, which makes them successful in real-world applications, is computational. They commonly have the ability to handle huge-size problems that are beyond the ability of more sophisticated and currently available methods. This is so because the building blocks of a projection algorithm are the projections onto the given individual sets (which are easy to perform), and the algorithmic structure is either sequential or simultaneous (or in-between).

The field of projection methods is vast, and we mention here only a few recent works that can give the reader some good starting points. Such a list includes, among many others, the works of Crombez [20, 21], the connection with variational inequalities; see, e.g., Noor [34] and Yamada [38], which is motivated by real-world problems of signal processing, and the many contributions of Bauschke and Combettes; see, e.g., Bauschke, Combettes, and Kruk [4] and references therein. Bauschke and Borwein [2] and Censor and Zenios [13, Chapter 5] provide reviews of the field.

Systems of linear equations, linear inequalities, or convex inequalities are all encompassed by the CFP, which has broad applicability in many areas of mathematics and the physical and engineering sciences. These include, among others, optimization theory (see, e.g., Eremin [24], Censor and Lent [12], and Chinneck [14]), approximation theory (see, e.g., Deutsch [22] and references therein), image reconstruction from projections in computerized tomography (see, e.g., Herman [26, 27]), and control theory (see, e.g., Boyd et al. [5].)

Combettes [19] and Kiwiel [31] have studied the subgradient projection method for consistent CFPs. Their work presents more general algorithmic steps and is formulated in Hilbert space. Some work has already been done on detecting infeasibility with certain subgradient projection methods by Kiwiel [29, 30]. However, our ap-

proach differs from the latter in that it aims at a subgradient projection method that "will work" regardless of the feasibility of the underlying CFP and which does not require the user to study in advance whether or not the CFP is consistent. Further questions arise such as that of combining our work, or the above quoted results, with Pierra's [36] product space formalism, as extended to handle inconsistent situations by Combettes [17]. These questions are currently under investigation.

2. Simultaneous subgradient projections with steering parameters. Subgradient projections have been incorporated in iterative algorithms for the solution of CFPs. The cyclic subgradient projections (CSP) method for the CFP was given by Censor and Lent [12] as follows.

ALGORITHM 2.1 (The CSP method).

Initialization: $x^0 \in R^n$ *is arbitrary.*

Iterative step: *Given* x^k, *calculate the next iterate* x^{k+1} *by*

$$x^{k+1} = \begin{cases} x^k - \alpha_k \dfrac{f_{i(k)}(x^k)}{\| t^k \|^2} t^k & \text{if } f_{i(k)}(x^k) > 0, \\ x^k & \text{if } f_{i(k)}(x^k) \leq 0, \end{cases} \tag{2.1}$$

where $t^k \in \partial f_{i(k)}(x^k)$ *is a subgradient of* $f_{i(k)}$ *at the point* x^k, *and the relaxation parameters* $\{\alpha_k\}_{k=0}^{\infty}$ *are confined to an interval* $\epsilon_1 \leq \alpha_k \leq 2 - \epsilon_2$, *for all* $k \geq 0$, *with some arbitrarily small* $\epsilon_1, \epsilon_2 > 0$.

Control: *Denoting* $I := \{1, 2, \ldots, m\}$, *the sequence* $\{i(k)\}_{k=0}^{\infty}$ *is an almost cyclic control sequence on* I. *This means (see, e.g.,* [13, *Definition* 5.1.1]*) that* $i(k) \in I$ *for all* $k \geq 0$, *and there exists an integer* $C \geq m$ *such that, for all* $k \geq 0$, $I \subseteq \{i(k+1), i(k+2), \ldots, i(k+C)\}$.

Observe that if $t^k = 0$, then $f_{i(k)}$ takes its minimal value at x^k, implying, by the nonemptiness of Q, that $f_{i(k)}(x^k) \leq 0$ so that $x^{k+1} = x^k$. The relations of the CSP method to other iterative methods for solving the convex feasibility problem and to the relaxation method for solving linear inequalities can be found, e.g., in [13, Chapter 5]; see also, Bauschke and Borwein [2, section 7]. Since sequential projection methods for CFPs commonly have fully simultaneous counterparts, the simultaneous subgradient projections (SSP) method of Dos Santos [23] and Iusem and Moledo [32] is a natural algorithmic development.

ALGORITHM 2.2 (The SSP method).

Initialization: $x^0 \in R^n$ *is arbitrary.*

Iterative step: (i) *Given* x^k, *calculate, for all* $i \in I = \{1, 2, \ldots, m\}$, *intermediate iterates* $y^{k+1,i}$ *by*

$$y^{k+1,i} = \begin{cases} x^k - \alpha_k \dfrac{f_i(x^k)}{\| t^k \|^2} t^k & \text{if } f_i(x^k) > 0, \\ x^k & \text{if } f_i(x^k) \leq 0, \end{cases} \tag{2.2}$$

where $t^k \in \partial f_i(x^k)$ *is a subgradient of* f_i *at the point* x^k, *and the relaxation parameters* $\{\alpha_k\}_{k=0}^{\infty}$ *are confined to an interval* $\epsilon_1 \leq \alpha_k \leq 2 - \epsilon_2$, *for all* $k \geq 0$, *with some arbitrarily small* $\epsilon_1, \epsilon_2 > 0$.

(ii) *Calculate the next iterate* x^{k+1} *by*

$$x^{k+1} = \sum_{i=1}^{m} w_i y^{k+1,i}, \tag{2.3}$$

where w_i *are fixed, user-chosen, positive weights with* $\sum_{i=1}^{m} w_i = 1$.

The convergence analysis for this algorithm is currently available only for consistent ($Q \neq \emptyset$) CFPs; see [23, 32]. In our experimental work, reported in what follows, we applied Algorithm 2.2 to CFPs without knowing whether or not they are consistent. Convergence is diagnosed by performing the plots of a *proximity function* that measures, in some manner, the infeasibility of the system. We used the weighted proximity function of the form

$$p(x) := (1/2) \sum_{i=1}^{m} w_i \parallel P_i(x) - x \parallel^2, \tag{2.4}$$

where $P_i(x)$ is the orthogonal projection of the point x onto Q_i. To combat instabilities in those plots that appeared occasionally in our experiments, we used *steering parameters* σ_k instead of the relaxation parameters α_k in Algorithm 2.2. To this end we need the following definition.

DEFINITION 2.3. *A sequence* $\{\sigma_k\}_{k=0}^{\infty}$ *of real numbers* $0 \leq \sigma_k < 1$ *is called a* steering sequence *if it satisfies the following conditions:*

$$\lim_{k \to \infty} \sigma_k = 0, \tag{2.5}$$

$$\sum_{k=0}^{\infty} \sigma_k = +\infty, \tag{2.6}$$

$$\sum_{k=0}^{\infty} \mid \sigma_k - \sigma_{k+m} \mid < +\infty. \tag{2.7}$$

A historical and technical discussion of these conditions can be found in [1]. The sequential and simultaneous Halpern–Lions–Wittmann–Bauschke algorithms discussed in Censor [10] employ the parameters of a steering sequence to "force" (steer) the iterates towards the solution of the best approximation problem. This steering feature of the steering parameters has a profound effect on the behavior of any sequence of iterates $\{x^k\}_{k=0}^{\infty}$. We return to this point in section 6.

ALGORITHM 2.4 (The SSP method with steering).

Initialization: $x^0 \in R^n$ *is arbitrary.*

Iterative step: (i) *Given* x^k, *calculate, for all* $i \in I = \{1, 2, \ldots, m\}$, *intermediate iterates* $y^{k+1,i}$ *by*

$$y^{k+1,i} = \begin{cases} x^k - \sigma_k \dfrac{f_i(x^k)}{\parallel t^k \parallel^2} t^k & \text{if } f_i(x^k) > 0, \\ x^k & \text{if } f_i(x^k) \leq 0, \end{cases} \tag{2.8}$$

where $t^k \in \partial f_i(x^k)$ *is a subgradient of* f_i *at the point* x^k, *and* $\{\sigma_k\}_{k=0}^{\infty}$ *is a sequence of steering parameters.*

(ii) *Calculate the next iterate* x^{k+1} *by*

$$x^{k+1} = \sum_{i=1}^{m} w_i y^{k+1,i}, \tag{2.9}$$

where w_i *are fixed, user-chosen, positive weights with* $\sum_{i=1}^{m} w_i = 1$.

3. Subgradient projections with strategical relaxation: Preliminaries. Considering the CFP (1.2), the *envelope* of the family of functions $\{f_i\}_{i=1}^m$ is the function

$$f(x) := \max\{f_i(x) \mid i = 1, 2, \ldots, m\}, \tag{3.1}$$

which is also convex. Clearly, the consistent CFP is equivalent to finding a point in

$$Q = \cap_{i=1}^m Q_i = \{x \in R^n \mid f(x) \leq 0\}. \tag{3.2}$$

The subgradient projections algorithmic scheme that we propose here employs a strategy for controlling the relaxation parameters in a specific manner, leaving enough user flexibility while giving some mathematical guarantees for the algorithm's behavior in the inconsistent case. It is described as follows.

ALGORITHM 3.1.

Initialization: *Let M be a positive real number, and let $x^0 \in R^n$ be any initial point.*

Iterative step: *Given the current iterate x^k, set*

$$I(x^k) := \{i \mid 1 \leq i \leq m \quad \textit{and} \quad f_i(x^k) = f(x^k)\}, \tag{3.3}$$

and choose a nonnegative vector $w^k = (w_1^k, w_2^k, \ldots, w_m^k) \in R^m$ such that

$$\sum_{i=1}^m w_i^k = 1 \quad \textit{and} \quad w_i^k = 0 \quad \textit{if} \quad i \notin I(x^k). \tag{3.4}$$

Let λ_k be any nonnegative real number such that

$$\max\left(0,\ f(x^k)\right) \leq \lambda_k M^2 \leq 2\max\left(0,\ f(x^k)\right) \tag{3.5}$$

and calculate

$$x^{k+1} = x^k - \lambda_k \sum_{i \in I(x^k)} w_i^k \xi_i^k, \tag{3.6}$$

where, for each $i \in I(x^k)$, we take a subgradient $\xi_i^k \in \partial f_i(x^k)$.

It is interesting to note that any sequence $\{x^k\}_{k=0}^\infty$ generated by this algorithm is well defined, no matter how x^0 and M are chosen. Similarly to other algorithms described above, Algorithm 3.1 requires computing the subgradients of convex functions. In case a function is differentiable, this reduces to gradient calculations. Otherwise, one can use the subgradient computing procedure presented in Butnariu and Resmerita [8].

The procedure described above was previously studied in Butnariu and Mehrez [7]. The main result there shows that the procedure converges to a solution of the CFP under two conditions: (i) that the solution set Q has a nonempty interior, and (ii) that the envelope f is uniformly Lipschitz on R^n, that is, there exists a positive real number L such that

$$|f(x) - f(y)| \leq L\,\|x - y\| \quad \text{for all} \quad x, y \in R^n. \tag{3.7}$$

Both conditions (i) and (ii) are restrictive, and it is difficult to verify their validity in practical applications. In the following we show that this method converges to the

solutions of consistent CFPs under less demanding conditions. In fact, we show that if the solution set Q of the given CFP has a nonempty interior, then the convergence of Algorithm 3.1 to a point in Q is ensured even if the function f is not uniformly Lipschitz on R^n (i.e., even if f does not satisfy condition (ii) above). However, verifying whether $\operatorname{int} Q \neq \emptyset$ prior to solving a CFP may be difficult or even impossible. Therefore, it is desirable to have alternative conditions, which may be easier to verify in practice, that can ensure convergence of our algorithm to solutions of the CFP, provided that such solutions exist. This is why we prove the convergence of Algorithm 3.1 to the solutions of consistent CFPs whenever the envelope f of the functions f_i involved in the given CFP is strictly convex. The strict convexity of the envelope function f associated with a consistent CFP implies that either the solution set Q of the CFP is a singleton, in which case $\operatorname{int} Q = \emptyset$, or that Q contains (at least) two different solutions of the CFP implying that $\operatorname{int} Q \neq \emptyset$. The verification of whether Q is a singleton or not is as difficult as deciding whether $\operatorname{int} Q \neq \emptyset$. By contrast, since f is strictly convex whenever each f_i is strictly convex, the verification of the strict convexity of f may be relatively easily done in some situations of practical interest, such as when each f_i is a quadratic convex function. In the latter case, strict convexity of f_i amounts to the positive definiteness of the matrix of its purely quadratic part.

It is interesting to note in this context that, when the envelope f of the CFP is not strictly convex, one may consider a "regularized" CFP in which each f_i, which is not strictly convex, is replaced by

$$\overline{f_i}(x) := f_i(x) + \alpha\|x\|^2 \tag{3.8}$$

for some positive real number α. Clearly, all $\overline{f_i}$ are strictly convex, and thus so is the envelope $\overline{f}$ of the regularized problem. Therefore, if the regularized problem has solutions, then our Algorithm 3.1 will produce the approximations of such solutions. Moreover, any solution of the regularized problem is a solution of the original problem, and thus by solving the regularized problem, we implicitly solve the original problem. The difficult part of this approach is that, even if the original CFP is consistent, then the regularized version of it may be inconsistent for all, or for some, values $\alpha > 0$. How to decide whether an $\alpha > 0$ exists such that the corresponding regularized CFP is consistent, and how to compute such an α (if any) are questions whose answers we do not know.

4. Subgradient projections with strategical relaxation: Convergence analysis. In order to discuss the convergence behavior of the subgradient projections method with strategical relaxation, recall that convex functions defined on the whole space R^n are continuous and, consequently, are bounded on bounded sets in R^n. Therefore, the application of Butnariu and Iusem [6, Proposition 1.1.11] or Bauschke and Borwein [2, Proposition 7.8] to the convex function f shows that it is Lipschitz on bounded subsets of R^n, i.e., for any nonempty bounded subset $S \subseteq R^n$, there exists a positive real number $L(S)$, called *a Lipschitz constant of f over the set S*, such that

$$|f(x) - f(y)| \leq L(S)\,\|x - y\| \text{ for all } x, y \in S. \tag{4.1}$$

Our next result is a convergence theorem for Algorithm 3.1 when applied to a consistent CFP. It was noted in the previous section that Algorithm 3.1 is well defined regardless of how the initial point x^0 or the positive constant M involved in the algorithm are chosen. However, this is no guarantee that a sequence $\{x_k\}_{k=0}^{\infty}$ generated by Algorithm 3.1 for the random choices of x^0 and M will converge to the solutions

of the CFP, even if such solutions exist. The theorem below shows a way of choosing x^0 and M, which ensures that, under some additional conditions for the problem data, the sequence $\{x_k\}_{k=0}^{\infty}$ generated by Algorithm 3.1 will necessarily approximate a solution of the CFP (provided that solutions exist). As shown in section 5 below, determining x^0 and M as required in the next theorem can be quite easily done for practically significant classes of CFPs. Also, as shown in section 6, determining x^0 and M in this manner enhances the self-adaptability of the procedure to the problem data and makes Algorithm 3.1 produce the approximations of the solutions of the CFP which, in many cases, are more accurate than those produced by other CFP solving algorithms. We denote with $B(x, r)$ the ball centered at x with radius r.

THEOREM 4.1. *If a positive number M and an initial point x^0 in Algorithm* 3.1 *are chosen so that $M \geq L(B(x^0, r))$ for some positive real number r satisfying the condition*

$$B(x^0, r/2) \cap Q \neq \emptyset \tag{4.2}$$

and if at least one of the following conditions holds:

(i) $B(x^0, r/2) \cap \operatorname{int} Q \neq \emptyset$,

(ii) *the function f is strictly convex,*

then any sequence $\{x^k\}_{k=0}^{\infty}$, generated by Algorithm 3.1*, converges to an element of Q.*

We present the proof of Theorem 4.1 as a sequence of lemmas. To do so, note that, if $\{x^k\}_{k=0}^{\infty}$ is generated by Algorithm 3.1, then for each integer $k \geq 0$, we have

$$x^{k+1} = x^k - \lambda_k \nu^k, \tag{4.3}$$

where

$$\nu^k := \sum_{i \in I(x^k)} w_i^k \xi_i^k \in \operatorname{conv} \cup_{i \in I(x^k)} \partial f_i(x^k). \tag{4.4}$$

Using (4.3), for any $z \in R^n$, we have

$$\left\|x^{k+1} - z\right\|^2 = \left\|x^k - z\right\|^2 + \lambda_k \left(\lambda_k \left\|\nu^k\right\|^2 - 2\left\langle \nu^k, x^k - z\right\rangle\right). \tag{4.5}$$

By Clarke [15, Proposition 2.3.12] we deduce that

$$\partial f(x^k) = \operatorname{conv} \cup_{i \in I(x^k)} \partial f_i(x^k), \tag{4.6}$$

and this implies that $\nu^k \in \partial f(x^k)$ because of (4.4). Therefore,

$$\left\langle \nu^k, z - x^k \right\rangle \leq f'_+(x^k; z - x^k), \tag{4.7}$$

where $f'_+(u; v)$ denotes the right-sided directional derivative at u in the direction v. Now suppose that M, r, and x^0 are chosen according to the requirements of Theorem 4.1, that is,

$$r > 0, M \geq L(B(x^0, r)) \text{ and } B(x^0, r/2) \cap Q \neq \emptyset. \tag{4.8}$$

Next we prove the following basic fact.

LEMMA 4.2. *If* (4.8) *is satisfied and if $z \in B(x^0, r/2) \cap Q$, then, for all $k \geq 0$, we have, for any sequence $\{x^k\}_{k=0}^{\infty}$, generated by Algorithm* 3.1*,*

$$x^{k+1} \in B(x^0, r) \text{ and } \left\|x^{k+1} - z\right\| \leq \left\|x^k - z\right\| \leq r/2. \tag{4.9}$$

Proof. We first show that, if for some integer $k \geq 0$,

$$x^k \in B(x^0, r) \text{ and } \left\|x^k - z\right\| \leq r/2, \tag{4.10}$$

then (4.9) holds. If $\lambda_k = 0$ or $\nu^k = 0$, then, by (4.3), we have $x^{k+1} = x^k$, which combined with (4.10), implies (4.9). Assume now that $\lambda_k \neq 0$ and $\nu^k \neq 0$. Since, by (4.10), $x^k \in B(x^0, r)$ by (4.8) and by [15, Proposition 2.1.2(a)], we deduce that

$$M \geq L(B(x^0, r)) \geq \left\|\nu^k\right\|. \tag{4.11}$$

According to (3.5), we also have $f(x^k) > 0$ (otherwise $\lambda_k = 0$). Since $f(z) \leq 0$ we obtain from the subgradient inequality

$$\left\langle \nu^k, x^k - z \right\rangle \geq f(x^k) - f(z) \geq f(x^k) > 0. \tag{4.12}$$

This and (4.11) imply that

$$2\left\langle \nu^k, x^k - z \right\rangle \geq 2f(x^k) \geq \lambda_k M^2 \geq \lambda_k \left\|\nu^k\right\|^2 \tag{4.13}$$

showing that the quantity inside the parentheses in (4.5) is nonpositive. Thus, we deduce that

$$\left\|x^{k+1} - z\right\| \leq \left\|x^k - z\right\| \leq r/2 \tag{4.14}$$

in this case too. This proves that if (4.10) is true for all $k \geq 0$, then so is (4.9). Now, we prove by induction that (4.10) is true for all $k \geq 0$. If $k = 0$, then (4.10) obviously holds. Suppose that (4.10) is satisfied for some $k = p$. As shown above, this implies that condition (4.9) is satisfied for $k = p$, and thus we have that

$$x^{p+1} \in B(x^0, r) \text{ and } \left\|x^{p+1} - z\right\| \leq r/2. \tag{4.15}$$

Hence, condition (4.10) also holds for $k = p + 1$. Consequently, condition (4.9) holds for $k = p + 1$, and this completes the proof. ∎

Observe that, according to Lemma 4.2, if $\{x^k\}_{k=0}^{\infty}$ is a sequence generated by Algorithm 3.1 and if the conditions (4.8) are satisfied, then there exists $z \in B(x^0, r/2) \cap Q$ and for any such z the sequence $\{\|x^k - z\|\}_{k=0}^{\infty}$ is nonincreasing and bounded from below and therefore convergent. Since the sequence $\{\|x^k - z\|\}_{k=0}^{\infty}$ is convergent, it is also bounded, and consequently, the sequence $\{x^k\}_{k=0}^{\infty}$ is bounded too. This shows that the next result applies to any sequence $\{x^k\}_{k=0}^{\infty}$ generated by Algorithm 3.1 under the assumptions of Theorem 4.1.

LEMMA 4.3. *If $\{x^k\}_{k=0}^{\infty}$ is a bounded sequence generated by Algorithm* 3.1*, then the sequence $\{x^k\}_{k=0}^{\infty}$ has accumulation points, and, for each accumulation point x^* of $\{x^k\}_{k=0}^{\infty}$, there exists a sequence of natural numbers $\{k_s\}_{s=0}^{\infty}$ such that the following limits exist:*

$$x^* = \lim_{s\to\infty} x^{k_s},\ \lambda_* = \lim_{s\to\infty} \lambda_{k_s}, \tag{4.16}$$

$$\xi_i^* = \lim_{s\to\infty} \xi_i^{k_s},\ w_i^* = \lim_{s\to\infty} w_i^{k_s} \text{ for all } i = 1, 2, \ldots, m, \tag{4.17}$$

$$\nu^* = \lim_{s\to\infty} \nu^{k_s}, \tag{4.18}$$

and we have

$$w^* := (w_1^*, w_2^*, \ldots, w_m^*) \in R_+^m \text{ and } \sum_{i\in I(x^*)} w_i^* = 1 \tag{4.19}$$

and

$$\nu^* = \sum_{i \in I(x^*)} w_i^* \xi_i^* \in \partial f(x^*). \tag{4.20}$$

Moreover, if $\lambda_* = 0$, then x^* is a solution of the CFP.

Proof. The sequence $\{x^k\}_{k=0}^{\infty}$ is bounded, and thus has accumulation points. Let x^* be an accumulation point of $\{x^k\}_{k=0}^{\infty}$, and let $\{x^{p_s}\}_{s=0}^{\infty}$ be a convergent subsequence of $\{x^k\}_{k=0}^{\infty}$ such that $x^* = \lim_{s\to\infty} x^{p_s}$. The function f is continuous (since it is real-valued and convex on R^n); hence, it is bounded on bounded subsets of R^n. Therefore, the sequence $\{f(x^{p_s})\}_{s=0}^{\infty}$ converges to $f(x^*)$, and the sequence $\{f(x^k)\}_{k=0}^{\infty}$ is bounded. By (3.5), the boundedness of $\{f(x^k)\}_{k=0}^{\infty}$ implies that the sequence $\{\lambda_k\}_{k=0}^{\infty}$ is bounded. Since, for every $i = 1, 2, \ldots, m$, the operator $\partial f_i : R^n \to 2^{R^n}$ is monotone, it is locally bounded (cf. Pascali and Sburlan [35, Theorem on p. 104]).

Consequently, there exists a neighborhood U of x^* on which all ∂f_i, $i = 1, 2, \ldots, m$ are bounded. Clearly, since $x^* = \lim_{s\to\infty} x^{p_s}$, the neighborhood U contains all but finitely many terms of the sequence $\{x^{p_s}\}_{s=0}^{\infty}$. This implies that the sequences $\{\xi_i^{p_s}\}_{s=0}^{\infty}$ are uniformly bounded, and therefore the sequence $\{\nu^{p_s}\}_{s=0}^{\infty}$ is bounded too.

Therefore, there exists a subsequence $\{k_s\}_{s=0}^{\infty}$ of $\{p_s\}_{s=0}^{\infty}$ such that the limits in (4.16)–(4.18) exist. Obviously, the vector $w^* = (w_1^*, w_2^*, \ldots, w_m^*) \in R_+^m$, and according to [7, Lemma 1], we also have $\sum_{i\in I(x^*)} w_i^* = 1$. This and (4.4) imply that $\nu^* = \sum_{i\in I(x^*)} w_i^* \xi_i^*$.

Observe that, since $\nu^{k_s} \in \partial f(x^{k_s})$ for all $s \geq 0$ and since ∂f is a closed mapping (cf. Phelps [37, Proposition 2.5]), we have that $\nu^* \in \partial f(x^*)$. Now, if $\lambda_* = 0$, then according to (3.5) and the continuity of f, we deduce that

$$0 \leq \max\{0, f(x^*)\} = \lim_{s\to\infty} \max\{0, f(x^{k_s})\} \leq \lim_{s\to\infty} \lambda_{k_s} M^2 = \lambda_* M^2 = 0, \tag{4.21}$$

which implies that $f(x^*) \leq 0$, that is, $x^* \in Q$. □

LEMMA 4.4. *Let $\{x^k\}_{k=0}^{\infty}$ be a sequence generated by Algorithm* 3.1. *If* (4.8) *is satisfied and if at least one of the conditions* (i) *or* (ii) *of Theorem* 4.1 *holds, then the sequence $\{x^k\}_{k=0}^{\infty}$ has accumulation points, and any such point belongs to Q.*

Proof. As noted above, when (4.8) is satisfied, then the sequence $\{x^k\}_{k=0}^{\infty}$ is bounded, and hence it has accumulation points. Let x^* be such an accumulation point, and let $\{k_s\}_{s=0}^{\infty}$ be the sequence of natural numbers associated with x^* whose existence is guaranteed by Lemma 4.3. Since, for any $z \in C \cap B(x^0, r/2)$, the sequence $\{\|x^k - z\|\}_{k=0}^{\infty}$ is convergent (cf. Lemma 4.2), we deduce that

$$\begin{aligned} \|x^* - z\| &= \lim_{s\to\infty} \left\|x^{k_s} - z\right\| = \lim_{k\to\infty} \left\|x^k - z\right\| = \lim_{s\to\infty} \left\|x^{k_s+1} - z\right\| \\ &= \|x^* - \lambda_* \nu^* - z\|. \end{aligned} \tag{4.22}$$

This implies that

$$\|x^* - z\|^2 = \|x^* - z\|^2 + \lambda_* \left(\lambda_* \|\nu^*\|^2 - 2\langle \nu^*, x^* - z\rangle\right). \tag{4.23}$$

If $\lambda_* = 0$, then $x^* \in Q$ by Lemma 4.3. Suppose that $\lambda_* > 0$. Then, by (4.23), we have

$$\lambda_* \|\nu^*\|^2 - 2\langle \nu^*, x^* - z\rangle = 0 \tag{4.24}$$

for all $z \in C \cap B(x^0, r/2)$. We distinguish now between two possible cases.

Case I: Assume that condition (i) of Theorem 4.1 is satisfied. According to (4.24), the set $Q \cap B(x^0, r/2)$ is contained in the hyperplane

$$H := \left\{ x \in R^n \mid \langle \nu^*, x \rangle = (1/2) \left(2 \langle \nu^*, x^* \rangle - \lambda_* \|\nu^*\|^2 \right) \right\}. \tag{4.25}$$

By condition (i) of Theorem 4.1, it follows that $\operatorname{int}(Q \cap B(x^0, r/2)) \neq \emptyset$, and this is an open set contained in $\operatorname{int} H$. So, unless $\nu^* = 0$ (in which case $H = R^n$), we have reached a contradiction because $\operatorname{int} H = \emptyset$. Therefore, we must have $\nu^* = 0$. According to Lemma 4.3, we have $0 = \nu^* \in \partial f(x^*)$, which implies that x^* is a global minimizer of f. Consequently, for any $z \in Q$, we have $f(x^*) \leq f(z) \leq 0$, that is, $x^* \in Q$.

Case II: Assume that condition (ii) of Theorem 4.1 is satisfied. According to (4.24), we have

$$\lambda_* \|\nu^*\|^2 = 2 \langle \nu^*, x^* - z \rangle . \tag{4.26}$$

By (3.5), the definition of M, and [15, Proposition 2.1.2] we deduce that

$$2f(x^{k_s}) \geq \lambda_{k_s} M^2 \geq \lambda_{k_s} \left\| \nu^{k_s} \right\|^2 \tag{4.27}$$

for all integers $s \geq 0$. Letting $s \to \infty$ we get

$$2f(x^*) \geq \lambda_* M^2 \geq \lambda_* \|\nu^*\|^2 = 2 \langle \nu^*, x^* - z \rangle , \tag{4.28}$$

where the last equality follows from (4.26). Consequently, we have

$$f(x^*) \geq \langle \nu^*, x^* - z \rangle \quad \text{for all} \quad z \in Q \cap B(x^0, r/2). \tag{4.29}$$

The convexity of f implies that, for all $z \in Q \cap B(x^0, r/2)$,

$$-f(x^*) \leq \langle \nu^*, z - x^* \rangle \leq f(z) - f(x^*) \leq -f(x^*). \tag{4.30}$$

Therefore, we have that

$$-f(x^*) = \langle \nu^*, z - x^* \rangle = f(z) - f(x^*) \text{ for all } \quad z \in Q \cap B(x^0, r/2). \tag{4.31}$$

Thus $f(z) = 0$, for all $z \in Q \cap B(x^0, r/2)$. Hence, using again the convexity of f, we deduce that, for all $\quad z \in Q \cap B(x^0, r/2)$,

$$f'_+(x^*; z - x^*) \leq f(z) - f(x^*) = -f(x^*) = \langle \nu^*, z - x^* \rangle \leq f'_+(x^*; z - x^*). \tag{4.32}$$

This implies that

$$f'_+(x^*; z - x^*) = \langle \nu^*, z - x^* \rangle = f(z) - f(x^*) \text{ for all } \quad z \in Q \cap B(x^0, r/2). \tag{4.33}$$

Since, by condition (ii) of Theorem 4.1, f is strictly convex, we also have (see [6, Proposition 1.1.4]) that

$$f'_+(x^*; z - x^*) < f(z) - f(x^*) \text{ for all } \quad z \in \left(Q \cap B(x^0, r/2) \right) \setminus \{x^*\}. \tag{4.34}$$

Hence, the equalities in (4.33) cannot hold unless $Q \cap B(x^0, r/2) = \{x^*\}$, and thus $x^* \in Q$. $\square$

The previous lemmas show that if (4.8) holds and if one of the conditions (i) or (ii) of Theorem 4.1 is satisfied, then the sequence $\{x^k\}_{k=0}^{\infty}$ is bounded, and all of its accumulation points are in Q. In fact, the results above say something more. Namely, in view of Lemma 4.2, they show that if (4.8) holds and if one of the conditions (i) or (ii) of Theorem 4.1 is satisfied, then all of the accumulation points x^* of $\{x^k\}_{k=0}^{\infty}$ are contained in $Q \cap B(x^0, r)$ because all x^k are in $B(x^0, r)$ by (4.9). In order to complete the proof of Theorem 4.1, it remains to show that the following result is true.

LEMMA 4.5. *Under the conditions of Theorem* 4.1 *any sequence* $\{x^k\}_{k=0}^{\infty}$*, generated by Algorithm* 3.1*, has at most one accumulation point.*

Proof. Observe that, under the conditions of Theorem 4.1, the conditions (4.8) are satisfied, and therefore the sequence $\{x^k\}_{k=0}^{\infty}$ is bounded. Let x^* be an accumulation point of $\{x^k\}_{k=0}^{\infty}$. By Lemma 4.4 we deduce that $x^* \in Q$, i.e., $f(x^*) \leq 0$. Consequently, for any natural number k we have

$$\langle \nu^k, x^k - x^* \rangle \geq f(x^k) - f(x^*) \geq f(x^k).$$

Now, using this fact, a reasoning similar to that which proves (4.13) but made with x^* instead of z leads to

$$2 \langle \nu^k, x^k - x^* \rangle \geq \lambda_k \left\| \nu^k \right\|^2$$

for all natural numbers k. This and (4.5) combined imply that the sequence $\{\|x^k - x^*\|\}_{k=0}^{\infty}$ is nonincreasing and therefore convergent. Consequently, if $\{x^{k_p}\}_{p=0}^{\infty}$ is a subsequence of $\{x^k\}_{k=0}^{\infty}$ such that $\lim_{p\to\infty} x^{k_p} = x^*$, we have

$$\lim_{k\to\infty} \left\| x^k - x^* \right\| = \lim_{p\to\infty} \left\| x^{k_p} - x^* \right\| = 0$$

showing that any accumulation point x^* of $\{x^k\}_{k=0}^{\infty}$ is exactly the limit of $\{x^k\}_{k=0}^{\infty}$. ∎

The application of Theorem 4.1 depends on our ability to choose numbers M and r and a vector x^0 such that condition (4.8) is satisfied. We show below that this can be done when the functions f_i of the CFP (1.2) are quadratic or affine, and there is some a priori known ball which intersects Q. In actual applications it may be difficult to a priori decide whether the CFP (1.2) has or does not have solutions. However, as noted above, Algorithm 3.1 is well defined and will generate sequences $\{x^k\}_{k=0}^{\infty}$ no matter how the initial data M, r, and x^0 are chosen. This leads to the question whether it is possible to decide if Q is empty or not by simply analyzing the behavior of sequences $\{x^k\}_{k=0}^{\infty}$ generated by Algorithm 3.1. A partial answer to this question is contained in the following result.

COROLLARY 4.6. *Suppose that the CFP* (1.2) *has no solution, and that the envelope* f *is strictly convex. Then, no matter how the initial vector* x^0 *and the positive number* M *are chosen, any sequence* $\{x^k\}_{k=0}^{\infty}$ *generated by Algorithm* 3.1*, has the following properties:*

(i) *If* $\{x^k\}_{k=0}^{\infty}$ *is bounded and*

$$\lim_{k\to\infty} \left\| x^{k+1} - x^k \right\| = 0, \tag{4.35}$$

then f *has a (necessarily unique) minimizer, and* $\{x^k\}_{k=0}^{\infty}$ *converges to that minimizer, while*

$$\lim_{k\to\infty} f(x^k) = \inf\{f(x) \mid x \in R^n\}. \tag{4.36}$$

(ii) *If f has no minimizer, then the sequence $\{x^k\}_{k=0}^{\infty}$ is unbounded, or the sequence $\{\|x^{k+1}-x^k\|\}_{k=0}^{\infty}$ does not converge to zero.*

Proof. Clearly, (ii) is a consequence of (i). In order to prove (i) observe that, since the CFP (1.2) has no solution, all values of f are positive. Also, if f has a minimizer, then this minimizer is unique because f is strictly convex.

If $\{x^k\}_{k=0}^{\infty}$ is bounded, then it has an accumulation point, say, x^*. By Lemma 4.3 there exists a sequence of positive integers $\{k_s\}_{s=0}^{\infty}$ such that (4.16) and (4.19)–(4.20) are satisfied. Using Lemma 4.3 again, we deduce that, if the limit λ_* in (4.16) is zero, then the vector $x^* = \lim_{s\to\infty} x^{k_s}$ is a solution of the CFP (1.2), i.e., $f(x^*) \leq 0$, contradicting the assumption that the CFP (1.2) has no solution. Hence, $\lambda_* > 0$. By (4.3), (4.35), and (4.16) we have that

$$0 = \lim_{s\to\infty} \lambda_{k_s} \nu^{k_s} = \lambda_* \nu^*. \tag{4.37}$$

Thus, we deduce that $\nu^* = 0$. From (4.19)–(4.20) and [15, Proposition 2.3.12] we obtain

$$0 = \nu^* = \sum_{i\in I(x^*)} w_i^* \xi_i^* \in \partial f(x^*) \tag{4.38}$$

showing that x^* is a minimizer of f. So, all of the accumulation points of $\{x^k\}_{k=0}^{\infty}$ coincide because f has no more than one minimizer. Consequently, the bounded sequence $\{x^k\}_{k=0}^{\infty}$ converges, and its limit is the unique minimizer of f. ∎

Remark 4.7. Checking numerically a condition such as (ii) in Corollary 4.6 or the condition in Corollary 4.9 below seems virtually impossible. But there is no escape from such situations in such mathematically oriented results. Condition (ii) in Corollary 4.6 is meaningful in the inconsistent case in which a feasible point does not exist, but a proximity function that "measures" the feasibility violation of the limit point can be minimized. An easy adaptation of the proof of Corollary 4.6 shows that, if the sequence $\{x^k\}_{k=0}^{\infty}$ has a bounded subsequence $\{x^{k_t}\}_{t=0}^{\infty}$ such that the limit $\lim_{t\to\infty}(x^{k_t+1} - x^{k_t}) = 0$, then all of the accumulation points of $\{x^{k_t}\}_{t=0}^{\infty}$ are the minimizers of f (even if f happens to be not strictly convex).

Remark 4.8. The fact that, for some choice of x^0 and M, a sequence $\{x^k\}_{k=0}^{\infty}$, generated by Algorithm 3.1, has the property that $\lim_{k\to\infty} f(x^k) = 0$ does not imply that the CFP (1.2) has a solution. For example, take in (1.2) $m = n = 1$ and $f_1(x) = e^{-x}$. Clearly, in this case (1.2) has no solution, and $f = f_1$. However, for $x^0 = 0$, $M = 1$, and $\lambda_k = (3/2)f(x^k)$, we have $\lim_{k\to\infty} f(x^k) = 0$.

A meaningful implication of Corollary 4.6 is the following result.

COROLLARY 4.9. *Suppose that the CFP* (1.2) *has no solution, and that f is strictly convex. Then, no matter how the initial vector x^0 and the positive number M are chosen in Algorithm* 3.1*, the following holds: If the series $\sum_{k=0}^{\infty} \|x^k - x^{k+1}\|$ converges, then the function f has a unique global minimizer and the sequence $\{x^k\}_{k=0}^{\infty}$, generated by Algorithm* 3.1*, converges to that minimizer, while the sequence $\{f(x^k)\}_{k=0}^{\infty}$ converges to* $\inf\{f(x) \mid x \in R^n\}$.

Proof. When $\sum_{k=0}^{\infty} \|x^k - x^{k+1}\|$ converges to some number S we have

$$\left\|x^0 - x^{k+1}\right\| \leq \sum_{\ell=0}^{k} \left\|x^\ell - x^{\ell+1}\right\| \leq S \tag{4.39}$$

for all integers $k \geq 0$. This implies that the sequence $\{x^k\}_{k=0}^{\infty}$ is bounded, and $\lim_{k\to\infty} \|x^k - x^{k+1}\| = 0$. Hence, by applying Corollary 4.6, we complete the proof. ∎

Remark 4.10. Finding an initial vector x^0, the radius r and a positive number M satisfying condition $M \geq L(B(x^0, r))$ (and satisfying (4.2) provided that Q is nonempty) when there is no a priori knowledge about the existence of a solution of the CFP can be quite easily done when at least one of the sets Q_i, say Q_{i_0}, is bounded and the functions f_i are differentiable. In this case it is sufficient to determine a vector x^0 and a positive number r large enough so that the ball $B(x^0, r/2)$ contains Q_{i_0}. Clearly, for such a ball, if Q is nonempty, then condition (4.2) holds. Once the ball $B(x^0, r)$ is determined, finding a number $M \geq L(B(x^0, r))$ can be done by taking into account that the gradients of the differentiable convex functions $f_i : R^n \to R$ are necessarily continuous, and therefore the numbers

$$L_i = \sup\{\|\nabla f_i(x)\| \mid x \in B(x^0, r)\} \tag{4.40}$$

are necessarily finite. Since $L := \max\{L_i \mid 1 \leq i \leq m\}$ is necessarily a Lipschitz constant of f over $B(x^0, r)$, one can take $M = L$.

Remark 4.11. The method of choosing x^0, r, and M presented in Remark 4.10 does not require a priori knowledge of the existence of a solution of the CFP and can be applied even when Q is empty. In such a case one should compute, along the iterative procedure of Algorithm 3.1, the sums $S_k = \sum_{\ell=0}^{k} \|x^\ell - x^{\ell+1}\|$. Theorem 4.1 and Corollary 4.9 then provide the following insights and tools for solving the CFP, provided that f is strictly convex:

- If along the computational process the sequence S_k remains bounded from above by some number S^*, while the sequence $\{f(x^k)\}_{k=0}^{\infty}$ stabilizes itself asymptotically at some *positive* value, then the given CFP has no solution, but the sequence $\{x^k\}_{k=0}^{\infty}$ still approximates a global minimum of f, which may be taken as a surrogate solution of the given CFP.
- If along the computational process the sequence S_k remains bounded from above by some number S^*, while the sequence $\{f(x^k)\}_{k=0}^{\infty}$ stabilizes itself asymptotically at some *nonpositive* value, then the given CFP has a solution, and the sequence $\{x^k\}_{k=0}^{\infty}$ approximates such a solution.

5. Implementation of Algorithm 3.1 for linear or quadratic functions. The application of Algorithm 3.1 does not require a priori knowledge of the constant r. However, in order to implement this algorithm so that the conditions for convergence will be guaranteed, we have to determine numbers r and M as required by Theorem 4.1. The method proposed in Remark 4.10 might yield a very large value of r. This is due to the mathematical generality of Remark 4.10. The quadratic and affine cases treated next seem to be restrictive from the theoretical/mathematical point of view, but their importance lies in the fact that they cover many significant real-world applications.

We deal first with the problem of determining a number M such that

$$M \geq L(B(x^0, r)) \tag{5.1}$$

provided that an $r > 0$ is given. Recall that, if $g : R^n \to R$ is a continuously differentiable function, then by Taylor's formula, we have that, whenever $x, y \in B(x^0, r)$, there exists a $u \in [x, y]$ such that

$$\begin{aligned} \mid g(y) - g(x) \mid &= \mid \langle \nabla g(u), y - x \rangle \mid \leq \|\nabla g(u)\| \, \|y - x\| \\ &\leq \|y - x\| \max\{\|\nabla g(u)\| \mid u \in B(x^0, r)\}. \end{aligned} \tag{5.2}$$

This shows that

$$\max\{\|\nabla g(u)\| \mid u \in B(x^0, r)\} \tag{5.3}$$

is a Lipschitz constant for g on $B(x^0, r)$. Suppose now that each function f_i is either linear or quadratic. Denote $I_1 = \{i \mid 1 \le i \le m,\ f_i \text{ is linear}\}$ and $I_2 = \{i \mid 1 \le i \le m,\ f_i \text{ is quadratic}\}$. Namely,

$$f_i(x) = \langle a^i, x\rangle + b_i \ \text{ for all } \ i \in I_1, \tag{5.4}$$

with $a^i \in R^n \backslash \{0\}$ and $b_i \in R$, and

$$f_i(x) = \langle x, U_i x\rangle + \langle a^i, x\rangle + b_i \text{ for all } \ i \in I_2, \tag{5.5}$$

where $U_i = (u^i_{\ell,k})$ is a symmetric positive semidefinite $n \times n$ matrix, $a^i \in R^n$, and $b_i \in R$. We have, of course,

$$\nabla f_i(x) = \begin{cases} a^i & \text{if } \ i \in I_1, \\ 2U_i x + a^i & \text{if } \ i \in I_2, \end{cases} \tag{5.6}$$

so that (5.3) can give us Lipschitz constants for each f_i over $B(x^0, r)$. Denote

$$L_i := \begin{cases} \|a^i\| & \text{if } i \in I_1, \\ 2\|U_i\|_\infty \left(\|x^0\| + r\right) + \|a^i\| & \text{if } i \in I_2, \end{cases} \tag{5.7}$$

where $\|U_i\|_\infty$ is the operator norm of U_i. Due to (4.6), this implies that $\cup_{x \in B(x^0, r)} \partial f(x) \subseteq B(0, L)$, where

$$L := \max\{L_i \mid 1 \le i \le m\}. \tag{5.8}$$

Taking $\xi \in \partial f(x)$ and $\zeta \in \partial f(y)$, for some $x, y \in B(x^0, r)$, we have

$$\begin{aligned} L\|x - y\| \ge \|\zeta\|\,\|x - y\| \ge \langle \zeta, y - x\rangle \ge f(y) - f(x) \\ \ge \langle \xi, y - x\rangle \ge -\|\xi\|\,\|x - y\| \ge -L\|x - y\|, \end{aligned} \tag{5.9}$$

which implies that

$$|f(y) - f(x)| \le L\|x - y\| \ \text{ for all } \ x, y \in B(x^0, r). \tag{5.10}$$

In other words, L is a Lipschitz constant of f over $B(x^0, r)$. Thus, given an $r > 0$, we can take M to be any number such that $M \ge L$. Note that choosing x^0 such that the corresponding r is small may speed up the computational process by reducing the number of iterations needed to reach a reasonably good approximate solution of the CFP. In general, determining a number r is straightforward when one has some information about the range of the variation of the coordinates of some solutions to the CFP.

For instance, if one knows a priori that the solutions of the CFP are vectors $x = (x_j)_{j=1}^n$ such that

$$\ell_j \le x_j \le u_j, \ 1 \le j \le n, \tag{5.11}$$

where, $\ell_j, u_j \in R$ for all j, then the set Q is contained in the hypercube of edge length $\delta = u_{\max} - \ell_{\min}$, whose faces are parallel to the axes of the coordinates, and centered at the point x^0 whose coordinates are $x^0_j = \frac{1}{2}(\ell_{\min} + u_{\max})$, where

$$\ell_{\min} := \min\{\ell_j \mid 1 \le j \le n\} \text{ and } u_{\max} := \max\{u_j \mid 1 \le j \le n\}. \tag{5.12}$$

Therefore, by choosing this x^0 as the initial point for Algorithm 3.1 and choosing $r = \sqrt{n}\delta$, condition (4.2) holds.

6. Computational results. In this section, we compare the performance of Algorithms 2.2, 2.4, and 3.1 by examining a few test problems. There are a number of degrees-of-freedom used to evaluate and compare the performance of the algorithms. These are the maximum number of iterations, the number of constraints, the lower and upper bounds of the box constraints, the values of the relaxation parameters, the initial values of the steering parameters, and the steering sequence. In all our experiments, the steering sequence of Algorithm 2.4 assumed the form

$$\sigma_k = \frac{\sigma}{k+1}, \tag{6.1}$$

with a fixed user-chosen constant σ. The main performance measure is the value of $f(x^k)$ plotted as a function of the iteration index k.

6.1. Test problem description. There are three types of constraints in our test problems: box constraints, linear constraints, and quadratic constraints. Some of the numerical values used to generate the constraints are uniformly distributed random numbers lying in the interval $\tau = [\tau_1, \tau_2]$, where τ_1 and τ_2 are user-chosen predetermined values.

The n box constraints are defined by

$$\ell_j \le x_j \le u_j, \quad j = 1, 2, \ldots, n, \tag{6.2}$$

where $\ell_j, u_j \in \tau$ are the lower and upper bounds, respectively. Each of the N_q quadratic constrains is generated according to

$$G_i(x) = \langle x, U_i x \rangle + \langle v^i, x \rangle + \beta_i, \quad i = 1, 2, \ldots, N_q. \tag{6.3}$$

Here U_i are the $n \times n$ matrices defined by

$$U_i = W_i \Lambda_i W_i^T, \tag{6.4}$$

where the $n \times n$ matrices Λ_i are diagonal and positive definite, given by

$$\Lambda_i = \operatorname{diag}\left(\delta_1^i, \delta_2^i, \ldots, \delta_n^i\right), \tag{6.5}$$

where $0 < \delta_1^i \le \delta_2^i \le \cdots \le \delta_n^i \in \tau$ are generated randomly. The matrices W_i are generated by orthonormalizing an $n \times n$ random matrix whose entries lie in the interval τ. Finally, the vector $v^i \in R^n$ is constructed so that all of its components lie in the interval τ, and similarly, the scalar $\beta_i \in \tau$. The N_ℓ linear constraints are constructed in a similar manner according to

$$L_i(x) = \langle y^i, x \rangle + \gamma_i, \quad i = 1, 2, \ldots, N_\ell. \tag{6.6}$$

Thus, the total number of constraints is $n + N_q + N_\ell$.

Table 6.1 summarizes the test cases used to evaluate and compare the performance of Algorithms 2.2, 2.4, and 3.1. In these eight experiments, we modified the value of the constant σ in (6.1), the interval τ, the number of constraints, the number of iterations, and the relative tolerance ε, used as a termination criterion between subsequent iterations.

In Table 6.1, Cases 1 and 2 represent small-scale problems with a total of 13 constraints, whereas Cases 4–6 represent midscale problems with a total of 130 constraints. Cases 6–8 examine the case of overrelaxation, wherein the initial steering (relaxation) parameter is at least 2.

TABLE 6.1
Test cases for performance evaluation.

Case	$\alpha/\sigma/\lambda$	τ	n	N_q	N_ℓ	Iterations	ε

6.2. Results. The results of our experiments are depicted in Figures 1–3. The results of Cases 1–3 are shown in Figures 1(a)–1(c), respectively. It is seen that, in Case 1, Algorithm 2.2 has better initial convergence than Algorithms 2.4 and 3.1. However, in Case 2, Algorithm 2.4 yields fast and smooth initial behavior, while Algorithm 2.2 oscillates chaotically. Algorithm 3.1 exhibits slow initial convergence, similarly to Case 1. In Case 3, Algorithm 3.1 supersedes the performance of the other two algorithms, since it continues to converge toward zero. However, none of the algo-

rithms detects a feasible solution, since none converged to the tolerance threshold after the maximum number of iterations.

The midsized problems of Cases 4 and 5 are depicted by Figures 2(a) and 2(b). Figure 2(a) shows that Algorithm 3.1 detects a feasible solution, while both Algorithms 2.2 and 2.4 fail to detect such a solution. The curve of Algorithm 3.1 in Figure 2(a) stops when it reaches the feasible point detection tolerance, which is 0.1. Once the point is detected, there is no need to further iterate, and the process stops. The curve for Algorithm 2.2 in this figure shows irregular behavior since it searches for a feasible solution without reaching the detection threshold of 0.1, and accumulated numerical errors start to affect it. Figure 2(b) shows a phenomenon similar to the one observed in the small-scale problem: Algorithm 3.1 continues to seek a feasible solution, while Algorithms 2.2 and 2.4 converge to a steady state, indicating the failure to detect a feasible solution.

In the experiments Cases 6–8, Algorithm 3.1 outperforms the other algorithms, arriving very close to finding feasible solutions. It should be observed that the behavior of Algorithm 3.1 observed above is the result of the way in which the relaxation parameters λ_k are self-regulating their sizes. In Algorithm 3.1 the relaxation parameter λ_k can be chosen (see (3.6)) to be any number of the form

$$\lambda_k = \beta_k \frac{\max(0, f(x^k))}{M^2} + 2(1-\beta_k)\frac{\max(0, f(x^k))}{M^2} = (2-\beta_k)\frac{\max(0, f(x^k))}{M^2}, \tag{6.7}$$

where β_k runs over the interval $[0, 1]$. Consequently, the size of λ_k can be very close to zero when x^k is close to a feasible solution (no matter how β_k is chosen in $[0, 1]$). Also, λ_k may happen to be much larger than 2 when x^k is far from a feasible solution, and the number $f(x^k)$ is large enough (note that $2 - \beta_k$ stays between 1 and 2). So, Algorithm 3.1 is naturally underrelaxing or overrelaxing the computational process according to the relative position of the current iterate x^k to the feasibility set of the problem. As our experiments show, in some circumstances, this makes Algorithm 3.1 behave better than the other procedures we compare with it. At the same time, the self-regulation of the relaxation parameters, which is essential in Algorithm 3.1, may happen to reduce the initial speed of convergence of this procedure, that is, Algorithm 3.1 may require more computational steps in order to reach a point x^k, which is close enough to the feasibility set such that its self-regulatory features are to be really advantageous for providing a very precise solution of the given problem (which the other procedures may fail to do since they may become stationary in the vicinity of the feasibility set). Another interesting feature of Algorithm 3.1, which differentiates it from the other algorithms we compare it with, is its essentially nonsimultaneous character: Algorithm 3.1 does not necessarily ask for $w_i^k > 0$ for all $i \in \{1, \ldots, m\}$. The set of positive weights w_i^k, which condition the progress of the algorithm at step k, essentially depends on the current iterate x^k (see (3.4)) and allows reducing the number of subgradients needed to be computed at each iterative step (in fact, one can content himself with only one $w_i^k > 0$, and thus with a single subgradient ξ_i^k). This may be advantageous in cases when computing subgradients is difficult and therefore time consuming.

The main observations can be summarized as follows:

1. Algorithm 3.1 exhibits faster initial convergence than the other algorithms in the vicinity of points with very small $f(x^k)$. When the algorithms reach points with small $f(x^k)$ values, then Algorithm 3.1 tends to further reduce the value of $f(x^k)$, while the other algorithms tend to converge onto a constant steady-state value.

2. The problem dimensions in our experiments have little impact on the behavior of the algorithms.
3. All the examined small-scale problems have no feasible solutions. This can be seen from the fact that all three algorithms stabilize around $f(x^k) = 50$.
4. The chaotic oscillations of Algorithm 2.2 in the underrelaxed case is due to the fact that this algorithm has no internal mechanism to self-adapt its progress to the distance between the current iterates and the sets whose intersections are to be found. This phenomenon can hardly happen in Algorithm 3.1 because its relaxation parameters are self-adapting to the size of the current difference between successive iterations. This is an important feature of this algorithm. However, this feature also renders it somewhat slower than the other algorithms.
5. In some cases, Algorithms 2.2 and 2.4 indicate that the problem has no solution. In contrast, Algorithm 3.1 continues to make progress and seems to indicate that the problem has a feasible solution. This phenomenon is again due to the self-adaptation mechanism and can be interpreted in one of the following ways: (a) The problem indeed has a solution, but Algorithms 2.2 and 2.4 are unable to detect it (because they stabilize too fast). Algorithm 3.1 detects a solution provided that it is given enough running time; (b) The problem has no solution, and then Algorithm 3.1 will stabilize close to zero, indicating that the problem has no solution, but this may be due to computing (round-off) errors. Thus, a very small perturbation of the functions involved in the problem may render the problem feasible.

7. Conclusions. We have studied here mathematically and experimentally subgradient projections methods for the convex feasibility problem. The behavior of the fully simultaneous subgradient projections method in the inconsistent case is not known. Therefore, we studied and tested two options. One is the use of steering parameters instead of relaxation parameters, and the other is a variable relaxation strategy, which is self-adapting. Our small-scale and midscale experiments are not, decisive in all aspects and call for further research. But one general feature of the algorithm with the self-adapting strategical relaxation is its stability (nonoscillatory) behavior, and its relentless improvement of the iterations towards a solution in all cases. At this time we have not yet refined enough our experimental setup. For example, by the iteration index k on the horizontal axes of our plots we consider a whole sweep through all the sets of the convex feasibility problem, regardless of the algorithm. This is a good first approximation by which to compare the different algorithms. More accurate comparisons should use actual run times. Also, several numerical questions still remain unanswered in this report. These include the effect of various values of the constant σ as well as algorithmic behavior for higher iteration indices. In light of the applications mentioned in section 1, higher dimensional problems must be included. These and other computational questions are currently investigated.

AN AUGMENTED PRIMAL-DUAL METHOD FOR LINEAR CONIC PROGRAMS*

FLORIAN JARRE† AND FRANZ RENDL‡

Abstract. We propose a new iterative approach for solving linear programs over convex cones. Assuming that Slater's condition is satisfied, the conic problem is transformed to the minimization of a convex differentiable function in the primal-dual space. This function shows similarities with the augmented Lagrangian function and is called "augmented primal-dual function" or "apd-function". The evaluation of the function and its derivative is cheap if the projection of a given point onto the cone can be computed cheaply, and if the projection of a given point onto the affine subspace defining the primal problem can be computed cheaply. For the special case of a semidefinite program, a certain regularization of the apd-function is analyzed. Numerical examples minimizing the apd-function with a conjugate gradient method illustrate the potential of the approach.

Key words. conic program, linear convergence, augmented primal-dual function

DOI. 10.1137/070687128

1. Introduction.

We present a new method for solving convex conic programs. The method is based on minimizing a convex differentiable "augmented primal-dual function" (apd-function) that is related to the augmented Lagrangian but less problem dependent and does not require any penalty parameter. If Slater's condition is satisfied, the problem of solving the conic program is equivalent to minimizing the apd-function. The evaluation of function value and gradient of the apd-function requires two conic projections and two projections on an affine subspace. If these projections are cheap, it is possible to minimize the apd-function by any descent method such as a conjugate gradient type method or a limited memory BFGS method. In our numerical examples we report results obtained with a conjugate gradient approach.

When applying this algorithm to the apd-function of a linear program in standard form with a system matrix $A \in \mathbb{R}^{m\times n}$, a factorization of the matrix AA^T can be computed in a preprocessing phase. Given this factorization the cost per iteration is of order $O(mn)$ arithmetic operations. When minimizing the apd-function of a linear program by Newton's method—at a cost of order $O(n^3)$ arithmetic operations per iteration—this algorithm converges in a finite number of iterations. We therefore anticipate that a conjugate gradient or BFGS approach will converge rapidly as well.

When applied to a semidefinite program having a unique and strictly complementary solution the algorithm is sublinearly convergent. We therefore derive a simple modification of the apd-function for which Newton's method is locally quadratically convergent. Generalizations of this modification to Cartesian products of the semidefinite cone, the second-order cone, and the positive orthant are straightforward.

Our approach is related to projection methods such as considered, for example, in [1]. New elements of this paper are a transformation of a conic problem into an affine-convex pair with cheap projections onto the affine set, a conjugate gradient acceleration, a regularization for the case of semidefinite programs, and promising numerical examples.

Several methods have been proposed in the literature to overcome the limits of interior point methods for solving large-scale semidefinite programs. We recall the spectral bundle method [8] which uses eigenvalue optimization. The low-rank factorization approach of Burer and Monteiro [2] treats semidefinite programs using nonlinear optimization techniques. The currently strongest computational results are reported in the papers by Toh [22] and by Kocvara and Stingl [11]. Toh uses an iterative solver for the augmented KKT system, and Kocvara and Stingl apply an iterative solver to a modified barrier problem. The approach presented in the current paper is closely related to the "boundary point method" from [18] and the regularization approaches in [13].

2. Linear conic programs. We consider linear conic programs of the form

$$(P) \qquad \text{minimize } \langle c, x\rangle \ \text{ s.t. } \ x \in K \cap (\mathcal{L} + b),$$

where K is a closed convex cone in a finite dimensional Euclidean space E, $\mathcal{L}$ is a linear subspace, and $b, c \in E$ are given data. We always assume that the dimension of E is denoted by n. Our practical applications refer to the cases where K is the positive orthant in $E = \mathbb{R}^n$ and where K is the cone of symmetric positive semidefinite matrices in $E = \mathcal{S}^l = \{X \in \mathbb{R}^{l\times l} \mid X = X^T\}$. Here, $n = l(l+1)/2$.

We always assume that K has a nonempty interior (no hidden equality constraints) and that K is pointed (in LP-notation this assumption means there are no free variables).

Often the set $\mathcal{L}$ is given in the form

$$(1) \qquad \mathcal{L} = \{\tilde{x} \mid A\tilde{x} = 0\} \qquad \text{and} \qquad \mathcal{L} + b = \{x \mid Ax = Ab\},$$

where A is a matrix or some other representation of a linear operator. In particular, our analysis yields an algorithm applicable to linear programs of the form

$$\text{minimize } c^T x \ \text{ s.t. } \ Ax = \bar{b}, \ \ x \geq 0,$$

where $\bar{b} := Ab$.

We use the dual program as introduced in [14], section 4.2,

$$(D) \qquad \text{minimize } \langle b, s\rangle \ \text{ s.t. } \ s \in K^D \cap (\mathcal{L}^\perp + c),$$

where $\mathcal{L}^\perp$ is the orthogonal complement of $\mathcal{L}$ and

$$K^D = \{s \in E \mid \langle s, x\rangle \geq 0 \ \forall x \in K\}$$

is the dual cone of K.

It is easily verified that weak duality holds, namely

$$\langle b, c\rangle \leq \langle c, x\rangle + \langle b, s\rangle$$

for all x, s that are feasible for (P) and (D). When (P) satisfies Slater's condition and (D) has a feasible solution, then strong duality holds; see [14], Theorem 4.2.1. In

this case, a point x is optimal for (P) if, and only if, there exists a point s feasible for (D) with

$$\langle b, c\rangle = \langle c, x\rangle + \langle b, s\rangle. \tag{2}$$

We denote such x and s by x^{opt} and s^{opt}.

3. Decomposing the conic program. The linear constraints of (P) and (D) (including (2)) are satisfied for all points in the affine space

$$\boldsymbol{A} := (\mathcal{L} + b) \times (\mathcal{L}^{\perp} + c) \cap \{(x; s) \mid \ \langle c, x\rangle + \langle b, s\rangle = \langle b, c\rangle\} \subset E \times E,$$

and the conic constraints are satisfied for all points in the cone

$$\boldsymbol{C} := K \times K^D \subset E \times E.$$

By the assumption on K, it follows that $\boldsymbol{C}$ is full dimensional, $\dim(\boldsymbol{C}) = 2n$. We assume that $\boldsymbol{A}$ is of dimension $n-1$. (In the case that $b \in \mathcal{L}$ and $c \in \mathcal{L}^{\perp}$ the set $\boldsymbol{A}$ is of dimension n. As we do not provide solutions in the relative interior of the solution set, this case is trivial with optimal solution $x^{opt} = s^{opt} = 0$.)

Solving (P) is equivalent to finding $z := (x; s) \in \boldsymbol{A} \cap \boldsymbol{C}$ where $\boldsymbol{A}$ is an affine subspace and $\boldsymbol{C}$ a convex cone. Moreover, as we will see, projections onto $\boldsymbol{A}$ and $\boldsymbol{C}$ are easily computable for the case of linear or semidefinite programming.

For a closed set $\mathcal{C}$ and a vector $\bar{z}$ we denote the distance of $\bar{z}$ to $\mathcal{C}$ by

$$d(\bar{z}, \mathcal{C}) := \min\{\|z - \bar{z}\|_2 \mid z \in \mathcal{C}\}.$$

Thus, solving (P) is also equivalent to finding z such that

$$\phi(z) := \frac{1}{2}(d(z, \boldsymbol{A})^2 + d(z, \boldsymbol{C})^2) = 0, \tag{3}$$

i.e., such that the differentiable convex function ϕ is minimized. (Differentiability of ϕ is shown in Lemma 1 below.)

When (P) is a linear program in standard form, the function $d(z, \boldsymbol{C})^2$ is of the form $\sum_i ((z_i)^-)^2$ where $(z_i)^- := \min\{0, z_i\}$. Thus, ϕ is closely related to the augmented Lagrangian function. We therefore call ϕ an augmented primal-dual function. It differs from the augmented Lagrangian in that the representation of the linear subspace $\mathcal{L}$ (i.e., the matrix A when $\mathcal{L}$ is of the form (1)) does not enter the representation of ϕ. In other words, ϕ is less "data dependent" than the augmented Lagrangian, and it depends on a larger number of unknowns. As we will see, however, the dependence on a large number of unknowns does not imply that computations with ϕ are numerically expensive.

LEMMA 1. *For a closed convex set $\mathcal{C}$ let*

$$\Pi_{\mathcal{C}} \text{ be the orthogonal projection}$$

(with respect to the Euclidean norm) onto $\mathcal{C}$. Then, given an algorithm for the evaluation of $\Pi_{\mathcal{C}}$, the distance $d(z, \mathcal{C}) = \|z - \Pi_{\mathcal{C}}(z)\|_2$ is easily computed. Moreover, a steepest descent step of step length 1 starting at z for minimizing the differentiable function $\phi_{\mathcal{C}}$ with

$$\phi_{\mathcal{C}}(z) := \frac{1}{2} d(z, \mathcal{C})^2$$

will lead to the nearest point minimizing d (i.e., to $\Pi_{\mathcal{C}}(z)$).

Proof. For completeness we provide an elementary proof of Lemma 1. It is easy to verify that $\Pi_{\mathcal{C}}$ is well defined (single-valued) and Lipschitz continuous with Lipschitz constant 1. We show that $\phi_{\mathcal{C}}(z)$ is a differentiable function and $\nabla\phi_{\mathcal{C}}(z) = z - \Pi_{\mathcal{C}}(z)$. Let $\hat{z} := \Pi_{\mathcal{C}}(z)$. Let Δz be arbitrary. We show that

$$\phi_{\mathcal{C}}(z + \lambda\Delta z) = \phi_{\mathcal{C}}(z) + \lambda\Delta z^T(z - \hat{z}) + o(|\lambda|).$$

First note that

$$2\phi_{\mathcal{C}}(z + \lambda\Delta z) \le \|\hat{z} - (z + \lambda\Delta z)\|_2^2 = \|\hat{z} - z\|_2^2 - 2\lambda(\hat{z} - z)^T\Delta z + O(\lambda^2).$$

On the other hand, let $\hat{z}(\lambda) := \Pi_{\mathcal{C}}(z+\lambda\Delta z)$. As $\hat{z}(\lambda) \in \mathcal{C}$ it follows $(\hat{z}(\lambda)-\hat{z})^T(z-\hat{z}) \le 0$, and $\|\hat{z}(\lambda) - \hat{z}\|_2 \le \|\lambda\Delta z\|_2$. It follows

$$2\phi_{\mathcal{C}}(z + \lambda\Delta z) = \|\hat{z}(\lambda) - (z + \lambda\Delta z)\|_2^2 = \|(\hat{z}(\lambda) - \hat{z}) + (\hat{z} - z) - \lambda\Delta z\|_2^2$$

$$\ge \|\hat{z} - z\|_2^2 - 2\lambda(\hat{z} - z)^T\Delta z - O(\lambda^2).$$

This completes the proof of Lemma 1. ∎

Unfortunately, the one-step convergence of the steepest descent method in Lemma 1 is lost when minimizing the sum $\phi(z) = \frac{1}{2}(d(z, \boldsymbol{A})^2 + d(z, \boldsymbol{C})^2)$ in (3).

Note that the projections onto $\boldsymbol{A}$ and $\boldsymbol{C}$—and thus the function ϕ—are easy to compute for the case of linear and semidefinite programming:

For the case of linear programming, $\boldsymbol{C}$ is the positive orthant in $\mathbb{R}^{2n}$, and the projection onto $\boldsymbol{C}$ can be performed in $O(n)$ arithmetic operations. In the case of semidefinite programming, $\boldsymbol{C}$ is the Cartesian product of the semidefinite cone with itself, and the projection onto $\boldsymbol{C}$ can be computed by performing the eigenvalue decompositions of two symmetric matrices (order l^3 operations).

In section 6 it is shown that also the projection onto $\boldsymbol{A}$ can be done efficiently for these two examples. If $\mathcal{L}$ is given as in (1) with $Ab \in \mathbb{R}^m$ and the Cholesky factorization of AA^T is computed in a preprocessing step before starting the algorithm, then the projection can be evaluated in $O(mn)$ operations.

4. Solving (*P*) and (*D*). As shown in the previous section, solving (P) and (D) is reduced to finding a point in the intersection of the two convex sets $\boldsymbol{A}$ and $\boldsymbol{C}$, both of which are explicitly given. In this section we assume that the intersection of $\boldsymbol{A}$ and $\boldsymbol{C}$ is nonempty.

4.1. Minimizing the distance between *A* and *C*. Standard projection methods solve the problem of finding a point in $\boldsymbol{A} \cap \boldsymbol{C}$ by the following *simple algorithm:*

ALGORITHM 1 (Alternating projections).

Initialization: Let $z^0 \in \boldsymbol{A}$ be given. Set $k = 0$.

1. *Set $\hat{z}^k := \Pi_{\boldsymbol{C}}(z^k)$.*
2. *Set $z^{k+1} := \Pi_{\boldsymbol{A}}(\hat{z}^k)$. Set $k = k + 1$. Go to Step 1.*

By Lemma 1, one iteration of Algorithm 1 can be interpreted as one steepest descent step for minimizing $\frac{1}{2}d(\,.\,, \boldsymbol{C})^2$ followed by a steepest descent step for minimizing $\frac{1}{2}d(\,.\,, \boldsymbol{A})^2$. In general, such method converges very slowly. We therefore consider an acceleration minimizing the sum of both functions by a conjugate gradient scheme:

4.2. Minimizing ϕ. The first simple approach for minimizing ϕ is a conjugate gradient type method with Polak–Ribière type update or Fletcher–Reeves type update of the search direction. For descent methods it is important to understand the behavior of the second derivative of the objective function.

For linear and semidefinite programming, the function ϕ is twice differentiable almost everywhere. (It is differentiable everywhere.) For linear programming the eigenvalues of the Hessian H of ϕ at any point z such that $H(z)$ exists are at most 2 (as each of the Hessians of $\frac{1}{2}d(\ .\ ,\boldsymbol{A})^2$ and $\frac{1}{2}d(\ .\ ,\boldsymbol{C})^2$ only has the eigenvalues zero and one.) The eigenvalues of H are nonnegative, but unfortunately, they may be zero or arbitrarily close to zero. This makes the application of descent methods for minimizing ϕ difficult. Before continuing our analysis of the function ϕ we reduce the number of degrees of freedom by restricting ϕ to a lower dimensional subspace:

Note that $\boldsymbol{A}$ is an affine subspace. We restrict ϕ to $\boldsymbol{A}$ and define the function $\tilde{\phi}$ by

$$\tilde{\phi}(\tilde{z}) := \phi(\tilde{z}) = \frac{1}{2}d(\tilde{z},\boldsymbol{C})^2 \qquad \text{for } \tilde{z} \in \boldsymbol{A}. \tag{4}$$

We stress that $\tilde{\phi}$ is not defined outside $\boldsymbol{A}$. To emphasize this fact we also denote the variable by $\tilde{z}$ rather than just z.

LEMMA 2. *The function $\tilde{\phi}$ is differentiable, and for $\tilde{z} \in \boldsymbol{A}$ its gradient is given by*

$$\nabla\tilde{\phi}(\tilde{z}) = \tilde{z} - \Pi_{\boldsymbol{A}}(\Pi_{\boldsymbol{C}}(\tilde{z})).$$

Proof. Let $\boldsymbol{A} = \boldsymbol{z} + \boldsymbol{L}$ where $\boldsymbol{z}$ is a fixed vector and $\boldsymbol{L}$ a linear subspace. Note that

$$\tilde{z} - \Pi_{\boldsymbol{A}}(\Pi_{\boldsymbol{C}}(\tilde{z})) = \Pi_{\boldsymbol{L}}(\tilde{z} - \Pi_{\boldsymbol{C}}(\tilde{z})).$$

By Lemma 1 it therefore suffices to recall the following more general simple statement:

If $\varphi : E \times E \to \mathbb{R}$ is a differentiable function, then the gradient of the restriction $\tilde{\varphi}$ of φ to $\boldsymbol{A}$ is given by

$$\nabla\tilde{\varphi}(\tilde{z}) = \Pi_{\boldsymbol{L}}(\nabla\varphi(\tilde{z})).$$

The gradient of $\tilde{\varphi}$ at $\tilde{z} \in \boldsymbol{A}$ is a vector $\tilde{w} \in \boldsymbol{L}$ such that

$$\tilde{\varphi}(\tilde{z} + \Delta\tilde{z}) = \tilde{\varphi}(\tilde{z}) + \tilde{w}^T\Delta\tilde{z} + o(\Delta\tilde{z})$$

for all sufficiently small $\Delta\tilde{z} \in \boldsymbol{L}$. The vector $w := \Pi_{\boldsymbol{L}}(\nabla\varphi(\tilde{z}))$ certainly lies in $\boldsymbol{L}$. For $\Delta\tilde{z} \in \boldsymbol{L}$ it follows from symmetry of $\Pi_{\boldsymbol{L}}$ that

$$\begin{aligned}
\tilde{\varphi}(\tilde{z}) + w^T\Delta\tilde{z} &= \varphi(\tilde{z}) + (\Pi_{\boldsymbol{L}}(\nabla\varphi(\tilde{z})))^T\Delta\tilde{z} \\
&= \varphi(\tilde{z}) + (\nabla\varphi(\tilde{z}))^T\Pi_{\boldsymbol{L}}\Delta\tilde{z} \\
&= \varphi(\tilde{z}) + (\nabla\varphi(\tilde{z}))^T\Delta\tilde{z} \\
&= \varphi(\tilde{z} + \Delta\tilde{z}) + o(\Delta\tilde{z}) \\
&= \tilde{\varphi}(\tilde{z} + \Delta\tilde{z}) + o(\Delta\tilde{z}).
\end{aligned}$$

This completes the proof. ∎

A steepest descent step with line search for minimizing $\tilde{\phi}$ starting at a point $\tilde{z} = z^k \in \boldsymbol{A}$ is the same as the computation of z^{k+1} with Algorithm 1 followed by an extrapolation along the line $z^k + \lambda(z^{k+1} - z^k)$. We briefly list a conjugate gradient acceleration of the steepest descent approach:

ALGORITHM 2 (CG-method for minimizing $\tilde{\phi}$).
Let $\tilde{z}^0 \in \boldsymbol{A}$ be given. Let $\Delta\tilde{z}^0 := -\nabla\tilde{\phi}(\tilde{z}^0)$. Set $k = 0$.

1. *Let $\lambda_k := argmin\{\tilde{\phi}(\tilde{z}^k + \lambda\Delta\tilde{z}^k) \mid \lambda > 0\}$.*
2. *Set $\tilde{z}^{k+1} := \tilde{z}^k + \lambda_k\Delta\tilde{z}^k$.*
3. *Compute $\Delta\tilde{z}^{k+1}$ from $\Delta\tilde{z}^k$ and $\nabla\tilde{\phi}(\tilde{z}^{k+1})$ using an update formula such as Polak–Ribière.*
4. *If k is a multiple of $(n-1)$, set $\Delta\tilde{z}^{k+1} := -\nabla\tilde{\phi}(\tilde{z}^{k+1})$ (restart).*
5. *Set $k := k+1$. Go to Step 1.*

The Polak–Ribière update introduced in [16] is analyzed in [4, 3]. Global convergence of suitable modifications of the algorithm can be established under rather weak conditions; see e.g. section 5.2 of [15].

Remark 1. The concept of Algorithm 2 is in some sense "complementary" to the boundary point method of [18]. The latter algorithm generates iterates within the primal-dual cone approaching the set of linear constraints, while the iterates in Algorithm 2 always satisfy the linear constraints and approach the primal-dual cone. The restriction to an affine space (rather than the nonlinear primal-dual cone) opens the door for CG- or limited memory BFGS-accelerations.

Remark 2. When $\boldsymbol{C}$ is polyhedral, and (P), (D) have a unique optimal solution z^{opt}, then the Hessian of $\tilde{\phi}$ is piecewise linear and positive definite near z^{opt} (since z^{opt} is necessarily strictly complementary!), and thus, Newton's method for minimizing $\tilde{\phi}$ converges in a finite number of iterations; see e.g., [7].

Now consider the case where $\boldsymbol{C}$ is not polyhedral. Below we give a very simple example with a unique, strictly complementary optimal solution z^{opt} of (P) and (D) such that there are directions $z^{opt} + \lambda\Delta\tilde{z}$ through z^{opt} along which the intersection of $\boldsymbol{A}$ and $\boldsymbol{C}$ is "tangential" (the function $\tilde{\phi}$ in (4) growing in the order of λ^4) and other directions along which the intersection of $\boldsymbol{A}$ and $\boldsymbol{C}$ is "transversal" ($\tilde{\phi}$ growing in the order of λ^2). This implies that the condition number of the Hessian of $\tilde{\phi}$ near z^{opt} is unbounded and the conjugate gradient method is likely to converge *sublinearly*! For the case of semidefinite programs, we therefore derive an acceleration for this situation.

5. Application to semidefinite programs. In this section we use the following notation common for semidefinite programs: The space of real symmetric $l \times l$-matrices is denoted by $\mathcal{S}^l$. The dimension of $\mathcal{S}^l$ is $n := l(l+1)/2$. The notation $X \succeq 0$ ($X \succ 0$) is used to indicate that $X \in \mathcal{S}^l$ is positive semidefinite (positive definite). The standard scalar product on the space of $l \times l$-matrices is given by

$$\langle C, X\rangle := C \bullet X := \operatorname{trace}(C^T X) = \sum_{i,j=1}^{l} C_{i,j}X_{i,j}.$$

For given matrices $A^{(i)} \in \mathcal{S}^l$, $i = 1, 2, \ldots, m$, we define a linear map $\mathcal{A} : \mathcal{S}^l \to \mathbb{R}^m$ by

$$\mathcal{A}(X) := \begin{bmatrix} A^{(1)} \bullet X \\ \vdots \\ A^{(m)} \bullet X \end{bmatrix}, \quad X \in \mathcal{S}^l.$$

The adjoint operator $\mathcal{A}^* : \mathbb{R}^m \to \mathcal{S}^l$ is given by

$$\mathcal{A}^*(y) = \sum_{i=1}^{m} y_i A^{(i)}, \quad y \in \mathbb{R}^m.$$

With these definitions, the standard pair of primal and dual linear semidefinite programs can now be stated as follows:

$$(P) \qquad \text{minimize} \quad C \bullet X \quad \text{subject to} \quad \mathcal{A}(X) = \bar{b}, \quad X \succeq 0$$

and

$$(D') \qquad \text{maximize} \quad \bar{b}^T y \quad \text{subject to} \quad \mathcal{A}^*(y) + S = C, \quad S \succeq 0.$$

The dual program is equivalent (in the sense that the optimal solutions coincide) to

$$(D) \qquad \text{minimize} \quad B \bullet S \quad \text{subject to} \quad S \in \mathcal{L}^\perp + C, \quad S \succeq 0,$$

where $B \in \mathcal{S}^l$ is such that $\mathcal{A}(B) = \bar{b}$ and $\mathcal{L} = \{X \in \mathcal{S}^l \mid \mathcal{A}(X) = 0\}$.

ASSUMPTION 1. *Throughout this section we assume that the matrices $A^{(i)}$ are linearly independent and that (P) and (D) are strictly feasible and that there is a unique and strictly complementary solution $Z^{opt} = (X^{opt}, S^{opt})$ of (P) and (D) satisfying $X^{opt} + S^{opt} \succ 0$.*

Simple example: We give a simple example of a pair of semidefinite programs (P) and (D) satisfying Assumption 1 such that the Hessian of $\tilde{\phi}$ (see (4)) has an unbounded condition number for $\bar{Z}$ near Z^{opt}. (The Hessian is not defined at Z^{opt}.) Let $m = 1$ and the data of (P) and (D) be given by

$$C := \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}, \qquad B := \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad \text{and} \quad A^{(1)} := \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}.$$

The primal-dual optimal solution $Z^{opt} = (X^{opt}, S^{opt}) = (B, C)$ is unique and strictly complementary. The space $\boldsymbol{L} := \mathcal{L} \times \mathcal{L}^\perp \cap \{(\Delta X, \Delta S) \mid C \bullet \Delta X + B \bullet \Delta S = 0\}$ is given by

$$\boldsymbol{L} = \left\{ \Delta Z = (\Delta X, \Delta S) = \left(\begin{pmatrix} 2a & -a \\ -a & b \end{pmatrix}, \begin{pmatrix} -b & -b \\ -b & 0 \end{pmatrix} \right) \mid \ a, b \in \mathbb{R} \right\}.$$

By construction, $Z^{opt} + \Delta Z \in \boldsymbol{A}$ for $\Delta Z \in \boldsymbol{L}$, and for small $|a|, |b|$ it is easily verified that

$$d(Z^{opt} + \Delta Z, \boldsymbol{C}) = O(|b|) \quad \text{if } a = 0, \qquad d(Z^{opt} + \Delta Z, \boldsymbol{C}) = O(a^2) \quad \text{if } b = 0.$$

Thus, the second directional derivative of $\tilde{\phi}$ is zero Z^{opt} along the direction $b = 0$ and positive along the direction $a = 0$. Minimizing $\tilde{\phi}$ by some conjugate gradient scheme will result in a very slow algorithm.

Discussion: Of course, the above example is not surprising. We have given a convex characterization of the optimal solution of a convex program as the intersection of two convex sets $\boldsymbol{A}$ and $\boldsymbol{C}$, each of which is easily computable. We do not have the property that this characterization is well conditioned under "reasonable assumptions." So far, a computable characterization of the optimal solution of a convex program with both properties—convexity and well conditionedness—is unknown. (The KKT conditions are well conditioned under suitable assumptions, see, e.g., [5], but the complementarity part of the KKT conditions is nonconvex.) This lack of a convex *and* well conditioned characterization of the optimal solution is responsible for the fact that most polynomial-time methods for convex programs use some homotopy approach to compute an optimal solution.

5.1. A local acceleration. We propose an acceleration that can be applied locally near the optimal solution $Z^{opt} = (X^{opt}, S^{opt})$ of (P) and (D), e.g., when the minimization of $\tilde{\phi}$ is turning slow.

Let $\hat{f}(Z) = \hat{f}(X,S) := \|XS - SX\|_F^2$. The nonconvex function $\hat{f}$ is minimized at Z^{opt}. It is differentiable and the derivative

$$\nabla_Z \hat{f}(Z) = 2\begin{pmatrix} S^2X + XS^2 - 2SXS \\ X^2S + SX^2 - 2XSX \end{pmatrix}$$

can be computed in order n^3 operations. More precisely, by exploiting the fact that $XS = (SX)^T$, it can be evaluated with three matrix-matrix multiplications: two for evaluating $2XSX - XXS - SXX = X(SX - XS) + (X(SX - XS))^T$, and one more for the second block of $\nabla\hat{f}(Z)$. Also the derivative of the restriction of $\hat{f}$ to $\boldsymbol{A}$ can be computed as in the proof of Lemma 2.

We therefore propose to solve (P) and (D) in two stages, the first one minimizing $\tilde{\phi}$ for $\tilde{Z} \in \boldsymbol{A}$, and when convergence of this stage is slow, starting a second stage minimizing $\tilde{\phi} + \hat{f}$ for $\tilde{Z} \in \boldsymbol{A}$. For both stages we may use a nonlinear CG-method as in Algorithm 2. The CG-method is n-step locally quadratically convergent if the objective function is three times differentiable near Z^{opt} and if the Hessian at Z^{opt} is positive definite; see e.g. [4, 3, 17]. In Theorem 1 below, we show a slightly weaker statement.

Note: In the following we will consider only points in $\boldsymbol{A}$. For compactness of notation we omit the additional identification $\tilde{Z}$ to indicate that $\tilde{Z} \in \boldsymbol{A}$ and shortly write $Z \in \boldsymbol{A}$. The restriction of $\phi + \hat{f}$ to $\boldsymbol{A}$ will be denoted by Ψ,

$$\Psi(Z) := \phi(Z) + \hat{f}(Z) \qquad \text{for } Z \in \boldsymbol{A}.$$

Again, we emphasize the restriction to $\boldsymbol{A}$.

THEOREM 1. *The gradient of Ψ is strongly semismooth and the generalized Hessian is positive definite at Z^{opt}.*

In short, $G(\ .\ ) := \nabla_Z \Psi(\ .\ )$ is strongly semismooth at the point Z, if for small $\|H\|$ the relation $G(Z+H) = G(Z) + \partial G(Z+H)[H] + O(\|H\|^2)$ holds true, where ∂G denotes any element of the generalized Jacobian of G in the sense of Clarke; see, e.g., Section 2.1 in [21]. By Theorem 3.2 in [19], Theorem 1 implies quadratic convergence of Newton's method for minimizing Ψ. We therefore anticipate that also conjugate gradient-type algorithms or limited-memory BFGS algorithms will converge rapidly.

Proof. Strong semismoothness of the gradient of Ψ at Z^{opt} follows from [20]; here, we prove positive definiteness of the generalized Hessian.

We start by noting that in spite of $\hat{f}$ not being convex, the eigenvalues of the Hessian of $\hat{f}$ at Z^{opt} are nonnegative since Z^{opt} is a minimizer of $\hat{f}$. Hence it suffices to show that either ϕ or $\hat{f}$ has a positive curvature along any given direction through Z^{opt}.

Let a perturbation $\Delta Z = (\Delta X, \Delta S)$ with $Z^{opt} + \Delta Z \in \boldsymbol{A}$ and $\|\Delta X\|_F^2 + \|\Delta S\|_F^2 = 1$ be given. It suffices to show that there exists a $\rho > 0$ independent of ΔZ such that

$$\phi(Z^{opt} + \lambda\Delta Z) + \hat{f}(Z^{opt} + \lambda\Delta Z) \geq \lambda^2\rho$$

for sufficiently small $\lambda > 0$. To this end we proceed in four steps.

Step 1: We apply ΔZ to the linearized primal dual system and relate the norm of ΔZ to the norm of the right-hand side:

By complementarity, $X^{opt}S^{opt} = 0 = S^{opt}X^{opt}$, and thus the matrices $X^{opt} \succeq 0$ and $S^{opt} \succeq 0$ commute. This guarantees that there exists a unitary matrix U and

diagonal matrices

$$\Lambda = \operatorname{diag}(\lambda_1, \lambda_2, \ldots, \lambda_l) \succeq 0 \quad \text{and} \quad \Sigma = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_l) \succeq 0 \tag{5}$$

such that

$$X^{opt} = U\Lambda U^T \quad \text{and} \quad S^{opt} = U\Sigma U^T. \tag{6}$$

By strict complementarity we may assume without loss of generality that there exists a $k \leq l$ such that

$$\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_k > 0 = \lambda_{k+1} = \cdots = \lambda_l$$

and

$$\sigma_1 = \sigma_2 = \cdots = \sigma_k = 0 < \sigma_{k+1} \leq \cdots \leq \sigma_l.$$

As shown in Corollary 1 in [6], the following system of $m + 2n$ linear equations for $2n + m$ unknowns $(\Delta X, \Delta S, \Delta y)$:

$$\begin{aligned} \mathcal{A}(\Delta X) &= p, \\ \mathcal{A}^*(\Delta y) + \Delta S &= Q, \\ \Pi_{\text{up}}(U^T(\Delta X S^{opt} + X^{opt}\Delta S)U) &= r, \end{aligned} \tag{7}$$

is nonsingular. Here, $\Pi_{\text{up}}(U^T(\Delta X S^{opt} + X^{opt}\Delta S)U)$ denotes the upper triangular part of the matrix $U^T(\Delta X S^{opt} + X^{opt}\Delta S)U$; the right-hand side of (7) consists of $p \in \mathbb{R}^m$, $Q \in \mathcal{S}^l$, and the upper triangular part r of an $l \times l$-matrix. For brevity we write $r \in \mathbb{R}^n$.

We eliminate the variable Δy from the second equation of (7). To this end let $\mathcal{F} : \mathcal{S}^l \to \mathbb{R}^{n-m}$ be a linear operator of full rank such that $\mathcal{F}(\mathcal{A}^*(y)) = 0$ for all $y \in \mathbb{R}^m$. Let $q := \mathcal{F}(Q)$. By construction of $\mathcal{F}$, also the linear system

$$M \begin{pmatrix} \Delta X \\ \Delta S \end{pmatrix} := \begin{pmatrix} \mathcal{A}(\Delta X) \\ \mathcal{F}(\Delta S) \\ \Pi_{\text{up}}(U^T(\Delta X S^{opt} + X^{opt}\Delta S)U) \end{pmatrix} = \begin{pmatrix} p \\ q \\ r \end{pmatrix} \tag{8}$$

has full rank. Here, $(p^T, q^T)^T \in \mathbb{R}^n$ and $r \in \mathbb{R}^n$.

First note that $\|(p^T, q^T, r^T)^T\| = \|M\Delta Z\| \geq 1/\|M^{-1}\|_2$ since $\|\Delta Z\| = 1$. From $Z^{opt} + \Delta Z \in \boldsymbol{A}$ it follows that $p = 0$ and $q = 0$. Hence, $\|r\|_2 \geq 1/\|M^{-1}\|_2$.

Step 2: We now perform a change of basis.

Note that problems (P) and (D) remain invariant when replacing B with X^{opt} and C with S^{opt}. Hence, from $Z^{opt} + \Delta Z \in \boldsymbol{A}$ it follows that

$$\begin{aligned} 0 &= C \bullet \Delta X + B \bullet \Delta S \\ &= S^{opt} \bullet \Delta X + X^{opt} \bullet \Delta S. \end{aligned} \tag{9}$$

Let $\widetilde{\Delta X} := U^T \Delta X U$ and $\widetilde{\Delta S} := U^T \Delta S U$. The last equation in (8) then states that

$$\Pi_{\text{up}}(\widetilde{\Delta X}\Sigma + \Lambda\widetilde{\Delta S}) = r, \tag{10}$$

while relation (9) and $UU^T = I$ imply that

$$0 = \widetilde{\Delta X} \bullet \Sigma + \widetilde{\Delta S} \bullet \Lambda. \tag{11}$$

As U is unitary, $\|\widetilde{\Delta X}\|_F = \|\Delta X\|_F$, $\|\widetilde{\Delta S}\|_F = \|\Delta S\|_F$.

We partition $\widetilde{\Delta X}$ conforming with the zero-structure of Λ and Σ,

$$\widetilde{\Delta X} = \begin{pmatrix} \widetilde{\Delta X}_{11} & \widetilde{\Delta X}_{12} \\ \widetilde{\Delta X}_{12}^T & \widetilde{\Delta X}_{22} \end{pmatrix},$$

where $\widetilde{\Delta X}_{11} \in \mathcal{S}^k$ and $\widetilde{\Delta X}_{22} \in \mathcal{S}^{l-k}$. Likewise we partition $\widetilde{\Delta S}$.

Step 3: Let

$$\epsilon := \min\{\lambda_k, \sigma_{k+1}, 1/\lambda_1, 1/\sigma_l\} \qquad \text{and} \qquad \mu := \epsilon/(2\|M^{-1}\|_2).$$

We show that $\phi(Z^{opt}+\lambda\Delta Z)$ grows at least as $\frac{1}{2}(\lambda\epsilon^2\mu/2n^2)^2$ whenever $\|\widetilde{\Delta X}_{22}\|_F \geq \mu$ or $\|\widetilde{\Delta S}_{11}\|_F \geq \mu$.

Assume that $\|\widetilde{\Delta X}_{22}\|_F \geq \mu$. We distinguish two cases:

1. The maximum diagonal element of $\widetilde{\Delta X}_{22}$ is at least $\mu/2n$. It then follows from (11) and the definition of ϵ that the smallest diagonal element (and hence the smallest eigenvalue) of the 2×2-block matrix $\mathrm{Diag}(\widetilde{\Delta X}_{22}, \widetilde{\Delta S}_{11})$ is less than or equal to $-\epsilon^2\mu/2n^2$. (Straightforward proof by contradiction.)

2. The maximum diagonal element of $\widetilde{\Delta X}_{22}$ is less than $\mu/2n$. Since $\|\widetilde{\Delta X}_{22}\|_F \geq \mu$ there is an element of $\widetilde{\Delta X}_{22}$ of absolute value at least μ/n. If this is a diagonal element, it must be negative, and in particular, the most negative diagonal element is less than $-\epsilon^2\mu/2n^2$ as in Case 1 above. If it is an off-diagonal element, the associated 2 by 2 submatrix of $\widetilde{\Delta X}_{22}$ has diagonal elements $\leq \mu/2n$ and off-diagonal elements with absolute value $\geq \mu/n$. Straightforward calculations show that it therefore must have an eigenvalue $\leq -\mu/2n$. By the interlacing property, $\widetilde{\Delta X}_{22}$ has an eigenvalue less than or equal to $-\mu/2n$.

Thus, in both cases, the distance of $Z^{opt} + \lambda\Delta Z$ to $\boldsymbol{C}$ is at least $\lambda\epsilon^2\mu/2n^2$, and the function ϕ grows quadratically with λ.

The same argument holds when $\|\widetilde{\Delta S}_{11}\|_F \geq \mu$.

Step 4: Now assume that $\|\widetilde{\Delta X}_{22}\|_F < \mu$ and $\|\widetilde{\Delta S}_{11}\|_F < \mu$, so that Step 3 cannot be applied. In this case we show that $\hat{f}(Z^{opt} + \lambda\Delta Z)$ locally grows at least as $\lambda^2/2\|M^{-1}\|_2^2$.

From (10) follows

$$\|r\|^2 \leq \|\Lambda_{11}\widetilde{\Delta S}_{11}\|_F^2 + \|\widetilde{\Delta X}_{12}\Sigma_{22} + \Lambda_{11}\widetilde{\Delta S}_{12}\|_F^2 + \|\widetilde{\Delta X}_{22}\Sigma_{22}\|_F^2. \tag{12}$$

The inequality $\|r\|_2 \geq 1/\|M^{-1}\|_2$, relation (12), and the definition of ϵ imply

$$\|\widetilde{\Delta X}_{12}\Sigma_{22} + \Lambda_{11}\widetilde{\Delta S}_{12}\|_F^2 \geq 1/\|M^{-1}\|_2^2 - 2\mu^2/\epsilon^2 \geq 1/2\|M^{-1}\|_2^2. \tag{13}$$

Observe that

$$\begin{aligned} \hat{f}(Z^{opt} + \lambda\Delta Z) &= \|(\Lambda + \lambda\widetilde{\Delta X})(\Sigma + \lambda\widetilde{\Delta S}) - (\Sigma + \lambda\widetilde{\Delta S})(\Lambda + \lambda\widetilde{\Delta X})\|_F^2 \\ &= \lambda^2(\|\Lambda\widetilde{\Delta S} + \widetilde{\Delta X}\Sigma - \Sigma\widetilde{\Delta X} - \widetilde{\Delta S}\Lambda\|_F^2) + O(\lambda^3) \\ &\geq 2\lambda^2\|\Lambda_{11}\widetilde{\Delta S}_{12} + \widetilde{\Delta X}_{12}\Sigma_{22}\|_F^2 + O(\lambda^3). \end{aligned}$$

For small λ, the third-order term is dominated, and

$$\hat{f}(Z^{opt} + \lambda\Delta Z) \geq \lambda^2\|\Lambda_{11}\widetilde{\Delta S}_{12} + \widetilde{\Delta X}_{12}\Sigma_{22}\|_F^2 \geq \lambda^2/2\|M^{-1}\|_2^2,$$

which completes the proof. ∎

6. Cheap computation of the projection onto $\boldsymbol{A}$. First note that a projection onto an $n-1$-dimensional affine subspace of $\mathbb{R}^{2n}$ can (after an initial factorization of the projection matrix) generally be done in order n^2 operations. To make our algorithm practical, we show that it can be done in a cheaper way for the particular sets $\boldsymbol{A}$ arising in linear programming. (Of course, the same reasoning applies to semidefinite programming replacing A^T with the adjoint $\mathcal{A}^*$.)

The computation of the projection below is closely related to rank-one update formulae for inverse matrices. There are two differences: We update a projection rather than an inverse matrix, and the matrix defining the projection is never explicitly formed. (The matrix defining the projection may be nonsparse while A and the Cholesky factor of AA^T used below may be sparse.)

We assume that $\mathcal{L}+b = \{x \mid Ax = Ab\} \subset \mathbb{R}^n$ where A has full row rank. Let a point $x \in \mathbb{R}^n$ be given. Then it is easy to verify that

$$x - \Pi_{\mathcal{L}+b}(x) = A^T(AA^T)^{-1}A(x-b) \quad \text{and} \quad \|x-\Pi_{\mathcal{L}+b}(x)\|_2^2 = (x-b)^T A^T(AA^T)^{-1}A(x-b).$$

Likewise, for $s \in \mathbb{R}^n$ we have

$$s - \Pi_{\mathcal{L}^\perp+c}(s) = (I - A^T(AA^T)^{-1}A)(s-c)$$

and

$$\|s - \Pi_{\mathcal{L}^\perp+c}(s)\|_2^2 = (s-c)^T(I - A^T(AA^T)^{-1}A)(s-c).$$

The factorization of AA^T can be computed once in a preprocessing stage at the beginning of Algorithm 2 and can then be used without modification throughout. It is the same matrix that is usually factored in interior-point methods. For semidefinite programs, however, the factorization of $\mathcal{A}\mathcal{A}^*$ may be substantially cheaper than the systems factored at each iteration of an interior point algorithm; prime examples are semidefinite programs arising from the semidefinite relaxation [12] of the max clique problem [10] that results in the factorization of dense matrices in interior point methods while $\mathcal{A}\mathcal{A}^*$ is a *diagonal* matrix.

After this preprocessing the projection of a point $z = (x; s)$ onto

$$\boldsymbol{A_1} := (\mathcal{L}+b) \times (\mathcal{L}^\perp + c)$$

can be computed (separately for x and s) in order mn operations, namely two backsolves using the factorization of AA^T and two matrix vector products of the form Ax, two matrix products of the form A^Ty, as well as some order-n-operations.

Let

$$\boldsymbol{A_2} := \{(x; s) \mid \ \langle c, x\rangle + \langle b, s\rangle = \langle b, c\rangle\},$$

so that $\boldsymbol{A} = \boldsymbol{A_1} \cap \boldsymbol{A_2} \neq \emptyset$. We now compute the projection onto $\boldsymbol{A}$ given the projection onto $\boldsymbol{A_1}$. To this end first observe that for any affine space $\boldsymbol{A_1} = \boldsymbol{L_1} + \boldsymbol{b_1}$ and any hyperplane $\boldsymbol{A_2}$ written in the form $\boldsymbol{A_2} = \{z \mid \langle a, z\rangle = \alpha\}$ we have

$$\begin{aligned}
\boldsymbol{A_1} \cap \boldsymbol{A_2} &= \boldsymbol{L_1} + \boldsymbol{b_1} \cap \{z \mid \langle a, z\rangle \qquad = \alpha\} \\
&= (\boldsymbol{L_1} \qquad \cap \{z \mid \langle a, z\rangle \qquad = \alpha - \langle a, \boldsymbol{b_1}\rangle\}) + \boldsymbol{b_1} \\
&= (\boldsymbol{L_1} \qquad \cap \{z \mid \langle a, \Pi_{\boldsymbol{L_1}} z\rangle = \alpha - \langle a, \boldsymbol{b_1}\rangle\}) + \boldsymbol{b_1} \\
&= (\boldsymbol{L_1} \qquad \cap \{z \mid \langle \Pi_{\boldsymbol{L_1}} a, z\rangle = \alpha - \langle a, \boldsymbol{b_1}\rangle\}) + \boldsymbol{b_1} \\
&= \boldsymbol{L_1} + \boldsymbol{b_1} \cap \{z \mid \langle \Pi_{\boldsymbol{L_1}} a, z\rangle = \alpha - \langle a - \Pi_{\boldsymbol{L_1}} a, \boldsymbol{b_1}\rangle\},
\end{aligned}$$

where the third line is trivially true for $z \in \boldsymbol{L_1}$ and the fourth line holds since $\Pi_{\boldsymbol{L_1}}$ is symmetric. Hence, in a first step we may project a onto $\boldsymbol{L_1}$ and update α. In our case, we project b onto $\mathcal{L}^\perp$ and c onto $\mathcal{L}$ and replace $\langle b, c\rangle$ with 0. Just like the factorization of AA^T, this form of preprocessing is done only once for the algorithm; see section 7.1.

We therefore assume without loss of generality that $\boldsymbol{A_1} \perp \boldsymbol{A_2}$. In this case, the projection onto $\boldsymbol{A_1} \cap \boldsymbol{A_2}$ is particularly simple; it is the projection onto $\boldsymbol{A_1}$ followed by the projection onto $\boldsymbol{A_2}$. (The order in which the projections are applied plays no role.) We recall that the projection onto a hyperplane $\boldsymbol{A_2}$ can be carried out in order n operations,

$$z \mapsto z + \frac{\alpha - \langle a, z\rangle}{\langle a, a\rangle} a.$$

As we have just seen, the projection onto $\boldsymbol{A}$ at each iteration of Algorithm 2 takes two back-solves with the factorization of AA^T, two matrix vector multiplications Ax, and two matrix vector multiplications $A^T y$.

Next, we show by adding slack variables that the intersection of two cones can be decomposed into the Cartesian product of two cones at the expense of additional linear equations. These additional linear equations merely double the computational effort of the projection onto the affine manifold. (This is in contrast to interior point methods where additional inequalities for the Lovász–Schrijver relaxation of the max-clique problem imply a very substantial increase in computation time at each iteration.)

6.1. The intersection of two cones. A very rewarding application targeted by the apd approach is the Lovász relaxation of the max-clique problem for which the matrix $\mathcal{A}\mathcal{A}^*$ is a diagonal matrix, while interior point methods factor a full matrix of the same size at each iteration. The Lovász–Schrijver relaxation is a sharper relaxation for which the semidefinite cone is replaced with the intersection of the semidefinite cone and the cone of matrices with nonnegative entries. Unfortunately, while the projection onto either of the two cones is straightforward, the projection onto their intersection is less trivial. We therefore present an approach that allows the application to problems of the form

$$(\hat{P}) \qquad \text{minimize } \langle c, x\rangle \ \text{ s.t. } \ x \in K \cap \hat{K} \cap (\mathcal{L} + b),$$

where K and $\hat{K}$ are both pointed closed convex cones such that the interior of $K \cap \hat{K}$ is nonempty. Again, we assume that $\mathcal{L} + b$ is given by a set of linear equations $Ax = \bar{b}$ for which a factorization of AA^T is computed once, and that projections onto K and $\hat{K}$ are easy to compute.

Problem $(\hat{P})$ is equivalent to

$$\text{minimize } \left\langle \begin{pmatrix} c \\ 0 \end{pmatrix}, \begin{pmatrix} x \\ \hat{x} \end{pmatrix} \right\rangle \ \text{ s.t. } \ \begin{pmatrix} x \\ \hat{x} \end{pmatrix} \in (K \times \hat{K}) \cap \left(\hat{\mathcal{L}} + \begin{pmatrix} b \\ b \end{pmatrix} \right),$$

where

$$\hat{\mathcal{L}} + \begin{pmatrix} b \\ b \end{pmatrix} =: \left\{ \begin{pmatrix} x \\ \hat{x} \end{pmatrix} \ \middle| \ Ax = \bar{b}, \ \ x = \hat{x} \right\}.$$

This is a problem of the form (P). By our assumption, projections onto $K \times \hat{K}$—and hence also projections onto its dual—are easy to compute. Thus, in order to apply

the apd algorithm it suffices to verify that projections onto $\hat{\mathcal{L}}$ are easily computable given a factorization of AA^T.

This, however, is readily seen as

$$\begin{pmatrix} A & 0 \\ I & -I \end{pmatrix} \begin{pmatrix} A^T & I \\ 0 & -I \end{pmatrix} = \begin{pmatrix} AA^T & A \\ A^T & 2I \end{pmatrix} = \begin{pmatrix} 2(AA^T)^{-1} & -(AA^T)^{-1}A \\ -A^T(AA^T)^{-1} & \frac{1}{2}(I + A^T(AA^T)^{-1}A) \end{pmatrix}^{-1}$$

provides the desired factorization.

7. Numerical results. Algorithm 2 has been implemented in Matlab and tested on some randomly generated linear semidefinite programs (SDP) as well as on some SDP coming from combinatorial optimization. Initially, the algorithm can be applied to minimize the function $\tilde{\phi}$ for $z \in \boldsymbol{A}$, and when this minimization slows down, a Phase 2 is started, where a "regularizing" function $\hat{f}$ is added to $\tilde{\phi}$.

Under standard assumptions, Theorem 1 guarantees that the term $\|XS - SX\|_F^2$ may serve as a regularizing function. Note that also the term $\|XS + SX\|_F^2$ is minimized at the optimal solution of the problem (P). Thus, at the point Z^{opt} it has nonnegative curvature as well and hence, Theorem 1 also applies to the function

$$\hat{f}(X,S) := \|XS\|_F^2 = \frac{1}{4}(\|XS - SX\|_F^2 + \|XS + SX\|_F^2).$$

This term yielded the best numerical results in our examples, and the results listed below refer to this regularizing term – while Theorem 1 is proved under slightly weaker conditions (namely just the term $\|XS - SX\|_F^2$).

7.1. Rescaling. We emphasize that Algorithm 2 is essentially a first-order method, and hence, it is sensitive to scaling of the data. Even for data that "looks nice" (all data integers of absolute value less than 10), the following rescaling may turn out to be crucial:

First, replace b with $\Pi_{\mathcal{L}^\perp} b$. (The set $\mathcal{L} + b$ remains invariant with this change!) Likewise, replace c with $\Pi_{\mathcal{L}} c$. Then set $b = b/\|b\|_2$, $c = c/\|c\|_2$, and rescale x, s accordingly. Note that by this normalization, the duality simplifies to $\langle b, s\rangle + \langle c, x\rangle = 0$, and in particular, the set $\boldsymbol{A_2}$ now is a linear subspace perpendicular to $\boldsymbol{A_1}$.

Moreover, the origin $x = 0$ has distance exactly 1 from $\mathcal{L} + b$, and likewise $s = 0$ has distance exactly 1 from $\mathcal{L}^\perp + c$. For a semidefinite program, the point $x^{(0)} = s^{(0)} = I/\sqrt{n}$ is a canonical starting point: Its duality gap satisfies $\langle x^{(0)}, s^{(0)}\rangle = 1$, and the distance of $x^{(0)}$ from $\mathcal{L} + b$ is bounded by 2, same as the distance of $s^{(0)}$ from $\mathcal{L}^\perp + c$.

While the above rescaling of b and c appears to be natural, it is certainly far from optimal. When convergence slows down, it may be possible to identify a more suitable scaling based on the current iterate. The numerical results below simply refer to the above scaling.

7.2. Preconditioning. We point out that the above rescaling may be generalized slightly. Indeed, let M be a nonsingular matrix, then the preconditioning $X \to MXM^T$, $B \to MBM^T$, $\mathcal{L} \to M\mathcal{L}M^T$ and $S \to M^{-T}SM^{-1}$, $C \to M^{-T}CM^{-1}$ results in an equivalent semidefinite program, and the solution of either program can easily be recovered from the solution of the other. Of course, the functions $\tilde{\phi}$ and $\hat{f}$ change when replacing X, S with $MXM^T, M^{-T}SM^{-1}$, and thus the performance of Algorithm 2 will vary. It is still an open question how to determine suitable scalings that accelerate Algorithm 2. When M is a diagonal matrix, the projections onto

TABLE 1

Randomly generated SDP. The column labeled apd contains the function value after 50 *iterations of our augmented primal-dual method. The normalized primal and dual errors, multiplied by* 1000 *are given in columns* 4 *and* 5*, and the column labeled mprw provides the value computed by the boundary point method from* [13].

600	40000	6004030	−0.08	−0.23	307.45	306.62
700	50000	7005030	−0.14	−0.33	315.48	313.20
800	70000	8007030	−0.08	−0.22	2332.98	2331.39
900	100000	90010030	−0.06	−0.15	955.33	954.22
1000	100000	100010030	−0.11	−0.23	3099.51	3096.36

$M\mathcal{L}M^T$ and its orthogonal complement can be performed just as cheaply as for $\mathcal{L}$ and $\mathcal{L}^\perp$.

Likewise, one may look at preconditionings of the form $\|XS\|_F^2 \to \|MXS\tilde{M}\|_F^2$ for some nonsingular $M, \tilde{M}$. Here, the function $\tilde{\phi}$ is not changed, and here as well, the selection of suitable preconditionings is subject to further research.

7.3. Preliminary computational results. To give some impressions of the practical behavior of our approach, we provide some computational results both on randomly generated SDP used in [13], and on instances from the DIMACS collection [9], related to the Lovász theta number in graphs.

We first give a short description of the random instances from [13]. The linear constraints are generated to have a sparse Cholesky factor of AA^T. To achieve this, each A_i is generated to have nonzero support only on a submatrix of small order. Then a positive definite matrix X is generated, defining $b := A(X)$. On the dual side, the selection of y and $S \succ 0$ gives $C = A^T(y) + S$. This insures strong duality. The generator is written in MATLAB and is available at http://www.math.uni-klu.ac.at/or/Software.

In Table 1 we provide some preliminary computational results. The parameters n and m indicate the size of the problem as defined before. The parameter "seed" is used to initialize the random number generator and makes the instances reproducible using MATLAB. The column "mprw" contains the optimal value of the SDP, computed with a relative error tolerance of 10^{-7}. These values can therefore be considered as reasonably accurate. We provide the objective value of our approach (in column "apd") after 50 function evaluations. We have used a "quick-and-dirty" implementation of our approach, without any parameter tuning. Therefore we stop after a preset number of iterations to give a first impression of the potential of our approach. We reach optimality, once the smallest eigenvalues of X and S are nonnegative. Therefore we also provide the following (relative) error measures in the table.

$$err_P := \frac{\lambda_{\min}(X)}{1 + \|X\|}, \quad err_D := \frac{\lambda_{\min}(S)}{1 + \|S\|}.$$

We note that in all these instances, the most negative normalized eigenvalue (which keeps us away from optimality) is of order 10^{-4}.

The second table contains results on computing the Lovász theta number of a graph G, given through its edge list. The problem is of the form:

$$\max \sum_{ij} x_{ij} \text{ such that } x_{ij} = 0 \forall i \neq j, [ij] \notin E(G), \ \operatorname{trace}(X) = 1, \ X \succeq 0.$$

TABLE 2
The theta number for some DIMACS graphs. The first column gives the name of the graph.

name	n	m	$10^3 \cdot err_P$	$10^3 \cdot err_D$	apd	mprw
brock400-1	400	20078	−0.30	−0.57	39.67	39.70
p-hat500-1	500	93182	−0.36	−0.68	13.13	13.07
keller5	776	74711	−0.96	−1.66	30.69	31.00
brock800-1	800	112096	−0.26	−0.33	42.19	42.22
p-hat1000-3	1000	127755	−2.15	−8.61	77.83	84.80

Here $E(G)$ denotes the edge set of G. In this SDP, one therefore asks to have a zero in each position of X outside the main diagonal corresponding to non-edges. In addition, the trace of X should be one. These constraints have the nice feature that AA^T is in fact diagonal. In Table 2 we include as before the total number of equations in the column labeled m. We note that again after 50 iterations, we get rather good approximations of the theta number in all instances except keller5 and p-hat1000-3. For these two instances, the most negative eigenvalues are much bigger (in absolute value), as in the other cases. This would indicate that further iterations are necessary to come closer to optimality. Indeed, running the keller5 instance for 150 iterations, we obtain a value of 30.98 with relative errors -0.49e-3 and -0.58e-3. The theta number of these instances was only recently computed in [13]; the resulting SDPs seem to be beyond the capabilities of standard SDP solvers.

A final word on computation times and number of iterations is in order. First, the number of iterations of "mprw" to reach the required accuracy level is typically around 200 for the instances in the first table. For the instances in Table 2, the number of iterations varies greatly, depending on the instance. It took about 500 iterations for keller5 and more than 1000 for the last instance. So it should come as no surprise that our approach also has a harder time on these instances. We should also mention that the computational effort for a single iteration of our method is at least twice the effort of the boundary point method from [13], because we project X and S individually, while in the boundary point method, only one projection is necessary.

All computations were done on a Pentium IV (2.1 Ghz, 2G memory) using Matlab. It took about 45 minutes for the largest instance, and a few minutes for the smallest one. Since this is a preliminary implementation, we expect that there is quite a bit of room for improvement. The present paper sets the theoretical stage for the new approach. A competitive implementation is beyond the scope of the current paper and will be presented in a separate study.

8. Concluding remarks. This paper proposes a reformulation of a linear program over a convex cone into the problem of minimizing a differentiable convex apd-function in a certain primal-dual space. The apd-function is related to the augmented Lagrangian function, but is slightly less data dependent. For large classes of conic programs including linear, semidefinite, and SOC problems, its function and gradient evaluations are rather cheap. For the case of a semidefinite program, a certain regularization of the apd-function is analyzed. Numerical examples minimizing the function with a conjugate gradient method illustrate the potential of the approach. Extensions for the case that Slater's condition is not satisfied and to other cones are the subject of future research.

Acknowledgments. The authors thank the anonymous referees for their comments that helped to improve the presentation of the paper.

EXISTENCE AND APPROXIMATION OF FIXED POINTS OF FIRMLY NONEXPANSIVE-TYPE MAPPINGS IN BANACH SPACES*

FUMIAKI KOHSAKA† AND WATARU TAKAHASHI‡

Abstract. A class of nonlinear operators in Banach spaces is proposed. We call each operator in this class a firmly nonexpansive-type mapping. This class contains the classes of firmly nonexpansive mappings in Hilbert spaces and resolvents of maximal monotone operators in Banach spaces. We study the existence and approximation of fixed points of firmly nonexpansive-type mappings in Banach spaces.

Key words. Banach space, convex optimization, firmly nonexpansive mapping, firmly nonexpansive-type mapping, fixed point theorem, monotone operator, nonexpansive mapping, proximal point algorithm

1. Introduction.

Let C be a nonempty closed convex subset of a (real) Hilbert space H. Then a mapping $T : C \to C$ is said to be *nonexpansive* if $\|Tx-Ty\| \le \|x-y\|$ for all $x, y \in C$. The mapping T is also said to be *firmly nonexpansive* if

$$\|Tx - Ty\|^2 \le \langle x - y, Tx - Ty\rangle \tag{1.1}$$

for all $x, y \in C$; see Bruck and Reich [7], Goebel and Kirk [14], and Goebel and Reich [15]. It is known that a mapping $T : C \to C$ is firmly nonexpansive if and only if

$$\|Tx - Ty\|^2 + \|(I - T)x - (I - T)y\|^2 \le \|x - y\|^2 \tag{1.2}$$

for all $x, y \in C$, where I is the identity operator on H. Martinet [23] showed that if C is a nonempty bounded closed convex subset of H and $T : C \to C$ is a firmly nonexpansive mapping, then for all $x \in C$, $\{T^n x\}$ converges weakly to an element of $F(T)$, where $F(T)$ is the set of fixed points of T. Since every firmly nonexpansive mapping T is *asymptotically regular*, that is, $\|T^{n+1}x - T^n x\| \to 0$ for all $x \in C$, the result of Martinet is a corollary of Opial's theorem [28]; see Goebel and Kirk [14] and Takahashi [41] on fixed point theory for nonexpansive mappings.

Fixed point theory for nonexpansive mappings can be applied to the problem of finding a point $u \in H$ satisfying

$$0 \in Au, \tag{1.3}$$

where $A : H \to 2^H$ is a maximal monotone operator defined in a Hilbert space H. This problem is related to convex optimization problems, minimax problems, variational inequality problems, equilibrium problems, and so on. We always identify

the set-valued mapping A with its graph $G(A) = \{(x, x^*) : x^* \in Ax\}$. Thus we write $A : H \to 2^H$ as follows: $A \subset H \times H$. By Browder [6] and Rockafellar [37], the maximal monotonicity of A implies that $R(I + rA) = H$ for all $r > 0$. Thus, for all $r > 0$, we can define the resolvent J_r of A by

$$J_r x = \{z \in H : x \in z + rAz\} = (I + rA)^{-1}(x) \tag{1.4}$$

for all $x \in H$. It is well known that $J_r : H \to H$ is a single-valued firmly nonexpansive mapping and (1.3) is equivalent to $J_r u = u$; see Rockafellar [38] and Takahashi [40, 41]. Therefore the problem (1.3) is reduced to a fixed point problem for a firmly nonexpansive mapping in the setting of Hilbert spaces.

In contrast to the case of Hilbert spaces, the resolvent of a maximal monotone operator is not generally a nonexpansive mapping in the case of Banach spaces. Recently, Matsushita and Takahashi [24, 25] introduced the class of *relatively nonexpansive mappings* in Banach spaces. They proved that if $A \subset E \times E^*$ is a maximal monotone operator defined in a strictly convex and uniformly smooth Banach space E such that $A^{-1}0$ is nonempty, $J : E \to E^*$ is the normalized duality mapping, $r > 0$, and $J_r = (J + rA)^{-1}J$, then J_r is a relatively nonexpansive mapping from E onto the domain $D(A)$ of A. They obtained weak and strong convergence theorems for a single relatively nonexpansive mapping in Banach spaces. See also Butnariu, Reich, and Zaslavski [9, 10], Censor and Reich [12], and Reich [33] for similar classes of nonlinear operators in Banach spaces.

The purpose of the present paper is to study the existence and approximation of fixed points of *firmly nonexpansive-type mappings* in Banach spaces. The class of firmly nonexpansive-type mappings contains the classes of firmly nonexpansive mappings in Hilbert spaces and resolvents of maximal monotone operators in Banach spaces. As we see below, the class of firmly nonexpansive-type mappings that have fixed points is contained in the class of strongly relatively nonexpansive mappings. Let E be a smooth Banach space, C be a nonempty closed convex subset of E, and J be the normalized duality mapping from E into E^*. Then we say that T is of *firmly nonexpansive type* if

$$\langle Tx - Ty, JTx - JTy\rangle \le \langle Tx - Ty, Jx - Jy\rangle \tag{1.5}$$

for all $x, y \in C$. Note that we do not assume the existence of fixed points of T. If E is a Hilbert space, then J is the identity operator on H, and hence (1.5) is reduced to (1.1). Since J is a monotone operator, every firmly nonexpansive-type mapping satisfies $\langle Tx - Ty, Jx - Jy\rangle \ge 0$ for all $x, y \in C$; that is, it is d-accretive in the sense of Alber and Reich [2].

Our paper is organized as follows: Section 2 is devoted to preliminaries. In section 3, we obtain a fixed point theorem for firmly nonexpansive-type mappings in Banach spaces (Theorem 3.2). In section 4, we prove some lemmas needed in section 5. In section 5, we show that every firmly nonexpansive-type mapping which has a fixed point is strongly relatively nonexpansive (Theorem 5.2) and then obtain a weak convergence theorem (Theorem 5.3). In section 6, we apply the obtained results to the proximal point algorithm for a monotone operator satisfying the range condition in Banach spaces.

2. Preliminaries. Throughout the present paper, every Banach space is real. Let $\mathbb{N}$ and $\mathbb{R}$ denote the sets of positive integers and real numbers, respectively. For a sequence $\{x_n\}$ in a Banach space E, the strong convergence and the weak convergence

of $\{x_n\}$ to $x \in E$ are denoted by $x_n \to x$ and $x_n \rightharpoonup x$, respectively. For a sequence $\{x_n^*\}$ of the dual space E^* of E, the weak* convergence of $\{x_n^*\}$ to $x^* \in E^*$ is also denoted by $x_n^* \overset{*}{\rightharpoonup} x^*$.

Let E be a Banach space and let $J : E \to E^*$ be the *normalized duality mapping* defined by

$$Jx = \{x^* \in E^* : \langle x, x^* \rangle = \|x\|^2 = \|x^*\|^2\} \tag{2.1}$$

for all $x \in E$. Let $S(E)$ be the unit sphere centered at the origin of E. Then the space E is said to be *smooth* if the limit

$$\lim_{t \to 0} \frac{\|x + ty\| - \|x\|}{t} \tag{2.2}$$

exists for all $x, y \in S(E)$. The space E is said to be *uniformly smooth* if the limit (2.2) converges uniformly in $x, y \in S(E)$. The norm of E is also said to be *uniformly Gâteaux differentiable* if for all $y \in S(E)$, the limit (2.2) converges uniformly in $x \in S(E)$. A Banach space E is said to be *strictly convex* if $\|(x+y)/2\| < 1$ whenever $x, y \in S(E)$ and $x \neq y$. The space E is also said to be *uniformly convex* if for all $\varepsilon \in (0, 2]$, there exists $\delta > 0$ such that $x, y \in S(E)$ and $\|x - y\| \geq \varepsilon$ imply $\|(x + y)/2\| \leq 1 - \delta$. The duality mapping J from a smooth Banach space E into E^* is said to be *weakly sequentially continuous* if $Jx_n \overset{*}{\rightharpoonup} Jx$ whenever $x_n \rightharpoonup x$. We know the following; see Cioranescu [13], Reich [32], and Takahashi [41] on geometry of Banach spaces:

1. If E is smooth, then J is single-valued;
2. if E is reflexive, then J is onto;
3. if E is strictly convex, then J is one-to-one; that is, $Jx \cap Jy \neq \emptyset$ implies that $x = y$;
4. if E is strictly convex, then J is strictly monotone, that is, if (x, x^*), $(y, y^*) \in J$ and $\langle x - y, x^* - y^* \rangle = 0$, then $x = y$.

Let E be a smooth Banach space. Following Alber [1] and Kamimura and Takahashi [18], let $\phi : E \times E \to \mathbb{R}$ be the mapping defined by

$$\phi(x, y) = \|x\|^2 - 2\langle x, Jy \rangle + \|y\|^2 \tag{2.3}$$

for all $x, y \in E$. Note that ϕ is the *Bregman distance* corresponding to $\|\cdot\|^2$; see Bregman [4], Butnariu and Iusem [8], and Censor and Lent [11]. If E is a Hilbert space, then we have $\phi(x, y) = \|x - y\|^2$ for all $x, y \in E$. We know that

$$(\|x\| - \|y\|)^2 \leq \phi(x, y) \leq (\|x\| + \|y\|)^2 \tag{2.4}$$

for all $x, y \in E$. If E is strictly convex, then

$$\phi(x, y) = 0 \Longleftrightarrow x = y. \tag{2.5}$$

It is also well known that

$$\phi(x, y) = \phi(x, z) + \phi(z, y) + 2\langle x - z, Jz - Jy \rangle \tag{2.6}$$

for all $x, y, z \in E$. If E is a Hilbert space, then this equality is reduced to

$$\|x - y\|^2 = \|x - z\|^2 + \|z - y\|^2 + 2\langle x - z, z - y \rangle \tag{2.7}$$

for all $x, y, z \in E$. It is easy to see from (2.6) that

$$\langle x - y, Jz - Jw \rangle = \frac{1}{2} \{\phi(x, w) + \phi(y, z) - \phi(x, z) - \phi(y, w)\} \tag{2.8}$$

for all $x, y, z, w \in E$. It is also easy to see that if $\{x_n\}$ and $\{y_n\}$ are bounded sequences of a smooth Banach space E, then $\|x_n - y_n\| \to 0$ implies that $\phi(x_n, y_n) \to 0$. The converse is also true if E is additionally assumed to be uniformly convex.

LEMMA 2.1 (Kamimura and Takahashi [18]). *Let E be a smooth and uniformly convex Banach space and let $\{x_n\}$ and $\{y_n\}$ be sequences of E such that $\{x_n\}$ or $\{y_n\}$ is bounded. If $\phi(x_n, y_n) \to 0$, then $\|x_n - y_n\| \to 0$.*

Let E be a smooth, strictly convex and reflexive Banach space. A set-valued mapping $A \subset E \times E^*$ with domain $D(A) = \{x \in E : Ax \neq \emptyset\}$ and range $R(A) = \bigcup\{Ax : x \in D(A)\}$ is said to be *monotone* if $\langle x - y, x^* - y^* \rangle \geq 0$ whenever $(x, x^*), (y, y^*) \in A$. A monotone operator $A \subset E \times E^*$ is also said to be *maximal monotone* if $A = B$ whenever $B \subset E \times E^*$ is a monotone operator such that $A \subset B$. The following theorem is well known:

THEOREM 2.2 (Browder [6] and Rockafellar [37]; see also Barbu [3] and Takahashi [40]). *Let E be a smooth, strictly convex and reflexive Banach space and let $A \subset E \times E^*$ be a monotone operator. A is maximal monotone if and only if $R(J + rA) = E^*$ for all $r > 0$.*

Let E be a smooth, strictly convex and reflexive Banach space, let C be a nonempty closed convex subset of E, and let $A \subset E \times E^*$ be a monotone operator satisfying

$$D(A) \subset C \subset J^{-1}R(J + rA) \tag{2.9}$$

for all $r > 0$. In view of Theorem 2.2, if A is maximal monotone, then (2.9) holds for $C = \overline{D(A)}$. Note that the result due to Rockafellar [36] ensures that $\overline{D(A)}$ is closed and convex; see also Barbu [3], Reich [30] and Takahashi [41]. If A satisfies (2.9), then for all $r > 0$, we can define the resolvent $J_r : C \to D(A)$ of A by

$$J_r x = \{z \in E : Jx \in Jz + rAz\} \tag{2.10}$$

for all $x \in C$. In other words, $J_r x = (J + rA)^{-1} Jx$ for all $x \in C$. For all $r > 0$, the *Yosida approximation* $A_r : C \to E^*$ of A is also defined by $A_r x = (Jx - JJ_r x)/r$ for all $x \in C$. We also denote by $A^{-1}0$ the set $\{z \in D(A) : 0 \in Az\}$. We know the following; see, for instance, Butnariu and Iusem [8], Kamimura [16], Kohsaka and Takahashi [19] and Matsushita and Takahashi [24]:

1. J_r is a single-valued mapping from C into $D(A)$ such that

   $$\phi(u, J_r x) + \phi(J_r x, x) \leq \phi(u, x) \tag{2.11}$$

   for all $(x, u) \in C \times A^{-1}0$;
2. $(J_r x, A_r x) \in A$ for all $x \in C$;
3. $F(J_r) = A^{-1}0$, where $F(J_r)$ is the set of fixed points of J_r.

Let C be a nonempty closed convex subset of a smooth Banach space E and let $T : C \to C$ be a mapping. The set of fixed points of T is denoted by $F(T)$. The mapping T is said to be *nonexpansive* if $\|Tx - Ty\| \leq \|x - y\|$ for all $x, y \in C$. A point $u \in C$ is said to be an *asymptotic fixed point* of T if C contains a sequence $\{x_n\}$ such that $x_n \rightharpoonup u$ and $\|x_n - Tx_n\| \to 0$; see [33]. The set of asymptotic fixed points of T is denoted by $\widehat{F}(T)$. Following [24, 25], we say that a mapping $T : C \to C$ is *relatively nonexpansive* if the following conditions are satisfied:

1. $F(T)$ is nonempty;
2. $\phi(u, Tx) \leq \phi(u, x)$ for all $(x, u) \in C \times F(T)$;
3. $\widehat{F}(T) = F(T)$.

If C is a nonempty closed convex subset of a Hilbert space and $T : C \to C$ is a nonexpansive mapping such that $F(T)$ is nonempty, then T is relatively nonexpansive. Following Reich [33], we say that a mapping $T : C \to C$ is *strongly relatively nonexpansive* if the following conditions are satisfied:

1. T is relatively nonexpansive;
2. if $\{x_n\}$ is a bounded sequence of C such that

$$\phi(u, x_n) - \phi(u, Tx_n) \to 0 \tag{2.12}$$

for some $u \in F(T)$, then $\phi(Tx_n, x_n) \to 0$.

Examples of relatively or strongly relatively nonexpansive mappings can be found in Kohsaka and Takahashi [20, 21], Matsushita and Takahashi [24, 25] and Reich [33].

Let C be a nonempty closed convex subset of a smooth Banach space E. Then a mapping $T : C \to C$ is said to be of *firmly nonexpansive type* if (1.5) is satisfied.

LEMMA 2.3. *Let E be a smooth, strictly convex and reflexive Banach space, let C be a nonempty closed convex subset of E, and let $A \subset E \times E^*$ be a monotone operator satisfying* (2.9). *Let r be a positive real number and let $J_r x = (J + rA)^{-1} Jx$ for all $x \in C$. Then $J_r : C \to D(A)$ is of firmly nonexpansive type.*

Proof. Let $x, y \in C$ be given. Then we have $(J_r x, A_r x), (J_r y, A_r y) \in A$. Since A is monotone, we have

$$\frac{1}{r}\langle J_r x - J_r y, Jx - JJ_r x - (Jy - JJ_r y)\rangle \geq 0. \tag{2.13}$$

Thus we have

$$\langle J_r x - J_r y, JJ_r x - JJ_r y\rangle \leq \langle J_r x - J_r y, Jx - Jy\rangle. \tag{2.14}$$

This shows that J_r is of firmly nonexpansive type. □

If C is a nonempty closed convex subset of a smooth, strictly convex and reflexive Banach space E, then for all $x \in E$, there exists a unique $z \in C$ (denoted by $\Pi_C(x)$) such that

$$\phi(z, x) = \min_{y \in C} \phi(y, x). \tag{2.15}$$

The mapping Π_C is called the *generalized projection* from E onto C; see Alber [1] and Alber and Reich [2]; see also Kamimura and Takahashi [18].

LEMMA 2.4. *Let E be a smooth, strictly convex and reflexive Banach space, let C be a nonempty closed convex subset of E, and let Π_C be the generalized projection from E onto C. Then $\Pi_C : E \to C$ is of firmly nonexpansive type.*

Proof. Let i_C be the indicator function for C; that is, $i_C(x) = 0$ if $x \in C$ and ∞ otherwise. Then $i_C : E \to (-\infty, \infty]$ is a proper lower semicontinuous convex function. Rockafellar's maximal monotonicity theorem [34, 35] ensures that the subdifferential $\partial i_C \subset E \times E^*$ of i_C is maximal monotone. In this case, it is known that ∂i_C is reduced to the normality operator N_C for C; that is,

$$N_C(x) = \{x^* \in E^* : \langle y - x, x^*\rangle \leq 0 \quad (\forall y \in C)\} \tag{2.16}$$

if $x \in C$ and $\emptyset$ if $x \in E \setminus C$. We also know that Π_C is the resolvent of N_C. In fact, we have

$$\begin{aligned} z = \Pi_C(x) &\Longleftrightarrow z = \arg\min_{y \in C} \phi(y, x) \\ &\Longleftrightarrow z = \arg\min_{y \in E} \{\phi(y, x) + i_C(x)\} \\ &\Longleftrightarrow 0 \in \partial(\phi(\cdot, x) + i_C)(z) \\ &\Longleftrightarrow 0 \in 2Jz - 2Jx + N_C(z) \\ &\Longleftrightarrow Jx \in Jz + 2^{-1} N_C(z) \\ &\Longleftrightarrow z = (J + 2^{-1} N_C)^{-1} Jx. \end{aligned} \tag{2.17}$$

Thus, Lemma 2.3 implies that Π_C is of firmly nonexpansive type. □

3. Fixed point theorem for firmly nonexpansive-type mappings. In this section, we study the existence of fixed points for firmly nonexpansive-type mappings in Banach spaces (Theorem 3.2). We need the following lemma:

LEMMA 3.1. *Let E be a smooth Banach space, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a mapping. Then T is of firmly nonexpansive type if and only if*

$$\phi(Tx, Ty) + \phi(Ty, Tx) + \phi(Tx, x) + \phi(Ty, y) \leq \phi(Tx, y) + \phi(Ty, x) \tag{3.1}$$

for all $x, y \in C$.

Proof. Let $x, y \in C$ be given. Then it follows from (2.8) that

$$\langle Tx - Ty, JTx - JTy \rangle \leq \langle Tx - Ty, Jx - Jy \rangle \tag{3.2}$$

is equivalent to

$$\begin{aligned} &\frac{1}{2} \{\phi(Tx, Ty) + \phi(Ty, Tx) - \phi(Tx, Tx) - \phi(Ty, Ty)\} \\ &\leq \frac{1}{2} \{\phi(Tx, y) + \phi(Ty, x) - \phi(Tx, x) - \phi(Ty, y)\}. \end{aligned} \tag{3.3}$$

This is also equivalent to (3.1). This completes the proof. □

Using the technique developed by Takahashi [39], we can prove the following fixed point theorem for firmly nonexpansive-type mappings in Banach spaces:

THEOREM 3.2. *Let E be a smooth, strictly convex and reflexive Banach space, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a firmly nonexpansive-type mapping. Then the following are equivalent:*

1. *There exists $x \in C$ such that $\{T^n x\}$ is bounded;*
2. *$F(T)$ is nonempty.*

Proof. It is obvious that (2) implies (1). We show that (1) implies (2). Suppose that there exists $x \in C$ such that $\{T^n x\}$ is bounded and let

$$S_n(z) = \frac{1}{n} \sum_{k=0}^{n-1} T^k z \tag{3.4}$$

for all $z \in C$ and $n \in \mathbb{N}$. Let $y \in C$ and $k \in \mathbb{N} \cup \{0\}$ be given. Then it follows from Lemma 3.1 and (2.6) that

$$\begin{aligned} &\phi(T^{k+1}x, Ty) + \phi(Ty, T^{k+1}x) + \phi(T^{k+1}x, T^k x) + \phi(Ty, y) \\ &\leq \phi(T^{k+1}x, y) + \phi(Ty, T^k x) \\ &= \phi(T^{k+1}x, Ty) + \phi(Ty, y) + 2\langle T^{k+1}x - Ty, JTy - Jy \rangle + \phi(Ty, T^k x). \end{aligned} \tag{3.5}$$

This implies that

$$\begin{aligned} 0 &\le 2\langle T^{k+1}x - Ty, JTy - Jy\rangle \\ &\quad + \phi(Ty, T^k x) - \phi(Ty, T^{k+1}x) - \phi(T^{k+1}x, T^k x) \\ &\le 2\langle T^{k+1}x - Ty, JTy - Jy\rangle + \phi(Ty, T^k x) - \phi(Ty, T^{k+1}x). \end{aligned} \tag{3.6}$$

Summing these inequalities with respect to $k = 0, 1, \ldots, n-1$, we have

$$0 \le 2\left\langle \sum_{k=0}^{n-1} T^{k+1}x - nTy, JTy - Jy \right\rangle + \phi(Ty, x) - \phi(Ty, T^n x). \tag{3.7}$$

Dividing (3.7) by n, we obtain

$$0 \le 2\langle S_n(Tx) - Ty, JTy - Jy\rangle + \frac{1}{n}\left\{\phi(Ty, x) - \phi(Ty, T^n x)\right\}. \tag{3.8}$$

Since $\{S_n(Tx)\}$ is bounded, we have a subsequence $\{S_{n_i}(Tx)\}$ such that $S_{n_i}(Tx) \rightharpoonup u \in C$. Tending $n_i \to \infty$ in (3.8), we have $0 \le 2\langle u - Ty, JTy - Jy\rangle$. Thus we have

$$0 \le \langle u - Ty, JTy - Jy\rangle \tag{3.9}$$

for all $y \in C$. Putting $y = u$ in (3.9), we have

$$0 \le \langle u - Tu, JTu - Ju\rangle = -\langle u - Tu, Ju - JTu\rangle. \tag{3.10}$$

Hence we have $\langle u - Tu, Ju - JTu\rangle \le 0$. On the other hand, since J is monotone, we have $\langle u - Tu, Ju - JTu\rangle \ge 0$. Therefore $\langle u - Tu, Ju - JTu\rangle = 0$. Since E is strictly convex, we obtain $Tu = u$. Thus T has a fixed point and the proof is completed. □

As direct consequences of Theorem 3.2, we obtain the following corollaries. Note that Corollary 3.4 actually holds for nonexpansive mappings in Hilbert spaces; see Reich [29] and Takahashi [41]:

COROLLARY 3.3. *Let E be a smooth, strictly convex and reflexive Banach space, let C be a nonempty bounded closed convex subset of E and let $T : C \to C$ be a firmly nonexpansive-type mapping. Then $F(T)$ is nonempty.*

COROLLARY 3.4. *Let H be a Hilbert space, let C be a nonempty closed convex subset of a Hilbert space H and let $T : C \to C$ be a firmly nonexpansive mapping. Then there exists $x \in C$ such that $\{T^n x\}$ is bounded if and only if $F(T)$ is nonempty.*

4. Lemmas. In this section, we show some properties for relatively nonexpansive mappings needed in section 5. For a bounded sequence $\{x_n\}$ of a reflexive Banach space E, let $\omega_{\mathrm{w}}(\{x_n\})$ be the set defined by

$$\omega_{\mathrm{w}}(\{x_n\}) = \left\{z \in E : \exists\{x_{n_i}\} \subset \{x_n\} \text{ s.t. } x_{n_i} \rightharpoonup z\right\}. \tag{4.1}$$

We first show the following lemmas:

LEMMA 4.1. *Let E be a smooth, strictly convex and reflexive Banach space and let $\{x_n\}$ be a bounded sequence of E such that $\lim_n \phi(u, x_n)$ exists for all $u \in \omega_{\mathrm{w}}(\{x_n\})$. If J is weakly sequentially continuous, then $\{x_n\}$ converges weakly.*

Proof. It suffices to show that $A = \omega_{\mathrm{w}}(\{x_n\})$ consists of one point. Since E is reflexive and $\{x_n\}$ is bounded, A is nonempty. Let $u, v \in A$. Then, by assumption,

$$\lim_{n\to\infty}\left\{\phi(u, x_n) - \phi(v, x_n)\right\} \tag{4.2}$$

exists. This implies that $\lim_n \langle v-u, Jx_n\rangle$ exists. Let $x_{n_i} \rightharpoonup u$ and $x_{m_j} \rightharpoonup v$. Since J is weakly sequentially continuous, we have $Jx_{n_i} \overset{*}{\rightharpoonup} Ju$ and $Jx_{m_j} \overset{*}{\rightharpoonup} Jv$. Then we have

$$\begin{aligned}\langle v-u, Ju\rangle &= \lim_{i\to\infty}\langle v-u, Jx_{n_i}\rangle \\ &= \lim_{n\to\infty}\langle v-u, Jx_n\rangle \\ &= \lim_{j\to\infty}\langle v-u, Jx_{m_j}\rangle = \langle v-u, Jv\rangle.\end{aligned} \tag{4.3}$$

Thus we obtain $\langle u-v, Ju-Jv\rangle = 0$. Since E is strictly convex, we have $u=v$. This completes the proof. ∎

LEMMA 4.2. *Let E be a smooth and uniformly convex Banach space, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a strongly relatively nonexpansive mapping. Then T is asymptotically regular; that is,*

$$\|T^{n+1}x - T^n x\| \to 0 \tag{4.4}$$

for all $x \in C$.

Proof. Let $x \in C$ and $u \in F(T)$ be given. By the relative nonexpansiveness of T, we have

$$\phi(u, T^{n+1}x) \le \phi(u, T^n x) \tag{4.5}$$

for all $n \in \mathbb{N}$. Thus $\lim_n \phi(u, T^n x)$ exists. By $(\|u\| - \|T^n x\|)^2 \le \phi(u, T^n x)$ for all $n \in \mathbb{N}$, $\{T^n x\}$ is bounded. On the other hand, we have

$$\lim_{n\to\infty}\{\phi(u, T^n x) - \phi(u, T^{n+1}x)\} = 0. \tag{4.6}$$

Since T is strongly relatively nonexpansive, we have $\lim_n \phi(T^{n+1}x, T^n x) = 0$. By Lemma 2.1, we obtain the desired conclusion. ∎

Using Lemma 4.1, we can prove the following lemma, which is an analogous result of Opial [28] for relatively nonexpansive mappings in Banach spaces:

LEMMA 4.3. *Let E be a smooth and uniformly convex Banach space, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a relatively nonexpansive mapping which is asymptotically regular. Then for all $x \in C$, the following hold:*

1. *$\{T^n x\}$ is bounded and $\omega_{\mathrm{w}}(\{T^n x\}) \subset F(T)$;*
2. *if J is weakly sequentially continuous, then $\{T^n x\}$ converges weakly to an element of $F(T)$.*

Proof. We first show the part (1). As in the proof of Lemma 4.2, it follows that $\{T^n x\}$ is bounded for all $x \in C$. Since T is asymptotically regular, we have $\omega_{\mathrm{w}}(\{T^n x\}) \subset \widehat{F}(T)$. Since T is relatively nonexpansive, we have $\widehat{F}(T) = F(T)$. Thus we have the conclusion.

We next show part (2). Assume that J is weakly sequentially continuous and let $u \in \omega_{\mathrm{w}}(\{T^n x\})$ be given. By the part (1), we have $u \in F(T)$. As in the proof of Lemma 4.2, we can show that $\lim_n \phi(u, T^n x)$ exists. Thus $\lim_n \phi(u, T^n x)$ exists for all $u \in \omega_{\mathrm{w}}(\{T^n x\})$. By Lemma 4.1, $\{T^n x\}$ converges weakly. Consequently, it converges weakly to an element of $F(T)$. ∎

5. Convergence theorem for firmly nonexpansive-type mappings. In this section, we prove a weak convergence theorem for firmly nonexpansive-type mappings in Banach spaces (Theorem 5.3). Before proving it, we show that every firmly

nonexpansive-type mapping with a fixed point is strongly relatively nonexpansive (Theorem 5.2).

LEMMA 5.1. *Let E be a strictly convex Banach space whose norm is uniformly Gâteaux differentiable, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a firmly nonexpansive-type mapping. Then $\widehat{F}(T) = F(T)$.*

Proof. Since $\widehat{F}(T) \supset F(T)$ is obvious, we prove $\widehat{F}(T) \subset F(T)$. Let $u \in \widehat{F}(T)$ be given. By the definition of $\widehat{F}(T)$, we have a sequence $\{x_n\}$ of C such that $x_n \rightharpoonup u$ and $\|x_n - Tx_n\| \to 0$. Then we have $Tx_n \rightharpoonup u$. Since the norm of E is uniformly Gâteaux differentiable, J is uniformly norm-to-weak* continuous on each bounded subset of E; see Reich [31] and Takahashi [41]. Hence it follows from $\|x_n - Tx_n\| \to 0$ that

$$\langle y, JTx_n - Jx_n \rangle \to 0 \tag{5.1}$$

for all $y \in E$.

On the other hand, since T is of firmly nonexpansive type, it follows from Lemma 3.1 that

$$\phi(Tx_n, Tu) + \phi(Tu, Tx_n) + \phi(Tx_n, x_n) + \phi(Tu, u) \le \phi(Tx_n, u) + \phi(Tu, x_n) \tag{5.2}$$

for all $n \in \mathbb{N}$. This implies that

$$\begin{aligned} &\phi(Tu, u) \\ &\le \phi(Tx_n, u) - \phi(Tx_n, Tu) + \phi(Tu, x_n) - \phi(Tu, Tx_n) - \phi(Tx_n, x_n) \\ &= 2\langle Tx_n, JTu - Ju \rangle + \|u\|^2 - \|Tu\|^2 \\ &\quad + 2\langle Tu, JTx_n - Jx_n \rangle + \|x_n\|^2 - \|Tx_n\|^2 - \phi(Tx_n, x_n) \\ &\le 2\langle Tx_n, JTu - Ju \rangle + \|u\|^2 - \|Tu\|^2 \\ &\quad + 2\langle Tu, JTx_n - Jx_n \rangle + (\|x_n\| + \|Tx_n\|)\|x_n - Tx_n\| \end{aligned} \tag{5.3}$$

for all $n \in \mathbb{N}$. Tending $n \to \infty$ in (5.3), it follows from (5.1) that

$$\begin{aligned} \phi(Tu, u) &\le 2\langle u, JTu - Ju \rangle + \|u\|^2 - \|Tu\|^2 \\ &= \phi(u, u) - \phi(u, Tu) = -\phi(u, Tu). \end{aligned} \tag{5.4}$$

Hence we have

$$\phi(Tu, u) + \phi(u, Tu) \le 0, \tag{5.5}$$

and hence $\phi(Tu, u) = \phi(u, Tu) = 0$. By the strict convexity of E, we obtain $Tu = u$. Therefore, $\widehat{F}(T) \subset F(T)$. This completes the proof. □

Using Lemma 5.1, we can show the following theorem:

THEOREM 5.2. *Let E be a strictly convex Banach space whose norm is uniformly Gâteaux differentiable, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a firmly nonexpansive-type mapping such that $F(T)$ is nonempty. Then T is strongly relatively nonexpansive.*

Proof. Let $(x, u) \in C \times F(T)$ be given. Then it follows from Lemma 3.1 that

$$\phi(Tx, Tu) + \phi(Tu, Tx) + \phi(Tx, x) + \phi(Tu, u) \le \phi(Tx, u) + \phi(Tu, x). \tag{5.6}$$

This implies that

$$\phi(u, Tx) + \phi(Tx, x) \le \phi(u, x). \tag{5.7}$$

So, we have $\phi(u,Tx) \leq \phi(u,x)$. On the other hand, it also follows from Lemma 5.1 that $\widehat{F}(T) = F(T)$. By assumption, $F(T)$ is nonempty. Thus T is relatively nonexpansive.

We finally show that T is strongly relatively nonexpansive. Let $\{x_n\}$ be a bounded sequence of C such that

$$\phi(u,x_n) - \phi(u,Tx_n) \to 0 \tag{5.8}$$

for some $u \in F(T)$. By (5.7), we have

$$\phi(Tx_n,x_n) \leq \phi(u,x_n) - \phi(u,Tx_n) \tag{5.9}$$

for all $n \in \mathbb{N}$. Then it follows from (5.8) and (5.9) that $\lim_n \phi(Tx_n,x_n) = 0$. Thus T is strongly relatively nonexpansive and the proof is completed. □

By Lemmas 4.2 and 4.3 and Theorem 5.2, we obtain the following weak convergence theorem for firmly nonexpansive-type mappings in Banach spaces:

THEOREM 5.3. *Let E be a uniformly convex Banach space whose norm is uniformly Gâteaux differentiable, let C be a nonempty closed convex subset of E, and let $T : C \to C$ be a firmly nonexpansive-type mapping such that $F(T)$ is nonempty. Then for all $x \in C$, the following hold:*

1. *$\{T^n x\}$ is bounded and $\omega_{\mathrm{w}}(\{T^n x\}) \subset F(T)$;*
2. *if J is weakly sequentially continuous, then $\{T^n x\}$ converges weakly to an element of $F(T)$.*

As a direct consequence of Theorem 5.3, we have the following result due to Martinet [23]; see also Bruck and Reich [7]:

COROLLARY 5.4 (Martinet [23]). *Let C be a nonempty closed convex subset of a Hilbert space H and let T be a firmly nonexpansive mapping from C into itself such that $F(T)$ is nonempty. Then for all $x \in C$, $\{T^n x\}$ converges weakly to an element of $F(T)$.*

6. Applications to the proximal point algorithm. In the final section, we study the proximal point algorithm for monotone operators in Banach spaces first introduced by Martinet [22] and generally studied by Rockafellar [38] in Hilbert spaces; see also Brézis and Lions [5], Bruck and Reich [7], and Nevanlinna and Reich [27]. This is an iterative procedure, which generates a sequence $\{x_n\}$ by the rule $x_1 = x \in H$ and

$$x_{n+1} = J_{r_n} x_n \quad (n = 1,2,\ldots), \tag{6.1}$$

where $A \subset H \times H$ is a maximal monotone operator defined in a Hilbert space H, $J_r = (I + rA)^{-1}$ for all $r > 0$, and $\{r_n\}$ is a sequence of positive real numbers. Rockafellar's theorem [38] ensures that if $A^{-1}0$ is nonempty and $\liminf_n r_n > 0$, then $\{x_n\}$ converges weakly to an element of $A^{-1}0$.

Using Lemma 2.3 and Theorem 3.2, we can study the existence of zeros of monotone operators in Banach spaces. This result is closely related to the result due to Matsushita and Takahashi [26].

THEOREM 6.1. *Let E be a smooth, strictly convex and reflexive Banach space and let $A \subset E \times E^*$ be a monotone operator and C be a nonempty closed convex subset of E satisfying* (2.9). *Let r be a positive real number and $J_r x = (J + rA)^{-1} Jx$ for all $x \in C$. Then $A^{-1}0$ is nonempty if and only if there exists $x \in C$ such that $\{J_r^n x\}$ is bounded. In particular, if $D(A)$ is bounded, then $A^{-1}0$ is nonempty.*

Proof. Let r be a positive real number. From Lemma 2.3, we know that $J_r : C \to D(A)$ is a firmly nonexpansive-type mapping. Since $D(A) \subset C$ from (2.9), we obtain the desired result from Theorem 3.2. If $D(A)$ is bounded, then $\{J_r^n x\}$ is bounded for all $x \in C$. So, $A^{-1}0$ is nonempty. □

Using Lemma 2.3 and Theorem 5.3, we finally study the convergence of the proximal point algorithm for monotone operators in Banach spaces; see Kamimura [16] and Kamimura, Kohsaka and Takahashi [17] for similar results on this subject.

THEOREM 6.2. *Let E be a uniformly convex Banach space whose norm is uniformly Gâteaux differentiable, let $A \subset E \times E^*$ be a monotone operator such that $A^{-1}0$ is nonempty and let C be a nonempty closed convex subset of E satisfying* (2.9). *Let r be a positive real number and let $J_r x = (J + rA)^{-1} Jx$ for all $x \in C$. If J is weakly sequentially continuous, then for all $x \in C$, $\{J_r^n x\}$ converges weakly to an element of $A^{-1}0$.*

Proof. Let r be a positive real number. Since E is uniformly convex, E is reflexive and strictly convex. So, from Lemma 2.3, we have that $J_r : C \to D(A)$ is a firmly nonexpansive-type mapping. From (2.9) and the part (2) of Theorem 5.3, we have the desired result. □

Acknowledgment. The authors would like to express their sincere appreciation to the anonymous referee for valuable comments on the original version of the manuscript.

GEOMETRIC DUALITY IN MULTIPLE OBJECTIVE LINEAR PROGRAMMING*

FRANK HEYDE† AND ANDREAS LÖHNE†

Abstract. We develop in this article a geometric approach to duality in multiple objective linear programming. This approach is based on a very old idea, the duality of polytopes, which can be traced back to the old Greeks. We show that there is an inclusion-reversing one-to-one map between the minimal faces of the image of the primal objective and the maximal faces of the image of the dual objective map.

Key words. duality theory, multiobjective optimization, linear programming, dual polytopes

AMS subject classifications. 90C29, 90C05, 90C46

DOI. 10.1137/060674831

1. Introduction.

Duality for multiple objective linear programs seems to have its origin in the 1970s; see, e.g., Kornbluth [13], Rödder [17], Isermann [9, 10], and Brumelle [2]. More recent expositions are Jahn [11, 12], Luc [15], and Göpfert and Nehse [4], where nonlinear problems are also considered.

As noticed in [4, p. 64], the practical relevance of vectorial duality theory is quite low in comparison with the relevance of duality in scalar optimization. Moreover, in the linear case there occurs some difficulties, such as a duality gap in the case $b = 0$ (where b is the right-hand side of the inequality constraints). In [6], this duality gap could be closed by using a set-valued approach. In [14, 7, 8], this set-valued approach is revisited from a lattice theoretic point of view. The aim of these papers is to work in an appropriate complete lattice in order to have a duality theory which can be formulated along the lines of the scalar duality theory. In particular, the infimum and supremum can be used to define solutions. Another goal (especially in [8]) is to have a "simple" dual problem. This means that the dual problem should not be more complicated than the primal problem.

Nevertheless, in all the mentioned references there is a basic difference from the present article. Instead of speaking about strong duality if the optimal values of a pair of dual optimization problems are equal, we deal with a duality relation between the polyhedral image set of the primal problem and the polyhedral image of the dual problem, which is similar to duality of polytopes (see Figure 1.1).

It is well known from the theory of convex polytopes (see, e.g., [5]) that two polytopes $\mathcal{P}$ and $\mathcal{P}^*$ in $\mathbb{R}^q$ are said to be dual to each other provided that there exists a one-to-one mapping Ψ between the set of all faces of $\mathcal{P}$ and the set of all faces of $\mathcal{P}^*$ such that Ψ is inclusion-reversing; i.e., faces $\mathcal{F}_1$ and $\mathcal{F}_2$ of $\mathcal{P}$ satisfy $\mathcal{F}_1 \subseteq \mathcal{F}_2$ if and only if the faces $\Psi(\mathcal{F}_1)$ and $\Psi(\mathcal{F}_2)$ satisfy $\Psi(\mathcal{F}_1) \supseteq \Psi(\mathcal{F}_2)$.

Denoting by $\mathcal{P}$ and $\mathcal{D}$ the images of the objective functions of our given problem (P) and its dual problem (D), respectively, we show that there is an inclusion reversing one-to-one map Ψ between the set of all K-maximal proper faces of $\mathcal{D}$ and the set of all weakly C-minimal proper faces of $\mathcal{P}$, where K and C are appropriate ordering

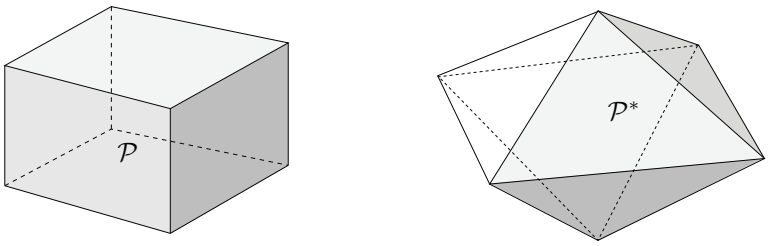

FIG. 1.1. *Example of a pair of dual polytopes in* $\mathbb{R}^3$.

cones. With the aid of such a map Ψ we can compute the weakly C-minimal faces of $\mathcal{P}$ whenever we know the K-maximal faces of $\mathcal{D}$ and vice versa. In particular, we are given by Ψ a one-to-one correspondence between weakly C-minimal vertices (facets) of $\mathcal{P}$ and K-maximal facets (vertices) of $\mathcal{D}$. It is worth mentioning that there is a connection between the lattice theoretic duality in [8] and the geometric duality in the present article. This is briefly discussed at the end of section 3.

In a forthcoming paper [3] we give an application of geometric duality, a dual variant of Benson's outer approximation algorithm [1].

2. Preliminaries. Let $\mathcal{A} \subseteq \mathbb{R}^q$, and let $\mathcal{C} \subseteq \mathbb{R}^q$ be a closed convex cone. Denoting by $\operatorname{ri}\mathcal{C}$ the relative interior of $\mathcal{C}$, we set

$$\operatorname{Min}_{\mathcal{C}}\mathcal{A} := \{y \in \mathcal{A} \mid (\{y\} - \operatorname{ri}\mathcal{C}) \cap \mathcal{A} = \emptyset\} \quad \text{and} \quad \operatorname{Max}_{\mathcal{C}}\mathcal{A} := \operatorname{Min}_{(-\mathcal{C})}\mathcal{A}.$$

In the following we consider two special ordering cones, namely,

$$C := \mathbb{R}^q_+ \quad \text{and} \quad K := \mathbb{R}_+ \cdot (0, 0, \ldots, 0, 1)^T = \{y \in \mathbb{R}^q \mid y_1 = \cdots = y_{q-1} = 0, y_q \geq 0\}.$$

Note that throughout this article elements of the vector space $\mathbb{R}^q$ (or $\mathbb{R}^m$ and $\mathbb{R}^n$, respectively) are considered to be column vectors.

For the choice $\mathcal{C} = C = \mathbb{R}^q_+$ we have $\operatorname{ri}\mathcal{C} = \operatorname{int} C$; hence

$$\operatorname{Min}_{C}\mathcal{A} = \{y \in \mathcal{A} \mid (\{y\} - \operatorname{int} C) \cap \mathcal{A} = \emptyset\}$$

coincides with the set of weakly C-minimal elements of $\mathcal{A}$. In case of $\mathcal{C} = K$ we have $\operatorname{ri} K = K \setminus \{0\}$; hence

$$\operatorname{Max}_{K}\mathcal{A} = \{y \in \mathcal{A} \mid (\{y\} + K \setminus \{0\}) \cap \mathcal{A} = \emptyset\}$$

coincides with the set of K-maximal elements of $\mathcal{A}$.

For the convenience of the reader, we recall some facts concerning the facial structure of polyhedral sets [18, section 3.2]. A polyhedral set is defined to be the intersection of a finite collection of closed half-spaces. Clearly, polyhedral sets are closed and convex. Let $\mathcal{A} \subseteq \mathbb{R}^q$ be a convex set. A convex subset $\mathcal{F} \subseteq \mathcal{A}$ is called a *face* of $\mathcal{A}$ if

$$\big(y^1, y^2 \in \mathcal{A}, \quad \lambda \in (0,1), \quad \lambda y^1 + (1-\lambda)y^2 \in \mathcal{F}\big) \quad \Rightarrow \quad y^1, y^2 \in \mathcal{F}.$$

A face $\mathcal{F}$ of $\mathcal{A}$ is called *proper* if $\emptyset \neq \mathcal{F} \neq \mathcal{A}$. A set $\mathcal{E} \subseteq \mathcal{A}$ is called an *exposed face* of $\mathcal{A}$ if there are $c \in \mathbb{R}^q$ and $\gamma \in \mathbb{R}$ such that $\mathcal{A} \subseteq \{y \in \mathbb{R}^q \mid c^T y \geq \gamma\}$ and $\mathcal{E} = \{y \in \mathbb{R}^q \mid c^T y = \gamma\} \cap \mathcal{A}$. The proper $(r-1)$-dimensional faces of an r-dimensional

polyhedral convex set $\mathcal{A}$ are called *facets* of $\mathcal{A}$. A point $y \in \mathcal{A}$ is called a vertex of $\mathcal{A}$ if $\{y\}$ is a face of $\mathcal{A}$. Let $\mathcal{A}$ be a polyhedral set in $\mathbb{R}^q$. Then $\mathcal{A}$ has a finite number of faces, each of which is exposed, and a polyhedral set. Every proper face of $\mathcal{A}$ is the intersection of those facets of $\mathcal{A}$ that contain it, and the relative boundary of $\mathcal{A}$ is the union of all the facets of $\mathcal{A}$. If $\mathcal{A}$ has a nonempty face of dimension s, then $\mathcal{A}$ has faces of all dimensions from s to $\dim \mathcal{A}$ (see [18, Theorem 3.2.2]).

If $\operatorname{int} \mathcal{A} \neq \emptyset$, then $\mathcal{A}$ is a q-dimensional polyhedral set; hence the facets of $\mathcal{A}$ are the $(q-1)$-dimensional faces of $\mathcal{A}$, i.e., the maximal (w.r.t. inclusion) proper faces. A subset $\mathcal{F} \subseteq \mathcal{A}$ is a proper face if and only if it is a proper exposed face, i.e., there is a supporting hyperplane $\mathcal{H}$ to $\mathcal{A}$ such that $\mathcal{F} = \mathcal{H} \cap \mathcal{A}$. We call a hyperplane $\mathcal{H} := \left\{ y \in \mathbb{R}^q \mid c^T y = \gamma \right\}$ (i.e., $c \neq 0$) supporting to $\mathcal{A}$ if

$$\forall y \in \mathcal{A} : c^T y \geq \gamma \qquad \wedge \qquad \exists y^0 \in \mathcal{A} : c^T y^0 = \gamma.$$

3. Main result. Throughout the article, let $m, n, q \in \mathbb{N}$ and $A \in \mathbb{R}^{m \times n}$, $M \in \mathbb{R}^{q \times n}$, $b \in \mathbb{R}^m$ be given, and let the ordering cones C and K be defined as above. Further we set $k = (1, \ldots, 1)^T \in \mathbb{R}^q$. We consider the following vector optimization problem:

$$\text{(P)} \qquad \operatorname{Min}_C M[\mathcal{X}], \quad \mathcal{X} := \{x \in \mathbb{R}^n \mid Ax \geq b\}.$$

We define a dual linear objective function by $D : \mathbb{R}^m \times \mathbb{R}^q \to \mathbb{R}^q$, $D(u,c) := \left(c_1, \ldots, c_{q-1}, b^T u\right)^T$ and consider the following dual vector optimization problem:

$$\text{(D)} \qquad \operatorname{Max}_K D[\mathcal{U}], \quad \mathcal{U} := \left\{(u,c) \in \mathbb{R}^m \times \mathbb{R}^q \mid (u,c) \geq 0,\ A^T u = M^T c,\ k^T c = 1\right\}.$$

Remark. The fact that the primal and dual problems are not symmetric is a feature shared by all attempts at duality for vector optimization problems. The special choice of the cone K for the dual problem reflects a parametric character of the dual problem. In fact, a point $D(\bar{u}, \bar{c})$ is a K-maximal point of $D[\mathcal{U}]$ if and only if, for $\bar{c}$ fixed, $\bar{u}$ maximizes $b^T u$ over the set $\{u \in \mathbb{R}^m \mid (u, \bar{c}) \in \mathcal{U}\}$.

It is our goal to show a duality relation between the sets

$$\begin{aligned} \mathcal{P} &:= M[\mathcal{X}] + C = \{y \in \mathbb{R}^q \mid \quad \exists x \in \mathcal{X} : \quad y \in \{Mx\} + C \quad \} \qquad \text{and} \\ \mathcal{D} &:= D[\mathcal{U}] - K = \{y \in \mathbb{R}^q \mid \exists (u,c) \in \mathcal{U} : \quad y \in \{D(u,c)\} - K \ \}. \end{aligned}$$

To this end we construct an inclusion-reversing one-to-one map Ψ between the K-maximal proper faces of $\mathcal{D}$ and the weakly C-minimal proper faces of $\mathcal{P}$.

Consider the coupling function $\varphi : \mathbb{R}^q \times \mathbb{R}^q \to \mathbb{R}$, defined by

$$\varphi(y,v) := \sum_{i=1}^{q-1} y_i v_i + y_q \left(1 - \sum_{i=1}^{q-1} v_i\right) - v_q.$$

Note that $\varphi(\cdot, v)$ and $\varphi(y, \cdot)$ are affine. Choosing the values of the primal and dual objective functions as arguments, we just get

$$\varphi(Mx, D(u,c)) = c^T Mx - b^T u. \tag{3.1}$$

The coupling function φ is used to define the following two set-valued maps:

$$\mathcal{H} : \mathbb{R}^q \rightrightarrows \mathbb{R}^q, \quad \mathcal{H}(v) := \{y \in \mathbb{R}^q \mid \varphi(y,v) = 0\},$$

$$\mathcal{H}^* : \mathbb{R}^q \rightrightarrows \mathbb{R}^q, \quad \mathcal{H}^*(y) := \{v \in \mathbb{R}^q \mid \varphi(y,v) = 0\}.$$

Of course, $\mathcal{H}(v)$ and $\mathcal{H}^*(y)$ are hyperplanes in $\mathbb{R}^q$ for all $v, y \in \mathbb{R}^q$. Using the notation

$$c(v) := \left(v_1, \ldots, v_{q-1}, 1 - \sum_{i=1}^{q-1} v_i \right)^T \qquad \text{and} \qquad c^*(y) := \left(y_1 - y_q, \ldots, y_{q-1} - y_q, -1 \right)^T,$$

it is easy to see that

$$\mathcal{H}(v) = \left\{ y \in \mathbb{R}^q \mid c(v)^T y = v_q \right\} \qquad \text{and} \qquad \mathcal{H}^*(y) = \left\{ v \in \mathbb{R}^q \mid c^*(y)^T v = -y_q \right\}.$$

Obviously, the set-valued maps $\mathcal{H}$ and $\mathcal{H}^*$ are injective. The map $\mathcal{H}$ is now used to define the function $\Psi : 2^{\mathbb{R}^q} \to 2^{\mathbb{R}^q}$:

$$\Psi(\mathcal{F}^*) := \bigcap_{v \in \mathcal{F}^*} \mathcal{H}(v) \cap \mathcal{P}.$$

Now we have the main result, which shows that Ψ is a duality map between $\mathcal{P}$ and $\mathcal{D}$.

THEOREM 3.1. *Ψ is an inclusion-reversing one-to-one map between the set of all K-maximal proper faces of $\mathcal{D}$ and the set of all weakly C-minimal proper faces of $\mathcal{P}$, and the inverse map is given by*

$$\Psi^{-1}(\mathcal{F}) = \bigcap_{y \in \mathcal{F}} \mathcal{H}^*(y) \cap \mathcal{D}. \tag{3.2}$$

Moreover, for every K-maximal proper face $\mathcal{F}^*$ of $\mathcal{D}$ it holds that $\dim \mathcal{F}^* + \dim \Psi(\mathcal{F}^*) = q - 1$.

The proof of this theorem is given in the last section.

Let us consider an important special case. Vertices as well as facets are actually the most important faces from the point of view of applications. Therefore we extract some corresponding conclusions from the above theorem.

COROLLARY 3.2. *The following statements are equivalent.*

(i) *v is a K-maximal vertex of $\mathcal{D}$.*

(ii) *$\mathcal{H}(v) \cap \mathcal{P}$ is a weakly C-minimal $(q-1)$-dimensional facet of $\mathcal{P}$.*

Moreover, if $\mathcal{F}$ is a weakly C-minimal $(q-1)$-dimensional facet of $\mathcal{P}$, there is some uniquely defined point $v \in \mathbb{R}^q$ such that $\mathcal{F} = \mathcal{H}(v) \cap \mathcal{P}$.

Proof. (i) $\Rightarrow$ (ii). Since $\mathcal{H}(v) \cap \mathcal{P} = \Psi(\{v\})$, Theorem 3.1 implies that $\mathcal{H}(v) \cap \mathcal{P}$ is a weakly C-minimal proper face of $\mathcal{P}$. Theorem 3.1 also implies that $\dim(\mathcal{H}(v) \cap \mathcal{P}) = q - 1 - \dim\{v\} = q - 1$.

(ii) $\Rightarrow$ (i). Let $\mathcal{H}(v) \cap \mathcal{P}$ be a weakly C-minimal $(q-1)$-dimensional facet of $\mathcal{P}$. By Theorem 3.1, $\Psi^{-1}(\mathcal{H}(v) \cap \mathcal{P})$ is a K-maximal vertex of $\mathcal{D}$, denoted by $\bar{v}$. It follows that $\Psi \circ \Psi^{-1}(\mathcal{H}(v) \cap \mathcal{P}) = \Psi(\{\bar{v}\})$ and hence $\mathcal{H}(v) \cap \mathcal{P} = \mathcal{H}(\bar{v}) \cap \mathcal{P}$, implying $\mathcal{H}(v) = \mathcal{H}(\bar{v})$ as $\dim(\mathcal{H}(v) \cap \mathcal{P}) = q - 1$. The mapping $\mathcal{H}$ being injective implies $v = \bar{v}$.

To show the last statement, let $\mathcal{F}$ be a weakly C-minimal $(q-1)$-dimensional facet of $\mathcal{P}$. Hence $\Psi^{-1}(\mathcal{F})$ is a K-maximal vertex of $\mathcal{D}$, denoted by v. It follows that $\mathcal{F} = \Psi \circ \Psi^{-1}(\mathcal{F}) = \Psi(\{v\}) = \mathcal{H}(v) \cap \mathcal{P}$. By $\dim(\mathcal{H}(v) \cap \mathcal{P}) = q - 1$ and $\mathcal{H}$ being injective, v is uniquely defined. ∎

COROLLARY 3.3. *The following statements are equivalent.*

(i) *y is a weakly C-minimal vertex of $\mathcal{P}$.*

(ii) *$\mathcal{H}^*(y) \cap \mathcal{D}$ is a K-maximal $(q-1)$-dimensional facet of $\mathcal{D}$.*

Moreover, if $\mathcal{F}^*$ is a K-maximal $(q-1)$-dimensional facet of $\mathcal{D}$, there is some uniquely defined point $y \in \mathbb{R}^q$ such that $\mathcal{F}^* = \mathcal{H}^*(y) \cap \mathcal{D}$.

Proof. (i) $\Rightarrow$ (ii). Let y be a weakly C-minimal vertex of $\mathcal{P}$. By Theorem 3.1, the set $\mathcal{F}^* := \Psi^{-1}(\{y\}) = \mathcal{H}^*(y) \cap \mathcal{D}$ is a K-maximal face of $\mathcal{D}$. From Theorem 3.1 we also conclude that $\dim \mathcal{F}^* = q - 1 - \dim \{y\} = q - 1$. Thus $\mathcal{F}^*$ is a facet of $\mathcal{D}$.

(ii) $\Rightarrow$ (i). Let $\mathcal{H}^*(y) \cap \mathcal{D}$ be a K-maximal $(q-1)$-dimensional facet of $\mathcal{D}$. By Theorem 3.1 $\Psi(\mathcal{H}^*(y) \cap \mathcal{D})$ is a weakly C-minimal vertex of $\mathcal{P}$, denoted by $\bar{y}$. It follows that $\Psi^{-1} \circ \Psi(\mathcal{H}^*(y) \cap \mathcal{D}) = \Psi^{-1}(\{\bar{y}\})$ and hence $\mathcal{H}^*(y) \cap \mathcal{D} = \mathcal{H}^*(\bar{y}) \cap \mathcal{D}$. Since $\dim(\mathcal{H}^*(y) \cap \mathcal{D}) = q - 1$ and $\mathcal{H}^*$ is injective, we get $y = \bar{y}$.

To show the last statement, let $\mathcal{F}^*$ be a K-maximal $(q-1)$-dimensional facet of $\mathcal{D}$. Hence $\Psi(\mathcal{F}^*)$ is a C-minimal vertex of $\mathcal{P}$, denoted by y. It follows that $\mathcal{F}^* = \Psi^{-1} \circ \Psi(\mathcal{F}^*) = \Psi^{-1}(\{y\}) = \mathcal{H}^*(y) \cap \mathcal{D}$. By $\dim(\mathcal{H}^*(y) \cap \mathcal{D}) = q - 1$ and $\mathcal{H}^*$ being injective, y is uniquely defined. ∎

Remark. In addition to the correspondence between the faces of $\mathcal{P}$ and $\mathcal{D}$, Theorem 3.1 provides a relationship between the optimal values of (P) and (D) in the following way. If $y \in \operatorname{Min}_C M[\mathcal{X}]$, then there exists some $v \in \operatorname{Max}_K D[\mathcal{U}]$ with $\varphi(y, v) = 0$ and if $v \in \operatorname{Max}_K D[\mathcal{U}]$, then there exists some $y \in \operatorname{Min}_C M[\mathcal{X}]$ with $\varphi(y, v) = 0$.

In [8] we developed a duality theory based on a lattice theoretic approach. The dual problem (D) in the present article is related to the set-valued dual problem in [8]. Indeed, both problems have the same constraints, given by $\mathcal{U}$. The set-valued objective map of the dual problem in [8] can be expressed by the objective function of (D) as $(u, c) \mapsto \mathcal{H}(D(u, c))$. Moreover, (u, c) being a weakly efficient solution for the dual problem (LD) in [8] is equivalent to $D(u, c)$ being a K-maximal point of $\mathcal{D}$.

4. Examples. The geometric duality is illustrated by the following two examples.

Example 1. Consider problem (P) with the following data:

$$M = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \qquad A = \begin{pmatrix} 0 & -1 \\ 2 & 1 \\ 1 & 1 \\ 1 & 2 \end{pmatrix}, \qquad b = \begin{pmatrix} -4 \\ 4 \\ 3 \\ 4 \end{pmatrix}.$$

The set $\mathcal{D}$ can be easily calculated as $\mathcal{D} = \operatorname{co}\left\{(\frac{1}{3}, \frac{4}{3})^T, (\frac{1}{2}, \frac{3}{2})^T, (\frac{2}{3}, \frac{4}{3})^T, (1, 0)^T\right\} - K$, where $\operatorname{co} \mathcal{A}$ denotes the convex hull of a set $\mathcal{A}$ (see Figure 4.1).

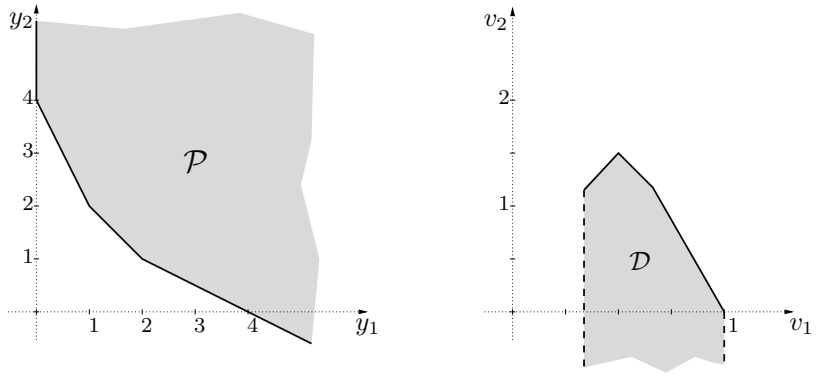

FIG. 4.1. *The three weakly C-minimal vertices of $\mathcal{P}$ correspond to the three K-maximal facets of $\mathcal{D}$, and the four weakly C-minimal facets of $\mathcal{P}$ correspond to the four K-maximal vertices of $\mathcal{D}$.*

Example 2. Consider problem (P) with the following data:

$$M = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \qquad A = \begin{pmatrix} 1 & 1 & 1 \\ -1 & -1 & 1 \\ -1 & 1 & -1 \\ 1 & -1 & -1 \end{pmatrix}, \qquad b = \begin{pmatrix} 1 \\ -1 \\ -1 \\ -1 \end{pmatrix}.$$

An easy computation shows that $\mathcal{D} = \operatorname{co}\left\{(0,0,0)^T, (1,0,0)^T, (0,1,0)^T, (\frac{1}{3},\frac{1}{3},\frac{1}{3})^T\right\} - K$ (see Figure 4.2).

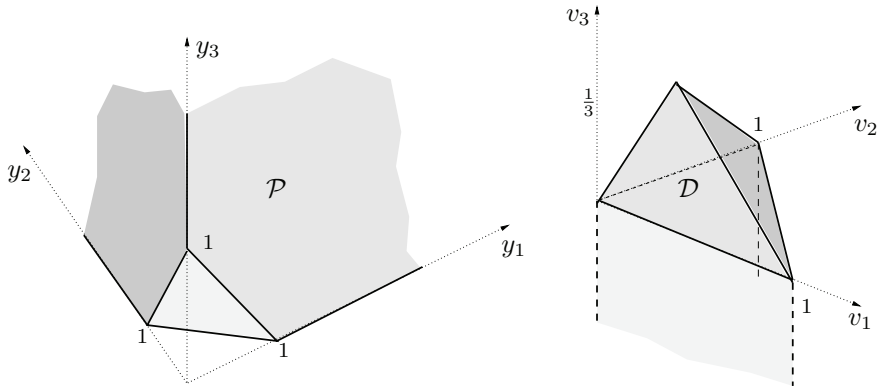

FIG. 4.2. *The three weakly C-minimal vertices of $\mathcal{P}$ correspond to the three K-maximal facets of $\mathcal{D}$, the six weakly C-minimal edges of $\mathcal{P}$ correspond to the six K-maximal edges of $\mathcal{D}$, and the four weakly C-minimal facets of $\mathcal{P}$ correspond to the four K-maximal vertices of $\mathcal{D}$.*

5. Proof of the main result. The proof of the main result is based on several auxiliary assertions, which are given below. There, the following pairs of dual scalar linear optimization problems, depending on parameters $v, y \in \mathbb{R}^q$, play an important role:

$$(\mathrm{P}_1(v)) \quad \min_{x\in\mathcal{X}} c(v)^T Mx \qquad \mathcal{X} := \{x \in \mathbb{R}^n \mid Ax \geq b\},$$

$$(\mathrm{D}_1(v)) \quad \max_{u\in\mathcal{T}(v)} b^T u \qquad \mathcal{T}(v) := \left\{u \in \mathbb{R}^m \mid u \geq 0, \;\; A^T u = M^T c(v)\right\},$$

$$(\mathrm{P}_2(y)) \quad \min_{(x,z)\in\mathcal{S}(y)} z \qquad \mathcal{S}(y) := \{(x,z) \in \mathbb{R}^n \times \mathbb{R} \mid Ax \geq b, \;\; Mx - kz \leq y\},$$

$$(\mathrm{D}_2(y)) \quad \max_{(u,c)\in\mathcal{U}} (b^T u - y^T c)$$

$$\mathcal{U} := \left\{(u,c) \in \mathbb{R}^m \times \mathbb{R}^q \mid (u,c) \geq 0, \;\; A^T u = M^T c, \;\; k^T c = 1\right\}.$$

Note that with the above notation it holds that

$$\mathcal{D} = \left\{v \in \mathbb{R}^q \mid c(v) \geq 0, \exists u \in \mathcal{T}(v) : b^T u \geq v_q\right\}. \tag{5.1}$$

We start with a characterization of weakly C-minimal points of $\mathcal{P}$.

LEMMA 5.1. *The following three statements are equivalent.*

(i) $y^0 \in \operatorname{Min}_C \mathcal{P}$.

(ii) *There is some $x^0 \in \mathbb{R}^n$ such that $(x^0, 0)$ solves $(\mathrm{P}_2(y^0))$.*

(iii) *There is some* $(u^0, c^0) \in \mathcal{U}$ *with* $b^T u^0 = {y^0}^T c^0$ *solving* $(\mathrm{D}_2(y^0))$.

Proof. (ii)⇒(i). If $(x^0, 0)$ solves $(\mathrm{P}_2(y^0))$, then $x^0 \in \mathcal{X}$ and $Mx^0 \leq y^0$; hence $y^0 \in \mathcal{P}$. Assume that there is some $y \in \mathcal{P}$ (i.e., there is some $x \in \mathcal{X}$ with $Mx \leq y$) with $y < y^0$; then there is some $z < 0$ such that $y \leq y^0 + kz$, whence $Mx - kz \leq y - kz \leq y^0$. Thus we have $(x, z) \in \mathcal{S}(y^0)$, where $z < 0$. This contradicts the optimality of $(x^0, 0)$.

(i)⇒(ii). If $y^0 \in \mathrm{Min}_C \mathcal{P}$, then there exists some $x^0 \in \mathcal{X}$ with $Mx^0 \leq y^0$; i.e., $(x^0, 0) \in \mathcal{S}(y^0)$. Assume that there is some $(x, z) \in \mathcal{S}(y^0)$ with $z < 0$. Let $y := y^0 + zk$. Then $y < y^0$ and $Mx \leq y^0 + kz = y$; i.e., $y \in \mathcal{P}$. This contradicts y^0 being weakly C-minimal.

(ii)⇔(iii). This holds by duality of $(\mathrm{P}_2(y^0))$ and $(\mathrm{D}_2(y^0))$. ∎

LEMMA 5.2. *Every K-maximal proper face of $\mathcal{D}$ contains a vertex.*

Proof. Let $\mathcal{F}^*$ be a K-maximal proper face of $\mathcal{D}$. It suffices to show that $\mathcal{F}^*$ contains no lines ([16, Cor. 18.5.3]). Assume on the contrary that $\mathcal{F}^*$ contains a line; i.e., there are $\bar{v} \in \mathcal{F}^*$ and $\psi \in \mathbb{R}^q \setminus \{0\}$ such that $\bar{v} + \lambda\psi \in \mathcal{F}^*$ for all $\lambda \in \mathbb{R}$. Since for every $v \in \mathcal{F}^* \subseteq \mathcal{D}$ it holds that $v_1 \geq 0, \ldots, v_{q-1} \geq 0$, we have $\psi_1 = \cdots = \psi_{q-1} = 0$. Thus, $\psi \neq 0$ implies $K \subseteq \{\lambda\psi \mid \lambda \in \mathbb{R}\}$. We get $\{\bar{v}\} + K \subseteq \mathcal{F}^*$, contradicting the K-maximality of $\mathcal{F}^*$. ∎

LEMMA 5.3. *Consider a hyperplane* $\mathcal{H}^* := \{v \in \mathbb{R}^q \mid {c^*}^T v = \gamma\}$. *Then the following statements are equivalent.*

(i) *$\mathcal{H}^*$ is a supporting hyperplane to $\mathcal{D}$ such that $\mathcal{H}^* \cap \mathcal{D}$ is K-maximal.*

(ii) *$\mathcal{H}^*$ is a supporting hyperplane to $D[\mathcal{U}]$, and $c_q^* < 0$.*

Proof. (i) ⇒ (ii). If $\mathcal{H}^*$ is a supporting hyperplane to $\mathcal{D}$, then there is some $v^0 \in \mathcal{D}$ with ${c^*}^T v^0 = \gamma$, and for $v \in \mathcal{D}$ it holds that ${c^*}^T v \geq \gamma$. By definition of $\mathcal{D}$ we have $\bar{v} := v^0 - e_q \in \mathcal{D}$ ($e_q = (0, \ldots, 0, 1)^T$), implying that $c_q^* \leq 0$. Since $c_q^* = 0$ would imply $\bar{v} \in \mathcal{H}^* \cap \mathcal{D}$ and $v^0 \in (\bar{v} + K \setminus \{0\}) \cap \mathcal{D}$, contradicting the maximality of $\mathcal{H}^* \cap \mathcal{D}$, we conclude that $c_q^* < 0$. As $v^0 \in \mathcal{D}$, there are $v^1 \in D[\mathcal{U}] \subseteq \mathcal{D}$ and $z \geq 0$ such that $v^0 = v^1 - e_q z$. Hence ${c^*}^T v^1 = {c^*}^T v^0 + c_q^* z \leq \gamma$. This implies ${c^*}^T v^1 = \gamma$. Therefore $\mathcal{H}^*$ is a supporting hyperplane to $D[\mathcal{U}]$.

(ii) ⇒ (i). If $\mathcal{H}^*$ is a supporting hyperplane to $D[\mathcal{U}]$, then there is some $v^0 \in D[\mathcal{U}]$ with ${c^*}^T v^0 = \gamma$ and for all $v \in D[\mathcal{U}]$ it holds that ${c^*}^T v \geq \gamma$. Since $c_q^* < 0$, it follows that ${c^*}^T v \geq \gamma$ for all $v \in D[\mathcal{U}] - K = \mathcal{D}$. By $v^0 \in \mathcal{D}$ and ${c^*}^T v^0 = \gamma$ we conclude that $\mathcal{H}^*$ is a supporting hyperplane to $\mathcal{D}$.

In order to show that $\mathcal{H}^* \cap \mathcal{D}$ is K-maximal, let $v^0 \in \mathcal{H}^* \cap \mathcal{D}$ be given. Hence, ${c^*}^T v^0 = \gamma$. For every $v \in v^0 + K \setminus \{0\}$ it holds that ${c^*}^T v < \gamma$, because of $c_q^* < 0$. Since ${c^*}^T v \geq \gamma$ for all $v \in \mathcal{D}$, we obtain $(v^0 + K \setminus \{0\}) \cap \mathcal{D} = \emptyset$. ∎

LEMMA 5.4. *Let $y \in \mathbb{R}^q$. The following statements are equivalent.*

(i) *y is a weakly C-minimal point of $\mathcal{P}$.*

(ii) *$\mathcal{H}^*(y) \cap \mathcal{D}$ is a K-maximal proper face of $\mathcal{D}$.*

Moreover, for every K-maximal proper face $\mathcal{F}^*$ of $\mathcal{D}$ there exists some $y \in \mathbb{R}^q$ such that $\mathcal{F}^* = \mathcal{H}^*(y) \cap \mathcal{D}$.

Proof. By Lemma 5.1, (i) is equivalent to the following:

(iii) There exists some $(u^0, c^0) \in \mathcal{U}$ with $y^T c^0 = b^T u^0$ solving $(\mathrm{D}_2(y))$.

Taking into account (3.1), we see that (iii) is equivalent to the following:

(iv) $\varphi(y, v) \geq 0$ for all $v \in D[\mathcal{U}]$, and there exists some $v^0 \in D[\mathcal{U}]$ with $\varphi(y, v^0) = 0$.

Statement (iv) is equivalent to the following:

(v) $\mathcal{H}^*(y)$ is a supporting hyperplane to $D[\mathcal{U}]$.

Regarding the fact that $\mathcal{H}^*(y) = \left\{v \in \mathbb{R}^q \mid c^*(y)^T v = -y_q\right\}$ with $c^*(y)_q = -1 < 0$, (v) is equivalent to (ii) by Lemma 5.3.

Let $\mathcal{F}^*$ be a K-maximal proper face of $\mathcal{D}$. Then there exists a supporting hyperplane $\mathcal{H}^* := \{v \in \mathbb{R}^q \mid {c^*}^T v = \gamma\}$ (i.e., $c^* \neq 0$) to $\mathcal{D}$ such that $\mathcal{F}^* = \mathcal{H}^* \cap \mathcal{D}$. By Lemma 5.3, we have $c_q^* < 0$. Setting

$$y := \left(\frac{\gamma - c_1^*}{c_q^*}, \ldots, \frac{\gamma - c_{q-1}^*}{c_q^*}, \frac{\gamma}{c_q^*} \right)^T,$$

we obtain $\mathcal{H}^* = \mathcal{H}^*(y)$. Hence $\mathcal{F}^* = \mathcal{H}^*(y) \cap \mathcal{D}$. □

LEMMA 5.5. *Consider a hyperplane* $\mathcal{H} := \{y \in \mathbb{R}^q \mid c^T y = \gamma\}$. *The following statements are equivalent.*

(i) $\mathcal{H}$ *is a supporting hyperplane to* $\mathcal{P}$.

(ii) $c \geq 0$, *and* $\mathcal{H}$ *is a supporting hyperplane to* $M[\mathcal{X}]$.

Proof. (i) $\Rightarrow$ (ii). If $\mathcal{H}$ is a supporting hyperplane to $\mathcal{P}$, then there is some $y^0 \in \mathcal{P}$ with $c^T y^0 = \gamma$ and for all $y \in \mathcal{P}$ it holds that $c^T y \geq \gamma$. By the definition of $\mathcal{P}$ we have $y^0 + w \in \mathcal{P}$ for all $w \in C = \mathbb{R}^q_+$; hence $c^T w \geq 0$ for all $w \in \mathbb{R}^q_+$. This implies $c \geq 0$. Since $y^0 \in \mathcal{P}$, there is $y^1 \in M[\mathcal{X}] \subseteq \mathcal{P}$ and $w \in C$ such that $y^0 = y^1 + w$. Hence $c^T y^1 = c^T y^0 - c^T w \leq \gamma$. This implies $c^T y^1 = \gamma$. Therefore $\mathcal{H}$ is a supporting hyperplane to $M[\mathcal{X}]$.

(ii) $\Rightarrow$ (i). If $\mathcal{H}$ is a supporting hyperplane to $M[\mathcal{X}]$, then there is some $y^0 \in M[\mathcal{X}]$ with $c^T y^0 = \gamma$, and for all $y \in M[\mathcal{X}]$ it holds that $c^T y \geq \gamma$. Since $c \geq 0$, it follows that $c^T y \geq \gamma$ for all $y \in M[\mathcal{X}] + \mathbb{R}^q_+$. By $y^0 \in \mathcal{P}$ and $c^T y^0 = \gamma$ we conclude that $\mathcal{H}$ is a supporting hyperplane to $\mathcal{P}$. □

LEMMA 5.6. *Every proper face of* $\mathcal{P}$ *is weakly* C*-minimal.*

Proof. Let $\mathcal{F}$ be a proper face of $\mathcal{P}$. There is a supporting hyperplane $\mathcal{H} := \{y \in \mathbb{R}^q \mid c^T y = \gamma\}$ (i.e., $c \neq 0$) to $\mathcal{P}$ such that $\mathcal{F} = \mathcal{H} \cap \mathcal{P}$. By Lemma 5.5 we have $c \geq 0$. Let $y \in \mathcal{F}$; then $y \in \mathcal{P}$ implying the existence of $x^0 \in \mathcal{X}$ such that $Mx^0 \leq y$; i.e., $(x^0, 0) \in \mathcal{S}(y)$ and $c^T y = \gamma$. Suppose that there are $x \in \mathcal{X}$ and $z < 0$ such that $Mx - kz \leq y$, i.e., $Mx < y$. Since $\mathcal{H} = \{y \in \mathbb{R}^q \mid c^T y = \gamma\}$ is a supporting hyperplane to $\mathcal{P}$ and $Mx \in \mathcal{P}$, we have $\gamma \leq c^T Mx < c^T y = \gamma$, a contradiction. Hence $(x, 0)$ solves $(\mathrm{P}_2(y))$. By Lemma 5.1 this implies that $y \in \mathrm{Min}_C \mathcal{P}$. □

LEMMA 5.7. *Let* $v \in \mathbb{R}^q$. *The following statements are equivalent.*

(i) v *is a* K*-maximal point of* $\mathcal{D}$.

(ii) $\mathcal{H}(v) \cap \mathcal{P}$ *is a weakly* C*-minimal proper face of* $\mathcal{P}$.

Moreover, for every proper face $\mathcal{F}$ *of* $\mathcal{P}$ *there exists some* $v \in \mathbb{R}^q$ *such that* $\mathcal{F} = \mathcal{H}(v) \cap \mathcal{P}$.

Proof. Taking into account (5.1), we conclude that (i) is equivalent to the following:

(iii) $c(v) \geq 0$, and there exists some $u^0 \in \mathbb{R}^m$ solving $(\mathrm{D}_1(v))$ such that $v_q = b^T u^0$.

By duality between $(\mathrm{P}_1(v))$ and $(\mathrm{D}_1(v))$, (iii) is equivalent to the following:

(iv) $c(v) \geq 0$, and there exists some $x^0 \in \mathbb{R}^n$ solving $(\mathrm{P}_1(v))$ such that $v_q = c(v)^T Mx^0$.

Statement (iv) is equivalent to the following:

(v) $c(v) \geq 0$, and $\mathcal{H}(v)$ is a supporting hyperplane to $M[\mathcal{X}]$.

By Lemmas 5.5 and 5.6, (v) is equivalent to (ii).

To show the last conclusion, let $\mathcal{F}$ be a proper face of $\mathcal{P}$. Hence there exists some supporting hyperplane $\mathcal{H} := \{y \in \mathbb{R}^q \mid c^T y = \gamma\}$ (i.e., $c \neq 0$) to $\mathcal{P}$ such that $\mathcal{F} = \mathcal{H} \cap \mathcal{P}$. By Lemma 5.5, we have $c \geq 0$. Without loss of generality we can assume that $k^T c = 1$ ($k = (1, \ldots, 1)^T$). Setting $v_i := c_i$ for $i = 1, \ldots, q-1$ and $v_q := \gamma$, we have $\mathcal{H} = \mathcal{H}(v)$. Hence $\mathcal{F} = \mathcal{H}(v) \cap \mathcal{P}$. □

Now we are able to give the proof of our main result.

Proof of Theorem 3.1. (a) We show that if $\mathcal{F}^*$ is a K-maximal proper face of $\mathcal{D}$, then $\Psi(\mathcal{F}^*)$ is a weakly C-minimal proper face of $\mathcal{P}$. By Lemma 5.7, $\mathcal{H}(v) \cap \mathcal{P}$ is a weakly C-minimal proper face of $\mathcal{P}$ for each $v \in \mathcal{F}^*$; hence $\Psi(\mathcal{F}^*)$ is a weakly C-minimal face of $\mathcal{P}$. It remains to show that $\Psi(\mathcal{F}^*)$ is nonempty. By Lemma 5.4 there is some $y^0 \in \operatorname{Min}_C \mathcal{P}$ such that $\mathcal{F}^* = \mathcal{H}^*(y^0) \cap \mathcal{D}$; hence $y^0 \in \Psi(\mathcal{F}^*)$.

(b) We prove that $\Psi^*(\mathcal{F}) := \bigcap_{y \in \mathcal{F}} \mathcal{H}^*(y) \cap \mathcal{D}$ is a K-maximal proper face of $\mathcal{D}$ if $\mathcal{F}$ is a weakly C-minimal proper face of $\mathcal{P}$. By Lemma 5.4, $\mathcal{H}^*(y) \cap \mathcal{D}$ is a K-maximal proper face of $\mathcal{D}$ for each $y \in \mathcal{F}$. Hence $\Psi^*(\mathcal{F})$ is a K-maximal proper face of $\mathcal{D}$ if this set is nonempty. Indeed, by Lemma 5.7, there is some $v^0 \in \operatorname{Max}_K \mathcal{D}$ such that $\mathcal{F} = \mathcal{H}(v^0) \cap \mathcal{P}$ implying $v^0 \in \Psi^*(\mathcal{F})$.

(c) In order to show that Ψ is a bijection and that $\Psi^{-1}(\mathcal{F}) = \bigcap_{y \in \mathcal{F}} \mathcal{H}^*(y) \cap \mathcal{D} =: \Psi^*(\mathcal{F})$, we have to show the following two statements: (c_1) $\Psi^*(\Psi(\mathcal{F}^*)) = \mathcal{F}^*$ for all K-maximal proper faces $\mathcal{F}^*$ of $\mathcal{D}$ and (c_2) $\Psi(\Psi^*(\mathcal{F})) = \mathcal{F}$ for all weakly C-minimal proper faces $\mathcal{F}$ of $\mathcal{P}$.

(c_1) First we show that $\mathcal{F}^* \subseteq \Psi^*(\Psi(\mathcal{F}^*))$. Assume the contrary; i.e., there is some $v^0 \in \mathcal{F}^*$ such that $v^0 \notin \Psi^*(\Psi(\mathcal{F}^*))$. Hence there exists some $y^0 \in \Psi(\mathcal{F}^*)$ such that $v^0 \notin \mathcal{H}^*(y^0) \cap \mathcal{D}$. This implies $v^0 \notin \mathcal{H}^*(y^0)$ since $v^0 \in \mathcal{D}$. It follows that $y^0 \notin \mathcal{H}(v^0)$, whence $y^0 \notin \Psi(\mathcal{F}^*)$, a contradiction. To show the opposite inclusion, let $y^0 \in \operatorname{Min}_C \mathcal{P}$ such that $\mathcal{F}^* = \mathcal{H}^*(y^0) \cap \mathcal{D}$. The existence of such a point y^0 is ensured by Lemma 5.4. It follows that $y^0 \in \Psi(\mathcal{F}^*)$. Hence $\Psi^*(\Psi(\mathcal{F}^*)) \subseteq \mathcal{H}^*(y^0) \cap \mathcal{D} = \mathcal{F}^*$.

(c_2) The proof works analogously using Lemma 5.7 instead of Lemma 5.4.

(d) Obviously, Ψ is inclusion-reversing.

(e) It remains to prove that $\dim \mathcal{F}^* + \dim \Psi(\mathcal{F}^*) = q-1$ for all K-maximal proper faces $\mathcal{F}^*$ of $\mathcal{D}$. Consider some fixed $\mathcal{F}^*$, and set $r := \dim \mathcal{F}^*$ and $s := \dim \Psi(\mathcal{F}^*)$. By the first part of the proof, $\mathcal{F} := \Psi(\mathcal{F}^*)$ is a weakly C-minimal face of $\mathcal{P}$. Hence there exist proper faces $\mathcal{F} \subsetneq \mathcal{F}_1 \subsetneq \mathcal{F}_2 \subsetneq \cdots \subsetneq \mathcal{F}_{q-1-s}$ (all of them being weakly C-minimal by Lemma 5.6) such that $\dim \mathcal{F}_{q-1-s} = q-1$. From the properties of Ψ, we conclude that $0 \le \dim \Psi^{-1}(\mathcal{F}_{q-1-s}) \le r - (q-1-s)$. Hence $r + s \ge q-1$. Since every K-maximal face of $\mathcal{D}$ has a vertex (Lemma 5.2), there are K-maximal faces $\mathcal{F}^* \supsetneq \mathcal{F}_1^* \supsetneq \mathcal{F}_2^* \supsetneq \cdots \supsetneq \mathcal{F}_r^*$ such that $\dim \mathcal{F}_r^* = 0$. It follows that $s + r \le \dim \Psi(\mathcal{F}_r^*) \le q-1$. Together we have $s + r = q - 1$. □

CONVERGENCE RATE OF AN OPTIMIZATION ALGORITHM FOR MINIMIZING QUADRATIC FUNCTIONS WITH SEPARABLE CONVEX CONSTRAINTS*

RADEK KUČERA†

Abstract. A new active set algorithm for minimizing quadratic functions with separable convex constraints is proposed by combining the conjugate gradient method with the projected gradient. It generalizes recently developed algorithms of quadratic programming constrained by simple bounds. A linear convergence rate in terms of the Hessian spectral condition number is proven. Numerical experiments, including the frictional three-dimensional (3D) contact problems of linear elasticity, illustrate the computational performance.

Key words. quadratic function, separable convex constraints, active set, conjugate gradient method, projected gradient, convergence rate

1. Introduction.

We shall be concerned with solving

$$\min_{x\in\Omega} f(x), \tag{1.1}$$

where $f(x) = \frac{1}{2}\, x^\top Ax - x^\top b$, $A \in \mathbb{R}^{n\times n}$ is symmetric positive definite, $b \in \mathbb{R}^n$, $\Omega = \Omega_1 \times \cdots \times \Omega_m$, and $\Omega_i = \{\boldsymbol{x}_i \in \mathbb{R}^{n_i} : f_i(\boldsymbol{x}_i) \le 0\}$ are defined by continuously differentiable convex functions $f_i : \mathbb{R}^{n_i} \to \mathbb{R}$ so that $n_i \ge 1$, $\sum_{i=1}^m n_i = n$. Let us note that the feasible set Ω is *separable* in the sense that each part $\boldsymbol{x}_i$ of $x = (\boldsymbol{x}_1^\top, \ldots, \boldsymbol{x}_m^\top)^\top$ is subject to one constraint $\boldsymbol{x}_i \in \Omega_i$.

This problem includes several independently investigated subproblems originating, for instance, in duality-based methods for the solution of contact problems of linear elasticity:

- If $n_i = 1$ and $f_i(x_i) \equiv l_i - x_i$ with l_i given, we obtain the *simple bound*

$$l_i \le x_i \tag{1.2}$$

  arising from two-dimensional contact problems [4].
- If $n_i = 2$, $\boldsymbol{x}_i = (x_{2i-1}, x_{2i})^\top$ and $f_i(\boldsymbol{x}_i) \equiv x_{2i-1}^2 + x_{2i}^2 - r_i^2$ with r_i given, we arrive at

$$x_{2i-1}^2 + x_{2i}^2 \le r_i^2 \tag{1.3}$$

  that can be interpreted as the *circular constraint*. A source of such constraints is an isotropic friction law for three-dimensional (3D) contact problems [8].
- If an anisotropic friction law is considered and if a finite element tearing and interconnecting (FETI) domain decomposition method is used for solving 3D

contact problems [11], then (1.3) is replaced by the *ellipsoidal constraint*,

$$(\boldsymbol{x}_i - \boldsymbol{s}_i)^\top \boldsymbol{F}_i (\boldsymbol{x}_i - \boldsymbol{s}_i) \le r_i^2,$$

with $\boldsymbol{F}_i \in \mathbb{R}^{2\times 2}$ positive definite and $\boldsymbol{s}_i = (s_{2i-1}, s_{2i})^\top$ given.

– Finally let us note that the unconstrained case may be described by $f_i(\boldsymbol{x}_i) = -1$.

Through the whole paper, we shall have in mind large-scale problems in which the Hessian matrix A is not formed explicitly. In this case, an iterative method is a suitable tool for solving (1.1) since it is the only action of A which is needed. A class of efficient algorithms appropriate for our research is based on the active set strategy that dates back at least to Polyak [13]. His algorithm solves quadratic programming problems constrained by simple bounds (1.2) using a restarted conjugate gradient method. After each start, a subset of variables is fixed at bounds (the active set) and the conjugate gradient method minimizes f with respect to remaining variables. The "inner" minimization is terminated if either the minimum is reached or an infeasible iteration is generated. In the first case, some of the fixed variables are released while, in the second case, new variables are added to the active set. In both cases, the value of f decreases so that the active set can never reappear, and therefore the algorithm converges in a finite number of steps.

As the Polyak algorithm suffers from several drawbacks, it was modified in order to exclude doubts about its efficiency; see discussions in [1, 5]. Here, we mention two improvements relevant for our more general constraints. Firstly, the exact solution of auxiliary "inner" problems can be replaced by an inexact one. We shall use a theoretically supported strategy of an adaptive precision control presented by Friedlander and Martínez [6] and by Dostál [2]. The basic idea is to control the "inner" precision by a ratio of the norms of a violation of the Karush–Kuhn–Tucker (KKT) conditions at fixed and free variables. Secondly, the qualitative progress has been achieved by Dostál and Schöberl [5] using the projected gradient for expanding the active set. It permits rapid changes in the active set without the necessity to perform computationally expensive steps (e.g., backtracking). Moreover, the algorithm has a linear convergence rate in terms of the spectral condition number of the Hessian matrix A.

The scheme of the later algorithm was successfully extended for solving 3D contact problems with an isotropic friction in [11]. As the constraints are circular (1.3), the algorithm does search not only for the active set corresponding to the solution, but also for the positions of the pairs $(x_{2i-1}, x_{2i})^\top$ lying on the boundaries of the circles $x_{2i-1}^2 + x_{2i}^2 = r_i^2$. It is easily seen that the finite terminating property cannot be expected in such cases, and therefore the convergence was proven in [10] by different arguments. On the other hand, it is relatively surprising that a linear convergence rate may be derived like for the simple bound case. This proof is the main goal of the paper.

Let us briefly outline the structure of the paper. After introducing notations in section 2, we prove that the KKT optimality conditions are equivalent to the zero projected gradient. Our algorithm for solving (1.1) is proposed in section 3 in a form suitable for theoretical analysis. Section 4 summarizes auxiliary statements on the projected gradient, while section 5 gives the main result of the paper concerning a linear convergence rate. A practical implementation of the algorithm for simple bounds (1.2) and circular constraints (1.3) is discussed in section 6, and finally, section 7 presents the results of numerical experiments.

2. Preliminaries and notations. We shall always assume that the feasible set Ω in (1.1) is nonempty. As f is the strictly convex function and Ω is the convex set,

the existence of a unique solution to (1.1) is guaranteed. We shall denote it by x^*. It is well known that x^* is fully determined by the KKT conditions [12]. Before giving their appropriate form, we shall introduce notations.

Recall that a continuously differentiable function $F : \Omega \to \mathbb{R}$ is convex iff

$$F(y) - F(x) \geq (y - x)^\top \nabla F(x) \quad \forall x, y \in \Omega, \tag{2.1}$$

where ∇F denotes the gradient of F. The gradient of the objective function f at x shall be denoted by

$$g = g(x) = Ax - b.$$

Let $\mathcal{M}$ denote the set of indices so that

$$\mathcal{M} = \{1, \ldots, m\}.$$

We shall use the following convention: if $x \in \mathbb{R}^n$ is a vector, then $x_i \in \mathbb{R}$ is its ith entry, $1 \leq i \leq n$, and $\boldsymbol{x}_i \in \mathbb{R}^{n_i}$ is its ith segment, $i \in \mathcal{M}$, so that $x = (\boldsymbol{x}_1^\top, \ldots, \boldsymbol{x}_m^\top)^\top$. We shall denote by $\|\boldsymbol{x}_i\|$ the Euclidean norm of $\boldsymbol{x}_i$.

In order to exclude pathological situations, we shall assume without loss of generality that f_i are not identically zero in Ω_i. In that case Ω_i has a nonempty interior, $\operatorname{int}\Omega_i = \{\boldsymbol{x}_i \in \mathbb{R}^{n_i} : f_i(\boldsymbol{x}_i) < 0\}$, and a possibly nonempty boundary $\partial\Omega_i = \{\boldsymbol{x}_i \in \mathbb{R}^{n_i} : f_i(\boldsymbol{x}_i) = 0\}$. The convexity of f_i implies that if $\partial\Omega_i \neq \emptyset$ and $\boldsymbol{x}_i \in \partial\Omega_i$, then $\nabla f_i(\boldsymbol{x}_i)$ is the outward normal vector to $\partial\Omega_i$ at $\boldsymbol{x}_i$; see Figure 2.1.a.

It is well known that the solution x^* to (1.1) is characterized by the existence of Lagrange multipliers λ_i^*, $i \in \mathcal{M}$, such that [12]

$$\boldsymbol{g}_i^* + \lambda_i^* \nabla f_i(\boldsymbol{x}_i^*) = \boldsymbol{0},\ f_i(\boldsymbol{x}_i^*) \leq 0,\ \lambda_i^* \geq 0,\ \lambda_i^* f_i(\boldsymbol{x}_i^*) = 0, \quad i \in \mathcal{M},$$

where $\boldsymbol{g}_i^*$ denotes the ith segment of $g^* = g(x^*)$. After eliminating λ_i^*, we obtain the following theorem.

THEOREM 2.1. *The vector $x^* \in \Omega$ is the solution to* (1.1) *iff for $i \in \mathcal{M}$:*

$$f_i(\boldsymbol{x}_i^*) < 0 \quad \textit{implies} \quad \boldsymbol{g}_i^* = \boldsymbol{0}, \tag{2.2}$$

$$f_i(\boldsymbol{x}_i^*) = 0 \quad \textit{implies} \quad \boldsymbol{g}_i^* + \frac{\|\boldsymbol{g}_i^*\|}{\|\nabla f_i(\boldsymbol{x}_i^*)\|} \nabla f_i(\boldsymbol{x}_i^*) = \boldsymbol{0}. \tag{2.3}$$

Conditions (2.2) and (2.3) are called the *inner KKT conditions* and the *boundary KKT conditions*, respectively.

As the feasible set Ω is separable, the projection $P_\Omega : \mathbb{R}^n \mapsto \Omega$ can be put together by the projections $P_{\Omega_i} : \mathbb{R}^{n_i} \mapsto \Omega_i$, $i \in \mathcal{M}$. Thus we define $P_\Omega(x)$ for any $x \in \mathbb{R}^n$ by

$$P_\Omega(x) = \begin{pmatrix} P_{\Omega_1}(\boldsymbol{x}_1) \\ \vdots \\ P_{\Omega_m}(\boldsymbol{x}_m) \end{pmatrix}, \tag{2.4}$$

where $P_{\Omega_i}(\boldsymbol{x}_i)$ are defined by

$$P_{\Omega_i}(\boldsymbol{x}_i) = \begin{cases} \boldsymbol{x}_i & \text{for } \boldsymbol{x}_i \in \Omega_i, \\ \boldsymbol{z}_i & \text{for } \boldsymbol{x}_i \notin \Omega_i, \end{cases}$$

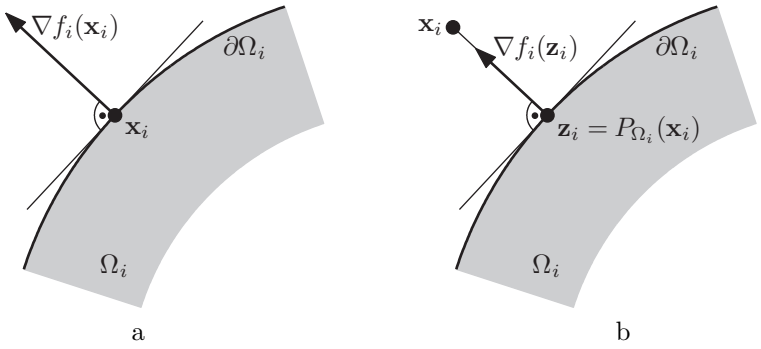

FIG. 2.1. (a) *The outward normal vector to* $\partial\Omega_i$*;* (b) *The projection to* $\partial\Omega_i$*.*

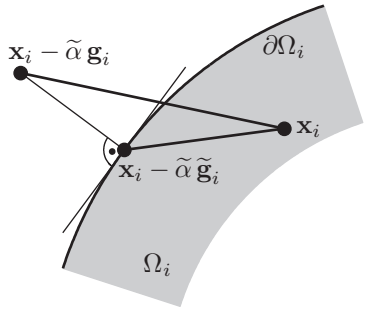

FIG. 2.2. *The projected gradient on* Ω_i*.*

with (see Figure 2.1.b)

$$f_i(\boldsymbol{z}_i) = 0, \tag{2.5}$$

$$\boldsymbol{z}_i + \frac{\|\boldsymbol{x}_i - \boldsymbol{z}_i\|}{\|\nabla f_i(\boldsymbol{z}_i)\|}\nabla f_i(\boldsymbol{z}_i) = \boldsymbol{x}_i. \tag{2.6}$$

Let us note that $\boldsymbol{z}_i$ is well defined by (2.5) and (2.6) because Ω_i is convex. The equality (2.6) yields orthogonality of P_{Ω_i} and, consequently, of P_Ω that is equivalent to the variational inequality

$$(x - P_\Omega(x))^\top (y - P_\Omega(x)) \le 0 \quad \forall x \in \mathbb{R}^n \ \forall y \in \Omega.$$

Let us define the *projected gradient* $\widetilde{g} = \widetilde{g}(x)$ at $x \in \Omega$ for fixed $\widetilde{\alpha} > 0$ by

$$\widetilde{g}(x) = \frac{1}{\widetilde{\alpha}}\left(x - P_\Omega\left(x - \widetilde{\alpha} g(x)\right)\right). \tag{2.7}$$

This definition enables us to describe the projection of the gradient step without P_Ω so that

$$P_\Omega(x - \widetilde{\alpha} g(x)) = x - \widetilde{\alpha}\widetilde{g}(x);$$

see Figure 2.2. In the next theorem, we prove that the zero project gradient represents an alternative optimality criterion to KKT conditions.

THEOREM 2.2. *The vector* $x^* \in \Omega$ *solves* (1.1) *iff* $\widetilde{g}(x^*) = 0$*.*

Proof. The equality $\widetilde{g}(x^*) = 0$ is equivalent to

$$\boldsymbol{x}_i^* = P_{\Omega_i}(\boldsymbol{x}_i^* - \widetilde{\alpha}\boldsymbol{g}_i^*), \quad i \in \mathcal{M}. \tag{2.8}$$

We shall prove that the KKT conditions (2.2) and (2.3) are equivalently satisfied. We distinguish two cases. (i) Let $f_i(\boldsymbol{x}_i^*) < 0$. Then $\boldsymbol{x}_i^* \in \operatorname{int}\Omega_i$, which is equivalent by (2.8) to $\boldsymbol{x}_i^* - \widetilde{\alpha}\boldsymbol{g}_i^* \in \operatorname{int}\Omega_i$. Therefore

$$\boldsymbol{x}_i^* = P_{\Omega_i}(\boldsymbol{x}_i^* - \widetilde{\alpha}\boldsymbol{g}_i^*) = \boldsymbol{x}_i^* - \widetilde{\alpha}\boldsymbol{g}_i^*$$

so that $\boldsymbol{g}_i^* = \boldsymbol{0}$, and therefore (2.2) holds. (ii) Let $f_i(\boldsymbol{x}_i^*) = 0$. Using (2.6) with $\boldsymbol{x}_i$ replaced by $\boldsymbol{x}_i^* - \widetilde{\alpha}\boldsymbol{g}_i^*$ and with $\boldsymbol{z}_i$ replaced by $\boldsymbol{x}_i^*$, we obtain after simple manipulation

$$\boldsymbol{g}_i^* + \frac{\|\boldsymbol{g}_i^*\|}{\|\nabla f_i(\boldsymbol{x}_i^*)\|}\nabla f_i(\boldsymbol{x}_i^*) = \boldsymbol{0}$$

so that (2.3) holds. ∎

We shall decompose $\mathcal{M}$ at $x \in \Omega$ on the *free set* $\mathcal{F}(x)$ and the *active set* $\mathcal{A}(x)$ as

$$\mathcal{F}(x) = \{i \in \mathcal{M} : f_i(\boldsymbol{x}_i) < 0\},$$
$$\mathcal{A}(x) = \{i \in \mathcal{M} : f_i(\boldsymbol{x}_i) = 0\}.$$

Analogously, we can decompose $\widetilde{g}$ on the *projected free gradient* $\widetilde{\varphi} = \widetilde{\varphi}(x)$ and the *projected boundary gradient* $\widetilde{\beta} = \widetilde{\beta}(x)$ so that

$$\widetilde{\boldsymbol{\varphi}}_i = \widetilde{\boldsymbol{g}}_i \quad \text{for } i \in \mathcal{F}(x), \quad \widetilde{\boldsymbol{\varphi}}_i = \boldsymbol{0} \quad \text{for } i \in \mathcal{A}(x), \tag{2.9}$$

$$\widetilde{\boldsymbol{\beta}}_i = \boldsymbol{0} \quad \text{for } i \in \mathcal{F}(x), \quad \widetilde{\boldsymbol{\beta}}_i = \widetilde{\boldsymbol{g}}_i \quad \text{for } i \in \mathcal{A}(x). \tag{2.10}$$

Thus, the inner KKT conditions (2.2) are satisfied iff $\widetilde{\varphi}(x) = 0$, and the boundary KKT conditions (2.3) are satisfied iff $\widetilde{\beta}(x) = 0$. Moreover, we define the *free gradient* $\varphi = \varphi(x)$ so that

$$\widetilde{\boldsymbol{\varphi}}_i = \widetilde{\boldsymbol{g}}_i \quad \text{for } i \in \mathcal{F}(x), \quad \widetilde{\boldsymbol{\varphi}}_i = \boldsymbol{0} \quad \text{for } i \in \mathcal{A}(x). \tag{2.11}$$

Finally let us denote the A-energy norm of $x \in \mathbb{R}^n$ by $\|x\|_A$. Thus $\|x\|_A = (x^\top Ax)^{1/2}$, and $\|x\| = \|x\|_I = (x^\top x)^{1/2}$ is the Euclidean norm. The analogous notation will be used for the induced matrix norm so that

$$\kappa(A) = \|A\|\|A^{-1}\|$$

is the spectral condition number of A.

3. Algorithm. In this section we present our algorithm for solving (1.1) in a form convenient for the analysis, while technical details are postponed to section 6. The algorithm exploits a given constant $\Gamma > 0$ to decide on interrupting conjugate gradient iterations and a fixed steplength $\widetilde{\alpha} \in (0, \|A\|^{-1}]$ defining the projected gradient.

We shall combine three steps to generate a sequence of iterates $\{x^k\}$ that approximates the solution to (1.1):

– the *expansion step*, which may add indices to the active set, is defined by

$$x^{k+1} = x^k - \widetilde{\alpha}\widetilde{\varphi}(x^k); \tag{3.1}$$

– the *proportioning step*, which may release indices from the active set, reads as

$$x^{k+1} = x^k - \widetilde{\alpha}\widetilde{\beta}(x^k); \tag{3.2}$$

– the *conjugate gradient step* is given by

$$x^{k+1} = x^k - \alpha_{cg}^k p^k, \quad \alpha_{cg}^k = \frac{g(x^k)^\top p^k}{(p^k)^\top A p^k}, \tag{3.3}$$

where the conjugate gradient directions p^k are constructed recurrently [7].

The conjugate gradient steps are used to carry out a minimization of the objective function f efficiently on the interior of the *face*

$$W_{\mathcal{A}(x^s)} = \{x \in \Omega : \boldsymbol{x}_i = \boldsymbol{x}_i^s \ \text{ for } \ i \in \mathcal{A}(x^s)\},$$

where x^s is determined by the expansion step or by the proportioning step. It requires that the parts of p^k corresponding to the indices of $\mathcal{A}(x^s)$ vanish, i.e., $\boldsymbol{p}_i^k = \mathbf{0}$ for $i \in \mathcal{A}(x^s)$. We can easily fulfill this requirement by adapting the classical recurrence generating p^k. We start (or restart) from $p^s = \varphi(x^s)$ and use

$$p^k = \varphi(x^k) - \gamma^k p^{k-1}, \quad \gamma^k = \frac{\varphi(x^k)^\top A p^{k-1}}{(p^{k-1})^\top A p^{k-1}}, \quad k > s. \tag{3.4}$$

The formulae (3.4) is used while the sequence of the conjugate gradient steps is unbroken. After changing the active set, we must always restart.

Later on, we shall need the following lemma.

LEMMA 3.1. *Let x^{k+1} be generated by the conjugate gradient step. Then*

$$f(x^{k+1}) \le f(x^k - \alpha\varphi(x^k)) \quad \forall \alpha \in \mathbb{R}.$$

Proof. It is a well-known property of the conjugate gradient method [7] that

$$f(x^{k+1}) = \min_{x \in x^s + \mathrm{Span}\{p^s, \dots, p^k\}} f(x). \tag{3.5}$$

As (3.4) implies $\varphi(x^k) \in \mathrm{Span}\{p^s, \dots, p^k\}$ and $x^k \in x^s + \mathrm{Span}\{p^s, \dots, p^{k-1}\}$, we obtain $x^k - \alpha\varphi(x^k) \in x^s + \mathrm{Span}\{p^s, \dots, p^k\}$. The lemma follows using (3.5). ∎

The last ingredient of our algorithm is the *releasing criterion*:

$$\widetilde{\beta}(x^k)^\top g(x^k) \le \Gamma^2 \widetilde{\varphi}(x^k)^\top g(x^k). \tag{3.6}$$

If this inequality holds, we call the iterate x^k *strictly proportional*. The criterion (3.6) is used to decide which of the steps will be performed.

ALGORITHM 3.1. *Let $x^0 \in \Omega$, $\Gamma > 0$, and $\widetilde{\alpha} \in (0, \|A\|^{-1}]$ be given. For $k \ge 0$ and x^k known, choose x^{k+1} by the following rules:*

(i) *If $\widetilde{g}(x^k) = 0$, set $x^{k+1} = x^k$.*

(ii) *If x^k is strictly proportional and $\widetilde{g}(x^k) \ne 0$, try to generate x^{k+1} by the conjugate gradient step. If $x^{k+1} \in \Omega$ and if it does not change the active set, then accept it, else generate x^{k+1} by the expansion step.*

(iii) *If x^k is not strictly proportional, then define x^{k+1} by the proportioning step.*

4. Properties of the projected gradient. In this section we summarize results necessary for the next analysis.

LEMMA 4.1. *It holds that*

$$\|\widetilde{\varphi}(x)\|^2 \le \widetilde{\varphi}(x)^\top g(x), \tag{4.1}$$

$$\|\widetilde{\beta}(x)\|^2 \le \widetilde{\beta}(x)^\top g(x), \tag{4.2}$$

$$\widetilde{\varphi}(x)^\top g(x) \le \varphi(x)^\top g(x). \tag{4.3}$$

Proof. The definition of the projected gradient (2.7) implies that

$$P_{\Omega_i}(\boldsymbol{x}_i - \widetilde{\alpha}\boldsymbol{g}_i) = \boldsymbol{x}_i - \widetilde{\alpha}\widetilde{\boldsymbol{g}}_i.$$

As P_{Ω_i} is orthogonal, we obtain

$$0 \ge (\boldsymbol{x}_i - \widetilde{\alpha}\boldsymbol{g}_i - P_{\Omega_i}(\boldsymbol{x}_i - \widetilde{\alpha}\boldsymbol{g}_i))^\top (\boldsymbol{x}_i - P_{\Omega_i}(\boldsymbol{x}_i - \widetilde{\alpha}\boldsymbol{g}_i)) = \widetilde{\alpha}^2(\widetilde{\boldsymbol{g}}_i - \boldsymbol{g}_i)^\top \widetilde{\boldsymbol{g}}_i$$

so that

$$\|\widetilde{\boldsymbol{g}}_i\|^2 \le \widetilde{\boldsymbol{g}}_i^\top \boldsymbol{g}_i. \tag{4.4}$$

Summing (4.4) over the indices of $\mathcal{F}(x)$ or $\mathcal{A}(x)$, we obtain (4.1) or (4.2), respectively. Using the well-known Cauchy inequality in (4.4), we get $\|\widetilde{\boldsymbol{g}}_i\| \le \|\boldsymbol{g}_i\|$, and therefore

$$\widetilde{\varphi}(x)^\top g(x) = \sum_{i\in\mathcal{F}(x)} \widetilde{\boldsymbol{g}}_i^\top \boldsymbol{g}_i \le \sum_{i\in\mathcal{F}(x)} \|\widetilde{\boldsymbol{g}}_i\|\|\boldsymbol{g}_i\| \le \sum_{i\in\mathcal{F}(x)} \boldsymbol{g}_i^\top \boldsymbol{g}_i = \varphi(x)^\top g(x). \qquad \square$$

LEMMA 4.2. *Let $d \in \mathbb{R}^n$, $d \ne 0$, and $x \in \Omega$. Then*

$$f(x) - f(x - \alpha d) \le \alpha d^\top g(x) \quad \forall \alpha \in \mathbb{R}. \tag{4.5}$$

Moreover, let $d^\top g(x) \ge 0$, and $\alpha_d = d^\top g(x)/d^\top A d$. Then

$$f(x) - f(x - \alpha d) \ge \frac{1}{2}\alpha d^\top g(x) \quad \forall \alpha \in [0, \alpha_d]. \tag{4.6}$$

Proof. The assertion (4.5) is equivalent to the convexity of f (compare with (2.1)). For $\alpha \in [0, \alpha_d]$, we derive

$$\begin{aligned} f(x - \alpha d) &= f(x) - \alpha d^\top g(x) + \frac{1}{2}\alpha^2 d^\top A d \\ &\le f(x) - \alpha d^\top g(x) + \frac{1}{2}\alpha\alpha_d d^\top A d \\ &= f(x) - \frac{1}{2}\alpha d^\top g(x). \qquad \square \end{aligned}$$

COROLLARY 4.3. *If d is replaced in (4.6) by φ, $\widetilde{\varphi}$, and $\widetilde{\beta}$, then the corresponding three inequalities hold for all $\alpha \in [0, \|A\|^{-1}]$.*

Proof. For $d = \varphi(x)$, we have

$$\alpha_d = \frac{\varphi(x)^\top g(x)}{\varphi(x)^\top A \varphi(x)} \ge \frac{\varphi(x)^\top \varphi(x)}{\|A\|\|\varphi(x)\|^2} = \|A\|^{-1}.$$

The same follows using Lemma 4.1 for $d = \widetilde{\varphi}(x)$ and $d = \widetilde{\beta}(x)$. $\square$

LEMMA 4.4. *Let $x \in \Omega$. Then*

$$f(x) - f(x - \alpha\widetilde{g}(x)) \leq \alpha(\widetilde{\varphi}(x)^\top g(x) + \widetilde{\beta}(x)^\top g(x)) \quad \forall \alpha \in \mathbb{R}.$$

Proof. Using (4.5), we obtain

$$f(x) - f(x - \alpha\widetilde{g}(x)) \leq \alpha\widetilde{g}(x)^\top g(x) = \alpha \left(\sum_{i \in \mathcal{F}(x)} \widetilde{\boldsymbol{g}}_i^\top \boldsymbol{g}_i + \sum_{i \in \mathcal{A}(x)} \widetilde{\boldsymbol{g}}_i^\top \boldsymbol{g}_i \right),$$

and the definitions (2.9) and (2.10) complete the proof. ∎

LEMMA 4.5. *Let $x^* \in \Omega$ denote the solution to* (1.1)*, λ_1 denote the smallest eigenvalue of A, and $x \in \Omega$. Then*

$$f(x) - f(x - \widetilde{\alpha}\widetilde{g}(x)) \geq \widetilde{\alpha}\lambda_1(f(x) - f(x^*)) \quad \forall \widetilde{\alpha} \in [0, \|A\|^{-1}].$$

Proof. For $\widetilde{\alpha} \in (0, \|A\|^{-1}]$, we define

$$F(y) = \widetilde{\alpha} f(y) + \frac{1}{2}(y - x)^\top (I - \widetilde{\alpha}A)(y - x).$$

Notice that $I - \widetilde{\alpha}A$ is positive semidefinite. Therefore

$$F(y) \geq \widetilde{\alpha} f(y),$$

$$\nabla F(y) = \widetilde{\alpha} g(y) + (I - \widetilde{\alpha}A)(y - x) = y - x + \widetilde{\alpha} g(x), \tag{4.7}$$

and $F(x) = \widetilde{\alpha} f(x)$, $\nabla F(x) = \widetilde{\alpha} g(x)$. Let us note that the Hessian of F is the identity I. Let $y \in \Omega$ be arbitrary. The convexity of F, (4.7), and the orthogonality of P_Ω yields

$$\begin{aligned} F(y) - F(P_\Omega(x - \widetilde{\alpha}g(x))) &\geq (y - P_\Omega(x - \widetilde{\alpha}g(x)))^\top \nabla F(P_\Omega(x - \widetilde{\alpha}g(x))) \\ &= -(y - P_\Omega(x - \widetilde{\alpha}g(x)))^\top (x - \widetilde{\alpha}g(x) - P_\Omega(x - \widetilde{\alpha}g(x))) \\ &\geq 0 \end{aligned}$$

so that

$$F(y) \geq F(P_\Omega(x - \widetilde{\alpha}g(x))) \quad \forall y \in \Omega.$$

Using $\widetilde{\alpha}\lambda_1 \leq \|A\|^{-1}\lambda_1 \leq 1$ and denoting $d = x^* - x$, we derive

$$\begin{aligned} f(x - \widetilde{\alpha}\widetilde{g}(x)) &= f(P_\Omega(x - \widetilde{\alpha}g(x))) \\ &\leq \widetilde{\alpha}^{-1} F(P_\Omega(x - \widetilde{\alpha}g(x))) \;\leq\; \widetilde{\alpha}^{-1} \min_{y \in \Omega} F(y) \;\leq\; \widetilde{\alpha}^{-1} \min_{t \in [0,1]} F(x + td) \\ &\leq \widetilde{\alpha}^{-1} F(x + \widetilde{\alpha}\lambda_1 d) \;=\; f(x) + \widetilde{\alpha}\lambda_1 d^\top g(x) + \frac{1}{2}\widetilde{\alpha}\lambda_1^2 d^\top d \\ &\leq (1 - \widetilde{\alpha}\lambda_1) f(x) + \widetilde{\alpha}\lambda_1 f(x) + \widetilde{\alpha}\lambda_1 d^\top g(x) + \frac{1}{2}\widetilde{\alpha}\lambda_1 d^\top A d \\ &= (1 - \widetilde{\alpha}\lambda_1) f(x) + \widetilde{\alpha}\lambda_1 f(x^*). \qquad \blacksquare \end{aligned}$$

Lemma 4.4 and Lemma 4.5 immediately imply the following result.

COROLLARY 4.6. *Let $x^* \in \Omega$ denote the solution to* (1.1)*, λ_1 denote the smallest eigenvalue of A, and $x \in \Omega$. Then*

$$\lambda_1(f(x) - f(x^*)) \leq \widetilde{\varphi}(x)^\top g(x) + \widetilde{\beta}(x)^\top g(x)$$

for all $\widetilde{\alpha} \in (0, \|A\|^{-1}]$ defining $\widetilde{\varphi}$ and $\widetilde{\beta}$.

5. Rate of convergence.

THEOREM 5.1. *Let $x^0 \in \Omega$, $\Gamma > 0$, and $\widetilde{\alpha} \in (0, \|A\|^{-1}]$ be given. Let $x^* \in \Omega$ denote the solution to (1.1), λ_1 denote the smallest eigenvalue of A, and $\widehat{\Gamma} = \max\{\Gamma, \Gamma^{-1}\}$. Let $\{x^k\}$ be the sequence generated by Algorithm 3.1. Then*

$$f(x^{k+1}) - f(x^*) \leq \eta \left(f(x^k) - f(x^*) \right), \tag{5.1}$$

where

$$\eta = 1 - \frac{\widetilde{\alpha}\lambda_1}{2 + 2\widehat{\Gamma}^2} < 1. \tag{5.2}$$

The error in the A-energy norm is bounded by

$$\|x^k - x^*\|_A^2 \leq 2\eta^k \left(f(x^0) - f(x^*) \right). \tag{5.3}$$

Proof. We shall estimate separately all three possible steps of Algorithm 3.1. As $\widetilde{\alpha} \in (0, \|A\|^{-1}]$, we can use the bound (4.6) for each of the steps due to Corollary 4.3.

Let us first assume that x^{k+1} is generated by the expansion step (3.1). Using (4.6), we obtain

$$f(x^{k+1}) = f(x^k - \widetilde{\alpha}\widetilde{\varphi}(x^k)) \leq f(x^k) - \frac{1}{2}\,\widetilde{\alpha}\widetilde{\varphi}(x^k)^\top g(x^k). \tag{5.4}$$

If x^{k+1} is generated by the conjugate gradient step (3.3), we use Lemma 3.1, (4.6), and (4.3) so that

$$\begin{aligned} f(x^{k+1}) &\leq f(x^k - \widetilde{\alpha}\varphi(x^k)) \\ &\leq f(x^k) - \frac{1}{2}\,\widetilde{\alpha}\varphi(x^k)^\top g(x^k) \leq f(x^k) - \frac{1}{2}\,\widetilde{\alpha}\widetilde{\varphi}(x^k)^\top g(x^k). \end{aligned} \tag{5.5}$$

Comparing (5.4) and (5.5), we may observe that we have the same estimates for both of the expansion and conjugate gradient steps. These steps are taken only when x^k is strictly proportional, i.e., when

$$\widetilde{\beta}(x^k)^\top g(x^k) \leq \Gamma^2 \widetilde{\varphi}(x^k)^\top g(x^k).$$

After using Corollary 4.6, we get

$$\widetilde{\varphi}(x^k)^\top g(x^k) \geq \frac{\lambda_1}{1 + \Gamma^2}(f(x^k) - f(x^*)). \tag{5.6}$$

The estimates (5.4), (5.5) combined with (5.6) imply that

$$\begin{aligned} f(x^{k+1}) - f(x^*) &\leq f(x^k) - f(x^*) - \frac{1}{2}\,\widetilde{\alpha}\widetilde{\varphi}(x^k)^\top g(x^k) \\ &\leq \left(1 - \frac{\widetilde{\alpha}\lambda_1}{2 + 2\Gamma^2}\right)(f(x^k) - f(x^*)). \end{aligned} \tag{5.7}$$

Let us finally assume that x^{k+1} is generated by the proportioning step (3.2). Again using (4.6), we obtain

$$f(x^{k+1}) = f(x^k - \widetilde{\alpha}\widetilde{\beta}(x^k)) \leq f(x^k) - \frac{1}{2}\,\widetilde{\alpha}\widetilde{\beta}(x^k)^\top g(x^k). \tag{5.8}$$

As the proportioning step is taken when

$$\widetilde{\beta}(x^k)^\top g(x^k) > \Gamma^2 \widetilde{\varphi}(x^k)^\top g(x^k),$$

Corollary 4.6 yields

$$\widetilde{\beta}(x^k)^\top g(x^k) \geq \frac{\lambda_1}{1+\Gamma^{-2}}(f(x^k) - f(x^*)). \tag{5.9}$$

The estimate (5.8) combined with (5.9) implies that

$$f(x^{k+1}) - f(x^*) \leq \left(1 - \frac{\widetilde{\alpha}\lambda_1}{2+2\Gamma^{-2}}\right)(f(x^k) - f(x^*)). \tag{5.10}$$

Comparing the inequalities (5.10) and (5.7), and taking into account that by definition $\Gamma \leq \widehat{\Gamma}$ and $\Gamma^{-1} \leq \widehat{\Gamma}$, we can see that (5.1) holds.

In order to prove the error bound (5.3), we use (5.1) and the fact that the solution x^* to (1.1) is characterized by the variational inequality $(x - x^*)^\top g(x^*) \geq 0$ for all $x \in \Omega$. We obtain

$$\begin{aligned} \|x^k - x^*\|_A^2 &= 2(f(x^k) - f(x^*) - (x^k - x^*)^\top g(x^*)) \\ &\leq 2(f(x^k) - f(x^*)) \ \leq \ 2\eta^k(f(x^0) - f(x^*)). \end{aligned}$$ □

Theorem 5.1 yields the best estimate for $\Gamma = \widehat{\Gamma} = 1$ and $\widetilde{\alpha} = \|A\|^{-1}$ when

$$\eta = 1 - \frac{1}{4}\kappa(A)^{-1}.$$

We shall see that this result is in agreement with numerical experiments.

6. Implementation. We shall give the details of the implementation of Algorithm 3.1. Firstly, we describe a general scheme of the algorithm independently on the type of constraints. Then we show how to compute projections on the feasible set in our numerical experiments.

6.1. A general algorithmic scheme. The presented implementation differs from Algorithm 3.1 in that it exploits the current conjugate gradient direction to generate an intermediate iteration $x^{k+1/2}$ before the expansion step that generates x^{k+1} from $x^{k+1/2}$. Such modification does not require any additional matrix-vector multiplication, and the estimate (5.1) remains valid [5].

We describe the algorithm in an easily understandable variant of the Matlab language, in which we do not distinguish a generation of variables by indices unless it is convenient for further references.

It should be noted that the presented implementation is not influenced by the type of constraints defining the feasible set Ω. The relation to constraints is hidden in the components $\widetilde{\beta}$, $\widetilde{\varphi}$ of the projected gradient $\widetilde{g}$, and in the feasible steplength α_f. The projected gradient can be directly evaluated by its definition (2.7) using P_Ω.

ALGORITHM 6.1. *Let $x^0 \in \Omega$, $\Gamma > 0$, $\widetilde{\alpha} \in (0, \|A\|^{-1}]$, and $\epsilon > 0$ be given.*

Set $k = 0$, $g = Ax^0 - b$, $p = \varphi(x^0)$. % *Initialization.*
while $\|\widetilde{g}(x^k)\| > \epsilon$
  if $\widetilde{\beta}(x^k)^\top g(x^k) \le \Gamma^2 \widetilde{\varphi}(x^k)^\top g(x^k)$
    $\alpha_{cg} = g^\top p / p^\top A p$ % *Conjugate gradient steplength.*
    $\alpha_f = \max\{\alpha : x^k - \alpha p \in \Omega\}$ % *Feasible steplength.*
    if $\alpha_{cg} < \alpha_f$ % *Conjugate gradient step.*
      $x^{k+1} = x^k - \alpha_{cg} p$, $g = g - \alpha_{cg} A p$, $\gamma = \varphi(x^{k+1})^\top A p / p^\top A p$, $p = \varphi(x^{k+1}) - \gamma p$
    else % *Expansion step.*
      $x^{k+1/2} = x^k - \alpha_f p$
      $x^{k+1} = x^{k+1/2} - \widetilde{\alpha}\widetilde{\varphi}(x^{k+1/2})$, $g = Ax^{k+1} - b$, $p = \varphi(x^{k+1})$
    end*if*
  else % *Proportioning step.*
    $x^{k+1} = x^k - \widetilde{\alpha}\widetilde{\beta}(x^k)$, $g = Ax^{k+1} - b$, $p = \varphi(x^{k+1})$
  end*if*
  $k = k + 1$
end*while*
$x = x^k$. % *Return step.*

6.2. Projections and the feasible steplength. In the previous sections, we have exploited the implicit definition of the projections given by (2.5) and (2.6). Now we shall show how to compute P_{Ω_i} for simple bounds (1.2) and circular constraints (1.3).

Let us consider the following variant of the problem (1.1):

$$\left\{\begin{array}{ll} \text{minimize} & f(x), \\ \text{subject to} & x_i \ge l_i,\ i = 1, \dots, m_1, \\ & x^2_{m_1+2i-1} + x^2_{m_1+2i} \le r_i^2,\ i = 1, \dots, m_2, \end{array}\right. \tag{6.1}$$

where $m_1 + 2m_2 < n$ and l_i, r_i are given. The feasible set Ω in (6.1) is described by Ω_i, $i = 1, \dots, m$, $m = m_1 + m_2 + 1$, of three different types. Recall that each of Ω_i is defined by $\Omega_i = \{\boldsymbol{x}_i \in \mathbb{R}^{n_i} : f_i(\boldsymbol{x}_i) \le 0\}$ where $f_i : \mathbb{R}^{n_i} \to \mathbb{R}$ is continuously differentiable and convex. Let us denote the feasible steplength with respect to the ith constraint by

$$\alpha_{f,i} = \max\{\alpha : \boldsymbol{x}_i - \alpha \boldsymbol{p}_i \in \Omega_i\}.$$

(1) Let $n_i = 1$, and $f_i(x_i) \equiv l_i - x_i$. Then $x_i \in \Omega_i$, $i = 1, \dots, m_1$ represent the simple bounds in (6.1). The set Ω_i describes the half-line so that the projection is given by

$$P_{\Omega_i}(x_i) = \left\{\begin{array}{ll} x_i & \text{for } l_i \le x_i, \\ l_i & \text{for } l_i > x_i \end{array}\right.$$

and the feasible steplength by

$$\alpha_{f,i} = \left\{\begin{array}{ll} (x_i - l_i)/p_i & \text{for } p_i > 0, \\ \infty & \text{for } p_i \le 0. \end{array}\right.$$

(2) Let $n_{m_1+i}=2$, $f_{m_1+i}(\boldsymbol{x}_{m_1+i}) \equiv \boldsymbol{x}_{m_1+i}^\top \boldsymbol{x}_{m_1+i} - r_i^2$, and $\boldsymbol{x}_{m_1+i} = (x_{m_1+2i-1}, x_{m_1+2i})^\top$. Then $\boldsymbol{x}_{m_1+i} \in \Omega_{m_1+i}$, $i=1,\dots,m_2$ represent the circular constraints in (6.1). The set Ω_{m_1+i} describes the circle with the center at the origin of $\mathbb{R}^2$ and with the radius r_i so that the projection is given by

$$P_{\Omega_{m_1+i}}(\boldsymbol{x}_{m_1+i}) = \begin{cases} \boldsymbol{x}_{m_1+i} & \text{for } \|\boldsymbol{x}_{m_1+i}\| \le r_i, \\ \dfrac{r_i}{\|\boldsymbol{x}_{m_1+i}\|}\,\boldsymbol{x}_{m_1+i} & \text{for } \|\boldsymbol{x}_{m_1+i}\| > r_i \end{cases}$$

and the feasible steplength by

$$\alpha_{f,m_1+i} = \begin{cases} (\boldsymbol{x}_i^\top \boldsymbol{p}_i + \sqrt{(\boldsymbol{x}_i^\top \boldsymbol{p}_i)^2 - (\|\boldsymbol{x}_i\|^2 - r_i^2)\|\boldsymbol{p}_i\|^2}\,)/\|\boldsymbol{p}_i\|^2 & \text{for } \boldsymbol{p}_i \neq 0, \\ \infty & \text{for } \boldsymbol{p}_i = 0. \end{cases}$$

(3) Let $n_m = n - m_1 - 2m_2$, $\boldsymbol{x}_m = (x_{m_1+2m_2+1}, \dots, x_n)^\top$, and $f_m(\boldsymbol{x}_m) = -1$. Then $\Omega_m = \mathbb{R}^{n_m}$, i.e., the components of $\boldsymbol{x}_m$ are unconstrained. For completeness, we define

$$P_{\Omega_m}(\boldsymbol{x}_m) = \boldsymbol{x}_m \quad \text{and} \quad \alpha_{f,m} = \infty.$$

Let us conclude that the projection P_Ω is put together by P_{Ω_i} as in (2.4) and the feasible steplength α_f is given by

$$\alpha_f = \min\{\alpha_{f,i} : i = 1, \dots, m\}.$$

7. Numerical tests. We shall assess the performance of the algorithm by three examples. The first one is the benchmark of [10], in which only circular constraints occur. The second example represents a one-dimensional obstacle problem comprising both simple bounds and circular constraints. A more realistic third example shows the solution of frictional 3D contact problems of linear elasticity by means of a sequence of problems (6.1).

Let us note that either we shall use Algorithm 6.1 with $x^0 = 0$, $\Gamma = 1$, $\widetilde{\alpha} = \|A\|^{-1}$, and $\epsilon = 10^{-5}\|b\|$, or we shall comment different choices.

Example 7.1. Let us consider the problem (6.1) for $n = 12$, $m_1 = 0$, and $m_2 = 6$ with the five-diagonal matrix A:

$$\begin{aligned} &A = (a_{ij}),\ a_{ii} = 4,\ a_{ii\pm1} = a_{ii\pm2} = -1, \\ &b = Ay, \\ &r = (2, 1, 0.5, 2, 10^{-3}, 154)^\top, \end{aligned}$$

and $y = (2, 1, 0.5, 0, 0, 11, 10^{-5}, -1, \sqrt{2}, -0.1, 4.1 \cdot 10^{-4}, 143)^\top$. The solution $x^* \in \mathbb{R}^{12}$ has three active constraints so that $\mathcal{A}(x^*) = \{2, 3, 5\}$. Here, we shall denote Algorithm 6.1 by QPC and the algorithm of [10] by QPQ. In Table 7.1 we compare QPQ and QPC by the number of matrix-vector multiplications for various Γ. The algorithm QPC has better performance in all cases. Moreover, the experiments are in agreement with the conclusions of Theorem 5.1.

In order to explain the progress, we mention the ideas of QPQ. This algorithm is constructed by the KKT conditions that are given here in Theorem 2.1. Introducing the *turned boundary gradient* $\beta = \beta(x)$ at $x \in \Omega$ as

$$\boldsymbol{\beta}_i = \boldsymbol{0} \quad \text{for } i \in \mathcal{F}(x), \quad \boldsymbol{\beta}_i = \boldsymbol{g}_i + \frac{\|\boldsymbol{g}_i\|}{\|\nabla f_i(\boldsymbol{x}_i)\|}\nabla f_i(\boldsymbol{x}_i) \quad \text{for } i \in \mathcal{A}(x),$$

TABLE 7.1
Comparisons of the algorithms QPQ and QPC.

Γ	100	10	5	1	0.5	0.4	0.2	0.1	0.05	0.01	0.001
QPQ	43	41	39	32	37	40	48	41	38	36	36
QPC	30	24	21	19	20	20	22	22	26	37	50

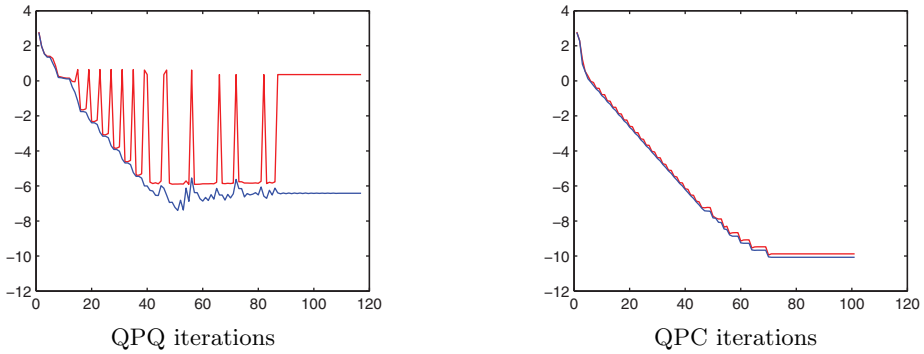

FIG. 7.1. *The iteration history of QPQ and QPC (logarithmic scale).*

we can define the *turned gradient* by $\nu = \nu(x) = \varphi(x) + \beta(x)$ where $\varphi(x)$ is the free gradient (2.9). The solution x^* to the problem (1.1) is then characterized by $\nu(x^*) = 0$. The proportioning step of QPC is replaced in QPQ by the step deactivation, in which β replaces $\tilde{\beta}$ (for a different steplength). It is easy to show that the deactivation step releases all indices from the current active set, for which the boundary KKT conditions (2.3) are not satisfied. After each release, the inner KKT conditions are violated usually on the same level. This observation is a practical consequence of the fact that the functions $\beta(x)$ and $\nu(x)$ are discontinuous (in contrast to $\tilde{\beta}$ and $\tilde{g}$). The typical situation is drawn in Figure 7.1 (left), where the norm of the projected gradient (solid) and the turned gradient (dotted) are depicted. In Figure 7.1 (right) we can see that oscillations arising in QPQ are eliminated in QPC. Comparing the stagnation levels, we can conclude that QPC is considerably more robust. Notice that the turned gradient did not curiously recognize the solution in QPQ due to round-off errors.

Example 7.2. In the second example, we solve

$$\text{minimize } \frac{1}{2}\int_0^1 \|\boldsymbol{x}'(t)\|^2\,dt - \int_0^1 \boldsymbol{x}(t)^\top \boldsymbol{f}(t)\,dt$$

subject to $\boldsymbol{x} = (X_1, X_2)^\top \in \mathcal{K}$, where

$$\mathcal{K} = \{\boldsymbol{x} \in (H_0^1(0,1))^2 :\ X_2(t) \geq l \text{ on } (0,0.5),\ \|\boldsymbol{x}(t)\| \leq r \text{ on } (0.5,1)\},$$

and $\boldsymbol{f}(t) = (36\pi^2 \sin 6\pi t, -4\pi^2 \sin 2\pi t)^\top$. This problem describes the loaded wire (see Figure 7.2) that is partially above the plan far off the distance l and partially inside the cylindrical tube of the radius r. A finite element discretization on a regular grid with n degrees of freedom leads to the problem (6.1) where $m_1 = m_2 = n/4$, $l_i = l$, and $r_i = r$. In tables below we summarize numbers of matrix-vector multiplications and information on active and free constraints as

$$n_{b,\mathcal{A}} : n_{b,\mathcal{F}} / n_{c,\mathcal{A}} : n_{c,\mathcal{F}},$$

where $n_{b,\mathcal{A}}$, $n_{b,\mathcal{F}}$, $n_{c,\mathcal{A}}$, and $n_{c,\mathcal{F}}$ are numbers of active simple bounds, free simple bounds, active circular constraints, and free circular constraints, respectively.

(i) Let $r = 2$ so that no circular constraint is active in the solution; see Table 7.2. In this case, Algorithm 6.1 reduces to a variant of the algorithm of [5] with the finite terminating property. Let us note that the column labeled $l = -1.5$ corresponds to the unconstrained problem, in which our algorithm became the conjugate gradient method.

(ii) Let $l = 0$ so that both simple bounds and circular constraints may be active in the solution; see Table 7.3. It turns out that the algorithm is more efficient in situations when the constraints are tighter, i.e., when r and l are near zero so that the number of active constraints is considerably higher than the number of free constraints.

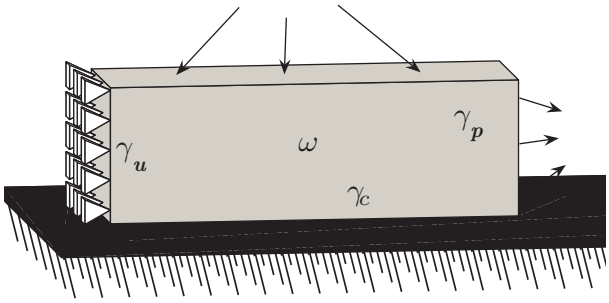

FIG. 7.3. *Geometry of the brick.*

Example 7.3. Let us consider the steel brick lying on a rigid foundation as it is shown in Figure 7.3. The brick occupies in the reference configuration the domain $\omega \subset \mathbb{R}^3$, whose boundary $\partial\omega$ is split into three nonempty disjoint parts γ_u, γ_p, and γ_c with different boundary conditions. The zero displacements are prescribed on γ_u, whereas the surface tractions act on γ_p. On γ_c, we consider the contact conditions, i.e., the nonpenetration and the effect of friction. The elastic behavior of the brick is described by Lamé equations that, after finite element discretization, lead to a symmetric positive definite stiffness matrix $K \in \mathbb{R}^{3n_c \times 3n_c}$ and to a load vector $f \in \mathbb{R}^{3n_c}$. Moreover, we introduce full rank matrices $N, T_1, T_2 \in \mathbb{R}^{m_c \times 3n_c}$ projecting displacements at contact nodes to normal and tangential directions, respectively, and we denote $B = \left(N^\top, T_1^\top, T_2^\top\right)^\top \in \mathbb{R}^{3m_c \times 3n_c}$. For more details about this model problem, we refer to [8]. Here, we shall use the dual formulation in terms of contact stresses.

We start with the contact problem with *Tresca friction* that reads as

$$\left\{\begin{array}{ll} \text{minimize} & \frac{1}{2}\lambda^\top Q\lambda - \lambda^\top h, \\ \text{subject to} & \lambda_{\nu,i} \geq 0,\ \lambda_{t_1,i}^2 + \lambda_{t_2,i}^2 \leq r_i^2,\ i = 1, \ldots, m_c, \\ & \lambda = (\lambda_\nu^\top, \lambda_{t_1}^\top, \lambda_{t_2}^\top)^\top,\ \lambda_\nu, \lambda_{t_1}, \lambda_{t_2} \in \mathbb{R}^{m_c}, \end{array}\right. \tag{7.1}$$

where $Q = BK^{-1}B^\top$, $h = BK^{-1}f$, and $r_i \geq 0$ are given slip bound values at contact nodes. Let us point out that λ_ν and $\lambda_{t_1}, \lambda_{t_2}$ represent normal and tangential contact stresses, respectively. It should be noted that the problem (7.1) can be solved by Algorithm 6.1 after rearranging the unknowns. In order to simplify notations, we denote $\mathbb{R}^{m_c}_+ = \{s \in \mathbb{R}^{m_c} : s_i \geq 0\}$.

The contact problem with *Coulomb friction* uses the friction law, in which the slip bound $r \in \mathbb{R}^{m_c}_+$ depends on the normal contact stress $\lambda_\nu \in \mathbb{R}^{m_c}_+$ by

$$r \equiv F\lambda_\nu,$$

where $F > 0$ is a coefficient of friction. As r is the input for (7.1) and λ_ν is the output, the problem with Tresca friction defines the mapping

$$\Psi : \mathbb{R}^{m_c}_+ \longmapsto \mathbb{R}^{m_c}_+ : r \longmapsto F\lambda_\nu.$$

It is easily seen that a fixed point of Ψ solves the problem with Coulomb friction, i.e., a point r such that $\Psi(r) = r$. Notice that Ψ is contractive for sufficiently small F,

TABLE 7.4
Contact problem with Coulomb friction.

dof		$F = 0.3$				$F = 0.6$			
$3n_c$	$3m_c$	*Time*	*Iter*	n_Q	n_Q/n	*Time*	*Iter*	n_Q	n_Q/n

28350	1890	1833	5	**947**	0.50	2222	6	**1169**	0.62

and then there is a unique fixed point. Moreover, successive approximations can be used for its computation:

$$r^0 \in \mathbb{R}^{m_c}_+ \text{ given;} \quad \text{for } k = 1, 2, \dots \text{ set } r^k = \Psi(r^{k-1}).$$

As the evaluation of Ψ requires us to solve (7.1), we can repeatedly apply Algorithm 6.1. In order to perform these computations efficiently, we initialize each iteration by results from the previous one. Finally we terminate if

$$\|r^k - r^{k-1}\|/\|r^k\| \le 10^{-4}.$$

In our numerical experiments, we consider the steel brick $\omega = (0,3)\times(0,1)\times(0,1)$ partitioned into $3N \times N \times N$ cubes by trilinear finite elements for $N = 4, 6, 8, 10, 12,$ and 14. The size of problems solved by Algorithm 6.1 is $n = 3m_c = 9N(N+1)$. In Table 7.4, we report CPU time in seconds (*time*), the number of successive approximations (*iter*), the total complexity by matrix-vector multiplications (n_Q), and the relative complexity (n_Q/n). The computations are carried out in Matlab 7 on Pentium(R)4, 3GHz, 512MB. The obtained results are promising; especially, n_Q is only mildly dependent on the finite element discretization so that the relative complexity considerably decreases for finer grids.

8. Comments and conclusions. We have analyzed a new active set algorithm for minimizing strictly convex quadratic functions with separable convex constraints. It generalizes a recently developed algorithm of quadratic programming constrained by simple bounds [5]. It should be noted that we did not need any requirement on nondegeneracy of the problem so that our algorithm is globally convergent for both the nondegenerate as well as the degenerate case.

The main goal is the proof of a linear convergence rate, which is in an optimal case described by the factor $\eta = 1 - \frac{1}{4}\kappa(A)^{-1}$ in terms of the condition number of the Hessian matrix A. Notice that η is not influenced by constraints. The key assumption is the restricted steplength $\widetilde{\alpha}$ defining the projected gradient $\widetilde{g}$, i.e., $\widetilde{\alpha} \le \|A\|^{-1}$, which means that the components $\widetilde{\varphi}$ and $\widetilde{\beta}$ of $\widetilde{g}$ are descent directions. We use them for adding/releasing indices to/from the active set in the step expansion/proportioning. Unfortunately, our analysis requires us to replace the conjugate gradient steplengths by $\widetilde{\alpha}$, which seems to be too restrictive, and the obtained convergence rate may be a bit pessimistic. That is the case for simple bound problems. If the constraints are conic (e.g., circular), the algorithm usually performs few valuable conjugate gradient steps combined with expansion steps, and then it alternates many proportioning steps with short conjugate gradient steps. The convergence rate is more realistic in such situations.

The algorithm presented here is an important ingredient in the numerical solution of 3D contact problems. It was shown in [3] that FETI domain decomposition methods are scalable for the frictionless contact. Our paper enables us to extend this result for frictional problems. It will be published in forthcoming papers.

Another class of algorithms relevant for our research (contact problems) is based on a specific semismooth Newton method that is identical again with an active set strategy [9]. The fundamental discrepancy is the fact that it allows infeasible iterates. In this case, the convergence rate is superlinear but requires a sufficiently accurate initial approximation. In general, the computational performance is comparable.

SUBDIFFERENTIAL CALCULUS RULES IN CONVEX ANALYSIS: A UNIFYING APPROACH VIA POINTWISE SUPREMUM FUNCTIONS*

A. HANTOUTE†, M. A. LÓPEZ‡, AND C. ZĂLINESCU§

Abstract. We provide a rule to calculate the subdifferential set of the pointwise supremum of an arbitrary family of convex functions defined on a real locally convex topological vector space. Our formula is given exclusively in terms of the data functions and does not require any assumption either on the index set on which the supremum is taken or on the involved functions. Some other calculus rules, namely chain rule formulas of standard type, are obtained from our main result via new and direct proofs.

Key words. convex analysis, convex subdifferential, pointwise supremum function, calculus rules

1. Introduction.

Many operations with convex functions preserve convexity, and so it is natural to ask if the subdifferential of the resulting function can be written in terms of the data functions. Specific to convex analysis is the classical operation of taking the pointwise supremum of an arbitrarily indexed family of convex functions. It has no equivalence in the classical theory of differentiable analysis and constitutes a largely used tool in convex optimization, in theory as well as in practice (see, for instance, [1], [10], and the references therein). In [5] and [8] certain specific techniques relying on the supremum function were applied in the framework of semi-infinite linear optimization.

In this paper, we provide explicit characterizations for the subdifferential mapping of the supremum function of an arbitrarily indexed family of convex functions, exclusively in terms of the data functions. The main virtue of our approach is that the index set over which the supremum is taken is arbitrary, without any algebraic or topological structure. Also the convex functions we consider in this paper are general, defined on a separated locally convex space, and not necessarily lower semicontinuous (lsc) or even proper. Further, we do not assume regularity conditions such as the continuity of the supremum function, the continuity of the data functions, conditions on their domains, and the like.

Since many convex functions can be written as the supremum of continuous affine mappings, numerous operations dealing with such (convex) functions can be formulated as a pointwise supremum of other functions whose subdifferentials can easily be characterized. Specifically, we have proved that our formulas also lead to other

calculus rules for the subdifferentials of certain operations with convex functions, such as the sum and the composition with affine applications. In this way, our approach gives rise to a unifying view of many well-known calculus rules in convex analysis.

Deriving calculus rules for subdifferentials is one of the first issues raised in convex analysis. Consequently, many earlier contributions dealing with pointwise supremum functions can be found in the literature. See, for instance, [26] to trace out the historical origins of the issue, as well as [2], [3], [4], [12], [13], [15], [20], [21], and [27]. This is why we make a short historical review of some of these results.

Consider the pointwise supremum $f := \sup_{t\in T} f_t$ of a collection of convex functions $f_t : X \to \mathbb{R} \cup \{+\infty\}$, $t \in T \neq \emptyset$, defined on a separated locally convex space X, and let $z \in \operatorname{dom} f$. When T is finite and each f_t is continuous at z, a basic result due to Dubovitskij and Milyutin asserts that (see, e.g., [13])

$$\partial f(z) = \operatorname{co}\left(\bigcup_{t\in T(z)} \partial f_t(z)\right),$$

where

$$T(z) := \{t \in T \mid f_t(z) = f(z)\},$$

and co stands for the convex hull. When T is a separated compact topological space and the function $(t, x) \to f_t(x)$ is upper semicontinuous with respect to t for each x, then assuming that each f_t is continuous at z, the following formula can be found, for instance, in [32, Thm. 2.4.18]:

$$\partial f(z) = \operatorname{cl}\left(\operatorname{co}\bigcup_{t\in T(z)} \partial f_t(z)\right),$$

where the closure, cl, is taken in the topological dual space X^* with respect to the weak* topology $w^* = \sigma(X^*, X)$.

According to [26], the last result was first established by Levin [15] for a finite-valued convex function defined on $\mathbb{R}^n$. The continuity assumption on the data functions is weakened in [29] and [21, Thm. 4].

Even in simple situations dealing with finitely many functions, the problem is involved so that simple examples in the Euclidean space show that these nice formulae above do not hold in general. Nevertheless, in order to overcome this difficulty, Brøndsted [2] used the concept of ε-subdifferential to establish the following formula, which is valid when $T = \{1, 2, \ldots, k\}$ and all of the functions $f_i,\ i = 1, 2, \ldots, k$ agree at z :

$$\partial f(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\left(\operatorname{co}\bigcup_{i=1}^{k} \partial_\varepsilon f_i(z)\right).$$

In the case of an infinite collection of convex functions (T infinite), and following [10, p. 405], the most elaborated results are due to Valadier in [27] where, in the context of normed vector spaces and assuming that the supremum function f is continuous at z, the subdifferential $\partial f(z)$ is expressed by considering not only z but all nearby points around it. More precisely, denoting by $\|\cdot\|$ the corresponding norm in X, the following formula is given in [27]:

$$\partial f(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\left[\operatorname{co}\left(\bigcup\{\partial f_t(y) \mid y \in X,\ t \in T : \|y - z\| \leq \varepsilon,\ f_t(z) \geq f(z) - \varepsilon\}\right)\right].$$

By using the concept of ε-subdifferential, Volle [28] obtained another characterization of $\partial f(z)$ where only the nominal point z appears but in terms of approximate subgradients:

$$\partial f(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\left[\operatorname{co}\left(\bigcup\{\partial_\varepsilon f_t(z) \mid t \in T : f_t(z) \geq f(z) - \varepsilon\}\right)\right].$$

It is worth noting that if either all of the functions f_t are affine or if the space X is Banach, then the last two formulas above are equivalent. The equivalence for affine functions is clear while in the Banach spaces setting this observation is partly due to Brøndsted–Rockafellar's theorem, expressing the ε-subdifferential by means of exact subdifferentials at nearby points. As it can be seen, the advantage of using such an enlargement of the subdifferential, namely, the ε-subdifferential, is to avoid qualifications type conditions. Such an idea is exploited in the survey paper [11] (see also references therein) to provide many calculus rules without requiring any regularity condition.

Recently, in [7], the following characterization for the subdifferential ∂f is given when $f_t : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$, $t \in T$, are proper convex functions and T is arbitrary:

$$\partial f(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\big[\operatorname{co}\big(\bigcup\{\partial_\varepsilon f_t(z) \mid t \in T : f_t(z) \geq f(z) - \varepsilon\}\big) + \mathrm{N}_{\operatorname{dom} f}(z)\big],$$

where $\mathrm{N}_{\operatorname{dom} f}(z)$ stands for the normal cone to the domain of f ($\operatorname{dom} f$) at z, provided that either the f_t's are lsc or that the relative interiors of their (effective) domains have a common point. In this setting, the formula above implies the one given by Volle [28], since $\mathrm{N}_{\operatorname{dom} f}(z) = \{\theta\}$ whenever z is a continuity point of the supremum function f. Further, when dealing with a finite number of functions the term $\mathrm{N}_{\operatorname{dom} f}(x)$ can be removed from the formula above which, consequently, entails the one of Brøndsted [2].

At this step, the purpose of the present paper is twofold. First, we extend the last formula from [7] to the setting of convex functions defined on locally convex spaces and which are not necessarily proper or lsc. To this aim, we consider those collections of functions satisfying the following closedness criterion, which holds for a broad class of convex functions and obviously covers the case of lsc functions:

$$\operatorname{cl} f = \sup_{t\in T} \operatorname{cl} f_t, \tag{1}$$

where $\operatorname{cl} f$ and $\operatorname{cl} f_t$ stand for the lsc hull of the convex functions f and f_t, respectively. Second, we give a unified approach for the framework of calculus rules in convex analysis. In fact, our characterization of ∂f also allows us to obtain formulas for the subdifferential of the resulting function in many operations as the sum of convex functions and the composition of an affine continuous mapping with a convex function. In this way, we provide direct and easier proofs for the basic chain rules when some supplementary qualification conditions are assumed.

The summary of the paper is as follows. In section 2 we introduce the main tools and basic results used in the paper. In section 3 we give the aimed formula for the subdifferential of the supremum of an arbitrary family of convex functions. After a series of auxiliary lemmas the main result is stated in Theorem 4. In it we use a closedness criterion which is studied in Corollary 9. We close this section by deriving some other formulae in Corollaries 7 (for affine functions), 8 (for finite-dimensional spaces or, more generally, when the relative interior of the domain of the supremum function f is not empty), 10 (Volle's formula), and 12 (Brøndsted's formula). In section 4 we introduce a unifying framework for deriving subdifferential calculus rules. Namely, in Theorem 13 we give a formula for the subdifferential of the sum of a convex function and another convex function precomposed with a continuous affine mapping. Theorem 13 constitutes a slight extension of Hiriart-Urruty–Phelps formula (Corollary 14). It also yields an easy derivation of the basic chain rule (Corollary 16) when some supplementary conditions are assumed, namely, the Moreau–Rockafellar constraint qualification.

2. Notations and basic tools. In this paper X and Y stand for (real) separated locally convex spaces. Their topological dual spaces are respectively denoted by X^* and Y^*. The spaces X and X^* (Y and Y^*) are paired in duality by the bilinear form $(x^*,x)\in X^*\times X\mapsto \langle x^*,x\rangle := \langle x,x^*\rangle := x^*(x)$ ($(y^*,y)\in Y^*\times Y\mapsto \langle y^*,y\rangle$, respectively). Throughout the paper, the sole topology defined on the dual spaces is the w^*–topology. The zero vectors in the involved spaces are all denoted by θ, and the neighborhoods of θ are called θ–neighborhoods. We use the notation $\overline{\mathbb{R}} := \mathbb{R}\cup\{-\infty,+\infty\}$.

We first recall some basic results of convex analysis which can be found, e.g., in the books [17] and [32] and the references therein (see also [10] and [22]). Given two nonempty sets A and B in X (or in X^*, Y, Y^*), we define the algebraic (or Minkowski) sum by

$$A+B := \{a+b \mid a\in A,\ b\in B\},\quad A+\emptyset := \emptyset + A := \emptyset; \tag{2}$$

moreover, if $\emptyset\neq\Lambda\subset\mathbb{R}$ we set

$$\Lambda A := \{\lambda a \mid \lambda\in\Lambda,\ a\in A\},\quad \Lambda\emptyset := \emptyset.$$

Furthermore, $\Lambda x := \Lambda\{x\}$, $\lambda A := \{\lambda\}A$, and $x+A := \{x\}+A$.

By $\operatorname{co} A$, $\operatorname{cone} A$, and $\operatorname{aff} A$, we denote the *convex hull,* the *conic hull,* and the *affine hull* of the set A, respectively. Moreover, $\operatorname{int} A$ is the *interior* of A, and $\operatorname{cl} A$ and $\overline{A}$ are indistinctly used for denoting the *closure* of A (w^*–*closure* if $A\subset X^*$ or $A\subset Y^*$). In this way, we set $\overline{\operatorname{co}}A := \operatorname{cl}(\operatorname{co} A)$ and $\overline{\operatorname{cone}}A := \operatorname{cl}(\operatorname{cone} A)$. We use $\operatorname{ri} A$ to denote the (topological) *relative interior* of A (i.e., the interior of A in the topology relative to $\operatorname{aff} A$ if $\operatorname{aff} A$ is closed, and the empty set otherwise). We shall use Greek letters for denoting real numbers.

The following properties are applied very often:

$$\operatorname{cl}(A+B) = \operatorname{cl}(A+\operatorname{cl} B), \tag{3}$$

and if A is convex,

$$\lambda\operatorname{ri} A + (1-\lambda)\operatorname{cl} A\subset \operatorname{ri} A \text{ for every } \lambda\in\ ]0,1]. \tag{4}$$

Associated with $A\neq\emptyset$ we consider the sets

$$\begin{aligned} A^\circ &:= \{x^*\in X^* \mid \langle x^*,x\rangle\geq -1 \text{ for all } x\in A\},\\ A^- &:= -(\operatorname{cone} A)^\circ = \{x^*\in X^* \mid \langle x^*,x\rangle\leq 0 \text{ for all } x\in A\}, \text{ and}\\ A^\perp &:= (-A^-)\cap A^- = \{x^*\in X^* \mid \langle x^*,x\rangle = 0 \text{ for all } x\in A\}, \end{aligned}$$

i.e., the (one-sided) *polar*, the *negative dual cone,* and the *orthogonal subspace* (or *annihilator*) of A, respectively. Observe that A° is a closed convex set containing θ, A^- is a closed convex cone, and $A^\perp$ is a closed linear subspace. Further, by the *bipolar theorem,* we have

$$A^{\circ\circ} = \overline{\operatorname{co}}(A\cup\{\theta\}) \text{ and } A^{--} = \overline{\operatorname{cone}}(\operatorname{co} A). \tag{5}$$

If $A\subset X$ is convex and $x\in X$, we define the *normal cone* to A at x as

$$\mathrm{N}_A(x) := \begin{cases} (A-x)^- & \text{if } x\in A,\\ \emptyset & \text{if } x\in X\setminus A. \end{cases}$$

As a consequence of this definition $N_\emptyset(x) = \emptyset$ for every $x \in X$. If $A \neq \emptyset$ is convex and closed, A_∞ represents its *recession cone* defined as

$$A_\infty := \{y \in X \mid x + \lambda y \in X \text{ for some } x \in X \text{ and all } \lambda \geq 0\}.$$

Given a function $f : X \longrightarrow \overline{\mathbb{R}}$, its *(effective) domain* and *epigraph* are defined by

$$\begin{aligned} \operatorname{dom} f &:= \{x \in X \mid f(x) < +\infty\}, \\ \operatorname{epi} f &:= \{(x, \alpha) \in X \times \mathbb{R} \mid f(x) \leq \alpha\}; \end{aligned}$$

moreover, when f is *proper*, that is, $\operatorname{dom} f \neq \emptyset$ and $f(x) > -\infty$ for all $x \in X$, we consider the *graph* of f as being defined by

$$\operatorname{gph} f := \{(x, f(x)) \in X \times \mathbb{R} \mid x \in \operatorname{dom} f\}.$$

So, for f proper one has $\operatorname{epi} f = \operatorname{gph} f + \mathbb{R}_+(\theta, 1)$. We say that f is *convex* if $\operatorname{epi} f$ is convex. In what follows we shall use the convention $+\infty - \infty := +\infty + (-\infty) := +\infty$. Assume that f is convex. The *lower closure* of f is the function $\operatorname{cl} f : X \longrightarrow \overline{\mathbb{R}}$ defined by

$$(\operatorname{cl} f)(x) := \inf\{t \mid (x, t) \in \operatorname{cl}(\operatorname{epi} f)\}.$$

Clearly we have $\operatorname{epi}(\operatorname{cl} f) = \operatorname{cl}(\operatorname{epi} f)$, which implies that $\operatorname{cl} f$ is a lsc convex function dominated by f; i.e., $\operatorname{cl} f \leq f$. Equivalently, we have

$$(\operatorname{cl} f)(x) = \liminf_{y \to x} f(y) \quad \forall x \in X.$$

Further, it can be checked that $\operatorname{cl}(\operatorname{dom}(\operatorname{cl} f)) = \operatorname{cl}(\operatorname{dom} f)$. If $(\operatorname{cl} f)(x) = f(x)$, then f is lsc at x. If there exists $x_0 \in X$ such that $(\operatorname{cl} f)(x_0) = -\infty$, then $(\operatorname{cl} f)(x) = -\infty$ for all $x \in \operatorname{dom}(\operatorname{cl} f)$. We shall denote by $\Lambda(X)$ the set of all the proper convex functions on X, and by $\Gamma(X)$ the subset of $\Lambda(X)$ consisting of the lsc functions; the sets $\Lambda(X^*)$ and $\Gamma(X^*)$ are defined in a similar way.

The *Fenchel conjugate* of f is the function $f^* : X^* \longrightarrow \overline{\mathbb{R}}$ given by

$$f^*(x^*) := \sup\{\langle x^*, x\rangle - f(x) \mid x \in X\}.$$

The functions f and $\operatorname{cl} f$ have the same conjugate; i.e., $f^* = (\operatorname{cl} f)^*$. The *biconjugate* of f is the function $f^{**} : X \longrightarrow \overline{\mathbb{R}}$ given by

$$f^{**}(x) := \sup\{\langle x^*, x\rangle - f^*(x^*) \mid x^* \in X^*\}.$$

Let us recall here that $f^* \in \Gamma(X^*)$ if and only if $\operatorname{dom} f \neq \emptyset$ and there exist $x^* \in X^*$ and $\alpha \in \mathbb{R}$ such that $f(x) \geq \langle x^*, x\rangle + \alpha$ for all $x \in X$; this happens, for instance, when $f \in \Gamma(X)$ in which case we have $f^{**} = f$.

The *support* and the *indicator* functions of $A \neq \emptyset$ are, respectively, defined as

$$\sigma_A(x^*) := \sup\{\langle x^*, a\rangle \mid a \in A\} \text{ for } x^* \in X^*,$$

and

$$\mathrm{I}_A(x) := \begin{cases} 0 & \text{if } x \in A, \\ +\infty & \text{if } x \in X \setminus A. \end{cases}$$

The function σ_A is sublinear, lsc, and satisfies

$$\sigma_A = \sigma_{\overline{\text{co}}A} = \text{I}^*_{\overline{\text{co}}A}. \tag{6}$$

Moreover, it is known that $(\text{dom}\,\sigma_A)^- = (\overline{\text{co}}A)_\infty$ (e.g., [29, p. 142]) or equivalently, by using (5),

$$\text{cl}(\text{dom}\,\sigma_A) = [(\overline{\text{co}}A)_\infty]^- . \tag{7}$$

If $A_1, \ldots, A_m \subset X$ are nonempty sets ($m \geq 2$), then clearly $\sigma_{A_1} + \cdots + \sigma_{A_m} = \sigma_{A_1+\cdots+A_m}$ and $\max\{\sigma_{A_1}, \ldots, \sigma_{A_m}\} = \sigma_{A_1\cup\cdots\cup A_m}$; moreover, if $1 \leq k < m$, then

$$\sigma_{A_1} + \cdots + \sigma_{A_k} + \max\left\{\sigma_{A_{k+1}}, \ldots, \sigma_{A_m}\right\} = \sigma_{A_1+\cdots+A_k+(A_{k+1}\cup\cdots\cup A_m)}.$$

Hence

$$\text{dom}\,\sigma_{A_1+\cdots+A_m} = \text{dom}\,\sigma_{A_1\cup\cdots\cup A_m} = \text{dom}\,\sigma_{A_1+\cdots+A_k+(A_{k+1}\cup\cdots\cup A_m)}.$$

Using (6) and (7) we get

$$\begin{aligned} [\overline{\text{co}}(A_1 + \cdots + A_m)]_\infty &= [\overline{\text{co}}(A_1 \cup \cdots \cup A_m)]_\infty \\ &= [\overline{\text{co}}\,(A_1 + \cdots + A_k + (A_{k+1} \cup \cdots \cup A_m))]_\infty . \end{aligned} \tag{8}$$

If f is convex and $\varepsilon \geq 0$, the *ε-subdifferential* of f at a point $x \in X$ such that $f(x) \in \mathbb{R}$ is the w^*–closed convex set

$$\partial_\varepsilon f(x) := \{x^* \in X^* \mid f(y) - f(x) \geq \langle x^*, y - x\rangle - \varepsilon \text{ for all } y \in X\}.$$

If $f(x) \notin \mathbb{R}$, then we set $\partial_\varepsilon f(x) := \emptyset$. In particular, for $\varepsilon = 0$ we get $\partial f(x) := \partial_0 f(x)$, the *subdifferential* of f at x. Given $x \in X$ and $\varepsilon \geq 0$ we recall the following properties: $\partial f(x) = \cap_{\varepsilon>0}\partial_\varepsilon f(x)$ and $\partial_\varepsilon f(x) = \partial_\varepsilon f(x) + \text{N}_{\text{dom}\,f}(x)$; moreover, as a simple computation shows (see also [32, Exer. 2.23]),

$$[\partial_\varepsilon f(x)]_\infty = \text{N}_{\text{dom}\,f}(x) \text{ for all } x \in \text{dom}\,f \text{ and } \varepsilon \geq 0 \text{ with } \partial_\varepsilon f(x) \neq \emptyset. \tag{9}$$

If f is not proper, then $\partial_\varepsilon f(x) = \emptyset$ for all $x \in X$. If f is lsc at x and $f(x) \in \mathbb{R}$, then

$$\partial_\varepsilon\,(\text{cl}\,f)\,(x) = \partial_\varepsilon f(x). \tag{10}$$

If $\partial f(x) \neq \emptyset$, then we have

$$(\text{cl}\,f)(x) = f(x) \text{ and } \partial\,(\text{cl}\,f)\,(x) = \partial f(x). \tag{11}$$

If $f \in \Lambda(X)$ and $f(x) \in \mathbb{R}$, then we have $\partial_\varepsilon f(x) \neq \emptyset$ for all $\varepsilon > 0$ if and only if f is lsc at x. Moreover, we have

$$\partial_\varepsilon f(x) = \{x^* \in X^* \mid f(x) + f^*(x^*) \leq \langle x^*, x\rangle + \varepsilon\} \text{ for all } \varepsilon \geq 0. \tag{12}$$

If A is convex and $x \in A$,

$$\partial \text{I}_A(x) = (\text{cone}(A - x))^- = \text{N}_A(x).$$

Finally, if $f \in \Gamma(X)$, then for every $x \in \text{dom}\,f$, $u \in X$ and $\varepsilon > 0$, we have (see [32, Thm. 2.4.11])

$$f'_\varepsilon(x, u) := \inf_{\lambda>0} \frac{f(x + \lambda u) - f(x) + \varepsilon}{\lambda} = \sigma_{\partial_\varepsilon f(x)}(u). \tag{13}$$

3. Calculus rules for the subdifferential of the supremum function. In this section we consider a nonempty family $\{f_t \mid t \in T\}$ of convex functions $f_t : X \to \overline{\mathbb{R}}$ defined on a (separated) real locally convex space X. The corresponding *pointwise supremum function* $f : X \to \overline{\mathbb{R}}$, given by

$$f(x) := \sup\{f_t(x) \mid t \in T\}, \tag{14}$$

is also convex; our main purpose in this section is to provide a formula for the subdifferential ∂f of f in terms exclusively of the data functions f_t, $t \in T$. The following simple example draws aside, in general, the possibility of writing ∂f in terms of ∂f_t, $t \in T$.

Example 1. [11, Ex. 2.1] Let $f_1, f_2 : \mathbb{R} \to \mathbb{R} \cup \{+\infty\}$ be defined by

$$f_1(x) = \begin{cases} -2\sqrt{x} & \text{if } x \geq 0, \\ +\infty & \text{if } x < 0, \end{cases} \quad \text{and } f_2(x) = f_1(-x)$$

so that $f := \max\{f_1, f_2\} = \mathrm{I}_{\{0\}}$. Then, we easily check that $\partial f(0) = \mathbb{R}$ while both $\partial f_1(0)$ and $\partial f_2(0)$ are empty.

Nevertheless, Theorem 4 below provides a characterization of ∂f, which involves the approximate subdifferentials of the data functions. To start with, we first establish two elementary lemmas.

LEMMA 1. *Let $h \in \Lambda(X)$ and $A \subset \operatorname{dom} h$ be a convex set. If $\operatorname{ri} A \neq \emptyset$, then $\inf_A h = \inf_{\operatorname{cl} A} h$.*

Proof. Set $\mu := \inf_A h$. Fix some $x_0 \in \operatorname{ri} A$ and consider $x \in \operatorname{cl} A$. Take $x_n := (1 - \frac{1}{n})x + \frac{1}{n}x_0$ for $n \geq 1$; then

$$\mu \leq h(x_n) \leq (1 - \tfrac{1}{n})h(x) + \tfrac{1}{n}h(x_0).$$

Taking the limit we get $\mu \leq h(x)$; hence $\mu \leq \inf_{\operatorname{cl} A} h$. □

The following simple result is an immediate consequence of (10) and (11).

LEMMA 2. *Let $h \in \Lambda(X)$ and $x \in \operatorname{dom} h$. If $\operatorname{cl} h \in \Lambda(X)$, then*

$$\partial_\varepsilon h(x) = \partial_{\operatorname{cl} h(x) - h(x) + \varepsilon} \operatorname{cl} h(x) \quad \textit{for all} \quad \varepsilon \in \mathbb{R}.$$

Hence $\partial_\varepsilon h(x) \neq \emptyset$ for $\varepsilon > h(x) - \operatorname{cl} h(x)$, and $\partial_\varepsilon h(x) = \emptyset$ for $\varepsilon < h(x) - \operatorname{cl} h(x)$.

From now on, we fix the following notations. Given $z \in X$ and $\varepsilon > 0$ we set

$$\mathcal{F}_z := \{L \subset X \mid L \text{ is a finite-dimensional linear subspace, with } z \in L\},$$

and

$$T_\varepsilon(z) := \{t \in T \mid f_t(z) \geq f(z) - \varepsilon\},$$

where f_t and f are defined as in (14).

The following lemma provides the first extension of Proposition 3 in [7] to general locally convex spaces; [7, Prop. 3] is established in $\mathbb{R}^n$ using subdifferential calculus for support functions. Here we give a direct proof, which, in particular, does not appeal to the Fenchel linearization of the functions f_t.

LEMMA 3. *Let $f_t \in \Gamma(X)$ for $t \in T \neq \emptyset$ and set $f := \sup_{t \in T} f_t$. Assume that $z \in \operatorname{dom} f$ and that $\operatorname{ri}(\operatorname{dom} f) \neq \emptyset$, then*

$$\partial f(z) = \bigcap_{\varepsilon > 0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t \in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z) \right) + \mathrm{N}_{\operatorname{dom} f}(z) \right) \quad \forall \alpha > 0.$$

Proof. Fix $\alpha > 0$. Denote by A the set in the right-hand side of the above equality. Without loss of generality (w.l.o.g.) we assume that $z = \theta$ and $f(\theta) = 0$. Set

$$T_\varepsilon := T_\varepsilon(\theta), \quad A_\varepsilon := \operatorname{co}\left(\bigcup_{t\in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z)\right).$$

Note first that, $A_\varepsilon \subset \partial_{(1+\alpha)\varepsilon} f(\theta)$, which together with $\mathrm{N}_{\operatorname{dom} f}(\theta) = (\partial_{(1+\alpha)\varepsilon} f_t(\theta))_\infty$, implies that $\operatorname{cl}(A_\varepsilon + \mathrm{N}_{\operatorname{dom} f}(\theta)) \subset \partial_{(1+\alpha)\varepsilon} f(\theta)$. Indeed,

$$\begin{aligned} \langle x, x^*\rangle &\le f_t(x) - f_t(\theta) + \alpha\varepsilon \\ &\le f(x) + (1+\alpha)\varepsilon \quad \forall t \in T_\varepsilon,\ \forall x^* \in \partial_{\alpha\varepsilon} f_t(\theta),\ \forall x \in X, \end{aligned} \tag{15}$$

whence $x^* \in \partial_{(1+\alpha)\varepsilon} f(\theta)$. Hence $A \subset \cap_{\varepsilon>0} \partial_{(1+\alpha)\varepsilon} f(\theta) = \partial f(\theta)$.

Let us prove now that $\partial f(\theta) \subset A$. Notice that $f = h^*$, where $h := \inf_{t\in T} f_t^* \ge f^* \ge 0$. Moreover, for $x^* \notin A_\varepsilon$ and $\varepsilon > 0$, we have that $h(x^*) \ge (1\wedge\alpha)\varepsilon := \min\{1, \alpha\}\varepsilon$. Indeed, if $t \in T_\varepsilon$, then $x^* \notin \partial_{\alpha\varepsilon} f_t(\theta)$, and so $f_t^*(x^*) \ge f_t(\theta) + f_t^*(x^*) > \langle\theta, x^*\rangle + \alpha\varepsilon = \alpha\varepsilon$, while, for $t \in T \setminus T_\varepsilon$ we have that $f_t^*(x^*) \ge \langle\theta, x^*\rangle - f_t(\theta) > -f(\theta) + \varepsilon = \varepsilon$. Hence $f_t^*(x^*) \ge (1 \wedge \alpha)\varepsilon$ for every $t \in T$, and so $h(x^*) \ge (1 \wedge \alpha)\varepsilon$. Take now $\bar{x}^* \in X^*$, which is not in $\operatorname{cl}(A_\varepsilon + \mathrm{N}_{\operatorname{dom} f}(\theta))$ for (some) $\varepsilon > 0$. Using a separation theorem, there exist $\bar{x} \in X$ and $\gamma > 0$ such that

$$\langle \bar{x}, \bar{x}^*\rangle > \gamma + \langle \bar{x}, x^*\rangle + \langle \bar{x}, u^*\rangle \text{ for all } x^* \in A_\varepsilon \text{ and all } u^* \in \mathrm{N}_{\operatorname{dom} f}(\theta). \tag{16}$$

It follows that $\bar{x} \in (\mathrm{N}_{\operatorname{dom} f}(\theta))^- = \operatorname{cl}(\mathbb{R}_+ \operatorname{dom} f)$. Furthermore, note that from (15) we get $\operatorname{dom} f \subset \operatorname{dom} \sigma_{A_\varepsilon}$, and so $C := \mathbb{R}_+(\operatorname{dom} f) \subset \operatorname{dom} \sigma_{A_\varepsilon} = \operatorname{dom}(\sigma_{A_\varepsilon} - \bar{x}^*)$. Since $\operatorname{aff} C = \operatorname{aff}(\operatorname{dom} f)$ and $\operatorname{ri}(\operatorname{dom} f) \ne \emptyset$, we have that $\operatorname{ri} C \ne \emptyset$. Using Lemma 1 for $\sigma_{A_\varepsilon} - \bar{x}^*$ and C we obtain that one can take $\bar{x} \in \operatorname{dom} f$.

For $\lambda \in]0, 1[$ we have

$$\begin{aligned} f(\lambda\bar{x}) &= \sup\{\langle \lambda\bar{x}, x^*\rangle - h(x^*) \mid x^* \in X^*\} \\ &= \max\left\{ \sup_{x^*\in A_\varepsilon} [\langle \lambda\bar{x}, x^*\rangle - h(x^*)], \sup_{x^*\in X^*\setminus A_\varepsilon} [\langle \lambda\bar{x}, x^*\rangle - h(x^*)] \right\}. \end{aligned}$$

But, $h \ge 0$ and $\langle \bar{x}, \bar{x}^*\rangle \ge \gamma + \sigma_{A_\varepsilon}(\bar{x})$ (being a consequence of (16)) allow us to write

$$\begin{aligned} \sup_{x^*\in A_\varepsilon} [\langle \lambda\bar{x}, x^*\rangle - h(x^*)] &\le \sup_{x^*\in A_\varepsilon} \langle \lambda\bar{x}, x^*\rangle = \lambda\sigma_{A_\varepsilon}(\bar{x}) \\ &\le \lambda(-\gamma + \langle \bar{x}, \bar{x}^*\rangle) < \langle \lambda\bar{x}, \bar{x}^*\rangle, \end{aligned}$$

while the fact that $h \ge (1 \wedge \alpha)\varepsilon$ on $X^* \setminus A_\varepsilon$ implies that

$$\begin{aligned} \sup_{x^*\in X^*\setminus A_\varepsilon} [\langle \lambda\bar{x}, x^*\rangle - h(x^*)] &\le \sup_{x^*\in X^*\setminus A_\varepsilon} \lambda [\langle \bar{x}, x^*\rangle - h(x^*)] + \sup_{x^*\in X^*\setminus A_\varepsilon} (1-\lambda)[-h(x^*)] \\ &\le \lambda h^*(\bar{x}) - (1-\lambda)(1\wedge\alpha)\varepsilon = \lambda f(\bar{x}) - (1-\lambda)(1\wedge\alpha)\varepsilon. \end{aligned}$$

Thus, since

$$\lambda f(\bar{x}) - (1-\lambda)(1\wedge\alpha)\varepsilon < \langle \lambda\bar{x}, x^*\rangle$$

for $\lambda \in]0, 1[$ sufficiently small, for such λ we have $f(\lambda\bar{x}) < \langle \lambda\bar{x}, x^*\rangle$, whence $x^* \notin \partial f(\theta)$ because $f(\theta) = 0$. The proof is complete. □

Now we are ready to give the main result of the paper in which we establish the formula of the subdifferential of the supremum function f defined in (14).

THEOREM 4. *Let $\{f_t \mid t \in T\}$ be a nonempty family of convex functions $f_t : X \to \overline{\mathbb{R}}$ and set $f := \sup_{t\in T} f_t$. Assume that*

$$\operatorname{cl} f = \sup\{\operatorname{cl} f_t \mid t \in T\}.$$

Then, for every $z \in X$, we have

$$\partial f(z) = \bigcap_{L\in\mathcal{F}_z,\varepsilon>0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z)\right) + \mathrm{N}_{L\cap\operatorname{dom} f}(z)\right) \quad \textit{for all } \alpha > 0.$$

Proof. Fix $\alpha > 0$ and denote by A the set in the right-hand side of the preceding equality.

Note first that the conclusion holds if $f(z) \notin \mathbb{R}$. Indeed, if $f(z) = +\infty$, then $\partial f(z) = \emptyset = \mathrm{N}_{L\cap\operatorname{dom} f}(z)$ for every $L \in \mathcal{F}_z$, and the conclusion holds trivially (taking into account (2)). If $f(z) = -\infty$, then $f_t(z) = -\infty$ for all $t \in T$, and so $\partial f(z) = \partial_{\alpha\varepsilon} f_t(z) = \emptyset$ for all $t \in T$ and all $\varepsilon > 0$, and again the conclusion holds trivially.

In the rest of the proof we assume that $f(z) \in \mathbb{R}$ and so, w.l.o.g., we take $z = \theta$ and $f(\theta) = 0$. To simplify the writing we use the notation

$$T_\varepsilon := T_\varepsilon(\theta), \quad A_\varepsilon := \operatorname{co}\left(\textstyle\bigcup_{t\in T_\varepsilon} \partial_{\alpha\varepsilon} f_t(\theta)\right), \quad \mathcal{F} := \mathcal{F}_\theta.$$

The inclusion $A \subset \partial f(\theta)$ easily follows by the definition of A_ε. Indeed, fix $x \in \operatorname{dom} f$, and let $L \in \mathcal{F}$. Then, by setting $E := L + \mathbb{R}x$ we get

$$\langle x, x^* + u^*\rangle \le \langle x, x^*\rangle \le f_t(x) - f_t(\theta) + \alpha\varepsilon \le f(x) + (1+\alpha)\varepsilon$$

for all $t \in T_\varepsilon$, $x^* \in \partial_{\alpha\varepsilon} f_t(\theta)$, and $u^* \in \mathrm{N}_{E\cap\operatorname{dom} f}(\theta)$, whence

$$\langle x, v^*\rangle \le f(x) + (1+\alpha)\varepsilon \text{ for all } v^* \in \operatorname{cl}\left(A_\varepsilon + \mathrm{N}_{E\cap\operatorname{dom} f}(\theta)\right).$$

Because $E \in \mathcal{F}$ and $\mathrm{N}_{E\cap\operatorname{dom} f}(\theta) \subset \mathrm{N}_{L\cap\operatorname{dom} f}(\theta)$, we deduce that

$$\langle x, v^*\rangle \le f(x) + (1+\alpha)\varepsilon \text{ for all } \varepsilon > 0 \text{ and } v^* \in A.$$

Hence $\langle x, v^*\rangle \le f(x) - f(\theta)$ for all $x \in \operatorname{dom} f$ and $v^* \in A$. Therefore, $A \subset \partial f(\theta)$. To prove the inclusion $\partial f(\theta) \subset A$ it suffices to assume that $\partial f(\theta) \ne \emptyset$ in which case, by (11),

$$\partial f(\theta) = \partial\left(\operatorname{cl} f\right)(\theta) \text{ and } (\operatorname{cl} f)(\theta) = f(\theta) = 0. \tag{17}$$

For this aim we shall introduce a family of functions satisfying the assumptions of Lemma 3.

Let us set $S := \{t \in T \mid \operatorname{cl} f_t \text{ is not proper}\}$. Then $\operatorname{cl} f_t$ takes its values in $\{-\infty, +\infty\}$ for $t \in S$ and so, because $(\operatorname{cl} f_t)(\theta) \le (\operatorname{cl} f)(\theta) = 0$ for $t \in T$, we obtain that $(\operatorname{cl} f_t)(\theta) = -\infty$ for $t \in S$; using our hypothesis we get $T \setminus S \ne \emptyset$.

Fix $L \in \mathcal{F}$ and define the family of functions $\{g_t \mid t \in T\} \subset \Gamma(X)$ by

$$g_t(x) := \begin{cases} \max\{(\operatorname{cl} f_t)(x), -1\} & \text{for } t \in S, \\ (\operatorname{cl} f_t)(x) & \text{for } t \in T \setminus S \end{cases}$$

and set

$$g(x) := \sup\{g_t(x) + \langle x, x^*\rangle \mid x^* \in L^\perp,\ t \in T\}.$$

(Observe that $g = \sup_{t\in T} g_t + \mathrm{I}_L$.) Then, since $g_t \geq \operatorname{cl} f_t$ for every $t \in T$, the current assumption yields

$$g = \sup_{t\in T} g_t + \mathrm{I}_L \geq \sup_{t\in T} \operatorname{cl} f_t + \mathrm{I}_L = \operatorname{cl} f + \mathrm{I}_L.$$

Furthermore, thanks to (17), there exists a convex neighborhood U of θ such that $(\operatorname{cl} f)(x) > -1$ for every $x \in U$. Hence for $x \in U \cap L$ we have either $(\operatorname{cl} f)(x) = +\infty \geq g(x)$ or $(\operatorname{cl} f)(x) < +\infty$; in this case for $t \in S$ one has $(\operatorname{cl} f_t)(x) = -\infty$, and so $g_t(x) = -1 \leq (\operatorname{cl} f)(x)$, while for $t \in T \setminus S$ one has $g_t(x) = (\operatorname{cl} f_t)(x) \leq (\operatorname{cl} f)(x)$. We deduce that $g(x) \leq (\operatorname{cl} f)(x)$ for $x \in U \cap L$. Therefore,

$$g(x) = (\operatorname{cl} f)(x) + \mathrm{I}_L(x) \quad \text{for every } x \in U. \tag{18}$$

Moreover, because $L \cap U \cap \operatorname{dom} f \subset L \cap U \cap \operatorname{dom}(\operatorname{cl} f) = U \cap \operatorname{dom} g$, we get

$$\mathrm{N}_{\operatorname{dom} g}(\theta) \subset \mathrm{N}_{L\cap \operatorname{dom} f}(\theta). \tag{19}$$

Now set

$$T'_\varepsilon := \{t \in T \mid g_t(\theta) \geq -\varepsilon\}.$$

Then $T'_\varepsilon \subset T_\varepsilon \setminus S$ for $\varepsilon \in]0,1[$. In fact, since $g_t(\theta) = -1$ for $t \in S$, we have that $T'_\varepsilon \subset T \setminus S$. Hence, for $t \in T'_\varepsilon$ we write $0 \geq f_t(\theta) \geq (\operatorname{cl} f_t)(\theta) = g_t(\theta) \geq -\varepsilon$, and so $t \in T_\varepsilon$. Moreover, for $t \in T'_\varepsilon$ we have that $\partial_{\alpha\varepsilon}(\operatorname{cl} f_t)(\theta) \subset \partial_{(1+\alpha)\varepsilon} f_t(\theta)$. Indeed, since we have $f_t(\theta) - (\operatorname{cl} f_t)(\theta) \leq f(\theta) - g_t(\theta) = g(\theta) - g_t(\theta) \leq \varepsilon$, Lemma 2 yields $\partial_{\alpha\varepsilon}(\operatorname{cl} f_t)(\theta) = \partial_{\alpha\varepsilon + f_t(\theta) - (\operatorname{cl} f_t)(\theta)} f_t(\theta) \subset \partial_{(1+\alpha)\varepsilon} f_t(\theta)$. In view of these observations we get

$$\operatorname{co}\left(\bigcup_{t\in T'_\varepsilon} \partial_{\alpha\varepsilon} g_t(\theta)\right) \subset \operatorname{co}\left(\bigcup_{t\in T'_\varepsilon} \partial_{(1+\alpha)\varepsilon} f_t(\theta)\right) \quad \text{for all } \varepsilon \in]0,1[. \tag{20}$$

Now we go back to the proof of the inclusion $\partial f(\theta) \subset A$. We apply Lemma 3 for the family $\{g_{(t,x^*)} \mid (t,x^*) \in T \times L^\perp\} \subset \Gamma(X)$ with $g_{(t,x^*)} := g_t + x^*$ and α (this is possible because $g = \sup\{g_{(t,x^*)} \mid (t,x^*) \in T \times L^\perp\}$ and $\operatorname{dom} g \subset L$, and so $\operatorname{ri}(\operatorname{dom} g) \neq \emptyset$, L being a finite-dimensional space). We obtain

$$\begin{aligned}\partial g(\theta) &= \bigcap_{\varepsilon>0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T'_\varepsilon, x^*\in L^\perp} \partial_{\alpha\varepsilon}(g_t + x^*)(\theta)\right) + \mathrm{N}_{\operatorname{dom} g}(\theta)\right)\\ &= \bigcap_{\varepsilon>0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T'_\varepsilon} \partial_{\alpha\varepsilon} g_t(\theta)\right) + L^\perp + \mathrm{N}_{\operatorname{dom} g}(\theta)\right).\end{aligned}$$

Then in view of the evident fact that $L^\perp + \mathrm{N}_{L\cap\operatorname{dom} f}(\theta) \subset \mathrm{N}_{L\cap\operatorname{dom} f}(\theta)$, and using (19) and (20), we get

$$\begin{aligned}\partial g(\theta) &\subset \bigcap_{\varepsilon\in]0,1[} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T'_\varepsilon} \partial_{\alpha\varepsilon} g_t(\theta)\right) + \mathrm{N}_{L\cap\operatorname{dom} f}(\theta)\right)\\ &\subset \bigcap_{\varepsilon\in]0,1[} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T_\varepsilon} \partial_{(1+\alpha)\varepsilon} f_t(\theta)\right) + \mathrm{N}_{L\cap\operatorname{dom} f}(\theta)\right).\end{aligned}$$

Hence, for each $\varepsilon \in]0,1[$ we obtain that, taking into account (17) and (18),

$$\begin{aligned}\partial f(\theta) \subset \partial(\operatorname{cl} f)(\theta) + L^{\perp} &= \partial(\operatorname{cl} f)(\theta) + \partial \mathrm{I}_L(\theta) \subset \partial\left(\operatorname{cl} f + \mathrm{I}_L\right)(\theta) \\ &= \partial g(\theta) \subset \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T_\varepsilon} \partial_{(1+\alpha)\varepsilon} f_t(\theta)\right) + \mathrm{N}_{L\cap \operatorname{dom} f}(\theta)\right)\end{aligned}$$

for all $\varepsilon \in]0,1[$. Since $\delta := \frac{\alpha}{1+\alpha}\varepsilon \in]0,\varepsilon[\subset]0,1[$ (for $\varepsilon \in]0,1[$), we also have that

$$\partial f(\theta) \subset \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T_\delta} \partial_{\alpha\varepsilon} f_t(\theta)\right) + \mathrm{N}_{L\cap \operatorname{dom} f}(\theta)\right) \subset \operatorname{cl}\left(A_\varepsilon + \mathrm{N}_{L\cap \operatorname{dom} f}(\theta)\right)$$

for all $\varepsilon \in]0,1[$. Since $\varepsilon \in]0,1[$ and $L \in \mathcal{F}$ were arbitrarily chosen, we obtain that

$$\partial f(\theta) \subset \bigcap_{L\in\mathcal{F},\varepsilon\in]0,1[} \operatorname{cl}\left(A_\varepsilon + \mathrm{N}_{L\cap \operatorname{dom} f}(\theta)\right) = \bigcap_{L\in\mathcal{F},\varepsilon>0} \operatorname{cl}\left(A_\varepsilon + \mathrm{N}_{L\cap \operatorname{dom} f}(\theta)\right) = A.$$

The proof is complete. □

Theorem 4 provides a complete description for ∂f only in terms of the data functions f_t, $t \in T$. Other descriptions will be provided in Theorem 6 below. We first establish the following lemma, which provides a straightforward infinite-dimensional extension of the corresponding statements in [7, Prop. 4].

LEMMA 5. *Let $T \neq \emptyset$ and $\{f_t \mid t \in T\} \subset \Gamma(X)$, and set $f := \sup\{f_t \mid t \in T\}$. Then, for every $z \in \operatorname{dom} f$, we have that*

$$\mathrm{N}_{\operatorname{dom} f}(z) = \{v^* \in X^* \mid (v^*, \langle v^*, z\rangle) \in [\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*)]_\infty\} \tag{21}$$

$$= \{v^* \in X^* \mid (v^*, \langle v^*, z\rangle) \in [\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{epi} f_t^*)]_\infty\} \tag{22}$$

$$= \{v^* \in X^* \mid (v^*, \langle v^*, z\rangle) \in (\operatorname{epi} f^*)_\infty\} \tag{23}$$

$$= \{v^* \in X^* \mid (v^*, \langle v^*, z\rangle) \in \operatorname{epi}(\sigma_{\operatorname{dom} f})\}. \tag{24}$$

Proof. We assume that f is proper. Statement (24) is just the definition of $\mathrm{N}_{\operatorname{dom} f}(z)$. As seen in Lemma 3, we have that

$$(\inf_{t\in T} f_t^*)^* = \sup_{t\in T} f_t^{**} = \sup_{t\in T} f_t = f.$$

Since f is proper we obtain that

$$f^* = (\inf_{t\in T} f_t^*)^{**} = \overline{\operatorname{co}}\left(\inf_{t\in T} f_t^*\right),$$

that is, $\operatorname{epi} f^* = \overline{\operatorname{co}}(\cup_{t\in T} \operatorname{epi} f_t^*)$; moreover, by [32, Exer. 2.23] one has $(\operatorname{epi} f^*)_\infty = \operatorname{epi}(\sigma_{\operatorname{dom} f})$. Using these two relations we get statements (22) and (23). To finish the proof, it suffices to establish the equality between the sets appearing in the right-hand sides of (21) and (22), say, $E_1(z)$ and $E_2(z)$, respectively, or simply the inclusion $E_2(z) \subset E_1(z)$, since the opposite inclusion is trivial. Indeed, because for any proper function $g : X \to \overline{\mathbb{R}}$ one has $\operatorname{gph} g + \mathbb{R}_+(\theta,1) = \operatorname{epi} g$, we obtain that

$$\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*) \subset \operatorname{cl}\,[\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*) + \mathbb{R}_+(\theta,1)] = \overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{epi} f_t^*) = \operatorname{epi} f^*.$$

Since f^* is proper, we have $[\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*)]_\infty \cap -[\mathbb{R}_+(\theta,1)]_\infty = \{(\theta,0)\}$, and so by [30, Cor. 3.12] (see also [16, Thm. 1.1]), we obtain that $\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*) + \mathbb{R}_+(\theta,1)$ is closed, whence $\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*) + \mathbb{R}_+(\theta,1) = \overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{epi} f_t^*)$, and

$$\begin{aligned}[\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{epi} f_t^*)]_\infty &= [\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*) + \mathbb{R}_+(\theta,1)]_\infty \\ &= [\overline{\operatorname{co}}\,(\cup_{t\in T} \operatorname{gph} f_t^*)]_\infty + \mathbb{R}_+(\theta,1).\end{aligned}$$

Take $v^* \in E_2(z)$; using the preceding relation, $(v^*, \langle v^*, z\rangle) = (x^*, \eta + \lambda)$ for some $(x^*, \eta) \in [\overline{\text{co}}\,(\cup_{t\in T} \text{gph}\, f_t^*)]_\infty$, and $\lambda \geq 0$. Moreover, since $\text{dom}\, f \times \{-1\} \subset \text{dom}\,(\sigma_{\text{epi}\, f^*}) \subset [(\text{epi}\, f^*)_\infty]^-$, we obtain that

$$\text{dom}\, f \times \{-1\} \subset [(\overline{\text{co}}\,(\cup_{t\in T} \text{epi}\, f_t^*))_\infty]^- \subset [(\overline{\text{co}}\,(\cup_{t\in T} \text{gph}\, f_t^*))_\infty]^-,$$

and so $\langle (x^*, \eta), (z, -1)\rangle \leq 0$. Since $v^* = x^*$, it follows that

$$\lambda = \langle (v^*, \eta), (z, -1)\rangle = \langle (x^*, \eta), (z, -1)\rangle \leq 0;$$

hence $\lambda = 0$, and so $(v^*, \langle v^*, z\rangle) = (x^*, \eta) \in [\overline{\text{co}}\,(\cup_{t\in T} \text{gph}\, f_t^*)]_\infty$. This shows that $v^* \in E_1(z)$. ∎

We have the following theorem in which, for simplicity, we suppose that $f_t \in \Gamma(X)$ for all $t \in T$.

THEOREM 6. *Let $T \neq \emptyset$ and $\{f_t \mid t \in T\} \subset \Gamma(X)$, and set $f := \sup_{t\in T} f_t$. Then, for every $z \in X$ and every $\alpha > 0$, we have that*

$$\partial f(z) = \bigcap_{L\in\mathcal{F}_z, \varepsilon>0} \overline{\text{co}}\Big(A_L + \bigcup_{t\in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z)\Big) = \bigcap_{L\in\mathcal{F}_z, \varepsilon>0} \overline{\text{co}}\Big(B_L + \bigcup_{t\in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z)\Big),$$

where

$$A_L := \left\{ v^* \in X^* \,\middle|\, (v^*, \langle v^*, z\rangle) \in \left[\overline{\text{co}}\Big((L^\perp \times \mathbb{R}_+) \cup \Big(\bigcup_{t\in T} \text{epi}\, f_t^*\Big)\Big)\right]_\infty \right\},$$

$$B_L := \left\{ v^* \in X^* \,\middle|\, (v^*, \langle v^*, z\rangle) \in \left[\overline{\text{co}}\Big((L^\perp \times \{0\}) \cup \Big(\bigcup_{t\in T} \text{gph}\, f_t^*\Big)\Big)\right]_\infty \right\}.$$

Proof. According to Theorem 4 it suffices to write $\text{N}_{L\cap\text{dom}\, f}(z)$ in terms of the data functions f_t for each $L \in \mathcal{F}_z$. Indeed, by Lemma 5 applied to the family $\{f_t \mid t \in T\} \cup \{\text{I}_L\} \subset \Gamma(X)$, we have $\text{N}_{L\cap\text{dom}\, f}(z) = A_L = B_L$; we used the fact that $(\text{I}_L)^* = \text{I}_{L^\perp}$, and so $\text{epi}\,(\text{I}_L)^* = \text{epi}\,(\text{I}_{L^\perp}) = L^\perp \times \mathbb{R}_+$ and $\text{gph}\,(\text{I}_L)^* = \text{gph}\,(\text{I}_{L^\perp}) = L^\perp \times \{0\}$. ∎

In the affine case (f_t affine) our formula takes a simpler form.

COROLLARY 7. *Assume that $T \neq \emptyset$ and $f := \sup\{\langle a_t^*, \cdot\rangle - \beta_t \mid t \in T\}$, with $a_t^* \in X^*$ and $\beta_t \in \mathbb{R}$. Then, for every $z \in X$, we have that*

$$\partial f(z) = \bigcap_{L\in\mathcal{F}_z, \varepsilon>0} \text{cl}\,(\text{co}\{a_t^* \mid t \in T_\varepsilon(z)\} + B_L),$$

where $T_\varepsilon(z) := \{t \in T \mid \langle a_t^*, z\rangle - \beta_t \geq f(z) - \varepsilon\}$ and

$$B_L := \left\{ v^* \in X^* \;\middle|\; (v^*, \langle v^*, z\rangle) \in \left[\overline{\text{co}}\left((L^\perp \times \{0\}) \cup \{(a_t^*, \beta_t) \mid t \in T\}\right)\right]_\infty \right\}.$$

In particular, for a given nonempty set $A \subset X^*$, we have that

$$\partial\sigma_A(z) = \bigcap_{L\in\mathcal{F}_z, \varepsilon>0} \text{cl}\left(\text{co}(A_\varepsilon) + \left[\overline{\text{co}}\left(L^\perp \cup A\right)\right]_\infty \cap \{z\}^\perp\right),$$

where $A_\varepsilon := \{a^* \in A \mid \langle z, a^*\rangle \geq \sigma_A(z) - \varepsilon\}$.

Proof. These formulae easily follow by Theorem 6, similarly as in [7, Prop. 1]. ∎

The following corollary gives us a simplified representation for the subdifferential set of f when $\text{ri}(\text{dom}\, f) \neq \emptyset$. This is also an extension of Lemma 3 when the functions f_t are not necessarily lsc.

COROLLARY 8. *Let $\{f_t \mid t \in T\}$ be a nonempty family of convex functions $f_t : X \to \overline{\mathbb{R}}$, and set $f := \sup_{t\in T} f_t$. Assume that* $\operatorname{ri}(\operatorname{dom} f) \neq \emptyset$. *Then, for every $z \in X$ and $\alpha > 0$, we have that*

$$\partial f(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t\in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z) \right) + \mathrm{N}_{\operatorname{dom} f}(z) \right).$$

Proof. The inclusion "$\supset$" follows immediately by Theorem 4, since we have $\mathrm{N}_{\operatorname{dom} f}(z) \subset \mathrm{N}_{L\cap\operatorname{dom} f}(z)$ for every $L \in \mathcal{F}_z$. To prove the inclusion "$\subset$", let $\alpha > 0$ be fixed, and let $\partial f(z) \neq \emptyset$ (otherwise the inclusion is obvious). We (may) assume that $z = \theta$ and $f(\theta) = 0$. Then it suffices to show that $\partial f(\theta) \subset \operatorname{cl}\big(\operatorname{co}\big(\bigcup_{t\in T_\varepsilon(\theta)} \partial_{\alpha\varepsilon} f_t(\theta)\big) + \mathrm{N}_{\operatorname{dom} f}(\theta)\big)$ for any given $\varepsilon > 0$. Let $V \in \mathcal{V}$, that is, V is a θ–neighborhood in X^*, and $L \in \mathcal{F}_\theta$ be such that $L^\perp \subset V$. We may suppose w.l.o.g. that $L \cap \operatorname{ri}(\operatorname{dom} f) \neq \emptyset$, which in particular, implies that $L \cap \operatorname{ri}(\mathbb{R}_+ \operatorname{dom} f) \neq \emptyset$. Using (4) we obtain that $\operatorname{cl}(L \cap \mathbb{R}_+ \operatorname{dom} f) = L \cap \operatorname{cl}(\mathbb{R}_+ \operatorname{dom} f)$; this implies that (see [32, p. 7])

$$\mathrm{N}_{L\cap\operatorname{dom} f}(\theta) = (L \cap \operatorname{cl}(\mathbb{R}_+ \operatorname{dom} f))^- = \operatorname{cl}(L^- + (\mathbb{R}_+ \operatorname{dom} f)^-) = \operatorname{cl}\left(L^\perp + \mathrm{N}_{\operatorname{dom} f}(\theta)\right).$$

So, by using once again Theorem 4 and (3), we obtain that

$$\begin{aligned} \partial f(\theta) &\subset \operatorname{cl}\left[\operatorname{co}\left(\textstyle\bigcup_{t\in T_\varepsilon(\theta)} \partial_{\alpha\varepsilon} f_t(\theta)\right) + \mathrm{N}_{L\cap\operatorname{dom} f}(\theta)\right] \\ &= \operatorname{cl}\left[\operatorname{co}\left(\textstyle\bigcup_{t\in T_\varepsilon(\theta)} \partial_{\alpha\varepsilon} f_t(\theta)\right) + L^\perp + \mathrm{N}_{\operatorname{dom} f}(\theta)\right] \\ &\subset \operatorname{co}\left(\textstyle\bigcup_{t\in T_\varepsilon(\theta)} \partial_{\alpha\varepsilon} f_t(\theta)\right) + \mathrm{N}_{\operatorname{dom} f}(\theta) + V. \end{aligned}$$

As V is an arbitrary θ–neighborhood, we get that

$$\begin{aligned} \partial f(\theta) &\subset \bigcap_{V\in\mathcal{V}} \left(\operatorname{co}\left(\bigcup_{t\in T_\varepsilon(\theta)} \partial_{\alpha\varepsilon} f_t(\theta) \right) + \mathrm{N}_{\operatorname{dom} f}(\theta) + V \right) \\ &= \operatorname{cl}\left(\operatorname{co}\left(\textstyle\bigcup_{t\in T_\varepsilon(\theta)} \partial_{\alpha\varepsilon} f_t(\theta)\right) + \mathrm{N}_{\operatorname{dom} f}(\theta)\right), \end{aligned}$$

which finishes the proof. □

From a geometric point of view the closedness criterion given in Theorem 4 is equivalent to

$$\operatorname{cl}\left(\bigcap_{t\in T} \operatorname{epi} f_t \right) = \bigcap_{t\in T} \operatorname{cl}(\operatorname{epi} f_t), \tag{25}$$

which is itself satisfied by a wide variety of convex functions as the following result shows.

COROLLARY 9. *Let $\{f_t \mid t \in T\}$ be a nonempty family of convex functions $f_t : X \to \overline{\mathbb{R}}$, and set $f := \sup_{t\in T} f_t$. Assume that one of the following conditions holds*:

(i) *All of the functions f_t, with $t \in T$ are lsc.*
(ii) *There exists $x_0 \in \operatorname{dom} f$ such that f_t is continuous at x_0 for every $t \in T$.*
(iii) *$T := \{1, \ldots, k, k+1\}$, and there exists $x_0 \in \cap_{i=1}^{k+1} \operatorname{dom} f_i$ such that $f_1, \ldots, f_k$ are continuous at x_0.*
(iv) *$X = \mathbb{R}^n$ and $\operatorname{dom} f \cap (\cap_{t\in T} \operatorname{ri}(\operatorname{dom} f_t))$ is nonempty.*

Then, we have that

$$\operatorname{cl} f = \sup\{\operatorname{cl} f_t \mid t \in T\},$$

and, consequently, for every $z \in X$ and $\alpha > 0$, it holds that

$$\partial f(z) = \bigcap_{L \in \mathcal{F}_z, \varepsilon > 0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{t \in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z) \right) + \mathrm{N}_{L \cap \operatorname{dom} f}(z) \right).$$

Proof. Setting $A_t := \operatorname{epi} f_t$ for $t \in T$ and $A := \operatorname{epi} f$, one has always $A = \cap_{t \in T} A_t$, and we have to show that $\operatorname{cl} A = \cap_{t \in T} \operatorname{cl}(A_t)$. The inclusion $\operatorname{cl} A \subset \cap_{t \in T} \operatorname{cl}(A_t)$ being obvious, it remains to prove that $\operatorname{cl} A \supset \cap_{t \in T} \operatorname{cl}(A_t)$ in each of the following cases.

(i) It is immediate.

(ii) First observe that [31, Lem. 13] is valid even if f is not proper. Consider $\mu > f(x_0)$. Applying this result we obtain that $y_0 := (x_0, \mu) \in \bigcap_{t \in T} \operatorname{int} A_t$. Now if $x \in \bigcap_{t \in T} \operatorname{cl} A_t$, then $(1 - \lambda)x + \lambda y_0 \in \bigcap_{t \in T} \operatorname{int} A_t \subset A$ for every $\lambda \in]0, 1[$, whence $x \in \operatorname{cl} A$.

(iii) Set $B := \bigcap_{t=1}^k A_t$. Then, similarly as in (ii), we can show that $y_0 := (x_0, \mu) \in A_{k+1} \cap \operatorname{int} B$. Hence

$$\operatorname{cl}\left(\bigcap_{t \in T} A_t\right) = \operatorname{cl}\left(A_{k+1} \cap B\right) = \operatorname{cl} A_{k+1} \cap \operatorname{cl} B = \operatorname{cl} A_{k+1} \cap \left(\bigcap_{t=1}^k \operatorname{cl} A_t\right) = \bigcap_{t \in T} \operatorname{cl} A_t.$$

(iv) This is practically [22, Thm. 9.4].

Taking into account Theorem 4, the final conclusion follows. □

The following result (for $\alpha = 1$) is due to Volle (see, e.g., [28, Thm. A]) and is originally established in the context of normed spaces.

COROLLARY 10. *Let $\{f_t \mid t \in T\}$ be a nonempty family of convex functions $f_t : X \to \overline{\mathbb{R}}$, and set $f := \sup_{t \in T} f_t$. Assume that f is finite and continuous at $z \in X$. Then, we have*

$$\partial f(z) = \bigcap_{\varepsilon > 0} \overline{\operatorname{co}}\left(\bigcup_{t \in T_\varepsilon(z)} \partial_{\alpha\varepsilon} f_t(z) \right) \quad \text{for all } \alpha > 0.$$

Proof. Because f is finite and continuous at z, we have that $z \in \operatorname{int}(\operatorname{dom} f)$, and so $\mathrm{N}_{\operatorname{dom} f}(z) = \{\theta\}$. Further, as $z \in \cap_{t \in T} \operatorname{int}(\operatorname{dom} f)$ Condition (ii) of Corollary 9 yields $\operatorname{cl} f = \sup\{\operatorname{cl} f_t \mid t \in T\}$. Of course, $\operatorname{ri}(\operatorname{dom} f) = \operatorname{int}(\operatorname{dom} f) \neq \emptyset$, and so the conclusion follows from Corollary 8. □

In order to derive Brøndsted's formula (Corollary 12 below) we shall need the following result on normal cones.

LEMMA 11. (i) *Let $g_1, \ldots, g_k \in \Gamma(X)$, $f \in \Gamma(Y)$, and consider a continuous affine mapping $A : X \to Y$, where X and Y are (separated) locally convex spaces. Then, for every $z \in \operatorname{dom}(g_1 + \cdots + g_k + f \circ A)$ and all $\varepsilon, \varepsilon_1, \ldots, \varepsilon_k > 0$, we have that*

$$\mathrm{N}_{\operatorname{dom}(g_1 + \cdots + g_k + f \circ A)}(z) = \left[\operatorname{cl}\left(\partial_{\varepsilon_1} g_1(z) + \cdots + \partial_{\varepsilon_k} g_k(z) + A_0^* \partial_\varepsilon f(Az) \right) \right]_\infty,$$

where A_0 is the linear part of A, and A_0^* is the adjoint of A_0.

(ii) *Let $\{f_1, \ldots, f_m\} \subset \Gamma(X)$, with $m \geq 2$ and $0 \leq k \leq m$. Then, for all $z \in \bigcap_{t=1}^m \operatorname{dom} f_t$ and all $\varepsilon_1, \ldots, \varepsilon_m > 0$, we have that*

$$\mathrm{N}_{\cap_{t=1}^m \operatorname{dom} f_t}(z) = \left[\operatorname{cl}\left(\partial_{\varepsilon_1} f_1(z) + \cdots + \partial_{\varepsilon_k} f_k(z) + \operatorname{co}\left(\partial_{\varepsilon_{k+1}} f_{k+1}(z) \cup \cdots \cup \partial_{\varepsilon_m} f_m(z) \right) \right) \right]_\infty,$$

where $C_1 + \cdots + C_k := \emptyset$ if $k = 0$ and $C_{k+1} \cup \cdots \cup C_m := \emptyset$ if $k = m$.

Proof. (i) Using (7) and (13), as well as the fact that $\mathbb{R}_+(B\cap C)=\mathbb{R}_+B\cap\mathbb{R}_+C$ when B and C are convex sets containing θ, we get that

$$\begin{aligned}
&[(\mathrm{cl}\,(\partial_{\varepsilon_1}g_1(z)+\cdots+\partial_{\varepsilon_k}g_k(z)+A_0^*\partial_\varepsilon f(Az)))_\infty]^-\\
&\quad=\mathrm{cl}(\mathrm{dom}(\sigma_{\partial_{\varepsilon_1}g_1(z)}+\cdots+\sigma_{\partial_{\varepsilon_k}g_k(z)}+\sigma_{\partial_\varepsilon f(Az)}\circ A_0))\\
&\quad=\mathrm{cl}\left(\mathrm{dom}((g_1)'_{\varepsilon_1}(z,\cdot))\cap\cdots\cap\mathrm{dom}((g_k)'_{\varepsilon_k}(z,\cdot))\cap A_0^{-1}\,\mathrm{dom}(f'_\varepsilon(Az,\cdot))\right)\\
&\quad=\mathrm{cl}\left(\mathbb{R}_+\left(\mathrm{dom}\,g_1-z\right)\cap\cdots\cap\mathbb{R}_+(\mathrm{dom}\,g_k-z)\cap A_0^{-1}\left(\mathbb{R}_+(\mathrm{dom}\,f-Az)\right)\right)\\
&\quad=\mathrm{cl}\left(\mathbb{R}_+\left(\mathrm{dom}(g_1+\cdots+g_k+f\circ A)-z\right)\right),
\end{aligned}$$

whence the conclusion follows using (5).

(ii) Taking $f=0$ in (i) and observing that $\mathrm{dom}(g_1+\cdots+g_k)=\bigcap_{t=1}^k\mathrm{dom}\,g_t$, we get that $\mathrm{N}_{\cap_{t=1}^k\mathrm{dom}\,g_t}(z)=[\mathrm{cl}\,(\partial_{\varepsilon_1}g_1(z)+\cdots+\partial_{\varepsilon_k}g_k(z))]_\infty$. The conclusion follows now using (8). □

The following result is due to Brøndsted (e.g., [2]); see also [7, Prop. 7] where such a formula is extended to families of infinitely many convex functions defined on $\mathbb{R}^n$.

COROLLARY 12. *Consider the convex functions $f_i:X\to\overline{\mathbb{R}}$ for $i=1,\dots,k$, and set $f:=\max\{f_1,\dots,f_k\}$. Assume that*

$$\mathrm{cl}\,f=\max\{\mathrm{cl}\,f_1,\dots,\mathrm{cl}\,f_k\}.$$

Given $z\in X$ such that $(\mathrm{cl}\,f)(z)=(\mathrm{cl}\,f_i)(z)$ for $i=1,\dots,k$, we have that

$$\partial f(z)=\bigcap\nolimits_{\varepsilon>0}\overline{\mathrm{co}}\left(\bigcup\nolimits_{i=1}^k\partial_\varepsilon f_i(z)\right).$$

Proof. It suffices to establish the inclusion "$\subset$" in the nontrivial case $\partial f(z)\neq\emptyset$. According to (11), the function f is proper and satisfies $f(z)=(\mathrm{cl}\,f)(z)\in\mathbb{R}$ and $\partial f(z)=\partial\,(\mathrm{cl}\,f)\,(z)$. Because

$$(\mathrm{cl}\,f_i)(z)\le f_i(z)\le f(z)=(\mathrm{cl}\,f)(z)=(\mathrm{cl}\,f_i)(z),$$

we obtain that $(\mathrm{cl}\,f_i)(z)=f_i(z)=f(z)\in\mathbb{R}$ for all $i\in T:=\{1,\dots,k\}$; hence the functions $\mathrm{cl}\,f_i$, with $i\in T$, are proper. Furthermore, using (10) we get

$$\partial_\varepsilon(\mathrm{cl}\,f_i)(z)=\partial_\varepsilon f_i(z)\ \text{for all}\ \varepsilon>0\ \text{and}\ i\in T. \tag{26}$$

Fix $\varepsilon>0$; it is clear that $T_\varepsilon(z)=T$. Let $V\in\mathcal{V}$, that is, V is a convex θ–neighborhood in X^*, and take $L\in\mathcal{F}_z$ such that $L^\perp\subset V$ ($\Leftrightarrow L^\perp\subset\frac{1}{2}V$). Applying Theorem 4 for $\{\mathrm{cl}\,f_1,\dots,\mathrm{cl}\,f_k\}$ and $\alpha=1$, we have that

$$\partial\,(\mathrm{cl}\,f)\,(z)\subset\mathrm{cl}\left(\mathrm{co}\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon(\mathrm{cl}\,f_i)(z)\right)+\mathrm{N}_{L\cap\mathrm{dom}(\mathrm{cl}\,f)}(z)\right).$$

But Lemma 11(ii) applied to $\{\mathrm{cl}\,f_1,\dots,\mathrm{cl}\,f_k,\mathrm{I}_L\}$ implies that

$$\mathrm{N}_{L\cap\mathrm{dom}(\mathrm{cl}\,f)}(z)=\left[\overline{\mathrm{co}}\left(L^\perp+\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon(\mathrm{cl}\,f_i)(z)\right)\right)\right]_\infty,$$

where we used the property $\partial_\varepsilon\mathrm{I}_L(z)=L^\perp$. Thus, taking into account (3) and (26), we get that

$$\begin{aligned}
\partial f(z)=\partial\,(\mathrm{cl}\,f)\,(z)&\subset\mathrm{cl}\left(\overline{\mathrm{co}}\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon(\mathrm{cl}\,f_i)(z)\right)+\left[\overline{\mathrm{co}}\left(L^\perp+\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon(\mathrm{cl}\,f_i)(z)\right)\right)\right]_\infty\right)\\
&\subset\mathrm{cl}\left(\overline{\mathrm{co}}\left(L^\perp+\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon f_i(z)\right)\right)+\left[\overline{\mathrm{co}}\left(L^\perp+\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon f_i(z)\right)\right)\right]_\infty\right)\\
&=\overline{\mathrm{co}}\left(L^\perp+\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon f_i(z)\right)\right)=\mathrm{cl}\left(L^\perp+\mathrm{co}\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon f_i(z)\right)\right)\\
&\subset L^\perp+\mathrm{co}\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon f_i(z)\right)+\tfrac{1}{2}V\subset\mathrm{co}\left(\bigcup\nolimits_{i\in T}\partial_\varepsilon f_i(z)\right)+V.
\end{aligned}$$

Consequently,

$$\partial f(z) \subset \bigcap_{V\in\mathcal{V}} \left(\operatorname{co}\left(\bigcup_{i\in T}\partial_\varepsilon f_i(z)\right)+V\right) = \overline{\operatorname{co}}\left(\bigcup_{i\in T}\partial_\varepsilon f_i(z)\right).$$

Finally, the conclusion follows by taking the intersection over $\varepsilon > 0$. ∎

4. Other calculus rules. Throughout this section, we consider two convex functions $f : Y \to \overline{\mathbb{R}}$ and $g : X \to \overline{\mathbb{R}}$, where X and Y are (separated) real locally convex spaces, and a continuous affine mapping $A : X \to Y$ defined by

$$Ax = A_0x + b,$$

where A_0 is the linear part of A and $b \in Y$. We denote by A_0^* the adjoint operator of A_0.

We show that our rule given in Theorem 4, providing formulas for the subdifferential of the supremum function, also gives calculus rules for other operations expressed by means of the convex function $g+f\circ A$. The resulting formulas are not new, but our aim here is to highlight the unifying character of Theorem 4, which also yields alternative proofs that do not rely on the commonly used approach based on conjugation theory [23].

At the first stage, we derive in the following theorem a slight extension of the Hiriart-Urruty–Phelps formula [11]. This allows us to express the subdifferential of $g + f \circ A$ in terms of the approximate subdifferentials of f and g. For comparative purposes, when the involved spaces X and Y are Banach, this is equivalent to writing $\partial(g + f \circ A)$ in terms of the subdifferentials of the data functions at nearby points (e.g., [14], [18], and [25]).

THEOREM 13. *Let us consider two convex functions $f : Y \to \overline{\mathbb{R}}$ and $g : X \to \overline{\mathbb{R}}$, where X and Y are (separated) real locally convex spaces, and a continuous affine mapping $A : X \to Y$, i.e., $Ax = A_0x + b$, where A_0 is the linear part of A and $b \in Y$. Assume that the following holds (when it makes sense):*

$$\operatorname{cl}(g + f \circ A) = (\operatorname{cl} g) + (\operatorname{cl} f) \circ A.$$

Then, for every $z \in X$, we have that

$$\partial(g + f \circ A)(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\left(\partial_\varepsilon g(z) + A_0^*\partial_\varepsilon f(Az)\right),$$

where A_0^* is the adjoint operator of A_0.

Proof. Let us set $\varphi := g + f \circ A$, and $\psi := (\operatorname{cl} g) + (\operatorname{cl} f) \circ A$. The inclusion " $\supset$ " always holds, and consequently, it suffices to establish the opposite one when $\partial\varphi(z) \neq \emptyset$. In such a case, by (11) and the current assumption, we have

$$(\operatorname{cl} g)(z) + (\operatorname{cl} f)(Az) = (\operatorname{cl}\varphi)(z) = \varphi(z) = g(z) + f(Az) \in \mathbb{R},$$

and

$$\partial\varphi(z) = \partial(\operatorname{cl}\varphi)(z) = \partial((\operatorname{cl} g) + (\operatorname{cl} f) \circ A)(z) = \partial\psi(z). \tag{27}$$

Hence, $(\operatorname{cl} g)(z) = g(z) \in \mathbb{R}$ and $(\operatorname{cl} f)(Az) = f(Az) \in \mathbb{R}$, and so $\operatorname{cl} f \in \Gamma(Y)$ and $\operatorname{cl} g \in \Gamma(X)$. Furthermore, according to (10), for every $\varepsilon \geq 0$, one has $\partial_\varepsilon(\operatorname{cl} g)(z) = \partial_\varepsilon g(z)$ and $\partial_\varepsilon(\operatorname{cl} f)(Az) = \partial_\varepsilon f(Az)$.

Now, by the Legendre–Fenchel linearization of $\operatorname{cl} f$, we write that for every $x \in X$,

$$\begin{aligned}\psi(x) &= (\operatorname{cl} g)(x) + (\operatorname{cl} f)(Ax)\\ &= (\operatorname{cl} g)(x) + \sup\{\langle y^*, Ax\rangle - f^*(y^*) \mid y^* \in \operatorname{dom} f^*\}\\ &= \sup\{(\operatorname{cl} g)(x) + \langle A_0^* y^*, x\rangle + \langle y^*, b\rangle - f^*(y^*) \mid y^* \in \operatorname{dom} f^*\}.\end{aligned}$$

So, applying Theorem 4 (with $\alpha = 1$) together with Corollary 9(i),

$$\partial\psi(z) = \bigcap_{L\in\mathcal{F}_z,\varepsilon>0} \operatorname{cl}\left(\operatorname{co}\left(\bigcup_{y^*\in T_\varepsilon(z)} \left(\partial_\varepsilon(\operatorname{cl} g)(z) + A_0^* y^*\right)\right) + \mathrm{N}_{L\cap\operatorname{dom}\psi}(z)\right),$$

where, by (12),

$$\begin{aligned}T_\varepsilon(z) &= \{y^* \in Y^* \mid (\operatorname{cl} g)(z) + \langle A_0^* y^*, z\rangle + \langle y^*, b\rangle - f^*(y^*) \geq \psi(z) - \varepsilon\}\\ &= \{y^* \in Y^* \mid (\operatorname{cl} f)(Az) + f^*(y^*) \leq \langle y^*, Az\rangle + \varepsilon\} = \partial_\varepsilon(\operatorname{cl} f)(Az).\end{aligned}$$

Hence

$$\partial\psi(z) = \bigcap_{L\in\mathcal{F}_z,\varepsilon>0} \operatorname{cl}\left(\partial_\varepsilon(\operatorname{cl} g)(z) + A_0^*\partial_\varepsilon f(Az) + \mathrm{N}_{L\cap\operatorname{dom}\psi}(z)\right).$$

Now let $V \in \mathcal{V}$ (that is, V is a convex θ–neighborhood in X^*), and let $L \in \mathcal{F}_z$ be such that $L^\perp \subset V$. Then, for every $\varepsilon > 0$, from Lemma 11(i) we get

$$\mathrm{N}_{L\cap\operatorname{dom}\psi}(z) = \left[\operatorname{cl}\left(\partial_\varepsilon(\operatorname{cl} g)(z) + A_0^*\partial_\varepsilon(\operatorname{cl} f)(Az) + L^\perp\right)\right]_\infty,$$

so that, by taking into account (3), (27) leads us to

$$\begin{aligned}\partial\varphi(z) = \partial\psi(z) &\subset \operatorname{cl}\left(\operatorname{cl}\left(\partial_\varepsilon(\operatorname{cl} g)(z) + A_0^*\partial_\varepsilon(\operatorname{cl} f)(Az) + L^\perp\right)\right.\\ &\qquad \left. + \left[\operatorname{cl}\left(\partial_\varepsilon(\operatorname{cl} g)(z) + A_0^*\partial_\varepsilon(\operatorname{cl} f)(Az) + L^\perp\right)\right]_\infty\right)\\ &= \operatorname{cl}\left(\partial_\varepsilon(\operatorname{cl} g)(z) + A_0^*\partial_\varepsilon(\operatorname{cl} f)(Az) + L^\perp\right)\\ &\subset \partial_\varepsilon(\operatorname{cl} g)(z) + A_0^*\partial_\varepsilon(\operatorname{cl} f)(Az) + V\\ &= \partial_\varepsilon g(z) + A_0^*\partial_\varepsilon f(Az) + V,\end{aligned}$$

and consequently,

$$\partial\varphi(z) \subset \textstyle\bigcap_{\varepsilon>0}\bigcap_{V\in\mathcal{V}}\left(\partial_\varepsilon g(z) + A_0^*\partial_\varepsilon f(Az) + V\right) = \bigcap_{\varepsilon>0}\operatorname{cl}\left(\partial_\varepsilon g(z) + A_0^*\partial_\varepsilon f(Az)\right).$$

The proof is complete. □

Taking f and g to be lsc in Theorem 13 we obtain the following result of Hiriart-Urruty–Phelps [9].

COROLLARY 14. *Let f, g, and A be as in Theorem* 13. *If f and g are, in addition, lsc, then for every $z \in X$, we have that*

$$\partial(g + f\circ A)(z) = \bigcap_{\varepsilon>0} \operatorname{cl}\left(\partial_\varepsilon g(z) + A_0^*\partial_\varepsilon f(Az)\right).$$

In Corollary 16 below we derive the well-known Moreau–Rockafellar's formula on the sum (e.g., [19], p. 47). But, first, we need the following lemma, which gives us information about the closure of convex functions. Its proof does not appeal to the framework of Fenchel duality.

LEMMA 15. *Let $f : Y \to \overline{\mathbb{R}}$ and $g : X \to \overline{\mathbb{R}}$ be convex functions, and $A : X \to Y$ be a continuous affine mapping. Assume that f is finite and continuous at Ax_0 for some $x_0 \in (\operatorname{dom} g) \cap A^{-1}(\operatorname{dom} f)$. Then*

$$\operatorname{cl}(f \circ A + g) = (\operatorname{cl} f) \circ A + (\operatorname{cl} g).$$

Proof. Because $\operatorname{cl} f \leq f$, $\operatorname{cl} g \leq g$, and $(\operatorname{cl} f) \circ A + (\operatorname{cl} g)$ is lsc, one has $(\operatorname{cl} f) \circ A + (\operatorname{cl} g) \leq \operatorname{cl}(f \circ A + g)$. Moreover, in our hypothesis f and $\operatorname{cl} f$ are proper. To establish the converse inequality it suffices to take

$$x \in (\operatorname{dom}(\operatorname{cl} g)) \cap A^{-1}(\operatorname{dom}(\operatorname{cl} f)) \subset (\operatorname{dom}(\operatorname{cl} g)) \cap A^{-1}(\operatorname{cl}(\operatorname{dom} f))$$

such that $(\operatorname{cl}(f \circ A + g))(x) > -\infty$.

Let us fix $\lambda \in]0, 1[$ and set $x_\lambda := \lambda x_0 + (1-\lambda)x$ $[\in (\operatorname{dom}(\operatorname{cl} g)) \cap A^{-1}(\operatorname{cl}(\operatorname{dom} f))]$. Since $Ax_0 \in \operatorname{int}(\operatorname{dom} f)$ and $Ax \in \operatorname{cl}(\operatorname{dom} f)$, (4) yields

$$Ax_\lambda = A(\lambda x_0 + (1-\lambda)x) = \lambda Ax_0 + (1-\lambda)Ax \in \operatorname{int}(\operatorname{dom} f),$$

and so f is continuous at Ax_λ. Now let $(x_i)_{i\in I} \subset X$ be a net which converges to x and satisfies $(\operatorname{cl} g)(x_\lambda) = \lim_i g(\lambda x_0 + (1-\lambda)x_i)$. Since $\lim_i f(\lambda Ax_0 + (1-\lambda)Ax_i) = f(Ax_\lambda) = (\operatorname{cl} f)(Ax_\lambda)$, we obtain that

$$\begin{aligned}(\operatorname{cl}(f \circ A + g))(x_\lambda) &\leq \liminf_i \big(f(\lambda Ax_0 + (1-\lambda)Ax_i) + g(\lambda x_0 + (1-\lambda)x_i)\big)\\ &= (\operatorname{cl} f)(\lambda Ax_0 + (1-\lambda)Ax) + (\operatorname{cl} g)(x_\lambda)\\ &\leq \lambda\big((\operatorname{cl} f)(Ax_0) + (\operatorname{cl} g)(x_0)\big) + (1-\lambda)\big((\operatorname{cl} f)(Ax) + (\operatorname{cl} g)(x)\big).\end{aligned}$$

Whence, as $\lambda \downarrow 0$ we get

$$\liminf_{\lambda\to 0}(\operatorname{cl}(f \circ A + g))(x_\lambda) \leq (\operatorname{cl} f)(Ax) + (\operatorname{cl} g)(x),$$

and so $(\operatorname{cl}(f \circ A + g))(x) \leq (\operatorname{cl} f)(Ax) + (\operatorname{cl} g)(x)$. The proof is complete. ∎

COROLLARY 16. *Let $f : Y \to \overline{\mathbb{R}}$ and $g : X \to \overline{\mathbb{R}}$ be convex functions, and $A : X \to Y$ be a continuous affine mapping with linear part A_0. Assume that f is finite and continuous at Ax_0 for some $x_0 \in (\operatorname{dom} g) \cap A^{-1}(\operatorname{dom} f)$. Then, for every $z \in X$, we have that*

$$\partial(f \circ A + g)(z) = A_0^* \partial f(Az) + \partial g(z).$$

Proof. It is enough to show that $\partial(f \circ A + g)(z) \subset A_0^* \partial f(Az) + \partial g(z)$. Taking into account Theorem 13 and Lemma 15, it suffices to prove that

$$\bigcap_{\varepsilon>0} \operatorname{cl}\big(A_0^* \partial_\varepsilon f(Az) + \partial_\varepsilon g(z)\big) \subset A_0^* \partial f(Az) + \partial g(z) \tag{28}$$

for the nontrivial case $\partial(g + f \circ A)(z) \neq \emptyset$; hence $z \in (\operatorname{dom} g) \cap A^{-1}(\operatorname{dom} f)$ and $g(z), f(Az) \in \mathbb{R}$.

Indeed, for x^* in the set from the left-hand side of (28) and for each $r = 1, 2, \ldots$, there are nets $(v_i^*)_{i\in I} \subset \partial_{1/r} f(Az)$ and $(u_i^*)_{i\in I} \subset \partial_{1/r} g(z)$ such that $u_i^* + A_0^* v_i^* \to x^*$; thus we may assume that, for every $i \in I$,

$$\langle u_i^* + A_0^* v_i^*, z - x_0\rangle \leq \langle x^*, z - x_0\rangle + 1.$$

Since $u_i^* \in \partial_{1/r} g(z)$ and $r \geq 1$, this implies that

$$\langle v_i^*, Az - Ax_0 \rangle \leq \langle u_i^*, x_0 - z \rangle + \langle x^*, z - x_0 \rangle + 1 \leq g(x_0) - g(z) + \langle x^*, z - x_0 \rangle + 2.$$

Because f is continuous at Ax_0, there exists a symmetric θ–neighborhood $U \subset Y$ such that $\sup_{y \in U} f(y + Ax_0) \leq f(Ax_0) + 1$. Hence, for all $y \in U$,

$$\begin{aligned} \langle v_i^*, y \rangle &= \langle v_i^*, Az - Ax_0 \rangle + \langle v_i^*, y + Ax_0 - Az \rangle \\ &\leq \langle v_i^*, Az - Ax_0 \rangle + f(y + Ax_0) - f(Az) + 1 \\ &\leq g(x_0) - g(z) + \langle x^*, z - x_0 \rangle + f(Ax_0) - f(Az) + 4 \leq \mu \end{aligned}$$

for some $\mu > 0$. This shows that $\inf\{\langle v_i^*, y \rangle \mid y \in U\} \geq -\mu$, and so $(v_i^*)_{i \in I} \subset (\mu^{-1} U)^\circ$. Hence, by Alaoglu–Bourbaki's Theorem we may suppose w.l.o.g. that $(v_i^*)_{i \in I}$ and $(u_i^*)_{i \in I}$ w^*–converge to some $v_r^* \in \partial_{1/r} f(Az) \cap (\mu^{-1} U)^\circ$ and $u_r^* \in \partial_{1/r} g(z)$, respectively, and so $x^* = u_r^* + A_0^* v_r^*$. By the same argument we may suppose that $(v_r^*)_r$ and $(u_r^*)_r$ also w^*–converge to some $v^* \in \partial f(Az)$ and $u^* \in \partial g(z)$ and $x^* = u^* + A_0^* v^* \in \partial g(z) + A_0^* \partial f(Az)$. The proof is complete. □

Concluding remarks. (1) The preceding proof still works under more general regularity conditions, as those studied in Theorem 2.8.3 of [32].

(2) It should be noted that Lemma 5 can be easily deduced from Corollary 2.6.3 of [32], which is itself an extension of Corollary 14.

(3) Our main result in section 3 gives the formula for the subdifferential of the pointwise supremum $f := \sup_{t \in T} f_t$ of an arbitrary family of convex functions $f_t : X \to \overline{\mathbb{R}}$, $t \in T$. An important special case, which commonly appears in applications, corresponds to the so-called continuous model (e.g., [13], [24], and [32, Thm. 2.4.18]); see also [6]. There, the index set T is a (separated) compact space, and the parametrized mappings $t \to f_t(x)$ are upper semicontinuous for every $x \in X$. Such a situation is intermediate between the finite ([29]) and the general cases, and it is approached in a forthcoming paper.

(4) For further examples (in $\mathbb{R}^n$) in relation with our formula given in Theorem 4, the reader is addressed to references [6] and [7].

A CLASS OF INTERIOR PROXIMAL-LIKE ALGORITHMS FOR CONVEX SECOND-ORDER CONE PROGRAMMING*

SHAOHUA PAN† AND JEIN-SHAN CHEN‡

Abstract. We propose a class of interior proximal-like algorithms for the second-order cone program, which is to minimize a closed proper convex function subject to general second-order cone constraints. The class of methods uses a distance measure generated by a twice continuously differentiable strictly convex function on $(0, +\infty)$, and includes as a special case the entropy-like proximal algorithm [Eggermont, *Linear Algebra Appl.*, 130 (1990), pp. 25–42], which was originally proposed for minimizing a convex function subject to nonnegative constraints. Particularly, we consider an approximate version of these methods, allowing the inexact solution of subproblems. Like the entropy-like proximal algorithm for convex programming with nonnegative constraints, we, under some mild assumptions, establish the global convergence expressed in terms of the objective values for the proposed algorithm, and we show that the sequence generated is bounded, and every accumulation point is a solution of the considered problem. Preliminary numerical results are reported for two approximate entropy-like proximal algorithms, and numerical comparisons are also made with the merit function approach [Chen and Tseng, *Math. Program.*, 104 (2005), pp. 293–327], which verify the effectiveness of the proposed method.

Key words. proximal method, measure of distance, second-order cone, second-order cone-convexity

1. Introduction.

We consider the following convex second-order cone programming (CSOCP):

$$\begin{array}{l} \min\ f(\zeta) \\ \text{subject to (s.t.)}\ \ A\zeta + b \succeq_{\mathcal{K}} 0, \end{array} \tag{1}$$

where $f : \mathbb{R}^m \to (-\infty, +\infty]$ is a closed proper convex function; A is an $n \times m$ matrix, with $n \geq m$; b is a vector in $\mathbb{R}^n$; $x \succeq_{\mathcal{K}} 0$ means $x \in \mathcal{K}$; and $\mathcal{K}$ is the Cartesian product of second-order cones (SOCs), also called Lorentz cones [14]. In other words,

$$\mathcal{K} = \mathcal{K}^{n_1} \times \mathcal{K}^{n_2} \times \cdots \times \mathcal{K}^{n_N}, \tag{2}$$

where $N, n_1, \ldots, n_N \geq 1$, $n_1 + n_2 + \cdots + n_N = n$, and

$$\mathcal{K}^{n_i} := \left\{(x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n_i - 1} \mid x_1 \geq \|x_2\|\right\},$$

with $\|\cdot\|$ denoting the Euclidean norm and $\mathcal{K}^1$ denoting the set of nonnegative reals $\mathbb{R}_+$. The CSOCP, as an extension of the standard second-order cone programming, has a wide range of applications from engineering, control, and finance to robust optimization and combinatorial optimization; see [1, 21, 23] and references therein.

Recently, the second-order cone programming (SOCP) and the SOC complementarity problem have received much attention in optimization. There exist many methods for solving the CSOCP, including the smoothing methods [10, 15], the smoothing-regularization method [17], the semismooth Newton method [22], and the merit function approach [8]. All of these methods are proposed by using some SOC complementarity function or merit function to reformulate the KKT optimality conditions of the CSOCP as a nonsmooth (or smoothing) system of equations or an unconstrained minimization problem. Notice that the CSOCP is a typical convex programming problem which has extensive applications. But, to the best of our knowledge, there are few convex programming methods developed for (or extended to) the CSOCP except the interior point method [33]. Hence, it is worthy to explore other types of convex programming methods for the CSOCP which are different from the aforementioned methods.

One such method is the proximal point algorithm for minimizing a convex function $f(\zeta)$ over $\mathbb{R}^m$, which generates a sequence $\{\zeta^k\}$ by the following iterative scheme:

$$\zeta^k = \operatorname*{argmin}_{\zeta\in\mathbb{R}^m}\left\{f(\zeta) + \frac{1}{2\mu_k}\|\zeta - \zeta^{k-1}\|^2\right\}, \tag{3}$$

where μ_k is a sequence of positive numbers. The method was originally introduced by Martinet [24] with the Moreau proximal approximation of f (see [25]), and then further developed by Rockafellar [30, 31]. Later, some researchers [5, 13, 32] proposed and studied nonquadratic proximal point algorithms by replacing the quadratic distance in (3) with a Bregman distance or an entropy-like distance.

The entropy-like proximal algorithm was designed for minimizing a convex function $f(\zeta)$ subject to nonnegative constraints $\zeta \geq 0$. In [12], Eggermont first introduced the Kullback–Leibler relative entropy, defined by

$$^1d(\zeta,\xi) = \sum_{i=1}^m \zeta_i \ln(\zeta_i/\xi_i) + \zeta_i - \xi_i \quad \forall \zeta \geq 0,\ \xi > 0,$$

and established the following entropy-like proximal point algorithm:

$$\begin{cases} \zeta^0 > 0, \\ \zeta^k = \operatorname*{argmin}_{\zeta>0}\left\{f(\zeta) + {\mu_k}^{-1} d(\zeta^{k-1},\zeta)\right\}. \end{cases} \tag{4}$$

Later, Teboulle [32] proposed to replace the usual Kullback–Leibler relative entropy with a new type of distance-like function, called φ-divergence, to define the entropy-like proximal map. Let $\varphi : \mathbb{R} \to (-\infty, +\infty]$ be a closed proper convex function satisfying certain conditions (see [18, 32]). The φ-divergence induced by φ is defined as

$$d_\varphi(\zeta,\xi) := \sum_{i=1}^m \xi_i \varphi(\zeta_i/\xi_i). \tag{5}$$

Based on the φ-divergence, Isume et al. [18, 19] generalized Eggermont's algorithm as

$$\begin{cases} \zeta^0 > 0, \\ \zeta^k = \operatorname*{argmin}_{\zeta>0}\left\{f(\zeta) + {\mu_k}^{-1} d_\varphi(\zeta,\zeta^{k-1})\right\}, \end{cases} \tag{6}$$

[1] The convention of $0 \ln 0 = 0$ is used throughout this paper.

and they obtained the convergence theorems under weaker assumptions. Clearly, when

$$\varphi(t) = -\ln t + t - 1 \quad (t > 0),$$

we have that $d_\varphi(\zeta, \xi) = d(\xi, \zeta)$, and consequently the algorithm reduces to Eggermont's.

Observing that the proximal-like algorithm (6) associated with $\varphi(t) = -\ln t + t - 1$ inherits the features of the interior point method as well as the proximal point method, Auslender [2] extended the algorithm to general linearly constrained convex minimization problems and variational inequalities on polyhedra. Then, is it possible to extend the algorithm to nonpolyhedra symmetric conic optimization problems and establish the corresponding convergence results? In this paper, we will explore its extension to the setting of SOCs and establish a class of interior proximal-like algorithms for the CSOCP. We should mention that the algorithm (6) with the entropy function $t \ln t - t + 1$ $(t \geq 0)$ was recently extended to convex semidefinite programming [11].

For simplicity, in the rest of this paper, we focus on the case where $\mathcal{K} = \mathcal{K}^n$. All of the analysis can be carried over to the general case where $\mathcal{K}$ has the direct product structure as (2). It is known that $\mathcal{K}^n$ is a closed convex cone with the interior given by

$$\operatorname{int}(\mathcal{K}^n) := \left\{(x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1} \mid x_1 > \|x_2\|\right\}.$$

For any x, y in $\mathbb{R}^n$, we write $x \succeq_{\mathcal{K}^n} y$ if $x - y \in \mathcal{K}^n$; and write $x \succ_{\mathcal{K}^n} y$ if $x - y \in \operatorname{int}(\mathcal{K}^n)$. In other words, we have that $x \succeq_{\mathcal{K}^n} 0$ if and only if $x \in \mathcal{K}^n$ and $x \succ_{\mathcal{K}^n} 0$ if and only if $x \in \operatorname{int}(\mathcal{K}^n)$. We denote $\mathcal{F}$ by the constraint set of the CSOCP, i.e.,

$$\mathcal{F} := \left\{\zeta \in \mathbb{R}^m \mid A\zeta + b \succeq_{\mathcal{K}^n} 0\right\}. \tag{7}$$

It is not difficult to verify that $\mathcal{F}$ is convex, and its interior $\operatorname{int}(\mathcal{F})$ is given by

$$\operatorname{int}(\mathcal{F}) := \left\{\zeta \in \mathbb{R}^m \mid A\zeta + b \succ_{\mathcal{K}^n} 0\right\}.$$

The proximal-like algorithm that we propose for the CSOCP is defined as follows:

$$\begin{cases} \zeta^0 \in \operatorname{int}(\mathcal{F}), \\ \zeta^k = \underset{\zeta \in \operatorname{int}(\mathcal{F})}{\operatorname{argmin}} \left\{ f(\zeta) + \mu_k^{-1} D(A\zeta + b, A\zeta^{k-1} + b) \right\}, \end{cases} \tag{8}$$

where $D : \mathbb{R}^n \times \mathbb{R}^n \to (-\infty, +\infty]$ is a closed proper convex function generated by a class of twice continuously differentiable strictly convex functions on $(0, +\infty)$, and the specific expression is given in section 3. The class of distance measures, as will be shown in section 3, includes as a special case the natural extension of $d_\varphi(x, y)$, with $\varphi(t) = -\ln t + t - 1$ to the SOCs. For the proximal-like algorithm (8), we particularly consider an approximate version which allows an inexact minimization of the subproblem (8) and establish its global convergence results under some mild assumptions. Numerical results are reported for two approximate entropy-like proximal algorithms, which verify the effectiveness of the proximal method proposed. In addition, numerical comparisons with the merit function approach [8] indicate that the condition number of the Hessian matrix $\nabla^2 f(\zeta)$ has a great influence on the numerical performance of the proximal-like algorithm and the merit function approach, but the

former seems to have no direct relation with the dense degree of test problems, but the latter tends to more function evaluations as the density increases.

The outline of this paper is as follows. In section 2, we review some basic concepts and properties associated with SOCs. In section 3, we state the definition of $D(x,y)$ and present some specific examples. Some favorable properties of $D(x,y)$ are investigated in section 4. In section 5, we describe an approximate proximal-like algorithm allowing inexact minimization in (8) and establish the global convergence of the algorithm. In section 6, we report our numerical experiences for the proposed proximal-like algorithm by solving some convex SOCPs. Finally, we conclude this paper in section 7.

Throughout this paper, I represents an identity matrix of suitable dimension, and $\mathbb{R}^n$ denotes the space of n-dimensional real column vectors. For a differentiable function h on $\mathbb{R}$, we denote h', h'', and h''' by its first, second, and third derivative, respectively. Given a set S, we denote $\bar{S}, \mathrm{int}(S)$, and $\mathrm{bd}(S)$ by the closure, the interior and the boundary of S, respectively. Note that a function is closed if and only if it is lower semicontinuous, and a function is proper if $f(\zeta) < \infty$ for at least one $\zeta \in \mathbb{R}^m$ and $f(\zeta) > -\infty$ for all $\zeta \in \mathbb{R}^m$. For a closed proper convex function $f : \mathbb{R}^m \to (-\infty, +\infty]$, we denote its domain by $\mathrm{dom} f := \{\, \zeta \in \mathbb{R}^m \mid f(\zeta) < \infty\}$ and the subdifferential of f at $\widehat{\zeta}$ by

$$\partial f(\widehat{\zeta}) := \left\{ w \in \mathbb{R}^m \mid f(\zeta) \geq f(\widehat{\zeta}) + \langle w, \zeta - \widehat{\zeta} \rangle \ \forall \zeta \in \mathbb{R}^m \right\}.$$

If f is differentiable at ζ, the notation $\nabla f(\zeta)$ represents the gradient at ζ of f.

2. Preliminaries. This section recalls some basic concepts and preliminary results related to SOCs that will be used in the subsequent analysis. For any $x = (x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$ and $y = (y_1, y_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$, we define their *Jordan product* as

$$x \circ y := (\langle x, y \rangle,\ y_1 x_2 + x_1 y_2). \tag{9}$$

We write x^2 to mean $x \circ x$ and write $x + y$ to mean the usual componentwise addition of vectors. Then $\circ$, $+$, and $e = (1, 0, \ldots, 0)^T \in \mathbb{R}^n$ have the following basic properties (see [14, 15]): (1) $e \circ x = x$ for all $x \in \mathbb{R}^n$. (2) $x \circ y = y \circ x$ for all $x, y \in \mathbb{R}^n$. (3) $x \circ (x^2 \circ y) = x^2 \circ (x \circ y)$ for all $x, y \in \mathbb{R}^n$. (4) $(x+y) \circ z = x \circ z + y \circ z$ for all $x, y, z \in \mathbb{R}^n$. The Jordan product is not associative. For example, for $n = 3$, let $x = (1, -1, 1)$ and $y = z = (1, 0, 1)$, then we have that $(x \circ y) \circ z = (4, -1, 4) \neq x \circ (y \circ z) = (4, -2, 4)$. However, it is power associated, i.e., $x \circ (x \circ x) = (x \circ x) \circ x$ for all $x \in \mathbb{R}^n$. Thus, we may, without fear of ambiguity, write x^m for the product of m copies of x and $x^{m+n} = x^m \circ x^n$ for all positive integers m and n. We stipulate that $x^0 = e$. Besides, $\mathcal{K}^n$ is not closed under Jordan product. For example, $x = (1, 1, 0), y = (2, -1, 3) \in \mathcal{K}^n$, but $x \circ y = (1, 1, 3) \notin \mathcal{K}^n$.

For each $x = (x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$, the *determinant* and the *trace* of x are defined by

$$\det(x) = x_1^2 - \|x_2\|^2, \quad \mathrm{tr}(x) = 2x_1. \tag{10}$$

In general, $\det(x \circ y) \neq \det(x)\det(y)$ unless $x_2 = \alpha y_2$ for some $\alpha \in \mathbb{R}$. A vector $x = (x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$ is said to be *invertible* if $\det(x) \neq 0$. If x is invertible, then there exists a unique $y = (y_1, y_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$ satisfying $x \circ y = y \circ x = e$. We call

this y the inverse of x and denote it by x^{-1}. In fact, we have that

$$x^{-1} = \frac{1}{x_1^2 - \|x_2\|^2}(x_1, -x_2) = \frac{1}{\det(x)}(\mathrm{tr}(x)e - x). \tag{11}$$

Hence, $x \in \mathrm{int}(\mathcal{K}^n)$ if and only if $x^{-1} \in \mathrm{int}(\mathcal{K}^n)$, and $(x^k)^{-1}$ is well-defined if $x \in \mathrm{int}(\mathcal{K}^n)$.

In the following, we recall from [15] that each $x = (x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$ admits a spectral factorization associated with $\mathcal{K}^n$ of the form

$$x = \lambda_1(x) \cdot u_x^{(1)} + \lambda_2(x) \cdot u_x^{(2)},$$

where $\lambda_i(x)$ and $u_x^{(i)}$ for $i = 1, 2$ are the spectral values and the associated spectral vectors of x, respectively, given by

$$\begin{aligned} \lambda_i(x) &= x_1 + (-1)^i \|x_2\|, \\ u_x^{(i)} &= \begin{cases} \frac{1}{2}\left(1,\ (-1)^i \frac{x_2}{\|x_2\|}\right) & \text{if } x_2 \neq 0; \\ \frac{1}{2}\left(1,\ (-1)^i \bar{x}_2\right) & \text{if } x_2 = 0, \end{cases} \end{aligned} \tag{12}$$

with $\bar{x}_2$ being any vector in $\mathbb{R}^{n-1}$ such that $\|\bar{x}_2\| = 1$. If $x_2 \neq 0$, then the factorization is unique. The spectral decomposition along with the Jordan algebra associated with SOC has some basic properties, whose proofs can be found in [14, 15]. Here, we list four of them that will often be used in the subsequent sections.

PROPERTY 2.1. *For any $x = (x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$ with the spectral values $\lambda_1(x), \lambda_2(x)$ and spectral vectors $u_x^{(1)}, u_x^{(2)}$ given as in* (12)*, the following results hold:*

(a) *$u_x^{(1)}$ and $u_x^{(2)}$ are orthogonal under Jordan product and have length $1/\sqrt{2}$, i.e.,*

$$u_x^{(1)} \circ u_x^{(2)} = 0, \quad \|u_x^{(1)}\| = \|u_x^{(2)}\| = 1/\sqrt{2}.$$

(b) *$u_x^{(1)}$ and $u_x^{(2)}$ are idempotent under Jordan product, i.e., $u_x^{(i)} \circ u_x^{(i)} = u_x^{(i)}$ for $i = 1, 2$.*

(c) *The determinant, the trace, and the Euclidean norm of x can be denoted by $\lambda_1(x), \lambda_2(x)$:*

$$\det(x) = \lambda_1(x)\lambda_2(x), \quad \mathrm{tr}(x) = \lambda_1(x) + \lambda_2(x), \quad \|x\|^2 = \frac{[\lambda_1(x)]^2 + [\lambda_2(x)]^2}{2}.$$

(d) *$\lambda_1(x)$ are nonnegative (positive) if and only if $x \in \mathcal{K}^n$ ($x \in \mathrm{int}(\mathcal{K}^n)$).*

LEMMA 2.1.

(a) *For any $x \in \mathbb{R}^n$, $x \succeq_{\mathcal{K}^n} 0 \Longleftrightarrow \langle x, y\rangle \geq 0$ for any $y \succeq_{\mathcal{K}^n} 0$.*

(b) *For any $x \in \mathbb{R}^n$, $x \succ_{\mathcal{K}^n} 0 \Longleftrightarrow \langle x, y\rangle > 0$ for any $y \succeq_{\mathcal{K}^n} 0$ and $y \neq 0$.*

(c) *For any $x, y \in \mathbb{R}^n$, let $\lambda_i(x)$ and $\lambda_i(y)$ for $i = 1, 2$ be their spectral values. Then,*

$$\lambda_1(x)\lambda_2(y) + \lambda_2(x)\lambda_1(y) \leq \mathrm{tr}(x \circ y) \leq \lambda_1(x)\lambda_1(y) + \lambda_2(x)\lambda_2(y).$$

Proof. Part (a) is direct by the self-duality of $\mathcal{K}^n$, and we next consider parts (b) and (c).

(b) Let $x = (x_1, x_2), y = (y_1, y_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$. The necessity follows from

$$\langle x, y\rangle = x_1 y_1 + x_2^T y_2 \geq x_1 y_1 - \|x_2\|\|y_2\| \geq x_1 y_1 - y_1\|x_2\| = y_1(x_1 - \|x_2\|) > 0,$$

where the first inequality is by Cauchy–Schwartz, the second is due to $y \succeq_{\mathcal{K}^n} 0$, and the third is since $x \succ_{\mathcal{K}^n} 0$ and $y \neq 0,\ y \succeq_{\mathcal{K}^n} 0$. Next, we prove the sufficiency. First, from $\langle x, y\rangle > 0$ for any $y \succeq_{\mathcal{K}^n} 0$ and $y \neq 0$, we deduce that $x_1 > 0$ by setting $y = e$. If $x_2 = 0$, then the conclusion follows. If $x_2 \neq 0$, then we set $y = (1, -\frac{x_2}{\|x_2\|})$. Clearly, $y \succeq_{\mathcal{K}^n} 0,\ y \neq 0$, and $0 < \langle x, y\rangle = x_1 - \|x_2\| = \lambda_1(x)$. By Property 2.1 (d), we then have $x \succ_{\mathcal{K}^n} 0$.

(c) For any $x = (x_1, x_2), y = (y_1, y_2) \in \mathbb{R} \times \mathbb{R}^{n-1}$, by (12) we can compute that

$$\lambda_1(x)\lambda_2(y) + \lambda_2(x)\lambda_1(y) = 2x_1y_1 - 2\|x_2\|\|y_2\| \leq 2(x_1y_1 + x_2^Ty_2) = \mathrm{tr}(x \circ y),$$
$$\lambda_1(x)\lambda_1(y) + \lambda_2(x)\lambda_2(y) = 2x_1y_1 + 2\|x_2\|\|y_2\| \geq 2(x_1y_1 + x_2^Ty_2) = \mathrm{tr}(x \circ y)\ .$$

Combining with the two inequalities above then yields the desired result. □

For any $h : \mathbb{R} \to \mathbb{R}$, the following vector-valued function was considered in [6, 15]:

$$h^{\mathrm{soc}}(x) = h[\lambda_1(x)] \cdot u_x^{(1)} + h[\lambda_2(x)] \cdot u_x^{(2)} \quad \forall x = (x_1, x_2) \in \mathbb{R} \times \mathbb{R}^{n-1}. \tag{13}$$

If h is defined only on a subset of $\mathbb{R}$, then h^{soc} is defined on the corresponding subset of $\mathbb{R}^n$. The definition in (13) is unambiguous whether $x_2 \neq 0$ or $x_2 = 0$. For the vector-valued function h^{soc} induced by h, we have the following results.

LEMMA 2.2. *Given a function $h : \mathrm{I}_{\mathbb{R}} \to \mathbb{R}$, let $h^{\mathrm{soc}} : S \to \mathbb{R}^n$ be the vector-valued function induced by h as in* (13)*, where $\mathrm{I}_{\mathbb{R}} \subseteq \mathbb{R}$ and $S \subseteq \mathbb{R}^n$. Then, the following results hold:*

(a) *For any $x \in S$, $\lambda_i[h^{\mathrm{soc}}(x)] = h[\lambda_i(x)]$ for $i = 1, 2$ and $\mathrm{tr}[h^{\mathrm{soc}}(x)] = \sum_{i=1}^2 h[\lambda_i(x)]$.*

(b) *If h is continuously differentiable on $\mathrm{I}_{\mathbb{R}}$, then h^{soc} is continuously differentiable on the set S, and its transposed Jacobian at $x = (x_1, x_2) \in S$ is given by the formula*

$$\nabla h^{\mathrm{soc}}(x) = h'(x_1)I \tag{14}$$

if $x_2 = 0$, and otherwise

$$\nabla h^{\mathrm{soc}}(x) = \begin{bmatrix} b & c\dfrac{x_2^T}{\|x_2\|} \\ c\dfrac{x_2}{\|x_2\|} & aI + (b-a)\dfrac{x_2x_2^T}{\|x_2\|^2} \end{bmatrix}, \tag{15}$$

where

$$a = \frac{h[\lambda_2(x)] - h[\lambda_1(x)]}{\lambda_2(x) - \lambda_1(x)},\ b = \frac{h'[\lambda_2(x)] + h'[\lambda_1(x)]}{2},\ c = \frac{h'[\lambda_2(x)] - h'[\lambda_1(x)]}{2}.$$

(c) *If h is continuously differentiable on $\mathrm{I}_{\mathbb{R}}$, then $\mathrm{tr}[h^{\mathrm{soc}}(x)]$ is continuously differentiable on the set S, and its gradient $\nabla \mathrm{tr}[h^{\mathrm{soc}}(x)] = 2\nabla h^{\mathrm{soc}}(x) \cdot e = 2(h')^{\mathrm{soc}}(x)$.*

(d) *If h is (strictly) convex on $\mathrm{I}_{\mathbb{R}}$, then $\mathrm{tr}[h^{\mathrm{soc}}(x)]$ is (strictly) convex on the set S.*

Proof. (a) The proof is direct by the definition of h^{soc} and the spectral value.

(b) The conclusion follows directly from [15, Propostion 5.2] or [6, Proposition 4].

(c) Since $\mathrm{tr}[h^{\mathrm{soc}}(x)] = 2\langle h^{\mathrm{soc}}(x), e\rangle$, by part (b) $\mathrm{tr}[h^{\mathrm{soc}}(x)]$ is obviously continuously differentiable. Applying the chain rule for the inner product of two functions yields

$$\nabla \mathrm{tr}[h^{\mathrm{soc}}(x)] = 2\nabla h^{\mathrm{soc}}(x) \cdot e,$$

where $\nabla h^{\mathrm{soc}}(x)$ is given by (14)–(15). By a simple computation, it is easy to verify that

$$\nabla h^{\mathrm{soc}}(x) \cdot e = h'[\lambda_1(x)]u_x^{(1)} + h'[\lambda_2(x)]u_x^{(2)} = (h')^{\mathrm{soc}}(x).$$

Combining the last two equalities immediately gives the second part of the conclusions.

(d) The proof is similar to that of [26, Lemma 3.2 (d)], and so we omit it. □

To close this section, we review the definition of SOC-convexity and SOC-monotonicity. The two concepts, such as the matrix-convexity and the matrix-monotonicity in the semidefinite programming, play an important role in the solution methods of SOCPs.

DEFINITION 2.1 (see [7]). *Given a function $h : \mathrm{I}_{\mathbb{R}} \to \mathbb{R}$, let $h^{\mathrm{soc}} : S \to \mathbb{R}^n$ be the vector-valued function defined as in* (13)*, where $\mathrm{I}_{\mathbb{R}} \subseteq \mathbb{R}$ and $S \subseteq \mathbb{R}^n$. Then,*

(a) *h is said to be SOC-monotone of order n on $\mathrm{I}_{\mathbb{R}}$ if for any $x, y \in S$,*

$$x \succeq_{\mathcal{K}^n} y \Longrightarrow h^{\mathrm{soc}}(x) \succeq_{\mathcal{K}^n} h^{\mathrm{soc}}(y).$$

(b) *h is said to be SOC-convex of order n on $\mathrm{I}_{\mathbb{R}}$ if for any $x, y \in S$ and $0 \le \beta \le 1$,*

$$h^{\mathrm{soc}}\Big(\beta x + (1-\beta)y\Big) \preceq_{\mathcal{K}^n} \beta h^{\mathrm{soc}}(x) + (1-\beta)h^{\mathrm{soc}}(y). \tag{16}$$

We say that h is SOC-convex (respectively, SOC-monotone) on $\mathrm{I}_{\mathbb{R}}$ if h is SOC-convex of all order n (respectively, SOC-monotone of all order n) on $\mathrm{I}_{\mathbb{R}}$. A function h is said to be SOC-concave on $\mathrm{I}_{\mathbb{R}}$ whenever $-h$ is SOC-convex on $\mathrm{I}_{\mathbb{R}}$. When h is continuous on $\mathrm{I}_{\mathbb{R}}$, the condition in (16) can be replaced by the more special condition:

$$h^{\mathrm{soc}}\left(\frac{x+y}{2}\right) \preceq_{\mathcal{K}^n} \frac{1}{2}\Big(h^{\mathrm{soc}}(x) + h^{\mathrm{soc}}(y)\Big). \tag{17}$$

Obviously, the set of SOC-monotone functions and the set of SOC-convex functions are both closed under positive linear combinations and under pointwise limits.

3. Distance-like functions in SOCs. In this section, we present the definition of the distance-like function $D(x, y)$ involved in the proximal-like algorithm (8) and some specific examples. Let $\phi : \mathbb{R} \to (-\infty, +\infty]$ be a closed proper convex function with $\mathrm{dom}\phi = [0, +\infty)$ and assume that

(C.1) ϕ is strictly convex on its domain.

(C.2) ϕ is twice continuously differentiable on $\mathrm{int}(\mathrm{dom}\phi)$, with $\lim_{t\to 0^+} \phi''(t) = +\infty$.

(C.3) $\phi'(t)t - \phi(t)$ is convex on $\mathrm{int}(\mathrm{dom}\phi)$.

(C.4) ϕ' is SOC-concave on $\mathrm{int}(\mathrm{dom}\phi)$.

In what follows, we denote by Φ the class of functions satisfying Conditions C.1–C.4.

Given a $\phi \in \Phi$, let ϕ^{soc} and $(\phi')^{\mathrm{soc}}$ be the vector-valued function given as in (13). We define $D(x, y)$ involved in the proximal-like algorithm (8) by

$$D(x,y) := \begin{cases} \mathrm{tr}\Big[\phi^{\mathrm{soc}}(y) - \phi^{\mathrm{soc}}(x) - (\phi')^{\mathrm{soc}}(x) \circ (y-x)\Big] & \forall x \in \mathrm{int}(\mathcal{K}^n), y \in \mathcal{K}^n, \\ +\infty & \text{otherwise.} \end{cases} \tag{18}$$

The function, as will be shown in the next section, possesses some favorable properties. Particularly, $D(x, y) \ge 0$ for any $x, y \in \mathrm{int}(\mathcal{K}^n)$, and $D(x, y) = 0$ if and only if $x = y$. Hence, $D(x, y)$ can be used to measure the distance between the two points in $\mathrm{int}(\mathcal{K}^n)$.

In the following, we concentrate on the examples of the distance-like function $D(x,y)$. For this purpose, we first give another characterization for Condition C.3.

LEMMA 3.1. *Let $\phi : \mathbb{R} \to (-\infty, +\infty]$ be a closed proper function with $\mathrm{dom}\phi = [0, +\infty)$. If ϕ is thrice continuously differentiable on $\mathrm{int}(\mathrm{dom}\phi)$, then ϕ satisfies Condition C.3 if and only if its derivative function ϕ' is exponentially convex,*[2] *or*

$$\phi'(t_1 t_2) \le \frac{1}{2}\Big(\phi'(t_1^2) + \phi'(t_2^2)\Big) \quad \forall t_1, t_2 > 0. \tag{19}$$

Proof. Since the function ϕ is thrice continuously differentiable on $\mathrm{int}(\mathrm{dom}\phi)$, ϕ satisfies Condition C.3 if and only if

$$\phi''(t) + t\phi'''(t) \ge 0 \quad (\forall t > 0).$$

Observe that the inequality is also equivalent to

$$t\phi''(t) + t^2\phi'''(t) \ge 0 \quad (\forall t > 0),$$

and hence substituting by $t = \exp(\theta)$ for $\theta \in \mathbb{R}$ into the inequality yields that

$$\exp(\theta)\phi''(\exp(\theta)) + \exp(2\theta)\phi'''(\exp(\theta)) \ge 0 \quad \forall \theta \in \mathbb{R}.$$

Since the left-hand side of this inequality is exactly $[\phi'(\exp(\theta))]''$, it means that $\phi'(\exp(\cdot))$ is convex on $\mathbb{R}$. Consequently, the first part of the conclusions follows.

Note that the convexity of $\phi'(\exp(\cdot))$ on $\mathbb{R}$ is equivalent to saying, for any $\theta_1, \theta_2 \in \mathbb{R}$,

$$\phi'(\exp(r\theta_1 + (1-r)\theta_2)) \le r\phi'(\exp(\theta_1)) + (1-r)\phi'(\exp(\theta_2)), \quad r \in [0,1],$$

which, by letting $t_1 = \exp(\theta_1)$ and $t_2 = \exp(\theta_2)$, can be rewritten as

$$\phi'(t_1^r t_2^{1-r}) \le r\phi'(t_1) + (1-r)\phi'(t_2) \ \ \forall t_1, t_2 > 0 \text{ and } r \in [0,1].$$

This is clearly equivalent to the statement in (19) due to the continuity of ϕ'. □

Remark 3.1. The exponential convexity was also used in the definition of the *self-regular* function [27] in which the authors denote Ω by the set of functions whose elements are twice continuously differentiable and exponentially convex on $(0, +\infty)$. By Lemma 3.1, clearly, if $h \in \Omega$, then the function $\int_0^t h(\theta)d\theta$ necessarily satisfies Condition C.3. For example, $\ln t$ belongs to Ω, and so $\int_0^t \ln\theta d\theta = t\ln t$ satisfies Condition C.3.

For the characterizations of the SOC-concavity, interested readers may refer to [7, 9]. Here, we present a lemma which states that the composition of two SOC-concave functions is SOC-concave under some conditions. By this lemma, we may conveniently obtain some new SOC-concave functions from the existing ones.

LEMMA 3.2. *Let $g : \mathrm{J}_{\mathbb{R}} \to \mathbb{R}$ and $h : \mathrm{I}_{\mathbb{R}} \to \mathrm{J}_{\mathbb{R}}$, where $\mathrm{J}_{\mathbb{R}} \subseteq \mathbb{R}$ and $\mathrm{I}_{\mathbb{R}} \subseteq \mathbb{R}$. If g is SOC-concave and SOC-monotone on $\mathrm{J}_{\mathbb{R}}$ and h is SOC-concave on $\mathrm{I}_{\mathbb{R}}$, then their composition $g(h(\cdot))$ is also SOC-concave on $\mathrm{I}_{\mathbb{R}}$. If, in addition, h is SOC-monotone on $\mathrm{I}_{\mathbb{R}}$, then $g(h(\cdot))$ is also SOC-monotone on $\mathrm{I}_{\mathbb{R}}$.*

Proof. For the sake of notation, let $g^{\mathrm{soc}} : \widehat{S} \to \mathbb{R}^n$ and $h^{\mathrm{soc}} : S \to \widehat{S}$ be the vector-valued functions associated with g and h, respectively, where $S \subseteq \mathbb{R}^n$ and $\widehat{S} \subseteq \mathbb{R}^n$.

[2] Which means the function $\phi'(\exp(\cdot)) : \mathbb{R} \to \mathbb{R}$ is convex on $\mathbb{R}$,

Define $\widehat{g}(t) = g(h(t))$. Then, for any $x \in S$, it follows from (11) and (13) that

$$\begin{aligned} g^{\rm soc}(h^{\rm soc}(x)) &= g^{\rm soc}\Big[h(\lambda_1(x))u_x^{(1)} + h(\lambda_2(x))u_x^{(2)}\Big] \\ &= g[h(\lambda_1(x))]u_x^{(1)} + g[h(\lambda_2(x))]u_x^{(2)} \\ &= \widehat{g}^{\rm soc}(x). \end{aligned} \tag{20}$$

We next prove that $\widehat{g}(t)$ is SOC-concave on $\mathrm{I}_{\mathbb{R}}$. For any $x, y \in S$ and $0 \le \beta \le 1$, from the SOC-concavity of $h(t)$ it follows that

$$h^{\rm soc}(\beta x + (1-\beta)y) \succeq_{\mathcal{K}^n} \beta h^{\rm soc}(x) + (1-\beta)h^{\rm soc}(y).$$

Using the SOC-monotonicity and SOC-concavity of g, we then obtain that

$$\begin{aligned} g^{\rm soc}\Big[h^{\rm soc}(\beta x + (1-\beta)y)\Big] &\succeq_{\mathcal{K}^n} g^{\rm soc}\Big[\beta h^{\rm soc}(x) + (1-\beta)h^{\rm soc}(y)\Big] \\ &\succeq_{\mathcal{K}^n} \beta g^{\rm soc}[h^{\rm soc}(x)] + (1-\beta)g^{\rm soc}[h^{\rm soc}(y)]. \end{aligned}$$

This together with (20) implies that for any $x, y \in S$ and $0 \le \beta \le 1$,

$$\widehat{g}^{\rm soc}\Big(\beta x + (1-\beta)y\Big) \succeq_{\mathcal{K}^n} \beta\widehat{g}^{\rm soc}(x) + (1-\beta)\widehat{g}^{\rm soc}(y).$$

Consequently, the function $\widehat{g}(t)$, i.e., $g(h(\cdot))$ is SOC-concave on $\mathrm{I}_{\mathbb{R}}$. The second part of the conclusions is obvious. □

PROPOSITION 3.1. (a) *The function $h(t) = t^r$, with $0 \le r \le 1$ is both SOC-concave and SOC-monotone on $[0, +\infty)$.*

(b) *$h(t) = -t^{-r}$, with $0 \le r \le 1$ is SOC-concave and SOC-monotone on $(0, +\infty)$.*

(c) *For all $u \le 0$, $h(t) = \frac{1}{u-t}$ is SOC-concave as well as SOC-monotone on $(0, +\infty)$.*

(d) *The function $\ln t$ is SOC-concave and SOC-monotone on $(0, +\infty)$.*

Proof. (a) The proof has been given by [7, Proposition 3.7], and we here omit it.

(b) The conclusion follows directly from [9, Corollary 4.2].

(c) Let $g(t) = -1/t$ and $\widehat{h}(t) = t - u$. Then, $h(t) = 1/(u-t)$ is exactly the composition of the two functions, i.e., $h(t) = g(\widehat{h}(t))$. From part (b), $g(t)$ is SOC-monotone and SOC-concave on $(0, +\infty)$; whereas by [7, Proposition 3.1 (b)] $\widehat{h}(t)$ is SOC-monotone and SOC-concave on $(0, +\infty)$. Thus, applying Lemma 3.2, we readily obtain the conclusion.

(d) The proof can be found in [9]. In view of the importance of $\ln t$, we here present a different proof by following the same line as [3]. Noting that

$$\ln t = \int_{-\infty}^{0} \left[\frac{1}{u-t} - \frac{u}{u^2+1}\right] du \quad (t > 0),$$

we have for any $x \in \mathrm{int}(\mathcal{K}^n)$ that

$$\ln x = \int_{-\infty}^{0} \left[(ue - x)^{-1} - \frac{u}{u^2+1}e\right] du. \tag{21}$$

For any $x = (x_1, x_2),\ y = (y_1, y_2) \in \mathrm{int}(\mathcal{K}^n)$ and any $0 \le \beta \le 1$, let

$$w = \ln(\beta x + (1-\beta)y) - \beta \ln x - (1-\beta)\ln y.$$

Then, by the definition of SOC-concavity, proving the SOC-concavity of $\ln t$ on $(0, +\infty)$ is equivalent to showing that $w \in \mathcal{K}^n$. From (21) and (11), it follows that

$$\begin{aligned} w &= \int_{-\infty}^{0} \left[(ue - \beta x - (1-\beta)y)^{-1} - \beta(ue - x)^{-1} - (1-\beta)(ue - y)^{-1}\right] du \\ &= \begin{pmatrix} \displaystyle\int_{-\infty}^{0} \left[\frac{u - \beta x_1 - (1-\beta)y_1}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta(u - x_1)}{\det(ue - x)} - \frac{(1-\beta)(u - y_1)}{\det(ue - y)}\right] du \\ \displaystyle\int_{-\infty}^{0} \left[\frac{\beta x_2 + (1-\beta)y_2}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta x_2}{\det(ue - x)} - \frac{(1-\beta)y_2}{\det(ue - y)}\right] du \end{pmatrix} \\ &:= \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}, \end{aligned}$$

where $w_1 \in \mathbb{R}$ and $w_2 \in \mathbb{R}^{n-1}$. However, by Proposition 3.1 (c) and Definition 2.1,

$$\Big(ue - \beta x - (1-\beta)y\Big)^{-1} - \beta(ue - x)^{-1} - (1-\beta)(ue - y)^{-1} \in \mathcal{K}^n,$$

which implies that

$$\frac{u - \beta x_1 - (1-\beta)y_1}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta(u - x_1)}{\det(ue - x)} - \frac{(1-\beta)(u - y_1)}{\det(ue - y)} \geq 0$$

and

$$\begin{aligned} &\left\| \frac{\beta x_2 + (1-\beta)y_2}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta x_2}{\det(ue - x)} - \frac{(1-\beta)y_2}{\det(ue - y)} \right\| \\ &\leq \frac{u - \beta x_1 - (1-\beta)y_1}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta(u - x_1)}{\det(ue - x)} - \frac{(1-\beta)(u - y_1)}{\det(ue - y)}. \end{aligned}$$

As a consequence,

$$\begin{aligned} w_1 &= \int_{-\infty}^{0} \left[\frac{u - \beta x_1 - (1-\beta)y_1}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta(u - x_1)}{\det(ue - x)} - \frac{(1-\beta)(u - y_1)}{\det(ue - y)}\right] du \\ &\geq 0 \end{aligned}$$

and

$$\begin{aligned} \|w_2\| &\leq \int_{-\infty}^{0} \left\| \left[\frac{\beta x_2 + (1-\beta)y_2}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta x_2}{\det(ue - x)} - \frac{(1-\beta)y_2}{\det(ue - y)}\right] \right\| du \\ &\leq \int_{-\infty}^{0} \left[\frac{u - \beta x_1 - (1-\beta)y_1}{\det(ue - \beta x - (1-\beta)y)} - \frac{\beta(u - x_1)}{\det(ue - x)} - \frac{(1-\beta)(u - y_1)}{\det(ue - y)}\right] du \\ &= w_1. \end{aligned}$$

This shows that $w \in \mathcal{K}^n$, and consequently $\ln t$ is SOC-concave on $(0, +\infty)$. By a similar argument, we can prove that $\ln t$ is SOC-monotone on $(0, +\infty)$. □

From Lemma 3.2 and Proposition 3.1, we may obtain the following corollary, which particularly shows that the modified logarithmic barrier function is SOC-concave.

COROLLARY 3.1. (a) *The modified logarithmic barrier function* $\ln(\alpha + t)$ *for* $\alpha > 0$ *is both SOC-concave and SOC-monotone on* $(-\alpha, +\infty)$.

(b) *For any* $\alpha > 0$ *and* $\beta > 0$, *the functions* $\ln(\alpha + \beta t^r)$, *with* $0 \leq r \leq 1$ *are SOC-concave and SOC-monotone on* $[0, +\infty)$.

(c) *For any $u > 0$, the functions $\frac{t}{u+t}$ are SOC-concave and SOC-monotone on $(0, +\infty)$.*

(d) *For all $u > 0$, the functions $\frac{-1}{\sqrt{u+t}}$ are SOC-concave and SOC-monotone on $(-u, +\infty)$.*

Proof. (a) The proof is due to Proposition 3.1(d), [7, Proposition 3.1], and Lemma 3.2 by letting $g : (0, +\infty) \to \mathbb{R}$ be $g(t) = \ln t$, and $h : (-a, +\infty) \to (0, +\infty)$ be $h(t) = a + t$.

(b) Let $g : (0, +\infty) \to \mathbb{R}$ be $g(t) = \ln t$, and $h : (0, +\infty) \to (0, +\infty)$ be $h(t) = a + \beta t^r$. The result follows from Proposition 3.1(a), Proposition 3.1(d), and Lemma 3.2.

(c) Let $g : (-1, 0) \to (0, 1)$ be $g(t) = 1 + t$, and $h : (0, +\infty) \to (-1, 0)$ be $h(t) = -u/(u+t)$. Then, we obtain the result from Proposition 3.1(c), [7, Proposition 3.1], and Lemma 3.2. The result also extends the conclusion of [7, Proposition 3.4].

(d) Let $g : (0, +\infty) \to (0, +\infty)$ be $g(t) = \sqrt{t}$, and $h : (-u, +\infty) \to (0, +\infty)$ be $h(t) = u + t$. Then, from Lemma 3.2 it follows that $g(h(t)) = \sqrt{u + t}$ is SOC-concave and SOC-monotone on $(-u, +\infty)$. Using Lemma 3.2 again with $g(t) = -1/t$ and $h(t) = \sqrt{u + t}$, we obtain the desired result. □

Now we present serval examples of $D(x, y)$ to close this section. From these examples, we may see that the conditions required by $\phi \in \Phi$ are not so strict, and the construction of the distance-like functions in SOCs can be completed by selecting a class of single variate convex functions.

Example 3.1. Let $\phi(t) = t \ln t - t + 1$ if $t \geq 0$, and $\phi(t) = +\infty$ if $t < 0$. It is easy to verify that ϕ satisfies Conditions C.1–C.3. Also, by Proposition 3.1(d), Condition C.4 also holds. From formula (13), it follows that, for any $y \in \mathcal{K}^n$ and $x \in \mathrm{int}(\mathcal{K}^n)$,

$$\phi^{\mathrm{soc}}(y) = y \circ \ln y - y + e \quad \text{and} \quad (\phi')^{\mathrm{soc}}(x) = \ln x.$$

Consequently, the distance-like function induced by ϕ is given by

$$D_1(x, y) = \mathrm{tr}\,(y \circ \ln y - y \circ \ln x + x - y) \quad \forall x \in \mathrm{int}(\mathcal{K}^n), y \in \mathcal{K}^n.$$

This function is precisely the natural extension of the entropy-like distance $d_\varphi(\cdot, \cdot)$, with $\varphi(t) = -\ln t + t - 1$ to the SOCs. In addition, comparing $D_1(x, y)$ with the distance-like function $H(x, y)$ in Example 3.1 of [26], we note that $D_1(x, y) = H(y, x)$, but the proximal-like algorithms corresponding to them are completely different.

Example 3.2. Let $\phi(t) = t \ln t + (1 + t) \ln(1 + t) - (1 + t) \ln 2$ if $t \geq 0$, and $\phi(t) = +\infty$ if $t < 0$. By computing, we can show that ϕ satisfies Conditions C.1–C.3. Furthermore, from Proposition 3.1(d) and Corollary 3.1(a), we learn that ϕ also satisfies Condition C.4. This means that $\phi \in \Phi$. For any $y \in \mathcal{K}^n$ and $x \in \mathrm{int}(\mathcal{K}^n)$, we can compute that

$$\begin{aligned} \phi^{\mathrm{soc}}(y) &= y \circ \ln y + (e + y) \circ \ln(e + y) - \ln 2(e + y), \\ (\phi')^{\mathrm{soc}}(x) &= (2 - \ln 2)e + \ln x + \ln(e + x). \end{aligned}$$

Therefore, the distance-like function generated by such a ϕ is given by

$$D_2(x, y) = \mathrm{tr}\Big[-\ln(e + x) \circ (e + y) + y \circ (\ln y - \ln x) + (e + y) \circ \ln(e + y) - 2(y - x)\Big]$$

for any $x \in \mathrm{int}(\mathcal{K}^n)$ and $y \in \mathcal{K}^n$. It should be pointed out that $D_2(x, y)$ is not the extension of $d_\varphi(\cdot, \cdot)$, with $\varphi(t) = \phi(t)$ given by [18] to the SOCs.

Example 3.3. Take $\phi(t) = t^{\frac{2r+3}{2}} + t^2$, with $0 \leq r < \frac{1}{2}$ if $t \geq 0$, and $\phi(t) = +\infty$ if $t < 0$. It is easy to verify that ϕ satisfies Conditions C.1–C.3. Furthermore, from

Proposition 3.1(a) it follows that ϕ satisfies Condition C.4. Thus, $\phi \in \Phi$. By a simple computation,

$$\phi^{\rm soc}(y) = y^{\frac{2r+3}{2}} + y^2 \quad \forall y \in \mathcal{K}^n \ \text{ and } \ (\phi')^{\rm soc}(x) = \frac{2r+3}{2} x^{\frac{2r+1}{2}} + 2x \quad \forall x \in {\rm int}(\mathcal{K}^n).$$

Hence, the distance-like function induced by ϕ has the following expression:

$$D_3(x,y) = {\rm tr}\left[\frac{2r+1}{2} x^{\frac{2r+3}{2}} + x^2 - y \circ \Big(\frac{2r+3}{2} x^{\frac{2r+1}{2}} + 2x\Big) + y^{\frac{2r+3}{2}} + y^2\right].$$

Example 3.4. Let $\phi(t) = t^{a+1} + at\ln t - at$, with $0 < a \le 1$ if $t \ge 0$, and $\phi(t) = +\infty$ if $t < 0$. It is easily shown that ϕ satisfies Conditions C.1–C.3. By Proposition 3.1(a) and Proposition 3.1(d), ϕ' is SOC-concave on $(0, +\infty)$. Hence, $\phi \in \Phi$. For any $y \in \mathcal{K}^n$ and $x \in {\rm int}(\mathcal{K}^n)$,

$$\phi^{\rm soc}(y) = y^{a+1} + ay \circ \ln y - ay \quad \text{and} \quad (\phi')^{\rm soc}(x) = (a+1)x^a + a\ln x.$$

Consequently, the distance-like function induced by ϕ has the following expression:

$$D_4(x,y) = {\rm tr}\Big[ax^{a+1} + ax - y \circ \Big((a+1)x^a + a\ln x\Big) + y^{a+1} + ay \circ \ln y - ay\Big].$$

4. Properties of distance-like functions. In what follows, we study some favorable properties of the function $D(x,y)$. We begin with two technical lemmas that will be used in the subsequent analysis. Among others, the first lemma is a direct consequence of Lemma 2.2 and the definition of Φ.

LEMMA 4.1. *Given a $\phi \in \Phi$, let $\phi^{\rm soc}$ and $(\phi')^{\rm soc}$ be the vector-valued functions given as in* (13)*. Then, we have the following results:*

(a) *$\phi^{\rm soc}(x)$ and $(\phi')^{\rm soc}(x)$ are well-defined on $\mathcal{K}^n$ and ${\rm int}(\mathcal{K}^n)$, respectively, and*

$$\lambda_i[\phi^{\rm soc}(x)] = \phi[\lambda_i(x)], \quad \lambda_i[(\phi')^{\rm soc}(x)] = \phi'[\lambda_i(x)], \quad i = 1, 2.$$

(b) *$\phi^{\rm soc}(x)$ and $(\phi')^{\rm soc}(x)$ are continuously differentiable on ${\rm int}(\mathcal{K}^n)$, with the transposed Jacobian at x given as in formulas* (14)–(15)*.*

(c) *${\rm tr}[\phi^{\rm soc}(x)]$ and ${\rm tr}[(\phi')^{\rm soc}(x)]$ are continuously differentiable on ${\rm int}(\mathcal{K}^n)$, and*

$$\begin{aligned} \nabla {\rm tr}\Big[\phi^{\rm soc}(x)\Big] &= 2\nabla\phi^{\rm soc}(x)\cdot e = 2(\phi')^{\rm soc}(x), \\ \nabla {\rm tr}\Big[(\phi')^{\rm soc}(x)\Big] &= 2\nabla(\phi')^{\rm soc}(x)\cdot e = 2(\phi'')^{\rm soc}(x). \end{aligned} \tag{22}$$

(d) *The function ${\rm tr}[\phi^{\rm soc}(x)]$ is strictly convex on ${\rm int}(\mathcal{K}^n)$.*

LEMMA 4.2. *Given a $\phi \in \Phi$ and a fixed point $z \in \mathbb{R}^n$, let $\phi_z : {\rm int}(\mathcal{K}^n) \to \mathbb{R}$ be given by*

$$\phi_z(x) := {\rm tr}\Big[-z \circ (\phi')^{\rm soc}(x)\Big]. \tag{23}$$

Then, the function $\phi_z(x)$ possesses the following properties:

(a) *$\phi_z(x)$ is continuously differentiable on ${\rm int}(\mathcal{K}^n)$, with $\nabla\phi_z(x) = -2\nabla(\phi')^{\rm soc}(x)\cdot z$.*

(b) *$\phi_z(x)$ is convex over ${\rm int}(\mathcal{K}^n)$ when $z \in \mathcal{K}^n$, and furthermore, it is strictly convex over ${\rm int}(\mathcal{K}^n)$ when $z \in {\rm int}(\mathcal{K}^n)$.*

Proof. (a) Since $\phi_z(x) = -2\langle(\phi')^{\rm soc}(x), z\rangle$ for any $x \in {\rm int}(\mathcal{K}^n)$, we have that $\phi_z(x)$ is continuously differentiable on ${\rm int}(\mathcal{K}^n)$ by Lemma 4.1(c). Moreover, applying the chain rule for the inner product of two functions readily yields $\nabla\phi_z(x) = -2\nabla(\phi')^{\rm soc}(x)\cdot z$.

(b) By the continuous differentiability of $\phi_z(x)$, to prove the convexity of ϕ_z on ${\rm int}(\mathcal{K}^n)$, it suffices to prove the following inequality:

$$\phi_z\left(\frac{x+y}{2}\right) \le \frac{1}{2}\Big(\phi_z(x)+\phi_z(y)\Big) \quad \forall x, y \in {\rm int}(\mathcal{K}^n). \tag{24}$$

By Condition C.4, ϕ' is SOC-concave on $(0,+\infty)$. Therefore, we have that

$$-(\phi')^{\rm soc}\left(\frac{x+y}{2}\right) \succeq_{\mathcal{K}^n} -\frac{1}{2}\Big[(\phi')^{\rm soc}(x)+(\phi')^{\rm soc}(y)\Big],$$

i.e.,

$$(\phi')^{\rm soc}\left(\frac{x+y}{2}\right) - \frac{1}{2}(\phi')^{\rm soc}(x) - \frac{1}{2}(\phi')^{\rm soc}(y) \succeq_{\mathcal{K}^n} 0.$$

Using Lemma 2.1(a) and the fact that $z \in \mathcal{K}^n$, we then obtain that

$$\left\langle z,\ (\phi')^{\rm soc}\left(\frac{x+y}{2}\right) - \frac{1}{2}(\phi')^{\rm soc}(x) - \frac{1}{2}(\phi')^{\rm soc}(y)\right\rangle \ge 0, \tag{25}$$

which in turn implies that

$$\Big\langle -z,\ (\phi')^{\rm soc}\left(\frac{x+y}{2}\right)\Big\rangle \le \frac{1}{2}\Big\langle -z,\ (\phi')^{\rm soc}(x)\Big\rangle + \frac{1}{2}\Big\langle -z,\ (\phi')^{\rm soc}(y)\Big\rangle.$$

The last inequality is exactly the one in (24). Hence, ϕ_z is convex on ${\rm int}(\mathcal{K}^n)$ for $z \in \mathcal{K}^n$.

To prove the second part of the conclusions, we need only to prove that the inequality in (25) holds strictly for any $x, y \in {\rm int}(\mathcal{K}^n)$ and $x \ne y$. By Lemma 2.1(b), this is also equivalent to proving the vector $(\phi')^{\rm soc}\left(\frac{x+y}{2}\right) - \frac{1}{2}(\phi')^{\rm soc}(x) - \frac{1}{2}(\phi')^{\rm soc}(y)$ is nonzero, since

$$(\phi')^{\rm soc}\left(\frac{x+y}{2}\right) - \frac{1}{2}(\phi')^{\rm soc}(x) - \frac{1}{2}(\phi')^{\rm soc}(y) \in \mathcal{K}^n \quad \text{and} \quad z \in {\rm int}(\mathcal{K}^n).$$

From Condition C.4, it follows that ϕ' is concave on $(0,+\infty)$, since the SOC-concavity implies the concavity. This, together with the strict monotonicity of ϕ', implies that ϕ' is strictly concave on $(0,+\infty)$. Using Lemma 2.2(d), we then have that ${\rm tr}[(\phi')^{\rm soc}(x)]$ is strictly concave on ${\rm int}(\mathcal{K}^n)$. This means that, for any $x, y \in {\rm int}(\mathcal{K}^n)$ and $x \ne y$,

$${\rm tr}\left[(\phi')^{\rm soc}\Big(\frac{x+y}{2}\Big)\right] - \frac{1}{2}{\rm tr}\left[(\phi')^{\rm soc}(x)\right] - \frac{1}{2}{\rm tr}\left[(\phi')^{\rm soc}(y)\right] > 0. \tag{26}$$

In addition, we note that the first element of $(\phi')^{\rm soc}\left(\frac{x+y}{2}\right) - \frac{1}{2}(\phi')^{\rm soc}(x) - \frac{1}{2}(\phi')^{\rm soc}(y)$ is

$$\frac{\phi'\Big(\lambda_1\Big(\frac{x+y}{2}\Big)\Big) + \phi'\Big(\lambda_2\Big(\frac{x+y}{2}\Big)\Big)}{2} - \frac{\phi'(\lambda_1(x)) + \phi'(\lambda_2(x))}{4} - \frac{\phi'(\lambda_1(y)) + \phi'(\lambda_2(y))}{4},$$

which, by Property 2.1(c), can be rewritten as

$$\frac{1}{2}\mathrm{tr}\left[(\phi')^{\mathrm{soc}}\Big(\frac{x+y}{2}\Big)\right]-\frac{1}{4}\mathrm{tr}\left[(\phi')^{\mathrm{soc}}(x)\right]-\frac{1}{4}\mathrm{tr}\left[(\phi')^{\mathrm{soc}}(y)\right].$$

This together with (26) shows that $(\phi')^{\mathrm{soc}}\left(\frac{x+y}{2}\right)-\frac{1}{2}(\phi')^{\mathrm{soc}}(x)-\frac{1}{2}(\phi')^{\mathrm{soc}}(y)$ is nonzero for any $x,y\in\mathrm{int}(\mathcal{K}^n)$ and $x\neq y$. Consequently, ϕ_z is strictly convex on $\mathrm{int}(\mathcal{K}^n)$. □

Now we are in a position to study the properties of the distance-like function $D(x,y)$.

PROPOSITION 4.1. *Given a $\phi\in\Phi$, let $D(x,y)$ be defined as in* (18)*. Then,*

(a) *$D(x,y)\geq 0$ for any $x\in\mathrm{int}(\mathcal{K}^n)$ and $y\in\mathcal{K}^n$, and $D(x,y)=0$ if and only if $x=y$;*

(b) *for any fixed $y\in\mathcal{K}^n$, $D(\cdot,y)$ is continuously differentiable on* $\mathrm{int}(\mathcal{K}^n)$*, with*

$$\nabla_x D(x,y)=2\nabla(\phi')^{\mathrm{soc}}(x)\cdot(x-y); \tag{27}$$

(c) *for any fixed $y\in\mathcal{K}^n$, the function $D(\cdot,y)$ is convex over* $\mathrm{int}(\mathcal{K}^n)$*, and for any fixed $y\in\mathrm{int}(\mathcal{K}^n)$, $D(\cdot,y)$ is strictly convex over* $\mathrm{int}(\mathcal{K}^n)$*;*

(d) *for any fixed $y\in\mathrm{int}(\mathcal{K}^n)$, the function $D(\cdot,y)$ is essentially smooth;*

(e) *for any fixed $y\in\mathcal{K}^n$, the level sets $L_D(y,\gamma):=\{x\in\mathrm{int}(\mathcal{K}^n):D(x,y)\leq\gamma\}$ for all $\gamma\geq 0$ are bounded.*

Proof. (a) By Lemma 4.1(c), for any $x\in\mathrm{int}(\mathcal{K}^n)$ and $y\in\mathcal{K}^n$, we can rewrite $D(x,y)$ as

$$D(x,y)=\mathrm{tr}[\phi^{\mathrm{soc}}(y)]-\mathrm{tr}[\phi^{\mathrm{soc}}(x)]-\langle\nabla\mathrm{tr}[\phi^{\mathrm{soc}}(x)],\ y-x\rangle.$$

Notice that $\mathrm{tr}[\phi^{\mathrm{soc}}(x)]$ is strictly convex on $\mathrm{int}(\mathcal{K}^n)$ by Lemma 4.1(d), and hence $D(x,y)\geq 0$ for any $x\in\mathrm{int}(\mathcal{K}^n)$ and $y\in\mathcal{K}^n$, and $D(x,y)=0$ if and only if $x=y$.

(b) By Lemma 4.1(b) and Lemma 4.1(c), the functions $\mathrm{tr}[\phi^{\mathrm{soc}}(x)]$ and $\langle(\phi')^{\mathrm{soc}}(x),x\rangle$ are continuously differentiable on $\mathrm{int}(\mathcal{K}^n)$. Noting that, for any $x\in\mathrm{int}(\mathcal{K}^n)$ and $y\in\mathcal{K}^n$,

$$D(x,y)=\mathrm{tr}[\phi^{\mathrm{soc}}(y)]-\mathrm{tr}[\phi^{\mathrm{soc}}(x)]-2\langle(\phi')^{\mathrm{soc}}(x),y-x\rangle;$$

we then have the continuous differentiability of $D(\cdot,y)$ on $\mathrm{int}(\mathcal{K}^n)$. Furthermore,

$$\begin{aligned}\nabla_x D(x,y)&=-\nabla\mathrm{tr}[\phi^{\mathrm{soc}}(x)]-2\nabla(\phi')^{\mathrm{soc}}(x)\cdot(y-x)+2(\phi')^{\mathrm{soc}}(x)\\&=-2(\phi')^{\mathrm{soc}}(x)+2\nabla(\phi')^{\mathrm{soc}}(x)\cdot(x-y)+2(\phi')^{\mathrm{soc}}(x)\\&=2\nabla(\phi')^{\mathrm{soc}}(x)\cdot(x-y).\end{aligned}$$

(c) By the definition of ϕ_z given as in (23), $D(x,y)$ can be rewritten as

$$D(x,y)=\mathrm{tr}[(\phi')^{\mathrm{soc}}(x)\circ x-\phi^{\mathrm{soc}}(x)]+\phi_y(x)+\mathrm{tr}[\phi^{\mathrm{soc}}(y)].$$

Thus, to prove the (strict) convexity of $D(\cdot,y)$ on $\mathrm{int}(\mathcal{K}^n)$, it suffices to show that

$$\mathrm{tr}[(\phi')^{\mathrm{soc}}(x)\circ x-\phi^{\mathrm{soc}}(x)]+\phi_y(x)$$

is (strictly) convex on $\mathrm{int}(\mathcal{K}^n)$. Let $\psi:(0,+\infty)\to\mathbb{R}$ be the function defined by

$$\psi(t):=\phi'(t)t-\phi(t). \tag{28}$$

Then, the vector-valued function induced by ψ via (13) is $(\phi')^{\rm soc}(x)\circ x-\phi^{\rm soc}(x)$, i.e.,

$$\psi^{\rm soc}(x)=(\phi')^{\rm soc}(x)\circ x-\phi^{\rm soc}(x). \tag{29}$$

From Condition C.3 and Lemma 2.2(d), it follows that $\mathrm{tr}[(\phi')^{\rm soc}(x)\circ x-\phi^{\rm soc}(x)]$ is convex over $\mathrm{int}(\mathcal{K}^n)$. In addition, by Lemma 4.2(b), $\phi_y(x)$ is convex on $\mathrm{int}(\mathcal{K}^n)$ if $y\in\mathcal{K}^n$, and it is strictly convex if $y\in\mathrm{int}(\mathcal{K}^n)$. Thus, we get the desired results.

(d) From [29, p. 251] and parts (a)–(b), to prove that $D(\cdot,y)$ is essentially smooth for any fixed $y\in\mathrm{int}(\mathcal{K}^n)$, it suffices to show that $\|\nabla_x D(x^k,y)\|\to+\infty$ for any $\{x^k\}\subset\mathrm{int}(\mathcal{K}^n)$, with $x^k\to x\in\mathrm{bd}(\mathcal{K}^n)$. We next prove the conclusion by the following two cases: $x_1>0$ and $x_1=0$. For the sake of notation, let $x^k=(x_1^k,x_2^k)\in\mathbb{R}\times\mathbb{R}^{n-1}$.

Case 1. $x_1>0$. In this case, $\|x_2\|=x_1>0$, since $x\in\mathrm{bd}(\mathcal{K}^n)$. Noting that $x^k\to x$, we have that $x_2^k\neq 0$ for all sufficiently large k. From the gradient formula (27),

$$\|\nabla_x D(x^k,y)\|=\|2\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)\|\geq\left|2[\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)]_1\right|, \tag{30}$$

where $[\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)]_1$ denotes the first element of the vector $\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)$. By the gradient formula (15), we can compute that

$$\begin{aligned}2[\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)]_1&=[\phi''(\lambda_2(x^k))+\phi''(\lambda_1(x^k))](x_1^k-y_1)\\&\quad+[\phi''(\lambda_2(x^k))-\phi''(\lambda_1(x^k))]\frac{(x_2^k-y_2)^Tx_2^k}{\|x_2^k\|}\\&=\phi''(\lambda_2(x^k))\left(\lambda_2(x^k)-y_1-y_2^Tx_2^k/\|x_2^k\|\right)\\&\quad-\phi''(\lambda_1(x^k))\left(y_1-y_2^Tx_2^k/\|x_2^k\|-\lambda_1(x^k)\right).\end{aligned} \tag{31}$$

Therefore,

$$\begin{aligned}\left|2[\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)]_1\right|&\geq\left|\phi''(\lambda_1(x^k))\left(y_1-y_2^Tx_2^k/\|x_2^k\|-\lambda_1(x^k)\right)\right|\\&\quad-\left|\phi''(\lambda_2(x^k))\left(\lambda_2(x^k)-y_1-y_2^Tx_2^k/\|x_2^k\|\right)\right|\\&\geq\left|\phi''(\lambda_1(x^k))\right|\cdot\left(\left|y_1-y_2^Tx_2^k/\|x_2^k\|\right|-\lambda_1(x^k)\right)\\&\quad-\left|\phi''(\lambda_2(x^k))\right|\cdot\left|\lambda_2(x^k)-y_1-y_2^Tx_2^k/\|x_2^k\|\right|\\&\geq\left|\phi''(\lambda_1(x^k))\right|\cdot\left(\lambda_1(y)-\lambda_1(x^k)\right)\\&\quad-\left|\phi''(\lambda_2(x^k))\right|\cdot\left|\lambda_2(x^k)-y_1-y_2^Tx_2^k/\|x_2^k\|\right|.\end{aligned}$$

Noting that $\lambda_1(x^k)\to\lambda_1(x)=0$, $\lambda_2(x^k)\to\lambda_2(x)>0$, and $\frac{y_2^Tx_2^k}{\|x_2^k\|}\to\frac{y_2^Tx_2}{\|x_2\|}$ as $k\to+\infty$, the second term in the right-hand side of the last inequality converges to a finite value, whereas the first term approaches to $+\infty$, since $|\phi''(\lambda_1(x^k))|\to+\infty$ by Condition C.2 and $\lambda_1(y)-\lambda_1(x^k)\to\lambda_1(y)>0$. This implies that as $k\to+\infty$,

$$\left|2[\nabla(\phi')^{\rm soc}(x^k)\cdot(x^k-y)]_1\right|\to+\infty.$$

Combining with the inequality (30) immediately yields $\|\nabla_x D(x^k,y)\|\to+\infty$.

Case 2. $x_1=0$. In this case, we necessarily have that $x=0$, since $x\in\mathcal{K}^n$. Considering that $x^k\to x$, it then follows that $x_2^k=0$ or $x_2^k>0$ for all sufficiently large k. If $x_2^k=0$ for all sufficiently large k, then from (14) we have that

$$\|\nabla_x D(x^k,y)\|=\|2\phi''(x_1^k)(x^k-y)\|\geq 2|\phi''(x_1^k)|\cdot|x_1^k-y_1|.$$

Since $y_1 > 0$ by $y \in \mathrm{int}(\mathcal{K}^n)$ and $x_1^k \to x_1 = 0$, applying Condition C.2 yields that the right-hand side tends to $+\infty$, and consequently $\|\nabla_x D(x^k, y)\| \to +\infty$ when $k \to +\infty$.

Next, we consider the case that $x_2^k > 0$ for all sufficiently large k. In this case, the inequalities (30)–(31) still hold. By Cauchy–Schwarz inequality,

$$\begin{aligned}\lambda_2(x^k) - y_1 - y_2^T x_2^k/\|x_2^k\| &\geq \lambda_2(x^k) - y_1 - \|y_2\| = \lambda_2(x^k) - \lambda_2(y),\\ y_1 - y_2^T x_2^k/\|x_2^k\| - \lambda_1(x^k) &\geq y_1 - \|y_2\| - \lambda_1(x^k) = \lambda_1(y) - \lambda_1(x^k).\end{aligned}$$

Since $\lambda_1(x^k), \lambda_2(x^k) \to 0$ as $k \to +\infty$ and $\lambda_1(y), \lambda_2(y) > 0$ by $y \in \mathrm{int}(\mathcal{K}^n)$, the last two inequalities imply that

$$\begin{aligned}\lambda_2(x^k) - y_1 - y_2^T x_2^k/\|x_2^k\| &\to -\lambda_2(y) < 0,\\ y_1 - y_2^T x_2^k/\|x_2^k\| - \lambda_1(x^k) &\to \lambda_1(y) > 0.\end{aligned}$$

On the other hand, by Condition C.2, when $k \to +\infty$,

$$\phi''(\lambda_2(x^k)) \to +\infty, \quad \phi''(\lambda_1(x^k)) \to +\infty.$$

The two sides show that the right-hand side of (31) approaches to $-\infty$ as $k \to +\infty$, and consequently, $2|[\nabla(\phi')^{\mathrm{soc}}(x^k) \cdot (x^k - y)]_1| \to +\infty$. Thus, from (30), it follows that $\|\nabla_x D(x^k, y)\| \to +\infty$ as $k \to +\infty$.

(e) From the definition of $D(x, y)$, it follows that, for any $x, y \in \mathrm{int}(\mathcal{K}^n)$,

$$\begin{aligned}D(x,y) &= \mathrm{tr}[\phi^{\mathrm{soc}}(y)] - \mathrm{tr}[\phi^{\mathrm{soc}}(x)] - \mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ y] + \mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ x]\\ &= \sum_{i=1}^{2} \phi(\lambda_i(y)) - \sum_{i=1}^{2} \phi(\lambda_i(x)) - \mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ y] + \mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ x], \qquad (32)\end{aligned}$$

where the second equality is from Lemma 4.1(a) and Property 2.1(c). Since

$$\begin{aligned}(\phi')^{\mathrm{soc}}(x) \circ x &= \left[\phi'(\lambda_1(x))u_x^{(1)} + \phi'(\lambda_2(x))u_x^{(2)}\right] \circ \left[\lambda_1(x)u_x^{(1)} + \lambda_2(x)u_x^{(2)}\right]\\ &= \phi'(\lambda_1(x))\lambda_1(x)u_x^{(1)} + \phi'(\lambda_2(x))\lambda_2(x)u_x^{(2)},\end{aligned}$$

we have from Lemma 2.2(a) that

$$\mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ x] = \sum_{i=1}^{2} \phi'(\lambda_i(x))\lambda_i(x).$$

In addition, by Lemma 2.1(c) and Lemma 4.1(a), we have that

$$\mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ y] \leq \sum_{i=1}^{2} \phi'(\lambda_i(x))\lambda_i(y).$$

Combining the last two inequalities with (32) yields that

$$\begin{aligned}D(x,y) &\geq \sum_{i=1}^{2} \left[\phi(\lambda_i(y)) - \phi(\lambda_i(x)) - \phi'(\lambda_i(x))\lambda_i(y) + \phi'(\lambda_i(x))\lambda_i(x)\right]\\ &= \sum_{i=1}^{2} \left[\phi(\lambda_i(y)) - \phi(\lambda_i(x)) - \phi'(\lambda_i(x))(\lambda_i(y) - \lambda_i(x))\right]\\ &= \sum_{i=1}^{2} d_B(\lambda_i(y), \lambda_i(x)),\end{aligned}$$

where $d_B : \mathbb{R}_+ \times \mathbb{R}_{++} \to \mathbb{R}$ is the function defined by

$$d_B(s,t) = \phi(s) - \phi(t) - \phi'(t)(s-t).$$

This implies that, for any fixed $y \in \mathcal{K}^n$ and $\gamma \geq 0$,

$$L_D(y,\gamma) \subseteq \left\{ x \in \mathrm{int}(\mathcal{K}^n) \;\Big|\; \sum_{i=1}^{2} d_B(\lambda_i(y), \lambda_i(x)) \leq \gamma \right\}. \tag{33}$$

Note that, for any fixed $s \geq 0$, the set $\{t > 0 : d_B(s,t) \leq 0\}$ equals to $\{s\}$ or $\emptyset$, and hence it is bounded. Thus, from [29, Corollary 8.7.1] and Condition C.3, it follows that the level sets $\{t > 0 : d_B(s,t) \leq \gamma\}$ for any fixed $s \geq 0$ are bounded. This together with (33) implies that the level sets $L_D(y,\gamma)$ are bounded for all $\gamma \geq 0$. □

PROPOSITION 4.2. *Given a $\phi \in \Phi$, let $D(x,y)$ be defined as in* (18). *Then, for all $x, y \in \mathrm{int}(\mathcal{K}^n)$ and $z \in \mathcal{K}^n$, we have the following inequality:*

$$\begin{aligned} D(x,z) - D(y,z) &\geq 2\langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot (z-y),\ y-x \rangle \\ &= 2\langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot (y-x),\ z-y \rangle. \end{aligned} \tag{34}$$

Proof. From the definition of $D(x,y)$ and $\phi_z(x)$ and equality (29), it follows that

$$\begin{aligned} D(x,z) - D(y,z) &= \mathrm{tr}[(\phi')^{\mathrm{soc}}(x) \circ x - \phi^{\mathrm{soc}}(x)] + \phi_z(x) \\ &\quad -\mathrm{tr}[(\phi')^{\mathrm{soc}}(y) \circ y - \phi^{\mathrm{soc}}(y)] - \phi_z(y) \\ &= \mathrm{tr}[\psi^{\mathrm{soc}}(x)] - \mathrm{tr}[\psi^{\mathrm{soc}}(y)] + \phi_z(x) - \phi_z(y) \\ &\geq \langle \nabla \mathrm{tr}[\psi^{\mathrm{soc}}(y)],\ x-y \rangle + \langle \nabla \phi_z(y),\ x-y \rangle \\ &= \langle 2(\psi')^{\mathrm{soc}}(y),\ x-y \rangle - \langle 2\nabla(\phi')^{\mathrm{soc}}(y) \cdot z,\ x-y \rangle, \end{aligned} \tag{35}$$

where the inequality is due to the convexity of $\mathrm{tr}[\psi^{\mathrm{soc}}(x)]$ and $\phi_z(x)$, and the last equality follows from Lemma 2.2(c) and Lemma 4.2(a). From the definition of ψ given as in (28), it is easy to compute that

$$\langle (\psi')^{\mathrm{soc}}(y),\ x-y \rangle = \langle (\phi'')^{\mathrm{soc}}(y) \circ y,\ x-y \rangle. \tag{36}$$

In addition, by the gradient formulas in (14)–(15), we can compute that

$$\nabla(\phi')^{\mathrm{soc}}(y) \cdot y = (\phi'')^{\mathrm{soc}}(y) \circ y, \tag{37}$$

which in turn implies that

$$\begin{aligned} &\langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot z,\ x-y \rangle \\ &= \langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot (y+z-y),\ x-y \rangle \\ &= \langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot y,\ x-y \rangle + \langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot (z-y),\ x-y \rangle \\ &= \langle (\phi'')^{\mathrm{soc}}(y) \circ y,\ x-y \rangle + \langle \nabla(\phi')^{\mathrm{soc}}(y) \cdot (z-y),\ x-y \rangle. \end{aligned}$$

This, together with (36) and (35), yields the first inequality in (34), whereas the second inequality follows from the symmetry of the matrix $\nabla(\phi')^{\mathrm{soc}}(y)$. □

Propositions 4.1–4.2 indicate that $D(x,y)$ possesses some favorable properties similar to those for d_φ. In the next section, we will employ these properties to establish the convergence for an approximate version of the proximal-like algorithm (8).

5. Approximate proximal-like algorithm. The proximal-like algorithm described as (8) for the CSOCP consists of a sequence of exact minimization. However, in practical computations, it is impossible to obtain the exact solution of these minimization problems. In this section, we consider an approximate version of this algorithm, which allows the inexact solution of the subproblems (8). Throughout this section, we make the following assumptions for the CSOCP:

(A1) $\inf\{f(\zeta) \mid \zeta \in \mathcal{F}\} := f_* > -\infty$ and $\mathrm{dom} f \cap \mathrm{int}(\mathcal{F}) \neq \emptyset$.

(A2) The matrix A is of maximal rank m.

Remark 5.1. Assumption A1 is elementary for the existence of the solution of the CSOCP. Assumption A2 is common in the solution of the SOCPs, which is clearly satisfied when $\mathcal{F} = \{\zeta \in \mathbb{R}^n \mid \zeta \succeq_{\mathcal{K}^n} 0\}$. Moreover, if we consider the linear SOCP

$$\begin{array}{l} \min\ \bar{c}^T x \\ \text{s.t. } \bar{A}x = \bar{b}, \quad x \in \mathcal{K}^n, \end{array} \tag{38}$$

where $\bar{A} \in \mathbb{R}^{m\times n}$, with $m \leq n$, $\bar{b} \in \mathbb{R}^m$ and $\bar{c} \in \mathbb{R}^n$, the assumption that $\bar{A}$ has full row rank m is standard. Consequently, its dual problem, given by

$$\begin{array}{l} \max\ \bar{b}^T y \\ \text{s.t. } \bar{c} - \bar{A}^T y \succeq_{\mathcal{K}^n} 0 \end{array} \tag{39}$$

satisfies assumption A2. This shows that we can solve the linear SOCP by applying the approximate proximal-like algorithm described below to the dual problem (39). In addition, from Lemma 1 in the appendix, we know that the recession cone of $\mathcal{F}$ is given by $0^+\mathcal{F} = \{d \in \mathbb{R}^m | \ Ad \succeq_{\mathcal{K}^n} 0\}$. This implies that assumption A2 is also satisfied when $\mathcal{F}$ is supposed to be bounded, since its recession cone $0^+\mathcal{F}$ now reduces to zero.

For the sake of notation, in what follows, we denote $\mathcal{D} : \mathrm{int}(\mathcal{F}) \times \mathcal{F} \to \mathbb{R}$ by

$$\mathcal{D}(\zeta, \xi) := D(A\zeta + b, A\xi + b). \tag{40}$$

From Proposition 4.1, we readily obtain the following properties of $\mathcal{D}(\zeta, \xi)$.

LEMMA 5.1. *Let $\mathcal{D}(\zeta, \xi)$ be defined by* (40)*. Then, under assumption* A2*, we have that*

(a) $\mathcal{D}(\zeta, \xi) \geq 0$ *for any* $\zeta \in \mathrm{int}(\mathcal{F})$ *and* $\xi \in \mathcal{F}$*, and* $\mathcal{D}(\zeta, \xi) = 0$ *if and only if* $\zeta = \xi$*;*

(b) *the function* $\mathcal{D}(\cdot, \xi)$ *for any fixed* $\xi \in \mathcal{F}$ *is continuously differentiable on* $\mathrm{int}(\mathcal{F})$*, with*

$$\nabla_\zeta \mathcal{D}(\zeta, \xi) = 2A^T \nabla(\phi')^{\mathrm{soc}}(A\zeta + b)A(\zeta - \xi); \tag{41}$$

(c) *for any fixed* $\xi \in \mathcal{F}$*, the function* $\mathcal{D}(\cdot, \xi)$ *is convex on* $\mathrm{int}(\mathcal{F})$*, and for any fixed* $\xi \in \mathrm{int}(\mathcal{F})$*, then* $\mathcal{D}(\cdot, \xi)$ *is strictly convex over* $\mathrm{int}(\mathcal{F})$*;*

(d) *for any fixed* $\xi \in \mathrm{int}(\mathcal{F})$*, the function* $\mathcal{D}(\cdot, \xi)$ *is essentially smooth;*

(e) *for any fixed* $\xi \in \mathcal{F}$*, the level sets* $L(\xi, \gamma) = \left\{\zeta \in \mathrm{int}(\mathcal{F}) : \mathcal{D}(\zeta, \xi) \leq \gamma\right\}$ *for all* $\gamma \geq 0$ *are bounded.*

Now we describe an approximate version of the proximal-like algorithm (APM) (8).

The APM. *Given a starting point* $\zeta^0 \in \mathrm{int}(\mathcal{F})$ *and constants* $\epsilon_k \geq 0$ *and* $\mu_k > 0$*, generate the sequence* $\{\zeta^k\} \subset \mathrm{int}(\mathcal{F})$ *satisfying*

$$g^k \in \partial_{\epsilon_k} f(\zeta^k), \tag{42}$$

$$\mu_k g^k + \nabla_\zeta \mathcal{D}(\zeta^k, \zeta^{k-1}) = 0, \tag{43}$$

where $\partial_\epsilon f$ *represents the* ϵ*-subdifferential of* f*.*

Remark 5.2. The APM can be regarded as an approximate version of the proximal algorithm (8) in the following sense. From the relation in (42) and the convexity of $\mathcal{D}(\cdot,\xi)$ over $\mathrm{int}(\mathcal{F})$ for any fixed $\xi \in \mathrm{int}(\mathcal{F})$, it follows that, for any $u \in \mathrm{int}(\mathcal{F})$,

$$f(u) \geq f(\zeta^k) + \langle u - \zeta^k, g^k \rangle - \epsilon_k$$

and

$$\mu_k^{-1}\mathcal{D}(u,\zeta^{k-1}) \geq \mu_k^{-1}\mathcal{D}(\zeta^k,\zeta^{k-1}) + \mu_k^{-1}\langle \nabla_\zeta \mathcal{D}(\zeta^k,\zeta^{k-1}),\ u-\zeta^k\rangle.$$

Adding the last two inequalities and using (43) yields that

$$f(u) + \mu_k^{-1}\mathcal{D}(u,\zeta^{k-1}) \geq f(\zeta^k) + \mu_k \mathcal{D}(\zeta^k,\zeta^{k-1}) - \epsilon_k.$$

This implies that

$$\zeta^k \in \epsilon_k - \mathrm{argmin}\left\{f(\zeta) + \mu_k^{-1}\mathcal{D}(\zeta,\zeta^{k-1})\right\}, \tag{44}$$

where, for a given function F and $\epsilon \geq 0$, the notation

$$\epsilon - \mathrm{argmin}\ F(\zeta) := \left\{\zeta^* : F(\zeta^*) \leq \inf F(\zeta) + \epsilon\right\}. \tag{45}$$

In the rest of this section, we focus on the convergence of the APM under assumptions A1 and A2. First, we prove that the APM generates a sequence $\{\zeta^k\} \subset \mathrm{int}(\mathcal{F})$, and consequently the APM is well-defined. This is implied by the following lemma.

LEMMA 5.2. *For any $\xi \in \mathrm{int}(\mathcal{F})$ and $\mu > 0$, we have that the following results hold:*

(a) *The function $F(\cdot) := f(\cdot) + \mu^{-1}\mathcal{D}(\cdot,\xi)$ has bounded level sets under assumption* A1.

(b) *If, in addition, assumption* A2 *holds, then there has a unique $\widehat{\zeta} \in \mathrm{int}(\mathcal{F})$ such that*

$$\widehat{\zeta} = \mathop{\mathrm{argmin}}_{\zeta \in \mathrm{int}(\mathcal{F})} \left\{f(\zeta) + \mu^{-1}\mathcal{D}(\zeta,\xi)\right\}, \tag{46}$$

and moreover, the minimum in the right-hand side is attained at $\widehat{\zeta}$ satisfying

$$-2\mu^{-1}A^T\nabla(\phi')^{\mathrm{soc}}(A\widehat{\zeta}+b)A(\widehat{\zeta}-\xi) \in \partial f(\widehat{\zeta}). \tag{47}$$

Proof. (a) Fix $\xi \in \mathrm{int}(\mathcal{F})$ and $\mu > 0$. By assumption A1 and the nonnegativity of $\mathcal{D}(\zeta,\xi)$, to show that $F(\zeta)$ has bounded level sets, it suffices to show that, for all $\nu \geq f_*$, the level sets $L(\nu) := \{\zeta \in \mathrm{int}(\mathcal{F}) \mid F(\zeta) \leq \nu\}$ are bounded. Notice that $L(\nu) \subseteq L(\xi, \mu(\nu - f_*))$ and $L(\xi,\gamma) := \{\zeta \in \mathrm{int}(\mathcal{F}) \mid \mathcal{D}(\zeta,\xi) \leq \gamma\}$ are bounded for all $\gamma \geq 0$ by Lemma 5.1 (e). Therefore, the sets $L(\nu)$ all $\nu \geq f_*$ are bounded.

(b) By Lemma 5.1(b), $F(\zeta)$ is a closed proper strictly convex function. Hence, if the minimum exists, it must be unique. From part (a), the minimizer $\widehat{\zeta}$ exists, and so it is unique. Under assumption A2, using the gradient formula in (41) and the optimality conditions for (46) then yields that

$$0 \in \partial f(\widehat{\zeta}) + 2\mu^{-1}A^T\nabla(\phi')^{\mathrm{soc}}(A\widehat{\zeta}+b)A(\widehat{\zeta}-\xi) + \partial\delta(\widehat{\zeta} \mid \mathcal{F}), \tag{48}$$

where $\delta(u \mid \mathcal{F}) = 0$ if $u \in \mathcal{F}$ and $+\infty$ otherwise. By Lemma 5.1(c) and [29, Theorem 26.1], we have that $\partial_\zeta \mathcal{D}(\zeta,\xi) = \emptyset$ for all $\zeta \in \mathrm{bd}(\mathcal{F})$. Hence, the relation in (48) implies that $\widehat{\zeta} \in \mathrm{int}(\mathcal{F})$. On the other hand, from [29, p. 226], we know that

$$\partial\delta(u \mid \mathcal{F}) = \{v \in \mathbb{R}^n \mid v \preceq_{\mathcal{K}^n} 0,\ \mathrm{tr}(v \circ u) = 0\}.$$

Using Lemma 2.1, we then obtain $\partial\delta(\widehat{\zeta} \mid \mathcal{F}) = \{0\}$. Thus, the proof is complete. ∎

Next, we investigate the properties of the sequence $\{\zeta^k\}$ generated by the APM.

PROPOSITION 5.1. *Let $\{\mu_k\}$ be any sequence of positive numbers and $\sigma_n = \sum_{k=1}^n \mu_k$. Let $\{\zeta^k\}$ be the sequence generated by the APM. Then,*

(a) $\mu_k[f(\zeta^k) - f(\zeta)] \le \mathcal{D}(\zeta^{k-1}, \zeta) - \mathcal{D}(\zeta^k, \zeta) + \mu_k\epsilon_k$ *for all* $\zeta \in \mathcal{F}$.

(b) $\mathcal{D}(\zeta^k, \zeta) \le D(\zeta^{k-1}, \zeta) + \mu_k\epsilon_k$ *for all* $\zeta \in \mathcal{F}$ *subject to* $f(\zeta) \le f(\zeta^k)$.

(c) $\sigma_n(f(\zeta^n) - f(\zeta)) \le \mathcal{D}(\zeta^0, \zeta) - D(\zeta^n, \zeta) + \sum_{k=1}^n \sigma_k\epsilon_k$ *for all* $\zeta \in \mathcal{F}$.

Proof. (a) For any $\zeta \in \mathcal{F}$, using the definition of the ϵ-subdifferential, we have that

$$f(\zeta) \ge f(\zeta^k) + \langle g^k,\ \zeta - \zeta^k\rangle - \epsilon_k, \tag{49}$$

where $g^k \in \partial_{\epsilon_k} f(\zeta^k)$. However, from (43) and (41), it follows that

$$g^k = -2\mu_k^{-1} A^T \nabla(\phi')^{\mathrm{soc}}(A\zeta^k + b)A(\zeta^k - \zeta^{k-1}).$$

Substituting this g^k into (49), we then obtain that

$$\mu_k[f(\zeta^k) - f(\zeta)] \le 2\Big\langle A^T \nabla(\phi')^{\mathrm{soc}}(A\zeta^k + b)A(\zeta^k - \zeta^{k-1}),\ \zeta - \zeta^k\Big\rangle + \mu_k\epsilon_k.$$

On the other hand, applying Proposition 4.2 at the points $x = A\zeta^{k-1} + b$, $y = A\zeta^k + b$, and $z = A\zeta + b$ and using the definition of $\mathcal{D}(\zeta, \xi)$ given by (40) yields that

$$\mathcal{D}(\zeta^{k-1}, \zeta) - \mathcal{D}(\zeta^k, \zeta) = 2\Big\langle A^T \nabla(\phi')^{\mathrm{soc}}(A\zeta^k + b)A(\zeta^k - \zeta^{k-1}),\ \zeta - \zeta^k\Big\rangle.$$

Combining the last two equations, we immediately obtain the result.

(b) The result follows directly from part (a) for any $\zeta \in \mathcal{F}$ such that $f(\zeta^k) \ge f(\zeta)$.

(c) First, from (44), it follows that

$$\zeta^k \in \epsilon_k - \operatorname{argmin}\left\{f(\zeta) + \mu_k^{-1}\mathcal{D}(\zeta, \zeta^{k-1})\right\}.$$

This implies that, for any $\zeta \in \operatorname{int}(\mathcal{F})$,

$$f(\zeta) + \mu_k^{-1}\mathcal{D}(\zeta, \zeta^{k-1}) \ge f(\zeta^k) + \mu_k^{-1}\mathcal{D}(\zeta^k, \zeta^{k-1}) - \epsilon_k.$$

Setting $\zeta = \zeta^{k-1}$ in this inequality and using Lemma 5.1(d) then yields that

$$f(\zeta^{k-1}) - f(\zeta^k) \ge \mu_k^{-1}\mathcal{D}(\zeta^k, \zeta^{k-1}) - \epsilon_k \ge -\epsilon_k.$$

Multiplying the above inequality by σ_{k-1} and summing over $k = 1, 2, \ldots, n$, we get

$$\sum_{k=1}^n \left[\sigma_{k-1} f(\zeta^{k-1}) - (\sigma_k - \mu_k) f(\zeta^k)\right] \ge -\sum_{k=1}^n \sigma_{k-1}\epsilon_k,$$

which, by noting that $\sigma_k = \mu_k + \sigma_{k-1}$ (with $\sigma_0 \equiv 0$), can be reduced to

$$\sigma_n f(\zeta^n) - \sum_{k=1}^n \mu_k f(\zeta^k) \le \sum_{k=1}^n \sigma_{k-1}\epsilon_k.$$

On the other hand, using part (a) and summing over $k = 1, 2, \ldots, n$, we have that

$$-\sigma_n f(\zeta) + \sum_{k=1}^n \mu_k f(\zeta^k) \le \mathcal{D}(\zeta^0, \zeta) - D(\zeta^n, \zeta) + \sum_{k=1}^n \mu_k\epsilon_k \quad \forall \zeta \in \mathcal{F}.$$

Adding the last two inequalities yields

$$\sigma_n(f(\zeta^n) - f(\zeta)) \le \mathcal{D}(\zeta^0, \zeta) - D(\zeta^n, \zeta) + \sum_{k=1}^{n} (\mu_k + \sigma_{k-1})\epsilon_k,$$

which proves (c) because $\mu_k + \sigma_{k-1} = \sigma_k$. ∎

We are now in a position to prove our main convergence result for the APM. For convenience, we denote the optimal set of the CSOCP by $\mathcal{X} := \{\zeta \mid f(\zeta) = f_*\}$.

PROPOSITION 5.2. *Let $\{\zeta^k\}$ be the sequence generated by the APM and $\sigma_n = \sum_{k=1}^{n} \mu_k$. Then, under assumptions* A1 *and* A2*, the following results hold.*

(a) *If $\sigma_n \to +\infty$ and $\mu_k^{-1}\sigma_k\epsilon_k \to 0$, then $\lim_{n\to+\infty} f(\zeta^n) \to f_*$.*

(b) *If the optimal set $\mathcal{X} \neq \emptyset$, $\sigma_n \to \infty$ and $\sum_{k=1}^{\infty} \mu_k\epsilon_k < \infty$, then the sequence ζ^k is bounded, and every accumulation point is a solution of the CSOCP.*

Proof. (a) From Proposition 5.1(c) and the nonnegativity of $\mathcal{D}(\zeta^n, \zeta)$, it follows that

$$f(\zeta^n) - f(\zeta) \le \sigma_n^{-1}\mathcal{D}(\zeta^0, \zeta) + \sigma_n^{-1} \sum_{k=1}^{n} \sigma_k\epsilon_k \quad \forall \zeta \in \mathcal{F}.$$

Taking the limit $\sigma_n \to +\infty$ to the two sides of the last inequality, we immediately have that the first term in the right-hand side goes to zero. In addition, applying Lemma 2 in the appendix with $a_{nk} := \sigma_n^{-1}\mu_k$ if $k \le n$ and $a_{nk} := 0$ otherwise and $u_k := \mu_k^{-1}\sigma_k\epsilon_k$, we obtain the second term in the right-hand side:

$$\sigma_n^{-1} \sum_{k=1}^{n} \sigma_k\epsilon_k = \sum_k a_{nk}u_k \to 0$$

because $\sigma_n \to +\infty$ and $\mu_k^{-1}\sigma_k\epsilon_k \to 0$. Therefore, we have that the

$$\lim_{n\to+\infty} f(\zeta^n) \le f_*.$$

This, together with the fact that $f(\zeta^n) \ge f_*$, implies the desired result.

(b) Suppose that $\zeta^* \in \mathcal{X}$. For any k, we have that $f(\zeta^k) \ge f(\zeta^*)$. From Proposition 5.1(b), it then follows that

$$\mathcal{D}(\zeta^k, \zeta^*) \le \mathcal{D}(\zeta^{k-1}, \zeta^*) + \mu_k\epsilon_k.$$

Since $\sum_{k=1}^{\infty} \mu_k\epsilon_k < +\infty$, using Lemma 3 in the appendix with $v_k := \mathcal{D}(\zeta^k, \zeta^*) \ge 0$ and $\beta_k := \mu_k\epsilon_k \ge 0$ yields that the sequence $\{\mathcal{D}(\zeta^k, \zeta^*)\}$ converges. Thus, by Proposition 5.1(e), the sequence $\{\zeta^k\}$ is bounded and consequently has an accumulation point. Without any loss of generality, let $\widehat{\zeta} \in \mathcal{F}$ be an accumulation point of $\{\zeta^k\}$. Then $\{\zeta^{k_j}\} \to \widehat{\zeta}$ for some $k_j \to +\infty$. Since f is lower semicontinuous, we get $f(\widehat{\zeta}) = \liminf_{k_j\to\infty} f(\zeta^{k_j})$. On the other hand, $f(\zeta^{k_j}) \to f_*$ by part (a). The two sides imply that $f(\widehat{\zeta}) = f_*$. Therefore, $\widehat{\zeta}$ is a solution of the CSOCP. The proof is thus complete. ∎

6. Numerical experiments. In this section, we present some preliminary numerical results for CSOCPs with a specific version of the concept APM, described as Algorithm 6.1 below, and compare the numerical performance of the algorithm

with that of the merit function approach [8]. The purpose of our numerical experiments is to verify the theoretical results obtained in the last section and to illustrate the effectiveness of the proximal-like method proposed.

ALGORITHM 6.1.

Given a sufficiently small $\tau > 0$, a sufficiently large M_0, and constants $\rho > 1$ and $\mu_1 > 0$. Choose a starting point $\zeta^0 \in \mathrm{int}(\mathcal{F})$ and set $k := 1$.

For $k = 1, 2, \cdots$ **until** $\mu_k \geq M_0$ **do**

1. Use an unconstrained minimization method to solve approximately the problem

$$\min_{\zeta \in \mathbb{R}^m} \; F_k(\zeta) := f(\zeta) + \mu_k^{-1} \mathcal{D}(\zeta, \zeta^{k-1}) \tag{50}$$

and obtain a ζ^k such that $\|\nabla f(\zeta^k) + \mu_k^{-1} \nabla_\zeta \mathcal{D}(\zeta^k, \zeta^{k-1})\| \leq \tau$.

2. Set $\mu_{k+1} = \rho \mu_k$ and $k := k + 1$, and then go back to Step 1.

End

Algorithm 6.1 is in fact a special APM with $\epsilon_k = \tau \|\zeta^k - \widehat{\zeta}^k\|$ and $\mu_k = \rho^{k-1}\mu_1$, where $\widehat{\zeta}^k$ is the solution of the subproblem (44), since using the strict convexity of $F_k(\zeta)$, we have that

$$F_k(\widehat{\zeta}^k) \geq F_k(\zeta^k) + \langle \nabla F_k(\zeta^k), \widehat{\zeta}^k - \zeta^k \rangle \geq F_k(\zeta^k) - \tau \|\zeta^k - \widehat{\zeta}^k\|,$$

which implies that

$$\zeta^k \in \epsilon_k - \mathrm{argmin} F_k(\zeta), \text{ with } \epsilon_k = \tau \|\zeta^k - \widehat{\zeta}^k\|.$$

Furthermore, such ϵ_k and μ_k at least satisfy the assumptions of Proposition 5.2(a), since

$$\sigma_n = \sum_{k=1}^{n} \mu_k \to +\infty, \quad \mu_k^{-1}\sigma_k \to \frac{\rho}{\rho - 1}, \quad \text{and} \quad \epsilon_k \to 0.$$

In our experiments, we employed the entropy-like distance functions from Example 3.1 and Example 3.2, respectively, for Algorithm 6.1. For convenience, let

$$\mathcal{D}_1(\zeta, \xi) := D_1(A\zeta + b, A\xi + b) \;\text{ and }\; \mathcal{D}_2(\zeta, \xi) := D_2(A\zeta + b, A\xi + b).$$

All numerical experiments were done on a personal computer with 2.8GHz CPU and 512MB memory. The computer codes were all written in Matlab 6.5. We chose a limited-memory BFGS method with 5 limited-memory vector-updates [4] to solve the minimization subproblem (50). In addition, we adopted a nonmonotone line search described as in [16] to seek a suitable steplength, i.e., we computed the smallest nonnegative integer l such that

$$F_k(\zeta^k + \beta^l d^k) \leq \mathcal{W}_k + \sigma \beta^l \nabla F_k(\zeta^k)^T d^k,$$

where d^k denotes the search direction at the kth iterate, and $\mathcal{W}_k = \max_{j=k-m_k,\ldots,k} F_k(\zeta^j)$ and where, for a given nonnegative integer $\hat{m}$ and s,

$$m_k = \begin{cases} 0 & \text{if } k \leq s, \\ \min\{m_{k-1} + 1, \hat{m}\} & \text{otherwise.} \end{cases}$$

Unless otherwise stated, we chose $\beta = 0.5$, $\sigma = 10^{-4}$, $\hat{m} = 5$, and $s = 5$ for the nonmontone line search, and the following parameters for Algorithm 6.1:

$$\tau = 10^{-5}, \quad M_0 = 1000, \quad \rho = 10, \quad \text{and} \quad \mu_1 = 1.$$

We applied Algorithm 6.1 for the following quadratic convex SOC program:

$$\begin{aligned} &\min \ \frac{1}{2}\zeta^T M\zeta + q^T\zeta \\ &\text{s.t. } \zeta \succeq_{\mathcal{K}^n} 0, \end{aligned} \tag{51}$$

where $M \in \mathbb{R}^{n\times n}$ is a symmetric positive semidefinite matrix and $q \in \mathbb{R}^n$ is a vector. In the experiment, the matrix M and the vector q were generated as follows: elements of q were chosen randomly from the interval $[-1, 1]$, and M was obtained by setting $M = DD^T$, where D was a sparse matrix with approximately *density* $\cdot\, n \cdot n$ nonzero entries, which were chosen from a normal distribution with mean -1 and variance 4. In this procedure, the number of nonzero entries of D is determined so that the nonzero density of M can be approximately estimated. To construct different types of $\mathcal{K}$, we chose n_i and N such that $n_1 + \cdots + n_N = 1000$ and $n_1 = \cdots = n_N = 100$. For each type of $\mathcal{K}$, we have solved 10 test problems with the matrix M of nonzero density 0.5%, 1% and 10%, respectively, and started Algorithm 6.1 from the initial point $\zeta^0 = (\bar{\zeta}^{n_i}, \ldots, \bar{\zeta}^{n_N})$, where $\bar{\zeta}^{n_i} = (2, \omega_i/\|\omega_i\|)$ for $i = 1, 2, \ldots, N$, with $\omega_i \in \mathbb{R}^{n_i-1}$ generated randomly by Matlab's **randn.m**. We also employed the merit function approach [8] to solve these test problems. In other words, we chose the same limited-memory BFGS method as used by Algorithm 6.1 to solve the unconstrained minimization reformulation for the KKT conditions of (51):

$$\min_{\zeta\in\mathbb{R}^n} \Psi_{\rm FB}(\zeta) := \frac{1}{2}\left\|(\zeta^2 + (M\zeta+q)^2)^{1/2} - \zeta - (M\zeta+q)\right\|^2. \tag{52}$$

For the merit function approach, we used the same starting point ζ^0 as Algorithm 6.1 and terminated the iterates once $\sqrt{2\Psi_{\rm FB}(\zeta)} \le 10^{-4}$.

The numerical results were listed in Tables 1–3 (see the appendix), where **Rcond** denotes the condition number of the matrix M computed by Matlab's **rcond.m**, **Gap** means the absolute dual gap, i.e., the value of the function $|\zeta^T(M\zeta+q)|$ at the final iteration, **NF** represents the number of function evaluations for $F_k(\zeta)$ or $\Psi_{\rm FB}(\zeta)$ to solve each problem, which for Algorithm 6.1 is the total sum of the function evaluations used for every subproblem, and **Cpu** represents the CPU time in seconds for solving each problem.

From Tables 1–3, we see that Algorithm 6.1 with $D_1(x, y)$ and $D_2(x, y)$ can solve almost all of the test problems within 10^5 function evaluations, except three test problems in Table 1 for which the merit function approach cannot yield the desired result within 5×10^4 function evaluations, too. Algorithm 6.1 requires more function evaluations than the merit function approach, especially for the problems with the matrix M of nonzero density 0.5% and 1%. This is reasonable since the APM is only a primal algorithm, whereas the merit function approach is a primal-dual one. When comparing Table 1 with Tables 2–3, we find that the condition number of M has a great influence on the numerical performance of Algorithm 6.1 and the merit function approach; for example, the two methods have the worst robustness when the condition number of M equals 0. In addition, from Tables 1–3, it seems that the number of function evaluations of Algorithm 6.1 is not influenced by the nonzero density of

M, but the merit function approach clearly requires more function evaluations as the nonzero density of M increases. Moreover, the merit function approach needs more CPU time at each iteration than Algorithm 6.1 due to an extra multiplication of the matrix M and the vector $\nabla_y \psi_{\rm FB}(\zeta, M\zeta + q)$ involved in the computation of $\nabla \Psi_{\rm FB}(\zeta)$. This accounts for the fact that Algorithm 6.1 is superior to the merit

function approach by the CPU time for the problems with the matrix M of nonzero density 10%.

We also applied Algorithm 6.1 for a nonlinear convex SOCP taken from [17].

Example 6.1. Consider the following nonlinear convex SOCP:

$$\begin{aligned} &\min\ \exp(\zeta_1-\zeta_3)+3(2\zeta_1-\zeta_2)^4+\sqrt{1+(3\zeta_2+5\zeta_3)^2}\\ &\text{s.t.}\ \begin{pmatrix} 4 & 6 & 3\\ -1 & 7 & -5\end{pmatrix}\zeta+\begin{pmatrix}-1\\ 2\end{pmatrix}\in\mathcal{K}^2,\quad \zeta\in\mathcal{K}^3. \end{aligned} \tag{53}$$

In order to obtain an initial interior point $\zeta^0\in\operatorname{int}(\mathcal{F})$ for Algorithm 6.1, we constructed the following conic optimization problem:

$$\begin{aligned} &\min\ w\\ &A\zeta+b+w\hat{e}\succeq_{\mathcal{K}}0,\\ &-w+w^*\geq 0,\\ &\mathcal{K}=\mathcal{K}^3\times\mathcal{K}^2, \end{aligned} \tag{54}$$

where $w^*\in\mathbb{R}$ is a constant and $\hat{e}=\begin{pmatrix}e_1\\ e_2\end{pmatrix}, A=\begin{bmatrix}A_1\\ A_2\end{bmatrix}, b=\begin{pmatrix}b_1\\ b_2\end{pmatrix}$, with

$$A_1=\begin{pmatrix}4 & 6 & 3\\ -1 & 7 & 5\end{pmatrix},\ A_2=I,\ b_1=(-1,2)^T,\ b_2=(0,0,0)^T, e_1=(1,0)^T,\ e_2=(1,0,0)^T.$$

It is easy to see that $\zeta=0,\ w=w_0$ belongs to $\operatorname{int}(\mathcal{F})$ only if $w_0>-\lambda_1(b_i),\ i=1,2$ and $w^*>w_0$, and furthermore, when solving (54) with Algorithm 6.1 from

TABLE 4

$\zeta = 0,\ w = w_0$, if some iterate (ζ^k, w^k) satisfying $w^k < 0$, then the corresponding ζ^k can be used as the starting point to solve (53). This way can also be used to find the starting interior point ζ^0 when applying Algorithm 6.1 for other problems with the form of (1). We have solved the test problem with Algorithm 6.1 from several starting points. The parameters for Algorithm 6.1 were the same as above except $M_0 = 10000$ and $\tau = 10^{-6}$. The numerical results were listed in Table 4, where **fopt** denotes the objective value at the final iteration. We see that the choice of ζ^0 has an influence on the numerical behavior of Algorithm 6.1.

From Tables 1–4, we may draw the following conclusions: the approximate proximal-like algorithm using $D_1(x, y)$ has the better numerical behavior than the one using $D_2(x, y)$ whether by the accuracy of solution or the number of function evaluations required, and the proximal-like algorithm with an appropriate distance measure is superior to the merit function approach by the CPU time for those dense problems.

7. Conclusions. In this paper, we extended the entropy-like proximal algorithm proposed by Eggermont [12] for convex programming subject to nonnegative constraints and proposed a class of interior proximal-like algorithms for solving the CSOCPs. These algorithms are based on a distance-like function generated by a closed proper convex function ϕ satisfying $\mathrm{dom}\phi = [0, +\infty)$ and Conditions (C.1)–(C.4). The given examples illustrated that the conditions required by ϕ are not very stringent. For the proposed proximal-like algorithm, we particularly considered an approximate version which allows inexact minimization steps, and we established the convergence properties under some mild assumptions. Numerical results were also reported for the algorithm with the entropy-like distance functions from Examples 3.1 and 3.2, and we made comparisons with those yielded by the merit function approach [8], which verify the effectiveness of the proposed method.

In our future research works, we will analyze the convergence rate of the proposed algorithms and investigate some practical versions of the algorithms. In addition, we will consider the extension of the class of interior proximal-like algorithms to general convex symmetric cone programming problems. It should be pointed out that the extension is not direct. The main difficulty is how to extend the characterizations of SOC-convexity [7, 9] to the setting of symmetric cones.

Appendix A.

LEMMA 1. *Let $\mathcal{F}$ be the set defined as in* (8). *Then its recession cone $0^+\mathcal{F}$ is given by*

$$0^+\mathcal{F} = \Big\{ d \in \mathbb{R}^m \mid Ad \succeq_{\mathcal{K}^n} 0 \Big\}. \tag{55}$$

Proof. Assume that $d \in \mathbb{R}^m$ such that $Ad \succeq_{\mathcal{K}^n} 0$. Then, for any $\lambda > 0$, $\lambda Ad \succeq_{\mathcal{K}^n} 0$. Considering that $\mathcal{K}^n$ is closed under the "+" operation, we have that, for any $\zeta \in \mathcal{F}$,

$$A(\zeta + \lambda d) + b = (A\zeta + b) + \lambda(Ad) \succeq_{\mathcal{K}^n} 0. \tag{56}$$

By [29, p. 61], this shows that every element in the set of the right-hand side of (55) is a recession direction of $\mathcal{F}$. Consequently, $\{d \in \mathbb{R}^m \mid Ad \succeq_{\mathcal{K}^n} 0\} \subseteq 0^+\mathcal{F}$.

Now take any $d \in 0^+\mathcal{F}$ and $\zeta \in \mathcal{F}$. Then, for any $\lambda > 0$, equation (56) holds. By Property 2.1(d), we then have $\lambda_1\Big[(A\zeta + b) + \lambda Ad\Big] \geq 0$ for any $\lambda > 0$. This implies that $\lambda_1(Ad) \geq 0$, since otherwise letting $\lambda \to +\infty$ and using the fact that

$$\begin{aligned}
\lambda_1\Big[(A\zeta + b) + \lambda Ad\Big] &= (A\zeta + b)_1 + \lambda(Ad)_1 - \|(A\zeta + b)_2 + \lambda(Ad)_2\| \\
&\leq (A\zeta + b)_1 + \lambda(Ad)_1 - \Big(\lambda\|(Ad)_2\| - \|(A\zeta + b)_2\|\Big) \\
&= \lambda\lambda_1(Ad) + \lambda_2(A\zeta + b),
\end{aligned}$$

we obtain that $\lambda_1[(A\zeta + b) + \lambda Ad] \to -\infty$. Thus, we prove that $Ad \succeq_{\mathcal{K}^n} 0$, and consequently $0^+\mathcal{F} \subseteq \{d \in \mathbb{R}^m \mid Ad \succeq_{\mathcal{K}^n} 0\}$. Combining with the above discussions then yields the result. □

LEMMA 2 (see [20, Theorem 2]). *Let $\{a_{nk}\}$ be a sequence of real numbers satisfying*

(i) $a_{nk} \geq 0$ $\forall n = 1, 2, \ldots,\ k = 1, 2, \ldots$.

(ii) $\sum_{k=1}^{\infty} a_{nk} = 1$ $\forall n = 1, 2, \ldots,$ *and* $\lim_{n\to+\infty} \sum_{k=1}^{n} a_{nk}u_k = u$ $\forall k = 1, 2, \ldots$.

If $\{u_k\}$ is a sequence such that $\lim_{k\to+\infty} u_k = u$, then $\lim_{k\to+\infty} a_{nk}u_k = u$.

LEMMA 3 (see [28, Chapter 2]). *Let $\{\upsilon_k\}$ and $\{\beta_k\}$ be nonnegative sequences of real numbers satisfying* (i) $\upsilon_{k+1} \leq \upsilon_k + \beta_k$, (ii) $\sum_{k=1}^{\infty} \beta_k < +\infty$. *Then the sequence $\{\upsilon_k\}$ is convergent.*

Acknowledgments. The authors would like to thank two anonymous referees for their helpful comments and suggestions on the revision of this paper. In particular, the influence of the condition number of M is observed by one referee.

DECENTRALIZED RESOURCE ALLOCATION IN DYNAMIC NETWORKS OF AGENTS*

HARIHARAN LAKSHMANAN† AND DANIELA PUCCI DE FARIAS‡

Abstract. We consider the problem of n agents that share m common resources. The objective is to derive an optimal allocation that maximizes a global objective expressed as a separable concave objective function. We propose a decentralized, asynchronous gradient-descent method that is suitable for implementation in the case where the communication between agents is described in terms of a dynamic network. This communication model accommodates situations such as mobile agents and communication failures. The method is shown to converge provided that the objective function has Lipschitz-continuous gradients. We further consider a randomized version of the same algorithm for the case where the objective function is nondifferentiable but has bounded subgradients. We show that both algorithms converge to near-optimal solutions and derive convergence rates in terms of the magnitude of the gradient of the objective function. We show how to accommodate nonnegativity constraints on the resources using the results derived. Experimental results with the problems of varying dimensions suggest that the algorithms are competitive with centralized approaches and scale well with problem size.

Key words. decentralized algorithms, resource allocation, nondifferentiable optimization

AMS subject classifications. 90C25, 91B32

DOI. 10.1137/060662228

1. Introduction.

We consider the problem of n agents that share m common resources. Agent i has utility function f_i. The optimal allocation of resources for maximizing the average of the utilities among agents is given by the following optimization problem:

$$\max_{\lambda_i \in \Re^m, i=1,\ldots,n} f(\lambda) = \frac{1}{n}\sum_{i=1}^{n} f_i(\lambda_i)$$

$$\text{such that (s.t.)} \sum_{i=1}^{n} \lambda_i = B, \tag{1}$$

where $B \in \Re^m$ corresponds to the total amount of resources.

We propose decentralized, asynchronous algorithms for a solution of (1). The first method applies in the case where $f_i, i = 1, \ldots, n$ are concave and differentiable with Lipschitz-continuous gradients. The second method applies in the case where $f_i, i = 1, \ldots, n$ are concave but not necessarily differentiable. We establish asymptotic convergence and convergence rates of both algorithms under mild conditions for communications among agents.

We assume that agents communicate through a network of dynamic topology in order to solve (1). At each iteration t, communication is represented by an undirected graph $G(t)$, where nodes correspond to agents and edges correspond to communication

links. We assume that communication is symmetric, so that if agent i communicates with agent j, then agent j also communicates with agent i. We also assume that the union of the communication graphs is connected over any sufficiently large, bounded period of time. This ensures that resource allocation to every agent is periodically influenced either directly or indirectly by the resource allocation to every other agent. This model of communication accommodates several practical scenarios, arising for instance, if agents are mobile and have limited communication range, or if communication links are subject to failure.

The decentralized algorithm for solving (1) in the case of differentiable utility functions has a simple gradient-descent structure. Starting with an initial feasible resource allocation, agents trade resources with their neighbors at each iteration in proportion to the difference in gradient for the respective utility functions. The algorithm has a natural interpretation. The local gradient computed by each agent can be thought of as the price the agent is willing to pay for additional resources. At each iteration, agents trade resources with their neighbors in proportion to the prices each is willing to pay for the resources.

It can be shown that a large class of separable convex optimization problems with linear constraints can be transformed to equivalent resource allocation problems. However, the functions f_i in the transformed resource allocation problem are usually not differentiable. Motivated by this setting, we consider the case where f_i is no longer differentiable but has bounded subgradients. It is shown in this case that a randomized version of a decentralized subgradient-descent algorithm converges with probability one to a near-optimal solution.

The subgradient-descent algorithm for the case of nondifferentiable utility functions can be interpreted as a stochastic approximation version of the gradient-descent method for differentiable functions applied to a smoothed version of the problem. The particular form of smoothing developed in this paper is motivated by several considerations. Adequate smoothing schemes must lead to a close approximation to the original function. Furthermore, as we build on the results for differentiable problems with a Lipschitz-continuous gradient, the gradient of the resulting smooth function must satisfy the same assumption with an adequate Lipschitz constant. Finally, another consideration in this paper is the computational effort involved in computing the gradient for the smoothed function. With this in mind, we propose a smooth approximation of the form $\hat{f}_i = \mathrm{E}[f_i(\lambda_i + Z_i)]$, where Z_i are vectors of zero-mean normal random variables. We show that, with an appropriate choice for the variance of Z_i, $\hat{f}_i$ is within ϵ of f_i, and its gradient is Lipschitz-continuous, with a Lipschitz constant on the order of $O(\sqrt{\log m}/\epsilon)$ so that it scales gracefully on the dimension m of variable λ_i. In addition, this form of smoothing lends itself to an application of a stochastic approximation scheme for gradient descent which, at each iteration, only requires an evaluation of a subgradient of f_i at a single point λ_i.

A comprehensive treatment of algorithms for various classes of resource allocation problems can be found in [13]. The algorithms introduced and analyzed in [13] are centralized in the sense that a central agent is assumed to have complete information about the problem and computes the optimal solution. In [1] and [5], decentralized resource allocation problems in the context of economics are investigated. The main difference in the approaches of [1, 5] as compared to the one presented here is the presence of a central agent who coordinates the computations performed by individual agents. A setting that is closer to ours is presented in [11], which introduces a completely decentralized algorithm for a resource allocation problem with twice differentiable separable convex objective functions. The algorithm assumes a sym-

metric and fixed communication graph for the agents at all iterations and performs a gradient projection at each iteration onto a subspace related to the communication graph. The same setting is considered in [8], which proposes a decentralized, weighted gradient algorithm for resource allocation problems with objective functions that are twice differentiable with bounded second derivatives. Dynamic communication graphs are considered in [6], which proposes an application-specific decentralized gradient algorithm for the problem of file allocation in distributed computer systems. Asynchronous gradient-descent methods are also considered in [14] for problems of unconstrained optimization with differentiable objective.

Most of the references regarding resource allocation problems in the literature, including the ones mentioned above, contain nonnegativity constraints on the resources (i.e., they require $\lambda_i \geq 0 \ \forall i$), whereas in our formulation resources may be negative. In Section 4, we show how the results in this paper can be applied to problems with nonnegativity constraints. The main motivation for problem (1) is that this formulation arises naturally in problems where a single, generic optimization problem must be solved in a decentralized way; this is the case, for instance, in problems of sequential decision making in teams of mobile agents as considered in [7].

A distributed algorithm for nondifferentiable optimization is presented in [9]. It is shown that a projected subgradient algorithm applied by each agent converges to the optimal solution. An important difference between the work presented in [9] and the work presented here is that the first requires that the long-run frequency of updates performed by each agent to be the same. Smoothing schemes for nondifferentiable optimization can also be found in the literature. [10] proposes a smoothing scheme for functions f_i described as the maximum of differentiable functions. The smoothed function is within ϵ of f_i and has Lipschitz constant on the order of $O(1/\epsilon)$, independent of the dimensions of the problem. A caveat of this approach is that computing the gradient of the smoothed function may require multiple evaluations of the subgradients of the original function. The particular form of smoothing considered here can also be found in the literature (see, e.g., [12]); however, we are unaware of results concerning the Lipschitz constant of the resulting smoothed function, which we develop in this paper.

The paper is organized as follows. In section 2, we describe the structure of communication among agents. In section 3, we introduce and we analyze the decentralized gradient-descent algorithm for problem (1) with differentiable objective functions that have Lipschitz-continuous gradients and its randomized version for problem (1) with nondifferentiable objective functions. In section 4 we describe a method to accommodate the nonnegativity constraints on the variables based on the results developed in section 3. In section 5, we present the results of numerical experiments, which illustrate the practical performance of the developed algorithms. In section 6, we conclude the paper. All proofs can be found in the appendix.

2. Communication between agents. In this section we describe the communication structure between agents. At iteration t, each agent i communicates with a set of agents denoted by $N_i(t)$. We assume that communication is symmetric; i.e., whenever agent i communicates with agent j, agent j also communicates with agent i. The communication between agents at time t can be represented by an undirected graph $G(t) = (N, E(t))$, where $N = \{1, \ldots, n\}$ represents the set of agents and the edge $(i, j) \in E(t)$ if and only if agent i communicates with agent j at time t. Let $E_{k,l} = \cup_{t=k}^{t=l-1} E(t)$. For a decentralized scheme to converge, the update of the variable associated with any agent must be periodically influenced by information from every other agent. This is ensured by the following assumption.

ASSUMPTION 2.1. *There exists a strictly increasing sequence* $\{T_z\}$ *of natural numbers, with* $T_1 = 1$ *such that* $G = (N, E_{T_z, T_{z+1}})$ *is connected for all* z *and* $(T_{z+1} - T_z) \leq \kappa$, *where* κ *is some natural number.*

3. Decentralized resource allocation. We assume that (1) has an optimal solution. Let $\lambda \in \Re^{nm} = (\lambda_1, \lambda_2, \ldots, \lambda_n)$, where $\lambda_i \in \Re^m$ for $i = 1, \ldots, n$.

ASSUMPTION 3.1. *There exists an optimal solution* $\lambda^* = (\lambda_1^*, \lambda_2^*, \ldots, \lambda_n^*)$ *to* (1).

For the rest of the paper, we let $\|\cdot\|$ denote the Euclidean norm.

3.1. The differentiable case. We now develop a decentralized algorithm for the case where f_i is concave and differentiable with a Lipschitz-continuous gradient.

ASSUMPTION 3.2. *There exists a constant* $L > 0$ *such that* $\|\nabla f_i(\lambda_i) - \nabla f_i(\bar{\lambda}_i)\| \leq L\|\lambda_i - \bar{\lambda}_i\|, \ \forall \lambda_i, \bar{\lambda}_i \in \Re^m$.

Recall that $f(\lambda) = \frac{1}{n}\sum_{i=1}^n f_i(\lambda_i)$. Hence

$$\begin{aligned}\|\nabla f(\lambda) - \nabla f(\bar{\lambda})\| &= \frac{1}{n}\sqrt{\sum_{i=1}^n \|\nabla f_i(\lambda_i) - \nabla f_i(\bar{\lambda}_i)\|^2} \\ &\leq \frac{1}{n}\sqrt{\sum_{i=1}^n L^2\|\lambda_i - \bar{\lambda}_i\|^2} \\ &= \frac{L}{n}\|\lambda - \bar{\lambda}\|.\end{aligned}$$

The second equality follows from the fact that $\|\lambda - \bar{\lambda}\| = \sqrt{\sum_{i=1}^n \|\lambda_i - \bar{\lambda}_i\|^2}$. Hence $\frac{L}{n}$ is a Lipschitz constant for the function f. The decentralized algorithm that we develop is based on the following lemma, which characterizes an optimal solution to (1) when functions f_i are all differentiable.

LEMMA 3.1. *A feasible solution* λ^* *of* (1) *is an optimal solution if and only if* $\nabla f_i(\lambda_i^*) = \nabla f_j(\lambda_j^*)$ *for all* i, j.

Let λ_i^t be the value of the variable associated with agent i at iteration t. We consider the following gradient-descent update rule for each agent i:

$$\lambda_i^{t+1} = \lambda_i^t + \gamma \sum_{j \in N_i(t)} \frac{1}{n}(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)). \tag{2}$$

Here γ is a common constant step size that all of the agents use for updates. It should be noted that, to perform updates at iteration t, agent i uses only the gradient information corresponding to its neighbors $N_i(t)$ for iteration t. Furthermore, each intermediate allocation λ^t generated by the algorithm is a feasible solution of (1).

LEMMA 3.2. *Suppose* λ^1 *is a feasible solution for* (1). *Then* λ^t, *where* λ_i^t *is defined by* (2), *is a feasible solution to* (1) *for all* t.

In order to analyze the convergence properties of the proposed algorithm, it is convenient to define $\tilde{v}(\lambda)$ for any allocation λ as follows:

$$\tilde{v}_i(\lambda) = \sum_{j \in N} \frac{1}{n}(\nabla f_i(\lambda_i) - \nabla f_j(\lambda_j)).$$

Note that $\tilde{v}(\lambda^t)$ is the direction of update when the communication graph $E(t)$ is complete. It can be verified that $\tilde{v}(\lambda^t)$ is also a scaled version of the projection of $\nabla f(\lambda^t)$ onto the subspace $\sum_{i=1}^n \lambda_i^t = B$, hence it represents the centralized update

direction at time t. From Lemma 3.1 it can be seen that a feasible solution λ is optimal if and only if $\|\tilde{v}(\lambda)\| = 0$. We now derive a theorem establishing the convergence of the algorithm based on (2). Under mild conditions on the set of optimal solutions, convergence to optimality is guaranteed. We also derive an upper bound on the rate at which the sequence $\{\|\tilde{v}(\lambda^{T_z})\|\}$ converges to zero. Recall that T_z is a sequence of strictly increasing natural numbers such that the union of the communication graphs between iterations T_z and T_{z+1} is connected. In what follows, let $\tilde{v}^t = \tilde{v}(\lambda^t)$.

THEOREM 3.1. *Suppose that Assumptions* 3.1 *and* 3.2 *hold. With a step size of* $\gamma = \frac{1}{2L}$,

1. *the sequence* $\{f(\lambda^t)\}$ *is monotonically nondecreasing;*
2. *the sequence* $\{\|\tilde{v}^{T_z}\|\}$ *converges to* 0*;*
3. $\min_{z=1,\ldots,p}(\|\tilde{v}^{T_z}\|^2) \leq \frac{3Ln^4\kappa(f(\lambda^*)-f(\lambda^1))}{4p}$ $\forall p$*;*
4. *if the set of optima is bounded,* $\{f(\lambda^t)\}$ *converges to* $f(\lambda^*)$.

3.2. The nondifferentiable case. In this section we consider concave objective functions that are not required to be differentiable at all points. To motivate our interest in such functions we consider the following optimization problem:

$$\max_{x_i, i=1,\ldots,n} \frac{1}{n}\sum_{i=1}^{n} g_i(x_i)$$
$$\text{s.t.} \quad \sum_{i=1}^{n} \mathbf{A_i} x_i \leq B, \tag{3}$$

where $x_i \in \Re^q$, $\mathbf{A_i} \in \Re^{m\times q}, i = 1,\ldots,n$, $B \in \Re^m$, and $g_i(x_i)$ is a concave function, $i = 1,\ldots,n$. Define $f_i(\lambda_i)$ as the optimal value for the following optimization problem:

$$f_i(\lambda_i) = \max_{x_i \in \Re^q} g_i(x_i)$$
$$\text{s.t.} \quad \mathbf{A_i} x_i \leq \lambda_i. \tag{4}$$

With this definition of f_i we see that problem (3) is equivalent to problem (1). Note that, if there are linear constraints that involve only the variables $x_{ij}, j = 1,\ldots,q$ for some i, then these constraints could be included directly in the problem defining f_i. Suppose that $f_i(\lambda_i)$ is well defined and is finite for all λ_i. It can then be shown that $f_i(\lambda_i)$ is a concave function. Thus we can potentially apply the decentralized algorithm developed in the previous section for finding an optimal solution to (3). However, $f_i(\lambda_i)$ is typically nondifferentiable even when $g_i(x_i)$ is. Hence Theorem 3.1 does not immediately apply to (3), as it relies on the assumption that the objective function is differentiable with a Lipschitz-continuous gradient. This motivates us to consider cases where $f_i,\ i = 1,\ldots,n$ are not necessarily differentiable at all points.

In this section, we relax Assumption 3.2 and consider the case where $f_i,\ i = 1,\ldots,n$ are nondifferentiable. We introduce a smooth approximation for f_i that is amenable to optimization via stochastic approximations and propose a randomized version of (2) to solve the smoothed problem. We show that the new scheme converges to a near-optimal solution of the original problem in a tractable number of iterations.

We assume that $f_i,\ i = 1,\ldots,n$ are concave and differentiable outside a set of measure zero. Denote by $\partial f_i(\lambda_i)$ the set of the subgradients of f_i at λ_i. Let $\nabla f_i(\lambda_i)$ be an element chosen arbitrarily from $\partial f_i(\lambda_i)$ for each λ_i. Let $\|\cdot\|_1$ denote the l_1 norm and recall that $\|\cdot\|$ denotes the Euclidean norm. We make the following assumption.

ASSUMPTION 3.3. *For all* i *and* λ_i, $\sup_{i,\lambda_i}\{\|v\|_1 : v \in \partial f_i(\lambda_i)\} \leq L < \infty$.

Note that $\sup_{i,\lambda_i}\{\|v\| : v \in \partial f_i(\lambda_i)\} \leq L < \infty$, since $\|v\| \leq \|v\|_1$ for all v. We now consider approximating f_i by a suitable differentiable function. In particular, let

$$\hat{f}_i(\lambda_i) = \mathrm{E}[f_i(\lambda_i + Z_i)],$$

where each $Z_i = (Z_{ij})_{j=1,\ldots,m}$ is a vector of m independently and identically distributed (i.i.d.) normal random variables [4], with a zero mean and variance equal to

$$\sigma = \frac{\sqrt{2}\epsilon}{\sqrt{\pi \log(m+1)}},$$

where ϵ is a parameter related to the accuracy of the approximation as will be clear from the following lemma. The following lemma shows that $\hat{f}_i$ is a concave and differentiable approximation to f_i and that its gradient $\nabla \hat{f}_i$ can be expressed in terms of ∇f_i.

LEMMA 3.3. *Let f_i and $\hat{f}_i$ be as given above. Then the following hold:*

1. *$\hat{f}_i$ is concave and differentiable, with gradient $\nabla \hat{f}_i(\lambda_i) = \mathrm{E}[\nabla f_i(\lambda_i + Z_i)]$;*
2. *$f_i(\lambda_i) \geq \hat{f}_i(\lambda_i) \geq f_i(\lambda_i) - 2.8\epsilon L$;*
3. *$\|\nabla \hat{f}_i(\lambda_i) - \nabla \hat{f}_i(\bar{\lambda}_i)\| \leq \frac{\sqrt{\log(m+1)}L}{\epsilon}\|\lambda_i - \bar{\lambda}_i\|$.*

Bearing in mind the previous lemma, we consider the problem of maximizing

$$\max_{\lambda} \hat{f}(\lambda) = \sum_{i=1}^{n} \frac{1}{n} \hat{f}_i(\lambda_i) \tag{5}$$
$$\text{s.t.} \sum_{i=1}^{n} \lambda_i = B.$$

Since $\hat{f}_i$ is differentiable with a Lipschitz-continuous gradient, Theorem 3.1 ensures that the update rule (2) leads to convergence. However, note that computing the gradient of $\hat{f}_i$ requires evaluating the expected value $\nabla \hat{f}_i(\lambda_i) = \mathrm{E}[\nabla f_i(\lambda_i + Z_i)]$, which is, in general, computationally expensive. Due to the special form of the smoothing scheme and, in particular, the fact that $\nabla \hat{f}_i$ is expressed as the expected value of the subgradient of f_i, we consider instead of (2) a stochastic approximation version of the update. In particular, we let

$$\lambda_i^{t+1} = \lambda_i^t + \gamma_t \sum_{j \in N_i(t)} \frac{1}{n}(\nabla f_i(\lambda_i^t + Z_i^t) - \nabla f_j(\lambda_j^t + Z_j^t)), \tag{6}$$

where $Z_i^t,\ t = 1, 2, \ldots$ is a sequence of i.i.d. vectors with the same distribution as Z_i.

For each λ, let $\tilde{v}(\lambda)$ be given by

$$\tilde{v}_i(\lambda) = \sum_{j \in N} \frac{1}{n}(\nabla \hat{f}_i(\lambda_i) - \nabla \hat{f}_j(\lambda_j)).$$

Let $\tilde{v}^t = \tilde{v}(\lambda^t)$, and note that $\tilde{v}^t$ corresponds to the expected direction of update when the communication graph is complete. From Lemma 3.1, it is clear that a feasible solution λ is optimal for (5) if and only if $\|\tilde{v}(\lambda)\| = 0$. Furthermore, from Lemma 3.3, if λ is optimal for (5), then it is also near-optimal for (1). The following theorem establishes that, if all agents apply (6), then $\|\tilde{v}^t\|$ converges to zero.

We make the following assumption on the step sizes γ_t.

ASSUMPTION 3.4. *The step sizes* γ_t *satisfy* $\gamma_t = \frac{\epsilon}{(2L\sqrt{\log(m+1)})}\beta_t$, *where* $0 \leq \beta_{t+1} \leq \beta_t \leq 1 \forall t$, $\sum_t \beta_t = \infty$, *and* $\sum_t \beta_t^2 < \infty$.

THEOREM 3.2. *Suppose that Assumptions* 3.3 *and* 3.4 *hold. Then with probability* 1*:*

1. *the sequence* $\{\|\tilde{v}^{T_z}\|\}$ *converges to* 0*;*
2. $\min_{z=1,\ldots,p} \mathrm{E}[\|\tilde{v}^{T_z}\|^2] \leq \frac{\frac{n^4\kappa L\sqrt{\log(m+1)}}{\epsilon}\left[3(f(\lambda^*)-f(\lambda^1)+2.8\epsilon L)+\sum_{t=1}^{t=\kappa p}\frac{4L\beta_t^2\epsilon}{\sqrt{\log(m+1)}}\right]}{4\sum_{z=2}^{p+1}\beta_{\kappa z}}$ $\forall p$*;*
3. *if the set of the optima of* (1) *is bounded, then* $\lim_{t\to\infty} f(\lambda^t) \geq f(\lambda^*) - 2.8\epsilon L$.

It is worth noting some aspects of Theorem 3.2. Unlike in the differentiable case, we cannot guarantee a monotonic increase in the objective function values. Hence the rate of convergence of the sequence $\{\mathrm{E}[\|\tilde{v}^{T_z}\|]\}$ to zero does not have as far-reaching implications as its counterpart in Theorem 3.1. Nevertheless, Theorem 3.2 ensures convergence to a near-optimal solution with probability one. Another substantial difference is on the assumption on step sizes and the corresponding effect on convergence rates. It is easy to see that convergence is ensured if $\beta_t = \frac{1}{t^q}$ for $0.5 < q \leq 1$. The resulting theoretical rate of convergence is clearly dependent on q; when $0.5 < q < 1$, $\frac{1}{x^q}$ is a decreasing function for $x \geq 1$. Hence, for $k \geq 1, \frac{1}{k^q} \geq \int_k^{k+1} \frac{1}{x^q}dx$, and so $\sum_{k=1}^{c} \frac{1}{k^q} \geq \int_1^{c+1} \frac{1}{x^q}dx = \frac{(c+1)^{1-q}-1}{1-q}$. Thus the number of iterations needed for $\mathrm{E}[\|\tilde{v}^{T_z}\|^2] \leq \epsilon$ is polynomial in the problem parameters. Similarly, when $q = 1$, $\frac{1}{x^q}$ is just $\frac{1}{x}$ and is a decreasing function as well for $x \geq 1$. Hence, for $k \geq 1$, $\frac{1}{k+1} \leq \int_k^{k+1} \frac{1}{x}dx$, and so $\sum_{k=1}^{c} \frac{1}{k} \leq 1 + \int_1^c \frac{1}{x}dx = \log(c) + 1$, and so the number of iterations needed for $\mathrm{E}[\|\tilde{v}^{T_z}\|^2] \leq \epsilon$ is exponential in the problem parameters. As is often observed in stochastic approximation methods, the impact of the choice of step sizes on the speed of the convergence of the algorithm is also verified in the numerical experiments.

4. Decentralized resource allocation with nonnegativity constraints. In this section, we use the results developed for (1) to solve the following resource allocation problem with nonnegativity constraints:

$$\begin{aligned} \max_{\lambda_i \in \Re^m, i=1,\ldots,n} \quad & f(\lambda) = \frac{1}{n}\sum_{i=1}^{n} f_i(\lambda_i) \\ \text{s.t.} \quad & \sum_{i=1}^{n} \lambda_i = B, \\ & \lambda_i \geq 0, i = 1, \ldots, n. \end{aligned} \tag{7}$$

We assume that f_i is concave and differentiable outside a set of measure zero. Also let Assumption 3.3 hold for f.

We now define $g_i(\lambda_i)$ as follows:

$$g_i(\lambda_i) = f_i(\lambda_i) + \sum_{j=1}^{m} L_g \min(\lambda_{ij}, 0),$$

where $L_g > 2L$. The following lemma shows that the function $g(\lambda)$ satisfies Assumption 3.3 and is necessary for applying the stochastic approximation version of the gradient-descent algorithm developed in 3.2.

LEMMA 4.1. *Under assumption* 3.3 *for* f,

1. *for all* i, $g_i(\lambda_i)$ *is concave and differentiable outside a set of measure zero;*
2. *for all* i *and* λ_i, $\sup_{i,\lambda_i}\{\|v\|_1 : v \in \partial g_i(\lambda_i)\} \leq L_m < \infty$, *where* $L_m = L + mL_g$.

It can be noted from the definition of g_i that if $\lambda_i \geq 0$, then $g_i(\lambda_i) = f_i(\lambda_i)$. The term $L_g \min(\lambda_{ij}, 0)$ in the above definition can be thought of as a penalty for negative λ_{ij}. This term ensures that solving (1) with g has a nonnegative optimal solution and is equivalent to solving (7) with f.

LEMMA 4.2. *The set of optimal solutions for* (1) *with* g *as the objective function is the same as the set of optimal solutions to* (7) *with* f *as the objective function.*

Since the set of the feasible solutions of (7) is bounded and closed and since f is assumed to be continuous, there exists an optimal solution to (7). Thus any algorithm that finds an optimal solution to (1) with g as the objective function also yields an optimal solution to (7) with f as the objective function.

Lemma 4.1 ensures that we can apply the stochastic approximation version of the gradient-descent algorithm for (1) with g as the objective function. Hence an optimal solution for (7) with f as the objective function can be found by applying the stochastic approximation version of the gradient-descent algorithm developed in 3.2 for (1) with g as the objective function. It should be pointed out that the Lipschitz constant of the smoothed problem, and consequently the convergence rate, is now of the order $O(\frac{m\sqrt{m}}{\epsilon})$ as compared to $O(\frac{\sqrt{m}}{\epsilon})$ for the results of section 3.2.

5. Numerical experiments. In this section, we present the results of numerical experiments, which illustrate the performance of the algorithms presented in the previous sections. We compare the proposed algorithms to centralized algorithms that use direction $\tilde{v}(\lambda)$ as the direction of update. Recall that $\tilde{v}(\lambda)$ is the direction of update if the current resource allocation is λ and the communication graph is complete. Recall also that, when f_i is differentiable, $\tilde{v}(\lambda)$ is the projection of ∇f onto the subspace $\sum_{i=1}^{n} \lambda_i^t = B$. Thus the centralized algorithm reduces to the classic gradient-descent method of nonlinear optimization in this case. We define $p^t = (\frac{f^t - f^0}{f^* - f^0}) \times 100$, where f^t is the objective function value after t iterations and f^* is the objective function value of the optimal solution, and we investigate how p^t converges to 100 in the centralized and decentralized algorithms.

5.1. Problem with differentiable objective function. We first consider a problem studied in [8], which is an instance of (1), with

$$f_i(x_i) = -\left(\frac{1}{2}a_i(x_i - c_i)^2 + \log(1 + e^{b_i(x_i - d_i)})\right), i = 1, \ldots, n.$$

The second derivative $f_i^{''}$ is given by

$$f_i^{''}(x_i) = -\left(a_i + b_i^2 \frac{e^{b_i(x_i - d_i)}}{(1 + e^{b_i(x_i - d_i)})^2}\right), \qquad i = 1, \ldots, n.$$

It can be verified that $f_i^{''}(x_i)$ has a lower bound $-(a_i + \frac{1}{4}b_i^2)$, $i = 1, \ldots, n$. It can be shown that, if a one-dimensional function is differentiable and its gradient is bounded by some constant, then the function is Lipschitz-continuous with the same constant. Since f_i is twice differentiable and $f_i^{''}$ is bounded, it follows that $f_i^{'}$ is Lipschitz-continuous, with constant $(a_i + \frac{1}{4}b_i^2)$, if we assume that $a_i \geq 0$. It follows that $f^{'}$ is Lipschitz-continuous, with constant $\frac{L}{n}$, where $L = \max_i(a_i + \frac{1}{4}b_i^2)$. Thus f satisfies Assumption 3.2.

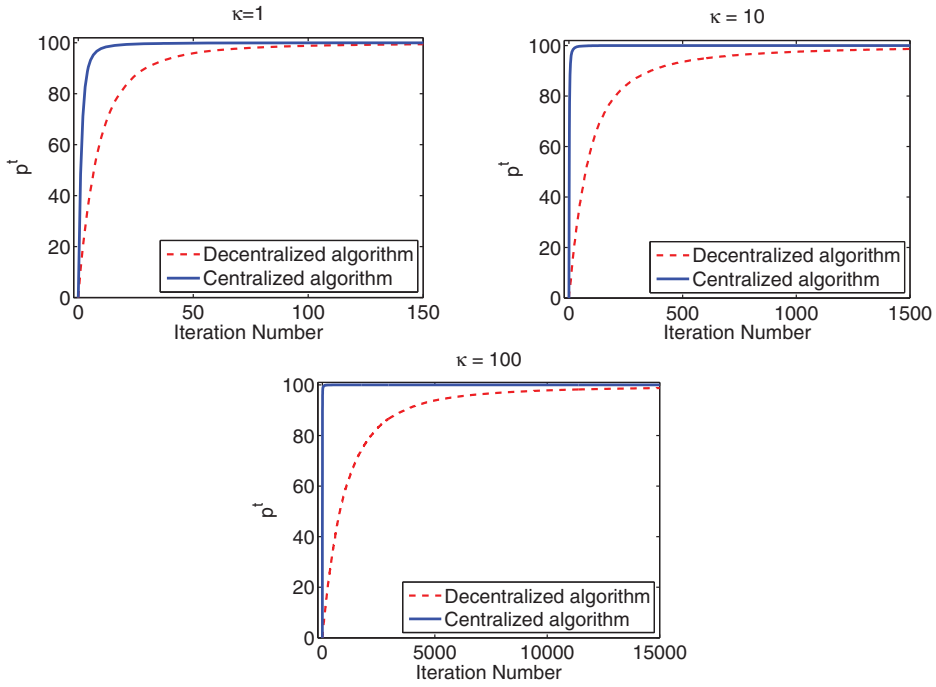

FIG. 1. *A comparison of the convergence behavior of the decentralized and centralized algorithms for various* κ.

We choose problem instances with 20 agents and as in [8]; the coefficients a_i, b_i, c_i, and d_i are generated randomly, with uniform distributions on $[0, 2], [-2, 2], [-10, 10]$, and $[-10, 10]$, respectively. Recall that, for our algorithm to converge, the union of communication graphs should be connected periodically. For a chosen κ, we let the edges $(i, i+1), i = 1, \ldots, n-1$ be a part of the communication graph $E(t)$ for some arbitrarily chosen t such that $m\kappa < t \leq (m+1)\kappa, m = 0, 1, \ldots$. This ensures that $G = (N, E_{m\kappa+1, m(\kappa+1)+1})$ is connected (recall that $E_{k,l} = \cup_{t=k}^{t=l-1} E(t)$). We let every other edge (i, j), with $j \neq i+1$, be a part of at the most one communication graph between iterations $m\kappa + 1$ and $(m+1)\kappa$, with a probability e_p. The parameter e_p controls the density of the graph, $G = (N, E_{m\kappa+1, m(\kappa+1)+1})$. The step size is chosen to be $\frac{1}{2L}$, with L as defined above. Figure 1 shows the convergence behavior of the algorithm for various values of the parameter κ, with $e_p = 0.1$. p^t in the figure represents the average of p^t for 10 randomly chosen problems. It can be seen from the figure that the performance of the decentralized algorithm is comparable to the centralized algorithm for $\kappa = 1$, even though the communication graph is not dense $(e_p = 0.1)$.

Figure 2 shows a comparison of the convergence behavior of the algorithms for problems with a varying number of agents. We fix $\kappa = 1$ in these problems, and $e_p = 0.1$. The other parameters are chosen as described above. We notice from Figure 2 that the scaling of the performance of decentralized algorithms with increasing number of agents is much better than $O(n^4)$ promised by Theorem 3.1.

5.2. Decentralized optimization of linear programming problems. We now consider a decentralized solution of linear programming problems using the randomized version of the decentralized subgradient-descent algorithm developed in this

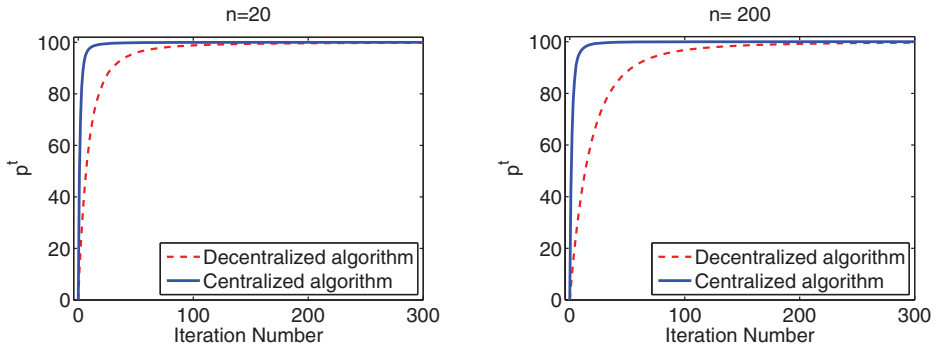

FIG. 2. *A comparison of the convergence behavior of the decentralized and centralized algorithms for various n.*

paper. This problem arises naturally in sequential decision-making problems in teams of mobile agents [7]. Consider the following linear programming problem:

$$\max_{x_i, i=1,\ldots,n} \frac{1}{n} \sum_{i=1}^{n} C_i^T x_i$$

$$\text{s.t.} \quad \sum_{i=1}^{n} \mathbf{A_i} x_i \leq B, \tag{8}$$

where $C_i, x_i \in \Re^q$, $\mathbf{A_i} \in \Re^{m \times q}, i = 1, \ldots, n$, and $B \in \Re^m$. It can be seen that (8) belongs to the class of problems identified by (3). Recall that, for a given $\lambda_i \in \Re^m$, $f_i(\lambda_i)$ is the optimal value of the following optimization problem:

$$\max_{x_i \in \Re^q} C_i^T x_i$$

$$\text{s.t.} \quad \mathbf{A_i} x_i \leq \lambda_i. \tag{9}$$

Suppose that the dual feasible sets defined by $S_i = \{\nu_i | \mathbf{A_i^T} \nu_i = C_i, \nu_i \geq 0\}$ are nonempty and bounded. It is known from linear programming theory that $f_i(\lambda_i) = \min_{p=1,\ldots,P} \lambda_i^T \nu_{ip}$, where ν_{ip} are the extreme points of the polyhedra defined by S_i. Hence $f_i(\lambda_i)$ is nondifferentiable and concave. Further ν_i' is a subgradient of $f_i(\lambda_i)$ at λ_i if and only if it is an optimal solution to the dual problem [3]. Thus if S_i is bounded, it can be seen that Assumption 3.3 is satisfied, and the convergence analysis of section 3.2 holds.

Let the columns of $\mathbf{A_i}$ be denoted as $\mathbf{a_{ij}}$, $j = 1, \ldots, q$. Also let $C_i = [C_{ij}], j = 1, \ldots, q$. Suppose that the column $\mathbf{a_{ik}} > 0$ and $C_{ik} > 0$ for some k such that $1 \leq k \leq q$, and suppose S_i is nonempty. The corresponding dual constraint is $\mathbf{a_{ik}}^T \nu_i = C_{ik}$ showing that S_i is bounded. For the experiments we choose $\mathbf{a_{i1}} = \mathbf{1}$, $i = 1, \ldots, n$, where $\mathbf{1}$ is a vector of ones of the appropriate size. We also choose $C_{i1} = 200$, $i = 1, \ldots, n$. The rest of the constraint matrix and the cost vector are chosen arbitrarily while ensuring that S_i is nonempty.

Although the theoretical results require a randomization of the direction of update, it was observed that both of the decentralized and the centralized versions of the algorithm converge without the required randomization. Unlike the decentralized algorithm for the differentiable case, there is flexibility in choosing step sizes. It was observed in the experiments that the practical performance of both the centralized

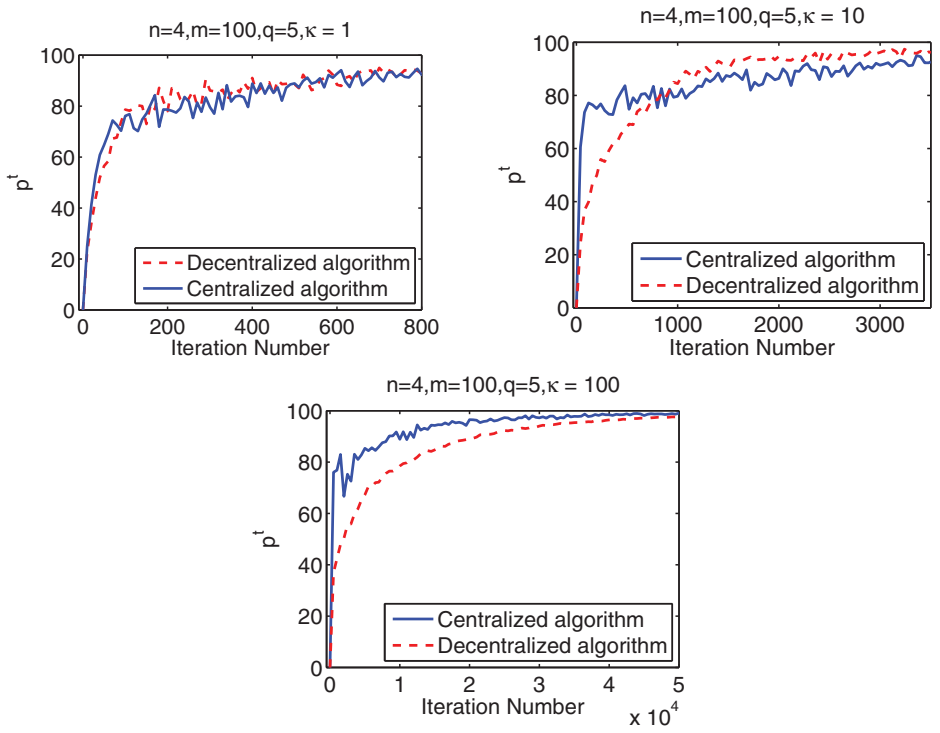

FIG. 3. *A comparison of the convergence behavior of the decentralized and centralized algorithms for various* κ.

algorithm and the decentralized algorithm, with or without the randomization of the direction of update, depends dramatically on the choice of step sizes. We present the results of the experiments where the direction of update was not randomized, as it provides better insight into the convergence behavior of the algorithm. It was observed that convergence was obtained in this case so long as $\sum_t \gamma_t = \infty$ and $\sum_t \gamma_t^2 < \infty$. We choose step sizes of the form $\gamma^t = \frac{\theta(t)}{2L\sqrt{\log m+1}}\beta^t$, where L is the common Lipschitz constant of the functions f_i, $i = 1, \ldots, n$. Since $C_{i1} = 200$ and $\mathbf{a_{i1}} = \mathbf{1}$ for all i, it can be verified from the dual constraint $\mathbf{a_{i1}}^T \nu_i = C_{i1}$ that $L = C_{i1} = 200$. β^t was chosen to be of the form $\frac{1}{1+w(t)t^{0.51}}$. Thus $\theta(t)$ and $w(t)$ control the rate at which γ^t goes to 0. We chose $w(t)$ as a monotonically nondecreasing function bounded above, and $\theta(t)$ as a monotonically nonincreasing function bounded below. This ensures that $\sum_t \gamma_t = \infty$ and $\sum_t \gamma_t^2 < \infty$. For our experiments, we chose $w(0) = 0$ and $w(z\kappa + j) = w(z\kappa)$ for $z = 0, 1, \ldots, j = 1, 2, \ldots, \kappa - 1$, and $w((z+1)\kappa) = \min\{w(z\kappa) + r_w, w_{\max}\}$. For all of the experiments we chose $r_w = 0.0001$ and $w_{\max} = 0.1$. We also chose $\theta(t+1) = \max\{\theta(t) - r_\theta, \theta_{\min}\}$. For these experiments, we chose $\theta(0) = 30$, $\theta_{\min} = 3$, and $r_\theta = 0.1$. We ensured that the union of the communication graphs are connected periodically in the same manner as described in section 5.1. For these experiments, we choose $e_p = 0.5$. Figure 3 presents a comparison of the performance of the decentralized algorithm with the centralized algorithm, for varying κ. In the figures, n represents the number of agents, q represents the number of variables per agent, and m represents the number of constraints.

Figure 4 presents a comparison of the performance of the decentralized algorithm, with the centralized algorithm for varying n. All parameters except $\theta(0)$ were chosen

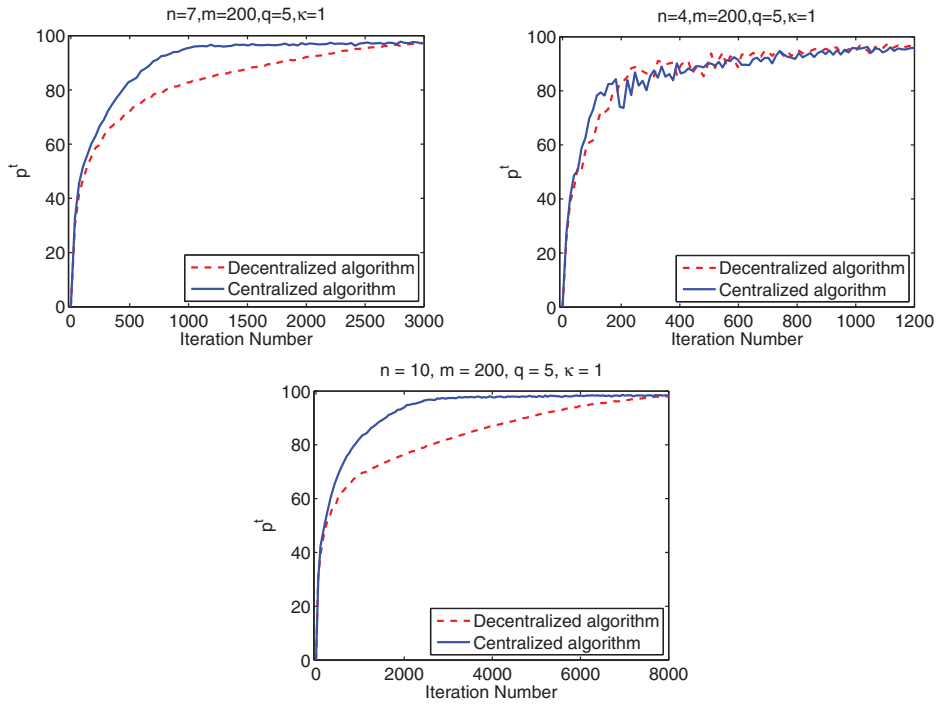

FIG. 4. *A comparison of the convergence behavior of the decentralized and centralized algorithms for various* n.

as described previously. $\theta(0)$ was chosen to be 50 for the experiments of Figure 4. It can be observed that the performance of the decentralized algorithm scales well with increasing n. The numerical experiments suggest that κ has a greater effect on the practical performance of the algorithm than n.

6. Discussion. In this paper, we proposed a decentralized gradient-descent algorithm for a general class of resource allocation problems. We first considered the case where the objective functions have Lipschitz-continuous gradients. We showed that the proposed algorithm converges and established that the rate at which the gradient projection converges to zero as a function of the number of agents in the network. Motivated by the need to develop decentralized algorithms for general convex optimization problems, we proposed a randomized subgradient-descent algorithm for the resource allocation problem with a possibly nondifferentiable objective function. We established an asymptotic convergence of the algorithm to a near-optimal solution and derived a convergence rate. Numerical experiments, both in the differentiable and in the nondifferentiable settings, suggested that the decentralized algorithms are competitive with the centralized versions of gradient and subgradient descent. The experiments also suggested that the performance of the decentralized randomized subgradient-descent algorithm depends dramatically on the choice of step sizes; how to set them up optimally while taking into account the structure of the communication network is a topic for future research.

An appealing feature of the developed algorithms is that the communication topology of the network of agents is allowed to be dynamic provided that the union of communication graphs of the agents is connected within a bounded time. This makes the algorithm particularly suitable in settings involving mobile agents or communi-

cation failures. We finally note that the formulation considered here goes beyond traditional resource allocation problems. In particular, we show in a related paper [7] that this algorithm is particularly suitable for a decentralized solution of a linear programming-based method for approximate dynamic programming for the problems of sequential decision making in the systems of mobile agents.

Appendix A. Proofs.

LEMMA 3.1. *A feasible solution λ^* of* (1) *is an optimal solution if and only if $\nabla f_i(\lambda_i^*) = \nabla f_j(\lambda_j^*)$ for all i, j.*

Proof. First note that we can eliminate one of the variables in (1) to make it unconstrained. For instance, if we let $\lambda_n = B - \sum_{i=1}^{n-1} \lambda_i$, (1) is equivalent to

$$\min_{\lambda} \bar{f}(\lambda) = \frac{1}{n} \sum_{i=1}^{n-1} \left(f_i(\lambda_i) + f_n \left(B - \sum_{i=1}^{n-1} \lambda_i \right) \right).$$

This is an unconstrained convex and differentiable optimization problem; hence a solution λ^* is optimal if and only if $\nabla \bar{f}(\lambda^*) = 0$. Noting that

$$\nabla_{\lambda_i} \bar{f}(\lambda^*) = \frac{1}{n} \left(\nabla f_i(\lambda_i^*) - \nabla f_n \left(B - \sum_{j=1}^{n-1} \lambda_j^* \right) \right),$$

we conclude that λ^* is optimal if and only if

$$\nabla f_i(\lambda_i^*) = \nabla f_j(\lambda_j^*) = \nabla f_n \left(B - \sum_{j=1}^{n-1} \lambda_j^* \right) = \nabla f_n(\lambda_n^*) \ \forall i, j < n. \qquad \square$$

LEMMA 3.2. *Suppose λ^1 is a feasible solution for* (1). *Then λ^t, where λ_i^t is defined by* (2), *is a feasible solution to* (1) *for all t.*

Proof. Suppose λ^t is a feasible solution for (1). Then

$$\begin{aligned} \sum_i \lambda_i^{t+1} &= \sum_i \lambda_i^t - \frac{\gamma}{n} \sum_i \sum_{j \in N_i(t)} (\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)) \\ &= B - \frac{\gamma}{n} \sum_{(i,j) \in E(t)} (\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t) + \nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)) \\ &= B. \end{aligned}$$

The second equality follows from the assumption that communication is symmetric. Thus λ^{t+1} is a feasible solution for (1), and the lemma follows by induction. $\square$

THEOREM 3.1. *Suppose that Assumptions* 3.1 *and* 3.2 *hold. With a step size of $\gamma = \frac{1}{2L}$,*

1. *the sequence $\{f(\lambda^t)\}$ is monotonically nondecreasing;*
2. *the sequence $\{\|\tilde{v}^{T_z}\|\}$ converges to* 0*;*
3. $\min_{z=1,\ldots,p}(\|\tilde{v}^{T_z}\|^2) \leq \frac{3Ln^4\kappa(f(\lambda^*)-f(\lambda^1))}{4p} \ \forall p$*;*
4. *if the set of optima is bounded, $\{f(\lambda^t)\}$ converges to $f(\lambda^*)$.*

The proof is based on a series of lemmas. Let the direction of update at time t be v^t. It can be seen from (2) that

$$v_i^t = \frac{1}{n} \sum_{j \in N_i(t)} (\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)).$$

We first show that v^t is aligned to the direction of the gradient.

LEMMA A.1. $\nabla f(\lambda^t)^T v^t = \frac{1}{n^2} \sum_{(i,j)\in E(t)} \|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2$.

Proof. We have that

$$\begin{aligned}\nabla f(\lambda^t)^T v^t &= \sum_{i\in N} \frac{1}{n} \nabla f_i(\lambda_i^t)^T \left(\frac{1}{n} \sum_{j\in N_i(t)} \nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t) \right) \\ &= \frac{1}{n^2} \sum_{i\in N} \nabla f_i(\lambda_i^t)^T \left(\sum_{j\in N_i(t)} \nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t) \right). \end{aligned} \tag{10}$$

Since communication is symmetric, for every term of the form $\nabla f_i(\lambda_i^t)^T(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t))$ in the above summation, there is a corresponding term of the form $\nabla f_j(\lambda_j^t)^T (\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t))$. Hence,

$$\begin{aligned}\nabla f(\lambda^t)^T v^t &= \frac{1}{n^2} \sum_{(i,j)\in E(t)} \nabla f_i(\lambda_i^t)^T (\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)) \\ &\quad + \nabla f_j(\lambda_j^t)^T (\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)) \\ &= \frac{1}{n^2} \sum_{(i,j)\in E(t)} \|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2. \qquad \square \end{aligned}$$

We now prove a lemma that establishes a relationship between $\|v^t\|$ and $\nabla f(\lambda^t)^T v^t$. We can interpret $\gamma \nabla f(\lambda^t)^T v^t$ as the approximate increase in the objective of (1) when using the direction v^t and a sufficiently small step size γ.

LEMMA A.2. $\|v^t\|^2 \le 2n \nabla f(\lambda^t)^T v^t$.

Proof. Using the Cauchy–Schwarz inequality, $(\sum_{i=1}^k c_i)^2 \le k \sum_{i=1}^k c_i^2$,

$$\begin{aligned}\|v_i^t\|^2 &\le |N_i(t)| \sum_{j\in N_i(t)} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2} \\ &\le n \sum_{j\in N_i(t)} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2}, \\ \|v^t\|^2 &= \sum_i \|v_i^t\|^2 \\ &\le n \sum_i \sum_{j\in N_i(t)} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2} \\ &= 2n \sum_{(i,j)\in E(t)} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2} \\ &= 2n \nabla f(\lambda^t)^T v^t. \end{aligned}$$

The last equality comes from Lemma A.1. $\square$

We now prove a lemma that establishes a relationship between $\|\tilde{v}^t\|$ and $\nabla f(\lambda^t)^T \tilde{v}^t$.

LEMMA A.3. $\|\tilde{v}^t\|^2 = n \nabla f(\lambda^t)^T \tilde{v}^t$.

Proof. We first have that

$$\begin{aligned}
\|\tilde{v}_i^t\|^2 &= \frac{\|\sum_{j\in N}(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t))\|^2}{n^2} \\
&= \sum_{j\in N} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2} \\
&\quad + 2 \sum_{((j,l)\in N^2, j<l)} \frac{(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t))^T(\nabla f_i(\lambda_i^t) - \nabla f_l(\lambda_l^t))}{n^2} \\
&= \sum_{j\in N} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2} \\
&\quad + \sum_{((j,l)\in N^2, j<l)} \\
&\quad \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2 + \|\nabla f_i(\lambda_i^t) - \nabla f_l(\lambda_l^t)\|^2 - \|\nabla f_j(\lambda_j^t) - \nabla f_l(\lambda_l^t)\|^2}{n^2} \\
&= (n-1)\left(\sum_{j\in N} \frac{\|(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t))\|^2}{n^2}\right) \\
&\quad - \sum_{((j,l)\in N^2, j<l, (j,l\neq i))} \frac{\|\nabla f_j(\lambda_j^t) - \nabla f_l(\lambda_l^t)\|^2}{n^2}, \\
\|\tilde{v}^t\|^2 &= \sum_{i\in N} \|\tilde{v}_i^t\|^2 \\
&= \sum_{i\in N}\left((n-1)\left(\sum_{(j\in N)} \frac{\|(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t))\|^2}{n^2}\right)\right. \\
&\qquad \left. - \sum_{((j,l)\in N^2, j<l, j,l\neq i)} \frac{\|\nabla f_j(\lambda_j^t) - \nabla f_l(\lambda_l^t)\|^2}{n^2}\right).
\end{aligned}$$

We note that $\|\tilde{v}^t\|^2 = \sum_{((i,j)\in N^2, i<j)} c_{ij}((\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2)/n^2)$. To determine c_{ij}, note that the term $\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2$ appears with a coefficient $(n-1)$ in $\|\tilde{v}_i^t\|^2$, $(n-1)$ in $\|\tilde{v}_j^t\|^2$, and with a coefficient -1 in $\|\tilde{v}_k^t\|^2$ for all $(k \in N, k \neq i, j)$. Hence, $c_{ij} = (n-1) + (n-1) - (n-2) = n$. Therefore,

$$\begin{aligned}
\|\tilde{v}^t\|^2 &= \sum_{((i,j)\in N^2, i<j)} c_{ij}\left(\frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2}\right) \\
&= n \sum_{((i,j)\in N^2, i<j)} \frac{\|\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t)\|^2}{n^2} \\
&= n\nabla f(\lambda^t)^T\tilde{v}^t. \qquad \square
\end{aligned}$$

Consider a decentralized direction of update v^t derived from an arbitrary connected graph $G = (N, E(t))$. We now compare the ratio of the approximate increase in the objective of (1) using v^t as the direction of update and for a sufficiently small step size γ to the approximate increase in the objective using $\tilde{v}^t$ as the direction of

update for the same step size. This ratio is given by

$$\frac{(\nabla f(\lambda^t)^T v^t)}{(\nabla f(\lambda^t)^T \tilde{v}^t)} = \frac{\sum_{(i,j)\in E(t)}(\|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2)}{\sum_{((i,j)\in N^2, i<j)}(\|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2)}. \tag{11}$$

The following lemma shows that this ratio is bounded away from 0 by a factor that depends only on the number of agents.

LEMMA A.4. *For all connected graphs $G = (N, E)$,*

$$\sum_{(i,j)\in E} \|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2 \geq \frac{8}{n^3} \sum_{((i,j)\in N^2, i<j)} \|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2.$$

For any vector X, let $(X)_k$ denote its kth component. We note that $(\sum_{(i,j)\in E} \|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2)/(\sum_{((i,j)\in N^2, i<j)} \|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2)$ is of the form $(\sum_{k=1}^m b_k)/(\sum_{k=1}^m c_k)$, where $b_k = \sum_{(i,j)\in E}((\nabla f_j(\lambda_j^t))_k - (\nabla f_i(\lambda_i^t))_k)^2$ and $c_k = \sum_{((i,j)\in N^2, i<j)}((\nabla f_j(\lambda_j^t))_k - (\nabla f_i(\lambda_i^t))_k)^2$, and we recall that $\lambda_j^t \in \Re^m$ for all $j \in N$. Let $r_k = \frac{b_k}{c_k}$. We show that if $c_k > 0$, then $r_k \geq \frac{8}{n^3}$. We define $r(E) = (\sum_{(i,j)\in E}(p_j - p_i)^2)/(\sum_{((i,j)\in N^2, i<j)}(p_j - p_i)^2)$ for arbitrary values of the scalars p_i, $i = 1, \ldots, n$, such that $\sum_{((i,j)\in N^2, i<j)}(p_j - p_i)^2 > 0$. We show that $r(E) \geq \frac{8}{n^3}$, which establishes that when $c_k > 0$, $r_k \geq \frac{8}{n^3}$. This result is based on a series of lemmas. We first establish that, for any fixed value of $p_i, i = 1, \ldots, n$, the worst possible value of r is achieved when G corresponds to a chain whose nodes have monotone values of p_i. Then we compute the worst possible value of r with respect to possible values of p_i.

We also assume that $p_i \neq p_j$ for all $i \neq j$, without loss of generality; since $\sum_{((i,j)\in N^2, i<j)}(p_j - p_i)^2 > 0$ by assumption, for any set of values $p_i, i = 1, \ldots, n$, we can always perturb the values to make them strictly distinct while making $r(E)$ in the resulting graph arbitrarily close to that in the original problem.

LEMMA A.5. *The graph $G = (N, E)$ that minimizes r over all possible sets E, under the constraint that G is a connected graph, is a tree.*

Proof. Take an arbitrary graph (N, E), and suppose that it is not a tree. Then we can convert it into a tree (N, E') by removing some edges from E. It is clear that $r(E') \leq r(E)$, therefore (N, E) cannot be optimal. ∎

LEMMA A.6. *If a certain graph (N, E) contains edges ij and jk such that $p_j < \min(p_i, p_k)$ or $p_j > \max(p_i, p_k)$, then it does not minimize r.*

Proof. Consider the first situation and suppose, without loss of generality, that $p_j < p_i < p_k$. Let $E' = E \backslash \{jk\} \cup \{ik\}$. The difference in the numerator of $r(E)$ and $r(E')$ is equal to $(p_j - p_k)^2 - (p_i - p_k)^2$, which is greater than 0. Therefore (N, E) cannot be optimal. A similar analysis holds when $p_j > \max(p_i, p_k)$. ∎

LEMMA A.7. *If a node j contains more than two neighbors, then it has two neighbors i and k such that $p_j < \min(p_i, p_k)$ or $p_j > \max(p_i, p_k)$.*

Proof. Suppose that i, k, and l are neighbors of j. Then at least two among the three values p_i, p_k, and p_l must be less than or greater than p_j. ∎

LEMMA A.8. *Consider the chain that links nodes $1, \ldots, n$ in increasing order of p_i. Then it minimizes r over all possible connected graphs.*

Proof. From the previous lemmas, we conclude that the optimal graph is a tree. Moreover, each node in the optimal tree must have at most two neighbors. We conclude that the optimal graph is a chain. From Lemma A.6, the nodes in the chain are in increasing or decreasing order of p_i, and the lemma follows. ∎

Proof of Lemma A.4. Without loss of generality, suppose that $p_1 < p_2 < \cdots < p_n$. Let $\Delta_i = p_{i+1} - p_i$. Note that, for all $j > i$, $p_j - p_i = \sum_{k=i}^{j-1} \Delta_k$. In view of the previous

lemmas, we have the following for every connected graph (N, E):

$$\begin{aligned}
r(E) &= \frac{\sum_{(i,j)\in E}(p_i - p_j)^2}{\sum_{((i,j)\in N^2, i<j)}(p_i - p_j)^2} \\
&\geq \frac{\sum_{i=1}^{n-1}(p_{i+1} - p_i)^2}{\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}(p_i - p_j)^2} = \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\left(\sum_{k=i}^{j-1}\Delta_k\right)^2} \\
&\geq \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\sum_{k=i}^{j-1}(j-i)\Delta_k^2} \\
&= \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{i=1}^{n-1}\sum_{k=i}^{n-1}\sum_{j=k+1}^{n}(j-i)\Delta_k^2} \\
&= \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{k=1}^{n-1}\Delta_k^2\sum_{i=1}^{k}\sum_{j=k+1}^{n}(j-i)} = \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{k=1}^{n-1}\Delta_k^2\sum_{i=1}^{k}\sum_{j=1}^{n-k}(j+k-i)} \\
&= \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{k=1}^{n-1}\Delta_k^2\sum_{i=1}^{k}\frac{(n-k)(n-k+1)}{2} + (k-i)(n-k)} \\
&= \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{k=1}^{n-1}\Delta_k^2\left(\frac{k(n-k)(n-k+1)}{2} + \frac{(n-k)(k)(k-1)}{2}\right)} \\
&= \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{k=1}^{n-1}\Delta_k^2\frac{k(n-k)(n)}{2}} \\
&\geq \frac{\sum_{i=1}^{n-1}\Delta_i^2}{\sum_{k=1}^{n-1}\Delta_k^2\frac{n^3}{8}} \\
&= \frac{8}{n^3}.
\end{aligned}$$

The second inequality follows from the Cauchy–Schwarz inequality.

We note from the definitions that if $c_k = 0$, then $b_k = 0$. Thus for $k = 1, \ldots, m$, either $b_k = c_k = 0$, or $r_k \geq \frac{8}{n^3}$. The Lemma is trivially true, if for $k = 1, \ldots, m$, $b_k = c_k = 0$. Suppose there exist some $\bar{k} \in (1, \ldots, m)$ such that $c_{\bar{k}} > 0$. Let K be the set of integers from 1 to m such that $c_k > 0$ for $k \in K$. K is not empty since it contains $\bar{k}$.

$$\begin{aligned}
\frac{\sum_{(i,j)\in E}(\|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2)}{\sum_{((i,j)\in N^2, i<j)}(\|\nabla f_j(\lambda_j^t) - \nabla f_i(\lambda_i^t)\|^2)} &= \frac{\sum_{k=1}^{m} b_k}{\sum_{k=1}^{m} c_k} \\
&= \frac{\sum_{k\in K} b_k}{\sum_{k\in K} c_k} \\
&\geq \frac{\sum_{k\in K}\frac{8}{n^3}c_k}{\sum_{k\in K} c_k} \\
&= \frac{8}{n^3}. \qquad \square
\end{aligned}$$

Let E_{T_z} be a subset of the edge set $E_{T_z, T_{z+1}}$ such that the graph (N, E_{T_z}) is a tree. By Assumption (2.1), the graph $(N, E_{T_z, T_{z+1}})$ is connected, and so E_{T_z} is well defined. Let the decentralized direction of update derived using $G = (N, E_{T_z})$ be denoted by $\bar{v}^{T_z}$. The following lemma shows that the approximate increase in the

objective in period $[T_z, T_{z+1}]$ using the direction of update v^t and a sufficiently small step size γ is comparable to the approximate increase in objective when the direction $\bar{v}^{T_z}$ is used for update at time T_z.

LEMMA A.9. $\nabla f(\lambda^{T_z})^T \bar{v}^{T_z} \leq \frac{3}{2}\kappa \sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t$.

Proof. We have that

$$\begin{aligned}\|\nabla f(\lambda^{t+1}) - \nabla f(\lambda^t)\|^2 &\leq \frac{L^2}{n^2}\|\gamma v^t\|^2 = \frac{1}{4n^2}\|v^t\|^2 \\ &\leq \frac{1}{4n^2} 2n(\nabla f(\lambda^t)^T v^t) = \frac{1}{2n}\nabla f(\lambda^t)^T v^t. \end{aligned} \tag{12}$$

The first inequality is true because of Assumption 3.2. The first equality is true because $\gamma = \frac{1}{2Ln}$. The second inequality follows from Lemma A.2. Let $t^i_{T_z}$ be the earliest time between time periods T_z and $T_{z+1}-1$ such that there is an edge $(i,j) \in E_{T_z}$ for agent i. It is clear that $T_z \leq t^i_{T_z} \leq T_{z+1} - 1$. Also, by definition, for $l = T_z, T_z + 1, \ldots, (t^i_{T_z} - 1)$, there is no edge $(i,p) \in E(l)$. Thus $\lambda_i^{t^i_{T_z}} = \lambda_i^{T_z}$, and $\nabla f_i(\lambda_i^{t^i_{T_z}}) = \nabla f_i(\lambda_i^{T_z})$. Letting $w_{ij}(t) = \frac{1}{n}(\nabla f_i(\lambda_i^t) - \nabla f_j(\lambda_j^t))$, we have that

$$\begin{aligned}\|w_{ij}(T_z)\| &= \frac{1}{n}\|\nabla f_i(\lambda_i^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{T_z})\| \\ &\leq \frac{1}{n}(\|\nabla f_i(\lambda_i^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{t^i_{T_z}})\| + \|\nabla f_j(\lambda_j^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{T_z})\|) \\ &\leq \frac{1}{n}\left(\|\nabla f_i(\lambda_i^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{t^i_{T_z}})\| + \sum_{t=T_z}^{t^i_{T_z}-1} \|\nabla f_j(\lambda_j^{t+1}) - \nabla f_j(\lambda_j^t)\|\right).\end{aligned}$$

From the Cauchy–Schwarz inequality,

$$\begin{aligned}\|w_{ij}(T_z)\|^2 \leq\ & \frac{(t^i_{T_z} - T_z + 1)}{n^2}\left(\|\nabla f_i(\lambda_i^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{t^i_{T_z}})\|^2 \right. \\ &\left. + \sum_{t=T_z}^{t^i_{T_z}-1} \|\nabla f_j(\lambda_j^{t+1}) - \nabla f_j(\lambda_j^t)\|^2\right) \\ \leq\ & \kappa\left(\frac{\|\nabla f_i(\lambda_i^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{t^i_{T_z}})\|^2}{n^2} + \sum_{t=T_z}^{t^i_{T_z}-1} \frac{\|\nabla f_j(\lambda_j^{t+1}) - \nabla f_j(\lambda_j^t)\|^2}{n^2}\right) \\ \leq\ & \kappa\left(\frac{\|\nabla f_i(\lambda_i^{t^i_{T_z}}) - \nabla f_j(\lambda_j^{t^i_{T_z}})\|^2}{n^2} + \frac{1}{2n}\sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t\right).\end{aligned}$$

The last inequality comes from (12) and from the fact that $\|\nabla f(\lambda^{t+1}) - \nabla f(\lambda^t)\|^2 = \sum_{i=1}^n \frac{\|\nabla f(\lambda_i^{t+1}) - \nabla f(\lambda_i^t)\|^2}{n^2}$. We finally have that

$$\begin{aligned}
\nabla f(\lambda^{T_z})^T \bar{v}^{T_z} &= \sum_{(i,j)\in E_{T_z}} \|w_{ij}(T_z)\|^2 \\
&\leq \sum_{(i,j)\in E_{T_z}} \kappa \left(\frac{\|\nabla f_i(\lambda_i^{t_{T_z}^i}) - \nabla f_j(\lambda_j^{t_{T_z}^i})\|^2}{n^2} + \frac{1}{2n} \sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t \right) \\
&\leq \kappa \left(\sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t + \frac{n-1}{2n} \sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t \right) \\
&\leq \frac{3}{2}\kappa \left(\sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t \right).
\end{aligned}$$

The first equality comes from Lemma A.1, with v^t replaced by $\bar{v}^{T_z}$. The second inequality comes from the fact that E_{T_z} is a subset of $E_{T_z,T_{z+1}}$ and from Lemma A.1. It is clear that Lemma A.1 is valid for all decentralized directions of update v derived using some communication graph G, where $v_i = \sum_{j\in N(i)} \frac{1}{n}(\nabla f_i(\lambda_i) - \nabla f_j(\lambda_j))$ and $N(i)$ is the set of neighbors of i in G. Hence Lemma A.1 is valid for $\bar{v}^{T_z}$. The second inequality holds because of Lemma A.1 and because there are exactly $n-1$ edges in the set E_{T_z}, as $G = (N, E_{T_z})$ is a tree. □

Proof of Theorem 3.1.

Proof of 1 *of Theorem* 3.1. First note that

$$\begin{aligned}
f(\lambda^{t+1}) - f(\lambda^t) &\geq \gamma \nabla f(\lambda^t)^T v^t - \frac{L}{2n}\|\gamma v^t\|^2 \\
&\geq \gamma \nabla f(\lambda^t)^T v^t - \frac{\gamma^2 L}{2n} 2n \nabla f(\lambda^t)^T v^t \\
&= \frac{1}{2L}\nabla f(\lambda^t)^T v^t - \frac{1}{4L}\nabla f(\lambda^t)^T v^t = \frac{1}{4L}\nabla f(\lambda^t)^T v^t. \qquad (13)
\end{aligned}$$

The first inequality comes from the descent lemma for differentiable functions [2]. The second inequality comes from Lemma A.2. The first equality comes from the fact that $\gamma = \frac{1}{2L}$. Since $\nabla f(\lambda^t)^T v^t$ is nonnegative, the sequence $\{f(\lambda^t)\}$ is monotonic and nondecreasing establishing the first part of the theorem.

Proof of 2 *of Theorem* 3.1. Since (1) is assumed to have an optimal solution, $f(\lambda^t)$ is bounded from above. We conclude from the first claim that $\{f(\lambda^t)\}$ converges, and $\{\nabla f(\lambda^t)^T v^t\}$ must converge to zero.

We now have that

$$\begin{aligned}
\|\tilde{v}^{T_z}\|^2 &= n \nabla f(\lambda^{T_z})^T \tilde{v}^{T_z} \\
&\leq \frac{n^4}{8} \nabla f(\lambda^{T_z})^T \bar{v}^{T_z} \leq \frac{3n^4}{16}\kappa \left(\sum_{t=T_z}^{T_{z+1}-1} \nabla f(\lambda^t)^T v^t \right),
\end{aligned}$$

where the first equality follows from Lemma A.3, the first inequality follows from Lemma A.4 and Lemma A.1, and the second inequality follows from Lemma A.9. The last inequality and the convergence of $\{\nabla f(\lambda^t)^T v^t\}$ to zero establishes the second part of the theorem.

Proof of 3 *of Theorem* 3.1. Note that

$$\begin{aligned} f(\lambda^{T_{z+1}}) - f(\lambda^{T_z}) &\geq \frac{1}{4L} \sum_{t=T_z}^{t=T_{z+1}-1} \nabla f(\lambda^t)^T v^t \\ &\geq \frac{1}{6L\kappa} \nabla f(\lambda^{T_z})^T \bar{v}^{T_z} \\ &\geq \frac{4}{3Ln^3\kappa} \nabla f(\lambda^{T_z})^T \tilde{v}^{T_z} \\ &= \frac{4}{3Ln^4\kappa} \|\tilde{v}^{T_z}\|^2. \end{aligned}$$

The first inequality comes from (13). The second inequality comes from Lemma A.9. The third inequality comes from Lemma A.4 and Lemma A.1, and the equality comes from Lemma A.3. Thus,

$$\begin{aligned} \sum_{z=1}^{p} f(\lambda^{T_{z+1}}) - f(\lambda^{T_z}) &\geq \frac{4}{3Ln^4\kappa} \sum_{z=1}^{p} \|\tilde{v}^{T_z}\|^2 \\ f(\lambda^{T_{p+1}}) - f(\lambda^1) &\geq \frac{4}{3Ln^4\kappa} \sum_{z=1}^{p} \|\tilde{v}^{T_z}\|^2 \\ f(\lambda^*) - f(\lambda^1) &\geq \frac{4}{3Ln^4\kappa} \sum_{z=1}^{p} \|\tilde{v}^{T_z}\|^2. \end{aligned}$$

The last inequality, together with the fact that $p(\min_{z=1,\ldots,p} \|\tilde{v}^{T_z}\|^2) \leq \sum_{z=1}^{p} \|\tilde{v}^{T_z}\|^2$, proves the third claim.

Proof of 4 *of Theorem* 3.1. If the set of optima of (1) is bounded, $\{\lambda : \|\tilde{v}(\lambda)\| \leq C\}$ is a bounded set for some $C > 0$. We conclude that λ^{T_z} has a converging subsequence $\lambda^{T_{z_k}}$. Let $\bar{\lambda}$ be the limit of $\lambda^{T_{z_k}}$. Since $\|\tilde{v}(\cdot)\|$ is a continuous function and $\|\tilde{v}(\lambda^{T_{z_k}})\|$ converges to zero, we conclude that $\tilde{v}(\bar{\lambda}) = 0$ and $\bar{\lambda}$ is optimal. Since f is continuous, we conclude that $\{f(\lambda^{T_{z_k}})\}$ converges to $f(\bar{\lambda}) = f(\lambda^*)$. Since $\{f(\lambda^t)\}$ converges, we conclude that it must converge to $f(\lambda^*)$. ∎

LEMMA 3.3. *Let f_i and $\hat{f}_i$ be as defined in section* 3.2. *Then the following hold:*

1. *$\hat{f}_i$ is concave and differentiable, with gradient $\nabla \hat{f}_i(\lambda_i) = \mathrm{E}[\nabla f_i(\lambda_i + Z_i)]$;*
2. *$f_i(\lambda_i) \geq \hat{f}_i(\lambda_i) \geq f_i(\lambda_i) - 2.8\epsilon L$;*
3. *$\|\nabla \hat{f}_i(\lambda_i) - \nabla \hat{f}_i(\bar{\lambda}_i)\| \leq \frac{\sqrt{\log(m+1)}L}{\epsilon} \|\lambda_i - \bar{\lambda}_i\|$.*

Proof of 1 *of Lemma* 3.3. For all $a \in [0, 1]$, we have that

$$\begin{aligned} \hat{f}_i(a\lambda_i + (1-a)\bar{\lambda}_i) &= \mathrm{E}[f_i(a\lambda_i + (1-a)\bar{\lambda}_i + Z_i)] \\ &\geq \mathrm{E}[af_i(\lambda_i + Z_i) + (1-a)f_i(\bar{\lambda}_i + Z_i)] = a\hat{f}_i(\lambda_i) + (1-a)\hat{f}_i(\bar{\lambda}_i). \end{aligned}$$

It follows that $\hat{f}_i$ is concave. Since f_i is nondifferentiable only on a set of measure zero, we have that

$$\begin{aligned} (\nabla f_i(\lambda_i + Z_i))_j &= \lim_{\delta \uparrow 0} \frac{f_i(\lambda_i + Z_i + \delta e_j) - f_i(\lambda_i + Z_i)}{\delta} \\ &= \lim_{\delta \downarrow 0} \frac{f_i(\lambda_i + Z_i + \delta e_j) - f_i(\lambda_i + Z_i)}{\delta}, \end{aligned}$$

with probability 1, where e_j is the vector with all entries equal to zero except for the jth entry, which is equal to one. Hence

$$\begin{aligned}\lim_{\delta\uparrow 0}\frac{\mathrm{E}[f_i(\lambda_i+Z_i+\delta e_j)]-\mathrm{E}[f_i(\lambda_i+Z_i)]}{\delta} &= \mathrm{E}\left[\lim_{\delta\uparrow 0}\frac{f_i(\lambda_i+Z_i+\delta e_j)-f_i(\lambda_i+Z_i)}{\delta}\right]\\ &= \mathrm{E}[(\nabla f_i(\lambda_i+Z_i))_j]\\ &= \mathrm{E}\left[\lim_{\delta\downarrow 0}\frac{f_i(\lambda_i+Z_i+\delta e_j)-f_i(\lambda_i+Z_i)}{\delta}\right]\\ &= \lim_{\delta\downarrow 0}\frac{\mathrm{E}[f_i(\lambda_i+Z_i+\delta e_j)]-\mathrm{E}[f_i(\lambda_i+Z_i)]}{\delta}.\end{aligned}$$

Note that $|\frac{f_i(\lambda_i+Z_i+\delta e_j)-f_i(\lambda_i+Z_i)}{\delta}| \le L$. Hence the exchanges between limit and expectation are valid by the bounded convergence theorem. It follows that $\hat{f}_i$ is differentiable, and its gradient is given by

$$\nabla\hat{f}_i(\lambda_i) = \mathrm{E}[\nabla f_i(\lambda_i+Z_i)].$$

Proof of 2 *of Lemma* 3.3. First, we have that

$$\begin{aligned}\hat{f}_i(\lambda_i) &= \mathrm{E}[f_i(\lambda_i+Z_i)]\\ &\le f_i(\lambda_i+EZ_i) = f_i(\lambda_i),\end{aligned}$$

where the inequality follows from the concavity of f_i and Jensen's inequality [4].

For the lower bound on $\hat{f}_i$, we have that

$$\begin{aligned}\hat{f}_i(\lambda_i) &= \mathrm{E}[f_i(\lambda_i+Z_i)]\\ &= \mathrm{E}[f_i(\lambda_i-Z_i)]\\ &\ge \mathrm{E}[f_i(\lambda_i)-Z_i^T\nabla f_i(\lambda_i-Z_i)]\\ &\ge f_i(\lambda_i)-\mathrm{E}[\max_j|Z_{ij}|]L,\end{aligned}\tag{14}$$

where $|Z_{ij}|$ is the modulus function. The first inequality follows from the concavity of f and the fact that $\nabla f_i(\lambda_i-Z_i)$ is a subgradient of f at λ_i-Z_i. The second inequality follows from the fact that $\|\nabla f_i(\lambda_i-Z_i)\|_1 \le L$.

We now show that $\mathrm{E}[\max_j|Z_{ij}|] \le 2.8\epsilon$. Note that this inequality and (14) prove the claim.

We first place a bound on $P(|Z_{ij}|>c)$, for $c>0$. We have that

$$\begin{aligned}P(|Z_{ij}|>c) &= \int_c^\infty \frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2}{2\sigma^2}}dz+\int_{-\infty}^{-c}\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2}{2\sigma^2}}dz = 2\int_c^\infty\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2}{2\sigma^2}}dz\\ &= 2e^{-\frac{c^2}{2\sigma^2}}\int_0^\infty\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2+2zc}{2\sigma^2}}dz\\ &= 2e^{-\frac{c^2}{2\sigma^2}}\left(\int_0^c\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2+2zc}{2\sigma^2}}dz+\int_c^\infty\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2+2zc}{2\sigma^2}}dz\right)\\ &\le 2e^{-\frac{c^2}{2\sigma^2}}\left(\int_0^c\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{zc}{\sigma^2}}dz+\int_c^\infty\frac{1}{\sqrt{2\pi}\sigma}e^{-\frac{z^2}{2\sigma^2}}dz\right)\\ &= 2e^{-\frac{c^2}{2\sigma^2}}\left(\frac{\sigma}{\sqrt{2\pi}c}\left(1-e^{-\frac{c^2}{\sigma^2}}\right)+\frac{1}{2}P(|Z_{ij}|>c)\right).\end{aligned}$$

Hence

$$P(|Z_{ij}| > c) \leq 2\left(\frac{\frac{e^{-\frac{c^2}{2\sigma^2}}\sigma}{\sqrt{2\pi}c}\left(1-e^{-\frac{c^2}{\sigma^2}}\right)}{1-e^{-\frac{c^2}{2\sigma^2}}}\right)$$
$$= \frac{2e^{-\frac{c^2}{2\sigma^2}}\sigma}{\sqrt{2\pi}c}\left(1+e^{-\frac{c^2}{2\sigma^2}}\right) \leq \frac{2e^{-\frac{c^2}{2\sigma^2}}\sqrt{2}\sigma}{\sqrt{\pi}c}.$$

It follows that, for all $c \geq \frac{2\epsilon}{\sqrt{\pi}}$,

$$P(\max_j |Z_{ij}| > c) \leq 2m\frac{e^{-\frac{c^2}{2\sigma^2}}\sqrt{2}\sigma}{\sqrt{\pi}c} \leq 2(m+1)\frac{e^{-\frac{c^2\pi\log(m+1)}{4\epsilon^2}}}{\sqrt{\pi\log(m+1)}}$$
$$= \frac{2e^{-\frac{\left(c^2-\frac{4\epsilon^2}{\pi}\right)\pi\log(m+1)}{4\epsilon^2}}}{\sqrt{\pi\log(m+1)}} \leq \frac{2e^{-\frac{\left(c-\frac{2\epsilon}{\sqrt{\pi}}\right)^2\pi\log(m+1)}{4\epsilon^2}}}{\sqrt{\pi\log(m+1)}}.$$

The first inequality follows from the union bound [4]. The second inequality follows from $c \geq \frac{2\epsilon}{\sqrt{\pi}}$. The last inequality follows from $(c-\frac{2\epsilon}{\sqrt{\pi}})^2 \leq c^2 - \frac{4\epsilon^2}{\pi}$ for all $c > \frac{2\epsilon}{\sqrt{\pi}}$.

Finally,

$$\begin{aligned}
&\mathrm{E}[\max_j |Z_{ij}|] \\
&= \int_0^\infty P(\max_j |Z_{ij}| > z)dz \\
&= \int_0^{\frac{2\epsilon}{\sqrt{\pi}}} P(\max_j |Z_{ij}| > z)dz + \int_{\frac{2\epsilon}{\sqrt{\pi}}}^\infty P(\max_j |Z_{ij}| > z)dz \\
&\leq \frac{2\epsilon}{\sqrt{\pi}} + \int_{\frac{2\epsilon}{\sqrt{\pi}}}^\infty \frac{2e^{-\frac{\left(z-\frac{2\epsilon}{\sqrt{\pi}}\right)^2\pi\log(m+1)}{4\epsilon^2}}}{\sqrt{\pi\log(m+1)}}dz \\
&= \frac{2\epsilon}{\sqrt{\pi}} + \frac{4\epsilon}{\sqrt{\pi\log(m+1)}}\int_{\frac{2\epsilon}{\sqrt{\pi}}}^\infty \frac{\sqrt{\log(m+1)}}{2\epsilon}e^{-\frac{\left(z-\frac{2\epsilon}{\sqrt{\pi}}\right)^2\pi\log(m+1)}{4\epsilon^2}}dz \\
&= \frac{2\epsilon}{\sqrt{\pi}} + \frac{4\epsilon}{\sqrt{\pi\log(m+1)}}\int_{\frac{2\epsilon}{\sqrt{\pi}}}^\infty \frac{1}{\sqrt{2\pi}}\frac{\sqrt{\pi\log(m+1)}}{\sqrt{2}\epsilon}e^{-\frac{\left(\frac{\sqrt{\pi\log(m+1)}\left(z-\frac{2\epsilon}{\sqrt{\pi}}\right)}{\sqrt{2}\epsilon}\right)^2}{2}}dz \\
&= \frac{2\epsilon}{\sqrt{\pi}} + \frac{2\epsilon}{\sqrt{\pi\log(m+1)}} \\
&\leq 2.8\epsilon.
\end{aligned}$$

The last equality comes from the identity $\frac{1}{\sqrt{2\pi}}\int_0^\infty e^{-\frac{t^2}{2}}dt = \frac{1}{2}$.

Proof of 3 *of Lemma* 3.3. Denote by $p(\cdot)$ the probability density function for Z_i; i.e., the joint probability density function for $Z_{i1}, \ldots, Z_{im}$. Then we have that

$$\nabla\hat{f}_i(\lambda_i) = \int_{\Re^m} p(z)\nabla f_i(\lambda_i + z)dz$$
$$= \int_{\Re^m} p(z-\lambda_i)\nabla f_i(z)dz.$$

It follows that

$$\begin{aligned}\|\nabla \hat{f}_i(\lambda_i) - \nabla \hat{f}_i(\bar{\lambda}_i)\| &= \left\| \int_{\Re^m} (p(z-\lambda_i) - p(z-\bar{\lambda}_i)) \nabla f_i(z) dz \right\| \\ &\le \int_{\Re^m} |p(z-\lambda_i) - p(z-\bar{\lambda}_i)| \|\nabla f_i(z)\| dz \\ &\le L \int_{\Re^m} |p(z-\lambda_i) - p(z-\bar{\lambda}_i)| dz. \qquad (15)\end{aligned}$$

Since $p(\cdot)$ is the joint distribution of m i.i.d. zero-mean Gaussian random variables, $p(z)$ is strictly decreasing on $\|z\|$. Hence

$$\begin{aligned}&\int_{\Re^m} |p(z-\lambda_i) - p(z-\bar{\lambda}_i)| dz \\ &\quad = \int_{\{z\in\Re^m : \|z-\lambda_i\| < \|z-\bar{\lambda}_i\|\}} \left(p(z-\lambda_i) - p(z-\bar{\lambda}_i)\right) dz \\ &\qquad + \int_{\{z\in\Re^m : \|z-\lambda_i\| > \|z-\bar{\lambda}_i\|\}} \left(p(z-\bar{\lambda}_i) - p(z-\lambda_i)\right) dz \\ &\quad = 2 \int_{\{z\in\Re^m : \|z-\lambda_i\| < \|z-\bar{\lambda}_i\|\}} \left(p(z-\lambda_i) - p(z-\bar{\lambda}_i)\right) dz \\ &\quad = 2 \int_{\{z\in\Re^m : \|z\| < \|z-(\bar{\lambda}_i-\lambda_i)\|\}} p(z) dz - 2 \int_{\{z\in\Re^m : \|z\| > \|z-(\lambda_i-\bar{\lambda}_i)\|\}} p(z) dz \\ &\quad = 2P(\|Z_i\| < \|Z_i - (\bar{\lambda}_i - \lambda_i)\|) - 2P(\|Z_i\| > \|Z_i - (\lambda_i - \bar{\lambda}_i)\|) \\ &\quad = 2P(2Z_i^T(\bar{\lambda}_i - \lambda_i) < \|\bar{\lambda}_i - \lambda_i\|^2) - 2P(2Z_i^T(\bar{\lambda}_i - \lambda_i) < -\|\bar{\lambda}_i - \lambda_i\|^2) \\ &\quad = 2P(-0.5\|\bar{\lambda}_i - \lambda_i\| < V < 0.5\|\bar{\lambda}_i - \lambda_i\|), \qquad (16)\end{aligned}$$

where

$$V = \frac{Z_i^T(\bar{\lambda}_i - \lambda_i)}{\|\bar{\lambda}_i - \lambda_i\|}.$$

It is easy to verify that V is normal with a zero mean and variance equal to $\sigma = \frac{\sqrt{2}\epsilon}{\sqrt{\pi \log(m+1)}}$. It follows that

$$\begin{aligned}P(-0.5\|\bar{\lambda}_i - \lambda_i\| < V < 0.5\|\bar{\lambda}_i - \lambda_i\|) &\le \frac{1}{\sqrt{2\pi}\sigma} \|\bar{\lambda}_i - \lambda_i\| \\ &= \frac{\sqrt{\log(m+1)}}{2\epsilon} \|\bar{\lambda}_i - \lambda_i\|. \qquad (17)\end{aligned}$$

The claim follows from (15), (16), and (17). □

THEOREM 3.2. *Suppose that Assumptions* 3.3 *and* 3.4 *hold. Then with probability* 1*:*

1. *the sequence* $\{\|\tilde{v}^{T_z}\|\}$ *converges to* 0*;*
2. $\min_{z=1,\ldots,p} \mathrm{E}[\|\tilde{v}^{T_z}\|^2] \le \dfrac{\frac{n^4\kappa L\sqrt{\log(m+1)}}{\epsilon}\left[3(f(\lambda^*) - f(\lambda^1) + 2.8\epsilon L) + \sum_{t=1}^{t=\kappa p} \frac{4L\beta_t^2\epsilon}{\sqrt{\log(m+1)}}\right]}{4\sum_{z=2}^{p+1}\beta_{\kappa z}}$ $\forall p$*;*
3. *if the set of the optima of* (1) *is bounded, then* $\lim_{t\to\infty} f(\lambda^t) \ge f(\lambda^*) - 2.8\epsilon L$.

The proof has the same structure as the proof of Theorem 3.1. Let the expected direction of update at time t be v^t:

$$v_i^t = \frac{1}{n} \sum_{j \in N_i(t)} (\nabla \hat{f}_i(\lambda_i^t) - \nabla \hat{f}_j(\lambda_j^t)).$$

Let δ^t be the random variable denoting the difference between the actual and the expected directions of update:

$$\delta_i^t = \sum_{j \in N_i(t)} \frac{1}{n} (\nabla f_i(\lambda_i^t + Z_i^t) - \nabla f_j(\lambda_j^t + Z_j^t)) - v_i^t.$$

Let $\mathcal{F}_t$ be the sigma-algebra [4] generated by $Z_i^\tau,\ i = 1, \ldots, n, \tau = 1, \ldots, t$. We have the following result about δ_i^t.

LEMMA A.10. *For all t, $\mathrm{E}[\delta^t | \mathcal{F}_{t-1}] = 0$ and $\mathrm{E}[\|\delta^t\|^2 | \mathcal{F}_{t-1}] < 8nL^2$, with probability* 1.

Proof. $\mathrm{E}[\delta_i^t | \mathcal{F}_{t-1}] = 0$ follows from $\nabla \hat{f}_i(\lambda_i) = \mathrm{E}[\nabla f_i(\lambda_i + Z_i^t)]$ for all i. Moreover,

$$\begin{aligned}
&\mathrm{E}[\|\delta_i^t\|^2 | \mathcal{F}_{t-1}] \\
&= \mathrm{E}\left[\left\| \sum_{j \in N_i(t)} \frac{\nabla f_i(\lambda_i^t + Z_i^t) - \nabla \hat{f}_i(\lambda_i^t) - \nabla f_j(\lambda_j^t + Z_j^t) + \nabla \hat{f}_j(\lambda_j^t)}{n} \right\|^2 | \mathcal{F}_{t-1} \right] \\
&= \frac{\mathrm{E}\left[\left\| N_i(t) \left(\nabla f_i(\lambda_i^t + Z_i^t) - \nabla \hat{f}_i(\lambda_i^t) \right) - \sum_{j \in N_i(t)} \left(\nabla f_j(\lambda_j^t + Z_j^t) - \nabla \hat{f}_j(\lambda_j^t) \right) \right\|^2 | \mathcal{F}_{t-1} \right]}{n^2} \\
&\leq \frac{N_i(t)^2 \mathrm{E}[\|\nabla f_i(\lambda_i^t + Z_i^t) - \nabla \hat{f}_i(\lambda_i^t)\|^2 | \mathcal{F}_{t-1}] + \sum_{j \in N_i(t)} \mathrm{E}[\|\nabla f_j(\lambda_j^t + Z_j^t) - \nabla \hat{f}_j(\lambda_j^t)\|^2 | \mathcal{F}_{t-1}]}{n^2} \\
&< 8L^2.
\end{aligned}$$

The last inequality follows from $N_i(t) < n$ and

$$\|\nabla f_j(\lambda_j^t + Z_j^t) - \nabla \hat{f}_j(\lambda_j^t)\| \leq \|\nabla f_j(\lambda_j^t + Z_j^t)\| + \|\nabla \hat{f}_j(\lambda_j^t)\| \leq 2L.$$

Finally,

$$\mathrm{E}[\|\delta^t\|^2 | \mathcal{F}_{t-1}] = \sum_i \mathrm{E}[\|\delta_i^t\|^2 | \mathcal{F}_{t-1}] < 8nL^2. \qquad \square$$

The following results follow immediately from Lemmas A.1–A.4 applied with $\hat{f}_i$ replacing f_i for all i:

$$\nabla \hat{f}(\lambda^t)^T v^t = \frac{1}{n^2} \sum_{(i,j) \in E(t)} \|\nabla \hat{f}_i(\lambda_i^t) - \nabla \hat{f}_j(\lambda_j^t)\|^2 \tag{18}$$

$$\|v^t\|^2 \leq 2n \nabla \hat{f}(\lambda^t)^T v^t \tag{19}$$

$$\|\tilde{v}^t\|^2 = n \nabla \hat{f}(\lambda^t)^T \tilde{v}^t \tag{20}$$

$$\sum_{(i,j) \in E} \|\nabla \hat{f}_j(\lambda_j^t) - \nabla \hat{f}_i(\lambda_i^t)\|^2 \geq \frac{8}{n^3} \sum_{((i,j) \in N^2, i<j)} \|\nabla \hat{f}_j(\lambda_j^t) - \nabla \hat{f}_i(\lambda_i^t)\|^2$$

$$\forall E : (N, E) \text{ is connected.} \tag{21}$$

Let E_{T_z} be a subset of the edge set $E_{T_z,T_{z+1}}$ such that the graph (N, E_{T_z}) is a tree. By Assumption 2.1, the graph $(N, E_{T_z,T_{z+1}})$ is connected and so E_{T_z} is well defined. As before, let the decentralized direction of update derived using $G = (N, E_{T_z})$ be denoted by $\bar{v}^{T_z}$. The following result is the counterpart of Lemma A.9.

LEMMA A.11. *Let* $L_\epsilon = \frac{\sqrt{\log(m+1)}L}{\epsilon}$.
$\nabla \hat{f}(\lambda^{T_z})^T \bar{v}^{T_z} \leq \kappa \sum_{t=T_z}^{t=T_{z+1}-1} [(1 + 2L_\epsilon^2 \gamma_t^2) \mathrm{E}[\nabla \hat{f}(\lambda^t)^T v^t | \mathcal{F}_{T_z-1}] + 8L^2 L_\epsilon^2 \gamma_t^2]$.

Proof. We have that

$$\begin{aligned}
\mathrm{E}[\|\nabla \hat{f}(\lambda^{t+1}) - \nabla \hat{f}(\lambda^t)\|^2 | \mathcal{F}_{t-1}] &\leq \frac{L_\epsilon^2}{n^2} \mathrm{E}[\|\gamma_t (v^t + \delta^t)\|^2 | \mathcal{F}_{t-1}] \\
&= \frac{L_\epsilon^2 \gamma_t^2}{n^2} (\|v^t\|^2 + \mathrm{E}[\|\delta^t\|^2 | \mathcal{F}_{t-1}]) \\
&\leq \frac{L_\epsilon^2 \gamma_t^2}{n^2} (2n \nabla \hat{f}(\lambda^t)^T v^t + 8nL^2). \qquad (22)
\end{aligned}$$

It follows from Lemma 3.3 that L_ϵ is a Lipschitz constant for the functions $\hat{f}_i$, $i = 1, \ldots, n$. Hence $\frac{L_\epsilon}{n}$ is a Lipschitz constant for $\hat{f}$, and the first inequality follows from this. The second inequality follows from (19) and Lemma A.10.

Let $t^i_{T_z}$ be the earliest time between the time periods T_z and $T_{z+1} - 1$ such that there is an edge $(i, j) \in E_{T_z}$ for agent i. It is clear that $T_z \leq t^i_{T_z} \leq T_{z+1} - 1$. Also, by definition, for $l = T_z, T_z + 1, \ldots, (t^i_{T_z} - 1)$, there is no edge $(i, p) \in E(l)$. Thus $\lambda_i^{t^i_{T_z}} = \lambda_i^{T_z}$, and $\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) = \nabla \hat{f}_i(\lambda_i^{T_z})$. Let $w_{ij}(t) = \frac{1}{n}(\nabla \hat{f}_i(\lambda_i^t) - \nabla \hat{f}_j(\lambda_j^t))$. Then

$$\begin{aligned}
\|w_{ij}(T_z)\| &= \frac{1}{n} \|\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{T_z})\| \\
&\leq \frac{1}{n} (\|\mathrm{E}[\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}}) | \mathcal{F}_{T_z-1}]\| \\
&\quad + \|\mathrm{E}[\nabla \hat{f}_j(\lambda_j^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{T_z}) | \mathcal{F}_{T_z-1}]\|) \\
&\leq \frac{1}{n} \left(\|\mathrm{E}[\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}}) | \mathcal{F}_{T_z-1}]\| \right. \\
&\qquad \left. + \sum_{t=T_z}^{t=t^i_{T_z}-1} \|\mathrm{E}[\nabla \hat{f}_j(\lambda_j^{t+1}) - \nabla \hat{f}_j(\lambda_j^t) | \mathcal{F}_{T_z-1}]\| \right).
\end{aligned}$$

From the Cauchy–Schwarz inequality,

$$\begin{aligned}
\|w_{ij}(T_z)\|^2 &\leq \frac{(t^i_{T_z} - T_z + 1)}{n^2} \left(\|\mathrm{E}[\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}}) | \mathcal{F}_{T_z-1}]\|^2 \right. \\
&\qquad \left. + \sum_{t=T_z}^{t=t^i_{T_z}-1} \|\mathrm{E}[\nabla \hat{f}_j(\lambda_j^{t+1}) - \nabla \hat{f}_j(\lambda_j^t) | \mathcal{F}_{T_z-1}]\|^2 \right) \\
&\leq \frac{\kappa}{n^2} \left(\mathrm{E}[\|\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}})\|^2 | \mathcal{F}_{T_z-1}] \right. \\
&\qquad \left. + \sum_{t=T_z}^{t=t^i_{T_z}-1} \mathrm{E}[\|\nabla \hat{f}_j(\lambda_j^{t+1}) - \nabla \hat{f}_j(\lambda_j^t)\|^2) | \mathcal{F}_{T_z-1}] \right)
\end{aligned}$$

$$\leq \kappa \left(\frac{\mathrm{E}[\|\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}})\|^2 | \mathcal{F}_{T_z-1}]}{n^2} + \frac{L_\epsilon^2}{n^2} \sum_{t=T_z}^{t=T_{z+1}-1} \gamma_t^2 (\mathrm{E}[2n \nabla \hat{f}(\lambda^t)^T v^t | \mathcal{F}_{T_z-1}] + 8nL^2) \right).$$

The last inequality follows from the fact that $\|\nabla \hat{f}(\lambda^{t+1}) - \nabla \hat{f}(\lambda^t)\|^2 = \frac{1}{n^2} \sum_{k=1}^n \|\nabla \hat{f}_k (\lambda_k^{t+1}) - \nabla \hat{f}_k(\lambda_k^t)\|^2 \geq \frac{1}{n^2} \|\nabla \hat{f}_j(\lambda_j^{t+1}) - \nabla \hat{f}_j(\lambda_j^t)\|^2$ and from (22). We finally have that

$$\begin{aligned}
\nabla \hat{f}(\lambda^{T_z})^T \bar{v}^{T_z} &= \sum_{(i,j) \in E_{T_z}} \|w_{ij}(T_z)\|^2 \\
&\leq \sum_{(i,j) \in E_{T_z}} \kappa \left(\frac{\mathrm{E}[\|\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}})\|^2 | \mathcal{F}_{T_z-1}]}{n^2} + \frac{L_\epsilon^2}{n^2} \sum_{t=T_z}^{t=T_{z+1}-1} \gamma_t^2 (\mathrm{E}[2n \nabla \hat{f}(\lambda^t)^T v^t | \mathcal{F}_{T_z-1}] + 8nL^2) \right) \\
&\leq \kappa \sum_{t=T_z}^{t=T_{z+1}-1} \left[(1 + 2L_\epsilon^2 \gamma_t^2) \mathrm{E}[\nabla \hat{f}(\lambda^t)^T v^t | \mathcal{F}_{T_z-1}] + 8L^2 L_\epsilon^2 \gamma_t^2 \right].
\end{aligned}$$

In the last inequality, we have used the fact that

$$\begin{aligned}
&\sum_{(i,j) \in E_{T_z}} \frac{\mathrm{E}[\|\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}})\|^2 | \mathcal{F}_{T_z-1}]}{n^2} \\
&\quad = \sum_{t=T_z}^{t=T_{z+1}-1} \sum_{\left((i,j) \in E_{T_z}, t^i_{T_z} = t\right)} \frac{\mathrm{E}[\|\nabla \hat{f}_i(\lambda_i^{t^i_{T_z}}) - \nabla \hat{f}_j(\lambda_j^{t^i_{T_z}})\|^2 | \mathcal{F}_{T_z-1}]}{n^2} \\
&\quad \leq \sum_{t=T_z}^{t=T_{z+1}-1} \mathrm{E}[\nabla \hat{f}(\lambda^t)^T v^t | \mathcal{F}_{T_z-1}]. \qquad \square
\end{aligned}$$

Proof of Theorem 3.2.

Proof of 1 *of Theorem* 3.2. We first have that

$$\begin{aligned}
\mathrm{E}[\hat{f}(\lambda^{t+1}) | \mathcal{F}_{t-1}] &\geq \hat{f}(\lambda^t) + \gamma_t \nabla \hat{f}(\lambda^t)^T v^t - \frac{L_\epsilon}{2n} \mathrm{E}[\|\gamma_t (v^t + \delta^t)\|^2 | \mathcal{F}_{t-1}] \\
&= \hat{f}(\lambda^t) + \gamma_t \nabla \hat{f}(\lambda^t)^T v^t - \frac{L_\epsilon}{2n} \|\gamma_t v^t\|^2 - \frac{L_\epsilon}{2n} \mathrm{E}[\|\gamma_t \delta^t\|^2 | \mathcal{F}_{t-1}] \\
&\geq \hat{f}(\lambda^t) + (\gamma_t - L_\epsilon \gamma_t^2) \nabla \hat{f}(\lambda^t)^T v^t - 4L_\epsilon L^2 \gamma_t^2. \qquad (23)
\end{aligned}$$

The first inequality comes from the descent lemma for differentiable functions [2]. The equality follows from $\mathrm{E}[\delta | \mathcal{F}_{t-1}] = 0$ from Lemma A.10. The second inequality follows from Lemma A.10 and (19).

Note that $\nabla \hat{f}(\lambda^t)^T v^t \geq 0$. This and Assumption 3.4 imply that the second term in (23) is also greater than or equal to zero. Moreover,

$$\sum_t 4L_\epsilon L^2 \gamma_t^2 < \infty.$$

Since $\hat{f}$ is bounded from above, we conclude by the supermartingale convergence theorem [4] that $\hat{f}(\lambda^t)$ converges with probability 1. Moreover, $\sum_t(\gamma_t - L_\epsilon\gamma_t^2)\nabla\hat{f}(\lambda^t)^T v^t < \infty$ with probability 1 and since $\sum_t \gamma_t = \infty$, we conclude that $\nabla\hat{f}(\lambda^t)^T v^t$ converges to zero with probability 1. Note that

$$\mathrm{E}[\nabla\hat{f}(\lambda^t)^T v^t | \mathcal{F}_{t-1}] = \nabla\hat{f}(\lambda^t)^T v^t$$

with probability 1, and we conclude that $\mathrm{E}[\nabla\hat{f}(\lambda^t)^T v_t | \mathcal{F}_{t-1}]$ also converges to zero with probability 1.

We now have that

$$\begin{aligned}
\|\tilde{v}^{T_z}\|^2 &= n\nabla\hat{f}(\lambda^{T_z})^T\tilde{v}^{T_z} \\
&\leq \frac{n^4}{8}\nabla\hat{f}(\lambda^{T_z})^T\bar{v}^{T_z} \\
&\leq \frac{n^4}{8}\kappa\sum_{t=T_z}^{t=T_{z+1}-1}\left[(1+2L_\epsilon^2\gamma_t^2)\mathrm{E}[\nabla\hat{f}(\lambda^t)^T v^t|\mathcal{F}_{T_z-1}] + 8L^2L_\epsilon^2\gamma_t^2\right] \\
&\leq \frac{n^4}{8}\kappa\sum_{t=T_z}^{t=T_{z+1}-1}\left[1.5\mathrm{E}[\nabla\hat{f}(\lambda^t)^T v^t|\mathcal{F}_{T_z-1}] + 2L^2\beta_t^2\right]. \qquad (24)
\end{aligned}$$

The equality follows from (20). The first inequality follows from (21) and (18). The second inequality follows from Lemma A.11. The third inequality follows from Assumption 3.4 on the step sizes γ_t. We conclude that $\|\tilde{v}^{T_z}\|$ converges to zero with probability 1.

Proof of 2 *of Theorem* 3.2. From (23), we have that

$$\begin{aligned}
\nabla\hat{f}(\lambda^t)^T v^t &\leq \frac{\mathrm{E}[\hat{f}(\lambda^{t+1})|\mathcal{F}_{t-1}] + 4L_\epsilon L^2\gamma_t^2 - \hat{f}(\lambda^t)}{\gamma_t(1-L_\epsilon\gamma_t)} \\
&\leq \frac{2(\mathrm{E}[\hat{f}(\lambda^{t+1})|\mathcal{F}_{t-1}] - \hat{f}(\lambda^t)) + \left(\frac{2L^2\beta_t^2}{L_\epsilon}\right)}{\gamma_t}. \qquad (25)
\end{aligned}$$

In the second inequality we have used $\gamma_t \leq \frac{1}{2L_\epsilon}$ from Assumption 3.4.

Combining (24) and (25), we have that

$$\begin{aligned}
\mathrm{E}[\|\tilde{v}^{T_z}\|^2] &\leq \frac{n^4}{8}\kappa\sum_{t=T_z}^{t=T_{z+1}-1}\left(\frac{3\mathrm{E}[\hat{f}(\lambda^{t+1}) - \hat{f}(\lambda^t)] + \left(\frac{3L^2\beta_t^2}{L_\epsilon}\right)}{\gamma_t} + 2L^2\beta_t^2\right) \\
&\leq \frac{n^4}{8\gamma_{\kappa z}}\kappa\sum_{t=T_z}^{t=T_{z+1}-1}\left[3\mathrm{E}[\hat{f}(\lambda^{t+1}) - \hat{f}(\lambda^t)] + \frac{3L^2\beta_t^2}{L_\epsilon} + \frac{L^2\beta_t^2}{L_\epsilon}\right].
\end{aligned}$$

The last inequality follows from Assumption 3.4 on the step sizes. It follows that

$$\begin{aligned}
\sum_{z=1}^{p}\gamma_{\kappa z}\mathrm{E}[\|\tilde{v}^{T_z}\|^2] &\leq \frac{n^4}{8}\kappa\sum_{t=1}^{t=T_{p+1}-1}\left[3\mathrm{E}[\hat{f}(\lambda^{t+1}) - \hat{f}(\lambda^t)] + \frac{4L^2\beta_t^2}{L_\epsilon}\right] \\
&\leq \frac{n^4}{8}\kappa\left[3(\hat{f}(\hat{\lambda}) - \hat{f}(\lambda^1)) + \sum_{t=1}^{t=\kappa p}\frac{4L^2\beta_t^2}{L_\epsilon}\right],
\end{aligned}$$

where $\hat{\lambda}$ denotes an optimal solution of (5). From Lemma 3.3, we have that $\hat{f}(\lambda^1) \geq f(\lambda^1) - 2.8\epsilon L$. We also have that $\hat{f}(\hat{\lambda}) \leq f(\hat{\lambda}) \leq f(\lambda^*)$. It follows that

$$\min_{z=1,\ldots,p} \mathrm{E}[\|\tilde{v}^{T_z}\|^2] \leq \frac{\frac{n^4\kappa L\sqrt{\log(m+1)}}{\epsilon}\left[3(f(\lambda^*) - f(\lambda^1) + 2.8\epsilon L) + \sum_{t=1}^{t=\kappa p} \frac{4L\beta_t^2\epsilon}{\sqrt{\log(m+1)}}\right]}{4\sum_{z=2}^{p+1}\beta_{\kappa z}} \quad \forall p.$$

Proof of 3 *of Theorem* 3.2. Since $f \geq \hat{f} \geq f - 2.8\epsilon L$, if (1) has a bounded set of optima, so does (5). Recall from the proof of the first claim that $\hat{f}(\lambda^t)$ converges with probability 1. Using the same argument as in the proof of the fourth claim of Theorem 3.1, we conclude that $\hat{f}(\lambda^t)$ converges to $\hat{f}(\hat{\lambda})$ with probability 1. We conclude that

$$\begin{aligned}\limsup_{t\to\infty} f(\lambda^t) &\geq \hat{f}(\hat{\lambda}) \\ &\geq \hat{f}(\lambda^*) \\ &\geq f(\lambda^*) - 2.8\epsilon L.\end{aligned}$$

The first inequality follows from $f(\lambda^t) \geq \hat{f}(\lambda^t)$ for all t from Lemma 3.3. The second inequality follows from the optimality of $\hat{\lambda}$. The third inequality follows from Lemma 3.3. ∎

LEMMA 4.1. *Under assumption* 3.3 *for* f,

1. *for all* i, $g_i(\lambda_i)$ *is concave and differentiable outside a set of measure zero;*
2. *for all* i *and* λ_i, $\sup_{i,\lambda_i}\{\|v\|_1 : v \in \partial g_i(\lambda_i)\} \leq L_m < \infty$, *where* $L_m = L + mL_g$.

Proof of 1 *of Lemma* 4.1. Let $h_j(\lambda_i) = L_g \min(\lambda_{ij}, 0)$. It is clear that h_j is a piecewise linear function. Recall that

$$g_i(\lambda_i) = f_i(\lambda_i) + \sum_{j=1}^{m} h_j(\lambda_i).$$

The concavity of g_i follows from the concavity of f and the functions h_j, $j = 1, \ldots, m$. The points of the nondifferentiability of f_i form a set of measure zero. The other points of nondifferentiability of g_i are points λ_i, where $\lambda_{ij} = 0$ for some j. These points form a set of measure zero. Thus g_i is differentiable outside a set of measure zero.

Proof of 2 *of Lemma* 4.1. Let $\mathbf{e}_j$ be the vector whose jth component is 1 and other components are 0. It is clear that, for λ_i with $\lambda_{ij} \neq 0$, h_j is differentiable and $\nabla h_j(\lambda_i) = L_g\mathbf{e}_j$ if $\lambda_{ij} < 0$ and $\nabla h_j(\lambda_i) = \mathbf{0}$ if $\lambda_{ij} > 0$, where $\mathbf{0}$ is the m-dimensional zero vector. For λ_i with $\lambda_{ij} = 0$, $\partial h_j(\lambda_i)$ consists of vectors of the form $\bar{L}\mathbf{e}_j$, where $0 \leq \bar{L} \leq L_g$. Thus, for all j, $\sup_{\lambda_i}\{\|v\|_1 : v \in \partial h_j(\lambda_i)\} = L_g$. It is known from the theory of convex functions that if $u = \sum_{j=1}^{k} u_j$ where u_j, $j = 1, \ldots, k$ are convex functions, then $\partial u(x) = \sum_{j=1}^{k} \partial u_j(x)$. Thus, if $\sup_x\{\|v\|_1 : v \in \partial u_j(x)\} \leq L_j$, then $\sup_x\{\|v\|_1 : v \in \partial u(x)\} \leq \sum_{j=1}^{k} L_j$. By assumption, $\sup_{\lambda_i}\{\|v\|_1 : v \in \partial f_i(\lambda_i)\} \leq L$. Hence $\sup_{\lambda_i}\{\|v\|_1 : v \in \partial g_i(\lambda_i)\} \leq L + \sum_{i=1}^{m} L_g = L + mL_g$.

LEMMA 4.2. *The set of optimal solutions for* (1) *with* g *as the objective function is the same as the set of optimal solutions to* (7) *with* f *as the objective function.*

Proof. Without loss of generality assume that $B > 0$. Consider some optimal solution λ^* for (7) with f as the objective function. Suppose there exists some feasible solution $\hat{\lambda}$ to (1), with $\hat{\lambda}_{ij} < 0$ for some i, j. We show that $g(\hat{\lambda}) < g(\lambda^*)$. This implies that solving (7) with g as the objective function is equivalent to solving (1) with g as

the objective function. Since $g(\lambda) = f(\lambda)$ when $\lambda \geq 0$, solving (7) with g is equivalent to solving (7) with f. Thus the set of optimal solutions for (1) with g and for (7) with f are the same proving the lemma.

Consider the following problem,

$$\begin{aligned} \max_{\lambda_p \in \Re^m, p=1,\ldots,n} g(\lambda) &= \frac{1}{n} \sum_{p=1}^{n} g_p(\lambda_p) \\ \text{s.t.} \qquad & \sum_{p=1}^{n} \lambda_p = B, \\ & \lambda_p \geq -|\hat{\lambda}_p|, p = 1, \ldots, n. \end{aligned} \tag{26}$$

It can be seen that λ^* and $\hat{\lambda}$ are feasible solutions to (26). We now show that $\hat{\lambda}$ cannot be an optimal solution to (26). Since $B > 0$, there exists some k such that $\hat{\lambda}_{kj} > 0$. Define $\bar{\lambda}$ so that it differs from $\hat{\lambda}$ only in the ij and kj components as follows:

$$\bar{\lambda}_{ij} = \hat{\lambda}_{ij} + \delta,$$

$$\bar{\lambda}_{kj} = \hat{\lambda}_{kj} - \delta.$$

We choose a $\delta > 0$ such that $\bar{\lambda}_{kj} > 0$ and $\bar{\lambda}_{ij} < 0$. It is clear that $\bar{\lambda}$ is a feasible solution to (26). We now have

$$\begin{aligned} g_i(\bar{\lambda}_i) &= f_i(\bar{\lambda}_i) + \sum_{l=1}^{m} h_l(\bar{\lambda}_i) \\ &\geq g_i(\hat{\lambda}_i) + \delta \left(L_g + \left(\nabla f_i(\bar{\lambda}_i) \right)_j \right). \end{aligned}$$

The inequality comes from the concavity of g_i and from the definition of $\bar{\lambda}$. Similarly

$$\begin{aligned} g_k(\bar{\lambda}_k) &= f_k(\bar{\lambda}_k) + \sum_{l=1}^{m} h_l(\bar{\lambda}_k) \\ &\geq g_k(\hat{\lambda}_k) - \delta \left(\nabla f_k(\bar{\lambda}_k) \right)_j. \end{aligned}$$

Hence

$$g_i(\bar{\lambda}_i) + g_k(\bar{\lambda}_k) \geq g_i(\hat{\lambda}_i) + g_k(\hat{\lambda}_k) + \delta \left(L_g + \left(\nabla f_i(\bar{\lambda}_i) \right)_j - \left(\nabla f_k(\bar{\lambda}_k) \right)_j \right).$$

Since $L_g > 2L$, we can conclude from the above that $g(\bar{\lambda}) > g(\hat{\lambda})$, and hence $\hat{\lambda}$ cannot be an optimal solution to (26).

It can be seen from the definition of (26) that its feasible set is bounded. Since g is continuous and since the feasible set of (26) is bounded and closed, it has at least one optimal solution by the extreme value theorem. The above argument, presented to establish the nonoptimality of $\hat{\lambda}$ for (26), holds for any feasible solution for (26) with at least one nonnegative component. Hence all optimal solutions of (26) are nonnegative. Since $g(\lambda) = f(\lambda)$ when $\lambda \geq 0$, solving (26) with g is equivalent to solving (7) with f, and hence λ^* is an optimal solution for (26). Hence $g(\hat{\lambda}) < g(\bar{\lambda}) \leq g(\lambda^*)$. □

GLOBAL OPTIMIZATION OF POLYNOMIALS USING THE TRUNCATED TANGENCY VARIETY AND SUMS OF SQUARES*

HÀ HUY VUI† AND PHẠM TIẾN SƠN‡

Dedicated to Professor Hoàng Tụy on his eightieth birthday

Abstract. This paper proposes a method for finding the global infimum of a multivariate polynomial f via sum of squares (SOS) relaxation over its truncated tangency variety. This variety is truncated of the set of all points $x \in \mathbb{R}^n$ where the level sets of f are tangent to the sphere in $\mathbb{R}^n$ centered in the origin and with radius $\|x\|$. It is demonstrated that:

- The infimum of f on $\mathbb{R}^n$ and on its truncated tangency variety coincide.
- A sums of squares certificate for nonnegativity of f on its truncated tangency variety.

These facts imply that we can find a natural sequence of semidefinite programs whose optimal values converge monotonically, increasing to the infimum of f. This opens up the possibility of solving previously intractable polynomial optimization problems.

Key words. global optimization, polynomials, sum of squares (SOS), semidefinite program (SDP), tangency variety.

1. Introduction.

We consider the global optimization problem

$$f^* := \inf\{f(x) \mid x \in \mathbb{R}^n\} \in \mathbb{R} \cup \{-\infty\},$$

where $x := (x_1, x_2, \ldots, x_n) \in \mathbb{R}^n$ is a real vector, and f is a multivariate polynomial. As is well known, the above optimization problem is NP-hard even when the degree of f is fixed to be four [16]. Since f^* is the greatest lower bound of f, it is equivalent to compute

$$f^* = \sup\{a \in \mathbb{R} \mid f - a \geq 0 \text{ on } \mathbb{R}^n\} \in \mathbb{R} \cup \{-\infty\}.$$

A lower bound can be computed efficiently using the sum of squares (SOS) relaxation

$$f^{sos} := \sup\{a \in \mathbb{R} \mid f - a \gtrsim_{sos} 0\} \in \mathbb{R} \cup \{-\infty\},$$

where the inequality $g \gtrsim_{sos} 0$ means that the polynomial g is SOS, i.e., a sum of squares of other polynomials. We refer to [10], [11], [18] [19], [20], and [21] for introductions to SOS techniques and their applications. The above SOS relaxation can be expressed as a *semidefinite program* (SDP for short), i.e., as the problem of minimizing (or maximizing) an affine linear function over the intersection of the cone of all positive semidefinite matrices with an affine subspace. In recent years, SDPs (see [27] for an introduction) have become more and more popular for obtaining good lower bounds (or even an optima solution) for global optimization problems with polynomials. For instance, in papers [3], [12], [17], [20], and [25], the authors have proposed

several methods to find semidefinite relaxations relying on sums of squares certificates and critical point theory. As one could expect, polynomials that do not attain a minimum on $\mathbb{R}^n$ (that are either unbounded from below or have a finite infimum that is not attained) are particularly hard to handle. In [3], this problem (among others) was solved by perturbing the coefficients of the polynomial to guarantee a minimum (in particular, boundedness from below). Though the results in [3] are quite good, we are convinced that one should also look for other methods that avoid perturbations and the danger of numerical ill-conditioning that comes along with them.

By proving SOS representations for polynomials positive on their real gradient variety, it was shown by Nie, Demmel and Sturmfels [17] that an approach without perturbation is possible. Recall that, the *real gradient variety* of a polynomial f, denoted by $V(\nabla f)$, is defined to be the following algebraic set:

$$V(\nabla f) := \{x \in \mathbb{R}^n \mid \nabla f(x) = 0\};$$

the *gradient ideal* of f is the ideal in $\mathbb{R}[x]$ generated by all partial derivatives of f:

$$(\nabla f) := \left\langle \frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \ldots, \frac{\partial f}{\partial x_n} \right\rangle \subseteq \mathbb{R}[x].$$

Here and in the following, we write $\mathbb{R}[x] := \mathbb{R}[x_1, x_2, \ldots, x_n]$ for the ring of all polynomials in n variables x with real coefficients. It has been shown that if the polynomial $f \in \mathbb{R}[x]$ is nonnegative on $V(\nabla f)$, then f is a SOS modulo its gradient ideal in the case where the ideal is radical. In the general case where the gradient ideal is not necessarily radical, the same thing still holds for polynomials positive on their real gradient variety. The following is essentially [17, Theorems 8 and 9] (confer also with recent works [13] and [25]).

THEOREM 1.1 (Nie, Demmel, and Sturmfels [17]). *For every $f \in \mathbb{R}[x]$ attaining a minimum on $\mathbb{R}^n$, the following are equivalent.*

(i) $f \geq 0$ *on* $\mathbb{R}^n$;
(ii) $f \geq 0$ *on* $V(\nabla f)$;
(iii) *For all $\epsilon > 0$, there exists a SOS s in $\mathbb{R}[x]$ and polynomials $\phi_1, \phi_2, \ldots, \phi_n$ such that*

$$f(x) + \epsilon = s(x) + \phi_1(x)\frac{\partial f}{\partial x_1} + \phi_2(x)\frac{\partial f}{\partial x_2} + \cdots + \phi_n(x)\frac{\partial f}{\partial x_n}.$$

Moreover, (ii) *and* (iii) *are equivalent for all $f \in \mathbb{R}[x]$.*

For each degree restriction $k \in \mathbb{N}$, the problem of computing the supremum over all $a \in \mathbb{R}$ such that

$$f(x) - a = s(x) + \phi_1(x)\frac{\partial f}{\partial x_1} + \phi_2(x)\frac{\partial f}{\partial x_2} + \cdots + \phi_n(x)\frac{\partial f}{\partial x_n}$$

for some SOS s in $\mathbb{R}[x]$ and polynomials $\phi_1, \phi_2, \ldots, \phi_n$ of degree at most k can be expressed as an SDP. Theorem 1.1 shows that the optimal values of the corresponding sequence of SDPs (indexed by k) tend to f^* provided that f attains a minimum on $\mathbb{R}^n$. However, for polynomials that do not attain a minimum, their method yields wrong answers (see, for example, [25]). In [17, section 7], the authors write:

> "This paper proposes a method for minimizing a multivariate polynomial $f(x)$ over its gradient variety. We assume that the infimum f^* is attained. This assumption is nontrivial, and we do not address the (important and difficult) question of how to verify that a given polynomial $f(x)$ has this property."

Shortly thereafter, combining considerable machinery from differential geometry and real algebraic geometry, Schweighofer [25] has shown that part of this limitation can be removed. Let us outline Schweighofer's approach. First, we introduce some definitions.

DEFINITION 1.1. *For any polynomial $f \in \mathbb{R}[x]$ and subset $S \subset \mathbb{R}^n$, the set $R_\infty(f,S)$ of asymptotic values of f on S consists of all $y \in \mathbb{R}$ for which there exists a sequence $\{x^k\}_{k\in\mathbb{N}}$ of points $x^k \in S$ such that $\lim_{k\to\infty} \|x^k\| = +\infty$ and $\lim_{k\to\infty} f(x^k) = y$.*

DEFINITION 1.2. *The preordering generated by polynomials $g_1, g_2, \ldots, g_m \in \mathbb{R}[x]$, denoted by $T(g_1, g_2, \ldots, g_m)$, is defined to be the following set of polynomials:*

$$T(g_1, g_2, \ldots, g_m) := \left\{ \sum_{\delta\in\{0,1\}^m} s_\delta g_1^{\delta_1} g_2^{\delta_2} \ldots g_m^{\delta_m} \mid s_\delta \text{ is a sum of squares in } \mathbb{R}[x] \right\}.$$

By definition, the elements of $T(g_1, g_2, \ldots, g_m)$ have obviously the geometric property that they are nonnegative on the *basic closed semialgebraic set*

$$\{x \in \mathbb{R}^n \mid g_1(x) \geq 0, g_2(x) \geq 0, \ldots, g_m(x) \geq 0\}.$$

The next theorem is a partial converse.

THEOREM 1.2 (see [25, Theorem 9]). *Let $f, g_1, g_2, , \ldots, g_m \in \mathbb{R}[x]$ and set*

$$S := \{x \in \mathbb{R}^n \mid g_1(x) \geq 0, g_2(x) \geq 0, \ldots, g_m(x) \geq 0\}.$$

Suppose that

(i) *f is bounded on S;*
(ii) *$R_\infty(f,S)$ is a finite subset of $\mathbb{R}_{>0} := \{y \in \mathbb{R} \mid y > 0\}$; and*
(iii) *$f > 0$ on S.*

Then $f \in T(g_1, g_2, \ldots, g_m)$.

DEFINITION 1.3. *For a polynomial $f \in \mathbb{R}[x]$, we call*

$$S(\nabla f) := \{x \in \mathbb{R}^n \mid 1 - \|\nabla f(x)\|^2 \|x\|^2 \geq 0\}$$

the principal gradient tentacle of f. Here and in the following, we use the notation $\|x\| := \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}$.

Given a polynomial f for which you want to compute f^*, the game will consist in finding a tentacle such that two things will hold at the same time:

- There exist suitable sums of squares certificates for nonnegativity on the tentacle; and
- The infimum of f on $\mathbb{R}^n$ and on the tentacle coincide.

These two properties seem to be hardly compatible. However, there is a sufficient condition to ensure that it is indeed the case.

DEFINITION 1.4 (see [22]). *We say that a polynomial $f \in \mathbb{C}[x]$ has only isolated singularities at infinity if $f \in \mathbb{C}$ (i.e., f is constant) or $d := \deg f \geq 1$ and there are only finitely many $z \in \mathbb{P}^{n-1}(\mathbb{C})$ such that*

$$\frac{\partial f_d}{\partial x_1} = \frac{\partial f_d}{\partial x_2} = \cdots = \frac{\partial f_d}{\partial x_n} = f_{d-1} = 0,$$

where $f = \sum_{i=0}^d f_i$ and each $f_i \in \mathbb{C}[x]$ is zero or homogeneous of degree i.

The above notion appears in the study of the topology of polynomial mappings. One may consult, for example, [1], [7], or [26] for more details.

The following result is a sums of squares certificate for nonnegativity of f on its principal gradient tentacle, which is suitable for optimization purposes. Its proof is based on Theorem 1.2.

THEOREM 1.3 (see [25, Theorem 25]). *Let $f \in \mathbb{R}[x]$ be bounded from below. Furthermore, suppose that f has only isolated singularities at infinity (which is always true in the case $n = 2$) or the principal gradient tentacle $S(\nabla f)$ is compact. Then the following are equivalent.*

(i) $f \geq 0$ *on* $\mathbb{R}^n$;
(ii) $f \geq 0$ *on* $S(\nabla f)$;
(iii) *For every* $\epsilon > 0$, *there are sums of squares of polynomials* s *and* t *in* $\mathbb{R}[x]$ *such that*

$$f(x) + \epsilon = s(x) + t(x)[1 - \|\nabla f(x)\|^2 \|x\|^2].$$

For each $k \in \mathbb{N}$, we define $f_k^* \in \mathbb{R} \cup \{\pm\infty\}$ as the supremum over all $a \in \mathbb{R}$ such that $f - a$ can be written as a sum

$$f(x) - a = s(x) + t(x)[1 - \|\nabla f(x)\|^2 \|x\|^2],$$

where s and t are sums of squares of polynomials with $\deg t \leq 2k$. Here and in the following, we use the convention that the degree of the zero polynomial is $-\infty$ so that $t = 0$ is allowed in the above definition. Then it is easy to see that Theorem 1.3 can be expressed in terms of the sequence $f_0^*, f_1^*, f_2^*, \ldots$ as follows.

THEOREM 1.4 (see [25, Theorem 30]). *Let $f \in \mathbb{R}[x]$ be bounded from below. Suppose that f has only isolated singularities at infinity (e.g., $n = 2$) or the principle gradient tentacle $S(\nabla f)$ is compact. Then the sequence $\{f_k^*\}_{k\in\mathbb{N}}$ converges monotonically increasing to f^*.*

As is well known, the problem of computing the supremum f_k^* can be translated into an SDP as described in [19], [20], and [21]. Theorem 1.4 shows that the optimal values of the corresponding sequence of SDPs (indexed by k) tend to f^* provided that f has only isolated singularities at infinity or the principal gradient tentacle $S(\nabla f)$ is compact. Unfortunately, it is not clear that these technical assumptions are necessary or not. So, Schweighofer presented in [25] a collection of higher gradient tentacles (see [25, Definition 41]) defined by the polynomial inequalities

$$1 - \|\nabla f(x)\|^{2N}(1 + \|x\|^2)^{N+1} \geq 0, \quad N \in \mathbb{N}.$$

Their advantage is that we have a sums of squares representation theorem ([25, Theorem 46]) applicable for *all* $f \in \mathbb{R}[x]$ bounded from below and N is large enough. However, the degree of the defining polynomial inequality for the Nth tentacle in this sequence will be roughly $2N$ times the degree of f. This has the disadvantage that the corresponding SDP relaxations get very big for large N. Also, we have to deal for each N with a sequence of SDPs. All in all, we have, therefore, a double sequence of SDPs. The following was formulated by Schweighofer as an open problem [25, Open Problem 33]:

Problem. *Do Theorems* 1.3 *and* 1.4 *hold without the hypothesis that f has only isolated singularities at infinity or the principal gradient tentacle $S(\nabla f)$ is compact?*

The aim of this paper is to find a solution valid to this problem in the general case, that is, when

- polynomials do not necessarily attain a minimum; and
- polynomials do not necessarily have isolated singularities at infinity.

Although we do not provide a direct answer to the problem, we will replace gradient tentacles by a semialgebraic subset of $\mathbb{R}^n$ for which a new sums of squares representation result of nonnegative polynomials is established. This semialgebraic subset will be called the *truncated tangency variety.* We show that the infimum of any polynomial $f \in \mathbb{R}[x]$ on $\mathbb{R}^n$ will coincide with the infimum on its truncated tangency variety (see Theorem 2.1 and Corollary 3.1). Then, we prove a general sums of squares certificate for nonnegativity of f on its truncated tangency variety which is suitable for optimization purposes. This representation theorem (Theorem 3.1) is of independent interest, and its proof is mainly based on Theorem 1.2.

The paper is organized as follows. The notion about the tangency variety, which plays an important role in the results, is recalled in section 2. The main result and its proof are given in section 3. In section 4 we discuss numerical experiments. Section 5 draws some conclusions.

2. The tangency variety. Throughout this paper let $f \in \mathbb{R}[x]$ be a nonconstant polynomial function. Adapting Durfee's definition [2] (see also [8]), let us define the tangency variety of f by

$$\Gamma(f) := \left\{ x \in \mathbb{R}^n \mid \operatorname{rank} \begin{pmatrix} \frac{\partial f}{\partial x_1} & \frac{\partial f}{\partial x_2} & \cdots & \frac{\partial f}{\partial x_n} \\ x_1 & x_2 & \cdots & x_n \end{pmatrix} \leq 1 \right\}.$$

Geometrically, the tangency variety $\Gamma(f)$ of f consists of all points $x \in \mathbb{R}^n$ where the level sets of f are tangent to the sphere in $\mathbb{R}^n$ centered in the origin and with radius $\|x\|$.

Remark 2.1. It is worth noting that we can replace the tangency variety $\Gamma(f)$ by the following algebraic set

$$\Gamma(a, f) := \left\{ x \in \mathbb{R}^n \mid \operatorname{rank} \begin{pmatrix} \frac{\partial f}{\partial x_1} & \frac{\partial f}{\partial x_2} & \cdots & \frac{\partial f}{\partial x_n} \\ x_1 - a_1 & x_2 - a_2 & \cdots & x_n - a_n \end{pmatrix} \leq 1 \right\},$$

where $a := (a_1, a_2, \ldots, a_n) \in \mathbb{R}^n$. Then all subsequent results will still hold with obvious modifications. The advantage is that if the center a is general enough, then the semialgebraic set $\Gamma(a, f) \setminus V(\nabla f)$ is a one-dimensional submanifold of $\mathbb{R}^n$. For details the reader may consult [8].

As expressed by the notation $\Gamma(f)$, polynomials f with the same gradient ∇f have the same tangency variety; in other words,

$$\Gamma(f + c) = \Gamma(f) \quad \text{for all} \quad c \in \mathbb{R}.$$

The following is a simple fact about the tangency variety $\Gamma(f)$.

LEMMA 2.1. *The tangency variety* $\Gamma(f)$ *is a nonempty, unbounded, and algebraic set.*

Proof. Obviously, $\Gamma(f)$ is an algebraic set. Let

$$A := \{x \in \mathbb{R}^n \mid f(x) = \min\{f(y) \mid \|y\| = \|x\|,\ y \in \mathbb{R}^n\}\}.$$

Then, the set A is nonempty and unbounded in $\mathbb{R}^n$. Moreover, it follows from Lagrange's multipliers theorem that $A \subset \Gamma(f)$. These facts prove the lemma. ∎

Another property of the tangency variety $\Gamma(f)$ is stated in the following result.

THEOREM 2.1. *We have*

$$\inf\{f(x) \mid x \in \mathbb{R}^n\} = \inf\{f(x) \mid x \in \Gamma(f)\}.$$

Proof. The statement follows immediately from the fact that the set

$$A = \{x \in \mathbb{R}^n \mid f(x) = \min\{f(y) \mid \|y\| = \|x\|,\ y \in \mathbb{R}^n\}\}.$$

is contained in $\Gamma(f)$. □

COROLLARY 2.1. *Let $f \in \mathbb{R}[x]$ be bounded from below. Then f^* is either a critical value of f or f^* is an asymptotic value of f on $\Gamma(f)$.*

Proof. It is an immediate consequence of Theorem 2.1. □

LEMMA 2.2. *$R_\infty(f, \Gamma(f))$ is a finite set.*

Proof. This proof is adapted from [5] (see also [6]). Let us define the *set of asymptotic critical values* of f by

$$K_\infty(f) := \{y \in \mathbb{R} | \text{there exists a sequence } \{x^k\}_{k\in\mathbb{N}} \subset \mathbb{R}^n \text{ such that } \lim_{k\to\infty} \|x^k\| = +\infty,\ \lim_{k\to\infty} f(x^k) = y, \text{ and } \lim_{k\to\infty} \|x^k\|\|\nabla f(x^k)\| = 0\}.$$

As is well known, the set $K_\infty(f)$ is always finite [9]. Hence, it suffices to show that $R_\infty(f, \Gamma(f)) \subset K_\infty(f)$. Assume that $y \in R_\infty(f, \Gamma(f))$; i.e., there exists a sequence $\{x^k\}_{k\in\mathbb{N}}$ of points $x^k \in \Gamma(f)$ such that $\lim_{k\to\infty} \|x^k\| = +\infty$ and $\lim_{k\to\infty} f(x^k) = y$. Then we can write $\nabla f(x^k) = \lambda_k x^k$ for some $\lambda_k \in \mathbb{R}$. By using a version at infinity of the Curve Selection Lemma (see [14], [15]), there exist a meromorphic curve $\varphi(\tau)$ and an analytic function $\lambda(\tau), \tau \in (0, \epsilon)$, such that

(a) $\nabla f[\varphi(\tau)] = \lambda(\tau)\varphi(\tau)$ for $\tau \in (0, \epsilon)$;
(b) $\lim_{\tau\to+0} \|\varphi(\tau)\| = +\infty$; and
(c) $\lim_{\tau\to+0} f[\varphi(\tau)] = y$.

We can write

$$f[\varphi(\tau)] - y = c_1\tau^\nu + \text{ higher order terms in } \tau,$$
$$\|\varphi(\tau)\| = c_2\tau^\rho + \text{ higher order terms in } \tau,$$

where c_1, c_2 are nonzero real numbers and

$$\nu > 0, \qquad \rho < 0.$$

We have

$$\frac{df[\varphi(\tau)]}{d\tau} = \left\langle \nabla f[\varphi(\tau)], \frac{d\varphi(\tau)}{d\tau} \right\rangle = \lambda(\tau) \left\langle \varphi(\tau), \frac{d\varphi(\tau)}{d\tau} \right\rangle.$$

(The second equality follows from Condition (a).) Hence,

$$2\frac{df[\varphi(\tau)]}{d\tau} = \lambda(\tau)\frac{d\|\varphi(\tau)\|^2}{d\tau}.$$

This, together with Condition (a), implies that

$$2\left|\frac{df[\varphi(\tau)]}{d\tau}\right| = \frac{\|\nabla f[\varphi(\tau)]\|}{\|\varphi(\tau)\|}\frac{d\|\varphi(\tau)\|^2}{d\tau}.$$

Then it is easy to see that

$$\|\nabla f[\varphi(\tau)]\|\|\varphi(\tau)\| = c\tau^\nu + \text{ higher order terms in } \tau$$

for some constant $c \neq 0$, which shows that $y \in K_\infty(f)$. The lemma is proved. □

3. Main results. Let $f \in \mathbb{R}[x]$ be a nonconstant polynomial function, and consider the following polynomials

$$g_{ij}(x) := x_j \frac{\partial f}{\partial x_i}(x) - x_i \frac{\partial f}{\partial x_j}(x), \quad 1 \le i < j \le n.$$

In what follows, we shall fix a real number $M \in f(\mathbb{R}^n)$ (for instance, we can set $M := f(0)$). Then by the truncated tangency variety of f we mean the set

$$\Gamma_M(f) := \{x \in \mathbb{R}^n \mid M - f(x) \ge 0,\ g_{ij}(x) = 0,\ 1 \le i < j \le n\}.$$

We begin with the following result of its own interest.

COROLLARY 3.1. *We have*

$$\inf\{f(x) \mid x \in \mathbb{R}^n\} = \inf\{f(x) \mid x \in \Gamma_M(f)\}.$$

Proof. Indeed, if $M = \inf_{x \in \mathbb{R}^n} f(x)$, then the truncated tangency variety $\Gamma_M(f)$ contains a global minimizer of f and there is nothing to prove. Otherwise, the result follows immediately from Theorem 2.1. ∎

LEMMA 3.1. *Let f be a polynomial in n real variables. If*

$$\inf\{f(x) \mid x \in \Gamma_M(f)\} > 0,$$

then f can be written as a sum

$$f(x) = s(x) + t(x)[M - f(x)] + \sum_{1 \le i < j \le n} \phi_{ij}(x) g_{ij}(x),$$

where $s, t, \phi_{ij} \in \mathbb{R}[x], 1 \le i < j \le n$, and s, t are sums of squares in $\mathbb{R}[x]$.

Proof. It is clear from the assumption that f is bounded and strictly positive on the truncated tangency variety $\Gamma_M(f)$. Moreover, the following inclusion holds:

$$R_\infty(f, \Gamma_M(f)) \subset R_\infty(f, \Gamma(f)).$$

This, together with Lemma 2.2, implies that $R_\infty(f, \Gamma_M(f))$ is a finite set of $\mathbb{R}_{>0}$.

On the other hand, we can write

$$\Gamma_M(f) = \{x \in \mathbb{R}^n \mid M - f(x) \ge 0,\ g_{ij}(x) \ge 0,\ -g_{ij}(x) \ge 0,\ 1 \le i < j \le n\}.$$

Therefore $f \in T(M - f, g_{ij}, -g_{ij})$ by Theorem 1.2, which completes the proof. ∎

Here comes one of the main results of this article, which is interesting on its own, but can later be read as a convergence result for a sequence of optimal values of SDPs (Theorem 3.2 below).

THEOREM 3.1. *Let f be a polynomial in n real variables. Then the following conditions are equivalent:*

(i) *$f \ge 0$ on $\mathbb{R}^n$;*
(ii) *$f \ge 0$ on $\Gamma_M(f)$;*
(iii) *For every $\epsilon > 0$, there are sums of squares of polynomials s and t in $\mathbb{R}[x]$ and polynomials $\phi_{ij}, 1 \le i < j \le n$, such that*

$$f(x) + \epsilon = s(x) + t(x)[M - f(x)] + \sum_{1 \le i < j \le n} \phi_{ij}(x) g_{ij}(x).$$

Proof. The implications (i) $\Leftrightarrow$ (ii) and (iii) $\Rightarrow$ (ii) are straightforward. For the implication (ii) $\Rightarrow$ (iii), we only have to apply Lemma 3.1 to $f+\epsilon$ instead of f. □

DEFINITION 3.1. *For all polynomials $f \in \mathbb{R}[x]$ and all $k \in \mathbb{N}$, we define $f_k^* \in \mathbb{R} \cup \{\pm\infty\}$ as the supremum over all $a \in \mathbb{R}$ such that $f-a$ can be written as a sum*

$$f(x) - a = s(x) + t(x)[M - f(x)] + \sum_{1 \le i < j \le n} \phi_{ij}(x) g_{ij}(x),$$

where s, t, ϕ_{ij} are polynomials of degree at most $2k$ and s, t are sums of squares in $\mathbb{R}[x]$.

As is well known, the problem of computing the supremum f_k^* can be reduced to an SDP. Moreover, by Theorem 3.1, the number f_k^* is a lower bound for the infimum f^* of the polynomial f, and this lower bound gets better as k increases

$$\cdots \le f_{k-1}^* \le f_k^* \le f_{k+1}^* \le \cdots \le f^*.$$

We have the following general result concerning the convergence of the lower bounds.

THEOREM 3.2. *Let f be a polynomial in n real variables. Then the sequence $\{f_k^*\}_{k\in\mathbb{N}}$ converges monotonically increasing to the infimum f^*.*

Proof. In fact, if $f^* = -\infty$, then it is easily seen from Theorem 3.1 that for every positive integer k, $f_k^* = -\infty$ and there is nothing to prove. Thus, we may as well assume that $f^* > -\infty$. Let ϵ be any positive constant. The polynomial $f - f^* + \epsilon$ is strictly positive on its truncated tangency variety $\Gamma_M(f - f^* + \epsilon) = \Gamma_M(f)$. By Theorem 3.1, there are sums of squares of polynomials s and t in $\mathbb{R}[x]$ and polynomials $\phi_{ij}, 1 \le i < j \le n$, such that

$$f(x) - f^* + \epsilon = s(x) + t(x)[M - f(x)] + \sum_{1 \le i < j \le n} \phi_{ij}(x) g_{ij}(x).$$

Hence, there exists an integer $k(\epsilon)$ such that

$$f_k^* \ge f^* - \epsilon \quad \text{for all } k \ge k(\epsilon).$$

Since the sequence $\{f_k^*\}_{k\in\mathbb{N}}$ is monotonically increasing, it follows that $\lim_{k\to\infty} f_k^* = f^*$, which completes the proof of Theorem 3.2. □

4. Numerical results. In this section we set $M = f(0)$, and the examples have been computed using the software MATLAB 7 and SOSTOOLS [23]. Most of the computations took a few seconds.

Example 4.1. Let us consider the following polynomial

$$f(x,y) := 2y^4(y+x)^4 + y^2(y+x)^2 + 2y(y+x) + y^2.$$

We have $f^* = -\frac{5}{8} = -0.6250$ and the polynomial f does not attain its infimum value. The computed optimal values of the truncated tangency relaxations are $f_0^* = -0.614$, $f_1^* = -0.59314$, $f_2^* = -0.57259$, and $f_3^* = -0.54373$. By Theorem 3.2, the sequence $f_0^*, f_1^*, f_2^*, \ldots$, converges monotonically to f^*. However, the computed values are larger than f^* so that there are obviously numerical problems. Confer [4] and [5, Example 2.1].

Example 4.2. Let us consider the following polynomial of two real variables:

$$f(x,y) := (xy-1)^2 + (x-1)^2.$$

It is easy to see that $f^* = f(1,1) = 0$. The computed optimal values of the truncated tangency relaxations are $f_0^* = 0.87482 \cdot 10^{-9}$, $f_1^* = 0.67891 \cdot 10^{-8}$, and $f_2^* = 0.87081 \cdot 10^{-8}$. Confer [6, Example 4.2].

Example 4.3. Let us consider the Motzkin polynomial

$$f(x,y) := x^2y^4 + x^4y^2 - 3x^2y^2 + 1,$$

which is nonnegative but *not* a sum of squares: $f^* = 0$ and $f^{sos} = -\infty$. The computed optimal values of the truncated tangency relaxations are $f_0^* = -30394$, $f_1^* = -0.67174$, $f_2^* = -0.15122$, and $f_3^* = 0.62693 \cdot 10^{-8}$. Confer [20, Example 2] and [25, Example 35].

Example 4.4. Let us consider the Berg polynomial $f := x^2y^2(x^2+y^2-1) \in \mathbb{R}[x,y]$. This polynomial is taken from [10]. It has global infimum value $f^* = -1/27 = -0.037037037\ldots$. However $f^{sos} = -33.157325$ is considerably smaller than f^*. If we minimize f over its truncated tangency variety with $k = 3$, then we get $f_3^* = -0.037037$. Confer [3, Example 4], [10, Example 3], [17, Example 3], and [25, Example 37].

Example 4.5. Let $f := (x^2+1)^2 + (y^2+1)^2 - 2(x+y+1)^2 \in \mathbb{R}[x,y]$. By computation, we obtain for all values f_0^*, f_1^*, f_2^* approximately -11.458. Confer [3, Example 3], [10, Example 2], and [25, Example 38].

Example 4.6. Consider the polynomial $f := (x+x^2y+x^4yz)^2 \in \mathbb{R}[x,y,z]$. It was shown by Schweighofer [25, Example 34] that the set $R_\infty(f, S(\nabla f))$ of asymptotic values of f on $S(\nabla f)$ is infinite. This fact implies that f has nonisolated singularities at infinity, and hence, it does not satisfy the assumptions of Theorem 1.3. On the other hand, it is clear that $f^* = 0$. By computation, we get $f_0^* = -0.49293 \cdot 10^{-9}$, $f_1^* = -0.17651 \cdot 10^{-6}$, and $f_2^* = -0.28173 \cdot 10^{-8}$.

Example 4.7. The Motzkin polynomial

$$f := x^2y^2(x^2+y^2-3z^2) + z^6 \in \mathbb{R}[x,y,z]$$

is nonnegative but *not* a sum of squares (see [24], [20]). We have $f^* = 0$ but $f^{sos} = -\infty$. The latter follows from the fact that f is homogeneous and not a sum of squares. By computation, we obtain for all values $f_0^* = -0.30767$, $f_1^* = -0.41528 \cdot 10^{-2}$, $f_2^* = -0.33994 \cdot 10^{-3}$, and $f_3^* = -0.15803 \cdot 10^{-3}$. Confer [17, Example 1] and [25].

Example 4.8. Consider once more the polynomial $f = (1-xy)^2 + y^2$. It does not attain its infimum $f^* = 0$ on $\mathbb{R}^2$ (see also [5], [6], and [25]). Since this polynomial is by definition a sum of squares, we have $f^{sos} = 0 = f^*$ and therefore $f_k^* = 0$ for all $k \in \mathbb{N}$ by definition. By computation, we get $f^{sos} \simeq 1.5142 \cdot 10^{-12}$, which is almost zero, but also $f_0^* = -0.12641 \cdot 10^{-3}$, $f_1^* = 0.12732 \cdot 10^{-1}$, and $f_2^* = 0.49626 \cdot 10^{-1}$, which shows that there are big numerical problems. In [25, Example 40], the author wrote:

> "We have verified that the corresponding SDPs have nevertheless been solved quite accurately. The problem is that small numerical errors in the coefficients of a polynomial can perturb its infimum quite a lot whenever the infimum is not attained (or attained very far from the origin). It should be subject to further research how to fight this problem."

Remark 4.1. One question still unanswered is whether the truncation is necessary. Numerical experiments seem to indicate that the truncation is not needed.

5. Conclusions. This paper proposes a method for computing numerically the infimum of a multivariate polynomial f over its truncated tangency variety. We have shown

- The infimum of f on $\mathbb{R}^n$ and on its truncated tangency variety coincide.
- A sums of squares certificate for nonnegativity of f on its truncated tangency variety.

These facts imply that we can find a natural sequence of SDPs whose optimal values f_k^* converge monotonically increasing to f^*.

Our method has two major problems (see also [25]). First, it turns out that solving semidefinite programs that arise from a polynomial that does not attain a minimum takes sometimes a surprisingly long time. Second, small numerical inaccuracies might lead to big changes in the infimum of a polynomial if the infimum is not attained. All two problems should be subject to further research. Polynomials not attaining a minimum remain hard to handle in practice. On the theoretical side, we have obtained new interesting characterizations of nonnegative polynomials.

Acknowledgments. Both authors wish to thank J. B. Lasserre and M. Schweighofer for many interesting and helpful discussions on the topic. We also thank the referees for their helpful comments.

ON STABILITY OF MULTISTAGE STOCHASTIC PROGRAMS*

CHRISTIAN KÜCHLER†

Abstract. We study the quantitative stability of linear multistage stochastic programs under perturbations of the underlying stochastic processes. It is shown that the optimal values behave Lipschitz continuously with respect to an L^p-distance. In order to establish continuity of the recourse function with respect to the current state of the stochastic process, we assume continuity of the conditional distributions in terms of a Fortet–Mourier metric. The main stability result holds for nonanticipative approximations of the underlying process and thus represents a rigorous justification of established discretization techniques.

Key words. stochastic programming, multistage, stability, probability metrics

Introduction. Many stochastic optimization problems of practical interest do not allow for an analytic solution, and numerical approaches require the underlying probability measure to have finite support. Whenever the initial probability measure does not meet these demands, it has to be approximated by an auxiliary measure. Thereby, it is reasonable to choose the approximating measure such that the optimal value and the set of optimal decisions of the auxiliary problem are close to those of the originial problem. Consequently, perturbation and stability analysis of stochastic programs is necessary for the development of reliable techniques for discretization and scenario reduction. While stability properties are well understood for nondynamic chance constrained and two-stage problems, cf. the recent survey by [18], it turned out that the multistage case is more intricate. Recently, the latter situation has been studied by a variety of authors, and thus the following references should not be considered to be exhaustive. Statistical bounds have been provided by [20]. Reference [13] established asymptotic stability of specific approximations for a general class of convex multistage problems in terms of epi-convergence. In doing so, he noticed that such quantitative results, as we discuss in this paper, require stronger assumptions. Indeed, the restriction on models with continuous decisions allowed [12] to establish such a quantitative stability result for their tree approximations. Reference [8] did not require regularity conditions on decisions and underlying processes. Consequently, their quantitative stability result, obtained by considering arbitrary perturbations of the underlying process, incorporates a term measuring the distance of the filtrations induced by the initial and the auxiliary process, respectively. Vanishing in the two-stage case, this filtration distance reflects the relevance of the information structure and of the nonanticipativity constraints for multistage decision problems. We refer also to [2] who studied the role of information in stochastic optimization problems and introduced and reviewed several concepts of distances between filtrations.

The recent approach of [7] aims to incorporate filtration distances into the construction of scenario trees. However, this requires some extra effort and, to the best

of our understanding, these distances are not taken into account by a variety of established techniques. Thus, the main purpose of this paper is to provide general conditions under which these somewhat delicate terms may be omitted.

One of the main difficulties seems to be that without additional assumptions neither the recourse function nor an optimal decision depend continuously on the current state of the underlying process in general. Reference [16] showed that under weak conditions, the optimal value can be approximated by *continuous decisions*. However, while this allows one to deduce convergence results, such as those due to [13], it does not lead to quantitative estimates. For deriving *continuity of the recourse function* and bounds based on a barycentric approximation scheme, [11] required the underlying processes to be autoregressive. He also indicated that *the key element in any scenario tree construction is the discretization of the conditional probabilities*. In particular, continuous dependency of these probabilities on the current state of the underlying process is necessary for potential continuity of the recourse function and can be seen as *continuity of the available information with respect to the current state*. It is illustrated by Example 2.6 of [8] that the latter property is indispensable in order to omit any filtration distances and to obtain a good approximation of the initial process by usual techniques which are based on stagewise clustering. Thus, we impose Lipschitz continuity of the conditional distributions to verify the same regularity for the recourse function in Theorem 1. With this at hand, we estimate in Theorem 2 the gap between the optimal value and the costs of a decision that is locally *calm*. This leads to our main result, Theorem 3, which provides an upper bound for the perturbation of the optimal value.

Notation and conventions. Random variables are denoted by bold letters, for example $\boldsymbol{\xi}$ or $\boldsymbol{x}$, in contrast to their realizations (i.e., elements of their support) which are denoted by ξ or x, respectively. Given some vectors $\xi_1, \dots, \xi_t$ in $\mathbb{R}^s$ with $s, t \in \mathbb{N}$, the notation ξ^t is used for the vector $(\xi_1, \dots, \xi_t)$. Furthermore, $\|\cdot\|$ denotes the maximum norm on $\mathbb{R}^n$ for the respective value $n \in \mathbb{N}$, and we set $\|\xi^t\| \triangleq \max_{i \le t} \|\xi_i\|$.

1. Problem formulation. On a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ we consider an $\mathbb{R}^s$-valued stochastic process $\boldsymbol{\xi} = (\boldsymbol{\xi}_t)_{t=1}^T$ with time horizon $T \in \mathbb{N}$ and the associated filtration $(\mathcal{F}_t)_{t=1}^T$ defined through $\mathcal{F}_t \triangleq \sigma(\boldsymbol{\xi}^t)$ for $t = 1, \dots, T$. We assume that $\mathcal{F}_1 = \{\Omega, \emptyset\}$, $\boldsymbol{\xi} \in L^p(\Omega, \mathcal{F}, \mathbb{P})$ for every $p \in [1, +\infty)$, and set for $t = 1, \dots, T$,

$$\mathbb{P}_t \triangleq \mathbb{P}\left[\boldsymbol{\xi}_t \in \cdot\,\right], \mathbb{P}^t \triangleq \mathbb{P}\left[\boldsymbol{\xi}^t \in \cdot\,\right] \quad \text{and} \quad \Xi_t \triangleq \operatorname{supp} \mathbb{P}_t \subset \mathbb{R}^s, \Xi^t \triangleq \operatorname{supp} \mathbb{P}^t \subset \mathbb{R}^{s \cdot t}.$$

Furthermore, we consider the *costs* $b_t(\cdot)$, the *technology matrices* $A_{t,1}(\cdot)$, and the *right-hand sides* $h_t(\cdot)$, which all are assumed to depend affinely on $\xi_t \in \Xi_t$ and map into $\mathbb{R}^m$, $\mathbb{R}^{n \cdot m}$, and $\mathbb{R}^n$, respectively, for some $m, n \in \mathbb{N}$ and $t = 1, \dots, T$. Together with the nonrandom *recourse matrices* $A_{t,0} \in \mathbb{R}^{m \cdot n}$ they define the set-valued mappings

$$\begin{aligned} &M_t : X_{t-1} \times \Xi_t \rightrightarrows X_t, \\ &\quad M_t(x_{t-1}, \xi_t) \triangleq \{x_t \in X_t \ : \ A_{t,0} x_t + A_{t,1}(\xi_t) x_{t-1} = h_t(\xi_t)\}, \end{aligned}$$

where $X_t \subset \mathbb{R}^m$ are certain nonempty, closed, and polyhedral sets, with $t = 1, \dots, T$. We assume complete recourse; i.e., $M_t(x_{t-1}, \xi_t)$ is nonempty for every $x_{t-1} \in X_{t-1}$ and every $\xi_t \in \Xi_t$. The objective function is given by

$$\begin{aligned} \varphi &: \mathbb{R}^{m \cdot T} \times \Xi^T \to \mathbb{R}, \\ \varphi\left(x_1, \dots, x_T, \xi^T\right) &\triangleq \sum_{t=1}^T \langle b_t(\xi_t), x_t \rangle . \end{aligned}$$

A tuple $\boldsymbol{x} = (\boldsymbol{x}_1, \dots, \boldsymbol{x}_T)$ of Borel-measurable mappings $\boldsymbol{x}_t : \Xi^t \to X_t$, $t = 1, \dots, T$, is called a *feasible decision* with respect to $\boldsymbol{\xi}$, if the recourse condition

$$\boldsymbol{x}_t\left(\boldsymbol{\xi}^t\right) \in M_t\left(\boldsymbol{x}_{t-1}\left(\boldsymbol{\xi}^{t-1}\right), \boldsymbol{\xi}_t\right) \tag{1}$$

is fulfilled $\mathbb{P}-$a.s. for $t = 1, \dots, T$. The class of feasible decisions $\boldsymbol{x}$ will be denoted by $\mathcal{S}(\boldsymbol{\xi})$ and, for the sake of notational convenience, we set $x_0 = 1$.

We study the following multistage stochastic optimization problem:

$$v(\boldsymbol{\xi}) \triangleq \inf_{\boldsymbol{x} \in \mathcal{S}(\boldsymbol{\xi})} \mathbb{E}\left[\varphi(\boldsymbol{x}(\boldsymbol{\xi}), \boldsymbol{\xi})\right], \tag{2}$$

and aim to establish an upper bound for the perturbation of $v(\boldsymbol{\xi})$ when $\boldsymbol{\xi}$ is replaced by another process $\tilde{\boldsymbol{\xi}}$.

Complete recourse and the polyhedral form of M_t allow one to conclude (see Example 9.35 of [17]) that M_t is Lipschitz continuous on $X_{t-1} \times \Xi_t$ with respect to the Pompeiu–Hausdorff distance $\mathbb{d}$ in the following sense. There exists a constant $M \geq 0$ with

$$\begin{aligned} \mathbb{d}\left(M_t(x_{t-1}, \xi_t), M_t\left(\hat{x}_{t-1}, \xi_t\right)\right) &\leq M \cdot \max\{1, \|\xi_t\|\} \cdot \|\hat{x}_{t-1} - x_{t-1}\| \quad \text{and} \\ \mathbb{d}\left(M_t(x_{t-1}, \xi_t), M_t\left(x_{t-1}, \hat{\xi}_t\right)\right) &\leq M \cdot \max\{1, \|x_{t-1}\|\} \cdot \left\|\hat{\xi}_t - \xi_t\right\|, \end{aligned}$$

for every $(x_{t-1}, \xi_t), (\hat{x}_{t-1}, \hat{\xi}_t) \in X_{t-1} \times \Xi_t$. We recall that the Pompeiu–Hausdorff distance between two sets $A, B \subset \mathbb{R}^m$ is defined by

$$\mathbb{d}(A, B) \triangleq \max\left\{\sup_{a \in A} \operatorname{dist}(a, B), \sup_{b \in B} \operatorname{dist}(b, A)\right\}.$$

Remark 1.1. Throughout this paper, the linearity of M_t is used only to obtain the claimed Lipschitz continuity. Analogously, we assume linear costs $\langle b_t(\xi_t), x_t\rangle$ only to ensure the existence of a constant $B \geq 0$ with

$$\begin{aligned} \|\langle b_t(\xi_t), x_t\rangle - \left\langle b_t\left(\hat{\xi}_t\right), x_t\right\rangle\| &\leq B\left\|\xi_t - \hat{\xi}_t\right\|\|x_t\| \quad \text{and} \\ \|\langle b_t(\xi_t), x_t\rangle - \langle b_t(\xi_t), \hat{x}_t\rangle\| &\leq B \max\{1, \|\xi_t\|\}\|x_t - \hat{x}_t\|. \end{aligned}$$

The integrability condition on $\boldsymbol{\xi}$ is assumed for notational simplicity. Actually, it suffices to have $\boldsymbol{\xi} \in L^p(\Omega, \mathcal{F}, \mathbb{P})$ for a sufficiently large $p \in \mathbb{R}_+$.

Furthermore, all results remain valid if M_t, h_t, and b_t depend on $\boldsymbol{\xi}^t$ instead of $\boldsymbol{\xi}_t$.

2. Continuity of the recourse function. Let $V_t : \Xi^t \times X_{t-1} \to \mathbb{R}$ be the recourse function at time t, which is defined recursively by $V_{T+1} \triangleq 0$ and the dynamic programming equation

$$V_t\left(\xi^t, x_{t-1}\right) \triangleq \inf_{x_t \in M_t(x_{t-1}, \xi_t)} \langle b_t(\xi_t), x_t\rangle + \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, x_t\right) \middle| \boldsymbol{\xi}^t = \xi^t\right] \quad \text{for } t = T, \dots, 1,$$

where the mapping $(x_t, \xi^t) \mapsto \mathbb{E}[V_{t+1}(\boldsymbol{\xi}^{t+1}, x_t)|\boldsymbol{\xi}^t = \xi^t]$ denotes the *regular conditional expectation* of $V_{t+1}(\cdot, \cdot)$ relative to $\mathcal{F}_t$. The value $V_t(\xi^t, x_{t-1})$ represents the minimal achievable expected future costs after having chosen $\boldsymbol{x}_{t-1} = x_{t-1}$, having observed $\{\boldsymbol{\xi}^t = \xi^t\}$, and before deciding on x_t. In particular, we have the identity $v(\boldsymbol{\xi}) = V_1(\boldsymbol{\xi}_1, x_0)$, and complete recourse implies that $V_t < +\infty$ holds true on $\Xi^t \times X_{t-1}$. It was proved by [6] that V_t is well-defined and measurable under the following assumption.

Assumption 2.1.

(i) There exists an integrable random variable $\boldsymbol{\eta}$ such that $\varphi(x, \boldsymbol{\xi}) \geq \boldsymbol{\eta}$ holds $\mathbb{P}-$a.s. for every $x \in \mathbb{R}^{m \cdot T}$.

(ii) For each $c \in \mathbb{R}$ the random level set $\{x \in \mathbb{R}^{m \cdot T} : \ \varphi(x, \boldsymbol{\xi}) \leq c\}$ is compact $\mathbb{P}-$a.s.

A decision $\boldsymbol{x} \in \mathcal{S}(\boldsymbol{\xi})$ is optimal if and only if the equality

$$V_t(\xi^t, \boldsymbol{x}_{t-1}(\xi^{t-1})) = \big\langle b_t(\xi_t), \boldsymbol{x}_t(\xi^t) \big\rangle + \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t(\xi^t)\right) \big| \, \boldsymbol{\xi}^t = \xi^t \right] \tag{3}$$

holds for $\mathbb{P}^t-$almost every $\xi^t \in \Xi^t$ and $t = 1, \ldots, T$. Moreover, for every Borel measurable mapping $\boldsymbol{x}_{t-1} : \Xi^{t-1} \to X_{t-1}$, there exists a measurable $\boldsymbol{x}_t : \Xi^t \to X_t$ such that relation (3) holds true for $\mathbb{P}^t-$almost every $\xi^t \in \Xi^t$. Actually, [6] allows one to show that the $\mathbb{P}^t$-null sets on which the latter property does not hold coincide for all measurable $\boldsymbol{x}_{t-1}$. Indeed, the following corollary is an immediate consequence of applying Lemma 4 of [6] within the proof of his Theorem 2.

COROLLARY 2.2. *For $t = 1, \ldots, T$, there is a Borel set $A^{t'} \subset \Xi^t$ with $\mathbb{P}^t[A^{t'}] = 1$ such that the following property holds.*

For every Borel measurable mapping $\boldsymbol{x}_{t-1} : \Xi^{t-1} \to X_{t-1}$ there exists a measurable $\boldsymbol{x}_t : \Xi^t \to X_t$ such that identity (3) *holds true for every $\xi^t \in A^{t'}$.*

We assume the decision $\boldsymbol{x}_t$ can be chosen to fulfill a certain growth condition:

Assumption 2.3. For $t = 1, \ldots, T$, there is a Borel set $A^{t'} \subset \Xi^t$ with $\mathbb{P}^t[A^{t'}] = 1$ and a constant $L \geq 1$ such that the following property holds.

For every Borel measurable mapping $\boldsymbol{x}_{t-1} : \Xi^{t-1} \to X_{t-1}$ there exists a measurable $\boldsymbol{x}_t : \Xi^t \to X_t$ such that identity (3) and the growth condition

$$\|\boldsymbol{x}_t(\xi^t)\| \leq L \cdot \max\left\{1, \|\boldsymbol{x}_{t-1}(\xi^{t-1})\|\right\} \cdot \max\left\{1, \|\xi^t\|\right\} \tag{4}$$

hold true for every $\xi^t \in A^{t'}$.

Remark 2.4. Unfortunately, the existence of decisions which are bounded in the above sense may be hard to verify, in general. However, (4) holds true for *every* $x_t \in M_t(x_{t-1}, \xi_t)$ if X_t is bounded, or, more generally, whenever the projection of X_t onto the kernel of the recourse matrix $A_{t,0}$ is bounded.

Furthermore, the linear growth condition (4) could be relaxed to polynomial growth, and then the growth rate in ξ^t of the Lipschitz constant in Theorem 1 and the subsequent results would change accordingly.

Assumptions 2.1 and 2.3 imply the existence of an optimal decision $\boldsymbol{x}$ satisfying

$$\|\boldsymbol{x}_t(\boldsymbol{\xi}^t)\| \leq L^t \cdot \max\left\{1, \|\boldsymbol{\xi}^t\|\right\}^{t-1} \qquad \mathbb{P}-\text{a.s. for } t = 1, \ldots, T. \tag{5}$$

Indeed, a tuple $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_T)$ of mappings with (1) and (3)–(5) can be constructed by recursion, and from Theorem 14.37 of [17] it follows that every $\boldsymbol{x}_t$ can be chosen to be measurable. Consequently, $\boldsymbol{x}$ is an optimal decision. Decisions fulfilling (4) and (5) will be denoted as *bounded* in the following.

To establish a quantitative stability result, we will study the continuity of V_t. Thereby, regularity properties of the mapping $x_{t-1} \mapsto V_t(\xi^t, x_{t-1})$ are well-known. We refer to [3] and [19] who derived convexity as well as piecewise linearity for the case of finite Ξ^T and to [11] who proved continuity under compactness assumptions on Ξ^T and $X_1, \ldots, X_T$. Thus, the following proposition can be seen as an adaption of these results to our Lipschitz continuous framework.

PROPOSITION 2.5. *The recourse function V_t is Lipschitz continuous with respect to the decision x_{t-1} in the following sense. For $t = 1, \ldots, T$, there exists a constant*

$\bar{M} > 0$ and a Borel set $A^{t''} \subset \Xi^t$ with $\mathbb{P}^t[A^{t''}] = 1$, such that for every $\xi^t \in A^{t''}$ the relation

$$\left|V_t(\xi^t, x_{t-1}) - V_t(\xi^t, \hat{x}_{t-1})\right| \leq [V_t]^x_{Lip}(\xi^t) \cdot \|x_{t-1} - \hat{x}_{t-1}\| \tag{6}$$

holds true for every $x_{t-1}, \hat{x}_{t-1} \in X_{t-1}$ with a (random) Lipschitz constant $[V_t]^x_{Lip}(\xi^t)$ satisfying

$$[V_t]^x_{Lip}(\xi^t) \leq \bar{M} \cdot \mathbb{E}\left[\max\left\{1, \left\|\boldsymbol{\xi}^T\right\|\right\}^{2+T-t} \;\middle|\; \boldsymbol{\xi}^t = \xi^t\right]. \tag{7}$$

Proof. The assertion is true for $V_{T+1} \equiv 0$. Assume it is true also for $s = t+1, \ldots, T$ with Lipschitz constants $[V_s]^x_{Lip}$ and that the difference on the left side of (6) is negative. Then, due to (3), there exists an $\boldsymbol{x}^*_t(\xi^t) \in M_t(x_{t-1}, \xi_t)$, such that the left side of (6) coincides for $\mathbb{P}^t$-a.e. ξ^t with

$$\begin{aligned} &- \left\langle b_t(\xi_t), \boldsymbol{x}^*_t\left(\xi^t\right)\right\rangle - \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}^*_t\left(\xi^t\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right] \\ &\quad + \inf_{\hat{x}_t \in M_t(\hat{x}_{t-1}, \xi_t)} \left\{\langle b_t(\xi_t), \hat{x}_t\rangle + \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \hat{x}_t\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right\}. \end{aligned} \tag{8}$$

Moreover, it follows from Corollary 2.2 that we may assume that the $\mathbb{P}^t(d\xi^t)$-null sets on which this identity does not hold coincide for all $x_{t-1} \in X_{t-1}$. Due to Theorem 14.37 of [17] we can choose a measurable $\hat{\boldsymbol{x}}^*_t$ with

$$\hat{\boldsymbol{x}}^*_t(\xi^t) \in \arg\min_{z \in M_t(\hat{x}_{t-1}, \xi_t)} \left\|z - \boldsymbol{x}^*_t(\xi^t)\right\|$$

to estimate (8) from above by

$$|\left\langle b_t(\xi_t), \boldsymbol{x}^*_t\left(\xi^t\right) - \hat{\boldsymbol{x}}^*_t\left(\xi^t\right)\right\rangle| + |\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, x^*_t\right) - V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \hat{x}^*_t\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]|.$$

From the linear growth of b_t and the Lipschitz continuity of V_{t+1} with respect to x_t, one concludes that this term is not greater than

$$\left(B\max\{1, \|\xi_t\|\} + \mathbb{E}\left[[V_{t+1}]^x_{Lip}\left(\boldsymbol{\xi}^{t+1}\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right) \cdot \left\|\boldsymbol{x}^*_t\left(\xi^t\right) - \hat{\boldsymbol{x}}^*_t\left(\xi^t\right)\right\|,$$

again $\mathbb{P}^t(d\xi^t)$–a.s. for every $x_{t-1}, \hat{x}_{t-1} \in X_{t-1}$. By definition of $\hat{\boldsymbol{x}}^*_t$ and Lipschitz continuity of M_t, the latter term is bounded from above by

$$\left(MB\max\left\{1, \|\xi_t\|^2\right\} + M\max\{1, \|\xi_t\|\} \cdot \mathbb{E}\left[[V_{t+1}]^x_{Lip}\left(\boldsymbol{\xi}^{t+1}\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right) \cdot \|x_{t-1} - \hat{x}_{t-1}\|.$$

An analoguous estimate holds whenever the difference on the left side of (6) is positive. Hence, $[V_t]^x_{Lip}(\xi^t)$ is given by the term in parentheses, from which we conclude by recursion that we can put

$$[V_t]^x_{Lip}(\xi^t) \triangleq B\sum_{i=t}^{T} M^{i-t+1}\mathbb{E}\left[\max\{1, \|\boldsymbol{\xi}_i\|^2\} \cdot \prod_{k=t}^{i-1}\max\{1, \|\boldsymbol{\xi}_k\|\} \;\middle|\; \boldsymbol{\xi}^t = \xi^t\right].$$

Thus, the asserted bound for $[V_t]^x_{Lip}$ results from a straightforward estimate. ∎

Establishing continuity of $\xi^t \mapsto V_t(\xi^t, x_{t-1})$ is more subtle since, unlike the decision variable x_{t-1}, the observation ξ^t impacts not only the Lipschitz continuous time coupling constraints at time t, but also the expectations about future realizations of

$\boldsymbol{\xi}$. Therefore, one can hardly expect V_t to be Lipschitz continuous with respect to ξ^t without having that *the conditional distribution of* $(\boldsymbol{\xi}_s)_{s=t+1}^T$ *under* $\{\boldsymbol{\xi}^t = \xi^t\}$ *depends continuously on* ξ^t with respect to some appropriate measure of distance. It is illustrated by Example 2.6 of [8] that without such a continuous dependency stability of optimal values in terms of an L^p-distance does not hold in general. Thus, for establishing recursively the continuity of V_t, we need that continuity of V_{t+1} with respect to ξ^{t+1} is passed down to the mapping $\xi^t \mapsto \mathbb{E}\left[V_{t+1}(\boldsymbol{\xi}^{t+1}, x_t)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]$. To this end, we introduce for $p \geq 1$ and a given Borel set $A^{t+1} \subset \Xi^{t+1}$ with $\mathbb{P}^{t+1}[A^{t+1}] = 1$ the class of functions

$$\mathbb{F}_p^{A^{t+1}}(\Xi^{t+1}) \triangleq \left\{ f : \Xi^{t+1} \to \mathbb{R} : (9) \text{ holds for } \xi^{t+1}, \hat{\xi}^{t+1} \in A^{t+1} \right\}$$

along with the Lipschitz condition

$$\left| f\left(\xi^{t+1}\right) - f\left(\hat{\xi}^{t+1}\right) \right| \leq \max\left\{1, \left\|\xi^{t+1}\right\|, \left\|\hat{\xi}^{t+1}\right\|\right\}^{p-1} \left\|\xi^{t+1} - \hat{\xi}^{t+1}\right\|. \tag{9}$$

We consider the following distance between probability measures P, Q on Ξ^{t+1}:

$$\zeta_p^{A^{t+1}}(P, Q) \triangleq \sup_{f \in \mathbb{F}_p^{A^{t+1}}(\Xi^{t+1})} \left| \int_{\Xi^{t+1}} f\left(\xi^{t+1}\right) P\left(d\xi^{t+1}\right) - \int_{\Xi^{t+1}} f\left(\xi^{t+1}\right) Q\left(d\xi^{t+1}\right) \right|.$$

Recall that, with the exception that we disregard the $\mathbb{P}^{t+1}$-null set $\Xi^{t+1} \setminus A^{t+1}$ within the definition of $\mathbb{F}_p^{A^{t+1}}$, the functional $\zeta_p^{A^{t+1}}$ corresponds to the *p-th order Fortet–Mourier distance*; see [15], [18]. Using this notation, the claimed continuity of the conditional distributions is specified by the following assumption.

Assumption 2.6. There exist constants $W, K > 0$, and $r \geq 0$, such that with

$$m_t \triangleq 1 + (T - t)(1 + r) \quad \text{for } t = 1, \ldots, T, \tag{10}$$

the following conditions are fulfilled.

(i) For every $t = 1, \ldots, T-1$, every Borel set $A^{t+1} \subset \Xi^{t+1}$ with $\mathbb{P}^{t+1}[A^{t+1}] = 1$, and $\mathbb{P}^t$-a.e. $\xi^t, \hat{\xi}^t \in \Xi^t$

$$\begin{aligned} &\zeta_{m_{(t+1)}+1}^{A^{t+1}}\left(\mathbb{P}\left[\boldsymbol{\xi}^{t+1} \in \cdot \,\middle|\, \boldsymbol{\xi}^t = \xi^t\right], \mathbb{P}\left[\boldsymbol{\xi}^{t+1} \in \cdot \,\middle|\, \boldsymbol{\xi}^t = \hat{\xi}^t\right]\right) \\ &\quad \leq K \max\left\{1, \|\xi^t\|, \|\hat{\xi}^t\|\right\}^{m_t - 1} \|\xi^t - \hat{\xi}^t\|. \end{aligned}$$

(ii) For every $t = 1, \ldots, T-1$ and $\mathbb{P}^t$-a.e. $\xi^t \in \Xi^t$

$$\mathbb{E}\left[\max\left\{1, \left\|\boldsymbol{\xi}^T\right\|\right\}^{1+T-t} \;\middle|\; \boldsymbol{\xi}^t = \xi^t \right] \leq W \cdot \max\left\{1, \left\|\xi^t\right\|\right\}^{m_t}.$$

Since the above assumption is crucial for the following continuity and stability results, it is discussed in the following remark.

Remark 2.7. Condition (i) is related to terms usually related to Markov processes, namely the *coefficient of ergodicity* and the *Feller property*; see, e.g., [4], [5], respectively. A similar assumption has been made by [1] to ensure stability of an optimal-stopping problem in a Markovian framework and by [12] for their study of consistency of tree approximations. It is also made implicitly by [11] by focusing on autoregressive processes. The more involved formulation of Assumption 2.6, allowing

for polynomially growing Lipschitz constants, is due to the fact that neither $\langle b_t(\xi_t), x_t\rangle$ nor M_{t+1} are uniformly Lipschitz continuous in ξ_t and x_t, unless both the support Ξ^T and the sets $X_t, t = 1, \dots, T$ are bounded. Indeed, under such a boundedness condition (i) may be significantly simplified; see Remark 2.8 below.

Lemma A.1 in the appendix provides conditions on $\boldsymbol{\xi}$, under which both (i) and (ii) hold true. In particular, this is the case if Ξ^T is finite. In the latter case one sees that ζ_p is the optimal value of a linear optimization problem that can be solved numerically to determine the constants K and r.

The following theorem shows that Assumption 2.6 indeed provides Lipschitz continuity of V_t with respect to ξ^t. We also refer to Proposition 2.7 of [11] which represents a corresponding continuity result.

THEOREM 1. *Suppose the Assumptions* 2.1*,* 2.3*, and* 2.6 *are fulfilled. For every* $t = 1, \dots, T$ *there is a constant* $C_t > 0$ *and a Borel set* $A^t \subset \Xi^t$ *with* $\mathbb{P}^t[A^t] = 1$ *such that*

$$\frac{1}{C_t \max\{1, \|x_{t-1}\|\}} V_t(\,\cdot\,, x_{t-1}) \in \mathbb{F}_{m_t+1}^{A^t}\left(\Xi^t\right)$$

holds true for every $x_{t-1} \in X_{t-1}$.

Proof. The assertion holds true for $V_{T+1} \equiv 0$; we show that it follows recursively for $t \leq T$. To this end, we proceed as in the proof of Proposition 2.5 and choose a measurable $\boldsymbol{x}_t^*$ with $\boldsymbol{x}_t^*(\xi^t) \in M_t(x_{t-1}, \xi_t)$ that fulfills (3) and $\|\boldsymbol{x}_t^*(\xi^t)\| \leq L \cdot \max\{1, \|x_{t-1}\|\} \cdot \max\{1, \|\xi^t\|\}$. Thus, we obtain

$$\begin{aligned}
&\left|V_t\left(\xi^t, x_{t-1}\right) - V_t\left(\hat{\xi}^t, x_{t-1}\right)\right| \\
&= \Bigg| \left\langle b_t\left(\xi_t\right), \boldsymbol{x}_t^*\left(\xi^t\right)\right\rangle + \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(\xi^t\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right] \\
&\quad - \inf_{\hat{x}_t \in M_t(x_{t-1}, \hat{\xi}_t)} \left\{ \left\langle b_t(\hat{\xi}_t), \hat{x}_t \right\rangle + \mathbb{E}\left[V_{t+1}(\boldsymbol{\xi}^{t+1}, \hat{x}_t) \middle|\, \boldsymbol{\xi}^t = \hat{\xi}^t \right] \right\} \Bigg|, \qquad (11)
\end{aligned}$$

which holds, due to Assumption 2.3, for every $\xi^t, \hat{\xi}^t \in A^{t'}$ with $\mathbb{P}^t[A^{t'}] = 1$ for all $x_{t-1} \in X_{t-1}$. We consider the case when the term under the norm is negative and choose a measurable $\hat{\boldsymbol{x}}_t^*$ with

$$\hat{\boldsymbol{x}}_t^*(\hat{\xi}^t) \in \operatorname{argmin}_{z \in M_t(x_{t-1}, \hat{\xi}_t)} \|z - \boldsymbol{x}_t^*(\xi^t)\|$$

to obtain the following upper bound for (11):

$$\begin{aligned}
&- \left\langle b_t(\xi_t), \boldsymbol{x}_t^*\left(\xi^t\right)\right\rangle - \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(\xi^t\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right] \\
&\quad + \left\langle b_t\left(\hat{\xi}_t\right), \hat{\boldsymbol{x}}_t^*\left(\hat{\xi}^t\right)\right\rangle + \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \hat{\boldsymbol{x}}_t^*\left(\hat{\xi}^t\right)\right)\middle|\, \boldsymbol{\xi}^t = \hat{\xi}^t\right]. \qquad (12)
\end{aligned}$$

Using linearity of b_t and Lipschitz continuity of M_t, the difference of the scalar product terms can be estimated by

$$\begin{aligned}
&\left|\left\langle b_t\left(\xi_t\right), \boldsymbol{x}_t^*\left(\xi^t\right)\right\rangle - \left\langle b_t\left(\hat{\xi}_t\right), \boldsymbol{x}_t^*\left(\xi^t\right)\right\rangle\right| \\
&\quad + \left|\left\langle b_t\left(\hat{\xi}_t\right), \boldsymbol{x}_t^*\left(\xi^t\right)\right\rangle - \left\langle b_t\left(\hat{\xi}_t\right), \hat{\boldsymbol{x}}_t^*\left(\hat{\xi}^t\right)\right\rangle\right| \\
&\leq B\|\xi_t - \hat{\xi}_t\| \cdot L \cdot \max\{1, \|x_{t-1}\|\} \max\left\{1, \|\xi^t\|\right\} \\
&\quad + B \max\left\{1, \left\|\hat{\xi}_t\right\|\right\} \cdot M \max\{1, \|x_{t-1}\|\} \|\xi_t - \hat{\xi}_t\| \\
&\leq B(L+M) \max\{1, \|x_{t-1}\|\} \max\left\{1, \|\xi^t\|, \|\hat{\xi}^t\|\right\} \|\xi_t - \hat{\xi}_t\|. \qquad (13)
\end{aligned}$$

The difference of the conditional expectations in (12) is bounded by

$$
\begin{aligned}
&|\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(\xi^t\right)\right) \mid \boldsymbol{\xi}^t = \xi^t\right] - \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(\xi^t\right)\right) \mid \boldsymbol{\xi}^t = \hat{\xi}^t\right]| \\
&\quad + |\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(\xi^t\right)\right) \mid \boldsymbol{\xi}^t = \hat{\xi}^t\right] - \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \hat{\boldsymbol{x}}_t^*\left(\hat{\xi}^t\right)\right) \mid \boldsymbol{\xi}^t = \hat{\xi}^t\right]| \\
&\quad \le C_{t+1} \max\left\{1, \|\boldsymbol{x}_t^*\left(\xi^t\right)\|\right\} \zeta_{m_{(t+1)}+1}^{A^{t+1}}\left(\mathbb{P}\left[\boldsymbol{\xi}^{t+1} \in \cdot \,\middle|\, \boldsymbol{\xi}^t = \xi^t\right], \mathbb{P}\left[\boldsymbol{\xi}^{t+1} \in \cdot \,\middle|\, \boldsymbol{\xi}^t = \hat{\xi}^t\right]\right) \\
&(14) \quad + \mathbb{E}\left[\left[V_{t+1}\right]_{Lip}^x\left(\boldsymbol{\xi}^{t+1}\right) \;\middle|\; \boldsymbol{\xi}^t = \hat{\xi}^t\right] M \max\left\{1, \|x_{t-1}\|\right\} \cdot \left\|\xi^t - \hat{\xi}^t\right\|,
\end{aligned}
$$

whereby the last inequality follows from the assertion for V_{t+1}, Proposition 2.5, and the Lipschitz continuity of M_t. This estimate holds true for every $\xi^t, \hat{\xi}^t \in A^{t''}$ for all $x_{t-1} \in X_{t-1}$, where $A^{t''}$ denotes the sets on which the assertions of Proposition 2.5 hold. Applying now condition (i) of Assumption 2.6 and the estimate (7), we see that the sum (14) does not exceed

$$
\begin{aligned}
&KC_{t+1} \max\left\{1, \left\|\boldsymbol{x}_t^*(\xi^t)\right\|\right\} \max\left\{1, \left\|\xi^t\right\|, \left\|\hat{\xi}^t\right\|\right\}^{m_t - 1} \left\|\xi^t - \hat{\xi}^t\right\| \\
&\quad + \bar{M} \cdot \mathbb{E}\left[\max\left\{1, \left\|\boldsymbol{\xi}^T\right\|\right\}^{1+T-t} \;\middle|\; \boldsymbol{\xi}^t = \xi^t\right] M \max\left\{1, \|x_{t-1}\|\right\} \cdot \left\|\xi^t - \hat{\xi}^t\right\|
\end{aligned}
$$

for every $\xi^t, \hat{\xi}^t \in A^{t'''}$. Thereby, $A^{t'''}$ denotes the set of $\mathbb{P}^t$-probability one on which Assumption 2.6 holds.

From condition (ii) of Assumption 2.6 and the boundedness of $\|\boldsymbol{x}_t^*\|$, we conclude that the latter sum is again bounded from above by

$$
(15) \qquad \left(KC_{t+1}L + \bar{M}WM\right) \max\left\{1, \left\|x_{t-1}\right\|\right\} \max\left\{1, \left\|\xi^t\right\|, \left\|\hat{\xi}^t\right\|\right\}^{m_t} \cdot \|\xi^t - \hat{\xi}^t\|.
$$

The upper bounds (13) and (15) remain valid if the term under the norm in (11) is positive. Piecing this all together, the assertion for V_t follows with $A^t \triangleq A^{t'} \cap A^{t''} \cap A^{t'''}$, and the Lipschitz constant C_t can be chosen by collecting the constants from (13) and (15); i.e.,

$$
C_t \triangleq B(M + L) + KC_{t+1}L + \bar{M}WM. \qquad \square
$$

In the following remark we sketch what can be simplified whenever the sets X_t and Ξ^T are bounded.

Remark 2.8. The constant m_t is chosen to be equal to the growth rate of the term $\max\{1, \|\xi^t\|, \|\hat{\xi}^t\|\}$ within an upper bound of (14). Assuming boundedness of the sets X_t for $t = 1, \ldots, T$ allows one to estimate the term $\max\{1, \|\boldsymbol{x}_t^*(\xi^t)\|\}$ in the first summand of (14) by some constant instead of estimating it by $\max\{1, \|\xi^t\|, \|\hat{\xi}^t\|\}$. Consequently, one can allow the growth rate of the ζ-terms in (14) and in Assumption 2.6 to increase from $m_t - 1$ to m_t.

If the set Ξ^T is bounded as well, then $[V_{t+1}]_{Lip}^x(\boldsymbol{\xi}^{t+1})$ is bounded by a constant, condition (i) of Assumption 2.6 may be simplified to

$$
\zeta_1^{A^{t+1}}\left(\mathbb{P}\left[\boldsymbol{\xi}^{t+1} \in \cdot \,\middle|\, \boldsymbol{\xi}^t = \xi^t\right], \mathbb{P}\left[\boldsymbol{\xi}^{t+1} \in \cdot \,\middle|\, \boldsymbol{\xi}^t = \hat{\xi}^t\right]\right) \le K\|\xi^t - \hat{\xi}^t\|,
$$

condition (ii) of Assumption 2.6 may be omitted, and the assertion of Theorem 1 can be written as $(1/C_t)\, V_t(\cdot, x_{t-1}) \in \mathbb{F}_1^{A^t}(\Xi^t)$, i.e., $(\xi^t, x_{t-1}) \mapsto V_t(\xi^t, x_{t-1})$ is uniformly Lipschitz continuous.

The optimality and boundedness conditions (3)–(5), as well as the continuity properties claimed in Assumption 2.6 and Theorem 1, hold on some Borel set $A \subset \Xi^T$ with $\mathbb{P}^T[A] = 1$. Since an approximation $\tilde{\boldsymbol{\xi}}$ may have its support in the set $\Xi^T \setminus A$, it is reasonable to modify the considered random variables on this $\mathbb{P}^T$-null set to appropriate versions which fulfill the claimed properties for *every* $\xi^T \in \Xi^T$. To this end, we recall that $\mathbb{P}^T[A] = 1$ and $\Xi^T = \operatorname{supp} \mathbb{P}^T$ imply that A is a dense subset of Ξ^T. For every $\hat{\xi}^T \in \Xi^T \setminus A$ we then consider a sequence $(\xi^T_{(n)})_{n\in\mathbb{N}} \subset A$ converging to $\hat{\xi}^T$ as n goes to infinity. The recourse function and the regular conditional distributions are modified in $\hat{\xi}^T$ by setting $V_t(\hat{\xi}^t, x_{t-1}) \triangleq \lim_{n\to\infty} V_t(\xi^t_{(n)}, x_{t-1})$ and

$$\mathbb{E}[g\left(\boldsymbol{\xi}^{t+1}\right) | \boldsymbol{\xi}^t = \hat{\xi}^t] \triangleq \lim_{n\to\infty} \mathbb{E}[g\left(\boldsymbol{\xi}^{t+1}\right) | \boldsymbol{\xi}^t = \xi^t_{(n)}]$$

for every Lipschitz continuous mapping g. A bounded optimal solution $\boldsymbol{x}^*$ can be appropriately modified in $\hat{\xi}^t$ by considering a subsequence $(\xi^T_{(n_k)})_{k\in\mathbb{N}}$ such that $\boldsymbol{x}^*_t(\xi^t_{(n_k)})$ converges toward some

$$z_t\left(\hat{\xi}^t\right) \in X_t$$

for $t = 1, \ldots, T$. Then we put $\boldsymbol{x}^*_t(\hat{\xi}^t) \triangleq z_t(\hat{\xi}^t)$, and we obtain that the above stated conditions and properties indeed hold for every $\xi^T \in \Xi^T$.

3. Approximations. Whenever an auxiliary process $\tilde{\boldsymbol{\xi}}$ is expected to approximate $\boldsymbol{\xi}$ with regard to the optimization problem (2), it is indispensable that $\tilde{\boldsymbol{\xi}}$ is nonanticipative with respect to $\boldsymbol{\xi}$. This is illustrated, for the sake of completeness, by Example A.3 in the appendix. Nonanticipativity is ensured in the following.

DEFINITION 3.1. *A stochastic process $\tilde{\boldsymbol{\xi}}$ on $(\Omega, \mathcal{F}, \mathbb{P})$ is called an* approximation of $\boldsymbol{\xi}$*, if there exist Borel-measurable mappings*

$$f_t : \Xi^t \to \Xi_t \text{ for } t = 1, \ldots, T,$$

fulfilling the following conditions:

(i) $\tilde{\boldsymbol{\xi}}_t = f_t(\boldsymbol{\xi}^t)$ *for* $t = 1, \ldots T$,
(ii) $f^T(\Xi^T) \subset \Xi^T$,
(iii) $f_1(\xi_1) = \xi_1$ *for every* $\xi_1 \in \Xi_1$, *and*
(iv) $f^T(\boldsymbol{\xi}) \in L^p(\Omega, \mathcal{F}, \mathbb{P})$ *for every* $p \in [1, \infty)$.

Thereby, $f^t(\xi^t)$ denotes the vector $(f_i(\xi^i))_{i=1}^t \in \mathbb{R}^{s\cdot t}$ for $t = 1, \ldots, T$. In the following, we use the notation f for the mapping $f^T(\cdot)$.

Remark 3.2. The nonanticipativity condition (i) is equivalent to $\sigma(\boldsymbol{\xi}^t)$-measurability of the random variable $\tilde{\boldsymbol{\xi}}_t$. Condition (ii) ensures that f^T maps onto realizations $\xi^T \in \Xi^T$ of the initial process and thus implies that the restriction of a decision $\boldsymbol{x}(\cdot) \in \mathcal{S}(\boldsymbol{\xi})$ on the set $f^T(\Xi^T)$ is a $\tilde{\boldsymbol{\xi}}$-feasible decision. The integrability condition (iv) is assumed again for the sake of simplicity. For the following results, it suffices that $f^T(\boldsymbol{\xi}) \in L^p(\Omega, \mathcal{F}, \mathbb{P})$ for a constant $p \in \mathbb{R}_+$ that is sufficiently large.

The following proposition relies heavily on the continuity of the recourse function stated in Theorem 1. It is shown that, although an optimal decision $\boldsymbol{x}^*(\cdot)$ is not continuous in general, its expected costs can be approximated by the decision $\boldsymbol{x}^*(f(\cdot))$ (which is piecewise constant whenever $\tilde{\boldsymbol{\xi}}$ has finite support). Although $\boldsymbol{x}^*(f(\cdot))$ may fail to fulfill the time-coupling constraints (1) with respect to $\boldsymbol{\xi}$, it can be used to construct a feasible decision. This will be carried out in the next section.

PROPOSITION 3.3. *Consider an optimal decision $\boldsymbol{x}^*$ which is bounded in the sense of* (5) *and an approximation mapping f according to Definition* 3.1.

Then there exists a constant $D > 0$ such that the following estimate holds:

$$|\varphi(\boldsymbol{x}^*(\boldsymbol{\xi}),\boldsymbol{\xi}) - \varphi(\boldsymbol{x}^*(f(\boldsymbol{\xi})),\boldsymbol{\xi})| \le D\mathbb{E}\left[\max\{1,\|\boldsymbol{\xi}\|,\|f(\boldsymbol{\xi})\|\}^{m_1}\cdot\|\boldsymbol{\xi}-f(\boldsymbol{\xi})\|\right], \tag{16}$$

where the constant m_1 is defined by (10).

Proof. Due to $f_1(\boldsymbol{\xi}_1) = \boldsymbol{\xi}_1$, we have to estimate

$$\left|\mathbb{E}\left[\sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \boldsymbol{x}_t^*\left(\boldsymbol{\xi}^t\right)\right\rangle\right] - \mathbb{E}\left[\sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \boldsymbol{x}_t^*\left(f^t\left(\boldsymbol{\xi}^t\right)\right)\right\rangle\right]\right|.$$

By the optimality of $\boldsymbol{x}^*$, the first expectation is equal to $\mathbb{E}\left[V_2(\boldsymbol{\xi}^2, \boldsymbol{x}_1^*)\right]$, and it follows from Theorem 1 and the boundedness of $\boldsymbol{x}_1^*$ (and $\boldsymbol{x}_0^* \triangleq 1$) that

$$\begin{aligned}\mathbb{E}\left[\left|V_2\left(\boldsymbol{\xi}^2,\boldsymbol{x}_1^*\right) - V_2\left(f^2\left(\boldsymbol{\xi}^2\right),\boldsymbol{x}_1^*\right)\right|\right] \\ \le LC_2\mathbb{E}\left[\max\left\{1,\|\boldsymbol{\xi}^2\|,\|f^2\left(\boldsymbol{\xi}^2\right)\|\right\}^{m_2}\|\boldsymbol{\xi}^2 - f^2\left(\boldsymbol{\xi}^2\right)\|\right]\end{aligned} \tag{17}$$

Thus, it remains to estimate

$$\left|\mathbb{E}\left[V_2\left(f^2\left(\boldsymbol{\xi}^2\right),\boldsymbol{x}_1^*\right) - \sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \boldsymbol{x}_t^*\left(f^t\left(\boldsymbol{\xi}^t\right)\right)\right\rangle\right]\right|. \tag{18}$$

To this end, we consider the following inequality

$$\begin{aligned}\Big|\mathbb{E}\Big[V_2\left(f^2\left(\boldsymbol{\xi}^2\right),\boldsymbol{x}_1^*\right) - \sum_{s=2}^{t-1}\langle b_s(\boldsymbol{\xi}_s), \boldsymbol{x}_s^*(f^s(\boldsymbol{\xi}^s))\rangle \\ - V_t\left(f^t\left(\boldsymbol{\xi}^t\right),\boldsymbol{x}_{t-1}^*\left(f^{t-1}\left(\boldsymbol{\xi}^{t-1}\right)\right)\right)\Big]\Big| \le D_t,\end{aligned} \tag{19}$$

whose left side coincides with (18) for $t = T+1$. It holds trivially for $t = 2$ with $D_2 = 0$, and we assume that it is also true for some $t \in \{2,\dots,T\}$ with a constant $D_t \ge 0$. To prove it recursively for $t+1$, we have to find an upper bound for

$$\begin{aligned}\Big|\mathbb{E}\big[V_t\left(f^t\left(\boldsymbol{\xi}^t\right),\boldsymbol{x}_{t-1}^*\left(f^{t-1}\left(\boldsymbol{\xi}^{t-1}\right)\right)\right) - \left\langle b_t\left(\boldsymbol{\xi}_t\right),\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\rangle \\ - V_{t+1}\left(f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right),\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\big]\Big|.\end{aligned} \tag{20}$$

To this end, we use again $\boldsymbol{x}^*$'s optimality to expand the first summand:

$$\begin{aligned}&\mathbb{E}\left[V_t\left(f^t\left(\boldsymbol{\xi}^t\right),\boldsymbol{x}_{t-1}^*\left(f^{t-1}\left(\boldsymbol{\xi}^{t-1}\right)\right)\right)\right] \\ &= \int\left\langle b_t\left(f_t\left(\xi^t\right)\right),\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\rangle + \mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1},\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\,\boldsymbol{\xi}^t = f^t\left(\xi^t\right)\right]\mathbb{P}^t\left(d\xi^t\right).\end{aligned} \tag{21}$$

Now, to estimate (20), we have to replace $b_t(f_t(\xi^t))$ by $b_t(\xi^t)$. The Lipschitz continuity of $b_t(\cdot)$ implies

$$\left|\left\langle b_t\left(f_t\left(\xi^t\right)\right),\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\rangle - \left\langle b_t\left(\xi_t\right),\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\rangle\right| \le B\cdot\left\|\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\|\cdot\left\|\xi^t - f^t\left(\xi^t\right)\right\|.$$

To estimate the difference of the V_{t+1}-terms in (20) and (21), we add and subtract the term $\mathbb{E}\left[V_{t+1}(f^{t+1}(\boldsymbol{\xi}^{t+1}), \boldsymbol{x}_t^*(f^t(\xi^t)))\middle|\, \boldsymbol{\xi}^t = \xi^t\right]$ and use the triangle inequality to estimate

$$\begin{aligned}
&\left|\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\, \boldsymbol{\xi}^t = f^t\left(\xi^t\right)\right]\right. \\
&\qquad \left. -\mathbb{E}\left[V_{t+1}\left(f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right), \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right| \\
&\quad \le \left|\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\, \boldsymbol{\xi}^t = f^t\left(\xi^t\right)\right]\right. \\
&\qquad \left. -\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right| \\
&\qquad + \left|\mathbb{E}\left[V_{t+1}\left(\boldsymbol{\xi}^{t+1}, \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right. \\
&\qquad \left. -\mathbb{E}\left[V_{t+1}\left(f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right), \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right)\middle|\, \boldsymbol{\xi}^t = \xi^t\right]\right|.
\end{aligned}$$

By applying Theorem 1 and Assumption 2.6 we conclude that this term is bounded for $\mathbb{P}^t$-almost every ξ^t by

$$\begin{aligned}
&KC_{t+1}\max\left\{1, \left\|\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\|\right\}\max\left\{1, \left\|\xi^t\right\|, \left\|f^t\left(\xi^t\right)\right\|\right\}^{m_t-1}\left\|\xi^t - f^t\left(\xi^t\right)\right\| \\
&+ C_{t+1}\max\left\{1, \left\|\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right)\right\|\right\} \\
&\quad \cdot\mathbb{E}\left[\max\left\{1, \left\|\boldsymbol{\xi}^{t+1}\right\|, \left\|f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right)\right\|\right\}^{m_{t+1}}\left\|\boldsymbol{\xi}^{t+1} - f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right)\right\|\middle|\, \boldsymbol{\xi}^t = \xi^t\right] \\
&\le (K+1)C_{t+1}L^t\mathbb{E}\left[\max\left\{1, \left\|\boldsymbol{\xi}^{t+1}\right\|, \left\|f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right)\right\|\right\}^{m_t+t-1}\left\|\boldsymbol{\xi}^{t+1}\right.\right. \\
&\qquad\qquad \left.\left. - f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right)\right\|\middle|\, \boldsymbol{\xi}^t = \xi^t\right],
\end{aligned}$$

where the inequality follows from boundedness of $\boldsymbol{x}_t^*$ and the relation $m_{t+1} \le m_t - 1$. Integration with respect to $\mathbb{P}^t(d\xi^t)$ and combining these estimates with (21) entails that (20) does not exceed

(22)
$$(B+(K+1)C_{t+1})L^t\mathbb{E}\left[\max\left\{1, \left\|\boldsymbol{\xi}^{t+1}\right\|, \left\|f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right)\right\|\right\}^{m_t+t-1}\cdot\left\|\boldsymbol{\xi}^{t+1} - f^{t+1}\left(\boldsymbol{\xi}^{t+1}\right)\right\|\right].$$

Hence, (19) holds for $t+1$ with D_{t+1} being equal to the sum of D_t and (22).

Due to the fact that both $m_t + t - 1$ and m_2 are smaller than m_1, the sum of (17) and (18) does not exceed

$$D\mathbb{E}\left[\max\{1, \|\boldsymbol{\xi}\|, \|f(\boldsymbol{\xi})\|\}^{m_1}\cdot\|\boldsymbol{\xi} - f(\boldsymbol{\xi})\|\right]$$

with $D \triangleq LC_2 + D_{T+1}$. This completes the proof. ∎

4. Calm decisions. One of the main difficulties in establishing the stability of the optimal value $v(\boldsymbol{\xi})$ with respect to perturbations of $\boldsymbol{\xi}$ is that optimal solutions do not depend continuously on the realization of $\boldsymbol{\xi}$, in general. Furthermore, the gap between $v(\boldsymbol{\xi})$ and the minimal expected costs which can be realized by, e.g., Lipschitz continuous solutions may be hard to estimate. In this section we shall introduce specific *calm* decisions and estimate the minimal expected costs realized by those decisions.

We consider an optimal decision $\boldsymbol{x}^*$ which is bounded in the sense of (5). The *calm modification of* $\boldsymbol{x}^*$ is defined by

$$\bar{\boldsymbol{x}}_1^* \triangleq \boldsymbol{x}_1^* \quad \text{and} \quad \bar{\boldsymbol{x}}_t^*\left(\xi^t\right) \in \operatorname{argmin}_{z \in M_t(\bar{\boldsymbol{x}}_{t-1}^*(\xi^{t-1}),\, \xi_t)}\left\|\boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right) - z\right\| \text{ for } t = 2, \ldots, T,$$

where, again due to Theorem 14.37 of [17], the latter mappings can be chosen to be measurable. Observe that $\boldsymbol{x}_t^*$ and $\bar{\boldsymbol{x}}_t^*$ coincide on the set $f^t(\Xi^t)$, i.e.,

$$\bar{\boldsymbol{x}}_t^*\left(f^t\left(\xi^t\right)\right) = \boldsymbol{x}_t^*\left(f^t\left(\xi^t\right)\right) \text{ for every } \xi^t \in \Xi^t. \tag{23}$$

Due to the Lipschitz continuity of M_t, the local variability of $\bar{\boldsymbol{x}}_t^*(\cdot)$ in ξ^t can be estimated recursively, and $\bar{\boldsymbol{x}}_t^*(\cdot)$ is indeed *calm locally around* $f^t(\xi^t)$ *for every* $\xi^t \in \Xi^t$ in the following sense.

PROPOSITION 4.1. *For every* $t = 1, \ldots, T$ *and every* $\xi^T \in \Xi^T$ *we have*

$$\left\|\bar{\boldsymbol{x}}_t^*\left(\xi^t\right) - \bar{\boldsymbol{x}}_t^*\left(f^t\left(\xi^t\right)\right)\right\| \le (T-1)M^{T-1}\max\left\{1, \left\|\xi^T\right\|, \left\|f^T\left(\xi^T\right)\right\|\right\}^{T-1}\left\|\xi^T - f^T\left(\xi^T\right)\right\|. \tag{24}$$

Proof. For $t = 1$, the difference on the left side of (24) vanishes. For $t > 1$ we use the identity (23) and the definition of $\bar{\boldsymbol{x}}_t^*(\xi^t)$ to write

$$\left\|\bar{\boldsymbol{x}}_t^*\left(\xi^t\right) - \bar{\boldsymbol{x}}_t^*\left(f^t\left(\xi^t\right)\right)\right\| = \inf_{z \in M_t\left(\bar{\boldsymbol{x}}_{t-1}^*\left(\xi^{t-1}\right), \xi_t\right)}\left\|z - \bar{\boldsymbol{x}}_t^*\left(f^t\left(\xi^t\right)\right)\right\|. \tag{25}$$

Using the inclusion $\bar{\boldsymbol{x}}_t^*(f^t(\xi^t)) \in M_t(\bar{\boldsymbol{x}}_{t-1}^*(f^{t-1}(\xi^{t-1})), f_t(\xi^t))$, we obtain that the right-hand side of (25) is not greater than the Pompeiu–Hausdorff distance of the sets $M_t(\bar{\boldsymbol{x}}_{t-1}^*(\xi^{t-1}), \xi^t)$ and $M_t(\bar{\boldsymbol{x}}_{t-1}^*(f^{t-1}(\xi^{t-1})), f_t(\xi^t))$. We then apply the triangle inequality with respect to this metric and use the Lipschitz continuity of M_t to conclude that the right-hand side of (25) is bounded from above by

$$\begin{aligned} &M\max\left\{1, \left\|\xi^t\right\|\right\}\ \left\|\bar{\boldsymbol{x}}_{t-1}^*\left(\xi^{t-1}\right) - \bar{\boldsymbol{x}}_{t-1}^*\left(f^{t-1}\left(\xi^{t-1}\right)\right)\right\| \\ &+M\max\left\{1, \left\|\bar{\boldsymbol{x}}_{t-1}^*\left(f^{t-1}\left(\xi^{t-1}\right)\right)\right\|\right\}\ \left\|f^t\left(\xi^t\right) - \xi^t\right\|. \end{aligned}$$

By boundedness of $\boldsymbol{x}_{t-1}$, the latter sum does not exceed

$$\begin{aligned} &M\max\{1, \|\xi^t\|\}\ \left\|\bar{\boldsymbol{x}}_{t-1}^*\left(\xi^{t-1}\right) - \bar{\boldsymbol{x}}_{t-1}^*\left(f^{t-1}\left(\xi^{t-1}\right)\right)\right\| \\ &+ML\max\left\{1, \left\|f^{t-1}\left(\xi^{t-1}\right)\right\|\right\}^{t-1}\ \left\|f^t\left(\xi^t\right) - \xi^t\right\|. \end{aligned}$$

Recursively, we obtain that the left side of (24) is bounded by

$$L\sum_{i=2}^{t} M^{t+1-i}\max\left\{1, \left\|f^{i-1}\left(\xi^{i-1}\right)\right\|\right\}^{i-1}\ \max\left\{1, \left\|\xi^t\right\|\right\}^{t-i}\ \left\|\xi^i - f^i\left(\xi^i\right)\right\|.$$

The assertion follows by a straightforward estimate. ∎

By combining Propositions 3.3 and 4.1, one immediately concludes the following theorem, which shows that the difference of the expected costs generated by $\boldsymbol{x}^*$ and $\bar{\boldsymbol{x}}^*$ can be estimated in terms of the deviation between $\boldsymbol{\xi}$ and $f(\boldsymbol{\xi})$.

THEOREM 2. *Suppose Assumptions* 2.1, 2.3, *and* 2.6 *are fulfilled. Consider an optimal decision* $\boldsymbol{x}^*$ *which is bounded in the sense of* (5) *and its calm modification* $\bar{\boldsymbol{x}}^*$.

Then there exists a constant $C > 0$ *such that the following estimate holds:*

$$\left|\mathbb{E}\varphi(\boldsymbol{x}^*(\boldsymbol{\xi}), \boldsymbol{\xi}) - \mathbb{E}\varphi(\bar{\boldsymbol{x}}^*(\boldsymbol{\xi}), \boldsymbol{\xi})\right| \le C\,\mathbb{E}\left[\max\{1, \|\boldsymbol{\xi}\|, \|f(\boldsymbol{\xi})\|\}^{m_1} \cdot \|\boldsymbol{\xi} - f(\boldsymbol{\xi})\|\right],$$

where the constant m_1 *is defined by* (10).

Proof. To prove the assertion, we have to estimate the following term:

$$\left|\mathbb{E}\left[\sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \boldsymbol{x}_t^*\left(\boldsymbol{\xi}^t\right)\right\rangle - \sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \bar{\boldsymbol{x}}_t^*\left(\boldsymbol{\xi}^t\right)\right\rangle\right]\right|. \tag{26}$$

Recall that, by Proposition 3.3, $\boldsymbol{x}^*(\boldsymbol{\xi})$ and $\boldsymbol{x}^*(f(\boldsymbol{\xi}))$ produce comparable costs. On the other hand, the difference between $\boldsymbol{x}^*(f(\boldsymbol{\xi}))$ and $\bar{\boldsymbol{x}}^*(\boldsymbol{\xi})$ can be estimated due to the calmness of the latter decision. Thus, we add and subtract the term

$$\mathbb{E}\left[\sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \boldsymbol{x}_t^*\left(f^t\left(\boldsymbol{\xi}^t\right)\right)\right\rangle\right]$$

to the expectation within (26). Using then the triangle inequality as well as Proposition 3.3, we conclude that (26) is not greater than the sum of

$$\left|\mathbb{E}\left[\sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \boldsymbol{x}_t^*\left(f^t\left(\boldsymbol{\xi}^t\right)\right)\right\rangle - \sum_{t=2}^{T}\left\langle b_t(\boldsymbol{\xi}_t), \bar{\boldsymbol{x}}_t^*\left(\boldsymbol{\xi}^t\right)\right\rangle\right]\right| \tag{27}$$

and the right-hand side of (16). It thus remains to estimate (27). By applying identity (23) as well as the calmness property of $\bar{\boldsymbol{x}}^*$ from Proposition 4.1, we obtain the following upper bound:

$$\begin{aligned}
&\mathbb{E}\left[\sum_{t=2}^{T} B\max\left\{1,\left\|\boldsymbol{\xi}^t\right\|\right\}(T-1)M^{T-1}\max\left\{1,\left\|\boldsymbol{\xi}^T\right\|,\left\|f^T\left(\boldsymbol{\xi}^T\right)\right\|\right\}^{T-1}\left\|\boldsymbol{\xi}^T - f^T\left(\boldsymbol{\xi}^T\right)\right\|\right]\\
&\leq (T-1)^2 BM^{T-1}\mathbb{E}\left[\max\left\{1,\left\|\boldsymbol{\xi}^T\right\|,\left\|f^T\left(\boldsymbol{\xi}^T\right)\right\|\right\}^{T}\left\|\boldsymbol{\xi}^T - f^T\left(\boldsymbol{\xi}^T\right)\right\|\right].
\end{aligned}$$

Finally, the sum of the latter term and the right-hand side of (16) is smaller than

$$C\,\mathbb{E}\left[\max\left\{1,\left\|\boldsymbol{\xi}^T\right\|,\left\|f^T\left(\boldsymbol{\xi}^T\right)\right\|\right\}^{m_1}\cdot\left\|\boldsymbol{\xi}^T - f^T\left(\boldsymbol{\xi}^T\right)\right\|\right],$$

with a constant $C \triangleq D + (T-1)^2\, B\, M^{T-1}$. □

5. Stability. In order to address the question of stability, we have to consider the following issue. Although we assume the existence of bounded optimal solutions to the initial problem (2), the perturbed problem may be unbounded. This is illustrated, for the sake of completeness, by Example A.4 in the Appendix. Heitsch, Römisch, and Strugarek [8] avoid such unfavorable cases by their Assumption (A2) of level-boundedness of the objective, *locally around* $\boldsymbol{\xi}$. We proceed by assuming that $\tilde{\boldsymbol{\xi}}$ fulfills Assumption 2.3 too; i.e., the perturbed problem $v(\tilde{\boldsymbol{\xi}})$ admits a bounded optimal solution. We now state our main result.

THEOREM 3. *Suppose Assumptions* 2.1*,* 2.3*, and* 2.6 *are fulfilled. Let* $\tilde{\boldsymbol{\xi}}$ *be an approximation of* $\boldsymbol{\xi}$ *according to Definition* 3.1*, which fulfills Assumption* 2.3*, too, and consider the constant* m_1 *defined by* (10)*.*

Then there exists a constant $\gamma > 0$*, such that*

$$\left|v(\boldsymbol{\xi}) - v\left(\tilde{\boldsymbol{\xi}}\right)\right| \leq \gamma\,\mathbb{E}\left[\max\left\{1,\left\|\boldsymbol{\xi}\right\|,\left\|\tilde{\boldsymbol{\xi}}\right\|\right\}^{m_1}\cdot\left\|\boldsymbol{\xi} - \tilde{\boldsymbol{\xi}}\right\|\right]$$

holds.

Proof. We denote the approximation mapping corresponding to $\tilde{\boldsymbol{\xi}}$ by f and consider a bounded optimal decision $\boldsymbol{x}^* \in \mathcal{S}(\boldsymbol{\xi})$ and the corresponding calm modification $\bar{\boldsymbol{x}}^*$ from section 4.

Applying Theorem 2 yields the following inequality:

$$\begin{aligned}
v\left(\tilde{\boldsymbol{\xi}}\right) - v(\boldsymbol{\xi}) &= v\left(\tilde{\boldsymbol{\xi}}\right) - \mathbb{E}\varphi(\boldsymbol{x}^*(\boldsymbol{\xi}), \boldsymbol{\xi})\\
&\leq v\left(\tilde{\boldsymbol{\xi}}\right) - \mathbb{E}\varphi(\bar{\boldsymbol{x}}^*(\boldsymbol{\xi}), \boldsymbol{\xi}) + C\mathbb{E}\left[\max\left\{1,\left\|\boldsymbol{\xi}\right\|,\left\|\tilde{\boldsymbol{\xi}}\right\|\right\}^{m_1}\cdot\left\|\boldsymbol{\xi} - \tilde{\boldsymbol{\xi}}\right\|\right].
\end{aligned} \tag{28}$$

Since the restriction of $\bar{\boldsymbol{x}}^*$ on $f(\Xi)$ is contained in $\mathcal{S}(\tilde{\boldsymbol{\xi}})$, we can write

$$\begin{aligned} v\left(\tilde{\boldsymbol{\xi}}\right) - \mathbb{E}\varphi(\bar{\boldsymbol{x}}^*(\boldsymbol{\xi}), \boldsymbol{\xi}) \\ &\leq \mathbb{E}\varphi\left(\bar{\boldsymbol{x}}^*\left(\tilde{\boldsymbol{\xi}}\right), \tilde{\boldsymbol{\xi}}\right) - \mathbb{E}\varphi(\bar{\boldsymbol{x}}^*(\boldsymbol{\xi}), \boldsymbol{\xi}) \\ &= \sum_{t=2}^{T} \mathbb{E}\left[\left\langle b_t\left(\tilde{\boldsymbol{\xi}}_t\right) - b_t(\boldsymbol{\xi}_t), \bar{\boldsymbol{x}}_t^*\left(\tilde{\boldsymbol{\xi}}^t\right)\right\rangle + \left\langle b_t(\boldsymbol{\xi_t}), \bar{\boldsymbol{x}}_t^*\left(\tilde{\boldsymbol{\xi}}^t\right) - \bar{\boldsymbol{x}}_t^*\left(\boldsymbol{\xi}^t\right)\right\rangle\right] \\ &\leq B\sum_{t=2}^{T} \mathbb{E}\left[\|\tilde{\boldsymbol{\xi}}_t - \boldsymbol{\xi}_t\| \left\|\bar{\boldsymbol{x}}_t^*\left(\tilde{\boldsymbol{\xi}}^t\right)\right\| + \max\left\{1, \|\boldsymbol{\xi}_t\|\right\} \left\|\bar{\boldsymbol{x}}_t^*\left(\tilde{\boldsymbol{\xi}}^t\right) - \bar{\boldsymbol{x}}_t^*\left(\boldsymbol{\xi}^t\right)\right\|\right]. \end{aligned} \tag{29}$$

Due to the fact that $\bar{\boldsymbol{x}}^*$ and $\boldsymbol{x}^*$ coincide on the set $f(\Xi^T)$, see (23), we obtain that $\bar{\boldsymbol{x}}^*$ fulfills the boundedness condition (5) on $f(\Xi^T)$. Using this boundedness as well as the calmness of $\bar{\boldsymbol{x}}^*$, each of the $T-1$ summands in (29) can be estimated. Thus, (29) is bounded from above by

$$H\mathbb{E}\left[\max\left\{1, \|\boldsymbol{\xi}\|, \|\tilde{\boldsymbol{\xi}}\|\right\}^T \cdot \|\boldsymbol{\xi} - \tilde{\boldsymbol{\xi}}\|\right], \tag{30}$$

with an appropriate constant $H > 0$, and we can use the relation $T \leq m_1$ to obtain

$$v\left(\tilde{\boldsymbol{\xi}}\right) - v(\boldsymbol{\xi}) \leq (C+H)\mathbb{E}\left[\max\left\{1, \|\boldsymbol{\xi}\|, \|\tilde{\boldsymbol{\xi}}\|\right\}^{m_1} \cdot \|\boldsymbol{\xi} - \tilde{\boldsymbol{\xi}}\|\right].$$

Now, we consider a bounded optimal decision $\tilde{\boldsymbol{x}}^*$ of $v(\tilde{\boldsymbol{\xi}})$. Following exactly the construction of section 4, we obtain a decision $\bar{\tilde{\boldsymbol{x}}}^* \in \mathcal{S}(\boldsymbol{\xi})$ that is calm in the sense of Proposition 4.1 and whose restriction on $f(\Xi^T)$ is optimal for $v(\tilde{\boldsymbol{\xi}})$. As in (29), it follows that

$$\begin{aligned} v(\boldsymbol{\xi}) - v\left(\tilde{\boldsymbol{\xi}}\right) &\leq \mathbb{E}\varphi\left(\bar{\tilde{\boldsymbol{x}}}^*(\boldsymbol{\xi}), \boldsymbol{\xi}\right) - \mathbb{E}\varphi\left(\bar{\tilde{\boldsymbol{x}}}^*\left(\tilde{\boldsymbol{\xi}}\right), \tilde{\boldsymbol{\xi}}\right) \\ &\leq B\sum_{t=2}^{T} \mathbb{E}\left[\max\left\{1, \|\boldsymbol{\xi}_t\|\right\} \left\|\bar{\tilde{\boldsymbol{x}}}_t^*\left(\tilde{\boldsymbol{\xi}}^t\right) - \bar{\tilde{\boldsymbol{x}}}_t^*\left(\boldsymbol{\xi}^t\right)\right\| + \|\tilde{\boldsymbol{\xi}}_t - \boldsymbol{\xi_t}\| \left\|\bar{\tilde{\boldsymbol{x}}}_t^*\left(\tilde{\boldsymbol{\xi}}^t\right)\right\|\right] \\ &\leq H\mathbb{E}\left[\max\left\{1, \|\boldsymbol{\xi}^T\|, \left\|\tilde{\boldsymbol{\xi}}^T\right\|\right\}^T \cdot \left\|\boldsymbol{\xi}^T - \tilde{\boldsymbol{\xi}}^T\right\|\right]. \end{aligned}$$

Applying again $T \leq m_1$ and setting $\gamma \triangleq C + H$ completes the proof. □

Remark 5.1. Since the purpose of this paper is to establish a stability result rather than the development of new approximation techniques, we restrict ourselves to refer to existing approaches based on conditional or unconditional clustering, which can be used to control the upper bound on $|v(\boldsymbol{\xi}) - v(\tilde{\boldsymbol{\xi}})|$ from Theorem 3. We mention here the recent approaches of [7], [1], [9], and [14].

Other approximation techniques, e.g., those proposed by [10], [12], are not based on projections of the initial process $\boldsymbol{\xi}$. Consequently, neither the joint distribution of $\boldsymbol{\xi}$ and $\tilde{\boldsymbol{\xi}}$ nor the underlying probability spaces are necessarily specified. However, under some weak regularity conditions our results may be applied to such cases as well. Indeed, one may choose the sample space $(\Xi^T \times \Xi^T, \mathcal{B}(\Xi^T) \otimes \mathcal{B}(\Xi^T), \mathbb{P}^T \otimes \tilde{\mathbb{P}}^T)$ as underlying probability space for both processes and define a nonanticipative coupling mapping $f : \Xi^T \to \Xi^T$ by, e.g., using successive projections. Thereby, $\mathcal{B}(\Xi^T)$ denotes the Borel sets of Ξ^T, and $\tilde{\mathbb{P}}^T$ denotes the distribution of the approximating process $\tilde{\boldsymbol{\xi}}$. Determining such a mapping f is closely related to *L^p-minimal metrics* and to *mass transportation problems*, see also Remark 2.3 of [8].

Appendix. The following lemma provides conditions under which the conditions of Assumption 2.6 hold true.

LEMMA A.1. *Assume the dynamics of the process* $\boldsymbol{\xi}$ *are given by the following scheme:*

$$\boldsymbol{\xi}_{t+1} = g_t\left(\boldsymbol{\xi}^t, \boldsymbol{\varepsilon}_{t+1}\right), \tag{31}$$

where $\boldsymbol{\varepsilon}_{t+1}$ *is a* $\mathbb{R}^n$*-valued random variable that is independent of* $\boldsymbol{\xi}^t$*, and* g_t *are measurable mappings from* $\mathbb{R}^{s\cdot t} \times \mathbb{R}^n$ *to* $\mathbb{R}^s$ *which satisfy the following Lipschitz and linear growth conditions:*

(i) $\|g_t(\xi^t, \varepsilon) - g_t(\hat{\xi}^t, \varepsilon)\| \le \max\{1, \|\xi^t\|, \|\hat{\xi}^t\|\}^r \|\xi^t - \hat{\xi}^t\| \, h(\|\varepsilon\|),$,

(ii) $\|g_t(\xi^t, \varepsilon)\| \le \max\{1, \|\xi^t\|\} \, k(\|\varepsilon\|),$

for all $\varepsilon \in \mathbb{R}^n$ *and* $\xi^t, \hat{\xi}^t \in \mathbb{R}^{s\cdot t}$*, some constant* $r \ge 1$ *and Borel-measurable mappings* $h, k \ge 1$*, such that* $h(\|\boldsymbol{\varepsilon}_{t+1}\|)$ *and* $k(\|\boldsymbol{\varepsilon}_{t+1}\|)$ *are in* L^p *for every* $p \in [1, +\infty)$*. Then* $\boldsymbol{\xi}$ *fulfills both conditions of Assumption* 2.6 *with the constants*

$$K \triangleq \mathbb{E}\left[k(\|\boldsymbol{\varepsilon}_{t+1}\|)^{m_1} h(\|\boldsymbol{\varepsilon}_{t+1}\|)\right] \quad \textit{and} \quad W \triangleq \mathbb{E}\left[\prod_{i=t+1}^{T} k(\|\boldsymbol{\varepsilon}_i\|)^{1+T-t}\right].$$

Proof. Consider $f \in \mathbb{F}_{1+m_{t+1}}(\Xi^{t+1})$. Then we obtain

$$\begin{aligned}
&\left|\mathbb{E}\left[f\left(\boldsymbol{\xi}^{t+1}\right) \middle| \boldsymbol{\xi}^t = \xi^t\right] - \mathbb{E}\left[f\left(\boldsymbol{\xi}^{t+1}\right) \middle| \boldsymbol{\xi}^t = \hat{\xi}^t\right]\right| \\
&= \left|\mathbb{E}\left[f\left(g_t\left(\xi^t, \boldsymbol{\varepsilon}_{t+1}\right)\right)\right] - \mathbb{E}\left[f\big(g_t\big(\hat{\xi}^t, \boldsymbol{\varepsilon}_{t+1}\big)\big)\right]\right| \\
&\le \mathbb{E}\left[\max\left\{1, \left\|g_t\left(\xi^t, \boldsymbol{\varepsilon}_{t+1}\right)\right\|, \left\|g_t\big(\hat{\xi}^t, \boldsymbol{\varepsilon}_{t+1}\big)\right\|\right\}^{m_{t+1}} \left\|g_t\big(\xi^t, \boldsymbol{\varepsilon}_{t+1}\big) - g_t\big(\hat{\xi}^t, \boldsymbol{\varepsilon}_{t+1}\big)\right\|\right] \\
&\le \mathbb{E}\left[\max\left\{1, \left\|g_t\left(\xi^t, \boldsymbol{\varepsilon}_{t+1}\right)\right\|, \left\|g_t\big(\hat{\xi}^t, \boldsymbol{\varepsilon}_{t+1}\big)\right\|\right\}^{m_{t+1}} h(\|\boldsymbol{\varepsilon}_{t+1}\|)\right] \\
&\quad \cdot \max\left\{1, \|\xi^t\|, \|\hat{\xi}^t\|\right\}^r \|\xi^t - \hat{\xi}^t\| \\
&\le \mathbb{E}\left[\max\left\{1, \|\xi^t\|, \|\hat{\xi}^t\|\right\}^{m_{t+1}} k(\|\boldsymbol{\varepsilon}_{t+1}\|)^{m_{t+1}} h(\|\boldsymbol{\varepsilon}_{t+1}\|)\right] \max\left\{1, \|\xi^t\|, \|\hat{\xi}^t\|\right\}^r \|\xi^t - \hat{\xi}^t\| \\
&= \mathbb{E}\left[k(\|\boldsymbol{\varepsilon}_{t+1}\|)^{m_{t+1}} h(\|\boldsymbol{\varepsilon}_{t+1}\|)\right] \cdot \max\left\{1, \|\xi^t\|, \|\hat{\xi}^t\|\right\}^{r+m_{t+1}} \|\xi^t - \hat{\xi}^t\|.
\end{aligned}$$

Due to the identity $r + m_{t+1} = m_t - 1$, this entails condition (i) of Assumption 2.6. The asserted form of K follows from $m_1 \ge m_t$ for $t = 1, \ldots, T$.

Furthermore, we apply (31) recursively to obtain the following estimate:

$$\left\|\boldsymbol{\xi}^T\right\| \le \max\left\{1, \left\|\boldsymbol{\xi}^t\right\|\right\} \prod_{i=t+1}^{T} k(\|\boldsymbol{\varepsilon}_i\|),$$

Raising both sides to the power of $1 + (T - t)$ and taking conditional expectations, $\mathbb{E}[\ \cdot\ |\boldsymbol{\xi}^t = \xi^t]$ verifies condition (ii) of Assumption 2.6. □

The conditions of Lemma A.1 are fulfilled, e.g., by a variety of time-series models. We provide the following simple example.

Example A.2. Let $\boldsymbol{\xi}$ be a GARCH process defined by the following difference equations:

$$\begin{aligned}
&\boldsymbol{\xi}_t = (\boldsymbol{w}_t, \boldsymbol{v}_t, \boldsymbol{\varepsilon}_t) \text{ with} \\
&\boldsymbol{v}_{t+1} \triangleq \sum_{i=0}^{s} (\beta_i v_{t-i} + \gamma_i \boldsymbol{\varepsilon}_{t-i}) \quad \text{and} \quad \boldsymbol{w}_{t+1} \triangleq \sum_{i=0}^{s} \alpha_i \boldsymbol{w}_{t-i} + \boldsymbol{v}_{t+1} \cdot \boldsymbol{\varepsilon}_{t+1}
\end{aligned}$$

for certain parameters $\alpha_i, \beta_i, \gamma_i \in \mathbb{R}$. Thereby, $\boldsymbol{v}$ represents the stochastic volatility process of $\boldsymbol{w}$ and $(\boldsymbol{\varepsilon}_t)_{t\geq 0}$ is a sequence of i.i.d. random variables, following a standard normal distribution. It is easy to see that $\boldsymbol{\xi}$ fulfills the conditions of Lemma A.1 with $r = 1$ and $h(\cdot), k(\cdot)$ being affine functions.

The following example shows that nonanticipativity with respect to the initial process is indispensable for an approximating process.

Example A.3. Consider $T = 3$ and the process $\boldsymbol{\xi}$ that is given by $\boldsymbol{\xi}_1 \equiv 0$ and the two independent random variables $\boldsymbol{\xi}_2$ and $\boldsymbol{\xi}_3$, both uniformly distributed on $[0, 1]$. For $n \in \mathbb{N}$ and $0 < \varepsilon < 1$ we introduce the grids $A^{(n)} \triangleq \{\frac{i}{n} : i = 1, \dots, n\}$ and the associated (right-continuous) projections $\pi_{A^{(n)}} : [0, 1] \to A^{(n)}$, defined by

$$\pi_{A^{(n)}}(z) \triangleq \max\left\{\frac{i}{n} \in A^{(n)} : \left|z - \frac{i}{n}\right| \leq \left|z - \frac{j}{n}\right| \text{ for all } \frac{j}{n} \in A^{(n)}\right\}.$$

Furthermore, we define processes $\boldsymbol{\xi}^{(n)}, n \in \mathbb{N}$, given by $\boldsymbol{\xi}_1^{(n)} \equiv 0$, $\boldsymbol{\xi}_3^{(n)} \triangleq \pi_{A^{(n)}}\boldsymbol{\xi}_3$, and

$$\boldsymbol{\xi}_2^{(n)} \triangleq \begin{cases} \pi_{A^{(n)}}\boldsymbol{\xi}_2 & \text{if } \boldsymbol{\xi}_3 \leq 1/2, \\ (\pi_{A^{(n)}}\boldsymbol{\xi}_2) + \frac{\varepsilon}{n} & \text{if } \boldsymbol{\xi}_3 > 1/2. \end{cases}$$

We remark that by observing $\boldsymbol{\xi}_2^{(n)}$ one knows whether $\boldsymbol{\xi}_3 > 1/2$ or not. Furthermore, the sequence $\boldsymbol{\xi}^{(n)}$ can be seen as an approximation of $\boldsymbol{\xi}$, since $\mathbb{E}[\|\boldsymbol{\xi} - \boldsymbol{\xi}^{(n)}\|] \leq \frac{1+2\varepsilon}{2n}$ holds.

We consider the following optimization problem

$$v(\boldsymbol{\xi}) \triangleq \min\left\{\mathbb{E}\left[\boldsymbol{x}_2 \cdot \boldsymbol{\xi}_2 + \boldsymbol{x}_3 \cdot \boldsymbol{\xi}_3\right] : \ \boldsymbol{x}_t \geq 0,\, \boldsymbol{x}_t \in \sigma(\boldsymbol{\xi}^t),\, t = 2, 3,\, \boldsymbol{x}_2 + \boldsymbol{x}_3 = 1 \text{ a.s.}\right\},$$

which is solved by $\boldsymbol{x}_2^* = \mathbb{1}_{\{\boldsymbol{\xi}_2 \leq 1/2\}}$ and $\boldsymbol{x}_3^* = 1 - \boldsymbol{x}_2^*$ with optimal value $v(\boldsymbol{\xi}) = 12/32$. When replacing $\boldsymbol{\xi}$ by $\boldsymbol{\xi}^{(n)}$, we use the decisions

$$\boldsymbol{x}_2^{(n)} = \mathbb{1}_{\{\boldsymbol{\xi}_2^{(n)} \leq 1/4\}} + \mathbb{1}_{\{\boldsymbol{\xi}_2^{(n)} \in\,]1/4,\, 3/4[\, \setminus A^{(n)}\}} \quad \text{and} \quad \boldsymbol{x}_3^{(n)} = 1 - \boldsymbol{x}_2^{(n)}$$

to obtain $\limsup_{n\to\infty} v(\boldsymbol{\xi}^{(n)}) \leq 11/32$. Obviously, convergence of $v(\boldsymbol{\xi}^{(n)})$ to $v(\boldsymbol{\xi})$ does not hold since the processes $\boldsymbol{\xi}^{(n)}$ do not fulfill the nonanticipativity condition (i) of Definition 3.1. With regard to the results of [8] and [12], convergence fails since the conditional distributions

$$\mathbb{P}[\boldsymbol{\xi}_3^{(n)} \in \cdot\, | \boldsymbol{\xi}_2^{(n)} = z]$$

do not converge toward $\mathbb{P}[\boldsymbol{\xi}_3 \in \cdot\, | \boldsymbol{\xi}_2 = z]$, and the filtration distance between $\boldsymbol{\xi}^{(n)}$ and $\boldsymbol{\xi}$ does not converge toward 0, respectively.

The following example shows that the perturbed problem $v(\tilde{\boldsymbol{\xi}})$ may be unbounded, even if the initial problem $v(\boldsymbol{\xi})$ admits a bounded optimal solution.

Example A.4. Consider some $\varepsilon \in (0, \frac{1}{4})$, $T = 2$, and the *stock prices* $\boldsymbol{\xi}_1 \equiv \frac{1}{2} + \varepsilon$ and $\boldsymbol{\xi}_2$, where the latter is uniformly distributed on $[0, 1]$. The optimal investment problem $v(\boldsymbol{\xi}) = \min_{x\geq 0}\, x \cdot \boldsymbol{\xi}_1 - \mathbb{E}[x \cdot \boldsymbol{\xi}_2] = \min_{x\geq 0} x \cdot \varepsilon$ is solved by $x = 0$. The process $\tilde{\boldsymbol{\xi}}$, defined by $\tilde{\boldsymbol{\xi}}_1 \triangleq \boldsymbol{\xi}_1$ and

$$\tilde{\boldsymbol{\xi}}_2 \triangleq \begin{cases} 1 & \text{if } \boldsymbol{\xi}_2 \geq \frac{1}{2} - 2\,\varepsilon, \\ 0 & \text{else} \end{cases},$$

is an approximation of $\boldsymbol{\xi}$ according to Definition 3.1. However, we see that $\mathbb{E}[\tilde{\boldsymbol{\xi}}_2] = \frac{1}{2} + 2\,\varepsilon$ and, consequently, $v(\tilde{\boldsymbol{\xi}}) = \min_{x\geq 0} -x \cdot \varepsilon = -\infty$.

Acknowledgments. The author is grateful to Professor Werner Römisch for his help and encouragement, to Stefan Vigerske for being perpetually willing for helpful discussions, and to Thomas Surowiec for proofreading the manuscript. The author also would like to thank the anonymous referees whose careful comments helped to clarify the presentation.

CONVERGENCE OF A CLASS OF SEMI-IMPLICIT TIME-STEPPING SCHEMES FOR NONSMOOTH RIGID MULTIBODY DYNAMICS*

BOGDAN I. GAVREA†, MIHAI ANITESCU‡, AND FLORIAN A. POTRA§

Abstract. In this work we present a framework for the convergence analysis in a measure differential inclusion sense of a class of time-stepping schemes for multibody dynamics with contacts, joints, and friction. This class of methods solves one linear complementarity problem per step and contains the semi-implicit Euler method, as well as trapezoidal-like methods for which second-order convergence was recently proved under certain conditions. By using the concept of a reduced friction cone, the analysis includes, for the first time, a convergence result for the case that includes joints. An unexpected intermediary result is that we are able to define a discrete velocity function of bounded variation, although the natural discrete velocity function produced by our algorithm may have unbounded variation.

Key words. rigid body, contact dynamics, friction, measure differential inclusion, complementarity problems

1. Introduction.

The dynamic rigid multibody contact problem is concerned with predicting the motion of several rigid bodies in contact, and it is one of the fundamental paradigms in modern computational science. It appears in the description of fuel motion in the pebble bed reactor [21], in the compaction of nanopowders [27, 9], and in the study of biological membranes [41, 26, 52, 22]. Such simulations are also used extensively in structural engineering [16], pedestrian evacuation dynamics [24], granular matter [40], robotics simulation and design [17], and virtual reality [1].

The problem of multibody rigid systems involving contact and friction is a *differential complementarity problem* (DCP). The DCP is part of a broader class of problems known as *differential variational inequalities*, which were recently intro-

duced in [36, 37]. Approaches used in the past for the numerical approximation of rigid multibody dynamics with contact and friction include piecewise DAE approaches [23], nonsmooth contact dynamics method [31, 25, 40, 11, 10], acceleration-force linear complementarity problem (LCP) approaches [8, 38, 50, 18, 19], penalty approaches [15, 43, 44, 35], and velocity-impulse LCP-based time-stepping methods [45, 48, 4, 3].

The DCP gives rise to event-driven time-stepping schemes that are solved in an acceleration-force framework. These types of schemes will detect the discontinuity events; and, if these events are isolated, they will treat the dynamics as differential algebraic equations (DAEs) on each smooth piece. For the corresponding DAEs, numerical schemes of high accuracy may be used. This approach is natural and appealing because it leads to high-order time-stepping schemes. The major weakness of such an approach is that it excludes the presence of impulsive forces in the absence of an impact. One fairly simple example where such forces occur was pointed out in 1895 by Painlevé [34], who argued that the equations of classical rigid body dynamics are incompatible with the Coulomb friction model. Recently it was shown that a solution of Painlevé's example exists in the sense of *measure differential inclusions* (MDIs) [46].

Time-stepping schemes that are not vulnerable to Painlevé-type examples integrate the dynamics at a velocity-impulse level, thereby allowing for impulsive forces at any time instant. Most of the time-stepping schemes that build a discrete model at a velocity-impulse level are based on Euler's method for solving ordinary differential equations (ODEs). In this context, the methods of Anitescu and Potra [4] and Stewart and Trinkle [45] are based on a semi-implicit Euler scheme, while the model of [5] is based on a linearly implicit Euler scheme. All three formulations require the solution of one LCP at each time step (see [14] for an extensive analysis of LCPs).

Recently, we proposed a new time-stepping scheme based on the trapezoidal method for solving ODEs [39]. The scheme solves one LCP at each noncollisional integration step. We have shown that the numerical velocity is uniformly bounded as the integration step approaches zero, and that the scheme has global second-order convergence under additional restrictions. In order to globally achieve this convergence, events such as collision, take-off (contact deletion), and stick-slip transitions have to be detected with sufficient accuracy. To do so, we have proposed detection strategies that use information only at the position-velocity level, thereby remaining consistent with the solution concept of MDIs. We have demonstrated that the scheme behaves well (its energy stays bounded for arbitrary large stiffness parameters) for stiffness introduced by springs and dampers attached to pairs of bodies in the system. The scheme was implemented in the simulation framework UMBRA [20] and has proved successful in industrial-scale applications.

1.1. Our contribution. The treatment of joints in time-stepping schemes is not new [4, 2]. What is novel in this work is that we prove that the solution produced by a class of time-stepping schemes that solves one LCP per step and that includes the methods presented in [4] and [39] converges to a solution of an MDI, in a sense to be defined in section 6, *even when joint constraints are present.* The main conceptual novelty is the reduced friction cone which allows us to reduce the treatment of bilateral constraints to one of unilateral constraints, without altering the pointedness property. It is conceivable that a proof of the convergence of linearized backward Euler schemes can be obtained from the one in the jointless case [47] for configurations with joints if the system is represented in coordinates which eliminate the joint constraints [23]. Nonetheless, from a practical perspective, this is inadvisable for the following reasons:

- The representation of the system using only independent coordinates can rarely be done explicitly, and a difficult nonlinear system needs to be solved at each time step [23, section 7.2]
- The equations governing the dynamics of the system where joints are (locally) eliminated by the use of independent coordinates involve second-order derivatives of the joint functions [7, section 9.2.1] which may be costly to obtain.

We note that the same reasons have prompted the search for methods that are specific to differential algebraic, as opposed to ordinary differential, equations [7].

In addition, we prove for the first time that certain trapezoidal-like methods [39] converge in the sense of MDIs. In doing that, we are able to define a discrete velocity function of bounded variation, although the natural discrete velocity function produced by our algorithm may have unbounded variation. Here, the *natural discrete velocity function* is defined as the unweighted discrete velocity obtained by the algorithm in section 4 (see (4.11) for the exact definition).

2. Notation and model. In our analysis, we use the notation and framework from [47, 4]. We assume that the state of the system of rigid bodies can be described by a generalized position vector $q \in \mathbb{R}^s$ and a generalized velocity vector $v \in \mathbb{R}^s$. We assume that the system is subject to equality, nonpenetration, contact, and Coulomb friction.

The *equality constraints* that we consider in this work are described by equations

$$\begin{aligned} \Theta^{(i)}(q) &= 0, \quad i = 1, 2, \ldots, m_J, \\ \nu^{(i)}(q)^T v &= 0, \quad i = m_J + 1, m_J + 2, \ldots, m, \end{aligned} \tag{2.1}$$

where $\Theta^{(i)}$, $i = 1, 2, \ldots, m_J$ and $\nu^{(i)}(q)$, $i = m_J + 1, m_J + 2, \ldots, m$ are sufficiently smooth functions. The first m_J equality constraints are holonomic and usually originate from the transcription of joint constraints [23], whereas the last $m - m_J$ constraints are Pfaffian constraints [32]. A holonomic constraint can be represented as a Pfaffian constraint, but the reverse is not necessarily true [32].

The force exerted by constraint (i), $i = 1, 2, \ldots, m_J$ on the system is $c_\nu^{(i)} \nu^{(i)}(q)$, where $\nu^{(i)}(q) = \nabla_q \Theta^{(i)}(q)$ is the gradient of $\Theta^{(i)}(q)$ and $c_\nu^{(i)}$ is the appropriate Lagrange multiplier [23]. To simplify our discussion we may refer to the constraints (2.1) as joint constraints, even if only the first m_J are technically such constraints.

The *nonpenetration constraints* are generated by the rigid body hypothesis according to which the bodies constituting the system cannot penetrate each other. We assume that, for any pair of bodies, we can define a signed distance function $\Phi^{(j)}(q)$ so that the noninterpenetration constraints can be written as

$$\Phi^{(j)}(q) \geq 0, \quad j = 1, 2, \ldots, p\,, \tag{2.2}$$

where p is the number of pairs of bodies of the system that could get in contact, which in most applications is substantially smaller than the number of all possible pairs of bodies. Details of how the functions $\Phi^{(j)}$ can be defined and calculated are presented in [1].

The contact and frictional constraints may be introduced by means of the active set and the friction cone. If $\Phi^{(j)}(q) > 0$, then the jth constraint doesn't contribute to the dynamics of the system. When $\Phi^{(j)}(q) = 0$, however, the contact impulse generated by the jth noninterpenetration constraint must lie inside the *contact friction*

cone:

$$FC^{(j)}(q) = \left\{ z_c = n^{(j)} {c_n}^{(j)} + \overline{D}^{(j)} \beta^{(j)} \,\middle|\, {c_n}^{(j)} \geq 0,\ \|\beta^{(j)}\|_2 \leq \mu^{(j)} c_n^{(j)} \right\}, \tag{2.3}$$

where we used the simplified notation $n^{(j)} := n^{(j)}(q) = \nabla_q \Phi^{(j)}(q)$ and $\overline{D}^{(j)} := \overline{D}^{(j)}(q)$. Here the columns of $\overline{D}^{(j)} \in \mathbb{R}^{s\times 2}$ span the friction space, and $\beta^{(j)} \in \mathbb{R}^2$ is the corresponding tangential impulse due to friction. The parameter $\mu^{(j)} \geq 0$, which may be different for each contact, is the friction coefficient, and the second inequality that involves it in (2.3) is the first part of the Coulomb law. By including the joint forces in the above multivalued map, we obtain what we call the *constraint friction cone* $\mathcal{FC}^{(j)}(q)$ corresponding to the jth contact. More precisely, we have

$$\mathcal{FC}^{(j)}(q) = \left\{ z = \widetilde{\nu}\widetilde{c}_\nu + n^{(j)} {c_n}^{(j)} + \overline{D}^{(j)} \beta^{(j)} \,\middle|\, {c_n}^{(j)} \geq 0,\ \|\beta^{(j)}\|_2 \leq \mu^{(j)} c_n^{(j)} \right\}, \tag{2.4}$$

where

$$\widetilde{\nu} = \left[\nu^{(1)}, \nu^{(2)}, \ldots, \nu^{(m)} \right], \quad \widetilde{c}_\nu = \left[c_\nu^{(1)}, c_\nu^{(2)}, \ldots, c_\nu^{(m)} \right], \tag{2.5}$$

with $\nu^{(i)} := \nu^{(i)}(q)$. Here we have used $[\cdot, \cdot, \ldots, \cdot]$ to denote a block matrix with the same number of rows as its blocks and $\lceil \cdot, \cdot, \ldots, \cdot \rfloor$ to denote a block matrix with the same number of columns as its blocks. The total friction cones are then defined by

$$FC(q) = \sum_{\Phi^{(j)}(q)=0} FC^{(j)}(q) \tag{2.6}$$

for the *total contact friction cone* and by

$$\mathcal{FC}(q) = \sum_{\Phi^{(j)}(q)=0} \mathcal{FC}^{(j)}(q) \tag{2.7}$$

for the *total constraint friction cone*. To simplify terminology, we will refer, unless specified in advance, to the cone in (2.7) as the *total friction cone*. Note that the definition above implies that the set of active contact constraints $\mathcal{A}$ is determined by

$$\mathcal{A} = \left\{ j \in \{1, \ldots, p\} \ :\ \Phi^{(j)}(q) = 0 \right\}$$

for given position q. The total friction cone can be approximated by a polyhedral cone [45]. That is, $\mathcal{FC}^{(j)}(q)$ is replaced by

$$\widehat{\mathcal{FC}}^{(j)}(q) = \left\{ z = \widetilde{\nu}\widetilde{c}_\nu + n^{(j)} {c_n}^{(j)} + D^{(j)} \beta^{(j)} \,\middle|\, {c_n}^{(j)} \geq 0,\ \beta^{(j)} \geq 0,\ \|\beta^{(j)}\|_1 \leq \mu^{(j)} c_n^{(j)} \right\}, \tag{2.8}$$

where $D^{(j)} := D^{(j)}(q) \in R^{s\times m_C}$ is a balanced matrix in the sense that if ${d_i}^{(j)}$ is a column of $D^{(j)}$, then there is another index k such that ${d_i}^{(j)} = -{d_k}^{(j)}$. In this way we can represent the frictional impulses by using a nonnegative vector of multipliers $\beta^{(j)} = (\beta^{(j)})_i \geq 0$, with the 2-norm being replaced by the 1-norm. Here the nonnegative integer m_C represents the number of edges used in the approximation of the full cone. The polyhedral approximation of the friction cone is then given by

$$\widehat{\mathcal{FC}}(q) = \sum_{j\in\mathcal{A}} \widehat{\mathcal{FC}}^{(j)}(q) = \left\{ z = \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{D}\widetilde{\beta} \,\middle|\, \widetilde{c}_n \geq 0,\ \widetilde{\beta} \geq 0,\ \|\beta^{(j)}\|_1 \leq \mu^{(j)} c_n^{(j)}\ \forall j \in \mathcal{A} \right\}, \tag{2.9}$$

where the block matrices $\widetilde{n}$, $\widetilde{c}_n$, $\widetilde{D}$, and $\widetilde{\beta}$ are defined by

$$\begin{aligned} \widetilde{n} &= \left[n^{(j_1)}, n^{(j_1)}, \ldots, n^{(j_a)}\right], \qquad \widetilde{c}_n = \left[c_n^{(j_1)}, c_n^{(j_2)}, \ldots, c_n^{(j_a)}\right], \\ \widetilde{D} &= \left[D^{(j_1)}, D^{(j_2)}, \ldots, D^{(j_a)}\right], \quad \widetilde{\beta} = \left[\beta^{(j_1)}, \beta^{(j_2)}, \ldots, \beta^{(j_a)}\right] \end{aligned} \tag{2.10}$$

for an active set $\mathcal{A} = \{j_1, j_2, \ldots, j_a\}$.

3. Total friction cone and regularity assumptions. A regularity assumption, the pointedness of the friction cone, is used to obtain convergence results in the contact-only case [6, 47]. We present here an extension of the pointedness assumption to the case including bilateral constraints.

DEFINITION 3.1. *We say that*

(3.1)
$$\begin{aligned} &\mathcal{FC}(q) \text{ is } \textbf{pointed} \Leftrightarrow \forall \left(\tilde{c}_\nu, \tilde{c}_n \geq 0, \tilde{\beta}\right) \neq 0 \text{ such that } \left\|\beta^{(j)}\right\|_2 \leq \mu^{(j)} c_n^{(j)} \ \forall j \in \mathcal{A} \\ &\qquad \text{we must have that } \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{\widetilde{D}}\widetilde{\beta} \neq 0. \end{aligned}$$

(3.2)
$$\begin{aligned} &\widehat{\mathcal{FC}}(q) \text{ is } \textbf{pointed} \Leftrightarrow \forall \left(\widetilde{c}_\nu, \widetilde{c}_n \geq 0, \widetilde{\beta} \geq 0\right) \neq 0 \text{ such that } \left\|\beta^{(j)}\right\|_1 \leq \mu^{(j)} c_n^{(j)} \ \forall j \in \mathcal{A} \\ &\qquad \text{we must have that } \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{D}\widetilde{\beta} \neq 0. \end{aligned}$$

This definition clearly implies that the joint-constraint matrix $\widetilde{\nu}$ is of full rank. Moreover, the pointed friction cone assumption is weaker than the linear independence of the columns of the matrix $(\widetilde{\nu}^T,\ \widetilde{n}^T,\ \widetilde{D}^T)^T$. Its name originates in the fact that, when there are no joint constraints, the condition is equivalent to the cone's not containing any proper linear subspace and thus being "pointed." An equivalent definition of the pointed friction cone assumption is given by the following condition [6]:

$$\begin{aligned} &\mathcal{FC}(q) \text{ is pointed} \Leftrightarrow \text{there exists } c_{\mathcal{FC}} > 0, \text{ such that } \left\|\left(\widetilde{c}_\nu, \widetilde{c}_n, \widetilde{\beta}\right)\right\| \leq c_{\mathcal{FC}}\|z\| \\ &\qquad \text{with } z = \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{\widetilde{D}}\widetilde{\beta} \in \mathcal{FC}(q). \end{aligned} \tag{3.3}$$

$$\begin{aligned} &\widehat{\mathcal{FC}}(q) \text{ is pointed} \Leftrightarrow \text{there exists } c_{\widehat{\mathcal{FC}}} > 0, \text{ such that } \left\|\left(\widetilde{c}_\nu, \widetilde{c}_n, \widetilde{\beta}\right)\right\| \leq c_{\widehat{\mathcal{FC}}}\|z\| \\ &\qquad \text{with } z = \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{\widetilde{D}}\widetilde{\beta} \in \widehat{\mathcal{FC}}(q). \end{aligned} \tag{3.4}$$

We say that the total friction cone $\mathcal{FC}(q)$ ($\widehat{\mathcal{FC}}(q)$) is **uniformly pointed** if the constant $c_{\mathcal{FC}}$ ($c_{\widehat{\mathcal{FC}}}$) can be taken the same for all possible configurations q. As noted in [2], the pointedness assumption is equivalent (in the frictionless case) to the existence of a force that will dissasemble all contacts without breaking the joints.

LEMMA 3.2. *Assume that $\mathcal{FC}(q)$ is pointed. Let*

$$z = \widetilde{n}\widetilde{c}_n + \widetilde{\widetilde{D}}\widetilde{\beta}, \ \text{ where } \ \widetilde{c}_n \geq 0, \ \widetilde{c}_n \neq 0, \ \ \left\|\beta^{(j)}\right\|_2 \leq \mu^{(j)} c_n^{(j)} \ \forall j \in \mathcal{A}.$$

That is, z is an element of the (full) friction cone obtained by excluding the bilateral constraints, with the normal impulses not all equal to 0. *Then,*

$$z \neq 0 \ \text{ and } \ z \notin \text{Range}(\widetilde{\nu}).$$

Proof. As suggested by the claim above, consider the set

$$FC(q) = \left\{ z_c = \widetilde{n}\widetilde{c}_n + \widetilde{\widetilde{D}}\widetilde{\beta} \,\middle|\, \widetilde{c}_n \geq 0, \ \left\|\beta^{(j)}\right\|_2 \leq \mu^{(j)} c_n^{(j)} \ \forall j \in \mathcal{A} \right\} \tag{3.5}$$

(note the difference in notation: caligraphic characters denote the friction cone that includes all constraint impulses, while roman letters denote the cone that containins only the contact impulses). Clearly the pointedness of $\mathcal{FC}(q)$ implies the pointedness of $FC(q)$. Therefore, by taking $z \in FC(q)$ with the normal impulses not all zero ($\widetilde{c}_n \neq 0$), we obtain $z \neq 0$. If $z \in \text{Range}(\widetilde{\nu})$, then $z = \widetilde{\nu}u$, $u \neq 0$, and therefore by taking $\overline{z} = -\widetilde{\nu}u + z$, we have $\overline{z} \in \mathcal{FC}(q)$, $\overline{z} = 0$ with a nonzero constraint impulse, a contradiction to the pointedness of $\mathcal{FC}(q)$. ∎

We will use this lemma to analyze the properties of the set

$$\widetilde{\nu}_\perp^T \mathcal{FC}(q) = \left\{ \widetilde{\nu}_\perp^T z \ : \ z \in \mathcal{FC}(q) \right\}.$$

Here $\widetilde{\nu}_\perp$ denotes the orthogonal complement of $\widetilde{\nu} \in \mathbb{R}^{s\times m}$. More precisely, $\widetilde{\nu}_\perp \in \mathbb{R}^{s\times(s-m)}$ such that $\widetilde{\nu}_\perp^T \widetilde{\nu} = 0$ and $\widetilde{\nu}_\perp^T \widetilde{\nu}_\perp = I$. It follows that, for any $x \in \mathbb{R}^s$, there exist unique vectors $u \in \mathbb{R}^m$ and $w \in \mathbb{R}^{s-m}$ such that the decomposition

$$x = \widetilde{\nu}u + \widetilde{\nu}_\perp w \tag{3.6}$$

holds. We have the following simple results.

LEMMA 3.3. *Assume that $\mathcal{FC}(q)$ is pointed. Then for all $j \in \mathcal{A}$, we have*

$$\widetilde{\nu}_\perp^T n^{(j)} \neq 0.$$

Proof. The proof follows immediately from Lemma 3.2. More precisely, assume that $\widetilde{\nu}_\perp^T n^{(j)} = 0$ for some $j \in \mathcal{A}$. Take $z = c_n^{(j)} n^{(j)}$, with ${c_n}^{(j)} > 0$ (note that $n^{(j)} \neq 0$). It follows that $\widetilde{\nu}_\perp^T z = 0$. Therefore, by the decomposition above, we must have $z \in \text{Range}(\widetilde{\nu})$, which contradicts the conclusion of Lemma 3.2. ∎

Remark 3.4. *We cannot say the same thing about $\widetilde{\nu}_\perp^T {\overline{d}_i}^{(j)}$, where ${\overline{d}_i}^{(j)}$ is a column of $\overline{D}^{(j)}$. Actually it is possible to have $\widetilde{\nu}_\perp^T {\overline{d}_i}^{(j)} = 0$, which shows once again that the pointedness assumption is weaker than the linear independence of the active set (active set here includes all constraints).*

Let us define

$${W_n}^{(j)} = \widetilde{\nu}_\perp^T n^{(j)} \ \text{ and } \ {\overline{W}_D}^{(j)} = \widetilde{\nu}_\perp^T \overline{D}^{(j)}.$$

As discussed above, all of the ${W_n}^{(j)}$ are nonzero vectors; thus, by adjoining all of them, we obtain a matrix that we denote by $\widetilde{W}_n$. By taking only those ${\overline{W}_D}^{(j)}$ that are nonzero and adjoining we obtain, in a similar fashion, a matrix denoted by $\widetilde{\overline{W}}_D$. Now let us define the *full reduced friction cone* $FC_r(q)$ by

$$\begin{aligned} FC_r(q) = \Big\{ z_r = \widetilde{W}_n \widetilde{\overline{c}}_n + \widetilde{\overline{W}}_D \widetilde{\overline{\beta}} \Big| \widetilde{\overline{c}}_n \geq 0, \ \left\| \overline{\beta}^{(j)} \right\|_2 \\ \leq \mu^{(j)} \overline{c}_n^{(j)}, \ \Big[\forall j \in \mathcal{A} \ \text{ such that (s.t.) } \ \left(\widetilde{\nu}_\perp(q)\right)^T \overline{D}^{(j)}(q) \neq 0 \Big] \Big\}, \end{aligned} \tag{3.7}$$

where the matrix $\widetilde{\overline{W}}_D$ is assumed to have only nonzero columns. In a similar fashion we introduce the *polyhedral reduced friction cone* $\widehat{FC}_r(q)$:

$$\begin{aligned} \widehat{FC}_r(q) = \Big\{ z_r = \widetilde{W}_n \widetilde{\overline{c}}_n + \widetilde{W}_D \widetilde{\overline{\beta}} \Big| \widetilde{\overline{c}}_n \geq 0, \ \widetilde{\overline{\beta}} \geq 0, \ \left\| \overline{\beta}^{(j)} \right\|_1 \\ \leq \mu^{(j)} \overline{c}_n^{(j)}, \ \Big[\forall j \in \mathcal{A} \text{ s.t. } \left(\widetilde{\nu}_\perp(q)\right)^T D^{(j)}(q) \neq 0 \Big] \Big\}. \end{aligned} \tag{3.8}$$

The active set used for the reduced friction cone is the same as the one used for the nonreduced one. However, the number of frictional contacts in the reduced cone may be smaller than the number in the nonreduced cone. We have the following result.

LEMMA 3.5. *If $\mathcal{FC}(q)$ ($\widehat{\mathcal{FC}}(q)$) is pointed for all q, then the full (polyhedral) reduced friction cone $FC_r(q)$ ($\widehat{FC}_r(q)$) is pointed for all q. Here the pointedness of $FC_r(q)$ ($\widehat{FC}_r(q)$) is to be understood in the sense of Definition* 3.1 *where the joint constraints are omitted. This is the same with applying this definition to the representations* (3.7) *and* (3.8).

Proof. Let q be any possible system configuration, and let z_r be an arbitrary element of $FC_r(q)$. Then z_r can be written as

$$z_r = \widetilde{\nu}_\perp^T \widetilde{n}\widetilde{c}_n + \widetilde{\nu}_\perp^T \widetilde{\overline{D}}\widetilde{\beta},$$

where we have already eliminated those columns of $\widetilde{\overline{D}}$ that are in the range of $\widetilde{\nu}$. This new matrix is denoted by $\widetilde{\overline{\overline{D}}}$, and the corresponding frictional impulses are given by the vector $\widetilde{\overline{\beta}}$. Note that, as shown above, all of the columns of $\widetilde{n}$ have nonzero components outside the range of $\widetilde{\nu}$. The normal and tangential impulses $(\widetilde{c}_n, \widetilde{\overline{\beta}})$ satisfy $c_n^{(j)} \geq 0$ for all $j \in \mathcal{A}$ and $\|\overline{\beta}^{(j)}\|_2 \leq \mu^{(j)} c_n^{(j)}$ for all $j \in \mathcal{A}$ such that $(\widetilde{\nu}_\perp(q))^T \overline{D}^{(j)}(q) \neq 0$.

Assume now that $z_r = 0$, with $\widetilde{c}_n \neq 0$ (a necessary condition for $(\widetilde{c}_n, \widetilde{\overline{\beta}}) \neq 0$). We want to reach a contradiction to the pointedness of the nonreduced cone. This immediately follows from the fact that

$$z_r = 0, \widetilde{c}_n \neq 0 \Rightarrow z_c = \widetilde{n}\widetilde{c}_n + \widetilde{\overline{D}}\widetilde{\beta} \in FC(q) \text{ satisfies } z_c = \widetilde{\nu}u,\ u \neq 0.$$

Here $\widetilde{\beta}$ is obtained from $\widetilde{\overline{\beta}}$ by adding zeros to the columns of $\widetilde{\overline{D}}$ missing in $\widetilde{\overline{\overline{D}}}$. By taking $\widetilde{c}_\nu = -u$, we obtain that $z := -\widetilde{\nu}u + z_c \in \mathcal{FC}(q)$ is zero, but $(\widetilde{c}_\nu, \widetilde{c}_n, \widetilde{\beta}) \neq 0$, which contradicts the pointedness of $\mathcal{FC}(q)$. Given that the argument can be carried out for any q for which $\mathcal{FC}(q)$ is pointed, we obtained the pointedness for $FC_r(q)$. Following the same argument, one proves the pointedness of the polyhedral reduced friction cone $\widehat{FC}_r(q)$. ∎

Remark 3.6. The pointedness of the reduced cones is equivalent to the usual notion of pointedness, that is, "a cone K is pointed $\Leftrightarrow K \cap (-K) = \{0\}$."

Now let $z = \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{\overline{D}}\widetilde{\beta} \in \mathcal{FC}(q)$. From the pointedness of the reduced cone there exists [47] a unitary vector $u_0 := u_0(q)$ and the constants $C_2 := C_2(q) > 0$, $C_3 := C_3(q) > 0$ such that, for any $z = \widetilde{\nu}\widetilde{c}_\nu + \widetilde{n}\widetilde{c}_n + \widetilde{\overline{D}}\widetilde{\beta} \in \mathcal{FC}(q)$, we have

$$u_0{}^T \widetilde{\nu}_\perp^T z \geq C_2 \|z_r\| \geq C_3 \|\widetilde{c}_n\|, \tag{3.9}$$

where $z_r = \widetilde{\nu}_\perp^T z$. This estimate is one of the main ingredients that will be later used in proving the uniform bound on the variation of the velocities.

We can visualize the friction cones $\mathcal{FC}(q)$ and $\widehat{\mathcal{FC}}(q)$ as mappings from $\mathbb{R}^s$ to the subsets of $\mathbb{R}^s$, that is, $\mathcal{FC}(q), \widehat{\mathcal{FC}}(q) : \mathbb{R}^s \to \mathcal{P}(\mathbb{R}^s)$. The graph of $\mathcal{FC}(\cdot)$ is defined by

$$graph(\mathcal{FC}) = \{(q, z(q)) \mid z(q) \in \mathcal{FC}(q)\}, \tag{3.10}$$

and similarly for $\widehat{\mathcal{FC}}(q)$. Clearly, from the constructions above, $\mathcal{FC}(q)$ and its approximation $\widehat{\mathcal{FC}}(q)$ are convex sets for each fixed q. Under the uniform pointedness assumption we obtain that these mappings have closed graphs.

LEMMA 3.7 (closed graph property of the friction cones). *Assume that* $\mathcal{FC}(q)$ $(\widehat{\mathcal{FC}}(q))$ *is uniformly pointed. Then the graph of* $\mathcal{FC}(\cdot)$ $(\widehat{\mathcal{FC}}(\cdot))$ *is closed.*

Proof. We will prove the result for $\mathcal{FC}(\cdot)$. A similar argument is used for the polyhedral approximation $\widehat{\mathcal{FC}}(\cdot)$. Consider a sequence $(q^n, z^n) \in graph(\mathcal{FC}(q^n))$, where z^n has the form $z^n = \widetilde{\nu}(q^n)c_\nu^n + \widetilde{n}(q^n)\widetilde{c}_n^n + \widetilde{\overline{D}}(q^n)\widetilde{\beta}^n$. Assume that $q^n \to q$ and $z^n \to z$ as $n \to \infty$. We want to show that $z \in \mathcal{FC}(q)$. From the uniform pointedness of $\mathcal{FC}(\cdot)$ we obtain that

$$\left\|\left(\widetilde{c}_\nu^n, \widetilde{c}_n^n, \widetilde{\beta}^n\right)\right\| \le C_{\mathcal{FC}}\|z^n\|,$$

where $C_{\mathcal{FC}}$ is independent of q^n. Given that $z^n \to z$, it follows from the above inequality that $\|(\widetilde{c}_\nu^n, \widetilde{c}_n^n, \widetilde{\beta}^n)\|$ is bounded, and therefore we can extract convergent subsequences $\widetilde{c}_\nu^{n_k} \to \widetilde{c}_\nu^*$, $\widetilde{c}_n^{n_k} \to \widetilde{c}_n^*$, and $\widetilde{\beta}^{n_k} \to \widetilde{\beta}^*$, where $\widetilde{c}_n^* \ge 0$ and $\|\beta^{(j),*}\|_2 \le \mu^{(j)}\|c_n^{(j),*}\|$ due to the similar inequalities satisfied by the corresponding subsequence. Using the fact that $\widetilde{\nu}(\cdot)$, $\widetilde{n}(\cdot)$, and $\widetilde{\overline{D}}(\cdot)$ are continuous, we have that the subsequence z^{n_k} converges to $z^* = \widetilde{\nu}(q)c_\nu^* + \widetilde{n}(q)\widetilde{c}_n^* + \widetilde{\overline{D}}(q)\widetilde{\beta}^* \in \mathcal{FC}(q)$. Given that z^{n_k}, with $z^{n_k} \to z^*$, is a subsequence of the convergent sequence z^n, with $z^n \to z$, we conclude that $z = z^* \in \mathcal{FC}(q)$, which proves our claim. ∎

Note that the closed graph property implies that the values of the multivalued mappings are closed. This can be easily seen by taking $q^n = q$ and $z^n \in \mathcal{FC}(q)$. An immediate consequence of the above lemma is the following corollary.

COROLLARY 3.8. *Assume that* $\mathcal{FC}(q)$ $(\widehat{\mathcal{FC}}(q))$ *is uniformly pointed. Then the graph of* $FC_r(\cdot)$ $(\widehat{FC}_r(\cdot))$ *is closed.*

Proof. Consider a sequence (q^n, z_r^n) such that $z_r^n \in FC_r(q^n)$ and $q^n \to q$, $z_r^n \to z_r$, as $n \to \infty$. By definition, $z_r^n = (\widetilde{\nu}_\perp(q^n))^T z^n$ for some $z^n \in \mathcal{FC}(q^n)$. Taking the limit, as $n \to \infty$, we conclude that $z^n \to z$. The fact that $\mathcal{FC}(\cdot)$ has a closed graph implies that $z \in \mathcal{FC}(q)$, which immediately leads to $z_r = (\widetilde{\nu}_\perp(q))^T z \in FC_r(q)$. ∎

4. The time-stepping scheme. We are interested in convergence properties for a family of linearly implicit time-stepping schemes that accommodate methods based on semi-implicit Euler methods [4, 46] as well as various instances of the trapezoidal method from [39]. The time-stepping scheme solves at each integration step an LCP. We will assume that only inelastic collisions are solved. In terms of the collision rule given in [4] which involves a Poisson rule with a compression phase followed by a decompression phase, for inelastic collisions only the former LCP needs to be solved, and therefore the algorithm will solve only one LCP per time step. The main difference between a noncollisional and a collisional integration step is that the latter uses a zero time step to get out of the compression phase.

Some of the results that we obtain, such as the uniform boundedness of the velocity sequence, will hold even in the case of partially elastic collisions, since we will assume that the number of collisions is bounded above with respect to the time step. Such a proof has been obtained for a different, though related, time-stepping scheme [4]. The problem, however, is that the Poisson rule is very difficult to prove (or, indeed, to state) in the framework of MDIs from section 6, where the notion of instantaneous reaction impulse does not truly appear. A possibility may be to consider the case of collisions with a Newton rule [19, 51], though the weak convergence concept we are using results in only almost everywhere convergence of the velocity. In turn, this results in difficulties when dealing with statements involving instantaneous velocity as is the case of Newton rules. We defer convergence issues involving partially elastic collisions to future research.

To write the integration step as a *mixed linear complementarity problem* (MLCP), we use the following approximations. The joint constraints are written at the velocity level and approximated by

$$\left(\nu^{(i)}\left(q^l\right)\right)^T\left(\alpha v^{l+1}+(1-\alpha)v^l\right)=0,\quad i=1,\dots,m,$$

where α is a scalar parameter $\alpha\in(0,1]$.

The nonpenetration and frictional constraints are approximated in the same fashion. We can write these as the following complementarity conditions:

$$\begin{aligned}
0\le\rho^{(j),l+1}&:=\left(n^{(j)}\left(q^l\right)\right)^T\left(\alpha v^{l+1}+(1-\alpha)v^l\right)\perp c_n^{(j),l+1}\ge 0,\quad j\in\mathcal{A},\\
0\le\sigma^{(j),l+1}&:=\lambda^{(j),l+1}e^{(j)}+\left(D^{(j)}\left(q^l\right)\right)^T\left(\alpha v^{l+1}+(1-\alpha)v^l\right)\perp\beta^{(j),l+1}\ge 0,\quad j\in\mathcal{A},\\
0\le\zeta^{(j),l+1}&:=\mu^{(j)}c_n^{(j),l+1}-e^{(j)^T}\beta^{(j),l+1}\perp\lambda^{(j),l+1}\ge 0,\quad j\in\mathcal{A}.
\end{aligned}$$

Here $e^{(j)}$ is a vector of dimension $m_C^{(j)}$ whose every entry is 1. The equations of motion in implicit form can be written as

$$M\left(v^{l+1}-v^l\right)-z^{l+1}=hk\left(t_{l+1},q^{l+1},v^{l+1}\right). \tag{4.1}$$

Here M is the mass matrix, which is assumed to be a constant symmetric positive definite matrix, z^{l+1} represent the contact and joint impulses, and $k(t_{l+1},q^{l+1},v^{l+1})$ are the inertial and applied forces acting at time t_{l+1}. Since the goal is to formulate the integration step as an LCP, we will linearize (4.1) as follows. The term

$$z^{l+1}=\widetilde{\nu}\left(q^{l+1}\right)\widetilde{c}_\nu^{l+1}+\widetilde{n}\left(q^{l+1}\right)\widetilde{c}_n^{l+1}+\widetilde{D}\left(q^{l+1}\right)\widetilde{\beta}^{l+1}$$

is replaced by

$$z^{l+1}=\widetilde{\nu}^l\widetilde{c}_\nu^{l+1}+\widetilde{n}^l\widetilde{c}_n^{l+1}+\widetilde{D}^l\widetilde{\beta}^{l+1},$$

where $\widetilde{\nu}^l=\widetilde{\nu}(q^l)$, $\widetilde{n}^l=\widetilde{n}(q^l)$ and $\widetilde{D}^l=\widetilde{D}(q^l)$. To linearize the term $k(t_{l+1},q^{l+1},v^{l+1})$ in (4.1), we first introduce the position update formula. Given a parameter $\gamma\in[0,1]$ (fixed at the beginning of the simulation), we obtain the position at time t_{l+1} by the formula

$$q^{l+1}=q^l+h\left((1-\gamma)v^l+\gamma v^{l+1}\right).$$

For the term $k(t_{l+1},q^{l+1},v^{l+1})$ we have

$$\begin{aligned}
k\left(t_{l+1},q^{l+1},v^{l+1}\right)&=f_C\left(v^{l+1}\right)+k_1\left(t_{l+1},q^{l+1},v^{l+1}\right)\\
&=F\left(v^{l+1}\right)v^{l+1}+k_1\left(t_{l+1},q^{l+1},v^{l+1}\right),
\end{aligned}$$

where $f_C(v^{l+1})=F(v^{l+1})v^{l+1}$ are the Coriolis forces and $k_1(t_{l+1},q^{l+1},v^{l+1})$ are the external forces. A discussion related to this representation of the Coriolis forces is given at the end of this section. We replace the Coriolis term by

$$F\left(v^{l+1}\right)v^{l+1}\approx F\left(v^l\right)\left((1-\alpha)v^l+\alpha v^{l+1}\right)=F\left(v^l\right)v^l+\alpha F\left(v^l\right)\left(v^{l+1}-v^l\right). \tag{4.2}$$

The term $k_1(t_{l+1},q^{l+1},v^{l+1})$ is approximated as follows:

$$\begin{aligned}
k_1\left(t_{l+1},q^{l+1},v^{l+1}\right)&\approx(1-\alpha)k_1\left(t_l,q^l,v^l\right)+\alpha k_1\left(t_{l+1},q^{l+1},v^{l+1}\right),\\
&\approx(1-\alpha)k_1\left(t_l,q^l,v^l\right)+\alpha k_1\left(t_{l+1},q^l,v^l\right)\\
&\quad+\alpha\left(\widetilde{k}_{1q}\left(q^{l+1}-q^l\right)+\widetilde{k}_{1v}^l\left(v^{l+1}-v^l\right)\right),\\
&\approx(1-\alpha)k_1\left(t_l,q^l,v^l\right)+\alpha k_1\left(t_{l+1},q^l,v^l\right)\\
&\quad+\alpha h\widetilde{k}_{1q}^l v^l+\alpha\left(\widetilde{k}_{1v}^l+\gamma h\widetilde{k}_{1q}^l\right)\left(v^{l+1}-v^l\right),
\end{aligned} \tag{4.3}$$

where

$$\widetilde{k}_{1q}^{l} \approx k_{1q}\left(t_{l+1}, q^{l}, v^{l}\right), \quad \widetilde{k}_{1v}^{l} \approx k_{1v}\left(t_{l+1}, q^{l}, v^{l}\right)$$

are approximations of the Jacobians k_{1q} and k_{1v}, respectively. Combining the equations of motion with the joint constraints described at the velocity level and the frictional contact constraints, we obtain the following time-stepping scheme:

$$q^{l+1} = q^{l} + h\left((1-\gamma)v^{l} + \gamma v^{l+1}\right), \tag{4.4a}$$

(4.4b)

$$\widetilde{M}^{l} v^{l+1} - \sum_{i=1}^{m} \nu^{(i),l} c_{\nu}^{(i),l+1} - \sum_{j\in\mathcal{A}} (n^{(j),l} c_{n}^{(j),l+1} + D^{(j),l}\beta^{(j),l+1}) = \widetilde{M}^{l} v^{l} + \widetilde{k}^{l},$$

$$\left(\nu^{(i),l}\right)^{T}\left(\alpha v^{l+1} + (1-\alpha)v^{l}\right) = 0\,,\ i = 1, 2, \ldots m, \tag{4.4c}$$

$$0 \le \rho^{(j),l+1} := \left(n^{(j),l}\right)^{T}\left(\alpha v^{l+1} + (1-\alpha)v^{l}\right) \perp c_{n}^{(j),l+1} \ge 0, \quad j \in \mathcal{A}, \tag{4.4d}$$

(4.4e)

$$0 \le \sigma^{(j),l+1} := \lambda^{(j),l+1} e^{(j)} + \left(D^{(j),l}\right)^{T}\left(\alpha v^{l+1} + (1-\alpha)v^{l}\right) \perp \beta^{(j),l+1} \ge 0, \quad j \in \mathcal{A},$$

$$0 \le \zeta^{(j),l+1} := \mu^{(j)} c_{n}^{(j),l+1} - {e^{(j)}}^{T}\beta^{(j),l+1} \perp \lambda^{(j),l+1} \ge 0, \quad j \in \mathcal{A}, \tag{4.4f}$$

where $\nu^{(i),l} = \nu^{(i)}(q^{l})$, $n^{(j),l} = n^{(j)}(q^{l})$, $D^{(j),l} = D^{(j)}(q^{l})$, and

$$\widetilde{M}^{l} = \left(M - \alpha h\left(F(v^{l}) + \widetilde{k}_{1v}^{l}\right) - \alpha\gamma h^{2}\,\widetilde{k}_{1q}^{l}\right),$$

$$\widetilde{k}^{l} = h\left((1-\alpha)k_{1}\left(t_{l}, q^{l}, v^{l}\right) + \alpha k_{1}\left(t_{l+1}, q^{l}, v^{l}\right)\right) + (1-\alpha)hF(v^{l})v^{l} + \alpha h^{2}\widetilde{k}_{1q}^{l} v^{l}. \tag{4.5}$$

We note that (4.4a)–(4.4f) represent an MLCP. If at time-step l the index set of active contact constraints is given by $\mathcal{A} = \{j_1, j_2, \ldots, j_a\}$ and if we use (2.5), (2.10) together with

(4.6)

$$\widetilde{\lambda} = \left[\lambda^{(j_1)}, \lambda^{(j_2)}, \ldots, \lambda^{(j_a)}\right],\ \widetilde{\zeta} = \left[\zeta^{(j_1)}, \zeta^{(j_2)}, \ldots, \zeta^{(j_a)}\right],\ \widetilde{E} = \operatorname{diag}\left(e^{(j_1)}, e^{(j_2)}, \ldots, e^{(j_a)}\right)$$

$$\widetilde{\sigma} = \left[\sigma^{(j_1)}, \sigma^{(j_2)}, \ldots, \sigma^{(j_a)}\right],\ \widetilde{\rho} = \left[\rho^{(j_1)}, \rho^{(j_2)}, \ldots, \rho^{(j_a)}\right],\ \widetilde{\mu} = \operatorname{diag}\left(\mu^{(j_1)}, \mu^{(j_2)}, \ldots, \mu^{(j_a)}\right),$$

then the matrix form of the integration step is given by

$$\begin{bmatrix} \widetilde{M}^{l} & -\widetilde{\nu}^{l} & -\widetilde{n}^{l} & -\widetilde{D}^{l} & 0 \\ \left(\widetilde{\nu}^{l}\right)^{T} & 0 & 0 & 0 & 0 \\ \left(\widetilde{n}^{l}\right)^{T} & 0 & 0 & 0 & 0 \\ \left(\widetilde{D}^{l}\right)^{T} & 0 & 0 & 0 & \widetilde{E} \\ 0 & 0 & \widetilde{\mu} & -\widetilde{E}^{T} & 0 \end{bmatrix} \begin{bmatrix} v^{l+1} \\ \widetilde{c}_{\nu}^{l+1} \\ \widetilde{c}_{n}^{l+1} \\ \widetilde{\beta}^{l+1} \\ \widetilde{\lambda}^{l+1} \end{bmatrix} - \begin{bmatrix} \widetilde{M}^{l} v^{l} + \widetilde{k}^{l} \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \widetilde{\rho}^{l+1} \\ \widetilde{\sigma}^{l+1} \\ \widetilde{\zeta}^{l+1} \end{bmatrix}, \tag{4.7}$$

$$0 \le \left[\widetilde{c}_{n}^{l+1}, \widetilde{\beta}^{l+1}, \widetilde{\lambda}^{l+1}\right] \perp \left[\widetilde{\rho}^{l+1}, \widetilde{\sigma}^{l+1}, \widetilde{\zeta}^{l+1}\right] \ge 0\,. \tag{4.8}$$

We denote by $\mathcal{L}(q^{l}, v^{l}, \widetilde{k}, h, \alpha, \gamma)$ the solution set of the MLCP (4.7).

We note that the choice $\alpha = \gamma = 1$ results in the scheme from [4, 5] (the former is obtained once we choose $\widetilde{k}_{1q} = 0$ and $\widetilde{k}_{1v} = 0$), and the choice $\alpha = \gamma = \frac{1}{2}$ results in a variant of the scheme from [39]. The choice $\gamma = \frac{1}{2}$, $\alpha = 1$ is similar to the midpoint

rule proposed by Moreau in [30, 31]. The time-stepping scheme in [39] detects (behind collisions) other type of events such as stick-slip transitions, take-off transitions, and changes in the active friction components. If the number of such changes is uniformly bounded as $h \to 0$, these transitions could be resolved in the same fashion in which collisions are here dealt with. For simplicity we restrict ourselves to collision detection only.

A collision occurs in the interval $(lh, (l+1)h]$ if $\Phi^{(j)}(q^l) > 0$ and $\Phi^{(j)}(\overline{q}^{l+1}) \leq 0$, where $\overline{q}^{l+1}$ is the position computed by the time-stepping scheme without including j in the active set at time t_{l+1}. The active set at t_{l+1} is taken as

$$\mathcal{A}(t_{l+1}) = \mathcal{A}^{l+1} = \left\{ j \ : \ \Phi^{(j)}(q^l) \leq 0 \right\}.$$

Whenever a collision is encountered, cubic interpolation is used to determine the precollision velocity and the position at which the collision occurs [39]. The detected position q^- and the precollision velocity v^- are used in the compression phase to obtain the new velocity. An MLCP of the same type as (4.7) is solved in the compression phase. More precisely, the solution set of the MLCP modeling the compression phase is $\mathcal{L}(q^-, v^-, 0, 0, 1, 1)$.

Collision detection may result in a nonuniform partition of the simulation interval $[0, T]$. More precisely, a collision may be detected at time t^* such that, for a given time-step h, $t^* \neq lh$ for any integer l. To make the upcoming proofs easier to follow, we enforce a uniform partition of $[0, T]$. When collision is detected at time $t^{*,l+1} \in (lh, (l+1)h]$, the collision is solved, resulting in the collision position $q^{-,l+1}$ and postcollision velocity $v^{+,l+1} \in \mathcal{L}(q^{-,l+1}, v^{-,l+1}, 0, 0, 1, 1)$. Instead of introducing the collision time t^* in the time partition of $[0, T]$ or solving another MLCP in the interval $(t^*, (l+1)h]$, we take

$$t_{l+1} = (l+1)h, \quad q^{l+1} = q^{-,l+1}, \text{ and } v^{l+1} = v^{+,l+1}.$$

Assuming that we do this for every collision and that the first integration step is not a collisional one, we have $t_l = lh$, for all l, and the scheme will keep a fixed time step throughout the integration process.

Note that, while this simplification possibly affects the accuracy of the scheme, our choice essentially represents only a notation convention. Indeed, if the external force k_1 does not depend on time, then the sequence of velocities and positions is identical to the one with the normal convention (where the collision time is considered one of the time points). If the force does depend on time, then the change in its value is only order $O(h)$, since from Assumption **(H7)**, which will be defined shortly, the number of collisions is bounded above and does not affect the convergence proofs.

We extend the numerical solution to time instants different from the ones given by the discrete solution, as follows. The velocity sequence $v^{h,\alpha}(t)$ is defined by

(4.9)
$$v^{h,\alpha}(t) = \begin{cases} v^{l+1,\alpha} & \text{if } t \in (lh, (l+1)h] \quad \text{and no collision in } (lh, (l+1)h], \\ v^{l+1} := v^{+,l+1} & \text{if } t \in (lh, (l+1)h] \quad \text{and collision detected in } (lh, (l+1)h], \\ v^0 & \text{if } t = 0, \end{cases}$$

where $v^{+,l+1}$ denotes the velocity at the end of the compression phase and where

$$v^{l+1,\alpha} = (1-\alpha)v^l + \alpha v^{l+1}. \tag{4.10}$$

The velocity function that uses no weighting is denoted by $v^h(\cdot)$ and is defined in a similar fashion:

(4.11)
$$v^h(t) = \begin{cases} v^{l+1} & \text{if } t \in (lh,(l+1)h] \quad \text{and no collision in } (lh,(l+1)h], \\ v^{l+1} := v^{+,l+1} & \text{if } t \in (lh,(l+1)h] \quad \text{and collision detected in } (lh,(l+1)h]. \end{cases}$$

For the position sequence, we take $q^{h,\alpha}(t)$ to be

(4.12a)
$$q^{h,\alpha}(t) = \begin{cases} \frac{1}{h}\left((t-t_l)q^{(l+1)} + (t_{l+1}-t)q^l\right) & \text{if } t \in (t_l = lh, t_{l+1} = (l+1)h], \\ q^0 & \text{if } t = 0, \end{cases}$$

(4.12b)
$$\text{where } q^{l+1} = \begin{cases} q^{(l)} + hv^{l+1,\alpha} & \text{if } t \in (lh,(l+1)h] \text{ and no collision in } (lh,(l+1)h], \\ q^{-,l+1} & \text{if } t \in (lh,(l+1)h] \text{ and collision detected in } (lh,(l+1)h]. \end{cases}$$

Here q^{l+1} is computed by the position update formula (4.4a), except for collisional instants (that is, a collision occurred in the $(lh,(l+1)h]$ interval), in which case $q^{l+1} := q^{-,l+1}$, where $q^{-,l+1}$ is the estimated collision position. Since the collision time $t^{*,l+1}$ is detected by solving

$$\Phi^{(j)}(\widetilde{q}(t)) = 0,$$

where $\widetilde{q} : [lh,(l+1)h] \to \mathbb{R}^s$ is the cubic interpolant of the data $\widetilde{q}(lh) = q^l$, $\frac{d\widetilde{q}}{dt}(lh) = v^l$, $\widetilde{q}((l+1)h) = \overline{q}^{l+1}$, $\frac{d\widetilde{q}}{dt}((l+1)h) = \overline{v}^{l+1}$ ($\overline{q}^{l+1}$ and $\overline{v}^{l+1}$ are obtained by applying a regular step with $j \notin \mathcal{A}$), and $q^{l+1} = q^{-,l+1} = \widetilde{q}(t^{*,l+1})$, we can guarantee that

$$\Phi^{(j)}\left(q^{l+1}\right) = \Phi^{(j)}\left(q^{-,l+1}\right) \geq -C_c h^2 \tag{4.13}$$

for a fixed constant C_c.

To obtain the convergence results, we use the following assumptions.

(H1) The nonpenetration constraints are twice continuously differentiable, and there exists B_H such that

$$\left\|\nabla_{qq}\Phi^{(j)}(q)\right\| \leq B_H \text{ for all } q \text{ and } j = 1,\ldots,p. \tag{4.14}$$

(H2) The functions $\Theta^{(i)}(q)$, $i = 1,\ldots,m$ are sufficiently smooth functions.

(H3) The generalized mass matrix M is constant, symmetric, and positive definite.

(H4) The total friction cone $\mathcal{FC}(q)$ is uniformly pointed with respect to all configurations q.

(H5) The norm of the external force increases at most linearly with the position and the velocity. That is,

$$\|k_1(t,q,v)\| \leq c_1 + c_2\|q\| + c_3\|v\|. \tag{4.15}$$

Here $k_1(q,v)$ denotes the external and inertial forces.
The Coriolis force is given by a bilinear operator

$$[f_C(v)]_i = \sum_{jk} f_{ijk} v_j v_k \ .$$

This is certainly true if the system is described by Newton–Euler equations in body coordinates [32, section 2.4], where the matrix $F(v)$ of entries

$$[F(v)]_{ij} = \sum_k f_{ijk} v_k$$

is antisymmetric in the sense that

$$u^T F(v)u = 0 \quad \forall u \ .$$

We also assume that the approximations $\tilde{k}_{1q}$ and $\tilde{k}_{1v}$ are bounded. More precisely,

$$\|\widetilde{k}_{1q}\| \le c_4, \ \ \|\widetilde{k}_{1v}\| \le c_5. \tag{4.16}$$

(H6) The contact data given by $\tilde{n}(q)$, $\tilde{D}(q)$ are globally Lipschitz continuous functions.

(H7) The number of collisions solved by the algorithm is uniformly upper bounded as $h \to 0$.

(H8) The external forces $k_1(t, q, v)$ are linear in v, and the approximation $\widetilde{k}_{1v}$ is constant.

Remark 4.1.

- Assumption **(H3)** is satisfied if we use the Newton–Euler formulation in body coordinates; see [32].
- Assumption **(H4)** implies that $\widetilde{\nu}(q)$ has uniform full rank. That is, there exists a constant $\kappa > 0$ such that

$$\sigma_{\min}(\widetilde{\nu}(q)) \ge \kappa \quad \forall\, q,$$

where $\sigma_{\min}(A)$ denotes the smallest singular value of the matrix A.

- Assumption **(H7)** is related to and implied by the assumption of non-Zeno behavior of the system: that the number of switching points in the dynamics (collisions and stick-slip transitions) is finite in any bounded time interval. [12, 42, 13]. While this is not unreasonable to expect when the restitution coefficient is 0 (as we assume here), we do not have a method of guaranteeing it a priori. We note that this is an issue only with trapezoidal-type schemes, and does not need to be assumed in the case of first-order schemes [6].
- The first part of assumption **(H8)** is fairly standard in a stability analysis of the time-stepping scheme. The second part is not needed to prove all of the results. More precisely, uniform boundedness of the numerical velocities as well as a uniform bound on the variation of the numerical velocities can be obtained without this assumption. We note that the **(H8)** assumption is satisfied when external forces include linear damping terms, by far the prevailing type of external velocity-dependent passive force.

The MLCP (4.7) has the same structure as the ones in [4, 39], and therefore the same solvability results can be used to show that the solution set $\mathcal{L}(q^l, v^l, \widetilde{k}, h, \alpha, \gamma)$ is not empty whenever the matrix $\widetilde{M}$ is positive definite. Since the mass matrix M is positive definite, the matrix $F(\cdot)$ is antisymmetric and the approximations used are bounded, it follows from (4.5) that $\widetilde{M}$ will be positive definite for sufficiently small values of h and for any value of the velocity.

Note also that in the presence of stiff forces the use of exact Jacobians k_{1q} and k_{1v} may force the simulation to choose a very small time-step h in order to ensure the positive definiteness of the matrix $\widetilde{M}$. In order to allow the simulation to proceed by using moderate values of the time-step h, appropriate negative semidefinite Jacobian approximations $\widetilde{k}_{1q}$ and $\widetilde{k}_{1v}$ may be used [39].

It is convenient for the proofs of the upcoming sections to separate the terms involving Coriolis forces in (4.4c). To this end, we introduce the following notation:

$$\begin{aligned} \overline{M}^l &= \left(M - \alpha h \widetilde{k}_{1v}^l - \alpha\gamma h^2 \widetilde{k}_{1q}^l\right), \\ \overline{k}^l &= h\left((1-\alpha)k_1\left(t_l, q^l, v^l\right) + \alpha k_1\left(t_{l+1}, q^l, v^l\right)\right) + \alpha h^2 \widetilde{k}_{1q}^l v^l. \end{aligned} \tag{4.17}$$

In terms of the new notation, (4.4c) is rewritten as

$$\overline{M}^l v^{l+1} - \sum_{i=1}^{m} \nu^{(i),l} c_\nu^{(i),l+1} - \sum_{j\in\mathcal{A}} \left(n^{(j),l} c_n^{(j),l+1} + D^{(j),l}\beta^{(j),l+1}\right) = \overline{M} v^l + \overline{k}^l + hF\left(v^l\right) v^{l+1,\alpha}. \tag{4.18}$$

5. Kinetic energy estimates. The following result establishes a uniform bound for the numerical velocities, as $h \to 0$. Since we are dealing only with inelastic collisions and the friction cone is uniformly pointed, the compression phase guarantees that the postcollision kinetic energy will be less than the precollision kinetic energy. Therefore we restrict the proof of the next result to the noncollisional case.

THEOREM 5.1. *If* **(H1)**–**(H8)** *are satisfied and* $\frac{1}{2} \le \alpha \le 1$, *then there is a constant* c *such that*

$$\left(v^l\right)^T M v^l \le \max\left\{\left(v^0\right)^T M v^0,\ \|q^0\| + 1\right\} e^{ct_l},\quad l = 0, 1, \ldots, \lfloor T/h \rfloor$$

for all sufficiently small h.

Proof. Suppose that no collisions are detected in the interval $[t_l, t_{l+1}]$. The new velocity v^{l+1} will be determined by solving the LCP (4.4c)–(4.4f).

Left multiplying (4.18) by $(v^{l+1,\alpha})^T$ and using the fact that $F(v^l)$ is a skew-symmetric matrix, we get that

$$\begin{aligned} \left(v^{l+1,\alpha}\right)^T \overline{M}^l v^{l+1} = \sum_{i=1}^{m} c_\nu^{(i),l+1}\left(\nu^{(i),l}\right)^T v^{l+1,\alpha} + \sum_{j\in\mathcal{A}}\Big\{ c_n^{(j),l+1}\left(n^{(j),l}\right)^T v^{l+1,\alpha} \\ + \left(\beta^{(j),l+1}\right)^T \left(D^{(j),l}\right)^T v^{l+1,\alpha}\Big\} + \left(v^{l+1,\alpha}\right)^T \overline{k}^l + \left(v^{l+1,\alpha}\right)^T \overline{M}^l v^l. \end{aligned} \tag{5.1}$$

Using (4.4c), we deduce that $(\nu^{(i),l})^T v^{l+1,\alpha} = 0$, $i = 1, 2, \ldots, m$. Also, using the contact constraints (4.4d), we obtain $c_n^{(j),l+1}(n^{(j),l})^T v^{l+1,\alpha} = 0$, $j \in \mathcal{A}$. Finally, from the frictional constraints (4.4e) and (4.4f), we get that

$$\begin{aligned} \left(\beta^{(j),l+1}\right)^T \left(D^{(j),l}\right)^T v^{l+1,\alpha} &= -\lambda^{(j),l+1}\left(\beta^{(j),l+1}\right)^T e^{(j)} \\ &= -\mu^{(j)} c_n^{(j),l+1} \lambda^{(j),l+1} \le 0\ \forall j \in \mathcal{A}. \end{aligned}$$

Then (5.1) implies that

$$\left(v^{l+1,\alpha}\right)^T \overline{M}^l v^{l+1} \le \left(v^{l+1,\alpha}\right)^T \overline{M}^l v^l + \left(v^{l+1,\alpha}\right)^T \overline{k}^l. \tag{5.2}$$

By expanding the left- and right-hand sides of the above inequality, we obtain

$$\begin{aligned}\left(v^{l+1,\alpha}\right)^T\overline{M}^l v^{l+1} &= \alpha {v^{l+1}}^T M v^{l+1} + (1-\alpha){v^l}^T M v^{l+1}\\ &\quad - h\alpha^2 {v^{l+1}}^T\left(\widetilde{k}^l_{1v} + \gamma h \widetilde{k}^l_{1q}\right) v^{l+1}\\ &\quad - h\alpha(1-\alpha){v^l}^T\left(\widetilde{k}^l_{1v} + \gamma h \overline{k}^l_{1q}\right) v^{l+1}, \qquad (5.3)\\ \left(v^{l+1,\alpha}\right)^T\left(\overline{M}^l v^l + \overline{k}^l\right) &= (1-\alpha){v^l}^T M v^l + \alpha {v^{l+1}}^T M v^l\\ &\quad - h\alpha^2 {v^{l+1}}^T\left(\widetilde{k}^l_{1v} + (\gamma-1) h \widetilde{k}^l_{1q}\right) v^l\\ &\quad - h\alpha(1-\alpha){v^l}^T\left(\widetilde{k}^l_{1v} + (\gamma-1) h \widetilde{k}^l_{1q}\right) v^l\\ &\quad + h\left(v^{l+1,\alpha}\right)^T\left((1-\alpha)k_1\left(t_{l+1}, q^l, v^l\right) + \alpha k_1\left(t_l, q^l, v^l\right)\right). \qquad (5.4)\end{aligned}$$

Using Assumption (4.15) **(H5)**, we are led to

$$\begin{aligned}\left(v^{l+1,\alpha}\right)^T\overline{M}^l v^{l+1} &\geq \alpha(1 - C_6 h)\|M^{1/2}v^{l+1}\|^2 - C_7 h\|M^{1/2}v^{l+1}\|\|M^{1/2}v^l\|\\ &\quad + (1-\alpha){v^l}^T M v^{l+1}, \qquad (5.5)\\ \left(v^{l+1,\alpha}\right)^T\left(\overline{M}^l v^l + \overline{k}^l\right) &\leq \alpha\left(-1 + \frac{1}{\alpha} + C_8 h\right)\|M^{1/2}v^l\|^2 + C_9 h\|M^{1/2}v^l\|\|M^{1/2}v^{l+1}\|\\ &\quad + C_{10}h(\alpha\|M^{1/2}v^{l+1}\| + (1-\alpha)\|M^{1/2}v^l\|)\\ &\quad \times(\|M^{1/2}v^l\| + \|q^l\| + 1) + \alpha {v^{l+1}}^T M v^l. \qquad (5.6)\end{aligned}$$

Let us denote

$$\rho_l = \left\|M^{1/2}v^l\right\|, \sigma_l = \left\|q^l\right\| + 1.$$

Note that $\alpha \geq \frac{1}{2}$ gives

$$2\alpha - 1 \geq 0 \Rightarrow (2\alpha-1)\left(v^{l+1}\right)^T M v^l \leq (2\alpha-1)\rho_{l+1}\rho_l. \qquad (5.7)$$

Dividing by α both sides of the inequality (5.2) and using the symmetry of the matrix M, the estimates (5.5)–(5.6), the implication (5.7), as well as the notation above, implies that

$$(1 - C_{11}h)\rho_{l+1}^2 \leq \left(-1 + \frac{1}{\alpha} + C_{11}h\right)\rho_l^2 + C_{11}h\sigma_l(\rho_l + \rho_{l+1}) + \left(2 - \frac{1}{\alpha}\right)\rho_l\rho_{l+1} \qquad (5.8)$$

for an appropriately defined constant C_{11}.

Consider now the case for which $\rho_l < \rho_{l+1}$. Dividing by ρ_{l+1} in (5.8) and using that $\rho_l/\rho_{l+1} < 1$ gives

$$(1 - C_{12}h)\rho_{l+1} \leq (1 + C_{12}h)\rho_l + C_{12}h\sigma_l \qquad (5.9)$$

for some constant $C_{12} \geq 0$ and all sufficiently small h. We can rewrite (5.9) in the form

$$\rho_{l+1} \leq (1 + C_{13}h)\rho_l + C_{13}h\sigma_l, \qquad (5.10)$$

with C_{13} appropriately chosen. It is straigthforward to see that, for the remaining case $\rho_{l+1} \leq \rho_l$, inequality (5.10) immediately follows. On the other hand, from (4.4a), we have

$$\|q^{l+1}\| \leq \|q^l\| + \|M^{-1/2}\| \left((1-\gamma)\|M^{1/2}v^l\| + \gamma\|M^{1/2}v^{l+1}\| \right). \tag{5.11}$$

Substituting the overestimate for ρ_{l+1}, (5.10), into (5.11) gives

$$\sigma_{l+1} \leq h\|M^{-1/2}\| \left(1 + \gamma C_{13} h\right) \rho_l + \left(1 + \gamma C_{13} h^2 \|M^{-1/2}\|\right) \sigma_l. \tag{5.12}$$

It follows that there is a constant C_{14} such that

$$\begin{aligned} \rho_{l+1} &\leq (1 + C_{14}h)\rho_l + C_{14}h\sigma_l, \\ \sigma_{l+1} &\leq C_{14}h\rho_l + (1 + C_{14}h)\sigma_l. \end{aligned}$$

By taking $c = 2C_{14}$, we have that, for all sufficiently small h, the following holds:

$$\left\| \begin{bmatrix} \rho_l \\ \sigma_l \end{bmatrix} \right\|_\infty \leq \left\| \begin{bmatrix} 1 + C_{14}h & C_{14}h \\ C_{14}h & 1 + C_{14}h \end{bmatrix} \right\|_\infty^l \left\| \begin{bmatrix} \rho_0 \\ \sigma_0 \end{bmatrix} \right\|_\infty = e^{ct_l} \left\| \begin{bmatrix} \rho_0 \\ \sigma_0 \end{bmatrix} \right\|_\infty,$$

which concludes the proof of our theorem. □

Remark 5.2. *The conclusion of Theorem* 5.1 *implies that both* $v^h(\cdot)$ *and* $v^{h,\alpha}(\cdot)$ *are uniformly bounded on* $[0, T]$, *as* $h \to 0$.

6. MDIs. In the following we use the setup and some of the results of [47]. Formally, we are looking at complementarity systems of the following form.

$$\frac{dq}{dt} = v, \tag{6.1}$$

$$M\frac{dv}{dt} = k(q, v) + \rho, \tag{6.2}$$

$$\Theta^{(i)}(q) = 0, \quad i = 1, 2, \ldots, m_J, \tag{6.3}$$

$$\nu^{(i)}(q)^T v = 0, \quad i = m_J + 1, m_J + 2, \ldots, m_J, \tag{6.4}$$

$$\Phi^{(j)}(q) \geq 0, \quad j = 1, \ldots, p, \tag{6.5}$$

$$\rho(t) = \overline{\rho}(t) + \sum_{j=1}^{p} \rho^{(j)}(t) \in \mathcal{FC}(q), \tag{6.6}$$

$$\overline{\rho}(t) \in \operatorname{span}\left\{ \nu^{(i)}(q(t)) \ : \ i = 1, \ldots, m \right\}, \tag{6.7}$$

$$\|\rho^{(j)}\|\Phi^{(j)}(q) = 0, \quad j = 1, 2, \ldots, p. \tag{6.8}$$

The differences between the above formulation and the one corresponding to the contact-only case consists in a different friction cone being used and the additional bilateral constraints enforced by (6.3). Here $\mathcal{FC}(q)$ is the total friction cone (it includes all constraint forces, bilateral and unilateral) as defined in the previous section. In what follows, we specify what we mean by a solution of (6.1)–(6.8). This is motivated by the fact that a strong solution may not exist in general [46].

In contact mechanics, measures appear as a result of the presence of impulsive forces, while inclusions appear as a result of the presence of Coulomb friction. Because of possible impulsive forces, the velocity of the system is no longer required to be an absolutely continuous function but rather a function of bounded variation.

We are going to replace the forces, as they are understood in general, by vector measures. A vector measure is defined in terms of its action on a continuous function. Assume now that $v : [0,T] \to \mathbb{R}^s$ is a function of bounded variation. That is, the total variation of v, $\bigvee_0^T v(\cdot)$, is finite. Here $\bigvee_0^T v(\cdot)$ is the supremum of the sums $\sum_{i=0}^{N-1} \|v(t_{i+1}) - v(t_i)\|$ over all finite partitions $a = t_0 < t_1 < \cdots < t_{N-1} < t_N = b$. We denote this by $v \in BV([0,T])$. It follows that the measure induced by v can be understood as a linear and continuous operator defined from $C([0,T])$, with values in $\mathbb{R}^s$. More precisely,

$$< dv, \phi >= \int_0^T \phi(t) dv(t), \tag{6.9}$$

where $\phi : [0,T] \to \mathbb{R}$ is continuous. The Riemann–Stieljes integral in (6.9), which exists because of $v(\cdot)$ being of bounded variation, can be approximated by finite Riemann sums:

$$\sum_{i=0}^{N-1} \phi(\tau_i)[v(t_{i+1}) - v(t_i)],$$

where $a = t_0 < \tau_1 < t_1 < \cdots < \tau_{N-1} < t_N = b$. Discontinuities in the velocity may lead to atoms of the measure dv. Therefore dv is not, in general, absolutely continuous with respect to the Lebesgue measure dt, and thus $\frac{dv}{dt}(\cdot)$ cannot be defined, in the usual sense, as a Radon–Nykodim derivative. To give a meaning to inclusions of the form

$$\frac{dv}{dt}(t) \in K(t), \quad \text{for } t \in [0,T], \tag{6.10}$$

we adopt the following definition [47].

DEFINITION 6.1 (MDI). *If $v \in BV([0,T])$ and $K(\cdot)$ is a convex-set valued mapping, we say that* (6.10) *holds if, for all continuous $\phi : [0,T] \to \mathbb{R}$, $\phi \geq 0$ and ϕ not identically zero, we have that*

$$\frac{\int_0^T \phi(t) dv(t)}{\int_0^T \phi(t) dt} \in \bigcup_{\tau : \phi(\tau) \neq 0} K(\tau).$$

DEFINITION 6.2 (weak solution of (6.1)–(6.8)). *We say that $q(t)$, $v(t)$ is a weak solution of* (6.1)–(6.8) *on $[0,T]$ if*

1. *$v(\cdot)$ is a function of bounded variation on $[0,T]$;*
2. *$q(\cdot)$ is an absolutely continuous function that satisfies*

$$q(t) = q(0) + \int_0^t v(\tau) d\tau \quad \text{for } t \in [0,T]; \tag{6.11}$$

3. *the measure $dv(t)$ must satisfy*

$$M \frac{dv}{dt} - k(q,v) \in \mathcal{FC}(q); \tag{6.12}$$

4. *$\Theta^{(i)}(q) = 0$, $i = 1, \ldots, m_J$ and $\nu^{(i)}(q)^T v = 0$ almost everywhere, $i = m_J + 1, m_J + 2, \ldots, m$;*
5. *$\Phi^{(j)}(q) \geq 0$, $j = 1, \ldots, p$.*

7. Uniform bound in variations. For the rest of the paper we consider (γ, α) satisfying

$$\gamma = \alpha \in \left[\frac{1}{2}, 1\right]. \tag{7.1}$$

Since $\gamma = \alpha$ and the number of collisions solved is uniformly upper bounded as $h \to 0$, we have, from (4.4a), that

$$q^{h,\alpha}(t) = q^{h,\alpha}(0) + \int_0^t v^{h,\alpha}(\tau) d\tau.$$

The uniform boundedness of the velocities implies that the sequence $\{q^{h,\alpha}(\cdot)\}$ is equicontinuous and equibounded. Therefore by the Arzela–Ascoli theorem, there exists a uniformly convergent subsequence, which we also denote by $q^{h,\alpha}(\cdot)$, that converges $q^{h,\alpha}(\cdot) \to q(\cdot)$ uniformly in $[0, T]$.

THEOREM 7.1. *$\bigvee_0^T v^{h,\alpha}(\cdot)$ is uniformly bounded as $h \to 0$, and there exists $v^*(\cdot)$ of bounded variation such that $v^{h,\alpha} \to v^*$ pointwise and $dv^{h,\alpha} \to dv^*$ weakly.*

We break the proof in five subsections, along the lines given in [47], with some modifications due to the presence of joint constraints. The main difference consists in the use of the reduced friction cone. In this context, using the regularity of the reduced friction cone, we first obtain a uniform bound on the sums $\sum_l \|\widetilde{c}_n^{l,h}\|$. This is used to obtain a similar result for the other constraint impulses. The proof then follows precisely the lines of [47], first by obtaining a local result for the velocity variation and then by using a compactness argument to extend this result to the entire time interval.

7.1. Use the regularity assumption on the reduced friction cone to obtain a bound on the sums $\sum_l \|\widetilde{c}_n^{l,h}\|$. Let $q(\cdot)$ be the limit of a uniformly convergent subsequence $q^{h,\alpha}(\cdot)$. Let t be a time instant in the interval $(0, T]$. From (3.9) it follows that there exist a unit vector $u_0(t)$ and a scalar $\zeta(t) > 0$ such that, for any $z = \widetilde{\nu}(q(t))\widetilde{c}_\nu + \widetilde{n}(q(t))\widetilde{c}_n + \widetilde{D}(q(t))\widetilde{\beta} \in \mathcal{FC}(q(t))$, we have

$$u_0{}^T(t)\widetilde{\nu}_\perp^T(q(t))z \geq \zeta(t)\|\widetilde{c}_n\|. \tag{7.2}$$

By the closed-graph property of the $\mathcal{FC}(q(t))$, it follows that there is $\eta(t) > 0$ and $h_0 > 0$ such that, for any t'' satisfying $|t'' - t| \leq \eta(t)$ and any $h \leq h_0$, we have

$$u_0{}^T(t)\widetilde{\nu}_\perp^T\left(q^h(t'')\right) z \geq \frac{1}{2}\zeta(t)\|\widetilde{c}_n\| \tag{7.3}$$

for any $z \in \mathcal{FC}(q^h(t''))$. Provided that both lh and $(l+1)h$ lie in the interval $[t - \eta(t), t + \eta(t)]$, the numerical scheme gives

$$\left(M - \alpha h \widetilde{k}_v^{l,h} - \alpha\gamma h^2 \widetilde{k}_q^{l,h}\right)\left(v^{l+1,h} - v^{l,h}\right) = \widetilde{k}^{l,h} + z^{l+1,h}, \tag{7.4}$$

with $z^{l+1,h} \in \widehat{\mathcal{FC}}(q^{(l),h})$. Let us denote

$$\tilde{\nu}_\perp^{l,h} := \widetilde{\nu}_\perp\left(q^{l,h}\right) \text{ and } \tilde{\nu}^{l,h} := \widetilde{\nu}\left(q^{l,h}\right).$$

From the joint constraint enforced at the velocity level, we have $(\widetilde{\nu}^{l,h})^T(\alpha v^{l+1,h} + (1-\alpha)v^{l,h}) = 0$ for all l. By using the orthogonal decomposition, we are led to

$$\begin{aligned} v^{l+1,h} &= \widetilde{\nu}_\perp^{l,h} w^{l+1,h} + \widetilde{\nu}^{l,h} u^{l+1,h}, \\ v^{l,h} &= \widetilde{\nu}_\perp^{l-1,h} w^{l,h} + \widetilde{\nu}^{l-1,h} u^{l,h}. \end{aligned} \tag{7.5}$$

Multiplying both equations in (7.5) on the left by $(\widetilde{\nu}_\perp^{l,h})^T M$ gives

$$\left(\widetilde{\nu}_\perp^{l,h}\right)^T M v^{l+1,h} = \left(\left(\widetilde{\nu}_\perp^{l,h}\right)^T M \widetilde{\nu}_\perp^{l,h}\right) w^{l+1,h} + \left(\widetilde{\nu}_\perp^{l,h}\right)^T M \widetilde{\nu}^{l,h} u^{l+1,h},$$

$$\left(\widetilde{\nu}_\perp^{l,h}\right)^T M v^{l,h} = \left(\left(\widetilde{\nu}_\perp^{l-1,h}\right)^T M \widetilde{\nu}_\perp^{l-1,h}\right) w^{l,h} + \left(\widetilde{\nu}_\perp^{l-1,h}\right)^T M \tilde{\nu}^{l-1,h} u^{l,h} + \mathcal{O}(h). \tag{7.6}$$

For the last equation in (7.6) we have used that $\widetilde{\nu}_\perp^{l,h} = \widetilde{\nu}_\perp^{l-1,h} + \mathcal{O}(h)$, which holds because of the sufficient smoothness of the joint gradients and the uniform boundness of the velocities. Thus, by using $\omega^{i+1,h} := ((\widetilde{\nu}_\perp^{i,h})^T M \widetilde{\nu}_\perp^{i,h}) w^{i+1,h}$ and $\omega^{i+1,h,\perp} := (\widetilde{\nu}_\perp^{i,h})^T M \widetilde{\nu}^{i,h} u^{i+1,h}$, we have, with respect to the new notation,

$$\left(\widetilde{\nu}_\perp^{l,h}\right)^T M v^{l+1,h} = \omega^{l+1,h} + \omega^{l+1,h,\perp} \text{ and } \left(\widetilde{\nu}_\perp^{l,h}\right)^T M v^{l,h} = \omega^{l,h} + \omega^{l,h,\perp} + \mathcal{O}(h). \tag{7.7}$$

We multiply (7.4) on the left by $\widetilde{\nu}_\perp^{l,h}$ to obtain

$$\omega^{l+1,h} - \omega^{l,h} + \omega^{l+1,h,\perp} - \omega^{l,h,\perp} = \widetilde{\nu}_\perp^{l,h} z^{l+1,h} + \mathcal{O}(h), \tag{7.8}$$

where we have used the fact that $\widetilde{k}_q^{l,h}$, $\widetilde{k}_v^{l,h}$, $\frac{1}{h}\widetilde{k}^{l,h}$ are uniformly bounded. It follows from (7.3) that

$$u_0{}^T(t)\left(\omega^{l+1,h} - \omega^{l,h} + \omega^{l+1,h,\perp} - \omega^{l,h,\perp}\right) + \mathcal{O}(h) \geq \frac{1}{2}\zeta(t)\|\widetilde{c}_n^{l+1,h}\|. \tag{7.9}$$

Set $l_{\min} = \lceil (t - \eta(t))/h \rceil$ and $l_{\max} = \lfloor (t + \eta(t))/h \rfloor$. Then

$$\sum_{l_{\min}}^{l_{\max}-1} u_0{}^T(t)\left(\omega^{l+1,h} - \omega^{l,h} + \omega^{l+1,h,\perp} - \omega^{l,h,\perp}\right) + \mathcal{O}(h(l_{\max} - l_{\min})) \geq \frac{1}{2}\zeta(t) \sum_{l_{\min}}^{l_{\max}-1} \left\|\widetilde{c}_n^{l+1,h}\right\|.$$

The sum on the left-hand side in the above inequality telescopes to

$$\begin{aligned}
&\sum_{l_{\min}}^{l_{\max}-1} u_0{}^T(t)\left(\omega^{l+1,h} - \omega^{l,h} + \omega^{l+1,h,\perp} - \omega^{l,h,\perp}\right) \\
&= u_0{}^T(t)\left(\omega^{l_{\max},h} - \omega^{l_{\min},h} + \omega^{l_{\max},h,\perp} - \omega^{l_{\min},h,\perp}\right) \\
&\leq \left\|\omega^{l_{\max},h}\right\| + \left\|\omega^{l_{\min},h}\right\| + \left\|\omega^{l_{\max},h,\perp}\right\| + \left\|\omega^{l_{\min},h,\perp}\right\|.
\end{aligned}$$

Using that $h(l_{\max} - l_{\min}) \leq \eta(t)$ and that $\omega^{l,h}$, $\omega^{l,h,\perp}$ are uniformly bounded (the uniform boundedness of the ω components results from the uniform boundedness of the velocities and the uniform linear independence of the columns of $\tilde{\nu}$) by a constant B_ω, we obtain

$$\sum_{l_{\min}}^{l_{\max}-1} \left\|\widetilde{c}_n^{l+1,h}\right\| \leq \frac{2}{\zeta(t)}\left(2B_\omega + C_1\eta(t)\right) \text{ uniformly as } h \to 0, \tag{7.10}$$

where the constant C_1 above corresponds to the term $\mathcal{O}(h(l_{\max} - l_{\min}))$.

7.2. Show that all of the other constraint impulses are bounded by the normal contact impulses. A bound on the tangential impulses $\tilde{\beta}^{l+1,h}$ is immediately obtained from the conic constraint:

$$\left\|\beta^{(j);l+1,h}\right\|_1 \leq \mu^{(j)} {c_n}^{(j);l+1,h}.$$

Thus, for the combined frictional impulses ${f_T}^{l+1,h} := \widetilde{D}^{l,h}\widetilde{\beta}^{l+1,h}$, we obtain

$$\sum_{l_{\min}}^{l_{\max}-1} \left\|{f_T}^{l+1,h}\right\| \leq C_2 \sum_{l_{\min}}^{l_{\max}-1} \left\|\tilde{c}_n^{l+1,h}\right\| \leq \frac{2C_2}{\zeta(t)}\left(2B_\omega + C_1\eta(t)\right), \tag{7.11}$$

with the last estimate holding uniformly as $h \to 0$. The constant C_2 above depends on the bounds on the frictional directions $d_i^{(j)}(q(\cdot))$, the friction coefficients, and the number of generators used in the polyhedral approximation of the friction cone.

To obtain a bound on $\sum_{l_{\min}}^{l_{\max}-1} \|{f_J}^{l+1,h,\alpha}\| := \sum_{l_{\min}}^{l_{\max}-1} \|\widetilde{\nu}^{l,h}(\alpha\tilde{c}^{l+1,h}+(1-\alpha)\tilde{c}^{l,h})\|$, we go back to

$$\left(M - \frac{h}{2}\widetilde{k}_v^{l,h} - \frac{h^2}{4}\widetilde{k}_q^{l,h}\right)\left(v^{l+1,h} - v^{l,h}\right) = \widetilde{k}^{l,h} + \widetilde{\nu}^{l,h}\widetilde{c}_\nu^{l+1,h} + \widetilde{n}^{l,h}\widetilde{c}_n^{l+1,h} + \widetilde{D}^{l,h}\widetilde{\beta}^{l+1,h},$$

which, together with the uniform bounds we have so far, implies that

$$v^{l+1,h} - v^{l,h} = M^{-1}\widetilde{\nu}^{l,h}\widetilde{c}_\nu^{l+1,h} + M^{-1}\widetilde{n}^{l,h}\widetilde{c}_n^{l+1,h} + M^{-1}\widetilde{D}^{l,h}\widetilde{\beta}^{l+1,h} + \mathcal{O}(h). \tag{7.12}$$

Equation (7.12), together with the uniform boundedness of the velocity sequence and the uniformly pointed friction cone assumption, implies that the impulse multipliers $\widetilde{c}_\nu^{l+1,h}, \widetilde{c}_n^{l+1,h}$, and $\widetilde{\beta}^{l+1,h}$ are bounded uniformly with respect to l. We define, for all indices l for which it makes sense, the following quantities:

$$\begin{aligned}
v^{l+1,h,\alpha} &:= \alpha v^{l+1,h} + (1-\alpha)v^{l,h},\\
\widetilde{c}_\nu^{l+1,h,\alpha} &:= \alpha\widetilde{c}_\nu^{l+1,h} + (1-\alpha)\widetilde{c}_\nu^{l,h},\\
\widetilde{c}_n^{l+1,h,\alpha} &:= \alpha\widetilde{c}_n^{l+1,h} + (1-\alpha)\widetilde{c}_n^{l,h},\\
\widetilde{\beta}^{l+1,h,\alpha} &:= \alpha\widetilde{\beta}^{l+1,h} + (1-\alpha)\widetilde{\beta}^{l,h}.
\end{aligned}$$

We note that the definition of our time-stepping scheme (4.4c) implies that

$$\left(\widetilde{\nu}^{l,h}\right)^T v^{l+1,h,\alpha} = 0, \tag{7.13}$$

and that the triangle inequality implies that

$$\left\|\widetilde{c}_n^{l,h,\alpha}\right\| \leq \alpha\left\|\widetilde{c}_n^{l+1,h}\right\| + (1-\alpha)\left\|\widetilde{c}_n^{l,h}\right\|, \quad \left\|\widetilde{\beta}^{l+1,h,\alpha}\right\| \leq \alpha\left\|\widetilde{\beta}^{l+1,h}\right\| + (1-\alpha)\left\|\widetilde{\beta}^{l,h}\right\|. \tag{7.14}$$

We multiply (7.12) by α and the same equation (7.12), with l replaced by $l-1$, by $(1-\alpha)$, and we add them. We obtain, by the uniform boundedness of the force multipliers and the uniform Lipschitz continuity of $\widetilde{\nu}(q)$, $\widetilde{n}(q)$, and $\widetilde{D}(q)$, that

$$v^{l+1,h,\alpha} - v^{l,h,\alpha} = M^{-1}\widetilde{\nu}^{l,h}\widetilde{c}_\nu^{l+1,h,\alpha} + M^{-1}\widetilde{n}^{l,h}\widetilde{c}_n^{l+1,h,\alpha} + M^{-1}\widetilde{D}^{l,h}\widetilde{\beta}^{l+1,h,\alpha} + \mathcal{O}(h). \tag{7.15}$$

We multiply (7.15) on the left by $(\widetilde{\nu}^{l,h})^T$ and use (7.13) at steps $l+1$ and l together with the fact that $\widetilde{\nu}^{l-1,h} = \widetilde{\nu}^{l,h} + \mathcal{O}(h)$. The result is

$$\mathcal{O}(h) = \left(\widetilde{\nu}^{l,h}\right)^T M^{-1}\widetilde{\nu}^{l,h}\widetilde{c}_\nu^{l+1,h,\alpha} + M^{-1}\widetilde{n}^{l,h}\widetilde{c}_n^{l+1,h,\alpha} + M^{-1}\widetilde{D}^{l,h}\widetilde{\beta}^{l+1,h,\alpha}.$$

Using the fact that the matrix $(\widetilde{\nu}^{l,h})^T M^{-1}\widetilde{\nu}^{l,h}$ is uniformly positive definite in the sense that its eigenvalues are bounded away from 0 uniformly with respect to $q^{l,h}$ as well as (7.14), we obtain a bound for the joint multipliers in terms of the normal contact impulses. More precisely, we have

$$\left\|\widetilde{c}_\nu^{l+1,h,\alpha}\right\| \le C_3\left\|\widetilde{c}_n^{l+1,h,\alpha}\right\| + \mathcal{O}(h) \le C_3\left(\alpha\left\|\widetilde{c}_n^{l+1,h,\alpha}\right\| + \left\|\widetilde{c}_n^{l,h,\alpha}\right\|\right) + \mathcal{O}(h),$$

where the constant C_3 can be chosen independent of l and h. Adding the above inequalities, we obtain

$$\sum_{l_{\min}}^{l_{\max}-1}\left\|{f_J}^{l+1,h,\alpha}\right\| := \sum_{l_{\min}}^{l_{\max}-1}\left\|\widetilde{\nu}^{l,h}\widetilde{c}_\nu^{l+1,h,\alpha}\right\| \le C_4\sum_{l_{\min}}^{l_{\max}-1}\left\|\widetilde{c}_n^{l+1,h,\alpha}\right\| \le \frac{2C_4}{\zeta(t)}\left(2B_\omega + C_1\eta(t)\right) + C_5\eta(t). \tag{7.16}$$

7.3. Obtain the bound for the variation of velocities on $[t-\eta(t), t+\eta(t)]$. As we have done in (7.4), denote by $z^{l+1,h,\alpha}$ the total constraint weighted impulse (combine total joint, normal, and tangential impulses) corresponding to step $l+1$, that is, $z^{l+1,h,\alpha} = \widetilde{\nu}^{l,h}\tilde{c}_\nu^{l+1,h,\alpha} + \widetilde{n}^{l,h}\widetilde{c}_n^{l+1,h,\alpha} + \widetilde{D}^{l,h}\widetilde{\beta}^{l+1,h,\alpha}$. From the derivations above we have that

$$\sum_{l_{\min}}^{l_{\max}-1}\left\|z^{l+1,h,\alpha}\right\| \le \frac{2C_6}{\zeta(t)}\left(2B_\omega + C_1\eta(t)\right) + C_7\eta(t), \tag{7.17}$$

where the constants above can be chosen independent of h. Now from (7.12) we have

$$\left\|v^{l+1,h,\alpha} - v^{l,h,\alpha}\right\| \le \left\|M^{-1}z^{l+1,h,\alpha}\right\| + \mathcal{O}(h),$$

and by adding, we obtain

$$\sum_{l_{\min}}^{l_{\max}-1}\left\|v^{l+1,h,\alpha} - v^{l,h,\alpha}\right\| \le \frac{2C_6}{\zeta(t)}\left(2B_\omega + C_1\eta(t)\right) + C_8\eta(t),$$

which shows that

$$\bigvee_{t-\eta(t)/2}^{t+\eta(t)/2} v^{h,\alpha}(\cdot) \text{ is uniformly bounded as } h \to 0.$$

7.4. Obtain the bound for the variation velocities on the entire time interval. Since $(t-\eta(t)/2, t+\eta(t)/2)$ is a covering of $[0,T]$, there is a finite subcovering

$$\{(t_i - \eta(t_i)/2, t_i + \eta(t_i)/2 \mid i = 1, \ldots, m_T\}.$$

Therefore, by summing the contributions corresponding to this finite set of subintervals, we obtain a uniform bound on $\bigvee_0^T v^{h,\alpha}(\cdot)$ as $h \to 0$. If we use the fact that $v^{h,\alpha}(\cdot)$ has bounded variation, then, by Helly's selection theorem, there exists a subsequence of $v^{h_k,\alpha}(\cdot)$ of $v^{h,\alpha}(\cdot)$ that converges pointwise to $v(\cdot)$ and has bounded variation. Since the limiting velocity $v(t)$ may not be well defined for every $t \in [0,T]$, *we assume without loss of generality,* [47], *that $v(\cdot)$ is right–continuous, i.e., $v(t) = v^+(t)$ for all* $t \in [0,T]$. The corresponding functions $q^{h_k,\alpha}(\cdot)$ converge to the indefinite integral of $v(\cdot)$ by the pointwise convergence theorem for Lebesgue integrals. We assume for simplicity that this is the entire sequence, and therefore $q^{h,\alpha}(\cdot) \to q(\cdot)$ and $v^{h,\alpha}(\cdot) \to v(\cdot)$.

7.5. Weak $*$ convergence. Since $\bigvee_0^T v^{h,\alpha}(\cdot)$ is uniformly bounded as $h \to 0$ and $v^{h,\alpha}(0) = v(0)$ and since $v^{h,\alpha}(\cdot) \to v(\cdot)$ pointwise, it follows that $dv^{h,\alpha} \to dv$ weakly *, that is,

$$\int_0^T \phi(t)^T dv^{h,\alpha}(t) \to \int_0^T \phi(t)^T dv(t)$$

for all continuous functions $\phi(t)$. Therefore, $dv^{h,\alpha}(\cdot) \to dv(\cdot)$ weak $*$ as Borel measures. The proof of Theorem 7.1 is complete.

8. Limits are solutions to the MDI. In this section we will use Assumptions **(H1)**–**(H8)** to prove that the limits are solutions to the rigid body MDI. We note that we cannot expect that the rigid body MDI will have unique solutions even in relatively simple cases [28, 48], a fact which can partly be justified by experimentally observed macroscopic behavior [28]. We therefore study the convergence of the subsequences of the time-stepping scheme to possibly multiple solutions of the rigid body MDI.

Assume (q, v) is a solution of the MDI of Definition (6.2). We write

$$v = \widetilde{\nu}(q)u + \widetilde{\nu}_\perp(q)w. \tag{8.1}$$

Since from the joint constraints the velocity v satisfies $(\widetilde{\nu}(q))^T v = 0$, we must have $u = 0$, which implies that the Borel measure dv (which is well defined since v is a function of bounded variation on $[0, T]$) satisfies $dv = d(\widetilde{\nu}_\perp(q)w)$. We can expand further to obtain, as detailed in Appendix A, that

$$\begin{aligned} dv = d\left(\widetilde{\nu}_\perp(q)w\right) &= \widetilde{\nu}_\perp(q)dw + \frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp(q)w\right) dq \\ &= \widetilde{\nu}_\perp(q)dw + \frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp(q)w\right) v dt = \widetilde{\nu}_\perp(q)dw + \left(\frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp(q)w\right)\right)\widetilde{\nu}_\perp(q)w dt, \end{aligned} \tag{8.2}$$

where for the second last equality we have used (6.11) and for the last one we have used the fact that u from (8.1) is zero. Note that the second term in the last equality of (8.2) is a measure which is absolutely continuous with respect to the Lebesque measure dt. Motivated by the analysis above, we introduce the following definition which gives the MDI on the reduced cone.

Definition 8.1 (reduced weak solution of (6.1)–(6.8)). *We say that $q(t)$, $w(t)$ is a reduced weak solution of* (6.1)–(6.8) *on* $[0, T]$ *if*

1. *$w(\cdot)$ is a function of bounded variation on $[0, T]$;*
2. *$q(\cdot)$ is an absolutely continuous function that satisfies*

$$q(t) = q(0) + \int_0^t \widetilde{\nu}_\perp(q(\tau))w(\tau)d\tau \quad \text{for } t \in [0, T]; \tag{8.3}$$

3. *the measure $dw(t)$ must satisfy*

$$\left(\left(\widetilde{\nu}_\perp(q)\right)^T M\widetilde{\nu}_\perp(q)\right)\frac{dw}{dt} - k_{w,\perp}(t, q, w) \in \mathcal{FC}_r(q), \tag{8.4}$$

where

$$k_{w,\perp}(t, q, w) = \left(\widetilde{\nu}_\perp(q)\right)^T k_w(t, q, w) \tag{8.5}$$

and

$$k_w(t, q, w) = k(t, q, \widetilde{\nu}_\perp(q)w) - M\left(\left(\frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp(q)w\right)\right)\widetilde{\nu}_\perp(q)w\right); \tag{8.6}$$

4. *$\Phi^{(j)}(q) \geq 0$, $j = 1, \ldots, p$.*

LEMMA 8.2. *If (q,w) is a reduced weak solution of* (6.1)–(6.8) *on* $[0,T]$ *in the sense of Definition* 8.1 *and* $\Theta^{(i)}(q(0))=0$, $i=1,2,\dots,m_J$, *then* $(q,v)=(q,\widetilde{\nu}_\perp(q)w)$ *is a weak solution of* (6.1)–(6.8) *on* $[0,T]$ *in the sense of Definition* 6.2.

Proof. By construction $(q,v)=(q,\widetilde{\nu}_\perp(q)w)$ and from conditions 1, 2, and 4 of Definition 8.1, it immediately follows that conditions 1, 2, and 5 of Definition 6.2 are satisfied. To prove that condition 4 of Definition 6.2 is satisfied, we use (8.3) to obtain, for $i=1,2,\dots,m_J$,

$$\begin{aligned}\Theta^{(i)}(q(t)) &= \Theta^{(i)}(q(0)) + \textstyle\int_0^t \left(\nu^{(i)}(q)\right)^T v(\tau)d\tau \\ &= \Theta^{(i)}(q(0)) + \textstyle\int_0^t \left(\left(\nu^{(i)}(q)\right)^T \widetilde{\nu}_\perp(q(\tau))\right) w(\tau)d\tau \\ &= \Theta^{(i)}(q(0)),\end{aligned}$$

where we have used the fact that $(\nu^{(i)})(q)^T\widetilde{\nu}_\perp(q)=0$, for $i=1,2,\dots,m_J$.

Since $\Theta^{(i)}(q(0))=0$, we have $\Theta^{(i)}(q(t))=0$ for all $t\in[0,T]$ and $i=1,2,\dots,m_J$. By a similar rationale we obtain that

$$\nu^{(i)}(q)^T v = \nu^{(i)}(q)^T\widetilde{\nu}_\perp(q)w$$

is zero almost everywhere for $i=m_J+1,m_J+2,\dots,m$, and therefore condition 4 of Definition 6.2 is satisfied.

To prove that (6.12) holds we mainly reverse the derivations in (8.2). That is, if (q,w) satisfies (8.4), then there exist $\overline{z}\in\mathcal{FC}(q)$ and a vector measure $\widetilde{d}_\nu\in\mathbb{R}^m$ such that

$$M\widetilde{\nu}_\perp(q)\frac{dw}{dt} - k_w(t,q,w) = \overline{z} + \widetilde{\nu}\widetilde{d}_\nu.$$

Since $\overline{z}\in\mathcal{FC}(q)$ implies that $\overline{z}+\widetilde{\nu}\widetilde{d}_\nu\in\mathcal{FC}(q)$ for any $\widetilde{d}_\nu\in\mathbb{R}^m$, we can write

$$M\widetilde{\nu}_\perp(q)\frac{dw}{dt} - k_w(t,q,w)\in\mathcal{FC}(q).$$

Using (8.2) together with (8.6) in the above inclusion gives

$$M\frac{dv}{dt} - k(t,q,w)\in\mathcal{FC}(q),$$

and therefore also condition 4 of Definition 6.2 is satisfied. This completes the proof of Lemma 8.2. ∎

8.1. The MDI for the limit. We start by writing (4.18) at step $(l+1)$ and step (l) as follows:

$$\overline{M}^l\left(v^{l+1}-v^l\right) - \left(\overline{k}^l + hF\left(v^l\right)v^{l+1,\alpha}\right) = z^{l+1}, \tag{8.7}$$

$$\overline{M}^{l-1}\left(v^{l}-v^{l-1}\right) - \left(\overline{k}^{l-1} + hF\left(v^{l-1}\right)v^{l,\alpha}\right) = z^{l}, \tag{8.8}$$

where $z^{k+1}\in\widehat{\mathcal{FC}}(q^k)$ and $\overline{M}^l$, $\overline{k}^l$ are given by (4.17).

Since the approximation $\widetilde{k}_{1q}$ is uniformly bounded, we have that

$$\overline{M}^k = M - \alpha h\widetilde{k}_{1v} + \mathcal{O}(h^2).$$

We now multiply (8.7) by α and (8.8) by $(1-\alpha)$ and add them up. We obtain

$$M\left(v^{l+1,\alpha}-v^{l,\alpha}\right)-\left(\alpha\overline{k}^{l}+(1-\alpha)\overline{k}^{l-1}\right)$$

$$-h\alpha\widetilde{k}_{1v}\left(v^{l+1,\alpha}-v^{l,\alpha}\right)-h\left(\alpha F\left(v^{l}\right)v^{l+1,\alpha}+(1-\alpha)F\left(v^{l-1}\right)v^{l,\alpha}\right)+\mathcal{O}(h^{2})=z^{l+1,\alpha}, \tag{8.9}$$

where we have used the fact that by Assumption **(H8)** $\widetilde{k}_{1v}^{l}$ is constant, i.e., $\widetilde{k}_{1v}^{l}=\widetilde{k}_{1v}$ for all l.

Using the fact that $F(\cdot)$ is a linear map, we have that

$$\begin{aligned}(1-\alpha)F\left(v^{l-1}\right)v^{l,\alpha}&=F\left((1-\alpha)v^{l-1}\right)v^{l,\alpha}\\&=F\left(v^{l,\alpha}\right)v^{l,\alpha}-\alpha F\left(v^{l}\right)v^{l,\alpha}.\end{aligned}$$

Then the Coriolis terms in (8.9) become

$$\alpha F\left(v^{l}\right)v^{l+1,\alpha}+(1-\alpha)F\left(v^{l-1}\right)v^{l,\alpha}=F\left(v^{l,\alpha}\right)v^{l,\alpha}+\alpha F\left(v^{l}\right)\left(v^{l+1,\alpha}-v^{l,\alpha}\right). \tag{8.10}$$

Since the sequence $v^{h}(\cdot)$ is uniformly bounded, $v^{h,\alpha}(t+h)\rightarrow v^{+}(t)$ and $v^{h,\alpha}(t)\rightarrow v(t)=v^{+}(t)$ a.e. on $[0,T]$, it follows that

$$F\left(v^{h}(t)\right)\left(v^{h,\alpha}(t+h)-v^{h,\alpha}(t)\right)\rightarrow 0 \text{ as } h\rightarrow 0,$$

for $t\in[0,T]-N$, where N is a set of Lebesque measure zero. The same reasoning applies for the term $\widetilde{k}_{1v}(v^{l+1,\alpha}-v^{l,\alpha})$, giving

$$\widetilde{k}_{1v}\left(v^{h,\alpha}(t+h)-v^{h,\alpha}(t)\right)\rightarrow 0 \text{ pointwise a.e. in } [0,T]. \tag{8.11}$$

Now by using the fact that $k_1(t,q,v)$ is linear in v as well as the fact that $\widetilde{k}_{1q}$ is bounded and $q^{l}=q^{l-1}+\mathcal{O}(h)$, we get that

$$\overline{k}^{h}(t):=\overline{k}^{h}\left(t,q^{h,\alpha}(t),v^{h,\alpha}(t)\right)\rightarrow k_1(t,q(t),v(t)) \text{ pointwise a.e. in } [0,T]. \tag{8.12}$$

Here

$$\begin{aligned}\overline{k}^{h}(t):=\overline{k}^{h}\left(t,q^{h,\alpha}(t),v^{h,\alpha}(t)\right)&=(1-\alpha)k_1\left(t,q^{h,\alpha}(t),v^{h,\alpha}(t)\right)\\&+\alpha k_1\left(t+h,q^{h,\alpha}(t),v^{h,\alpha}(t)\right)+\alpha\widetilde{k}_{1q}\left(t,q^{h,\alpha}(t),v^{h,\alpha}\right)\end{aligned}$$

is the function equivalent to the quantity $\frac{1}{h}\overline{k}^{l}$ from (4.17). Equation (8.12) implies that

$$\alpha\overline{k}^{h}(t)+(1-\alpha)\overline{k}^{h}(t-h)\rightarrow k_1\left(t,q^{h,\alpha}(t),v^{h,\alpha}(t)\right) \text{ pointwise a.e. in } [0,T]. \tag{8.13}$$

Using Assumptions **(H2)** and **(H6)**, we can write $z^{l+1,\alpha}$ in (8.9) as

$$z^{l+1,\alpha}=\overline{z}^{l+1}+\mathcal{O}\left(h\left\|v^{l+1,\alpha}-v^{l,\alpha}\right\|\right),$$

with $\overline{z}^{l+1}\in\widehat{\mathcal{FC}}(q^{l})$. This implies that, for all h sufficiently small,

$$M\frac{dv}{dt}^{h,\alpha}-\widehat{k}^{h}(t)\in\widehat{\mathcal{FC}}\left(q^{h,\alpha}(t)\right)\subset\mathcal{FC}\left(q^{h,\alpha}(t)\right), \tag{8.14}$$

where

$$\widehat{k}^h(t) = \alpha\overline{k}^h(t) + (1-\alpha)\overline{k}^h(t-h) + \left(\widetilde{k}_{1v} + F\left(v^h(t)\right)\right)\left(v^{h,\alpha}(t+h) - v^{h,\alpha}(t)\right) + F\left(v^{h,\alpha}(t)\right)v^{h,\alpha}(t) + \mathcal{O}(h) + \mathcal{O}\left(h\left\|v^{l+1,\alpha} - v^{l,\alpha}\right\|\right).$$

From (8.11)–(8.13) we can easily see that

$$\widehat{k}^h(t) \to k(t, q(t), v(t) = F(v(t))v(t) + k_1(t, q(t), v(t)) \text{ pointwise a.e. in } [0, T].$$

We now write

$$v^{h,\alpha}(t) = \widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)w^{h,\alpha}(t) + \widetilde{\nu}\left(q^{h,\alpha}(t)\right)u^{h,\alpha}(t),$$

which gives

$$u^{h,\alpha}(t) = \left(\left(\widetilde{\nu}\left(q^{h,\alpha}(t)\right)\right)^T\widetilde{\nu}\left(q^{h,\alpha}(t)\right)\right)^{-1}\left(\widetilde{\nu}(q^{h,\alpha}(t))\right)^T v^{h,\alpha}(t). \tag{8.15}$$

Using a Taylor expansion together with Assumption **(H2)**, we obtain

$$\begin{aligned}\left(\widetilde{\nu}(q^{h,\alpha}(t))\right)^T v^{h,\alpha}(t) &= \left(\widetilde{\nu}(q^{h,\alpha}(t_l))\right)^T v^{h,\alpha}(t) \\ &\quad + \left(\frac{\partial}{\partial q}\left(\widetilde{\nu}^T(q)v^{h,\alpha}(t)\right)\Big|_{q=q^{h,\alpha}(t_l)}\right)\left(q^{h,\alpha}(t) - q^{h,\alpha}(t_l)\right) \\ &\quad + \mathcal{O}\left(\left\|q^{h,\alpha}(t) - q^{h,\alpha}(t_l)\right\|^2\right).\end{aligned} \tag{8.16}$$

Since the definition of the time-stepping scheme enforces $(\widetilde{\nu}(q^{h,\alpha}(t_l))^T v^{h,\alpha}(t) = 0$ for all $t \in (t_l, t_{l+1}]$ and since $q^{h,\alpha}(t) - q^{h,\alpha}(t_l) = (t - t_l)v^{h,\alpha}(t)$ for all $t \in [t_l, t_{l+1}]$, we have

$$\left(\widetilde{\nu}(q^{h,\alpha}(t))\right)^T v^{h,\alpha}(t) = (t-t_l)\left(\frac{\partial}{\partial q}\left(\widetilde{\nu}^T(q)v^{h,\alpha}(t)\right)\Big|_{q=q^{h,\alpha}(t_l)}\right)v^{h,\alpha}(t) + \mathcal{O}\left(h^2\right). \tag{8.17}$$

Combining (8.15) and (8.17) gives

$$\begin{aligned}&\left(\widetilde{\nu}_\perp(q^{h,\alpha}(t))\right)^T M\left(\widetilde{\nu}(q^{h,\alpha}(t))u^{h,\alpha}(t) - \widetilde{\nu}(q^{h,\alpha}(t-h))u^{h,\alpha}(t-h)\right) \\ &\qquad = \mathcal{O}\left(h\left\|v^{h,\alpha}(t) - v^{h,\alpha}(t-h)\right\|\right) + \mathcal{O}(h^2).\end{aligned} \tag{8.18}$$

Using a similar methodology one also gets

$$\begin{aligned}&\widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)w^{h,\alpha}(t) - \widetilde{\nu}_\perp\left(q^{h,\alpha}(t-h)\right)w^{h,\alpha}(t-h) \\ &\quad = \widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\left(w^{h,\alpha}(t) - w^{h,\alpha}(t-h)\right) \\ &\qquad - \left(\frac{\partial}{\partial q}\left(\widetilde{\nu}^T(q)w^{h,\alpha}(t-h)\right)\Big|_{q=q^{h,\alpha}(t)}\right)\left(q^{h,\alpha}(t) - q^{h,\alpha}(t-h)\right) + \mathcal{O}(h^2) \\ &\quad = \widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\left(w^{h,\alpha}(t) - w^{h,\alpha}(t-h)\right) \\ &\qquad + h\left(\frac{\partial}{\partial q}\left(\widetilde{\nu}^T(q)w^{h,\alpha}(t-h)\right)\Big|_{q=q^{h,\alpha}(t)}\right)v^{h,\alpha}(t) + \mathcal{O}(h^2) \\ &\quad = \widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\left(w^{h,\alpha}(t) - w^{h,\alpha}(t-h)\right) \\ &\qquad + h\left(\frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp^T(q)w^{h,\alpha}(t-h)\right)\Big|_{q=q^{h,\alpha}(t)}\right)\widetilde{\nu}_\perp(q^{h,\alpha}(t))w^{h,\alpha}(t) + \mathcal{O}(h^2),\end{aligned} \tag{8.19}$$

where for the last equality, we have used (8.17), which give $h\widetilde{\nu}(q^{h,\alpha}(t))u^{h,\alpha}(t) = \mathcal{O}(h^2)$. We use (8.19) to write

(8.20)
$$\begin{aligned}
&\left(\widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\right)^T M\Big(\widetilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)w^{h,\alpha}(t) - \widetilde{\nu}_\perp\left(q^{h,\alpha}(t-h)\right)w^{h,\alpha}(t-h)\Big)\\
&\quad = \left(\left(\widetilde{\nu}_\perp^T M\widetilde{\nu}_\perp\right)\left(q^{h,\alpha}(t)\right)\right)\left(w^{h,\alpha}(t) - w^{h,\alpha}(t-h)\right)\\
&\qquad + h\left(\widetilde{\nu}_\perp(q^{h,\alpha}(t))\right)^T M\left(\frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp^T(q)w^{h,\alpha}(t-h)\right)\Big|_{q=q^{h,\alpha}(t)}\right)\widetilde{\nu}_\perp(q^{h,\alpha}(t))w^{h,\alpha}(t)\\
&\qquad + \mathcal{O}(h^2).
\end{aligned}$$

Multiplying (8.14) on the left by $(\tilde{\nu}_\perp(q^{h,\alpha}(t))^T$ and using (8.18) and (8.20), we obtain

(8.21)
$$\begin{aligned}
&\left(\tilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\right)^T M\tilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\frac{dw}{dt}^{h,\alpha}\\
&\quad - \left(\widehat{k}^h_{w,\perp}(t) + \mathcal{O}\left(\left\|v^{h,\alpha}(t) - v^{h,\alpha}(t-h)\right\|\right) + \mathcal{O}(h)\right) \in \widehat{\mathcal{FC}}_r\left(q^{h,\alpha}(t)\right) \subset \mathcal{FC}_r\left(q^{h,\alpha}(t)\right),
\end{aligned}$$

where

$$\begin{aligned}
\widehat{k}^h_{w,\perp}(t) &= \left(\tilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\right)^T\\
&\quad\times\left(\widehat{k}^h(t) - M\left(\frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp^T(q)w^{h,\alpha}(t-h)\right)\Big|_{q=q^{h,\alpha}(t)}\right)\widetilde{\nu}_\perp(q^{h,\alpha}(t))w^{h,\alpha}(t)\right).
\end{aligned} \tag{8.22}$$

Given that $q^{h,\alpha}(\cdot) \to q(\cdot)$ uniformly on $[0,T]$, $v^{h,\alpha}(\cdot) \to v(\cdot)$ a.e. on $[0,T]$ and $u^{h,\alpha}(\cdot) \to 0$ on $[0,T]$, we have

$$\left(\tilde{\nu}_\perp\left(q^{h,\alpha}(t)\right)\right)^T M\tilde{\nu}_\perp\left(q^{h,\alpha}\right) \to (\tilde{\nu}_\perp(q(t))^T M\tilde{\nu}_\perp(q(t) \text{ uniformly in } [0,T], \tag{8.23}$$

$$\widehat{k}^h_{w,\perp}(t) \to k_{w,\perp}(t,q(t),w(t)) \text{ pointwise a.e. on } [0,T]. \tag{8.24}$$

To obtain the MDI for the limits (q,w) we invoke [49, Theorem 4], stated in Appendix B, taking into account that (8.21), (8.23), and (8.24) are satisfied. In our case, the requirement of [49, Theorem 4] that $\min\{\|z\| | z \in K(w)\}$ is uniformly bounded is immediately satisfied because $K(w)$ are cones and always contain the zero element. Given also (8.23)–(8.24) as well as the fact that, from Lemma 3.5, $\mathcal{FC}_r(q)$ is uniformly pointed, we can apply the above result directly to obtain that the limits (q,w) satisfy the inclusion (8.4).

To complete this subsection, we note that, for any $t \in [0,T]$, we have that

$$\begin{aligned}
q^{h,\alpha}(t) - q^{h,\alpha}(0) &= \textstyle\int_{t_1}^{t_2} v^{h,\alpha}(\tau)d\tau\\
&= \textstyle\int_{t_1}^{t_2} \widetilde{\nu}_\perp\left(q^{h,\alpha}(\tau)\right)w^{h,\alpha}(\tau) + \widetilde{\nu}(q^{h,\alpha}(\tau))u^{h,\alpha}(\tau)d\tau.
\end{aligned}$$

Since $u^{h,\alpha}(\cdot) \to 0 = u(\cdot)$ (this results from (8.15) and (8.16) together with $(\widetilde{\nu}(q^{h,\alpha}(t_l))^T v^{h,\alpha}(t) = 0)$ as $h \to 0$ pointwise on $[0,T]$ and $q^{h,\alpha}(0) = q(0)$, we obtain that

$$q(t) = q(0) + \int_0^t \widetilde{\nu}_\perp(q(\tau))w(\tau)$$

as required by (8.3).

8.2. Feasibility of the limiting trajectories.

LEMMA 8.3. *Assume that*

$$\Theta^{(i)}\left(q^0\right) = 0, \;\; \Phi^{(j)}\left(q^0\right) \geq 0, \; i = 1, \ldots, m_J, \; j = 1, \ldots, p.$$

Then the limit $q(\cdot)$ is feasible in the sense that

$$\Theta^{(i)}(q(t)) = 0, \; i = 1, \ldots, m_J, \, \Phi^{(j)}(q(t)) \geq 0, \; j = 1, \ldots, p \text{ for all } t \in [0, T],$$

and

$$\nu^{(i)}(q(t)) = 0 \text{ a.e. } t \in [0, T], \; i = m_J + 1, m_J + 2, \ldots, m.$$

Proof. To prove the first part we note that by using the definition of the time-stepping scheme, the fact that the numerical velocities v^l are uniformly bounded as well as the fact that the algorithm solves a finite number of collisions in $[0, T]$, we obtain, for $i = 1, 2, \ldots, m$, that

$$\left\| \left(\nu^{(i)}\left(q^{h,\alpha}(t)\right)\right)^T v^{h,\alpha}(t) \right\| \leq C_1 h, \;\; \text{a.e. in } \; [0, T].$$

Taking the limit as $h \to 0$ gives

$$\left(\nu^{(i)}(q(t))\right)^T v(t) = 0 \;\; \text{a.e. in } \; [0, T], \; i = 1, 2, \ldots, m.$$

The last statement implies that for all $t \in [0, T]$ and all $i = 1, \ldots, m_J$, we have that

$$\begin{aligned} \Theta^{(i)}(q(t)) &= \Theta^{(i)}\left(q^0\right) + \textstyle\int_0^t \left(\nu^{(i)}(q(\tau))\right)^T v(\tau) d\tau \\ &= \Theta^{(i)}\left(q^0\right) \\ &= 0. \end{aligned}$$

To prove the second part, assume first that $\Phi^{(j)}(q^0) = 0$ for some $j \in \{1, \ldots, p\}$. This implies that $j \in \mathcal{A}$, and therefore

$$\left(n^{(j)}\left(q^0\right)\right)^T \left(\alpha v^1 + (1 - \alpha) v^0\right) = 0.$$

Using this we obtain that $\Phi^{(j)}(q^1) = \Phi^{(j)}(q^0) + \mathcal{O}(h^2)$ which implies, by assumption **(H1)**, that

$$\Phi^{(j)}\left(q^1\right) \geq -C_2 h^2,$$

where the constant C_2 depends on the uniform bound for the velocities and the constant B_H in (4.14). Assuming $\Phi^{(j)}(q^1) \leq 0$, i.e., $j \in \mathcal{A}$ at step 2, we can bound (in the same fashion as we did above) the negative part of $\Phi^{(j)}(\cdot)$ at the next step by $\Phi^{(j)}(q^2) \geq -2C_2 h^2$. We can continue this process until the first k for which $\Phi^{(j)}(q^k) \leq 0$ and $\Phi^{(j)}(q^{k+1}) > 0$. We obtain the estimate:

$$\Phi^{(j)}\left(q^l\right) \geq -l C_2 h^2 \geq -(C_2 \cdot T) h, \; l = 0, \ldots, k, \tag{8.25}$$

where to obtain the last inequality we have used that $k \leq l_{\max} = \left\lfloor \frac{T}{h} \right\rfloor$.

If $\Phi^{(j)}(q^0) > 0$, the only way to obtain $\Phi^{(j)}(q^k) < 0$ for some k is to have at least one collision occurring. Assume that this kth time step is the first collisional time step. We can guarantee by the collision-detection algorithm that $\Phi^{(j)}(q^k) \geq -C_3 h^2$ (for a fixed constant C_3), where q^k is the detected position for the collision. When computing the solution at step $(k + 1)$, the index j is a component of the active set. We have two possibilities for step $(k + 1)$:

- The nonpenetration constraint (j) leaves the active set , i.e., $\Phi^j(q^{k+1}) > 0$, in which case we can restart recursively; or,
- The nonpenetration constraint (j) remains in the active set , i.e., $\Phi^{(j)}(q^{k+1}) \leq 0$. In this case, we have $\Phi^{(j)}(q^{(k+1)}) \geq -(C_3 + C_2)h^2$. Continuing like this until step $(k + r + 1)$ where either take-off occurs or $(k + r + 1) \geq \frac{T}{h}$, we obtain the estimate

$$\Phi^{(j)}\left(q^{k+l}\right) \geq -(C_3 + lC_2)h^2 \geq -C_4 h,\ l = 0, \ldots, r. \tag{8.26}$$

Since the number of changes in the active set is uniformly upper bounded as $h \to 0$, we can separate the two cases above and combine (8.25)–(8.26) to obtain

$$\Phi^{(j)}\left(q^{l}\right) \geq -Ch,\ 0 \leq l \leq \left\lfloor \frac{T}{h} \right\rfloor.$$

It follows that $\Phi^{(j)}(q^{h,\alpha}(t)) \geq -Ch$ for h sufficiently small and all $t \in [0, T]$. Taking the limit as $h \to 0$ we obtain $\Phi^{(j)}(q(t)) \geq 0$, $t \in [0, T]$. ∎

We summarize the analysis above in the following result.

THEOREM 8.4. *Assume that $\gamma = \alpha \in [\frac{1}{2}, 1]$, and conditions* **(H1)**–**(H8)** *hold. Then there exists a subsequence $h_k \to 0$ such that*

1. *$q^{h_k,\alpha}(\cdot) \to q(\cdot)$ uniformly;*
2. *$v^{h_k,\alpha}(\cdot) \to v(\cdot)$ pointwise a.e;*
3. *$dv^{h_k,\alpha}(\cdot) \to dv(\cdot)$ weak * as Borel measures in $[0, T]$, and every such subsequence converges to a solution $(q(\cdot), v(\cdot))$ of the MDI (6.11)–(6.12).*

Therefore, $q(t), v(t)$ is a weak solution of our model.

9. Examples. In this section we present two numerical examples that illustrate some of the theoretical points made in this work. We mention that an example, involving a double pendulum colliding with a wall, of our scheme converging in the case that involves joints and collisions (and thus, discontinuities in the velocity solution) was already presented in [39].

9.1. A simple joint example. As an introductory example, consider the dynamics of the system $\ddot{q} = 0$, subject to the joint constraint $q = 0$, to which we apply the scheme (4.4) with parameters $\alpha = \frac{1}{2}$ and $\gamma = \frac{1}{2}$. If the initial conditions are $q = 0$ and $\dot{q} = 0$, then the exact solution satisfies $q(t) = 0$.

To model the effect of errors on initial conditions, we start with $q = 0$, $\dot{q} = \epsilon$. Our scheme produces $q^{l,\alpha} = 0$ and $v^l = (-1)^l \epsilon$. The total variation of the velocity for the time interval T is $\frac{2\epsilon T}{h}$, where h is the time step. Therefore, no matter how small the initial error, the total variation is unbounded, and the resulting velocity function does not converge pointwise as $h \to 0$. On the other hand, we can immediately see that $v^{l,\alpha} = 0$, and that the velocity function defined in our main result has bounded variation and is convergent pointwise. This also validates the fact that our bounded variation for $v^{l,\alpha}$ result holds irrespective of the initial error in constraint satisfaction, and that the same result cannot be proved for v^l (though for the case with exact satisfaction of the initial constraints we could neither prove nor disprove bounded variation of the velocity sequence).

Of course, this difficulty will disappear if we make $\epsilon = 0$. But on one hand, in practical examples exact satisfaction of the constraints is difficult to guarantee. And on the other hand, this example is indicative of the fact that $v^{l,\alpha}$ has a more stable behavior than v^l.

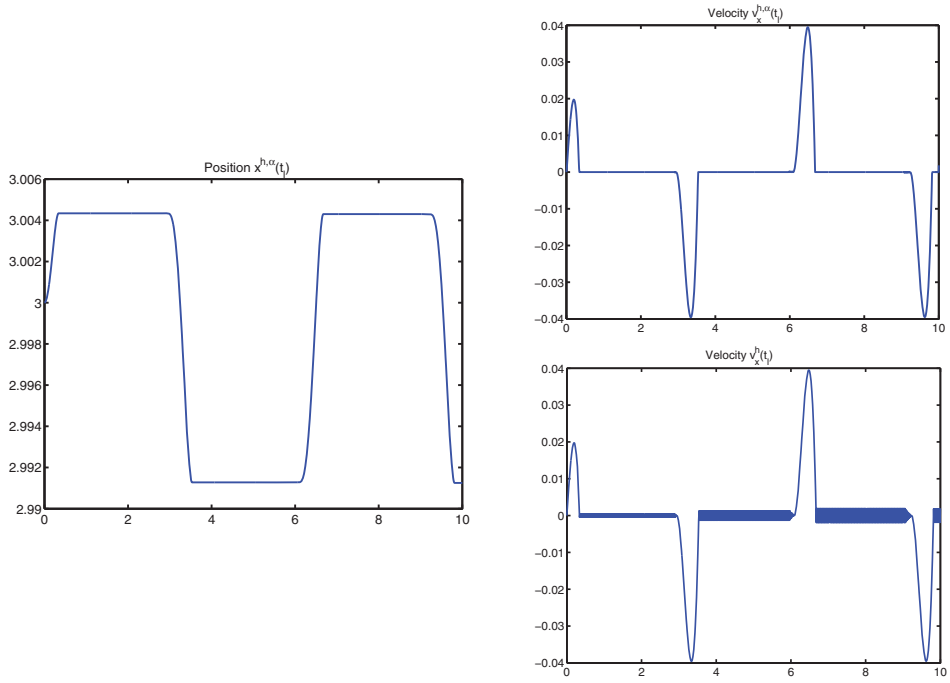

FIG. 9.1. *Numerical position and velocities for $T = 10$ (s), $\alpha = \gamma = 1/2$, and $h = 0.01$. The plot on the left shows positions $q_1^{h,\alpha}(t_l)$, while the two plots on the right show the velocity sequences $v_1^{h,\alpha}(t_l)$ at the top and $v_1^{h}(t_l)$ at the bottom.*

9.2. An example with stick-slip behavior. We want to further motivate our choice for the velocity sequence by looking at a very simple example, [39], with stick-slip behavior. In that example, a block of mass $m = 1$ is subjected to an exterior force $k(t) = 8\cos(t)$ and is sliding on a flat table with friction coefficient $\mu = 0.8$. The initial position of the block is $q_0 = (3, 0)^T$, and the initial velocity is $v_0 = (0, 0)^T$. The gravity $G = (0, -mg)^T$ is calculated, with $g = 9.81$. We compare the weighted numerical velocity sequence $v^{h,\alpha}(t)$ to the sequence $v^h(t)$ for $\alpha = \gamma = \frac{1}{2}$. The positions $q^{h,\alpha}(t_l)$ and velocities $v^h(t_l), v^{h,\alpha}(t_l)$, with $\alpha = \gamma = \frac{1}{2}$ are shown in Figure 9.1, and they indicate a typical stick-slip behavior. We note that the numerical velocities exhibit a quite different behavior, in line with our observations from the preceding sections. We see that, starting with the onset of sticking, the velocity sequence v^l exhibits oscillations that are not present in the sequence $v^{l,\alpha}$, which has the value 0 during the sticking phase. As opposed to the previous example, we do not obtain unbounded variation, though the total variation of the two velocity solutions is different. Nonetheless, the example illustrates the difficulty in obtaining a good behavior of the total variation of the velocity solution v^l, as opposed to $v^{l,\alpha}$, and justifies our choice of the latter for our convergence result.

10. Conclusions. In this work, we have defined a convergence framework for a class of time-stepping schemes for multirigid-body dynamics with joints, contact, and friction. In our framework the numerical solution is shown to converge to the solution of an MDI. *The novelty of our approach resides in the fact that convergence in an MDI sense of an LCP time-stepping scheme is proved, for the first time, for the case*

that involves joint constraints as well. We note that such a proof does not directly follow from representing a joint constraint (an equality constraint) as two opposite inequality constraints (contact constraints) and applying previous convergence results [46, 47], because the resulting system cannot possibly have a pointed friction cone, since any action can be realized with infinite multipliers by cancellation. The situation is analogous to the loss of the Mangasarian–Fromovitz constraint qualification in nonlinear programming when one equality constraint is represented as two inequality constraints [33]. In this work, results for cases involving joints are proved by defining the MDI with respect to an appropriately defined reduced friction cone.

The convergence framework presented here accommodates time-stepping methods based on semiexplicit Euler methods [4, 46] as well as various instances of the trapezoidal method that have been shown to have second-order convergence under certain assumptions [39]. An important step in the convergence proof, following the technique developed in [47], is the proof of the bounded variation of the discrete velocity sequence. We show that, although this may not hold for most trapezoidal-like methods for the natural discrete velocity sequence ($v(t) = v^{(l+1)}$, for $t \in (t_l, t_{l+1}]$, which is the one used in the seminal work [47]), it does hold for the modified velocity sequence $v(t) = \alpha v^{(l+1)} + (1-\alpha)v^{(l)}$ for $t \in (t_l, t_{l+1}]$, where α is the parameter used in the enforcement of the linearization of the geometrical constraints (contact and joint constraints). This point is reinforced by numerical examples.

Appendix A. The details in the derivation of (8.2). In this section we present the details of obtaining (8.2). The main result that we use can be found in [29, p. 9], and it is listed below.

LEMMA A.1 (see [29, p. 9]). *If u_1, $u_2 \in \mathrm{BV}([0,T],\mathbb{R}^k)$, then $d(u_1^T u_2)$ is a real Borel measure on $[0,T]$, which we write $d(u_1^T u_2) \in \mathcal{B}([0,T],\mathbb{R})$ and*

$$\begin{aligned} d\left(u_1^T u_2\right) &= \left(u_2^-\right)^T du_1 + \left(u_1^+\right)^T du_2 \\ &= \left(u_2^+\right)^T du_1 + \left(u_1^-\right)^T du_2, \end{aligned} \tag{A.1}$$

where for a function $f \in \mathrm{BV}([0,T],\mathbb{R}^k)$, f^+ (f^-) denotes the right-limit (left-limit) of f. More precisely $f^+(t) = \lim_{s\to t,\ s>t} f(s)$ ($f^-(t) = \lim_{s\to t,\ s<t} f(s)$), with the convention that if t is the right (left) endpoint of $[0,T]$, we take $f^+(t) = f(t)$ ($f^-(t) = f(t)$). Note that since f is of bounded variation, these limits exist for all t in $[0,T]$.

Proving (8.2). We recall that $q : [0,T] \to \mathbb{R}^s$ is a Lipschitz continuous function, $v = \widetilde{\nu}_\perp(q)w \in \mathrm{BV}([0,T],\mathbb{R}^s)$, and $\widetilde{\nu}_\perp : \mathbb{R}^s \to \mathbb{R}^{s\times(s-m)}$ is sufficiently smooth. We further assume that $v(\cdot) = v^+(\cdot)$ (Note that since $q(\cdot)$ is continuous and $\widetilde{\nu}_\perp(\cdot)$ is uniformly full column rank, this also implies that $w(\cdot)$ is equal to its right limit). To prove (8.2) the steps itemized below are followed.

- **Chain rule:** $d(\widetilde{\nu}_\perp(q)w) = \widetilde{\nu}_\perp(q)dw + \frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp(q)w\right) dq$.
  For every $i \in \{1,\dots,s\}$ we apply (A.1), with

  $$u_1 = \left(\widetilde{\nu}_\perp(q)\right)_i \text{ and } u_2 = w.$$

  Here if A is a given matrix, A_i denotes its ith row written in column format. Since $q(\cdot)$ is Lipschitz continuous and $\widetilde{\nu}_\perp(\cdot)$ is sufficiently smooth, it follows that $u_1 \in \mathrm{BV}([0,T],\mathbb{R}^{s-m})$ and $u_1^+(t) = u_1^-(t) = u_1(t)$ for all $t \in [0,T]$. We also have $u_2 = w \in \mathrm{BV}([0,T],\mathbb{R}^{s-m})$. Using (A.1) we obtain

  $$(dv)_i = \left(d\left(\widetilde{\nu}_\perp(q)\right)_i\right)^T w + \left(\left(\widetilde{\nu}_\perp(q)\right)_i\right)^T dw, \tag{A.2}$$

where we have used the continuity of u_1 and right continuity of u_2. Since $\widetilde{\nu}_\perp(\cdot)$ is sufficiently smooth, we can write

$$d\left(\widetilde{\nu}_\perp(q)\right)_i = \left(\frac{\partial}{\partial q}\left(\left(\widetilde{\nu}_\perp\right)_i\right)(q)\right) dq, \tag{A.3}$$

where the $(s-m)\times s$ matrix in the right-hand side is the Jacobian of $(\widetilde{\nu}_\perp(q))_i$. Using (A.3) in (A.2) for all i gives the desired result, i.e.,

$$d\left(\widetilde{\nu}_\perp(q)w\right) = \widetilde{\nu}_\perp(q)dw + \frac{\partial}{\partial q}\left(\widetilde{\nu}_\perp(q)w\right) dq. \tag{A.4}$$

- **The differential vector measure induced by q:** $dq = vdt$.
  Since

$$q(t) = q(0) + \int_0^t v(\tau)d\tau,$$

for all $t \in [0,T]$ and v is bounded on $[0,T]$, it follows that dq is absolutely continuous w.r.t. the Lebesque measure dt, and the Radon–Nicodym derivative is

$$v = \frac{dq}{dt}.$$

Therefore we may write $dq = vdt$. Note that the Radon–Nicodym derivative (w.r.t. the Lebesque measure) is uniquely determined up to a set of (Lebesque) measure 0.

Appendix B. Theorem 4, [49]. *Suppose that $q_{\hat{n}}(\cdot)$ are continuous, $v_{\hat{n}}(\cdot)$ have uniformly bounded variation, and $k_{\hat{n}}(\cdot)$ are uniformly bounded, all on $[0,T]$, and $q_{\hat{n}}(\cdot) \to q(\cdot)$ uniformly, $v_{\hat{n}}(\cdot) \to v(\cdot)$ pointwise a.e., and $k_{\hat{n}}(\cdot) \to k(\cdot)$ pointwise a.e. Suppose also that $K : \mathbb{R}^n \Rightarrow \mathcal{C}(\mathbb{R}^n)$ has closed graph, $\min\{\|z\| | z \in K(w)\}$ is uniformly bounded, and $K(w)$ is pointed for all $w \in \mathbb{R}^n$. Then if*

$$\frac{dv_{\hat{n}}}{dt}(t) \in K(q_{\hat{n}}(t)) - k_{\hat{n}}(t)$$

for all $\hat{n}$, the limit satisfies

$$\frac{dv}{dt}(t) \in K(q(t)) - k(t).$$

Here $\mathcal{C}(\mathbb{R}^n)$ denotes all of the closed and convex subsets of $\mathbb{R}^n$.

Acknowledgments. We are grateful to two anonymous referees for suggestions that have substantially improved the paper and, in particular, for the suggestion of including nonholonomic constraints. We are grateful to Jeff Trinkle and Vijay Kumar for support and creative discussions.

AN ACTIVE-SET NEWTON METHOD FOR MATHEMATICAL PROGRAMS WITH COMPLEMENTARITY CONSTRAINTS*

A. F. IZMAILOV† AND M. V. SOLODOV‡

Abstract. For a mathematical program with complementarity constraints (MPCC), we propose an active-set Newton method, which has the property of local quadratic convergence under the MPCC linear independence constraint qualification (MPCC-LICQ) and the standard second-order sufficient condition (SOSC) for optimality. Under MPCC-LICQ, this SOSC is equivalent to the piecewise SOSC on branches of MPCC, which is weaker than the special MPCC-SOSC often employed in the literature. The piecewise SOSC is also more natural than MPCC-SOSC because, unlike the latter, it has an appropriate second-order necessary condition as its counterpart. In particular, our assumptions for local quadratic convergence are weaker than those required by standard SQP when applied to MPCC and are equivalent to assumptions required by piecewise SQP for MPCC. Moreover, each iteration of our method consists of solving a linear system of equations instead of a quadratic program. Some globalization issues of the local scheme are also discussed, and illustrative examples and numerical experiments are presented.

Key words. mathematical program with complementarity constraints, active set method, Newton method, SQP, second-order sufficiency, quadratic convergence

1. Introduction.

We consider a *mathematical program with complementarity constraints* (MPCC)

$$\min\ f(x) \quad \text{s.t.} \quad G(x) \geq 0,\ H(x) \geq 0,\ \langle G(x), H(x)\rangle \leq 0, \tag{1.1}$$

where $f : \mathbf{R}^n \to \mathbf{R}$ is a smooth function and G, $H : \mathbf{R}^n \to \mathbf{R}^m$ are smooth mappings (twice differentiable and possessing Lipschitzian second derivatives in a neighborhood of the solution of interest). We note that "usual" equality and inequality constraints can be added to our problem setting without any substantial difficulties. We shall consider the case when the problem has only complementarity constraints for the sake of simplicity. Note also that the last constraint in (1.1) could be written as an equality, which is more standard in the complementarity literature. However, it is known that in the context of MPCC, there are good numerical reasons to use the inequality formulation for this constraint. Also, this makes the associated set of Lagrange multipliers smaller, which has both numerical and theoretical advantages. MPCC is perhaps one of the most important instances of a *mathematical program*

with equilibrium constraints, which has recently attracted considerable attention in the optimization literature; see [15, 16].

In order to explain the contribution of this work, some preliminaries from MPCC theory will be needed. To this end, let

$$L(x,\,\lambda) = f(x) - \langle \lambda_G,\, G(x)\rangle - \langle \lambda_H,\, H(x)\rangle + \lambda_0 \langle G(x),\, H(x)\rangle$$

be the standard Lagrangian of problem (1.1), where $x \in \mathbf{R}^n$ and $\lambda = (\lambda_G,\, \lambda_H,\, \lambda_0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$. As for any other mathematical program (MP), stationary points of (1.1) and the associated Lagrange multipliers are characterized by the Karush–Kuhn–Tucker (KKT) optimality system:

$$\begin{gathered} \frac{\partial L}{\partial x}(x,\,\lambda) = 0, \quad \lambda_0 \geq 0, \quad \langle G(x),\, H(x)\rangle \leq 0, \\ \lambda_G \geq 0,\ G(x) \geq 0,\ \langle \lambda_G,\, G(x)\rangle = 0, \quad \lambda_H \geq 0,\ H(x) \geq 0,\ \langle \lambda_H,\, H(x)\rangle = 0. \end{gathered} \tag{1.2}$$

In the above, we omit the condition $\lambda_0 \langle G(x),\, H(x)\rangle = 0$, because it is redundant (it follows from $\langle G(x),\, H(x)\rangle = 0$, which is implied by feasibility of x in (1.1)). For $\bar{x} \in \mathbf{R}^n$, let $\Lambda(\bar{x})$ stand for the set of Lagrange multipliers associated with $\bar{x}$, that is, the set of $\lambda = \bar{\lambda} = (\bar{\lambda}_G,\, \bar{\lambda}_H,\, \bar{\lambda}_0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$ satisfying (1.2) for $x = \bar{x}$. As is well known and can be easily checked, MPCC constraints violate the Mangasarian–Fromovitz constraint qualification and, even more so, the linear independence constraint qualification (LICQ), at every feasible point. Therefore, in general, $\bar{x}$ being a local solution of (1.1) does not guarantee that the set of Lagrange multipliers $\Lambda(\bar{x})$ is nonempty. Nevertheless, $\Lambda(\bar{x})$ happens to be nonempty in many cases of interest, and this became one of the common settings in MPCC literature.

Define further the so-called *MPCC-Lagrangian* of problem (1.1):

$$\mathcal{L}(x,\,\mu) = f(x) - \langle \mu_G,\, G(x)\rangle - \langle \mu_H,\, H(x)\rangle,$$

where $x \in \mathbf{R}^n$ and $\mu = (\mu_G,\, \mu_H) \in \mathbf{R}^m \times \mathbf{R}^m$. To a feasible point $\bar{x}$ we associate the index sets

$$\begin{gathered} I_G = I_G(\bar{x}) = \{i = 1, \ldots, m \mid G_i(\bar{x}) = 0\},\ I_H = I_H(\bar{x}) = \{i = 1, \ldots, m \mid H_i(\bar{x}) = 0\}, \\ I_0 = I_G \cap I_H. \end{gathered} \tag{1.3}$$

A feasible point $\bar{x}$ of (1.1) is said to be a *strongly stationary point* of this problem if there exists an *MPCC-multiplier* $\bar{\mu} = (\bar{\mu}_G,\, \bar{\mu}_H) \in \mathbf{R}^m \times \mathbf{R}^m$ satisfying

$$\frac{\partial \mathcal{L}}{\partial x}(\bar{x},\, \bar{\mu}) = 0,\ (\bar{\mu}_G)_{I_H \setminus I_G} = 0,\ (\bar{\mu}_H)_{I_G \setminus I_H} = 0,\ (\bar{\mu}_G)_{I_0} \geq 0,\ (\bar{\mu}_H)_{I_0} \geq 0, \tag{1.4}$$

where y_I stands for the subvector of the vector y, with components $y_i, i \in I$. Without nonnegativity conditions in (1.4), $\bar{x}$ is called a *weakly stationary point* of (1.1).

We say that *MPCC linear independence constraint qualification* (MPCC-LICQ) holds at $\bar{x}$ if the gradients

$$G_i'(\bar{x}),\ i \in I_G, \quad H_i'(\bar{x}),\ i \in I_H \quad \text{are linearly independent.} \tag{1.5}$$

It was shown in [18, Theorem 2] that if MPCC-LICQ holds at a local solution $\bar{x}$ of (1.1), then this point is strongly stationary, and the associated MPCC-multiplier $\bar{\mu}$ is unique.

The following proposition summarizes some results obtained in [7, Proposition 4.1] and [9, Proposition 1], which will be used in what follows. Its proof can be obtained by a direct computation. Let

$$\bar{\nu} = \max\left\{0,\ \max_{i\in I_G\setminus I_H}\left(-\frac{(\bar{\mu}_G)_i}{H_i(\bar{x})}\right),\ \max_{i\in I_H\setminus I_G}\left(-\frac{(\bar{\mu}_H)_i}{G_i(\bar{x})}\right)\right\}. \tag{1.6}$$

PROPOSITION 1.1. *A feasible point $\bar{x}$ of problem* (1.1) *is a stationary point of this problem if and only if it is a strongly stationary point of this problem. Moreover, if $\bar{\lambda} = (\bar{\lambda}_G, \bar{\lambda}_H, \bar{\lambda}_0)$ is a Lagrange multiplier associated with $\bar{x}$, then $\bar{\mu} = (\bar{\mu}_G, \bar{\mu}_H)$ defined by*

$$(\bar{\mu}_G)_i = \left(\bar{\lambda}_G\right)_i - \bar{\lambda}_0 H_i(\bar{x}),\ i \in I_G \setminus I_H, \quad (\bar{\mu}_G)_i = \left(\bar{\lambda}_G\right)_i,\ i \in I_H, \tag{1.7}$$

$$(\bar{\mu}_H)_i = \left(\bar{\lambda}_H\right)_i - \bar{\lambda}_0 G_i(\bar{x}),\ i \in I_H \setminus I_G, \quad (\bar{\mu}_H)_i = \left(\bar{\lambda}_H\right)_i,\ i \in I_G, \tag{1.8}$$

is an MPCC-multiplier associated with $\bar{x}$. Conversely, if $\bar{\mu} = (\bar{\mu}_G, \bar{\mu}_H)$ is an MPCC-multiplier associated with $\bar{x}$, then any $\bar{\lambda} = (\bar{\lambda}_G, \bar{\lambda}_H, \bar{\lambda}_0)$ satisfying (1.7)–(1.8) *and*

$$\bar{\lambda}_0 \geq \bar{\nu}, \tag{1.9}$$

with $\bar{\nu}$ defined in (1.6)*, is a Lagrange multiplier associated with $\bar{x}$.*

Furthermore, for any $\xi \in \mathbf{R}^n$ and any $\bar{\lambda} = (\bar{\lambda}_G, \bar{\lambda}_H, \bar{\lambda}_0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$ and $\bar{\mu} = (\bar{\mu}_G, \bar{\mu}_H) \in \mathbf{R}^m \times \mathbf{R}^m$ satisfying (1.7)–(1.8)*, it holds that*

$$\frac{\partial^2 L}{\partial x^2}\left(\bar{x}, \bar{\lambda}\right)[\xi, \xi] = \frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x}, \bar{\mu})[\xi, \xi] + 2\bar{\lambda}_0 \sum_{i=1}^{m} \langle G_i'(\bar{x}), \xi\rangle \langle H_i'(\bar{x}), \xi\rangle. \tag{1.10}$$

In particular, if $\bar{\mu}$ is the unique MPCC-multiplier associated with $\bar{x}$ (e.g., under MPCC-LICQ (1.5)), then $\Lambda(\bar{x})$ is the ray defined by (1.7)–(1.9), with its origin corresponding to $\bar{\lambda}_0 = \bar{\nu}$.

It can be easily checked that the standard critical cone of problem (1.1) at $\bar{x}$ is given by

$$C(\bar{x}) = \left\{\xi \in \mathbf{R}^n \;\middle|\; \begin{array}{l} G'_{I_G\setminus I_H}(\bar{x})\xi = 0,\ H'_{I_H\setminus I_G}(\bar{x})\xi = 0,\ G'_{I_0}(\bar{x})\xi \geq 0,\ H'_{I_0}(\bar{x})\xi \geq 0, \\ \langle f'(\bar{x}), \xi\rangle \leq 0 \end{array}\right\}. \tag{1.11}$$

We say that *MPCC–second-order sufficient condition* (MPCC-SOSC) holds at a strongly stationary point $\bar{x}$ of problem (1.1), with the associated MPCC-multiplier $\bar{\mu}$, if

$$\frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x}, \bar{\mu})[\xi, \xi] > 0 \quad \forall\, \xi \in C(\bar{x}) \setminus \{0\}. \tag{1.12}$$

Note that, for every $\xi \in C(\bar{x})$, we obtain from (1.11) that (1.10) takes the form

$$\frac{\partial^2 L}{\partial x^2}\left(\bar{x}, \bar{\lambda}\right)[\xi, \xi] = \frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x}, \bar{\mu})[\xi, \xi] + 2\bar{\lambda}_0 \sum_{i\in I_0} \langle G_i'(\bar{x}), \xi\rangle \langle H_i'(\bar{x}), \xi\rangle, \tag{1.13}$$

where the last term in the right-hand side is nonnegative. Thus, according to Proposition 1.1, MPCC-SOSC implies the usual SOSC

$$\frac{\partial^2 L}{\partial x^2}\left(\bar{x}, \bar{\lambda}\right)[\xi, \xi] > 0 \quad \forall\, \xi \in C(\bar{x}) \setminus \{0\} \tag{1.14}$$

for any $\bar{\lambda}$ satisfying (1.7)–(1.9). In particular, under MPCC-LICQ (1.5), MPCC-SOSC (1.12) (with the unique MPCC-multiplier $\bar{\mu}$) implies SOSC (1.14), with any $\bar{\lambda}$ in the ray $\Lambda(\bar{x})$, including the origin of this ray.

It is important to point out that MPCC-SOSC is a rather strong condition. In particular, it cannot be linked to any second-order necessary condition for (1.1). By this we mean that a solution of (1.1) that satisfies MPCC-LICQ (1.5) (and thus is strongly stationary) does not have to satisfy the condition obtained from (1.12) by replacing the strict inequality by nonstrict. In our developments, we shall be making use of a SOSC weaker than (1.12), which also happens to be much more natural, because it is related to an appropriate second-order necessary condition for (1.1), as explained below.

For each partition (I_1, I_2) of I_0 (i.e., a pair of index sets such that $I_1 \cup I_2 = I_0$, $I_1 \cap I_2 = \emptyset$), define the *branch* (or *piece*) *MP* at $\bar{x}$ by

$$\begin{array}{ll} \min & f(x) \\ \text{s.t.} & G_{(I_G \setminus I_H) \cup I_1}(x) = 0,\ H_{(I_H \setminus I_G) \cup I_2}(x) = 0,\ G_{I_2}(x) \geq 0,\ H_{I_1}(x) \geq 0. \end{array} \tag{1.15}$$

There is a finite number of such branch MPs, $\bar{x}$ is feasible for each of them, and in a neighborhood of $\bar{x}$ the feasible set of (1.1) is a union of feasible sets of all branch MPs. It is not difficult to see that the union of the critical cones of all branch MPs at $\bar{x}$ is given by

$$C_2(\bar{x}) = \left\{ \xi \in \mathbf{R}^n \;\middle|\; \begin{array}{l} \langle f'(\bar{x}),\, \xi \rangle \leq 0,\ G'_{I_G \setminus I_H}(\bar{x})\xi = 0,\ H'_{I_H \setminus I_G}(\bar{x})\xi = 0, \\ G'_{I_0}(\bar{x})\xi \geq 0,\ H'_{I_0}(\bar{x})\xi \geq 0,\ \langle G'_i(\bar{x}),\, \xi \rangle \langle H'_i(\bar{x}),\, \xi \rangle = 0,\ i \in I_0 \end{array} \right\}, \tag{1.16}$$

where the subscript "2" indicates that, unlike $C(\bar{x})$, this set takes into account the second-order information about the last constraint in (1.1). By direct comparison of (1.11) and (1.16), we have that

$$C_2(\bar{x}) \subset C(\bar{x}). \tag{1.17}$$

We say that *piecewise SOSC* holds at a strongly stationary point $\bar{x}$ of problem (1.1), with an associated MPCC-multiplier $\bar{\mu}$, if

$$\frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x},\, \bar{\mu})[\xi,\, \xi] > 0 \quad \forall\, \xi \in C_2(\bar{x}) \setminus \{0\}. \tag{1.18}$$

From (1.4), it evidently follows that if $\bar{\mu} = (\bar{\mu}_G,\, \bar{\mu}_H)$ is an MPCC-multiplier associated with $\bar{x}$, then the pair $((\bar{\mu}_G)_{I_G},\, (\bar{\mu}_H)_{I_H})$ is a Lagrange multiplier associated with $\bar{x}$ for the branch MP (1.15). It follows that piecewise SOSC (1.18) implies SOSC for each branch at $\bar{x}$. This, in turn, guarantees that $\bar{x}$ is a strict local solution of (1.1). Thus, piecewise SOSC is indeed sufficient for optimality, even though it is evidently weaker than MPCC-SOSC (see (1.17)).

It is important to emphasize that under MPCC-LICQ (1.5), the condition obtained from (1.18) by replacing the strict inequality by nonstrict is necessary for optimality [18, Theorem 7]. In this sense, piecewise SOSC (1.18) is a more natural assumption than MPCC-SOSC (1.12), as the latter has no relation to any second-order necessary optimality condition.

Suppose that MPCC-LICQ (1.5) and piecewise SOSC (1.18) (with the unique MPCC-multiplier $\bar{\mu}$) hold at a strongly stationary point $\bar{x}$ of problem (1.1). From (1.13) and [9, Proposition 2], it follows that in this case either SOSC (1.14) holds

with all $\bar{\lambda}$ in the ray $\Lambda(\bar{x})$, or possibly there exists $\hat{\nu} \geq \bar{\nu}$ such that SOSC (1.14) does not hold for all $\bar{\lambda}$ corresponding to $\bar{\lambda}_0 \in [\bar{\nu}, \hat{\nu}]$, and holds for all $\bar{\lambda}$ corresponding to $\bar{\lambda}_0 > \hat{\nu}$. Conversely, if SOSC (1.14) holds for some $\bar{\lambda} \in \Lambda(\bar{x})$, from (1.13) and (1.16), taking also into account (1.17), it is easy to see that piecewise SOSC (1.18) holds as well. Thus, under MPCC-LICQ, SOSC (with some multiplier) is equivalent to piecewise SOSC.

Despite the inevitable violation of standard constraint qualifications, there exists some numerical evidence of good performance of sequential quadratic programming (SQP) algorithms for MPCCs (see [6]). Moreover, [7] gives some theoretical justification for local superlinear convergence of the SQP algorithm for MPCC under a set of assumptions that includes MPCC-LICQ and MPCC-SOSC, among other things. However, it is very easy to provide examples satisfying all *natural* in MPCC context requirements (say, MPCC-LICQ and piecewise SOSC), and such that SQP does not possess superlinear convergence; see, e.g., the example in [7, section 7.3], discussed also in detail in [11, section 6]. This means that the existing evidence supporting the use of standard optimization algorithms (say, SQP) for MPCC cannot be regarded as completely satisfactory, and it still makes sense to develop special algorithms which take into account special structure of MPCC, and which are guaranteed to achieve quadratic convergence under more natural assumptions.

Let us recall now the main idea of the piecewise SQP algorithm, suggested originally in [17] for MPs with linear complementarity constraints and then extended in [15] to the nonlinear case. An iteration of piecewise SQP is organized as follows: identify *any* branch MP valid at the solution $\bar{x}$ that is being approximated, and perform a step of standard SQP for this branch. In order to identify a valid branch MP, it suffices to (over)estimate the sets $I_G \setminus I_H$ and $I_H \setminus I_G$ (see (1.15)). Locally, this comes for free, with no significant computational cost and with no assumptions needed. However, in order to justify the overall superlinear convergence of piecewise SQP, one needs to guarantee superlinear convergence of SQP for each branch, and dual convergence to the same multiplier for all branches. This results in the following set of assumptions: MPCC-LICQ (1.5) and piecewise SOSC (1.18) at the solution $\bar{x}$.

In this paper, we suggest a local algorithm based on the following idea (to some extent motivated by the development in [13]). Instead of an arbitrary valid branch, we identify the index sets I_G and I_H and perform the Newton–Lagrange steps for the following purely equality-constrained *tightened MP*:

$$\min\ f(x) \quad \text{s.t.} \quad G_{I_G}(x) = 0,\ H_{I_H}(x) = 0. \tag{1.19}$$

Note that this problem is not a branch MP, in general, but its feasible set is contained in the feasible sets of all branch MPs.

For quadratic convergence of the Newton–Lagrange method for (1.19), we need to assume MPCC-LICQ (1.5) and SOSC for this problem, the latter being evidently guaranteed by piecewise SOSC (1.18). Local identification of I_G and I_H uses the procedure suggested in [4] and the error bound following from [8, Lemma 2] and [5, Theorem 2] (see (2.6)). The identification technique based on this combination of tools (first used for problems without any regularity assumptions on constraints in [10]) still costs nothing computationally. The error bound requires some $\bar{\lambda} \in \Lambda(\bar{x})$ satisfying SOSC (1.14). According to our discussion above, the existence of such $\bar{\lambda}$ can again be guaranteed under MPCC-LICQ (1.5) and piecewise SOSC (1.18). Hence, we obtain local quadratic convergence of our algorithm under the same set of assumptions as for piecewise SQP: MPCC-LICQ (1.5) and piecewise SOSC (1.18) at $\bar{x}$. At the same

time, our local algorithm enjoys the advantage of being quadratic program (QP)-free: it requires solving only one linear system per iteration. Of course, within a local framework, this may not always be a big advantage. Note, however, that globalized Algorithm 3.2 in section 3.1 is QP-free globally.

2. Local algorithms. As is well known, the KKT system (1.2) can be written in the form

$$\Phi(x,\,\lambda) = 0,$$

where $\Phi : \mathbf{R}^n \times (\mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}) \to \mathbf{R}^n \times \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$,

$$\Phi(x,\,\lambda) = \left(\frac{\partial L}{\partial x}(x,\,\lambda),\, \rho(\lambda_G,\, G(x)),\, \rho(\lambda_H,\, H(x)),\, \rho(\lambda_0,\, -\langle G(x),\, H(x)\rangle)\right),$$

and $\rho : \mathbf{R} \times \mathbf{R} \to \mathbf{R}$ is a complementarity function (that is, a function such that $\rho(a,\,b) = 0 \iff a \geq 0,\ b \geq 0,\ ab = 0$) applied componentwise. In what follows, we shall make use of two complementarity functions, namely, the natural residual $\rho(a,\,b) = \min\{a,\,b\}$ and the Fischer–Burmeister function $\rho(a,\,b) = \sqrt{a^2+b^2} - a - b$. The corresponding version of Φ will be denoted by Φ_{NR} and Φ_{FB}, respectively. As is well known, both these mappings are semismooth (and in particular, locally Lipschitz). Moreover, according to [19], these two complementarity functions are equivalent in terms of their growth rates. This means that, throughout the paper, Φ_{NR} can actually be replaced by Φ_{FB} without any changes in the analysis or results.

ALGORITHM 2.1. `Preliminary step.` Fix $\theta \in (0,\,1)$. Choose $x^0 \in \mathbf{R}^n$, $\lambda^0 = (\lambda_G^0,\, \lambda_H^0,\, \lambda_0^0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$.

`Identification step.` Compute the index sets

$$I_G = I_G\left(x^0,\,\lambda^0\right) = \left\{i = 1,\ldots,m \mid G_i\left(x^0\right) \leq \|\Phi_{NR}\left(x^0,\,\lambda^0\right)\|^\theta\right\}, \tag{2.1}$$

$$I_H = I_H\left(x^0,\,\lambda^0\right) = \left\{i = 1,\ldots,m \mid H_i\left(x^0\right) \leq \|\Phi_{NR}\left(x^0,\,\lambda^0\right)\|^\theta\right\}. \tag{2.2}$$

`Main step.` Generate the sequence $\{(x^k,\,\mu^k)\}$, with $\mu^k = (\mu_G^k,\,\mu_H^k) \in \mathbf{R}^m \times \mathbf{R}^m$, as follows.

• Generate the sequence $\{(x^k,\,(\mu_G^k)_{I_G},\,(\mu_H^k)_{I_H})\}$ by the Newton–Lagrange method for tightened MP (1.19) (that is, the Newton method applied to the Lagrange optimality system of this problem) starting from $(x^0,\,(\mu_G^0)_{I_G},\,(\mu_H^0)_{I_H})$, with $(\mu_G^0)_{I_G}$ and $(\mu_H^0)_{I_H}$ defined by

$$\left(\mu_G^0\right)_i = \left(\lambda_G^0\right)_i - \lambda_0^0 H_i\left(x^0\right),\ i \in I_G \setminus I_H, \quad \left(\mu_G^0\right)_i = \left(\lambda_G^0\right)_i,\ i \in I_G \cap I_H, \tag{2.3}$$

$$\left(\mu_H^0\right)_i = \left(\lambda_H^0\right)_i - \lambda_0^0 G_i\left(x^0\right),\ i \in I_H \setminus I_G, \quad \left(\mu_H^0\right)_i = \left(\lambda_H^0\right)_i,\ i \in I_G \cap I_H. \tag{2.4}$$

• Set

$$\left(\mu_G^k\right)_{I_H \setminus I_G} = 0, \quad \left(\mu_H^k\right)_{I_G \setminus I_H} = 0 \quad \forall\, k = 0, 1, \ldots. \tag{2.5}$$

THEOREM 2.1. *Let $\bar{x}$ be a local solution of MPCC* (1.1)*, and assume that MPCC-LICQ* (1.5) *holds at $\bar{x}$. Furthermore, let $\bar{\mu}$ be the (unique) MPCC-multiplier associated with $\bar{x}$, and suppose that $(x^0,\,\lambda^0)$ is close enough to $(\bar{x},\,\bar{\lambda})$, with some $\bar{\lambda} \in \Lambda(\bar{x})$ satisfying SOSC* (1.14).

Then Algorithm 2.1 *correctly generates the sequence $\{(x^k,\,\mu^k)\}$, which converges quadratically to $(\bar{x},\,\bar{\mu})$.*

Proof. According to [8, Lemma 2] and [5, Theorem 2], SOSC (1.14) implies the existence of $c > 0$ such that the error bound

$$\operatorname{dist}((x, \lambda), \{\bar{x}\} \times \Lambda(\bar{x})) \leq c\|\Phi_{NR}(x, \lambda)\| \tag{2.6}$$

holds for all $(x, \lambda) \in \mathbf{R}^n \times (\mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R})$ close enough to $(\bar{x}, \bar{\lambda})$. Since (x^0, λ^0) is close enough to $(\bar{x}, \bar{\lambda})$, from [4, Theorem 2.2] it follows that the index sets $I_G = I_G(x^0, \lambda^0)$ and $I_H = I_H(x^0, \lambda^0)$, computed according to (2.1) and (2.2), coincide with $I_G = I_G(\bar{x})$ and $I_H = I_H(\bar{x})$, respectively, defined in (1.3).

Furthermore, the point $\bar{x}$ is a local solution of tightened MP (1.19), and MPCC-LICQ (1.5) means that LICQ holds at $\bar{x}$ for the constraints of (1.19). In particular, $\bar{x}$ is a stationary point of (1.19), and from (1.4) it evidently follows that $((\bar{\mu}_G)_{I_G}, (\bar{\mu}_H)_{I_H})$ is the unique Lagrange multiplier associated with this stationary point.

Stationarity of $\bar{x}$ in (1.19) evidently implies that

$$\langle f'(\bar{x}), \xi\rangle = 0 \quad \forall\, \xi \in \ker G'_{I_G}(\bar{x}) \cap \ker H'_{I_H}(\bar{x}),$$

where $\ker A$ stands for the kernel (null space) of a linear operator A. Hence, by (1.11),

$$\ker G'_{I_G}(\bar{x}) \cap \ker H'_{I_H}(\bar{x}) \subset C(\bar{x}).$$

From Proposition 1.1 (see (1.10)) and SOSC (1.14), it now follows that

$$\frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x}, \bar{\mu})[\xi, \xi] = \frac{\partial^2 L}{\partial x^2}\left(\bar{x}, \bar{\lambda}\right)[\xi, \xi] > 0 \quad \forall\, \xi \in \left(\ker G'_{I_G}(\bar{x}) \cap \ker H'_{I_H}(\bar{x})\right) \setminus \{0\},$$

and according to the equalities $(\bar{\mu}_G)_{I_H \setminus I_G} = 0$ and $(\bar{\mu}_H)_{I_G \setminus I_H} = 0$ in (1.4), the latter means that SOSC holds at $\bar{x}$ for tightened MP (1.19) (with the unique associated multiplier $((\bar{\mu}_G)_{I_G}, (\bar{\mu}_H)_{I_H})$.

Finally, since (x^0, λ^0) is close enough to $(\bar{x}, \bar{\lambda})$, the pair $((\mu^0_G)_{I_G}, (\mu^0_H)_{I_H})$ defined by (2.3)–(2.4) will be close enough to $((\bar{\mu}_G)_{I_G}, (\bar{\mu}_H)_{I_H})$ (recall that, according to Proposition 1.1, the latter satisfies (1.7)–(1.8)). From the standard convergence result for the Newton–Lagrange method, it now follows that the sequence $\{(x^k, (\mu^k_G)_{I_G}, (\mu^k_H)_{I_H})\}$ is correctly defined and converges quadratically to the point $(\bar{x}, (\bar{\mu}_G)_{I_G}, (\bar{\mu}_H)_{I_H})$. At the same time, according to (1.4) and (2.5), it holds that

$$\left(\mu^k_G\right)_{I_H \setminus I_G} = (\bar{\mu}_G)_{I_H \setminus I_G} = 0, \quad \left(\mu^k_H\right)_{I_G \setminus I_H} = (\bar{\mu}_H)_{I_G \setminus I_H} = 0 \quad \forall\, k = 0, 1, \ldots.$$

This completes the proof. ∎

Let us discuss briefly the assumptions of Theorem 2.1. These assumptions are, in a sense, "minimal." In particular, none of them can be removed, as illustrated next.

MPCC-LICQ (1.5) is needed for nondegeneracy of constraints of tightened MP (1.19), which is clearly necessary for the approach to be valid; otherwise, the linearized constraints of tightened MP can be inconsistent arbitrarily close to a solution. To this end, consider, e.g., $n = 2$, $m = 1$, $f(x) = x_2^2/2$, $G(x) = x_1 + x_1^2/2$, and $H(x) = x_1 + x_1^2$. Then $\bar{x} = 0$ is a strongly stationary point of (1.1) satisfying SOSC (1.14) but violating MPCC-LICQ (1.5). It is easily seen that linearization of tightened MP (1.19) at any $x \in \mathbf{R}^2$ with $x_1 \neq 0$ is inconsistent.

The role of SOSC (1.14) is twofold. First, it is used for identification of the index sets I_G and I_H. To see that without SOSC identification can be incorrect, consider $n = 2$, $m = 1$, $f(x) = x_1$, $G(x) = x_1$, and $H(x) = x_2$. Then $\bar{x} = 0$ is a solution of (1.1) satisfying MPCC-LICQ (1.5) but violating SOSC (1.14) (one can

even add, e.g., $|x_2|^3$ to the objective function in order to make this solution strict). Take $\lambda^0 = (1, 0, 0) \in \Lambda(\bar{x})$, and let $x_1^0 \geq 0$, $x_2^0 \geq 0$. Then $\|\Phi_{NR}(x^0, \lambda^0)\| = x_1^0$, and for any fixed $\theta \in (0, 1)$, by taking $x_2^0 = (x_1^0)^{\theta/2}$, we obtain a point $x^0 = (x_1^0, x_2^0)$ which can be arbitrarily close to $\bar{x}$, while (2.2) will always (incorrectly) identify I_H as empty at such point.

Finally, even if the identification is correct, SOSC (1.14) is still needed as it guarantees SOSC for tightened MP (1.19). Let, e.g., $n = 2$, $m = 1$, $f(x) = x_1 + |x_2|^3$, $G(x) = x_1$, and $H(x) \equiv 1$. Then $\bar{x} = 0$ is a solution satisfying MPCC-LICQ (1.5) but violating SOSC (1.14). Moreover, tightened MP is also violating SOSC. It can be checked directly that the convergence rate of the Newton–Lagrange method for tightened MP (1.19) is only linear.

Note that the presented algorithm appears more suitable for globalization than, say, piecewise SQP. This is because Algorithm 2.1 uses as a dual starting point an approximation of Lagrange multiplier rather than an approximation of MPCC-multiplier. The proximity to points satisfying KKT system (1.2) (and hence, to Lagrange multipliers) can be controlled via some globally defined merit functions (like the norm of Φ_{NR} or Φ_{FB}). By contrast, the definition (1.4) of MPCC-multipliers involves the index sets I_G and I_H depending on a specific $\bar{x}$, and it seems difficult to suggest a reasonable globally defined merit function characterizing MPCC-multipliers.

Furthermore, having in mind globalization of convergence, it can be useful to consider a modified algorithm, with `Identification step` being performed not only once (at the beginning of the process) but before each iteration of `Main step`. Identification is a very cheap procedure and, therefore, this modification will not increase computational costs significantly. However, in this case we will need to generate not only the sequence $\{(x^k, \mu^k)\}$ but also an appropriate sequence $\{\lambda^k\} \subset \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$, and redefine I_G and I_H accordingly:

$$I_G = I_G\left(x^k, \lambda^k\right) = \left\{i = 1, \ldots, m \mid G_i\left(x^k\right) \leq \|\Phi_{NR}\left(x^k, \lambda^k\right)\|^\theta\right\}, \tag{2.7}$$

$$I_H = I_H\left(x^k, \lambda^k\right) = \left\{i = 1, \ldots, m \mid H_i\left(x^k\right) \leq \|\Phi_{NR}\left(x^k, \lambda^k\right)\|^\theta\right\} \tag{2.8}$$

for each $k = 0, 1, \ldots$. Clearly, for all the conclusions of Theorem 2.1 to remain valid for this modified algorithm, it suffices to show that $\{\lambda^k\}$ stays close to $\bar{\lambda}$, which can be achieved by keeping it close to λ^0. In particular, one can just take $\lambda^k = \lambda^0$ $\forall\, k = 1, 2, \ldots$. Another option, which seems more suitable for globalization purposes (and which is more in the spirit of SQP methods), is realized in the following method.

ALGORITHM 2.2. `Preliminary step.` Fix $\theta \in (0, 1)$. Set $k = 0$ and choose $x^0 \in \mathbf{R}^n$ and $\lambda^0 = (\lambda_G^0, \lambda_H^0, \lambda_0^0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$.

`Identification step.` Define the index sets I_G and I_H according to (2.7) and (2.8). If $k = 0$, define $(\mu_G^0)_{I_G}$ and $(\mu_H^0)_{I_H}$ according to (2.3)–(2.4).

`Main step.` Compute (x^{k+1}, μ^{k+1}) as follows.

• The triple $(x^{k+1}, (\mu_G^{k+1})_{I_G}, (\mu_H^{k+1})_{I_H})$ is generated by the step of Newton–Lagrange method for tightened MP (1.19) from the point $(x^k, (\mu_G^k)_{I_G}, (\mu_H^k)_{I_H})$.

• Set $(\mu_G^{k+1})_{I_H \setminus I_G} = 0$, $(\mu_H^{k+1})_{I_G \setminus I_H} = 0$.

Set

$$\nu_{k+1} = \max\left\{0, \max_{i \in I_G \setminus I_H}\left(-\frac{\left(\mu_G^{k+1}\right)_i}{H_i(x^{k+1})}\right), \max_{i \in I_H \setminus I_G}\left(-\frac{\left(\mu_H^{k+1}\right)_i}{G_i(x^{k+1})}\right)\right\}, \tag{2.9}$$

and define $\lambda^{k+1} = (\lambda_G^{k+1}, \lambda_H^{k+1}, \lambda_0^{k+1})$ as follows:

$$\lambda_0^{k+1} = \max\left\{\nu_{k+1}, \lambda_0^k\right\}, \tag{2.10}$$

$$(2.11)\quad \left(\lambda_G^{k+1}\right)_i = \left(\mu_G^{k+1}\right)_i + \lambda_0^{k+1} H_i\left(x^{k+1}\right), i \in I_G \setminus I_H,\ \left(\lambda_G^{k+1}\right)_i = \left(\mu_G^{k+1}\right)_i, i \in I_H,$$

$$(2.12)\quad \left(\lambda_H^{k+1}\right)_i = \left(\mu_H^{k+1}\right)_i + \lambda_0^{k+1} G_i\left(x^{k+1}\right), i \in I_H \setminus I_G,\ \left(\lambda_H^{k+1}\right)_i = \left(\mu_H^{k+1}\right)_i, i \in I_G.$$

Adjust k by 1 and go to `Identification step`.

For purposes of convergence analysis, we need to introduce some auxiliary dual estimates. Suppose that, for some $k = 0, 1, \ldots$, Algorithm 2.2 correctly defined x^k, λ^k, and μ^k. Define $\hat{\lambda}^k = (\hat{\lambda}_G^k, \hat{\lambda}_H^k, \hat{\lambda}_0^k) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$ as follows:

$$(2.13)\quad \hat{\lambda}_0^k = \lambda_0^k,$$

$$(2.14)\quad \left(\hat{\lambda}_G^k\right)_i = (\bar{\mu}_G)_i + \lambda_0^k H_i(\bar{x}),\ i \in I_G \setminus I_H, \quad \left(\hat{\lambda}_G^k\right)_i = (\bar{\mu}_G)_i,\ i \in I_H,$$

$$(2.15)\quad \left(\hat{\lambda}_H^k\right)_i = (\bar{\mu}_H)_i + \lambda_0^k G_i(\bar{x}),\ i \in I_H \setminus I_G, \quad \left(\hat{\lambda}_H^k\right)_i = (\bar{\mu}_H)_i,\ i \in I_G.$$

According to (1.7)–(1.8) and (2.13)–(2.15), it holds that

$$(2.16)\quad \|\hat{\lambda}^k - \bar{\lambda}\| \le \left(1 + \max\left\{\max_{i \in I_G \setminus I_H} H_i(\bar{x}), \max_{i \in I_H \setminus I_G} G_i(\bar{x})\right\}\right) |\lambda_0^k - \bar{\lambda}_0|,$$

and hence, $\hat{\lambda}^k$ is close to $\bar{\lambda}$ provided (x^k, λ^k) is close enough to $(\bar{x}, \bar{\lambda})$.

From Theorem 2.1, we obtain that if (x^k, λ^k) is close enough to $(\bar{x}, \bar{\lambda})$, then the points x^{k+1} and μ^{k+1} will be correctly defined by Algorithm 2.2, and

$$(2.17)\quad \left\|x^{k+1} - \bar{x}\right\| = O\left(\left\|\left(x^k - \bar{x}, \mu^k - \bar{\mu}\right)\right\|^2\right) = O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right),$$

$$(2.18)\quad \left\|\mu^{k+1} - \bar{\mu}\right\| = O\left(\left\|\left(x^k - \bar{x}, \mu^k - \bar{\mu}\right)\right\|^2\right) = O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right).$$

Furthermore, according to (1.6)–(1.8), (2.9), (2.11)–(2.15), (2.17), and (2.18), we obtain the estimates

$$(2.19)\quad |\nu_{k+1} - \bar{\nu}| = O\left(\left\|x^{k+1} - \bar{x}\right\|\right) + O\left(\left\|\mu^{k+1} - \bar{\mu}\right\|\right) = O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right),$$

$$\begin{aligned}(2.20)\quad \left\|\lambda^{k+1} - \hat{\lambda}^k\right\| &= O\left(\left\|x^{k+1} - \bar{x}\right\|\right) + O\left(\left\|\mu^{k+1} - \bar{\mu}\right\|\right) + O\left(|\lambda_0^{k+1} - \lambda_0^k|\right) \\ &= O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right) + O\left(|\lambda_0^{k+1} - \lambda_0^k|\right),\end{aligned}$$

$$\begin{aligned}(2.21)\quad \left\|\lambda^{k+1} - \bar{\lambda}\right\| &= O\left(\left\|x^{k+1} - \bar{x}\right\|\right) + O\left(\left\|\mu^{k+1} - \bar{\mu}\right\|\right) + O\left(|\lambda_0^{k+1} - \bar{\lambda}_0|\right) \\ &= O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right) + O\left(|\lambda_0^{k+1} - \bar{\lambda}_0|\right).\end{aligned}$$

Let us consider separately the two cases

$$(2.22)\quad \bar{\lambda}_0 > \bar{\nu} \quad \text{or} \quad \bar{\lambda}_0 = \bar{\nu}$$

(see (1.9)).

LEMMA 2.2. *Let $\bar{x}$ be a local solution of MPCC* (1.1)*, and assume that MPCC-LICQ* (1.5) *holds at $\bar{x}$. Furthermore, suppose that, for some $k = 0, 1, \ldots$, Algorithm* 2.2 *generated points x^k, λ^k, and μ^k such that (x^k, λ^k) is close enough to $(\bar{x}, \bar{\lambda})$, with some $\bar{\lambda} \in \Lambda(\bar{x})$ satisfying SOSC* (1.14).

Then the points x^{k+1}, λ^{k+1}, and μ^{k+1} will be correctly generated by Algorithm 2.2*, and if the first relation in* (2.22) *holds, with $\bar{\nu}$ defined according to* (1.6)*, then*

$$\lambda_0^{k+1} = \lambda_0^k, \tag{2.23}$$

$$\left\|\lambda^{k+1} - \hat{\lambda}^k\right\| = O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right). \tag{2.24}$$

Proof. By the first relation in (2.22), we obtain that if (x^k, λ^k) is close enough to $(\bar{x}, \bar{\lambda})$, then

$$\lambda_0^k > \bar{\lambda}_0 - \left(\bar{\lambda}_0 - \bar{\nu}\right)/2 = \left(\bar{\nu} + \bar{\lambda}_0\right)/2, \quad \nu_{k+1} < \bar{\nu} + \left(\bar{\lambda}_0 - \bar{\nu}\right)/2 = \left(\bar{\nu} + \bar{\lambda}_0\right)/2,$$

with inequality in the last relation being implied by (2.16) and (2.19). Thus $\lambda_0^k > \nu_{k+1}$, and by (2.10), we obtain (2.23). Estimate (2.24) follows from (2.20) and (2.23). ∎

LEMMA 2.3. *Under the assumptions of Lemma* 2.2*, if the second relation in* (2.22) *holds, with $\bar{\nu}$ defined according to* (1.6)*, then the following estimates are valid.*

If $\lambda_0^{k+1} = \nu_{k+1}$, then

$$\left\|\lambda^{k+1} - \bar{\lambda}\right\| = O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right), \tag{2.25}$$

$$\left\|\hat{\lambda}^{k+1} - \bar{\lambda}\right\| = O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right). \tag{2.26}$$

If $\lambda_0^{k+1} = \lambda_0^k$, then (2.24) *holds.*

Proof. If $\lambda_0^{k+1} = \nu_{k+1}$, then by (2.16), (2.19), (2.21), and the second relation in (2.22), we obtain the estimates

$$\begin{aligned}
\left\|\lambda^{k+1} - \bar{\lambda}\right\| &= O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right) + O\left(\left|\lambda_0^{k+1} - \bar{\lambda}_0\right|\right) \\
&= O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right) + O\left(\left|\nu_{k+1} - \bar{\nu}\right|\right) = O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right), \\
\left\|\hat{\lambda}^{k+1} - \bar{\lambda}\right\| &= O\left(\left|\lambda_0^{k+1} - \bar{\lambda}_0\right|\right) = O\left(\left|\nu_{k+1} - \bar{\nu}\right|\right) = O\left(\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right).
\end{aligned}$$

This proves (2.25) and (2.26).

If $\lambda_0^{k+1} = \lambda_0^k$, then estimate (2.24) follows immediately from (2.20). ∎

We are now in position to prove convergence of Algorithm 2.2.

THEOREM 2.4. *Under the assumptions of Theorem* 2.1*, Algorithm* 2.2 *correctly generates the sequence $\{(x^k, \lambda^k, \mu^k)\}$ such that $\{(x^k, \mu^k)\}$ converges quadratically to $(\bar{x}, \bar{\mu})$. Moreover, if the first relation in* (2.22) *holds, then the sequence $\{(x^k, \lambda^k)\}$ converges quadratically to $(\bar{x}, \hat{\lambda}^0)$, with $\hat{\lambda}^0$ defined according to* (2.13)–(2.15)*, and $\hat{\lambda}^0 \in \Lambda(\bar{x})$.*

Proof. If the first relation in (2.22) holds, then employing (2.13)–(2.15), (2.16), (2.17), and Lemma 2.2 (see (2.23) and (2.24)), it can be shown (by standard argument) that if (x^0, λ^0) is close enough to $(\bar{x}, \bar{\lambda})$, then each further step of Algorithm 2.2 will produce a pair (x^{k+1}, λ^{k+1}), with $\lambda_0^{k+1} = \lambda_0^k = \lambda_0^0$, and this new pair will be close to $(\bar{x}, \hat{\lambda}^k) = (\bar{x}, \hat{\lambda}^0)$, which in turn is close to $(\bar{x}, \bar{\lambda})$. Then by the same argument as in the proof of Theorem 2.1, for any k, the index sets $I_G(x^k, \lambda^k)$ and $I_H(x^k, \lambda^k)$ computed according to (2.7) and (2.8) will coincide with $I_G = I_G(\bar{x})$ and $I_H = I_H(\bar{x})$ defined in (1.3), respectively. This means that Algorithm 2.2 generates

exactly the same trajectory $\{(x^k, \mu^k)\}$ as Algorithm 2.1, and quadratic convergence follows now from Theorem 2.1. Furthermore, quadratic convergence of $\{(x^k, \lambda^k)\}$ to $(\bar{x}, \hat{\lambda}^0)$ follows from (2.17), (2.24), and the above-established equality $\hat{\lambda}^k = \hat{\lambda}^0$ $\forall\, k$. Finally, $\hat{\lambda}^0 \in \Lambda(\bar{x})$ according to (2.13)–(2.15), the first relation in (2.22), and Proposition 1.1.

We proceed with the case when the second relation in (2.22) holds. Again we need to show that if (x^0, λ^0) is close enough to $(\bar{x}, \bar{\lambda})$, then $\{(x^k, \lambda^k)\}$ stays close to $(\bar{x}, \bar{\lambda})$. Then the needed assertion will follow the same way as for the previous case.

From (2.16)–(2.17) and (2.24)–(2.26), it follows that, for any $q \in (0, 1/2]$, there exists $\varepsilon > 0$ such that for all (x^k, λ^k) satisfying $\|x^k - \bar{x}\| < \varepsilon$ and $\|\lambda^k - \bar{\lambda}\| < \varepsilon$ the following estimates are valid.

If $\lambda_0^{k+1} = \nu_{k+1}$, then

$$\left\|(x^{k+1} - \bar{x},\, \lambda^{k+1} - \bar{\lambda})\right\| \le q \left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|, \tag{2.27}$$

$$\left\|\left(x^{k+1} - \bar{x},\, \hat{\lambda}^{k+1} - \bar{\lambda}\right)\right\| \le q \left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|. \tag{2.28}$$

If $\lambda_0^{k+1} = \lambda_0^k$, then

$$\left\|\left(x^{k+1} - \bar{x},\, \lambda^{k+1} - \hat{\lambda}^k\right)\right\| \le q \left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\|. \tag{2.29}$$

Let (x^0, λ^0) be close enough to $(\bar{x}, \bar{\lambda})$, so that

$$\left\|\left(x^0 - \bar{x},\, \lambda^0 - \hat{\lambda}^0\right)\right\| < \delta, \quad \left\|\left(x^0 - \bar{x},\, \hat{\lambda}^0 - \bar{\lambda}\right)\right\| < \delta, \tag{2.30}$$

where $\delta > 0$ satisfies the inequality

$$(q+1)\delta \le \varepsilon \tag{2.31}$$

(see (2.16)). We now prove by induction that $\forall\, k = 1, 2, \ldots$, it holds that

$$\left\|\left(x^k - \bar{x},\, \lambda^k - \hat{\lambda}^k\right)\right\| < \delta, \tag{2.32}$$

$$\left\|\left(x^k - \bar{x},\, \hat{\lambda}^k - \bar{\lambda}\right)\right\| < \delta, \tag{2.33}$$

$$\left\|(x^k - \bar{x},\, \lambda^k - \bar{\lambda})\right\| < \varepsilon. \tag{2.34}$$

Let $k = 1$. If $\lambda_0^1 = \nu_1$, then by (2.27), (2.30), and (2.31), we obtain

$$\left\|(x^1 - \bar{x},\, \lambda^1 - \bar{\lambda})\right\| \le q \left\|\left(x^0 - \bar{x},\, \lambda^0 - \hat{\lambda}^0\right)\right\| < q\delta < \varepsilon, \tag{2.35}$$

i.e., (2.34) holds for $k = 1$. Furthermore, by (2.28), (2.30), and by the inequality $q < 1$,

$$\left\|\left(x^1 - \bar{x},\, \hat{\lambda}^1 - \bar{\lambda}\right)\right\| \le q \left\|\left(x^0 - \bar{x},\, \lambda^0 - \hat{\lambda}^0\right)\right\| < q\delta < \delta, \tag{2.36}$$

i.e., (2.33) holds for $k = 1$. Finally, by (2.35), (2.36), and by the inequality $q \le 1/2$,

$$\left\|\left(x^1 - \bar{x},\, \lambda^1 - \hat{\lambda}^1\right)\right\| \le \left\|(x^1 - \bar{x},\, \lambda^1 - \bar{\lambda})\right\| + \left\|\hat{\lambda}^1 - \bar{\lambda}\right\| < 2q\delta \le \delta,$$

i.e., (2.32) holds for $k = 1$.

On the other hand, if $\lambda_0^1 = \lambda_0^0$, then by (2.13)–(2.15) $\hat{\lambda}^1 = \hat{\lambda}^0$, and by (2.29), (2.30),

$$\left\|\left(x^1 - \bar{x},\, \lambda^1 - \hat{\lambda}^0\right)\right\| \le q\left\|\left(x^0 - \bar{x},\, \lambda^0 - \hat{\lambda}^0\right)\right\| < q\delta,$$

and hence, by the inequality $q < 1$, we have that

$$\left\|\left(x^1 - \bar{x},\, \lambda^1 - \hat{\lambda}^1\right)\right\| = \left\|\left(x^1 - \bar{x},\, \lambda^1 - \hat{\lambda}^0\right)\right\| < q\delta < \delta, \tag{2.37}$$

i.e., (2.32) holds for $k = 1$. Furthermore, by (2.30), we have that

$$\left\|\left(x^1 - \bar{x},\, \hat{\lambda}^1 - \bar{\lambda}\right)\right\| = \left\|\left(x^1 - \bar{x},\, \hat{\lambda}^0 - \bar{\lambda}\right)\right\| < \delta,$$

i.e., (2.33) holds for $k = 1$. Finally, by (2.31), (2.33) for $k = 1$, and (2.37), we obtain

$$\left\|(x^1 - \bar{x},\, \lambda^1 - \bar{\lambda})\right\| \le \left\|\left(x^1 - \bar{x},\, \lambda^1 - \hat{\lambda}^1\right)\right\| + \left\|\hat{\lambda}^1 - \bar{\lambda}\right\| < q\delta + \delta \le \varepsilon,$$

i.e., (2.34) holds for $k = 1$.

Now suppose that the hypothesis is valid for $k = s$. If $\lambda_0^{s+1} = \nu_{s+1}$, then by (2.27), (2.30), and (2.31), we obtain that

$$\left\|(x^{s+1} - \bar{x},\, \lambda^{s+1} - \bar{\lambda})\right\| \le q\left\|\left(x^s - \bar{x},\, \lambda^s - \hat{\lambda}^s\right)\right\| < q\delta < \varepsilon, \tag{2.38}$$

i.e., (2.34) holds for $k = s + 1$. Furthermore, by (2.28), (2.30), and by the inequality $q < 1$,

$$\left\|\left(x^{s+1} - \bar{x},\, \hat{\lambda}^{s+1} - \bar{\lambda}\right)\right\| \le q\left\|\left(x^s - \bar{x},\, \lambda^s - \hat{\lambda}^s\right)\right\| < q\delta < \delta, \tag{2.39}$$

i.e., (2.33) holds for $k = s+1$. Finally, by (2.38), (2.39), and by the inequality $q \le 1/2$,

$$\left\|\left(x^{s+1} - \bar{x},\, \lambda^{s+1} - \hat{\lambda}^{s+1}\right)\right\| \le \left\|(x^{s+1} - \bar{x},\, \lambda^{s+1} - \bar{\lambda})\right\| + \left\|\hat{\lambda}^{s+1} - \bar{\lambda}\right\| < 2q\delta \le \delta,$$

i.e., (2.32) holds for $k = s + 1$.

On the other hand, if $\lambda_0^{s+1} = \lambda_0^s$, then by (2.13)–(2.15) $\hat{\lambda}^{s+1} = \hat{\lambda}^s$, and by (2.29), (2.30), we have that

$$\left\|\left(x^{s+1} - \bar{x},\, \lambda^{s+1} - \hat{\lambda}^s\right)\right\| \le q\left\|\left(x^s - \bar{x},\, \lambda^s - \hat{\lambda}^s\right)\right\| < q\delta,$$

and hence, by the inequality $q < 1$,

$$\left\|\left(x^{s+1} - \bar{x},\, \lambda^{s+1} - \hat{\lambda}^{s+1}\right)\right\| = \left\|\left(x^{s+1} - \bar{x},\, \lambda^{s+1} - \hat{\lambda}^s\right)\right\| < q\delta < \delta, \tag{2.40}$$

i.e., (2.32) holds for $k = s + 1$. Furthermore, by (2.30), we obtain

$$\left\|\left(x^{s+1} - \bar{x},\, \hat{\lambda}^{s+1} - \bar{\lambda}\right)\right\| = \left\|\left(x^{s+1} - \bar{x},\, \hat{\lambda}^s - \bar{\lambda}\right)\right\| < \delta,$$

i.e., (2.33) holds for $k = s + 1$. Finally, by (2.31), (2.33) for $k = s + 1$, and (2.40), we derive that

$$\left\|(x^{s+1} - \bar{x},\, \lambda^{s+1} - \bar{\lambda})\right\| \le \left\|\left(x^{s+1} - \bar{x},\, \lambda^{s+1} - \hat{\lambda}^{s+1}\right)\right\| + \left\|\hat{\lambda}^{s+1} - \bar{\lambda}\right\| < q\delta + \delta \le \varepsilon,$$

i.e., (2.34) holds for $k = s + 1$. This completes the proof by induction. □

3. Globalization issues. In this section, we discuss some possible ways of globalizing the local scheme presented above. The first approach is based on a generic outer phase steering the iterates toward stationary points. This globalization uses a test of linear decrease for the KKT residual to decide when active-set steps are successful. We also give a specific implementation of this approach along the lines of hybrid semismooth Newton methods for mixed complementarity problems, for which both global convergence and superlinear rate of convergence can be formally proved under reasonable assumptions. The second approach below is based on SQP. It is therefore quite close in spirit to existing algorithms, and can be easily incorporated into them. However, this method may converge to weakly (i.e., not only strongly) stationary points. We do not provide a formal convergence analysis for this method. The reason is that such analysis would primarily concern the study of global convergence properties of standard linesearch SQP algorithms for MPCCs, which is a general issue not related specifically to local algorithms suggested above.

3.1. Hybrid globalization. We next show how our local algorithm can be embedded into any globally convergent scheme. By this we mean that having chosen and fixed some outer-phase global strategy which is guaranteed to produce primal-dual iterates converging to stationary (in some sense) points of MPCC (1.1), the role of our local method is to force quadratic convergence rate under natural assumptions stated above. The key to this construction is the proof that close to a solution with stated properties, the Newton–Lagrange step for (1.19) provides quadratic (hence, also arbitrarily fast linear) decrease for the Fischer–Burmeister residual Φ_{FB} of the KKT system (1.2) for MPCC (1.1).

ALGORITHM 3.1. `Preliminary step.` Fix θ, $q \in (0, 1)$. Set $k = 0$, and choose $x^0 \in \mathbf{R}^n$ and $\lambda^0 = (\lambda_G^0, \lambda_H^0, \lambda_0^0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$.

`Identification step.` Define the index sets I_G and I_H according to (2.7) and (2.8). If $k = 0$, or if I_G or I_H does not coincide with its counterpart computed at the previous iteration, or if $I_G \cup I_H \neq \{1, \ldots, m\}$, go to `Outer-phase step`.

`Active-set step.` If the current point (x^k, λ^k) was generated by `Outer-phase step`, set $\tilde{k} = k$, store $(x^{\tilde{k}}, \lambda^{\tilde{k}})$, and define $(\mu_G^k)_{I_G}$ and $(\mu_H^k)_{I_H}$ by

$$(\mu_G^k)_i = (\lambda_G^k)_i - \lambda_0^k H_i(x^k), \ i \in I_G \setminus I_H, \tag{3.1}$$

$$(\mu_H^k)_i = (\lambda_H^k)_i - \lambda_0^k G_i(x^k), \ i \in I_H \setminus I_G, \tag{3.2}$$

$$(\mu_G^k)_i = (\lambda_G^k)_i, \ (\mu_H^k)_i = (\lambda_H^k)_i, \ i \in I_G \cap I_H. \tag{3.3}$$

Compute (x^{k+1}, μ^{k+1}) as follows.
• The triple $(x^{k+1}, (\mu_G^{k+1})_{I_G}, (\mu_H^{k+1})_{I_H})$ is generated by the step of Newton–Lagrange method for tightened MP (1.19) from the point $(x^k, (\mu_G^k)_{I_G}, (\mu_H^k)_{I_H})$.
• $(\mu_G^{k+1})_{I_H \setminus I_G} = 0$, $(\mu_H^{k+1})_{I_G \setminus I_H} = 0$.

If there exists $i \in I_G \setminus I_H$ such that $H_i(x^{k+1}) = 0$, or there exists $i \in I_H \setminus I_G$ such that $G_i(x^{k+1}) = 0$, go to `Outer-phase step`. Otherwise, define $\lambda^{k+1} = (\lambda_G^{k+1}, \lambda_H^{k+1}, \lambda_0^{k+1})$ according to (2.9)–(2.12). If the point (x^{k+1}, λ^{k+1}) is well defined and satisfies the condition

$$\left\|\Phi_{FB}(x^{k+1}, \lambda^{k+1})\right\| \leq q \left\|\Phi_{FB}(x^k, \lambda^k)\right\|, \tag{3.4}$$

adjust k by 1, and go to `Identification step`.

`Outer-phase step.` If the current point (x^k, λ^k) was generated by `Active-set step`, set $k = \tilde{k}$ and $(x^k, \lambda^k) = (x^{\tilde{k}}, \lambda^{\tilde{k}})$.

Compute (x^{k+1}, λ^{k+1}) according to the outer-phase strategy. Adjust k by 1, and go to `Identification step`.

Global convergence properties of Algorithm 3.1 are quite transparent. By (3.4), we immediately obtain the following result.

THEOREM 3.1. *Let $\{(x^k, \lambda^k)\}$ be a trajectory generated by Algorithm* 3.1*, and suppose that all the iterates in this trajectory with k large enough are generated by* `Active-set step` *of the algorithm. Then*

$$\Phi_{FB}\left(x^k, \lambda^k\right) \to 0 \quad as \quad k \to \infty. \tag{3.5}$$

In particular, the primal part of any accumulation point of $\{(x^k, \lambda^k)\}$ is strongly stationary for (1.1)*, while the dual part is an associated Lagrange multiplier.*

Except for the case considered in Theorem 3.1, the only other possibility is that all the iterates are generated by the outer-phase strategy (because unsuccessful active-set iterates are eventually discarded). In this case, the method inherits global convergence of the outer strategy. Possible choices of outer strategies will be discussed below.

To prove quadratic convergence of Algorithm 3.1, some work is required. We start with the following dual estimate.

LEMMA 3.2. *Let $\bar{x}$ be a strongly stationary point of MPCC* (1.1)*, and assume that MPCC-LICQ* (1.5) *holds at $\bar{x}$. Let $\bar{\lambda} \in \Lambda(\bar{x})$.*

Then there exists $c > 0$ such that, for each (x^k, λ^k) close enough to $(\bar{x}, \bar{\lambda})$, it holds that

$$\left\|\lambda^k - \hat{\lambda}^k\right\| \le c \operatorname{dist}\left(\lambda^k, \Lambda(\bar{x})\right), \tag{3.6}$$

where $\hat{\lambda}^k$ is defined according to (2.13)–(2.15).

Proof. We argue by contradiction. If $\lambda^k \in \Lambda(\bar{x})$, then by Proposition 1.1 and by (2.13)–(2.15), we have that $\lambda^k = \hat{\lambda}^k$, and (3.6) holds with any $c \ge 0$. Suppose that there exists a sequence $\{(x^k, \lambda^k)\}$ convergent to $(\bar{x}, \bar{\lambda})$ such that $\lambda^k \notin \Lambda(\bar{x})$ $\forall\, k$, and

$$\left\|\lambda^k - \hat{\lambda}^k\right\| / \operatorname{dist}\left(\lambda^k, \Lambda(\bar{x})\right) \to \infty \text{ as } k \to \infty. \tag{3.7}$$

Let $\bar{\lambda}^k$ be the orthogonal projection of λ^k onto $\Lambda(\bar{x})$. Then (3.7) is equivalent to

$$\left\|\lambda^k - \bar{\lambda}^k\right\| / \left\|\lambda^k - \hat{\lambda}^k\right\| \to 0 \text{ as } k \to \infty. \tag{3.8}$$

For each k, we have that

$$\left(\lambda^k - \hat{\lambda}^k\right) / \left\|\lambda^k - \hat{\lambda}^k\right\| = \left(\lambda^k - \bar{\lambda}^k\right) / \left\|\lambda^k - \hat{\lambda}^k\right\| + \left(\bar{\lambda}^k - \hat{\lambda}^k\right) / \left\|\lambda^k - \hat{\lambda}^k\right\|.$$

Observe that in this equality the left-hand side has unit norm and belongs to the "vertical" hyperplane $\lambda_0 = 0$; the first term in the right-hand side tends to 0 as $k \to \infty$, by (3.8); while the second term in the right-hand side belongs to the straight line containing the ray $\Lambda(\bar{x})$ (see Proposition 1.1 and (2.13)–(2.15)), which does not belong to the "vertical" hyperplane. The contradiction is now evident. ∎

THEOREM 3.3. *Let $\{(x^k, \lambda^k)\}$ be a trajectory generated by Algorithm* 3.1*, and suppose that this trajectory has an accumulation point $(\bar{x}, \bar{\lambda})$, with $\bar{x}$ being a strongly stationary point of problem* (1.1) *and $\bar{\lambda}$ being an associated Lagrange multiplier, satisfying MPCC-LICQ* (1.5) *and SOSC* (1.14)*.*

Then the entire trajectory $\{(x^k, \lambda^k)\}$ *converges to* $(\bar{x}, \bar{\lambda})$*, and the rate of convergence is quadratic.*

Proof. Let (x^k, λ^k) be close to $(\bar{x}, \bar{\lambda})$. Furthermore, let (x^{k+1}, λ^{k+1}) be computed by the `Active-set step` of Algorithm 3.1 (this point is correctly defined, according to Theorem 2.4).

We next construct $\bar{\lambda}^{k+1} \in \Lambda(\bar{x})$ satisfying the estimate

$$\left\|\lambda^{k+1} - \bar{\lambda}^{k+1}\right\| = O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right). \tag{3.9}$$

This is done separately for the two possible cases in (2.22).

If the first relation in (2.22) holds, we define $\bar{\lambda}^{k+1} = \hat{\lambda}^k$. In this case, by Proposition 1.1, by (2.13)–(2.15), and by the proximity of λ_0^k to $\bar{\lambda}_0$, we have that $\hat{\lambda}^k \in \Lambda(\bar{x})$. The estimate (3.9) now follows from (2.24). Let the second relation in (2.22) hold. If $\lambda_0^{k+1} = \nu_{k+1}$, then set $\bar{\lambda}^{k+1} = \bar{\lambda}$. In this case, estimate (3.9) follows from (2.25). If $\lambda_0^{k+1} = \lambda_0^k$, then $\lambda_0^k > \nu_{k+1}$, and we define $\bar{\lambda}^{k+1}$ as follows.

If $\lambda_0^k \geq \bar{\nu}$, then set $\bar{\lambda}^{k+1} = \hat{\lambda}^k$. In this case, $\hat{\lambda}^k \in \Lambda(\bar{x})$ according to Proposition 1.1 and (2.13)–(2.15), and estimate (3.9) follows from (2.24).

If $\lambda_0^k < \bar{\nu}$, then $\nu_{k+1} < \lambda_0^k < \bar{\nu}$, and by (2.16), (2.19), and the second relation in (2.22), we have that

$$\left\|\hat{\lambda}^k - \bar{\lambda}\right\| = O\left(\left|\lambda_0^k - \bar{\lambda}_0\right|\right) = O(|\nu_{k+1} - \bar{\nu}|) = O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^2\right). \tag{3.10}$$

Set $\bar{\lambda}^{k+1} = \bar{\lambda}$. Then estimate (3.9) follows from (2.24), (3.10), and from the inequality

$$\left\|\lambda^{k+1} - \bar{\lambda}^{k+1}\right\| \leq \left\|\lambda^{k+1} - \hat{\lambda}^k\right\| + \left\|\hat{\lambda}^k - \bar{\lambda}\right\|.$$

Set $\varphi_{FB}(x, \lambda) = \|\Phi_{FB}(x, \lambda)\|^2$, $x \in \mathbf{R}^n$, $\lambda \in \mathbf{R} \times \mathbf{R}^m \times \mathbf{R}^m$. As is well known, the function φ_{FB} is smooth, and since $(\bar{x}, \bar{\lambda}^{k+1})$ is a global unconstrained minimizer of this function, we obtain the equalities

$$\varphi_{FB}\left(\bar{x}, \bar{\lambda}^{k+1}\right) = 0, \quad \varphi'_{FB}\left(\bar{x}, \bar{\lambda}^{k+1}\right) = 0. \tag{3.11}$$

Recall that, under our assumptions, the error bound (2.6) holds for all (x, λ) close enough to $(\bar{x}, \bar{\lambda})$. Then, by (2.17), (3.9), (3.11), and by Lemma 3.2, we obtain that

$$\begin{aligned}
&\left\|\Phi_{FB}\left(x^{k+1}, \lambda^{k+1}\right)\right\|^2 = \varphi_{FB}\left(x^{k+1}, \lambda^{k+1}\right) \\
&= \varphi_{FB}\left(x^{k+1}, \lambda^{k+1}\right) - \varphi_{FB}\left(\bar{x}, \bar{\lambda}^{k+1}\right) \\
&= \left\langle \varphi'_{FB}\left(\bar{x}, \bar{\lambda}^{k+1}\right), \left(x^{k+1} - \bar{x}, \lambda^{k+1} - \bar{\lambda}^{k+1}\right)\right\rangle + O\left(\left\|\left(x^{k+1} - \bar{x}, \lambda^{k+1} - \bar{\lambda}^{k+1}\right)\right\|^2\right) \\
&= O\left(\left\|\left(x^{k+1} - \bar{x}, \lambda^{k+1} - \bar{\lambda}^{k+1}\right)\right\|^2\right) = O\left(\left\|\left(x^k - \bar{x}, \lambda^k - \hat{\lambda}^k\right)\right\|^4\right) \\
&= O\left(\left(\|x^k - \bar{x}\| + \operatorname{dist}\left(\lambda^k, \Lambda\left(\bar{x}\right)\right)\right)^4\right) = O\left(\left\|\Phi_{NR}(x^k, \lambda^k)\right\|^4\right) = O\left(\left\|\Phi_{FB}(x^k, \lambda^k)\right\|^4\right),
\end{aligned}$$

where the last relation follows from the equivalence of $\|\Phi_{NR}(\cdot)\|$ and $\|\Phi_{FB}(\cdot)\|$ in terms of their growth rates [19].

Evidently, the above relation implies (3.4) for any fixed $q \in (0, 1)$, if (x^k, λ^k) is close enough to $(\bar{x}, \bar{\lambda})$. This implies that the `Active-set step` will be accepted, and Algorithm 3.1 will be further working identically to the (local) Algorithm 2.2. The result now follows from Theorem 2.4. □

One possible choice of the outer-phase algorithm is the elastic mode SQP method discussed in section 3.2 below. Another possibility is to use the merit function φ_{FB} in order to organize the outer phase as well, by means of globalizing the semismooth Newton method applied to the equation $\Phi_{FB}(x, \lambda) = 0$. The resulting algorithm is in the spirit of the method for complementarity problems in [14], and its extension to globalization of an active-set method for mixed complementarity problems in [3, section 3]. One advantage of such a scheme is that one can guarantee the overall monotonicity of the sequence $\{\|\Phi_{FB}(x^k, \lambda^k)\|\}$, and thus no backup safeguards are needed when entering the active-set phase (i.e., global convergence can be proved without such safeguards). That is why we present this scheme as a separate algorithm.

ALGORITHM 3.2. `Preliminary step.` Fix $\theta, q, \varepsilon, \tau \in (0, 1)$, $\delta, \gamma > 0$. Set $k = 0$, and choose $x^0 \in \mathbf{R}^n$ and $\lambda^0 = (\lambda_G^0, \lambda_H^0, \lambda_0^0) \in \mathbf{R}^m \times \mathbf{R}^m \times \mathbf{R}$.

`Identification step.` Define the index sets I_G and I_H according to (2.7) and (2.8). If $k = 0$ or if I_G or I_H does not coincide with its counterpart computed at the previous iteration or if $I_G \cup I_H \neq \{1, \ldots, m\}$, go to `SNM–FB step`.

`Active-set step.` If the current point (x^k, λ^k) was generated by `SNM–FB step`, define $(\mu_G^k)_{I_G}$ and $(\mu_H^k)_{I_H}$ by (3.1)–(3.3). Compute (x^{k+1}, μ^{k+1}) as follows.

• The triple $(x^{k+1}, (\mu_G^{k+1})_{I_G}, (\mu_H^{k+1})_{I_H})$ is generated by the step of Newton–Lagrange method for tightened MP (1.19) from the point $(x^k, (\mu_G^k)_{I_G}, (\mu_H^k)_{I_H})$.

• $(\mu_G^{k+1})_{I_H \setminus I_G} = 0$, $(\mu_H^{k+1})_{I_G \setminus I_H} = 0$.

If there exists $i \in I_G \setminus I_H$ such that $H_i(x^{k+1}) = 0$ or there exists $i \in I_H \setminus I_G$ such that $G_i(x^{k+1}) = 0$, go to `SNM–FB step`. Otherwise, define $\lambda^{k+1} = (\lambda_G^{k+1}, \lambda_H^{k+1}, \lambda_0^{k+1})$ according to (2.9)–(2.12). If the point (x^{k+1}, λ^{k+1}) is well-defined and satisfies the condition (3.4), adjust k by 1, and go to `Identification step`.

`SNM–FB step.` Compute $\Lambda_k \in \partial_B \Phi_{FB}(x^k, \lambda^k)$ and

$$\left(x^{k+1}, \lambda^{k+1}\right) = \left(x^k, \lambda^k\right) - \Lambda_k^{-1} \Phi_{FB}\left(x^k, \lambda^k\right).$$

If this point is well-defined and (3.4) holds, and satisfies the condition, adjust k by 1, and go to `Identification step`.

If x^{k+1} is well-defined but (3.4) does not hold, set $d^k = x^{k+1} - x^k$. If

$$\left\langle \varphi'_{FB}\left(x^k, \lambda^k\right), d^k \right\rangle \leq -\gamma \|d^k\|^\delta,$$

go to `Linesearch step`.

`Gradient step.` Set $d^k = -\varphi'_{FB}(x^k, \lambda^k)$.

`Linesearch step.` Compute the stepsize parameter α_k according to the Armijo rule: $\alpha_k = \tau^s$, where s is the smallest nonnegative integer satisfying

$$\varphi_{FB}\left(\left(x^k, \lambda^k\right) + \tau^s d^k\right) \leq \varphi_{FB}\left(x^k, \lambda^k\right) + \varepsilon \tau^s \left\langle \varphi'_{FB}\left(x^k, \lambda^k\right), d^k \right\rangle.$$

Set $(x^{k+1}, \lambda^{k+1}) = (x^k, \lambda^k) + \alpha_k d^k$, adjust k by 1, and go to `Identification step`.

THEOREM 3.4. *Let $\{(x^k, \lambda^k)\}$ be a trajectory generated by Algorithm* 3.2.

Then any accumulation point $(\bar{x}, \bar{\lambda})$ of $\{(x^k, \lambda^k)\}$ satisfies $\varphi'_{FB}(\bar{x}, \bar{\lambda}) = 0$.

Furthermore, if there exists an infinite subsequence of $\{(x^k, \lambda^k)\}$ such that all the iterates in this subsequence are generated by `Active-set step`*, then* (3.5) *holds. In that case, the primal part of any accumulation point of $\{(x^k, \lambda^k)\}$ is strongly stationary in* (1.1)*, while the dual part is an associated Lagrange multiplier.*

Proof. If there exists an infinite subsequence of $\{(x^k, \lambda^k)\}$ such that all the iterates in this subsequence are generated by `Active-set step` of the algorithm, then (3.5) follows immediately from (3.4) and the fact that the values of φ_{FB} are nonincreasing

along the trajectories of the algorithm. The only other possibility is that the "tail" of the trajectory is generated by the outer-phase algorithm, in which case the result can be obtained extending [14, Theorem 3.1] to the setting of mixed complementarity problems. □

Finally, to obtain the rate of convergence result, one should just repeat the proof of Theorem 3.3, with Algorithm 3.1 replaced by Algorithm 3.2.

THEOREM 3.5. *Let* $\{(x^k, \lambda^k)\}$ *be a trajectory generated by Algorithm* 3.2*, and suppose that this trajectory has an accumulation point* $(\bar{x}, \bar{\lambda})$*, with* $\bar{x}$ *being a strongly stationary point of problem* (1.1) *and* $\bar{\lambda}$ *being an associated Lagrange multiplier, satisfying MPCC-LICQ* (1.5) *and SOSC* (1.14)*.*

Then the entire trajectory $\{(x^k, \lambda^k)\}$ *converges to* $(\bar{x}, \bar{\lambda})$*, and the rate of convergence is quadratic.*

We have thus developed a QP-free algorithm for MPCC, with justified global convergence and quadratic rate of convergence under MPCC-LICQ and the usual SOSC (1.14).

3.2. Globalization based on SQP with linesearch. Introducing slack variables, MPCC (1.1) can be equivalently written in the form

$$\min_{(x,\,y,\,z)} f(x) \quad \text{s.t.} \quad G(x) = y,\ H(x) = z,\ y \geq 0,\ z \geq 0,\ \langle y, z\rangle \leq 0. \tag{3.12}$$

As is well known, this reformulated MPCC has the same properties (MPCC constraint qualifications and SOSC) as (1.1), while being preferable for numerical solution by SQP [6, 7].

We first discuss the outer (elastic mode SQP) phase of the algorithm stated below. When SQP is applied to MPCC, under natural assumptions SQP subproblems can be infeasible, even arbitrarily close to a solution. Thus some kind of constraints relaxation (known as *elastic mode*; see, e.g., [1]) has to be used. Let $u^k = (x^k, y^k, z^k) \in \mathbf{R}^n \times \mathbf{R}^m \times \mathbf{R}^m$ be the current primal iterate, and let $\lambda_0^k \geq 0$ be the current estimate of the Lagrange multiplier corresponding to the last constraint in (3.12). We suggest partial relaxation of SQP constraints, which gives the following subproblems:

$$\begin{array}{ll} \min\limits_{(d,\,t)} & \left\langle f'\left(x^k\right), \xi\right\rangle + \frac{1}{2}\langle \mathcal{H}_k\xi, \xi\rangle + \lambda_0^k\langle \eta, \zeta\rangle + ct \\ \text{s.t.} & -te \leq y^k - G\left(x^k\right) + \eta - G'\left(x^k\right)\xi \leq te, \\ & -te \leq z^k - H\left(x^k\right) + \zeta - H'\left(x^k\right)\xi \leq te, \\ & y^k + \eta \geq 0,\ z^k + \zeta \geq 0,\ \left\langle y^k, z^k\right\rangle + \left\langle z^k, \eta\right\rangle + \left\langle y^k, \zeta\right\rangle \leq 0, \end{array} \tag{3.13}$$

where $d = (\xi, \eta, \zeta) \in \mathbf{R}^n \times \mathbf{R}^m \times \mathbf{R}^m$, $t \in \mathbf{R}$, $\mathcal{H}_k$ is an $n \times n$ positive definite symmetric matrix, $c > 0$ is the (penalty) parameter, and $e \in \mathbf{R}^m$ is the vector of ones.

If (d^k, t_k) is a solution of (3.13), then the next iterate is defined by $u^{k+1} = u^k + \alpha_k d^k$, where $\alpha_k \in (0, 1]$ is the stepsize parameter. Choosing $y^0 \geq 0$ and $z^0 \geq 0$, by the first two constraints in the last line of (3.13), it evidently holds that $y^k \geq 0$ and $z^k \geq 0$ for all k. The last three constraints in (3.13) are then always consistent (for example, $\eta = -y^k$ and $\zeta = 0$ satisfies this part of constraints), while the other constraints in (3.13) are consistent due to the elastic mode. It follows that subproblems (3.13) are always feasible. Furthermore, the objective function in (3.13) is bounded below on the nonempty feasible set. Hence, by the Frank–Wolfe theorem [2, Theorem 2.8.1], the subproblem (3.13) has a solution.

Taking into account that $y^k \geq 0$ and $z^k \geq 0$ for all k, the following penalty function can be used in the linesearch procedure for choosing the stepsize parameter:

for $u = (x,\, y,\, z) \in \mathbf{R}^n \times \mathbf{R}^m \times \mathbf{R}^m$,

$$\varphi_c(u) = f(x) + c\psi(u) + c\langle y,\, z\rangle, \quad \psi(u) = \|(y,z) - (G(x), H(x))\|_\infty\,. \tag{3.14}$$

If $(d^k,\, t^k)$ is a solution of SQP subproblem (3.13), then, by direct computation of directional derivative and by standard argument, it can be seen that d^k is a direction of descent for φ_c, provided c is large enough. This justifies the linesearch procedure along the direction obtained from (3.13).

Now let $\lambda^k = (\lambda_G^k,\, \lambda_H^k,\, \lambda_0^k)$ be the current estimate of the Lagrange multipliers corresponding to inequality constraints in (3.12). It can be easily seen that such λ^k is a natural approximation of Lagrange multipliers of the original MPCC (1.1). Define the index sets I_G and I_H according to (2.7) and (2.8), respectively. Once we have reasons to believe that the index sets I_G and I_H give a correct identification, we shall set the corresponding slacks to zero ($y_{I_G}^k = 0,\, z_{I_H}^k = 0$) and switch to the inner (active-set) phase. We note that identification cannot be correct if $I_G \cup I_H \neq \{1, \ldots, m\}$. Another sign of incorrect identification is when the sets I_G and I_H are not yet stable (i.e., change from one iteration to the next). The inner phase consists in applying SQP to the tightened MP

$$\min_{(x,\,y,\,z)} f(x) \quad \text{s.t.} \quad G(x) = y,\ H(x) = z,\ y_{I_G} = 0,\ z_{I_H} = 0, \tag{3.15}$$

i.e., we find a solution d^k of

$$\begin{aligned} \min{}_d \quad & \left\langle f'\left(x^k\right),\, \xi\right\rangle + \tfrac{1}{2}\langle \mathcal{H}_k\xi,\, \xi\rangle \\ \text{s.t.} \quad & y^k - G\left(x^k\right) + \eta - G'\left(x^k\right)\xi = 0,\ y_{I_G}^k + \eta_{I_G} = 0, \\ & z^k - H\left(x^k\right) + \zeta - H'\left(x^k\right)\xi = 0,\ z_{I_H}^k + \zeta_{I_H} = 0, \end{aligned} \tag{3.16}$$

and set $u^{k+1} = u^k + \alpha_k d^k$, with some $\alpha_k \in (0,\, 1]$. Infeasibility of the active-set subproblem (3.16) is again one of the signs of incorrect identification, in which case we go back to the outer phase. We shall show below that if the subproblem (3.16) is feasible, its solution provides a direction of descent for the same penalty function (3.14) that is used in the outer phase. This justifies incorporating the active-set phase into the global SQP framework.

Having in mind fast local convergence, the matrices $\mathcal{H}_k$ in (3.13) and (3.16) should in some specific sense (i.e., not necessarily on the whole space) "approximate" the Hessians with respect to x of the Lagrangians of (3.12) and (3.15), respectively, at the limiting primal-dual solution. It can be easily checked that both these Hessians coincide with $\frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x},\, \bar{\mu})$, where $\bar{x}$ is the primal limiting solution, while $\bar{\mu} = (\bar{\mu}_G,\, \bar{\mu}_H)$ is the part of dual limiting solution, corresponding to the first two constraints in (3.12) and (3.15). (For problem (3.12), $\bar{\mu}$ is an MPCC-multiplier associated with $\bar{x}$, by necessity. For problem (3.15), this is the case as well, if the index sets I_G and I_H are correctly identified and provided $\bar{x}$ is a strongly stationary point of MPCC (1.1) with unique associated MPCC-multiplier.) In order to approximate $\frac{\partial^2 \mathcal{L}}{\partial x^2}(\bar{x},\, \bar{\mu})$, one might need to compute an approximation $\mu^k = (\mu_G^k,\, \mu_H^k)$ of $\bar{\mu}$. Within the inner phase, these estimates can be computed directly as Lagrange multipliers corresponding to the first two constraints in (3.16). Within the outer phase, they can be derived from λ^k by the equalities

$$\mu_G^k = \lambda_G^k - \lambda_0^k H\left(x^k\right), \quad \mu_H^k = \lambda_H^k - \lambda_0^k G\left(x^k\right) \tag{3.17}$$

(note that these formulas do not use identification of active indices).

We proceed to formally state the proposed algorithm.

ALGORITHM 3.3. `Preliminary step.` Fix $\theta, \varepsilon, \tau \in (0, 1)$, and $c > 0$. Set $k = 0$, and choose $u^0 = (x^0, y^0, z^0) \in \mathbf{R}^n \times \mathbf{R}^m_+ \times \mathbf{R}^m_+$ and $\lambda^0 = (\lambda^0_G, \lambda^0_H, \lambda^0_0) \in \mathbf{R}_+ \times \mathbf{R}^m_+ \times \mathbf{R}^m_+$.

`Identification step.` Define the index sets I_G and I_H according to (2.7) and (2.8). If $k = 0$ or if I_G or I_H does not coincide with its counterpart computed at the previous iteration or if $I_G \cup I_H \neq \{1, \ldots, m\}$, go to `Elastic mode SQP step`.

`Active-set step.` If d^{k-1} was generated by `Elastic mode SQP step`, set $\tilde{k} = k$, store $u^{\tilde{k}}$ and $\lambda^{\tilde{k}}$, redefine $u^k = (x^k, y^k, z^k)$ by setting $y^k_{I_G} = 0$, $z^k_{I_H} = 0$, and define $\mu^k = (\mu^k_G, \mu^k_H)$ by (3.1)–(3.3). and

$$\left(\mu^k_G\right)_i = 0,\ i \in I_H \setminus I_G, \quad \left(\mu^k_H\right)_i = 0,\ i \in I_G \setminus I_H. \tag{3.18}$$

Using μ^k, choose an $n \times n$ positive definite symmetric matrix $\mathcal{H}_k$. If (3.16) is infeasible, go to `Elastic mode SQP step`.

Compute $d^k = (\xi^k, \eta^k, \zeta^k)$ as a solution of (3.16) and $\mu^{k+1} = (\mu^{k+1}_G, \mu^{k+1}_H)$ as an associated Lagrange multiplier corresponding to the first two constraints in (3.16). Set $\tilde{x}^{k+1} = x^k + \xi^k$. If there exists $i \in I_G \setminus I_H$ such that $H_i(\tilde{x}^{k+1}) = 0$ or there exists $i \in I_H \setminus I_G$ such that $G_i(\tilde{x}^{k+1}) = 0$, go to `Elastic mode SQP step`. Otherwise, define $\lambda^{k+1} = (\lambda^{k+1}_G, \lambda^{k+1}_H, \lambda^{k+1}_0)$ according to (2.9)–(2.12), with x^{k+1} replaced by $\tilde{x}^{k+1}$, and go to `Linesearch step`.

`Elastic mode SQP step.` If d^{k-1} was generated by `Active-set step`, redefine $u^k = (x^k, y^k, z^k)$ by setting

$$y^k_i = 0 \quad \forall\, i = 1, \ldots, m \text{ such that } y^k_i < 0, \tag{3.19}$$

$$z^k_i = 0 \quad \forall\, i = 1, \ldots, m \text{ such that } z^k_i < 0 \tag{3.20}$$

and if

$$\varphi_c\left(u^k\right) > \varphi_c\left(u^{\tilde{k}}\right), \tag{3.21}$$

then set $k = \tilde{k}$, $u^k = u^{\tilde{k}}$, and $\lambda^k = \lambda^{\tilde{k}}$.

Using $\mu^k = (\mu^k_G, \mu^k_H)$ computed according to (3.17), choose an $n \times n$ positive definite symmetric matrix $\mathcal{H}_k$.

Compute (d^k, t^k) as a solution of (3.13) and $\lambda^{k+1} = (\lambda^{k+1}_G, \lambda^{k+1}_H, \lambda^{k+1}_0)$ as an associated Lagrange multiplier corresponding to inequality constraints in (3.13).

`Linesearch step.` Compute the stepsize parameter α_k according to the Armijo rule: $\alpha_k = \tau^s$, where s is the smallest nonnegative integer satisfying

$$\varphi_c\left(u^k + \tau^s d^k\right) \leq \varphi_c\left(u^k\right) + \varepsilon\tau^s \varphi'_c\left(u^k; d^k\right). \tag{3.22}$$

Set $u^{k+1} = u^k + \alpha_k d^k$, adjust k by 1, and go to `Identification step`.

Observe that the active-set iterations always start with $u^k = (x^k, y^k, z^k)$ satisfying complementarity. Indeed, the SQP iterations in the elastic mode start with $y^k \geq 0$, $z^k \geq 0$ and maintain nonnegativity. Furthermore, active-set iterations start with $(y^k)_{I_G} = 0$, $(z^k)_{I_H} = 0$, where $I_G \cup I_H = \{1, \ldots, m\}$. The only way complementarity can be violated during a sequence of active-set steps is when some component of y or z becomes negative. Obviously, this can happen only for indices which are not in I_G in the case of y and not in I_H in the case of z. Once a component becomes negative, this index is immediately added to the corresponding set (see (2.7), (2.8)), which makes the sets change. In such a case, we get out of the active-set phase, restore nonnegativity (see (3.19), (3.20)), and if such a point breaks monotonicity

of the sequence of the penalty function values (that is, if (3.21) happens), we go back to the last iterate preceding the active-set phase (which was determined to be premature).

We next show that when within `Active-set step` of Algorithm 3.3 the subproblem (3.16) is feasible, the generated direction d^k is of descent for the penalty function (3.14) at u^k, and hence the linesearch procedure along this direction is well-defined.

LEMMA 3.6. *Let $d^k = (\xi^k, \eta^k, \zeta^k)$ and $\mu^{k+1} = (\mu_G^{k+1}, \mu_H^{k+1})$ be computed within* `Active-set step` *of Algorithm* 3.3 *from the primal-dual solution of* (3.16).

Then

$$\varphi_c'\left(u^k; d^k\right) \le -\left\langle \mathcal{H}_k \xi^k, \xi^k \right\rangle - \left(c - \left\|\mu^{k+1}\right\|_1\right) \psi\left(u^k\right). \tag{3.23}$$

In particular, d^k is a direction of descent for φ_c, provided either $\xi^k \neq 0$ or $c > \|\mu^{k+1}\|_1$ and $\psi(u^k) > 0$.

Proof. First note that, as observed above, $y^k \ge 0$, $z^k \ge 0$, because otherwise the index sets would have changed, and we would not be solving (3.16). Furthermore, recall that we set

$$y_{I_G}^k = 0, \quad z_{I_H}^k = 0 \tag{3.24}$$

when the algorithm enters the active-set phase. Moreover, these equalities are preserved within this phase, because the last line in (3.16) implies

$$\eta_{I_G}^k = 0, \quad \zeta_{I_H}^k = 0. \tag{3.25}$$

We thus have that whenever $z_i^k > 0$, it holds that $i \notin I_H$. Since the algorithm can enter the active-set phase only with $I_G \cup I_H = \{1, \ldots, m\}$, we have that $i \in I_G$. Therefore, $y_i^k = 0$ by the first equality in (3.24), and hence $\eta_i^k = 0$ by the first equality in (3.25). This shows that $\langle z^k, \eta^k \rangle = 0$. Analogously, $\langle y^k, \zeta^k \rangle = 0$. It follows that the directional derivative of the term in the definition (3.14) of φ_c that penalizes complementarity violation is equal to zero.

By direct computation of the directional derivative and by standard argument,

$$\psi'\left(u^k; d^k\right) = -\psi\left(u^k\right). \tag{3.26}$$

Furthermore, by the Lagrange optimality conditions for (3.16), it holds that

$$f'\left(x^k\right) + \mathcal{H}_k \xi^k - \left(G'\left(x^k\right)\right)^{\mathrm{T}} \mu_G^{k+1} - \left(H'\left(x^k\right)\right)^{\mathrm{T}} \mu_H^{k+1} = 0, \tag{3.27}$$

$$\left(\mu_G^{k+1}\right)_{I_H \setminus I_G} = 0, \quad \left(\mu_H^{k+1}\right)_{I_G \setminus I_H} = 0. \tag{3.28}$$

Taking again into account the structure of constraints in (3.16), from (3.24)–(3.28) we obtain

$$\begin{aligned}
&\left\langle f'\left(x^k\right), \xi^k \right\rangle = -\left\langle \mathcal{H}_k \xi^k, \xi^k \right\rangle + \left\langle \mu_G^{k+1}, G'\left(x^k\right)\xi^k \right\rangle + \left\langle \mu_H^{k+1}, H'\left(x^k\right)\xi^k \right\rangle \\
&= -\left\langle \mathcal{H}_k \xi^k, \xi^k \right\rangle + \sum_{i \in I_G} \left(\mu_G^{k+1}\right)_i \left(y_i^k - G_i\left(x^k\right) + \eta_i^k\right) \\
&\quad + \sum_{i \in I_H} \left(\mu_H^{k+1}\right)_i \left(z_i^k - H_i\left(x^k\right) + \zeta_i^k\right) \\
&= -\left\langle \mathcal{H}_k \xi^k, \xi^k \right\rangle + \sum_{i \in I_G} \left(\mu_G^{k+1}\right)_i \left(y_i^k - G_i\left(x^k\right)\right) + \sum_{i \in I_H} \left(\mu_H^{k+1}\right)_i \left(z_i^k - H_i\left(x^k\right)\right) \\
&\le -\left\langle \mathcal{H}_k \xi^k, \xi^k \right\rangle + \left\|\mu^{k+1}\right\|_1 \psi\left(u^k\right),
\end{aligned}$$

where $\mu^{k+1} = (\mu_G^{k+1}, \mu_H^{k+1})$. Combining the latter with (3.26), we obtain (3.23). ∎

If $\xi^k = 0$ and $\psi(u^k) = 0$, we obtain from (3.14) and from the constraints of (3.16) that $d^k = 0$ and the point u^k is feasible in (3.12). Furthermore, (3.27) and (3.28) show that x^k is a weakly stationary point of (1.1). Otherwise, the linesearch procedure is well-defined and results in the decrease of the penalty function value with respect to $\varphi_c(u^k)$. Overall, the method generates iterates such that the sequence $\{\varphi_c(u^k)\}$ is nonincreasing, as in standard SQP framework.

4. Numerical examples. In this section, we illustrate behavior of the algorithms discussed above by some numerical examples. In what follows, `Linearization` is the linesearch SQP method with $\mathcal{H}_k$ being the identity matrix, applied to the original problem formulation (without slacks), while `SQP−slacks` is the linesearch SQP method with $\mathcal{H}_k = \frac{\partial^2 \mathcal{L}}{\partial x^2}(x^k, \mu^k)$ applied to the problem formulation with slacks. The first simple choice of $\mathcal{H}_k$ is motivated by robustness (if $\mathcal{H}_k$ is not positive definite, then the subproblems sometimes do not have a solution, while more sophisticated choices of positive definite matrices require complex quasi-Newton implementations). The second choice of $\mathcal{H}_k$ is motivated by its efficiency (when subproblems are solvable). SQP-type methods were all implemented in their basic form, without elastic mode (which corresponds to setting $t = 0$), without any attempts to modify $\mathcal{H}_k$ with respect to the two alternative choices above, and without any tools for avoiding the Maratos effect. While without a doubt important for any professional implementation, all those details have no real bearing for illustrating our proposal for forcing fast local convergence by the active-set phase. Linesearch parameters were chosen as follows: $\varepsilon = 0.1$ and $\tau = 0.5$. We used the simplest update rule for penalty parameters: $c_0 = \|\lambda^1\|_\infty + 1$, and then for each $k = 1, 2, \ldots$, we set $c_k = c_{k-1}$ if $c_{k-1} \geq \|\lambda^{k+1}\|_\infty$, and $c_k = \|\lambda^{k+1}\|_\infty + 1$ otherwise. The other implemented methods are the following. `SNM−FB` is Algorithm 3.2 without `Active-set step` and with parameters $\delta = 2.1$, $\gamma = 10^{-9}$, $\varepsilon = 10^{-4}$, and $\tau = 0.5$. `Linearization+AS` and `SQP−slacks+AS` are the modifications of algorithms `Linearization` and `SQP−slacks`, respectively, supplied with the option of switching to `Active-set step`, implemented as specified in Algorithm 3.1. Finally, `SNM−FB+AS` is precisely Algorithm 3.2. The identification test parameter and the linear decrease parameter were chosen as follows: $\theta = 0.5$, $q = 0.9$. All computations were performed in Matlab environment, with the QP-subproblems solved by the built-in Matlab QP-solver. We used the stopping criterion of the form

$$\left\|\Phi_{FB}\left(x^k, \lambda^k\right)\right\| < 10^{-7}. \tag{4.1}$$

We start with reporting some local runs of the algorithms discussed above for the following example, which is a modified version of `ralph2` in MacMPEC [12]. A separate consideration of this example is due to the fact that it is known to violate MPCC-SOSC, and so we expect that our method may behave better than SQP. The problem `ralph2` is modified by introducing higher-order nonlinear terms, in order to prevent the tendency for finite termination, which is quite common for SQP in the cases of "simple" (affine) constraints.

Example 4.1. The problem

$$\min x_1^2 + x_2^2 - 4x_1x_2 + x_2^3 \text{ s.t. } x_1 + x_2^2/2 \geq 0, x_2 - x_1^2 \geq 0, \left(x_1 + x_2^2/2\right)\left(x_2 - x_1^2\right) \leq 0,$$

has two local solutions $\bar{x}^1 = (0, 0)$ and $\bar{x}^2 = (1, 1)$, the latter being global, both satisfying MPCC-LICQ (1.5). The first solution satisfies piecewise SOSC (1.18) but violates MPCC-SOSC (1.12), while the second satisfies MPCC-SOSC (1.12).

We use the primal starting points close to $\bar{x}^1$ to facilitate convergence to this solution. Selected results for $\lambda_G^0 = 0.01$, $\lambda_H^0 = 0.02$, $\lambda_0^0 = 5$ are presented in Table 4.1.

TABLE 4.1
Example 4.1*, local runs.*

Algorithm	$x^0 = 10^{-3}\times$				
	(10, 1)	(7, 3)	(5, 5)	(3, 7)	(1, 10)
SQP−slacks	11	10	10	10	4
SNM−FB	9	9	10	10	5
SQP−slacks+AS	**3**	**3**	**3**	**3**	**3**
SNM−FB+AS	**4**	**3**	**3**	**3**	**3**

For each run, we report the number of iterations before convergence was declared. Bold-faced numbers mean that convergence was achieved by active-set steps.

These results evidently demonstrate that, in this case, the active-set phase is useful. And this is precisely our message—we do not claim that it should always result in faster convergence than that for some nonmodified method, but it is easy to incorporate, is useful at least *sometimes*, and works as it is supposed to. To give some more validation of our claim, in the rest of this section we present numerical results for global convergence of our algorithms on some small test problems derived from MacMPEC [12]. The set of test problems was obtained as follows. We select all the problems in MacMPEC satisfying the following criteria: they have no more than 10 variables, and they do not have any inequality constraints apart from complementarity constraints (to be consistent with the problem setting of the paper). This makes 37 problems. Furthermore, we ignore the simple bounds (again in order to be consistent with the problem setting of the paper), which of course may sometimes affect the solutions/stationary points of these problems. Finally, `ralph1` suggests two different objective functions, and we use both, labeling the corresponding problems `ralph11` and `ralph12`. Thus, we end up with 38 problems.

We performed the runs of each algorithm from the same randomly generated starting points. Primal starting points were generated in a cubic neighborhood around the solution (a feasible point with the objective function value equal to the optimal value reported in MacMPEC; these points were found in the course of our experiments), with the edge of the cube equal to 20. Dual starting points for equality constraints were generated the same way, but around 0, while for dual starting points corresponding to the complementarity constraints multipliers there was the additional nonnegativity restriction. In the process of collecting information, we disregard the runs when at least one of the QP-employing algorithms fails because of a failure of the QP solver (such failures must be avoided in professional implementations by using elastic mode and modifications of the Hessian, or quasi-Newton updates with appropriate line-search, etc.; in any case these failures are concerned with the outer phase, rather than the use of the active-set step). Thus, we keep generating random starting points until we have 100 that do not cause QP solver failures.

When reporting the results, we count the cases of failure (when convergence was not achieved after 50 steps), the cases of convergence (to KKT points), and provide some details about convergence. We are not concerned whether the obtained KKT point is a local/global solution or not (this, once again, has to do mostly with behavior of the outer phase).

Columns of Tables 4.2 and 4.3 contain average/summarized information on the performance of each algorithm for 100 runs from random starting points. First row of each cell contains average characteristics over successful runs: iteration count, last active-set steps, overall count of active-set steps. Thus the average number of useless

active-set steps (eventually disregarded by backup safeguards) for Linearization+AS and SQP−slack+AS equals the difference between the third and the second number. Second row of each cell contains the overall number of failures and those cases when convergence was achieved by active-set steps. Note that what should be compared is the behavior of a given outer-phase algorithm with and without using the AS step. For Linearization and SNM−FB, in many cases using active-set step helps in terms of either robustness, efficiency, or both. SQP−slacks is very efficient by itself, and

in our implementation, active-set steps sometimes improve or harm it just slightly, being overall comparable. Recall, however, Example 4.1, which puts in evidence that active-set steps do outperform SQP in the case where MPCC-SOSC does not hold. Also, it should be kept in mind that SQP−slacks (just as standard SQP) does not possess fully justified superlinear convergence, unlike active-set steps. One can see from Tables 4.2 and 4.3 that, apart from being intended for the cases of weaker SOSC, active-set step usually does not harm at all, neither robustness nor efficiency. The

number of disregarded active-set steps remains very low. In many cases, active-set step is used just once, on the last iteration, which means that the corresponding outer-phase algorithm without active-set step could not possibly converge faster (usually it converges slower, at least in the cases of `Linearization` and `SNM−FB`). In some cases, the active-set strategy helps seriously.

A REGULARIZED SMOOTHING NEWTON METHOD FOR SYMMETRIC CONE COMPLEMENTARITY PROBLEMS*

LINGCHEN KONG†, JIE SUN‡, AND NAIHUA XIU†

Abstract. This paper extends the regularized smoothing Newton method in vector complementarity problems to symmetric cone complementarity problems (SCCP), which includes the nonlinear complementarity problem, the second-order cone complementarity problem, and the semidefinite complementarity problem as special cases. In particular, we study strong semismoothness and Jacobian nonsingularity of the total natural residual function for SCCP. We also derive the uniform approximation property and the Jacobian consistency of the Chen–Mangasarian smoothing function of the natural residual. Based on these properties, global and quadratical convergence of the proposed algorithm is established.

Key words. symmetric cone complementarity problem, monotonicity, natural residual function, regularized smoothing method, quadratic convergence

AMS subject classifications. 65K05, 90C33

DOI. 10.1137/060676775

1. Introduction.

We are interested in the following symmetric cone complementarity problem (SCCP): Find vectors $x, y \in \mathcal{J}$ such that

$$x \in K, \quad y = F(x) \in K, \quad \langle x, y \rangle = 0, \tag{1.1}$$

where $\mathcal{J}$ is an n-dimensional real Euclidean space, $\mathcal{A} := (\mathcal{J}, \langle \cdot, \cdot \rangle, \circ)$ is a Euclidean Jordan algebra, K is a symmetric cone in $\mathcal{A}$ (see section 2), and $F : \mathcal{J} \to \mathcal{J}$ is a continuously differentiable mapping. Problem (1.1) includes the semidefinite complementarity problem (SDCP), the second-order cone complementarity problem (SOCCP), and the nonlinear complementarity problem (NCP) as special cases. The SCCP has wide applications; in particular, it may arise from the KKT system of a nonlinear optimization problem. The SCCP has been the focal point of some recent research; see, e.g., [12, 13, 14, 22, 23, 29, 33, 37].

We intend to design an algorithm for SCCPs, which is called the regularized smoothing Newton method. In the setting of NCP, various regularized smoothing methods have been tested, which, in addition to their simplicity of implementation, have the advantage of being able to solve some ill-posed problems. Recently, there are some papers studying the smoothing Newton methods with or without regularization for SOCCP and SDCP; see, e.g., [3, 4, 5, 6, 7, 11, 15, 16, 32, 35]. These papers either address the case of SOCCP or that of SDCP, but to our knowledge, there are no discussions on this type of algorithms under the general framework of SCCP.

In this paper, with the help of the Euclidean Jordan algebra, we analyze the strong semismoothness and Jacobian nonsingularity of a natural residual function

(the so-called total NR-function). We also show the level-boundedness of the natural merit function of the total NR-function for SCCP under monotonicity and strict feasibility assumptions. We then construct the Chen–Mangasarian smoothing function of the natural residual for SCCP. Our work provides a theoretical and computational framework for solving general nonlinear SCCP. In particular, we derive the uniform approximation property and the Jacobian consistency of this smoothing function. These properties form a basis for establishing quadratic convergence of Newton-type algorithms. Finally, we state a globally and quadratically convergent algorithm for solving monotone SCCP that was originated from a similar algorithm of Hayashi, Yamashita, and Fukushima [15] for SOCCP. Many analytic tools we used are taken from the recent work by Sun and Sun [30], in which the differential properties of the Löwner's operator and spectral functions are studied in the space of Euclidean Jordan algebras.

This paper is organized as follows. In section 2, we briefly describe Euclidean Jordan algebra and some of its properties used in our analysis. We also derive new results on the Jacobian and the Clarke generalized Jacobian of Löwner operators. In section 3, we introduce and characterize the total NR-function for SCCP. In section 4, we present the Chen–Mangasarian smoothing function in the context of SCCPs and discuss its properties. In section 5, we introduce the regularized smoothing Newton method for SCCP and discuss its convergence.

The following notations will be used throughout this paper. Let $\mathcal{X}$ and $\mathcal{Y}$ be two finite dimensional real Euclidean spaces. For a given set $S \subseteq \mathcal{X}$, int$S$ and conv$S$ denote the interior and convex hull of S, respectively. Let dist(a, S) be $\min\{\|a-b\| : b \in S\}$ for $a \in \mathcal{X}$, where $\|\cdot\|$ is the norm on $\mathcal{X}$ induced by the inner product $\langle\cdot,\cdot\rangle$. We write $x \succeq_K y$ (respectively, $x \succ_K y$) to mean $x - y \in K$ (respectively, $x - y \in \text{int}K$) for vectors $x, y \in \mathcal{J}$. Also, we write $A \succeq B$ ($A \succ B$) to mean $A - B$ being positive semidefinite (positive definite) for operators A and B from $\mathcal{J}$ into itself. Let I be the identity operator, i.e., $Ix = x$ for all $x \in \mathcal{J}$. We say that the operator A is invertible (or nonsingular) if the equation $Ax = 0$ has a unique solution $x = 0$. For an operator A, A^T denotes the adjoint operator of A.

2. Preliminaries.

2.1. Euclidean Jordan algebras. We give a brief introduction to Euclidean Jordan algebras. Details on Euclidean Jordan algebras can be found in Koecher's lecture notes [19] and the monograph by Faraut and Korányi [10].

A *Euclidean Jordan algebra (EJA)* is a triple $(\mathcal{J}, \langle\cdot,\cdot\rangle, \circ) \triangleq \mathcal{A}$, where $(\mathcal{J}, \langle\cdot,\cdot\rangle)$ is a real n-dimensional inner product space and $(x, y) \mapsto x \circ y : \mathcal{J} \times \mathcal{J} \to \mathcal{J}$ is a bilinear mapping which satisfies the following conditions:

(i) $x \circ y = y \circ x$ for all $x, y \in \mathcal{J}$,
(ii) $x \circ (x^2 \circ y) = x^2 \circ (x \circ y)$ for all $x, y \in \mathcal{J}$ where $x^2 := x \circ x$,
(iii) $\langle x \circ y, z\rangle = \langle x, y \circ z\rangle$ for all $x, y, z \in \mathcal{J}$.

We call $x \circ y$ the *Jordan product* of x and y. In general, the Jordan product is not associative; i.e., $(x \circ y) \circ z \neq x \circ (y \circ z)$ for all $x, y, z \in \mathcal{J}$. In addition, we assume that there exists an element e (called the *identity* element) such that $x \circ e = e \circ x = x$ for all $x \in \mathcal{J}$. The following are some basic facts about Euclidean Jordan algebras.

- Given a Euclidean Jordan algebra $\mathcal{A}$, define *the set of squares* as $K := \{x^2 : x \in \mathcal{J}\}$. From Theorem III 2.1 in [10], K is a *symmetric cone* in $\mathcal{A}$. In other words, K is a self-dual closed convex cone, and for any two elements $x, y \in \text{int}K$, there exists an invertible linear transformation $\Gamma : \mathcal{J} \to \mathcal{J}$ such that $\Gamma(K) = K$ and $\Gamma(x) = y$.

- For $x \in \mathcal{J}$, let $m := m(x)$ be the smallest positive integer such that the set $\{e, x, x^2, \ldots, x^m\}$ is linearly dependent. Then m is said to be the *degree* of x, which is denoted by $\deg(x)$.
- The *rank* of $\mathcal{A}$ denoted by $\mathrm{rk}(\mathcal{A})$ is defined as $\mathrm{rk}(\mathcal{A}) \triangleq \max\{\deg(x) : x \in \mathcal{J}\}$. Let $\dim(\mathcal{J})$ denote the dimension of $\mathcal{J}$. Obviously, $\mathrm{rk}(\mathcal{A}) \le \dim(\mathcal{J})$.
- An element $c \in \mathcal{J}$ is an *idempotent* if $c^2 = c \neq 0$. An idempotent element is *primitive* if it cannot be written as a sum of two idempotents.
- A *complete system of orthogonal idempotents* in $\mathcal{A}$ is a finite set $\{c_1, c_2, \ldots, c_k\}$ of idempotents where $c_i \circ c_j = 0$ for all $i \neq j$, and $c_1 + c_2 + \cdots + c_k = e$.
- A *Jordan frame* in $\mathcal{A}$ is a complete system of orthogonal primitive idempotents. The number of elements of any Jordan frame equals the positive integer $\mathrm{rk}(\mathcal{A})$.

Example 2.1. Let $\mathbb{R}^n$ denote the space of n-dimensional real column vectors, and $\mathbb{R}^n_+$ be the nonnegative orthant. Consider $\mathbb{R}^n$ with the (usual) inner product and Jordan product defined, respectively, by $\langle x, y\rangle := \sum_{i=1}^n x_i y_i$ and $x \circ y := x * y$, where x_i denotes the ith component of x, etc., and $x * y$ denotes the componentwise product of vectors x and y. Then $(\mathbb{R}^n, \langle\cdot,\cdot\rangle, *)$ forms a Euclidean Jordan algebra with $\mathrm{rk}((\mathbb{R}^n, \langle\cdot,\cdot\rangle, *)) = \dim(\mathbb{R}^n) = n$ and $\mathbb{R}^n_+$ as its cone of squares. The identity element is the n-vector of ones, and the set $\{e_1, e_2, \ldots, e_n\}$ is the unique Jordan frame where e_i is the ith coordinate vector for $i \in \{1, 2, \ldots, n\}$.

Example 2.2. Consider $\mathbb{R}^n (n \ge 2)$ where any x is written as $x = (x_1, x_2^T)^T$ with $x_1 \in \mathbb{R}$ and $x_2 \in \mathbb{R}^{n-1}$. The inner product is the same as usual, and the Jordan product is defined by

$$x \circ y = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \circ \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} := \begin{pmatrix} \langle x, y\rangle \\ x_1 y_2 + y_1 x_2 \end{pmatrix}.$$

Then $\Lambda^n := (\mathbb{R}^n, \langle\cdot,\cdot\rangle, \circ)$ forms a Euclidean Jordan algebra, and its cone of squares (*Lorentz cone or second-order cone*) is specified by $\Lambda^n_+ := \{(x_1, x_2^T)^T : \ x_1 \ge \|x_2\|\}$, where $\|\cdot\|$ denotes the 2-norm. The identity element in Λ^n is $e = \binom{1}{0}$. The set $\{c_1, c_2\}$ is a Jordan frame given by $c_i = \frac{1}{2}\binom{1}{(-1)^i\ \omega}$ for $i = 1, 2$ with any $\omega \in \mathbb{R}^{n-1}$ satisfying $\|\omega\| = 1$.

Example 2.3. Let $\mathbb{S}^n$ denote the set of all $n \times n$ real symmetric matrices with the inner product and Jordan product defined, respectively, by $\langle X, Y\rangle := \mathrm{Trace}(XY)$ and $X \circ Y := (XY + YX)/2$. Thus $(\mathbb{S}^n, \langle\cdot,\cdot\rangle, \circ)$ forms a Euclidean Jordan algebra, and its cone of squares $\mathbb{S}^n_+$ is the set of all positive semidefinite symmetric matrices. The identity element in this setting is the identity matrix E. The set $\{E_1, E_2, \ldots, E_n\}$ is a Jordan frame where E_i is the diagonal matrix with one in the ii-entry and zeros elsewhere for $i \in \{1, 2, \ldots, n\}$.

We now review the following spectral decomposition theorem of an element in a Euclidean Jordan algebra.

THEOREM 2.4. *(Spectral Decomposition Type* II *(Theorem* III.1.2, [10]*)) Let $\mathcal{A}$ be a Euclidean Jordan algebra with rank r. Then for $x \in \mathcal{J}$ there exist a Jordan frame $\{c_1, c_2, \ldots, c_r\}$ and real numbers $\lambda_1(x), \lambda_2(x), \ldots, \lambda_r(x)$ such that*

$$x = \lambda_1(x)c_1 + \lambda_2(x)c_2 + \cdots + \lambda_r(x)c_r. \tag{2.1}$$

The numbers $\lambda_i(x)$ $(i = 1, 2, \ldots, r)$ are the eigenvalues of x. We call (2.1) *the spectral decomposition (or the spectral expansion) of x.*

Note that the Jordan frame $\{c_1, c_2, \ldots, c_r\}$ in (2.1) depends on x. We do not write this dependence explicitly for simplicity of notation. (The same for $\{b_1, b_2, \ldots, b_{\bar{r}}\}$

below.) Let $\sigma(x)$ be the set of all distinct eigenvalues of x. Then $\sigma(x)$ contains at least one element and at most r. For each $\mu_i(x) \in \sigma(x)$, denote $N_i(x) := \{j : \lambda_j(x) = \mu_i(x)\}$ and $b_i \stackrel{\Delta}{=} \sum_{j\in N_i(x)} c_j$. Then the set $\{b_i : \mu_i(x) \in \sigma(x)\}$ is a complete system of orthogonal idempotents, and its uniqueness is guaranteed by Theorem III.1.1 in [10]. Let $\bar{r}$ be the number of elements in this set. We then have the spectral decomposition of type I stated in [10]; i.e.,

$$x = \mu_1(x)b_1 + \mu_2(x)b_2 + \cdots + \mu_{\bar{r}}(x)b_{\bar{r}}.$$

Next, we recall the Peirce decomposition theorem on the space $\mathcal{J}$, where a Jordan frame $\{c_1, c_2, \ldots, c_r\}$ is fixed beforehand. In this case, define the following subspaces

$$J_{ii} \stackrel{\Delta}{=} \{x \in \mathcal{J} : x \circ c_i = x\} \quad \text{and} \quad J_{ij} \stackrel{\Delta}{=} \left\{x \in \mathcal{J} : x \circ c_i = \frac{1}{2}x = x \circ c_j\right\},\ i \neq j, \tag{2.2}$$

for $i, j \in \{1, 2, \ldots, r\}$. In the second-order cone (SOC) case, we have $J_{12} \stackrel{\Delta}{=} \{x \in \mathbb{R}^n : x_1 = 0, \langle x_2, w\rangle = 0\}$, where w is characterized by the Jordan frame as in Example 2.2.

THEOREM 2.5 (Theorem IV.2.1, [10]). *Let $\{c_1, c_2, \ldots, c_r\}$ be a given Jordan frame in a Euclidean Jordan algebra $\mathcal{A}$ of rank r. Then $\mathcal{J}$ is the orthogonal direct sum of spaces J_{ij} $(i \leq j)$. Furthermore,*

(i) $J_{ij} \circ J_{ij} \subseteq J_{ii} + J_{jj}$;
(ii) $J_{ij} \circ J_{jk} \subseteq J_{ik}$, *if* $i \neq k$;
(iii) $J_{ij} \circ J_{kl} = \{0\}$, *if* $\{i, j\} \cap \{k, l\} = \emptyset$.

For each $x \in \mathcal{J}$, we define the *Lyapunov transformation* $L(x) : \mathcal{J} \to \mathcal{J}$ by $L(x)y = x \circ y$ for all $y \in \mathcal{J}$, which is a symmetric operator in the sense that $\langle L(x)y, z\rangle = \langle y, L(x)z\rangle$ for all $y, z \in \mathcal{J}$. Meanwhile, the operator $Q(x) \stackrel{\Delta}{=} 2L^2(x) - L(x^2)$ is called the *quadratic representation* of x. We say two elements $x, y \in \mathcal{J}$ *operator commute* if $L(x)L(y) = L(y)L(x)$. Lemma X.2.2 in [10] gives the following characterization of operator commutativity.

THEOREM 2.6. *Two elements x and y of a Euclidean Jordan algebra of rank r are operator commute if and only if they share a common Jordan frame.*

Thus, for a given Jordan frame $\{c_1, c_2, \ldots, c_r\}$, it is easy to see that c_i, c_j operator commute and $L(c_i)L(c_j) = L(c_j)L(c_i)$ for any $i, j \in \{1, 2, \ldots, r\}$. So do b_i and b_j for any $i, j \in \{1, 2, \ldots, \bar{r}\}$.

2.2. The Jacobian of Löwner operators. We review differentiability and semismoothness of a vector-valued function, which was called the Löwner operator by Sun and Sun [30] in recognition of Löwner's contribution [21]. We also present some new results on the Jacobian and the Clarke generalized Jacobian of the Löwner operator, which are basic and useful in the subsequent analysis.

DEFINITION 2.7. *Let $x = \sum_{j=1}^r \lambda_j(x)c_j$ and $g : \mathbb{R} \to \mathbb{R}$ be a real-valued function. We define the Löwner operator (function) $G : \mathcal{J} \to \mathcal{J}$ as*

$$G(x) \stackrel{\Delta}{=} \sum_{j=1}^{r} g(\lambda_j(x))c_j = g(\lambda_1(x))c_1 + g(\lambda_2(x))c_2 + \cdots + g(\lambda_r(x))c_r. \tag{2.3}$$

When $g(t) = t_+ = \max\{0, t\}(t \in \mathbb{R})$, this becomes the *metric projection operator*

$$P_K(x) \stackrel{\Delta}{=} (\lambda_1(x))_+c_1 + (\lambda_2(x))_+c_2 + \cdots + (\lambda_r(x))_+c_r \tag{2.4}$$

onto the symmetric cone K. Note that $x \in K$ (respectively, $x \in \mathrm{int}K$) if and only if $\lambda_i(x) \geq 0$ (respectively, $\lambda_i(x) > 0$) $(i = 1, 2, \ldots, r)$. For any $x \in K$, we define $\sqrt{x} \stackrel{\Delta}{=} \sum_{j=1}^r \sqrt{\lambda_j(x)}c_j$ for $x \in K$.

We consider the differentiability of the Löwner operator $G(\cdot)$. Suppose that g is differentiable at $\tau_i, i = 1, 2, \ldots, r$. Define *the first divided difference* $g^{[1]}(\tau)$ of g at $\tau \stackrel{\Delta}{=} (\tau_1, \tau_2, \ldots, \tau_r)^T \in \mathbb{R}^r$ as the $r \times r$ symmetric matrix with the ijth entry given by

$$[g^{[1]}(\tau)]_{ij} = [\tau_i, \tau_j]_g \stackrel{\Delta}{=} \begin{cases} \dfrac{g(\tau_i) - g(\tau_j)}{\tau_i - \tau_j} & \text{if } \tau_i \neq \tau_j, \\ g'(\tau_i) & \text{if } \tau_i = \tau_j, \end{cases} \quad i, j = 1, 2, \ldots, r. \tag{2.5}$$

A direct implication of Theorem 3.2 in [30] is the following property of the Jacobian of the Löwner operator $G(\cdot)$.

THEOREM 2.8. *Let $x = \sum_{j=1}^{r} \lambda_j(x) c_j = \sum_{i=1}^{\bar{r}} \mu_i(x) b_i$. Then, $G(\cdot)$ is (continuously) differentiable at x if and only if for each $j \in \{1, 2, \ldots, r\}$, g is (continuously) differentiable at $\lambda_j(x)$. In this case, the Jacobian $\nabla G(x)$ is given by*

$$\nabla G(x) = 2 \sum_{i \neq j, i, j=1}^{r} [\lambda_i(x), \lambda_j(x)]_g L(c_i) L(c_j) + \sum_{i=1}^{r} g'(\lambda_i(x)) Q(c_i) \tag{2.6}$$

or equivalently

$$\nabla G(x) = 2 \sum_{i \neq j,\ i, j=1}^{\bar{r}} [\mu_i(x), \mu_j(x)]_g L(b_i) L(b_j) + \sum_{i=1}^{\bar{r}} g'(\mu_i(x)) Q(b_i). \tag{2.7}$$

Furthermore, $\nabla G(x)$ is a linear and symmetric operator from $\mathcal{J}$ into itself.

As a consequence of Theorem 2.8, we obtain the following result in the case of $\mathrm{rk}(\mathcal{A})$=$\dim(\mathcal{J})$.

COROLLARY 2.9. *Suppose that $\mathrm{rk}(\mathcal{A}) = \dim(\mathcal{J}) = n$ and $x = \sum_{j=1}^{n} \lambda_j(x) c_j = \sum_{i=1}^{\bar{n}} \mu_i(x) b_i$. If $G(\cdot)$ is (continuously) differentiable at x, then it holds that*

$$\nabla G(x) = \sum_{i=1}^{n} g'(\lambda_i(x)) L(c_i) = \sum_{i=1}^{\bar{n}} g'(\mu_i(x)) L(b_i). \tag{2.8}$$

Proof. Since $\mathrm{rk}(\mathcal{A})$=$\dim(\mathcal{J}) = n$, it follows from Theorem 3.5 in [20] that there is a unique Jordan frame $\{c_1, c_2, \ldots, c_n\}$ in $\mathcal{A}$. Thus, through Theorem 2.5, any element $h \in \mathcal{J}$ can be expressed by $h = \sum_{i=1}^{n} h_i c_i$ with $h_i \in \mathbb{R}$ $(i = 1, 2, \ldots, n)$. Therefore,

$$L(c_i)L(c_j)h = L(c_j)L(c_i)h = c_i \circ (c_j \circ h) = \begin{cases} c_i \circ (h_j c_j) = 0 & \text{if } i \neq j, \\ c_i \circ (h_i c_i) = c_i \circ h & \text{if } i = j. \end{cases}$$

This implies that $L(c_i)L(c_j) = 0$ $(i \neq j)$ and $L(c_i)L(c_i) = L(c_i)$ for any $i, j \in \{1, 2, \ldots, n\}$. Hence $Q(c_i) = L(c_i)$. Formula (2.8) is then an implication of Theorem 2.8. ∎

As an application of Corollary 2.9, we consider the Jacobian of the Löwner operator on $\mathbb{R}^n$.

Example 2.10. Suppose that $\mathcal{A} = (\mathbb{R}^n, \langle \cdot, \cdot \rangle, *)$ as in Example 2.1. Let $x = \sum_{i=1}^{n} x_i e_i$. One can easily verify that $L(e_i) = e_i e_i^T = E_i$ $(i = 1, 2, \ldots, n)$. Note that $\mathrm{rk}((\mathbb{R}^n, \langle \cdot, \cdot \rangle, *)) = \dim(\mathbb{R}^n) = n$. It is obvious via Corollary 2.9 that

$$\nabla G(x) = \sum_{i=1}^{n} g'(x_i) L(e_i) = \mathrm{Diag}\{g'(x_1), g'(x_2), \ldots, g'(x_n)\}.$$

The next theorem presents a sufficient condition which guarantees that the Jacobian $\nabla G(x)$ is positive semidefinite (respectively, positive definite). Here $\nabla G(x)$ is called *positive semidefinite* (*respectively, positive definite*) if $\langle h, \nabla G(x)h\rangle \geq 0$ for all $h \in \mathcal{J}$ (respectively, $\langle h, \nabla G(x)h\rangle > 0$ for all $0 \neq h \in \mathcal{J}$).

THEOREM 2.11. *Let $x = \sum_{j=1}^{r} \lambda_j(x)c_j$. If g is (continuously) differentiable at $\lambda_j(x)$ for each $j \in \{1, 2, \ldots, r\}$ and $g'(t) \geq 0$ for all $t \in \mathbb{R}$, then $G(\cdot)$ is (continuously) differentiable at x and the Jacobian $\nabla G(x)$ is positive semidefinite. Moreover, the Jacobian is positive definite if the condition $g'(t) \geq 0$ is replaced by $g'(t) > 0$.*

Proof. Let $x = \sum_{j=1}^{r} \lambda_j(x)c_j$. By Theorem 2.5, any element $h \in \mathcal{J}$ can be expressed by $h = \sum_{i=1}^{r} h_i c_i + \sum_{1\leq k<l\leq r} h_{kl}$ where $h_i \in \mathbb{R}$ $(i = 1, 2, \ldots, r)$ and $h_{kl} \in J_{kl}$ $(1 \leq k < l \leq r)$. Theorem 2.5 also implies that $c_j \circ \sum_{i=1}^{r} h_i c_i = h_j c_j$ and $c_j \circ \sum_{1\leq k<l\leq r} h_{kl} = \frac{1}{2}\left(\sum_{k<j} h_{kj} + \sum_{l>j} h_{jl}\right)$. It therefore holds that

$$c_j \circ h = h_j c_j + \frac{1}{2}\left(\sum_{k=1}^{j-1} h_{kj} + \sum_{l=j+1}^{r} h_{jl}\right), \tag{2.9}$$

where $\sum_{k=1}^{j-1} h_{kj} \triangleq 0$ if $j = 1$ and $\sum_{l=j+1}^{r} h_{jl} \triangleq 0$ if $j = r$. Furthermore, Theorem 2.5 implies that

$$\langle h, c_j \circ (c_i \circ h)\rangle = \langle c_j \circ h, c_i \circ h\rangle = \frac{1}{4}\langle h_{ji}, h_{ji}\rangle = \frac{1}{4}\|h_{ji}\|^2, \ \forall j \neq i, \tag{2.10}$$

and

$$Q(c_j)h = 2c_j \circ (c_j \circ h) - c_j \circ h = h_j c_j, \quad j = 1, 2, \ldots, r. \tag{2.11}$$

Meanwhile, noting that $c_j^2 = c_j$, one has $\langle h, c_j\rangle = \langle c_j \circ h, c_j\rangle = h_j\langle c_j, c_j\rangle = h_j\|c_j\|^2$. Combining this with (2.6), (2.10), and (2.11) and noting that $L(c_j)L(c_i)h = c_j\circ(c_i\circ h)$, one has

$$\begin{aligned}
\langle h, \nabla G(x)h\rangle &= \left\langle h, \sum_{j\neq i,j,i=1}^{r} 2(g^{[1]}(\lambda(x)))_{ji} c_j \circ (c_i \circ h) + \sum_{j=1}^{r} (g^{[1]}(\lambda(x)))_{jj} h_j c_j \right\rangle \\
&= \sum_{j\neq i,j,i=1}^{r} 2(g^{[1]}(\lambda(x)))_{ji}\langle h, c_j \circ (c_i \circ h)\rangle + \sum_{j=1}^{r} (g^{[1]}(\lambda(x)))_{jj} h_j \langle h, c_j\rangle \\
&= \frac{1}{2}\sum_{j\neq i,j,i=1}^{r} (g^{[1]}(\lambda(x)))_{ji}\|h_{ji}\|^2 + \sum_{j=1}^{r} (g^{[1]}(\lambda(x)))_{jj} h_j^2\|c_j\|^2.
\end{aligned}$$

If $g'(t) \geq 0$ $(g'(t) > 0)$ for all $t \in \mathbb{R}$, then by (2.5) we can easily get $(g^{[1]}(\lambda(x)))_{ji} \geq 0$ $((g^{[1]}(\lambda(x)))_{ji} > 0)$ for all $j \neq i, j, i = 1, 2, \ldots, r$. Hence, $\langle h, \nabla G(x)h\rangle \geq 0$ for all $h \in \mathcal{J}$ ($\langle h, \nabla G(x)h\rangle > 0$ for all $0 \neq h \in \mathcal{J}$) through the above equation. ∎

We proceed to study the semismoothness of the Löwner operator $G(\cdot)$. Semismoothness was originally introduced by Mifflin [24] for functionals. Qi and Sun [26] extended the concept of semismoothness to vector-valued functions and developed a systematic theory that employs semismoothness in the analysis of the superlinear convergence of Newton methods for solving systems of nondifferentiable equations.

We briefly review some concepts and results of the semismoothness from [26]. Let $F : C \subseteq \mathcal{X} \to \mathcal{Y}$ be a locally Lipschitz function on an open set C. By Rademacher's theorem, F is almost everywhere differentiable (in the sense of Fréchet) in C. Let D_F

be the set of points where F is differentiable. Let $F'(x)$ denote the *derivative* of F at $x \in D_F$ and let $\nabla F(x)$ denote the *Jacobian* of F at x, which is the adjoint operator of $F'(x)$, in the sense of $\langle y, \nabla F(x)z\rangle = \langle F'(x)y, z\rangle$ for all $y \in \mathcal{X}$ and $z \in \mathcal{Y}$. Then, the *Clarke generalized Jacobian* of F at x is defined by $\partial F(x) \stackrel{\Delta}{=} \mathrm{conv}\{\partial_B F(x)\}$, where $\partial_B F(x) \stackrel{\Delta}{=} \{\lim_{\bar{x}\to x, \bar{x}\in D_F} \nabla F(\bar{x})\}$. Observe that $\partial F(x) = \{\nabla F(x)\}$ if F is smooth (continuously differentiable) at x. We say F is *directionally differentiable* at x along the direction d if

$$F'(x,d) \stackrel{\Delta}{=} \lim_{t\downarrow 0} \frac{F(x+td)-F(x)}{t} \quad \text{exists},$$

where $F'(x,d)$ is called the *directional derivative* of F at x along the direction d; and F is directionally differentiable at x if F is directionally differentiable at x along any direction $d \neq 0$.

Employing the above concepts, we can define (strong) semismoothness of a function F.

DEFINITION 2.12. *A directionally differentiable and locally Lipschitz function $F : C \subseteq \mathcal{X} \to \mathcal{Y}$ is semismooth at $x \in C$ if $V^T d - F'(x;d) = o(\|d\|)$ for any $d \neq 0, d \in \mathcal{X}$ sufficiently small and $V \in \partial F(x+d)$. In particular, if $o(\|d\|)$ can be replaced by $O(\|d\|^2)$, F is called strongly semismooth.*

By combining Theorem 3.3 with Proposition 3.3 in [30], we have the following result on (strong) semismoothness of the Löwner operator $G(\cdot)$.

LEMMA 2.13. *Let $x = \sum_{j=1}^r \lambda_j(x)c_j$. Then $G(\cdot)$ is (strongly) semismooth at x if and only if for each $j \in \{1,2,\ldots,r\}$, g is (strongly) semismooth at $\lambda_j(x)$. In particular, the metric projection operator P_K is strongly semismooth on $\mathcal{J}$.*

We are ready to extend Theorems 2.8 and 2.11 to the case of a semismooth Löwner operator $G(\cdot)$. Let g be semismooth at τ_i $(i = 1,2,\ldots,r)$ and ∂g denote the generalized Jacobian of g in the sense of Clarke. Define *the first generalized divided difference* $g^{[1,\partial]}$ of g at τ as the set of all $r \times r$ symmetric matrices, where the ijth entry $(g^{[1,\partial]}(\tau))_{ij}$ of the element $g^{[1,\partial]}(\tau) \in g^{[1,\partial]}$ is given by a set $\{[\tau_i,\tau_j]_g\}$ for $i,j = 1,2,\ldots,r$, where

$$\{[\tau_i,\tau_j]_g\} = \begin{cases} \left\{\dfrac{g(\tau_i)-g(\tau_j)}{\tau_i-\tau_j}\right\} & \text{if } \tau_i \neq \tau_j, \\ \partial g(\tau_i) & \text{if } \tau_i = \tau_j. \end{cases}$$

THEOREM 2.14. *Let $x \in \mathcal{J}$. Then $G(\cdot)$ is (strongly) semismooth at x if and only if g is (strongly) semismooth at every eigenvalue of x. In this case, the Clarke generalized Jacobian $\partial G(x)$ satisfies*

$$\overline{\partial} G(x) \supseteq \partial G(x) \supseteq \underline{\partial} G(x)$$

with the sets $\overline{\partial} G(x)$ and $\underline{\partial} G(x)$ being given, respectively, by

$$\overline{\partial} G(x) \stackrel{\Delta}{=} \mathrm{conv}\left[\bigcup_{\{c_1,\ldots,c_r\}\in\mathcal{C}(x)} \partial_{c_1,\ldots,c_r} G(x)\right],$$

$$\underline{\partial} G(x) \stackrel{\Delta}{=} \left\{ 2 \sum_{i\neq j,\ i,j=1}^{\bar{r}} [\mu_i(x),\mu_j(x)]_g L(b_i(x))L(b_j) + \sum_{i=1}^{\bar{r}} \partial g(\mu_i(x)) Q(b_i) \right\},$$

where $\mathcal{C}(x)$ is the set consisting of all Jordan frames in the spectral decomposition type

II *of* x, *and* $\partial_{c_1,\ldots,c_r} G(x) \triangleq \{2\sum_{i\neq j,\ i,j=1}^{r}\{[\lambda_i(x),\lambda_j(x)]_g\}L(c_i)L(c_j)+\sum_{i=1}^{r}\partial g(\lambda_i(x))Q(c_i)\}$.

Proof. The first part of the theorem follows from Lemma 2.13. For the second part, we first show $\overline{\partial}G(x) \supseteq \partial G(x)$. By the definitions of $\overline{\partial}G$ and ∂G we need to prove only that $\bigcup_{\{c_1,\ldots,c_r\}\in\mathcal{C}(x)} \partial_{c_1,\ldots,c_r} G(x) \supseteq \partial_B G(x)$. Taking any $V \in \partial_B G(x)$, by the definition of $\partial_B G(x)$ there exists a vector $h \triangleq h(V) \in \mathcal{J}$ such that $V = \lim_{h\to 0, x+h\in D_G} \nabla G(x+h)$. In order to show $V \in \bigcup_{\{c_1,\ldots,c_r\}\in\mathcal{C}(x)} \partial_{c_1,\ldots,c_r} G(x)$, we proceed as follows.

Take any $\{c_1,\ldots,c_r\} \in \mathcal{C}(x)$ and let $x = \sum_{j=1}^{r}\lambda_j(x)c_j = \sum_{i=1}^{\bar{r}}\mu_i(x)b_i(x)$ with $\lambda_1(x) \geq \lambda_2(x) \geq \cdots \geq \lambda_r(x)$ and $\mu_1(x) > \mu_2(x) > \cdots > \mu_{\bar{r}}(x)$. For the above $h \in \mathcal{J}$, let $x+h \triangleq \sum_{j=1}^{r}\lambda_j(x+h)c_j(x+h)$ with $\lambda_1(x+h) \geq \lambda_2(x+h) \geq \cdots \geq \lambda_r(x+h)$. By Theorem 2.4 and the argument after it, in the sense of set convergence (see, e.g., [27]), one has

$$\lim_{h\to 0, x+h\in D_G}\{\lambda(x+h)\} = \{\lambda(x)\},$$

where $\lambda(x+h) \triangleq (\lambda_1(x+h),\lambda_2(x+h),\ldots,\lambda_r(x+h))^T$ and $\lambda(x) \triangleq (\lambda_1(x),\lambda_2(x),\ldots,\lambda_r(x))^T$. Similarly, using "lim sup" in the sense of set convergence, we have

$$\limsup_{h\to 0, x+h\in D_G}\{(c_1(x+h),c_2(x+h),\ldots,c_r(x+h))\} \subseteq \mathcal{C}(x). \tag{2.12}$$

Notice that for any $i,j = 1,2,\ldots,r$,

$$\limsup_{h\to 0, x+h\in D_G}\{[\lambda_i(x+h),\lambda_j(x+h)]_g\}\begin{cases} = \left\{\dfrac{g(\lambda_i(x))-g(\lambda_j(x))}{\lambda_i(x)-\lambda_j(x)}\right\} & \text{if } \lambda_i(x)\neq\lambda_j(x), \\ \subseteq \partial g(\lambda_i(x)) & \text{if } \lambda_i(x)=\lambda_j(x). \end{cases}$$

Thus,

$$\limsup_{h\to 0, x+h\in D_G}\{[\lambda_i(x+h),\lambda_j(x+h)]_g\} \subseteq \{[\lambda_i(x),\lambda_j(x)]_g\}. \tag{2.13}$$

Also, it holds by (2.6) that for $x+h \in D_G$,

$$\begin{aligned}\nabla G(x+h) = {} & 2\sum_{i\neq j,\ i,j=1}^{r}[\lambda_i(x+h),\lambda_j(x+h)]_g L(c_i(x+h))L(c_j(x+h)) \\ & +\sum_{i=1}^{r} g'(\lambda_i(x+h))Q(c_i(x+h)).\end{aligned}$$

This, together with (2.12), (2.13), and the continuity property of $L(x)$ and $Q(x)$, leads to

$$\begin{aligned}&\limsup_{h\to 0, x+h\in D_G}\{\nabla G(x+h)\} \\ &\subseteq \bigcup_{\{c_1,\ldots,c_r\}\in\mathcal{C}(x)}\left\{2\sum_{i\neq j,\ i,j=1}^{r}\{[\lambda_i(x),\lambda_j(x)]_g\}L(c_i)L(c_j)+\sum_{i=1}^{r}\partial g(\lambda_i(x))Q(c_i)\right\}.\end{aligned}$$

Clearly, $V = \lim_{h\to 0, x+h\in D_G}\nabla G(x+h) \in \limsup_{h\to 0, x+h\in D_G}\{\nabla G(x+h)\}$. This implies that $V \in \bigcup_{\{c_1,\ldots,c_r\}\in\mathcal{C}(x)} \partial_{c_1,\ldots,c_r} G(x)$ by the definition of $\partial_{c_1,\ldots,c_r} G(x)$.

We next prove $\partial G(x) \supseteq \underline{\partial} G(x)$. For any $W(x) \in \underline{\partial} G(x)$ with $x = \sum_{i=1}^{\bar{r}} \mu_i(x) b_i(x)$ and $\mu_1(x) > \mu_2(x) > \cdots > \mu_{\bar{r}}(x)$, by the definition of $\underline{\partial} G(x)$ we have

$$W(x) = 2 \sum_{i \neq j,\ i,j=1}^{\bar{r}} [\mu_i(x), \mu_j(x)]_g L(b_i(x)) L(b_j(x)) + \sum_{i=1}^{\bar{r}} w_i Q(b_i(x))$$

with $w_i \in \partial g(\mu_i(x))$ $(i = 1, 2, \ldots, \bar{r})$. Since g is semismooth at $\mu_i(x)$, $\partial g(\mu_i(x))$ and $\partial_B g(\mu_i(x))$ are well-defined and $\dim(\partial g(\mu_i(x))) = 1$. Let D_g be the set consisting of all the differentiable points of g. By Carathéodory theorem (see [27]), for any given $w_i \in \partial g(\mu_i(x))$ there exist $t_i \in [0, 1]$ and two subsequences $\{h_{i,0}\}$ and $\{h_{i,1}\}$ converging to 0 with $\mu_i(x) + h_{i,0}, \mu_i(x) + h_{i,1} \in D_g$ such that

$$w_{i,l_i} \triangleq \lim_{h_{i,l_i} \to 0, \mu_i(x) + h_{i,l_i} \in D_g} g'(\mu_i(x) + h_{i,l_i}) \in \partial_B g(\mu_i(x)), \quad l_i \in \{0, 1\} \tag{2.14}$$

and

$$w_i = t_i w_{i,0} + (1 - t_i) w_{i,1}. \tag{2.15}$$

Based on the set $\{h_{i,l_i} : l_i \in \{0, 1\},\ i = 1, 2, \ldots, \bar{r}\}$, we construct a set $\mathcal{H}$ by

$$\mathcal{H} \triangleq \left\{ \sum_{i=1}^{\bar{r}} h_{i,l_i} b_i(x) \ : \ l_i \in \{0, 1\} \right\}.$$

Let $l \triangleq (l_1, l_2, \ldots, l_{\bar{r}})$ and $h_l \triangleq \sum_{i=1}^{\bar{r}} h_{i,l_i} b_i(x)$ with $l_i \in \{0, 1\}$. Then the set $\mathcal{H}$ can be rewritten as $\mathcal{H} \triangleq \{h_l \ : \ l \in \{0, 1\}^{\bar{r}}\}$, which includes $2^{\bar{r}}$ elements. Meanwhile, for each element h_l, we have

$$x + h_l = \sum_{i=1}^{\bar{r}} (\mu_i(x) + h_{i,l_i}) b_i(x).$$

Moreover, taking sufficiently small $\|h_l\|$, we have $\mu_1(x) + h_{1,l_1} > \mu_2(x) + h_{2,l_2} > \cdots > \mu_{\bar{r}}(x) + h_{\bar{r},l_{\bar{r}}}$, and hence $\mu_i(x + h_l) = \mu_i(x) + h_{i,l_i}$, $b_i(x + h_l) = b_i(x)$ by the uniqueness of spectral decomposition type I. Thus, $x + h_l \in D_G$ by $\mu_i(x) + h_{i,l_i} \in D_g$, and from (2.7) and (2.14) we obtain

$$\begin{aligned}
W_l(x) &\triangleq \lim_{h_l \to 0, x + h_l \in D_G} \nabla G(x + h_l) \\
&= 2 \lim_{h_l \to 0, x + h_l \in D_G} \left[\sum_{i \neq j,\ i,j=1}^{\bar{r}} [\mu_i(x) + h_{i,l_i}, \mu_j(x) + h_{j,l_j}]_g L(b_i(x)) L(b_j(x)) \right. \\
&\qquad \left. + \sum_{i=1}^{\bar{r}} g'(\mu_i(x) + h_{i,l_i}) Q(b_i(x)) \right] \\
&= 2 \sum_{i \neq j,\ i,j=1}^{\bar{r}} [\mu_i(x), \mu_j(x)]_g L(b_i(x)) L(b_j(x)) + \sum_{i=1}^{\bar{r}} w_{i,l_i} Q(b_i(x)).
\end{aligned}$$

Therefore, $W_l(x) \in \partial_B G(x)$ for every $l \in \{0, 1\}^{\bar{r}}$. This implies that

$$\mathcal{W}(x) \triangleq \operatorname{conv}\{W_l(x) \ : \ l \in \{0, 1\}^{\bar{r}}\} \subseteq \partial G(x). \tag{2.16}$$

To prove $W(x) \in \partial G(x)$, it suffices to claim that $W(x) \in \mathcal{W}(x)$. In fact, from expressions of $W(x)$ and $W_l(x)$, it is easy to see that $w \overset{\Delta}{=} (w_1, w_2, \ldots, w_{\bar{r}})$ given above lies in the hypercube whose extreme points are defined by w_{i,l_i} with $l_i \in \{0,1\}, i = 1,2,\ldots,\bar{r}$. Hence, $W(x)$ must be a convex combination of points $\{W_l(x) : l \in \{0,1\}^{\bar{r}}\}$. The proof is completed. □

Remark 2.15. From Theorem 2.14, we easily observe that if $x \in \mathcal{J}$ has distinct eigenvalues $\lambda_1(x), \ldots, \lambda_r(x)$ and $\mathcal{C}(x)$ has an element, then $\underline{\partial} G(x) = \partial G(x) = \overline{\partial} G(x)$. However, if x has the multiple eigenvalues or $\mathcal{C}(x)$ contains many elements, the sets $\underline{\partial} G(x)$, $\partial G(x)$, and $\overline{\partial} G(x)$ may be different as the following example shows.

Let $\mathcal{A} = \Lambda^n$ $(n \geq 3)$ and $x = \sum_{i=1}^{2} \lambda_i c_i$ as in Example 2.2. Take $G(x) = P_K(x)$ where $g(t) = t_+$, and let $x = 0$. Then $\lambda_1 = \lambda_2 = 0$, and there are infinitely many Jordan frames at $x = 0$. The direct calculation yields $\overline{\partial} P_{\Lambda^n_+}(0) = \mathrm{conv}\{4[0,1]L(c_1)L(c_2) + [0,1]Q(c_1) + [0,1]Q(c_2)\}$ and $\underline{\partial} P_{\Lambda^n_+}(0) = \mathrm{conv}\{0, E\}$ where $\mathrm{conv}\{0, E\} = \{\alpha E : 0 \leq \alpha \leq 1\}$. Note that $\partial P_{\Lambda^n_+}(0) = \mathrm{conv}\{0, E, S\}$ by Proposition 4.8 in [15] where S satisfies

$$S = 4 \times \frac{1+\beta}{2} L(c_1)L(c_2) + 0 \times Q(c_1) + Q(c_2),$$

where $\frac{1+\beta}{2} \in [0,1]$. A simple calculation checks that $\underline{\partial} P_{\Lambda^n_+}(0) \subset \partial P_{\Lambda^n_+}(0) \subset \overline{\partial} P_{\Lambda^n_+}(0)$. □

Remark 2.16. Suppose that $\mathrm{rk}(\mathcal{A}) = \dim(\mathcal{J}) = n$ and $x = \sum_{j=1}^{n} \lambda_j(x) c_j = \sum_{i=1}^{\bar{n}} \mu_i(x) b_i$ as in the case of Corollary 2.9. If $G(\cdot)$ is (strongly) semismooth at x, we derive by Theorem 2.14 that $\underline{\partial} G(x) \subseteq \partial G(x) \subseteq \overline{\partial} G(x)$, where

$$\overline{\partial} G(x) = \sum_{i=1}^{n} \partial g(\lambda_i(x)) L(c_i), \quad \underline{\partial} G(x) = \sum_{i=1}^{\bar{n}} \partial g(\mu_i(x)) L(b_i).$$

Especially, when $\mathcal{A} = (\mathbb{R}^n, \langle\cdot,\cdot\rangle, *)$ as in Example 2.10 and $x = \sum_{i=1}^{n} x_i e_i = \sum_{i=1}^{\bar{n}} y_i$ $(\sum_{j \in N(i)} e_j)$, in the similar way to the second part in the proceeding proof, one has $\overline{\partial} G(x) \subseteq \partial G(x)$. Hence,

$$\overline{\partial} G(x) = \partial G(x) = \sum_{i=1}^{n} \partial g(x_i) E_i = \mathrm{Diag}\{\partial g(x_1), \ldots, \partial g(x_n)\},$$

$$\underline{\partial} G(x) = \sum_{i=1}^{\bar{n}} \partial g(y_i) \left(\sum_{j \in N(i)} E_j \right) = \mathrm{Diag}\{\partial g(y_1) I_1, \ldots, \partial g(y_{\bar{n}}) I_{\bar{n}}\},$$

where I_i is the $|N(i)| \times |N(i)|$ identity matrix for $i = 1, 2, \ldots, \bar{n}$. Moreover, letting $G(x) = P_K(x)$ and $x = 0$, we derive

$$\overline{\partial} P_{\mathbb{R}^n_+}(0) = \partial P_{\mathbb{R}^n_+}(0) = \left\{ \begin{pmatrix} [0,1] & 0 & \cdots & 0 \\ 0 & [0,1] & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & [0,1] \end{pmatrix} \right\}$$
$$\supset \{\alpha E, 0 \leq \alpha \leq 1\} = \underline{\partial} P_{\mathbb{R}^n_+}(0). \qquad \square$$

Theorem 2.14 provides an approximation to the Clarke generalized Jacobian, which can be successfully employed to prove the positive semidefiniteness of $\partial G(\cdot)$.

THEOREM 2.17. *If g is (strongly) semismooth at every eigenvalue of x and $\partial g(t) \subseteq \mathbb{R}_+$ ($\partial g(t) \subseteq \mathbb{R}_{++}$) for all $t \in \mathbb{R}$, then the function $G(\cdot)$ is (strongly) semismooth at x, and all the element $V \in \partial G(x)$ are positive semidefinite (positive definite). Moreover, when $\partial g(t) \subseteq \mathbb{R}_{++}$, there exists a scalar $\alpha(x) > 0$ such that $V \succeq \alpha(x) I \succ 0$.*

Proof. By Theorem 2.14 and the definition of $\overline{\partial} G$, it suffices to demonstrate that if $\partial g(t) \subseteq \mathbb{R}_{++}$ for all $t \in \mathbb{R}$, then for any $\{c_1, \ldots, c_r\} \in \mathcal{C}(x)$ and $V \in \partial_{c_1,\ldots,c_r} G(x)$ there is a scalar $\alpha(x)$ such that $V \succeq \alpha(x) I \succ 0$. In this case, one has $x = \sum_{i=1}^r \lambda_i(x) c_i$ and

$$V = 2 \sum_{i \neq j,\ i,j=1}^{r} \nu_{ij}(x) L(c_i) L(c_j) + \sum_{i=1}^{r} \nu_{ii}(x) Q(c_i)$$

with $\nu_{ij}(x) \in \{[\lambda_i(x), \lambda_j(x)]_g\}$. Note that $\partial g(\lambda_j(x)) \subseteq \mathbb{R}_{++}$ is a closed convex set for every $j = 1, \ldots, r$. Taking

$$\alpha(x) \triangleq \min_{i,j} \{[\lambda_i(x), \lambda_j(x)]_g\},$$

by (2.5) and the given assumptions we have $\alpha(x) > 0$ and hence $\alpha(x) I \succ 0$.

We now prove $\bar{V} \triangleq V - \alpha(x) I \succeq 0$, that is, $\langle h, \bar{V} h \rangle \geq 0$ for any $h \in \mathcal{J}$. In fact, from (2.6) with $g(\lambda) = \lambda$, we have

$$I = 2 \sum_{i \neq j,\ i,j=1}^{r} L(c_i) L(c_j) + \sum_{i=1}^{r} Q(c_i).$$

Thus,

$$\bar{V} = 2 \sum_{i \neq j,\ i,j=1}^{r} [\nu_{ij}(x) - \alpha(x)] L(c_i) L(c_j) + \sum_{i=1}^{r} [\nu_{ii}(x) - \alpha(x)] Q(c_i)$$

with $[\nu_{ij}(x) - \alpha(x)] \geq 0$ for any $i, j = 1, \ldots, r$. Modeling the proof of Theorem 2.11, we immediately derive the desired result. □

Furthermore, we can obtain the bounded property of ∂G if ∂g is a bounded set.

COROLLARY 2.18. *Under the assumptions of Theorem 2.17, for any $V \in \partial G(x)$ and scalars $a, b \in \mathbb{R}$ with $a \leq b$, there hold*

(i) *If $\partial g(t) \subseteq [a, b]$, then $aI \preceq V \preceq bI$.*

(ii) *If $\partial g(t) \subseteq (a, b)$ with $a < b$, then $aI \prec V \prec bI$.*

Proof. Let $f(t) = g(t) - at$. Note that $\partial g(t) \subseteq [a, b]$, then $\partial f(t) \subseteq \mathbb{R}_+$. By Theorem 2.17, one has $V - aI \succeq 0$ for any $V \in \partial G(x)$. On the other hand, letting $\bar{f}(t) = bt - g(t)$, one has $\partial \bar{f}(t) \subseteq \mathbb{R}_+$ and hence $bI - V \succeq 0$ for any $V \in \partial G(x)$. These two arguments show part (i). Similarly, we can verify Part (ii). □

3. The total NR-function. For problem (1.1), we define the *natural residual function* (NR-function) $\Phi_{NR} : \mathcal{J} \times \mathcal{J} \to \mathcal{J}$ by

$$\Phi_{NR}(x, y) \triangleq x - P_K(x - y), \tag{3.1}$$

and the *total NR-function* $H_{NR} : \mathcal{J} \times \mathcal{J} \to \mathcal{J} \times \mathcal{J}$ by

$$H_{NR}(x, y) \triangleq \begin{pmatrix} \Phi_{NR}(x, y) \\ F(x) - y \end{pmatrix}. \tag{3.2}$$

Moreover, we specify function $\Psi_{NR} : \mathcal{J} \times \mathcal{J} \to \mathbb{R}$ by

$$\Psi_{NR}(x,y) \triangleq \frac{1}{2}\|H_{NR}(x,y)\|^2 = \frac{1}{2}\|\Phi_{NR}(x,y)\|^2 + \frac{1}{2}\|F(x)-y\|^2. \tag{3.3}$$

From Proposition 6 in [12], we know that

$$\Phi_{NR}(x,y) = 0 \iff x \in K,\ y \in K,\ \langle x,y\rangle = 0.$$

Therefore, problem (1.1) can be reformulated as a nonsmooth system of nonlinear equations: $H_{NR}(x,y) = 0$. Based on this system, we may establish various solution methods, such as nonsmooth and smoothing Newton methods, see, e.g., [9, 17] for the case of NCP. In this paper, our aim is to present a globally and quadratically convergent regularized smoothing Newton method for SCCP. For this purpose, we need to investigate strong semismoothness of H_{NR}, nonsingularity of ∂H_{NR}, and level-boundedness of Ψ_{NR}.

First, we present a result concerning the strong semismoothness of H_{NR}. Since the proof is similar to that of Theorem 4.6 in [15], it is omitted.

THEOREM 3.1. *Let $F : \mathcal{J} \to \mathcal{J}$ be continuously differentiable. Then the function H_{NR} defined by* (3.2) *is semismooth at any $(x,y) \in \mathcal{J} \times \mathcal{J}$. Moreover, if ∇F is locally Lipschitzian, then H_{NR} is strongly semismooth at any $(x,y) \in \mathcal{J} \times \mathcal{J}$.*

Next, we address Clarke generalized Jacobian ∂H_{NR}. Let $T \in \partial H_{NR}(x,y)$ for any $(x,y) \in \mathcal{J} \times \mathcal{J}$. Then T has the following form:

$$T = \begin{pmatrix} I - V & \nabla F(x) \\ V & -I \end{pmatrix}, \tag{3.4}$$

where $V \in \partial P_K(x-y)$. Since ∂t_+ equals $\{1\}$ for $t > 0$, $[0,1]$ for $t = 0$, and $\{0\}$ for $t < 0$, by Corollary 2.18 (i) we have $0 \preceq V \preceq I$.

The nonsingularity result on T is well-known for NCP (see, e.g., [9]) or SOCCP (see, e.g., [11]). In a similar manner, we can easily show that it is still true for SCCP, which does not need a further proof. We say that $F : \mathcal{J} \to \mathcal{J}$ is *monotone* (*strongly monotone*) if for all $(x,y) \in \mathcal{J} \times \mathcal{J}$, $\langle x-y, F(x)-F(y)\rangle \geq 0$ ($\langle x-y, F(x)-F(y)\rangle \geq \varepsilon\|x-y\|^2$ with some $\varepsilon > 0$).

THEOREM 3.2. *Let $F : \mathcal{J} \to \mathcal{J}$ be continuously differentiable, and T be given by* (3.4).

(a) *If F is monotone and $0 \prec V \prec I$, then T is invertible for any $(x,y) \in \mathcal{J} \times \mathcal{J}$.*

(b) *If F is strongly monotone and $0 \preceq V \preceq I$, then T is invertible for any $(x,y) \in \mathcal{J} \times \mathcal{J}$.*

It should be noted that if V is a linear and symmetric operator from $\mathcal{J}$ into itself, then the results in this theorem are still true.

We end this section by stating a well-known result on the boundedness of the level sets $\mathrm{Lev}_\alpha(\Psi_{NR}) \triangleq \{(x,y) \in \mathcal{J} \times \mathcal{J} : \Psi_{NR}(x,y) \leq \alpha\}$ for $\alpha \in \mathbb{R}$, which can ensure that the sequence generated by a descent method for solving $\min \Psi_{NR}(x,y)$ has at least one accumulation point. For more details, see, e.g., [25, 36].

THEOREM 3.3. *Let Ψ_{NR} be defined by* (3.3). *If $F(x)$ is strongly monotone and locally Lipschitzian, then the level sets $Lev_\alpha(\Psi_{NR})$ are bounded for all $\alpha \in \mathbb{R}$.*

4. The Chen–Mangasarian smoothing function. In the previous section, we know that the total NR-function shares the strong semismoothness property because of that of the NR-function. In order to establish the desired smoothing Newton methods, we need to smoothen the NR-function and the total NR-function. This section deals with this issue.

In the literature on NCP, there are two well-known classes of the smoothing functions, i.e., the Chen–Mangasarian smoothing function and the smoothed Fischer–Burmeister function. Recently, they were successfully extended to SDCP [6, 31] and SOCCP [11]. In what follows, we first study an extension of the Chen–Mangasarian smoothing function.

DEFINITION 4.1. *Let $F : \mathcal{X} \to \mathcal{Y}$ be a nondifferentiable function. A function $F_u : \mathcal{X} \to \mathcal{Y}$ with a parameter vector $u \in \mathbb{R}^q_+$ is called a smoothing function of F if it has the following properties:*

(a) *F_u is continuously differentiable for any $u \in \mathbb{R}^q_{++}$;*

(b) *$\lim_{u \downarrow 0} F_u(x) = F(x)$ for any $x \in \mathcal{X}$, where $u \downarrow 0$ means $u \in \mathbb{R}^q_{++}, u \to 0$.*

We say F_u is a uniformly smooth approach function of F if there is a scalar $\kappa > 0$ such that

$$\|F_u(x) - F(x)\| \le \kappa \|u\|, \quad \forall u \in \mathbb{R}^q_{++}, \ \forall x \in \mathcal{X}.$$

Let $\varrho \in \mathbb{R}_{++}$. For NR-function Φ_{NR} as in (3.1), we define the *Chen–Mangasarian smoothing function* $\Phi_\varrho : \mathcal{J} \times \mathcal{J} \to \mathcal{J}$ as

$$\Phi_\varrho(x, y) = x - \Pi_\varrho(x - y), \tag{4.1}$$

where $\Pi_\varrho : \mathcal{J} \to \mathcal{J}$ is specified by $\Pi_\varrho(z) \triangleq \varrho G(z/\varrho)$ and $G \in \mathcal{CM}$. Here, $\mathcal{CM}$ denotes the set of Löwner operators defined by (2.3) with $g : \mathbb{R} \to \mathbb{R}_+$, a continuously differentiable convex function satisfying

$$\lim_{t \to -\infty} g(t) = 0, \ \lim_{t \to \infty} (g(t) - t) = 0 \ \text{ and } \ 0 < g'(t) < 1 \ \text{ for all } \ t \in \mathbb{R}. \tag{4.2}$$

Two known cases of function g are as follows: One is the CHKS function $g(t) = (\sqrt{t^2 + 4} + t)/2$, which was proposed by Chen and Harker [1], Kanzow [18], and Smale [28], and the other is the neural network function $g(t) = \ln(e^t + 1)$, which was used in neural networks [2]. Based on the above definitions and Theorem 2.4, we below derive formulae for Φ_ϱ.

PROPOSITION 4.2. *Let Φ_ϱ be given by (4.1). Then it holds that $\Phi_\varrho(x, y) = x - \varrho \sum_{i=1}^r g(\lambda_i/\varrho) c_i$ where λ_i, c_i $(i = 1, 2, \ldots, r)$ are given by $x - y = \sum_{i=1}^r \lambda_i c_i$. Moveover, one has*

$$\Phi_0(x, y) \triangleq \lim_{\varrho \downarrow 0} \Phi_\varrho(x, y) = x - P_K(x - y).$$

Proof. The first part is trivial. Note that $\lim_{\varrho \downarrow 0} \varrho g(\lambda_i/\varrho) = (\lambda_i)_+$ by (4.2). This derives that $\lim_{\varrho \downarrow 0} \Phi_\varrho(x, y) = x - \sum_{i=1}^r (\lambda_i)_+ c_i$. The second part holds by (2.4). ∎

4.1. Uniformly smooth approximation. The following proposition claims that Φ_ϱ is a uniformly smooth approximation of Φ_{NR}.

PROPOSITION 4.3. *Let Φ_ϱ be given by (4.1). Then, for any scalars $\varrho > \nu \ge 0$, we have*

$$g(0)(\varrho - \nu)e \succeq_K \Phi_\nu(x, y) - \Phi_\varrho(x, y) \succ_K 0, \quad \forall x, y \in \mathcal{J}. \tag{4.3}$$

Proof. In order to prove the proposition, we first consider the case where $\varrho > \nu > 0$. By Proposition 4.2, it is easy to verify $\Phi_\nu(x, y) - \Phi_\varrho(x, y) = \sum_{i=1}^r (\varrho g(\lambda_i/\varrho) - \nu g(\lambda_i/\nu)) c_i$ where λ_i and c_i are given by $x - y = \sum_{i=1}^r \lambda_i c_i$. Noting that for every $i = 1, 2, \ldots, r$, $0 < \varrho g(\lambda_i/\varrho) - \nu g(\lambda_i/\nu) \le g(0)(\varrho - \nu)$ by Lemma 3.1 in [34], we have

$$g(0)(\varrho - \nu)e = \sum_{i=1}^r g(0)(\varrho - \nu) c_i \succeq_K \Phi_\nu(x, y) - \Phi_\varrho(x, y) \succ_K 0. \tag{4.4}$$

This shows that (4.3) holds in the case of $\varrho > \nu > 0$, and that $-\Phi_\nu$ is monotone in $\nu > 0$ with respect to the partial ordering $\succ_K$. Taking $\nu \to 0^+$ in (4.4), one has $g(0)\varrho e \succeq_K \Phi_0(x,y) - \Phi_\varrho(x,y) \succ_K 0$. That is, (4.4) also holds for $\varrho > \nu = 0$. The proof is completed. □

4.2. Differentiability. Let $g : \mathbb{R} \to \mathbb{R}_+$ be a continuously differentiable convex function satisfying (4.2). As in [34] for the setting of NCP and in [15] for the context of SOCCP, we define for any $\varrho > 0$,

$$\gamma_\varrho(t) \triangleq \varrho g(t/\varrho), \tag{4.5}$$

$$\gamma_0(t) \triangleq \lim_{\varrho \downarrow 0} \gamma_\varrho(t) = \max\{0, t\}, \tag{4.6}$$

$$\gamma_0^+(t) \triangleq \lim_{\varrho \downarrow 0} \gamma'_\varrho(t) = \begin{cases} 0 & \text{for } t < 0, \\ g'(0) & \text{for } t = 0, \\ 1 & \text{for } t > 0. \end{cases} \tag{4.7}$$

Let $z = \sum_{j=1}^r \lambda_j(z) c_j(z)$. By $\Pi_\varrho(z) = \varrho G(z/\varrho)$ with $G \in \mathcal{CM}$, Theorem 2.8 leads to

$$\nabla \Pi_\varrho(z) = \nabla G(z/\varrho) = 2 \sum_{i \neq j, i, j=1}^r a_{ij} L(c_i(z)) L(c_j(z)) + \sum_{i=1}^r a_{ii} Q(c_i(z)), \tag{4.8}$$

where for all $i, j = 1, 2, \ldots, r$,

$$a_{ij} = [\lambda_i(z)/\varrho, \lambda_j(z)/\varrho]_g = \begin{cases} \dfrac{g(\lambda_i(z)/\varrho) - g(\lambda_j(z)/\varrho)}{\lambda_i(z)/\varrho - \lambda_j(z)/\varrho} & \text{if } \lambda_i(z) \neq \lambda_j(z), \\ g'(\lambda_i(z)/\varrho) & \text{if } \lambda_i(z) = \lambda_j(z). \end{cases}$$

By (4.5), we have $\gamma'_\varrho(t) = g'(t/\varrho)$. Therefore

$$a_{ij} = [\lambda_i(z), \lambda_j(z)]_{\gamma_\varrho} = \begin{cases} \dfrac{\gamma_\varrho(\lambda_i(z)) - \gamma_\varrho(\lambda_j(z))}{\lambda_i(z) - \lambda_j(z)} & \text{if } \lambda_i(z) \neq \lambda_j(z), \\ \gamma'_\varrho(\lambda_i(z)) & \text{if } \lambda_i(z) = \lambda_j(z). \end{cases} \tag{4.9}$$

By (4.2) and (4.9), one has $0 < a_{ij} < 1$. Thus, by Corollary 2.18 (ii), it holds $I \succ \nabla \Pi_\varrho(z) \succ 0$. In summary, we have the following conclusion.

PROPOSITION 4.4. *The function Π_ϱ is continuously differentiable, and $I \succ \nabla \Pi_\varrho(z) \succ 0$.*

Furthermore, by applying Theorem 2.8 and the chain rule, we immediately obtain the differential property of the Chen–Mangasarian smoothing function Φ_ϱ, which does not need a proof.

PROPOSITION 4.5. *For any $\varrho > 0$, the Chen–Mangasarian smoothing function Φ_ϱ, defined by* (4.1)*, is continuously differentiable and its Jacobian is given by*

$$\nabla \Phi_\varrho(x,y) = \begin{pmatrix} I - \nabla \Pi_\varrho(x-y) \\ \nabla \Pi_\varrho(x-y) \end{pmatrix} = \begin{pmatrix} I - \nabla G((x-y)/\varrho) \\ \nabla G((x-y)/\varrho) \end{pmatrix}.$$

4.3. Jacobian consistency. Like strong semismoothness, Jacobian consistency plays an important role in establishing rapid convergence of smoothing Newton methods. This concept was originally introduced by Chen, Qi, and Sun [8] for variational

inequalities, and was recently used by Hayashi, Yamashita, and Fukushima [15] analyzing the regularized smoothing method for SOCCP, where their Jacobian consistency contains two parameters. We state a more general definition as follows.

DEFINITION 4.6. *Suppose that $F : \mathcal{X} \to \mathcal{Y}$ is a continuous function and ∂F exists. Let F_u be a smoothing function of F. We say that F_u satisfies the Jacobian consistency if*

$$\lim_{u \downarrow 0} \operatorname{dist}(\nabla F_u(x), \partial F(x)) = 0, \quad \text{for any } x \in \mathcal{X}. \tag{4.10}$$

To show Jacobian consistency of the Chen–Mangasarian smoothing function Φ_ϱ, we first look at the function $\Pi_\varrho(z)$. Define $b_{ij} \stackrel{\Delta}{=} \lim_{\varrho \downarrow 0} a_{ij}$ for all $i, j = 1, 2, \ldots, r$. From (4.5)–(4.7) and (4.9), we derive that

$$b_{ij} = \begin{cases} \frac{\gamma_0(\lambda_i(z)) - \gamma_0(\lambda_j(z))}{\lambda_i(z) - \lambda_j(z)} & \text{if } \lambda_i(z) \neq \lambda_j(z), \\ \gamma_0^+(\lambda_i(z)) & \text{if } \lambda_i(z) = \lambda_j(z). \end{cases} \tag{4.11}$$

Obviously, by (4.2), $0 \leq b_{ij} \leq 1$. By the direct calculation, one has

$$\lim_{\varrho \downarrow 0} \nabla \Pi_\varrho(z) = 2 \sum_{i \neq j, i, j=1}^{r} b_{ij} L(c_i(z)) L(c_j(z)) + \sum_{i=1}^{r} b_{ii} Q(c_i(z)). \tag{4.12}$$

Rewriting z as $z = \sum_{i=1}^{\bar{r}} \mu_i(z) b_i(z)$, from Theorem 2.8 we deduce

$$\nabla \Pi_\varrho(z) = 2 \sum_{i \neq j,\ i, j=1}^{\bar{r}} [\mu_i(z), \mu_j(z)]_{\gamma_\varrho} L(b_i(z)) L(b_j(z)) + \sum_{i=1}^{\bar{r}} \gamma_\varrho'(\mu_i(z)) Q(b_i(z)).$$

In a similar manner as in (4.12), we derive that

$$\lim_{\varrho \downarrow 0} \nabla \Pi_\mu(z) = 2 \sum_{i \neq j,\ i, j=1}^{\bar{r}} [\mu_i(z), \mu_j(z)]_{\gamma_0} L(b_i(z)) L(b_j(z)) + \sum_{i=1}^{\bar{r}} \gamma_0^+(\mu_i(z)) Q(b_i(z)).$$

Take $\partial_\Pi^0(z) \stackrel{\Delta}{=} \lim_{\varrho \downarrow 0} \nabla \Pi_\mu(z)$. It follows from Theorem 2.14 that $\partial_\Pi^0(z) \in \underline{\partial} P_K(z) \subseteq \partial P_K(z)$. Summarizing the preceding argument, we have the following.

LEMMA 4.7. *Let $\partial_\Pi^0(z) = \lim_{\varrho \downarrow 0} \nabla \Pi_\varrho(z)$. Then $\partial_\Pi^0(z) \in \partial P_K(z)$ for any $z \in \mathcal{J}$. Thus Π_ϱ satisfies the Jacobian consistency.*

Combining Lemma 4.7 with Proposition 4.5, the Jacobian consistency of Φ_ϱ is immediate.

PROPOSITION 4.8. *Φ_ϱ satisfies the Jacobian consistency.*

In the end of this section, we further consider the function g satisfying both (4.2) and the following

$$g(t) - t = g(-t), \quad \forall t \in \mathbb{R}. \tag{4.13}$$

For instance, $(\sqrt{t^2 + 4} + t)/2$ and $\ln(e^t + 1)$ are such two functions. Can we get a more specific result than Proposition 4.8 in this case? To settle this question, we need the following lemma from [15].

LEMMA 4.9 (Lemma 4.10, [15]). *Let g be a continuously differentiable convex function satisfying* (4.2) *and* (4.13). *Let γ_ϱ, γ_0, and γ_0^+ be given by* (4.5)–(4.7). *Then it holds that*

(a) $\gamma_\varrho(t) - \gamma_0(t) = \gamma_\varrho(-t) - \gamma_0(-t)$ *for any* $t \in \mathbb{R}$;
(b) $\left|\gamma_\varrho'(t) - \gamma_0^+(t)\right| = \left|\gamma_\varrho'(|t|) - \gamma_0^+(|t|)\right|$ *for any* $t \in \mathbb{R}$;
(c) $\left|\gamma_\varrho'(0) - \gamma_0^+(0)\right| = 0 < \left|\gamma_\varrho'(t_2) - \gamma_0^+(t_2)\right| \le \left|\gamma_\varrho'(t_1) - \gamma_0^+(t_1)\right|$ *for any* $t_i \in \mathbb{R}(i = 1, 2)$ *such that* $0 < |t_1| \le |t_2|$.

For $z = \sum_{j=1}^r \lambda_j(z)c_j(z)$, let $N(z)$ be the index set specified by $N(z) \triangleq \{i : \lambda_i(z) \neq 0\}$. Define the function $\tilde{\lambda} : \mathcal{J} \to \mathbb{R}_+$ by

$$\tilde{\lambda}(z) \triangleq \begin{cases} \min_{i\in N(z)} |\lambda_i(z)| & \text{for } N(z) \neq \emptyset, \\ 0 & \text{for } N(z) = \emptyset. \end{cases} \tag{4.14}$$

Obviously, $\tilde{\lambda}(z) = 0$ if and only if $z = 0$. When $z \neq 0$, by (4.5) and the continuous differentiability of g, there is a scalar $\varsigma \in (0, \tilde{\lambda}(z))$ such that $\gamma_\varrho'(\varsigma) = \frac{\gamma_\varrho(\tilde{\lambda}(z)) - \gamma_\varrho(0)}{\tilde{\lambda}(z)}$; meanwhile, noting that g is convex, one has $\gamma_\varrho'(t) \le \frac{\gamma_\varrho(\tilde{\lambda}(z)) - \gamma_\varrho(0)}{\tilde{\lambda}(z)}$ for any $t \in (0, \varsigma)$. So, in the case of $z \neq 0$, there exists a positive integer l such that $\frac{1}{2^l}\tilde{\lambda}(z) \in (0, \varsigma)$.

Based on the preceding argument, we define the function $\lambda^\star : \mathcal{J} \to \mathbb{R}_+$ by

$$\lambda^\star(z) \triangleq \begin{cases} \frac{1}{2^l}\tilde{\lambda}(z) & \text{for } N(z) \neq \emptyset, \\ 0 & \text{for } N(z) = \emptyset, \end{cases} \tag{4.15}$$

where l is the smallest positive integer such that

$$\gamma_\varrho'\left(\frac{1}{2^l}\tilde{\lambda}(z)\right) \le \frac{\gamma_\varrho\left(\tilde{\lambda}(z)\right) - \gamma_\varrho(0)}{\tilde{\lambda}(z)}. \tag{4.16}$$

Then $\lambda^\star(z)$ is well-defined and $0 < \lambda^\star(z) < \tilde{\lambda}(z)$. Thus, it holds by Lemma 4.9 (c) that

$$\begin{aligned} \left|\gamma_\varrho'(\lambda_i(z)) - \gamma_0^+(\lambda_i(z))\right| &\le \left|\gamma_\varrho'\left(\tilde{\lambda}(z)\right) - \gamma_0^+\left(\tilde{\lambda}(z)\right)\right| \\ &\le \left|\gamma_\varrho'\left(\lambda^\star(z)\right) - \gamma_0^+\left(\lambda^\star(z)\right)\right|, \ i = 1, 2, \ldots, r. \end{aligned} \tag{4.17}$$

Now we are ready to claim that $\Pi_\varrho(z)$ not only satisfies the Jacobian consistency but also has the stronger Jacobian property.

THEOREM 4.10. *Let* $\partial_\Pi^0(z) = \lim_{\varrho\downarrow 0} \nabla\Pi_\varrho(z)$. *Suppose* g *is a continuously differentiable convex function satisfying* (4.2) *and* (4.13). *Let* $\gamma_\varrho, \gamma_0, \gamma_0^+$, *and* $\lambda^\star$ *be given by* (4.5)–(4.7) *and* (4.15), *respectively. Then there exists a scalar* $\bar{M} > 0$ *such that*

$$\left\|\nabla\Pi_\varrho(z) - \partial_\Pi^0(z)\right\| \le \bar{M}\left|\gamma_\varrho'\left(\lambda^\star(z)\right) - \gamma_0^+\left(\lambda^\star(z)\right)\right|, \quad \forall \varrho \in \mathbb{R}_{++}, \ \forall\, z \in \mathcal{J}.$$

Proof. Let $z = \sum_{j=1}^r \lambda_j(z)c_j(z)$. Then from (4.8) and (4.12) we obtain

$$\nabla\Pi_\varrho(z) - \partial_\Pi^0(z) = 2\sum_{i\neq j, i,j=1}^r (a_{ij} - b_{ij})L(c_i(z))L(c_j(z)) + \sum_{i=1}^r (a_{ii} - b_{ii})Q(c_i(z)).$$

To prove the theorem, it is enough to show $|a_{ij} - b_{ij}| \le |\gamma_\varrho'(\lambda^\star(z)) - \gamma_0^+(\lambda^\star(z))|$ for every $i, j = 1, 2, \ldots, r$. We consider below two cases.

Case (i): $0 = \lambda_i(z) < |\lambda_j(z)|$. By (4.9) and (4.11), the direct calculation yields

$$\begin{aligned}|a_{ij} - b_{ij}| &= \left| \frac{\gamma_\varrho(0) - \gamma_\varrho(\lambda_j(z))}{0 - \lambda_j(z)} - \frac{\gamma_0(0) - \gamma_0(\lambda_j(z))}{0 - \lambda_j(z)} \right| \\ &= \left| \frac{\gamma_\varrho(\lambda_j(z)) - \gamma_\varrho(0)}{\lambda_j(z)} - 1 \right| \\ &= 1 - \frac{\gamma_\varrho(\lambda_j(z)) - \gamma_\varrho(0)}{\lambda_j(z)} \\ &\le 1 - \gamma'_\varrho\left(\lambda^\star(z)\right) \\ &= \left|\gamma'_\varrho\left(\lambda^\star(z)\right) - \gamma_0^+\left(\lambda^\star(z)\right)\right|,\end{aligned}$$

where the second equality follows from the fact $\frac{\gamma_0(0)-\gamma_0(\lambda_j(z))}{0-\lambda_j(z)} = 1$ by (4.6), the third one from $0 < \frac{\gamma_\varrho(\lambda_j(z))-\gamma_\varrho(0)}{\lambda_j(z)} = \frac{g(\lambda_j(z)/\varrho)-g(0)}{\lambda_j(z)/\varrho} < 1$ by (4.2), the inequality from (4.15), and the last equality from $\gamma_0^+\left(\lambda^\star(z)\right) = 1$ by (4.15) and (4.7).

Case (ii): Otherwise, one has $|a_{ij} - b_{ij}| \le \left|\gamma'_\varrho\left(\tilde{\lambda}(z)\right) - \gamma_0^+\left(\tilde{\lambda}(z)\right)\right|$, whose proof is perfectly similar to that in [15] and is omitted for brevity. □

5. Regularized smoothing function and algorithm. Based on the proceeding results, we shall develop the Chen–Mangasarian class of regularized smoothing functions for SCCP, and derive the regularized smoothing Newton method for solving the monotone SCCP.

For the given F in (1.1) and a parameter $\varepsilon > 0$, we define a new function $F_\varepsilon : \mathcal{J} \to \mathcal{J}$ as

$$F_\varepsilon(x) \triangleq F(x) + \varepsilon x. \tag{5.1}$$

Again, define functions $H_{\varrho,\varepsilon} : \mathcal{J} \times \mathcal{J} \to \mathcal{J} \times \mathcal{J}$ and $\Psi_{\varrho,\varepsilon} : \mathcal{J} \times \mathcal{J} \to \mathbb{R}$ by

$$H_{\varrho,\varepsilon}(x,y) \triangleq \begin{pmatrix} \Phi_\varrho(x,y) \\ F_\varepsilon(x) - y \end{pmatrix}, \tag{5.2}$$

$$\Psi_{\varrho,\varepsilon}(x,y) \triangleq \frac{1}{2}\|H_{\varrho,\varepsilon}(x,y)\|^2 = \frac{1}{2}\|\Phi_\varrho(x,y)\|^2 + \frac{1}{2}\|F_\varepsilon(x) - y\|^2. \tag{5.3}$$

Then, $H_{\varrho,\varepsilon}$ is a smoothing approximation of the regularized SCCP involving F_ε with $\varepsilon > 0$. Obviously, if F is monotone, then F_ε is strongly monotone for any $\varepsilon > 0$. In addition, if F is also locally Lipschitzian, then $\Psi_{\varrho,\varepsilon}$ is level-bounded for any $\varrho \ge 0$ and $\varepsilon > 0$ via Theorem 3.3.

The proposed method applies the Newton algorithm to the system $H_{\varrho,\varepsilon}(x,y) = 0$ with ϱ and ε properly adjusted at each iteration, so that a solution of the original SCCP is eventually obtained by taking the limits as $\varrho \downarrow 0$ and $\varepsilon \downarrow 0$.

For this purpose, we deal with $H_{\varrho,\varepsilon}$. From Proposition 4.5, we obtain

$$\nabla H_{\varrho,\varepsilon}(x,y) = \begin{pmatrix} I - \nabla\Pi_\varrho(x-y) & \nabla F(x) + \varepsilon I \\ \nabla\Pi_\varrho(x-y) & -I \end{pmatrix}, \tag{5.4}$$

where $\nabla\Pi_\varrho(\cdot)$ is specified by (4.8).

From (5.4) and Proposition 4.4, one can easily get the nonsingularity of $\nabla H_{\varrho,\varepsilon}$. The proof is omitted.

THEOREM 5.1. *Let $F : \mathcal{J} \to \mathcal{J}$ be continuously differentiable. For parameters $\varrho > 0$ and $\varepsilon > 0$, let $\Phi_\varrho(x,y), F_\varepsilon(x)$, and $H_{\varrho,\varepsilon}(x,y)$ be defined by* (4.1), (5.1), *and*

(5.2), *respectively. If* F *is monotone, then* $\nabla H_{\varrho,\varepsilon}$, *given by* (5.4), *is invertible for any* $(x,y) \in \mathcal{J} \times \mathcal{J}$.

In view of (5.4), we also deduce the Jacobian consistency of $H_{\varrho,\varepsilon}$.

THEOREM 5.2. *Let* $F : \mathcal{J} \to \mathcal{J}$ *be continuously differentiable. For parameters* $\varrho > 0$ *and* $\varepsilon > 0$, *let* $\Phi_\varrho(x,y), F_\varepsilon(x)$, *and* $H_{\varrho,\varepsilon}(x,y)$ *be defined by* (4.1), (5.1), *and* (5.2), *respectively. Then* $H_{\varrho,\varepsilon}$ *satisfies the Jacobian consistency.*

Proof. It holds by (5.4) and $\partial^0_\Pi(z) = \lim_{\varrho \downarrow 0} \nabla \Pi_\varrho(z)$ that

$$\partial^0_\Pi H(x,y) \triangleq \lim_{(\varrho,\varepsilon)\downarrow(0,0)} \nabla H_{\varrho,\varepsilon}(x,y) = \begin{pmatrix} I - \partial^0_\Pi(x-y) & \nabla F(x) \\ \partial^0_\Pi(x-y) & -I \end{pmatrix}. \tag{5.5}$$

This implies from (3.4) and Lemma 4.7 that $\partial^0_\Pi H(x,y) \in \partial H_{NR}(x,y)$ for any $(x,y) \in \mathcal{J} \times \mathcal{J}$. The desired conclusion holds obviously. □

Furthermore, applying Theorems 4.10 and 5.2, we estimate the upper bound of the distance $\operatorname{dist}(\nabla H_{\varrho,\varepsilon}(x,y), \partial H_{NR}(x,y))$.

THEOREM 5.3. *Let* $F : \mathcal{J} \to \mathcal{J}$ *be continuously differentiable, and* g *be a continuously differentiable convex function satisfying* (4.2) *and* (4.13). *Suppose* γ_ϱ, γ_0, *and* γ_0^+ *are given by* (4.5)–(4.7), *and let* $\lambda^\star$ *be defined by* (4.15). *Then, there exists a scalar* $M > 0$ *such that*

$$\operatorname{dist}(\nabla H_{\varrho,\varepsilon}(x,y), \partial H_{NR}(x,y)) \le M(|\gamma'_\varrho(\lambda^\star(x-y)) - \gamma_0^+(\lambda^\star(x-y))| + \varepsilon),$$

for any $\varrho > 0, \varepsilon \ge 0$ *and any* $(x,y) \in \mathcal{J} \times \mathcal{J}$.

Proof. By (5.4), (5.5), and the fact $\partial^0_\Pi H(x,y) \in \partial H_{NR}(x,y)$, one has for any $\varrho > 0, \varepsilon \ge 0$, and any $(x,y) \in \mathcal{J} \times \mathcal{J}$,

$$\begin{aligned} \operatorname{dist}(\nabla H_{\varrho,\varepsilon}(x,y), \partial H_{NR}(x,y)) &\le ||\nabla H_{\varrho,\varepsilon}(x,y) - \partial^0_\Pi H(x,y)|| \\ &\le \tilde{M}(\|\nabla \Pi_\varrho(x-y)) - \partial^0_\Pi(x-y))\| + \varepsilon) \\ &\le \tilde{M}(\bar{M}|\gamma'_\varrho(\lambda^\star(x-y)) - \gamma_0^+(\lambda^\star(x-y))| + \varepsilon), \end{aligned}$$

where $\tilde{M}$ in the second inequality is a positive scalar, the third follows from Theorem 4.10. The desired holds immediately. □

In the end of this paper, we describe an algorithm which is a word-for-word extension of the one by Hayashi, Yamashita, and Fukushima [15] for SOCCP, and state the corresponding convergence theorem, which can be obtained by Theorems 5.1–5.3 and following the proof of Theorem 4.13 in [15].

ALGORITHM Set $w \triangleq (x,y)$ and $w^{(k)} \triangleq (x^{(k)}, y^{(k)})$. Choose $\eta, \rho \in (0,1), \bar{\eta} \in (0, \eta], \sigma \in (0, 1/2), \kappa > 0$, and $\hat{\kappa} > 0$.

Step 0 Choose $w^{(0)} \in \mathcal{J} \times \mathcal{J}$ and $\beta_0 \in (0, \infty)$. Let $\varrho_0 \triangleq \|H_{NR}(w^{(0)})\|$ and $\varepsilon_0 \triangleq \|H_{NR}(w^{(0)})\|$. Set $k \triangleq 0$.

Step 1 Terminate if $\|H_{NR}(w^{(k)})\| = 0$.

Step 2

Step 2.0 Set $v^{(0)} \triangleq w^{(0)}$ and $j \triangleq 0$.

Step 2.1 Find a vector $\hat{d}^{(j)}$ such that

$$H_{\varrho_k,\varepsilon_k}\left(v^{(j)}\right) + \nabla H_{\varrho_k,\varepsilon_k}\left(v^{(j)}\right)^T \hat{d}^{(j)} = 0.$$

Step 2.2 If $\|H_{\varrho_k,\varepsilon_k}(v^{(j)} + \hat{d}^{(j)})\| \le \beta_k$, then let $w^{(k+1)} \triangleq v^{(j)} + \hat{d}^{(j)}$ and go to Step 3. Otherwise, go to Step 2.3.

Step 2.3 Find the smallest nonnegative integer m such that

$$\Psi_{\varrho_k,\varepsilon_k}\left(v^{(j)}+\rho^m\hat{d}^{(j)}\right)\le(1-2\sigma\rho^m)\Psi_{\varrho_k,\varepsilon_k}\left(v^{(j)}\right).$$

Let $m_j\triangleq m$, $\tau_j\triangleq\rho^{m_j}$, and $v^{(j+1)}\triangleq v^{(j)}+\tau_j\hat{d}^{(j)}$.

Step 2.4 If $\|H_{\varrho_k,\varepsilon_k}(v^{(j+1)})\|\le\beta_k$, then let $w^{(k+1)}\triangleq v^{(j+1)}$ and go to Step 3. Otherwise, set $j\triangleq j+1$ and go back to Step 2.1.

Step 3 Update the parameters as follows:

$$\begin{aligned}\varrho_{k+1}:&=\min\left\{\kappa\left\|H_{NR}\left(w^{(k+1)}\right)\right\|^2,\varrho_0\bar{\eta}^{k+1},\bar{\varrho}\Big(\lambda^\star\left(x^{(k+1)}-y^{(k+1)}\right),\hat{\kappa}\right.\\&\qquad\left.\left\|H_{NR}\left(w^{(k+1)}\right)\right\|\Big)\right\},\\\varepsilon_{k+1}:&=\min\left\{\kappa\left\|H_{NR}\left(w^{(k+1)}\right)\right\|^2,\varepsilon_0\bar{\eta}^{k+1}\right\},\\\beta_{k+1}:&=\beta_0\eta^{k+1},\end{aligned}$$

where $\lambda^\star$ is given by (4.15), and $\bar{\varrho}(t,\delta)$ is determined so that $|\gamma'_\varrho(t)-\gamma_0^+(t)|<\delta$ for any $\varrho\in(0,\bar{\varrho}(t,\delta))$.

Step 4 Set $k\triangleq k+1$. Go back to Step 1.

Note that by (4.14)–(4.16) it is not hard to calculate $\lambda^\star$ for NCP, SOCCP, and SDCP cases.

THEOREM 5.4. *Let $F:\mathcal{J}\to\mathcal{J}$ be a continuously differentiable and monotone function, and $\{w^{(k)}\}$ be a sequence generated by the Algorithm. If the solution set of SCCP*(1.1) *is nonempty and bounded, then $\{w^{(k)}\}$ is bounded, and every accumulation point is a solution of SCCP*(1.1). *In addition, if ∇F is locally Lipschitzian and every accumulation point of $\{\nabla H_{\varrho_k,\varepsilon_k}(w^{(k)})\}$ is nonsingular, then the sequence $\{w^{(k)}\}$ converges to a solution w^* of SCCP*(1.1) *quadratically.*

Acknowledgments. The authors are very grateful to the anonymous referees for their constructive comments and valuable suggestions. The authors thank Defeng Sun and Levent Tunçel for helpful discussions.

VARIATIONAL ANALYSIS OF PSEUDOSPECTRA*

ADRIAN S. LEWIS† AND C. H. JEFFREY PANG†

Abstract. The ϵ-pseudospectrum of a square matrix A is the set of eigenvalues attainable when A is perturbed by matrices of spectral norm not greater than ϵ. The pseudospectral abscissa is the largest real part of such an eigenvalue, and the pseudospectral radius is the largest absolute value of such an eigenvalue. We find conditions for the pseudospectrum to be Lipschitz continuous in the set-valued sense and hence find conditions for the pseudospectral abscissa and the pseudospectral radius to be Lipschitz continuous in the single-valued sense. Our approach illustrates diverse techniques of variational analysis. The points at which the pseudospectrum is not Lipschitz (or more properly, does not have the Aubin property) are exactly the critical points of the resolvent norm, which in turn are related to the coalescence points of pseudospectral components.

Key words. pseudospectrum, variational analysis, Lipschitz multifunction, Aubin property, nonsmooth analysis, normal cone

1. Introduction.

Analysis using eigenvalues is prevalent in many different areas of applied mathematics. As we consider perturbations to an $n \times n$ complex matrix A with spectrum $\Lambda(A)$, we are led to study the ϵ-pseudospectrum $\Lambda_\epsilon : M^n \rightrightarrows \mathbb{C}$, which is a set-valued map defined by

$$\Lambda_\epsilon(A) = \{z \mid \exists E \in M^n \text{ such that } \|E\| \leq \epsilon, z \in \Lambda(A+E)\},$$

where M^n is the space of matrices of size $n \times n$. A well-known equivalent formulation, assuming $\|\cdot\| = \|\cdot\|_2$ as we do throughout, is

$$\Lambda_\epsilon(A) = \{z \mid \underline{\sigma}(A - zI) \leq \epsilon\},$$

where $\underline{\sigma}(A)$ denotes the smallest singular value of the matrix A. As discussed extensively in [22], the function $z \mapsto (zI - A)^{-1}$ is called the *resolvent* of the matrix A. Thus the pseudospectra of A are just upper-level sets of the *resolvent norm* function $n_A : \mathbb{C} \backslash \Lambda(A) \to \mathbb{R}_+$ defined by

$$n_A(z) := \left\|(zI - A)^{-1}\right\| = \frac{1}{\underline{\sigma}(A - zI)}.$$

Pseudospectra may be more informative than eigenvalues in applications where matrices are nonnormal [22, 13].

The continuity of the spectrum is well known [14]. One immediate question is whether continuity extends to Λ_ϵ. Since Λ_ϵ is a set-valued map, we ask whether we have continuity in the Hausdorff metric, and it is known that the answer is yes [17, Theorem 2.3.7].

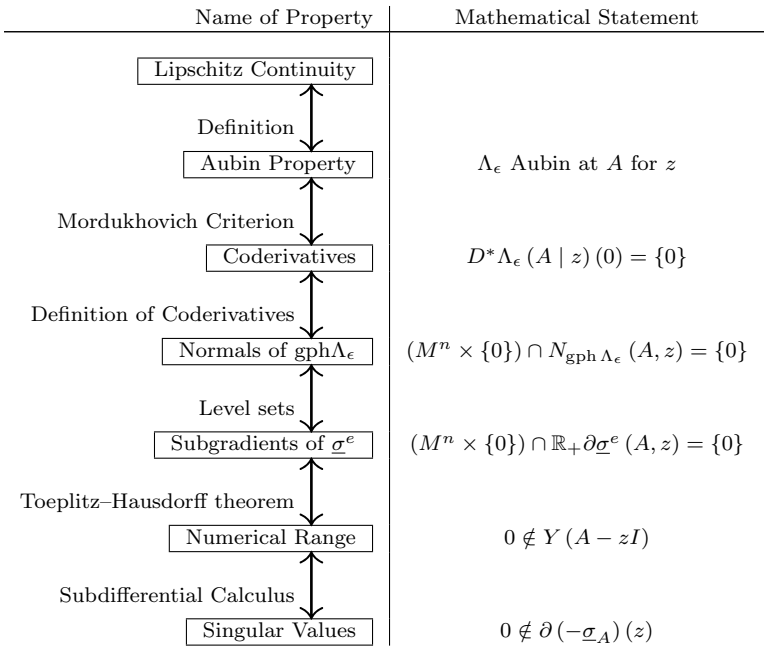

FIG. 1. *Equivalences of properties summarized in Theorem* 5.2.

Does the pseudospectrum mapping Λ_ϵ have stronger continuity properties? One of the main contributions of this paper is to find conditions under which the map Λ_ϵ is Lipschitz continuous. The ingredients of our analysis are variational-analytic techniques from the last couple of decades, as described in Rockafellar and Wets [21], Clarke et al. [10], and Mordukhovich [20]. In particular, we should note that there are technical details involved in the generalization of Lipschitz continuity to set-valued maps. Our proof (of the main results in Theorem 5.2 and Proposition 6.3) may be described loosely by Figure 1. The reader may find the schematic outline helpful as the argument proceeds.

For the moment, we remark on the notation

$$\underline{\sigma}_A(z) = \underline{\sigma}^e(A, z) = \frac{1}{n_A(z)}$$

and $Y(A - zI)$, which refers to the set of the inner products of associated left and right singular vectors (see page 1050). N refers to the normal cone, ∂ refers to the subdifferential and D^* refers to the coderivative. We expand more on the notation of Figure 1 (see page 1051).

In Figure 1, the six properties on the right on A and z are equivalent. For a given matrix A, we call points z not satisfying these equivalent properties "resolvent-critical" because they are smooth or nonsmooth critical points of the norm of the resolvent n_A. When the multiplicity of the smallest singular value of $A - zI$ is one, this property is equivalent to z being a "degenerate point" (in the sense of [4, Definition 4.5, Corrigendum]) or not "regular" in the sense of [5, Definition 4.4]. Points not resolvent-critical are exceptional for several aspects of pseudospectra, notably the quadratic convergence of the pseudospectral abscissa algorithm in [5].

As well as our main result equating the absence of the Aubin property with resolvent-criticality, we derive a variety of other properties of resolvent-critical points proving, in particular, that points where pseudospectral components coalesce as ϵ grows are resolvent-critical.

As an application of the Lipschitz continuity of $\Lambda_\epsilon : M^n \rightrightarrows \mathbb{C}$, we find conditions for the Lipschitz continuity (in the single-valued sense) and the strict differentiability of the pseudospectral abscissa $\alpha_\epsilon : M^n \to \mathbb{R}$, and the pseudospectral radius $\rho_\epsilon : M^n \to \mathbb{R}_+$ defined by

$$\begin{aligned} \alpha_\epsilon(A) &:= \max\{\mathrm{Re}\,(\lambda) \mid \lambda \in \Lambda_\epsilon(A)\}, \\ \rho_\epsilon(A) &:= \max\{|\lambda| \mid \lambda \in \Lambda_\epsilon(A)\}. \end{aligned}$$

We write $MSV : M^n \rightrightarrows \mathbb{C}^n \times \mathbb{C}^n$, with

$$\begin{aligned} MSV(A) := \{(u,v) \mid\ & u, v \text{ minimal left and} \\ & \text{right singular vectors of } A\}. \end{aligned}$$

In the above definition of MSV, u, v are *minimal left and right singular vectors* of A if they are unit vectors satisfying

$$\begin{aligned} \underline{\sigma}(A)\, u &= Av \\ \text{and } \underline{\sigma}(A)\, v &= A^H u, \end{aligned}$$

where A^H is the Hermitian transpose of A. A key tool in our analysis is the set

$$Y(A) := \left\{v^H u \mid (u,v) \in MSV(A)\right\}.$$

We prove that the set $Y(A - zI)$ is the subgradient set at z of the function $-\underline{\sigma}_A : \mathbb{C} \to \mathbb{R}_-$, where $\underline{\sigma}_A(z) = \underline{\sigma}(A - zI)$.

Related to Λ_ϵ is the mapping $\Lambda_\epsilon^c : M^n \rightrightarrows \mathbb{C}$ defined by $\Lambda_\epsilon^c(A) = \{z \mid \underline{\sigma}(A - zI) \geq \epsilon\}$. This mapping turns out to be easier to analyze because $-\underline{\sigma}(\cdot)$ has the property of subdifferential regularity (as defined in [21]) except at where it is zero. We show that the normal cone $N_{\Lambda_\epsilon^c(A)}(\bar{z})$ is $\mathbb{R}_+(Y(A - \bar{z}I))$. This establishes a link between the variational properties of $-\underline{\sigma}_A$ and Λ_ϵ^c, and the Aubin property.

Notation. For future reference, Tables 1 and 2 summarize the mappings that appear throughout the paper.

Unless otherwise stated, our notation follows [21]. See also the table of notation in [21, page 725]. The term "regular" means subdifferentially regular in the sense of [21, Definition 7.25]. Table 2 summarizes the symbols we use.

The "^{H}" in A^H and v^H represent the Hermitian transpose of a matrix or vector, while the "*" in L^* represents the adjoint of the linear operator L. Note that D^* stands for the coderivative instead. The real inner product on $A, B \in M^n$ is defined by $\mathrm{Re\ tr}\,\left(A^H B\right)$.

Outline. The paper is organized as follows. Section 2 studies the continuity properties of the pseudospectra Λ_ϵ and its "complement" Λ_ϵ^c via more general feasible-set mappings. In sections 3, 4, and 5, we prove the main result that Λ_ϵ has the Aubin property at A for z if and only if $0 \notin Y(A - zI)$, with section 3 containing general results on variational analysis and the singular value decomposition, section 4 performing subdifferential calculus, and section 5 finishing the proof of the main result.

TABLE 1
Summary of definitions.

Name/domain/range	Definition
$\bar{\sigma} : M^n \to \mathbb{R}_+$	$\bar{\sigma}(A)$ is maximum singular value of A
$\underline{\sigma} : M^n \to \mathbb{R}_+$	$\underline{\sigma}(A)$ is minimum singular value of A
$\underline{\sigma}^e : M^n \times \mathbb{C} \to \mathbb{R}_+$	$\underline{\sigma}^e(A, z) = \underline{\sigma}(A - zI)$
$\underline{\sigma}_A : \mathbb{C} \to \mathbb{R}_+$	$\underline{\sigma}_A(z) = \underline{\sigma}(A - zI)$
$\Lambda_\epsilon : M^n \rightrightarrows \mathbb{C}$	$\Lambda_\epsilon(A) = \{z \mid \underline{\sigma}(A - zI) \leq \epsilon\}$
$\Lambda : M^n \rightrightarrows \mathbb{C}$	$\Lambda(A) = \Lambda_0(A) = \{\text{eigenvalues of } A\}$
$\Lambda_\epsilon^c : M^n \rightrightarrows \mathbb{C}$	$\Lambda_\epsilon^c(A) = \{z \mid \underline{\sigma}(A - zI) \geq \epsilon\}$
$\alpha_\epsilon : M^n \to \mathbb{R}$	$\alpha_\epsilon(A) = \max_{z \in \Lambda_\epsilon(A)} \operatorname{Re} z$
$\rho_\epsilon : M^n \to \mathbb{R}_+$	$\rho_\epsilon(A) = \max_{z \in \Lambda_\epsilon(A)} \lvert z \rvert$
$W : M^n \rightrightarrows \mathbb{C}$	Numerical range/ field of values[15, Definition 1.1.1]
$MSV : M^n \rightrightarrows \mathbb{C}^n \times \mathbb{C}^n$	See Definition 3.2
$Y : M^n \rightrightarrows \mathbb{C}$	See Definition 3.2

In section 6, we show how the Lipschitz constant for the map Λ_ϵ can be calculated. Section 7 gives conditions for the Lipschitz continuity and strict differentiability of the pseudospectral abscissa α_ϵ and the pseudospectral radius ρ_ϵ. Finally, we present properties of resolvent-critical points in section 8. We prove, in particular, that the points at which the components of $\Lambda_\epsilon(A)$ coalesce as ϵ grows are resolvent-critical, and we pose some questions about resolvent-critical points.

2. Feasible-set mappings and continuity of pseudospectra. The pseudospectral mapping $\Lambda_\epsilon : M^n \rightrightarrows \mathbb{C}$ has two inputs: $\epsilon \in \mathbb{R}_+$ and the matrix in the argument of $\Lambda_\epsilon(\cdot)$. As $\mathbb{R}_+$ is one-dimensional, the variation of $\Lambda_\epsilon(A)$ for a fixed matrix A and variable ϵ is easier to visualize, as implemented in EigTool [24]. Some attractive results in this direction have been obtained in [7, 8, 18, 1, 17] and elsewhere. By contrast, in this work we study how Λ_ϵ behaves for a fixed ϵ and a varying matrix argument, primarily taking a more abstract and systematic approach than [6].

We study pseudospectra using the language of set-valued analysis as described in the monograph [21]. We take the definition of inner semicontinuity and outer semicontinuity in [21, section 5B].

In the next two propositions, let $f : \mathbb{R}^n \times \mathbb{R}^d \to \mathbb{R}^m$ be a continuous function, and let $T : \mathbb{R}^d \rightrightarrows \mathbb{R}^n$ be the mapping defined by

$$T(w) = \{x \mid f(x, w) \in D\}, \tag{2.1}$$

where D is a closed set.

PROPOSITION 2.1. *T is outer semicontinuous.*

Proof. We just need to check that T has a closed graph (by [21, Theorem 5.7]), which is easy. □

Note that the ϵ-pseudospectrum can be written as

$$\begin{aligned}\Lambda_\epsilon(A) &= \{z \mid \underline{\sigma}^e(A, z) \le \epsilon\} \\ &= \{z \mid \underline{\sigma}^e(A, z) \in (-\infty, \epsilon]\}.\end{aligned}$$

If we apply Proposition 2.1, we can deduce that Λ_ϵ is outer semicontinuous. In a similar manner, Λ^c_ϵ, defined by $\Lambda^c_\epsilon(A) = \{z \mid \underline{\sigma}^e(A, z) \ge \epsilon\}$, is also outer semicontinuous.

Turning to inner semicontinuity, we begin with a technical result.

PROPOSITION 2.2. *Let*

$$Q := \mathrm{cl}\{x \mid f(x, \bar{w}) \in \mathrm{int}(D)\},$$

so $Q \subset T(\bar{w})$. We have

(a) $Q \subset \liminf_{w \to \bar{w}} T(w) \subset T(\bar{w})$.

In the case where $m = 1$:

(b) *If $D = (-\infty, \alpha]$, then*

$$\begin{aligned}Q = \{&x \mid f(x, \bar{w}) = \alpha \text{ , } x \text{ is not a local minimizer of } f(\cdot, \bar{w})\} \\ &\cup \{x \mid f(x, \bar{w}) < \alpha\}.\end{aligned}$$

(c) *If $D = [\alpha, \infty)$, then*

$$\begin{aligned}Q = \{&x \mid f(x, \bar{w}) = \alpha \text{ , } x \text{ is not a local maximizer of } f(\cdot, \bar{w})\} \\ &\cup \{x \mid f(x, \bar{w}) > \alpha\}.\end{aligned}$$

(d) *If $\alpha > 0$, f is positively homogeneous (that is, $\lambda f(\cdot) = f(\lambda \cdot)$ for $\lambda > 0$) and either $D = (-\infty, \alpha]$ or $D = [\alpha, \infty)$, then $Q = \liminf_{w \to \bar{w}} T(w)$.*

Proof. Property (a) is easy and standard. See, for example, the techniques in [2, 16].

Statements (b) and (c) are clear by the definition of Q, so we proceed to prove statement (d) for the case $D = (-\infty, \alpha]$. (The case $D = [\alpha, \infty)$ is similar and is omitted.) From statement (a), we just need to prove that if $\bar{x} \notin Q$, then $\bar{x} \notin \liminf_{w \to \bar{w}} T(w)$. Suppose that $\bar{x} \notin Q$. We need to consider only $\bar{x} \in T(\bar{w})$, so we can assume that $\bar{x}$ is a minimizer of $f(\cdot, \bar{w})$ and $f(\bar{x}, \bar{w}) = \alpha$. Then there is a neighborhood $\mathbb{B}_\delta(\bar{x})$ about $\bar{x}$ such that $f(x, \bar{w}) \ge f(\bar{x}, \bar{w}) = \alpha$ if $x \in \mathbb{B}_\delta(\bar{x})$. If $\|x - \bar{x}\| < \delta/2$, then

$$\left\| \frac{1}{1 + \frac{1}{j}} x - \bar{x} \right\| < \delta \text{ if } j \text{ is large.}$$

This means that

$$\begin{aligned} f\left(x, \left(1+\frac{1}{j}\right)\bar{w}\right) &= \left(1+\frac{1}{j}\right) f\left(\frac{1}{1+\frac{1}{j}}x, \bar{w}\right) \\ &\geq \left(1+\frac{1}{j}\right)\alpha \quad \left(\text{because } \left\|\left(\frac{1}{1+\frac{1}{j}}\right)x - \bar{x}\right\| < \delta\right) \\ &> \alpha, \end{aligned}$$

which implies that $\mathbb{B}_{\delta/2}(\bar{x}) \cap T((1+\frac{1}{j})\bar{w}) = \emptyset$ if j is large enough. So for the sequence $(1+\frac{1}{j})\bar{w} \to \bar{w}$ as $j \to \infty$, we cannot find a subsequence x_j such that $x_j \in T((1+\frac{1}{j})\bar{w})$ and $x_j \to \bar{x}$, and this means that $\bar{x} \notin \liminf_{w\to\bar{w}} T(w)$. ∎

The following corollary is immediate from the definition of inner semicontinuity.

COROLLARY 2.3. *If $T(\bar{w}) = Q$, then T is continuous at $\bar{w}$. Furthermore, if f is positively homogeneous, then the converse holds as well.*

Proof. The mapping T is continuous if and only if it is both inner and outer semicontinuous. Apply the last two propositions. ∎

Now that we have established conditions for outer and inner semicontinuity for feasible-set mappings, we shall study the continuity of the pseudospectrum Λ_ϵ and Λ_ϵ^c. Let us consider the case $\epsilon = 0$ first. The map $\Lambda_0^c : M^n \rightrightarrows \mathbb{C}$ is not interesting as $\Lambda_0^c(A) = \mathbb{C}$ for all matrices A. We are then led to consider the spectrum $\Lambda_0 = \Lambda$, which is well known to be continuous [14, Appendix D].

To extend to $\epsilon > 0$, we may apply Propositions 2.1 and 2.2, combined with the fact that $\underline{\sigma}_A(\cdot)$ has no local minimum other than at the eigenvalues [22, Theorem 2.4(i)], to prove the following result. This result is not new and can be found, for example, in [17, Corollary 2.3.8].

PROPOSITION 2.4. *$\Lambda_\epsilon : M^n \rightrightarrows \mathbb{C}$ is continuous for $\epsilon \geq 0$.*

For $\Lambda_\epsilon^c : M^n \rightrightarrows \mathbb{C}$, we obtain the following using Proposition 2.2(d).

PROPOSITION 2.5. *$\Lambda_\epsilon^c : M^n \rightrightarrows \mathbb{C}$ is outer semicontinuous, but it is inner semicontinuous at a matrix A if and only if there is no local maximizer $\bar{z}$ to $\underline{\sigma}_A : \mathbb{C} \to \mathbb{R}_+$, with $\underline{\sigma}_A(\bar{z}) = \epsilon$.*

Example 2.6. The mapping Λ_ϵ^c is not continuous at some points. For a concrete example of the noncontinuity of Λ_ϵ^c, consider the point $0 \in \Lambda_1^c(\bar{A})$, where $\bar{A} = \operatorname{diag}(1, -1, i, -i)$ and $\epsilon = 1$. Here $\Lambda_1(\bar{A})$ consists of the union of balls of radius 1 around the diagonal entries, and so we observe that 0 is a local maximum of $\underline{\sigma}_{\bar{A}}$. This exhibits an example of the discontinuity of Λ_1^c as $\liminf_{A\to\bar{A}} \Lambda_1^c(A) \subsetneq \Lambda_1^c(\bar{A})$.

Next, we consider Lipschitz continuity. First, we define the Pompieu–Hausdorff distance.

DEFINITION 2.7 (see [21, Example 4.13]). *For $C, D \subset \mathbb{R}^n$ closed and nonempty, the* Pompieu–Hausdorff distance $\mathbf{d}(C, D)$ *is defined as*

$$\mathbf{d}(C, D) := \inf\{\eta \geq 0 \mid C \subset D + \eta\mathbb{B}, D \subset C + \eta\mathbb{B}\}.$$

Lipschitz continuity is thus defined as follows.

DEFINITION 2.8 (see [21, Definitions 9.26, 9.28]). *A mapping $S : \mathbb{R}^n \rightrightarrows \mathbb{R}^m$ is* Lipschitz continuous *if it is nonempty–closed-valued and there exists $\kappa \in \mathbb{R}_+$, a Lipschitz constant, such that $\mathbf{d}(S(x), S(x')) \leq \kappa|x - x'|$ for all $x, x' \in \mathbb{R}^n$, or*

$$S(x') \subset S(x) + \kappa|x' - x|\,\mathbb{B} \text{ for all } x, x' \in \mathbb{R}^n.$$

The infimum of all κ such that there exists a neighborhood V of $\bar{x}$ such that

$$S(x') \subset S(x) + \kappa |x' - x| \mathbb{B} \text{ for all } x, x' \in V$$

is the Lipschitz modulus *for S at $\bar{x}$ and is denoted by* $\operatorname{lip}_\infty S(\bar{x})$.

The Aubin property, which is a localized Lipschitz property, is defined as follows.

DEFINITION 2.9 (see [21, Definition 9.36] Aubin property and graphical modulus). *A mapping $S : \mathbb{R}^n \rightrightarrows \mathbb{R}^m$ has the* Aubin property at $\bar{x}$ for $\bar{u}$, *where $\bar{x} \in \mathbb{R}^n$ and $\bar{u} \in S(\bar{x})$, if* $\operatorname{gph} S$ *is locally closed at $(\bar{x}, \bar{u})$ and there are neighborhoods V of $\bar{x}$ and W of $\bar{u}$, and a constant $\kappa \in \mathbb{R}_+$ such that*

$$S(x') \cap W \subset S(x) + \kappa |x' - x| \mathbb{B} \text{ for all } x, x' \in V.$$

The graphical modulus *of S at $\bar{x}$ for $\bar{u}$, denoted by* $\operatorname{lip} S(\bar{x} \mid \bar{u})$, *is the infimum of all such κ that satisfy the formula above.*

If the function f in the feasible-set mapping in formula (2.1) in page 1052 is smooth, we understand the Aubin Property quite well through [21, Example 9.51]. If $D = (-\infty, \bar{\alpha}]$, we can also analyze the nonsmooth case. In what follows, ∂ and ∂^∞ denote, respectively, the subgradient set and the horizon subgradient set [21, Definition 8.3].

Assumptions (a), (b), and (c) in the result below are standard for computing normals to level sets (see, for example, [21, Proposition 10.3].) Assumption (d) is needed to apply a chain rule.

THEOREM 2.10. *Consider the set-valued map $C : \mathbb{R}^d \rightrightarrows \mathbb{R}^n$ defined via a level set representation*

$$C(p) = \{x \mid F(x, p) \leq \bar{\alpha}\},$$

with $F : \mathbb{R}^n \times \mathbb{R}^d \to \mathbb{R}$. Suppose that

(a) $F(\bar{x}, \bar{p}) = \bar{\alpha}$,

(b) $(0, 0) \notin \partial F(\bar{x}, \bar{p})$,

(c) *F is regular at $(\bar{x}, \bar{p})$,*

(d) $(0, y_2) \in \partial^\infty F(\bar{x}, \bar{p}) \implies y_2 = 0$.

Then C has the Aubin property at $\bar{p}$ for $\bar{x}$ if and only if $0 \notin \partial F_{\bar{p}}(\bar{x})$, where $F_{\bar{p}} : \mathbb{R}^n \to \mathbb{R}$ is defined by $F_{\bar{p}}(x) := F(x, \bar{p})$. In this case,

$$\operatorname{lip} C(\bar{p} \mid \bar{x}) = \max_{\substack{(a,b) \in N_{\operatorname{gph} C}(\bar{p}, \bar{x}) \\ \|b\| = 1}} \|a\|,$$

If $F(\bar{x}, \bar{p}) < \bar{\alpha}$, then C has the Aubin property at $\bar{p}$ for $\bar{x}$, with $\operatorname{lip} C(\bar{p} \mid \bar{x}) = 0$.

Proof. The Mordukhovich criterion [21, Theorem 9.40] tells us that C has the Aubin property at $\bar{p}$ for $\bar{x}$ if and only if $D^* C(\bar{p} \mid \bar{x})(0) = \{0\}$, where D^* denotes the coderivative [21, Definition 8.33]. This holds if and only if

$$(z, 0) \in N_{\operatorname{gph} C}(\bar{p}, \bar{x}) \text{ implies } z = 0. \tag{2.2}$$

This property is equivalent to

$$(0, z) \in N_{\operatorname{gph} C^{-1}}(\bar{x}, \bar{p}) \text{ implies } z = 0.$$

Conditions (a), (b), and (c) allow us to conclude that

$$N_{\operatorname{gph} C^{-1}}(\bar{x}, \bar{p}) = (\operatorname{pos} \partial F(\bar{x}, \bar{p})) \cup \partial^\infty F(\bar{x}, \bar{p}) \tag{2.3}$$

through a result on level sets [21, Proposition 10.3], or

$$(0,z) \in (\text{pos } \partial F(\bar{x},\bar{p})) \cup \partial^{\infty} F(\bar{x},\bar{p}) \text{ implies } z = 0,$$

and by condition (d), this is in turn equivalent to

$$(0,z) \in \text{pos } \partial F(\bar{x},\bar{p}) \text{ implies } z = 0. \tag{2.4}$$

We define $L_{\bar{p}} : \mathbb{R}^n \to \mathbb{R}^n \times \mathbb{R}^d$ by $L_{\bar{p}}(x) = (x,\bar{p})$. The adjoint $L^*_{\bar{p}} : \mathbb{R}^n \times \mathbb{R}^d \to \mathbb{R}^n$ is given by $L^*_{\bar{p}}(x,p) = x$. We have $F_{\bar{p}} = F \circ L_{\bar{p}}$, and so by a chain rule [21, Theorem 10.6] and condition (d), $\partial F_{\bar{p}}(\bar{x}) = L^*_{\bar{p}} \partial F(\bar{x},\bar{p})$. Thus

$$\begin{aligned} \partial F_{\bar{p}}(\bar{x}) &= L^*_{\bar{p}} \partial F(\bar{x},\bar{p}) \\ &= \{y \mid \exists z \text{ such that } (y,z) \in \partial F(\bar{x},\bar{p})\}. \end{aligned}$$

If $0 \in \partial F_{\bar{p}}(\bar{x})$, then there exists z such that $(0,z) \in \partial F(\bar{x},\bar{p})$, but condition (b) implies $z \neq 0$, which contradicts statement (2.4). If $0 \notin \partial F_{\bar{p}}(\bar{x})$, this means that there is no z such that $(0,z) \in \partial F(\bar{x},\bar{p})$ and implies statement (2.4). So $0 \notin \partial F_{\bar{p}}(\bar{x})$ is equivalent to C not having the Aubin property at $\bar{p}$ for $\bar{x}$ as claimed.

The calculation of the value lip $C(\bar{p} \mid \bar{x})$ follows from the definition of the coderivative $D^*C(\bar{p} \mid \bar{x})$ and its relation to the normal cone through the Mordukhovich criterion. If $F(\bar{x},\bar{p}) < \bar{\alpha}$, then the normal cone is $\{(0,0)\}$, giving us the required value of lip $C(\bar{p} \mid \bar{x})$. ∎

To obtain the Lipschitz modulus from the graphical modulus, one may use [21, Theorem 9.38], but Proposition 6.2 is sufficient for our purposes in this paper.

In sections 3 to 6, we will be using the general principle illustrated in Theorem 2.10 to study where the pseudospectrum Λ_ϵ has the Aubin property and also to illustrate how this can identify where Λ_ϵ is Lipschitz continuous and give a value of the Lipschitz constant.

One may immediately try to apply Theorem 2.10 to show that Λ_ϵ has the Aubin property for A at z. In this case, $p = A$, $x = z$, and so $C(p) = \Lambda_\epsilon(A)$, $F(x,p) = \underline{\sigma}(A - zI) = \underline{\sigma}^e(A,z)$. However, $\underline{\sigma}^e$ is not a regular function, but this can be overcome by studying $-\underline{\sigma}^e$ instead, which is regular if $A - zI$ is nonsingular. This is what we will do in the analysis that follows.

3. General results. First, we are interested in finding out whether the functions $-\underline{\sigma}^e$ and $\frac{1}{\underline{\sigma}^e}$ enjoy similar regularity properties so that we can deduce properties of $\underline{\sigma}^e$. We recall a result on the reciprocals of functions.

PROPOSITION 3.1 (see [20, Corollary 1.111(iii)]). *For any function $h : \mathbb{R}^n \to \mathbb{R}$ at z where $h(z) > 0$, we have $\partial h(z) = h(z)^2 \, \partial\left(-\frac{1}{h}\right)(z)$, and h is regular at z if and only if $-\frac{1}{h}$ is regular there.*

The set of minimal singular vectors of A, $MSV(A)$, is defined below.

DEFINITION 3.2. *For a matrix A, the left and right singular vectors corresponding to the smallest singular value of A are the pairs $(u,v) \in \mathbb{C}^n \times \mathbb{C}^n$, $\|u\| = \|v\| = 1$, which appear in the appropriate columns of U and V in some singular value decomposition $A = USV^H$ of A. We refer to u and v as* minimal singular vectors*, and we denote the set of pairs of minimal singular vectors of A as $MSV(A)$. Furthermore, we define $Y : M^n \rightrightarrows \mathbb{C}$ by*

$$Y(A) := \left\{v^H u \mid (u,v) \in MSV(A)\right\}.$$

An equivalent definition given in the introduction is to have pairs of unit vectors (u,v) satisfying the equations $\underline{\sigma}(A)\,u = Av$ and $\underline{\sigma}(A)\,v = A^H u$.

The following result summarizes a complete characterization of left and right minimal singular vectors when we have one particular singular value decomposition, which is helpful for the case where the smallest singular value is multiple.

PROPOSITION 3.3. *Consider a matrix $A \in M^n$ with singular value decomposition (for unit vectors u_j, v_j)*

$$A = \sum_{j=1}^{n} \sigma_j u_j v_j^H = USV^H,$$

where $\sigma_1 = \sigma_2 = \cdots = \sigma_m < \sigma_j$ for all $j > m$. Define matrices $\bar{U} = (u_1\, u_2 \cdots u_m)$ and $\bar{V} = (v_1\, v_2 \cdots v_m)$. Then

$$MSV(A) = \left\{ \left(\bar{U}q, \bar{V}q\right) \mid q \in \mathbb{C}^m, \|q\| = 1 \right\}$$

if A is invertible (in other words, $\sigma_1 > 0$) and

$$MSV(A) = \left\{ \left(\bar{U}q_1, \bar{V}q_2\right) \mid q_1, q_2 \in \mathbb{C}^m, \|q_1\| = \|q_2\| = 1 \right\}$$

if A is singular.

Proof. The equations $Av = \underline{\sigma}(A)\, u$ and $A^H u = \underline{\sigma}(A)\, v$ require u to be an eigenvector for AA^H and v to be an eigenvector for $A^H A$, and so they lie in the subspaces spanned by the columns of $\bar{U}$ and $\bar{V}$, respectively. We have assumed that these columns are placed at the left of U and V. Then let $v = \bar{V}q$. As we want a v of unit length, we must have $\|q\| = 1$. Since A is invertible, $\underline{\sigma} := \underline{\sigma}(A) > 0$, and so

$$u = \frac{1}{\underline{\sigma}} Av = \frac{1}{\underline{\sigma}} USV^H \bar{V}q = \frac{1}{\underline{\sigma}} US \begin{pmatrix} I \\ 0 \end{pmatrix} q = U \begin{pmatrix} I \\ 0 \end{pmatrix} q = U \begin{pmatrix} q \\ 0 \end{pmatrix} = \bar{U}q.$$

Thus $MSV(A) \subset \left\{ \left(\bar{U}q, \bar{V}q\right) \mid q \in \mathbb{C}^m, \|q\| = 1 \right\}$. The reverse is straightforward.

If A is singular, then as before, $u = \bar{U}q_1$ and $v = \bar{V}q_2$ for some unit vectors q_1, q_2. It is evident that u and v satisfy the relations $\underline{\sigma}(A)\, u = Av$ and $\underline{\sigma}(A)\, v = A^H u$, so we are done. ∎

The significance of $Y(A)$ will become clear later in sections 4 and 5. We first show a result on $Y(A)$.

PROPOSITION 3.4. *If A is invertible, then $Y(A)$ is convex.*

Proof. We make the observation that the set $Y(A)$ can be determined as follows. Let $\bar{U}$ and $\bar{V}$ be as described in Proposition 3.3. The numerical range of a matrix $B \in M^n$ is the set $\left\{ v^H B v \mid v \in \mathbb{C}^n, \|v\| = 1 \right\}$, denoted by $W(B)$, and is convex by the Toeplitz–Hausdorff theorem [15, Property 1.2.2]. Then

$$\begin{aligned} Y(A) &= \left\{ v^H u \mid (u, v) \in MSV(A) \right\} \\ &= \left\{ q^H \bar{V}^H \bar{U} q \mid \|q\| = 1 \right\} \text{ (by Proposition 3.3)} \\ &= W\left(\bar{V}^H \bar{U}\right), \text{ the numerical range of } \bar{V}^H \bar{U}, \end{aligned}$$

establishing the convexity of $Y(A)$. ∎

For singular matrices A, $Y(A)$ need not be convex. Take, for example, the singular value decomposition

$$A = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

With this matrix,

$$Y(A) = \left\{ q_1 \begin{pmatrix} 0 & 1 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \end{pmatrix} q_2 \mid q_1, q_2 \in \mathbb{C}, |q_1| = |q_2| = 1 \right\}$$
$$= \{ q \in \mathbb{C} \mid |q| = 1 \},$$

which is not convex.

4. Subdifferential calculus. This section collects some results about subdifferential calculus involving $\underline{\sigma}^e : M^n \times \mathbb{C} \to \mathbb{R}_+$, where $\underline{\sigma}^e(A, z) = \underline{\sigma}(A - zI)$. As suggested in Figure 1, there is a link between the subdifferential $\partial \underline{\sigma}^e(A, z)$ and normal cone $N_{\operatorname{gph} \Lambda_\epsilon}(A, z)$ for $\underline{\sigma}^e(A, z) = \epsilon$. Before we can apply the appropriate theorems in [21], we have to calculate $\partial \underline{\sigma}^e(A, z)$, establish regularity properties, and characterize whether $0 \in \partial \underline{\sigma}^e(A, z)$.

When the smallest singular value is simple, $\underline{\sigma}$ and $\underline{\sigma}^e$ are analytic, as the next lemmas assert.

We remind the reader that the spaces M^n and $M^n \times \mathbb{C}$ have (real) inner products defined by

$$\langle A, B \rangle = \operatorname{Re} \operatorname{tr} \left(A^H B \right) \text{ for } A, B \in M^n$$

and

$$\langle (X, x), (Y, y) \rangle = \operatorname{Re} \left(\operatorname{tr} \left(X^H Y \right) + x^H y \right) \text{ for } X, Y \in M^n \text{ and } x, y \in \mathbb{C}.$$

LEMMA 4.1. *If the invertible matrix A has a simple smallest singular value, then the function $\underline{\sigma} : M^n \to \mathbb{R}_+$ is real-analytic at A, with gradient*

$$\nabla \underline{\sigma}(A) = uv^H$$

for any $(u, v) \in MSV(A)$.

The proof for the above lemma is standard (for example, [4, Theorem 7.1]), while the lemma below follows by noticing that $\underline{\sigma}^e = \underline{\sigma} \circ L$ and applying the chain rule, where $L : M^n \times \mathbb{C} \to \mathbb{C}$ is defined by $L(A, z) = A - zI$.

LEMMA 4.2. *If $z \notin \Lambda(A)$ and $A - zI$ has a simple smallest singular value, then the function $\underline{\sigma}^e : M^n \times \mathbb{C} \to \mathbb{R}_+$ is real-analytic at (A, z), with gradient*

$$\nabla \underline{\sigma}^e(A, z) = \left(uv^H, -v^H u \right)$$

for any $(u, v) \in MSV(A - zI)$.

The next two results are generalizations of Lemmas 4.1 and 4.2 to the nonsmooth case, and they calculate the subgradients needed in the main result in section 5.

PROPOSITION 4.3. *Suppose $z \notin \Lambda(A)$. Then*

$$\partial \left(-\underline{\sigma}^e \right)(A, z) = conv \left\{ \left(-uv^H, v^H u \right) \mid (u, v) \in MSV(A - zI) \right\}.$$

Furthermore, $-\underline{\sigma}^e$ is regular at (A, z) and globally Lipschitz.

Proof. We consider the functions

$$\bar{\sigma}^e : M^n \times \mathbb{C} \to \mathbb{R}_+, \ \iota : M^n \to M^n \text{ and } L : M^n \times \mathbb{C} \to M^n$$

defined by

$$\bar{\sigma}^e(A, z) = \bar{\sigma} \left((A - zI)^{-1} \right), \ \iota(B) = B^{-1} \text{ and } L(A, z) = A - zI.$$

That is, $\bar{\sigma}^e = \bar{\sigma} \circ \iota \circ L$. To evaluate the subdifferential of this function, we apply a chain rule [21, Theorem 10.6]. Given a matrix B, we seek to evaluate $\nabla (\iota \circ L)(A,z)^*(B)$, which is, by the chain rule, $\nabla L(A,z)^*(\nabla \iota(A - zI)^*(B))$.

As $\bar{\sigma}$ is everywhere Lipschitz, $\partial^\infty \bar{\sigma}(\iota \circ L(A,z)) = \{0\}$. Furthermore, since $\bar{\sigma}$ is convex, it is regular at $\iota \circ L(A,z)$, and so the conditions for [21, Theorem 10.6] are satisfied.

It is easy to check the identity $L^*(B) = (B, -\mathrm{tr}B)$. (Note that L is linear so $\nabla L = L$ and $\nabla L^* = L^*$.) Using the binomial expansion

$$(M + \Delta)^{-1} = M^{-1} - M^{-1}\Delta M^{-1} + o(\Delta),$$

it follows that $\nabla \iota(M)(B) = -M^{-1}BM^{-1}$, so $\nabla \iota(M)^*(B) = -M^{-H}BM^{-H}$ follows easily.

Next, we evaluate $\partial \bar{\sigma}^e(A,z)$. Let the singular value decomposition of $(A - zI)$ be USV^H. Then the singular value decomposition of $(A - zI)^{-1}$ is $VS^{-1}U^H$, and $(A - zI)^{-H} = US^{-1}V^H$. So

$$\partial \bar{\sigma}^e(A,z) = \nabla L(A,z)^* \nabla \iota(A - zI)^* \partial \bar{\sigma}\left((A - zI)^{-1}\right).$$

We know that

$$\partial \bar{\sigma}(B) = \mathrm{conv}\left\{uv^H \mid \|u\| = \|v\| = 1, Bv = \bar{\sigma}(B)u, B^H u = \bar{\sigma}(B)v\right\}.$$

(See, for example, [23].) Therefore,

$$\partial \bar{\sigma}\left((A - zI)^{-1}\right) = \mathrm{conv}\left\{vu^H \mid (u,v) \in MSV(A - zI)\right\}.$$

Then for any $(u,v) \in MSV(A - zI)$, we have

$$\begin{aligned}
\nabla L(A,z)^* \nabla \iota(A - zI)^* \left(vu^H\right) &= \nabla L(A,z)^* \left(-US^{-1}V^H vu^H US^{-1}V^H\right) \\
&= \underline{\sigma}(A - zI)^{-2} \nabla L(A,z)^* \left(-uv^H\right) \\
&= \underline{\sigma}(A - zI)^{-2} \left(-uv^H, \mathrm{tr}\ \left(uv^H\right)\right) \\
&= \underline{\sigma}(A - zI)^{-2} \left(-uv^H, v^H u\right),
\end{aligned}$$

and so

$$\partial \bar{\sigma}^e(A,z) = \underline{\sigma}(A - zI)^{-2} \mathrm{conv}\left\{\left(-uv^H, v^H u\right) \mid (u,v) \in MSV(A - zI)\right\}.$$

By Proposition 3.1, we conclude that

$$\begin{aligned}
\partial\left(-\underline{\sigma}^e\right)(A,z) &= \partial\left(-\frac{1}{\bar{\sigma}^e}\right)(A,z) \\
&= \bar{\sigma}^e(A,z)^{-2} \partial \bar{\sigma}^e(A,z) \\
&= \mathrm{conv}\left\{\left(-uv^H, v^H u\right) \mid (u,v) \in MSV(A - zI)\right\}.
\end{aligned}$$

The function $-\underline{\sigma}^e$ is regular at (A,z) because $\bar{\sigma}$ is regular and both the chain rule [21, Theorem 10.6] and Proposition 3.1 guarantee the preservation of regularity. Also, the function $-\underline{\sigma}^e$ is globally Lipschitz because $-\underline{\sigma}^e = -\underline{\sigma} \circ L$ is the composition of two globally Lipschitz functions. □

From the definition of $\Lambda_\epsilon(A) = \{z \mid \underline{\sigma}_A(z) \leq \epsilon\}$, where $\underline{\sigma}_A : \mathbb{C} \to \mathbb{R}_+$ is defined by $\underline{\sigma}_A(z) = \underline{\sigma}(A - zI)$, it is clear that the functions $\underline{\sigma}$ and $\underline{\sigma}_A$ figure prominently in the study of pseudospectra. The following two results can be seen as nonsmooth analogues of [4, Theorem 7.1 and Corollary 7.2]. Even though $\underline{\sigma}$ and $\underline{\sigma}_A$ are not necessarily smooth, we are able to prove that $-\underline{\sigma}$ and $-\underline{\sigma}_A$ are regular and calculate their subgradients.

PROPOSITION 4.4. *The function $-\underline{\sigma}$ is regular at every nonsingular matrix $A \in M^n$, with*

$$\partial(-\underline{\sigma})(A) = -\operatorname{conv}\left\{uv^H \mid (u,v) \in MSV(A)\right\}.$$

Proof. Define $L_{M^n} : M^n \to M^n \times \mathbb{C}$ by $L_{M^n}(A) = (A, 0)$, so we have $-\underline{\sigma}_A = (-\underline{\sigma}^e) \circ L_{M^n}$. Clearly L_{M^n} is smooth, with $\nabla L_{M^n} = I \times \mathbf{0}$ at all points. $(\nabla L_{M^n})^* : M^n \times \mathbb{C} \to M^n$ is just the natural projection. Thus, by appealing to [21, Theorem 10.6] and Proposition 4.3, we get what we need. ∎

PROPOSITION 4.5. *For a matrix A, consider the function $\underline{\sigma}_A : \mathbb{C} \to \mathbb{R}_+$ defined by $\underline{\sigma}_A(z) = \underline{\sigma}(A - zI)$. If $z \notin \Lambda(A)$, then*

$$\partial(-\underline{\sigma}_A)(z) = Y(A - zI),$$

and $-\underline{\sigma}_A$ is regular at z and globally Lipschitz.

Proof. The proof is similar to the proof above, but we work through the details for completeness. We note $-\underline{\sigma}_A = (-\underline{\sigma}^e) \circ L_A$, where $L_A : \mathbb{C} \to M^n \times \mathbb{C}$, $L_A(z) = (A, z)$. Clearly L_A is smooth, with $\nabla L_A = \mathbf{0} \times I$ at all points. Furthermore, $(\nabla L_A)^* : M^n \times \mathbb{C} \to \mathbb{C}$ is just the natural projection. Thus, by appealing to a chain rule [21, Theorem 10.6] and Proposition 4.3, we have

$$\begin{aligned}\partial(-\underline{\sigma}_A)(z) &= (\nabla L_A)^* \partial(-\underline{\sigma}^e)(A, z)\\ &= Y(A - zI).\end{aligned}$$

As in Proposition 4.3, $\underline{\sigma}_A$ is globally Lipschitz because it is a composition of two globally Lipschitz functions. ∎

We note that the assumptions that $A - zI$ is nonsingular in Proposition 4.3 and A is nonsingular in Proposition 4.4 cannot be dropped in the proposition below.

PROPOSITION 4.6. *If $z \in \Lambda(A)$, then $-\underline{\sigma}^e$ is not regular at (A, z). Similarly, $-\underline{\sigma}$ is not regular at A if A is singular.*

Proof. Take $\bar{U}$ and $\bar{V}$ to the matrices corresponding to the minimal left and right singular vectors of $A - zI$ in the statement of Proposition 3.3. For small $\epsilon > 0$, we have

$$\begin{aligned}-\underline{\sigma}^e\left(A + \epsilon\bar{U}\bar{V}^H, z\right) &= -\underline{\sigma}^e(A, z) - \epsilon\\ \text{and } -\underline{\sigma}^e\left(A - \epsilon\bar{U}\bar{V}^H, z\right) &= -\underline{\sigma}^e(A, z) - \epsilon.\end{aligned}$$

Hence if $(B, x) \in \hat{\partial}(-\underline{\sigma}^e)(A, z)$, we have

$$\begin{aligned}-\underline{\sigma}^e\left(A \pm \epsilon\bar{U}\bar{V}^H, z\right) &\geq -\underline{\sigma}^e(A, z) + \left\langle (B, x), \left(\pm\epsilon\bar{U}\bar{V}^H, 0\right)\right\rangle + o(\epsilon)\\ \implies -\epsilon &\geq \epsilon\left\langle (B, x), \left(\pm\bar{U}\bar{V}^H, 0\right)\right\rangle + o(\epsilon).\end{aligned}$$

Dividing by ϵ throughout and taking limits as $\epsilon \downarrow 0$, we have

$$\begin{aligned}&-1 \geq \left\langle (B, x), \left(\pm\bar{U}\bar{V}^H, 0\right)\right\rangle\\ \implies &-2 \geq \left\langle (B, x), \left(\bar{U}\bar{V}^H, 0\right)\right\rangle + \left\langle (B, x), \left(-\bar{U}\bar{V}^H, 0\right)\right\rangle = 0,\end{aligned}$$

which is obviously a contradiction. This means that $\hat{\partial}\left(-\underline{\sigma}^e\right)(A,z) = \emptyset$. To show that $\partial\left(-\underline{\sigma}^e\right)(A,z) \neq \emptyset$, we note that for small $\epsilon > 0$, we have

$$\left(-u_1 v_1^H, v_1^H u_1\right) \in \hat{\partial}\left(-\underline{\sigma}^e\right)\left(A + \epsilon \bar{U}\bar{V}^H, z\right)$$

by Proposition 4.3, where the minimal left and right singular vectors u_1, v_1 are defined in the statement of Proposition 3.3. Taking $\epsilon \downarrow 0$, this ensures that $(-u_1 v_1^H, v_1^H u_1) \in \partial(-\underline{\sigma}^e)(A,z)$, and thus $\partial\left(-\underline{\sigma}^e\right)(A,z) \neq \emptyset$. Since $\partial\left(-\underline{\sigma}^e\right)$ and $\hat{\partial}\left(-\underline{\sigma}^e\right)$ differ and appealing to [21, Corollary 8.11], $-\underline{\sigma}^e$ is not regular at (A,z). The proof for $-\underline{\sigma}$ is similar. ∎

PROPOSITION 4.7. *The resolvent norm $n_A : \mathbb{C} \to \mathbb{R}$ defined by $n_A(z) = \|(zI - A)^{-1}\|$ is regular at every point where $z \notin \Lambda(A)$, with*

$$\partial n_A(z) = n_A(z)^2\, Y(A - zI).$$

Proof. From the identity $n_A = 1/\underline{\sigma}_A$ and Propositions 3.1 and 4.5, we note the following calculations:

$$\begin{aligned}\partial n_A(z) =& n_A(z)^2\, \partial\left(-\frac{1}{n_A}\right)(z)\\ =& n_A(z)^2\, \partial\left(-\underline{\sigma}_A\right)(z)\\ =& n_A(z)^2\, Y(A - zI).\end{aligned}$$ ∎

This motivates the following definition.

DEFINITION 4.8. *A point $z \in \mathbb{C}$ is* resolvent-critical *for a square matrix A if either $z \in \Lambda(A)$ or $0 \in Y(A - zI)$.*

Thus resolvent-critical points that are not eigenvalues are simply critical points of the resolvent norm n_A (in the nonsmooth sense). Recall that, for a locally Lipschitz function f, $\partial^\circ f(x)$, the convex hull of $\partial f(x)$, is the *Clarke subdifferential* of f at x and that $\bar{x}$ is *Clarke-critical* if $0 \in \partial^\circ f(\bar{x})$. Since $\underline{\sigma}_A$ is globally Lipschitz, the following holds as well.

THEOREM 4.9. *For a given matrix A, the following are equivalent:*

(1) *z is resolvent-critical.*

(2) *z is Clarke-critical for $-\underline{\sigma}_A$.*

(3) *z is Clarke-critical for $\underline{\sigma}_A$.*

Proof. Since $\underline{\sigma}_A$ is Lipschitz, we have $\partial^\circ\left(-\underline{\sigma}_A\right)(z) = -\partial^\circ \underline{\sigma}_A(z)$ by [9, Proposition 2.3.1]. This means that (2) and (3) are equivalent.

Next we prove that (1) implies (2). If z is resolvent-critical, then either z is an eigenvalue of A or $0 \in \partial\left(-\underline{\sigma}_A\right)(z)$. In the second case, z is Clarke-critical for $-\underline{\sigma}_A$ because $\partial\left(-\underline{\sigma}_A\right)(z) \subset \partial^\circ\left(-\underline{\sigma}_A\right)(z)$. In the first case, z is a maximizer of $-\underline{\sigma}_A$, and so z is Clarke-critical.

Lastly, we prove that (2) implies (1). If z is not resolvent-critical, then z is not an eigenvalue, and $0 \notin \partial\left(-\underline{\sigma}_A\right)(z)$. But $\partial\left(-\underline{\sigma}_A\right)(z) = \partial^\circ\left(-\underline{\sigma}_A\right)(z)$ by the regularity of $-\underline{\sigma}_A$ at z, so we are done. ∎

Example 4.10. Table 3 shows some examples where 0 is a resolvent-critical point of A. (In the third example, the resolvent-critical point is close to 0 but not exactly at 0.) These plots were obtained with EigTool [24]. The curves represent the boundaries of the pseudospectra $\Lambda_\epsilon(A)$ for $\epsilon = 10^\alpha$, where α is the number corresponding to the line generated by EigTool in the legend on the right. The third example is found in [12].

TABLE 3
Examples of pseudospectra for Example 4.10.

A	Diagram
$\begin{pmatrix} 1 & 1 \\ 0 & -1 \end{pmatrix}$	Smooth Saddle $\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$	Nonsmooth Saddle $-\begin{pmatrix} 1 & 5 & 5^2 & 5^3 & 5^4 \\ 0 & 1 & 5 & 5^2 & 5^3 \\ 0 & 0 & 1 & 5 & 5^2 \\ 0 & 0 & 0 & 1 & 5 \\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}$	Local minimum of n_A 
We also have an alternative proof to [4, Theorem 9.2] after the remark below.

Remark 4.11. The set

$$G(z) = \left\{ v^H (A - zI) v \mid v \in V(z), \|v\| = 1 \right\},$$

where the subspace $V(z) \subset \mathbb{C}^n$ is spanned by all right singular vectors of $A - zI$ as defined in [4, Section 9], is equal to $\underline{\sigma}(A - zI) Y(A - zI)$.

PROPOSITION 4.12. *If $\bar{z}$ is not resolvent-critical and $\underline{\sigma}_A(\bar{z}) = \epsilon$, then the set $\Lambda_\epsilon^c(A)$ is Clarke regular at $\bar{z}$, with normal cone $N_{\Lambda_\epsilon^c(A)}(\bar{z}) = \operatorname{pos}(Y(A - \bar{z}I))$.*

Proof. This involves applying Proposition 4.5 to a result on level sets [21, Proposition 10.3]. ∎

The conditions below on $\partial\underline{\sigma}^e(A,z)$ and $\partial(-\underline{\sigma}^e)(A,z)$ are needed in a manner similar to condition (b) in Theorem 2.10 in the proof of our main result.

PROPOSITION 4.13. *The condition* $(0,0) \in \partial\underline{\sigma}^e(A,z)$ *holds if and only if* $z \in \Lambda(A)$. *Also, if* $z \notin \Lambda(A)$, *then* $(0,0) \notin \partial(-\underline{\sigma}^e)(A,z)$.

Proof. If $\underline{\sigma}^e(A,z) = 0$, then (A,z) is a local minimizer, and thus $(0,0) \in \partial\underline{\sigma}^e(A,z)$. On the other hand, if $\underline{\sigma}^e(A,z) > 0$, we need to prove that $(0,0) \notin \partial\underline{\sigma}^e(A,z)$. We try to evaluate $\hat{\partial}\underline{\sigma}^e(A,z)$. From Proposition 4.3, we know that at points where the multiplicity of the singular value $\underline{\sigma}(A - zI)$ is greater than one, $\underline{\sigma}^e$ is not differentiable. By [21, Corollary 9.21], $\hat{\partial}\underline{\sigma}^e(A,z) = \emptyset$ at these points. For points where the multiplicity of the singular value is one, the norm calculation tells us that the only point in $\hat{\partial}\underline{\sigma}^e(A,z)$ has norm at least one; the only element in $\hat{\partial}\underline{\sigma}^e(A,z)$ is of the form $\left(uv^H, -v^H u\right)$, and the matrix part already contributes one to the norm. So it is impossible that $(0,0) \in \partial\underline{\sigma}^e(A,z)$.

Next, we move on to $\partial(-\underline{\sigma}^e)(A,z)$. Take $\bar{U}, \bar{V}$ to be the matrix corresponding to the left and right singular vectors of $A - zI$ in the sense of Proposition 3.3. Note that $\left(\bar{U}\bar{V}^H, 0\right)$ represents a direction of linear descent, as

$$-\underline{\sigma}^e\left(A + \epsilon\bar{U}\bar{V}^H, z\right) = -\underline{\sigma}^e(A,z) - \epsilon$$

for small ϵ, and so we have $(0,0) \notin \hat{\partial}(-\underline{\sigma}^e)(A,z)$. Due to regularity (Proposition 4.3), we have $(0,0) \notin \partial(-\underline{\sigma}^e)(A,z)$. ∎

Despite the fact that $\underline{\sigma}^e$ is not regular, we are still able to calculate the subdifferential $\partial\underline{\sigma}^e(A,z)$.

PROPOSITION 4.14. *If* $z \notin \Lambda(A)$, *then*

$$\partial\underline{\sigma}^e(A,z) = \left\{\left(uv^H, -v^H u\right) \mid (u,v) \in MSV(A - zI)\right\}.$$

Proof. We observe that

$$\begin{aligned}\partial\underline{\sigma}^e(A,z) &\subset -\partial(-\underline{\sigma}^e)(A,z)\\ &= \operatorname{conv}\left\{\left(uv^H, -v^H u\right) \mid (u,v) \in MSV(A - zI)\right\}\end{aligned}$$

by [21, Corollary 9.21] and Proposition 4.3. Next, note that if $(B,w) \in \partial\underline{\sigma}^e(A,z)$, then

$$(B,w) \in \operatorname{conv}\left\{\left(uv^H, -v^H u\right) \mid (u,v) \in MSV(A - zI)\right\},$$

and so we may write $(B,w) = \sum_{i=1}^k \lambda_i\left(u_i v_i^H, -v_i^H u_i\right)$ for a convex combination of left and right singular vectors u_i, v_i corresponding to the smallest singular value. But since the 2-norm is a strictly convex norm, $\|B\| < 1$ if $k > 1$ and (u_i, v_i)'s are not complex multiples each other. We take a closer look: (B,w) can be written as a limit of $(B_i, w_i) = \nabla\underline{\sigma}^e(A_i, z_i)$, where $(A_i, z_i) \to (A,z)$ by [21, Corollary 9.21]. Since $\|B_i\| = 1$, it follows that $\|B\| = 1$.

With this, we conclude that $(B,w) = (uv^*, -v^*u)$ for some $(u,v) \in MSV(A - zI)$, and so

$$\partial\underline{\sigma}^e(A,z) \subset \left\{\left(uv^H, -v^H u\right) \mid (u,v) \in MSV(A - zI)\right\}.$$

To prove the other containment, note that, for any $(u,v) \in MSV(A - zI)$, we have

$$\begin{aligned}\hat{\partial}\underline{\sigma}^e\left(A - \delta uv^H, z\right) &= \left\{\nabla\underline{\sigma}^e\left(A - \delta uv^H, z\right)\right\}\\ &= \left\{\left(uv^H, -v^H u\right)\right\}\end{aligned}$$

for $0 < \delta < \epsilon$ by Lemma 4.2. Taking limits as $\delta \downarrow 0$, we have $\left(uv^H, -v^H u\right) \in \partial \underline{\sigma}^e (A, z)$, which completes the proof. ∎

5. Main result. Before proving our main result, we make a statement about the normal cones $N_{\operatorname{gph} \Lambda_\epsilon^c} (A, z)$ and $N_{\operatorname{gph} \Lambda_\epsilon} (A, z)$. We make use of properties that we have established in section 4 to establish the link between level sets and normal vectors.

PROPOSITION 5.1. *If* $\epsilon = \underline{\sigma}^e (A, z) > 0$, *then*

$$N_{\operatorname{gph} \Lambda_\epsilon^c} (A, z) = \operatorname{pos} \operatorname{conv} \left\{ \left(-uv^H, v^H u\right) \mid (u, v) \in MSV (A - zI) \right\},$$
$$N_{\operatorname{gph} \Lambda_\epsilon} (A, z) = \operatorname{pos} \left\{ \left(uv^H, -v^H u\right) \mid (u, v) \in MSV (A - zI) \right\}.$$

Proof. Apply a result on level sets [21, Proposition 10.3], Proposition 4.13, and the fact that $-\underline{\sigma}^e$ is Lipschitz to get

$$N_{\operatorname{gph} \Lambda_\epsilon^c} (A, z) = \operatorname{pos} \left(\partial \left(-\underline{\sigma}^e\right) (A, z)\right).$$

Next, apply Proposition 4.3 to deduce the first result.

By [21, Proposition 10.3] and Proposition 4.14, we have

$$\begin{aligned} N_{\operatorname{gph} \Lambda_\epsilon} (A, z) &\subset \operatorname{pos} \partial \underline{\sigma}^e (A, z) \\ &= \operatorname{pos} \left\{ \left(uv^H, -v^H u\right) \mid (u, v) \in MSV (A - zI) \right\}. \end{aligned}$$

Furthermore, if $\underline{\sigma} (A - zI)$ is simple, then $\underline{\sigma}^e$ is smooth and regular at (A, z) by Lemma 4.2, and so the above inclusion holds with equality.

For the opposite containment, take any $(u, v) \in MSV (A - zI)$. Consider the pair

$$(A_\delta, z_\delta) := \left((1 + \delta) A - \epsilon \delta u v^H, (1 + \delta) z\right) \text{ for small } \delta > 0.$$

At these points, $\underline{\sigma}^e$ is smooth (and thus regular) because the singular value is of multiplicity one with corresponding singular vectors (u, v), and $\underline{\sigma}^e (A_\delta, z_\delta) = \epsilon$. Thus

$$\left(uv^H, -v^H u\right) \in \hat{N}_{\operatorname{gph} \Lambda_\epsilon} \left((1 + \delta) A - \epsilon \delta u v^H, (1 + \delta) z\right).$$

Taking $\delta \downarrow 0$, we see that $\left(uv^H, -v^H u\right) \in N_{\operatorname{gph} \Lambda_\epsilon} (A, z)$. Since $N_{\operatorname{gph} \Lambda_\epsilon} (A, z)$ is a cone, we have the formula for $N_{\operatorname{gph} \Lambda_\epsilon} (A, z)$ as claimed. ∎

The following is the main result that summarizes the links between Figure 1 in the introduction.

THEOREM 5.2. *Consider a point* $z \notin \Lambda (A)$. *Let* $\epsilon = \underline{\sigma}^e (A, z)$. *Then the following are equivalent:*

(1) z *is not resolvent-critical for* A.
(2) Λ_ϵ^c *has the Aubin property at* A *for* z.
(3) Λ_ϵ *has the Aubin property at* A *for* z.

Proof. For the purposes of the proof, we introduce several other properties:

(4) $(M^n \times \{0\}) \cap N_{\operatorname{gph} \Lambda_\epsilon^c} (A, z) = \{0\}$.
(5) $D^* \Lambda_\epsilon^c (A \mid z) (0) = \{0\}$.
(6) $(M^n \times \{0\}) \cap N_{\operatorname{gph} \Lambda_\epsilon} (A, z) = \{0\}$.
(7) $D^* \Lambda_\epsilon (A \mid z) (0) = \{0\}$.

Properties (4) and (5) are equivalent because $\alpha \in D^* \Lambda_\epsilon^c (A \mid z) (\beta)$ if and only if $(\alpha, -\beta) \in N_{\operatorname{gph} \Lambda_\epsilon^c} (A, z)$ by the definition of coderivatives [21, Definition 8.33].

Properties (5) and (2) are equivalent by the Mordukhovich Criterion [21, Theorem 9.40]. The same goes for properties (6), (7), and (3).

Next, we show the equivalence of properties (1) and (4). We apply Proposition 5.1 to reduce property (4) to

$$(M^n \times \{0\}) \cap \operatorname{pos conv} \left\{ \left(-uv^H, v^H u\right) \mid (u,v) \in MSV\,(A - zI) \right\} = \{0\}\,.$$

$(1 \Rightarrow 4)$ Suppose that z is not resolvent-critical, that is, $0 \notin Y\,(A - zI)$, and yet property (4) fails. Then there is some nonzero pair with second coordinate (the one in $\mathbb{C}$) zero lying in

$$\operatorname{pos conv} \left\{ \left(-uv^H, v^H u\right) \mid (u,v) \in MSV\,(A - zI) \right\}.$$

This means that there is a convex combination of pairs $\left(-uv^H, v^H u\right)$ such that their second coordinate is zero. Then $0 \in Y\,(A - zI)$ (appealing to Proposition 3.4), a contradiction.

$(1 \Leftarrow 4)$ If property (1) fails, there are minimal left and right singular vectors u, v such that $v^H u = 0$, and then $\left(-uv^H, v^H u\right)$ is a nonzero element in

$$(M^n \times \{0\}) \cap \operatorname{pos conv} \left\{ \left(-uv^H, v^H u\right) \mid (u,v) \in MSV\,(A - zI) \right\}.$$

So we have proved the equivalence of properties (1) and (4). We proceed to prove the equivalence of properties (1) and (6). We lose regularity, but nevertheless, the proof still looks similar.

$(1 \Rightarrow 6)$ We prove $(4 \Rightarrow 6)$. If $0 \notin Y\,(A - zI)$, then $(M^n \times \{0\}) \cap N_{\operatorname{gph} \Lambda_\epsilon^c}\,(A, z) = \{0\}$. But Proposition 5.1 gives

$$\begin{aligned} \{0\} &\subset (M^n \times \{0\}) \cap N_{\operatorname{gph} \Lambda_\epsilon}\,(A, z) \\ &\subset (M^n \times \{0\}) \cap -N_{\operatorname{gph} \Lambda_\epsilon^c}\,(A, z) \\ &= \{0\}\,. \end{aligned}$$

$(1 \Leftarrow 6)$. If property (1) fails, there are minimal left and right singular vectors u, v such that $v^H u = 0$, and thus $\left(uv^H, -v^H u\right)$ is a nonzero element in $(M^n \times \{0\}) \cap N_{\operatorname{gph} \Lambda_\epsilon}\,(A, z)$. ∎

When we consider fixing the matrix A and increasing ϵ, it is natural to ask whether the map $\epsilon \mapsto \Lambda_\epsilon\,(A)$ is Lipschitz.

PROPOSITION 5.3. *Given $z \in \mathbb{C}$, the map $\epsilon \mapsto \Lambda_\epsilon\,(A)$ has the Aubin property at $\underline{\sigma}_A\,(z)$ for z if and only if $0 \notin \partial \underline{\sigma}_A\,(z)$, whereas the map $\epsilon \mapsto \Lambda_\epsilon^c\,(A)$ has the Aubin property at $\underline{\sigma}_A\,(z)$ for z if and only if $0 \notin \partial\,(-\underline{\sigma}_A)\,(z)$ (or equivalently, assuming $z \notin \Lambda\,(A)$, z is not resolvent-critical for A).*

Proof. A straightforward application of [21, Theorem 9.41(b)] on $\underline{\sigma}_A$ gives us $0 \notin \partial \underline{\sigma}_A\,(z)$ if and only if the map $\epsilon \mapsto \operatorname{lev}_{\leq \epsilon} \underline{\sigma}_A = \Lambda_\epsilon\,(A)$ has the Aubin property at ϵ for z, which is the first part of what we seek to prove. The second part is similar, using Proposition 4.5. ∎

A particular example worked out in full detail exploiting this is highlighted in [6].

It is natural to ask whether there are any differences between Theorem 5.2 and the two parts of Proposition 5.3, and it comes down to comparing $\partial\,(-\underline{\sigma}_A)$ and $\partial \underline{\sigma}_A$. In general, if z is not an eigenvalue of A,

$$-\partial \underline{\sigma}_A\,(z) \subset \partial\,(-\underline{\sigma}_A)\,(z) = Y\,(A - zI)$$

by Proposition 4.5 and [21, Corollary 9.21], but the inclusion can be strict. Consider the matrix $\bar{A} = \operatorname{diag}(1, -1, i, -i)$ in Example 2.6. Here,

$$\partial\left(-\underline{\sigma}_{\bar{A}}\right)(0) = \{a + bi \mid |a| + |b| \leq 1\},$$

so 0 is resolvent-critical while $\partial\underline{\sigma}_{\bar{A}}(0) = \{1, -1, i, -i\}$.

6. Lipschitz continuity of pseudospectra. The results in the last section study the Aubin property of the pseudospectra Λ_ϵ. The next natural step is to evaluate the graphical modulus and investigate the Lipschitz continuity of Λ_ϵ.

If $\underline{\sigma}(A - zI) = \epsilon > 0$, then from Proposition 5.1 and the definition of the coderivative, we can deduce the formula for $D^*\Lambda_\epsilon^c(A \mid z)(c)$. To keep the expressions compact, we understand that (u_i, v_i) ranges over $MSV(A - zI)$ whenever u_i, v_i appear in the formulas below. We have

$$\begin{aligned}
&D^*\Lambda_\epsilon^c(A \mid z)(c)\\
&= \left\{-k\sum_i \lambda_i u_i v_i^H \mid c = -k\sum_i \lambda_i v_i^H u_i, \sum_i \lambda_i = 1, \lambda_i \geq 0, k \geq 0\right\}\\
&= \begin{cases} \left\{c\frac{\sum_i \lambda_i u_i v_i^H}{\sum_i \lambda_i v_i^H u_i} \mid \sum_i \lambda_i v_i^H u_i \neq 0\right\} & \text{if } c \neq 0,\\ \operatorname{pos}\left\{\sum_i \lambda_i u_i v_i^H \mid \sum_i \lambda_i v_i^H u_i = 0\right\} & \text{if } c = 0, \end{cases}
\end{aligned}$$

and

$$\begin{aligned}
&D^*\Lambda_\epsilon(A \mid z)(c)\\
&= \left\{kuv^H \mid c = kv^H u, k \geq 0, (u, v) \in MSV(A - zI)\right\}\\
&= \begin{cases} \left\{c\frac{uv^H}{v^H u} \mid (u, v) \in MSV(A - zI), v^H u \neq 0\right\} & \text{if } c \neq 0,\\ \operatorname{pos}\left\{uv^H \mid (u, v) \in MSV(A - zI), v^H u = 0\right\} & \text{if } c = 0. \end{cases}
\end{aligned}$$

We can then calculate the graphical moduli for Λ_ϵ and Λ_ϵ^c in the theorem below.

THEOREM 6.1. *We have the following graphical moduli:*

$$\operatorname{lip}\Lambda_\epsilon(A \mid z) = \begin{cases} 1/d(0, Y(A - zI)) & \text{if } \underline{\sigma}(A - zI) = \epsilon,\\ 0 & \text{if } \underline{\sigma}(A - zI) < \epsilon, \end{cases}$$

$$\operatorname{lip}\Lambda_\epsilon^c(A \mid z) = \begin{cases} 1/d(0, Y(A - zI)) & \text{if } \underline{\sigma}(A - zI) = \epsilon,\\ 0 & \text{if } \underline{\sigma}(A - zI) > \epsilon. \end{cases}$$

(Here, we interpret $1/0 = +\infty$*.)*

Proof. It is clear that if $\underline{\sigma}(A - zI) < \epsilon$, then (A, z) lies in the interior of $\operatorname{gph}\Lambda_\epsilon$, so $N_{\operatorname{gph}\Lambda_\epsilon}(A, z) = \{(0, 0)\}$, and so

$$\operatorname{lip}\Lambda_\epsilon(A \mid z) = |D^*\Lambda_\epsilon(A \mid z)|^+ = 0.$$

Similarly, $\operatorname{lip}\Lambda_\epsilon^c(A \mid z) = 0$ if $\underline{\sigma}(A - zI) > \epsilon$.

If $\underline{\sigma}(A - zI) = \epsilon$ and $0 \in Y(A - zI)$, then Λ_ϵ and Λ_ϵ^c do not have the Aubin property at A for z, and so

$$\operatorname{lip}\Lambda_\epsilon(A \mid z) = \operatorname{lip}\Lambda_\epsilon^c(A \mid z) = \infty.$$

By the Mordukhovich criterion [21, Theorem 9.40] and the definition of outer norms [21, Section 9D], we have $\operatorname{lip}\Lambda_\epsilon^c(A \mid z)$ to be

$$\sup_{c \neq 0} \sup_{d \in D^*\Lambda_\epsilon^c(A|z)(c)} \frac{\|d\|}{|c|},$$

or, in other words, the infimum of all κ such that

$$d \in D^* \Lambda_\epsilon^c (A \mid z)(c) \implies \|d\| \leq \kappa |c|. \tag{6.1}$$

In view of the formula for $D^* \Lambda_\epsilon^c (A \mid z)$, formula (6.1) is equivalent to

$$\left\| \sum \lambda_i u_i v_i^H \right\| \leq \kappa \left| \sum \lambda_i v_i^H u_i \right| \tag{6.2}$$

for all $(u_i, v_i) \in MSV(A - zI), \lambda_i \geq 0, \sum \lambda_i = 1$. To prove that $\operatorname{lip} \Lambda_\epsilon^c (A \mid z) = 1/d(0, Y(A - zI))$, it remains to prove that formula (6.2) is equivalent to

$$\kappa \geq 1/d(0, Y(A - zI)). \tag{6.3}$$

Suppose that κ satisfies formula (6.2). Then for $y \in Y(A - zI)$, we have some $(u, v) \in MSV(A - zI)$ such that $y = v^H u$. Then

$$\begin{aligned} \kappa |y| &= \kappa \left| v^H u \right| \\ &\geq \left\| u v^H \right\| \\ &= 1. \end{aligned}$$

Formula (6.3) follows. Next, suppose that κ satisfies formula (6.3). If $(u_i, v_i) \in MSV(A - zI)$, $\lambda_i \geq 0$ and $\sum \lambda_i = 1$, we have $\sum \lambda_i v_i^H u_i \in Y(A - zI)$ by the convexity of $Y(A - zI)$. Thus

$$\begin{aligned} \left\| \sum \lambda_i u_i v_i^H \right\| &\leq \sum \lambda_i \left\| u_i v_i^H \right\| \\ &= 1 \\ &\leq \kappa \left| \sum \lambda_i v_i^H u_i \right|. \end{aligned}$$

Formula (6.2) follows, and so $\operatorname{lip} \Lambda_\epsilon^c (A \mid z) = 1/d(0, Y(A - zI))$. Similar and simpler calculations give us $\operatorname{lip} \Lambda_\epsilon (A \mid z) = 1/d(0, Y(A - zI))$. ∎

We next turn to the Lipschitz constant for the pseudospectral mapping Λ_ϵ. We want to find $\operatorname{lip}_\infty \Lambda_\epsilon (\bar{A})$, the Lipschitz modulus of the pseudospectral map at $\bar{A}$. For a set-valued map $S : \mathbb{R}^n \rightrightarrows \mathbb{R}^m$, we are able to calculate $\operatorname{lip}_\infty S(\bar{x})$ from the graphical modulus easily with the following formula.

PROPOSITION 6.2 (see [20, Theorem 1.42]). *If $S : \mathbb{R}^n \rightrightarrows \mathbb{R}^m$ is outer semicontinuous and S is locally bounded at $\bar{x}$, then*

$$\operatorname{lip}_\infty S(\bar{x}) = \max_{y \in S(\bar{x})} \operatorname{lip} S(\bar{x} \mid y).$$

Thus the Lipschitz constants for Λ_ϵ are easily obtained.

PROPOSITION 6.3. *The following expressions are equal:*

(i) $\operatorname{lip}_\infty \Lambda_\epsilon (A)$,

(ii) $\max_{z \in \Lambda_\epsilon(A)} \{\operatorname{lip} \Lambda_\epsilon (A \mid z)\}$,

(iii) $\max_{z : \underline{\sigma}(A - zI) = \epsilon} \{1/d(0, Y(A - zI))\}$,

(iv) $\max_z \left\{ 1/\left| v^H u \right| \mid (u, v) \in MSV(A - zI), \underline{\sigma}(A - zI) = \epsilon \right\}$.

Proof. The expressions (i) and (ii) are equal by Proposition 6.2 and the fact that Λ_ϵ is compact and locally bounded. Then expressions (ii) and (iii) are equal by Theorem 6.1, and expression (iv) is just an expansion of the definition of $Y(\cdot)$ applied to expression (iii). ∎

7. Pseudospectral abscissa and pseudospectral radius. In this section we apply our results on Lipschitz continuity of pseudospectra to reexplore earlier work on the pseudospectral abscissa and pseudospectral radius in [4, 5, 19, 22].

DEFINITION 7.1. *Define the* ϵ-pseudospectral abscissa $\alpha_\epsilon : M^n \to \mathbb{R}$ *by*

$$\alpha_\epsilon(A) = \max_{z \in \Lambda_\epsilon(A)} \operatorname{Re}(z),$$

and the ϵ-pseudospectral radius $\rho_\epsilon : M^n \to \mathbb{R}_+$ *by*

$$\rho_\epsilon(A) = \max_{z \in \Lambda_\epsilon(A)} |z|.$$

Note that if $\epsilon > 0$, then $\rho_\epsilon(A) > 0$. We shall establish the continuity properties of α_ϵ and ρ_ϵ. We begin with another routine piece of theory on parametric minimization.

COROLLARY 7.2 (to [21, Corollary 10.14]). *Suppose that* $F : \mathbb{R}^m \rightrightarrows \mathbb{R}^n$ *is outer semicontinuous and maps to compact sets. Define* $p : \mathbb{R}^m \to \mathbb{R}$ *and* $P : \mathbb{R}^m \rightrightarrows \mathbb{R}^n$ *below by*

$$p(u) = \min_{x \in F(u)} g(x), \quad P(u) = \arg\min_{x \in F(u)} g(x),$$

where the lower semicontinuous function $g : \mathbb{R}^n \to \mathbb{R}$ *is differentiable at all points in* $P(\bar{u})$ *for some given* $\bar{u} \in \mathbb{R}^m$*. Then* p *is*

(a) *Lipschitz continuous around* $\bar{u}$ *if* F *has the Aubin property at* $\bar{u}$ *for* $\bar{x}$ *for all* $\bar{x} \in P(\bar{u})$*, with*

$$\operatorname{lip} p(\bar{u}) \le \max\{|y| : y \in S\} < \infty,$$

where $S = \{y \mid \bar{x} \in P(\bar{u}), y \in D^*F(\bar{u} \mid \bar{x})(\nabla g(\bar{x}))\}$*;*

(b) *strictly differentiable at* $\bar{u}$ *with* $\nabla p(\bar{u}) = \bar{y}$ *if* $S = \{\bar{y}\}$.

Proof. Let $f : \mathbb{R}^n \times \mathbb{R}^m \to \bar{\mathbb{R}}$ be defined by

$$f(x,u) = \delta_{\operatorname{gph} F}(u,x) + g(x) = \begin{cases} g(x) & \text{if } x \in F(u), \\ \infty & \text{otherwise.} \end{cases}$$

Then

$$p(u) = \inf_x f(x,u), \quad P(u) = \arg\min_x f(x,u).$$

Since F is outer semicontinuous, $\operatorname{gph} F$ is closed, so f is proper and lower semicontinuous.

Next, we prove f is level bounded in x locally uniformly in u. That is, for each $\bar{u} \in \mathbb{R}^m$ and $\alpha \in \mathbb{R}$, there is a neighborhood V of $\bar{u}$ along with a bounded set $B \subset \mathbb{R}^n$ such that $\{x \mid f(x,u) \le \alpha\} \subset B$ for all $u \in V$. Note that $f(x,u) \le \alpha$ means that $x \in F(u)$ and $g(x) \le \alpha$. Since F is outer semicontinuous, choose V such that $F(u) \subset F(\bar{u}) + \mathbb{B}$ for all $u \in V$, by the characterization of outer semicontinuity in [21, Proposition 5.12]. The set B can be chosen to be $F(\bar{u}) + \mathbb{B}$, and we are done.

Following the notation in [21, Corollary 10.13], for any $\bar{x} \in P(\bar{u})$,

$$\begin{aligned} M(\bar{x},\bar{u}) &:= \{y \mid (0,y) \in \partial f(\bar{x},\bar{u})\} \\ &= \{y \mid (y,0) \in \partial \delta_{\operatorname{gph} F}(\bar{u},\bar{x}) + \{(0, \nabla g(\bar{x}))\}\} \\ &\qquad \text{(by [21, Exercise 8.8(c)])} \\ &= \{y \mid (y, -\nabla g(\bar{x})) \in N_{\operatorname{gph} F}(\bar{u},\bar{x})\} \\ &\qquad \text{(by [21, Exercise 8.14])} \\ &= D^*F(\bar{u} \mid \bar{x})(\nabla g(\bar{x})) \\ &\qquad \text{(by [21, Definition 8.33]).} \end{aligned}$$

Also,

$$\begin{aligned} M_\infty(\bar{x},\bar{u}) &:= \{y \mid (0,y) \in \partial^\infty f(\bar{x},\bar{u})\} \\ &= \{y \mid (y,0) \in \partial^\infty \delta_{\mathrm{gph} F}(\bar{u},\bar{x})\} \\ &= \{y \mid (y,0) \in N_{\mathrm{gph}\, F}(\bar{u},\bar{x})\} \\ &= D^* F(\bar{u} \mid \bar{x})(0). \end{aligned}$$

This means that $Y_\infty(\bar{u}) := \bigcup_{\bar{x}\in P(\bar{u})} M_\infty(\bar{x},\bar{u}) = \{0\}$, so part (a) of [21, Corollary 10.14] applies. Furthermore, $Y(\bar{u})$, where $Y(\cdot)$ is defined in [21, Corollary 10.13], is

$$\begin{aligned} Y(\bar{u}) &:= \bigcup_{\bar{x}\in P(\bar{u})} M(\bar{x},\bar{u}) \\ &= \bigcup_{\bar{x}\in P(\bar{u})} D^* F(\bar{u} \mid \bar{x})(\nabla g(\bar{x})), \end{aligned}$$

and so

$$\begin{aligned} \mathrm{lip}\, p(\bar{u}) &\le \max_{y\in Y(\bar{u})} |y| \\ &= \max\{|y| : \bar{x} \in P(\bar{u}), y \in D^* F(\bar{u} \mid \bar{x})(\nabla g(\bar{x}))\} < \infty. \end{aligned}$$

The rest of the claim follows by [21, Corollary 10.14]. □

The continuity of α_ϵ and ρ_ϵ can be proved by the following proposition when the conditions for Lipschitz continuity are absent. The proof is routine.

PROPOSITION 7.3. *Suppose that $F : \mathbb{R}^m \rightrightarrows \mathbb{R}^n$ is continuous and maps to compact sets. If p, P, and g are defined as in Corollary 7.2 with g continuous, then p is continuous and P is outer semicontinuous.*

As a consequence of Corollary 7.2, we obtain the following result.

COROLLARY 7.4. *The pseudospectral abscissa α_ϵ and pseudospectral radius ρ_ϵ are Lipschitz continuous at a matrix A if $\mathrm{lip}_\infty \Lambda_\epsilon(A) < \infty$, with Lipschitz constants bounded above by $\mathrm{lip}_\infty \Lambda_\epsilon(A)$.*

Proof. Following the notation in Corollary 7.2, take $F = \Lambda_\epsilon$ and $g(x) = \langle -1, x\rangle$. Then $\alpha_\epsilon = -p$, and we obtain

$$\begin{aligned} \mathrm{lip}\, \alpha_\epsilon(A) &\le \max\{|y| : y \in D^*\Lambda_\epsilon(A \mid z)(-1) \\ &\qquad , z \in \Lambda_\epsilon(A), \mathrm{Re}(z) = \alpha_\epsilon(A)\} \\ &= \max\{1/d(0, \mathbb{R}_- \cap Y(A - zI)) : \\ &\qquad z \in \Lambda_\epsilon(A), \mathrm{Re}(z) = \alpha_\epsilon(A)\} \end{aligned}$$

using our derivative computation before Theorem 6.1. If we take $g(x) = -|x|$ instead, then $\rho_\epsilon = -p$, and

$$\begin{aligned} \mathrm{lip}\, \rho_\epsilon(A) &\le \max\left\{|y| : y \in D^*\Lambda_\epsilon(A \mid z)\left(-\frac{z}{|z|}\right), \right. \\ &\qquad \left. z \in \Lambda_\epsilon(A), |z| = \rho_\epsilon(A)\right\} \\ &= \max\left\{1/d\left(0, \mathbb{R}_+\left(\frac{z}{|z|}\right) \cap Y(A - zI)\right) : \right. \\ &\qquad \left. z \in \Lambda_\epsilon(A), |z| = \rho_\epsilon(A)\right\}. \end{aligned}$$

The upper bounds for lip $\alpha_\epsilon(A)$ and lip $\rho_\epsilon(A)$ obtained above are both not greater than $\text{lip}_\infty \Lambda_\epsilon(A)$ by Proposition 6.3, and so we are done. ∎

8. Resolvent-critical points. Resolvent-critical points are crucial throughout our analysis. They are also, for example, explicitly excluded in the analysis of the quadratic convergence of the algorithm for finding the pseudospectral abscissa in [5]. We investigate their properties further.

PROPOSITION 8.1. *All resolvent-critical points lie in the numerical range of A.*

Proof. Suppose that z is resolvent-critical. Then there exists a right singular vector v of $(A - zI)$ such that $v^H(A - zI)v = 0$, which implies that $v^H Av = zv^H v = z$ if $|v| = 1$. This means that z lies in the numerical range of A. ∎

PROPOSITION 8.2. *For ϵ large enough such that $\Lambda_\epsilon(A)$ contains the numerical range of A, $W(A)$, in its interior, the map $\Lambda_\epsilon : M^n \rightrightarrows \mathbb{C}$ is strictly continuous at A for any point in $\Lambda_\epsilon(A)$, and thus Lipschitz continuous at a neighborhood of A. For α_ϵ and ρ_ϵ to be Lipschitz continuous, we just need the interior of* $\operatorname{conv}\Lambda_\epsilon(\mathrm{A})$ *to contain $W(A)$.*

Proof. For the first part, if $\Lambda_\epsilon(A)$ contains $W(A)$ in its interior, then the points in the boundary of Λ_ϵ are not resolvent-critical by the previous result. Apply Proposition 6.3.

For the second part, by the proof of Corollary 7.4, it suffices to show that if z satisfies $\text{Re}\, z = \alpha_\epsilon(A)$ and $\underline{\sigma}(A - zI) = \epsilon$, then $z \notin W(A)$. But if z satisfies these conditions, then $z \in \operatorname{conv}\Lambda_\epsilon(A)$. The same goes for ρ_ϵ. ∎

Remark 8.3. In Table 3 in page 1061, the third example of a 5×5 matrix illustrates that a resolvent-critical can lie outside the convex hull of the spectrum of A. There is a resolvent-critical point close to 0, but the convex hull of the eigenvalues is just $\{-1\}$.

With all that we have done so far, the following is a natural consequence of [3, Corollary 8].

COROLLARY 8.4 (to [3, Corollary 8]). *Given a matrix A, the set of resolvent-critical values $\{\underline{\sigma}_A(z) \mid z$ resolvent critical for $A\}$ is finite.*

Proof. This is just the (semialgebraic) set of Clarke-critical values of $\underline{\sigma}_A$ by Theorem 4.9, which is finite by [3, Corollary 8]. ∎

With the above result, we arrive at the following appealing result.

COROLLARY 8.5. *Given a matrix A, the mappings Λ_ϵ, α_ϵ, and ρ_ϵ are Lipschitz around A for all but finitely many $\epsilon \geq 0$, so, in particular, for all small $\epsilon > 0$.*

Proof. This is a direct consequence of Theorem 5.2 and Corollaries 8.4 and 7.4. ∎

Remark 8.6. The conditions that guarantee Lipschitz continuity of the pseudospectral abscissa α_ϵ in the result above are much more general than the conditions in [4, Corollary 8.3]. Firstly, we do not need the assumption that active eigenvalues are nonderogatory made in [4, Corollary 8.3], and our current result holds for all but finitely many ϵ.

Here is another general observation on resolvent-critical points.

THEOREM 8.7. *For a fixed A, the set of resolvent-critical points is compact, semialgebraic with empty interior, and contains eigenvalues as isolated points.*

Proof. Denote the set of resolvent-critical points by S_A. The set S_A is bounded by Proposition 8.1. It is clear that S_A is semialgebraic. As $\underline{\sigma}_A$ is Lipschitz, $\partial^\circ(-\underline{\sigma}_A)$ has closed graph by [9, Proposition 2.1.5(b)], and thus S_A is closed.

Suppose that S_A does not have empty interior. Note that $\underline{\sigma}_A$ has to be constant on a component by Corollary 8.4, and this would mean that $\underline{\sigma}_A$ is constant on a set of

nonempty interior, which contradicts the fact that $\underline{\sigma}_A$ cannot have minimizers other than at the eigenvalues of A [4, Theorem 4.2]. Thus S_A has empty interior.

Lastly, S_A can be written as a union of curves and points in $\mathbb{C}$. If an eigenvalue, say $\bar{z}$, is not an isolated point in S_A, then it is on some curve. This would mean that $\underline{\sigma}_A$ is zero on a curve, which contradicts the fact that $\underline{\sigma}_A$ is zero only on the set of eigenvalues, which is a finite set. Thus all eigenvalues are isolated in S_A. ∎

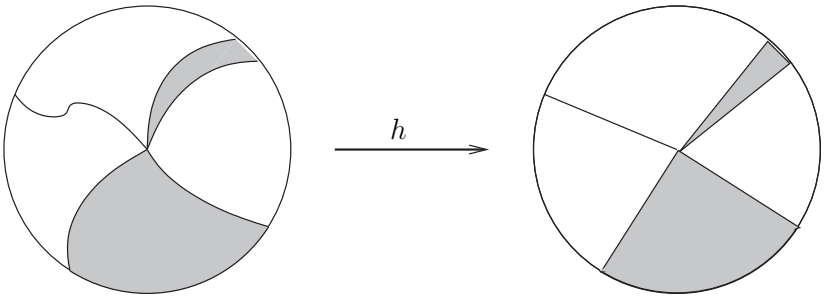
We call $\Lambda'_\epsilon(A) = \{z \mid \underline{\sigma}(A - zI) < \epsilon\}$ the *strict pseudospectrum* of A. The set $\Lambda'_\epsilon(A)$ consists of at most n components (since each component must contain an eigenvalue [22]), and the number of components is clearly a decreasing function of ϵ. There will be some points $\bar{z} \in \mathbb{C}$ where some components meet as ϵ increases. If $\Lambda'_\epsilon(A)$ has n components and $\bar{z}$ lies on the boundary of two components of $\Lambda'_\epsilon(A)$, then the distance between A and the set of matrices with repeated eigenvalues is ϵ and is attained by some matrix $\bar{A}$ having $\bar{z}$ as a repeated eigenvalue (see [1, Theorem 5.1]): It turns out that such points are resolvent-critical as the next theorem will show, generalizing [1, Proposition 4.10].

THEOREM 8.8. *If $\bar{z}$ is a common boundary point of two or more distinct components of $\Lambda'_\epsilon(A)$, then $\bar{z}$ is a resolvent-critical point.*

Proof. To reduce notation, let us assume that $\bar{z} = 0$. The rest of the proof will follow by a translation. We look at the structure of $\Lambda_\epsilon(A)$ around 0, where $\epsilon > 0$. Since $\Lambda_\epsilon(A)$ is semialgebraic, $\Lambda_\epsilon(A)$ is locally conic about 0 by [11, Theorem 4.10]. That is, there is an $r > 0$ and a semialgebraic homeomorphism

$$h : \Lambda_\epsilon(A) \cap r\mathbb{B} \to [0,1](\Lambda_\epsilon(A) \cap r(\text{bdry } \mathbb{B}))$$

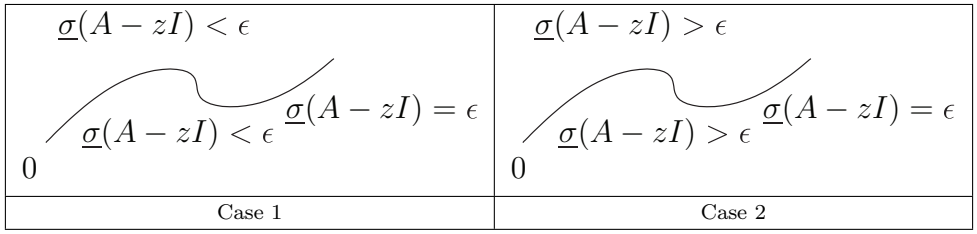
between the two spaces. Since $(\Lambda_\epsilon(A) \cap r(\text{bdry } \mathbb{B}))$ is a finite union of arcs, it follows that the boundary of $\Lambda_\epsilon(A) \cap r\mathbb{B}$ would consist of curves which start from 0 and end at somewhere on $r(\text{bdry } \mathbb{B})$. The diagram below illustrates this.



We use a proof by contradiction. Suppose that 0 is not resolvent-critical. Then $0 \notin Y(A)$, and by Proposition 4.12, $\Lambda^c_\epsilon(A)$ is Clarke regular at 0, with normal cone $N_{\Lambda^c_\epsilon(A)}(0) = \mathbb{R}_+ Y(A)$. Note that $N_{\Lambda^c_\epsilon(A)}(0)$ is pointed, otherwise $0 \in Y(A)$, contradicting the assumption that 0 is not resolvent-critical.

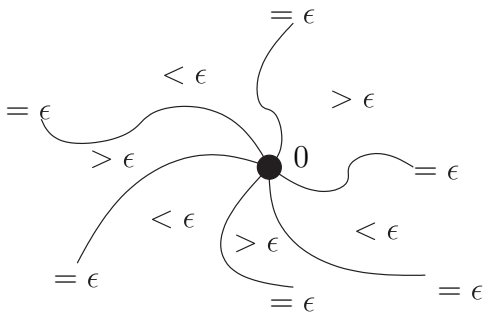
The set $\{z \mid \underline{\sigma}(A - zI) = \epsilon\}$ is semialgebraic and has empty interior since the only local minimizers of $\underline{\sigma}_A$ are eigenvalues of A [4, Theorem 4.2], and so it is a union of smooth curves. We now prove that the curves are boundaries of both $\Lambda_\epsilon(A)$ and $\Lambda^c_\epsilon(A)$. By considering the sign of $\underline{\sigma}_A - \epsilon$ on either side of such a curve, we distinguish three cases. In the following diagram, both Case 1 and Case 2 cannot hold, because the local maxima and local minima of $\underline{\sigma}_A$ are resolvent-critical, and this would make 0

resolvent-critical as well, since the set of resolvent-critical points is closed by Theorem 8.7.

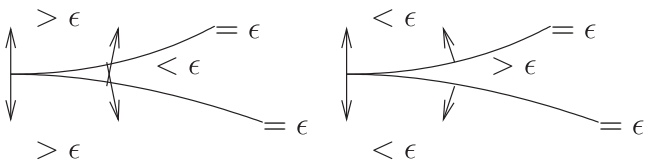


Case 1 | Case 2

Therefore, the general diagram would be as below, with the value of $\underline{\sigma}_A$ alternating above and below ϵ as we circle the origin, crossing the curves where $\underline{\sigma}_A = \epsilon$.



Two different arcs cannot be tangent at 0 since $N_{\Lambda_\epsilon^c(A)}(0)$ will otherwise not be pointed, as the diagrams below show.



Since $\Lambda_\epsilon^c(A)$ is Clarke regular at 0, its tangent cone $T_{\Lambda_\epsilon^c(A)}(0)$ is convex, so the picture above can contain only one sector where $\underline{\sigma}_A > \epsilon$. It now follows that 0 cannot be the boundary point of two components of $\Lambda_\epsilon'(A)$. This completes the proof. ∎

If we can prove the following about the pseudospectral abscissa α_ϵ, then we can conclude that the pseudospectral abscissa is Lipschitz continuous.

CONJECTURE 8.9. *The points where the pseudospectral abscissa α_ϵ are attained are not resolvent-critical.*

A natural question to ask after Theorem 8.7 is the following.

CONJECTURE 8.10. *The number of resolvent-critical points is finite.*

Acknowledgments. We wish to thank Michael Overton for discussions about much of section 8, in particular, leading to Corollary 8.5. We also thank Diethard Klatte and two anonymous referees for a wide range of comments and suggestions, which greatly improved the article.

ON THE SECOND-ORDER FEASIBILITY CONE: PRIMAL-DUAL REPRESENTATION AND EFFICIENT PROJECTION*

ALEXANDRE BELLONI† AND ROBERT M. FREUND‡

Abstract. We study the second-order feasibility cone $\mathcal{F} = \{y \in \mathbb{R}^n : \|My\| \le g^T y\}$ for given data (M, g). We construct a new representation for this cone and its dual based on the spectral decomposition of the matrix $M^T M - gg^T$. This representation is used to efficiently solve the problem of projecting an arbitrary point $x \in \mathbb{R}^n$ onto $\mathcal{F}$: $\min_y\{\|y - x\| : \|My\| \le g^T y\}$, which aside from theoretical interest also arises as a necessary subroutine in the rescaled perceptron algorithm. We develop a method for solving the projection problem to an accuracy ε, whose computational complexity is bounded by $O(mn^2 + n \ln\ln(1/\varepsilon) + n \ln\ln(1/\min\{\text{width}(\mathcal{F}), \text{width}(\mathcal{F}^*)\}))$ operations. Here $\text{width}(\mathcal{F})$ and $\text{width}(\mathcal{F}^*)$ denote the width of $\mathcal{F}$ and $\mathcal{F}^*$, respectively. We also perform computational tests that indicate that the method is extremely efficient in practice.

1. Introduction and main results. Our notation is as follows: let K^* denote the dual of a convex cone $K \subset \mathbb{R}^k$, i.e., $K^* := \{z \in \mathbb{R}^k : z^T y \ge 0 \text{ for all } y \in K\}$. A convex cone K is *regular* if it is closed, has nonempty interior, and contains no lines, in which case K^* is also regular; see Rockafellar [7]. Define the standard second-order cone in $\mathbb{R}^k$ to be $\mathcal{Q}^k := \{y \in \mathbb{R}^k : \|(y_1, \ldots, y_{k-1})\| \le y_k\}$, where $\|\cdot\|$ denotes the Euclidean norm. Let $B(y, r)$ denote the Euclidean ball of radius r centered at y.

Given data $(M, g) \in (\mathbb{R}^{m\times n}, \mathbb{R}^n)$, our interest lies in the second-order feasibility cone

$$\mathcal{F} := \left\{y \in \mathbb{R}^n : \|My\| \le g^T y\right\} = \left\{y \in \mathbb{R}^n : \left(My, g^T y\right) \in \mathcal{Q}^{m+1}\right\}$$

and its dual cone $\mathcal{F}^*$.

We first take care of some trivial cases. When $\text{rank}(M) = 0$, it follows trivially that $\mathcal{F} = \{y \in \mathbb{R}^n : g^T y \ge 0\}$, whereby $\mathcal{F}$ is either a half-space or all of $\mathbb{R}^n$, depending on whether $g \ne 0$ or $g = 0$, respectively. When $\text{rank}(M) = 1$, $M = fc^T$ for some f, c, and $\|My\| = \|f\|\|c^T y|$ for any y. This implies that $\mathcal{F} = \{y \in \mathbb{R}^n : (g - \|f\|c)^T y \ge 0,\ (g + \|f\|c)^T y \ge 0\}$, and hence $\mathcal{F}$ is the intersection of either one or two half-spaces. We dispose of these trivial cases by making the following assumption about the data.

Assumption 1. $\text{rank}(M) \ge 2$ and $g \ne 0$.

We now describe our main representation result for $\mathcal{F}$ and $\mathcal{F}^*$. It is elementary to establish that $M^T M - gg^T$ has at most one negative eigenvalue, and we can write its eigendecomposition as $M^T M - gg^T = QDQ^T$, where Q is orthonormal ($Q^{-1} = Q^T$) and D is the diagonal matrix of eigenvalues. For notational convenience we denote D_i and Q_i as the ith diagonal component of D and the ith column of Q, respectively. By

reordering the columns of Q, we can presume that $D_1 \geq \cdots \geq D_n$ and $D_1, \ldots, D_{n-1} \geq 0$. By choosing either Q_n or $-Q_n$, we can further presume that $g^T Q_n \geq 0$. We implicitly assume Q and D can be computed to within machine precision (in the relative sense) in $O(mn^2)$ operations, consistent with computational practice.

Our interest lies mainly in the case when $\mathcal{F}$ is a regular cone, so we will hypothesize that $\mathcal{F}$ is a regular cone for the remainder of this section. This hypothesis implies that $n-1 \leq \text{rank}(M) \leq \min\{n, m\}$. (We indicate how to amend our results and proofs to relax this hypothesis at the end of sections 2 and 3.) Our main representation result is as follows.

THEOREM 1. *Suppose that $\mathcal{F}$ is a regular cone. Then $D_1, \ldots, D_{n-1} > 0 > D_n$, and*

(i) $\mathcal{F} = \{y : y^T Q D Q^T y \leq 0,\ y^T Q_n \geq 0\}$;
(ii) $\mathcal{F}^* = \{z : z^T Q D^{-1} Q^T z \leq 0,\ z^T Q_n \geq 0\}$;
(iii) *if $y \in \mathcal{F}$ and $\alpha \geq 0$, then $z := -\alpha Q D Q^T y \in \mathcal{F}^*$. Furthermore, if $y \in \partial\mathcal{F}$, then $z \in \partial\mathcal{F}^*$ and $z^T y = 0$;*
(iv) *if $z \in \mathcal{F}^*$ and $\alpha \geq 0$, then $y := -\alpha Q D^{-1} Q^T z \in \mathcal{F}$. Furthermore, if $z \in \partial\mathcal{F}^*$, then $y \in \partial\mathcal{F}$ and $z^T y = 0$.*

Note that (i) and (ii) of Theorem 1 describe easily computable representations of $\mathcal{F}$ and $\mathcal{F}^*$ that have the same computational structure, in that checking membership in each cone uses similar data, operations, etc., in a manner that is symmetric between the dual cones. Parts (iii) and (iv) indicate that the same matrices in (i) and (ii) can be used constructively to map points on the boundary of one cone to their orthogonal counterpart in the dual cone.

Remark 1 (geometry of $\mathcal{F}$ and $\mathcal{F}^*$). Examining (i) and the property that $D_n < 0$, the orthonormal transformation $y \to s := Q^T y$ maps $\mathcal{F}$ onto the axes-aligned ellipsoidal cone $\mathcal{S} := \{s \in \mathbb{R}^n : \sqrt{\sum_{j=1}^{n-1} D_i s_i^2} \leq \sqrt{|D_n|} s_n\}$ so that $\mathcal{F}$ is the image of $\mathcal{S}$ under Q, $\mathcal{F} = \{y : \sqrt{\sum_{i=1}^{n-1} D_i (Q_i^T y)^2} \leq \sqrt{|D_n|} Q_n^T y\}$, and $\mathcal{F}^* = \{z : \sqrt{\sum_{i=1}^{n-1} (1/D_i)(Q_i^T z)^2} \leq \sqrt{1/|D_n|} Q_n^T z\}$. This establishes that $\mathcal{F}$ is indeed simply an ellipsoidal cone whose axes are the eigenvectors of Q with dilations corresponding to the eigenvalues of $M^T M - g g^T$. From this perspective, the representation of $\mathcal{F}^*$ via (ii) makes natural geometric sense. Also, the central axis of both $\mathcal{F}$ and $\mathcal{F}^*$ is the ray $\{\alpha Q_n : \alpha \geq 0\}$. Last of all, note that $-\mathcal{F} = \{y : y^T Q D Q^T y \leq 0,\ y^T Q_n \leq 0\}$ and $-\mathcal{F}^* = \{z : z^T Q D^{-1} Q^T z \leq 0,\ z^T Q_n \leq 0\}$.

It turns out that the eigendecomposition of $M^T M - g g^T = Q D Q^T$, while useful both conceptually and algorithmically (as we shall see), is not even necessary for the above representation of $\mathcal{F}$ and $\mathcal{F}^*$. Indeed, Theorem 1 can alternatively be stated replacing $Q D Q^T$ and $Q D^{-1} Q^T$ by $M^T M - g g^T$ and $(M^T M - g g^T)^{-1}$. Under the further hypothesis that $\text{rank}(M) = n$, the theorem can be restated as follows.

COROLLARY 1. *Suppose that $\mathcal{F}$ is a regular cone and* $\text{rank}(M) = n$. *Then*

(i) $\mathcal{F} = \{y : \sqrt{y^T (M^T M) y} \leq g^T y\}$;
(ii) $\mathcal{F}^* = \{z : \sqrt{z^T (M^T M)^{-1} z} \leq \frac{g^T (M^T M)^{-1} z}{\sqrt{g^T (M^T M)^{-1} g - 1}}\}$;
(iii) *if $y \in \mathcal{F}$ and $\alpha \geq 0$, then $z := -\alpha (M^T M - g g^T) y \in \mathcal{F}^*$. Furthermore, if $y \in \partial\mathcal{F}$, then $z \in \partial\mathcal{F}^*$ and $z^T y = 0$;*
(iv) *if $z \in \mathcal{F}^*$ and $\alpha \geq 0$, then $y := -\alpha [(M^T M)^{-1} - \frac{(M^T M)^{-1} g g^T (M^T M)^{-1}}{g^T (M^T M)^{-1} g - 1}] z \in \mathcal{F}$. Furthermore, if $z \in \partial\mathcal{F}^*$, then $y \in \partial\mathcal{F}$ and $z^T y = 0$.*

The proofs of Theorem 1 and Corollary 1 are presented in section 2, along with proofs that all of the stated quantities are well defined: in particular, D^{-1} exists and $g^T (M^T M)^{-1} g - 1 > 0$ under the given hypotheses.

These representation results are used to solve the following dual pair of optimization problems, where $x \in \mathbb{R}^n$ is a *given* point:

$$\begin{array}{lll} \mathcal{P}: \ t^* := \min_y & \|y - x\| & \mathcal{D}: \ t^* := \max_z \quad -x^T z \\ \text{s.t.} & y \in \mathcal{F}, & \text{s.t.} \quad \|z\| \le 1 \\ & & \quad\ z \in \mathcal{F}^*. \end{array} \tag{1}$$

The problem $\mathcal{P}$ is the classical projection problem onto the cone $\mathcal{F}$, whose solution is the point in $\mathcal{F}$ closest to x, and strong duality is easily established for this pair of problems. The problem $\mathcal{D}$ arises as a necessary subroutine in the rescaled perceptron algorithm in [2]: the subroutine needs to efficiently solve $\mathcal{D}$ using $x = x^k$ that arises at each outer iteration k of the algorithm. It is this latter problem that motivated our interest in efficiently representing $\mathcal{F}^*$ and solving both $\mathcal{P}$ and $\mathcal{D}$. Notice that $\mathcal{P}/\mathcal{D}$ involve intersections of a Euclidean ball and a second-order feasibility cone. This dual pair of problems is therefore a modest generalization of the trust region problem of optimizing a quadratic function over a Euclidean ball, for which Ye [10] showed how to combine a binary search and Newton's method to obtain double-logarithmic complexity. Using the representation results above and extending ideas from [10], we develop an algorithm for solving (1) in section 3. The complexity of the algorithm depends on the *widths* of the cones $\mathcal{F}$ and $\mathcal{F}^*$, where the width τ_K of a cone K is defined to be the radius of the largest ball contained in K that is centered at unit distance from the origin:

$$\tau_K := \max_{y,r} \{r : B(y, r) \subset K, \ \|y\| \le 1\}.$$

It readily follows from Theorem 1 that the widths of $\mathcal{F}$ and $\mathcal{F}^*$ are simple functions of the largest and smallest positive eigenvalues and the negative eigenvalue of $M^T M - gg^T$, and it is straightforward to derive the following:

$$\tau_{\mathcal{F}} = \sqrt{\frac{|D_n|}{|D_n| + D_1}} \quad \text{and} \quad \tau_{\mathcal{F}^*} = \sqrt{\frac{1/|D_n|}{1/|D_n| + 1/D_{n-1}}}.$$

The main complexity result, which is proved in section 3, is as follows.

THEOREM 2. *Suppose that $\mathcal{F}$ is a regular cone, and $x \in \mathbb{R}^n$ satisfying $\|x\| = 1$ is given. Then feasible solutions (y, z) of $(\mathcal{P}, \mathcal{D})$ satisfying a duality gap of at most σ are computable in $O(mn^2 + n \ln\ln(1/\sigma) + n \ln\ln(1/\min\{\tau_{\mathcal{F}}, \tau_{\mathcal{F}^*}\}))$ operations.*

In section 4, we complement this theoretical computational complexity bound with experimental computational results that indicate that the method is also extremely efficient in practice.

Last of all, we note that the hypothesis that $\mathcal{F}$ is regular can be removed with no loss of strength of the results herein but with substantial expositional overhead. The case when $\mathcal{F}$ is nonregular is discussed at the end of sections 2 and 3.

2. Proofs of representation results. Recall the eigendecomposition of $M^T M - gg^T = QDQ^T$, with $D_1 \ge \cdots \ge D_n$. A simple dimension argument establishes that $M^T M - gg^T$ has at most one negative eigenvalue, whereby $D_1, \ldots, D_{n-1} \ge 0$. By choosing either Q_n or $-Q_n$, we can ensure that $g^T Q_n \ge 0$. In preparation for the proof of Theorem 1, we first prove some preliminary results.

PROPOSITION 1. *Suppose that* **int** $\mathcal{F} \ne \emptyset$. *Then $D_n < 0$, and there exists y satisfying $\|My\| < g^T y$.*

Proof. We first suppose that there exists $\bar{y}$ that satisfies $\|M\bar{y}\| < g^T\bar{y}$. In this case it easily follows that $0 > \bar{y}^T(M^TM - gg^T)\bar{y} = \bar{y}^TQDQ^T\bar{y}$, whereby $D_n < 0$. Next suppose that every $y \in \mathcal{F}$ satisfies $\|My\| = g^Ty$, and let $\bar{y} \in \mathbf{int}\ \mathcal{F}$. Since $\bar{y} \in \mathbf{int}\ \mathcal{F}$, we have $\|M(\bar{y} + \beta d)\| = g^T(\bar{y} + \beta d)$ for all $d \in B(0,1)$ and all sufficiently small positive β. Squaring the previous equation, then rearranging and cancelling terms yields $2(d^TM^TM\bar{y} - \bar{y}^Tgg^Td) + \beta(d^TM^TMd - d^Tgg^Td) = 0$, which is true only if $g^Td = 0 \Rightarrow Md = 0$. This in turn implies that $\mathrm{rank}(M) = 1$, violating Assumption 1. Therefore there exists y satisfying $\|My\| < g^Ty$. ∎

One characterization of $\mathcal{F}^*$ is as follows:

$$\mathcal{F}^* = \mathbf{cl}\ \left\{M^T\lambda + g\alpha : \|\lambda\| \le \alpha\right\}. \tag{2}$$

This result admits an elementary proof by a separating hyperplane argument and has been part of the folklore of convex analysis for several decades. For a standard proof, see, for example, Theorem 3.1 of Berman [3] applied to the second-order cone. The lack of closure of $\mathcal{T} := \{M^T\lambda + g\alpha : \|\lambda\| \le \alpha\}$ can arise easily. Let $M = \left[\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$ and $g = \left[\begin{smallmatrix} 1 \\ 0 \end{smallmatrix}\right]$. In this case, $\mathcal{T} = \{(-\lambda_1 + \alpha, \lambda_2) \mid \|(\lambda_1, \lambda_2)\| \le \alpha\}$. It is easy to verify that $(0,1) \notin \mathcal{T}$ but $(\varepsilon, 1) \in \mathcal{T}$ for every $\varepsilon > 0$ (set $\lambda_1 = \frac{1}{2\varepsilon} - \frac{\varepsilon}{2}$, $\lambda_2 = 1$, and $\alpha = \frac{1}{2\varepsilon} + \frac{\varepsilon}{2}$), which shows that $\mathcal{T}$ is not closed. For an analysis of cases when $\mathcal{T}$ is guaranteed to be closed, see Pataki [5].

Proof of Theorem 1. Since $\mathbf{int}\ \mathcal{F} \neq \emptyset$, Proposition 1 implies that $D_n < 0$, and so, for the sake of this proof, we rescale (M, g) by $1/\sqrt{|D_n|}$ in order to conveniently satisfy $D_n = -1$. (i) Define $\mathcal{H} := \{y : y^TQDQ^Ty \le 0,\ y^TQ_n \ge 0\}$ and $\mathcal{L} := \{y : y^TQDQ^Ty \le 0,\ y^Tg \ge 0\}$. We need to prove that $\mathcal{H} = \mathcal{F}$. It is straightforward to check that $\mathcal{F} = \mathcal{L}$ and, indeed, $\mathbf{int}\ \mathcal{F} = \mathbf{int}\ \mathcal{L} = \{y : y^TQDQ^Ty < 0,\ y^Tg > 0\}$ from Proposition 1, and this also readily establishes that $Q_n \in \mathbf{int}\ \mathcal{F}$. For any y we can write

$$y^TQ_n = y^T\left(-QDQ^T\right)Q_n = y^T\left(gg^T - M^TM\right)Q_n = \left(My, g^Ty\right)^T\left(-MQ_n, g^TQ_n\right), \tag{3}$$

where the final term's two parenthetic vectors lie in $\mathbb{R}^{m+1}$. Notice that $(-MQ_n, g^TQ_n) \in \mathbf{int}\ \mathcal{Q}^{m+1}$, since $Q_n \in \mathbf{int}\ \mathcal{F}$. If $y \in \mathcal{F}$, then both vectors in the last term of (3) are in $\mathcal{Q}^{m+1}$; hence $y^TQ_n \ge 0$ follows from the self-duality of $\mathcal{Q}^{m+1}$. Therefore $y \in \mathcal{H}$, showing that $\mathcal{F} \subset \mathcal{H}$. Next suppose that $y \in \mathcal{H}$. Then $y \in \mathcal{F}$ unless $g^Ty < 0$, in which case $-y \in \mathcal{F}$. Using (3) we have

$$0 \le y^TQ_n = \left(My, g^Ty\right)^T\left(-MQ_n, g^TQ_n\right) = -\left(-My, -g^Ty\right)^T\left(-MQ_n, g^TQ_n\right) \le 0,$$

again because the two vectors in the last term lie in the self-dual cone $\mathcal{Q}^{m+1}$. This implies that equality holds throughout, and hence $(-My, -g^Ty) = (0,0)$ since $(-MQ_n, g^TQ_n) \in \mathbf{int}\ \mathcal{Q}^{m+1}$, yielding the contradiction that $g^Ty = 0$. This establishes that $\mathcal{F} \subset \mathcal{H}$, completing the proof of (i).

(ii) Having established (i), suppose that $D_i = 0$ for some $i \in \{1, \ldots, n-1\}$. Then $(\theta Q_i)^TQDQ^T(\theta Q_i) = 0$ and $Q_n^T(\theta Q_i) = 0$, whereby $\theta Q_i \in \mathcal{F}$ for all θ, violating the hypothesis that $\mathcal{F}$ is regular. Therefore $D_i > 0$ for all $i \in \{1, \ldots, n-1\}$, and hence D^{-1} exists. Define $\mathcal{J} := \{z : z^TQD^{-1}Q^Tz \le 0,\ z^TQ_n \ge 0\}$. Suppose that $z \in \mathcal{J}$

and $y \in \mathcal{F}$, in which case

$$y^T z = y^T Q Q^T z = \sum_{i=1}^{n-1} D_i^{\frac{1}{2}} \left(Q_i^T y\right) D_i^{-\frac{1}{2}} \left(Q_i^T z\right) + y^T Q_n z^T Q_n$$
$$\geq -\sqrt{\sum_{i=1}^{n-1} D_i \left(Q_i^T y\right)^2} \sqrt{\sum_{i=1}^{n-1} D_i^{-1} \left(Q_i^T z\right)^2} + y^T Q_n z^T Q_n \geq 0,$$

where the first inequality is an application of the Cauchy–Schwarz inequality and the second inequality follows, since $z \in \mathcal{J}$ and $y \in \mathcal{F}$ using part (i). Thus $z \in \mathcal{F}^*$, which shows that $\mathcal{J} \subset \mathcal{F}^*$. Next let $\bar{Q}$ denote the matrix of the first $n-1$ columns of Q, and let $\bar{D}$ denote the diagonal matrix composed of the $n-1$ diagonal components $D_1, \ldots, D_{n-1}$. Then from part (i) we have $\mathcal{F} = \{y : \sqrt{y^T \bar{Q} \bar{D} \bar{Q}^T y} \leq Q_n^T y\} = \{y : \|\bar{D}^{\frac{1}{2}} \bar{Q}^T y\| \leq Q_n^T y\}$, and using (2) we know that $\mathcal{F}^* = \mathbf{cl}\, \mathcal{T}$, where $\mathcal{T} = \{\bar{Q}\bar{D}^{\frac{1}{2}}\lambda + Q_n \alpha : \|\lambda\| \leq \alpha\}$. Let $z \in \mathcal{T}$, where $z = \bar{Q}\bar{D}^{\frac{1}{2}}\lambda + Q_n\alpha$ and $\|\lambda\| \leq \alpha$. Then

$$z^T Q D^{-1} Q^T z = \left(\bar{Q}\bar{D}^{\frac{1}{2}}\lambda + Q_n\alpha\right)^T Q D^{-1} Q^T \left(\bar{Q}\bar{D}^{\frac{1}{2}}\lambda + Q_n\alpha\right) = \lambda^T\lambda - \alpha^2 \leq 0,$$

and furthermore $Q_n^T z = \alpha \geq 0$, whereby $z \in \mathcal{J}$. Thus $\mathcal{T} \subset \mathcal{J}$. It then follows that $\mathcal{F}^* = \mathbf{cl}\, \mathcal{T} \subset \mathbf{cl}\, \mathcal{J} = \mathcal{J}$, which completes the proof of (ii).

To prove (iii), notice that $Q_n^T z = -\alpha D_n Q_n^T y \geq 0$ and

$$z^T Q D^{-1} Q^T z = \alpha^2 y^T Q D Q^T Q D^{-1} Q^T Q D Q^T y = \alpha^2 y^T Q D Q^T y \leq (=)\ 0,$$

since $y \in \mathcal{F}$ ($y \in \partial\mathcal{F}$) implies that $y^T Q D Q^T y \leq (=)\ 0$, and hence $z \in \mathcal{F}^*$ ($z \in \partial\mathcal{F}^*$) from part (ii). Furthermore $y^T z = -\alpha y^T Q D Q^T y = 0$ when $y \in \partial\mathcal{F}$, completing the proof of (iii). The proof of (iv) follows similar logic. ∎

Before proving Corollary 1 we first prove the following.

PROPOSITION 2. *Suppose that* $\mathbf{int}\ \mathcal{F} \neq \emptyset$ *and* $\mathrm{rank}(M) = n$. *Then* $g^T(M^TM)^{-1}g > 1$ *and* $\bar{y} := (M^TM)^{-1}g \in \mathbf{int}\ \mathcal{F}$.

Proof. Let $\alpha := g^T(M^TM)^{-1}g > 0$, since $g \neq 0$ from Assumption 1. From Proposition 1 we know there exists $\hat{y}$ satisfying $\|M\hat{y}\| < g^T\hat{y}$ and rescale $\hat{y}$ if necessary so that $g^T\hat{y} = \alpha$. Notice that $\bar{y}$ optimizes the function $f(y) = y^TM^TMy - 2g^Ty$, whose optimal objective function value is $-\alpha$. Therefore

$$-\alpha \leq \hat{y}^TM^TM\hat{y} - 2g^T\hat{y} < \alpha^2 - 2\alpha,$$

which implies that $\alpha^2 > \alpha > 0$, and hence $\alpha > 1$. Next observe that $\|M\bar{y}\| = \sqrt{\bar{y}^TM^TM\bar{y}} = \sqrt{\alpha} < \alpha = g^T\bar{y}$, whereby $\bar{y} \in \mathbf{int}\ \mathcal{F}$. ∎

Proof of Corollary 1. (i) is a restatement of the definition of $\mathcal{F}$, (iii) is a restatement of part (iii) of Theorem 1, and (iv) is a restatement of part (iv) of Theorem 1 using the Sherman–Morrison formula

$$QD^{-1}Q^T = \left(M^TM - gg^T\right)^{-1} = \left(M^TM\right)^{-1} - \frac{(M^TM)^{-1}gg^T\left(M^TM\right)^{-1}}{g^T\left(M^TM\right)^{-1}g - 1},$$

together with the fact from Proposition 2 that $g^T(M^TM)^{-1}g > 1$.

It remains to prove (ii). Let $\mathcal{K} := \{z \in \mathbb{R}^n : z^TQD^{-1}Q^Tz \leq 0\}$. Then from Theorem 1 we have $\mathcal{K} = \mathcal{F}^* \cup -\mathcal{F}^*$. Let $\bar{y} = (M^TM)^{-1}g$, and note that $\bar{y} \in \mathbf{int}\ \mathcal{F}$

from Proposition 2. Define $\mathcal{H} := \{z \in \mathbb{R}^n : \bar{y}^T z \geq 0\}$, and note that $\mathcal{H} \cap \mathcal{F}^* = \mathcal{F}^*$ and $\mathcal{H} \cap -\mathcal{F}^* = \{0\}$. Therefore $\mathcal{F}^* = \mathcal{K} \cap \mathcal{H} = \{z \in \mathbb{R}^n : z^T Q D^{-1} Q^T z \leq 0,\ g^T (M^T M)^{-1} z \geq 0\}$. Using the Sherman–Morrison formula we obtain

$$\mathcal{F}^* = \left\{ z^T \left((M^T M)^{-1} - \frac{\left(M^T M\right)^{-1} g g^T \left(M^T M\right)^{-1}}{g^T \left(M^T M\right)^{-1} g - 1} \right) z \leq 0,\ g^T \left(M^T M\right)^{-1} z \geq 0 \right\},$$

which after rearranging yields the expression in (ii). ∎

Remark 2 (the case when $\mathcal{F}$ is not regular). Let Z and N partition the set of indices according to zero and nonzero values of D_i. If $D_n = 0$, then one can show that $\mathcal{F}$ is a half-subspace in the subspace spanned by the Q_i for $i \in Z$. If $D_n > 0$, then $\mathcal{F} = \{0\}$. If $D_n < 0$, then $\mathcal{F}$ has an interior, and we can interpret $D_i^{-1} = \infty$ for $i \in Z$. Then Theorem 1 remains valid if we interpret "$z^T Q D^{-1} Q^T z \leq 0$" in (ii) as "$\sum_{i \in N} D_i (Q^T z)_i^2 \leq 0,\ (Q^T z)_i^2 = 0$ for $i \in Z$," and "$y := -\alpha Q D^{-1} Q^T z$" in (iv) as "$Q_i^T y := -\alpha D_i^{-1} Q_i^T z$ for $i \in N$ and $Q_i^T y$ is set *arbitrarily* for $i \in N$."

3. An algorithm for approximately solving (1).

3.1. Basic properties of (1) and the polar problem pair. Returning to (1) where x is the given vector, consider the following conditions in (y, z, θ):

$$\begin{array}{l} y - \theta z = x, \\ y \in \mathcal{F}, \\ z \in \mathcal{F}^*, \\ \|z\| \leq 1, \\ \theta \geq 0,\ \theta \|z\| = \theta. \end{array} \tag{4}$$

Examining (4), we see that x is decomposed into $x = y - \theta z$, where $y \in \mathcal{F}$ and $-\theta z \in -\mathcal{F}^*$ and (y, z) is feasible for the problems (1). Let G denote the duality gap for (1), namely, $G = \|y - x\| + x^T z$. We also consider the following pair of conic problems that are "polar" to (1):

$$\begin{array}{lll} \mathcal{P}^\circ:\ f^* := \min_v & \|v - x\| & \mathcal{D}^\circ:\ f^* := \max_w \quad -x^T w \\ \text{s.t.} & v \in -\mathcal{F}^*, & \text{s.t.} \quad \|w\| \leq 1 \\ & & \qquad w \in -\mathcal{F}, \end{array} \tag{5}$$

together with the following conditions in (v, w, ρ):

$$\begin{array}{l} v - \rho w = x, \\ v \in -\mathcal{F}^*, \\ w \in -\mathcal{F}, \\ \|w\| \leq 1, \\ \rho \geq 0,\ \rho \|w\| = \rho; \end{array} \tag{6}$$

here x is decomposed into $x = v - \rho w$, where now (v, w) is feasible for the problems (5), $-\rho w \in \mathcal{F}$, and $v \in -\mathcal{F}^*$. Let G° denote the duality gap for (5), namely, $G^\circ = \|v - x\| + x^T w$.

It is a straightforward exercise to show that conditions (4) together with the complementarity condition $y^T z = 0$ constitute necessary and sufficient optimality conditions for (1), and similarly, (6) together with $v^T w = 0$ are necessary and sufficient for optimality for (5). Furthermore, the solutions of (4) and (6) transform to one another:

$$\begin{array}{rcl} (y, z, \theta) & \rightarrow & (v, w, \rho) = (-\theta z, -y/\|y\|, \|y\|), \\ (v, w, \rho) & \rightarrow & (y, z, \theta) = (-\rho w, -v/\|v\|, \|v\|), \end{array}$$

with necessary modifications for the cases when $y = 0$ (set $w = 0$) and/or $v = 0$ (set $z = 0$).

PROPOSITION 3. *Suppose* (y, z, θ) *satisfy* (4) *and* (v, w, ρ) *satisfy* (6). *Then* (y, z) *and* (v, w) *are feasible for their respective problems with respective duality gaps:*

(i) $G = y^T z$;
(ii) $G^\circ = v^T w$.

Furthermore,

(iii) *if* (y, z) *is optimal for* (1), *then* $t^* = \theta$;
(iv) *if* (v, w) *is optimal for* (5), *then* $f^* = \rho$;
(v) $(t^*)^2 + (f^*)^2 = \|x\|^2$.

Proof. To prove (i), observe that $y^T z = z^T x + \theta\|z\|^2 = z^T x + \theta\|z\| = z^T x + \|y - x\| = G$, and a similar argument establishes (ii). To prove (iii), observe that $t^* = \|x - y\| = \|\theta z\| = \theta$ with similar arguments for (iv). To prove (v), notice that (y, z, θ) satisfy (4), and $y^T z = 0$ if and only if (y, z) is optimal for (1), in which case it is easy to verify that $(v, w, \rho) \leftarrow (-\theta z, -y/\|y\|, \|y\|)$ satisfy (6) and (v, w) is optimal for (5). Therefore $\|x\|^2 = (y - \theta z)^T(y - \theta z) = y^T y + \theta^2 = \rho^2 + \theta^2 = (f^*)^2 + (t^*)^2$. ∎

PROPOSITION 4. *If* $Q_n^T x \le 0$, *then* $t^* \ge \tau_{\mathcal{F}^*}\|x\|$.

Proof. We assume for the proof that $\|x\| = 1$, since t^*, f^* scale positively with $\|x\|$. If $f^* = 0$, the result follows trivially since $\tau_{\mathcal{F}^*} \le 1$, and $t^* = 1$ from Proposition 3. If $f^* > 0$, define $c = -\frac{t^*}{f^*}Q_n$, and note that $\|c\| = \frac{t^*}{f^*}$. By definition of the width, $B(c, \frac{t^*}{f^*}\tau_{\mathcal{F}^*}) \subset -\mathcal{F}^*$. Note that $\|x - c\| = \sqrt{x^T x + 2\frac{t^*}{f^*}Q_n^T x + \frac{t^{*2}}{f^{*2}}Q_n^T Q_n} \le \sqrt{1 + \frac{t^{*2}}{f^{*2}}} = \frac{1}{f^*}$. Therefore $\frac{1}{f^*\|x-c\|} \ge 1$.

Next observe that $c + \frac{\tau_{\mathcal{F}^*}\|c\|(x-c)}{\|x-c\|} \in -\mathcal{F}^*$, which is equivalent to $c + \frac{\tau_{\mathcal{F}^*}t^*(x-c)}{f^*\|x-c\|} \in -\mathcal{F}^*$. By the previous inequality, we have $c + \tau_{\mathcal{F}^*}t^*(x - c) \in -\mathcal{F}^*$. Thus we have

$$f^* \le \|c + \tau_{\mathcal{F}^*}t^*(x - c) - x\| = (1 - \tau_{\mathcal{F}^*}t^*)\|x - c\| \le (1 - \tau_{\mathcal{F}^*}t^*)\frac{1}{f^*}.$$

Therefore, $1 - t^{*2} = f^{*2} \le 1 - \tau_{\mathcal{F}^*}t^*$, which implies that $\tau_{\mathcal{F}^*} \le t^*$. ∎

PROPOSITION 5. *Given* x *satisfying* $\|x\| = 1$ *and* $Q_n^T x \le 0$, *suppose that* (v, w, ρ) *satisfies* (6), *with duality gap* $G^\circ \le \sigma\tau_{\mathcal{F}^*}/2$ *for* (5), *where* $\sigma \le 1$. *Consider the assignment* $(y, z, \theta) \leftarrow (-\rho w, -v/\|v\|, \|v\|)$ *(with the necessary modification that* $y = 0$ *if* $v = 0$*). Then* (y, z, θ) *satisfies* (4), *with duality gap* $G \le \sigma$ *for* (1).

Proof. Note that $y^T z = \frac{(w^T v)\rho}{\|v\|} \le \frac{\sigma\tau_{\mathcal{F}^*}\rho}{2\|v\|}$, and we have the following relations: (i) $w^T v \le \sigma\tau_{\mathcal{F}^*}/2 \le 1/2$, (ii) $\|v\| = \theta = \|y - x\| \ge t^* \ge \tau_{\mathcal{F}^*}$ from Proposition 4, and (iii) $\rho = \|v - x\| = v^T w - w^T x \le 1/2 + f^* \le 3/2$ from Proposition 3. Therefore $y^T z \le \frac{\tau_{\mathcal{F}^*}\sigma}{2}\frac{3}{2}\frac{1}{\tau_{\mathcal{F}^*}} \le \sigma$. ∎

3.2. The six cases. We assume here that the given x has unit norm, i.e., $\|x\| = 1$, and that we seek feasible solutions to (1) with a duality gap at most σ, where $\sigma \le 1$. Armed with Propositions 3, 4, and 5, we now show how to compute a feasible solution (y, z) of (1) with duality gap $G \le \sigma$. Our method is best understood with the help of Figure 1. We know from section 3.1 and the conditions (4) and/or (6) that we need to decompose x into the sum of a vector in $\mathcal{F}$ plus a vector in $-\mathcal{F}^*$ and that the central axes of $\mathcal{F}$ and $-\mathcal{F}$ are the rays corresponding to Q_n and $-Q_n$, respectively. Define the "dividing hyperplane" $L_{\mathcal{F}} := \{y : Q_n^T y = 0\}$ perpendicular to the central axes of $\mathcal{F}$ and $-\mathcal{F}$, and define $L_{\mathcal{F}}^+ := \{y \in \mathbb{R}^n : Q_n^T y \ge 0\}$ and $L_{\mathcal{F}}^- := -L_{\mathcal{F}}^+$. We divide $L_{\mathcal{F}}^+$ into three regions: region 1 corresponds to points in $\mathcal{F}$, region 2 corresponds to points in $L_{\mathcal{F}}^+$ "near" the dividing hyperplane (where our nearness criterion will be defined

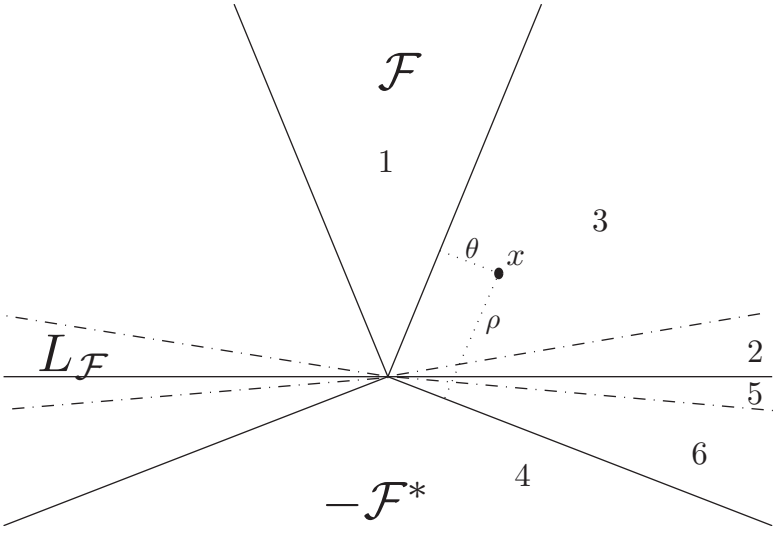

FIG. 1. *The geometry of the sets $\mathcal{F}$, $-\mathcal{F}^*$, and $L_{\mathcal{F}}$ and the six cases. The central axes of $\mathcal{F}$ and $-\mathcal{F}^*$ are the rays generated by $\pm Q_n$, respectively, which are orthogonal to the hyperplane $L_{\mathcal{F}}$. The regions corresponding to the six cases are shown as well.*

shortly), and region 3 corresponds to points in $L_{\mathcal{F}}^+ \setminus \mathcal{F}$ that are "far" from $L_{\mathcal{F}}$. We divide $L_{\mathcal{F}}^-$ similarly, into regions 4, 5, and 6. For each of the three regions in $L_{\mathcal{F}}^+$, we will work with the problem pair (1) and show how to compute a feasible solution (y, z) of (1) with duality gap $G \leq \sigma$. For each of the three regions in $L_{\mathcal{F}}^-$, we will instead work with the problem pair (5) and show how to compute a feasible solution (w, s) of (5) with duality gap $G^\circ \leq \sigma\tau_{\mathcal{F}^*}/2$, whereby from Proposition 5 we obtain a feasible solution (y, z) of (1) with duality gap $G \leq \sigma$. We will consider six cases, one for each of the regions described above and in Figure 1.

We first describe how we choose whether x is in region 2 or 3. For $x \in L_{\mathcal{F}}^+ \setminus \mathcal{F}$, define

$$\varepsilon_{\mathcal{P}} = \varepsilon_{\mathcal{P}}(x) := \frac{Q_n^T x \sqrt{|D_n|}}{\sqrt{\sum_{i=1}^{n-1} D_i \left(Q_i^T x\right)^2}}, \tag{7}$$

and notice that $x \in L_{\mathcal{F}}^+$ implies that $\varepsilon_{\mathcal{P}} \geq 0$, $x \notin \mathcal{F}$ implies that $\varepsilon_{\mathcal{P}} < 1$, and smaller values of $\varepsilon_{\mathcal{P}}$ correspond to $Q_n^T x$ closer to zero and hence x closer to $L_{\mathcal{F}}$. We specify a tolerance $\bar{\varepsilon}_{\mathcal{P}}$ and determine whether x is in region 2 or 3 depending on whether $\varepsilon_{\mathcal{P}} \leq \bar{\varepsilon}$ or $\varepsilon_{\mathcal{P}} > \bar{\varepsilon}$, respectively, where we set $\bar{\varepsilon} = \bar{\varepsilon}_{\mathcal{P}} := \sigma\tau_{\mathcal{F}}$.

Case 1: $Q_n^T x \geq 0$ *and* $x^T Q D Q^T x \leq 0$. From Theorem 1 we know that $x \in \mathcal{F}$. Then it is elementary to show that $(y, z, \theta) \leftarrow (x, 0, 0)$ satisfy (4), with $y^T z = 0$, whereby from Proposition 3 the duality gap is $G = 0$.

Case 2: $Q_n^T x \geq 0$ *and* $x^T Q D Q^T x > 0$, $\varepsilon_{\mathcal{P}} \leq \bar{\varepsilon}_{\mathcal{P}} := \sigma\tau_{\mathcal{F}}$. Let $\hat{y}$ solve the following system of equations:

$$\begin{aligned} [I + 1/|D_n| D] Q^T \hat{y} &= Q^T x - e_n Q_n^T x, \\ Q_n^T \hat{y} &= 0, \end{aligned} \tag{8}$$

where $e_n = (0, \ldots, 0, 1) \in \mathbb{R}^n$. Notice that the last row of the first equation system

has all zero entries. Therefore this system is not overdetermined, and one can write the closed-form solution $(Q^T\hat{y})_i = (Q^T x)_i/(1 + 1/|D_n|D_i)$ for $i = 1, \ldots, n-1$ and $(Q^T\hat{y})_n = 0$, in the transformed variables $\hat{s} := Q^T\hat{y}$. Having computed $\hat{y}$, next compute $\alpha := \sqrt{\hat{y}^T QDQ^T\hat{y}}/\sqrt{|D_n|}$, and then make the following assignments to variables:

$$\begin{aligned}
&\bar{y} \leftarrow \hat{y} + \alpha Q_n,\\
&\theta \leftarrow \sqrt{\bar{y}^T QD^2Q^T\bar{y}}/|D_n|,\\
&z \leftarrow -QDQ^T\bar{y}/(|D_n|\theta),\\
&y \leftarrow \bar{y} + Q_n^T x Q_n.
\end{aligned}$$

PROPOSITION 6. *Suppose that* $\|x\| = 1$, $\sigma \le 1$, *and* $\varepsilon_{\mathcal{P}} \le \bar{\varepsilon} < 1$ *and that* (y, z, θ) *are computed according to Case* 2 *above. Then* (y, z, θ) *is feasible for* (4) *with duality gap* $G \le \bar{\varepsilon}/\tau_{\mathcal{F}}$ *for* (1).

Applying Proposition 6 using $\bar{\varepsilon} = \bar{\varepsilon}_{\mathcal{P}} := \sigma\tau_{\mathcal{F}}$ ensures that the resulting duality gap satisfies $G \le \bar{\varepsilon}/\tau_{\mathcal{F}} = \sigma$. Note that the complexity of the computations in Case 2 is $O(mn^2)$ (assuming that square roots are sufficiently accurately computed in $O(1)$ operations).

Proof of Proposition 6. It is easy to establish that $(Q_1^T x, \ldots, Q_{n-1}^T x) \ne 0$, and hence $\alpha > 0$. This in turn implies that $Q_n^T\bar{y} = \alpha > 0$, and hence $\theta > 0$, so z is well defined. It is straightforward to verify that

$$\bar{y}^T QDQ^T\bar{y} = (\hat{y} + \alpha Q_n)^T QDQ^T(\hat{y} + \alpha Q_n) = \hat{y}^T QDQ^T\hat{y} - \alpha^2|D_n| = 0,$$

which shows via Theorem 1 that $\bar{y} \in \mathcal{F}$, and therefore $z \in \mathcal{F}^*$ and $z^T\bar{y} = 0$. It is also straightforward to verify that $\|z\| = 1$. Finally, we have from (8) that

$$\begin{aligned}
[I + 1/|D_n|D]Q^T\bar{y} &= [I + 1/|D_n|D]\left(Q^T\hat{y} + \alpha e_n\right)\\
&= [I + 1/|D_n|D]\left(Q^T\hat{y}\right) = Q^T\left(x - Q_n Q_n^T x\right)
\end{aligned}$$

(where the second equality above follows since the last row and column of the matrix are zero); hence $\bar{y} + 1/|D_n|QDQ^T\bar{y} = x - Q_n Q_n^T x$. Substituting the values of y, z, θ into this expression yields $y - \theta z = x$, which then shows that (y, z, θ) satisfy (4). Therefore from Proposition 3 (y, z) is feasible for (1) with duality gap

$$\begin{aligned}
G = z^T y = z^T\bar{y} + z^T Q_n Q_n^T x \le Q_n^T x &= \frac{\varepsilon_{\mathcal{P}}\sqrt{\sum_{i=1}^{n-1} D_i(Q_i^T x)^2}}{\sqrt{|D_n|}}\\
&\le \frac{\bar{\varepsilon}\sqrt{D_1}}{\sqrt{|D_n|}} \le \frac{\bar{\varepsilon}\sqrt{D_1 + |D_n|}}{\sqrt{|D_n|}} = \bar{\varepsilon}/\tau_{\mathcal{F}}. \qquad \square
\end{aligned}$$

Case 3*:* $Q_n^T x \ge 0$ *and* $x^T QDQ^T x > 0$, $\varepsilon_{\mathcal{P}} > \bar{\varepsilon}_{\mathcal{P}} := \sigma\tau_{\mathcal{F}}$. Here x is on the same side of the dividing hyperplane $L_{\mathcal{F}}$ as $\mathcal{F}$ but is neither in $\mathcal{F}$ nor close enough to $L_{\mathcal{F}}$ in the nearness measure. Consider the following univariate function in γ:

$$f(\gamma) := x^T Q[I + \gamma D]^{-1} D[I + \gamma D]^{-1} Q^T x = \sum_{i=1}^{n} \frac{D_i\left(x^T Q_i\right)^2}{(1 + D_i\gamma)^2}, \tag{9}$$

shown canonically in Figure 2.

Notice that $f(0) = x^T QDQ^T x > 0$, and since $D_n < 0$, we have $f(\gamma) \to -\infty$ as $\gamma \to 1/|D_n|$. Furthermore, $f'(\gamma) = -2\sum_{i=1}^{n} D_i^2(x^T Q_i)^2(1 + \gamma D_i)^{-3} < 0$ for $\gamma \in$

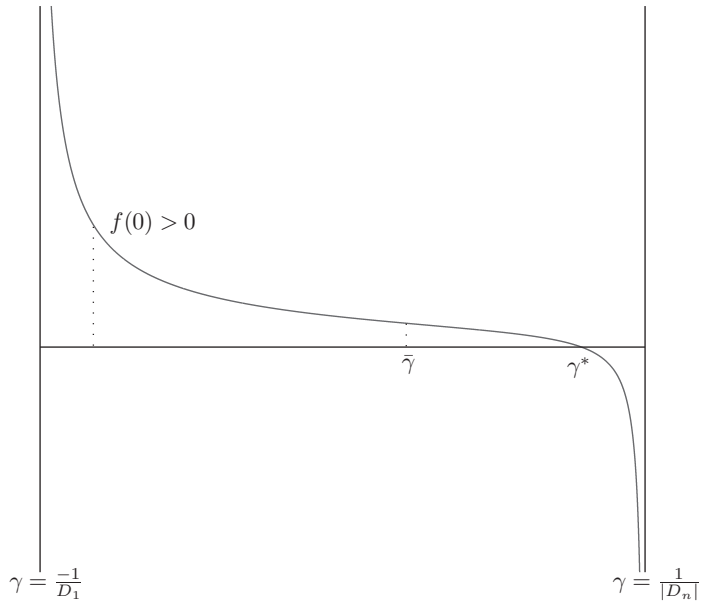

FIG. 2. *The function f on the interval $(-1/D_1, 1/|D_n|)$. Among many desirable properties, f is strictly decreasing and analytic and has a unique root $\gamma^* \in (0, 1/|D_n|)$. Moreover, f is convex over $(-1/D_1, \bar{\gamma})$ and concave over $(\bar{\gamma}, 1/|D_n|)$, where $\bar{\gamma}$ is the unique point satisfying $f''(\bar{\gamma}) = 0$. Note that one can have $\gamma^* \leq \bar{\gamma}$ or $\gamma^* \geq \bar{\gamma}$.*

$[0, 1/|D_n|)$. Therefore $f(\gamma)$ is strictly decreasing in the domain $[0, 1/|D_n|)$, whereby from the mean value theorem there is a unique value $\gamma^* \in (0, 1/|D_n|)$ for which $f(\gamma^*) = 0$. We show in section 5 how to combine a binary search and Newton's method to very efficiently compute $\gamma \in (0, 1/|D_n|)$ satisfying $f(\gamma) \leq 0$ and $f(\gamma) \approx 0$ (and $\gamma \approx \gamma^*$). Presuming that this can be done very efficiently, consider the following variable assignment:

$$\begin{array}{l} y \leftarrow Q\left[I + \gamma D\right]^{-1} Q^T x, \\ \theta \leftarrow \gamma\sqrt{y^T Q D^2 Q^T y}, \\ z \leftarrow -\gamma Q D Q^T y/\theta. \end{array} \tag{10}$$

We now show that (y, θ, z) satisfy (4). First note that $Q_n^T y = Q_n^T x/(1 - \gamma|D_n|) > 0$, and furthermore this shows that $\theta > 0$, and so z is well defined. By the hypothesis that $f(\gamma) \leq 0$ we have

$$y^T Q D Q^T y = x^T Q[I + \gamma D]^{-1} D[I + \gamma D]^{-1} Q^T x = f(\gamma) \leq 0,$$

which implies that $y \in \mathcal{F}$, and hence $z \in \mathcal{F}^*$ from Theorem 1. It is also straightforward to verify that $\|z\| = 1$. Finally, rearranging the formula for y yields $x = y + \gamma Q D Q^T y = y - \theta z$, which shows that (4) is satisfied. From Proposition 3, (y, z) is feasible for (1), and using the above assignments the duality gap works out to be

$$G = y^T z = -f(\gamma)/\sqrt{x^T Q D^2 [I + \gamma D]^{-2} Q^T x},$$

whereby G will be small if $f(\gamma) \approx 0$. To make this more precise requires a detailed analysis of a binary search and Newton's method, which is postponed to section 5 where we will prove the following.

PROPOSITION 7. *Suppose that* $\|x\| = 1$, $1 > \varepsilon_{\mathcal{P}} > \bar{\varepsilon}$, *and* $g > 0$ *is a given gap tolerance. If* $Q_n^T x > 0$ *and* $x^T Q D Q^T x > 0$, *then a solution* (y, z, θ) *of* (4) *with duality gap* $G \leq g$ *for* (1) *is computable in* $O(n \ln\ln(1/\tau_{\mathcal{F}} + 1/\bar{\varepsilon} + 1/g))$ *operations.*

Substituting $\bar{\varepsilon} = \bar{\varepsilon}_{\mathcal{P}} := \sigma\tau_{\mathcal{F}}$ and $g = \sigma$, it follows that the complexity of computing a feasible of solution of (y, z) of (1) with duality gap at most σ is $O(n \ln\ln(1/\tau_{\mathcal{F}} + 1/\sigma))$=$O(n \ln\ln(1/\min\{\tau_{\mathcal{F}}, \tau_{\mathcal{F}^*}\} + 1/\sigma))$ operations.

Case 4: $Q_n^T x \leq 0$ *and* $x^T Q D^{-1} Q^T x \leq 0$. From Theorem 1 we know that $x \in -\mathcal{F}^*$. Then it is elementary to show that $(y, z, \theta) \leftarrow (0, -x/\|x\|, \|x\|)$ satisfy (4), with $y^T z = 0$, whereby from Proposition 3 the duality gap is $G = 0$.

Before describing how we treat Cases 5 and 6 (corresponding to regions 5 and 6), we need to describe how we choose whether x is in region 5 or 6. We use a parallel concept to that used to distinguish regions 2 and 3, except that $\mathcal{F}$ is replaced by $-\mathcal{F}^*$; see Figure 1. For $x \in L_{\mathcal{F}}^- \setminus -\mathcal{F}^*$, define the following quantity analogous to (7):

$$\varepsilon_{\mathcal{P}^*} = \varepsilon_{\mathcal{P}^*}(x) := \frac{-Q_n^T x \sqrt{1/|D_n|}}{\sqrt{\sum_{i=1}^{n-1} (1/D_i) \left(Q_i^T x\right)^2}}, \tag{11}$$

and notice that $x \in L_{\mathcal{F}}^-$ implies $\varepsilon_{\mathcal{P}^*} \geq 0$, $x \notin -\mathcal{F}^*$ implies $\varepsilon_{\mathcal{P}^*} < 1$, and smaller values of $\varepsilon_{\mathcal{P}^*}$ correspond to $Q_n^T x$ closer to zero and hence x closer to $L_{\mathcal{F}}$. We specify a tolerance $\bar{\varepsilon}_{\mathcal{P}^*}$ and determine whether x is in region 5 or 6 depending on whether $\varepsilon_{\mathcal{P}^*} \leq \bar{\varepsilon}$ or $\varepsilon_{\mathcal{P}^*} > \bar{\varepsilon}$, respectively, where we set $\bar{\varepsilon} = \bar{\varepsilon}_{\mathcal{P}^*} := \sigma\tau_{\mathcal{F}^*}^2/2$.

Case 5: $Q_n^T x \leq 0$ *and* $x^T Q D^{-1} Q^T x > 0$, *and* $\varepsilon_{\mathcal{P}^*} \leq \bar{\varepsilon}_{\mathcal{P}^*} := \sigma\tau_{\mathcal{F}^*}^2/2$. This case is an exact analogue of Case 2, with $\mathcal{F}$ replaced by $-\mathcal{F}^*$ and the pair (1) replaced by (5). Therefore the methodology of Case 2 can be used to compute (v, w, ρ) satisfying (6), and hence (v, w) is feasible for (5). Applying Proposition 6 to the context of the polar pair (5) with $\bar{\varepsilon} = \bar{\varepsilon}_{\mathcal{P}^*}$, it follows that the duality gap for (5) will be $G^\circ = v^T w$ and will satisfy $G^\circ \leq \bar{\varepsilon}/\tau_{\mathcal{F}^*} = \sigma\tau_{\mathcal{F}^*}^2/(2\tau_{\mathcal{F}^*}) \leq \sigma\tau_{\mathcal{F}^*}/2$. Converting (v, w, ρ) to (y, z, θ) using Proposition 5, we obtain (y, z) feasible for (1) with duality gap $G \leq \sigma$. Here the complexity of the computations is of the same order as Case 2.

Case 6: $Q_n^T x \leq 0$ *and* $x^T Q D^{-1} Q^T x > 0$, *and* $\varepsilon_{\mathcal{P}^*} > \bar{\varepsilon}_{\mathcal{P}^*} := \sigma\tau_{\mathcal{F}^*}^2/2$. In concert with the previous case, this case is an exact analogue of Case 3, with $\mathcal{F}$ replaced by $-\mathcal{F}^*$ and the pair (1) replaced by (5). Therefore the methodology of Case 3 can be used to compute (v, w, ρ) satisfying (6), and hence (v, w) is feasible for (5). Applying Proposition 7 to the context of the polar pair (5) with $\bar{\varepsilon} = \bar{\varepsilon}_{\mathcal{P}^*}$ and $g = \sigma\tau_{\mathcal{F}^*}/2$, it follows that a solution (v, w, ρ) of (6) with duality gap $G^\circ \leq g = \sigma\tau_{\mathcal{F}^*}/2$ for (5) is computable in $O(n \ln\ln(1/\tau_{\mathcal{F}^*} + 1/\bar{\varepsilon} + 1/g)) = O(n \ln\ln(1/\min\{\tau_{\mathcal{F}}, \tau_{\mathcal{F}^*}\} + 1/\sigma))$ operations. Converting (v, w, ρ) to (y, z, θ) using Proposition 5, we obtain (y, z) feasible for (1) with duality gap $G \leq \sigma$.

Proof of Theorem 2. The spectral decomposition of $M^T M - gg^T = QDQ^T$ is assumed to take $O(mn^2)$ operations. The computations in Cases 1 and 4 are trivial after checking the conditions of the cases, which is $O(mn^2)$ operations, and similarly for Cases 2 and 5. Regarding Cases 3 and 6, the discussion in the description of these cases establishes the desired operation bound. ∎

Remark 3 (the case when $\mathcal{F}$ is not regular, again). As in Remark 2, let Z and N partition the set of indices according to zero and nonzero values of D_i. Consider the case when $D_n < 0$ (the cases when $D_n > 0$ and $D_n = 0$ were discussed in Remark 2). We interpret $D_i^{-1} = \infty$ for $i \in Z$. Consider the orthonormal transformation $Q^T x$ and $Q^T y$, $Q^T z$ of the given vector x and the variables y, z. Then for $i \in Z$ simply set $Q_i^T y = Q_i^T x$ and $Q_i^T z = 0$ and work in the lower-dimensional problem in the subspace spanned by Q_i, $i \in N$.

4. Comparison with interior-point methods. The primal-dual pair of problems (1) can be reformulated as second-order cone programs; one formulation of the primal problem is $\max_{y,t}\{-t : (My, g^T y) \in \mathcal{Q}^{m+1},\ (y - x, t) \in \mathcal{Q}^{n+1}\}$, for example. It then follows from interior-point complexity theory that approximate solutions to (1) with duality gap at most δ can be computed in $O(\ln(1/\delta))$ interior-point iterations. This iteration bound follows from Theorem 2.4.1 of Renegar [6], noting that an interior starting feasible solution with good symmetry is easy to precompute. Unlike the complexity bound for the proposed method in Theorem 2, the interior-point method bound has a stronger dependence on the duality gap δ (global linear convergence), but, unlike the proposed method, there is no dependence on the widths $\tau_{\mathcal{F}}, \tau_{\mathcal{F}^*}$. Therefore from a complexity viewpoint one cannot assert that one algorithm dominates the other. (There is a theory of local quadratic convergence for interior-point methods (see, for example, [1]) that could possibly be used to prove a weaker interior-point method dependence on δ for this class of problems.) In terms of computational practice, it is relevant to compare the two methods on randomly generated problems. We generated 100 relatively sparse random problem instances ((M, g) has density, respectively, 10% and 30% on average) for each of dimensions $(m, n) = (2n, n)$ for $n = 10$, 20, 50, 100, 200, and 500 and solved them using both our method and the conic convex interior-point method software SDPT3s [9]. All computation was performed in MatLab on a recent model laptop computer. We used MatLab's EIG command to compute the eigendecomposition for $M^T M - gg^T$ for our proposed method. Table 1 shows our computational results. Columns 2 and 3 of the table show the average theoretical iteration bound and the average actual iterations of our method. Columns 5, 6, and 7 report running time information. Note as expected that the eigendecomposition is the dominant computation in our method. Our method substantially outperforms SDPT3, as one would expect, since SDPT3 is not optimized for the problem class (1).

A fairer comparison can be done by presuming that the problem instances are preprocessed and transformed by the eigendecomposition, replacing $Q^T y$ with y, whereby the second-order cone formulation takes the diagonal form:

$$\max_{y,t} \left\{ -t : \left(\sqrt{D_1} y_1, \ldots, \sqrt{D_{n-1}} y_{n-1}, \sqrt{|D_n|} y_n \right) \in \mathcal{Q}^n,\ (y - x, t) \in \mathcal{Q}^{n+1} \right\},$$

and SDPT3 naturally exploits the sparse structure of this problem. We generated 100 random problem instances each, for a range of n from $n = 20$ to $n = 5000$, where each instance was generated by randomly choosing D but ensuring that $\tau_{\mathcal{F}} = \tau_{\mathcal{F}^*} = 10^{-7}$. These instances need no eigendecomposition for our method; also SDPT3 can take good advantage of the problem's natural sparsity as well. Table 2 shows our

computational results. Our method still substantially outperforms SDPT3 but not as dramatically when n is very large. However, the running time numbers in Table 2 are the running time until the stopping criteria are met for each method. The stopping criteria for SDPT3 includes stopping when the duality gap is sufficiently small or when insufficient progress is made in satisfying primal/dual feasibility/optimality. For the diagonal problems generated, this latter stopping criteria is unfortunately encountered quite often: the relative error of the final solution from SDPT3 was at least 0.01 for 65% of the diagonal problem instances and was at least 0.001 for 81% of the instances. In fact, SDPT3 stopped with a relative error of at most 10^{-6} in only 2% of the instances. In contrast, our proposed method terminated with a relative error of 10^{-12} in all instances.

5. Proof of Proposition 7. This section is devoted to the proof of Proposition 7. Our algorithmic approach is motivated by Ye [10], and it consists of a combination of a binary search and Newton's method to approximately solve $f(\gamma) = 0$ for the function f given in (9). An alternate approach would be to use interpolation methods as presented and analyzed in Melman [4], for which global quadratic convergence is proved but there is no complexity analysis of associated constants. While Proposition 7 indicates that a solution (y, z, θ) of (4) with duality gap $G \leq g$ for (1) can be computed extremely efficiently, unfortunately our proof is not nearly as efficient as we or the reader might wish. We assume throughout this section that the hypotheses of Proposition 7 hold. We start with a review of Smale's main result for Newton's method in [8].

5.1. Newton's method and Smale's results. Let g be an analytic function, and consider the Newton iterate from a given point $\hat{\gamma}$:

$$\gamma^+ = \hat{\gamma} - \frac{g(\hat{\gamma})}{g'(\hat{\gamma})},$$

and let $\{\gamma_k\}_{k\geq 0}$ denote the sequence of points generated starting from $\hat{\gamma} = \gamma_0$.

DEFINITION 1. *A point* γ_0 *is said to be an approximate zero of* g *if*

$$|\gamma_k - \gamma_{k-1}| \leq (1/2)^{2^{k-1}-1}|\gamma_1 - \gamma_0| \quad \textit{for } k \geq 1.$$

For an approximate zero γ_0, let $\gamma^* = \lim_{k\to\infty} \gamma_k$. Then γ^* is a zero of g, and Newton's method starting from γ_0 converges quadratically to γ^* from the very first iteration. The main result in [8] can be restated as follows.

THEOREM 3 (Smale [8]). *Let g be an analytic function. If $\hat{\gamma}$ satisfies*

$$\sup_{k>1}\left|\frac{g^{(k)}(\hat{\gamma})}{k!g'(\hat{\gamma})}\right|^{1/(k-1)} \leq \frac{1}{8}\left|\frac{g'(\hat{\gamma})}{g(\hat{\gamma})}\right|, \tag{12}$$

then $\hat{\gamma}$ is an approximate zero of g. Furthermore, if $\hat{\gamma}$ is an approximate zero of g, then $|\gamma_k - \gamma^*| \leq 2(1/2)^{2^{k-1}}|\gamma_1 - \gamma_0|$ for all $k \geq 1$.

5.2. Properties of $f(\gamma)$. We employ the change of variables $s = Q^T x$, whereby from the hypotheses of Proposition 7 we have $s_n > 0$, $s^T Ds > 0$, and $\varepsilon_{\mathcal{P}} = s_n\sqrt{|D_n|}/\sqrt{\sum_{j=1}^{n-1} D_i s_i^2} > \bar{\varepsilon}$. We consider computing a zero of our function of interest:

$$f(\gamma) = s^T\left(I+\gamma D\right)^{-2} Ds = \sum_{i=1}^{n}\frac{D_i s_i^2}{(1+\gamma D_i)^2}. \tag{13}$$

LEMMA 1. *Under the hypotheses of Proposition 7, f has the following properties:*

(i) *$f(0) > 0$, $\lim_{\gamma\to 1/|D_n|} f(\gamma) = -\infty$, and f has a unique root $\gamma^* \in (0, 1/|D_n|)$.*

(ii) *f is analytic on $(-1/D_1, 1/|D_n|)$, and for $k \geq 1$ the kth derivative of f is*

$$\begin{aligned} f^{(k)}(\gamma) &= (-1)^k(k+1)!s^T\left(I+\gamma D\right)^{-(k+2)} D^{k+1}s \\ &= (-1)^k(k+1)!\sum_{i=1}^{n}\frac{D_i^{k+1}s_i^2}{(1+\gamma D_i)^{k+2}}. \end{aligned}$$

(iii) $\displaystyle\sup_{k>1}\left|\frac{f^{(k)}(\gamma)}{k!f'(\gamma)}\right|^{1/(k-1)} \leq \frac{3}{2}\max\left\{\frac{D_1}{1+\gamma D_1},\ \frac{|D_n|}{1-\gamma|D_n|}\right\}.$

(iv) $\displaystyle\frac{1-\varepsilon_{\mathcal{P}}}{|D_n|+\varepsilon_{\mathcal{P}}D_1} \leq \gamma^* \leq \frac{1-\varepsilon_{\mathcal{P}}}{|D_n|}$, *where $\varepsilon_{\mathcal{P}}$ is given by (7).*

(v) *There exists a unique value $\bar{\gamma} \in (-1/D_1, 1/|D_n|)$ such that f is convex on $(-1/D_1, \bar{\gamma}]$ and concave on $[\bar{\gamma}, 1/|D_n|)$.*

Proof. (i) follows from the mean value theorem and the observation that f is decreasing on $(0, 1/|D_1|)$, and (ii) follows using a standard derivation. To prove (iii) observe that

$$\begin{aligned} \left|\frac{f^{(k)}(\gamma)}{k!f'(\gamma)}\right|^{1/(k-1)} &= \left|\frac{(k+1)!}{2k!}\right|^{1/(k-1)}\left|\frac{s^T\left(I+\gamma D\right)^{-(k+2)}D^{k+1}s}{s^T\left(I+\gamma D\right)^{-3}D^2 s}\right|^{1/(k-1)} \\ &\leq \frac{3}{2}\left|\frac{s^T\left(I+\gamma D\right)^{-3/2}D\left[\left(I+\gamma D\right)^{-1}D\right]^{k-1}D\left(I+\gamma D\right)^{-3/2}s}{s^T\left(I+\gamma D\right)^{-3/2}D^2\left(I+\gamma D\right)^{-3/2}s}\right|^{1/(k-1)} \\ &\leq \frac{3}{2}\max_{v\neq 0}\left|\frac{v^T P^{k-1}v}{v^T v}\right|^{1/(k-1)} \\ &= \frac{3}{2}\max_{i=1,\ldots,n}\left\{\frac{|D_i|}{1+\gamma D_i}\right\}, \end{aligned}$$

where $P = \left(I+\gamma D\right)^{-1}D$. Therefore

$$\left|\frac{f^{(k)}(\gamma)}{k!f'(\gamma)}\right|^{1/(k-1)} \leq \frac{3}{2}\max_{i=1,\ldots,n}\left\{\frac{|D_i|}{1+\gamma D_i}\right\} \leq \frac{3}{2}\max\left\{\frac{D_1}{1+\gamma D_1},\ \frac{|D_n|}{1-\gamma|D_n|}\right\},$$

which proves (iii). To prove the first inequality of (iv), note that

$$f(\gamma) = \sum_{i=1}^{n} \frac{D_i s_i^2}{(1+\gamma D_i)^2} \geq \frac{1}{(1+\gamma D_1)^2} \sum_{i=1}^{n-1} D_i s_i^2 - \frac{|D_n| s_n^2}{(1+\gamma D_n)^2}.$$

The right-hand side of the expression above equals zero only at $\tilde{\gamma} := \frac{1-\varepsilon_{\mathcal{P}}}{|D_n|+\varepsilon_{\mathcal{P}} D_1}$. This implies that $f(\tilde{\gamma}) \geq 0$, whereby $\tilde{\gamma} \leq \gamma^*$, since f is strictly decreasing. For the second inequality note that $\varepsilon_{\mathcal{P}} \in (0,1)$ since $s_n > 0$ and $s^T D s > 0$. We have $f(\gamma) < \sum_{i=1}^{n-1} s_i^2 D_i \ - |D_n| s_n^2/(1+\gamma D_n)^2$, and substituting $\gamma = \frac{1-\varepsilon_{\mathcal{P}}}{|D_n|}$ into this strict inequality yields $f(\frac{1-\varepsilon_{\mathcal{P}}}{|D_n|}) < 0$, which then implies that $\gamma^* < \frac{1-\varepsilon_{\mathcal{P}}}{|D_n|}$. To prove (v), examine the derivatives of f in (ii), and notice that $f^{(k)}(\gamma) < 0$ for any odd value of k, whereby f'' is strictly decreasing. Let $\bar{\gamma}$ be the unique point in $(-1/D_1, 1/|D_n|)$ such that $f''(\bar{\gamma}) = 0$. Since f'' is strictly decreasing, f is convex on $(-1/D_1, \bar{\gamma})$ and concave on $(\bar{\gamma}, 1/|D_n|)$. □

Figure 2 illustrates the geometry underlying some of the analytical properties of f described by Lemma 1.

Remark 4. In the interval $(\frac{-1}{D_1}, \frac{1}{2|D_n|} - \frac{1}{2D_1}]$ the maximum in (iii) of Lemma 1 is $\frac{D_1}{1+\gamma D_1}$, and in the interval $[\frac{1}{2|D_n|} - \frac{1}{2D_1}, \frac{1}{|D_n|})$ the maximum is $\frac{|D_n|}{1+\gamma D_n}$.

5.3. Locating an approximate zero of f by binary search. From Lemma 1 we know that $\gamma^* \in (0, \bar{U}]$, where $\bar{U} := (1-\bar{\varepsilon})/|D_n|$. We will cover this interval with subintervals and use a binary search to locate an approximate zero of f, motivated by the method of Ye [10]. Noticing from Remark 4 that the maximum in (iii) of Lemma 1 depends on the "midpoint" $M := \frac{1}{2|D_n|} - \frac{1}{2D_1}$, we will consider two types of subintervals: the *left intervals* will cover $[0, \max\{0, M\}]$, and the *right intervals* will cover $[\max\{0, M\}, \bar{U}]$. (Of course, in the case when $M \leq 0$, there is no need to create the left intervals.)

The left intervals will be of the form $[L^{i-1}, L^i]$, where $L^i := \frac{1}{D_1}((\frac{13}{12})^i - 1)$ for $i = 0, 1, \ldots$. If $M \leq 0$, we do not consider creating these intervals. The right intervals will have the form $[R^i, R^{i-1}]$, where $R^i := \frac{1}{|D_n|} - (\frac{1}{|D_n|} - \bar{U})(\frac{13}{12})^i$ for $i = 0, 1, \ldots$.

Let $[a, b]$ denote one of these intervals (either $[L^{i-1}, L^i]$ or $[R^i, R^{i-1}]$ for some i). Note that if $f(a) \geq 0$ and $f(b) \leq 0$, then $\gamma^* \in [a, b]$. Supposing that this is the case, it follows from Lemma 1 that f is either convex on $[a, \gamma^*]$ or concave on $[\gamma^*, b]$ (or both), and consider starting Newton's method from $\hat{\gamma} = a$ in the first case or $\hat{\gamma} = b$ in the second case. Then the Newton step

$$\gamma^+ = \hat{\gamma} - \frac{f(\hat{\gamma})}{f'(\hat{\gamma})}$$

satisfies

$$\left| \frac{f(\hat{\gamma})}{f'(\hat{\gamma})} \right| = |\gamma^+ - \hat{\gamma}| \leq |\gamma^* - \hat{\gamma}| \leq b - a, \tag{14}$$

where the first inequality follows from either the convexity of f on $[a, \gamma^*]$ or the concavity of f on $[\gamma^*, b]$. In particular, we have

$$|f(\hat{\gamma})| \leq |f'(\hat{\gamma})||\gamma^* - \hat{\gamma}|, \tag{15}$$

which relates the value of the function at an approximate solution and the error in our approximation.

LEMMA 2. *Under the hypotheses of Proposition 7 the intervals described herein have the following properties:*

(i) *The total number of left intervals and right intervals needed to cover* $[0, \bar{U}]$ *is* $K_L := \lceil \frac{\ln(1/2)+2\ln(1/\tau_{\mathcal{F}})}{\ln(13/12)} \rceil^+$ *and* $K_R := \lceil \frac{\ln(1/\bar{\varepsilon})}{\ln(13/12)} \rceil$, *respectively.*

(ii) *Let* $[a, b]$ *denote one of these intervals, and suppose that* $f(a) \geq 0$ *and* $f(b) \leq 0$. *Then either* a *or* b *is an approximate zero of* f, *and* $\gamma^* \in [a, b]$.

(iii) $R^{i-1} - R^i \leq \frac{1}{12|D_n|}$ *for* $i = 1, \ldots, K_R$ *and* $L^i - L^{i-1} \leq \frac{1}{12|D_n|}$ *for* $i = 1, \ldots, K_L$.

Proof. We first prove (i) for the right intervals. We have $R^0 = \bar{U}$ and

$$R^{K_R} = \frac{1}{|D_n|} - \frac{\bar{\varepsilon}}{|D_n|}\left(\frac{13}{12}\right)^{K_R} \leq \frac{1}{|D_n|} - \frac{\bar{\varepsilon}}{|D_n|}\frac{1}{\bar{\varepsilon}}\min\left\{1, \frac{|D_n|}{2D_1} + \frac{1}{2}\right\}$$
$$= \max\left\{0, \frac{1}{2|D_n|} - \frac{1}{2D_1}\right\} = \max\{0, M\},$$

and thus the right intervals cover $[\max\{0, M\}, \bar{U}]$. Note that, using the above reasoning, one easily shows that, because $K_R \leq 1 + \ln(1/\bar{\varepsilon})/\ln(13/12)$, one also has

$$\left(\frac{13}{12}\right)^{K_R} \leq \frac{13}{12\bar{\varepsilon}}. \tag{16}$$

For the left intervals, first consider the case when $M \geq 0$. Then $|D_n| \leq D_1$ and $\tau_{\mathcal{F}} \leq \frac{1}{\sqrt{2}}$, whereby there is no need to take the nonnegative part in the definition of K_L. We have $L^0 = 0$ and

$$L^{K_L} = \frac{1}{D_1}\left(\left(\frac{13}{12}\right)^{K_L} - 1\right) \geq \frac{1}{D_1}\left(\frac{1}{2\tau_{\mathcal{F}}^2} - 1\right) = \frac{1}{D_1}\left(\frac{D_1 + |D_n|}{2|D_n|} - 1\right) = M,$$

and thus the left intervals cover $[0, M] = [0, \max\{0, M\}]$. Note that, using the above reasoning, one easily shows that, because $K_L \leq 1 + \frac{\ln(1/2)+2\ln(1/\tau_{\mathcal{F}})}{\ln(13/12)}$, one also has

$$\left(\frac{13}{12}\right)^{K_L} \leq \frac{13}{24\tau_{\mathcal{F}}^2}. \tag{17}$$

When $M \leq 0$ there is nothing to prove.

To prove (ii), we consider the two cases of $[a, b]$ being either a left or right interval. If $[a, b]$ is a left interval, then $M \geq 0$ and $b = a(13/12) + \frac{1}{12D_1}$. In this case, for one of $\hat{\gamma} = a$ or $\hat{\gamma} = b$, we have for all $k > 1$:

$$\frac{1}{8}\left|\frac{f'(\hat{\gamma})}{f(\hat{\gamma})}\right| \geq \frac{1/8}{b-a} = \frac{1/8}{(1/12)(a + 1/D_1)} \geq \frac{3}{2}\frac{D_1}{1 + \hat{\gamma}D_1} \geq \left|\frac{f^{(k)}(\hat{\gamma})}{k!f'(\hat{\gamma})}\right|^{1/(k-1)},$$

where the first inequality uses (14), the second inequality uses $a \leq \hat{\gamma}$, and the third inequality uses Remark 4 and the fact that $\hat{\gamma} \leq M$ in conjunction with Lemma 1. Therefore $\hat{\gamma}$ is an approximate zero of f. If $[a, b]$ is a right interval, then $a = b(13/12) - \frac{1}{12|D_n|}$ and $M \leq a \leq b$. In this case, for one of $\hat{\gamma} = a$ or $\hat{\gamma} = b$, we have for all $k > 1$:

$$\frac{1}{8}\left|\frac{f'(\hat{\gamma})}{f(\hat{\gamma})}\right| \geq \frac{1/8}{b-a} = \frac{1/8}{b - b(13/12) + \frac{1}{12|D_n|}} = \frac{1/8}{\frac{1}{12}\left(\frac{1}{|D_n|} - b\right)} = \frac{3}{2}\,\frac{|D_n|}{1 - b|D_n|}$$
$$\geq \frac{3}{2}\,\frac{|D_n|}{1 - \hat{\gamma}|D_n|} \geq \left|\frac{f^{(k)}(\hat{\gamma})}{k!f'(\hat{\gamma})}\right|^{1/(k-1)},$$

where the first inequality uses (14), the second inequality uses $M \le a \le \hat{\gamma} \le b$, and the third inequality uses Remark 4 and the fact that $\hat{\gamma} \ge M$ in conjunction with Lemma 1. Therefore $\hat{\gamma}$ is an approximate zero of f.

To prove (iii), for the right intervals

$$R^{i-1} - R^i = \frac{\bar{\varepsilon}}{13|D_n|}\left(\frac{13}{12}\right)^i \le \frac{\bar{\varepsilon}}{13|D_n|}\left(\frac{13}{12}\right)^{K_R} \le \frac{13}{12}\frac{1}{13|D_n|} = \frac{1}{12|D_n|},$$

by the definition of K_R, and the second inequality derives from (16).

For the left intervals, we can assume $M \ge 0$ (otherwise they are not constructed), in which case $D_1 \ge |D_n|$. In this case, we have

$$L^i - L^{i-1} = \frac{1}{13D_1}\left(\frac{13}{12}\right)^i \le \frac{1}{13D_1}\left(\frac{13}{12}\right)^{K_L} \le \frac{1}{13D_1}\frac{13}{24\tau_{\mathcal{F}}^2} = \frac{1}{24}\left(\frac{1}{D_1} + \frac{1}{|D_n|}\right) \le \frac{1}{12|D_n|},$$

by the definition of K_L, and the second inequality derives from (17). ∎

Based on these properties, consider the following method for locating an approximate zero of f. Perform a binary search on the end points of the intervals, testing the end points to locate an interval $[a, b]$ for which $f(a) \ge 0$ and $f(b) \le 0$. Then either a or b is an approximate zero of f. Then initiate Newton's method from *both* a and b either in parallel or iterate-sequentially. Notice that, in order to perform a binary search on the left and right intervals, there is no need to compute and evaluate f for all of the end points. In fact, the operation complexity of a binary search will be $O(n \ln K_L)$ and $O(n \ln K_R)$, respectively, since each function evaluation of f requires $O(n)$ operations.

5.4. Computing a solution of (1) with duality gap at most σ. Under the hypotheses of Proposition 7, suppose that $[a, b]$ is one of the constructed intervals, $f(a) \ge 0$, and $f(b) \le 0$. Then, from Lemmas 1 and 2, $\gamma^* \in [a, b]$ and either f is convex on $[a, \gamma^*]$ or concave on $[\gamma^*, b]$ (or both). We first analyze the latter case, i.e., when f is concave on $[\gamma^*, b]$, whereby b is an approximate zero of f, and we analyze the iterates of Newton's method for k iterations starting at $\gamma_0 = b$. Let $\gamma := \gamma_k$ be the final iterate. It follows from the concavity of f on $[\gamma^*, b]$ that $\gamma \ge \gamma^*$ and consequently $f(\gamma) \le 0$. Then the analysis in Case 3 shows that the assignment (10) yields a feasible solution of (1) with duality gap $G = -f(\gamma)/\sqrt{s^T D^2 [I + \gamma D]^{-2} s}$. The following result bounds the value of this duality gap.

LEMMA 3. *Let $g \in (0, 1]$ be the desired duality gap for* (1)*, and let*

$$k = 1 + \left\lceil \frac{\ln\ln\left(\left(\frac{1}{3g}\right)\left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2}\right)\right) - \ln\ln 2}{\ln 2} \right\rceil.$$

Under the hypotheses of Proposition 7 *and the setup above where b is an approximate zero of f, let $\gamma_0 := b$ and $\gamma_1, \ldots, \gamma_k$ be the Newton iterates, and define $\gamma := \gamma_k$. Then the assignment* (10) *will be feasible for* (1) *with duality gap at most g.*

Proof. We have $|f(\gamma)| \le |f'(\gamma)|\,|\gamma^* - \gamma|$ from the concavity of f on $[\gamma^*, b]$. Also, we have

$$|f'(\gamma)| = 2\sum_{i=1}^{n} \frac{D_i^2 s_i^2}{(1 + \gamma D_i)^3} \le 2\sum_{i=1}^{n-1} \frac{D_i^2 s_i^2}{(1 + \gamma D_i)^2} + 2\frac{D_n^2 s_n^2}{(1 + \gamma D_n)^2}\frac{1}{(1 + \gamma D_n)}.$$

Substitute $\frac{1}{1+\gamma D_n} = 1 + \frac{-\gamma D_n}{1+\gamma D_n}$ to obtain

$$|f'(\gamma)| \le 2\sum_{i=1}^{n} \frac{D_i^2 s_i^2}{(1+\gamma D_i)^2} - 2\frac{\gamma D_n^3 s_n^2}{(1+\gamma D_n)^3}.$$

Let $G = y^T z$ denote the duality gap. Then

$$\begin{aligned}
G &= \frac{-f(\gamma)}{\sqrt{s^T D^2 [I+\gamma D]^{-2} s}} \le \frac{|f'(\gamma)|\ |\gamma^* - \gamma|}{\sqrt{s^T D^2 [I+\gamma D]^{-2} s}} \\
&\le \frac{2\sum_{i=1}^{n} \frac{D_i^2 s_i^2}{(1+\gamma D_i)^2} + 2\frac{\gamma |D_n|^3 s_n^2}{(1+\gamma D_n)^3}}{\sqrt{s^T D^2 [I+\gamma D]^{-2} s}} |\gamma^* - \gamma| \\
&= \left(2\sqrt{s^T D^2 [I+\gamma D]^{-2} s} + 2\frac{\gamma |D_n|^3 s_n^2}{(1+\gamma D_n)^3 \sqrt{s^T D^2 [I+\gamma D]^{-2} s}} \right) |\gamma^* - \gamma| \\
&\le \left(2D_1 + 2\frac{|D_n|}{1+\gamma D_n} + 2\frac{\gamma D_n^2 s_n}{(1+\gamma D_n)^2} \right) |\gamma^* - \gamma|,
\end{aligned}$$

where we used $\sqrt{s^T D^2 [I+\gamma D]^{-2} s} \ge |D_n| s_n / (1+\gamma D_n)$ in the last inequality. Next note that $\gamma \le \bar{U} = \frac{1-\bar{\varepsilon}}{|D_n|}$, which implies that $\frac{1}{\bar{\varepsilon}} \ge \frac{1}{1+\gamma D_n}$. Therefore, recalling that γ is the kth iterate, we have

$$\begin{aligned}
G &\le 2|\gamma^* - \gamma| \left(D_1 + \frac{|D_n|}{\bar{\varepsilon}} + \frac{(1-\bar{\varepsilon}) D_n^2}{|D_n| \bar{\varepsilon}^2} \right) \\
&\le 2|\gamma^* - \gamma| |D_n| \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2} \right) \\
&\le 4|\gamma_1 - \gamma_0| |D_n| \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2} \right) \left(\frac{1}{2} \right)^{2^{k-1}} \\
&\le 4\frac{1}{12|D_n|} |D_n| \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2} \right) \left(\frac{1}{2} \right)^{2^{k-1}} \\
&= \frac{1}{3} \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2} \right) \left(\frac{1}{2} \right)^{2^{k-1}},
\end{aligned}$$

where we used Theorem 3 for the third inequality and Lemma 2 for the fourth inequality. Substituting the value of k above yields $G \le g$. ∎

Last of all, we analyze the case when f is convex on $[a, \gamma^*]$, whereby a is an approximate zero of f, and we analyze the iterates of Newton's method for k iterations starting at $\gamma_0 = a$. Let γ_k be the final iterate. It follows from the convexity of f on $[a, \gamma^*]$ that $\gamma_k \le \gamma^*$ and consequently $f(\gamma_k) \ge 0$, in which case the assignment (10) is not necessarily feasible for (1). However, invoking Theorem 3, we know that $\gamma_k + 2(1/2)^{2^{k-1}} |\gamma_1 - \gamma_0| \ge \gamma^*$, we also know that $\bar{U} \ge \gamma^*$, and we can set $\gamma := \min\{\gamma_k + 2(1/2)^{2^{k-1}} |\gamma_1 - \gamma_0|, \bar{U}\}$. Then the analysis in Case 3 shows that the assignment (10) yields a feasible solution of (1), with duality gap $G = -f(\gamma)/\sqrt{s^T D^2 [I+\gamma D]^{-2} s}$. The following result bounds the value of this duality gap.

LEMMA 4. *Let $g \in (0,1]$ be the desired duality gap for* (1)*, and let*

$$k = 1 + \left\lceil \frac{\ln\ln\left(\left(\frac{16}{3g} \right) \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2} \right) \right) - \ln\ln 2}{\ln 2} \right\rceil.$$

Under the hypotheses of Proposition 7 and the setup above where a is an approximate zero of f, let $\gamma_0 := a$ and $\gamma_1, \ldots, \gamma_k$ be the Newton iterates, and define $\gamma := \min\{\gamma_k + 2(1/2)^{2^{k-1}}|\gamma_1 - \gamma_0|, \bar{U}\}$. Then the assignment (10) will be feasible for (1) with duality gap at most g.

Proof. Define $\delta := \gamma - \gamma_k$, and it follows that $\delta \geq 0$ and $\gamma_k + \delta \leq \bar{U}$. Furthermore,

$$\begin{aligned}\delta &\leq 2(1/2)^{2^{k-1}}|\gamma_1 - \gamma_0| \\ &\leq \frac{2}{\left(\frac{16}{3g}\right)[1/\tau_{\mathcal{F}}^2 + 1/\bar{\varepsilon}^2]\,12|D_n|} \\ &\leq \frac{\min\{\bar{\varepsilon}^2, \tau_{\mathcal{F}}^2\}}{|D_n|} \leq \frac{\min\{\bar{\varepsilon}, \tau_{\mathcal{F}}^2/(1-\tau_{\mathcal{F}}^2)\}}{|D_n|} = \min\{\bar{\varepsilon}/|D_n|, 1/D_1\}.\end{aligned} \tag{18}$$

Therefore $\delta \leq \bar{\varepsilon}/|D_n|$, whereby $1 + \gamma_k D_n + 2\delta D_n = 1 - (\gamma_k + \delta)|D_n| - \delta|D_n| \geq 1 + \bar{\varepsilon} - 1 - \bar{\varepsilon} = 0$, where we also used $\gamma_k + \delta \leq \bar{U} = (1 - \bar{\varepsilon})/|D_n|$. Therefore

$$1 + \gamma_k D_n \leq 2(1 + (\gamma_k + \delta)D_n) \leq 2(1 + tD_n) \quad \text{for all} \quad t \in [\gamma_k, \gamma_k + \delta]. \tag{19}$$

We also have from (18) that $\delta \leq 1/D_1 \leq 1/D_i \leq 1/D_i + \gamma_k$ for $i = 1, \ldots, n-1$; hence

$$1 + \gamma_k D_i + \delta D_i \leq 2(1 + \gamma_k D_i), \ i = 1, \ldots, n-1. \tag{20}$$

The duality gap of the assignment (10) is

$$G = y^T z = \frac{-f(\gamma)}{\sqrt{s^T D^2 [I + \gamma D]^{-2} s}} = \frac{-f(\gamma_k + \delta)}{\sqrt{s^T D^2 [I + (\gamma_k + \delta) D]^{-2} s}}.$$

We now proceed to bound the numerator and denominator of the rightmost expression. For the numerator we have

$$-f(\gamma_k + \delta) = |f(\gamma_k + \delta)| = \left| f(\gamma_k) + \int_{\gamma_k}^{\gamma_k + \delta} f'(t)dt \right|.$$

However, observe that $f(\gamma_k) \geq 0$, $f(\gamma_k + \delta) \leq 0$, and $f'(t) \leq 0$ for all $t \in [0, 1/|D_n|)$, whereby

$$|f(\gamma_k + \delta)| \leq \int_{\gamma_k}^{\gamma_k + \delta} |f'(t)|dt.$$

Using (19) for $t \in [\gamma_k, \gamma_k + \delta]$, we have

$$\begin{aligned}|f'(t)| &= 2\sum_{i=1}^{n-1} \frac{D_i^2 s_i^2}{(1 + tD_i)^3} + 2\frac{D_n^2 s_n^2}{(1 + tD_n)^3} \\ &\leq 2\sum_{i=1}^{n-1} \frac{D_i^2 s_i^2}{(1 + \gamma_k D_i)^3} + 16\frac{D_n^2 s_n^2}{(1 + \gamma_k D_n)^3} \leq 8|f'(\gamma_k)|,\end{aligned}$$

and it follows that $-f(\gamma_k + \delta) \leq 8\delta|f'(\gamma_k)|$. To bound the denominator, simply notice from (20) and $1 + \gamma_k D_n + \delta D_n \leq 1 + \gamma_k D_n$ that $\sqrt{s^T D^2 [I + (\gamma_k + \delta) D]^{-2} s} \geq (1/2)\sqrt{s^T D^2 [I + \gamma_k D]^{-2} s}$. Therefore

$$G = \frac{-f(\gamma_k + \delta)}{\sqrt{s^T D^2 [I + (\gamma_k + \delta) D]^{-2} s}} \leq 16\frac{\delta|f'(\gamma_k)|}{\sqrt{s^T D^2 [I + \gamma_k D]^{-2} s}}.$$

Next notice from the logic from the proof of Lemma 3 that

$$\frac{|f'(\gamma_k)|}{\sqrt{s^T D^2 [I+\gamma_k D]^{-2} s}} \leq 2|D_n| \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2}\right);$$

therefore

$$G \leq 32\delta|D_n| \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2}\right) \leq 32|D_n| \left(\frac{1}{\tau_{\mathcal{F}}^2} + \frac{1}{\bar{\varepsilon}^2}\right) \frac{2}{\left(\frac{16}{3g}\right)[1/\tau_{\mathcal{F}}^2 + 1/\bar{\varepsilon}^2]\, 12|D_n|} = g,$$

where the last inequality uses the second inequality of (18). ∎

Proof of Proposition 7. Note from the discussion at the end of section 5.3 that the operation complexity of the binary search is $O(n \ln K_L + n \ln K_R) = O(n \ln \ln(1/\tau_{\mathcal{F}} + 1/\bar{\varepsilon}))$ from Lemma 2. The number of Newton steps is $O(\ln \ln(1/\tau_{\mathcal{F}} + 1/\bar{\varepsilon} + 1/g))$ from Lemmas 3 and 4, with each Newton step requiring $O(n)$ operations, yielding the desired complexity bound. ∎

Acknowledgments. We are grateful to two anonymous referees for their suggestions on ways to improve the paper.

RELAXED ALTERNATING PROJECTION METHODS*

ANDRZEJ CEGIELSKI† AND AGNIESZKA SUCHOCKA†

Abstract. In this paper we deal with the von Neumann alternating projection method $x_{k+1} = P_A P_B x_k$ and with its generalization of the form $x_{k+1} = P_A(x_k + \lambda_k(P_A P_B x_k - x_k))$, where A, B are closed and convex subsets of a Hilbert space $\mathcal{H}$ and $\operatorname{Fix} P_A P_B \neq \varnothing$. We do not suppose that $A \cap B \neq \varnothing$. We give sufficient conditions for the weak convergence of the sequence (x_k) to $\operatorname{Fix} P_A P_B$ in the general case and in the case A is a closed affine subspace. We present also the results of preliminary numerical experiments.

Key words. alternating projection method, Fejér monotonicity, weak convergence

1. Introduction. Let $\mathcal{H}$ be a real Hilbert space equipped with a scalar product $\langle \cdot, \cdot \rangle$ and with the norm $\| \cdot \|$ induced by $\langle \cdot, \cdot \rangle$. Further, let $A, B \subset \mathcal{H}$ be nonempty, convex, and closed subsets. In the practical considerations one often needs to find an element of the intersection $A \cap B$ or, more generally, to solve the following problem:

$$\text{find } a^* \in A \text{ and } b^* \in B \text{ such that } \|a^* - b^*\| = \inf_{a \in A, b \in B} \|a - b\|. \tag{1}$$

We suppose that this infimum is attained. Of course, $a^* = b^*$ if and only if $A \cap B \neq \varnothing$. Several optimization problems, e.g., the convex feasibility problem, can be reduced to problem (1) (see, e.g., [18, section 2.9] for details). Problems of this kind have many practical applications, e.g., in signal reconstruction (see, e.g., [8] or [18, Chapter 6]), in image reconstruction, or in intensity modulated radiation therapy (see, e.g., [7, 10, 18, 9, 14]), where the convex subsets are described by a large and sparse system of linear equalities or inequalities.

An important method generating sequences which converge weakly to a solution of problem (1) is the von Neumann alternating projection (AP) method (see, e.g., [11, Chapter 9] or [1, section 4]). In this method the metric projections onto A and B are successively applied. Recall that for a closed and convex subset $D \subset \mathcal{H}$ and for any $u \in \mathcal{H}$ there exists the uniquely determined metric projection $P_D u$. Furthermore, a point $y \in D$ is the projection $P_D u$ if and only if

$$\langle u - y, z - y \rangle \leq 0 \text{ for all } z \in D; \tag{2}$$

i.e., inequality (2) characterizes the metric projection $P_D u$ (see, e.g., [12, Lemma 12.1] or [1, section 1]). It is known that $a^* \in A$ and $b^* \in B$ realize the distance between A and B if and only if $a^* = P_A b^*$ and $b^* = P_B a^*$, i.e., $a^* \in \operatorname{Fix} P_A P_B$ or $b^* \in \operatorname{Fix} P_B P_A$ (see, e.g., [1, Lemma 2.2(i)]). Therefore, it is enough to find an element of $\operatorname{Fix} P_A P_B$ in order to find a solution of problem (1). In this paper we construct a generalization of the von Neumann alternating projection method and prove its Fejér monotonicity

with respect to the solution set $\operatorname{Fix} P_A P_B$, as well as prove the weak convergence of the method to a solution. Recall that a sequence $(x_k) \subset \mathcal{H}$ is called *Fejér monotone* with respect to a subset $D \subset \mathcal{H}$ if for all $z \in D$ there holds $\|x_{k+1} - z\| \leq \|x_k - z\|$, $k = 1, 2, \ldots$.

Consider a sequence $(x_k) \subset \mathcal{H}$ generated by the following iterative scheme:

$$\begin{aligned} &x_0 \in A \text{ – arbitrary,} \\ &x_{k+1} = P_A(x_k + \lambda_k \sigma_k (P_A P_B x_k - x_k)), \end{aligned} \tag{3}$$

where the *relaxation parameter* $\lambda_k \in [0, 2]$ and the *step size* $\sigma_k \geq 0$. We call method (3) the *relaxed alternating projection (RAP) method*. If $\lambda_k = \sigma_k = 1$, we obtain the *von Neumann AP method*:

$$\begin{aligned} &x_0 \in A \text{ – arbitrary,} \\ &x_{k+1} = P_A P_B x_k \end{aligned} \tag{4}$$

(see, e.g., [1]). Some modifications of the AP method (4) for $A \cap B \neq \varnothing$ and for B being an obtuse cone, different from (3), were proposed in [5, section 3], where the projection P_B in (4) is replaced by the reflection $R_B = 2P_B - I$.

One can show that any sequence (x_k) generated by the AP method (4) converges weakly to an element $x^* \in \operatorname{Fix} P_A P_B$ (see, e.g., [1, Theorem 4.8 and Lemma 2.2]). Note that $\operatorname{Fix} P_A P_B \neq \varnothing$ since we have supposed that the infimum in (1) is attained. If $A \cap B \neq \varnothing$, then any sequence (x_k) generated by the RAP method (3) converges weakly to an element $x^* \in \operatorname{Fix} P_A P_B = A \cap B$ if $\sigma_k = 1$ and $\lambda_k \in [\varepsilon, 2 - \varepsilon]$, where $\varepsilon > 0$ (see, e.g., [2, Corollary 3.22] for a more general result). Gurin, Polyak, and Raik have proposed the following step size in order to accelerate the convergence of the RAP method in the case $A \cap B \neq \varnothing$:

$$\sigma_k = \frac{\|P_B x_k - x_k\|^2}{\langle P_B x_k - x_k, P_A P_B x_k - x_k \rangle} \tag{5}$$

(see [13, Theorem 4]). Recently, the idea of [13] was applied in the case A and B are subspaces of $\mathcal{H}$ (see [4, Theorem 3.23]) and in the case A is a closed affine subspace of $\mathcal{H}$ with $A \cap B \neq \varnothing$ (see [3, Corollary 4.11]). Unfortunately, the weak convergence of the RAP method with the relaxation parameter $\lambda_k \in [\varepsilon, 2 - \varepsilon]$ and the step size $\sigma_k = 1$ or the step size defined by (5) is not guaranteed if $A \cap B = \varnothing$. A new question arises in this context: What should we impose on the relaxation parameters λ_k and on the step sizes σ_k in order to obtain the weak convergence of the RAP method (3) to an element $x^* \in \operatorname{Fix} P_A P_B$, without assumption $A \cap B \neq \varnothing$? The answers to these questions are contained in Theorem 15, which is the main result of the paper.

In sections 2 and 3 we give some sufficient conditions for the quasi nonexpansivity of operators determining RAP methods. Recall that an operator $U : C \to \mathcal{H}$ is *quasi-nonexpansive* if for all $x \in C$ and for all $z \in \operatorname{Fix} U$ there holds the inequality

$$\|Ux - z\| \leq \|x - z\|$$

(see, e.g., [16]). Quasi-nonexpansive operators are also known in the literature under the name *attracting* operators (see, e.g., [2, Definition 2.1]) or *Fejér monotone* operators or mappings (see, e.g., [17, Definition 2.1]. In section 4 we show the weak convergence of RAP methods to a fixed point of the operator $P_A P_B$ for special choices of step sizes σ_k. In section 5 we present the results of preliminary numerical experiments.

2. Quasi nonexpansivity of relaxed alternating projections. Let A, B be nonempty, closed, and convex subsets of $\mathcal{H}$. Define the operator of *alternating projections* $T : A \to A$ by the equality

$$T = P_A P_B.$$

For a constant $\lambda \in [0, 2]$ we call the operator $T_\lambda = (1 - \lambda)I + \lambda T$ the *relaxation* of T and the operator $P_A T_\lambda$ the *projected relaxation* of T. Furthermore, for a relaxation parameter $\lambda \in [0, 2]$ we call the operator $T_{\sigma,\lambda} : A \to A$ defined by

$$T_{\sigma,\lambda} x = P_A(x + \lambda\sigma(x)(Tx - x)) \tag{6}$$

the RAP operator, where the nonnegative *step size function* $\sigma(x)$ depends on x; i.e., σ is a function, $\sigma : A \to \mathbb{R}_+ = [0, +\infty)$. Of course, $T_{\sigma,\lambda} = T$ if $\sigma(x) = 1$ for all $x \in A$ and $\lambda = 1$. The operator T defines the AP method since the iteration (4) can be written in the form $x_{k+1} = Tx_k$. Similarly, for a function $\sigma : A \to \mathbb{R}_+$ and for a sequence of relaxation parameters (λ_k) the operator $T_{\sigma,\lambda}$ defines the RAP method by the equality

$$x_{k+1} = T_{\sigma,\lambda_k} x_k, \tag{7}$$

which is equivalent to (3) with $\sigma_k = \sigma(x_k)$. First we give some properties of the operators T and $T_{\sigma,\lambda}$, which we use later to show the quasi nonexpansivity of $T_{\sigma,\lambda}$ and the weak convergence of a sequence generated by the recurrence (7) for special choices of the step size function $\sigma : A \to \mathbb{R}_+$.

LEMMA 1. *Let $\sigma(x) > 0$ for all $x \in A$, and let $\lambda > 0$. Then* $\operatorname{Fix} T_{\sigma,\lambda} = \operatorname{Fix} T$.

Proof. Denote by $N_D(y) = \{u \in \mathcal{H} : \langle u - y, z - y\rangle \le 0 \text{ for all } z \in D\}$ the *normal cone* to a closed and convex subset $D \subset \mathcal{H}$ at the point $y \in D$. By the equivalence

$$y = P_D u \Leftrightarrow u - y \in N_D(y), \tag{8}$$

where $D \subset \mathcal{H}$ is a closed and convex subset (see, e.g., [15, Chapter 1, Proposition 5.3.3]), and by the obvious fact that $N_D(y)$ is a cone, we have

$$\begin{aligned} x \in \operatorname{Fix} T_{\sigma,\lambda} &\Leftrightarrow P_A(x + \lambda\sigma(x)(Tx - x)) = x \\ &\Leftrightarrow \lambda\sigma(x)(Tx - x) \in N_A(x) \Leftrightarrow Tx - x \in N_A(x) \\ &\Leftrightarrow x = P_A Tx = Tx \Leftrightarrow x \in \operatorname{Fix} T, \end{aligned}$$

which completes the proof. □

It is easily seen that the characterization (2) of the metric projection $P_D u$ is equivalent to the condition

$$\langle z - u, P_D u - u\rangle \ge \|P_D u - u\|^2 \text{ for any } u \in \mathcal{H} \text{ and } z \in D. \tag{9}$$

Denote by $\delta = \mathrm{d}(A, B) = \inf_{x\in A, y\in B} \|x - y\|$ the distance between the subsets A and B. As we have supposed in section 1, δ is attained, and, consequently, $\operatorname{Fix} T \ne \varnothing$.

LEMMA 2. *Let $z \in \operatorname{Fix} T$. Then for any $x \in A$ there holds the inequality*

$$\langle z - x, Tx - x\rangle \ge \|Tx - P_B x\|^2 - \tilde{\delta}\|P_B x - x\| + \langle P_B x - x, Tx - x\rangle, \tag{10}$$

where $\tilde{\delta} \in [\delta, \|Tx - P_B x\|]$ is an upper bound of the distance δ.

Proof. Let $w = P_B z$. Observe that $\|z - w\| = \delta$ (see, e.g., [1, Lemma 2.2(i)]). We have by the characterization (2) of the metric projection and by the Cauchy–Schwarz inequality

$$\begin{aligned}\langle z - P_B x, P_B x - x\rangle &= \langle z - w, P_B x - x\rangle + \langle w - P_B x, P_B x - x\rangle \\ &\geq \langle z - w, P_B x - x\rangle \\ &\geq -\|z - w\| \cdot \|P_B x - x\| = -\delta\|P_B x - x\|.\end{aligned}$$

Therefore, if we apply condition (9) we obtain

$$\begin{aligned}\langle z - x, Tx - x\rangle &= \langle z - P_B x, Tx - x\rangle + \langle P_B x - x, Tx - x\rangle \\ &= \langle z - P_B x, Tx - P_B x\rangle + \langle z - P_B x, P_B x - x\rangle \\ &\quad + \langle P_B x - x, Tx - x\rangle \\ &\geq \|Tx - P_B x\|^2 - \delta\|P_B x - x\| + \langle P_B x - x, Tx - x\rangle.\end{aligned}$$

Now (10) follows from the inequality $\delta \leq \tilde{\delta}$. ∎

Let $x \in A$. Let

$$\bar{\delta} = \bar{\delta}(x) = \|Tx - P_B x\|. \tag{11}$$

Let

$$\tilde{\delta} = \tilde{\delta}(x) \in [\delta, \bar{\delta}(x)] \tag{12}$$

be an upper bound of the distance δ, and let $T_{\sigma,\lambda}$ be defined by (6), where the function $\sigma : A \to \mathbb{R}_+$ is given by

$$\sigma(x) = \frac{\|Tx - P_B x\|^2 - \tilde{\delta}\|P_B x - x\| + \langle P_B x - x, Tx - x\rangle}{\|Tx - x\|^2} \tag{13}$$

for $x \notin \operatorname{Fix} T$ and $\sigma(x) = 1$ for $x \in \operatorname{Fix} T$. For $x \in A$ define

$$\alpha(x) = \begin{cases} \sphericalangle(x - P_B x, Tx - P_B x) & \text{if } x \notin \operatorname{Fix} T \text{ and } P_B x \notin A, \\ 0 & \text{if } x \in \operatorname{Fix} T \text{ or } P_B x \in A, \end{cases} \tag{14}$$

where the symbol $\sphericalangle(a, b)$ denotes the angle between two nonzero vectors $a, b \in \mathcal{H}$, i.e., $\sphericalangle(a, b) = \arccos \frac{\langle a,b\rangle}{\|a\| \cdot \|b\|}$. Note that $\alpha(x)$ is well defined since $x - P_B x$ and $Tx - P_B x$ are obviously nonzero vectors in the first case of (14). Furthermore, we have by the characterization of the metric projection $P_A(P_B x)$

$$\langle P_B x - x, P_B x - Tx\rangle \geq \|P_B x - Tx\|^2 > 0 \tag{15}$$

and, consequently,

$$0 < \frac{\|P_B x - Tx\|}{\|P_B x - x\|} \leq \cos\alpha(x). \tag{16}$$

LEMMA 3. *Let $x \in A$, and let the step size $\sigma(x)$ be defined by* (13). *Then*

$$\sigma(x) \geq \frac{1}{1 + \cos\alpha(x)} \geq \frac{1}{2}. \tag{17}$$

Proof. Inequality (17) is clear if $x \in \operatorname{Fix} T$ or $P_B x \in A$. Suppose now that $x \notin \operatorname{Fix} T$ and $P_B x \notin A$. Let $a = P_B x - x$, $b = Tx - x$, and $c = P_B x - Tx$. Of course, $a, b, c \neq 0$ and $\alpha(x) = \sphericalangle(a, c)$. Observe that $b = a - c$, $\tilde{\delta} \leq \|c\|$, and that the function $y \longmapsto \frac{y+\rho}{y+2\rho}$ is increasing for $y > -2\rho$. Therefore, for $\rho = 1 - \cos\alpha(x)$, we have

$$\begin{aligned}
\sigma(x) &= \frac{\|c\|^2 - \tilde{\delta}\|a\| + \langle a, b\rangle}{\|b\|^2} \\
&\geq \frac{\|c\|^2 - \|a\| \cdot \|c\| + \langle a, b\rangle}{\|b\|^2} \\
&= \frac{\|c\|^2 - \|a\| \cdot \|c\| + \langle a, a - c\rangle}{\|a - c\|^2} \\
&= \frac{(\|a\| - \|c\|)^2 + \|a\| \cdot \|c\| - \langle a, c\rangle}{(\|a\| - \|c\|)^2 + 2(\|a\| \cdot \|c\| - \langle a, c\rangle)} \\
&= \frac{\left(1 - \frac{\|c\|}{\|a\|}\right)\left(\frac{\|a\|}{\|c\|} - 1\right) + 1 - \cos\alpha(x)}{\left(1 - \frac{\|c\|}{\|a\|}\right)\left(\frac{\|a\|}{\|c\|} - 1\right) + 2(1 - \cos\alpha(x))} \\
&\geq \frac{(1 - \cos\alpha(x))\left(\frac{1}{\cos\alpha(x)} - 1\right) + 1 - \cos\alpha(x)}{(1 - \cos\alpha(x))\left(\frac{1}{\cos\alpha(x)} - 1\right) + 2(1 - \cos\alpha(x))} \\
&= \frac{1}{1 + \cos\alpha(x)} \geq \frac{1}{2},
\end{aligned}$$

which completes the proof. ∎

LEMMA 4. *Let $x \in A$ be such that $Tx \notin \operatorname{Fix} T$. Then $\alpha(x) \in (0, \frac{\pi}{2})$ and, consequently, the vectors $x - P_B x$ and $Tx - P_B x$ are linearly independent.*

Proof. Suppose that $\alpha(x) = 0$, i.e.,

$$Tx - P_B x = \gamma(x - P_B x) \tag{18}$$

for some $\gamma > 0$. By the equivalence (8) we have $x - P_B x \in N_B(P_B x)$ and, consequently, $\gamma(x - P_B x) \in N_B(P_B x)$, and again by the equivalence (8),

$$P_B(P_B x + \gamma(x - P_B x)) = P_B x. \tag{19}$$

Now we obtain by (18) and (19)

$$\begin{aligned}
TTx &= T(P_B x + \gamma(x - P_B x)) \\
&= P_A P_B(P_B x + \gamma(x - P_B x)) \\
&= P_A P_B x = Tx,
\end{aligned}$$

a contradiction with the assumption $Tx \notin \operatorname{Fix} T$. Therefore, $\alpha(x) > 0$. Furthermore, $\alpha(x) < \frac{\pi}{2}$ by (16). Consequently, the vectors $x - P_B x$ and $Tx - P_B x$ are linearly independent. ∎

Remark 5. According to Lemma 4, we can stop the RAP algorithm (3) with $Tx_k \in \operatorname{Fix} T$ if we state that $P_B x_k - x_k$ and $Tx_k - P_B x_k$ are linearly dependent.

Let $x \in A$ be such that $Tx \notin \operatorname{Fix} T$. Let $y \in \operatorname{aff}(x, P_B x, Tx)$ be a solution of the system

$$\langle P_B x - y, P_B x - x\rangle = \tilde{\delta}\|P_B x - x\|, \tag{20}$$

$$\langle P_B x - y, Tx - P_B x\rangle = -\|Tx - P_B x\|^2, \tag{21}$$

where $\tilde{\delta} \in [\delta, \|Tx - P_B x\|]$. By Lemma 4 such a solution is defined uniquely.

LEMMA 6. *Let $x \in A$ be such that $Tx \notin \operatorname{Fix} T$. The step size $\sigma(x)$ given by* (13) *is characterized by the equality*

$$\langle x + \sigma(x)(Tx - x) - y, Tx - x\rangle = 0. \tag{22}$$

Proof. For y being a solution of the system (20)–(21) and for any σ we have

$$\begin{aligned}
&\langle x + \sigma(Tx - x) - y, Tx - x\rangle \\
&= \langle x - y, Tx - x\rangle + \sigma\|Tx - x\|^2 \\
&= \langle x - P_B x, Tx - x\rangle + \langle P_B x - y, Tx - x\rangle + \sigma\|Tx - x\|^2 \\
&= \langle x - P_B x, Tx - x\rangle + \langle P_B x - y, Tx - P_B x\rangle \\
&\quad + \langle P_B x - y, P_B x - x\rangle + \sigma\|Tx - x\|^2 \\
&= \langle x - P_B x, Tx - x\rangle - \|Tx - P_B x\|^2 + \tilde{\delta}\|P_B x - x\| + \sigma\|Tx - x\|^2.
\end{aligned}$$

Therefore, equalities (22) and (13) are equivalent. ∎

LEMMA 7. *Let $z \in \operatorname{Fix} T$, $x \in A$, and let $\sigma(x)$ be defined by* (13). *There holds the inequality*

$$\langle z - x, Tx - x\rangle \geq \sigma(x)\|Tx - x\|^2.$$

Proof. The lemma follows directly from Lemma 2 and from equality (13). ∎

THEOREM 8. *Let $x \in A$, and let $\sigma(x)$ be given by* (13). *Then for any $z \in \operatorname{Fix} T$ and for any $\lambda \geq 0$ there holds the inequality*

$$\|T_{\sigma,\lambda}x - z\|^2 \leq \|x - z\|^2 - \lambda(2 - \lambda)\sigma^2(x)\|Tx - x\|^2. \tag{23}$$

Consequently, the operator $T_{\sigma,\lambda}$ defined by (6) *is quasi-nonexpansive for $\lambda \in [0, 2]$.*

Proof. Let $z \in \operatorname{Fix} T$, $x \in A$, and $\lambda \geq 0$. Of course, $z = P_A z$. We have by the nonexpansivity of the metric projection P_A and by Lemma 7

$$\begin{aligned}
\|T_{\sigma,\lambda}x - z\|^2 &= \|P_A(x + \lambda\sigma(x)(Tx - x)) - z\|^2 \\
&= \|P_A(x + \lambda\sigma(x)(Tx - x)) - P_A z\|^2 \\
&\leq \|x + \lambda\sigma(x)(Tx - x) - z\|^2 \\
&= \|x - z\|^2 + \lambda^2\sigma^2(x)\|Tx - x\|^2 - 2\lambda\sigma(x)\langle z - x, Tx - x\rangle \\
&\leq \|x - z\|^2 + \lambda^2\sigma^2(x)\|Tx - x\|^2 - 2\lambda\sigma^2(x)\|Tx - x\|^2 \\
&= \|x - z\|^2 - \lambda(2 - \lambda)\sigma^2(x)\|Tx - x\|^2,
\end{aligned}$$

and we see that $T_{\sigma,\lambda}$ is quasi-nonexpansive if $\lambda \in [0, 2]$. ∎

Remark 9. Let $A \cap B \neq \varnothing$, and let $x \in A \setminus B$. We have $\delta = 0$, and the step size given by (13) with $\tilde{\delta} = 0$ has the form

$$\sigma(x) = \frac{\|Tx - P_B x\|^2 + \langle P_B x - x, Tx - x\rangle}{\|Tx - x\|^2}. \tag{24}$$

Gurin, Polyak, and Raik have proposed the relaxation parameter $\lambda = 1$ and the following step size $\sigma(x)$ in the relaxed alternating projection method:

$$\sigma(x) = \frac{\|P_B x - x\|^2}{\langle P_B x - x, Tx - x\rangle} \tag{25}$$

(see [13, equality (15)]). Observe that the step size $\sigma(x)$ defined by (25) is the unique solution of the equality

$$\langle x + \sigma(x)(Tx - x) - P_B x, P_B x - x\rangle = 0.$$

Consider two cases of the RAP method with the step size (25):

(i) If A, B are subspaces of H, then

$$\sigma(x) = \frac{\langle x, x - Tx\rangle}{\|Tx - x\|^2}.$$

In this case the RAP method is equivalent to an acceleration method of Bauschke et al. (see [4, equality (3.1.2) and Theorem 3.23]).

(ii) If A is a closed affine subspace, then $\langle P_B x - x, Tx - x\rangle = \|Tx - x\|^2$ and

$$\sigma(x) = \frac{\|P_B x - x\|^2}{\|Tx - x\|^2}.$$

In this case the RAP method is equivalent to the extrapolated alternating projection method (see [3, equality (4.35)]).

LEMMA 10. *Let $A \cap B \neq \varnothing$, and let $x \in A \setminus B$. Then we have*

$$\frac{\|Tx - P_B x\|^2 + \langle P_B x - x, Tx - x\rangle}{\|Tx - x\|^2} \geq \frac{\|P_B x - x\|^2}{\langle P_B x - x, Tx - x\rangle}; \tag{26}$$

i.e., the step size $\sigma(x)$ defined by (24) *is not shorter than the one proposed by Gurin, Polyak, and Raik* (*equality* (25)). *Furthermore, both step sizes are equal if A is a closed affine subspace.*

Proof. Observe that $\delta = 0$ since $A \cap B \neq \varnothing$ and that $x \notin \operatorname{Fix} T$ since $\operatorname{Fix} T = A \cap B$ for $A \cap B \neq \varnothing$. It follows from the characterization of the metric projection $P_A(P_B x)$ that

$$\langle x - Tx, P_B x - Tx\rangle \leq 0. \tag{27}$$

If we apply inequality (27), the Cauchy–Schwarz inequality, the nonexpansivity of the metric projection P_A, and the fact $x \neq Tx$ we easily obtain

$$0 < \|Tx - x\|^2 \leq \langle P_B x - x, Tx - x\rangle \leq \|P_B x - x\|^2. \tag{28}$$

A simple computation shows that

$$\begin{aligned}&\frac{\|Tx - P_B x\|^2 + \langle P_B x - x, Tx - x\rangle}{\|Tx - x\|^2}\\ &= \frac{\|Tx - x\|^2 + \|P_B x - x\|^2 - \langle P_B x - x, Tx - x\rangle}{\|Tx - x\|^2}.\end{aligned}$$

If we apply the last equality, we easily see that (26) is equivalent to the inequality

$$\left(\|P_B x - x\|^2 - \langle P_B x - x, Tx - x\rangle\right)\left(\langle P_B - x, Tx - x\rangle - \|Tx - x\|^2\right) \geq 0,$$

which is true by (28). Suppose now that A is a closed affine subspace. The equality in (26) follows easily from the fact that $\langle Tx - P_B x, Tx - x\rangle = 0$ for A being an affine subspace. ∎

3. Quasi nonexpansivity of the RAP operator for closed and affine A. In this section we suppose that $A \subset \mathcal{H}$ is a closed affine subspace. In this case $x + \sigma(Tx - x) \in A$ for any $x \in A$ and $\sigma \in \mathbb{R}$, where $T = P_A P_B$. Consequently, the RAP operator $T_{\sigma,\lambda} : A \to A$ defined by (6) has the form

$$T_{\sigma,\lambda}(x) = x + \lambda\sigma(x)(Tx - x) \tag{29}$$

and one iteration of the RAP method has the form

$$x_{k+1} = x_k + \lambda_k \sigma_k (Tx_k - x_k). \tag{30}$$

It is known that for A being an affine subspace the operator $T = P_A P_B$ restricted to A is firmly nonexpansive [6, Proposition 3(i)] and that the RAP method converges to an element of $\operatorname{Fix} T$ for $\sigma_k = 1$ and for $\lambda_k \in [\varepsilon, 2 - \varepsilon]$, where $\varepsilon > 0$ [6, Theorem 1] (see, e.g., [12, Chapter 12] for the definition and the properties of firmly nonexpansive operators). We generalize these results. We start with the following lemma.

LEMMA 11. *Let $A \subset \mathcal{H}$ be a closed affine subspace and $B \subset \mathcal{H}$ be a closed and convex subset. For all $x, y \in A$ there holds the inequality*

$$\langle Tx - Ty, x - y\rangle \geq \|Tx - Ty\|^2 + (\|Tx - P_B x\| - \|Ty - P_B y\|)^2.$$

Proof. Since the metric projection P_A is a firmly nonexpansive operator (see, e.g., [2, Fact 1.5]), we have for any $u, v \in \mathcal{H}$

$$\langle Tu - Tv, P_B u - P_B v\rangle \geq \|Tu - Tv\|^2. \tag{31}$$

Further, for any $u, v \in A$ we have, by the affinity of A,

$$\langle Tu - P_B u, u - P_B u\rangle = \|Tu - P_B u\|^2 \tag{32}$$

and

$$\langle P_B v - Tv, u - Tu\rangle = 0. \tag{33}$$

The characterization of the metric projection $P_B v$ yields

$$\langle P_B u - P_B v, v - P_B v\rangle \leq 0 \tag{34}$$

for any $u, v \in \mathcal{H}$. Now let $x, y \in A$. It follows from (31)–(34) and from the Cauchy–Schwarz inequality that

$$\begin{aligned}
&\langle Tx - Ty, x - y\rangle \\
&= \langle Tx - Ty, P_B x - P_B y\rangle + \langle Tx - Ty, (x - P_B x) - (y - P_B y)\rangle \\
&\geq \|Tx - Ty\|^2 \\
&\quad + \langle (Tx - P_B x) + (P_B x - P_B y) + (P_B y - Ty), (x - P_B x) - (y - P_B y)\rangle \\
&= \|Tx - Ty\|^2 + \langle Tx - P_B x, x - P_B x\rangle - \langle Tx - P_B x, y - P_B y\rangle \\
&\quad + \langle P_B x - P_B y, x - P_B x\rangle + \langle P_B y - P_B x, y - P_B y\rangle \\
&\quad + \langle P_B y - Ty, x - P_B x\rangle + \langle Ty - P_B y, y - P_B y\rangle \\
&\geq \|Tx - Ty\|^2 + \|Tx - P_B x\|^2 - (\langle Tx - P_B x, y - Ty\rangle \\
&\quad - \langle P_B x - Tx, Ty - P_B y\rangle) + \langle P_B y - Ty, x - Tx\rangle \\
&\quad + \langle P_B y - Ty, Tx - P_B x\rangle + \|Ty - P_B y\|^2 \\
&\geq \|Tx - Ty\|^2 + \|Tx - P_B x\|^2 - 2\|P_B x - Tx\| \cdot \|Ty - P_B y\| \\
&\quad + \|Ty - P_B y\|^2 \\
&= \|Tx - Ty\|^2 + (\|Tx - P_B x\| - \|Ty - P_B y\|)^2,
\end{aligned}$$

which completes the proof. ∎

COROLLARY 12 (Combettes [6]). *Let $A \subset \mathcal{H}$ be a closed affine subspace and $B \subset \mathcal{H}$ be a closed and convex subset. Then the operator $T : A \to A$, $T = P_A P_B$, is firmly nonexpansive.*

Let the function $\sigma : A \to \mathbb{R}_+$ be defined by

$$\sigma(x) = 1 + \frac{\left(\|Tx - P_B x\| - \tilde{\delta}\right)^2}{\|Tx - x\|^2}, \tag{35}$$

for $x \notin \operatorname{Fix} T$ and $\sigma(x) = 1$ for $x \in \operatorname{Fix} T$, where $\tilde{\delta}$ is given by (12).

LEMMA 13. *Let $z \in \operatorname{Fix} T$, $x \in A$, and let $\sigma(x)$ be defined by* (35). *There holds the inequality*

$$\langle z - x, Tx - x\rangle \geq \sigma(x)\|Tx - x\|^2.$$

Proof. The lemma is obvious for $x \in \operatorname{Fix} T$. Now let $x \notin \operatorname{Fix} T$. Since $\delta = \|Tz - P_B z\|$ we have by Lemma 11 that

$$\begin{aligned}
\langle z - x, Tx - x\rangle &= \|Tx - x\|^2 + \langle z - Tx, Tx - x\rangle \\
&= \|Tx - x\|^2 + \langle Tz - Tx, z - x\rangle - \|Tz - Tx\|^2 \\
&\geq \|Tx - x\|^2 + (\|Tx - P_B x\| - \|Tz - P_B z\|)^2 \\
&= \left(1 + \frac{(\|Tx - P_B x\| - \delta)^2}{\|Tx - x\|^2}\right)\|Tx - x\|^2 \\
&\geq \left(1 + \frac{\left(\|Tx - P_B x\| - \tilde{\delta}\right)^2}{\|Tx - x\|^2}\right)\|Tx - x\|^2,
\end{aligned}$$

and the lemma follows now from equality (35). ∎

COROLLARY 14. *Let $A \subset \mathcal{H}$ be a closed affine subspace and $B \subset \mathcal{H}$ be a closed and convex subset. Further, let $T_{\sigma,\lambda} : A \to A$ be defined by* (29), *where σ is defined by* (35). *Then for any $x \in A$, $z \in \operatorname{Fix} T$, and $\lambda \geq 0$ there holds the inequality*

$$\|T_{\sigma,\lambda}x - z\|^2 \leq \|x - z\|^2 - \lambda(2 - \lambda)\sigma^2(x)\|Tx - x\|^2, \tag{36}$$

and, consequently, $T_{\sigma,\lambda}$ is quasi-nonexpansive for $\lambda \in [0, 2]$.

Proof. Let $x \in A$, $z \in \operatorname{Fix} T$, and $\lambda \geq 0$. We have by Lemma 13 that

$$\begin{aligned}
\|T_{\sigma,\lambda}x - z\|^2 &= \|x + \lambda\sigma(x)(Tx - x) - z\|^2 \\
&= \|x - z\|^2 + \lambda^2\sigma^2(x)\|Tx - x\|^2 - 2\lambda\sigma(x)\langle z - x, Tx - x\rangle \\
&\leq \|x - z\|^2 - \lambda(2 - \lambda)\sigma^2(x)\|Tx - x\|^2.
\end{aligned}$$

Now we see that for $\lambda \in [0, 2]$ the operator $T_{\sigma,\lambda}$ is quasi-nonexpansive. ∎

4. Convergence of the RAP method. We consider in this section two cases of the RAP method (3) with $\lambda_k \in [\varepsilon, 2 - \varepsilon]$ for $\varepsilon > 0$:

(i) $A, B \subset \mathcal{H}$ are closed convex subsets, and the step size σ_k is given by

$$\sigma_k = \frac{\|Tx_k - P_B x_k\|^2 - \tilde{\delta}_k\|P_B x_k - x_k\| + \langle P_B x_k - x_k, Tx_k - x_k\rangle}{\|Tx_k - x_k\|^2}. \tag{37}$$

(ii) $A \subset \mathcal{H}$ is a closed affine subspace, $B \subset \mathcal{H}$ is a closed convex subset, and the step size σ_k is given by

$$\sigma_k = 1 + \frac{\left(\|Tx_k - P_B x_k\| - \tilde{\delta}_k\right)^2}{\|Tx_k - x_k\|^2}. \tag{38}$$

In both cases $\tilde{\delta}_k = \tilde{\delta}(x_k) \in [\delta, \bar{\delta}_k]$, where $\bar{\delta}_k = \bar{\delta}(x_k) = \|Tx_k - P_B x_k\|$.

THEOREM 15. *In both cases* (i) *and* (ii) *the sequence* (x_k) *converges weakly to an element* $x^* \in \operatorname{Fix} T$.

Proof. By Lemma 1 we have $\operatorname{Fix} T_{\sigma,\lambda} = \operatorname{Fix} T$. If we set $x = x_k$ in inequality (23) or in inequality (36) if A is a closed and affine subspace, we obtain in both cases for any $z \in \operatorname{Fix} T$

$$\|x_{k+1} - z\|^2 \le \|x_k - z\|^2 - \lambda_k(2 - \lambda_k)\sigma_k^2 \|Tx_k - x_k\|^2.$$

Therefore, $(\|x_k - z\|)$ converges as a nonincreasing sequence. Consequently,

$$\|Tx_k - x_k\| \to 0 \tag{39}$$

since for σ_k given by (37) we have $\sigma_k \ge \frac{1}{2}$ (see Lemma 3), for a closed affine subspace A and for σ_k given by (38) we have $\sigma_k \ge 1$, and $\lambda_k(2 - \lambda_k) \ge \varepsilon^2 > 0$. Let (x_{n_k}) be any weakly convergent subsequence of (x_k), and let $x \in A$ be the weak limit of x_{n_k}. Note that such a subsequence exists since (x_k) is bounded. Since T is nonexpansive we have by (39) that $x \in \operatorname{Fix} T$ (see, e.g., [2, Fact 1.2]). We have proved that all weak cluster points of (x_k) lie in $\operatorname{Fix} T$. Furthermore, $\operatorname{Fix} T$ is closed and convex (see, e.g., [1, Lemma 2.2(ii)]). Since the sequence (x_k) is Fejér monotone with respect to $\operatorname{Fix} T$, it converges weakly to some point $x^* \in \operatorname{Fix} T$; see [2, Theorem 2.16(ii)]. ∎

5. The results of preliminary numerical experiments. In this section we present the results of preliminary numerical tests for problem (1), where $\mathcal{H} = \mathbb{R}^n$.

5.1. Problems. We consider the following test problems:

P1. $A = B(z_1, 1)$ and $B = B(z_2, 1)$ are two balls in $\mathbb{R}^n$ with centers $z_1, z_2 \in \mathbb{R}^n$ and radius one. We consider this problem for various distances $d = \|z_1 - z_2\|$. Of course, $\delta = \mathrm{d}(A, B) = \max\{0, d - 2\}$, and, consequently, $A \cap B \ne \varnothing$ if and only if $d \le 2$. Without loss of generality we suppose that $n = 2$ and $z_1 = (0, d)$ for $d \in \mathbb{R}_+$ and $z_2 = (0, 0)$. We set $x_0 = (1, d) \in \mathbb{R}^2$ as the starting point. The exact solution of (1) can be easily evaluated analytically for the test problem P1, $x^* = (0, d-1)$ for $d \ge 2$ and $x^* = (\sqrt{4 - d^2}/2, d/2)$ for $d < 2$.

P2. A is a hyperplane and $B = B(z, 1)$ is a ball in $\mathbb{R}^n$. We consider this problem for various distances $d = \inf_{y \in A} \|z - y\|$. Of course, $\delta = \mathrm{d}(A, B) = \max\{0, d - 1\}$, and, consequently, $A \cap B \ne \varnothing$ if and only if $d \le 1$. Without loss of generality we suppose that $n = 2$ and $A = \{(\xi_1, \xi_2) \in \mathbb{R}^2 : \xi_2 = d\}$ for $d \in \mathbb{R}_+$ and $B = B((0, 0), 1)$. We set $x_0 = (3, d) \in \mathbb{R}^2$ as the starting point. The exact solution of (1) can be easily evaluated analytically for the test problem P1, $x^* = (0, d)$ for $d \ge 1$ and $x^* = (\sqrt{1 - d^2}, d)$ for $d < 1$.

Note that in all problems the starting point $x_0 \in \mathbb{R}^n$ belongs to A.

5.2. Tests. Now we present the results of numerical tests for the following methods:

- AP. The von Neumann alternating projection method (4), applied to problem (1),

TABLE 1
*Comparison of the AP, GPR, and RAP*1(i) *methods for problem* P1 *in case* $A \cap B \neq \emptyset$.

Method →		AP	GPR	RAP1(i)		
$\lambda \rightarrow$				1	$\frac{3}{2}$	2
d	ε	k	k	k	k	k
1.9	10^{-1}	2	1	1	1	1
	10^{-2}	6	2	2	1	1
	10^{-3}	11	3	3	1	1
1.99	10^{-1}	7	2	2	1	2
	10^{-2}	43	3	3	1	2
	10^{-3}	97	4	4	1	2
2	10^{-1}	25	3	3	1	2
	10^{-2}	2499	6	6	2	2
	10^{-3}	249999	10	9	4	3

- RAP1. The relaxed alternating projection method (3), where the step size σ_k is defined by (37), applied to problem (1),
- RAP2. The relaxed alternating projection method (3), where the step size σ_k is defined by (38), applied to problem (1) with affine A,
- GPR. The method proposed by Gurin, Polyak, and Raik, i.e., the relaxed alternating projection method (3), where the step size σ_k is defined by (5), applied to problem (1) with $A \cap B \neq \varnothing$.

In the presented tests we employ various values of constant relaxation parameter $\lambda_k = \lambda \in (0, 2)$. For the RAP1 and RAP2 methods we consider two cases:

(i) The value δ is known, and we set $\tilde{\delta}_k = \delta$ in (37) and in (38).

(ii) We set $\tilde{\delta}_k = \bar{\delta}_k = \|Tx_k - P_B x_k\|$ in (37) and in (38).

For both test problems P1 and P2 we know the exact solution x^* of (1) and we apply the condition $\|x_k - x^*\| \leq \varepsilon$ or $x_k \in A \cap B$ as the stopping criterion. Let k denote the number of iterations after which the corresponding algorithm terminates. All tested methods were programmed in MATLAB 6.1.

In Table 1 we present the numerical results of the AP, GPR, and RAP1(i) methods for problem P1 with $A \cap B \neq \varnothing$ for various distances d between the centers of two balls and for various optimality tolerances ε. The results of RAP1(i) are presented for three values of relaxation parameter λ (note that the AP and GPR methods are originally constructed only for $\lambda = 1$). The results for $\lambda = 1$ are repeated in Figure 1. We see that for all optimality tolerances the behavior of the RAP1(i) and GPR methods is similar and is considerably better than for the AP method. Observe that RAP1(i) behaves a little bit better if $\lambda > 1$.

In Table 2 we compare the AP, RAP1(i), and RAP1(ii) methods for problem P1 for various optimality tolerances ε. We consider here both cases: $A \cap B \neq \varnothing$ ($d \leq 2$) as well as $A \cap B = \varnothing$ ($d > 2$). The results for $d > 2$ are repeated in Figure 2. Note that we cannot apply GPR if $A \cap B = \varnothing$. Observe that RAP1(i) behaves essentially better than RAP1(ii) and the AP method. The most considerable differences are in case $d = 2$. In this case RAP1(i) behaves very well, while RAP1(ii) as well as the AP method converge very slowly because of zigzagging (the angle between the vectors $P_B x_k - x_k$ and $P_A P_B x_k - P_B x_k$ is close to π for x_k closed to the solution x^*).

In Table 3 we present the results of numerical tests for problem P2. We compare RAP2(i) ($\tilde{\delta}_k = \delta$) and RAP2(ii) ($\tilde{\delta}_k = \bar{\delta}_k$). In the second case $\sigma_k = 1$ for both methods. Furthermore, for $\lambda = 1$ RAP2(ii) reduces to the AP method. We set $d = 1$ (the hyperplane A is tangent to B in the solution x^*). For such d the termination

parameter λ on the convergence. Furthermore, the behavior of RAP2(i) is essentially better (we use here the known distance δ between A and B) than that of RAP2(ii).

Preliminary numerical experiments show that both relaxed alternating projection methods behave essentially better than the original alternating projection method if the distance $\delta = d(A, B)$ is known. The most significant difference in the behavior of both methods with respect to the AP method can be observed if $A \cap B$ consists of one point or the distance δ is close to zero and the subsets A and B are almost "parallel" close to the solution.

Acknowledgment. The authors wish to thank the anonymous referee for his helpful remarks.

FIXED-POINT CONTINUATION FOR ℓ_1-MINIMIZATION: METHODOLOGY AND CONVERGENCE*

ELAINE T. HALE†, WOTAO YIN†, AND YIN ZHANG†

Abstract. We present a framework for solving the large-scale ℓ_1-regularized convex minimization problem:

$$\min \|x\|_1 + \mu f(x).$$

Our approach is based on two powerful algorithmic ideas: operator-splitting and continuation. Operator-splitting results in a fixed-point algorithm for any given scalar μ; continuation refers to approximately following the path traced by the optimal value of x as μ increases. In this paper, we study the structure of optimal solution sets, prove finite convergence for important quantities, and establish q-linear convergence rates for the fixed-point algorithm applied to problems with $f(x)$ convex, but not necessarily strictly convex. The continuation framework, motivated by our convergence results, is demonstrated to facilitate the construction of practical algorithms.

Key words. ℓ_1 regularization, fixed-point algorithm, q-linear convergence, continuation, compressed sensing

DOI. 10.1137/070698920

1. Introduction.

Under suitable conditions, minimizing the ℓ_1-norm is equivalent to minimizing the so-called "ℓ_0-norm," that is, the number of nonzeros in a vector. The former is always more computationally tractable than the latter. Thus, minimizing or limiting the magnitude of $\|x\|_1$ has long been recognized as a practical avenue for obtaining sparse solutions x. Some early work is in the area of geophysics, where sparse spike train signals are often of interest, and data may include large sparse errors [10, 39, 55, 57]. The signal processing and statistics communities use the ℓ_1-norm to describe a signal with just a few waveforms or a response quantity with just a few explanatory variables [9, 24, 44, 58]. More references on ℓ_1-regularization for signal processing and statistics can be found in [46].

In this work, we present an algorithmic framework and related convergence analysis for solving general problems of the form

$$\min_{x\in\mathbb{R}^n} \|x\|_1 + \mu f(x), \tag{1.1}$$

where $f : \mathbb{R}^n \to \mathbb{R}$ is differentiable and convex, but not necessarily strictly convex, and $\mu > 0$. Interesting special cases of this problem include

$$\min_{x\in\mathbb{R}^n} \|x\|_1 + \frac{\mu}{2}\|Ax - b\|_2^2, \tag{1.2}$$

and its generalization

$$\min_{x\in\mathbb{R}^n} \|x\|_1 + \frac{\mu}{2}\|Ax-b\|_M^2, \tag{1.3}$$

where $M \in \mathbb{R}^{m\times m}$ is a positive definite matrix, $\|x\|_M := \sqrt{x^\top Mx}$ is the associated M-norm, $A \in \mathbb{R}^{m\times n}$ is dense, $m \le n$ or even $m \ll n$, and n is large.

As a general principle, a sparse solution, $x \in \mathbb{R}^n$, of an underdetermined linear system of equations, $Ax = b$, may be obtained by minimizing the ℓ_1-norm of x. If the "observation" b is contaminated with noise, then an appropriate norm of the residual $Ax-b$ should be minimized or constrained. Such considerations yield several related optimization problems. For instance, if there is Gaussian noise distributed as $N(0,\sigma^2 I)$ in b, then the ℓ_1-regularized least squares problem (1.2) would be appropriate, as would the least absolute shrinkage and selection operator (LASSO) problem (6.3) [58].

Such problems are of fundamental importance to *compressed sensing*. Compressed sensing is the name assigned to the idea of encoding a large sparse signal using a relatively small number of linear measurements, and minimizing the ℓ_1-norm (or its variants) in order to decode the signal. Recent results reported by Candes et al. [4, 5, 6], Donoho et al. [16, 20, 61], and others ([54, 60], for example) stimulated the current burst of research in this area. Applications of compressed sensing include compressive imaging [56, 65, 66], medical imaging [42], multisensor and distributed compressed sensing [1], analog-to-information conversion [36, 37, 38, 59], and missing data recovery [67]. Compressed sensing is attractive for these and other potential applications because it reduces the number of measurements required to obtain a given amount of information. The tradeoff is the addition of a nontrivial decoding process that consists of solving problems like (1.2), where the data matrix A is usually either random or has its rows taken from an orthogonal matrix such as a discrete cosine transform (DCT) matrix. Such data matrices are invariably dense and large in applications of interest. Thus we are motivated to study algorithms that do not require any linear system solves or matrix factorizations, and are able to take advantage of available fast transforms like FFT and DCT.

1.1. Our approach and main results. The objective function in (1.1) is the sum of two convex functions. While the ℓ_1-norm term is not smooth, it is easily transformed into a linear function plus some linear constraints, such that standard interior-point methods utilizing a direct linear solver can be applied to, say, problem (1.2). However, such a standard approach is too costly for large-scale problems with dense data.

Our approach is based on operator splitting. It is well known in convex analysis that minimizing a convex function $\phi(x)$ is equivalent to finding a zero of the subdifferential $\partial\phi(x)$, i.e., finding x such that $\mathbf{0} \in \partial\phi(x) := T(x)$, where T is a maximal monotone operator [53]. In many cases, one can split ϕ into the sum of two convex functions, $\phi = \phi_1 + \phi_2$, which implies the decomposition of T into the sum of two maximal monotone operators T_1 and T_2, i.e., $T = T_1 + T_2$. For $\tau > 0$, if T_2 is single-valued and $(I + \tau T_1)$ is invertible, then

$$\begin{aligned} \mathbf{0} \in T(x) &\iff \mathbf{0} \in (x + \tau T_1(x)) - (x - \tau T_2(x)) \\ &\iff (I - \tau T_2)x \in (I + \tau T_1)x \\ &\iff x = (I + \tau T_1)^{-1}(I - \tau T_2)x. \end{aligned} \tag{1.4}$$

Equation (1.4) leads to the *forward-backward splitting* algorithm for finding a zero of T:

$$x^{k+1} := (I + \tau T_1)^{-1}(I - \tau T_2)x^k, \tag{1.5}$$

which is a fixed-point algorithm. For the minimization problem (1.1), $T_2 = \mu\nabla f$ and $(I + \tau T_1)^{-1}$ is component-wise shrinkage (or soft-thresholding), which is related to the ℓ_1-norm term in (1.1) and is described fully in sections 3 and 4 below.

The forward-backward splitting method was first proposed by Lions and Mercier [40] and Passty [51] at about the same time in 1979. Over the years, this scheme and its modifications have been extensively studied by various authors, including, to name a few, Mercier [45], Gabay [30], Glowinsky and Le Tallec [31], Eckstein [22], Chen and Rockafellar [8], Haubruge, Nguyen, and Strodiot [33], Noor [48], and Tseng [62]. The idea of splitting operators can be traced back to the mid-1950's in the works of Peaceman and Rachford [52] and Douglas and Rachford [21] for solving second-order elliptic and parabolic partial differential equations.

General convergence theory exists for forward-backward splitting methods [8, 30, 45]. Unfortunately, it requires rather strong conditions on T_2, or on T as a whole. In short, when reduced to our setting with $\phi_1 = \|x\|_1$ and $\phi_2 = \mu f(x)$, the classical convergence theory requires either f or the whole objective in (1.1) to be strictly convex (though such strong assumptions may be weakened with modifications to the basic algorithm [62]). An anonymous referee brought our attention to the recent paper [12] by Combettes and Wajs, which applies forward-backward splitting methods to various concrete forms of minimizing a sum of two convex functions, including problem (1.1). Combettes and Wajs [12] show that the fixed-point iterations (1.5), and some extensions of it, converge to a global minimum without a strict convexity assumption.

In the present work, we aim to address the following two questions, "Can stronger convergence results be obtained for algorithm (1.5) applied to problem (1.1)?" and "Can algorithm (1.5) be computationally competitive when applied to problem (1.2) or (1.3)?" Our answers to both questions are affirmative.

On the theoretical side, we have obtained finite convergence for some interesting quantities (cf. Theorems 4.5 and 4.7) and q-linear[1] rates of convergence (cf. Proposition 4.9 and Theorems 4.10 and 4.11) without assuming strict convexity, nor uniqueness of solution. Furthermore, we show that these q-linear rates of convergence are not determined by the conditioning of the Hessian of f, as is normally the case for gradient-type methods, but by that of a "reduced" Hessian whose condition number can be much smaller than that of the full Hessian when the solution x is sparse.

On the computational side, we devised a continuation strategy that significantly reduces the number of iterations required for a given value of μ. Our extensive numerical results, which will be presented in a separate paper [32] due to space limitation, indicate that our algorithm is especially well suited for large-scale instances of problem (1.2) when x^* is sufficiently sparse and A is a partial transform matrix such as a partial DCT matrix. In comparison with several recently developed algorithms, our algorithm appears to be the most robust, and in many cases also the fastest.

1.2. Related work. Recently, solving problems (1.1) or (1.2), especially (1.2), has been actively studied by many authors, largely because of its newly found applications in signal and image processing. These problems can be solved by the forward-backward operator-splitting method given by (1.5) if one substitutes T_1 and T_2 by the subdifferential of $\|x\|_1$ and the gradient of $\mu f(x)$, respectively, resulting in the formula (3.1) of section 3. Becau se the operator-splitting approach was priorly not widely known in signal and image processing areas, in most recent works the

[1] $\{x^k\}$ converges to x^* q-linearly, where q stands for "quotient," if $\limsup_k \|x^{k+1} - x^*\|/\|x^k - x^*\| < 1$.

fixed-point iteration (3.1), namely (1.5) specialized to (1.1), was derived by different authors, often independently, based on different motivations and approaches.

Here we mention a number of recent works that proposed, derived, or analyzed the fixed-point iteration scheme (1.5) or its variants when applied to either problem (1.2) or (1.1). These contributions include [29] by Figueiredo and Nowak, [15] by De Mol and Defrise, [13] by Daubechies, Defrise, and De Mol, [2] by Aubert, Bect, Blanc-Feraud, and Chambolle, [25, 26, 27] by Elad et al., and [**?**] by Darbon and Osher (though this list is unavoidably nonexhaustive). Some of these works were done independently around the same time, such as the two earlier papers [29] and [15]. Although the derivations and analyses in these papers were conducted through different means other than forward-backward operator splitting, the theoretical and numerical results in these papers contribute to a better understanding on the behavior of the fixed-point iterations (1.5) when applied to problem (1.2) or (1.1). For example, the authors of [2] and those of [13] analyzed the model (1.2) and independently proved global convergence without a strict convexity assumption, while classic convergence results for forward-backward operator splitting require stronger assumptions, and the authors of [26] proposed extensions and enhancements to the basic fixed-point iterations to improve its practical performance. As is already mentioned, Combettes and Wajs [12] recently established global convergence of the fixed-point iterations (1.5) when applied to (1.1) without a strict convexity assumption. A more recent paper by Combettes and Pesquet [11] studies closely related proximal soft-thresholding algorithms.

Alternative algorithms for the unconstrained ℓ_1-problem (1.3) include an iterative linear solver in an interior-point framework [35] by Kim et al., a gradient projection and Barzilai–Borwein method applied to an equivalent box-constrained QP [28] by Figueiredo, Nowak, and Wright, a direct and accelerated projected gradient method [14] by Daubechies, Fornasier, and Loris, an accelerated multistep gradient method [47] with an error convergence rate $O(1/k^2)$ by Nesterov, and a "two-step" shrinkage-based algorithm [3] by Bioucas–Dias and Figueiredo. In [64], Van den Berg and Friedlander apply an iterative method for solving the LASSO problem (6.3).

1.3. Notation and organization. For simplicity, we let $\|\cdot\| := \|\cdot\|_2$, the Euclidean norm, unless otherwise specified. The *support* of $x \in \mathbb{R}^n$ is $\mathrm{supp}(x) := \{i : x_i \neq 0\}$. Let

$$g(x) := \nabla f(x)$$

be the gradient of $f(x)$; in particular, $g(x) = A^\top M(Ax - b)$ for f defined by (1.3), that is

$$f = \frac{1}{2}\|Ax - b\|_M^2. \tag{1.6}$$

For a set E, we use $|E|$ to denote its cardinality. For any symmetric matrix $B \in \mathbb{R}^{n\times n}$, we denote its eigenvalues as $\lambda_i(B)$, $i = 1, \ldots, n$, and its maximum and minimum eigenvalues as, respectively, $\lambda_{\max}(B)$ and $\lambda_{\min}(B)$.

The signum function of $t \in \mathbb{R}$ is

$$\mathrm{sgn}(t) := \begin{cases} +1 & t > 0, \\ 0 & t = 0, \\ -1 & t < 0, \end{cases}$$

while the signum multifunction (i.e., set-valued function) of $t \in \mathbb{R}$ is

$$\mathrm{SGN}(t) := \partial|t| = \begin{cases} \{+1\} & t > 0, \\ [-1,1] & t = 0, \\ \{-1\} & t < 0, \end{cases}$$

which is also the subdifferential of $|t|$. For $x \in \mathbb{R}^n$, we define $\mathrm{sgn}(x) \in \mathbb{R}^n$ and $\mathrm{SGN}(x) \subset \mathbb{R}^n$ component-wise as $(\mathrm{sgn}(x))_i := \mathrm{sgn}(x_i)$ and $(\mathrm{SGN}(x))_i := \mathrm{SGN}(x_i)$, $i = 1, 2, \ldots, n$, respectively. Clearly,

$$\mathrm{sgn}(x) = \mathrm{sgn}(x') \iff \mathrm{SGN}(x) = \mathrm{SGN}(x'),\ \forall\ x, x'.$$

For $x, y \in \mathbb{R}^n$, let $x \odot y \in \mathbb{R}^n$ denote the component-wise product of x and y, i.e., $(x \odot y)_i = x_i y_i$. Furthermore, vector operators such as $|x|$ and $\max\{x, y\}$ are defined to operate component-wise as well, analogous to the definitions of sgn and SGN.

For any index set $I \subseteq \{1, 2, \ldots, n\}$ (later, we will use index sets E and L), x_I is defined as the subvector of x of length $|I|$ consisting only of components x_i, $i \in I$. Similarly, if g is a vector-valued function, then $g_I(x)$ denotes the subvector of $g(x)$ consisting of $g_i(x)$, $i \in I$.

This paper is organized as follows. In section 2, we recall the classic optimality (or in general, stationarity) conditions for problem (1.1), and then characterize the optimal solution sets of problems (1.1) and (1.3). In section 3, we present a fixed-point optimality condition for (1.1). This optimality condition motivates a fixed-point algorithm and introduces the shrinkage operator, the properties of which conclude section 3. In section 4, we present our results on the convergence and rates of convergence of the fixed-point algorithm; the proofs of the main results are given in section 5. We motivate and propose a continuation method in section 6, support this proposal with a few numerical results, and briefly discuss some possible extensions. Finally, we conclude the paper in section 7.

2. Optimality and optimal solution sets. Recall that $f(x)$ in (1.1) is convex, and let X^* be the set of optimal solutions of (1.1). It is well known from convex analysis (see, for example, [53]) that an optimality condition for (1.1) is

$$x \in X^* \iff \mathbf{0} \in \mathrm{SGN}(x) + \mu g(x), \tag{2.1}$$

where $\mathbf{0}$ is the zero vector in $\mathbb{R}^n$, or equivalently,

$$x \in X^* \iff \mu g_i(x) \begin{cases} = -1, & x_i > 0, \\ \in [-1,1], & x_i = 0, \\ = 1, & x_i < 0. \end{cases} \tag{2.2}$$

It follows readily from (2.2) that $\mathbf{0}$ is an optimal solution of (1.1) if and only if $\mu\|g(\mathbf{0})\|_\infty \leq 1$; therefore, it is easy to check whether $\mathbf{0}$ is a solution of (1.1).

We note that the solution set X^* may have more than one element. The following theorem establishes some properties of X^* that are of interest in their own right, but will also be useful in later developments.

THEOREM 2.1. *Let $f \in C^2$ be convex and X^* be the set of optimal solutions of* (1.1)*, which is nonempty.*

1. *If $x^1 \in X^*$ and $x^2 \in X^*$, then $g(x^1) = g(x^2)$.*

2. *$x \in X^*$ if and only if $g(x) \equiv g^*$, where for $i = 1, 2, \ldots, n$,*

$$\mu g_i^* \begin{cases} = -1, & \max\{x_i : x \in X^*\} > 0, \\ = +1, & \min\{x_i : x \in X^*\} < 0, \\ \in [-1, 1], & \text{otherwise.} \end{cases} \tag{2.3}$$

3. *X^* is contained in a single orthant of $\mathbb{R}^n$; more precisely*

$$X^* \subset O := \{x \in \mathbb{R}^n : -\mathrm{sgn}^+(g_i^*)x_i \geq 0, \forall i\}, \tag{2.4}$$

where $\mathrm{sgn}^+(\cdot)$ is equal to $\mathrm{sgn}(\cdot)$ except that $\mathrm{sgn}^+(0) := 1$, i.e.,

$$\mathrm{sgn}^+(t) := \begin{cases} +1 & t \geq 0, \\ -1 & t < 0. \end{cases}$$

(In addition, we let $\mathrm{sgn}^+(x)$ be defined component-wise for any $x \in \mathbb{R}^n$.)

Furthermore, if $f(x)$ is the quadratic defined as in (1.6), then

4. *If $x^1 \in X^*$ and $x^2 \in X^*$, then $Ax^1 = Ax^2$.*
5. *$\|x\|_1$ and $\|Ax - b\|_M$ are constant for all $x \in X^*$.*
6. *X^* is a bounded polyhedron, i.e., a polytope.*

Proof. We prove the statements one by one.

1. This part will be proven later as Corollary 4.2 under Assumption 1, which is slightly weaker than what is assumed for this theorem. That proof is independent of this theorem and the results that follow from it.
2. (2.3) follows directly from part 1 and (2.2) applied to all $x \in X^*$.
3. From (2.1) and (2.3), if there exists an $x \in X^*$ with a strictly positive (negative) x_i, then $\mu g_i^* = -1$ ($\mu g_i^* = 1$), so all other $x \in X^*$ must satisfy $x_i \geq 0$ ($x_i \leq 0$). Consequently, X^* lies in the orthant O.
4. From part 1 and for the quadratic $f(x)$ so specified, $g(x^1) - g(x^2) = A^\top MA(x^1 - x^2) = \mathbf{0}$, which immediately implies that $A(x^1 - x^2) = \mathbf{0}$, given that M is symmetric positive definite.
5. From part 4, Ax is constant over $x \in X^*$, and so is $\|Ax - b\|_M$. Since (1.3) has a unique optimal objective value, $\|x\|_1$ must also be constant.
6. Defining $p = -\mathrm{sgn}^+(g^*)$, from the definition of O we have

$$p^\top x = \|x\|_1, \ \forall x \in O.$$

Consider the linear program

$$\min_x \left\{ p^\top x : Ax = c, \ x \in O \right\}, \tag{2.5}$$

where $c = Ax$ for any $x \in X^*$. It is easy to verify that an optimal solution $\bar{x}$ of (2.5) satisfies both $\|\bar{x}\|_1 = \|x\|_1$ and $\|A\bar{x} - b\|_M = \|Ax - b\|_M$ for any $x \in X^*$ and vice versa. So (2.5) is equivalent to (1.3), as long as c and O (or equivalently, g^*) are known. Consequently, X^*, as the solution set of the linear program (2.5), must be a polyhedron and must be bounded since $\|x\|_1$ is constant for all $x \in X^*$.

This completes the proof. ∎

3. A fixed-point algorithm.

3.1. Optimality as a fixed-point equation. We start with another optimality condition for problem (1.1): for any scalar $\tau > 0$, $x^* \in X^*$ if and only if

$$x^* = \operatorname{sgn}(x^* - \tau g(x^*)) \odot \max\left\{|x^* - \tau g(x^*)| - \frac{\tau}{\mu}, \mathbf{0}\right\}. \tag{3.1}$$

The derivation of (3.1) can be found, for example, in [12].

It is straightforward to verify that optimality condition (3.1) can be replaced by

$$x^* = \operatorname{sgn}(x^* - d(x^*) \odot g(x^*)) \odot \max\left\{|x^* - d(x^*) \odot g(x^*)| - \frac{d(x^*)}{\mu}, \mathbf{0}\right\}, \tag{3.2}$$

where the positive scalar τ in (3.1) is replaced by any mapping d from $\mathbb{R}^n$ to $\mathbb{R}^n$ such that $(d(x))_i = d_i(x_i) > 0$. The algorithm based on (3.1), and its analysis as well, can be readily extended to those based on (3.2) (see [26] for a study of such an extension).

The right-hand side of the fixed-point equation (3.1) is a composition of two mappings from $\mathbb{R}^n$ to $\mathbb{R}^n$ defined as

$$h(\cdot) := I(\cdot) - \tau g(\cdot), \tag{3.3}$$

$$s_\nu(\cdot) := \operatorname{sgn}(\cdot) \odot \max\{|\cdot| - \nu, 0\}, \text{ where } \nu > 0. \tag{3.4}$$

Intuitively, $h(\cdot)$ resembles a gradient descent step for $f(x)$ with the stepsize $\tau > 0$, and $s_\nu(\cdot)$ reduces the magnitude of each nonzero component of the input vector by an amount less than or equal to ν, thus reducing the ℓ_1-norm. Later we will also use s_ν as a mapping from $\mathbb{R}$ to $\mathbb{R}$ in composition with $h_i(\cdot) = (h(\cdot))_i$ from $\mathbb{R}^n$ to $\mathbb{R}$.

Equation (3.1) leads to *the fixed-point iterations*

$$x^{k+1} = s_\nu \circ h\left(x^k\right) \text{ with } \tau > 0,\ \nu = \tau/\mu, \tag{3.5}$$

which can be derived by operator-splitting or other means as has been done by the authors mentioned in subsection 1.2. As many others before us, we originally derived the fixed-point scheme (3.5) from a totally different approach, and later found that it can be interpreted as the forward-backward splitting algorithm (1.5) with

$$T_1(x) = \partial\|x\|_1/\mu, \text{ and } T_2(x) = g(x),$$

since simple calculations show that

$$s_\nu = (I + \tau T_1)^{-1}, \text{ and } h = I - \tau T_2.$$

However, some special properties of the operator s_ν, given below, will allow us to obtain strong convergence results that do not directly follow from the existing theory for forward-backward splitting algorithms applied to more general operators.

The main algorithm of the paper, Algorithm 1, is based on (3.5) and will be presented in subsection 6.2 along with choices for τ and μ.

3.2. Properties of the shrinkage operator. It is easy to verify that $s_\nu(y)$ is the unique solution of

$$\min_{x \in \mathbb{R}^n} \nu\|x\|_1 + \frac{1}{2}\|x - y\|^2$$

for any $y \in \mathbb{R}^n$. Wavelet analysts refer to $s_\nu(\cdot)$ as the soft-thresholding [19] or wavelet shrinkage [7] operator. For convenience, we will refer to $s_\nu(\cdot)$ as the *shrinkage operator*.

The two lemmas below establish some useful properties of the shrinkage operator. Both make immediate use of the component-wise separability of s_ν, that is, for all indices i

$$(s_\nu(y))_i = s_\nu(y_i).$$

The alternative representation of s_ν in Lemma 3.1 will be used to prove Lemma 3.2. Lemma 3.2 proves a number of component-wise properties of s_ν, including nonexpansiveness. These results will be used to prove convergence results for (3.5) that are not implied by convergence results in [12].

With a slight abuse of notation, we let $\mathcal{P}(x)$ denote the projection of a vector $x \in \mathbb{R}^k$ onto the k-cube $[-\nu, \nu]^k$ for any positive integer k, since the projection onto any k-cube is done component-wise. Now Lemma 3.1 below can be trivially verified by enumerating all possible cases.

LEMMA 3.1. *The shrinkage operator can be written as*

$$s_\nu(y) = y - \mathcal{P}(y), \quad \forall\ y \in \mathbb{R}^n, \tag{3.6}$$

and the equation holds component-wise; i.e., $(s_\nu(y))_i \equiv s_\nu(y_i) = y_i - \mathcal{P}(y_i)$. *Moreover, both* $s_\nu(y)$ *and* $\mathcal{P}(y)$ *are component-wise monotone.*

LEMMA 3.2. *The operator* $s_\nu(\cdot)$ *is component-wise nonexpansive and for any* $y^1, y^2 \in \mathbb{R}^n$,

$$\left|s_\nu\left(y_i^1\right) - s_\nu\left(y_i^2\right)\right| = \left|y_i^1 - y_i^2\right| - \left|\mathcal{P}\left(y_i^1\right) - \mathcal{P}\left(y_i^2\right)\right|, \ \forall i. \tag{3.7}$$

Consequently, s_ν *is nonexpansive in any* ℓ_p *(quasi-)norm with* $p \geq 0$, *and if* h *is nonexpansive in a given norm, then* $s_\nu \circ h$ *is as well. Moreover, consider the case when*

$$\left|s_\nu\left(y_i^1\right) - s_\nu\left(y_i^2\right)\right| = \left|y_i^1 - y_i^2\right|, \tag{3.8}$$

which we refer to as the no-shrinkage condition. We have, for each index i:

1. (3.8) $\implies \mathcal{P}(y_i^1) = \mathcal{P}(y_i^2)$, $\operatorname{sgn}(y_i^1) = \operatorname{sgn}(y_i^2)$, $s_\nu(y_i^1) - s_\nu(y_i^2) = y_i^1 - y_i^2$.
2. (3.8) *and* $y_i^1 \neq y_i^2 \implies |y_i^1| \geq \nu$, $|y_i^2| \geq \nu$ *and* $|y_i^1| \neq |y_i^2|$.
3. (3.8) *and* $|y_i^2| < \nu \implies |y_i^1| < \nu$, $y_i^1 = y_i^2$, $s_\nu(y_i^1) = s_\nu(y_i^2) = 0$.
4. (3.8) *and* $|y_i^2| \geq \nu \implies |y_i^1| \geq \nu$.
5. $|y_i^2| \geq \nu$ *and* $\operatorname{sgn}(y_i^1) \neq \operatorname{sgn}(y_i^2) \implies |s_\nu(y_i^1) - s_\nu(y_i^2)| \leq |y_i^1 - y_i^2| - \nu$.
6. $s_\nu(y_i^1) \neq 0 = s_\nu(y_i^2) \implies |y_i^1| > \nu$, $|y_i^2| \leq \nu$, $|s_\nu(y_i^1) - s_\nu(y_i^2)| \leq |y_i^1 - y_i^2| - (\nu - |y_i^2|)$.

Proof. For ease of notation, we drop the subscript i and let $p^1 = y_i^1$ and $p^2 = y_i^2$. Without loss of generality we assume that $p^1 \geq p^2$. Hence, from the monotonicity of s_ν and $\mathcal{P}$ we have $s_\nu(p^1) \geq s_\nu(p^2)$ and $\mathcal{P}(p^1) \geq \mathcal{P}(p^2)$. Therefore,

$$\begin{aligned}\left|s_\nu\left(p^1\right) - s_\nu\left(p^2\right)\right| &= s_\nu\left(p^1\right) - s_\nu\left(p^2\right) = p^1 - p^2 - \left(\mathcal{P}\left(p^1\right) - \mathcal{P}\left(p^2\right)\right) \\ &= \left|p^1 - p^2\right| - \left|\mathcal{P}\left(p^1\right) - \mathcal{P}\left(p^2\right)\right|,\end{aligned}$$

which proves (3.7).

Next, we move to proving parts 5 and 6, omitting the proofs for parts 1 through 4 since, given (3.6) and (3.7), they all can be similarly and easily verified.

For part 5, it suffices to show that $|\mathcal{P}(p^1)-\mathcal{P}(p^2)| \geq \nu$. Without loss of generality, we assume that $p^1 > 0$ and $p^2 < 0$. Hence, $\mathcal{P}(p^1) \geq 0$, $\mathcal{P}(p^2) = -\nu$, and $|\mathcal{P}(p^1) - \mathcal{P}(p^2)| = \mathcal{P}(p^1) - \mathcal{P}(p^2) \geq \nu$.

Finally, we verify part 6. First, it is easy to see that $|p^1| > \nu$ and $|p^2| \leq \nu$. Hence, $|\mathcal{P}(p^1)| = \nu$ and $\mathcal{P}(p^2) = p^2$, and $|\mathcal{P}(p^1) - \mathcal{P}(p^2)| \geq |\mathcal{P}(p^1)| - |\mathcal{P}(p^2)| = \nu - |p^2|$. ∎

4. Convergence analysis. In this section, we study the convergence of the fixed-point iterations (3.5) applied to the general ℓ_1-regularized minimization problem (1.1) and the quadratic case (1.3). Assumption 1 below, which states that f is a convex function with bounded Hessian in a neighborhood of an optimal solution of (1.1), is sufficient for our global convergence result and will be applied throughout. Further assumptions (primarily on the rank of a particular minor of the Hessian of f) will be made to obtain linear convergence rate results in section 4.2.

Assumption 1. Problem (1.1) has an optimal solution set $X^* \neq \emptyset$, and there exists a bounded convex set $\Omega \supset X^*$ such that $f \in C^2(\Omega)$, $H(x) := \nabla^2 f(x) \succeq 0$ for $x \in \Omega$ and

$$\hat{\lambda}_{\max} := \max_{x \in \Omega} \lambda_{\max}(H(x)) < \infty. \tag{4.1}$$

For simplicity, we will use a constant parameter τ in the fixed-point iterations (3.5): $x^{k+1} = s_\nu(x^k - \tau g(x^k))$, where

$$\nu = \tau/\mu. \tag{4.2}$$

In particular, we will always choose

$$\tau \in \left(0, 2/\hat{\lambda}_{\max}\right), \tag{4.3}$$

which guarantees that $h(\cdot) = I(\cdot) - \tau g(\cdot)$ is nonexpansive in Ω, and contractive in the range space of H in the quadratic case. Our analysis can be extended to the case of variable τ, but this would require more complicated notation and a reduction of clarity.

4.1. Global and finite convergence. From the mean-value theorem, we recall that for any $x, x' \in \Omega$

$$g(x) - g(x') = \left(\int_0^1 H(x' + t(x - x'))\,\mathrm{d}t\right)(x - x') := \bar{H}(x, x')(x - x'). \tag{4.4}$$

This fact is used to verify the nonexpansiveness of h and the result that noncontraction between any two points under h implies that the gradient of f is equal at those points.

LEMMA 4.1. *Under Assumption* 1 *and the choice of* τ *specified in* (4.3), $h(\cdot) = I(\cdot) - \tau g(\cdot)$ *is nonexpansive in* Ω, *i.e., for any* $x, x' \in \Omega$,

$$\|h(x) - h(x')\| \leq \|x - x'\|. \tag{4.5}$$

Moreover, $g(x) = g(x')$ *whenever equality holds in* (4.5).

Proof. Let $\bar{H} := \bar{H}(x, x')$. We first note that

$$h(x) - h(x') = x - x' - \tau(g(x) - g(x')) = \left(I - \tau\bar{H}\right)(x - x').$$

Hence, in view of (4.3),

$$\begin{aligned}\|h(x)-h(x')\| &= \left\|\left(I-\tau\bar{H}\right)(x-x')\right\| \\ &\le \max\left\{\left|1-\tau\lambda_{\max}\left(\bar{H}\right)\right|,\left|1-\tau\lambda_{\min}\left(\bar{H}\right)\right|\right\}\|x-x'\| \\ &\le \max\{|1-\tau\hat{\lambda}_{\max}|,1\}\|x-x'\| \\ &\le \|x-x'\|.\end{aligned}$$

To prove the second statement, let $s := x - x'$ and $p := \bar{H}^{1/2}s$. Then

$$\begin{aligned}\|h(x)-h(x')\| = \|x-x'\| &\iff \left\|s-\tau\bar{H}s\right\| = \|s\| \\ &\iff -2\tau\, s^T\bar{H}s + \tau^2 s^T\bar{H}^2 s = 0 \\ &\iff \tau p^T\bar{H}p = 2p^Tp \\ &\implies \tau\,\frac{p^T\bar{H}p}{p^Tp} = 2 \text{ if } p\neq 0,\end{aligned}$$

which contradicts (4.3) since $\frac{p^T\bar{H}p}{p^Tp} \le \hat{\lambda}_{\max} < \frac{2}{\tau}$. Hence, $p = 0$ so that

$$g(x) - g(x') = \bar{H}^{1/2}p = 0$$

whenever h is noncontractive. □

Since any two fixed points, say x and x', of the nonexpansive mapping $s_\nu \circ h$ must satisfy the equality

$$\|x-x'\| = \|s_\nu\circ h(x) - s_\nu\circ h(x')\| = \|h(x)-h(x')\|, \tag{4.6}$$

Lemma 4.1 shows that the gradient of f evaluated at any two fixed points must be equal. Hence, we have the following corollary and the first statement of Theorem 2.1.

COROLLARY 4.2 (Constant optimal gradient). *Under Assumption* 1, *there is a vector* $g^* \in \mathbb{R}^n$ *such that*

$$g(x^*) \equiv g^*, \ \ \forall x^* \in X^*. \tag{4.7}$$

We will use the following partition of all indices $\{1,\dots,n\}$ into L and E to obtain finite convergence for components in L and linear convergence for components in E.

DEFINITION 4.3. *Let* $X^* \neq \emptyset$ *be the solution set of* (1.1) *and* g^* *be the vector specified in Corollary* 4.2. *Define*

$$L := \{i : \mu|g_i^*| < 1\} \ \ \textit{and} \ \ E := \{i : \mu|g_i^*| = 1\}. \tag{4.8}$$

It is clear from the optimality condition (2.2) that $L \cup E = \{1,2,\dots,n\}$,

$$\operatorname{supp}(x^*) \subseteq E, \text{ and } x_i^* = 0, \ \ \forall i \in L, \ \forall x^* \in X^*. \tag{4.9}$$

There are examples in which $\operatorname{supp}(x^*) \neq E$, so the two vectors $|x^*|$ and $\mathbf{1} - \mu|g^*|$ are always complementary, but may not be strictly complementary.

The positive scalar ω defined below will also play a key role in the finite convergence property of the fixed-point iterations:

DEFINITION 4.4. *Let* g^* *be the vector specified in Corollary* 4.2. *Define*

$$\omega := \min\{\nu(1-\mu|g_i^*|) : i \in L\}. \tag{4.10}$$

From the definition, clearly $\omega > 0$. In addition, since (4.9) implies that for all $x^* \in X^*$ and all $i \in L$

$$\nu(1 - \mu|g_i^*|) = \nu - \tau|g_i^*| = \nu - |x_i^* - \tau g_i(x^*)| = \nu - |h_i(x^*)|,$$

and consequently, for any $x^* \in X^*$,

$$\min\{\nu - |h_i(x^*)| : i \in L\} = \omega > 0. \tag{4.11}$$

We now claim that Assumption 1 is sufficient for obtaining convergence of the fixed-point iterations (3.5) and finite convergence for components in L and signs in E. We reiterate that under similar conditions, convergence has been established in [12].

THEOREM 4.5 (the general case). *Under Assumption* 1, *the sequence* $\{x^k\}$ *generated by the fixed-point iterations* (3.5) *applied to problem* (1.1) *from any starting point* $x^0 \in \Omega$ *converges to some* $x^* \in X^* \cap \Omega$. *In addition, for all but finitely many iterations, we have*

$$x_i^k = x_i^* = 0, \ \ \forall i \in L, \tag{4.12}$$

$$\operatorname{sgn}\left(h_i\left(x^k\right)\right) = \operatorname{sgn}\left(h_i\left(x^*\right)\right) = -\mu g_i^*, \ \ \forall i \in E, \tag{4.13}$$

where the numbers of iterations not satisfying (4.12) *and* (4.13) *do not exceed* $\|x^0 - x^*\|^2/\omega^2$ *and* $\|x^0 - x^*\|^2/\nu^2$, *respectively, for* ω *defined in* (4.10) *and* $\nu = \tau/\mu$.

The proof of Theorem 4.5 is rather lengthy and is therefore relegated to the next section. A majority of the proof concerns the finite convergence properties which are new. For the sake of completeness, we also include a proof for global convergence which is known.

In light of this theorem, every starting point $x^0 \in \Omega$ determines a converging sequence $\{x^k\}$ whose limit is a solution of (1.1). Generally, the solutions of (1.1) may be nonunique, as it is not difficult to construct simple examples for which different starting points lead to different solutions.

We recall that x_E and g_E^* are defined as the subvectors of x and g^* with components x_i and g_i^*, $i \in E$, respectively. Without loss of generality, we assume $E = \{1, 2, \ldots, |E|\}$, and let $(x_E; \mathbf{0})$ denote the vector in $\mathbb{R}^n$ obtained from x by setting the components x_i $\forall i \in L$ to zero. The following corollary enables one to apply any convergence results for the gradient projection method to the fixed-point iterations (3.5).

COROLLARY 4.6. *Under Assumption* 1 *and starting from some* $x^0 \in \Omega$, *after a finite number of iterations the fixed-point iterations* (3.5) *reduce to gradient projection iterations for minimizing* $\phi(x_E)$ *over a constraint set* O_E, *where*

$$\phi(x_E) := -(g_E^*)^\top x_E + f((x_E; \mathbf{0})), \ \ \textit{and} \tag{4.14}$$

$$O_E = \{x_E \in \mathbb{R}^{|E|} : -\operatorname{sgn}(g_E^*) \odot x_E \geq 0\}. \tag{4.15}$$

Specifically, we have $x^{k+1} = (x_E^{k+1}; \mathbf{0})$ *in which*

$$x_E^{k+1} := P_{O_E}\left(x_E^k - \tau \nabla \phi\left(x_E^k\right)\right), \tag{4.16}$$

where P_{O_E} *is the orthogonal projection onto* O_E, *and* $\nabla\phi(x_E) = -g_E^* + g_E((x_E; \mathbf{0}))$.

Proof. From Theorem 4.5, there exists $K > 0$ such that for $k \geq K$ (4.12)–(4.13) hold. Let $k > K$. Since $x_i^k = 0$ for $i \in L$, it suffices to consider $i \in E$. For

$i \in E$, we have $x_i^k \geq 0$ if $\operatorname{sgn}(h_i(x^{k-1})) = 1$ (equivalently, $g_i^* < 0$) and $x_i^k \leq 0$ if $\operatorname{sgn}(h_i(x^{k-1})) = -1$ ($g_i^* > 0$). Therefore, for any i, $-g_i^* x_i^k \geq 0$ for all $k > K$. Hence, $x^k \in O$ according to the definition (2.4) of O and $x_E^k \in O_E$.

For $i \in E$, we calculate the quantity

$$\begin{aligned} y_i^{k+1} &:= x_i^k - \tau \left(\nabla \phi \left(x^k\right)\right)_i \\ &= x_i^k - \tau \left(-g_i^* + g_i \left(x^k\right)\right) \\ &= h_i \left(x^k\right) + \nu \mu g_i^* \\ &= \operatorname{sgn}\left(h_i \left(x^k\right)\right) \left(\left|h_i \left(x^k\right)\right| - \nu\right), \end{aligned}$$

where (4.13) was used to obtain the last expression. Clearly, the fixed-point iterations (3.5) restricted to the components $i \in E$ are

$$\left(x_E^{k+1}\right)_i = s_\nu \circ h_i \left(x^k\right) = \begin{cases} y_i^{k+1}, & -g_i^* y_i^{k+1} \geq 0, \\ 0, & \text{otherwise.} \end{cases}$$

Equivalently,

$$\left(x_E^{k+1}\right)_i = \left(P_{O_E} \left(x_E^k - \tau \nabla \phi \left(x_E^k\right)\right)\right)_i,$$

which completes the proof. □

Finally, a stronger global convergence result for convex quadratic functions, namely, f as in (1.6), follows directly from the general convergence result. We note that Assumption 1 is no longer necessary if the convex quadratic is bounded below. Due to the importance of the quadratic case, we state a separate theorem.

THEOREM 4.7 (the quadratic case). *Let f be a convex quadratic function that is bounded below, H be its Hessian, and τ satisfy*

$$0 < \tau < 2/\lambda_{\max}(H). \tag{4.17}$$

Then the sequence $\{x^k\}$, generated by the fixed-point iterations (3.5) *from any starting point x^0, converges to some $x^* \in X^*$. In addition,* (4.12)–(4.13) *hold for all but finitely many iterations.*

4.2. Linear rate of convergence. Let $\{x^k\}$ be generated by the fixed-point iterations (3.5) starting from any $x^0 \in \Omega$. We know that the sequence converges to some point in X^*. Throughout this subsection, we let $x^0 \in \Omega$,

$$x^* := \lim_{k \to \infty} x^k,$$

and study the rate of convergence of $\{x^k\}$ to x^* under different assumptions. Note that $\Omega = \mathbb{R}^n$ if f is convex quadratic, and recall that a sequence $\{\|x^k - x^*\|\}$ converges to zero q-linearly if its q_1-factor is less than one, i.e., if

$$q_1 := \limsup_{k \to \infty} \frac{\|x^{k+1} - x^*\|}{\|x^k - x^*\|} < 1,$$

while it is r-linearly convergent if it is bounded by a q-linearly convergent sequence.

As we will show, under appropriate assumptions q-linear convergence holds for any $\tau \in (0, 2/\hat{\lambda}_{\max})$. However, the q_1-factor may vary with different choices of τ. In particular, we consider choices of the form

$$\tau(\lambda) := \frac{\gamma(\lambda)}{\gamma(\lambda) + 1} \frac{2}{\hat{\lambda}_{\max}}, \quad \gamma(\lambda) := \frac{\hat{\lambda}_{\max}}{\lambda}, \tag{4.18}$$

where $\hat{\lambda}_{\max}$ is defined in (4.1) and $\lambda > 0$ will take different values under different assumptions. It is easy to see that $\tau(\lambda) \in (0, 2/\hat{\lambda}_{\max})$ since $\gamma(\lambda) > 0$.

Some of our assumptions will involve the matrix H_{EE}:

DEFINITION 4.8. *Let $H(x)$ denote the Hessian of f evaluated at $x \in \Omega$, and*

$$H_{EE}(x) := [H_{i,j}(x)]_{i,j \in E}$$

denote the square submatrix of H corresponding to the index set E defined in (4.8).

Based on Corollary 4.6, we first apply existing convergence results for the gradient projection method applied to (4.16).

PROPOSITION 4.9. *Let Assumption* 1 *hold. If* (i) *$H_{EE}(x^*)$ has full rank, or* (ii) *f is defined as in* (1.6)*, then $\{\|x^k\|_1 + \mu f(x^k)\}$ converges to $\|x^*\| + \mu f(x^*)$ q-linearly and $\{x^k\}$ converges to x^* r-linearly.*

Under the first condition, the above result follows from [50] and [41], while under the second condition it follows from [41]. However, by directly analyzing the original fixed-point iterations, we can strengthen the convergence rate of $\{x^k\}$ from r-linear to q-linear. Theorem 4.10 does this under the assumption that $H_{EE}(x^*)$ is full rank; Theorem 4.11 instead assumes that $\operatorname{supp}(x^*) = E$. We first define

$$\bar{H}^k \equiv \bar{H}\left(x^k, x^*\right) := \int_0^1 H\left(x^* + t\left(x^k - x^*\right)\right) dt. \tag{4.19}$$

THEOREM 4.10. *Let Assumption* 1 *hold, and assume that*

$$\lambda^E_{\min} := \lambda_{\min}(H_{EE}(x^*)) > 0. \tag{4.20}$$

Then for any $\tau \in (0, 2/\hat{\lambda}_{\max})$, $\{x^k\}$ converges to x^* q-linearly. Moreover, if τ is chosen as in (4.18) *with $\lambda = \lambda^E_{\min}$, then the q_1-factor satisfies*

$$q_1 \leq \frac{\gamma\left(\lambda^E_{\min}\right) - 1}{\gamma\left(\lambda^E_{\min}\right) + 1}. \tag{4.21}$$

Proof. Without loss of generality, we assume that all iteration counts, k, are large enough so that $x^k_i = x^*_i = 0$ for all $i \in L$, and that the spectrum of $\bar{H}^k_{EE}$ falls in the interval $[\lambda^E_{\min} - \epsilon, \hat{\lambda}_{\max}]$ for an arbitrary $\epsilon > 0$. (The first assumption on k is valid because of the finite convergence properties of Theorem 4.5; the second follows from the continuity of the Hessian.) Since $x^k_i = x^*_i = 0$, $\forall i \in L$, the mean-value theorem yields

$$h_E\left(x^k\right) - h_E\left(x^*\right) = x^k_E - x^*_E - \tau\left(g_E\left(x^k\right) - g_E\left(x^*\right)\right) = \left(I - \tau \bar{H}^k_{EE}\right)\left(x^k_E - x^*_E\right).$$

Recall that $x^{k+1} = s_\nu \circ h(x^k)$ and $s_\nu(\cdot)$ is nonexpansive. Hence,

$$\begin{aligned}
\left\|x^{k+1} - x^*\right\| &\equiv \left\|x^{k+1}_E - x^*_E\right\| \\
&\leq \left\|h_E\left(x^k_E\right) - h_E\left(x^*_E\right)\right\| \\
&\leq \left\|I - \tau \bar{H}^k_{EE}\right\| \left\|x^k_E - x^*_E\right\| \\
&\leq \max\left\{\left|1 - \tau\hat{\lambda}_{\max}\right|, \left|1 - \tau\lambda^E_{\min}\right| + \tau\epsilon\right\} \left\|x^k_E - x^*_E\right\| \\
&\equiv \max\left\{\left|1 - \tau\hat{\lambda}_{\max}\right|, \left|1 - \tau\lambda^E_{\min}\right| + \tau\epsilon\right\} \left\|x^k - x^*\right\|.
\end{aligned}$$

Clearly, $\max\{|1-\tau\hat{\lambda}_{\max}|, |1-\tau\lambda^E_{\min}|+\tau\epsilon\}$ is less than one for any $\tau \in (0, 2/\hat{\lambda}_{\max})$ and ϵ sufficiently small; in particular, it equals the right-hand side of (4.21) plus $\tau\epsilon$ when $\tau = \tau(\lambda^E_{\min})$. Since ϵ is arbitrary, (4.21) must hold. ∎

THEOREM 4.11. *Let Assumption* 1 *hold, and also assume that* x^* *satisfies* (i) $\mathrm{supp}(x^*) = E$ *or, equivalently, the strict complementarity condition*

$$|x^*| + (1-\mu|g^*|) > 0, \tag{4.22}$$

and (ii) *the range space* $\mathcal{R}(H_{EE}(x))$ *of* $H_{EE}(x)$ *is invariant in a neighborhood* N^* *of* x^*. *Whenever* $H_{EE}(x^*) \neq \mathbf{0}$, *let*

$$\lambda^{\mathcal{R}}_{\min} := \lambda_{\min}\left(V^\top H_{EE}(x^*)V\right) > 0, \tag{4.23}$$

where V *is any orthonormal basis of* $\mathcal{R}(H_{EE}(x^*))$.

If $H_{EE}(x^*) = \mathbf{0}$, *then* $x^k = x^*$ *for all* k *sufficiently large; otherwise* $\{x^k\}$ *converges to* x^* *q-linearly for any* $\tau \in (0, 2/\hat{\lambda}_{\max})$. *In the latter case, if* τ *is chosen as in* (4.18) *with* $\lambda = \lambda^{\mathcal{R}}_{\min}$, *then the* q_1*-factor satisfies*

$$q_1 \leq \frac{\gamma\left(\lambda^{\mathcal{R}}_{\min}\right)-1}{\gamma\left(\lambda^{\mathcal{R}}_{\min}\right)+1}. \tag{4.24}$$

The proof of this theorem is given in section 5.2. We note that $\mathcal{R}(H_{EE}(x))$ is invariant near x^* if either f is a quadratic function or $H_{EE}(x^*)$ has full rank.

Since Assumption 1 is not required in the proof of global convergence for convex quadratic f, we can directly derive the following results for this case, which is the situation one encounters with compressed sensing. The proof, which is similar to those of Theorems 4.10 and 4.11, is left to the reader.

COROLLARY 4.12. *Let* f *be a convex quadratic function that is bounded below, and* $\{x^k\}$ *be the sequence generated by the fixed-point iterations* (3.5) *with* $\tau \in (0, 2/\lambda_{\max}(H))$.

1. *If* H_{EE} *has full rank, then* $\{x^k\}$ *converges to* x^* *q-linearly. Moreover, if* τ *is chosen as in* (4.18) *with* $\lambda = \lambda_{\min}(H_{EE})$, *then the* q_1*-factor satisfies*

$$q_1 \leq \frac{\gamma(\lambda_{\min}(H_{EE}))-1}{\gamma(\lambda_{\min}(H_{EE}))+1}.$$

2. *Let* x^* *satisfy the strict complementarity condition* (4.22). *Then if* $H_{EE} = \mathbf{0}$, $\{x^k\}$ *converges to* x^* *in a finite number of steps. Otherwise* $\{x^k\}$ *converges to* x^* *q-linearly, and if* τ *is chosen as in* (4.18) *with* $\lambda := \lambda_{\min}(V^\top H_{EE}V)$, *where* V *is an orthonormal basis for the range space of* H_{EE}, *then the* q_1*-factor satisfies*

$$q_1 \leq \frac{\gamma\left(\lambda_{\min}\left(V^\top H_{EE}V\right)\right)-1}{\gamma\left(\lambda_{\min}\left(V^\top H_{EE}V\right)\right)+1}.$$

4.3. Discussion. The assumptions of Theorems 4.10 and 4.11 usually hold for compressed sensing reconstruction problems posed as in (1.3) or (1.2), in which case A is often a Gaussian random matrix or has rows randomly chosen from an orthogonal matrix such as an FFT, DCT, or wavelets transform matrix. It is well known that a randomly generated matrix is full rank with probability one (unless elements of the matrix are generated from a restricted space) [23]. Therefore, when $A \in \mathbb{R}^{m\times n}$

is a random matrix, the reduced Hessian for problem (1.3), i.e., $A_E^\top M A_E$, where A_E consists of columns of A with indices in E, will have full rank with probability one as long as $|E| \leq m$, which is generally the case. A similar argument can be made for partial orthogonal matrices. We believe that the strict complementarity assumption in Theorem 4.11 should also hold for random matrices with a prevailing probability, though we do not currently have a proof for this. We have observed the general convergence behavior predicted by our theorems empirically in computational studies; see section 6.2.

In our convergence theorems, the choice of τ is restricted by the upper bound $2/\hat{\lambda}_{\max}$, where $\hat{\lambda}_{\max}$ is an upper bound for the largest eigenvalue of the Hessian. In compressed sensing applications, the quantity $\hat{\lambda}_{\max}$ is often easily obtained when $M = I$. When A is a partial orthogonal matrix, $\hat{\lambda}_{\max} = \lambda_{\max}(A^\top A) = 1$ and $\tau \in (0, 2)$ will suffice. When A is a Gaussian random matrix (with elements independently drawn from the standard normal distribution), well-known random matrix theory (see [34] or [23], for example) yields

$$n\left(1 - \sqrt{\frac{m}{n}}\right)^2 \leq \lambda_i\left(A^\top A\right) \leq n\left(1 + \sqrt{\frac{m}{n}}\right)^2$$

with prevailing probability for large n. In either case, upper bounding τ is not an issue as long as $M = I$.

For simplicity, we have used a fixed $\tau \in (0, 2/\hat{\lambda}_{\max})$ in our analysis. However, this requirement could be relaxed in the later stages of the iterations when the actions of the mapping $h = I - \tau g$ concentrate on a "reduced space." In this stage, h can remain contractive even if the maximum eigenvalue bound on the Hessian is replaced by that on the reduced Hessian, which will generally increase the upper bound on τ. For example, consider the quadratic problem (1.2) where A is a partial orthogonal matrix. Then $\lambda_{\max}(A^\top A) = 1$, but $\lambda_{\max}(A_E^\top A_E) < 1$, such that h remains contractive even if τ is chosen close to $2/\lambda_{\max}(A_E^\top A_E) > 2$. Such a dynamic strategy, though theoretically feasible, is not straightforward to implement. It should be an interesting topic for further research.

5. Proofs of convergence results. In this section, Theorems 4.5 and 4.11 are proved through several technical results that lead to the final arguments.

5.1. Proof of Theorem 4.5. The lemma below establishes a sufficient condition for $x \in \Omega$ to be a fixed point of $s_\nu \circ h(\cdot)$.

LEMMA 5.1. *Under Assumption* 1, *if*

$$\|s_\nu \circ h(x) - s_\nu \circ h(x^*)\| \equiv \|s_\nu \circ h(x) - x^*\| = \|x - x^*\|, \tag{5.1}$$

then x is a fixed point, and therefore a solution of (1.1)*; that is,*

$$x = s_\nu \circ h(x). \tag{5.2}$$

Proof. Recall that s_ν is component-wise nonexpansive and h is nonexpansive in $\|\cdot\|$. From (5.1),

$$\|x - x^*\| = \|s_\nu \circ h(x) - s_\nu \circ h(x^*)\| \leq \|h(x) - h(x^*)\| \leq \|x - x^*\|. \tag{5.3}$$

Hence, both inequalities hold as equalities. In particular, the no-shrinkage condition (3.8) holds for $y^1 = h(x)$ and $y^2 = h(x^*)$, so Part 1 of Lemma 3.2 yields

$$s_\nu \circ h(x) - s_\nu \circ h(x^*) = h(x) - h(x^*).$$

Rewriting this equation, we get

$$s_\nu \circ h(x) = x - \tau(g(x) - g(x^*)),$$

and since the last inequality in (5.3) also holds as equality, we have $g(x) - g(x^*) = 0$ according to Lemma 4.1, and hence the conclusion. ∎

The next lemma establishes the finite convergence properties stated in Theorem 4.5.

LEMMA 5.2. *Let Assumption* 1 *hold and* $\{x^k\}$ *be generated by the fixed-point iterations* (3.5) *starting from any* $x^0 \in \Omega$. *Then*

1. $x_i^k = 0\ \forall i \in L$ *for all but at most* $\|x^0 - x^*\|^2/\omega^2$ *iterations;*
2. $\operatorname{sgn}(h_i(x^k)) = \operatorname{sgn}(h_i(x^*)) = -\mu g_i^*,\ \forall\ i \in E$, *for all but at most* $\|x^0 - x^*\|^2/\nu^2$ *iterations.*

Proof. We fix any $x^* \in X^*$ and consider $x_i^k \neq 0$ for some $i \in L$. In view of the nonexpansiveness of $s_\nu(\cdot)$ and the related property in Lemma 3.2 part 6, we have

$$\begin{aligned}\left|x_i^{k+1} - x_i^*\right|^2 &= \left|s_\nu \circ h_i\left(x^k\right) - s_\nu \circ h_i(x^*)\right|^2 \\ &\leq \left(\left|h_i\left(x^k\right) - h_i(x^*)\right| - (\nu - h_i(x^*))\right)^2 \\ &\leq \left|h_i\left(x^k\right) - h_i(x^*)\right|^2 - \omega^2,\end{aligned}$$

where the last inequality follows from (4.11). The component-wise nonexpansiveness of $s_\nu(\cdot)$ and the nonexpansiveness of $h(\cdot)$ imply that

$$\left\|x^{k+1} - x^*\right\|^2 \leq \left\|h\left(x^k\right) - h(x^*)\right\|^2 - \omega^2 \leq \left\|x^k - x^*\right\|^2 - \omega^2.$$

Therefore, the number of iterations where $x_i^k \neq 0$ for some $i \in L$ cannot be more than $\|x^0 - x^*\|^2/\omega^2$. This proves the first statement.

For the second statement, we recall (3.1) and note that if $i \in \operatorname{supp}(x^*)$

$$0 \neq x_i^* = \operatorname{sgn}(h_i(x^*)) \max\{|h_i(x^*)| - \nu, 0\},$$

so that $|h_i(x^*)| > \nu$ for $i \in \operatorname{supp}(x^*)$. On the other hand,

$$|h_i(x^*)| = \tau|g^*| = \tau/\mu = \nu,\ \forall i \in E \setminus \operatorname{supp}(x^*).$$

Therefore,

$$|h_i(x^*)| \geq \nu,\ \forall i \in E.$$

Now if $\operatorname{sgn}(h_i(x^k)) \neq \operatorname{sgn}(h_i(x^*))$ for some $i \in E$, then Lemma 3.2, Part 5 implies

$$\begin{aligned}\left|x_i^{k+1} - x_i^*\right|^2 &= \left|s_\nu \circ h_i\left(x^k\right) - s_\nu \circ h_i(x^*)\right|^2 \\ &\leq \left(\left|h_i\left(x^k\right) - h_i(x^*)\right| - \nu\right)^2 \\ &\leq \left|h_i\left(x^k\right) - h_i(x^*)\right|^2 - \nu^2.\end{aligned}$$

Hence, the number of iterations for which $\operatorname{sgn}(h_i(x^k)) \neq \operatorname{sgn}(h_i(x^*))$ for some $i \in E$ cannot be more than $\|x^0 - x^*\|^2/\nu^2$. Moreover, it follows directly from the definitions of E in (4.8), h in (3.3), and g^* in (2.3), and the equation $\tau = \nu\mu$, that $\operatorname{sgn}(h_i(x^*)) = -\mu g_i^*$ for all $i \in E$. ∎

Based on these lemmas, we provide a short proof of Theorem 4.5 for the sake of completeness.

Proof of Theorem 4.5. To show that $\{x^k\}$ converges, we (i) show that $\{x^k\}$ has a limit point, (ii) argue that it must be a fixed point because it satisfies the condition (5.1) of Lemma 5.1, and (iii) prove its uniqueness.

Since $s_\nu \circ h(\cdot)$ is nonexpansive, $\{x^k\}$ lies in a compact subset of Ω and must have a limit point, say,

$$\bar{x} = \lim_{j\to\infty} x^{k_j}.$$

Since for any given fixed point x^* the sequence $\{\|x^k - x^*\|\}$ is monotonically nonincreasing, it has a limit which can be written as

$$\lim_{k\to\infty} \left\|x^k - x^*\right\| = \|\bar{x} - x^*\|, \tag{5.4}$$

where $\bar{x}$ can be any limit point of $\{x^k\}$. That is, all limit points, if more than one exists, must have an equal distance to any given fixed point $x^* \in X^*$.

By the continuity of $s_\nu \circ h(\cdot)$, the image of $\bar{x}$,

$$s_\nu \circ h(\bar{x}) = \lim_{j\to\infty} s_\nu \circ h\left(x^{k_j}\right) = \lim_{j\to\infty} x^{k_j+1},$$

is also a limit point of $\{x^k\}$. Therefore, from (5.4) we have

$$\|s_\nu \circ h(\bar{x}) - s_\nu \circ h(x^*)\| = \|\bar{x} - x^*\|,$$

which allows us to apply Lemma 5.1 to $\bar{x}$ and establish the optimality of $\bar{x}$.

By setting $x^* = \bar{x} \in X^*$ in (5.4), we establish the convergence of $\{x^k\}$ to its unique limit point $\bar{x}$:

$$\lim_{k\to\infty} \left\|x^k - \bar{x}\right\| = 0.$$

Finally, the finite convergence results (4.12)–(4.13) were proved in Lemma 5.2. ∎

5.2. Proof of Theorem 4.11. The next lemma gives a useful update formula for k sufficiently large and $i \in \operatorname{supp}(x^*)$.

LEMMA 5.3. *Under Assumption* 1, *after a finite number of iterations*

$$x_i^{k+1} = x_i^k - \tau\left(g_i\left(x^k\right) - g_i^*\right), \quad \forall i \in \operatorname{supp}(x^*). \tag{5.5}$$

Proof. Since $x^k \to x^* \in X^*$ and $h(\cdot)$ is component-wise continuous, $h_i(x^k) \to h_i(x^*)$. The fact that $|h_i(x^*)| > \nu$ for $i \in \operatorname{supp}(x^*)$ implies that after a finite number of iterations we have $|h_i(x^k)| > \nu$ for $i \in \operatorname{supp}(x^*)$. This gives

$$\begin{aligned} x_i^{k+1} &= \operatorname{sgn}\left(h_i\left(x^k\right)\right)\left(\left|h_i\left(x^k\right)\right| - \nu\right) \\ &= h_i\left(x^k\right) - \nu \operatorname{sgn}\left(h_i\left(x^k\right)\right) \\ &= x_i^k - \tau g_i\left(x^k\right) - (\tau/\mu)\left(-\mu g_i^*\right) \\ &= x_i^k - \tau\left(g_i\left(x^k\right) - g_i^*\right), \end{aligned}$$

for any $i \in \operatorname{supp}(x^*)$. ∎

Proof of Theorem 4.11. Without loss of generality, we can assume that k is large enough so that (5.5) holds and $x^k \in N^*$, where N^* is defined in Theorem 4.11.

Since $x_i^k = 0$ for any $i \in L$, it suffices to consider the rate of convergence of x_i^k for $i \in E = \text{supp}(x^*)$, where equality follows from the strict complementarity assumption on x^*.

Let $\bar{H}^k$ be defined as in (4.19). By assumption, the range and null spaces of $\bar{H}_{EE}^k$ are now invariant for all k. Let $P = VV^\top \in \mathbb{R}^{|E|\times|E|}$ be the orthogonal projection onto the range space of $H_{EE}(x^*)$ such that $I-P$ is the orthogonal projection onto the null space of $H_{EE}(x^*)$. Also recall that x_E denotes the subvector of x corresponding to the index set E.

Since $E = \text{supp}(x^*)$, Lemma 5.3 implies that

$$x_E^{k+1} = x_E^k - \tau \left(g\left(x^k\right) - g(x^*)\right)_E = x_E^k - \tau \bar{H}_{EE}^k \left(x_E^k - x_E^*\right). \tag{5.6}$$

At each iteration, the update, $-\tau \bar{H}_{EE}^k(x_E^k - x_E^*)$, stays in the range space of $H_{EE}(x^*)$. This implies that the null space components of the iterates have converged to the null space components of x^*, namely, for all k sufficiently large,

$$(I-P)\left(x_E^k - x_E^*\right) \equiv \mathbf{0}. \tag{5.7}$$

If $H_{EE}(x^*) = 0$, then the range space is empty and the update vanishes such that $x^k = x^*$ after a finite number of steps.

Now assume that $H_{EE}(x^*) \neq 0$ so that $\lambda_{\min}^{\mathcal{R}} > 0$ exists. It suffices to consider the rate of convergence of $\{Px_E^k\}$ to Px_E^*. It follows from (5.6) and (5.7) that

$$x_E^{k+1} - x_E^* = P\left(x_E^{k+1} - x_E^*\right) = P\left(I - \tau \bar{H}_{EE}^k\right) P\left(x_E^k - x_E^*\right). \tag{5.8}$$

By a routine continuity argument, we know that there exists an arbitrarily small constant $\epsilon > 0$ such that for all k sufficiently large the eigenvalues of $V^\top H_{EE}^k V$ satisfy

$$\hat{\lambda}_{\max} \geq \lambda_i\left(V^\top H_{EE}^k V\right) \geq \lambda_{\min}^{\mathcal{R}} - \epsilon > 0, \quad \forall i.$$

Consequently, given the definition of τ in (4.18) and noting that $P^2 = P = VV^\top$, we calculate from (5.8):

$$\begin{aligned}
\left\|x_E^{k+1} - x_E^*\right\| &\leq \left\|P\left(I - \tau \bar{H}_{EE}^k\right) P\right\| \left\|x_E^k - x_E^*\right\| \\
&= \left\|I - \tau V^\top \bar{H}_{EE}^k V\right\| \left\|x_E^k - x_E^*\right\| \\
&= \max\left\{\left|1 - \tau\hat{\lambda}_{\max}\right|, \left|1 - \tau\lambda_{\min}^{\mathcal{R}}\right| + \tau\epsilon\right\} \left\|x_E^k - x_E^*\right\| \\
&= \left(\frac{\gamma\left(\lambda_{\min}^{\mathcal{R}}\right) - 1}{\gamma\left(\lambda_{\min}^{\mathcal{R}}\right) + 1} + \tau\epsilon\right) \left\|x_E^k - x_E^*\right\|,
\end{aligned} \tag{5.9}$$

which implies (4.24) since ϵ can be arbitrarily small. □

6. A continuation method. Our algorithm for solving (1.1), that is,

$$\min_{x\in\mathbb{R}^n} \|x\|_1 + \mu f(x), \tag{6.1}$$

consists of applying the fixed-point iterations

$$x^{k+1} = s_\nu \circ h\left(x^k\right) := \text{sgn}\left(x^k - \tau g\left(x^k\right)\right) \odot \max\left\{\left|x^k - \tau g\left(x^k\right)\right| - \nu, 0\right\}, \ \mu\nu = \tau$$

(see (3.5) and (4.3)) within the continuation (or path-following) framework described below. Further extensions that may improve our algorithm are certainly possible, but are beyond the scope of this paper.

6.1. Homotopy algorithms in statistics. Statisticians often solve (1.2) (which is (1.1) with $f(x) = \frac{1}{2}\|Ax - b\|^2$) in the context of regression. In Bayesian terminology, this corresponds to maximizing the *a posteriori* probability for recovering the signal x from the measurement $b = Ax + \epsilon$, where the prior on x is Laplacian and ϵ is Gaussian white noise. Practically, such a procedure may be preferred over standard least squares because a sparse solution of (1.2) explicitly identifies the most significant regressor variables.

As intimated in the Introduction, variations on (1.2) may be used in different applications and contexts. For example, problem (1.2) is closely related to this quadratically constrained ℓ_1-minimization problem

$$\min_x \left\{ \|x\|_1 \;\middle|\; \|Ax - b\|^2 \le \sigma^2 \chi^2_{1-\alpha,m} \right\}, \tag{6.2}$$

which is often used when an estimated noise level σ is available. Alternatively, one can constrain the size of $\|x\|_1$ and minimize the sum of squares of the residual $Ax - b$:

$$\min_x \left\{ \frac{1}{2}\|Ax - b\|^2 \;\middle|\; \|x\|_1 \le t \right\}. \tag{6.3}$$

Statisticians often refer to the above problem as the Least Absolute Shrinkage and Selection Operator (LASSO) [58].

Problems (1.2), (6.2), and (6.3) are equivalent in the sense that once the value of one of μ, σ, or t is fixed, there are values for the other two quantities such that all three problems have the same solution. For a detailed explanation, please see [53].

Least Angle Regression (LARS) (see [24], for example) is a method for solving (6.3). LARS starts with the zero vector and gradually increases the number of nonzeros in the approximation x. In fact, it generates the full path of solutions that results from setting the right-hand side of the constraint to every value in the interval $[0, t]$. Thus, LARS is a homotopy algorithm. The construction of the path of solutions is facilitated by the fact that it is piecewise linear, such that any segment can be generated given the solutions at turning points, which are the points at which at least one component changes from zero to nonzero or vice versa. Thus LARS and other homotopy algorithms [43, 49, 63] solve (6.3) by computing the solutions at the turning points encountered as t increases from 0 to a given value. These algorithms require the solution of a least squares problem at every iteration, where the derivative matrix of the residuals consists of the columns of A associated with the nonzero components of the current iterate. For large-scale problems, solving these intermediate least squares problems may prove costly, especially when the solution is only moderately sparse, and/or A is a partial fast transform matrix that is not stored explicitly.

We found it helpful for our algorithm to adopt a continuation strategy similar to homotopy in the sense that we solve (1.1) for an increasing sequence of μ values. However, our algorithm does not track turning points or solve any least squares subproblems, and so only approximately follows the solution path.

6.2. A continuation strategy. The convergence analysis indicates that the speed of the fixed-point algorithm is determined by the values of $\nu = \tau/\mu$ and ω (see Theorem 4.5), and the spectral properties of the Hessian of $f(x)$ (see Theorems 4.10 and 4.11). The signs of $h_i(x^k)$ evolve to agree with those of $h_i(x^*)$ for $i \in E$ faster for larger ν (equivalently, for smaller μ). Similarly, large ω implies fast convergence of the $|x_i^k|$, $i \in L$, to zero. Once the finite convergence properties of Theorem 4.5 are satisfied, all action is directed towards reducing the errors in the E components, and the (worst-

case) convergence rate is dictated by $\|I - \tau \bar{H}_{EE}\|$, which can be considerably smaller than $\|I - \tau \bar{H}\|$, especially when $|E| \ll n$.

In general, we have little or no control over the value of ω, nor the spectral properties of the Hessian. On the other hand, we do have the freedom to choose τ and $\nu = \tau/\mu$. For fixed τ we found $\tau \in [1/\hat{\lambda}_{\max}, 2/\hat{\lambda}_{\max})$ to be superior to $\tau \in (0, 1/\hat{\lambda}_{\max})$. Beyond this, τ does not have much effect on ν and can be chosen empirically or based on considerations concerning $||I - \tau \bar{H}_{EE}||$. The value of μ, on the other hand, while it must eventually be equal to some specified value $\bar{\mu}$, can in the meantime be chosen freely to produce a wide range of ν values. Thus, since larger ν means faster convergence, we propose a continuation strategy for μ. In particular, if problem (6.1) is to be solved with $\bar{\mu}$, we propose solving a sequence of problems (6.1) defined by an increasing sequence $\{\mu_j\}$, as opposed to fixing $\nu = \tau/\bar{\mu}$. When a new problem, associated with μ_{j+1}, is to be solved, the approximate solution for the current (μ_j) problem is used as the starting point. In essence, this framework approximately follows the path $x^*(\mu)$ in the interval $[\mu_1, \bar{\mu}]$, where for any given μ value $x^*(\mu)$ is an optimal solution for (6.1). This path is well defined if the solution to (6.1) is unique for $\mu \in [\mu_1, \bar{\mu}]$. Even if this is not the case, it is reassuring to observe that the algorithm itself is well-defined. A formal statement of our fixed-point continuation method is given in Algorithm 1.

ALGORITHM 1 Fixed-point Continuation (FPC) Algorithm

Require: A, b, x^0, and $\bar{\mu}$

Select $0 < \mu_1 < \mu_2 < \cdots < \mu_L = \bar{\mu}$. Set $x = x^0$.
for $\mu = \mu_1, \mu_2, \ldots, \mu_L$ **do**
  while "not converged" **do**
    Select τ and set $\nu = \tau/\mu$
    $x \leftarrow s_\nu \circ h(x)$
  end while
end for

Our computational experience indicates that the performance of this continuation strategy can be far superior to that of directly applying the fixed-point iterations (3.5) with a specified value $\bar{\mu}$. This is evident in Figure 6.1, where the convergence behavior

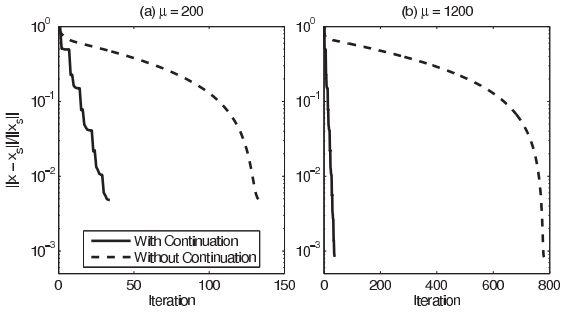

FIG. 6.1. *Convergence acceleration via continuation. The relative error, $\|x^k - x^*\|/\|x^*\|$, and iteration data were obtained by applying the FPC algorithm with or without continuation to two instances of problem* (1.2)*, where in each instance A is a 512×1024 partial DCT matrix, $b = Ax^*$ plus noise for a given sparse x^*, and $\mu = 200$ in the first case and 1200 in the second. The plots show that as μ increases, the advantages of continuation become more pronounced.*

of the two approaches (with and without continuation) is plotted for two values of $\bar{\mu}$, and is in line with the observations of [18, 43, 49, 58]. Moreover, since $x^*(\mu)$ tends to be sparser for smaller μ, the reduced Hessian $\bar{H}_{EE}$ tends to be smaller and better conditioned in this case, such that the continuation strategy should improve the convergence rate for the components with indices in E in addition to the rate of finite convergence of $\mathrm{sgn}(h_i(x^k))$, $i \in E$. Overall, this fixed-point continuation algorithm produces competitive solution times (as compared to other state-of-the-art algorithms) for compressed sensing problems. For instance, we were able to reconstruct signals of length 2,097,152 in 2.5 to 7.5 minutes, depending on the level of sparsity and noise, when A was a $1{,}048{,}576 \times 2{,}097{,}152$ partial DCT matrix (using Matlab 7.3 on a Dell Optiplex GX620 with a 3.2 GHz processor and 4 GB RAM).

In principle, our fixed-point continuation algorithm can be used to solve problems (6.2) and (6.3) in addition to (6.1). Take the LASSO problem (6.3) as an example. When we start our algorithm with a small μ value, the corresponding optimal $\|x\|_1$ is also small; subsequent increases in μ correspond to increases in the optimal $\|x\|_1$. We can stop the process once $\|x\|_1$ approximately equals t, backtracking if necessary. As interesting as such extensions may be, they are not in the scope of the current paper. Indeed, as we observed in our computational study [32], a strength of this algorithmic framework is that a simple implementation is sufficient to obtain good results.

7. Conclusions. We investigated the use of the forward-backward operator splitting technique, combined with a continuation (path-following) strategy, for solving ℓ_1-norm regularized convex optimization problems. Our theoretical analysis yields convergence results stronger than what could be obtained from applying existing general theory to our setting. In particular, we established finite convergence for some quantities and q-linear convergence rates without assuming strict convexity. Interestingly, our rate of convergence results imply, in a general sense, that sparser solutions correspond to faster rates of convergence, which agrees with what has been observed in practice. Our convergence analysis, however, is only for the fixed-point algorithm (3.5) with a fixed μ value. It remains an important, yet more difficult, research issue to study convergence behavior associated with specific continuation strategies.

We have conducted a comprehensive computational study to compare our fixed-point continuation (FPC) algorithm with three recent state-of-the-art compressed sensing recovery algorithms [17, 28, 35]. The numerical results, too lengthy to be included in the present paper, will be reported in a subsequent paper [32]. In brief, these numerical results indicate that FPC's overall performance is competitive with, and is often superior to, these state-of-the-art algorithms. The strong performance of FPC in computing sparse solutions to compressed sensing problems is certainly encouraging. However, it remains a research issue to carefully evaluate and possibly enhance the performance of FPC on other ℓ_1-regularized optimization problems where solutions are not necessarily very sparse.

POLYHEDRAL RESULTS FOR 1-RESTRICTED SIMPLE 2-MATCHINGS*

DAVID HARTVIGSEN† AND YANJUN LI‡

Abstract. A simple 2-matching in a graph is a subgraph whose connected components are nontrivial paths and cycles. A simple 2-matching is called 1-restricted if each connected component has two or more edges. In this paper we consider the problem of finding maximum weight 1-restricted simple 2-matchings (which is a relaxation of the traveling salesman problem). We present an integer programming formulation for this problem, characterize the extreme points of the linear programming relaxation, and characterize the graphs for which the linear programming relaxation has all integral extreme points. We show how to recognize these graphs in polynomial time. We also introduce a new class of blossom-type inequalities that tighten the general linear programming relaxation. A complete description of the convex hull of 1-restricted simple 2-matchings is unknown.

Key words. matchings, combinatorial optimization, polyhedral combinatorics, traveling salesman problem

1. Introduction.

All graphs $G = (V, E)$ considered in this paper are undirected and (except where noted) have no parallel edges or loops. We associate a real weight with every $e \in E$. A *simple* 2*-matching* in a graph is a subgraph all of whose nodes have degree 1 or 2. (Sometimes in the literature a simple 2-matching is defined as a subset of edges. For convenience in this paper, we use the subgraph definition.) Hence the connected components of a simple 2-matching are nontrivial paths and cycles. The *weight* of a simple 2-matching is the sum of the weights of the edges in the matching. A well-studied problem in the literature is to find a maximum weight simple 2-matching in a graph. A polyhedral characterization and polynomial-time algorithm (due to Edmonds [5] and Johnson [16], respectively; see also [8]), as well as a number of structural theorems (e.g., see Belck [1] and Gallai [9]) are known for this problem, among other things (see [21] for an excellent survey). In this paper we present some analogous results for a restricted version of this problem, which we describe next.

A k*-restricted simple* 2*-matching* is a simple 2-matching such that each connected component has more than k edges. Hence 0-restricted simple 2-matchings are equivalent to simple 2-matchings, and 1-restricted simple 2-matchings are equivalent to simple 2-matchings that contain no "isolated edges." We are interested in the problem of finding maximum weight k-restricted simple 2-matchings. Solutions to this problem on complete graphs, with nonnegative weights, can be shown to provide increasingly accurate approximate solutions for the traveling salesman problem as k increases (see [6]; although k-restricted simple 2-matchings are not discussed in [6], their approach can easily be seen to apply to our problem).

In this paper we begin by introducing an integer programming formulation, call it IP, for the problem of finding a maximum weight 1-restricted simple 2-matching in a graph G. This formulation includes a new class of constraints, which we call *edge-adjacency constraints*. We let $A(G)$ denote the feasible points in the linear programming relaxation of IP, and we let $R(G)$ denote the convex hull of integral points in $A(G)$. (Hence the extreme points of $R(G)$ are precisely the 0,1 incidence vectors of 1-restricted simple 2-matchings of G.)

The paper then contains four main results. The first result characterizes the extreme points of $A(G)$. We find that they have a simple structure with components in $\{0, \frac{1}{2}, 1\}$. This result then yields our second result in which we characterize the graphs G for which $A(G)$ has all integral extreme points. (That is, we characterize when $A(G) = R(G)$.) This characterization has the following form: $A(G) = R(G)$ if and only if G contains no subgraph which is a 1-*restricted odd cycle* (to be defined later). Although 1-restricted odd cycles are fairly simple to describe, they can be arbitrarily large; hence it is not immediately obvious how to polynomially determine if a graph contains one. Our third result addresses this issue. In it we present a second (more technical) characterization of the graphs with no 1-restricted odd cycle that yields a polynomial time test for this property. Our final result is a new class of inequalities (based on a new structure called a 1-*restricted blossom*) that are valid for $R(G)$ and cut off all the fractional extreme points in $A(G)$. These inequalities generalize the edge-adjacency inequalities as well as the well-known blossom inequalities for the simple 2-matching polyhedron (see [5]). We also show that the 1-restricted blossom inequalities, together with the description of $A(G)$, do not yield a complete description of $R(G)$. Finding such a description is an open problem.

Thus we characterize an apparently new class of polyhedra with integral extreme points. (The class has variable coefficients in $\{0, \pm 1\}$ and is easily seen to not be totally unimodular.) Furthermore, the linear system for this polyhedron has a size that is polynomial in the size of the associated graph. It immediately follows that, for graphs containing no 1-restricted odd cycle, we can find a maximum weight 1-restricted simple 2-matching in strongly polynomial time (using the algorithm of Tardos [22]).

Before outlining the paper, let us consider some related work in the literature. The problem of finding maximum weight 1-restricted simple 2-matchings in general graphs, for the special case that all weights equal 1 (i.e., $w \equiv 1$), was considered in [10], where a polynomial-time algorithm and several structural theorems were presented. A related problem involves C_k-*free* 2-*matchings*, which are simple 2-matchings that contain no cycles of length $\leq k$. An algorithm to find a maximum, with $w \equiv 1$, C_3-free 2-matching appears in [11] and an algorithm to find a maximum, with $w \equiv 1$, C_4-free 2-matching in bipartite graphs appears in [12] (see also [19]). The problem of finding a maximum weight C_4-free 2-matching in bipartite graphs has been observed to be NP-hard (see [23], [3], and [20]). The problem of finding a maximum, with $w \equiv 1$, C_5-free 2-matching (in general graphs) is also known to be NP-hard (see [2] for a proof due to Papadimitiou). Related work can be found in [2], [4], and [7].

Let us discuss one other related area of research. A *k-piece* is a connected graph with maximum degree equal to k. A *k-piece packing* in a graph is a subgraph whose connected components are k-pieces. The *node-max k-piece packing problem* is to find a k-piece packing in a graph that contains a maximum number of nodes; the *edge-max k-piece packing problem* is to find a k-piece packing in a graph that contains a maximum number of edges. Observe that the node-max and edge-max 1-piece packing problems are equivalent to the classical matching problem. However, for higher values of k, the node-max and edge-max problems are different from one another. Finally,

note that the edge-max 2-piece packing problem is identical to the maximum, with $w \equiv 1$, 1-restricted simple 2-matching problem.

The node-max 2-piece packing problem was recently studied by Kaneko in [17], where he presented a Tutte-type theorem. This result was extended in [18] by Kano, Katona, and Király, where the authors presented a Tutte–Berge-type theorem. These results were further extended by Hartvigsen, Hell, and Szabó in [13], where the authors presented a polynomial time algorithm and Tutte-type and Tutte–Berge-type theorems for the node-max k-piece packing problem. Finally, a Gallai–Edmonds decomposition theorem for the general problem is presented in [15] by Janata, Loebl, and Szabó. Other research of this type has been recently surveyed in [14] by Hell (see also [21]).

Let us finish this section by outlining the paper. Section 2 contains some basic notation and definitions and section 3 contains our characterization of the extreme points of $A(G)$. Section 4 contains our characterization of the graphs G for which $A(G)$ has all integral extreme points plus several related results. In section 5 we introduce a new class of blossom-like inequalities that are valid for all integral points of $A(G)$. We show that these inequalities cut off all fractional extreme points of $A(G)$, but they do not yield a complete description of $R(G)$.

2. Notation and an IP formulation. In this section we introduce some notation and terminology, and we present an integer programming formulation of the problem of finding a maximum weight 1-restricted simple 2-matching. We begin with a few definitions.

Let $G = (V, E)$ be a graph. For $v \in V$, let $\delta(v)$ denote the subset of edges incident with v. For $uv \in E$, let $adj(uv)$ denote the set of edges incident with exactly one node in $\{u, v\}$; that is, $adj(uv) = \delta(u) + \delta(v) - uv$. For $S \subseteq E$, let $x(S) = \sum_{e \in S} x_e$. Given a subgraph $G' = (V', E')$ of G, a vector $x \in \{0, 1\}^E$ is called the 0-1 *incidence vector* for G' if $x_e = 1$ for every $e \in E'$, and $x_e = 0$ otherwise. We denote this vector $\chi^{E'}$. We use the term *cycle* to refer to a connected subgraph all of whose nodes have degree 2; and we use the term *path* to refer to a connected subgraph such that exactly two nodes have degree 1 and the remaining nodes have degree 2.

Let $A(G)$ denote the set of points $x \in \mathbb{R}^E$ that satisfy the following system:

$$x(\delta(v)) \leq 2 \quad \forall\, v \in V, \tag{1}$$

$$x_e \leq 1 \quad \forall\, e \in E, \tag{2}$$

$$x_e - x(adj(e)) \leq 0 \quad \forall\, e \in E, \tag{3}$$

$$x_e \geq 0 \quad \forall\, e \in E. \tag{4}$$

Observe that the integral points in $A(G)$ are precisely the 0-1 incidence vectors of 1-restricted simple 2-matchings in G. The key to this working is the new type of constraints (3), which we call *edge-adjacency constraints*. These constraints say that if an edge e is in the matching (i.e., $x_e = 1$), then at least one edge adjacent to e must also be in the matching.

Hence, for a weight vector $w \in \mathbb{R}^E$,

$$\max\ wx \ \text{ s.t. } x \in A(G),\ x \text{ integral}$$

is an integer programming formulation for the problem of finding a maximum weight 1-restricted simple 2-matching.

Let $R(G)$ denote the convex hull of the 0-1 incidence vectors of 1-restricted simple 2-matchings of G. Thus, $R(G) \subseteq A(G)$. In the next section we characterize the

extreme points of $A(G)$ and in the section following that we characterize the graphs G for which $A(G) = R(G)$.

3. Characterization of the extreme points of $A(G)$. Our main result in this section is a characterization of the extreme points of $A(G)$ on a general graph $G = (V, E)$. We then present a characterization of the extreme points of (1–2) and (4), whose integer solutions are the incidence vectors of classic simple 2-matchings. An interesting resemblance between these two characterizations is exhibited.

Let x be a feasible solution to $A(G)$ for a graph G. We say x_e and e are *fractional* if $0 < x_e < 1$, and we call x_e the *value* of e. An edge $e = uv$ of G is called 1-*tight* if e has value 1, one edge incident to u has value $\frac{1}{2}$, one edge incident to v has value $\frac{1}{2}$, and the remaining edges adjacent to e have value 0. Observe that 1-tight edges satisfy (3) at equality. Let G' denote a graph obtained from G by contracting a set of edges. (*Contracting* an edge is the operation of deleting the edge and identifying its endnodes. Observe that a graph resulting from a contraction can have parallel edges.) The nodes of G' resulting from contractions are called *shrunk*; the remaining nodes of G' are called *real*. The edges of G' inherit values from x in the obvious manner. Next we give our characterization of the extreme points of $A(G)$.

THEOREM 1. *A point $x \in A(G)$ is extreme if and only if it satisfies both of the following conditions:*

(i) *The point x has only values 0, $\frac{1}{2}$, and 1.*

(ii) *Let G^c be the graph obtained from G by contracting all the 1-tight edges. Then the edges of G^c with value $\frac{1}{2}$ form node-disjoint odd cycles, and every real node in such an odd cycle is incident with an edge with value 1.*

Before we give a proof of Theorem 1, we show in Figure 1 an example of an extreme point of $A(G)$. A subgraph of G is shown in Figure 1(a) with the x values given next to the edges, and the corresponding subgraph of G^c after contraction of the 1-tight edges is shown in Figure 1(b). Observe that edge uv of G is a 1-tight edge. Edge uv is contracted and becomes the shrunk node s in G^c. All the edges of the illustrated subgraph of G^c with value $\frac{1}{2}$ form node-disjoint odd cycles, and every node of such an odd cycle, except the shrunk node, is incident with an edge with value 1.

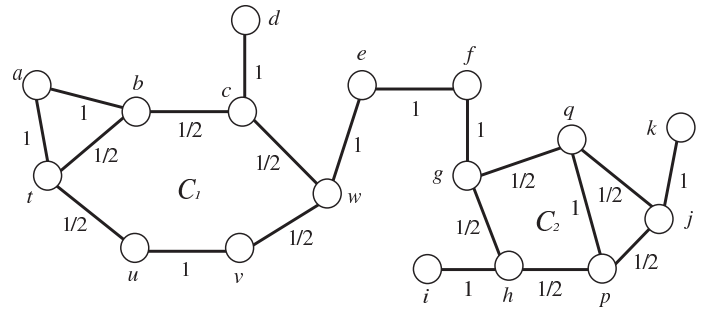
We use the following definition and lemmas in our proof of Theorem 1. Let $x \in A(G)$ for a graph $G = (V, E)$. We say an edge $e \in E$ is *adjacency tight (with respect to x)* if e satisfies inequality (3) at equality and is adjacent to at least one fractional edge.

LEMMA 2. *Let x be an extreme feasible solution to $A(G)$ for a graph G. If e_1 and e_2 are adjacency-tight edges of G, then e_1 is not adjacent to e_2.*

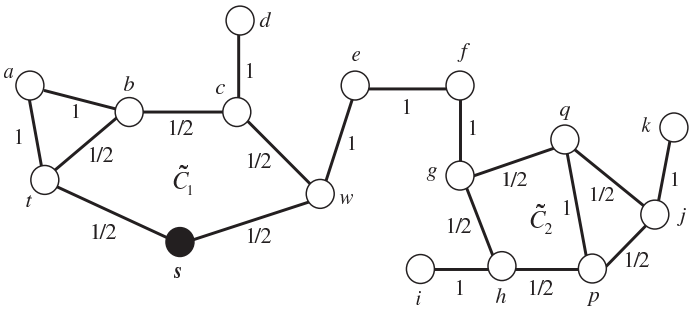
Proof. Let x be an extreme feasible solution to $A(G)$ for a graph G and let e_1 and e_2 be adjacency-tight edges that are adjacent to each other. We derive a contradiction.

First, observe that $x_{e_1} > 0$, since e_1 is adjacency tight. Similarly, $x_{e_2} > 0$. Furthermore, $x_{e_1} \geq x_{e_2}$ because e_1 is adjacency tight. Similarly, $x_{e_2} \geq x_{e_1}$. So $x_{e_1} = x_{e_2}$. Suppose there is an edge $e' \neq e_2$ that is adjacent to e_1 and satisfies $x_{e'} > 0$. Then e_1 being adjacency tight and $x_{e_2} > 0$ imply $x_{e_1} > x_{e_2}$, which is a contradiction. It follows that x_{e_1} and x_{e_2} are fractional, since if they were both equal to 1, then they would not be adjacent to at least one fractional edge. Finally, set $x^1 = x + \epsilon\chi^{\{e_1,e_2\}}$ and $x^2 = x - \epsilon\chi^{\{e_1,e_2\}}$ for some small $\epsilon > 0$. It is easy to see that $x = \frac{1}{2}x^1 + \frac{1}{2}x^2$ and that both x^1 and x^2 are feasible solutions to $A(G)$. Therefore, x is not extreme, which is a contradiction. ∎

LEMMA 3. *Let $x \in A(G)$ for a graph G and let edge $e = uv$ be adjacency-tight.*



(a) subgraph of G



(b) subgraph of G^c

FIG. 1. *An example of an extreme point of* $A(G)$.

(i) *If* u *and* v *are each incident with a fractional edge different from* e*, then* $0 < x(\delta(u)) < 2$ *and* $0 < x(\delta(v)) < 2$.

(ii) *If* e *is adjacent to exactly one fractional edge, then* e *is fractional in* G *and* $0 < x(\delta(u)) < 2$ *and* $0 < x(\delta(v)) < 2$.

Proof. First we prove (i). Clearly, since u and v are incident with fractional edges, $x(\delta(u)) > 0$ and $x(\delta(v)) > 0$. Suppose $x(\delta(u)) = 2$. Then

$$x_e + x(\delta(u) - e) = 2.$$

Because e is adjacency tight, we have that

$$x_e = x(\delta(u) - e) + x(\delta(v) - e).$$

If we solve the first equation for $x(\delta(u) - e)$ and substitute this into the second equation, we get

$$2 - 2x_e = -x(\delta(v) - e).$$

Since the maximum value that x_e can take is 1, $x(\delta(v) - e) \leq 0$, so we have a contradiction and the result follows.

To prove (ii), let e' be the single fractional edge adjacent to e. If e is also adjacent to an edge with value 1, then $x(adj(e)) > 1$ and e cannot be adjacency tight. Hence

e' is the only edge adjacent to e with nonzero value. So e has the same value as e' and the conclusion follows. This completes the proof. □

Proof. (Theorem 1) We first prove that if $x \in A(G)$ is extreme, then it satisfies (i) and (ii) in the statement of the Theorem.

Given an extreme point $x \in A(G)$, let G' be the graph resulting from contracting each adjacency-tight edge of G. Observe that by Lemma 2, each shrunk node of G' corresponds to a unique edge of G. Let F be the subgraph of G' that is induced by the fractional edges of G'. Observe that if F is empty, then there cannot be any adjacency-tight edges; hence the result follows immediately (since all the values of x are 0, 1), so let us assume F is nonempty.

Claim 1. Every connected component of F contains a cycle.

Proof of Claim 1: Suppose not. Then F must contain a connected component that is a tree. Let P be a path in F whose endnodes have degree 1 in F. Observe that if an endnode, say v, of P was obtained by shrinking an edge, say e, then e is fractional: If $x_e = 1$, then v cannot have degree 1 in F, since e is adjacency-tight; if $x_e = 0$, then e was not adjacency-tight. Partition the edges of P into two sets, say B (blue) and R (red), so that no two adjacent edges have the same color. If an endnode v of P is shrunk, then add the corresponding edge of G to the same set, B or R, that contains the edge of P incident with v. Define x^1 and x^2 on E as follows: $x^1 = x + \epsilon(\chi^B - \chi^R)$ and $x^2 = x + \epsilon(\chi^R - \chi^B)$, where $\epsilon > 0$. Observe that $x = \frac{1}{2}x^1 + \frac{1}{2}x^2$. It remains to show that, for sufficiently small ϵ, x^1 and x^2 are feasible solutions to $A(G)$, which contradicts x being extreme.

Clearly this is true for inequalities (2) and (4), for sufficiently small $\epsilon > 0$, since all the edges whose values are changed are fractional. It is also easy to see that this property holds for inequalities (3) for all edges of P (since (3) is not tight for them), for all edges inside shrunk nodes of P, and for all edges not in P, but adjacent to edges in P (which cannot be adjacency tight). So let us consider inequalities (1). Again, the property clearly holds for all real nodes of P. So consider a shrunk node v of P that was obtained by shrinking the edge v_1v_2 of G. Suppose v is an interior node of P. If v_1 is adjacent in G to the two edges of P that are adjacent to v, then $x(\delta(v_1))$ and $x(\delta(v_2))$ have the same values in x^1 and x^2. Otherwise, using Lemma 3(i), we have that $0 < x(\delta(v_1)) < 2$ and $0 < x(\delta(v_2)) < 2$. Suppose v is an endnode of P. Lemma 3(ii) implies that $0 < x(\delta(v_1)) < 2$ and $0 < x(\delta(v_2)) < 2$. Claim 1 now follows.

Claim 2. F does not contain an even cycle.

Proof of Claim 2: Again, suppose this is not the case. Let C be an even cycle of F. Partition the edges of C into two sets, say B (blue) and R (red), and define x^1 and x^2 on E, as in the proof of Claim 1. Using the same logic as in the proof of Claim 1, one can show that x is not an extreme feasible solution, which is a contradiction.

Claim 3. None of the nodes on an odd cycle in F is incident with a fractional edge other than the two edges incident to it in the cycle.

Proof of Claim 3: By contradiction. Let C be an odd cycle in F, let v be a node on F, and let vv' be an edge of F not in C. Let us assume v' is not on C. (If v' were on C, then vv' would form an even cycle with a portion of F, which has been ruled out in Claim 2.) To begin, let P be the path vv'. Let us extend the graph P by repeatedly adding an edge of F to the endnode of P that is different from v, until one of the following happens:

Case 1: The new edge of P has an endnode with degree 1 in F.

Case 2: The new edge of P contains a node in C, which is different from v.

Case 3: The new edge of P contains a node of P (possibly v).

Case 1: Let w denote the endnode of P not on C. Partition the edges of $C \cup P$ into two sets, say B (blue) and R (red), so the two edges of C incident with v have the same color and no other two adjacent edges of $C \cup P$ have the same color. If w is shrunk, then add the corresponding edge of G to the same set, B or R, that contains the edge of P incident with w. Let B^C, B^P, R^C, R^P denote the edges of B in C, the edges of B in P, and so on. Define x^1 and x^2 on E as follows: $x^1 = x + \epsilon(\chi^{B^C} + 2\chi^{B^P} - \chi^{R^C} - 2\chi^{R^P})$ and $x^2 = x + \epsilon(\chi^{R^C} + 2\chi^{R^P} - \chi^{B^C} - 2\chi^{B^P})$, where $\epsilon > 0$. Observe that $x = \frac{1}{2}x^1 + \frac{1}{2}x^2$. It remains to show that, for sufficiently small ϵ, x^1 and x^2 are feasible solutions to $A(G)$, which contradicts x being extreme. (The following logic is quite close to that used in Claim 1.)

Clearly this is true for inequalities (2) and (4), for sufficiently small $\epsilon > 0$, since all the edges whose values are changed are fractional. It is also easy to see that this property holds for inequalities (3) for all edges of $C \cup P$ (since (3) is not tight for them), for all edges inside shrunk nodes of $C \cup P$, and for all edges not in $C \cup P$, but adjacent to edges in $C \cup P$ (which cannot be adjacency tight). So let us consider inequalities (1). Again, the property clearly holds for all real nodes of $C \cup P$. So consider a shrunk node u of $C \cup P$ that was obtained by shrinking the edge u_1u_2 of G. Suppose $u \neq w$. If u_1 is adjacent in G to all the edges of $C \cup P$ that are adjacent to u, then $x(\delta(u_1))$ and $x(\delta(u_2))$ have the same values in x^1 and x^2. Otherwise, using Lemma 3(i), we have that $0 < x(\delta(u_1)) < 2$ and $0 < x(\delta(u_2)) < 2$. Suppose $u = w$. Lemma 3(ii) implies that $0 < x(\delta(u_1)) < 2$ and $0 < x(\delta(u_2)) < 2$. Case 1 now follows.

Case 2: It is evident that $C \cup P$ contains an even cycle, and hence we can apply Claim 2.

Case 3: $C \cup P$ must consist of two odd cycles, say C and C', connected by a path, say Q (possibly of length 0), that shares only its endnodes, say v and v', with C and C', respectively.

Partition the edges of $C \cup Q \cup C'$ into two sets, say B (blue) and R (red), so the two edges of C incident with v have the same color, the two edges of C' incident with v' have the same color, and no other two adjacent edges of $C \cup Q \cup C'$ have the same color. Let $D = C \cup C'$ and let B^D, B^Q, R^D, R^Q denote the edges of B in D, the edges of B in Q, and so on. Define x^1 and x^2 on E as follows: $x^1 = x + \epsilon(\chi^{B^D} + 2\chi^{B^Q} - \chi^{R^D} - 2\chi^{R^Q})$ and $x^2 = x + \epsilon(\chi^{R^D} + 2\chi^{R^Q} - \chi^{B^D} - 2\chi^{B^Q})$, where $\epsilon > 0$. The argument then proceeds as above, which finishes the proof of the claim.

Claim 4. For any odd cycle C in F, x has value 1 on every contracted edge that corresponds to a shrunk node of C, and $x(\delta(v)) = 2$ on every real node v of C.

Proof of Claim 4: Let C be an odd cycle in F and let v be a shrunk node on C obtained from contracting edge $e = v_1v_2$ in G. Let e_1 and e_2 be the two edges of C incident with v. Since e_1 and e_2 are fractional and e is adjacency tight, $x_e > 0$. Let us assume that e is fractional in G and then derive a contradiction.

Partition the edges of C into two sets, say B (blue) and R (red), so the two edges of C incident with v have the same color, say B, and no other two adjacent edges of C have the same color. Define x^1 and x^2 on E as follows: $x^1 = x + \epsilon(\chi^R - \chi^B + 2\chi^e)$ and $x^2 = x + \epsilon(\chi^B - \chi^R - 2\chi^e)$, where $\epsilon > 0$. Observe that $x = \frac{1}{2}x^1 + \frac{1}{2}x^2$. It remains to show that, for sufficiently small ϵ, x^1 and x^2 are feasible solutions to $A(G)$, which contradicts x being extreme.

Arguing as in the proof of Claim 1, it is not difficult to show that this is true for inequalities (2), (3), and (4). So let us consider inequality (1).

Case 1: e_1 and e_2 are adjacent to v_1 in G. Observe that v_2 cannot be adjacent to a fractional edge in G by Claim 3. Furthermore, v_2 cannot be adjacent to an edge at

value 1, since e is fractional and adjacency tight. Hence $x(\delta(v_2)) < 1$. Since $x(\delta(v_1))$ remains unchanged in x^1 and x^2, the result follows.

Case 2: e_1 and e_2 are adjacent to v_1 and v_2, respectively, in G. Then by Lemma 3(i), $0 < x(\delta(v_1)) < 2$ and $0 < x(\delta(v_2)) < 2$; so, again, the result follows.

Now we prove that $x(\delta(v)) = 2$ on every real node v of C. Let us assume that v is a real node on C satisfying $x(\delta(v)) < 2$. Proceed just as we did for the previous case that v is shrunk (except we don't have the edge e). The result follows as before, except showing that x^1 and x^2 satisfy (1) for sufficiently small ϵ is immediate because $x(\delta(v)) < 2$.

Claim 5. Every odd cycle in F consists of edges with value $\frac{1}{2}$.

Proof of Claim 5: Consider an odd cycle C in F. Let $u_1, u_2, \ldots, u_{2m+1}$ be the cycle nodes and let $u_1u_2, u_2u_3, \ldots, u_{2m}u_{2m+1}, u_{2m+1}u_1$ be the cycle edges. Let $x_{u_1u_2} = \alpha$, where $0 < \alpha < 1$. By Claim 3 and Claim 4, every real node on C is incident with an edge of G with value 1, and every shrunk node on C is incident with no other nonzero-value edge of G' except the two adjacent cycle edges. Therefore, we have $x_{u_2u_3} = 1-\alpha$, $x_{u_3u_4} = \alpha, \ldots, x_{u_{2m}u_{2m+1}} = 1 - \alpha$, and $x_{u_{2m+1}u_1} = \alpha$. Since $x_{u_1u_2} + x_{u_{2m+1}u_1} = 1$, $\alpha = \frac{1}{2}$. Claim 5 is proved.

It follows from the above five claims that if a feasible solution x is extreme, then it satisfies (i) and (ii).

Now we prove that if a feasible solution x satisfies (i) and (ii), then it is extreme. Assume, by contradiction, that there are two different feasible solutions x^1 and x^2 such that their convex combination is x. We will derive a contradiction by showing $x = x^1 = x^2$.

First, we clearly see that $x = x^1 = x^2$ on the edges of G that have value 0 or 1. Now consider an odd cycle C in F whose edges have value $\frac{1}{2}$. For every node v of C, (ii) implies that $x_C(\delta(v)) = 1$. This follows from the fact that the inequality (1) is tight at v if v is a real node, and the inequality (3) is tight on edge e if v was obtained by shrinking e. Hence, the inequality (1) or (3) is also tight for x^1 and x^2 at v, which means that $x^1_C(\delta(v)) = x^2_C(\delta(v)) = 1$ at every node v of C. Let $u_1, u_2, \ldots, u_{2m+1}$ be the nodes of C and let $u_1u_2, u_2u_3, \ldots, u_{2m}u_{2m+1}, u_{2m+1}u_1$ be the cycle edges. Let $x^1_{u_1u_2} = \alpha$, where $0 < \alpha < 1$. By a similar argument as in Claim 5, we see that x^1 has value $\frac{1}{2}$ on all the cycle edges of C, and so does x^2. Therefore, $x = x^1 = x^2$ on all the odd cycles in F, which yields a contradiction. □

As an interesting analog to the result of Theorem 1, the extreme points of (1–2) and (4) are characterized by the following theorem.

THEOREM 4. *A feasible solution x to* (1–2) *and* (4) *is extreme if and only if it satisfies both of the following conditions:*

(i) *The solution x has only values* 0, $\frac{1}{2}$, *and* 1*;*

(ii) *The edges with value $\frac{1}{2}$ form node-disjoint odd cycles, and every node of such an odd cycle is incident with an edge with value* 1.

The proof of Theorem 4 is similar to but simpler than that of Theorem 1, so it is not given in this paper. For comparison purposes, we provide in Figure 2 an example of an extreme point of (1–2) and (4). Some similarities between this figure and Figure 1 can be observed.

4. Characterization and recognition of the graphs for which $A(G) = R(G)$. The main purpose of this section is to characterize, in two ways, the graphs G for which the extreme points of $A(G)$ are incidence vectors of 1-restricted simple 2-matchings. That is, we characterize the graphs G for which $A(G) = R(G)$. The first characterization is conceptually simple and is in terms of an excluded subgraph. Its

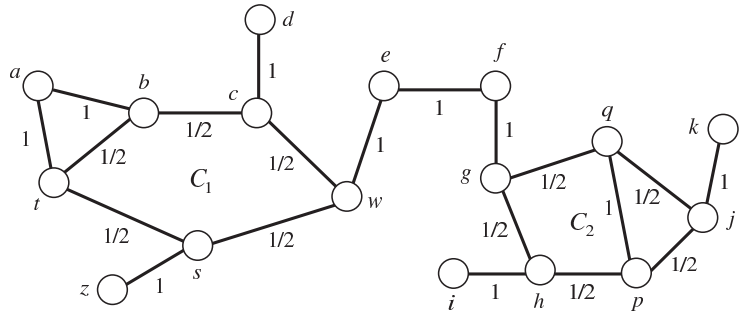


FIG. 2. *An example of an extreme point of* (1–2) *and* (4).

proof follows easily from the extreme point result in the previous section. The second characterization is a bit more technical, but it immediately leads to a polynomial time recognition algorithm for the graphs G such that $A(G) = R(G)$. These two characterizations are stated in the first subsection. The algorithm and some related results and observations appear in the second subsection. A proof of the second characterization appears in the third subsection.

4.1. Characterization theorems. We begin this section by defining a class of graphs that yields our first characterization of the graphs G such that $A(G) = R(G)$. After a few more definitions, we next state our second characterization result.

DEFINITION 5. *A graph $G = (V, E)$ is a* 1-restricted odd cycle *if it contains a cycle C and a set of edges M such that*

(i) *Every node of C is incident with exactly one edge of M;*

(ii) *Every edge of M is incident with one or two nodes of C;*

(iii) *Every node not in C is incident with one or two edges of M;*

(iv) $E = E(C) \cup M$*;*

(v) $|E(C)\backslash M|$ *is odd.*

An edge of M with exactly one node in C is called a petal *of C. An edge of M that has two nodes in C but is not an edge of C is called a* chord *of C. A node not in C is called a* tip*. A node of C that occurs in a petal or chord is called an* attachment node*. Two attachment nodes of C, say u and v, are called* adjacent *if there exists a path from u to v on C that contains no other attachment nodes. Such a path is called an* attachment node path*.*

In Figure 3, an example of 1-restricted odd cycle with 15 nodes is shown. There are 13 nodes in cycle C: $a, b, \ldots, m$. The set M has eight edges (shown as bold), while $E(C)\backslash M$ has nine edges (shown as non-bold). There are three petals an, bn and co, one chord hk, two tips n and o, and five attachment nodes a, b, c, h and k. If this 1-restricted odd cycle is a subgraph of a graph G, by Theorem 1, a fractional extreme point of $A(G)$ can be constructed by setting each bold edge to 1, each non-bold edge to $\frac{1}{2}$, and any remaining edges in G to 0.

As a consequence of Theorem 1, the following necessary and sufficient conditions hold for $A(G) = R(G)$.

THEOREM 6. *For a graph G, $A(G) = R(G)$ if and only if G does not contain a* 1*-restricted odd cycle.*

Proof. If G contains a 1-restricted odd cycle consisting of a cycle C and a set of edges M, by Theorem 1, we can construct a fractional extreme point of $A(G)$ by assigning value 1 to each edge in M, assigning value $\frac{1}{2}$ to each edge in $E(C)\backslash M$, and assigning value 0 to the remaining edges of G. Hence, $A(G) \neq R(G)$.

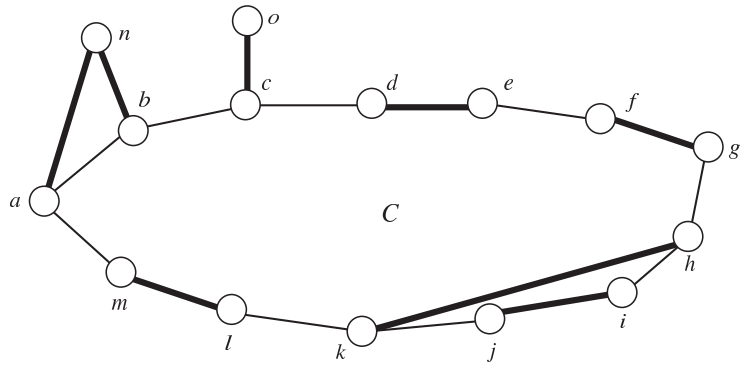

FIG. 3. *An example of a* 1*-restricted odd cycle.*

If $A(G) \neq R(G)$, $A(G)$ must contain a fractional extreme point that is characterized by Theorem 1. Choose an arbitrary odd cycle of G^c, say C_0, whose edges all have value $\frac{1}{2}$. Let S_1 be the set of 1-tight edges of G with exactly one endnode incident with an edge of C_0. Let S_2 be the set of 1-tight edges of G with each endnode incident with an edge of C_0. Let R be the set of edges of G that have value 1 and are incident with the real nodes of C_0. By Definition 5, we find a 1-restricted odd cycle of G defined as follows: Let C be the cycle that consists of the edges of C_0 and S_2, and let M be the edge set that is the union of S_1, S_2, and R. □

Next we define a special class of 1-restricted odd cycles that plays an important role in our second characterization theorem and the corresponding recognition algorithm for the class of graphs that have no 1-restricted odd cycles.

DEFINITION 7. *Let G be a* 1*-restricted odd cycle with a cycle C and a set of edges M. G is called a* fundamental 1-restricted odd cycle *if C does not have a chord in M and it is one of the following types:*

(i) *C contains* 0 *mod* 4 *edges and exactly two petals.*

(ii) *C contains* 1 *mod* 4 *edges and exactly one petal.*

(iii) *C contains* 2 *mod* 4 *edges and no petals.*

(iv) *C contains* 3 *mod* 4 *edges and exactly three petals.*

Note that, for the fundamental 1-restricted odd cycles of types (i) and (iv), the attachment node paths are odd; for the fundamental 1-restricted odd cycles of types (ii), C has odd length. The following proposition describes a relationship between the 1-restricted odd cycles and the fundamental 1-restricted odd cycles in a graph.

PROPOSITION 8. *A graph contains a* 1*-restricted odd cycle if and only if it contains a fundamental* 1*-restricted odd cycle.*

Proof. Since every fundamental 1-restricted odd cycle is a 1-restricted odd cycle, it is sufficient to show that if a graph G contains a 1-restricted odd cycle, then it contains a fundamental 1-restricted odd cycle. Let C be the cycle and M be the set of edges for the 1-restricted odd cycle.

Case 1: The 1-restricted odd cycle in G has no chord in M.

If $|E(C)|$ is 0 mod 4, then, since $|E(C)\backslash M|$ is odd, C must have at least two petals in M. Let e_1 and e_2 be any two petals whose respective attachment nodes, v_1 and v_2, are adjacent. Then we know that the two paths P_1 and P_2 in C between v_1 and v_2 are odd. We define a subgraph with a cycle C' and a set of edges M' as follows: $C' = C$, M' consists of e_1 and e_2 and some edges in P_1 and P_2 such that every node of C is incident with exactly one edge of M'. Since $|E(C)|$ is 0 mod 4, $|E(C')\backslash M'|$ is odd. Hence, the constructed subgraph is a fundamental 1-restricted odd cycle of type (i).

If $|E(C)|$ is 1 mod 4, C must have at least one petal in M. Let e be any such petal. Now we define a subgraph with a cycle C' and a set of edges M': $C' = C$; M' consists of e and some edges in C such that every node of C is incident with exactly one edge of M'. Since $|E(C)|$ is 1 mod 4, $|E(C')\backslash M'|$ is odd. So the constructed subgraph is a fundamental 1-restricted odd cycle of type (ii).

If $|E(C)|$ is 2 mod 4, we define a subgraph with a cycle C' and a set of edges M' as follows: $C' = C$; M' consists of some edges in C such that every node of C is incident with exactly one edge of M'. Since $|E(C)|$ is 2 mod 4, $|E(C')\backslash M'|$ is odd. The constructed subgraph is a fundamental 1-restricted odd cycle of type (iii).

If $|E(C)|$ is 3 mod 4, since $|E(C)\backslash M|$ is odd, C must have at least three petals in M. Let e_1, e_2 and e_3 be any three petals with respective attachment nodes v_1, v_2, and v_3. Suppose v_1 and v_2 are adjacent and that v_2 and v_3 are adjacent. Let P_1 be the attachment node path for v_1 and v_2 and let P_2 be the attachment node path for v_2 and v_3. Let P_3 be the path from v_1 to v_3 in C that does not contain v_2. Observe that P_1, P_2, and P_3 are each odd. We define a subgraph with a cycle C' and a set of edges M' as follows: $C' = C$, M' consists of e_1, e_2, and e_3 and some edges in P_1, P_2, and P_3 such that every node of C is incident with exactly one edge of M'. Since $|E(C)|$ is 3 mod 4, $|E(C')\backslash M'|$ is odd. Therefore, the constructed subgraph is a fundamental 1-restricted odd cycle of type (iv).

Case 2: The 1-restricted odd cycle in G has at least one chord in M.

It suffices to show that we can construct another 1-restricted odd cycle with a cycle C' satisfying $V(C') \subset V(C)$. Let e be a chord of C in M, let v_1 and v_2 be the attachment nodes of e, and let P_1 and P_2 be the two paths in C between v_1 and v_2. Since $|E(C)\backslash M|$ is odd, one of $|E(P_1)\backslash M|$ and $|E(P_2)\backslash M|$ is even. Assume that $|E(P_1)\backslash M|$ is even. We define a subgraph with a cycle C' and a set of edges M' as follows: C' contains P_1 and e, M' consists of the two edges on P_2 incident with v_1 or v_2 and the edges in M incident with the nodes in P_1. Apparently, $|E(C')\backslash M'|$ is odd and $V(C') \subset V(C)$. Also, one can easily verify that the constructed subgraph is a 1-restricted odd cycle. □

We next consider how to determine if a graph has a fundamental 1-restricted odd cycle. We would like to find a nice characterization of the graphs without fundamental 1-restricted odd cycles that leads to a polynomial-time recognition algorithm of such graphs. In order to do so, we need to define the following special graphs.

DEFINITION 9. *A k mod 4 ear, for $k = 0, 1, 2$ or 3, in a graph G is either*

(i) *a nontrivial path P with k mod 4 edges whose two endnodes have degree more than 2 in G and whose interior nodes, if any, have degree 2 in G; or*

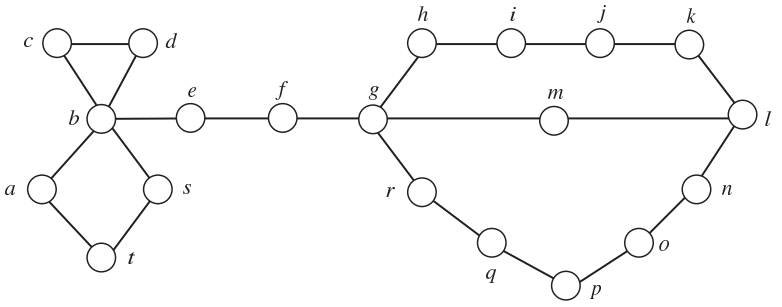
(ii) *a nontrivial cycle with k mod 4 edges that contains at most one node of degree more than 2 in G.*

DEFINITION 10. *The reduced graph G^R of a given graph G is defined as follows:*

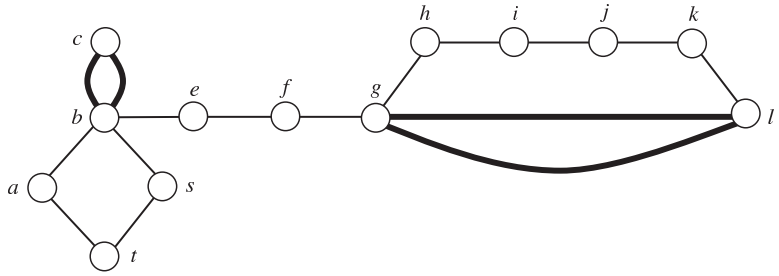
(i) *For every 2 mod 4 ear in G, replace it with a single edge (which is a loop if the ear is a cycle) so that all nodes in G of degree more than 2 maintain their degrees in G^R;*

(ii) *For every 3 mod 4 ear in G, replace it with a path of length 2 or two parallel edges (if the ear is a cycle) so that all the nodes in G of degree more than 2 maintain their degrees in G^R.*

In Figure 4, a graph G and its reduced graph G^R are given to illustrate Definitions 9 and 10. G has three maximal 2-connected subgraphs: the subgraph induced by b, c, and d; the subgraph induced by a, b, s, and t; and the subgraph induced by $g, h, i, j, k, l, m, n, o, p, q$, and r. G has a 0 *mod* 4 ear with edges ab, bs, st, and ta; a 1 *mod* 4 ear with gh, hi, ij, jk, and kl; two 2 *mod* 4 ears: one with gm and ml, the



Graph G



Reduced graph G^R

FIG. 4. *An example of G and G^R.*

other with ln, no, op, pq, qr, and rg; a 3 *mod* 4 ear with bc, cd, and db. The 3 *mod* 4 ear in G is shrunk to two parallel (bold) edges bc in G^R, and two 2 *mod* 4 ears are shrunk to two parallel (bold) edges gl.

One can easily verify that the graph G in Figure 4 has no subgraph that is a fundamental 1-restricted odd cycle. We also observe that G contains at most one odd-length ear in each maximal 2-connected subgraph and G^R is bipartite. The following theorem characterizes the graphs without fundamental 1-restricted odd cycles, which results in a polynomial time algorithm for recognizing the graphs that contain no 1-restricted odd cycles. The algorithm is given in section 4.2 and the proof of Theorem 11 is given in section 4.3.

THEOREM 11. *A connected graph G contains no fundamental* 1*-restricted odd cycle as a subgraph if and only if either G is K_4 (a complete graph with four nodes), or G is a cycle of length* 1 *mod* 4*, or G contains at most one odd-length ear in each maximal* 2*-connected subgraph and G^R is bipartite.*

4.2. Some related results and observations. In this subsection we gather some consequences of the characterization theorems stated in the previous subsection. Chief among them are polynomial time algorithms for recognizing graphs without 1-restricted odd cycles and for finding maximum weight 1-restricted simple 2-matchings in such graphs. We also state some related results for the problem of finding maximum weight (0-restricted) simple 2-matchings.

We begin by observing that the characterization theorems in the previous section yield two simple-to-describe classes of graphs that contain no 1-restricted odd cycles. The first class is trees. The second class contains any graph constructed as follows:

Take an arbitrary graph and replace every edge with a nontrivial path of length 0 *mod* 4. It is easy to see that any such graph does not contain odd-length ears and its reduced graph is bipartite.

We have characterized the graphs for which the system (1–4) has all integral extreme points. Since all entries in the constraint matrix are in $\{0, \pm 1\}$, it is natural to ask if, in this case, this matrix is totally unimodular. Consider a graph G with two adjacent edges: ab and bc. The two rows formed by the constraints 1 for node b and the constraints 3 for edge ab contain the submatrix $\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$, whose determinant is -2. Hence the constraint matrix is not totally unimodular.

We next observe that Theorem 11 immediately yields a polynomial-time algorithm to determine if a connected graph G contains a 1-restricted odd cycle, that is, to determine if $A(G) = R(G)$. Here is an outline of the algorithm: If G is K_4 or a cycle of length 1 *mod* 4, then $A(G) = R(G)$. Otherwise, identify the maximal 2-connected subgraphs of G and the odd-length ears in each maximal 2-connected subgraph. If a maximal 2-connected subgraph has more than one odd-length ear, then $A(G) \neq R(G)$. Otherwise, construct G^R. If G^R is bipartite, then $A(G) = R(G)$. Otherwise, $A(G) \neq R(G)$.

Another observation is that for graphs that contain no 1-restricted odd cycles, we can find a maximum weight 1-restricted simple 2-matching in strongly polynomial time. Here is how: For any such graph $G = (V, E)$, construct the system (1–4). Now apply the algorithm of Tardos [22] to this system. Tardos's algorithm finds an optimal solution to a linear program in a number of steps which is polynomially bounded in the size of the variable coefficient matrix; and, for our problem, the size of this matrix is polynomial since the system (1–4) has a number of entries which is polynomial in $|V|$ and $|E|$ and those entries are all in $\{0, \pm 1\}$.

Let us end this section by stating some analogous results to those in the previous section for the case of simple 2-matchings (i.e., 0-restricted simple 2-matchings). First, a graph G is called a 0-*restricted odd cycle* if it satisfies conditions (i)–(v) for a 1-restricted odd cycle (see Definition 5) plus the following condition: (vi) $E(C) \cap M = \emptyset$. Figure 2 contains two 0-restricted odd cycles: The first has an odd cycle C_1 (with nodes b, c, w, s, and t) and $M = \{at, ab, cd, ew, sz\}$; the second has an odd cycle C_2 (with nodes g, q, j, p, and h) and $M = \{fg, pq, jk, hi\}$. The following result is analogous to Theorem 6, and can be proved in a similar manner.

THEOREM 12. *For a graph G, the inequalities* (1–2) *and* (4) *define the convex hull of incidence vectors of simple* 2*-matchings of G if and only if G does not contain a* 0*-restricted odd cycle.*

THEOREM 13. *A connected graph G contains no* 0*-restricted odd cycle as a subgraph if and only if either G is K_4 or every odd cycle in G contains at least one node of degree* 2*.*

Proof. The sufficiency follows immediately, so let us prove the necessity. We assume G contains no 0-restricted odd cycle as a subgraph. An odd cycle in G is called *full* if every node of the cycle has a degree greater than 2 in G. If G contains no odd cycles or if all the odd cycles of G are not full, then the result follows. So let us assume G contains a full odd cycle. We show that G is K_4 or we derive a contradiction. Let C be the shortest full odd cycle in G. Clearly C can have no chord, since a chord implies that G has a shorter full odd cycle than C; contradiction. Since C does not induce a 0-restricted odd cycle, there must exist three edges of G, say v_1w, v_2w, and v_3w, where $v_1, v_2, v_3 \in V(C)$, and $w \notin V(C)$. If the edges v_1v_2, v_2v_3, v_1v_3 are not edges of C, then it is easy to see that there exists a shorter full cycle than C; contradiction. Hence C is a triangle and C together with w induces a

K_4. So, either G is K_4, or, since G is connected, there is an edge of G, not in the K_4, incident with an edge of the K_4, implying the existence of a 0-restricted odd cycle; again, a contradiction. □

Theorem 13 suggests the following polynomial-time algorithm for recognizing the graphs that contain no 0-restricted odd cycle: Given a graph G that is not K_4, remove all the ears of G that have length more than 1 and check if the resulting graph is bipartite. If yes, then G contains no 0-restricted odd cycle; otherwise, any odd cycle in the resulting graph yields a 0-restricted odd cycle.

4.3. Proof of Theorem 11. In this section we prove Theorem 11. To do this we present three lemmas from which the theorem immediately follows.

LEMMA 14. *If a connected graph G contains no fundamental 1-restricted odd cycle, then G contains at most one odd-length ear in each maximal 2-connected subgraph, or $G = K_4$.*

Proof. Assume that G contains no fundamental 1-restricted odd cycle, but G contains a maximal 2-connected subgraph B that contains two or more odd-length ears. We show that this leads to either a contradiction or that $G = K_4$.

Let us choose two odd-length ears in B, one with distinct endnodes u and v and the other with distinct endnodes w and z. Since B is a maximal 2-connected subgraph, there exist two node-disjoint paths in B, say from u to w and from v to z, that form a cycle C with two odd-length ears. Let us assume that we have found such a cycle C that has a minimum number of edges. It follows that C cannot contain any chord, otherwise we would have a shorter such cycle. Hence every node of u, v, w, and z is incident with an edge, the other endnode of which is not in C. We call such an edge a *petal-edge*.

If C has length 0 *mod* 4, then we obtain a fundamental 1-restricted odd cycle by adding to C the petal-edges at u and v, a contradiction. If C has length 1 *mod* 4, then we obtain a fundamental 1-restricted odd cycle by adding to C the petal-edge at u, a contradiction. If C has length 2 *mod* 4, then C is a fundamental 1-restricted odd cycle, a contradiction.

Finally, suppose that C has length 3 *mod* 4. Because the paths from u to v and from w to z in C have odd length and because C has odd length, the path from u to w in C is odd and the path from v to z is even, or vice versa. Without loss of generality, assume that the path from u to w is odd. Add to C three petal-edges from u, v, and w. Let this subgraph be G'. If G' has two or three nodes not in C, then it is a fundamental 1-restricted odd cycle. So let us assume that G' has only one node a that is not in C. Thus the degrees of u, v and w in G' are 3.

Observe that C has three odd paths: from u to v; from u to w; and from v to z to w. If one of these paths has length more than one, then we have a fundamental 1-restricted odd cycle. To see this, suppose without loss of generality that the path from v to z to w has length more than 1. Arbitrarily choose one of the other paths, say the one from u to v, and consider the cycle C' that consists of au, av, and the path from u to v. The length of C' is either 1 *mod* 4 or 3 *mod* 4, and in either case we can construct a fundamental 1-restricted odd cycle based on it, a contradiction. Thus all three of our paths in C have length 1. It follows that the graph induced by C and the node a is K_4. It is now easy to see that either $G = K_4$ or we can construct a fundamental 1-restricted odd cycle based on it (since G is connected). □

LEMMA 15. *If a graph G contains no fundamental 1-restricted odd cycle, if G contains at most one odd-length ear in each maximal 2-connected subgraph, and if G is not a cycle of length 1 mod 4, then G^R is bipartite.*

Proof. By contradiction, suppose that the conclusion does not hold for some graph G; i.e., G^R contains an odd cycle C.

If C is a loop in G^R or the maximal 2-connected subgraph containing C has no odd-length ear in G or the maximal 2-connected subgraph has an odd-length ear but C does not contain the corresponding ear in G^R, then it is not hard to see that the cycle in G corresponding to C has length 2 *mod* 4, which implies that G has a fundamental 1-restricted odd cycle, a contradiction.

Now we assume that C contains an ear that corresponds to an odd-length ear in G. So this odd-length ear in G is an odd-length path in G.

Case 1: The odd-length path in G has length 1 *mod* 4.

So the remaining path in C has even length. We see that the path in G that corresponds to the remaining path in C has an even number of ears with length 2 *mod* 4. Therefore, the corresponding path in G has length 0 *mod* 4, and C corresponds to cycle of length 1 *mod* 4 in G. By assumption, this cycle cannot be the entire graph G; hence G contains a fundamental 1-restricted odd cycle with cycle C, a contradiction.

Case 2: The odd-length path in G has length 3 *mod* 4.

So the corresponding path in G^R has length 2, and hence the remaining path in C has odd length. It follows that the path in G that corresponds to the remaining path in C has an odd number of ears with length 2 *mod* 4. This implies that the corresponding path in G has length 2 *mod* 4, and C corresponds to a cycle of length 1 *mod* 4 in G, which again yields a fundamental 1-restricted odd cycle, a contradiction. ∎

LEMMA 16. *If $G = K_4$ or G contains at most one odd-length ear in each maximal 2-connected subgraph and G^R is bipartite, then G contains no fundamental 1-restricted odd cycle.*

Proof. If $G = K_4$, then we see by inspection that G contains no fundamental 1-restricted odd cycle. By contradiction, now suppose that $G \neq K_4$ and G contains a fundamental 1-restricted odd cycle G' with cycle C and G^R is bipartite.

Case 1: C has 0 *mod* 4 edges.

By definition, C has two petal edges whose attachment nodes in C are separated by two odd-length paths. Observe that each such odd-length path must contain an odd-length ear. Hence, G has at least two odd-length ears, a contradiction.

Case 2: C has 2 *mod* 4 edges.

Then C contains an even number of odd-length ears. If this number is greater than or equal to 2, then we get the contradiction. So let us assume that the number of odd-length ears in C is 0. Then C must contain an odd number of ears of length 2 *mod* 4; hence the cycle in G^R that corresponds to C is odd, a contradiction.

Case 3: C has 3 *mod* 4 edges.

Then C is the union of three odd-length paths between the attachment nodes. Therefore, C must contain at least three odd-length ears, a contradiction.

Case 4: C has 1 *mod* 4 edges.

Then C contains an odd number of odd-length ears. If the number of odd-length ears is greater than or equal to 3, then we get a contradiction. So we assume that C contains exactly one odd-length ear. If this odd-length ear is a cycle, then C corresponds to an odd cycle in G^R, a contradiction.

Suppose the odd-length ear is a path P. If P has length 1 *mod* 4, then $C \backslash P$ has length 0 *mod* 4 and hence contains an even number of ears of length 2 *mod* 4. Therefore, C corresponds to an odd cycle in G^R, a contradiction. If P has length 3 *mod* 4, then $C \backslash P$ has length 2 *mod* 4 and hence contains an odd number of ears of length 2 *mod* 4. Again, C corresponds to an odd cycle in G^R, a contradiction. ∎

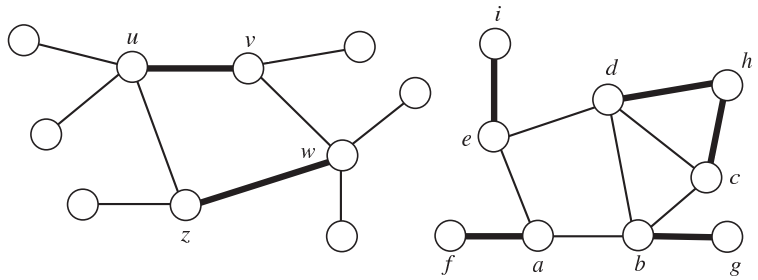


FIG. 5. *An example of a* 1*-restricted blossom.*

5. A class of blossom-type valid inequalities. In this section, we introduce a new class of inequalities, called the 1-restricted blossom inequalities, and we show they are valid for $R(G)$. These inequalities are similar to the classical blossoms both in structure and in that they have Chvátal rank of 1. We show that no fractional extreme solution to $A(G)$ satisfies all the 1-restricted blossom inequalities. However, we also show, with a small example, that the 1-restricted blossom inequalities together with inequalities (1–4) do not yield a complete description of $R(G)$. We begin with a few definitions.

A pair (B, T) is called a 1-*restricted blossom* of a graph G if the following two conditions are satisfied:

1. B is a set of nodes of G (called the *center* of the blossom).
2. T is an odd cardinality set of edges of G such that
   - Each edge in T is incident with one or two nodes of B; and
   - Each node of B is incident with exactly one edge in T.

   As a matter of notation:
   - Let T_i, for $i = 1, 2$, be the edges in T incident with exactly i nodes of B;
   - Let B_i, for $i = 1, 2$, be the nodes in B incident with an edge in T_i;
   - Let E^+ be the edges of T plus the edges with both ends in B_1; and
   - Let E^- be the edges with both ends in B_2, but not in T_2; plus the edges with one end in B_2 and one end not in B.

See Figure 5 for an example of a 1-restricted blossom. The pair (B, T) of the blossom given in Figure 5 is defined as follows:

$$\begin{aligned}
&T \equiv T_1 \cup T_2, \quad B \equiv B_1 \cup B_2,\\
&T_1 \equiv \{af, bg, ch, dh, ei\}, \quad T_2 \equiv \{uv, wz\},\\
&B_1 \equiv \{a, b, c, d, e\}, \quad B_2 \equiv \{u, v, w, z\},\\
&E^+ \equiv \{\text{all the edges of the right component plus } uv \text{ and } wz\},\\
&E^- \equiv \{\text{all the edges of the left component except } uv \text{ and } wz\}.
\end{aligned}$$

We associate the following inequality, called a 1-*restricted blossom inequality*, with each 1-restricted blossom (B, T):

$$\sum_{e \in E^+} x_e - \sum_{e \in E^-} x_e \leq |B_1| + \frac{|T| - 1}{2}. \tag{5}$$

Observe that when T contains a single edge, say uv, and $B = \{u, v\}$, then inequality (5) is the edge-adjacency constraint for uv. Furthermore, it is not hard to see that

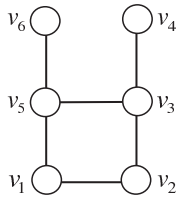

FIG. 6. *An example that has a facet-defining inequality with variable coefficient* 2.

(B,T) and the inequality (5) define a standard 2-matching blossom and inequality (see [5]) when $B_2, T_2 = \emptyset$ (which implies $E^- = \emptyset$). Hence the 1-restricted blossom inequalities are a common generalization of the edge-adjacency constraints and the standard 2-matching blossom inequalities.

PROPOSITION 17. *Any inequality* (5) *is valid for* $R(G)$.

Proof. Every 1-restricted simple 2-matching satisfies the following inequalities:

$$x(\delta(v)) \leq 2 \quad \forall\, v \in B_1, \tag{6}$$

$$x_e - x(adj(e)) \leq 0 \quad \forall\, e \in T_2, \tag{7}$$

$$x_e \leq 1 \quad \forall\, e \in T. \tag{8}$$

Adding up all the inequalities (6–8), dividing both sides by 2, and rounding down the variable coefficients and the right-hand side, we obtain inequality (5) that is valid for all the 1-restricted simple 2-matchings. □

PROPOSITION 18. *There is no fractional extreme point of* $A(G)$ *that satisfies all the inequalities* (5).

Proof. Consider an arbitrary fractional extreme point x for $A(G)$, as described in Theorem 1. Let C' be an odd cycle of G^c whose edges have value $\frac{1}{2}$ in x. Let C be the cycle in G that corresponds to C', and let M be the edges in G that have value 1 in x and are adjacent to one or two nodes of C. It is easy to see that C and M define a 1-restricted odd cycle in G as in Definition 5. If we let B denote the nodes of C and let $T = M$, then (B,T) is a 1-restricted blossom. It is easy to check that x satisfies all the inequalities (6–8) for (B,T) at equality. Since (5) is obtained by adding the inequalities (6–8) and rounding down, it follows that x violates (5) for (B,T). □

We next claim that the system (1–4, 5) is not sufficient to characterize $R(G)$ for all graphs G. To see this, first notice that the variable coefficients of every inequality in (1–4, 5) are 0, 1, or -1. To prove the claim we now present, for a specific graph G, a complete description of the facet-defining inequalities of $R(G)$, where one of the inequalities has a variable coefficient 2.

Consider the graph G consisting of a cycle of length 4 with two petals as shown in Figure 6. By Theorem 1, $A(G)$ has a unique fractional extreme point $f = (x_{v_1v_2}, x_{v_2v_3}, x_{v_3v_4}, x_{v_3v_5}, x_{v_5v_1}, x_{v_5v_6}) = (1, \frac{1}{2}, 1, \frac{1}{2}, \frac{1}{2}, 1)$. Now we show that we only need (1–4) and inequality

$$2x_{v_1v_2} - x_{v_2v_3} + x_{v_3v_4} - x_{v_5v_1} + x_{v_5v_6} \leq 2 \tag{9}$$

to give a complete description of $R(G)$.

First, we prove the validity of (9). Observe that G is a 1-restricted blossom (B,T), where $B = \{v_1, v_2, v_3, v_5\}$ and $T = \{v_1v_2, v_3v_4, v_5v_6\}$. The 1-restricted blossom inequality for (B,T) is

$$x_{v_1v_2} + x_{v_3v_4} + x_{v_3v_5} + x_{v_5v_6} \leq 3. \tag{10}$$

The inequalities (3) on edges v_1v_2, v_3v_4, and v_5v_6 are

$$x_{v_1v_2} - x_{v_2v_3} - x_{v_5v_1} \leq 0, \tag{11}$$

$$x_{v_3v_4} - x_{v_2v_3} - x_{v_3v_5} \leq 0, \tag{12}$$

$$x_{v_5v_6} - x_{v_3v_5} - x_{v_5v_1} \leq 0. \tag{13}$$

The inequality (2) on edge v_1v_2 is

$$x_{v_1v_2} \leq 1. \tag{14}$$

By doing $2 \times (10) + 2 \times (11) + (12) + (13) + 2 \times (14)$, we get a valid equality $6x_{v_1v_2} - 3x_{v_2v_3} + 3x_{v_3v_4} - 3x_{v_5v_1} + 3x_{v_5v_6} \leq 8$. Dividing both sides of this inequality by 3 and then rounding down the variable coefficients and right-hand side, we obtain the valid inequality (9) for $R(G)$. By a simple combinatorial argument, one can also show that all the 1-restricted simple 2-matchings of G satisfy this inequality.

Next, we prove that inequality (9) induces a facet that, together with (1–4), are enough to describe $R(G)$. Inequality (9) is facet-defining for $R(G)$, because it is satisfied as equality by the following linearly independent incidence vectors $(x_{v_1v_2}, x_{v_2v_3}, x_{v_3v_4}, x_{v_3v_5}, x_{v_5v_1}, x_{v_5v_6})$ of six 1-restricted simple 2-matchings of G:

$$x^1 = (1,0,0,0,1,1), \quad x^2 = (1,1,1,0,0,0), \quad x^3 = (1,0,1,1,1,0),$$
$$x^4 = (1,1,0,1,0,1), \quad x^5 = (1,1,1,0,1,1), \quad x^6 = (0,0,1,1,0,1).$$

Consider the following six inequalities from (1–4):

$$x_{v_1v_2} \leq 1, \tag{15}$$

$$x_{v_2v_3} + x_{v_3v_4} + x_{v_3v_5} \leq 2, \tag{16}$$

$$x_{v_3v_5} + x_{v_5v_1} + x_{v_5v_6} \leq 2, \tag{17}$$

$$x_{v_1v_2} - x_{v_2v_3} - x_{v_5v_1} \leq 0, \tag{18}$$

$$-x_{v_2v_3} + x_{v_3v_4} - x_{v_3v_5} \leq 0, \tag{19}$$

$$-x_{v_3v_5} - x_{v_5v_1} + x_{v_5v_6} \leq 0. \tag{20}$$

The equations from (15–20) are independent and give a unique solution $f = (1, \frac{1}{2}, 1, \frac{1}{2}, \frac{1}{2}, 1)$, which is the only fractional extreme point of $A(G)$. Observe that x^1, x^2, x^3, x^4, and x^5 satisfy (15) at equality, but x^6 does not; x^2, x^3, x^4, x^5, and x^6 satisfy (16) at equality, but x^1 does not; x^1, x^3, x^4, x^5, and x^6 satisfy (17) at equality, but x^2 does not; x^1, x^2, x^3, x^4, and x^6 satisfy (18) at equality, but x^5 does not; x^1, x^2, x^3, x^5, and x^6 satisfy (19) at equality, but x^4 does not; x^1, x^2, x^4, x^5 and x^5 satisfy (20) at equality, but x^3 does not. Hence, (15–20) are facet-defining inequalities of $A(G)$. Also observe that x^6 satisfies (16–20) at equality, but not (15); x^1 satisfies (15, 17–20) at equality, but not (16); x^2 satisfies (15–16, 18–20) at equality, but not (17); x^5 satisfies (15–17, 19–20) at equality, but not (18); x^4 satisfies (15–18, 20) at equality, but not (19); x^3 satisfies (15–19) at equality, but not (20). Geometrically, we see that the simplex defined by the convex hull of f, x^1, x^2, x^3, x^4, x^5, and x^6 is contained in $A(G)$, and the facets of the simplex are induced by inequalities (9, 15–20). Therefore, we conclude that inequalities (1–4, 9) give a complete description of $R(G)$.

6. Conclusion and future research. In this paper, we have presented a natural integer programming formulation for the problem of finding maximum weight

1-restricted simple 2-matchings, we have characterized the extreme points of the linear programming relaxation, and we have characterized when the relaxation has all integral extreme points. We have introduced a new class of inequalities that tightens this linear programming relaxation, but we know that this system is not sufficient to completely characterize the integral hull. So an obvious direction for future research is to look for a complete polyhedral description and a polynomial-time algorithm for the problem of finding maximum weight 1-restricted simple 2-matchings (or to show the problem is NP-hard). Another research direction would be to consider similar questions for the problem of finding maximum weight k-restricted simple 2-matchings, when $k > 1$.

PARALLEL SPACE DECOMPOSITION OF THE MESH ADAPTIVE DIRECT SEARCH ALGORITHM*

CHARLES AUDET†, J. E. DENNIS JR.‡, AND SÉBASTIEN LE DIGABEL†

Abstract. This paper describes a parallel space decomposition (PSD) technique for the mesh adaptive direct search (MADS) algorithm. MADS extends a generalized pattern search for constrained nonsmooth optimization problems. The objective of the present work is to obtain good solutions to larger problems than the ones typically solved by MADS. The new method (PSD-MADS) is an asynchronous parallel algorithm in which the processes solve problems over subsets of variables. The convergence analysis based on the Clarke calculus is essentially the same as for the MADS algorithm. A practical implementation is described, and some numerical results on problems with up to 500 variables illustrate the advantages and limitations of PSD-MADS.

Key words. parallel space decomposition, mesh adaptive direct search (MADS), asynchronous parallel algorithm, nonsmooth optimization, convergence analysis.

1. Introduction.

This paper considers optimization problems of the form

$$(\mathcal{P}) \qquad \min_{x\in\Omega} f(x),$$

with the objective function $f : \Omega \subset \mathbb{R}^n \to \mathbb{R}\cup\{\infty\}$. Our motivation is to treat $\mathcal{P}$ when n grows large. The feasible region Ω is assumed to satisfy a nonsmooth constraint qualification, which we will discuss later, and we assume only the presence of an oracle to tell whether or not a given $x \in \mathbb{R}^n$ is feasible. We are concerned primarily with cases where $f(x)$ or the oracle are given by black-box computer simulations, which are assumed to evaluate in finite time. This is common in engineering design. Indeed, the reason we allow $f(x)$ to take on the value ∞ is that, for many such problems, no value of $f(x)$ is returned, even for some $x \in \Omega$, because of the internal workings of the simulation used to drive the design. See [2, 3, 10, 13, 21, 27, 32, 42].

There are other useful derivative-free direct search methods designed for problems similar to $\mathcal{P}$. These include the Nelder–Mead simplex [43], the DIRECT algorithm [20, 24, 30], frame-based methods [16, 44], the generalized pattern search (GPS) [7, 14, 49], the asynchronous parallel pattern search (APPS) approach [25, 29, 36, 34, 35], and the mesh adaptive direct search (MADS) [1, 8]. Related is the implicit filter method [31], though it does use a coarse difference gradient approximation. The reader may consult [31, 33, 37] for a survey of some of these direct search methods.

Using these methods to solve expensive problems with more than a few dozen variables may be impractical, since they may need a large number of costly black-box evaluations. Dennis and Wu [18] reviewed different parallel methods for continuous optimization and concluded that a combination of GPS and the parallel variable distribution (PVD) of Ferris and Mangasarian [19] should be considered:

> "... parallel variable distribution and parallel direct searches seem an interesting pairing...."

The present paper is based on this remark.

PVD is an evolution of the block-Jacobi technique of [11], which optimizes in parallel a series of reduced subproblems on the subspaces of the original variables of $\mathcal{P}$. Dennis and Torczon [17] described a first parallel version of GPS, which evaluates the black-box in parallel and synchronizes at each iteration to compare solutions and update the current iterates. The APPS [25, 36], removes this synchronization barrier. In APPS, each process explores the space of variables using its own set of directions and does not wait for the other processes to terminate. APPS is expected to be more efficient than the synchronous version of [17], especially if the black-box has heterogeneous behavior that depends on the point where it is evaluated. A convergence analysis is presented in [35] for the smooth case.

Our work applies a decomposition of the variables of $\mathcal{P}$ based on the block-Jacobi technique of [11] that inspired the PVD method of [19]. This allows a natural parallel application of MADS to smaller subproblems, in an asynchronous way. The new algorithm, called PSD-MADS (parallel space decomposition-MADS, can be interpreted as a particular instance of MADS, thus inheriting the main results of the MADS convergence analysis. The paper focuses on the definition of the PSD-MADS frameworks and on its convergence analysis, and not on the choice of the subproblem variables. In our practical implementation of the algorithm, a simple random strategy is used, and it performs well.

The paper is divided as follows: section 2 gives an overview of the PSD and MADS methods. Section 3 presents the new asynchronous parallel algorithm PSD-MADS, and section 4 ensures that the main convergence results of MADS are maintained by showing that the entire PSD-MADS algorithm may be interpreted as a specific MADS instance. An implementation of PSD-MADS is described in section 5, with some numerical results on problems with a number of variables ranging from 20 to 500. Finally, section 6 gives some conclusions and proposes possible extensions of PSD-MADS.

2. Relevant literature. This section presents an overview of PSD methods. The MADS, its convergence analysis, and a practical implementation are also described in detail.

2.1. PSD methods. PSD methods decompose $\mathcal{P}$ into a finite number of smaller dimension subproblems, which can be solved in parallel with one process assigned to each subproblem.

Define $N = \{1, 2, \ldots, n\}$, where n is the number of variables of the optimization problem $\mathcal{P}$, and $Q = \{1, 2, \ldots, q\}$, where q is the number of available processes. Each process $p \in Q$ works on a nonempty subset $N_p \subseteq N$ of the variables. The other variables are fixed, based on the incumbent solution $x^* \in \Omega$, the current best known solution. More precisely, process $p \in Q$ works on the optimization subproblem

$$(\mathcal{P}_p(x^*)) \qquad \min_{x \in \Omega_p(x^*)} f(x),$$

with $\Omega_p(x^*) = \left\{x \in \Omega \ : x_i = x_i^* \ \forall i \in \overline{N}_p\right\}$ and $\overline{N}_p = N \setminus N_p$. The subproblem $\mathcal{P}_p(x^*)$ contains $n_p = |N_p|$ free variables, indexed by N_p. In section 5, we propose a simple and random strategy to build the subsets N_p.

The block-Jacobi method in [11] is an iterative two-step algorithm and may be described in a very general way as follows. At each iteration, the first step, the *parallelization*, consists of solving the subproblems in parallel, and the second step, the *synchronization*, gathers the subproblem solutions and constructs the next iterate. Similar methods are described in [26, 41, 50].

A variant of the method was introduced by Ferris and Mangasarian [19], as the PVD for a differentiable objective function f with continuous partial derivatives. In order to solve the subproblems more efficiently, the PVD method allows a priori fixed variables to change in a limited fashion, along directions typically based on ∇f. These variables are denoted as "forget-me-not" terms.

The convergence analysis in [19] requires that subproblems be solved to optimality. In the unconstrained case, if ∇f exists and is Lipschitz, then the accumulation points of the generated sequences are stationary points. In addition, if f is assumed to be convex, the convergence rate is shown to be linear. When Ω is nonempty, closed, convex, block-separable, and the functions defining it are also continuously differentiable, convergence results are still available. When there are general constraints, Ferris and Mangasarian recommend transforming the problem into unconstrained problems via penalty functions. This strategy is untested as far as we know, and we prefer to avoid estimating penalty constants.

These are parallel synchronous algorithms because the synchronization step waits for all of the processes to end. The conclusion of [19] states that an asynchronous version of the algorithm would increase efficiency. This is done in [40] for unconstrained problems, where the synchronization step is dropped at the expense of the convergence analysis.

The extensions of the PVD method are given in [45, 46, 47] with similar convergence results to those in [19] under less restrictive conditions. For example, subproblems do not need to be solved to complete optimality, as, for example, when one Newton-like iteration is used. A convergence analysis for the constrained case is given with either block-separability or convexity assumptions on the structure of Ω.

In the above references, no practical and generic strategy is given concerning the choice of the subproblem variables (sets N_p). However, the sets do need to form a partition of N, and they are fixed throughout the entire process. In the PSD [22] the subspaces can be chosen differently at each iteration.

Fukushima [23] extends the PVD method to a more general framework for unconstrained problems. The sets of subproblem variables are not fixed through the iterations and are not required to form a partition of N, but they must span N. In particular, an overlapping of the subproblem variables is allowed. Some experiments with such methods are given in [51].

More recently, the multidisciplinary optimization via adaptive response surfaces (MOVARS) algorithm [12] combines the GPS method with the synchronous PVD framework (including the "forget-me-not" terms from [19]) on fixed subsets N_p, but there is no convergence analysis.

In most of the references of this section, f is assumed to be at least differentiable, and constraints, if they are considered, are block-separable or convex. These are not reasonable assumptions for our target class of engineering design problems, and thus our convergence analysis does not rely on the analysis of [19] or its extensions. Rather, by incorporating MADS with its weaker hypotheses, we will inherit the MADS con-

vergence analysis. It will also give us greater flexibility concerning the way to handle constraints, the amount of work devoted to the subproblems, the lack of necessity for a synchronization step, and for the choice of the subsets N_p. Concerning this last issue, we remind the reader that we will not propose an elaborated strategy for this, as the focus of the paper is first to define the new method.

2.2. MADS. We now summarize the MADS algorithm [8] for problem $\mathcal{P}$, which extends the GPS algorithm for linearly constrained optimization [14, 49].

The constraints defining Ω are handled by the extreme barrier approach, as in [8, 38, 39]. This means that trial points outside Ω are simply rejected by setting their objective function value to ∞. Of course, this requires that the user provides a feasible initial point $x_0 \in \Omega$. We make the standard assumption that all of the trial points generated by the algorithm lie in a compact set.

MADS is an iterative algorithm where the black-box functions are evaluated at some trial points that are either accepted as new iterates because they are feasible and decrease the objective or are rejected.

All trial points generated by these algorithms are constructed to lie on a mesh

$$M(\Delta) \;=\; \left\{x + \Delta D z \;:\; x \in V,\; z \in \mathbb{N}^{n_D}\right\} \subset \mathbb{R}^n, \tag{1}$$

where the set V, called the *cache*, is a data structure memorizing all previously evaluated points so that no double evaluations occur, $\Delta \in \mathbb{R}^+$ represents a mesh size parameter, and D is an $n \times n_D$ matrix representing a fixed finite set of n_D directions in $\mathbb{R}^n$. More precisely, D is called the set of mesh directions and is chosen so that $D = GZ$, where G is a nonsingular $n \times n$ matrix and Z is an $n \times n_D$ integer matrix. The definition given by (1) differs slightly from the one in [8]. There the mesh was indexed by the iteration number instead of being parameterized by Δ. The reason for this difference is that our parallel algorithm will be working simultaneously on different size meshes originally generated at different iterations. Note also that in order to simplify the notation, the mesh size parameter Δ used here is the equivalent of Δ^m in [8].

Each iteration is divided into three steps: the search, the poll, and an update step determining the success of the iteration and producing the next iterate. The search and poll are treated specially in that the poll need not be carried out at an iteration if the search finds a better point. At each iteration, the algorithm attempts to generate an improved incumbent solution on the current mesh $M(\Delta_k)$, where Δ_k is the mesh size parameter at iteration k. The search step is very flexible and allows for trial points anywhere on the mesh. The way of generating these points is free of any rules, as long as they remain on the current mesh $M(\Delta_k)$ and that the search terminates in finite time. Some search strategies can be tailored for a specific application, while others are generic, such as the use of Latin hypercube sampling [48], or variable neighborhood search [4]. In summary, if one wants to define a MADS algorithm with a specific search, all that needs to be done to ensure convergence is to show that the search requires finite time and generates a finite number of trial points lying on the mesh.

The poll step explores the mesh $M(\Delta_k)$ near the current iterate x_k, and its rules ensure theoretical convergence of the algorithm. The way of choosing the directions used to generate the poll points is the difference between GPS and MADS. In GPS, the set of normalized potential poll directions must be chosen from a finite set that is fixed across all iterations. In MADS, the normalized directions may be chosen to be asymptotically dense in the unit sphere, which allows better coverage. We use the

MADS
[0] INITIALIZATION
$x_0 \in \Omega$, $\Delta_0 > 0$, $k \leftarrow 0$
[1] POLL AND SEARCH STEPS
objective: find a $y \in M(\Delta_k) \cap \Omega$ *such that* $f(y) < f(x_k)$
SEARCH STEP (optional)
evaluate the functions on a finite number of $M(\Delta_k)$ points
POLL STEP (optional if the search step succeeded)
generate n_{dir} MADS directions $d_i \in \mathbb{R}^n$
evaluate the functions on the MADS frame
$P_k = \{x_k + \Delta_k d_i : i = 1, 2, \ldots, n_{dir}\} \subseteq M(\Delta_k)$
[2] UPDATES
$x_{k+1} \leftarrow y$ (iteration success) OR x_k (iteration failure)
$\Delta_{k+1} \leftarrow \tau^{\omega_k} \Delta_k$ (reduced if iteration fails)
$k \leftarrow k + 1$
GOTO **[1]** IF no stopping condition is verified

FIG. 1. *High-level description of the* MADS *algorithm. The directions* d_i *are positive integer combinations of the columns of* D*. The search or poll steps can be stopped before all evaluations are terminated (opportunistic strategy).*

terminology of [16, 44] and say that at iteration k, the set of trial poll points is called the frame P_k. The set of directions used to construct P_k is denoted D_k, and it is not a subset of D.

In the last step of the kth iteration, the mesh size parameter is updated according to $\Delta_{k+1} \leftarrow \tau^{\omega_k} \Delta_k$, where $\tau > 1$ is a fixed rational number and ω_k is an integer that depends on the success of the iteration. When no improvement is made, the iteration is said to fail, and ω_k is taken to be an integer in the interval $[\omega^-; -1]$ with $\omega^- \leq -1$, forcing the next trial poll points to be closer to the current iterate. When a new best iterate is found, the iteration is said to succeed, and Δ_k is possibly increased with ω_k in $[0; \omega^+]$, with the integer $\omega^+ \geq 0$. Specific values for τ, ω^-, and ω^+ are suggested in section 2.4.

A high-level description of the algorithm is summarized in Figure 1. We encourage the reader to consult [8] for a complete description.

2.3. MADS convergence analysis. We will summarize the main convergence results for MADS given in [8]. These results assume that constraints are treated by the extreme barrier approach, and they constitute a hierarchical series of results relying on the Clarke calculus [15] for nonsmooth functions.

The main theorem is that, under a local Lipschitz assumption on f and under the assumption that the set of all normalized poll directions is dense in the unit sphere, the algorithm produces a Clarke stationary point. More precisely, MADS generates a point $\hat{x} \in \Omega$ at which the Clarke generalized directional derivatives of f in all of the directions in the Clarke tangent cone at $\hat{x}$ are nonnegative. The only assumptions needed are that f is Lipschitz near $\hat{x}$ and the constraint qualification that the hypertangent cone of Ω at $\hat{x}$ is nonempty. A corollary to this result in the unconstrained case is that if f is strictly differentiable near $\hat{x}$, then $\nabla f(\hat{x}) = 0$.

The convergence result that requires the least assumptions on f and Ω, the zeroth order result, is that MADS generates a limit point $\hat{x}$, which is the limit of mesh local minimizers on meshes that get infinitely fine. The notion of local optimality is, with respect to the current poll set, defined using a positive spanning set of directions.

More formally, MADS generates a convergent subsequence of iterates $\{x_k\}_{k\in K} \subset \Omega$ such that $x_k \to \hat{x}$, and $f(x_k) \leq f(x_k + \Delta_k d_k)$ for all directions d_k in a positive spanning set D_K, and $\|\Delta_k d_k\| \to 0$.

The price to pay for our new capability to handle a large number of variables is that this last convergence result will be lost. We will consider a MADS algorithm whose poll set contains a single element instead of being built using a positive spanning set of directions. We will refer to this as a *single-poll* MADS algorithm, and it still retains the property of generating asymptotically dense polling directions.

The next section discusses the LTMADS (lower-triangular MADS) implementation of the MADS algorithm. LTMADS uses positive bases to construct the poll sets. It is stated that the union of these normalized directions forms a dense set because if one looks closely at the proof in [8], one sees that it is the subset of single-poll normalized MADS directions that grows dense in the unit sphere. Thus, with the assumption of local Lipschitz continuity, the main convergence result guaranteeing a Clarke stationary point holds.

2.4. The LTMADS implementation of MADS. MADS is a general class of algorithms, where the search and poll steps need to satisfy certain conditions for the convergence results to hold. In particular, one of these conditions is that the total set of normalized poll directions used by the algorithm be dense in the unit sphere. In [8], after the definition of the MADS framework, a practical implementation is given. This implementation is named LTMADS, since it implies the random construction of a lower-triangular matrix. At this moment, LTMADS is the only published MADS implementation, and all MADS codes in section 5.2 correspond to LTMADS.

LTMADS fixes τ to 4, $\omega^- = -1$, $\omega^+ = 1$, and the set of mesh directions $D = [-I_n \; I_n]$, where I_n represents the $n \times n$ identity matrix. The mesh is based on the nonnegative integer value $\ell = -\log_4(\Delta_k)$, $\Delta_k = 4^{-\ell}$, and directions are constructed randomly using a lower-triangular matrix. One of these directions is a special case and is fixed for each value of ℓ. This direction, called $b(\ell)$, has one coordinate (the largest in absolute value) set to $\pm 2^\ell$ so that poll points are within $\sqrt{\Delta_k}$ of the poll center x_k in the ℓ_∞ norm.

The result stated in [6, 8] is that with probability one, the series of normalized directions $b(\ell)$ grows dense in the unit sphere. In LTMADS, the direction $b(\ell)$ is augmented at each iteration with other directions to form a positive spanning set of polling directions. We can, as explained in the preceding section, construct a single-poll MADS algorithm with dense polling directions using only the $b(\ell)$ directions, but the zeroth order convergence result of MADS is lost. Also, because we are not polling at each iteration in a positive spanning set of directions, the mesh size might drop too quickly with this single-poll version of MADS, and so the search step is of extra importance. This is the key to the PSD-MADS algorithm described in the next section: one process executes a single-poll MADS algorithm, while the work of the other processes may be interpreted as a search step.

3. PSD of MADS (PSD-MADS). This section describes the combination of MADS with a PSD method. The resulting algorithm is called PSD-MADS. It is an asynchronous parallel algorithm where a master process decides on the subsets $N_p \subseteq N$ and assigns the resulting optimization subproblems $\mathcal{P}_p(x^*)$ to slaves. The slaves apply MADS to attempt to improve the incumbent solution x^*. No synchronization step is performed. When a slave completes its assigned task, the master assigns a new subproblem with a possibly new N_p and x^*.

3.1. General description of PSD-MADS. Although PSD-MADS is an asynchronous parallel algorithm, the notion of iteration is kept, and it corresponds to two successive calls by the master to one special slave, called the *pollster* slave, described more precisely in section 3.2. The pollster slave executes a single-poll MADS algorithm on the entire problem $\mathcal{P}$, while the other slaves, called the *regular* slaves, work on the subproblems $\mathcal{P}_p(x^*)$. This task partition between the pollster and the regular slaves allows the convergence analysis of section 4, where it is shown that the pollster slave executes a valid MADS algorithm, thus inheriting the convergence results of [8]. Note that the pollster slave's task requires the fewest function values of any of the poll steps.

Each subproblem $\mathcal{P}_p(x^*)$ is a subproblem of $\mathcal{P}$ with a reduced number of variables indexed by the set N_p. When an optimization process terminates, the slave communicates its progress to the master. If it has found an improved solution, then that becomes the new incumbent solution. The slave immediately starts work on a new subproblem assigned by the master. There is no need to synchronize all of the slaves.

With several MADS instances executing in parallel, it is necessary to define different mesh size parameters. First, Δ_j^p corresponds to the mesh $M(\Delta_j^p)$ used at iteration j of the MADS algorithm performed by a regular slave s_p. The mesh size parameter is denoted differently for the pollster slave, with Δ_k^1 (notice the same iteration counter k used both for the pollster slave and PSD-MADS). The number Δ_k^1 is called the *pollster mesh size parameter* at iteration k of PSD-MADS. Finally, an additional mesh size parameter Δ_k^M is called the *master mesh size parameter*. The mesh $M(\Delta_k^M)$ is never used explicitly, but it is useful for comparing the two other meshes $M(\Delta_k^1)$ and $M(\Delta_j^p)$. At iteration k of PSD-MADS and at iteration j of the MADS algorithm performed on a subproblem $\mathcal{P}_p(x^*)$ by a regular slave s_p for $p \in \{2, 3, \ldots, q-2\}$, the PSD-MADS construction ensures that

$$\Delta_k^1 \leq \Delta_k^M \leq \Delta_j^p. \tag{2}$$

Inequalities (2) are formally proved in the convergence analysis of section 4, where PSD-MADS is interpreted as a valid single-poll MADS instance performed by the pollster slave. An additional hypothesis on the different meshes $M(\Delta_k^M)$, $M(\Delta_k^1)$, and $M(\Delta_j^p)$ is necessary.

Hypothesis 3.1. If two mesh size parameters Δ and Δ' satisfy $\Delta = \tau^\omega \Delta'$, where $\omega \in \mathbb{N}$, then $M(\Delta) \subseteq M(\Delta')$.

This assumption holds for the PSD-MADS implementation given in section 5.

The q processes are partitioned into a master, $q-2$ slaves, and a cache server (process number $q-1$), which memorizes all points that have been evaluated. The $q-2$ slaves include the pollster slave (process number 1) and $q-3$ regular slaves. The notation s_p, with $p \in Q \setminus \{q-1, q\}$, is used to identify the $q-2$ processes assigned as slaves, and $Q_{reg} = \{2, 3, \ldots, q-2\}$ is the set of the indices of the $q-3$ regular slaves. The qth process is used as the master, which defines the lower-dimensional subproblems $\mathcal{P}_p(x^*)$ and communicates them to the slaves.

An advantage of applying the PSD method to MADS instead of another optimization method is that most of the conditions necessary for convergence in the other PSD methods mentioned in section 2.1 can be relaxed (the smoothness of the functions, the conditions on the constraints, no synchronization step, and no restrictions on the choice of the sets N_p).

This new algorithm is not a particular case of the method in [23], which generalizes many parallel variable decomposition methods, since general constraints are allowed,

POLLSTER ($p = 1$)

starting point x_0
Output : *pollster solution* x_p
solve problem $\mathcal{P}$: MADS(pollster)
terminate after a single evaluation
send x_p to master

FIG. 2. *Pseudocode for pollster slave.* MADS*(pollster) considers all n variables with a single-poll direction and terminates after one iteration.*

and f is not assumed to be smooth. PSD-MADS also differs from the recent MOVARS algorithm [12], which does require N_p to partition the variables, because it provides a convergence analysis, it dynamically changes the sets N_p, and it is an asynchronous parallel method. The next sections describe precisely the role of each process.

3.2. The pollster slave s_1, on $M(\Delta_k^1)$. The pollster slave s_1 has a special role; its set of variables is always fixed to $N_1 = N$, so that it works on the original problem $\mathcal{P}$. Due to its greater impact on the algorithm and to distinguish s_1 from the other slaves, we call it the pollster slave, or, simply, the pollster.

To reduce the expected high number of evaluations done by the successive pollster instances, a single-poll MADS algorithm is used (the poll directions are reduced to a single element), with the conditions that the union of all of the normalized directions used throughout the algorithm are dense in the unit sphere and that the norms of those directions are in proper relation with the mesh size parameter.

Moreover, the pollster is limited to only one MADS iteration, with no search step and one poll step. It follows that, at most, one function evaluation will be performed (zero function evaluation if the unique poll trial point is found in the cache), and the pollster mesh size parameter Δ_k^1 will not be updated (this is done by the master).

The notation MADS(pollster) or MADS(s_1) refers to the single-poll MADS algorithm performed by the pollster. MADS(pollster) is defined so that its mesh size parameter Δ_k^1 cannot be larger than the master mesh size Δ_k^M at iteration k of PSD-MADS (see (2)).

The pollster pseudocode is shown in Figure 2. The pollster mesh size is updated by the master. The best obtained solution corresponds to x_p, which is sent to the master. The convergence analysis in section 4 is based on the pollster and on the fact that consecutive runs of MADS(s_1) form a valid single-poll MADS instance on $\mathcal{P}$.

3.3. The regular slaves s_2 to s_{q-2}, on $M(\Delta_j^p)$. The regular slaves s_p, $p \in Q_{reg}$ work on subsets N_p of N and use the positive spanning sets of directions. The MADS algorithm working on problem $\mathcal{P}_p(x^*)$ and performed by slave s_p is designated by MADS(s_p).

Subproblem $\mathcal{P}_p(x^*)$ is defined as an $|N_p|$-variable problem, since all of the variables in $N \setminus N_p$ are fixed. Trial points generated by MADS(s_p) are then in $\mathbb{R}^n$, with some coordinates fixed. The values of these fixed coordinates are directly taken from the starting point for MADS(s_p), i.e., x^*, the incumbent solution. The user supplies a parameter $bbe_{\max} > 0$ that indicates the maximum allowed number of black-box calls for the application of MADS to the optimization of a subproblem.

The pseudocode for the regular slaves is shown in Figure 3. MADS(s_p) generates the trial points on meshes of sizes Δ_j^p, where j is the iteration counter of the subprob-

FIG. 3. *Pseudocode for slaves processes. Does not include pollster slave, which is specifically described in Figure* 2.

lem algorithm. The initial mesh size Δ_0^p for MADS(s_p) is set by the master. The value of the parameter $\Delta_{\min}^p$ also is supplied by the master and equals Δ_k^M, where k is the PSD-MADS iteration at which MADS(s_p) started. Finally, we impose that no mesh size for MADS(s_p), $p \in Q_{reg}$ exceeds the PSD-MADS initial mesh size Δ_0^{user} provided by the user. MADS(s_p) terminates if $bbe_{\max}$ evaluations are made, or if a minimal mesh size $\Delta_{\min}^p$ is reached. The final mesh size (Δ_{stop}^p) and the best solution found (x_p) are sent to the master.

The union of all regular slaves MADS(s_p) instances is interpreted as a search step for the total problem single-poll MADS algorithm. This is important to the convergence analysis in section 4.

3.4. The cache server—$(q-1)$th process. The cache server is a specialized process that simply memorizes all evaluated points. Each time a process generates a trial point, the cache server is interrogated. This is done to avoid unnecessary expensive function evaluations in case this point has already been evaluated. The cache server provides the global availability of any improvement made by any slave. This is interpreted in section 5 as a search step (the *cache search*) by the regular slaves on their subproblems.

3.5. The master—qth process. The master process coordinates the work of the $q-2$ slaves. It waits for slave results, updates data, and assigns work to slaves. It evaluates only the black-box functions at the starting point x_0.

The master process provides the master mesh size Δ_k^M at iteration k of PSD-MADS, which is the link between the mesh sizes Δ_k^1 and Δ_j^p on which the different MADS(s_p), $p \in Q_{reg}$ work. The initial master mesh size $\Delta_0^M = \Delta_0^{user}$ is set by the user.

The master process updates the pollster mesh size Δ_k^1, after a pollster instance terminates. If no improvement is made by any slave s_1 to s_{q-1} during iteration k, the iteration is a failure, and the pollster mesh size is reduced. If the iteration succeeds, then the pollster mesh size is increased. In all cases, the pollster mesh size is smaller than the master mesh size (2). The value of the pollster mesh size is also kept less than or equal to Δ_0^{user}.

For all regular slaves s_2 to s_{q-2}, the minimal mesh size $\Delta_{\min}^p$ is set to the current value of Δ_k^M. This, as is explained in more detail in the convergence analysis, leads to the fact that, at iteration k of PSD-MADS, no regular slave can generate trial points

on meshes finer than $M(\Delta_k^M)$ and that all of the slaves work, in fact, on the pollster mesh of size Δ_k^1.

The master process pseudocode is described in Figure 4, and the pollster mesh size update is detailed in Figure 5. The pseudocode for the master process implies that, when the master mesh size is updated, it is always possible to find an integer $\alpha_k \in [0; w^+]$ such that $\tau^{\alpha_k}\Delta_k^1 \leq \min_{p \in Q_{reg}} \Delta_{\min}^p$. The next proposition shows that $\alpha_k = 0$ is always a candidate.

FIG. 6. *A detailed pseudocode of the apparent pollster algorithm, the algorithm from the point of view of the pollster slave. At every moment, a finite number of $M(\Delta_k^1)$ points are evaluated in parallel by other slaves. These evaluations are considered within the opportunistic search step. Δ_k^M is updated by the master after the poll step.*

Proof. At iteration 0, $\Delta_0^1 = \Delta_0^M = \Delta_0^{user} = \min_{p\in Q_{reg}} \Delta_{\min}^p$ so $\alpha_0 = 0$, and therefore it exists. Then $\Delta_1^M = \Delta_0^{user}$ and $\min_{p\in Q_{reg}} \Delta_{\min}^p$ at iteration 1 is equal to Δ_0^{user}. Figure 5 ensures that Δ_1^1 is bounded above by Δ_0^{user}, and therefore $\alpha_1 = 0$ is a possible value.

Suppose, by way of induction, that, for some $k \geq 2$, the proposition is true at iteration $k-1$. It follows that $\Delta_k^M = \tau^{\alpha_{k-1}}\Delta_{k-1}^1 \leq \min_{p\in Q_{reg}} \Delta_{\min}^p$, and as it corresponds to new values for $\Delta_{\min}^p$, $p \in Q_{reg}$, and the new smaller possible value of $\min_{p\in Q_{reg}} \Delta_{\min}^p$ at iteration k remains Δ_k^M. The largest value that Δ_k^1 may take is also Δ_k^M, which shows $\alpha_k = 0$ validates the result. □

This proof allows all values of α_k to be zero, but, in practice, nonzero values are likely. For example, if iteration 1 failed and $\Delta_1^1 = \Delta_0^{user}$, then the following mesh updates are possible: $\Delta_2^M \leftarrow \Delta_0^{user}$ ($\alpha_1 = 0$) and $\Delta_2^1 \leftarrow \Delta_0^{user}/4$. $\min_{p\in Q_{reg}} \Delta_{\min}^p$ is still equal to Δ_0^{user} at iteration 2, and so α_2 can be either 0 or 1.

4. Convergence analysis of PSD-MADS. It is shown here that the entire algorithm may be interpreted as a single-poll MADS algorithm applied to the original problem $\mathcal{P}$ and that conditions are met so that the main convergence results from [8] hold. These conditions are that the regular slaves generate a finite number of trial points lying on the pollster mesh and that all of these trial points can be interpreted as a search step with the pollster slave providing the poll step. This is detailed in Figure 6, and we refer to it as the *apparent pollster algorithm*. This algorithm is another way of interpreting the PSD-MADS algorithm described by the pseudocodes in Figures 2, 3, 4, and 5. Iteration k of the apparent pollster algorithm corresponds to the iteration k of PSD-MADS (used by the master process), and the notions of iteration success and failure remain the same.

The convergence analysis in this section proves that the apparent pollster algorithm is a single-poll MADS algorithm with the following components:

- A search step performed by regular slaves $s_2, s_3, \ldots, s_{q-2}$ on meshes of coarseness larger than or equal to Δ_k^M;

- A poll step at iteration k (the same k used by the master process in Figure 4) performed by one call to the pollster slave s_1 on a mesh of size $\Delta_k^1 \leq \Delta_k^M$;
- A mesh update performed by the master process with $\Delta_{k+1}^1 \leftarrow \tau^{\omega_k}\Delta_k^1$ and the integer $\omega_k \in \begin{cases} [0;\omega^+] & \text{iteration success,} \\ [\omega^-;-1] & \text{iteration failure.} \end{cases}$

The master mesh size parameter Δ_k^M at iteration k is the link described by inequalities (2) between the mesh size of MADS(pollster) and the different mesh sizes of MADS(s_p). It is updated by the master with the MADS(pollster) mesh (via $\Delta_{stop}^p = \Delta_k^1$), in such a way that, at every iteration k of the apparent pollster algorithm, Δ_k^1 satisfies $\Delta_k^1 \leq \Delta_k^M$. This Δ_k^M update by the master in the apparent pollster algorithm occurs when the mesh size Δ_k^1 is updated, and while its value does not change during the poll step, it can possibly be updated during the search step, since that is performed in parallel. This possible change of the Δ_k^M value within the search step of the apparent pollster algorithm is governed by the fact that Δ_k^M cannot be exceeded by any regular slave mesh size ($\Delta_k^M \leq \min_{p\in Q_{reg}} \Delta_{\min}^p$).

To show that the apparent pollster algorithm is a valid single-poll MADS algorithm applied to the original problem $\mathcal{P}$ and that the convergence conditions of [8] hold, the search trial points, whose evaluations are performed at any time in parallel by the other slaves, must remain finite in number and on the current pollster mesh at iteration k, Δ_k^1. This will be shown via the following propositions.

PROPOSITION 4.1. *The mesh size parameter at iteration j of the* MADS *algorithm performed by a slave s_p, $p \in Q_{reg}$ on a subproblem $\mathcal{P}_p(x^*)$ satisfies $\Delta_j^p = \tau^{-\eta_j}\Delta_0^{user}$ for some integer $\eta_j \geq 0$. This can be extended to the pollster slave at iteration k, with $\Delta_k^1 = \tau^{-\eta_k}\Delta_0^{user}$.*

Proof. We first show that the proposition is true for the first optimization subproblem solved by a regular slave s_p, $p \in Q_{reg}$. The initial mesh size parameter used for this MADS instance is Δ_0^{user}, and with the standard MADS mesh update rules, at iteration j, $\Delta_j^p = \tau^{\omega_{j-1}}\Delta_{j-1}^p = \cdots = \tau^{\sum_{i=0}^{j-1}\omega_i}\Delta_0^{user}$. Then $\eta_j = -\sum_{i=0}^{j-1}\omega_i \geq 0$, because no mesh size can be larger than Δ_0^{user}.

Suppose now that the proposition is true for the rth MADS instance performed by s_p. In particular, the last mesh size parameter of this instance can be written $\Delta_{stop}^p = \tau^{-\eta_{stop}}\Delta_0^{user}$, where η_{stop} is a nonnegative integer. From the algorithm described in Figure 4, the first mesh size parameter of the $(r+1)$th MADS instance performed by s_p is $\Delta_0^p = \tau^\gamma\Delta_{stop}^p$, with $\gamma \in \mathbb{Z}$. Then, at iteration j of the $(r+1)$th instance, $\Delta_j^p = \tau^{\sum_{i=0}^{j-1}\omega_i}\Delta_0^p$ and $\eta_j = -\sum_{i=0}^{j-1}\omega_i - \gamma + \eta_{stop} \geq 0$ because $\Delta_j^p \leq \Delta_0^{user}$. The proposition can be extended to the pollster slave with the same induction proof on k. ∎

PROPOSITION 4.2. *At iteration k of* PSD-MADS*, and at iteration j of the* MADS *algorithm performed by s_p ($p \in Q_{reg}$) on a subproblem $\mathcal{P}_p(x^*)$, there exists a nonnegative integer β_j such that $\Delta_j^p = \tau^{\beta_j}\Delta_k^M$.*

Proof. From the algorithm in Figure 4, the master mesh size parameter, at iteration k of PSD-MADS, can be written $\Delta_k^M = \tau^{\alpha_k - 1}\Delta_{k-1}^1$, with $\alpha_{k-1} \in \mathbb{N}$, and $\Delta_{k-1}^1 = \tau^{-\eta_{k-1}}\Delta_0^{user}$, with $\eta_{k-1} \in \mathbb{N}$, from Proposition 4.1. From the same proposition, the mesh size parameter at iteration j of MADS(s_p), $p \in Q_{reg}$ can be written $\Delta_j^p = \tau^{-\eta_j}\Delta_0^{user}$, $\eta_j \in \mathbb{N}$. Then, $\Delta_j^p = \tau^{\beta_j}\Delta_k^M$, with $\beta_j = \eta_{k-1} - \eta_j - \alpha_{k-1}$. The minimal mesh size parameter $\Delta_{\min}^p$ considered by MADS(s_p) corresponds to Δ_i^M, where $i \leq k$ is an anterior iteration of PSD-MADS. The current value of Δ_k^M was chosen to be smaller than $\min_{p\in Q_{reg}} \Delta_{\min}^p \leq \Delta_i^M$. Then, $\Delta_k^M \leq \Delta_i^M \leq \Delta_j^p$, and β_j is a nonnegative integer. ∎

An immediate corollary, with Hypothesis 3.1, is that at iterations k of PSD-MADS and j of MADS(s_p), $p \in Q_{reg}$, $M(\Delta_j^p) \subseteq M(\Delta_k^M)$.

PROPOSITION 4.3. *At iteration k of* PSD-MADS*, every trial point generated by the* MADS *algorithm performed by s_p, $p \in Q_{reg}$ on any subproblem $\mathcal{P}_p(x^*)$, lies on the pollster mesh $M(\Delta_k^1)$.*

Proof. From the algorithm in Figure 4, the pollster and master mesh size parameters at iteration k of PSD-MADS are linked with $\Delta_k^M = \tau^{\alpha_k}\Delta_k^1$, $\alpha_k \in \mathbb{N}$. With Hypothesis 3.1 and Proposition 4.2, at iteration j of MADS(s_p), $M(\Delta_j^p) \subseteq M(\Delta_k^M) \subseteq M(\Delta_k^1)$. Since all MADS($s_p$) trial points are constructed on $M(\Delta_j^p)$, they also lie on $M(\Delta_k^1)$. ∎

This series of propositions ensures that all of the trial points of the search step of the apparent pollster at iteration k, performed in parallel by regular slaves, lie on the current pollster mesh Δ_k^1. In addition, their number remains finite as the time between two iterations, corresponding to a single-point poll, is finite (with the hypothesis that the black-box evaluates or is terminated to return ∞, in finite time). The PSD-MADS algorithm, viewed from the perspective of the pollster slave, thus executes a valid single-poll MADS search, and the main convergence results of [8] remain valid. Let $\hat{x}$ be the limit of a subsequence of PSD-MADS incumbents at unsuccessful iterations. Then

- If f is Lipschitz near $\hat{x} \in \Omega$, then the Clarke derivative satisfies $f^\circ(\hat{x}; v) \geq 0$ for all $v \in T_\Omega^H(\hat{x})$, the hypertangent cone to Ω at $\hat{x}$;
- In the unconstrained case and if f is strictly differentiable at $\hat{x}$, $\nabla f(\hat{x}) = 0$.

As mentioned in section 2.3, the fact that the single-poll version of MADS is used sacrifices the zeroth order result of [8], i.e., $\hat{x}$ cannot be said to be the limit of local optima on meshes that get infinitely fine.

5. A practical implementation of PSD-MADS. This section proposes a practical implementation of the PSD-MADS algorithm described in section 3 based on the LTMADS implementation proposed in [8] and summarized in section 2.4. Numerical tests complete the implementation description.

5.1. PSD-MADS implementation.

Verification of Hypothesis 3.1. The above convergence analysis relies on Hypothesis 3.1. An easy way to satisfy this hypothesis is to simply choose τ to be an integer. Indeed, consider the mesh point $x \in M(\Delta)$ and mesh size $\Delta \in \mathbb{R}$. From the mesh definition (1), x can be written as $y + \Delta \sum_{i=1}^{n_D} z_i d_i$, where y belongs to V, the set of currently evaluated points, and z_i are nonnegative integers. Now, if $\Delta' = \tau^\omega \Delta$, where $\omega \in \mathbb{N}$ and $1 \leq \tau \in \mathbb{N}$, then x can be rewritten as $x = y + \Delta' \sum_{i=1}^{n_D} \tau^\omega z_i d_i$. It follows that $\tau^\omega z_i \in \mathbb{N}$, $i = 1, 2, \ldots, n_D$, and therefore $x \in M(\Delta')$. We have shown that $M(\Delta) \subseteq M(\Delta')$, and thus Hypothesis 3.1 is satisfied. In the proposed PSD-MADS implementation, the LTMADS fixed value of $\tau = 4$ is used.

Directions used by the pollster. The LTMADS direction $b(\ell)$ is used in the single-poll MADS algorithm executed by the pollster slave. The union of normalized directions $b(\ell)$, $\ell = 1, 2, \ldots$, is dense in the unit sphere with probability one, and MADS(pollster) with the $b(\ell)$ direction respects the conditions for a valid single-poll MADS algorithm.

Sets N_p of subproblem variables. This paper does not focus on the choice of the subproblem variables. Rather, we use this very simple strategy: let the sets N_p, $p \in Q_{reg} = \{2, 3, \ldots, q-2\}$, be randomly generated by the master using a

uniform distribution before each subproblem parameter set is sent to a regular slave process. In order to keep an easy parametrization of this PSD-MADS implementation, the number of variables for each subproblem is fixed throughout the entire algorithm $|N_2| = |N_3| = \cdots = |N_{q-2}| = ns$, where ns is a parameter chosen by the user (recall that, for the pollster, $N_1 = N$). Notice also that ns is not required to satisfy $(q-3)ns \geq N$. Furthermore, when MADS(s_p), $p \in Q_{reg}$ succeeds in improving the incumbent, the same set N_p is kept for the next run performed by the slave s_p.

Mesh update rules. The mesh directions of definition (1) are the standard LTMADS $2n$ directions $D = [-I_n \; I_n]$. The following mesh size parameter updates are in accordance with the LTMADS mesh update rules:

- **Regular slaves mesh size Δ_j^p (at iteration j of MADS(s_p), $p \in Q_{reg}$):** After an iteration fails, the mesh size is updated with $\Delta_{j+1}^p \leftarrow \Delta_j^p/4$ ($\omega_j = -1$ in Figure 1). If a poll step is successful, $\Delta_{j+1}^p \leftarrow 4\Delta_j^p$ ($\omega_j = 1$). In the next search step, if a successful point is found in the cache server, set $\Delta_{j+1}^p \leftarrow 4\Delta_{cache}$, where Δ_{cache} is the mesh size used to generate this point. Equation (3) summarizes these updates as follows:

$$\Delta_{j+1}^p \leftarrow \begin{cases} \min\left\{\Delta_0^{user}, 4\Delta_j^p\right\} & \text{poll success,} \\ \min\left\{\Delta_0^{user}, 4\Delta_{cache}\right\} & \text{cache search success,} \\ \Delta_j^p/4 & \text{iteration failure.} \end{cases} \tag{3}$$

  If $\Delta_{j+1}^p < \Delta_{\min}^p$ or if the number of new function evaluations exceeds $bbe_{\max}$, MADS(s_p) terminates and communicates $\Delta_{stop}^p = \Delta_j^p$ to the master. The next optimization performed by this slave will start with an initial mesh size parameter Δ_0^p equal to $4^\gamma \Delta_{stop}^p$, with $\gamma = 1$ if at least one success was achieved since the beginning of the current optimization (even by another slave), or else $\gamma = -1$. However, this may lead to a value smaller than $\Delta_{\min}^p = \Delta_k^M$, and, in this case, set $\Delta_0^p \leftarrow \Delta_k^M$.
  The Δ_0^p choice for the next MADS(s_p) is summarized by

$$\Delta_0^p \text{ (next MADS}(s_p)) \leftarrow \begin{cases} \min\left\{\Delta_0^{user}, 4\Delta_{stop}^p\right\} & \text{success,} \\ \max\left\{\Delta_k^M, \Delta_{stop}^p/4\right\} & \text{else.} \end{cases} \tag{4}$$

- **Master mesh size Δ_k^M at iteration k of PSD-MADS:** The update of the master mesh size is performed by the master after a pollster instance terminates. Δ_{k+1}^M is bounded below by the mesh size parameter of the terminated pollster Δ_k^1 and above by the minimum of all $\Delta_{\min}^p$ values currently used by regular slaves. These $\Delta_{\min}^p$ values correspond to previous master mesh sizes. It would be possible to choose the parameter α_k in Figure 4 at each update so that Δ_{k+1}^M is fixed to Δ_0^{user}, with α_k equal to the η_k from Proposition 4.1. However, such a strategy would not be efficient, as regular slaves would always generate trial points on the same mesh $M(\Delta_0^{user})$. The master mesh size has then to be reduced somehow through the PSD-MADS evolution. However, it should not be reduced too rapidly, or the algorithm would progress slowly or even terminate prematurely in practice.
  We propose the following strategy: From Figure 4, Δ_k^M is updated by $\Delta_{k+1}^M \leftarrow 4^{\alpha_k}\Delta_k^1$, with $\alpha_k \in \mathbb{N}$, and from Proposition 4.1, $\Delta_k^1 = 4^{-\eta_k}\Delta_0^{user}$, with some $\eta_k \in \mathbb{N}$. If iteration k succeeded, set $\alpha_k = \eta_k = \log_4\left(\Delta_0^{user}/\Delta_k^1\right)$ (maximal Δ_k^M increase), and else $\alpha_k = \eta_k - \lfloor(\eta_k + 1)/3\rfloor$ (attenuated Δ_k^M increase). In both cases, if Δ_{k+1}^M is greater than at least one of the regular slave's mesh

size $\Delta^p_{\min}$, then Δ^M_{k+1} is set to the least $\Delta^p_{\min}$ values. This can be summarized by the following:

$$\Delta^M_{k+1} \leftarrow \begin{cases} \min\left\{\Delta_0^{user}, \min\limits_{p\in Q_{reg}} \Delta^p_{\min}\right\} & \text{iteration success,} \\ \min\left\{4^{-\lfloor(\eta_k+1)/3\rfloor}\Delta_0^{user}, \min\limits_{p\in Q_{reg}} \Delta^p_{\min}\right\} & \text{iteration failure.} \end{cases} \tag{5}$$

For example, if $\Delta_0^{user} = \Delta^p_{\min} = 1$ for each $p \in Q_{reg}$ and if the pollster instance fails with a pollster mesh size of $\Delta^1_k = 1/16$, then the master mesh size Δ^M_{k+1} is set to $1/4$ ($\eta_k = 2$, $\alpha_k = 1$).

- **Pollster mesh size $\boldsymbol{\Delta^1_k}$ at iteration $\boldsymbol{k}$ of PSD-MADS:** In the case of an iteration success, Δ^1_{k+1} is set to Δ^M_{k+1} ($\omega_k = \alpha_k \in \mathbb{N}$), or else $\Delta^1_{k+1} = \Delta^1_k/4$ ($\omega_k = -1$):

$$\Delta^1_{k+1} \leftarrow \begin{cases} \Delta^M_{k+1} = \min\left\{\Delta_0^{user}, \min\limits_{p\in Q_{reg}} \Delta^p_{\min}\right\} & \text{iteration success,} \\ \Delta^1_k/4 & \text{iteration failure.} \end{cases} \tag{6}$$

MADS parameters for MADS(s_p), $p \in Q_{reg}$. The regular slaves $p \in Q_{reg}$ solve MADS(s_p) using the standard MADS $2|N_p|$ directions. All polls are opportunistic, meaning that a subproblem optimization terminates as soon as a better point is found. The one-point dynamic search strategy of [8] is also performed: it consists, after a successful poll step, in evaluating, within a single-point search, the black-box functions at a mesh point located further along the same successful direction.

In addition to the poll and the one-point dynamic search, MADS(s_p) performs a specialized search step, which simply consists in querying the cache server for the best available feasible point. This special search step generates no additional function evaluation and allows every regular slave to know the best points eventually obtained by other slaves. Note that this search step has no obligation to give a point lying on the current mesh of MADS(s_p), but this does not influence the convergence analysis as it is based on the pollster s_1, and as the point given by this search must come from another slave, thus lying on $M(\Delta^M_k)$.

Practical termination criteria. The regular slaves $p \in Q_{reg}$ terminate MADS(s_p) as soon as the mesh size parameter Δ^p_j drops below $\Delta^p_{\min} = \Delta^M_k$ (where k is the PSD-MADS iteration at which MADS(s_p) was started) or after a finite number of $bbe_{\max}$ black-box function evaluations are made. The PSD-MADS algorithm is stopped after an overall limit of $bbe^{global}_{\max}$ black-box evaluations is reached.

5.2. Numerical experiments. The PSD-MADS implementation described in section 5.1 is tested here, on two different problems. The implementation of MADS used to optimize subproblems corresponds to LTMADS and is the research version of the NOMAD C++ code [5]. The parallel master/slaves paradigm is achieved with MPI with $q = 6$ or 14 processes.

PSD-MADS is compared to three other parallel algorithms, on the same number q of processes: First, the pGPS method described in [17], which corresponds to the unmodified GPS method where evaluations are made in parallel. Second, pMADS, which is the trivial adaptation of pGPS that uses LTMADS instead of GPS. pGPS and pMADS are both synchronous parallel algorithms. The third method is APPS version 5.0.1 [25, 36], the only available GPS asynchronous parallel algorithm.

The first problem (referred as Problem A) considered for the tests is the G2 example from [28]. It has been chosen for its difficulty and for its variable size: our tests involve $n = 20, 50, 250$, and 500 variables. Problem A is written as follows:

$$\min_{x\in\mathbb{R}^n} f(x) = -\left|\frac{\sum_{i=1}^{n}\cos^4 x_i - 2\prod_{i=1}^{n}\cos^2 x_i}{\sqrt{\sum_{i=1}^{n} i x_i^2}}\right|$$

$$\text{subject to}\begin{cases} -\prod_{i=1}^{n} x_i + 0.75 \le 0, \\ \sum_{i=1}^{n} x_i - 7.5n \le 0, \\ 0 \le x_i \le 10, \quad i = 1, 2, \ldots, n. \end{cases}$$

The problem is treated as a black-box, and an upper limit of $100n$ function evaluations is imposed. The feasible starting point for all methods is the center of the bound constrained domain $x_0 = [5\ 5\ \ldots\ 5]^T \in \Omega$. The best known value from [28], for $n = 20$, is $f(x) = -0.803619$. In [28], various genetic algorithms gave good solutions, after several hundred thousand evaluations. Here, after a maximum of 2000 evaluations, PSD-MADS achieved $f(x) \simeq -0.76$.

The second test problem (Problem B) was designed for the MOVARS algorithm [12]. It has $n = 60$ variables and one constraint with two different versions: $G \ge 250$, or $G \ge 500$ (see [12] for a more complete description). An infeasible starting point is provided in [12], but cannot be used in the present work, since constraints are treated with the extreme barrier approach. The feasible starting points considered here for the two versions of Problem B have been obtained by minimizing the constraint violation $(\max\{0, 250 - G\})^2$ or $(\max\{0, 500 - G\})^2$, from the starting point of [12], with the pMADS algorithm. These optimizations required three evaluations for $G \ge 250$, with the resulting feasible point x_0 giving $f(x_0) = 3678.35$ and 74 evaluations for $G \ge 500$, and $f(x_0) = 3014$. These evaluations costs are considered in Figure 8. The feasible starting points, our source code for Problem B, and our best points are available on the website www.gerad.ca/Charles.Audet (see [5]). Our results for Problem B are not compared with the MOVARS algorithm results because numerical values are not given in [12]. The best solutions found gave $f(x) = 13.565$ for $G \ge 250$, and $f(x) = 245.866$ for $G \ge 500$.

The various results of this section are measured considering two quantities: z represents the best value of the objective function of problem $\mathcal{P}$, and *bbe* represents the total number of black-box evaluations. One evaluation is counted for the calls to both the objective f and the constraints of Ω.

The most representative cost of a black-box optimization algorithm is the number of black-box evaluations. For this reason, no speedup curves are given, and q is kept constant for each problem ($q = 14$ for Problem A and $q = 6$ for Problem B). Still, the durations of executions are given. The PSD-MADS method was not conceived in order to reduce the time to obtain a solution. Instead, we seek to obtain better solutions than a nondecomposing algorithm for problems with a large number of variables ($20 \le n \le 500$).

For all of our tests, the termination criteria is the maximum total number of black-box evaluations, which is $bbe_{\max}^{global} = 100n$ for Problem A and $bbe_{\max}^{global} = 3000$ for Problem B (as in [12]).

The initial (and maximal) mesh size parameter is $\Delta_0^{user} = 2$ for Problem A. For Problem B, due to scaling reasons, the value of Δ_0^{user} differs for each variable and is set to be 0.2 times the range of the variables (i.e., $\Delta_0^{user} = 0.3$ for the 15 first variables, 0.35 for the next 30 variables, and 0.44 for the last 15 variables). These values have been decided empirically to give good results with standard MADS and APPS runs. The linear nature of the second constraint of Problem A is exploited by APPS. Since PSD-MADS and pMADS involve randomness in the polling directions, 30 runs are made for each test. The parallel execution of pGPS and APPS can affect their determinism; however, this effect was ignored, and one run was performed for each test.

To measure the quality of the solutions found, the best (z_{best}), worst (z_{worst}), and average (z_{avg}) values of the objective function value z at the $100n$th evaluation are reported. Another measure is S_{avg}, representing the area between a curve z versus *bbe* and the line $z = -0.8$ for Problem A (no run gave $z < -0.8$), and $z = 0$ for Problem B. Wall clock time expressed in seconds are reported in the column t_{avg}. Best runs are obtained with small values for all of these quantities.

PSD-MADS was tested on Problem A with $n = 20$ and 50 by varying $bbe_{\max}$, the maximum number of black-box evaluations for each regular subproblem, and ns, the number of variables in each subproblem. The number of processes has been set to $q = 14$ in order to fully exploit 12 processors. Good results were obtained by setting $bbe_{\max} = 10$ and having the regular slaves working on small dimensional subspaces $ns = 2$. These values are kept for $n > 50$. For Problem B, $bbe_{\max}$ is kept to 10. The best results have been obtained by distributing the 60 variables amongst 3 regular slaves with $q = 6$ and $ns = 20$.

Table 1 and Figures 7 and 8 summarize the numerical results. For all instances of Problem A, APPS outperforms pGPS, but neither does as well as PSD-MADS. In the three larger instances of Problem A, the worst f value produced by PSD-MADS is always better than all of the other methods'f values. For Problem B, pGPS outperforms APPS, and better results are obtained with pMADS and PSD-MADS, with a small advantage to PSD-MADS. In all of the curves in Figures 7 and 8, one can notice that pMADS is always the fastest to descend, but PSD-MADS overtakes it and produces better solutions. Finally, we remark that APPS terminates in the least wall clock time on smaller problems, albeit with a less optimal function value. However, for problems with 250 and 500 variables, the wall clock time grows significantly worse. This is in accordance with the remark in [25] stating that APPS targets problems with less than 100 variables.

We conclude this section with some advice for readers interested in testing Psd-Mads. First, we think that the Psd-Mads decomposition is beneficial for problems with more than 20 variables. For these problems, at least 3 processors are necessary. Furthermore, since the master and cache server processes are not demanding in terms of Cpu, 5 processes can be executed on the 3 processors, whose work will be mainly devoted to two regular slaves and the pollster. Two regular slaves is the minimum number to benefit from the decomposition. So, even if only a few processors are available, it is still worthwhile to try this method. Finally, if the user has no particular strategy to choose the subsets of variables in each subproblem, we recommend to equally distribute the variables to the regular slaves. If the user knows that some of the variables are more likely to produce descent than others, then some subproblems can be devoted to these variables, while single-poll Mads can be used on the subproblems of less important variables.

6. Discussion and possible extensions. This paper introduced Psd-Mads, a new Psd technique with less restrictive conditions than usual Psd methods on the functions to be optimized and on the sets of variables in the subproblems. It is shown that the algorithm, from any starting point, produces a subsequence of iterates converging to a solution satisfying local optimality conditions (global convergence to local solutions), based on Clarke calculus and on the Mads convergence analysis. A practical implementation is described, with a small number of parameters ($bbe_{\max}$ and ns), and very encouraging results have been obtained on a difficult problem from the literature, with up to 500 variables.

We presented a first basic implementation of Psd-Mads with a very simple and generic strategy to choose the sets of variables. An obvious extension is a better strategy to decide on the sets of variables in the subproblems. Of course, it is not clear how to do this, in general, or we would have done it here. However, for some applications, the user may have special knowledge that would help in this task. For example, the user might put similarly scaled variables in the same subproblem.

It would also be interesting to incorporate the Pvd idea of the "forget-me-not" terms and allow some basic changes in the subproblems for fixed variables. A third possibility would be to perform some additional search steps in the slave subspaces. Another possible extension would be to reintroduce the synchronization step of the original block-Jacobi method but without the parallel barrier. This "recomposition" step could be performed in parallel by one of the regular slaves, from a pool of successful points, in order to create a problem similar to the one in [19]. Finally, the constraints of Ω could be treated with the progressive barrier [9], instead of the extreme barrier approach. This would allow for infeasible iterates, including the starting point.

Acknowledgments. We would like to thank anonymous referees for their constructive remarks and comments.

SMOOTH OPTIMIZATION WITH APPROXIMATE GRADIENT*

ALEXANDRE D'ASPREMONT†

Abstract. We show that the optimal complexity of Nesterov's smooth first-order optimization algorithm is preserved when the gradient is computed only up to a small, uniformly bounded error. In applications of this method to semidefinite programs, this means in some instances computing only a few leading eigenvalues of the current iterate instead of a full matrix exponential, which significantly reduces the method's computational cost. This also allows sparse problems to be solved efficiently using sparse maximum eigenvalue packages.

Key words. smooth optimization, first-order methods, semidefinite programming

1. Introduction.

In [13] it was shown that smooth convex minimization problems of the form:

$$\begin{array}{ll} \text{minimize} & f(x) \\ \text{subject to} & x \in Q, \end{array}$$

where f is a convex function with Lipschitz continuous gradient and Q is a sufficiently simple compact convex set, could be solved with a complexity of $O(1/\sqrt{\epsilon})$, where ϵ is the precision target. Furthermore, it can be shown that this complexity bound is optimal for that class of problems (see [14] for a discussion). More recently, [15] showed that this method could be combined with a smoothing argument to produce an $O(1/\epsilon)$ complexity bound for nonsmooth problems where the objective has a saddle-function format. In particular, this meant that a broad class of semidefinite optimization problems could be solved with significantly lower memory requirements than interior point methods and a better complexity bound than classic first-order methods (bundle, subgradient, etc.).

Here, we show that substituting an approximate gradient, which may allow significant computation and storage savings, does not affect the optimal complexity of the algorithm in [13]. It is somewhat intuitive that an algorithm which exhibits good numerical performance in practice should be robust to at least some numerical error in the objective function and gradient computations since all implementations are necessarily computing these quantities up to some multiple of machine precision. Our objective here is to make that robustness explicit in order to design optimal schemes using only approximate gradient information.

For nonsmooth problems, when the objective function $f(x)$ can be expressed as a saddle function on a compact set, the method in [15] starts by computing a smooth (i.e., with Lipschitz continuous gradient), uniform ϵ-approximation of the objective function $f(x)$; it then uses the smooth minimization algorithm in [13] to solve the approximate problem. When this smoothing technique is applied to semidefinite

optimization, computing exact gradients requires forming a matrix exponential, which is often the dominant numerical step in the algorithm.

Although there are many different methods for computing this matrix exponential (see [11] for a survey), their complexity is comparable to that of a full eigenvalue decomposition of the matrix. In problem instances where only a few leading eigenvalues suffice to approximate this exponential, the per iteration complexity of the algorithm described here becomes comparable to that of classical first-order methods such as the bundle method (see [6]) or subgradient methods (see [19], for example), which have a global complexity bound of $O(1/\epsilon^2)$ (see [14]), while keeping the optimal complexity of $O(1/\epsilon)$ of the algorithm in [15].

We apply this result to a maximum eigenvalue minimization problem (or semidefinite program with constant trace). We first recall the complexity bound derived in [16] based on a smoothing argument, using exact gradients. We produce a rough theoretical estimate of the number of eigenvalues required for convergence when approximate gradients are used. We then derive an explicit condition on the quality of the gradient approximation to guarantee convergence and compute a bound on the number of iterations. We show both on randomly generated problem instances and on problems generated from biological data sets that actual computational savings vary significantly with problem structure but can be substantial in some cases.

The paper is organized as follows. In the next section, we prove convergence of the algorithm in [13] when only an approximate gradient is used. In section 3 we describe how these results can be applied to semidefinite optimization. Finally, in the last section we test their performance on semidefinite relaxation and maximum eigenvalue minimization problems.

2. Smooth optimization with approximate gradient. Following the results and notations in [15, section 3], we study the problem:

$$\begin{array}{ll} \text{minimize} & f(x) \\ \text{subject to} & x \in Q, \end{array} \tag{2.1}$$

where $Q \subset \mathbf{R}^n$ is a compact convex set and f is a convex function with Lipschitz continuous gradient, such that

$$\|\nabla f(x) - \nabla f(y)\|^* \leq L\|x-y\|, \quad x, y \in Q,$$

for some $L > 0$, which also means

$$f(y) \leq f(x) + \langle \nabla f(x), y - x\rangle + \frac{1}{2}L\|y-x\|^2, \quad x, y \in Q. \tag{2.2}$$

The key difference here is that the *oracle* information we obtain for ∇f is *noisy*. Note that the function values are not required to compute iterates in the algorithm described here, so even if our knowledge of function values $f(x)$ is noisy, we will always use exact values in the proofs that follow. At each iteration, we obtain $\tilde{\nabla} f(x)$ satisfying

$$\left|\left\langle \tilde{\nabla} f(x) - \nabla f(x), y - z\right\rangle\right| \leq \delta \quad x, y, z \in Q, \tag{2.3}$$

for some precision level $\delta > 0$. Throughout the paper, we assume that Q is simple enough so that this condition can be checked efficiently. As in [13], we also assume that certain projection operators on Q can be computed efficiently, and we refer the

reader to the end of this section for more details. Here, $d(x)$ is a prox-function for the set Q, i.e., continuous and strongly convex on Q with parameter σ (see [14] or [7] for a discussion of regularization techniques using strongly convex functions). We let x_0 be the center of Q for the prox-function $d(x)$ so that

$$x_0 \triangleq \operatorname{argmin}_{x\in Q} d(x),$$

assuming without loss of generality that $d(x_0) = 0$, we then have

$$d(x) \geq \frac{1}{2}\sigma\|x - x_0\|^2. \tag{2.4}$$

We denote by $\tilde{T}_Q(x)$ a solution to the following subproblem:

$$\tilde{T}_Q(x) \triangleq \operatorname{argmin}_{y\in Q} \left\{ \langle \tilde{\nabla} f(x), y - x\rangle + \frac{1}{2}L\|y - x\|^2 \right\}. \tag{2.5}$$

We let $y_0 = \tilde{T}_Q(x_0)$, where x_0 is defined above. We recursively define three sequences of points: the current iterate $\{x_k\}$, the corresponding $y_k = \tilde{T}_Q(x_k)$, together with

$$z_k \triangleq \operatorname{argmin}_{x\in Q} \left\{ \frac{L}{\sigma} d(x) + \sum_{i=0}^{k} \alpha_i \big[f(x_i) + \langle \tilde{\nabla} f(x_i), x - x_i\rangle \big] \right\}, \tag{2.6}$$

and a step size sequence $\{\alpha_k\} \geq 0$ with $\alpha_0 \in (0, 1]$ so that

$$\begin{aligned} x_{k+1} &= \tau_k z_k + (1 - \tau_k) y_k, \\ y_{k+1} &= \tilde{T}_Q(x_{k+1}), \end{aligned} \tag{2.7}$$

where $\tau_k = \alpha_{k+1}/A_{k+1}$ with $A_k = \sum_{i=0}^{k} \alpha_i$. We implicitly assume here that the two subproblems defining y_k and z_k can be solved very efficiently (in the examples that follow, they amount to Euclidean projections). We will show recursively that for a good choice of step sequence α_k, the iterates x_k and y_k satisfy the following relationship (denoted by $\mathcal{R}_k$):

$$A_k f(y_k) \leq \psi_k + A_k g(k, \delta) \quad (\mathcal{R}_k),$$

where $g(k, \delta)$ measures the accumulated gradient approximation error and will be bounded in Lemma 2.1, and

$$\psi_k \triangleq \min_{x\in Q} \left\{ \frac{L}{\sigma} d(x) + \sum_{i=0}^{k} \alpha_i \big[f(x_i) + \langle \tilde{\nabla} f(x_i), x - x_i\rangle \big] \right\}.$$

First, using $d(x) \geq \frac{1}{2}\sigma\|x - x_0\|^2$, then inequality (2.2) and condition (2.3), we have

$$\psi_0 = \min_{x\in Q} \left\{ \frac{L}{\sigma} d(x) + \alpha_0 \big[f(x_0) + \langle \tilde{\nabla} f(x_0), x - x_0\rangle \big] \right\} \geq \alpha_0 f(y_0) - \alpha_0 \delta,$$

which is $\mathcal{R}_0$. We can then bound the approximation error in the following result.

LEMMA 2.1. *Let α_k be a step sequence satisfying:*

$$0 < \alpha_0 \leq 1 \quad \textit{and} \quad \alpha_k^2 \leq A_k, \quad k \geq 0; \tag{2.8}$$

suppose that $(\mathcal{R}_k)$ *holds with* x_{k+1} *and* y_{k+1} *are defined as in* (2.7)*, and then* $(\mathcal{R}_{k+1})$ *holds with*

$$g(k+1,\delta) = (1-\tau_k)g(k,\delta) + \tau_k 3\delta,$$

where $\tau_k \in [0,1]$ *and* $g(0,\delta) = \alpha_0\delta$.

Proof. Let us assume that $(\mathcal{R}_k)$ holds. Because $d(x)$ is strongly convex with parameter σ, the function

$$\frac{L}{\sigma}d(x) + \sum_{i=0}^{k} \alpha_i \big[f(x_i) + \langle \tilde{\nabla} f(x_i), x - x_i\rangle\big]$$

is strongly convex with parameter L. Using this property and the definition of z_k, we obtain

$$\begin{aligned}\psi_{k+1} &= \min_{x\in Q}\left\{\frac{L}{\sigma}d(x) + \sum_{i=0}^{k+1} \alpha_i \big[f(x_i) + \langle \tilde{\nabla} f(x_i), x - x_i\rangle\big]\right\}\\ &\geq \min_{x\in Q}\left\{\psi_k + \frac{1}{2}L\|x-z_k\|^2 + \alpha_{k+1}\big[f(x_{k+1}) + \langle \tilde{\nabla} f(x_{k+1}), x - x_{k+1}\rangle\big]\right\}.\end{aligned}$$

Now, using $(\mathcal{R}_k)$ and then the convexity of $f(x)$, we get

$$\begin{aligned}&\psi_k + A_k g(k,\delta) + \alpha_{k+1}\big[f(x_{k+1}) + \langle \tilde{\nabla} f(x_{k+1}), x - x_{k+1}\rangle\big]\\ &\geq A_k f(y_k) + \alpha_{k+1}\big[f(x_{k+1}) + \langle \tilde{\nabla} f(x_{k+1}), x - x_{k+1}\rangle\big]\\ &\geq A_k[f(x_k) + \langle \nabla f(x_{k+1}), y_k - x_{k+1}\rangle] + \alpha_{k+1}\big[f(x_{k+1}) + \langle \tilde{\nabla} f(x_{k+1}), x - x_{k+1}\rangle\big],\end{aligned}$$

and condition (2.3), together with (2.7), implies that:

$$\begin{aligned}&A_k[f(x_k) + \langle \nabla f(x_{k+1}), y_k - x_{k+1}\rangle] + \alpha_{k+1}\big[f(x_{k+1}) + \langle \tilde{\nabla} f(x_{k+1}), x - x_{k+1}\rangle\big]\\ &\geq A_{k+1}f(x_{k+1}) + \langle \nabla f(x_{k+1}), A_k y_k - A_k x_{k+1} + \alpha_{k+1}(x - x_{k+1})\rangle - \alpha_{k+1}\delta\\ &= A_{k+1}f(x_{k+1}) + \alpha_{k+1}\langle \nabla f(x_{k+1}), x - z_k\rangle - \alpha_{k+1}\delta.\end{aligned}$$

Because α_k satisfies (2.8), we have $\tau_k^2 \leq A_{k+1}^{-1}$ and can combine the last three inequalities to get

$$\begin{aligned}\psi_{k+1} &\geq A_{k+1}f(x_{k+1}) - A_k g(k,\delta) - \alpha_{k+1}\delta\\ &\quad + \min_{x\in Q}\left\{\frac{1}{2}L\|x-z_k\|^2 + \alpha_{k+1}\langle \nabla f(x_{k+1}), x - z_k\rangle\right\}\\ &\geq A_{k+1}\Bigg[f(x_{k+1}) - (1-\tau_k)g(k,\delta) - \tau_k\delta\\ &\quad + \min_{x\in Q}\left\{\frac{1}{2}L\tau_k^2\|x-z_k\|^2 + \tau_k\langle \nabla f(x_{k+1}), x - z_k\rangle\right\}\Bigg].\end{aligned} \tag{2.9}$$

Let us define $y \triangleq \tau_k x + (1-\tau_k)y_k$ so that $y - x_{k+1} = \tau_k(x - z_k)$, with

$$\begin{aligned}&\min_{x\in Q}\left\{\frac{1}{2}L\tau_k^2\|x-z_k\|^2 + \tau_k\langle \nabla f(x_{k+1}), x - z_k\rangle\right\}\\ &= \min_{\{y\in\tau_k Q + (1-\tau_k)y_k\}}\left\{\frac{1}{2}L\|y - x_{k+1}\|^2 + \langle \nabla f(x_{k+1}), y - x_{k+1}\rangle\right\}.\end{aligned}$$

Combining condition (2.3) with the fact that $y - x_{k+1} = \tau_k(x - z_k)$ for some $x, z_k \in Q$, we get

$$\begin{aligned}&\min_{\{y\in\tau_kQ+(1-\tau_k)y_k\}}\left\{\frac{1}{2}L\|y-x_{k+1}\|^2+\langle\nabla f(x_{k+1}),y-x_{k+1}\rangle\right\}\\&\geq\min_{\{y\in\tau_kQ+(1-\tau_k)y_k\}}\left\{\frac{1}{2}L\|y-x_{k+1}\|^2+\left\langle\tilde{\nabla}f(x_{k+1}),y-x_{k+1}\right\rangle\right\}-\tau_k\delta.\end{aligned}$$

Now, because Q is convex, we must have $\tau_kQ + (1-\tau_k)y_k \subset Q$ and

$$\begin{aligned}&\min_{\{y\in\tau_kQ+(1-\tau_k)y_k\}}\left\{\frac{1}{2}L\|y-x_{k+1}\|^2+\left\langle\tilde{\nabla}f(x_{k+1}),y-x_{k+1}\right\rangle\right\}-\tau_k\delta\\&\geq\min_{y\in Q}\left\{\frac{1}{2}L\|y-x_{k+1}\|^2+\left\langle\tilde{\nabla}f(x_{k+1}),y-x_{k+1}\right\rangle\right\}-\tau_k\delta.\end{aligned}$$

By the definition of $y_{k+1} = \tilde{T}_Q(x_{k+1})$ and using condition (2.3), we get

$$\begin{aligned}&\min_{y\in Q}\left\{\frac{1}{2}L\|y-x_{k+1}\|^2+\left\langle\tilde{\nabla}f(x_{k+1}),y-x_{k+1}\right\rangle\right\}-\tau_k\delta\\&=\frac{1}{2}L\|\tilde{T}_Q(x_{k+1})-x_{k+1}\|^2+\left\langle\tilde{\nabla}f(x_{k+1}),\tilde{T}_Q(x_{k+1})-x_{k+1}\right\rangle-\tau_k\delta\\&\geq\frac{1}{2}L\|y_{k+1}-x_{k+1}\|^2+\left\langle\nabla f(x_{k+1}),y_{k+1}-x_{k+1}\right\rangle-2\tau_k\delta,\end{aligned}$$

and inequality (2.2) gives

$$\begin{aligned}&\frac{1}{2}L\|y_{k+1}-x_{k+1}\|^2+\langle\nabla f(x_{k+1}),y_{k+1}-x_{k+1}\rangle-2\tau_k\delta\\&\geq f(y_{k+1})-f(x_{k+1})-2\tau_k\delta.\end{aligned}$$

Combining these inequalities with the inequality on ψ_{k+1} in (2.9), we finally get

$$\psi_{k+1}\geq A_{k+1}\left[f(y_{k+1})-(1-\tau_k)g(k,\delta)-3\tau_k\delta\right],$$

which is the desired result. □

We can use this result to study the convergence of the following algorithm given only approximate gradient information.

Smooth minimization with approximate gradient.

Starting from x_0, the prox center of the set Q, we iterate:

1. compute $\tilde{\nabla}f(x_k)$,
2. compute $y_k = \tilde{T}_Q(x_k)$,
3. compute $z_k = \operatorname{argmin}_{x\in Q}\{\frac{L}{\sigma}d(x) + \sum_{i=0}^{k}\alpha_i[f(x_i) + \langle\tilde{\nabla}f(x_i), x - x_i\rangle]\}$,
4. update x using $x_{k+1} = \tau_k z_k + (1-\tau_k)y_k$.

Again, because solving for y_k and z_k can often be done very efficiently, the dominant numerical step in this algorithm is the evaluation of $\tilde{\nabla}f(x_k)$. If the step size sequence α_k satisfies the conditions of Lemma 2.1, we can show the following convergence result.

THEOREM 2.2. *Suppose α_k satisfies* (2.8)*, with the iterates x_k and y_k defined in* (2.6) *and* (2.7)*, and then for any $k \geq 0$ we have:*

$$f(y_k) - f(x^\star) \leq \frac{Ld(x^\star)}{A_k \sigma} + 3\delta,$$

where $x^\star$ is an optimal solution to problem (2.1)*.*

Proof. If α_k satisfies the hypotheses of Lemma 2.1, we have

$$A_k f(y_k) \leq \psi_k + A_k g(k, \delta),$$

where $A_k = \sum_{i=0}^{k} \alpha_i$ and $g(k, \delta) \leq 3\delta$. Now, because $f(x)$ is convex, we also have

$$\psi_k \leq \frac{L}{\sigma} d(x^\star) + A_k f(x^\star) + A_k 3\delta,$$

which yields the desired result. □

When $d(x^\star) < +\infty$ (e.g., if Q is bounded), if we set the step sequence as $\alpha_k = (k+1)/2$ and δ to some fraction of the target precision ϵ (here $\epsilon/6$), A_k grows as $O(k^2)$, and Theorem 2.2 ensures that the algorithm will converge to an ϵ solution in less than

$$\sqrt{\frac{8Ld(x^\star)}{\sigma\epsilon}} \tag{2.10}$$

iterations. In practice, of course, $d(x^\star)$ needs to be bounded a priori, and L is often hard to evaluate. A notable exception is when $f(x)$ is a smooth approximation (as in [15, 16], for example), in which case L is known explicitly as a function of the precision. We have implicitly assumed, as in [13], that the set Q is simple enough so that the complexity of solving the two minimization subproblems in steps 2 and 3 of the algorithm is low relative to that of approximating the gradient. We also implicitly assumed that the set Q is simple enough so that condition (2.3) can be checked efficiently. In the numerical experiments of section 4, for example, steps 2 and 3 are Euclidean projections on the unit box, and condition (2.3) is a simple inequality on the leading eigenvalues of the current iterate.

3. Semidefinite optimization. Here, we describe in detail how the results of the previous section can be applied to semidefinite optimization. We consider the following maximum eigenvalue problem:

$$\begin{array}{ll} \text{minimize} & \lambda^{\max}\left(A^T y + c\right) - b^T y \\ \text{subject to} & y \in Q, \end{array} \tag{3.1}$$

in the variable $y \in \mathbf{R}^m$, with parameters $A \in \mathbf{R}^{m \times n^2}$, $b \in \mathbf{R}^m$, and $c \in \mathbf{R}^{n^2}$. Let us remark that when Q is equal to $\mathbf{R}^m$, the dual of this program is a semidefinite program with constant trace written:

$$\begin{array}{ll} \text{maximize} & c^T x \\ \text{subject to} & Ax = b, \\ & \mathbf{Tr}(x) = 1, \\ & x \succeq 0, \end{array} \tag{3.2}$$

in the variable $x \in \mathbf{R}^{n^2}$, where $\mathbf{Tr}(x) = 1$ means that the matrix obtained by reshaping the vector x has trace equal to one and $x \succeq 0$ means that this same matrix is symmetric, positive semidefinite.

3.1. Smoothing technique. As in [12], [16], [3], or [2], we can find a uniform ϵ-approximation to $\lambda^{\max}(X)$ with Lipschitz continuous gradient. Let $\mu > 0$ and $X \in \mathbf{S}_n$, and we define

$$f_\mu(X) = \mu \log \left(\sum_{i=1}^n e^{\lambda_i(X)/\mu} \right) = \mu \log \left(e^{\frac{\lambda^{\max}(X)}{\mu}} \left(1 + \sum_{i=2}^n e^{\frac{\lambda_i(X) - \lambda^{\max}(X)}{\mu}} \right) \right),$$

where $\lambda_i(X)$ is the i^{th} eigenvalue of X. This is also:

$$f_\mu(X) = \lambda^{\max}(X) + \mu \log \mathbf{Tr} \left(\exp \left(\frac{X - \lambda^{\max}(X)\mathbf{I}}{\mu} \right) \right), \tag{3.3}$$

which requires computing a matrix exponential at a numerical cost of $O(n^3)$. We then have

$$\lambda^{\max}(X) \leq f_\mu(X) \leq \lambda^{\max}(X) + \mu \log n,$$

so if we set $\mu = \epsilon / \log n$, $f_\mu(X)$ becomes a uniform ϵ-approximation of $\lambda^{\max}(X)$. In [16] it was shown that $f_\mu(X)$ has a Lipschitz continuous gradient with constant

$$L = \frac{1}{\mu} = \frac{\log n}{\epsilon}.$$

The gradient $\nabla f_\mu(X)$ can also be computed explicitly as

$$\frac{\exp \left(\frac{X - \lambda^{\max}(X)\mathbf{I}}{\mu} \right)}{\mathbf{Tr} \left(\exp \left(\frac{X - \lambda^{\max}(X)\mathbf{I}}{\mu} \right) \right)}, \tag{3.4}$$

using the same matrix exponential as in (3.3). Let $\|y\|$ be some norm on $\mathbf{R}^m$ and $d(x)$ a strongly convex prox-function with parameter $\sigma > 0$. As in [16], we define

$$\|A\| = \max_{\|h\|=1} \|A^T h\|_2,$$

where $\|A^T h\|_2 = \max_i |\lambda_i(A^T h)|$. The algorithm detailed in [15], where *exact* function values and gradients are computed, will find an ϵ solution to (3.1) after at most

$$\frac{2\|A\|}{\epsilon} \sqrt{\frac{\log n}{\sigma} d(y^\star)} \tag{3.5}$$

iterations, each iteration requiring a matrix exponential computation.

3.2. Spectrum and expected performance gains. The complexity estimate above is valid when the matrix exponential in (3.3) is computed exactly, at a cost of $O(n^3)$. As we will see below, only a few leading eigenvalues are sometimes required to satisfy conditions (2.3) and obtain a comparable complexity estimate at a much lower numerical cost. To illustrate the potential complexity gains, let us pick a matrix $X \in \mathbf{S}_n$ whose coefficients are centered independent normal variables with the second moment given by σ^2/n. From Wigner's semicircle law, $\lambda^{\max}(X) \sim 2\sigma$ as n goes to infinity, and the eigenvalues of X are asymptotically distributed according to the density

$$p(x) = \frac{1}{2\pi\sigma^2} \sqrt{4\sigma^2 - x^2},$$

which means that, in the limit, the proportion of eigenvalues required to reach a precision of γ in the exponential is given by

$$P_\lambda \triangleq P\left(e^{\frac{\lambda_i(X)-\lambda^{\max}(X)}{\mu}} \leq \gamma\right) = \int_{-2\sigma}^{2\sigma+\epsilon\frac{\log\gamma}{\log n}} \frac{1}{2\pi\sigma^2}\sqrt{4\sigma^2-x^2}dx.$$

Since the problems under consideration are relaxations of sparse principal component analysis (PCA), we can also consider the case where $X \in \mathbf{S}_n$ is sampled from the Wishart distribution. In that case, the eigenvalues are distributed according to the Marčenko–Pastur distribution (see [10]), and the above proportion becomes

$$P_\lambda = P\left(e^{\frac{\lambda_i(X)-\lambda^{\max}(X)}{\mu}} \leq \gamma\right) = \int_{-2\sigma}^{2\sigma+\epsilon\frac{\log\gamma}{\log n}} \frac{\sqrt{x(4\sigma-x)}}{2\pi x}dx.$$

With $n = 5000$, $\gamma = 10^{-6}$, and $\epsilon = 10^{-2}$, we get $nP_\lambda = 2.3$, so the approximations above would suggest that, in theory, it is only necessary to compute about three eigenvalues per iteration to get an approximation with precision $\gamma = 10^{-6}$. In practice, however, the results of section 4 show that these rough estimates should be significantly tempered.

3.3. Global complexity bound. Let us now focus on the following program:

$$\begin{array}{ll} \text{minimize} & \lambda^{\max}\left(A^Ty+c\right) \\ \text{subject to} & \|y\| \leq \beta, \end{array} \tag{3.6}$$

where the set Q is here explicitly given by

$$Q = \{y \in \mathbf{R}^p : \ \|y\| \leq \beta\}$$

for some $\beta > 0$ with $\|.\|$ the Euclidean norm here. We can pick $\|x\|^2/2$ as a prox-function for Q, which is strongly convex with convexity parameter 1. Let $\lambda(X) \in \mathbf{R}^n$ be the eigenvalues of the matrix $X = A^Ty + c$, in decreasing order, with $u_i(X) \in \mathbf{R}^n$ an orthonormal set of eigenvectors. The gradient matrix of $\exp(X/\mu)$ is written:

$$\nabla f_\mu(X) = \left(\sum_{i=1}^n e^{\frac{\lambda_i(X)}{\mu}}\right)^{-1} \sum_{i=1}^n e^{\frac{\lambda_i(X)}{\mu}} u_i(X)u_i(X)^T.$$

Suppose we compute only the first m eigenvalues and use them to approximate this gradient by

$$\tilde{\nabla} f_\mu(X) = \left(\sum_{i=1}^m e^{\frac{\lambda_i(X)}{\mu}}\right)^{-1} \sum_{i=1}^m e^{\frac{\lambda_i(X)}{\mu}} u_i(X)u_i(X)^T,$$

and we get the following bound on the error:

$$\|\nabla f_\mu(X) - \tilde{\nabla} f_\mu(X)\| \leq \frac{\sqrt{2}(n-m)e^{\frac{\lambda_m(X)-\lambda_1(X)}{\mu}}}{\left(\sum_{i=1}^m e^{\frac{\lambda_i(X)-\lambda_1(X)}{\mu}}\right)}.$$

In this case, with $X = A^Ty - c$ here, condition (2.3) means that we only need to compute m eigenvalues with m such that

$$\frac{\sqrt{2}(n-m)e^{\frac{\lambda_m(X)-\lambda_1(X)}{\mu}}}{\left(\sum_{i=1}^m e^{\frac{\lambda_i(X)-\lambda_1(X)}{\mu}}\right)} \leq \frac{\delta}{\sigma^{\max}(A)}, \tag{3.7}$$

where $\sigma^{\max}(A)$ is the largest singular value of the matrix A. Using the result in [16], if we define $\|A\| = \max_{\|h\|=1} \|Ah\|_2$ and set $\delta = \epsilon/6$, the algorithm in section 2 will then converge to an ϵ solution of problem (3.6) in at most

$$\frac{4\|A\|\beta}{\epsilon}\sqrt{\log n} \tag{3.8}$$

iterations. This bound on the number of iterations is independent of m in condition (3.7), i.e., the number of eigenvalues required at each iteration. The cost per iteration, however, varies with problem structure as each iteration requires computing m leading eigenvalues, which can be performed in $O(mn^2)$ operations. Note that partial eigenvalue decompositions only access the matrix through matrix-vector products (see [8]); hence, they can handle sparse problems very efficiently. The threshold δ can be adjusted empirically to trade off between the number of iterations and the numerical cost of each iteration. Unfortunately, we can't directly infer a bound on m from the structure of A, so in the next section we study the link between m and the matrix spectrum in numerical examples.

4. Examples and numerical performance. In this section, we illustrate the behavior of the approximate gradient algorithm on various semidefinite optimization problems. Overall, while there appears to be a direct link between problem structure and complexity (i.e., the number of eigenvalues required in the gradient approximation) in the first sparse PCA example discussed below, we will observe on random maximum eigenvalue minimization problems that predicting complexity based on overall problem structure remains an open numerical question in general.

4.1. Sparse principal component analysis. Based on the results in [3], the problem of finding a sparse leading eigenvector of a matrix $C \in \mathbf{S}_n$ can be written

$$\begin{array}{ll} \text{maximize} & x^T C x \\ \text{subject to} & \|x\|_2 = 1, \\ & \mathbf{Card}(x) \leq k, \end{array} \tag{4.1}$$

where $\mathbf{Card}(x)$ is the number of nonzero coefficients in x, and admits the following semidefinite relaxation:

$$\begin{array}{ll} \text{maximize} & \mathbf{Tr}(CX) - \rho \mathbf{1}^T |X| \mathbf{1} \\ \text{subject to} & \mathbf{Tr}(X) = 1, \\ & X \succeq 0, \end{array} \tag{4.2}$$

which is a semidefinite program in the variable $X \in \mathbf{S}^n$, where $\rho > 0$ is the penalty controlling the sparsity of the solution. Its dual is given by

$$\begin{array}{ll} \text{minimize} & \lambda^{\max}(C + U) \\ \text{subject to} & |U_{ij}| \leq \rho, \quad i, j = 1, \ldots, n, \end{array} \tag{4.3}$$

which is of the form (3.1) with

$$Q = \{U \in \mathbf{S}_n : \ |U_{ij}| \leq \rho, \ i, j = 1, \ldots, n\}.$$

The smooth algorithm detailed in section 2 is explicitly described for this problem in [3] and implemented in a numerical package called DSPCA which we have used in the examples here. To test its performance, we generate a matrix M with uniformly distributed coefficients in $[0, 1]$. We let $e \in \mathbf{R}^{250}$ be a sparse vector with

$$e = (1, 0, 1, 0, 1, 0, 1, 0, 1, 0, 0, 0, \ldots).$$

We then form a test matrix $C = M^T M + vee^T$, where v is a signal-to-noise ratio.

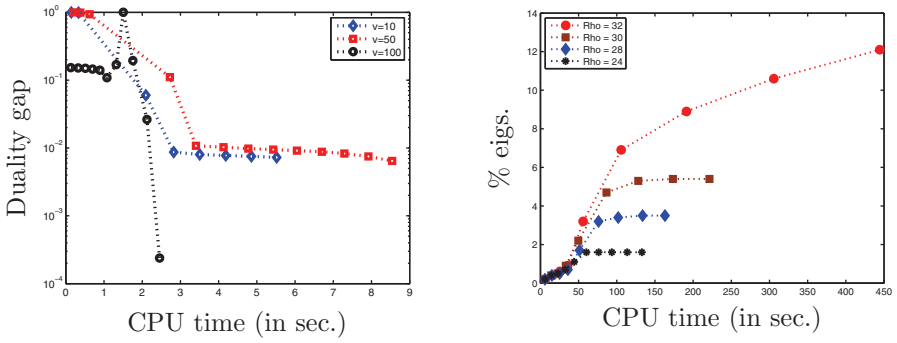

FIG. 4.1. *Left: Duality gap versus CPU time for various values of the signal-to-noise ratio v. Right: Percentage of eigenvalues required versus CPU time, for various values of the penalty parameter ρ controlling sparsity.*

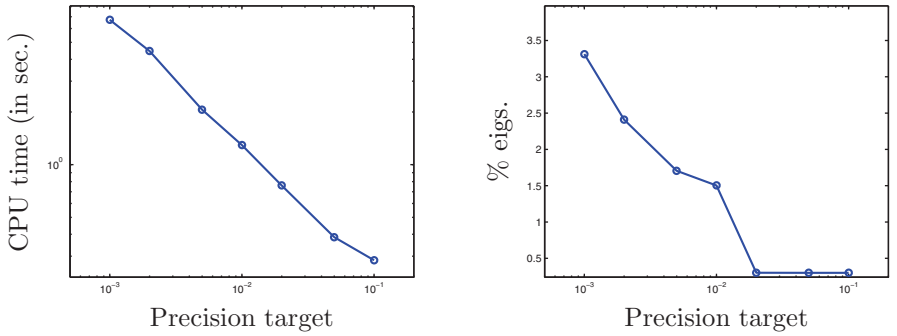

FIG. 4.2. *Left: CPU time (in seconds) versus target precision in loglog scale. Right: Average percentage of eigenvalues required at each iteration versus target precision, in semilog scale.*

In Figure 4.1 on the left, we plot duality gap versus CPU time used for values of the signal-to-noise ratio v ranging from 10 to 100. In Figure 4.1 on the right, we plot the number of eigenvalues required against computing time using a covariance matrix of dimension $n = 500$ sampled from the colon cancer data set in [1] and a noisy rank one matrix. Finally, we measure total computing time versus problem dimension n on this same data set, by solving problem (4.2) for increasingly large submatrices of the original covariance matrix. In each of these examples, we stop after the duality gap has been reduced by 10^{-2}, which is enough here to identify sparse principal components. In Figure 4.2 on the left, we plot computing time versus target precision in loglog scale, on a sparse PCA problem of size 200 extracted from the colon cancer data set. In the previous section, we have seen that precision impacts computing time both through the total number of iterations in (3.5) and through condition (3.7) on the number of eigenvalues required in the gradient approximation. In this example, we observe that CPU time increases a little bit slower than the upper bound of $O(1/\epsilon)$ given in (4.2). In Figure 4.2 on the right, we plot the average percentage of eigenvalues required at each iteration versus target precision, in semilog scale. We observe, on this example of dimension 200, that for low target precisions one eigenvalue is often enough to approximate the gradient but that this number quickly increases for higher precision targets. Note that in all cases, the precision targets are significantly lower than those achieved by interior point methods (usually at least 10^{-8}), but the cost

TABLE 4.1
CPU time (in seconds) versus problem dimension n for full and partial eigenvalue matrix exponential computations.

	$n = 100$	$n = 200$	$n = 500$
Rank one, full	3.2	8.0	14.7
Rank one, **partial**	0.4	0.75	1.6
Colon, full	2.6	18.1	274.3
Colon, **partial**	0.3	1.3	17.7

per iteration and storage requirements of the first-order algorithms detailed here are also significantly lower.

In Table 4.1, we then compare total CPU time using a full precision matrix exponential against CPU time using only a partial eigenvalue decomposition to approximate this exponential. Note that other classic methods for computing the matrix exponential, such as Padé approximations (see [11]), did not provide a significant performance benefit and are not included here. Both exact and approximate gradient codes are fully written in C, with partial eigenvalue decompositions computed using the FORTRAN package ARPACK (see [8]) with calls to vendor-optimized BLAS and LAPACK for matrix operations. To improve stability, the size of the Lanczos basis in ARPACK was set at four times the number of eigenvectors required. We observe that, on these problems, the partial eigenvalue decomposition method is about ten times faster.

4.2. Matrix structure and complexity: Open numerical issues. The previous section showed how the spectrum of the current iterate impacts the complexity of the algorithm detailed in this paper: a steeply decreasing spectrum allows fewer eigenvalues to be computed in the matrix exponential approximation, and a wider gap between eigenvalues improves the convergence rate of these eigenvalue computations. In this section, we study the number of eigenvalues required in randomly generated maximum eigenvalue minimization problems. Because of the measure concentration phenomenon, there is nothing really random about the spectrum of large-scale, naively generated semidefinite optimization problems, so we begin by detailing a simple method for generating random matrices with a given spectrum.

Generating random matrices with a given spectrum. Suppose $X \in \mathbf{S}_n$ is a matrix with normally distributed coefficients, $X_{ij} \sim \mathcal{N}(0,1)$, $i, j = 1, \ldots, n$. If we write its QR decomposition, $X = QR$ with $Q,\ R \in \mathbf{R}^{n\times n}$, then the orthogonal matrix Q is Haar distributed on the orthogonal group $\mathcal{O}_n$ (see [4], for example). This means that to generate a random matrix with given spectrum $\lambda \in \mathbf{R}^n$, we generate a normally distributed matrix X, compute its QR decomposition, and the matrix $Q\,\mathrm{diag}(\lambda)Q^T$ will be uniformly distributed on the set of symmetric matrices with spectrum λ.

Maximum eigenvalue minimization. We now form random maximum eigenvalue minimization problems and then study how the number of required eigenvalues in the gradient computation evolves as the solution approaches optimality. We solve the following problem:

$$\begin{array}{ll} \text{minimize} & \lambda^{\max}\left(A^T y + c\right) \\ \text{subject to} & \|y\| \leq \beta, \end{array}$$

in the variable $y \in \mathbf{R}^m$, where $c \in \mathbf{R}^{n^2}$, $A \in \mathbf{R}^{m\times n^2}$, and $\beta > 0$ is an upper bound on the norm of the solution. In Figure 4.3 we plot percentage of eigenvalues required in the gradient computation versus duality gap for randomly generated

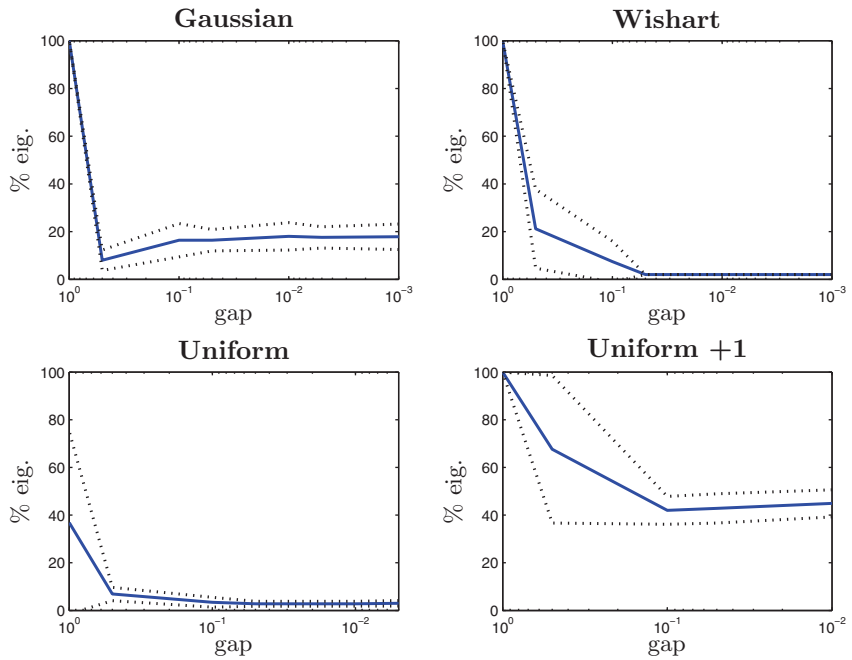

FIG. 4.3. *Average percentage of eigenvalues required (solid line) versus duality gap on randomly generated maximum eigenvalue minimization problems, for various problem matrix distributions. Dashed lines are at plus and minus one standard deviation.*

problem instances where $n = 50$ and $m = 25$. The first two plots use data matrices with Gaussian and Wishart distributions, whose spectrum are distributed according to Wigner's semicircle law and the Marčenko–Pastur distribution, respectively. The last two plots use the procedure described above to generate matrices with uniform spectrum on $[0, 1]$ and uniform spectrum on $[0, 1]$ with one eigenvalue set to 5. We observe that the number of eigenvalues required in the algorithm varies significantly with matrix spectrum.

Problem structure and effective complexity. The results on sparse PCA in section 4.1 and on the random problems of this section show that problem structure has a significant impact on performance. Predicting how many eigenvalues will be required at each iteration based on structural properties of the problem is an important but difficult question. In particular, the number of eigenvalues required in the Gaussian case is much higher than what the asymptotic analysis in section 3.2 predicted. Furthermore, in the sparse PCA example, complexity seems to vary with problem structure somewhat intuitively: a higher signal-to-noise ratio means lower complexity, and a higher sparsity target means higher complexity. However, this is not the case in the random problems studied here; two unstructured problems (uniform and Wishart) have low complexity, while one requires computing many more eigenvalues per iteration (Gaussian), and a more structured example (uniform plus rank one) also requires many eigenvalues. Overall then, predicting effective complexity (i.e., the number of eigenvalues required at each iteration) based on problem structure remains a difficult open question at this point.

Also, it is well known empirically (see [17], [9], and [18], among others) that the largest eigenvalues of $A^T y - c$ in (3.1) tend to coalesce near the optimum, thus

potentially increasing the number of eigenvalues required when computing $\tilde{\nabla} f(x)$ and the number of iterations required for computing leading eigenvalues (see [5], for example), but in these references, too, no a priori link between coalescence and problem structure is established. This coalescence phenomenon is never apparent in the numerical examples studied here, perhaps because it appears only at the much higher precision targets reached by interior point methods.

Acknowledgments. The author would like to thank Noureddine El Karoui for very useful comments.

A NEW UNBLOCKING TECHNIQUE TO WARMSTART INTERIOR POINT METHODS BASED ON SENSITIVITY ANALYSIS*

JACEK GONDZIO† AND ANDREAS GROTHEY†

Abstract. One of the main drawbacks associated with Interior Point Methods (IPMs) is the perceived lack of an efficient warmstarting scheme which would enable the use of information from a previous solution of a similar problem. Recently there has been renewed interest in the subject. A common problem with warmstarting for IPM is that an advanced starting point which is close to the boundary of the feasible region, as is typical, might lead to blocking of the search direction. Several techniques have been proposed to address this issue. Most of these aim to lead the iterate back into the interior of the feasible region—we classify them as either "modification steps" or "unblocking steps" depending on whether the modification is taking place before solving the modified problem to prevent future problems, or during the solution if and when problems become apparent. A new "unblocking" strategy is suggested which attempts to directly address the issue of blocking by performing sensitivity analysis on the Newton step with the aim of increasing the size of the step that can be taken. This analysis is used in a new technique to warmstart interior point methods: we identify components of the starting point that are responsible for blocking and aim to improve these by using our sensitivity analysis. The relative performance of a selection of different warmstarting techniques suggested in the literature and the new proposed unblocking by sensitivity analysis is evaluated on the warmstarting test set based on a selection of NETLIB problems proposed by [Benson and Shanno, *Comput. Optim. Appl.*, 38 (2007), pp. 371–399]. Warmstarting techniques are also applied in the context of solving nonlinear programming problems as a sequence of quadratic programs solved by interior point methods. We also apply the warmstarting technique to the problem of finding the complete efficient frontier in portfolio management problems (a problem with 192 million variables—to our knowledge the largest problem to date solved by a warmstarted IPM). We find that the resulting best combined warmstarting strategy manages to save between 50 and 60% of interior point iterations, consistently outperforming similar approaches reported in current optimization literature.

Key words. interior-point methods, warm-start, quadratic programming

1. Introduction.

Since their introduction, Interior Point Methods (IPMs) have been recognized as an invaluable tool to solve linear, quadratic, and nonlinear programming problems, in many cases outperforming traditional simplex and active set-based approaches. This is especially the case for large scale problems. One of the weaknesses of IPMs is, however, that unlike their active set-based competitors, they cannot easily exploit an advanced starting point obtained from the preceding solution process of a similar problem. Many optimization problems require the solution of a sequence of closely related problems, either as part of an algorithm (e.g., SQP, Branch & Bound) or as a direct application to a problem (e.g., finding the efficient frontier in portfolio optimization). Because of their weakness in warmstarting, IPMs have not made as big an impact in these areas.

Over the years there have been several attempts to improve the warmstarting capabilities of IPMs [5, 8, 15, 6, 1, 2, 10]. All of these, apart from [1, 2], involve

remembering a primal/dual iterate encountered during the solution of the original problem and using this (or some modification of it) as a starting point for the modified problem. All of these papers (apart from [2]) deal with the linear programming (LP) case, whereas we are equally interested in the quadratic programming (QP) case.

A typical way in which a 'bad' starting point manifests itself is *blocking*: The Newton direction from this point leads far outside the positive orthant, resulting in only a very small fraction of it to be taken. Consequently, the next iterate will be close to the previous one, and the search direction will likely block again. In our observation this blocking is usually due only to a small number of components of the Newton direction. We therefore suggest an unblocking strategy which attempts to modify these blocking components without disturbing the primal-dual direction too much. The unblocking strategy is based on performing sensitivity analysis of the primal-dual direction with respect to the components of the current primal/dual iterate.

As a separate thread to the paper, it is our feeling that a wealth of warmstarting heuristics have been proposed by various authors, each demonstrating improvements over a coldstarted IPM. However, there has been no attempt at comparing these in a unified environment, or indeed investigating how these might be combined. This paper will give an overview of some of the warmstarting techniques that have been suggested and explore what benefit can be obtained from combining them.

This will also set the scene for evaluating the new unblocking strategy derived in this paper, within a variety of different warmstarting settings.

We continue by stating the notation used in this paper. In section 3, we review traditionally used warmstart strategies. In section 4 we present the new unblocking techniques based on sensitivity analysis. Numerical comparisons as to the efficiency of the suggested techniques are reported in section 5. In section 6, we draw our conclusions.

2. Notation and background. The infeasible primal dual interior point methods applied to solve the quadratic programming problem

$$\begin{aligned} \min \quad & c^T x + \frac{1}{2} x^T Q x \\ \text{s.t.} \quad & Ax = b \\ & x \geq 0 \end{aligned} \tag{1}$$

can be motivated from the KKT conditions for (1)

$$c + Qx - A^T y - z = 0 \tag{2a}$$

$$Ax = b \tag{2b}$$

$$XZe = \mu e \tag{2c}$$

$$x, z \geq 0, \tag{2d}$$

where the zero right-hand side of the complementary products has been replaced by the centrality parameter $\mu > 0$. The set of solutions to (2) for different values of μ is known as the *central path*. It is beneficial in this context to consider two neighborhoods of the central path, the N_2 neighborhood

$$N_2(\theta) := \left\{ (x, y, z) : Ax = b, A^T y - Qx + z = c, \|XZe - \mu e\|_2 \leq \theta \right\}$$

and the wider $N_{-\infty}$ neighborhood

$$N_{-\infty}(\gamma) := \left\{ (x, y, z) : Ax = b, A^T y - Qx + z = c, x_i z_i \geq \gamma \mu \right\}.$$

Assume that at some stage during the algorithm the current iterate is (x, y, z). Our variant of the predictor-corrector algorithm [4, 7] will calculate a predictor direction $(\Delta x_p, \Delta y_p, \Delta z_p)$ as the Newton direction for system (2) and a small μ-target $(\mu^0 \approx 0.001\frac{x^T z}{n})$:

$$\begin{array}{lll} -Q\Delta x_p + A^T\Delta y_p + \Delta z_p = c + Qx - A^T y - z = \xi_c \\ A\Delta x_p \qquad\qquad\quad = b - Ax \qquad\quad = \xi_b \\ X\Delta z_p + Z\Delta x_p \qquad = \mu^0 e - XZe \qquad = r_{xz}, \end{array} \tag{3}$$

which can be further condensed by using the third equation to eliminate Δz_p

$$\begin{bmatrix} -Q - X^{-1}Z & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta x_p \\ \Delta y_p \end{bmatrix} = \begin{bmatrix} r_x \\ r_y \end{bmatrix} := \begin{bmatrix} \xi_c - X^{-1} r_{xz} \\ \xi_b \end{bmatrix} \tag{4a}$$

$$\Delta z_p = X^{-1} r_{xz} - X^{-1} Z \Delta x_p. \tag{4b}$$

As in Mehrotra's predictor-corrector algorithm [13], we calculate maximal primal and dual stepsizes for the predictor direction

$$\bar{\alpha}_p = \max\{\alpha > 0 : x + \alpha\Delta x_p \geq 0\}, \quad \bar{\alpha}_d = \max\{\alpha > 0 : z + \alpha\Delta z_p \geq 0\}$$

and determine a target μ-value by

$$\mu = \frac{[(x + \bar{\alpha}_p\Delta x_p)^T (z + \bar{\alpha}_d \Delta z_p)]^3}{n(x^T z)^2}.$$

With these we compute the corrector direction $(\Delta x_c, \Delta y_c, \Delta z_c)$ by

$$\begin{array}{ll} A^T\Delta y_c + \Delta z_c &= 0 \\ A\Delta x_c &= 0 \\ X\Delta z_c + Z\Delta x_c &= (\mu - \mu^0)e - \Delta X_p \Delta Z_p e, \end{array} \tag{5}$$

and finally the new primal and dual stepsizes and the new iterate (x^+, z^+) as

$$\begin{aligned} \alpha_p &= 0.995 \max\{\alpha > 0 : x + \alpha(\Delta x_p + \Delta x_c) \geq 0\} \\ \alpha_d &= 0.995 \max\{\alpha > 0 : z + \alpha(\Delta z_p + \Delta z_c) \geq 0\} \\ x^+ &= x + \alpha_p(\Delta x_p + \Delta x_c), \quad z^+ = z + \alpha_d(\Delta z_p + \Delta z_c). \end{aligned}$$

Our main interest is generating a good starting point for the QP problem (1) — the *modified problem* — from the solution of a previously solved similar QP problem

$$\begin{array}{ll} \min & \tilde{c}^T x + \frac{1}{2} x^T \tilde{Q} x \\ \text{s.t.} & \tilde{A}x = \tilde{b} \\ & x \geq 0, \end{array} \tag{6}$$

the *original problem*. The difference between the two problems, i.e., the change from the original problem to the second problem, is denoted by

$$(\Delta A, \Delta Q, \Delta c, \Delta b) = \big(A - \tilde{A}, Q - \tilde{Q}, c - \tilde{c}, b - \tilde{b}\big).$$

3. Warmstart heuristics. Unlike the situation in the Simplex Method, for IPMs it is not a good strategy to use the optimal solution of a previously solved problem as the new starting point for a similar problem. This is because problems are often ill-conditioned; hence the final solution of the original problem might be far away from the central path of the modified problem. Furthermore, [9] demonstrates that the predictor direction tends to be parallel to nearby constraints, resulting in difficulties to drop misidentified nonbasic variables.

Over the years numerous contributions [11, 5, 8, 15, 6] have addressed this problem, with renewed interest in the subject from [1, 2, 10] over the last year. With the exception of [1, 2] which use an L_1-penalty reformulation of the problem that has better warmstarting capabilities, all remedies follow a common theme: They identify an advanced center [5], a point close to the central path of the original problem (usually a nonconverged iterate), and **modify** it in such a manner that the modified point is close to the central path of the new problem. Further, in the first few iterations of the reoptimization, additional techniques which address the issue of getting stuck at nearby constraints may be employed. In this paper these will be called **unblocking heuristics**. The generic IPM warmstarting algorithm is as follows:

Algorithm: Generic Interior Point Warmstart

1. Solve the original problem (6) by an Interior Point Algorithm. From it choose one of (or a selection of) the iterates $(\tilde{x}, \tilde{y}, \tilde{z}, \tilde{\mu})$ encountered during the solution process. We will assume that this iterate (or any one of these iterates) satisfies

$$\begin{aligned} \tilde{c} + \tilde{Q}\tilde{x} - \tilde{A}^T\tilde{y} - \tilde{z} &= 0 \\ \tilde{b} - \tilde{A}\tilde{x} &= 0 \\ \tilde{x}_i\tilde{z}_i \approx \tilde{\mu} \qquad & \forall i = 1, \ldots, n. \end{aligned}$$

2. **Modify** the chosen iterate to obtain a starting point (x, y, z, μ) for the modified problem.

3. Solve the modified problem by an Interior Point Algorithm using (x, y, z, μ) as the starting point. During the first few iterations of the IPM a special **unblocking step** might be taken.

The question arises as to what should guide the construction of modification and unblocking steps. It is well known that for a feasible method (i.e., $\xi_b = \xi_c = 0$), a well-centered point (i.e., in $N_2(\theta)$ or $N_{-\infty}(\gamma)$) and a small target decrease ($\mu \lessapprox \mu^0$), and the Newton step is feasible. Analysis by [15] and [6] identifies two factors that lead to the ability of IPMs to absorb infeasibilities ξ_b, ξ_c present at the starting point. Firstly, the larger the value of μ the more infeasibility can be absorbed in one step. Secondly, the centrality of the iterate: from a well-centered point the IPM can again absorb more infeasibilities. Using these general guidelines, a number of different warmstarting techniques have been suggested. We review some of them here:

Modification Steps:

(i) *Shift small components*: [11] shift $\tilde{x}, \tilde{z}$ by $h_x = \epsilon D^{-1}e, h_z = \epsilon De$, where $D = \text{diag}\{\|a_j\|_1\}$ and a_j is the jth column of A to ensure $x_i z_i \geq \gamma\mu$ for some small $\gamma > 0$, i.e., improve centrality by aiming for a point in $N_{-\infty}(\gamma)$.

(ii) References [15, 10] suggest a *Weighted Least Squares Step* (WLS) that finds the minimum step (with respect to a weighted 2-norm) from the starting point, to

a point that is both primal and dual feasible. The WLS step does not necessarily preserve positiveness of the iterate. To overcome this, [15] suggests keeping a selection of potential warmstart iterates and retracing to one corresponding to a large μ, which will guarantee that the WLS step is feasible. Since we do not want to remember several different points from the solution of the original problem, we will take a fraction of the WLS step should the full step be infeasible. Mehrotra's starting point [13] can be seen as a (damped) WLS step from the origin.

(iii) References [15, 10] further suggest a *Newton Modification Step*, i.e., an interior point step (3) correcting only for the primal and dual infeasibilities introduced by the change of problem, with no attempt to improve centrality: (3) is solved with $r_{xz} = 0$. Again only a fraction of this step might be taken.

Unblocking Heuristics

(i) *Splitting Directions*: Reference [6] advocates computing separate search directions aimed at achieving primal feasibility, dual feasibility, and centrality separately. These are combined into the complete step by taking the maximum of each step that can be taken without violating the positivity of the iterates. A possible interpretation of this strategy is to emulate a gradual change from the original problem to the modified problem where for each change the modification step is feasible.

(ii) *Higher Order Correctors*: The $\Delta X_p \Delta Z_p$ component in (5) is a correction for the linearization error in $XZe - \mu e = 0$. A corrector of this type can be repeated several times. Reference [5] employs this idea by additionally correcting only for small complementary products to avoid introducing additional blocking. This is used in [6] as an unblocking technique with the interpretation of choosing a target complementary vector $\bar{t} \approx \mu e$ in such a way that a large step in the resulting Newton direction is feasible, aiming to absorb as much of the primal/dual infeasibility as possible in the first step.

(iii) *Change Diagonal Scaling:* Reference [9] investigates changing elements in the scaling matrix $\Theta = XZ^{-1}$ to make nearby constraints repelling rather than attracting to the Newton step. However, we are not aware of any implementation of this technique in a warmstarting context.

A number of additional interesting techniques are listed here and described below:

(i) *Dual adjustment*: Adjust advanced starting point $\tilde{z}$ to compensate for changes to c, A, and Q in the dual feasibility constraint (2a).

(ii) *Additional centering* iterations before the advanced starting point is used.

(iii) Unblocking of the step direction by *sensitivity analysis*.

We will give a brief description of the first two of these strategies. The third (unblocking by sensitivity analysis) is the subject of section 4.

Dual adjustment

Using $(\tilde{x}, \tilde{y}, \tilde{z})$ as a starting point in problem (1) will result in the initial dual infeasibility

$$\xi_c = c + Q\tilde{x} - A^T\tilde{y} - \tilde{z} = \Delta c + \Delta Q\tilde{x} - \Delta A^T\tilde{y}.$$

Setting $z = \tilde{z} + \Delta z$, where $\Delta z = \Delta c + \Delta Q\tilde{x} - \Delta A^T\tilde{y}$, would result in a point satisfying the dual feasibility constraint (2a). However, the conditions $z \geq 0$ and $x_i z_i \approx \mu$ are likely violated by this, so instead we set

$$z_i = \max\{\tilde{z}_i + \Delta z_i, \min\{\sqrt{\mu}, \tilde{z}_i/2\}\};$$

i.e., we try to absorb as much of the dual infeasibility into z as possible without decreasing z either below $\sqrt{\mu}$ or half its value.

Adjusting the saved iterate $(\tilde{x}, \tilde{y}, \tilde{z})$ in a minimal way to absorb primal/dual infeasibilities is similar in spirit to the WLS modification step. Unlike this, however, direct adjustment of z is much cheaper to compute.

Additional centering iterations

The aim of improving the centrality of the saved iterate can also be achieved by performing an additional pure centering iteration, i.e., choose $\xi_c = \xi_b = 0, \mu^0 = x^T z/n$ in (3), in the original problem before saving the iterate as a starting point for the new problem. This pure centering iteration could be performed with respect to the original or the modified problem. In the latter case, this is similar in spirit to the Newton Modification Step of [15, 10] (whereas [15, 10] use $r_{xz} = 0$, we use $r_{xz} = \mu^0 e - \tilde{X}\tilde{Z}$ with $\mu^0 = \tilde{x}^T\tilde{z}/n$. In the case of a perfectly centered saved iterate—as we hope to achieve at least approximately by the previous centering in the original problem—these two are identical). We refer to these as centering iteration at the *beginning* of solving the modified problem or at the *end* of solving the original problem.

In the next section we will derive the unblocking strategy based on sensitivity analysis.

4. Unblocking by sensitivity analysis.

4.1. Sensitivity analysis. In this section we will lay the theoretical foundations for our proposed unblocking strategy. Much of it is based on the observation that the advanced starting information (x, y, z, μ) with which to start the solution of the modified problem is to some degree arbitrary. It is therefore possible to treat it as parameters to the solution process and to explore how certain properties of the solution process change as the starting point is changed. In particular we are interested in the primal and dual stepsizes that can be taken for the Newton direction computed from this point.

At some iterate (x, y, z) of the IPM, the primal-dual direction $(\Delta x, \Delta y, \Delta z)$ is obtained as the solution to the system (3) or (4) for some target value μ^0. If we think of (x, y, z) as the advanced starting point, the step $(\Delta x, \Delta y, \Delta z)$ can be obtained as a function of the current point (x, y, z). The aim of this section is to derive a procedure by which the sensitivity of $\Delta x(x, y, z)$, $\Delta y(x, y, z)$, $\Delta z(x, y, z)$, that is the first derivatives of these functions can be computed.

First note that the value of y has no influence on the new step $\Delta x, \Delta z$. This is because after substituting for ξ_b, ξ_c, r_{xz} in (4a)

$$\begin{bmatrix} -Q - X^{-1}Z & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} = \begin{bmatrix} c + Qx - A^T y - \mu X^{-1} e \\ b - Ax \end{bmatrix}$$

we can rewrite this as

$$\begin{bmatrix} -Q - X^{-1}Z & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ y^{(k+1)} \end{bmatrix} = \begin{bmatrix} c + Qx - \mu X^{-1} e \\ b - Ax \end{bmatrix} \tag{7}$$

with $\Delta y = y^{(k+1)} - y$. In effect (7) solves for the new value of $y^{(k+1)} = y^{(k)} + \Delta y$ directly, whereas all influence of y onto $\Delta x, \Delta z$ has been removed. Notice also that only the step components in x, z variables can lead to a blocking of the step; therefore we are interested only in the functional relationship and sensitivity for the functions $\Delta x = \Delta x(x, z), \Delta z = \Delta z(x, z)$. To this end we start by differentiating with respect to

x_i in (3):

$$-Q\frac{\mathrm{d}\Delta x}{\mathrm{d}x_i} + A^T\frac{\mathrm{d}\Delta y}{\mathrm{d}x_i} + \frac{\mathrm{d}\Delta z}{\mathrm{d}x_i} = Qe_i, \tag{8a}$$

$$A\frac{\mathrm{d}\Delta x}{\mathrm{d}x_i} = -Ae_i, \tag{8b}$$

$$X\frac{\mathrm{d}\Delta z}{\mathrm{d}x_i} + Z\frac{\mathrm{d}\Delta x}{\mathrm{d}x_i} + \Delta Ze_i = -Ze_i. \tag{8c}$$

Note that this result is independent of the value of μ^0 that is used as a target. Similarly, differentiating with respect to y_i yields

$$-Q\frac{\mathrm{d}\Delta x}{\mathrm{d}y_i} + A^T\frac{\mathrm{d}\Delta y}{\mathrm{d}y_i} + \frac{\mathrm{d}\Delta z}{\mathrm{d}y_i} = -A^Te_i \tag{9a}$$

$$A\frac{\mathrm{d}\Delta x}{\mathrm{d}y_i} = 0 \tag{9b}$$

$$X\frac{\mathrm{d}\Delta z}{\mathrm{d}y_i} + Z\frac{\mathrm{d}\Delta x}{\mathrm{d}y_i} = 0, \tag{9c}$$

and finally differentiating with respect to z_i yields

$$-Q\frac{\mathrm{d}\Delta x}{\mathrm{d}z_i} + A^T\frac{\mathrm{d}\Delta y}{\mathrm{d}z_i} + \frac{\mathrm{d}\Delta z}{\mathrm{d}z_i} = -e_i \tag{10a}$$

$$A\frac{\mathrm{d}\Delta x}{\mathrm{d}z_i} = 0 \tag{10b}$$

$$X\frac{\mathrm{d}\Delta z}{\mathrm{d}z_i} + Z\frac{\mathrm{d}\Delta x}{\mathrm{d}z_i} + \Delta Xe_i = -Xe_i. \tag{10c}$$

Taking all three systems together we have

$$\begin{bmatrix} -Q & A^T & I \\ A & 0 & 0 \\ Z & 0 & X \end{bmatrix} \begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}x} & \frac{\mathrm{d}\Delta x}{\mathrm{d}y} & \frac{\mathrm{d}\Delta x}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}x} & \frac{\mathrm{d}\Delta y}{\mathrm{d}y} & \frac{\mathrm{d}\Delta y}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}x} & \frac{\mathrm{d}\Delta z}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} \end{bmatrix} = \begin{bmatrix} Q & -A^T & -I \\ -A & 0 & 0 \\ -Z-\Delta Z & 0 & -X-\Delta X \end{bmatrix}. \tag{11}$$

Under the assumption that A has full row rank, the system matrix is nonsingular, therefore

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}x_i} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}x_i} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}x_i} \end{bmatrix} = \begin{bmatrix} -e_i \\ 0 \\ 0 \end{bmatrix} + \Delta z_i \begin{bmatrix} -Q & A^T & I \\ A & 0 & 0 \\ Z & 0 & X \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 0 \\ -e_i \end{bmatrix} \tag{12a}$$

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}y_i} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}y_i} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}y_i} \end{bmatrix} = \begin{bmatrix} 0 \\ -e_i \\ 0 \end{bmatrix} \tag{12b}$$

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}z_i} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}z_i} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}z_i} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ -e_i \end{bmatrix} + \Delta x_i \begin{bmatrix} -Q & A^T & I \\ A & 0 & 0 \\ Z & 0 & X \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 0 \\ -e_i \end{bmatrix}, \tag{12c}$$

where the system common to (12a/12c)

$$\begin{bmatrix} -Q & A^T & I \\ A & 0 & 0 \\ Z & 0 & X \end{bmatrix} \begin{bmatrix} \widetilde{d\Delta x} \\ \widetilde{d\Delta y} \\ \widetilde{d\Delta z} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ -e_i \end{bmatrix} \tag{13}$$

can be solved by using the third line to substitute for $\widetilde{d\Delta z}$ as

$$\begin{bmatrix} -Q - X^{-1}Z & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \widetilde{\mathrm{d}\Delta x} \\ \widetilde{\mathrm{d}\Delta y} \end{bmatrix} = \begin{bmatrix} X^{-1}e_i \\ 0 \end{bmatrix} \tag{14a}$$

$$\widetilde{\mathrm{d}\Delta z} = -X^{-1}Z\widetilde{\mathrm{d}\Delta x} - X^{-1}e_i. \tag{14b}$$

There are a few insights to be gained from these formulas. First, they confirm that the step $(\Delta x, \Delta z)$ does not depend on y.

Second, the *sensitivity* of the primal-dual step with respect to the current iterate (x, y, z)—unlike the step $(\Delta x, \Delta y, \Delta z)$ itself—does not depend on the target value μ^0 either. We will exploit this property when constructing a warmstart heuristic that uses the sensitivity information.

Finally we can get the complete sensitivity information with respect to (x_i, z_i) for a given component i by solving a single system of linear equations with the same augmented system matrix that has been used to obtain the step $(\Delta x, \Delta y, \Delta z)$ (and for which a factorization is available); the solution of n such systems will likewise retrieve the complete sensitivity information.

Although this system matrix is already factorized as part of the normal interior point algorithm, and backsolves are an order of magnitude cheaper than the factorization, obtaining the complete sensitivity information is prohibitively expensive. The aim of the following section is therefore to propose a warmstarting heuristic that uses the sensitivity information derived above, but requires only a few, rather than all n backsolves.

4.2. Unblocking the primal-dual direction using sensitivity information. Occasionally, despite all our attempts, a starting point might result in a Newton direction that leads to blocking: i.e., only a very small step can be taken along it. We do not want to abandon the advanced starting information at this point, but rather try to *unblock* the search direction. To this end we will make use of the sensitivity analysis presented in section 4.1. The following Lemma 1 gives conditions under which a step (d_x, d_z) can be expected to unblock based on the sensitivity analysis.

LEMMA 1. *A necessary and sufficient condition for a step (d_x, d_z) to unblock to first order to a given level ρl, i.e.,*

$$x + d_x + \Delta x + \frac{\mathrm{d}\Delta x}{\mathrm{d}x} d_x + \frac{\mathrm{d}\Delta x}{\mathrm{d}z} d_z \geq \rho l, \tag{15a}$$

$$z + d_z + \Delta z + \frac{\mathrm{d}\Delta z}{\mathrm{d}x} d_x + \frac{\mathrm{d}\Delta z}{\mathrm{d}z} d_z \geq \rho l, \tag{15b}$$

is that there exists vectors d_x, d_z, t_x, t_y, t_z of appropriate dimensions that satisfy the system of equations

$$At_x = 0 \tag{16a}$$

$$-Qt_x + A^T t_y + t_z = 0 \tag{16b}$$

$$Zt_x + Xt_z = -\Delta Z d_x - \Delta X d_z \tag{16c}$$

$$t_x \geq -x - \Delta x + \rho l \tag{16d}$$

$$t_z \geq -z - \Delta z + \rho l \tag{16e}$$

Proof. Note that the relations of (11),(12) can be more concisely written as

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}x} + I & \frac{\mathrm{d}\Delta x}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}x} & \frac{\mathrm{d}\Delta y}{\mathrm{d}y} + I & \frac{\mathrm{d}\Delta y}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}x} & \frac{\mathrm{d}\Delta z}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} + I \end{bmatrix} = - \begin{bmatrix} -Q & A^T & I \\ A & 0 & 0 \\ Z & 0 & X \end{bmatrix}^{-1} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ \Delta Z & 0 & \Delta X \end{bmatrix}. \tag{17}$$

Conditions (15) are equivalent to the existence of (d_x, d_y, d_z) such that

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}x} + I & \frac{\mathrm{d}\Delta x}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}x} & \frac{\mathrm{d}\Delta y}{\mathrm{d}y} + I & \frac{\mathrm{d}\Delta y}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}x} & \frac{\mathrm{d}\Delta z}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} + I \end{bmatrix} \begin{bmatrix} d_x \\ d_y \\ d_z \end{bmatrix} \geq \begin{bmatrix} -x - \Delta x + \rho l \\ -\infty \\ -z - \Delta z + \rho l \end{bmatrix}, \tag{18}$$

where d_y is an arbitrary vector (note that $\frac{\mathrm{d}\Delta x}{\mathrm{d}y} = \frac{\mathrm{d}\Delta z}{\mathrm{d}y} = 0$). This, on the other hand, is satisfied, if and only if there exists (t_x, t_y, t_z) such that

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}x} + I & \frac{\mathrm{d}\Delta x}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta y}{\mathrm{d}x} & \frac{\mathrm{d}\Delta y}{\mathrm{d}y} + I & \frac{\mathrm{d}\Delta y}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}x} & \frac{\mathrm{d}\Delta z}{\mathrm{d}y} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} + I \end{bmatrix} \begin{bmatrix} d_x \\ d_y \\ d_z \end{bmatrix} = \begin{bmatrix} t_x \\ t_y \\ t_z \end{bmatrix} \geq \begin{bmatrix} -x - \Delta x + \rho l \\ -\infty \\ -z - \Delta z + \rho l \end{bmatrix}. \tag{19}$$

Now using (17) to substitute for the matrix of derivatives, multiplying both sides of the equality with the augmented system matrix and multiplying out we see that (19) is equivalent to

$$\begin{bmatrix} 0 \\ 0 \\ -\Delta X d_z - \Delta Z d_x \end{bmatrix} = \begin{bmatrix} -Q & A^T & I \\ A & 0 & 0 \\ Z & 0 & X \end{bmatrix} \begin{bmatrix} t_x \\ t_y \\ t_z \end{bmatrix}, \quad \begin{bmatrix} t_x \\ t_y \\ t_z \end{bmatrix} \geq \begin{bmatrix} -x - \Delta x + \rho l \\ -\infty \\ -z - \Delta z + \rho l \end{bmatrix}$$

that is to (16). ∎

The sensitivity analysis thus gives us conditions that an unblocking direction needs to satisfy. However it is unclear if a direction (d_x, d_z) and the corresponding (t_x, t_y, t_z) to satisfy the conditions of Lemma 1 exist. We can however prove existence of such a direction by assuming that we know the analytic center $\hat{p} = (\hat{x}, \hat{y}, \hat{z})$ of the problem (or indeed any strictly primal-dual feasible point) and denote by $\underline{\hat{p}}, \hat{\bar{p}}$ its largest and smallest component:

$$0 < \underline{\hat{p}} \leq \hat{x}_i, \hat{z}_i \leq \hat{\bar{p}}$$

LEMMA 2. *For all $l : 0 < l < \min\{\underline{\hat{p}}/4, 1\}$, $\rho < 1$ and fixed μ and γ there exists a $c = c(\gamma, \mu)$ such that for all starting points (x, y, z) and corresponding blocking step*

$(\Delta x, \Delta y, \Delta z)$ *obtained from* (3) *with* $\mu^0 = \mu^+$ *satisfying*

$$x^T z/n = \mu, \quad x_i z_i \geq \gamma\mu, \quad x_i \leq b_u, z_i \leq b_u, \quad \mu^+ \leq \frac{1}{2}\gamma\mu,$$
$$z + \Delta z \geq -le, \quad x + \Delta x \geq -le,$$

there exists a step $(d_x, d_z) : \|d_x, d_z\|_\infty \leq c(1+\rho)l$ *that unblocks to first order to level* ρL*, i.e., that satisfies conditions* (15).

Proof. With $\alpha = 2(1+\rho)l/\underline{\hat{p}}$ set

$$t_x = \alpha(\hat{x} - (x + \Delta x)),$$
$$t_y = \alpha(\hat{y} - (y + \Delta y)),$$
$$t_z = \alpha(\hat{z} - (z + \Delta z)).$$

We will show that (t_x, t_y, t_z) satisfies (16a/b/d/e), that we can construct a corresponding (d_x, d_z) satisfying (16c), and finally that $(t_x, t_y, t_z), (d_x, d_z) = \mathcal{O}((1+\rho)l)$.

First we notice that both $\hat{p} = (\hat{x}, \hat{y}, \hat{z})$ and $(x + \Delta x, y + \Delta y, z + \Delta z)$ are primal and dual feasible (although in the latter case, of course, not positive). Hence, their difference (and therefore (t_x, t_y, t_z)) satisfies (16a/b).

To proof (16d) we need to distinguish the two cases: $x_i + \Delta x_i < \rho l$ and $x_i + \Delta x_i \geq \rho l$. In the first case $x_i + \Delta x_i < \rho l$ we have

$$\hat{x}_i - (x_i + \Delta x_i) \geq \underline{\hat{p}} - \rho l \geq \frac{1}{2}\underline{\hat{p}},$$

where the last inequality is due to $\rho \leq 1$ and $l \leq \underline{\hat{p}}/4$. Then

$$t_{x,i} = \frac{2(1+\rho)l}{\underline{\hat{p}}}(\hat{x}_i - (x_i + \Delta x_i)) \geq \frac{2(1+\rho)l}{\underline{\hat{p}}}\frac{1}{2}\underline{\hat{p}} = (1+\rho)l \geq -x_i - \Delta x_i + \rho l.$$

In the second case $x_i + \Delta x_i \geq \rho l$, we note that $\hat{x}_i \geq \underline{\hat{p}} \geq 4l \geq \rho l$. Since $2(1+\rho) \leq 4$ we have $0 < \alpha \leq 1$, and hence

$$x_i + \Delta x_i + \alpha(\hat{x}_i - (x_i + \Delta x_i)) = (1-\alpha)(x_i + \Delta x_i) + \alpha\hat{x}_i \geq \rho l,$$

which proves (16d). (16e) is proven in the same manner.

Next we establish a bound for $\|t_x\|, \|t_z\|$. Since $\mu^+ < \gamma\mu/2$ we have from the last equation of (3):

$$x_i\Delta z_i + z_i\Delta x_i = \mu^+ - x_i z_i \leq \frac{1}{2}\gamma\mu - \gamma\mu = -\frac{1}{2}\gamma\mu < 0, \tag{20}$$

and hence at least one of $\Delta x_i, \Delta z_i$ must be negative. Assume w.l.o.g. that $\Delta x_i < 0$. Then $x_i + \Delta x_i \geq -l$ implies

$$|\Delta x_i| = -\Delta x_i \leq l + x \leq l + b_u.$$

We can make no further assumptions on the sign of Δz_i. If $\Delta z_i < 0$, then $|\Delta z_i|$ is bounded in the same way as Δx_i. If, on the other hand, $\Delta z_i \geq 0$, then (20) together with $x_i \geq \gamma/z_i > \gamma/b_u$ implies

$$\Delta z_i < -z_i\Delta x_i/x_i < b_u(l + b_u)b_u/\gamma = b_u^2(l + b_u)/\gamma.$$

Since we can reasonably assume that $b_u^2/\gamma > 1$, we have

$$\|\Delta x\|, \|\Delta z\| \le b_u^2(1+b_u)/\gamma.$$

From this we get

$$\|t_x\| = \alpha\|\hat{x} - (x+\Delta x)\| \le \frac{2(1+\rho)l}{\underline{\hat{p}}}(\hat{\bar{p}} + b_u + b_u^2(1+b_u)/\gamma) = c_1(1+\rho)l,$$

where $c_1 = c_1(\gamma) = 2(\hat{\bar{p}} + b_u + b_u^2(1+b_u)/\gamma)/\underline{\hat{p}}$. $\|t_z\| \le c_1(1+\rho)l$ follows in the same manner.

Finally we know from (20) that for all i at least one of $x_i\Delta z_i, z_i\Delta x_i$ must be less than $-\gamma\mu/4$. Assume w.l.o.g. $z_i\Delta x_i < -\gamma\mu/4$, and then we get

$$\Delta x_i < -\frac{\gamma\mu}{4z_i} < 0. \tag{21}$$

Therefore we can set

$$d_{z,i} = -\frac{z_i t_{x,i} + x_i t_{z,i}}{\Delta x_i}, \quad d_{x,i} = 0 \tag{22}$$

(and vice versa if $x_i\Delta z_i < -\gamma\mu/4$) to construct a direction (d_x, d_z) that satisfies (16c). It remains to be shown that $(d_x, d_z) = \mathcal{O}((1+\rho)l)$:

From (21) we know

$$|\Delta x_i| = -\Delta x_i > \frac{\gamma\mu}{4z_i} > \frac{\gamma\mu}{4b_u};$$

hence (22) gives

$$|d_{z,i}| \le (b_u c_1(1+\rho)l + b_u c_1(1+\rho)l)/\frac{\gamma\mu}{4b_u} = \frac{8b_u^2 c_1}{\gamma\mu}(1+\rho)l := c(1+\rho)l$$

with $c = c(\gamma,\mu) = (8b_u^2 c_1)/(\gamma\mu)$. ∎

We can now proof the main result of this section.

THEOREM 1. *There exists $L > 0$ such that for all $l : 0 < l < L$ and all starting points (x,y,z) and their corresponding blocking step $(\Delta x, \Delta y, \Delta z)$ obtained from* (3) *with $\mu^0 = \mu^+$ that satisfy*

$$x^T z/n = \mu, \quad x_i z_i \ge \gamma\mu, \quad x_i, z_i \le b_u, \quad \mu^+ < \frac{1}{2}\gamma\mu, \quad x + \Delta x \ge -le, \quad z + \Delta z \ge -le,$$

there is a step (d_x, d_z) that unblocks, i.e.,

$$x + d_x + \Delta x(x+d_x, z+d_z) \ge 0,$$
$$z + d_z + \Delta z(x+d_x, z+d_z) \ge 0.$$

Proof. Set $\epsilon = \frac{1}{10c}$. From the differentiability of $\Delta x(x,z), \Delta z(x,z)$ there exists a δ such that for all $(d_x, d_z) : \|(d_x, d_z)\|_\infty \le \delta$:

$$\begin{aligned} \left\| \Delta x(x+d_x, z+d_z) - \Delta x - \frac{\mathrm{d}\Delta x}{\mathrm{d}x} d_x - \frac{\mathrm{d}\Delta x}{\mathrm{d}z} d_z \right\| &\le \epsilon\|(d_x, d_z)\|, \\ \left\| \Delta z(x+d_x, z+d_z) - \Delta z - \frac{\mathrm{d}\Delta z}{\mathrm{d}x} d_x - \frac{\mathrm{d}\Delta z}{\mathrm{d}z} d_z \right\| &\le \epsilon\|(d_x, d_z)\|. \end{aligned} \tag{23}$$

Now set $\rho = \frac{1}{4}$ and $L = \min\{\frac{\hat{p}}{4}, \frac{4}{5}\frac{\delta}{c}\}$. Then from Lemma 2 there exists (d_x, d_z) : $\|(d_x, d_z)\|_\infty \le c\frac{5}{4}l \le \delta$ such that

$$x + d_x + \Delta x + \frac{\mathrm{d}\Delta x}{\mathrm{d}x}d_x + \frac{\mathrm{d}\Delta x}{\mathrm{d}z}d_z \ge \rho l e = \frac{1}{4}le,$$
$$z + d_z + \Delta z + \frac{\mathrm{d}\Delta z}{\mathrm{d}x}d_x + \frac{\mathrm{d}\Delta z}{\mathrm{d}z}d_z \ge \rho l e = \frac{1}{4}le,$$

and therefore

$$\begin{aligned} & x_i + d_{x,i} + \Delta x_i(x + d_x, z + d_z) \\ & \quad = x_i + d_{x,i} + \Delta x_i + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}x}d_x + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}z}d_z \\ & \qquad - \left(\Delta x_i + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}x}d_x + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}z}d_z - \Delta x_i(x + d_x, z + d_z)\right) \\ & \quad \ge \frac{1}{4}l - \epsilon\|(d_x, d_z)\| = \frac{1}{4}l - \frac{1}{10c}\|(d_x, d_z)\| \\ & \quad \ge \frac{1}{4}l - \frac{1}{10c}c\frac{5}{4}l \ge \frac{1}{8}l > 0, \end{aligned}$$

and the same for the z components. □

The insight gained from this theorem is that our proposed unblocking strategy is sound in principle: If the negative components of the prospective next iterate $(x+\Delta x, z+\Delta z)$ are bounded in size by L, then there exists an unblocking perturbation (d_x, d_z) of the current iterate. The size of this perturbation is $\mathcal{O}(L)$. Unfortunately the construction of (d_x, d_z) relies on the knowledge of the analytic center $\hat{p}$ of the problem (or at least any other strictly primal/dual feasible point). Therefore the construction used in the proof cannot be implemented in practice. In the following section we will derive an implementable heuristic.

4.3. Implementation. There is a principle difficulty with finding a solution to the *unblocking equations* (16). Theorem 1 guarantees that a solution (of bounded size) exists. The system (15):

$$x + d_x + \Delta x + \frac{\mathrm{d}\Delta x}{\mathrm{d}x}d_x + \frac{\mathrm{d}\Delta x}{\mathrm{d}z}d_z \ge \rho L,$$
$$z + d_z + \Delta z + \frac{\mathrm{d}\Delta z}{\mathrm{d}x}d_x + \frac{\mathrm{d}\Delta z}{\mathrm{d}z}d_z \ge \rho L$$

seems to imply that we could gather the complete sensitivity information ($\frac{\mathrm{d}\Delta x}{\mathrm{d}x}$, $\frac{\mathrm{d}\Delta x}{\mathrm{d}z}$, $\frac{\mathrm{d}\Delta z}{\mathrm{d}x}$, $\frac{\mathrm{d}\Delta z}{\mathrm{d}z}$), requiring n backsolves to do so, and find d_x, d_z to satisfy

$$\begin{bmatrix} \frac{\mathrm{d}\Delta x}{\mathrm{d}x} + I & \frac{\mathrm{d}\Delta x}{\mathrm{d}z} \\ \frac{\mathrm{d}\Delta z}{\mathrm{d}x} & \frac{\mathrm{d}\Delta z}{\mathrm{d}z} + I \end{bmatrix} \begin{bmatrix} d_x \\ d_z \end{bmatrix} \ge \begin{bmatrix} -x - \Delta x + \rho L \\ -z - \Delta z + \rho L \end{bmatrix}. \tag{24}$$

However, the system matrix in (24) is singular (actually of rank n) as can be seen from (17); hence it is unclear if a solution (d_x, d_z) exists at all.

In the results of Theorem 1 we get around this difficulty by assuming the knowledge of the analytic center, something that does not hold in practice. The only

solution we can suggest is to use the sensitivity information in a heuristic targeted at unblocking the search direction.

The idea is based on the observation that typically only a few components of the Newton step $(\Delta x, \Delta z)$ are blocking seriously and that these can be effectively influenced by changing the corresponding components of (x, z) only. One potential danger of aiming solely at unblocking the step direction is that we might have to accept a significant worsening of centrality or feasibility of the new iterate, which is clearly not in our interest. The proposed strategy attempts to avoid this as well by minimizing the perturbation (d_x, d_z) to the current point.

The heuristic that we are proposing is based on the assumption that a change in the ith component x_i, z_i will have a strong influence on the ith component of the step $\Delta x_i, \Delta z_i$, so changing only x_i, z_i components corresponding to blocking components of the step might be sufficient. Indeed our strategy will identify a (small) index set $\mathcal{I}$ of most blocking components, obtain the sensitivity information with respect to these components, and attempt to unblock each $(\Delta x_i, \Delta z_i)$ by changes to component i of (x, z) *only*. Since usually only Δx_i or Δz_i but not both are blocking, allowing perturbations in both x_i or z_i leaves one degree of freedom, which will be used to minimize the size of the required unblocking step.

The assumption made above can be justified as follows: according to (12), the sensitivity $\mathrm{d}(\Delta x, \Delta z)/\mathrm{d}x_i$ (and similarly $\mathrm{d}/\mathrm{d}z_i$) is made up of two components: the ith unit vector e_i and the solution to (13), which according to (14) is the weighted projection of the ith unit vector onto the null space of A.

Our implemented unblocking strategy is thus as follows:

Algorithm: Unblocking Strategy

---

1) Choose the size of the unblocking set $|\mathcal{I}|$, a target unblocking level $t > 1$, and bounds $0 < \underline{\gamma} < 1 < \bar{\gamma}$ on the acceptable change to a component.

2) find the set $\mathcal{I}$ of most blocking components (in x or z)

   `for all` i in 10% most blocking components `do`

3) find sensitivity of $(\Delta x, \Delta z)$ with respect to (x_i, z_i)

4) find the change $(d_{x,i}, d_{z,i})$ needed in x_i or z_i to unblock component i

5) change either x_i or z_i depending on where the change would be *more effective*.

   `next` i

6) update $x = x + d_x$ and $z = z + d_z$ and recompute the affine scaling direction

---

Steps 4) and 5) of the above algorithm need further clarification: For each blocking component x_i (or z_i) we have $x_i + \alpha_x \Delta x_i < 0$ for small positive values of α_x, or $\Delta x_i / x_i \ll -1$. From the sensitivity analysis we know $\frac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i}$, the rate of change of Δx_i when x_i changes. We are interested in the necessary change $d_{x,i}$ to x_i such that the search direction is unblocked, that is to say

$$\frac{\Delta x_i + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i} d_{x,i}}{x_i + d_{x,i}} \geq -t, \quad (t \approx 5);$$

in other words a step of $\alpha_p \geq 1/t$ $(1/t \approx 0.2)$ will be possible. From this requirement

we get the provisional change

$$\widetilde{d_{x,i}} = -\frac{tx_i + \Delta x_i}{t + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i}}.$$

We need to distinguish several cases:

(i) $\dfrac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i} \le \dfrac{\Delta x_i}{x_i}$:

A step in positive direction would lead to even more blocking. A negative step will unblock. However, we are not prepared to let $x_i + d_{x,i}$ approach zero; hence we choose

$$\overline{d_{x,i}} = \max\{\widetilde{d_{x,i}}, (\underline{\gamma} - 1)x_i\}.$$

(ii) $\dfrac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i} > \dfrac{\Delta x_i}{x_i}$:

A positive step would weaken the blocking. However, if $\frac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i} < -t$, the target unblocking level $-t$ can never be reached (and the provisional $\widetilde{d_{x,i}}$ is negative). In this case (and also if the provisional $\widetilde{d_{x,i}}$ is very large) we choose the maximal step that we are prepared to take:

$$\overline{d_{x,i}} = \begin{cases} d_{max} & \text{if } \widetilde{d_{x,i}} < 0, \\ \min\{\widetilde{d_{x,i}}, d_{max}\} & \text{otherwise} \end{cases}$$

with $d_{max} = (\bar{\gamma} - 1)x_i$.

Alternatively we can unblock a blocking Δx_i by changing z_i. The required provisional change $\widetilde{d_{z,i}}$ can be obtained from

$$\frac{\Delta x_i + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}z_i} d_{z,i}}{x_i} \ge -t$$

as

$$\widetilde{d_{z,i}} = -\frac{tx_i + \Delta x_i}{\frac{\mathrm{d}\Delta x_i}{\mathrm{d}z_i}}.$$

In this case $\widetilde{d_{z,i}}$ indicates the correct sign of the change, but for $\frac{\mathrm{d}\Delta x_i}{\mathrm{d}z_i}$ close to zero the provisional step might be very large. We apply the same safeguards as for the step in x to obtain

$$\overline{d_{z,i}} = \begin{cases} \max\{\widetilde{d_{z,i}}, (\underline{\gamma} - 1)z_i\} & \widetilde{d_{z,i}} < 0, \\ \min\{\widetilde{d_{z,i}}, d_{max}\} & \widetilde{d_{z,i}} \ge 0, \end{cases}$$

where $d_{max} = (\bar{\gamma} - 1)z_i$. Since our aim was to reduce the blocking level from $-\Delta x_i / x_i$ to t, we can evaluate the effectiveness of the suggested changes $\overline{d_{x,i}}, \overline{d_{z,i}}$ by

$$p_x = \frac{\text{(old blocking level)} - \text{(new blocking level)}}{\text{(old blocking level)} - \text{(target blocking level)}} = \frac{-\frac{\Delta x_i}{x_i} + \frac{\Delta x_i + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}x_i}\overline{d_{x,i}}}{x_i + \overline{d_{x,i}}}}{-\frac{\Delta x_i}{x_i} + t}$$

and

$$p_z = \frac{-\frac{\Delta x_i}{x_i} + \frac{\Delta x_i + \frac{\mathrm{d}\Delta x_i}{\mathrm{d}z_i}\overline{d_{z,i}}}{x_i}}{-\frac{\Delta x_i}{x_i} + t}.$$

Given these quantities we use $p_x/|\overline{d_{x,i}}|, p_z/|\overline{d_{z,i}}|$ as measures of the *relative effectiveness* of changing the x_i, z_i component. Our strategy is to first change the component for which this ratio is larger, and, should the corresponding p_x, p_z be less than 1, add a proportional change in the other component, i.e., if $p_x/|\overline{d_{x,i}}| > p_z/|\overline{d_{z,i}}|$:

$$d_{x,i} = \overline{d_{x,i}},$$
$$d_{z,i} = \min\{(1-p_x)/p_z, 1\}\overline{d_{z,i}}.$$

An analogous derivation can be performed to unblock the z-component Δz_i of the search direction.

The analysis in the previous section was aimed at unblocking the primal-dual direction corresponding to a fixed target value μ^0. We are, however, interested in using this analysis in the context of a predictor-corrector method. This seems to complicate the situation, since the predictor-corrector direction is now the result of a two-step procedure. As pointed out earlier, however, while the primal-dual direction and subsequently the length of the step that can be taken along it does depend on the target μ^0 value, the sensitivity of this step does not depend on μ^0. This leads us to the following strategy: We obtain the sensitivity with respect to the most blocking components after the predictor step and use these to unblock the combined predictor-corrector (and higher order corrector steps) separately following the above heuristic.

5. Numerical results. In order to evaluate the relative merit of the suggested warmstarting schemes, we have run a selection of numerical tests. In the first instance we have used a warmstarting setup based on the NETLIB LP test set as described in [1, 10] to evaluate a selection of the described heuristics.

In a second set of tests we have used the best warmstart settings from the first set and used these to warmstart the NETLIB LP test set, a selection of QP problems from [12] as well as some large scale QP problems arising from the problem of finding the efficient frontier in portfolio optimization and solving a nonlinear capacitated Multi-Commodity Network Flow problem (MCNF).

All warmstarting strategies have been implemented in our interior point solver OOPS [7]. For all tests we save the first iterate in the original problem solution process for which the relative duality gap satisfies

$$\frac{(c^Tx + 0.5x^TQx) - (b^Ty - 0.5x^TQx)}{(c^Tx + 0.5x^TQx) + 1} = \frac{x^Tz}{(c^Tx + 0.5x^TQx) + 1} \leq 0.01$$

for use as a warmstarting point. We do not attempt to find an "optimal" value for $\bar{\mu}$: our motivation is primarily to evaluate unblocking techniques in order to recover from "bad" warmstarting situations; furthermore it is likely that the optimal $\bar{\mu}$ is highly problem (and perturbation) dependent. On the contrary, we assume that a 2-digit approximate optimal solution of the original problem should be a good starting point for the perturbed problem.

5.1. The NETLIB warmstarting test set. In order to compare our results more easily to other contributions, we use the NETLIB warmstarting testbed suggested by [1]. This uses the smaller problems from the NETLIB LP test set as the original problems and considers changes to the right-hand side b, the objective vector c, the system matrix A, and different perturbation sizes δ. The perturbed problem instances are randomly generated as follows:

For perturbations to b and c we first generate a uniform-[0,1] distributed random number for every vector component. Should this number be less than $\min\{0.1, 20/n\}$

TABLE 1
Higher order correctors as unblocking device.

	b			c			A			
	0.1	0.01	0.001	0.1	0.01	0.001	0.1	0.01	0.001	total
base	6.4	5.6	6.1	14.5	8.5	6.4	10.2	7.0	7.2	8.1
hoc	6.0	5.4	5.6	11.3	7.6	6.3	8.6	6.5	6.8	7.2

(n being the dimension of the vector), this component is marked for modification. That is, we modify on average 10% (but at most 20) of the components. For all marked components we will generate a second uniform-$[-1, 1]$ distributed random number r. The new component $\tilde{b_i}$ is generated from the old one b_i as

$$\tilde{b_i} = \begin{cases} \delta r & |b_i| \leq 10^{-6}, \\ (1 + \delta r) b_i & \text{otherwise.} \end{cases}$$

For perturbations to A we proceed in the same manner, perturbing the vector of nonzero elements in A as before. For the results presented in this paper we have solved each problem for each warmstart strategy for 10 random perturbations of each type (b, c, and A). We will use these to evaluate the merit of each of the considered modifications and unblocking heuristics. A list of the considered NETLIB problems can be obtained from Tables 6–9.

In the numerical test performed we were guided by two objectives: first to evaluate if and how the various warmstarting strategies presented in section 3 can be combined, and second to evaluate the merit of the proposed unblocking strategy. In order to save on the total amount of computation, we will use the following strategy: Every warmstarting heuristic is tested against a *base* warmstarting code and against the best combination found so far. If a heuristic is found to be advantageous, it will be added to the *best* benchmark strategy for the future tests.

5.1.1. Higher order correctors. We investigate the use of higher-order correctors as an unblocking device. The interior point code OOPS applied for these calculations uses higher-order correctors by default if the Mehrotra corrector step (5) has been successful (i.e., it leads to larger stepsizes α_P, α_D than the predictor step). When using higher order correctors as an unblocking device, we will attempt them even if the Mehrotra corrector has been rejected. Table 1 gives results with and without forcing higher order correctors (`hoc` and `base`, respectively). The numbers reported are the average number of iterations of the warmstarted problem over all problems in the test set and all 10 random perturbations. Problem instances which are infeasible or unbounded after the perturbation have been discarded. Clearly the use of higher order correctors is advantageous. We therefore recommend the use of higher order correctors in all circumstances in the context of warmstarting. All following tests are performed with the use of higher order correctors.

5.1.2. Centering steps. We explore the benefit of using centering steps as a technique to facilitate warmstarting. These are performed either at the end of the solution process for the original problem before the advanced center is returned (`end`) or at the beginning of the modified problem solution, before any reduction of the barrier μ is applied (`beg`). As pointed out earlier the latter corresponds to the Newton corrector step of [15]. We have tested several settings of `end` and `beg` corresponding to the number of steps of this type being taken. The additional centering iterations are included in the numbers reported. Results are summarized in Table 2.

	WLS-0.1	6.3	5.9	5.9	10.0	7.9	6.8	7.4	6.7	7.7	7.2

Compared with the base, strategy $(1, 0)$ is the best, whereas compared to the best (which just includes higher-order correctors at this point), strategy $(1, 2)$ is preferable. Due to the theoretical benefits of working with a well-centered point, we will use centering strategy $(1, 2)$ in the *best* benchmark strategy for the following tests.

5.1.3. z-adjustment/WLS-step. We have evaluated the benefit of attempting to absorb dual infeasibilities into the z value of the warmstart vector, together with the related WLS heuristic (which attempts to find a least squares correction to the saved iterate such that the resulting point is primal/dual feasible). The results are summarized in Table 3. Surprisingly there is a clear advantage of the simple z-adjustment heuristic, whereas the (computationally more expensive and more sophisticated) WLS step (`WLS-0.01`) hardly improves on the base strategy. Our only explanation for this behavior is that for our fairly low saved μ-value (2-digit approximate optimal solution to the original problem) the full WLS direction is usually infeasible, so only a fractional step in it can be taken. The z-adjustment, on the other hand, has a more sophisticated fallback strategy which considers adjustment for each component separately, so it is not quite as easily affected by blocking in the modification direction. Reference [15] suggests employing the WLS step together with a backtracking strategy, which saves several iterates from the original problem for different μ and chooses one for which the WLS step does not block. We have emulated this by trying the WLS step for a larger μ (`WLS-0.1`). Any gain of a larger portion of the WLS step being taken, however, is offset by the starting point now being further away from optimality, resulting in an increase of the number of iterations. We have added the z-adjustment heuristic to our *best* benchmark strategy.

5.1.4. Splitting directions. This analyzes the effectiveness of using the computations of separate primal, dual, and centrality correcting directions as in [6] as an unblocking strategy. The results given in Table 4 correspond to different numbers of initial iterations in the solution process of the modified problem using this technique.

As can be seen there is no demonstrable benefit from using this unblocking technique, we have therefore left it out of all subsequent tests.

5.1.5. Unblocking by sensitivity. Finally we have tested the effectiveness of our unblocking scheme based on using sensitivity information. We are considering employing this heuristic for up to the first three iterations. The parameters we have used are $|\mathcal{I}| \leq 0.1n$ (i.e., the worst 10% of components are unblocked), $t = 5$, $\bar{\gamma} = 10$, and $\underline{\gamma} = 0.1$. Results are summarized in Table 5. Unlike the other tests, we have not only tested the unblocking strategy against the base and the best but also against two further setups to evaluate the effectiveness of the strategy to recover from blocking in different environments.

As can be seen there is a clear benefit in employing this heuristic in all tests. The results are less pronounced when comparing against the *best* strategy, but even here there is a clear advantage of performing one iteration of the unblocking strategy.

5.2. Results for best warmstart strategy. After these tests we have combined the best setting for all of the considered warmstart heuristics and give more detailed results on the NETLIB test set as well as for a selection of large scale quadratic programming problems.

Tables 6–9 compare the best combined warmstarting strategy for all test problems with a cold start. We give in each case the average number of iterations over 10 random perturbations. Column `red` gives the average percentage iteration reduction achieved by employing the warmstart. An entry "`-`" denotes that all corresponding perturbations of the problem were either infeasible or unbounded. As can be seen we are able to save between 50% and 60% of iterations on all considered problems.

5.3. Comparison with LOQO results. To judge the competitiveness of our best combined warmstarting strategy, we have compared the results on the NETLIB test set with those reported by [1] which use a different warmstarting methodology. Figure 1 gives a summary of this comparison. The four lines on the left graph give the number of iterations needed for each of the 30 NETLIB problems reported in Tables 6–9 averaged over all perturbations for OOPS and LOQO [1], using a warmstart and a coldstart. As can be seen the default version of OOPS (solid line) needs fewer iterations than LOQO (dotted line). The warmstarted versions of each code

(solid and dotted lines with markers, respectively) need significantly fewer iterations on average than their coldstarted siblings, with warmstarted OOPS being the most effective strategy over all. This plot indicates only the best combination of interior point code and warmstarting strategy without giving any insight into the relative effectiveness of the warmstarting approaches themselves. In order to measure the efficiency of the warmstart approaches, the second plot in Figure 1 compares the number of iterations *saved* by each warmstarting strategy as compared with its respective coldstarted variant. As can be seen our suggested warmstart implemented in OOPS is able to save around 50-60% of iterations, outperforming the LOQO warmstart which averages around 30% saved iterations.

5.4. Medium scale QP problems. We realize that the NETLIB testbed proposed in [1] includes only small LP problems. While this makes it ideal for the extensive testing that we have reported in the previous section, there is some doubt over whether the achieved warmstarting performance can be maintained for quadratic and (more realistic) large scale problems. In order to counter such criticism we have conducted warmstarting tests on two selections of small to medium scale QP problems as well as two sources of large scale quadratic programming. For the small and medium scale tests we have used the quadratic programming collection of Maros

and Meszaros [12]. This includes QP problems from the CUTE test set as well as quadratic modifications of the NETLIB LP test set used in the previous comparisons. We have excluded problems that either have free variables (since OOPS currently has no facility to deal with free variables effectively), or where random perturbations of the problem data yield the problem primal or dual infeasible. The same methodology in perturbing the problems as for the NETLIB LP test set has been used, apart that perturbations in the objective function will now perturb random elements of c and Q. The results are displayed in Table 10. As for the LP case we list for each problem and perturbation the average number of iterations needed by OOPS when coldstarted and when warmstarted with the best strategy found in section 5.1 over the 10 random runs and 3 perturbation sizes. We also state the percentage of iterations saved by the warmstart. A blank entry indicates that all 30 random perturbations lead to primal or dual infeasible problems. The results demonstrate a similar performance of our best combined warmstarting strategy as obtained earlier for the LP problems.

5.5. Large scale QP problems. Finally we have evaluated our warmstart strategy in the context of two sources of large scale quadratic problems. In the first

instance we have solved the capacitated MCNF problem

$$
\begin{aligned}
\min \quad & \sum_{(i,j)\in\mathcal{E}} \frac{x_{ij}}{K_{ij}-x_{ij}}, \\
\text{s.t.} \quad & \sum_{k\in\mathcal{D}} x_{ij}^{(k)} \le K_{ij}, \qquad \forall (i,j)\in\mathcal{E}, \\
& Nx^{(k)} = d^{(k)}, \qquad \forall k\in\mathcal{D}, \\
& x^{(k)} \ge 0, \qquad \forall k\in\mathcal{D},
\end{aligned} \tag{25}
$$

where N is the node-arc incidence matrix of the network, $d^{(k)}, k\in\mathcal{D}$ are the demand points, K_{ij} is the capacity of each arc (i,j), and x_{ij} is the flow along the arc. This is a nonlinear problem formulation. We have solved it by SQP using the interior point code OOPS as the QP solver and employing our best combined warmstart strategy between QP solutions. We have tested this on nine different MCNF models using from 4–300 nodes, up to 600 arcs, and up to 7021 commodities. The largest problem in the selection has $353,400$ variables. All solutions have required more than 10 SQP iterations. Table 11 gives the average number of IPM iterations for each SQP iteration both for cold- and warmstarting the IPM.

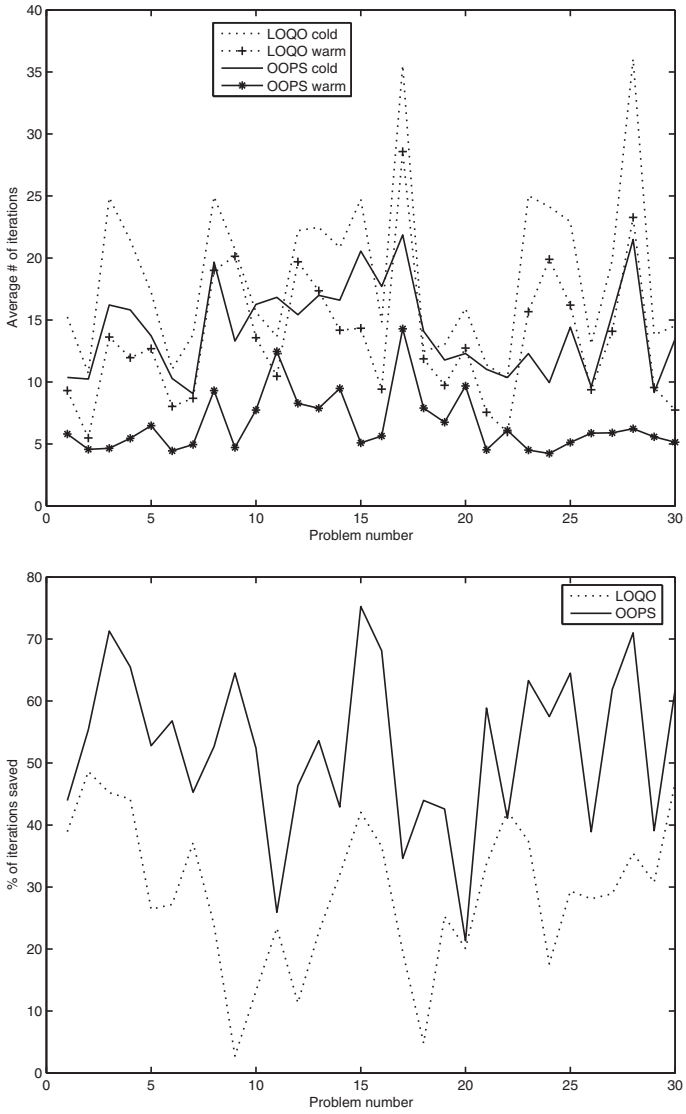

FIG. 1. *Results of LOQO and OOPS on warmstarting NETLIB problems.*

As before we achieve between 50 and 60% reduction in the number of interior point iterations.

Our last test example consists of calculating the complete efficient frontier in a Markowitz Portfolio Selection problem (see [14]). A Portfolio Selection problem aims to find the optimal investment strategy in a selection of assets over time. If the value of the portfolio at the end of the time horizon is denoted by the random variable X, the Markowitz formulation of the portfolio selection problem requires one to maximize the final expected wealth $\mathbb{E}(X)$ and minimize the associated risk, measured as the variance $\mathrm{Var}(X)$ which are combined into a single objective:

$$\min -\mathbb{E}(X) + \rho \mathrm{Var}(X) \tag{26}$$

which leads to a QP problem. We use the multistage stochastic programming version of this model (described in [7]). This formulation leads to very large problem sizes.

The parameter ρ in (26) is known as the *Risk Aversion Parameter* and captures the investor's attitude to risk. A low value of ρ will lead to a riskier strategy with a higher value for the final expected wealth, but a higher risk associated with it.

Often the investor's attitude to risk is difficult to capture a priori in a single parameter. A better decision tool is the efficient frontier, a plot of $\mathbb{E}(X)$ against the corresponding $\mathrm{Var}(X)$ values for different settings of ρ. Computing the efficient frontier requires the solution of a series of problems for different values of ρ. Apart from this all the problems in the sequence are identical, which makes them prime candidates for a warmstarting strategy (although see [3] for a different approach). Table 12 gives results for four different problem sizes with up to 192 million variables and 70 million constraints. For each problem the top line gives the number of iterations a coldstarted IPM needs to solve the problem for a given value of ρ, whereas the middle line gives the number of iterations when warmstarting each problem from the one with the next lowest setting of ρ. The last line gives the percentage saving in IPM iterations. Again we are able to save in the range of 50 and 60% of IPM iterations. As far as we are aware these are the largest problems to date for which an interior point warmstart has been employed.

6. Conclusions. In this paper we have compared the effectiveness of various interior point warmstarting schemes on the NETLIB base test set suggested by [1]. We have categorized warmstarting strategies into *modification* strategies and *unblocking* strategies. *Modification* strategies are aimed at modifying an advanced iterate from a previous solution of a nearby problem before it is used to warmstart an IPM, whereas unblocking strategies aim to directly address the negative effect known as blocking which typically affects a "bad" warmstart in the first few iterations. We suggest a new unblocking strategy based on sensitivity analysis of the step direction with respect to the current point. In our numerical tests we obtain an optimal combination of modification and unblocking strategies (including the new strategy based on sensitivity analysis) and are subsequently able to save an average of 50 and 60% of interior point iterations on a range of LP and QP problems varying from the small scale NETLIB test set to problems with over 192 million variables.

Acknowledgment. We would like to thank the anonymous referees for their constructive comments that helped to improve this paper.

THE EXACT FEASIBILITY OF RANDOMIZED SOLUTIONS OF UNCERTAIN CONVEX PROGRAMS*

M. C. CAMPI† AND S. GARATTI‡

Abstract. Many optimization problems are naturally delivered in an uncertain framework, and one would like to exercise prudence against the uncertainty elements present in the problem. In previous contributions, it has been shown that solutions to uncertain convex programs that bear a high probability to satisfy uncertain constraints can be obtained at low computational cost through constraint randomization. In this paper, we establish new feasibility results for randomized algorithms. Specifically, the *exact* feasibility for the class of the so-called *fully-supported* problems is obtained. It turns out that all fully-supported problems share the same feasibility properties, revealing a deep kinship among problems of this class. It is further proven that the feasibility of the randomized solutions for all other convex programs can be bounded based on the feasibility for the prototype class of fully-supported problems. The feasibility result of this paper outperforms previous bounds and is not improvable because it is exact for fully-supported problems.

Key words. uncertain optimization, randomized methods, convex optimization, semi-infinite programming, robust optimization, chance-constrained

1. Introduction.

Uncertain convex optimization [21, 24, 25] deals with convex optimization in which the constraints are imprecisely known:

$$\begin{aligned} \text{UP}: \ & \min_{x \in \mathcal{X} \subseteq \mathbb{R}^d} c^T x \\ & \text{subject to: } x \in \mathcal{X}_\delta, \quad \delta \in \Delta, \end{aligned} \tag{1}$$

where UP stands for uncertain program, $\delta \in \Delta$ is an uncertain parameter, and $\mathcal{X}$ and $\mathcal{X}_\delta$ are convex and closed sets. Oftentimes, Δ is a set of infinite cardinality. The fact that the optimization objective is linear and does not carry any dependence on δ, that is, it is certain, is without loss of generality.

UP encompasses as special cases uncertain linear programs (LP), uncertain quadratic programs (QP), uncertain second-order cone programs (SOCP), and uncertain semi-definite programs (SDP) and plays a central role in many design endeavors such as [1, 15, 17, 14, 9, 24, 11, 6].

Dealing with uncertainty can be done along two distinct approaches. The first one consists in enforcing satisfaction of *all* constraints; that is, one optimizes the cost $c^T x$ over the set $\bigcap_{\delta \in \Delta} \mathcal{X}_\delta$ (see [2, 16, 3, 4]). Alternatively, one may want to satisfy the constraints with "high probability." Along this second approach one sees the uncertainty parameter δ as a random element with a probability $\mathbb{P}$ and seeks a solution that violates at most a fraction of constraints having small $\mathbb{P}$-probability (chance-constrained solution). Depending on the optimization problem at hand, $\mathbb{P}$

can have different interpretations. Sometimes, it is the actual probability with which the uncertainty parameter δ takes on value in Δ. Other times, it simply describes the relative importance attributed to different instances of δ. The use of a probabilistic description of uncertainty has a long history in optimization theory and dates back to the work [10] of Charnes and Cooper in the 1950s that in effect gave birth to the chance-constrained approach. See also [21, 22, 12, 25] for more information and [5] for a more in-depth comparison between deterministic and probabilistic uncertain optimization.

It is a fact that finding a solution carrying a high probability of constraint satisfaction is in general a very difficult task to achieve [21]. To circumvent this computational issue, recently, methodologies relying on the randomization over the set of constraints have been introduced [11, 5, 20, 6, 13]. Specifically, in [5, 6], the following randomized program RP_N is introduced, where N constraints $\delta^{(1)}, \ldots, \delta^{(N)}$ randomly extracted according to $\mathbb{P}$ in an independent fashion are simultaneously enforced:

$$\mathrm{RP}_N : \min_{x \in \mathcal{X} \subseteq \mathbb{R}^d} c^T x$$
$$\text{subject to: } x \in \bigcap_{i \in \{1,\ldots,N\}} \mathcal{X}_{\delta^{(i)}}.$$

RP_N is also known as "scenario program."

The distinctive feature of RP_N is that it is a program with a *finite* number of constraints, and, as such, it can be solved at low computational cost provided that N is not too large;[1] it is indeed a fact that RP_N has opened up new resolution avenues in uncertain optimization. On the other hand, the obvious question to ask is how feasible the solution of RP_N is; that is, how large the fraction of original constraints in Δ that are possibly violated by the solution x_N^* of RP_N is. Papers [5, 6] have pioneered a feasibility theory showing that x_N^* is feasible for the vast majority of the other unseen constraints—those that have not been used when optimizing according to RP_N—and this result holds in full generality, independently of the structure of the set of constraints Δ and the probability $\mathbb{P}$. So the vast majority of constraints take care of themselves, without explicitly accounting for them.

To allow for a sharper comparison with the results presented in this paper, we feel advisable to first recall in some detail the results in [5, 6]. The following notion of violation probability from [5] is central.

DEFINITION 1 (violation probability). *The* violation probability *of a given $x \in \mathcal{X}$ is defined as $V(x) = \mathbb{P}\{\delta \in \Delta : x \notin \mathcal{X}_\delta\}$.*

The problem addressed in [5, 6] is to evaluate if and when the violation probability of x_N^*, namely, $V(x_N^*)$, is below a satisfying level ϵ. To state the result precisely, note that $V(x_N^*)$ is a random variable since the solution x_N^* of RP_N is, due to the fact that it depends on the random extractions $\delta^{(1)}, \ldots, \delta^{(N)}$. Thus, $V(x_N^*) \leq \epsilon$ may hold for certain extractions $\delta^{(1)}, \ldots, \delta^{(N)}$, while $V(x_N^*) > \epsilon$ may be true for others. The following quantification of the "bad" extractions where $V(x_N^*) > \epsilon$ is the key result of [6]:

$$\mathbb{P}^N\{V(x_N^*) > \epsilon\} \leq \binom{N}{d}(1-\epsilon)^{N-d}. \tag{2}$$

[1] Depending on Δ and $\mathbb{P}$, the generation of N randomly extracted scenarios $\delta^{(1)}, \ldots, \delta^{(N)}$ from Δ can in itself be a nontrivial problem, and the reader is referred to [27, 8, 7] for further discussion on this issue.

Moving a fundamental step forward with respect to [6], in this paper we establish the validity of relation

$$\mathbb{P}^N\{V(x_N^*) > \epsilon\} = \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i} \tag{3}$$

(note that (3) holds with "="; that is, it is not a bound) for the prototype class of *fully-supported* problems according to Definition 3 in section 2. This result sheds new light on a deep kinship among all fully-supported problems, proving that their randomized solutions share the same violation properties, and writes a final word on the violation assessment for this type of problems.

It is further proven in this paper that the right-hand side of (3) is an upper bound for all convex problems; that is,

$$\mathbb{P}^N\{V(x_N^*) > \epsilon\} \leq \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i} \tag{4}$$

holds for all convex problems. Thus, in a real optimization problem one does not need to verify whether the problem is fully-supported or not, and $\sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}$ can always be used as an upper bound for $\mathbb{P}^N\{V(x_N^*) > \epsilon\}$. This result (4) (i) cannot be improved (being tight for the prototype class of fully-supported problems) and (ii) outperforms the previous bound from [6] at times by a huge extent (note that when $\epsilon \to 0$, the previous bound (2) tends to $\binom{N}{d}$, while the new bound (4) goes naturally to 1!).

2. Main result. The technical result of this paper is precisely stated in this section, followed by a discussion on the significance of the result.

For a fixed integer m and fixed given constraints $\delta^{(1)}, \ldots, \delta^{(m)}$, program

$$\begin{aligned} \mathrm{P}_m : & \min_{x \in \mathcal{X} \subseteq \mathbb{R}^d} c^T x \\ & \text{subject to: } x \in \bigcap_{i \in \{1,\ldots,m\}} \mathcal{X}_{\delta^{(i)}} \end{aligned} \tag{5}$$

is called a *finite instance with m constraints* of the uncertain optimization program UP in (1). For the time being, we make the following assumption.

Assumption 1. Every P_m is feasible, and its feasibility domain has a nonempty interior. Moreover, the solution x_m^* of P_m exists and is unique.

The existence and uniqueness of x_m^* are here assumed to streamline the presentation. The reader is referred to point 5 in the discussion in section 2.1 to see how these assumptions can be removed.

We recall the following fundamental definition and proposition. Definition 2 was introduced in [5], while Proposition 1 was originally stated in a slightly different but equivalent way in [18].

DEFINITION 2 (support constraint). *Constraint $\delta^{(r)}$, $r \in \{1, \ldots, m\}$, is a* support constraint *for P_m if its removal changes the solution of P_m.*

PROPOSITION 1. *The number of support constraints for P_m is at most d, the size of x.*

Suppose now that Δ is endowed with a σ-algebra $\mathcal{D}$ and that a probability $\mathbb{P}$ over $\mathcal{D}$ is assigned. Further assume that m constraints $\delta^{(1)}, \ldots, \delta^{(m)}$ are randomly extracted from Δ according to $\mathbb{P}$ in an independent fashion. Differently stated, the

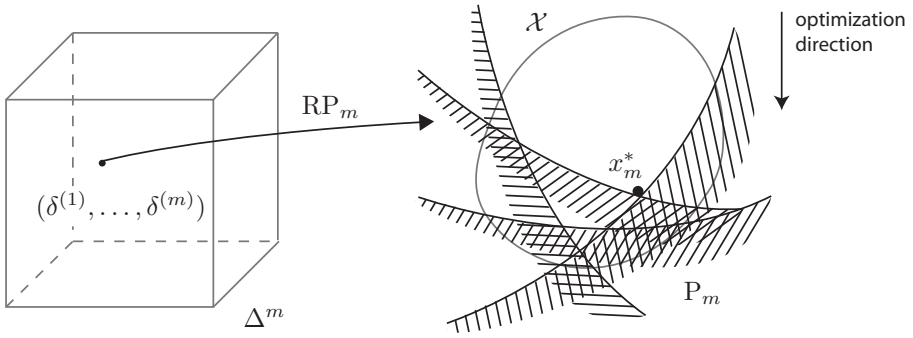

FIG. 1. *RP_m, a map from constraint multiextractions to finite instances P_m of the optimization problem.*

multiextraction $(\delta^{(1)}, \ldots, \delta^{(m)})$ is a random element from the probability space Δ^m equipped with the product probability $\mathbb{P}^m$. Each multiextraction $(\delta^{(1)}, \ldots, \delta^{(m)})$ generates a program P_m, and the map from Δ^m to P_m programs is a *randomized program* RP_m; see Figure 1. Note that this is the same as RP_N in section 1 with the only difference being that we have used here m to indicate the number of constraints, a choice justified by the fact that in this section m plays the role of a generic running argument taking on any integer value, while N represents in section 1 the fixed number of constraints picked by the user for the implementation of the randomized scheme.

We are now ready to introduce the notion of a *fully-supported* problem.

DEFINITION 3 (fully-supported problem). *A finite instance P_m, with $m \geq d$, is fully-supported if the number of support constraints of P_m is* exactly *d. Problem UP is fully-supported if, for any $m \geq d$, RP_m is fully-supported with probability* 1.

The main result of this paper is now stated in the following theorem.

THEOREM 1. *Under Assumption* 1,[2] *it holds that*

$$\mathbb{P}^N\{V(x_N^*) > \epsilon\} \leq \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}; \tag{6}$$

moreover, the bound is tight for all fully-supported *uncertain optimization problems; that is,*

$$\mathbb{P}^N\{V(x_N^*) > \epsilon\} = \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}. \tag{7}$$

The proof is given in section 3. The measurability of $\{V(x_N^*) > \epsilon\}$, as well as the measurability of other sets, is assumed in this paper.

One interpretation of Theorem 1 is that the randomized solution is, with high probability, a feasible solution for a chance-constrained problem; see [21].

2.1. Discussion. The following comments are in order.

1. Equation (7) delivers the *exact* probability distribution of the violation $V(x_N^*)$ for all fully-supported problems. Since (7) holds independently of the nature and characteristics of the fully-supported problem, it establishes a fundamental kinship among problems of this prototype class.

[2]See point 5 in section 2.1 for relaxations of this assumption.

TABLE 1

β_{old}	$1.3\ 10^{3}$	2.9	$5.1\ 10^{-3}$	$7.5\ 10^{-6}$	$9.9\ 10^{-9}$

TABLE 2
N vs. N_{old} for different values of ϵ ($\beta = 10^{-5}$, $d = 10$).

ϵ	0.1	0.05	0.025	0.01	0.005	0.0025	0.001
N	285	581	1171	2942	5895	11749	29513
N_{old}	579	1344	3035	8675	18943	41008	112686

Bound (6) further asserts that all possible sources of non-fully-supportedness can only improve the feasibility properties of the problem.

2. The quantity $\beta := \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}$ in the right-hand side of (6) and (7) is the tail of a binomial distribution and goes rapidly (exponentially) to zero as N increases. Letting $\beta_{\text{old}} := \binom{N}{d}(1-\epsilon)^{N-d}$ (bound in (2) from [6]), Table 1 provides a comparison between β and β_{old}.

3. A typical use of Theorem 1 consists in selecting ϵ (violation parameter) and β (confidence parameter) in $(0, 1)$ and then computing the smallest number N of constraints to be extracted in order to guarantee that $\mathbb{P}^N\{V(x_N^*) > \epsilon\} \leq \beta$ by solving equation $\beta = \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}$ for N. In Table 2, the values of N and of N_{old} obtained by using the bound in (2) are displayed for different values of ϵ, $\beta = 10^{-5}$ and $d = 10$.

4. A simple example illustrates Theorem 1.

$N = 1650$ points are independently extracted in $\mathbb{R}^2$ according to an unknown probability density $\mathbb{P}$, and the strip of smaller vertical width that contains all of the points is constructed; see Figure 2.

In mathematical terms—letting the points be $(u^{(i)}, y^{(i)})$, $i = 1, \ldots, N$, where u is the horizontal coordinate and y is the vertical coordinate—this amounts to solving the following program:

$$\begin{aligned} \mathrm{P}_N : \min_{x_1, x_2, x_3 \in \mathbb{R}^3} \ & x_1 \\ \text{subject to: } & \left| y^{(i)} - [x_2 u^{(i)} + x_3] \right| \leq x_1, \quad i = 1, \ldots, N, \end{aligned}$$

where $[x_2 u^{(i)} + x_3]$ is the median line of the strip and x_1 is the semiwidth of the strip.

What guarantee do we have that the strip contains at least 99% of the probability mass of $\mathbb{P}$?

One can easily recognize that this question is the same as asking for a guarantee, or a probability, that the violation is less than $\epsilon = 0.01$, and the answer can be found in Theorem 1: this probability is no less than $1 - \sum_{i=0}^{2} \binom{1650}{i} 0.01^i (1-0.01)^{1650-i} \approx 1 - 10^{-5}$. As a matter of fact, this probability is exact since, as it can be verified, this problem is fully-supported.

We can further ask for a different geometrical construction and look for the disk of smaller radius that contains all points; see Figure 3. Again, we are facing a finite

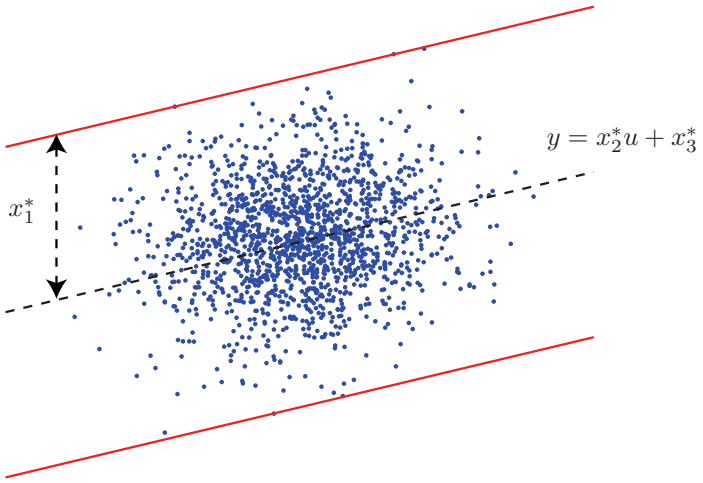

FIG. 2. *Strip of smaller vertical width.*

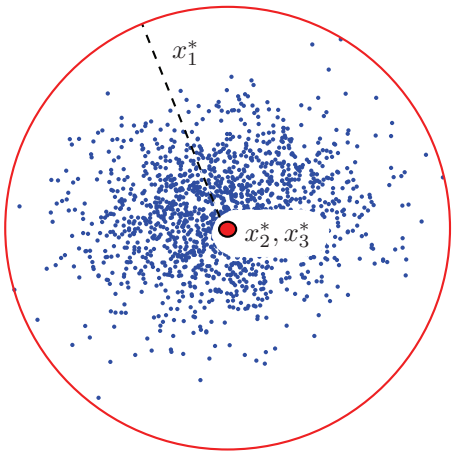

FIG. 3. *Disk of smaller radius.*

convex program

$$\mathrm{P}_N : \min_{x_1,x_2,x_3\in\mathbb{R}^3} x_1$$
$$\text{subject to: } \sqrt{(u^{(i)}-x_2)^2+(y^{(i)}-x_3)^2} \le x_1, \quad i=1,\dots,N,$$

where (x_2, x_3) is the center of the disk and x_1 is its radius, and again we can claim with confidence $1-10^{-5}$ that the constructed disk will contain at least 99% of the probability mass. In this disk case, the figure $1-10^{-5}$ is a lower bound since the problem is not fully-supported, as it can be easily recognized by noting that a configuration with two points away from each other and all of the other points concentrated near the midposition of the first two points generates a disk where the segment joining the first two points is a diameter and only these two points are of support.

Finally, let us compare the probability $1-10^{-5}$ with the probability that would have been obtained by applying the previous bound (2) from [6]. Applying the latter,

we would find that this probability is no smaller than $1 - 48.4 = -47.4$, a negative number clearly devoid of any meaning and that does not allow us to draw any conclusion as far as the confidence is concerned.

5. Here we discuss the assumption of the existence and uniqueness of the solution of P_m. Suppose first that the solution exists but it may be nonunique. Then, the tie can be broken by selecting among the optimal solutions the one with the minimum Euclidian norm, and one can prove that Theorem 1 holds unchanged.

If we further relax the assumption that the solution exists (note that the solution may not exist even if P_m is feasible since the solution can drift away to infinity), extending Theorem 1 we can show that

$$\mathbb{P}^N\{x_N^* \text{ exists, and } V(x_N^*) > \epsilon\} \leq \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i},$$

where x_N^* is unique after applying the tie-break rule as above. In words, this result says that, when a solution is found, its violation exceeds ϵ with small probability only. In normal problems the nonexistence of the solution is a rare event whose probability exponentially vanishes with N.

3. Proof of Theorem 1. We first prove that $\mathbb{P}^N\{V(x_N^*) > \epsilon\} = \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}$ for *fully-supported* problems and then that $\mathbb{P}^N\{V(x_N^*) > \epsilon\} \leq \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}$ for every problem.

PART 1: $\mathbb{P}^N\{V(x_N^*) > \epsilon\} = \sum_{i=0}^{d-1} \binom{N}{i} \epsilon^i (1-\epsilon)^{N-i}$ FOR FULLY-SUPPORTED PROBLEMS. Consider the solution x_d^* of RP_d (recall that d is the size of x), and let

$$F(\alpha) := \mathbb{P}^d\{V(x_d^*) \leq \alpha\} \tag{8}$$

be the probability distribution of the violation of x_d^*. It is a remarkable fact that this distribution is

$$F(\alpha) = \alpha^d, \tag{9}$$

independent of the problem type.

To prove (9), we have to consider multiextractions of m elements, where m is a generic integer greater than or equal to d. To each multiextraction $(\delta^{(1)}, \ldots, \delta^{(m)}) \in \Delta^m$, associate the indexes of the corresponding d support constraints (this is always possible except for a probability 0 set because the problem is *fully-supported*).[3] Further, group all multiextractions having the same indexes. In this way, $\binom{m}{d}$ sets $S_{\mathcal{I}}$ are constructed forming a partition (up to a probability 0 set) of Δ^m, where $\mathcal{I} \subset \{1, \ldots, m\}$ is a set of cardinality d containing the indexes of the support constraints. We claim that the probability of each of these sets is

$$\mathbb{P}^m\{S_{\mathcal{I}}\} = \int_0^1 (1-\alpha)^{m-d} F(\mathrm{d}\alpha), \tag{10}$$

where $F(\alpha)$ is defined in (8); using (10), later on in the proof, we shall show that $F(\alpha)$ must have the expression in (9).
