ERROR BOUNDS IN METRIC SPACES AND APPLICATION TO THE PERTURBATION STABILITY OF METRIC REGULARITY*

HUYNH VAN NGAI† AND MICHEL THÉRA‡

Abstract. This paper was motivated by the need to establish some new characterizations of the metric regularity of set-valued mappings. Through these new characterizations it was possible to investigate the global/local perturbation stability of the metric regularity and to extend a result by Ioffe [*Set-Valued Anal.*, 9 (2001), pp. 101–109] on the perturbation stability of the global metric regularity when the image space is not necessarily complete. It was also possible to give a characterization of the local metric regularity and to derive a local version of the perturbation stability of the metric regularity. In this work we also describe an application of this perturbation stability and give a simple proof of a result on the error bound of 2-regular mappings established by Izmailov and Solodov [*Math. Program.*, 89 (2001), pp. 413–435] and generalized by He and Sun [*Math. Oper. Res.*, 30 (2005), pp. 701–717].

Key words. error bound, perturbation stability, metric regularity, generalized equations

1. Introduction.

Let X and Y be metric spaces endowed with metrics both denoted by $d(\cdot,\cdot)$. The open ball with center x and radius $r > 0$ is denoted by $B(x, r)$. We recall that a set-valued (multivalued) mapping $F : X \rightrightarrows Y$ is a mapping which assigns to every $x \in X$ a subset (possibly empty) $F(x)$ of Y. As usual, we use the notation $\text{gph } F := \{(x, y) \in X \times Y : y \in F(x)\}$ for the graph of F, $\text{Dom } F := \{x \in X : F(x) \neq \emptyset\}$ for the domain of F, and $F^{-1} : Y \rightrightarrows X$ for the inverse of F. This inverse (which always exists) is defined by $F^{-1}(y) := \{x \in X : y \in F(x)\}, y \in Y$, and satisfies

$$(x, y) \in \text{gph } F \iff (y, x) \in \text{gph } F^{-1}.$$

It is well known that a large amount of problems, for instance, inequalities and equalities systems, variational inequalities, or systems of optimality conditions, are covered by the solvability of a generalized equation (in the terminology of Robinson).

For a given $y \in Y$, determine $x \in X$ such that $y \in F(x)$.

In general F is of the form $f + T$, where $f : X \to Y$ and $T : X \rightrightarrows Y$. An important subcase is furnished by variational inequalities, that is, the problem of finding a solution to the equation $y \in f(x) + N_C(x)$, where $T = N_C$ is the normal-cone operator. For each $x \in \mathbb{R}^n$, the set $N_C(x)$ is the normal cone (in the sense of convex analysis) to a closed convex set C of $\mathbb{R}^n$ at x.

A central issue in variational analysis is to investigate the behavior of the set of solutions of a generalized equation associated to F, that is, the behavior of the

set $F^{-1}(y)$ when y and/or F itself are perturbed. A key to this is the concept of metric regularity. Recall that a mapping F is said to be *metrically regular* on a region $V \subseteq X \times Y$ with modulus τ if there exists a real $\tau > 0$ such that

$$d(x, F^{-1}(y)) \leq \tau d(y, F(x)) \quad \text{for all } (x, y) \in V, \tag{1.1}$$

where $d(x, C)$ denotes, as usual, the distance from x to a set C and is defined by $d(x, C) = \inf_{z \in C} d(x, z)$, with the convention that $d(x, S) = +\infty$ whenever S is empty. In the case, for example, of a set-valued mapping F with closed and convex graph, the Robinson–Ursescu theorem says that F is metrically regular at (x_0, y_0) if and only if y_0 is an interior point to the range of F, i.e., to Dom F^{-1}.

If relation (1.1) holds for all (x, y) close to a given $(\bar{x}, \bar{y}) \in X \times Y$, then we say that F is *(locally) metrically regular* around $(\bar{x}, \bar{y})$. According to the long history of metric regularity there is abundant literature on conditions ensuring this property. This concept goes back to Lyusternik [29] and Graves [18] in connection to the extension to nonlinear operators of the celebrated Banach open mapping theorem. For a detailed account the reader is referred to the works [2, 6, 7, 8, 9, 11, 14, 20, 21, 23, 27, 28, 30, 31, 32, 33, 34, 38, 41] and the references given therein for many theoretical results on the metric regularity as well as its various applications.

In the present paper, we are concerned with the stability of the metric regularity with respect to perturbations of F. Historically, it follows from Banach that when F is a bounded linear operator between two Banach spaces X and Y, if F is surjective, then all operators G sufficiently close to F have the metric regularity property (or equivalently, the covering property). This classical result has been extended to the case of continuously Fréchet differentiable mappings by Lyusternik [29] and Graves [18] for the local metric regularity and by Dmitruk, Miljiutin, and Osmolovskii [13] for the global case. In [15] Dontchev, Lewis, and Rockafellar, and [16], Dontchev and Lewis have studied the case of set-valued mappings under perturbations of a single-valued mapping; that is, perturbation mappings of the form $F(x) + g(x)$, where F is a set-valued mapping and g is a single-valued mapping.

Recently, in [22], Ioffe studied the general case when perturbation mappings are not necessarily expressed in the form $F(x)+g(x)$. He constructed a measure of "closedness" between two set-valued mappings allowing him to significantly extend the classical result (on the global covering property) of Dmitruk, Miljiutin, and Osmolovskii to the general case of set-valued mappings.

Inspired by the work of Ioffe [22], our main objective in this paper is to use the theory of error bounds to study stability of global and/or local metric regularity of set-valued mappings under a perturbation of F. The approach based on error bounds to investigate the metric regularity has been recently used by Azé, Corvellec, and Lucchetti [3] and by Ngai and Théra [35] to study implicit multifunctions in smooth spaces. Especially in the survey paper by Azé [2], it was shown that this approach is powerful to provide a unified theory of the metric regularity. The organization of this paper is as follows. In section 2, we prove new characterizations of the global/ local error bound in complete metric spaces. Using this result, we derive in section 3 a new criterion assuring the metric regularity. Based on this criterion, we extend the result by Ioffe [22] on the perturbation stability of global metric regularity when the image space is not necessarily complete. We establish in section 4 a characterization of the local metric regularity. Based on this characterization, we derive the local version of the perturbation stability of metric regularity. As an application, we use this perturbation stability result to give a simple proof of a result on error bounds of

2-regular mappings established by Izmailov and Solodov [24] and extended by He and Sun [19].

2. Error bound in complete metric spaces. Let X be a metric space. Let $f : X \to \mathbb{R} \cup \{+\infty\}$ be a given function. As usual, $\mathrm{dom} f := \{x \in X : f(x) < +\infty\}$ denotes the domain of f. We set

$$S := \{x \in X : f(x) \leq 0\}. \tag{2.1}$$

We use the symbol $[f(x)]_+$ to denote $\max(f(x), 0)$. We shall say that the system (2.1) admits *an error bound* if there exists a real $c > 0$ such that

$$d(x, S) \leq c\big[f(x)\big]_+ \quad \text{for all } x \in X. \tag{2.2}$$

For $x_0 \in S$, we shall say that the system (2.1) has an error bound at x_0 when there exist real $c > 0$ and $\varepsilon > 0$ such that relation (2.2) is satisfied for all x around x_0, i.e., in an open ball $B(x_0, \varepsilon)$ with center x_0 and radius ε.

Several conditions using subdifferential operators or directional derivatives and ensuring the error bound in Banach spaces have been established, for example, in [10, 26, 37, 35, 40]. Recently, Azé [1] and Azé and Corvellec [5] have used the so-called strong slope introduced by De Giorgi, Marino, and Tosques in [12] to prove criteria for error bounds in complete metric spaces.

The following result, whose proof is strictly based on the Ekeland variational principle [17], gives an estimation for the distance $d(\bar{x}, S)$ from a given point $\bar{x}$ outside of S to the set S in complete metric spaces. Such an estimation using the Fréchet subdifferential in Asplund spaces has been established in [36].

THEOREM 2.1. *Let X be a complete metric space, and let $f : X \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous function and $\bar{x} \notin S$. Then, setting*

$$m(\bar{x}) := \inf \left\{ \sup_{y \in X, y \neq x} \frac{f(x) - [f(y)]_+}{d(x, y)} \;:\; \begin{array}{l} d(x, \bar{x}) < d(\bar{x}, S) \\ f(x) \leq f(\bar{x}) \end{array} \right\}, \tag{2.3}$$

one has

$$m(\bar{x}) d(\bar{x}, S) \leq f(\bar{x}). \tag{2.4}$$

Here and in what follows the convention $0.(+\infty) = 0$ is used.

Proof. As the conclusion holds trivially if $f(\bar{x}) = +\infty$, let us suppose that $\bar{x} \in \mathrm{dom} f$. If $S = \emptyset$, then, obviously, applying the Ekeland variational principle, one obtains $m(\bar{x}) = 0$. Hence, the conclusion follows from the convention $0.(+\infty) = 0$. Now, assume that $S \neq \emptyset$ and consider the function $g : X \to \mathbb{R} \cup \{+\infty\}$ defined by $g(x) = [f(x)]_+$. Let $\varepsilon \in (0, 1)$ be given. Obviously, since $\inf_{x \in X} g(x) = 0$, we can write

$$g(\bar{x}) = \inf_{x \in X} g(x) + \frac{g(\bar{x})}{(1 - \varepsilon) d(\bar{x}, S)} (1 - \varepsilon) d(\bar{x}, S).$$

By virtue of the Ekeland variational principle [17], we can select $z \in X$ satisfying $d(z, \bar{x}) \leq (1 - \varepsilon) d(\bar{x}, S)$ and $f(z) = g(z) \leq g(\bar{x}) = f(\bar{x})$ such that the function

$$g(\cdot) + \frac{g(\bar{x})}{(1 - \varepsilon) d(\bar{x}, S)} d(\cdot, z)$$

attains a minimum at z. That is,

$$[f(x)]_+ + \frac{f(\bar{x})}{(1-\varepsilon)d(\bar{x},S)}d(x,z) \geq f(z) \quad \text{for all } x \in X. \tag{2.5}$$

Since $d(z,\bar{x}) < d(\bar{x},S)$, thanks to the definition of $m(\bar{x})$, just select a point $y \in X, y \neq z$ such that

$$\frac{f(z)-[f(y)]_+}{d(z,y)} \geq m(\bar{x}) - \varepsilon.$$

Therefore, from (2.5), we obtain

$$\frac{f(\bar{x})}{(1-\varepsilon)d(\bar{x},S)} \geq \frac{f(z)-[f(y)]_+}{d(z,y)} \geq m(\bar{x}) - \varepsilon.$$

Taking the limit as ε goes to zero we obtain (2.4), establishing the proof. ∎

The following corollary of Theorem 2.1 gives characterizations of the error bound.

COROLLARY 2.2. *Let X be a complete metric space, and let $f : X \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous function. Let $\tau \in (0,+\infty)$; $r \in (0,+\infty]$ be given. Consider the following statements.*

(i) *$d(x,S) \leq \tau[f(x)]_+$ for all $x \in X$ with $f(x) < r$.*

(ii) *For each $x \in X \setminus S$ with $f(x) < r$ and for any $\varepsilon > 0$, there exists $z \in X$ such that*

$$0 < d(x,z) < (\tau+\varepsilon)(f(x) - [f(z)]_+). \tag{2.6}$$

(iii) *For each $x \in X \setminus S$ with $f(x) < r$ and for any $\varepsilon > 0$, there exists $z \in X$ with $f(z) \geq 0$ such that (2.6) holds.*

(iv) *For each $x \in X \setminus S$ with $f(x) < r$ and for any $\varepsilon > 0$, there exists $z \in X$ with $f(z) > 0$ such that (2.6) holds.*

Then, one has (i) ⇔ (ii) ⇐ (iii) ⇐ (iv). *In addition, if X is a Banach space and f is a continuous function, then all of the statements are equivalent.*

Proof. The implications (iv) ⇒ (iii) ⇒ (ii) are obvious. (ii) ⇒ (i) follows directly from Theorem 2.1.

Let $x \in X \setminus S$ with $f(x) < r$, and let $\varepsilon > 0$ be given. For (i) ⇒ (ii), take $z \in S$ such that $d(x,z) < (1+\varepsilon/\tau)d(x,S)$. Then, obviously, one has $d(x,z) \leq (\tau+\varepsilon)(f(x) - [f(z)]_+)$.

Now let X be a Banach space and f be a continuous function. For (ii) ⇒ (iii), let $z \in X$ such that (2.6) is satisfied. When $f(z) \leq 0$; since $f(x) > 0$ and the function f is continuous, we can find $y \in [x,z] := \{tx + (1-t)z : \ t \in [0,1]\}$ such that $f(y) = 0$. Hence,

$$0 < d(x,y) \leq d(x,z) < (\tau+\varepsilon)f(x) = (\tau+\varepsilon)(f(x) - f(y)).$$

Finally, for (iii) ⇒ (iv), let $z \in X$ with $f(z) \geq 0$ satisfying (2.6). If $f(z) > 0$, then the conclusion obviously holds. Suppose that $f(z) = 0$. Let $A \subseteq \mathbb{R}$ be defined by $A = \{t \in [0,1] : f(tx+(1-t)z) \leq 0\}$. Since A is nonempty, closed, and bounded in $\mathbb{R}$, we may define $\max A := t_0$ with $t_0 \in [0,1)$. For each $t \in (t_0,1)$ if $y_t := tx + (1-t)z$, then $f(y_t) > 0$. Pick a real $\delta > 0$ such that $\frac{1-t_0}{1-\delta(\tau+\varepsilon)} < 1$. Noticing that $f(y_{t_0}) = 0$ and using the continuity of f, we can find $t_1 \in (t_0,1)$ such that $f(y_t) < \delta d(x,z)$ for all $t \in (t_0,t_1)$. Then for all $t \in (t_0,t_1)$, one has

$$\begin{aligned} d(x,y_t) &= (1-t)d(x,z) < (1-t)(\tau+\varepsilon)f(x) \\ &< (1-t)(\tau+\varepsilon)(f(x) - f(y_t)) + (1-t)(\tau+\varepsilon)\delta d(x,z). \end{aligned}$$

Thus,

$$d(x, y_t) < \frac{(1-t)(\tau+\varepsilon)}{1-\delta(\tau+\varepsilon)}(f(x) - f(y_t)) < (\tau+\varepsilon)(f(x) - f(y_t)),$$

which completes the proof. □

Note that (iv) ⇒ (i) has been established by Wu and Ye in [40]. Similarly, we also obtain characterizations for the local error bound.

COROLLARY 2.3. *Let X be a complete metric space, and let $f : X \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous function. Let $\bar{x} \in S, \tau \in (0, +\infty)$ and $\eta \in (0, +\infty)$ be given. Consider the following statements.*

(i) *$d(x, S) \le \tau[f(x)]_+$ for all $x \in B(\bar{x}, \eta/2)$.*

(ii) *For each $x \in B(\bar{x}, \eta) \setminus S$ and for any $\varepsilon > 0$, there exists $z \in X$ such that*

$$0 < d(x, z) < (\tau+\varepsilon)(f(x) - [f(z)]_+). \tag{2.7}$$

(iii) *For each $x \in B(\bar{x}, \eta) \setminus S$ and for any $\varepsilon > 0$, there exists $z \in X$ with $f(z) \ge 0$ such that (2.7) holds.*

(iv) *For each $x \in B(\bar{x}, \eta) \setminus S$ and for any $\varepsilon > 0$, there exists $z \in X$ with $f(z) > 0$ such that (2.7) holds.*

Then, one has (iv) ⇒ (iii) ⇒ (ii) ⇒ (i). *Conversely, if* (i) *holds, then* (ii) *holds with $\eta/2$ instead of η. In addition, if X is a Banach space and f is a continuous function, then the three statements* (ii), (iii), *and* (iv) *are equivalent.*

Recall from [12, 5, 4] that the strong slope $|\nabla f|(x)$ of a lower semicontinuous function f at $x \in \mathrm{dom} f$ is the quantity defined by $|\nabla f|(x) = 0$ if x is a local minimum of f, otherwise,

$$|\nabla f|(x) = \limsup_{y \to x} \frac{f(x) - f(y)}{d(x, y)}.$$

For $x \notin \mathrm{dom} f$, we set $|\nabla f|(x) = +\infty$. Obviously, for all $\bar{x} \notin S$, one has

$$m(\bar{x}) \ge \inf\{|\nabla f|(x) : d(x, \bar{x}) < d(\bar{x}, S),\ f(x) \le f(\bar{x})\}.$$

Therefore, Theorem 2.1 implies directly the following result, which is also a corollary of Theorem 2.1 in Azé and Corvellec [5].

COROLLARY 2.4 (see [5, Theorem 2.1]). *Let X be a complete metric space and let $f : X \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous function. Let $\tau \in (0, +\infty)$ and $r \in (0, +\infty]$ be given. If there exists $m > 0$ such that $|\nabla f|(x) \ge m$ for all $x \in X \setminus S$ with $f(x) < r$, then*

$$m d(x, S) \le [f(x)]_+ \quad \text{for all} \quad x \in X; f(x) < r.$$

Let a real $\gamma > 0$ be given. By noting that for all $x \in X$ with $f(x) > 0$, $|\nabla f^\gamma|(x) = \gamma f^{\gamma-1}(x)|\nabla f|(x)$, one obtains the following error bound with exponent γ.

COROLLARY 2.5. *Let X be a complete metric space, and let $f : X \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous function. If there exists $m > 0$ such that*

$$\gamma f^{\gamma-1}(x)|\nabla f|(x) \ge m \quad \text{for all } x \in X \setminus S \text{ with } f(x) < r,$$

then

$$m d(x, S) \le [f(x)]_+^\gamma \quad \text{for all } x \in X; f(x) < r.$$

3. Perturbation stability of global metric regularity. Let X, Y be metric spaces and $F : X \rightrightarrows Y$ be a set-valued mapping. First, let us recall the notion of metric regularity (see, for example, [22, 21]).

DEFINITION 3.1. *Let $V \subseteq X \times Y$ be a given subset of $X \times Y$. The mapping F is said to be metrically regular on V with modulus $\tau > 0$ if*

$$d(x, F^{-1}(y)) \leq \tau d(y, F(x)) \quad \text{for all } (x, y) \in V. \tag{3.1}$$

It is worth pointing out that (see [22]) F is metrically regular with modulus τ if and only if F *covers* on V with a constant not smaller than $a = \tau^{-1}$. By the notion of covering we mean that for any $t > 0$ and any triplet (x, y, v) such that

$$(x, y) \in V, y \neq v \in F(x), d(y, v) < t,$$

there exists $u \in X$ such that $y \in F(u)$ and $ad(u, x) \leq t$.

The following theorem gives a characterization of the metric regularity on a subset V of the form

$$V = V(F, R) = \{(x, y) \in X \times Y : d(y, F(x)) < R\},$$

where $R \in (0, +\infty]$.

In what follows, we make use of the lower semicontinuous envelope $(x, y) \mapsto \varphi(x, y)$ of the function $(x, y) \mapsto d(y, F(x))$, i.e., for each $(x, y) \in X \times Y$,

$$\varphi(x, y) := \liminf_{(u,v)\to(x,y)} d(v, F(u)) = \liminf_{u\to x} d(y, F(u)).$$

THEOREM 3.2. *Let X be a complete metric space, and let Y be a metric space, (which is not necessarily complete). Let $F : X \rightrightarrows Y$ be a set-valued mapping with a closed graph and $V := V(F, R)$ for some $R \in (0, +\infty]$. Then the following statements are equivalent*:

(i) *For all $(x, y) \in V$, one has*

$$d(x, F^{-1}(y)) \leq \tau d(y, F(x)).$$

(ii) *Let $(x, y) \in X \times Y$ with $y \notin F(x)$; $\varphi(x, y) < R$ and let $\varepsilon > 0$. Then for every sequence $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ converging to x, there exists a sequence $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ with $\lim_{n\to\infty} d(u_n, x) > 0$ such that*

$$\limsup_{n\to\infty} \frac{d(y, F(x_n)) - d(y, F(u_n))}{d(x_n, u_n)} > \frac{1}{\tau + \varepsilon}. \tag{3.2}$$

(iii) *Let $(x, y) \in X \times Y$ with $y \notin F(x)$; $\varphi(x, y) < R$ and let $\varepsilon > 0$. Then, for every sequence $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ converging to x with*

$$\lim_{n\to\infty} d(y, F(x_n)) = \liminf_{u\to x} d(y, F(u)),$$

there exists a sequence $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ with $\lim_{n\to\infty} d(u_n, x) > 0$ such that (3.2) *holds.*

Proof. (ii) $\Rightarrow$ (iii) is obvious. For (i) $\Rightarrow$ (ii), take some $\varepsilon > 0$ and $(x, y) \in X \times Y$ with $y \notin F(x)$; $\varphi(x, y) < R$. Let $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ be a sequence converging to x. We

consider the following two cases.

Case 1. $\limsup_{n\to\infty} d(y, F(x_n)) < R$. Since gph F is closed when n is sufficiently large, say $n \geq n_0$, hence, $y \notin F(x_n)$ and, moreover, $d(y, F(x_n)) < R$. Hence $d(x_n, F^{-1}(y)) \leq \tau d(y, F(x_n))$. For each integer n, pick $u_n \in F^{-1}(y)$ such that $d(x_n, u_n) < (1 + \varepsilon/\tau) d(x_n, F^{-1}(y))$. By relabeling if necessary, we can assume that $\lim d(x, u_n)$ exists. Then using the closedness of gph F, we have $\lim d(x, u_n) > 0$ and for all $n \geq n_0$,

$$d(x_n, u_n) < (1 + \varepsilon/\tau) d(x_n, F^{-1}(y)) \leq (\tau + \varepsilon)\big[d(y, F(x_n)) - d(y, F(u_n))\big].$$

This shows that (3.2) holds.

Case 2. $\limsup_{n\to\infty} d(y, F(x_n)) \geq R$. Let $\{z_n\}_{n\in\mathbb{N}} \subseteq X$ be a sequence converging to x such that

$$\lim_{n\to\infty} d(y, F(z_n)) = \varphi(x, y) (< R).$$

By using the argument of Case 1 applied to $\{z_n\}_{n\in\mathbb{N}}$ instead of $\{x_n\}_{n\in\mathbb{N}}$, we can find a sequence $\{u_n\}_{n\in\mathbb{N}}$ with $\lim d(x, u_n) > 0$ and some $n_0 \in \mathbb{N}$ such that for all $n \geq n_0$, one has

$$d(z_n, u_n) \leq (\tau + \varepsilon)\Big[d(y, F(z_n)) - d(y, F(u_n))\Big].$$

Hence

$$\begin{aligned}\limsup_{n\to\infty} \frac{d(y, F(x_n)) - d(y, F(u_n))}{d(x_n, u_n)} &\geq \limsup_{n\to\infty} \frac{d(y, F(z_n)) - d(y, F(u_n))}{d(x_n, u_n)} \\ &> \frac{1}{\tau + \varepsilon} \limsup_{n\to\infty} \frac{d(z_n, u_n)}{d(x_n, u_n)} = \frac{1}{\tau + \varepsilon}.\end{aligned}$$

Thus, relation (3.2) holds.

Let us prove (iii) $\Rightarrow$ (i). Let $(x, y) \mapsto \varphi(x, y)$ denote the lower semicontinuous envelope of the function $(x, y) \mapsto d(y, F(x))$. Then, $0 \leq \varphi(x, y) \leq d(y, F(x))$ for all $(x, y) \in X \times Y$. Observe that for each $y \in Y$, $F^{-1}(y) = \{x \in X : \ \varphi(x, y) = 0\}$. Indeed, let $(x, y) \in X \times Y$. Obviously, if $x \in F^{-1}(y)$, then $\varphi(x, y) = 0$. Conversely, suppose $\varphi(x, y) = 0$. There exists a sequence $\{x_n\}_{n\in\mathbb{N}}$ with limit x such that $d(y, F(x_n))$ converges to 0. Then, we can find a sequence $\{z_n\}_{n\in\mathbb{N}} \subseteq Y$ such that $z_n \in F(x_n)$ and $d(y, z_n) \to 0$. Since the graph of F is closed, then $(x, y) \in$ gph F, i.e., $x \in F^{-1}(y)$. From this and by virtue of Corollary 2.2, it suffices to show that for each $(x, y) \in X \times Y$, with $y \notin F(x)$; $\varphi(x, y) < R$ and for any $\varepsilon \in (0, 1)$ there exists $u \in X$ with $u \neq x$ such that

$$d(x, u) \leq (\tau + \varepsilon)(\varphi(x, y) - \varphi(u, y)).$$

To see this, let $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ be a sequence with limit x and $d(y, F(x_n)) \to \varphi(x, y)$ as $n \to \infty$. Then $(x_n, y) \in V$ and $x_n \notin F^{-1}(y)$ when n is sufficiently large, say $n \geq n_0$. Let $\{u_n\}_{n\in\mathbb{N}}$ be a sequence of elements in X satisfying (3.2) with respect to the sequence $\{x_n\}_{n\in\mathbb{N}}$. Pick $\delta \in (0, \lim d(u_n, x))$. Then there exists an index $n_1 \geq n_0$ such that for all $n \geq n_1$, one has $d(x_n, u_n) \geq \delta$; $d(x_n, x) < \epsilon\delta$;

$$d(y, F(x_n)) < \varphi(x, y) + \frac{\varepsilon}{\tau + \varepsilon} d(x_n, u_n)$$

and

$$d(x_n, u_n) < (\tau + \varepsilon)(d(y, F(x_n)) - d(y, F(u_n))).$$

Hence,

$$d(x_n, u_n) < (1-\varepsilon)^{-1}(\tau+\varepsilon)(\varphi(x,y) - \varphi(u_n, y)).$$

It follows that for $n \geq n_1$,

$$d(x, u_n) \leq (1+\varepsilon)d(x_n, u_n) < (1-\varepsilon)^{-1}(\tau+\varepsilon)(1+\varepsilon)(\varphi(x,y) - \varphi(u_n, y)).$$

As $\varepsilon \in (0,1)$ is arbitrary, the proof is complete. □

Based on Theorem 3.2, we can now prove an extension of a result by Ioffe [22, Theorem 2] on perturbation stability of metric regularity. Precisely, we extend Ioffe's result to the case where the image space Y is not necessarily complete. It is worth noting that the following proof is more simple than the one given in [22] that is based on a criterion of metric regularity [22, Theorem 6] which depends heavily on the completeness of Y.

Let X be a metric space and Y be a normed linear space. Let $F, \Phi : X \rightrightarrows Y$ be two set-valued mappings. For $(x,r) \in X \times (0, +\infty)$, let us denote the following quantity introduced by Ioffe [22] by

$$\sigma_{F,\Phi}(x,r) := \sup_{\eta \in \Phi(x)} \inf_{v \in F(x)} \sup_{d(u,x)<r, w \in F(u)} \inf_{\xi \in \Phi(u)} \|\eta - v + w - \xi\|. \tag{3.3}$$

Note that when $\Phi(x) := F(x) + G(x)$, where $G : X \rightrightarrows Y$ is a set-valued mapping, then (see [22])

$$\sigma_{F,\Phi}(x,r) \leq \sup_{d(x,u)<r} e(G(x), G(u)) := \sup_{d(x,u)<r} \sup_{y \in G(x)} d(y, G(u)) \quad \text{for all } (x,u) \in X \times X. \tag{3.4}$$

THEOREM 3.3. *Let X be a complete metric space and Y be a normed linear space. Let $F, \Phi : X \rightrightarrows Y$ be set-valued mappings with closed graphs. Suppose that F is metrically regular on $V(F,R)$ for some $R \in (0, +\infty]$ with modulus $\tau > 0$. If there exists $\lambda \in (0, \tau^{-1})$ such that*

$$\sigma_{F,\Phi}(x,r) \leq \lambda r \quad \text{for all } x \in X,\ r \in (0, \tau R), \tag{3.5}$$

then Φ is metrically regular on $V(\Phi, R)$ with modulus $(\tau^{-1} - \lambda)^{-1}$.

Proof. It suffices to show that statement (iii) in Theorem 3.2 is verified. Indeed, let $(x,y) \in X \times Y$ with $y \notin \Phi(x)$; $\liminf_{u \to x} d(y, \Phi(u)) < R$. Let $\{x_n\}_{n \in \mathbb{N}} \subseteq X$ be a sequence converging to x with $\lim_{n\to\infty} d(y, \Phi(x_n)) = \liminf_{u \to x} d(y, \Phi(u))$. Then $(x_n, y) \in V(\Phi, R)$ and $y \notin \Phi(x_n)$ for large n, say $n \geq n_0$. For each $n \geq n_0$, let $\delta_n \in (0, \varepsilon)$ sufficiently small such that $(1+\delta_n)d(y, \Phi(x_n)) < R$ and $\delta_n \to 0$ as $n \to \infty$. Take $\eta_n \in \Phi(x_n)$ such that

$$\|y - \eta_n\| < (1+\delta_n) d(y, \Phi(x_n)).$$

Set $r_n = (1+\delta_n)\tau d(y, \Phi(x_n)) (< \tau R)$. By (3.5), we can find $v_n \in F(x_n)$ such that

$$\sup_{d(u,x_n)<r_n, w \in F(u)} \inf_{\xi \in \Phi(u)} \|\eta_n - v_n + w - \xi\| < (1+\delta_n)\lambda r_n. \tag{3.6}$$

Setting $z_n := y - \eta_n + v_n$, then, obviously, $(x_n, z_n) \in V(F,R)$. Moreover, since assumption F is metrically regular on $V(F,R)$ with modulus τ, one has

$$d(x_n, F^{-1}(z_n)) \leq \tau d(z_n, F(x_n)) \leq \tau \|z_n - v_n\| = \tau \|y - \eta_n\| < (1+\delta_n)\tau d(y, \Phi(x_n)) := r_n.$$

Therefore, there exists $u_n \in F^{-1}(z_n)$ such that $d(x_n, u_n) < r_n$. Hence, relation (3.6) implies that

$$\inf_{\xi \in \Phi(u_n)} \|\eta_n - v_n + z_n - \xi\| < (1+\delta_n)\lambda r_n,$$

that is, $d(y, \Phi(u_n)) < (1+\delta_n)\lambda r_n$. It follows that

$$\limsup_{n\to\infty} d(y, \Phi(u_n)) \le \lambda\tau \liminf_{u\to x} d(y, \Phi(u)) < \liminf_{u\to x} d(y, \Phi(u)),$$

and, consequently, $\liminf_{n\to\infty} d(u_n, x_n) > 0$. Moreover,

$$\begin{aligned} d(y, \Phi(x_n)) - d(y, \Phi(u_n)) &> r_n[(1+\delta_n)^{-1}\tau^{-1} - (1+\delta_n)\lambda] \\ &> d(x_n, u_n)[(1+\delta_n)^{-1}\tau^{-1} - (1+\delta_n)\lambda]. \end{aligned}$$

By letting $n \to \infty$, we obtain

$$\limsup_{n\to\infty} \frac{d(y, \Phi(x_n)) - d(y, \Phi(u_n))}{d(x_n, u_n)} \ge \tau^{-1} - \lambda.$$

This completes the proof. □

Recall that a set-valued mapping $G : X \rightrightarrows Y$ is said to be Lipschitz on X with a constant $\lambda > 0$ if

$$e(G(x), G(u)) \le \lambda d(x, u) \quad \text{for all } (x, u) \in X \times X, \tag{3.7}$$

where, $e(G(x), G(u)) = \sup_{y\in G(x)} d(y, G(u))$. If for some $\bar{x} \in X$ (3.7) holds for all $(x, u) \in B(\bar{x}, \delta) \times B(\bar{x}, \delta)$ for some $\delta > 0$, then we say that G is Lipschitzian around $\bar{x}$.

By relation (3.4), Theorem 3.3 yields the following corollary (see [22, Corollary 3]).

COROLLARY 3.4. *Let X be a complete metric space, and let Y be a normed linear space. Let $F, G : X \rightrightarrows Y$ be set-valued mappings such that both F and $\Phi := F + G$ have closed graphs. Suppose that F is metrically regular on $V(F, R)$ with modulus $\tau > 0$ and G is Lipschitz on X with constant $\lambda \in (0, \tau^{-1})$. Then, Φ is metrically regular on $V(\Phi, R)$ with modulus $(\tau^{-1} - \lambda)^{-1}$.*

4. Perturbation stability of local metric regularity. In this section, we consider the local case of perturbation stability of metric regularity. Let $(\bar{x}, \bar{y}) \in \operatorname{gph} F$. The mapping F is said to be metrically regular at $\bar{x}$ with respect to $\bar{y}$ with modulus $\tau \in (0, +\infty)$ if there exist neighborhoods U of $\bar{x}$ and V of $\bar{y}$ such that

$$d(x, F^{-1}(y)) \le \tau d(y, F(x)) \quad \text{for all } (x, y) \in U \times V. \tag{4.1}$$

First, we prove a characterization of the local metric regularity, which is a local version of Theorem 3.2. Similar to section 2, let $\varphi(\cdot, \cdot)$ denote the lower semicontionuous envelope function of the mapping $d(\cdot, F(\cdot))$.

THEOREM 4.1. *Let X be a complete metric space, and let Y be a metric space. Let $F : X \rightrightarrows Y$ be a set-valued mapping with a closed graph, and let $(\bar{x}, \bar{y}) \in \operatorname{gph} F$ and $\tau \in (0, +\infty)$ be given. Then the following statements are equivalent:*

(i) *There exists a neighborhood $U \times V \subseteq X \times Y$ of $(\bar{x}, \bar{y})$ and such that*

$$d(x, F^{-1}(y)) \le \tau d(y, F(x)) \quad \textit{for all } (x, y) \in U \times V;$$

(ii) *There exists a neighborhood* $U \times V \subseteq X \times Y$ *of* $(\bar{x}, \bar{y})$ *such that for any* $(x, y) \in U \times V$ *with* $y \notin F(x)$, *any* $\varepsilon > 0$, *and any sequence* $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ *converging to* x *with*

$$\limsup_{n\to\infty} d(y, F(x_n)) \leq d(y, F(x)),$$

there exists a sequence $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ *with* $\lim_{n\to\infty} d(u_n, x) > 0$ *such that*

$$\limsup_{n\to\infty} \frac{d(y, F(x_n)) - d(y, F(u_n))}{d(x_n, u_n)} > \frac{1}{\tau + \varepsilon}. \tag{4.2}$$

(iii) *There exist a neighborhood* $U \times V \subseteq X \times Y$ *of* $(\bar{x}, \bar{y})$ *and a real* $\gamma \in (0, +\infty)$ *such that for any* $(x, y) \in U \times V$ *with* $y \notin F(x)$ *and* $\varphi(x, y) < \gamma$ *and any* $\varepsilon > 0$, *then for any sequence* $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ *converging to* x *with*

$$\lim_{n\to\infty} d(y, F(x_n)) = \liminf_{u\to x} d(y, F(u)),$$

we can find a sequence $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ *with* $\lim_{n\to\infty} d(u_n, x) > 0$ *such that* (4.2) *holds.*

Proof. (ii) $\Rightarrow$ (iii) is obvious, while (i) $\Rightarrow$ (ii) is similar to the proof of the respective implication in Theorem 3.2. It remains to prove (iii) $\Rightarrow$ (i). Let us remind the reader that

$$\varphi(x, y) = \liminf_{u\to x} d(y, F(u)), (x, y) \in X \times Y.$$

Then, for all $y \in Y$, $F^{-1}(y) = \{x \in X : \varphi(x, y) = 0\}$. Let $U \times V := B(\bar{x}, \alpha) \times B(\bar{y}, \beta)$ and τ, γ as in (iii). Let $\varepsilon \in (0, \tau/2)$ be given and set $\delta = \min\{\alpha, \frac{\alpha}{6(\tau+2\varepsilon)}, \beta, \gamma/4\}$. If y is fixed in $B(\bar{y}, \delta)$, then

$$\varphi(\bar{x}, y) \leq d(y, F(\bar{x})) \leq d(y, \bar{y}) < \delta.$$

Hence

$$\varphi(\bar{x}, y) \leq \inf_{x\in X} \varphi(x, y) + \delta.$$

By virtue of the Ekeland variational principle [17] (applied to the function $x \mapsto \varphi(x, y)$), we can select $z \in X$ satisfying $d(\bar{x}, z) \leq \delta(\tau + 2\varepsilon)$ and $\varphi(z, y) \leq \varphi(\bar{x}, y) (< \delta)$ such that

$$\varphi(z, y) \leq \varphi(x, y) + \frac{1}{\tau + 2\epsilon} d(x, z) \quad \text{for all } x \in X.$$

It follows that for any sequence $\{z_n\}_{n\in\mathbb{N}} \subseteq X$ converging to z with

$$\lim_{n\to\infty} d(y, F(z_n)) = \liminf_{u\to z} d(y, F(u)),$$

for all $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ with $\lim_{n\to\infty} d(u_n, z) > 0$, one always has

$$\limsup_{n\to\infty} \frac{d(y, F(z_n)) - d(y, F(u_n))}{d(z_n, u_n)} \leq \limsup_{n\to\infty} \frac{\varphi(z, y) - \varphi(u_n, y)}{d(z, u_n)} \leq \frac{1}{\tau + 2\varepsilon} < \frac{1}{\tau + \varepsilon}.$$

Therefore, by assumption we must have $z \in F^{-1}(y)$. Consequently, $B(\bar{x}, 2\delta\tau) \cap F^{-1}(y) \neq \emptyset$.

Now take $(x,y) \in B(\bar{x}, 2\delta\tau) \times B(\bar{y}, \delta)$. We distinguish two cases.

Case 1. $d(y, F(x)) \geq \gamma$. Since $B(\bar{x}, 2\delta\tau) \cap F^{-1}(y) \neq \emptyset$, then

$$d(x, F^{-1}(y)) \leq d(x, \bar{x}) + d(\bar{x}, F^{-1}(y)) < 2\delta\tau + 2\delta\tau = 4\delta\tau \leq \tau d(y, F(x)). \tag{4.3}$$

Case 2. $d(y, F(x)) < \gamma$. Let $z \in X$ with $d(x,z) < d(x, F^{-1}(y))$; $\varphi(z,y) \leq \varphi(x,y)$. One has

$$d(z, \bar{x}) \leq d(z,x) + d(x, \bar{x}) \leq d(\bar{x}, F^{-1}(y)) + 2d(x, \bar{x}) < 6\delta\tau.$$

Thus, $z \in B(x, \alpha)$. Let $\{z_n\}_{n\in\mathbb{N}} \subseteq X$ be an arbitrary sequence converging to z with

$$\lim_{n\to\infty} d(y, F(z_n)) = \varphi(z,y) (< \gamma).$$

According to (iii), we can find a sequence $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ with $\lim_{n\to\infty} d(u_n, z) > 0$ such that

$$\limsup_{n\to\infty} \frac{d(y, F(z_n)) - d(y, F(u_n))}{d(z_n, u_n)} > \frac{1}{\tau + \varepsilon}.$$

It follows that

$$\limsup_{n\to\infty} \frac{\varphi(z,y) - \varphi(u_n, y)}{d(z, u_n)} > \frac{1}{\tau + \varepsilon}. \tag{4.4}$$

Consequently,

$$m(x) := \inf \left\{ \sup_{u\in X, u\neq z} \frac{\varphi(z,y) - \varphi(u,y)}{d(z,u)} : \begin{array}{l} d(z,x) < d(x, F^{-1}(y)) \\ \varphi(z,y) \leq \varphi(x,y) \end{array} \right\} > \frac{1}{\tau + \varepsilon}.$$

By virtue of Theorem 2.1 and as ε is arbitrarily small, we obtain

$$d(x, F^{-1}(y)) \leq \tau d(y, F(x)) \quad \text{for all } (x,y) \in B(\bar{x}, 2\delta\tau) \times B(\bar{y}, \delta),$$

where $\delta = \min\{\alpha, \alpha\tau^{-1}/6, \beta, \gamma/4\}$. The proof is complete. □

REMARK 4.2. (i) *In* [16], *Dontchev and Lewis have established a characterization of the local metric regularity under the assumptions that the function* $(x,y) \mapsto d(x, F(y))$ *is locally lower semicontinuous (and both* X, Y *are complete). Note that, when this condition is satisfied, Theorem* 4.1 *yields directly Lemma* 1.7 *in* [16].

(ii) *When both* X, Y *are complete metric spaces, a characterization using the strong slope has been established by Azé–Corvellec in* [5, Theorem 5.3].

REMARK 4.3. *Obviously,* (i), (ii), (iii) *are equivalent to the following*:

(iv) *There exist a neighborhood* $U \times V \subseteq X \times Y$ *of* $(\bar{x}, \bar{y})$ *and a real* $\tau \in (0, +\infty)$ *such that for any* $(x,y) \in V$ *with* $y \notin F(x)$ *and any* $\varepsilon > 0$, *then for all sequences* $\{x_n\}_{n\in\mathbb{N}} \subseteq X$ *converging to* x *with*

$$\lim_{n\to\infty} d(y, F(x_n)) = \liminf_{u\to x} d(y, F(u)),$$

there exists a sequence $\{u_n\}_{n\in\mathbb{N}} \subseteq X$ *with* $\lim_{n\to\infty} d(u_n, x) > 0$ *such that* (4.2) *holds.*

Now let X be a complete metric space, and let Y be a normed linear space. Let $F, \Phi : X \rightrightarrows Y$ be set-valued mappings and $(\bar{x}, \bar{y}) \in \text{gph } F \cap \text{gph } \Phi$ be given. To study the perturbation stability of local metric regularity, instead of $\sigma_{F,\Phi}(x, r)$ used in the global case, we will use the following quantity:

(4.5)
$$\sigma_{F,\Phi}(x, t_1, t_2, r) := \sup_{\eta \in \Phi(x) \cap B(\bar{y}, t_1)} \inf_{v \in F(x) \cap B(\bar{y}, t_2)} \sup_{d(u,x) < r, w \in F(u)} \inf_{\xi \in \Phi(u)} \|\eta - v + w - \xi\|,$$

with $x \in X$; $t_1, t_2, r \in (0, +\infty)$.

THEOREM 4.4. *Let X be a complete metric space and Y be a normed linear space. Let $F, \Phi : X \rightrightarrows Y$ be set-valued mappings with closed graphs. Let $(\bar{x}, \bar{y}) \in \text{gph } F \cap \text{gph } \Phi$ be given. Suppose that there exist reals $\alpha, \beta > 0$ and $\tau > 0$ such that*

$$d(x, F^{-1}(y)) \leq \tau d(y, F(x)) \quad \text{for all } (x, y) \in B(\bar{x}, \alpha) \times B(\bar{y}, \beta). \tag{4.6}$$

If there exist positive reals $t_1, t_2, s, \lambda, \delta$ with $t_2 < (0, \beta), \lambda \in (0, \tau^{-1})$ such that

$$\sigma_{F,\Phi}(x, t_1, t_2, r) \leq \lambda r \quad \text{for all } x \in B(\bar{x}, \delta),\ r \in (0, s), \tag{4.7}$$

then Φ is metrically regular around $\bar{x}$ with respect to $\bar{y}$ with modulus $(\tau^{-1} - \lambda)^{-1}$.

Proof. It suffices to show that statement (iii) of Theorem 4.1 applies to the mapping Φ around $(\bar{x}, \bar{y})$. Set

$$\gamma = \min\{t_1/2, \beta - t_2, \delta\tau^{-1}, s\tau^{-1}\}; a := \min\{\alpha, \delta\}; b := \min\{\beta, t_1 - \gamma\}.$$

Let $(x, y) \in B(\bar{x}, a) \times B(\bar{y}, b)$ with $y \notin \Phi(x)$ and $\liminf_{u \to x} d(y, \Phi(u)) < \gamma$. Let $\{x_n\}_{n \in \mathbb{N}}$ be a sequence in X such that $d(x_n, x) \to 0$ and $d(y, \Phi(x_n)) \to \liminf_{u \to x} d(y, \Phi(u))$. Without loss of generality, we can assume that $x_n \in B(\bar{x}, a)$ and $d(y, \Phi(x_n)) < \gamma$ for all $n \in \mathbb{N}$. Pick a sequence $\{\varepsilon_n\}_{n \in \mathbb{N}}$ of positive reals converging to zero and satisfying $(1 + \varepsilon_n) d(y, \Phi(x_n)) < \gamma$ for all $n \in \mathbb{N}$. For each integer n take $\eta_n \in \Phi(x_n)$ such that

$$\|y - \eta_n\| < (1 + \varepsilon_n) d(y, \Phi(x_n)). \tag{4.8}$$

Then,

$$\|\eta_n - \bar{y}\| \leq \|\eta_n - y\| + \|y - \bar{y}\| < \gamma + b \leq t_1.$$

If $r_n := (1 + \varepsilon_n)\tau d(y, \Phi(x_n))$, then $r_n \in (0, s)$. Therefore by (4.7), for each n there exists $v_n \in F(x_n) \cap B(\bar{y}, t_2)$ such that

$$\sup_{d(u,x) < r_n, w \in F(u)} \inf_{\xi \in \Phi(u)} \|\eta_n - v_n + w - \xi\| < (1 + \varepsilon_n)\lambda r_n. \tag{4.9}$$

Set $z_n := y - \eta_n + v_n$. Then

$$\|z_n - \bar{y}\| \leq \|y - \eta_n\| + \|v_n - \bar{y}\| < \gamma + t_2 \leq \beta,$$

that is, $z_n \in B(\bar{y}, \beta)$. According to relation (4.6), we can select $u_n \in F^{-1}(z_n)$ such that

$$\begin{aligned} d(x_n, u_n) &\leq (1 + \varepsilon_n)\tau d(z_n, F(x_n)) \leq (1 + \varepsilon_n)\tau \|z_n - v_n\| \\ &< (1 + \varepsilon_n)\tau d(y, \Phi(x_n)) := r_n < \tau\gamma \leq s. \end{aligned}$$

Therefore, by (4.9),

$$\inf_{\xi\in\Phi(u_n)} \|\eta_n - v_n + z_n - \xi\| < (1+\varepsilon_n)\lambda r_n,$$

i.e., $d(y,\Phi(u_n)) < (1+\varepsilon_n)\lambda r_n$. Next, similar to the argument developed in the proof of Theorem 3.3, we obtain $\lim_{n\to\infty} d(x,u_n) > 0$ and that

$$\limsup_{n\to\infty} \frac{d(y,\Phi(x_n)) - d(y,\Phi(u_n))}{d(x_n,u_n)} > \tau^{-1} - \lambda.$$

By virtue of Theorem 4.1 (and its proof), we derive

$$d(x,\Phi^{-1}(y)) \le \tau d(y,\Phi(x)) \quad \text{for all } (x,y)\in B(\bar{x},2c\tau)\times B(\bar{y},c),$$

where $c = \min\{a, a\tau^{-1}/6, b, \gamma/4\}$. This completes the proof. □

The following corollary generalizes a result established by Dontchev, Lewis, and Rockafellar [15, Theorem 3.3].

COROLLARY 4.5. *Let X be a complete metric space, and let Y be a normed linear space. Let $F, G : X \rightrightarrows Y$ be set-valued mappings such that both F and $\Phi := F + G$ have closed graphs. Let $(\bar{x},\bar{y}) \in \operatorname{gph} F$ and suppose that G is single-valued at $\bar{x}$ with $G(\bar{x}) := \bar{z}$. If F is metrically regular at $\bar{x}$ with respect to $\bar{y}$ with modulus $\tau > 0$ and G is locally Lipschitz around $\bar{x}$ with constant $\lambda \in (0,\tau^{-1})$, then Φ is metrically regular at $\bar{x}$ with respect to $\bar{y}+\bar{z}$ with modulus $(\tau^{-1}-\lambda)^{-1}$.*

Proof. By translation, if necessary, without loss of generality, we can assume that $G(\bar{x}) = 0$. That is, $(\bar{x},\bar{y}) \in \operatorname{gph} F \cap \operatorname{gph} \Phi$. Let $\alpha, \beta > 0$ such that

$$d(x,F^{-1}(y)) \le \tau d(y,F(x)) \quad \text{for all } (x,y)\in B(\bar{x},\alpha)\times B(\bar{y},\beta).$$

Let $\delta \in (0, \beta\lambda^{-1}/4)$ be such that G is Lipschitz on $B(\bar{x},\delta)$ with constant λ, i.e.,

$$\sup_{y\in G(x)} \inf_{u\in G(u)} \|y-u\| \le \lambda d(x,u) \quad \text{for all } x,u \in B(\bar{x},\delta).$$

By considering $u := \bar{x}$, we get $\sup_{y\in G(x)} \|y\| \le \lambda d(x,\bar{x}) < \lambda\delta$ for all $x \in B(\bar{x},\delta)$. Take $x \in B(\bar{x},\delta/2)$ and $r \in (0,\delta/2)$. For any $\eta := \eta_1 + y \in \Phi(x) \cap B(\bar{y},\beta/4)$, with $\eta_1 \in F(x), y \in G(x)$, then

$$\|\eta_1 - \bar{y}\| \le \|y\| + \|\eta - \bar{y}\| < \lambda\delta + \beta/4 < \beta/2.$$

Hence, $\eta_1 \in F(x) \cap B(\bar{y},\beta/2)$ and by virtue of the definition of $\sigma_{F,\Phi}(x,\beta/4,\beta/2,r)$, we obtain

$$\begin{aligned}\sigma_{F,\Phi}(x,\beta/4,\beta/2,r) &\le \sup_{y\in G(x)} \sup_{d(u,x)<r, w\in F(u)} \inf_{\xi\in\Phi(u)} \|y+w-\xi\| \\ &\le \sup_{y\in G(x)} \sup_{d(u,x)<r} \inf_{p\in G(u)} \|y-p\| \le \lambda r.\end{aligned}$$

Thus, all assumptions of Theorem 4.4 are satisfied with $t_1 = \beta/4$; $t_2 = \beta/2$; and $s = \delta/2$. This shows that Φ is metrically regular around $\bar{x}$ with respect to $\bar{y}$ with modulus $(\tau^{-1}-\lambda)^{-1}$. □

REMARK 4.6. *From the proofs of Theorem 4.4 and the preceding corollary, we see that if F is globally metrically regular (that is, $\alpha = \beta = +\infty$ in Theorem 4.5) with modulus τ, then there exists a constant $c > 0$ depending only on τ such that for any*

locally Lipschitzian mapping $G : X \rightrightarrows Y$ on $B(\bar{x}, \delta)$ with constant $\lambda \in (0, \tau^{-1})$ and $G(\bar{x}) := \bar{z}$, one has

$$d(x, \Phi^{-1}(y)) \leq d(y, \Phi(x)) \quad \text{for all } (x, y) \in B(\bar{x}, 2c\tau\delta) \times B(\bar{y} + \bar{z}, c\delta),$$

where $\Phi := F + G$.

Next, we give the following perturbation stability result using the quantity $\sigma_{F,\Phi}(x, r)$ as in the global perturbation stability (section 3), but with an additional suitable condition.

THEOREM 4.7. *Let X be a complete metric space and Y be a normed linear space. Let $F, \Phi : X \rightrightarrows Y$ be set-valued mapping with closed graphs. Let $(\bar{x}, \bar{y}) \in \text{gph } F$ and $(\bar{x}, \bar{z}) \in \text{gph } \Phi$ be given. Suppose that F is metrically regular with modulus $\tau > 0$ and that the following two conditions are satisfied.*

(i) *There exist positive reals s, λ, δ with $\lambda \in (0, \tau^{-1})$ such that*

$$\sigma_{F,\Phi}(x, , r) \leq \lambda r \quad \text{for all } x \in B(\bar{x}, \delta), r \in (0, s); \tag{4.10}$$

(ii) $\lim_{x \to \bar{x}} e(F(x) - \bar{y}, \Phi(x) - \bar{z}) = 0$, *where* $e(F(x) - \bar{y}, \Phi(x) - \bar{z}) = \sup_{u \in F(x) - \bar{y}} d(u, \Phi(x) - \bar{z})$.

Then Φ is metrically regular around $\bar{x}$ with respect to $\bar{z}$ with modulus $(\tau^{-1} - \lambda)^{-1}$.

Proof. By translation, considering $\Phi + \bar{y} - \bar{z}$ instead of Φ, we can assume that $\bar{z} = \bar{y}$. Let $\alpha, \beta > 0$ such that

$$d(x, F^{-1}(y)) \leq \tau d(y, F(x)) \quad \text{for all } (x, y) \in B(\bar{x}, \alpha) \times B(\bar{y}, \beta).$$

By (ii), we can find $\delta_1 \in (0, \delta/2)$ such that

$$e(F(x), \Phi(x)) < \beta/4 \quad \text{for all } x \in B(\bar{x}, \delta_1). \tag{4.11}$$

Set

$$\gamma = \min\{\delta_1/2, \beta/4, s\tau^{-1}, \beta\alpha^{-1}/4\}; a = \min\{\alpha, \delta_1/2\}; b = \beta/4.$$

Similar to the proof of Theorem 4.4, it suffices to show that statement (iii) of Theorem 4.1 is satisfied for the mapping Φ around $(\bar{x}, \bar{y})$. Indeed, let $(x, y) \in B(\bar{x}, a) \times B(\bar{y}, b)$ with $y \notin \Phi(x)$ and $d(y, \Phi(x)) < \gamma$. Let $\{x_n\}_{n \in \mathbb{N}}$; $\{\varepsilon_n\}_{n \in \mathbb{N}}$; $\{r_n\}_{n \in \mathbb{N}}$; $\{\eta_n\}_{n \in \mathbb{N}}$; $\{v_n\}_{n \in \mathbb{N}}$; $\{z_n\}_{n \in \mathbb{N}}$ as in the proof of Theorem 4.4. Then, by relations (4.10) and (4.11), one has

$$\|\eta_n - v_n\| < \sup_{d(u,x) < r_n, w \in F(u)} \inf_{\xi \in \Phi(u)} \|w - \xi\| + (1 + \varepsilon_n)\lambda r_n < \beta/4 + \beta/4 = \beta/2.$$

Consequently, $z_n := y - \eta_n + v_n \in B(\bar{y}, \beta)$. We conclude as in the proof of Theorem 4.4. □

Noticing that if $G : X \rightrightarrows Y$ is locally Lipschitz around $\bar{x}$, then (ii) holds trivially for $\Phi := F + G$. We obtain the following corollary, where, the assumption that G is single-valued at $\bar{x}$ in Corollary 4.5 can be removed.

COROLLARY 4.8. *Let X be a complete metric space, and let Y be a normed linear space. Let $F, G : X \rightrightarrows Y$ be set-valued mappings such that both F and $\Phi := F + G$ have closed graphs. Let $(\bar{x}, \bar{y}) \in \text{gph } F$ and $\bar{z} \in G(\bar{x})$. If F is metrically regular at $\bar{x}$ with respect to $\bar{y}$ with modulus $\tau > 0$ and G is locally Lipschitz around $\bar{x}$ with constant $\lambda \in (0, \tau^{-1})$, then Φ is metrically regular at $\bar{x}$ with respect to $\bar{y} + \bar{z}$ with modulus $(\tau^{-1} - \lambda)^{-1}$.*

In [24, Theorem 1], Izmailov and Solodov established an error bound for so-called strongly 2-regular mappings for which the classical regular condition is not satisfied. Then, this result has been extended by He and Sun [19, Theorems 3.1, 4.2] to the case of cone inclusion constraints. Such proofs are based on the set-valued contraction mapping principle. To end this paper, we use Theorem 4.4 to generalize Theorem 1 in [24] and Theorem 4.2 in [19].

Let X be a Banach space, and let Y be a normed linear space. Let $f : X \to Y$ be a given mapping and $K \subseteq Y$ be a closed convex cone. Consider the following inclusion:

$$S := \{x \in X : f(x) \in K\}. \tag{4.12}$$

Let $\bar{x} \in S$ be given. As in [24, 19], we make use of the following hypotheses:

(H1) f is continuously differentiable on a neighborhood V of $\bar{x}$ in X.

(H2) Denote by $Y_1 \subseteq Y$ the closed subspace spanned by $f'(\bar{x})(X) - K$. Then we suppose that Y_1 has a closed complementary subspace Y_2 in Y (which is not the case in general).

Let P and Q denote the projectors from Y onto Y_2 and Y_1, respectively.

(H3) $Pf' : V \to \mathcal{L}(X, Y)$ is Lipschitzian on V with Lipschitz constant L.

(H4) Pf' is B-directionally differentiable at $\bar{x}$ with derivative $(Pf')'(\bar{x}, \cdot)$, i.e.,

$$Pf'(\bar{x} + h) = Pf'(\bar{x}) + (Pf')'(\bar{x}, h) + o(\|h\|), h \in V - \bar{x}.$$

For $h \in X$, set

$$F(h)(u) = f'(\bar{x})(u) + (Pf')'(\bar{x}, h)(u); \quad F(h, K)(u) := (F(h))(u) - K, \quad u \in X,$$
$$\|F(h, K)^{-1}\| := \sup_{y \in Y, \|y\|=1} d(0, F(h, K)^{-1}(y)).$$

Corollary 4.9. *Suppose that assumptions (H1)–(H4) are satisfied. Let K_1 and K_2 be two closed convex cones such that $K_1 + K_2 = K$. If there exists $\nu > 0$ such that*

$$\sup\{\|F(h, K)^{-1}\| : h \in \mathbb{T}_\nu; \|h\| = 1\} := \mu < +\infty, \tag{4.13}$$

where $\mathbb{T}_\nu = \{h \in X : d(f'(\bar{x})(h), K_1) \le \nu,\ d((Pf')'(\bar{x}, h)h, K_2) \le \nu\}$, then there exist $\tau > 0$, $\delta > 0$ such that

$$d(x, S) \le \tau\Big[d(Q(f(x) - f(\bar{x}), K_1) + \|x - \bar{x}\|^{-1} d(P(f(x) - f(\bar{x})), K_2)\Big] \quad \text{for all } x \in B(\bar{x}, \delta) \setminus \{\bar{x}\}. \tag{4.14}$$

In the proof, we make use of the following lemmas.

Lemma 4.10 (Izmailov–Solodov [24, Lemma 1]). *Suppose that the assumptions (H1)–(H3) are fulfilled. Then for any $\varepsilon > 0$ there exists $\delta > 0$ such that*

$$\|Q(f(x) - f(\bar{x})) - f'(\bar{x})(x - \bar{x})\| \le \varepsilon\|x - \bar{x}\| \quad \text{for all } x \in B(\bar{x}, \delta).$$

In addition, assume that Pf' is B-directionally differentiable at $\bar{x}$ with respect to a cone C, i.e., for all $h \in C$, Pf' has a directional derivative at $\bar{x}$ with respect to every $h \in C$ and

$$Pf'(\bar{x} + h) = Pf'(\bar{x}) + (Pf')'(\bar{x}, h) + o(\|h\|), h \in (V - \bar{x}) \cap C,$$

then one has

$$\left\| P(f(x)-f(\bar{x}))-\frac{1}{2}(Pf')'(\bar{x},x-\bar{x})(x-\bar{x})\right\| \\ \leq \varepsilon\|x-\bar{x}\|^2 \quad \textit{for all } x\in B(\bar{x},\delta)\cap(\bar{x}+C).$$

The following lemma is a refinement of Lemma 2 in [24].

LEMMA 4.11. *Suppose that the hypotheses* $(H1)$–$(H3)$ *are verified. Then for any* $\varepsilon,\gamma>0$, *there exists* $\delta>0$ *such that* $B(\bar{x},(1+\gamma)\delta)\subseteq V$ *and for all* $x\in B(\bar{x},\delta)$, *all* $u,v\in B(0,\gamma\|x-\bar{x}\|)$, *one has*

$$\|Q(f(x+u)-f(x+v))-f'(\bar{x})(u-v)\|\leq\varepsilon\|u-v\|.$$

In addition, assume that Pf' *is* B*-directionally differentiable at* $\bar{x}$ *with respect to a cone* C; *then one has*

$$\|P(f(x+u)-f(x+v))-(Pf')'(\bar{x},x-\bar{x})(u-v)\|\leq(\varepsilon+L\gamma)\|x-\bar{x}\|\|u-v\|$$

for all $x\in B(\bar{x},\delta)\cap(\bar{x}+C)$, *and all* $u,v\in B(0,\gamma\|x-\bar{x}\|)$.

Proof. Let $\varepsilon,\gamma>0$ be given. Let $\delta>0$ such that $B(\bar{x},(1+\gamma)\delta)\subseteq V$ and

$$\|Qf'(x)-Qf'(\bar{x})\|+\|Pf'(x)-Pf'(\bar{x})\|<\varepsilon \quad \text{for all } x\in B(\bar{x},(1+\gamma)\delta).$$

Let $x\in B(\bar{x},\delta)$, u, $v\in B(0,\gamma\|x-\bar{x}\|)$. By virtue of the mean value theorem (M.V.T), there exists $\theta\in[0,1]$ such that

$$Q(f(x+u)-f(x+v))=Qf'(z)(u-v),\ \text{with } z:=x+\theta u+(1-\theta)v.$$

Hence,

$$\|Q(f(x+u)-f(x+v))-Qf'(\bar{x})(u-v)\|=\|Qf'(z)-Qf'(\bar{x})\|\|u-v\|\leq\varepsilon\|u-v\|.$$

For the second part, in addition, let $\delta>0$ such that

$$\|Pf'(\bar{x}+th)-Pf'(\bar{x})-t(Pf')'(\bar{x},h)\|<\varepsilon t, h\in(V-\bar{x})\cap C, t\in[0,\delta]. \tag{4.15}$$

Let $x\in B(\bar{x},\delta)$, $u,v\in B(0,\gamma\|x-\bar{x}\|)$ be given. As above, by (M.V.T), noting that Pf' is Lipschitzian on V, one has

$$\|P(f(x+u)-f(x+v))-Pf'(x)(u-v)\|\leq L\gamma\|x-\bar{x}\|\|u-v\|.$$

On the other hand, by (4.15), note that $Pf'(\bar{x})=0$,

$$\|Pf'(x)(u-v)-(Pf')'(\bar{x},x-\bar{x})(u-v)\|\leq\varepsilon\|x-\bar{x}\|\|u-v\|.$$

Combining this inequality and the previous inequality, we derive the conclusion. □

Proof of Corollary 4.9. By Lemmas 4.10 and 4.11, for any ε with $0<\varepsilon<\min\{\mu^{-1}/2,\nu/2\}$, there exist $\delta,\gamma>0$ such that $B(\bar{x},(1+\gamma)\delta)\subseteq V$ and for all $x\in B(\bar{x},\delta)$, all $u,v\in B(0,\gamma\|x-\bar{x}\|)$, one has

$$\|Q(f(x)-f(\bar{x}))-f'(\bar{x})(x-\bar{x})\|\leq\varepsilon\|x-\bar{x}\|,$$

$$\|P(f(x)-f(\bar{x}))-\frac{1}{2}(Pf')'(\bar{x})(x-\bar{x})(x-\bar{x})\|\leq\varepsilon\|x-\bar{x}\|^2 \tag{4.16}$$

$$\|Q(f(x+u)-f(x+v))-f'(\bar{x})(u-v)\|\leq\varepsilon\|u-v\|, \tag{4.17}$$

and

$$\|P(f(x+u)-f(x+v))-(Pf')'(\bar{x},x-\bar{x})(u-v)\|\le\varepsilon\|x-\bar{x}\|\|u-v\|. \tag{4.18}$$

Let $x\in B(\bar{x},\delta)\setminus\{\bar{x}\}$ and set $h=(x-\bar{x})/\|x-\bar{x}\|$. We distinguish the following two cases.

Case 1. $h\notin\mathbb{T}_\nu$. By (4.16), one obviously derives

$$\begin{aligned}d(Q(f(x)-f(\bar{x})),K_1)&\ge\|x-\bar{x}\|\big(d(f'(\bar{x})(h),K_1)-\varepsilon\big),\\ \|x-\bar{x}\|^{-1}d(P(f(x)-f(\bar{x})),K_2)&\ge\|x-\bar{x}\|\left(\frac{1}{2}d((Pf')'(\bar{x},h)h,K_2)-\varepsilon\right).\end{aligned}$$

Hence

$$\begin{aligned}&d(Q(f(x)-f(\bar{x})),K_1)+\|x-\bar{x}\|^{-1}d(P(f(x)-f(\bar{x})),K_2)\\&\quad\ge(\nu/2-\varepsilon)\|x-\bar{x}\|\ge(\nu/2-\varepsilon)d(x,S).\end{aligned}$$

Case 2. $h\in\mathbb{T}_\nu$. Let $g:X\to Y$ and $\Phi:X\rightrightarrows Y$ defined by, $u\in X$,

$$\begin{aligned}g(u)&:=Q(f(x+u)-f(\bar{x}))+\|x-\bar{x}\|^{-1}P(f(x+u)-f(\bar{x}))-F(h)(u),\ \text{and}\\ \Phi(u)&=F(h,K)(u)+g(u).\end{aligned}$$

One has

$$\begin{aligned}\|g(u)-g(v)\|\le{}&\|P(f(x+u)-f(x+v))-(Pf')'(\bar{x},x-\bar{x})(u-v)\|\\&+\|x-\bar{x}\|^{-1}\|P(f(x+u)-f(x+v))-(Pf')'(\bar{x},x-\bar{x})(u-v)\|.\end{aligned}$$

Then by relations (4.17) and (4.18), g is Lipschitz on $B(0,\gamma\|x-\bar{x}\|)$ with constant 2ε. Note that $F(h,K)(\cdot)$ is a closed convex process, since (4.13) and by virtue of Theorem 1 in [39] due to Robinson, $F(h,K)$ is (globally) metrically regular with modulus μ. Therefore, by Corollary 4.5, Φ is metrically regular around 0 with respect to $g(0)=Q(f(x)-f(\bar{x}))+\|x-\bar{x}\|^{-1}P(f(x)-f(\bar{x}))$ with modulus $(\mu^{-1}-2\varepsilon)^{-1}$. Moreover, according to Remark 4.6, there exists a constant $c>0$ depending only on μ such that

$$\begin{aligned}d(u,\Phi^{-1}(y))\le(\mu^{-1}-2\varepsilon)^{-1}d(y,\Phi(u))\quad&\text{for all }(u,y)\in B(0,2c\tau\gamma\|x-\bar{x}\|)\\&\times B(g(0),c\gamma\|x-\bar{x}\|).\end{aligned} \tag{4.19}$$

Hence, if $d(0,\Phi(0))=d(g(0),K)\ge c\gamma\|x-\bar{x}\|$, then

$$d(Q(f(x)-f(\bar{x})),K_1)+\|x-\bar{x}\|^{-1}d(P(f(x)-f(\bar{x})),K_2)\ge d(g(0),K)\ge c\gamma d(x,S);$$

otherwise, taking a sequence $\{z_n\}_{n\in\mathbb{N}}\subseteq K$ with $\lim_{n\to\infty}\|g(0)-z_n\|=d(g(0),K)$, one has (note that $x+\Phi^{-1}(z_n)\subseteq S$)

$$\begin{aligned}d(x,S)&\le\liminf d(0,\Phi^{-1}(z_n))\le(\mu^{-1}-2\varepsilon)^{-1}\liminf d(z_n,\Phi(0))\\&=(\mu^{-1}-2\varepsilon)^{-1}d(g(0),K).\end{aligned}$$

Consequently, one obtains

$$d(x,S)\le(\mu^{-1}-2\varepsilon)^{-1}\big(d(Q(f(x)-f(\bar{x})),K_1)+\|x-\bar{x}\|^{-1}d(P(f(x)-f(\bar{x})),K_2)\big).$$

Combining the two cases, we establish the proof. □

In [25], Izmailov and Solodov have established a locally covering property at a point of so-called 2-regular mappings. We next give a new simple proof of that result, which is based on Corollary 4.5.

COROLLARY 4.12 (see [25, Theorem 4.1]). *Let X, Y be Banach spaces. Suppose that the assumptions $(H1)$–$(H3)$ hold with $K = \{0\}$ and that the mapping $Pf'(\cdot)$ has a directional derivative at the point $\bar{x}$ in a direction $h \in X$ with $\|h\| = 1$, satisfying $f'(\bar{x})(h) = 0$ and $(Pf')'(\bar{x}, h)(h) = 0$. If the mapping f is 2-regular at $\bar{x}$ with respect to h, i.e., the continuous linear mapping*

$$u \mapsto F(h)(u) := f'(\bar{x})(u) + (Pf')'(\bar{x}, h)(u)$$

from X to Y is surjective, then there exist a neighborhood W of $f(\bar{x})$ in Y and a constant $C > 0$ such that

$$d(\bar{x}, f^{-1}(y)) \le C\|f(\bar{x}) - y)\|^{1/2} \quad \text{for all } y \in W.$$

Proof. We can assume $f(\bar{x}) = 0$ without loss of generality. Since $F(h)(\cdot)$ is surjective, then by the open mapping principle,

$$M := \sup\{d(0, F(h)^{-1}(y)) : y \in Y, \|y\| = 1\} < +\infty.$$

For each $t > 0$, set $x_t := x + th$. Using Lemmas 4.10 and 4.11, for any ε, $\gamma > 0$ with $2\varepsilon + L\gamma \in (0, M^{-1})$, we can find $\delta \in (0, 1)$ such that $B(\bar{x}, (1+\gamma)\delta) \subseteq V$ and that for all $t \in (0, \delta)$, all $u, v \in B(0, \gamma t)$, one has

$$\|Q(f(x_t))\| \le \varepsilon t, \quad \|P(f(x_t))\| \le \varepsilon t^2 \tag{4.20}$$

$$\|Q(f(x_t + u) - f(x_t + v)) - f'(\bar{x})(u - v)\| \le \varepsilon\|u - v\|, \tag{4.21}$$

and

$$\|P(f(x_t + u) - f(x_t + v)) - t(Pf')'(\bar{x}, h)(u - v)\| \le (\varepsilon + L\gamma)t\|u - v\|. \tag{4.22}$$

Similar to the proof of Case 2 in Corollary 4.9, defining $g_t : X \to Y$ and $\Phi_t : X \to Y$ by

$$g_t(u) := Q(f(x_t + u)) + t^{-1}P(f(x_t + u)) - F(h)(u)$$

and

$$\Phi_t(u) = F(h)(u) + g_t(u) = Q(f(x_t + u)) + t^{-1}P(f(x_t + u)),$$

there exists a constant $c > 0$ depending only on M such that

$$d(u, \Phi_t^{-1}(y)) \le (M^{-1} - 2\varepsilon - L\gamma)^{-1}\|y - \Phi_t(u)\|$$
$$\text{for all } (u, y) \in B(0, 2c\tau\gamma t) \times B(g_t(0), c\gamma t). \tag{4.23}$$

Therefore, we obtain (for $\tau = (M^{-1} - 2\varepsilon - L\gamma)^{-1}$)

$$\begin{aligned} d(0, \Phi_t^{-1}(y) &= d(x_t, f^{-1}(y)) \\ &\le \tau\Big[\|Q(f(x_t) - y)\| + t^{-1}\|P(f(x_t) - y)\|\Big] \quad \text{for all } y \in B(g_t(0), c\gamma t). \end{aligned}$$

Take $\varepsilon \in (0, M^{-1}/2)$ such that $\varepsilon < c\gamma/2$. From (4.20) it yields $\|g_t(0)\| \le 2\varepsilon t$. Set $\eta := \min\{\delta, c\gamma - 2\varepsilon\}^2$. Now let $y \in B(0, \eta)$ and take $t = \|y\|^{1/2}$. Then, obviously, $y \in B(g_t(0), c\gamma t)$. Hence, from (4.23), we obtain

$$\begin{aligned} d(\bar{x}, f^{-1}(y)) &\le d(x_t, f^{-1}(y)) + t \le \tau(\|Q(f(x_t) - y)\| + t^{-1}\|P(f(x_t) - y)\|) + t \\ &\le \tau(\|Qy\| + t^{-1}\|Py\|) + 2\varepsilon t + t \le \tau(\|y\| + 2(\varepsilon + 1)\|y\|^{1/2}), \end{aligned}$$

establishing the proof. □

BRANCH-AND-CUT FOR THE MAXIMUM FEASIBLE SUBSYSTEM PROBLEM*

MARC E. PFETSCH†

Abstract. This paper presents a branch-and-cut algorithm for the NP-hard maximum feasible subsystem problem: For a given infeasible linear inequality system, determine a feasible subsystem containing as many inequalities as possible. The complementary problem, where one has to remove as few inequalities as possible in order to make the system feasible, can be formulated as a set covering problem. The rows of this formulation correspond to irreducible infeasible subsystems, which can be exponentially many. It turns out that the main issue of a branch-and-cut algorithm for the maximum feasible subsystem problem (MAX FS) is to efficiently find such infeasible subsystems. We present three heuristics for the corresponding NP-hard separation problem and discuss cutting planes from the literature, such as set covering cuts of Balas and Ng, Gomory cuts, and $\{0, \frac{1}{2}\}$-cuts. Furthermore, we compare a heuristic of Chinneck and a simple greedy algorithm. The main contribution of this paper is an extensive computational study on a variety of instances arising in a number of applications.

1. Introduction.

In the *maximum feasible subsystem problem* (MAX FS), we are given an infeasible linear inequality system $\Sigma : \{A\boldsymbol{x} \leq \boldsymbol{b}\}$, with $A \in \mathbb{R}^{m\times n}$, $\boldsymbol{b} \in \mathbb{R}^m$, and have to find a feasible subsystem containing as many inequalities as possible. This NP-hard combinatorial optimization problem has a number of interesting applications in a wide range of fields, for instance, in linear programming [29, 31, 36], statistical discriminant analysis and machine learning [4, 19, 43], telecommunications [54], and computational biology [61]. Additional applications and a survey can be found in [4] and [5], respectively.

The complementary problem of MAX FS amounts to removing as few inequalities of Σ as possible so that the resulting system is feasible. To achieve feasibility, one has to remove at least one inequality from each *irreducible infeasible subsystem* (IIS), i.e., an infeasible subsystem of Σ for which every proper subsystem is feasible. Introducing a binary variable y_i for each inequality of Σ, the complementary problem can be formulated as a set covering problem and is therefore called MIN IIS COVER:

$$\begin{array}{lll} \min & \sum_{i=1}^m y_i & \\ \text{such that} & \sum_{i\in I} y_i \geq 1 & \text{for all IISs } I, \\ & \boldsymbol{y} \in \{0,1\}^m. & \end{array} \tag{1}$$

Since the number of IISs can be exponential in the size of the system Σ (see Chakravarti [28] and Pfetsch [53]), IISs have to be generated dynamically in order to solve this formulation of MIN IIS COVER efficiently.

Clearly, the set of all inequalities not contained in a solution of MAX FS form a solution of MIN IIS COVER and vice versa. Hence, these two problems are equivalent when solving to optimality and are both strongly NP-hard; see Johnson and Preparata [39], Sankaran [58], and Chakravarti [28]. In terms of approximability, however, they differ: MAX FS does not admit a polynomial-time approximation scheme, unless P = NP, but there exists a 2-approximation; see Amaldi and Kann [9]. MIN IIS COVER is harder to approximate: Unless P = NP, it cannot be approximated in polynomial time within any constant factor; see Amaldi and Kann [10].

In this paper, we present a branch-and-cut approach for MAX FS via formulation (1) for MIN IIS COVER. A key issue of this approach is to find violated *IIS-inequalities*, i.e., the inequalities arising from IISs in (1). The corresponding separation problem is NP-hard, and we present three heuristics for it (see section 3.2). Two of these methods generate either a feasible solution for MIN IIS COVER or a (hopefully violated) IIS-inequality. As long as no feasible solution has been generated, the process is iterated, which often produces many useful IIS-inequalities. The additional benefit is reasonably good primal solutions, which can be improved by a simple greedy algorithm. This combination leads to an effective primal heuristic. Additionally, we examine the application of inequalities of Balas and Ng [18] for set covering problems, $\{0, \frac{1}{2}\}$-cuts, and Gomory cuts.

The emphasis of this paper is on an extensive computational study of the branch-and-cut implementation. Our aim is to show the potential and the limits of such an approach by performing tests on three problem sets: random infeasible inequality systems (section 4.2), problems arising in digital video broadcasting (section 4.3), and classification problems (section 4.4).

The theoretical foundation for our approach appears in Amaldi, Pfetsch, and Trotter [12], where algorithmic and geometric questions concerning IISs are studied and the feasible subsystem polytope is investigated. (The polyhedral results carry over to the polytope for MIN IIS COVER by a simple affine transformation.) The work presented here is an improved version of part of the author's Ph.D. thesis [53].

In the literature to date, only two exact approaches towards MIN IIS COVER have appeared. Parker and Ryan [52] discuss an iterative approach that generates IISs in each step and then solves an integer program. This approach turns out to be impractical for harder instances. Codato and Fischetti [33] present a branch-and-cut algorithm for MIN IIS COVER in a more general context. We discuss these approaches in more detail in the next section. Our algorithm improves upon both methods and is currently the best available exact approach (see section 4).

The outline of this paper is as follows. In section 2 we review solution approaches for MAX FS. In section 3 we describe the main ingredients of our branch-and-cut implementation. We discuss a way to check the feasibility of solutions for MIN IIS COVER, three methods to separate IIS-inequalities, primal heuristics, preprocessing, branching, inequalities by Balas and Ng, and other used cutting planes. In section 4 we extensively test the implementation on the abovementioned problem sets. We close with some conclusions in section 5.

We use the following notation. We define $[n] := \{1, \dots, n\}$ for $n \in \mathbb{N}$ and typeset vectors in bold font. For a set $S \subseteq [n]$ and a vector $\boldsymbol{x} \in \mathbb{R}^n$, define

$$\boldsymbol{x}(S) = \sum_{i \in S} x_i \,.$$

The *support* of a vector $\boldsymbol{x} \in \mathbb{R}^n$ is $\operatorname{supp}(\boldsymbol{x}) := \{i \in [n] \,:\, x_i \neq 0\}$. By $\mathbb{1}$ we denote a vector of all 1's of appropriate dimension.

2. Alternative solution approaches. In this section we give a short overview of solution approaches for MAX FS and MIN IIS COVER.

In the context of linear programming, attention was first devoted to the problem of identifying IISs with a small and possibly minimum number of inequalities (see Greenberg and Murphy [36], Chinneck [30], and Chinneck and Dravnieks [32]). The goal is to help the modeler resolve infeasibility of large linear programs (LPs). Since minimum cardinality covers of IISs reveal essential information about infeasibility of the model and are often smaller than IISs, emphasis has shifted towards their identification. Chinneck [29, 31] developed extended greedy heuristics for MAX FS/MIN IIS COVER and provided computational results; see section 4.4.

For the application of MIN IIS COVER to classification problems (see section 4.4), several heuristics were proposed, based on nonlinear programming formulations of MAX FS (Bennett and Bredensteiner [19], Bennett and Mangasarian [20], and Mangasarian [43]).

An exact integer programming approach for MIN IIS COVER appeared in Parker and Ryan [52] and Parker [51]. Their idea is to consider the formulation in (1) with a partial list of IISs. If there exist IISs that are not covered by a solution to this formulation, they are added and the process is iterated. Otherwise, an optimal solution to MIN IIS COVER is found. Parker and Ryan discuss several methods of generating IISs at each step and consider heuristics for solving the set covering problem (only the last instance has to be solved exactly).

We reimplemented a basic version of their algorithm, where the set covering problems are solved to optimality. This implementation turned out to be inferior to our branch-and-cut implementation: It could not solve within one hour instances solved by our branch-and-cut approach within a few minutes. We therefore refrained from performing further experiments.

There is a straightforward mixed integer programming formulation for MIN IIS COVER containing a binary variable with a "big-M" for each of the inequalities of Σ, so that an inequality is relaxed when the corresponding binary variable is 1. This formulation has the typical numerical problems of big-M formulations and is in general inefficient for MAX FS; see Parker [51]. If there are fixed bounds on the variables, however, one can obtain a tight formulation. This leads to a quite efficient approach; see Rossi, Sassano, and Smriglio [54] and Codato and Fischetti [33]. In fact, Codato and Fischetti propose a general way of removing the "big-M" from this type of formulation and apply it to classification instances. In this context, it leads to the formulation (1), and their solution method is, in fact, a branch-and-cut method for MIN IIS COVER, independent from our approach. Computational results show that their approach is faster compared to the big-M formulation. In section 4.4 we compare our implementation with their approach.

Versions of the classical *relaxation method* of Agmon [3] and Motzkin and Schoenberg [47] for solving linear inequality systems can be applied to minimize the sum of violations in infeasible linear inequality systems. Randomized variants of this method were proposed by Amaldi [4] to solve MAX FS. Amaldi and Hauser [8] and Amaldi, Belotti, and Hauser [6] establish probabilistic convergence guarantees to an optimal solution of MAX FS under appropriate conditions. Computational results for digital video broadcasting data, classification instances, and huge systems arising in computational biology are given in [6].

Amaldi, Bruglieri, and Casale [7] propose a two-step heuristic in which first a linearization of an exact bilinear formulation of MAX FS is used to derive a feasible

subsystem. In the second step, a reduced problem is solved to optimality in order to identify inequalities that can be added to the first system while preserving feasibility. This turns out to be competitive with respect to the method of Codato and Fischetti and an integer programming solver applied to the "big-M" formulation for the whole system.

3. Ingredients for branch-and-cut. In the following we assume that the reader is familiar with the branch-and-cut approach. More information can be found in Nemhauser and Wolsey [48], Padberg and Rinaldi [50], Thienel [60], and Caprara and Fischetti [26]. A description and computational study of Gomory cuts is given in Balas et al. [17].

Recall that we are given the infeasible system $\Sigma : \{A\boldsymbol{x} \leq \boldsymbol{b}\}$, where $A \in \mathbb{R}^{m\times n}$ and $\boldsymbol{b} \in \mathbb{R}^m$. Depending on the application, *mandatory* variable bounds can be present; i.e., these bounds may not be removed for obtaining a feasible system (see sections 4.3 and 4.4). This can easily be dealt with in the branch-and-cut approach. Furthermore, weighted versions of Min IIS Cover are easy to handle, too.

Without loss of generality we can restrict attention to inequality systems in the form of Σ: Clearly, bounds on variables and "greater or equal" inequalities can be transformed to this format. Equations can be replaced by a pair of opposing inequalities. Since any point satisfies at least one inequality out of each pair, an optimal solution to the new instance contains $m^* + m_E$ inequalities if and only if an optimal solution to the original instance with m^* linear relations exists; here m_E is the number of equations. Thus, from a computational point of view, it suffices to handle systems in the form of Σ. Polyhedral results for the two cases, however, may differ; see [12, 53] for more information.

To simplify notation, we identify an inequality of Σ with its index. Then $S(\Sigma) := [m]$ is the set of constraints of Σ. With this notation, $I \subseteq S(\Sigma)$ is an IIS of Σ if and only if all proper subsets of I are feasible. We call a set $C \subseteq S(\Sigma)$ an *IIS-cover* if it intersects every IIS of Σ.

In the rest of this section we give a more detailed account of the main aspects of our implementation: the recognition problem for IIS-covers, the separation problem of IIS-inequalities, pool handling, primal heuristics, preprocessing, branching, and other cutting planes.

3.1. Recognition problem for IIS-covers. We consider the following fundamental problem: Given a subset $C \subseteq S(\Sigma)$, check whether it is an IIS-cover and if this is not the case, generate a witness, i.e., an IIS which is not covered. Our approach is based on the following theorem.

Theorem 1 (Gleeson and Ryan [35]). *Let $\Sigma : \{A\boldsymbol{x} \leq \boldsymbol{b}\}$ be an infeasible system. Then the IISs of Σ are in one-to-one correspondence with the supports of the vertices of the polyhedron*

$$P(\Sigma) := \{\, \boldsymbol{y} \in \mathbb{R}^m \,:\, \boldsymbol{y}^{\mathrm{T}}A = \boldsymbol{0},\ \boldsymbol{y}^{\mathrm{T}}\boldsymbol{b} = -1,\ \boldsymbol{y} \geq \boldsymbol{0} \,\}.$$

Note that the vertices of $P(\Sigma)$ are uniquely defined by their supports. This theorem is strongly related to the Farkas lemma, which states that $P(\Sigma) \neq \varnothing$ if and only if Σ is infeasible; see, e.g., Schrijver [59]. The polyhedron $P(\Sigma)$ is called the *alternative polyhedron* of Σ.

To apply Theorem 1, we define for $S \subseteq S(\Sigma)$ the polyhedron

$$P_S(\Sigma) := \{\, \boldsymbol{y} \in P(\Sigma) \,:\, y_i = 0,\ i \in S \,\},$$

which might be empty. We need the following fact.

LEMMA 2 (Parker and Ryan [52]). *The set $C \subseteq S(\Sigma)$ is an IIS-cover if and only if $P_C(\Sigma) = \varnothing$.*

Proof. The system defining $P(\Sigma)$, in which all variables indexed by C are removed, has no solution if and only if $P_C(\Sigma) = \varnothing$. By the Farkas lemma, the former is the case if and only if Σ with inequalities indexed by C removed is feasible, i.e., C is an IIS-cover. □

Recognizing whether $C \subseteq S(\Sigma)$ is an IIS-cover is now easy: If $P_C(\Sigma) = \varnothing$, by Lemma 2, C is an IIS-cover. Otherwise, let $\boldsymbol{v}$ be a vertex of $P_C(\Sigma)$. Then we have $\operatorname{supp}(\boldsymbol{v}) \cap C = \varnothing$, showing that $\operatorname{supp}(\boldsymbol{v})$ is an IIS that is uncovered (by Theorem 1). This provides a polynomial-time algorithm for the problem, since finding a vertex of a polyhedron can be done in polynomial time; see Grötschel, Lovász, and Schrijver [37]. Note that by Theorem 1 and Lemma 2, $P_C(\Sigma)$ always has a vertex if it is nonempty.

This recognition test in fact suffices for a rudimentary branch-and-cut algorithm, since we can now test feasibility of a vector $\boldsymbol{y} \in \{0,1\}^m$ for (1) by testing whether $\operatorname{supp}(\boldsymbol{y})$ is an IIS-cover.

3.2. Separation of IIS-inequalities. IIS-inequalities play a prominent role in the formulation (1) for MIN IIS COVER. In fact, it can be shown that the inequality arising from the IIS I defines a facet of the polytope

$$P_{IISC} = \operatorname{conv}\{\, \boldsymbol{y} \in \{0,1\}^m \,:\, y(S) \geq 1 \text{ for all IISs } S \,\},$$

as long as $|I| > 1$; see Amaldi, Pfetsch, and Trotter [12]. Therefore, the following *separation problem for IIS-inequalities* is crucial: Given a vector $\boldsymbol{y}^* \in [0,1]^m$, check whether there exists an IIS I so that its corresponding inequality is violated by $\boldsymbol{y}^*$, i.e., $\boldsymbol{y}^*(I) < 1$. The recognition problem for IIS-covers is a special case, where $\boldsymbol{y}^*$ is the incidence vector of the set to be tested. In the general case, however, we have the following.

PROPOSITION 3 (Amaldi, Pfetsch, and Trotter [12]). *The separation problem for IIS-inequalities is* NP*-hard.*

In this section, we therefore present three heuristics for the separation problem. All of these heuristics may fail to produce a violated IIS-inequality.

The heuristics build on the following reformulation of the separation problem: Compute

$$\lambda := \min\{\, \boldsymbol{y}^*(S) \,:\, S = \operatorname{supp}(\boldsymbol{v}),\ \boldsymbol{v} \text{ vertex of } P(\Sigma) \,\}. \tag{2}$$

If $\lambda < 1$, by Theorem 1, $\operatorname{supp}(\boldsymbol{v})$ provides an IIS whose IIS-inequality is violated; otherwise no such IIS exists (we define $\lambda = \infty$ if $P(\Sigma) = \varnothing$).

3.2.1. Method 1: "Single." The first quite intuitive idea for separating an IIS-inequality, already used by Parker and Ryan [52], is to approximate (2) by the following LP:

$$\min\{\, (\boldsymbol{y}^*)^{\mathrm{T}} \boldsymbol{p} \,:\, \boldsymbol{p} \in P(\Sigma) \,\}.$$

A vertex solution provides an IIS, whose corresponding inequality is not necessarily violated, but in practice often is.

This method generates only one IIS at a time. We also experimented with solving the above LP by the simplex algorithm and then testing whether the support of each vertex on the path to the optimum is an IIS whose inequality is violated. In our experiments this variant was inefficient and will not be considered further.

3.2.2. Method 2: "Extend." We extend Method 1 as follows. Let S be the support of $\boldsymbol{y}^*$. Applying Lemma 2, we can check whether S is an IIS-cover by finding a vertex solution of

$$\min\{\, (\boldsymbol{y}^*)^{\mathrm{T}}\boldsymbol{p} \,:\, \boldsymbol{p} \in P_S(\Sigma)\,\}$$

if one exists. If the LP is feasible, the result gives us a vertex which corresponds to an IIS; otherwise we found an IIS-cover, i.e., a primal solution for Min IIS Cover.

This approach can be iterated when S is not an IIS-cover. Let I be the IIS obtained in this case. We enlarge S greedily by an element of I and iterate. In our implementation, we choose an element of I that is contained in the maximal number of IISs we have found so far. At termination this yields an IIS-cover. This procedure is related to a primal heuristic proposed by Ryan [57].

The IISs found by this approach have several nice properties. First, the new IISs are different from all IISs that were known before the run if the current solution $\boldsymbol{y}^*$ of the LP-relaxation satisfies $y^*(I) \geq 1$ for each previously found IIS I. This follows since at least one element of each I is contained in S, and hence I cannot be generated again. Second, the corresponding inequalities are always violated, since they have empty intersection with $S \supseteq \operatorname{supp}(\boldsymbol{y}^*)$; i.e., $\boldsymbol{y}^*(I) = 0 < 1$ for each produced IIS I. Third, by construction of the set S, the generated IISs are pairwise different.

This method turns out to be quite effective for generating many violated IIS-inequalities. Furthermore, we obtain a primal solution in each run, which can be improved to very good solutions; see section 3.4. When the current LP-relaxation contains many cuts, however, the support of $\boldsymbol{y}^*$ tends to be large and often is already an IIS-cover or close to one, and the method cannot produce new IISs; this often happens in the deeper regions of the branch-and-bound tree. This might even be desirable, since this saves time for high depths. Nevertheless, this situation can be changed, as indicated by the next method.

3.2.3. Method 3: "Round." The idea of Method 2 can be further extended by using the fact that an arbitrary set S can be used at the start. In the extension, we choose $\alpha \in [0,1]$ and initially let $S := \{i : y^*_i \geq \alpha\}$. In the implementation we start with $\alpha = 0.1$ and then increase α by 0.1 until S is not an IIS-cover (in this case the above procedure is started). We terminate with a failure if α exceeds 0.6.

The fact that S is smaller for larger α has two effects: First, the number of steps needed to greedily obtain an IIS-cover is larger, and hence the number of generated IISs is increased. Second, the method also computes IISs in the deeper regions of the tree.

Again, in each step an IIS is generated, which is not covered by S, except in the last step where we obtain an IIS-cover. In contrast to the method "extend," the generated IISs are not necessarily new, and their corresponding inequalities may not be violated by $\boldsymbol{y}^*$.

3.3. Pool for IIS-inequalities. The above three methods tend to produce many IISs, which we store in a pool. It turns out that the best performance of the algorithm is achieved by checking the pool for violated inequalities in *every* node of the tree. Of course, the pool should be as small as possible without losing important inequalities. Therefore, the pool is equipped with an aging mechanism which removes IISs whose inequality has not been active for some time.

The computational results presented in section 4 indicate that only a small fraction of the total number of IISs needs to be generated by our branch-and-cut implementation; indeed, for larger problems there are far too many IISs to be enumerated

completely (cf. Table 2 in section 4.2). Hence, the size of the pool can be relatively small.

3.4. Primal heuristics. Chinneck [31] proposed a greedy heuristic for MIN IIS COVER, which we use as an initial primal heuristic. The basic tool is a so-called *elastic LP* in which the inequalities $\Sigma : \{A\boldsymbol{x} \leq \boldsymbol{b}\}$ are relaxed by adding slack variables and the sum of violations is minimized:

$$\begin{aligned} &\min \mathbb{1}^{\mathrm{T}}\boldsymbol{s} \\ &\text{s.t. } A\boldsymbol{x} - \boldsymbol{s} \leq \boldsymbol{b}, \\ &\boldsymbol{s} \geq 0. \end{aligned}$$

Starting with $S = \varnothing$, in each iteration $S \subseteq S(\Sigma)$ is enlarged by an inequality that yields the largest drop in the elastic LP objective if its objective coefficient is set to 0. The method stops once the objective is 0, i.e., S is a MIN IIS COVER. To speed up the solution, in each iteration only inequalities from a candidate set are checked. Chinneck proposes a measure based on the violation and dual variables to generate the candidate set. We refer to [31] for details.

For a heuristic running in the tree, we use a primal heuristic that greedily decreases the size of a given IIS-cover until a minimal one is obtained. We start this heuristic from IIS-covers produced by the separation methods in section 3.2, if available (otherwise we use a simple rounding heuristic). We start with C being an IIS-cover to be improved. We consider each element from C in the order of increasing fractional value of the current LP-solution $\boldsymbol{y}^*$. We remove an element if the remaining set is an IIS-cover (which is checked by the method in section 3.1).

3.5. Preprocessing. In a preprocessing step we search for small IISs. Such small IISs are of interest since their corresponding IIS-inequalities provide "strong" cuts and are hard to find by other methods.

We first check for IISs of cardinality one, e.g., $\boldsymbol{0x} \leq -1$. Then we check for IISs that involve one inequality and bounds on the variables (if present). Such IISs often occur when variable bounds are mandatory; see, e.g., section 4.4. In this case, a single inequality might be infeasible with the bounds and counts as an IIS. Furthermore, we look for IISs of cardinality two, which are easy to find by comparing their normal vectors and right-hand sides. Identifying other types of IISs would require higher computational effort.

3.6. Branching. As a branching rule, we apply *reliability branching*, introduced by Achterberg, Koch, and Martin [2]. It performs strong branching on a subset of the variables, which are chosen based on their so-called pseudocosts during branching. If in strong branching one of the child nodes turns out to be infeasible, the corresponding variable is fixed to the complementary value; if both children are infeasible, the current node can be pruned.

We also experimented with constraint branching rules. For instance, we used the well-known rule of Ryan and Foster [56]. This rule was superior to a simple variable branching, but inferior to reliability branching both in terms of computation time and the number of branch-and-bound nodes. We therefore selected reliability branching for all tests.

3.7. Inequalities for set covering. Many facet-defining inequalities for the set covering polytope have been investigated; see Ceria, Nobili, and Sassano [27] and

Borndörfer [22]. However, few (problem-specific) polynomial-time separable inequalities for set covering are known. For many classes of inequalities the complexity status is unknown, but is likely to be NP-hard.

We experimented with the aggregated cycle cuts of Borndörfer and Weismantel [23, 24]. Unfortunately, on our test problems their separation heuristic almost never found a violated inequality. Furthermore, it remains an interesting open problem to identify problem-specific inequalities for MIN IIS COVER.

A class of inequalities for set covering that we use in our implementation were proposed by Balas and Ng [18]. To describe these inequalities, consider the set covering polytope $P_{SC}(D) = \operatorname{conv}\{\boldsymbol{y} \in \{0,1\}^m : D\boldsymbol{y} \geq \mathbb{1}\}$, where $D = (d_{ij}) \in \{0,1\}^{k\times m}$. Assume $\boldsymbol{a}^{\mathrm{T}}\boldsymbol{y} \geq \beta$, with $\boldsymbol{a} \in \mathbb{Z}^m$ and $\beta \in \mathbb{Z}$, defines a facet of $P_{SC}(D)$. It is well known that if $\beta > 0$, then $\boldsymbol{a} \geq \boldsymbol{0}$, and if $\beta = 1$, then $\boldsymbol{a}$ is a row of D (see, e.g., [18]).

Balas and Ng showed that for every facet defining inequality $\boldsymbol{a}^{\mathrm{T}}\boldsymbol{y} \geq 2$ with $\boldsymbol{a} \in \mathbb{Z}^n$, there exists a set $S \subseteq [k]$ such that $\boldsymbol{a} = \boldsymbol{a}^S$, where

$$a_j^S = \begin{cases} 0 & \text{if } d_{ij} = 0 \text{ for all } i \in S, \\ 2 & \text{if } d_{ij} = 1 \text{ for all } i \in S, \\ 1 & \text{otherwise} \end{cases} \qquad \text{for } j = 1, \ldots, m.$$

These inequalities can also be obtained by a Chvátal–Gomory rounding procedure. Furthermore, Balas and Ng discuss conditions under which $\boldsymbol{a}^{S\mathrm{T}}\boldsymbol{y} \geq 2$ defines a facet of $P_{SC}(D)$.

The separation problem for the above inequalities is NP-hard; see Amaldi and Pfetsch [11]. However, when the size of S is fixed, the separation problem can be solved in polynomial time by enumeration. In our implementation we enumerate sets S of *cardinality three* and check whether the inequalities $\boldsymbol{a}^{S\mathrm{T}}\boldsymbol{y} \geq 2$ are violated by the current LP-solution. Note that sets S of cardinality two are uninteresting, since in this case $\boldsymbol{a}^{S\mathrm{T}}\boldsymbol{y} \geq 2$ is the sum of two IIS-inequalities and hence is never violated if the IIS-inequalities are satisfied.

Additionally, we try to strengthen these cuts: If an inequality is violated, we greedily enlarge the set S as long as the violation of the resulting inequality increases. See section 4 for computational results.

3.8. General purpose inequalities. In our computational experiments we used Gomory (mixed integer) cuts as implemented in SCIP (see section 4); see the books of Nemhauser and Wolsey [48] or Schrijver [59] for a description.

Further, we used $\{0, \frac{1}{2}\}$-cuts introduced by Caprara and Fischetti [25]. Codato and Fischetti [33] identified these cuts as important for solving MIN IIS COVER. We implemented these cuts along the lines of Hansen, Labbé, and Schindl [38]. See also Andreello, Caprara, and Fischetti [13] for a computational study of $\{0, \frac{1}{2}\}$-cuts. Note that in our implementation $\{0, \frac{1}{2}\}$-cuts are produced only for set covering and nonnegativity inequalities; in particular, they do not depend on $\{0, \frac{1}{2}\}$-cuts produced earlier.

We also experimented with mixed integer rounding cuts (CMIR) (see Marchand and Wolsey [44]) and strengthened Chvátal–Gomory cuts (see Letchford and Lodi [42]) as they are implemented in SCIP. The results were, however, discouraging, and we therefore do not present them.

4. Computational results. In this section we discuss computational results of our branch-and-cut implementation for MIN IIS COVER. The algorithm was implemented in `C++` and uses version 0.90 of the framework SCIP by Achterberg [1].

CPLEX 10.11 is used as the basic LP solver. The computations were performed on a 3.4 GHz Pentium 4 machine with 3 GB of main memory and 1 MB cache running Linux. All instances used in the following can be obtained from the web page [45].

We use best-first search as a node selection scheme and the branching rule explained in section 3.6. All separation routines are called only every tenth level of the tree, except that the pool of IIS-inequalities is checked in every node of the tree. In nodes in which cuts are separated, we proceed until no more violated cuts can be found. SCIP chooses among the generated cuts according to an orthogonality measure; see, for instance, Andreello, Caprara, and Fischetti [13]. We perform reduced cost fixing at every node of the tree.

Before presenting computational results, we want to discuss the influence of the limited precision used for solving LPs. The basic question that has to be repeatedly answered in our context is whether a given system is infeasible or not. Today's LP solvers are tuned towards quickly finding an optimal solution of a feasible LP. Sometimes their bases are not really optimal, but this has only a negligible effect on the objective function value; see Koch [41]. When checking infeasibility, however, small errors can lead to completely wrong decisions. The answer depends on the particular instance, the solution method of the LP solver, its parameters, e.g., the precision (usually around 10^{-6}), and often also the preprocessing and starting basis. Being aware of the possibility that we might produce wrong results, as a safeguard, we confirmed that the final solution is really an IIS-cover for the original system.

Currently, using exact LP solvers, like the ones included in `lrs` [15] or `cdd` [34] is computationally too expensive. In the future, codes that use dynamically adjusted precision might help; see Applegate et al. [14].

4.1. The Netlib problems. The Netlib library [49] contains a well-known set of 29 infeasible linear inequality systems. We do not report results on these data since these instances all can be solved within seconds, except for numerical difficulties with the problem `gran`. They were also solved to optimality by Parker [51] and Parker and Ryan [52]; for more computational results on these problems, see Chinneck [31] and Pfetsch [53].

4.2. Random problems. We consider random inequality systems to compare different cut strategies in the branch-and-cut implementation. We used difficult random instances that nevertheless can be solved within approximately one hour of computation time. In contrast, the instances discussed in the following sections vary highly in size and complexity: Most are either solved within seconds or cannot be solved to optimality in reasonable time.

The infeasible random inequality systems are generated as follows: Each coefficient and the right-hand side were chosen to be a random integer in the range -100 to 100. We generated five instances for each of the combinations $(5, 100)$, $(10, 80)$, $(15, 80)$, $(20, 90)$, $(25, 90)$, where the first component is the dimension n of the space and the second one is the number m of inequalities. Each system turned out to be infeasible (this almost always happens as soon as $m > 2 \cdot n$; see Motzkin [46]) and is almost completely dense. Note that all the instances in the following sections are dense as well.

In Theorem 1, the alternative polyhedra of these random systems are nondegenerate with high probability. It is currently unknown whether Max FS and Min IIS Cover restricted to such systems are NP-hard.

TABLE 1

Results of the branch-and-cut algorithm on random inequality systems *for different IIS separation strategies. The numbers are averages over five instances of each size. The last line gives the averages over each column.*

	∅:	134469.0	1049.73	38916.5	170658.7	1470.77	30965.4	61593.1	915.75	53285.4

We first compare the three different strategies to separate IIS-inequalities of section 3.2. Table 1 provides a comparison of methods "single" (section 3.2.1), "extend" (section 3.2.2), and "round" (section 3.2.3). Columns labeled "nodes" give the average number of nodes in the branch-and-bound tree, those labeled "time" are the average CPU times in seconds, and those labeled "IISs" give the average number of IISs found during the optimization; here averages are taken over the five instances of each size. To eliminate the influence of primal heuristics we initialized all runs with the optimal solution.

Among the three IIS-inequality separation versions, method "round" outperforms methods "single" and "extend" in the number of nodes and in the total computation time, although method "single" is sometimes a bit faster. Method "round" also generates the highest number of IISs. Based on this result, we decided to use method "round" in the following experiments.

Table 2 shows the total number of IISs and the number of IISs found by method "round" for small random instances generated in the same manner as above. By Theorem 1, the IISs correspond to vertices of the alternative polyhedron. We enumerated the vertices with `lrs` [15]. Since the alternative polyhedra are nondegenerate, the IISs can be generated in time polynomial in the input and output size; see Avis and Fukuda [16]. Note that for general polyhedra this is not possible unless P = NP; see Khachiyan et al. [40].

We could not enumerate or count the IISs for larger instances. From Table 2, however, it can be expected that the total number of IISs for the instances used in Table 1 is much higher. We conclude that the branch-and-cut implementation needs only a small part of the total set of IISs (the number of IISs for instance $(5, 70)$ is two orders of magnitudes larger than the average number of IISs found by any of the variants in Table 1).

TABLE 2

The number of IISs found by method "round" for random problems and the total number of IISs.

n	m	Found	Total
5	30	11	1986
5	40	101	44816
5	50	520	204833
5	60	526	614853
5	70	453	1818718

TABLE 3

Results of the branch-and-cut algorithm on random inequality systems *for different cut generation strategies; all variants use method "round" as a basis. Given are the average values over all* 25 *instances.*

Type	Nodes	Time	Root	# BaNg	# Gom.	#$\{0, \frac{1}{2}\}$
round	61593.1	915.75	6.54	0.0	0.0	0.0
BaNg	58796.4	1054.39	6.80	6134.0	0.0	0.0
Gom.	58434.7	1164.56	7.00	0.0	10440.6	0.0
$\{0, \frac{1}{2}\}$	61479.1	957.37	6.54	0.0	0.0	43.0
BaNg & Gom.	57911.9	1298.49	7.22	6955.3	10234.8	0.0
BaNg & $\{0, \frac{1}{2}\}$	60197.0	1080.89	6.78	5738.6	0.0	31.0
Gom. & $\{0, \frac{1}{2}\}$	58852.8	1158.42	7.01	0.0	10441.2	56.8
all	60092.7	1365.63	7.19	6699.5	10335.6	46.2

Table 3 lists computational results for all combinations of method "round" with Balas/Ng cuts (BaNg), Gomory cuts (Gom.), and $\{0, \frac{1}{2}\}$-cuts. The values are averages over all 25 instances. Column "root" gives the dual bound after the root node. The last three columns list the number of cuts found for the respective methods. Again, we initialize the algorithms with the optimal solution. All cuts are separated every ten levels of the tree.

The studied combinations on average reduce the number of nodes with respect to the method "round" alone; the best combination in this respect are Balas/Ng and Gomory cuts. Furthermore, all combinations, except $\{0, \frac{1}{2}\}$-cuts, improve the root dual bound with respect to the basic version. The studied methods, however, increase the CPU time needed. The main slowdown comes from the fact that the intermediate LPs become harder to solve. The corresponding separation times are acceptable, however. The average separation times for the version that uses all three methods are 1.8% (BaNg), 17.0% (Gomory), 1.0% ($\{0, \frac{1}{2}\}$). We conclude that the basic version "round" alone is fastest on random systems.

Table 4 shows average results for method "round" on random instances with $m = 80$ inequalities. It can be observed that the optimal values of the random problems tend to decrease when increasing the dimension. This often makes the problems more tractable. But of course, the solution of the intermediate LPs over the alternative polyhedron is more time consuming.

4.3. Digital video broadcasting problems. In this section we present results for problems arising in an application of MAX FS in telecommunications, which is described by Rossi, Sassano, and Smriglio [54]. Here, to plan the digital video broadcasting (DVB) network of Italy, transmitters have to be placed and their emission

TABLE 4

frequency and power have to be chosen as to maximize the area coverage, subject to quality constraints. A subproblem of this can be modeled as a linear inequality system. Interference of the signals leads to areas where the digital signal cannot be received, resulting in an infeasible system. Maximizing the total weight of satisfied inequalities then amounts to maximizing the area coverage.

Linearizing the model leads to numerically challenging problems. The coefficients take values between 10^{-11} and 10^{11}, and the resulting LPs are very instable. We tackled the problems by scaling the original instances before starting the branch-and-cut algorithm. This helps but nevertheless leaves hard problems. Without scaling, however, the algorithm terminated early with a completely wrong solution.

We could compute optimal solutions for the smallest instances used in Amaldi, Belotti, and Hauser [6] and Amaldi, Bruglieri, and Casale [7]; see Table 5. Here, column "dual" gives the final lower bound, "best" denotes the value of the best primal solution obtained (i.e., the primal bound), and "gap" is the gap between the dual bound and primal bound in percent, i.e., (best − dual)/dual · 100.0. The dimension of these instances is always 487, and the variable bounds ($0 \le \boldsymbol{x} \le 1$) are mandatory. We separate $\{0, \frac{1}{2}\}$-cuts every 10th level of the tree. Our primal heuristic of section 3.4 is run every 40th level. Note that these instances can be solved faster using the "big-M" formulation (resulting in the same optimal solution values); see [6, 7].

4.4. Classification problems. One of the historically first applications of MIN IIS COVER is the design of linear classifiers; see Amaldi [4], Mangasarian [43], Bennett and Bredensteiner [19], and Rubin [55].

In this application, one is given m points $\boldsymbol{p}_1, \dots, \boldsymbol{p}_m$ in $\mathbb{R}^N$, each belonging to one of two possible *classes* P_1 and P_2; i.e., P_1 and P_2 partition the set $\{\boldsymbol{p}_1, \dots, \boldsymbol{p}_m\}$. Each of the N components of the points stores a measurement of an attribute (or feature) relevant for the concrete application. The goal is to strictly separate these points in $\mathbb{R}^N$ by an oriented hyperplane defined by $\boldsymbol{a}^{\mathrm{T}}\boldsymbol{x} \le \beta$, with $\boldsymbol{a} \in \mathbb{R}^N$ and $\beta \in \mathbb{R}$. The points in P_1 should satisfy the inequality $\boldsymbol{a}^{\mathrm{T}}\boldsymbol{x} < \beta$, and the points in P_2 should satisfy $\boldsymbol{a}^{\mathrm{T}}\boldsymbol{x} > \beta$. Hence, we are looking for $(\boldsymbol{a}, \beta) \in \mathbb{R}^n$, with $n := N + 1$, so that the number of misclassified points

$$|\{\boldsymbol{p} \in P_1 \,:\, \boldsymbol{a}^{\mathrm{T}}\boldsymbol{p} \ge \beta\}| + |\{\boldsymbol{p} \in P_2 \,:\, \boldsymbol{a}^{\mathrm{T}}\boldsymbol{p} \le \beta\}|$$

is minimized. This minimization is performed in order to maximize the chance that a new point can be correctly classified. Note that with this formulation points in $\{\boldsymbol{x} \,:\, \boldsymbol{a}^{\mathrm{T}}\boldsymbol{x} = \beta\}$ are counted twice (the models can be modified to eliminate this).

In the following we will discuss two equivalent ways to model this problem via MIN IIS COVER and present computational results for different data sets. In the first model no bounds on the variables are present, while in the second all variables are bounded except one.

For the first model we use variables $(\boldsymbol{a}, \beta) \in \mathbb{R}^n$ and the following inequalities:

$$\boldsymbol{p}^{\mathrm{T}}\boldsymbol{a} - \beta \begin{cases} < 0 & \text{if } \boldsymbol{p} \in P_1 \\ > 0 & \text{if } \boldsymbol{p} \in P_2 \end{cases} \qquad \text{for each } \boldsymbol{p} \in \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_m\}.$$

Since $(\boldsymbol{a}, \beta)$ are unbounded we can scale them to obtain

$$\boldsymbol{p}^{\mathrm{T}}\boldsymbol{a} - \beta \begin{cases} \leq -1 & \text{if } \boldsymbol{p} \in P_1 \\ \geq 1 & \text{if } \boldsymbol{p} \in P_2 \end{cases} \qquad \text{for each } \boldsymbol{p} \in \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_m\}.$$

Of course, any other positive value instead of 1 can be taken in order to obtain a numerically more stable system.

The second model is due to Rubin [55]. It uses variables $\boldsymbol{a} \in \mathbb{R}^N$ and β, $\gamma \in \mathbb{R}$ in the following system:

$$\begin{aligned} \boldsymbol{p}^{\mathrm{T}}\boldsymbol{a} - \beta + \gamma \leq 0 \quad & \text{if } \boldsymbol{p} \in P_1, \\ \boldsymbol{p}^{\mathrm{T}}\boldsymbol{a} - \beta - \gamma \geq 0 \quad & \text{if } \boldsymbol{p} \in P_2, \\ -\mathbb{1} \leq \boldsymbol{a} \leq \mathbb{1}, & \\ \gamma \geq 0.001. & \end{aligned}$$

Hence, the coefficients of the normal vector $\boldsymbol{a}$ are bounded to lie within the interval $[-1, 1]$, while β is unbounded. Of course, the lower bound 0.001 for γ can be replaced by any suitably small positive number. For instances arising from this model the variable bounds are mandatory.

Note that in both models it might happen that the systems are feasible, i.e., the points are completely separable (in which case we need only solve one LP).

In our first test we use the first model and classification data from the UCI Repository of Machine Learning Databases (Blake and Merz [21]). The problem characteristics are given in Table 6. For some instances we had to remove incomplete data sets. A complete description of the instances is available at the UCI Repository.

TABLE 6

Characteristics of the classification instances. *Column "N" lists the number of attributes. The column labeled "$m^\star$" gives the number of original data sets and column "m" gives the number of data sets remaining after removing incomplete ones. The rightmost column gives additional notes, e.g., the name of the instance in the UCI database.*

Most of these twelve instances are also used by Chinneck [31] for testing his heuristic for MAX FS/MIN IIS COVER.

Table 7 lists the results of the branch-and-cut implementation on these instances with method "round" of section 3.2.3. The computation time was limited to *five hours* (18000 sec.). The columns have the same meaning as in sections 4.2 and 4.3.

Column "Chi" gives results obtained by the heuristic of Chinneck (see section 3.4); its running times are negligible and therefore not listed. Our implementation found the same solutions as Chinneck [31], except for the instances `glass` and `wpbc`, for which Chinneck obtained solutions of size 39 and 10, respectively. Our primal heuristic described in section 3.4 is run every tenth level. It could improve the initial solutions for models `glass`, `heart`, and `tic-tac-toe`. We conclude that the heuristic of Chinneck generates very good starting solutions, while our primal heuristic sometimes helps to find better solutions.

The results of Table 7 show that most instances are quite hard to solve and about half of them could not be solved within the time bound of five hours. Because of their size, only few nodes could be processed.

We also conducted experiments with the same data but using the second model instead of the first. Intuitively this should result in better numerical properties of the LPs that have to be solved during the algorithm. The results are, however, comparable to the ones shown in Table 7, and we therefore do not present them here.

Table 8 compares the gaps of the different cut strategies. The table displays only instances for which the optimal solutions could not be found within five hours. It turns

TABLE 8
Classification problems: *Comparison of the* gaps *of different variants of cutting planes. Only instances for which a positive gap remains after five hours are shown. The notation is as in Table* 3. *The last line contains the averages over each column.*

Name	Round	BaNg	Gom.	$\{0, \frac{1}{2}\}$	BaNg Gom.	BaNg $\{0, \frac{1}{2}\}$	Gom. $\{0, \frac{1}{2}\}$	all
bupa	39.3	46.7	40.0	41.9	44.0	45.0	41.5	45.5
glass	10.0	12.7	10.0	10.6	12.2	12.7	9.8	12.4
heart	23.6	23.8	22.6	24.2	25.4	25.2	27.8	26.0
pima	95.7	101.8	95.0	98.6	103.2	101.4	94.1	105.4
wpbc	48.7	47.8	44.6	49.8	49.0	49.0	45.6	50.5
∅:	43.5	46.6	42.4	45.0	46.7	46.7	43.8	48.0

out that all variants find the same final primal solutions, although at different times during the computation. Note that this actually compares the interplay of cutting strategies and our primal heuristic. On the average, the smallest gaps are produced by taking Gomory cuts, then method "round," Gomory and $\{0, \frac{1}{2}\}$-cuts, $\{0, \frac{1}{2}\}$-cuts alone, Balas/Ng cuts, Balas/Ng cuts and Gomory cuts, Balas/Ng cuts and $\{0, \frac{1}{2}\}$-cuts, and finally all cuts together. The main reason why all cuts together produce the worst results (on average) is that this combination could explore the fewest number of nodes. We conclude that the additional cutting planes do not yield a big improvement over method "round" alone. Although Gomory cuts produce the smallest gaps, the studied cutting planes do not seem to be crucial for solving these instances.

Our second test set consists of data from Codato and Fischetti [33] and uses the second model. The data again originate from the UCI Repository of Machine Learning Databases, but are preprocessed in a way we could not reconstruct. Hence, the results for these instances and the instances of Table 6 may not be comparable (there are three instances which seem to arise from the same original data: `breast-cancer` ↔ `breast-cancer-2`, `iris.1` ↔ `iris-150`, `wpbc` ↔ `WPBC194`). Instances `Breast-Cancer-2` and `Breast-Cancer-400` seem to be different from those used in Codato and Fischetti [33].

Table 9 shows the results of method "round" on these instances. The notation is as in Table 3. Note that here the dimension is $n = N + 2$, because we use the second model. Most of the instances could be solved within a few seconds. This is the first time that the complete set could be solved to optimality: No optimal solution to the harder instances (`Flags-169`, `Horse-colic-185`, `Horse-colic-253`, and `Solar-flare-1066`) was previously available. Our implementation solves all instances except these four in under a minute. Although we worked on a faster computer, it nevertheless seems fair to say that our code considerably improves upon the results of Codato and Fischetti [33].

5. Conclusions. In this paper we described a branch-and-cut implementation for the Max FS/Min IIS Cover problem, which is the best exact method currently available. The findings of the extensive computational results can be roughly summarized as follows: With respect to the implementation, the best cutting plane strategy is to find as many (violated) IIS-inequalities as possible. Additionally applying Balas/Ng, Gomory, or $\{0, \frac{1}{2}\}$-cuts does not significantly help to improve the performance: On random instances they do not improve the running time, but usually help to reduce the number of nodes. Gomory cuts only slightly help to reduce the gaps for classification instances, and the other cuts do not improve the gap.

With respect to the problem data, the considered instances vary greatly in their properties and difficulty. Depending on the particular data, quite large instances can be solved to optimality, but there are also relatively small instances which turn out to be extremely hard to solve. As shown by the DVB problems, one has to be careful with numerically instable instances.

An interesting open issue is the existence of problem-specific cutting planes and whether they can be efficiently separated. Another question is whether other valid inequalities for the set covering problem could help improve the performance of the implementation.

Acknowledgments. The author thanks Tobias Achterberg for help with the SCIP implementation and Edoardo Amaldi and Les Trotter for helpful discussions. Furthermore, he thanks Edoardo Amaldi and Pietro Belotti for providing the DVB instances of section 4.3, and Gianni Codato and Matteo Fischetti for the data used in section 4.4.

LAGRANGIAN-DUAL FUNCTIONS AND MOREAU–YOSIDA REGULARIZATION*

FANWEN MENG†, GONGYUN ZHAO‡, MARK GOH§, AND ROBERT DE SOUZA†

Abstract. In this paper, we consider the Lagrangian-dual problem of a class of convex optimization problems. We first discuss the semismoothness of the Lagrangian-dual function φ. This property is then used to investigate the second-order properties of the Moreau–Yosida regularization η of the function φ, e.g., the semismoothness of the gradient g of the regularized function η. We show that φ and g are piecewise C^2 and semismooth, respectively, for certain instances of the optimization problem. We establish a relationship between the original problem and the Fenchel conjugate of the regularization of the corresponding Lagrangian dual problem. We also find some instances of the optimization problem whose Lagrangian-dual function φ is not piecewise smooth. However, its regularized function still possesses nice second-order properties. Finally, we provide an alternative way to study the semismoothness of the gradient under the structure of the epigraph of the dual function.

Key words. Lagrangian dual, Moreau–Yosida regularization, piecewise C^k functions, semismoothness, Fenchel conjugate

1. Introduction.

Consider the following convex program:

$$\begin{aligned} \min_{x\in\mathbb{R}^n} \quad & f(x) \\ \text{s.t.} \quad & Ax = a, \\ & f_i(x) \le 0, \quad i \in \hat{I} = \{1, 2, \ldots, \theta\}, \end{aligned} \tag{1}$$

where f, f_i, $i = 1, 2, \ldots, \theta$, are smooth and convex on $\mathbb{R}^n$, and where $A \in \mathbb{R}^{m\times n}$ with $\operatorname{rank}(A) = m$ and $0 < m < n$.

It is known that many practical problems can be converted to problem (1) above. For instance, some recently studied multistage stochastic programming models can be formulated as (1). See [19, Chapter 1] for the detailed modeling in this regard.

Let $\mathcal{F} := \{x \in \mathbb{R}^n : f_i(x) \le 0, i \in \hat{I}\}$. In many circumstances, particularly in multistage stochastic programming, f and $\mathcal{F}$ are separable, while the constraint $Ax = a$ is nonseparable. Thus, we seek to relax the constraint $Ax = a$ using the Lagrangian dual of problem (1) as follows:

$$\min\{\varphi(v) \mid v \in \mathbb{R}^m\}, \tag{2}$$

where

$$\varphi(v) = \sup\{-f(x) + v^T(Ax - a) \mid x \in \mathcal{F}\}. \tag{3}$$

In these circumstances, the subproblem in (3) is separable, and then is solvable through the well-developed parallel algorithms. This makes the evaluation of φ much easier in general. However, an obstacle in solving problem (2) is that the function φ is nondifferentiable. To overcome this and noticing that the underlying function φ is convex on $\mathbb{R}^m$, we then use the well-known regularization of Moreau [14] and Yosida [23] to convert (2) into a smooth problem as follows:

$$\min\{\eta(v) \mid v \in \mathbb{R}^m\}, \tag{4}$$

where η is the Moreau–Yosida regularization of φ as defined below,

$$\eta(v) = \min_{w \in \mathbb{R}^m} \left\{ \varphi(w) + \frac{1}{2}||w - v||_M^2 \right\}, \quad v \in \mathbb{R}^m, \tag{5}$$

M is a symmetric positive definite $m \times m$ matrix, and $\|v\|_M^2 = v^T M v$ for any $v \in \mathbb{R}^m$.

It is well known that the set of minimizers of problem (4) is exactly the set of minimizers of (2). It can be shown that η is continuously differentiable and that its gradient $g = \nabla\eta$ is globally Lipschitz continuous with modulus $||M||$. For the properties of the Moreau–Yosida regularization, the reader is referred to [8, 7]. For the problem discussed in the present paper, there are some advantages of using the Moreau–Yosida regularization, as given next.

Fukushima and Qi [7] have shown that superlinear convergence can be guaranteed by using approximate solutions of the problem (5) to construct search directions for minimizing η. While finding an exact solution for a nonsmooth function φ is difficult, the computation of an approximate solution is relatively easier. We can, e.g., consider a parameterized function $\varphi(w, \mu)$, where $\varphi(w, \mu) \to \varphi(w)$ as $\mu \to 0$ and $\varphi(w, \mu)$ is smooth for any $\mu > 0$ as in the case of the barrier function method. This method was utilized for solving multistage stochastic nonlinear problems recently in [24], in which the underlying stochastic problem was formulated as problem (1). For any prescribed accuracy, we can now choose an appropriate $\mu > 0$ such that the minimizer of $\varphi(w, \mu) + (1/2)\|w - v\|_M^2$ is a desirable approximate solution to (5).

It is interesting that both the parameterized function $\varphi(\cdot, \mu)$ and the regularized function η (without parameter) are used to smooth the nonsmooth function φ. However, they function in different ways and have different properties: the former is successful in global convergence, while the latter can speed up local convergence. Incorporating the parameterizations into the Moreau–Yosida regularization can be a way to combine advantages in both approaches.

Besides the parameterizations mentioned above, there are many other methods for computing approximate minimizers of φ. Each of these methods can be incorporated into the Moreau–Yosida regularization, giving rise to an enhanced method for minimizing the nonsmooth function φ. Hence establishing the theoretical framework of the Moreau–Yosida regularization can benefit a variety of algorithms.

For the problem under consideration, one of the most important properties about the Moreau–Yosida regularization is the semismoothness of the gradient of the regularized function, which has played a key role in establishing the superlinear convergence of the generalized Newton method for nonsmooth convex problems by combining the Moreau–Yosida regularization scheme in (5) [7].

The concept of semismooth functions, an important subclass of Lipschitz functions, was first introduced by Mifflin [12]. In order to study the superlinear convergence of Newton method for solving nondifferentiable equations, Qi and Sun [16] extended the definition of semismoothness to vector-valued functions. After the work of Qi and Sun, semismoothness was extensively used to establish superlinear/quadratic convergence of Newton's method for solving the convex best interpolation problem [4, 5], nondifferentiable equations in which the underlying functions are slant differentiable functions [1], and complementarity problems and variational inequalities [6], for instance.

In this paper, we will focus on a special case of semismooth functions, *piecewise C^k functions*, which is a large class of locally Lipschitz continuous functions, found in most practical problems [20, 17]. In the past few years, many people have studied the piecewise smoothness of nonsmooth functions and designed algorithms based on Newton's method for solving the associated nonsmooth equations or nonlinear optimization problems. For example, the analysis was mainly focused on the concept of piecewise C^k functions in [10, 13, 21], where the authors have considered properties of g for some specific classes of φ. Specifically, Sun and Han [21] showed the semismoothness of g if φ is the maximum of several twice continuously differentiable convex functions under a constant rank constraint qualification (CRCQ). Later, Meng and Hao [10] derived the same result for the case of unconstrained problem (1) with the objective function f being a piecewise C^2 function under a weaker sequential constant rank constraint qualification. In [13], Mifflin, Qi, and Sun investigated the case where φ is piecewise C^2 which is a generalization of the maximum of convex C^2 functions under a so-called affine independence preserving constraint qualification (AIPCQ).

Having motivated the importance of the notions of semismoothness and the Moreau–Yosida regularization in nonsmooth analysis, in this paper we will investigate properties of the Lagrangian-dual function φ and the gradient of its Moreau–Yosida regularization η. Further, studying the properties of Lagrangian-dual function φ has its own interest as well; see [22] and the references therein, for instance. Since piecewise smooth functions as a special class of semismooth functions possess more enjoyable properties than semismooth functions [12, 16, 17, 20], we will concentrate on the study of piecewise smoothness of φ and the gradient g of the regularized function η in the context. We have adopted two different methods in analyzing properties of g. In terms of the first method, the main tool used in this study is based on Proposition 1 (see section 2), which was established by Mifflin, Qi, and Sun [13] using the notion of piecewise smoothness. We will first study the piecewise smoothness of φ. This property will then be used to show the semismoothness of g. For the problem with the linear objective function $f(x) = c^T x$, we can show that the function φ is piecewise C^2 and satisfies AIPCQ, and thus g is semismooth by Proposition 1 if all f_i's are affine functions or all $\nabla^2 f_i$'s are positive definite. We also present an example whose region $\mathcal{F}$ is defined by a linear constraint and a strictly convex constraint. In this example, the function φ is, surprisingly, *not* piecewise C^2, and, equally surprisingly, the gradient g of the regularization of φ *is* still semismooth. For general convex objective functions f and constraint functions f_j, it is completely unknown how smooth φ and g should be. This issue is considered by analyzing some special cases where the objective function possesses a positive definite Hessian. The second method is mainly based on the metric projection operator under the structure of the epigraph of the Lagrangian-dual function. Using the projection mapping, the study of the properties of g is equivalently converted to the study of the properties of solutions

to a system of nonsmooth equations. The analysis is basically based on the framework established by Meng, Sun, and Zhao [11] recently. The results obtained complement and enrich the framework of piecewise smooth functions [20, 17] and also enhance the recent results on the Moreau–Yosida regularization [11].

Another topic of interest is the study of the duality of the original problem (1). It is well known that the duality theory is a fundamental issue in optimization both theoretically and numerically. For problem (1) with a linear objective, we derive an interesting result regarding the original problem and the Fenchel conjugate of Moreau–Yosida regularization of its Lagrangian-dual function, characterizing a relationship between the conjugate and the Lagrangian-dual. This provides a new way to look at the Lagrangian-dual and the Moreau–Yosida regularization. We believe that the established results complement the dual theory in optimization, particularly the theory of Magnanti [9] to some extent.

The rest of the paper is organized as follows. In section 2, basic definitions and properties are collected. The analysis of problems with the linear objective functions covers the next two sections. Section 3 investigates the piecewise smoothness of the function φ. Section 4 studies the semismoothness of the gradient g and the conjugate of the Moreau–Yosida regularization. Illustrative examples are presented in sections 3 and 4. Section 5 discusses the case of general convex objective functions. Section 6 concludes.

2. Preliminaries. In this section, we briefly recall some concepts, such as semismoothness, piecewise smoothness, and AIPCQ, which will be used in the rest of this paper.

It is known that the regularized function η is a continuously differentiable convex function defined on $\mathbb{R}^m$, even though φ may be nondifferentiable. The gradient of η at v (see [8]) is

$$g(v) \equiv \nabla\eta(v) = M(v - p(v)), \qquad v \in \mathbb{R}^m, \tag{6}$$

where $p(v)$ represents the unique solution of the minimization problem in (5). In order to use Newton method or modified Newton's methods for solving (4), it is important to study the Hessian of η, i.e., the Jacobian of g. Note that, in general, g may not be differentiable. To extend the definition of Jacobian to certain classes of nonsmooth functions, Qi and Sun [16] introduced the definition of semismoothness [12] for vector-valued functions. See [16] for details.

A remarkable feature of semismoothness is that superlinear or quadratic convergence of a generalized Newton method for solving nonsmooth equations can be obtained under the assumption of semismoothness. See [7, 15, 16] for the relevant discussions. Note that in general a direct verification of semismoothness is difficult. Some equivalent definitions of semismooth functions and further studies on semismoothness can be found in [11, 15] and the references therein. As for the underlying Lagrangian dual function φ, it has a special feature; i.e., φ is piecewise smooth. We shall make use of this special feature to investigate the semismoothness of g in the subsequent analysis. We now give a definition of piecewise smooth functions below, which is slightly different from the one given in [20].

DEFINITION 1. *A continuous function $\psi : \mathbb{R}^n \to \mathbb{R}^l$ is said to be a* piecewise C^k *function on a set $D \subseteq \mathbb{R}^n$ if there exist a finite index set $I = \{1, \ldots, q\}$, closed sets $D_1, \ldots, D_q$, open sets $U_1, \ldots, U_q$ (or relatively open with respect to the affine hull of D), and functions $\psi_1, \ldots, \psi_q$ such that*

(i) *$D \subseteq \cup_{j=1}^{q} D_j$ and $D_j \subseteq U_j$ for each $j \in I$,*

(ii) $\psi_j \in C^k(U_j)$ *for each* $j \in I$,
(iii) $\psi(u) = \psi_j(u)$ *for any* $u \in D \cap D_j$ *and each* $j \in I$.
We refer to $\{(D_j, U_j, \psi_j)\}_{j\in I}$ *as a* representation *of* ψ.

Remark 1. If the closure of D is contained by every U_j, then Definition 1 can simply be stated as follows. A continuous function ψ is a *piecewise* C^k function on the set $D \subseteq \mathbb{R}^n$ if there exists a finite set of functions $\psi_j \in C^k(U_j)$ for $j = 1, \ldots, q$ such that for any $u \in D$, $\psi(u) \in \{\psi_1(u), \ldots, \psi_q(u)\}$.

Note that for the Moreau–Yosida regularization of a piecewise smooth function to be smooth, the pieces ψ_j must be joined together properly. Mifflin, Qi, and Sun [13] introduced the following constraint qualification—AIPCQ. For any $u \in D$, we write

$$I(u) = \{i \in I : u \in D_i\}.$$

Definition 2. *The* AIPCQ *is said to hold for a piecewise smooth function* ψ *at* u *if for every subset* $K \subseteq I(u)$ *for which there exists a sequence* $\{u^k\}$ *with* $\{u^k\} \to u$, $K \subseteq I(u^k)$, *and the vectors*

$$\left\{ \begin{pmatrix} \nabla\psi_i(u^k) \\ 1 \end{pmatrix} : i \in K \right\} \tag{7}$$

being linearly independent, it follows that the vectors

$$\left\{ \begin{pmatrix} \nabla\psi_i(u) \\ 1 \end{pmatrix} : i \in K \right\} \tag{8}$$

are linearly independent.

Remark 2. The set $I(u)$ defined in this paper and the corresponding set in [13], denoted by $I'(u)$, are slightly different. In [13], they define

$$I'(u) = \{j \in I : \psi_j(u) = \psi(u)\}.$$

Since $u \in D_j$ implies $\psi_j(u) = \psi(u)$, we have $I(u) \subseteq I'(u)$. For $u \in U_j \setminus D_j$, $\psi_j(u)$ can be set to any value (as long as $\psi_j \in C^k(U_j)$); hence we can assume, without loss of generality, that $\psi_j(u) \neq \psi(u)$ for all $u \in U_j \setminus D_j$. Under this assumption,

$$I(u) = I'(u) \qquad \forall\, u \in D.$$

By virtue of the AIPCQ, Mifflin, Qi, and Sun [13] derived the following result, which will be used in the analysis of this paper.

Proposition 1. *Suppose that the convex function* φ *is piecewise* C^2 *on* $\mathbb{R}^m$ *and that the AIPCQ holds at the proximal point* $p(v)$ *for a given* $v \in \mathbb{R}^m$. *Then there exists an open neighborhood* $\mathcal{N}(v)$ *about* v *such that the gradient* g *of the function* η, *the Moreau–Yosida regularization of* φ, *is piecewise* C^1 *(smooth) on* $\mathcal{N}(v)$. *Hence* g *is semismooth at* v.

3. Piecewise smoothness of φ. In this section, we will study the piecewise smoothness of the Lagrangian-dual function φ for the case $f(x) = c^T x$ in (3), which is defined by

$$\varphi(v) = \sup\{-c^T x + v^T(Ax - a) \mid x \in \mathcal{F}\}. \tag{9}$$

The piecewise smoothness is an important characteristic of the Lagrangian-dual function φ. The investigation of this characteristic is helpful to optimization methods

which use the Lagrangian dual. Hence the results in this section are significant in their own right. In the next section, the piecewise smoothness of φ will then be used to prove the semismoothness of the gradient of the Moreau–Yosida regularization. Denote

$$\Omega := \{u = A^T v - c : v \in \mathbb{R}^m\}.$$

Clearly, Ω is an m-dimensional affine set in $\mathbb{R}^n$ since $\mathrm{rank}(A) = m$. We make the following assumptions throughout the paper.

Assumption 1. $c \notin \{A^T s : s \in \mathbb{R}^m\}$.

Assumption 2. $f_i \in C^2(\mathbb{R}^n)$ for all $i \in \hat{I}$.

Assumption 3. $\mathcal{F} \neq \emptyset$ and $\Omega \cap \mathcal{F}^b \neq \emptyset$.

Here, $\mathcal{F}^b$ denotes the *barrier cone* of the convex set $\mathcal{F}$ defined by

$$\mathcal{F}^b = \{y \in \mathbb{R}^n \mid \exists\, \beta \in \mathbb{R} \text{ such that } y^T x \leq \beta \ \ \forall\, x \in \mathcal{F}\}.$$

Remark 3. If $c = A^T s$ for some $s \in \mathbb{R}^m$, then $Ax = a$ implies $c^T x = s^T Ax = s^T a$. This means that any feasible solution of (1) is an optimal solution. Assumption 1 should rule out this degenerate case. Assumption 1 can also be written as $0 \notin \Omega$. Assumption 2 is a natural assumption of smoothness. The motivation of Assumption 3 is to guarantee the properness of the function φ, as shown by Lemma 1 below.

Define ζ, the *support function* of $\mathcal{F}$ in $\mathbb{R}^n$, as follows

$$\zeta(u) = \delta^*(u \mid \mathcal{F}) := \sup\{\langle u, x\rangle \mid x \in \mathcal{F}\}, \quad u \in \mathbb{R}^n. \tag{10}$$

Then the Lagrangian-dual function φ defined in (9) can be rewritten as

$$\varphi(v) = \zeta(A^T v - c) - a^T v. \tag{11}$$

We now define some notation which will be used in the paper.

(i) Q is said to be a *facet* of $\mathcal{F}$ if there exists an index subset $I_Q \subset \hat{I}$ such that $Q = \{x \in \mathcal{F} : f_i(x) = 0, \forall i \in I_Q\}$. I_Q is referred to as the *index set of the facet* Q.

(ii) For a convex function $h : \mathbb{R}^s \to \bar{\mathbb{R}} = \mathbb{R} \cup \{+\infty\}$, the *domain* of h, denoted by $\mathrm{dom}h$, is defined by $\mathrm{dom}h := \{z \in \mathbb{R}^s : h(z) < +\infty\}$.

Lemma 1. *The Lagrangian-dual function φ is a proper convex function on $\mathbb{R}^m$ if and only if Assumption* 3 *holds. One also has*

$$\mathrm{dom}\varphi = \{v \in \mathbb{R}^m \mid A^T v - c \in \mathcal{F}^b\}.$$

Proof. It is evident that $\varphi(v)$ can never be $-\infty$ if $\mathcal{F} \neq \emptyset$, and if $\mathcal{F} = \emptyset$, then $\varphi \equiv -\infty$.

By (11), we have

$$\mathrm{dom}\varphi = \{v \in \mathbb{R}^m \mid A^T v - c \in \mathrm{dom}\zeta\}.$$

Hence, $\mathrm{dom}\varphi \neq \emptyset$ if and only if $\Omega \cap \mathrm{dom}\zeta \neq \emptyset$. Since ζ is the support function of $\mathcal{F}$, it is easy to see that

$$\mathrm{dom}\zeta = \mathcal{F}^b.$$

Therefore, the second condition in Assumption 3 is a necessary and sufficient condition for $\mathrm{dom}\varphi \neq \emptyset$. ∎

PROPOSITION 2. *If ζ is piecewise C^2 on a set $D \subseteq \mathbb{R}^n \setminus \{0\}$, then φ is piecewise C^2 on the set $E := \{v : A^T v - c \in D\} \subseteq \mathbb{R}^m$ under Assumption* 1.

Proof. Since ζ is piecewise C^2, there exist closed sets D_i, open sets U_i, and functions $\zeta_i \in C^2(U_i)$, $i \in l$, where l is a finite index set, which satisfy Definition 1. Let

$$\varphi_i(v) := \zeta_i(A^T v - c) - a^T v, \quad E_i := \{v : A^T v - c \in D_i\}, \quad V_i := \{v : A^T v - c \in U_i\}.$$

Then it is evident that $\varphi_i \in C^2(V_i)$, E_i is closed, and V_i is open. Furthermore, $\varphi_i (i \in l)$ satisfy (i)–(iii) in Definition 1. Hence φ is a piecewise C^2 function. ∎

PROPOSITION 3. *Suppose that f_i is an affine function on $\mathbb{R}^n$ for every $i \in \hat{I}$. Then the function φ defined in* (9) *is a piecewise C^2 function on its domain. Especially, φ is piecewise affine on its domain.*

Proof. By Proposition 2, it suffices to show that ζ is piecewise C^2 on $\Omega \cap \mathrm{dom}\zeta$. According to the remark after Definition 1, it suffices to show that there exist twice continuously differentiable functions ζ_j on $\mathbb{R}^n (= U_j)$, $j \in \hat{J}$ a finite index set, such that for any $u \in \Omega \cap \mathrm{dom}\zeta$

$$\zeta(u) \in \{\zeta_j(u) : j \in \hat{J}\}. \tag{12}$$

It is known that the polyhedral $\mathcal{F}$ can be represented by its vertices $\{x_1, \ldots, x_p\}$ and extreme rays $\{r_1, \ldots, r_q\}$ in the form

$$\mathcal{F} = \left\{ x = \sum_{i=1}^{p} \alpha_i x_i + \sum_{i=1}^{q} \lambda_i r_i \ : \ \alpha_i \geq 0, \sum_{i=1}^{p} \alpha_i = 1, \lambda_i \geq 0 \right\}.$$

Define

$$\bar{\mathcal{F}} = \left\{ x = \sum_{i=1}^{p} \alpha_i x_i + \sum_{i=1}^{q} \lambda_i r_i \ : \ \alpha_i \geq 0, \sum_{i=1}^{p} \alpha_i = 1, \, 0 \leq \lambda_i \leq 1 \right\}.$$

We claim that, for any $u \in \mathrm{dom}\zeta$, $\sup\{u^T x : x \in \mathcal{F}\} = \sup\{u^T x : x \in \bar{\mathcal{F}}\}$. Assume by contradiction that there exist a $u \in \mathrm{dom}\zeta$ and a $\bar{x} \in \mathcal{F} \setminus \bar{\mathcal{F}}$ such that $u^T \bar{x} > \sup\{u^T x : x \in \bar{\mathcal{F}}\}$. Denote $J := \{i : \lambda_i > 1\}$, where the λ_i's are the coefficients in the representation of $\bar{x}$. Let $\hat{x} \in \bar{\mathcal{F}}$ be defined by the same representation of $\bar{x}$ except for changing the λ_i, $i \in J$, to 1. Then $\bar{x} - \hat{x} = \sum_{i \in J} (\lambda_i - 1) r_i$. Since $\hat{x} \in \bar{\mathcal{F}}$, we have $u^T \hat{x} < u^T \bar{x}$, i.e.,

$$\sum_{i \in J} (\lambda_i - 1) u^T r_i > 0.$$

Thus there exists at least an $\bar{i} \in J$ with $u^T r_{\bar{i}} > 0$. For any fixed $x_0 \in \mathcal{F}$ and any $\lambda \geq 0$, $x_0 + \lambda r_{\bar{i}} \in \mathcal{F}$. Thus $\zeta(u) \geq u^T x_0 + \lambda u^T r_{\bar{i}} \to +\infty$ as $\lambda \to +\infty$, which contradicts the fact $u \in \mathrm{dom}\zeta$. This shows that for any $u \in \mathrm{dom}\zeta$

$$\zeta(u) = \sup\{u^T x \mid x \in \bar{\mathcal{F}}\}.$$

Note that $\bar{\mathcal{F}}$ is a bounded polytope. Without loss of generality, let $\{\bar{x}_1, \ldots, \bar{x}_k\}$ be all vertices of $\bar{\mathcal{F}}$, and define $\zeta_j(u) = \bar{x}_j^T u$. Then $\zeta_j \in C^2(\mathbb{R}^n)$ (here $U_j = \mathbb{R}^n$). For any $u \in \Omega \cap \mathrm{dom}\zeta$, because $u \neq 0$ by Assumption 1, the set of maximizers of $\zeta(u)$ must contain at least a vertex, say $\bar{x}_j$, of $\bar{\mathcal{F}}$. It follows that

$$\zeta(u) = \bar{x}_j^T u = \zeta_j(u),$$

which shows (12). Thus, $\zeta(u)$ is piecewise C^2 on its domain. Evidently, $\zeta(u)$ is also piecewise affine on its domain, and so is φ. □

Next, we consider the case where all $\nabla^2 f_i$ ($i \in \hat{I}$) are positive definite. Our analysis will proceed as follows. For each facet Q (of any dimension) of $\mathcal{F}$, we will define an open set U and a C^2 function on U. Roughly speaking, we first define a mapping from x-space to an open set in u-space (actually the mapping is defined on enlarged spaces), prove that this mapping is bijective, and then use the inverse of this mapping to define a function on the open set in u-space. For any facet Q of $\mathcal{F}$ with the index set I_Q, we define

$$W := \left\{ (x,\lambda) \in \mathbb{R}^n \times \mathbb{R}^{|I_Q|} : f_i(x) = 0,\ i \in I_Q,\ \sum_{i\in I_Q} \lambda_i \nabla^2 f_i(x) \succ 0 \right\}, \tag{13}$$

where $B \succ 0$ means that the matrix B is symmetric positive definite,

$$U := \left\{ u = \sum_{i\in I_Q} \lambda_i \nabla f_i(x) \in \mathbb{R}^n : (x,\lambda) \in W \right\}. \tag{14}$$

Note that for $(x,\lambda) \in W$, x is not required to be in Q. Actually, x need not be in $\mathcal{F}$. Without loss of generality, let $I_Q = \{1,\dots,k\}$. Denote $\tilde{f} = (f_1,\dots,f_k)^T$, and define a mapping $\Gamma : \mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R}^{n+k}$ by

$$\Gamma(x,\lambda) := \begin{pmatrix} \sum_{i=1}^k \lambda_i \nabla f_i(x) \\ \tilde{f}(x) \end{pmatrix}. \tag{15}$$

Note that the Karush–Kuhn–Tucker (KKT) conditions for problem (10) can be written as

$$\Gamma(x,\lambda) = (u;0).$$

The following lemma plays a fundamental role in our analysis.

LEMMA 2. *Let W, U be defined by* (13), (14), *respectively. Suppose that for any $x \in \mathbb{R}^n$ all $\nabla^2 f_i(x)$ ($i \in I_Q$) are positive definite and $\{\nabla f_i(x)\}_{i\in I_Q}$ are linearly independent. Then* (i) *U is an open set in $\mathbb{R}^n$; and* (ii) *there exists a continuously differentiable bijective mapping $\xi = (\xi_x, \xi_\lambda) : U \to W$ such that for all $u \in U$, $\Gamma(\xi_x(u), \xi_\lambda(u)) = (u;0)$; i.e., ξ is the inverse mapping of Γ restricted on U.*

Proof. (i) For any $(\bar{x},\bar{\lambda}) \in W$, let $(\bar{u};\bar{v}) = \Gamma(\bar{x},\bar{\lambda})$. Then $\bar{u} = \sum_{j=1}^k \bar{\lambda}_j \nabla f_j(\bar{x})$ and $\bar{v} = 0$. In the following, we seek to show that $\bar{u}$ is an interior point of U. Let us denote $\nabla\tilde{f} := (\nabla f_1,\dots,\nabla f_k) \in \mathbb{R}^{n\times k}$. Then, $\nabla\tilde{f}(x)$ has full column rank, i.e., $\operatorname{rank}(\nabla\tilde{f}(x)) = k$, by assumption. By the continuity of $\nabla^2 f_i$, $i \in \hat{I}$, there exists a neighborhood of $(\bar{x},\bar{\lambda})$, denoted by $\mathcal{N}_x$, such that $\sum_{i=1}^k \lambda_i \nabla^2 f_i(x) \succ 0$ for all $(x,\lambda) \in \mathcal{N}_x$. Thus, the Jacobian of Γ,

$$\nabla\Gamma(x,\lambda) = \begin{pmatrix} \sum_{i=1}^k \lambda_i \nabla^2 f_i(x) & \nabla\tilde{f}(x) \\ \nabla\tilde{f}(x)^T & 0 \end{pmatrix},$$

is nonsingular on $\mathcal{N}_x$. By the inverse function theorem, there exists a neighborhood of $(\bar{u},\bar{v})$, denoted by $\mathcal{N}_u$, such that there exists an inverse mapping Ψ of Γ defined on

$\mathcal{N}_u$, and for any $(u,v) \in \mathcal{N}_u$, $\Psi(u,v) \in \mathcal{N}_x$ and $\Gamma(\Psi(u,v)) = (u;v)$. In particular, for any $(u,v) \in \mathcal{N}_u$ with $v = \bar{v} = 0$, $(x,\lambda) = \Psi(u,0)$ satisfies

$$u = \sum_{i=1}^{k} \lambda_i \nabla f_i(x), \qquad \tilde{f}(x) = 0, \qquad \sum_{i=1}^{k} \lambda_i \nabla^2 f_i(x) \succ 0. \tag{16}$$

This implies $(x,\lambda) \in W$ and thus $u \in U$ for all $(u,0) \in \mathcal{N}_u$. Since $U_0 := \{u : (u,0) \in \mathcal{N}_u\}$ is an open set in $\mathbb{R}^n$, and $\bar{u} \in U_0 \subset U$, $\bar{u}$ is an interior point of U. Thus U is open.

(ii) Since the Jacobian $\nabla\Gamma(x,\lambda)$ is nonsingular and continuous on the entire set W and since Γ maps W onto $U \times \{0\}$, the inverse mapping Ψ of Γ defined in (i) is a continuously differentiable bijective mapping from $U \times \{0\}$ onto W. Define a mapping $\xi : U \to W$ by $\xi(u) = \Psi(u,0)$. Then ξ is continuously differentiable and bijective, and $\Gamma(\xi(u)) = (u;0)$. □

As a consequence of Lemma 2, we obtain the following result.

LEMMA 3. *Let $\zeta_Q(u) = u^T \xi_x(u)$, where ξ_x is defined in Lemma 2. Then $\zeta_Q \in C^2(U)$, and for any $u \in U$*

$$\nabla\zeta_Q(u) = \xi_x(u). \tag{17}$$

Proof. From Lemma 2 and the first equation of $\Gamma(\xi(u)) = (u;0)$, it follows that

$$u = \sum_{i \in I_Q} \xi_{\lambda_i}(u) \nabla f_i(\xi_x(u)).$$

Thus,

$$\begin{aligned} \nabla\zeta_Q(u) &= \xi_x(u) + \nabla\xi_x(u)u \\ &= \xi_x(u) + \nabla\xi_x(u) \textstyle\sum_{i \in I_Q} \xi_{\lambda_i}(u) \nabla f_i(\xi_x(u)) \\ &= \xi_x(u) + \textstyle\sum_{i \in I_Q} \xi_{\lambda_i}(u) \nabla\xi_x(u) \nabla f_i(\xi_x(u)). \end{aligned}$$

According to the second equation in $\Gamma(\xi(u)) = (u;0)$, we have $f_i(\xi_x(u)) = 0$ for all $u \in U$ and $i \in I_Q$. Differentiating these functions, we obtain $\nabla\xi_x(u)\nabla f_i(\xi_x(u)) = 0$ for all $i \in I_Q$. Hence,

$$\sum_{i \in I_Q} \xi_{\lambda_i}(u) \nabla\xi_x(u) \nabla f_i(\xi_x(u)) = 0.$$

Thus, it follows that

$$\nabla\zeta_Q(u) = \xi_x(u).$$

By Lemma 2, $\xi_x(u)$ is continuously differentiable on U. Therefore, ζ_Q is twice continuously differentiable on U. □

The following proposition is one of the main results in this paper, showing the piecewise smoothness of the function φ.

PROPOSITION 4. *For φ defined by (9), suppose that, for all $i \in \hat{I}$, $\nabla^2 f_i(x)$ are positive definite, and for any facet Q of $\mathcal{F}$ with the index set I_Q, $\{\nabla f_i(x)\}_{i \in I_Q}$ are linearly independent. Then φ is piecewise C^2 on its domain.*

Proof. Let us first consider the function ζ defined by (10) on the set D, where $D = \Omega \cap \mathrm{dom}\zeta$. Let $\{Q_1, \ldots, Q_q\}$ be the set of all facets of $\mathcal{F}$. Let W_i, U_i, and ξ_i be

defined in (13), (14), and Lemma 2 for the facet $Q_i = \{x \in \mathcal{F} : f_l(x) = 0,\ l \in I_i\}$. Define

$$D_i := \Omega \cap \left\{ u = \sum_{l \in I_i} \lambda_l \nabla f_l(x) : x \in Q_i,\ \lambda_l \geq 0 \right\}, \tag{18}$$

which is evidently a closed set. By Lemma 2, U_i is open. Define $\zeta_i(u) := u^T \xi_{ix}(u)$. In what follows, we show that (i), (ii), and (iii) in Definition 1 hold.

(i) For any $u \in \mathrm{ri}D$, by [18, Theorem 23.4 and Corollary 23.5.3], there exists an optimal solution x^* to problem (10), which together with a Lagrangian multiplier $\bar{\lambda}^*$ satisfies the KKT conditions:

$$\begin{aligned} & u = \textstyle\sum_{i=1}^{\theta} \bar{\lambda}_i^* \nabla f_i(x^*), \\ & \bar{\lambda}_i^* \geq 0, \\ & f_i(x^*) \leq 0, \\ & \bar{\lambda}_i^* f_i(x^*) = 0, \quad i = 1, 2, \ldots, \theta. \end{aligned} \tag{19}$$

Because $u \neq 0$ by Assumption 1, x^* must lie on some facets of $\mathcal{F}$. Let $Q_j = \{x \in \mathcal{F} : f_i(x) = 0,\ i \in I_j\}$ be the *smallest* facet at x^*. By "smallest" we mean that for any $i \notin I_j$, $f_i(x^*) \neq 0$. Then $\bar{\lambda}_i^* = 0$ for all $i \notin I_j$. Let λ^* denote the subvector of $\bar{\lambda}^*$ consisting of components in I_j. Then $u = \sum_{i \in I_j} \lambda_i^* \nabla f_i(x^*)$, which together with $\lambda^* \geq 0$ and $x^* \in Q_j$ implies $u \in D_j$. This shows that $\mathrm{ri}D \subseteq \cup_{i=1}^q D_i$. Thereby, $D \subseteq \cup_{i=1}^q D_i$ since each D_i is closed.

For any $u \in D_j$, let $\bar{x} \in Q_j$ and $\bar{\lambda} \geq 0$ represent u as in (18). $\bar{\lambda} \neq 0$, since $u \neq 0$ by Assumption 1. This implies that $\sum_{i \in I_j} \bar{\lambda}_i \nabla^2 f_i(\bar{x}) \succ 0$, since all $\nabla^2 f_i$ are positive definite. Thus $(\bar{x}, \bar{\lambda}) \in W_j$ and $u \in U_j$. This shows $D_j \subseteq U_j$.

(ii) By Lemma 3, $\zeta_i \in C^2(U_i)$ for $i = 1, \ldots, q$.

(iii) For any $u \in D \cap D_j$, let $\bar{x} \in Q_j$ and $\bar{\lambda} \geq 0$ represent u as in (18). Let $\bar{\lambda}^*$ be defined by $\bar{\lambda}_i^* = \bar{\lambda}_i$ for $i \in I_j$ and $\bar{\lambda}_i^* = 0$ for $i \notin I_j$. Then $(\bar{x}, \bar{\lambda}^*)$ satisfies the KKT conditions (19). Thus $\zeta(u) = u^T \bar{x}$. On the other hand, the second part of (i) shows that $(\bar{x}, \bar{\lambda}) \in W_j$. Using the relation in (18), we have $(u; 0) = \Gamma_j(\bar{x}, \bar{\lambda})$, where Γ_j is the mapping defined in (15). Since ξ_j is the inverse of Γ_j restricted on U_j, $\xi_j(u) = (\bar{x}, \bar{\lambda})$. By definition, we have

$$\zeta_j(u) = u^T \xi_{jx}(u) = u^T \bar{x}.$$

Thus $\zeta(u) = \zeta_j(u)$ for any $u \in D \cap D_j$.

The above shows that ζ is piecewise C^2 on $D(= \Omega \cap \mathrm{dom}\zeta)$. By virtue of Proposition 2, φ is piecewise C^2 on its domain. □

Remark 4. In Propositions 3 and 4 we conclude that φ is piecewise C^2 convex under the assumption that the constraints for $\mathcal{F}$ are either all linear or all have positive definite Hessian matrices. A natural question arises: Can φ be piecewise C^2 for more general $\mathcal{F}$? The following example considers an $\mathcal{F}$ which is defined by a linear constraint and a strictly convex constraint with a positive definite Hessian, and gives a negative answer to the above question.

Example 1. Let

$$\varphi(v) = \sup\{-c^T x + v^T(Ax - a) \mid x \in \mathcal{F}\},$$

where

$$A = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \qquad c = (0, 0, -1)^T, \qquad a = (0, 0)^T,$$

and

$$\mathcal{F} = \{x \in \mathbb{R}^3 : x_1^2 + x_2^2 + x_3^2 - 1 \le 0,\ x_3 \le 0\}.$$

Since $\mathcal{F}$ is bounded, $\mathcal{F}^b = \mathbb{R}^3$ and $\mathrm{dom}\varphi = \mathbb{R}^2$. One can verify that Assumptions 1, 2, and 3 are satisfied. It is easy to see that

$$\varphi(v) = \sup\{(v_1, v_2, 1)^T x \mid x \in \mathcal{F}\},$$

and that the maximizer is $x = (v_1/\|v\|, v_2/\|v\|, 0)^T$ if $v \neq 0$ and is any point on $\mathcal{F} \cap \{(x_1, x_2, x_3) \mid x_3 = 0\}$ if $v = 0$. It follows that

$$\varphi(v) = \sqrt{v_1^2 + v_2^2}.$$

Obviously, φ is smooth at any point $v \neq 0$. So for any nonzero $v \in \mathbb{R}^2$, the gradient and the Hessian of φ can be written as

$$\nabla\varphi(v) = \begin{pmatrix} v_1/\sqrt{v_1^2 + v_2^2} \\ v_2/\sqrt{v_1^2 + v_2^2} \end{pmatrix},$$

$$\nabla^2\varphi(v) = \begin{pmatrix} v_2^2/(v_1^2 + v_2^2)^{3/2} & -v_1v_2/(v_1^2 + v_2^2)^{3/2} \\ -v_1v_2/(v_1^2 + v_2^2)^{3/2} & v_1^2/(v_1^2 + v_2^2)^{3/2} \end{pmatrix}.$$

It is evident that $\nabla^2\varphi(v)$ is unbounded as $v \to 0$ ($v \neq 0$), (either $\frac{\partial^2\varphi(v)}{\partial v_1^2} \to \infty$ if $|v_1| \le |v_2|$, or $\frac{\partial^2\varphi(v)}{\partial v_2^2} \to \infty$ if $|v_1| \ge |v_2|$).

To show φ is not piecewise C^2 on its domain $\mathbb{R}^2$, let (E_j, V_j, φ_j) be any piece representing φ in a neighborhood of $v = 0$, namely, $0 \in E_j \subset V_j$ and φ_j is a function on V_j satisfying $\varphi_j(v) = \varphi(v)$ for all $v \in E_j$. Since $\nabla^2\varphi_j(v) = \nabla^2\varphi(v)$ wherever φ is twice differentiable, we have $\nabla^2\varphi_j(v) \to \infty$ as $v \to 0$ ($E_j \ni v \neq 0$). Since the origin is an interior point of V_j, $\varphi_j \notin C^2(V_j)$. Therefore, φ is not a piecewise C^2 function on its domain.

4. Semismoothness of the gradient of η and its conjugate. In this section, we will study the semismoothness of the gradient of the Moreau–Yosida regularization of φ as discussed in section 3, where $f(x) = c^T x$. We will also investigate the properties of the conjugate of η and explore its relations with the original problem.

4.1. Semismoothness of the gradient of η. Our study on the semismoothness of g is based on the theory established by Mifflin, Qi, and Sun [13]. In their paper, they assume that φ is piecewise C^2 convex on the whole space $\mathbb{R}^m$, i.e., $\mathrm{dom}\varphi = \mathbb{R}^m$. We follow this assumption in this section. By Lemma 1, $\mathrm{dom}\varphi = \mathbb{R}^m$ if and only if $\Omega \subset \mathcal{F}^b$. Therefore, we make the following assumption in this section to replace Assumption 3.

Assumption 4. $\mathcal{F} \neq \emptyset$ and $\Omega \subset \mathcal{F}^b$.

To show the semismoothness of g, we shall first show that φ defined in (3) satisfies AIPCQ in the following two cases: (i) all f_i are affine, and (ii) all f_i possess positive

definite Hessian matrices. Suppose that $\varphi(v)$ is a piecewise smooth function with the representation $\{(E_i, V_i, \varphi_i)\}_{i\in I}$. For any $v \in \mathbb{R}^m$, define

$$I(v) := \{i \in I : v \in E_i\}.$$

LEMMA 4. *Suppose for every $i \in \hat{I}$ that f_i is an affine function on $\mathbb{R}^n$. Then for the piecewise affine function $\varphi(v)$ defined by* (9)*, the AIPCQ holds at every v on $\mathbb{R}^m$.*

Proof. Suppose that φ is represented by $\{\varphi_i\}_{i\in I}$, where $\varphi_i(v) = \beta_i^T v - \alpha_i$. For any $w \in \mathbb{R}^m$ and any index set $K \subseteq I(w)$,

$$\left\{ \begin{pmatrix} \nabla\varphi_i(w) \\ 1 \end{pmatrix} : i \in K \right\} = \left\{ \begin{pmatrix} \beta_i \\ 1 \end{pmatrix} : i \in K \right\}$$

is a set of constant vectors. Therefore the AIPCQ holds at any $v \in \mathbb{R}^m$. ∎

Now we consider the case that the set $\mathcal{F}$ is defined by all convex functions f_j with positive definite Hessian matrices. In the proof of Proposition 4, we have defined a representation $\{(D_j, U_j, \zeta_j)\}_{j\in I}$ of ζ. This representation induces a representation $\{(E_j, V_j, \varphi_j)\}_{j\in I}$ of φ as defined in the proof of Proposition 2; we will use these notations below.

Because the value of $\varphi_j(v)$, $v \in V_j \setminus E_j$, does not affect the representation of φ, it therefore can be set to any value. For simplicity, in what follows, we assume that

$$\varphi_j(v) \neq \varphi(v) \qquad \forall j \in I,\ v \in V_j \setminus E_j \tag{20}$$

(see also Remark 2).

LEMMA 5. *Suppose that the conditions of Proposition* 4 *are satisfied. Let $\{(E_j, V_j, \varphi_j)\}_{j\in I}$ be a representation of φ. Then, for any $v \in \mathrm{dom}\varphi$ and any $i, j \in I$, $\nabla\varphi_i(v) = \nabla\varphi_j(v)$ if $\varphi_i(v) = \varphi_j(v) = \varphi(v)$.*

Proof. It suffices to show that for any $u \in \Omega \cap \mathrm{dom}\zeta$ and any $i, j \in I$, $\nabla\zeta_i(u) = \nabla\zeta_j(u)$ if $\zeta_i(u) = \zeta_j(u) = \zeta(u)$, where $\{(D_j, U_j, \zeta_j)\}_{j\in I}$ is the corresponding representation of ζ. Let $u \in U_i$ and $\xi_i : U_i \to W_i$ be defined as in Lemma 2. If we can show that $\zeta_i(u) = \zeta(u)$ implies that $\xi_{ix}(u)$ is indeed the unique maximizer x^* of problem (9) for the given u, then the fact $\nabla\zeta_i(u) = \xi_{ix}(u)$ (Lemma 3) leads readily to $\nabla\zeta_i(u) = x^* = \nabla\zeta_j(u)$, provided that $\zeta_i(u) = \zeta_j(u) = \zeta(u)$.

Now, if $\zeta_i(u) = \zeta(u)$, then (20) (applying to ζ) and $u \in U_i$ imply $u \in D_i$. By definition of (18), $x = \xi_{ix}(u) \in Q_i \subset \mathcal{F}$; i.e., $\xi_{ix}(u)$ is a feasible solution of problem (9). So, $u^T\xi_{ix}(u) = \zeta_i(u) = \zeta(u)$ implies that $\xi_{ix}(u)$ is a unique optimal solution x^* of problem (9) for a given u. ∎

The above lemma actually holds true for φ with $\mathrm{dom}\varphi \neq \mathbb{R}^m$. This lemma will be used to prove Lemma 6. In addition to it, we obtain a property of the function φ as a by-product, namely, φ is indeed differentiable on the relative interior of $\mathrm{dom}\varphi$, because the subdifferential $\partial\varphi(v)$ at any point $v \in \mathrm{ri}(\mathrm{dom}\varphi)$ is a singleton.

LEMMA 6. *Suppose that the conditions of Proposition* 4 *are satisfied. Then, for the piecewise C^2 function φ, the AIPCQ holds at each $v \in \mathbb{R}^m$.*

Proof. Let $v \in \mathbb{R}^m$ and $K \subseteq I(v)$. If $|K| = 1$, the vectors in the set in (8) are evidently linearly independent (actually, the set is a singleton). So the conditions for AIPCQ are satisfied. If $|K| \geq 2$, then for any $w \neq v$ with $K \subseteq I(w)$ and for any $i \neq j \in K$, $\varphi_i(w) = \varphi_j(w) = \varphi(w)$ implies that $\nabla\varphi_i(w) = \nabla\varphi_j(w)$ by Lemma 5. Thus the set of vectors in (7) can never be linearly independent. This means that the conditions for AIPCQ hold automatically. ∎

From the piecewise C^2 smoothness of φ shown in section 3 and the qualification AIPCQ verified in this section, we have the semismoothness of g, as stated below.

PROPOSITION 5. *Let φ be defined by* (9). *Suppose that Assumptions* 1, 2, *and* 4 *are satisfied. Suppose that f_i, $i \in \hat{I}$, are either all affine or all possess positive definite Hessian matrices. In the latter case suppose that for any facet Q of $\mathcal{F}$ with the index set I_Q, $\{\nabla f_i(x)\}_{i\in I_Q}$ are linearly independent. Then the gradient $g(v)(= \nabla\eta(v))$ of the Moreau–Yosida regularization η is piecewise smooth, and thereby semismooth, on $\mathbb{R}^m$.*

Proof. The proof follows directly from Propositions 1, 3, and 4, and Lemmas 4 and 6. □

Remark 5. The above proposition shows that g is semismooth if constraints defining $\mathcal{F}$ either are all linear or all possess positive definite Hessian matrices. In Example 1 of section 3, we found that, for some simple mixed constraints, the Lagrangian-dual function φ is not piecewise C^2. Actually, the second-order derivatives of φ tend to infinity at some point. Since the semismoothness of g is closely related to the piecewise C^2 smoothness of φ, we might expect that for this example g is not semismooth either. However, the gradient g of the Moreau–Yosida regularization of this function φ is semismooth, as shown below.

Example 2 (Example 1 (continued)). It is known that $\varphi(v) = \sqrt{v_1^2 + v_2^2}$. For convenience in description we set $M = I$, so we have

$$\eta(v) = \min\left\{\sqrt{w_1^2 + w_2^2} + \frac{1}{2}\|w - v\|^2 \mid w \in \mathbb{R}^2\right\}.$$

It is easy to verify that, for $\|v\| \le 1$,

$$\eta(v) = (v_1^2 + v_2^2)/2, \qquad p(v) = (0,\ 0)^T,$$

and for $\|v\| \ge 1$,

$$\eta(v) = \sqrt{v_1^2 + v_2^2} - 1/2, \qquad p(v) = (1 - 1/\|v\|)v.$$

Let $\hat{V}_1 = \{v \in \mathbb{R}^2 : \|v\| \le 1\}$ and $\hat{V}_2 = \{v \in \mathbb{R}^2 : \|v\| \ge 1\}$. By (6), it suffices to study the semismoothness of p. For $v \in \mathrm{int}\hat{V}_1$, the Jacobian of p is

$$J(p(v)) = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}, \tag{21}$$

and for $v \in \mathrm{int}\hat{V}_2$,

$$J(p(v)) = \begin{pmatrix} 1 - v_2^2/\|v\|^3 & v_1v_2/\|v\|^3 \\ v_1v_2/\|v\|^3 & 1 - v_1^2/\|v\|^3 \end{pmatrix}. \tag{22}$$

From the Jacobian of p above, we can see that p is smooth on the interior of $\hat{V}_i$ $(i = 1, 2)$. Thus we need only to investigate the semismoothness of p on the region where the two sets meet, namely, $\{v \in \mathbb{R}^2 : \|v\| = 1\}$. Let $\bar{v} = (\bar{v}_1, \bar{v}_2)^T$ be any point on this region; we will show that p is semismooth at $\bar{v}$. By the definition of semismoothness [16], it suffices to show that

$$\lim_{h'\to h, t\to 0+} \{Vh' : V \in \partial p(\bar{v} + th')\} \tag{23}$$

exists for any $h \in \mathbb{R}^2$. Let $S_1(\bar{v}) = \{h \in \mathbb{R}^2 : h^T\bar{v} < 0\}$, $S_2(\bar{v}) = \{h \in \mathbb{R}^2 : h^T\bar{v} > 0\}$, $S_3(\bar{v}) = \{h \in \mathbb{R}^2 : h^T\bar{v} = 0\}$. Write $v' = \bar{v}+th'$. Then $\|v'\|^2 = \|\bar{v}\|^2+2t\bar{v}^Th'+t^2\|h'\|^2$.

If $h \in S_1(\bar{v})$ or $h \in S_2(\bar{v})$, then for any sufficiently small $t > 0$ and h' close to h, $v' \in \mathrm{int}\hat{V}_1$ or $v' \in \mathrm{int}\hat{V}_2$. It is evident that the limit in (23) exists.

If $h \in S_3(\bar{v})$, then for any sufficiently small $t > 0$ and h' close to h there are the following three cases: if $\|v'\| < 1$, we have

$$\lim_{h'\to h,t\to 0+} Vh' = \lim_{h'\to h,t\to 0+} \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} h'_1 \\ h'_2 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \tag{24}$$

If $\|v'\| > 1$, we have

$$\begin{aligned} \lim_{h'\to h,t\to 0+} Vh' &= \lim_{h'\to h,t\to 0+} \begin{pmatrix} 1 - {v'_2}^2/\|v'\|^3 & v'_1v'_2/\|v'\|^3 \\ v'_1v'_2/\|v'\|^3 & 1 - {v'_1}^2/\|v'\|^3 \end{pmatrix} \begin{pmatrix} h'_1 \\ h'_2 \end{pmatrix} \\ &= \lim_{h'\to h,t\to 0+} \begin{pmatrix} (1 - {v'_2}^2/\|v'\|^3)h'_1 + (v'_1v'_2/\|v'\|^3)h'_2 \\ (v'_1v'_2/\|v'\|^3)h'_1 + (1 - {v'_1}^2/\|v'\|^3)h'_2 \end{pmatrix}. \end{aligned} \tag{25}$$

Since

$$\begin{aligned} &\lim_{h'\to h,t\to 0+}[(1 - {v'_2}^2/\|v'\|^3)h'_1 + (v'_1v'_2/\|v'\|^3)h'_2] \\ &= (1 - \bar{v}_2^2/\|\bar{v}\|^3)h_1 + (\bar{v}_1\bar{v}_2/\|\bar{v}\|^3)h_2 = (1 - \bar{v}_2^2)h_1 + \bar{v}_1\bar{v}_2h_2 \\ &= \bar{v}_1^2h_1 + \bar{v}_1\bar{v}_2h_2 = \bar{v}_1(h_1\bar{v}_1 + h_2\bar{v}_2) = 0, \end{aligned}$$

and similarly, $\lim_{h'\to h,t\to 0+}[(v'_1v'_2/\|v'\|^3)h'_1 + (1 - {v'_1}^2/\|v'\|^3)h'_2] = 0$, by (24), we have

$$\lim_{h'\to h,t\to 0+} Vh' = (0, 0)^T. \tag{26}$$

Hence, Vh' tends to the same limit in these two cases by (24) and (26).

If $\|v'\| = 1$, by the definition of the generalized Jacobian, V is a convex combination of the Jacobians in (21) and (22) (with v replaced by v'). Thus, Vh' tends to the same limit, namely 0, as the above two cases.

Thereby, the limit in (23) exists if $h \in S_3(\bar{v})$. The above shows that p is semismooth on $\mathbb{R}^2$. Therefore, g is semismooth on $\mathbb{R}^2$ as well.

4.2. Conjugate of the Moreau–Yosida regularization. In this subsection, we investigate the relationship between the original problem with the linear objective and the Fenchel conjugate of Moreau–Yosida regularization of its Lagrangian-dual function.

First, recall the notion of Fenchel conjugate. Let ϕ be a real-valued convex function on $\mathbb{R}^l$. The *Fenchel conjugate*, denoted by ϕ^*, of ϕ is defined by (see [18])

$$\phi^*(x) := \sup\{\langle x^*, x\rangle - \phi(x) \mid x^* \in \mathbb{R}^l\} \quad \forall\, x \in \mathbb{R}^l.$$

Note that η, the Moreau–Yosida regularization of φ defined in (9), can be rewritten as

$$\eta(v) = (\pi_1 \square \pi_2)(v) := \inf\{\pi_1(v - w) + \pi_2(w) : w \in \mathbb{R}^m\}, \quad v \in \mathbb{R}^m, \tag{27}$$

where "$\square$" denotes the *infimal convolution* operation [18], $\pi_1(v) := \frac{1}{2}\|v\|_M^2, \pi_2(v) := \varphi(v)$, as defined in (9). Evidently, both π_1 and π_2 are proper convex functions; then by [18, Theorem 5.4], η is a convex function.

Using the conjugate operator, it is not hard to derive that

$$\pi_1^*(v) = \tfrac{1}{2}\|v\|^2_{M^{-1}} \quad \forall\, v \in \mathbb{R}^m.$$

Hence, we have $\mathrm{dom}\pi_1^* = \mathbb{R}^m$. Thereby, it follows from [8, Corollary 2.1.3] that

$$\eta^*(v) = \pi_1^*(v) + \pi_2^*(v) \quad \forall\, v \in \mathbb{R}^m.$$

Next, we study the conjugate of π_2. To ease notation, we define a mapping $\mathcal{A} : \mathbb{R}^m \to \mathbb{R}^n$ by

$$\mathcal{A}(v) = A^T v - c.$$

Then we have

$$\delta^*(A^T v - c \mid \mathcal{F}) = \zeta \circ \mathcal{A}(v), \quad v \in \mathbb{R}^m,$$

where ζ is defined in (10). Since $\mathrm{dom}\zeta = \mathcal{F}^b$, so $\zeta \circ \mathcal{A}$ is a closed convex function on $\mathbb{R}^m$ under Assumption 3. Thus, by [18, Theorem 16.3], it follows that

$$(\zeta \circ \mathcal{A})^*(v) = \mathrm{cl} \inf_{x \in \mathbb{R}^n} \{\zeta^*(x) - \langle -c, x\rangle \mid Ax = v\}.$$

Since $\mathcal{F}$ is closed, we then have

$$\begin{aligned}(\zeta \circ \mathcal{A})^*(v) &= \mathrm{cl} \inf_{x \in \mathbb{R}^n} \{(\delta^*(x \mid \mathcal{F}))^* + \langle c, x\rangle \mid Ax = v\} \\ &= \mathrm{cl} \inf_{x \in \mathbb{R}^n} \{\delta(x \mid \mathcal{F}) + \langle c, x\rangle \mid Ax = v\} \\ &= \mathrm{cl}\inf\{\langle c, x\rangle \mid Ax = v, x \in \mathcal{F}\}.\end{aligned}$$

On the other hand, by definition of conjugate, we have

$$\begin{aligned}\pi_2^*(v) &= \sup\{\langle v + a, v'\rangle - \sup\{\langle A^T v' - c, x\rangle \mid x \in \mathcal{F}\} \mid v' \in \mathrm{dom}\pi_2\} \\ &= \sup\{\langle v + a, v' - \zeta \circ \mathcal{A}(v')\rangle \mid v' \in \mathrm{dom}\pi_2\} \\ &= \sup\{\langle v + a, v' - \zeta \circ \mathcal{A}(v')\rangle \mid v' \in \mathrm{dom}(\zeta \circ \mathcal{A})\} \\ &= (\zeta \circ \mathcal{A})^*(v + a).\end{aligned}$$

Thus, we obtain the conjugate of π_2 as follows:

$$\pi_2^*(v) = \mathrm{cl}\inf\{\langle c, x\rangle \mid Ax = v + a, x \in \mathcal{F}\}.$$

We now derive an interesting result on the conjugate of Moreau–Yosida regularization of the Lagrangian-dual function as follows.

PROPOSITION 6. *Assume $\Omega \cap \mathcal{F}^b \neq \emptyset$. Then, for any $v \in \mathbb{R}^m$,*

$$\begin{aligned}&\mathrm{cl}\inf\{\langle c, x\rangle \mid Ax - a = v,\ x \in \mathcal{F}\} \\ &= \eta^*(v) - \tfrac{1}{2}\|v\|^2_{M^{-1}}.\end{aligned}$$

From Proposition 6, we can see that the optimal value function of the underlying parametric optimization problem can be represented by the conjugate function of

the regularized dual function of the (unperturbed) original problem, together with a quadratic function in terms of the perturbation parameter v. Note that the expression is taken under the *closure* and *infimal* operations on the set of objective values due to the fact that the minimum of the set of objective values of the corresponding feasible points might not exist in general.

Next we investigate under which situations these two operations can be replaced by the usual minimization operator so as to simplify the analysis on conventional minimization problems. We need the following assumption in the rest of this subsection.

Assumption 5. $\Omega \cap \mathrm{ri}\mathcal{F}^b \neq \emptyset$.

Note that under Assumption 5 and by virtue of [8, Theorem 2.2.3], we have

$$(\zeta \circ \mathcal{A})^*(v) = \min\{\langle c, x\rangle \mid Ax = v,\ x \in \mathcal{F}\} \quad \forall\, v \in \mathrm{dom}(\zeta \circ \mathcal{A})^*.$$

Let (P_v) denote the perturbed problem

$$\begin{aligned} \min_{x\in\mathbb{R}^n} \quad & \langle c, x\rangle \\ \text{s.t.} \quad & Ax - a = v, \\ & x \in \mathcal{F}, \end{aligned}$$

where v serves as the perturbation parameter. We refer to the original problem (1) where the objective function is taken as an affine function, denoted by (P_0), to the unperturbed problem. We denote the optimal value function of (P_v) by $f_{\mathrm{val}}(v)$. Accordingly, $f_{\mathrm{val}}(0)$ denotes the optimal value of the original problem (1) or (P_0).

Then, we derive the following result immediately by virtue of Proposition 6.

Proposition 7. *Suppose that Assumption* 5 *holds. Then*

$$f_{\mathrm{val}}(v) = \eta^*(v) - \tfrac{1}{2}\|v\|^2_{M^{-1}}$$

for any $v \in dom(\zeta \circ \mathcal{A})^* - a$.

Note that the above result enhances Proposition 6. It provides a new and interesting characteristic of convex conjugates in perturbation analysis. Note that the result is valid only if the parameter v belongs to the set $\mathrm{dom}(\zeta \circ \mathcal{A})^* - a$. Also, this result has a potential role in studying sensitivity analysis and some stochastic programs, both theoretically and numerically.

The next immediate question is about the nonemptiness of the domain of $(\zeta \circ \mathcal{A})^*$. Consider the case when the original problem (P_0) is bounded below; by definition, it follows that

$$\begin{aligned} & (\zeta \circ \mathcal{A})^*(a) \\ &= \min\{\langle c, x\rangle \mid Ax = a,\ x \in \mathcal{F}\} < \infty. \end{aligned}$$

Thus, $a \in \mathrm{dom}(\zeta \circ \mathcal{A})^*$. This implies that $\mathrm{dom}(\zeta \circ \mathcal{A})^*$ is nonempty, and so is $\mathrm{dom}(\zeta \circ \mathcal{A})^* - a$.

Before ending this section, we derive the following result based on the above arguments.

Proposition 8. *Suppose that the original problem, namely,*

$$\begin{aligned} \min_{x\in\mathbb{R}^n} \quad & \langle c, x\rangle \\ \text{s.t.} \quad & Ax = a, \\ & f_i(x) \leq 0, \quad i \in \hat{I} = \{1, \ldots, \theta\}, \end{aligned}$$

is bounded below. Then, dom$(h \circ \mathcal{A})^* \neq \emptyset$ *and* $a \in dom(h \circ \mathcal{A})^*$.

Furthermore, let $\{v^k\}$ *be a sequence in dom*$(h \circ \mathcal{A})^* - a$ *satisfying* $v^k \to 0$ *as* $k \to \infty$*; then*

$$\lim_{v^k \to 0} \eta^*(v^k) = \lim_{v^k \to 0} \left(f_{\text{val}}(v^k) + \tfrac{1}{2}\|v^k\|^2_{M^{-1}} \right)$$
$$= f_{\text{val}}(0) = \min\{\langle c, x\rangle \mid Ax - a = 0,\ x \in \mathcal{F}\}.$$

Remark 6. Note that Assumption 4 used in section 4.1 is obviously stronger than Assumption 5. In other words, the former implies the latter, but not vice versa. Hence, the results obtained in Propositions 6–8 will be valid under Assumption 4. In Proposition 8, we assume that problem (P_0) is bounded below. This assumption is natural and reasonable in optimization. Proposition 8 tells us that the optimal value of the unperturbed optimization problem (the original problem) can be achieved by solving a sequence of the conjugates which corresponds to the perturbed problems, in which affine equality constraints are perturbed on the right-hand side, and setting the perturbation parameters driven to zero. This result helps us to better understand the conjugate and Lagrange dual, and it might serve to study multistage stochastic nonlinear convex programs.

Also, this kind of perturbation problem is closely related to the perturbation problems discussed in [3]. In [9], Magnanti showed the equivalence between Fenchel dual and Lagrangian dual problems where the convex conjugate was employed. We believe that the results established in this subsection complement his theory to some extent. In addition, note that η is originally obtained from the Moreau–Yosida regularization by relaxing the original problem using the Lagrangian dual. Its conjugate η^*, as shown in Propositions 6–8, is related to the parametric (or perturbed) problem of the original problem. From this observation, we see that the perturbation analysis and Lagrangian dual are closely linked under the conjugate operation and Moreau–Yosida regularization. Besides the usual optimization methods, it also provides another possible option for solving some optimization problems, i.e., by solving the induced conjugate.

5. General convex objectives functions. In this section, we investigate the piecewise smoothness and semismoothness of the Lagrangian-dual function φ and the gradient g for the case of the general convex objective functions in (1). We will also provide an alternative way to study the semismoothness of the gradient g based on the structure of the epigraph of φ.

5.1. Convex objective functions with positive definite Hessian. We now discuss the case for the general convex objective functions in (1). Consider the following Lagrangian-dual function φ in (3):

$$\varphi(v) = \sup\{-f(x) + v^T(Ax - a) \mid x \in \mathcal{F}\}.$$

When analyzing the piecewise smoothness of φ in section 3, we frequently use the fact that the optimal solutions of problem (9) lie on the boundary (or facets) of the set $\mathcal{F}$. This fact is guaranteed by Assumption 1, namely $u = A^T v - c \neq 0$, for the linear objective function $f(x) = c^T x$. For nonlinear objective functions, Assumption 1 cannot be made. Thus, multiple optimal solutions of problem (3) may appear in the interior of $\mathcal{F}$, and the piecewise C^2 smoothness of φ may probably be destroyed. This conjecture is confirmed by the following example where $\nabla^2\varphi$ is unbounded in some area, and thus φ is not piecewise C^2.

Example 3. Let

$$f(x) = \begin{cases} 0 & \text{if} \quad \rho \le 1, \\ (\rho - 1)^4 & \text{if} \quad \rho > 1, \end{cases}$$

where $x \in \mathbb{R}^2$ and $\rho = \sqrt{x_1^2 + x_2^2}$, and let

$$A = \begin{pmatrix} 1 & 1 \end{pmatrix}, \quad a = 0, \quad \mathcal{F} = \{x \in \mathbb{R}^2 : x_1^2 + x_2^2 \le 4\}.$$

Obviously, $f(x)$ is convex and twice continuously differentiable on $\mathbb{R}^2$. After some manipulations we obtain

$$\varphi(v) = \sqrt{2}|v| + (3/4)|v|^{4/3}$$

for v in a neighborhood of zero, namely $\mathcal{N} = \{v \in \mathbb{R} : |v| < 2\sqrt{2}\}$. Since $\mathcal{F}$ is bounded, the effective domain of φ is the whole space $\mathbb{R}$. On $\mathbb{R} \setminus \mathcal{N}$, the function φ has a different form. For our purpose, the investigation of φ within $\mathcal{N}$ suffices. Thus we do not elaborate φ outside $\mathcal{N}$. For any $0 \ne v \in \mathcal{N}$, the first- and second-order derivatives of φ are

$$\varphi'(v) = \sqrt{2}\,\mathrm{sign}(v) + v^{1/3}, \qquad \varphi''(v) = (1/3)v^{-2/3}.$$

Now for any nonzero $v \to 0$, we have $\varphi''(v) \to \infty$. Using the same arguments as in Example 1, we can see that φ cannot be piecewise C^2 in the neighborhood $\mathcal{N}$.

This example shows that we cannot extend the results in sections 3 and 4 to problems with arbitrary convex objective functions. However, if the objective function $f(x)$ possesses a positive definite Hessian, we can obtain results similar to those in sections 3 and 4. Also, in this case, the constraints need not be strictly convex.

PROPOSITION 9. *Let φ be defined by* (3)*, where f and f_i, $i \in \hat{I}$, are C^2 convex functions on $\mathbb{R}^n$. Suppose that the Hessian of f is positive definite, and for any facet Q of $\mathcal{F}$ with the index set I_Q and for any $x \in Q$, $\{\nabla f_i(x)\}_{i \in I_Q}$ are linearly independent. Suppose also that $\mathcal{F}$ is nonempty and bounded. Then the Lagrangian-dual function φ is piecewise C^2, and the gradient g of the Moreau–Yosida regularization η is piecewise smooth, and thereby semismooth, on $\mathbb{R}^m$.*

Proof. Similar to the analysis in section 3, we shall construct a piece corresponding to each facet of $\mathcal{F}$. There is one major difference we should highlight. For the problem with a nonlinear objective function, maximizers of the problem (3) can lie on the boundary as well as in the interior of $\mathcal{F}$, while in the case of linear objective functions, Assumption 1 prohibits interior maximizers. Thus, in the present case, an additional piece corresponding to the interior of $\mathcal{F}$ is needed.

Here we define the function ζ slightly differently from the approach in (10):

$$\zeta(u) = \sup\{u^T x - f(x) \mid x \in \mathcal{F}\}. \tag{28}$$

Then $\varphi(v) = \zeta(A^T v) - a^T v$. For each facet Q (on the boundary) of $\mathcal{F}$, we still construct a piece by a slightly different definition:

$$W := \left\{ (x, \lambda) \in \mathbb{R}^n \times \mathbb{R}^{|I_Q|} : f_i(x) = 0,\ i \in I_Q,\ \nabla^2 f(x) + \sum_{i \in I_Q} \lambda_i \nabla^2 f_i(x) \succ 0 \right\},$$

$$U := \left\{ u = \nabla f(x) + \sum_{i \in I_Q} \lambda_i \nabla f_i(x) \in \mathbb{R}^n : (x, \lambda) \in W \right\},$$

and

$$\Gamma(x,\lambda) := \begin{pmatrix} \nabla f(x) + \sum_{i\in I_Q} \lambda_i \nabla f_i(x) \\ \tilde{f}(x) \end{pmatrix}.$$

Then the result of Lemma 2 can be analogously proved, and a piece can be constructed.

In addition, a piece corresponding the interior of $\mathcal{F}$ will be constructed as follows. Since $\nabla^2 f(x) \succ 0$, for any $u \in \mathbb{R}^n$,

$$\nabla f(x) = u$$

has a unique solution, denoted by $\xi_{0x}(u)$. In other words, $\xi_{0x}(u)$ is the unique maximizer of the unconstrained problem

$$\max_{x\in\mathbb{R}^n} \{u^T x - f(x)\}.$$

Now, this piece is defined by $U_0 = \mathbb{R}^n$, $\zeta_0(u) = u^T \xi_{0x}(u) - f(\xi_{0x}(u))$, and $D_0 = \mathrm{cl} D_{\mathrm{int}}$, where $D_{\mathrm{int}} = \{u \mid \xi_{0x}(u) \in \mathrm{int}\mathcal{F}\}$. For any $u \in D_{\mathrm{int}}$, since the unique maximizer $\xi_{0x}(u)$ of the objective function $u^T x - f(x)$ is in the interior of the set $\mathcal{F}$, $\xi_{0x}(u)$ is the optimal solution to the constrained problem (28), too. Thus

$$\zeta(u) = u^T \xi_{0x}(u) - f(\xi_{0x}(u)) = \zeta_0(u). \tag{29}$$

Since ζ and ζ_0 are continuous, thus $\zeta(u) = \zeta_0(u)$ also holds for all $u \in D_0$. It is also easy to verify that

$$\nabla\zeta_0(u) = \xi_{0x}(u) \qquad \forall\, u \in U_0. \tag{30}$$

Now an analogue of the proof of Proposition 4 is valid to prove the piecewise-C^2 smoothness of ζ with the representation $\{(D_0, U_0, \zeta_0), (D_1, U_1, \zeta_2), \ldots, (D_q, U_q, \zeta_q)\}$. (The only difference is that now the nonnegative vector $\bar{\lambda}$ need not be nonzero since $u \neq 0$ is not assumed. Still, $\nabla^2 f(x) + \sum \bar{\lambda}_i \nabla^2 f_i(x) \succ 0$ because $\nabla^2 f(x) \succ 0$. This implies that the Jacobian of Γ is invertible.) Therefore, φ is piecewise C^2 on its domain.

The proof of the piecewise smoothness of g follows from Lemmas 5 and 6 and Proposition 5. The proofs of Lemmas 5 and 6 do not directly rely on Assumption 1, and thus they can be extended without changing to the representation $\{(E_0, V_0, \varphi_0), (E_1, V_1, \varphi_1), \ldots, (E_q, V_q, \varphi_q)\}$ of the Lagrangian-dual function φ of the present problem. □

5.2. Piecewise smoothness under the structure of the epigraph. In this subsection, we investigate the piecewise smoothness and the semismoothness of g using a different approach. In the analysis we will employ the piecewise smoothness or the semismoothness of the metric projection mapping under the structure of the epigraph of the underlying function. Our analysis is based on the framework of [11].

Recently, Meng, Sun, and Zhao [11] investigated the Moreau–Yosida regularization of a lower semicontinuous convex function, $\gamma : Z \to \mathbb{R} \cup \{+\infty\}$, and derived the semismoothness of the solution to the Moreau–Yosida regularization under the structure of the epigraph of γ. Here, Z is a finite dimensional vector space equipped with a scalar product, and the Moreau–Yosida regularization of γ is defined in the form of

$$\begin{aligned} \hat{\gamma}_\epsilon(u) := \min & \left\{\gamma(z) + \tfrac{\epsilon}{2}\langle u - z, u - z\rangle\right\} \\ \text{s.t. } & z \in Z, \end{aligned} \tag{31}$$

where ϵ is a positive number. Let Υ be the epigraph of γ; i.e., $\Upsilon := \mathrm{epi}(\gamma) = \{(u,t) \in Z \times \mathbb{R} \mid t \geq \gamma(u)\}$. Noticing that Υ is a closed convex set, problem (31) then can be written as

$$\begin{array}{ll} \min & \left\{ \frac{1}{\epsilon} t + \frac{1}{2} \langle u - z, u - z \rangle \right\} \\ \text{s.t.} & (z,t) \in \Upsilon. \end{array} \tag{32}$$

For any closed convex set D of Z and $z \in Z$, let $\Pi_D(z)$ denote the metric projection of z onto D, namely,

$$\Pi_D(z) := \mathrm{argmin} \left\{ \tfrac{1}{2} \|d - z\|^2 \mid d \in D \right\}.$$

Let $(z(u), t(u))$ be the unique optimal solution of (32), where $t(u) := \gamma(z(u))$. Define the mapping H by

$$H(z,t,u) := \begin{pmatrix} z \\ t \end{pmatrix} - \Pi_\Upsilon(G(z,t,u)),$$

where $G(z,t,u) := (u^T \;\; t - 1/\epsilon)^T$. Then, it follows from [11] that

$$H(z(u), t(u), u) = 0, \quad G(z(u), t(u), u) \notin \Upsilon \quad \forall\, u \in Z.$$

The following proposition is taken from [11, Theorem 4].

PROPOSITION 10. *For $u_0 \in Z$, let $z_0 := z(u_0)$ and $t_0 := \gamma(z(u_0))$. Then, $(z(\cdot), t(\cdot))$ is semismooth at u_0 if $\Pi_\Upsilon(G(z_0,t_0,u_0))_z \in \mathrm{int}(\mathrm{dom}\gamma)$ and $\Pi_\Upsilon(\cdot)$ is semismooth at $G(z_0,t_0,u_0)$.*

Here we consider the case where $M = \lambda I$ in the Moreau–Yosida regularization as defined in (5), where I is the identity matrix of $\mathbb{R}^{m \times m}$ and $\lambda > 0$. For $v \in \mathbb{R}^m$, let $w(v)$ denote the unique solution of (5), $s(v) := \varphi(w(v))$, and $\mathrm{epi}(\varphi)$ denote the epigraph of φ. Evidently, $(w(v), s(v))$ is the unique solution of

$$\begin{array}{ll} \min & \left\{ \frac{1}{\lambda} s + \frac{1}{2} \langle v - w, v - w \rangle \right\} \\ \text{s.t.} & (w,s) \in \mathrm{epi}(\varphi), \end{array}$$

which is a reformulation of (5). Note that

$$g(v) = \nabla \eta(v) = \lambda(v - w(v)).$$

Hence to study the semismoothness of g, we need only to study the properties of $w(\cdot)$. Set

$$\Phi(w,s,v) := \begin{pmatrix} w \\ s \end{pmatrix} - \begin{pmatrix} w - v \\ 1/\lambda \end{pmatrix} = \begin{pmatrix} v \\ s - 1/\lambda \end{pmatrix}.$$

According to Proposition 10 and following the arguments as in [11], we then have the following result.

PROPOSITION 11. *For $\bar{v} \in \mathbb{R}^m$, let $\bar{w} := w(\bar{v})$, $\bar{s} := \varphi(w(\bar{v}))$. Suppose that $\Pi_{\mathrm{epi}(\varphi)}(\Phi(\bar{w}, \bar{s}, \bar{v}))_w \in \mathrm{int}(\mathrm{dom}\varphi)$ and $\Pi_{\mathrm{epi}(\varphi)}(\cdot)$ is semismooth at $\Phi(\bar{w}, \bar{s}, \bar{v})$. Then $(w(\cdot), s(\cdot))$ is semismooth at $\bar{v}$. Thereby, g is semismooth at $\bar{v}$.*

Furthermore, if φ is finite valued everywhere and $\Pi_{\mathrm{epi}(\varphi)}(\cdot)$ is semismooth on $\mathbb{R}^m \times \mathbb{R}$, then g is semismooth on $\mathbb{R}^m$.

Similar to the mapping H above, we define a mapping Ξ corresponding to the regularization (5),

$$\Xi(w,s,v) := \begin{pmatrix} w \\ s \end{pmatrix} - \Pi_{\mathrm{epi}(\varphi)}(\Phi(w,s,v)).$$

Thus, for any $v \in \mathbb{R}^m$

$$\Xi(w(v), s(v), v) = 0. \tag{33}$$

We now obtain the following result concerning the piecewise smoothness of g.

PROPOSITION 12. *Let $\bar{v} \in \mathbb{R}^m$. Suppose that* (i) $\Pi_{\mathrm{epi}(\varphi)}(\Phi(\bar{w},\bar{s},\bar{v}))_w \in \mathrm{int}(\mathrm{dom}\varphi)$, *and* (ii) $\Pi_{\mathrm{epi}(\varphi)}(\cdot)$ *is piecewise C^k on a neighborhood $\mathcal{N}_1$ of $(\bar{v}, \varphi(w(\bar{v})) - 1/\lambda)$, where $\bar{w} = w(\bar{v})$ and $\bar{s} = \varphi(w(\bar{v}))$. Then, $(w(\cdot), s(\cdot))$ is piecewise C^k on a neighborhood $\mathcal{N}_2$ of $\bar{v}$. Thereby, g is piecewise C^k on $\mathcal{N}_2$. In particular, g is semismooth on a neighborhood of $\bar{v}$.*

Proof. Define a mapping $\aleph : \mathbb{R}^m \times \mathbb{R} \times \mathbb{R}^m \to \mathbb{R}^m \times \mathbb{R} \times \mathbb{R}^m$ by

$$\aleph(w,s,v) = \begin{pmatrix} \Xi(w,s,v) \\ v - \bar{v} \end{pmatrix}.$$

By assumption, since $\Pi_{\mathrm{epi}(\varphi)}(\cdot)$ is piecewise C^k on $\mathcal{N}_1$, it is easy to see that $\aleph(\cdot)$ is piecewise C^k on some neighborhood of $(\bar{w},\bar{s},\bar{v})$, and

$$\aleph(\bar{w},\bar{s},\bar{v}) = 0. \tag{34}$$

Next, we show that every matrix in $\partial\aleph(\bar{w},\bar{s},\bar{v})$ is nonsingular [2]. To do so, it is not hard to see that we only need to show the nonsingularity of $\pi_{(w,s)}\partial\Xi(\bar{w},\bar{s},\bar{v})$. For any $V \in \pi_{(w,s)}\partial\Xi(\bar{w},\bar{s},\bar{v})$, it follows that there exists $W \in \partial\Pi_{\mathrm{epi}(\varphi)}(\Phi(\bar{w},\bar{s},\bar{v}))$ such that

$$V = I_{m+1} - W\left(I_{m+1} - \begin{bmatrix} I_m & 0 \\ 0 & 0 \end{bmatrix}\right),$$

where W is a convex combination of some finitely many matrices in $\partial_B\Pi_{\mathrm{epi}(\varphi)}(\Phi(\bar{w}, \bar{s},\bar{v}))$. Suppose $W_i \in \partial_B\Pi_{\mathrm{epi}(\varphi)}(\Phi(\bar{w},\bar{s},\bar{v}))$ and $\lambda_i \geq 0$, $i = 1,\ldots,\nu$, satisfying $\sum_{i=1}^{\nu}\lambda_i = 1$, such that $W = \sum_{i=1}^{\nu}\lambda_i W_i$, where each W_i is in the form of $W_i = \left[\begin{smallmatrix} U_i & \alpha_i \\ \alpha_i^T & \beta_i \end{smallmatrix}\right]$ with $U_i \in \mathbb{R}^{m\times m}$, $\alpha_i \in \mathbb{R}^m$, and $\beta_i \geq 0$. Thus,

$$W = \begin{bmatrix} \sum_{i=1}^{\nu}\lambda_i U_i & \sum_{i=1}^{\nu}\lambda_i\alpha_i \\ \sum_{i=1}^{\nu}\lambda_i\alpha_i^T & \sum_{i=1}^{\nu}\lambda_i\beta_i \end{bmatrix}.$$

To ease the notation, we write $W = \left[\begin{smallmatrix} U & \alpha \\ \alpha^T & \beta \end{smallmatrix}\right]$. Then, by [11, Proposition 3], there exists $\varrho_i \in (0,1)$, $i = 1,\ldots,\nu$, such that

$$0 \leq \beta_i \leq \varrho_i < 1 \qquad \forall\, i.$$

Hence,

$$0 \leq \beta < 1. \tag{35}$$

Then, we have

$$V = I_{m+1} - \begin{bmatrix} U & \alpha \\ \alpha^T & \beta \end{bmatrix} \left(I_{m+1} - \begin{bmatrix} I_m & 0 \\ 0 & 0 \end{bmatrix} \right)$$

$$= I_{m+1} - \begin{bmatrix} U & \alpha \\ \alpha^T & \beta \end{bmatrix} \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}$$

$$= I_{m+1} - \begin{bmatrix} 0 & \alpha \\ 0 & \beta \end{bmatrix} = \begin{bmatrix} I_m & -\alpha \\ 0 & 1-\beta \end{bmatrix}.$$

This together with (35) implies that $\det V = 1 - \beta > 0$ for any $V \in \pi_{(w,s)} \partial \Xi(\bar{w}, \bar{s}, \bar{v})$. So, $\Xi(w, s, v)$ is coherently oriented with respect to w and s at $(\bar{w}, \bar{s}, \bar{v})$ [17, 20]. Thereby, $\pi_{(w,s)} \partial \Xi(\bar{w}, \bar{s}, \bar{v})$ is nonsingular, and so is $\partial \aleph(\bar{w}, \bar{s}, \bar{v})$. Then, by [15, Theorem 6], $\aleph$ is a locally Lipschitz homeomorphism near $(\bar{w}, \bar{s}, \bar{v})$, and $\operatorname{sgn} \det V = \operatorname{ind}(\aleph, (\bar{w}, \bar{s}, \bar{v})) = \pm 1$ for any $V \in \partial_B \aleph(\bar{w}, \bar{s}, \bar{v})$. Further, noticing that $\aleph(\cdot)$ is coherently oriented at $(\bar{w}, \bar{s}, \bar{v})$ and is piecewise C^k on a neighborhood of $(\bar{w}, \bar{s}, \bar{v})$, then by [17, Theorem 5], it follows that $\aleph$ is a PC^k-homeomorphism near $(\bar{w}, \bar{s}, \bar{v})$. Thus, the desired results follow immediately. This completes the proof. □

Remark 7. The condition $\Pi_{\mathrm{epi}(\varphi)}(\Phi(\bar{w}, \bar{s}, \bar{v}))_w \in \mathrm{int}(\mathrm{dom}\varphi)$ in Proposition 12 holds automatically if φ is finite valued everywhere. The obtained results complement and enrich the framework of piecewise smooth functions [20, 17], and also enhance the recent results on the Moreau–Yosida regularization [11].

6. Conclusion. The Lagrangian dual is widely used for large-scale problems. A significant feature of the Lagrangian-dual function φ is the piecewise smoothness, which is studied in this paper and employed in the analysis of the Moreau–Yosida regularization of φ. We investigate the semismoothness of the gradient g of the Moreau–Yosida regularization of φ, which plays a key role in the superlinear or quadratic convergence analysis of generalized Newton methods for solving nonsmooth equations. As to problem (1) with the linear objective function, we show that the Lagrangian-dual function φ is piecewise C^2 and the gradient g is piecewise smooth and thereby semismooth if the inequality constraints in (1) either are all affine or all possess positive definite Hessian matrices. An example with an affine constraint and a strictly convex constraint is constructed. We find that the Lagrangian-dual function of this problem is *not* piecewise C^2, and that the gradient g of its Moreau–Yosida regularization *is* still semismooth. However, whether or not g is semismooth for general mixed affine and strictly convex constraints is still left unanswered. We also investigate problem (1) with a convex objective function. We show with an example that φ may not be piecewise C^2 for the problem with a general convex objective function. For problem (1) with an objective function which possesses a positive definite Hessian, φ and g can again be shown to be piecewise C^2 and semismooth, respectively. We have also provided an alternative way to study the semismoothness/piecewise smoothness of g under the structure of the epigraph of the Lagrangian dual function using the projection operator. For problem (1) with a linear objective, we have also established an interesting result characterizing the relations between the original problem and the Fenchel conjugate of the regularization of the Lagrangian dual problem. For future research, we will examine under which conditions the projection mapping over the epigraph of the Lagrangian-dual function φ is piecewise smooth or semismooth.

Acknowledgment. We would like to thank the two anonymous referees for their constructive suggestions, which helped improve the presentation of this paper.

LINEAR REGULARITY FOR A COLLECTION OF SUBSMOOTH SETS IN BANACH SPACES*

XI YIN ZHENG† AND KUNG FU NG‡

Abstract. Using variational analysis, we study the linear regularity for a collection of finitely many closed sets. In particular, we extend duality characterizations of the linear regularity for a collection of finitely many closed convex sets to the possibly nonconvex setting. Moreover, the sharpest linear regularity constant can also be dually represented under the subsmoothness assumption.

Key words. approximate projection theorem, linear regularity, normal cone, subsmoothness

DOI. 10.1137/060659132

1. Introduction.

Linear regularity is a well-known notion in mathematical programming and approximation theory. In particular, it plays a key role in establishing a linear convergence rate of iterates generated by the cyclic projection algorithm for finding the projection from a point to the intersection of finitely many closed convex sets (see [3] and references therein).

In this paper, we study the linear regularity of a collection $\{A_1, \ldots, A_n\}$ of finitely many closed sets in a Banach space X. Here we say that the collection is locally linearly regular at $a \in \bigcap_{i=1}^n A_i$ (resp., linearly regular) if there exists $\tau \in (0, +\infty)$ such that

$$d\left(x, \bigcap_{i=1}^n A_i\right) \le \tau \sum_{i=1}^n d(x, A_i) \quad \text{for all } x \text{ close to } a \tag{1.1}$$

$$\left(\text{resp.,} \quad d\left(x, \bigcap_{i=1}^n A_i\right) \le \tau \sum_{i=1}^n d(x, A_i) \quad \text{for all } x \in X\right).$$

Linear regularity has been well studied by many authors in the case when each A_i is a closed convex set (see [2, 3, 4, 5, 18, 25] and references therein). In 1972, Jameson [12] established a dual characterization for the linear regularity of a collection of two closed convex cones. Pang [21] and Lewis and Pang [15] provided necessary conditions for the linear regularity of a collection of finitely many closed convex sets in terms of the normal cone. Afterwards, Bauschke, Borwein, and Li [4] established some sufficient conditions in the same line. Recently, it was proved (cf. [2, 20, 25]) that if $\{A_1, \ldots, A_n\}$ is a collection of closed convex sets in a Banach space X, then the following statements are equivalent:

(C1) $\{A_1, \ldots, A_n\}$ is linearly regular.
(C2) There exists $\tau \in (0, +\infty)$ such that

$$N\left(\bigcap_{i=1}^{n} A_i, x\right) \cap B_{X^*} \subset \tau \sum_{i=1}^{n} N(A_i, x) \cap B_{X^*} \quad \text{for all } x \in \bigcap_{i=1}^{n} A_i,$$

where X^* denotes the dual space of X and B_{X^*} denotes the closed unit ball of X^*.
(C3) There exists $\tau \in (0, +\infty)$ such that for any $x \in \bigcap_{i=1}^{n} A_i$,

$$\text{(SC)} \qquad N\left(\bigcap_{i=1}^{n} A_i, x\right) = \sum_{i=1}^{n} N(A_i, x)$$

and

$$\inf\left\{\sum_{i=1}^{n} \|x_i^*\| : \ x_i^* \in N(A_i, x) \text{ and } x^* = \sum_{i=1}^{n} x_i^*\right\} \le \tau \|x^*\| \quad \forall x^* \in N\left(\bigcap_{i=1}^{n} A_i, x\right).$$

In the terminology of Deutsch, Li, and Ward [11], (SC) means that the collection has the strong conical hull intersection property (strong CHIP) at x, which has been extensively studied in variational analysis (cf. [4, 5, 10, 11, 16]).

In this paper, we will study the nonconvex case. In view of the fact that a collection $\{A_1, \ldots, A_n\}$ of closed convex sets is linearly regular with a constant τ if and only if $\{A_1, \ldots, A_n\}$ is locally linearly regular at each $a \in \mathrm{bd}(\bigcap_{i=1}^{n} A_i)$ with the same constant, it is natural to adopt the local version when one considers a collection of closed sets. While the equivalences among (C1), (C2), and (C3) are no longer valid if one drops the convexity assumption of some A_i, a natural substitute of convexity in this respect is the subsmoothness, a notion recently introduced and studied by Aussel, Daniilidis, and Thibault [1], which is a generalization of the well-known notion of the prox-regularity (cf. [6, 7, 9, 23, 24] and references therein).

In section 2, we recall some notions in variational analysis and provide some properties of the subsmoothness. In section 3, as an application of the Ekeland variational principle, we provide a kind of approximate projection result for a closed set, which is very useful for our analysis. In section 4, in terms of the subsmoothness and the approximate projection result, we establish sufficient and/or necessary conditions for the local linear regularity of a collection of finitely many subsmooth sets, and extend the equivalences among (C1), (C2), and (C3) to the nonconvex case. Moreover, the constants τ satisfying (1.1) are represented quantitatively by duality formulas.

2. Subsmoothness of a closed set. First we provide some notions in variational analysis. For a closed subset A of a Banach space X and $a \in A$, let $T_c(A, a)$ and $T(A, a)$ denote respectively the Clarke tangent cone and the contingent cone of A at a, which are respectively defined by

$$T_c(A, a) = \liminf_{x \xrightarrow{A} a, t \to 0^+} \frac{A - x}{t} \quad \text{and} \quad T(A, a) = \limsup_{t \to 0^+} \frac{A - a}{t},$$

where $x \xrightarrow{A} a$ means that $x \to a$ with $x \in A$. Thus, $v \in T_c(A, a)$ if and only if, for each sequence $\{a_n\}$ in A converging to a and each sequence $\{t_n\}$ in $(0, \infty)$ decreasing to 0, there exists a sequence $\{v_n\}$ in X converging to v such that $a_n + t_n v_n \in A$ for all n, while $v \in T(A, a)$ if and only if there exist a sequence $\{v_n\}$ converging to v and a sequence $\{t_n\}$ in $(0, \infty)$ decreasing to 0 such that $a + t_n v_n \in A$ for all n.

We denote by $N_c(A,a)$ the Clarke normal cone of A at a, that is,

$$N_c(A,a) := \{x^* \in X^* : \ \langle x^*, h\rangle \le 0 \ \text{ for all } h \in T_c(A,a)\}.$$

For $\varepsilon \ge 0$ and $a \in A$, the nonempty set

$$\hat{N}_\varepsilon(A,a) := \left\{ x^* \in X^* : \ \limsup_{x \xrightarrow{A} a} \frac{\langle x^*, x-a\rangle}{\|x-a\|} \le \varepsilon \right\}$$

is called the set of Fréchet ε-normals of A at a. When $\varepsilon = 0$, $\hat{N}_\varepsilon(A,a)$ is a convex cone which is called the Fréchet normal cone of A at a and is denoted by $\hat{N}(A,a)$.

Let $N(A,a)$ denote the limiting normal cone of A at a, that is,

$$N(A,a) = \limsup_{x \xrightarrow{A} a, \varepsilon \to 0^+} \hat{N}_\varepsilon(A,x).$$

Thus, $x^* \in N(A,a)$ if and only if there exists a sequence $\{(x_n, \varepsilon_n, x_n^*)\}$ in $A \times R_+ \times X^*$ such that $(x_n, \varepsilon_n) \to (a,0)$, $x_n^* \overset{w^*}{\to} x^*$, and $x_n^* \in \hat{N}_{\varepsilon_n}(A, x_n)$ for each n. It is known that

$$\hat{N}(A,a) \subset N(A,a) \subset N_c(A,a)$$

(cf. [17] and [18]).

If A is convex, then $T_c(A,a) = T(A,a)$ and

$$N_c(A,a) = \hat{N}(A,a) = \{x^* \in X^* : \ \langle x^*, x\rangle \le \langle x^*, a\rangle \ \text{ for all } x \in A\}.$$

Recall that a Banach space X is called an Asplund space if every continuous convex function on X is Fréchet differentiable at each point of a dense subset of X. It is well known (cf. [22]) that X is an Asplund space if and only if every separable subspace of X has a separable dual space. In particular, every reflexive Banach space is an Asplund space. When X is an Asplund space, Mordukhovich and Shao [18] proved that

$$N_c(A,a) = \mathrm{cl}^*(\mathrm{co}(N(A,a))) \quad \text{and} \quad N(A,a) = \limsup_{x \xrightarrow{A} a} \hat{N}(A,x), \tag{2.1}$$

where $\mathrm{cl}^*(\cdot)$ denotes the closure with respect to the weak* topology w^*.

Recall that a closed set A in X is said to be prox-regular at $a \in A$ if there exist $\sigma, r > 0$ such that

$$\langle x^* - u^*, x - u\rangle \ge -\sigma \|x-u\|^2$$

whenever $x, u \in A \cap B(a,r)$, $x^* \in N_c(A,x) \cap B_{X^*}$, and $u^* \in N_c(A,u) \cap B_{X^*}$. Readers can find some interesting properties of the prox-regularity in [23] and [24].

As a generalization of the prox-regularity, Aussel, Daniilidis, and Thibault [1] introduced and studied the subsmoothness. A closed set A in X is said to be subsmooth at $a \in A$ if for any $\varepsilon > 0$ there exists $r > 0$ such that

$$\langle x^* - u^*, x - u\rangle \ge -\varepsilon \|x-u\| \tag{2.2}$$

whenever $x, u \in A \cap B(a,r)$, $x^* \in N_c(A,x) \cap B_{X^*}$, and $u^* \in N_c(A,u) \cap B_{X^*}$.

Taking $x^* = 0$, (2.2) reduces to $\langle u^*, x-u\rangle \le \varepsilon\|x-u\|$. On the other hand, noting that $\langle x^*-u^*, x-u\rangle \ge -2\varepsilon\|x-u\|$ if $\langle x^*, u-x\rangle \le \varepsilon\|x-u\|$ and $\langle u^*, x-u\rangle \le \varepsilon\|x-u\|$, it follows that A is subsmooth at $a \in A$ if and only if for any $\varepsilon > 0$ there exists $r > 0$ such that

$$\langle u^*, x-u\rangle \le \varepsilon\|x-u\| \quad \text{for all } x \in A \cap B(u,r) \tag{2.3}$$

whenever $u \in A \cap B(a,r)$ and $u^* \in N_c(A,u) \cap B_{X^*}$. Thus, for any $\varepsilon > 0$ there exists $r > 0$ such that

$$N_c(A,u) \subset \hat{N}_\varepsilon(A,u) \quad \text{for all } u \in A \cap B(a,r),$$

provided that A is subsmooth at a. Hence

$$\text{subsmoothness of } A \text{ at } a \Longrightarrow N_c(A,a) = \hat{N}(A,a). \tag{2.4}$$

Usually, A is said to be Clarke regular at a if $N_c(A,a) = \hat{N}(A,a)$.

It is known (cf. [17, Corollary 1.96]) that $\hat{N}(A,u) \cap B_{X^*} = \hat{\partial} d(\cdot, A)(u)$ for $u \in A$, where $\hat{\partial}$ denotes the Fréchet subdifferential. Hence $x^* \in \hat{N}(A,u) \cap B_{X^*}$ if and only if for any $\varepsilon > 0$ there exists $r > 0$ such that

$$\langle x^*, x-u\rangle \le d(x,A) + \varepsilon\|x-u\| \quad \text{for all } x \in B(u,r). \tag{2.5}$$

The following proposition shows that a strengthened condition similar to (2.5) provides a characterization of the subsmoothness.

PROPOSITION 2.1. *Let A be a closed subset of X. Then A is subsmooth at $a \in A$ if and only if for any $\varepsilon > 0$ there exists $r > 0$ such that*

$$\langle u^*, x-u\rangle \le d(x,A) + \varepsilon\|x-u\| \quad \text{for all } x \in B(a,r) \tag{2.6}$$

whenever $u \in A \cap B(a,r)$ and $u^* \in N_c(A,u) \cap B_{X^*}$.

Proof. Since $d(x,A) = 0$ for all $x \in A$, (2.6) implies (2.3). Hence, the sufficiency part holds. Conversely, suppose that A is subsmooth at $a \in A$. Let $\varepsilon > 0$ and take $r > 0$ such that

$$\langle u^*, z-u\rangle \le \frac{\varepsilon}{2}\|z-u\| \quad \text{for all } z \in A \cap B(a,2r) \tag{2.7}$$

whenever $u \in A \cap B(a,r)$ and $u^* \in N_c(A,u) \cap B_{X^*}$. Let $x \in B(a,r)$, $u \in A \cap B(a,r)$, and $u^* \in N_c(A,u) \cap B_{X^*}$. Then $d(x,A) \le \|x-a\| < r$. Thus, there exists a sequence $\{u_n\}$ in $A \cap B(x,r)$ such that $\|x-u_n\| \to d(x,A)$. Hence $\|u_n - a\| \le \|u_n - x\| + \|x-a\| < 2r$. It follows from (2.7) that

$$\begin{aligned}\langle u^*, x-u\rangle &= \langle u^*, x-u_n\rangle + \langle u^*, u_n-u\rangle \\ &\le \|x-u_n\| + \frac{\varepsilon}{2}\|u_n-u\| \\ &\le \|x-u_n\| + \frac{\varepsilon}{2}(\|u_n-x\| + \|x-u\|).\end{aligned}$$

Letting $n \to \infty$, one has

$$\langle u^*, x-u\rangle \le d(x,A) + \frac{\varepsilon}{2}(d(x,A) + \|x-u\|) \le d(x,A) + \varepsilon\|x-u\|.$$

This shows that the necessity part holds. The proof is completed. ∎

PROPOSITION 2.2. *Let X, Y be Banach spaces, Ω be a closed convex subset of Y, and $g : X \to Y$ be a continuously differentiable function. Let $a \in g^{-1}(\Omega)$ and suppose that $g'(a)$ is surjective, where $g'(a)$ denotes the derivative of g at a. Then there exists a neighborhood U of a such that $g^{-1}(\Omega)$ is subsmooth at each point of $g^{-1}(\Omega) \cap U$.*

Proof. Since $g'(a)$ is surjective, there exists $l > 0$ such that $2lB_Y \subset g'(a)(B_X)$. Since $x \mapsto g'(x)$ is continuous, it follows that there exists $r > 0$ such that

$$lB_Y \subset g'(x)(B_X) \quad \text{for all } x \in B(a, r). \tag{2.8}$$

We first establish the following inclusion:

$$N_c(g^{-1}(\Omega), u) \subset g'(u)^*(N(\Omega, g(u))) \quad \text{for all } u \in g^{-1}(\Omega) \cap B(a, r). \tag{2.9}$$

Suppose to the contrary that there exists $u \in g^{-1}(\Omega) \cap B(a, r)$ such that

$$x^* \in N_c(g^{-1}(\Omega), u) \setminus g'(u)^*(N(\Omega, g(u))). \tag{2.10}$$

Since the adjoint operator $g'(u)^*$ is weak*-weak* continuous and $g'(u)$ is surjective (by (2.8)), $g'(u)^*(N(\Omega, g(u))) \cap B_{X^*}$ is weakly* closed. This and the Krein–Smulian theorem imply that $g'(u)^*(N(\Omega, g(u)))$ is weakly* closed. By (2.10) and the separation theorem, there exists $h_0 \in X$ such that

$$\begin{aligned} \langle x^*, h_0\rangle &> \sup\{\langle g'(u)^*(y^*), h_0\rangle : \ y^* \in N(\Omega, g(u))\} \\ &= \sup\{\langle y^*, g'(u)(h_0)\rangle : \ y^* \in N(\Omega, g(u))\}. \end{aligned}$$

It follows from the convexity of Ω that $\langle x^*, h_0\rangle > 0$ and $g'(u)(h_0) \in T_c(\Omega, g(u))$. Take an arbitrary sequence $\{x_n\}$ in $g^{-1}(\Omega)$ converging to u, and an arbitrary sequence $\{t_n\}$ in $(0, +\infty)$ decreasing to 0. Then $g(x_n) \overset{\Omega}{\to} g(u)$, and hence there exists a sequence $y_n \to g'(u)(h_0)$ such that $g(x_n) + t_n y_n \in \Omega$ for all n. Since g is continuously differentiable, (2.8) and the Lyusternik–Graves theorem (cf. [20, Theorem 1.57]) imply that

$$d(x_n + t_n h_0, g^{-1}(g(x_n) + t_n y_n)) \le L\|g(x_n + t_n h_0) - g(x_n) - t_n y_n\| \tag{2.11}$$

for some $L \in (0, +\infty)$ and all n large enough. Noting that

$$g(x_n + t_n h_0) - g(x_n) = g'(u)(t_n h_0) + o(t_n),$$

it follows that for each n large enough there exists $\tilde{x}_n \in X$ such that

$$\tilde{x}_n \in g^{-1}(g(x_n) + t_n y_n) \subset g^{-1}(\Omega)$$

and

$$\|x_n + t_n h_0 - \tilde{x}_n\| \le 2L(t_n\|g'(u)(h_0) - y_n\| + \|o(t_n)\|).$$

This and $y_n \to g'(u)(h_0)$ imply that $h_n := \frac{\tilde{x}_n - x_n}{t_n} \to h_0$ and $x_n + t_n h_n = \tilde{x}_n \in g^{-1}(\Omega)$. This shows that $h_0 \in T_c(g^{-1}(\Omega), u)$, which is not possible because $x^* \in N_c(g^{-1}(\Omega), u)$ and $\langle x^*, h_0\rangle > 0$. This shows that (2.9) holds. Let $z \in g^{-1}(\Omega) \cap B(a, \frac{r}{2})$ and $\varepsilon > 0$. Then there exists $\delta \in (0, \frac{r}{2})$ such that

$$\|g'(u_1) - g'(u_2)\| < \frac{l\varepsilon}{2} \quad \text{for any } u_1, u_2 \in B(z, 2\delta). \tag{2.12}$$

Let $u \in g^{-1}(\Omega) \cap B(z,\delta)$ and $u^* \in N_c(g^{-1}(\Omega),u) \cap B_{X^*}$. Then, by (2.9), there exists $y^* \in N(\Omega, g(u))$ such that $u^* = (g'(u))^*(y^*)$. Take $y \in B_Y$ such that $\|y^*\| \le 2\langle y^*, y\rangle$. By (2.8), there exists $v \in B_X$ such that $ly = g'(u)(v)$. Hence,

$$l\|y^*\| \le 2\langle y^*, g'(u)(v)\rangle = 2\langle u^*, v\rangle \le 2.$$

By the convexity of Ω, one has

$$\langle y^*, g(x) - g(u)\rangle \le 0 \quad \text{for all } x \in g^{-1}(\Omega).$$

Noting that

$$\langle u^*, x-u\rangle = \langle (g'(u))^*(y^*), x-u\rangle = \langle y^*, g'(u)(x-u)\rangle,$$

it follows that for any $x \in g^{-1}(\Omega) \cap B(u,\delta)$,

$$\begin{aligned}\langle u^*, x-u\rangle &\le \langle y^*, g'(u)(x-u) - (g(x)-g(u))\rangle \\ &\le \frac{2}{l}\|g(x)-g(u)-g'(u)(x-u)\| \\ &\le \frac{2}{l}\|g'(u+\theta(x-u))-g'(u)\|\|x-u\|,\end{aligned}$$

where $\theta \in (0,\ 1)$. Since $\|u+\theta(x-u)-z\| \le \|u-z\| + \theta\|x-u\| < 2\delta$, it follows from (2.12) that

$$\langle u^*, x-u\rangle \le \varepsilon\|x-u\| \quad \text{for any } x \in g^{-1}(\Omega) \cap B(z,\delta).$$

Therefore, $g^{-1}(\Omega)$ is subsmooth at z. The proof is complete. □

We don't know whether Proposition 2.2 holds if the continuous differentiability of g on X is weakened to the strict differentiability of g at a.

The following Proposition 2.3 demonstrates an interesting fact that, in an Asplund space, the subsmoothness on an open subset of A can be described in terms of the Fréchet normal cone (rather than the Clarke normal cone). To do this, we need the following lemma.

LEMMA 2.1. *Let A be a closed subset of X and $a \in A$. Suppose that for any $\varepsilon > 0$ there exists $r > 0$ such that*

$$\langle u^*, x-a\rangle \le \varepsilon\|x-a\| \ \text{ for all } x \in A \cap B(a,r), \ \text{ for all } u^* \in \hat{N}(A,a) \cap B_{X^*}. \tag{2.13}$$

Then $\hat{N}(A,a)$ is weak closed.*

Proof. Let ε be an arbitrary number in $(0,\ +\infty)$ and take $r > 0$ such that (2.13) holds. Since $\hat{N}(A,a)$ is convex, by the Krein–Smulian theorem it suffices to show that $\hat{N}(A,a) \cap B_{X^*}$ is weakly* closed. Let $\{u_j^*\}$ be a net in $\hat{N}(A,a) \cap B_{X^*}$ convergent to $x^* \in X^*$ with respect to the weak* topology. Then, $x^* \in B_{X^*}$ (because B_{X^*} is weakly* closed) and $\langle u_j^*, x\rangle \to \langle x^*, x\rangle$ for all $x \in X$. It follows from (2.13) that $\langle x^*, x-a\rangle \le \varepsilon\|x-a\|$ for all $x \in A \cap B(a,r)$. This and the arbitrariness of ε imply that $x^* \in \hat{N}(A,a)$. Hence $x^* \in \hat{N}(A,a) \cap B_{X^*}$. This shows that $\hat{N}(A,a) \cap B_{X^*}$ is weakly* closed. The proof is complete. □

PROPOSITION 2.3. *Let A be a closed subset of X, and U be an open subset of X. Suppose that X is an Asplund space. Then A is subsmooth at each point of $A \cap U$ if and only if for any $z \in A \cap U$ and $\varepsilon > 0$ there exists $r > 0$ such that* (2.3) *holds whenever $u \in \mathrm{bd}(A) \cap B(z,r)$ and $u^* \in \hat{N}(A,u) \cap B_{X^*}$.*

Proof. Since $\hat{N}(A,x) \subset N_c(A,x)$ for all $x \in A$, the necessity part is clear. For the sufficiency part, we need only show that $N_c(A,z) = \hat{N}(A,z)$ for any $z \in A \cap U$. Let $z \in A \cap U$ and $z^* \in N(A,z)$. Since X is an Asplund space, there exists a sequence $\{(u_n, u_n^*)\}$ in $X \times X^*$ such that

$$u_n \xrightarrow{A} z, \quad u_n^* \xrightarrow{w^*} z^*, \quad \text{and} \quad u_n^* \in \hat{N}(A,u_n).$$

Hence, there exists $M \in (0,\ +\infty)$ such that each $\|u_n^*\| < M$. For any $\varepsilon > 0$, take $r > 0$ such that (2.3) holds for any $u \in B(z,r) \cap \mathrm{bd}(A)$ and $u^* \in \hat{N}(A,u) \cap B_{X^*}$. Without loss of generality, we assume that $u_n \in B(z,r)$ for all n. It follows from (2.3) that

$$\left\langle \frac{u_n^*}{M}, x - u_n \right\rangle \le \varepsilon \|x - u_n\| \quad \text{for all } x \in B(u_n,r) \cap A.$$

Letting $n \to \infty$, one has

$$\left\langle \frac{z^*}{M}, x - z \right\rangle \le \varepsilon \|x - z\| \quad \text{for all } x \in B(z,r) \cap A.$$

This implies that $\limsup_{x \xrightarrow{A} z} \frac{\langle z^*, x-z\rangle}{\|x-z\|} \le 0$, and so $z^* \in \hat{N}(A,z)$. Hence, $N(A,z) \subset \hat{N}(A,z)$. Since the converse inclusion automatically holds, $N(A,z) = \hat{N}(A,z)$. Since X is an Asplund space, it follows from (2.1) that $N_c(A,z) = \mathrm{cl}^*(\mathrm{co}(\hat{N}(A,z)))$. Noting that $\hat{N}(A,z)$ is a convex cone, this means that $N_c(A,z) = \mathrm{cl}^*(\hat{N}(A,z))$. It follows from Lemma 2.1 that $N_c(A,z) = \hat{N}(A,z)$. The proof is complete. □

A natural question is: Can the open set U in Proposition 2.3 be replaced by a singleton $\{a\}$ with $a \in A$? That is, is A subsmooth at a given point a of A if for any $\varepsilon > 0$ there exists $r > 0$ such that (2.3) holds whenever $u \in \mathrm{bd}(A) \cap B(a,r)$ and $u^* \in \hat{N}(A,u) \cap B_{X^*}$?

While we don't have the answer to this question, we can prove the following result similar to the proof of Proposition 2.3.

PROPOSITION 2.4. *Let X be an Asplund space, A be a closed subset of X, and $a \in A$. Then the following two statements are equivalent:*

(i) *For any $\varepsilon > 0$ there exists $r > 0$ such that* (2.3) *holds whenever $u \in A \cap B(a,r)$ and $u^* \in N(A,u) \cap B_{X^*}$.*

(ii) *For any $\varepsilon > 0$ there exists $r > 0$ such that* (2.3) *holds whenever $u \in A \cap B(a,r)$ and $u^* \in \hat{N}(A,u) \cap B_{X^*}$.*

Remark 2.1. Let X, A, and a be as in Proposition 2.4. Then A is Clarke regular at a when (ii) of Proposition 2.4 holds. Indeed, by Proposition 2.4, $N(A,a) = \hat{N}(A,a)$. It follows from (2.1) that

$$N_c(A,a) = \mathrm{cl}^*(\mathrm{co}(\hat{N}(A,a))) = \mathrm{cl}^*(\hat{N}(A,a)).$$

This and Lemma 2.1 show that A is Clarke regular at a.

3. Approximate projection theorem in Banach spaces. Using the Bronstead–Rockafellar theorem, it was proved in [19] that if A is a closed convex nonempty subset of a Banach space X and $x \in X \setminus A$, then for any $\gamma \in (0,\ 1)$ there exist $a \in \mathrm{bd}(A)$ and $a^* \in N(A,a)$ with $\|a^*\| = 1$ such that

$$\gamma \|x - a\| < \min\{d(x,A),\ \langle a^*, x - a\rangle\}. \tag{3.1}$$

By virtue of the well-known Ekeland variational principle, we provide below a nonconvex generalization of the above projection result, which will play a key role in the proofs of our main results in section 4.

THEOREM 3.1. *Let X be a Banach space (resp., Asplund space) and A be a closed nonempty subset of X. Let $\gamma \in (0,\ 1)$. Then for any $x \notin A$ there exist $a \in \mathrm{bd}(A)$ and $a^* \in N_c(A,a)$ (resp., $a^* \in \hat{N}(A,a)$) with $\|a^*\| = 1$ such that (3.1) holds.*

Proof. First suppose that X is an Asplund space. Let $x \in X\backslash A$. Then $d(x,A) > 0$. Let $\varepsilon \in (0,\ +\infty)$ be such that

$$\varepsilon < \frac{(1-\gamma^{\frac{1}{2}})d(x,A)}{4+(2+2\gamma^{\frac{1}{2}})d(x,A)}, \tag{3.2}$$

and take $z_0 \in A$ such that $\|z_0 - z\| < d(x,A) + \varepsilon$. Let $\phi(z) := \|z-x\| + \delta_A(z)$ for all $z \in X$. Then ϕ is a proper lower semicontinuous function and $\phi(z_0) < \inf_{z\in X}\phi(z) + \varepsilon$. By the Ekeland variational principle, there exists $\bar{z} \in A$ such that $\phi(\bar{z}) \le \phi(z_0)$ and $\phi(\bar{z}) \le \phi(z) + \varepsilon\|z-\bar{z}\|$ for all $z \in X$. Hence

$$\|\bar{z} - x\| < d(x,A) + \varepsilon, \tag{3.3}$$

and the continuous convex function $f(z) := \|z-x\| + \varepsilon\|z-\bar{z}\|$ attains its global minimum over A at $\bar{z}$. Noting that $\varepsilon < d(x,A)$, it follows from [17, Theorem 2.33] that there exist $z_1, a \in B(\bar{z},\varepsilon)$ such that

$$z_1 \neq x, \quad a \in A, \quad \text{and} \quad 0 \in \partial f(z_1) + \hat{N}(A,a) + \varepsilon B_{X^*},$$

where ∂ denotes the subdifferential in the sense of convex analysis. Hence there exist $z_1^*, z_2^* \in X^*$ such that

$$\|z_1^*\| = 1, \quad \|z_2^*\| < 2\varepsilon, \quad \langle z_1^*, z_1 - x\rangle = \|z_1 - x\|, \quad \text{and} \quad -z_1^* + z_2^* \in \hat{N}(A,a).$$

It follows from (3.3) that $\|x-a\| < d(x,A) + 2\varepsilon$. This and (3.2) imply that

$$\gamma^{\frac{1}{2}}\|x-a\| < d(x,A). \tag{3.4}$$

Let $a^* := \frac{-z_1^*+z_2^*}{\|-z_1^*+z_2^*\|}$. Then, $a^* \in \hat{N}(A,a)$ and so $a \in \mathrm{bd}(A)$. Note that

$$\begin{aligned}
\langle a^*, x-a\rangle &= \frac{\langle z_1^*, z_1 - x\rangle + \langle z_1^*, a - z_1\rangle + \langle z_2^*, x-a\rangle}{\|-z_1^*+z_2^*\|} \\
&\ge \frac{\|z_1-x\| - 2\varepsilon - 2\varepsilon\|x-a\|}{1+2\varepsilon} \\
&\ge \frac{(1-2\varepsilon)\|x-a\| - 4\varepsilon}{1+2\varepsilon} \\
&\ge \frac{(1-2\varepsilon)d(x,A) - 4\varepsilon}{1+2\varepsilon}.
\end{aligned}$$

This and (3.2) imply that $\gamma^{\frac{1}{2}}d(x,A) < \langle a^*, x-a\rangle$. It follows from (3.4) and $\gamma \in (0,\ 1)$ that (3.1) holds. When X is a general Banach space, the conclusion can be similarly proved (with [8, Corollary, p. 52] replacing [17, Theorem 2.33]). The proof is complete. □

Remark 3.1. When X is a general Banach space, the Clarke normal cone in Theorem 3.1 cannot be replaced by the Fréchet normal cone. Indeed, take X to be

a non-Asplund space (e.g., let $X := l_1$). Then, by [17, Corollary 2.21], there exists a proper closed nonempty subset A of X such that $\hat{N}(A,a) = \{0\}$ for any $a \in \mathrm{bd}(A)$. It follows that for any $x \in X \setminus A$ there does not exist $a \in \mathrm{bd}(A)$ and $a^* \in \hat{N}(A,a)$ with $\|a^*\| = 1$ such that (3.1) holds.

Remark 3.2. In general, in Theorem 3.1 one cannot take $\gamma = 1$ even when A is a closed convex set. For example, let X be a nonreflexive Banach space. Then, by the James theorem there exists $x^* \in X^*$ with $\|x^*\| = 1$ such that

$$\langle x^*, z\rangle < 1 \quad \text{for all } z \in B_X. \tag{3.5}$$

Let $A := \{x \in X : \langle x^*, x\rangle \le 1\}$. We claim that $\langle a^*, x-a\rangle < \|x-a\|$ for any $x \in X\setminus A$, any $a \in A$, and any $a^* \in N(A,a)$ with $\|a^*\| = 1$. Indeed, suppose to the contrary that there exist $x_0 \in X \setminus A$, $a_0 \in A$, and $a_0^* \in N(A,a_0)$ with $\|a_0^*\| = 1$ such that $\langle a_0^*, x_0 - a_0\rangle = \|x_0 - a_0\|$. Then $a_0 \in \mathrm{bd}(A)$; that is, $\langle x^*, a_0\rangle = 1$. By the definition of A, it is clear that $N(A,a_0) = R_+x^*$ and so $a_0^* = x^*$. Hence $\langle x^*, \frac{x_0-a_0}{\|x_0-a_0\|}\rangle = 1$, contradicting (3.5).

4. Main results. In this section, we establish some relationships concerning the local linear regularity of a collection of closed sets in a Banach space. The following proposition, which can be proved by Theorem 3.1 and convex analysis techniques, provides a relationship between the local linear regularity and the linear regularity for a collection of finitely many closed convex sets.

PROPOSITION 4.1. *Let X be a Banach space and $C_1, \ldots, C_n$ be closed convex subsets of X such that $\bigcap_{i=1}^n C_i \neq \emptyset$. Then $\{C_1, \ldots, C_n\}$ is linearly regular if and only if there exists $\tau \in (0, +\infty)$ such that $\{C_1, \ldots, C_n\}$ is locally linearly regular at each point of $\mathrm{bd}(\bigcap_{i=1}^n C_i)$ with the same constant τ.*

In view of Proposition 4.1, we see that it is pertinent to study the local linear regularity for a collection of nonconvex closed sets. For convenience, let us fix some notation. Let $\{A_1, \ldots, A_n\}$ be a collection of closed sets in a Banach space X with intersection A containing a:

$$a \in A := \bigcap_{i=1}^n A_i.$$

The modulus of the linear regularity of the collection $\{A_1, \ldots, A_n\}$ at a is denoted by $\eta(A;a)$ and defined by

$$\eta(A;a) := \inf\{\tau > 0 : \ (1.1) \text{ holds}\}.$$

Thus, $\eta(A;a) < +\infty$ if and only if $\{A_1, \ldots, A_n\}$ is locally linearly regular at a.

We will provide necessary and/or sufficient conditions for the local linear regularity and establish formulas for the modulus $\eta(A;a)$. Let $\tau, \delta \in (0, +\infty)$. For convenience of presenting our results, we list the following inclusions:

$$\hat{N}(A,u) \cap B_{X^*} \subset \tau \sum_{i=1}^n N_c(A_i,u) \cap B_{X^*} \quad \text{for all } u \in A \cap B(a,\delta), \tag{4.1}$$

$$N_c(A,u) \cap B_{X^*} \subset \tau \sum_{i=1}^n N_c(A_i,u) \cap B_{X^*} \quad \text{for all } u \in A \cap B(a,\delta). \tag{4.2}$$

In terms of these two inclusions, we define the following quantities:

$$\beta_c^f(\delta) := \inf\{\tau > 0 : \ (4.1) \text{ holds}\} \quad \text{and} \quad \beta_c(\delta) := \inf\{\tau > 0 : \ (4.2) \text{ holds}\}.$$

THEOREM 4.1. *Let X be a Banach space. Then*

$$\lim_{\delta\to 0^+} \beta_c^f(\delta) \le \eta(A;a). \tag{4.3}$$

If each A_i is subsmooth at a, then

$$\lim_{\delta\to 0^+} \beta_c(\delta) \ge \eta(A;a). \tag{4.4}$$

Consequently, if each A_i is subsmooth at a and if A is Clarke regular at all its points close to a, then

$$\eta(A;a) = \lim_{\delta\to 0^+} \beta_c^f(\delta). \tag{4.5}$$

Proof. If $\eta(A;a) = +\infty$, then (4.3) holds trivially. Next assume that $\eta(A;a) < \infty$. Let $\tau \in (\eta(A;a),\ +\infty)$. Then there exists $\delta_0 > 0$ such that

$$d(x,A) \le \tau \sum_{i=1}^n d(x,A_i) \quad \text{for all } x \in B(a,\delta_0). \tag{4.6}$$

Let $u \in A \cap B(a, \frac{\delta_0}{2})$ and $x^* \in \hat{N}(A,u) \cap B_{X^*}$. Let k be an arbitrary natural number. Then there exists $r \in (0,\ \frac{\delta_0}{2})$ such that (2.5) holds with $\varepsilon = \frac{1}{k}$. Noting that $B(u,r) \subset B(a,\delta_0)$, it follows from (4.6) that

$$\langle x^*, x-u\rangle \le \tau \sum_{i=1}^n d(x,A_i) + \frac{1}{k}\|x-u\| \quad \text{for all } x \in B(u,r).$$

This and [8, Proposition 2.3.3] imply that there exist $u_{k,i}^* \in X^*$ and $x_k^* \in \frac{1}{k}B_{X^*}$ $(i = 1,\dots,n)$ such that

$$u_{k,i}^* \in \partial_c d(\cdot,A_i)(u) \subset N_c(A_i,u) \cap B_{X^*} \quad \text{and} \quad x^* = \tau \sum_{i=1}^n u_{k,i}^* - x_k^*,$$

where ∂_c denotes the Clarke subdifferential. Since B_{X^*} is weakly* compact and $N_c(A,x)$ is weakly* closed, without loss of generality (consider generalized subsequences if necessary) we assume that $u_{k,i}^* \xrightarrow{w^*} u_i^* \in N_c(A_i,u) \cap B_{X^*}$ as $k \to \infty$. Hence

$$x^* = \tau \sum_{i=1}^n u_i^* \in \tau \sum_{i=1}^n N_c(A_i,u) \cap B_{X^*}.$$

This shows that (4.1) holds for any $\delta \in (0,\ \frac{\delta_0}{2})$, and so $\lim_{\delta\to 0^+} \beta_c^f(\delta) \le \tau$. Letting $\tau \to \eta(A;a)$, it follows that (4.3) holds.

Now suppose that each A_i is subsmooth at a. Since (4.4) holds trivially if $\lim_{\delta\to 0^+} \beta_c(\delta) = +\infty$, we assume that $\lim_{\delta\to 0^+} \beta_c(\delta) < +\infty$. Let τ be an arbitrary number in $(\lim_{\delta\to 0^+} \beta_c(\delta),\ +\infty)$. Then there exists $\delta > 0$ such that (4.2) holds. Consider any $\varepsilon \in (0,\ \frac{1}{2})$ with $\tau\varepsilon < 1$. By Proposition 2.1 there exists $\delta_1 \in (0,\ \delta)$ such that

$$\langle x_i^*, x-a_i\rangle \le d(x,A_i) + \frac{\varepsilon}{n}\|x-a_i\| \quad \text{for all } x \in B(a,\delta_1) \tag{4.7}$$

whenever $a_i \in A_i \cap B(a, \delta_1)$, $x_i^* \in N_c(A_i, a_i) \cap B_{X^*}$, and $i = 1, \ldots, n$. Let $r := \frac{\delta_1}{2}$ and $x \in B(a, r) \setminus A$. Then $d(x, A) \le \|x - a\| < r$. Let $\gamma \in (\max\{\frac{d(x,A)}{r}, \tau\varepsilon\}, 1)$. By Theorem 3.1, there exist $z \in \mathrm{bd}(A)$ and $x^* \in N_c(A, z)$ with $\|x^*\| = 1$ such that

$$\langle x^*, x - z\rangle \ge \gamma\|x - z\| \tag{4.8}$$

and $\gamma\|x - z\| \le d(x, A)$. Thus, $\|x - z\| \le \frac{d(x,A)}{\gamma} < r$. Hence

$$\|z - a\| \le \|z - x\| + \|x - a\| < 2r = \delta_1 < \delta.$$

It follows from (4.2) that there exists $x_i^* \in N_c(A_i, z) \cap B_{X^*}$ such that $x^* = \tau \sum_{i=1}^n x_i^*$. By (4.7), one has

$$\langle x^*, x - z\rangle = \tau \sum_{i=1}^n \langle x_i^*, x - z\rangle \le \tau \sum_{i=1}^n \left(d(x, A_i) + \frac{\varepsilon}{n}\|x - z\| \right).$$

This and (4.8) imply that $(\gamma - \tau\varepsilon)\|x - z\| \le \tau \sum_{i=1}^n d(x, A_i)$ and hence

$$d(x, A) \le \frac{\tau}{\gamma - \tau\varepsilon} \sum_{i=1}^n d(x, A_i)$$

(because $z \in A$). Therefore, $\eta(A; a) \le \frac{\tau}{\gamma - \tau\varepsilon}$. It follows that (4.4) holds by letting $\gamma \to 1^-$, $\varepsilon \to 0^+$, and $\tau \to \lim_{\delta \to 0^+} \beta_c(\delta)$. The last assertion of the theorem is obvious and this completes the proof. □

The following example shows that if the subsmoothness assumption is dropped in Theorem 4.1, then inequality (4.4) is not necessarily true even when X is finite dimensional.

Example 4.1. Let $X = R^2$, $A_1 = \{(s, t) \in R^2 : st \le 0\}$, and

$$A_2 = \{(s, t) \in R_+^2 : (s - 1)^2 + t^2 \le 1 \text{ and } s^2 + (t - 1)^2 \le 1\}.$$

By the definition of the Clarke tangent cone, it is easy to verify that $T_c(A_1, (0, 0)) = \{(0, 0)\}$. This means that $N_c(A_1, (0, 0)) = X^*$. Hence

$$N_c(A_1 \cap A_2, (0, 0)) \cap B_{X^*} \subset N_c(A_1, (0, 0)) \cap B_{X^*} + N_c(A_2, (0, 0)) \cap B_{X^*}.$$

On the other hand, for every natural number k, let $x_k = (\frac{1}{k}, (\frac{2}{k} - \frac{1}{k^2})^{\frac{1}{2}})$. Noting that $A_1 \cap A_2 = \{(0, 0)\}$, it is easy to verify that

$$d(x_k, A_1 \cap A_2) = \left(\frac{2}{k}\right)^{\frac{1}{2}}, \quad d(x_k, A_1) = \frac{1}{k} \quad \text{and} \quad d(x_k, A_2) = 0.$$

Hence, $\frac{d(x_k, A_1 \cap A_2)}{d(x_k, A_1) + d(x_k, A_2)} = (2k)^{\frac{1}{2}} \to +\infty$. This shows that $\{A_1, A_2\}$ is not locally linearly regular at $(0, 0)$.

The following proposition shows that the last assertion of Theorem 4.1 remains true even if the Clarke regularity assumption on the intersection A is dropped, provided that X is an Asplund space, but we don't know if this is also so for a general Banach space.

PROPOSITION 4.2. *Let X be an Asplund space and each A_i be subsmooth at a. Then* (4.5) *holds.*

Applying the Asplund space version of Theorem 3.1, by virtue of Theorem 4.1 together with the obvious modification of the proof of inequality (4.4), one can obtain the proof of Proposition 4.2.

The following result (together with Theorem 4.1) implies that, under the local linear regularity assumption, the subsmoothness and Clarke regularity of each A_i imply the subsmoothness and Clarke regularity of the intersection A.

PROPOSITION 4.3. *Let X be an Asplund space and $\lim_{\delta\to 0^+}\beta_c^f(\delta) < +\infty$. Suppose that each A_i is Clarke regular at all points of A close to a. Then A is Clarke regular at all points of A close to a. If, in addition, each A_i is subsmooth at a, then A is subsmooth at a.*

Proof. Take $\delta > 0$ such that each A_i is Clarke regular at each point of $A\cap B(a,\delta)$. Then

$$N_c(A_i,u) = \hat{N}(A_i,u) \quad \text{for all } u \in A\cap B(a,\delta). \tag{4.9}$$

Considering smaller δ if necessary, one can find $\tau \in (\lim_{\delta\to 0^+}\beta_c^f(\delta),\ +\infty)$ such that (4.1) holds. We claim that

$$N_c(A,u) = \hat{N}(A,u) \quad \text{for all } u \in A\cap B(a,\delta). \tag{4.10}$$

Let $u \in A\cap B(a,\delta)$ and $u^* \in N(A,u)$. By (2.1), there exists a sequence $\{(u_k,u_k^*)\}$ in $(A\cap B(a,\delta))\times X^*$ such that $u_k \to u$ and $u_k^* \overset{w^*}{\to} u^*$ with $u_k^* \in \hat{N}(A,u_k)$ for all k. It follows that $\{u_k^*\}$ is bounded. Without loss of generality, we assume that each $u_k^* \in B_{X^*}$ (if necessary, replace (u_k^*,u^*) by $(\gamma u_k^*,\gamma u^*)$ with small a constant $\gamma > 0$). By (4.1), there exist $u_k^*(i) \in N_c(A_i,u_k)\cap B_{X^*}$ such that $u_k^* = \tau\sum_{i=1}^n u_k^*(i)$. We can also assume that

$$u_k^*(i) \overset{w^*}{\to} u^*(i) \in N(A_i,u)\cap B_{X^*}, \quad i = 1,\dots,n \tag{4.11}$$

(passing to subsequences if necessary). Hence, $u^* = \tau\sum_{i=1}^n u^*(i)$. On the other hand, by the definition of the Fréchet normal cone it is easy to verify that

$$\sum_{i=1}^n \hat{N}(A_i,u) \subset \hat{N}(A,u) \quad \text{for all } u \in A. \tag{4.12}$$

It follows from (4.9) and (4.11) that $u^* \in \hat{N}(A,u)$. Therefore, $N(A,u) \subset \hat{N}(A,u)$, and so $N(A,u) = \hat{N}(A,u)$. Since $\hat{N}(A,u)$ is a convex cone, this and (2.1) imply that $N_c(A,u) = \mathrm{cl}^*(\hat{N}(A,u))$. Thus, to prove (4.10), it suffices to show that $\hat{N}(A,u)\cap B_{X^*}$ is weakly* closed (by the Krein–Smulian theorem). Let $\{x_\alpha^*\}$ be a net in $\hat{N}(A,u)\cap B_{X^*}$ convergent to $x^* \in X^*$ with respect to the weak* topology. Then $x^* \in B_{X^*}$ (because B_{X^*} is weakly* compact). By (4.1), there exist $x_\alpha^*(i) \in N_c(A_i,u)\cap B_{X^*}$ $(i = 1,\dots,n)$ such that $x_\alpha^* = \tau\sum_{i=1}^n x_\alpha^*(i)$. Since every Clarke normal cone $N_c(A_i,u)$ is weakly* closed, we can assume that $x_\alpha^*(i) \overset{w^*}{\to} x^*(i) \in N_c(A_i,u)\cap B_{X^*}$ (passing to a subnet if necessary). Hence $x^* = \tau\sum_{i=1}^n x^*(i)$. It follows from (4.9) and (4.12) that $x^* \in \hat{N}(A,u)\cap B_{X^*}$. This shows that $\hat{N}(A,u)\cap B_{X^*}$ is weakly* closed.

Next suppose that each A_i is subsmooth at a. Then, for any $\varepsilon > 0$ there exists $r \in (0,\ \delta)$ such that

$$\langle u^*, x-u\rangle \le \frac{\varepsilon\|x-u\|}{n\tau} \quad \text{for all } x \in A_i\cap B(u,r) \tag{4.13}$$

whenever $u \in A_i \cap B(a,r)$ and $u^* \in N_c(A_i,u) \cap B_{X^*}$. Let $u \in A \cap B(a,r)$ and $u^* \in N_c(A,u) \cap B_{X^*}$. Then, by $0 < r < \delta$, (4.1), and (4.10), there exists $u_i^* \in N_c(A_i,u) \cap B_{X^*}$ such that $u^* = \tau \sum_{i=1}^n u_i^*$. It follows from (4.13) that

$$\langle u^*, x-u\rangle = \tau \sum_{i=1}^n \langle u_i^*, x-u\rangle \le \varepsilon \|x-u\| \text{ for all } x \in A \cap B(u,r).$$

This shows that A is subsmooth at a. The proof is complete. □

We don't know whether Proposition 4.3 can be extended to the Banach space setting. The difficulty lies in the fact that the two equalities in (2.1) (which are essential in our present proof of the proposition) are no longer valid for a general Banach space.

In view of Proposition 4.1, the following corollary can be regarded as a nonconvex extension of the equivalences among (C1), (C2), and (C3) mentioned in section 1 (note that a closed convex set is Clarke regular and subsmooth at all its points).

COROLLARY 4.1. *Let $a \in A$ and consider the following statements:*

(i) $\{A_1,\dots,A_n\}$ *is locally linearly regular at a.*

(ii) *There exist $\tau,\delta \in (0,\ +\infty)$ such that* (4.1) *holds.*

(iii) *There exist $\tau,\delta \in (0,\ +\infty)$ such that* (4.2) *holds.*

(iv) *There exist $\tau,\delta \in (0,\ +\infty)$ such that for any $u \in A \cap B(a,\delta)$,*

$$(*)\quad \inf\left\{\sum_{i=1}^n \|x_i^*\| : \sum_{i=1}^n x_i^* = x^* \text{ and } x_i^* \in N(A_i,u)\right\} \le \tau\|x^*\| \quad \text{for all } x^* \in N(A,u).$$

Then, the following statements hold:

(1) (i)⇒(ii) *always holds.*

(2) (iii)⇒(i) *holds if each A_i is subsmooth at a.*

(3) (i)–(iv) *are equivalent if each A_i is subsmooth and A is Clarke regular at all points of A close to a.*

(4) (i)⇔(ii) *holds if each A_i is subsmooth at a and X is an Asplund space.*

Proof. By Theorem 4.1 and Proposition 4.2, we need only show that (iii) and (iv) are equivalent under the assumption in (3). By the subsmoothness and regularity assumptions, there exists $\delta_0 \in (0,\ +\infty)$ such that

$$(4.14)\ \hat{N}(A,u) = N_c(A,u) \text{ and } N(A_i,u) = N_c(A_i,u) \quad \text{for all } u \in A \cap B(a,\delta_0).$$

Suppose that there exist $\tau > 0$ and $\delta \in (0,\ \delta_0)$ such that (4.2) holds. Let $u \in A \cap B(a,\delta)$ and $x^* \in N(A,u) \setminus \{0\}$. Then, by (4.2) and (4.14), there exists $x_i^* \in N(A_i,u) \cap B_{X^*}$ such that $\frac{x^*}{\|x^*\|} = \tau \sum_{i=1}^n x_i^*$. Letting $z_i^* = \tau\|x^*\|x_i^*$, it follows that $z_i^* \in N(A_i,u)$, $x^* = \sum_{i=1}^n z_i^*$, and $\sum_{i=1}^n \|z_i^*\| \le n\tau\|x^*\|$. Hence,

$$\inf\left\{\sum_{i=1}^n \|x_i^*\| : \sum_{i=1}^n x_i^* = x^* \text{ and } x_i^* \in N(A_i,u)\right\} \le n\tau\|x^*\|.$$

This shows that (iii)⇒(iv) holds.

Conversely, suppose that there exist $\tau > 0$ and $\delta \in (0,\ \delta_0)$ such that $(*)$ holds for any $u \in A \cap B(a,\delta)$. Let $u \in A \cap B(a,\delta)$ and $x^* \in N_c(A,u) \cap B_{X^*}$. By $(*)$ and (4.14), for every natural number k there exist $x_i^*(k) \in N_c(A_i,u)$ such that

$$(4.15)\qquad x^* = \sum_{i=1}^n x_i^*(k) \quad \text{and} \quad \sum_{i=1}^n \|x_i^*(k)\| \le \left(\tau + \frac{1}{k}\right)\|x^*\| \le \tau + \frac{1}{k}.$$

Since $(\tau+1)B_{X^*}$ is weakly* compact and each $N(A_i,u)$ is weakly* closed, we can assume that $x_i^*(k) \overset{w^*}{\to} x_i^* \in N(A_i,u)$ as $k \to \infty$ (passing to a generalized subsequence if necessary). It follows from (4.15) that $x^* = \sum_{i=1}^n x_i^*$ and $\sum_{i=1}^n \|x_i^*\| \le \tau$ (because the dual norm of X^* is lower semicontinuous with respect to the weak* topology). Therefore, $x_i^* \in \tau(N_c(A_i,u) \cap B_{X^*})$ and $x^* \in \tau \sum_{i=1}^n N_c(A_i,u) \cap B_{X^*}$. Hence, (4.2) holds. This shows that (iv)⇒(iii) holds. The proof is complete. □

Under the assumption in (3) of Corollary 4.1, (4.2) implies that

$$N(A,u) = \sum_{i=1}^n N(A_i,u) \tag{SC}$$

for all $u \in A$ close to a. In the case when each A_i is convex, (SC) and $(*)$ mean that $\{A_1,\dots,A_n\}$ has strong conical hull intersection property (strong CHIP) at u and $\{N(A_1,u),\dots,N(A_n,u)\}$ has property (G), respectively. These two properties have been well studied in convex analysis (see [2, 4, 5, 11] and references therein).

The following corollary is immediate from Propositions 2.2 and 4.3, Theorem 4.1, and Corollary 4.1.

COROLLARY 4.2. *Let X,Y be Banach spaces and $f_i : X \to Y$ be a continuously differentiable function ($i = 1,\dots,n$). Let C_i be a closed convex subset of Y and $A_i := f_i^{-1}(C_i)$ ($i = 1,\dots,n$). Let $a \in A$, and suppose that each $f_i'(a)$ is surjective. Then the following statements hold:*

(1) (i)⇒(ii) *holds.*

(2) (iii) *implies any one of* (i)–(iv).

(3) *If X is an Asplund space, then* (i)—(iv) *are equivalent.*

Where (i)–(iv) *are as in Corollary* 4.1.

Recently, Kruger [13, 14] studied a different kind of regularity of $\{A_1,\dots,A_n\}$ at a defined by $0 < \lim_{\rho\to 0^+} \frac{1}{\rho} \sup\{r \ge 0 : \bigcap_{i=1}^n (A_i - a_i) \cap (a + \rho B_X) \ne \emptyset, \text{ for all } a_i \in rB_X\}$.

Acknowledgment. The authors wish to thank the referees for careful reading of the paper and many valuable comments, which helped to improve our presentation.

RELAXATION-BASED BOUNDS FOR SEMI-INFINITE PROGRAMS*

ALEXANDER MITSOS†, PANAYIOTIS LEMONIDIS†, CHA KUN LEE†, AND PAUL I. BARTON†‡

Abstract. Finite formulations are presented for the calculation of lower and upper bounds on the optimal solution value of semi-infinite programs (SIPs) involving smooth, potentially nonconvex objective function and constraints. The lower bounding problem is obtained by a formulation that combines the first- and second-order KKT necessary conditions of the lower-level problem with a discretization of the parameter set. The resulting mathematical program with equilibrium constraints (MPEC) is a relaxation of the original SIP and furnishes valid lower bounds. If the parameter set is subdivided, the optimal solution value of the lower bounding problem converges to the optimal solution value of the SIP. The upper bounding problem is based on convex and linear relaxations of the lower-level problem resulting in a restriction of the SIP. If the parameter set is subdivided, the constructed relaxations converge to the original lower-level program. The existence of SIP Slater points ensures convergence of the upper bounding problems to the optimal solution value of the SIP. Several alternatives for the upper bounding problem are presented and discussed. Numerical results are presented for a number of test problems from the literature.

1. Introduction.

Semi-infinite programs (SIPs) are optimization problems that involve a finite number of decision variables subject to an infinite number of constraints. We consider SIPs of the form

$$\begin{aligned} f^* = \min_{\mathbf{x}} \; & f(\mathbf{x}) \\ \text{s.t. } & g(\mathbf{x},\mathbf{p}) \leq 0 \quad \forall \mathbf{p} \in P \subset \mathbb{R}^{n_p}, \\ & \mathbf{x} \in X \subset \mathbb{R}^{n_x}, \end{aligned} \tag{1.1}$$

without any convexity/concavity assumptions and with $|P| \leq +\infty$. Regular inequality and equality constraints would not change anything significant in the proposed bounding methods and are only omitted for simplicity.

The infinite number of constraints of similar functional form that arise in SIP typically originate from design problems that impose either a constraint for any given point in time or for every point in a geometric region. SIPs are encountered in diverse scientific and engineering applications such as Chebyshev approximation, including the design of digital and FIR filters [24, 34], optimal control systems [38], neural networks [33], kinetic model reduction [11, 36], robust optimization [9], the design of water and air pollution control models [23], and the design of adaptive array processors [28].

Traditional algorithms for nonlinear SIPs can be categorized as either discretization or local-reduction methods [41]. In discretization approaches [14, 25, 37, 43, 49,

‡Corresponding author.

58] a sequence of subproblems is solved in which the objective function of (1.1) is minimized subject to a subset of the constraints indexed by the finite set $P_D \subset P$, which is generated from a uniform or adaptive grid on P. Under the assumptions that the resulting finite nonlinear programs (NLPs) are solved to global optimality, the discretization is exhaustive, and the cardinality of the set P_D tends to infinity, it can be shown that the accumulation points of discretization algorithms are global minima of the original SIP [14, 58]. In local reduction methods, a local solution of the SIP is also found by solving a sequence of finite NLPs. However, in contrast to discretization methods, the finite subset of constraints is not generated from a grid on the parameter set P, but rather from finding implicitly all the local maxima $\bar{\mathbf{p}}(\mathbf{x})$ of $g(\mathbf{x},\cdot)$ on P for each $\mathbf{x} \in X$. Under relatively strong assumptions on the problem structure, the set of local maxima is finite, and the SIP can, at least conceptually, be reduced to an equivalent finite problem. The accumulation points of local-reduction algorithms are local minima of the original SIP. Based on this reduction principle, a number of exact penalty and Lagrangian approaches have been suggested [16, 17, 39, 50]. Discretization and local-reduction-based methods generate approximations of local and global minima of nonconvex SIPs. On finite termination, these approximations are not guaranteed to be feasible points of the original SIP. For more thorough reviews of applications and algorithmic contributions in semi-infinite programming, the reader is referred to [23, 26, 40, 41, 55, 57].

An alternative to considering a finite subset of the constraints is to reformulate (1.1) as the following nonsmooth problem:

$$\begin{aligned} &\min_{\mathbf{x}\in X} f(\mathbf{x}) \\ &\text{s.t.} \quad g^U(\mathbf{x}) \equiv \max_{\mathbf{p}\in P} g(\mathbf{x},\mathbf{p}) \leq 0. \end{aligned} \tag{1.2}$$

The superscript U denotes the (exact) upper bound of $g(\mathbf{x},\cdot)$ on P. To determine feasibility of a candidate point $\bar{\mathbf{x}} \in X$, the *lower-level* or *inner problem* must be solved to global optimality,

$$g^U(\bar{\mathbf{x}}) = \max_{\mathbf{p}\in P} g(\bar{\mathbf{x}},\mathbf{p}). \tag{1.3}$$

Obviously, if $g^U(\bar{\mathbf{x}}) \leq 0$, then $\bar{\mathbf{x}}$ is feasible in (1.1); otherwise it is not. Recently, a method to generate guaranteed feasible points for SIP was proposed by Bhattacharjee and coworkers [12, 13]. Assuming that the host set X is compact and P is an interval, the functions f and $g(\cdot,\mathbf{p})$ are continuously differentiable on an open set containing X for all $\mathbf{p} \in P$, $g(\mathbf{x},\cdot)$ is continuous on P for all $\mathbf{x} \in X$, and there exist SIP Slater points arbitrarily close to all global minima, the method generates guaranteed feasible points and an ε-optimal estimate of the global solution of the SIP on finite termination. To generate these feasible points, interval arithmetic [32, 42] is used to construct an interval extension of the constraining function $g(\mathbf{x},\cdot)$ with respect to the parameter set P, i.e., an interval-valued function $G : X \to \mathbb{IR} : \mathbf{x} \mapsto [G^L(\mathbf{x}), G^U(\mathbf{x})]$ satisfying in particular

$$g^U(\mathbf{x}) \leq G^U(\mathbf{x}) \quad \forall \mathbf{x} \in X,$$

where $\mathbb{IR}$ is the set of all intervals in $\mathbb{R}$. For each $\mathbf{x} \in X$, $G^U(\mathbf{x})$ is a valid upper bound for $g^U(\mathbf{x})$ and thus a relaxation of the inner problem (1.3); see also section 3. Therefore, the following interval constrained reformulation (ICR) is a valid restriction

of (1.1):

$$\begin{aligned} &\min_{\mathbf{x}\in X} f(\mathbf{x}) \\ &\text{s.t.} \quad G^U(\mathbf{x}) \leq 0. \end{aligned}$$

Under subdivision of the parameter set P, it can be shown [12, 13] that $G^U(\mathbf{x})$ converges to $g^U(\mathbf{x})$, and therefore the ICR provides feasible points with objective function value arbitrarily close to the global solution value of the SIP.

In a work concurrent with this paper, Floudas and Stein [19] propose an alternative relaxation of (1.3) and thus a valid restriction of (1.1) furnishing feasible points. Their method relies on constructing a concave relaxation of the constraining function g on the parameter set P using the αBB method [4], replacing the resulting convex lower-level problem with its necessary and sufficient KKT conditions and solving the resulting mathematical program with equilibrium constraints (MPEC) with NCP functions.

In this paper we propose finite formulations that generate lower and upper bounds on the optimal objective value of (1.1). Generating upper and lower bounds is not only a necessary subproblem in algorithms such as the one by Bhattacharjee et al. [13] for the global solution of SIPs, but also a useful problem in its own right. Generating a feasible point and an associated upper bound to the optimal objective value of SIPs is, for instance, used in kinetic model reduction [36]. A lower bound can be used for a conservative estimate of the distance of the obtained upper bound from the optimal solution value.

For the lower bounding problem we use a combination of the first- and second-order KKT necessary conditions in conjunction with a discretization of the parameter set. For the upper bounding problem we extend the idea from [12, 13] of relaxing the lower-level problem (1.3) in order to restrict the outer problem and thus find guaranteed feasible points. For relaxation of the lower-level problem we employ convex and linear relaxation techniques. In section 2 we present definitions and assumptions needed in the subsequent sections. In section 3 we provide a brief introduction to interval methods and convex relaxation techniques and discuss restrictions and relaxations of SIPs. In section 4 we combine and extend ideas from the literature to create a KKT-based lower bounding problem that is formulated and solved as a mixed-integer nonlinear program (MINLP). In section 5 we introduce relaxation-based upper bounding problems that are formulated using either αBB or McCormick's techniques and solved using either a KKT-based (MPEC) or a linearization approach. In section 6 we provide numerical results for the proposed bounding formulations applied to literature examples and comment on their relative performance. Finally, in section 7 we provide conclusions and suggestions for future work in both semi-infinite and generalized semi-infinite programs (GSIP). GSIPs differ from SIPs in that the host set for $\mathbf{p}$ in the lower-level problem depends on $\mathbf{x}$; see, e.g., [47].

2. Definitions and assumptions. In this section we present the assumptions required for construction of the bounding problems proposed in what follows. Note that for the sake of simplicity we do not present the weakest assumptions possible.

ASSUMPTION 1 (host sets). *The host sets $X \subset \mathbb{R}^{n_x}$, $P \subset \mathbb{R}^{n_p}$ are Cartesian products of (compact) intervals; i.e., for all variables and parameters explicit bounds are known ($X = [\mathbf{x}^L, \mathbf{x}^U]$ and $P = [\mathbf{p}^L, \mathbf{p}^U]$).*

The set of vertices of P is denoted P_e. Based on Assumption 1,

$$P_e = \left\{ \mathbf{p} \in P : p_j \in \{p_j^L, p_j^U\},\ \forall j = 1, \ldots, n_p \right\},$$

and the cardinality of P_e is given by $|P_e| = 2^{n_p}$.

ASSUMPTION 2 (basic properties of functions). *The functions $f : X \to \mathbb{R}$ and $g : X \times P \to \mathbb{R}$ are twice continuously differentiable on some open set containing X and $X \times P$, respectively. Moreover, the constraint g is a factorable composite function* [30] *of univariate functions with known convex underestimating and overestimating functions.*

By $g_{p_j} : X \times P \to \mathbb{R}$ we denote the partial derivative of g with respect to p_j. Similarly by $g_{x_j} : X \times P \to \mathbb{R}$ we denote the partial derivative of g with respect to x_j. For nonsmooth relaxations we will make use of subgradients, as follows:

DEFINITION 2.1 (subgradient). *Let $Z \subset \mathbb{R}^{n_z}$ be a nonempty convex set and $h : Z \to \mathbb{R}$ be concave. A vector $\mathbf{d} \in Z$ is called a* subgradient *of h at $\bar{\mathbf{z}} \in Z$ if*

$$h(\mathbf{z}) \leq h(\bar{\mathbf{z}}) + \mathbf{d}^T(\mathbf{z} - \bar{\mathbf{z}}) \qquad \forall \mathbf{z} \in Z.$$

The definition for convex functions is analogous, with the direction of the inequality reversed. Existence of subgradients on the interior of Z is guaranteed, and for differentiable functions the unique subgradient is the gradient [10].

Noting that under Assumptions 1 and 2 the SIP (1.1) is equivalent to the nonsmooth problem (1.2), the following definition is motivated.

DEFINITION 2.2 (lower-level program). *For a fixed $\mathbf{x} \in X$ we denote*

$$\begin{aligned} &\max_{\mathbf{p}} g(\mathbf{x}, \mathbf{p}) \\ &s.t.\ \mathbf{p}^L \leq \mathbf{p} \leq \mathbf{p}^U \end{aligned} \tag{2.1}$$

the inner program *or* lower-level program *and $g^U(\mathbf{x})$ its optimal objective value.*

DEFINITION 2.3 (relaxation of functions). *Given a convex set $C \subset \mathbb{R}^{n_z}$ and a function $h : C \to \mathbb{R}$, a convex function $h^u : C \to \mathbb{R}$ is a* convex relaxation *(or* convex underestimator*) of h on C if*

$$h^u(\mathbf{z}) \leq h(\mathbf{z}) \quad \forall \mathbf{z} \in C,$$

and a concave function $h^o : C \to \mathbb{R}$ is a concave relaxation *(or* concave overestimator*) of h on C if*

$$h^o(\mathbf{z}) \geq h(\mathbf{z}) \quad \forall \mathbf{z} \in C.$$

The convex envelope $\bar{h}^u : C \to \mathbb{R}$ *of h on C is a convex relaxation of h on C such that for any convex relaxation h^u of h on C*

$$h^u(\mathbf{z}) \leq \bar{h}^u(\mathbf{z}) \quad \forall \mathbf{z} \in C.$$

Similarly, the concave envelope $\bar{h}^o : C \to \mathbb{R}$ *of h on C is a concave relaxation of h on C such that for any concave relaxation h^o of h on C*

$$\bar{h}^o(\mathbf{z}) \leq h^o(\mathbf{z}) \quad \forall \mathbf{z} \in C.$$

DEFINITION 2.4 (relaxation of programs). *Let $Z^D, Z^E \subset \mathbb{R}^{n_z}$, and consider the optimization problems*

$$\inf_{\mathbf{z} \in Z^D} f^D(\mathbf{z}) \quad \text{and} \quad \inf_{\mathbf{z} \in Z^E} f^E(\mathbf{z}).$$

If $Z^D \subset Z^E$ *and* $f^E(\mathbf{z}) \leq f^D(\mathbf{z})\ \forall \mathbf{z} \in Z^D$*, the optimization problem* $\inf_{\mathbf{z}\in Z^E} f^E(\mathbf{z})$ *is said to be a* relaxation *of* $\inf_{\mathbf{z}\in Z^D} f^D(\mathbf{z})$*. Similarly, the optimization problem* $\inf_{\mathbf{z}\in Z^D} f^D(\mathbf{z})$ *is said to be a* restriction *of* $\inf_{\mathbf{z}\in Z^E} f^E(\mathbf{z})$ [22].

A direct consequence of relaxations/restrictions is that for the programs in the above definition, $\inf_{\mathbf{z}\in Z^E} f^E(\mathbf{z}) \leq \inf_{\mathbf{z}\in Z^D} f^D(\mathbf{x})$. For maximization problems the above inequalities are reversed.

DEFINITION 2.5 (convex program). *The minimization problem* $\inf_{\mathbf{z}\in Z} f(\mathbf{z})$ *is called convex if* $Z \subset \mathbb{R}^{n_z}$ *is convex and* f *is convex on* Z*. Similarly the maximization problem* $\sup_{\mathbf{z}\in Z} f(\mathbf{z})$ *is called convex if* $Z \subset \mathbb{R}^{n_z}$ *is convex and* f *is concave on* Z*.*

DEFINITION 2.6 (convex relaxation of programs). *Let* $Z^D, Z^E \subset \mathbb{R}^{n_z}$*. The optimization problem* $\inf_{\mathbf{z}\in Z^E} f^E(\mathbf{z})$ *is a* convex relaxation *of* $\inf_{\mathbf{z}\in Z^D} f^D(\mathbf{z})$ *if it is a convex program and a relaxation of* $\inf_{\mathbf{z}\in Z^D} f^D(\mathbf{z})$*.*

DEFINITION 2.7 (diameter of a set). *Let* $Z \subset \mathbb{R}^{n_z}$*. The diameter of* Z*, denoted* $w(Z)$*, is the maximal distance between two points in* Z*:*

$$w(Z) = \sup_{\mathbf{z}_1,\mathbf{z}_2\in Z} ||\mathbf{z}_1 - \mathbf{z}_2||.$$

DEFINITION 2.8 (subdivision). *A* subdivision *of the set* P *is a finite collection of subsets* $P^i \subset P$ *with index set* I *such that*

$$P = \bigcup_{\tau\in I} P_\tau \qquad \textit{and} \qquad \operatorname{int}(P_{\tau_1}) \cap \operatorname{int}(P_{\tau_2}) = \emptyset \quad \forall \tau_1, \tau_2 \in I : \tau_1 \neq \tau_2.$$

A subdivision of P *with index set* I_2 *is a* refinement *of the subdivision with index set* I_1 *if for all* $\tau_2 \in I_2$ *there exists* $\tau_1 \in I_1$ *such that* $P_{\tau_2} \subset P_{\tau_1}$ *and for some* $\tau_2 \in I_2$ *there exists* $\tau_1 \in I_1$ *such that* $P_{\tau_2} \subset P_{\tau_1}$ *and* $P_{\tau_2} \neq P_{\tau_1}$*. A sequence of refined subdivisions with index sets* $I_1, I_2, \ldots, I_k$ *is called* exhaustive *if for* $k \to \infty$ *for all* $\tau_k \in I_k$ *the diameter of the set corresponding to* τ_k *vanishes,* $w(P_{\tau_k}) \to 0$*.*

Note that unlike partitions in a branch-and-bound procedure, in a subdivision no subsets P_τ of the host set P are fathomed.

3. Background. In both the lower and upper bounding problems, techniques from interval arithmetic and from convex, concave, and linear relaxations of mathematical programs are employed. Therefore, to aid in the understanding of the bounding procedures, we provide some brief background on these concepts.

3.1. Interval extensions. Consider a continuous function $h : Z \to \mathbb{R}$, where Z is an n_z-dimensional interval defined as

$$Z = [z_1^L, z_1^U] \times \cdots \times [z_{n_z}^L, z_{n_z}^U] = [\mathbf{z}^L, \mathbf{z}^U].$$

The image of Z under h is denoted by the scalar interval $\bar{h}(Z) = [h^L(Z), h^U(Z)]$. Consider also an interval-valued function $H : Z \to \mathbb{IR} : Y \mapsto [H^L(Y), H^U(Y)]$. H is an *inclusion function* for h over Z if the following relation holds:

$$[h^L(Y), h^U(Y)] = \bar{h}(Y) \subset H(Y) = [H^L(Y), H^U(Y)] \quad \forall Y \in \mathbb{IR}^{n_z} : Y \subset Z.$$

The natural interval extension is an example of such an inclusion function. It is derived by replacing each variable z_i with the corresponding interval $[z_i^L, z_i^U]$, decomposing the resulting expression into compositions of elementary operations (multiplication, addition, etc.) and intrinsic functions (exponential, exponentiation, monomial, logarithmic, etc.), and evaluating them using the rules of interval arithmetic [32, 42].

The tightness of inclusion functions can be quantified using the Hausdorff metric $q(\bar{h}(Z), H(Z))$, which is defined as

$$q(\bar{h}(Z), H(Z)) = \max(|h^L(Z) - H^L(Z)|, |h^U(Z) - H^U(Z)|).$$

An inclusion function is convergent with a convergence order β if constants $\gamma \geq 0$ and $\delta \geq 0$ exist such that

$$\begin{aligned} q(\bar{h}(Y), H(Y)) &\leq \gamma w(Y)^\beta, \\ w(H(Y)) &\leq \delta w(Y)^\beta, \end{aligned}$$

for each $Y \in \mathbb{IR}^{n_z} : Y \subset Z$. Note that in general the constants γ, δ depend on the function h and the host set Z.

If subdivision of Z is employed and convergent inclusion functions are taken for each of the resulting subintervals, a tighter estimate of the image of Z under h is obtained. Assuming that the subdivision of Z is given by a collection of nondegenerate intervals Z^k for some finite m, i.e., $Z = \bigcup_{k=1}^m Z^k$, the range of the inclusion is defined as

$$H_m(Z) = \left[\min_k H^L(Z^k), \max_k H^U(Z^k)\right] = [H_m^L(Z), H_m^U(Z)].$$

It can be shown that the following relationship holds:

$$\bar{h}(Z) \subset H_m(Z) \subset H(Z) \Leftrightarrow [h^L(Z), h^U(Z)] \subset [H_m^L(Z), H_m^U(Z)] \subset [H^L(Z), H^U(Z)].$$

Finally, if the subdivision of Z is exhaustive, then the bounds from the inclusion functions converge to the bounds of the true range of the function

$$\lim_{m\to\infty} H_m^L(Z) = h^L(Z) \quad \text{and} \quad \lim_{m\to\infty} H_m^U(Z) = h^U(Z).$$

Natural interval extensions have a first-order convergence rate, while Taylor models (standard or optimally centered forms) have a second-order convergence rate [6] but are typically more expensive to evaluate. For a thorough discussion, the reader is referred to the literature, e.g., [6, 32]. Furthermore, it should be noted that interval methods can be automated; see, e.g., [53, 54].

3.2. Convex relaxation. Most deterministic global optimization algorithms, such as spatial branch-and-bound and outer approximation, rely on the construction of convex relaxations. Given a box-constrained NLP

$$\begin{aligned} &\max_{\mathbf{z}} h(\mathbf{z}) \\ &\text{s.t. } \mathbf{z} \in [\mathbf{z}^L, \mathbf{z}^U] \equiv Z \subset \mathbb{R}^{n_z} \end{aligned} \tag{3.1}$$

with a nonconcave objective function $h(\mathbf{z})$, the goal is to construct a convex maximization problem, i.e., a program with convex constraints and a concave objective function, whose optimal objective value overestimates the optimal solution value of (3.1). Convex and concave envelopes or tight relaxations are known for a variety of simple nonlinear terms [46, 3, 52], and this allows the construction of convex and concave relaxations for a quite general class of functions through several methods [30, 4, 46, 21]. All the methods proposed in the literature essentially rely on a few key ideas and elements. McCormick's results [30] allow the construction of convex

and concave relaxations of functions defined by recursive compositions of elementary operations and intrinsic functions. Floudas and coworkers [2, 3, 5] have proposed convex relaxations for arbitrary twice continuously differentiable functions by the addition of a simple, sufficiently negative function that is known to be convex; concave relaxations are handled similarly. Both approaches can also introduce auxiliary variables and constraints. Smith and Pantelides [46] formalized the use of auxiliary variables, while Gatzke, Tolsma, and Barton [21] demonstrated how these methods can be combined and automated. Tawarmalani and Sahinidis [52, 51] proposed to further relax the convex relaxations via linearization to take advantage of the scalability and reliability of linear programming (LP) solvers. Wang and Chang [56] proposed piecewise-affine relaxations based on linearization. While many combinations of the above ideas are conceivable, we consider three extreme cases of convex relaxation that are of particular interest for the relaxation of the lower-level program.

3.2.1. Nonsmooth concave overestimation. The first alternative we consider is to construct a concave relaxation of the objective function in (3.1) by successively applying McCormick's composition theorem, without the introduction of auxiliary variables and constraints. McCormick [30] presents convex and concave relaxations of a function

$$h^t(\mathbf{z}) = T(t(\mathbf{z})) + U(u(\mathbf{z}))V(v(\mathbf{z})),$$

where $T, U, V : \mathbb{R} \to \mathbb{R}$ are continuous and $t, u, v : Z \to \mathbb{R}$ are continuous on Z. Assuming that convex and concave relaxations are known for all functions (t, u, v and T, U, V), and bounds are known for the ranges of the inner functions (t, u, v), McCormick's composition result provides convex and concave relaxations for h^t on Z.

Consider, for instance, $T(t(\mathbf{z}))$ and let t^u and t^o be convex and concave relaxations of t on Z. Let further $t(\mathbf{z}) \in [t^L, t^U]$ for all $\mathbf{z} \in Z$, and T^u, T^o be convex and concave relaxations of T on $[t^L, t^U]$. Let, finally, $w_{min} \in \arg\min_{w \in [t^L, t^U]} T^u(w)$ and $w_{max} \in \arg\max_{w \in [t^L, t^U]} T^o(w)$. Then

$$T^u\left(\text{mid}\{t^u(\mathbf{z}), t^o(\mathbf{z}), w_{min}\}\right),$$
$$T^o\left(\text{mid}\{t^u(\mathbf{z}), t^o(\mathbf{z}), w_{max}\}\right)$$

are respectively a convex and concave relaxation of the composite function $T(t)$ on Z. For the product of two functions see Appendix B.

Recursive application of McCormick's result allows the derivation of convex and concave relaxations for complicated expressions termed *factorable* expressions. Assuming that the objective function h in (3.1) is factorable, we denote $h^{o,mc} : Z \to \mathbb{R}$ the concave relaxation constructed by the recursive application of the composition theorem. Since $h^{o,mc}(\mathbf{z}) \geq h(\mathbf{z})$ for all $\mathbf{z} \in Z$, the optimal objective value of

$$\max_{\mathbf{z} \in Z} h^{o,mc}(\mathbf{z}) \tag{3.2}$$

overestimates the optimal objective value of (3.1). While convex, (3.2) is not necessarily smooth, and therefore standard optimization techniques relying on the satisfaction of KKT conditions are not applicable in general. Since it is box-constrained, the linearization (using subgradients) at an arbitrary interior point $\bar{\mathbf{z}} \in \text{int}(Z)$ results in a linear program which is a further relaxation (and trivially smooth),

$$\max_{\mathbf{z} \in Z} h^{o,mc,lin}(\mathbf{z}),$$

where $h^{o,mc,lin}(\mathbf{z}) = h(\bar{\mathbf{z}}) + \mathbf{d}^{\mathrm{T}}(\mathbf{z} - \bar{\mathbf{z}})$ for some subgradient $\mathbf{d}$. While the existence of subgradients is guaranteed, obtaining them within the McCormick relaxation requires some development. The reader is referred to [8] for this development. Note also that a subgradient is guaranteed to exist even at boundary points under mild assumptions, e.g., differentiability of the univariate intrinsic functions on their domains.

3.2.2. Smooth concave overestimation without auxiliary variables. The second alternative we consider is based on the ideas of αBB relaxation by Adjiman and coworkers [4, 3, 1] and γBB relaxation by Akrotirianakis and Floudas [5]. To avoid the introduction of auxiliary variables and constraints, which add complications, we deviate from the framework presented in these references. Instead of splitting the nonlinear objective h into the sum of concave terms, special nonconcave terms, and general nonconcave terms, we apply the relaxation to the original function. Note also that we consider the simplest variant of uniform diagonal shift of the Hessian matrix.

Since univariate quadratic terms are convex,

$$h^{o,\alpha}(\mathbf{z}) = h(\mathbf{z}) + \alpha \sum_{i=1}^{n_z} (z_i - z_i^L)(z_i^U - z_i)$$

is concave for sufficiently large values of α. Moreover, for any $\mathbf{z} \in Z$,

$$h^{o,\alpha}(\mathbf{z}) \geq h(\mathbf{z}) \qquad \forall \alpha \geq 0.$$

The smallest possible value for α is obtained by finding the largest eigenvalue of the Hessian matrix on Z, i.e., by the global solution of a nonconvex optimization problem. Instead, Adjiman et al. [3] have proposed efficient methods for overestimating α. One such method is the application of Gerschgorin's theorem and estimating

$$\frac{1}{2} \max_{\mathbf{z} \in Z} \max_i \max \left\{ 0, H_{ii}(\mathbf{z}) + \sum_{j \neq i} |H_{ij}(\mathbf{z})| \right\}$$

using interval arithmetic on the Hessian matrix. Note that $H_{ij} = \frac{\partial^2 h}{\partial z_i \partial z_j}$.

Since $h^{o,\alpha}(\mathbf{z}) \geq h(\mathbf{z})$ for all $\mathbf{z} \in Z$ and all $\alpha \geq 0$, the optimal objective value of

$$\max_{\mathbf{z} \in Z} h^{o,\alpha}(\mathbf{z}) \tag{3.3}$$

overestimates the optimal objective value of (3.1). The formulated relaxation (3.3) is a box-constrained maximization problem with a smooth concave objective function. The polyhedral feasible set along with the concavity of the objective function make the first-order KKT conditions necessary and sufficient for a global maximum. Standard, gradient-based optimization algorithms can reliably solve (3.3). Finally, since (3.3) is box-constrained, the linearization at an arbitrary point $\bar{\mathbf{z}} \in Z$ results in a linear program which is a further relaxation.

The application of γBB relaxation [5] is analogous. In this method, relaxation is achieved by the addition of exponential terms,

$$h^{o,\gamma}(\mathbf{z}) = h(\mathbf{z}) + \sum_{i=1}^{n_z} \left(1 - e^{\gamma_i (z_i - z_i^L)}\right) \left(1 - e^{\gamma_i (z_i^U - z_i)}\right).$$

3.2.3. Smooth concave overestimation with auxiliary variables. The third alternative we consider is the introduction of auxiliary variables $\mathbf{w}$ and constraints as described in [21]. First, a factorable representation of the nonconcave function h is developed, introducing a new variable w_i for each distinct factor. Subsequently, the bounds for the auxiliary variables $\mathbf{w}$ are propagated via natural interval extensions from the bounds on $\mathbf{z}$ and the auxiliary variables already introduced. At the next step an equivalent equality constrained program is generated by introducing the definition of each factor as an equality constraint and replacing each occurrence of a nonconvex function with the relevant factor. Then, each nonlinear equality constraint is rewritten as a pair of inequalities. Finally, the inequalities are relaxed by relaxing each nonlinear expression; if the (smooth) convex and concave envelopes (or tight relaxations) of a nonlinear expression are known, these are introduced; otherwise convex and concave relaxations are computed by the αBB or γBB method. Nonsmoothness in an envelope can be represented by multiple smooth convex inequalities (e.g., the bilinear case). Sums of linear terms are also replaced by new variables w_i along with a linear equality constraint.

In the special case that the objective function contains additive univariate convex terms, these terms can be directly overestimated by the secant without auxiliary variables. Similarly, additive concave terms in the objective are left unchanged. The resulting program is

$$
\begin{aligned}
&\max_{\mathbf{z},\mathbf{w}} h^{o,ex}(\mathbf{z},\mathbf{w}) \\
&\text{s.t. } t_i^u(\mathbf{z},\mathbf{w}) - w_j \le 0, \quad i \in I_j^u, \quad j = 1,\dots,n_w, \\
&\qquad w_j - t_i^o(\mathbf{z},\mathbf{w}) \le 0, \quad i \in I_j^o, \quad j = 1,\dots,n_w, \\
&\qquad\qquad \mathbf{t}^l(\mathbf{z},\mathbf{w}) = \mathbf{0}, \\
&\qquad\qquad\qquad \mathbf{z} \in Z, \\
&\qquad\qquad\qquad \mathbf{w} \in [\mathbf{w}^L, \mathbf{w}^U] \subset \mathbb{R}^{n_w},
\end{aligned}
\tag{3.4}
$$

where $\mathbf{t}^l$, $\mathbf{t}^u$, and $\mathbf{t}^o$ denote affine, convex, and concave functions, respectively, and the objective function $h^{o,ex}$ is concave. The (possibly empty) finite index sets I_j^u and I_j^o represent the multiple smooth convex inequalities. By construction, the optimal solution value of (3.4) overestimates the optimal solution value of (3.1). It is a convex program with linear equality constraints and differentiable convex inequality constraints. Due to convexity, the KKT conditions are sufficient for a global minimum, and we employ this for the upper bounding procedure. The number of auxiliary variables and constraints introduced depends on the problem size and on the problem structure. Since it is bounded by a multiple of the number of factors in the McCormick factorization, it is typically a small multiple of the number of variables.

The existence of a Slater point provides a constraint qualification [10, p. 325], and in this case the first-order KKT conditions are also necessary for a local and global minimum. While typically the existence of a Slater point is expected, to the best of our knowledge it has not been proved in general for this type of convex relaxations.

Note that since the procedure described here is analogous to the procedure used when constructing natural interval extensions, which in turn are used to calculate bounds for the auxiliary variables, the relaxation provided by (3.4) is expected to be at least as tight as the natural interval extension of h over Z. Moreover, by the introduction of auxiliary variables the relaxations can furnish tighter relaxations than the ones furnished by McCormick's composition theorem without auxiliary variables

[51, p. 128].

A further relaxation of (3.4) can be performed via linearization of the objective function and the constraints [51]. A weaker linear relaxation can be obtained by removing all nonlinear constraints. Finally, an even weaker linear relaxation is generated by removing all constraints but the variable bounds to obtain a box-constrained program.

3.3. Restrictions/relaxations of SIP. Recall that SIPs can be interpreted as the nonsmooth program (1.2). A restriction of the lower-level program (1.3), pointwise in $\mathbf{x}$, leads to an underestimation of the optimal solution value $g^U(\mathbf{x})$. Therefore, the constraint $g^U(\mathbf{x}) \leq 0$ is relaxed. Similarly, a relaxation of the lower-level program (1.3), pointwise in $\mathbf{x}$, leads to an overestimation of the optimal solution value $g^U(\mathbf{x})$, and the constraint $g^U(\mathbf{x}) \leq 0$ is restricted. In other words, a restriction of the lower-level program results in a relaxation of the SIP, and similarly a relaxation of the lower-level program results in a restriction of the SIP.

To be of practical significance, the restrictions and relaxations of the lower-level program have to be valid for the entire set X. Discretization methods replace the host set P with a finite set $P_D \subset P$, uniformly in $\mathbf{x}$. This is a restriction of the lower-level program, since its feasible set is replaced by a subset and results in a relaxation of the SIP. If the resulting NLP is solved to global optimality, a lower bound to the SIP is obtained. On the other hand, the ICR proposal of Bhattacharjee and coworkers [12, 13] does not alter the feasible set of the lower-level program, but overestimates the objective function of the lower-level program pointwise in $\mathbf{x}$. This overestimation leads to a relaxation of the lower-level program and a restriction of the SIP. Any feasible point of the resulting NLP gives an upper bound to the SIP. Similarly, the work by Floudas and Stein [19] and our proposed upper bounds are based on a convex relaxation of the lower-level program resulting in a restriction of the SIP.

4. KKT-based lower bound. In single-level optimization lower bounds are typically obtained by the solution of a convex relaxation. As discussed in the introduction, a well established relaxation of SIPs is obtained by replacing the infinite set P with a finite subset P_D. Stein and Still [48] solve GSIP with a convex lower-level program satisfying a constraint qualification via an equivalent representation as a MPEC and remark that under nonconvexity this approach would give a lower bound. Here we combine these two ideas. We also propose a simple method for calculating bounds on the KKT multipliers which, depending on the solution method employed for the lower bounding problem, are either helpful or required [31]. Finally, we propose a simple method of employing (partially) the second-order KKT necessary conditions. The formulated lower bounding problem is computationally more expensive than either of the two known ideas. However, the lower bound furnished is at least as tight as either of the existing ones, since the solution obtained simultaneously satisfies both conditions. Moreover, numerical examples in section 6 show that the lower bound proposed may even be tighter than either of the two existing ideas.

A valid relaxation of the constraint "$\mathbf{p}$ is a global maximum of the lower-level program" is the constraint "$\mathbf{p}$ is a local maximum of the lower-level program." By Assumption 2, for each $\mathbf{x} \in X$ the function $g(\mathbf{x}, \cdot)$ is differentiable on some open set containing P, and therefore by linearity of the constraints in the lower-level program (2.1) the KKT conditions are necessary for a local maximum. The solution value of the following MPEC, for which the parameters $\mathbf{p}$ and the KKT multipliers $\boldsymbol{\mu}$ have been added to the set of variables, provides a valid lower bound for (1.1):

$$
\begin{aligned}
f^{LBD} = \min_{\mathbf{x},\mathbf{p},\boldsymbol{\mu}} \; & f(\mathbf{x}) \\
\text{s.t.} \; & -g_{p_j}(\mathbf{x},\mathbf{p}) + \mu_j - \mu_{n_p+j} = 0, \quad j = 1,\dots,n_p, \\
& \mu_j(p_j - p_j^U) = 0, \quad j = 1,\dots,n_p, \\
& \mu_{n_p+j}(-p_j + p_j^L) = 0, \quad j = 1,\dots,n_p, \\
& g(\mathbf{x},\mathbf{p}) \le 0, \\
& g(\mathbf{x},\hat{\mathbf{p}}) \le 0 \quad \forall \hat{\mathbf{p}} \in P_D, \\
& 0 \le \mu_j \le \mu_j^{max}, \quad j = 1,\dots,2n_p, \\
& \mathbf{x} \in X, \qquad \mathbf{p} \in P.
\end{aligned} \tag{4.1}
$$

Recall that g_{p_j} denotes the partial derivative of g with respect to p_j. To obtain a valid lower bound for (1.1) the above MPEC must be solved to global optimality. Another alternative is to further relax (4.1).

Recall that replacing the infinite set P with the finite subset P_D is a restriction of the lower-level program, and therefore a relaxation of the SIP. On the other hand, the addition of the parameters and KKT multipliers to the variable list is a relaxation of the optimality constraint in the lower-level program. The necessity of the KKT conditions ensures that the introduced constraints are feasible. The promise of this relaxation is that when P is subdivided and the subdivisions are successively refined in an exhaustive manner, for some τ, the only KKT points in P_τ will be global maxima of the lower-level program for the obtained $\bar{\mathbf{x}}$; see also the subsection devoted to convergence.

The multiplier bounds $\boldsymbol{\mu}^{max}$ need not be exact. Finite bounds are needed for some of the solution methods employed for (4.1) as well as the reformulation via integer programming used in this paper, and tighter bounds will typically accelerate the solution of (4.1). However, if the bounds on the KKT multipliers are underestimated, the lower bounding problem may be invalid (by excluding some feasible $\mathbf{x}$), irrespective of the algorithm used to solve (4.1).

4.1. Bounds on the KKT multipliers. In the following we discuss how to obtain the bounds $\boldsymbol{\mu}^{max}$ for the KKT multipliers $\boldsymbol{\mu}$ in the lower bounding problem (4.1).

PROPOSITION 4.1 (multiplier bounds). *Valid upper bounds for the KKT multipliers $\boldsymbol{\mu}$ in* (4.1) *are given by*

$$
\mu_j^{max} = \max_{\mathbf{x}\in X, \mathbf{p}\in P, p_j = p_j^U} g_{p_j}(\mathbf{x},\mathbf{p}), \quad j = 1,\dots,n_p, \tag{4.2}
$$

$$
\mu_{n_p+j}^{max} = -\min_{\mathbf{x}\in X, \mathbf{p}\in P, p_j = p_j^L} g_{p_j}(\mathbf{x},\mathbf{p}), \quad j = 1,\dots,n_p. \tag{4.3}
$$

Proof. Consider an arbitrary but fixed index $j \in \{1,2,\dots,n_p\}$. The KKT multipliers $\mu_j \ge 0$ and $\mu_{n_p+j} \ge 0$ must satisfy the stationarity and complementary slackness conditions

$$
-g_{p_j}(\mathbf{x},\mathbf{p}) + \mu_j - \mu_{n_p+j} = 0, \tag{4.4}
$$

$$
\mu_j(p_j - p_j^U) = 0, \tag{4.5}
$$

$$
\mu_{n_p+j}(-p_j + p_j^L) = 0. \tag{4.6}
$$

Note first that for $p_j \in (p_j^L, p_j^U)$ we obtain $\mu_j = 0$ from (4.5) and $\mu_{n_p+j} = 0$ from (4.6). In the following we therefore consider only $p_j \in \{p_j^L, p_j^U\}$.

For $p_j = p_j^U$ we obtain $\mu_{n_p+j} = 0$ from (4.6), and since any μ_j satisfies (4.5), μ_j is calculated by (4.4) as

$$\mu_j = g_{p_j}(\mathbf{x}, \mathbf{p}).$$

Therefore, the largest value that μ_j can take is given by the maximum of the partial derivative g_{p_j} over X and P, constrained by $p_j = p_j^U$,

$$\mu_j^{max} = \max_{\mathbf{x}\in X, \mathbf{p}\in P, p_j = p_j^U} g_{p_j}(\mathbf{x}, \mathbf{p}).$$

Similarly for $p_j = p_j^L$ we obtain $\mu_j = 0$ from (4.5), and since any μ_{n_p+j} satisfies (4.6), μ_{n_p+j} is calculated by (4.4) as

$$\mu_{n_p+j} = -g_{p_j}(\mathbf{x}, \mathbf{p}).$$

Therefore the largest value that μ_{n_p+j} can take is given by the maximum of the negative partial derivative $-g_{p_j}$ over X and P such that $p_j = p_j^L$,

$$\mu_{n_p+j}^{max} = \max_{\mathbf{x}\in X, \mathbf{p}\in P, p_j = p_j^L} (-g_{p_j}(\mathbf{x}, \mathbf{p})) = -\min_{\mathbf{x}\in X, \mathbf{p}\in P, p_j = p_j^L} g_{p_j}(\mathbf{x}, \mathbf{p}). \qquad \square$$

Note that in the optimization problems (4.2), (4.3), p_j is fixed and is used only as a dummy variable. In general, solving the above optimization programs is expensive, and we therefore propose to overestimate the bounds by interval extensions over $X \times P$ (with p_j fixed). When nonpositive values are obtained for the bounds, i.e., when the partial derivative g_{p_j} is nonpositive for $p_j = p_j^U$ or nonnegative for $p_j = p_j^L$, the corresponding variable and the complementary slackness conditions can be eliminated. In a branch-and-bound procedure such as the one proposed by Bhattacharjee et al. [13], where the host set of X is branched and the host set P subdivided, this elimination criterion is likely to be valid in some subsets of X and P.

4.2. Implementation with integer variables. Due to the complementary slackness conditions, (4.1) violates the Mangasarian–Fromowitz constraint qualification (MFCQ) [48] and is difficult to solve [7]. Stein and Still [48] solve their MPEC by regularizing the complementary slackness conditions via NCP functions and solving a sequence of regularized NLPs. Each of these NLPs is an approximation to (4.1), but it can be easily verified that it provides a valid lower bound. In the limit (4.1) is solved. General-purpose global NLP solvers such as BARON [44] obtain lower bounds on (4.1) by constructing convex relaxations of the equality constraints as pairs of inequalities. To ensure convergence, bounds on the KKT multipliers are needed. Fortuny-Amat and McCarl [20] reformulate the complementary slackness conditions of the inner program in a class of bilevel programs using integer variables and the big-M formulation to obtain an MINLP. To do so bounds are needed for the multipliers, as well as for the constraints. In the special case of SIP, since the lower-level problem contains only box constraints, bounds on the constraints are readily available, and the big-M reformulation is particularly simple. Moreover, due to the simple structure of the lower-level program the KKT multipliers can be eliminated. Let y_j be an integer variable used to indicate whether $p_j = p_j^U$; i.e., let $y_j = 0$ imply $p_j < p_j^U$ and $y_j = 1$ imply $p_j = p_j^U$. Similarly, let y_{n_p+j} be an integer variable used to indicate whether $p_j = p_j^L$; i.e., let $y_{n_p+j} = 0$ imply $p_j > p_j^L$ and $y_{n_p+j} = 1$ imply $p_j = p_j^L$. We claim

that MPEC (4.1) is equivalent to the following MINLP:

$$
\begin{aligned}
f^{LBD} = \min_{\mathbf{x},\mathbf{p},\mathbf{y}} & f(\mathbf{x}) \\
\text{s.t. } & g_{p_j}(\mathbf{x},\mathbf{p}) \le y_j \mu_j^{max}, && j=1,\dots,n_p, \\
& p_j^U - p_j \le \left(p_j^U - p_j^L\right)(1-y_j), && j=1,\dots,n_p, \\
& -g_{p_j}(\mathbf{x},\mathbf{p}) \le y_{n_p+j}\mu_{n_p+j}^{max}, && j=1,\dots,n_p, \\
& p_j - p_j^L \le \left(p_j^U - p_j^L\right)\left(1-y_{n_p+j}\right), && j=1,\dots,n_p, \\
& y_j + y_{n_p+j} \le 1, && j=1,\dots,n_p, \\
& g(\mathbf{x},\mathbf{p}) \le 0 && \\
& g(\mathbf{x},\hat{\mathbf{p}}) \le 0 && \forall \hat{\mathbf{p}} \in P_D, \\
& \mathbf{y} \in \{0,1\}^{2n_p}, && \\
& \mathbf{x} \in X, \qquad \mathbf{p} \in P, &&
\end{aligned}
\tag{4.7}
$$

where $\boldsymbol{\mu}^{max}$ are calculated by (4.2), (4.3). The reason we employ this reformulation is because the use of binary variables allows more flexibility, such as the introduction of second-order KKT conditions.

Note that if (4.2) furnishes $\mu_j^{max} \le 0$, then y_j is eliminated, and the two inequalities containing y_j are replaced by $g_{p_j}(\mathbf{x},\mathbf{p}) \le 0$. Similarly, if (4.3) gives $\mu_{n_p+j}^{max} \le 0$, then y_{n_p+j} is eliminated, and the two inequalities containing y_{n_p+j} are replaced by $g_{p_j}(\mathbf{x},\mathbf{p}) \ge 0$. It is very simple to verify the validity of these eliminations.

PROPOSITION 4.2 (validity of MPEC formulation). *If values for $\boldsymbol{\mu}^{max}$ are calculated by* (4.2), (4.3)*, then MPEC* (4.1) *is equivalent to* (4.7).

Proof. The two problems have the same objective function, which depends only on the original variables $\mathbf{x}$, and therefore it suffices to show that the projection of the feasible sets on X is the same. Note also that both formulations contain the constraints from the discretization of P, namely $g(\mathbf{x},\hat{\mathbf{p}}) \le 0$, for all $\hat{\mathbf{p}} \in P_D$, and we can ignore these.

1. $\bar{\mathbf{x}}$ *is feasible in* (4.1) $\Rightarrow$ $\bar{\mathbf{x}}$ *is feasible in* (4.7).
   Let $\bar{\mathbf{x}}$ be feasible in (4.1). Therefore, there exist $\bar{\boldsymbol{\mu}}$, $\bar{\mathbf{p}}$ such that $(\bar{\mathbf{x}},\bar{\mathbf{p}},\bar{\boldsymbol{\mu}})$ satisfy the constraints of (4.1). We will show that there also exists $\bar{\mathbf{y}}$ such that $(\bar{\mathbf{x}},\bar{\mathbf{p}},\bar{\mathbf{y}})$ is feasible in (4.7). For an arbitrary but fixed $j \in \{1,2,\dots,n_p\}$ consider the following cases:
   (a) $\bar{p}_j \in (p_j^L, p_j^U)$. From the complementary slackness conditions we obtain $\bar{\mu}_j = \bar{\mu}_{n_p+j} = 0$, and therefore from the stationarity condition $g_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) = 0$. Pick now $\bar{y}_j = \bar{y}_{n_p+j} = 0$. The first five constraints of (4.7) become
   $$
   \begin{aligned}
   & g_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) \le 0, \\
   & p_j^U - \bar{p}_j \le \left(p_j^U - p_j^L\right), \\
   & g_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) \ge 0, \\
   & \bar{p}_j - p_j^L \le \left(p_j^U - p_j^L\right), \\
   & 0 + 0 \le 1,
   \end{aligned}
   $$
   and are clearly satisfied.
   (b) $\bar{p}_j = p_j^U$. From the complementary slackness condition we obtain $\bar{\mu}_{n_p+j} = 0$, and therefore from the stationarity condition $g_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) \ge 0$. Pick now

$\bar{y}_j = 1$, $\bar{y}_{n_p+j} = 0$. The first five constraints of (4.7) become

$$\begin{aligned} g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) &\leq \mu_j^{max}, \\ 0 &\leq 0, \\ g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) &\geq 0, \\ p_j^U - p_j^L &\leq \left(p_j^U - p_j^L\right), \\ 1 + 0 &\leq 1, \end{aligned}$$

and are satisfied; recall also the calculation of μ_j^{max} from (4.2).

(c) $\bar{p}_j = p_j^L$. This case is analogous to the previous case.

Since we also have $g(\bar{\mathbf{x}}, \bar{\mathbf{p}}) \leq 0$, the desired result is shown.

2. $\bar{\mathbf{x}}$ *is feasible in* (4.7) $\Rightarrow$ $\bar{\mathbf{x}}$ *is feasible in* (4.1) . Let $\bar{\mathbf{x}}$ be feasible in (4.7). Therefore, there exist $\bar{\mathbf{y}}$, $\bar{\mathbf{p}}$ such that $(\bar{\mathbf{x}}, \bar{\mathbf{p}}, \bar{\mathbf{y}})$ satisfy the constraints of (4.7). We will show that there also exists $\bar{\boldsymbol{\mu}}$, such that $(\bar{\mathbf{x}}, \bar{\mathbf{p}}, \bar{\boldsymbol{\mu}})$ is feasible in (4.1). For an arbitrary but fixed $j \in \{1, 2, \ldots, n_p\}$ consider the following cases:

(a) $\bar{p}_j \in (p_j^L, p_j^U)$. The constraint $p_j^U - \bar{p}_j \leq \left(p_j^U - p_j^L\right)(1 - \bar{y}_j)$ directly gives $\bar{y}_j = 0$, and therefore we obtain $g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) \leq 0$. Similarly we obtain $\bar{y}_{n_p+j} = 0$ and $g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) \geq 0$. We therefore have $g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) = 0$. Pick $\bar{\mu}_j = \bar{\mu}_{n_p+j} = 0$ and note that the first three constraints of (4.1) are satisfied.

(b) $\bar{p}_j = p_j^U$. Similarly to the previous case we obtain $\bar{y}_{n_p+j} = 0$ and $g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}}) \geq 0$. Pick $\bar{\mu}_j = g_{p_j}(\bar{\mathbf{x}}, \bar{\mathbf{p}})$ and $\bar{\mu}_{n_p+j} = 0$ and note that the first three constraints of (4.1) are satisfied.

(c) $\bar{p}_j = p_j^L$. This case is analogous to the previous case.

Since we also have $g(\bar{\mathbf{x}}, \bar{\mathbf{p}}) \leq 0$, the desired result is shown. ∎

4.3. Second-order conditions. Typically, some infeasible points $\bar{\mathbf{x}}$ have a lower objective value than the optimal objective value $f(\bar{\mathbf{x}}) < f^*$, for otherwise (1.1) is essentially unconstrained. Moreover, while for these points $\max_{\mathbf{p}\in P} g(\bar{\mathbf{x}}, \mathbf{p}) > 0$, it is possible that $\min_{\mathbf{p}\in P} g(\bar{\mathbf{x}}, \mathbf{p}) \leq 0$. Therefore, since the parameters are added to the variable list, the solution of (4.1) tends to furnish such points $\bar{\mathbf{x}}$ along with points $\bar{\mathbf{p}}$ which are stationary points (e.g., unconstrained minima) of the lower-level program, because for the given $\bar{\mathbf{x}}$ these are the least restrictive for the constraint $g(\bar{\mathbf{x}}, \mathbf{p}) \leq 0$. The second-order KKT conditions can partially alleviate this phenomenon. The second-order constraint qualification is trivially satisfied for the box-constrained lower-level problem. Instead of the full second-order conditions we propose a simple necessary check, by requiring that the second derivative with respect to each parameter be nonpositive unless this parameter is at one of its bounds. With the use of the binary variables described above, this condition can be formulated as

$$g_{p_j p_j}(\mathbf{x}, \mathbf{p}) \leq (y_j + y_{n_p+j})\, g_{p_j p_j}^{max}, \qquad j = 1, \ldots, n_p,$$

where $g_{p_j p_j}^{max}$ is an upper bound for the second derivative $g_{p_j p_j}$ on $X \times P$. Similarly to the bounds on the KKT multipliers, it suffices to take a bound satisfying

$$g_{p_j p_j}^{max} \geq \max_{\mathbf{x}\in X, \mathbf{p}\in P, p_j \in \{p_j^L, p_j^U\}} g_{p_j p_j}(\mathbf{x}, \mathbf{p}).$$

This bound can be calculated by interval extensions on $X \times P$. Note that a negative bound is acceptable here.

4.4. Validity and convergence of lower bounding problem. In discretization approaches, tightening of the lower bounds can be achieved by gradually increasing the cardinality of the finite set of parameters considered, i.e., increasing the number of constraints. Methods for efficient convergence of the proposed lower bounding problem to the optimal solution value of the SIP are outside the scope of this paper, and here we only briefly discuss basic convergence properties. We will show that a subdivision of P leads to convergence of the lower bound.

Suppose that the host set P is subdivided into a collection of subsets $P_\tau \subset P$ with index set I, satisfying $P_\tau = [\mathbf{p}_\tau^L, \mathbf{p}_\tau^U]$. We now require matrices of variables $\mathbf{P}$ and $\mathbf{Y}$ whose columns are indexed by the set I, i.e., for $\tau \in I$ the vectors $\mathbf{p}_\tau \in P_\tau$ and $\mathbf{y}_\tau \in \{0,1\}^{2n_p}$ represent columns of $\mathbf{P}$ and $\mathbf{Y}$, respectively. The lower bounding problem (4.7) with the inclusion of the second-order conditions now becomes

$$
\begin{aligned}
f^{I,LBD} = \min_{\mathbf{x},\mathbf{P},\mathbf{Y}} \; & f(\mathbf{x}) \\
\text{s.t. } & g_{p_{j,\tau}}(\mathbf{x}, \mathbf{p}_\tau) \le y_{j,\tau}\mu_{j,\tau}^{max}, && j = 1,\dots,n_p, \quad \tau \in I, \\
& p_{j,\tau}^U - p_{j,\tau} \le \left(p_{j,\tau}^U - p_{j,\tau}^L\right)(1 - y_{j,\tau}), && j = 1,\dots,n_p, \quad \tau \in I, \\
& -g_{p_j}(\mathbf{x}, \mathbf{p}_\tau) \le y_{n_p+j,\tau}\mu_{n_p+j,\tau}^{max}, && j = 1,\dots,n_p, \quad \tau \in I, \\
& p_{j,\tau} - p_{j,\tau}^L \le \left(p_{j,\tau}^U - p_{j,\tau}^L\right)\left(1 - y_{n_p+j,\tau}\right), && j = 1,\dots,n_p, \quad \tau \in I, \\
& y_{j,\tau} + y_{n_p+j,\tau} \le 1, && j = 1,\dots,n_p, \quad \tau \in I, \\
& g_{p_j p_j}(\mathbf{x}, \mathbf{p}_\tau) \le (y_{j,\tau} + y_{n_p+j,\tau})\, g_{p_j p_j,\tau}^{max}, && j = 1,\dots,n_p, \quad \tau \in I, \\
& g(\mathbf{x}, \mathbf{p}_\tau) \le 0, && \tau \in I, \\
& g(\mathbf{x}, \hat{\mathbf{p}}) \le 0 && \forall \hat{\mathbf{p}} \in P_D, \\
& \mathbf{Y} \in \{0,1\}^{2n_p \times |I|}, \\
& \mathbf{p}_\tau \in P_\tau, && \tau \in I, \\
& \mathbf{x} \in X.
\end{aligned}
\tag{4.8}
$$

Note that, to ensure the existence of a KKT point in each subset P_τ, it is necessary to use the interior bounds in the KKT conditions ($p_{j,\tau}^U$ as opposed to p_j^U).

PROPOSITION 4.3 (validity of the lower bounding problem). *The optimal solution value $f^{I,LBD}$ obtained by* (4.8) *is a valid lower bound to the optimal objective value of SIP* (1.1)*, or* (4.8) *is a relaxation of* (1.1)*.*

Proof. Since the objective function in (4.8) is the same as in (1.1), it suffices to show that if a point $\bar{\mathbf{x}}$ is feasible in (1.1), then it is feasible in (4.8). This is done by showing that one can pick points $\bar{\mathbf{P}}$, $\bar{\mathbf{Y}}$ satisfying the constraints.

Let $\bar{\mathbf{x}}$ be feasible in (1.1); i.e., $g(\bar{\mathbf{x}}, \mathbf{p}) \le 0$ for all $\mathbf{p} \in P$. Since $P_D \subset P$, we obtain directly $g(\bar{\mathbf{x}}, \hat{\mathbf{p}}) \le 0$ for all $\hat{\mathbf{p}} \in P_D$. For each $\tau \in I$, pick $\bar{\mathbf{p}}_\tau \in \arg\max_{\mathbf{p}_\tau \in P_\tau} g(\bar{\mathbf{x}}, \mathbf{p}_\tau)$. Since $P_\tau \subset P$, we directly obtain $\bar{\mathbf{p}}_\tau \in P$ and therefore $g(\bar{\mathbf{x}}, \bar{\mathbf{p}}_\tau) \le 0$. Since each program $\max_{\mathbf{p}_\tau \in P_\tau} g(\bar{\mathbf{x}}, \mathbf{p}_\tau)$ is box-constrained, it satisfies the linear constraint qualification, and the first and second-order KKT conditions are necessary for a maximum. As a consequence, in analogy to the proof of Proposition 4.2, one can pick $\bar{\mathbf{y}}_\tau$ that satisfy the first six constraints of (4.8). ∎

PROPOSITION 4.4 (convergence of lower bounding problem). *Consider a sequence of successively refined subdivisions with index set I_k. Consider the relaxation of* (4.8) *(with $P_D = \emptyset$ and without the KKT necessary conditions),*

$$
\begin{aligned}
f^{LBD,k} = \min_{\mathbf{x},\mathbf{P}}\ & f(\mathbf{x}) \\
s.t.\ & g(\mathbf{x},\mathbf{p}_\tau) \le 0, \quad \tau \in I_k, \\
& \mathbf{p}_\tau \in P_\tau, \quad \tau \in I_k, \\
& \mathbf{x} \in X.
\end{aligned} \tag{4.9}
$$

If the subdivision is exhaustive, then for $k \to \infty$, $f^{LBD,k} \to f^*$.

Note that since the subdivision is refined, essentially an implicit discretization is defined, and convergence results for discretizations are well known, e.g., [41]. Therefore the proof of Proposition 4.4 is based on the proof of Theorem 2.8 of [41].

Proof. Since the subdivision is successively refined, the sequence of lower bounds obtained is nondecreasing. Moreover, by Proposition 4.3 we have $f^{LBD,k} \le f^*$. Therefore, $f^{LBD,k}$ converges for $k \to \infty$. Denote its limit f^{lim} and note that $f^{lim} \le f^*$.

Since X is compact, a subsequence $\mathbf{x}^{k_i}$ which converges to $\mathbf{x}^{lim,i}$ with $f(\mathbf{x}^{lim,i}) = f^{lim}$ exists. Note now that the solution of (4.9) furnishes $\mathbf{p}_\tau^{k_i}$ for each $\mathbf{x}^{k_i}$ satisfying $g(\mathbf{x}^{k_i}, \mathbf{p}_\tau^{k_i}) \le 0$ for all $\tau \in I_k$ Since the subdivision is exhaustive, for k_i large enough and some τ the points $\mathbf{p}_\tau^{k_i}$ are arbitrarily close to points in $\arg\max_{\mathbf{p}\in P} g(\mathbf{x}^{lim,i}, \mathbf{p})$. The continuity of g therefore implies $g^U(\mathbf{x}^{lim,i}) \le 0$, or $\mathbf{x}^{lim,i}$ is feasible for the original SIP. Therefore, $f^{lim} \ge f^*$. ∎

5. Upper bounding problems. The basic principle of our upper bounding proposals is the same as that of Bhattacharjee and coworkers [12, 13], namely that a relaxation of the lower-level program leads to a restriction of the semi-infinite constraint and thus a restriction of the SIP. Here, instead of using an inclusion function based on interval analysis, we employ convex relaxations and/or linear relaxations. First, we extend the convex relaxations to the parametric case. Subsequently, we describe the alternatives and then discuss some basic convergence properties.

5.1. Parametric concave relaxations. We are interested in constructing a concave relaxation of the lower-level program $\max_{\mathbf{p}\in P} g(\mathbf{x},\mathbf{p})$ for each $\mathbf{x} \in X$ and hence a parametric concave relaxation. Procedures for parametric relaxations are not available in the literature in the extent needed for our upper bounding proposals. Relaxations have been used in parametric optimization, but the focus has been on LP-relaxations of parametric mixed integer linear programs; see, e.g., Ohtake and Nishida [35]. In nonlinear programming, convex relaxations have been applied to the right-hand side case, e.g., [18], in which the dependence on the parameter is very simple. Relaxations have also been constructed for optimization with dynamic systems embedded, e.g., [45], where the role of the integration variable is similar to a parameter, but the focus is different than what is needed here.

5.1.1. Nonsmooth concave relaxation. Here we extend the procedure described in section 3.2.1 for concave relaxation and linearization, using the composition results of McCormick, to the parametric case. In particular we need to describe how concave relaxations on P can be calculated for joint terms in $\mathbf{x}$ and $\mathbf{p}$. By Assumption 2, the constraint g can be decomposed in such a way that all joint terms are of the form

$$v_j(\mathbf{x},\mathbf{p}) = t(\mathbf{x}) + u(\mathbf{x})v_i(\mathbf{x},\mathbf{p}),$$

where, for v_i, convex and concave relaxations ($v_i^u(\mathbf{x},\cdot)$, $v_i^o(\mathbf{x},\cdot)$) as well as bounds ($v_i^L(\mathbf{x})$, $v_i^U(\mathbf{x})$) are known on P for each $\mathbf{x} \in X$. The convex and concave relaxations

of $v_j(\mathbf{x},\cdot)$ on P are given by

$$v_j^u(\mathbf{x},\mathbf{p}) = \min\{t(\mathbf{x}) + u(\mathbf{x})v_i^u(\mathbf{x},\mathbf{p}), t(\mathbf{x}) + u(\mathbf{x})v_i^o(\mathbf{x},\mathbf{p})\},$$
$$v_j^o(\mathbf{x},\mathbf{p}) = \max\{t(\mathbf{x}) + u(\mathbf{x})v_i^u(\mathbf{x},\mathbf{p}), t(\mathbf{x}) + u(\mathbf{x})v_i^o(\mathbf{x},\mathbf{p})\},$$

and the bounds of $v_j(\mathbf{x},\cdot)$ on P are given by

$$v_j^L(\mathbf{x},\mathbf{p}) = \min\{t(\mathbf{x}) + u(\mathbf{x})v_i^L(\mathbf{x},\mathbf{p}), t(\mathbf{x}) + u(\mathbf{x})v_i^U(\mathbf{x},\mathbf{p})\},$$
$$v_j^U(\mathbf{x},\mathbf{p}) = \max\{t(\mathbf{x}) + u(\mathbf{x})v_i^L(\mathbf{x},\mathbf{p}), t(\mathbf{x}) + u(\mathbf{x})v_i^U(\mathbf{x},\mathbf{p})\}.$$

By recursive application any factorable function can be handled, generally with a nesting of min and max statements. Note at this point the similarity to the ICR proposal by Bhattacharjee, Green, and Barton [12]. Note also that propagating subgradients from v_i to v_j is straightforward and constructing linearizations poses no significant challenge over the NLP case considered in [8].

Example 5.1. Consider a simple SIP for which $x \in [-1,1]$, $p \in [-1,1]$, $f = -x$, and $g = e^{x\,p^2} - 1$. The feasible set is easily calculated to be $x \le 0$, and therefore the optimal solution value is 0 at $x = 0$. A factorable representation of $g(x,p)$ is given by

$$v_1 = p^2,$$
$$v_2 = x\,v_1,$$
$$v_3 = e^{v_2} - 1.$$

Since p^2 is convex, its convex envelope on P is given by $v_1^u = p^2$, and its concave envelope on P is given by $v_1^o = 1$; its bounds are given by $v_1^L = 0$ and $v_1^U = 1$. For the term v_2 we obtain convex and concave envelopes as $v_2^u = \min\{xv_1^u, xv_1^o\}$ and $v_2^o = \max\{xv_1^u, xv_1^o\}$. Its bounds are given by $v_2^L = \min\{x \cdot 0, x \cdot 1\} = \min\{0, x\}$ and $v_2^U = \max\{0, x\}$. For the term v_3 we need to invoke McCormick's composition theorem. The exponential function e^z is convex, and therefore its concave envelope is given by the secant $T^o = e^{z^L} + \frac{z - z^L}{z^U - z^L}(e^{z^U} - e^{z^L})$, and the convex envelope is given by the function itself $T^u = e^z$. Moreover, the exponential function is monotone increasing, and therefore $\arg\min_{z\in[z^L,z^U]} e^z = \{z^L\}$ and $\arg\max_{z\in[z^L,z^U]} e^z = \{z^U\}$. Therefore, $\mathrm{mid}\{v_2^u, v_2^o, w_{min}\} = v_2^u$ and $\mathrm{mid}\{v_2^u, v_2^o, w_{max}\} = v_2^o$. By McCormick's composition theorem,

$$e^{v_2^u} - 1 = e^{\min\{xp^2, x\}} - 1$$

is a convex underestimator of $g(\mathbf{x},\cdot)$ on P and

$$e^{v_2^L} + \frac{v_2^o - v_2^L}{v_2^U - v_2^L}\left(e^{v_2^U} - e^{v_2^L}\right) - 1$$
$$= e^{\min\{0,x\}} + \frac{\max\{xp^2, x\} - \min\{0,x\}}{\max\{0,x\} - \min\{0,x\}}\left(e^{\max\{0,x\}} - e^{\min\{0,x\}}\right) - 1$$

is a concave overestimator of $g(\mathbf{x},\cdot)$ on P.

5.1.2. Smooth concave relaxations without auxiliary variables. We now consider the extension of the smooth overestimation of the lower-level program via the addition of known concave terms; compare section 3.2.2. Without loss of generality we consider the αBB relaxations, which is also handled in [19]. Use of the γBB

relaxations is analogous. The αBB overestimation $g^{o,\alpha}(\mathbf{x},\cdot)$ of $g(\mathbf{x},\cdot)$ on P is given by

$$g^{o,\alpha}(\mathbf{x},\mathbf{p}) = g(\mathbf{x},\mathbf{p}) + \alpha \sum_{i=1}^{n_p} (p_i - p_i^L)(p_i^U - p_i).$$

For sufficiently large values of α, the overestimating function $g^{o,\alpha}(\mathbf{x},\cdot)$ is partially concave on P for each $\mathbf{x} \in X$.

In principle α can be taken as a function of $\mathbf{x}$, but since no closed form for the calculation of α exists in general and introducing an $\mathbf{x}$-dependence may lead to nonsmooth constraints with respect to $\mathbf{x}$, we refrain from doing this. Instead we obtain α via interval extensions of the eigenvalue estimates of the Hessian matrix on $X \times P$. This overestimation guarantees the desired concavity with the drawback that the relaxations are weaker than necessary. The relaxed lower-level program

$$\max_{\mathbf{p}\in P} g^{o,\alpha}(\mathbf{x},\mathbf{p})$$

is a box-constrained maximization program with a smooth concave objective function. Note that for convergence of $g^{o,\alpha}$ to g it is sufficient to subdivide P, without partitioning X. Within a branch-and-bound procedure, it is advisable, though, to recalculate α for each node, since this accelerates convergence.

Example 5.2. Recall Example 5.1. The second derivative of g with respect to p is given by $(2x + 4x^2p^2)e^{xp^2}$. Calculating the natural interval extension of the second derivative on $X \times P$ gives $6e$. A concave overestimator of $g(x,\cdot)$ on P is therefore given by

$$e^{x\,p^2} - 1 + 3e(p+1)(1-p) = e^{x\,p^2} - 1 + 3e(1-p^2).$$

5.1.3. Smooth concave relaxation with auxiliary variables. We now consider the alternative of introducing auxiliary variables and constraints; compare also section 3.2.3. This is similar to the nonsmooth concave relaxation. By Assumption 2, g can be decomposed in such a way that the joint terms are of the form

$$t(\mathbf{x}) + u(\mathbf{x})w_i,$$

where w_i is a previously introduced variable (or a parameter p_i). If such terms directly appear as a summand in g, no relaxation is needed. Otherwise a new variable w_j is introduced along with a linear equality constraint

$$w_j = t(\mathbf{x}) + u(\mathbf{x})w_i.$$

The bounds on this new auxiliary variable can in principle be calculated as functions of $\mathbf{x}$. Since our final goal is a smooth program with respect to $\mathbf{x}$ we calculate the bounds on this auxiliary variable by taking natural interval extensions with respect to both $\mathbf{p}$ and $\mathbf{x}$. In general this is a further relaxation.

For instance, the term x_ip_j would be replaced by a new variable $w_k \in [w_k^L, w_k^U]$ and a constraint $w_k = x_ip_j$, where the variable bounds are given by $w_k^L = \min\{x_i^Lp_j^L, x_i^Lp_j^U, x_i^Up_j^L, x_i^Up_j^U\}$ and $w_k^U = \max\{x_i^Lp_j^L, x_i^Lp_j^U, x_i^Up_j^L, x_i^Up_j^U\}$.

To obtain a compact presentation we augment the parameters $\mathbf{p}$ with the auxiliary variables and denote these $\tilde{\mathbf{p}} \in \tilde{P} \subset \mathbb{R}^{n_{\tilde{p}}}$. Also, we lump the box and auxiliary constraints into inequality constraints formed from the functions $\mathbf{u} : X \times \mathbb{R}^{n_{\tilde{p}}} \to \mathbb{R}^{n_u}$.

The presence of linear equalities is omitted for simplicity. The relaxed lower-level program is then given by

$$\begin{aligned} &\max_{\tilde{\mathbf{p}}\in\mathbb{R}^{n_{\tilde{p}}}} g^{o,ex}(\mathbf{x},\tilde{\mathbf{p}}) \\ &\text{s.t. } \mathbf{u}(\mathbf{x},\tilde{\mathbf{p}}) \leq \mathbf{0}. \end{aligned} \tag{5.1}$$

The resulting restriction of (1.1),

$$\begin{aligned} f_{gsip}^{UBD,ex} = &\min_{\mathbf{x}\in X} f(\mathbf{x}) \\ &\text{s.t. } g^{o,ex}(\mathbf{x},\tilde{\mathbf{p}}) \leq 0 \quad \forall \tilde{\mathbf{p}} \in \mathbb{R}^{n_{\tilde{p}}} : \mathbf{u}(\mathbf{x},\tilde{\mathbf{p}}) \leq \mathbf{0}, \end{aligned}$$

is a GSIP. By construction, for all $\mathbf{x} \in X$ there exists a $\tilde{\mathbf{p}}$ such that $\mathbf{u}(\mathbf{x},\tilde{\mathbf{p}}) \leq \mathbf{0}$ and the GSIP can be reformulated to a bilevel program [47].

Example 5.3. *Recall Example* 5.1 *and the factorable presentation of* $g = e^{x\,p^2} - 1$. *The nonlinear term* p^2 *is replaced by an auxiliary variable* $\tilde{p}_2 \in [0,1]$ *along with two convex inequality constraints*

$$\begin{aligned} \tilde{p}_1^2 - \tilde{p}_2 &\leq 0, \\ \tilde{p}_2 - 1 &\leq 0. \end{aligned}$$

The joint term $x\tilde{p}_2$ *is replaced by a new auxiliary variable* $\tilde{p}_3 \in [0,1]$ *(bounds incidentally exact) along with a linear (in* $\tilde{\mathbf{p}}$*) equality constraint*

$$\tilde{p}_3 - x\tilde{p}_2 = 0.$$

The exponential term $e^{\tilde{p}_3}$ *is convex and can be overestimated by the secant*

$$e^{\tilde{p}_3^L} + \frac{\tilde{p}_3 - \tilde{p}_3^L}{\tilde{p}_3^U - \tilde{p}_3^L}\left(e^{\tilde{p}_3^U} - e^{\tilde{p}_3^L}\right) = e^0 + \frac{\tilde{p}_3 - 0}{1-0}\left(e^1 - e^0\right) = 1 + \tilde{p}_3(e-1).$$

Since the exponential term directly appears in g*, no additional auxiliary variable is introduced. The concave relaxation of the lower-level program is given by*

$$\begin{aligned} &\max_{\tilde{\mathbf{p}}} \tilde{p}_3(e-1) \\ &s.t.\ \tilde{p}_1^2 - \tilde{p}_2 \leq 0, \\ &\qquad \tilde{p}_2 - 1 \leq 0, \\ &\qquad \tilde{p}_3 - x\tilde{p}_2 = 0, \\ &\qquad \tilde{\mathbf{p}} \in [-1,1] \times [0,1] \times [0,1]. \end{aligned}$$

5.2. KKT-based upper bound. In the following we describe how to obtain an upper bound from the solution of an MPEC. The first step in obtaining the upper bound is to construct a relaxation of (2.1), i.e., a maximization problem with constraints that are partially convex on $\mathbf{p} \in P$ for each $\mathbf{x} \in X$ and an objective function that is partially concave on $\mathbf{p} \in P$ for each $\mathbf{x} \in X$ and overestimates $g(\mathbf{x},\cdot)$ on P. This relaxation of the lower-level program results in a restriction of the SIP.

The next step is to replace the resulting SIP with an MPEC similar to the one described for the lower bounding problem. A basic requirement for this transformation is differentiability of the relaxed lower-level program, and therefore only the smooth relaxations described in section 5.1 are applicable. Moreover, for the MPEC to be a

valid restriction, the KKT conditions need to be sufficient only for a global maximum. This is ensured by the (partial) convexity of the programs. Note that necessity of the KKT conditions is not required. If the relaxed lower-level program attains its maximum only at points that are not KKT points, the MPEC will be infeasible. A local solution of the formulated MPEC is a valid upper bound to the original SIP. Therefore, unlike the lower bounding problem, obtaining rigorous bounds on the KKT multipliers is not necessary (it is still helpful). If the bounds on the KKT multipliers are underestimated, the upper bounding problem is further restricted and therefore remains valid, but may be rendered infeasible.

PROPOSITION 5.1 (validity of KKT-based upper bounding problem). *Consider a (generalized) SIP whose lower-level program is a relaxation of the lower-level program* (1.1) *for each* $\mathbf{x} \in X$ *and as such has a nonempty feasible set for each* $\mathbf{x} \in X$. *Suppose that for each* $\mathbf{x} \in X$ *the first-order KKT conditions are sufficient for a global maximum of the lower-level program. Construct an MPEC with* $\mathbf{x}$, $\mathbf{p}$, *and the KKT multipliers of the relaxed lower-level program* $\boldsymbol{\mu}$ *as variables, the same objective function as* (1.1), *the constraint*

$$g^o(\mathbf{x}, \mathbf{p}) \leq 0,$$

along with the constraints of the lower-level program and its first-order KKT conditions, and a finite bound on the KKT multipliers

$$\mu_j \leq \mu_j^{max}.$$

If $\bar{\mathbf{x}}, \bar{\mathbf{p}}, \bar{\boldsymbol{\mu}}$ *is a feasible point of this MPEC, then* $\bar{\mathbf{x}}$ *is a feasible point of* (1.1).

Proof. Any feasible point $\bar{\mathbf{x}}, \bar{\mathbf{p}}, \bar{\boldsymbol{\mu}}$ of the constructed MPEC is also feasible in the MPEC without the bounds on the KKT multipliers. Since the first-order KKT conditions are sufficient for a global maximum of the lower-level program, $\bar{\mathbf{p}}$ is a global maximum of the lower-level program for $\mathbf{x} = \bar{\mathbf{x}}$. The constraint $g^o(\bar{\mathbf{x}}, \bar{\mathbf{p}}) \leq 0$ therefore ensures that the optimal solution value of the relaxed lower-level program satisfies $g^{o,U}(\bar{\mathbf{x}}) \leq 0$. Therefore, because g^o is a concave overestimator, also the optimal solution value of the original lower-level program satisfies $g^U(\bar{\mathbf{x}}) \leq 0$, or $\mathbf{x}$ is feasible in (1.1). Finally, adding an upper bound on the on the KKT multipliers is a third restriction. ∎

At this point a comparison with the interval inclusion approach by Bhattacharjee and coworkers [12, 13] is warranted. The MPEC problems typically have many more additional variables and constraints than the ICR and therefore are significantly harder to solve. Moreover, the stationarity and complementary slackness constraints are equality constraints, and state-of-the-art finitely terminating algorithms guarantee the feasibility of nonlinear equality constrained problems only within a tolerance. In some cases (see below) it can be shown that despite this approximation the generated points are guaranteed feasible in (1.1). On the other hand, typically, convex relaxations are tighter than interval extensions. As a consequence the proposed upper bounds will typically be tighter than those furnished by the ICR.

5.2.1. Smooth concave overestimation without auxiliary variables. We now consider a KKT-based upper bound based on the αBB method; such a bound has also been proposed in Floudas and Stein [19], and here we present some additional concepts, namely how to obtain bounds on the KKT multipliers and how to estimate the maximal constraint violation. As described in section 5.1.2, the smooth relaxation of the lower-level program via αBB results in a box-constrained maximization program

with a smooth concave objective function. Therefore, the first-order KKT conditions are necessary and sufficient for a global maximum and

$$
\begin{aligned}
f^{UBD,\alpha} = \min_{\mathbf{x},\mathbf{p},\boldsymbol{\mu}} \; & f(\mathbf{x}) \\
\text{s.t.} \; & -g^{o,\alpha}_{p_j}(\mathbf{x},\mathbf{p}) + \mu_j - \mu_{n_p+j} = 0, \quad j = 1,\dots,n_p, \\
& \mu_j(p_j - p_j^U) = 0, \quad j = 1,\dots,n_p, \\
& \mu_{n_p+j}(-p_j + p_j^L) = 0, \quad j = 1,\dots,n_p, \\
& g^{o,\alpha}(\mathbf{x},\mathbf{p}) \le 0, \\
& 0 \le \mu_j \le \mu_j^{max}, \quad j = 1,\dots,2n_p, \\
& \mathbf{x} \in X, \quad \mathbf{p} \in P,
\end{aligned}
\tag{5.2}
$$

is equivalent to the restricted SIP for sufficiently large $\boldsymbol{\mu}^{max}$. Note that the number of variables in (5.2) is equal to the original number of variables n_x plus up to three times the number of parameters ($3n_p$). In addition to the box constraints there are up to $3n_p$ equality constraints and one (most likely nonconvex) inequality constraint. Similar to the lower bounding problem, a reformulation to an MINLP is possible by introducing binary variables and eliminating the KKT multipliers.

The calculation of bounds on the KKT multipliers is equivalent to (4.2), (4.3), replacing g with $g^{o,\alpha}$. We first note that

$$
g^{o,\alpha}_{p_j}(\mathbf{x},\mathbf{p}) = g_{p_j}(\mathbf{x},\mathbf{p}) + \alpha(p_j^U - p_j) - \alpha(p_j - p_j^L).
$$

Therefore

$$
\begin{aligned}
\max_{\mathbf{x}\in X,\mathbf{p}\in P,p_j=p_j^U} g^{o,\alpha}_{p_j}(\mathbf{x},\mathbf{p}) &= -\alpha(p_j^U - p_j^L) + \max_{\mathbf{x}\in X,\mathbf{p}\in P,p_j=p_j^U} g_{p_j}(\mathbf{x},\mathbf{p}), \\
\max_{\mathbf{x}\in X,\mathbf{p}\in P,p_j=p_j^L} -g^{o,\alpha}_{p_j}(\mathbf{x},\mathbf{p}) &= \max_{\mathbf{x}\in X,\mathbf{p}\in P,p_j=p_j^L} -\left(g_{p_j}(\mathbf{x},\mathbf{p}) - \alpha(p_j^U - p_j^L)\right) \\
&= \alpha(p_j^U - p_j^L) - \min_{\mathbf{x}\in X,\mathbf{p}\in P,p_j=p_j^L} g_{p_j}(\mathbf{x},\mathbf{p}).
\end{aligned}
$$

Similar to the lower bounding problem, whenever a bound is nonpositive (function monotone) the corresponding variable and complementary slackness conditions are eliminated. For the γBB relaxation [5] the derivatives of the underestimating terms with respect to p_j are variable-dependent, but, evaluated at the variable bounds, they are given by $\gamma(e^{\gamma(p_j^U - p_j^L)} - 1)$ for $p_j = p_j^L$ and $\gamma(1 - e^{\gamma(p_j^U - p_j^L)})$ for $p_j = p_j^U$. Therefore, the calculation of bounds on the KKT multipliers is analogous.

As stated above, typical finitely terminating NLP solvers only approximate equality constraints. We will show that the feasibility of the points furnished can be easily verified, or the extent of constraint violation estimated.

PROPOSITION 5.2 (maximal constraint violation). *Consider $\bar{\mathbf{x}} \in X$, $\bar{\mathbf{p}} \in P$, and $\bar{\boldsymbol{\mu}} \ge \mathbf{0}$ such that $(\bar{\mathbf{x}},\bar{\mathbf{p}},\bar{\boldsymbol{\mu}})$ is an approximate feasible point of (5.2) in the sense of ε_{tol}-violation of the equality constraints*

$$
|-g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \bar{\mu}_j - \bar{\mu}_{n_p+j}| \le \varepsilon_{tol}, \quad j = 1,\dots,n_p, \tag{5.3}
$$

$$
|\bar{\mu}_j(\bar{p}_j - p_j^U)| \le \varepsilon_{tol}, \quad j = 1,\dots,n_p, \tag{5.4}
$$

$$
|\bar{\mu}_{n_p+j}(-\bar{p}_j + p_j^L)| \le \varepsilon_{tol}, \quad j = 1,\dots,n_p, \tag{5.5}
$$

$$
g^{o,\alpha}(\bar{\mathbf{x}},\bar{\mathbf{p}}) \le 0.
$$

Then $\bar{\mathbf{x}}$ *is an approximately feasible point of* (1.1) *in the sense*

$$g^U(\bar{\mathbf{x}}) \equiv \max_{\mathbf{p}\in P} g(\bar{\mathbf{x}},\mathbf{p}) \leq \varepsilon_{tol} \sum_{j=1}^{n_p} (1 + p_j^U - p_j^L).$$

Proof. Since $g^{o,\alpha}$ is a concave overestimator of g for each $\bar{\mathbf{x}}$ we have

$$g^U(\bar{\mathbf{x}}) \leq g^{o,\alpha,U}(\bar{\mathbf{x}}) \equiv \max_{\mathbf{p}\in P} g^{o,\alpha}(\bar{\mathbf{x}},\mathbf{p}). \tag{5.6}$$

Since $g^{o,\alpha}$ is partially concave on the convex set P we obtain [10, p. 675]

$$g^{o,\alpha}(\bar{\mathbf{x}},\mathbf{p}) \leq g^{o,\alpha}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_p} g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j) \qquad \forall \mathbf{p} \in P,$$

and therefore also

$$g^{o,\alpha,U}(\bar{\mathbf{x}}) \leq \max_{\mathbf{p}\in P} \left(g^{o,\alpha}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_p} g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j) \right).$$

The maximum of the above sum over P is attained at a vertex of P, and therefore

$$g^{o,\alpha,U}(\bar{\mathbf{x}}) \leq g^{o,\alpha}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_p} \max\left\{ g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j^U - \bar{p}_j), g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j^L - \bar{p}_j) \right\}. \tag{5.7}$$

Since $\bar{\boldsymbol{\mu}} \geq \mathbf{0}$ from (5.3) we obtain

$$\begin{aligned} |g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})| &\leq \bar{\mu}_j + \varepsilon_{tol}, \\ |g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})| &\leq \bar{\mu}_{n_p+j} + \varepsilon_{tol}, \end{aligned}$$

and therefore by (5.4), (5.5)

$$\begin{aligned} |g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j^U - \bar{p}_j)| &\leq \varepsilon_{tol}(1 + p_j^U - \bar{p}_j) \leq \varepsilon_{tol}(1 + p_j^U - p_j^L), \\ |g^{o,\alpha}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j^L - \bar{p}_j)| &\leq \varepsilon_{tol}(1 + \bar{p}_j - p_j^L) \leq \varepsilon_{tol}(1 + p_j^U - p_j^L). \end{aligned}$$

Combining the above inequalities with (5.6) and (5.7), we obtain the desired result. ∎

A practical way of ensuring that the points furnished by (5.2) are indeed feasible is to replace the constraint $g^{o,\alpha}(\mathbf{x},\mathbf{p}) \leq 0$ with $g^{o,\alpha}(\mathbf{x},\mathbf{p}) \leq -\varepsilon_{tol} \sum_{j=1}^{n_p}(1 + p_j^U - p_j^L)$. Note that this is a further restriction, and therefore again a valid upper bound is obtained.

5.2.2. Concave overestimation with auxiliary variables. We now consider the alternative of introducing auxiliary variables and constraints, (cf. section 5.1.3), which resulted in a lower-level program of the type (5.1). By convexity, the KKT

conditions are sufficient for a global maximum of the lower-level program and

$$
\begin{aligned}
f^{UBD,ex} = \min_{\mathbf{x},\tilde{\mathbf{p}},\boldsymbol{\mu}} \; & f(\mathbf{x}) \\
\text{s.t.} \; & -\boldsymbol{\nabla}_{\tilde{\mathbf{p}}} g^{o,ex}(\mathbf{x},\tilde{\mathbf{p}}) + \boldsymbol{\mu}^{\mathrm{T}} \boldsymbol{\nabla}_{\tilde{\mathbf{p}}} \mathbf{u}(\mathbf{x},\tilde{\mathbf{p}}) = \mathbf{0}, \\
& \mu_j u_j(\mathbf{x},\tilde{\mathbf{p}}) = 0, \quad j = 1,\ldots,n_u, \\
& g^{o,ex}(\mathbf{x},\tilde{\mathbf{p}}) \leq 0, \\
& \mathbf{u}(\mathbf{x},\tilde{\mathbf{p}}) \leq \mathbf{0}, \\
& \mu_j^{min} \leq \mu_j \leq \mu_j^{max}, \quad j = 1,\ldots,n_u, \\
& \mathbf{x} \in X, \quad \tilde{\mathbf{p}} \in \mathbb{R}^{n_{\tilde{p}}},
\end{aligned}
\tag{5.8}
$$

provides a valid upper bound of (1.1), where for inequality constraints $\mu_j^{min} = 0$. Recall that the number of variables in the lower-level problem $n_{\tilde{p}}$ and the number of KKT multipliers n_u depend on the number and type of factors in the factorable representation. Here a reformulation as an MINLP is possible by the introduction of binary variables, but elimination of the KKT multipliers does not seem possible in general.

At this point a discussion of potential disadvantages of (5.8) is warranted. The KKT conditions may not be necessary for problems of the type (5.1) since it has not been shown that the formulated constraints satisfy some constraint qualification (see also section 3.2.3). Moreover, obtaining valid upper bounds on the KKT multipliers is not always possible, so replacing the restricted SIP with an MPEC may be a further restriction and render the upper bounding program infeasible. To ensure convergence of the upper bounding problem this issue has to be addressed. Finally, through the introduction of extra variables, providing tight bounds on the maximal constraint violation seems intractable.

Example 5.4. Recall Example 5.1 and the relaxed lower-level program constructed in Example 5.3. The following MPEC is obtained as the upper bounding problem:

$$
\begin{aligned}
\min_{x,\tilde{\mathbf{p}},\boldsymbol{\mu}} \; & -x \\
s.t. \quad & 2\mu_1\tilde{p}_1 + \mu_4 - \mu_5 = 0, \\
& -\mu_1 + \mu_2 - x\mu_3 + \mu_6 - \mu_7 = 0, \\
& -(e-1) + \mu_3 + \mu_8 - \mu_9 = 0, \\
& \mu_1(\tilde{p}_1^2 - \tilde{p}_2) = 0, \\
& \mu_2(\tilde{p}_2 - 1) = 0, \\
& \mu_3(\tilde{p}_3 - x\tilde{p}_2) = 0, \\
& \mu_4(\tilde{p}_1 - 1) = 0, \\
& \mu_5(-1 - \tilde{p}_1) = 0, \\
& \mu_6(\tilde{p}_2 - 1) = 0, \\
& \mu_7(-\tilde{p}_2) = 0, \\
& \mu_8(\tilde{p}_3 - 1) = 0, \\
& \mu_9(-\tilde{p}_2) = 0, \\
& \tilde{p}_3(e-1) \leq 0, \\
& \tilde{p}_1^2 - \tilde{p}_2 \leq 0, \\
& \tilde{p}_2 - 1 \leq 0, \\
& \tilde{p}_3 - x\tilde{p}_2 = 0,
\end{aligned}
$$

$$\begin{aligned}
&\mu_3 \in [\mu_3^{min}, \mu_3^{max}],\\
&\mu_j \in [0, \mu_j^{max}], \quad j = 1, \ldots, 9 : j \neq 3,\\
&x \in [-1, 1],\\
&\tilde{\mathbf{p}} \in [-1, 1] \times [0, 1] \times [0, 1].
\end{aligned}$$

5.3. Linearization-based upper bound. Similar to the MPEC-based upper bounds, the first step in the linearization-based upper bounds is to construct a convex relaxation of the lower-level program and thus a restriction of (1.1):

$$\begin{aligned}
&\min_{\mathbf{x}\in X} f(\mathbf{x})\\
&\text{s.t. } g^o(\mathbf{x}, \mathbf{p}) \leq 0 \quad \forall \mathbf{p} \in P,
\end{aligned}$$

where $g^o : X \times P \to \mathbb{R}$ is partially concave on P for each $\mathbf{x} \in X$ and $g^o(\mathbf{x}, \mathbf{p})$ overestimates $g(\mathbf{x}, \mathbf{p})$. Note that for the approach involving auxiliary variables a somewhat different treatment is needed, and this is described in section 5.3.3.

The second step further restricts the generated SIP by linearizing at an arbitrary interior point $\bar{\mathbf{p}} \in \text{int}(P)$, pointwise in X, and creating the following SIP:

$$\begin{aligned}
&\min_{\mathbf{x}\in X} f(\mathbf{x})\\
&\text{s.t. } g^{o,lin}(\mathbf{x}, \mathbf{p}) \leq 0 \quad \forall \mathbf{p} \in P,
\end{aligned} \tag{5.9}$$

where $g^{o,lin}(\mathbf{x}, \mathbf{p}) \equiv g^o(\mathbf{x}, \bar{\mathbf{p}}) + \sum_{j=1}^{n_p} g^o_{p_j}(\mathbf{x}, \bar{\mathbf{p}})(p_j - \bar{p}_j)$. Here g_{p_j} denotes a partial derivative or, with an abuse of notation, subgradient. An equivalent nonsmooth reformulation of (5.9) is the following problem:

$$\begin{aligned}
&\min_{\mathbf{x}\in X} f(\mathbf{x})\\
&\text{s.t. } \max_{\mathbf{p}\in P} g^{o,lin}(\mathbf{x}, \mathbf{p}) \leq 0.
\end{aligned} \tag{5.10}$$

Since $g^{o,lin}$ is affine in $\mathbf{p}$, the maximum of $g^{o,lin}(\mathbf{x}, \cdot)$ on P will be attained at one of the vertices P_e of P for each $\mathbf{x}$ in X. Therefore an equivalent finite representation of (5.10) is

$$\begin{aligned}
&\min_{\mathbf{x}\in X} f(\mathbf{x})\\
&\text{s.t. } g^{o,lin}(\mathbf{x}, \mathbf{p}) \leq 0 \quad \forall \mathbf{p} \in P_e.
\end{aligned} \tag{5.11}$$

While for any $\bar{\mathbf{p}} \in P$ the formulated finite NLP (5.11) is a valid restriction of (1.1), the choice of $\bar{\mathbf{p}}$ greatly affects the strength of the generated upper bounds. Compared to the MPEC-based upper bound, this linearization approach presents the inherent advantage that it avoids the use of equality constraints (complementarity and stationarity conditions), and any feasible point of (5.11) is guaranteed feasible for (1.1). On the other hand, the MPEC approach introduces a polynomial (in the number of inner variables or in the number of inner variables and nonconvex terms) number of constraints, whereas the linearization approach introduces a potentially exponential number of constraints. Moreover, the linearization approach produces bounds that are at best as tight as the MPEC-based ones, assuming that both problems are solved to global optimality.

If either of the two following relationships holds for variable p_j,

$$\max_{\mathbf{x}\in X} g^o_{p_j}(\mathbf{x},\bar{\mathbf{p}}) \le 0,$$
$$\min_{\mathbf{x}\in X} g^o_{p_j}(\mathbf{x},\bar{\mathbf{p}}) \ge 0,$$

the number of constraints can be reduced. The following procedure describes how to obtain the (sufficient) subset of extreme points P_{e^*} that needs to be considered in problem (5.11):

- Initialize $P_{e^*} := P_e$.
- **FOR** $j = 1,\dots,n_p$ **DO**
  - **IF** $\max_{\mathbf{x}\in X} g^o_{p_j}(\mathbf{x},\bar{\mathbf{p}}) \le 0$ **THEN** $P_{e^*} := \{\mathbf{p}\in P_{e^*} : p_j = p_j^L\}$
    ELSE IF $\min_{\mathbf{x}\in X} g^o_{p_j}(\mathbf{x},\bar{\mathbf{p}}) \ge 0$ **THEN** $P_{e^*} := \{\mathbf{p}\in P_{e^*} : p_j = p_j^U\}$.

  END

Evaluating the above optimization programs is expensive, and we propose to estimate them using interval extensions.

5.3.1. Smooth concave overestimation without auxiliary variables. Recall that the concave relaxation of g on P using αBB techniques has the form

$$g^{o,\alpha}(\mathbf{x},\mathbf{p}) = g(\mathbf{x},\mathbf{p}) + \alpha\sum_{j=1}^{n_p}(p_j - p_j^L)(p_j^U - p_j),$$

and the linearized approximation of the αBB concave relaxation around a point $\bar{\mathbf{p}}\in P$ is

$$g^{o,\alpha,lin}(\mathbf{x},\mathbf{p}) = g^{o,\alpha}(\mathbf{x},\bar{\mathbf{p}}) + \sum_{j=1}^{n_p} g_{p_j}(\mathbf{x},\bar{\mathbf{p}})(p_j-\bar{p}_j) + \alpha\sum_{j=1}^{n_p}(-2\bar{p}_j + p_j^L + p_j^U)(p_j-\bar{p}_j).$$

Therefore, the αBB-based linearized upper bounding problem is of the form

$$\min_{\mathbf{x}\in X} f(\mathbf{x})$$
$$\text{s.t. } g^{o,\alpha,lin}(\mathbf{x},\mathbf{p}) \le 0 \quad \forall \mathbf{p}\in P_{e^*},$$

where P_{e^*} is calculated by the following procedure:

- Initialize $P_{e^*} := P_e$.
- **FOR** $j = 1,\dots,n_p$ **DO**
  - **IF** $\max_{\mathbf{x}\in X} g_{p_j}(\mathbf{x},\bar{\mathbf{p}}) \le \alpha(2\bar{p}_j - p_j^L - p_j^U)$ **THEN** $P_{e^*} := \{\mathbf{p}\in P_{e^*} : p_j = p_j^L\}$
    ELSE IF $\min_{\mathbf{x}\in X} g_{p_j}(\mathbf{x},\bar{\mathbf{p}}) \ge \alpha(2\bar{p}_j - p_j^L - p_j^U)$ **THEN** $P_{e^*} := \{\mathbf{p}\in P_{e^*} : p_j = p_j^U\}$.

  END

Again we propose to estimate the above optimization problems by interval extensions.

5.3.2. Nonsmooth concave overestimation without auxiliary variables. Similar to the aforementioned technique, the goal of this method is to introduce a concave overestimator of the constraint g with respect to the inner variables $\mathbf{p}$ using the McCormick technique, and then to linearize the resulting expression around an arbitrary point $\bar{\mathbf{p}}\in P$.

As described in section 5.1.1 and demonstrated in Example 5.1, the value of $\mathbf{x}$ can influence the functional form of the convex and concave overestimators. Therefore,

the linearized constraint $g^{o,mc,lin}(\cdot,\mathbf{p}) \leq 0$ evaluated at the vertices of the parameter set $\mathbf{p} \in P_e$ is typically nonsmooth with respect to $\mathbf{x}$. This is very similar to the ICR by Bhattacharjee, Green, and Barton [12], and we propose to work around the nonsmoothness in the same way, namely to use both constraints for each min / max statement resulting from a joint term in $\mathbf{x}$ and $\mathbf{p}$. This is a further restriction and as such provides a valid upper bound. For nested min / max statements the number of constraints becomes exponential in the number min / max statements. Alternatives such as the MINLP reformulation in [12] are also possible.

Similar to the linearization of the smooth concave overestimation, the set of vertices at which the constraints are evaluated can be reduced if the subgradients $g^{o,mc}(\mathbf{x},\cdot)$ at $\bar{\mathbf{p}}$ have positive or negative elements for all $\mathbf{x} \in X$.

Example 5.5. Recall Example 5.1. Linearizing the McCormick relaxation at $\bar{p} = 0$ gives

$$\begin{aligned} &e^{\min\{0,x\}} + \frac{\max\{x,0\} - \min\{0,x\}}{\max\{0,x\} - \min\{0,x\}} \left(e^{\max\{0,x\}} - e^{\min\{0,x\}}\right) - 1 \\ &= e^{\max\{0,x\}} - 1 = \max\{e^0, e^x\} - 1 = \max\{1, e^x\} - 1 = \max\{0, e^x - 1\}. \end{aligned}$$

Introducing the constraint $\max\{0, e^x - 1\} \leq 0$ would give a nonsmooth NLP, and we instead use two constraints corresponding to $x \geq 0$ and $x \leq 0$. In principle these constraints are evaluated at the vertices of P, but since the subgradient at $\bar{p} = 0$ is given by 0, the constraints are introduced only for one parameter value. The resulting single-level program is

$$\begin{aligned} \min_{x \in [-1,1]} \; & -x \\ \text{s.t. } & 0 \leq 0, \\ & e^x - 1 \leq 0. \end{aligned}$$

Incidentally, the above NLP is convex and has the same feasible set as the original program and therefore the same optimal solution point and value.

5.3.3. Smooth concave overestimation with auxiliary variables. A method to create a valid upper bound for (1.1) based on smooth concave overestimation of $g(\mathbf{x},\cdot)$ using auxiliary variables was presented in section 5.2.2. Recall that the following GSIP is a restriction of (1.1):

$$\begin{aligned} &\min_{\mathbf{x} \in X} f(\mathbf{x}) \\ &\text{s.t. } g^{o,ex}(\mathbf{x},\tilde{\mathbf{p}}) \leq 0 \quad \forall \tilde{\mathbf{p}} \in \mathbb{R}^{n_{\tilde{p}}} : \mathbf{u}(\mathbf{x},\tilde{\mathbf{p}}) \leq \mathbf{0}, \end{aligned} \tag{5.12}$$

where the parameters $\tilde{\mathbf{p}}$ contain the original parameters $\mathbf{p}$ and auxiliary parameters representing expressions of the variables and parameters. Bounds on the auxiliary parameters are propagated through interval extensions. The linearization approaches require that the set of parameter vertices be easily calculated, which is not the case here. Therefore, a further restriction of (5.12) is obtained by dropping the lower-level constraints with the exception of the bound constraints

$$\begin{aligned} &\min_{\mathbf{x} \in X} f(\mathbf{x}) \\ &\text{s.t. } g^{o,ex}(\mathbf{x},\tilde{\mathbf{p}}) \leq 0 \quad \forall \tilde{\mathbf{p}} \in \tilde{P}, \end{aligned} \tag{5.13}$$

and therefore further relaxing the lower-level program and thus further restricting (5.12). Taking into consideration that $g^{o,ex}(\mathbf{x},\cdot)$ is partially concave on $\tilde{P}$ for each $\mathbf{x} \in X$ and similar to the linearization approaches already presented, the following linearization of (5.13) around an arbitrary point $\bar{\mathbf{p}} \in \tilde{P}$ furnishes an upper bound for (1.1):

$$\begin{aligned} &\min_{\mathbf{x}\in X} f(\mathbf{x}) \\ &\text{s.t. } g^{o,ex}(\mathbf{x},\bar{\mathbf{p}}) + \sum_{j=1}^{n_{\tilde{p}}} g^{o,ex}_{p_j}(\mathbf{x},\bar{\mathbf{p}})(\tilde{p}_j - \bar{p}_j) \le 0 \quad \forall \tilde{\mathbf{p}} \in \tilde{P}_e, \end{aligned}$$

where $\tilde{P}_e$ denotes the set of vertices of $\tilde{P}$. Recall that the set of vertices considered can be reduced if the functions can be demonstrated to be monotone with respect to some parameters.

5.4. Relaxation over X and P. The upper bounding methodologies that have been presented so far rely on creating a function g^o that is partially concave with respect to the parameters $\mathbf{p}$ pointwise for each $\mathbf{x} \in X$. Another way of creating a valid overestimator of g is to construct a jointly concave function $g^{o,j}$ on $X \times P$, i.e., with respect to both the variables $\mathbf{x}$ and the parameters $\mathbf{p}$, using either McCormick or αBB concave relaxation methods, that satisfies

$$g^{o,j}(\mathbf{x},\mathbf{p}) \ge g(\mathbf{x},\mathbf{p}) \quad \forall (\mathbf{x},\mathbf{p}) \in X \times P.$$

Then, the following SIP is a restriction of (1.1):

$$\begin{aligned} &\min_{\mathbf{x}\in X} f(\mathbf{x}) \\ &\text{s.t. } g^{o,j}(\mathbf{x},\mathbf{p}) \le 0 \quad \forall \mathbf{p} \in P. \end{aligned} \tag{5.14}$$

Note that for convergence both host sets (X and P) need to be refined.

5.4.1. Linearization. Similar to the linearization approaches that have been presented so far, and since $g^{o,j}$ is concave on $X \times P$, we can linearize (5.14) around an arbitrary interior point $(\bar{\mathbf{x}},\bar{\mathbf{p}}) \in \operatorname{int}(X \times P)$ to obtain the following restriction of (1.1):

$$\begin{aligned} &\min_{\mathbf{x}\in X} f(\mathbf{x}) \\ &\text{s.t. } g^{o,j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_x} g^{o,j}_{x_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(x_j - \bar{x}_j) + \sum_{j=1}^{n_p} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j) \le 0 \quad \forall \mathbf{p} \in P_e, \end{aligned} \tag{5.15}$$

where g_{x_j} and g_{p_j} denote partial derivatives or, with an abuse of notation, subgradients. By the separability and linearity of the constraint in (5.16), a single inequality constraint is needed; i.e., P_e can be replaced by a single point $\mathbf{p}^*$ calculated by the following procedure:

- **FOR** $j = 1,\dots,n_p$ **DO**
  - **IF** $g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) \le 0$ **THEN** $p^*_j = p^L_j$ **ELSE** $p^*_j = p^U_j$.

  END

Indeed, by construction of $\mathbf{p}^*$ for each $j = 1,\dots,n_p$, we have

$$\max_{\mathbf{p}\in P} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j) = \max_{\mathbf{p}\in P^e} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j) = g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p^*_j - \bar{p}_j).$$

Therefore, we also obtain for each $\mathbf{x} \in X$

$$\begin{aligned}
&\max_{\mathbf{p}\in P} g^{o,j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_x} g^{o,j}_{x_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(x_j - \bar{x}_j) + \sum_{j=1}^{n_p} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j)\\
&= \max_{\mathbf{p}\in P^e} g^{o,j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_x} g^{o,j}_{x_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(x_j - \bar{x}_j) + \sum_{j=1}^{n_p} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p_j - \bar{p}_j)\\
&= g^{o,j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_x} g^{o,j}_{x_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(x_j - \bar{x}_j) + \sum_{j=1}^{n_p} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p^*_j - \bar{p}_j).
\end{aligned}$$

Therefore the following NLP with a single linear inequality constraint,

$$\begin{aligned}
&\min_{\mathbf{x}\in X} f(\mathbf{x})\\
&\text{s.t. } g^{o,j}(\bar{\mathbf{x}},\bar{\mathbf{p}}) + \sum_{j=1}^{n_x} g^{o,j}_{x_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(x_j - \bar{x}_j) + \sum_{j=1}^{n_p} g^{o,j}_{p_j}(\bar{\mathbf{x}},\bar{\mathbf{p}})(p^*_j - \bar{p}_j) \le 0,
\end{aligned}$$

provides a valid upper bound for (1.1).

This approach will obviously furnish looser upper bounds than the ones produced by the MPEC and linearization approaches that rely on the concave overestimation of g only with respect to the parameters $\mathbf{p}$. However, a single linear inequality is required, compared to the polynomial or exponential number of nonlinear constraints. Again, the choice of $\bar{\mathbf{p}}$ greatly affects the tightness of the proposed upper bound.

5.4.2. MPEC formulation. Similar to the MPEC approach that was described in section 5.2, a possible bounding problem is to replace the lower-level problem of (5.14) with its equivalent KKT conditions and solve the resulting problem to obtain an upper bound. Although this method would produce valid upper bounds, there are two distinct drawbacks compared to the MPEC approach that relies on concave relaxation of g only with respect to $\mathbf{p}$. First, the process of creating a concave overestimator of g on $X \times P$ will replace convex and nonconvex, with respect to $\mathbf{x}$, terms by concave ones which does not seem to simplify the solution of the resulting problem. Secondly, the generated relaxation will be weaker. Note that, even using αBB techniques, the value of α would be greater than or equal to the value of α that corresponds to the concave relaxation only on P because the Hessian increases in size. In conclusion, this method does not seem to produce either tighter bounds or simpler constraint expressions and will, therefore, not be analyzed further.

5.5. Convergence of upper bounding problems. The various alternatives described restrict the SIP (1.1) by overestimating the function $g(\mathbf{x},\cdot)$ pointwise in X. In the nonsmooth interpretation of SIP (1.2) the parametric optimal solution value of the lower-level program $g^U(\mathbf{x})$ is overestimated, obtaining

$$\begin{aligned}
&\min_{\mathbf{x}\in X} f(\mathbf{x})\\
&\text{s.t.} \quad g^{o,U}(\mathbf{x}) \le 0,
\end{aligned}$$

with $g^{o,U}(\mathbf{x}) \ge g^U(\mathbf{x})$. As described in section 3, this relaxation of the lower-level program leads to a restriction of the SIP. In general, this restriction excludes some feasible points and may even render the upper bounding problem infeasible. To ensure

that the upper bound converges to the optimal solution value, a subdivision of the parameter host set P, as in [13], is deemed necessary. As in the lower bounding problem, for the subdivision additional variables and/or constraints will be introduced. Methods for efficient convergence are outside the scope of this paper, and here we only briefly discuss basic convergence properties.

Similarly to the ICR of Bhattacharjee and coworkers [12, 13] and the proposal by Floudas and Stein [19], an exhaustive subdivision of the parameter set P leads to a pointwise convergence of $g^{o,U}$ to g^U. Therefore, points $\bar{\mathbf{x}}$ satisfying $\max_{\mathbf{p}\in P} g(\bar{\mathbf{x}}, \mathbf{p}) < 0$, i.e., SIP Slater points, become feasible in the upper bounding problems for a sufficiently fine subdivision. As a consequence, if the upper bounding problems are solved to global optimality and SIP Slater points exist arbitrarily close to a global minimum of (1.1), the upper bound converges to the optimal solution value.

6. Implementation and numerical results.

6.1. Implementation. The proposed lower and upper bounding problems potentially contain nonconvex objective function and/or constraints. Aiming to obtain the best possible bounds, we solve all the problems globally with BARON version 7.5 [44], available through GAMS version 22.1 [15], on a 64-bit Xeon 3.2GHz processor running Linux 2.6.13.

As is typical in NLP and MINLP solvers, BARON allows the violation of inequality and equality tolerances by a positive tolerance. For the lower bounding problem this is a further relaxation and thus of no concern, but it is a limitation for the upper bounding problems involving equality constraints. Note that the inequality constraint $g(\mathbf{x}, \mathbf{p}) \leq 0$ can be further restricted to $g(\mathbf{x}, \mathbf{p}) \leq -\varepsilon$, for an ε equal to the constraint violation of the NLP solver, and therefore does not pose a significant problem. To obtain good estimates we set the smallest possible value (10^{-9}) for the relevant tolerances (`conttol, boxtol, inttol`). The absolute and relative termination criteria, i.e., the difference between the lower and upper bounds in the subproblems, are set to 10^{-4}. Our previous numerical experiments with similar programs have shown slow convergence for problems involving third-order monomials, e.g., x^3, and for consistency purposes we systematically encode third-order monomials as a product of a square and a linear term, e.g., $x^2\, x$, and fourth-order monomials as the product of two squares, e.g., $x^2\, x^2$.

The complementary slackness conditions in the lower bounding problem are formulated using the big-M formulation, since binary variables are needed for the second-order conditions. In the upper bounding problem the complementary slackness conditions are left as nonlinear equations. For the discretization approach in the lower bounding problems we follow the heuristic in [13] and define the discretization set P_D as the upper right endpoints, i.e., $P_D = \{\mathbf{p}^U\}$. For the linearizations the midpoint of P is used.

Since the problems considered are relatively small, for the αBB relaxations we obtain the smallest possible α through the solution of a global optimization problem. This is done in the spirit of obtaining the tightest possible bounds. On the other hand, the bounds on the KKT multipliers and the second derivatives are estimated using the natural interval extensions capabilities of DAEPACK [53, 54]. For the MPEC-based upper bound using relaxation with extra variables, the upper bound for the KKT multipliers is set to 10^3. Note that overestimating the bounds for the multipliers typically increases the computational requirements (in CPU seconds) to solve the problems.

6.2. Numerical results. As a test set we use the well-established problems by Watson [57], summarized in Appendix A. Since BARON and DAEPACK currently do not support trigonometric functions, we only use those examples that do not involve trigonometric functions. For all problems we used $\mathbf{x} \in [-10, 10]^{n_x}$.

Tables 6.1 and 6.2 respectively contain the computational requirement as reported by BARON (through the GAMS attribute `resusd`) and the bounding values obtained. No distinction is made for times below 0.01s. In three cases (all KKT-based upper bounding problems) we distinguish between the time to find the optimal solution value and to confirm it (number in brackets) because the two computational requirements differ dramatically. The first column (label) has the label of the problem, while the column labeled f^* contains the best known solution for the problem. The following four columns show the results from the lower bounding problems. P_D denotes discretization, KKT-1 results by applying the necessary first-order KKT conditions, KKT-2 by applying the necessary first- and second-order KKT conditions, and P_D+KKT by combining the necessary first- and second-order KKT conditions with discretization. The next six columns contain the upper bounds obtained by our upper bounding proposals, labeled by the corresponding sections. The final column (ICR) is the interval constrained reformulation by Bhattacharjee, Green, and Barton [12]. To ensure that we have comparable solution times we reproduced the ICR from [12]. In Table 6.1 the best lower and upper bounds for each problem are highlighted by a bold font.

6.3. Conclusions from numerical experiments. The proposed lower and upper bounding problems bracket the optimal solution value quite successfully. Furthermore, the bounds furnished are often exact, and in some cases both the upper and the lower bounds are exact. The computational requirement for obtaining upper and lower bounds is quite low for the small-scale problems considered; note that for the case of a KKT-based upper bound with extra variables, the computational requirement for confirming the global solution is quite high for three problems involving two

parameters. Recall also from sections 4.4 and 5.5 and [12, 13, 19] that subdivision methods would tighten the bounds in the cases for which they are not exact.

The combination of discretization and KKT conditions produces tighter lower bounds than either of the methods taken alone. Moreover, the additional constraints accelerate convergence compared to when only the KKT conditions are used. Similarly the addition of the second-order consideration can help accelerate convergence and/or furnish a tighter bound.

As expected, the KKT-based upper bounds using extra variables (section 5.2.2) can be significantly tighter than the ICR-based, at the expense of a higher computational cost. Surprisingly, the linearization-based bounds using auxiliary variables (section 5.3.3) produced bounds as tight as the ones based on the KKT conditions; we believe that this is due to the problem structure. The bounds based on smooth relaxation without extra variables (sections 5.2.1 and 5.3.1) are relatively weak. We want to again point out that we deviated from the αBB relaxation described by Adjiman and Floudas [4] and considered the constraint as a whole. Note finally that the number of parameters in the problems considered is small ($n_p \in \{1, 2\}$), and therefore the effect of the exponential number of constraints in the linearization (sections 5.3.1, 5.3.2, and 5.3.3) is not apparent.

7. Conclusions and future work. We consider SIPs that involve nonconvex functions and present lower and upper bounding problems. For the lower bounding problem we combine and extend literature ideas based on discretization and the necessary KKT conditions of the lower-level program. The upper bounding problem is constructed based on a convex relaxation of the lower-level program which results in a restriction of the SIP, similarly to the ICR of Bhattacharjee and coworkers [12, 13]. The resulting lower-level programs are replaced by the sufficient KKT conditions or further relaxed by linearization. The proposed upper bounding methodology is more expensive than ICR, but often leads to tighter upper bounds. What the method of choice is will most likely depend on the problem size and structure. Therefore further experimentation with a large set of problems of various sizes is of interest. To that extent an automation of the convex relaxation such as the one proposed by Gatzke, Tolsma, and Barton [21] is deemed necessary. Furthermore, the comparison of different solvers is also of interest.

Many of the ideas proposed can be refined, such as the second-order check for the lower bound, which, currently, is relatively weak. Another example is to produce good heuristics for the parameter values around which to linearize. A third example is that for the αBB method we calculated α uniformly over X by taking interval extensions on $X \times P$; instead it would be interesting to consider a method similar to what we developed for the McCormick relaxations, and calculate different α for different subsets of X.

We considered global solution of all bounding problems, which is computationally expensive. For the lower bounding problem a further convex relaxation could be solved with a local solver. For the upper bounding problem local methods could be applied, but these may fail. For implementation within a branch-and-bound framework for the global solution of SIP there is a trade-off between expensive and tight versus cheap and loose bounds. A promising heuristic is to solve these problems with a global solver such as BARON [44] and a loose termination criterion.

It seems very promising to combine some of the ideas presented. A simple combination is to periodically employ the tighter and more expensive bounding problems. A more elaborate combination is to use a KKT-based upper bounding problem but

solve the resulting MPEC only approximately to obtain a point $\bar{\mathbf{x}}$ and an estimate for the corresponding optimal solution of the relaxed lower-level problem $\bar{\mathbf{p}}$. Then the feasibility of $\bar{\mathbf{x}}$ can be probed by linearizing the concave lower-level problem around $\bar{\mathbf{p}}$. This approach is difficult to implement with black-box NLP solvers, but could be easily implemented in a framework such as the NCP approach by Floudas and Stein [19]. The promise of the combination is that an approximate solution of the MPEC will provide a point $\bar{\mathbf{p}}$ which is suitable for linearization.

In this paper we consider a single semi-infinite constraint. An interesting extension is to consider many semi-infinite constraints, for which several alternatives for extending our proposals could be applied. One possibility is to consider many lower-level programs by the introduction of as many sets of parameters $\mathbf{p}^i$ as there are constraints. Another alternative is to introduce an SOS-1 set of binary variables

$$\mathbf{y} \in \{0,1\}^{n_g}, \qquad \sum_{i=1}^{n_g} y_i = 1, \qquad y_j = 1 \Leftrightarrow g_i(\mathbf{x},\mathbf{p}) \geq \max_i g_i(\mathbf{x},\mathbf{p}),$$

where n_g is the number of constraints. Then a logical constraint

$$(y_j = 1) \Rightarrow \mathbf{p} \text{ is a KKT point of } g_j$$

can be implemented.

In this paper we assumed that the parameter host set is explicitly given as a box. An interesting extension is to consider general host sets. Another interesting extension is to generalized semi-infinite constraints. In a forthcoming publication [27] we analyze which of the proposed methods can be extended to GSIP and provide numerical results from an extensive test set.

In discretization approaches tightening of lower bounds can be achieved by gradually increasing the cardinality of the finite set of parameters considered, and therefore increasing the number of constraints [13]. Bhattacharjee et al. [13] employed a subdivision approach to tighten the upper bound, which also leads to an increase in the number of constraints. For our proposed lower and upper bounding problems a subdivision of P is also deemed necessary for convergence, and this will lead to an increase in the number of constraints. Moreover, for the bounding problems based on MPEC, an increase in the number of variables is also expected, making the solution of the MPEC increasingly expensive for finer subdivisions. A possible heuristic is to include the KKT-based upper bound only for a subset of the sets P^i and to use the interval extensions for the rest.

Appendix A. Test set. For consistency purposes we use the problem labels of Watson [57].

2.

$$\begin{aligned} P &= [0,1], \\ f(\mathbf{x}) &= \frac{1}{3}x_1^2 + x_2^2 + \frac{1}{2}x_1, \\ g(\mathbf{x},p) &= (1 - x_1^2\,p^2)^2 - x_1\,p^2 - x_2^2 + x_2. \end{aligned}$$

5.

$$\begin{aligned} P &= [0,1], \\ f(\mathbf{x}) &= e^{x_1} + e^{x_2} + e^{x_3}, \\ g(\mathbf{x},p) &= \frac{1}{1+p^2} - x_1 - x_2\,p - x_3\,p^2. \end{aligned}$$

6.

$$\begin{aligned} P &= [0,1], \\ f(\mathbf{x}) &= (x_1 - 2\,x_2 + 5\,x_2^2 - x_2^2\,x_2 - 13)^2 + (x_1 - 14x_2 + x_2^2 + x_2^3 - 29)^2, \\ g(\mathbf{x},p) &= x_1^2 + 2\,x_2\,p^2 + e^{x_1+x_2} - e^p. \end{aligned}$$

Note that in [12] the exponent is missing in the first term of the objective function.

7.

$$\begin{aligned} P &= [0,1]^2, \\ f(\mathbf{x}) &= x_1^2 + x_2^2 + x_3^2, \\ g(\mathbf{x},\mathbf{p}) &= x_1\,(p_1 + p_2^2 + 1) + x_2\,(p_1\,p_2 - p_2^2) + x_3\,(p_1\,p_2 + p_2^2 + p_2) + 1. \end{aligned}$$

8.

$$\begin{aligned} P &= [0,1]^2, \\ f(\mathbf{x}) &= x_1 + \frac{1}{2}x_2 + \frac{1}{2}x_3 + \frac{1}{3}x_4 + \frac{1}{4}x_5 + \frac{1}{3}x_6, \\ g(\mathbf{x},\mathbf{p}) &= e^{p_1^2+p_2^2} - x_1 - x_2\,p_1 - x_3\,p_2 - x_4\,p_1^2 - x_5\,p_1\,p_2 - x_6\,p_2^2. \end{aligned}$$

Note that presumably in Watson's collection [57] the coefficient of x_4 in the objective function is mistyped. This is suggested by the optimal solution value reported in [57] and by the symmetry of the problem with respect to the variables x_4 and x_6.

9.

$$\begin{aligned} P &= [-1,1]^2, \\ f(\mathbf{x}) &= -4\,x_1 - \frac{2}{3}(x_4 + x_6), \\ g(\mathbf{x},\mathbf{p}) &= x_1 + x_2\,p_1 + x_3\,p_2 + x_4\,p_1^2 + x_5\,p_1\,p_2 + x_6\,p_2^2 - 3 - (p_1 - p_2)^2\,(p_1 + p_2)^2. \end{aligned}$$

N.

$$\begin{aligned} P &= [-1,1], \\ f(\mathbf{x}) &= x_2, \\ g(\mathbf{x},p) &= 2\,x_1^2\,p^2 - p^4 + x_1^2 - x_2. \end{aligned}$$

Appendix B. McCormick relaxations of the product of two functions. In this section we will show the convex and concave relaxations for a product of two functions $g_1(\mathbf{z})g_2(\mathbf{z})$ on $Z \subset \mathbb{R}^{n_z}$; compare also the treatment of trilinear terms in [29].

Assume that there exist convex functions g_1^u and g_2^u and concave functions g_1^o and g_2^o that satisfy

$$\begin{aligned} g_1^u(\mathbf{z}) \le g_1(\mathbf{z}) \le g_1^o(\mathbf{z}) \quad \forall \mathbf{z} \in Z, \\ g_2^u(\mathbf{z}) \le g_2(\mathbf{z}) \le g_2^o(\mathbf{z}) \quad \forall \mathbf{z} \in Z. \end{aligned}$$

Furthermore, let $G_1^L, G_1^U, G_2^L, G_2^U$ satisfy

$$\begin{aligned} G_1^L \le g_1(\mathbf{z}) \le G_1^U \quad \forall \mathbf{z} \in Z, \\ G_2^L \le g_2(\mathbf{z}) \le G_2^U \quad \forall \mathbf{z} \in Z. \end{aligned}$$

Then using the following definitions,

$$\alpha_1(\mathbf{z}) = \begin{cases} G_2^L g_1^u(\mathbf{z}) & \text{if } G_2^L \ge 0, \\ G_2^L g_1^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\alpha_2(\mathbf{z}) = \begin{cases} G_1^L g_2^u(\mathbf{z}) & \text{if } G_1^L \ge 0, \\ G_1^L g_2^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\beta_1(\mathbf{z}) = \begin{cases} G_2^U g_1^u(\mathbf{z}) & \text{if } G_2^U \ge 0, \\ G_2^U g_1^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\beta_2(\mathbf{z}) = \begin{cases} G_1^U g_2^u(\mathbf{z}) & \text{if } G_1^U \ge 0, \\ G_1^U g_2^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\gamma_1(\mathbf{z}) = \begin{cases} G_2^L g_1^u(\mathbf{z}) & \text{if } G_2^L \le 0, \\ G_2^L g_1^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\gamma_2(\mathbf{z}) = \begin{cases} G_1^U g_2^u(\mathbf{z}) & \text{if } G_1^U \le 0, \\ G_1^U g_2^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\delta_1(\mathbf{z}) = \begin{cases} G_2^U g_1^u(\mathbf{z}) & \text{if } G_2^U \le 0, \\ G_2^U g_1^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

$$\delta_2(\mathbf{z}) = \begin{cases} G_1^L g_2^u(\mathbf{z}) & \text{if } G_1^L \le 0, \\ G_1^L g_2^o(\mathbf{z}) & \text{otherwise,} \end{cases}$$

valid convex and concave (g^u and g^o) relaxations of g on Z are given by

$$\begin{aligned} g^u(\mathbf{z}) \ge \max\{\alpha_1(\mathbf{z}) + \alpha_2(\mathbf{z}) - G_1^L G_2^L, \beta_1(\mathbf{z}) + \beta_2(\mathbf{z}) - G_1^U G_2^U\}, \\ g^o(\mathbf{z}) \le \min\{\gamma_1(\mathbf{z}) + \gamma_2(\mathbf{z}) - G_1^U G_2^L, \delta_1(\mathbf{z}) + \delta_2(\mathbf{z}) - G_1^L G_2^U\}. \end{aligned}$$

Acknowledgments. We would like to thank Benoît Chachuat for fruitful discussions. We are also grateful to the anonymous reviewers for the thorough analysis and detailed comments that considerably improved this paper.

PRIMAL-DUAL AFFINE SCALING INTERIOR POINT METHODS FOR LINEAR COMPLEMENTARITY PROBLEMS*

FLORIAN A. POTRA†

Abstract. A first order affine scaling method and two mth order affine scaling methods for solving monotone linear complementarity problems (LCPs) are presented. All three methods produce iterates in a wide neighborhood of the central path. The first order method has $O(nL^2(\log nL^2)(\log\log nL^2))$ iteration complexity. If the LCP admits a strict complementary solution, then both the duality gap and the iteration sequence converge superlinearly with Q-order two. If $m = \Omega(\log(\sqrt{n}L))$, then both higher order methods have $O(\sqrt{n})L$ iteration complexity. The Q-order of convergence of one of the methods is $(m+1)$ for problems that admit a strict complementarity solution, while the Q-order of convergence of the other method is $(m+1)/2$ for general monotone LCPs.

Key words. linear complementarity, interior point, affine scaling, large neighborhood, superlinear convergence

1. Introduction.

The primal-dual affine scaling direction plays a special role in the theory and practice of interior point methods. It turns out that the search direction used by most primal-dual interior point methods is a convex combination $(1-\gamma)w + \gamma\overline{w}$ of the primal-dual affine scaling method w and the centering direction $\overline{w}$ (see the monographs [35, 48, 49]). Optimality is improved along the affine scaling direction, while centrality is improved on the centering direction. The first interior point method of this type was proposed, in the context of linear programming (LP), by Kojima, Mizuno, and Yoshise [15]. They proved that the algorithm had $O(nL)$ iteration complexity, the same as Karmarkar's algorithm [12]. Shortly after that, they improved the algorithm and generalized it for monotone linear complementarity problems (LCP) [14]. The improved algorithm has $O(\sqrt{n}L)$ iteration complexity. This iteration complexity was first obtained by Renegar [34] for an interior point method that follows the primal central path of LP, and it remains the best iteration complexity known to date. The algorithm of [14] follows the primal-dual central path. Starting with a point $z^0 \in \mathcal{N}_2(\alpha)$ in a (small) neighborhood of the primal-dual central path, the algorithm takes at each iteration a unit step along the direction $(1-\gamma)w + \gamma\overline{w}$, where $\gamma = 1 - \alpha/\left((1-\alpha)\sqrt{n}\right)$, producing a sequence of iterates $\left(z^k\right)$ that remains in $\mathcal{N}_2(\alpha)$. A similar algorithm was independently proposed and investigated by Monteiro and Adler for LP [21], and for quadratic programming (QP) [22].

While the algorithms mentioned above attain the best known iteration complexity, their practical performance is not satisfactory because they generate points in a small neighborhood of the central path and use a fixed stepsize (of one) along a direction that is dominated by the centering direction. In order to alleviate some of these problems, Kojima, Mizuno, and Yoshise [16] proposed a potential reduction algorithm for LCPs

*Received by the editors September 20, 2006; accepted for publication (in revised form) August 27, 2007; published electronically February 6, 2008. This work was supported by the National Science Foundation under grant 0139701, and by the National Institute of Health under grant R01GM075298-01.

†Department of Mathematics and Statistics, University of Maryland Baltimore County, 1000 Hilltop Circle, Baltimore, MD 22150 (potra@math.umbc.edu).

with $O(\sqrt{n}L)$ iteration complexity. The search direction is of the same type with $\gamma = 1/(1+\sqrt{n})$. However, instead of taking a fixed stepsize along this direction, a line search is performed in order to ensure that the iterates remain strictly feasible, and that the Tanabe–Todd–Ye potential function [43, 44] is reduced by a fixed constant at each iteration.

Although the potential reduction method of [16] is more flexible than the short step path following methods of [14, 21, 22], it cannot attain superlinear convergence since its search direction has a fixed centering component. There are basically three ways to obtain superlinear convergence: to take $\gamma = 0$ every second step, to use a sequence of γ's that converges to zero, or to take $\gamma = 0$ at every step. The methods from the first category are called predictor-corrector methods, while the methods from the last category are called affine scaling methods and form the subject of the present paper.

Zhang, Tapia, and Dennis [52] gave sufficient conditions for a class of interior point methods to produce a sequence of iterates with duality gap converging superlinearly to zero. However, no example of an algorithm satisfying those conditions and having polynomial complexity was given. The results of [52] were generalized for LCP in [53]. The first interior point method having both polynomial complexity and superlinear convergence was the predictor-corrector method of Mizuno, Todd, and Ye (MTY). This method was proposed for LP in [20], where it was shown to have $O(\sqrt{n}L)$ iteration complexity. Shortly after that, Ye et al. [51] proved that the duality gap of the iterates produced by MTY converges quadratically to zero. MTY was generalized to LCP in [11], and the resulting algorithm was proved to have $O(\sqrt{n}L)$ iteration complexity under general conditions, and superlinear convergence under the assumption that the LCP has a (perhaps not unique) strictly complementary condition (i.e., the LCP is nondegenerate) and the iteration sequence converges. From [3] it follows that the latter assumption always holds. Subsequently, Ye and Anstreicher [50] proved that MTY converges quadratically, assuming only that the LCP is nondegenerate. The nondegeneracy assumption is not restrictive, since according to [24] a large class of interior point methods, which contains MTY, can have only linear convergence if this assumption is violated.

The largest step path following method (LSPF) determines γ at each iteration such that the duality gap is minimized under the constraint that the point obtained by taking a unit step along the search direction $(1-\gamma)w + \gamma\overline{w}$ remains in $\mathcal{N}_2(\alpha)$. McShane [17] proved that LSPF has $O(\sqrt{n}L)$ iteration complexity for general (monotone) LCPs and superlinear convergence under the assumption that the LCP is nondegenerate and the iteration sequence converges. The superlinear convergence is a consequence of the fact that the γ's converge to zero. Gonzaga [6] proved superlinear convergence assuming only nondegeneracy and showed that, with the addition of a computationally trivial safeguard, LSPF achieves Q-quadratic convergence. We mention that the convergence of the iteration sequence generated by LSPF follows from the general results of Bonnans and Gonzaga [3].

It took considerable effort to obtain superlinear convergence results for potential reduction algorithms. One of the first results of this type was obtained for LP by Tunçel [46]. His algorithm uses a direction of the form $(1-\gamma)w + \gamma\overline{w}$, where γ converges to zero at the same rate as the duality gap. The stepsize along this direction is obtained by minimizing a special, nonsmooth, potential function. The algorithm has $O(nL)$ iteration complexity for general LPs and Q-quadratic convergence of the duality gap under the assumption that the LP is nondegenerate. This

assumption is rather strong since it implies that the Jacobian of the corresponding LCP is nonsingular at the solution. This strong restriction was removed by Tütüncü [47], who proposed a potential reduction method with $O(nL)$ iteration complexity and Q-quadratic convergence of both the duality gap and the iteration sequence for general LPs. The search direction is the reduced Newton direction of a multiplicative variant of the Tanabe–Todd–Ye potential function, which is not exactly of the form $(1-\gamma)w+\gamma\overline{w}$, but it is shown that it asymptotically approaches the affine scaling direction, thus ensuring superlinear convergence. The algorithm uses the largest stepsize along this direction such that the feasibility of the iterates is maintained and the original Tanabe–Todd–Ye potential function is reduced by a fixed quantity at each iteration.

All the superlinear convergence results mentioned above are obtained either for LP, which always has a strictly complementary solution, or for LCPs that admit such a solution. As mentioned before, a large class of first order interior point methods cannot have superlinear convergence without this assumption [24]. In order to obtain superlinear convergence for degenerate LCPs one has to either use nonstandard interior point methods or to consider higher order methods. The first approach was first taken by Mizuno [18], who used the so-called step variant of the Tapia indicator [5] to identify the variables that are not strictly complementary, and modified the MTY algorithm in order to accelerate the convergence to zero of those variables. Mizuno's result was refined in [33, 32]. The drawback of this approach is that it needs the estimation of the partition of the optimal face in order to achieve superlinear convergence. The second approach was taken by Sturm [42], who constructed a second order MTY-type algorithm that has $O(\sqrt{n}L)$ iteration complexity and Q-superlinear convergence of order 1.5 for degenerate LCPs. By using mth order derivatives, Stoer, Wechs, and Mizuno [41] constructed higher order MTY-type algorithms with Q-order $m+1$ for nondegenerate LCPs and $(m+1)/2$ for degenerate LCPs. The complexity of the predictor-corrector algorithm for degenerate LCPs from [41] is analyzed in [38]. It follows that for monotone LCPs with feasible starting points the algorithm has $O(\sqrt{n}L)$ iteration complexity.

The path following interior point algorithms described in the paragraph above use a small neighborhood of the central path. However, extensive numerical experiments show convincingly that predictor-corrector methods perform better when using large neighborhoods of the central path. Predictor-corrector methods of MTY type are more difficult to develop and analyze in such neighborhoods, since the correctors are rather inefficient there. For example, it is known that one needs $O(n)$ corrector steps in order to reduce the δ_∞ proximity measure by a factor of .5 (see [2]). Therefore a straightforward generalization of the MTY algorithm would have $O(n^{1.5}L)$ iteration complexity. Gonzaga [7] proposed an interior point method in the $\mathcal{N}_\infty(\alpha)$ neighborhood of the central path, where a predictor is followed by an a priori unknown number of correctors, with $O(nL)$-iteration complexity [7]. No superlinear convergence results are known for this algorithm. An interior point method for LP, acting in a large neighborhood of the central path defined by a self-regular proximity measure, with $O(\sqrt{n}L\log n)$ iteration complexity and superlinear convergence, was proposed in [26]. The first order predictor-corrector method from [30] uses the wide $\mathcal{N}_\infty^-(\alpha)$ neighborhood, takes one predictor followed by exactly one corrector at each iteration, and has $O(nL)$ iteration complexity for general monotone LCPs and Q-quadratic convergence for nondegenerate LCPs. The mth order predictor-corrector methods of [30] also use the $\mathcal{N}_\infty^-(\alpha)$ neighborhood, and their Q-order of convergence

is $m+1$ for nondegenerate LCPs and $(m+1)/2$ for degenerate LCPs. If $m = n^{\omega}$, for some $\omega > 0$, then they have $O(\sqrt{n}L)$ iteration complexity. We note that the mth order method uses two matrix factorizations and m backsolves per iteration, so that if $\omega < 1$, then the computational cost per iteration is dominated by the cost of the two matrix factorizations. The results of [30] were generalized for sufficient LCPs in [31]. An mth order interior point algorithm for sufficient linear complementarity problems in the $\mathcal{N}_{\infty}^{-}(\alpha)$ neighborhood, that requires only one matrix factorization and m backsolves per iteration, was proposed by Stoer [37]. The Q-order of convergence is m for nondegenerate problems. The algorithm is modified in [36] so that its asymptotic Q-order of convergence is $m+1$ for nondegenerate LCPs and $(m+1)/2$ for degenerate LCPs. No complexity results have been proved for the algorithms in [36, 37].

Primal-dual affine scaling methods use the pure primal-dual affine scaling method at each iteration. The first method of this type was proposed by Monteiro, Adler, and Resende [23]. Their algorithm takes a small fixed step (of length $1/(nL)$) along this direction and has $O(nL^2)$ iteration complexity. Because of the fixed stepsize, the duality gap is reduced only by a factor of $(1 - 1/(nL))$ at each iteration, and therefore the algorithm cannot be superlinearly convergent. Moreover, only the first nL^2 iterates are guaranteed to be feasible, so that the algorithm may not produce an infinite sequence. In the same paper, Monteiro, Adler, and Resende [23] propose an mth order affine scaling method for QP with $O(n^{\frac{m+1}{2m}} L^{\frac{m+1}{2m}})$ iteration complexity. They again use a small fixed stepsize (depending on n, m, and L) so that the algorithm cannot have superlinear convergence. In order to overcome the inherent inefficiency caused by the use of a fixed stepsize, Mizuno and Nagasawa [19] proposed an affine scaling method for LP, where at each iteration the stepsize is determined by a line search that ensures the feasibility of the iterates and the fact that the Tanabe–Todd–Ye potential function remains bounded. By choosing the parameter defining the potential function equal to $1/L$, they obtain $O(nL^2)$ iteration complexity. However, no superlinear convergence results are obtained. Tunçel [45] analyzes a variant of this affine scaling where Tunçel's potential function [46] is used instead of the Tanabe–Todd–Ye potential function. The iteration complexity of the resulting algorithm is again $O(nL^2)$ when the parameter δ defining this potential function is equal to $1/(2L)$. The first affine scaling method with polynomial complexity and superlinear convergence was obtained, to our knowledge, by Monteiro and Wright [25] for LCPs. The stepsize along the affine scaling direction is obtained in such a way that the iterates are feasible and remain in neighborhood of the central path depending on two parameters η and δ. This neighborhood, which is closely related to Tunçel's potential function, is relatively narrow for large values of the duality gap, but it widens considerably as the duality gap approaches zero. It is shown that by choosing $\delta = \Theta(1/L)$, one obtains $O(nL^2)$ iteration complexity for monotone LCPs. It is shown that if the LCP has a strictly complementary solution, then the Q-order of convergence of the duality gap is $2 - \delta\xi$, where $\xi = 1$ for skew-symmetric problems and $\xi = 2$ otherwise. As a byproduct Monteiro and Wright show that Tunçel's affine scaling method [45] for LP has Q-order $2 - \delta$.

We note that the primal-dual affine scaling direction considered in this paper is sometime called the classical primal-dual affine scaling direction, in order to distinguish it from the so-called Dikin primal-dual affine scaling direction considered by Jansen, Roos, and Terlaky [8] for LP and generalized for LCP in [9]. The corresponding Dikin-type primal-dual affine scaling algorithms have $O(nL)$ iteration complexity. By using an mth order Dikin primal-dual affine scaling direction, Jansen et al. [10]

have obtained an algorithm with $O(n^{\frac{m+1}{2m}}L)$ iteration complexity. Unlike the algorithms from [8, 9], which used a small fixed stepsize, the algorithm from [10] may take a larger stepsize, which is determined at each iteration such that the new point remains in the $\mathcal{N}_\infty(\alpha)$ neighborhood of the central path. No superlinear results have been proved for Dikin-type primal-dual affine scaling algorithms. In fact, since the Dikin primal-dual affine scaling direction contains an important centering component, no superlinear convergence is expected for such algorithms.

In the present paper we present an affine scaling algorithm that uses the $\mathcal{N}_\infty^-(\alpha)$ neighborhood of the central path. It has $O(nL^2\phi(nL^2))$ iteration complexity for general monotone LCPs, where $\phi(t) = (\log t)(\log\log t)$. If the LCP admits a strictly complementary solution, then the duality gap converges Q-superlinearly to zero and the iteration sequence converges Q-superlinearly to a strictly complementary solution. The Q-orders of convergence of both sequences are equal to two. We also present two mth order affine scaling methods having $O((\sqrt{n}L)^{\frac{m+1}{m}}(\phi(\sqrt{n}L))^{\frac{1}{m}})$ iteration complexity for monotone LCPs. By taking $m = \Omega(\log(\sqrt{n}L))$, we obtain $O(\sqrt{n}L)$ iteration complexity, the best iteration complexity known so far for LP, QP, and monotone LCP. We note that both algorithms use one matrix factorization and m backsolves per iteration. This requires $O(n^3 + mn^2)$ arithmetic operations per iteration. Therefore if $\log(\sqrt{n}L) \ll n$, then the cost of an iteration is dominated by the cost of the matrix factorization.

If the LCP admits a strictly complementary solution, then the iterates produced by the first algorithm converge Q-superlinearly to a strictly complementary solution, and the corresponding duality gaps converge Q-superlinearly to zero. The Q-orders of convergence of both sequences are equal to $m+1$. If $m \geq 2$, then the second algorithm produces a sequence of iterates that converges Q-superlinearly to a maximal complementarity solution, even for degenerate LCPs, with Q-order $(m+1)/2$. The sequence of duality gaps converges Q-superlinearly to zero with the same Q-order. To our knowledge this is the first affine scaling method acting in the $\mathcal{N}_\infty^-(\alpha)$ neighborhood of the central path that has $O(\sqrt{n}L)$ iteration complexity and Q-superlinear convergence in the absence of strict complementarity.

Conventions. We denote by $\mathbb{N}$ the set of all nonnegative integers. $\mathbb{R}$, $\mathbb{R}_+$, $\mathbb{R}_{++}$ denote the sets of real, nonnegative real, and positive real numbers, respectively. For any real number κ, $\lceil\ \kappa\ \rceil$ denotes the smallest integer greater than or equal to κ. Given a vector x, the corresponding upper case symbol denotes, as usual, the diagonal matrix X defined by the vector. The symbol e represents the vector of all ones, with dimension given by the context.

We denote componentwise operations on vectors by the usual notation for real numbers. Thus, given two vectors u, v of the same dimension, uv, u/v, etc. will denote the vectors with components u_iv_i, u_i/v_i, etc. This notation is consistent as long as componentwise operations always have precedence in relation to matrix operations. Note that $uv \equiv Uv$, and if A is a matrix, then $Auv \equiv AUv$, but in general $A(uv) \neq (Au)v$. Also if f is a scalar function and v is a vector, then $f(v)$ denotes the vector with components $f(v_i)$. For example, if $v \in \mathbb{R}^n_+$ and $\lambda \in \mathbb{R}$, then $\sqrt{v}$ denotes the vector with components $\sqrt{v_i}$, and $\lambda - v$ denotes the vector with components $\lambda - v_i$. Traditionally the vector $\lambda - v$ is written as $\lambda e - v$, where e is the vector of all ones. Inequalities are to be understood in a similar fashion. For example, if $v \in \mathbb{R}^n$, then $v \geq 3$ means that $v_i \geq 3$, $i = 1, \ldots, n$. Traditionally this is written as $v \geq 3\,e$. If $\|.\|$ is a vector norm on $\mathbb{R}^n$ and A is a matrix, then the operator norm induced by $\|.\|$ is defined by $\|A\| = \max\{\|Ax\|\ ;\ \|x\| = 1\}$. As a particular case we note that if U is the

diagonal matrix defined by the vector u, then $\| U \|_2 = \| u \|_\infty$.

We frequently use the $O(\cdot)$ and $\Omega(\cdot)$ notation to express asymptotic relationships between functions. The most common usage will be associated with a sequence $\{x^k\}$ of vectors and a sequence $\{\tau_k\}$ of positive real numbers. In this case $x^k = O(\tau_k)$ means that there is a constant K (dependent on problem data) such that for every $k \in \mathbb{N}$, $\left\|x^k\right\| \leq K\tau_k$. Similarly, if $x^k > 0$, $x^k = \Omega(\tau_k)$ means that $(x^k)^{-1} = O(1/\tau_k)$. If we have both $x^k = O(\tau_k)$ and $x^k = \Omega(\tau_k)$, we write $x^k = \Theta(\tau_k)$.

If $x, s \in \mathbb{R}^n$, then the vector $z \in \mathbb{R}^{2n}$ obtained by concatenating x and s is denoted by $z = \lceil\, x,\, s \,\rfloor = \left[\, x^T,\, s^T \,\right]^T$, and the mean value of xs is denoted by $\mu(z) = \frac{x^T s}{n}$.

2. The linear complementarity problem and its central path.

2.1. The horizontal linear complementarity problem. Given two matrices $Q, R \in \mathbb{R}^{n \times n}$ and a vector $b \in \mathbb{R}^n$, the horizontal linear complementarity problem (HLCP) consists of finding a pair of vectors $z = \lceil\, x,\, s \,\rfloor$ such that

$$\begin{aligned} xs &= 0, \\ Qx + Rs &= b, \\ x, s &\geq 0. \end{aligned} \tag{2.1}$$

The standard (monotone) LCP is obtained by taking $R = -I$ and Q positive semidefinite. There are other formulations of the LCP as well but, as shown in [1], all popular formulations are equivalent, and the behavior of a large class of interior point methods is identical on those formulations, so that it is sufficient to prove results for only one of the formulations. We have chosen HLCP because of its symmetry. The LP problem, and the QP problem, can be formulated as HLCPs. Therefore, the HLCP provides a convenient general framework for studying interior point methods.

Throughout this paper we assume that the HLCP is monotone, in the sense that

$$Qu + Rv = 0 \quad \text{implies } u^T v \geq 0 \text{ for any } u, v \in \mathbb{R}^n\,.$$

This condition is satisfied if the HLCP is a reformulation of a QP [4]. If the HLCP is a reformulation of an LP, then the following stronger condition holds,

$$Qu + Rv = 0 \quad \text{implies } u^T v = 0 \text{ for any } u, v \in \mathbb{R}^n\,,$$

and HLCP is called skew-symmetric in this case. The following proposition contains two simple properties of a monotone HLCP.

PROPOSITION 2.1. *If HLCP is monotone, then the $n \times 2n$-matrix (Q, R) has full rank, and*

$$(u^T \overline{v} + \overline{u}^T v)^2 \leq 4 \left(u^T v\right) \left(\overline{u}^T \overline{v}\right) \qquad \forall \lceil\, u,\, v \,\rfloor, \lceil\, \overline{u}\,,\, \overline{v} \,\rfloor \in \operatorname{Ker}(Q, R)\,.$$

Proof. The full rank property follows from [3]. If $Qu + Rv = Q\overline{u} + R\overline{v} = 0$, then $Q(u + \lambda\overline{u}) + R(v + \lambda\overline{v}) = 0$ for any $\lambda \in \mathbb{R}$, so that

$$0 \leq (u + \lambda\overline{u})^T (v + \lambda\overline{v}) = u^T v + \lambda(u^T \overline{v} + \overline{u}^T v) + \lambda^2 \overline{u}^T \overline{v} \qquad \forall \lambda \in \mathbb{R}\,.$$

Since the right-hand side above is a nonnegative quadratic function in λ, its discriminant must be nonpositive, which proves the second part of the proposition. ∎

In the skew-symmetric case we can often obtain sharper estimates, due to the following consequence of Proposition 2.1.

COROLLARY 2.2. *If HLCP is skew-symmetric, then* $u^T\overline{v}+\overline{u}^Tv=0$ *for all* $u,v,\overline{u},\overline{v}$ *satisfying* $Qu+Rv=Q\overline{u}+R\overline{v}=0$.

Let us denote the set of all feasible points of HLCP by

$$\mathcal{F}=\{z=\lceil\, x,\, s\,\rfloor\in\mathbb{R}^{2n}_{+}\ :\ Qx+Rs=b\},$$

and the solution set (or the optimal face) of HLCP by

$$\mathcal{F}^*=\{z^*=\lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}\ :\ x^*s^*=0\}.$$

The structure of $\mathcal{F}^*$ is very important in the analysis of interior point methods. Let us define three subsets $\mathcal{B}$, $\mathcal{N}$, and $\mathcal{J}$ of the index set $\{1,\dots,n\}$ by

$$\mathcal{B}=\{i=1,\dots,n\,|\,x_i^*>0 \text{ for at least one } \lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}^*\},$$

$$\mathcal{N}=\{i=1,\dots,n\,|\,s_i^*>0 \text{ for at least one } \lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}^*\},$$

$$\mathcal{J}=\{i=1,\dots,n\,|\,x_i^*=s_i^*=0\ \forall\lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}^*\}.$$

One can prove that $\mathcal{B}$, $\mathcal{N}$, and $\mathcal{J}$ form a partition of $\{1,\dots,n\}$ and that there exists a solution $\lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}^*$ such that $x^*_{\mathcal{B}}>0$ and $s^*_{\mathcal{N}}>0$. Such a solution is called a *maximal complementarity solution*, since one can prove that, for any $\lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}^*$, $x_i^*>0\Rightarrow i\in\mathcal{B}$ and $s_j^*>0\Rightarrow j\in\mathcal{N}$. If the solution of the HLCP is unique, then it is a maximal complementarity solution. Otherwise it can be shown that the relative interior of $\mathcal{F}^*$ is composed of maximal complementarity solutions.

If the set $\mathcal{J}$ is empty, then a maximal complementarity solution is called a strictly complementary solution. Let us denote by $\mathcal{F}^c$ the set of all such solutions, i.e.,

$$\mathcal{F}^c=\{z^*=\lceil\, x^*,\, s^*\,\rfloor\in\mathcal{F}^*:x^*+s^*>0\}\,.$$

We say that the HLCP is nondegenerate if it has a strictly complementary solution. If the set J is nonempty, then we say that the HLCP is degenerate.

The set

$$\mathcal{F}^0=\mathcal{F}\bigcap\mathbb{R}^{2n}_{++}$$

is called the set of strictly feasible points, or the set of interior points.

2.2. The central path and its analyticity. It is known (see [13]) that if $\mathcal{F}^0$ is nonempty, then for any vector $p\in\mathbb{R}^n_{++}$ and any parameter $\tau>0$ the nonlinear system

$$\begin{aligned} xs&=\tau p,\\ Qx+Rs&=b \end{aligned}\tag{2.2}$$

has a unique positive solution $z(\tau,p)=\lceil\, x(\tau,p),\, s(\tau,p)\,\rfloor$. For a fixed p, the curve

$$\mathcal{C}(p)=\{z(\tau,p)\ :\ \tau>0\}$$

is called the weighted central path of the HLCP with weight vector p. It turns out that if the HLCP is nondegenerate, then $z(\tau,p)$ is an analytic function in $\tau>0$ and $p>0$, which has an analytic continuation at $\tau=0$. In case the HLCP is degenerate, then $z(\tau,p)$ is analytic in $\rho=\sqrt{\tau}$, which also has an analytic continuation at $\rho=0$.

Moreover, all the derivatives of z are bounded on any compact set contained in the domain of analyticity of z. More precisely, the following results follow from the more general results of [39, 40].

THEOREM 2.3. *If HLCP is monotone and $\mathcal{F}^0$ is nonempty, then (2.2) has a unique positive solution $z(\tau,p) = \lceil\, x(\tau,p),\, s(\tau,p)\,\rfloor$ for any $(\tau,p) \in \mathbb{R}^{n+1}_{++}$, and the following properties hold:*

A. *If the HLCP is nondegenerate, then $z(\tau,p)$ can be analytically extended to an open neighborhood of $\mathbb{R}_+ \times \mathbb{R}^n_{++}$, and for any compact set $\mathcal{K} \subset \mathbb{R}_+ \times \mathbb{R}^n_{++}$ and any integer $i \in \mathbb{N}$ there are constants $c(\mathcal{K},i)$ such that*

$$\left\| \frac{\partial^i z(\tau,p)}{\partial \tau^i} \right\|_2 \le c(\mathcal{K},i) \qquad \forall (\tau,p) \in \mathcal{K},\ i = 0,1,2,\ldots.$$

B. *If the HLCP is degenerate, then $\overline{z}(\rho,p) := z(\rho^2,p)$ can be analytically extended to an open neighborhood of $\mathbb{R}_+ \times \mathbb{R}^n_{++}$, and for any compact set $\mathcal{K} \subset \mathbb{R}_+ \times \mathbb{R}^n_{++}$ and any integer $i \in \mathbb{N}$ there are constants $\overline{c}(\mathcal{K},i)$ such that*

$$\left\| \frac{\partial^i \overline{z}(\rho,p)}{\partial \rho^i} \right\|_2 \le \overline{c}(\mathcal{K},i) \qquad \forall (\tau,p) \in \mathcal{K},\ i = 0,1,2,\ldots.$$

If $p = e$, the vector of all ones, then $\mathcal{C} = \mathcal{C}(e)$ is simply called the central path of the HLCP. The distance of a point $z \in \mathcal{F}$ to the central path $\mathcal{C}$ can be quantified by different proximity measures. The following proximity measures have been extensively used in the interior point literature:

$$\delta_2(z) := \left\| \frac{xs}{\mu(z)} - e \right\|_2, \quad \delta_\infty(z) := \left\| \frac{xs}{\mu(z)} - e \right\|_\infty, \quad \delta^-_\infty(z) := \left\| \left[\frac{xs}{\mu(z)} - e \right]^- \right\|_\infty,$$

where $[v]^-$ denotes the negative part of the vector v, i.e., $[v]^- = -\max\{-v, 0\}$.

By using the above proximity measures, we can define the following neighborhoods of the central path:

$$\mathcal{N}_2(\eta) = \{ z \in \mathcal{F}^0 \ :\ \delta_2(z) \le \eta \},$$
$$\mathcal{N}_\infty(\eta) = \{ z \in \mathcal{F}^0 \ :\ \delta_\infty(z) \le \eta \},$$
$$\mathcal{N}^-_\infty(\eta) = \{ z \in \mathcal{F}^0 \ :\ \delta^-_\infty(z) \le \eta \},$$

where $0 < \eta < 1$ is a given parameter. We have

$$\mathcal{C} \subset \mathcal{N}_2(\eta) \subset \mathcal{N}_\infty(\eta) \subset \mathcal{N}^-_\infty(\eta), \quad \lim_{\eta \downarrow 0} \mathcal{N}^-_\infty(\eta) = \mathcal{C}, \quad \lim_{\eta \uparrow 1} \mathcal{N}^-_\infty(\eta) = \mathcal{F}. \tag{2.3}$$

3. The first order affine scaling method.

3.1. The algorithm. In the remainder of this paper we will work with $\mathcal{N}^-_\infty(\eta)$. We note that this neighborhood can be written under the form

$$\mathcal{N}^-_\infty(\eta) = \mathcal{D}(1-\eta), \text{ where } \mathcal{D}(\beta) = \{ z \in \mathcal{F}^0 \ :\ xs \ge \beta \mu(z) \}.$$

At each step of our algorithm we are given a point $z = \lceil\, x,\, s\,\rfloor \in \mathcal{D}(\beta)$, and we compute the affine scaling direction $w = \lceil\, u,\, v\,\rfloor$ by solving the following linear system:

$$\begin{cases} su + xv = -xs, \\ Qu + Rv = 0. \end{cases} \tag{3.1}$$

This search direction coincides, up to a scalar factor, with the first derivative to central path $z(\tau,p)$ that passes through $p=xs/\mu$ at $\tau=\mu$. Indeed, by differentiating (2.2), we obtain

$$\left\{\begin{array}{l} s(\tau,p)\frac{\partial}{\partial\tau}x(\tau,p)+x(\tau,p)\frac{\partial}{\partial\tau}s(\tau,p)=\frac{xs}{\mu}, \\ \qquad\qquad Q\frac{\partial}{\partial\tau}x(\tau,p)+R\frac{\partial}{\partial\tau}s(\tau,p)=0. \end{array}\right. \tag{3.2}$$

Given that $x(\mu,p)=x$ and $s(\mu,p)=s$, we obtain

$$u=-\mu\frac{\partial}{\partial\tau}x(\tau,p)\,,\qquad v=-\mu\frac{\partial}{\partial\tau}s(\tau,p)\,. \tag{3.3}$$

It turns out that the duality gap has the fastest local decrease along this direction. Indeed if we denote by

$$z(\theta)=z+\theta w \tag{3.4}$$

a point along this direction, we have

$$\begin{aligned} x(\theta)s(\theta)&=(x+\theta u)(s+\theta v)=(1-\theta)xs+\theta^2uv, \\ \mu(\theta)&=\frac{(x+\theta u)^T(s+\theta v)}{n}=(1-\theta)\mu+\theta^2\frac{u^Tv}{n}\,. \end{aligned} \tag{3.5}$$

In the skew-symmetric case we have $u^Tv=0$, while in the monotone case, according to Lemma 3.1, we have $0\le u^Tv\le .25n\mu$, so that we can write

$$\mu(\theta)\le(1-\theta+.25\theta^2)\mu\le(1-.5\theta)^2\mu\,,\qquad \mu'(\theta)\le(.5\theta-1)\mu\,. \tag{3.6}$$

Given that $\mu(\theta)$ is decreasing on the interval $[0,2]$, we compute the steplength $\overline{\theta}$ as

$$\overline{\theta}=\max\left\{\hat{\theta}\in[0,1]\ :\ z(\theta)\in\mathcal{D}(\beta_+)\ \forall\theta\in[0,\hat{\theta}\,]\right\}\,, \tag{3.7}$$

where

$$\beta_+=\beta-\alpha. \tag{3.8}$$

We obtain thus a new point satisfying

$$z^+=z(\overline{\theta}\,)\in\mathcal{D}(\beta_+), \tag{3.9}$$

and the process can be repeated. The initial value for β is $\overline{\beta}$, and the α's are chosen as the terms of a monotone sequence of nonnegative numbers satisfying the following two conditions:

$$\sum_{k=0}^{\infty}\alpha_k\le\overline{\beta}\,-\underline{\beta}\,,\qquad \sum_{k=0}^{\infty}\sqrt{\alpha_k}=\infty.$$

This ensures the global convergence of the algorithm. In order to obtain good polynomial complexity we have chosen

$$\alpha_k=\frac{\nu(\overline{\beta}\,-\underline{\beta})}{(\exp(1)+k+1)\log^{1+\nu}(\exp(1)+k+1)}\,,\quad k=0,1,\ldots, \tag{3.10}$$

where $0 < \nu \leq 1$ is a given parameter. For this choice we have

$$\sum_{k=0}^{\infty} \alpha_k < \nu(\overline{\beta} - \underline{\beta}) \int_e^{\infty} \frac{dt}{t \log^{1+\nu} t} = \overline{\beta} - \underline{\beta}\,,$$

and, as we will see in the next section,

$$\sum_{k=0}^{K} \sqrt{\alpha_k} = \Omega\left(\frac{\sqrt{K}}{\log^{\frac{1+\nu}{2}} K}\right).$$

We end this section by formally defining our iterative procedure, as follows.

ALGORITHM 1. Given real parameters $0 < \underline{\beta} < \overline{\beta} < 1$, $0 < \nu \leq 1$, and a vector $z^0 \in \mathcal{D}(\overline{\beta}\,)$:

Set $k \leftarrow 0\,,\ \beta_0 \leftarrow \overline{\beta}$ and consider the sequence (3.10);
repeat
Set $z \leftarrow z^k\,,\ \alpha \leftarrow \alpha_k\,,\ \beta \leftarrow \beta_k\,,\ \beta_+ \leftarrow \beta - \alpha\,;$
Compute direction $w = \lceil\, u,\, v \,\rfloor$ by solving (3.1);
Compute steplength $\overline{\theta}$ from (3.7);
Compute z^+ from (3.9);
Set $\theta_k \leftarrow \overline{\theta}\,,\ z^{k+1} \leftarrow z^+\,,\ \mu_{k+1} \leftarrow \mu(z^+)\,,\ \beta_{k+1} \leftarrow \beta_+;$
Set $k \leftarrow k + 1$.
continue

3.2. Technical results. In order to analyze Algorithm 1 we need to establish some properties of the solution of a linear system of the form

$$\left\{ \begin{array}{r} su + xv = a, \\ Qu + Rv = 0. \end{array} \right. \tag{3.11}$$

By using the notation

$$D = X^{-1/2} S^{1/2}\,, \tag{3.12}$$

this system can be written as

$$\left\{ \begin{array}{r} Du + D^{-1}v = (xs)^{-1/2} a, \\ QD^{-1}(Du) + RD(D^{-1}v) = 0. \end{array} \right. \tag{3.13}$$

Since the pair (QD^{-1}, RD) is monotone, one can easily prove the following results (see, for example, [29, Lemma 3.1]).

LEMMA 3.1. *If HLCP is monotone, then for any $z = \lceil\, x,\, s \,\rfloor \in \mathbb{R}^{2n}_{++}$ and any $a \in \mathbb{R}^n$ the linear system* (3.11) *has a unique solution $w = \lceil\, u,\, v \,\rfloor$, and the following properties are satisfied:*

(i) $\| Du \|_2^2 + \left\| D^{-1}v \right\|_2^2 \leq \left\| (xs)^{-1/2} a \right\|_2^2\,;$
(ii) $\|uv - \frac{u^T v}{n}\, e\|_2 \leq \| uv \|_2 \leq \frac{1}{2\sqrt{2}} \left\| (xs)^{-1/2} a \right\|_2^2\,;$
(iii) $\| uv \|_\infty \leq \frac{1}{4} \left\| (xs)^{-1/2} a \right\|_2^2\,;$
(iv) $u^T v \leq \frac{1}{4} \left\| (xs)^{-1/2} a \right\|_2^2\,.$

The proof of global convergence of Algorithm 1 requires explicit lower bounds for the series $\sum_{k=0}^{K-1} \alpha_k^{1/(m+1)}$ for K sufficiently large. Given that

$$\sum_{k=0}^{K-1} \alpha_k^{\frac{1}{m+1}} > \left(\nu(\overline{\beta} - \underline{\beta})\right)^{\frac{1}{m+1}} \int_{\exp(1)+1}^{K+\exp(1)+1} \frac{dt}{t^{\frac{1}{m+1}} \log^{\frac{1+\nu}{m+1}} t}\,, \tag{3.14}$$

it remains to find an explicit lower bound depending on K of the integral appearing on the right-hand-side of the above inequality. To this effect we will use the following results.

LEMMA 3.2. *Let f and g be two continuous, nonnegative, and nonincreasing real functions defined on the interval $[\gamma, \delta]$. If f is convex, then*

$$\int_\gamma^\delta f(t)g(t)dt \geq f\left(\frac{\gamma+\delta}{2}\right) \int_\gamma^\delta g(t)dt\,.$$

Proof. Let us define $\zeta = (\gamma+\delta)/2$. From the convexity of f it follows that f has lateral derivatives $f'(\zeta-0) \leq f'(\zeta+0) \leq 0$ at ζ and that

$$f(t) \geq f(\zeta) + m(t-\zeta) \qquad \forall m \in [f'(\zeta-0), f'(\zeta+0)]\,,\ \forall t \in [\gamma,\delta]\,.$$

Since g is nonnegative and nonincreasing we deduce that

$$f(t)g(t) \geq f(\zeta)g(t) + mg(\zeta)(t-\zeta) \qquad \forall m \in [f'(\zeta-0), f'(\zeta+0)]\,,\ \forall t \in [\gamma,\delta]\,,$$

and the statement of our lemma follows by fixing m and taking the integral with respect to t of both sides of the above inequality. ∎

COROLLARY 3.3. *If $0 < \omega < 1$, $\eta > 0$, and $\varsigma \geq 2\gamma > 2$, then*

$$\int_\gamma^{\gamma+\varsigma} \frac{dt}{t^\omega \log^\eta t} \geq \frac{\varsigma^{1-\omega}}{\log^\eta \varsigma}\,.$$

Proof. Given that the function $t \to \log^{-\eta}(t)$ is convex for $t > 1$, we can apply Lemma 3.2 to obtain

$$\int_\gamma^{\gamma+\varsigma} \frac{dt}{t^\omega \log^\eta t} \geq \frac{(\gamma+\varsigma)^{1-\omega} - \gamma^{1-\omega}}{(1-\omega)\log^\eta(\gamma+.5\varsigma)} \geq \frac{(\gamma+\varsigma)^{1-\omega} - \gamma^{1-\omega}}{(1-\omega)\log^\eta \varsigma}\,.$$

Therefore it remains to prove that

$$(\gamma+\varsigma)^{1-\omega} - \gamma^{1-\omega} \geq (1-\omega)\varsigma^{1-\omega}\,.$$

Dividing both sides of the above inequality by $\varsigma^{1-\omega}$ and denoting $\sigma = \gamma/\varsigma$, $\tau = 1-\omega$, this reduces to proving that

$$\phi(\tau,\sigma) := (1+\sigma)^\tau - \sigma^\tau - \tau \geq 0\,,\ \forall \tau \in [0,1] \qquad \forall \sigma \in [0,.5]\,.$$

Since

$$\frac{\partial \phi}{\partial \sigma} = \tau\left((1+\sigma)^{\tau-1} - \sigma^{\tau-1}\right) \leq 0,$$

we deduce that

$$\phi(\tau,\sigma) \geq \psi(\tau) := \phi(\tau,.5) \qquad \forall \tau \in [0,1]\,,\ \forall \sigma \in [0,.5]\,.$$

We have

$$\psi(\tau) = 1.5^\tau - .5^\tau - \tau\,, \quad \psi(0) = 0\,,\ \psi(1) = 0,$$
$$\psi'(\tau) = 1.5^\tau \log 1.5 - .5^\tau \log .5 - 1\,, \quad \psi'(0) > 0\,,\ \psi'(1) < 0,$$
$$\psi''(\tau) = 1.5^\tau \log^2 1.5 - .5^\tau \log^2 .5\,, \quad \psi''(0) < 0\,,\ \psi''(1) > 0,$$
$$\psi'''(\tau) = 1.5^\tau \log^3 1.5 - .5^\tau \log^3 .5 > 0\,, \quad \forall \tau \in [0,1]\,.$$

The positivity of ψ''' implies that ψ'' has a unique zero $\tau_2 \in [0,1]$, which in turn shows that ψ' is decreasing on $[0,\tau_2]$ and increasing on $[\tau_2,1]$. Hence ψ' has a unique zero $\tau_1 \in [0,\tau_2]$. This shows that ψ increases on $[0,\tau_1]$ and decreases on $[\tau_1,1]$. Therefore ψ is positive on $(0,1)$. □

Using this corollary together with the following lemma, we will be able to obtain explicit upper bounds on the number of steps required by Algorithm 1 to reduce the duality gap below any desired tolerance.

LEMMA 3.4. *The function* $h : [\exp(1),\infty) \to [\exp(1),\infty)$ *given by* $h(t) = t/\log t$ *is increasing and bijective, and its inverse* $h^{-1} : [\exp(1),\infty) \to [\exp(1),\infty)$ *satisfies the inequalities*

$$t\log t < h^{-1}(t) < t\left(1 + \frac{\log\log t}{\log t - 1}\right)\log t < 2t\log t \qquad \forall t \in (e,\infty)\,.$$

Proof. The first part of the lemma follows immediately from the fact that

$$h'(t) = \frac{\log t - 1}{\log^2 t} > 0 \qquad \forall t \in (e,\infty)\,.$$

In order to prove the second part we denote by l and u the lower and upper bounds above and show that $h(l) < t < h(u)$. We have obviously

$$h(l) = \frac{t\log t}{\log(t\log t)} = \frac{t\log t}{\log t + \log\log t} < t\,,$$

which proves the first inequality. Finally, by using the inequality $\log(1+\alpha) < \alpha$, we obtain

$$h(u) = \frac{t\left(1 + \frac{\log\log t}{\log t - 1}\right)\log t}{\log(t\log t) + \log\left(1 + \frac{\log\log t}{\log t - 1}\right)} > \frac{t\left(1 + \frac{\log\log t}{\log t - 1}\right)\log t}{\log t + \log\log t + \frac{\log\log t}{\log t - 1}} = t\,. \qquad \square$$

COROLLARY 3.5. *If* $\sigma > \exp(1)\,,\ \nu > 0\,,\ m > 0\,,$ *then*

$$\tau \geq \left(2\left(1 + \frac{1+\nu}{m+1}\log\frac{1+\nu}{m}\right)\frac{m+1}{m}\log\sigma\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} \quad \textit{implies} \quad \frac{\tau^{\frac{m}{m+1}}}{\log^{\frac{1+\nu}{m+1}}\tau} \geq \sigma\,.$$

Proof. By noticing that

$$\frac{\tau^{\frac{m}{m+1}}}{\log^{\frac{1+\nu}{m+1}}\tau} = \left(\frac{\tau^{\frac{m}{1+\nu}}}{\frac{1+\nu}{m}\log\tau^{\frac{m}{1+\nu}}}\right)^{\frac{1+\nu}{m+1}}\,,$$

we can write the last inequality in the statement of Corollary 3.5 under the equivalent form

$$\frac{\tau^{\frac{m}{1+\nu}}}{\log \tau^{\frac{m}{1+\nu}}} \geq \frac{(1+\nu)\,\sigma^{\frac{m+1}{1+\nu}}}{m}\,.$$

According to Lemma 3.4 this inequality is satisfied if

$$\tau \geq \left(\frac{2(1+\nu)\,\sigma^{\frac{m+1}{1+\nu}}}{m}\,\log\frac{(1+\nu)\,\sigma^{\frac{m+1}{1+\nu}}}{m}\right)^{\frac{1+\nu}{m}} =: rhs\,.$$

The right-hand side of the above inequality can be majorized as follows:

$$\begin{aligned}
rhs &= \left(\frac{2(1+\nu)}{m}\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} \left(\log\frac{(1+\nu)\,\sigma^{\frac{m+1}{1+\nu}}}{m}\right)^{\frac{1+\nu}{m}} \\
&= \left(\frac{2(1+\nu)}{m}\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} \left(\left(1+\frac{\log\frac{1+\nu}{m}}{\log\sigma^{\frac{m+1}{1+\nu}}}\right)\log\sigma^{\frac{m+1}{1+\nu}}\right)^{\frac{1+\nu}{m}} \\
&\leq \left(\frac{2(1+\nu)}{m}\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} \left(\left(1+\frac{1+\nu}{m+1}\log\frac{1+\nu}{m}\right)\log\sigma^{\frac{m+1}{1+\nu}}\right)^{\frac{1+\nu}{m}} \\
&= \left(\frac{2(1+\nu)}{m}\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} \left(\left(1+\frac{1+\nu}{m+1}\log\frac{1+\nu}{m}\right)\frac{m+1}{1+\nu}\log\sigma\right)^{\frac{1+\nu}{m}} \\
&= \left(2\left(1+\frac{1+\nu}{m+1}\log\frac{1+\nu}{m}\right)\frac{m+1}{m}\log\sigma\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}},
\end{aligned}$$

which proves the corollary. □

LEMMA 3.6. *The function* $g : [\exp(\exp(1)),\infty) \to [\exp(\exp(1)),\infty)$ *given by* $g(t) = t/\log\log t$ *is increasing and bijective, and its inverse satisfies*

$$t\log\log t < g^{-1}(t) < t\left(1+\frac{\log\log\log t}{(\log\log t)\log t - 1}\right)\log\log t < 2.072\,t\log\log t\,.$$

Proof. The first part of the lemma follows immediately from the fact that

$$g'(t) = \frac{-1+(\log\log t)\log t}{(\log\log t)^2\log t} > 0 \qquad \forall t \in (5.8313,\infty)\,.$$

In order to prove the second part we denote by l and u the lower and upper bounds above and show that $g(l) < t < g(u)$. We have obviously

$$g(l) = \frac{t\log\log t}{\log\log(t\log\log t)} = \frac{t\log\log t}{\log\log t + \log\log\log t} < t\,,$$

which proves the first inequality. By using the inequality $\log(1+\alpha) < \alpha$, we obtain

$$g(u) = \frac{t\left(1+\frac{\log\log\log t}{(\log\log t)\log t-1}\right)\log\log t}{\log\left(\log t+\log\log\log t+\log\left(1+\frac{\log\log\log t}{(\log\log t)\log t-1}\right)\right)}$$

$$> \frac{t\left(1+\frac{\log\log\log t}{(\log\log t)\log t-1}\right)\log\log t}{\log\left(\log t+(\log\log\log t)\left(1+\frac{1}{(\log\log t)\log t-1}\right)\right)}$$

$$> \frac{t\left(1+\frac{\log\log\log t}{(\log\log t)\log t-1}\right)\log\log t}{\log\log t+\frac{\log\log\log t}{\log t}\frac{(\log\log t)\log t}{(\log\log t)\log t-1}} = t\,.$$

Finally, it is easily checked that

$$\max_{t\geq\exp(\exp(1))}\frac{\log\log\log t}{(\log\log t)\log t-1} < 0.072\,. \qquad \square$$

3.3. Polynomial complexity. In the next theorem we show that Algorithm 1 is well defined, and we give bounds on the decrease of the duality gap at each iteration.

THEOREM 3.7. *If HLCP is monotone, then Algorithm* 1 *is well defined and produces a sequence of points* $\left(z^k\right)_{k=0}^{\infty}$, *with* $z^k \in \mathcal{D}(\beta_k) \subset \mathcal{D}(\underline{\beta})$. *If* $n \geq 5$, *then the following relations hold:*

$$\theta_k \geq \sqrt{2\alpha_k/n}\,, \quad \mu_{k+1} \leq \left(1-\sqrt{\alpha_k/n}\right)\mu_k\,, \qquad k=0,1,\ldots,$$

$$\mu_k \leq \mu_0 \exp\left(-\sqrt{\frac{\nu\left(\overline{\beta}-\underline{\beta}\right)k}{n\log^{1+\nu}k}}\right)\,, \qquad k=8,9,\ldots.$$

Proof. The relation $z^k \in \mathcal{D}(\beta_k)$ is ensured by the line search (3.7). Now let $z \in \mathcal{D}(\beta)$ be given, and define

$$p = \frac{xs}{\mu}\,, \qquad q = \frac{uv}{\mu}\,.$$

From our hypothesis and from Lemma 3.1 it follows that

$$p \geq \beta e\,, \quad \|\,q\,\|_\infty \leq \frac{n}{4}\,, \quad \left\|\,q-(e^Tq/n)e\,\right\|_2 \leq \|\,q\,\|_2 \leq \frac{n}{2\sqrt{2}}\,, \quad \frac{u^Tv}{\mu} = e^Tq \leq \frac{n}{4}\,.$$

Using (3.5) and (3.6), we deduce that

$$\frac{x(\theta)s(\theta)}{\mu(\theta)} = \frac{(1-\theta)p+\theta^2q}{1-\theta+(e^Tq/n)\theta^2}$$

$$= \frac{(1-\theta)p+\beta(e^Tq/n)\theta^2e+\beta\theta^2(q-(e^Tq/n)e)+(1-\beta)\theta^2q}{1-\theta+(e^Tq/n)\theta^2}$$

$$\geq \beta e - \frac{\left\|\,\beta(q-(e^Tq/n)e)+(1-\beta)q\,\right\|_2\theta^2}{1-\theta}\,e$$

$$\geq \beta e - \frac{\|\,q\,\|_2\,\theta^2}{1-\theta}\,e\,. \tag{3.15}$$

If $n \geq 5$, then $\sqrt{2\alpha/n} \leq \sqrt{2\alpha_0/5} < 1-1/\sqrt{2}$ for any values of the parameters defining our algorithm, and in this case we can easily verify that

$$\frac{\| q \|_2 \, \theta^2}{1-\theta} \leq \frac{n\theta^2}{(1-\theta)2\sqrt{2}} \leq \alpha \qquad \forall \theta \in [0, \sqrt{2\alpha/n}\,] \, .$$

It follows that $\overline{\theta} \geq \sqrt{2\alpha/n}$, and therefore

$$\mu_+ = \mu\left(\overline{\theta}\right) \leq \mu\left(\sqrt{2\alpha/n}\right) \leq \left(1 - \sqrt{2\alpha/n} + .5\alpha/n\right)\mu$$

$$\leq \left(1 - \left(1 - .25\sqrt{2\alpha_0/5}\right)\sqrt{2\alpha/n}\right)\mu < \left(1 - \sqrt{\alpha/n}\right)\mu \, .$$

Hence we have proved that

$$\mu_{j+1} \leq \left(1 - \sqrt{\alpha_j/n}\right)\mu_j \, , \qquad j = 0, 1, \ldots .$$

By repeatedly applying the above inequality, we deduce that

$$\mu_k \leq \mu_0 \prod_{j=0}^{k-1} \left(1 - \sqrt{\alpha_j/n}\right) .$$

Using the inequality $\log(1-t) < -t$, (3.14), $k \geq 8 > 2(\exp(1)+1)$, and Corollary 3.3, we obtain

$$\log\left(\frac{\mu_k}{\mu_0}\right) \leq \sum_{j=0}^{k-1} \log\left(1 - \sqrt{\alpha_j/n}\right) \leq -\sum_{j=0}^{k-1} \sqrt{\alpha_j/n} \leq -\sqrt{\frac{\nu\left(\overline{\beta} - \underline{\beta}\right)k}{n \log^{1+\nu} k}} \, ,$$

which completes the proof of our theorem. □

In the following corollary we give an explicit upper bound for the number of iterations required by Algorithm 1 to obtain a solution of the HLCP with prescribed accuracy. More precisely, given any $\epsilon > 0$, we have to find an upper bound for the number

$$K_\epsilon := \min\left\{K \ : \ x^{k\,T} s^k \leq \epsilon \ \forall k \geq K\right\} . \tag{3.16}$$

The upper bound will depend on n and

$$L_\epsilon := \log\left(\frac{x^{0\,T} s^0}{\epsilon}\right) . \tag{3.17}$$

COROLLARY 3.8. *If* $nL_\epsilon^2 > \exp(2)/\left(\nu(\overline{\beta} - \underline{\beta})\right)$, *then*

$$K_\epsilon \leq \left\lceil \frac{7^{1+\nu}}{\nu(\overline{\beta} - \underline{\beta})} \, nL_\epsilon^2 \log^{1+\nu}\left(nL_\epsilon^2\right) \right\rceil .$$

Proof. From Theorem 3.7 we deduce that $x^{k\,T} s^k \leq \epsilon$ for any K with the property

$$\frac{K^{1/2}}{\log^{(1+\nu)/2} K} \geq \sigma := \left(\nu(\overline{\beta} - \underline{\beta})\right)^{-1/2} \sqrt{n} L_\epsilon \, .$$

Since $\sigma > \exp(1)$, we can use Corollary 3.5 to show that

$$K_\epsilon \leq \overline{K}_\epsilon := \left(4\,(1+\log 2)\log\sigma\right)^{1+\nu}\sigma^2,$$

and the statement of our corollary follows by noticing that

$$4\,(1+\log 2)\log\sigma = 2\,(1+\log 2)\left(\log\left(nL_\epsilon^2\right) - \log\left(\nu(\overline{\beta}-\underline{\beta})\right)\right)$$

$$\leq 4\,(1+\log 2)\left(\log\left(nL_\epsilon^2\right)-1\right) < 4\,(1+\log 2)\log\left(nL_\epsilon^2\right) < 7\log\left(nL_\epsilon^2\right). \qquad \square$$

If ν is a positive constant independent of n and L_ϵ, then Algorithm 1 is independent of the dimension of the problem and the stopping criterion $x^{k\,T}s^k \leq \epsilon$. However, by letting ν depend on n and L_ϵ, we can slightly improve the computational complexity.

COROLLARY 3.9. *If*

$$nL_\epsilon^2 \geq \max\left\{\exp\left(\exp(1)\right),\ \frac{2.072\exp(2)}{\overline{\beta}-\underline{\beta}}\log\log\left(\frac{\exp(2)}{\overline{\beta}-\underline{\beta}}\right)\right\},$$

and we take $\nu = (\log\log(nL_\epsilon^2))^{-1}$ *in Algorithm* 1, *then*

$$K_\epsilon \leq \left\lceil \frac{134}{\overline{\beta}-\underline{\beta}}\,nL_\epsilon^2\log\left(nL_\epsilon^2\right)\log\log\left(nL_\epsilon^2\right)\right\rceil.$$

Proof. From Lemma 3.6 we deduce that $nL_\epsilon^2 \geq \exp(2)/(\nu(\overline{\beta}-\underline{\beta}))$, and Corollary 3.8 can be applied. The desired result follows immediately by noticing that $\log^\nu(nL_\epsilon^2) = \exp(1)$ and $7^{1+\nu}\exp(1) \leq 49\exp(1) < 134$. $\square$

We note that although for $\nu = (\log\log(nL_\epsilon))^{-1}$ Algorithm 1 depends on ϵ, it will produce an (infinite) sequence $z^k \in \mathcal{D}(\underline{\beta})$ with $\lim_{k\to\infty}\mu_k = 0$. As we mentioned in the introduction, this is not the case with the primal-dual affine-scaling algorithm of Monteiro, Adler, and Resende [23]. Given a starting point $z^0 \in \mathcal{C}$ on the central path and a tolerance $\epsilon > 0$, their algorithm produces a finite sequence of points $\left(z^k\right)$ by taking at each iteration a fixed stepsize $\theta_\epsilon = 1/\left(n\lceil\log L_\epsilon\rceil\right)$, i.e.,

$$z^{k+1} = z^k + \theta_\epsilon w^k, \qquad k = 0,1,\ldots,\overline{K}_\epsilon := \frac{\lceil n\log L_\epsilon\rceil}{\theta_\epsilon}.$$

It is shown that $z^k \in \mathcal{N}_\infty(\overline{\alpha}_k)$, with $\overline{\alpha}_k < n\overline{K}_\epsilon\overline{\theta}_\epsilon^{\,2} = 1\,, k = 0,1,\ldots,\overline{K}_\epsilon$, which implies the feasibility of z^k for $k \leq \overline{K}_\epsilon$. However, the positivity of z^k is no longer guaranteed for $k > \overline{K}_\epsilon$, so that the algorithm is not defined for $k > \overline{K}_\epsilon$. Since the algorithm of [23] uses a fixed (and small) steplength it cannot have superlinear convergence. Moreover since this algorithm produces only a finite sequence, we cannot even talk about its order of convergence. In contrast, in the next subsection we will show that the Q-order of convergence of Algorithm 1 is two.

3.4. Superlinear convergence. The main ingredient in the proof of superlinear convergence is provided by the following lemma, which is easily obtained by applying Theorem 2.3 with

$$\mathcal{K} = \mathcal{K}(\underline{\beta},\overline{\mu}) = \left\{(\tau,p)\ :\ 0 \leq \tau \leq \overline{\mu}\,,\ e^Tp = n\,,\ p \geq \underline{\beta}\,e\right\} \tag{3.18}$$

and (3.3).

LEMMA 3.10. *If HLCP* 2.1 *is monotone and has a strictly complementary solution, then for any* $\beta \in (0,1)$ *and any* $\overline{\mu} > 0$ *there is constant* $c = c(\beta, \overline{\mu})$ *such that the affine-scaling direction given by* (3.1) *satisfies*

$$\| u \|_2 \le c\,\mu\,, \quad \| v \|_2 \le c\,\mu \qquad \forall z \in \left\{ \lceil x,\, s \rfloor \in \mathcal{D}(\beta) \;:\; \mu = \frac{x^T s}{n} \le \overline{\mu} \right\}.$$

In the next theorem we prove that under the strict complementarity assumption the sequence (μ_k) converges to zero with Q-order 2. We recall that the Q-order of a sequence of positive numbers (η_k) that converges to zero is defined as

$$\mathcal{Q}(\eta_k) = \sup\{\omega \in (1,\infty) \;:\; \exists \Gamma \in \mathbb{R}_{++}\,,\, \forall k \in \mathbb{N}\,,\, \eta_{k+1} \le \Gamma \eta_k^{\omega}\}\,.$$

It is known (see [27]) that for $\overline{\omega} > 1$ we have $\overline{\omega} = \mathcal{Q}(\eta_k)$ if and only if

$$\overline{\omega} = \liminf \frac{\log \eta_{k+1}}{\log \eta_k}\,.$$

THEOREM 3.11. *If HLCP is monotone and has a strictly complementary solution, then the sequence* $\left(z^k\right)$ *produced by Algorithm* 1 *converges Q-superlinearly to a strictly complementary solution* $z^* \in \mathcal{F}^c$*, and the sequence of the corresponding complementarity gaps* (μ_k) *converges Q-superlinearly to zero. Moreover, the Q-orders of convergence of these sequences satisfy* $\mathcal{Q}\left(z^k\right) = \mathcal{Q}(\mu_k) \ge 2$.

Proof. From Theorem 3.7 it follows that $(\tau_k, p^k) := (\mu_k, (x^k s^k)/\mu_k) \in \mathcal{K}(\underline{\beta}, \mu_0)$ $\forall k \ge 0$, so that by using Lemma 3.10 we deduce that there is a constant $c = c(\underline{\beta}, \mu_0)$ such that

$$\| u \|_2 \le c\,\mu\,,\ \| v \|_2 \le c\,\mu \qquad \text{at each iteration } k = 0, 1, \ldots. \tag{3.19}$$

For k sufficiently large we have $\mu = \mu_k < 1$, so that $\log \mu_k < 0$, and by using Theorem 3.7, we obtain

$$0 \le \frac{\log \alpha_k}{\log \mu_k} \le \frac{\log\left(\nu\left(\overline{\beta} - \underline{\beta}\right)\right) - \log\left((k + \exp(1) + 1)\log^{1+\nu}(k + \exp(1) + 1)\right)}{\log \mu_0 - \sqrt{\frac{\nu\left(\overline{\beta} - \underline{\beta}\right)k}{n \log^{1+\nu} k}}}\,.$$

It follows that $\lim_{k\to\infty} \frac{\log \alpha_k}{\log \mu_k} = 0$, which implies $\lim_{k\to\infty} \frac{\mu_k}{\alpha_k} = 0$, so that for k sufficiently large we have $\mu = \mu_k < \alpha_k c^{-2} = \alpha c^{-2}$. By using (3.15) and the notation from the proof of Theorem 3.7,

$$0 < \theta < 1 \quad \text{and} \quad \frac{\| q \|_2\, \theta^2}{1-\theta} \le \alpha \text{ imply} \quad z(\theta) \in \mathcal{D}(\beta_+)\,.$$

Given that

$$\frac{\| q \|_2\, \theta^2}{1-\theta} \le \frac{\| u \|_2 \| v \|_2\, \theta^2}{(1-\theta)\mu} \le \frac{c^2 \mu \theta^2}{1-\theta} \le \alpha \qquad \forall \theta \in \left(0,\, 1 - \frac{c^2\mu}{\alpha}\right),$$

it follows that $\overline{\theta} \ge 1 - \frac{c^2\mu}{\alpha}$, and therefore

$$\mu_+ = \mu\left(\overline{\theta}\right) \le \mu\left(1 - \frac{c^2\mu}{\alpha}\right) \le \frac{c^2\mu^2}{\alpha} + \frac{u^T v}{n} \le \left(\frac{1}{\alpha} + \frac{1}{n}\right) c^2 \mu^2 \le \frac{2c^2}{\alpha}\mu^2\,.$$

By taking logarithms we obtain

$$\frac{\log \mu_+}{\log \mu} \geq 2 + \frac{\log\left(2c^2\right)}{\log \mu} - \frac{\log \alpha}{\log \mu}.$$

Since the right-hand side of the above inequality tends to zero as $k \to \infty$, we deduce that $\liminf \frac{\log \mu_{k+1}}{\log \mu_k} \geq 2$. Hence $\mathcal{Q}(\mu_k) \geq 2$. On the other hand, we have $\left\| z^{k+1} - z^k \right\|_2 \leq \left\| w^k \right\|_2 \leq \sqrt{2} c \mu_k$, and by applying Theorem 2 of [28], we deduce the convergence of the sequence $\left(z^k\right)$ to a strictly complementary solution $z^* \in \mathcal{F}^c$ and the fact that $\mathcal{Q}\left(z^k\right) = \mathcal{Q}(\mu_k)$. □

4. Higher order affine scaling methods.

4.1. The higher order affine scaling directions. The higher order affine scaling directions to be considered in this section are related to the higher order derivatives of the central path. As we have seen in section 2, the central path $z(\tau, p) = \lceil x(\tau, p),\, s(\tau, p) \rfloor$ passing through a positive vector $p \in \mathbb{R}^n_{++}$ is analytic in τ if HLCP has a strictly complementary solution, and in $\rho = \sqrt{\tau}$ in the general case. By repeatedly differentiating the equations of the central path,

$$\begin{aligned} x(\tau, p) s(\tau, p) &= \tau p, \\ Q x(\tau, p) + R s(\tau, p) &= b, \end{aligned} \tag{4.1}$$

with respect to τ, we obtain

$$\begin{cases} s(\tau,p)\frac{\partial}{\partial \tau} x(\tau,p) + x(\tau,p)\frac{\partial}{\partial \tau} s(\tau,p) = p, \\ Q\frac{\partial}{\partial \tau} x(\tau,p) + R\frac{\partial}{\partial \tau} s(\tau,p) = 0, \end{cases}$$

$$\begin{cases} s(\tau,p)\frac{\partial^i}{\partial \tau^i} x(\tau,p) + x(\tau,p)\frac{\partial^i}{\partial \tau^i} s(\tau,p) = -\sum_{j=1}^{i-1} \begin{pmatrix} i \\ j \end{pmatrix} \frac{\partial^j}{\partial \tau^j} x(\tau,p) \frac{\partial^{i-j}}{\partial \tau^{i-j}} s(\tau,p), \\ Q\frac{\partial^i}{\partial \tau^i} x(\tau,p) + R\frac{\partial^i}{\partial \tau^i} s(\tau,p) = 0, \end{cases}$$

$$i = 2, 3, \ldots.$$

If we reparameterize the central path equations in terms of $\rho = \sqrt{\tau}$, then the derivatives with respect to ρ of $\overline{z}(\rho, p) = \lceil \overline{x}(\rho, p),\, \overline{s}(\rho, p) \rfloor := z(\rho^2, p)$ are given by

$$\begin{cases} \overline{s}(\rho,p)\frac{\partial}{\partial \rho} \overline{x}(\rho,p) + \overline{x}(\rho,p)\frac{\partial}{\partial \rho} \overline{s}(\rho,p) = 2\rho p, \\ Q\frac{\partial}{\partial \rho} \overline{x}(\rho,p) + R\frac{\partial}{\partial \rho} \overline{s}(\rho,p) = 0, \end{cases}$$

$$\begin{cases} \overline{s}(\rho,p)\frac{\partial^2}{\partial \rho^2} \overline{x}(\rho,p) + \overline{x}(\rho,p)\frac{\partial^2}{\partial \rho^2} \overline{s}(\rho,p) = 2p - 2\frac{\partial}{\partial \rho} \overline{x}(\rho,p)\frac{\partial}{\partial \rho} \overline{s}(\rho,p), \\ Q\frac{\partial^2}{\partial \rho^2} \overline{x}(\rho,p) + R\frac{\partial^2}{\partial \rho^2} \overline{s}(\rho,p) = 0, \end{cases}$$

$$\begin{cases} \overline{s}(\rho,p)\frac{\partial^i}{\partial \rho^i} \overline{x}(\rho,p) + \overline{x}(\rho,p)\frac{\partial^i}{\partial \rho^i} \overline{s}(\rho,p) = -\sum_{j=1}^{i-1} \begin{pmatrix} i \\ j \end{pmatrix} \frac{\partial^j}{\partial \rho^j} \overline{x}(\rho,p) \frac{\partial^{i-j}}{\partial \rho^{i-j}} \overline{s}(\rho,p), \\ Q\frac{\partial^i}{\partial \rho^i} \overline{x}(\rho,p) + R\frac{\partial^i}{\partial \rho^i} \overline{s}(\rho,p) = 0, \end{cases}$$

$$i = 3, 4, \ldots.$$

If HLCP is a reformulation of an LP problem, then it is known that it has a strictly complementary solution. In general it is very difficult to establish whether HLCP has

a strictly complementary solution. However, if this is the case, the algorithm should take advantage of this information. In order to treat the two cases in a unified manner we define

$$\vartheta = \begin{cases} 0 & \text{if HLCP is known to be nondegenerate,} \\ 1 & \text{otherwise.} \end{cases} \tag{4.2}$$

At each step of our higher order affine-scaling interior point method we have a point $z = \lceil\, x,\, s \,\rfloor \in \mathcal{D}(\beta)$, and we consider the vectors

$$w^i = \lceil\, u^i,\, v^i \,\rfloor := \begin{cases} \dfrac{(-1)^i \mu^i}{i!} \left\lceil\, \dfrac{\partial^i}{\partial \tau^i} x(\tau, p),\ \dfrac{\partial^i}{\partial \tau^i} s(\tau, p) \,\right\rfloor \Bigg|_{\substack{p = \frac{xs}{\mu}, \\ \tau = \mu,}} & \text{if } \vartheta = 0, \\[2ex] \dfrac{(-1)^i \mu^{i/2}}{i!} \left\lceil\, \dfrac{\partial^i}{\partial \rho^i} \overline{x}\,(\rho, p),\ \dfrac{\partial^i}{\partial \rho^i} \overline{s}\,(\rho, p) \,\right\rfloor \Bigg|_{\substack{p = \frac{xs}{\mu}, \\ \rho = \sqrt{\mu},}} & \text{if } \vartheta = 1. \end{cases} \tag{4.3}$$

4.2. The higher order algorithm. It is easily seen that the vectors (4.3) can be obtained by solving the following m systems of linear equations:

$$\begin{cases} su^1 + xv^1 = -(1+\vartheta)xs, \\ Qu^1 + Rv^1 = 0, \end{cases}$$

$$\begin{cases} su^2 + xv^2 = \vartheta xs - u^1 v^1, \\ Qu^2 + Rv^2 = 0, \end{cases} \tag{4.4}$$

$$\begin{cases} su^i + xv^i = -\sum_{j=1}^{i-1} u^j v^{i-j}, \\ Qu^i + Rv^i = 0, \end{cases} \qquad i = 3, \ldots, m.$$

The m linear systems above have the same matrix, so that their numerical solution requires only one matrix factorization and m backsolves. This involves $O(n^3) + m\,O(n^2)$ arithmetic operations.

We note that for $\vartheta = 0$, $w^1 = \lceil\, u^1,\, v^1 \,\rfloor$ is just the affine scaling direction considered in section 3.

Given the vectors $w^i = \lceil\, u^i,\, v^i \,\rfloor$ defined by (4.4), we consider the polynomial

$$z(\theta) = z + \sum_{i=1}^{m} w^i \theta^i\,, \tag{4.5}$$

which represents the mth order Taylor expansion around $\theta = 0$ of the function $\theta \to z\,((1-\theta)\mu, xs/\mu)$ in case $\vartheta = 0$, and of the function $\theta \to \overline{z}\,(\sqrt{(1-\theta)\mu}, xs/\mu)$ in case $\vartheta = 1$.

We have $z(0) = z \in \mathcal{D}(\beta)$ and define

$$\check{\theta} = \sup\left\{ \tilde{\theta} \in (0,1] \ :\ z(\theta) \in \mathcal{D}(\beta_+)\ , \forall\, \theta \in [0,\, \tilde{\theta}] \right\}\,, \tag{4.6}$$

where β_+ is given by (3.8). From (4.4)–(4.5) we deduce that

$$x(\theta)s(\theta) = (1-\theta)^{1+\vartheta} xs + \sum_{i=m+1}^{2m} \theta^i h^i \,,$$

$$\mu(\theta) = (1-\theta)^{1+\vartheta} \mu + \sum_{i=m+1}^{2m} \theta^i (e^T h^i/n) \,,$$

$$\text{where } h^i = \sum_{j=i-m}^{m} u^j v^{i-j} \,. \tag{4.7}$$

Therefore the computation of (4.6) involves the solution of a system of polynomial inequalities of order $2m$ in θ. Good lower bounds of the exact solution can be obtained by a line search procedure. In what follows we will give simple lower bounds that will be used in the proof of global convergence.

Given $\check{\theta}$ or a suitable convenient lower bound, we compute

$$\overline{\theta} = \operatorname{argmin} \left\{ \mu(\theta) \;:\; \theta \in [\,0, \check{\theta}\,] \right\} \tag{4.8}$$

and obtain a new point

$$z^+ = z(\overline{\theta}\,) \,. \tag{4.9}$$

We have $z^+ \in \mathcal{D}(\beta_+)$ by construction, and the process can be repeated. Our higher order affine-scaling method is thus defined by the following iterative procedure.

ALGORITHM 2. Given real parameters $0 < \underline{\beta} < \overline{\beta} < 1$, $0 < \nu \le 1$, integer $m \ge 2$, Boolean variable $\vartheta \in \{0, 1\}$, and a vector $z^0 \in \mathcal{D}(\overline{\beta}\,)$:

Set $k \leftarrow 0$, $\beta_0 \leftarrow \overline{\beta}$ and consider the sequence (3.10);
repeat
  Set $z \leftarrow z^k$, $\alpha \leftarrow \alpha_k$, $\beta \leftarrow \beta_k$;
  Compute $w^1, \ldots, w^m$ by solving (4.4);
  Set $\beta_+ = \beta - \alpha$;
  Compute steplength $\overline{\theta}$ from (4.6), (4.8);
  Compute z^+ from (4.9);
  Set $\theta_k \leftarrow \overline{\theta}$, $z^{k+1} \leftarrow z^+$, $\mu_{k+1} \leftarrow \mu(z^+)$, $\beta_{k+1} \leftarrow \beta_+$;
  Set $k \leftarrow k+1$.
continue

4.3. Global convergence. The computational complexity of Algorithm 2 is the same for $\vartheta = 0$ and $\vartheta = 1$. One could eventually obtain slightly better constants if $\vartheta = 0$ and/or if HLCP is skew-symmetric, but in what follows we will obtain bounds in the monotone case that are independent of ϑ.

LEMMA 4.1. *If HLCP is monotone and if* $z = \lceil\, x, s \,\rfloor \in \mathcal{D}(\beta)$, *then the vectors* h^i *defined by* (4.4), (4.7) *satisfy*

$$\| h^i \|_2 \le \frac{2\beta\mu}{i} \left(4\sqrt{n/\beta} \right)^i \,, \quad \left| e^T h^i \right| \le \frac{\beta\mu}{i} \left(4\sqrt{n/\beta} \right)^i \,,$$

$$i = m+1, \ldots, 2m \,.$$

Proof. First let us prove that the quantities $\eta_i := \left\| Du^i + D^{-1}v^i \right\|_2$ satisfy

$$\sqrt{\| Du^i \|_2^2 + \| D^{-1}v^i \|_2^2} \le \eta_i \le 2\overline{\alpha}_i \sqrt{\beta\mu} \left(\frac{1+\vartheta}{2} \sqrt{n/\beta} \right)^i ,$$

$$i = 1, 2, \ldots, m ,$$

where the sequence

$$\overline{\alpha}_i := \frac{1}{i} \begin{pmatrix} 2i-2 \\ i-1 \end{pmatrix} \le \frac{1}{i} 4^i$$

satisfies the following recurrence scheme:

$$\overline{\alpha}_1 = 1, \quad \overline{\alpha}_i = \sum_{j=1}^{i-1} \overline{\alpha}_j \, \overline{\alpha}_{i-j} .$$

The first part of the inequality follows immediately, since by using (4.4) and the monotony of the HLCP, we deduce that $u^{i\,T} v^i \ge 0$. Hence

$$\left\| Du^i + D^{-1}v^i \right\|_2^2 = \left\| Du^i \right\|_2^2 + 2u^{i\,T} v^i + \left\| D^{-1}v^i \right\|_2^2 \ge \left\| Du^i \right\|_2^2 + \left\| D^{-1}v^i \right\|_2^2 .$$

By multiplying the first equations of (4.4) with $(xs)^{-1/2}$, we obtain

$$Du^1 + D^{-1}v^1 = -(1+\vartheta)(xs)^{1/2},$$

$$Du^2 + D^{-1}v^2 = \vartheta(xs)^{1/2} - (xs)^{-1/2} u^1 v^1,$$

$$Du^i + D^{-1}v^i = -(xs)^{-1/2} \sum_{j=1}^{i-1} Du^j D^{-1} v^{i-j} , \quad i = 3, \ldots, m .$$

Because $z \in \mathcal{D}(\beta)$ we have $(xs)^{-1/2} \le 1/\sqrt{\beta\mu}$, and, using Lemma 3.1, we deduce that

$$\eta_1 = (1+\vartheta)\sqrt{n\mu} ,$$

$$\eta_2^2 = \vartheta^2 n\mu - 2\vartheta u^{1\,T} v^1 + \left\| (xs)^{-1/2} u^1 v^1 \right\|_2^2 \le \vartheta^2 n\mu + \frac{\left\| u^1 v^1 \right\|_2^2}{\beta\mu}$$

$$\le \vartheta^2 n\mu + \frac{\eta_1^4}{8\beta\mu} \le \vartheta^2 n\mu + \frac{(1+\vartheta)^4 n^2 \mu}{8\beta} < \frac{(1+\vartheta)^4 n^2 \mu}{4\beta} ,$$

$$\eta_i \le \frac{1}{\sqrt{\beta\mu}} \sum_{j=1}^{i-1} \left\| Du^j \right\|_2 \left\| D^{-1}v^{i-j} \right\|_2 , \quad i = 3, \ldots, m .$$

Since

$$\left\| Du^j \right\|_2 \left\| D^{-1}v^{i-j} \right\|_2 + \left\| Du^{i-j} \right\|_2 \left\| D^{-1}v^j \right\|_2$$

$$\le \left(\left\| Du^j \right\|_2^2 + \left\| D^{-1}v^j \right\|_2^2 \right)^{1/2} \left(\left\| Du^{i-j} \right\|_2^2 + \left\| D^{-1}v^{i-j} \right\|_2^2 \right)^{1/2} \le \eta_j \, \eta_{i-j} ,$$

we obtain

$$\eta_i \le \frac{1}{2\sqrt{\beta\mu}} \sum_{j=1}^{i-1} \eta_j \, \eta_{i-j} \,, \quad i = 3, \ldots, m \,.$$

The required inequalities are then proved by mathematical induction (see [55, 54]).

The upper bound for $\left\| h^i \right\|_2$, $i = m+1, m+2, \ldots, 2m$, can be obtained by writing

$$\begin{aligned}
\left\| h^i \right\|_2 &\le \sum_{j=i-m}^{m} \left\| Du^j \right\|_2 \left\| D^{-1} v^{i-j} \right\|_2 \le \sum_{j=1}^{i-1} \left\| Du^j \right\|_2 \left\| D^{-1} v^{i-j} \right\|_2 \\
&= \frac{1}{2} \sum_{j=1}^{i-1} \left(\left\| Du^j \right\|_2 \left\| D^{-1} v^{i-j} \right\|_2 + \left\| Du^{i-j} \right\|_2 \left\| D^{-1} v^j \right\|_2 \right) \\
&\le \frac{1}{2} \sum_{j=1}^{i-1} \sqrt{\| Du^j \|_2^2 + \| D^{-1} v^j \|_2^2} \sqrt{\| Du^{i-j} \|_2^2 + \| D^{-1} v^{i-j} \|_2^2} \\
&\le \frac{1}{2} \sum_{j=1}^{i-1} \eta_j \, \eta_{i-j} \le 2\beta\mu \left(\frac{1+\vartheta}{2} \sqrt{n/\beta} \right)^i \sum_{j=1}^{i-1} \overline{\alpha}_j \, \overline{\alpha}_{i-j} \\
&= 2\beta\mu \left(\frac{1+\vartheta}{2} \sqrt{n/\beta} \right)^i \overline{\alpha}_i \le \frac{2\beta\mu}{i} \left(2(1+\vartheta)\sqrt{n/\beta} \right)^i \le \frac{2\beta\mu}{i} \left(4\sqrt{n/\beta} \right)^i \,.
\end{aligned}$$

Finally by using Proposition 2.1 and Lemma 3.1 (iv), we have

$$\begin{aligned}
\left| e^T h^i \right| &= \left| \sum_{j=i-m}^{m} u^{j\,T} v^{i-j} \right| \le \frac{1}{2} \sum_{j=1}^{i-1} \left| u^{j\,T} v^{i-j} + u^{i-j\,T} v^j \right| \\
&\le \sum_{j=1}^{i-1} \sqrt{u^{j\,T} v^j} \sqrt{u^{i-j\,T} v^{i-j}} \le \frac{1}{4} \sum_{j=1}^{i-1} \eta_j \, \eta_{i-j} \le \beta\mu \left(\frac{1+\vartheta}{2} \sqrt{n/\beta} \right)^i \sum_{j=1}^{i-1} \overline{\alpha}_j \, \overline{\alpha}_{i-j} \\
&= \beta\mu \left(\frac{1+\vartheta}{2} \sqrt{n/\beta} \right)^i \overline{\alpha}_i \le \frac{\beta\mu}{i} \left(2(1+\vartheta)\sqrt{n/\beta} \right)^i \le \frac{\beta\mu}{i} \left(4\sqrt{n/\beta} \right)^i \,. \qquad \square
\end{aligned}$$

In the following lemma we give a lower bound for the maximum stepsize along the higher order direction.

LEMMA 4.2. *If HLCP is monotone, $z \in \mathcal{D}(\beta)$, and $n \ge 5$, then the maximum stepsize $\check{\theta}$ defined in* (4.6) *satisfies the following inequality:*

$$\check{\theta} \ge \widehat{\theta} := \frac{\beta^{\frac{m-1}{2(m+1)}}}{4\sqrt{n}} \left(\frac{\alpha}{2} \right)^{\frac{1}{m+1}} \,,$$

and

$$\mu\left(\widehat{\theta}\right) \le \left(1 - \widehat{\theta}/2\right) \mu \,.$$

Proof. We have $z(\theta) \in \mathcal{D}(\beta_+)$ if and only if $x(\theta)s(\theta) - (\beta-\alpha)\mu(\theta)e \geq 0$. Using the fact that $z = z(0) \in \mathcal{D}(\beta)$, we can write

$$
\begin{aligned}
& x(\theta)s(\theta) - (\beta-\alpha)\mu(\theta)e \\
&= (1-\theta)^{1+\vartheta} xs + \sum_{i=m+1}^{2m} \theta^i h^i - (\beta-\alpha)\left((1-\theta)^{1+\vartheta}\mu + \frac{1}{n}\sum_{i=m+1}^{2m} \theta^i e^T h^i\right) e \\
&\geq (1-\theta)^{1+\vartheta}\beta\mu e + \sum_{i=m+1}^{2m} \theta^i h^i - (\beta-\alpha)\left((1-\theta)^{1+\vartheta}\mu + \sum_{i=m+1}^{2m} \theta^i \frac{e^T h^i}{n}\right) e \\
&= (1-\theta)^{1+\vartheta}\alpha\mu e + \sum_{i=m+1}^{2m} \theta^i h^i - (\beta-\alpha)\sum_{i=m+1}^{2m} \theta^i \frac{e^T h^i}{n} e \\
&= (1-\theta)^{1+\vartheta}\alpha\mu e + (\beta-\alpha)\sum_{i=m+1}^{2m} \theta^i \left(h^i - \frac{e^T h^i}{n} e\right) + (1-\beta+\alpha)\sum_{i=m+1}^{2m} \theta^i h^i \\
&\geq (1-\theta)^{1+\vartheta}\alpha\mu e - \sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 e\,.
\end{aligned}
$$

Therefore,

$$
z \in \mathcal{D}(\beta) \;\text{ and }\; \sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 \leq (1-\theta)^{1+\vartheta}\alpha\mu \quad \text{imply} \quad z(\theta) \in \mathcal{D}(\beta-\alpha)\,. \tag{4.10}
$$

From Lemma 4.1 it follows that

$$
\sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 \leq 2\beta\mu \sum_{i=m+1}^{2m} \frac{1}{i}\left(4\theta\sqrt{n/\beta}\right)^i\,.
$$

For any $t \in (0,1]$ we have

$$
\sum_{i=m+1}^{2m} \frac{t^i}{i} \leq t^{m+1} \sum_{i=m+1}^{2m} \frac{1}{i} < t^{m+1} \int_m^{2m} \frac{du}{u} = t^{m+1}\log 2 < .7\, t^{m+1}\,.
$$

Hence,

$$
\theta \leq \frac{t\sqrt{\beta}}{4\sqrt{n}} \quad \text{and} \quad t \leq 1 \quad \text{imply} \quad \sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 \leq 1.4\beta\mu t^{m+1}\,.
$$

On the other hand if $n \geq 5$, then

$$
\theta \leq \frac{t\sqrt{\beta}}{4\sqrt{n}} \quad \text{and} \quad t \leq 1 \quad \text{imply} \quad (1-\theta)^{1+\vartheta} \geq \left(1 - \frac{t\sqrt{\beta}}{4\sqrt{n}}\right)^{1+\vartheta} \geq \left(1 - \frac{1}{4\sqrt{5}}\right)^2 > .7.
$$

By taking $t = (\alpha/(2\beta))^{1/(m+1)}$, we deduce that if $n \geq 5$, then

$$
z(\theta) \in \mathcal{D}(\beta-\alpha) \qquad \forall \theta \in \left[0, \widehat{\theta}\right]\,,
$$

which proves that $\check{\theta} \geq \widehat{\theta}$. Taking again $t = (\alpha/(2\beta))^{1/(m+1)}$, we have $\widehat{\theta} = \frac{t\sqrt{\beta}}{4\sqrt{n}}$, so that we can write

$$\frac{\mu(\widehat{\theta})}{\mu} = \left(1-\widehat{\theta}\right)^{1+\vartheta} + \sum_{i=m+1}^{2m} \widehat{\theta}^{\,i}\, \frac{e^T h^i}{n\mu} \leq 1 - \widehat{\theta} + \frac{\beta}{n} \sum_{i=m+1}^{2m} \frac{t^i}{i}$$

$$< 1 - \frac{t\sqrt{\beta}}{4\sqrt{n}} + \frac{.7\,\beta t^{m+1}}{n} = 1 - \frac{t\sqrt{\beta}}{4\sqrt{n}} \left(1 - \frac{2.8\,\sqrt{\beta} t^m}{\sqrt{n}}\right).$$

Using the definition of t, $n \geq 5$, $0 < \nu \leq 1$, and the fact that

$$\alpha \leq \alpha_0 = \frac{\nu(\overline{\beta} - \underline{\beta})}{(\exp(1)+1)\log^{1+\nu}(\exp(1)+1)} < \frac{1}{(\exp(1)+1)\log^2(\exp(1)+1)},$$

we obtain

$$\frac{2.8\,\sqrt{\beta} t^m}{\sqrt{n}} \leq \frac{2.8\,\sqrt{\beta}}{\sqrt{5}} \left(\frac{\alpha}{2\beta}\right)^{\frac{m}{m+1}} \leq \frac{2.8\,\sqrt{\beta}}{\sqrt{5}} \left(\frac{\alpha}{2\beta}\right)^{\frac{1}{2}} \leq \frac{2\,\sqrt{\alpha}}{\sqrt{5}} \leq \frac{2\,\sqrt{\alpha_0}}{\sqrt{5}} < \frac{1}{2}.$$

It follows that $\mu(\widehat{\theta}) < (1 - \frac{t\sqrt{\beta}}{8\sqrt{n}})\mu$, which completes the proof. □

THEOREM 4.3. *If HLCP is monotone, then Algorithm 2 is well defined and produces a sequence of points* $\left(z^k\right)_{k=0}^{\infty}$, *with* $z^k \in \mathcal{D}(\beta_k) \subset \mathcal{D}(\underline{\beta})$. *If* $n \geq 5$, *then the following relations hold:*

$$\mu_{k+1} \leq \left(1 - \widehat{\theta}_k/2\right)\mu_k, \quad \widehat{\theta}_k \geq \frac{\underline{\beta}^{\frac{m-1}{2(m+1)}}}{4\sqrt{n}} \left(\frac{\alpha_k}{2}\right)^{\frac{1}{m+1}}, \qquad k = 0, 1, \ldots,$$

$$\mu_k \leq \mu_0 \exp\left(-\frac{\overline{\kappa}\nu^{\frac{1}{m+1}} k^{\frac{m}{m+1}}}{\sqrt{n}\log^{\frac{1+\nu}{m+1}} k}\right), \quad \overline{\kappa} := \frac{\underline{\beta}^{\frac{1}{6}} \left(\overline{\beta} - \underline{\beta}\right)^{\frac{1}{3}}}{2^{\frac{10}{3}}}, \qquad k = 8, 9, \ldots.$$

Proof. We have $z^k \in \mathcal{D}(\beta_k)$ by construction and $\mu_{k+1} \leq (1 - \widehat{\theta}_k/2)\mu_k$ by virtue of Lemma 4.2. It follows that

$$\mu_k \leq \mu_0 \prod_{j=0}^{k-1} \left(1 - \widehat{\theta}_j/2\right),$$

and by using the inequality $\log(1-t) < -t$, (3.14), $k \geq 8$, and Corollary 3.3, we obtain

$$\log\left(\frac{\mu_k}{\mu_0}\right) \leq \sum_{j=0}^{k-1} \log\left(1 - \widehat{\theta}_j/2\right) \leq -\frac{1}{2}\sum_{j=0}^{k-1} \widehat{\theta}_j \leq -\frac{\underline{\beta}^{\frac{m-1}{2(m+1)}}}{8\sqrt{n}} \sum_{j=0}^{k-1} \left(\frac{\alpha_j}{2}\right)^{\frac{1}{m+1}}$$

$$< -\frac{\underline{\beta}^{\frac{m-1}{2(m+1)}} \left(\nu(\overline{\beta} - \underline{\beta})\right)^{\frac{1}{m+1}} k^{\frac{m}{m+1}}}{2^{3+\frac{1}{m+1}}\sqrt{n}\log^{\frac{1+\nu}{m+1}} k} \leq -\frac{\underline{\beta}^{\frac{1}{6}} \left(\overline{\beta} - \underline{\beta}\right)^{\frac{1}{3}} \nu^{\frac{1}{m+1}} k^{\frac{m}{m+1}}}{2^{\frac{10}{3}}\sqrt{n}\log^{\frac{1+\nu}{m+1}} k},$$

which completes the proof of our theorem. □

In the next corollary we give an upper bound for the maximum number of iterations, K_ϵ, required by Algorithm 2 to obtain an approximate solution of the HLCP

with duality gap ϵ (see (3.16)). The upper bound is given in terms of the constants $\nu, \overline{\beta}, \underline{\beta}, m$ defining Algorithm 2, the dimension n, and the quantity L_ϵ from (3.17) which depends on ϵ and the starting point.

COROLLARY 4.4. *If* $\sqrt{n}L_\epsilon \geq (\overline{\kappa}\nu^{\frac{1}{m+1}})^{-1}\exp(1)$, *then*

$$K_\epsilon \leq \left\lceil \frac{6^{\frac{1+\nu}{m}}}{\overline{\kappa}^{\frac{m+1}{m}}\nu^{\frac{1}{m}}} \left(\sqrt{n}L_\epsilon\right)^{\frac{m+1}{m}} \log^{\frac{1+\nu}{m}}\left(\sqrt{n}L_\epsilon\right) \right\rceil .$$

Proof. From Theorem 4.3 we deduce that $x^{k\,T}s^k \leq \epsilon$ for any K with the property

$$\frac{K^{\frac{m}{m+1}}}{\log^{\frac{1+\nu}{m+1}} K} \geq \sigma := \left(\overline{\kappa}\nu^{\frac{1}{m+1}}\right)^{-1} \sqrt{n}L_\epsilon .$$

According to Corollary 3.5 it follows that

$$K_\epsilon \leq \overline{K}_\epsilon := \left(2\left(1+\frac{1+\nu}{m+1}\log\frac{1+\nu}{m}\right)\frac{m+1}{m}\log\sigma\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} .$$

By noticing that under our hypothesis $1+\nu \leq 2 \leq m$, $0 < \overline{\kappa} < 1$, we obtain

$$\sigma \geq \left(\overline{\kappa}\nu^{\frac{1}{m+1}}\right)^{-2}\exp(1) > \exp(1) ,$$

$$\log\sigma = \log\left(\sqrt{n}L_\epsilon\right) + \log\left(\left(\overline{\kappa}\nu^{\frac{1}{m+1}}\right)^{-1}\right)$$

$$< \log\left(\sqrt{n}L_\epsilon\right) + \log\left(\left(\overline{\kappa}\nu^{\frac{1}{m+1}}\right)^{-1}\exp(1)\right) \leq 2\log\left(\sqrt{n}L_\epsilon\right) ,$$

$$\overline{K}_\epsilon \leq (3\log\sigma)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}} \leq \left(6\log\left(\sqrt{n}L_\epsilon\right)\right)^{\frac{1+\nu}{m}} \sigma^{\frac{m+1}{m}}$$

$$\leq \frac{6^{\frac{1+\nu}{m}}}{\overline{\kappa}^{\frac{m+1}{m}}\nu^{\frac{1}{m}}} \left(\sqrt{n}L_\epsilon\right)^{\frac{m+1}{m}} \log^{\frac{1+\nu}{m}}\left(\sqrt{n}L_\epsilon\right) . \qquad \square$$

If ν is a positive constant independent of n and L_ϵ, then Algorithm 1 is independent of the dimension of the problem and the stopping criterion $x^{k\,T}s^k \leq \epsilon$. However, by letting ν depend on n and L_ϵ, we can slightly improve the computational complexity.

COROLLARY 4.5. *If*

$$\sqrt{n}L_\epsilon \geq \max\left\{\exp\left(\exp(1)\right) , \frac{2.072\exp(1)}{\overline{\kappa}}\log\log\left(\frac{\exp(1)}{\overline{\kappa}}\right)\right\} ,$$

and if we take $\nu = (\log\log(\sqrt{n}L_\epsilon))^{-1}$ *in Algorithm* 2, *then*

$$K_\epsilon \leq \left\lceil \frac{36^{\frac{1}{m}}\exp(1/m)}{\overline{\kappa}^{\frac{m+1}{m}}} \left(\sqrt{n}L_\epsilon\right)^{\frac{m+1}{m}} \left(\log\left(\sqrt{n}L_\epsilon\right)\log\log\left(\sqrt{n}L_\epsilon\right)\right)^{\frac{1}{m}} \right\rceil .$$

Proof. Using Lemma 3.6, we deduce that

$$\frac{\sqrt{n}L_\epsilon}{\log^{\frac{1}{m}}\log(\sqrt{n}L_\epsilon)} \geq \frac{\sqrt{n}L_\epsilon}{\log\log(\sqrt{n}L_\epsilon)} \geq \frac{\exp(1)}{\overline{\kappa}}\,,$$

which shows that Corollary 4.4 can be applied for our choice of ν. By noticing that $\log^{\frac{\nu}{m}}(\sqrt{n}L_\epsilon) = \exp(1/m)$ and $6^{1+\nu} \leq 6^2 = 36$, we obtain the desired result. ∎

COROLLARY 4.6. *Assume that*

$$\sqrt{n}L_\epsilon \geq \max\left\{\exp\left(\exp(1)\right)\,,\ \frac{2.072\exp(1)}{\overline{\kappa}}\log\log\left(\frac{\exp(1)}{\overline{\kappa}}\right)\right\}\,,$$

and consider Algorithm 2 with $\nu = (\log\log(\sqrt{n}L_\epsilon))^{-1}$. *Then the following implications hold:*

$$m \geq \log\log\log(\sqrt{n}L_\epsilon) \Rightarrow K_\epsilon \leq \left\lceil \frac{36^{\frac{1}{m}}\exp(1+1/m)}{\overline{\kappa}^{\frac{m+1}{m}}}\left(\sqrt{n}L_\epsilon\right)^{\frac{m+1}{m}}\log^{\frac{1}{m}}\left(\sqrt{n}L_\epsilon\right)\right\rceil\,,$$

$$m \geq \log\log(\sqrt{n}L_\epsilon) \Rightarrow K_\epsilon \leq \left\lceil \frac{36^{\frac{1}{m}}\exp(2+1/m)}{\overline{\kappa}^{\frac{m+1}{m}}}\left(\sqrt{n}L_\epsilon\right)^{\frac{m+1}{m}}\right\rceil\,,$$

$$m \geq \log(\sqrt{n}L_\epsilon) \Rightarrow K_\epsilon \leq \left\lceil \frac{36^{\frac{1}{m}}\exp(3+1/m)}{\overline{\kappa}^{\frac{m+1}{m}}}\sqrt{n}L_\epsilon\right\rceil\,.$$

4.4. Higher order convergence. As seen in the previous subsection, the computational complexity of Algorithm 2 is basically the same for $\vartheta = 1$ and $\vartheta = 0$. By contrast its asymptotic convergence properties depend on ϑ. In what follows we show that Algorithm 2 with $\vartheta = 1$ is superlinearly convergent for general problems. However, if the problem is known to have a strictly complementary solution, it is advantageous to take $\vartheta = 0$ in order to obtain a higher order of convergence.

LEMMA 4.7. *Assume HLCP is monotone, and consider the linear systems* (4.4), *where we take* $\vartheta = 1$ *for general problems and* $\vartheta = 0$ *for problems that are known to have a strictly complementary solution. Then for any* $\beta \in (0,1)$, *any* $\overline{\mu} > 0$, *and any integer* $m \geq 2$, *there is constant* $c = c(\beta, \overline{\mu}, m)$ *such that the solution* $u^1, v^1, \ldots, u^m, v^m$ *of* (4.4) *satisfies*

$$\left\|\, u^i \,\right\|_2 \leq c\,\mu^{\frac{i}{1+\vartheta}}\,, \quad \left\|\, v^i \,\right\|_2 \leq c\,\mu^{\frac{i}{1+\vartheta}} \qquad \forall z \in \left\{ \lceil\, x,\, s \,\rfloor \in \mathcal{D}(\beta)\ :\ \mu = \frac{x^T s}{n} \leq \overline{\mu}\ \right\}.$$

Proof. Use (4.3) and apply Theorem 2.3 with $\mathcal{K}$ given by (3.18). ∎

THEOREM 4.8. *Assume that HLCP is monotone, and consider Algorithm* 2, *where we take* $\vartheta = 1$ *for general problems and* $\vartheta = 0$ *for problems that are known to have a strictly complementary solution. Then the sequence* $\left(z^k\right)$ *produced by this algorithm converges Q-superlinearly to a maximal complementary solution* $z^* \in \mathcal{F}^c$, *and the sequence of the corresponding complementarity gaps* (μ_k) *converges Q-superlinearly to zero. Moreover, the Q-orders of convergence of these sequences satisfy*

$$\mathcal{Q}\left(z^k\right) = \mathcal{Q}\left(\mu_k\right) \geq \frac{m+1}{1+\vartheta}\,.$$

Proof. Since we are analyzing asymptotic properties we may assume $\mu_k < 1$. By using Theorem 4.3, we obtain

$$0 \leq \frac{\log \alpha_k}{\log \mu_k} \leq \frac{\log\left(\nu\left(\overline{\beta} - \underline{\beta}\right)\right) - \log\left((k+\exp(1)+1)\log^{1+\nu}(k+\exp(1)+1)\right)}{\log \mu_0 - \frac{\overline{\kappa}\nu^{\frac{1}{m+1}} k^{\frac{m}{m+1}}}{\sqrt{n}\log^{\frac{1+\nu}{m+1}} k}}.$$

It follows that $\lim_{k\to\infty} \frac{\log \alpha_k}{\log \mu_k} = 0$, which implies

$$\lim_{k\to\infty} \frac{\mu_k^{\frac{m-\vartheta}{1+\vartheta}}}{\alpha_k} = 0\,.$$

From Theorem 4.3 it follows that $(\tau_k, p^k) := \left(\mu_k, \left(x^k s^k\right)/\mu_k\right) \in \mathcal{K}\left(\underline{\beta}, \mu_0\right)\ \forall k \geq 0$, so that by using Lemma 4.7, we deduce that there is a constant $c = c\left(\underline{\beta}, \mu_0, m\right)$ such that

$$\left\| u^i \right\|_2 \leq c\,\mu^{\frac{i}{1+\vartheta}}\,, \quad \left\| v^i \right\|_2 \leq c\,\mu^{\frac{i}{1+\vartheta}} \quad \text{at each iteration } k = 0, 1, \ldots. \tag{4.11}$$

From (4.7) it follows that

$$\left\| h^i \right\|_2 \leq \sum_{j=i-m}^{m} \left\| u^j \right\|_2 \left\| v^{i-j} \right\|_2 \leq mc^2\mu^{\frac{i}{1+\vartheta}}\,.$$

For k sufficiently large we have $\mu^{\frac{1}{1+\vartheta}} \leq 1/2$, so that

$$\sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 \leq \sum_{i=m+1}^{2m} \left\| h^i \right\|_2 \leq mc^2\mu^{\frac{m+1}{1+\vartheta}} \sum_{i=0}^{m-1} \mu^{\frac{i}{1+\vartheta}} \leq 2mc^2\mu^{\frac{m+1}{1+\vartheta}} = \overline{c}\,\mu^{\frac{m+1}{1+\vartheta}}\,,$$

with $\overline{c} := 2mc^2$. For k sufficiently large we have $(\overline{c}/\alpha)\mu^{\frac{m-\vartheta}{1+\vartheta}} < 1$, and therefore

$$\sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 \leq (1-\theta)^{1+\vartheta}\alpha\mu \qquad \forall \theta \in \left[0, \hat{\theta}\right]\,,\ \hat{\theta} = 1 - (\overline{c}/\alpha)^{\frac{1}{1+\vartheta}}\,\mu^{\frac{m-\vartheta}{(1+\vartheta)^2}}\,.$$

According to (4.6) and (4.10) we have $\check{\theta} \geq \hat{\theta}$, so that by using (4.8) we obtain

$$\begin{aligned}
\mu_+ = \mu\left(\overline{\theta}\right) &\leq \mu\left(\hat{\theta}\right) = (1-\hat{\theta})^{1+\vartheta}\mu + \sum_{i=m+1}^{2m} \hat{\theta}^{\,i}(e^T h^i/n) \\
&\leq (1-\hat{\theta})^{1+\vartheta}\mu + \frac{1}{\sqrt{n}} \sum_{i=m+1}^{2m} \hat{\theta}^{\,i} \left\| h^i \right\|_2 \leq (1-\hat{\theta})^{1+\vartheta}\left(1 + \frac{\alpha}{\sqrt{n}}\right)\mu \\
&\leq \overline{c}\left(\frac{1}{\alpha} + \frac{1}{\sqrt{n}}\right)\mu^{\frac{m+1}{1+\vartheta}} \leq \frac{2\overline{c}}{\alpha}\,\mu^{\frac{m+1}{1+\vartheta}}\,.
\end{aligned}$$

By taking logarithms we obtain

$$\frac{\log \mu_+}{\log \mu} \geq \frac{m+1}{1+\vartheta} + \frac{\log(2\overline{c})}{\log \mu} - \frac{\log \alpha}{\log \mu}\,.$$

Since the right-hand side of the above inequality tends to zero as $k \to \infty$, we deduce that

$$\mathcal{Q}(\mu_k) = \liminf \frac{\log \mu_{k+1}}{\log \mu_k} \geq \frac{m+1}{1+\vartheta}.$$

For k sufficiently large we have $(c\mu)^{\frac{1}{1+\vartheta}} < 1 - 1/\sqrt{2}$, so that by using Lemma 4.7, we obtain

$$\left\|z^+ - z\right\|_2 \leq \sum_{i=1}^{m} \left\|w^i\right\|_2 \leq \sqrt{2} \sum_{i=1}^{m} (c\mu)^{\frac{i}{1+\vartheta}} = \sqrt{2} \frac{(c\mu)^{\frac{1}{1+\vartheta}} - (c\mu)^{\frac{m+1}{1+\vartheta}}}{1 - (c\mu)^{\frac{1}{1+\vartheta}}} \leq 2(c\mu)^{\frac{1}{1+\vartheta}}.$$

Finally, by applying Theorem 2 of [28], we deduce the convergence of the sequence $\left(z^k\right)$ to a maximal complementary solution $z^* \in \mathcal{F}^*$ and the fact that $\mathcal{Q}\left(z^k\right) = \mathcal{Q}(\mu_k)$. □

Acknowledgments. The author would like to thank Josef Stoer and two anonymous referees for carefully reading the manuscript and suggesting several improvements.

DUAL CHARACTERIZATION AND SCALARIZATION FOR BENSON PROPER EFFICIENCY*

JING-HUI QIU†

Abstract. By using dual cones and their properties, we establish a fundamental dual characterization and scalarization for Benson proper efficient points without any additional assumption on the ordering cone. From this, we obtain several scalarization theorems and Lagrange multiplier theorems for Benson proper minimizers of optimization problems with nearly cone-subconvexlike set-valued maps. The related known results are improved, and some new criteria for checking Benson proper efficiency are deduced.

Key words. locally convex space, dual cone, scalarization, nearly cone-subconvexlike set-valued map, Benson proper efficiency, Lagrange multiplier theorem

1. Introduction.

One of the most important problems in vector optimization is to find efficient points of sets. However, some efficient points exhibit certain abnormal properties. In order to get rid of such anomalous efficient points, Kuhn and Tucker [12] and Geoffrion [4] introduced the concept of proper efficiency. Since then, a number of different definitions of proper efficiency have been introduced and investigated. Benson [1] introduced a definition of proper efficiency for vector optimization, which has already been shown to have many desirable properties. There have been significant studies on Benson proper efficiency in vector optimization of vector-valued maps and set-valued maps. For example, under the assumption that the ordering cone has a weakly compact base, Song [21, 22] established a number of interesting criteria for checking Benson proper efficient solutions of vector optimization problems with weakened convex and nonconvex set-valued maps. Chen and Rong [2] and Li [13] characterized the Benson proper efficiency for generalized cone-subconvexlike vector-valued maps and cone-subconvexlike set-valued maps, respectively, in terms of scalarization, Lagrange multiplier, saddle point criterion, and duality under the assumption that the ordering cone is locally compact (or, equivalently, the ordering cone has a compact base). Gasimov [3] considered nonconvex optimization problems in normed spaces ordered by convex cones with bounded bases and characterized the Benson proper efficient points as minimal points of some type of cone-monotone functions. Hernández, Jiménez, and Novo [8] introduced Benson vectorial proper efficiency and proved scalarization theorems for the Benson vectorial proper efficiency in optimization problems with some algebraic type of cone-subconvexlike set-valued maps. Recently, Yang, Li, and Wang [24], Sach [19], and Xu and Liu [23] considered a more extensive class of set-valued maps, i.e., nearly cone-subconvexlike set-valued maps, and presented, respectively, scalarization theorems, saddle point theorems, and Lagrange multiplier theorems for vector optimization problems with such set-valued maps. We observe that in [24, 19, 23] the assumption that the ordering cone has a

compact base or a weakly compact base is also exploited. In this paper, by using the theory of dual cones and the theory of polars (see [11]), we show a fundamental dual characterization and scalarization for Benson proper efficient points without any additional assumption on the ordering cone. From this, we deduce some special scalarization theorems of Benson proper efficiency under various assumptions on the ordering cone or on the underlying space. Applying these results to vector optimization, we obtain scalarization theorems and Lagrange multiplier theorems for Benson proper minimizers of optimization problems with nearly cone-subconvexlike set-valued maps. The related known theorems are improved, and some new versions for checking Benson proper efficiency are deduced. The paper is organized as follows. In section 2, we characterize the solidness of dual cones in the various polar topologies on dual spaces and give the representations of the interiors of dual cones, which are useful for the scalarization of proper efficiency. In section 3, by using the polarity of cones (see [11]), we give a fundamental dual characterization and scalarization theorem for Benson proper efficient points of a given set, where we need only to assume that the ordering cone is a closed convex cone. From this, we deduce some particular scalarization theorems of Benson proper efficiency under various additional assumptions. In particular, we show that our method is also valid for dealing with Benson vectorial proper efficiency. In section 4, applying the results in section 3, we obtain several scalarization theorems for Benson proper minimizers in vector optimization problems with nearly cone-subconvexlike set-valued maps. Finally in section 5, we deduce some Lagrange multiplier theorems.

2. The interior of a dual cone. In order to give the scalarization of Benson proper efficiency, we need to study dual cones and their properties. Dual cones have been studied in many different settings; see, e.g., [20, 10, 6, 7, 16] and their references. We shall characterize the solidness of dual cones and give the representations of the interiors of dual cones in the different polar topologies on duals. First we present some notations (see, e.g., [9, 11, 18, 20]).

In this paper, we always assume, unless stated otherwise, that Y is a real locally convex Hausdorff topological vector space (denoted by l.c.s.), $Y^{\#}$ is its algebraic dual, and Y^* is its topological dual. For any nonempty set $A \subset Y$, $\mathrm{int}A$ and $\mathrm{cl}A$ denote its topological interior and its closure in Y, respectively. Also, $\mathrm{co}(A)$ and $\Gamma(A)$ denote the *convex hull* and the *absolutely convex hull* of A, respectively. The set $\{f \in Y^* : |f(a)| \leq 1 \ \forall a \in A\}$, denoted by A°, is called the *absolute polar* of A taken in Y^*; the set $\{f \in Y^* : f(a) \leq 1 \ \forall a \in A\}$, denoted by A^r, is called the *real polar* of A taken in Y^*. Besides, A^+ and A^- denote the set $\{f \in Y^* : f(a) \geq 0 \ \forall a \in A\}$ and the set $\{f \in Y^* : f(a) \leq 0 \ \forall a \in A\}$, respectively. Mutually, for any nonempty set $A' \subset Y^*$, we may define the absolute polar and the real polar of A' taken in Y as follows: $A'^\circ = \{y \in Y : |f(y)| \leq 1 \ \forall f \in A'\}$ and $A'^r = \{y \in Y : f(y) \leq 1 \ \forall f \in A'\}$. A nonempty set $C \subset Y$ is said to be a cone if $\lambda c \in C$ for any $c \in C$ and any $\lambda \geq 0$ and a convex cone if in addition $C + C \subset C$. A cone C is said to be pointed if $C \cap (-C) = \{0\}$. Here 0 denotes the zero vector of the vector space Y. For a convex cone C in Y, the dual cone of C is defined as

$$C^+ := \{f \in Y^* : f(c) \geq 0 \ \forall c \in C\}.$$

The quasi interior of C^+ is defined as

$$C^{+i} := \{f \in Y^* : f(c) > 0 \ \forall c \in C \backslash \{0\}\}.$$

A convex cone C with $\text{int}C \neq \emptyset$ is said to be a solid cone. A convex subset B of a convex cone C is said to be a base of C if $0 \notin \text{cl}(B)$ and $C = \text{cone}(B)$, where $\text{cone}(B)$ denotes the cone generated by B, i.e., $\text{cone}(B) := [0,\infty)B = \{\lambda b : \lambda \geq 0,\ b \in B\}$. Obviously, a convex cone with a base is pointed. Moreover, a convex cone C has a base if and only if $C^{+i} \neq \emptyset$. For a base B of C, we define B^{st} to be the set

$$\{f \in Y^* : \text{there exists } \delta > 0 \text{ such that } f(b) \geq \delta > 0\ \forall b \in B\}.$$

For any l.c.s. Y, we have an abundance of possible ways of introducing a locally convex topology on the dual Y^*. If $\mathcal{M}$ is any total saturated class of bounded subsets of Y (see [9, 11, 20]), the topology of uniform convergence on the sets M of $\mathcal{M}$ is a locally convex topology on Y^*. We denote it by $\mathcal{T}_{\mathcal{M}}$. Obviously $\{M^\circ : M \in \mathcal{M}\}$ is a 0-neighborhood base in $(Y^*, \mathcal{T}_{\mathcal{M}})$. Particularly, we denote the topologies on Y^* of uniform convergence on bounded subsets, weakly compact (absolutely) convex subsets, and finite subsets of Y by $\beta(Y^*, Y)$, $\tau(Y^*, Y)$, and $\sigma(Y^*, Y)$, which are called the strong topology, Mackey topology, and weak topology, respectively.

LEMMA 2.1. *Let Y be an l.c.s. and $C \subset Y$ be a convex cone. If there exists a locally convex topology $\mathcal{T}$ on Y^* such that $\text{int}_{\mathcal{T}}C^+ \neq \emptyset$, where $\text{int}_{\mathcal{T}}C^+$ denotes the interior of C^+ in $(Y^*, \mathcal{T})$, then $\text{int}_{\mathcal{T}}C^+ \subset C^{+i}$.*

Proof. Take any $f \in \text{int}_{\mathcal{T}}C^+$, and then there exists an absolutely convex 0-neighborhood W in $(Y^*, \mathcal{T})$ such that $f + W \subset C^+$. For any $c \in C\backslash\{0\}$, there exists $g \in Y^*$ such that $g(c) < 0$. Since W is absorbing in Y^*, there exists $\epsilon > 0$ such that $\epsilon g \in W$. Thus

$$f + \epsilon g \in f + W \subset C^+.$$

Hence

$$(f + \epsilon g)(c) \geq 0 \quad \text{and} \quad f(c) \geq -\epsilon g(c) > 0.$$

That is, $f \in C^{+i}$. □

THEOREM 2.1. *Let Y be an l.c.s. and $C \subset Y$ be a convex cone. Then $\text{int}_{\mathcal{T}_{\mathcal{M}}}C^+ \neq \emptyset$ if and only if C has a base $B \in \mathcal{M}$. In this case, $\text{int}_{\mathcal{T}_{\mathcal{M}}}C^+ = B^{st}$.*

Proof. (i) Let C have a base $B \in \mathcal{M}$. Then B is convex, $0 \notin \text{cl}(B)$, and $C = \text{cone}(B)$. By the Hahn–Banach separation theorem, there exists $f \in Y^*$ and $\delta > 0$ such that

$$0 < \delta \leq f(b)\ \ \forall b \in B.$$

Take any fixed ϵ with $0 < \epsilon < \delta$. Since $B \in \mathcal{M}$, ϵB° is a 0-neighborhood in $(Y^*, \mathcal{T}_{\mathcal{M}})$. For any $g \in \epsilon B^\circ$, we have $(f + g)(b) \geq \delta - \epsilon > 0$ for all $b \in B$, which implies that $f + g \in C^+$. That is, $f + \epsilon B^\circ \subset C^+$. Thus, $f \in \text{int}_{\mathcal{T}_{\mathcal{M}}}C^+$ and $\text{int}_{\mathcal{T}_{\mathcal{M}}}C^+ \neq \emptyset$.

(ii) Conversely, assume that $\text{int}_{\mathcal{T}_{\mathcal{M}}}C^+ \neq \emptyset$. Then there exists $f \in \text{int}_{\mathcal{T}_{\mathcal{M}}}C^+$. By Lemma 2.1, $f \in C^{+i}$. Moreover, there exists $M \in \mathcal{M}$ such that $f + M^\circ = f - M^\circ \subset C^+$. Let $B := (f = 1) \cap C$, where $(f = 1)$ denotes the set $\{y \in Y : f(y) = 1\}$. Clearly, B is a base of C. For any $b \in B$ and any $g \in M^\circ$, we have $(f - g)(b) \geq 0$. Thus $g(b) \leq f(b) = 1$ for all $b \in B$, for all $g \in M^\circ$. Since M° is circled, we have $|g(b)| \leq 1$ for all $b \in B$, for all $g \in M^\circ$. From this, $B \subset M^{\circ\circ} = \text{cl}\,\Gamma(M)$. Since $\mathcal{M}$ is saturated, $\text{cl}\,\Gamma(M) \in \mathcal{M}$, and hence $B \in \mathcal{M}$. Thus we have shown that C has a base $B \in \mathcal{M}$.

(iii) Assume that $\text{int}_{\mathcal{T}_{\mathcal{M}}}C^+ \neq \emptyset$ or, equivalently, C has a base $B \in \mathcal{M}$. We are going to prove that $\text{int}_{\mathcal{T}_{\mathcal{M}}}C^+ = B^{st}$. Let $f \in B^{st}$. Then there exists $\delta > 0$ such that

$f(b) \geq \delta$ for all $b \in B$. Take ϵ such that $0 < \epsilon < \delta$. Then $f + \epsilon B^\circ \subset C^+$. Obviously ϵB° is a 0-neighborhood in $(Y^*, \mathcal{T}_\mathcal{M})$ and $f \in \text{int}_{\mathcal{T}_\mathcal{M}} C^+$. Conversely, let $f \in \text{int}_{\mathcal{T}_\mathcal{M}} C^+$. Then there exists $M \in \mathcal{M}$ such that $f - M^\circ \subset C^+$. Since B is a base of C, there exist $g \in Y^*$ and $\delta > 0$ such that $g(b) \geq \delta > 0$ for all $b \in B$. Observe that M° is absorbing in Y^*, and there exists $\epsilon > 0$ such that $\epsilon g \in M^\circ$. Thus $f - \epsilon g \in C^+$. From this, we obtain

$$(f - \epsilon g)(b) \geq 0 \quad \forall b \in B.$$

Hence

$$f(b) \geq \epsilon g(b) \geq \epsilon\delta > 0 \quad \forall b \in B.$$

That is, $f \in B^{st}$. □

In the following we denote by $\text{int}_\tau C^+$ and $\text{int}_\beta C^+$ the interior of C^+ in $(Y^*, \tau(Y^*, Y))$ and in $(Y^*, \beta(Y^*, Y))$, respectively. By Theorem 2.1, we immediately obtain the following corollaries.

COROLLARY 2.1 (refer to [10, Theorem 3.8.6] and [16, Theorem 2.3]). *Let Y be an l.c.s. and $C \subset Y$ be a convex cone. Then $\text{int}_\tau C^+ \neq \emptyset$, i.e., C^+ is a solid cone in $(Y^*, \tau(Y^*, Y))$, if and only if C has a relatively weakly compact base B. In this case, $\text{int}_\tau C^+ = B^{st}$.*

Remark 2.1. Let $C \subset Y$ be a closed convex cone. Then $\text{int}_\tau C^+ \neq \emptyset$ if and only if C has a weakly compact base. In this case, $\text{int}_\tau C^+ = B^{st} = C^{+i}$.

COROLLARY 2.2 (refer to [16, Theorem 2.2]). *Let Y be an l.c.s. and $C \subset Y$ be a convex cone. Then $\text{int}_\beta C^+ \neq \emptyset$ if and only if C has a bounded base B. In this case, $\text{int}_\beta C^+ = B^{st}$.*

3. Dual characterization and scalarization for Benson proper efficiency. Let Y be an l.c.s. and $C \subset Y$ be a convex cone, and then C can specify a partial order in Y as follows:

$$\text{for } \ x, y \in Y, \ \ x \leq_c y \ \text{ if and only if } \ y - x \in C.$$

It is clear that the partial order "$\leq_c$" satisfies the following properties:

(i) $x \leq_c x$;

(ii) if $x \leq_c y$ and $y \leq_c z$, then $x \leq_c z$.

If the ordering cone C is pointed, then the partial order also satisfies the following:

(iii) if $x \leq_c y$ and $y \leq_c x$, then $x = y$.

Moreover, if we assume that the ordering cone C is closed, then we have: if $x_\delta \to x_0$ and every $x_\delta \leq y$, then $x_0 \leq y$.

Let A be a nonempty subset of Y and a point $\bar{y} \in A$. Then $\bar{y} \in A$ is called an efficient point of A with respect to the ordering cone C, denoted by $\bar{y} \in \text{Min}[A, C]$, if $(A - \bar{y}) \cap (-C) = \{0\}$. A point $\bar{y} \in A$ is called a Benson proper efficient point (see [1]) of A with respect to the ordering cone C, denoted by $\bar{y} \in \text{PMin}[A, C]$, if

$$\text{cl cone}(A + C - \bar{y}) \cap (-C) \ = \ \{0\}.$$

Obviously, $\text{PMin}[A, C] \subset \text{Min}[A, C]$. Also, we observe that, if there exists a nonempty subset A of Y such that $\text{PMin}[A, C] \neq \emptyset$, then C must be pointed. First we give the following general dual characterization and scalarization for Benson proper efficiency.

THEOREM 3.1. *Let $C \subset Y$ be a closed convex cone, $\bar{y} \in A \subset Y$, and $\text{co}A$ denote the convex hull of A. Then the following statements are equivalent:*

(i) $\bar{y} \in \text{PMin}[\text{co}A, C]$;

(ii) $(C^+ - C^+ \cap (A-\bar{y})^+)$ *is dense in* $(Y^*, \mathcal{T})$, *where* $\mathcal{T}$ *is any locally convex topology on* Y^* *which is compatible with the dual pair* $\langle Y^*, Y\rangle$ *(i.e.,* $(Y^*, \mathcal{T})^* = Y$*);*

(iii) *for any weakly compact convex set* $K \subset C$ *and* $0 \notin K$, *there exists* $f \in C^+ \cap K^{st}$ *such that* $f(A) \geq f(\bar{y})$*;*

(iv) *for any* $c \in C,\ c \neq 0$, *there exists* $f \in C^+$ *such that* $f(c) > 0$ *and* $f(A) \geq f(\bar{y})$.

Proof. (i)⇒(ii): $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$ means that

$$\mathrm{cl}\,\mathrm{cone}(C + \mathrm{co}(A) - \bar{y}) \cap (-C) = \{0\}. \tag{1}$$

By the theorem of bipolars, (1) is equivalent to

$$[\mathrm{cl}\,\mathrm{cone}(C + \mathrm{co}(A) - \bar{y}) \cap (-C)]^r = Y^*. \tag{2}$$

By the theory of polars (see [11, p. 247]),

$$\begin{aligned}[\mathrm{cl}\,\mathrm{cone}(C + \mathrm{co}(A) - \bar{y}) \cap (-C)]^r &= \mathrm{cl}_{\mathcal{T}}\,\mathrm{co}((C + \mathrm{co}(A) - \bar{y})^- \cup C^+) \\ &= \mathrm{cl}_{\mathcal{T}}(-C^+ \cap (\mathrm{co}(A) - \bar{y})^+ + C^+) \\ &= \mathrm{cl}_{\mathcal{T}}(C^+ - C^+ \cap (A - \bar{y})^+).\end{aligned}$$

Combining this with (2), we have

$$\mathrm{cl}_{\mathcal{T}}(C^+ - C^+ \cap (A-\bar{y})^+) = Y^*, \text{ i.e., } C^+ - C^+ \cap (A-\bar{y})^+ \text{ is dense in } (Y^*, \mathcal{T}).$$

(ii)⇒(iii): Let K be a weakly compact convex subset of C and $0 \notin K$. By Theorem 2.1, $K^{st} = \mathrm{int}_\tau(\mathrm{cone}(K))^+ \neq \emptyset$. By (ii), we have

$$(C^+ \cap (A-\bar{y})^+ - C^+) \cap K^{st} \neq \emptyset.$$

Hence there exist $f \in C^+ \cap (A-\bar{y})^+$ and $g \in C^+$ such that $f - g \in K^{st}$; i.e., there exists $\delta > 0$ such that $(f-g)(K) \geq \delta > 0$. From this we know that $f \in K^{st}$. Obviously $f \in C^+ \cap K^{st}$ and $f(A) \geq f(\bar{y})$.

(iii)⇒(iv): It is obvious.

(iv)⇒(i): Assume that $\bar{y} \notin \mathrm{PMin}[\mathrm{co}A, C]$; then there exists

$$z \in \mathrm{cl}\,\mathrm{cone}(C + \mathrm{co}A - \bar{y}) \cap (-C) \quad \text{and} \quad z \neq 0.$$

Clearly $-z \in C$ and $-z \neq 0$. By (iv), there exists $f \in C^+ \cap (A-\bar{y})^+$ such that $f(-z) > 0$, i.e., $f(z) < 0$. On the other hand, since $z \in \mathrm{cl}\,\mathrm{cone}(C + \mathrm{co}A - \bar{y})$ and $f \in C^+ \cap (A-\bar{y})^+ = C^+ \cap (\mathrm{co}A - \bar{y})^+ \subset [\mathrm{cone}(C + \mathrm{co}A - \bar{y})]^+$, we have $f(z) \geq 0$, a contradiction! □

From Theorem 3.1 we can deduce some particular scalarization theorem for Benson proper efficiency.

THEOREM 3.2. *Let* $C \subset Y$ *be a closed convex cone and* $\bar{y} \in A \subset Y$. *If there exists a locally convex topology* $\mathcal{T}$ *on* Y^* *such that* $(Y^*, \mathcal{T})^* = Y$ *and* $\mathrm{int}_{\mathcal{T}} C^+ \neq \emptyset$, *then the following statements are equivalent:*

(i) $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$*;*

(ii) *there exists* $f \in \mathrm{int}_{\mathcal{T}} C^+$ *such that* $f(A) \geq f(\bar{y})$*;*

(iii) *there exists* $f \in C^{+i}$ *such that* $f(A) \geq f(\bar{y})$.

Proof. (i)⇒(ii): Since $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$, by Theorem 3.1,

$$C^+ - C^+ \cap (A-\bar{y})^+ \text{ is dense in } (Y^*, \mathcal{T}).$$

By the assumption that $\text{int}_{\mathcal{T}}C^+ \neq \emptyset$, we have

$$(C^+ - C^+ \cap (A-\bar{y})^+) \cap (-\text{int}_{\mathcal{T}}C^+) \neq \emptyset.$$

That is, there exists $g \in C^+$, $f \in C^+ \cap (A-\bar{y})^+$, and $h \in \text{int}_{\mathcal{T}}C^+$ such that $g-f=-h$. Thus

$$f = g + h \in C^+ + \text{int}_{\mathcal{T}}C^+ = \text{int}_{\mathcal{T}}C^+ \quad \text{and} \quad f(A) \geq f(\bar{y}).$$

(ii)⇒(iii): By Lemma 2.1, $\text{int}_{\mathcal{T}}C^+ \subset C^{+i}$. Hence the implication is obvious.

(iii)⇒(i): Assume that there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$. Since $f \in C^{+i} \subset C^+$ and $f(A-\bar{y}) \geq 0$, we have $f(C + \text{co}A - \bar{y}) \geq 0$ and hence

$$f(\text{cl cone}(C + \text{co}A - \bar{y})) \geq 0. \tag{3}$$

On the other hand, $f(C) \geq 0$ and hence

$$f(-C) \leq 0. \tag{4}$$

Let $z \in \text{cl cone}(C + \text{co}A - \bar{y}) \cap (-C)$, and then by (3) and (4) we have $f(z) \geq 0$ and $f(z) \leq 0$, which leads to $f(z) = 0$. Since $-z \in C$, $f(-z) = 0$, and $f \in C^{+i}$, we conclude that $-z = 0$ and hence $z = 0$. Thus we have shown that

$$\text{cl cone}(C + \text{co}A - \bar{y}) \cap (-C) = \{0\}. \qquad \square$$

COROLLARY 3.1. *Let $C \subset Y$ be a closed convex cone with a weakly compact base B and $\bar{y} \in A \subset Y$. Then the following statements are equivalent:*

(i) $\bar{y} \in \text{PMin}[\text{co}A, C]$;

(ii) *there exists $f \in B^{st}$ such that $f(A) \geq f(\bar{y})$;*

(iii) *there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$.*

Proof. The result follows immediately from Corollary 2.1, Remark 2.1, and Theorem 3.2. $\square$

COROLLARY 3.2 (refer to [24, Theorem 6.2]). *Let $C \subset Y$ be a closed convex cone with a compact base B and $\bar{y} \in A \subset Y$. Then the statements* (i), (ii), *and* (iii) *in Corollary* 3.1 *are equivalent.*

As we know, every compact set is weakly compact, but a weakly compact set may be noncompact. In fact, the closed unit ball (or its translation) in an infinite-dimensional reflexive Banach space is weakly compact and not compact. Hence Corollary 3.1 contains and improves Corollary 3.2. In the following we construct a closed convex pointed cone C having a base B with the following properties: $\text{int}C = \emptyset$, B is weakly compact, B is not compact, and $\text{int}(C^+) \neq \emptyset$.

Example 3.1. As in [14, p. 326], a matrix $A = (a_{j.k})_{j,\,k\in N}$ of nonnegative numbers is called a Köthe matrix if A satisfies the following conditions:

(i) for each $j \in N$, there exists a $k \in N$ such that $a_{j,k} > 0$;

(ii) $a_{j,k} \leq a_{j,k+1}$ for all $j, k \in N$.

Now let $A = (a_{j,k})_{j,k\in N}$ be a given Köthe matrix such that

(C1) $a_{2j,\,k} < \frac{1}{j}\, a_{2j,\,k+1}$, for all $j, k \in N$;

(C2) $a_{2j-1,\,k} = a_{2j-1,\,k+1}$.

For $1 < p < \infty$, we define

$$\lambda^p(A) := \left\{ x = (x_j)_{j\in N} \in R^N : |x\|_k := \left(\sum_{j=1}^{\infty} |x_j a_{j,k}|^p \right)^{\frac{1}{p}} < \infty \ \forall k \in N \right\}.$$

Then $\lambda^p(A)$ is a reflexive Fréchet space (see [14, Lemma 27.1 and Proposition 27.3]). By condition (C1) we see that the topology induced by $\|\ \|_{k+1}$ is strictly finer than one induced by $\|\ \|_k$, and hence we conclude that $\lambda^p(A)$ is not normable. By condition (C2) and [14, Theorem 27.9], we know that $\lambda^p(A)$ is not a Montel space. Here a reflexive l.c.s. in which every closed bounded set is compact is called a Montel space (see, e.g., [20, p. 141]). Thus there exists a closed convex bounded set B in $\lambda^p(A)$ which is not compact. Without loss of generality, we may assume that $0 \notin B$. Since $\lambda^p(A)$ is reflexive, we know that B is weakly compact. Let $C := \text{cone}(B)$. Then C is a closed convex pointed cone, and C has a weakly compact base B which is noncompact. Moreover, we assert that $\text{int}C = \emptyset$. If not, then $\text{int}C \neq \emptyset$, with C having a bounded base B, will imply that $\lambda^p(A)$ is normable, contradicting condition (C1). Finally, since B is weakly compact, by Corollary 2.1 we know that $\text{int}_\tau(C^+) \neq \emptyset$ (certainly, we also have $\text{int}_\beta C^+ \neq \emptyset$).

When Y is a separable normed space, we can obtain a scalarization result for Benson proper efficient points without any restriction on the ordering cone.

COROLLARY 3.3 (see [5, Theorem 3.2]). *Let $(Y, \|\ \|)$ be a separable normed space, $C \subset Y$ be a closed convex pointed cone, and $\bar{y} \in A \subset Y$. Then $\bar{y} \in \text{PMin}[\text{co}A, C]$ if and only if there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$.*

Proof. Assume that $\bar{y} \in \text{PMin}[\text{co}A, C]$. Then by Theorem 3.1, for any $c \in C,\ c \neq 0$, there exists $f \in C^+ \cap (A - \bar{y})^+$ such that $f(c) > 0$. Put $\bar{f} = f/\|f\|$. Then $\bar{f} \in U^\circ \cap C^+ \cap (A - \bar{y})^+$ and $\bar{f}(c) > 0$, where U denotes the closed unit ball in $(Y, \|\ \|)$. Since $(Y, \|\ \|)$ is separable, $U^\circ \cap C^+ \cap (A - \bar{y})^+$ with the topology induced by $\sigma(Y^*, Y)$ is a compact metric space and hence is separable. Let $\{f_1, f_2, \ldots\}$ be a countable dense subset of $U^\circ \cap C^+ \cap (A - \bar{y})^+$. Then for any $c \in C,\ c \neq 0$, there exists $n \in N$ such that $f_n(c) > 0$. Since $\{f_1, f_2, \ldots\} \subset U^\circ$ and U is absorbing, we may define

$$f(x) = \sum_{n=1}^{\infty} \frac{1}{2^n} f_n(x), \quad x \in Y.$$

Then $f \in U^\circ \cap C^+ \cap (A - \bar{y})^+$ and for all $c \in C \backslash \{0\}$, $f(c) > 0$. Clearly $f \in C^{+i}$ and $f(A) \geq f(\bar{y})$.

Conversely, assume that there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$. Then as shown in the proof of (iii)⇒(i) in Theorem 3.1, we can deduce that $\bar{y} \in \text{PMin}[\text{co}A, C]$. □

Remark 3.1. In fact, by using the theory of strictly extreme points and strictly exposed points (see [17]), we see that every closed convex pointed cone in separable normed spaces automatically has a base.

Next we try to give another class of scalarization results for Benson proper efficiency. A closed convex cone C in Y is said to have a *countable weakly compact base* if there exists a base B of C such that $B = \cup_{n=1}^{\infty} K_n$, where every K_n is a weakly compact convex set. As in [15, p. 249], an l.c.s. Y is said to have the *countable neighborhood property* (denoted by c.n.p.) if, given any sequence $\{U_n\}_{n \in N}$ of 0-neighborhoods in Y, there are $\alpha_n > 0$ such that $U := \cap_{n=1}^{\infty} \alpha_n U_n$ is a 0-neighborhood in Y. We know that every (DF)-space has the c.n.p. (see [15, p. 249]). The class of (DF)-space was introduced by Grothendieck (see [20, p. 154]). It comprises all of the strong duals of metrizable locally convex spaces and all normed spaces; for details, see [9, 11, 14, 20]. Now we introduce a weaker property, the *weak countable neighborhood property*, as follows: an l.c.s. Y is said to have the weak countable neighborhood property (denoted by w.c.n.p.) if, given any sequence $\{f_n\}_{n \in N}$ in Y^*, there are $\alpha_n > 0$ such that $U := \cap_{n=1}^{\infty} \alpha_n f_n^\circ$ is a 0-neighborhood in $(Y, \tau(Y, Y^*))$. Here f_n° denotes the polar of

the singleton $\{f_n\}$, i.e., $f_n^\circ = \{y \in Y : |f(y)| \leq 1\}$. Obviously, the c.n.p. implies the w.c.n.p., and the w.c.n.p. is duality invariant. Also, we observe that an l.c.s. Y has the w.c.n.p. if and only if for every sequence $\{f_n\}_{n\in N}$ in Y^* there are $\lambda_n > 0$ such that the closed (absolutely) convex hull of $\{\lambda_n f_n\}_{n\in N}$ in $(Y^*, \sigma(Y^*, Y))$ is $\sigma(Y^*, Y)$-compact.

Example 3.2 (a closed convex pointed cone with a countable weakly compact base and without any bounded base). Let $X := (l^1, \|\ \|_1)$ and $Y = X^* = l^\infty$ with the Mackey topology $\tau(l^\infty, l^1)$. Let $C = \{y = (\eta_n) \in l^\infty : \eta_n \geq 0\ \forall n \in N\}$. Then clearly C is a convex pointed cone. Let $e_n \in l^1$ denote the sequence whose only nonzero term is a 1 in the nth place. Then $C = \cap_{n=1}^\infty \{y \in l^\infty : \langle y, e_n\rangle \geq 0\}$, as the intersection of the closed sets $\{y \in l^\infty : \langle y, e_n\rangle \geq 0\}$, is closed in Y. Thus, C is a closed convex pointed cone in Y. We shall see that C has no bounded base, but it has a countable weakly compact base. If C has a bounded base, then by Corollary 2.2, $\mathrm{int}_\beta C^+ \neq \emptyset$. Clearly, $C^+ = \{x = (\xi_n) \in l^1 : \xi_n \geq 0\ \forall n \in N\}$. Let $x = (\xi_n) \in \mathrm{int}_\beta C^+$. Then there exists $\epsilon > 0$ such that $x + \epsilon U \subset C^+$, where U denotes the closed unit ball in $(l^1, \|\ \|_1)$, i.e., $U = \{x \in l^1 : \|x\|_1 \leq 1\}$. Since $\xi_n \to 0$, we may take n large enough such that $0 \leq \xi_n < \epsilon$. Thus, $\xi_n - \epsilon < 0$, and hence $x - \epsilon e_n \notin C^+$, which contradicts that $x + \epsilon U \subset C^+$. This shows that C has not any bounded base. Take fixed $x' = (\xi_n') \in l^1$, with every $\xi_n' > 0$, and let $B := \{y = (\eta_n) \in C : \langle y, x'\rangle = \sum_{n=1}^\infty \xi_n' \eta_n = 1\}$. Then B is a base of C. We observe that $B = \cup_{n=1}^\infty (B \cap nU^\circ)$, where every $B \cap nU^\circ$ is $\sigma(l^\infty, l^1)$-compact, i.e., $\sigma(Y, Y^*)$-compact. That is, B is a countable weakly compact base of C.

Example 3.3 (an l.c.s. has the w.c.n.p. but does not have the c.n.p.). Let $(Y, \mathcal{T})$ be an infinite dimensional l.c.s. such that the strong dual $(Y^*, \beta(Y^*, Y))$ is a complete metrizable l.c.s. For any sequence $\{f_n\}_{n\in N}$ in Y^*, there are $\lambda_n > 0$ such that $\lambda_n f_n \to 0$ in $(Y^*, \beta(Y^*, Y))$. Since $(Y^*, \beta(Y^*, Y))$ is complete and metrizable, the closed convex hull of $\{\lambda_n f_n\}_{n\in N}$ is compact in $(Y^*, \beta(Y^*, Y))$ and hence compact in $(Y^*, \sigma(Y^*, Y))$. Thus $(Y, \mathcal{T})$ has the w.c.n.p. From this we know that $(Y, \sigma(Y, Y^*))$ has the w.c.n.p. However, we shall see that $(Y, \sigma(Y, Y^*))$ does not have the c.n.p. Assume the contrary. Let $\{f_n\}_{n\in N} \subset Y^*$ be a countable infinite set whose members are linearly independent. Then there exist $\alpha_n > 0$ such that $\cap_{n=1}^\infty \alpha_n f_n^\circ$ is a 0-neighborhood in $(Y, \sigma(Y, Y^*))$, where f_n° denotes the polar of the singleton $\{f_n\}$. Hence there exists $\epsilon > 0$ such that

$$\epsilon \bigcap_{i=1}^m g_i^\circ = \bigcap_{i=1}^n (|g_i| \leq \epsilon) \subset \bigcap_{n=1}^\infty \alpha_n f_n^\circ.$$

Taking polars in the two sides of the above containment, we obtain

$$\left(\epsilon \bigcap_{i=1}^m g_i^\circ\right)^\circ \supset \left(\bigcap_{n=1}^\infty \alpha_n f_n^\circ\right)^\circ.$$

By using the theory of polars (see [11, p. 247]), we have

$$\frac{1}{\epsilon} \mathrm{cl}\,\Gamma\left(\bigcup_{i=1}^m g_i^{\circ\circ}\right) \supset \mathrm{cl}\,\Gamma\left(\bigcup_{n=1}^\infty \frac{1}{\alpha_n} f_n^{\circ\circ}\right).$$

From this,

$$\bigcup_{n=1}^\infty \frac{1}{\alpha_n} f_n \subset \frac{1}{\epsilon}\,\Gamma(\{g_1, g_2, \ldots, g_m\}).$$

This contradicts the assumption that the set $\{f_n : n \in N\}$ is linearly independent.

COROLLARY 3.4. *Let Y be an l.c.s. with the w.c.n.p. and $C \subset Y$ be a closed convex cone with a countable weakly compact base B. Then $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$ if and only if there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$.*

Proof. We need only to give the proof of one direction. We assume that $B = \cup_{n=1}^{\infty} K_n$, where every K_n is a weakly compact set. Let $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$. By Theorem 3.1, for every $K_n \subset C$, there exists $f_n \in C^+$ and $\delta_n > 0$ such that $f_n(K_n) \geq \delta_n$ and $f_n(A) \geq f_n(\bar{y})$. Since Y has the w.c.n.p., there are $\lambda_n > 0$ such that the closed convex hull of $\{\lambda_n f_n\}_{n\in N}$ in $(Y^*, \sigma(Y^*, Y))$ is $\sigma(Y^*, Y)$-compact. From this, we can deduce that

$$\sum_{n=1}^{\infty} \frac{1}{2^n} \lambda_n f_n \ \text{ is convergent in } \ (Y^*, \sigma(Y^*, Y)).$$

Let $f := \sum_{n=1}^{\infty} \frac{1}{2^n} \lambda_n f_n$. Then $f \in Y^*$ and $f(B) > 0$ for all $b \in B$. Clearly, $f \in C^{+i}$ and $f(A) \geq f(\bar{y})$. □

COROLLARY 3.5. *Let (X, d) be a Fréchet space (i.e., a complete metrizable l.c.s.) and $Y = X^*$ with a locally convex topology $\mathcal{T}$ such that $(Y, \mathcal{T})^* = X$. Let $C \subset Y$ be a closed convex cone with a base B. Then $\bar{y} \in \mathrm{Pmin}[\mathrm{co}A, C]$ if and only if there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$.*

Proof. Since $(Y^*, \beta(Y^*, Y)) = (X, d)$ is a complete metrizable l.c.s., as shown in Example 3.3, we know that Y has the w.c.n.p. On the other hand, let $U_1 \supset U_2 \supset \cdots$ be a base of 0-neighborhoods in (X, d), and then $Y = \cup_{n=1}^{\infty} n U_n^{\circ}$. Thus $B = \cup_{n=1}^{\infty} (n U_n^{\circ} \cap B) = \cup_{n=1}^{\infty} K_n$, where $K_n := n U_n^{\circ} \cap B$ is $\sigma(X^*, X)$-compact, i.e., $\sigma(Y, Y^*)$-compact. Applying Corollary 3.4, we conclude that $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$ if and only if there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$. □

By using Corollary 3.5, we immediately obtain the following.

COROLLARY 3.6. *Let Y be a semireflexive (DF)-space (particularly, let Y be a reflexive Banach space). Let $C \subset Y$ be a closed convex cone with a base. Then $\bar{y} \in \mathrm{PMin}[\mathrm{co}A, C]$ if and only if there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$.*

Remark 3.2. Even for reflexive Banach spaces, we cannot expect to obtain the result as for separable normed spaces (see Corollary 3.3), since in such spaces there might exist a closed convex pointed cone without any base.

Example 3.4 (see [11, p. 137]). Let A be an uncountable index set of cardinality d, and let $x = (\xi_\alpha)_{\alpha\in A}$ be a vector with d coordinates, of which at most countably many are nonzero. For $1 < p < \infty$, define

$$\|x\|_p = \left(\sum_{\alpha\in A} |\xi_\alpha|^p \right)^{\frac{1}{p}}.$$

Let l_d^p denote the space $\{x = (\xi_\alpha)_{\alpha\in A} : \|x\|_p < \infty\}$ with the norm $\| \ \|_p$. Then l_d^p is a Banach space with the dual l_d^q, where $\frac{1}{p} + \frac{1}{q} = 1$. Obviously l_d^p is a reflexive Banach space. Put $C := \{x = (\xi_\alpha) \in l_d^p : \xi_\alpha \geq 0 \ \forall \alpha \in A\}$. Then C is a closed convex pointed cone in l_d^p. However, C has no bases. If not, there exists $f = (\eta_\alpha)_{\alpha\in A} \in (l_d^p)^* \cong l_d^q$ such that $f \in C^{+i}$. Particularly, for every $\alpha \in A$, $f(e_\alpha) > 0$, i.e., $\eta_\alpha > 0$. But this is impossible since at most countably many η_α are nonzero.

Remark 3.3. Yang, Li, and Wang [24] introduced *nearly C-subconvexlike set-valued maps*, and Sach [19] introduced *nearly C-subconvexlike sets*. Let Y be an l.c.s. and $\bar{y} \in A \subset Y$. The set A is said to be *nearly C-subconvexlike* at $\bar{y}$ if $\mathrm{cl\,cone}(A - \bar{y} + C)$

is convex. In this case, $\operatorname{cl}\operatorname{cone}(A-\bar{y}+C) = \operatorname{cl}\operatorname{cone}(\operatorname{co}A-\bar{y}+C)$, and hence the statement $\bar{y}\in \operatorname{PMin}[\operatorname{co}A, C]$ in Theorems 3.1 and 3.2 and Corollaries 3.1, 3.2, 3.3, 3.4, 3.5, and 3.6 can be replaced by $\bar{y}\in \operatorname{PMin}[A, C]$.

In [8], Hernández, Jiménez, and Novo introduced and studied the Benson-vectorial proper efficiency in real linear spaces. We shall see that our method (for example, Theorem 3.2) also can be applied to the scalarization of Benson-vectorial proper efficiency. As in [8], let Y be a real linear space and $A\subset Y$ be nonempty. The *core* (*algebraic interior*) and the *intrinsic core* (*relatively algebraic interior*) of A are defined, respectively, as follows:

$$\operatorname{cor}(A)=\{y\in A:\ \forall v\in Y,\ \exists t>0,\ \forall \alpha\in[0,t],\ y+\alpha v\in A\},$$

$$\operatorname{icr}(A)=\{y\in A:\ \forall v\in \operatorname{span}[A-A],\ \exists t>0,\ \forall \alpha\in[0,t],\ y+\alpha v\in A\}.$$

The *vectorial closure* of A is defined as follows:

$$\operatorname{vcl}(A)\ =\ \{y\in Y;\ \exists v\in Y,\ \forall t>0,\ \exists \alpha\in(0,t],\ y+\alpha v\in A\}.$$

If A is convex, then $y\in\operatorname{vcl}(A)$ if and only if there exists $a\in A$ such that $[a,y)\subset A$. A set A is said to be *vectorially closed* if $A=\operatorname{vcl}(A)$. If Y is endowed with the finest locally convex topology γ (which is also called *convex core topology*), then $(Y,\gamma)^*=Y^{\#}$; i.e., every linear functional on (Y,γ) is continuous (see [18, pp. 22 and 43]). Let C be a convex cone in Y. Then in this case we have

$$C^+=\{f\in Y^{\#}:\ f(c)\geq 0\ \forall c\in C\};$$

$$C^{+i}=\{f\in Y^{\#}:\ f(c)>0\ \forall c\in C\backslash\{0\}\}.$$

We need the following two lemmas.

LEMMA 3.1. *If $B\subset Y$ is convex and $\operatorname{icr}(B)\neq\emptyset$, then $\operatorname{vcl}(B)=\operatorname{cl}_\gamma(B)$.*

Proof. Obviously, $\operatorname{vcl}(B)\subset\operatorname{cl}_\gamma(B)$. Conversely, assume that $x\notin\operatorname{vcl}(B)$, and we shall see that $x\notin\operatorname{cl}_\gamma(B)$. For convenience, we assume that $x=0$. Take any fixed $x_0\in\operatorname{icr}(B)$. Then $[x_0,0)\not\subset B$. Hence there exists $\lambda,\ 0<\lambda<1$, such that $\lambda x_0\notin B$ and certainly $\lambda x_0\notin\operatorname{icr}(B)$. By the separation theorem in real linear spaces, there exists $f\in Y^{\#}$ such that $f(\operatorname{icr}(B))<f(\lambda x_0)$. Particularly, we have

$$f(x_0)\ <\ f(\lambda x_0)\ =\ \lambda f(x_0).$$

From this, we conclude that $f(x_0)<0$. Thus

$$f(\operatorname{icr}(B))\ <\ \lambda f(x_0)\ <\ 0,$$

which implies that $f(B)\leq\lambda f(x_0)<0$ and hence $0\notin\operatorname{cl}_\gamma(B)$. □

LEMMA 3.2. *If $\operatorname{cor}(C^+)\neq\emptyset$, then $\operatorname{cor}(C^+)=\operatorname{int}_\sigma(C^+)=\operatorname{int}_\tau(C^+)=\operatorname{int}_\beta(C^+)$. Here $\operatorname{int}_\sigma(C^+)$, $\operatorname{int}_\tau(C^+)$, and $\operatorname{int}_\beta(C^+)$ denote, respectively, the interiors of C^+ in $(Y^{\#},\sigma(Y^{\#},Y))$, $(Y^{\#},\tau(Y^{\#},Y))$, and $(Y^{\#},\beta(Y^{\#},Y))$.*

Proof. Let $f\in\operatorname{cor}(C^+)$. Then there exists an absolutely convex absorbing set W in $Y^{\#}$ such that $f+W\subset C^+$. Since C^+ is $\sigma(Y^{\#},Y)$-closed, we have $f+\operatorname{cl}_\sigma(W)\subset C^+$, where $\operatorname{cl}_\sigma(W)$ denotes the closure of W in $(Y^{\#},\sigma(Y^{\#},Y))$. In fact, on $Y^{\#}$, the topologies $\beta(Y^{\#},Y)$, $\tau(Y^{\#},Y)$, and $\sigma(Y^{\#},Y)$ coincide, and they are barrelled spaces (see [18, pp. 64 and 75]). Thus the barrel $\operatorname{cl}_\sigma(W)$ is a 0-neighborhood in $(Y^{\#},\sigma(Y^{\#},\sigma(Y^{\#},Y))$ and $f\in\operatorname{int}_\sigma C^+$. The converse containment $\operatorname{int}_\sigma(C^+)\subset\operatorname{cor}(C^+)$ is obvious. □

As in [8], a point $\bar{y} \in A$ is called a Benson-vectorial proper efficient point of A with respect to the convex cone C, denoted by $\bar{y} \in \mathrm{PVMin}[A, C]$, if $\mathrm{vcl}[\mathrm{cone}(A - \bar{y} + C)] \cap (-C) = \{0\}$. Now we can give a scalarization result for Benson-vectorial proper efficient points.

COROLLARY 3.7. *Let Y be a real linear space, $C \subset Y$ be a vectorially closed cone with $\mathrm{cor}(C^+) \neq \emptyset$, and $\bar{y} \in A \subset Y$. Moreover, assume that $\mathrm{icr}[\mathrm{cone}(A-\bar{y})+\mathrm{icr}(C)] \neq \emptyset$. Then the following statements are equivalent:*

(i) $\bar{y} \in \mathrm{PVMin}[\mathrm{co}A, C]$;

(ii) *there exists $f \in \mathrm{cor}(C^+)$ such that $f(A) \geq f(\bar{y})$;*

(iii) *there exists $f \in C^{+i}$ such that $f(A) \geq f(\bar{y})$.*

In particular, if $\mathrm{cone}(A-\bar{y}) + \mathrm{icr}(C)$ is convex, then statement (i) *can be replaced by the following:*

(i)′ $\bar{y} \in \mathrm{PVMin}[A, C]$.

Proof. (i)⇒(ii): Since $\mathrm{icr}[\mathrm{cone}(A-\bar{y})+\mathrm{icr}(C)] \neq \emptyset$, we know that $\mathrm{icr}[\mathrm{cone}(\mathrm{co}A - \bar{y}) + \mathrm{icr}(C)] \neq \emptyset$. Clearly, $\mathrm{cone}(\mathrm{co}A - \bar{y}) + \mathrm{icr}(C)$ is convex. By Lemma 3.1 we have

$$\mathrm{vcl}[\mathrm{cone}(\mathrm{co}A - \bar{y}) + \mathrm{icr}(C)] = \mathrm{cl}_\gamma[\mathrm{cone}(\mathrm{co}A - \bar{y}) + \mathrm{icr}(C)] = \mathrm{cl}_\gamma[\mathrm{cone}(\mathrm{co}A - \bar{y}) + C].$$

On the other hand, $\mathrm{cor}(C^+) \neq \emptyset$ implies that $\mathrm{icr}(C) \neq \emptyset$. Furthermore, C is convex and $C = \mathrm{vcl}(C)$. By Lemma 3.1 we have $\mathrm{cl}_\gamma(C) = \mathrm{vcl}(C) = C$ and C is γ-closed. Thus statement (i) becomes

$$\mathrm{cl}_\gamma[\mathrm{cone}(\mathrm{co}A - \bar{y} + C)] \cap (-C) = \{0\},$$

where C is a closed convex pointed cone in (Y, γ). That is, $\bar{y} \in A$ is a Benson proper efficient point of $\mathrm{co}A$ with respect to C in (Y, γ). By Lemma 3.2, we have $\mathrm{int}_\sigma(C^+) = \mathrm{cor}(C^+) \neq \emptyset$. Observing that the topological dual of $(Y^\#, \sigma(Y^\#, Y))$ is Y, we can apply Theorem 3.2 and conclude that there exists $f \in \mathrm{cor}(C^+)$ such that $f(A) \geq f(\bar{y})$.

(ii)⇒ (iii): It is obvious.

(iii)⇒ (i): If not, there exists $c_0 \in C,\ c_0 \neq 0$, such that

$$-c_0 \in \mathrm{vcl}[\mathrm{cone}(\mathrm{co}A - \bar{y} + C)].$$

Since $f \in C^{+i}$, we have $f(c_0) > 0$, and so $f(-c_0) < 0$. On the other hand, $f \in C^+$ and $f(A) \geq f(\bar{y})$ imply that

$$f(\mathrm{vcl}[\mathrm{cone}(\mathrm{co}A - \bar{y} + C)]) \geq 0,$$

so $f(-c_0) \geq 0$, a contradiction!

Moreover, if $\mathrm{cone}(A - \bar{y}) + \mathrm{icr}(C)$ is convex, then

$$\mathrm{cone}(A - \bar{y}) + \mathrm{cir}(C) = \mathrm{cone}(\mathrm{co}A - \bar{y}) + \mathrm{icr}(C).$$

Hence we have $\mathrm{PVMin}[\mathrm{co}A, C] = \mathrm{PVMin}[A, C]$, and statement (i) can be replaced by (i)′. □

By Corollary 3.7, we can deduce the scalarization results in [8]. As in [8], let X be a nonempty set, Y be a real linear space, $C \subset Y$ be an ordering cone, and $F : X \to 2^Y$ be a set-valued map. Consider the following unconstrained optimization problem:

(P) $C - \mathrm{Min}F(x)$, subject to $x \in X$.

A pair $(\bar{x}, \bar{y}) \in X \times Y$ is said to be a Benson-vectorial proper minimizer of (P) if $\bar{y} \in F(\bar{x})$ and $\bar{y} \in \mathrm{PVMin}[F(X), C]$, i.e.,

$$\mathrm{vcl}[\mathrm{cone}(F(X) - \bar{y} + C)] \cap (-C) = \{0\}.$$

If $\operatorname{icr}(C) \neq \emptyset$, then a set-valued map $F : X \to 2^Y$ is said to be relatively solid C-subconvexlike on X (see [8]) if the following conditions are satisfied:

(i) $F(X) + \operatorname{icr}(C)$ is convex,

(ii) $\operatorname{icr}[F(X) + \operatorname{icr}(C)] \neq \emptyset$.

Substituting A in Corollary 3.7 by $F(X)$, we immediately obtain the following scalarization result (see [8, Theorems 4 and 5 and Corollary 2]).

COROLLARY 3.8. *Let C be a vectorially closed convex cone and $\operatorname{cor}(C^+) \neq \emptyset$. Let F be a relatively solid C-subconvexlike on X. Then $(\bar{x}, \bar{y})$ is a Benson-vectorial proper minimizer of* (P) *if and only if there exists $f \in C^{+i}$ such that $f(F(X)) \geq f(\bar{y})$.*

4. Benson proper minimizers in vector optimization problems with set-valued maps. In the following, we assume that X is a nonempty set, Y and Z are l.c.s., and $C \subset Y$ and $D \subset Z$ are closed convex cones. Let $F : X \to 2^Y$ and $G : X \to 2^Z$ be set-valued maps with nonempty values.

Consider the following constrained vector optimization problem with set-valued maps:

$$\text{(VP)} \quad C - \operatorname{Min} F(x) \quad \text{s.t.} \quad G(x) \cap (-D) \neq \emptyset, \quad x \in X.$$

Denote the *feasible set* of (VP) by

$$\Gamma = \{x \in X : G(x) \cap (-D) \neq \emptyset\}$$

and the image of Γ under F by

$$F(\Gamma) = \bigcup_{x \in \Gamma} F(x).$$

Li [13] introduced the concept of *Benson proper efficiency* for set-valued vector optimization problems as follows.

DEFINITION 4.1. *A point $\bar{x} \in \Gamma$ is called a* Benson properly efficient solution *of* (VP) *if*

$$F(\bar{x}) \cap \operatorname{PMin}[F(\Gamma), C] \neq \emptyset.$$

A point $(\bar{x}, \bar{y})$ is called a Benson proper minimizer *of* (VP) *if*

$$\bar{y} \in F(\bar{x}) \cap \operatorname{PMin}[F(\Gamma), C].$$

In recent years, much attention has been paid to generalized convexity of set-valued maps. Let us recall some notions (see [24]).

A set-valued map F is said to be *C-convexlike* on Γ if $F(\Gamma) + C$ is convex, to be *C-subconvexlike* on Γ if $F(\Gamma) + \operatorname{int} C$ is convex, and to be *nearly C-convexlike* on Γ if $\operatorname{cl}(F(\Gamma) + C)$ is convex. Recently, a new generalized convexity for set-valued maps, called *near C-subconvexlikeness*, was introduced in [24]. A set-valued map F is said to be *nearly C-subconvexlike* on Γ if $\operatorname{cl}\operatorname{cone}(F(\Gamma) + C)$ is convex. We know that C-convexlikeness $\Rightarrow$ C-subconvexlikeness (when $\operatorname{int} C \neq \emptyset$) $\Rightarrow$ near C-convexlikeness $\Rightarrow$ near C-subconvexlikeness, and none of the converses is true (see [24]). Hence near C-subconvexlikeness is the weakest convexity among the above four kinds of generalized convexity. Also, we observe that the former three kinds of generalized convexity are invariant by translations. Using the results in section 3, we can easily obtain the following scalarization theorems for Benson proper efficiency in optimization problems with nearly C-subconvexlike objectives.

THEOREM 4.1. *Let $\bar{x} \in \Gamma$, $\bar{y} \in F(\bar{x})$, and $F - \bar{y}$ be nearly C-subconvexlike on Γ. The point $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if, for any weakly compact convex set $K \subset C$ and $0 \notin K$, there exists $f \in C^+ \cap K^{st}$ such that $f(F(\Gamma)) \geq f(\bar{y})$.*

Proof. Clearly, $F - \bar{y}$ being nearly C-subconvexlike on Γ means that $\operatorname{cl}\operatorname{cone}(F(\Gamma) - \bar{y} + C)$ is convex. By taking $A = F(\Gamma)$ in Theorem 3.1 (and in Remark 3.3) we immediately obtain the result. □

Similarly, from Theorem 3.2 and Corollaries 3.1, 3.2, 3.3, 3.4, 3.5, and 3.6 we can obtain the following scalarization results. In the following, we always assume that $\bar{x} \in \Gamma$, $\bar{y} \in F(\bar{x})$, and $F - \bar{y}$ is nearly C-subconvexlike on Γ.

THEOREM 4.2. *Let the ordering cone $C \subset Y$ satisfy $\operatorname{int}_{\mathcal{T}} C^+ \neq \emptyset$, where $\mathcal{T}$ is any locally convex topology on Y^* compatible with the dual pair $\langle Y, Y^* \rangle$. Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if there exists $f \in C^{+i}$ (or $f \in \operatorname{int}_{\mathcal{T}} C^+$) such that $f(F(\Gamma)) \geq f(\bar{y})$.*

COROLLARY 4.1. *Let the ordering cone $C \subset Y$ have a weakly compact base B. Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if there exists $f \in C^{+i}$ (or $f \in B^{st}$) such that $f(F(\Gamma)) \geq f(\bar{y})$.*

Remark 4.1. Under the assumption that the ordering cone C has a compact base (equivalently, C is locally compact), Li [13, Theorem 4.2] and Cheng and Rong [2, Theorem 4.1], respectively, established the scalarization theorems on the Benson proper minimizer of (VP) with C-subconvexlike set-valued maps and with generalized C-subconvexlike vector-valued maps. Under the assumption that the ordering cone C is locally compact and under the assumption that $F - \bar{y}$ is nearly C-subconvexlike, Yang, Li, and Wang [24, Theorem 6.2] gave the scalarization theorem on the Benson proper minimizer of (VP). Since C-subconvexlikeness for set-valued maps is invariant by translations and it implies near C-subconvexlikeness, and since a vector-valued map may be regarded as a special set-valued map, Theorems 4.1 and 4.2 and Corollary 4.1 generalize and improve [13, Theorem 4.2] and [2, Theorem 4.1]. Moreover, it is easy to see that our results also generalize and improve [24, Theorem 6.2] (please refer to Example 3.1).

COROLLARY 4.2 (see [5, Theorem 3.2]). *Let $(Y, \|\ \|)$ be a separable normed space and $C \subset Y$ be a closed convex pointed cone. Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if there exists $f \in C^{+i}$ such that $f(F(\Gamma)) \geq f(\bar{y})$.*

COROLLARY 4.3. *Let Y be an l.c.s. with the w.c.n.p. and $C \subset Y$ be a closed convex cone with a countable weakly compact base B. Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if there exists $f \in C^{+i}$ such that $f(F(\Gamma)) \geq f(\bar{y})$.*

COROLLARY 4.4. *Let Y be the dual of a Fréchet space (E, d) and Y have a locally convex topology compatible with the dual pair $\langle E, Y \rangle$. Let $C \subset Y$ be a closed convex cone with a base. Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if there exists $f \in C^{+i}$ such that $f(F(\Gamma)) \geq f(\bar{y})$.*

COROLLARY 4.5. *Let Y be a semireflexive (DF)-space (particularly, a reflexive Banach space) and $C \subset Y$ be a closed convex cone with a base. Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of* (VP) *if and only if there exists $f \in C^{+i}$ such that $f(F(\Gamma)) \geq f(\bar{y})$.*

5. Lagrange multipliers. In this section, under the weaker assumption we present two Lagrange multiplier theorems which show that a Benson proper minimizer of the constrained set-valued vector optimization problem (VP) is exactly a Benson proper minimizer for an appropriate unconstrained set-valued vector optimization problem. Let $L(Z, Y)$ (respectively, $\mathcal{L}(Z, Y)$) be the set of all linear maps (respectively,

continuous linear maps) from Z to Y. Also, $T \in L(Z,Y)$ (respectively, $T \in \mathcal{L}(Z,Y)$) is said to be nonnegative with respect to the cones C and D, denoted by $T \in L_+(Z,Y)$ (respectively, $T \in \mathcal{L}_+(Z,Y)$), if $T(C) \subset D$. We say that (VP) satisfies the *generalized Slater constraint qualification* if there exists $x' \in X$ such that $G(x') \cap (-\mathrm{int}D) \neq \emptyset$ (see, e.g., [13, Definition 2.2]). Here we introduce its extension as follows.

DEFINITION 5.1. *We say that* (VP) *satisfies the conelike generalized Slater constraint qualification if*

$$\mathrm{cl}[\Lambda(G(X))] \cap (-\mathrm{int}D) \neq \emptyset,$$

where $\Lambda(G(X))$ *denotes the set* $\{\sum_{i=1}^{n} \lambda_i z_i : \ n \in N,\ \lambda_i \geq 0,\ z_i \in G(X),\ i = 1,2,\ldots,n\}$.

Remark 5.1. Since

$$\mathrm{cl}[\Lambda(G(X))] \cap (-\mathrm{int}D) \ \subset \ \mathrm{cl}[\Lambda(G(X)) \cap (-\mathrm{int}D)],$$

the condition that $\mathrm{cl}[\Lambda(G(X))] \cap (-\mathrm{int}D) \neq \emptyset$ in Definition 5.1 is equivalent to $\Lambda(G(X)) \cap (-\mathrm{int}D) \neq \emptyset$.

We easily see that the above condition is strictly weaker than the generalized Slater constraint qualification.

Example 5.1. Let $X = \{(x_1,x_2) \in R^2 : \ x_1 \leq 0,\ x_2 \leq 0,\ 1 \leq x_1^2 + x_2^2 \leq 4\}$, $Z = R^2$, and $D \subset Z$ be the cone

$$\left\{(x_1,x_2) \in R^2 : \ x_1 \geq 0,\ x_2 \geq 0,\ \frac{\sqrt{3}}{3}x_1 \leq x_2 \leq \sqrt{3}x_1\right\}.$$

Define a set-valued map $G : X \to 2^Z$ as follows:

$$(x_1,x_2) \to G((x_1,x_2))$$
$$= \begin{cases} \{(\rho x_1, 0) : \rho \geq 0\} & \text{if } (x_1,x_2) \in X \cap \{(x_1,x_2) \in R^2 : \sqrt{3}x_1 < x_2 < \frac{\sqrt{3}}{3}x_1\}; \\ \{(x_1,x_2)\} & \text{if } (x_1,x_2) \in X \backslash \{(x_1,x_2) \in R^2 : \sqrt{3}x_1 < x_2 < \frac{\sqrt{3}}{3}x_1\}. \end{cases}$$

Obviously, for any $(x_1,x_2) \in X$,

$$G((x_1,x_2)) \cap (-\mathrm{int}D) = \emptyset.$$

But

$$-\Lambda(G(X)) \cap (-\mathrm{int}D) \neq \emptyset.$$

This shows that the set-valued map G does not satisfy the generalized Slater constraint qualification, but it satisfies the conelike generalized Slater constraint qualification.

The following Theorems 5.1, 5.2, and 5.3 improve and extend [13, Theorems 5.1 and 5.2], [2, Theorem 5.1], and [23, Theorem 3.1].

THEOREM 5.1. *Let* Y *and* Z *be l.c.s.,* $C \subset Y$ *be a closed convex pointed cone,* $D \subset Z$ *be a convex cone with nonempty interior,* $\bar{x} \in \Gamma$, *and* $\bar{y} \in F(\bar{x})$. *Furthermore, let* $(F - \bar{y}, G)$ *be nearly* $C \times D$*-subconvexlike on* X *and* (VP) *satisfy the conelike generalized Slater constraint qualification. If there exists* $f \in C^{+i}$ *such that* $f(F(\Gamma)) \geq f(\bar{y})$, *then there exists* $T \in \mathcal{L}_+(Z,Y)$ *such that*

$$T(G(\bar{x}) \cap (-D)) = \{0\} \ \text{ and } \ \bar{y} \in \mathrm{PMin}[(F+TG)(X), C].$$

Proof. Set $B := (f = 1) \cap C$. Then B is a base of C. By the hypothesis, $f \in C^{+i}$ and $f(F(\Gamma) - \bar{y}) \geq 0$, so $f(\mathrm{cl}\,\mathrm{cone}(F(\Gamma) - \bar{y} + C)) \geq 0$. Also, clearly $f(-B) = \{-1\}$. Let V be an absolutely convex 0-neighborhood in Y, with $V \subset \{y \in Y : |f(y)| < \frac{1}{4}\}$. Then

$$(\mathrm{cl}\,\mathrm{cone}(F(\Gamma) - \bar{y} + C) + V) \cap -(B + V) = \emptyset. \tag{5}$$

From (5), $V \cap (-B - V) = \emptyset$, and hence $0 \notin \mathrm{cl}(B + V)$. Thus $B + V$ is a base of $\mathrm{cone}(B+V)$, and clearly $\mathrm{cone}(B+V)$, and has nonempty interior. Denote $\mathrm{cone}(B+V)$ by $C_V(B)$. We assert that

$$\mathrm{cone}((F - \bar{y}, G)(X)) \cap (-\mathrm{int}C_V(B), -\mathrm{int}D) = \emptyset. \tag{6}$$

First we observe that any element of $\mathrm{cone}((F - \bar{y}, G)(X))$ may be written in the following form:

$$\alpha(y - \bar{y}, z) \in Y \times Z, \quad \text{where } \alpha \geq 0,\ y \in F(x),\ z \in G(x),\ x \in X.$$

We show (6) according to the following two cases.

Case 1. If $x \in \Gamma$, then $\alpha(y - \bar{y}) \in \mathrm{cone}(F(\Gamma) - \bar{y})$. Combining this with (5), we can deduce that

$$\alpha(y - \bar{y}) \notin -\mathrm{int}C_V(B).$$

Hence

$$\alpha(y - \bar{y}, z) \notin (-\mathrm{int}C_V(B), -\mathrm{int}D).$$

Case 2. If $x \notin \Gamma$, then $G(x) \cap (-D) = \emptyset$. Since $z \in G(x)$, we have $z \notin -D$ and $\alpha z \notin -\mathrm{int}D$. Hence we also have

$$\alpha(y - \bar{y}, z) \notin (-\mathrm{int}C_V(B), -\mathrm{int}D).$$

Thus we have shown (6). From this, we have

$$(\mathrm{cone}((F - \bar{y}, G)(X)) + (C, D)) \cap (-\mathrm{int}C_V(B), -\mathrm{int}D) = \emptyset.$$

Noting that $(-\mathrm{int}C_V(B), -\mathrm{int}D)$ is open in $Y \times Z$, we conclude that

$$\mathrm{cl}[\mathrm{cone}((F - \bar{y}, G)(X)) + (C, D)] \cap (-\mathrm{int}C_V(B), -\mathrm{int}D) = \emptyset. \tag{7}$$

By the assumption that $(F - \bar{y}, G)$ is nearly $C \times D$-subconvexlike on X, we know that $\mathrm{cl}[\mathrm{cone}((F - \bar{y}, G)(X)) + (C, D)]$ is a closed convex set, which does not intersect the open convex set $(-\mathrm{int}C_V(B), -\mathrm{int}D)$ in $Y \times Z$. By the Hahn–Banach separation theorem, there exists $(\varphi, \psi) \in (Y \times Z)^* = Y^* \times Z^*$, $(\varphi, \psi) \neq (0, 0)$, such that

$$\begin{aligned} (\varphi, \psi)(\mathrm{cone}((F - \bar{y}, G)(X)) + (C, D)) \geq 0 &> (\varphi, \psi)(-\mathrm{int}C_V(B), -\mathrm{int}D) \\ &= \varphi(-\mathrm{int}C_V(B)) + \psi(-\mathrm{int}D). \end{aligned}$$

From this, we have

$$\varphi(F(x) - \bar{y}) + \psi(G(x)) \geq 0 \quad \forall x \in X, \tag{8}$$

$$\varphi \in (C_V(B))^+, \tag{9}$$

and

$$\psi \in D^+. \tag{10}$$

Since $\bar{x} \in \Gamma$, we have $G(\bar{x}) \cap (-D) \neq \emptyset$. Take any $\bar{z} \in G(\bar{x}) \cap (-D)$. By (10) we have

$$\psi(\bar{z}) \leq 0. \tag{11}$$

By taking $x = \bar{x}$ in (8), we obtain

$$\varphi(F(\bar{x}) - \bar{y}) + \psi(G(\bar{x})) \geq 0.$$

Since $\bar{y} \in F(\bar{x})$ and $\bar{z} \in G(\bar{x})$, we have

$$\psi(\bar{z}) \geq 0. \tag{12}$$

Combining (11) and (12), we have $\psi(\bar{z}) = 0$, and hence

$$\psi(G(\bar{x}) \cap (-D)) = \{0\}. \tag{13}$$

Next we show that $\varphi \neq 0$. If not, we assume that $\varphi = 0$. Then $\psi \in D^+ \backslash \{0\}$. From (8) and $\varphi = 0$, we have

$$\psi(G(X)) \geq 0. \tag{14}$$

On the other hand, (VP) satisfies the conelike generalized Slater constraint qualification, so

$$\Lambda(G(X)) \cap (-\mathrm{int}D) \neq \emptyset.$$

That is, there exist $n \in N$, $\lambda_i \geq 0$, and $z_i \in G(X)$ for $i = 1, 2, \ldots, n$ such that $\sum_{i=1}^{n} \lambda_i z_i \in -\mathrm{int}D$. Since $\psi \in D^+ \backslash \{0\}$, we have

$$\sum_{i=1}^{n} \lambda_i \psi(z_i) = \psi\left(\sum_{i=1}^{n} \lambda_i z_i\right) < 0.$$

Thus there exists some i, $1 \leq i \leq n$, such that $\psi(z_i) < 0$, where $z_i \in G(X)$. This contradicts (14). Therefore, $\varphi \neq 0$ and $\varphi \in (C_V(B))^+ \backslash \{0\}$. From this, we know that $\varphi(B + V) \geq 0$, and hence there exists $\delta > 0$ such that $\varphi(B) \geq \delta > 0$, so $\varphi \in B^{st}$. Obviously, there exists $\bar{c} \in C = \mathrm{cone}(B)$ such that $\varphi(\bar{c}) = 1$. Define $T \in \mathcal{L}(Z, Y)$ as follows:

$$T(z) = \psi(z)\,\bar{c} \quad \forall z \in Z. \tag{15}$$

Since $\psi(D) \geq 0$ and $\bar{c} \in C$, we have

$$T(D) \subset C, \quad \text{i.e.,} \quad T \in \mathcal{L}_+(Z, Y).$$

By (13) and the definition of T, we have

$$T(G(\bar{x}) \cap (-D)) = \psi(G(\bar{x}) \cap (-D))\,\bar{c} = \{0\}.$$

For any $x \in X$, any $y \in F(x)$, and any $z \in G(x)$, we have

$$\begin{aligned} \varphi(y - \bar{y} + Tz) &= \varphi(y - \bar{y}) + \varphi(Tz) \\ &= \varphi(y - \bar{y}) + \varphi(\psi(z)\bar{c}) \\ &= \varphi(y - \bar{y}) + \psi(z) \geq 0, \end{aligned} \tag{16}$$

where the final inequality is due to (8). By (16) and $\varphi \in B^{st} \subset C^{+i}$, we have

$$\varphi(\mathrm{cl\,cone}((F+TG)(X)-\bar{y}+C)) \geq 0. \tag{17}$$

On the other hand,

$$\varphi(-C\backslash\{0\}) < 0. \tag{18}$$

Combining (17) and (18), we conclude that

$$\mathrm{cl\,cone}((F+TG)(X)-\bar{y}+C)\cap(-C) = \{0\}.$$

That is,

$$\bar{y} \in \mathrm{PMin}[(F+TG)(X), C].$$

Thus we complete the proof. □

THEOREM 5.2. *Let $F: X \to 2^Y$ and $G: X \to 2^Z$ be set-valued maps and $C \subset Y$ and $D \subset Z$ be convex cones. Let $\Gamma = \{x \in X : G(x)\cap(-D) \neq \emptyset\}$, $\bar{x} \in \Gamma$, and $\bar{y} \in F(\bar{x})$. If there exists $T \in L_+(Z,Y)$ such that $\bar{y} \in \mathrm{PMin}[(F+TG)(X), C]$, then $\bar{y} \in \mathrm{PMin}[F(\Gamma), C]$.*

Proof. For any $x \in \Gamma$, there exists $z_x \in G(x)\cap(-D)$. Since $T(-D) \subset -C$, we have $Tz_x \in -C$. Thus

$$\{0\} \subset Tz_x + C \subset TG(x) + C.$$

From this,

$$F(x)-\bar{y} \subset F(x)-\bar{y}+TG(x)+C \quad \forall x \in \Gamma.$$

That is,

$$\begin{aligned} F(\Gamma)-\bar{y} &\subset (F+TG)(\Gamma)+C-\bar{y} \\ &\subset (F+TG)(X)+C-\bar{y}. \end{aligned}$$

Since C is a convex cone, it is easy to see that

$$F(\Gamma)-\bar{y}+C \subset (F+TG)(X)+C-\bar{y}$$

and certainly

$$\mathrm{cl\,cone}(F(\Gamma)-\bar{y}+C) \subset \mathrm{cl\,cone}((F+TG)(X)+C-\bar{y}). \tag{19}$$

By the assumption that $\bar{y} \in \mathrm{PMin}[(F+TG)(X), C]$, we have

$$\mathrm{cl\,cone}((F+TG)(X)+C-\bar{y})\cap(-C) = \{0\}.$$

Combining this with (19), we conclude that

$$\mathrm{cl\,cone}(F(\Gamma)-\bar{y}+C)\cap(-C) = \{0\}, \quad \text{that is,} \quad \bar{y} \in \mathrm{PMin}[F(\Gamma), C]. \qquad \square$$

Here it is not necessary that T be continuous. Also, we need not assume that $0 \in TG(\bar{x})$ in advance. Please compare this result with [13, Theorem 5.2]. Combining Theorems 5.1 and 5.2 and the results in section 4, we obtain the following.

THEOREM 5.3. *Let $\bar{x} \in \Gamma$, $\bar{y} \in F(\bar{x})$, $F - \bar{y}$ be nearly C-subconvexlike on Γ, $(F - \bar{y}, G)$ be nearly $C \times D$-subconvexlike on X, and* (VP) *satisfy the conelike generalized Slater constraint qualification. Assume that one of the following conditions is satisfied:*

(i) *the ordering cone $C \subset Y$ has a weakly compact base (or a compact base);*

(ii) *Y is a separable normed space;*

(iii) *Y is an l.c.s. with the w.c.n.p., and C has a countable weakly compact base;*

(iv) *Y is the dual of a Fréchet space E, endowed with a locally convex topology compatible with the dual pair $\langle E, Y\rangle$, and the ordering cone C has a base;*

(v) *Y is a semireflexive (DF)-space (particularly, Y is a reflexive Banach space), and the ordering cone C has a base.*

Then $(\bar{x}, \bar{y})$ is a Benson proper minimizer of (VP) *if and only if there exists $T \in \mathcal{L}_+(Z, Y)$ such that*

$$T(G(\bar{x}) \cap (-D)) = \{0\} \quad \text{and} \quad \bar{y} \in \mathrm{PMin}[(F + TG)(X), C].$$

CONSTRAINT QUALIFICATIONS FOR CONVEX INEQUALITY SYSTEMS WITH APPLICATIONS IN CONSTRAINED OPTIMIZATION*

CHONG LI†, K. F. NG‡, AND T. K. PONG‡

Abstract. For an inequality system defined by an infinite family of proper convex functions, we introduce some new notions of constraint qualifications in terms of the epigraphs of the conjugates of these functions and study relationships between these new constraint qualifications and other well-known constraint qualifications including the basic constraint qualification studied by Hiriart-Urrutty and Lemarechal and by Li, Nahak, and Singer. Extensions of known results to more general settings are presented, and applications to particular important problems, such as conic programming and approximation theory, are also studied.

Key words. convex inequality system, basic constraint qualification, strong conical hull intersection property, best constrained approximation, conic programming

1. Introduction.

Many problems in optimization and approximation theory can be recast into one of the following two types: one is a system of convex inequalities

$$g_i(x) \le 0 \quad \text{for each } i \in I, \tag{1.1}$$

and the other is a minimization problem

$$\begin{aligned} &\text{Minimize} && f(x), \\ &\text{s.t.} && x \in C,\ g_i(x) \le 0,\ i \in I, \end{aligned} \tag{1.2}$$

where C is a convex set, not necessarily closed. Many authors have studied these two problems with various degrees of generality imposed on the index set I, the family of functions $\{g_i : i \in I\}$, or on the underlying space; see, for example, [4, 5, 6, 13, 14, 15, 16, 17, 18, 19, 21, 23, 29, 30, 31, 32, 33, 34, 35, 36] and references therein.

A special case of (1.1) occurs when each g_i is the indicator function of a closed convex set C_i; that is, one considers a family of closed convex sets $\{C_i : i \in I\}$. In [13], Deutsch, Li, and Ward introduced the notion of the strong conical hull intersection property (the strong CHIP) for a family of finitely many closed convex sets in a Hilbert space in connection with the reformulation of some best approximation problems. Their work was recently extended in [32, 34] to the setting of a normed linear space with I being an infinite set.

For the case when $\{g_i : i \in I\}$ is a finite family of continuous convex functions on a finite dimensional vector space, the notion of basic constraint qualification (BCQ) was

introduced by Hiriart-Urrutty and Lemarechal (see [19]). The notion was extended to cover the case of an infinite family of continuous convex functions with a continuous sup-function $\sup_{i\in I} g_i$ by Li, Nahak, and Singer (see [36]), who also studied many aspects of the BCQ in relation to other constraint qualifications. Recall from [32,33,36] that the inequality system (1.1) is said to satisfy the BCQ at $x \in S := \{x \in X : g_i(x) \le 0,\ i \in I\}$ if

$$N_S(x) = \text{cone} \bigcup_{i\in I(x)} \partial\, g_i(x)$$

(see the next section for notation and definitions). The concept of a BCQ relative to C was introduced in [31, 32, 33] in order to take care of the abstract constraint set C. In these papers, under some continuity assumption such as the one used in [36], the system (1.1) with the family $\{\delta_C;\, g_i,\ i \in I\}$ was considered in place of $\{g_i :\ i \in I\}$.

Constraint qualifications involving epigraphs (first introduced in [8,9]) have been extensively used by many authors (see, for example, [4, 5, 6, 7, 8, 9, 10, 15, 16, 24, 25, 26, 27, 28, 29, 35]). Particularly in connection with the study of a conic programming problem (see Example 2.1 below), Jeyakumar and coworkers [25, 26, 29] and Boţ and Wanka [7] studied several new constraint qualifications (such as what they called the condition (**C***) and the CCCQ; see [26, 29] for their definitions). Inspired by these works as well as that of Dinh, Goberna, and López in [15] (especially with regard to the new optimality conditions for (1.2)), we define the following concept: the inequality system (1.1) is said to have the conical epigraph hull property (conical EHP) if

$$\text{epi}\, \sigma_S = \text{cone} \bigcup_{i\in I} \text{epi}\, g_i^*, \tag{1.3}$$

where $S = \{x : g_i(x) \le 0\ \ \forall i \in I\}$. In particular, (1.3) reduces to the sum of epigraph constraint qualification (SECQ) introduced in [35] if $g_i = \delta_{C_i}$ for some family of closed convex sets $\{C_i :\ i \in I\}$. We show that by suitably choosing the family $\{g_i : i \in I\}$, the conical EHP reduces to the closed cone constraint qualification (CCCQ) defined in [7, 26]. In section 4, we derive some relationships between the EHP, the BCQ, and the Pshenichyni–Levin–Valadier property (PLV property). We also give some applications involving the strong CHIP and the convex Farkas–Minkowski systems (studied by Li, Nahak, and Singer in [36]).

In this paper, we consider (1.2) under minimal assumptions: f is a proper convex lower semicontinuous function and $\{g_i : i \in I\}$ is a family of proper convex functions (not necessarily lower semicontinuous) defined on a locally convex Hausdorff topological vector space X with proper sup-function, where I is an arbitrary index set. The last three sections of this paper are on applications of results obtained in section 4. An optimality condition (of Lagrange type) for (1.2) is established in section 5, and as a consequence we provide an improved version of [16, Theorem 3] on a characterization of minimizers for the problem (1.2); our argument differs from [16] and allows us to treat the case when each g_i is not necessarily lower semicontinuous. In particular, our results here cover the interesting conic programming case in which the feasible solution set is not necessarily closed (as the involved functions are not necessarily lower semicontinuous). Several known results in the conic programming problem (see [24,26,29]) are extended/improved in section 6. Finally, we study a best approximation problem in section 7.

2. Notation and preliminary results. The notation used in the present paper is standard (cf. [11, 19, 40]). In particular, we assume throughout the whole paper

(unless otherwise specified) that X is a real locally convex Hausdorff topological vector space, and we let X^* denote the dual space of X, whereas $\langle x^*, x\rangle$ denotes the value of a functional x^* in X^* at $x \in X$, i.e., $\langle x^*, x\rangle = x^*(x)$. Let A be a set in X. The interior (resp., closure, convex hull, convex cone hull, linear hull, affine hull, boundary) of A is denoted by $\operatorname{int} A$ (resp., $\overline{A}$, $\operatorname{co} A$, $\operatorname{cone} A$, $\operatorname{span} A$, $\operatorname{aff} A$, $\operatorname{bd} A$). The positive polar cone $A^{\oplus}$ and the negative polar cone $A^{\ominus}$ are defined respectively by

$$A^{\oplus} := \{x^* \in X^* \ : \ \langle x^*, z\rangle \geq 0 \ \forall z \in A\}$$

and

$$A^{\ominus} := \{x^* \in X^* \ : \ \langle x^*, z\rangle \leq 0 \ \forall z \in A\}.$$

The normal cone of A at $z_0 \in A$ is denoted by $N_A(z_0)$ and is defined by $N_A(z_0) = (A - z_0)^{\ominus}$. The indicator function δ_A and the support function σ_A of A are respectively defined by

$$\delta_A(x) := \begin{cases} 0, & x \in A, \\ \infty, & \text{otherwise}, \end{cases}$$

and

$$\sigma_A(x^*) := \sup_{x \in A} \langle x^*, x\rangle \quad \text{for each } x^* \in X^*.$$

Let f and g be proper functions respectively defined on X and X^*. Let f^*, g^* denote their conjugate functions, that is,

$$f^*(x^*) := \sup\{\langle x^*, x\rangle - f(x) : \ x \in X\} \quad \text{for each } x^* \in X^*,$$

$$g^*(x) := \sup\{\langle x^*, x\rangle - g(x^*) : \ x^* \in X^*\} \quad \text{for each } x \in X.$$

The epigraph of a function f on X is denoted by $\operatorname{epi} f$ and defined by

$$\operatorname{epi} f := \{(x, r) \in X \times \mathbb{R} : \ f(x) \leq r\}.$$

For a proper convex function f, the subdifferential of f at $x \in X$, denoted by $\partial f(x)$, is defined by

$$\partial f(x) := \{x^* \in X^* : \ \ f(x) + \langle x^*, y - x\rangle \leq f(y) \quad \text{for each } y \in X\}.$$

Moreover, the Young's equality holds (cf. [40, Theorem 2.4.2(iii)]):

$$f(x) + f^*(x^*) = \langle x^*, x\rangle \quad \text{if and only if } x^* \in \partial f(x). \tag{2.1}$$

In particular,

$$(x^*, \langle x^*, x\rangle - f(x)) \in \operatorname{epi} f^* \quad \text{for each } x^* \in \partial\, f(x). \tag{2.2}$$

We also define

$$\operatorname{im} \partial f := \{y^* \in X^* : \ y^* \in \partial f(x) \text{ for some } x \in X\}$$

and

$$\operatorname{dom} \partial f := \{x \in X : \ \partial f(x) \neq \emptyset\}.$$

For a convex subset A of X, the following statements are standard and easily verified:

$$\sigma_A = \delta_A^*, \quad N_A(x) = \partial \delta_A(x) \quad \text{for each } x \in A, \tag{2.3}$$

$$\sigma_A(x^*) = \langle x^*, x\rangle \Leftrightarrow x^* \in N_A(x) \Longleftrightarrow (x^*, \langle x^*, x\rangle) \in \operatorname{epi} \sigma_A \text{ for each } (x, x^*) \in A \times X^*. \tag{2.4}$$

Moreover, for each $(x^*, \alpha) \in X^* \times \mathbb{R}$,

$$(x^*, \alpha) \in \operatorname{epi} \sigma_A \Longleftrightarrow \langle x^*, x\rangle \le \alpha \quad \text{for each } x \in A. \tag{2.5}$$

Let $\{A_i : i \in J\}$ be a family of subsets of X containing the origin. The set $\sum_{i\in J} A_i$ is defined by

$$\sum_{i\in J} A_i = \begin{cases} \left\{\sum_{i\in J_0} a_i : a_i \in A_i, \emptyset \ne J_0 \subseteq J \text{ being finite}\right\} & \text{if } J \ne \emptyset, \\ \{0\} & \text{if } J = \emptyset. \end{cases}$$

In the remainder of this paper, let $\{g_i : i \in I\}$ denote a family of proper convex functions on X, where I is an index set. Let G denote the sup-function of $\{g_i : i \in I\}$, that is,

$$G(x) := \sup\{g_i(x) : i \in I\} \quad \text{for each } x \in X.$$

We always assume that the sup-function is proper. Let S denote the solution set of the inequality system (1.1) defined by $\{g_i : i \in I\}$, that is,

$$S := \{x : g_i(x) \le 0 \ \forall\, i \in I\} = \{x : G(x) \le 0\}.$$

For each $x \in X$, we define

$$I(x) = \{i \in I : g_i(x) = G(x) = 0\}$$

and

$$\tilde{I}(x) := \{i \in I : g_i(x) = G(x)\}.$$

The consideration of optimization problem (1.2) abounds in the literature. We end this section with one such example (which will be discussed in detail in section 6). Consider the following conic programming problem that has been studied in [6] and has also been studied in [2, 7, 24, 25, 26, 27, 28, 29] for the special case when X, Z are Banach spaces and $g : X \to Z$ is K-convex continuous.

Example 2.1. Suppose that X, Z are locally convex Hausdorff topological vector spaces, $C \subseteq X$ is a convex set, and $K \subseteq Z$ is a closed convex cone. Define an order on Z by saying that $y \le_K x$ if $y - x \in -K$. We attach a greatest element ∞ with respect to $\le_K$ and denote $Z^\bullet := Z \cup \{+\infty\}$. The following operations are defined on $Z^\bullet$: for any $z \in Z$, $z + \infty = \infty + z = \infty$ and $t\infty = \infty$ for all $t \ge 0$.

Consider the following conic programming problem:

$$\begin{array}{ll} \text{Minimize} & f(x), \\ \text{s.t.} & x \in C,\ g(x) \in -K, \end{array} \tag{2.6}$$

where $f : X \to \mathbb{R} \cup \{+\infty\}$ is a proper convex lower semicontinuous function and $g : X \to Z^\bullet$ is K-convex in the sense that for every $u, v \in X$ and every $t \in [0, 1]$,

$$g(tu + (1-t)v) \leq_K tg(u) + (1-t)g(v)$$

(see [2, 5, 6, 22, 25]). As in [5], we define for each $\lambda \in K^\oplus$

$$(\lambda g)(x) := \begin{cases} \langle \lambda, g(x) \rangle & \text{if } x \in \operatorname{dom} g, \\ +\infty & \text{otherwise,} \end{cases} \tag{2.7}$$

where $\operatorname{dom} g := \{x \in X : g(x) \in Z\}$. It is easy to see that g is K-convex if and only if $(\lambda g)(\cdot) : X \to \mathbb{R} \cup \{+\infty\}$ is a convex function for each $\lambda \in K^\oplus$. The problem (2.6) can be equivalently stated as

$$\begin{aligned} &\text{Minimize} && f(x), \\ &\text{s. t.} && \delta_C(x) \leq 0,\ (\lambda g)(x) \leq 0 \quad \text{for each } \lambda \in K^\oplus. \end{aligned}$$

Thus (2.6) can be viewed as an example of (1.2) by letting $I = K^\oplus \cup \{i_0\}$ with $i_0 \notin I$ and

$$g_{i_0} = \delta_C,\ g_\lambda = \lambda g \quad \text{for each } \lambda \in K^\oplus. \tag{2.8}$$

3. The BCQ. We begin with the following definitions adopted from [32, 36]. In the remainder, we shall adopt the convention that $\operatorname{cone} A = \{0\}$ when A is an empty set.

DEFINITION 3.1. *Let C be a convex set in X. The family $\{g_i : i \in I\}$ is said to satisfy*

(i) *the PLV property at $x \in X$ if*

$$\partial G(x) = \operatorname{co} \bigcup_{i \in \bar{I}(x)} \partial g_i(x); \tag{3.1}$$

(ii) *the BCQ at $x \in S$ if*

$$N_S(x) = \operatorname{cone} \bigcup_{i \in I(x)} \partial g_i(x); \tag{3.2}$$

(ii′) *the BCQ relative to C at $x \in C \cap S$ if*

$$N_{C \cap S}(x) = N_C(x) + \operatorname{cone} \bigcup_{i \in I(x)} \partial g_i(x); \tag{3.3}$$

(iii) *the PLV property (resp., the BCQ, the BCQ relative to C) if* (3.1) *(resp.,* (3.2)*,* (3.3)*) holds for each $x \in X$ (resp., $x \in S$, $x \in C \cap S$).*

Remark 3.1. In [16, Definition 2] (under the assumption that each g_i is lower semicontinuous), the property that the family $\{g_i : i \in I\}$ satisfies the BCQ relative to C was also described as the system $\{\delta_C;\ g_i,\ i \in I\}$ being locally Farkas–Minkowski(FM).

A relationship between the notions (ii) and (ii)′ in Definition 3.1 is shown in the following proposition.

PROPOSITION 3.1. *Consider a convex set C and $x \in C \cap S$. Then the family $\{g_i : i \in I\}$ satisfies the BCQ relative to C at x if and only if the family $\{\delta_C;\ g_i,\ i \in I\}$*

satisfies the BCQ at x. Consequently, the family $\{g_i : i \in I\}$ satisfies the BCQ relative to C if and only if the family $\{\delta_C; g_i, i \in I\}$ satisfies the BCQ.

Proof. Take $j \notin I$ and set $g_j := \delta_C$. Writing $J := I \cup \{j\}$, the family $\{\delta_C; g_i, i \in I\}$ becomes $\{g_i : i \in J\}$ such that $C \cap S = \{y \in X : g_i(y) \leq 0 \ \forall i \in J\}$ and $J(x) = \{j\} \cup I(x)$, where for $x \in C \cap S$,

$$J(x) := \left\{ i \in J : \ g_i(x) = \max \left\{ \sup_{i \in I} g_i(x), \delta_C(x) \right\} = 0 \right\}.$$

Then by (2.3),

$$N_C(x) + \operatorname{cone} \bigcup_{i \in I(x)} \partial\, g_i(x) = \operatorname{cone} \bigcup_{i \in J(x)} \partial\, g_i(x).$$

Thus the first assertion follows. The second follows immediately from the first. ∎

Remark 3.2.

(i) We have

$$\partial\, G(x) \supseteq \operatorname{co} \bigcup_{i \in \tilde{I}(x)} \partial\, g_i(x) \quad \text{for each } x \in X. \tag{3.4}$$

Indeed, let $i \in \tilde{I}(x)$ and $y^* \in \partial\, g_i(x)$. Then $g_i(x) = G(x)$. Since $y^* \in \partial g_i(x)$ and g_i is proper, $g_i(x) \neq +\infty$. Now it follows that

$$\langle y^*, y - x \rangle \leq g_i(y) - g_i(x) \leq G(y) - G(x) \quad \text{for each } y \in X. \tag{3.5}$$

This shows that $y^* \in \partial\, G(x)$, and so (3.4) is proved. Thus, the family $\{g_i : i \in I\}$ has the PLV property at $x \in X$ if and only if

$$\partial\, G(x) \subseteq \operatorname{co} \bigcup_{i \in \tilde{I}(x)} \partial\, g_i(x). \tag{3.6}$$

Hence, the family $\{g_i : i \in I\}$ has the PLV property if and only if (3.6) holds for each $x \in \operatorname{dom} \partial\, G$.

(ii) If $i \in I(x)$ and $y^* \in \partial\, g(x)$, then $G(x) = 0$. It follows from (3.5) that $y^* \in N_S(x)$. Thus

$$N_S(x) \supseteq \operatorname{cone} \bigcup_{i \in I(x)} \partial\, g_i(x) \quad \text{for each } x \in S. \tag{3.7}$$

Therefore, the family $\{g_i : i \in I\}$ satisfies the BCQ at $x \in S$ if and only if

$$N_S(x) \subseteq \operatorname{cone} \bigcup_{i \in I(x)} \partial\, g_i(x). \tag{3.8}$$

(iii) Note that if $x \in \operatorname{int} S$, then $N_S(x) = \{0\}$. Recalling our convention $\operatorname{cone} \emptyset = \{0\}$ (see Definition 3.1(ii)), it follows from (3.7) that

$$\{0\} = N_S(x) = \operatorname{cone} \bigcup_{i \in I(x)} \partial\, g_i(x) \quad \text{for each } x \in \operatorname{int} S.$$

Hence, the family $\{g_i : i \in I\}$ satisfies the BCQ if and only if (3.8) holds for each $x \in S \backslash \operatorname{int} S$.

(iv) Applying parts (ii) and (iii) to the family of functions $\{\delta_C;\ g_i,\ i \in I\}$ in place of $\{g_i :\ i \in I\}$ and invoking Proposition 3.1, we obtain that the family $\{g_i :\ i \in I\}$ satisfies the BCQ relative to C at x if and only if we have

$$N_{C\cap S}(x) \subseteq N_C(x) + \operatorname{cone} \bigcup_{i\in I(x)} \partial\, g_i(x), \tag{3.9}$$

and that the family $\{g_i :\ i \in I\}$ satisfies the BCQ relative to C if and only if (3.9) holds for each $x \in (C \cap S)\backslash \operatorname{int}(C \cap S)$.

Recall from [13, 32, 34] that a family of convex sets $\{C_i :\ i \in I\}$ is said to have the strong conical hull intersection property (the strong CHIP) at $x \in \bigcap_{i\in I} C_i$ if

$$N_{\bigcap_{i\in I} C_i}(x) = \sum_{i\in I} N_{C_i}(x). \tag{3.10}$$

If (3.10) holds for every $x \in \bigcap_{i\in I} C_i$, then we say that the family has the strong CHIP.

PROPOSITION 3.2. *Let $x \in C \cap S$, and suppose that the family $\{g_i : i \in I\}$ satisfies the BCQ at x. Then $\{C, S\}$ has the strong CHIP at x if and only if the family $\{g_i :\ i \in I\}$ satisfies the BCQ relative to C at x.*

Proof. By the given assumption, (3.2) holds. Hence we have the following equivalences:

$$\begin{aligned}
&\{C, S\} \text{ has the strong CHIP at } x \\
&\quad\Leftrightarrow N_{C\cap S}(x) = N_C(x) + N_S(x) \\
&\quad\Leftrightarrow N_{C\cap S}(x) = N_C(x) + \operatorname{cone} \bigcup_{i\in I(x)} \partial\, g_i(x) \\
&\quad\Leftrightarrow \{g_i :\ i \in I\} \text{ satisfies the BCQ relative to } C \text{ at } x. \qquad \square
\end{aligned}$$

Recall from [21] that the inequality system $f \le 0$ satisfies the weak BCQ at $x \in S_f\backslash \operatorname{int} S_f$ if

$$N_{S_f}(x) \subseteq \operatorname{cone} \partial\, f(x) + N_{\operatorname{dom} f}(x), \tag{3.11}$$

where $S_f := \{x \in X :\ f(x) \le 0\}$. The following proposition describes a relationship between the BCQ and the weak BCQ .

PROPOSITION 3.3. *Let f be a proper convex function on X and $x \in S_f\backslash \operatorname{int} S_f$. Then the family $\{f, \delta_{\operatorname{dom} f}\}$ satisfies the BCQ at x if and only if the inequality system $f \le 0$ satisfies the weak BCQ at x.*

Proof. Write $g_1 = f$ and $g_2 = \delta_{\operatorname{dom} f}$. If x satisfies, in addition, that $f(x) < 0$, then both the necessary condition and the sufficient condition in the statement of the proposition are satisfied. In fact, since $x \notin \operatorname{int} S_f$, [21, Lemma 2.2] states that

$$N_{S_f}(x) = N_{\operatorname{dom} f}(x).$$

Consequently (3.11) holds, and the family $\{f, \delta_{\operatorname{dom} f}\}$ satisfies the BCQ at x because of (2.3) and $I(x) = \{2\}$ (as $f(x) < 0$).

Therefore, to complete our proof we need only consider the case when $f(x) = 0$. For this case note that $I(x) = \{1, 2\}$. Thus, by (2.3), the family $\{f, \delta_{\mathrm{dom}\, f}\}$ satisfies the BCQ at x if and only if

$$N_{S_f}(x) = \mathrm{cone}\, \partial f(x) + N_{\mathrm{dom}\, f}(x). \tag{3.12}$$

Since the inclusion $N_{S_f}(x) \supseteq \mathrm{cone}\, \partial f(x) + N_{\mathrm{dom}\, f}(x)$ holds trivially (thanks to $f(x) = 0$ and Remark 3.2(ii) as applied to $\{f, \delta_{\mathrm{dom}\, f}\}$), (3.11) and (3.12) are equivalent. This completes the proof. □

4. The epigraph hull property. Recall that the meaning of $\{g_i : i \in I\}, G$, X, S, and I has been specified in section 2. The sup-function G is sometimes denoted by $\sup_{i\in I} g_i$. Recall also that we always assume that G is proper.

DEFINITION 4.1. *The family $\{g_i : i \in I\}$ is said to have the following:*

(i) *the convex EHP if*

$$\mathrm{epi} \left(\sup_{i\in I} g_i\right)^* = \mathrm{co} \bigcup_{i\in I} \mathrm{epi}\, g_i^*; \tag{4.1}$$

(ii) *the conical EHP if*

$$\mathrm{epi}\, \sigma_S = \mathrm{cone} \bigcup_{i\in I} \mathrm{epi}\, g_i^*. \tag{4.2}$$

Remark 4.1. It is routine to show that

$$\mathrm{epi} \left(\sup_{i\in I} g_i\right)^* \supseteq \mathrm{co} \bigcup_{i\in I} \mathrm{epi}\, g_i^* \quad \text{and} \quad \mathrm{epi}\, \sigma_S \supseteq \mathrm{cone} \bigcup_{i\in I} \mathrm{epi}\, g_i^*.$$

Thus the family has the convex EHP (resp., conical EHP) if and only if

$$\mathrm{epi} \left(\sup_{i\in I} g_i\right)^* \subseteq \mathrm{co} \bigcup_{i\in I} \mathrm{epi}\, g_i^*, \quad (\text{resp.}, \quad \mathrm{epi}\, \sigma_S \subseteq \mathrm{cone} \bigcup_{i\in I} \mathrm{epi}\, g_i^*.)$$

Results in the following proposition are known: for (i) see [35] and for (ii) see [16, 23, 30]. Recall that we have assumed that $\sup_{i\in I} g_i$ is proper.

PROPOSITION 4.1. *Suppose in addition that each g_i is lower semicontinuous. Then the following assertions regarding epigraphs hold:*

(i)

$$\mathrm{epi} \left(\sup_{i\in I} g_i\right)^* = \overline{\mathrm{co} \bigcup_{i\in I} \mathrm{epi}\, g_i^*}^{w^*}. \tag{4.3}$$

(ii)

$$\mathrm{epi}\, \sigma_S = \mathrm{epi}\, \delta_S^* = \overline{\mathrm{cone} \bigcup_{i\in I} \mathrm{epi}\, g_i^*}^{w^*} \quad \textit{if } S \textit{ is nonempty.} \tag{4.4}$$

COROLLARY 4.1. *Let $\{g_i : i \in I\}$ be as in the preceding proposition. Then the following assertions are valid:*

(i) *$\{g_i : i \in I\}$ has the convex EHP if and only if*

$$\mathrm{co} \bigcup_{i\in I} \mathrm{epi}\, g_i^* \quad \textit{is } w^*\textit{-closed;}$$

(ii) $\{g_i : i \in I\}$ *has the conical EHP if and only if*

$$\operatorname{cone} \bigcup_{i \in I} \operatorname{epi} g_i^* \quad \textit{is } w^*\textit{-closed,}$$

provided that $S \neq \emptyset$.

Proof. Since $G = \sup_{i \in I} g_i$ is proper, (4.3) holds. Thus (i) is seen to hold. Similarly, (ii) holds by (4.4), provided that $S \neq \emptyset$. □

Remark 4.2. In [16, Definition 1] and [17, Definition 3.1] (under the assumption that each g_i is lower semicontinuous), the system $\{\delta_C;\ g_i,\ i \in I\}$ is said to be FM if

$$\operatorname{epi} \sigma_C + \operatorname{cone} \bigcup_{i \in I} \operatorname{epi} g_i^* \quad \text{is } w^*\text{-closed.}$$

Letting $i_0 \notin I$ and writing $g_{i_0} := \delta_C$, one sees that $\{\delta_C; g_i,\ i \in I\}$ being FM is equivalent to $\{g_i,\ i \in I \cup \{i_0\}\}$ having conical EHP.

The following example shows that the lower semicontinuity assumption for $\{g_i : i \in I\}$ cannot be dropped in Proposition 4.1. In other words, Corollary 4.1 fails without a lower semicontinuity assumption on $\{g_i : i \in I\}$.

Example 4.1. Consider the real Hilbert space l^2 of square-summable series, and let Ω_+ be the convex subset defined by

$$\Omega_+ := \{x \in l^2 : x_i \geq 0\ \forall i \in \mathbb{N},\ x_i \neq 0 \text{ for at most finitely many } i\},$$

where x_i denotes the ith coordinate of x. Let $I = \{t \in \mathbb{R} : t > 0\}$, and define a family $\{g_t : t \in I\}$ of proper convex functions by

$$g_t(x) := \begin{cases} -t \sum_{i=1}^{\infty} i x_i & \text{if } x \in \Omega_+, \\ +\infty & \text{otherwise,} \end{cases} \quad \text{for each } t \in I.$$

Note in particular that $g_t(\cdot) \leq 0$ on $\operatorname{dom} g_t$, $\operatorname{dom} g_t = \Omega_+$, and $\{x : g_t(x) \leq 0\} = \Omega_+$ for each $t \in I$. Thus $S := \bigcap_{t \in I} \{x : g_t(x) \leq 0\} = \Omega_+$.

Let $y := (1, \frac{1}{2}, \dots, \frac{1}{n}, \dots)$ and $y_n := (1, \frac{1}{2}, \dots, \frac{1}{n}, 0, \dots)$ for each natural number n. Then $y \in l^2 \backslash \Omega_+$ and $y_n \in \Omega_+$ for each n. Furthermore, one has that $y_n \to y$ and

$$\lim g_t(y_n) = \lim_{n \to \infty} -nt = -\infty < g_t(y) = +\infty \quad \text{for each } t \in I$$

(so each g_t is not lower semicontinuous); consequently, $\overline{g_t}(y) = -\infty$, where $\overline{g_t}$ denotes the closure of the function g_t (cf. [40, p. 62]). Since $g_t^* = \overline{g_t}^*$ by [40, Theorem 2.3.1(iv)], we see that

$$g_t^*(x^*) = \overline{g_t}^*(x^*) \geq \langle x^*, y \rangle - \overline{g}_t(y) = +\infty \quad \text{for each } x^* \in l^2 \text{ and } t \in I.$$

Thus

$$\operatorname{epi} g_t^* = \emptyset \quad \text{for each } t \in I.$$

On the other hand, $(\sup_{t \in I} g_t)^* = \sigma_{\Omega_+}$, which is proper since $\Omega_+ \neq \emptyset$. Hence the lower semicontinuity assumption in Proposition 4.1 cannot be dropped.

PROPOSITION 4.2. *The family* $\{g_i, \delta_{\operatorname{dom} g_i} : i \in I\}$ *has the conical EHP if and only if the family* $\{tg_i, \delta_{\operatorname{dom} g_i} : i \in I, t > 0\}$ *has the convex EHP.*

Proof. By definition, the family $\{g_i, \delta_{\operatorname{dom} g_i} : i \in I\}$ has the conical EHP if and only if

$$\operatorname{epi} \sigma_S = \operatorname{cone} \bigcup_{i\in I} (\operatorname{epi} g_i^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i}), \tag{4.5}$$

while the family $\{tg_i, \delta_{\operatorname{dom} g_i} : i \in I, t > 0\}$ has the convex EHP if and only if

$$\operatorname{epi} \sigma_S = \operatorname{co} \bigcup_{i\in I} \left[\bigcup_{t>0} \operatorname{epi} (tg_i)^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i} \right], \tag{4.6}$$

thanks to the easily checked equality $\delta_S = \sup_{t>0, i\in I} tg_i$. It suffices to prove that the sets on the right-hand side of (4.5) and of (4.6) are equal. To do this, recall from [40, Theorem 2.3.1(v)] that $(tG)^*(x^*) = tG^*(\frac{x^*}{t})$ for each $t > 0$ and $x^* \in X^*$. It follows that

$$\operatorname{epi} (tg_i)^* = t \operatorname{epi} g_i^* \quad \text{for each } i \in I \text{ and } t > 0.$$

Since $\operatorname{epi} \sigma_{\operatorname{dom} g_i}$ is a cone, it follows that

$$\begin{aligned}
\operatorname{co} \bigcup_{i\in I} \left[\bigcup_{t>0} \operatorname{epi} (tg_i)^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i} \right] &= \operatorname{co} \bigcup_{i\in I} \left[\bigcup_{t>0} t \operatorname{epi} g_i^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i} \right] \\
&= \operatorname{co} \bigcup_{i\in I} \bigcup_{t>0} t (\operatorname{epi} g_i^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i}) \\
&= \operatorname{co} \bigcup_{i\in I} \bigcup_{t\geq 0} t (\operatorname{epi} g_i^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i}) \\
&= \operatorname{cone} \bigcup_{i\in I} (\operatorname{epi} g_i^* \cup \operatorname{epi} \sigma_{\operatorname{dom} g_i}),
\end{aligned}$$

where the third equality holds because $(0, 0) \in \operatorname{epi} \sigma_{\operatorname{dom} g_i}$ for each $i \in I$. This completes the proof. □

Remark 4.3. The first part of the second conclusion of the following theorem was also independently obtained in [16, Corollary 2] for the special case when g_i were assumed to be lower semicontinuous.

THEOREM 4.1. *The following assertions are valid:*

(i) *If the family $\{g_i : i \in I\}$ has the convex EHP, then it has the PLV property. The converse implication also holds if* $\operatorname{dom} G^* \subseteq \operatorname{im} \partial G$.

(ii) *Suppose $S \neq \emptyset$. If the family $\{g_i : i \in I\}$ has the conical EHP, then it satisfies the BCQ. The converse implication also holds if* $\operatorname{dom} \sigma_S \subseteq \operatorname{im} \partial \delta_S$.

Proof. (i) Suppose that the family $\{g_i : i \in I\}$ has the convex EHP. By Remark 3.2(i), it suffices to show that (3.6) holds for each $x \in \operatorname{dom} \partial G$. Take $x^* \in \partial G(x)$. By (2.2), $(x^*, \langle x^*, x\rangle - G(x)) \in \operatorname{epi} G^*$. Now (4.1) implies that $(x^*, \langle x^*, x\rangle - G(x))$ can be represented as

$$(x^*, \langle x^*, x\rangle - G(x)) = \sum_{i\in J} \lambda_i (x_i^*, \alpha_i),$$

for some finite subset $J \subseteq I$, $(x_i^*, \alpha_i) \in \operatorname{epi} g_i^*$, $i \in J$, and $0 < \lambda_i \leq 1$ with $\sum_{i\in J} \lambda_i = 1$. This implies

$$\langle x^*, x\rangle - G(x) = \sum_{i\in J} \lambda_i \alpha_i \geq \sum_{i\in J} \lambda_i g_i^*(x_i^*) \geq \sum_{i\in J} \lambda_i (\langle x_i^*, x\rangle - g_i(x)). \tag{4.7}$$

The equalities hold throughout (4.7) because $\langle x^*, x\rangle = \sum_{i\in J} \lambda_i \langle x_i^*, x\rangle$ and $g_i(x) \leq G(x)$ for each i. As $\lambda_i \neq 0$ for each $i \in J$, it follows that $g_i(x) = G(x)$ and $g_i^*(x_i^*) = \langle x_i^*, x\rangle - g_i(x)$ for each $i \in J$. Thus $J \subseteq \tilde{I}(x)$ and $x_i^* \in \partial\, g_i(x)$ for $i \in J$, thanks to (2.1). Hence

$$x^* = \sum_{i\in \tilde{I}(x)} \lambda_i x_i^* \in \operatorname{co} \bigcup_{i\in \tilde{I}(x)} \partial\, g_i(x);$$

i.e., the family $\{g_i : i \in I\}$ has the PLV property. This proves the first part of (i).

Now we assume $\operatorname{dom} G^* \subseteq \operatorname{im} \partial\, G$ and prove the converse implication. In view of Remark 4.1, we need to show only that

$$\operatorname{epi} G^* \subseteq \operatorname{co} \bigcup_{i\in I} \operatorname{epi} g_i^*. \tag{4.8}$$

Take $(y^*, \alpha) \in \operatorname{epi} G^*$. Then $y^* \in \operatorname{dom} G^*$, and by assumption there exists $x \in X$ such that $y^* \in \partial\, G(x)$. Now (3.1) implies that y^* can be represented as

$$y^* = \sum_{i\in J} \lambda_i y_i^*$$

for some finite subset $J \subseteq \tilde{I}(x)$, $y_i^* \in \partial\, g_i(x)$ for each $i \in J$, and $0 < \lambda_i \leq 1$ with $\sum_{i\in J} \lambda_i = 1$. Note that, for each $i \in J$, $\langle y_i^*, x\rangle - G(x) = g_i^*(y_i^*)$ because $y_i^* \in \partial\, g_i(x)$ and $G(x) = g_i(x)$. Since

$$\alpha \geq \langle y^*, x\rangle - G(x) = \sum_{i\in J} \lambda_i (\langle y_i^*, x\rangle - g_i(x)),$$

there exists a set $\{\alpha_i : i \in J\}$ of real numbers such that

$$\alpha = \sum_{i\in J} \lambda_i \alpha_i \quad \text{and} \quad g_i^*(y_i^*) = \langle y_i^*, x\rangle - g_i(x) \leq \alpha_i \quad \text{for each } j \in J.$$

This implies that $(y_i^*, \alpha_i) \in \operatorname{epi} g_i^*$ for each i and thus $(y^*, \alpha) \in \operatorname{co} \bigcup_{i\in I} \operatorname{epi} g_i^*$. Hence (4.8) is proved.

(ii) Suppose that the family has the conical EHP. We wish to show that it satisfies the BCQ, that is, to show that (3.8) holds for each $x \in S \backslash \operatorname{int} S$ (see Remark 3.2(iii)). Take $x \in S \backslash \operatorname{int} S$ and $x^* \in N_S(x)$. Since the set on the right-hand side of (3.8) contains the origin, we assume without loss of generality that $x^* \neq 0$. By (2.4), $(x^*, \langle x^*, x\rangle) \in \operatorname{epi} \sigma_S$. Now (4.2) implies that $(x^*, \langle x^*, x\rangle)$ can be represented as

$$(x^*, \langle x^*, x\rangle) = \sum_{i\in J} \lambda_i (x_i^*, \alpha_i),$$

for some finite subset $J \subseteq I$, $(x_i^*, \alpha_i) \in \operatorname{epi} g_i^*$, $\lambda_i > 0$, $i \in J$. Then we have

$$\langle x^*, x\rangle = \sum_{i\in J} \lambda_i \alpha_i \geq \sum_{i\in J} \lambda_i g_i^*(x_i^*) \geq \sum_{i\in J} \lambda_i (\langle x_i^*, x\rangle - g_i(x)). \tag{4.9}$$

Since $\langle x^*, x\rangle = \sum_{i\in J} \lambda_i \langle x_i^*, x\rangle$ and $g_i(x) \leq 0$ for each $i \in J$, the equalities in (4.9) hold throughout. Since $\lambda_i \neq 0$ for each $i \in J$, we obtain that for each $i \in J$

$$g_i(x) = 0 \tag{4.10}$$

and

$$g_i^*(x_i^*) = \langle x_i^*, x\rangle. \tag{4.11}$$

It follows from (4.10) that $J \subseteq I(x)$. Also, summing up (4.10) and (4.11), we obtain for each $i \in J$ that

$$g_i^*(x_i^*) + g_i(x) = \langle x_i^*, x\rangle,$$

which, by (2.1), is equivalent to $x_i^* \in \partial g_i(x)$. Thus we have

$$x^* = \sum_{i\in J} \lambda_i x_i^* \in \operatorname{cone} \bigcup_{i\in I(x)} \partial\, g_i(x).$$

Therefore the family $\{g_i : i \in I\}$ satisfies the BCQ.

We now turn to the converse implication. Assume $\operatorname{dom}\sigma_S \subseteq \operatorname{im}\partial\,\delta_S$. In view of Remark 4.1, we need to show only that

$$\operatorname{epi}\sigma_S \subseteq \operatorname{cone}\bigcup_{i\in I} \operatorname{epi} g_i^*. \tag{4.12}$$

Take $(y^*, \alpha) \in \operatorname{epi}\sigma_S$. Since $(0,0)$ clearly belongs to the right-hand side of (4.12), we assume without loss of generality that $(y^*, \alpha) \neq (0,0)$. Now, since $y^* \in \operatorname{dom}\sigma_S \subseteq \operatorname{im}\partial\,\delta_S$, there exists $x_0 \in S$ such that $y^* \in \partial\,\delta_S(x_0) = N_S(x_0)$ by (2.3). The definition of BCQ implies that y^* can be expressed as

$$y^* = \sum_{i\in J} \lambda_i y_i^*$$

for some finite subset $J \subseteq I(x_0)$, $y_i^* \in \partial\, g_i(x_0)$, and $\lambda_i \geq 0$ for each $i \in J$. Note that, for each $i \in J$, $\langle y_i^*, x_0\rangle = g_i^*(y_i^*)$ because $y_i^* \in \partial\, g_i(x_0)$ and $g_i(x_0) = G(x_0) = 0$. On the other hand, since $\alpha \geq \langle y^*, x_0\rangle = \sum_{i\in J} \lambda_i \langle y_i^*, x_0\rangle$, there exists a set $\{\alpha_i : i \in J\}$ of real numbers such that

$$\alpha = \sum_{i\in J} \lambda_i \alpha_i \quad \text{and} \quad g_i^*(y_i^*) = \langle y_i^*, x_0\rangle \leq \alpha_i \quad \text{for each } i \in J.$$

This implies that $(y_i^*, \alpha_i) \in \operatorname{epi} g_i^*$ for each i and thus $(y^*, \alpha) \in \operatorname{cone}\bigcup_{i\in I} \operatorname{epi} g_i^*$. Hence (4.12) is proved. □

Recall from [35] that a family of convex sets $\{C_i : i \in I\}$ in X with nonempty intersection satisfies the sum of epigraphs constraint qualification (SECQ) if

$$\operatorname{epi}\sigma_{\bigcap_{i\in I} C_i} = \sum_{i\in I} \operatorname{epi}\sigma_{C_i}. \tag{4.13}$$

The following proposition is on the relationships between the strong CHIP, the SECQ for a family of convex sets, and the conical EHP for the family consisting of the corresponding indicator functions.

PROPOSITION 4.3. *Let $\{C_i : i \in I\}$ be a family of convex sets in X with nonempty intersection. Then the following assertions are valid:*

(i) *The family $\{C_i : i \in I\}$ has the strong CHIP if and only if the family of functions $\{\delta_{C_i} : i \in I\}$ has the BCQ.*

(ii) *The family $\{C_i : i \in I\}$ satisfies the SECQ if and only if the family of functions $\{\delta_{C_i} : i \in I\}$ has the conical EHP.*

Proof. Consider the family of functions $\{\delta_{C_i} : i \in I\}$, i.e., $g_i := \delta_{C_i}$ for each $i \in I$. Then,

$$S := \left\{x : \sup_{i\in I} \delta_{C_i}(x) \le 0\right\} = \{x : \delta_{\bigcap_{i\in I} C_i}(x) \le 0\} = \bigcap_{i\in I} C_i \neq \emptyset.$$

Also, $G(x) := \sup_{i\in I} \delta_{C_i}(x) = \delta_{\bigcap_{i\in I} C_i}(x)$ and $G(x) = 0$ for each $x \in S$. Moreover, since $\delta_{C_i}(x) = 0$ for each $x \in S$ and each $i \in I$, it follows that $I(x) = I$ for each $x \in S$.

(i) For each $x \in S$, we have from (2.3) that

$$\operatorname{cone} \bigcup_{i\in I(x)} \partial\, \delta_{C_i}(x) = \operatorname{cone} \bigcup_{i\in I} \partial\, \delta_{C_i}(x) = \operatorname{cone} \bigcup_{i\in I} N_{C_i}(x)$$

$$= \sum_{i\in I} \operatorname{cone} N_{C_i}(x) = \sum_{i\in I} N_{C_i}(x).$$

Therefore, when $\{\delta_{C_i} : i \in I\}$ replaces $\{g_i : i \in I\}$, we see that (3.2) and (3.10) are equivalent, and so (i) is proved.

(ii) Note that each $\operatorname{epi} \sigma_{C_i}$ is a cone, and so

$$\operatorname{cone} \bigcup_{i\in I} \operatorname{epi} \sigma_{C_i} = \sum_{i\in I} \operatorname{cone} (\operatorname{epi} \sigma_{C_i}) = \sum_{i\in I} \operatorname{epi} \sigma_{C_i}.$$

Therefore, when $\{\delta_{C_i} : i \in I\}$ replaces $\{g_i : i \in I\}$, we see that (4.2) and (4.13) are equivalent, and so (ii) is proved. □

COROLLARY 4.2 (see [35]). *Let $\{C_i : i \in I\}$ be a family of convex sets in X with nonempty intersection. If the family satisfies the SECQ, then it has the strong CHIP. The converse implication also holds if $\operatorname{dom} \sigma_S \subseteq \operatorname{im} \partial\, \delta_S$, where $S = \bigcap_{i\in I} C_i$.*

Proof. The corollary follows from Proposition 4.3 and Theorem 4.1(ii) (applied to the family of functions $\{\delta_{C_i} : i \in I\}$ in place of $\{g_i : i \in I\}$). □

Adopting a definition given in [36, Definition 5.3] originally in a more restrictive case, we say that a linear inequality

$$\langle a^*, x\rangle \le b \tag{4.14}$$

(where $a^* \in X^*$ and $b \in \mathbb{R}$) is a consequence relation of (1.1) if every $x \in S$ satisfies (4.14). Moreover, the system (1.1) is said to be a convex FM system if every linear consequence relation of the system (1.1) is also a consequence relation of some finite subsystem of it. The following result was independently obtained in [16, Proposition 1] under the additional assumption that each g_i is lower semicontinuous.

PROPOSITION 4.4. *Suppose that $S \neq \emptyset$ and that the family $\{g_i : i \in I\}$ has the conical EHP. Then the system* (1.1) *is a convex FM system.*

Proof. Let $a^* \in X^*$ and $b \in \mathbb{R}$ be such that $\langle a^*, x\rangle \le b$ for each $x \in S$. This means that

$$(a^*, b) \in \operatorname{epi} \sigma_S,$$

thanks to (2.5). Since the family $\{g_i : i \in I\}$ has the conical EHP, it follows from (4.2) that

$$(a^*, b) \in \operatorname{cone} \bigcup_{i\in I} \operatorname{epi} g_i^*.$$

Thus, there exists a finite subset $J \subseteq I$ such that

$$(a^*, b) \in \operatorname{cone} \bigcup_{i\in J} \operatorname{epi} g_i^* \subseteq \operatorname{epi} \sigma_{S_J},$$

where $S_J := \{x \in X : g_i(x) \le 0 \ \forall i \in J\}$, and the inclusion follows from Remark 4.1. Again by (2.5), one has $\langle a^*, x\rangle \le b$ for each $x \in S_J$. This completes the proof. □

The following corollary was proved by Li, Nahak, and Singer in [36, Proposition 5.4] under the additional assumptions that $X = \mathbb{R}^n$, S is compact, and each g_i is continuous. (Recall that if S is a weakly compact convex set and X is a normed linear space, then $\operatorname{dom} \sigma_S \subseteq \operatorname{im} \partial\delta_S$; see [35, Proposition 3.1].) A similar result was obtained in [16, Proposition 3], in which they assumed the family of lower semicontinuous functions to have BCQ at a point z and deduced that every linear consequence relation (4.14) of the system (1.1) with $b = \langle a^* z\rangle$ is a consequence relation of some finite subsystem of it.

COROLLARY 4.3. *Suppose that $S \ne \emptyset$ and that the family $\{g_i : i \in I\}$ satisfies the BCQ. Suppose further that* $\operatorname{dom} \sigma_S \subseteq \operatorname{im} \partial\, \delta_S$. *Then* (1.1) *is a convex FM system.*

Proof. By Theorem 4.1(ii), the assumptions imply that the family $\{g_i : i \in I\}$ has the conical EHP. Hence the conclusion follows from Proposition 4.4. □

5. Optimality conditions. Let X be a locally convex Hausdorff topological vector space as before. We use $\Gamma(X)$ to denote the class of all proper convex lower semicontinuous functions on X as in [40]. For a subset of X, we define

$$\mathcal{F}_A := \{f \in \Gamma(X) : \operatorname{dom} f \cap A \ne \emptyset,\ \operatorname{epi} \sigma_A + \operatorname{epi} f^* \text{ is } w^*\text{-closed}\}.$$

Since $\operatorname{epi} \sigma_A = \operatorname{epi} \sigma_{\overline{A}}$ for any convex set A,

$$f \in \mathcal{F}_A \Leftrightarrow f \in \mathcal{F}_{\overline{A}}. \tag{5.1}$$

It is known from [4, Theorem 3.2] that if $f \in \mathcal{F}_A$ and closed convex set A are such that $\operatorname{epi} \sigma_A + \operatorname{epi} f^*$ is w^*-closed, then the subdifferential sum formula holds:

$$f \in \mathcal{F}_A \Rightarrow \partial\,(f + \delta_A)(x) = \partial\, f(x) + \partial\, \delta_A(x) \quad \text{for each } x \in A \cap \operatorname{dom} f.$$

Thus, (5.1) entails that

$$f \in \mathcal{F}_A \Rightarrow \partial\,(f + \delta_{\overline{A}})(x) = \partial\, f(x) + \partial\, \delta_{\overline{A}}(x) \quad \text{for each } x \in \overline{A} \cap \operatorname{dom} f. \tag{5.2}$$

As in [40], let $\Lambda(X)$ denote the class of all proper convex functions on X. Let $f \in \Lambda(X)$, and recall that the meanings of $\{g_i : i \in I\}, G,\ X,\ S$, and I have been specified in section 2 and that we always assume that G is proper. We consider the following minimization problem:

$$\begin{aligned} &\text{Minimize} && f(x), \\ &\text{s.t.} && g_i(x) \le 0,\ i \in I. \end{aligned} \tag{5.3}$$

Clearly, $\overline{x} \in S$ is a minimizer of (5.3) if and only if it is a minimizer of (5.4) defined as follows:

$$\begin{array}{ll} \text{Minimize} & f(x), \\ \text{s.t.} & x \in S. \end{array} \tag{5.4}$$

The following theorem gives a characterization for a feasible point $\overline{x}$ to be a minimizer. Note in particular that it improves a result in [16, Theorem 4] as far as the lower semicontinuity of the functions g_i is relaxed. See also [6] for other related results. For $h \in \Lambda(X)$, let $\operatorname{cont} h$ denote the set of all points at each of which h is continuous, that is,

$$\operatorname{cont} h := \{x \in X : \ h \text{ is continuous at } x\}.$$

THEOREM 5.1. *Let $\overline{x}$ be a feasible point of* (5.3). *Then the following statements are equivalent:*

(i) *The family $\{g_i : i \in I\}$ satisfies the BCQ at $\overline{x}$.*

(ii) *For each $f \in \mathcal{F}_S$, $\overline{x}$ is a minimizer of* (5.4) *with $\overline{S}$ in place of S if and only if there exist a finite subset $J \subseteq I(\overline{x})$ and $\lambda_i \geq 0$, $i \in J$, such that*

$$0 \in \partial f(\overline{x}) + \sum_{i \in J} \lambda_i \partial g_i(\overline{x}). \tag{5.5}$$

(iii) *For any $f \in \Lambda(X)$ such that $\operatorname{cont} f \cap S \neq \emptyset$, $\overline{x}$ is a minimizer of* (5.4) *if and only if there exist a finite subset $J \subseteq I(\overline{x})$ and $\lambda_i \geq 0$, $i \in J$, such that* (5.5) *holds.*

(iv) *For each continuous linear functional f, $\overline{x}$ is a minimizer of* (5.4) *if and only if there exist a finite subset $J \subseteq I(\overline{x})$ and $\lambda_i \geq 0$, $i \in J$, such that* (5.5) *holds.*

Proof. Recall a well-known result in convex analysis (cf. [40, Theorem 2.5.7]) that if $f \in \Lambda(X)$ and A is a convex subset, then

$$\overline{x} \text{ minimizes } f \text{ on } A \Longleftrightarrow \overline{x} \text{ minimizes } (f + \delta_A) \text{ on } X \Longleftrightarrow 0 \in \partial(f + \delta_A)(\overline{x}). \tag{5.6}$$

We now first prove (i)⇒(ii). Fix $f \in \mathcal{F}_S$. By (5.2), we have

$$\partial\,(f + \delta_{\overline{S}})(x) = \partial\, f(x) + \partial\, \delta_{\overline{S}}(x) \quad \text{for each } x \in \overline{S} \cap \operatorname{dom} f. \tag{5.7}$$

By (2.3), we know further that

$$\partial\, \delta_{\overline{S}}(x) = N_{\overline{S}}(x) = N_S(x) \quad \text{for each } x \in S. \tag{5.8}$$

Thus by (5.6), (5.7), and (5.8), the assumption (i) implies the following equivalences:

$$\overline{x} \text{ minimizes } f \text{ on } \overline{S} \Longleftrightarrow 0 \in \partial\, f(\overline{x}) + N_S(\overline{x}) \Longleftrightarrow 0 \in \partial\, f(\overline{x}) + \operatorname{cone} \bigcup_{i \in I(\overline{x})} \partial\, g_i(\overline{x}).$$

The implication (i)⇒(ii) is now clear.

Next, we prove (i)⇒(iii). Let $f \in \Lambda(X)$ be such that $\operatorname{cont} f \cap S \neq \emptyset$. Then [40, Theorem 2.8.7(iii)] states that

$$\partial\,(f + \delta_S)(x) = \partial\, f(x) + \partial\, \delta_S(x) \quad \text{for each } x \in S \cap \operatorname{dom} f. \tag{5.9}$$

Thus the implication (i)⇒(iii) is seen to hold by (5.6) and (5.9).

To show the implication (ii)⇒(iv), let f be a continuous linear functional on X. Then $\inf_{x\in S} f(x) = \inf_{x\in\overline{S}} f(x)$ and $f \in \mathcal{F}_{\overline{S}}$ by [15, Remark 5.6]. The latter condition is equivalent to $f \in \mathcal{F}_S$, thanks to (5.1). Since $\overline{x} \in S$, the implication (ii)⇒(iv) is clear.

The implication (iii)⇒(iv) is immediate.

Finally, we turn to the proof of (iv)⇒(i). We need to show that (3.8) holds for $x = \overline{x}$. Let $y^* \in N_S(\overline{x})$. Then $\overline{x}$ is a minimizer of the following optimization problem:

$$\begin{aligned} &\text{Minimize} && -\langle y^*, x\rangle,\\ &\text{s.t.} && x \in S. \end{aligned}$$

By (iv), there exist a finite subset $J \subseteq I(\overline{x})$ and $\lambda_i \geq 0$, $i \in J$, such that

$$0 \in -y^* + \sum_{i\in J} \lambda_i \partial\, g_i(\overline{x}).$$

Thus

$$y^* \in \sum_{i\in J} \lambda_i \partial\, g_i(\overline{x}) \subseteq \operatorname{cone} \bigcup_{i\in I(\overline{x})} \partial\, g_i(\overline{x}).$$

Therefore $\overline{x}$ satisfies (3.8), as required. This completes the proof. □

Let A be a convex set in X and $a \in A$. In the literature there are several unequivalent conditions on "the relative interior" of A such as

$$a \in U \cap \overline{\operatorname{aff} A} \subseteq A \tag{5.10}$$

and

$$a \in U \cap \operatorname{aff} A \subseteq A, \tag{5.11}$$

where U is a neighborhood of a. For example, (5.10) was considered in [3, 20] and (5.11) in [2, 40]. As (5.11) is not needed for our present study, we will follow the terminology of [3, 20] to say that a is in the relative interior of A and denoted by $a \in \operatorname{ri} A$ if there exists a neighborhood of a such that (5.10) holds.

Remark 5.1. If $0 \in \operatorname{ri} A$ and $x_0 \in \overline{A}$, then $tx_0 \in \operatorname{ri} A$ for each $t \in [0, 1)$. To see this, consider the Minkowski functional $p_A(x) := \inf\{\lambda :\ \lambda^{-1}x \in A\}$ for each $x \in \overline{\operatorname{span} A}$. By considering A and $\overline{A}$ as subsets of $\overline{\operatorname{span} A}$, we have $\operatorname{ri} A = \{x \in \overline{\operatorname{span} A} :\ p_A(x) < 1\}$ and $\overline{A} = \{x \in \overline{\operatorname{span} A} :\ p_A(x) \leq 1\}$ (cf. [40, Proposition 1.1.1(ii)]). Since $p_A(x_0) \leq 1$, we have $p_A(tx_0) = tp_A(x_0) < 1$ for each $t \in [0, 1)$. Thus $tx_0 \in \operatorname{ri} A$, as required.

For $f \in \Lambda(X)$, define

$$\operatorname{cont}_A f = \{x \in \operatorname{dom} f \cap \overline{\operatorname{aff} A} :\ \ f|_{\overline{\operatorname{aff} A}} \text{ is continuous at } x\}.$$

Remark 5.2. If $0 \in \operatorname{cont}_A f$ and $x_0 \in \operatorname{dom} f \cap \overline{\operatorname{span} A}$, then $tx_0 \in \operatorname{cont}_A f$ for all $t \in [0, 1)$. To see this, consider $\operatorname{dom} f \cap \overline{\operatorname{span} A}$ as a subset of $\overline{\operatorname{span} A}$; in particular, $0 \in \operatorname{cont}_A f \subseteq \operatorname{int}(\operatorname{dom} f \cap \overline{\operatorname{span}} A)$. Since $x_0 \in \operatorname{dom} f \cap \overline{\operatorname{span} A}$, it follows that $tx_0 \in \operatorname{int}(\operatorname{dom} f \cap \overline{\operatorname{span}} A)$ for all $t \in [0, 1)$. Consequently, by the convexity of f, $tx_0 \in \operatorname{cont}_A f$ for all $t \in [0, 1)$ thanks to [40, Theorem 2.2.9] because $f|_{\overline{\operatorname{span} A}}$ is continuous at 0.

LEMMA 5.1. *Consider the problem* (5.4)*, and let* $f \in \Lambda(X)$*. Suppose that*

$$(\operatorname{dom} f \cap \operatorname{ri} S) \cup (\overline{S} \cap \operatorname{cont}_S f) \neq \emptyset. \tag{5.12}$$

Then

$$\inf_{x\in S} f(x) = \inf_{x\in \overline{S}} f(x). \tag{5.13}$$

Proof. By (5.12), we assume without loss of generality that

$$0 \in (\operatorname{dom} f \cap \operatorname{ri} S) \cup (\overline{S} \cap \operatorname{cont}_S f).$$

Let $\lambda > \inf_{x\in\overline{S}} f(x)$ and take $x_0 \in \overline{S}$ such that $\lambda > f(x_0)$. To show (5.13) it suffices to show that $\lambda > \inf_{x\in S} f(x)$. By the convexity we have

$$f(tx_0) \le tf(x_0) + (1-t)f(0) \quad \text{for each } t \in [0,1]. \tag{5.14}$$

Letting $t \uparrow 1$ in (5.14), we obtain

$$\limsup_{t\to 1^-} f(tx_0) \le \lim_{t\to 1^-} [tf(x_0) + (1-t)f(0)] = f(x_0) < \lambda. \tag{5.15}$$

This and Remark 5.1 imply that $\inf_{x\in S} f(x) \le f(x_0)$ if $0 \in \operatorname{ri} S$ (so $tx_0 \in \operatorname{ri} S$ for each $t \in [0,1)$). It remains to consider the case when $0 \in \overline{S} \cap \operatorname{cont}_S f$. But then Remark 5.2 entails that tx_0 is a continuity point of $f|_{\overline{\operatorname{span} S}}$ if $t \in [0,1)$. Noting $tx_0 \in \overline{S}$, it follows from (5.15) that $f(x_t) < \lambda$ for $x_t \in S$ close enough to tx_0, provided that $t < 1$ is sufficiently near to 1. Therefore $\inf_{x\in\overline{S}} f(x) < \lambda$ in any case. This completes the proof. □

Remark 5.3. For two convex sets A, C in a Banach space X, recall from [34] that an $a \in A$ belongs to $\operatorname{rint}_{\overline{\operatorname{aff} C}} A$ if $a \in B(a,\epsilon) \cap \overline{\operatorname{aff} C} \subseteq A$ for some $\epsilon > 0$. Note that if X is a Banach space and $f \in \Gamma(X)$, then

$$\operatorname{rint}_{\overline{\operatorname{aff} S}} \operatorname{dom} f \subseteq \operatorname{cont}_S f. \tag{5.16}$$

To see this we assume without loss of generality that $0 \in S$. Then $\overline{\operatorname{aff} S} = \overline{\operatorname{span} S}$ is a Banach space. Since $f|_{\overline{\operatorname{aff} S}} \in \Gamma(\overline{\operatorname{aff} S})$, (5.16) follows from [40, Theorem 2.2.20].

COROLLARY 5.1. *Under the assumption of Theorem* 5.1*, for any* $\overline{x} \in S$*, the following statements are equivalent:*

(i) *The family* $\{g_i : i \in I\}$ *satisfies the BCQ at* $\overline{x}$*.*

(ii′) *For each* $f \in \mathcal{F}_S$ *satisfying* (5.12)*,* $\overline{x}$ *is a minimizer of* (5.4) *if and only if there exist a finite subset* $J \subseteq I(\overline{x})$ *and* $\lambda_i \ge 0$*,* $i \in J$*, such that* (5.5) *holds.*

Proof. Suppose that (i) holds. Then Theorem 5.1(ii) holds. Let $f \in \mathcal{F}_S$ satisfy (5.12). Then $\inf_{x\in S} f(x) = \inf_{x\in\overline{S}} f(x)$ by Lemma 5.1. Since $\overline{x} \in S$, applying Theorem 5.1(ii) to this f, (ii′) is seen to hold. Conversely, suppose that (ii′) holds. Then part (iv) (and so part (i)) of Theorem 5.1 holds because any continuous linear functional f on X belongs to $\mathcal{F}_S$ (by [15, Remark 5.6] and (5.1)) and satisfies (5.12) (since $\operatorname{dom} f = X$). The proof is complete. □

The following result was proved in [15, Theorem 5.5] under the additional assumption that each g_i is continuous, which was recently extended in [16, Theorem 3] to the setting that some g_i are allowed to be merely lower semicontinuous.

COROLLARY 5.2. *Suppose that* $f \in \mathcal{F}_S$ *and that the family* $\{g_i : i \in I\}$ *has the conical EHP. Assume that either* S *is closed or the condition* (5.12) *is satisfied. Let* $\overline{x} \in S$*. Then* $\overline{x}$ *is a minimizer of* (5.4) *if and only if there exist a finite subset* $J \subseteq I(\overline{x})$ *and* $\lambda_i \ge 0$*,* $i \in J$*, such that*

$$0 \in \partial f(\overline{x}) + \sum_{i\in J} \lambda_i \partial g_i(\overline{x}).$$

Proof. Since the family $\{g_i : i \in I\}$ has the conical EHP, it has the BCQ at $\overline{x}$ by Theorem 4.1(ii). Moreover, (5.13) holds by the assumptions and Lemma 5.1. Since $\overline{x} \in S$ it follows that $\overline{x}$ is a minimizer of (5.4) if and only if $\overline{x}$ is a minimizer of (5.4) but with $\overline{S}$ in place of S. Thus the corollary follows from the implication (i)⇒(ii) in Theorem 5.1. □

The following example shows that (5.13) and the related corollaries may fail if the assumption (5.12) is dropped.

Example 5.1. Define $S := \{(x,y) \in \mathbb{R}^2 : x \geq 0\} \backslash \{(0,y) \in \mathbb{R}^2 : y < 1\}$ and

$$f(x,y) := \begin{cases} \frac{y^2}{2} & \text{if } x = 0, \\ +\infty & \text{otherwise.} \end{cases}$$

Then f is proper convex lower semicontinuous, S is convex, and $\overline{S} = \{(x,y) \in \mathbb{R}^2 : x \geq 0\}$. Note that in this case $\operatorname{dom} f = \{(0,y) \in \mathbb{R}^2 : y \in \mathbb{R}\}$, which is disjoint from the set $\operatorname{ri} S = \operatorname{int} S = \{(x,y) \in \mathbb{R}^2 : x > 0\}$. It is easy to see that $\inf_{(x,y)\in S} f(x,y) = f(0,1) = \frac{1}{2}$ but $\inf_{(x,y)\in \overline{S}} f(x,y) = f(0,0) = 0$. Thus (5.13) fails.

Next we wish to show that $f \in \mathcal{F}_S$. To do this, note first that for each $(x,y) \in \mathbb{R}^2$

$$f^*(x,y) = \sup\{\langle (u,v),(x,y)\rangle - f(u,v) : (u,v) \in \operatorname{dom} f\} = \frac{y^2}{2},$$

and that

$$\sigma_S(x,y) = \sup_{u\geq 0, v\in\mathbb{R}} \langle (u,v),(x,y)\rangle = \begin{cases} 0 & \text{if } x \leq 0 \text{ and } y = 0, \\ +\infty & \text{otherwise.} \end{cases}$$

It is easy to see by the definition that

$$\operatorname{epi} f^* = \left\{(x,y,r) \in \mathbb{R}^3 : \frac{y^2}{2} \leq r\right\} \quad \text{and} \quad \operatorname{epi} \sigma_S = \{(x,0,r) \in \mathbb{R}^3 : x \leq 0,\ r \geq 0\}.$$

Therefore, $\operatorname{epi} f^* + \operatorname{epi} \sigma_S = \operatorname{epi} f^*$. This implies that $\operatorname{epi} f^* + \operatorname{epi} \sigma_S$ is weak*-closed. Since f is proper and $\operatorname{dom} f \cap S \neq \emptyset$, we see that $f \in \mathcal{F}_S$.

Now, note that $(0,1)$ is the minimizer of the following problem:

$$\begin{aligned} &\text{Minimize} && f(x,y), \\ &\text{s.t.} && \delta_S(x,y) \leq 0. \end{aligned}$$

Note also that $\partial f(0,1) = \{(x,1) : x \in \mathbb{R}\}$ and that $N_S(0,1) = \{\lambda(-1,0) : \lambda \geq 0\}$. Hence the optimality condition $(0,0) \in \partial f(0,1) + N_S(0,1)$ fails even though $f \in \mathcal{F}_S$ and the family $\{\delta_S\}$ has the BCQ property.

6. Applications to conic programming. We continue our study of the conic programming problem with notation as explained in Example 2.1. It can be checked in a straightforward manner that the following facts are true. They are known when g is continuous on X; see [24, 30]. Some related results can be founded in [17].

Fact 6.1. $\operatorname{cone} \bigcup_{\lambda\in K^\oplus} \operatorname{epi} (\lambda g)^* = \bigcup_{\lambda\in K^\oplus} \operatorname{epi} (\lambda g)^*$.

Fact 6.2. $\operatorname{cone} \bigcup_{\lambda\in K^\oplus} \partial(\lambda g)(x) = \bigcup_{\lambda\in K^\oplus} \partial(\lambda g)(x)$ for each $x \in X$.

Fact 6.3. $\operatorname{cone} \bigcup_{\substack{\lambda\in K^\oplus \\ \lambda g(x)=0}} \partial(\lambda g)(x) = \bigcup_{\substack{\lambda\in K^\oplus \\ \lambda g(x)=0}} \partial(\lambda g)(x) = Ng(x)_0$ for each $x \in X$,

where $Ng(x)_0$ is defined by

$$Ng(x)_0 := \left\{u^* \in X^* : (u^*, u^*(x)) \in \bigcup_{\lambda\in K^\oplus} \operatorname{epi} (\lambda g)^*\right\}.$$

Generalizing the corresponding notions in [24, 26, 29] to suit our present non-continuous situation, we make the following definitions (it is routine to see that the notions in the following definition coincide with corresponding ones in [24, 26, 29] in the case when $g : X \to Z$ is continuous).

DEFINITION 6.1. *For g, C, K as in Example* 2.1, *we say that*

(i) *the condition* (**C**$*$) *holds if the family* $\{\lambda g : \lambda \in K^{\oplus}\}$ *has the conical EHP;*

(ii) *the closed cone constraint qualification (CCCQ) holds if the family* $\{\delta_C, \lambda g : \lambda \in K^{\oplus}\}$ *has the conical EHP;*

(iii) *the pair* $\{C, g^{-1}(-K)\}$ *has the sharpened strong CHIP at* $x \in C \cap g^{-1}(-K)$ *if* $N_{C\cap g^{-1}(-K)}(x) = N_C(x) + Ng(x)_0$.

The following notion of K-lower semicontinuity was introduced in [37] and extended in [1, 12] for functions $g : X \to Z^{\bullet}$. It was also considered in [5].

DEFINITION 6.2. *For g, K as in Example* 2.1, *the function g is said to be K-lower semicontinuous at $x_0 \in X$ if for each neighborhood V of zero in Z and any $b \in Z$ with $b \leq_K g(x_0)$ there exists a neighborhood U of zero in X such that*

$$g(x_0 + U) \subseteq b + V + K \cup \{\infty\}. \tag{6.1}$$

Clearly, if $g : X \to Z$ is continuous, then g is K-convex lower semicontinuous. Below we give an example of a function that is K-convex lower semicontinuous but not continuous.

Example 6.1. Let $X = l^1$ and $Z = l^1$ respectively under the l^∞-norm $\|\cdot\|_\infty$ and the l^1-norm $\|\cdot\|_1$, and let g denote the identity map from X into Z. Then g has the desired properties (that g is not continuous is well known). To see this, let us fix a nonzero element $c \in X$, and let K denote its kernel in Z, that is, $K := \{z \in Z : \langle c, z\rangle = 0\}$. By a well-known result (cf. [39, p. 24]), the distance to each $z \in Z$ from the closed subspace K satisfies the so-called Ascoli formula,

$$d(z, K) = \frac{|\langle c, z\rangle|}{\|c\|_\infty} \quad \text{for each } z \in Z,$$

and it follows that

$$d(z, K) \leq \alpha\|z\|_\infty \quad \text{for each } z \in Z,$$

where $\alpha := \frac{\|c\|_1}{\|c\|_\infty}$; in particular we have

$$d(g(x), K) \leq \alpha\|g(x)\|_\infty \quad \text{for each } x \in X.$$

This implies that g is K-lower semicontinuous at $x_0 := 0$ (for $\epsilon > 0$ and $V = \{z \in Z : \|z\|_1 < \epsilon\}$, and (6.1) holds with $U = \{x \in X : \|x\|_\infty < \frac{\epsilon}{\alpha}\}$). By the linearity of g, we conclude that g is K-lower semicontinuous on the whole X.

PROPOSITION 6.1. *Let g, K be as in Example* 2.1. *Suppose that g is K-lower semicontinuous and that* $\operatorname{dom} g$ *is closed. Then for each $\lambda \in K^{\oplus}$, λg is lower semicontinuous.*

Proof. Let $\lambda \in K^{\oplus}\backslash\{0\}$, and let $x_0 \in X$. To show the lower semicontinuity of λg at x_0, we assume without loss of generality that $x_0 \in \operatorname{dom} g$ (thanks to the assumption that $\operatorname{dom} g$ is closed). Let $\epsilon > 0$. By the continuity of λ, take a neighborhood V of zero in Z such that $|\lambda(v)| < \epsilon$ for each $v \in V$. By definition of K-lower semicontinuity, there exists a neighborhood U of x_0 in X such that (6.1) holds. Let $u \in x_0 + U$.

By (6.1), there exist $v_1 \in V$ and $k \in K \cup \{\infty\}$ such that $g(u) = g(x_0) + v_1 + k$. For the case when $k \in K$, we have

$$\lambda g(x_0) = \langle \lambda, g(x_0)\rangle \leq \langle \lambda, g(u) - v_1\rangle < \lambda g(u) + \epsilon.$$

For the case when $k = \infty$, one has $g(u) = \infty$, i.e., $u \notin \operatorname{dom} g$. Thus, it follows from definition that $\lambda g(x_0) - \epsilon < \lambda g(u) = \infty$. Therefore, λg is lower semicontinuous at x_0. □

Example 6.2 below shows that the converse of Proposition 6.1 is not true.

Example 6.2. Let $X = L^2[0,1]$ and $Z = L^2[0,1]$ respectively under the $\|\cdot\|_1$-norm and $\|\cdot\|_2$-norm. Let $K = \{0\}$, and let $Z^\bullet := Z \cup \{+\infty\}$ as in Example 2.1. Let $D = \{x \in X : \ \|x\|_2 \leq 1\}$, and let $g(x) = x + \delta_D(x)$. Then g is not continuous on D (as there exists a sequence $\{x_n\}$ in X such that each $\|x_n\|_2 = 1$ but $\|x_n\|_1 = \frac{1}{n}$; for example, let $x_n = n\chi_{[0,1/n^2]}$ be the characteristic function of the interval $[0, 1/n^2]$), and so g is not $\{0\}$-lower semicontinuous.

Let $\lambda \in Z^* = \{0\}^\oplus$. We claim that λg is lower semicontinuous. Let $r \in \mathbb{R}$ and let

$$A_r := \{x \in X : \ \lambda g(x) \leq r\}.$$

It suffices to show that A_r is closed in X. To do this, let $x \in X$ and $\{x_n\}$ be a sequence in A_r such that $\|x_n - x\|_1 \to 0$. By an elementary result in Lebesgue theory (see [38, Proposition 18, p. 95]), there exists a subsequence $\{x_{n_k}\}$ convergent to x almost everywhere. By Fatou's lemma and the fact that $A_r \subseteq D$ (by (2.7)), it follows that

$$\int_0^1 |x|^2 dt \leq \liminf_k \int_0^1 |x_{n_k}|^2 dt \leq 1,$$

and thus $x \in D$. Let $\epsilon > 0$. Since $\lambda \in L^2[0,1]$, there exists a simple function h such that $\|\lambda - h\|_2 < \epsilon$. Noting $\|x - x_n\|_2 \leq 2$ (as $x, x_n \in D$), it follows from the Hölder inequality that

$$\begin{aligned}\lambda g(x) - \lambda g(x_n) = \langle \lambda, x - x_n\rangle &= \langle \lambda - h, x - x_n\rangle + \langle h, x - x_n\rangle \\ &\leq 2\epsilon + \|h\|_\infty \|x - x_n\|_1 \to 2\epsilon.\end{aligned}$$

This implies that

$$\lambda g(x) \leq \liminf_n \lambda g(x_n) + 2\epsilon \leq r + 2\epsilon,$$

and hence that $\lambda g(x) \leq r$ as $\epsilon > 0$ is arbitrary. Therefore $x \in A_r$ and A_r is closed, as we wished to show.

By Fact 6.1, Corollary 4.1, and Proposition 6.1, the following remark is obvious.

Remark 6.1. Let g, C, K be as in Example 2.1. Suppose in addition that g is K-lower semicontinuous and that $\operatorname{dom} g$ is closed. Then the condition (**C***) holds if and only if

$$\textstyle\bigcup_{\lambda \in K^\oplus} \operatorname{epi}(\lambda g)^* \quad \text{is } w^*\text{-closed};$$

more generally, the CCCQ holds if and only if

$$\operatorname{epi}\sigma_C + \textstyle\bigcup_{\lambda \in K^\oplus} \operatorname{epi}(\lambda g)^* \quad \text{is } w^*\text{-closed}.$$

(Thus, conditions (**C***) and CCCQ defined in Definition 6.1 agree with the ones defined in [26, 29] for the continuous case.)

COROLLARY 6.1. *The following equivalence holds for any* $x \in C \cap g^{-1}(-K)$*:*

$$\begin{aligned}&\text{The family } \{\delta_C, \lambda g :\ \lambda \in K^{\oplus}\} \text{ satisfies the BCQ at } x\\ &\quad\Leftrightarrow \{C, g^{-1}(-K)\} \text{ has the sharpened strong CHIP at } x.\end{aligned}$$

Proof. Note first that $\{x : \delta_C(x) \le 0, \lambda g(x) \le 0, \lambda \in K^{\oplus}\} = C \cap g^{-1}(-K)$. Hence the family $\{\delta_C, \lambda g :\ \lambda \in K^{\oplus}\}$ satisfies the BCQ at x if and only if

$$N_{C\cap g^{-1}(-K)}(x) = N_C(x) + \operatorname{cone} \bigcup_{\substack{\lambda\in K^{\oplus}\\ \lambda g(x)=0}} \partial(\lambda g)(x),$$

which is equivalent to saying that $\{C, g^{-1}(-K)\}$ has the sharpened strong CHIP at x, by Fact 6.3. □

The next two corollaries were respectively proved in [24, Propositions 3.3 and 3.4] under the additional assumption that g is continuous.

COROLLARY 6.2. *If* g, C, K *are as in Example* 2.1 *and the CCCQ holds, then*

$$N_{C\cap g^{-1}(-K)}(x) = N_C(x) + \bigcup_{\substack{\lambda\in K^{\oplus}\\ \lambda g(x)=0}} \partial\,(\lambda g)(x) \quad \text{for each } x \in C \cap g^{-1}(-K); \tag{6.2}$$

that is, $\{C, g^{-1}(-K)\}$ *has the sharpened strong CHIP at each point in* $C \cap g^{-1}(-K)$*. In particular, if the condition* (**C**$*$) *holds, then*

$$N_{g^{-1}(-K)}(x) = \bigcup_{\substack{\lambda\in K^{\oplus}\\ \lambda g(x)=0}} \partial\,(\lambda g)(x) \quad \text{for each } x \in g^{-1}(-K). \tag{6.3}$$

Proof. We need prove only the first assertion. Define $I := K^{\oplus} \cup \{i_0\}$, $i_0 \notin K^{\oplus}$, and consider $\{g_i :\ i \in I\}$ as defined in (2.8). Then $S := \{x :\ g_i(x) \le 0\}$ is exactly $C \cap g^{-1}(-K)$, and the active index set $I(x)$ is exactly $\{i_0\} \cup \{\lambda \in K^{\oplus} :\ \lambda g(x) = 0\}$. Thus (6.2) simply means that the family $\{g_i :\ i \in I\}$ has the BCQ, and hence the result follows from Remark 6.1 and Theorem 4.1. □

COROLLARY 6.3. *If* g, C, K *are as in Example* 2.1 *and the condition* (**C**$*$) *holds, then for each* $x \in C \cap g^{-1}(-K)$ *the family* $\{C, g^{-1}(-K)\}$ *satisfies the strong CHIP at* x *if and only if it satisfies the sharpened strong CHIP at* x*.*

Proof. By the given assumption, (6.3) holds; that is, $N_{g^{-1}(-K)}(x) = Ng(x)_0$ for each $x \in g^{-1}(-K)$. Consequently, the following equivalence holds for each $x \in C \cap g^{-1}(-K)$:

$$N_{C\cap g^{-1}(-K)}(x) = N_C(x) + N_{g^{-1}(-K)}(x) \Leftrightarrow N_{C\cap g^{-1}(-K)}(x) = N_C(x) + Ng(x)_0.$$

Thus the result is clear. □

7. Applications to best approximation theory. Let us recall from [14] that for a system of finitely many closed convex sets $\{D, C_i :\ i \in I\}$ in a Hilbert space, where $C_i = \{x \in X :\ \langle a_i, x\rangle \le b_i\}$ for some $a_i \in X$ and $b_i \in \mathbb{R}$, $i \in I$, the following statements are equivalent for each $x_0 \in D \cap \bigcap_{i\in I} C_i$:

(i) $\{D, C_i :\ i \in I\}$ has the strong CHIP at each x_0.

(ii) For each $x \in X$, $P_{D\cap\bigcap_{i\in I} C_i}(x) = x_0$ if and only if there exists a finite set $I_0 \subseteq I$ such that $P_D(x - \sum_{i\in I_0} a_i) = x_0$,

where $P_A(x)$ denotes the projection of the point x onto a convex set A. This important result has been extended in many aspects. For example, [32] discussed an extension to the case of an infinite system, and [31] discussed a family of functions in place of that of closed convex sets.

Recall that for a Banach space X and its dual X^*, the duality map $\Phi : X \rightrightarrows X^*$ is defined by $\Phi(x) := \{x^* : \|x\|^2 = \|x^*\|^2 = \langle x^*, x\rangle\}$ (cf. [40, section 3.7]). Let $\{g_i : i \in I\}$, X, C, S, and I be as in section 2.

THEOREM 7.1. *Suppose that X is a Banach space, and let $x_0 \in C \cap S$. Consider the following statements:*

(i) *$\{\delta_C; g_i, i \in I\}$ satisfies the BCQ at x_0.*

(ii) *For each $x \in X$, $x_0 \in P_{C\cap S}(x)$ if and only if*

$$\Phi(x - x_0) \cap \left(N_C(x_0) + \operatorname{cone} \bigcup_{i\in I(x_0)} \partial\, g_i(x_0) \right) \neq \emptyset. \tag{7.1}$$

Then (i)⇒(ii). *If we further assume that X is reflexive and smooth, then* (ii)⇔(i).

Proof. We regard the family $\{\delta_C; g_i, i \in I\}$ as $\{g_j : j \in J\}$ by letting $J = I \cup \{i_+\}$ and $g_j := \delta_C$, where $i_+ \notin I$. It follows that

$$J(x_0) := \left\{ j \in J : g_j(x_0) = \max\left\{ \sup_{i\in I} g_i(x_0), \delta_C(x_0) \right\} \right\} = \{i_+\} \cup I(x_0).$$

Suppose that (i) holds and let $x \in X$. Note that $x_0 \in P_{C\cap S}(x)$ if and only if x_0 minimizes the function $\frac{1}{2}\|\cdot - x\|^2$ over the set $\{x : \delta_C(x) = 0,\ g_i(x) \leq 0\ \forall i \in I\}$. Since $\Phi(x - x_0) = -\partial\,(\frac{1}{2}\|\cdot - x\|^2)(x_0)$ (cf. [40, p. 230]) and since the family $\{g_j : j \in J\}$ satisfies the BCQ at x_0, it follows from (2.3) and Theorem 5.1(iii) that $x_0 \in P_{C\cap S}(x)$ if and only if

$$\begin{aligned} &\Phi(x - x_0) \cap \left(N_C(x_0) + \operatorname{cone} \bigcup_{i\in I(x_0)} \partial\, g_i(x_0) \right) \\ &\quad = \Phi(x - x_0) \cap \left(\operatorname{cone} \bigcup_{j\in J(x_0)} \partial\, g_j(x_0) \right) \neq \emptyset. \end{aligned}$$

Thus (ii) holds.

Now we assume in addition that X is reflexive and smooth, and turn to proving (ii)⇒(i). By (3.9), we need to show that

$$N_{C\cap S}(x_0) \subseteq N_C(x_0) + \operatorname{cone} \bigcup_{i\in I(x_0)} \partial\, g_i(x_0). \tag{7.2}$$

To do this, take $y^* \in N_{C\cap S}(x_0)$. By the given assumptions, Φ is bijective (cf. [40, Theorem 3.7.2(vi) and p. 230]). Thus there exists $u = \Phi^{-1}(y^*)$, and it follows that $x_0 \in P_{C\cap S}(x_0 + u)$ by a well-known result (cf. [40, Corollary 3.8.5]). Therefore, by (ii), (7.1) holds with $x = x_0 + u$. Thus we obtain from (7.1) that

$$y^* = \Phi(x_0 + u - x_0) \in N_C(x_0) + \operatorname{cone} \bigcup_{i\in I(x_0)} \partial\, g_i(x_0).$$

This shows that (7.2) holds, as required. This completes the proof. ∎

COROLLARY 7.1. *Suppose that X in Theorem 7.1 is a Hilbert space, and let $x_0 \in C \cap S$. Then the following statements are equivalent:*

(i) *$\{\delta_C;\ g_i,\ i \in I\}$ satisfies the BCQ at x_0.*

(ii) *For each $x \in X$, $x_0 = P_{C\cap S}(x)$ if and only if*

$$x - x_0 \in N_C(x_0) + \operatorname{cone} \bigcup_{i\in I(x_0)} \partial\, g_i(x_0). \tag{7.3}$$

(iii) *For each $x \in X$, $x_0 = P_{C\cap S}(x)$ if and only if there exist finite subset $J \subseteq I(x_0)$, $\lambda_i \geq 0$, $u_i \in \partial\, g_i(x_0)$, $i \in J$, such that*

$$x_0 = P_C\left(x - \sum_{i\in J} \lambda_i u_i\right).$$

Proof. The equivalence of (ii) and (iii) is standard in Hilbert spaces. The equivalence of (i) and (ii) follows from Theorem 7.1, since (7.1) and (7.3) are now identical (because Φ is the identity map for Hilbert spaces) ∎

COROLLARY 7.2. *Suppose in Corollary 7.1 that the family $\{\delta_C;\ g_i,\ i \in I\}$ has the conical EHP. Then for each $x \in X$ and $x_0 \in C \cap S$, $P_{C\cap S}(x) = x_0$ if and only if there exist a finite set $I_0 \subseteq I(x_0)$, $x_i \in \partial\, g_i(x)$, and $\lambda_i \geq 0$ for each $i \in I_0$ such that $P_C(x - \sum_{i\in I_0} \lambda_i x_i) = x_0$.*

Proof. Since the family $\{\delta_C;\ g_i,\ i \in I\}$ has the conical EHP, it satisfies the BCQ by Theorem 4.1(ii). The result now follows from Corollary 7.1. ∎

For the next two corollaries, let g, C, and K be as in Example 2.1. These two corollaries were established, respectively, in [28] and [29] but under the additional assumption that g is continuous.

COROLLARY 7.3. *Suppose that X is a Hilbert space, and let $x_0 \in C \cap g^{-1}(-K)$. Then the following statements are equivalent:*

(i) *$\{\delta_C, \lambda g :\ \lambda \in K^{\oplus}\}$ satisfies the BCQ at x_0.*

(ii) *The pair $\{C, g^{-1}(-K)\}$ has the sharpened strong CHIP at x_0, that is,*

$$N_{C\cap g^{-1}(-K)}(x_0) = N_C(x_0) + \bigcup_{\substack{\lambda\in K^{\oplus}\\ \lambda g(x_0)=0}} \partial\,(\lambda g)(x_0).$$

(iii) *For each $x \in X$, $x_0 = P_{C\cap g^{-1}(-K)}(x)$ if and only if $x_0 = P_C(x - l)$ for some $l \in \bigcup_{\substack{\lambda\in K^{\oplus}\\ \lambda g(x_0)=0}} \partial\,(\lambda g)(x_0)$.*

Proof. By Fact 6.3 and Remark 6.1, (i)⇔(ii). The equivalence (i)⇔(iii) follows from Corollary 7.1 as applied to $I := K^{\oplus}$ and $g_\lambda := \lambda g$ (so $I(x_0) = \{\lambda \in K^{\oplus} : \lambda g(x_0) = 0\}$). ∎

COROLLARY 7.4. *Suppose that X is a Hilbert space and that $(\mathbf{C}*)$ holds. Let $x_0 \in C \cap g^{-1}(-K)$ and $x \in X$. Assume that $\{C, g^{-1}(-K)\}$ has the strong CHIP at x_0. Then the following statements are equivalent:*

(i) *$x_0 = P_{C\cap g^{-1}(-K)}(x)$.*

(ii) *$x_0 = P_C(x - l)$ for some $l \in \bigcup_{\substack{\lambda\in K^{\oplus}\\ \lambda g(x_0)=0}} \partial\,(\lambda g)(x_0)$.*

Proof. By Corollary 6.3, the given assumptions imply that $\{C, g^{-1}(-K)\}$ has the sharpened strong CHIP at x_0. By the implication (ii)⇒(iii) in the preceding corollary, the result is now clear. ∎

Acknowledgment. The authors would like to express their sincere thanks to the three anonymous referees for many helpful comments and for pointing out the references [1, 4, 5, 6, 12, 16, 17, 37].

MULTIOBJECTIVE OPTIMIZATION THROUGH A SERIES OF SINGLE-OBJECTIVE FORMULATIONS*

CHARLES AUDET†, GILLES SAVARD†, AND WALID ZGHAL‡

Abstract. This work deals with bound constrained multiobjective optimization (MOP) of nonsmooth functions for problems where the structure of the objective functions either cannot be exploited, or are absent. Typical situations arise when the functions are computed as the result of a computer simulation. We first present definitions and optimality conditions as well as two families of single-objective formulations of MOP. Next, we propose a new algorithm called BiMads for the biobjective optimization (BOP) problem (i.e., MOP with two objective functions). The property that Pareto points may be ordered in BOP and not in MOP is exploited by our algorithm. BiMads generates an approximation of the Pareto front by solving a series of single-objective formulations of BOP. These single-objective problems are solved using the recent Mads (mesh adaptive direct search) algorithm for nonsmooth optimization. The Pareto front approximation is shown to satisfy some first order necessary optimality conditions based on the Clarke calculus. Finally, BiMads is tested on problems from the literature designed to illustrate specific difficulties encountered in biobjective optimization, such as a nonconvex or disjoint Pareto front, local Pareto fronts, or a nonuniform Pareto front.

1. Introduction.

In many real-world problems, decisions depend on multiple and conflicting criteria. For example, in portfolio management, two criteria are usually considered: the return of the portfolio and its volatility risk [22]. There is usually no unique solution that is simultaneously optimal for all criteria, multiobjective optimization (MOP) aims at identifying the best trade-offs between these criteria. In this paper, we consider multiobjective programming under bound constraints, which may be stated as

$$\text{MOP}: \quad \min_{x \in X} \; F(x) = (f_1(x),\; f_2(x), \ldots,\; f_p(x))$$

with

$$F : \mathbb{R}^n \to \mathbb{R}^p \;\text{ and }\; X = \{x \in \mathbb{R}^n : a \le x \le b\},$$

where n is the number of variables, p is the number of objective functions, and $a \in (\mathbb{R} \cup \{-\infty\})^n$ and $b \in (\mathbb{R} \cup \{+\infty\})^n$ are bound vectors. Throughout this paper, X is assumed to be full dimensional, i.e., $a < b$ componentwise. The solution of MOP consists of the set of best trade-off points selected according to the Pareto dominance

relation presented in section 2.1. The image under the mapping F of these points is called the *Pareto front*.

In this paper, we present an algorithm that generates an approximation of the Pareto front by only using function values. We are interested in problems in which the structure of the objective functions is either absent, unreliable, or cannot be exploited. A typical example is when the evaluation of F requires a computer simulation, i.e., the value $F(x)$ is only returned after a long series of computer operations. Some examples in single-objective optimization of such blackbox problems are detailed in [1, 5, 7, 19, 23].

The method proposed in this work is called BiMads as it is designed to approximate the Pareto front of a biobjective optimization problem (BOP) by using the recent Mads (mesh adaptive direct search) algorithm [4]. BiMads essentially solves a series of bound-constrained single-objective formulations of BOP using Mads with increasingly stringent stopping criteria. The series of formulations is constructed in a way to attempt a uniform coverage of the Pareto front, even in the case where the Pareto front is nonconvex or disjoint.

This paper is organized as follows. A brief overview of multiobjective optimization and some methods from the literature are presented in section 2. Some necessary optimality conditions that make use of the Clarke calculus [8] are also presented. Two classes of single-objective formulations are introduced in section 3: the *single-objective normalized formulation* and the *single-objective product formulation*. Then, the algorithm BiMads is detailed in section 4 for solving BOP. Finally, in section 5, BiMads is tested on problems from the literature [15] designed to underline specific difficulties encountered in biobjective optimization, such as a nonconvex or disjoint Pareto front, local Pareto fronts, or a nonuniform Pareto front. A new performance measure is proposed. It provides an indication of the coverage of the Pareto front by the set of points produced by the algorithm.

2. Multiobjective optimization. This section summarizes some key notions in multiobjective optimization such as Pareto dominance and solution approaches from the literature.

2.1. Pareto dominance. Comparison of optimal solutions requires an order relation, called dominance relation, between the different points [26]. Several dominance relations such as the Geoffrion's dominance [18] and the lexicographical dominance [16] have been proposed. The most commonly used relies on Pareto dominance shown below.

Definition 2.1. *Let $u, v \in X$ be two decision vectors. We define the following:*

- *$u \preceq v$ (u weakly dominates v) if and only if $f_i(u) \leq f_i(v)$ for all $i \in \{1, 2, \ldots, p\}$.*
- *$u \prec v$ (u dominates v) if and only if $u \preceq v$ and $f_j(u) < f_j(v)$ for at least one $j \in \{1, 2, \ldots, p\}$.*
- *$u \sim v$ (u is indifferent to v) if and only if u does not dominate v and v does not dominate u.*

Definition 2.1 is illustrated in Figure 2.1 for a biobjective problem in which $X \subset \mathbb{R}^3$. The feasible region X is projected on the objective space; the image of X under the mapping F is denoted by $Y \subseteq \mathbb{R}^p$, and is delimited by the curve in the right part of the figure.

Figure 2.1 also highlights three zones in the objective space, relative to the feasible point $x_1 \in X$. The *dominated zone* is the set of points which are dominated by x_1. The *dominance zone* is the set of points that dominate x_1. The *indifference zone* is

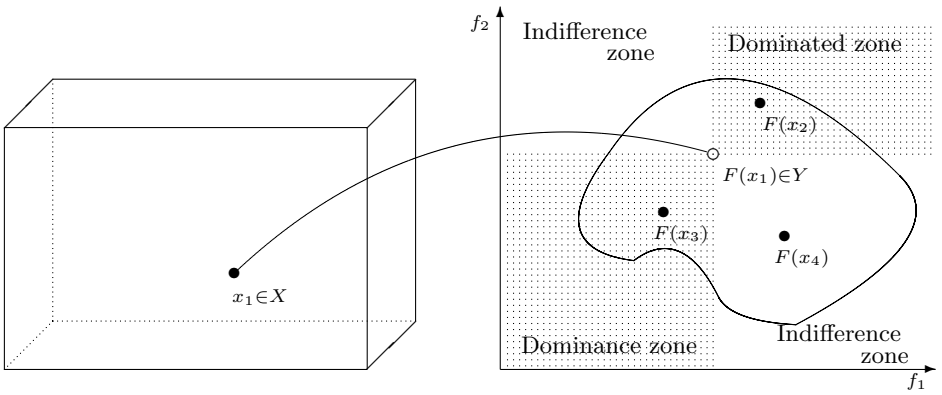

FIG. 2.1. *Pareto dominance illustrated on a biobjective problem with* 3 *variables.*

the set of points which are indifferent to x_1. In Figure 2.1, x_1 dominates x_2 but is dominated by x_3 and indifferent to x_4, i.e., $x_3 \prec x_1 \prec x_2$ and $x_1 \sim x_4$. Furthermore, x_4 is also indifferent to both x_2 and x_3, i.e., $x_2 \sim x_4 \sim x_3$.

The above dominance relation provides an optimality definition for multiobjective programming. We distinguish between local and global Pareto optimality.

DEFINITION 2.2. *A point $x^* \in X$ is said to be globally Pareto optimal if and only if there is no $x \in X$ such that $x \prec x^*$. If x^* is globally Pareto optimal, then $F(x^*)$ is called globally efficient.*

Some computational methods do not guarantee global optimality but ensure at best local optimality, as shown below.

DEFINITION 2.3. *A point $\tilde{x} \in X$ is said to be locally Pareto optimal if and only if there exits some $\epsilon > 0$ and $\sigma > 0$ for which the set $\{x \in B_\epsilon(\tilde{x}) \cap X \ : \ x \prec \tilde{x}$ and $F(x) \in B_\sigma(F(\tilde{x}))\}$ is empty, where $B_\epsilon(\tilde{x})$ denotes an open ball around $\tilde{x}$ of radius ϵ and $B_\sigma(F(\tilde{x}))$ denotes an open ball around $F(\tilde{x})$ of radius σ. If $\tilde{x}$ is locally Pareto optimal, then $F(\tilde{x})$ is called locally efficient.*

The two notions are illustrated in Figure 2.2. The point $\tilde{x} \in X$ is locally Pareto optimal while all points that map to the boundary of Y in the shaded area are globally Pareto optimal. Pareto optimality will henceforth refer to global Pareto optimality unless noted otherwise. The set of globally Pareto optimal points is called globally Pareto optimal set and denoted by $X_{\mathcal{P}}$. The image under the mapping F of $X_{\mathcal{P}}$ defines the solution set of the multiobjective problem. This set is called the *global Pareto front* or simply the *Pareto front* and is denoted by $Y_{\mathcal{P}} \in \mathbb{R}^p$. The image of a set of locally Pareto optimal points is called a *local Pareto front*.

Figure 2.2 also depicts two important points in the objective space. The *ideal point* $\ell \in (\mathbb{R} \cup -\infty)^p$ is defined as the vector whose components are the individual minima of each objective function

$$\ell \ = \ \left(\min_{x \in X} f_1(x), \ \min_{x \in X} f_2(x), \ldots, \ \min_{x \in X} f_p(x) \right)^T .$$

The *nadir point* $u \in (\mathbb{R} \cup \infty)^p$ is defined as the vector whose components are the

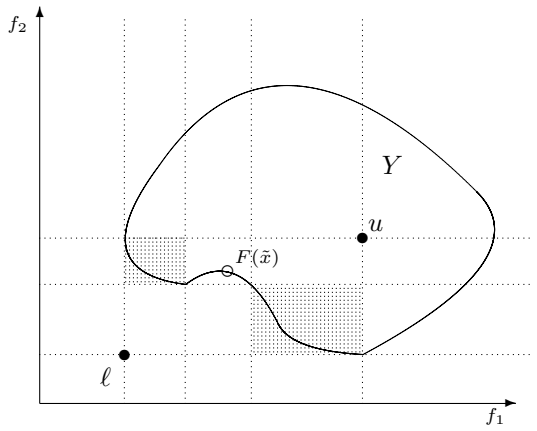

FIG. 2.2. *Pareto front and ideal and nadir points of a biobjective problem.*

individual maxima in the Pareto front of each objective function

$$u = \left(\max_{x \in X_{\mathcal{P}}} f_1(x), \max_{x \in X_{\mathcal{P}}} f_2(x)^T, \ldots, \max_{x \in X_{\mathcal{P}}} f_p(x) \right)^T.$$

2.2. Classes of methods for MOP. Several methods have been proposed for multiobjective optimization. There are some exact methods for linear multiobjective optimization [6, 2]. In the nonlinear case, several heuristic methods generate a set of points $Y_{\mathcal{L}}$ that gives an approximation $Y_{\mathcal{P}}$ of the Pareto front. A survey of heuristic approaches may be found in [17].

Two natural strategies arise when developing heuristics for MOP [28]. One strategy consists of making sure that the algorithm generates trial points whose images rapidly converge to some point of the Pareto front $Y_{\mathcal{P}}$. The second strategy is to spread out these approximations of Pareto points so that they achieve a well-distributed nondominated set $Y_{\mathcal{L}}$.

We next discuss different classes of methods for MOP. A first class of methods consists of reformulating MOP into a series of single-objective programs by aggregating the objective functions. Three methods of this class are presented as follows: A linear weighting method, an approximation to some reference point, and a weighted geometric mean approach. We also briefly discuss the normal-boundary intersection algorithm (NBI) [14].

Linear weighting method. The linear weighting method (LWM) [9] consists of converting the MOP into a single-objective optimization problem by minimizing a convex combination of objectives

$$\text{LWM}: \quad \min_{x \in X} \sum_{i=1}^{p} w_i f_i(x),$$

where $w_i \geq 0$ for $i = 1, 2, \ldots, p$ are weights such that $\sum_{i=1}^{p} w_i = 1$. Any optimal solution of LWM is Pareto optimal for MOP. Hence, solving LC for different weight combinations produces a subset of Pareto solutions. A well-known difficulty of this method is that it cannot generate any point in the nonconvex part of the Pareto front $Y_{\mathcal{P}}$ as illustrated in Figure 2.3. No value of the weights w_1 and w_2 can lead an algorithm on the optimization problem LWM to any point near the efficient point $F(x^*)$,

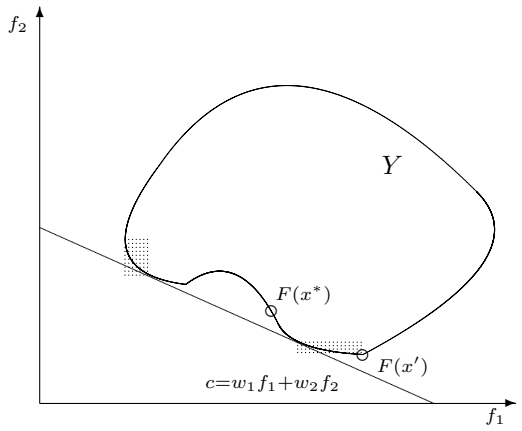

FIG. 2.3. *The linear weighting method may only generate a subset of the Pareto front.*

and the only points of the Pareto front that can be generated are those belonging to the shaded areas in Figure 2.3. These shaded areas are significantly smaller than those of Figure 2.2, delimiting the Pareto front.

A second difficulty with the linear weighting method is that the same point may be found by several weight combinations, as illustrated by $F(x')$ in Figure 2.3.

These two difficulties are such that the main drawback with the linear weighting method is the lack of uniformity of the Pareto front approximation distribution.

Approximation to a reference point. This method consists of finding a feasible solution $x \in X$ such that $F(x)$ is close to some reference point $r \in \mathbb{R}^p$ [26, 27]. Often, the ideal point defined in section 2.1 is used as the reference point, i.e., $r = \ell$. The problem is formulated as follows:

$$PI_r: \quad \min_{x \in X} \ \|F(x) - r\|_q \ = \ \left(\sum_{i=1}^{p} |f_i(x) - r_i|^q \right)^{1/q},$$

where $\|.\|_q$ is the q-norm with $1 \leq q \leq \infty$. The method using $\|.\|_2$ norm is illustrated in Figure 2.4 for a biobjective problem. Solving PI_r with different reference points produces a set of points which approximates the Pareto front. In Figure 2.4, the method applied with ℓ as a reference point generates an efficient point $F(x^*)$. As opposed to the weighting method, the approximation to the reference point may generate points in the nonconvex part of the Pareto front. However, it may generate nonefficient points, as illustrated in Figure 2.4 by the generation of $F(x)$ from the reference point r.

Weighted geometric mean and NBI approaches. The weighted geometric mean approach consists of converting the MOP to a single-objective optimization problem by maximizing the weighted geometric mean of differences between the components of the nadir point u defined in section 2.1 and the objective functions

$$\text{WGMP}: \quad \begin{array}{lll} \max\limits_{x} & \prod\limits_{i=1}^{p} (u_i - f_i(x))^{\lambda_i} & \\ \text{s.t.} & f_i(x) \leq u_i, & \text{for } i = 1, 2, \ldots, p, \\ & x \in X, & \end{array}$$

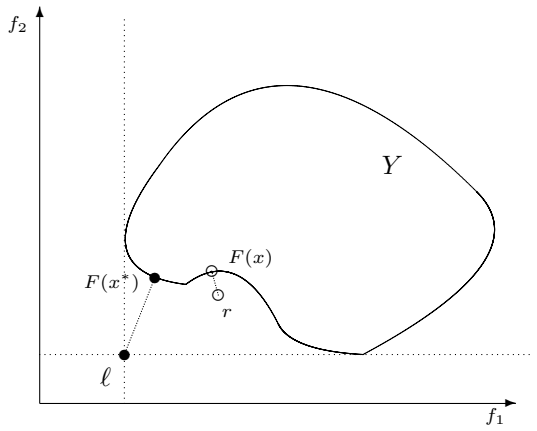

FIG. 2.4. *The approximation to a reference point may lead to a nonefficient point.*

where $\lambda_i > 0$ for $i = 1, 2, \ldots, p$. Lootsma, Athan, and Papalambros [21] show that if all objective functions $f_1, f_2, \ldots, f_p$ are convex, then a solution of WGMP is Pareto optimal. A difficulty with this approach is that the resulting problem WGMP now contains p general constraints instead of only bound constraints. This approach has some similarities to what we propose in section 3, but we do not add any supplementary constraints.

The NBI approach of Das [13] produces an approximation of the Pareto front by solving a series of single-objective optimization problems NBI_β, in which an additional equality constraints tying the objective function values are added:

$$\text{NBI}_\beta: \quad \begin{array}{ll} \max\limits_{x,t} & t \\ \text{s.t.} & \phi\beta + t\hat{n} = \quad F(x) \\ & x \in X, \end{array}$$

where β are barycentric coordinates, $\phi\beta$ represents a point in the convex hull of individual minima (CHIM), and $\hat{n}$ denotes the unit vector normal to the CHIM simplex, pointing towards origin. Solution of NBI_β is the intersection of the normal to CHIM and the boundary of Y closest to the origin. Solving NBI_β for various values of β gives an approximation of the Pareto front. This approach may be impracticable in the blackbox optimization context.

2.3. Necessary optimality conditions for multiobjective optimization. This section contains necessary optimality conditions for multiobjective optimization that extend the first order optimality condition for single-objective optimization. The convergence analysis makes use of the Clarke calculus [8] for nonsmooth functions. For a locally Lipschitz function $f : \mathbb{R}^n \to \mathbb{R}$, Clarke [8] defines the *generalized directional derivative* of f evaluated at $\tilde{x} \in X$ in the tangent direction $v \in \mathbb{R}^n$ as

$$f^\circ(\tilde{x}; v) = \limsup_{y \to \tilde{x},\ t \downarrow 0} \frac{f(y + tv) - f(y)}{t}. \tag{2.1}$$

A point $\tilde{x} \in X$ is said to be a Clarke stationary point of f over the bound constraints domain X if the generalized derivative is nonnegative for any direction in the tangent cone $T_X(\tilde{x})$, to X at $\tilde{x}$. The *generalized gradient* is defined to be the set $\partial f(\hat{x}) = \{s \in \mathbb{R}^n : f^\circ(\hat{x}; v) \geq v^T s \text{ for all } v \in \mathbb{R}^n\}$.

The following theorem presents a necessary condition for Pareto optimality of (MOP) analogue to optimality conditions for set-valued functions [11] rewritten with our notation.

THEOREM 2.4. *Let f_i be Lipschitz near $\tilde{x} \in X$, $i = 1, 2, \ldots, p$. If $\tilde{x}$ is locally Pareto optimal, then for any d in the tangent cone $T_X(\tilde{x})$ there exists $\hat{\jmath} \in \{1, 2, \ldots, p\}$ for which*

$$f_{\hat{\jmath}}^{\circ}(\tilde{x}; d) \geq 0.$$

Assuming strict differentiability [20] of each objective functions f_i at $\tilde{x} \in X$, for $i = 1, 2, \ldots, p$ leads to the following corollary [17]. Strict differentiability of f_i at $\tilde{x}$ is just the requirement that the generalized gradient is a singleton, i.e., that $\partial f_i(\tilde{x}) = \{\nabla f(\tilde{x})\}$ in addition to the requirement that f_i is Lipschitz near $\tilde{x}$. F is called strictly differentiable at $\tilde{x} \in X$ if f_i are strictly differentiable $\tilde{x}$ for $i = 1, 2, \ldots, p$.

COROLLARY 2.5. *Let F be strictly differentiable at $\tilde{x} \in X$. If $\tilde{x}$ is locally Pareto optimal, then for any d in the tangent cone $T_X(\tilde{x})$ there exists some $\hat{\jmath} \in \{1, 2, \ldots, p\}$ such that $\nabla f_{\hat{\jmath}}(\tilde{x})^T d \geq 0$. The point $\tilde{x}$ is called a* KKT-properly efficient solution for MOP.

3. Single-objective formulations of multiobjective optimization. We propose to solve MOP through a series of single-objective optimization problems. Each single-objective optimization problem relies on a reference point r in the objective space $\mathbb{R}^p$ and must satisfy the requirements presented in the following definition.

DEFINITION 3.1. *Consider the single-objective optimization problem:*

$$R_r \ : \ \min_{x \in X} \psi_r(x) \quad \textit{with} \quad \psi_r(x) = \phi_r(f_1(x), f_2(x), \ldots, f_p(x)),$$

where $\phi_r : \mathbb{R}^p \to \mathbb{R}$ is parameterized with respect to some reference point $r \in \mathbb{R}^p$. Then R_r is called a single-objective formulation at r of MOP *if the following conditions hold:*

- *If F is Lipschitz near some $\tilde{x} \in X$, then ψ_r is also Lipschitz near $\tilde{x} \in X$.*
- *If F is Lipschitz near some $\tilde{x} \in X$ with $F(\tilde{x}) < r$ componentwise, and if $d \in T_X(\tilde{x})$ is such that $f_i^{\circ}(\tilde{x}; d) < 0$ for $i = 1, 2, \ldots, p$, then $\psi_r^{\circ}(\tilde{x}; d) < 0$.*

The first condition ensures that the formulation preserves local Lipschitz continuity while the second involves Clarke descent directions for all f_i's and ψ_r. Assuming more smoothness on the function ϕ_r leads to the following theorem.

THEOREM 3.2. *Let R_r be a single-objective formulation at $r \in \mathbb{R}^p$ of MOP. If F and ψ_r are strictly differentiable at some $\tilde{x} \in X$ with $F(\tilde{x}) < r$ componentwise, and if $d \in T_X(\tilde{x})$ is such that $\nabla f_i(\tilde{x})^T d < 0$ for $i = 1, 2, \ldots, p$, then $\nabla \psi_r(\tilde{x})^T d < 0$.*

Proof. Strict differentiability of ϕ_r and F at $\tilde{x}$ ensures strict differentiability of ψ_r at $\tilde{x}$ with $\nabla \psi_r(\tilde{x})^T d = \psi_r^{\circ}(\tilde{x}; d)$. It follows from the second condition of Definition 3.1 that $\nabla \phi_r(\tilde{x})^T d < 0$ if $\nabla f_i(\tilde{x})^T d = f_i^{\circ}(\tilde{x}; d) < 0$ for $i = 1, 2, \ldots, p$. ∎

The next two subsections introduce two single-objective formulations: the *single-objective normalized formulation* and the *single-objective product formulation*. Both formulations are similar to the weighted geometric mean approach described in section 2.2 but have the advantage of not introducing nonlinear constraints to the bound-constrained domain X.

3.1. Single-objective normalized formulation. Let $r \in \mathbb{R}^p$ be a reference point in the objective space and $s \in \mathbb{R}^p$ be a positive scaling factor. The *single-objective normalized formulation* is defined as

$$\hat{R}_r \ : \quad \min_{x \in X} \hat{\psi}_r \quad \text{with} \quad \hat{\psi}_r(x) = \hat{\phi}_r(f_1(x), f_2(x), \ldots, f_p(x)) = \max_{i \in \{1,2,\ldots,p\}} \frac{f_i(x) - r_i}{s_i}.$$

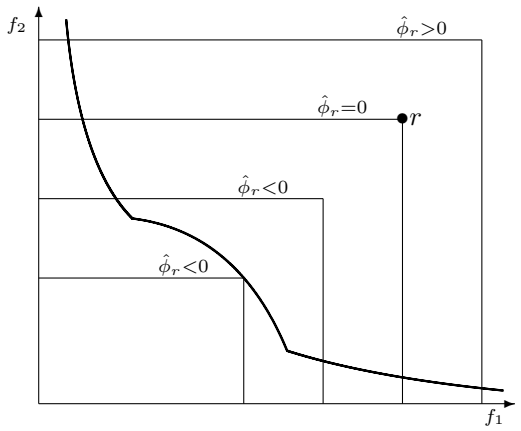

FIG. 3.1. *Level sets in objective space of the single-objective normalized formulation $\hat{R}_r$ for a BOP.*

Level sets of the function $\hat{\phi}_r$ in the objective function space are represented by horizontal and vertical lines in Figure 3.1 for a BOP.

The next theorem shows that $\hat{R}_r$ is a single-objective formulation of MOP.

THEOREM 3.3. *$\hat{R}_r$ is a single-objective formulation at r of MOP in the sense of Definition* 3.1.

Proof. Let F be Lipschitz near $x \in X$. Now, choose $j \in \operatorname{argmax}_{i\in\{1,2,\ldots,p\}} \frac{f_i(x)-r_i}{s_i}$ and for some $y \in X$, let $k \in \operatorname{argmax}_{i\in\{1,2,\ldots,p\}} \frac{f_i(y)-r_i}{s_i}$. It follows that

$$|\hat{\psi}_r(x) - \hat{\psi}_r(y)| = \begin{cases} \frac{f_j(x)-r_j}{s_j} - \frac{f_k(y)-r_k}{s_k} \le \frac{f_j(x)-r_j}{s_j} - \frac{f_j(y)-r_j}{s_j} = \frac{f_j(x)-f_j(y)}{s_j} \\ \text{or} \\ \frac{f_k(y)-r_k}{s_k} - \frac{f_j(x)-r_j}{s_j} \le \frac{f_k(y)-r_k}{s_k} - \frac{f_k(x)-r_k}{s_k} = \frac{f_k(y)-f_k(x)}{s_k}. \end{cases}$$

Hence, $|\hat{\psi}_r(x) - \hat{\psi}_r(y)| \le \max_{i\in\{1,2,\ldots,p\}} \frac{|f_i(x)-f_i(y)|}{s_i} \le \frac{\max(\lambda_1,\lambda_2,\ldots,\lambda_p)}{\min(s_1,s_2,\ldots,s_p)}\|x-y\|$, where λ_i denotes the Lipschitz constant of f_i for $i = 1, 2, \ldots, p$. The second condition of Definition 3.1 follows directly from [8, Proposition 2.3.12]. ∎

Based on the $\hat{R}_r$ formulation, the next proposition gives a necessary condition for a Pareto optimal solution for MOP.

PROPOSITION 3.4. *If there exists some vectors $r \in \mathbb{R}^p$ and $s \in \mathbb{R}^p_+$ such that $\tilde{x}$ is the unique optimal solution of $\hat{R}_r$, then $\tilde{x}$ is Pareto optimal for MOP.*

Proof. Let $\tilde{x}$ the unique optimal solution of $\hat{R}_r$ and $x \in X$, $x \neq \tilde{x}$. Then $\hat{\psi}(\tilde{x}) < \hat{\psi}(x)$ and, consequently, there exists some index $j \in \{1, 2, \ldots, p\}$ for which $\frac{f_j(\tilde{x})-r_j}{s_j} < \frac{f_j(x)-r_j}{s_j}$. It follows that $f_j(\tilde{x}) < f_j(x)$ and thus x does not dominate $\tilde{x}$. Hence, $\tilde{x}$ is Pareto optimal. ∎

The same argument ensures that a unique local optimal solution of $(\hat{R}_r)$ is locally Pareto optimal.

3.2. Single-objective product formulation. Let $r \in \mathbb{R}^p$ be a reference point in the objective space. The *single-objective product formulation* is defined as

$$\tilde{R}_r \quad : \quad \min_{x\in X} \tilde{\psi}_r \quad \text{with} \quad \hat{\psi}_r(x) = \tilde{\phi}_r(f_1(x), f_2(x), \ldots, f_p(x)) = -\prod_{i=1}^{p}((r_i - f_i(x))_+)^2,$$

where $(r_i - f_i(x))_+ = \max\{r_i - f_i(x), 0\}$ for $i = 1, 2, \ldots, p$. An advantage of $\tilde{R}_r$ over $\hat{R}_r$ is that the function of p variables ϕ_r is continuously differentiable in the entire space, and therefore, the formulation preserves the differentiability of the original problem. More precisely, if $F(x)$ is continuously differentiable near $\tilde{x} \in X$, then $\tilde{\psi}_r$ will also be continuously differentiable near $\tilde{x} \in X$; and if $F(x)$ is strictly differentiable near $\tilde{x} \in X$, then $\tilde{\psi}_r$ will also be strictly differentiable near $\tilde{x} \in X$.

$\tilde{R}_r$ is obtained from WGMP presented in section 2.2 with $\lambda_k = 2$ for $k = 1, 2, \ldots, p$ by treating the additional constraints introduced by WGMP in the objective function. The level sets of the $\tilde{R}_r$ formulation for a biobjective problem are depicted by thin curves in Figure 3.2. The level set $\tilde{R}_r = 0$ consists of the entire shaded region.

The next theorem shows that $\tilde{R}_r$ is a single-objective formulation of MOP.

THEOREM 3.5. *$\tilde{R}_r$ is a single-objective formulation at r of MOP in the sense of Definition* 3.1.

Proof. Let F be Lipschitz near $x \in X$. $\tilde{\psi}_r$ is Lipschitz near x as product of Lipschitz functions is also Lipschitz.

To prove the second condition of Definition 3.1, we first compute the generalized directional derivative of $\tilde{\psi}_r$ evaluated at $\tilde{x} \in X$ satisfying $F(\tilde{x}) < r$, componentwise, in some tangent direction $d \in T_X(\tilde{x})$. In order to simplify the presentation, let us define the function $c_i(x) = r_i - f_i(x)$ for $i = 1, 2, \ldots, p$. It follows from [8, Proposition 2.3.13] that

$$\begin{aligned}\tilde{\psi}_r^\circ(\tilde{x}; d) &\le -2\sum_{i=1}^{p}\Big((c_i(\tilde{x}; d)_+)^\circ (c_i(\tilde{x})_+)\prod_{j\neq i}(c_j(\tilde{x})_+)^2\Big)\\ &= -2\sum_{i=1}^{p}\Big(c_i^\circ(\tilde{x}; d)(c_i(\tilde{x})_+)\prod_{j\neq i}(c_j(\tilde{x})_+)^2\Big).\end{aligned}$$

Since, $c_i^\circ(\tilde{x}; d) = -f_i^\circ(\tilde{x}; d)$, we have

$$\tilde{\psi}_r^\circ(\tilde{x}; d) \;\le\; \sum_{i=1}^{p}\Big(f_i^\circ(\tilde{x}; d)((r_i - f_i(\tilde{x}))_+)\prod_{j\neq i}((r_j - f_j(\tilde{x}))_+)^2\Big).$$

It follows that if $f_i^\circ(\tilde{x}; d) < 0$ for $i = 1, 2, \ldots, p$, then $\tilde{\psi}_r^\circ(\tilde{x}; d) < 0$. ∎

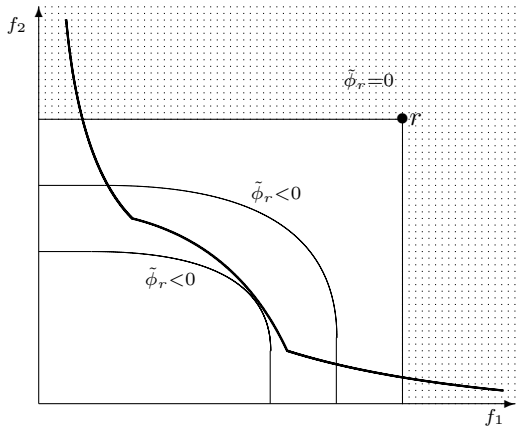

FIG. 3.2. *Level sets in objective space of the single-objective product formulation $\tilde{R}_r$ for a BOP.*

Based on the $\tilde{R}_r$ formulation, the next proposition shows that an optimal solution of $\tilde{R}_r$ with nonzero value is Pareto optimal.

PROPOSITION 3.6. *If there exists a vector $r \in \mathbb{R}^p$ such that $\tilde{x}$ is an optimal solution of $\tilde{R}_r$ with $\tilde{\psi}_r(\tilde{x}) < 0$, then $\tilde{x}$ is Pareto optimal for MOP.*

Proof. Assume that $x \in X$ satisfies $x \prec \tilde{x}$. Therefore, $f_i(x) \leq f_i(\tilde{x})$ for $i \in \{1, 2, \ldots, p\}$ with at least one strict inequality. It follows that $\tilde{\psi}_r(x) < \tilde{\psi}_r(\tilde{x}) < 0$, which contradicts the optimality of $\tilde{x}$ for the $\tilde{R}_r$ formulation. □

The same argument can be given to prove that a local optimal of $\tilde{R}_r$ with nonzero value is locally Pareto optimal.

4. A new algorithm for biobjective programming. This section focuses on the biobjective optimization problem BOP. BOP is the only instance of MOP that possesses an ordering property of the Pareto front. Based on this ordering property and on the aggregation approach presented in section 3, a new algorithm BIMADS is proposed to solve BOP. BIMADS essentially generates a sequence of single-objective formulations of BOP and solves them sequentially using the MADS algorithm [4] with increasingly stringent stopping criteria.

This section is divided as follows. An overview of the MADS algorithm is given in section 4.1 and BIMADS is presented in section 4.2. Convergence and uniformity analysis of BIMADS are proposed in section 4.3.

4.1. The MADS algorithm for single-objective optimization. MADS [4] is a direct search method for the minimization of a nonsmooth function $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ under general constraints $x \in \Omega \neq \emptyset \subseteq \mathbb{R}^n$. MADS is a generalization of Torczon's [25] pattern search algorithms. Pattern search algorithms rely on a fixed finite set of directions to explore the space of variables and the convergence analysis [3] is confined to these directions. MADS overcomes this limitation by allowing an infinite set of directions. We next summarize the main steps of MADS. The following definitions are from [4]. (The reader is invited to consult [4] for the specific details of this method.)

MADS is an iterative algorithm that attempts at each iteration to improve the current incumbent value (i.e., the best feasible objective function value found so far) by evaluating f on some trial points that lie on the *current mesh*.

DEFINITION 4.1. *At iteration k, the current mesh is defined to be the following union:*

$$M_k = \bigcup_{x \in S_k} \{x + \Delta_k^m D z : z \in \mathbb{N}^{n_D}\},$$

where S_k is the set of points where the objective function f had been evaluated by the start of iteration k.

The mesh is constructed from a finite set of n_D directions $D \subset \mathbb{R}^n$ scaled by a positive *mesh size parameter* $\Delta_k^m \in \mathbb{R}_+$. Each iteration of MADS consists of two steps. The first, called the SEARCH step, allows evaluation of f at any finite number of feasible mesh points to get eventually a better incumbent. Then the second step, called the POLL, is invoked. The POLL step consists of a local exploration of the space of optimization variables. The set of trial points considered during the POLL is called MADS *frame* and is denoted by P_k. P_k is constructed using a current incumbent solution x_k (called the *frame center*) and the poll and mesh size parameters Δ_k^p and Δ_k^m to obtain a positive spanning set of directions D_k. A formal definition of MADS *frame* P_k is given below.

DEFINITION 4.2. *At iteration k, the* MADS *frame is defined to be the set*

$$P_k = \{x_k + \Delta_k^m d : d \in D_k\} \subset M_k,$$

where D_k is a positive spanning set such that $0 \notin D_k$ and for each $d \in D_k$,

- *d can be written as a nonnegative integer combination of the directions in D: $d = Du$ for some vector $u \in \mathbb{N}^{n_{D_k}}$ that may depend on the iteration number k,*
- *the distance from the frame center x_k to a frame point $x_k + \Delta_k^m d \in P_k$ is bounded above by a constant times the poll size parameter: $\Delta_k^m \|d\| \leq \Delta_k^p \max\{\|d'\| : d' \in D\}$,*
- *limits (as defined in Coope and Price [10]) of the normalized sets $\mathcal{D}_k = \left\{\frac{d}{\|d\|} : d \in D_k\right\}$ are positive spanning sets.*

If the value of f at a trial feasible point x is less than the current incumbent value, then x is called an *improved mesh point*, and the iteration is called a *successful iteration*. The next iteration will be initiated with the newly found incumbent solution and with a mesh size parameter equal to or larger than the previous one. When the iteration fails in generating an improved mesh point, the mesh size parameter is reduced to increase the mesh resolution in order to allow the evaluation of f at trial points closer to the incumbent solution. The MADS algorithm is stated formally below.

A GENERAL MADS ALGORITHM

- INITIALIZATION: Let $x_0 \in \Omega$, $\Delta_0^m \leq \Delta_0^p$, D satisfy the requirements given in [4]. Set the iteration counter $k \leftarrow 0$.
- SEARCH AND POLL STEP: Perform the SEARCH and possibly the POLL steps (or only part of them) until an improved mesh point x_{k+1} is found on the mesh M_k (see Definition 4.1).
  - OPTIONAL SEARCH: Evaluate f on a finite subset of trial points on the mesh M_k.
  - LOCAL POLL: Evaluate f on the frame P_k (see Definition 4.2).
- PARAMETER UPDATE: Update Δ_{k+1}^m according to [4]. Set $k \leftarrow k + 1$ and go back to the SEARCH and POLL step.

The MADS convergence analysis ensures that some optimality conditions hold at a limit point $\hat{x}$ which is the limit of mesh local optimizers on meshes that get infinitely fine. A hierarchy of convergence results based on local smoothness of f and Ω near $\hat{x}$ is developed in [4]. In particular, if f is Lipschitz near $\hat{x}$, then $f^\circ(\hat{x}; d) \geq 0$ for every $d \in T_\Omega^H(\hat{x})$, where $T_\Omega^H(\hat{x})$ denotes the hypertangent cone [24] to Ω at $\hat{x}$.

Our new algorithm uses MADS as a tool to solve single-objective blackbox optimization problems.

4.2. The BIMADS algorithm for biobjective optimization. The general scheme of BIMADS is presented in Figure 4.1, and is more fully described in the following paragraphs. BIMADS is an iterative algorithm that constructs sets of points that approximate the Pareto optimal set $X_\mathcal{P}$. At each iteration, the set of nondominated points (with respect to all points generated so far) is denoted by $X_\mathcal{L}$. The image under the mapping F of $X_\mathcal{L}$ is denoted by $Y_\mathcal{L} \in \mathbb{R}^p$. $Y_\mathcal{L}$ gives an approximation of the Pareto front $Y_\mathcal{P}$.

At the initialization step, the algorithm solves the two single-objective problems:

$$\min_{x \in X} f_1(x) \quad \text{and} \quad \min_{x \in X} f_2(x) \tag{4.1}$$

INITIALIZATION:

- Apply the MADS algorithm from x_0 to solve $\min_{x\in X} f_1(x)$ and $\min_{x\in X} f_2(x)$.
- Let $X_{\mathcal{L}} = \{x^1, x^2, \ldots, x^J\}$ be an ordered list of pairwise nondominated points such that $f_1(x^1) < f_1(x^2) < \cdots < f_1(x^J)$ and $f_2(x^1) > f_2(x^2) > \cdots > f_2(x^J)$.
  Initialize the weight $w(x) = 0$ for all $x \in X$ and, let $\delta > 0$.

MAIN ITERATIONS: Repeat

- REFERENCE POINT DETERMINATION:
  – If $J > 2$, let $\hat{\jmath} \in \operatorname{argmax}_{j=2,\ldots,J-1} \delta^j = \frac{||F(x^j)-F(x^{j-1})||^2+||F(x^j)-F(x^{j+1})||^2}{w(x^j)+1}$, and define the reference point $r = (f_1(x^{\hat{\jmath}+1}), f_2(x^{\hat{\jmath}-1}))$.
  – If $J = 2$, let $x^{\hat{\jmath}} = x^2$, define the reference point $r = (f_1(x^2), f_2(x^1))$, and set $\delta^{\hat{\jmath}} = \frac{||F(x^2)-F(x^1)||^2}{w(x^2)+1}$.
  – If $J = 1$, let $x^{\hat{\jmath}} = x^1$, $\delta^{\hat{\jmath}} = \frac{\delta}{w(x^{\hat{\jmath}})+1}$ and apply the MADS algorithm from $x^{\hat{\jmath}}$ to solve $\min_{x\in X} f_1(x)$ and $\min_{x\in X} f_2(x)$. Terminate MADS when the mesh size parameter Δ^m drops below $\Delta(\delta^{\hat{\jmath}}) = O(\delta^{\hat{\jmath}})$ and continue to the step UPDATE $X_{\mathcal{L}}$.
- SINGLE-OBJECTIVE FORMULATION MINIMIZATION:
  Solve a single-objective formulation R_r using the MADS algorithm from starting point $x^{\hat{\jmath}}$. Terminate MADS when the mesh size parameter Δ^m drops below $\Delta(\delta^{\hat{\jmath}}) = O(\delta^{\hat{\jmath}})$ or if a maximal number of objective evaluations is attained.
- UPDATE $X_{\mathcal{L}}$:
  Add to $X_{\mathcal{L}}$ all nondominated points found in the current iteration, remove dominated points from $X_{\mathcal{L}}$, and order the resulting list of points.
  Increase weights: $w(x^{\hat{\jmath}}) \leftarrow w(x^{\hat{\jmath}}) + 1$ for each $x \in X_{\mathcal{L}}$.

FIG. 4.1. *Scheme of the* BIMADS *algorithm for the biobjective programming.*

using the MADS algorithm from a user-defined starting point $x_0 \in X$. A first list $X_{\mathcal{L}}$ of nondominated points is obtained from the set of all trial mesh points generated by the two runs of MADS. The cardinality of this set is denoted by J. The sets $X_{\mathcal{L}}$ and $Y_{\mathcal{L}}$ are sorted in ascending order of f_1 value. The ordering property gives a simple way to measure the gaps between nondominated points by evaluating Euclidean distances between successive solutions in $Y_{\mathcal{L}}$. This strategy allows the evaluation of the solutions coverage along $Y_{\mathcal{L}}$ in order to determine a reference point. Note that solving problems with more than two objective functions requires the use of other techniques to measure the coverage in the absence of ordering property. Alternatively, a recursive application of BIMADS could be considered. In future work, we aim at studying the different alternatives and selecting the best one. Each iteration of BIMADS consists of three steps. First, the ordered list $Y_{\mathcal{L}}$ is used to identify a reference point r in the space of objectives. If $J > 2$, the strategy considers the weighted sum δ^j of squared distances from each nondominated point $F(x_j) \in Y_{\mathcal{L}}$ to its predecessor $F(x_{j-1})$ and successor $F(x_{j+1})$ for $j = 2, 3, \ldots, J-1$. Hence, a point $F(x^{\hat{\jmath}})$ is identified from the list $Y_{\mathcal{L}}$ that maximizes the measure δ^j. If $J = 2$, $x^{\hat{\jmath}}$ is set to x^2, the reference point r is set to $(f_1(x^2), f_2(x^1))$, and $\delta^{\hat{\jmath}}$ is set to be equal to the weighted squared distance between the two nondominated points. The weights are updated in a way to reduce frequent definitions of r around the same point by increasing $w(x^j)$ by one at the end

of the iteration. If $J = 1$, i.e., if a single point x^1 dominates all others generated so far, then the algorithm solves again the two single-objective problems (4.1).

Two measures of the uniformity distribution are introduced:

- the *coverage measure* $\tilde{c} = \max_{j=1,\ldots,J} \delta^j$ and
- the *weighted coverage measure* $\tilde{c}_w = \max_{j=1,\ldots,J} \frac{\delta^j}{w(x^j)+1}$.

A small value of the coverage measure indicates that the Pareto front approximation does not contain large gaps.

The left part of Figure 4.2 illustrates the reference point r selection when $J > 2$. The symbol "$\cdot$" is used for points generated by BiMads in the objective space, the symbol "$*$" is used for nondominated points found by the algorithm.

The second step of the iteration consists of solving the single-objective formulation R_r using the Mads algorithm. The image of the trial points produced by this algorithm will most likely lie in the dominance zone with respect to r. The right part of Figure 4.2 illustrates some trial points generated by Mads. Each run of Mads terminates when the mesh size parameter Δ^m drops below $\Delta(\delta^j) = O(\delta^j)$ or if a maximal number of objective evaluations is attained.

Finally, at the end of each iteration the set of nondominated points $X_{\mathcal{L}}$ is updated. New nondominated points are added and dominated ones are removed. The new set is represented in Figure 4.2 by stars.

These three steps are iterated by BiMads. In practice, termination is either set to a fixed number of iterations, or when δ^j drops below a predetermined threshold. Observe that other single-objective optimization algorithms could be applied for solving R_r. Nevertheless, we choose Mads to solve the single-objective formulation since it is designed for blackbox optimization problems, which corresponds to the practical problems that we plan to solve in future works and is still providing rigorous convergence analysis for these blackbox problems.

4.3. Convergence analysis. In this section, the quality of points produced by BiMads is studied and convergence results for BiMads are presented. We will make the standard assumptions of blackbox optimization that all trial points generated by the algorithm lie in a bounded set. The following theorem shows that BiMads produces points satisfying the necessary optimality conditions for biobjective opti-

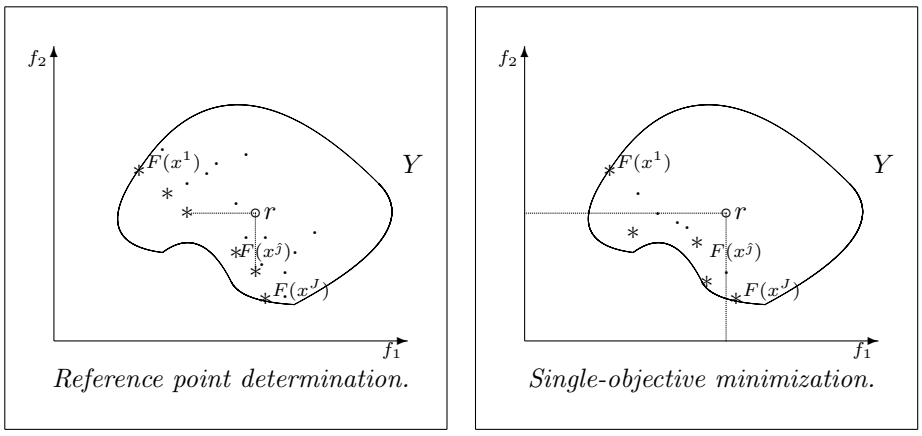

FIG. 4.2. *An iteration of* BiMads.

mization presented in section 2.3 when the objective functions are Lipschitz. We denote by R_r a single-objective formulation of BOP at some reference point $r \in \mathbb{R}^p$, as defined in Definition 3.1.

THEOREM 4.3. *Let f_1 and f_2 be Lipschitz near a limit point $\hat{x} \in X$ generated by* MADS *applied to a single-objective formulation R_r of BOP at some reference point $r \in \mathbb{R}^p$, then*

$$\text{for any } d \in T_X(\hat{x}), \text{there exists } j \in \{1,2\} \text{ such that } f_j^\circ(\hat{x};d) \geq 0,$$

where $T_X(\hat{x})$ is the tangent cone at $\hat{x}$.

Proof. The solution $\hat{x}$ produced by MADS is a stationary point of R_r on X [4], i.e., for all $d \in T_X(\hat{x}), R_r^\circ(\hat{x},d) \geq 0$. The second condition appearing in the definition of single-objective formulation in subsection 3.1 ensures that for any $d \in T_X(\hat{x})$, there exists an index $j \in \{1,2\}$ for which $f_j^\circ(\hat{x};d) \geq 0$. ∎

A corollary to this result is derived when f_1 and f_2 are strictly differentiable at $\hat{x}$.

COROLLARY 4.4. *Let f_1, f_2, and ψ_r be strictly differentiable at a limit $\hat{x} \in X$ generated by* MADS *applied to a single-objective formulation R_r of BOP at some reference point $r \in \mathbb{R}^p$, then $\hat{x}$ is KKT-properly efficient solution of BOP:*

$$\text{for any } d \in T_X(\hat{x}), \text{there exists } j \in \{1,2\} \text{ such that } \nabla f_j(\hat{x})^T d \geq 0,$$

where $T_X(\hat{x})$ is the tangent cone at $\hat{x}$.

Proof. Let $d \in T_X(\hat{x})$. According to [4], $\hat{x}$ is a KKT stationary point of R_r on X. Hence, $\nabla \psi_r(\hat{x})^T d \geq 0$. The contraposition of Theorem 3.2 ensures that there exists $j \in \{1,2\}$ such that $\nabla f_j(\hat{x})^T d \geq 0$. ∎

In addition to convergence analysis, an analysis of uniformity of solutions distribution in $Y_{\mathcal{L}}$ may be derived. The uniformity analysis makes use of the *weighted coverage measure* $\tilde{c}_w$ introduced in section 4.2. We introduce the index η to represent the BIMADS iteration number. The next theorem shows that the $\tilde{c}_w^\eta$ goes to zero with an infinite number of MADS runs.

THEOREM 4.5. *The weighted coverage measure $\tilde{c}_w^\eta$ of the pairwise nondominated points list $Y_{\mathcal{L}}^\eta$ found at* MADS *run η satisfies $\lim_{\eta\to\infty} \tilde{c}_w^\eta = 0$.*

Proof. By contradiction, suppose that there exists some scalar $L > 0$ for which $c_w^\eta > L$ for all iterations $\eta > 0$. Therefore, we get $\delta^{\hat{\jmath}^\eta} \geq \frac{\delta^{\hat{\jmath}^\eta}}{w(\hat{\jmath}^\eta)+1} > L$ for all iterations $\eta > 0$. Furthermore, since each run η of MADS terminates when the mesh size parameter Δ^m drops below $\Delta(\delta^{\hat{\jmath}^\eta}) = O(\delta^{\hat{\jmath}^\eta})$, it follows that

$$\text{there exists } \underline{\delta} > 0 : \Delta_k^\eta \geq \underline{\delta} \text{ for all iterations } k \text{ and for all runs } \eta, \tag{4.2}$$

where Δ_k^η is the mesh size at iteration k for the MADS run number η. Moreover, since the feasible set X is bounded, there exists $\bar{\delta} > 0$ such that $\Delta_k^\eta \leq \bar{\delta}$ for all $\eta > 0$ and $k > 0$. Let x_0^η be the starting point of run η. We want to show that under the aforementioned assumptions, all trial points lie on a mesh which is independent of the run and iteration numbers.

Consider $x_{k_0}^{\eta_0}$ the k_0th trial point generated in run η_0. According to [4], we have

$$x_{k_0}^{\eta_0} = x_0^{\eta_0} + D \sum_{i=0}^{k_0-1} \Delta_i^{\eta_0} z_i^{\eta_0},$$

where D is the set of $n_D \in \mathbb{N}$ directions satisfying the requirements in [4], $z_i^{\eta_0} \in \mathbb{N}^{n_D}$, and $\Delta_i^{\eta_0}$ is the mesh size at iteration i of the MADS run η_0. The starting point $x_0^{\eta_0}$ was generated as η_1th trial point of a prior run $0 \le \eta_1 < \eta_0$. Indeed, from $x_{k_0}^{\eta_0}$, we can construct the finite series of points

$$x_{k_0}^{\eta_0}, x_0^{\eta_0} = x_{k_1}^{\eta_1}, x_0^{\eta_1} = x_{k_2}^{\eta_2}, \ldots, x_0^{\eta_p} = x_{k_{p+1}}^{0}, x_0^0,$$

such that $\eta_0 > \eta_1 > \cdots > \eta_p > 0$ are decreasing integers and $x_{k_l}^{\eta_l}$ was generated at run η_l from the starting point $x_0^{\eta_l}$. This starting point was generated as the η_{l+1}th trial point of run η_{l+1}, i.e., $x_0^{\eta_l} = x_{k_{l+1}}^{\eta_{l+1}}$. $x_0^{\eta_p}$ was generated as the k_{p+1}th trial point of the first run. With this notation, we get that for $l = 1, 2, \ldots, p$,

$$x_{k_l}^{\eta_l} = x_0^{\eta_l} + D \sum_{i=0}^{k_l-1} \Delta_i^{\eta_l} z_i^{\eta_l},$$

where $z_i^{\eta_l} \in \mathbb{N}$. Therefore, we get

$$\begin{aligned}
x_{k_0}^{\eta_0} &= x_0^{\eta_0} + D \sum_{i=0}^{k_0-1} \Delta_i^{\eta_0} z_i^{\eta_0} \\
&= x_{k_1}^{\eta_1} + D \sum_{i=0}^{k_0-1} \Delta_i^{\eta_0} z_i^{\eta_0} \\
&= x_0^{\eta_1} + D \left(\sum_{i=0}^{k_0-1} \Delta_i^{\eta_0} z_i^{\eta_0} + \sum_{i=0}^{k_1-1} \Delta_i^{\eta_1} z_i^{\eta_1} \right) \\
&= x_{k_2}^{\eta_2} + D \left(\sum_{i=0}^{k_0-1} \Delta_i^{\eta_0} z_i^{\eta_0} + \sum_{i=0}^{k_1-1} \Delta_i^{\eta_1} z_i^{\eta_1} \right) \\
&\quad \cdots \\
&= x_0^0 + D \left(\sum_{l=0}^{p+1} \sum_{i=0}^{k_l-1} \Delta_i^{\eta_l} z_i^{\eta_l} \right).
\end{aligned}$$

Torczon's [25] showed that if $\Delta_i^{\eta_l}$ are multiple of integer powers of some rational number (which is the case in the present algorithm since Δ_0^{η} are identical for all runs η), and if all iterates lie in a bounded set, and if (4.2) holds, then $x_{k_0}^{\eta_0}$ belongs to a mesh that depends on $D, \underline{\delta}, \bar{\delta}$. Thus Torczon's proof shows that $x_{k_0}^{\eta_0}$ belongs to a mesh that is independent of the iteration and run numbers. Consequently, there exists a point selected infinitely many times by BIMADS around which to refine $Y_{\mathcal{L}}^{\eta}$ without varying $\delta^{\hat{\jmath}^{\eta}}$ value. Hence, $w(\hat{\jmath}^{\eta}) \to \infty$ and thus $c_w^{\eta} \to 0$. This contradicts the assumption that c_w^{η} is bounded below by $L > 0$. ∎

5. Numerical results on test problems. The behavior of BIMADS is evaluated using test problems from Deb [15]. The functions of these biobjective problems are constructed in such a way that

$$\begin{aligned}
&f_1(x) = f_1(x_1, x_2, \ldots, x_m) \quad \text{and} \\
&f_2(x) = g(x_{m+1}, x_{m+2}, \ldots, x_n) h(f_1(x_1, x_2, \ldots, x_m), g(x_{m+1}, x_{m+2}, \ldots, x_n)).
\end{aligned}$$

The function f_1 depends on m variables $x_1, x_2, \ldots, x_m$ with $m < n$ and f_2 is a function of n variables. The function g depends on $n - m$ variables $x_{m+1}, x_{m+2}, \ldots, x_n$ which do not appear in the function f_1; h is a function of the function values f_1 and g.

Difficulties in test problems are introduced by choosing appropriate functions f_1, g, and h [15]:

- Convexity and discontinuity in the Pareto front is handled by the function h.
- Convergence to the true Pareto front is handled by the function g.
- Diversity in the Pareto front is handled by the function f_1.

The test problems that we consider are defined through specific choices of f_1, g, and h.

The algorithm is coded in C++ and uses the NOMAD 0.6 [12] implementation of MADS as a subroutine to solve each single-objective formulation. The point $x_0 = (0.51, 0.51)$ is used as a starting point to initialize the algorithm, and the initial mesh is set to 0.01. Two termination criteria are selected for each run of MADS on the single-objective formulations:

- Poll size termination: the run ends when the mesh size parameter Δ^m drops below $\frac{\delta^j}{1000}$, where δ^j is defined in Figure 4.1.
- Truth evaluations termination: the run ends after 50 evaluations of the reformulated objective function unless indicated explicitly.

In our numerical experiments, BIMADS generates either 10 or 30 single-objective formulations, and therefore, calls MADS 10 or 30 times. This strategy generates at most 500 and 1500 evaluations of objective function, respectively.

For each test problem, a figure containing four graphs is presented: two of them for each single-objective formulations, and two of them for the runs involving 10 or 30 calls to MADS.

Each graph represents the function values of all trial points generated by BIMADS using the "$\cdot$" symbol. The symbol "$*$" is used for nondominated points found by the algorithm. The curves represent the global and local Pareto fronts, or the boundary of the image Y of X. For each series of experiments, the quality of the approximation $Y_{\mathcal{L}}$ provided by the algorithm BIMADS is discussed according to the two key issues presented in section 2: convergence of solutions to the Pareto curve $Y_{\mathcal{P}}$ and uniformity of the solutions distribution in $Y_{\mathcal{L}}$. The coverage measure $\tilde{c}$ introduced in (4.2) is displayed for each test problems.

5.1. Convex and nonconvex of Pareto fronts. Convexity of Pareto front is affected by the function h. Deb [15] proposes the following function:

$$h(f_1, g) = \begin{cases} 1 - (\frac{f_1}{g})^\alpha & \text{if } f_1 \leq g, \\ 0 & \text{otherwise.} \end{cases} \tag{5.1}$$

The parameter α controls the shape of the Pareto front. The Pareto front is nonconvex if $\alpha > 1$ and convex otherwise. Note that the global Pareto solutions are obtained at the global minimum of the function g. We consider the following functions for g and f_1:

$$g(x_2) = \begin{cases} 4 - 3\exp\left(-\dfrac{x_2 - 0.2}{0.02}\right)^2 & \text{if } 0 \leq x_2 \leq 0.4, \\ 4 - 2\exp\left(-\dfrac{x_2 - 0.7}{0.2}\right)^2 & \text{if } 0.4 \leq x_2 \leq 1, \end{cases}$$

$$f_1(x_1) = 4x_1,$$

where both x_1 and $x_2 \in [0, 1]$.

Three series of tests are generated with different values of α. In the first test, the global Pareto front is convex. In the second one, the global Pareto front is nonconvex. Finally, in the third test, the global Pareto front is convex but the local Pareto front is nonconvex.

Convex global Pareto front. By setting α to 0.25 in problem (5.1), we obtain a biobjective problem with the convex global Pareto front. Results obtained by applying BiMads with 10 runs of Mads and 30 runs of Mads are illustrated in Figure 5.1. The figure shows that all nondominated points $Y_{\mathcal{L}}$ found by BiMads belong to the global Pareto curve $Y_{\mathcal{P}}$ for all series of test. Furthermore, the figure suggests that BiMads achieves a well distributed and well spread nondominated points in the global Pareto front for each formulation.

Nonconvex global Pareto front. By setting α to 4 in problem (5.1), we obtain a biobjective problem with nonconvex global Pareto front. Results obtained by applying BiMads with 10 runs of Mads and 30 runs of Mads are shown in Figure 5.2. Except for the first test corresponding to results of BiMads with 10 runs of Mads applied to single-objective normalized formulation, all tests generate nondominated solutions $Y_{\mathcal{L}}$ in the global Pareto front $Y_{\mathcal{P}}$. A well spread Pareto solutions is obtained using 30 runs of Mads.

Nonconvex local optimal front and convex global front. We set $\alpha = 0.25 + 3.75(g(x_2) - 1)$ [15] in problem (5.1). The resulting problem is hard to solve for algorithms that exploit the shape of the Pareto curve [15]. Results obtained by applying BiMads with 10 runs of Mads and 30 runs of Mads are shown in Figure 5.3. Using 10 runs of Mads, BiMads generates a set of nondominated points $Y_{\mathcal{L}}$ close to the Pareto curve $Y_{\mathcal{P}}$. The approximation quality is better using the single-objective product formulation. Using 30 runs of Mads, all nondominated points found by

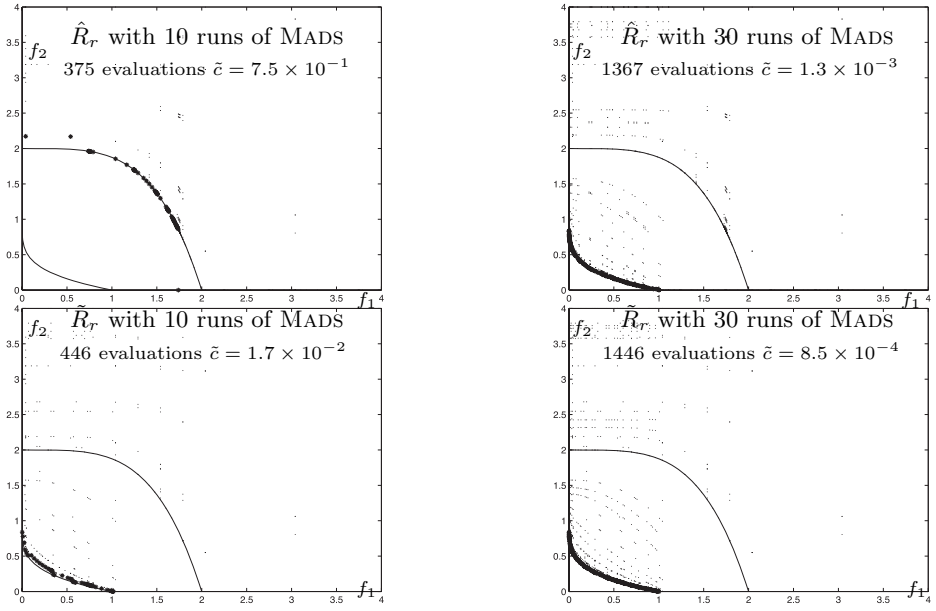

FIG. 5.3. *Nonconvex local optimal front and convex global front:* BIMADS *with* 10 *and* 30 *optimization runs of* MADS.

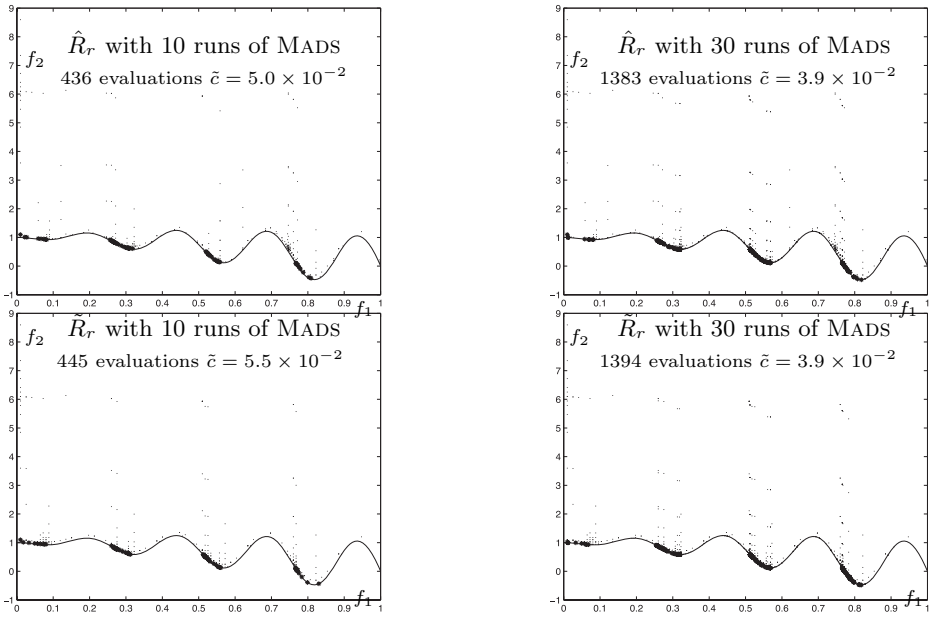

FIG. 5.4. *Discontinuous global front:* BIMADS *with* 10 *and* 30 *optimization runs of* MADS.

BIMADS lie on the global Pareto curve, i.e., $Y_{\mathcal{L}} \subset Y_{\mathcal{P}}$. The nondominated points $Y_{\mathcal{L}}$ are well spread among the Pareto curve.

5.2. Discontinuous Pareto front. Deb [15] proposes a family of test problems in which the Pareto front is discontinuous:

$$\begin{aligned} h(f_1, g) &= 1 - \left(\frac{f_1}{g}\right)^{\alpha} - \tfrac{f_1}{g}\sin(2\pi q f_1), \\ f_1(x_1) &= x_1, \\ g(x_2) &= 1 + 10x_2, \end{aligned}$$

where x_1, $x_2 \in [0, 1]$, $\alpha > 0$, and q is the number of discontinuous regions. We use the same values for α and q as in [15], i.e., $\alpha = 2$ and $q = 4$. Results obtained by applying BIMADS with 10 and 30 runs of MADS are shown in Figure 5.4.

Figure 5.4 shows that BIMADS generates nondominated solutions $Y_{\mathcal{L}}$ in all four discontinuous Pareto regions. The solutions $Y_{\mathcal{L}}$ are well distributed among the Pareto curve $Y_{\mathcal{P}}$. Table 5.1 displays the coverage measure $\tilde{c}$ for each of the four disjoint regions. The table also reports the mean value μ and standard deviation σ of $\tilde{c}$ over these regions. Moreover, using 30 optimization runs of MADS, results obtained by applying $\tilde{R}_r$ formulation are slightly better than those obtained by applying $\hat{R}_r$ formulation.

5.3. Biased search space. In order to make the convergence to the Pareto front more problematic, Deb [15] proposes the following function g:

$$g(x_2) = 1 + x_2^{\gamma},$$

TABLE 5.1
Coverage measure $\tilde{c}$ *of each discontinuous Pareto region.*

$\tilde{c}$	$\hat{R}_r$ formulation					
Region	1	2	3	4	μ	σ
10 runs	.0078	.0039	.0098	.0433	.0162	.0182
30 runs	.0100	.0054	.0040	.0025	.0054	.0032
$\tilde{c}$	$\tilde{R}_r$ formulation					
Region	1	2	3	4	μ	σ
10 runs	.0076	.0033	.0091	.0552	.0188	.0243
30 runs	.0012	.0030	.0029	.0059	.0032	.0019

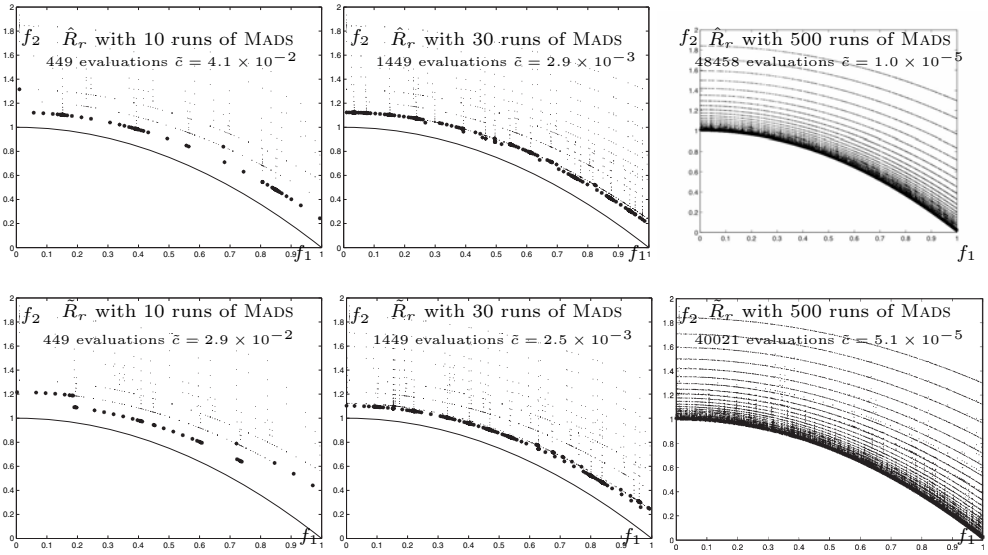

FIG. 5.5. *Biased search:* BIMADS *with* 10, 30, *and* 500 *optimization runs of* MADS.

where γ is a real parameter that controls the biasness in the search space. To complete the illustrative example, the following functions for f_1 and h are used [15]:

$$f_1(x_1) = x_1,$$
$$h(f_1, g) = 1 - \left(\frac{f_1}{g}\right)^2.$$

Results obtained for $\gamma = 0.25$ by applying BIMADS with 10 and 30 runs of MADS are shown in the top part of Figure 5.5. The nondominated solutions found by the algorithm approach the global Pareto curve; but no solution lies on the Pareto curve. Deb [15] observes that if $\gamma < 1$, then the density of solutions increases by moving away from the Pareto front. Hence, by randomly generating 50,000 solutions for $\gamma = 0.25$, not even one solution lies near the Pareto optimal front [15]. For comparison purposes, the maximal number of function evaluations was raised to 50,000 (i.e., the number of runs of MADS was increased to 500 and the maximal number of function evaluations was raised to 100 for each run). Results are shown in the bottom of Figure 5.5. By increasing the objective evaluations number, all nondominated points $Y_{\mathcal{L}}$ found by BIMADS lie on the global Pareto front $Y_{\mathcal{P}}$. The points are well spread along $Y_{\mathcal{P}}$.

5.4. Nonuniformly represented Pareto front. Nonuniformity of solution along the Pareto front is achieved by choosing a nonlinear function for f_1. An example

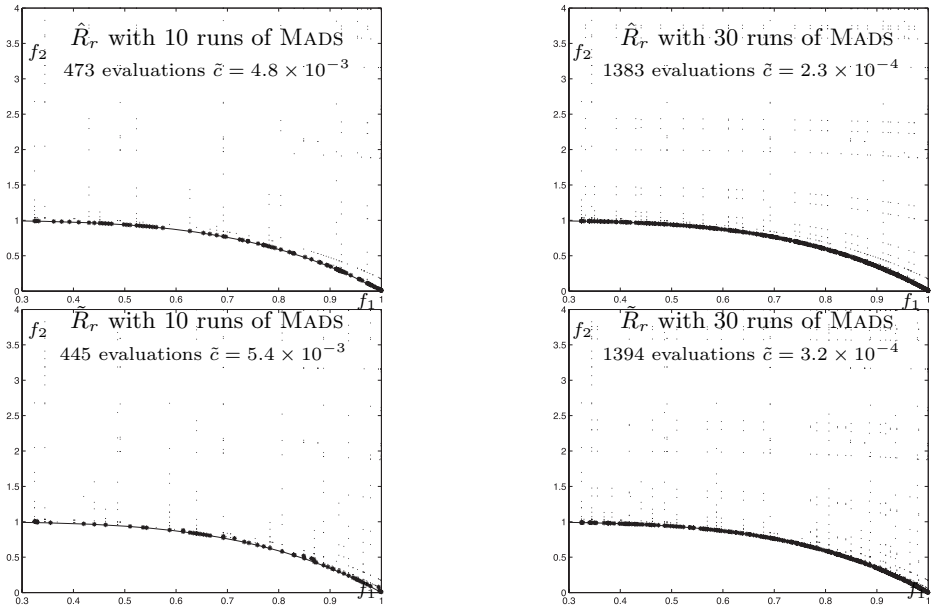

FIG. 5.6. *Nonuniformly represented Pareto front:* BIMADS *with* 10 *and* 30 *optimization runs of* MADS.

is given in [15] with the following functions:

$$f_1(x_1) = 1 - \exp(-4x_1)\sin^4(5\pi x_1),$$

$$h(f_1, g) = \begin{cases} 1 - (\frac{f_1}{g})^4 & \text{if } f_1 \leq g, \\ 0 & \text{otherwise,} \end{cases}$$

$$g(x_2) = \begin{cases} 4 - 3\exp(-\frac{x_2 - 0.2}{0.02})^2 & \text{if } 0 \leq x_2 \leq 0.4, \\ \\ 4 - 2\exp(-\frac{x_2 - 0.7}{0.2})^2 & \text{if } 0.4 \leq x_2 \leq 1. \end{cases}$$

Using 500 uniformly-spaced points in x_1, Deb [15] shows that the corresponding Pareto curve is biased for solutions for which f_1 value is near 1: most of the generated solutions have the function value $f_1 = 1$. Thereby, solutions cluster around $f_1 = 1$ values. Results obtained by applying BIMADS with 10 and 30 runs of MADS are shown in Figure 5.6. BIMADS overcomes the bias around $f_1 = 1$ values. Both methods find well spread nondominated solutions $Y_{\mathcal{L}}$ belonging to the Pareto curve $Y_{\mathcal{P}}$. With 30 iterations run, the Pareto solutions are more uniformly distributed.

6. Discussion. We proposed a new solution approach for MOP ensuring some first-order necessary optimality conditions for nonsmooth functions. In addition to the convergence analysis, a new analysis of uniformity is proposed. Our new algorithm BIMADS for biobjective optimization BOP was presented and applied to six problems from the literature designed to highlight some intrinsic difficulties of BOP. The algorithm performance is evaluated by studying the quality of solution set in terms of proximity to the Pareto front and uniformity of solutions distribution.

Results for all test problems are summarized in Table 6.1. The entries of Table 6.1 are mean value μ and standard deviation σ of the coverage measure $\tilde{c}$ over the six test problems.

TABLE 6.1
Coverage measure $\tilde{c}$ *for test problems.*

$\tilde{c}$	$\hat{R}_r$ formulation		$\tilde{R}_r$ formulation	
Runs	μ	σ	μ	σ
10 runs	.1714	.349	.0177	.0105
30 runs	.0025	.002	.0017	.0013

Table 6.1 shows that the uniformity of Pareto solutions distribution is sensitive to the number of runs and the formulation adopted. The best results are obtained by applying 30 runs of MADS using the $\tilde{R}_r$ formulation. This may be in part due to the fact that $\tilde{R}_r$ does not introduce additional nonsmoothness as $\hat{R}_r$ does.

In future work, we plan to apply BIMADS to larger and nonsmooth real engineering problems. We also plan to study the case where blackbox constraints are present. A simple way to do so would be to treat the constraints by the barrier approach to reject all infeasible points as done by MADS. However, the convergence analysis would not be trivial for nonsmooth functions. Another aspect that we wish to study is the use of parallelism in the biobjective framework, and the extension to problems with more than two objective functions.

WELL POSED OPTIMIZATION PROBLEMS AND NONCONVEX CHEBYSHEV SETS IN HILBERT SPACES*

FRANCESCA FARACI† AND ANTONIO IANNIZZOTTO†

Abstract. A result on the existence and uniqueness of metric projection for certain sets is proved, by means of a saddle point theorem. A conjecture, based on such a result and aiming for the construction of a nonconvex Chebyshev set in a Hilbert space, is presented.

Key words. Chebyshev sets, Hilbert spaces, metric projections

DOI. 10.1137/06067496X

1. Introduction.

In the present paper we deal with the classical problem of convexity of Chebyshev sets: we are going to present a conjecture, aimed at the construction of a nonconvex Chebyshev set in a Hilbert space. First, let us introduce some definitions and results which we are going to employ.

In what follows, we follow the surveys by Vlasov [10] and Balaganskiĭ and Vlasov [2]; we also refer the reader to a recent paper by Cobzaş [3] for a state-of-the-art description of the theory. Let X be a (real) Banach space, M be a subset of X: for every $x \in X$, we define the *distance* from x to M as

$$d(x, M) := \inf_{y \in M} \|x - y\|.$$

Also, we define the *metric projection* onto M as the set-valued function $P_M : X \to 2^M$ mapping $x \in X$ into the (possibly empty) set

$$P_M(x) := \{y \in M \ : \ \|x - y\| = d(x, M)\}.$$

DEFINITION 1. *A subset M of X is a* Chebyshev set *if $P_M(x)$ is a singleton for every $x \in X$.*

An important family of Chebyshev sets, in certain Banach spaces, is that of *convex closed* sets, as the following classical result proves (in the form of a characterization).

THEOREM 1 (see [10, Theorem 0.6]). *The following are equivalent:*

- *X is strictly convex and reflexive;*
- *every convex closed subset of X is Chebyshev.*

Obviously, every Chebyshev set in a Banach space is closed, but it is not known, in general, whether a Chebyshev set is necessarily convex. So, the following question is a natural one and represents one of the most celebrated and challenging open problems in the theory of best approximation: *does a class of Banach spaces containing nonconvex Chebyshev sets exist?*

For strictly convex, smooth, finite-dimensional spaces, the answer is negative, as proved by Efimov and Stechkin in [5]. However, the problem is still open in the case of infinite-dimensional Banach spaces. Note that completeness is a fundamental

assumption here: for instance, Johnson in [7] has proved the existence of a nonconvex Chebyshev set in a pre-Hilbert space with infinite dimension.

A partial answer is known under a twofold restriction, that is, for the case of *approximatively compact* Chebyshev sets in uniformly convex, smooth spaces. We will rapidly overview this result, since it will be useful in what follows. Let us give the following definition.

DEFINITION 2. *Let M be a subset of X, x be a point of X: a* minimizing sequence *in M for x is a sequence $\{y_n\}$ in M such that $\|x - y_n\| \to d(x, M)$. M is* approximatively compact *if, for every $x \in X$, each minimizing sequence in M for x admits a subsequence $\{y_{n_k}\}$ converging to an element of M.*

We note that, in the above framework, the limit of $\{y_{n_k}\}$ lies in $P_M(x)$. Under such restrictions, Efimov and Stechkin proved in [6] the following result.

THEOREM 2. *Let X be a uniformly convex, smooth Banach space, and M be a Chebyshev set in X. Then, the following are equivalent:*

- *M is convex;*
- *M is approximatively compact;*
- *M is sequentially weakly closed.*

We observe that, whenever M is a Chebyshev set, approximative compactness is equivalent to the following property for all $x \in X$:

(S) each minimizing sequence in M for x converges to an element of M.

Obviously, the limit of each minimizing sequence in M for x is the unique point of $P_M(x)$.

In particular, we are interested in the problem of convexity of Chebyshev sets in Hilbert spaces, which was studied by Asplund in [1]. In [8], Klee put forward the conjecture that, in an infinite-dimensional Hilbert space, nonconvex Chebyshev sets do exist. To support his conjecture, he proposed the following example: in the Hilbert space ℓ^2, let

$$K := \left\{ \{x_n\} \in \ell^2 \ : \ \sum_{n=1}^{\infty} n x_n^2 < 1 \right\}$$

and define

$$M := \left\{ \{x_n\} \in \ell^2 \ : \ d(\{x_n\}, K) \geq 1 \right\};$$

then M is not convex and, for every $\{x_n\} \notin K$, $P_M(\{x_n\})$ is a singleton, while for $\{x_n\} \in K$, $P_M(\{x_n\}) = \emptyset$.

Our approach is similar to that of Klee, though set in a more general framework. It is based on the following result (see section 2 for the proof).

THEOREM 3. *Let X be a Hilbert space, C be a nonempty subset of X, K be the closed convex hull of C, and $x_0 \in X \setminus K$. Then, for all real $t > 0$, denoting*

$$M_t := \{ y \in X \ : \ d(y, C) \geq t \},$$

the set $P_{M_t}(x_0)$ is a singleton, towards which each minimizing sequence in M_t for x_0 converges.

In connection with the above result, we present a conjecture.

CONJECTURE 1. *There exist a Hilbert space X, a subset C of X, and a real number $t > 0$ such that the set M_t satisfies the following conditions:*

(A_1) *M_t is not convex;*

(A_2) *for every x lying in the closed convex hull of C, $P_{M_t}(x)$ is a singleton.*

Our motivation is the following: suppose X, C, and t comply with Conjecture 1; then, due to Theorem 3, M_t would be a nonconvex Chebyshev set in X.

We believe that our conjecture is likely to be proved, as, due to the definition of M_t, condition (A_1) is very easy to fulfill (the same is not true for condition (A_2), of course). Also, we observe that, by Theorem 2, if Conjecture 1 is true, then M_t cannot be approximatively compact (or, equivalently, sequentially weakly closed): that is, since condition (S) holds for all $x \notin K$, there must be at least one point $x \in K$ and a minimizing sequence in M_t for x which does not converge.

Our result relies on the general method introduced by Ricceri in [9], where some minimization problems, related to C^1 functionals with locally Lipschitz derivative, are studied following a new approach based on a classical saddle point theorem, which we recall here in a form suitable to our purposes.

THEOREM 4 (see [11, Theorem 49.A]). *Let Λ be a compact real interval, and $\Phi : X \times \Lambda \to \mathbb{R}$ be a function such that*

- *$\Phi(\cdot, \lambda)$ is continuous and convex for all $\lambda \in \Lambda$;*
- *$\Phi(x, \cdot)$ is continuous and concave for all $x \in X$;*
- *there exists $\lambda_0 \in \Lambda$ such that $\Phi(\cdot, \lambda_0)$ is coercive.*

Then there exists a pair $(\bar{x}, \bar{\lambda}) \in X \times \Lambda$ such that

$$\Phi(\bar{x}, \bar{\lambda}) = \min_{x \in X} \Phi(x, \bar{\lambda}) = \max_{\lambda \in \Lambda} \Phi(\bar{x}, \lambda).$$

2. The results. Our first step is the following general result.

THEOREM 5. *Let X be a Hilbert space, C be a nonempty subset of X, $x_0 \in X$, and for all $\lambda \in [0, 1]$ let $I_\lambda : X \to \mathbb{R}$ be defined by*

$$I_\lambda(x) = \|x - x_0\|^2 - \lambda d^2(x, C).$$

Moreover, assume the following condition:

(D) *x_0 is not a global minimizer of the functional I_1.*

Then there exists a positive $\tau \in \mathbb{R} \cup \{+\infty\}$, $\tau > d(x_0, C)$ such that for all $t \in]d(x_0, C), \tau[$, denoting

$$M_t := \{y \in X \ : \ d(y, C) \geq t\},$$

the set $P_{M_t}(x_0)$ is a singleton, towards which each minimizing sequence in M_t for x_0 converges.

Proof. First we prove that the functional I_1 is convex: indeed, it can be expressed as

$$I_1(x) = \sup_{y \in C} \left[2\langle y - x_0, x\rangle + \|x_0\|^2 - \|y\|^2\right],$$

so it is convex as the supremum of a family of convex functions. From this, it readily follows that I_λ is strictly convex for all $\lambda \in [0, 1[$.

We denote by Q the set of global minimizers of I_1, and we put

$$\rho := d(x_0, Q) \quad (\rho = +\infty \text{ if } Q = \emptyset), \tag{2.1}$$

so by condition (D), since Q is closed, we have $\rho > 0$. Then we set

$$\tau := \sup_{x \in B(x_0, \rho)} d(x, C) \quad (\tau = +\infty \text{ if } \rho = +\infty).$$

It is easily seen that

$$\tau > d(x_0, C).$$

Indeed, clearly $\tau \geq d(x_0, C)$; moreover, assuming $\tau = d(x_0, C)$, for all $x \in B(x_0, \rho)$ we would have

$$I_1(x) = \|x - x_0\|^2 - d^2(x, C) \geq -d^2(x_0, C) = I_1(x_0),$$

so x_0 would be a local minimizer of the convex functional I_1, which, in turn, would imply $x_0 \in Q$, against condition (D).

Choose an arbitrary $t \in]d(x_0, C), \tau[$. We observe that $d(x_0, M_t) \in]0, \rho[$: indeed, $d(x_0, M_t) > 0$ as $x_0 \notin M_t$ and the latter is a closed set; on the other hand, $d(x_0, M_t) < \rho$ since, as $t < \tau$, there exists $x \in B(x_0, \rho) \cap M_t$, so

$$d(x_0, M_t) \leq \|x_0 - x\| < \rho.$$

We are going to apply Theorem 4 with $\Lambda = [0, 1]$ and

$$\Phi(x, \lambda) = \|x - x_0\|^2 + \lambda \left(t^2 - d^2(x, C)\right).$$

Such a function complies with all the hypotheses of Theorem 4 (with an arbitrary $\lambda_0 \in [0, 1[$), and hence there exists a pair $(\bar{x}, \bar{\lambda}) \in X \times \Lambda$ satisfying

$$\begin{aligned} \|\bar{x} - x_0\|^2 + \bar{\lambda}\left(t^2 - d^2(\bar{x}, C)\right) &= \inf_{x \in X} \left[\|x - x_0\|^2 - \bar{\lambda} d^2(x, C)\right] + \bar{\lambda} t^2 \\ &= \|\bar{x} - x_0\|^2 + \sup_{\lambda \in \Lambda} \left[\lambda \left(t^2 - d^2(\bar{x}, C)\right)\right]. \end{aligned} \tag{2.2}$$

The above equality has very important consequences for the proof. First we prove that

$$d(\bar{x}, C) \leq t. \tag{2.3}$$

Arguing by contradiction, we suppose $d(\bar{x}, C) > t$: then, from (2.2) it would follow that $\bar{\lambda} = 0$, which, in turn, would imply $\bar{x} = x_0$ and so $d(\bar{x}, C) < t$, against our assumption. Then we prove that

$$\bar{\lambda} < 1. \tag{2.4}$$

Again, we argue by contradiction and assume $\bar{\lambda} = 1$: hence, from (2.2) we would deduce that $\bar{x} \in Q$, so by (2.1), $\|\bar{x} - x_0\| \geq \rho$; the latter inequality, together with (2.3), yields

$$I_1(\bar{x}) \geq \rho^2 - t^2.$$

Recalling that $t < \tau$, we note that there exists $y \in B(x_0, \rho)$ such that $d(y, C) > t$ and so

$$I_1(y) < \rho^2 - t^2,$$

against the fact that $\bar{x} \in Q$. Now we can improve (2.3) and get

$$d(\bar{x}, C) = t \tag{2.5}$$

(in particular, $\bar{x} \in M_t$). Indeed, if $d(\bar{x}, C) < t$, from (2.2) it would follow that $\bar{\lambda} = 1$, against (2.4).

Now we are in a position to prove our assertion. With this aim in mind, we observe that, by (2.2), $\bar{x}$ is a global minimizer of the functional $I_{\bar{\lambda}}$; moreover, by (2.4), $I_{\bar{\lambda}}$ is strictly convex, continuous, and coercive, so $\bar{x}$ is its only minimizer, and every sequence $\{x_n\}$ in X, such that $I_{\bar{\lambda}}(x_n) \to I_{\bar{\lambda}}(\bar{x})$, weakly converges to $\bar{x}$ (see [4, Example 8, p. 3]).

We now prove that $P_{M_t}(x_0) = \{\bar{x}\}$, that is, that for every $y \in M_t$, $y \neq \bar{x}$, we have $\|y - x_0\| > \|\bar{x} - x_0\|$. Indeed, by what has been argued above, $I_{\bar{\lambda}}(y) > I_{\bar{\lambda}}(\bar{x})$, which, by (2.5), implies

$$\|y - x_0\|^2 > \|\bar{x} - x_0\|^2 + \bar{\lambda}\left(d^2(y, C) - t^2\right) \geq \|\bar{x} - x_0\|^2.$$

Finally, we prove that condition (S) holds for the point x_0, that is, that every sequence $\{y_n\}$ in M_t such that $\|y_n - x_0\| \to \|\bar{x} - x_0\|$ converges to $\bar{x}$. Indeed, for all $n \in \mathbb{N}$ we have

$$I_{\bar{\lambda}}(y_n) \leq \|y_n - x_0\|^2 - \bar{\lambda} t^2,$$

and the right-hand side tends to $I_{\bar{\lambda}}(\bar{x})$, so, by what has been stated above, $\{y_n\}$ weakly converges to $\bar{x}$; then, by well-known results, the weak convergence implies the strong convergence. Thus, the proof is complete. □

Our thesis, in the language of optimization theory, can be expressed by saying that, for every $t \in]d(x_0, C), \tau[$, the problem of minimizing on M_t the distance from x_0 is *Tykhonov well posed* (see [4]).

Remark 1. Under the same assumptions as in Theorem 5, an analogous result is achieved for the set

$$N_t := \{y \in X \ : \ d(y, C) = t\}$$

for all $t \in]d(x_0, C), \tau[$.

Our main hypothesis, namely condition (D), is indeed very general. In particular, it is fulfilled whenever x_0 does not belong to the closed convex hull of C. Thus, Theorem 3 is easily deduced from Theorem 5, as follows.

Proof of Theorem 3. Let us fix $t > 0$; then one of the following cases occurs:

- If $d(x_0, C) \geq t$, then $x_0 \in M_t$, so obviously $P_{M_t}(x_0) = \{x_0\}$, and each minimizing sequence in M_t for x_0 tends to x_0.
- If $d(x_0, C) < t$, then we apply Theorem 5. With this aim in mind, we prove that the functional I_1 is unbounded from below. Indeed, since $x_0 \notin K$, we can apply the separation theorem in its strongest form, assuring the existence of an element $\bar{y} \in X$, $\bar{y} \neq 0$, and of a positive ε such that

$$\langle \bar{y}, x \rangle \leq \langle \bar{y}, x_0 \rangle - \varepsilon \quad \text{for all } x \in K.$$

For all $\mu > 0$ we get

$$\begin{aligned} I_1(x_0 + \mu\bar{y}) &= \|\mu\bar{y}\|^2 - \inf_{x \in C} \|x_0 + \mu\bar{y} - x\|^2 \\ &= \sup_{x \in C} \left(-\|x_0 - x\|^2 + 2\mu\langle \bar{y}, x - x_0 \rangle\right) \\ &\leq -d^2(x_0, C) - 2\mu\varepsilon, \end{aligned}$$

so clearly

$$\lim_{\mu\to+\infty} I_1(x_0+\mu\bar{y}) = -\infty.$$

Thus, the set Q is empty: in particular, condition (D) is fulfilled. The thesis of Theorem 5 follows, with $\tau = +\infty$, which concludes the proof. □

REGULARITY CONDITIONS VIA QUASI-RELATIVE INTERIOR IN CONVEX PROGRAMMING*

RADU IOAN BOŢ†, ERNÖ ROBERT CSETNEK†, AND GERT WANKA†

Abstract. We give some new regularity conditions for Fenchel duality in separated locally convex vector spaces, written in terms of the notion of quasi interior and quasi-relative interior, respectively. We provide also an example of a convex optimization problem for which the classical generalized interior-point conditions given so far in the literature cannot be applied, while the one given by us is applicable. By using a technique developed by Magnanti, we derive some duality results for the optimization problem with cone constraints and its Lagrange dual problem, and we show that a duality result recently given in the literature for this pair of problems has self-contradictory assumptions.

Key words. convex programming, Fenchel duality, Lagrange duality, quasi-relative interior

DOI. 10.1137/07068432X

1. Introduction. Usually there is a so-called duality gap between the optimal objective values of a primal convex optimization problem and its dual problem. A challenge in convex analysis is to give sufficient conditions which guarantee strong duality, the situation when the optimal objective values of the two problems are equal and the dual problem has an optimal solution. Several generalized interior-point conditions were given in the past in order to eliminate the above-mentioned duality gap. Along the classical interior, some generalized interior notions were used, such as the core [14], the intrinsic core [9], or the strong quasi-relative interior [2], in order to give regularity conditions which guarantee strong duality. For an overview of these conditions we invite the reader to consult [8], [16] (see also [17] for more on this subject).

Unfortunately, for infinite-dimensional convex optimization problems, also in practice, it can happen that the duality results given in the past cannot be applied because, for instance, the interior of the set involved in the regularity condition is empty. This is the case, for example, when we deal with the positive cones

$$l^p_+ = \{x = (x_n)_{n\in\mathbb{N}} \in l^p : x_n \geq 0 \ \forall n \in \mathbb{N}\}$$

and

$$L^p_+(T,\mu) = \{u \in L^p(T,\mu) : u(t) \geq 0, \text{ a.e.}\}$$

of the spaces l^p and $L^p(T,\mu)$, respectively, where (T,μ) is a σ-finite measure space and $p \in [1,\infty)$. Moreover, also the strong quasi-relative interior (which is the weakest generalized interior notion from the one mentioned above) of these cones is empty. For this reason, for a convex set, Borwein and Lewis introduced the notion of the quasi-relative interior [3], which generalizes all of the above-mentioned interior notions. They proved that the quasi-relative interiors of l^p_+ and $L^p_+(T,\mu)$ are nonempty.

The research of the second author was supported by a Graduate Fellowship of the Free State Saxony, Germany.

In this paper, we start by considering the primal optimization problem with the objective function being the sum of two proper convex functions defined on a separated locally convex vector space, to which we attach its Fenchel dual problem, stated in terms of the conjugates of the two functions. We give a new regularity condition for Fenchel duality based on the notion of the quasi-relative interior of a convex set using a separation theorem given by Cammaroto and Di Bella in [4]. Further, two stronger regularity conditions are also given. We provide an appropriate example for which our duality results are applicable, while the other generalized interior-point conditions given in the past fail, justifying the theory developed in this paper. Then we state duality results for the case when the objective function of the primal problem is the sum of a proper convex function with the composition of another proper convex function with a continuous linear operator. Let us notice that for this case Borwein and Lewis in [3] also gave some conditions by means of the quasi-relative interior, but they considered a more restrictive case, namely, that the codomain of the linear operator is finite-dimensional. We consider the more general case, when both of the spaces are infinite-dimensional.

In 1974 Magnanti proved that "Fenchel and Lagrange duality are equivalent" in the sense that the classical Fenchel duality result can be deduced from the classical Lagrange duality result, and vice versa (see [13]). By using this technique we derive some Lagrange duality results for the convex optimization problem with cone constraints, written in terms of the quasi-relative interior. Let us notice that another condition for Lagrange duality, stated also in terms of the quasi-relative interior, was given recently by Cammaroto and Di Bella in [4]. We show that this result has self-contradictory assumptions. Let us mention that also in [11] some regularity conditions, in terms of the quasi-relative interior, have been introduced. However, most of these conditions require the interior of a cone to be nonempty, and this fails for many optimization problems as we pointed out above.

The paper is structured as follows. In the next section we give some definitions and results which will be used later in the paper. Section 3 is devoted to the theory of Fenchel duality. We give here the announced regularity conditions written in terms of the quasi-relative interior. By using an idea due to Magnanti we derive in section 4 some duality results for the optimization problem with cone constraints and its Lagrange dual problem.

2. Preliminary notions and results. Consider X, a separated locally convex vector space, and X^*, its topological dual space. We denote by $\langle x^*, x\rangle$ the value of the linear continuous functional $x^* \in X^*$ at $x \in X$. Further, let $\mathrm{id}_X : X \to X$, $\mathrm{id}_X(x) = x$, for all $x \in X$, be the *identity function* of X. The *indicator function* of $C \subseteq X$, denoted by δ_C, is defined as $\delta_C : X \to \overline{\mathbb{R}} = \mathbb{R} \cup \{\pm\infty\}$,

$$\delta_C(x) = \begin{cases} 0 & \text{if } x \in C, \\ +\infty & \text{otherwise.} \end{cases}$$

For a function $f : X \to \overline{\mathbb{R}}$ we denote by $\mathrm{dom}(f) = \{x \in X : f(x) < +\infty\}$ its *domain* and by $\mathrm{epi}(f) = \{(x, r) \in X \times \mathbb{R} : f(x) \leq r\}$ its *epigraph*. We call f *proper* if $\mathrm{dom}(f) \neq \emptyset$ and $f(x) > -\infty$ for all $x \in X$. We also denote by $\widehat{\mathrm{epi}}(f) = \{(x, r) \in X \times \mathbb{R} : (x, -r) \in \mathrm{epi}(f)\}$ the symmetric of $\mathrm{epi}(f)$ with respect to the x-axis. For a given real number α, $f - \alpha : X \to \overline{\mathbb{R}}$ is, as usual, the function defined by $(f - \alpha)(x) = f(x) - \alpha$ for all $x \in X$. Given two functions $f : M_1 \to M_2$ and $g : N_1 \to N_2$, where M_1, M_2, N_1, N_2 are nonempty sets, we define the function $f \times g : M_1 \times N_1 \to M_2 \times N_2$ by $f \times g(m, n) = (f(m), g(n))$ for all $(m, n) \in M_1 \times N_1$.

The *Fenchel–Moreau conjugate* of f is the function $f^* : X^* \to \overline{\mathbb{R}}$ defined by

$$f^*(x^*) = \sup_{x \in X} \{\langle x^*, x\rangle - f(x)\} \ \forall x^* \in X^*.$$

For a subset C of X we denote by $\operatorname{co} C$, $\operatorname{aff} C$, $\operatorname{cl} C$, and $\operatorname{int} C$ its *convex hull*, *affine hull*, *closure*, and *interior*, respectively. The set $\operatorname{cone} C := \bigcup_{\lambda \geq 0} \lambda C$ is the *cone generated by* C. The following property, the proof of which we omit since it presents no difficulty, will be used throughout the paper: If C is convex, then

$$\operatorname{cone} \operatorname{co}(C \cup \{0\}) = \operatorname{cone} C. \tag{1}$$

The *normal cone* of C at $x \in C$ is defined as $N_C(x) = \{x^* \in X^* : \langle x^*, y - x\rangle \leq 0, \ \forall y \in C\}$.

DEFINITION 2.1 (see [3]). *Let C be a convex subset of X. The* quasi-relative interior *of C is the set*

$$\operatorname{qri} C = \{x \in C : \operatorname{cl} \operatorname{cone}(C - x) \text{ is a linear subspace of } X\}.$$

We give the following useful characterization of the quasi-relative interior of a convex set.

PROPOSITION 2.2 (see [3]). *Let C be a convex subset of X and $x \in C$. Then $x \in \operatorname{qri} C$ if and only if $N_C(x)$ is a linear subspace of X^*.*

In the following we consider another interior notion for a convex set, which is close to the one of the quasi-relative interior.

DEFINITION 2.3. *Let C be a convex subset of X. The* quasi interior *of C is the set*

$$\operatorname{qi} C = \{x \in C : \operatorname{cl} \operatorname{cone}(C - x) = X\}.$$

The following characterization of the quasi interior of a convex set was given in [6], where the space X was considered a reflexive Banach space. One can prove that this property is true even in a separated locally convex vector space.

PROPOSITION 2.4. *Let C be a convex subset of X and $x \in C$. Then $x \in \operatorname{qi} C$ if and only if $N_C(x) = \{0\}$.*

Proof. Assume first that $x \in \operatorname{qi} C$, and take an arbitrary element $x^* \in N_C(x)$. One can easily see that $\langle x^*, z\rangle \leq 0$ for all $z \in \operatorname{cl} \operatorname{cone}(C - x)$. Thus $\langle x^*, z\rangle \leq 0$ for all $z \in X$, which is nothing else than $x^* = 0$.

In order to prove the opposite implication we consider an arbitrary $\bar{x} \in X$ and prove that $\bar{x} \in \operatorname{cl} \operatorname{cone}(C - x)$. By assuming the contrary, by a separation theorem (see, for instance, Theorem 1.1.5 in [17]), one has that there exists $x^* \in X^* \setminus \{0\}$ and $\alpha \in \mathbb{R}$ such that

$$\langle x^*, z\rangle < \alpha < \langle x^*, \bar{x}\rangle \ \forall z \in \operatorname{cl} \operatorname{cone}(C - x).$$

Let $y \in C$ be fixed. For all $\lambda > 0$ it holds that $\langle x^*, y - x\rangle < \frac{1}{\lambda}\alpha$, and this implies that $\langle x^*, y - x\rangle \leq 0$. As this inequality is true for every arbitrary $y \in C$, we obtain that $x^* \in N_C(x)$. But this leads to a contradiction, and in this way the conclusion follows. □

It follows from the definitions above that $\operatorname{qi} C \subseteq \operatorname{qri} C$ and $\operatorname{qri}\{x\} = \{x\}$ for all $x \in X$. Moreover, if $\operatorname{qi} C \neq \emptyset$, then $\operatorname{qi} C = \operatorname{qri} C$. Although this property is given in [12] in the case of a real normed space, it holds also in an arbitrary separated

locally convex vector space, as follows by the properties given above. If X is a finite-dimensional space, then $\operatorname{qi} C = \operatorname{int} C$ (cf. [12]) and $\operatorname{qri} C = \operatorname{ri} C$ (cf. [3]), where $\operatorname{ri} C$ is the *relative interior* of C.

Useful properties of the quasi-relative interior are listed below. For the proof of (i)–(viii) we refer to [1] and [3].

PROPOSITION 2.5. *Let us consider C and D two convex subsets of X, $x \in X$, and $\alpha \in \mathbb{R}$. Then:*

(i) $\operatorname{qri} C + \operatorname{qri} D \subseteq \operatorname{qri}(C + D)$;
(ii) $\operatorname{qri}(C \times D) = \operatorname{qri} C \times \operatorname{qri} D$;
(iii) $\operatorname{qri}(C - x) = \operatorname{qri} C - x$;
(iv) $\operatorname{qri}(\alpha C) = \alpha \operatorname{qri} C$;
(v) $t \operatorname{qri} C + (1-t)C \subseteq \operatorname{qri} C$, $\forall t \in (0,1]$, *and hence* $\operatorname{qri} C$ *is a convex set;*
(vi) *if C is an affine set, then* $\operatorname{qri} C = C$;
(vii) $\operatorname{qri}(\operatorname{qri} C) = \operatorname{qri} C$.

If $\operatorname{qri} C \neq \emptyset$, *then:*

(viii) $\operatorname{cl} \operatorname{qri} C = \operatorname{cl} C$;
(ix) $\operatorname{cl} \operatorname{cone} \operatorname{qri} C = \operatorname{cl} \operatorname{cone} C$.

Proof. (ix) The inclusion $\operatorname{cl} \operatorname{cone} \operatorname{qri} C \subseteq \operatorname{cl} \operatorname{cone} C$ is obvious. We prove that $\operatorname{cone} C \subseteq \operatorname{cl} \operatorname{cone} \operatorname{qri} C$. Consider $x \in \operatorname{cone} C$ arbitrary. There exist $\lambda \geq 0$ and $c \in C$ such that $x = \lambda c$. Take $x_0 \in \operatorname{qri} C$. By applying property (v) we get $tx_0 + (1-t)c \in \operatorname{qri} C$ for all $t \in (0,1]$, so $\lambda t x_0 + (1-t)x = \lambda(tx_0 + (1-t)c) \in \operatorname{cone} \operatorname{qri} C$ for all $t \in (0,1]$. By passing to the limit as $t \searrow 0$ we obtain $x \in \operatorname{cl} \operatorname{cone} \operatorname{qri} C$, and hence the desired conclusion follows. □

The next lemma plays an important role in this paper.

LEMMA 2.6. *Let A and B be nonempty convex subsets of X such that* $\operatorname{qri} A \cap B \neq \emptyset$. *If* $0 \in \operatorname{qi}(A - A)$, *then* $0 \in \operatorname{qi}(A - B)$.

Proof. Take $x \in \operatorname{qri} A \cap B$, and let $x^* \in N_{A-B}(0)$ be arbitrary. We get $\langle x^*, a - b \rangle \leq 0$, for all $a \in A$, for all $b \in B$. This implies that

$$\langle x^*, a - x \rangle \leq 0 \ \forall a \in A, \tag{2}$$

that is, $x^* \in N_A(x)$. As $x \in \operatorname{qri} A$, $N_A(x)$ is a linear subspace of X^*, and hence $-x^* \in N_A(x)$, which is nothing else than

$$\langle x^*, x - a \rangle \leq 0 \ \forall a \in A. \tag{3}$$

The relations (2) and (3) give us $\langle x^*, a' - a'' \rangle \leq 0$, for all $a', a'' \in A$, so $x^* \in N_{A-A}(0)$. Since $0 \in \operatorname{qi}(A - A)$ we have $N_{A-A}(0) = \{0\}$ (cf. Proposition 2.4), and we get $x^* = 0$. As x^* was arbitrary chosen we obtain $N_{A-B}(0) = \{0\}$, and, by using again Proposition 2.4, the conclusion follows. □

Next we give useful separation theorems in terms of the notion of the quasi-relative interior.

THEOREM 2.7. *Let C be a convex subset of X and $x_0 \in C$. If $x_0 \notin \operatorname{qri} C$, then there exists $x^* \in X^*, x^* \neq 0$, such that*

$$\langle x^*, x \rangle \leq \langle x^*, x_0 \rangle \ \forall x \in C.$$

Vice versa, if there exists $x^* \in X^*$, $x^* \neq 0$, such that

$$\langle x^*, x \rangle \leq \langle x^*, x_0 \rangle \ \forall x \in C$$

and

$$0 \in \operatorname{qi}(C - C),$$

then $x_0 \notin \operatorname{qri} C$.

Proof. Suppose that $x_0 \notin \operatorname{qri} C$. According to Proposition 2.2, $N_C(x_0)$ is not a linear subspace of X^*, and hence there exists $x^* \in N_C(x_0)$, $x^* \neq 0$. By using the definition of the normal cone, we get that $\langle x^*, x\rangle \leq \langle x^*, x_0\rangle$ for all $x \in C$.

Conversely, assume that there exists $x^* \in X^*$, $x^* \neq 0$, such that $\langle x^*, x\rangle \leq \langle x^*, x_0\rangle$ for all $x \in C$ and $0 \in \operatorname{qi}(C - C)$. We obtain

$$\langle x^*, x - x_0\rangle \leq 0 \ \forall x \in C, \tag{4}$$

that is, $x^* \in N_C(x_0)$. If we suppose that $x_0 \in \operatorname{qri} C$, then $N_C(x_0)$ is a linear subspace of X^*, and hence $-x^* \in N_C(x_0)$. By combining this with (4) we get $\langle x^*, x - x_0\rangle = 0$ for all $x \in C$. The last relation implies $\langle x^*, x\rangle = 0$ for all $x \in C - C$, and from here one has further that $\langle x^*, x\rangle = 0$ for all $x \in \operatorname{cl}\operatorname{cone}(C - C) = X$. But this can be the case just if $x^* = 0$, which is a contradiction. In conclusion, $x_0 \notin \operatorname{qri} C$. □

Remark 2.8. In [5], [6] a similar separation theorem in the case when X is a real normed space is given. For the second part of the above theorem the authors require that the following condition must be fulfilled:

$$\operatorname{cl}(T_C(x_0) - T_C(x_0)) = X,$$

where

$$T_C(x_0) = \big\{y \in X : y = \lim_{n\to\infty} \lambda_n(x_n - x_0), \lambda_n > 0 \ \forall n \in \mathbb{N},$$
$$x_n \in C \ \forall n \in \mathbb{N} \text{ and } \lim_{n\to\infty} x_n = x_0\big\}$$

is called the *contingent cone* to C at $x_0 \in C$. In general, we have the following inclusion: $T_C(x_0) \subseteq \operatorname{cl}\operatorname{cone}(C - x_0)$. If the set C is convex, then $T_C(x_0) = \operatorname{cl}\operatorname{cone}(C - x_0)$ (cf. [10]). As $\operatorname{cl}(\operatorname{cl} E + \operatorname{cl} F) = \operatorname{cl}(E + F)$, for arbitrary sets E, F in X and $\operatorname{cone} A - \operatorname{cone} A = \operatorname{cone}(A - A)$, if A is a convex subset of X such that $0 \in A$, the condition $\operatorname{cl}(T_C(x_0) - T_C(x_0)) = X$ can be reformulated as follows: $\operatorname{cl}\operatorname{cone}(C - C) = X$ or, equivalently, $0 \in \operatorname{qi}(C - C)$. Indeed, we have

$$\operatorname{cl}[\operatorname{cl}\operatorname{cone}(C - x_0) - \operatorname{cl}\operatorname{cone}(C - x_0)] = X \Leftrightarrow \operatorname{cl}[\operatorname{cone}(C - x_0) - \operatorname{cone}(C - x_0)] = X$$
$$\Leftrightarrow \operatorname{cl}\operatorname{cone}(C - C) = X \Leftrightarrow 0 \in \operatorname{qi}(C - C).$$

This means that Theorem 2.7 is a generalization to the case of separated locally convex vector spaces of the separation theorem given in [5], [6] in the framework of real normed spaces.

The condition $x_0 \in C$ in Theorem 2.7 is essential (see [6]). However, if x_0 is an arbitrary element of X, we can also give a separation theorem by using the following result due to Cammaroto and Di Bella (Theorem 2.1 in [4]). The mentioned authors use this theorem in order to prove their strong duality result (Theorem 2.2 in [4]). Unfortunately, as we will show in section 4, this result has self-contradictory assumptions.

THEOREM 2.9 (see [4]). *Let S and T be nonempty convex subsets of X with $\operatorname{qri} S \neq \emptyset$, $\operatorname{qri} T \neq \emptyset$, and such that $\operatorname{cl}\operatorname{cone}(\operatorname{qri} S - \operatorname{qri} T)$ is not a linear subspace of X. Then there exists $x^* \in X^*$, $x^* \neq 0$, such that $\langle x^*, s\rangle \leq \langle x^*, t\rangle$ for all $s \in S$, $t \in T$.*

The following result is a direct consequence of Theorem 2.9.

COROLLARY 2.10. *Let C be a convex subset of X such that $\operatorname{qri} C \neq \emptyset$ and $\operatorname{cl}\operatorname{cone}(C - x_0)$ is not a linear subspace of X, where $x_0 \in X$. Then there exists $x^* \in X^*, x^* \neq 0$, such that $\langle x^*, x\rangle \leq \langle x^*, x_0\rangle$ for all $x \in C$.*

Proof. We take, in Theorem 2.9, $S := C$ and $T := \{x_0\}$. Then we apply Proposition 2.5 (iii) and (ix) to obtain the conclusion. □

3. Fenchel duality. In this section we give some new Fenchel duality results stated in terms of the quasi interior and quasi-relative interior, respectively.

Consider the convex optimization problem

$$(P_F) \quad \inf_{x\in X}\{f(x)+g(x)\},$$

where X is a separated locally convex vector space and $f, g : X \to \overline{\mathbb{R}}$ are proper convex functions such that $\operatorname{dom}(f) \cap \operatorname{dom}(g) \neq \emptyset$. The Fenchel dual problem to (P_F) is the followiing:

$$(D_F) \quad \sup_{x^*\in X^*}\{-f^*(-x^*)-g^*(x^*)\}.$$

We denote by $v(P_F)$ and $v(D_F)$ the optimal objective values of the primal and the dual problem, respectively. Weak duality always holds; that is, $v(D_F) \leq v(P_F)$. For strong duality, the case when $v(P_F) = v(D_F)$ and (D_F) has an optimal solution, several generalized interior-point regularity conditions were given in the literature. In order to recall them we need the following generalized interior notions. For a convex subset C of X we have:

- $\operatorname{core} C := \{x \in C : \operatorname{cone}(C - x) = X\}$, the *core* of C [14], [17];
- $\operatorname{icr} C := \{x \in C : \operatorname{cone}(C - x)$ is a linear subspace$\}$, the *intrinsic core* of C [1], [9], [17];
- $\operatorname{sqri} C := \{x \in C : \operatorname{cone}(C - x)$ is a closed linear subspace$\}$, the *strong quasi-relative interior* of C [2], [17].

We have the following inclusions:

$$\operatorname{core} C \subseteq \operatorname{sqri} C \subseteq \operatorname{qri} C \text{ and } \operatorname{core} C \subseteq \operatorname{qi} C \subseteq \operatorname{qri} C.$$

If X if finite-dimensional, then $\operatorname{qri} C = \operatorname{sqri} C = \operatorname{icr} C = \operatorname{ri} C$ [3], [8] and $\operatorname{core} C = \operatorname{qi} C = \operatorname{int} C$ [12], [14].

Consider now the following regularity conditions:

(i) $0 \in \operatorname{int}(\operatorname{dom}(f) - \operatorname{dom}(g))$;
(ii) $0 \in \operatorname{core}(\operatorname{dom}(f) - \operatorname{dom}(g))$ (cf. [14]);
(iii) $0 \in \operatorname{icr}(\operatorname{dom}(f) - \operatorname{dom}(g))$ and $\operatorname{aff}(\operatorname{dom}(f) - \operatorname{dom}(g))$ is a closed linear subspace (cf. [8]);
(iv) $0 \in \operatorname{sqri}(\operatorname{dom}(f) - \operatorname{dom}(g))$ (cf. [15]).

Let us notice that all of these conditions guarantee strong duality if we suppose the additional hypotheses that the functions f and g are lower semicontinuous and X is a Fréchet space. Between the above conditions we have the following relation: (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) $\Leftrightarrow$ (iv) [8].

Trying to give a similar regularity condition for strong duality by means of the notion of the quasi-relative interior of a convex set, a natural question arises: Is the condition $0 \in \operatorname{qri}(\operatorname{dom}(f) - \operatorname{dom}(g))$ sufficient for strong duality? The following example (which can be found in [8]) gives us a negative answer, and this means that we need additional assumptions in order to guarantee Fenchel duality (see Theorem 3.5).

Example 3.1. As in [8], we consider $X = l^2$, the Hilbert space consisting of all sequences $x = (x_n)_{n\in\mathbb{N}}$ such that $\sum_{n=1}^{\infty} x_n^2 < \infty$. Consider also the sets

$$C = \{x \in l^2 : x_{2n-1} + x_{2n} = 0 \ \forall n \in \mathbb{N}\},$$

$$S = \{x \in l^2 : x_{2n} + x_{2n+1} = 0 \ \forall n \in \mathbb{N}\}.$$

The sets C and S are closed linear subspaces of l^2 and $C \cap S = \{0\}$. Define the functions $f, g : l^2 \to \overline{\mathbb{R}}$ by $f = \delta_C$ and $g(x) = x_1$ if $x \in S$ and $+\infty$ otherwise. One can see that f and g are proper, convex, and lower semicontinuous functions with $\mathrm{dom}(f) = C$ and $\mathrm{dom}(g) = S$. As was shown in [8], $v(P_F) = 0$ and $v(D_F) = -\infty$, so we have a duality gap between the optimal objective values of the primal problem and its Fenchel dual. Moreover, $S - C$ is dense in l^2; thus $\mathrm{cl}\,\mathrm{cone}(\mathrm{dom}(f) - \mathrm{dom}(g)) = \mathrm{cl}(C - S) = l^2$. The last relation implies that $0 \in \mathrm{qi}(\mathrm{dom}(f) - \mathrm{dom}(g))$, hence $0 \in \mathrm{qri}(\mathrm{dom}(f) - \mathrm{dom}(g))$.

Let us notice that if $v(P_F) = -\infty$, by the weak duality follows that also strong duality holds. This is the reason why we suppose in the following that $v(P_F) \in \mathbb{R}$.

LEMMA 3.2. *The following relation is always true:*

$$0 \in \mathrm{qri}(\mathrm{dom}(f) - \mathrm{dom}(g)) \Rightarrow (0,1) \in \mathrm{qri}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))].$$

Proof. One can see that $\widehat{\mathrm{epi}}(g - v(P_F)) = \{(x,r) \in X \times \mathbb{R} : r \leq -g(x) + v(P_F)\}$. Let us prove first that $(0,1) \in \mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))$. Since $\inf_{x \in X}[f(x) + g(x)] = v(P_F) < v(P_F) + 1$, there exists $x' \in X$ such that $f(x') + g(x') < v(P_F) + 1$. Then $(0,1) = (x', v(P_F) + 1 - g(x')) - (x', -g(x') + v(P_F)) \in \mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))$.

Now let $(x^*, r^*) \in N_{\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))}(0,1)$. We have

$$\langle x^*, x - x' \rangle + r^*(\mu - \mu' - 1) \leq 0 \ \forall (x,\mu) \in \mathrm{epi}(f) \ \forall (x',\mu') \in \widehat{\mathrm{epi}}(g - v(P_F)). \tag{5}$$

For $(x,\mu) := (x_0, f(x_0))$ and $(x',\mu') := (x_0, -g(x_0) + v(P_F) - 2)$ in (5), where $x_0 \in \mathrm{dom}(f) \cap \mathrm{dom}(g)$ is fixed, we get $r^*(f(x_0) + g(x_0) - v(P_F) + 1) \leq 0$, and hence $r^* \leq 0$. As $\inf_{x \in X}[f(x) + g(x)] = v(P_F) < v(P_F) + 1/2$, there exists $x_1 \in X$ such that $f(x_1) + g(x_1) < v(P_F) + 1/2$. By taking now $(x,\mu) := (x_1, f(x_1))$ and $(x',\mu') := (x_1, -g(x_1) + v(P_F) - 1/2)$ in (5) we obtain $r^*(f(x_1) + g(x_1) - v(P_F) - 1/2) \leq 0$, and so $r^* \geq 0$. Thus $r^* = 0$, and (5) gives: $\langle x^*, x - x' \rangle \leq 0$ for all $x \in \mathrm{dom}(f)$ for all $x' \in \mathrm{dom}(g)$. Hence $x^* \in N_{\mathrm{dom}(f) - \mathrm{dom}(g)}(0)$. Since $N_{\mathrm{dom}(f) - \mathrm{dom}(g)}(0)$ is a linear subspace of X^* (cf. Proposition 2.2), we have $\langle -x^*, x - x' \rangle \leq 0$ for all $x \in \mathrm{dom}(f)$ for all $x' \in \mathrm{dom}(g)$, and so $-(x^*, r^*) = (-x^*, 0) \in N_{\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))}(0,1)$, showing that $N_{\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))}(0,1)$ is a linear subspace of $X^* \times \mathbb{R}$. Hence, by applying again Proposition 2.2, we get $(0,1) \in \mathrm{qri}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))]$. □

PROPOSITION 3.3. *Assume that* $0 \in \mathrm{qi}[(\mathrm{dom}(f) - \mathrm{dom}(g)) - (\mathrm{dom}(f) - \mathrm{dom}(g))]$. *Then* $N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0)$ *is a linear subspace of* $X^* \times \mathbb{R}$ *if and only if* $N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0) = \{(0,0)\}$.

Proof. The sufficiency is trivial. In the following let us suppose that the set $N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0)$ is a linear subspace of $X^* \times \mathbb{R}$. Take $(x^*, r^*) \in N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0)$. Then

$$\langle x^*, x - x' \rangle + r^*(\mu - \mu') \leq 0 \ \forall (x,\mu) \in \mathrm{epi}(f) \ \forall (x',\mu') \in \widehat{\mathrm{epi}}(g - v(P_F)). \tag{6}$$

Let $x_0 \in \mathrm{dom}\, f \cap \mathrm{dom}(g)$ be fixed. By taking $(x,\mu) := (x_0, f(x_0)) \in \mathrm{epi}(f)$ and $(x',\mu') := (x_0, -g(x_0) + v(P_F) - 1/2) \in \widehat{\mathrm{epi}}(g - v(P_F))$ in the previous inequality, we get $r^*(f(x_0) + g(x_0) - v(P_F) + 1/2) \leq 0$, implying $r^* \leq 0$. As the set $N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0)$ is a linear subspace of $X^* \times \mathbb{R}$, the same argument applies also for $(-x^*, -r^*)$, implying $-r^* \leq 0$. In this way we get $r^* = 0$. The inequality (6) and the relation $(-x^*, 0) \in N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0)$ imply that

$$\langle x^*, x - x' \rangle = 0 \ \forall (x,\mu) \in \mathrm{epi}(f) \ \forall (x',\mu') \in \widehat{\mathrm{epi}}(g - v(P_F)),$$

which is nothing else than $\langle x^*, x - x' \rangle = 0$ for all $x \in \mathrm{dom}(f)$ for all $x' \in \mathrm{dom}(g)$, and thus $\langle x^*, x \rangle = 0$ for all $x \in \mathrm{dom}(f) - \mathrm{dom}(g)$. Since x^* is linear and continuous, the last relation implies that $\langle x^*, x \rangle = 0$ for all $x \in \mathrm{cl}\,\mathrm{cone}[(\mathrm{dom}(f) - \mathrm{dom}(g)) - (\mathrm{dom}(f) - \mathrm{dom}(g))] = X$; hence $x^* = 0$, and the conclusion follows. □

Remark 3.4. (a) By (1) one can see that $\mathrm{cl}\,\mathrm{cone}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}] = \mathrm{cl}\,\mathrm{cone}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))]$. Hence one has the following sequence of equivalences: $N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0)$ is a linear subspace of $X^* \times \mathbb{R} \Leftrightarrow (0,0) \in \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}] \Leftrightarrow \mathrm{cl}\,\mathrm{cone}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]$ is a linear subspace of $X \times \mathbb{R} \Leftrightarrow \mathrm{cl}\,\mathrm{cone}(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F)))$ is a linear subspace of $X \times \mathbb{R}$. The relation $N_{\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]}(0,0) = \{(0,0)\}$ is equivalent to $(0,0) \in \mathrm{qi}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]$ (cf. Proposition 2.4), so in the case $0 \in \mathrm{qi}[(\mathrm{dom}(f) - \mathrm{dom}(g)) - (\mathrm{dom}(f) - \mathrm{dom}(g))]$ the conclusion of the previous proposition can be reformulated as follows:

$$\mathrm{cl}\,\mathrm{cone}(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \text{ is a linear subspace of } X \times \mathbb{R} \Leftrightarrow$$
$$(0,0) \in \mathrm{qi}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]$$

or, equivalently,

$$(0,0) \in \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}] \Leftrightarrow$$
$$(0,0) \in \mathrm{qi}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}].$$

(b) One can prove that the primal problem (P_F) has an optimal solution if and only if $(0,0) \in \mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))$. This means that if we suppose that the primal problem has an optimal solution and $0 \in \mathrm{qi}[(\mathrm{dom}(f) - \mathrm{dom}(g)) - (\mathrm{dom}(f) - \mathrm{dom}(g))]$, then the conclusion of the previous proposition can be rewritten as follows: $N_{(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F)))}(0,0)$ is a linear subspace of $X^* \times \mathbb{R}$ if and only if $N_{(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F)))}(0,0) = \{(0,0)\}$ or, equivalently,

$$(0,0) \in \mathrm{qri}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))] \Leftrightarrow (0,0) \in \mathrm{qi}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))].$$

We give now the first strong duality result for (P_F) and its Fenchel dual (D_F). Let us notice that for the functions f and g we suppose just convexity properties, and we do not use any closedness type of condition.

THEOREM 3.5. *Suppose that* $0 \in \mathrm{qi}[(\mathrm{dom}(f) - \mathrm{dom}(g)) - (\mathrm{dom}(f) - \mathrm{dom}(g))]$, $0 \in \mathrm{qri}(\mathrm{dom}(f) - \mathrm{dom}(g))$, *and* $(0,0) \notin \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}\, f - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]$. *Then* $v(P_F) = v(D_F)$, *and* (D_F) *has an optimal solution.*

Proof. Lemma 3.2 ensures that $(0,1) \in \mathrm{qri}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))]$, and hence $\mathrm{qri}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))] \neq \emptyset$. The condition $(0,0) \notin \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}\, f - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]$, together with the relation $\mathrm{cl}\,\mathrm{cone}\,\mathrm{co}[(\mathrm{epi}\, f - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}] = \mathrm{cl}\,\mathrm{cone}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))]$, implies that $\mathrm{cl}\,\mathrm{cone}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))]$ is not a linear subspace of $X \times \mathbb{R}$. We apply Corollary 2.10 with $C := \mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))$ and $x_0 = (0,0)$. Thus there exists $(x^*, \lambda) \in X^* \times \mathbb{R}$, $(x^*, \lambda) \neq (0,0)$ such that

$$\langle x^*, x \rangle + \lambda\mu \geq \langle x^*, x' \rangle + \lambda\mu' \ \forall (x, \mu) \in \widehat{\mathrm{epi}}(g - v(P_F)) \ \forall (x', \mu') \in \mathrm{epi}(f). \tag{7}$$

We claim that $\lambda \leq 0$. Indeed, if $\lambda > 0$, then for $(x, \mu) := (x_0, -g(x_0) + v(P_F))$ and $(x', \mu') := (x_0, f(x_0) + n), n \in \mathbb{N}$, where $x_0 \in \mathrm{dom}(f) \cap \mathrm{dom}(g)$ is fixed, we obtain

from (7): $\langle x^*, x_0\rangle + \lambda(-g(x_0) + v(P_F)) \geq \langle x^*, x_0\rangle + \lambda(f(x_0) + n)$ for all $n \in \mathbb{N}$. By passing to the limit as $n \to +\infty$ we obtain a contradiction. Next we prove that $\lambda < 0$. Suppose that $\lambda = 0$. Then from (7) we have $\langle x^*, x\rangle \geq \langle x^*, x'\rangle$ for all $x \in \operatorname{dom}(g)$ for all $x' \in \operatorname{dom}(f)$, and hence $\langle x^*, x\rangle \leq 0$ for all $x \in \operatorname{dom}(f) - \operatorname{dom}(g)$. By using the second part of Theorem 2.7, we obtain $0 \notin \operatorname{qri}(\operatorname{dom}(f) - \operatorname{dom}(g))$, which contradicts the hypothesis. Thus we must have $\lambda < 0$, and so we obtain from (7):

$$\left\langle \frac{1}{\lambda}x^*, x \right\rangle + \mu \leq \left\langle \frac{1}{\lambda}x^*, x' \right\rangle + \mu', \forall (x, \mu) \in \widehat{\operatorname{epi}}(g - v(P_F)), \forall (x', \mu') \in \operatorname{epi}(f).$$

Let be $r \in \mathbb{R}$ such that

$$\mu' + \langle x_0^*, x'\rangle \geq r \geq \mu + \langle x_0^*, x\rangle \ \forall (x, \mu) \in \widehat{\operatorname{epi}}(g - v(P_F)) \ \forall (x', \mu') \in \operatorname{epi}(f),$$

where $x_0^* := \frac{1}{\lambda}x^*$. The first inequality shows that $f(x) \geq \langle -x_0^*, x\rangle + r$ for all $x \in X$, that is, $f^*(-x_0^*) \leq -r$. The second one gives us $-g(x) + v(P_F) + \langle x_0^*, x\rangle \leq r$ for all $x \in X$; hence $g^*(x_0^*) \leq r - v(P_F)$, and so we have $-f^*(-x_0^*) - g^*(x_0^*) \geq r + v(P_F) - r = v(P_F)$. This implies that $v(D_F) \geq v(P_F)$. As the opposite inequality is always true, we get $v(P_F) = v(D_F)$, and x_0^* is an optimal solution of the problem (D_F). □

The above theorem combined with Remark 3.4(b) gives us the following result.

COROLLARY 3.6. *Suppose that the primal problem (P_F) has an optimal solution, $0 \in \operatorname{qi}[(\operatorname{dom}(f) - \operatorname{dom}(g)) - (\operatorname{dom}(f) - \operatorname{dom}(g))]$, $0 \in \operatorname{qri}(\operatorname{dom}(f) - \operatorname{dom}(g))$, and $(0, 0) \notin \operatorname{qri}[\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))]$. Then $v(P_F) = v(D_F)$, and (D_F) has an optimal solution.*

Remark 3.7. The condition $0 \in \operatorname{qi}[(\operatorname{dom}(f) - \operatorname{dom}(g)) - (\operatorname{dom}(f) - \operatorname{dom}(g))]$ implies that

$$0 \in \operatorname{qri}(\operatorname{dom}(f) - \operatorname{dom}(g)) \Leftrightarrow 0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g)).$$

Indeed, denote by $C := \operatorname{dom}(f) - \operatorname{dom}(g)$. Obviously $0 \in \operatorname{qi} C$ implies that $0 \in \operatorname{qri} C$. Suppose now that $0 \in \operatorname{qri} C$, and let $x^* \in N_C(0)$ be arbitrary. We have $\langle x^*, x\rangle \leq 0$ for all $x \in C$. Since $N_C(0)$ is a linear subspace of X^*, we obtain $\langle x^*, x\rangle = 0$ for all $x \in C$. We get further $\langle x^*, x\rangle = 0$ for all $x \in \operatorname{cl}\operatorname{cone}(C - C) = X$, which implies that $x^* = 0$. Thus $N_C(0) = \{0\}$, and the conclusion follows.

Some stronger versions of Theorem 3.5 and Corollary 3.6, respectively, follow.

THEOREM 3.8. *Suppose that $0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$ and $(0, 0) \notin \operatorname{qri}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0, 0)\}]$. Then $v(P_F) = v(D_F)$, and (D_F) has an optimal solution.*

Proof. We have $\operatorname{dom}(f) - \operatorname{dom}(g) \subseteq (\operatorname{dom}(f) - \operatorname{dom}(g)) - (\operatorname{dom}(f) - \operatorname{dom}(g))$, so the condition $0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$ implies that $0 \in \operatorname{qi}[(\operatorname{dom}(f) - \operatorname{dom}(g)) - (\operatorname{dom}(f) - \operatorname{dom}(g))]$ and $0 \in \operatorname{qri}(\operatorname{dom}(f) - \operatorname{dom}(g))$. Then we apply Theorem 3.5 to obtain the conclusion. □

COROLLARY 3.9. *Suppose that the primal problem (P_F) has an optimal solution, $0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$, and $(0, 0) \notin \operatorname{qri}[\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))]$. Then $v(P_F) = v(D_F)$, and (D_F) has an optimal solution.*

THEOREM 3.10. *Suppose that $\operatorname{dom}(f) \cap \operatorname{qri}\operatorname{dom}(g) \neq \emptyset$, $0 \in \operatorname{qi}(\operatorname{dom}(g) - \operatorname{dom}(g))$, and $(0, 0) \notin \operatorname{qri}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0, 0)\}]$. Then $v(P_F) = v(D_F)$, and (D_F) has an optimal solution.*

Proof. We apply Lemma 2.6 with $A := \operatorname{dom}(g)$ and $B := \operatorname{dom}(f)$. We get $0 \in \operatorname{qi}(\operatorname{dom}(g) - \operatorname{dom}(f))$ or, equivalently, $0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$. We obtain the result by applying Theorem 3.8. □

COROLLARY 3.11. *Suppose that the primal problem* (P_F) *has an optimal solution,* $\mathrm{dom}(f) \cap \mathrm{qri}\,\mathrm{dom}(g) \neq \emptyset$, $0 \in \mathrm{qi}(\mathrm{dom}(g) - \mathrm{dom}(g))$, *and* $(0,0) \notin \mathrm{qri}[\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))]$. *Then* $v(P_F) = v(D_F)$, *and* (D_F) *has an optimal solution.*

Remark 3.12. (a) We introduced above three new regularity conditions for Fenchel duality. As one can easily see from the proof of these results, the relation between these conditions is the following one: The regularity condition given in Theorem 3.10 (Corollary 3.11) implies the one given in Theorem 3.8 (Corollary 3.9), which implies the one given in Theorem 3.5 (Corollary 3.6).

(b) If we renounce the condition $(0,0) \notin \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F))) \cup \{(0,0)\}]$, or, respectively, $(0,0) \notin \mathrm{qri}(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F)))$, in the case when the primal problem has an optimal solution, then the duality results given above may fail. By using again Example 3.1 we show that these conditions are essential in our theory. Let us notice that for the problem in Example 3.1 the conditions $0 \in \mathrm{qi}[(\mathrm{dom}(f) - \mathrm{dom}(g)) - (\mathrm{dom}(f) - \mathrm{dom}(g))]$ and $0 \in \mathrm{qri}(\mathrm{dom}(f) - \mathrm{dom}(g))$ are fulfilled. We prove in the following that in the aforementioned example we have $(0,0) \in \mathrm{qri}(\mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F)))$. Note that the scalar product on l^2, $\langle \cdot, \cdot \rangle : l^2 \times l^2 \to \mathbb{R}$, is given by $\langle x, y \rangle = \sum_{n=1}^{\infty} x_n y_n$ for all $x = (x_n)_{n \in \mathbb{N}}, y = (y_n)_{n \in \mathbb{N}} \in l^2$. Also, for $k \in \mathbb{N}$, we denote by $e^{(k)}$ the element in l^2 which has on the kth position 1 and on the other positions 0, that is, $e_n^{(k)} = 1$, if $n = k$ and $e_n^{(k)} = 0$, for all $n \in \mathbb{N} \backslash \{k\}$. We have $\mathrm{epi}(f) = C \times [0, \infty)$. Further, $\widehat{\mathrm{epi}}(g - v(P_F)) = \{(x,r) \in l^2 \times \mathbb{R} : r \leq -g(x)\} = \{(x,r) \in l^2 \times \mathbb{R} : x = (x_n)_{n \in \mathbb{N}} \in S, r \leq -x_1\} = \{(x, -x_1 - \varepsilon) \in l^2 \times \mathbb{R} : x = (x_n)_{n \in \mathbb{N}} \in S, \varepsilon \geq 0\}$. Then $A := \mathrm{epi}(f) - \widehat{\mathrm{epi}}(g - v(P_F)) = \{(x - x', x_1' + \varepsilon) : x \in C, x' = (x_n')_{n \in \mathbb{N}} \in S, \varepsilon \geq 0\}$. Take $(x^*, r) \in N_A(0,0)$, where $x^* = (x_n^*)_{n \in \mathbb{N}}$. We have

$$\langle x^*, x - x' \rangle + r(x_1' + \varepsilon) \leq 0 \ \forall x \in C \ \forall x' = (x_n')_{n \in \mathbb{N}} \in S \ \forall \varepsilon \geq 0. \tag{8}$$

By taking in (8) $x' = 0$ and $\varepsilon = 0$ we get $\langle x^*, x \rangle \leq 0$ for all $x \in C$. As C is a linear subspace of X we have

$$\langle x^*, x \rangle = 0 \ \forall x \in C. \tag{9}$$

Since $e^{(2k-1)} - e^{(2k)} \in C$, for all $k \in \mathbb{N}$, the relation (9) implies that

$$x_{2k-1}^* - x_{2k}^* = 0 \ \forall k \in \mathbb{N}. \tag{10}$$

From (8) and (9) we obtain

$$\langle -x^*, x' \rangle + r(x_1' + \varepsilon) \leq 0 \ \forall x' = (x_n')_{n \in \mathbb{N}} \in S \ \forall \varepsilon \geq 0. \tag{11}$$

By taking $\varepsilon = 0$ and $x' := me^1 \in S$ in (11), where $m \in \mathbb{Z}$ is arbitrary, we get $m(-x_1^* + r) \leq 0$ for all $m \in \mathbb{Z}$, and thus $r = x_1^*$. For $\varepsilon = 0$ in (11) we obtain $-\sum_{n=1}^{\infty} x_n^* x_n' + r x_1' \leq 0$ for all $x' \in S$. By taking into account that $r = x_1^*$, we get $-\sum_{n=2}^{\infty} x_n^* x_n' \leq 0$ for all $x' \in S$. As S is a linear subspace of X it follows that $\sum_{n=2}^{\infty} x_n^* x_n' = 0$ for all $x' \in S$, but, since $e^{(2k)} - e^{(2k+1)} \in S$ for all $k \in \mathbb{N}$, the above relation shows that

$$x_{2k}^* - x_{2k+1}^* = 0 \ \forall k \in \mathbb{N}. \tag{12}$$

By combining (10) with (12) we get $x^* = 0$ (since $x^* \in l^2$). Because $r = x_1^*$, we also have $r = 0$. Thus $N_A(0,0) = \{(0,0)\}$, and Proposition 2.4 gives us the desired conclusion.

(c) Since in all of the strong duality results given above one must have that $0 \in \operatorname{qi}[(\operatorname{dom}(f) - \operatorname{dom}(g)) - (\operatorname{dom}(f) - \operatorname{dom}(g))]$, in view of Remark 3.4, the condition $(0,0) \notin \operatorname{qri}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}]$ (respectively, $(0,0) \notin \operatorname{qri}[\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))]$) is equivalent to $(0,0) \notin \operatorname{qi}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}]$ (respectively, $(0,0) \notin \operatorname{qi}[\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))]$).

(d) We have the following relation:

$$(0,0) \in \operatorname{qi}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}] \Rightarrow 0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g)).$$

Indeed, $(0,0) \in \operatorname{qi}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}] \Leftrightarrow \operatorname{cl}\operatorname{cone}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}] = X \times \mathbb{R}$; hence $\operatorname{cl}\operatorname{cone}(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) = X \times \mathbb{R}$. Since $\operatorname{cl}\operatorname{cone}(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \subseteq \operatorname{cl}\operatorname{cone}(\operatorname{dom}(f) - \operatorname{dom}(g)) \times \mathbb{R}$, this implies that $\operatorname{cl}\operatorname{cone}(\operatorname{dom}(f) - \operatorname{dom}(g)) = X$, that is, $0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$. Hence

$$0 \notin \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g)) \Rightarrow (0,0) \notin \operatorname{qi}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}].$$

Nevertheless, in the regularity conditions given above one cannot substitute the condition $(0,0) \notin \operatorname{qri}\operatorname{co}[(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))) \cup \{(0,0)\}]$ by the "nice-looking" one $0 \notin \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$, since in all three strong duality theorems the other hypotheses we consider imply that $0 \in \operatorname{qi}(\operatorname{dom}(f) - \operatorname{dom}(g))$ (cf. Remark 3.7).

Example 3.13. Consider again the space $X = l^2$ equipped with the norm $\|\cdot\| : l^2 \to \mathbb{R}$, $\|x\|^2 = \sum_{n=1}^{\infty} x_n^2$ for all $x = (x_n)_{n\in\mathbb{N}} \in l^2$. We define the functions $f, g : l^2 \to \overline{\mathbb{R}}$ by

$$f(x) = \begin{cases} \|x\| & \text{if } x \in x_0 - l^2_+, \\ +\infty & \text{otherwise} \end{cases}$$

and

$$g(x) = \begin{cases} \langle c, x\rangle & \text{if } x \in l^2_+, \\ +\infty & \text{otherwise,} \end{cases}$$

where $l^2_+ = \{(x_n)_{n\in\mathbb{N}} \in l^2 : x_n \geq 0, \forall n \in \mathbb{N}\}$ is the positive cone, $x_0 = (\frac{1}{n})_{n\in\mathbb{N}}$, and $c = (\frac{1}{2^n})_{n\in\mathbb{N}}$. Note that $v(P_F) = \inf_{x\in l^2}\{f(x) + g(x)\} = 0$, and the infimum is attained at $x = 0$. We have $\operatorname{dom}(f) = x_0 - l^2_+ = \{(x_n)_{n\in\mathbb{N}} \in l^2 : x_n \leq \frac{1}{n}, \forall n \in \mathbb{N}\}$ and $\operatorname{dom}(g) = l^2_+$. Since $\operatorname{qri} l^2_+ = \{(x_n)_{n\in\mathbb{N}} \in l^2 : x_n > 0, \forall n \in \mathbb{N}\}$ (cf. [3]), we get $\operatorname{dom}(f) \cap \operatorname{qri}\operatorname{dom}(g) = \{(x_n)_{n\in\mathbb{N}} \in l^2 : 0 < x_n \leq \frac{1}{n}, \forall n \in \mathbb{N}\} \neq \emptyset$. Also, $\operatorname{cl}\operatorname{cone}(\operatorname{dom}(g) - \operatorname{dom}(g)) = l^2$, so $0 \in \operatorname{qi}(\operatorname{dom}(g) - \operatorname{dom}(g))$. Further, $\operatorname{epi}(f) = \{(x,r) \in l^2 \times \mathbb{R} : x \in x_0 - l^2_+, \|x\| \leq r\} = \{(x, \|x\| + \varepsilon) \in l^2 \times \mathbb{R} : x \in x_0 - l^2_+, \varepsilon \geq 0\}$ and $\widehat{\operatorname{epi}}(g - v(P_F)) = \{(x,r) \in l^2 \times \mathbb{R} : r \leq -g(x)\} = \{(x,r) \in l^2 \times \mathbb{R} : r \leq -\langle c, x\rangle, x \in l^2_+\} = \{(x, -\langle c, x\rangle - \varepsilon) : x \in l^2_+, \varepsilon \geq 0\}$. We get $\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F)) = \{(x - x', \|x\| + \varepsilon + \langle c, x'\rangle + \varepsilon') : x \in x_0 - l^2_+, x' \in l^2_+, \varepsilon, \varepsilon' \geq 0\} = \{(x - x', \|x\| + \langle c, x'\rangle + \varepsilon) : x \in x_0 - l^2_+, x' \in l^2_+, \varepsilon \geq 0\}$.

In the following we prove that $(0,0) \notin \operatorname{qri}(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F)))$. By assuming the contrary we would have that the set $\operatorname{cl}(\operatorname{cone}(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))))$ is a linear subspace. Since $(0,1) \in \operatorname{cl}(\operatorname{cone}(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))))$ (take $x = x' = 0$ and $\varepsilon = 1$) we must have that also $(0,-1)$ belongs to this set. On the other hand, one can easily see that for all (x,r) belonging to $\operatorname{cl}(\operatorname{cone}(\operatorname{epi}(f) - \widehat{\operatorname{epi}}(g - v(P_F))))$ it holds that $r \geq 0$. This leads to the desired contradiction.

Hence the conditions of Corollary 3.11 are fulfilled, and thus strong duality holds. Let us notice that the regularity conditions given in Corollaries 3.6 and 3.9 are also fulfilled (see Remark 3.12(a)).

On the other hand, l^2 is a Fréchet space (being a Hilbert space), the functions f and g are lower semicontinuous, and, as $\operatorname{sqri}(\operatorname{dom}(f) - \operatorname{dom}(g)) = \operatorname{sqri}(x_0 - l^2_+) = \emptyset$, none of the constraint qualifications (i)–(iv) presented in the beginning of this section can be applied for this optimization problem.

As for all $x^* \in l^2$ it holds that

$$g^*(x^*) = \begin{cases} 0 & \text{if } x^* \in c - l^2_+, \\ +\infty & \text{otherwise} \end{cases}$$

and (see Theorem 2.8.7 in [17])

$$f^*(-x^*) = \inf_{x_1^*+x_2^*=-x^*} \{\|\cdot\|^*(x_1^*) + \delta^*_{x_0-l^2_+}(x_2^*)\} = \inf_{\substack{x_1^*+x_2^*=-x^*, \\ \|x_1^*\|\leq 1, x_2^* \in l^2_+}} \{\langle x_2^*, x_0\rangle\},$$

the optimal objective value of the Fenchel dual problem is

$$\begin{aligned} v(D_F) &= \sup_{x^* \in X^*} \{-f^*(-x^*) - g^*(x^*)\} \\ &= \sup_{\substack{x_2^* \in l^2_+ - c - x_1^*, \\ \|x_1^*\|\leq 1, x_2^* \in l^2_+}} \{\langle -x_2^*, x_0\rangle\} = \sup_{x_2^* \in l^2_+} \{\langle -x_2^*, x_0\rangle\} = 0, \end{aligned}$$

and $x_2^* = 0$ is the optimal solution of the dual.

In the following, by using the results introduced above, we give regularity conditions for the following convex optimization problem:

$$(P_A) \quad \inf_{x \in X} \{f(x) + (g \circ A)(x)\},$$

where X and Y are separated locally convex vector spaces with their topological dual spaces X^* and Y^*, respectively, $A : X \to Y$ is a linear continuous mapping, $f : X \to \overline{\mathbb{R}}$, and $g : Y \to \overline{\mathbb{R}}$ are proper convex functions such that $A(\operatorname{dom}(f)) \cap \operatorname{dom}(g) \neq \emptyset$. The Fenchel dual problem to (P_A) is (cf. [17])

$$(D_A) \quad \sup_{y^* \in Y^*} \{-f^*(-A^*y^*) - g^*(y^*)\},$$

where $A^* : Y^* \to X^*$ is the *adjoint operator* of A, defined in the usual way: $\langle A^*y^*, x\rangle = \langle y^*, Ax\rangle$ for all $(y^*, x) \in Y^* \times X$. We denote by $v(P_A)$ and $v(D_A)$ the optimal objective values of the primal and the dual problem, respectively. We suppose also that $v(P_A) \in \mathbb{R}$. In the following theorem the set

$$A \times \mathrm{id}_{\mathbb{R}}(\operatorname{epi}(f)) = \{(Ax, r) \in Y \times \mathbb{R} : f(x) \leq r\}$$

is the image of $\operatorname{epi}(f)$ through the operator $A \times \mathrm{id}_{\mathbb{R}}$.

THEOREM 3.14. *Suppose that* $0 \in \operatorname{qi}[(A(\operatorname{dom}(f)) - \operatorname{dom}(g)) - (A(\operatorname{dom}(f)) - \operatorname{dom}(g))]$, $0 \in \operatorname{qri}(A(\operatorname{dom}(f)) - \operatorname{dom}(g))$, *and* $(0,0) \notin \operatorname{qri}\operatorname{co}[(A \times \mathrm{id}_{\mathbb{R}}(\operatorname{epi}(f)) - \widehat{\operatorname{epi}}(g - v(P_A))) \cup \{(0,0)\}]$. *Then* $v(P_A) = v(D_A)$, *and* (D_A) *has an optimal solution.*

Proof. Let us introduce the following functions: $F, G : X \times Y \to \overline{\mathbb{R}}$, $F(x,y) = f(x) + \delta_{\{x \in X : Ax = y\}}(x)$, and $G(x,y) = g(y)$. The functions F and G are proper and convex, and $\inf_{(x,y)\in X\times Y}[F(x,y) + G(x,y)] = \inf_{x\in X}\{f(x) + (g \circ A)(x)\} = v(P_A)$. Moreover, $\operatorname{dom}(F) = \operatorname{dom}(f) \times A(\operatorname{dom}(f))$ and $\operatorname{dom}(G) = X \times \operatorname{dom}(g)$, so $\operatorname{dom}(F) \cap \operatorname{dom}(G) \neq \emptyset$. Further,

$$\operatorname{dom}(F) - \operatorname{dom}(G) = X \times (A(\operatorname{dom}(f)) - \operatorname{dom}(g)).$$

By combining the last relation with the hypotheses, we obtain $(0,0) \in \mathrm{qi}[(\mathrm{dom}(F) - \mathrm{dom}(G)) - (\mathrm{dom}(F) - \mathrm{dom}(G))]$ and $(0,0) \in \mathrm{qri}(\mathrm{dom}(F) - \mathrm{dom}(G))$. Since $\mathrm{epi}(F) = \{(x, Ax, r) : f(x) \leq r\}$ and $\widehat{\mathrm{epi}}(G - v(P_A)) = \{(x, y, r) : r \leq -G(x,y) + v(P_A)\} = X \times \widehat{\mathrm{epi}}(g - v(P_A))$, we obtain

$$\mathrm{epi}(F) - \widehat{\mathrm{epi}}(G - v(P_A)) = X \times (A \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f)) - \widehat{\mathrm{epi}}(g - v(P_A))),$$

and this means that $(0,0,0) \notin \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}(F) - \widehat{\mathrm{epi}}(G - v(P_A))) \cup \{(0,0,0)\}]$. Theorem 3.5 yields for F and G:

$$\inf_{(x,y)\in X\times Y}[F(x,y) + G(x,y)] = \max_{(x^*,y^*)\in X^*\times Y^*}\{-F^*(-x^*,-y^*) - G^*(x^*,y^*)\}.$$

On the other hand, $F^*(x^*,y^*) = f^*(x^* + A^*y^*)$ for all $(x^*,y^*) \in X^* \times Y^*$, and

$$G^*(x^*,y^*) = \begin{cases} g^*(y^*) & \text{if } x^* = 0, \\ +\infty & \text{otherwise.} \end{cases}$$

Therefore, $\max_{(x^*,y^*)\in X^*\times Y^*}\{-F^*(-x^*,-y^*) - G^*(x^*,y^*)\} = \max_{y^*\in Y^*}\{-f^*(-A^*y^*) - g^*(y^*)\}$, and the conclusion follows. □

COROLLARY 3.15. *Suppose that the primal problem (P_A) has an optimal solution, $0 \in \mathrm{qi}[(A(\mathrm{dom}(f)) - \mathrm{dom}(g)) - (A(\mathrm{dom}(f)) - \mathrm{dom}(g))]$, $0 \in \mathrm{qri}(A(\mathrm{dom}(f)) - \mathrm{dom}(g))$, and $(0,0) \notin \mathrm{qri}[A \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f)) - \widehat{\mathrm{epi}}(g - v(P_A))]$. Then $v(P_A) = v(D_A)$, and (D_A) has an optimal solution.*

THEOREM 3.16. *Suppose that $0 \in \mathrm{qi}(A(\mathrm{dom}(f)) - \mathrm{dom}(g))$ and $(0,0) \notin \mathrm{qri}\,\mathrm{co}[(A \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f)) - \widehat{\mathrm{epi}}(g - v(P_A))) \cup \{(0,0)\}]$. Then $v(P_A) = v(D_A)$, and (D_A) has an optimal solution.*

Proof. By considering the functions F and G from the proof of Theorem 3.14, we have $\mathrm{cl}\,\mathrm{cone}(\mathrm{dom}(F) - \mathrm{dom}(G)) = X \times \mathrm{cl}\,\mathrm{cone}(A(\mathrm{dom}(f)) - \mathrm{dom}(g)) = X \times Y$, and thus $(0,0) \in \mathrm{qi}(\mathrm{dom}(F) - \mathrm{dom}(G))$. Also we have $(0,0,0) \notin \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}(F) - \widehat{\mathrm{epi}}(G - v(P_A))) \cup \{(0,0,0)\}]$. Theorem 3.8 yields for F and G:

$$\inf_{(x,y)\in X\times Y}[F(x,y) + G(x,y)] = \max_{(x^*,y^*)\in X^*\times Y^*}\{-F^*(-x^*,-y^*) - G^*(x^*,y^*)\},$$

and the conclusion follows. □

COROLLARY 3.17. *Suppose that the primal problem (P_A) has an optimal solution, $0 \in \mathrm{qi}(A(\mathrm{dom}(f)) - \mathrm{dom}(g))$, and $(0,0) \notin \mathrm{qri}[A \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f)) - \widehat{\mathrm{epi}}(g - v(P_A))]$. Then $v(P_A) = v(D_A)$, and (D_A) has an optimal solution.*

THEOREM 3.18. *Suppose that $A(\mathrm{dom}(f)) \cap \mathrm{qri}\,\mathrm{dom}(g) \neq \emptyset$, $0 \in \mathrm{qi}(\mathrm{dom}(g) - \mathrm{dom}(g))$ and $(0,0) \notin \mathrm{qri}\,\mathrm{co}[(A \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f)) - \widehat{\mathrm{epi}}(g - v(P_A))) \cup \{(0,0)\}]$. Then $v(P_A) = v(D_A)$, and (D_A) has an optimal solution.*

Proof. Consider again the functions F and G defined as in the proof of Theorem 3.14. We have $\mathrm{dom}(F) \cap \mathrm{qri}\,\mathrm{dom}(G) = (\mathrm{dom}(f) \times (A(\mathrm{dom}(f))) \cap (X \times \mathrm{qri}\,\mathrm{dom}(g))) = \mathrm{dom}(f) \times (A(\mathrm{dom}(f)) \cap \mathrm{qri}\,\mathrm{dom}(g)) \neq \emptyset$. Also, $\mathrm{cl}\,\mathrm{cone}(\mathrm{dom}(G) - \mathrm{dom}(G)) = X \times \mathrm{cl}\,\mathrm{cone}(\mathrm{dom}(g) - \mathrm{dom}(g)) = X \times Y$, and hence $(0,0) \in \mathrm{qi}(\mathrm{dom}(G) - \mathrm{dom}(G))$. Moreover, $(0,0,0) \notin \mathrm{qri}\,\mathrm{co}[(\mathrm{epi}(F) - \widehat{\mathrm{epi}}(G - v(P_A))) \cup \{(0,0,0)\}]$. Theorem 3.10 yields for F and G:

$$\inf_{(x,y)\in X\times Y}[F(x,y) + G(x,y)] = \max_{(x^*,y^*)\in X^*\times Y^*}\{-F^*(-x^*,-y^*) - G^*(x^*,y^*)\},$$

and the conclusion follows. □

COROLLARY 3.19. *Suppose that the primal problem* (P_A) *has an optimal solution,* $A(\mathrm{dom}(f)) \cap \mathrm{qri}\,\mathrm{dom}(g) \neq \emptyset$, $0 \in \mathrm{qi}(\mathrm{dom}(g) - \mathrm{dom}(g))$, *and* $(0,0) \notin \mathrm{qri}[A \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f)) - \widehat{\mathrm{epi}}(g - v(P_A))]$. *Then* $v(P_A) = v(D_A)$, *and* (D_A) *has an optimal solution.*

4. Lagrange duality. By using an approach due to Magnanti (cf. [13]), in this section we derive from the results in the previous section some duality results concerning the Lagrange dual problem. We work in the following setting. Let X be a real linear topological space and S a nonempty subset of X. Let Y be a separated locally convex space partially ordered by a convex cone C. Let $f : S \to \mathbb{R}$ and $g : S \to Y$ be two functions such that the function $(f,g) : S \to \mathbb{R} \times Y$, defined by $(f,g)(x) = (f(x), g(x))$, for all $x \in S$, is convexlike with respect to the cone $\mathbb{R}_+ \times C \subseteq \mathbb{R} \times Y$; that is, the set $(f,g)(S) + \mathbb{R}_+ \times C$ is convex. Let us notice that this property implies that the sets $f(S) + [0,\infty)$ and $g(S) + C$ are convex (the reverse implication does not always hold). Consider the optimization problem

$$(P_L) \qquad \inf_{\substack{x \in S \\ g(x) \in -C}} f(x),$$

where the constraint set $T = \{x \in S : g(x) \in -C\}$ is assumed to be nonempty. The Lagrange dual problem associated to (P_L) is

$$(D_L) \qquad \sup_{\lambda \in C^*} \inf_{x \in S} [f(x) + \langle \lambda, g(x) \rangle],$$

where $C^* = \{x^* \in X^* : \langle x^*, x \rangle \geq 0, \forall x \in C\}$ is the *dual cone* of C. Let us denote by $v(P_L)$ and $v(D_L)$ the optimal objective values of the primal and the dual problem, respectively. A regularity condition for strong duality between (P_L) and (D_L) was proposed in Theorem 2.2 in [4]. We show first that this theorem has self-contradictory assumptions. To this end we prove the following lemma.

LEMMA 4.1. *Suppose that* $\mathrm{cl}(C - C) = Y$ *and there exists* $\overline{x} \in S$ *such that* $g(\overline{x}) \in -\mathrm{qri}\, C$. *Then the following assertions are true:*

(a) $0 \in \mathrm{qi}(g(S) + C)$;

(b) $\mathrm{cl}\,\mathrm{cone}[\mathrm{qri}(g(S) + C)]$ *is a linear subspace of* Y.

Proof. (a) We apply Lemma 2.6 with $A := -C$ and $B := g(S) + C$. The condition $\mathrm{cl}(C - C) = Y$ implies that $0 \in \mathrm{qi}(A - A)$, while the Slater-type condition $g(\overline{x}) \in -\mathrm{qri}\, C$ ensures that $g(\overline{x}) \in \mathrm{qri}\, A \cap B$. Hence, by Lemma 2.6 we obtain $0 \in \mathrm{qi}(A - B)$, that is, $0 \in \mathrm{qi}(-g(S) - C)$, which is nothing else than $0 \in \mathrm{qi}(g(S) + C)$.

(b) From (a) it follows that $0 \in \mathrm{qri}(g(S) + C)$. By applying Proposition 2.5(vii) we get $0 \in \mathrm{qri}(\mathrm{qri}(g(S) + C))$, which is nothing else than $\mathrm{cl}\,\mathrm{cone}[\mathrm{qri}(g(S) + C)]$ is a linear subspace of Y. □

In order to get strong duality between (P_L) and (D_L) in Theorem 2.2 in [4] the authors ask that the following hypotheses are fulfilled: $\mathrm{cl}(C - C) = Y$, there exists $\overline{x} \in S$ such that $g(\overline{x}) \in -\mathrm{qri}\, C$, $\mathrm{qri}(g(S) + C) \neq \emptyset$, and $\mathrm{cl}\,\mathrm{cone}[\mathrm{qri}(g(S) + C)]$ is not a linear subspace of Y. The previous lemma proves that these assumptions are in contradiction.

Next we prove some Lagrange duality results written in terms of the quasi interior and quasi-relative interior, respectively. As in the previous section, we may suppose that $v(P_L)$ is a real number.

Consider the following convex set:

$$\mathcal{E}_{v(P_L)} = \{(f(x) + \alpha - v(P_L), g(x) + y) : x \in S, \alpha \geq 0, y \in C\} \subseteq \mathbb{R} \times Y.$$

Let us notice that the set $-\mathcal{E}_{v(P_L)}$ is in analogy with the *conic extension*, a notion used by Giannessi in the theory of image space analysis (see [7]). One can easily prove that the primal problem (P_L) has an optimal solution if and only if $(0,0) \in \mathcal{E}_{v(P_L)}$. Let us introduce the functions $f_1, f_2 : \mathbb{R} \times Y \to \overline{\mathbb{R}}$,

$$f_1(y_0, y_1) = \begin{cases} y_0 & \text{if } (y_0, y_1) \in \mathcal{E}_{v(P_L)} + (v(P_L), 0), \\ +\infty & \text{otherwise,} \end{cases}$$

and $f_2 = \delta_{\mathbb{R}\times(-C)}$. It holds that

$$\operatorname{dom}(f_1) - \operatorname{dom}(f_2) = \mathbb{R} \times (g(S) + C). \tag{13}$$

Moreover, as pointed out by Magnanti (cf. [13]), we have

$$\inf_{(y_0,y_1)\in\mathbb{R}\times Y} \{f_1(y_0, y_1) + f_2(y_0, y_1)\} = \inf_{\substack{x\in S \\ g(x)\in -C}} f(x) = v(P_L) \tag{14}$$

and

$$\sup_{(y_0^*,y_1^*)\in\mathbb{R}\times Y^*} \{-f_1^*(-y_0^*, -y_1^*) - f_2^*(y_0^*, y_1^*)\} = \sup_{\lambda\in C^*} \inf_{x\in S} [f(x) + \langle \lambda, g(x)\rangle] = v(D_L). \tag{15}$$

With this approach, we can derive from the strong duality results given for Fenchel duality corresponding strong duality results for Lagrange duality.

THEOREM 4.2. *Suppose that* $0 \in \operatorname{qi}[(g(S) + C) - (g(S) + C)]$, $0 \in \operatorname{qri}(g(S) + C)$, *and* $(0,0) \notin \operatorname{qri}\operatorname{co}(\mathcal{E}_{v(P_L)} \cup \{(0,0)\})$. *Then* $v(P_L) = v(D_L)$, *and* (D_L) *has an optimal solution.*

Proof. The hypotheses of the theorem and (13) imply that the conditions $(0,0) \in \operatorname{qi}[(\operatorname{dom}(f_1) - \operatorname{dom}(f_2)) - (\operatorname{dom}(f_1) - \operatorname{dom}(f_2))]$ and $(0,0) \in \operatorname{qri}(\operatorname{dom}(f_1) - \operatorname{dom}(f_2))$ are fulfilled. Further, $\operatorname{epi}(f_1) = \{(y_0, y_1, r) \in \mathbb{R}\times Y\times\mathbb{R} : (y_0, y_1) \in \mathcal{E}_{v(P_L)} + (v(P_L), 0), y_0 \le r\} = \{(f(x)+\alpha, g(x)+y, r) : x \in S, \alpha \ge 0, y \in C, f(x)+\alpha \le r\}$, and $\widehat{\operatorname{epi}}(f_2 - v(P_L)) = \{(y_0, y_1, r) \in \mathbb{R} \times Y \times \mathbb{R} : r \le -f_2(y_0, y_1) + v(P_L)\} = \{(y_0, y_1, r) \in \mathbb{R} \times Y \times \mathbb{R} : y_0 \in \mathbb{R}, y_1 \in -C, r \le v(P_L)\} = \mathbb{R} \times (-C) \times (-\infty, v(P_L)]$. Thus $\operatorname{epi}(f_1) - \widehat{\operatorname{epi}}(f_2 - v(P_L)) = \operatorname{epi}(f_1) + \mathbb{R} \times C \times [-v(P_L), +\infty) = \{(f(x) + \alpha + a, g(x) + y, r - v(P_L) + \varepsilon) : x \in S, \alpha \ge 0, a \in \mathbb{R}, y \in C, \varepsilon \ge 0, f(x) + \alpha \le r\} = \{(f(x) + \alpha + a, g(x) + y, f(x) + \alpha + \varepsilon - v(P_L)) : x \in S, \alpha \ge 0, a \in \mathbb{R}, y \in C, \varepsilon \ge 0\}$, and this means that

$$\operatorname{epi}(f_1) - \widehat{\operatorname{epi}}(f_2 - v(P_L)) = \mathbb{R} \times \{(g(x) + y, f(x) + \alpha - v(P_L)) : x \in S, \alpha \ge 0, y \in C\}.$$

Thus $(0,0,0) \in \operatorname{qri}\operatorname{co}[(\operatorname{epi}(f_1) - \widehat{\operatorname{epi}}(f_2 - v(P_L))) \cup \{(0,0,0)\}]$ if and only if $(0,0) \in \operatorname{qri}\operatorname{co}(\mathcal{E}_{v(P_L)} \cup \{(0,0)\})$. Now we can apply Theorem 3.5 for f_1 and f_2, and we obtain

$$\inf_{(y_0,y_1)\in\mathbb{R}\times Y} \{f_1(y_0, y_1) + f_2(y_0, y_1)\} = \max_{(y_0^*,y_1^*)\in\mathbb{R}\times Y^*} \{-f_1^*(-y_0^*, -y_1^*) - f_2^*(y_0^*, y_1^*)\}.$$

By (14) and (15) the conclusion follows. □

COROLLARY 4.3. *Suppose that the primal problem* (P_L) *has an optimal solution,* $0 \in \operatorname{qi}[(g(S) + C) - (g(S) + C)]$, $0 \in \operatorname{qri}(g(S) + C)$, *and* $(0,0) \notin \operatorname{qri}\mathcal{E}_{v(P_L)}$. *Then* $v(P_L) = v(D_L)$, *and* (D_L) *has an optimal solution.*

Further, like for Fenchel duality, other Lagrange duality results can be stated.

THEOREM 4.4. *Suppose that* $0 \in \operatorname{qi}(g(S)+C)$ *and* $(0,0) \notin \operatorname{qri}\operatorname{co}(\mathcal{E}_{v(P_L)}\cup\{(0,0)\})$. *Then* $v(P_L) = v(D_L)$, *and* (D_L) *has an optimal solution.*

Proof. This is a direct consequence of the previous theorem since $g(S)+C \subseteq (g(S)+C)-(g(S)+C)$, and so the condition $0 \in \operatorname{qi}(g(S)+C)$ implies that $0 \in \operatorname{qi}[(g(S)+C)-(g(S)+C)]$ and $0 \in \operatorname{qri}(g(S)+C)$. □

COROLLARY 4.5. *Suppose that the primal problem (P_L) has an optimal solution, $0 \in \operatorname{qi}(g(S)+C)$, and $(0,0) \notin \operatorname{qri}\mathcal{E}_{v(P_L)}$. Then $v(P_L)=v(D_L)$, and (D_L) has an optimal solution.*

THEOREM 4.6. *Suppose that $\operatorname{cl}(C-C)=Y$ and there exists $\overline{x} \in S$ such that $g(\overline{x}) \in -\operatorname{qri} C$. If $(0,0) \notin \operatorname{qri}\operatorname{co}(\mathcal{E}_{v(P_L)} \cup \{(0,0)\})$, then $v(P_L)=v(D_L)$, and (D_L) has an optimal solution.*

Proof. The condition $(0,0) \notin \operatorname{qri}\operatorname{co}(\mathcal{E}_{v(P_L)} \cup \{(0,0)\})$ implies that $(0,0,0) \notin \operatorname{qri}\operatorname{co}[(\operatorname{epi}(f_1) - \widehat{\operatorname{epi}}(f_2 - v(P_L))) \cup \{(0,0,0)\}]$ (cf. the proof of Theorem 4.2). Further, we have $\operatorname{dom}(f_1) \cap \operatorname{qri}\operatorname{dom}(f_2) = [\mathcal{E}_{v(P_L)} + (v(P_L),0)] \cap \operatorname{qri}(\mathbb{R} \times (-C)) = [\mathcal{E}_{v(P_L)} + (v(P_L),0)] \cap [\mathbb{R} \times (-\operatorname{qri} C)]$. From the Slater-type condition we get that $(f(\overline{x}), g(\overline{x})) \in [\mathcal{E}_{v(P_L)} + (v(P_L),0)] \cap [\mathbb{R} \times (-\operatorname{qri} C)]$, and hence $\operatorname{dom}(f_1) \cap \operatorname{qri}\operatorname{dom}(f_2) \neq \emptyset$. Moreover, $\operatorname{cl}\operatorname{cone}(\operatorname{dom}(f_2) - \operatorname{dom}(f_2)) = \operatorname{cl}\operatorname{cone}[\mathbb{R} \times (C-C)] = \mathbb{R} \times \operatorname{cl}(C-C) = \mathbb{R} \times Y$, and hence $(0,0) \in \operatorname{qi}(\operatorname{dom}(f_2) - \operatorname{dom}(f_2))$. By Theorem 3.10 for f_1 and f_2 we obtain

$$\inf_{(y_0,y_1) \in \mathbb{R} \times Y} \{f_1(y_0,y_1) + f_2(y_0,y_1)\} = \max_{(y_0^*,y_1^*) \in \mathbb{R} \times Y^*} \{-f_1^*(-y_0^*,-y_1^*) - f_2^*(y_0^*,y_1^*)\},$$

and by using again (14) and (15) the conclusion follows. □

COROLLARY 4.7. *Suppose that the primal problem (P_L) has an optimal solution, $\operatorname{cl}(C-C)=Y$, and there exists $\overline{x} \in S$ such that $g(\overline{x}) \in -\operatorname{qri} C$. If $(0,0) \notin \operatorname{qri}\mathcal{E}_{v(P_L)}$, then $v(P_L)=v(D_L)$, and (D_L) has an optimal solution.*

Remark 4.8. Let us notice that from the above results one can derive duality theorems for the case when, in the set of constraints, one has also equalities defined by affine functions. Indeed, consider the optimization problem

$$(P_L^{aff}) \quad \inf_{\substack{x \in S \\ g(x) \in -C \\ h(x)=0}} f(x),$$

where $h: X \to Z$ is an affine mapping and Z is a real normed space (the hypotheses regarding the functions f and g remain the same as in the beginning of this section). The Lagrange dual problem associated to (P_L^{aff}) is

$$(D_L^{aff}) \quad \sup_{\substack{\lambda \in C^* \\ \mu \in Z^*}} \inf_{x \in S} [f(x) + \langle \lambda, g(x) \rangle + \langle \mu, h(x) \rangle],$$

where Z^* is the topological dual space of Z.

By using Theorems 4.2 and 4.4 one can formulate Lagrange duality theorems for (P_L^{aff}) and (D_L^{aff}) by noticing that the primal problem can be reformulated as

$$\inf_{\substack{x \in S \\ g(x) \in -C \\ h(x)=0}} f(x) = \inf_{\substack{x \in S \\ u(x) \in -(C \times \{0\})}} f(x),$$

where $u: S \to Y \times Z$, $u(x) = (g(x), h(x))$. For the optimization problem with equality and cone constraints some regularity conditions have been given in [5] by using the notion of the quasi-relative interior. Along them in the strong duality theorem (Theorem 3.1 in [5]) a "separation assumption," called by the authors *Assumption S*, is imposed. Unfortunately, this assumption is not only a sufficient condition for having

strong duality, as claimed in the paper, but actually an equivalent formulation of this situation (this makes the other regularity conditions inoperative). More than that, in the proof of Theorem 3.1 in [5] a mistake occurred, namely, in the relation after inequality (8) when trying to prove the "nonverticality" of the separating hyperplane.

The approach we propose above offers a viable alternative for dealing with Lagrange duality for this class of optimization problems.

Acknowledgments. The authors are thankful to two anonymous reviewers for comments and remarks which have improved the quality of the paper.

A SHORT ALGEBRAIC PROOF OF THE FARKAS LEMMA*

DAVID BARTL†

Abstract. The purpose of this paper is to present a generalization of the Farkas lemma with a short algebraic proof. The generalization lies in the fact that we formulate the Farkas lemma in the setting of two vector spaces over a common linearly ordered field where one of the vector spaces is also linearly ordered. At the end of the paper, we mention the key theorem and two theorems of the alternative, namely Motzkin's theorem and Tucker's theorem.

Key words. Farkas lemma, systems of linear inequalities, theorems of the alternative, linearly ordered vector spaces, Motzkin's theorem, Tucker's theorem, key theorem

1. Introduction.

There are many proofs of the Farkas lemma [9], which is usually formulated in the setting of a finite-dimensional real vector space $\mathbb{R}^n$. Broyden [3] distinguishes three classes of proofs: algebraic, algorithmic, and geometric. The Farkas lemma is often the starting point when proving the duality theorem for linear programming (see, e.g., [18]) or when proving some other theorems of the alternative. Overviews of such theorems can be found in [21, 10, 12, 11, 4, 5, 3, 2]; see also [8, 19]. Out of the mentioned works, only the paper of Fan [10], the book of Chernikov [4], and the paper of Bartl [2] deal with the topic of linear inequalities in the setting of a general vector space, whose dimension may be infinite and no topology or any additional structure is assumed on it. While Fan [10] works within a real vector space, Chernikov [4] and Bartl [2] assume the more general setting of a vector space over a linearly ordered field.

Confining our attention to the Farkas lemma and speaking in broad terms, we need a "base" vector space, a linearly ordered field, and the additive group of the field with its ordering to formulate the Farkas lemma given by Chernikov [4, Lemma 2.4, p. 119]. But Bartl [2] showed that it is possible to substitute any linearly ordered vector space instead of the additive group of the field, thus generalizing the result. The resulting duality theorem for linear programming is also presented in [2].

Though the author's proof of the Farkas lemma [2, Lemma 4.1] is elementary and its main idea is easy to comprehend, the proof is rather long. In this paper, we give another proof—which is based on a different idea and, moreover, is significantly shorter—of the same result.

In addition to the algebraic approach, which we shall use in the following sections to prove the result, and as already mentioned above, other approaches are also possible. See, e.g., [6, 18] or [22, 20, 1, 15] for the algorithmic or geometric approach, respectively. Though the algebraic approach allows us to obtain quite a general version of the Farkas lemma, the geometric one permits a very illustrative exposition—see [7], where the geometric approach is applied within a finite-dimensional space. This is a certain "trade-off" between the approaches that has to be considered.

2. Notation. Throughout this paper, the symbol F denotes a linearly ordered field; we do *not* assume the commutativity of the field so that F may even be a skew field. The symbol W denotes a vector space over the field F. The dimension of the vector space W may be finite or infinite and we do not assume any other structure (such as topology) on it; it plays the role of the underlying "base" vector space. The symbol V stands for a linearly ordered vector space over the linearly ordered field F. In what follows, we shall see it plays the role of the vector space of "objective values." The ordering of the (possibly skew) field F and that of the space V will be denoted by the symbols "$\leq$" and "$\preceq$," respectively.

Recall that the following five statements must hold true for all $u, v \in V$, and any scalar $\lambda \in F$ so that V is a linearly ordered vector space over the linearly ordered field F: first, $u \preceq v$ if and only if $u - v \preceq 0$; second, $u \succeq 0$ or $u \preceq 0$; third, if $u \succeq 0$ and $u \preceq 0$, then $u = 0$; fourth, if $u \succeq 0$ and $v \succeq 0$, then $u + v \succeq 0$; fifth, if $\lambda \geq 0$ and $u \succeq 0$, then $\lambda u \succeq 0$. It is possible to substitute the additive group of the field F with its ordering "$\leq$" for the space V and its ordering "$\preceq$." Hence, five analogous statements must also hold true when assuming $u, v \in F$, and writing "$\leq$" instead of "$\preceq$."

We shall use the symbol γ to denote a given linear mapping $\gamma\colon W \to V$. It assigns an "objective value" $\gamma(x)$ to any point x of the "base" vector space W.

Now, let m be a nonnegative natural number. Then F^m is the (left) vector space over the (possibly skew) field F of all m-component column vectors whose entries come from the field F. Analogously, the V^m is the space of all m-component columns with entries from the space V. If $\boldsymbol{\lambda} \in F^m$ or $\boldsymbol{u} \in V^m$, then the ith component of the respective column is λ_i or u_i for $i = 1, \ldots, m$. We symbolically write $\boldsymbol{\lambda} = (\lambda_i)_{i=1}^m$ and $\boldsymbol{u} = (u_i)_{i=1}^m$. The transposition of a column is indicated by the letter T in the superscript so that $\boldsymbol{\lambda}^T$ and $\boldsymbol{u}^T$ are the respective rows. The symbol $\boldsymbol{o}$ denotes the origin of the space F^m or V^m (depending on the context) and inequalities like $\boldsymbol{u} \succeq \boldsymbol{o}$, $\boldsymbol{\lambda} \geq \boldsymbol{o}$, $\boldsymbol{\lambda} > \boldsymbol{o}$, etc. are to be understood componentwise.

The symbol A stands for a linear mapping $A\colon W \to F^m$. If $x \in W$, then Ax is a column vector and its ith component is $\alpha_i(x)$ for $i = 1, \ldots, m$. It follows that $\alpha_1, \ldots, \alpha_m$ are the respective linear forms on the vector space W and we have $A = (\alpha_i)_{i=1}^m$.

Let $u \in V$ be a given vector. The linear mapping assigning the scalar multiple of the vector u to any scalar $\mu \in F$ is denoted by writing the Greek letter ι before u so that we have the linear mapping $\iota u\colon F \to V$ and $\iota u(\mu) = \mu u$ for all $\mu \in F$. Analogously, if ι is written before a given scalar $\lambda \in F$, then we have the linear mapping $\iota\lambda\colon F \to F$ and $\iota\lambda(\mu) = \mu\lambda$ for all $\mu \in F$. (As the field F may be skew, it is essential that the given scalar λ is multiplied by the scalar μ from the left.)

Having a vector $u \in V$ and a linear form α defined on the vector space W, then $\iota u\alpha$ denotes the composition of the mappings $\alpha\colon W \to F$ and $\iota u\colon F \to V$. Similarly, given yet a scalar $\lambda \in F$, then $\iota u \iota\lambda\alpha$ is the composition of the form α with $\iota\lambda\colon F \to F$ and ιu.

If the letter ι stands before a row $\boldsymbol{u}^T$, where $\boldsymbol{u} \in V^m$, then it is to be inserted into the row and put before each of its entries. The row can be multiplied by a column vector (from the right) in the usual manner. We obtain the linear mapping $\iota\boldsymbol{u}^T\colon F^m \to V$ and we have $\iota\boldsymbol{u}^T\boldsymbol{\mu} = \mu_1 u_1 + \cdots + \mu_m u_m$ for all $\boldsymbol{\mu} \in F^m$. The same applies when ι stands before a row $\boldsymbol{\lambda}^T$, where $\boldsymbol{\lambda} \in F^m$; we then obtain the linear mapping $\iota\boldsymbol{\lambda}^T\colon F^m \to F$.

Consequently, given a linear mapping $A\colon W \to F^m$, then $\iota\boldsymbol{u}^T A\colon W \to V$ or $\iota\boldsymbol{\lambda}^T A\colon W \to F$, where $\boldsymbol{u} \in V^m$ and $\boldsymbol{\lambda} \in F^m$, is the respective composed linear map-

ping. We have $\iota\boldsymbol{u}^T A = \iota u_1\alpha_1 + \cdots + \iota u_m\alpha_m$ and $\iota\boldsymbol{u}^T Ax = (\alpha_1(x))u_1 + \cdots + (\alpha_m(x))u_m$ for any $x \in W$. Analogous formulas could be written for the mapping $\iota\boldsymbol{\lambda}^T A$.

3. The Farkas lemma. We state the generalized version of the Farkas lemma [2, Lemma 4.1] now. Putting $V = F$, i.e., substituting the additive group of the field F with its ordering for the linearly ordered vector space V, we obtain the formulation of the Farkas lemma given by Chernikov [4, Lemma 2.4, p. 119]. Substituting the field of reals $\mathbb{R}$ with the standard ordering for the linearly ordered field F, still assuming $V = F$, we obtain the Farkas lemma formulated in the setting of a real (possibly infinite-dimensional) vector space. In this setting, Fan [10, Theorem 4] proved Haar's theorem (cf. [13, 14]) which—still within this setting, but not in general—is a strengthening of the Farkas lemma. When $V = F = \mathbb{R}$ and the "base" vector space is finite-dimensional, $W = \mathbb{R}^n$, we then obtain the classical formulation of the Farkas lemma [9, section IV]. Substituting the vector space $\mathbb{R}^N$ with the lexicographic ordering for V, while the dimension of W may be finite or infinite, we then obtain the lexicographic version of the Farkas lemma [2, Theorem 1.5].

LEMMA 1 (Farkas lemma). *Let $A\colon W \to F^m$ and $\gamma\colon W \to V$ be linear mappings. Then the implication $Ax \preceq \boldsymbol{o} \Rightarrow \gamma(x) \preceq 0$ or*

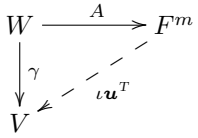
$$\alpha_1(x) \le 0 \wedge \cdots \wedge \alpha_m(x) \le 0 \implies \gamma(x) \preceq 0 \tag{1}$$

holds for all $x \in W$ if and only if

$$\exists u_1, \dots, u_m \succeq 0\colon\ \iota u_1\alpha_1 + \cdots + \iota u_m\alpha_m = \gamma\,, \tag{2}$$

i.e., $\iota\boldsymbol{u}^T A = \gamma$ for some $\boldsymbol{u} \in V^m$ satisfying $\boldsymbol{u} \succeq \boldsymbol{o}$ componentwise.

While the implication $\Leftarrow$ of Lemma 1 is trivial, the implication $\Rightarrow$ yields the following commutative diagram:



In words, if the given linear mappings A and γ satisfy implication (1) for all $x \in W$, then there exists a linear mapping $\iota\boldsymbol{u}^T\colon F^m \to V$ that makes the diagram commute; in addition, we have $\boldsymbol{u} \succeq \boldsymbol{o}$ componentwise.

We prove an alternative formulation of the Farkas lemma, which is given below. It can be easily seen that both formulations, i.e., Lemmas 1 and 2, are logically equivalent.

LEMMA 2 (Farkas lemma). *Let $A\colon W \to F^m$ and $\gamma\colon W \to V$ be linear mappings. Then either* (A) *there exists an $x \in W$ such that $\alpha_1(x) \ge 0, \dots, \alpha_m(x) \ge 0$, and $\gamma(x) \prec 0$, or* (B) *there exist nonnegative vectors $u_1, \dots, u_m \in V$ such that $\gamma = \iota u_1\alpha_1 + \cdots + \iota u_m\alpha_m$. The alternatives* (A) *and* (B) *exclude each other.*

Proof. We proceed by induction. The statement is trivial for $m = 0$ because either (A) there exists an $x \in W$ such that $\gamma(x) \ne 0$, in which case we may assume w.l.o.g. that $\gamma(x) \prec 0$, or (B) it holds that $\gamma(x) = 0$ for all $x \in W$.

Let us assume that the statement is valid for a nonnegative natural number m. We prove the assertion for $m + 1$. We have to prove that either (A) there exists an $x \in W$ such that $\alpha_1(x) \ge 0, \dots, \alpha_m(x) \ge 0$, $\alpha_{m+1}(x) \ge 0$, and $\gamma(x) \prec 0$, or (B) there exist vectors $u_1, \dots, u_m, u_{m+1} \succeq 0$ such that $\gamma = \iota u_1\alpha_1 + \cdots + \iota u_m\alpha_m + \iota u_{m+1}\alpha_{m+1}$.

By the induction hypothesis, either (a) there exists an $x \in W$ such that $\alpha_1(x) \geq 0$, $\ldots$, $\alpha_m(x) \geq 0$, and $\gamma(x) \prec 0$, or (b) there exist vectors $u_1, \ldots, u_m \succeq 0$ such that $\gamma = \iota u_1 \alpha_1 + \cdots + \iota u_m \alpha_m$.

We are finished in the case (b) for it suffices to put $u_{m+1} = 0$ so that the case (B) arises. In the case (a), there are two cases: either (aa) it holds that $\alpha_{m+1}(x) \geq 0$, or (ab) it holds that $\alpha_{m+1}(x) < 0$. We are finished again in the case (aa) because the case (A) arises. It remains to consider the case (ab) in the rest of the proof.

Having an $\bar{x} := x$ such that $\alpha_1(\bar{x}) \geq 0, \ldots, \alpha_m(\bar{x}) \geq 0$, $\alpha_{m+1}(\bar{x}) < 0$, and $\gamma(\bar{x}) \prec 0$, it is easy to see that the system

$$\alpha_1(x) \geq 0 \wedge \cdots \wedge \alpha_m(x) \geq 0 \wedge \alpha_{m+1}(x) \geq 0 \quad \text{and} \quad \gamma(x) \prec 0 \tag{3}$$

has a solution—therefore, the case (A) arises—if and only if the system

$$\alpha_1(x) \geq 0 \wedge \cdots \wedge \alpha_m(x) \geq 0 \wedge \alpha_{m+1}(x) = 0 \quad \text{and} \quad \gamma(x) \prec 0 \tag{4}$$

has a solution.

We find $\lambda_1, \ldots, \lambda_m \in F$ and a $v \in V$ so that $\alpha_i(\bar{x}) - \iota\lambda_i\alpha_{m+1}(\bar{x}) = 0$ and $\gamma(\bar{x}) - \iota v\alpha_{m+1}(\bar{x}) = 0$. We have $\lambda_i = (\alpha_{m+1}(\bar{x}))^{-1}\alpha_i(\bar{x})$ and $v = (\alpha_{m+1}(\bar{x}))^{-1}\gamma(\bar{x})$. As $\alpha_{m+1}(\bar{x}) < 0$, further $\alpha_i(\bar{x}) \geq 0$ and $\gamma(\bar{x}) \prec 0$, it is obvious that $\lambda_i \leq 0$ for $i = 1, \ldots, m$ and that $v \succ 0$.

Let us denote $\alpha'_i = \alpha_i - \iota\lambda_i\alpha_{m+1}$ and $\gamma' = \gamma - \iota v\alpha_{m+1}$. Hence $\alpha'_i(\bar{x}) = 0$ and $\gamma'(\bar{x}) = 0$, where $i = 1, \ldots, m$. It is very easy to see that the last system (4) has a solution—equivalently, the case (A) arises—if and only if the system

$$\alpha'_1(x) \geq 0 \wedge \cdots \wedge \alpha'_m(x) \geq 0 \wedge \alpha_{m+1}(x) = 0 \quad \text{and} \quad \gamma'(x) \prec 0 \tag{5}$$

has a solution.

Using the induction hypothesis again, we obtain that either (aba) there exists an $x' \in W$ such that $\alpha'_1(x') \geq 0, \ldots, \alpha'_m(x') \geq 0$, and $\gamma(x') \prec 0$, or (abb) there exist vectors $u'_1, \ldots, u'_m \succeq 0$ such that $\gamma' = \iota u'_1\alpha'_1 + \cdots + \iota u'_m\alpha'_m$.

Assume the case (aba) first. To solve system (5), we are looking for a point $x \in W$ such that $\alpha_{m+1}(x) = 0$ and $\alpha'_i(x) = \alpha'_i(x')$ for $i = 1, \ldots, m$ and $\gamma'(x) = \gamma'(x')$. We utilize the fact that $\alpha'_i(\bar{x}) = 0$ for $i = 1, \ldots, m$ and $\gamma'(\bar{x}) = 0$. Considering the point $x := x' - \mu\bar{x}$, where $\mu = (\alpha_{m+1}(x'))(\alpha_{m+1}(\bar{x}))^{-1}$, we can see that the case (A) arises.

In the remaining case (abb), we have

$$\begin{aligned} \gamma' &= \iota u'_1\alpha'_1 + \cdots + \iota u'_m\alpha'_m\,, \\ \gamma - \iota v\alpha_{m+1} &= \iota u'_1\alpha_1 - \iota u'_1\iota\lambda_1\alpha_{m+1} + \cdots + \iota u'_m\alpha_m - \iota u'_m\iota\lambda_m\alpha_{m+1}\,, \\ \gamma &= \iota u'_1\alpha_1 + \cdots + \iota u'_m\alpha_m + \iota(v - \lambda_1 u'_1 - \cdots - \lambda_m u'_m)\alpha_{m+1}\,. \end{aligned}$$

Hence, putting $u_i := u'_i$ for $i = 1, \ldots, m$ and $u_{m+1} = v - \lambda_1 u'_1 - \cdots - \lambda_m u'_m$, it is obvious that $u_{m+1} \succ 0$, and we can see that the case (B) arises. □

The presented proof of the Farkas lemma is a modified proof of a lemma due to Tucker [21, Lemma, p. 5]. Tucker himself notes that he uses an argument adapted from a certain unpublished proof by Gale. Indeed, the proof is quite similar to Gale's later published proof of the Farkas lemma [11, Theorem 2.6, p. 44]. Though Tucker [21] notes that he could also work with any linearly ordered field, both Tucker [21] and Gale [11] assume the setting of a finite-dimensional vector space only.

Close to Tucker's original lemma [21, Lemma, p. 5] is the following result. We prove it as a consequence of Lemma 2.

LEMMA 3. *Let $A\colon W \to F^m$ be a linear mapping. Then for any $i = 1, \dots, m$ there exist a componentwise nonnegative vector $\boldsymbol{\lambda} \in F^m$ and a point $x \in W$ such that*

$$\iota\boldsymbol{\lambda}^T A = o\,, \qquad Ax \geq \boldsymbol{o}, \qquad \text{and} \qquad \lambda_i + \alpha_i(x) > 0\,,$$

where o is the zero linear form $o\colon W \to F$.

Proof. Choose an $i = 1, \dots, m$. We use Lemma 2, putting $V = F$, i.e., substituting the additive group of the field F with its ordering for the linearly ordered vector space V, and $\gamma = -\alpha_i$ in it. Then either there exists an $x \in W$ such that $\alpha_1(x) \geq 0, \dots, \alpha_{i-1}(x) \geq 0$, $\alpha_{i+1}(x) \geq 0, \dots, \alpha_m(x) \geq 0$, and $\alpha_i(x) > 0$, or there exist $\lambda_1, \dots, \lambda_{i-1}, \lambda_{i+1}, \dots, \lambda_m \geq 0$ such that $\iota\lambda_1\alpha_1 + \dots + \iota\lambda_{i-1}\alpha_{i-1} + \iota\lambda_{i+1}\alpha_{i+1} + \dots + \iota\lambda_m\alpha_m = -\alpha_i$. Put $\boldsymbol{\lambda} = \boldsymbol{o}$ in the first case, and put $x = 0$ and $\lambda_i = 1$ in the latter one. ∎

4. Key theorem, Motzkin's theorem, and Tucker's theorem. In this section, we briefly mention the key theorem [21, Theorem 1], [12, section 4], [3, Theorem 1.2], [2, Theorem 5.3] and two of its consequences: Motzkin's theorem [16], [17, Theorem D6, p. 60], [21, Corollary 2A part (ii)], [2, Theorem 5.1] and Tucker's theorem [21, Corollary 2A part (i)], [2, Theorem 5.2].

THEOREM 4 (key theorem). *Let $A\colon W \to F^m$ be a linear mapping. Then there exist a componentwise nonnegative column vector $\boldsymbol{\lambda} \in F^m$ and a point $x \in W$ so that*

$$\iota\boldsymbol{\lambda}^T A = o\,, \qquad Ax \geq \boldsymbol{o}, \qquad \text{and} \qquad \boldsymbol{\lambda} + Ax > \boldsymbol{o}\,,$$

where o is the zero linear form $o\colon W \to F$.

Proof. By Lemma 3, there exist points $x_1, \dots, x_m \in W$ and nonnegative columns $\boldsymbol{\lambda}_1, \dots, \boldsymbol{\lambda}_m \in F^m$ such that

$$\iota\boldsymbol{\lambda}_i^T A = o\,, \qquad Ax_i \geq \boldsymbol{o}, \qquad \text{and} \qquad \lambda_{ii} + \alpha_i(x_i) > 0$$

for $i = 1, \dots, m$. So it suffices to put $x = x_1 + \dots + x_m$ and $\boldsymbol{\lambda} = \boldsymbol{\lambda}_1 + \dots + \boldsymbol{\lambda}_m$. ∎

The two subsequent theorems involve two linear mappings, $A\colon W \to F^m$ and $B\colon W \to F^n$, where m and n are nonnegative natural numbers. Hence, either of the mappings A or B may be null. The alternatives (A) and (B) exclude each other in both theorems, and both Theorems 5 and 6 share the initial part of their proofs.

THEOREM 5 (Motzkin's theorem). *Either* (A) *there exists an $x \in W$ such that $Ax > \boldsymbol{o}$, $Bx \geq \boldsymbol{o}$, or* (B) *there exist $\boldsymbol{\lambda} \in F^m$ and $\boldsymbol{\mu} \in F^n$ satisfying $\boldsymbol{\lambda} \geq \boldsymbol{o}$, $\boldsymbol{\lambda} \neq \boldsymbol{o}$, $\boldsymbol{\mu} \geq \boldsymbol{o}$, and such that $\iota\boldsymbol{\lambda}^T A + \iota\boldsymbol{\mu}^T B = o$.*

THEOREM 6 (Tucker's theorem). *Either* (A) *there exists an $x \in W$ such that $Ax \geq \boldsymbol{o}$, $Ax \neq \boldsymbol{o}$, $Bx \geq \boldsymbol{o}$, or* (B) *there exist $\boldsymbol{\lambda} \in F^m$ and $\boldsymbol{\mu} \in F^n$ satisfying $\boldsymbol{\lambda} > \boldsymbol{o}$, $\boldsymbol{\mu} \geq \boldsymbol{o}$, and such that $\iota\boldsymbol{\lambda}^T A + \iota\boldsymbol{\mu}^T B = o$.*

Proof. By Theorem 4, there exist an $x \in W$ and componentwise nonnegative $\boldsymbol{\lambda} \in F^m$ and $\boldsymbol{\mu} \in F^n$ such that

$$\begin{matrix} Ax \geq \boldsymbol{o}\,, \\ Bx \geq \boldsymbol{o}\,, \end{matrix} \qquad \iota\boldsymbol{\lambda}^T A + \iota\boldsymbol{\mu}^T B = o, \qquad \text{and} \qquad \begin{matrix} \boldsymbol{\lambda} + Ax > \boldsymbol{o}\,, \\ \boldsymbol{\mu} + Bx > \boldsymbol{o}\,. \end{matrix}$$

If $\boldsymbol{\lambda} = \boldsymbol{o}$, then $Ax > \boldsymbol{o}$; we have thus obtained Theorem 5. If $Ax = \boldsymbol{o}$, then $\boldsymbol{\lambda} > \boldsymbol{o}$; we have then obtained Theorem 6. ∎

As in the previous section, both of the presented proofs are modifications of Tucker's proofs [21, Theorem 1, Corollary 2A]. To conclude, it is interesting that the ideas of the proofs by Gale [11] and Tucker [21] can be used to obtain the currently presented more general results.

Acknowledgments. The author acknowledges that the idea to apply Tucker's original proof to prove Lemma 2 arose during his discussion about the main results of Tucker's paper [21] with Ms. Kateřina Lokajová. The author is indebted to an anonymous referee for comments that helped him to improve the paper and for pointing out some references. Last but not least, the author is very grateful to Professor R. G. Bland who suggested simplifications of the proof of Lemma 2 and whose ideas are incorporated in the proof presented here.

A CLASS OF INEXACT VARIABLE METRIC PROXIMAL POINT ALGORITHMS*

L. A. PARENTE†, P. A. LOTITO‡, AND M. V. SOLODOV§

Abstract. For the problem of solving maximal monotone inclusions, we present a rather general class of algorithms, which contains hybrid inexact proximal point methods as a special case and allows for the use of a variable metric in subproblems. The global convergence and local linear rate of convergence are established under standard assumptions. We demonstrate the advantage of variable metric implementation in the case of solving systems of smooth monotone equations by the proximal Newton method.

Key words. proximal point methods, variable metric, maximal monotone operators, approximation

1. Introduction.

Given a maximal monotone operator $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$, we consider the classical problem of finding a zero of T, i.e., $z \in \mathbb{R}^n$ such that

$$0 \in T(z). \tag{1.1}$$

As is well known, many important problems can be cast in this framework. Some examples are convex optimization, min-max problems, and monotone variational inequalities over convex sets; see, e.g., [23].

Given some $z^k \in \mathbb{R}^n$, the current approximation to a solution of (1.1), the proximal point iteration [19, 22] generates z^{k+1} as the solution of the regularized subproblem

$$0 \in c_k T(z) + z - z^k, \tag{1.2}$$

where $c_k > 0$ is the regularization parameter. As is well known, the proximal point method serves as a basis for developing and analyzing various useful computational techniques, such as splitting methods for variational problems (e.g., [18, 31, 13, 33, 34, 24]), the methods of multipliers (e.g., [21, 15]), and bundle methods for nonsmooth optimization (see, e.g., [16, 3]), to name a few. In computational context, it is important to handle approximate solutions of subproblems; this will be discussed a little further. Also, it is attractive to allow for the use of a variable metric (or preconditioning). Motivated by the latter issue, we shall consider the following *generalized* proximal subproblem:

$$0 \in c_k M_k T(z) + z - z^k, \tag{1.3}$$

where M_k is a symmetric positive definite matrix. The case of the classical (exact) iteration (1.2) corresponds to taking $M_k = I$ (the identity matrix) in (1.3). Given the presence of the matrix M_k, we could in principle dispense with the scalar parameter c_k in (1.3). We prefer, however, to keep it because this appears convenient in some parts of the convergence analysis and in our application to solving systems of monotone equations, discussed in section 5.

To handle approximate solutions, we shall use an extension to the variable metric setting of the rules proposed in [27, 26] and unified in [30]. In those algorithms, the *relative* error in the approximation needs only to be bounded (above, by one), which is a numerically sound requirement, and inexact values of the operator T are allowed, which is useful in various applications [29, 28, 24]. Specifically, to solve (1.3) approximately, the task would be to compute a triplet $(\hat{z}^k, \hat{v}^k, \varepsilon_k) \in \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}_+$ such that

$$\begin{cases} \hat{v}^k \in T^{\varepsilon_k}(\hat{z}^k), \\ c_k M_k \hat{v}^k + \hat{z}^k - z^k = \delta^k, \end{cases}$$
$$\|\delta^k\|^2_{M_k^{-1}} + 2c_k\varepsilon_k \le \sigma_k^2 \left(\|c_k M_k \hat{v}^k\|^2_{M_k^{-1}} + \|\hat{z}^k - z^k\|^2_{M_k^{-1}} \right),$$

where $\sigma_k \in [0, 1)$ is the error tolerance (relaxation) parameter, by $\|\cdot\|_M$ we denote the norm induced by a symmetric positive definite matrix $M \in \mathcal{M}^n_{++}$, i.e.,

$$\|z\|_M = \sqrt{\langle z, Mz \rangle},$$

and $T^\varepsilon : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$ is the ε-enlargement of a maximal monotone operator T [5, 6], defined as

$$T^\varepsilon(z) := \{v \in \mathbb{R}^n \mid \langle w - v, y - z \rangle \ge -\varepsilon \ \forall y \in \mathbb{R}^n, \forall w \in T(y)\}, \ \varepsilon \ge 0.$$

We note that, to check the above criterion, one does not need to invert the matrix M_k, as will be explained in what follows. The presented approximation rule is constructive and has advantages in some situations, when compared to the original [22] (and its variations, e.g., [32, 11, 7]), where essentially one has $\varepsilon_k = 0$ and $\sum_{k=0}^\infty \|\delta^k\| < \infty$ (in the setting of $M_k = I$). We refer the reader to [26, 29, 28, 24] for some applications where the relative-error criterion appears useful. It will also play a central role in the method discussed in section 5.

Most proximal-related schemes in the literature that use variable metrics typically deal only with the special case of optimization, i.e., the case where the operator T is the subdifferential of a convex function [2, 20, 17, 10]. To our knowledge, the exception is [7] and some of the subsequent results [8, 9]. We note that our use of a variable metric is different from [7], where (exact) iteration is of the form

$$z^{k+1} = z^k + M_k((I + c_k T)^{-1} - I)z^k.$$

The exact iteration of solving (1.3) can be written as

$$z^{k+1} = (I + c_k M_k T)^{-1} z^k,$$

and the two are the same only when $M_k = I$. It should be noted, however, that [7] does not require M_k to be symmetric, and in this respect our development can be more restrictive for some applications. On the other hand, global convergence of the method of [7] requires a rather technical assumption about the matrices M_k.

Specifically, the assumption of [7, Hypothesis (H2)] is that there exists a nonempty bounded subset Ω of $T^{-1}(0)$ such that

$$\|(M_k - I)D_k(z^k)\| \leq \gamma_k \|D_k(z^k)\| \quad \text{for all } k,$$

where

$$D_k = (I + c_k T)^{-1} - I,$$

$$\gamma_k = \frac{\|D_k(z^k)\|}{2t_k + 3\|D_k(z^k)\|}, \quad \text{with } t_k = \sup_{z \in \Omega} \|z - z^k\|.$$

This assumption essentially means that matrices M_k should not deviate from the identity too much, in the given sense, and it is in general unverifiable (unless one takes $M_k = I$) and globally quite restrictive. The only assumption we make in our global convergence analysis is, by comparison, rather mild:

$$\frac{1}{1+\eta_k} M_k \preceq M_{k+1}, \ \eta_k > 0 \quad \text{for all } k, \quad \sum_{k=0}^{\infty} \eta_k < \infty, \tag{1.4}$$

where, for $A, B \in \mathcal{M}^n_{++}$, by $A \preceq B$ we mean that $B - A$ is a positive semidefinite matrix. This condition does not introduce any essential restrictions on the choice of the matrix M_{k+1} for a given k (for a particular k, the choice of η_k is rather flexible), and it is always satisfied if we take $M_k \preceq M_{k+1}$. Also, [7] does not allow approximations of the operator T and requires error terms to be summable, basically following [22]. In the aspect of inexact solution of subproblems, our conditions (already mentioned above) are more flexible and constructive.

A few more words about our notation are in order. By $\mathcal{M}^n_{++}$ we denote the space of symmetric positive definite matrices. For $M \in \mathcal{M}^n_{++}$, $\lambda_{min}(M)$ and $\lambda_{max}(M)$ stand for the minimal and the maximal eigenvalues of M, respectively. For any $A \preceq B$, it holds that $\|z\|_A \leq \|z\|_B$. In particular, if

$$0 < \lambda_l \leq \lambda_{min}(M) \leq \lambda_{max}(M) \leq \lambda_u,$$

then for any $x \in \mathbb{R}^n$ it holds that

$$\lambda_l \|x\|^2 \leq \|x\|^2_M \leq \lambda_u \|x\|^2, \quad \frac{1}{\lambda_u}\|x\|^2 \leq \|x\|^2_{M^{-1}} \leq \frac{1}{\lambda_l}\|x\|^2. \tag{1.5}$$

By $\langle x, y \rangle$ we denote the usual inner product between $x, y \in \mathbb{R}^n$. For a matrix $M \in \mathcal{M}^n_{++}$, we denote $\langle x, y \rangle_M = \langle Mx, y \rangle$. For a closed convex set $\Omega \subseteq \mathbb{R}^n$ and a matrix $M \in \mathcal{M}^n_{++}$, the "skewed" projection operator onto Ω under the matrix M is given by

$$P_{\Omega,M}(z) = \arg\min_{x \in \Omega} \frac{1}{2}\langle x - z, M(x - z)\rangle = \arg\min_{x \in \Omega} \frac{1}{2}\|x - z\|^2_M;$$

i.e., it is the projection operator with respect to the norm $\|\cdot\|_M$. Then the associated distance from $z \in \mathbb{R}^n$ to Ω is defined as $\operatorname{dist}(z, \Omega)_M = \|z - P_{\Omega,M}(z)\|$.

2. Approximate solutions of the generalized proximal subproblem. Given a maximal monotone operator $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$, $z \in \mathbb{R}^n$, $c > 0$, and $M \in \mathcal{M}^n_{++}$, consider the generalized proximal point subproblem

$$0 \in cMT(y) + y - z, \tag{2.1}$$

with respect to $y \in \mathbb{R}^n$. This is clearly equivalent to

$$0 \in cT(y) + M^{-1}(y - z),$$

and the fact that the inclusion above has a solution follows, e.g., from [4, Proposition 3].

We next define the notion of approximate solutions of generalized proximal subproblems. Consider the system

$$\begin{cases} v \in T(y), \\ 0 = cMv + y - z, \end{cases} \tag{2.2}$$

which is equivalent to (2.1).

DEFINITION 2.1. *We say that a triplet $(y, v, \varepsilon) \in \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}_+$ is an approximate solution of the proximal system* (2.2) *with error tolerance $\sigma \in [0, 1)$ if*

$$v \in T^{\varepsilon}(y)$$

and

$$\|cMv + y - z\|^2_{M^{-1}} + 2c\varepsilon \leq \sigma^2(\|cMv\|^2_{M^{-1}} + \|y - z\|^2_{M^{-1}}). \tag{2.3}$$

Note that the exact solution of (2.2) corresponds to taking $\varepsilon = 0 = \sigma$ in the definition above. We next establish some properties of approximate solutions of generalized proximal systems.

LEMMA 2.2. *Let $z \in \mathbb{R}^n, c > 0$, and $M \in \mathcal{M}^n_{++}$. A triplet $(y, v, \varepsilon) \in \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}_+$ being an approximate solution of the proximal system* (2.2) *with error tolerance $\sigma \in [0, 1)$ is equivalent to the conditions*

$$v \in T^{\varepsilon}(y), \quad \langle v, z - y\rangle - \varepsilon \geq \frac{1 - \sigma^2}{2c} \left(\|cMv\|^2_{M^{-1}} + \|y - z\|^2_{M^{-1}}\right). \tag{2.4}$$

In addition, it holds that

$$\frac{c(1 - \rho)}{1 - \sigma^2}\|Mv\|_{M^{-1}} \leq \|y - z\|_{M^{-1}} \leq \frac{c(1 + \rho)}{1 - \sigma^2}\|Mv\|_{M^{-1}}, \tag{2.5}$$

where $\rho = \sqrt{1 - (1 - \sigma^2)^2}$.

Furthermore, the three conditions

1. $0 \in T(z)$,
2. $v = 0$,
3. $y = z$

are equivalent and imply that $\varepsilon = 0$.

Proof. Rearranging terms in (2.3), we have

$$\begin{aligned} \sigma^2(\|cMv\|^2_{M^{-1}} + \|y - z\|^2_{M^{-1}}) &\geq 2c\varepsilon + \|cMv\|^2_{M^{-1}} + \|y - z\|^2_{M^{-1}} + 2\langle cMv, y - z\rangle_{M^{-1}} \\ &= 2c\varepsilon + \|cMv\|^2_{M^{-1}} + \|y - z\|^2_{M^{-1}} - 2c\langle v, z - y\rangle, \end{aligned}$$

which gives the inequality in (2.4).

By using $\varepsilon \geq 0$ and the Cauchy–Schwarz inequality, we obtain

$$\begin{aligned} \frac{1 - \sigma^2}{2c}(\|cMv\|^2_{M^{-1}} + \|y - z\|^2_{M^{-1}}) &\leq \langle v, z - y\rangle - \varepsilon \\ &\leq \langle Mv, z - y\rangle_{M^{-1}} \leq \|Mv\|_{M^{-1}}\|y - z\|_{M^{-1}}. \end{aligned}$$

By denoting $t = \|y - z\|_{M^{-1}}$ and resolving the quadratic inequality

$$t^2 - \frac{2\|cMv\|_{M^{-1}}}{1-\sigma^2}t + \|cMv\|^2_{M^{-1}} \leq 0$$

with respect to t, we obtain (2.5).

Finally, suppose that $0 \in T(z)$. Since $v \in T^\varepsilon(y)$, we have

$$\langle v - 0, y - z\rangle \geq -\varepsilon \quad \Rightarrow \quad \langle v, z - y\rangle - \varepsilon \leq 0.$$

By using now (2.4), we have $cMv = 0$ (so that $v = 0$) and $y - z = 0$.

If we assume that $v = 0$, then (2.4) implies that $y = z$ and vice versa. In either case, $0 \in T(z)$. From (2.4) it is also clear that all of these conditions imply that $\varepsilon = 0$. □

The next result shows how to make progress towards a solution of the original problem (1.1), by using the obtained approximate solution of the generalized proximal subproblem.

LEMMA 2.3. *Let $z \in \mathbb{R}^n, y \in \mathbb{R}^n, \varepsilon \geq 0$, and $v \in T^\varepsilon(y)$. Suppose that*

$$\langle v, z - y\rangle - \varepsilon > 0.$$

Then, for any $z^* \in T^{-1}(0)$, any $M \in \mathcal{M}^n_{++}$, and any $\tau \geq 0$, it holds that

$$\|z^* - z^+\|^2_{M^{-1}} \leq \|z^* - z\|^2_{M^{-1}} - (1 - (1-\tau)^2)a^2\|Mv\|^2_{M^{-1}},$$

where

$$z^+ := z - \tau a M v$$

and

$$a := \frac{\langle v, z - y\rangle - \varepsilon}{\|Mv\|^2_{M^{-1}}}.$$

Proof. Define the closed half-space

$$H = \{w \in \mathbb{R}^n \mid \langle v, w - y\rangle - \varepsilon \leq 0\}.$$

By the assumption, $z \notin H$. Let $\bar{z}$ be the skewed projection of z onto H, under the matrix M^{-1}. As is easily seen,

$$\bar{z} = P_{H,M^{-1}}(z) = z - aMv.$$

For any $x \in H$, it holds that

$$\langle x - \bar{z}, v\rangle = \langle x - z + aMv, v\rangle = \langle x - z, v\rangle + \frac{\langle v, z - y\rangle - \varepsilon}{\|Mv\|^2_{M^{-1}}}\langle Mv, v\rangle = \langle x - y, v\rangle - \varepsilon \leq 0.$$

Hence,

$$\langle x - \bar{z}, z^+ - z\rangle_{M^{-1}} = \langle x - \bar{z}, M^{-1}(-\tau a M v)\rangle = -\tau a\langle x - \bar{z}, v\rangle \geq 0.$$

Observe that $\bar{z} - z^+ = (\tau - 1)aMv$. We then obtain

$$\begin{aligned}
\|x - z\|^2_{M^{-1}} &= \|x - z^+\|^2_{M^{-1}} + \|z^+ - z\|^2_{M^{-1}} + 2\langle x - z^+, z^+ - z\rangle_{M^{-1}} \\
&= \|x - z^+\|^2_{M^{-1}} + \|z^+ - z\|^2_{M^{-1}} + 2\langle \bar{z} - z^+, z^+ - z\rangle_{M^{-1}} \\
&\quad +2\langle x - \bar{z}, z^+ - z\rangle_{M^{-1}} \\
&\geq \|x - z^+\|^2_{M^{-1}} + \|z^+ - z\|^2_{M^{-1}} + 2\langle \bar{z} - z^+, z^+ - z\rangle_{M^{-1}} \\
&= \|x - z^+\|^2_{M^{-1}} + (\tau a)^2\|Mv\|^2_{M^{-1}} + 2(\tau - 1)a(-\tau a)\|Mv\|^2_{M^{-1}} \\
&= \|x - z^+\|^2_{M^{-1}} + (1 - (1 - \tau)^2)a^2\|Mv\|^2_{M^{-1}}.
\end{aligned}$$

Suppose that $z^* \in T^{-1}(0)$. Since $v \in T^{\varepsilon}(y)$, we have

$$\langle v - 0, y - z^*\rangle \geq -\varepsilon.$$

This shows that $z^* \in H$. We can then set $x = z^*$ in the chain of inequalities above to complete the proof. □

3. The algorithm. Lemma 2.3 shows that, with a proper choice of parameters, a step in the direction obtained from an approximate solution of the generalized proximal system, scaled by the chosen metric, brings us closer to the solution set of the original problem. This suggests the following scheme, which we shall call the variable metric hybrid inexact proximal point method.

ALGORITHM 3.1. **Initialization:** *Choose* $z^0 \in \mathbb{R}^n$, $c > 0$, $\bar{\sigma} \in (0, 1)$, $\theta \in (0, 1)$, *and* $0 < \lambda_l < \lambda_u$. *Set* $k := 0$.

Inexact proximal step: *Choose* $c_k \geq c$, *a symmetric positive definite matrix* M_k *satisfying* $\lambda_l \leq \lambda_{min}(M_k) \leq \lambda_{max}(M_k) \leq \lambda_u$, *and the error tolerance parameter* $\sigma_k \in [0, \bar{\sigma})$. *Find* $\hat{z}^k \in \mathbb{R}^n, \hat{v}^k \in \mathbb{R}^n$, *and* $\varepsilon_k \geq 0$ *such that*

$$\begin{cases} \hat{v}^k \in T^{\varepsilon_k}(\hat{z}^k), \\ \delta^k = c_k M_k \hat{v}^k + \hat{z}^k - z^k \end{cases} \tag{3.1}$$

and

$$\|\delta^k\|^2_{M_k^{-1}} + 2c_k\varepsilon_k \leq \sigma_k^2 \left(\|c_k M_k \hat{v}^k\|^2_{M_k^{-1}} + \|\hat{z}^k - z^k\|^2_{M_k^{-1}}\right). \tag{3.2}$$

Iterates update: *If* $\hat{z}^k = z^k$, *stop. Otherwise, choose* $\tau_k \in [1 - \theta, 1 + \theta]$, *and set*

$$z^{k+1} = z^k - \tau_k a_k M_k \hat{v}^k, \quad a_k = \frac{\langle \hat{v}^k, z^k - \hat{z}^k\rangle - \varepsilon_k}{\|M_k \hat{v}^k\|^2_{M_k^{-1}}}.$$

Set $k := k + 1$, *and go to the inexact proximal step.*

We note that it is not necessary to calculate the inverse of M_k in order to implement Algorithm 3.1 (in particular, for checking the condition (3.2) and computing a_k). Indeed, by (1.5), the condition (3.2) is satisfied if

$$\|\delta^k\|^2 + 2\lambda_u c_k \varepsilon_k \leq \frac{\lambda_u \sigma_k^2}{\lambda_l}\left(\|c_k M_k \hat{v}^k\|^2 + \|\hat{z}^k - z^k\|^2\right).$$

Alternatively, in the latter relation, instead of λ_l and λ_u one can use any other (in particular, tighter) lower and upper bounds for the eigenvalues of M_k. Also, the scalar a_k can be calculated as

$$a_k = \frac{\langle \hat{v}^k, z^k - \hat{z}^k\rangle - \varepsilon_k}{\langle M_k \hat{v}^k, \hat{v}^k\rangle}.$$

The next result shows that some specific realizations of Algorithm 3.1 allow for the simple update

$$z^{k+1} = z^k - c_k M_k \hat{v}^k.$$

This is the update that we shall use for our application in section 5. Specifically, we have the following.

PROPOSITION 3.1. *If the inequality in* (3.2) *is replaced by the stronger condition* $\|\delta^k\|^2_{M_k^{-1}} + 2c_k\varepsilon_k \le \sigma_k^2\|\hat{z}^k - z^k\|^2_{M_k^{-1}}$, *and we choose* $\sigma_k \le \theta$, *then there exists* $\tau_k \in (1-\sigma_k, 1+\sigma_k) \subset (0,2)$ *such that* $\tau_k a_k = c_k$.

Proof. In the case of interest, $\hat{v}^k \neq 0$ and $\hat{z}^k \neq z^k$. By using the triangle inequality, from $\|\delta^k\|_{M_k^{-1}} \le \sigma_k\|\hat{z}^k - z^k\|_{M_k^{-1}}$ we obtain

$$\|\hat{z}^k - z^k\|_{M_k^{-1}} - c_k\|M_k\hat{v}^k\|_{M_k^{-1}} \le \sigma_k\|\hat{z}^k - z^k\|_{M_k^{-1}}$$

and

$$c_k\|M_k\hat{v}^k\|_{M_k^{-1}} - \|\hat{z}^k - z^k\|_{M_k^{-1}} \le \sigma_k\|\hat{z}^k - z^k\|_{M_k^{-1}},$$

implying that

$$(1-\sigma_k)\frac{\|\hat{z}^k - z^k\|_{M_k^{-1}}}{\|M_k\hat{v}^k\|_{M_k^{-1}}} \le c_k \le (1+\sigma_k)\frac{\|\hat{z}^k - z^k\|_{M_k^{-1}}}{\|M_k\hat{v}^k\|_{M_k^{-1}}}. \tag{3.3}$$

Furthermore, by the Cauchy–Schwarz inequality, since $\varepsilon_k \ge 0$ we have

$$a_k = \frac{\langle \hat{v}^k, z^k - \hat{z}^k\rangle - \varepsilon_k}{\|M_k\hat{v}^k\|^2_{M_k^{-1}}} \le \frac{\langle M_k\hat{v}^k, z^k - \hat{z}^k\rangle_{M_k^{-1}}}{\|M_k\hat{v}^k\|^2_{M_k^{-1}}} \le \frac{\|\hat{z}^k - z^k\|_{M_k^{-1}}}{\|M_k\hat{v}^k\|_{M_k^{-1}}}.$$

Finally, since

$$\begin{aligned}\langle \hat{v}^k, \hat{z}^k - z^k\rangle &= \langle M_k\hat{v}^k, \hat{z}^k - z^k\rangle_{M_k^{-1}} \\ &= \frac{\|c_kM_k\hat{v}^k + \hat{z}^k - z^k\|^2_{M_k^{-1}} - \|\hat{z}^k - z^k\|^2_{M_k^{-1}} - \|c_kM_k\hat{v}^k\|^2_{M_k^{-1}}}{2c_k},\end{aligned}$$

by using (2.5) and (3.3), we obtain

$$\begin{aligned}a_k &= \frac{\|\hat{z}^k - z^k\|^2_{M_k^{-1}} + \|c_kM_k\hat{v}^k\|^2_{M_k^{-1}} - \left(\|c_kM_k\hat{v}^k + \hat{z}^k - z^k\|^2_{M_k^{-1}} + 2c_k\varepsilon_k\right)}{2c_k\|M_k\hat{v}^k\|^2_{M_k^{-1}}} \\ &\ge \frac{c_k}{2} + (1-\sigma_k^2)\frac{\|\hat{z}^k - z^k\|^2_{M_k^{-1}}}{\|c_kM_k\hat{v}^k\|^2_{M_k^{-1}}} \ge \frac{c_k}{2}\left(1 + \frac{1-\sigma_k^2}{(1+\sigma_k)^2}\right) = \frac{c_k}{1+\sigma_k}.\end{aligned}$$

Hence,

$$(1-\sigma_k)a_k \le c_k \le (1+\sigma_k)a_k,$$

which establishes the claim. ∎

4. Convergence analysis. If Algorithm 3.1 terminates at some iteration k, then $z^k = \hat{z}^k$, and, by Lemma 2.2, z^k is a solution. We next consider the case when infinite sequences $\{z^k\}, \{\hat{z}^k\}, \{\hat{v}^k\}$, and $\{\varepsilon_k\}$ are generated. For any k, we have $\hat{v}^k \neq 0$, $\hat{z}^k \neq z^k$, and by Lemma 2.2,

$$\langle \hat{v}^k, z^k - \hat{z}^k \rangle - \varepsilon_k \geq \frac{1-\sigma_k^2}{2c_k} \left(\|c_k M_k \hat{v}^k\|^2_{M_k^{-1}} + \|\hat{z}^k - z^k\|^2_{M_k^{-1}} \right) > 0.$$

By the definition of a_k, we then conclude that

$$a_k \geq \frac{1-\sigma_k^2}{2c_k} \left(\frac{\|c_k M_k \hat{v}^k\|^2_{M_k^{-1}} + \|\hat{z}^k - z^k\|^2_{M_k^{-1}}}{\|M_k \hat{v}^k\|^2_{M_k^{-1}}} \right). \tag{4.1}$$

By the Cauchy–Schwarz inequality,

$$\|c_k M_k \hat{v}^k\|^2_{M_k^{-1}} + \|\hat{z}^k - z^k\|^2_{M_k^{-1}} \geq 2c_k \|M_k \hat{v}^k\|_{M_k^{-1}} \|\hat{z}^k - z^k\|_{M_k^{-1}}.$$

By combining this relation with (4.1), we obtain

$$a_k \|M_k \hat{v}^k\|_{M_k^{-1}} \geq (1-\sigma_k^2) \|\hat{z}^k - z^k\|_{M_k^{-1}}. \tag{4.2}$$

Combining (4.1) and (2.5), and using the definition of ρ_k, gives the following lower bound for a_k:

$$\begin{aligned} a_k &\geq \frac{(1-\sigma_k^2)c_k}{2} \left(1 + \frac{\|\hat{z}^k - z^k\|^2_{M_k^{-1}}}{\|c_k M_k \hat{v}^k\|^2_{M_k^{-1}}} \right) \\ &\geq \frac{(1-\sigma_k^2)c_k}{2} \left(1 + \left(\frac{1-\rho_k}{1-\sigma_k^2} \right)^2 \right) \\ &= \frac{c_k \left(\left(1-\sigma_k^2\right)^2 + \left(1 - \sqrt{1-(1-\sigma_k^2)^2} \right)^2 \right)}{2\left(1-\sigma_k^2\right)} \\ &= \frac{c_k \left(1 - \sqrt{1-(1-\sigma_k^2)^2} \right)}{1-\sigma_k^2} \\ &= \frac{(1-\sigma_k^2)c_k}{1+\sqrt{1-(1-\sigma_k^2)^2}}. \end{aligned} \tag{4.3}$$

Hence, the parameter a_k is bounded away from zero:

$$a_k \geq \frac{(1-\bar{\sigma}^2)c}{1+\sqrt{1-(1-\bar{\sigma}^2)^2}} > 0. \tag{4.4}$$

We proceed to establish the global convergence of Algorithm 3.1.

PROPOSITION 4.1. *Suppose that $T^{-1}(0) \neq \emptyset$ and condition (1.4) holds. Then any sequences generated by Algorithm 3.1 have the following properties:*

1. *$\{z^k\}$ is bounded.*
2. *$\sum_{k=0}^{\infty} \|a_k M_k \hat{v}^k\|^2 < \infty$.*
3. *$\lim_{k\to\infty} \|\hat{z}^k - z^k\| = \lim_{k\to\infty} \|\hat{v}^k\| = \lim_{k\to\infty} \|\varepsilon_k\| = 0$.*

Proof. By condition (1.4), it holds that

$$\prod_{k=0}^{\infty}(1+\eta_k) = p < \infty,$$

and, for all k,

$$M_{k+1}^{-1} \preceq (1+\eta_k)M_k^{-1}.$$

By (1.5), for all k we have

$$\lambda_u^{-1}\|z\|^2 \leq \lambda_{min}(M_k^{-1})\|z\|^2 \leq \|z\|^2_{M_k^{-1}} \leq \lambda_{max}(M_k^{-1})\|z\|^2 \leq \lambda_l^{-1}\|z\|^2 \quad \forall\, z \in \mathbb{R}^n.$$

By using (4.1) and Lemma 2.3, we have that for any $z^* \in T^{-1}(0)$ it holds that

$$\begin{aligned}\|z^* - z^{k+1}\|^2_{M_k^{-1}} &\leq \|z^* - z^k\|^2_{M_k^{-1}} - (1-(1-\tau_k)^2)a_k^2\|M_k\hat{v}^k\|^2_{M_k^{-1}}\\ &\leq \|z^* - z^k\|^2_{M_k^{-1}} - (1-\theta^2)\|a_k M_k\hat{v}^k\|^2_{M_k^{-1}}.\end{aligned}$$

Hence,

$$\begin{aligned}\lambda_u^{-1}\|z^* - z^{k+1}\|^2 &\leq \|z^* - z^{k+1}\|^2_{M_{k+1}^{-1}}\\ &\leq (1+\eta_k)\|z^* - z^{k+1}\|^2_{M_k^{-1}}\\ &\leq (1+\eta_k)\left(\|z^* - z^k\|^2_{M_k^{-1}} - (1-\theta^2)\|a_k M_k\hat{v}^k\|^2_{M_k^{-1}}\right)\\ &\leq (1+\eta_k)\|z^* - z^k\|^2_{M_k^{-1}} - (1-\theta^2)\|a_k M_k\hat{v}^k\|^2_{M_k^{-1}}.\end{aligned}$$

By applying this inequality consecutively, we obtain

$$\lambda_u^{-1}\|z^* - z^{k+1}\|^2 \leq \prod_{i=0}^{k}(1+\eta_i)\|z^* - z^0\|^2_{M_0^{-1}} - (1-\theta^2)\sum_{i=0}^{k}\|a_i M_i\hat{v}^i\|^2_{M_i^{-1}}. \tag{4.5}$$

We therefore have, for any k,

$$\|z^* - z^k\|^2 \leq \lambda_u \prod_{i=0}^{k-1}(1+\eta_i)\|z^* - z^0\|^2_{M_0^{-1}} \leq \frac{p\lambda_u}{\lambda_l}\|z^* - z^0\|^2, \tag{4.6}$$

which shows that the sequence $\{z^k\}$ is bounded. From (4.5), we also have

$$(1-\theta^2)\sum_{i=0}^{k}\|a_i M_i\hat{v}^i\|^2_{M_i^{-1}} \leq \prod_{i=0}^{k}(1+\eta_i)\|z^* - z^0\|^2_{M_0^{-1}}.$$

By passing onto the limit when $k \to \infty$ in this relation, we obtain

$$\sum_{k=0}^{\infty}\|a_k M_k\hat{v}^k\|^2 \leq \lambda_u \sum_{k=0}^{\infty}\|a_k M_k\hat{v}^k\|^2_{M_k^{-1}} \leq \frac{p\lambda_u}{1-\theta^2}\|z^* - z^0\|^2_{M_0^{-1}} < \infty.$$

This proves the second item in the assertion and, as a consequence, that

$$\lim_{k\to\infty}\|a_k M_k\hat{v}^k\| = 0.$$

From (4.2) and Lemma 2.2, we then conclude that

$$\lim_{k\to\infty} \|M_k \hat{v}^k\| = 0 \quad \text{and} \quad \lim_{k\to\infty} \|\hat{z}^k - z^k\| = 0.$$

Since the matrices M_k are uniformly positive definite, we also have $\lim_{k\to\infty} \hat{v}^k = 0$. Also, since $\varepsilon_k \le \langle \hat{v}^k, z^k - \hat{z}^k \rangle$, it follows that $\lim_{k\to\infty} \varepsilon_k = 0$. □

We are now in a position to complete the proof of global convergence of Algorithm 3.1. Given the properties established in Proposition 4.1, the argument is close to standard; we include it mainly for completeness.

THEOREM 4.2. *Suppose that* $T^{-1}(0) \neq \emptyset$ *and condition* (1.4) *holds. Then any sequence* $\{z^k\}$ *generated by Algorithm* 3.1 *converges to an element of* $T^{-1}(0)$.

Proof. By Proposition 4.1, the sequence $\{z^k\}$ is bounded. Therefore, it has some accumulation point, say, $\bar{z} \in \mathbb{R}^n$. Let $\{z^{k_j}\}$ be any subsequence converging to this accumulation point: $\lim_{j\to\infty} z^{k_j} = \bar{z}$. Since $\lim_{k\to\infty} \|\hat{z}^k - z^k\| = 0$, we have $\hat{z}^{k_j} \to \bar{z}$. For any $z \in \mathbb{R}^n$ and any $u \in T(z)$, $\langle u - v^{k_j}, z - \hat{z}^{k_j} \rangle \ge -\varepsilon_{k_j}$. Hence,

$$\langle u - 0, z - \hat{z}^{k_j} \rangle \ge \langle v^{k_j}, z - \hat{z}^{k_j} \rangle - \varepsilon_{k_j}.$$

Since $v^{k_j} \to 0$, $\varepsilon_{k_j} \to 0$, and $\hat{z}^{k_j} \to \bar{z}$, by passing onto the limit when $j \to \infty$ we obtain

$$\langle u - 0, z - \bar{z} \rangle \ge 0.$$

As $z \in \mathbb{R}^n$ and $u \in T(z)$ were arbitrarily chosen, and T is maximal monotone, the above relation shows that $0 \in T(\bar{z})$; i.e., $\bar{z}$ is a solution.

Suppose that there exists another subsequence $\{z^{t_i}\}$ converging to $\tilde{z} \neq \bar{z}$. Fix some $d \in (0, \|\tilde{z} - \bar{z}\|)$. Since $\tilde{z}$ and $\bar{z}$ are limits of corresponding subsequences, there exists an index i_0 such that for all $i \ge i_0$

$$\|z^{t_i} - \tilde{z}\| < \frac{d}{2}\sqrt{\frac{\lambda_l}{p\lambda_u}},$$

where $p = \prod_{k=0}^{\infty}(1 + \eta_k)$, and there exists an index j_0 such that for all $j \ge j_0$

$$k_j > t_{i_0} \text{ and } \|z^{k_j} - \bar{z}\| < \frac{d}{2}.$$

Therefore,

$$\|z^{k_j} - \tilde{z}\| > \frac{d}{2} \quad \forall j \ge j_0.$$

Since, as already established above, $\tilde{z} \in T^{-1}(0)$, the same reasoning used to obtain (4.6) gives, for any $j \ge j_0$,

$$\frac{d}{2} < \|z^{k_j} - \tilde{z}\| \le \sqrt{\frac{p\lambda_u}{\lambda_l}}\|z^{t_{i_0}} - \tilde{z}\| < \frac{d}{2},$$

which is a contradiction.

Hence, $\{z^k\}$ has the unique accumulation point, which is a solution. □

We proceed with a convergence rate analysis of Algorithm 3.1. To this end, we first establish an *error bound* for the exact solution of the generalized proximal system

$$\begin{cases} v \in T(y), \\ 0 = cMv + y - z. \end{cases} \tag{4.7}$$

We note that the obtained bound is for the distance both in terms of y and in terms of v, and it does not involve any unknown constants. Specifically, we have the following.

LEMMA 4.3. *Let y^*, v^* be the exact solution of the proximal system* (4.7)*, with some $c > 0$, $z \in \mathbb{R}^n$, and $M \in \mathcal{M}^n_{++}$. Then for any $y \in \mathbb{R}^n$ and any $v \in T^\varepsilon(y)$, it holds that*

$$\|y - y^*\|^2_{M^{-1}} + c^2\|Mv - Mv^*\|^2_{M^{-1}} \le \|cMv + y - z\|^2_{M^{-1}} + 2c\varepsilon.$$

Proof. By using $cMv^* + y^* - z = 0$, we obtain

$$\begin{aligned}\|cMv + y - z\|^2_{M^{-1}} &= \|cMv + y - z - (cMv^* + y^* - z)\|^2_{M^{-1}}\\ &= \|cMv - cMv^* + y - y^*\|^2_{M^{-1}}\\ &= c^2\|Mv - Mv^*\|^2_{M^{-1}} + \|y - y^*\|^2_{M^{-1}} + 2c\langle v - v^*, y - y^*\rangle\\ &\ge c^2\|Mv - Mv^*\|^2_{M^{-1}} + \|y - y^*\|^2_{M^{-1}} - 2c\varepsilon. \qquad \square\end{aligned}$$

We shall show linear convergence of Algorithm 3.1 under the assumption that T^{-1} has the following Lipschitzian property at zero: There exist some $L_1 > 0$ and $L_2 > 0$ such that

$$T^{-1}(v) \subset T^{-1}(0) + L_1\|v\|\mathcal{B} \quad \forall v \in L_2\mathcal{B},$$

where $\mathcal{B} = \{x \in \mathbb{R}^n \mid \|x\| \le 1\}$. Note that this condition does not imply that the solution set $T^{-1}(0)$ is a singleton. The equivalent form of this local Lipschitzian property, used below, is

$$\operatorname{dist}(z, T^{-1}(0)) \le L_1 \min_{v \in T(z)} \|v\| \quad \forall\, z \in \{z' \in \operatorname{dom} T \mid \min_{v \in T(z')} \|v\| \le L_2\}. \tag{4.8}$$

We shall prove the linear convergence rate under one of the following two alternative assumptions on algorithm parameters. One is that $\bar\sigma$ is sufficiently small, while c is sufficiently large (note that those are user-chosen parameters). The other is that

$$\frac{1}{1+\eta_k} M_k \preceq M_{k+1} \preceq (1+\eta_k)M_k,\ \eta_k > 0\ \forall\, k, \quad \sum_{k=0}^{\infty} \eta_k < \infty, \tag{4.9}$$

which is a strengthening of the condition (1.4) used for global convergence. Asymptotically, (4.9) means that the matrices should not differ too much on subsequent iterations (a natural requirement in a neighborhood of a solution).

THEOREM 4.4. *In addition to the assumptions of Theorem* 4.2*, suppose that condition* (4.8) *is satisfied.*

Then, for sufficiently small choices of σ_k and sufficiently large choices of c_k, the sequence $\{z^k\}$ generated by Algorithm 3.1 *converges to an element of $T^{-1}(0)$ at a linear rate. If $c_k \to \infty$ and $\sigma_k \to 0$, the rate of convergence is superlinear.*

If condition (4.9) *holds, then for any choice of parameters $\bar\sigma$ and c, there exists $k_0 \in \mathbb{N}$ such that the sequence $\{z^k\}$ converges at the linear rate in the norm induced by $M^{-1}_{k_0}$.*

Proof. For each k, let τ_k, a_k, z^k be as defined in Algorithm 3.1, and let $x^k, w^k \in T(x^k)$ be the exact solution of the proximal system

$$\begin{cases} w \in T(x), \\ 0 = b_k M_k w + x - z^k, \end{cases}$$

where $b_k = \tau_k a_k$. Since $\hat{v}^k \in T^{\varepsilon_k}(\hat{z}^k)$, by Lemma 4.3 and the definition of a_k, it follows that

$$\begin{aligned}
&\|x^k - \hat{z}^k\|^2_{M_k^{-1}} + b_k^2 \|M_k \hat{v}^k - M_k w^k\|^2_{M_k^{-1}} \\
&\leq \|b_k M_k \hat{v}^k + \hat{z}^k - z^k\|^2_{M_k^{-1}} + 2b_k \varepsilon_k \\
&= \|b_k M_k \hat{v}^k + \hat{z}^k - z^k\|^2_{M_k^{-1}} \\
&\quad -2b_k \left(a_k \|M_k \hat{v}^k\|^2_{M_k^{-1}} + \langle M_k \hat{v}^k, z^k - \hat{z}^k \rangle_{M_k^{-1}} \right) \\
&= \|\hat{z}^k - z^k\|^2_{M_k^{-1}} + (\tau_k^2 - 2\tau_k) \|a_k M_k \hat{v}^k\|^2_{M_k^{-1}}.
\end{aligned}$$

By using (4.2), we then obtain

(4.10)
$$\|x^k - \hat{z}^k\|^2_{M_k^{-1}} + b_k^2 \|M_k \hat{v}^k - M_k w^k\|^2_{M_k^{-1}} \leq \left(\tau_k^2 - 2\tau_k + \frac{1}{(1-\sigma_k^2)^2} \right) \|a_k M_k \hat{v}^k\|^2_{M_k^{-1}}.$$

By using further the definitions of w^k and $\hat{v}^k$, this gives

$$\|x^k - \hat{z}^k\|^2_{M_k^{-1}} + \|x^k - z^{k+1}\|^2_{M_k^{-1}} \leq \left(\tau_k^2 - 2\tau_k + \frac{1}{(1-\sigma_k^2)^2} \right) \|a_k M_k \hat{v}^k\|^2_{M_k^{-1}}. \tag{4.11}$$

From (4.10), we also have

$$\|M_k \hat{v}^k - M_k w^k\|^2_{M_k^{-1}} \leq \left(1 - \frac{2}{\tau_k} + \frac{1}{\tau_k^2 (1-\sigma_k^2)^2} \right) \|M_k \hat{v}^k\|^2_{M_k^{-1}}.$$

Since $\hat{v}^k \to 0$ (see Proposition 4.1), the last relation implies that $w^k \to 0$. Hence, there exists $k_1 \in \mathbb{N}$ such that $\|w^k\| < L_2$ for all $k > k_1$. By (4.8), we then have

$$\operatorname{dist}(x^k, T^{-1}(0)) \leq L_1 \|w^k\| \quad \forall k > k_1.$$

Therefore, for $k > k_1$,

$$\begin{aligned}
\operatorname{dist}(x^k, T^{-1}(0))^2_{M_k^{-1}} &\leq \frac{1}{\lambda_l} \operatorname{dist}(x^k, T^{-1}(0))^2 \leq \frac{L_1^2}{\lambda_l} \|w^k\|^2 \\
&\leq \frac{L_1^2}{\lambda_l^2} \|w^k\|^2_{M_k} = \frac{L_1^2}{\lambda_l^2} \|M_k w^k\|^2_{M_k^{-1}} \\
&= \frac{L_1^2}{\lambda_l^2 b_k^2} \|z^k - x^k\|^2_{M_k^{-1}}. \qquad (4.12)
\end{aligned}$$

Let $\bar{x}^k$ be the skewed projection of x^k onto $T^{-1}(0)$ under the norm induced by M_k^{-1}, i.e.,

$$\bar{x}^k := P_{T^{-1}(0), M_k^{-1}}(x^k).$$

Then, for $k > k_1$, we have

$$\begin{aligned}
\operatorname{dist}(z^{k+1}, T^{-1}(0))_{M_k^{-1}} &\leq \|z^{k+1} - \bar{x}^k\|_{M_k^{-1}} \\
&\leq \|z^{k+1} - x^k\|_{M_k^{-1}} + \operatorname{dist}(x^k, T^{-1}(0))_{M_k^{-1}} \\
&\leq \|z^{k+1} - x^k\|_{M_k^{-1}} + \frac{L_1}{\lambda_l b_k} \|z^k - x^k\|_{M_k^{-1}} \\
&\leq \|z^{k+1} - x^k\|_{M_k^{-1}} + \frac{L_1}{\lambda_l b_k} \|x^k - \hat{z}^k\|_{M_k^{-1}} + \frac{L_1}{\lambda_l b_k} \|\hat{z}^k - z^k\|_{M_k^{-1}},
\end{aligned}$$

where the third inequality is by (4.12). By the Cauchy–Schwarz inequality, it holds that

$$\begin{aligned}
&\frac{L_1}{\lambda_l b_k}\|x^k-\hat{z}^k\|_{M_k^{-1}}+\|x^k-z^{k+1}\|_{M_k^{-1}}\\
&\le\sqrt{1+\frac{L_1^2}{\lambda_l^2 b_k^2}}\,\sqrt{\|x^k-\hat{z}^k\|^2_{M_k^{-1}}+\|x^k-z^{k+1}\|^2_{M_k^{-1}}}\\
&\le\sqrt{\left(1+\frac{L_1^2}{\lambda_l^2 b_k^2}\right)\left(\tau_k^2-2\tau_k+\frac{1}{(1-\sigma_k^2)^2}\right)}\,\|a_k M_k\hat{v}^k\|_{M_k^{-1}},
\end{aligned}$$

where the second inequality follows from (4.11). By combining the latter relation with (4.13) and using also (4.2), we obtain

$$\begin{aligned}
&\operatorname{dist}(z^{k+1},T^{-1}(0))_{M_k^{-1}}\\
&\le\left(\sqrt{\left(1+\frac{L_1^2}{\lambda_l^2 b_k^2}\right)\left(\tau_k^2-2\tau_k+\frac{1}{(1-\sigma_k^2)^2}\right)}+\frac{L_1}{\lambda_l b_k(1-\sigma_k^2)}\right)\|a_k M_k\hat{v}^k\|_{M_k^{-1}}.
\end{aligned}\tag{4.13}$$

Define

$$\mu_k:=\sqrt{\alpha_k^2+1}\sqrt{\beta_k^2-1}+\alpha_k\beta_k,\tag{4.14}$$

where

$$\alpha_k:=\frac{L_1\left(1+\sqrt{1-(1-\sigma_k^2)^2}\right)}{\lambda_l c_k(1-\sigma_k^2)(1-\theta)}\le\frac{L_1\left(1+\sqrt{1-(1-\bar{\sigma}^2)^2}\right)}{\lambda_l c(1-\bar{\sigma}^2)(1-\theta)}=:\alpha,\tag{4.15}$$

$$\beta_k:=\frac{1}{1-\sigma_k^2}\le\frac{1}{1-\bar{\sigma}^2}=:\beta.\tag{4.16}$$

With those definitions, by using (4.13) and (4.3), we conclude that

$$\operatorname{dist}(z^{k+1},T^{-1}(0))_{M_k^{-1}}\le\mu_k\|a_k M_k\hat{v}^k\|_{M_k^{-1}}.\tag{4.17}$$

Let $\bar{z}^k:=P_{T^{-1}(0),M_k^{-1}}(z^k)$. By Lemma 2.3, it holds that

$$\operatorname{dist}(z^k,T^{-1}(0))^2_{M_k^{-1}}\ge\|\bar{z}^k-z^{k+1}\|^2_{M_k^{-1}}+(1-(1-\tau_k)^2)a_k^2\|M_k\hat{v}^k\|^2_{M_k^{-1}}\tag{4.18}$$

$$\ge\operatorname{dist}(z^{k+1},T^{-1}(0))^2_{M_k^{-1}}+(1-\theta^2)a_k^2\|M_k\hat{v}^k\|^2_{M_k^{-1}}.\tag{4.19}$$

By using (4.17), we then conclude that

$$\operatorname{dist}(z^k,T^{-1}(0))^2_{M_k^{-1}}\ge\left(1+\frac{1-\theta^2}{\mu_k^2}\right)\operatorname{dist}(z^{k+1},T^{-1}(0))^2_{M_k^{-1}}.\tag{4.20}$$

Therefore,

$$\operatorname{dist}(z^{k+1},T^{-1}(0))\le\frac{\mu_k\sqrt{\lambda_u}}{\sqrt{\lambda_l(\mu_k^2+1-\theta^2)}}\operatorname{dist}(z^k,T^{-1}(0)).\tag{4.21}$$

By the definitions (4.15) and (4.16), by taking c_k sufficiently large we can make α_k arbitrarily small, and by taking σ_k sufficiently small we can make β_k arbitrarily close

to one. By the definition (4.14), this means that we can make μ_k arbitrarily small, so that the scalar in the right-hand side of (4.21) is less than one. Then (4.21) shows that the sequence $\{\operatorname{dist}(z^k, T^{-1}(0))\}$ converges linearly to zero. Also, the inequality (4.19) shows that this sequence is Fejér-monotone with respect to the set $T^{-1}(0)$ (for the given norm). For Fejér-monotone sequences, linear convergence of $\{\operatorname{dist}(z^k, T^{-1}(0))\}$ is equivalent to the linear convergence rate of $\{z^k\}$ to its limit (see, e.g., [1]).

By the same argument as above, if $c_k \to \infty$ and $\sigma_k \to 0$, then $\mu_k \to 0$, and (4.21) shows a superlinear convergence rate.

Assume now that the condition (4.9) holds. Then

$$\begin{aligned}\frac{1}{(1+\eta_k)}\operatorname{dist}(z, T^{-1}(0))^2_{M_k^{-1}} &= \inf_{y\in T^{-1}(0)} \frac{1}{(1+\eta_k)}\|z-y\|^2_{M_k^{-1}} \\ &\le \inf_{y\in T^{-1}(0)} \|z-y\|^2_{M_{k+1}^{-1}} \\ &= (1+\eta_k)\operatorname{dist}(z, T^{-1}(0))^2_{M_{k+1}^{-1}} \\ &\le \inf_{y\in T^{-1}(0)} (1+\eta_k)\|z-y\|^2_{M_k^{-1}} \\ &= (1+\eta_k)\operatorname{dist}(z, T^{-1}(0))^2_{M_k^{-1}}. \end{aligned} \tag{4.22}$$

Define

$$\mu = \sqrt{\alpha^2+1}\sqrt{\beta^2-1} + \alpha\beta,$$

with α and β given by (4.15) and (4.16), respectively. Note that $\mu > \mu_k$ for all k.

Since $\prod_{i=0}^{\infty}(1+\eta_i) < \infty$, there exists $k_2 \in \mathbb{N}$ such that

$$\prod_{i=k_2}^{\infty}(1+\eta_i) < \frac{\sqrt{\mu^2+1-\theta^2}}{\mu}.$$

From (4.20), by applying (4.22) consecutively, for any $k \ge k_0 := \max\{k_1, k_2\}$, we have

$$\begin{aligned}&\left(\prod_{i=k_0}^{\infty}\frac{1}{(1+\eta_i)}\right)\operatorname{dist}(z^{k+1}, T^{-1}(0))^2_{M_{k_0}^{-1}} \\ &\le \left(\prod_{i=k_0}^{k-1}\frac{1}{(1+\eta_i)}\right)\operatorname{dist}(z^{k+1}, T^{-1}(0))^2_{M_{k_0}^{-1}} \\ &\le \operatorname{dist}(z^{k+1}, T^{-1}(0))^2_{M_k^{-1}} \\ &\le \frac{\mu^2}{\mu^2+1-\theta^2}\operatorname{dist}(z^k, T^{-1}(0))^2_{M_k^{-1}} \\ &\le \left(\prod_{i=k_0}^{k-1}(1+\eta_i)\right)\frac{\mu^2}{\mu^2+1-\theta^2}\operatorname{dist}(z^k, T^{-1}(0))^2_{M_{k_0}^{-1}} \\ &\le \left(\prod_{i=k_0}^{\infty}(1+\eta_i)\right)\frac{\mu^2}{\mu^2+1-\theta^2}\operatorname{dist}(z^k, T^{-1}(0))^2_{M_{k_0}^{-1}}. \end{aligned}$$

In particular,

$$\operatorname{dist}(z^{k+1}, T^{-1}(0))_{M_{k_0}^{-1}} \le \nu \operatorname{dist}(z^k, T^{-1}(0))_{M_{k_0}^{-1}},$$

where

$$\nu := \frac{\mu}{\sqrt{\mu^2 + 1 - \theta^2}} \prod_{i=k_0}^{\infty} (1 + \eta_i) < 1,$$

as claimed. □

5. A variable metric proximal Newton method. In this section, we show how the proposed variable metric approach can be used to obtain a computational advantage when solving a system of monotone differentiable equations

$$F(x) = 0, \tag{5.1}$$

where $F : \mathbb{R}^n \to \mathbb{R}^n$. Problems of this type appear, for example, in smooth multiplier methods for monotone complementarity problems [14]. We start with describing the method and giving its theoretical justification and then report on our numerical experiments.

5.1. Description and justification of the method. In [25, 29], it has been shown that hybrid inexact proximal point schemes (with a fixed metric) can be used to construct Newton methods for monotone problems with a very attractive combination of global and local convergence properties. In particular, global convergence from any starting point to a solution is guaranteed, regardless of any degeneracy along the trajectory, which is not true in the case of more standard merit function-based globalizations that can get stuck at stationary points of the function that are not global minimizers. Fast local convergence for nondegenerate problems is also preserved, in a natural way. We refer the reader to [25, 29] for more detailed discussion.

When the Newton step is computed for the proximal subproblem (with the fixed metric $M_k = I$)

$$c_k F(z) + (z - z^k) = 0,$$

as in [25], one needs to solve the system of linear equations

$$c_k F(z^k) + (c_k \nabla F(z^k) + I)d = 0, \tag{5.2}$$

with respect to $d \in \mathbb{R}^n$. The crucial point is that, under natural assumptions, this single Newton step is enough to obtain an acceptable approximate solution of the proximal subproblem. Note that the above system is, in general, *asymmetric*. For future comparison, note that to compute LU factorization of the matrix $c_k \nabla F(z^k) + I$ and then the solution d^k, the number of arithmetic operations required is $2(n^3/3 + n^2)$. If to solve the linear system one uses instead of matrix factorization the conjugate gradient method, calculation of $(\nabla F(z^k))^\top \nabla F(z^k)$ is needed. Apart from extra computational cost (which is not negligeable when n is large), the latter is in general a dense matrix even when $\nabla F(z^k)$ is sparse. In what follows, we show how choosing a special variable metric can reduce the number of calculations in the case of using matrix factorizations and can preserve sparsity if the conjugate gradient method is used.

The idea is to choose a metric in such a way that, instead of solving a general asymmetric linear system, we will have to solve one triangular system and one symmetric system (with a positive definite matrix). As we shall see, this has a number of advantages.

Consider the proximal subproblem

$$0 = c_k M_k F(z) + (z - z^k). \tag{5.3}$$

We shall compute the Newton step for its equivalent formulation

$$0 = c_k F(z) + A_k(z - z^k),$$

where A_k plays the role of the inverse of M_k (no matrices are actually inverted, of course; we simply choose A_k and work with it throughout, as explained next). The Newton step for the latter equation is given by

$$c_k F(z^k) + (c_k \nabla F(z^k) + A_k) d^k = 0. \tag{5.4}$$

In what follows, we shall show that, with proper choices of parameters, the point

$$y^k = z^k + d^k \tag{5.5}$$

is an acceptable approximate solution of (5.3), in the sense of Algorithm 3.1 (even more specifically, in the sense of Proposition 3.1). Then the next iterate is given by

$$z^{k+1} = z^k - c_k M_k F(y^k),$$

which can be implemented as solving the system of linear equations

$$c_k F(y^k) + A_k s = 0, \tag{5.6}$$

with respect to $s \in \mathbb{R}^n$, and setting

$$z^{k+1} = z^k + s^k. \tag{5.7}$$

As A_k we suggest to take the symmetrization of the upper triangular part of the matrix $-c_k \nabla F(z^k)$ with appropriate diagonal elements, so that it is positive definite. One choice is

$$(A_k)_{i,j} := \begin{cases} -c_k(\nabla F(z^k))_{i,j} & \text{for} \quad i < j, \\ (A_k)_{j,i} & \text{for} \quad i > j, \\ 1 + \sum_{i \neq j} |(A_k)_{i,j}| & \text{for} \quad i = j. \end{cases} \tag{5.8}$$

Since A_k is symmetric and strictly diagonally dominant, it is positive definite by the Gerschgorin theorem [12, Theorem 3.5.9], and

$$\lambda_{min}(A_k) \geq 1. \tag{5.9}$$

The proposed implementation, therefore, consists of solving the linear system (5.4) with the triangular matrix $c_k \nabla F(z^k) + A_k$ and the linear system (5.6) with the symmetric positive definite matrix A_k. If the Cholesky factorization is used for the latter, the total cost of the iteration is $n^3/3 + 2n^2 + n^2/2$ arithmetic operations. The savings compared to the fixed metric (asymmetric) implementation discussed above amounts to $n^2(n/3 - 1/2)$, which is significant for large n. If instead of matrix factorization the conjugate gradient method is used to solve (5.6), it is important that it works directly with the symmetric matrix A_k, which is sparse if $\nabla F(z^k)$ is also. Recall that, in the case of solving the asymmetric system, the method has to work with $(c_k \nabla F(z^k) + I)^\top (c_k \nabla F(z^k) + I)$, which is in general dense even when $\nabla F(z^k)$ is sparse.

To validate our proposal, it remains to show that the single Newton step defined by (5.4) produces a point acceptable by the approximation criterion of Algorithm 3.1 and that this strategy does not increase too much the overall number of iterations of the method as compared to the asymmetric fixed metric implementation. We deal with the first issue next and then present some numerical experiments to address the second.

Let $M_k = A_k^{-1}$. By (5.9), we have

$$\lambda_{max}(M_k) \leq 1. \tag{5.10}$$

In particular, we can take $\lambda_u = 1$ in Algorithm 3.1. Since d^k is the solution of the linear system (5.4), we have

$$d^k = y^k - z^k = -c_k M_k F(z^k) - c_k M_k \nabla F(z^k) d^k. \tag{5.11}$$

To prove the claim that this Newton step is sufficient to solve the proximal subproblem within the required tolerance, we have to show that

$$\|c_k M_k F(y^k) + d^k\|^2_{M_k^{-1}} \leq \sigma_k^2 \left(\|c_k M_k F(y^k)\|^2_{M_k^{-1}} + \|d^k\|^2_{M_k^{-1}} \right). \tag{5.12}$$

Let ∇F be Lipschitz-continuous with modulus $\gamma > 0$ (on the bounded set containing the sequences $\{z^k\}$ and $\{y^k\}$, whose boundedness has been already established). It then holds that

$$\|F(y^k) - F(z^k) - \nabla F(z^k) d^k\| \leq \frac{\gamma}{2} \|d^k\|^2.$$

Since it follows from (5.11) that

$$-c_k F(z^k) - c_k \nabla F(z^k) d^k = M_k^{-1} d^k,$$

we obtain

$$\|c_k F(y^k) + M_k^{-1} d^k\| \leq \frac{\gamma c_k}{2} \|d^k\|^2. \tag{5.13}$$

Furthermore, by recalling (5.10), we have

$$\|c_k F(y^k) + M_k^{-1} d^k\|^2 \geq \|c_k F(y^k) + M_k^{-1} d^k\|^2_{M_k} = \|c_k M_k F(y^k) + d^k\|^2_{M_k^{-1}}. \tag{5.14}$$

Also, by using (5.10) and (5.11), we obtain

$$\begin{aligned} \|d^k\|^2 &\leq \|d^k\|^2_{M_k^{-1}} \\ &= \langle d^k, M_k^{-1}(-c_k M_k F(z^k) - c_k M_k \nabla F(z^k) d^k) \rangle \\ &= -c_k \langle d^k, F(z^k) \rangle - c_k \langle d^k, \nabla F(z^k) d^k \rangle \\ &\leq c_k \|d^k\| \|F(z^k)\|, \end{aligned}$$

where we have used the fact that $\nabla F(z^k)$ is positive semidefinite (by the monotonicity of F). Hence,

$$\|d^k\| \leq c_k \|F(z^k)\|.$$

By combining this relation with (5.13) and (5.14), we conclude that

$$\|c_k M_k F(y^k) + d^k\|_{M_k^{-1}} \leq \frac{\gamma c_k^2 \|F(z^k)\|}{2} \|d^k\| \leq \frac{\gamma c_k^2 \|F(z^k)\|}{2} \|d^k\|_{M_k^{-1}},$$

where (5.10) was also taken into account. Therefore, by choosing the regularization parameter

$$0 < c_k \leq \frac{\sqrt{2}\sigma_k}{\sqrt{\gamma \|F(z^k)\|}},$$

we obtain (5.12). This analysis also shows that we are in the setting of Proposition 3.1, so that the step $z^{k+1} = z^k + c_k M_k F(y^k)$ is admissible (implemented above as solving the linear system (5.6)).

If an estimate for the Lipschitz constant γ of ∇F is not available, c_k can be obtained by an Armijo-type line-search procedure. Alternatively, instead of making one Newton step for each subproblem, we can make several, until the relative error approximation criterion is satisfied. In our computational experience, however, one Newton step was always enough. Moreover, by assuming the nonsingularity of ∇F at the solution, for k large enough one can take $c_k = \frac{\sqrt{2}\sigma_k}{\sqrt{\|F(z^k)\|}}$, without any line search, and make a single Newton step. The superlinear rate of convergence can be established by analysis analogous to [25].

5.2. Numerical experiments. We have compared the proximal Newton methods, with a fixed metric and a variable metric, on the following examples.

Let $F : \mathbb{R}^n \to \mathbb{R}^n$ be given by

$$F(z) = \tilde{F}(z) + Hz,$$

where

$$\tilde{F}_i(z) = \frac{1 + (-1)^{i+1}}{2} f(z_i),$$

$f : \mathbb{R} \to \mathbb{R}$ is a monotone function with a Lipschitz-continuous derivative, and H is the $n \times n$ matrix given by

$$(H)_{i,j} = \begin{cases} n/2 & \text{for } i = j = 1, \\ 5n & \text{for } i = 1 \text{ and } j = n, \\ -5n & \text{for } i = n \text{ and } j = 1, \\ n + i - 1 & \text{for } i = j \text{ and } i \notin \{1, n\}, \\ 1 & \text{for } j = n \text{ and } i \notin \{1, n\}, \\ 1 & \text{for } j < i \text{ and } i \neq n, \\ -1 & \text{for } i = n \text{ and } j \notin \{1, n\}, \\ 0 & \text{elsewhere.} \end{cases}$$

It can be seen that H is positive semidefinite (because $(H + H^\top)/2$ is diagonally dominant), but it is not positive definite (because $e_n^\top H e_n = 0$, where e_n is the nth vector of the canonical basis). This fact and the monotonicity of f imply that F is monotone. Note that, for $n = 2k$ with $k \in \mathbb{N}$, F is not strictly monotone, even if f is strictly monotone.

It can be seen that its Jacobian $\nabla F(z)$ is Lipschitz-continuous with the same Lipschitz constant as f', and, for any $z \in \mathbb{R}^n$, $\nabla F(z)$ is a nonsymmetric matrix, with a sparse upper triangular part.

We have coded both the Newton proximal method (NPM) and the variable metric Newton proximal method (VMNPM) by using Scilab 4.0 (INRIA-ENPC, see www.scilab.org). An iteration of NPM consists of solving the system of equations (5.2), while VMNPM is the procedure given by (5.4)–(5.7), with A_k defined in (5.8). For both methods, the regularization parameter is taken as $c_k = \sqrt{2/\|F(z^k)\|}$.

In the case of solving linear systems by matrix factorization, the comparison is exactly as predicted by the arithmetic operations counts, mentioned above. The variable metric approach requires more iterations, but already for moderate dimensions

(say, $n = 500$) the cheaper iteration cost starts to pay off, with the advantage growing with n, as predicted by the operations counts. We shall not report this comparison here, for the sake of brevity.

Instead, we shall report results for solving the linear systems by the conjugate gradient method. The Scilab `sparse` utility is used to take advantage of structure. As already pointed out, the matrix $(c_k\nabla F(z^k) + I)^\top(c_k\nabla F(z^k) + I)$ in the fixed metric approach is essentially dense, while the matrix A_k in the variable metric approach preserves structure.

The comparison of the respective performances, for three different choices of f, on a 1.66 GHz, 512 MB RAM Intel Centrino processor PC is shown in Table 5.1. The first column shows the dimension, then the number of iterations, the computation time in seconds, and the norm of the residual at termination. The last column shows the ratio between the computational times.

Figure 5.1 compares the computational time evolution for both methods. The performance of the NPM is almost the same for the three functions involved, and

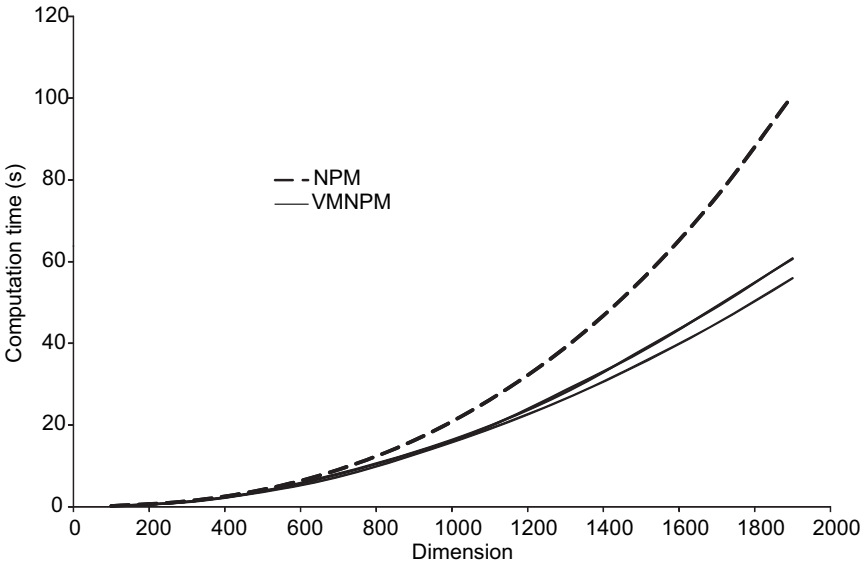

FIG. 5.1. *Performance comparison.*

it is not distinguishable in the graphic scale, while the performance of the VMNPM presents little variations for the three examples. As we have anticipated, the variable metric proximal Newton method outperforms the Newton proximal method already for moderate dimensions, with the advantage becoming more and more significant as n grows.

A CONDITION NUMBER FOR MULTIFOLD CONIC SYSTEMS*

DENNIS CHEUNG†, FELIPE CUCKER‡, AND JAVIER PEÑA§

Abstract. Let $A : Y \to X$ be a linear map and $K \subseteq X$ be a regular closed convex cone. Consider the problem of finding a nontrivial solution to the conic feasibility problem $Ay \in K$. Condition numbers for this problem (as well as for related ones) are studied to quantify various issues concerning properties of the conic feasibility problem. Some issues especially relevant are the behavior of the problem under data perturbations, the geometry of the set of solutions, and the complexity analyses of algorithms that solve the problem. In this paper we define and characterize a condition number that exploits the possible factorization of K as a product of simpler cones. This condition number extends both Renegar's condition number and the one we defined in [*Math. Program.*, 91 (2001), pp. 163–174] for polyhedral conic systems. We see these results as a step in developing a theory of conditioning that takes into account the structure of the problem.

1. Introduction.

1.1. Multifold conic systems and condition. Let X, Y be real finite-dimensional vector spaces (not necessarily of the same dimension) endowed with norms $\| \ \|_X$ and $\| \ \|_Y$, and let $K \subseteq X$ be a regular closed convex cone (a precise definition is in section 2 below). Denote by $L(Y, X)$ the space of linear maps from Y to X endowed with the operator norm. Given $A \in L(Y, X)$, consider the feasibility problem: decide whether there exists a nontrivial $y \in Y$ satisfying

$$Ay \in K. \tag{1.1}$$

This format encompasses, after homogenization, a large class of feasibility problems. For example, the linear programming feasibility problem corresponds to $K = \mathbb{R}^n_+$, the nonnegative orthant in $\mathbb{R}^n$, and semidefinite programming corresponds to $K = \mathbf{S}^n_+$, the set of $n \times n$ positive semidefinite matrices. Consider also the *alternative* feasibility problem

$$A^*x^* = 0, \ x^* \in K^*, \tag{1.2}$$

where X^*, Y^* are the dual spaces of X, Y, respectively, $A^* \in L(X^*, Y^*)$ is the adjoint of A, and $K^* \subseteq X^*$ is the dual cone of K.

The problem (1.1) is strictly feasible if there exists $y \in Y$ such that $Ay \in \mathsf{int}(K)$. Let $\mathcal{D}$ denote the set of instances $A \in L(Y, X)$ for which (1.1) is strictly feasible.

Observe that $A \in \mathcal{D}$ if and only if $AY - K = X$, i.e., if and only if the conic system

$$Ay - c \in K, \tag{1.3}$$

is feasible for every $c \in X$.

Likewise, the problem (1.2) is strictly feasible if there exists $x^* \in \mathsf{int}(K^*)$ such that $A^*x^* = 0$. Let $\mathcal{P}$ denote the set of instances $A \in L(Y, X)$ such that A^* is surjective and (1.2) is strictly feasible. Observe that $A \in \mathcal{P}$ if and only if $A^*K^* = Y^*$, i.e., if and only if the conic system

$$A^*x^* = b^*,\ x^* \in K^*, \tag{1.4}$$

is feasible for every $b^* \in Y^*$.

It is easy to see that the sets $\mathcal{D}$ and $\mathcal{P}$ are open, and $\mathcal{P} = \overline{D}^c$. The sets $\mathcal{D}$ and $\mathcal{P}$ are the set of "well-posed" feasible instances for problems (1.1) and (1.2), respectively. The boundary $\Sigma := \partial\mathcal{D} = \partial\mathcal{P}$ is the set of "ill-posed" instances. Given $A \in \Sigma$, arbitrarily small perturbations of A may yield instances in both $\mathcal{D}$ and $\mathcal{P}$.

The feasibility problems (1.1) and (1.2) can be solved via algorithms (such as interior-point or ellipsoid methods). The theoretical running time of such algorithms grows as A approaches Σ. Consequently, a complexity analysis of these algorithms has been carried out in terms of a measure capturing this distance. Similar remarks hold as well, with natural modifications, for linear conic optimization problems with constraints of the form (1.3) or (1.4). A general analysis of such a type for interior-point methods is due to Renegar [30, 31], who introduced the condition number

$$C(A) = \frac{\|A\|}{\mathsf{dist}(A, \Sigma)} = \frac{\|A\|}{\min_{\widetilde{A} \in \Sigma} \|\widetilde{A} - A\|}. \tag{1.5}$$

Renegar's condition number is thus the normalized inverse of the distance to ill-posedness. The condition number $C(A)$ can also be used in the complexity analysis of the ellipsoid method [17] and in the round-off analysis of interior-point algorithms [10]. For the linear programming feasibility problem ($K = \mathbb{R}^n_+$), the quantities $C(A)$ and $\ln C(A)$ have also been analyzed as random variables when A is random [7, 13]. Bounds for the expected value of $C(A)$ (or for that of $\ln C(A)$) yield average case bounds for the algorithms mentioned above.

It is often the case that a feasibility problem of the form (1.1) is actually the coupling of a number of similar feasibility problems. More precisely, if $X = X_1 \times \cdots \times X_r$ and $K = K_1 \times \cdots \times K_r$, where each $K_j \subseteq X_j$ is a regular closed convex cone, then (1.1) can be written as

$$\begin{aligned} A_1 y &\in K_1 \\ &\vdots \\ A_r y &\in K_r, \end{aligned} \tag{1.6}$$

where each $A_j \in L(Y, X_j)$ is the projection of $A \in L(Y, X)$ onto $L(Y, X_j)$. In this *multifold* case, it may well be the case that $C(A)$ is large, but a natural preconditioning, such as component normalization, could remove the seemingly bad conditioning. This limitation of $C(A)$ may yield a nonessential overestimate on the conditioning of the problem (1.6). The latter in turn often leads to results concerning the geometry of the set of feasible solutions, as well as complexity estimates of algorithms that are overly

conservative. Consequently, some condition-based analyses such as those in [10, 27] are presented in terms of the condition number of a problem after performing some appropriate preprocessing steps on the data. In the case of linear programming (i.e., when $X = \mathbb{R}^n$, $K = \mathbb{R}^n_+$, $r = n$, and $K_j = \mathbb{R}_+$) another condition number $\mathscr{C}(A)$ was introduced in [6] (extending ideas in [19]) exploiting the multifold structure of $\mathbb{R}^n_+$. This condition number is close in spirit to $C(A)$ but is invariant under row scaling and is defined (in the feasible case) in terms of a *best conditioned* solution to (1.6). This condition number can also be used in the analysis of algorithms (e.g., the analysis in [10] carries over to $\mathscr{C}(A)$) and has also been studied as a random variable [8, 11, 20].

In this paper we show that the definition and key characterization of $\mathscr{C}(A)$ extend to the general multifold conic system (1.6) for a particular class of norms in X. An immediate consequence of our results is a maxmin characterization of $C(A)$, which emphasizes the close relationship between $C(A)$ and $\mathscr{C}(A)$. In the special case when the multifold structure of (1.6) is ignored, our work is closely related to previous characterizations of the distance to ill-posedness of the system $Ay \in K$ by Freund and Vera [18] and by Cánovas et al. [5]. More precisely, Theorem 1.1 without scaling on the components of (1.6) follows from [18, Thms. 7 and 10]. Furthermore, Theorem 1.1 without scaling also holds for an infinite family of linear inequalities as was shown in [5, Thm. 7]. On the other hand, an extension of the condition number $\mathscr{C}(A)$ to general conic systems was proposed by Lara and Tunçel [22]. However, that condition number conveys only information about the geometry of the set of feasible solutions of (1.6) and does not have a direct relationship to the distance to ill-posedness of $Ay \in K$.

The central results in our paper, namely, Theorems 1.1 and 1.2, can be seen as steps in the development of a theory of *structured condition numbers* in the spirit introduced by Peña [28, 29] and Lewis [23].

1.2. Statement of the main results. Given a triple (X, K, e), with X a finite-dimensional normed space, $K \subseteq X$ a regular closed convex cone, and $e \in \mathsf{int}(K)$ a given point, define $\lambda_{\min} : X \to \mathbb{R}$ as

$$x \mapsto \max\{t \in \mathbb{R} : x - te \in K\}. \tag{1.7}$$

Notice that $\lambda_{\min}$ is *positively homogeneous*, i.e., it satisfies

$$\lambda_{\min}(sx) = s\lambda_{\min}(x) \quad \text{for all} \quad s \geq 0 \quad \text{and} \quad x \in X,$$

and *superlinear*, i.e., it satisfies

$$\lambda_{\min}(x + u) \geq \lambda_{\min}(x) + \lambda_{\min}(u) \quad \text{for all} \quad x, u \in X.$$

Notice also that $x \in K \Leftrightarrow \lambda_{\min}(x) \geq 0$ and $x \in \mathsf{int}(K) \Leftrightarrow \lambda_{\min}(x) > 0$.

We next proceed with conditioning.

For $j = 1, \ldots, r$, let $e_j \in \mathsf{int}(K_j)$ be fixed and $\lambda^j_{\min} : X_j \to \mathbb{R}$ denote the function (1.7) corresponding to the triple (X_j, K_j, e_j).

Let $\mathbb{R}_{++} = (0, +\infty)$ and $\alpha \in \mathbb{R}^r_{++}$ be given. Define the *condition value* of a point $y \in Y \setminus \{0\}$ to be

$$v_{A,\alpha}(y) := \min_{j=1,\ldots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j \|y\|}. \tag{1.8}$$

Observe that y is a strict solution to (1.6) if and only if $v_{A,\alpha}(y) > 0$. Define the best conditioned value $\overline{v}_{A,\alpha}$ to be

$$\overline{v}_{A,\alpha} := \max_{y \neq 0} v_{A,\alpha}(y).$$

Notice that $A \in \mathcal{D}$ if and only if $\overline{v}_{A,\alpha} > 0$, $A \in \Sigma$ if and only if $\overline{v}_{A,\alpha} = 0$, and $A \in \mathcal{P}$ if and only if $\overline{v}_{A,\alpha} < 0$. Notice also that this is valid for all $\alpha \in \mathbb{R}^r_{++}$.

For $a \in X$ and $\delta > 0$ let

$$\mathbb{B}_X(a, \delta) := \{x \in X : \|x - a\| \leq \delta\}.$$

We shall say that the triple (X, K, e) satisfies the *norm compatibility condition* if $\|e\| = 1$ and the following condition holds:

$$\mathbb{B}_X(e, 1) \subseteq K. \tag{NC}$$

We will see in section 2 below that a natural, canonical norm can be associated to any triple (X, K, e) such that the triple satisfies the norm compatibility condition for this canonical norm.

We are now ready to state our main results (we delay their proofs to section 3).

THEOREM 1.1. *If each one of the triples (X_j, K_j, e_j), $j = 1, \ldots, r$, satisfies the norm compatibility condition* (NC)*, then*

$$|\overline{v}_{A,\alpha}| = \min_{\widetilde{A} \in \Sigma} \max_{j=1,\ldots,r} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j}, \tag{1.9}$$

where the norms in the right-hand side are the operator norms induced by the norms in Y and X_j.

It is customary to define condition numbers either as a relativized distance to ill-posedness or as the condition of a best conditioned solution. Theorem 1.1 shows that both choices lead to the same notion by taking the *condition number with respect to α* to be

$$C_\alpha(A) := \frac{1}{|\overline{v}_{A,\alpha}|}$$

and requiring the norm in X to satisfy $\|(x_1, \ldots, x_r)\| = \max_{j=1,\ldots,r} \|x_j\|$. Note that the distance to ill-posedness in the right-hand side in Theorem 1.1 is relativized by the vector α.

In the previous development we have assumed that $\alpha_j > 0$ for $j = 1, \ldots, r$. From a perturbation theory viewpoint this corresponds to assuming that all of the A_j can be perturbed and that the magnitude of these perturbations are weighted (or relativized) by the α_j.

We next consider the case where some blocks are rigid, i.e., cannot be perturbed. This amounts to setting the corresponding α_j to zero. To that end, assume that $B \cup N = \{1, \ldots, r\}$ is a partition of $\{1, \ldots, r\}$, with $B \neq \emptyset$. Let $X_N = \prod_{j \in N} X_j$, $K_N = \prod_{j \in N} K_j$, and $A_N = \prod_{j \in N} A_j$. Write also $\alpha_N = (\alpha_j)_{j \in N}$ and $\alpha_B = (\alpha_j)_{j \in B}$. If we allow only perturbations in the blocks A_j for $j \in B$, then the following extension of Theorem 1.1 holds.

THEOREM 1.2. *Assume that each one of the triples (X_j, K_j, e_j), $j = 1, \ldots, r$, satisfies the norm compatibility condition. Then, for $A \notin \Sigma$,*

$$\left| \max_{\substack{A_N y \in K_N \\ y \neq 0}} \min_{j \in B} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j \|y\|} \right| = \min_{\substack{\widetilde{A} \in \Sigma \\ \widetilde{A}_N = A_N}} \max_{j \in B} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j} \tag{1.10}$$

with the convention that the left-hand side above is $+\infty$ if

$$\{y : A_N y \in K_N,\ y \neq 0\} = \emptyset$$

and the right-hand side is $+\infty$ *if*

$$\{\widetilde{A} \in \Sigma : \widetilde{A}_N = A_N\} = \emptyset.$$

Furthermore, (1.10) *can be seen as a limit case of* (1.9) *in Theorem* 1.1. *More precisely, for* $A \notin \Sigma$,

$$\left| \max_{\substack{A_N y \in K_N \\ y \neq 0}} \min_{j \in B} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j \|y\|} \right| = \lim_{\substack{\alpha_B \text{ fixed} \\ \alpha_N \downarrow 0}} |\overline{v}_{A,\alpha}|$$

and

$$\min_{\substack{\widetilde{A} \in \Sigma \\ \widetilde{A}_N = A_N}} \max_{j \in B} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j} = \lim_{\substack{\alpha_B \text{ fixed} \\ \alpha_N \downarrow 0}} \min_{\widetilde{A} \in \Sigma} \max_{j=1,\ldots,r} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j}.$$

Remark 1.3. The identity (1.10) in Theorem 1.2 does not necessarily hold if $A \in \Sigma$. For instance, consider the example $r = 2$, $B = \{1\}$, $\alpha_1 = 1$, $X_1 = \mathbb{R}$, $X_2 = Y = \mathbb{R}^2$, $K_1 = \mathbb{R}_+$, $K_2 = \mathbb{R}^2_+$, $A_1 = [\,1\ 0\,]$, and $A_2 = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right]$. In this example $A \in \Sigma$, and thus the right-hand side in (1.10) is zero, but a simple calculation shows that the left-hand side is one.

Nevertheless, when $A \in \Sigma$, a modified version of (1.10) holds if the set of ill-posed instances Σ is redefined by taking into account the relationship between the rigid part $A_N Y$ and the cone K_N.

1.3. Geometric interpretation of $\overline{v}_{A,\alpha}$. When $A \in \mathcal{D}$, any point $\overline{y} \in Y$ that satisfies

$$v_{A,\alpha}(\overline{y}) = \overline{v}_{A,\alpha}$$

can be interpreted as a best conditioned point for (1.1). Notice that in this case the best condition value $\overline{v}_{A,\alpha}$ satisfies

$$\overline{v}_{A,\alpha} = \max\{\delta > 0 : \exists y \in Y, \|y\| = 1, \text{ such that (s.t.) } \|x_i\| \leq \delta \alpha_i \Rightarrow Ay + x \in K\}.$$

In particular, $\mathbb{B}_Y(\overline{y}, \rho)$ is contained in the feasible solution set of (1.1) for $\rho = \min_{j=1,\ldots,r} \frac{\overline{v}_{A,\alpha}\alpha_j}{\|A_j\|}$. Furthermore, from Theorem 1.1 and [28, Thm. 2.11], it follows that, for $A \in \mathcal{D}$, the best condition value $\overline{v}_{A,\alpha}$ satisfies

$$\overline{v}_{A,\alpha} = \max\left\{\delta > 0 : \|x_i\| \leq \delta \alpha_i \Rightarrow x \in \{Ay - K : \|y\| \leq 1\}\right\}.$$

In other words, $\overline{v}_{A,\alpha} \prod \mathbb{B}_{X_i}(0, \alpha_i)$ is the largest multiple of $\prod \mathbb{B}_{X_i}(0, \alpha_i)$ contained in the set

$$\{Ay + K : \|y\| \leq 1\}.$$

Likewise, from Theorem 1.1 and [28, Thm. 2.8], it follows that, for $A \in \mathcal{P}$, the best condition value $\overline{v}_{A,\alpha}$ satisfies the following geometric property:

(1.11)
$$|\overline{v}_{A,\alpha}| = \max\left\{\delta > 0 : \|y^*\|^* \leq \delta \Rightarrow y^* \in \left\{A^* x^* : x^* \in K^*, \sum \alpha_i \|x_i^*\|^* \leq 1\right\}\right\}.$$

In other words, $\mathbb{B}_{Y^*}(0, |\overline{v}_{A,\alpha}|)$ is the largest (dual) ball centered at 0 that is contained in the set

$$\left\{A^*x^* : x^* \in K^*, \sum \alpha_i \|x_i^*\|^* \leq 1\right\}.$$

The identity (1.11) yields the existence of *well-conditioned* solutions to (1.2), as is stated more precisely in section 2.4 below.

We also note that the above geometric interpretations of $\overline{v}_{A,\alpha}$ can be extended to the case when some of the components of α are zero. Specifically, if $B \cup N = \{1, \ldots, r\}$ is a partition of $\{1, \ldots, r\}$ such that $\alpha_B > 0$ and $\alpha_N = 0$, then the statements above hold as long as $\overline{v}_{A,\alpha}$ is replaced with

$$\max_{\substack{A_N y \in K_N \\ y \neq 0}} \min_{j \in B} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j \|y\|}.$$

2. Canonical norm and examples. In this section we recall some basic notions, describe various cones, exhibit explicit descriptions of their corresponding functions $\lambda_{\min}$ and canonical norms, and show how Theorems 1.1 and 1.2 apply in a number of situations.

2.1. Cones and norms. A *pointed cone* in $\mathbb{R}^n$ is a set $K \subseteq \mathbb{R}^n$ satisfying
(i) for every $x \in \mathbb{R}^n$, if $x \in K$, then $\lambda x \in K$ for all $\lambda \geq 0$, and
(ii) $K \cap -K = \{0\}$.
A cone is *regular* if it is pointed and has a nonempty interior. In what follows we assume that all cones are closed, convex, and regular.

We first show that the norm compatibility condition for a given triple (X, K, e) can be alternatively stated in terms of other geometric objects. To do so, recall [19] that the *width* of K is given by $\tau_K = \max\{r \in \mathbb{R} \mid \mathbb{B}(x, r) \subseteq K, \|x\| = 1\}$ and the *center* of K is the point $f \in K$ where τ_K is attained. It follows from the regularity of K that $0 < \tau_K \leq 1$.

PROPOSITION 2.1. *Assume that* $\|e\| = 1$. *The following conditions are equivalent:*
(NC) $\mathbb{B}(e, 1) \subseteq K$.
(NC') $|\lambda_{\min}(x) - \lambda_{\min}(u)| \leq \|x - u\|$ *for all* $x, u \in X$.
(W) $\tau_K = 1$ *and* e *is the center of* K.
(L) $\|s\|^* = \langle e, s\rangle$ *for all* $s \in K^*$.

Proof. To prove the equivalence between (NC) and (NC'), first observe that (NC') can be equivalently phrased as

(NC") $\qquad |\lambda_{\min}(x + d) - \lambda_{\min}(x)| \leq 1 \quad$ for all $d \in \mathbb{B}(e, 1)$ and $x \in X$.

Assume that (NC") holds. Then in particular for all $d \in \mathbb{B}(e, 1)$ we have

$$\lambda_{\min}(e + d) - \lambda_{\min}(e) \geq -1.$$

So

$$\lambda_{\min}(e + d) \geq -1 + \lambda_{\min}(e) = 0,$$

and consequently $e + d \in K$. Since this holds for all $d \in \mathbb{B}(e, 1)$, we get (NC).

Conversely, assume that (NC) holds. Let $d \in \mathbb{B}(e, 1)$ and $x \in X$ be given. By the construction of $\lambda_{\min}$ we have

$$x - \lambda_{\min}(x)e \in K,$$

and by (NC) we have

$$d + e \in K.$$

Hence $x + d - (\lambda_{\min}(x) - 1)e \in K$. Consequently $\lambda_{\min}(x + d) \geq \lambda_{\min}(x) - 1$ by the construction of $\lambda_{\min}$. Thus

$$\lambda_{\min}(x + d) - \lambda_{\min}(x) \geq -1. \tag{2.1}$$

On the other hand, again by the construction of $\lambda_{\min}$ and by (NC), we have

$$x + d - \lambda_{\min}(x + d)e \in K$$

and

$$-d + e \in K.$$

Hence $x - (\lambda_{\min}(x + d) - 1)e \in K$. Consequently $\lambda_{\min}(x) \geq \lambda_{\min}(x + d) - 1$, i.e.,

$$\lambda_{\min}(x + d) - \lambda_{\min}(x) \leq 1. \tag{2.2}$$

We thus get (NC") from (2.1) and (2.2).

Condition (NC) amounts to saying that $\tau_K = 1$ and that e is the center of K. Hence the equivalence of (NC) and (W). Finally, the equivalence between (W) and (L) is shown in [17, Proposition 2.1]. □

Remark 2.2. (i) Any triple (X, K, e) can be endowed with the following *canonical norm* $\| \ \|_{\mathbf{c}}$ so that (X, K, e) satisfies the norm compatibility condition:

$$\|x\|_{\mathbf{c}} := \min\{\alpha \geq 0 : x + \alpha e \in K,\ -x + \alpha e \in K\}.$$

This canonical norm plays a central role in primal-dual interior-point methods for self-scaled cones. In such a context, it is generally denoted as $| \ |_e$. See, e.g., [25, 26, 32].

(ii) In case the norms of some X_j do not satisfy (NC), one may extend Theorem 1.1 to obtain inequalities involving the widths τ_{K_j} of the respective cones.

As some of the examples below illustrate, the canonical norm $\|x\|_{\mathbf{c}}$ above coincides with commonly used norms in a number of cases.

Example 1 (cone of squares in Euclidean Jordan algebras). Consider $(X, K, e) = (\mathcal{E}, \mathcal{K}, e)$, where $\mathcal{E}$ is an Euclidean Jordan algebra, $\mathcal{K}$ is the closure of the cone of squares in $\mathcal{E}$, and $e \in \mathcal{K}$ is the identity element [14]. In this case

$$\lambda_{\min}(x) = \min_{j=1,\ldots,q} \lambda_j(x),$$

and the canonical norm is the spectral norm

$$\|x\|_{\mathbf{c}} = \max_{j=1,\ldots,q} |\lambda_j(x)|,$$

where the $\lambda_j(x)$, $j = 1, \ldots, q$, are the Jordan algebra eigenvalues of x, i.e., the eigenvalues of the characteristic polynomial $\det(\lambda e - x)$ for a suitable homogeneous polynomial det [14, Chap. 3].

Examples 2–7 specialize Example 1 above. They provide explicit expressions for $\lambda_{\min}(\ )$ and $\| \ \|_{\mathbf{c}}$ for some specific Jordan algebras. It should be noted that the explicit expressions in Examples 2–4 have been known in optimization for some time (see [16, sect. 2] and [25, sect. 3]).

Example 2 (nonnegative orthant). Consider $(X, K, e) = (\mathbb{R}^n, \mathbb{R}^n_+, (1, \ldots, 1))$. In this case $q = n,\ \lambda_j(x) = x_j,\ j = 1, \ldots, n$. Consequently,

$$\lambda_{\min}(x) = \min_j x_j, \quad \|x\|_{\mathbf{c}} = \|x\|_\infty = \max_j |x_j|.$$

Example 3 (second-order cone). Consider $(X, K, e) = (\mathbb{R}^{n+1}, \mathcal{Q}^n, (1, 0, \ldots, 0))$, where $\mathcal{Q}^n$ is the *second-order cone* defined to be

$$\mathcal{Q}^n := \{x = (x_0, \overline{x}), \overline{x} \in \mathbb{R}^n : x_0 \geq \|\overline{x}\|_2\}.$$

In this case $q = 2,\ \lambda_1(x) = x_0 - \|\overline{x}\|_2,\ \lambda_2(x) = x_0 + \|\overline{x}\|_2$. Consequently,

$$\lambda_{\min}(x) = x_0 - \|\overline{x}\|_2, \quad \|x\|_{\mathbf{c}} = |x_0| + \|\overline{x}\|_2.$$

Example 4 (semidefinite cone). Consider $(X, K, e) = (\mathbf{S}^n, \mathbf{S}^n_+, \mathrm{I})$, where $\mathbf{S}^n$ is the set of $n \times n$ symmetric matrices, $\mathbf{S}^n_+$ is the subset of those which are positive semidefinite, and I is the identity matrix. In this case

$$\lambda_{\min}(x) = \min_{j=1,\ldots,n} \lambda_j(x) \qquad \text{and} \qquad \|x\|_{\mathbf{c}} = \max_{j=1,\ldots,n} |\lambda_j(x)|,$$

where $\lambda_j(x),\ j = 1, \ldots, n$, are the usual eigenvalues of x, i.e., the roots of $p(\lambda) := \det(\lambda \mathrm{I} - x)$.

Example 5 (cones of positive semidefinite Hermitian matrices). Consider (X, K, e), where X is the real vector space $\mathrm{Herm}(n, \mathbb{C})$ of $n \times n$ Hermitian matrices with complex entries, K is the cone of positive semidefinite Hermitian matrices in X, and e is the $n \times n$ identity matrix. In this case $q = n,\ \lambda_j(x),\ j = 1, \ldots, n$, are the usual eigenvalues of x, i.e., the roots of $p(\lambda) := \det(\lambda \mathrm{I} - x)$ which, it is well known, are real.

Example 6 (cones of positive semidefinite Hermitian matrices with quaternions entries). Consider (X, K, e), where X is the real vector space $\mathrm{Herm}(n, \mathbb{H})$ of $n \times n$ Hermitian matrices with quaternion entries, K is the cone of positive semidefinite Hermitian matrices in X, and e is the $n \times n$ identity matrix. In this case $q = n$ and $\lambda_j(x),\ j = 1, \ldots, n$, are the roots (as a univariate polynomial in λ) of the "characteristic polynomial" $\det(\lambda e - x)$ of X. This polynomial is defined as follows [15]. Let J be the $2n \times 2n$ matrix $\left[\begin{smallmatrix} 0 & \mathrm{I}_n \\ -\mathrm{I}_n & 0 \end{smallmatrix}\right]$. Then $\mathrm{Herm}(n, \mathbb{H})$ can be written as $\{z \in \mathrm{Herm}(2n, \mathbb{C}) : \overline{z} J = J z\}$, and, for $z \in \mathrm{Herm}(n, \mathbb{H})$,

$$\det(z) = \mathrm{Pf}(Jz),$$

where $\mathrm{Pf}(Jz)$ is the *Pfaffian* of Jz, i.e., the unique polynomial satisfying $\mathrm{Pf}(J) = 1$ and $\mathrm{Pf}(Jz)^2 = \det(Jz)$. Again, it is well known that the $\lambda_j(x),\ j = 1, \ldots, n$, are real. (For a more detailed discussion on Pfaffians, see, e.g., [21].)

Example 7 (cones of squares in the Albert algebra). Consider (X, K, e), where X is the real vector space of 3×3 Hermitian matrices with octonion entries [2, 9], K is the cone of squares in X, i.e., $K = \{x^2 : x \in X\}$, and e is the 3×3 identity matrix. In this case $q = 3$ and $\lambda_j(x),\ j = 1, 2, 3$, are the roots of the characteristic polynomial

$$p(\lambda) = \det(\lambda e - x) = \lambda^3 - \mathrm{trace}(x)\lambda^2 + \sigma(x)\lambda - \det(x),$$

where $\mathrm{trace}(x), \sigma(x), \det(x)$ are defined as follows [12, 15]. For a, b, c octonions and $p, m, n \in \mathbb{R}$,

$$x = \begin{bmatrix} p & a & \overline{b} \\ \overline{a} & m & c \\ b & \overline{c} & n \end{bmatrix},$$

$$\begin{aligned}\operatorname{trace}(x) &= p + m + n,\\ \sigma(x) &= pm + mn + pn - |a|^2 - |b|^2 - |c|^2,\\ \det(x) &= pmn + b(ac) + \overline{b(ac)} - n|a|^2 - m|b|^2 - p|c|^2.\end{aligned}$$

Note that we write $b(ac)$ to emphasize the order of the multiplications in the nonassociative ring of octonions. Just as in the previous examples, λ_1, λ_2, and λ_3 are real.

Example 8 (hyperbolicity cones). Let $e \in \mathbb{R}^n$ and $p \in \mathbb{R}[X_1, \ldots, X_n]$ be a *complete hyperbolic polynomial* in the direction e, i.e., a homogeneous polynomial satisfying that, for all $x \in \mathbb{R}^n$, the univariate polynomial $\lambda \mapsto p(\lambda e - x)$ has only real roots, and at least one of them is nonzero for $x \neq 0$. (For a detailed exposition on hyperbolic polynomials, see, e.g., [3, 33].) Consider $(X, K, e) = (\mathbb{R}^n, C(p, e), e)$, where $C(p, e)$ is the closure of the *hyperbolicity cone* for p in the direction e; i.e., $C(p, e)$ is the closure of the connected component of the set $\{x : p(x) > 0\}$ that contains e. In this case

$$\lambda_{\min}(x) = \min_{j=1,\ldots,d} \lambda_j(x),$$

where $\lambda_j(x)$, $j = 1, \ldots, d = \deg(p)$, are the roots of the polynomial $\lambda \mapsto p(\lambda e - x)$, and

$$\|x\|_{\mathbf{c}} = \max_{j=1,\ldots,d} |\lambda_j(x)|.$$

Example 9 (nonnegative, finitely spanned, functions on a compact domain). Assume that $d \in \mathbb{N}$, $D \subseteq \mathbb{R}^n$ is a nonempty compact set, and $f_0, \ldots, f_d$ are continuous, real-valued functions defined on D, with $f_0(x) = 1$, for all $x \in D$. Consider the triple (X, K, e), where

$$X = \operatorname{span}\{f_0, \ldots, f_d\},$$

$$K = \{f \in X : f(x) \geq 0 \text{ for all } x \in D\},$$

and $e \in X$ is the constant function f_0. In this case, for $f \in X$,

$$\lambda_{\min}(f) = \min_{x \in D} f(x)$$

and

$$\|f\|_{\mathbf{c}} = \max_{x \in D} |f(x)|.$$

2.2. Cone reducibility. Assume that X is a finite-dimensional inner product space. Then the map $u \mapsto \langle u, \cdot \rangle$ defines an isomorphism between X and its dual space X^*. The *dual* of a cone $K \subseteq X$ is identified via this isomorphism with the cone

$$K^* = \{u \in X : \langle u, x \rangle \geq 0 \text{ for all } x \in K\}.$$

We say that K is *self-dual* if $K^* = K$. We say that K is *homogeneous* if for all $x, u \in \mathsf{int}(K)$ there exists $g \in \operatorname{Aut}(\mathsf{int}(K))$ such that $gx = u$, where $\operatorname{Aut}(\mathsf{int}(K)) = \{g \in \operatorname{GL}(X) : g(\mathsf{int}(K)) = \mathsf{int}(K)\}$. Here $\operatorname{GL}(X)$ is the general linear group over X. A cone is *symmetric* if it is self-dual and homogeneous [14].

Symmetric cones coincide with *self-scaled cones,* a class of cones that plays a central role in interior-point methods [25]. Nesterov and Todd identified the properties

of self-scaled cones as the fundamental building blocks for the development of symmetric primal-dual interior-point algorithms [26, 32] for conic programs over these cones. Symmetric cones have been extensively studied in other areas of mathematics. It can also be shown that they coincide with the cones of squares of Euclidean Jordan algebras (cf. Example 1). Furthermore, they satisfy a unique factorization property; namely, they can be written in a unique way (up to ordering) as a product of cones in the classes described in Examples 3–7 above [14].

Because second-order conic feasibility over a single second-order cone can be solved in closed form, all interesting examples of second-order conic feasiblity problems are written in terms of a nontrivial product of second-order cones (see, e.g., [1, 24]).

Given X and K, one may wonder how the canonical norm and the minimum-eigenvalue constructs depend on different factorizations of (X, K). The following proposition settles this question.

PROPOSITION 2.3. *Let $X = X_1 \times \cdots \times X_r$, $K = K_1 \times \cdots \times K_r$, and $e = (e_1, \ldots, e_r)$, with $e_j \in \mathsf{int}(K_j)$. Then, for all $x = (x_1, \ldots, x_r) \in X$,*

(i)

$$\lambda_{\min}(x) = \min\{\lambda^1_{\min}(x_1), \ldots, \lambda^r_{\min}(x_r)\}.$$

where $\lambda^j_{\min}$ is the minimum eigenvalue associated to (X_j, K_j, e_j) and $\lambda_{\min}$ that associated to (X, K, e).

(ii)

$$\|x\|_{\mathbf{c}} = \max_{j=1,\ldots,r} \|x_j\|_{\mathbf{c},j},$$

where $\| \ \|_{\mathbf{c},j}$ is the canonical norm associated to (X_j, K_j, e_j) and $\| \ \|_{\mathbf{c}}$ that associated to (X, K, e). In particular, the restriction of $\| \ \|_{\mathbf{c}}$ to X_j is $\| \ \|_{\mathbf{c},j}$.

Proof. From (1.7) it follows that, for $x = (x_1, \ldots, x_r) \in X$,

$$\begin{aligned}
\lambda_{\min}(x) &= \max\{t \in \mathbb{R} : x - te \in K\} \\
&= \max\{t \in \mathbb{R} : x_j - te_j \in K_j \ \text{ for } \ j = 1, \ldots, r\} \\
&= \min_{j=1,\ldots,r} \max\{t \in \mathbb{R} : x_j - te_j \in K_j\} \\
&= \min\{\lambda^1_{\min}(x_1), \ldots, \lambda^r_{\min}(x_r)\}.
\end{aligned}$$

This shows part (i). For part (ii) we first claim that

$$B = B_1 \times \cdots \times B_r. \tag{2.3}$$

Indeed, given $d = (d_1, \ldots, d_r) \in X$,

$$\begin{aligned}
d \in B &\Leftrightarrow e + d, e - d \in K \\
&\Leftrightarrow e_j + d_j, e_j - d_j \in K_j \ \text{ for } \ j = 1, \ldots, r \\
&\Leftrightarrow d_j \in B_j \ \text{ for } \ j = 1, \ldots, r \\
&\Leftrightarrow d \in B_1 \times \cdots \times B_r.
\end{aligned}$$

From (2.3) it follows that, for $x = (x_1, \dots, x_r) \in X$,

$$\begin{aligned}\|x\|_{\mathbf{c}} &= \inf\left\{t : \frac{1}{t}x \in B\right\}\\ &= \inf\left\{t : \frac{1}{t}x_j \in B_j \ \text{ for } \ j = 1, \dots, r\right\}\\ &= \max_{j=1,\dots,r} \inf\left\{t : \frac{1}{t}x_j \in B_j\right\}\\ &= \max_{j=1,\dots,r} \|x_j\|_{\mathbf{c},j}. \qquad \square\end{aligned}$$

We have already mentioned that we endow $L(Y, X)$ with the operator norm with respect to the norms in Y and X. Therefore, the canonical norm in X induces a *canonical norm in* $L(Y, X)$. In particular, in the case where $X = X_1 \times \cdots \times X_r$, Proposition 2.3(ii) yields the relation

$$\|A\|_{\mathbf{c}} = \max_{j=1,\dots,r} \|A_j\|_{\mathbf{c},j}$$

for the canonical norms in $L(Y, X)$ and those in $L(Y, X_j)$, $j = 1, \dots, r$.

Remark 2.4. Note that the factorization mentioned above together with Proposition 2.3(ii) and Examples 3–7 yield expressions for the canonical norm for every symmetric cone. If the factorization is explicit, then the expressions for the canonical norm are explicit as well.

2.3. Condition numbers and the choice of $\boldsymbol{\alpha}$. We mentioned in section 1.1 the role of Renegar's condition number in the analysis of algorithms for conic feasibility problems. We also mentioned there that, in the case of polyhedral cones, the condition number $\mathscr{C}(A)$ exploited the reducibility of the cone $\mathbb{R}^n_+$. We next show how these condition numbers are obtained by appropriately selecting α.

Assume a factorization $X = X_1 \times \cdots \times X_r$ and $K = K_1 \times \cdots \times K_r$. Basic choices for α are

(1) $\alpha_j = \|A\|$ for $j = 1, \dots, r$;
(2) $\alpha_j = \|A_j\|$ for $j = 1, \dots, r$.

The first choice leads to Renegar's condition number $C(A)$ for the norm in $L(Y, X)$ defined by

$$\|A\| = \max_{j=1,\dots,r} \|A_j\| \tag{2.4}$$

because in this case

$$C_\alpha(A) = \frac{\|A\|}{\min\limits_{\widetilde{A}\in\Sigma} \max\limits_{j=1,\dots,r} \|A_j - \widetilde{A}_j\|} = \frac{\|A\|}{\min\limits_{\widetilde{A}\in\Sigma} \|A - \widetilde{A}\|} = C(A).$$

Theorem 1.1 then takes the form of a minmax characterization of the distance to ill-posedness (and therefore of $C(A)$). We note that this can also be obtained from [18, Thms. 7 and 10].

The second choice of α above leads to (extensions of) the condition number $\mathscr{C}(A)$ introduced in [7].

The discusion above assumes that $\alpha_j > 0$ for all $j = 1, \dots, r$. If some cones are rigid, say, $K = K_1 \times \cdots \times K_r \times K_N$ with $\alpha_j > 0$ for $j = 1, \dots, r$ and $\alpha_N = 0$, then,

by letting $B = \{1, \dots, r\}$, one defines

$$C(A) = \frac{\|A_B\|}{\min\limits_{\substack{\widetilde{A}\in\Sigma \\ \widetilde{A}_N = A_N}} \max\limits_{j\in B} \|A_j - \widetilde{A}_j\|}$$

and

$$\mathscr{C}(A) = \frac{1}{\left| \max\limits_{\substack{A_N y \in K_N \\ y\neq 0}} \min\limits_{j\in B} \dfrac{\lambda^j_{\min}(A_j y)}{\|A_j\|\,\|y\|} \right|}.$$

The proof of the following proposition is an immediate consequence of the fact that $\|A_j\| \leq \|A\|$ for all $j = 1, \dots, r$.

PROPOSITION 2.5. *For all $A \in L(Y, X)$, $\mathscr{C}(A) \leq C(A)$. This holds as well if some factors of A are rigid.*

We next see how the choices of α above materialize in the case of polyhedral conic systems.

Example 2 (revisited). Recall that $X = \mathbb{R}^n$, $Y = \mathbb{R}^m$, and $K = \mathbb{R}^n_+$.

(i) Consider the case $r = 1$. We do not decompose K. In this case we take $e = (1, \dots, 1)$ and, as we have seen, $\|x\| = \|x\|_\infty$. This induces the canonical norm in $L(Y, X)$ given by

$$\|A\| = \|A\|_{Y\infty} = \max_{\|y\|=1} \|Ay\|_\infty = \max_{\|y\|=1} \max_{j=1,\dots,n} |A_j y|.$$

We now take $\alpha = \|A\|$. Theorem 1.1 and the fact that $\lambda_{\min}(x) = \min_{j=1,\dots,n} x_j$ give then the following characterization of Renegar's condition number:

$$C(A) = \frac{\|A\|}{\mathsf{dist}(A, \Sigma)} = \frac{\|A\|}{\left| \max\limits_{\|y\|=1} \min\limits_{j=1,\dots,n} Ay \right|}. \tag{2.5}$$

(ii) Consider now the case where $r = n$. Here we take $K_j = [0, +\infty)$ and $e_j = 1$ for $j = 1, \dots, r$. We obtain the canonical norm $\|x\| = |x|$ and the minimum-eigenvalue $\lambda_{\min}(x) = x$. The former induces the canonical norm in $L(Y, X)$ given by

$$\|A\| = \max_{j=1,\dots,n} \|A_j\| = \max_{j=1,\dots,n} \max_{\|y\|=1} |A_j y|,$$

that is, as in case (i) above. Again, take $\alpha_j = \|A\|$ for all j. Then, not surprisingly, Theorem 1.1 characterizes $C(A)$ by (2.5) as well.

(iii) We now take r, K_j, and e_j as in (ii) but choose instead $\alpha_j = \|A_j\| = \max_{\|y\|=1} |A_j y|$. In this case Theorem 1.1 gives us the well-known [7] characterization of $\mathscr{C}(A)$:

$$\mathscr{C}(A) := \frac{1}{|\overline{v}_{A,\alpha}|} = \frac{1}{\min\limits_{\widetilde{A}\in\Sigma} \max\limits_{j=1,\dots,n} \frac{\|A_j - \widetilde{A}_j\|}{\|A_j\|}}.$$

(iv) For $M \in \mathbb{R}^{n\times m}$ consider the system

$$\begin{aligned} My &\geq 0, \\ y &\geq 0. \end{aligned}$$

This system can be thought of as a special case of the above with $A = (M, \mathrm{I})$. The identity matrix I, however, should be considered to be rigid (not subject to perturbations) and its corresponding α_{I} then be set to 0.

By taking $r = 2$ (two blocks, corresponding to M and I) and $\alpha_M = \|M\| = \max_{j=1,\dots,n} \max_{\|y\|=1} |M_j y|$, we obtain (in the right-hand side of (1.10)) Renegar's condition number, and Theorem 1.2 shows that

$$C(M) := \frac{\|M\|}{\min\limits_{\widetilde{M}\in\Sigma} \|M - \widetilde{M}\|} = \frac{\|M\|}{\min\limits_{\widetilde{M}\in\Sigma} \max\limits_{j=1,\dots,n} \|M_j - \widetilde{M}_j\|} = \frac{\|M\|}{\left|\max\limits_{y\geq 0} \min\limits_{j=1,\dots,n} \frac{M_j y}{\|y\|}\right|}.$$

Finally, by taking $r = n$ and $\alpha_j = \|M_j\| = \max_{\|y\|=1} |M_j y|$, $j = 1, \dots, n$, we obtain $\mathscr{C}(M)$ in the left-hand side of (1.10), and now Theorem 1.2 shows that

$$\mathscr{C}(M) := \frac{1}{\left|\max\limits_{y\geq 0} \min\limits_{j=1,\dots,n} \frac{M_j y}{\|M_j\|\|y\|}\right|} = \frac{1}{\min\limits_{\widetilde{M}\in\Sigma} \max\limits_{j=1,\dots,n} \frac{\|M_j - \widetilde{M}_j\|}{\|M_j\|}}.$$

We have revisited Example 2 to see how Theorems 1.1 and 1.2, together with appropriate choices of α, yield characterizations of $C(A)$ and $\mathscr{C}(A)$ in the case of polyhedral conic systems, possibly with rigid components. The other examples in section 2.1, and arbitrary products of them, may be similarly dealt with. We will not do so to avoid being repetitious.

2.4. Well-conditioned solutions. As was noted in section 1.3, for $A \in \mathcal{D}$ any point $\overline{y} \in Y$ that satisfies

$$v_{A,\alpha}(\overline{y}) = \overline{v}_{A,\alpha} \tag{2.6}$$

can be interpreted as a best conditioned solution for (1.1). Indeed, from (2.6) it follows that $A\overline{y} \in \mathsf{int}(K)$ and for each $i = 1, \dots, r$

$$\frac{\mathsf{dist}(A_i\overline{y}, \partial K_i)}{\|\overline{y}\|} \geq \overline{v}_{A,\alpha}\, \alpha_i.$$

The following proposition provides an analogous statement for $A \in \mathcal{P}$.

PROPOSITION 2.6. *Assume that each one of the triples (X_j, K_j, e_j), $j = 1, \dots, r$, satisfies the norm compatibility condition* (NC) *and $A \in \mathcal{P}$. Then there exists $\overline{x} \in \mathsf{int}(K^*)$ such that $A^*\overline{x} = 0$ and for each $i = 1, \dots, r$*

$$\frac{\mathsf{dist}(\overline{x}_i, \partial K_i^*)}{\|\overline{x}_i\|} \geq \frac{|\overline{v}_{A,\alpha}|\, \alpha_i\, \tau_{K_i^*}}{r\|A_i\| + |\overline{v}_{A,\alpha}|\alpha_i}. \tag{2.7}$$

In particular, if $\alpha_i = \|A_i\|$, $i = 1, \dots, r$, then there exists $\overline{x} \in K^*$ such that $A^*\overline{x} = 0$ and for each $i = 1, \dots, r$

$$\frac{\mathsf{dist}(\overline{x}_i, \partial K_i^*)}{\|\overline{x}_i\|} \geq \frac{|\overline{v}_{A,\alpha}|\tau_{K_i^*}}{r + |\overline{v}_{A,\alpha}|} \geq \frac{|\overline{v}_{A,\alpha}|\tau_{K_i^*}}{r+1}.$$

Proof. For each $i = 1, \dots, r$, let $f_i^* \in K_i^*$ be the center of K_i^*, i.e., $\|f_i^*\|^* = 1$ and $\mathsf{dist}(f_i^*, \partial K_i^*) = \tau_{K_i^*}$. Define $\widetilde{x} \in K^*$ and $y^* \in Y^*$ as follows:

$$\widetilde{x}_i := \frac{|\overline{v}_{A,\alpha}|}{r\|A_i\|} f_i^*,\ y^* := -A^*\widetilde{x}.$$

It is immediate that $\|y^*\|^* \leq |\overline{v}_{A,\alpha}|$, so by (1.11) there exists $x^* \in K^*$ such that $A^*x^* = y^* = -A^*\widetilde{x}$ and $\sum_{i=1}^r \alpha_i \|x_i^*\|^* \leq 1$. Thus the point $\overline{x} := x^* + \widetilde{x} \in K^*$ satisfies $A^*\overline{x} = 0$. To finish, we next show that $\overline{x}$ satisfies (2.7). Since $\sum_{i=1}^r \alpha_i \|x_i^*\|^* \leq 1$, it follows that $\|x_i^*\|^* \leq 1/\alpha_i$ for each $i = 1, \ldots, r$. Hence

$$\|\overline{x}_i\| \leq \|x_i^*\| + \|\widetilde{x}_i\| \leq \frac{1}{\alpha_i} + \frac{|\overline{v}_{A,\alpha}|}{r\|A_i\|} = \frac{r\|A_i\| + |\overline{v}_{A,\alpha}|\alpha_i}{r\|A_i\|\alpha_i}. \tag{2.8}$$

On the other hand, since $\mathsf{dist}(f_i^*, \partial K_i^*) = \tau_{K_i^*}$, it follows that

$$\mathsf{dist}(\overline{x}_i, \partial K_i^*) \geq \frac{|\overline{v}_{A,\alpha}|\tau_{K_i^*}}{r\|A_i\|}. \tag{2.9}$$

Inequality (2.7) then follows from (2.8) and (2.9). ∎

3. Proof of the main results. The result is trivial when $\overline{v}_{A,\alpha} = 0$. Therefore, we will assume that $\overline{v}_{A,\alpha} \neq 0$. For ease of exposition, we split the proof of Theorem 1.1 into two parts, namely, Propositions 3.1 and 3.2.

PROPOSITION 3.1.

$$|\overline{v}_{A,\alpha}| \leq \min_{\widetilde{A} \in \Sigma} \max_{j=1,\ldots,r} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j}.$$

Proof. Assume that $\widetilde{A}$ is such that

$$\max_{j=1,\ldots,r} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j} < |\overline{v}_{A,\alpha}|.$$

We need to prove that $\widetilde{A} \notin \Sigma$, i.e., $\widetilde{A} \in \mathcal{P} \cup \mathcal{D}$.

Let $\overline{y}_A \in Y$ be such that $v_{A,\alpha}(\overline{y}_A) = \overline{v}_{A,\alpha}$. Assume without loss of generality that $\|\overline{y}_A\| = 1$. Because each (X_j, K_j, e_j) satisfies the norm compatibility condition, it follows from Proposition 2.1 that, for all $\widetilde{A}$ and $y \in Y \setminus \{0\}$,

$$\begin{aligned} \frac{|\lambda^j_{\min}(A_j y) - \lambda^j_{\min}(\widetilde{A}_j y)|}{\alpha_j} &\leq \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j} \|y\| \\ &\leq \max_{j=1,\ldots,r} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j} \|y\| \\ &< |\overline{v}_{A,\alpha}| \|y\|. \end{aligned} \tag{3.1}$$

In particular

$$\frac{|\lambda^j_{\min}(A_j \overline{y}_A) - \lambda^j_{\min}(\widetilde{A}_j \overline{y}_A)|}{\alpha_j} < |\overline{v}_{A,\alpha}|. \tag{3.2}$$

We now consider the cases $\overline{v}_{A,\alpha} < 0$ and $\overline{v}_{A,\alpha} > 0$ separately.

Case 1: $\overline{v}_{A,\alpha} > 0$. In this case $A \in \mathcal{D}$. From (1.8), (3.2), and the equality $v_{A,\alpha}(\overline{y}_A) = \overline{v}_{A,\alpha}$, we get, for $j = 1, \ldots, r$,

$$\begin{aligned} \frac{\lambda^j_{\min}(\widetilde{A}_j \overline{y}_A)}{\alpha_j} &\geq \frac{\lambda^j_{\min}(A_j \overline{y}_A)}{\alpha_j} - \frac{|\lambda^j_{\min}(A_j \overline{y}_A) - \lambda^j_{\min}(\widetilde{A}_j \overline{y}_A)|}{\alpha_j} \\ &> \overline{v}_{A,\alpha} - \overline{v}_{A,\alpha} = 0. \end{aligned}$$

Therefore

$$v_{\widetilde{A}}(\overline{y}_A) = \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(\widetilde{A}_j \overline{y}_A)}{\alpha_j} > 0,$$

which shows that $\overline{y}_A$ is a strict solution for $\widetilde{A}$ and, consequently, that $\widetilde{A} \in \mathcal{D}$.

Case 2: $\overline{v}_{A,\alpha} < 0$. In this case $A \in \mathcal{P}$. Let y be any point in $Y \setminus \{0\}$. Since $\overline{v}_{A,\alpha} < 0$, we must have $v_{A,\alpha}(y) \le \overline{v}_{A,\alpha} < 0$. Let $\overline{j} = \overline{j}(y)$ be such that $\frac{\lambda^{\overline{j}}_{\min}(A_{\overline{j}} y)}{\alpha_{\overline{j}} \|y\|} = v_{A,\alpha}(y)$. We claim that $\lambda^{\overline{j}}_{\min}(\widetilde{A}_{\overline{j}} y) < 0$. Indeed, by (3.1),

$$\begin{aligned}
&\left|\lambda^{\overline{j}}_{\min}(A_{\overline{j}} y) - \lambda^{\overline{j}}_{\min}(\widetilde{A}_{\overline{j}} y)\right| < -\overline{v}_{A,\alpha} \alpha_{\overline{j}} \|y\| \le -v_{A,\alpha}(y) \alpha_{\overline{j}} \|y\| \\
&\Rightarrow \lambda^{\overline{j}}_{\min}(\widetilde{A}_{\overline{j}} y) - \lambda^{\overline{j}}_{\min}(A_{\overline{j}} y) < -v_{A,\alpha}(y) \alpha_{\overline{j}} \|y\| \\
&\Rightarrow \lambda^{\overline{j}}_{\min}(\widetilde{A}_{\overline{j}} y) - v_{A,\alpha}(y) \alpha_{\overline{j}} \|y\| < -v_{A,\alpha}(y) \alpha_{\overline{j}} \|y\| \\
&\Rightarrow \lambda^{\overline{j}}_{\min}(\widetilde{A}_{\overline{j}} y) < 0.
\end{aligned}$$

Hence, for all $y \in Y \setminus \{0\}$ there exists j such that $\lambda^j_{\min}(\widetilde{A}_j y) < 0$. It follows that

$$\overline{v}_{\widetilde{A},\alpha} = \max_{y \ne 0} v_{\widetilde{A},\alpha}(y) = \max_{y \ne 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(\widetilde{A}_j y)}{\alpha_j \|y\|} < 0,$$

that is, $\widetilde{A} \in \mathcal{P}$. ∎

Recall that, given vector spaces X and Y and a linear mapping $A \in L(Y, X)$, its *adjoint* $A^* \in L(X^*, Y^*)$ is the unique linear mapping that satisfies

$$\langle v, Ay \rangle = \langle A^* v, y \rangle \quad \text{for all } v \in X^*,\ y \in Y.$$

Proposition 3.2.

$$|\overline{v}_{A,\alpha}| \ge \min_{\widetilde{A} \in \Sigma} \max_{j=1,\dots,r} \frac{\|A_j - \widetilde{A}_j\|}{\alpha_j}.$$

Proof. We consider the cases $\overline{v}_{A,\alpha} < 0$ and $\overline{v}_{A,\alpha} > 0$ separately.

Case 1: $\overline{v}_{A,\alpha} < 0$. In this case $A \notin \mathcal{D}$, so it suffices to show that for all $\delta > 0$ there exists $\widetilde{A} \in \mathcal{D}$ such that, for all $j = 1, \dots, r$, $\|A_j - \widetilde{A}_j\| \le \alpha_j(|\overline{v}_{A,\alpha}| + \delta)$. Let $\overline{y}_A \in Y$ be such that $v_A(\overline{y}_A) = \overline{v}_{A,\alpha}$. Assume without loss of generality that $\|\overline{y}_A\| = 1$. By the Hahn–Banach theorem [34, Thm. 5.20], there exists $v \in Y^*$ such that $\langle v, \overline{y}_A \rangle = \|\overline{y}_A\| = 1$ and $\|v\|^* = 1$. For $j = 1, \dots, r$, consider $\widetilde{A}_j \in L(Y, X_j)$ given by

$$\widetilde{A}_j = A_j - \alpha_j(\overline{v}_{A,\alpha} - \delta)\langle v, \cdot \rangle e_j.$$

We claim that $\widetilde{A} \in \mathcal{D}$. To see this, first notice that, for all $j = 1, \dots, r$, $A_j \overline{y}_A - \overline{v}_{A,\alpha} e_j \in K_j$ because

$$\overline{v}_{A,\alpha} = v_{A,\alpha}(\overline{y}_A) \le \frac{\lambda^j_{\min}(A_j \overline{y}_A)}{\alpha_j} = \max\{t \mid A_j \overline{y}_A - \alpha_j t e_j \in K_j\}.$$

Therefore,

$$\widetilde{A}_j \overline{y}_A = A_j \overline{y}_A - \alpha_j(\overline{v}_{A,\alpha} - \delta)\langle v, \overline{y}_A \rangle e_j = (A_j \overline{y}_A - \alpha_j \overline{v}_{A,\alpha} e_j) + \alpha_j \delta e_j \in \mathsf{int}(K_j)$$

since K_j is convex and $e_j \in \mathsf{int}(K_j)$. This shows that $\overline{y}_A$ is a strict solution for $\widetilde{A}$. To finish, just observe that $\|A_j - \widetilde{A}_j\| = \alpha_j \|(\overline{v}_{A,\alpha} - \delta)\langle v, \cdot\rangle e_j\| \leq \alpha_j |\overline{v}_{A,\alpha} - \delta| \|v\|^* \|e_j\| = \alpha_j(|\overline{v}_{A,\alpha}| + \delta)$.

Case 2: $\overline{v}_{A,\alpha} > 0$. In this case $A \in \mathcal{D}$, so it suffices to show that there exists $\widetilde{A} \notin \mathcal{D}$ such that, for all $j = 1, \ldots, r$, $\|A_j - \widetilde{A}_j\| \leq \alpha_j \overline{v}_{A,\alpha}$. Let $e = (e_1, \ldots, e_r) \in K = K_1 \times \cdots \times K_r$. Let $B_j = \frac{1}{\alpha_j} A_j$ and $B = [B_1, \ldots, B_r] \in L(Y, X)$. From Proposition 2.3(i) and the positive homogeneity of $\lambda_{\min}$ it follows that for $y \in Y \setminus \{0\}$

$$\begin{aligned} v_{A,\alpha}(y) &= \min_{j=1,\ldots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j \|y\|} = \frac{1}{\|y\|} \min_{j=1,\ldots,r} \lambda^j_{\min}(B_j y) \\ &= \frac{1}{\|y\|} \lambda_{\min}(By) = \frac{1}{\|y\|} \max\{t : By - te \in K\}. \end{aligned}$$

Then, by taking maxima on both sides above,

$$\overline{v}_{A,\alpha} = \max_{y \neq 0} v_{A,\alpha}(y) = \max_{\|y\|=1} \max\{t : By - te \in K\}.$$

Since $\overline{v}_{A,\alpha} > 0$ we may rewrite the above as a maximum over a convex set

$$\overline{v}_{A,\alpha} = \max_{\substack{By - te \in K \\ \|y\| \leq 1}} t. \tag{3.3}$$

Consider the Lagrangian dual (see [4]) of the right-hand side of (3.3):

$$\begin{aligned} \min_{x \in K^*} \max_{\substack{\|y\| \leq 1 \\ t \in \mathbb{R}}} t + \langle x, By - te\rangle &= \min_{x \in K^*} \max_{\substack{\|y\| \leq 1 \\ t \in \mathbb{R}}} t(1 - \langle x, e\rangle) + \langle x, By\rangle \\ &= \min_{\substack{x \in K^* \\ \langle x, e\rangle = 1}} \max_{\|y\| \leq 1} \langle B^* x, y\rangle \\ &= \min_{\substack{x \in K^* \\ \langle x, e\rangle = 1}} \|B^* x\|^*. \end{aligned} \tag{3.4}$$

Since both (3.3) and (3.4) are convex programs and satisfy the Slater condition, by [4, Thm. 4.3.7], they attain the same optimal value $\overline{v}_{A,\alpha}$. Hence there exists $\overline{x} \in K^*$ such that $\|B^*\overline{x}\|^* = \overline{v}_{A,\alpha}$ and $\langle \overline{x}, e\rangle = 1$. Let $\widetilde{A}_j = A_j - \alpha_j \langle B_j^* \overline{x}_j, \cdot\rangle e_j = A_j - \langle A_j^* \overline{x}_j, \cdot\rangle e_j$. We claim that $\widetilde{A} \notin \mathcal{D}$. Indeed, otherwise, there would exist $y \in Y$ and $\epsilon > 0$ such that $\widetilde{A}y - \epsilon e \in K$ and, therefore,

$$\begin{aligned} 0 &\leq \langle \overline{x}, \widetilde{A}y - \epsilon e\rangle \qquad (\text{because } \overline{x} \in K^*) \\ &= \langle \overline{x}, Ay - (\langle A^*\overline{x}, y\rangle + \epsilon)e\rangle \\ &= -\epsilon \qquad (\text{because } \langle \overline{x}, e\rangle = 1) \\ &< 0, \end{aligned}$$

which is a contradiction. Hence $\widetilde{A} \notin \mathcal{D}$. To finish, observe that

$$\frac{\|\widetilde{A}_j - A_j\|}{\alpha_j} = \|\langle B_j^* \overline{x}_j, \cdot\rangle e_j\| = \|B_j^* \overline{x}_j\|^* \leq \|B^* \overline{x}\|^* = \overline{v}_{A,\alpha}. \qquad \square$$

We next prove Theorem 1.2. We will need the following result.

LEMMA 3.3. *Assume that $A \notin \Sigma$. If the system*

$$A_N y \in \partial K_N, \quad A_B y \in \mathsf{int}(K_B)$$

has a nontrivial solution, then so does the system

$$A_N y \in \mathsf{int}(K_N), \quad A_B y \in \mathsf{int}(K_B).$$

Proof. Let $\mathbf{1} = (1, 1, \ldots, 1) \in \mathbb{R}^d$. By hypothesis, $v_{A,\mathbf{1}}(y) = 0$ and so $\overline{v}_{A,\mathbf{1}} \geq 0$. Since $A \notin \Sigma$, $\overline{v}_{A,\mathbf{1}} > 0$, and so there is $y' \neq 0$ such that $v_{A,\mathbf{1}}(y') > 0$. But this implies that $A_N y' \in \mathsf{int}(K_N)$ and $A_B y' \in \mathsf{int}(K_B)$). ∎

Proof of Theorem 1.2. We first show that

$$\{y \neq 0 \mid A_N y \in K_N\} = \emptyset \iff \{\widetilde{A} \in \Sigma \mid \widetilde{A}_N = A_N\} = \emptyset.$$

This will show that the left-hand side in (1.10) is $+\infty$ if and only if so is the right-hand side.

For the only if direction, assume that there exists $\widetilde{A}_B$ such that $\mathscr{A} = (\widetilde{A}_B, A_N) \in \Sigma$. The latter implies that $\overline{v}_{\mathscr{A},\mathbf{1}} = 0$. Hence, there exists $\overline{y} \in S_Y := \{y \in Y \mid \|y\| = 1\}$ such that $\min_{j=1,\ldots,r} \lambda^j_{\min}(\mathscr{A}_j \overline{y}) = 0$ and, therefore, such that $\lambda^j_{\min}(\mathscr{A}_j \overline{y}) \geq 0$ for $j = 1, \ldots, r$. But this implies that $A_N \overline{y} \in K_N$.

For the if direction, assume that there exists $\overline{y} \neq 0$ such that $A_N \overline{y} \in K_N$. Let $\mathcal{A} = (0, A_N)$. Then, for all $y \neq 0$, and since $0y = 0 \in \partial K_B$,

$$v_{\mathcal{A},\mathbf{1}}(y) = \min_{j=1,\ldots,r} \lambda^j_{\min}(\mathcal{A}_j y) \leq 0.$$

This implies that $\overline{v}_{\mathcal{A},\mathbf{1}} \leq 0$. But $v_{\mathcal{A},\mathbf{1}}(\overline{y}) = 0$ since $A_N \overline{y} \in K_N$. Therefore $\overline{v}_{\mathcal{A},\mathbf{1}} = 0$, which implies that $\mathcal{A} \in \Sigma$.

We now assume that the sets above are nonempty and take limits when $\alpha_N \to 0$. We will show that both the left- and right-hand sides of (1.9) tend to the corresponding sides in (1.10) when $\alpha_N \to 0$. Equation (1.10) will therefore hold since Theorem 1.1 does.

Recall that the left-hand side in the equality of Theorem 1.1 is

$$\left| \max_{y \in S_Y} \min_{j=1,\ldots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} \right|.$$

For any $y \in S_Y$ such that $A_N y \in \mathsf{int}(K_N)$, we have

$$\begin{aligned} & \forall j \in N \ \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} > 0 \\ \implies & \forall j \in N \ \lim_{\alpha_j \to 0} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} = +\infty \\ \implies & \lim_{\alpha_N \to 0} \min_{j=1,\ldots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} = \min_{j \in B} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j}. \end{aligned} \tag{3.5}$$

On the other hand, for any $y \in S_Y$ such that $A_N y \notin K_N$,

$$\lim_{\alpha_N \to 0} \min_{j=1,\ldots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} = -\infty. \tag{3.6}$$

Finally, for any $y \in S_Y$ such that $A_N y \in \partial K_N$, we have

$$\lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} = \begin{cases} 0 & \text{if } A_B y \in \mathsf{int}(K_B), \\ \min_{j \in B} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} & \text{otherwise.} \end{cases} \tag{3.7}$$

By taking the maximum over $y \in S_Y$ on the equalities (3.5), (3.6), and (3.7) and using Lemma 3.3, it follows that

$$\max_{y \in S_Y} \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} = \max_{\substack{y \in S_Y \\ A_N y \in K_N}} \min_{j \in B} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j}.$$

Hence to show that the left-hand side in (1.9) tends to the left-hand side in (1.10) when $\alpha_N \to 0$, we need to show that

$$\max_{y \in S_Y} \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} = \lim_{\alpha_N \to 0} \max_{y \in S_Y} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j}. \tag{3.8}$$

If $\{y \neq 0 \mid A_N y \in K_N\} = \emptyset$, then from (3.6) if follows that both sides of (3.8) are $-\infty$. Assume that $\{y \neq 0 \mid A_N y \in K_N\} \neq \emptyset$. From Lemma 3.3 and (3.5) it follows that both sides of (3.8) are finite. Let $\epsilon > 0$ be given. By Lemma 3.3, (3.5), (3.6), and (3.7) there exists $y_\epsilon \in S_Y$ such that $A_N y_\epsilon \in \mathsf{int}(K_N)$ and

$$\max_{y \in S_Y} \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} - \epsilon < \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y_\epsilon)}{\alpha_j}.$$

Thus

$$\begin{aligned} \max_{y \in S_Y} \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} - \epsilon &< \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y_\epsilon)}{\alpha_j} \\ &\leq \lim_{\alpha_N \to 0} \max_{y \in S_Y} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j}. \end{aligned}$$

This shows that the left-hand side in (3.8) is smaller than or equal to the right-hand side. For the reverse inequality let $\epsilon > 0$ be given. By Lemma 3.3, (3.5), (3.6), and (3.7) there exists $y_\epsilon \in S_Y$ such that $A_N y_\epsilon \in \mathsf{int}(K_N)$ and

$$\lim_{\alpha_N \to 0} \max_{y \in S_Y} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} - \epsilon < \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y_\epsilon)}{\alpha_j}.$$

Hence (3.5) yields

$$\begin{aligned} \lim_{\alpha_N \to 0} \max_{y \in S_Y} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j} - \epsilon &< \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y_\epsilon)}{\alpha_j} \\ &= \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y_\epsilon)}{\alpha_j} \\ &\leq \max_{y \in S_Y} \lim_{\alpha_N \to 0} \min_{j=1,\dots,r} \frac{\lambda^j_{\min}(A_j y)}{\alpha_j}. \end{aligned}$$

Therefore the right-hand side of (3.8) is also smaller than or equal to the left-hand side.

Next, we show that the right-hand side of (1.9), namely,

$$\min_{\widetilde{A}\in\Sigma}\max_{j=1,\dots,r}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j},$$

tends to the right-hand side of (1.10) when $\alpha_N\to 0$. Take $\widetilde{A}\in\Sigma$. Then

$$\begin{aligned}\widetilde{A}_N\neq A_N &\Longrightarrow \exists j\in N\ \|A_j-\widetilde{A}_j\|\neq 0\\ &\Longrightarrow \exists j\in N\ \lim_{\alpha_j\to 0}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j}=+\infty\\ &\Longrightarrow \lim_{\alpha_N\to 0}\max_{j=1,\dots,r}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j}=+\infty.\end{aligned}$$

This implies that

$$\lim_{\alpha_N\to 0}\min_{\widetilde{A}\in\Sigma}\max_{j=1,\dots,r}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j}=\lim_{\alpha_N\to 0}\min_{\substack{\widetilde{A}\in\Sigma\\ \widetilde{A}_N=A_N}}\max_{j=1,\dots,r}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j}. \tag{3.9}$$

But if $\widetilde{A}_N=A_N$, then $\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j}=0$ for all $j\in N$. Therefore,

$$\lim_{\alpha_N\to 0}\min_{\substack{\widetilde{A}\in\Sigma\\ \widetilde{A}_N=A_N}}\max_{j=1,\dots,r}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j}=\min_{\substack{\widetilde{A}\in\Sigma\\ \widetilde{A}_N=A_N}}\max_{j\in B}\frac{\|A_j-\widetilde{A}_j\|}{\alpha_j},$$

and the claimed limit follows. ∎

A TRUST REGION SPECTRAL BUNDLE METHOD FOR NONCONVEX EIGENVALUE OPTIMIZATION*

P. APKARIAN†, D. NOLL‡, AND O. PROT‡

Abstract. We present a nonsmooth optimization technique for nonconvex maximum eigenvalue functions and for nonsmooth functions which are infinite maxima of eigenvalue functions. We prove global convergence of our method in the sense that for an arbitrary starting point, every accumulation point of the sequence of iterates is critical. The method is tested on several problems in feedback control synthesis.

Key words. eigenvalue optimization, trust region method, proximity control, spectral bundle, output feedback control, H_∞-synthesis

1. Introduction.

Eigenvalue optimization has a wide spectrum of applications in physics, engineering, statistics, and finance. This spectrum includes composite materials [15], quantum computational chemistry [60], optimal system design [47, 8], shape optimization [17], pole placement in linear system theory, robotics [44], relaxations of combinatorial optimization problems [26, 39], experimental design [55, 58], and much more. Many of these problems are nonconvex, but even in the realm of convexity, eigenvalue optimization has a prominent place. Semidefinite programming (SDP) is an important class of convex programs, which may be solved by way of eigenvalue optimization [48].

The idea of solving large semidefinite programs via eigenvalue optimization can be traced back to [16, 25, 41]. It results from the insight that interior-point methods are not the appropriate choice when problems are sizable. Due to its importance in practice, eigenvalue optimization has been intensively studied since the 1980s. Early contributions are Wolfe [59], Cullum, Donath, and Wolfe [16], Polak and Wardi [54], and Fletcher [19]. Starting in the late 1980s, Overton contributed a series of papers ([49, 50], and [51] with Womersley), where in particular Newton-type methods are discussed. Oustry [48] presents a synthesis of first and second order methods suited for convex maximum eigenvalue functions.

Here our interest is in nonconvex eigenvalue programs, which arise frequently in automatic control applications and especially in controller synthesis. In particular, solving bilinear matrix inequalities (BMIs) is a prominent application, which may be addressed via nonconvex eigenvalue optimization. In [45, 46] we have shown how to adapt the approach of [41, 48] to handle nonconvex situations. Applications and extensions of these ideas are presented in [4, 1, 57, 10, 5, 6].

The goal of the present paper is twofold. In the first part we investigate how to expand on the idea of Helmberg and Rendl's spectral bundle method [25] in order to deal with nonconvex eigenvalue programs. Nonconvexity requires a new approximation technique, complementing the convex mechanism used in [25]. We achieve our goal by a trust region approach or, what is equivalent, by a dual approach using proximity control. This method has antecedents in classical bundling, such as in Lemaréchal [36, 37, 38], Lemaréchal, Nemirovskii, and Nesterov [40], and Kiwiel [31, 32, 33]. Extensions of the convex case to include bound constraints are given in [23].

In the second part we extend our method to address more general classes of functions which are infinite suprema of maximum eigenvalue functions. This includes optimization of the H_∞-norm, an important application in feedback control synthesis. Optimization of the H_∞-norm has been pioneered by Polak and coworkers. See, for instance, [42, 43, 52], and the references given there. Our own approach to optimizing the H_∞-norm is developed in [4, 1, 5].

The structure of the paper is as follows. After some preparations in sections 2–5, the algorithm is presented in section 6. Convergence analysis follows in sections 7 and 8. The semi-infinite case, which includes optimization of the H_∞-norm, is presented in section 9. While the main objective of this work is the convergence analysis of our method, we have added several numerical tests for eigenvalue programs in section 10 to validate the algorithm. Numerical tests for the H_∞-norm and for related problems are presented in [7].

Notation. Our terminology follows [28] and [14]. We let $\|\cdot\|$ denote the Euclidean norm on the space $\mathbb{R}^n$ equipped with the scalar product $x^\top y$, while the space $\mathbb{S}^m$ of $m \times m$ symmetric matrices is equipped with the scalar product $X \bullet Y = \mathrm{Tr}(XY)$. The corresponding matrix norm is also denoted by $\|\cdot\|$. For $X \in \mathbb{S}^m$, $X \preceq 0$ means X is negative semidefinite.

2. Elements from nonsmooth analysis. Recall that the maximum eigenvalue function $\lambda_1 : \mathbb{S}^m \to \mathbb{R}$ is convex but generally nonsmooth and defined on the space $\mathbb{S}^m$ of $m \times m$ symmetric or Hermitian matrices. We consider composite functions of the form $f = \lambda_1 \circ F$, where $F : \mathbb{R}^n \to \mathbb{S}^m$ is a class C^2 operator. Notice that f is nonsmooth, due to nonsmoothness of λ_1, and nonconvex unless F is an affine operator. The case where F is affine and therefore f convex has been studied by many authors [16, 25, 41]. Here our interest is focused on handling nonconvex f.

Notice that as a composite function, f has a favorable structure. In particular, the Clarke subdifferential [14] is given by the chain rule

$$\partial f(x) = F'(x)^\star \partial\lambda_1\left(F(x)\right),$$

where $\partial\lambda_1(X)$ is the usual subdifferential of convex analysis at $X \in \mathbb{S}^m$, and where $F'(x)$ is the derivative of F, $F'(x)^\star$ its adjoint, mapping $\mathbb{S}^m$ back into $\mathbb{R}^n$. Recall that λ_1 is itself highly structured, as it is the support function of the convex compact set

$$\mathcal{G} = \{G \in \mathbb{S}^m : G \succeq 0, \mathrm{Tr}(G) = 1\}.$$

That means $\lambda_1(X) = \max\{G \bullet X : G \in \mathcal{G}\}$, and therefore (cf. [28, I, sect. 5.1, p. 275])

$$\partial\lambda_1(X) = \{G \in \mathcal{G} : G \bullet X = \lambda_1(X)\}.$$

3. First local model. Consider the minimization of $f = \lambda_1 \circ F$ over $\mathbb{R}^n$ and suppose $x \in \mathbb{R}^n$ is the current iterate. In order to generate a descent step from x to y, we may consider the following convex model of f around x:

$$\phi(y;x) = \lambda_1 \left(F(x) + F'(x)(y-x)\right), \tag{1}$$

where $y \mapsto F(x) + F'(x)(y-x)$ is the first order affine approximation of $F(y)$ in a neighborhood of x. Clearly $\phi(x;x) = f(x)$, and $f = \phi$ in those cases where F itself is affine (see, e.g., [16, 48, 25]). Taylor's theorem suggests that $\phi(y;x) \approx f(y)$ for y sufficiently close to x. This observation is made precise by the following.

PROPOSITION 1. *For every bounded set $B \subset \mathbb{R}^n$ there exists a constant $L > 0$ such that*

$$|f(y) - \phi(y;x)| \leq L\|y-x\|^2 \tag{2}$$

for all $x, y \in B$.

Proof. Notice that for any given matrices $A, E \in \mathbb{S}^m$, the estimate

$$\lambda_m(E) \leq \lambda_1(A+E) - \lambda_1(A) \leq \lambda_1(E)$$

is satisfied. This is also known as Weyl's theorem. Now as F is of class C^2, expanding at $x \in B$ gives $F(y) = F(x) + F'(x)(y-x) + R(y;x)$ with $\|R(y;x)\| \leq L\|y-x\|^2$ for some constant $L > 0$ and all $x, y \in B$. Using $X = F(x)$, $D = F'(x)(y-x)$, we have $f(y) = \lambda_1 \left(X + D + R(y;x)\right)$. We now apply Weyl's theorem with $A = X + D$, $E = R(y;x)$, which gives

$$\begin{aligned} |f(y) - \phi(y;x)| &= |\lambda_1(X+D) - \lambda_1(X+D+R(y;x))| \\ &\leq \max\left\{|\lambda_1\left(R(y;x)\right)|, |\lambda_m\left(R(y;x)|\right\}\right. \\ &\leq \|R(y;x)\| \leq L\|y-x\|^2 \end{aligned}$$

for all $x, y \in B$. That proves the claim. ∎

4. Second local model. Along with (1) we consider a second local model of f in a neighborhood of the current iterate x, which we update recursively. Notice that

$$\phi(y;x) = \max\left\{G \bullet \left[F(x) + F'(x)(y-x)\right] : G \in \mathcal{G}\right\},$$

where $\mathcal{G} = \{G \in \mathbb{S}^m : \mathrm{Tr}(G) = 1, G \succeq 0\}$ as before. This suggests the following approximation $\phi_k(y;x)$ of f, where $\mathcal{G}$ is replaced by a smaller and easier-to-compute subset $\mathcal{G}_k \subset \mathcal{G}$. We will generate a sequence $\mathcal{G}_k \subset \mathcal{G}$ of such approximations and let

$$\phi_k(y;x) = \max\left\{G \bullet \left[F(x) + F'(x)(y-x)\right] : G \in \mathcal{G}_k\right\}. \tag{3}$$

Clearly $\phi_k \leq \phi$. The idea is that we generate descent steps for the $\phi_k(\cdot;x)$, which will ultimately lead to descent in f at x, as the agreement between f and ϕ_k improves at each step k. The minimal requirement for $\mathcal{G}_k$ is the following and is obvious.

LEMMA 2. *Suppose $\mathcal{G}_k$ contains a subgradient of the form $G = ee^\top \in \mathcal{G}$, where e is a normalized eigenvector associated with $\lambda_1\left(F(x)\right)$. Then $\phi_k(x;x) = f(x)$.*

5. Proximity control. Let x be our current iterate. In order to generate a new trial step, we use the current model $\phi_k(\cdot;x)$ and compute the solution y^{k+1} of the unconstrained optimization program,

$$\text{minimize} \quad \phi_k(y;x) + \tfrac{\tau_k}{2}\|y-x\|^2, \quad y \in \mathbb{R}^n, \tag{4}$$

where $\tau_k \geq 0$ is the proximity parameter, and where the term $\frac{\tau_k}{2}\|y-x\|^2$ is referred

to as the proximity control. It is well known (see, e.g., [28, II, Prop. 2.2.3, p. 291]) that (4) is equivalent to a trust region program of the form

$$\begin{aligned} &\text{minimize} && \phi_k(y;x), \quad y \in \mathbb{R}^n \\ &\text{subject to} && \|y-x\| \le t_k, \end{aligned} \tag{5}$$

where $t_k > 0$ is the trust region radius. Indeed, minima of (5) and minima of (4) are in one-to-one correspondence in the following sense: If y^{k+1} is a minimum of (4) for fixed $\tau_k > 0$, then y^{k+1} also solves (5) with $t_k := \|y^{k+1} - x\|$ and associated multiplier $\tau_k > 0$. Conversely, if y^{k+1} solves (5) and if the associated multiplier τ_k is strictly positive, then y^{k+1} solves (4) with that proximity parameter $\tau_k > 0$. The case $\tau_k = 0$ in (4) obviously corresponds to those cases in (5) where the trust region constraint is inactive.

With the models ϕ and ϕ_k we introduce two levels of approximation of f, so it is not surprising that two mechanisms to adjust the degree of exactness are applied. First, in order to control the agreement between f and ϕ, we need to adjust t_k at each step, which is done indirectly via the management of τ_k. If the agreement between f and ϕ is good, we increase t_k, which corresponds to decreasing τ_k, while we have to reduce t_k when agreement is bad, achieved indirectly by increasing τ_k. Second, we update $\mathcal{G}_k$ into $\mathcal{G}_{k+1}$ after each trial y^{k+1} in order to drive ϕ_k closer to ϕ, and thereby also closer to f. We use the standard terminology in nonsmooth optimization. If the solution y^{k+1} of (4) is not used as the next iterate, we call it a null step. If y^{k+1} is accepted and becomes the next iterate x^+, we speak of a serious step.

In order to test the quality of the trial steps y^{k+1}, we use the quotient

$$\rho_k = \frac{f(x) - f(y^{k+1})}{f(x) - \phi_k(y^{k+1};x)}. \tag{6}$$

Fixing constants $0 < \gamma < \Gamma < 1$, we say that f and $\phi_k(\cdot;x)$ are in good agreement when $\rho_k > \Gamma$, and we say that the agreement is bad if $\rho_k < \gamma$. The bad case includes, in particular, situations where $\rho_k \le 0$. Since always $f(x) - \phi_k(y^{k+1};x) > 0$, unless $0 \in \partial f(x)$, we deduce that $\rho_k \le 0$ corresponds to cases where $f(x) - f(y^{k+1}) \le 0$, that is, where the proposed step y^{k+1} is not even a descent step for f. In our algorithm we use the following rule: y^{k+1} is accepted as soon as $\rho_k \ge \gamma$, i.e., as soon as the step is not bad. The question is then what we shall do when agreement between f and ϕ_k is bad, i.e., when $\rho_k < \gamma$.

Here we compute a second test parameter,

$$\widetilde{\rho}_k := \frac{f(x) - \phi(y^{k+1};x)}{f(x) - \phi_k(y^{k+1};x)},$$

and we compare it to a second control parameter $\widetilde{\gamma}$, where $\gamma < \widetilde{\gamma} < \frac{1}{2}$. We then have two possibilities. If $\rho_k < \gamma$ and also $\widetilde{\rho}_k < \widetilde{\gamma}$, then we do not change τ_k, but improve the approximation $\mathcal{G}_{k+1}$ so that ϕ_{k+1} gets closer to ϕ. On the other hand, if $\rho_k < \gamma$, but $\widetilde{\rho}_k \ge \widetilde{\gamma}$, then ϕ and f are not in good agreement, while ϕ_k is already close to ϕ. Driving ϕ_k even closer to ϕ in that case alone will therefore not improve the situation. Here we have to decrease the trust region radius t_k, or what comes down to the same, increase the proximity control parameter τ_k. While doing this, we still update $\mathcal{G}_k$ to a better $\mathcal{G}_{k+1}$, i.e., we still let ϕ_k approach ϕ, so this process is always applied.

6. Aggregate subgradients. As our convergence analysis will show, the approximations $\mathcal{G}_k \subset \mathcal{G}$ need only satisfy the following three conditions:

(G_1) $G_0 = e_0 e_0^\top \in \mathcal{G}_k$ for some normalized eigenvector e_0 associated with $\lambda_1\,(F(x))$.

(G_2) $G_{k+1} = e_{k+1}e_{k+1}^\top \in \mathcal{G}_{k+1}$ for some normalized eigenvector e_{k+1} associated with $\lambda_1\big(F(x) + F'(x)(y^{k+1} - x)\big)$.

(G_3) $G_k^* \in \mathcal{G}_{k+1}$ for some of the $G_k^* \in \mathcal{G}_k$, where the maximum $\phi_k(y^{k+1}; x)$ is attained, and which satisfies $0 = F'(x)^\star G_k^* + \tau_k(y^{k+1} - x)$.

Below we will discuss practical choices of the sets $\mathcal{G}_k$, combining ideas from [25], [48], [24], and [45]. We let $\mathcal{G}_k$ consist of sets of the form

$$\alpha_k \overline{G}_k + Q_k Y_k Q_k^\top, \tag{7}$$

where $Y_k \in \mathbb{S}^{r_k}$ has $Y_k \succeq 0$, $\alpha_k + \mathrm{Tr}(Y_k) = 1$, $0 \le \alpha_k \le 1$, where Q_k is an $m \times r_k$ matrix whose $r_k \ge 1$ columns form an orthogonal basis of an invariant subspace of $F(x) + F'(x)(y^{k+1} - x)$, and where $\overline{G}_k \in \mathcal{G}$ is the aggregate subgradient. We assume that at least one normalized eigenvector e_k associated with the maximum eigenvalue $\lambda_1\big(F(x) + F'(x)(y^k - x)\big)$ is in the span of the columns of Q_k, and moreover, that e_0 is in the span of the columns of Q_k at all times. The idea is to build the new set $\mathcal{G}_{k+1}$ along the same lines, using an updating strategy, which we now explain.

Let y^{k+1} be the solution of program (4), obtained with the help of $\mathcal{G}_k$, and suppose it is a null step. The necessary optimality condition gives $0 \in \partial\phi_k(y^{k+1}; x) + \tau_k(y^{k+1} - x)$. Due to the structure of ϕ_k and (7), this means there exist $G_k^* \in \mathcal{G}_k$ such that

$$0 = F'(x)^\star G_k^* + \tau_k(y^{k+1} - x), \quad G_k^* = \alpha_k^* \overline{G}_k + Q_k Y_k^* Q_k^\top, \tag{8}$$

where $0 \le \alpha_k^* \le 1$, $Y_k^* \succeq 0$, and $\alpha_k^* + \mathrm{Tr}(Y_k^*) = 1$. Now the simplest method is to let

$$\overline{G}_{k+1} = \alpha_k^* \overline{G}_k + Q_k Y_k^* Q_k^\top, \tag{9}$$

the new aggregate subgradient. Helmberg and Rendl [25] use a refinement of (9), which is suited for large problem size: Let $Y_k^* = PDP^\top$ be a spectral decomposition of the $r_k \times r_k$ matrix Y_k^*. Decompose $P = [P_1 P_2]$ with corresponding spectra D_1 and D_2 so that P_1 contains as columns those eigenvectors associated with the large eigenvalues of Y_k^*, and P_2 are the remaining columns. Now put

$$\overline{G}_{k+1} = \big(\alpha_k^* \overline{G}_k + Q_k P_2 D_2 P_2^\top Q_k^\top\big) \,/\, (\alpha_k^* + \mathrm{Tr}(D_2))\,, \tag{10}$$

the new aggregate subgradient, which is an element of $\mathcal{G}$. In this way only the minor part of Y_k^* is kept in the aggregate subgradient. The dominant part of Y_k^* is retained in the next eigenbasis by letting $Q_k P_1$ be part of Q_{k+1}. Moreover, in view of axiom (G_2), one eigenvector e_{k+1} of the maximum eigenvalue of $F(x) + F'(x)(y^{k+1} - x)$ is computed and included in Q_{k+1}. In order to guarantee axiom (G_1), we also keep at least one normalized eigenvector e_0 associated with the maximum eigenvalue of $F(x)$ in Q_{k+1}.

Altogether, $\mathcal{G}_{k+1}$ consists of all $\alpha\overline{G}_{k+1} + Q_{k+1}Y_{k+1}Q_{k+1}^\top$, where $0 \le \alpha \le 1$, $Y_{k+1} \succeq 0$, and $\alpha + \mathrm{Tr}(Y_{k+1}) = 1$, and where Q_{k+1} has the properties above. For this construction we have the following.

LEMMA 3. *The sets $\mathcal{G}_k$ so defined satisfy the rules (G_1)–(G_3). In particular, $\phi_k(x; x) = f(x)$, $\phi_{k+1}(y^{k+1}; x) = \phi(y^{k+1}; x)$, $\phi_{k+1}(y^{k+1}; x) \ge \phi_k(y^{k+1}; x)$, and condition (8) hold for every k.*

Remark. In a traditional bundle method we would refer to $\overline{g}_k = F'(x)^\star \overline{G}_k$ as the aggregate subgradient. Here we use the term aggregate for both $\overline{g}_k$ and $\overline{G}_k$ because

there is no risk of ambiguity. But are both elements really needed? The authors of [25] point out that storing $\bar{g}_k$ is cheaper than storing $\overline{G}_k$, so naturally they work in g-space and not in G-space.

Now observe an important difference of our present case with the convex case in [25], where $F'(x)^* = A^*$ is independent of x. Since our $F'(x)^*$ depends on x, as soon as a serious step $x \to x^+$ is taken, $\bar{g}_k = F'(x)^*\overline{G}_k$ is no longer useful at x^+, because it is no longer a subgradient of f at x^+. However, $\overline{G}_k$ is still useful. It suffices to replace $\bar{g}_k$ by $\bar{g}_k^+ := F'(x^+)^*\overline{G}_k$, which is a subgradient for f at x^+. So if we want to "recycle" old aggregates in the next serious loop, we have to store $\overline{G}_k$ and not $\bar{g}_k$. On the other hand, if we are happy to keep aggregates only within one single inner loop, then we do not need $\overline{G}_k$ and our case is similar to [25].

Remark. Conditions (G_1)–(G_3) leave a lot of freedom for the choice of the bases Q_k. In [24] Helmberg and Oustry investigate the convex case and discuss ways to combine their two approaches [25] and [48] into a unified method. An alternative approach is Polak and Wardi [54]. For nonconvex eigenvalue functions we have proposed in [45, 46] an extension of Oustry's approach.

Spectral bundle algorithm for $\min_{x\in\mathbb{R}^n} f(x)$.

Parameters: $0 < \gamma < \widetilde{\gamma} < \Gamma < 1$.

0. **Initialize outer loop.** Find initial iterate x and compute $f(x)$.
1. **Outer loop.** Stop if $0 \in \partial f(x)$ at current outer iterate x. Otherwise goto inner loop.
2. **Initialize inner loop.** Let $\mathcal{G}_1 \subset \partial\lambda_1(F(x))$, $\overline{G}_1 = \frac{1}{m} I_m$, put inner loop counter $k = 1$, and choose $\tau_1 > 0$. If old value for τ from previous sweep is memorized, use it to initialize τ_1.
3. **Tangent program.** At counter k with given $\tau_k > 0$ and $\mathcal{G}_k$ solve
$$\min_{y\in\mathbb{R}^n} \phi_k(y;x) + \frac{\tau_k}{2}\|y - x\|^2.$$
Solution is y^{k+1}. Find $G_k^* \in \mathcal{G}_k$ where (3) at y^{k+1} is attained. Write $G_k^* = \alpha_k^*\overline{G}_k + Q_k Y_k Q_k^\top$ according to (7).
4. **Acceptance test.** Compute $f(y_{k+1})$ and check whether
$$\rho_k = \frac{f(x) - f(y^{k+1})}{f(x) - \phi_k(y^{k+1};x)} \geq \gamma.$$
If this is the case, put $x^+ = y^{k+1}$ (serious step). Compute new memory element τ^+ as
$$\tau^+ = \begin{cases} \dfrac{\tau_k}{2} & \text{if } \rho_k > \Gamma, \\ \tau_k & \text{else} \end{cases}$$
Then go back to step 1 to commence a new sweep of outer loop. On the other hand, if $\rho_k < \gamma$, then continue inner loop with step 5.
5. **Agreement test.** Compute $\phi(y^{k+1};x)$ and control parameter
$$\widetilde{\rho}_k = \frac{f(x) - \phi(y^{k+1};x)}{f(x) - \phi_k(y^{k+1};x)}.$$
Put
$$\tau_{k+1} = \begin{cases} \tau_k & \text{if } \rho_k < \gamma \text{ and } \widetilde{\rho}_k < \widetilde{\gamma}, \\ 2\tau_k & \text{if } \rho_k < \gamma \text{ and } \widetilde{\rho}_k \geq \widetilde{\gamma}. \end{cases}$$
6. **Aggregate subgradient.** Compute new set $\mathcal{G}_{k+1}$ according to (7), with (G_1)–(G_3) satisfied. New aggregate subgradient is $\overline{G}_{k+1} = G_k^*$.
7. **Inner loop.** Increase counter $k \to k+1$ and go back to step 3.

7. Convergence analysis of inner loop. We have to show that the inner loop is finite, that is, finds a trial point y^{k+1} accepted in step 4 after a finite number k of steps. We prove this by showing that if the inner loop turns forever, that is, $\rho_k < \gamma$ for all k, then $0 \in \partial f(x)$. (Since the inner loop is not entered when $0 \in \partial f(x)$, this is an argument by contradiction.) There are two subcases to be discussed, depending on the decision in step 5. These will be addressed in Lemmas 4 and 5.

Our first concern is when $\rho_k < \gamma$ but $\widetilde{\rho}_k \geq \widetilde{\gamma}$. This is indeed the situation where we are far from the convex case. Namely, $\widetilde{\rho}_k \geq \widetilde{\gamma}$ means that ϕ_k is in good agreement with ϕ, but unfortunately $\rho_k < \gamma$ says that ϕ is not a good model of f, which is usually due to the fact that f is nonconvex in a neighborhood of the current x. In consequence, ϕ_k cannot be expected to be a good model of f either. This is addressed in step 5 of the algorithm by increasing the proximity parameter τ_k, which as we know is equivalent to reducing the trust region radius. This is the only way to improve the agreement between ϕ and f.

LEMMA 4. *Suppose the algorithm generates an infinite sequence of trial steps y^{k+1} such that always $\rho_k < \gamma$. Then $\widetilde{\rho}_k < \widetilde{\gamma}$ for some k_0 and all $k \geq k_0$.*

Proof. (i) Assume on the contrary that $\rho_k < \gamma$ for all k, but at the same time $\widetilde{\rho}_k \geq \widetilde{\gamma}$ for infinitely many $k \in \mathbb{N}$. Then according to the update rule in step 5 of the algorithm, the sequence τ_k tends to $+\infty$. As a consequence of the necessary optimality condition we have $0 \in \partial\phi_k(y^{k+1}; x) + \tau_k(y^{k+1} - x)$. Now observe that due to the special form (7), the subgradients of all functions $\phi_k(\cdot; x)$ are uniformly bounded by $\|F'(x)^\star\|$. Given that $\tau_k \to \infty$, we then must have $y^{k+1} \to x$. Using $\tau_k(x - y^{k+1}) \in \partial\phi_k(y^{k+1}; x)$ calls for the subgradient inequality, which gives

$$\tau_k \left(x - y^{k+1}\right)^\top \left(x - y^{k+1}\right) \leq \phi_k(x; x) - \phi_k(y^{k+1}; x) = f(x) - \phi_k(y^{k+1}; x),$$

the latter by Lemma 3. In other words,

$$\frac{\tau_k \|x - y^{k+1}\|^2}{f(x) - \phi_k(y^{k+1}; x)} \leq 1. \tag{11}$$

(ii) Now we expand the test parameters as follows:

$$\begin{aligned}
\widetilde{\rho}_k &= \rho_k + \frac{f(y^{k+1}) - \phi(y^{k+1}; x)}{f(x) - \phi_k(y^{k+1}; x)} \\
&\leq \rho_k + \frac{L\|x - y^{k+1}\|^2}{f(x) - \phi_k(y^{k+1}; x)} \qquad \text{(using Proposition 1)} \\
&\leq \rho_k + \frac{L}{\tau_k} \qquad \text{(using (11))}.
\end{aligned}$$

Since $\tau_k \to \infty$, we deduce $\limsup_{k\to\infty} \widetilde{\rho}_k \leq \limsup_{k\to\infty} \rho_k \leq \gamma$, contradicting $\widetilde{\rho}_k \geq \widetilde{\gamma} > \gamma$ for infinitely many k. ∎

Remark. Notice that the proof of Lemma 4 uses Lemma 3, which in turn exploits axiom (G_1). Axioms (G_2) and (G_3) will be needed in the next lemma.

As a consequence of Lemma 4 we see that the algorithm, when faced with the bad case $\rho_k < \gamma$, will continue to increase τ_k, until eventually $\widetilde{\rho}_k < \widetilde{\gamma}$, too. From some index k_0 onwards, we will then be in the first case in step 5 of the algorithm, where the parameter τ_k is frozen, i.e., $\tau_k =: \tau$ for $k \geq k_0$. We then have no easy argument to deduce $y^{k+1} \to x$. Here, indeed, we will have to exploit properties (G_2) and (G_3) of the update rule $\mathcal{G}_k \to \mathcal{G}_{k+1}$. We follow the line of [25, Lemma 4.2].

LEMMA 5. *Let x be the current iterate and suppose the algorithm generates an infinite sequence of trial steps y^{k+1}, where $\rho_k < \gamma$ for all k while $\widetilde{\rho}_k < \widetilde{\gamma}$ for some k_0 and all $k \geq k_0$. Then $0 \in \partial f(x)$.*

Proof. (i) As we mentioned already, $\rho_k < \gamma$ and $\widetilde{\rho}_k < \gamma$ for all $k \geq k_0$ implies that in step 5 of the algorithm, $\tau_k =: \tau$ is frozen for $k \geq k_0$. A priori we therefore do not know whether $y^{k+1} \to x$, as we did in the proof of Lemma 4. This complicates the following analysis.

(ii) Let us introduce the function

$$\psi_k(y;x) = \phi_k(y;x) + \tfrac{\tau}{2}\|y-x\|^2;$$

then by its definition, y^{k+1} is the global minimum of $\psi_k(\cdot;x)$ for $k \geq k_0$. Let $G_k^* \in \mathcal{G}_k$ be the subgradient where the supremum $\phi_k(y^{k+1};x)$ is attained and which is retained in $\mathcal{G}_{k+1}$ in accordance with rule (G_3) and also with step 3 of the algorithm. That means

$$\phi_k(y^{k+1};x) = G_k^* \bullet \left[F(x) + F'(x)(y^{k+1}-x)\right], \tag{12}$$

and also

$$\psi_k(y^{k+1};x) = G_k^* \bullet \left[F(x) + F'(x)(y^{k+1}-x)\right] + \tfrac{\tau}{2}\|y^{k+1}-x\|^2. \tag{13}$$

We introduce the function

$$\psi_k^*(y;x) = G_k^* \bullet [F(x) + F'(x)(y-x)] + \tfrac{\tau}{2}\|y-x\|^2.$$

Then $\psi_k^*(y^{k+1};x) = \psi_k(y^{k+1};x)$ and

$$\psi_k^*(y;x) \leq \psi_{k+1}(y;x) \tag{14}$$

for $k \geq k_0$, because $G_k^* \in \mathcal{G}_{k+1}$. We claim that

$$\psi_k^*(y;x) = \psi_k^*(y^{k+1};x) + \tfrac{\tau}{2}\|y-y^{k+1}\|^2. \tag{15}$$

An easy way to see this is to observe that ψ_k^* is quadratic and expand it, using $\nabla\psi_k^*(y;x) = F'(x)^\star G_k^* + \tau(y-x)$ and $\nabla^2\psi_k^*(y;x) = \tau I$. Then clearly,

$$\psi_k^*(y;x) = \psi_k^*(y^{k+1};x) + \nabla\psi_k^*(y^{k+1};x)^\top(y-y^{k+1}) + \tfrac{\tau}{2}(y-y^{k+1})^\top(y-y^{k+1}).$$

Formula (15) will therefore be established as soon as we show that the first order term in this expansion vanishes. But this term is

$$\begin{aligned}
&\nabla\psi_k^*(y^{k+1};x)^\top(y-y^{k+1}) \\
&\quad = \left(F'(x)^\star G_k^*\right)^\top(y-y^{k+1}) + \tau(y^{k+1}-x)^\top(y-y^{k+1}) \\
&\quad = \tau(x-y^{k+1})^\top(y-y^{k+1}) + \tau(y^{k+1}-x)^\top(y-y^{k+1}) \quad \text{(using (8))} \\
&\quad = 0.
\end{aligned}$$

That proves formula (15).

(iii) From (ii) we have

$$\begin{aligned}
\psi_k(y^{k+1};x) &\le \psi_k^*(y^{k+1};x) + \tfrac{\tau}{2}\|y^{k+2}-y^{k+1}\|^2 \quad (\text{using } \psi_k^*(y^{k+1};x) = \psi_k(y^{k+1};x)) \\
&= \psi_k^*(y^{k+2};x) \qquad (\text{using (15)}) \\
&\le \psi_{k+1}(y^{k+2};x) \qquad (\text{using (14)}) \\
&\le \psi_{k+1}(x;x) \qquad (y^{k+2} \text{ is minimizer of } \psi_{k+1}) \qquad (16) \\
&= \phi_{k+1}(x;x) \le \phi(x;x).
\end{aligned}$$

We deduce that the sequence $\psi_k(y^{k+1};x)$ is monotonically increasing and bounded above by $\phi(x;x)$. It therefore converges to some $\psi^* \le \phi(x;x)$.

Going back to (16) with this information, we see that the term $\frac{\tau}{2}\|y^{k+2}-y^{k+1}\|^2$ is now squeezed in between two convergent terms with the same limit ψ^*, and must therefore tend to zero. Consequently, $\|y^{k+1}-x\|^2-\|y^{k+2}-x\|^2$ also tends to 0, because the sequence y^k is bounded. (Boundedness of the y^{k+1} was already used in the proof of the previous lemma and follows from the particular form (7) of the subgradients and the fact that the sequence τ_k is nondecreasing and therefore bounded away from 0.)

Recalling $\phi_k(y;x) = \psi_k(y;x) - \frac{\tau}{2}\|y-x\|^2$, we deduce, using both convergence results, that

$$\begin{aligned}
&\phi_{k+1}(y^{k+2};x) - \phi_k(y^{k+1};x) \\
&\qquad = \psi_{k+1}(y^{k+2};x) - \psi_k(y^{k+1};x) - \tfrac{\tau}{2}\|y^{k+2}-x\|^2 + \tfrac{\tau}{2}\|y^{k+1}-x\|^2 \to 0. \qquad (17)
\end{aligned}$$

(iv) Let e_{k+1} be the normalized eigenvectors of $F(x)+F'(x)(y^{k+1}-x)$ associated with λ_1, which we pick in step 5 of the algorithm and according to rule (G_2). Then $g_k = F'(x)^\star e_{k+1}e_{k+1}^\top$ is a subgradient of $\phi_{k+1}(\cdot;x)$ at y^{k+1}. Hence by the subgradient inequality

$$\phi_{k+1}(y^{k+1};x) + g_k^\top\left(y-y^{k+1}\right) \le \phi_{k+1}(y;x).$$

Since $\phi_{k+1}(y^{k+1};x) = \phi(y^{k+1};x)$ by Lemma 3, respectively, rule (G_2), we have the estimate

$$\phi(y^{k+1};x) + g_k^\top\left(y-y^{k+1}\right) \le \phi_{k+1}(y;x). \qquad (18)$$

Now observe that

$$\begin{aligned}
0 &\le \phi(y^{k+1};x) - \phi_k(y^{k+1};x) \\
&= \phi(y^{k+1};x) + g_k^\top\left(y^{k+2}-y^{k+1}\right) - \phi_k(y^{k+1};x) - g_k^\top\left(y^{k+2}-y^{k+1}\right) \\
&\le \phi_{k+1}(y^{k+2};x) - \phi_k(y^{k+1};x) + \|g_k\|\left\|y^{k+2}-y^{k+1}\right\| \qquad (\text{using (18)}),
\end{aligned}$$

and this term tends to 0 due to (17), because $y^{k+2}-y^{k+1} \to 0$, and because the sequence g_k is bounded. We deduce that $\phi(y^{k+1};x) - \phi_k(y^{k+1};x) \to 0$.

(v) We now show that $\phi_k(y^{k+1};x) \to f(x)$, and then of course also $\phi(y^{k+1};x) \to f(x)$. Assume, contrary to what is claimed, that $\limsup_{k\to\infty} f(x) - \phi_k(y^{k+1};x) =: \eta > 0$. Choose $\delta > 0$ such that $\delta < (1-\widetilde{\gamma})\eta$. It follows from part (iv) that there exists $k_1 \geq k_0$ such that

$$\phi(y^{k+1};x) - \delta \leq \phi_k(y^{k+1};x) \tag{19}$$

for all $k \geq k_1$. Using $\widetilde{\rho}_k \leq \widetilde{\gamma}$ for $k \geq k_1$ then gives

$$\begin{aligned} \widetilde{\gamma}\left(\phi_k(y^{k+1};x) - f(x)\right) &\leq \phi(y^{k+1};x) - f(x) \\ &\leq \phi_k(y^{k+1};x) + \delta - f(x), \end{aligned} \tag{20}$$

which implies $\widetilde{\gamma}\eta \geq \eta - \delta$. This contradicts the choice of δ and therefore shows $\eta = 0$.

(vi) Having shown $\phi(y^{k+1};x) \to f(x)$ and $\phi_k(y^{k+1};x) \to f(x)$, we argue that $y^{k+1} \to x$. This follows from the definition of y^{k+1}, because

$$\psi_k(y^{k+1};x) = \phi_k(y^{k+1};x) + \tfrac{\tau}{2}\|y^{k+1}-x\|^2 \leq \psi_k(x;x) = \phi_k(x;x) = f(x).$$

Since $\phi_k(y^{k+1};x) \to f(x)$, we have indeed $\|y^{k+1}-x\| \to 0$ by a sandwich argument.

To finish the proof, let us show that $0 \in \partial f(x)$. Notice first that the necessary optimality condition gives $0 \in \partial\psi_k(y^{k+1};x) = \partial\phi_k(y^{k+1};x) + \tau(y^{k+1}-x)$, which implies

$$\tau(x - y^{k+1}) \in \partial\phi_k(y^{k+1};x).$$

The subgradient inequality gives

$$\begin{aligned} \tau(x-y^{k+1})^\top(y-y^{k+1}) &\leq \phi_k(y;x) - \phi_k(y^{k+1};x) \\ &\leq \phi(y;x) - \phi_k(y^{k+1};x) \quad (\text{using } \phi_k \leq \phi) \end{aligned}$$

for every y. Passing to the limit, observing $\tau(y^{k+1}-x) \to 0$ and $\phi_k(y^{k+1};x) \to \phi(x;x)$, we obtain the estimate

$$0 \leq \phi(y;x) - \phi(x;x)$$

for every y, which by convexity of $\phi(\cdot;x)$ implies $0 \in \partial\phi(x;x)$. Since $\partial\phi(x;x) = \partial f(x)$, we have shown $0 \in \partial f(x)$, as claimed. □

Remark. Various modifications of our algorithm may be considered. For instance, whenever a null step y^{k+1} is made, that is, $\rho_k < \gamma$, we should first check whether y^{k+1} gives descent in f:

$$f(x) - f(y^{k+1}) \geq \delta_1 > 0. \tag{21}$$

If this is not the case, the trust region radius is certainly too large, so we should increase τ_k right away. As presented, this will also happen, but after several null steps, bringing ϕ_k closer to ϕ, until the criterion in step 4 is met.

In the same vein, even when y^{k+1} gives descent in f, but slightly, so that $\rho_k > \gamma$ fails, we may check whether

$$\sigma_k := \frac{f(x) - f(y^{k+1})}{f(x) - \phi(y^{k+1};x)} \geq \delta_2 \tag{22}$$

for some $\frac{1}{2} < \delta_2 < 1$. If $\sigma_k < \delta_2$, then f and ϕ are not in good agreement. In this case, our algorithm will keep τ_k fixed and will start driving ϕ_k closer to ϕ. Eventually this will lead to a moment where $\widetilde{\rho}_k \geq \widetilde{\gamma}$, and then τ_k will be increased to $2\tau_k$. As above one may argue that in this case we have lost time, because we have brought ϕ_k closer to ϕ even though ϕ is too far away from f, only to notice in the end that we could not avoid increasing τ_k. This loss of time and energy could be avoided by adding the test (22). If $\sigma_k < \delta_2$, then we increase τ_k right away but keep incrementing ϕ_k. The convergence analysis of this is covered by the two central lemmas of this section.

8. Convergence analysis of the outer loop. All we have to do now is piece things together and show subsequence convergence of the sequence of serious steps x^j retained in the outer loop. We have the following.

THEOREM 6. *Let $f = \lambda_1 \circ F$ be a maximum eigenvalue function and let $x^1 \in \mathbb{R}^n$ be such that the set $\{x \in \mathbb{R}^n : f(x) \leq f(x^1)\}$ is compact. Then every accumulation point of the sequence x^j of serious steps generated by the algorithm is a critical point of f.*

Proof. (i) From the previous section we know that the inner loop always ends after a finite number of steps k with a new x^+ satisfying the acceptance test, unless we have finite termination due to $0 \in \partial f(x)$. Excluding this case, let us assume that x^j is the sequence of serious steps, satisfying the acceptance test in step 4 of the algorithm. Since y^{k+1} accepted in step 4 becomes the new x^{j+1}, that means

$$f(x^j) - f(x^{j+1}) \geq \gamma \left(f(x^j) - \phi_{k_j}(x^{j+1}; x^j) \right), \tag{23}$$

where j is the counter of the outer loop, k the counter of the inner loop, and where at the outer step j the inner loop was stopped at $k = k_j$. Now recall from the construction that $\tau_{k_j}\left(x^j - x^{j+1}\right) \in \partial\phi_{k_j}(x^{j+1}; x^j)$. The subgradient inequality for $\phi_{k_j}(\cdot; x^j)$ at x^{j+1} therefore gives

$$\tau_{k_j}\left(x^j - x^{j+1}\right)^\top (x^j - x^{j+1}) \leq \phi_{k_j}(x^j; x^j) - \phi_{k_j}(x^{j+1}; x^j) = f(x^j) - \phi_{k_j}(x^{j+1}; x^j),$$

using $\phi_{k_j}(x^j; x^j) = f(x^j)$. That means

$$\tau_{k_j}\|x^{j+1} - x^j\|^2 \leq f(x^j) - \phi_{k_j}(x^{j+1}; x^j) \leq \gamma^{-1}\left(f(x^j) - f(x^{j+1})\right)$$

using (23). Summing up from $j = 1$ to $j = J - 1$ gives

$$\sum_{j=1}^{J-1} \tau_{k_j}\|x^{j+1} - x^j\|^2 \leq \gamma^{-1} \sum_{j=1}^{J-1} f(x^j) - f(x^{j+1}) = \gamma^{-1}\left(f(x^1) - f(x^J)\right),$$

which is bounded above due to the hypothesis that $\{x \in \mathbb{R}^n : f(x) \leq f(x^1)\}$ is bounded. We deduce convergence of the series

$$\sum_{j=1}^{\infty} \tau_{k_j}\|x^{j+1} - x^j\|^2 < \infty.$$

In particular, $\tau_{k_j}\|x^{j+1} - x^j\|^2 \to 0$.

(ii) Let us prove that this implies $g_j := \tau_{k_j}\left(x^j - x^{j+1}\right) \to 0$, $(j \to \infty)$. Assume on the contrary that there exists an infinite subset $\mathcal{N}$ of $\mathbb{N}$ and some $\mu > 0$ such that $\|g_j\| = \tau_{k_j}\|x^j - x^{j+1}\| \geq \mu > 0$ for every $j \in \mathcal{N}$. In tandem with the summability of $\tau_{k_j}\|x^j - x^{j+1}\|^2$ shown in part (i) this could only mean $x^j - x^{j+1} \to 0$, and at the

same time, $\tau_{k_j} \to \infty$, $j \in \mathcal{N}$. We now argue that there exists yet another infinite subsequence $\mathcal{N}'$ of $\mathbb{N}$ with $\tau_j \to \infty$, $(j \in \mathcal{N}')$, such that for each $j \in \mathcal{N}'$, the doubling rule in step 5 of the algorithm was applied at least once before the step $x^{j+1} = y^{k_j+1}$ was accepted. Indeed, to construct $\mathcal{N}'$ we let, for every $j \in \mathcal{N}$, $j' \leq j$ be that outer-loop instant where the τ-parameter was increased for the last time before j, and we let $\mathcal{N}'$ consist of all these j', $j \in \mathcal{N}$. It is possible that $j' = j$, but in general we may have $j' < j$, and we know only that

$$2\tau_{j'-1} \leq \tau_{j'} \quad \text{and} \quad \tau_{j'} \geq \tau_{j'+1} \geq \cdots \geq \tau_j.$$

However, since $\tau_j \to \infty$, $j \in \mathcal{N}$, we know that we must have $\tau_{j'} \to \infty$, $j' \in \mathcal{N}'$. Since the doubling rule was applied at least once at the outer-loop counter j', $\mathcal{N}'$ is as claimed.

Let us say that for $j \in \mathcal{N}'$ the doubling rule was applied for the last time at stage $\tau_{k_j-\nu_j}$ for some $\nu_j \geq 1$. That means, $\tau_{k_j-\nu_j+1} = 2\tau_{k_j-\nu_j}$, while the τ-parameter remained unchanged during the following inner steps before acceptance:

$$\tau_{k_j} = \tau_{k_j-1} = \cdots = \tau_{k_j-\nu_j+1} = 2\tau_{k_j-\nu_j}. \tag{24}$$

Now recall that in step 5 of the algorithm we have $\rho_k < \gamma$ and $\widetilde{\rho}_k \geq \widetilde{\gamma}$ for those k where the trial step was not accepted and the doubling rule was applied. Since this is the case at stage $k_j - \nu_j$ we have

$$\rho_{k_j-\nu_j} = \frac{f(x^j) - f(y^{k_j-\nu_j+1})}{f(x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j)} < \gamma$$

and

$$\widetilde{\rho}_{k_j-\nu_j} = \frac{f(x^j) - \phi(y^{k_j-\nu_j+1}; x^j)}{f(x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j)} \geq \widetilde{\gamma}.$$

By (24) we now have

$$\frac{1}{2}\tau_{k_j}\left(x^j - y^{k_j-\nu_j+1}\right) \in \partial\phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j).$$

Using the subgradient inequality for $\phi_{k_j-\nu_j}(\cdot; x^j)$ at $y^{k_j-\nu_j+1}$ and $\phi_{k_j-\nu_j}(x^j; x^j) = f(x^j)$, we obtain

$$\begin{aligned}\frac{1}{2}\tau_{k_j}\left(x^j - y^{k_j-\nu_j+1}\right)^\top\left(x^j - y^{k_j-\nu_j+1}\right) &\leq \phi_{k_j-\nu_j}(x^j; x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j)\\ &= f(x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j),\end{aligned}$$

which could also be written as

$$\frac{\tau_{k_j}\|x^j - y^{k_j-\nu_j+1}\|^2}{f(x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j)} \leq 2. \tag{25}$$

Substituting (25) into the expression for $\widetilde{\rho}_{k_j-\nu_j}$ and expanding gives

$$\begin{aligned}\widetilde{\rho}_{k_j-\nu_j} &= \rho_{k_j-\nu_j} + \frac{f(y^{k_j-\nu_j+1}) - \phi(y^{k_j-\nu_j+1}; x^j)}{f(x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j)}\\ &\leq \rho_{k_j-\nu_j} + \frac{L\|x^j - y^{k_j-\nu_j+1}\|^2}{f(x^j) - \phi_{k_j-\nu_j}(y^{k_j-\nu_j+1}; x^j)} \qquad \text{(using Proposition 1)}\\ &\leq \rho_{k_j-\nu_j} + \frac{2L}{\tau_{k_j}} \qquad \text{(using (25))}.\end{aligned}$$

Here Proposition 1 is applied to the set B of all x^j and $y^{k_j-\nu_j+1}$, $j \in \mathcal{N}'$, which is bounded because $\|y^{k_j-\nu_j+1}\| \le \|F'(x^j)^\star\|$ due to (7), and because the serious steps x^j belong to the level set $\{x \in \mathbb{R}^n : f(x) \le f(x^1)\}$, which is bounded by hypothesis. Since $\rho_{k_j-\nu_j} < \gamma$ and $L/2\tau_{k_j} \to 0$, we have $\limsup_{j\to\infty} \widetilde{\rho}_{k_j-\nu_j} \le \gamma$ in the estimate above, contradicting $\widetilde{\rho}_{k_j-\nu_j} \ge \widetilde{\gamma} > \gamma$ for all $j \in \mathcal{N}'$.

(iii) Having shown that $g_j := \tau_{k_j}(x^j - x^{j+1}) \to 0$, $(j \to \infty)$, let us argue that every accumulation point $\bar{x}$ of the sequence x^j of serious steps must be a critical point. Notice again that since $\{x \in \mathbb{R}^n : f(x) \le f(x^1)\}$ is compact by hypothesis, and since our algorithm is of descent type in the serious steps, the sequence x^j is bounded. Select a convergent subsequence $x^j \to \bar{x}$, $j \in \mathcal{N}$. The same argument applies to the sequence x^{j+1}, $j \in \mathcal{N}$. We may therefore assume that this sequence also has a limit, $\tilde{x}$. Notice that in general we might have $\tilde{x} \ne \bar{x}$. Only in those cases where the τ_{k_j}, $j \in \mathcal{N}$, are bounded away from 0 can we conclude that $x^{j+1} - x^j \to 0$, $j \in \mathcal{N}$. In general, however, according to step 4 of the algorithm, the τ-parameter may very well shrink to 0, and here $x^j - x^{j+1} \to 0$ cannot be assured.

Since g_j is a subgradient of $\phi_{k_j}(\cdot; x^j)$ at $x^{j+1} = y^{k_j+1}$, we have

$$\begin{aligned} g_j^\top h &\le \phi_{k_j}(x^{j+1}+h; x^j) - \phi_{k_j}(x^{j+1}; x^j) \\ &\le \phi(x^{j+1}+h; x^j) - \phi_{k_j}(x^{j+1}; x^j) \qquad (\text{using } \phi_{k_j} \le \phi) \end{aligned}$$

for every test vector h. Now we use the fact that $y^{k_j+1} = x^{j+1}$ was accepted in step 4 of the algorithm, which means

$$\gamma^{-1}\left(f(x^j) - f(x^{j+1})\right) \ge f(x^j) - \phi_{k_j}(x^{j+1}; x^j).$$

Combining these two estimates gives

$$\begin{aligned} g_j^\top h &\le \phi(x^{j+1}+h; x^j) - f(x^j) + f(x^j) - \phi_{k_j}(x^{j+1}; x^j) \\ &\le \phi(x^{j+1}+h; x^j) - f(x^j) + \gamma^{-1}\left(f(x^j) - f(x^{j+1})\right). \end{aligned}$$

Passing to the limit $j \in \mathcal{N}$ and using, in the order named, $g_j \to 0$, $x^{j+1} \to \tilde{x}$, $x^j \to \bar{x}$, and $f(\bar{x}) = \phi(\bar{x}; \bar{x})$, implies

$$0 \le \phi(\tilde{x}+h; \bar{x}) - \phi(\bar{x}; \bar{x})$$

for every test vector h, where the last term $f(x^j) - f(x^{j+1}) \to 0$ by monotonicity. Choosing $h = \bar{x} - \tilde{x} + h'$ therefore implies

$$0 \le \phi(\bar{x}+h'; \bar{x}) - \phi(\bar{x}; \bar{x})$$

for every test vector $h' \in \mathbb{R}^n$, which proves $0 \in \partial\phi(\bar{x}; \bar{x})$. Hence also $0 \in \partial f(\bar{x})$. ∎

In practical tests we observe convergence, and the theoretical possibility of a sequence of iterates with several accumulation points never occurs. This is explained to some extent by the following.

COROLLARY 7. *Suppose $f = \lambda_1 \circ F$ is convex in a closed and bounded neighborhood Ω of x^* and that the iterates (serious steps) x^j remain in Ω. Then the sequence x^j converges to some local minimum $x^\sharp \in \Omega$ with $f(x^*) = f(x^\sharp)$.*

Proof. As the sequence of serious steps x^j satisfies the acceptance condition in step 4 of the algorithm, we are in a situation similar to the one in the convex algorithm

discussed in [25]. The argument presented there can be used and shows convergence to a local minimum $x^\sharp \in \Omega$. □

Remark. The present trust region method should be compared to the approach of Fuduli, Gaudioso, and Giallombardo [20, 21] for general nonsmooth and nonconvex locally Lipschitz functions, where the authors design a trust region with the help of the first order affine approximations $a(y) = g^\top(y - y^{k+1}) + f(y^{k+1})$, $g \in \partial f(y^{k+1})$ of the objective f at the trial points y^{k+1}. As these affine models are not support functions to the objective, the authors classify them according to whether $a(x) > f(x)$ or $a(x) \le f(x)$, using this information to devise a trust region around the current x. Their approach is certainly appealing, because it uses genuine information from the objective f. In contrast, our method uses information from the model $\phi(\cdot; x)$ at the trial points y^{k+1}.

9. Minimizing the H_∞-norm. In this section we extend our algorithm to a larger class of functions which are suprema of an infinite family of maximum eigenvalue functions. The application we have primarily in mind is the H_∞-norm, but the results are applicable to a much larger class.

To introduce our case, we consider a parametrized family of stable linear time-invariant dynamical systems

$$P(\theta) : \begin{cases} \dot{x} = A(\theta)x + B(\theta)w, \\ z = C(\theta)x + D(\theta)w \end{cases} \tag{26}$$

with data $A(\theta) \in \mathbb{R}^{n_x \times n_x}$, $B(\theta) \in \mathbb{R}^{n_w \times n_x}$, $C(\theta) \in \mathbb{R}^{n_x \times n_z}$, $D(\theta) \in \mathbb{R}^{n_w \times n_z}$ depending smoothly on a decision parameter $\theta \in \mathbb{R}^n$. The transfer function of $P(\theta)$ is $G(\theta, s) = C(\theta)\left(sI - A(\theta)\right)^{-1} B(\theta) + D(\theta)$. Here n_x is the order of the system, $x(t)$ its state, n_w the number of inputs, $w(t)$ the input vector, n_z the number of outputs, and $z(t)$ the output vector. As a typical example, in feedback control synthesis, $P(\theta)$ may represent a closed-loop system, depending on the unknown (to be designed) feedback controller θ. The closed-loop transfer function then depends on the decision vector θ, which regroups the controller gains and possibly other decision parameters, e.g., from the open-loop system [44], or scalings/multipliers in robust synthesis [7].

Typically, the performance of the unknown feedback controller might be assessed in the H_∞-norm. Recall that the H_∞-norm $\|G(\theta, \cdot)\|_\infty$ of a stable system is the $L^2(j\mathbb{R}) \to L^2(j\mathbb{R})$ operator norm of the channel $w \to z$, where $z(s) = G(\theta, s)w(s)$. An explicit expression is

$$\|G(\theta, \cdot)\|_\infty = \sup_{\omega \in \mathbb{R} \cup \{\infty\}} \overline{\sigma}\left(G(\theta, j\omega)\right) = \sup_{\omega \in \mathbb{R} \cup \{\infty\}} \lambda_1\left(G(\theta, j\omega)^H G(\theta, j\omega)\right)^{1/2},$$

where X^H is the conjugate transpose of a matrix X. We are interested in that choice of θ which minimizes the H_∞-norm,

$$\min_{\theta \in \mathbb{R}^n} \|G(\theta, \cdot)\|_\infty. \tag{27}$$

We introduce the function

$$f(\theta) = \|G(\theta, \cdot)\|_\infty^2,$$

which is then an infinite maximum of maximum eigenvalue functions

$$f(\theta) = \max_{\omega \in \mathbb{R} \cup \{\infty\}} f(\theta, \omega), \qquad f(\theta, \omega) = \lambda_1\left(F(\theta, \omega)\right),$$

where

$$F(\theta,\omega) = G(\theta,j\omega)^H G(\theta,j\omega) \in \mathbb{S}^m.$$

Program (27) is semi-infinite with two sources of nonsmoothness: the infinite maximum operator and the nonsmoothness of each maximum eigenvalue function $f(\cdot,\omega)$.

Yet another difficulty arises in (27). Namely, given the fact that the H_∞-norm is defined only for stable transfer functions, the objective function $f(\theta)$ is defined only on the set $\mathcal{S}$ of those parameters θ where $G(\theta,\cdot)$ is stable. In other words, program (27) has the hidden constraint $\theta \in \mathcal{S}$. But $\mathcal{S}$ is an open set, because $G(\theta,\cdot)$ depends continuously on θ, so $\theta \in \mathcal{S}$ is not a constraint in the usual sense of mathematical programming. The following known fact is therefore useful.

LEMMA 8. *Suppose $(A(\theta),B(\theta),C(\theta),D(\theta))$ is observable and controllable for every $\theta \in \mathcal{S}$. Then $\|G(\theta,\cdot)\|_\infty \to +\infty$ for $\theta \in \mathcal{S}$ and $\theta \to \bar{\theta} \in \partial\mathcal{S}$. In other words, $f(\theta) = \|G(\theta,\cdot)\|_\infty^2$ behaves like a barrier function as θ approaches the boundary $\partial\mathcal{S}$ of the hidden constraint $\mathcal{S}$.*

The following result is yet another key property for the analysis of f; see, e.g., [11], [10, Lemma 1] for a proof.

LEMMA 9. *Suppose $G(\theta)$ is stable, i.e., $\theta \in \mathcal{S}$. Then the set $\Omega(\theta) = \{\omega \in \mathbb{R}\cup\{\infty\} : f(\theta) = f(\theta,\omega)\}$ of active frequencies is either finite or $\Omega(\theta) = \mathbb{R}\cup\{\infty\}$, i.e., $f(\theta) = f(\theta,\omega)$ for every $\omega \in \mathbb{R}\cup\{\infty\}$.*

We refer to $\Omega(\theta)$ as the set of active frequencies at θ. A system where $\Omega(\theta) = \mathbb{R}\cup\{\infty\}$ is called *all-pass*. In practical cases, iterates θ where $G(\theta,\cdot)$ is all-pass are rarely encountered.

For the following we switch back to the more standard notation in optimization, where the decision variable θ is denoted by $x \in \mathbb{R}^n$. Let x be our current iterate and consider the case where $\Omega(x) = \{\omega_1,\ldots,\omega_p\}$ is finite. Any Ω with $\Omega(x) \subset \Omega \subset \mathbb{R}\cup\{\infty\}$ is called an extension of $\Omega(x)$. For a given extension Ω we consider the function $f_\Omega(y) = \max_{\omega\in\Omega} f(y,\omega)$. If Ω is finite, then f_Ω is a maximum eigenvalue function, namely, $f_\Omega(y) = \lambda_1(F_\Omega(y))$, where $F_\Omega(y)$ is block diagonal with diagonal blocks $F(y,\omega)$, $\omega \in \Omega$ arranged in any convenient order. We have $f_\Omega \le f$ and $f_{\Omega(x)}(x) = f_\Omega(x) = f(x)$ for every extension Ω of $\Omega(x)$. The subdifferential of f at x is determined by $\Omega(x)$ in as much as

$$\partial f(x) = \partial f_\Omega(x) = \partial f_{\Omega(x)}(x).$$

Our goal is to extend the eigenvalue optimization algorithm to the case of the H_∞-norm. We use the following simple idea:

i. For a finite extension Ω of $\Omega(x)$ we know how to generate descent steps for f_Ω at x, because f_Ω is a maximum eigenvalue function.
ii. Suppose y^{k+1} is a serious step for f_Ω satisfying the acceptance test in step 4 of the algorithm. If Ω is large enough, f_Ω is close to f, so that we may hope that the acceptance test will also be satisfied for f.

This leads to a convergent algorithm for the H_∞-norm. What is needed is an increasing sequence $\Omega^1 \subset \Omega^2 \subset \cdots$ of finite sets whose union is dense in $\mathbb{R}_\infty$. Then we use the scheme of our algorithm to generate descent steps for f_{Ω_ℓ}, where $\Omega(x)\cup\Omega^\ell \subset \Omega_\ell$. If the approximation of f by f_{Ω_ℓ} is not good enough, we replace Ω_ℓ by the larger $\Omega_{\ell+1}$, where $\Omega(x)\cup\Omega^{\ell+1} \subset \Omega_{\ell+1}$, etc. This approach is inspired by the theory of consistent approximations of [53].

Spectral bundle algorithm for program (27).

Parameters $0 < \gamma^\sharp < \gamma < \frac{1}{2}$.	
0.	**Initialize outer loop.** Choose initial x such that $f(x) < \infty$.
1.	**Outer loop.** If $0 \in \partial f(x)$ at current x stop, else goto inner loop.
2.	**Initialize inner loop.** Let $x_1 = x$ and choose finite Ω_1 containing $\Omega(x_1)$. Put inner loop counter $\ell = 1$.
3.	**Subprogram.** At inner loop counter ℓ and current Ω_ℓ, f_{Ω_ℓ}, $\phi_{\Omega_\ell}(\cdot;x)$, and $\phi^k_{\Omega_\ell}(\cdot;x)$ use inner loop of the first algorithm (with counter k) to generate trial step x_ℓ satisfying the test $\dfrac{f(x)-f_{\Omega_\ell}(x_\ell)}{f(x)-\phi^k_{\Omega_\ell}(x_\ell;x)} \geq \gamma.$
4.	**Reality check.** Test whether $\dfrac{f(x)-f(x_\ell)}{f(x)-\phi^k_{\Omega_\ell}(x_\ell;x)} \geq \gamma^\sharp.$
5.	**Decision.** If this is the case, let $x^+ = x_\ell$ and go back to step 1. Otherwise add new frequencies to the set Ω_ℓ to obtain $\Omega_{\ell+1}$ and go back to step 3.

Here $\phi_{\Omega_\ell}(\cdot;x)$ relates to f_{Ω_ℓ} as $\phi(\cdot;x)$ relates to f in the algorithm of section 6, and, similarly, $\phi^k_{\Omega_\ell}(\cdot;x)$ used here plays the role of $\phi_k(\cdot;x)$ there.

Remarks. (i) Notice that our algorithm now has three iterative levels: the outer loop generating the serious iterates $x, x^+, x^{++}, \ldots$; the inner loop with counter ℓ, which corresponds in fact to the outer loop in the first algorithm, now applied to the function f_{Ω_ℓ}; and the innermost loop, which corresponds to the inner loop in the first algorithm, and which has its own counter k.

(ii) Notice that Ω_ℓ could in principle be *any* increasing sequence of finite sets of frequencies whose union is dense, but it is preferable to adapt this sequence to the local situation at the current iterate x. Ideas of how $\Omega_\ell(x)$ could be chosen at each step are discussed in [4].

THEOREM 10. *Suppose $(A(x), B(x), C(x), D(x))$ is observable and controllable for every $x \in \mathcal{S}$. Let x^1 be a starting point such that $f(x^1) < \infty$ and such that $\{x \in \mathbb{R}^n : f(x) \leq f(x^1)\}$ is bounded. Suppose the approximating sequence Ω_k is such that $f_{\Omega_k} \to f$ uniformly on bounded sets as $k \to \infty$. Then every accumulation point of the sequence of iterates x^j generated by the above algorithm with starting point x^1 is a critical point of f.*

Proof. (i) Observe first that due to the barrier property of the objective, the boundedness of the initial level set, and the fact that our method is of descent type in the outer iterates, every accumulation point $\bar{x}$ of the sequence of serious iterates x^j is necessarily inside the stability region $\mathcal{S}$. This means criticality of $\bar{x}$ is still described by $0 \in \partial f(\bar{x})$. In other words, the hidden constraint $x \in \mathcal{S}$ can be disregarded in what follows.

(ii) Let x be the current iterate of the outer loop and consider the inner loop with function f_{Ω_ℓ} and its models ϕ_{Ω_ℓ} and $\phi^k_{\Omega_\ell}$ for a fixed set Ω_ℓ. Applying the lemmas of section 7 to the maximum eigenvalue function f_{Ω_ℓ} shows finite termination of step 3 of the semi-infinite algorithm at a suitable x_ℓ (that is, after a finite number of steps y^{k+1}, where k is the counter of the innermost loop). Notice here that Lemmas 4 and 5 do not use compactness of the level sets of the objective, which is good news, because the objective is f_{Ω_ℓ}, and we know nothing about compactness of the level sets of f_{Ω_ℓ}. Only compactness of the level set of f is assumed in the statement. Instead, what made that argument in section 7 work was the special structure (7) of the subgradients

of the maximum eigenvalue function, and this applies to each f_{Ω_ℓ}.

(iii) The trial iterate x_ℓ found in step 3 corresponds in fact to the latest y^{k+1} of the innermost loop in the terminology of section 7, and the test in step 3 is precisely the acceptance test in the first algorithm. But being built on f_{Ω_ℓ}, x_ℓ does not necessarily pass the reality check in step 4, so a restart with a larger $\Omega_{\ell+1}$ may be required. What we have to prove, then, is that after a finite number of such updates $\Omega_\ell \to \Omega_{\ell+1}$, the $x_\ell = y^{k+1}$ will pass the test in step 4 and become the new outer iterate x^+. This is where we have to use the fact that f_{Ω_ℓ} gets closer to f as Ω_ℓ increases. More precisely, exploiting again the special structure of the subgradients of the different λ_1 involved, and using that $F'(z,\omega)$ is uniformly bounded for z in a bounded set and $\omega \in \mathbb{R}\cup\{\infty\}$, we see that the sequence of trial steps x_ℓ is bounded. Since $f_{\Omega_\ell} \to f$ uniformly on bounded sets, we conclude using $\gamma^\sharp < \gamma$ that ultimately the test in step 3 is sharper than the test in step 4. That proves finiteness of the loop in ℓ.

(iv) Finally, relabeling the outer iterates $x, x^+, \ldots$ as x^j, we are back in the situation analyzed in section 8. Using compactness of $\{x \in \mathbb{R}^n : f(x) \le f(x^1)\}$, we can use the same argument, now involving the parameter $\gamma^\sharp$ from step 4 of the algorithm. This completes the argument. □

Remark. The theory of consistent approximations [53] allows us in principle to apply this method in a fairly general context. However, a difficulty arises in step 4 of the algorithm, where the reality check requires computing values $f(x_\ell)$. This is what makes the case of the H_∞-norm special, because here we have an efficient way to compute function values [11]. The same idea can be used to solve problems with integral quadratic constraints (IQCs); see [7, 3].

10. Numerical tests. We present numerical tests with BMIs arising in feedback controller synthesis. Consider a closed-loop system of the form (26), where $A(K)$, $B(K), \ldots$ depend on the feedback controller K to be designed. The bounded real lemma [12] asserts that the closed-loop transfer channel $w \to z$ has H_∞-norm bounded by γ_∞ if and only if there exists a Lyapunov matrix $X \succ 0$ such that

$$\widetilde{\mathcal{B}}(K,X,\gamma_\infty) = \begin{bmatrix} A(K)^\top X + XA(K) & XB(K) & C(K)^\top \\ B(K)^\top X & -\gamma_\infty I & D(K)^\top \\ C(K) & D(K) & -\gamma_\infty I \end{bmatrix} \prec 0.$$

Fixing a small threshold $\epsilon > 0$, we consider the following nonlinear semidefinite program:

$$\begin{aligned} \text{minimize} \quad & \gamma_\infty \\ \text{subject to} \quad & \widetilde{\mathcal{B}}(K,X,\gamma_\infty) \preceq -\epsilon I, \\ & \epsilon I - X \preceq 0, \end{aligned}$$

which may be solved as an eigenvalue optimization program with decision variable $x = (\mathbf{vec}(K), \mathbf{svec}(X), \gamma_\infty)$ if exact penalization is used. To this end, put $\mathcal{B}(K,X,\gamma_\infty) := \mathrm{diag}[\epsilon I - X; \widetilde{B}(K,X,\gamma_\infty)]$ and fix a penalty parameter $\alpha > 0$ to solve the eigenvalue program $\min_x \lambda_1\left(\gamma_\infty I + \alpha\mathcal{B}(K,X,\gamma_\infty)\right)$. An alternative approach is to fix the performance level γ_∞ and to solve the eigenvalue program

$$\min_{K,X} \lambda_1\left(\mathcal{B}(K,X,\gamma_\infty)\right) \tag{28}$$

until a value < 0 is found. The gain γ_∞ could then be updated a few times to improve performance. This approach has been adopted in our numerical tests, while the exact

penalty approach was used in [8]. Further testing of this approach for control problems with IQCs is presented in [7].

10.1. Numerical implementation. We have performed six numerical experiments using models known in the control literature (VTOL helicopter, chemical reactor, transport airplane, piezoelectric actuator, coupled springs model, and binary distillation tower). This allows comparison with previous studies. We present both static and reduced order controller designs. The state space matrices of these models can be found in [35, 8], with the results of H_2 and H_∞ synthesis problems.

To solve the nonconvex eigenvalue optimization problem (28), we use our MATLAB implementation of the spectral bundle algorithm. The tangent subproblem to compute the trial step y^+ requires minimizing a quadratic cost function subject to an SDP constraint (an LMI (linear matrix inequality)). In order to solve the tangent subproblem efficiently, our specSDP routine [8] was used.

10.1.1. Initialization of the algorithm. The parameter values of the spectral bundle algorithm in section 6 have been set to $\gamma = 0.01$, $\tilde{\gamma} = 0.4$, and $\Gamma = 0.6$. We use $\text{tol} = 10^{-5}$ as a tolerance parameter to stop the algorithm as soon as progress in function values is minor, that is, $f(x) - f(x^+) < 10^{-5}(|f(x)| + 1)$.

Initialization of the variables X and K in program (28) is a difficult task. Indeed, the cost function (28) is nonconvex and the behavior of the algorithm could dramatically change for a bad choice of X and K. For instance, simple initializations such as $K = 0$ and $X = I$ are bound to fail. We have decided to start with a closed-loop stabilizing K, which is easily obtained via minimization of the spectral abscissa $\alpha(K) = \max \text{Re}\Lambda(A(K))$, where $\Lambda(A(K))$ is the spectrum of $A(K)$; see [9]. Once the initial K^0 is fixed in (28), minimizing the cost function with respect to X alone is a convex program, which can be solved using standard LMI techniques. A possible way to initialize X is therefore to choose X^0 optimal with respect to K^0. Unfortunately, this often leads to numerical problems since X^0 can be ill-conditioned and have an exceedingly large norm. We have observed during our numerical testing that the algorithm may crash because of the difference of magnitude between X and K. To avoid these effects, we have sometimes used a scaled version of X^0 to obtain decision variables K^0, X^0 of the same order of magnitude.

Initializing γ_∞ is easier, because the standard full order H_∞ controller gives a lower bound.

A delicate point is the initialization and choice of the number $r_k \in \mathbb{N}$ defining the dimension of the set $\mathcal{G}_k$ used to define the local model ϕ_k at each sweep k. As there does not seem to be any theoretical way to set the value of r_k, we have adjusted it heuristically during the computations. Figure 1 compares, for the helicopter model, static choices $r_k = \text{const}$ and displays the behavior of the algorithm for $r_k \in \{1, 2, 3, 4\}$. The ratio $f_i(x_k)/f_4(x_k)$ is plotted for $i = 1, \ldots, 3$, and $k = 1, \ldots, 100$, where $f_i(x_k)$ is the value of the cost function for $r_k = i$, and for the kth step x_k of the algorithm. As we can see in this plot, after some iterations, the algorithm behaves best for $r_k = 4$, indicating that larger r_k should give better results. The results in [48] seem to indicate that r_k should be chosen in such a way that the gap between λ_{r_k} and λ_{r_k+1} is as large as possible, but our testing in [2, 4, 8] has not confirmed this. The situation is far from clear, and dynamic choices of r_k ought to be tested. The advantage of our present approach motivated by [25] over the line motivated by [48] is that convergence of the method no longer hinges on the choice of r_k, respectively, r_ϵ.

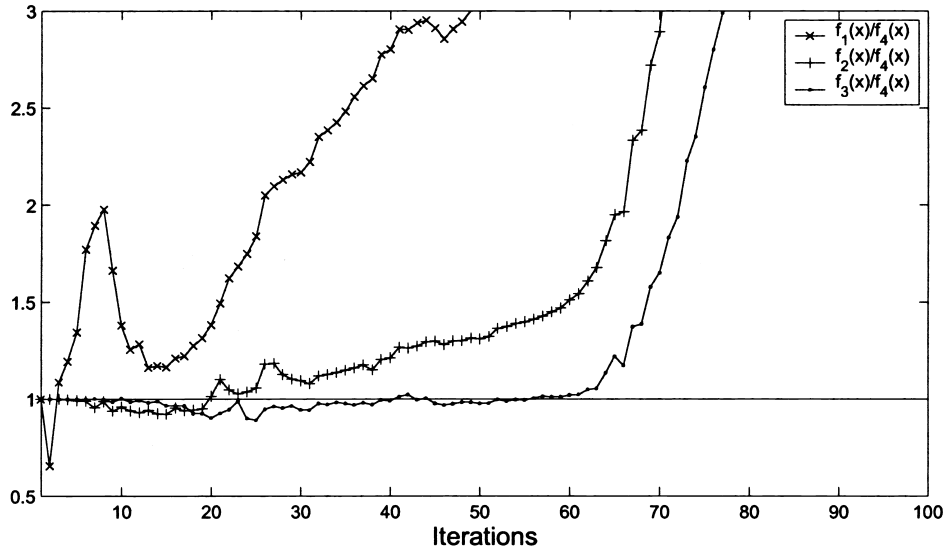

FIG. 1. *Behavior of the cost function during iterations for different values of r_k. This plot shows the ratio $f_i(x_k)/f_4(x_k)$, where $f_i(x_k)$ is the value of the cost function at step x_k for $r_k = i$.*

10.1.2. Nonsmooth optimality tests. To check whether the algorithm has reached a critical point, respectively, a minimum $x^* = (X^*, K^*)$, we have implemented two nonsmooth tests of optimality. The first one uses the ϵ-*enlarged subdifferential* of [48] for the maximum eigenvalue function, $\delta_\epsilon \lambda_1(X)$, to compute the criticality measure

$$\sigma_\epsilon = \operatorname{dist}\left(0, \delta_\epsilon f(x^*)\right),$$

where $f(x) = \lambda_1\left(\mathcal{B}(K, X, \gamma_\infty)\right) = \lambda_1(F(x))$. This parameter is the minimum value of the small size semidefinite program (computed using specSDP [8]):

$$\text{minimize } \left\{||F'(x^*)^\star G||_2 : \quad G \in \delta_\epsilon \lambda_1\left(\mathcal{B}(X^*, K^*, \gamma_\infty)\right)\right\},$$

where $\delta_\epsilon \lambda_1(X) = \left\{Q_\epsilon Y Q_\epsilon^\top \ : \ Y \succeq 0, \operatorname{Tr}(Y) = 1\right\}$. Here Q_ϵ is an $m \times r_\epsilon$ matrix whose r_ϵ columns form an orthonormal basis of eigenvectors associated with those eigenvalues $\lambda_i(X)$ satisfying

$$i \in I_\epsilon := \left\{i \ : \ \lambda_i(X) > \lambda_1(X) - \epsilon\right\}.$$

The number $r_\epsilon := \max\{i \ : \ i \in I_\epsilon\}$ is called the ϵ-*multiplicity* of $\lambda_1(X)$. In [48] it is shown that $\partial\lambda_1(X) \subset \delta_\epsilon \lambda_1(X) \subset \partial_\epsilon \lambda_1(X)$, so that ϵ could be roughly interpreted in the following way: If $0 \in \delta_\epsilon f(x^*) = F'(x^*)^\star \delta_\epsilon \lambda_1\left(\mathcal{B}(X^*, K^*, \gamma_\infty)\right)$, then it is not possible to further decrease f locally around x^* by more than ϵ. See [45, Lemma 2] for more details on this optimality test. Notice that this test may indeed be used as a stopping test in step 1 of the algorithm.

Our second optimality test is heuristic and is designed for a posteriori testing of criticality. It uses random perturbations x of $x^* = (X^*, K^*)$ to see whether the cost function value can be further decreased locally. Denoting by n_v the number of real optimization variables, we generate $100n_v$ random perturbations around $x^* = (X^*, K^*)$. The cost function values $f(X_i, K_i)$ for each perturbation $i = 1, \ldots, 100n_v$

are used to define

$$m_f := \min_i f(X_i, K_i),\ M_f := \max_i f(X_i, K_i),$$

and

$$p_f = \frac{\#\{i : f(X_i, K_i) < f(X^*, K^*)\}}{100 n_v}.$$

Parameter p_f (in percent) gives the proportion of perturbations for which the cost function value is improved.

10.2. Numerical results for H_∞-synthesis. Tables 1 and 2 present results obtained with the spectral bundle algorithm applied to the H_∞-synthesis problem. Table 1 is for static controllers, and Table 2 is for dynamic controllers. Comparison of performance γ_∞ with results in the literature, for static controllers $n_k = 0$, is given in Table 3. Table 4 gives some measured CPU times for three models on the static synthesis case. All numerical experiments have been performed on a Linux computer with a 2Ghz processor.

10.2.1. VTOL helicopter. State space data for the VTOL helicopter model are from [35, 8]; the model is described in [30]. The H_∞ gain was fixed at $\gamma_\infty = 0.1542$, the optimization variables were initialized as $K = [1, 1]^\top$, and $X = I$. The algorithm successfully solved the problem and obtained the H_∞ controller

$$K_\infty = \begin{bmatrix} 14.06432 \\ 239.5975 \end{bmatrix}.$$

We decided to look for a dynamic controller of order $n_k = 2$ with prescribed closed-loop performance $\gamma_\infty = 0.133$. The algorithm was initialized with a closed-loop stabilizing K^0 and $X^0 = I$. The optimal Lyapunov matrix X with respect to the given K^0 was used neither in the static nor in the dynamic case, because it has a very high norm and is likely to introduce numerical problems. The algorithm successfully computed

$$A_K = \begin{bmatrix} 1.672546 & 1.851477 \\ 1.849434 & 1.670218 \end{bmatrix},\ B_K = \begin{bmatrix} 73.76900 \\ 73.68110 \end{bmatrix},$$

$$C_K = \begin{bmatrix} 1.309171 & 1.308932 \\ 3.245753 & 3.241668 \end{bmatrix} \text{e-2},\ D_K = \begin{bmatrix} 0.4300008 \\ 0.7486698 \end{bmatrix}.$$

10.2.2. Chemical reactor. The chemical reactor model and numerical data can be found in [29]. We fixed the performance level $\gamma_\infty = 1.1830$ and initialized our algorithm with a closed-loop stabilizing K^0 together with the associated optimal X^0 (scaled for numerical convenience). This kind of initialization was used for both static and dynamic cases. The obtained static controller is

$$K_\infty = \begin{bmatrix} -3.791707 & -9.704666 \\ -7.166853 & -35.27994 \end{bmatrix}.$$

We also computed a dynamic controller of order 2. For $\gamma_\infty = 1.1420$, we obtained

$$A_K = \begin{bmatrix} -2.197969 & -0.341903 \\ -0.334860 & 2.205355 \end{bmatrix},\ B_K = \begin{bmatrix} 0.4983757 & 1.096069 \\ -6.452330 & -13.82350 \end{bmatrix},$$

$$C_K = \begin{bmatrix} -0.1090918 & 1.556743 \\ -0.2769249 & 3.964105 \end{bmatrix},\ D_K = \begin{bmatrix} -3.637238 & -6.382226 \\ -3.506708 & -19.39329 \end{bmatrix}.$$

The criticality measure was quite low in the static and the dynamic case, with $\sigma_\epsilon = 2.0041\text{e-}4$, respectively, $\sigma_\epsilon = 9.7570\text{e-}4$. In the static case, for the purpose of testing, we run the algorithm with a more severe stopping criterion to see if criticality decreased further. The stopping criteria were

$$f(x) - f(x^+) < 10^{-5}(|f(x)| + 1) \text{ and } ||x - x^+|| < 10^{-5}(||x|| + 1). \tag{29}$$

With this rule the algorithm stops after 26448 iterations. The final point verifies $\lambda_1(\widetilde{\mathcal{B}}) = -0.0079$ and criticality measure $\sigma_\epsilon = 4.2865\text{e-}06$, with $r_\epsilon = 4$ and $\epsilon = 1.3813\text{e-}5$. At this numerical precision, we can consider that the algorithm has reached a critical point.

10.2.3. Transport airplane. Model and state space data for the transport airplane are from [22]. We used a closed-loop stabilizing K^0 and the associated optimal X^0 for initialization. For $\gamma_\infty = 3.1770$, our algorithm computed the static controller

$$K_\infty = \begin{bmatrix} 0.6340988 & -0.5964908 & -0.7923650 & 5.166775e-2 & 1.055142 \end{bmatrix}.$$

In the static case we have also made a test of the algorithm with the stopping criterion (29). We have observed that the criticality of the final point of the algorithm has decreased: $\sigma_0 = 2.4819\text{e-}5$ after 241 iterations. Again, we can consider that the algorithm has reached a critical point with regard to the chosen numerical precision.

We failed to find a dynamic controller of order 2 for the airplane model. We computed a dynamic controller of order 1 with performance $\gamma_\infty = 2.860$. The H_∞ controller is

$$A_K = \begin{bmatrix} -0.4589498 \end{bmatrix},$$

$$B_K = \begin{bmatrix} -1.133331 & 1.441023 & 1.107071 & -0.116483 & -1.873279 \end{bmatrix}\text{e-}2,$$

$$C_K = \begin{bmatrix} -7.108071\text{e-}3 \end{bmatrix},$$

$$D_K = \begin{bmatrix} 1.740566 & -0.8878559 & -0.9477933 & 0.1000800 & 2.542508 \end{bmatrix}.$$

10.2.4. Piezoelectric actuator. The model of the piezoelectric actuator can be found in [13]. This study turned out to be one of the most difficult. As can be seen in Tables 1 and 2, the spectral bundle algorithm at first failed to solve the control problem both in the static and in the dynamic case. The algorithm converged to a couple (X^*, K^*) with slightly positive objective value around 1.45e-5 for the dynamical case, with the criticality parameter σ_ϵ quite small in both cases, indicating optimality. While it is perfectly possible that our algorithm, which is a local optimization method, may converge to a local minimum with positive values, failing to solve the underlying control problem, the present case turned out to be special. Namely, upon testing

the obtained controller K^*, we realized that it *is* closed-loop stabilizing and therefore solves the control problem. What happened is that the X^* computed by our algorithm was not suitable, as it fails to solve the Lyapunov inequality. Nonetheless, within the prescribed numerical precision both stopping tests indicated a local minimum.

The static controller for $\gamma_\infty = 0.0578$ reads

$$K_\infty = \left[\begin{array}{ccc} -0.3880673 & -1.837152 & -10.00377 \end{array} \right] \text{e+7},$$

and the dynamical controller of order 2, for $\gamma_\infty = 0.030$, is

$$A_K = \left[\begin{array}{cc} -6.770630 & -7.974432\text{e-}1 \\ -7.973471\text{e-}1 & -5.118056 \end{array} \right] \text{e+6},$$

$$B_K = \left[\begin{array}{ccc} 8.842279\text{e-}2 & 4.722429\text{e-}1 & 2.812368 \\ 3.574044\text{e-}2 & 1.910070\text{e-}1 & 1.136064 \end{array} \right] \text{e+7},$$

$$C_K = \left[\begin{array}{cc} -1.167814 & -4.720797\text{e-}1 \end{array} \right] \text{e+6},$$

$$D_K = \left[\begin{array}{ccc} -4.930334\text{e-}1 & -1.977292 & -1.480471\text{e+}1 \end{array} \right] \text{e+7}.$$

The described phenomenon indicates the numerical difficulty of synthesis problems with joint variable $x = (X, K)$, where important disparities between the numerical ranges of the two variables K and X may occur. In particular, the Lyapunov matrix X may be very ill-conditioned. The idea to keep K^* and compute a new Lyapunov variable X associated with K^* using a convex technique is systematically used in D-K iterations, where K and X variables are optimized alternatingly. The advantage of this approach is that both subproblems are then convex and can be solved by standard SDP solvers. However, intensive testing [27, 18] has shown that D-K techniques tend to get stalled and should in general be avoided. We believe that joint minimization in $x = (X, K)$ is the method of choice, despite the indicated difficulties. This does not exclude occasional restarts.

10.3. Coupled springs model. This is model CSE1 from [35] and consists of a string of coupled springs with dash-pots and masses. Input forces act on both the left and on the right ends of the spring system. The feedback controller has to stabilize the positions of the masses. We focus on the synthesis of a dynamic controller of order 4. To begin with, an initial closed-loop stabilizing controller was computed. Then X^0 was set to identity. An optimal controller was then synthesized for the performance level $\gamma_\infty = 0.0235$. The algorithm stopped at (K^*, X^*) with criticality measure sufficiently low in comparison with the numerical precision: $\sigma_\epsilon = 4.36e-6$, with $r_\epsilon = 5$ and $\epsilon = 3.64e-5$.

10.4. Distillation tower. Finally, to test the efficiency of the algorithm on a larger model, we used the BDT2 model from COMPL$_e$IB library [35], a binary distillation tower with 82 states, 4 outputs, and 4 controller inputs. The complete model is described in [56, section 12.4]. As can be seen in Table 1, the number of optimization variables $n_v = 3419$ is large in comparison with the previous examples. It should be highlighted that approximatively 99.5% (3403) of these variables are needed for the Lyapunov matrix X^*, but only 0.5% (16) are needed for controller K^*.

Synthesis of a static controller K_∞ was obtained for the performance level $\gamma_\infty = 1.0722$. An initial stabilizing controller K^0 was computed with its corresponding optimal Lyapunov matrix X^0. The synthesized controller is

$$K_\infty := \begin{bmatrix} 5.748949e-1 & 1.751953 & 9.954549e-1 & 3.725248e-1 \\ -6.313297e-1 & 1.133587 & 9.815346e-1 & 2.909215 \\ 1.986992 & 1.789245 & 3.988785e-1 & 2.468048 \\ -1.061248e-1 & 5.597463e-1 & 3.635867 & 4.772583 \end{bmatrix}.$$

Criticality was fairly low compared to the numerical precision: $\sigma_\epsilon = 1.27e-3$ with $r_\epsilon = 6$ and $\epsilon = 6.20e-5$. However, the same numerical phenomenon as in the piezoelectric actuator example was observed: (X^*, K^*) was not a stationary point, and the cost could be further reduced by using a convex optimization technique to compute a new Lyapunov matrix X with K^* fixed.

A FIRST-ORDER CONVERGENCE ANALYSIS OF TRUST-REGION METHODS WITH INEXACT JACOBIANS*

ANDREA WALTHER†

Abstract. A class of trust-region sequential quadratic programming algorithms for the solution of minimization problems with nonlinear equality constraints is analyzed. The considered class of optimization methods does not require the exact evaluation of the constraint Jacobian in each optimization step but uses only an approximation of this first-order derivative information. Hence, the presented approach is especially well suited for equality constrained optimization problems where the Jacobian of the constraints is dense. The accuracy requirements for the presented first-order global convergence result are based on the feasibility and the optimality of the iterates. The corresponding criteria can be verified easily during the optimization process to adjust the approximation quality of the constraint Jacobian.

Key words. trust-region algorithms, inexact Jacobians, global convergence

1. Introduction.

Trust-region successive quadratic programming (SQP) algorithms have been applied efficiently to solve a wide range of nonlinear optimization problems given by

$$\min_{x \in \mathbb{R}^N} f(x) \qquad \text{subject to } \; c(x) = 0, \tag{1}$$

where the objective $f : \mathbb{R}^N \to \mathbb{R}$ and the vector of the constraints $c : \mathbb{R}^N \to \mathbb{R}^M$ with $N \geq M$ are given smooth functions. For the majority of the trust-region SQP type algorithms, the computation of the next iterate requires the solution of a linear system of the form

$$A(x_k)A(x_k)^T v = b,$$

where

$$A(x) = (\nabla c_1(x), \ldots, \nabla c_M(x))^T \in \mathbb{R}^{M \times N}$$

is the exact matrix of the constraint gradients at x. Furthermore, a representation $Z(x)$ of the null space of $A(x)$ is needed frequently for the computation of the next step. For these reasons, the explicit forming and factoring of the constraint Jacobian $A(x)$ provides an efficient step calculation if $A(x)$ is sparse and well structured; see, e.g., [1]. As an alternative, one may use iterative system solves up to a certain accuracy, for example, Krylov subspace or multigrid methods, for the step calculation in each iteration; see, e.g., [17, 20, 29]. However, both approaches may result in very time-consuming computations, especially if the Jacobian of the constraints is dense or unstructured. Therefore, we present and analyze in this paper a class of trust-region SQP algorithms that does not require the exact evaluation of the constraint Jacobian or an iterative solution of a linear system with a system matrix that involves the con-

†Institute of Scientific Computing, Technische Universität Dresden, 01062 Dresden, Germany (andrea.walther@tu-dresden.de).

straint Jacobian. Instead the proposed algorithm works only with an approximation of this first-order information. Hence, the algorithm presented here is well suited for optimization problems of moderate size but with a special structure of the constraint Jacobian. The corresponding applications cover the wide range of periodic adsorption processes including for example the purification of hydrogen. In these cases, the Jacobian of the equality constraints is dense due to the periodicity of the underlying chemical process. As a consequence, the run-time needed for the optimization process may be dominated significantly by the computation of the dense Jacobian and its factorization; see, e.g., [19]. For these optimization tasks and problems with a similar structure, the algorithm proposed in this paper may allow a considerable reduction of the computing time required to calculate a solution.

For numerous optimization problems, the considered system is described by ordinary or partial differential equations the discretization of which yields the equality constraints. Exploiting the direct sensitivity equation or the adjoint differential equation, one can evaluate products of the Jacobian $A(x)$ and a given vector v, i.e., $A(x)v$ and $A(x)^T v$. Related derivative information can be computed also by applying automatic differentiation [14]. Hence, it is reasonable to assume that one can evaluate exact products of the Jacobian multiplied from the right or from the left by a given vector. However, the computation of the complete Jacobian matrix $A(x)$ may be very time consuming, especially if $A(x)$ is dense or unstructured, since many Jacobian-vector products are required to build the full matrix $A(x)$ in these cases. Therefore, we present an algorithm that uses only Jacobian-vector and vector-Jacobian products but avoids the calculation and factorization of $A(x)$ in each optimization step or the iterative solve of a linear system involving $A(x)$ as part of the system matrix.

To solve the optimization problem (1), we follow the approach proposed by Byrd [2] and Omojokun [23]. For composite-step trust-region methods that employ exact information, a comprehensive treatment of the convergence properties can be found in [7]. Implementations of the Byrd–Omojokun trust-region method are used successfully to solve equality constrained nonlinear problems (NLPs) [1, 20]. Related implementations using augmented Lagrangian merit functions are proposed and analyzed in [9]. Extensions of this approach to a more general class of trust-region methods can be found in [8]. Box trust-region methods are analyzed in [13]. More recently, trust-region methods without penalty functions have been developed by Fletcher and others [10, 11, 12] as well as Ulbrich and Ulbrich [26].

The effects of inexact problem information on the global convergence of inexact SQP methods can be found, for example, in [18, 21, 27]. In a line search setting, the effects of inexact information on the global convergence are studied in [3]. For an inexact composite step trust-region SQP method a first proof of global convergence is given in [17], where the analysis is focused on inexactness arising from iterative system solves. Our analysis and assumptions on inexactness differ from [17] in the following way: we do not consider a splitting of the variables into state and control variables. Hence, we allow general unstructured approximations of the Jacobian $A(x)$ and the corresponding null space representation as well as inexactness due to iterative solves. The proofs of first-order convergence given in this paper are based on ideas presented in [4]. Since we concentrate our analysis on the effects of inexact Jacobian information, the present paper does not examine the performance of the algorithm in the presence of dependent constraint gradients. Therefore, we assume in contrast to [4] throughout that the constraint Jacobian has full rank. Furthermore, we do not incorporate inequality constraints as in [4], since the efficient handling of inequalities in the case of inexact constraint Jacobians is subject of further research.

This paper has the following structure. In section 2 we introduce the notation and the main assumptions that are used for the proof of global first-order convergence. Subsequently, we discuss our inexact trust-region SQP algorithm in section 3. The well-posedness of this algorithm will be shown in section 4. Section 5 contains the proof of global convergence to first-order critical points. Finally, some conclusions and possible extensions are presented in section 6.

2. Notation and assumptions. The Lagrangian of (1) is defined by

$$\mathcal{L}(x,\lambda) = f(x) + \lambda^T c(x).$$

Assuming that a suitable constraint qualification is fulfilled, the first-order optimality conditions yield for an optimal solution x_* of (1) that

$$\begin{aligned}\nabla_x \mathcal{L}(x_*,\lambda_*) &= \nabla f(x_*) + A(x_*)^T\lambda_* = 0,\\ \nabla_\lambda \mathcal{L}(x_*,\lambda_*) &= c(x_*) = 0\end{aligned}$$

holds for a certain Lagrange multiplier $\lambda_* \in \mathbb{R}^M$. To apply an SQP trust-region algorithm, we approximately solve in the kth iteration the quadratic program

$$\begin{aligned}&\min_{d\in\mathbb{R}^N} \nabla f(x_k)^T d + \frac{1}{2} d^T B_k d\\ &\text{subject to } A(x_k)d + c(x_k) = 0,\\ &\|d\| \le \Delta_k,\end{aligned} \tag{2}$$

to compute a new step d_k for a given iterate x_k, a given trust-region radius Δ_k, and Lagrange multipliers λ_k. Here and throughout, B_k may stand for the exact second-order information $\nabla^2_{xx}\mathcal{L}(x_k,\lambda_k)$. Then, the functions $f(\cdot)$ and $c(\cdot)$ have to be twice continuously differentiable. Alternatively, one may use a symmetric matrix approximating the Hessian $\nabla^2_{xx}\mathcal{L}(x_k,\lambda_k)$. Furthermore, $\|\cdot\|$ denotes the Euclidean norm $\|\cdot\|_2$.

Since problem (2) may have no feasible solution, relaxation strategies were studied; see, e.g., [5, 24, 25]. As an alternative to overcome this difficulty, one can use a composite-step method. Following the approach of Byrd and Omojokun, we define the merit function

$$\phi(x;\mu) = f(x) + \mu\|c(x)\|$$

with the penalty parameter $\mu > 0$ to judge the progress toward the solution. This merit function is exact but nondifferentiable due to the Euclidean norm in the second term. A model of $\phi(\cdot;\mu_k)$ around an iterate x_k is given by the function

$$m_k(d) = f(x_k) + \nabla f(x_k)^T d + \frac{1}{2} d^T B_k d + \mu_k\|c(x_k) + A(x_k)d\|.$$

For measuring the progress of our algorithm, we define for a given iterate x_k and a step d the actual reduction in the merit function as

$$\operatorname{ared}_k(d) = \phi(x_k;\mu_k) - \phi(x_k + d;\mu_k). \tag{3}$$

The predicted reduction in the merit function is defined as the change of the model m_k caused by a step d, i.e.,

$$\begin{aligned}\operatorname{pred}_k(d) &= m_k(0) - m_k(d)\\ &= -\nabla f(x_k)^T d - \frac{1}{2} d^T B_k d + \mu_k(\|c(x_k)\| - \|c(x_k) + A(x_k)d\|).\end{aligned} \tag{4}$$

We suppose that for each iteration k one can provide an approximation A_k of the exact Jacobian $A(x_k)$ and an approximation Z_k of an exact null space basis $Z(x_k)$ with $A(x_k)Z(x_k) = 0$ and $A_k Z_k = 0$. Hence, we refer to the exact matrix information as $A(x_k)$ and $Z(x_k)$ and to the corresponding approximation as A_k and Z_k, respectively. The approximation of the derivative matrices using quasi-Newton update formulas fits into this setting. For this purpose, one may employ the well-known symmetric rank one (SR1) update formula to approximate the Hessian $\nabla^2_{xx}\mathcal{L}(x_k, \lambda_k)$. This approach is examined for unconstrained optimization in [6]. The two-sided rank one (TR1) update formula as proposed in [15] can be used to approximate the constraint Jacobian. Another possibility would be to compute the required Hessian-vector products exactly employing, for example, automatic differentiation. For the first-order information, the exact information $A(x_k)$ and $Z(x_k)$ could be computed for the iterate k and used for the following iterates as long as the restrictions on the inexactness are fulfilled. This is a promising approach since the iterates converge frequently in a tangential way toward the optimal solution. This observation holds when the Hessian is approximated for example by a quasi-Newton formula and the exact Jacobian of the constraints is used. We observe the same behavior in our first numerical experiments for numerous test problems using the TR1 update to approximate the Jacobian. Therefore, the changes in the null space will be hopefully rather small at the end of the optimization procedure.

To prove the convergence results presented in this paper, we define $D \equiv N - M$ and make the following assumptions:

(AS1) $A(x_k)$ has full row rank for all iterates x_k with $\sigma_D(A(x_k)) \geq \hat{\sigma} > 0$, where $\sigma_D(A(x_k))$ denotes the smallest singular value of $A(x_k)$.

(AS2) A_k has full row rank for all iterations with $\sigma_D(A_k) \geq \tilde{\sigma} > 0$.

(AS3) $Z_k \in \mathbb{R}^{N\times D}$ has full column rank D for all iterates x_k with $\sigma_D(Z_k) \geq \check{\sigma} > 0$ and remains bounded.

(AS4) The sequence $\{f(x_k)\}$ is bounded below. The sequences $\{\nabla f(x_k)\}$, $\{c(x_k)\}$, $\{A(x_k)\}$, and $\{B_k\}$ are bounded.

(AS5) The functions $\nabla f(\cdot)$, $c(\cdot)$, and $A(\cdot)$ are Lipschitz continuous on an open convex set $\mathcal{X}$ containing all iterates.

(AS6) The gradients $\nabla f(x)$, $\nabla_x \mathcal{L}(x, \lambda)$, the gradient-vector product $\nabla f(x)^T d$ and the products $A(x)v$, $w^T A(x)$ can be evaluated exactly.

(AS7) For fixed x_k, the approximation Z_k can be improved in a finite number of steps such that an exact null space representation $Z(x_k)$ is obtained.

Assumption AS1 is needed to prove the feasibility of all limit points and to derive upper bounds for the normal steps in section 5. A similar assumption is made in [17, sec. 3.3] to prove first-order global convergence. In the paper [4], the upper bound for the normal step is derived using an assumption similar to AS1. Furthermore, the analysis in [4] explicitly studies the rank deficiency of the constraint Jacobian $A(x_k)$ and its influence on the overall algorithm. That is, the iterates could converge either to a feasible point or to a limit point failing the linear independence constraint qualification. Therefore, an assumption similar to AS1 is not made for this part of [4]. However, the present paper focuses mainly on the convergence of a trust-region algorithm with inexact Jacobian information. For that reason, we decided not to explore the possibility that $A(x_k)$ is rank deficient since this would complicate the analysis considerably. The convergence to a limit point not satisfying the linear independence constraint qualification may be the subject of future research.

In AS7, we assume that we can improve the approximation Z_k such that it represents an exact null space $Z(x_k)$ of $A(x_k)$ after a finite number of improvement steps.

This is possible, for example, for the TR1 approach by performing M rank one updates without changing the current iterate x_k since the TR1 update procedure yields the exact Jacobian $A(x_k)$ for fixed x_k after at most M updates. This can be verified in the following way. Starting with an approximation $\tilde{A}_0 = A_k$ one performs M TR1 updates of the form

$$\tilde{A}_{i+1} \equiv \tilde{A}_i + \frac{(y_i - \tilde{A}_i v_i)(\tau_i^T - w_i^T \tilde{A}_i)}{(\tau_i^T - w_i^T \tilde{A}_i) v_i}$$

with $y_i \equiv A(x_k)v_i$ and $\tau_i \equiv w_i^T A(x_k)$ for arbitrary linearly independent vectors v_i and w_i chosen such that $(\tau_i^T - w_i^T \tilde{A}_i)v_i \neq 0$ holds. Due to the heredity of the rank one update, one obtains after M updates that

$$w_i^T \tilde{A}_M = w_i^T A(x_k) \qquad \text{for all} \qquad i = 0, \ldots, M-1.$$

The proof of this identity is similar to the proof of a related result for the SR1 update and can be found in [28]. Since the w_i, $0 \leq i < M$, are M linearly independent vectors, it follows that $\tilde{A}_M = A(x_k)$. Using an equivalent update procedure for a factorized null space representation, one obtains an exact null space representation $Z_k = Z(x_k)$ after at most M updates [16]. If one freezes the Jacobian and null space information as proposed above, one can evaluate new exact Jacobian information if the restrictions on the inexactness are no longer valid. This approach ensures that assumption AS7 holds. Hence, one can use the approximation $Z_k = Z_{k-1}$ and improve the approximation of the null space if required.

All other assumptions are either standard assumptions required also for the global convergence analysis in other papers, i.e., AS4 and AS5, or motivated by the applications that we had in mind when designing the algorithm, i.e., AS2, AS3, and AS6.

3. A Jacobian-free trust-region method. To apply a composite step trust-region method as proposed by Byrd and Omojokun, we first compute a normal step n that lies well inside the trust-region radius and that attempts to satisfy the linear constraints in (2). Subsequently, we take a tangential step t toward optimality. Putting both steps together, we obtain the total step $d = n + t$.

3.1. The normal subproblem. For the current iterate x_k, we compute a normal step n_k that best satisfies the linearized constraints by solving the *normal subproblem*

$$\begin{aligned} &\min_{n \in \mathbb{R}^N} \ \|c(x_k) + A(x_k)n\|^2 \\ &\text{subject to } \|n\| \leq \tilde{\Delta}_k \end{aligned} \tag{5}$$

with $\tilde{\Delta}_k = \kappa \Delta_k$ and $\kappa \in (0, 1)$. This optimization problem may have infinitely many solutions. The exact Cauchy step for (5) is given by

$$n_k^C = -\alpha_k^C A(x_k)^T c(x_k), \tag{6}$$

where α_k^C is the optimal solution of the problem

$$\begin{aligned} &\min_{\alpha \geq 0} \ \|c(x_k) - \alpha A(x_k)A(x_k)^T c(x_k)\| \\ &\text{subject to } \|\alpha A(x_k)^T c(x_k)\| \leq \tilde{\Delta}_k. \end{aligned} \tag{7}$$

Hence, due to our assumption AS6 that we can evaluate $A(x_k)v$ and $A(x_k)^T w$ for given v and w exactly, we are able to compute the exact Cauchy step. Nevertheless, employing only the exact Cauchy step may yield very slow convergence [22]. To accelerate the optimization process, one could use in addition also the exact Newton step. This global minimizer of the unconstrained version of (5) is given by

$$n^N(x_k) = -A(x_k)^+ c(x_k) = -A(x_k)^T (A(x_k)A(x_k)^T)^{-1} c(x_k).$$

However, we do not want to compute the vector $(A(x_k)A(x_k)^T)^{-1}c(x_k)$ exactly. Alternatively, if one assumes that an approximation $(A_k A_k^T)^{-1}c(x_k)$ can be evaluated at low computational cost, for example, by maintaining a factorized approximation of $A(x_k)$ as described in [16], then one could use the approximation

$$n_k^N = -A(x_k)^T (A_k A_k^T)^{-1} c(x_k)$$

of the exact Newton step. In combination with the exact Cauchy step, then one may compute the inexact dogleg step of Powell by setting

$$n_k^D = \eta n_k^N + (1-\eta) n_k^C$$

with $\eta = 1$ if $\|n_k^N\| \leq \tilde{\Delta}_k$. Otherwise $\eta \in [0,1]$ would be adjusted such that the length of n_k^D is equal to $\tilde{\Delta}_k$.

For obtaining convergence, one has to analyze the reduction in the linearized constraints caused by the normal step. For that purpose, we define the *normal predicted reduction* for a vector n as

$$\text{npred}_k(n) = \|c(x_k)\| - \|c(x_k) + A(x_k)n\| \tag{8}$$

and require that the normal step n_k computed in the kth iteration satisfies the following condition.

Normal Cauchy decrease condition. *An approximate solution n_k of the normal subproblem* (5) *must satisfy*

$$\text{npred}_k(n_k) \geq \gamma_n \text{npred}_k(n_k^C) \tag{9}$$

for some constant $\gamma_n > 0$.

To guarantee that a sufficient normal Cauchy decrease is achieved, one may use the exact Cauchy step itself as a normal step. Then (9) is obviously fulfilled with $\gamma_n = 1$. If one uses the inexact dogleg step, one can ensure that (9) holds by maximizing $\text{npred}_k(.)$ over the dogleg path. For our convergence analysis, the normal steps n_k have to fulfill the *range space condition*

$$\exists\, v_k \in \mathbb{R}^M \quad \text{such that} \quad n_k = A^T(x_k)v_k, \quad \text{i.e.,} \quad n_k \perp \ker\left(A(x_k)\right), \tag{10}$$

holds for all iterations $k \in \mathbb{N}$. Note that the normal steps n_k^D, n_k^C, and a linear combination of n_k^D and n_k^C are of the form $A^T(x_k)v_k$ such that they fulfill (10).

Since $\alpha = 0$ is feasible for the optimization problem (7), it follows from (9) that

$$\text{npred}_k(n_k) \geq 0 \tag{11}$$

holds. One can improve the bound on the normal predicted reduction as shown, for example, in [7, Lemma 15.4.17] and [4, Lemma 2]. The main ingredients of the proofs are the normal Cauchy decrease condition and the property $\|A(x_k)u_k^C\| > 0$

for $u_k^C \equiv -A(x_k)^T c(x_k) \neq 0$ due to the full rank of $A(x_k)$, i.e., assumption AS1, and $u_k^C \perp \ker(A(x_k))$. Since the inexactness of the Jacobian does not influence the derivation of the result, we skip the proof of the following lemma. It can be proved exactly along the lines of Lemma 2 in [4].

LEMMA 3.1. *Suppose that assumption* AS1 *holds. Let n_k be an approximate solution of the normal subproblem* (5) *such that* (9) *holds. Then*

$$\|c(x_k)\|\mathrm{npred}_k(n_k) \geq \frac{\gamma_n}{2}\|A(x_k)^T c(x_k)\| \min\left\{\tilde{\Delta}_k, \frac{\|A(x_k)^T c(x_k)\|}{\|A(x_k)\|^2}\right\}. \tag{12}$$

3.2. The tangential subproblem. Given a current iterate x_k, we compute the tangential step towards optimality. Usually, one tries to maintain linearized feasibility, i.e., the exact tangential step $t(x_k) = Z(x_k)p_k$ should be in the exact null space of the constraints. Since we have only an approximation Z_k of the exact null space $Z(x_k)$ available, we will have to safeguard the computation of the tangential step $t_k = Z_k p_k$ by limiting the amount of inexactness, as will be explained later.

However, first we concentrate on computing an approximate solution of the inexact *tangential subproblem*

$$\begin{aligned} \min_{p\in\mathbb{R}^{N-M}} \ & (\nabla f(x_k)+B_k n_k)^T Z_k p + \frac{1}{2} p^T Z_k^T B_k Z_k p, \\ & \|Z_k p\| \leq \hat{\Delta}_k, \end{aligned} \tag{13}$$

with $\hat{\Delta}_k = (1-\kappa)\Delta_k$.

The steepest descent direction in the null space basis variables for this optimization problem at $p = 0$ is given by

$$p_k^C = -Z_k^T(\nabla f(x_k)+B_k n_k); \tag{14}$$

see, e.g., [4, 17]. For judging the improvement provided by the tangential step, we define the *tangential predicted reduction* produced by a tangential step $t = Z_k p$ as change in the objective function of the tangential subproblem. Hence, we have

$$\mathrm{tpred}_k(t) = -(\nabla f(x_k)+B_k n_k)^T t - \frac{1}{2} t^T B_k t.$$

To ensure global convergence of our trust-region algorithm, we will impose the following condition on the tangential step.

Tangential Cauchy decrease condition. *An approximate solution t_k of the tangential subproblem* (13) *must satisfy*

$$\mathrm{tpred}_k(t_k) \geq \gamma_t \,\mathrm{tpred}_k(\theta_k^C Z_k p_k^C) \tag{15}$$

for some constant $\gamma_t > 0$, where θ_k^C solves the problem

$$\begin{aligned} & \min_{\theta\geq 0}\left[-\mathrm{tpred}_k(\theta Z_k p_k^C)\right] \\ & \text{subject to } \ \|\theta Z_k p_k^C\| \leq \hat{\Delta}_k. \end{aligned} \tag{16}$$

Since $\theta = 0$ is feasible for the optimization problem (16), it follows that

$$\mathrm{tpred}_k(t_k) \geq 0. \tag{17}$$

For deriving a sharper bound on the tangential predicted reduction that is needed for the convergence analysis, we cite the following result [4, Lemma 1].

LEMMA 3.2. *Consider the one-dimensional problem*

$$\min_{z\geq 0} \psi(z) \equiv \frac{1}{2}az^2 - bz$$
$$\text{subject to } z \leq y,$$

where $b \geq 0$ *and* $y > 0$. *Then the optimal value* ψ_* *satisfies*

$$\psi_* \leq -\frac{b}{2}\min\left\{y, \frac{b}{|a|}\right\} \quad \textit{if } a \neq 0 \qquad \textit{and} \qquad \psi_* \leq -by \quad \textit{if } a = 0.$$

The derivation of a tighter lower bound for the tangential predicted reduction is based also on the representation of the null space of the constraint Jacobian. In the corresponding proofs of [7, Lemma 15.4.2] and [4, Lemma 3], the steepest descent direction is computed with an exact null space representation. The same holds true for the corresponding estimate in [17, section 3.1.2]. We do not require that an exact null space representation is available but use only the inexact tangential subproblem (13). Therefore, we state the full proof of the following result, where we use ideas applied to prove Lemma 3 in [4].

LEMMA 3.3. *Suppose that assumptions* AS3 *and* AS4 *hold. Let* t_k *be an approximate solution of the tangential subproblem* (13) *that satisfies* (15). *Then*

$$\text{tpred}_k(t_k) \geq \hat{\gamma}\|p_k^C\| \min\left\{\hat{\Delta}_k, \|p_k^C\|\right\} \tag{18}$$

for a constant $\hat{\gamma} > 0$.

Proof. Inequality (18) clearly holds if $p_k^C = 0$. Hence, we now assume that $p_k^C \neq 0$. Then, problem (16) is equivalent to

$$\begin{aligned} &\min_{\theta\geq 0} -\frac{1}{2}(p_k^C)^T Z_k^T B_k Z_k p_k^C \theta^2 - \|p_k^C\|^2\theta \\ &\quad \text{subject to } \theta \leq \frac{\hat{\Delta}_k}{\|Z_k p_k^C\|}. \end{aligned} \tag{19}$$

First assume that $(p_k^C)^T Z_k^T B_k Z_k p_k^C \neq 0$. Lemma 3.2 applied to problem (19) yields

$$-\text{tpred}_k(\theta_k^C Z_k p_k^C) \leq -\frac{1}{2}\|p_k^C\|^2 \min\left\{\frac{\hat{\Delta}_k}{\|Z_k p_k^C\|}, \frac{\|p_k^C\|^2}{|(p_k^C)^T Z_k^T B_k Z_k p_k^C|}\right\}.$$

Combining this inequality with (15) and using norm inequalities, we obtain

$$\text{tpred}_k(t_k) \geq \frac{\gamma_t}{2}\|p_k^C\| \min\left\{\frac{\hat{\Delta}_k}{\|Z_k^T Z_k\|^{1/2}}, \frac{\|p_k^C\|}{\|Z_k^T B_k Z_k\|}\right\}.$$

Since we assume that the approximations $\{Z_k\}$ remain bounded, we have that $\{Z_k^T Z_k\}$ are bounded. In addition, $\{B_k\}$ is bounded, which yields that $Z_k^T B_k Z_k$ is bounded. Hence, we can deduce from the last inequality that there exists a positive constant $\hat{\gamma}$ such that (18) holds.

We do not assume that B_k has full rank. Therefore, it may happen even if $p_k^C \neq 0$ that $(p_k^C)^T Z_k^T B_k Z_k p_k^C = 0$. Then the solution of (19) is given by $\theta_k^C = \frac{\hat{\Delta}_k}{\|Z_k p_k^C\|}$. It follows that

$$-\mathrm{tpred}_k(\theta_k^C Z_k p_k^C) \leq -\|p_k^C\|^2 \frac{\hat{\Delta}_k}{\|Z_k p_k^C\|} \leq -\|p_k^C\| \frac{\hat{\Delta}_k}{\|Z_k^T Z_k\|^{1/2}} \ .$$

Since $\{Z_k\}$ remains bounded, this inequality proves the assertion. □

To accelerate the convergence, one may use not the steepest descent direction given by (14) but an approximation of the Newton step. For this purpose, we may apply the Steihaug CG algorithm (see, e.g., [4, 22]) as long as (15) is fulfilled for the tangential step t_k.

The matrix Z_k only approximates the null space $Z(x_k)$ of the exact Jacobian $A(x_k)$. Hence, one has for the combined step $d_k = n_k + t_k$ that the identity $A(x_k)d_k = A(x_k)n_k$ is not necessarily valid. Therefore, we obtain for the predicted reduction (4) of the function m_k the equation

$$\begin{aligned}\mathrm{pred}_k(d_k) = & -\nabla f(x_k)^T(n_k + t_k) - \frac{1}{2}(n_k + t_k)^T B_k(n_k + t_k) \\ & + \mu_k(\|c(x_k)\| - \|c(x_k) + A(x_k)(n_k + t_k)\|) \\ = & \ \mathrm{tpred}(t_k) + \mu_k \mathrm{npred}(n_k) + \chi_k + \mathrm{err}_k(d_k),\end{aligned}$$

where

$$\chi_k = -\nabla f(x_k)^T n_k - \frac{1}{2} n_k^T B_k n_k, \tag{20}$$

$$\mathrm{err}_k(d_k) = \mu_k(\|c(x_k) + A(x_k)n_k\| - \|c(x_k) + A(x_k)d_k\|).$$

As can be seen, $\mathrm{err}_k(d_k)$ is a measure for the error in Z_k, i.e., in the approximation of $Z(x_k)$. Since the usual identity for the predicted reduction is not valid, we define an inexact predicted reduction

$$\mathrm{ipred}_k(d_k) = \mathrm{tpred}(t_k) + \mu_k \mathrm{npred}(n_k) + \chi_k \tag{21}$$

by omitting the error term. We will use this inexact measure for our trust-region algorithm. However, to ensure well-posedness and convergence for the considered class of trust-region methods, we need a bound on the error term $\mathrm{err}_k(d_k)$. Obviously, one can derive that

$$\begin{aligned}|\mathrm{err}_k(d_k)| &= \mu_k \big| \|c(x_k) + A(x_k)n_k\| - \|c(x_k) + A(x_k)d_k\| \big| \\ &\leq \mu_k \|A(x_k)t_k\| \leq \mu_k \, \nu \Delta_k^2.\end{aligned}$$

Hence, one may use a criterion like

$$\|A(x_k)t_k\| \leq \nu \Delta_k^2 \tag{22}$$

for a constant $\nu > 0$ to bound the inexactness that is due to the tangential step. This inequality can be easily verified by evaluating one Jacobian-vector product. Similar requirements on the inexactness can be found in [17, section 4.1.4] in the context of the convergence analysis of inexact trust-region methods for PDE-constrained optimization problems and in [7, section 10.4] for trust-region methods in the unconstrained

case. However, using (22) it may happen that $\mathrm{pred}_k(d_k)$ may become negative if $\mathrm{err}_k(d_k)$ is large relative to $\mathrm{ipred}_k(d_k)$. For this reason, we will use the direct criterion

$$-\mathrm{err}_k(d_k) < (1-\eta-(1-\eta)/2)\,\mathrm{ipred}_k(d_k) \tag{23}$$

for a constant $\eta \in (0,1)$. This inequality can be used to control the error in the inexact predicted reduction and therefore allows us to ensure well-posedness of the algorithm. Note that one only has to bound a negative $\mathrm{err}_k(d_k)$ since a positive error leads to an even larger $\mathrm{pred}_k(d_k)$. If (23) holds, one has

$$\begin{aligned} \mathrm{pred}_k(d_k) &= \mathrm{ipred}_k(d_k) + \mathrm{err}_k(d_k) \\ &> \mathrm{ipred}_k(d_k) - (1-\eta-(1-\eta)/2)\,\mathrm{ipred}_k(d_k) \\ &> (\eta + (1-\eta)/2)\,\mathrm{ipred}_k(d_k) \geq 0 \end{aligned} \tag{24}$$

if $\mathrm{ipred}_k(d_k) \geq 0$. Once more, (23) can be easily verified by evaluating two Jacobian-vector products.

3.3. The trust-region algorithm. After specifying the computation of the normal and tangential step, we can now state a detailed description of our algorithm for solving the NLP (1).

Algorithm I.

Start: Set initial values x_0, λ_0, $\mu_{-1} > 0$, A_0, Z_0, Δ_0, $\rho \in (0,1)$, $\eta \in (0,1)$, $\omega \in (0, \frac{1}{2})$, and $\nu > 0$

for $k = 0, 1, \ldots$

1. Compute a normal step n_k such that (9) and (10) hold.
2. Compute a tangential step t_k such that (15) holds.
   Compute the total step $d_k = n_k + t_k$.
3. Compute the smallest value $\tilde{\mu}_k$ such that

$$\mathrm{ipred}_k(d_k) = \mathrm{tpred}(t_k) + \tilde{\mu}_k \mathrm{npred}(n_k) + \chi_k \geq \rho\,\tilde{\mu}_k\,\mathrm{npred}_k(n_k). \tag{25}$$

   If $\tilde{\mu}_k \leq \mu_{k-1}$, set $\mu_k = \mu_{k-1}$, otherwise set $\mu_k = \max\{\tilde{\mu}_k, 1.5\mu_{k-1}\}$.
4. If (23) does not hold, update A_k and Z_k and go to step 1.
5. If
$$\mathrm{ared}_k(d_k) < \eta\,\mathrm{ipred}_k(d_k)$$
   decrease Δ_k by a constant factor and go to 1.
6. Set $x_{k+1} = x_k + d_k$ and choose a Δ_{k+1} such that $\Delta_{k+1} \geq \Delta_k$
7. Compute new A_{k+1}, Z_{k+1}, and Lagrange multipliers λ_{k+1} using

$$\lambda_{k+1} = -(A_{k+1}A_{k+1}^T)^{-1}A(x_{k+1})\nabla f(x_{k+1}) \tag{26}$$

   such that $\|Z_{k+1}^T A(x_{k+1})^T \lambda_{k+1}\| \leq \omega \|Z_{k+1}^T \nabla f(x_{k+1})\|$.
8. If $Z_{k+1}^T \nabla f(x_{k+1}) = 0$ and $c(x_{k+1}) = 0$ go to 7 to improve Z_{k+1},
   else increase k by 1 and go to 1.

Algorithm I represents a Byrd–Omojokun trust-region algorithm that takes the inexactness of the Jacobian and its null space representation into account. To clarify this point we will discuss now each step of Algorithm I and compare it to a standard Byrd–Omojokun approach. The computation of a normal direction in step 1 is identical to a standard approach where the normal Cauchy decrease condition and the range

space condition have to be fulfilled. Note that the inexactness of the Jacobian may enter into the normal direction due to the choice of the normal step. The tangential direction computed in step 2 has to fulfill the tangential Cauchy decrease condition, i.e., a standard requirement for a Byrd–Omojokun algorithm.

In step 3, χ_k can be of any sign. Furthermore, we have that $\mathrm{npred}_k(n_k)$ and $\mathrm{tpred}_k(t_k)$ are nonnegative due to (11) and (17). Hence, if $\mathrm{npred}_k(n_k) > 0$ holds it follows that $\mathrm{ipred}_k(d_k) \geq \rho\,\mu_k\,\mathrm{npred}_k(n_k)$ is valid when

$$\mu_k \geq \frac{-\chi_k}{(1-\rho)\mathrm{npred}_k(n_k)}.$$

This lower bound is a sufficient condition but is not necessary, as condition (25) may hold also for smaller values of μ_k. If $\mathrm{npred}_k(n_k) = 0$ one can conclude from Lemma 3.1 that $c(x_k) = 0$ due to assumption AS1. Therefore, $n_k = 0$ solves the normal subproblem (5). The solution of (5) must be unique because of the range space condition (10). It follows for $\mathrm{npred}_k(n_k) = 0$ that $n_k = 0$, $\chi_k = 0$, and that (25) is satisfied for any value of μ_k.

The additional test on (23) in step 4 ensures that the inexactness of the Jacobian and its null space representation does not harm the tangential direction too much. Due to assumption AS7, we need only a finite number of improvement steps for fixed x_k to obtain an exact $Z_k = Z(x_k)$ such that (23) is fulfilled.

Steps 5 and 6 are standard update procedures of a trust-region algorithm. One only has to remember that $\mathrm{ipred}(d_k)$ is not equal to the predicted reduction $\mathrm{pred}(d_k)$ due to the inexactness allowed here. We will see later that the algorithm converges despite this inexactness.

In step 7, we compute an approximation Z_{k+1} of the exact null space such that the inexactness is limited to a certain amount in the direction λ_{k+1}. Such an approximation can be found due to assumption AS7. Subsequently, we test whether the approximation Z_{k+1} is good enough. A stationary point of the NLP (1) would satisfy the equations

$$Z(x_{k+1})^T \nabla f(x_{k+1}) = 0, \qquad c(x_{k+1}) = 0$$

due to the first-order optimality condition. However, we do not have an exact null space representation $Z(x_{k+1})$. Therefore, in step 8 we check whether x_{k+1} is a stationary point of the inexact problem, i.e., whether the equations

$$Z_{k+1}^T \nabla f(x_{k+1}) = 0, \qquad c(x_{k+1}) = 0$$

hold. If this is the case but x_{k+1} is not a Karush–Kuhn–Tucker (KKT) point of the NLP (1), we have that $Z(x_{k+1})^T \nabla f(x_{k+1}) \neq 0$. Hence, our approximation Z_{k+1} of the null space $Z(x_{k+1})$ must be improved to obtain well-posedness. Due to assumption AS7, we need only a finite number of improvement steps for fixed x_k to obtain $Z_{k+1}^T \nabla f(x_{k+1}) \neq 0$. Hence, it follows that there can be only an infinite cycling between steps 7 and 8 if x_{k+1} is an KKT point of the NLP (1).

4. Well-posedness of Algorithm I. An important property of a trust-region algorithm is the well-posedness. Here, one has to show that the trust-region radius cannot shrink to zero if an iterate x_k is not a stationary point of the NLP (1). For this purpose, we analyze the relation of the actual and predicted reduction. We will employ ideas used in the proof of Lemma 4 in [4]. In addition, we must take into account the inexactness of the Jacobian and its null space representation. That is, we

have to ensure that the error term $\mathrm{err}_k(d_k)$ does not dominate the model. In step 4 of Algorithm I, we require that (23) holds. Employing this inequality, we can prove the following result that is related to Lemma 4 in [4].

LEMMA 4.1. *Assume that the assumptions* AS4, AS5, *and* AS7 *hold on the open convex set $\mathcal{X}$ containing all iterates. Then there exists a positive constant ζ such that for any iterate x_k and any step $d_k = n_k + t_k$ generated by Algorithm* I *with $[x_k, x_k + d_k] \subset \mathcal{X}$ and $\mathrm{ared}_k(d_k) \leq \eta\, \mathrm{ipred}_k(d_k)$, it follows that*

$$0 \leq \eta \mathrm{ipred}_k(d_k) - \mathrm{ared}_k(d_k) \leq \zeta(1 + \mu_k)\Delta_k^2 \tag{27}$$

Proof. Since $A(\cdot)$ is Lipschitz continuous, there exists a constant $\zeta' > 0$ such that

$$\begin{aligned} \big|\, \|c(x_k + d_k)\| - \|c(x_k) + A(x_k)d_k\,\| \big| &\leq \|c(x_k + d_k) - c(x_k) - A(x_k)d_k\,\| \\ &\leq \sup_{\tilde{x}\,\in[x_k, x_k+d_k]} \|A(\tilde{x}) - A(x_k)\|\, \|d_k\| \\ &\leq \zeta' \Delta_k^2\,. \end{aligned}$$

As in Lemma 4 of [4], the last inequality, the definitions (3) and (4), the Lipschitz continuity of ∇f, and the boundedness of B yield

$$\begin{aligned} |\,\mathrm{pred}_k(d_k) - \mathrm{ared}_k(d_k)\,| &\leq \Big| f(x_k + d_k) - f(x_k) - \nabla f(x_k)^T d_k - \frac{1}{2} d_k^T B_k d_k \\ &\quad + \ \mu_k(\|c(x_k + d_k)\| - \|c(x_k) + A(x_k)d_k\|) \Big| \\ &\leq \zeta(1 + \mu_k)\Delta_k^2 \end{aligned}$$

for some positive constant ζ. Combining the last two inequalities with the bound (23) on the error and therefore (24), we obtain

$$\begin{aligned} 0 < \eta \mathrm{ipred}_k(d_k) - \mathrm{ared}_k(d_k) &\leq \left(\eta + \frac{1 - \eta}{2}\right) \mathrm{ipred}_k(d_k) - \mathrm{ared}_k(d_k) \\ &\leq \mathrm{pred}_k(d_k) - \mathrm{ared}_k(d_k) \leq \zeta(1 + \mu_k)\Delta_k^2\,. \end{aligned}$$

∎

Next, we have to prove that Algorithm I cannot generate an infinite cycling between steps 1 and 5. To show that an acceptable step is determined with a finite number of reductions of Δ_k even if the Jacobian and its null space representation are inexact, we employ two properties. First, it follows for $c(x_k) = 0$ from (8), (11), and assumption AS1 that $\mathrm{npred}_k(n_{k,i}) = 0$, $n_{k,i} = 0$, and therefore $p_k^C = -Z_k^T \nabla f(x_k) \neq 0$ due to steps 7 and 8 of Algorithm I. Second, it follows for $c(x_k) \neq 0$ from assumption AS1 that $A(x_k)^T c(x_k) \neq 0$. Using these properties of our inexact setting, the proof of the following result is similar to the one of Proposition 1 in [4] taking the modified estimate (27) into account. Therefore, we only will state the parts of the proof that differ from the proof of [4, Proposition 1].

PROPOSITION 4.2. *Let assumption* AS1 *hold. Suppose that x_k is not a stationary point of the NLP* (1). *Then there exists a Δ_k^0 such that*

$$\mathrm{ared}_k(d_k) \geq \eta\, \mathrm{ipred}_k(d_k)$$

for any $\Delta \in (0, \Delta_k^0)$.

Proof. Let the iterate x_k be fixed. To prove the assertion, we assume that there is a subsequence indexed by i of trust radii $\Delta_{k,i}$ such that $\Delta_{k,i}$ converges to zero and

that $\text{ared}_k(d_{k,i}) < \eta\,\text{ipred}_k(d_{k,i})$ for the corresponding steps $d_{k,i} = n_{k,i} + t_{k,i}$ and the penalty parameter $\mu_{k,i}$ for all i.

For $\eta \in (0,1)$, the inequality $\text{ared}_k(d_{k,i}) < \eta\,\text{ipred}_k(d_{k,i})$ yields

$$\left(\eta + \frac{1-\eta}{2}\right)\text{ipred}_k(d_{k,i}) - \text{ared}_k(d_{k,i}) > \frac{1-\eta}{2}\text{ipred}_k(d_{k,i}) \geq 0.$$

Then, it follows from Lemma 4.1 in combination with $\Delta_{k,i} \to 0$ that

$$\text{ipred}_k(d_{k,i}) = (1+\mu_{k,i})o(\|d_{k,i}\|). \tag{28}$$

This equation can be used exactly along the lines of the proof of Proposition 1 in [4] to produce a contradiction proving the assertion of the proposition. Therefore, we skip the rest of the proof here. □

Hence, to obtain well-posedness of Algorithm I even in the presence of inexact first-order information one has to ensure that the approximation Z_k of the exact null space representation is not too bad. In our approach the effects of the inexactness are bounded for the tangential step by the additional condition (23). This suffices to show the bound (27). Additionally, the test on the quality of Z_k in steps 7 and 8 of Algorithm I ensures that there cannot be an infinite cycling between steps 1 and 5, i.e., an acceptable step can be computed with a finite number of iterations. Note that only the inexactness of the null space approximation Z_k but not the inexactness of the constraint Jacobian approximation A_k has to be controlled to achieve well-posedness.

5. Convergence analysis. Comparing the following theorem with its counterpart in [4], one finds that the result presented here is less general. This is due to the fact that we concentrate the analysis in this paper mainly on the influence of inexact Jacobian information. That is, we do not want to study the performance of Algorithm I in the presence of dependent constraint gradients as in [4] but focus on the effects caused by inexact constraint Jacobian information. Therefore, we assume in contrast to [4] that the exact constraint Jacobian $A(x_k)$ has full row rank, i.e., assumption AS1 holds. Otherwise, the iterates generated by Algorithm I may converge to a limit point failing the linear independence constraint qualification. For the derivation of the next result, it is not required to handle the inexactness of A_k and Z_k directly. The inexact first-order information are taken into account by Lemma 4.1 which is used in the proof of the following assertion. Due to the estimate in Lemma 4.1 that differs from [4, Proposition 1], we state the parts of the proof that differ from [4, Lemma 7] but skip the rather long remaining parts of the proof.

THEOREM 5.1 (feasibility of all limit points). *Assume that* AS1–AS7 *hold. Then we have*

$$\lim_{k\to\infty} c(x_k) = 0.$$

Proof. We define the function

$$\Psi(x) = \|A(x)^T c(x)\|\,.$$

Using the assumptions AS4 and AS5, we obtain that there are constants $\epsilon_1, \epsilon_2, \epsilon_3 > 0$ such that

$$\begin{aligned} |\Psi(x) - \Psi(x_l)| &= \|A(x)^T c(x) - A(x)^T c(x_l) + A(x)^T c(x_l) - A(x_l)^T c(x_l)\| \\ &\leq \epsilon_1 \|x - x_l\| \ + \epsilon_2 \|x - x_l\| \leq \epsilon_3 \|x - x_l\| \end{aligned} \tag{29}$$

holds for any two points x and x_l in $\mathcal{X}$. Now, consider an arbitrary iterate x_l with $\Psi_l \equiv \Psi(x_l) \neq 0$. First, we will show that Algorithm I accepts all sufficiently small steps that are in a neighborhood of the iterate x_l. If the current step d_k is acceptable, nothing has to be shown; otherwise one has $\mathrm{ared}_k(d_k) < \eta\,\mathrm{ipred}_k(d_k)$ and Lemma 4.1 can be applied. We define the ball

$$\mathcal{B}_l = \{x \,:\, \|x - x_l\| < \Psi_l/(2\epsilon_3)\}\,.$$

Applying (29) yields for any $x \in \mathcal{B}_l$ that $\Psi(x) \geq \Psi_l/2 > 0$. It follows that there exists a constant $\bar{c}$ with $\|c(x)\| \geq \bar{c} > 0$. Using Lemma 3.1 and assumption AS4 yields the existence of a constant $\epsilon_4 > 0$ such that for any iterate $x_k \in \mathcal{B}_l$ the inequality

$$\mathrm{ipred}_k(d_k) \geq \rho\,\mu_k \mathrm{npred}_k(n_k) \geq \mu_k \epsilon_4 \Psi_l \min\{\tilde{\Delta}_k, \Psi_l\} \tag{30}$$

holds. For sufficient small Δ_k it follows that

$$\mathrm{ipred}_k(d_k) \geq \mu_k \epsilon_4 \Psi_l \tilde{\Delta}_k. \tag{31}$$

Employing this inequality together with the estimate that was derived in the proof of Lemma 4.1, we have

$$0 \leq \frac{\left(\eta + \frac{1-\eta}{2}\right)\mathrm{ipred}_k(d_k) - \mathrm{ared}_k(d_k)}{\mathrm{ipred}_k(d_k)} \leq \frac{\zeta(1+\mu_k)\Delta_k^2}{\mu_k \epsilon_4 \Psi_l \tilde{\Delta}_k}$$

and therefore

$$\mathrm{ared} \geq \eta \mathrm{ipred}_k(d_k) + \left(\frac{1-\eta}{2} - \frac{\zeta(1+\mu_k)\Delta_k}{\mu_k \epsilon_4 \Psi_l}\right)\mathrm{ipred}_k(d_k)\,.$$

For Δ_k sufficiently small, the second term on the right-hand side is nonnegative. Hence, for all $x_k \in \mathcal{B}_l$ and all such Δ_k, we have

$$\mathrm{ared}_k(d_k) \geq \eta\,\mathrm{ipred}_k(d_k), \tag{32}$$

which results in acceptance of d_k due to step 4 of Algorithm I. The remainder of this proof follows exactly along the lines of [4, Lemma 7]. ∎

To prove the first-order optimality of all limit points, we need that the normal step can be bounded by the normal predicted reduction and that the penalty factor μ_k eventually becomes constant. For that purpose, we present the next two lemmas. For the proofs of the following two results, it is not necessary to handle the inexactness of A_k and Z_k directly. Nevertheless, we state the two proofs since the derivation differs slightly from the proofs contained in [4] due to the different setting.

LEMMA 5.2 (upper bound on normal step). *Let assumptions* AS1 *and* AS4 *be fulfilled. Then there exists a positive constant γ such that*

$$\|n_k\| \leq \gamma\,\mathrm{npred}_k(n_k). \tag{33}$$

Proof. Using Lemma 3.1, we have for the normal step

$$\|c(x_k)\|\mathrm{npred}_k(n_k) \geq \frac{\gamma_n}{2}\|A(x_k)^T c(x_k)\| \min\left\{\tilde{\Delta}_k, \frac{\|A(x_k)^T c(x_k)\|}{\|A(x_k)\|^2}\right\}.$$

If $c(x_k) = 0$, then inequality (33) is trivially satisfied. Therefore assume $c(x_k) \neq 0$. Since $A(x_k)$ is supposed to remain bounded there exists a constant $\bar{\sigma} = \sup_k \|A(x_k)\|$. Together with assumption AS1, this gives

$$\text{npred}_k(n_k) \geq \frac{\gamma_n}{2}\hat{\sigma} \min\left\{\tilde{\Delta}_k, \frac{\hat{\sigma}\|c(x_k)\|}{\bar{\sigma}^2}\right\}. \tag{34}$$

Now, we have to consider two cases. First, let $\|c(x_k)\| \geq \hat{\sigma}\tilde{\Delta}_k/2$. Using $\bar{\sigma} \geq \hat{\sigma}$ and the trust-region constraint, we obtain

$$\text{npred}_k(n_k) \geq \frac{\gamma_n}{2}\hat{\sigma} \min\left\{1, \frac{\hat{\sigma}^2}{2\bar{\sigma}^2}\right\}\tilde{\Delta}_k \geq \frac{\gamma_n\hat{\sigma}^3}{4\bar{\sigma}^2}\|n_k\|.$$

This yields (33). Second, assume that $\|c(x_k)\| < \hat{\sigma}\tilde{\Delta}_k/2$. To derive the upper bound (33) in this case, we employ (10) and Lemma 3.1. Hence, there exists a vector $v_k \in \mathbb{R}^M$ such that

$$\begin{aligned}\|c(x_k)\|^2 &\geq \|c(x_k) + A(x_k)n_k\|^2 \\ &= \|c(x_k)\|^2 + 2c(x_k)^T A(x_k)n_k + \|A(x_k)A(x_k)^T v_k\|^2.\end{aligned}$$

One obtains

$$\|A(x_k)A(x_k)^T v_k\|^2 \leq -2c(x_k)^T A(x_k)n_k.$$

Using the Cauchy–Schwarz inequality, it follows that

$$\|A(x_k)A(x_k)^T v_k\| \leq 2\|c(x_k)\|.$$

Due to assumption AS1, this inequality implies that

$$\|n_k\| = \|A(x_k)^T v_k\| \leq \frac{2}{\hat{\sigma}}\|c(x_k)\|.$$

Employing the last inequality and (34), we have

$$\begin{aligned}\text{npred}_k(n_k) &\geq \frac{\gamma_n}{2}\hat{\sigma} \min\left\{\tilde{\Delta}_k, \frac{\hat{\sigma}\|c(x_k)\|}{\bar{\sigma}^2}\right\} \geq \frac{\gamma_n}{2}\hat{\sigma} \min\left\{\frac{2}{\hat{\sigma}}, \frac{\hat{\sigma}}{\bar{\sigma}^2}\right\}\|c(x_k)\| \\ &\geq \gamma_n \min\left\{\frac{2}{\hat{\sigma}}, \frac{\hat{\sigma}}{\bar{\sigma}^2}\right\}\|n_k\|,\end{aligned}$$

which concludes the proof. □

LEMMA 5.3 (bound on hpred and constant μ_k for $k \geq k_1$). *Suppose that assumptions* AS1 *and* AS4 *are satisfied. Then the sequence of penalty parameters* $\{\mu_k\}$ *is bounded. Furthermore, there exist an index* k_1 *and positive constants* $\bar{\mu}$ *and* ξ *such that* $\mu_k = \bar{\mu}$ *holds for all* $k \geq k_1$ *and*

$$\text{ipred}_k(d_k) \geq \xi \text{tpred}_k(t_k). \tag{35}$$

Proof. The sequences $\{\nabla f(x_k)\}$ and $\{B_k\}$ are bounded due to assumption AS4. It follows from (8) that $\text{npred}_k(n_k) \leq \|c(x_k)\|$. Furthermore, $\|c(x_k)\|$ is bounded due to assumption AS4. Hence, $\text{npred}_k(n_k)$ is bounded. Using (33), we obtain that there exists a constant ξ_1 such that

$$-\nabla f(x_k)^T n_k - \frac{1}{2}n_k^T B_k n_k \geq -\xi_1 \text{npred}_k(n_k).$$

Then, we can deduce from the definition (21) of $\mathrm{ipred}_k(d_k)$ that

$$\mathrm{ipred}_k(d_k) \geq \mathrm{tpred}(t_k) + \mu_k \mathrm{npred}(n_k) - \xi_1 \mathrm{npred}_k(n_k). \tag{36}$$

Employing that $\mathrm{npred}_k(n_k) \geq 0$ and $\mathrm{tpred}_k(t_k) \geq 0$, we can derive from this inequality that (25) in step 3 of Algorithm I holds for $\mu_k \geq \xi_1/(1-\rho)$. Hence, if μ_k becomes larger than $\xi_1/(1-\rho)$, it will never be increased. Taking into account that Algorithm I increases μ_k by a constant factor this yields that after some iterate, e.g., k_1, μ_k will remain unchanged at some value $\bar{\mu}$.

Then, it follows from (21) and (25) that

$$\mathrm{ipred}_k(d_k) \geq \mathrm{tpred}(t_k) - \xi_1 \mathrm{npred}_k(n_k) \geq \mathrm{tpred}(t_k) - \frac{\xi_1}{\rho\,\mu_k} \mathrm{ipred}_k(d_k).$$

Hence, (35) is satisfied with $1/\xi = 1 + \xi_1/(\rho\,\bar{\mu})$. ∎

Now, the field is prepared to prove the main result of this paper, namely, the convergence to a first-order critical point from an arbitrary starting point. That is, we prove global convergence for our trust-region method given by Algorithm I. For this purpose, we have to take the inexactness of Z_k explicitly into account: the bound on the error in the null space representation provided by step 7 of Algorithm I is directly required to prove the following result. Therefore, we state the full proof, where we also employ ideas from [4, Lemma 12].

THEOREM 5.4 (all limit points are first-order optimal). *Suppose that* AS1–AS7 *hold. Then, it follows that*

$$\lim_{k\to\infty} \nabla_x \mathcal{L}(x_k, \lambda_k) = \lim_{k\to\infty} (\nabla f(x_k) + A(x_k)^T \lambda_k) = 0,$$

where the multipliers λ_k are defined as in (26).

Proof. Step 7 of Algorithm I ensures that

$$\|Z_k^T A(x_k)^T \lambda_k\| \leq \omega \|Z_k^T \nabla f(x_k)\|$$

for $\omega \in (0, \frac{1}{2})$ and $k > 0$. This yields for $q_k = \nabla_x \mathcal{L}(x_k, \lambda_k)$

$$\begin{aligned} \|Z_k^T q_k\| &= \|Z_k^T (\nabla f(x_k) + A(x_k)^T \lambda_k)\| \geq \|Z_k^T \nabla f(x_k)\| - \|Z_k^T A(x_k)^T \lambda_k\| \\ &\geq (1-\omega) \|Z_k^T \nabla f(x_k)\| \geq \frac{1-\omega}{\omega} \|Z_k^T A(x_k)^T \lambda_k\|. \end{aligned}$$

Setting $\varrho = \omega/(1-\omega) \in (0,1)$, we obtain

$$\varrho \|Z_k^T q_k\| \geq \|Z_k^T A(x_k)^T \lambda_k\|.$$

It follows that there exists a constant γ_1' such that AS3 and AS4 yield

$$\begin{aligned} \|p_k^C\| &= \| - Z_k^T (\nabla f(x_k) + B_k n_k)\| \\ &= \| - Z_k^T \nabla f(x_k) - Z_k^T A(x_k)^T \lambda_k + Z_k^T A(x_k)^T \lambda_k - Z_k^T B_k n_k\| \\ &= \| - Z_k^T q_k + Z_k^T A(x_k)^T \lambda_k - Z_k^T B_k n_k\| \\ &\geq \check{\sigma} \|q_k\| - \varrho \check{\sigma} \|q_k\| - \gamma_1' \|n_k\| = (1-\varrho) \check{\sigma} \|q_k\| - \gamma_1' \|n_k\| \end{aligned}$$

is valid.

To obtain a contradiction, suppose that $\lim_{k\to\infty} q_k = 0$ does not hold. Then, there exists a constant $\vartheta > 0$ such that $0 < \vartheta \leq \frac{1}{4} \limsup_{k\to\infty} \|q_k\|$. Lemma 5.1

ensures that $c(x_k) \to 0$. Together with Lemma 5.2 this yields $\|n_k\| \to 0$. Hence, there is an arbitrarily large l such that for the iterate x_l and all $k \geq l$, we have $\|q_l\| > 3\vartheta$ and $\gamma_1'\|n_k\| < (1-\varrho)\check{\sigma}\vartheta$. Let γ_L be the Lipschitz constant for q_k. We define the ball $\mathcal{B}_l = \{x : \|x - x_l\| \leq \vartheta/\gamma_L\}$. Now, assume that the iterates x_k with $k > l$ do not leave $\mathcal{B}_l$. Then, it follows for all k that

$$\begin{aligned}\|p_k^C\| &\geq (1-\varrho)\check{\sigma}(\|q_l\| - \|q_l - q_k\|) - \gamma_1'\|n_k\| \\ &\geq (1-\varrho)\check{\sigma}(3\vartheta - \vartheta - \vartheta) = (1-\varrho)\check{\sigma}\vartheta > 0.\end{aligned}$$

Employing Lemmas 3.3 and 5.3 gives with $\gamma_2' = \xi\,\hat{\gamma}(1-\varrho)\check{\sigma}$ that

$$\operatorname{ipred}_k(d_k) \geq \xi \operatorname{tpred}_k(t_k) \geq \gamma_2'\,\vartheta \min\{\hat{\Delta}_k, (1-\varrho)\check{\sigma}\,\vartheta\}. \tag{37}$$

Furthermore, the boundedness of $f(x_k)$ due to AS4 and the boundedness of the μ_k due to Lemma 5.3 gives

$$\phi(x_k;\mu_k) = f(x_k) + \mu_k\|c(x_k)\| \geq K \tag{38}$$

for a constant $K \in \mathbb{R}$. This yields that $\operatorname{ipred}_k(d_k) \to 0$. Together with (37) this implies $\hat{\Delta}_k \to 0$. Taking l sufficiently large yields for any $k \geq l$ with $x_k \in \mathcal{B}_l$ that $\hat{\Delta}_k \leq \min\{1, (1-\varrho)\check{\sigma}\vartheta\}$ and therefore

$$\operatorname{ipred}_k(d_k) \geq \gamma_2'\,\vartheta\hat{\Delta}_k. \tag{39}$$

If $x_k \in \mathcal{B}_l$, we employ the same argument as in the proof of Theorem 5.1 to show that an acceptable step is generated for sufficiently small Δ_k. Hence, if $x_k \in \mathcal{B}_l$ for all $k > l$, then Δ_k would eventually stop decreasing. However, this contradicts the fact that $\hat{\Delta}_k \to 0$. Thus the sequence $\{x_k\}$ must leave $\mathcal{B}_l$ for some $k > l$.

In that case, suppose that x_{k+1} is the first iterate after x_l that is not contained in $\mathcal{B}_l$. We deduce from (39) and $\hat{\Delta}_k = (1-\kappa)\Delta_k$ that

$$\begin{aligned}\phi(x_{k+1};\mu_{k+1}) &\leq \phi(x_l;\mu_l) - \eta\sum_{j=l}^{k}\operatorname{ipred}(x_j,\mu_j) \\ &\leq \phi(x_l;\mu_l) - \gamma_2'\vartheta(1-\kappa)\sum_{j=l}^{k}\Delta_j \\ &\leq \phi(x_l;\mu_l) - \gamma_2'(1-\kappa)\vartheta^2/\gamma_L.\end{aligned} \tag{40}$$

One can derive the last inequality from the fact x_{k+1} has left the ball $\mathcal{B}_l$ with radius ϑ/γ_L. The sequence $\{\phi(x_k;\mu_k)\}$ is decreasing and bounded below due to (38). Hence, it converges. This is a contradiction to the fact that l can be chosen arbitrarily large in (40) and the fact that $\vartheta > 0$. Therefore, $q_k \to 0$. ∎

Once more, one only has to limit the error due to the inexact null space representation Z_k for the proof of global convergence. Therefore, an implementation of Algorithm I will have to handle the approximation of the null space representation carefully. One possibility is to employ the TR1 update of the Jacobian that also provides an approximation of the null space representation [16]. We will present corresponding numerical results in a forthcoming paper [28].

6. Conclusion. In this paper, we have proposed and analyzed for the first time a class of trust-region methods based only on inexact information on the constraint Jacobian and the null space representation without any assumption on the method to approximate these matrices. Using two conditions measuring the inexactness of the null space representation, we prove global first-order convergence for the presented algorithm under quite mild conditions. The two required conditions on the inexactness can be easily verified during the optimization process.

Due to the nondifferentiable merit function and the weak assumptions on the inexactness, one may need to accelerate the convergence rate using additional safe-guard strategies for the inexactness possibly in combination with a second-order correction or a watch-dog technique.

In addition to this subject, future work will also comprise the handling of inequality constraints. The introduction of slack variables in combination with interior point techniques would be one possibility. Alternatively, one may analyze projection methods to incorporate, for example, bound constraints.

Acknowledgments. The author is very thankful to Lorenz T. Biegler for numerous discussions on trust-region methods. Furthermore, the author is grateful to Jorge Nocedal and Hubert Schwetlick for their motivating comments on the subject of this paper. The valuable comments and hints of the anonymous referees are also gratefully acknowledged.

GLOBAL CONVERGENCE OF A NONSMOOTH NEWTON METHOD FOR CONTROL-STATE CONSTRAINED OPTIMAL CONTROL PROBLEMS*

MATTHIAS GERDTS†

Abstract. We investigate a nonsmooth Newton method for the numerical solution of optimal control problems subject to mixed control-state constraints. The necessary conditions are stated in terms of a local minimum principle. By use of the Fischer–Burmeister function the local minimum principle is transformed into an equivalent nonlinear and nonsmooth equation in appropriate Banach spaces. This nonlinear and nonsmooth equation is solved by a nonsmooth Newton's method. We prove the global convergence and the locally superlinear convergence under certain regularity conditions. The globalized method is based on the minimization of the squared residual norm. Numerical examples for the Rayleigh problem conclude the article.

Key words. optimal control, nonsmooth Newton method, control-state constraints, global convergence

1. Introduction. We consider the following optimal control problem (OCP) subject to mixed control-state constraints:

$$\text{(OCP)}\qquad \begin{array}{ll} \text{Minimize} & \displaystyle\int_0^1 f_0(x(t),u(t))dt \\ \text{w.r.t.} & x \in W^{1,\infty}([0,1],\mathbb{R}^{n_x}), u \in L^\infty([0,1],\mathbb{R}^{n_u}), \\ \text{subject to (s.t.)} & x'(t) = f(x(t),u(t)) \text{ a.e. in } [0,1], \\ & \psi(x(0),x(1)) = 0, \\ & c(x(t),u(t)) \le 0 \text{ a.e. in } [0,1]. \end{array}$$

Without loss of generality the discussion is restricted to autonomous problems on the fixed time interval $[0,1]$. The functions $f_0 : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}$, $f : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_x}$, $\psi : \mathbb{R}^{n_x} \times \mathbb{R}^{n_x} \to \mathbb{R}^{n_\psi}$, $c : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \to \mathbb{R}^{n_c}$ are supposed to be at least twice continuously differentiable w.r.t. to all arguments. As usual, the Banach space $L^\infty([0,1],\mathbb{R}^n)$ consists of all measurable functions $h : [0,1] \to \mathbb{R}^n$ with

$$\|h\|_\infty := \operatorname*{ess\,sup}_{0\le t\le 1} \|h(t)\| < \infty,$$

where $\|\cdot\|$ denotes the Euclidian norm on $\mathbb{R}^n$. The Banach space $W^{1,\infty}([0,1],\mathbb{R}^n)$ consists of all absolutely continuous functions $h : [0,1] \to \mathbb{R}^n$ with

$$\|h\|_{1,\infty} := \max\{\|h\|_\infty, \|h'\|_\infty\} < \infty.$$

Several approaches toward the numerical solution of OCP have been investigated in the literature. The so-called direct discretization method is based on a discretization of the infinite dimensional OCP and leads to a finite dimensional nonlinear program;

†School of Mathematics, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK (gerdtsm@maths.bham.ac.uk).

see, e.g., Gerdts [10]. The latter can be solved numerically by suitable programming methods such as, e.g., sequential quadratic programming. The direct discretization method turns out to be very robust in practice. Nevertheless, the computational effort grows at a nonlinear rate with the number of grid points used for discretization. Convergence results for discretized OCPs can be found in Dontchev and others [7, 6], Hager [15], and Malanowski, Büskens, and Maurer [23].

The so-called indirect method for OCPs attempts to satisfy the necessary conditions that are provided by the well-known minimum principle numerically; see Hartl, Sethi, and Vickson [16] for an overview on minimum principles. The exploitation of the minimum principle leads to a nonlinear multipoint boundary value problem that has to be solved numerically; see Oberle and Grimm [28] for an implementation of a multiple shooting algorithm. Although the indirect method usually leads to the most accurate solutions, it suffers from the drawback that it requires a good initial guess in order to converge. One crucial task is to estimate the sequence of active and inactive intervals of the control-state constraint.

We refer to Büskens [3], Gerdts [12], chapter one of Grötschel, Krumke, and Rambau [13], Ioffe and Tihomirov [17], and the literature cited therein for an overview on direct discretization methods and indirect methods.

Our intention is to analyze the local and global convergence properties of an alternative method—the nonsmooth Newton method. The method is based on a nonsmooth reformulation of the necessary optimality conditions and it was introduced for the problem class OCP in Gerdts [11]. A brief outline of the essential ideas of the algorithm is as follows. The reformulation of the necessary conditions leads to the nonsmooth equation

$$F(z) = 0, \qquad F : Z \to Y,$$

where Z and Y are appropriate Banach spaces. Application of the globalized nonsmooth Newton's method generates sequences $\{z^k\}$, $\{d^k\}$, and $\{\alpha_k\}$ related by the iteration

$$z^{k+1} = z^k + \alpha_k d^k, \qquad k = 0, 1, 2, \ldots .$$

Herein, the search direction d^k is the solution of the linear operator equation $V_k(d^k) = -F(z^k)$ and the step length $\alpha_k > 0$ is determined by a line-search procedure of Armijo's type for a suitably defined merit function. The linear operator V_k is chosen from an appropriately defined generalized Jacobian $\partial_* F(z^k)$.

The nonsmooth Newton method was investigated in finite dimensions by, among others, Qi [29] and Qi and Sun [30]. Extensions to infinite spaces can be found in Kummer [19, 20], Chen, Nashed, and Qi [4], and Ulbrich [31, 32]. Our approach follows the general framework of Ulbrich [31, 32], which was used to solve certain OCPs subject to partial differential equations. The novelty of this paper is the application to the problem class OCP. The application of the nonsmooth Newton method to this problem class has not been investigated in detail before. The structure of the problem is exploited and leads to a new global convergence result in section 4. Moreover, sufficient conditions for the nonsingularity of the operator V_k are derived in section 3.

The paper is organized as follows. Section 2 introduces the nonsmooth Newton method and establishes the locally superlinear convergence under comparatively mild assumptions. In section 3, details of the computation of the search direction are shown. It turns out that the search direction solves a linear boundary value problem

with a differential-algebraic equation (DAE). If a certain operator is invertible, the so-called index of the DAE is 1 and the DAE can be transformed easily into an ordinary differential equation. A sufficient condition for the existence of the inverse operator is provided. Section 4 analyzes the global convergence properties of the nonsmooth Newton's method. Finally, numerical illustrations are presented in section 5.

2. Local convergence of the nonsmooth Newton method. The (augmented) Hamilton function $H : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_x} \times \mathbb{R}^{n_c} \to \mathbb{R}$ is defined by

$$H(x, u, \lambda, \eta) := f_0(x, u) + \lambda^\top f(x, u) + \eta^\top c(x, u).$$

We summarize the well-known minimum principle for OCP. Throughout the rest of the paper we will use the abbreviation $f[t]$ for $f(x(t), u(t))$ and likewise for other functions with time-dependent arguments. Moreover, for an index set I and a vector c with components c_i we define $c_I := (c_i)_{i\in I}$.

Let (x_*, u_*) be a (weak) local minimum of OCP and, in addition to the smoothness assumptions made above, let the following assumptions be satisfied at (x_*, u_*):

(i) Linear independence: there exist $\alpha > 0$ and $\beta > 0$ such that

$$\|c'_{I_\alpha(t),u}[t]^\top \zeta\| \geq \beta\|\zeta\|$$

for all ζ of appropriate dimension. Herein, the index set I_α is defined by $I_\alpha(t) := \{i \in \{1, \dots, n_c\} \mid c_i[t] \geq -\alpha\}$.

(ii) Controllability: for every $q \in \mathbb{R}^{n_\psi}$ there exists a solution of the linear system

$$\begin{aligned} x'(t) - f'_x[t]x(t) - f'_u[t]u(t) &= 0,\\ \psi'_{x_0}x(0) + \psi'_{x_1}x(1) &= q,\\ c'_x[t]x(t) + c'_u[t]u(t) + S_\alpha(t)\sigma(t) &= 0, \end{aligned}$$

where $S_\alpha(t) := \operatorname{diag}(c_{i,\alpha}(t))$ and $c_{i,\alpha}(t) := \min\{c_i[t] + \alpha, 0\}$.

Under these assumptions, Malanowski [22, p. 86] shows in Theorem 4.3 the regularity of the Lagrange multipliers associated with OCP. In particular, the multiplier l_0 associated with the objective function can be normalized to one and the linear operator defined by the linear system in (ii) is surjective under the assumptions (i) and (ii); see Lemma 4.1 in Malanowski [22]. Under assumptions (i) and (ii) there exist Lagrange multipliers $\lambda_* \in W^{1,\infty}([0, 1], \mathbb{R}^{n_x})$, $\eta_* \in L^\infty([0, 1], \mathbb{R}^{n_c})$, and $\sigma_* \in \mathbb{R}^{n_\psi}$ with

$$x'_*(t) - f(x_*(t), u_*(t)) = 0, \tag{2.1}$$

$$\lambda'_*(t) + H'_x(x_*(t), u_*(t), \lambda_*(t), \eta_*(t))^\top = 0, \tag{2.2}$$

$$\psi(x_*(0), x_*(1)) = 0, \tag{2.3}$$

$$\lambda_*(0) + \psi'_{x_0}(x_*(0), x_*(1))^\top\sigma_* = 0, \tag{2.4}$$

$$\lambda_*(1) - \psi'_{x_1}(x_*(0), x_*(1))^\top\sigma_* = 0, \tag{2.5}$$

$$H'_u(x_*(t), u_*(t), \lambda_*(t), \eta_*(t))^\top = 0. \tag{2.6}$$

Furthermore, the complementarity conditions hold a.e. in $[0, 1]$:

$$\eta_*(t) \geq 0, \qquad c(x_*(t), u_*(t)) \leq 0, \qquad \eta_*(t)^\top c(x_*(t), u_*(t)) = 0. \tag{2.7}$$

Remark 2.1. Similar necessary conditions can be found in Neustadt [27, Ch. VI.3] and Zeidan [34, Th. 3.1]. A regularity condition based on a controllability condition

can be found in Zeidan [34, Prop. 4.2]. The regularity assumptions (i) and (ii) with suitable extensions occur in the context of sufficient conditions [25], convergence of discretization methods [6], and sensitivity analysis [26].

Unfortunately, these necessary conditions are not directly solvable for the variable $(x_*, u_*, \lambda_*, \eta_*, \sigma_*)$ owing to the complementarity conditions. Therefore, the subsequent considerations aim at the reformulation of this set of equalities and inequalities as an equivalent system of equations, which will be solved by a generalized version of Newton's method. Notice that if the mixed-control state constraints were not present in the optimal control problem, then the generalized version of Newton's method will coincide with the (classical) Lagrange–Newton method. The Lagrange–Newton method for control constrained optimal control problems was analyzed in Alt and Malanowski [1]; later it was extended to problems involving pure state constraints in Alt and Malanowski [2]. Under suitable conditions, the authors obtain a locally quadratic convergence rate for problems with control constraints in the first paper (Theorem 4) and a superlinear convergence rate for problems with control and state constraints in the second (Theorem 5.2). This is more than we are able to show for our approach so far, as only a locally superlinear convergence rate will be established in this paper. The results of Alt and Malanowski [1, 2] suggest that it might be possible to improve the local convergence rate of our method.

The convex and locally Lipschitz continuous Fischer–Burmeister function $\varphi : \mathbb{R}^2 \to \mathbb{R}$ is defined by

$$\varphi(a, b) := \sqrt{a^2 + b^2} - a - b, \tag{2.8}$$

(cf. Fischer [8]). The Fischer–Burmeister function has the nice property that $\varphi(a, b) = 0$ holds if and only if $a, b \geq 0$ and $ab = 0$. Hence, the complementarity conditions (2.7) are equivalent with the equality

$$\varphi(-c_i(x_*(t), u_*(t)), \eta_{i,*}(t)) = 0, \qquad i = 1, \ldots, n_c,$$

that has to hold almost everywhere in $[0, 1]$. Rather than working with the derivative of φ, which does not exist at the origin, we will work with Clarke's generalized Jacobian of φ:

$$\partial\varphi(a, b) = \begin{cases} \left\{ \left(\dfrac{a}{\sqrt{a^2 + b^2}} - 1, \dfrac{b}{\sqrt{a^2 + b^2}} - 1 \right) \right\} & \text{if } (a, b) \neq (0, 0), \\ \left\{ (s, r) \in \mathbb{R}^2 \;\middle|\; (s + 1)^2 + (r + 1)^2 \leq 1 \right\} & \text{if } (a, b) = (0, 0). \end{cases}$$

Notice that $\partial\varphi(a, b)$ is a nonempty, convex, and compact set. Let the Banach spaces

$$\begin{aligned} Z &= W^{1,\infty}([0, 1], \mathbb{R}^{n_x}) \times L^\infty([0, 1], \mathbb{R}^{n_u}) \times W^{1,\infty}([0, 1], \mathbb{R}^{n_x}) \times L^\infty([0, 1], \mathbb{R}^{n_c}) \times \mathbb{R}^{n_\psi}, \\ Y_1 &= L^\infty([0, 1], \mathbb{R}^{n_x}) \times L^\infty([0, 1], \mathbb{R}^{n_x}) \times \mathbb{R}^{n_\psi} \times \mathbb{R}^{n_x} \times \mathbb{R}^{n_x} \times L^\infty([0, 1], \mathbb{R}^{n_u}), \\ Y_2 &= L^\infty([0, 1], \mathbb{R}^{n_c}) \end{aligned}$$

be equipped with the maximum norm for product spaces and $z_* = (x_*, u_*, \lambda_*, \eta_*, \sigma_*)$. Then, the necessary conditions (2.1)–(2.7) are equivalent with the nonlinear equation

$$F(z_*) = \begin{pmatrix} F_1(z_*) \\ F_2(z_*) \end{pmatrix} = 0, \tag{2.9}$$

where $F_1 : Z \to Y_1$ and $F_2 : Z \to Y_2$ denote the smooth and the nonsmooth part of $F : Z \to Y := Y_1 \times Y_2$, respectively:

$$F_1(z)(\cdot) := \begin{pmatrix} x'(\cdot) - f(x(\cdot), u(\cdot)) \\ \lambda'(\cdot) + H'_x(x(\cdot), u(\cdot), \lambda(\cdot), \eta(\cdot))^\top \\ \psi(x(0), x(1)) \\ \lambda(0) + \psi'_{x_0}(x(0), x(1))^\top \sigma \\ \lambda(1) - \psi'_{x_1}(x(0), x(1))^\top \sigma \\ H'_u(x(\cdot), u(\cdot), \lambda(\cdot), \eta(\cdot))^\top \end{pmatrix}, \quad F_2(z)(\cdot) := \omega(z(\cdot)), \tag{2.10}$$

where $\omega = (\omega_1, \ldots, \omega_{n_c})^\top : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_x} \times \mathbb{R}^{n_c} \times \mathbb{R}^{n_\psi} \to \mathbb{R}^{n_c}$ and

$$\omega_i(\bar{x}, \bar{u}, \bar{\lambda}, \bar{\eta}, \bar{\sigma}) := \varphi(-c_i(\bar{x}, \bar{u}), \bar{\eta}_i), \qquad i = 1, \ldots, n_c. \tag{2.11}$$

The standard approach to solve (2.9) numerically would be to apply the classical Newton method. Unfortunately, the derivative $F'(z^k)$ does not exist since the component F_2 is not differentiable. Hence, we have to find a substitute for the derivative F' in the classical Newton method. In finite dimensional spaces, such a substitute for locally Lipschitz continuous functions may be chosen from the generalized Jacobian of F defined by

$$\partial F(z) := \operatorname{co}\left\{ V \;\middle|\; V = \lim_{\substack{z_i \in D_F \\ z_i \to z}} F'(z_i) \right\},$$

where D_F denotes the set of points where F is differentiable [5]. However, in infinite dimensional spaces it is more difficult to define an appropriate generalized Jacobian since locally Lipschitz continuous functions in general are not differentiable almost everywhere. Motivated by the chain rule in finite dimensions we define the point to set mapping $\partial_* F : Z \rightrightarrows \mathcal{L}(Z, Y)$ according to

$$\partial_* F(z^k)(z) := \left\{ \begin{pmatrix} F'_1(z^k)(z) \\ -S\,(c'_x[\cdot]x + c'_u[\cdot]u) + R\eta \end{pmatrix} \;\middle|\; \begin{array}{l} S = \operatorname{diag}(s_1, \ldots, s_{n_c}), \\ R = \operatorname{diag}(r_1, \ldots, r_{n_c}), \\ (s_i, r_i) \in \partial\varphi[\cdot] \text{ a.e.}, \\ s_i(\cdot), r_i(\cdot) \text{ measurable} \end{array} \right\}$$

and use this set as a generalized Jacobian. The same idea was introduced earlier in Ulbrich [31, Def. 3.35]. Notice that the first component F_1 of F in (2.10) is continuously Fréchet-differentiable with

$$F'_1(z^k)(z) = \begin{pmatrix} x'(\cdot) - f'_x[\cdot]x(\cdot) - f'_u[\cdot]u(\cdot) \\ \lambda'(\cdot) + H''_{xx}[\cdot]x(\cdot) + H''_{xu}[\cdot]u(\cdot) + H''_{x\lambda}[\cdot]\lambda(\cdot) + H''_{x\eta}[\cdot]\eta(\cdot) \\ \psi'_{x_0}x(0) + \psi'_{x_1}x(1) \\ \lambda(0) + \psi''_{x_0x_0}(\sigma^k, x(0)) + \psi''_{x_0x_1}(\sigma^k, x(1)) + \left(\psi'_{x_0}\right)^\top \sigma \\ \lambda(1) - \psi''_{x_1x_0}(\sigma^k, x(0)) - \psi''_{x_1x_1}(\sigma^k, x(1)) - \left(\psi'_{x_1}\right)^\top \sigma \\ H''_{ux}[\cdot]x(\cdot) + H''_{uu}[\cdot]u(\cdot) + H''_{u\lambda}[\cdot]\lambda(\cdot) + H''_{u\eta}[\cdot]\eta(\cdot) \end{pmatrix},$$

provided that the functions f_0, f, c, ψ are twice continuously differentiable w.r.t. all arguments. All functions are evaluated at $z^k = (x^k, u^k, \lambda^k, \eta^k, \sigma^k) \in Z$.

Replacing the nonexisting Jacobian F' in the classical Newton method by the generalized Jacobian $\partial_* F(z^k)$ leads to the following algorithm.

ALGORITHM 2.2. LOCAL NONSMOOTH NEWTON'S METHOD.

(0) *Choose* z^0.

(1) *If some stopping criterion is satisfied, stop.*

(2) *Choose an arbitrary* $V_k \in \partial_* F(z^k)$ *and compute the search direction* d^k *from the linear equation*

$$V_k(d^k) = -F(z^k).$$

(3) *Set* $z^{k+1} = z^k + d^k$, $k = k+1$, *and goto* (1).

The assumptions needed to prove local convergence of the method are similar to those in [29], [30], [18], and [31]. $\partial_* F(z)$ is called nonsingular if for every $V \in \partial_* F(z)$ the inverse operator V^{-1} exists and if it is linear and bounded, i.e., $V^{-1} \in \mathcal{L}(Y, Z)$.

THEOREM 2.3. *Let* z_* *be a zero of* F. *Suppose that there exist constants* $\Delta > 0$ *and* $C > 0$ *such that for every* $z \in U_\Delta(z_*)$ *the generalized Jacobian* $\partial_* F(z)$ *is nonsingular and* $\|V^{-1}\|_{\mathcal{L}(Y,Z)} \le C$ *for every* $V \in \partial_* F(z)$.

(i) *Let*

$$\|F(z) - F(z_*) - V(z - z_*)\|_Y = o(\|z - z_*\|_Z) \qquad \forall V \in \partial_* F(z) \tag{2.12}$$

as $\|z - z_*\|_Z \to 0$. *Then, for* z^0 *sufficiently close to* z_* *the nonsmooth Newton method converges superlinearly to* z_*.

(ii) *Let*

$$\|F(z) - F(z_*) - V(z - z_*)\|_Y = \mathcal{O}(\|z - z_*\|_Z^{1+p}) \qquad \forall V \in \partial_* F(z) \tag{2.13}$$

as $\|z - z_*\|_Z \to 0$. *Then, for* z^0 *sufficiently close to* z_* *the nonsmooth Newton method converges at order* $1 + p$ *to* z_*.

Furthermore, if $F(z^k) \neq 0$ *for all* k, *then the residual values converge superlinearly:*

$$\lim_{k \to \infty} \frac{\|F(z^{k+1})\|_Y}{\|F(z^k)\|_Y} = 0.$$

Proof. Due to the first assumption, the algorithm is well defined in some neighborhood of z_*. It holds that

$$V_k(z^{k+1} - z_*) = V_k(z^k + d^k - z_*) = V_k(z^k - z_*) + V_k d^k = V_k(z^k - z_*) - F(z^k) + F(z_*).$$

The assertions in (i) and (ii) follow from

$$\begin{aligned} \|z^{k+1} - z_*\|_Z &= \|V_k^{-1}\left(V_k(z^k - z_*) - F(z^k) + F(z_*)\right)\|_Y \\ &\le \|V_k^{-1}\|_{\mathcal{L}(Y,Z)} \cdot \|F(z^k) - F(z_*) - V_k(z^k - z_*)\|_Y \\ &\le C \cdot \|F(z^k) - F(z_*) - V_k(z^k - z_*)\|_Y \\ &= \begin{cases} o(\|z^k - z_*\|_Z) & \text{in case (i)}, \\ \mathcal{O}(\|z^k - z_*\|_Z^{1+p}) & \text{in case (ii)}. \end{cases} \end{aligned} \tag{2.14}$$

Let $\varepsilon > 0$ be arbitrary. According to (2.14) there exists $\delta > 0$ with

$$\|z^{k+1} - z_*\|_Z \le \varepsilon \|z^k - z_*\|_Z \quad \text{whenever} \quad \|z^k - z_*\|_Z \le \delta.$$

Notice that for any $\delta > 0$ there exists some $k_0(\delta)$ such that $\|z^k - z_*\| \le \delta$ for every $k \ge k_0(\delta)$ since z^k converges to z_*. By the local Lipschitz continuity of F we get

$$\|F(z^{k+1})\|_Y = \|F(z^{k+1}) - F(z_*)\|_Y \le L\|z^{k+1} - z_*\|_Z \le L\varepsilon \|z^k - z_*\|_Z$$

locally around z_* and the Newton iteration implies

$$\|z^{k+1} - z^k\|_Z \le \|V_k^{-1}\|_{\mathcal{L}(Y,Z)} \cdot \|F(z^k)\|_Y \le C\|F(z^k)\|_Y.$$

Thus,

$$\begin{aligned}\|z^k - z_*\|_Z &\le \|z^{k+1} - z^k\|_Z + \|z^{k+1} - z_*\|_Z \\ &\le C\|F(z^k)\|_Y + \|z^{k+1} - z_*\|_Z \\ &\le C\|F(z^k)\|_Y + \varepsilon\|z^k - z_*\|_Z\end{aligned}$$

and

$$\|z^k - z_*\|_Z \le \frac{C}{1-\varepsilon}\|F(z^k)\|_Y.$$

Finally,

$$\|F(z^{k+1})\|_Y \le L\varepsilon\|z^k - z_*\|_Z \le \frac{L\varepsilon C}{1-\varepsilon}\|F(z^k)\|_Y.$$

Since $F(z^k) \neq 0$ and ε may be arbitrarily small, this shows the last assertion. ∎

Remark 2.4.

- The properties (2.12) and (2.13) can be written as

$$\sup_{V \in \partial_* F(z)} \|F(z) - F(z_*) - V(z - z_*)\|_Y = o(\|z - z_*\|_Z),$$
$$\sup_{V \in \partial_* F(z)} \|F(z) - F(z_*) - V(z - z_*)\|_Y = \mathcal{O}(\|z - z_*\|_Z^{1+p})$$

  as $\|z - z_*\|_Z \to 0$ and are referred to as semismoothness and p-order semismoothness of F at z_*; see Ulbrich [31, Def. 3.1].
- It suffices if the assumptions are satisfied for certain elements of $\partial_* F$ provided that only these elements are used in the algorithm. For the upcoming computations we used the element corresponding to the choices

$$s_i(t) = \begin{cases} -1 & \text{if } c_i[t] = 0,\ \eta_i(t) = 0, \\ \frac{-c_i[t]}{\sqrt{c_i[t]^2 + \eta_i(t)^2}} - 1 & \text{otherwise,} \end{cases}$$
$$r_i(t) = \begin{cases} 0 & \text{if } c_i[t] = 0,\ \eta_i(t) = 0, \\ \frac{\eta_i(t)}{\sqrt{c_i[t]^2 + \eta_i(t)^2}} - 1 & \text{otherwise.} \end{cases}$$

The first component F_1 is continuously Fréchet-differentiable if f_0, f, c, ψ are twice continuously differentiable. The Fréchet-differentiability immediately yields (2.12) for the component F_1. If the second derivatives of f_0, f, c, ψ are even locally Lipschitz continuous, then F_1' also satisfies a local Lipschitz condition of type

$$\|F_1'(z + d) - F_1'(z)\|_{\mathcal{L}(Z,Y_1)} \le L\|d\|_Z.$$

Using this property and the mean-value theorem we find

$$\begin{aligned}\|F_1(z + d) - F_1(z) - F_1'(z + d)(d)\|_{Y_1} &\le \int_0^1 \|(F_1'(z + td) - F_1'(z + d))(d)\|_{Y_1} dt \\ &\le \int_0^1 \|F_1'(z + td) - F_1'(z + d)\|_{\mathcal{L}(Z,Y_1)} dt \cdot \|d\|_Z \\ &\le \frac{L}{2}\|d\|_Z^2\end{aligned}$$

and thus (2.13) with $p = 1$ holds for F_1.

The second component $F_2(z)(t) = \omega(z(t))$ of F in (2.10) is a superposition operator as in [31, Sec. 3.3] with the difference that F_2 maps from some subset of L^∞ to L^∞. This allows us to consider the operator F_2 pointwise since $\|z - z_*\|_Z \to 0$ implies $\|z(t) - z_*(t)\| \to 0$ a.e. in $[0,1]$. Let us summarize some well-known results for finite dimensions. The Fischer–Burmeister function $\varphi : \mathbb{R}^2 \to \mathbb{R}$ is 1-order semismooth (and particularly semismooth) according to Fischer [9, Lem. 20]. Furthermore, due to a result of Mifflin, the composition $g = g_1 \circ g_2$ of semismooth functions g_1, g_2 is again semismooth [9, p. 527]. Similarly, the composition of 1-order semismooth functions is again 1-order semismooth [9, Th. 19]. In particular, continuously differentiable functions are semismooth and functions having a locally Lipschitz continuous first derivative are 1-order semismooth. Consequently, the function ω in (2.11) is semismooth if the function c is continuously differentiable. Moreover, ω is 1-order semismooth if c' is locally Lipschitz continuous. With these remarks the semismoothness and the 1-order semismoothness of the superposition operator $F_2 : Z \to Y_2$ in (2.10) and (2.11) are established by the following lemma.

LEMMA 2.5. *Consider the operator*

$$g : L^\infty([0,1], \mathbb{R}^n) \to L^\infty([0,1], \mathbb{R}^m), \qquad z \mapsto g(z)(t) = \omega(z(t)).$$

It holds that

(i) *g is semismooth at z (in the sense of Remark 2.4) if $\omega : \mathbb{R}^n \to \mathbb{R}^m$ is semismooth at $z(t) \in \mathbb{R}^n$ for a.e. $t \in [0,1]$.*

(ii) *g is p-order semismooth at z (in the sense of Remark 2.4) if ω is uniformly p-order semismooth at z, i.e., there exists $C_z > 0$ such that for almost every $\bar{z} \in \{z(t) \in \mathbb{R}^n \mid t \in [0,1]\}$ it holds that*

$$\max_{V \in \partial\omega(\bar{z}+h)} \|\omega(\bar{z}+h) - \omega(\bar{z}) - Vh\| \le C_z \|h\|^{1+p} \qquad \text{as} \qquad \|h\| \to 0.$$

Proof. Define $\rho : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^m$ by

$$\rho(x,h) := \max_{V \in \partial\omega(x+h)} \|\omega(x+h) - \omega(x) - Vh\|.$$

(i) Owing to the semismoothness of ω at $z(t)$ for a.e. $t \in [0,1]$ it holds that

$$a(t) = \frac{\rho(z(t), d(t))}{\|d\|_\infty} = \frac{o(\|d(t)\|)}{\|d\|_\infty} \to 0$$

as $\|d(t)\| \to 0$ for a.e. $t \in [0,1]$. Since $\|d\|_\infty \to 0$ implies $\|d(t)\| \to 0$ a.e., it holds that $\|\rho(z(\cdot), d(\cdot))\|_\infty = \|a\|_\infty \cdot \|d\|_\infty = o(\|d\|_\infty)$.

(ii) The uniform p-order semismoothness of ω at z yields

$$\rho(z(t), d(t)) \le C_z \|d(t)\|^{1+p} \le C_z \|d\|_\infty^{1+p}$$

a.e. in $[0,1]$, where C_z does not depend on t. The assertion follows from $\|\rho(z(\cdot), d(\cdot))\|_\infty \le C_z \|d\|_\infty^{1+p}$. ∎

Application of the lemma and the previous considerations yield the following result.

THEOREM 2.6. *Let z_* be a zero of F. Suppose that there exist constants $\Delta > 0$ and $C > 0$ such that for every $z \in U_\Delta(z_*)$ the generalized Jacobian $\partial_* F(z)$ is nonsingular and $\|V^{-1}\|_{\mathcal{L}(Y,Z)} \le C$ for every $V \in \partial_* F(z)$.*

The nonsmooth Newton's method converges locally at a superlinear rate if f_0, f, c, ψ are twice continuously differentiable.

Proof. The assertion follows from Lemma 2.5 since the Fischer–Burmeister function is semismooth at every $(a,b)^\top \in \mathbb{R}^2$ and thus ω in (2.11) is semismooth everywhere provided that c is continuously differentiable. ∎

Remark 2.7. Unfortunately, the quadratic convergence of the method could not be established for the following reason. The Fischer–Burmeister function is twice continuously differentiable at every argument $(a,b)^\top \neq (0,0)^\top$, but the second derivative is getting unbounded for $(a,b) \to (0,0)$. Hence, the assumption in (ii) of Lemma 2.5 can be satisfied at z_* only if $\eta_i(t)$ and $c_i(x_*(t),u_*(t))$ do not approach zero simultaneously. Thus, a uniform strict complementarity condition

$$|\eta_{*,i}(t)| + |c_i(x_*(t),u_*(t))| \geq \alpha \tag{2.15}$$

has to hold a.e. in $[0,1]$ for all $i = 1,\dots,n_c$ and some $\alpha > 0$.

Unfortunately, as a rule for problems of type OCP, η_i or u is continuous and thus condition (2.15) is not satisfied, except for the trivial case that a constraint is nowhere active or active everywhere.

3. Computation of the search direction. For brevity we neglect the arguments whenever possible. The linear operator equation $V_k(d^k) = -F(z^k)$ in step 2 of Algorithm 2.2 reads as

$$\begin{aligned}&\begin{pmatrix} x' \\ \lambda' \end{pmatrix} - \begin{pmatrix} f'_x & 0 \\ -H''_{xx} & -H''_{x\lambda} \end{pmatrix}\begin{pmatrix} x \\ \lambda \end{pmatrix} - \begin{pmatrix} f'_u & 0 \\ -H''_{xu} & -H''_{x\eta} \end{pmatrix}\begin{pmatrix} u \\ \eta \end{pmatrix} \\ &\quad = -\begin{pmatrix} (x^k)' - f \\ (\lambda^k)' + (H'_x)^\top \end{pmatrix}\end{aligned} \tag{3.1}$$

and

$$\begin{aligned}&\begin{pmatrix} \psi'_{x_0} & 0 & 0 \\ (\psi'_{x_0}{}^\top \sigma^k)'_{x_0} & I & \psi'_{x_0}{}^\top \\ -(\psi'_{x_1}{}^\top \sigma^k)'_{x_0} & 0 & -\psi'_{x_1}{}^\top \end{pmatrix}\begin{pmatrix} x(0) \\ \lambda(0) \\ \sigma \end{pmatrix} + \begin{pmatrix} \psi'_{x_1} & 0 & 0 \\ (\psi'_{x_0}{}^\top \sigma^k)'_{x_1} & 0 & 0 \\ -(\psi'_{x_1}{}^\top \sigma^k)'_{x_1} & I & 0 \end{pmatrix}\begin{pmatrix} x(1) \\ \lambda(1) \\ \sigma \end{pmatrix} \\ &= -\begin{pmatrix} \psi(x^k(0),x^k(1)) \\ \lambda^k(0) + \psi'_{x_0}{}^\top \sigma^k \\ \lambda^k(1) - \psi'_{x_1}{}^\top \sigma^k \end{pmatrix}\end{aligned} \tag{3.2}$$

and

$$\mathcal{A}\begin{pmatrix} u \\ \eta \end{pmatrix} + \begin{pmatrix} H''_{ux} & H''_{u\lambda} \\ -Sc'_x & 0 \end{pmatrix}\begin{pmatrix} x \\ \lambda \end{pmatrix} = -\begin{pmatrix} H'_u \\ \omega(z^k(\cdot)) \end{pmatrix}, \tag{3.3}$$

where

$$\mathcal{A} := \begin{pmatrix} H''_{uu} & (c'_u)^\top \\ -Sc'_u & R \end{pmatrix}. \tag{3.4}$$

Herein, every function is evaluated at the current iterate z^k. If the inverse operator $\mathcal{A}^{-1}$ exists, (3.3) can be solved for u and η according to

$$\begin{pmatrix} u \\ \eta \end{pmatrix} = -\mathcal{A}^{-1}\left[\begin{pmatrix} H''_{ux} & H''_{u\lambda} \\ -Sc'_x & 0 \end{pmatrix}\begin{pmatrix} x \\ \lambda \end{pmatrix} + \begin{pmatrix} H'_u \\ \omega(z^k(\cdot)) \end{pmatrix}\right]. \tag{3.5}$$

A sufficient condition for the nonsingularity of $\mathcal{A}$ is given in Theorem 3.2. The constant σ in (3.2) can be viewed as a solution of the differential equation $\sigma' = 0$. Introducing (3.5) into the differential equation (3.1), augmenting this system by $\sigma' = 0$,

and taking into account the boundary conditions (3.2), yields the linear boundary value problem for $\xi = (x, \lambda, \sigma)^\top$:

$$\xi' = B\xi + b, \qquad E_0\xi(0) + E_1\xi(1) = q, \tag{3.6}$$

where

$$B = \begin{pmatrix} f'_x & 0 & 0 \\ -H''_{xx} & -H''_{x\lambda} & 0 \\ 0 & 0 & 0 \end{pmatrix} - \begin{pmatrix} f'_u & 0 \\ -H''_{xu} & -H''_{x\eta} \\ 0 & 0 \end{pmatrix} \mathcal{A}^{-1} \begin{pmatrix} H''_{ux} & H''_{u\lambda} & 0 \\ -Sc'_x & 0 & 0 \end{pmatrix},$$

$$b = -\left[\begin{pmatrix} (x^k)' - f \\ (\lambda^k)' + H'_x{}^\top \\ 0 \end{pmatrix} + \begin{pmatrix} f'_u & 0 \\ -H''_{xu} & -H''_{x\eta} \\ 0 & 0 \end{pmatrix} \mathcal{A}^{-1} \begin{pmatrix} H'_u \\ \omega(z^k(\cdot)) \end{pmatrix} \right],$$

$$E_0 = \begin{pmatrix} \psi'_{x_0} & 0 & 0 \\ (\psi'_{x_0}{}^\top \sigma^k)'_{x_0} & I & \psi'_{x_0}{}^\top \\ -(\psi'_{x_1}{}^\top \sigma^k)'_{x_0} & 0 & -\psi'_{x_1}{}^\top \end{pmatrix},$$

$$E_1 = \begin{pmatrix} \psi'_{x_1} & 0 & 0 \\ (\psi'_{x_0}{}^\top \sigma^k)'_{x_1} & 0 & 0 \\ -(\psi'_{x_1}{}^\top \sigma^k)'_{x_1} & I & 0 \end{pmatrix},$$

$$q = -\begin{pmatrix} \psi(x^k(0), x^k(1)) \\ \lambda^k(0) + \psi'_{x_0}{}^\top \sigma^k \\ \lambda^k(1) - \psi'_{x_1}{}^\top \sigma^k \end{pmatrix}.$$

Hence, in each iteration of Algorithm 2.2 we have to solve the linear boundary value problem (3.6).

If the operator $\mathcal{A}$ is not invertible, the situation becomes more involved. In this case, (3.3) imposes algebraic constraints and (3.1) and (3.3) form a DAE with an index of at least 2. Actually, the case when $\mathcal{A}$ is invertible corresponds to the index 1 case. We will not go into detail here and leave this problem open for future research.

We state a sufficient condition for the existence and boundedness of the inverse operator of $\mathcal{A}$ in (3.4). The proof of this condition uses the Banach lemma [21, Th. 3].

LEMMA 3.1 (Banach lemma). *Let X_1 and X_2 be Banach spaces and $M, \Delta : X_1 \to X_2$ linear and continuous operators. Let M^{-1} exist and let $\|M^{-1}\Delta\| < 1$. Then, the operator $M + \Delta$ possesses an inverse $(M + \Delta)^{-1}$ and*

$$\|(M + \Delta)^{-1}\| \le \frac{1}{1 - \|M^{-1}\Delta\|} \|M^{-1}\|.$$

The following sufficient conditions for the boundedness of $\mathcal{A}^{-1}$ aim at the formulation of conditions that do not assume that the underlying process z satisfies the first-order necessary optimality conditions. This is important in view of globalization of the method as the iterate z^k may be arbitrary.

THEOREM 3.2. *Let $z = (x, u, \lambda, \eta, \sigma) \in Z$ be given. Define the index sets*

$$I_>(t) := \{i \in \{1, \dots, n_c\} \mid c_i[t] = 0,\ \eta_i(t) > 0\},$$
$$J_\gamma(t) := \{i \in \{1, \dots, n_c\} \mid |c_i[t]| \le \gamma\eta_i(t),\ \eta_i(t) \ge 0\}, \qquad \gamma > 0.$$

Let the following assumptions hold at z:

(i) *Let there exist constants* C_1, C_2, C_3 *such that a.e. in* $[0,1]$ *it holds that*

$$\|H''_{uu}[t]\| \le C_1, \quad \|c'_u[t]^\top\| \le C_2, \quad \|c'_u[t]\| \le C_3.$$

(ii) *(Coercivity) Let there exist a constant* $\alpha > 0$ *such that a.e. in* $[0,1]$ *it holds that*

$$d^\top H''_{uu}[t]d \ge \alpha\|d\|^2 \quad \forall \quad d \in \mathbb{R}^{n_u} \ : \ c'_{I_>(t),u}[t]d = 0.$$

(iii) *(Linear independence) Let there exist constants* $\gamma > 0$ *and* $\beta > 0$ *such that a.e. in* $[0,1]$ *it holds that*

$$\|c'_{J_\gamma(t),u}[t]^\top\zeta\| \ge \beta\|\zeta\| \quad \forall\ \zeta \text{ of appropriate dimension.}$$

Then, a.e. in $[0,1]$ *the inverse operator* $\mathcal{A}^{-1}(t)$ *exists and it holds that* $\|\mathcal{A}^{-1}(t)\| \le C$ *for some constant* C.

Proof. In what follows we will make use of the following notation. For an index set $I \subseteq \{1,\dots,n_c\}$ let $S_I := \operatorname{diag}(s_i \mid i \in I)$, $R_I := \operatorname{diag}(r_i \mid i \in I)$, and $A_I := \big(c'_{i,u} \mid i \in I\big)$. Moreover, $I^c := \{1,\dots,n_c\} \setminus I$ denotes the complementary index set of the index set I and $Q := H''_{uu}$.

Without loss of generality, using row and column permutations the operator $\mathcal{A}$ in (3.4) can be partitioned as

$$\mathcal{A}(t) = \begin{pmatrix} Q(t) & A_{I_\varepsilon(t)}(t)^\top & A_{I^c_\varepsilon(t)}(t)^\top \\ -S_{I_\varepsilon(t)}(t)A_{I_\varepsilon(t)}(t) & R_{I_\varepsilon(t)}(t) & 0 \\ -S_{I^c_\varepsilon(t)}(t)A_{I^c_\varepsilon(t)}(t) & 0 & R_{I^c_\varepsilon(t)}(t) \end{pmatrix},$$

where $I_\varepsilon(t)$ is a suitable index set depending on a constant $0 < \varepsilon < 1$. The idea behind this partition is to collect all indices i with $-\varepsilon \le r_i(t) \le 0$ in the set $I_\varepsilon(t)$, i.e.,

$$I_\varepsilon(t) := \{i \in \{1,\dots,n_c\} \mid \ -\varepsilon \le r_i(t) \le 0\}.$$

Consequently, the index set $I^c_\varepsilon(t)$ is given by

$$I^c_\varepsilon(t) = \{i \in \{1,\dots,n_c\} \mid \ -2 \le r_i(t) < -\varepsilon\}.$$

Recall that a.e. in $[0,1]$ we have $(s_i(t), r_i(t)) \in \{(s,r) \in \mathbb{R}^2 \mid (s+1)^2+(r+1)^2 \le 1\}$ and hence a.e. in $[0,1]$ it holds $-2 \le s_i(t) \le 0$ and $-2 \le r_i(t) \le 0$ for all $i \in \{1,\dots,n_c\}$.

Owing to these considerations, a.e. in $[0,1]$ the matrices $R_{I^c_\varepsilon}$ and S_{I_ε} are nonsingular and the following estimates hold (w.r.t. the spectral norm):

$$\|R_{I_\varepsilon}\| \le \varepsilon, \quad \varepsilon < \|R_{I^c_\varepsilon}\| \le 2, \quad \frac{1}{2} \le \|R^{-1}_{I^c_\varepsilon}\| < \frac{1}{\varepsilon},$$

$$0 \le \|S_{I^c_\varepsilon}\| \le 2, \quad 1 - \sqrt{\varepsilon(2-\varepsilon)} \le \|S_{I_\varepsilon}\| \le 2, \quad \frac{1}{2} \le \|S^{-1}_{I_\varepsilon}\| \le \frac{1}{1-\sqrt{\varepsilon(2-\varepsilon)}}.$$

Herein, and in what follows as well, we omit the explicit dependence on t for brevity.

In order to show the nonsingularity of $\mathcal{A}$ we investigate the linear equation

$$\begin{pmatrix} Q & A^\top_{I_\varepsilon} & A^\top_{I^c_\varepsilon} \\ -S_{I_\varepsilon}A_{I_\varepsilon} & R_{I_\varepsilon} & 0 \\ -S_{I^c_\varepsilon}A_{I^c_\varepsilon} & 0 & R_{I^c_\varepsilon} \end{pmatrix} \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix} = \begin{pmatrix} e_1 \\ e_2 \\ e_3 \end{pmatrix}$$

and we will show that $\|\mathcal{A}w\| \geq C\|w\|$ holds for all $w = (w_1, w_2, w_3)^\top$ and some $C > 0$. Since S_{I_ε} and $R_{I_\varepsilon^c}$ are nonsingular, we obtain

$$\begin{pmatrix} Q + A_{I_\varepsilon^c}^\top R_{I_\varepsilon^c}^{-1} S_{I_\varepsilon^c} A_{I_\varepsilon^c} & A_{I_\varepsilon}^\top \\ A_{I_\varepsilon} & -S_{I_\varepsilon}^{-1} R_{I_\varepsilon} \end{pmatrix} \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} = \begin{pmatrix} e_1 - A_{I_\varepsilon^c}^\top R_{I_\varepsilon^c}^{-1} e_3 \\ -S_{I_\varepsilon}^{-1} e_2 \end{pmatrix},$$

$$w_3 = R_{I_\varepsilon^c}^{-1} \left(e_3 + S_{I_\varepsilon^c} A_{I_\varepsilon^c} w_1 \right). \tag{3.7}$$

We will now show that the operator

$$M_\varepsilon := \begin{pmatrix} Q + T & A_{I_\varepsilon}^\top \\ A_{I_\varepsilon} & 0 \end{pmatrix}, \qquad T = A_{I_\varepsilon^c}^\top R_{I_\varepsilon^c}^{-1} S_{I_\varepsilon^c} A_{I_\varepsilon^c},$$

is nonsingular for $\varepsilon > 0$ sufficiently small and that there exists a constant $K > 0$ independent of ε with $\|M_\varepsilon^{-1}\| \leq K$. Notice that T is symmetric and positive semidefinite as $R_{I_\varepsilon^c}^{-1} S_{I_\varepsilon^c}$ is a diagonal matrix with nonnegative entries.

We need to specify the index set I_ε in more detail. It holds that

$$\begin{aligned} I_\varepsilon = \{ & i \in \{1, \ldots, n_c\} \mid |c_i| \leq \delta \eta_i,\ \eta_i > 0 \} \\ & \cup \{ i \in \{1, \ldots, n_c\} \mid c_i = 0,\ \eta_i = 0,\ r_i \geq -\varepsilon \}, \end{aligned} \tag{3.8}$$

where $\delta = \frac{\sqrt{\varepsilon(2-\varepsilon)}}{1-\varepsilon}$. This can be seen as follows. If $|c_i| \leq \delta \eta_i$ and $\eta_i > 0$, then

$$r_i = \frac{\eta_i}{\sqrt{c_i^2 + \eta_i^2}} - 1 \geq \frac{\eta_i}{\sqrt{\delta^2 \eta_i^2 + \eta_i^2}} - 1 = \frac{1}{\sqrt{1+\delta^2}} - 1 = -\left(1 - \frac{1}{\sqrt{1+\delta^2}}\right) = -\varepsilon.$$

Notice that for those indices with $c_i = 0 = \eta_i$ the corresponding values (s_i, r_i) can be chosen arbitrarily from the set $\{(s, r) \in \mathbb{R}^2 \mid (s+1)^2 + (r+1)^2 \leq 1\}$. This explains the second set on the right-hand side of (3.8). On the other hand, if $\eta_i < 0$, then $r_i < -1$. If $\eta_i = 0$ and $c_i \neq 0$, then $r_i = -1$. If $|c_i| > \delta \eta_i$ and $\eta_i > 0$, then as above $r_i < -\varepsilon$. Finally, if $c_i = 0 = \eta_i$ and $r_i < -\varepsilon$, then evidently $r_i \notin I_\varepsilon$.

Notice that $I_> \subseteq I_\varepsilon$ for every $\varepsilon > 0$ as $c_i = 0$ and $\eta_i > 0$ implies $r_i = 0$. Hence,

$$\{ d \in \mathbb{R}^{n_u} \mid A_{I_\varepsilon} d = 0 \} \subseteq \{ d \in \mathbb{R}^{n_u} \mid A_{I_>} d = 0 \} \qquad \forall \varepsilon > 0$$

and (ii) implies

$$d^\top (Q + T) d \geq d^\top Q d \geq \alpha \|d\|^2 \quad \forall \quad d \in \mathbb{R}^{n_u} \ :\ A_{I_\varepsilon} d = 0. \tag{3.9}$$

Now, choose $\varepsilon > 0$ such that $\frac{\sqrt{\varepsilon(2-\varepsilon)}}{1-\varepsilon} \leq \gamma$. Then, $I_\varepsilon \subseteq J_\gamma$ and assumption (iii) imply

$$\|A_{I_\varepsilon}^\top \tilde{\zeta}\| = \|A_{I_\varepsilon}^\top \tilde{\zeta} + A_{J_\gamma \setminus I_\varepsilon}^\top \cdot 0\| \geq \beta \|(\tilde{\zeta}, 0)\| = \beta \|\tilde{\zeta}\| \tag{3.10}$$

for every $\tilde{\zeta}$ of appropriate dimension.

Using (3.9), (3.10), assumption (i), and the same arguments as Hager [14] in the proof of Lemma 3.2, it can be shown that the matrix M_ε is nonsingular and there exists a constant K with $\|M_\varepsilon^{-1}\| \leq K$ for every $\varepsilon > 0$ satisfying $\frac{\sqrt{\varepsilon(2-\varepsilon)}}{1-\varepsilon} \leq \gamma$. It is important to point out that the constant K depends on the constants $C_1, C_2, C_3, \alpha, \beta$ but not on ε.

The operator

$$\Gamma = \begin{pmatrix} Q + T & A_{I_\varepsilon}^\top \\ A_{I_\varepsilon} & -S_{I_\varepsilon}^{-1} R_{I_\varepsilon} \end{pmatrix} = M_\varepsilon + \begin{pmatrix} 0 & 0 \\ 0 & -S_{I_\varepsilon}^{-1} R_{I_\varepsilon} \end{pmatrix} =: M_\varepsilon + \Delta_\varepsilon$$

can be viewed as a perturbation of M_ε with

$$\|\Delta_\varepsilon\| = \|S_{I_\varepsilon}^{-1} R_{I_\varepsilon}\| \le \|S_{I_\varepsilon}^{-1}\| \cdot \|R_{I_\varepsilon}\| \le \frac{\varepsilon}{1-\sqrt{\varepsilon(2-\varepsilon)}}.$$

Let $\varepsilon > 0$ be such that

$$\frac{\varepsilon}{1-\sqrt{\varepsilon(2-\varepsilon)}} < \frac{1}{K}, \qquad \frac{\sqrt{\varepsilon(2-\varepsilon)}}{1-\varepsilon} \le \gamma.$$

Then, $\|\Delta_\varepsilon\| < \frac{1}{\|M_\varepsilon^{-1}\|}$ and according to the Banach lemma, Lemma 3.1, Γ^{-1} exists and there is a constant $\tilde{K}$ with

$$\|\Gamma^{-1}\| \le \tilde{K}.$$

Equation (3.7) yields the estimates

$$\begin{aligned}\|(w_1, w_2)\| &\le \|\Gamma^{-1}\| \left(\|e_1\| + \|A_{I_\varepsilon^c}^\top\| \cdot \|R_{I_\varepsilon^c}^{-1}\| \cdot \|e_3\| + \|S_{I_\varepsilon}^{-1}\| \cdot \|e_2\| \right) \\ &\le \tilde{K} \left(1 + \frac{C_2}{\varepsilon} + \frac{1}{1-\sqrt{\varepsilon(2-\varepsilon)}} \right) \|e\| \\ &=: \tilde{C}\|e\|\end{aligned}$$

and

$$\|w_3\| \le \|R_{I_\varepsilon^c}^{-1}\| \left(\|e_3\| + \|S_{I_\varepsilon^c}\| \cdot \|A_{I_\varepsilon}\| \cdot \|w_1\| \right) \le \frac{1}{\varepsilon} \left(1 + 2C_3\tilde{C} \right) \|e\|.$$

The triangle inequality yields $\|w\| \le \|(w_1, w_2)\| + \|w_3\| \le C\|e\|$, where $C = \tilde{C} + \frac{1}{\varepsilon}(1 + 2C_3\tilde{C})$, and the assertion follows with Ljusternik and Sobolew [21, Th. 1]. □

Remark 3.3. Assumptions (ii) and (iii) of Theorem 3.2 are related to the linear independence condition and the Legendre–Clebsch condition which were imposed in assumptions (A1) and (B) in [25] and in assumptions (A3) and (A4) in [24]. However, they differ in some details. In particular, as the proof indicates, the region of validity of the uniform linear independance condition in (iii) has to be coupled to the value of the multiplier η.

It remains to establish the nonsingularity and the boundedness of the inverse of the linear operator defining the boundary value problem (3.6). This operator $G : W^{1,\infty}([0,1], \mathbb{R}^{2n_x+n_\psi}) \to L^\infty([0,1], \mathbb{R}^{2n_x+n_\psi}) \times \mathbb{R}^{2n_x+n_\psi} =: \Omega$ is defined by

$$G(\xi)(t) = \begin{pmatrix} \xi'(t) - B(t)\xi(t) \\ E_0\xi(0) + E_1\xi(1) \end{pmatrix}$$

with $\|(\omega_1, \omega_2)\|_\Omega = \max\{\|\omega_1\|_\infty, \|\omega_2\|\}$.

THEOREM 3.4. *Let the following assumptions be satisfied:*

(i) *Let there exist a constant C such that a.e. in $[0,1]$ it holds that $\|B(t)\| \le C$.*

(ii) *Let there exist $\kappa > 0$ such that for all $\zeta \in \mathbb{R}^{2n_x+n_\psi}$ it holds that*

$$\| \left(E_0\Phi(0) + E_1\Phi(1) \right) \zeta \| \ge \kappa\|\zeta\|,$$

where Φ is a fundamental solution with $\Phi'(t) = B(t)\Phi(t)$, $\Phi(0) = I$.

Then, the inverse operator G^{-1} exists and it holds $\|G^{-1}\| \le K$ for some constant K.

Proof. The proof uses a similar reasoning as Malanowski and Maurer [24, sect. 4]. Consider the boundary value problem

$$\begin{aligned} \xi'(t) - B(t)\xi(t) &= \omega_1(t), \\ E_0 x(0) + E_1 x(1) &= \omega_2. \end{aligned} \tag{3.11}$$

Since $\|G^{-1}\| = \frac{1}{\inf\{\|G(\xi)\| \mid \|\xi\|_{1,\infty}=1\}}$, we must show that $\|(\omega_1,\omega_2)\|_\Omega \geq \|\xi\|_{1,\infty}/K$ for all $(\omega_1,\omega_2) \in \Omega$ and ξ solving the above linear equation.

Consider the initial value problem

$$\tilde{\xi}'(t) = B(t)\tilde{\xi}(t) + \omega_1(t), \qquad \tilde{\xi}(0) = 0.$$

The solution is given implicitly by

$$\tilde{\xi}(t) = \int_0^t B(\tau)\tilde{\xi}(\tau) + \omega_1(\tau)d\tau.$$

Gronwall's lemma yields

$$\|\tilde{\xi}(t)\| \leq \int_0^t \|B\|_\infty \|\tilde{\xi}(\tau)\| + \|\omega_1(\tau)\| d\tau \leq \|\omega_1\|_\infty \exp(\|B\|_\infty) \leq \|\omega_1\|_\infty \exp(C).$$

Similarly, we find

$$\|\xi(t)\| \leq (\|\xi(0)\| + \|\omega_1\|_\infty)\exp(C).$$

For the fundamental system Φ we obtain

$$\|\Phi(t)\| \leq 1 + \|B\|_\infty \int_0^t \|\Phi(\tau)\| d\tau \leq \exp(\|B\|_\infty) \leq \exp(C).$$

Using the solution formula for linear differential equations we find

$$\xi(t) = \Phi(t)\left(\xi(0) + \int_0^t \Phi(\tau)^{-1}\omega_1(\tau)d\tau\right) = \Phi(t)\xi(0) + \tilde{\xi}(t).$$

Moreover,

$$\left(E_0\Phi(0) + E_1\Phi(1)\right)\xi(0) = \omega_2 - E_1\Phi(1)\int_0^1 \Phi(\tau)^{-1}\omega_1(\tau)d\tau = \omega_2 - E_1\tilde{\xi}(1).$$

It follows that

$$\kappa\|\xi(0)\| \leq \|\omega_2\| + \|E_1\|\|\tilde{\xi}(1)\| \leq \|\omega_2\| + \|E_1\|\|\omega_1\|_\infty \exp(C)$$

and thus

$$\begin{aligned} \|\xi(0)\| &\leq \frac{1}{\kappa}\left(\|\omega_2\| + \|E_1\|\|\omega_1\|_\infty \exp(C)\right) \\ &\leq \frac{1}{\kappa}\left(1 + \|E_1\|\exp(C)\right)\max\{\|\omega_2\|, \|\omega_1\|_\infty\} \\ &=: \kappa_1\|(\omega_1,\omega_2)\|_\Omega. \end{aligned}$$

Hence,

$$\|\xi(t)\| \leq (\|\xi(0)\| + \|\omega_1\|_\infty)\exp(C) \leq (\kappa_1 + 1)\exp(C)\|(\omega_1,\omega_2)\|_\Omega.$$

With $\kappa_2 := (\kappa_1 + 1)\exp(C)$ we proved $\|\xi\|_\infty \le \kappa_2 \|(\omega_1, \omega_2)\|_\Omega$. As

$$\|\xi'(t)\| \le \|B(t)\|\|\xi(t)\| + \|\omega_1(t)\| \le C\kappa_2 \|(\omega_1, \omega_2)\|_\Omega + \|\omega_1\|_\infty$$

holds, we have

$$\|\xi'\|_\infty \le (1 + C\kappa_2)\|(\omega_1, \omega_2)\|_\Omega.$$

With $K := \max\{\kappa_2, 1 + C\kappa_2\}$ we obtain $\|\xi\|_{1,\infty} \le K\|(\omega_1, \omega_2)\|_\Omega$, which shows the assertion. □

Remark 3.5. An alternative way to show the (unique) solvability of the boundary value problem (3.6) can be found in sections 3 and 4 of Malanowski and Maurer [24]. The idea is to interpret the boundary value problem (3.6) as the first-order necessary optimality conditions for a linear-quadratic accessory problem. Then, the unique solvability of the accessory problem is shown under a complete controllability condition and a coercivity condition for the objective function. The latter will be satisfied if—in addition to other assumptions—a suitably defined Riccati equation has a bounded solution.

A combination of Theorems 2.6, 3.2, and 3.4 leads to the following result.

THEOREM 3.6. *Let z_* be a zero of F. Suppose that there exists a constant $\Delta > 0$ such that for every $z \in U_\Delta(z_*)$ the assumptions of Theorems* 3.2 *and* 3.4 *hold with uniform constants. Then, the generalized Jacobian $\partial_* F(z)$ is nonsingular and there exists a constant $C > 0$ such that $\|V^{-1}\|_{\mathcal{L}(Y,Z)} \le C$ for every $V \in \partial_* F(z)$. Moreover, the assertions of Theorem* 2.6 *hold.*

4. Globalization. One reason that the Fischer–Burmeister function is appealing is that its square

$$\phi(a, b) := \varphi(a, b)^2 = \left(\sqrt{a^2 + b^2} - a - b\right)^2$$

is continuously differentiable with $\phi'(a, b) = 2\varphi(a, b)v$, where $v \in \partial\varphi(a, b)$ is arbitrary. Hence, the mappings

$$(\bar{x}, \bar{u}, \bar{\eta}) \in \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^{n_c} \mapsto \phi(-c_i(\bar{x}, \bar{u}), \bar{\eta}_i), \quad i = 1, \dots, n_c,$$

are continuously differentiable by the chain rule. This allows us to globalize the local nonsmooth Newton's method using the squared L^2-norm of F as a merit function:

$$\begin{aligned}
\Theta(z) &:= \frac{1}{2}\|F(z)\|_2^2 \\
&= \frac{1}{2}\int_0^1 \|x'(t) - f(x(t), u(t))\|^2 \, dt \\
&\quad + \frac{1}{2}\int_0^1 \left\|\lambda'(t) + H'_x(x(t), u(t), \lambda(t), \eta(t))^\top\right\|^2 dt \\
&\quad + \frac{1}{2}\int_0^1 \|H'_u(x(t), u(t), \lambda(t), \eta(t))\|^2 \, dt + \frac{1}{2}\sum_{i=1}^{n_c}\int_0^1 \phi(-c_i(x(t), u(t)), \eta_i(t)) dt \\
&\quad + \frac{1}{2}\|\psi(x(0), x(1))\|^2 + \frac{1}{2}\|\lambda(0) + \psi'_{x_0}(x(0), x(1))^\top \sigma\|^2 \\
&\quad + \frac{1}{2}\|\lambda(1) - \psi'_{x_1}(x(0), x(1))^\top \sigma\|^2.
\end{aligned}$$

Θ is Fréchet-differentiable in Z if f_0, f, c, ψ are twice continuously differentiable. An analysis of the derivative of Θ reveals that for d^k with $V_k(d^k) = -F(z^k)$ it holds

$$\Theta'(z^k)(d^k) = -2\Theta(z^k) = -\|F(z^k)\|_2^2. \tag{4.1}$$

As a consequence, d^k is a direction of descent of Θ at z^k and the line search in the following global version of the nonsmooth Newton's method is well defined unless z^k is a zero of F.

ALGORITHM 4.1. GLOBAL NONSMOOTH NEWTON'S METHOD.

(0) *Choose* z^0, $\beta \in (0,1)$, $\sigma \in (0, 1/2)$.

(1) *If some stopping criterion is satisfied, stop.*

(2) *Chose an arbitrary* $V_k \in \partial_* F(z^k)$ *and compute the search direction* d^k *from*

$$V_k(d^k) = -F(z^k).$$

(3) *Find smallest* $i_k \in \mathbb{N}_0$ *with*

$$\Theta(z^k + \beta^{i_k} d^k) \leq \Theta(z^k) + \sigma \beta^{i_k} \Theta'(z^k)(d^k)$$

and set $\alpha_k = \beta^{i_k}$.

(4) *Set* $z^{k+1} = z^k + \alpha_k d^k$, $k = k+1$, *and goto* (1).

The upcoming global convergence proof extends the proof presented in Jiang [18] for finite dimensions into infinite dimensions.

THEOREM 4.2. *Let the inverse operators* V_k^{-1} *exist for all* k *and let* $C > 0$ *be a constant such that* $\|V_k^{-1}\|_{\mathcal{L}(Y,Z)} \leq C$ *holds for all* k. *Let* z_* *be an accumulation point of the sequence* $\{z^k\}$ *generated by the global nonsmooth Newton method.*

Then, z_* *is a zero of* F.

Proof. Let $\{z^{k_j}\}_{j\in\mathbb{N}}$ be a subsequence with $z^{k_j} \to z_*$ and $F(z^{k_j}) \neq 0$. Then, $\Theta'(z^{k_j})(d^{k_j}) = -2\Theta(z^{k_j}) = -\|F(z^{k_j})\|_2^2 < 0$. The line search is well defined by the differentiability of Θ.

(i) Case 1: Assume

$$\alpha := \liminf_{j\to\infty} \alpha_{k_j} > 0.$$

Then

$$0 \leq \Theta(z^{k_j+1}) \leq \Theta(z^{k_j+1}) \leq \Theta(z^{k_j}) + \sigma\alpha_{k_j}\Theta'(z^{k_j})(d^{k_j}) = \Theta(z^{k_j})\left(1 - 2\sigma\alpha_{k_j}\right).$$

With $\sigma \in (0, 1/2)$ and $\alpha \leq \alpha_{k_j} \leq 1$ it follows that $0 < 1 - 2\sigma\alpha_{k_j} \leq 1 - 2\sigma\alpha < 1$, and repeated application yields

$$0 \leq \Theta(z^{k_j}) \leq \Theta(z^{k_0})\,(1 - 2\sigma\alpha)^j \to 0.$$

By the continuity of F, z_* is a zero of F.

(ii) Case 2: Assume that there is a subsequence $\{z^k\}_{k\in J}$, $J \subseteq \{k_j \mid j \in \mathbb{N}\}$ with $\alpha_k \to 0$, $k \in J$.

The sequence $\{d^k\}$ is bounded since $\{V_k^{-1}\}$ is bounded and

$$0 \leq \|d^k\|_Z = \|V_k^{-1}(F(z^k))\|_Z \leq C\|F(z^k)\|_Y \leq C\|F(z^0)\|_Y.$$

Unfortunately, the boundedness of $\{d^k\}$ in an infinite dimensional space does not imply that there exists a convergent subsequence. However, since d^k is

bounded in $Z = W^{1,\infty}([0,1],\mathbb{R}^{n_x}) \times L^\infty([0,1],\mathbb{R}^{n_u}) \times W^{1,\infty}([0,1],\mathbb{R}^{n_x}) \times L^\infty([0,1],\mathbb{R}^{n_c}) \times \mathbb{R}^{n_\psi}$, it is also bounded in the space $\hat{Z} := W^{1,2}([0,1],\mathbb{R}^{n_x}) \times L^2([0,1],\mathbb{R}^{n_u}) \times W^{1,2}([0,1],\mathbb{R}^{n_x}) \times L^2([0,1],\mathbb{R}^{n_c}) \times \mathbb{R}^{n_\psi}$. $\hat{Z}$ is a Hilbert space and thus reflexive. According to Theorem III.3.7 in [33], there exists a weakly convergent subsequence $\{d^k\}$, $k \in \hat{J} \subseteq J$. Hence, there exists some $d_* \in \hat{Z}$ such that for every element $g \in \hat{Z}^*$ it holds that

$$g(d^k) \to g(d_*). \tag{4.2}$$

Herein, $\hat{Z}^*$ denotes the topological dual space of $\hat{Z}$. The derivative $\Theta'(z_*)(\cdot)$ is an element of Z^* and an investigation reveals that it is essentially made up of linear functionals of type

$$g_1(z) = \int_0^1 h_1(z_*(t))z(t)dt, \qquad g_2(z) = \int_0^1 h_2(z_*(t))z'(t)dt$$

with essentially bounded functions $h_1(z_*(\cdot))$ and $h_2(z_*(\cdot))$. Thus, by application of the Cauchy–Schwartz inequality, the functionals g_1 and g_2 are also linear continuous functionals on $\hat{Z}$ and thus g_1, g_2, and in particular $\Theta'(z_*)(\cdot)$ can be viewed as elements of $\hat{Z}^*$.
Hence, (4.2) holds for $g(\cdot) = \Theta'(z_*)(\cdot)$:

$$\Theta'(z_*)(d^k) \to \Theta'(z_*)(d_*).$$

Furthermore, due to the continuity of $\Theta'(\cdot)$ (in Z) for every $\varepsilon > 0$ there exists $\delta > 0$ such that for every $\|z^k - z_*\|_Z \le \delta$ it holds that

$$\begin{aligned}
|\Theta'(z^k)(d^k) - \Theta'(z_*)(d^k)| &= \|d^k\|_Z \left|\Theta'(z^k)\left(\frac{d^k}{\|d^k\|_Z}\right) - \Theta'(z_*)\left(\frac{d^k}{\|d^k\|_Z}\right)\right| \\
&\le \|d^k\|_Z \cdot \sup_{\|d\|_Z=1} |\Theta'(z^k)(d) - \Theta'(z_*)(d)| \\
&= \|d^k\|_Z \cdot \|\Theta'(z^k) - \Theta'(z_*)\|_{\mathcal{L}(Z,\mathbb{R})} \le \varepsilon \|d^k\|_Z.
\end{aligned}$$

For arbitrary $\varepsilon > 0$ we find

$$\begin{aligned}
|\Theta'(z^k)(d^k) - \Theta'(z_*)(d_*)| &\le |\Theta'(z^k)(d^k) - \Theta'(z_*)(d^k)| \\
&\quad + |\Theta'(z_*)(d^k) - \Theta'(z_*)(d_*)| \\
&\le \varepsilon \|d^k\|_Z + |\Theta'(z_*)(d^k) - \Theta'(z_*)(d_*)|.
\end{aligned}$$

Since $\varepsilon > 0$ was arbitrary and since d^k is weakly convergent it holds that

$$\Theta'(z^k)(d^k) \to \Theta'(z_*)(d_*) \qquad \text{as } k \to \infty,\ k \in \hat{J}.$$

In a similar way, the Fréchet differentiability of Θ yields

$$\begin{aligned}
&\left|\frac{1}{\alpha_k}\left(\Theta(z^k + \alpha_k d^k) - \Theta(z^k)\right) - \Theta'(z_*)(d_*)\right| \\
&\le \left|\frac{1}{\alpha_k}\left(\Theta(z^k + \alpha_k d^k) - \Theta(z^k)\right) - \Theta'(z^k)(d^k)\right| + \left|\Theta'(z^k)(d^k) - \Theta'(z_*)(d_*)\right| \\
&\le \frac{1}{\alpha_k} o(\|\alpha_k d^k\|_Z) + \left|\Theta'(z^k)(d^k) - \Theta'(z_*)(d^k)\right| + \left|\Theta'(z_*)(d^k) - \Theta'(z_*)(d_*)\right| \\
&\le \|d^k\|_Z \frac{o(\alpha_k\|d^k\|_Z)}{\alpha_k\|d^k\|_Z} + \varepsilon\|d^k\|_Z + \left|\Theta'(z_*)(d^k) - \Theta'(z_*)(d_*)\right|.
\end{aligned}$$

Since d^k is weakly convergent it holds that

$$\frac{1}{\alpha_k}\left(\Theta(z^k+\alpha_k d^k)-\Theta(z^k)\right)\to\Theta'(z_*)(d_*)\qquad\text{as } k\to\infty,\ k\in\hat{J}.$$

The line search in step 3 of the algorithm yields

$$\begin{aligned}\frac{\Theta(z^k+\alpha_k d^k)-\Theta(z^k)}{\alpha_k}&\le\sigma\Theta'(z^k)(d^k),\\ \frac{\Theta(z^k+\frac{\alpha_k}{\beta}d^k)-\Theta(z^k)}{\frac{\alpha_k}{\beta}}&>\sigma\Theta'(z^k)(d^k).\end{aligned}$$

Passing to the limit and exploiting the previous considerations yields

$$\sigma\Theta'(z_*)(d_*)=\Theta'(z_*)(d_*).$$

Since $\sigma\in(0,1/2)$ this only holds for $\Theta'(z_*)(d_*)=0$. Thus, we have shown

$$-\|F(z^k)\|_2^2=\Theta'(z^k)(d^k)\to\Theta'(z_*)(d_*)=0.$$

By the continuity of F, z_* is a zero of F. □

The previous result shows only that each accumulation point is a zero of F. It would be nice to have also the fast local convergence properties of the local method. The locally superlinear convergence would follow from the local convergence theorem, Theorem 2.3, if we were able to show that $\alpha_k=1$ satisfies Armijo's rule for all sufficiently large k. But unfortunately, this leads to a two-norm discrepancy. The proof of Theorem 2.3 showed the superlinear convergence of the values $\|F(z^k)\|_Y$, i.e., for any $\varepsilon>0$ there exists $\delta>0$ such that for all $\|z-z_*\|\le\delta$ it holds that

$$\|z+d-z_*\|_Z\le\varepsilon\|z-z_*\|_Z,\qquad\|F(z+d)\|_Y\le\varepsilon\|F(z)\|_Y,$$

where $d=-V^{-1}F(z)$, $V\in\partial_*F(z)$. In particular, with $z=z^k$ and $d=d^k$ there exists $\delta>0$ such that for all $\|z^k-z_*\|_Z\le\delta$ it holds that

$$\|z^k+d^k-z_*\|_Z\le\frac{1}{2}\|z^k-z_*\|_Z,\qquad\|F(z^k+d^k)\|_Y\le\sqrt{1-2\sigma}\|F(z^k)\|_Y.$$

Unfortunately, we would need this property not for the norm $\|\cdot\|_Y$ but for the norm $\|\cdot\|_2$ since then

$$\Theta(z^k+d^k)=\frac{1}{2}\|F(z^k+d^k)\|_2^2\le\frac{1-2\sigma}{2}\|F(z^k)\|_2^2=(1-2\sigma)\Theta(z^k),$$

respectively,

$$\Theta(z^k+d^k)\le\Theta(z^k)-2\sigma\Theta(z^k)=\Theta(z^k)+\sigma\Theta'(z^k)(d^k),$$

i.e., Armijo's line search would accept $\alpha_k=1$ and $z^{k+1}=z^k+d^k$. Furthermore, $\|z^{k+1}-z_*\|_Z\le\frac{1}{2}\|z^k-z_*\|_Z\le\delta$ and we are in the same situation as above and the argument could be repeated.

Unfortunately, the superlinear convergence of the residual norms $\|F(z^k)\|_2$ could not be established by now. An additional assumption is needed to prove the fast local convergence.

THEOREM 4.3. *Let the assumptions of Theorem* 4.2 *be valid. Let, in addition, there exist a constant* $K > 0$ *such that*

$$\|F(z^k)\|_Y \le K\|F(z^k)\|_2$$

holds for $\{z^k\}$ *with* $z^k \to z_*$. *Then, for sufficiently large* k *the step length* $\alpha_k = 1$ *is accepted and the global method turns into the local one.*

Proof. Owing to the previous considerations it remains to show that

$$\lim_{k\to\infty} \frac{\|F(z^{k+1})\|_2}{\|F(z^k)\|_2} = 0.$$

Recall that $\|\cdot\|_Y$ is essentially the L^∞-norm. Hence, there exits a constant $C_1 > 0$ with $\|y\|_2 \le C\|y\|_Y$ for all $y \in Y$. Together with the superlinear convergence of the values $\|F(z^k)\|_Y$ in Theorem 2.3 for every $\varepsilon > 0$ and for sufficiently large k it holds that

$$\|F(z^k + d^k)\|_2 \le C\|F(z^k + d^k)\|_Y \le\ C\varepsilon\|F(z^k)\|_Y \le C \cdot K \cdot \varepsilon\|F(z^k)\|_2.$$

Since ε was arbitrary, this shows the superlinear convergence of the values $\|F(z^k)\|_2$. ∎

5. Numerical results. All computations were performed on a PC with 3 GHz processing speed. We used $\|F(z^k)\|^2 \le 10^{-15}$ as a stopping criterion in the nonsmooth Newton method.

5.1. Rayleigh problem, version 1. We illustrate the method for the Rayleigh problem [26, p. 39]. Minimize

$$\int_0^{4.5} u(t)^2 + x_1(t)^2 dt \tag{5.1}$$

subject to

$$\begin{aligned} x_1' &= x_2, & x_1(0) &= -5, \\ x_2' &= -x_1 + x_2\left(1.4 - 0.14x_2^2\right) + 4u, & x_2(0) &= -5, \end{aligned} \tag{5.2}$$

and

$$u + \frac{1}{6}x_1 \le 0.$$

With $x = (x_1, x_2)^\top$, $\lambda = (\lambda_1, \lambda_2)^\top$, $\sigma = (\sigma_1, \sigma_2)^\top$ the Hamilton function reads as

$$H(x, u, \lambda, \eta) = u^2 + x_1^2 + \lambda_1 x_2 + \lambda_2\left(-x_1 + x_2\left(1.4 - 0.14x_2^2\right) + 4u\right) + \eta\left(u + \frac{1}{6}x_1\right).$$

With $z = (x, u, \lambda, \eta, \sigma)$ the function F in (2.9) is given by

$$F(z) = \begin{pmatrix} x_1' - x_2 \\ x_2' - \left(-x_1 + x_2\left(1.4 - 0.14x_2^2\right) + 4u\right) \\ \lambda_1' + 2x_1 - \lambda_2 + \frac{1}{6}\eta \\ \lambda_2' + \lambda_1 + \lambda_2\left(1.4 - 0.42x_2^2\right) \\ x_1(0) + 5 \\ x_2(0) + 5 \\ \lambda_1(0) + \sigma_1 \\ \lambda_2(0) + \sigma_2 \\ \lambda_1(4.5) \\ \lambda_2(4.5) \\ 2u + 4\lambda_2 + \eta \\ \varphi\left(-\left(u + \frac{1}{6}x_1\right), \eta\right) \end{pmatrix}.$$

TABLE 5.1
Output of globalized nonsmooth Newton method for the first version of Rayleigh's problem for $N = 100$ subintervals and Euler discretization: local quadratic convergence.

13	0.100000E+01	0.152582E-25	0.598877E-12

In each iteration of the nonsmooth Newton method we have to solve the linear boundary value problem (3.2), (3.6) for x, λ, σ. We leave the details of the boundary value problem (3.2), (3.6) and equation (3.5) to the reader. We note that for all $(s+1)^2 + (r+1)^2 \leq 1$ it holds

$$\det \mathcal{A} = \det \begin{pmatrix} 2 & 1 \\ -s & r \end{pmatrix} = 2r + s \neq 0$$

and thus the operator $\mathcal{A}$ in (3.4) is invertible. The differential equations are discretized on $[0, 4.5]$ using forward Euler's method with N equidistant subintervals. The occurring derivatives $(x^k)'$ and $(\lambda^k)'$ are approximated by finite forward differences. Moreover, it turned out that it is advisable to scale the boundary conditions and the transversality conditions in the merit function by the step size $h = 1/N$. The boundary value problem was solved by the single shooting method. Table 5.1 shows the output of the globalized nonsmooth Newton method, i.e., step size α, residual norm $\|F\|^2$, and $\|d^k\|$ during iteration. The iterations show the rapid quadratic convergence at the end of the iteration sequence. Recall that only a locally superlinear convergence rate was established in Theorem 2.6.

The following table summarizes results for different step sizes. The number of iterations differs only by one, which indicates—at least numerically—the mesh independence of the method. Furthermore, the CPU time grows at a linear rate with N.

N	CPU time [s]	Iterations
100	0.027	13
500	0.136	14
1000	0.271	14
2000	0.505	14
4000	1.083	14
8000	2.065	14

Figure 5.1 illustrates the iterates of the nonsmooth Newton's method. Notice the small inactive arc of the control-state constraint at the end of the time interval.

For comparison reasons the same optimal control problem was solved alternatively by a direct discretization method as in Gerdts [10] with Euler discretization and $N = 100$ subintervals. For this method the overall CPU time was 3.81 CPU seconds on the same processor. Furthermore, for the direct discretization method the CPU time grows nonlinearly with N. Hence, if all regularity assumptions are fulfilled, the nonsmooth Newton's method is an extremely efficient method.

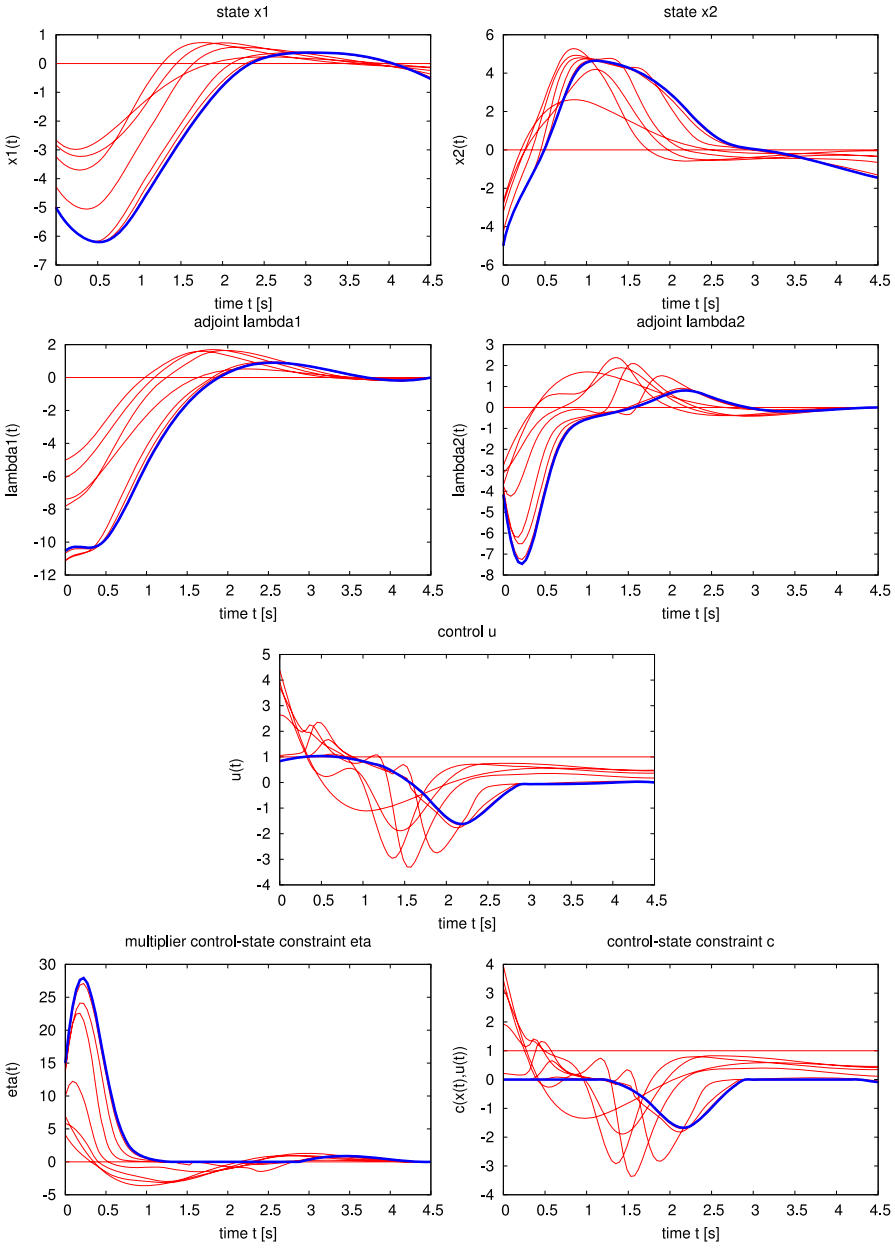

FIG. 5.1. *Numerical solution of the first version of Rayleigh's problem for* $N = 100$ *Euler steps: intermediate iterates (thin lines) and converged solution (thick lines).*

5.2. Rayleigh problem, version 2. We consider a slight variation of the Rayleigh problem where boundary conditions are added and the control-state constraint is replaced by box constraints for the control [26, p. 39]. Minimize (5.1) subject to (5.2) and $x_1(4.5) = 0$, $x_2(4.5) = 0$ and

$$-1 \le u \le 1.$$

With $x = (x_1, x_2)^\top$, $\lambda = (\lambda_1, \lambda_2)^\top$, $\sigma = (\sigma_1, \dots, \sigma_4)^\top$, $\eta = (\eta_1, \eta_2)^\top$ the Hamilton function reads as

$$H(x,u,\lambda,\eta) = u^2 + x_1^2 + \lambda_1 x_2 + \lambda_2\left(-x_1 + x_2\left(1.4 - 0.14x_2^2\right) + 4u\right) + \eta_1(u-1) + \eta_2(-u-1).$$

With $z = (x, u, \lambda, \eta, \sigma)$ the function F in (2.9) is given by

$$F(z) = \begin{pmatrix} x_1' - x_2 \\ x_2' - \left(-x_1 + x_2\left(1.4 - 0.14x_2^2\right) + 4u\right) \\ \lambda_1' + 2x_1 - \lambda_2 \\ \lambda_2' + \lambda_1 + \lambda_2\left(1.4 - 0.42x_2^2\right) \\ x_1(0) + 5 \\ x_2(0) + 5 \\ x_1(4.5) \\ x_2(4.5) \\ \lambda_1(0) + \sigma_1 \\ \lambda_2(0) + \sigma_2 \\ \lambda_1(4.5) - \sigma_3 \\ \lambda_2(4.5) - \sigma_4 \\ 2u + 4\lambda_2 + \eta_1 - \eta_2 \\ \varphi\left(-(u-1), \eta_1\right) \\ \varphi\left(-(-u-1), \eta_2\right) \end{pmatrix}.$$

Again, we leave the details of the linear boundary value problem (3.2), (3.6) and equation (3.5) to the reader. An investigation of the generalized differential of φ yields

$$\det \mathcal{A} = \det \begin{pmatrix} 2 & 1 & -1 \\ -s_1 & r_1 & 0 \\ s_2 & 0 & r_2 \end{pmatrix} = 2r_1r_2 + r_1s_2 + r_2s_1 \neq 0$$

for any $(s_1, r_1) \in \partial\varphi(-(u-1), \eta_1)$ and $(s_2, r_2) \in \partial\varphi(-(-u-1), \eta_2)$. Figure 5.2 illustrates the iterates of the nonsmooth Newton method for $N = 100$. Table 5.2 shows more detailed information about the iterations, i.e., step size α, residual norm $\|F\|^2$, and $\|d^k\|$. Again, the boundary conditions and the transversality conditions in the merit function were scaled by the step size $h = 1/N$. The iterations show the rapid quadratic convergence at the end of the iteration sequence. Recall that only a locally superlinear convergence rate was established in Theorem 2.6.

The number of iterations remains nearly constant, which indicates—at least numerically—the mesh independence of the method. Furthermore, the CPU time grows at a linear rate with N.

N	CPU time [s]	Iterations
100	0.049	17
500	0.204	15
1000	0.502	18
2000	0.848	16
4000	1.785	17
8000	3.713	17

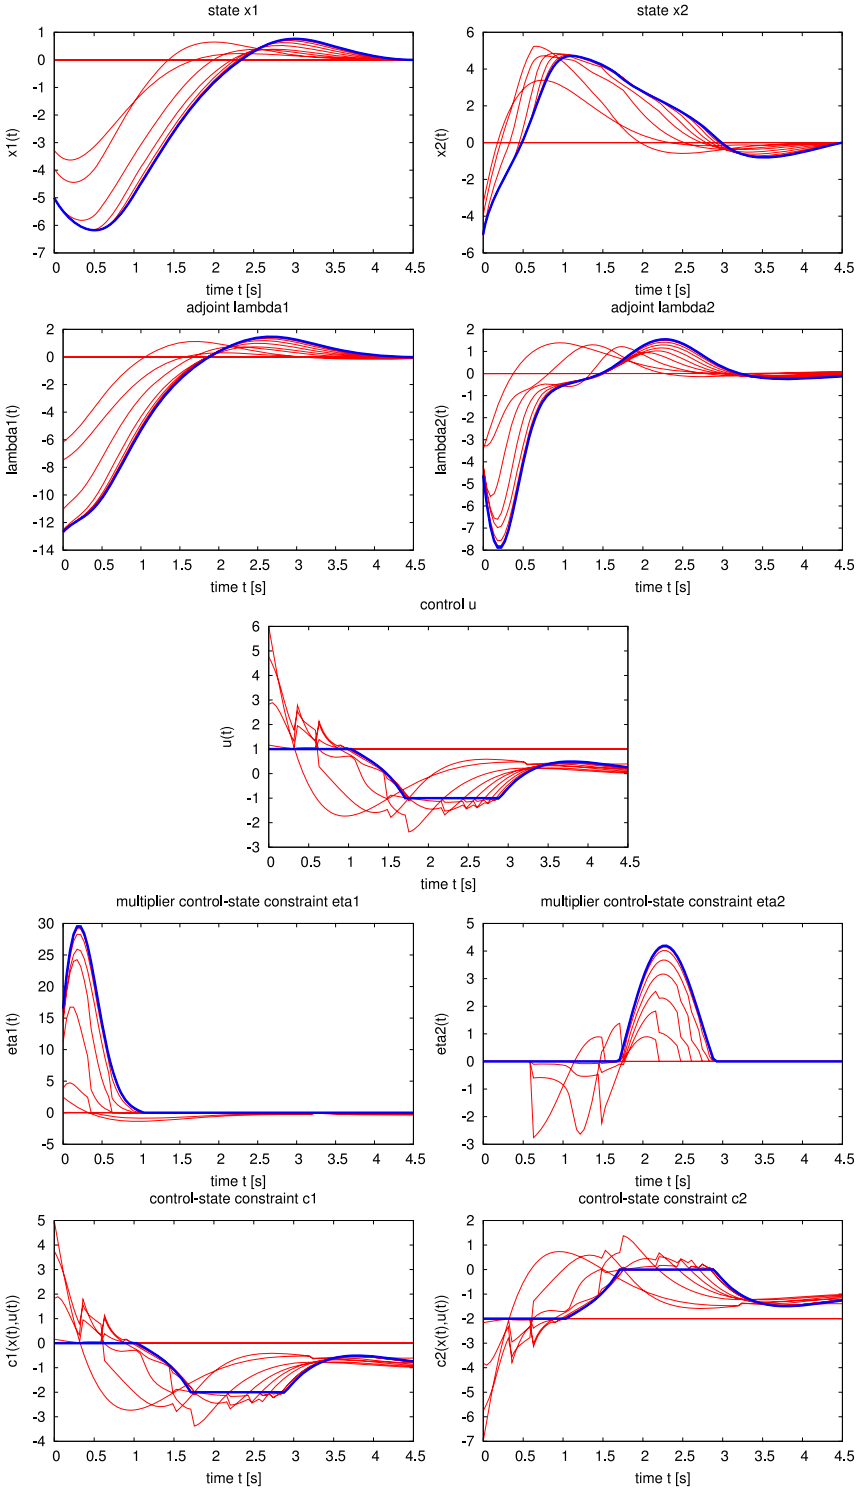

FIG. 5.2. *Numerical solution of the second version of Rayleigh's problem for* $N = 100$ *Euler steps: intermediate iterates (thin lines) and converged solution (thick lines).*

TABLE 5.2
Output of globalized nonsmooth Newton's method for the second version of Rayleigh's problem for $N = 100$ subintervals and Euler discretization: local quadratic convergence.

ITER	ALPHA	||F||^2	||d^k||
0	0.000000E+00	0.205000E+04	0.301353E+08
1	0.898145E-07	0.205000E+04	0.772399E+06
2	0.442969E-05	0.204999E+04	0.137827E+04

...			
14	0.100000E+01	0.485899E-04	0.165212E+00
15	0.100000E+01	0.710910E-07	0.678731E-02
16	0.100000E+01	0.108957E-12	0.842304E-05
17	0.100000E+01	0.271474E-24	0.130452E-10

Again, the same optimal control problem was solved alternatively by a direct discretization method as in Gerdts [10] with Euler discretization and $N = 100$ subintervals. Herein, for better comparableness the control constraints $-1 \leq u \leq 1$ are not viewed as simple box constraints but are treated algorithmically as two nonlinear mixed control-state constraints. For the direct method the overall CPU time was 2.41 CPU seconds. As mentioned before, the CPU time grows at a nonlinear rate with N. Again, if all regularity assumptions are fulfilled, the nonsmooth Newton method turns out to be extremely efficient.

Acknowledgments. The author thanks the anonymous referees for very detailed and helpful comments and suggestions that helped to improve the paper.

AN INEXACT SQP METHOD FOR EQUALITY CONSTRAINED OPTIMIZATION*

RICHARD H. BYRD†, FRANK E. CURTIS‡, AND JORGE NOCEDAL§

Abstract. We present an algorithm for large-scale equality constrained optimization. The method is based on a characterization of inexact sequential quadratic programming (SQP) steps that can ensure global convergence. Inexact SQP methods are needed for large-scale applications for which the iteration matrix cannot be explicitly formed or factored and the arising linear systems must be solved using iterative linear algebra techniques. We address how to determine when a given inexact step makes sufficient progress toward a solution of the nonlinear program, as measured by an exact penalty function. The method is globalized by a line search. An analysis of the global convergence properties of the algorithm and numerical results are presented.

Key words. large-scale optimization, constrained optimization, sequential quadratic programming, inexact linear system solvers, Krylov subspace methods

1. Introduction.

In this paper we discuss an algorithm for equality constrained optimization problems of the form

$$\begin{aligned} &\min_{x\in\mathbb{R}^n} \quad f(x) \\ &\text{subject to (s.t.)} \quad c(x) = 0, \end{aligned} \tag{1.1}$$

where $f : \mathbb{R}^n \to \mathbb{R}$ and $c : \mathbb{R}^n \to \mathbb{R}^t$ are smooth nonlinear functions. Our interest is in methods for very large problems with $t \leq n$ for which the exact computation of steps in contemporary methods can be prohibitively expensive. One class of problems of this type that demands algorithmic improvements are those where the constraint functions are defined by systems of partial differential equations (PDEs).

One of the leading methods for solving constrained optimization problems is sequential quadratic programming (SQP). (In fact, modern interior point methods reduce to SQP when inequality constraints are not present in the problem formulation [18].) Algorithms in this class enjoy global convergence guarantees and typically require few iterations and function evaluations to locate a solution point. A drawback of many contemporary SQP algorithms, however, is that they require explicit representations of exact derivative information and the solution of one or more linear systems during every iteration. The acquisition of these quantities is particularly cumbersome in large-scale settings and the factorization of large iteration matrices is often impractical.

One way to overcome these difficulties is to solve the SQP subproblems approximately using iterative linear algebra techniques. The main purpose of this paper is to determine the accuracy with which the SQP subproblems must be solved in order to ensure global convergence in the context of a practical algorithm for problem (1.1). We both propose such a method and analyze its global behavior.

Our method resembles those in the class of inexact Newton methods for solving nonlinear systems of equations. There are, however, important differences between the two approaches. Inexact Newton methods for systems of equations are controlled by forcing parameters that ensure that the norm of the entire residual of the Newton equations decreases at every iteration [8]. Our approach, on the other hand, is based on a requirement that the step decreases a local approximation of a merit function while also satisfying bounds on the primal and dual components of the residual. We present sets of easily calculable conditions that handle these two components of the residual as separate quantities when determining if a given inexact solution is appropriate for the algorithm to follow. Such a solution may, for example, allow for an increase in the residual corresponding to primal feasibility provided it yields a substantial decrease in dual feasibility, or vice versa. The behavior of these components also helps determine when it is appropriate to increase the penalty parameter in the merit function.

A variety of methods for constrained optimization with inexactness in step computations have been proposed. Jäger and Sachs [14] describe an inexact reduced SQP method in Hilbert space. Lalee, Nocedal, and Plantenga [16], Byrd, Hribar, and Nocedal [5], and Heinkenschloss and Vicente [13] propose composite step trust region approaches where the step is computed as an approximate solution to an SQP subproblem. Similarly, Walther [22] provides a composite step method that allows incomplete constraint Jacobian information. Leibfritz and Sachs [17] analyze an interior point method that benefits from a reformulation of the quadratic programming subproblems as mixed linear complementarity problems. Our approach has some features in common with the algorithms of Biros and Ghattas [1, 2], Haber and Ascher [11], and Prudencio, Byrd, and Cai [20] as we follow a full space SQP method and perform a line search to promote convergence. Unlike these papers, however, we present conditions that guarantee the global convergence of inexact SQP steps.

This paper is organized as follows. In section 2 we provide an overview of our approach and globalization strategy. Section 3 contains details about the most crucial aspect of our algorithm, namely, the sets of conditions used to determine if a given inexact SQP solution is considered an acceptable step. The well-posedness of our approach is also discussed, the accountability of which allows us to present global convergence guarantees under common conditions in section 4. Section 5 provides numerical results to illustrate the robustness of our method. We focus on problems for which overall algorithm performance has been seen to be sensitive to the quality of inexact subproblem solutions. Closing remarks and issues related to extensions of this work are presented in section 6.

2. Outline of the algorithm. Let us formalize a basic SQP approach before clarifying the novelties of our algorithm. The Lagrangian function corresponding to problem (1.1) is

$$\mathcal{L}(x, \lambda) \triangleq f(x) + \lambda^T c(x), \tag{2.1}$$

where $\lambda \in \mathbb{R}^t$ are Lagrange multipliers. If f and c are continuously differentiable, then the first-order optimality conditions for x^* to be an optimal solution to problem (1.1)

state that there exist multipliers λ^* such that (x^*, λ^*) is a solution to the nonlinear system of equations

$$\nabla \mathcal{L}(x, \lambda) = \begin{bmatrix} g(x) + A(x)^T \lambda \\ c(x) \end{bmatrix} = 0, \tag{2.2}$$

where $g(x)$ is the gradient of the objective function and $A(x)$ is the Jacobian of $c(x)$. The components in (x, λ) are referred to as the primal and dual variables, respectively.

An SQP algorithm defines an appropriate displacement d_k in the primal space from the kth iterate x_k as the minimizer of a quadratic model of the objective subject to a linearization of the constraints. The quadratic program can be defined as

$$\begin{aligned} \min_{d \in \mathbb{R}^n} \quad & f(x_k) + g(x_k)^T d + \tfrac{1}{2} d^T W(x_k, \lambda_k) d \\ \text{s.t.} \quad & c(x_k) + A(x_k) d = 0, \end{aligned} \tag{2.3}$$

where

$$W(x, \lambda) \approx \nabla^2_{xx} \mathcal{L}(x, \lambda) = \nabla^2_{xx} f(x) + \sum_{i=1}^{t} \lambda^i \nabla^2_{xx} c^i(x)$$

is equal to, or is a symmetric approximation for, the Hessian of the Lagrangian. Here, $c^i(x)$ and λ^i denote the ith constraint function and its corresponding dual variable, respectively. If the constraint Jacobian $A(x_k)$ has full row rank and $W(x_k, \lambda_k)$ is positive definite on the null space of $A(x_k)$, then a solution to (2.3) is well defined in this context. An alternative characterization of the SQP step d_k is given by the fact that it can equivalently be obtained under similar assumptions as part of the solution to the primal-dual system (see [18])

$$\begin{bmatrix} W(x_k, \lambda_k) & A(x_k)^T \\ A(x_k) & 0 \end{bmatrix} \begin{bmatrix} d_k \\ \delta_k \end{bmatrix} = - \begin{bmatrix} g(x_k) + A(x_k)^T \lambda_k \\ c(x_k) \end{bmatrix} \tag{2.4}$$

constructed by applying Newton's method to (2.2).

An explicit representation of the primal-dual matrix

$$\begin{bmatrix} W(x_k, \lambda_k) & A(x_k)^T \\ A(x_k) & 0 \end{bmatrix} \tag{2.5}$$

and an exact solution of (2.4) can be expensive to obtain, particularly when the factors of (2.5) are not very sparse. We are interested, therefore, in identifying inexact solutions of (2.4) that can also be considered appropriate steps for the algorithm to accept during a given iteration. Such inexact solutions can be obtained in a variety of ways, such as by applying an iterative linear system solver to the primal-dual system. Regardless of the method chosen, for an inexact solution (d_k, δ_k) we define the residual vectors (ρ_k, r_k) by the equation

$$\begin{bmatrix} W(x_k, \lambda_k) & A(x_k)^T \\ A(x_k) & 0 \end{bmatrix} \begin{bmatrix} d_k \\ \delta_k \end{bmatrix} = - \begin{bmatrix} g(x_k) + A(x_k)^T \lambda_k \\ c(x_k) \end{bmatrix} + \begin{bmatrix} \rho_k \\ r_k \end{bmatrix}. \tag{2.6}$$

The step can then be appraised based on properties of the residual vector and other quantities related to the SQP subproblem formulation (2.3). For convex problems, an inexact Newton method intended for nonlinear equations will suffice, provided

that $W(x_k, \lambda_k)$ is the exact Hessian of the Lagrangian [8]. That is, the norm of the right-hand-side vector in (2.4) can serve as a merit function, and convergence can be guaranteed by systematically decreasing this value. For nonconvex problems, however, a step that decreases the first-order optimality error may move away from a minimizer, or may be trapped near a stationary point of the Lagrangian. Thus, merit functions more appropriate to constrained optimization should be considered.

We now outline the algorithm and globalization strategy that will be developed in detail in the following sections. An integral part of the approach is the mechanism used to determine if a trial primal-dual solution (d, δ) to (2.4) is acceptable during a given iteration. For this purpose, we make use of the merit function

$$\phi(x; \pi) \triangleq f(x) + \pi \|c(x)\|, \tag{2.7}$$

where $\pi > 0$ is known as the penalty parameter and $\|\cdot\|$ denotes a norm on $\mathbb{R}^t$. We observe that $\phi(x; \pi)$ is not continuously differentiable, but it is exact in the sense that if π is greater than a certain threshold, then a first-order optimal point of (1.1) is a stationary point of $\phi(x; \pi)$. That is, the directional derivative of $\phi(x; \pi)$ in a direction d, denoted by $D\phi(d; \pi)$, is nonnegative at x^* for all $d \in \mathbb{R}^n$. The challenge is to compute inexact SQP steps and a value for π that ensure progress in the merit function $\phi(x; \pi)$ during every iteration.

Upon the calculation and acceptance of the search direction d_k for a particular value π_k of the penalty parameter, we perform a backtracking line search to compute a steplength coefficient α_k satisfying the Armijo condition

$$\phi(x_k + \alpha_k d_k; \pi_k) \leq \phi(x_k; \pi_k) + \eta \alpha_k D\phi(d_k; \pi_k) \tag{2.8}$$

for some $0 < \eta < 1$. Accordingly, a primal-dual step will be accepted only if its primal component is a descent direction for the merit function.

In summary, our approach follows a standard line search SQP framework. During each iteration, a step is computed as an inexact solution to the primal-dual system (2.6) satisfying appropriate conditions that deem the step acceptable. The penalty parameter is then set based on properties of the computed step, after which a backtracking line search is performed to compute a steplength coefficient α_k satisfying the Armijo condition (2.8). Finally, the iterate is updated along with function and derivative information at the new point. The novelty of our approach, i.e., the precise definition of what constitutes an acceptable step, and the convergence properties of this algorithm are considered in the remainder of this paper.

We drop functional notation throughout the rest of the paper when values are clear from the context and delimit iteration number information for functions as with variables; i.e., we denote $g_k \triangleq g(x_k)$ and similarly for other quantities. All norms are considered Euclidean (or l_2) norms unless otherwise indicated, though much of our analysis will apply for any norm.

3. Step computation and selection. An intuitive condition that one may impose on an inexact SQP step is that the directional derivative of the merit function along the primal component d_k must be sufficiently negative. Such a condition could be used in the development of a globally convergent SQP approach, but quantifying an appropriate steepness of the directional derivative is a difficult task in practice.

As an alternative, let us borrow from an approach commonly employed in trust region methods that begins by considering a local model of the merit function $\phi(x; \pi)$ around the current iterate x_k and the changes in the merit function it predicts for

steps in the primal space. The model has the form

$$m_k(d;\pi) \triangleq f_k + g_k^T d + \max\{\tfrac{1}{2} d^T W_k d, 0\} + \pi \|c_k + A_k d\|,$$

where the max term yields a quadratic model of the objective or a linear one depending on the curvature of W_k along d. With this approximation, we can estimate the reduction in the merit function given by a step d_k by evaluating

$$\begin{aligned} \Delta m_k(d_k;\pi_k) &\triangleq m_k(0;\pi_k) - m_k(d_k;\pi_k) \\ &= -g_k^T d_k - \max\{\tfrac{1}{2} d_k^T W_k d_k, 0\} + \pi_k(\|c_k\| - \|c_k + A_k d_k\|) \\ &= -g_k^T d_k - \max\{\tfrac{1}{2} d_k^T W_k d_k, 0\} + \pi_k(\|c_k\| - \|r_k\|), \end{aligned} \tag{3.1}$$

where the residual $r_k = c_k + A_k d_k$ as in (2.6).

At the heart of our approach is the claim that a given primal-dual step is often beneficial for the algorithm to follow provided the following condition is satisfied.

Model Reduction Condition. *A step (d_k, δ_k) computed in an inexact SQP algorithm must satisfy*

$$\Delta m_k(d_k;\pi_k) \geq \sigma \pi_k \max\{\|c_k\|, \|r_k\| - \|c_k\|\} \tag{3.2}$$

for some $0 < \sigma < 1$ and appropriate $\pi_k > 0$.

We will see the effects of this condition below and in section 4. In particular, (3.2) will indeed ensure that the directional derivative of the merit function is sufficiently negative along the primal step component d_k while also providing a mechanism for determining appropriate values of the penalty parameter. We note that conditions similar to the model reduction condition (3.2) are presented in the context of the inexact composite-step SQP algorithm proposed by Heinkenschloss and Vicente [13]. However, their conditions are applicable only to a step that has been decomposed into basic and nonbasic components, as accuracy is imposed on the components separately. Their approach also differs from the one treated here in that they use a trust region and assume that an approximate reduced Hessian is available.

3.1. Step acceptance conditions. An acceptable step will be required to satisfy one of two sets of conditions. We refer to the conditions as termination tests in reference to algorithms that apply an iterative solver to the primal-dual system (2.4), as in this framework the conditions are used to determine when to terminate the iteration. Each termination test will allow us to ensure that the step satisfies (3.2) for an appropriate value of the penalty parameter and enforces requirements on the residuals (ρ_k, r_k) to ensure convergence to a local solution of (1.1). In addition, the tests impose restrictions on when the algorithm is allowed to increase the penalty parameter in order to satisfy the model reduction condition (3.2).

The first termination test addresses those steps providing a sufficiently large reduction in the model of the merit function for the most recent value of the penalty parameter. We assume that an initial value $\pi_{-1} > 0$ is given.

Termination Test I. *Let $0 < \sigma, \kappa < 1$ be given constants. A step (d_k, δ_k) computed in an inexact SQP algorithm is acceptable if the model reduction condition* (3.2) *holds for $\pi_k = \pi_{k-1}$ and*

$$\left\| \begin{bmatrix} \rho_k \\ r_k \end{bmatrix} \right\| \leq \kappa \left\| \begin{bmatrix} g_k + A_k^T \lambda_k \\ c_k \end{bmatrix} \right\| \tag{3.3}$$

for the residuals (ρ_k, r_k) defined by (2.6).

We claim that Termination Test I allows for productive steps to be taken that may have been computed in a relatively cheap manner, say, after only a few iterations of an iterative solver applied to the primal-dual system (2.4). For steps satisfying this test, given that a sufficient reduction in the model of the merit function has been obtained we need only enforce a generally loose bound on the residual vector. For even greater flexibility one can in fact choose $\kappa \geq 1$ in Termination Test I if the additional condition

$$\|\rho_k\| \leq \max\{\kappa_1 \|g_k + A_k^T \lambda_k\|, \kappa_2 \|c_k\|\}, \quad 0 < \kappa_1 < 1, \ 0 < \kappa_2, \tag{3.4}$$

is enforced. This may be useful, say, when applying our step acceptance criteria when steps are not computed directly via (2.4) or when the use of a left preconditioner for (2.4) produces steps corresponding to residuals larger in norm than the right-hand-side vector $(g_k + A_k^T \lambda_k, c_k)$. All the results in the following sections hold if Termination Test I has $\kappa < 1$ or if (3.4) is included when $\kappa \geq 1$.

The second termination test addresses those steps providing a sufficiently large reduction in the linear model of the constraints.

Termination Test II. *Let $0 < \epsilon < 1$ and $0 < \beta$ be given constants. A step (d_k, δ_k) computed in an inexact SQP algorithm is acceptable if*

$$\|r_k\| \leq \epsilon \|c_k\| \tag{3.5a}$$

$$\text{and} \quad \|\rho_k\| \leq \beta \|c_k\|, \tag{3.5b}$$

where the residuals (ρ_k, r_k) are defined by (2.6).

A step satisfying Termination Test II may not satisfy the model reduction condition (3.2) for $\pi_k = \pi_{k-1}$. Thus, for such steps we require that the penalty parameter be increased to satisfy

$$\pi_k \geq \frac{g_k^T d_k + \max\{\frac{1}{2} d_k^T W_k d_k, 0\}}{(1-\tau)(\|c_k\| - \|r_k\|)} \triangleq \pi_k^{trial} \tag{3.6}$$

for a given $0 < \tau < 1$. Notice from (3.5a) and $0 < \epsilon < 1$ that the denominator in the above expression is positive and along with (3.1) the rule (3.6) implies

$$\Delta m_k(d_k; \pi_k) \geq \tau \pi_k (\|c_k\| - \|r_k\|) \geq \tau(1-\epsilon)\pi_k \|c_k\|. \tag{3.7}$$

Therefore, when (3.5a) is satisfied, the model reduction condition (3.2) holds with $\sigma = \tau(1-\epsilon)$.

In summary, a step (d_k, δ_k) will be required to satisfy Termination Test I or II. In each case, the model reduction condition (3.2) will hold; Termination Test I demands it explicitly and the rule (3.6) is used to enforce it when Termination Test II is satisfied. For consistency between Termination Test I and II and (3.6), one should set $\sigma = \tau(1-\epsilon)$ for Termination Test I.

The complete algorithm is the following. We refer to our step acceptance criteria as SMART tests because they can be characterized as sufficient merit function approximation reduction termination tests.

Algorithm A: Inexact SQP with SMART Tests.
Given parameters $0 < \kappa, \epsilon, \tau, \sigma, \eta < 1$ and $\beta > 0$
Initialize x_0, λ_0, and $\pi_{-1} > 0$
for $k = 0, 1, 2, \ldots$, until a convergence test for (1.1) is satisfied
Compute f_k, g_k, c_k, W_k, and A_k and set $\pi_k \leftarrow \pi_{k-1}$ and $\alpha_k \leftarrow 1$

Compute a step (d_k, δ_k) satisfying Termination Test I or II
if Termination Test II is satisfied and (3.6) does not hold, set $\pi_k \leftarrow \pi_k^{trial} + 10^{-4}$
Perform a backtracking line search to obtain α_k satisfying (2.8)
Set $(x_{k+1}, \lambda_{k+1}) \leftarrow (x_k, \lambda_k) + \alpha_k(d_k, \delta_k)$
endfor

In practice, the step can be computed by producing a sequence of candidate steps $\{(d, \delta)\}$ via the application of an iterative solver to (2.4). The corresponding residuals $\{(\rho, r)\}$ can then be computed and Termination Tests I and II can be evaluated during each iteration or after a few steps of the iterative solver. The constants $(\kappa, \epsilon, \beta)$ should be tuned for a specific application and can significantly influence the practical performance of the algorithm. In particular, the value for β should be chosen to reflect the relationship between the scales of the primal and dual feasibility measures. The scale dependence of such a parameter is not ideal, but a bound similar to (3.5b) is used to ensure the boundedness of the penalty parameter π_k (as we show in Lemma 4.7) if the rule (3.6) is enforced. Since such a method for setting the penalty parameter has proved to work well in practice [23], we employ this update rule in the algorithms in this paper and define β and (3.5b) as given. The constants (τ, σ, η) generally can be set to default values, or, in the case of σ, to promote consistency between Termination Tests I and II. Further discussion of appropriate values for the constants and an example implementation of Algorithm A are given in section 5.

3.2. Well-posedness of the algorithm. It is important to verify that the iterates specified by Algorithm A can be always be computed in practice.

Suppose that (x_k, λ_k) is an iterate that does not satisfy the optimality conditions (2.2). We argue here that whenever A_k has full row rank and W_k is positive definite on the null space of A_k, a sufficiently accurate solution to (2.4) will satisfy either Termination Test I or II. If $c(x_k) \neq 0$, then for (ρ_k, r_k) sufficiently small we have that (3.5), and thus Termination Test II, will be satisfied. Otherwise, if $c(x_k) = 0$, then (3.3) will be satisfied for (ρ_k, r_k) sufficiently small. Then, since W_k is positive definite on the null space of A_k, the solution of (2.4) is the solution to problem (2.3), which means that the solution lies in the null space of A_k and corresponds to a nonpositive objective value of (2.3) (since $d = 0$ is feasible). Therefore, by computing a step with (ρ_k, r_k) sufficiently small, it can easily be seen that (3.2), and thus Termination Test I, will be satisfied.

Once an acceptable step is obtained, we must ensure that a positive steplength parameter α_k can be calculated to satisfy the Armijo condition (2.8). We consider this issue by first presenting the following result.

LEMMA 3.1. *The directional derivative of the merit function $\phi(x; \pi)$ along a step d satisfies*

$$D\phi(d; \pi) \leq g^T d - \pi(\|c\| - \|r\|).$$

Proof. Applying Taylor's theorem, we find for some constant $\gamma_1 > 0$

$$\begin{aligned}
\phi(x + \alpha d; \pi) - \phi(x; \pi) &= f(x + \alpha d) - f(x) + \pi(\|c(x + \alpha d)\| - \|c(x)\|) \\
&\leq \alpha g^T d + \gamma_1 \pi \alpha^2 \|d\|^2 + \pi(\|c(x) + \alpha A d\| - \|c(x)\|) \\
&= \alpha g^T d + \gamma_1 \pi \alpha^2 \|d\|^2 + \pi(\|(1 - \alpha)c(x) + \alpha r\| - \|c(x)\|) \\
&\leq \alpha(g^T d - \pi(\|c(x)\| - \|r\|)) + \gamma_1 \pi \alpha^2 \|d\|^2,
\end{aligned}$$

where $r = c(x) + Ad$ as in (2.6). Dividing both sides by α and taking the limit as $\alpha \to 0$ yields the result. ∎

Given this result, we present the following consequence of our model reduction condition. (A stronger result will be given as Lemma 4.6.)

LEMMA 3.2. *If the model reduction condition* (3.2) *holds for a step* (d_k, δ_k) *and penalty parameter* π_k*, then the directional derivative of the merit function satisfies* $D\phi(d_k; \pi_k) \leq 0$.

Proof. Observe from (3.1) that the inequality (3.2) can be rewritten as

$$g_k^T d_k - \pi_k(\|c_k\| - \|r_k\|) \leq -\max\{\tfrac{1}{2} d_k^T W_k d_k, 0\} - \sigma \pi_k \max\{\|c_k\|, \|r_k\| - \|c_k\|\},$$

so, by Lemma 3.1, a step (d_k, δ_k) satisfying (3.2) yields

$$\begin{aligned} D\phi(d_k; \pi_k) &\leq g_k^T d_k - \pi_k(\|c_k\| - \|r_k\|) \\ &\leq -\max\{\tfrac{1}{2} d_k^T W_k d_k, 0\} - \sigma \pi_k \max\{\|c_k\|, \|r_k\| - \|c_k\|\}, \end{aligned} \tag{3.8}$$

which yields the result. ∎

We have shown under common conditions that an acceptable inexact SQP step (d_k, δ_k) can always be computed by Algorithm A and that steps satisfying the model reduction condition (3.2) correspond to directions of nonincrease for the merit function $\phi(x; \pi_k)$. These results allow us to show that the Armijo condition (2.8) is satisfied by some positive α_k (see Lemma 4.8), and so Algorithm A is well-posed.

We mention in passing that, as a corollary to Lemma 3.1, we may avoid the exact computation of the directional derivative of the merit function along a step d by defining the estimate

$$\tilde{D}\phi(d; \pi) \triangleq g^T d - \pi(\|c\| - \|r\|). \tag{3.9}$$

As such, the Armijo condition (2.8) can be substituted by

$$\phi(x_k + \alpha_k d_k; \pi_k) \leq \phi(x_k; \pi_k) + \eta \alpha_k \tilde{D}\phi(d_k; \pi_k). \tag{3.10}$$

All the analysis in this paper holds when either (2.8) or (3.10) is observed in the line search procedure of Algorithm A. For convenience, we choose to use (3.10).

4. Global analysis. Let us begin our investigation of the global behavior of Algorithm A by making the following assumptions about the problem and the set of computed iterates.

ASSUMPTIONS 4.1. *The sequence* $\{x_k, \lambda_k\}$ *generated by Algorithm* A *is contained in a convex set* Ω *and the following properties hold:*

(a) *The functions* f *and* c *and their first and second derivatives are bounded on* Ω.

(b) *The sequence* $\{\lambda_k\}$ *is bounded.*

(c) *The constraint Jacobians* A_k *have full row rank and their smallest singular values are bounded below by a positive constant.*

(d) *The sequence* $\{W_k\}$ *is bounded.*

(e) *There exists a positive constant* $\mu > 0$ *such that for any* $u \in \mathbb{R}^n$ *with* $u \neq 0$ *and* $A_k u = 0$ *we have* $u^T W_k u \geq \mu \|u\|^2$.

These assumptions are fairly standard for a line search method [12, 19]. Assumption 4.1(a) is a little weaker than the common assumption that the iterates are contained in a compact set. Assumptions 4.1(b) and (c) are strong; we use them to simplify the analysis in order to focus on the issues related to inexactness. It would be of interest in future studies of inexact SQP methods to relax these assumptions. Assuming that W_k is positive definite on the null space of the constraints is natural

for line search algorithms, for otherwise there would be no guarantee of descent. We comment further on the validity of Assumption 4.1(b) in section 6.

We now assume that during iteration k we have obtained an acceptable step (d_k, δ_k) with residuals (ρ_k, r_k) defined by (2.6). We consider the decomposition

$$d_k = u_k + v_k, \tag{4.1}$$

where u_k lies in the null space of the constraint Jacobian A_k and v_k lies in the range space of A_k^T. We do not intend to compute the components explicitly; the decomposition is only for analytical purposes [4, 6]. We refer to u_k, which by definition satisfies $A_k u_k = 0$, as the tangential component and v_k as the normal component of the step.

Our analysis hinges on our ability to classify the effects of two types of steps: those lying sufficiently in the null space of the constraints and those sufficiently orthogonal to the linearized feasible region. We show that such a distinction can be made by observing the relative magnitudes of the normal and tangential components of the primal component d_k.

We first present a result related to the magnitude of the normal step.

LEMMA 4.2. *For all k, the normal component v_k is bounded in norm and for some $\gamma_2 > 0$ satisfies*

$$\|v_k\|^2 \le \gamma_2 \max\{\|c_k\|, \|r_k\|\}. \tag{4.2}$$

Furthermore, for all k such that Termination Test II *is satisfied, there exists $\gamma_3 > 0$ such that*

$$\|v_k\| \le \gamma_3(\|c_k\| - \|r_k\|). \tag{4.3}$$

Proof. From $A_k v_k = -c_k + r_k$ and the fact that v_k lies in the range space of A_k^T, it follows that

$$v_k = A_k^T(A_k A_k^T)^{-1}(-c_k + r_k),$$

and so

$$\|v_k\| \le \|A_k^T(A_k A_k^T)^{-1}\|(\|c_k\| + \|r_k\|). \tag{4.4}$$

This, along with (3.3), the fact that Assumptions 4.1(a) and (b) imply that $\|c_k\|$ and $\|g_k + A_k^T\lambda_k\|$ are bounded, and the fact that Assumptions 4.1(a) and (c) imply that $\|A_k^T(A_k A_k^T)^{-1}\|$ is bounded, implies v_k is bounded in norm for all k. The inequality (4.4) also yields

$$\begin{aligned} \|v_k\|^2 &\le \left(\|A_k^T(A_k A_k^T)^{-1}\|(\|c_k\| + \|r_k\|)\right)^2 \\ &\le \left(2\|A_k^T(A_k A_k^T)^{-1}\| \max\{\|c_k\|, \|r_k\|\}\right)^2 \\ &= \left[4\|A_k^T(A_k A_k^T)^{-1}\|^2 \max\{\|c_k\|, \|r_k\|\}\right] \max\{\|c_k\|, \|r_k\|\}, \end{aligned} \tag{4.5}$$

where (3.3) and Assumptions 4.1(a), (b), and (c) also imply that the bracketed expression in (4.5) is bounded. Thus, (4.2) holds. Finally, if Termination Test II is satisfied, then from (3.5a) and (4.4) we have

$$\begin{aligned} \|v_k\| &\le \|A_k^T(A_k A_k^T)^{-1}\|(1+\epsilon)\|c_k\| \\ &\le \|A_k^T(A_k A_k^T)^{-1}\| \left(\tfrac{1+\epsilon}{1-\epsilon}\right)(\|c_k\| - \|r_k\|), \end{aligned}$$

and so (4.3) holds. ∎

A similar result can be proved for the tangential component.

LEMMA 4.3. *The tangential components* $\{u_k\}$ *are bounded in norm.*

Proof. Assumption 4.1(e), the fact that u_k lies in the null space of the constraint Jacobian A_k, and the first block equation of (2.6) yield

$$\begin{aligned}\mu\|u_k\|^2 &\leq u_k^T W_k u_k \\ &= -g_k^T u_k + \rho_k^T u_k - u_k^T W_k v_k \\ &\leq (\|g_k\| + \|\rho_k\| + \|W_k v_k\|)\|u_k\|,\end{aligned}$$

and so

$$\|u_k\| \leq (\|g_k\| + \|\rho_k\| + \|W_k v_k\|)/\mu.$$

The result follows from the facts that Assumptions 4.1, Lemma 4.2, and the bounds (3.3) and (3.5b) imply that all terms in the right-hand side of this inequality are bounded. ∎

We now turn to the following result addressing the relative magnitudes of the normal and tangential components of a given step.

LEMMA 4.4. *There exists a constant* $\gamma_4 > 0$ *such that if* $\|u_k\|^2 \geq \gamma_4\|v_k\|^2$*, then* $\frac{1}{2}d_k^T W_k d_k \geq \frac{\mu}{4}\|u_k\|^2$.

Proof. Assumption 4.1(e) implies that for any γ_4 such that $\|u_k\|^2 \geq \gamma_4\|v_k\|^2$ we have

$$\begin{aligned}\tfrac{1}{2}d_k^T W_k d_k &= \tfrac{1}{2}u_k^T W_k u_k + u_k^T W_k v_k + \tfrac{1}{2}v_k^T W_k v_k \\ &\geq \tfrac{\mu}{2}\|u_k\|^2 - \|u_k\|\|W_k\|\|v_k\| - \tfrac{1}{2}\|W_k\|\|v_k\|^2 \\ &\geq \left(\frac{\mu}{2} - \frac{\|W_k\|}{\sqrt{\gamma_4}} - \frac{\|W_k\|}{2\gamma_4}\right)\|u_k\|^2.\end{aligned}$$

Thus, Assumption 4.1(d) implies the result holds for a sufficiently large $\gamma_4 > 0$. ∎

With the above results, we can now formalize a distinction between two types of steps. Let $\gamma_4 > 0$ be chosen large enough as described in Lemma 4.4 and consider the sets of indices

$$\begin{aligned}K_1 &\triangleq \{k : \|u_k\|^2 \geq \gamma_4\|v_k\|^2\} \\ \text{and}\quad K_2 &\triangleq \{k : \|u_k\|^2 < \gamma_4\|v_k\|^2\}.\end{aligned}$$

Most of the remainder of our analysis will be dependent on these sets and the corresponding quantity

$$\Theta_k \triangleq \begin{cases} \|u_k\|^2 + \|c_k\|, & k \in K_1, \\ \max\{\|c_k\|, \|r_k\|\}, & k \in K_2. \end{cases}$$

The relevance of Θ_k will be seen in the following three lemmas as a quantity that can be used for bounding the length of the primal step and the directional derivative of the merit function, which will then provide a lower bound for the sequence of steplength coefficients $\{\alpha_k\}$.

LEMMA 4.5. *There exists* $\gamma_5 > 1$ *such that for all* k*,*

$$\|d_k\|^2 \leq \gamma_5\Theta_k$$

and hence

$$\|d_k\|^2 + \|c_k\| \leq 2\gamma_5\Theta_k. \tag{4.6}$$

Proof. For $k \in K_1$, we find

$$\begin{aligned} \|d_k\|^2 &= \|u_k\|^2 + \|v_k\|^2 \\ &\le \left(1 + \tfrac{1}{\gamma_4}\right) \|u_k\|^2 \\ &\le \left(1 + \tfrac{1}{\gamma_4}\right) (\|u_k\|^2 + \|c_k\|). \end{aligned}$$

Similarly, Lemma 4.2 implies that for $k \in K_2$

$$\begin{aligned} \|d_k\|^2 &= \|u_k\|^2 + \|v_k\|^2 \\ &< (\gamma_4 + 1)\|v_k\|^2 \\ &\le (\gamma_4 + 1)\gamma_2 \max\{\|c_k\|, \|r_k\|\}. \end{aligned}$$

To establish (4.6) we note that $\Theta_k + \|c_k\| \le 2\Theta_k$ for all k. ∎

The directional derivative of the merit function can be bounded in a similar manner.

LEMMA 4.6. *There exists $\gamma_6 > 0$ such that for all k,*

$$\tilde{D}\phi(d_k; \pi_k) \le -\gamma_6 \Theta_k.$$

Proof. Recalling (3.8) and (3.9) we have

$$\tilde{D}\phi(d_k; \pi_k) \le -\max\{\tfrac{1}{2} d_k^T W_k d_k, 0\} - \sigma \pi_k \max\{\|c_k\|, \|r_k\| - \|c_k\|\}. \tag{4.7}$$

By Lemma 4.4, we have that $\frac{1}{2} d_k^T W_k d_k \ge \frac{\mu}{4} \|u_k\|^2$ for $k \in K_1$ and thus

$$\tilde{D}\phi(d_k; \pi_k) \le -\tfrac{\mu}{4} \|u_k\|^2 - \sigma \pi_k \|c_k\|.$$

Similarly, for $k \in K_2$ we have from (4.7) that

$$\begin{aligned} \tilde{D}\phi(d_k; \pi_k) &\le -\sigma \pi_k \max\{\|c_k\|, \|r_k\| - \|c_k\|\} \\ &\le -\tfrac{1}{2} \sigma \pi_k \max\{\|c_k\|, \|r_k\|\}. \end{aligned}$$

The result holds for $\gamma_6 = \min\{\frac{\mu}{4}, \frac{1}{2}\sigma\pi_k\}$, which is bounded away from zero as $\{\pi_k\}$ is nondecreasing. ∎

Another important property of Algorithm A is that under Assumptions 4.1 the penalty parameter remains bounded. We prove this result in the following lemma, illustrating the importance of the bound (3.5b).

LEMMA 4.7. *The sequence of penalty parameters $\{\pi_k\}$ is bounded above and $\pi_k = \pi_{\bar{k}}$ for all $k \ge \bar{k}$ for some $\bar{k} \ge 0$.*

Proof. Recall that the penalty parameter is increased during iteration k of Algorithm A only if Termination Test II is satisfied. Therefore, for the remainder of this proof let us assume that Termination Test II is satisfied and so the inequalities in (3.5) hold. By (3.6) the parameter π_k is chosen to satisfy the first inequality in (3.7), namely,

$$\Delta m_k(d_k; \pi_k) \ge \tau \pi_k (\|c_k\| - \|r_k\|), \tag{4.8}$$

where, according to the first block equation of (2.6), we can rewrite the model reduction as

$$\begin{aligned} \Delta m_k(d_k; \pi_k) &= \pi_k(\|c_k\| - \|r_k\|) - g_k^T d_k - \max\{\tfrac{1}{2} d_k^T W_k d_k, 0\} \\ &= \pi_k(\|c_k\| - \|r_k\|) \\ &\quad + \begin{cases} -g_k^T v_k - \frac{1}{2} v_k^T W_k v_k - \rho_k^T u_k + \frac{1}{2} u_k^T W_k u_k & \text{if } \frac{1}{2} d_k^T W_k d_k \ge 0 \\ -g_k^T v_k - (\rho_k - W_k v_k)^T u_k + u_k^T W_k u_k & \text{otherwise.} \end{cases} \end{aligned}$$

The result follows from our ability to bound the terms in the second line of this expression with respect to the constraint reduction.

If $\frac{1}{2}d_k^T W_k d_k \geq 0$, then under Assumptions 4.1 we have that Lemmas 4.2 and 4.3 and the bounds (3.5) on the residuals (ρ_k, r_k) imply that there exists $\gamma_7, \gamma_7' > 0$ such that

$$\begin{aligned} -g_k^T v_k - \tfrac{1}{2}v_k^T W_k v_k - \rho_k^T u_k + \tfrac{1}{2}u_k^T W_k u_k &\geq -\|g_k\|\|v_k\| - \tfrac{1}{2}\|W_k\|\|v_k\|^2 - \|\rho_k\|\|u_k\| \\ &\geq -\gamma_7(\|v_k\| + \|\rho_k\|) \\ &\geq -\gamma_7\left(\gamma_3 + \tfrac{\beta}{1-\epsilon}\right)(\|c_k\| - \|r_k\|) \\ &= -\gamma_7'(\|c_k\| - \|r_k\|). \end{aligned}$$

Similarly, if $\frac{1}{2}d_k^T W_k d_k < 0$, then under Assumptions 4.1 we again find that Lemmas 4.2 and 4.3 and the bounds (3.5) on the residuals (ρ_k, r_k) imply that there exists $\gamma_8, \gamma_8' > 0$ such that

$$\begin{aligned} -g_k^T v_k - (\rho_k - W_k v_k)^T u_k + u_k^T W_k u_k &\geq -\|g_k\|\|v_k\| - \|\rho_k\|\|u_k\| - \|v_k\|\|W_k\|\|u_k\| \\ &\geq -\gamma_8(\|v_k\| + \|\rho_k\|) \\ &\geq -\gamma_8\left(\gamma_3 + \tfrac{\beta}{1-\epsilon}\right)(\|c_k\| - \|r_k\|) \\ &= -\gamma_8'(\|c_k\| - \|r_k\|). \end{aligned}$$

These results together imply

$$\Delta m_k(d_k; \pi_k) \geq (\pi_k - \max\{\gamma_7', \gamma_8'\})(\|c_k\| - \|r_k\|),$$

and so (4.8) is always satisfied for

$$\pi_k \geq \max\{\gamma_7', \gamma_8'\}/(1-\tau).$$

Therefore, if $\pi_{\bar{k}} \geq \max\{\gamma_7', \gamma_8'\}/(1-\tau)$ for some $\bar{k} \geq 0$, then $\pi_k = \pi_{\bar{k}}$ for $k \geq \bar{k}$. This, along with the fact that whenever Algorithm A increases the penalty parameter it does so by at least a positive finite amount, proves the result. ∎

The previous three lemmas can be used to bound the sequence of steplength coefficients.

LEMMA 4.8. *The sequence $\{\alpha_k\}$ is bounded below and away from zero.*

Proof. Recall that the line search requires (3.10), which we rewrite for convenience as

$$\phi(x_k + \alpha_k d_k; \pi_k) - \phi(x_k; \pi_k) \leq \eta\alpha_k \tilde{D}\phi(d_k; \pi_k).$$

Suppose that the line search fails for some $\bar{\alpha} > 0$, so

$$\phi(x_k + \bar{\alpha} d_k; \pi_k) - \phi(x_k; \pi_k) > \eta\bar{\alpha} \tilde{D}\phi(d_k; \pi_k).$$

From the proof of Lemma 3.1 and (3.9) we have

$$\phi(x_k + \bar{\alpha} d_k; \pi_k) - \phi(x_k; \pi_k) \leq \bar{\alpha}\tilde{D}\phi(d_k; \pi_k) + \bar{\alpha}^2\gamma_1\pi_k\|d_k\|^2,$$

so

$$(\eta - 1)\tilde{D}\phi(d_k; \pi_k) \leq \bar{\alpha}\gamma_1\hat{\pi}\|d_k\|^2.$$

Here, $\hat{\pi}$ is a finite upper bound for the sequence $\{\pi_k\}$ whose existence follows from Lemma 4.7. Lemmas 4.5 and 4.6 then yield

$$(1-\eta)\gamma_6\Theta_k < \bar{\alpha}\gamma_1\gamma_5\hat{\pi}\Theta_k,$$

so

$$\bar{\alpha} > (1-\eta)\gamma_6/(\gamma_1\gamma_5\hat{\pi}).$$

Thus, α_k need never be set below $(1-\eta)\gamma_6/(\gamma_1\gamma_5\hat{\pi})$ for (3.10) to be satisfied. ∎

We can now present the following result related to the lengths of the primal components of the steps computed in Algorithm A and the convergence of the iterates toward the feasible region of problem (1.1).

LEMMA 4.9. *Algorithm* A *yields*

$$\lim_{k\to\infty}\|c_k\| = 0 \quad \textit{and} \quad \lim_{k\to\infty}\|d_k\| = 0.$$

Proof. For all k, it can easily be seen that

$$\phi(x_k;\pi_k) - \phi(x_k+\alpha_k d_k;\pi_k) \geq \gamma_9\Theta_k$$

for some $\gamma_9 > 0$ follows from (3.10) and Lemmas 4.6 and 4.8. By Lemma 4.7 the algorithm eventually computes, during iteration $\bar{k} \geq 0$, a finite value $\pi_{\bar{k}}$ beyond which the penalty parameter will never be increased. Therefore, the penalty parameter remains unchanged for $k \geq \bar{k}$, and for all $k > \bar{k}$ (4.6) implies

$$\begin{aligned}\phi(x_{\bar{k}};\pi_{\bar{k}}) - \phi(x_k;\pi_{\bar{k}}) &= \sum_{j=\bar{k}}^{k-1}(\phi(x_j;\pi_{\bar{k}}) - \phi(x_{j+1};\pi_{\bar{k}})) \\ &\geq \gamma_9\sum_{j=\bar{k}}^{k-1}\Theta_j \\ &\geq \frac{\gamma_9}{2\gamma_5}\sum_{j=\bar{k}}^{k-1}(\|d_j\|^2 + \|c_j\|).\end{aligned}$$

The result follows from the above and the fact that Assumption 4.1(a) implies $\phi(x;\pi_{\bar{k}})$ is bounded below. ∎

We are now ready to present the main result of this section.

THEOREM 4.10. *Algorithm* A *yields*

$$\lim_{k\to\infty}\left\|\begin{bmatrix} g_k + A_k^T\lambda_k \\ c_k \end{bmatrix}\right\| = 0.$$

Proof. Recall that $\alpha_k \leq 1$ for all k and from Lemma 4.8 we have that $\{\alpha_k\}$ is bounded below and away from zero. An expansion of the first block of the optimality conditions (2.2) yields

$$\|g_{k+1} + A_{k+1}^T\lambda_{k+1}\| \leq \|g_k + A_k^T\lambda_k + \alpha_k(\nabla_{xx}^2\mathcal{L}_k d_k + A_k^T\delta_k)\| + \alpha_k^2 E(d_k,\delta_k),$$

where

$$E(d_k,\delta_k) = O(\|d_k\|^2 + \|d_k\cdot\delta_k\|).$$

This, along with the first block equation in (2.6) and Assumptions 4.1, implies

$$\begin{aligned}
&\|g_{k+1} + A_{k+1}^T \lambda_{k+1}\| \\
&\quad \leq \|g_k + A_k^T \lambda_k + \alpha_k (W_k d_k + A_k^T \delta_k) + \alpha_k (\nabla_{xx}^2 \mathcal{L}_k - W_k) d_k\| + \alpha_k^2 E(d_k, \delta_k) \\
&\quad \leq \|g_k + A_k^T \lambda_k + \alpha_k (\rho_k - g_k - A_k^T \lambda_k)\| + \alpha_k \|(\nabla_{xx}^2 \mathcal{L}_k - W_k) d_k\| + \alpha_k^2 E(d_k, \delta_k) \\
&\quad \leq (1 - \alpha_k)\|g_k + A_k^T \lambda_k\| + \alpha_k \|\rho_k\| + \alpha_k E'(d_k, \delta_k),
\end{aligned} \tag{4.9}$$

where

$$E'(d_k, \delta_k) = O(\|d_k\| + \|d_k\|^2 + \|d_k \cdot \delta_k\|). \tag{4.10}$$

The bounds (3.3) and (3.5b) and the triangle inequality imply

$$\|\rho_k\| \leq \max\{\kappa(\|g_k + A_k^T \lambda_k\| + \|c_k\|), \beta \|c_k\|\},$$

which, along with (4.9) and the boundedness of $\{\alpha_k\}$, implies that for some $0 < \gamma_{10} < 1$ and $\gamma_{11} > 0$ we have

$$\|g_{k+1} + A_{k+1}^T \lambda_{k+1}\| \leq \max\{(1 - \gamma_{10})\|g_k + A_k^T \lambda_k\|, \gamma_{11}\|c_k\|\} + \alpha_k E'(d_k, \delta_k). \tag{4.11}$$

The boundedness of $\{\alpha_k\}$, Lemma 4.9, and the fact that Assumption 4.1(b) implies δ_k is bounded in norm imply, along with (4.10), that

$$\lim_{k \to \infty} \alpha_k E'(d_k, \delta_k) = 0. \tag{4.12}$$

Consider an arbitrary $\hat{\gamma} > 0$. Lemma 4.9 and the limit (4.12) imply that there exists $k' \geq 0$ such that for all $k \geq k'$ we have

$$\gamma_{11}\|c_k\| < (1 - \gamma_{10})\hat{\gamma} \quad \text{and} \quad \alpha_k E'(d_k, \delta_k) < \tfrac{1}{2}\gamma_{10}\hat{\gamma}. \tag{4.13}$$

Suppose $k \geq k'$ and $\|g_k + A_k^T \lambda_k\| > \hat{\gamma}$. We find from (4.11) that

$$\begin{aligned}
\|g_{k+1} + A_{k+1}^T \lambda_{k+1}\| &\leq (1 - \gamma_{10})\|g_k + A_k^T \lambda_k\| + \tfrac{1}{2}\gamma_{10}\hat{\gamma} \\
&\leq \|g_k + A_k^T \lambda_k\| - \tfrac{1}{2}\gamma_{10}\hat{\gamma}.
\end{aligned}$$

Therefore, $\{\|g_k + A_k^T \lambda_k\|\}$ decreases monotonically by at least a constant amount for $k \geq k'$ while $\{\|g_k + A_k^T \lambda_k\|\} > \hat{\gamma}$, so we eventually find $\|g_k + A_k^T \lambda_k\| \leq \hat{\gamma}$ for some $k = k'' \geq k'$. Then, for $k \geq k''$ we find from (4.11) and (4.13) that

$$\begin{aligned}
\|g_{k+1} + A_{k+1}^T \lambda_{k+1}\| &\leq (1 - \gamma_{10})\hat{\gamma} + \tfrac{1}{2}\gamma_{10}\hat{\gamma} \\
&\leq (1 - \tfrac{1}{2}\gamma_{10})\hat{\gamma},
\end{aligned}$$

so $\|g_k + A_k^T \lambda_k\| \leq \hat{\gamma}$ for all $k \geq k''$. Since the above holds for any $\hat{\gamma} > 0$, we have

$$\lim_{k \to \infty} \|g_k + A_k^T \lambda_k\| = 0,$$

and so the result follows with the above and the result of Lemma 4.9. ∎

5. An implementation. This section contains a description of a particular implementation of Algorithm A and corresponding numerical results to illustrate the robustness of our approach. Note that, for the greatest level of generality within our framework, we implemented Termination Test I with $\kappa \geq 1$ and (3.4) included. A study of the efficiency of the new algorithm in realistic applications is devoted to a separate study [7].

We developed a Matlab implementation of Algorithm A in which the generalized minimum residual (GMRES) method [21] was used for the step computation, for which we adapted the implementation by Kelley [15]. The GMRES method does not exploit the symmetry of the matrix (2.5) in the primal-dual system (2.6), but the stability of the approach is ideal for illustrating the robustness of Algorithm A.

In terms of the input parameters defined throughout the paper, we make the following general comments on their practical effects. First, the values $(\kappa, \kappa_1, \kappa_2)$ and (ϵ, β) should receive special attention as they may greatly affect the ease with which Termination Tests I and II, and therefore the model reduction condition (3.2), are satisfied; larger values for these constants allow for more steps to satisfy at least one of the tests at a given point. In general, looser bounds in Termination Tests I and II will result in cheaper step computations, but these savings must be balanced against possible increases in the number of outer iterations required to find a solution. These parameters and (σ, τ) may also affect the number of iterations required until the penalty parameter stabilizes, an important phenomenon in the analysis of section 4; e.g., larger values of (ϵ, β) may lead to more increases or larger values of π_k or both. In general, however, we claim that the parameters (σ, τ) can be set to default values or to promote consistency between the two termination tests, as we do in (5.3) below.

The stopping condition for the overall nonlinear program is given by

$$\|g_k + A_k^T \lambda_k\|_\infty \leq \max\{\|g_k\|_\infty, 1\}\epsilon_{opt}, \tag{5.1}$$

$$\|c_k\|_\infty \leq \max\{\|c_0\|_\infty, 1\}\epsilon_{feas}, \tag{5.2}$$

where $0 < \epsilon_{opt}, \epsilon_{feas} < 1$ and x_0 is the starting point (e.g., see [23]).

The following algorithm was implemented in Matlab and will be referred to as `isqp`. The `termination` variable is used to indicate the successful or unsuccessful termination of the solver near a local solution of problem (1.1).

ALGORITHM B: INEXACT SQP WITH GMRES AND SMART TESTS.
Given parameters $0 < \epsilon_{feas}, \epsilon_{opt}, \kappa_1, \epsilon, \tau, \sigma, \eta, \alpha_{\min} < 1$ and $0 < k_{\max}, \beta, \kappa, \kappa_2$
Initialize x_0, λ_0, and $\pi_{-1} > 0$
Set `termination` $\leftarrow$ `success`
for $k = 0, 1, 2, \ldots, k_{max}$, or until (5.1) and (5.2) are satisfied
  Compute f_k, g_k, c_k, W_k, and A_k and set $\pi_k \leftarrow \pi_{k-1}$ and $\alpha_k \leftarrow 1$
  for $j = 0, 1, 2, \ldots, n + t$, or until Termination Test I or II is satisfied
    Set (d_k, δ_k) as the jth GMRES solution
  endfor
  if $\tilde{D}\phi(d_k; \pi) > 0$ for all $\pi \geq \pi_k$, set `termination` $\leftarrow$ `failure` and **break**
  if Termination Test II is satisfied and (3.6) does not hold, set $\pi_k \leftarrow \pi_k^{trial} + 10^{-4}$
  while (3.10) is not satisfied and $\alpha_k \geq \alpha_{\min}$, set $\alpha_k \leftarrow \alpha_k/2$
  if $\alpha_k < \alpha_{\min}$, set `termination` $\leftarrow$ `failure` and **break**
  Set $(x_{k+1}, \lambda_{k+1}) \leftarrow (x_k, \lambda_k) + \alpha_k(d_k, \delta_k)$
endfor
if (5.1) or (5.2) is not satisfied, set `termination` $\leftarrow$ `failure`
return `termination`

TABLE 5.1
Input parameter values used for Algorithm B.

Parameter	Value	Parameter	Value
ϵ_{feas}	10^{-6}	η	10^{-8}
ϵ_{opt}	10^{-6}	$\alpha_{\min}$	10^{-8}
κ_1	0.1	$k_{\max}$	1000
ϵ	0.1	κ	1
τ	0.1	π_{-1}	1

We recognize three types of failures in the above approach. First, due to the iteration limit $(n + t)$ imposed on the inner **for** loop, or if the positive definiteness of Assumption 4.1(e) is violated, GMRES may not provide a solution satisfying Termination Test I or II. In this case, we will try to use the step d_k anyway, and, if necessary, we will try increasing π_k to yield a positive value for the directional derivative $D\phi(d_k; \pi_k)$. However, if the directional derivative is nonnegative for any value $\pi \geq \pi_{k-1}$ of the penalty parameter, then the step is an ascent direction for the merit function and the algorithm terminates. Second, if the steplength coefficient must be cut below a given $\alpha_{\min}$ in order to obtain a step satisfying the Armijo condition, then the search direction is deemed unsuitable and the algorithm fails. Since we have a descent direction, this failure can occur only due to finite precision arithmetic errors or if $\alpha_{\min}$ is too large relative to the curvature of the functions. Finally, if the algorithm terminates without satisfying the nonlinear program stopping conditions (5.1) and (5.2), then the maximum number of iterations has been reached. Though there exist techniques for continuing a stagnated run of the algorithm when an ascent direction for the merit function or a short steplength coefficient is computed, we implement naïve failure tests in Algorithm B to aggressively challenge the robustness of our approach.

Table 5.1 contains a listing of the input parameters implemented in our code. For the remaining parameters, we set, as is generally appropriate,

$$\sigma \leftarrow \tau(1 - \epsilon) \tag{5.3}$$

$$\text{and} \quad \kappa_2 \leftarrow \beta \leftarrow \max\left\{ \frac{\|g_0 + A_0^T \lambda_0\|}{\|c_0\| + 1}, 1 \right\}.$$

As previously mentioned, this value for σ promotes consistency between Termination Tests I and II and (3.6). Such a value for κ_2 and β aims to reflect the relationship in scale between the primal and dual feasibility measures.

We compare Algorithm B with an inexact method that only enforces a reduction in the entire primal-dual residual. Our implementation of this approach, also done in Matlab, is identical to Algorithm B except that the GMRES stopping test

for $j = 0, 1, 2, \ldots, n + t$, *or until Termination Test* I *or* II *is satisfied*

is replaced by

for $j = 0, 1, 2, \ldots, n + t$, *or until* (3.3) *is satisfied*,

where $0 < \kappa < 1$ for (3.3) is a given constant. We performed multiple runs of this algorithm, which we call `ires`, for each problem in the test set and will refer to each run by the particular value of κ used.

The algorithms described above were run for 44 equality constrained problems from the CUTEr [3, 10] and COPS [9] collections. Problems from the CUTEr set for

TABLE 5.2

Algorithm success rates; comparison between an inexact SQP method based on the entire residual of the Newton equations and `isqp`*, the algorithm proposed in this paper.*

Algorithm	`ires`										`isqp`
κ	2^{-1}	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}	2^{-9}	2^{-10}	-
% Solved	45%	66%	68%	80%	80%	77%	82%	82%	86%	86%	100%

which AMPL models were available were selected based on size—fewer than 10,000 variables—and two moderately sized COPS problems were chosen. We note that W_k was set to the exact Hessian of the Lagrangian and that a multiple of the identity matrix was added to W_k, when necessary, to satisfy the positive definiteness of Assumption 4.1(e). Also, as the results provided in this section are intended only as a simple illustration of the robustness of our approach, we did not implement a preconditioner for the primal-dual system for our numerical experiments and, in fact, this was not an issue as many of the problems are relatively small in size. We stress, however, that preconditioning is an essential part of any implementation for many large-scale problems.

Table 5.2 provides the percentage of problems successfully solved for each of the solvers. All the failures for the `ires` algorithm occurred because either the directional derivative $D\phi(d_k;\pi)$ of the merit function was nonnegative for all allowable values of the penalty parameter $\pi \geq \pi_{k-1}$ or the backtracking line search reduced the steplength coefficient α_k below the given tolerance $\alpha_{\min}$. Thus, we find that even for relatively small values of the tolerance parameter κ, the primal component d_k provided by GMRES can yield a value for the directional derivative $D\phi(d_k;\pi)$ of the merit function that is not sufficiently negative for any $\pi \geq \pi_{k-1}$. In other words, `ires` runs the risk of computing near-exact solutions of the primal-dual system (2.4) that correspond to directions of insufficient decrease for the merit function $\phi(x;\pi_k)$.

6. Final remarks. In this paper we have developed an inexact SQP algorithm for equality constrained optimization that is globally convergent under common conditions. The novelties of the approach are centered around a pair of SMART tests for controlling the level of inexactness in the step computation procedure. We close with some remarks about the assumptions used in the paper, the rate of convergence of our approach, and possible extensions of this work.

First, let us recall the boundedness of the multipliers stated in Assumption 4.1(b). Our analysis does not guarantee that the multipliers remain bounded in general; in fact, Algorithm A does not exert direct control over them. We can ensure that $\{\lambda_k\}$ remains bounded, however, by adding to Termination Test I a requirement of the form

$$\|\rho_k\| \leq \kappa' \max\{\|g_k\|, \|A_k\|\}$$

for a constant $\kappa' > 0$. Such a condition ensures that ρ_k is bounded independently of the multipliers λ_k, so then (2.6) and Assumptions 4.1 will imply that $\{\lambda_k\}$ is bounded. An alternative would be to include a safeguard in the algorithm by which the multiplier estimate λ_k is set to a nominal value, say, $\lambda_k = 0$, if $\|g_k + A_k^T\lambda_k\|$ is larger than a given constant.

Second, the rate of convergence of Algorithm A may be slow for a given problem. One can ensure a fast convergence rate, however, by imposing at each step a

requirement of the form

$$\left\| \begin{bmatrix} \rho_k \\ r_k \end{bmatrix} \right\| \leq \kappa_k \left\| \begin{bmatrix} g_k + A_k^T \lambda_k \\ c_k \end{bmatrix} \right\|, \tag{6.1}$$

where $0 < \{\kappa_k\} < 1$ [8]. Then, tightening the values of κ_k during any point of a run of Algorithm A will influence the convergence rate if unit steplengths are taken. For example, if $\kappa_k \leq \hat{\kappa} < 1$ for all large k, then the rate of convergence is linear with rate $\hat{\kappa}$. If, in addition, $\kappa_k \to 0$, then the rate of convergence is superlinear [8]. In practice, the exact penalty function (2.7) can reject unit steps even close to the solution, but this difficulty can be overcome by the use of a second-order correction or nonmonotone techniques [18]. In this manner, we can be sure that the rate of convergence of Algorithm A will be fast once the penalty parameter is stabilized.

Incidentally, by implementing such an approach, where we require the step provided by the iterative linear system solver to satisfy both (6.1) and Termination Test I or II, one can directly observe the extra cost associated with evolving the `ires` algorithm described in the previous section into a robust method. In our experiments we found this extra cost to be minimal for the problems in our test set. For example, let us define a third algorithm, call it `isqp-ires`, that imposes inequality (6.1) along with our termination tests within the step computation of Algorithm B, where $\kappa = \kappa_k = 2^{-5}$ for all k. Note that the key differences between `isqp-ires` and `isqp` are that we have now implemented $\kappa < 1$ for (3.3) and that an inequality of the form (3.3)/(6.1) is also enforced in Termination Test II. Now, if we compare `isqp-ires` with `ires` (with $\kappa = 2^{-5}$), we can observe the extra cost required to satisfy our termination tests beyond simply attaining an accurate solution to the primal-dual system (2.4). It turns out that for the 35 problems solved by both these algorithms, an average of only 0.5 extra total GMRES iterations over the entire run of the algorithm were required by `isqp-ires`. Moreover, by observing the termination tests for the iterative solver, the 9 problems left unsolved by `ires` (approximately 20% of the total number of 44 problems) were all solved successfully by `isqp-ires`. Indeed, the extra cost is minimal with respect to the added robustness.

In addition it is worth noting that imposing condition (6.1) with sufficiently small κ_k implies that the bound (3.4) would automatically be satisfied, and the bounds (3.5) of Termination Test II are satisfied in the case where $\|c_k\|$ is greater than some constant times $\|g_k + A_k^T \lambda_k\|$.

Finally, it would be of interest to analyze the behavior of inexact SQP methods in the presence of Jacobian singularities and when $W_k = \nabla_{xx}^2 \mathcal{L}_k$ for some k with W_k not positive definite in the null space of the constraint Jacobian A_k. However, such an analysis can be complex and would have taken the focus away from the intended scope of this paper. Therefore, we chose to discuss the design of inexact SQP methods in the benign context of Assumptions 4.1.

Acknowledgments. The authors are thankful to Eldad Haber and Nick Gould for productive discussions on this work.

CONSTRAINT NONDEGENERACY, STRONG REGULARITY, AND NONSINGULARITY IN SEMIDEFINITE PROGRAMMING*

ZI XIAN CHAN† AND DEFENG SUN‡

Abstract. It is known that the Karush–Kuhn–Tucker (KKT) conditions of semidefinite programming can be reformulated as a nonsmooth system via the metric projector over the cone of symmetric and positive semidefinite matrices. We show in this paper that the primal and dual constraint nondegeneracies, the strong regularity, the nonsingularity of the B-subdifferential of this nonsmooth system, and the nonsingularity of the corresponding Clarke's generalized Jacobian, at a KKT point, are all equivalent. Moreover, we prove the equivalence between each of these conditions and the nonsingularity of Clarke's generalized Jacobian of the smoothed counterpart of this nonsmooth system used in several globally convergent smoothing Newton methods. In particular, we establish the quadratic convergence of these methods under the primal and dual constraint nondegeneracies, but without the strict complementarity.

1. Introduction.

The standard semidefinite programming (SDP) problem takes the form

$$\begin{array}{ll} \min & \langle C, X\rangle \\ \text{s.t.} & \mathcal{A}X = b\,, \\ & X \in \mathcal{S}^n_+\,, \end{array} \tag{1}$$

where $C \in \mathcal{S}^n$, the linear space of all $n \times n$ real symmetric matrices, $\langle\cdot,\cdot\rangle$ is the usual Frobenius inner product in $\mathcal{S}^n$, $\mathcal{A}$ is a linear operator from $\mathcal{S}^n$ to $\Re^m$, $b \in \Re^m$, and $\mathcal{S}^n_+$ is the cone of all $n \times n$ positive semidefinite matrices in $\mathcal{S}^n$. Let $\mathcal{A}^* : \Re^m \to \mathcal{S}^n$ be the adjoint of $\mathcal{A}$. The dual form of the SDP problem (1) is

$$\begin{array}{ll} \max & b^T y \\ \text{s.t.} & \mathcal{A}^* y + S = C\,, \\ & S \in \mathcal{S}^n_+\,. \end{array} \tag{2}$$

The Karush–Kuhn–Tucker (KKT) conditions, i.e., the first order optimality conditions, for the SDP problem (1) and its dual (2) are

$$\left\{ \begin{array}{l} \mathcal{A}^* y + S = C\,, \\ \mathcal{A}X = b\,, \\ \mathcal{S}^n_+ \ni X \perp S \in \mathcal{S}^n_+\,, \end{array} \right. \tag{3}$$

where "$X \perp S$" means that X and S are perpendicular to each other, i.e., $\langle X, S\rangle = 0$. Any point $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ satisfying (3) is called a KKT point.

Due to its mathematical elegance and wide applications, the research on SDP has been extremely active after the discovery of polynomial time interior point algorithms [1, 27] for solving this problem. For an excellent survey on this, see [47]. Our research in this paper is motivated by [42] on various characterizations of strong regularity, one of the most important concepts in sensitivity and perturbation analysis, introduced by Robinson in his seminal paper [32], for a local optimal solution of the general nonlinear SDP problem. The basic question we want to ask here is: *What does the strong regularity mean for the SDP problem* (1) *and its dual* (2)?

Certainly, all conditions equivalent to the strong regularity presented in [42] for the general nonlinear SDP problem apply to the SDP problem (1), too. However, due to the special structure of the SDP problem (1) and its dual, one may be able to obtain more insightful characterizations about the strong regularity. This is exactly the primary objective of this paper.

For the purpose of achieving this objective, we study the B-subdifferential and Clarke's generalized Jacobian of the nonsmooth system reformulated from (3). We show that the primal and dual constraint nondegeneracies, the strong regularity, the nonsingularity of the B-subdifferential of this nonsmooth system, and the nonsingularity of the corresponding Clarke's generalized Jacobian, at a KKT point $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$, are all equivalent. The equivalence of the nonsingularity of the B-subdifferential and the nonsingularity of Clarke's generalized Jacobian comes as a surprise, at least to the authors, as we know that the nonsingularity of the B-subdifferential is only a necessary condition for the strong regularity, while the nonsingularity of Clarke's generalized Jacobian is a sufficient condition for the strong regularity (for more discussions, see [15, 28]). It is true, by [42, Theorem 4.1], that the nonsingularity of Clarke's generalized Jacobian is also necessary for the strong regularity in the context of SDP problems. However, it is never known if the nonsingularity of the B-subdifferential is sufficient, too. Here, the unique structure exhibited in SDP problems (1) and (2) plays a key role for us in proving these conditions equivalent. Consequently, the quadratic convergence of some local nonsmooth Newton-type methods studied in [18, 14] follows from any one of these equivalent conditions. In fact, by combining the two papers [18, 19, 14], we know that the primal and dual constraint nondegeneracies are sufficient for the nonsingularity of the B-subdifferential. On the other hand, our equivalent results imply that they are also necessary for the nonsingularity of the B-subdifferential.

The second objective of this paper, largely motivated by the first, is to study under what conditions the globally convergent smoothing Newton methods studied in [9, 10, 20, 46] for solving SDP problems (1) and (2) possess local quadratic convergence, without assuming the strict complementary condition. We achieve this objective by showing that the nonsingularity of the B-subdifferential of one smoothed system used in [9, 10, 20, 46] and the nonsingularity of Clarke's generalized Jacobian of this smoothed system are both equivalent to any of the above-stated equivalent conditions, in particular, the primal and dual constraint nondegeneracies.

The organization of this paper is as follows. In section 2, we study some useful properties of the B-subdifferential and Clarke's generalized Jacobian for Lipschitz functions, particularly for the metric projector over $\mathcal{S}^n_+$ and its smoothed counterpart. The promised equivalent conditions are given in section 3. In section 4, we prove the quadratic convergence of some smoothing Newton methods under the primal and

dual constraint nondegenerate conditions, but without the strict complementarity condition. We give our conclusions in section 5.

2. Generalized Jacobians. Assume that $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{Z}$ are three finite dimensional real vector spaces, each equipped with a scalar product $\langle\cdot,\cdot\rangle$ and its induced norm $\|\cdot\|$, $\mathcal{O}$ is an open set in $\mathcal{Y}$, and $\Xi : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Z}$ is a locally Lipschitz continuous function on the open set $\mathcal{O}$. By the well-known Rademacher theorem [37, section 9.J], we know that Ξ is almost everywhere F(réchet)-differentiable in $\mathcal{O}$. Denote by $\mathcal{D}_\Xi$ the set of all points in $\mathcal{O}$ where Ξ is F-differentiable. Then Clarke's generalized Jacobian of Ξ at $y \in \mathcal{O}$ is defined as follows [12]:

$$\partial\Xi(y) := \mathrm{conv}\{\, \partial_B\Xi(y)\,\},$$

where "conv" denotes the convex hull and the B-subdifferential $\partial_B\Xi(y)$, a name coined by Qi in [29], of Ξ at y takes the form

$$\partial_B\Xi(y) := \{V \,:\, V = \lim_{k\to\infty} \Xi'(y^k)\,,\; y^k \to y\,,\; y^k \in \mathcal{D}_\Xi\}.$$

The next lemma, which is originally proven in [42, Lemma 2.1] under the additional assumption of directional differentiability, is a useful property about characterizing the B-subdifferential of composite functions. Here we drop the condition of directional differentiability and provide a self-contained proof as it may have applications in other places where the directional differentiability is not readily available.

LEMMA 1. *Let $\Psi : \mathcal{X} \to \mathcal{Y}$ be a continuously differentiable function on an open neighborhood $\widehat{N}$ of $\bar{x}$ and $\Xi : \mathcal{O} \subseteq \mathcal{Y} \to \mathcal{Z}$ be a locally Lipschitz continuous function on an open set $\mathcal{O}$ containing $\bar{y} := \Psi(\bar{x})$. Define $\Phi : \widehat{N} \to \mathcal{Z}$ by $\Phi(x) := \Xi(\Psi(x))$, $x \in \widehat{N}$. Suppose that $\Psi'(\bar{x}) : \mathcal{X} \to \mathcal{Y}$ is onto. Then there exists an open neighborhood of $\bar{x}$ such that Φ is F-differentiable at x in this neighborhood if and only if Ξ is F-differentiable at $\Psi(x)$ and*

$$\partial_B\Phi(\bar{x}) = \partial_B\Xi(\bar{y})\Psi'(\bar{x})\,. \tag{4}$$

Proof. Shrink $\widehat{N}$, if necessary, assume that $\Psi(\widehat{N}) \subseteq \mathcal{O}$, and for each $x \in \widehat{N}$, $\Psi'(x)$ is onto. Then Φ is Lipschitz continuous on $\widehat{N}$.

We shall first show that Φ is F-differentiable at $x \in \widehat{N}$ if and only if Ξ is F-differentiable at $\Psi(x)$, which, by the definition of the B-subdifferential, implies

$$\partial_B\Phi(\bar{x}) \subseteq \partial_B\Xi(\bar{y})\Psi'(\bar{x}).$$

By the definition of Φ, we know that if Ξ is F-differentiable at $\Psi(x)$, then Φ is F-differentiable at $x \in \widehat{N}$. Now, assume that Φ is F-differentiable at $x \in \widehat{N}$. Since $A := \Psi'(x)$ is onto, AA^* is invertible, where $A^* : \mathcal{Y} \to \mathcal{X}$ is the adjoint of A. For any $\Delta y \in \mathcal{Y}$, let

$$\Delta x := A^*(AA^*)^{-1}\Delta y\,.$$

Then, for any $\mathcal{Y} \ni \Delta y \to 0$, we have

$$\begin{aligned}
&\|\Xi(\Psi(x)+\Delta y)-\Xi(\Psi(x))-\Phi'(x)(A^*(AA^*)^{-1}\Delta y)\| \\
&=\|\Xi(\Psi(x)+A\Delta x)-\Phi(x)-\Phi'(x)(\Delta x)\| \\
&\le \|\Phi(x+\Delta x)-\Phi(x)-\Phi'(x)(\Delta x)\|+O(\|\Xi(\Psi(x+\Delta x))-\Xi(\Psi(x)+A\Delta x)\|) \\
&=o(\|\Delta x\|)+O(\|\Psi(x+\Delta x)-(\Psi(x)+A\Delta x)\|) \\
&=o(\|\Delta x\|)+O(\|\Psi(x+\Delta x)-\Psi(x)-\Psi'(x)(\Delta x)\|) \\
&=\ o(\|\Delta x\|)=o(\|\Delta y\|)\,,
\end{aligned}$$

which implies that Ξ is F-differentiable at $\Psi(x)$. This proves the first part of our conclusion.

Next, we show that the following inclusion holds:

$$\partial_B\Phi(\bar{x}) \supseteq \partial_B\Xi(\bar{y})\Psi'(\bar{x}).$$

This part's proof follows exactly the proof of the second part of Lemma 2.1 in [42]. Let $W \in \partial_B\Xi(\bar{y})$ be an arbitrary element. Then there exists a sequence $\{y^k\}$ in $\mathcal{O}$ converging to $\bar{y}$ such that Ξ is F-differentiable at y^k and $W = \lim_{k\to\infty}\Xi'(y^k)$. Let $\overline{A} := \Psi'(\bar{x})$. By applying the classical inverse function theorem to

$$\Psi\big(\bar{x}+\overline{A}^*(y-\bar{y})\big)-\Psi(\bar{x})=0,$$

we obtain that there exists a sequence $\{\tilde{y}^k\}$ in $\mathcal{O}$ converging to $\bar{y}$ such that

$$\Psi\big(\bar{x}+\overline{A}^*(\tilde{y}^k-\bar{y})\big)-\Psi(\bar{x})=y^k-\Psi(\bar{x})$$

for all k sufficiently large. Let $\tilde{x}^k := \bar{x}+\overline{A}^*(\tilde{y}^k-\bar{y})$. Then $y^k=\Psi(\tilde{x}^k)$ and Φ is F-differentiable at $\tilde{x}^k$ with

$$\Phi'(\tilde{x}^k)=\Xi'(y^k)\Psi'(\tilde{x}^k).$$

By using the fact that $\tilde{y}^k \to \bar{y}$ implies $\tilde{x}^k \to \bar{x}$, we know that there exists a $V \in \partial_B\Phi(\bar{x})$ such that

$$W\Psi'(\bar{x})=\lim_{k\to\infty}\Xi'(y^k)\lim_{k\to\infty}\Psi'(\tilde{x}^k)=\lim_{k\to\infty}\Phi'(\tilde{x}^k)=V\in\partial_B\Phi(\bar{x}).$$

The proof is completed. □

For any nonempty closed convex set $K \subseteq \mathcal{Z}$, let $\Pi_K : \mathcal{Z} \to \mathcal{Z}$ denote the metric projector over K. That is, for any $y \in \mathcal{Z}$, $\Pi_K(y)$ is the unique optimal solution to the convex programming problem

$$\begin{array}{ll} \min & \dfrac{1}{2}\langle z-y, z-y\rangle \\ \text{s.t.} & z \in K. \end{array} \tag{5}$$

Since the metric projector $\Pi_K(\cdot)$ is globally Lipschitz continuous with modulus 1 [49], $\Pi_K(\cdot)$ is F-differentiable almost everywhere in $\mathcal{Z}$. Thus, for any $y \in Z$, $\partial\Pi_K(y)$ is well defined. In particular, it is shown in [25, Proposition 1] that for any $y \in \mathcal{Z}$, $V \in \partial\Pi_K(y)$ is self-adjoint and satisfies

$$V \succeq V^2, \quad \text{i.e., } \langle d, Vd\rangle \ge \langle d, V^2 d\rangle \quad \forall\, d \in \mathcal{Z}\,. \tag{6}$$

In our subsequent analysis, we need a finer characterization about the B-subdifferential and Clarke's generalized Jacobian of $\Pi_{\mathcal{S}^n_+}(\cdot)$ and its smoothed counterpart. We write $A \succeq 0$ and $A \succ 0$ to mean that A is a symmetric positive semidefinite matrix and a symmetric positive definite matrix, respectively. For any $A \in \mathcal{S}^n$, let $A_+ := \Pi_{\mathcal{S}^n_+}(A)$ be the metric projection of A onto $\mathcal{S}^n_+$ under the usual Frobenius inner product in $\mathcal{S}^n$. Assume that A has the spectral decomposition

$$A = P\Lambda P^T, \tag{7}$$

where Λ is the diagonal matrix of eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n$ of A and P is a corresponding orthogonal matrix of orthonormal eigenvectors. Then

$$A_+ = P\Lambda_+ P^T,$$

where Λ_+ is the diagonal matrix whose diagonal entries are the nonnegative parts of the respective diagonal entries of Λ. The formula for A_+ has been used by statisticians for several decades, e.g., [38, Theorem 1]. Higham [16] and Tseng [48] brought it to the attention of the optimization community. Define three index sets of positive, zero, and negative eigenvalues of A, respectively, as

$$\alpha := \{i : \lambda_i > 0\}, \quad \beta := \{i : \lambda_i = 0\}, \quad \gamma := \{i : \lambda_i < 0\}.$$

Write

$$\Lambda = \begin{bmatrix} \Lambda_\alpha & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \Lambda_\gamma \end{bmatrix} \quad \text{and} \quad P = \begin{bmatrix} P_\alpha & P_\beta & P_\gamma \end{bmatrix}$$

with $P_\alpha \in \Re^{n\times|\alpha|}$, $P_\beta \in \Re^{n\times|\beta|}$, and $P_\gamma \in \Re^{n\times|\gamma|}$. For this eigenvalue vector $\lambda \in \Re^n$, define the corresponding symmetric matrix $U \in \mathcal{S}^n$ with entries

$$U_{ij} := \frac{\max\{\lambda_i, 0\} + \max\{\lambda_j, 0\}}{|\,\lambda_i\,| + |\,\lambda_j\,|}, \quad i, j = 1, \ldots, n, \tag{8}$$

where $0/0$ is defined to be 1.

We know from Bonnans, Cominetti, and Shapiro [5, 6] that $\Pi_{\mathcal{S}^n_+}$ is directionally differentiable everywhere in $\mathcal{S}^n$, and from Sun and Sun [43] that $\Pi_{\mathcal{S}^n_+}$ is strongly semismooth everywhere in $\mathcal{S}^n$ and the directional derivative $\Pi'_{\mathcal{S}^n_+}(A; H)$ of $\Pi_{\mathcal{S}^n_+}$ at A with direction $H \in \mathcal{S}^n$ is given by

$$\Pi'_{\mathcal{S}^n_+}(A; H) = P \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\beta} & \Pi_{\mathcal{S}^{|\beta|}_+}(\widetilde{H}_{\beta\beta}) & 0 \\ \widetilde{H}^T_{\alpha\gamma} \circ U^T_{\alpha\gamma} & 0 & 0 \end{bmatrix} P^T, \tag{9}$$

where $\widetilde{H} := P^T H P$ and "$\circ$" denotes the Hadamard product. For a general discussion on (strongly) semismooth functions, see [26, 29, 31]. The tangent cone of $\mathcal{S}^n_+$ at A_+, in the sense of convex analysis [36], can be characterized as

$$\mathcal{T}_{\mathcal{S}^n_+}(A_+) = \{B \in \mathcal{S}^n : B = \Pi'_{\mathcal{S}^n_+}(A_+; B)\} = \{B \in \mathcal{S}^n : [\,P_\beta\ P_\gamma\,]^T B\,[\,P_\beta\ P_\gamma\,] \succeq 0\}.$$

Note, however, that the characterization of $\mathcal{T}_{\mathcal{S}^n_+}(A_+)$ was first obtained by Arnold [3] without using the directional derivative $\Pi'_{\mathcal{S}^n_+}(A_+; H)$. The linearity space of $\mathcal{T}_{\mathcal{S}^n_+}(A_+)$,

i.e., the largest linear space in $\mathcal{T}_{\mathcal{S}^n_+}(A_+)$, denoted by $\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(A_+)\right)$, then takes the following form:

$$\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(A_+)\right) = \{B \in \mathcal{S}^n \,:\, P_\beta^T B P_\beta = 0,\ \ P_\beta^T B P_\gamma = 0,\ \ P_\gamma^T B P_\gamma = 0\}\,. \tag{10}$$

The critical cone of $\mathcal{S}^n_+$ at $A \in \mathcal{S}^n$, associated with the convex optimization problem (5) with $K = \mathcal{S}^n_+$, is defined as

$$\begin{array}{rcl} \mathcal{C}(A;\mathcal{S}^n_+): & = & \mathcal{T}_{\mathcal{S}^n_+}(A_+) \cap (A_+ - A)^\perp \\ & = & \{B \in \mathcal{S}^n \,:\, P_\beta^T B P_\beta \succeq 0,\ P_\beta^T B P_\gamma = 0,\ P_\gamma^T B P_\gamma = 0\}\,, \end{array} \tag{11}$$

where $(A_+ - A)^\perp := \{B \in \mathcal{S}^n \,:\, \langle B, A_+ - A\rangle = 0\}$. Therefore, the affine hull of $\mathcal{C}(A;\mathcal{S}^n_+)$, which we denote $\mathrm{aff}(\mathcal{C}(A;\mathcal{S}^n_+))$, can be written as

$$\mathrm{aff}\left(\mathcal{C}(A;\mathcal{S}^n_+)\right) = \left\{B \in \mathcal{S}^n \,:\, P_\beta^T B P_\gamma = 0,\ P_\gamma^T B P_\gamma = 0\right\}. \tag{12}$$

In the case that $\beta = \emptyset$ holds, i.e., the case that A is nonsingular, $\Pi_{\mathcal{S}^n_+}(\cdot)$ is F-differentiable at A and (9) reduces to the famous result of Löwner [22]:

$$\Pi'_{\mathcal{S}^n_+}(A)H = P\begin{bmatrix} \widetilde{H}_{\alpha\alpha} & U_{\alpha\gamma}\circ\widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\gamma}\circ U^T_{\alpha\gamma} & 0 \end{bmatrix} P^T \quad \forall\, H \in \mathcal{S}^n\,. \tag{13}$$

From (13), one may compute the B-subdifferential and Clarke's generalized Jacobian of $\Pi_{\mathcal{S}^n_+}(\cdot)$ by their definitions.[1] This has been done by a number of authors [9, 20, 23, 24, 28]. One difficulty in obtaining good formulas for $\partial_B\Pi_{\mathcal{S}^n_+}(A)$ and $\partial\Pi_{\mathcal{S}^n_+}(A)$ is that they both depend on the orthogonal matrices P in the spectral decomposition of A. This difficulty can be overcome by employing the following link developed by Pang, Sun, and Sun [28] on $\partial_B\Pi_{\mathcal{S}^n_+}(A)$ and the B-subdifferential of $\Theta(\cdot) := \Pi'_{\mathcal{S}^n_+}(A;\cdot)$ at the origin

$$\partial_B\Pi_{\mathcal{S}^n_+}(A) = \partial_B\Theta(0)\,. \tag{14}$$

This link leads to the following useful result on $\partial_B\Pi_{\mathcal{S}^n_+}(A)$ and $\partial\Pi_{\mathcal{S}^n_+}(A)$. See Sun [42, Proposition 2.2] for a short proof.

PROPOSITION 2. *Suppose that $A \in \mathcal{S}^n$ has the spectral decomposition as in (7). Then a $V \in \partial_B\Pi_{\mathcal{S}^n_+}(A)$ (respectively, $\partial\Pi_{\mathcal{S}^n_+}(A)$) if and only if there exists a $V_{|\beta|} \in \partial_B\Pi_{\mathcal{S}^{|\beta|}_+}(0)$ (respectively, $\partial\Pi_{\mathcal{S}^{|\beta|}_+}(0)$) such that*

$$V(H) = P\begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma}\circ\widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\beta} & V_{|\beta|}(\widetilde{H}_{\beta\beta}) & 0 \\ \widetilde{H}^T_{\alpha\gamma}\circ U^T_{\alpha\gamma} & 0 & 0 \end{bmatrix} P^T \quad \forall\, H \in \mathcal{S}^n, \tag{15}$$

where $\widetilde{H} := P^T H P$.

Proposition 2 simply says that in order to compute $\partial_B\Pi_{\mathcal{S}^n_+}(A)$ and $\partial\Pi_{\mathcal{S}^n_+}(A)$, one needs only to fix an arbitrary orthogonal matrix P satisfying (7) and compute the

[1] Note that in numerical computations it is generally impossible to compute exactly the spectral decomposition of A as in (7). Instead, the right-hand side of (7) is the true spectral decomposition of a nearby matrix of A [8]. Consequently, the numerically computed subdifferentials are actually for this nearby matrix. In this paper, we will not address this numerical issue further.

corresponding "caged" part $\partial_B \Pi_{\mathcal{S}_+^{|\beta|}}(0)$ (hence $\partial \Pi_{\mathcal{S}_+^{|\beta|}}(0)$), which is much easier to handle. To see this, let $\mathcal{Q}_{|\beta|}$ be the set of all orthogonal matrices of order $|\beta| \times |\beta|$ and

$$\Re_>^{|\beta|} := \{ z \in \Re^{|\beta|} \,:\, z_1 \geq \cdots \geq z_{|\beta|} \ \text{ and } z_i \neq 0 \ \forall\, i \,\}.$$

Let $p : \Re \to \Re$ be the "plus" function defined by $p(t) \equiv \max(0, t)$, $t \in \Re$. For any $z \in \Re_>^{|\beta|}$, let $p^{[1]}(z)$ represent the first divided difference matrix used in matrix analysis for $p(\cdot)$ at z [4]:

$$\big[\, p^{[1]}(z) \,\big]_{ij} = \begin{cases} \dfrac{p(z_i) - p(z_j)}{z_i - z_j} \in [0,1] & \text{if } z_i \neq z_j, \\ p'(z_i) \in \{0, 1\} & \text{if } z_i = z_j, \end{cases} \qquad i, j = 1, \ldots, n\,. \tag{16}$$

Then, by (9) and (13), one can readily draw the conclusion that $V_{|\beta|} \in \partial_B \Pi_{\mathcal{S}_+^{|\beta|}}(0)$ if and only if there exist $Q \in \mathcal{Q}_{|\beta|}$ and $\Omega \in \mathcal{U}_{|\beta|}$ such that

$$V_{|\beta|}(Z) = Q\,[\,\Omega \circ (Q^T Z Q)\,]\,Q^T \quad \forall\, Z \in \mathcal{S}^{|\beta|}\,, \tag{17}$$

where

$$\mathcal{U}_{|\beta|} := \{\, \Omega \,:\, \Omega = \lim_{k \to \infty} p^{[1]}(z^k), \ \ z^k \to 0, \ z^k \in \Re_>^{|\beta|} \,\}\,.$$

In [23], Malick and Sendov gave a detailed account on the structure of $\mathcal{U}_{|\beta|}$. In this paper, we do not need the exact structure of $\mathcal{U}_{|\beta|}$ except for the following fact that for any $\Omega \in \mathcal{U}_{|\beta|}$,

$$\Omega_{ij} \in [0, 1], \quad i, j = 1, \ldots, |\beta|\,.$$

Note that both the zero mapping $V_{|\beta|}^0 \equiv 0$ and the identity mapping $V_{|\beta|}^{\mathcal{I}} = \mathcal{I}$ from $\mathcal{S}^{|\beta|} \to \mathcal{S}^{|\beta|}$ are elements in $\partial_B \Pi_{\mathcal{S}_+^{|\beta|}}(0)$. Let V^0 and $V^{\mathcal{I}}$ be defined by (15) with $V_{|\beta|}$ being replaced by $V_{|\beta|}^0$ and $V_{|\beta|}^{\mathcal{I}}$, respectively. Define

$$\mathrm{ex}\,(\partial_B \Pi_{\mathcal{S}_+^n}(A)) := \{\, V^0, \ V^{\mathcal{I}} \,\}. \tag{18}$$

Using the fact that both V^0 and $V^{\mathcal{I}}$ are elements in $\partial_B \Pi_{\mathcal{S}_+^n}(A)$, we have

$$\mathrm{ex}\,(\partial_B \Pi_{\mathcal{S}_+^n}(A)) \subseteq \partial_B \Pi_{\mathcal{S}_+^n}(A)\,.$$

Since $\Pi_{\mathcal{S}_+^n}(\cdot)$ is not differentiable everywhere, several papers [9, 10, 20, 46] on smoothing Newton methods, for solving the SDP problem and beyond, consider the following smoothed counterpart of $\Pi_{\mathcal{S}_+^n}(\cdot)$:

$$\Phi(\varepsilon, A) := \big[\, A + \sqrt{\varepsilon^2 I + A^2}\,\big]/2, \quad (\varepsilon, A) \in \Re \times \mathcal{S}^n\,, \tag{19}$$

where we use I to represent the identity matrix of appropriate dimension. Note that the function $\Phi(\cdot, \cdot)$ is continuously differentiable around any $(\varepsilon, A) \in \Re \times \mathcal{S}^n$ if $\varepsilon^2 I + A^2$ is nonsingular and when $\varepsilon = 0$, $\Phi(0, A) = \Pi_{\mathcal{S}_+^n}(A)$. Furthermore, $\Phi(\cdot, \cdot)$ is globally Lipschitz continuous and strongly semismooth at any $(0, A) \in \Re \times \mathcal{S}^n$ [46]. For some extensions on these properties, see [44].

Let $\phi : \Re^2 \to \Re$ be defined by

$$\phi(\varepsilon, t) = \left[\, t + \sqrt{\varepsilon^2 + t^2}\,\right]/2, \quad (\varepsilon, t) \in \Re \times \Re\,.$$

Let A have the spectral decomposition in (7). Then, by matrix analysis [4, 17], we have

$$\Phi(\varepsilon, A) = P \begin{bmatrix} \phi(\varepsilon, \lambda_1) & & \\ & \ddots & \\ & & \phi(\varepsilon, \lambda_n) \end{bmatrix} P^T\,.$$

For any $(\varepsilon, x) \in \Re \times \Re^n$ such that $\varepsilon^2 + x_i^2 > 0$ for all i, we use $\widehat{U}(\varepsilon, x) \in \mathcal{S}^n$ to represent the first divided difference matrix for $\phi(\varepsilon, \cdot)$ at x given by

$$\left[\,\widehat{U}(\varepsilon, x)\,\right]_{ij} = \begin{cases} \dfrac{\phi(\varepsilon, x_i) - \phi(\varepsilon, x_j)}{x_i - x_j} \in [0, 1] & \text{if } x_i \neq x_j, \\ \phi'_{x_i}(\varepsilon, x_i) \in [0, 1] & \text{if } x_i = x_j, \end{cases} \quad i, j = 1, \ldots, n\,. \tag{20}$$

Then, according to Lemma 2.3 in [46], we know that for any $\varepsilon \in \Re$ such that $\varepsilon^2 + \lambda_i^2 > 0$ for all i (i.e., $\varepsilon^2 I + A^2$ is nonsingular), and any $(\tau, H) \in \Re \times \mathcal{S}^n$, we have

$$\Phi'(\varepsilon, A)(\tau, H) = P\,[\,\widehat{U}(\varepsilon, \lambda) \circ (P^T H P) + \tau D(\varepsilon, \lambda)\,]\,P^T \tag{21}$$

and

$$\Phi'((0, A); (\tau, H)) = P \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}_{\alpha\beta}^T & \Phi_{|\beta|}(\tau, \widetilde{H}_{\beta\beta}) & 0 \\ \widetilde{H}_{\alpha\gamma}^T \circ U_{\alpha\gamma}^T & 0 & 0 \end{bmatrix} P^T, \tag{22}$$

where $\widetilde{H} = P^T H P$, $D(\varepsilon, \lambda) \in \mathcal{S}^n$ is the diagonal matrix given by

$$D(\varepsilon, \lambda) = \begin{bmatrix} \phi'_\varepsilon(\varepsilon, \lambda_1) & & \\ & \ddots & \\ & & \phi'_\varepsilon(\varepsilon, \lambda_n) \end{bmatrix}, \tag{23}$$

$U \in \mathcal{S}^n$ is defined by (8), and for any $(t, Z) \in \Re \times \mathcal{S}^{|\beta|}$,

$$\Phi_{|\beta|}(t, Z) := \left[\, Z + \sqrt{t^2 I + Z^2}\,\right]/2\,. \tag{24}$$

Define $\Psi : \Re \times \mathcal{S}^n \to \Re \times \mathcal{S}^n$ by

$$\Psi(\tau, H) := (\tau, P^T H P), \quad (\tau, H) \in \Re \times \mathcal{S}^n,$$

and $\Xi : \Re \times \mathcal{S}^n \to \mathcal{S}^n$ by

$$\Xi(t, M) := P \begin{bmatrix} M_{\alpha\alpha} & M_{\alpha\beta} & U_{\alpha\gamma} \circ M_{\alpha\gamma} \\ M_{\alpha\beta}^T & \Phi_{|\beta|}(t, M_{\beta\beta}) & 0 \\ M_{\alpha\gamma}^T \circ U_{\alpha\gamma}^T & 0 & 0 \end{bmatrix} P^T\,, \tag{25}$$

where $(t, M) \in \Re \times \mathcal{S}^n$. Write $\Gamma(\cdot, \cdot) \equiv \Phi'((0, A); (\cdot, \cdot))$. Then, we have

$$\Gamma(\tau, H) = \Xi(\Psi(\tau, H)), \quad (\tau, H) \in \Re \times \mathcal{S}^n\,. \tag{26}$$

Since for any $(\tau, H) \in \Re \times \mathcal{S}^n$, $\Psi'(\tau, H) : \Re \times \mathcal{S}^n \to \Re \times \mathcal{S}^n$ is onto, we know from the first part of Lemma 1 that Γ is F-differentiable at $(\tau, H) \in \Re \times \mathcal{S}^n$ if and only if Ξ is F-differentiable at $\Psi(\tau, H)$, which is equivalent to the nonsingularity of $\tau^2 I + (\widetilde{H}_{\beta\beta})^2$, where $\widetilde{H} = P^T H P$. Thus, we have the following lemma.

LEMMA 3. *For any $(\tau, H) \in \Re \times \mathcal{S}^n$, let $\widetilde{H} = P^T H P$. Then $\Gamma(\cdot,\cdot) \equiv \Phi'((0, A); (\cdot,\cdot))$ is F-differentiable at $(\tau, H) \in \Re \times \mathcal{S}^n$ if and only if $\tau^2 I + (\widetilde{H}_{\beta\beta})^2$ is nonsingular.*

The following lemma establishes the equivalence between $\partial_B \Phi(0, A)$ and $\partial_B \Gamma(0, 0)$, which is analogous to (14) for operators $\Pi_{\mathcal{S}^n_+}$ and Θ. Its proof largely follows that given in [28, Lemma 11], but with new difficulties to overcome.

LEMMA 4. *Suppose that $A \in \mathcal{S}^n$ has the spectral decomposition in (7). For $\Gamma(\cdot,\cdot) \equiv \Phi'((0, A); (\cdot,\cdot))$, it holds that*

$$\partial_B \Phi(0, A) = \partial_B \Gamma(0, 0)\,. \tag{27}$$

Proof. Let $V \in \partial_B \Phi(0, A)$. Then, by (21), (22), and the definition of $\partial_B \Phi(0, A)$, there exists a sequence $\{(\varepsilon_k, A^k)\}$ in $\Re \times \mathcal{S}^n$ converging to $(0, A)$ with $\varepsilon_k^2 I + (A^k)^2$ being nonsingular such that $V = \lim_{k\to\infty} \Phi'(\varepsilon_k, A^k)$. Let $A^k \equiv P^k \Lambda^k (P^k)^T$ be the orthogonal decomposition of A^k, where Λ^k is the diagonal matrix whose diagonal entries are the eigenvalues $\lambda_1^k \geq \cdots \geq \lambda_n^k$ of A^k and P^k is a corresponding matrix of orthonormal eigenvectors. Writing each Λ^k in the same form as Λ,

$$\Lambda^k = \begin{bmatrix} \Lambda_\alpha^k & 0 & 0 \\ 0 & \Lambda_\beta^k & 0 \\ 0 & 0 & \Lambda_\gamma^k \end{bmatrix},$$

we have $\Lambda = \lim_{k\to\infty} \Lambda^k$, which implies that Λ_α^k and Λ_γ^k are nonsingular matrices for all k sufficiently large and $\lim_{k\to\infty} \Lambda_\beta^k = 0$. For each k, let $U^k \equiv \widehat{U}(\varepsilon_k, \lambda^k)$ be defined by (20) and $D^k \equiv D(\varepsilon_k, \lambda^k)$ be defined by (23), respectively. Then, for an arbitrarily chosen $(\tau, H) \in \Re \times \mathcal{S}^n$ with $\widetilde{H}^k = (P^k)^T H P^k$, we obtain from (21) that

$$\Phi'(\varepsilon_k, A^k)(\tau, H) = P^k \left[U^k \circ (P^k)^T H P^k + \tau D^k \right] (P^k)^T\,. \tag{28}$$

By taking a subsequence if necessary, we may assume that $\{P^k\}$ is a convergent sequence with limit $P^\infty \equiv \lim_{k\to\infty} P^k$. This matrix P^∞ will play the role of the matrix P in the spectral decomposition (7). Without causing any confusion, we will simply use P, rather than P^∞, in our subsequent analysis. Since both $\{U^k\}$ and $\{D^k\}$ are uniformly bounded, by further taking subsequences if necessary, we may assume that both sequences $\{U^k\}$ and $\{D^k\}$ converge. Taking limits on both sides of (28), we obtain

$$P^T V(\tau, H) P = \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}_{\alpha\beta}^T & \lim\limits_{k\to\infty} U_{\beta\beta}^k \circ \widetilde{H}_{\beta\beta} & 0 \\ \widetilde{H}_{\alpha\gamma}^T \circ U_{\alpha\gamma}^T & 0 & 0 \end{bmatrix}$$

$$+ \tau \begin{bmatrix} 0 & 0 & 0 \\ 0 & \lim\limits_{k\to\infty} D_\beta^k & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

where

$$D^k_\beta = \begin{bmatrix} \phi'_\varepsilon(\varepsilon_k, \lambda^k_{|\alpha|+1}) & & \\ & \ddots & \\ & & \phi'_\varepsilon(\varepsilon_k, \lambda^k_{|\alpha|+|\beta|}) \end{bmatrix}.$$

For each k, define

$$M^k := P \begin{bmatrix} 0 & 0 & 0 \\ 0 & \Lambda^k_\beta & 0 \\ 0 & 0 & 0 \end{bmatrix} P^T.$$

Let $\widetilde{M}^k := P^T M^k P$. Because $\varepsilon_k^2 I + (\widetilde{M}^k_{\beta\beta})^2 = \varepsilon_k^2 I + (\Lambda^k_\beta)^2$ is nonsingular, Γ is F-differentiable at (ε_k, M^k) with

$$\begin{aligned}
\Gamma'(\varepsilon_k, M^k)(\tau, H) &= \lim_{t \downarrow 0} \left\{ \frac{\Gamma(\varepsilon_k + t\tau, M^k + tH) - \Gamma(\varepsilon_k, M^k)}{t} \right\} \\
&= P \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\beta} & \lim\limits_{t \downarrow 0} \dfrac{\Phi_{|\beta|}(\varepsilon_k + t\tau, \Lambda^k_\beta + t\widetilde{H}_{\beta\beta}) - \Phi_{|\beta|}(\varepsilon_k, \Lambda^k_\beta)}{t} & 0 \\ \widetilde{H}^T_{\alpha\gamma} \circ U^T_{\alpha\gamma} & 0 & 0 \end{bmatrix} P^T \\
&= P \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\beta} & U^k_{\beta\beta} \circ \widetilde{H}_{\beta\beta} + \tau D^k_\beta & 0 \\ \widetilde{H}^T_{\alpha\gamma} \circ U^T_{\alpha\gamma} & 0 & 0 \end{bmatrix} P^T,
\end{aligned}$$

where we have applied (21) to $\Phi_{|\beta|}$ defined by (24) at $(\varepsilon_k, \Lambda^k_\beta)$. Thus,

$$V(\tau, H) = \lim_{k \to \infty} \Gamma'(\varepsilon_k, M^k)(\tau, H).$$

Since $(\tau, H) \in \Re \times \mathcal{S}^n$ is arbitrary, it follows that $V \in \partial_B \Gamma(0, 0)$.

Conversely, let $V \in \partial_B \Gamma(0, 0)$. Since, from Lemma 3, Γ is F-differentiable at $(\varepsilon, M) \in \Re \times \mathcal{S}^n$ if and only if $\varepsilon^2 I + (\widetilde{M}_{\beta\beta})^2$ is nonsingular with $\widetilde{M} = P^T M P$, there exists a sequence $\{(\varepsilon_k, M^k)\} \in \Re \times \mathcal{S}^n$ converging to $(0, 0)$ such that $\varepsilon_k^2 I + (\widetilde{M}^k_{\beta\beta})^2$ is nonsingular for each k and $V = \lim_{k \to \infty} \Gamma'(\varepsilon_k, M^k)$, where $\widetilde{M}^k = P^T M^k P$. Let $\widetilde{M}^k_{\beta\beta}$ have the spectral decomposition

$$\widetilde{M}^k_{\beta\beta} = Q^k \widetilde{\Lambda}^k_\beta (Q^k)^T,$$

where $Q^k \in \mathcal{Q}_{|\beta|}$ is an orthogonal matrix in $\mathcal{S}^{|\beta|}$ and $\widetilde{\Lambda}^k_\beta$ is the diagonal matrix whose diagonal entries are the eigenvalues $\tilde{z}^k_1 \geq \cdots \geq \tilde{z}^k_{|\beta|}$ of $\widetilde{M}^k_{\beta\beta}$. Let $\tilde{\lambda}^k \in \Re^n$ be such that if $i \in \alpha \cup \gamma$, then $\tilde{\lambda}^k_i = \lambda_i$ and if $i \in \beta$, $\tilde{\lambda}^k_i$ is the $(i - |\alpha|)$th eigenvalue of $\widetilde{M}^k_{\beta\beta}$, i.e.,

$\tilde{z}^k_{(i-|\alpha|)}$. Then, by (22), for any $(\tau, H) \in \Re \times \mathcal{S}^n$ we have

(29)

$$\Gamma'(\varepsilon_k, M^k)(\tau, H) = \lim_{t\downarrow 0} \left\{ \frac{\Gamma(\varepsilon_k + t\tau, M^k + tH) - \Gamma(\varepsilon_k, M^k)}{t} \right\}$$

$$= P \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\beta} & \lim\limits_{t\downarrow 0} \dfrac{\Phi_{|\beta|}(\varepsilon_k + t\tau, \widetilde{M}^k_{\beta\beta} + t\widetilde{H}_{\beta\beta}) - \Phi_{|\beta|}(\varepsilon_k, \widetilde{M}^k_{\beta\beta})}{t} & 0 \\ \widetilde{H}^T_{\alpha\gamma} \circ U^T_{\alpha\gamma} & 0 & 0 \end{bmatrix} P^T$$

with $\widetilde{H} = P^T H P$ and

$$\lim_{t\downarrow 0} \quad \frac{\Phi_{|\beta|}(\varepsilon_k + t\tau, \widetilde{M}^k_{\beta\beta} + t\widetilde{H}_{\beta\beta}) - \Phi_{|\beta|}(\varepsilon_k, \widetilde{M}^k_{\beta\beta})}{t}$$

$$= Q^k \left(\lim_{t\downarrow 0} \frac{\Phi_{|\beta|}(\varepsilon_k + t\tau, \widetilde{\Lambda}^k_\beta + t(Q^k)^T \widetilde{H}_{\beta\beta} Q^k) - \Phi_{|\beta|}(\varepsilon_k, \widetilde{\Lambda}^k_\beta)}{t} \right) (Q^k)^T$$

$$= Q^k \left[\, \widetilde{\Omega}^k \circ \left(\, (Q^k)^T \widetilde{H}_{\beta\beta} Q^k \, \right) + \tau \widetilde{S}^k \, \right] (Q^k)^T \,, \tag{30}$$

where we have used (21) for $\Phi_{|\beta|}$ and the fact that $\Phi_{|\beta|}$ is F-differentiable at $(\varepsilon_k, \widetilde{\Lambda}^k_\beta)$ because $\varepsilon_k^2 I + (\widetilde{\Lambda}^k_\beta)^2$ is nonsingular,

$$(\widetilde{\Omega}^k)_{ij} = \begin{cases} \dfrac{\phi(\varepsilon_k, \tilde{z}^k_i) - \phi(\varepsilon_k, \tilde{z}^k_j)}{\tilde{z}^k_i - \tilde{z}^k_j} & \text{if } \tilde{z}^k_i \neq \tilde{z}^k_j, \\ \phi'_{\tilde{z}^k_i}(\varepsilon, \tilde{z}^k_i) & \text{if } \tilde{z}^k_i = \tilde{z}^k_j, \end{cases} \qquad i, j = 1, \ldots, |\beta| \,,$$

and

$$\widetilde{S}^k = \begin{bmatrix} \phi'_\varepsilon(\varepsilon_k, \tilde{z}^k_1) & & \\ & \ddots & \\ & & \phi'_\varepsilon(\varepsilon_k, \tilde{z}^k_{|\beta|}) \end{bmatrix}.$$

Define

$$A^k = A + P \begin{bmatrix} 0 & 0 & 0 \\ 0 & \widetilde{M}^k_{\beta\beta} & 0 \\ 0 & 0 & 0 \end{bmatrix} P^T \quad \text{and} \quad \widetilde{A}^k = P^T A^k P = \begin{bmatrix} \Lambda_\alpha & 0 & 0 \\ 0 & \widetilde{M}^k_{\beta\beta} & 0 \\ 0 & 0 & \Lambda_\gamma \end{bmatrix}.$$

Since, for each k, $\varepsilon_k^2 I + (\widetilde{M}^k_{\beta\beta})^2$ is nonsingular, the matrix $\varepsilon_k^2 I + (A^k)^2 = P[\varepsilon_k^2 I + (\widetilde{A}^k)^2]P^T$ is also nonsingular. Thus, Φ is F-differentiable at (ε_k, A^k). Let

$$P^k \equiv [\; P^k_\alpha \quad P^k_\beta \quad P^k_\gamma \;] = [\; P_\alpha \quad P_\beta Q^k \quad P_\gamma \;]$$

and $\widetilde{\Lambda}^k$ be the diagonal matrix whose diagonal entries are components of $\tilde{\lambda}^k$. Then

$$A^k = P^k \widetilde{\Lambda}^k (P^k)^T \,,$$

which, together with (21), implies that for any $(\tau, H) \in \Re \times \mathcal{S}^n$, we have

$$\Phi'(\varepsilon_k, A^k)(\tau, H) = P^k \left[\widetilde{U}^k \circ ((P^k)^T H P^k) + \tau \widetilde{D}^k \right] (P^k)^T , \tag{31}$$

where $\widetilde{U}^k \equiv \widehat{U}(\varepsilon_k, \tilde{\lambda}^k)$ and $\widetilde{D}^k \equiv D(\varepsilon_k, \tilde{\lambda}^k)$. Since $\{Q^k\}$, $\{\widetilde{U}^k\}$, and $\{\widetilde{D}^k\}$ are all uniformly bounded, by taking subsequences if necessary, we may assume that all these three sequences converge. By simple computations, we obtain

$$\lim_{k\to\infty} \widetilde{U}^k_{ij} = \begin{cases} 1 & \text{if } i \in \alpha,\ j \in \alpha \cup \beta, \\ U_{ij} & \text{if } i \in \alpha,\ j \in \gamma, \\ \lim\limits_{k\to\infty} (\widetilde{\Omega}^k)_{(i-|\alpha|)(j-|\alpha|)} & \text{if } i \in \beta,\ j \in \beta, \\ 0 & \text{if } i \in \beta \cup \gamma,\ j \in \gamma, \end{cases} \qquad i, j = 1, \ldots, n,$$

and

$$\lim_{k\to\infty} \widetilde{D}^k = \begin{bmatrix} 0 & 0 & 0 \\ 0 & \lim\limits_{k\to\infty} \widetilde{S}^k & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

which, together with (31), (29), and (30), imply that for any $(\tau, H) \in \Re \times \mathcal{S}^n$,

$$\lim_{k\to\infty} (P^k)^T \left[\Gamma'(\varepsilon_k, M^k)(\tau, H) - \Phi'(\varepsilon_k, A^k)(\tau, H) \right] P^k = 0 .$$

Consequently, we can conclude $V(\tau, H) = \lim_{k\to\infty} \Phi'(\varepsilon_k, A^k)(\tau, H)$ for all $(\tau, H) \in \Re \times \mathcal{S}^n$, which implies $V \in \partial_B \Phi(0, A)$. Hence, (27) holds. □

Lemma 4 allows us to completely characterize $\partial_B \Phi(0, A)$ (hence, $\partial \Phi(0, A)$).

PROPOSITION 5. *Suppose that $A \in \mathcal{S}^n$ has the spectral decomposition in* (7)*. Then a $V \in \partial_B \Phi(0, A)$ (respectively, $\partial \Phi(0, A)$) if and only if there exists a $V_{|\beta|} \in \partial_B \Phi_{|\beta|}(0, 0)$ (respectively, $\partial \Phi_{|\beta|}(0, 0)$) such that*

$$V(\tau, H) = P \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \widetilde{H}_{\alpha\gamma} \\ \widetilde{H}^T_{\alpha\beta} & V_{|\beta|}(\tau, \widetilde{H}_{\beta\beta}) & 0 \\ \widetilde{H}^T_{\alpha\gamma} \circ U^T_{\alpha\gamma} & 0 & 0 \end{bmatrix} P^T \tag{32}$$

for all $(\tau, H) \in \Re \times \mathcal{S}^n$, where $\widetilde{H} = P^T H P$.

Proof. We need only to prove that (32) holds for $V \in \partial_B \Phi(0, A)$ and $V_{|\beta|} \in \partial_B \Phi_{|\beta|}(0, 0)$ as the case for Clarke's generalized Jacobian can be proved similarly.

Let $\Psi(\tau, H) := (\tau, P^T H P)$ for any $(\tau, H) \in \Re \times \mathcal{S}^n$, and let $\Xi : \Re \times \mathcal{S}^n \to \mathcal{S}^n$ be defined by (25). Then, since $\Psi'(\tau, H) : \Re \times \mathcal{S}^n \to \Re \times \mathcal{S}^n$ is onto, we know from Lemma 1 that

$$\partial_B \Gamma(0, 0) = \partial_B \Xi(0, 0) \Psi'(0, 0) ,$$

which, together with (27) in Lemma 4, completes the proof. □

Just as in the case for the metric projector $\Pi_{\mathcal{S}^n_+}$, Proposition 5 says that in order to compute $\partial_B \Phi(0, A)$ and $\partial \Phi(0, A)$, one needs only to fix P and compute the corresponding easy part $\partial_B \Phi_{|\beta|}(0, 0)$ (hence, $\partial \Phi_{|\beta|}(0, 0)$). For any $(\varepsilon, z) \in \Re \times \Re^{|\beta|}$ with $\varepsilon^2 + z_i^2 > 0$ for all i, let $\widehat{\Omega}(\varepsilon, z)$ be defined by (20) with n and x being replaced by

$|\beta|$ and z, respectively. Then, by (22) and (21), one can readily draw the conclusion that $V_{|\beta|} \in \partial_B \Phi_{|\beta|}(0,0)$ if and only if there exist $Q \in \mathcal{Q}_{|\beta|}$ and $\Omega \in \widehat{\mathcal{U}}_{|\beta|}$ such that

$$V_{|\beta|}(0,Z) = Q\,[\,\Omega \circ (Q^T Z Q)\,]\,Q^T \quad \forall\, Z \in \mathcal{S}^{|\beta|}\,, \tag{33}$$

where

$$\widehat{\mathcal{U}}_{|\beta|} := \big\{\Omega \,:\, \Omega = \lim_{k\to\infty} \widehat{\Omega}(\varepsilon_k, z^k),\ (\varepsilon_k, z^k) \to (0,0),$$

$$(z^k)_1 \geq \cdots \geq (z^k)_{|\beta|},\ \varepsilon_k^2 + (z_i^k)^2 > 0\ \forall\, i\big\}.$$

Note that for any $\Omega \in \widehat{\mathcal{U}}^{\beta}$, it holds that $\Omega_{ij} \in [0,1], \quad i,j = 1,\ldots,|\beta|$.

The next proposition establishes a link between $\partial_B \Pi_{\mathcal{S}^n_+}(A)$ and $\partial_B \Phi(0,A)$, and so a link between $\partial \Pi_{\mathcal{S}^n_+}(A)$ and $\partial \Phi(0,A)$.

Proposition 6. *For any $V_0 \in \partial_B \Pi_{\mathcal{S}^n_+}(A)$, there exists $V \in \partial_B \Phi(0,A)$ such that*

$$V_0(H) = V(0,H) \quad \forall\, H \in \mathcal{S}^n\,. \tag{34}$$

Proof. By comparing Proposition 2, together with (17), with Proposition 5, together with (33), we can derive the conclusion directly. □

We conclude this section by presenting a useful inequality for elements in $\partial \Phi(0,A)$, which is analogous to (6) for the metric projector Π_K with $K = \mathcal{S}^n_+$.

Proposition 7. *For any $V \in \partial \Phi(0,A)$, it holds that*

$$\langle H - V(0,H), V(0,H)\rangle \geq 0 \quad \forall\, H \in \mathcal{S}^n\,. \tag{35}$$

Proof. Let $V \in \partial \Phi(0,A)$. Then, by Carathéodory's theorem, there exist a positive integer κ and $V^i \in \partial_B \Phi(0,A)$, $i = 1,\ldots,\kappa$, such that V is the convex combination of $V^1,\ldots,V^\kappa$. Let $t_1,\ldots,t_\kappa$ be such that $V = \sum_{i=1}^{\kappa} t_i V^i$, where $t_i \geq 0$, $i = 1,\ldots,\kappa$, and $\sum_{i=1}^{\kappa} t_i = 1$.

From Sun, Sun, and Qi [46, Proposition 3.1], we know that for each $i \in \{1,\ldots,\kappa\}$,

$$\langle H - V^i(0,H), V^i(0,H)\rangle \geq 0 \quad \forall\, H \in \mathcal{S}^n\,. \tag{36}$$

In order to prove that (35) holds for V, let $\theta(X) := \langle X, X\rangle$, $X \in \mathcal{S}^n$. By the convexity of θ, we have for any $H \in \mathcal{S}^n$ that

$$\theta(V(0,H)) = \theta\left(\sum_{i=1}^{\kappa} t_i V^i(0,H)\right) \leq \sum_{i=1}^{\kappa} t_i\,\theta(V^i(0,H)) = \sum_{i=1}^{\kappa} t_i \langle V^i(0,H), V^i(0,H)\rangle\,,$$

which, together with (36) and the definition of θ, implies

$$\langle V(0,H), V(0,H)\rangle \leq \sum_{i=1}^{\kappa} t_i \langle H, V^i(0,H)\rangle = \left\langle H, \sum_{i=1}^{\kappa} t_i V^i(0,H)\right\rangle = \langle H, V(0,H)\rangle\,.$$

Thus, (35) holds. □

3. Equivalent conditions. Let $\mathcal{X}$ and $\mathcal{Y}$ be two finite dimensional real vector spaces each equipped with a scalar product $\langle \cdot, \cdot \rangle$ and its induced norm $\| \cdot \|$. Let $g : \mathcal{X} \to \mathcal{Y}$ be a continuously differentiable function and K be a nonempty and closed convex set in $\mathcal{Y}$. Consider the following feasible problem:

$$g(x) \in K\,, \quad x \in \mathcal{X}\,. \tag{37}$$

Assume that $\bar{x} \in \mathcal{X}$ is a feasible solution to (37). Let $\mathcal{T}_K(g(\bar{x}))$ be the tangent cone of K and $\mathcal{N}_K(g(\bar{x}))$ be the normal cone of K at $g(\bar{x})$, respectively. We write $\mathrm{lin}(\mathcal{T}_K(g(\bar{x})))$ for the linearity space of $\mathcal{T}_K(g(\bar{x}))$. Then we can define the following nondegeneracy condition for problem (37).

DEFINITION 8. *We say that a feasible point $\bar{x}$ to problem* (37) *is constraint nondegenerate if*

$$g'(\bar{x})\mathcal{X} + \mathrm{lin}\big(\mathcal{T}_K(g(\bar{x}))\big) = \mathcal{Y}\,. \tag{38}$$

The concept of nondegeneracy for the abstract problem (37) first appeared in Robinson [33, 34]. The name "constraint nondegeneracy" was coined by Robinson in [35]. The nondegenerate constraint condition (38) including its various equivalent forms was extensively used in [7, 40] for sensitivity and stability analysis in optimization and variational inequalities. If $\mathcal{Y}$ is the Euclidean space $\Re^m$ and $K = \{0\}^{m_1} \times \Re^{m_2}_+$ with $m_1 + m_2 = m$, then the constraint nondegenerate condition (38) is equivalent to the well-known linear independence constraint qualification [33, 40]. Here we shall apply Definition 8 to both the SDP problem (1) and its dual (2) to define the primal constraint nondegeneracy and the dual constraint nondegeneracy, respectively.

DEFINITION 9. *We say that the primal constraint nondegeneracy holds at a feasible solution $\overline{X} \in \mathcal{S}^n_+$ to the SDP problem* (1) *if*

$$\begin{bmatrix} \mathcal{A} \\ \mathcal{I} \end{bmatrix} \mathcal{S}^n + \begin{bmatrix} \{0\} \\ \mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})\big) \end{bmatrix} = \begin{bmatrix} \Re^m \\ \mathcal{S}^n \end{bmatrix} \tag{39}$$

or, equivalently,

$$\mathcal{A}\,\mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})\big) = \Re^m\,, \tag{40}$$

where $\mathcal{I}$ is the identity mapping from $\mathcal{S}^n$ to $\mathcal{S}^n$. Similarly, we say that the dual constraint nondegeneracy holds at a feasible solution $(\bar{y}, \overline{S}) \in \Re^m \times \mathcal{S}^n_+$ to the dual problem (2) *if*

$$\begin{bmatrix} \mathcal{A}^* & \mathcal{I} \\ 0 & \mathcal{I} \end{bmatrix} \begin{pmatrix} \Re^m \\ \mathcal{S}^n \end{pmatrix} + \begin{bmatrix} \{0\} \\ \mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big) \end{bmatrix} = \begin{bmatrix} \mathcal{S}^n \\ \mathcal{S}^n \end{bmatrix} \tag{41}$$

or, equivalently,

$$\mathcal{A}^*\Re^m + \mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big) = \mathcal{S}^n\,. \tag{42}$$

Note that in the literature constraint nondegeneracy is called different names. Shapiro and Fan [41] and Shapiro [39] termed it transversality. Primal constraint nondegeneracy and dual constraint nondegeneracy are better known as primal nondegeneracy and dual nondegeneracy, respectively, in the interior point methods community. See, for example, Alizadeh, Haeber, and Overton [2]. To avoid potential

confusion, we will stick to Robinson's terminology here and interpret different usages of constraint nondegeneracy in terms of Definition 9.

Let $\overline{Z} \equiv (\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point satisfying the KKT conditions (3). Since $\mathcal{S}^n_+$ is a self-dual cone, from [13] we know that

$$\begin{aligned} \mathcal{S}^n_+ \ni X \perp S \in \mathcal{S}^n_+ &\Longleftrightarrow -X \in \mathcal{N}_{\mathcal{S}^n_+}(S) \\ &\Longleftrightarrow S - \Pi_{\mathcal{S}^n_+}[S - X] = X - \Pi_{\mathcal{S}^n_+}[X - S] = 0\,. \end{aligned} \tag{43}$$

Therefore, $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ satisfies (3) if and only if $(\overline{X}, \bar{y}, \overline{S})$ is a solution to the nonsmooth system of equations

$$F(X, y, S) \equiv \begin{bmatrix} C - \mathcal{A}^* y - S \\ \mathcal{A}X - b \\ S - \Pi_{\mathcal{S}^n_+}[S - X] \end{bmatrix} = \begin{bmatrix} C - \mathcal{A}^* y - S \\ \mathcal{A}X - b \\ X - \Pi_{\mathcal{S}^n_+}[X - S] \end{bmatrix} = 0\,, \tag{44}$$

where $(X, y, S) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$.

Note that both the KKT conditions (3) and the nonsmooth system (44) can be written as the following special generalized equation:

$$0 \in \begin{bmatrix} C - \mathcal{A}^* y - S \\ \mathcal{A}X - b \\ X \end{bmatrix} + \begin{bmatrix} \mathcal{N}_{\mathcal{S}^n}(X) \\ \mathcal{N}_{\Re^m}(y) \\ \mathcal{N}_{\mathcal{S}^n_+}(S) \end{bmatrix}. \tag{45}$$

In [32], Robinson introduced an important concept called strong regularity for a solution of generalized equations. Here we define only the strong regularity for (45) rather than for the general problems.

DEFINITION 10. *Let $\mathcal{Z} \equiv \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$. We say that a KKT point $\overline{Z} \equiv (\overline{X}, \bar{y}, \overline{S}) \in \mathcal{Z}$ is a strongly regular solution of the generalized equation* (45) *if there exist neighborhoods $\mathcal{B}$ of the origin $0 \in \mathcal{Z}$ and $\mathcal{V}$ of $\overline{Z}$ such that for every $\delta \in \mathcal{B}$, the generalized equation*

$$\delta \in \begin{bmatrix} C - \mathcal{A}^* y - S \\ \mathcal{A}X - b \\ X \end{bmatrix} + \begin{bmatrix} \mathcal{N}_{\mathcal{S}^n}(X) \\ \mathcal{N}_{\Re^m}(y) \\ \mathcal{N}_{\mathcal{S}^n_+}(S) \end{bmatrix} \tag{46}$$

has a unique solution in $\mathcal{V}$, denoted by $Z_{\mathcal{V}}(\delta)$, and the mapping $Z_{\mathcal{V}} : \mathcal{B} \to \mathcal{V}$ is Lipschitz continuous.

Recall that F is said to be a locally Lipschitz homeomorphism near $\overline{Z}$ if there exists an open neighborhood $\mathcal{V}$ of $\overline{Z}$ such that the restricted mapping $F|_{\mathcal{V}}: \mathcal{V} \to F(\mathcal{V})$ is Lipschitz continuous and bijective, and its inverse is also Lipschitz continuous. The following result, which holds in a more general framework, shows that F is a locally Lipschitz homeomorphism near $\overline{Z}$ if and only if $\overline{Z}$ is a strongly regular solution of the generalized equation (45). This is almost intuitively true. For the sake of completeness, however, we include a short proof.

LEMMA 11. *Let $\mathcal{Z} \equiv \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$. Let $F : \mathcal{Z} \to \mathcal{Z}$ be defined by* (44) *and $\overline{Z}$ be a KKT point of the SDP problem. Then, it holds that F is a locally Lipschitz homeomorphism near $\overline{Z}$ if and only if $\overline{Z}$ is a strongly regular solution of the generalized equation* (45).

Proof. "$\Longrightarrow$" Assume that F is a locally Lipschitz homeomorphism near $\overline{Z}$. Then, there exists an open neighborhood $\mathcal{V}$ of $\overline{Z}$ such that $F(\mathcal{V})$ is an open neighborhood of the origin $0 \in \mathcal{Z}$, and for any $\hat{\delta} \in F(\mathcal{V})$, the equation $F(Z) = \hat{\delta}$ has a unique solution $\widehat{Z}_{\mathcal{V}}(\hat{\delta})$ in $\mathcal{V}$ and $\widehat{Z}_{\mathcal{V}} : F(\mathcal{V}) \to \mathcal{V}$ is Lipschitz continuous.

For any $\delta = (\delta^1, \delta^2, \delta^3) \in \mathcal{B} \equiv \frac{1}{2}F(\mathcal{V})$, let $Z(\delta) = (X(\delta), y(\delta), S(\delta))$ be a solution, if one exists, to (46). Write $\delta \equiv (\delta^1, \delta^2, \delta^3) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$. Then we have

$$\begin{bmatrix} C - \mathcal{A}^* y(\delta) - S(\delta) \\ \mathcal{A}X(\delta) - b \\ (S(\delta) + \delta^3) - \Pi_{\mathcal{S}^n_+}[\,(S(\delta) + \delta^3) - X(\delta)\,] \end{bmatrix} = \begin{bmatrix} \delta^1 \\ \delta^2 \\ \delta^3 \end{bmatrix},$$

i.e.,

$$F(X(\delta), y(\delta), S(\delta) + \delta^3) = \begin{bmatrix} \delta^1 - \delta^3 \\ \delta^2 \\ \delta^3 \end{bmatrix}.$$

Then $Z(\delta)$ uniquely exists in $\mathcal{V}$ and

$$Z(\delta) = \widehat{Z}_{\mathcal{V}}(\delta^1 - \delta^3, \delta^2, \delta^3) - \begin{bmatrix} 0 \\ 0 \\ \delta^3 \end{bmatrix}.$$

Hence, $Z(\cdot)$ is Lipschitz continuous on $\mathcal{B}$.

"$\Longleftarrow$" Assume that $\overline{Z}$ is a strongly regular solution of the generalized equation (45). Then, there exist neighborhoods $\mathcal{B}$ of the origin $0 \in \mathcal{Z}$ and $\mathcal{V}$ of $\overline{Z}$, and a locally Lipschitz function $Z_{\mathcal{V}} : \mathcal{B} \to \mathcal{V}$ such that for any $\delta \in \mathcal{B}$, $Z_{\mathcal{V}}(\delta)$ is the unique solution in $\mathcal{V}$ to (46). By reversing the arguments in the first part of the proof, we can conclude that for any $\hat{\delta} \equiv (\hat{\delta}^1, \hat{\delta}^2, \hat{\delta}^3) \in (\frac{1}{2}\mathcal{B}) \cap (\,\mathcal{S}^n \times \Re^m \times \mathcal{S}^n\,)$, $F(Z) = \hat{\delta}$ has a unique solution

$$\widehat{Z}(\hat{\delta}) \in \mathcal{V} \text{ given by } \widehat{Z}(\hat{\delta}) = Z_{\mathcal{V}}(\hat{\delta}^1 + \hat{\delta}^3, \hat{\delta}^2, \hat{\delta}^3) + \begin{bmatrix} 0 \\ 0 \\ \hat{\delta}^3 \end{bmatrix},$$

which implies that $\widehat{Z}(\cdot)$ is Lipschitz continuous on $\frac{1}{2}\mathcal{B}$. Thus, F is Lipschitz homeomorphism near $\overline{Z}$. □

The concept of strong regularity for general nonlinear semidefinite programming is closely related to another concept called the strong second order sufficient condition as shown by Sun in [42]. Here we will only present the strong second order sufficient condition in terms of the SDP problem (1). First, for any $B \in \mathcal{S}^n$, we define a linear-quadratic function $\Upsilon_B : \mathcal{S}^n \times \mathcal{S}^n \to \Re$.

DEFINITION 12 ([42, Definition 2.1]). *For any given $B \in \mathcal{S}^n$, define the linear-quadratic function $\Upsilon_B : S^n \times \mathcal{S}^n \to \Re$, which is linear in the first argument and quadratic in the second argument, by*

$$\Upsilon_B(S, H) := 2\langle S, HB^\dagger H\rangle, \quad (S, H) \in \mathcal{S}^n \times \mathcal{S}^n,$$

where $B^\dagger$ is the Moore–Penrose pseudoinverse of B.

Let $\overline{X} \in \mathcal{S}^n_+$ be an optimal solution to the SDP problem (1). Denote $\mathcal{M}(\overline{X})$ by the set of points $(y, S) \in \Re^m \times \mathcal{S}^n$ such that $(\overline{X}, y, S)$ is a KKT point, i.e., for any

$(y,S)\in\mathcal{M}(\overline{X})$, $(\overline{X},y,S)$ satisfies the KKT conditions (3). Let $(\bar{y},\overline{S})\in\mathcal{M}(\overline{X})$. Write $\overline{A}\equiv\overline{X}-\overline{S}$. By using the fact that $\mathcal{S}^n_+\ni\overline{X}\perp\overline{S}\in\mathcal{S}^n_+$, we may assume that $\overline{A}$ has the spectral decomposition as in (7) by replacing A with $\overline{A}$ and

(47)
$$\overline{A}=P\begin{bmatrix}\Lambda_\alpha & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & \Lambda_\gamma\end{bmatrix}P^T,\ \overline{X}=P\begin{bmatrix}\Lambda_\alpha & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & 0\end{bmatrix}P^T,\ \overline{S}=P\begin{bmatrix}0 & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & -\Lambda_\gamma\end{bmatrix}P^T.$$

Write $P=[\ P_\alpha\quad P_\beta\quad P_\gamma\ ]$. Then, according to (10) and (12), we have

$$\text{(48)}\qquad \mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})\right)=\{B\in\mathcal{S}^n\,:\,P_\beta^TBP_\beta=0,\ \ P_\beta^TBP_\gamma=0,\ \ P_\gamma^TBP_\gamma=0\},$$

$$\text{(49)}\qquad \mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\right)=\{B\in\mathcal{S}^n\,:\,P_\alpha^TBP_\alpha=0,\ \ P_\alpha^TBP_\beta=0,\ \ P_\beta^TBP_\beta=0\},$$

and

$$\mathrm{aff}\left(\mathcal{C}(\overline{A};\mathcal{S}^n_+)\right)=\left\{B\in\mathcal{S}^n\,:\,P_\beta^TBP_\gamma=0,\ P_\gamma^TBP_\gamma=0\right\}.$$

Define

$$\begin{aligned}\mathrm{app}(\bar{y},\overline{S}) &:= \left\{B\in\mathcal{S}^n\,:\,\mathcal{A}B=0,\ \ B\in\mathrm{aff}\left(\mathcal{C}(\overline{A};\mathcal{S}^n_+)\right)\right\}\\ &= \{B\in\mathcal{S}^n\,:\,\mathcal{A}B=0,\ \ P_\beta^TBP_\gamma=0,\ \ P_\gamma^TBP_\gamma=0\}.\end{aligned}\qquad\text{(50)}$$

Then we can state the strong second order sufficient condition for the SDP problem tailored from Sun [42] for the general nonlinear SDP problem.

DEFINITION 13. *Let $\overline{X}\in\mathcal{S}^n_+$ be an optimal solution to the SDP problem* (1). *We say that the strong second order sufficient condition holds at $\overline{X}$ if*

$$\text{(51)}\qquad \sup_{(y,S)\in\mathcal{M}(\overline{X})}\{-\Upsilon_{\overline{X}}(-S,H)\}>0\quad\forall\,0\neq H\in\Big\{\bigcap_{(y,S)\in\mathcal{M}(\overline{X})}\mathrm{app}(y,S)\Big\}.$$

The strong second order sufficient condition (51) may look very complicated. When $\mathcal{M}(\overline{X})$ is a singleton, the following result gives a very simple characterization.

LEMMA 14. *Let $\overline{X}\in\mathcal{S}^n_+$ be an optimal solution to the SDP problem* (1). *Assume that $\mathcal{M}(\overline{X})=\{(\bar{y},\overline{S})\}$. Let $\overline{X}$ and $\overline{S}$ have the spectral decompositions as in* (47). *Then the strong second order sufficient condition* (51) *holds at $\overline{X}$ if and only if, for any $H\in\mathcal{S}^n$, the following conditions hold*

$$\text{(52)}\qquad \mathcal{A}H=0,\ P_\beta^THP_\gamma=0,\ P_\gamma^THP_\gamma=0,\ \textit{and}\ P_\alpha^THP_\gamma=0\implies H=0.$$

Proof. For any $H\in\mathcal{S}^n$, write $\widetilde{H}=P^THP$. Since $\mathcal{M}(\overline{X})=\{(\bar{y},\overline{S})\}$, the strong second order sufficient condition (51) becomes

$$-\Upsilon_{\overline{X}}(-\overline{S},H)\ >\ 0\quad\forall\,H\in\mathrm{app}(\bar{y},\overline{S})\backslash\{0\},$$

which, by the definition of $\Upsilon_{\overline{X}}(-\overline{S},H)$ and (47), is equivalent to

$$2\sum_{i\in\alpha,j\in\gamma}\frac{-\lambda_j}{\lambda_i}(\widetilde{H}_{ij})^2>0\qquad\forall\,H\in\mathrm{app}(\bar{y},\overline{S})\backslash\{0\}.$$

For details, see [42]. Then, by (50), the strong second order sufficient condition (51) holds at $\overline{X}$ if and only if

$$\mathcal{A}H = 0,\ \widetilde{H}_{\beta\gamma} = 0,\ \widetilde{H}_{\gamma\gamma} = 0,\ \text{and}\ H \neq 0 \implies \widetilde{H}_{\alpha\gamma} \neq 0 \quad \forall\, H \in \mathcal{S}^n\,,$$

which is equivalent to (52). This completes the proof. □

Next, we shall establish a link between the strong second order sufficient condition and the dual constraint nondegeneracy.[2]

PROPOSITION 15. *Let $\overline{X} \in \mathcal{S}^n_+$ be an optimal solution to the SDP problem* (1). *Under the assumption $\mathcal{M}(\overline{X}) = \{(\bar{y}, \overline{S})\}$, the following are equivalent:*

(i) *The strong second order sufficient condition* (51) *holds at $\overline{X}$.*

(ii) *The dual constraint nondegenerate condition* (42) *holds at $(\bar{y}, \overline{S})$.*

Proof. Let $\overline{X}$ and $\overline{S}$ have the spectral decompositions as in (47). For any $H \in \mathcal{S}^n$, let $\widetilde{H} = P^T H P$. We prove "(i) $\Longrightarrow$ (ii)" first. By Lemma 14, (i) holds if and only if we have the following implication:

$$\mathcal{A}H = 0,\ \widetilde{H}_{\beta\gamma} = 0,\ \widetilde{H}_{\gamma\gamma} = 0,\ \text{and}\ \widetilde{H}_{\alpha\gamma} = 0 \Longrightarrow H = 0\ \forall\, H \in \mathcal{S}^n\,. \tag{53}$$

Suppose, for the sake of contradiction, that the dual constraint nondegenerate condition (42) does not hold at $(\bar{y}, \overline{S})$. Then, we have

$$[\,\mathcal{A}^*\Re^m\,]^\perp \cap \big[\,\mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big)\big]^\perp \neq \{0\}. \tag{54}$$

Take an arbitrary $0 \neq \overline{H} \in [\,\mathcal{A}^*\Re^m\,]^\perp \cap \big[\,\mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big)\,\big]^\perp$. We obtain from $\overline{H} \in [\,\mathcal{A}^*\Re^m\,]^\perp$ that

$$\langle \overline{H}, \mathcal{A}^* y\rangle = 0\ \ \forall\, y \in \Re^m \Longrightarrow \langle \mathcal{A}\overline{H}, y\rangle = 0\ \ \forall\, y \in \Re^m \Longrightarrow \mathcal{A}\overline{H} = 0 \tag{55}$$

and from $\overline{H} \in \big[\,\mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big)\,\big]^\perp$ that

$$\langle P^T\overline{H}P, P^T B P\rangle = \langle \overline{H}, B\rangle = 0\ \ \forall\, B \in \mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big)\,,$$

which, together with (49), implies

$$P_\alpha^T \overline{H} P_\gamma = 0, \quad P_\beta^T \overline{H} P_\gamma = 0, \quad \text{and}\ \ P_\gamma^T \overline{H} P_\gamma = 0\,. \tag{56}$$

By making use of (53), (55), and (56), we obtain $\overline{H} = 0$, which contradicts the choice of $\overline{H}$. This contradiction shows that (ii) holds.

Next, we show "(ii) $\Longrightarrow$ (i)." Since the dual constraint nondegenerate condition (42) holds at $(\bar{y}, \overline{S})$, for any $H \in \mathcal{S}^n$ such that $\mathcal{A}H = 0$, $\widetilde{H}_{\beta\gamma} = 0$, $\widetilde{H}_{\gamma\gamma} = 0$, and $\widetilde{H}_{\alpha\gamma} = 0$, there exist $y \in \Re^m$ and $S \in \mathrm{lin}\big(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\big)$ such that

$$H = \mathcal{A}^* y + S\,,$$

which, together with (49), implies

$$\begin{aligned}
\langle H, H\rangle &= \langle H, \mathcal{A}^* y + S\rangle = \langle \mathcal{A}H, y\rangle + \langle H, S\rangle = 0 + \langle P^T H P, P^T S P\rangle \\
&= \left\langle \begin{bmatrix} \widetilde{H}_{\alpha\alpha} & \widetilde{H}_{\alpha\beta} & 0 \\ \widetilde{H}_{\alpha\beta}^T & \widetilde{H}_{\beta\beta} & 0 \\ 0 & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & 0 & P_\alpha^T S P_\gamma \\ 0 & 0 & P_\beta^T S P_\gamma \\ P_\gamma^T S P_\alpha & P_\gamma^T S P_\beta & P_\gamma^T S P_\gamma \end{bmatrix} \right\rangle = 0\,.
\end{aligned}$$

[2] A similar statement for the dual SDP problem (2) also holds. We omit it here for brevity.

Therefore, by Lemma 14, it follows that (i) holds. □

Let $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point satisfying the KKT conditions (3), and let F be defined by (44). As we menioned in the introduction, by combining the two papers [14] and [18], we know that if the primal constraint nondegeneracy holds at $\overline{X}$ and the dual constraint nondegeneracy holds at $(\bar{y}, \overline{S})$, then every element in $\partial_B F(\overline{X}, \bar{y}, \overline{S})$ is nonsingular. Actually, Proposition 15 and [42, Proposition 3.2] allow us to prove even the nonsingularity of Clarke's generalized Jacobian $\partial F(\overline{X}, \bar{y}, \overline{S})$ under the same primal and dual constraint nondegenerate conditions.

PROPOSITION 16. *Let $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point. Assume that the primal constraint nondegenerate condition* (40) *holds at $\overline{X}$ and the dual constraint nondegenerate condition* (42) *holds at $(\bar{y}, \overline{S})$, respectively. Then, every element in $\partial F(\overline{X}, \bar{y}, \overline{S})$ is nonsingular.*

Proof. Since the primal constraint nondegenerate condition (40) implies that $\mathcal{M}(\overline{X}) = \{(\bar{y}, \overline{S})\}$, we know from Proposition 15 that the strong second order sufficient condition (51) holds at $\overline{X}$. Consequently, by [42, Proposition 3.2], every element in $\partial F(\overline{X}, \bar{y}, \overline{S})$ is nonsingular. □

Proposition 16 says that the primal and dual constraint nondegenerate conditions are sufficient for the nonsingularity of all elements in $\partial F(\overline{X}, \bar{y}, \overline{S})$. Next, we shall show that the nonsingularity of only two elements in $\partial_B F(\overline{X}, \bar{y}, \overline{S})$ will imply both the primal and dual constraint nondegenerate conditions.

From Lemma 1, we know that $W \in \partial_B F(\overline{X}, \bar{y}, \overline{S})$ if and only if there exists a $V \in \partial_B \Pi_{\mathcal{S}^n_+}(\overline{A})$ such that

$$W(\Delta X, \Delta y, \Delta S) = \begin{bmatrix} -\mathcal{A}^*(\Delta y) - \Delta S \\ \mathcal{A}(\Delta X) \\ \Delta X - V(\Delta X - \Delta S) \end{bmatrix} \tag{57}$$

for all $(\Delta X, \Delta y, \Delta S) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$, where $\overline{A} \equiv \overline{X} - \overline{S}$. Let $\mathrm{ex}\,(\partial_B \Pi_{\mathcal{S}^n_+}(\overline{A}))$ be defined by (18). For $V^0, V^{\mathcal{I}} \in \mathrm{ex}\,(\partial_B \Pi_{\mathcal{S}^n_+}(\overline{A}))$, let W^0 and $W^{\mathcal{I}}$ be defined by (57), respectively. Denote

$$\mathrm{ex}\,(\partial_B F(\overline{X}, \bar{y}, \overline{S})) := \left\{ W^0, W^{\mathcal{I}} \right\} \subseteq \partial_B F(\overline{X}, \bar{y}, \overline{S}). \tag{58}$$

PROPOSITION 17. *Let $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point. If both W^0 and $W^{\mathcal{I}}$ in $\mathrm{ex}\,(\partial_B F(\overline{X}, \bar{y}, \overline{S}))$ are nonsingular, then the primal constraint nondegenerate condition* (40) *holds at $\overline{X}$ and the dual constraint nondegenerate condition* (42) *holds at $(\bar{y}, \overline{S})$, respectively.*

Proof. First we show that the nonsingularity of W^0 implies the primal constraint nondegenerate condition (40). Assume on the contrary that (40) does not hold. Since, equivalently, (39) fails to hold, too, we have

$$\left\{ \begin{bmatrix} \mathcal{A} \\ I \end{bmatrix} \mathcal{S}^n \right\}^{\perp} \cap \begin{bmatrix} 0 \\ \mathrm{lin}\,(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})) \end{bmatrix}^{\perp} \neq \begin{bmatrix} 0 \\ 0 \end{bmatrix} \in \begin{bmatrix} \Re^m \\ \mathcal{S}^n \end{bmatrix},$$

which implies that there exists $0 \neq (\Delta y, \Delta S) \in \{[\begin{smallmatrix} \mathcal{A} \\ I \end{smallmatrix}] \mathcal{S}^n\}^{\perp} \cap \left[\begin{smallmatrix} 0 \\ \mathrm{lin}\,(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})) \end{smallmatrix}\right]^{\perp}$. We obtain from $(\Delta y, \Delta S) \in \{[\begin{smallmatrix} \mathcal{A} \\ I \end{smallmatrix}] \mathcal{S}^n\}^{\perp}$ that

$$\left\langle (\Delta y, \Delta S), (\mathcal{A}H, H) \right\rangle = 0 \quad \forall\, H \in \mathcal{S}^n \Longrightarrow \mathcal{A}^*(\Delta y) + \Delta S = 0, \tag{59}$$

and from $(\Delta y, \Delta S) \in \begin{bmatrix} 0 \\ \mathrm{lin}\,(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})) \end{bmatrix}^{\perp}$ we obtain that

$$\left\langle P^T(\Delta S)P, P^T H P \right\rangle = \left\langle \Delta S, H \right\rangle = 0 \quad \forall\, H \in \mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{X})\right),$$

which, together with (48), implies

$$P_\alpha^T(\Delta S)P_\alpha = 0, \quad P_\alpha^T(\Delta S)P_\beta = 0, \quad \text{and} \quad P_\alpha^T(\Delta S)P_\gamma = 0\,. \tag{60}$$

Let $U \in \mathcal{S}^n$ be defined by (8). Recall from Proposition 2 that for $V^0 \in \mathrm{ex}\,(\partial_B \Pi_{\mathcal{S}^n_+}(\overline{A}))$, it holds that

$$V^0(\Delta S) = P \begin{bmatrix} P_\alpha^T(\Delta S)P_\alpha & P_\alpha^T(\Delta S)P_\beta & U_{\alpha\gamma} \circ (P_\alpha^T(\Delta S)P_\gamma) \\ \left(P_\alpha^T(\Delta S)P_\beta\right)^T & 0 & 0 \\ \left(P_\alpha^T(\Delta S)P_\gamma\right)^T \circ U_{\alpha\gamma}^T & 0 & 0 \end{bmatrix} P^T,$$

which, together with (60), implies $V^0(\Delta S) = 0 \in \mathcal{S}^n$. Therefore, by (57) and (59), we have for $\Delta X \equiv 0$ that

$$W^0(\Delta X, \Delta y, \Delta S) = \begin{bmatrix} -\mathcal{A}^*(\Delta y) - \Delta S \\ \mathcal{A}\,(\Delta X) \\ \Delta X - V^0(\Delta X - \Delta S) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ V^0(\Delta S) \end{bmatrix} = 0\,,$$

which implies that W^0 is singular. This contradiction shows that the primal constraint nondegenerate condition (40) holds at $\overline{X}$.

Next, we show that the nonsingularity of $W^{\mathcal{I}}$ implies the dual constraint nondegenerate condition (42). Suppose not. Then,

$$[\mathcal{A}^*\Re^m]^{\perp} \cap \left[\,\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\right)\,\right]^{\perp} \neq \{0\}\,.$$

Let $0 \neq \Delta X \in [\mathcal{A}^*\Re^m]^{\perp} \cap \left[\,\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\right)\,\right]^{\perp}$. We obtain from $\Delta X \in [\mathcal{A}^*\Re^m]^{\perp}$ that

$$\langle \Delta X, \mathcal{A}^* y \rangle = 0 \quad \forall\, y \in \Re^m \Longrightarrow \mathcal{A}(\Delta X) = 0 \tag{61}$$

and from $\Delta X \in \left[\,\mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\right)\,\right]^{\perp}$ that

$$\left\langle P^T(\Delta X)P, P^T S P \right\rangle = \left\langle \Delta X, S \right\rangle = 0 \quad \forall\, S \in \mathrm{lin}\left(\mathcal{T}_{\mathcal{S}^n_+}(\overline{S})\right),$$

which, together with (49), implies

$$P_\alpha^T(\Delta X)P_\gamma = 0, \quad P_\beta^T(\Delta X)P_\gamma = 0, \quad \text{and} \quad P_\gamma^T(\Delta X)P_\gamma = 0\,. \tag{62}$$

From Proposition 2, for $V^{\mathcal{I}} \in \mathrm{ex}\,(\partial_B \Pi_{\mathcal{S}^n_+}(\overline{A}))$, it holds that

$$V^{\mathcal{I}}(\Delta X) = P \begin{bmatrix} P_\alpha^T(\Delta X)P_\alpha & P_\alpha^T(\Delta X)P_\beta & U_{\alpha\gamma} \circ (P_\alpha^T(\Delta X)P_\gamma) \\ \left(P_\alpha^T(\Delta X)P_\beta\right)^T & P_\beta^T(\Delta X)P_\beta & 0 \\ \left(P_\alpha^T(\Delta X)P_\gamma\right)^T \circ U_{\alpha\gamma}^T & 0 & 0 \end{bmatrix} P^T,$$

which, together with (62), implies $V^{\mathcal{I}}(\Delta X) = \Delta X$. Therefore, by (57) and (61), we have for $(\Delta y, \Delta S) \equiv (0,0) \in \Re^m \times \mathcal{S}^n$ that

$$W^{\mathcal{I}}(\Delta X, \Delta y, \Delta S) = \begin{bmatrix} -\mathcal{A}^*(\Delta y) - \Delta S \\ \mathcal{A}(\Delta X) \\ \Delta X - V^{\mathcal{I}}(\Delta X - \Delta S) \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \Delta X - V^{\mathcal{I}}(\Delta X) \end{bmatrix} = 0\,,$$

which implies that $W^{\mathcal{I}}$ is singular. This contradiction shows that the dual constraint nondegenerate condition (42) holds at $(\bar{y}, \overline{S})$. This completes the proof. ∎

Now, we are ready to state our main result of this paper.

THEOREM 18. *Let $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point satisfying the KKT conditions* (3)*, and let F be defined by* (44)*. Then, the following are all equivalent:*

(i) *The KKT point $(\overline{X}, \bar{y}, \overline{S})$ is a strongly regular solution of the generalized equation* (45)*.*

(ii) *The function F is a locally Lipschitz homeomorphism near $(\overline{X}, \bar{y}, \overline{S})$.*

(iii) *The primal constraint nondegenerate condition* (40) *holds at $\overline{X}$, and the dual constraint nondegenerate condition* (42) *holds at $(\bar{y}, \overline{S})$.*

(iv) *Every element in $\partial F(\overline{X}, \bar{y}, \overline{S})$ is nonsingular.*

(v) *Every element in $\partial_B F(\overline{X}, \bar{y}, \overline{S})$ is nonsingular.*

(vi) *The two elements in $\mathrm{ex}\left(\partial_B F(\overline{X}, \bar{y}, \overline{S})\right)$ are nonsingular.*

Proof. We already know from Lemma 11 that (i) $\Longleftrightarrow$ (ii) and from Propositions 16 and 17 that (iii) $\Longleftrightarrow$ (iv) $\Longleftrightarrow$ (v) $\Longleftrightarrow$ (vi). Furthermore, Clarke's inverse function theorem for Lipschitz functions [11, 12] implies that (iv) $\Longrightarrow$ (ii). The proof of this theorem will be complete if one can show that (ii) $\Longrightarrow$ (v). However, the latter has been known to be true since 1991 [21] (Gowda [15] even obtained a stronger conclusion than this by employing the degree theory). ∎

Remark 19. Note that the relations (i) $\Longleftrightarrow$ (ii) $\Longleftrightarrow$ (iv) even hold for the general nonlinear semidefinite programming case [42, Theorem 4.1], whose proof further relies on a number of important results achieved by Bonnans and Shapiro in their excellent monograph [7] on sensitivity analysis in optimization and variational inequalities. Here, the structure displayed uniquely by the SDP problem (1) allows us to derive these relations directly by avoiding the detour employed in [42] for the nonlinear SDP problem. An SDP example satisfying (iii) but with the strict complementary condition failing to hold can be found in [2]. See also [20].

4. Quadratic convergence of smoothing Newton methods. In this section, we shall show how the theoretical results obtained in sections 2 and 3 can be used to provide a quadratic convergence analysis on smoothing Newton methods for solving the nonsmooth equation $F(X, y, S) = 0$, where F is defined by (44). Let $\Phi : \Re \times \mathcal{S}^n \to \mathcal{S}^n$ be defined by (19). We then introduce the following smoothing function for F:

$$G(\varepsilon, X, y, S) \equiv \begin{bmatrix} C - \mathcal{A}^* y - S \\ \mathcal{A}X - b \\ S - \Phi(\varepsilon, S - X) \end{bmatrix} = \begin{bmatrix} C - \mathcal{A}^* y - S \\ \mathcal{A}X - b \\ X - \Phi(\varepsilon, X - S) \end{bmatrix}, \tag{63}$$

where $(\varepsilon, X, y, S) \in \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$. The above function G is continuously differentiable around any $(\varepsilon, X, y, S) \in \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ when $\varepsilon \neq 0$ and has been used by several authors [9, 10, 20, 46] to design smoothing Newton methods for solving SDP problems (1) and (2).

Define $E : \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n \to \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ by

$$E(\varepsilon, X, y, S) \equiv \begin{bmatrix} \varepsilon \\ G(\varepsilon, X, y, S) \end{bmatrix}, \quad (\varepsilon, X, y, S) \in \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n. \tag{64}$$

Then we have

$$F(X, y, S) = 0 \Longleftrightarrow E(\varepsilon, X, y, S) = 0 \quad \forall\, (\varepsilon, X, y, S) \in \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n.$$

Let $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point satisfying the KKT conditions (3). Then

$$E(0, \overline{X}, \bar{y}, \overline{S}) = 0\,.$$

Write $\overline{A} \equiv \overline{X} - \overline{S}$. Let $\overline{A}$, $\overline{X}$, and $\overline{S}$ have the spectral decompositions as in (47). Let the linear-quadratic function $\Upsilon_{\overline{X}}(\cdot,\cdot)$ be defined as in Definition 12. Then, we have the following result, which will play a key role in our analysis of quadratic convergence of smoothing Newton methods.

PROPOSITION 20. *Let $V \in \partial\Phi(0, \overline{A})$. Then, for any ΔX and ΔS in $\mathcal{S}^n$ such that $\Delta X = V(0, \Delta X - \Delta S)$, it holds that*

$$\langle \Delta X, \Delta S\rangle \le \Upsilon_{\overline{X}}(-\overline{S}, \Delta X)\,. \tag{65}$$

Proof. Let ΔX and ΔS be in $\mathcal{S}^n$ such that $\Delta X = V(0, \Delta X - \Delta S)$. Write $\Delta\widetilde{X} \equiv P^T(\Delta X)P$ and $\Delta\widetilde{S} \equiv P^T(\Delta S)P$. Let $\Phi_{|\beta|}$ be defined by (24). Then, by Proposition 5, there exists $V_{|\beta|} \in \partial\Phi_{|\beta|}(0,0)$ such that

$$V(0, \Delta X - \Delta S) = P \begin{bmatrix} \Delta\widetilde{H}_{\alpha\alpha} & \Delta\widetilde{H}_{\alpha\beta} & U_{\alpha\gamma} \circ \Delta\widetilde{H}_{\alpha\gamma} \\ (\Delta\widetilde{H}_{\alpha\beta})^T & V_{|\beta|}(0, \Delta\widetilde{H}_{\beta\beta}) & 0 \\ (\Delta\widetilde{H}_{\alpha\gamma})^T \circ U_{\alpha\gamma}^T & 0 & 0 \end{bmatrix} P^T\,,$$

where $\Delta\widetilde{H} \equiv \Delta\widetilde{X} - \Delta\widetilde{S}$ and $U \in \mathcal{S}^n$ is defined by (8). Thus, by using $\Delta X = V(0, \Delta X - \Delta S)$, we obtain

$$\Delta\widetilde{S}_{\alpha\alpha} = 0, \quad \Delta\widetilde{S}_{\alpha\beta} = 0, \quad \Delta\widetilde{X}_{\beta\gamma} = 0, \quad \Delta\widetilde{X}_{\gamma\gamma} = 0, \tag{66}$$

$$\Delta\widetilde{X}_{\beta\beta} = V_{|\beta|}(0, \Delta\widetilde{X}_{\beta\beta} - \Delta\widetilde{S}_{\beta\beta})\,, \tag{67}$$

and

$$\Delta\widetilde{X}_{\alpha\gamma} - U_{\alpha\gamma} \circ \Delta\widetilde{X}_{\alpha\gamma} = -U_{\alpha\gamma} \circ \Delta\widetilde{S}_{\alpha\gamma}\,. \tag{68}$$

By applying Proposition 7 to $\Phi_{|\beta|}$ and using (67), we obtain

$$\begin{aligned} &\langle \Delta\widetilde{X}_{\beta\beta}, -\Delta\widetilde{S}_{\beta\beta}\rangle \\ &= \big\langle V_{|\beta|}(0, \Delta\widetilde{X}_{\beta\beta} - \Delta\widetilde{S}_{\beta\beta}), (\Delta\widetilde{X}_{\beta\beta} - \Delta\widetilde{S}_{\beta\beta}) - V_{|\beta|}(0, \Delta\widetilde{X}_{\beta\beta} - \Delta\widetilde{S}_{\beta\beta})\big\rangle \ge 0\,, \end{aligned} \tag{69}$$

Therefore, from (66), (68), and (69), we have

$$\begin{aligned} \langle \Delta X, \Delta S\rangle &= \langle \Delta\widetilde{X}, \Delta\widetilde{S}\rangle \\ &= \langle \Delta\widetilde{X}_{\beta\beta}, \Delta\widetilde{S}_{\beta\beta}\rangle + 2\langle \Delta\widetilde{X}_{\alpha\gamma}, \Delta\widetilde{S}_{\alpha\gamma}\rangle \\ &\le 2\langle \Delta\widetilde{X}_{\alpha\gamma}, \Delta\widetilde{S}_{\alpha\gamma}\rangle \\ &= 2\sum_{i\in\alpha, j\in\gamma} \frac{\lambda_j}{\lambda_i}((\Delta\widetilde{X})_{ij})^2\,, \end{aligned}$$

which, together with the fact that

$$\Upsilon_{\overline{X}}(-\overline{S}, \Delta X) = 2\sum_{i\in\alpha, j\in\gamma} \frac{\lambda_j}{\lambda_i}((\Delta\widetilde{X})_{ij})^2\,,$$

shows that (65) holds. □

The following result relates the nonsingularity of $\partial_B E(0, \overline{X}, \bar{y}, \overline{S})$ and $\partial E(0, \overline{X}, \bar{y}, \overline{S})$ to both the primal constraint nondegeneracy and the dual constraint nondegeneracy.

PROPOSITION 21. *Let $(\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be a KKT point satisfying the KKT conditions* (3)*, and let E be defined by* (64)*. Then the following are equivalent:*

(i) *The primal constraint nondegenerate condition* (40) *holds at $\overline{X}$, and the dual constraint nondegenerate condition* (42) *holds at $(\bar{y}, \overline{S})$.*

(ii) *Every element in $\partial_B E(0, \overline{X}, \bar{y}, \overline{S})$ is nonsingular.*

(iii) *Every element in $\partial E(0, \overline{X}, \bar{y}, \overline{S})$ is nonsingular.*

Proof. Since "(iii) $\Longrightarrow$ (ii)" holds trivially and "(ii) $\Longrightarrow$ (i)" follows from Proposition 6 and Theorem 18 directly, we need only to show "(i) $\Longrightarrow$ (iii)." So in the remaining part of our proof we always assume that part (i) holds.

Let W be an arbitrary element in $\partial E(0, \overline{X}, \bar{y}, \overline{S})$. We need to show that W is nonsingular. Let $(\Delta\varepsilon, \Delta X, \Delta y, \Delta S) \in \Re \times \mathcal{S}^n \times \Re^m \times \Re^n$ be such that

$$W(\Delta\varepsilon, \Delta X, \Delta y, \Delta S) = 0.$$

Then, by Lemma 1, there exists $V \in \partial\Phi(0, \overline{A})$ such that

$$W(\Delta\varepsilon, \Delta X, \Delta y, \Delta S) = \begin{bmatrix} \Delta\varepsilon \\ -\mathcal{A}^*(\Delta y) - \Delta S \\ \mathcal{A}(\Delta X) \\ \Delta X - V(\Delta\varepsilon, \Delta X - \Delta S) \end{bmatrix} = 0\,,$$

which implies that $\Delta\varepsilon = 0$. Thus, we have

$$W(0, \Delta X, \Delta y, \Delta S) = \begin{bmatrix} 0 \\ -\mathcal{A}^*(\Delta y) - \Delta S \\ \mathcal{A}(\Delta X) \\ \Delta X - V(0, \Delta X - \Delta S) \end{bmatrix} = 0\,. \tag{70}$$

Since the primal constraint nondegenerate condition (40) implies $\mathcal{M}(\overline{X}) = \{(\bar{y}, \overline{S})\}$, we know from Proposition 15 that the strong second order sufficient condition (51) holds at $\overline{X}$ and takes the form

$$-\Upsilon_{\overline{X}}(-\overline{S}, H) > 0 \quad \forall\, 0 \neq H \in \mathrm{app}(\bar{y}, \overline{S})\,, \tag{71}$$

where the set $\mathrm{app}(\bar{y}, \overline{S})$ is defined by (50). From Proposition 5, (70), and (50), we know that

$$\Delta X \in \mathrm{app}(\bar{y}, \overline{S})\,. \tag{72}$$

By the second and the third equations of (70), we obtain that

$$0 = \langle \Delta X, -\mathcal{A}^*(\Delta y) - \Delta S\rangle + \langle \Delta y, \mathcal{A}(\Delta X)\rangle = \langle \Delta X, -\Delta S\rangle\,,$$

which, together with Proposition 20 and the last equation of (70), implies that

$$\Upsilon_{\overline{X}}(-\overline{S}, \Delta X) \geq 0\,.$$

Hence, from (71) and (72), we can conclude that

$$\Delta X = 0\,.$$

Thus, from (70), we get

$$\begin{bmatrix} \mathcal{A}^*(\Delta y) + \Delta S \\ V(0, -\Delta S) \end{bmatrix} = 0\,, \tag{73}$$

which, by Proposition 5, gives rise to

$$P_\alpha^T(\Delta S)P_\alpha = 0, \quad P_\alpha^T(\Delta S)P_\beta = 0, \text{ and } P_\alpha^T(\Delta S)P_\gamma = 0\,. \tag{74}$$

From (39), which is equivalent to the primal constraint nondegenerate condition (40), we know that there exist $X \in \mathcal{S}^n$ and $S \in \operatorname{lin}\left(\mathcal{T}_{\mathcal{S}_+^n}(\overline{X})\right)$ such that

$$\mathcal{A}\,X = \Delta y \quad \text{and} \quad X + S = \Delta S\,,$$

which, together with (74), (49), and the first equation of (73), imply

$$\begin{aligned} \langle \Delta y, \Delta y\rangle + \langle \Delta S, \Delta S\rangle &= \langle \mathcal{A}\,X, \Delta y\rangle + \langle X + S, \Delta S\rangle \\ &= \langle \mathcal{A}\,X, \Delta y\rangle + \langle X, -\mathcal{A}^*(\Delta y)\rangle + \langle S, \Delta S\rangle \\ &= \langle S, \Delta S\rangle = \langle P^T S P, P^T(\Delta S)P\rangle = 0\,. \end{aligned}$$

Thus, $\Delta y = 0$ and $\Delta S = 0$, which, together with $\Delta\varepsilon = 0$ and $\Delta X = 0$, imply the following:

$$W(\Delta\varepsilon, \Delta X, \Delta y, \Delta S) = 0 \Longrightarrow (\Delta\varepsilon, \Delta X, \Delta y, \Delta S) = 0\,.$$

This shows that W is nonsingular. So, the proof is completed. □

The significance of Proposition 21 is that it allows us to offer a quadratic convergence analysis on several globally convergent smoothing Newton methods presented in [9, 10, 20, 46] for solving the SDP problem even when the strict complementarity condition is not satisfied, i.e., when the condition $\overline{X} + \overline{S} \succ 0$ fails to hold. Instead of working on these different smoothing Newton methods one by one (with some necessary modifications), for simplicity we use only the smoothing Newton method presented in [46] as an example of how this objective can be achieved.

For any $(\varepsilon, X, y, S) \in \Re \times \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$, write $Z \equiv (X, y, S)$ and define $f(\varepsilon, Z) := \|E(\varepsilon, Z)\|^2$ and $\theta(\varepsilon, Z) := r \min\{1, f(\varepsilon, Z)\}$. Let $\bar{\varepsilon} \in (0, \infty)$ and $r \in (0, 1)$ be such that $r\bar{\varepsilon} < 1$. The smoothing Newton method presented in [46] can then be stated as follows.

Algorithm I (a squared smoothing Newton method).

Step 0. Select constants $\delta \in (0, 1)$ and $\sigma \in (0, 1/2)$. Let $\varepsilon_0 := \bar{\varepsilon}$, $Z^0 \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ be an arbitrary point, and $k := 0$.

Step 1. If $E(\varepsilon_k, Z^k) = 0$, then stop. Otherwise, let $\theta_k := \theta(\varepsilon_k, Z^k)$.

Step 2. Compute $(\Delta\varepsilon_k, \Delta Z^k)$ by

$$E(\varepsilon_k, Z^k) + E'(\varepsilon_k, Z^k)(\Delta\varepsilon_k, \Delta Z^k) = \theta_k \begin{bmatrix} \bar{\varepsilon} \\ 0 \end{bmatrix}. \tag{75}$$

Step 3. Let l_k be the smallest nonnegative integer l satisfying

$$f(\varepsilon_k + \delta^l \Delta\varepsilon_k, Z^k + \delta^l \Delta Z^k) \le [\,1 - 2\sigma(1 - r\bar{\varepsilon})\delta^l\,] f(\varepsilon_k, Z^k)\,. \tag{76}$$

Define $(\varepsilon_{k+1}, Z^{k+1}) := (\varepsilon_k + \delta^{l_k}\Delta\varepsilon_k, Z^k + \delta^{l_k}\Delta Z^k)$.

Step 4. Replace k by $k+1$ and go to Step 1.

The well posedness of Algorithm I hinges on the nonsingularity of $E'(\varepsilon, Z)$ for any $\varepsilon > 0$, which is equivalent to the surjectivity of the linear operator $\mathcal{A} : \mathcal{S}^n \to \Re^m$ [46]. The two conditions required for quadratic convergence of Algorithm I are (i) the strong semismoothness of the smoothing function E and (ii) the nonsingularity of all $W \in \partial_B E(0, Z^*)$ (or all $W \in \partial E(0, Z^*)$). However, (i) has been proven in [46] and (ii) can be derived from Proposition 21 under both the primal constraint nondegeneracy and the dual constraint nondegeneracy. Thus, by employing the standard convergence analysis detailed in [30] for the vector version of the squared smoothing Newton method, we have the following convergence theorem. For more explanation, see [46].

THEOREM 22. *Assume that $\mathcal{A} : \mathcal{S}^n \to \Re^m$ is onto. Then an infinite sequence $\{(\varepsilon_k, Z^k)\}$ is generated by Algorithm* I *and each accumulation point $(0, \overline{Z})$ of $\{(\varepsilon_k, Z^k)\}$ is a solution of $E(\varepsilon, Z) = 0$. Let $\overline{Z} = (\overline{X}, \bar{y}, \overline{S}) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$. If the primal constraint nondegenerate condition* (40) *holds at $\overline{X}$ and the dual constraint nondegenerate condition* (42) *holds at $(\bar{y}, \overline{S})$, then the whole sequence $\{(\varepsilon_k, Z^k)\}$ converges to $(0, \overline{Z})$,*

$$\| (\varepsilon_{k+1}, Z^{k+1}) - (0, \overline{Z}) \| = O(\| (\varepsilon_k, Z^k) - (0, \overline{Z}) \|^2), \tag{77}$$

and

$$\varepsilon_{k+1} = O(\varepsilon_k^2)\,. \tag{78}$$

Note that in Theorem 22, the quadratic convergence does not rely on the strict complementarity—one common condition that was assumed in all known smoothing Newton methods for solving the SDP problem (1) and its dual, as far as we know. The smoothing function G can certainly take other forms. For example, in order to improve the global convergence of Algorithm I, one may consider Tikhonov-type regularized smoothing functions such as

(79)

$$G(\varepsilon, X, y, S) := \begin{bmatrix} C - \mathcal{A}^* y - S + \varepsilon X \\ \mathcal{A}X - b + \varepsilon y \\ S - \Phi\big(\varepsilon, S - (X + \varepsilon S)\big) \end{bmatrix} = \begin{bmatrix} C - \mathcal{A}^* y - S + \varepsilon X \\ \mathcal{A}X - b + \varepsilon y \\ X - \Phi\big((X + \varepsilon S) - S\big) + \varepsilon S \end{bmatrix}.$$

The quadratic convergence of Algorithm I will not be affected because, by Lemma 1, the set $\partial_B E(0, X, S, Y)$ is still kept the same for any $(X, y, S) \in \mathcal{S}^n \times \Re^m \times \mathcal{S}^n$ if one replaces the smoothing function G in (64) by the one given in (79).

5. Conclusions. In this paper, we presented several equivalent links among the primal and dual constraint nondegenerate conditions, the strong regularity, and the nonsingularity of both the B-subdifferential and Clarke's generalized Jacobian of a nonsmooth system at a KKT point in the context of linear semidefinite programming. These links were further used to derive for the first time a quadratic convergence analysis of globally convergent smoothing Newton methods without assuming the strict complementarity. Variational analysis on the metric projector over the cone

of positive semidefinite matrices and its smoothed counterpart plays a fundamental role in achieving these. Given the fact that the metric projector over the more general symmetric cone behaves quite similarly to the metric projector over the cone of positive semidefinite matrices [45], one is tempted to wonder if the results obtained in this paper can be extended to linear symmetric cone programming. We leave this interesting question as our future research topic.

Acknowledgments. The authors are grateful to the referees and the associate editor for their helpful suggestions on improving the quality of this paper. Defeng Sun would also like to thank Jong-Shi Pang and Alexander Shapiro for discussions on the constraint nondegeneracy when they visited National University of Singapore during 2002–2005.

CONVERGENCE OF NEW INERTIAL PROXIMAL METHODS FOR DC PROGRAMMING*

PAUL-EMILE MAINGÉ† AND ABDELLATIF MOUDAFI†

Abstract. We present iterative methods for finding the critical points and/or the minima of extended real valued functions of the form $\phi = \psi + g - h$, where ψ is a differentiable function and g and h are convex, proper, and lower semicontinuous. The underlying idea relies upon the discretization of a first order dissipative dynamical system which allows us to preserve the local feature and to obtain some convergence results. The main theorems not only recover known convergence results in this field but also provide a theoretical basis for the development of new iterative methods.

Key words. DC minimization, proximal mappings, critical points, subdifferentials

1. Introduction.

In recent years there has been very active research in nonconvex programming. A great deal of the work involves global optimization, whose main tools and solution methods are developed according to the spirit of combinatorial optimization. Apart from this combinatorial approach to global continuous optimization, the convex analysis approach to nonconvex programming has been much less studied, and only on DC programming. In this paper these works are extended in a natural and logical way to find critical points of a nonconvex objective function $\phi : \mathcal{H} \to \overline{\mathbb{R}}$ of the form $\phi := \psi + g - h$, namely,

$$\mathcal{P}(\phi, \mathcal{H}) : \qquad \min_{x \in \mathcal{H}} (\psi(x) + g(x) - h(x)),$$

where ψ is differentiable (not necessarily convex) and g and h are convex, lower semicontinuous proper functions on a real Hilbert space $\mathcal{H}$ endowed with inner product and induced norm, respectively denoted by $\langle ., . \rangle$ and $|.|$.

Indeed, we wish to make an extension of DC programming—not too large to allow us the use of the arsenal of powerful tools in convex analysis and convex optimization but sufficiently wide to cover most real-world nonconvex optimization problems. The convexity of the two DC components and the differentiability of ψ of the objective function will be used to develop appropriate tools from both theoretical and algorithmic viewpoints. There is a great interest for this class of objective functions (see, for instance, [18, 28]). Let us mention that $\mathcal{P}(\phi, \mathcal{H})$, in the special case when $g = \delta_C$, the indicator function of a nonempty closed convex set C, becomes $\mathcal{P}(\psi - h, C) : \min_{x \in C}(\psi(x) - h(x))$, which includes constrained convex maximization problems. When $\psi \equiv 0$, ϕ is called a DC function. It is worth mentioning that the class of DC functions contains all lower-$\mathcal{C}^2$ functions and constitutes a minimal realistic extension of the class of convex functions. It has been successfully used in many nonconvex applications such as multicommodity network, image restoration processing, and semilinear elliptic problems arising in plasma physics and fluid mechanics

†GRIMMAG, Département Scientifique Interfacultaire, Université des Antilles-Guyane, Campus de Schoelcher, 97230 Cedex, Martinique (F.W.I.) (Paul-Emile.Mainge@martinique.univ-ag.fr, Abdellatif.Moudafi@martinique.univ-ag.fr).

and seems particularly well suited to model several nonconvex industrial problems (computer vision, fuel mixture, molecular biology, etc.). Some interesting optimality conditions related to $\mathcal{P}(\phi, \mathcal{H})$ in the more general setting of Banach spaces are given by Penot [23] (see also [10, 11, 17] for the case when $\psi \equiv 0$).

(i) [23, Proposition 2.1]) A necessary condition for $\bar{x}$ to be a local minimizer of ϕ is $\partial^F h(\bar{x}) \subset \partial^F(\psi + g)(\bar{x})$, where ∂^F is the Fréchet subdifferential. Because of the regularity of the function ψ and the convexity of the functions g and h, we have

$$\partial^F(\psi + g)(\bar{x}) = \partial^F g(\bar{x}) + \nabla\psi(\bar{x}),\ \partial^F g = \partial g, \quad \text{and } \partial^F h = \partial h,$$

where ∂ denotes the standard Fenchel subdifferential of convex analysis, so that this necessary condition may be rewritten as $\partial h(\bar{x}) \subset \partial g(\bar{x}) + \nabla\psi(\bar{x})$.

(ii) [23, Corollary 2.4]) Conversely, when $\mathcal{H}$ is finite dimensional, $\bar{x}$ is a local strict minimizer of ϕ provided that $\partial h(\bar{x}) \subset \text{int}(\partial g(\bar{x})) + \nabla\psi(\bar{x})$.

Being aware that such optimality conditions are not easily reached from the numerical viewpoint, we will focus on the problem of finding critical points of ϕ, namely,

$$\text{find } \bar{x} \in S := \{x \in \mathcal{H};\quad (\nabla\psi(x) + \partial g(x)) \cap \partial h(x) \neq \emptyset\}. \tag{1.1}$$

In contrast with the combinatorial approach, from which many algorithms have been studied, there have been very few algorithms for solving DC programs from the convex analysis approach (see, for instance, [24, 27]). DC algorithms, based on local optimality conditions and duality in DC programming, have been introduced by Pham Dinh Tao [24] as an extension of the subgradient algorithms to DC programming. Due to its local character it cannot guarantee the globality of computed solutions for general DC programs. It is worth mentioning that x^* is a global solution to a DC problem (i.e., when $\psi \equiv 0$) if and only if

$$\partial_\varepsilon h(x^*) \subset \partial_\varepsilon g(x^*) \quad \forall \varepsilon \geq 0.$$

Unfortunately, as we can foresee, the conditions are rather difficult to use for devising solution methods to DC programs.

Another important feature of the DC structure, which must be taken into account while studying solution algorithms, is the regularization techniques in DC programming. To the best of our knowledge, the corresponding scheme, which has been studied in [27], is the most recent algorithm in the special case of DC functions. Each of its iterates consists in combining an ascent subgradient step on h with a proximal step on g (see [27]). An approximate version of this algorithm using the ϵ-subdifferential was also discussed in Moudafi and Maingé [20]. They proved that if the sequence generated by their method is bounded, then every cluster-point is a critical point of ϕ.

It is worth noting, for instance, that by using suitable DC decompositions of convex functions we can obtain almost standard algorithms for convex and nonconvex programming. The choice of the DC decomposition in the objective function strongly depends on the very specific structure of the problem being considered. In practice, for solving problem (1.1), we try to choose g and h such that the sequences x_n and q_n generated by (1.4) can be easily calculated: i.e., either they are in explicit form or their computations are inexpensive. Let us remember that the convergence of most of the numerical methods in convex minimization are obtained under the condition of the existence of a local minimizer (which then is a global minimizer) for the objective function. In the present setting of nonconvex minimization, the existence of local minima does not imply the existence of global minima, even if the objective function

is bounded from below. Therefore, one may expect not to succeed in proving the boundedness of the iterates of the proposed numerical algorithms, except for some restrictive assumptions.

Let us now come to the original aspect of our approach. In order to solve (1.1), we suggest and analyze a new and promising iterative method obtained by coupling the ϵ-subdifferential of h and the approximate proximal mapping of g. These new schemes generalize the algorithms proposed in [27] and most of the existing methods in convex minimization, e.g., the proximal point algorithm (see [9, 16, 25]), the standard projected gradient algorithm (see [21, 15]), and the inertial proximal algorithm and its approximate variants (see [1, 2, 12, 19]). Furthermore, our proposed algorithm is based upon an implicit discretization of the following first order dissipative dynamical system discussed in [3] (see also [5]):

$$\left[\begin{array}{l} x^{(1)}(t) + \beta\nabla\phi(x(t)) + ax(t) + by(t) = 0, \\ y^{(1)}(t) + ax(t) + by(t) = 0, \\ x(0) = x_0, \quad y(0) = y_0, \end{array}\right. \tag{1.2}$$

where ϕ is assumed to be a convex differentiable function, where the initial data x_0 and y_0 belong to $\mathcal{H}$ and where $\beta > 0$, $b > 0$, and $a + b > 0$.

Let us also specify the motivation for this dynamical system in view of building iterative schemes. Most of the existing numerical methods for minimizing a function, whether in the convex setting or not, are based upon a discretization of some continuous equations with appropriate convergence properties. The algorithm of Sun, Sampaio, and Candido [27], the standard proximal point algorithm, and the gradient method come from the first order steepest descent equation $x^{(1)}(t) + \nabla\phi(x(t)) = 0$. Conversely, the inertial proximal method is inspired by the heavy ball with friction dynamical system $x^{(2)}(t)+\alpha x^{(1)}(t)+\nabla\phi(x(t)) = 0$. The latter system was introduced by Attouch, Goudon, and Redont [6] for overcoming some of the drawbacks of the steepest descent method. It turns out that when ϕ is convex, the two trajectories of the last two equations weakly converge to minimizers of ϕ. Nevertheless, there is a tremendous difference between them. By contrast with the steepest descent method, the heavy ball with friction dynamical system is no longer a descent method. In the latter case, it is not the function $\phi(x(t))$ which decreases along trajectories in general but the energy of the system $E(t) := \frac{1}{2}|x^{(1)}(t)|^2 + \phi(x(t))$. Consequently, the latter benefits from interesting properties for the exploration of local minima of ϕ (see [6] for more details). It also appears that its trajectories may exhibit oscillations which are not desirable. In view of numerical optimization purposes, Alvarez and Pérez [4] have studied the "continuous Newton" method $\nabla^2\phi(x(t))x^{(1)}(t) + \nabla\phi(x(t)) = 0$. See also [8], where an ordinary differential equation model within the framework of a preconditioned gradient method is considered, the objective being the developement of an implicit scheme to approximate the preconditioned search direction at every iteration, without a priori knowledge of the Hessian of the objective function. If one combines this last system with the heavy ball system with friction, the system thus obtained,

$$x^{(2)}(t) + \alpha x^{(1)}(t) + \beta\nabla^2\phi(x(t))x^{(1)}(t) + \nabla\phi(x(t)) = 0, \tag{1.3}$$

inherits most of the advantages of the two preceding systems and corrects both of the above-mentioned drawbacks: the term $\nabla^2\phi(x(t))x^{(1)}(t)$ is a clever geometric damping term, while the acceleration term $x^{(2)}(t)$ makes the Newton dynamical system well-posed, even if $\nabla^2\phi(x(t))$ is degenerate (see Attouch and Redont [7] for a first study of

this question). It is worth mentioning that (1.3) is a second order system both in time and in space. Furthermore, it was proved that (1.3) is equivalent in some sense to the system (1.2) which is first order in time and with no occurrence of the Hessian (see [3] and [5] for more details). This matter opens new interesting perspectives such as considering (1.3) for nonsmooth functions which are only lower semicontinuous or involving constraints, with clear applications to mechanics and PDEs (wave equations, shocks). Moreover, the following theorem related to (1.2) is proved.

THEOREM 1.1 (see [3]). *Let ϕ satisfy the following hypotheses:*

- *ϕ is defined and continuously differentiable on $\mathcal{H}$,*
- *ϕ is bounded from below, and*
- *the gradient $\nabla\phi$ is Lipschitz continuous on the bounded subsets.*

Assume further that $\beta > 0$, $b > 0$, $b + a > 0$ in (1.2). Then the following properties hold.

(i) *For each $(x_0, y_0) \in \mathcal{H} \times \mathcal{H}$, there exists a unique solution (x, y) of (1.2) defined on the whole interval $[0, +\infty)$, which satisfies the initial conditions $x(0) = x_0$, $y(0) = y_0$; (x,y) belongs to $C^1(0, \infty; \mathcal{H}) \times C^2(0, \infty; \mathcal{H})$ and satisfies the initial conditions $x(0) = x_0$ and $y(0) = y_0$.*

(ii) *For every trajectory $(x(t), y(t))$ of (1.2) and for $\lambda \in [\beta(\sqrt{a+b} - \sqrt{b})^2, \beta(\sqrt{a+b} + \sqrt{b})^2]$, the energy $F_\lambda : (x, y) \in \mathcal{H} \times \mathcal{H} \to \lambda\phi(x) + \frac{1}{2}|ax + by|^2$ is a Lyapounov function of (1.2); the energy $F_\lambda(x(t), y(t))$ is decreasing on $[0, +\infty)$ and bounded from below and hence converges to some real value as $t \to +\infty$. Moreover, we have*

- *$x^{(1)}$ and $y^{(1)}$ in $L^2(0, +\infty; \mathcal{H})$,*
- *$\lim_{t\to+\infty} \phi(x(t))$ exists,*
- *$\lim_{t\to+\infty} y^{(1)}(t) = 0$, and*
- *$\nabla\phi(x) \in L^2(0, +\infty; \mathcal{H})$ and $\lim_{t\to+\infty} x^{(1)}(t) + \beta\nabla\phi(x(t)) = 0$.*

(iii) *Assuming, in addition, that x is in $L^\infty(0, +\infty; \mathcal{H})$, we have*

- *$\nabla\phi(x)$, y, $x^{(1)}$ are bounded on $[0, +\infty)$,*
- *$\lim_{t\to+\infty} x^{(1)}(t) = 0$, and*
- *$\lim_{t\to+\infty} \nabla\phi(x(t)) = 0$.*

It then seems natural to investigate implicit and/or nonimplicit discretization of (1.2) for numerical and theoretical optimization purposes, because an accurate discrete version of an equation is supposed to preserve the essential properties of the continuous one. Moreover, this approach permits us to avoid the use of the Hessian of the function and thus, from a numerical point of view, its aproximation and the related computational cost (see, for instance, [8]). Now, in order to introduce and analyze convergence properties of a proximal iteration called DPM (dissipative proximal method) for finding critical points of $\mathcal{P}(\phi, \mathcal{H})$ which is motivated by the above arguments and inspired by the system (1.2), let us recall the following definitions.

Given $f : \mathcal{H} \to \mathbb{R} \cup \{+\infty\}$, a convex, proper, and lower semicontinuous function,

- the ϵ-subdifferential of f at any point x in the domain of f is defined by

$$\partial_\epsilon f(x) := \{p_x \in \mathcal{H}; \quad f(y) - f(x) \geq \langle y - x, p_x\rangle - \epsilon \quad \forall y \in \mathcal{H}\}.$$

Clearly, $\partial_\epsilon f(x)$ is an enlargement of $\partial f(x)$ in the sense that $\partial_0 f(x) = \partial f(x)$ and $0 \leq \epsilon_1 \leq \epsilon_2 \Rightarrow \partial_{\epsilon_1} f(x) \subset \partial_{\epsilon_2} f(x)$. The use of elements in $\partial_\epsilon f(x)$ instead of $\partial f(x)$ allows an extra degree of freedom, which is of very practical interest in various applications.

- The approximate proximal mapping of f (denoted $J_c^{\partial_\epsilon f}$ or $prox_{cf}^\epsilon$) is defined for any $c > 0$ by $J_c^{\partial_\epsilon f} := (I + c\partial_\epsilon f)^{-1}$.

- The conjugate function of f is defined by $f^*(y) = \sup_{x\in\mathcal{H}} (\langle y, x\rangle - f(y))$. If $k : \mathcal{H} \to \mathbb{R} \cup \{+\infty\}$ is also a convex, proper, and lower semicontinuous function, by Toland's duality, we have $\inf_{x\in\mathcal{H}}(f(x) - k(x)) = \inf_{x\in\mathcal{H}}(k^*(x) - f^*(x))$.

Finally, we will use the usual notation

$$\Gamma_0(\mathcal{H}) := \{v : \mathcal{H} \to \mathbb{R} \cup \{+\infty\}; \quad v \text{ is convex, proper, and lower semicontinuous}\}$$

and adopt in what follows the convention $+\infty - (+\infty) = +\infty$.

Now, choose parameters λ, μ, (ϵ_n), α, γ, ν, τ such that

- $\lambda > 0$, $\mu > 0$, $(\epsilon_n) \subset [0, +\infty)$;
- $\alpha + \gamma > 0$ and $\gamma > 0$; and
- $\nu > 0$ and $\tau > -(2 + \alpha)/(2\gamma)$.

Consider then Algorithm DPM (for finding critical points of $\psi(x) + g(x) - h(x)$):

$$\left[\begin{array}{l} \text{Initialization: } (x_0, y_0) \text{ in } \mathcal{H} \times \mathcal{H}. \\ \\ \text{Step 1: Compute} \quad q_n \in \partial_{\epsilon_n} h(x_n). \\ \\ \text{Step 2: Compute} \\ \quad x_{n+1} \in J_\lambda^{\partial_{\epsilon_n} g}[x_n - \lambda\,(\nabla\psi(x_n) - q_n) - \mu(\alpha x_n + \gamma y_n)]. \\ \\ \text{Step 3: Compute} \\ \quad y_{n+1} = y_n - \dfrac{1}{k}[\alpha x_n + \gamma y_n + \nu\alpha(x_{n+1} - x_n)], \\ \quad \text{where } k := \left(1 + \tau\gamma + \frac{(\alpha+\gamma)}{2}\right). \end{array}\right. \tag{1.4}$$

Let us observe that under the conditions $\gamma > 0$ and $\tau > -(2 + \alpha)/(2\gamma)$, we have $k \geq \gamma/2 > 0$, so that Step 3 in (1.4) makes sense and hence (1.4) is well defined.

The goal of this paper is to provide a broad framework for the design and the analysis of promising algorithms based on a discretization of the new system (1.2). This framework will not only lead to a unified convergence analysis of some existing algorithms in convex optimization and DC programming but will also propose original and theoretically interesting results and will serve as a basis for the development of a new class of algorithms. More specifically, we would like to emphasize that the method proposed by [27] is nothing but the special case of DPM when $\alpha = \gamma = 0$ and g, h are convex functions. The classical proximal algorithm is recovered by taking $\psi = h \equiv 0$ and $\mu = 0$, and the inertial proximal method initiated in [1] for convex minimization (see also [2]) corresponds to the particular case of DPM when $\psi = h \equiv 0$, $\gamma > 0$, $\alpha > 0$, and the parameters τ and ν satisfy

$$\tau = -\tfrac{1}{2\gamma}(\alpha + 2) + \tfrac{1}{2} \text{ and } \nu = 1 + \tfrac{1}{\alpha}. \tag{1.5}$$

Indeed, it is easy to verify that in this case $k = \gamma$ and $\alpha(1 - \nu) = -1$; then Step 2 becomes $y_{n+1} = -\frac{\alpha}{\gamma}\,(x_n + \nu(x_{n+1} - x_n))$, which (in Step 1) entails

$$\alpha x_n + \gamma y_n = \alpha x_n - \alpha\,(x_{n-1} + \nu(x_n - x_{n-1})) = \alpha(1-\nu)(x_n - x_{n-1}) = -(x_n - x_{n-1}),$$

so that DPM reduces to

$$x_{n+1} \in J_\lambda^{\partial_{\epsilon_n} g}\,(x_n + \mu\,(x_n - x_{n-1}))\,.$$

Under suitable conditions on the parameters and a summability condition on the errors, we prove a discrete version of the main theorem, Theorem 1.1, in a more general context. More precisely, we prove that the proposed algorithm generates an asymptotically regular sequence (x_n) and that its weak-cluster points are in S. Moreover, in the convex case we obtain the weak convergence of the whole sequence to a minimizer of the function under consideration.

2. Preliminaries. To begin, let us state a remark which will be useful in what follows.

Remark 2.1. Step 3 in (1.4) is equivalent to each of the following equalities:

$$\begin{aligned}
&\text{(i)} - k(y_{n+1}-y_n) = \alpha x_n + \gamma y_n + \nu\alpha(x_{n+1}-x_n),\\
&\quad \text{where} \quad k := \left(1+\tau\gamma+\tfrac{(\alpha+\gamma)}{2}\right);\\
&\text{(ii)} \quad y_n - y_{n+1} = a[\nu x_{n+1} + (1-\nu)x_n] + b[\tau y_{n+1} + (1-\tau)y_n],\\
&\quad \text{where } a = \tfrac{2\alpha}{2+\alpha+\gamma} \text{ and } b = \tfrac{2\gamma}{2+\alpha+\gamma}.
\end{aligned} \tag{2.1}$$

The fact that Step 3 in (1.4) is equivalent to equality (2.1)(i) is obvious. To complete the verification, we will see that (2.1)(ii) is in turn equivalent to (2.1)(i). Indeed, by an elementary computation (2.1)(ii) is equivalent to

$$\frac{2+\alpha+\gamma}{2}(y_n - y_{n+1}) = \alpha\nu(x_{n+1}-x_n) + \alpha x_n + \gamma\tau(y_{n+1}-y_n) + \gamma y_n;$$

in other words,

$$-\left(\frac{2+\alpha+\gamma}{2}+\gamma\tau\right)(y_n - y_{n+1}) = \alpha\nu(x_{n+1}-x_n) + \alpha x_n + \gamma y_n,$$

which is (2.1)(i).

Now, let us clarify the link between (1.2) and (1.4).

Remark 2.2. To see the connection between (1.2) and (1.4), one may observe that Step 2 in (1.4) is equivalent to the monotone inclusion

$$x_{n+1} - x_n + \lambda\left(\partial_{\epsilon_n} g(x_{n+1}) + \nabla\psi(x_n) - q_n\right) + \mu[\alpha x_n + \gamma y_n] \ni 0, \tag{2.2}$$

while by (2.1)(i) we have

$$\alpha x_n + \gamma y_n = -k(y_{n+1}-y_n) - \nu\alpha(x_{n+1}-x_n),$$

where $k := (1+\tau\gamma+\frac{(\alpha+\gamma)}{2})$, so that we deduce

$$(1-\mu\nu\alpha)(x_{n+1}-x_n) + \lambda(\partial_{\epsilon_n} g(x_{n+1}) + \nabla\psi(x_n) - q_n) - \mu k(y_{n+1}-y_n) \ni 0,$$

namely,

$$\frac{(1-\mu\nu\alpha)}{\mu k}(x_{n+1}-x_n) + \frac{\lambda}{\mu k}[\partial_{\epsilon_n} g(x_{n+1}) + \nabla\psi(x_n) - q_n] - (y_{n+1}-y_n) \ni 0. \tag{2.3}$$

Setting $\beta := \lambda/(\mu k\Delta t)$ (for some positive Δt), we obtain

$$\frac{(1-\mu\nu\alpha)}{\mu k}(x_{n+1}-x_n) + \Delta t\beta[\partial_{\epsilon_n} g(x_{n+1}) + \nabla\psi(x_n) - q_n] - (y_{n+1}-y_n) \ni 0.$$

Hence, for $\mu = \frac{1}{k+\nu\alpha}$, one has $1 - \mu\nu\alpha = \mu k$, and we get

$$\frac{1}{\Delta t}(x_{n+1} - x_n) + \beta[\partial_{\epsilon_n} g(x_{n+1}) + \nabla\psi(x_n) - q_n] - \frac{1}{\Delta t}(y_{n+1} - y_n) \ni 0, \tag{2.4}$$

which in light of (2.1)(ii) can be viewed as a discrete variant of (1.2).

The following lemma will be needed in the next sections.

LEMMA 2.1. *Let w be a differentiable function on $\mathcal{H}$ with an L-Lipschitz continuous gradient for some $L \in]0, +\infty[$ and $u, v \in \Gamma_0(\mathcal{H})$. Then for any points s and t in $\mathcal{H}$, we have*

$$\forall p \in \partial_\epsilon u(t), \quad \forall q \in \partial_\epsilon v(s),$$
$$(w + u - v)(t) - (w + u - v)(s) \le \langle \nabla w(s) + p - q, t - s\rangle + L|t - s|^2 + 2\epsilon.$$

Proof. Taking $u \in \Gamma_0(\mathcal{H})$ and $p \in \partial_\epsilon u(s)$, we have $u(t) - u(s) \le \langle p, t - s\rangle + \epsilon$. Moreover, taking $v \in \Gamma_0(\mathcal{H})$ and $q \in \partial_\epsilon v(s)$, we also have $v(s) - v(t) \le \langle q, s - t\rangle + \epsilon$. Then, by combining the two previous inequalities, we get

$$(u - v)(t) - (u - v)(s) \le \langle p - q, t - s\rangle + 2\epsilon. \tag{2.5}$$

Now, by a classical result there exists $c_\theta := \theta s + (1 - \theta)t$ for some $\theta \in]0, 1[$ such that $w(t) = w(s) + \langle \nabla w(c_\theta), t - s\rangle$, that is, $w(t) - w(s) = \langle \nabla w(c_\theta) - \nabla w(s), t - s\rangle + \langle \nabla w(s), t - s\rangle$. Since ∇w is L-Lipschitz continuous on $\mathcal{H}$, we then obtain

$$w(t) - w(s) \le L|s - t|^2 + \langle \nabla w(s), t - s\rangle,$$

which in light of (2.5) yields the desired result. □

In what follows, $E_n(\delta)$, the discrete energy of the method (1.4), is defined for $n \ge 1$ and $\delta > 0$ by

$$E_n(\delta) = \delta\phi(x_n) + \frac{1}{2}|ax_n + by_n|^2 - 2\delta \sum_{j=0}^{n-1} \epsilon_j, \tag{2.6}$$

where $a = \frac{2\alpha}{2+\alpha+\gamma}$ and $b = \frac{2\gamma}{2+\alpha+\gamma}$.

It is worth mentioning that (2.6) has the same form as the one used in [3] and will permit us to make a connection with the framework developed by Attouch, Bolte, and Redont [5]. Indeed, applying the continuous steepest descent method to the functional

$$E(\delta) : (x, y) \to \frac{1}{b^2}\phi(x) + \frac{1}{2}|ax + by|^2 \tag{2.7}$$

(i.e., $E_n(\delta)$ with $\delta = \frac{1}{b^2}, \epsilon_j = 0$ for $j = 1 \cdots n - 1$) provides the following first order system which is close to (1.2):

$$\left[\begin{array}{l} x^{(1)}(t) + \frac{1}{b^2}\partial\phi(x(t)) + a(ax(t) + by(t)) \ni 0, \\ y^{(1)}(t) + b(ax(t) + by(t)) = 0. \end{array}\right.$$

The latter was introduced by Attouch, Bolte, and Redont [5] in view of minimizing ϕ, which in light of [5, Proposition 6.1.1], is equivalent to minimizing the functional $E(\frac{1}{b^2})$.

3. Asymptotic convergence of DPM. The following lemma contains a useful property of the discrete energy.

LEMMA 3.1. *Let ψ be a differentiable function on $\mathcal{H}$ with an L-Lipschitz continuous gradient for some $L \in]0,+\infty[$ and $g, h \in \Gamma_0(\mathcal{H})$. Then, the two sequences (x_n) and (y_n) generated by scheme (1.4) satisfy the following inequality: $\forall \delta > 0, \forall n \geq 1$,*

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) \leq & \left(-\delta \tfrac{1-\mu\nu\alpha}{\lambda} + \delta L - aC_1\right)|x_{n+1}-x_n|^2 - bC_2|y_{n+1}-y_n|^2 \\ & + \left(\frac{\delta\mu k}{\lambda} - (aC_2+bC_1)\right)\langle x_{n+1}-x_n, y_{n+1}-y_n\rangle, \end{aligned} \tag{3.1}$$

where $k := (1+\tau\gamma+\frac{(\alpha+\gamma)}{2})$, $C_2 := [1+b(\tau-1/2)]$, and $C_1 := a(\nu-1/2)$. $(E_j(\delta))_{j\geq 0}$ is the discrete energy defined in (2.6), and a, b stand for the two parameters defined in (2.1)(ii).

Proof. From (2.3), there exists $p_{n+1} \in \partial_{\epsilon_n} g(x_{n+1})$ such that

$$\frac{1-\mu\nu\alpha}{\mu k}|x_{n+1}-x_n|^2 + \frac{\lambda}{\mu k}\langle p_{n+1}+\nabla\psi(x_n)-q_n, x_{n+1}-x_n\rangle + \langle y_n - y_{n+1}, x_{n+1}-x_n\rangle = 0,$$

that is,

$$\begin{aligned} & \langle p_{n+1}+\nabla\psi(x_n)-q_n, x_{n+1}-x_n\rangle \\ & \qquad = \frac{\mu k}{\lambda}\left(-\frac{1-\mu\nu\alpha}{\mu k}|x_{n+1}-x_n|^2 + \langle y_{n+1}-y_n, x_{n+1}-x_n\rangle\right). \end{aligned} \tag{3.2}$$

Thanks to definition (2.6) of the energy function, we have

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) = & \delta(\phi(x_{n+1})-\phi(x_n)) - 2\delta\epsilon_n \\ & + \left\langle a(x_{n+1}-x_n)+b(y_{n+1}-y_n), a\frac{x_{n+1}+x_n}{2} + b\frac{y_{n+1}+y_n}{2}\right\rangle. \end{aligned} \tag{3.3}$$

By virtue of (2.1)(ii), we also have

$$\begin{aligned} & y_n - y_{n+1} - a\frac{x_{n+1}+x_n}{2} - b\frac{y_{n+1}+y_n}{2} \\ & \qquad = a[\nu x_{n+1} + (1-\nu)x_n] - a\frac{x_{n+1}+x_n}{2} \\ & \qquad\quad + b[\tau y_{n+1} + (1-\tau)y_n] - b\frac{y_{n+1}+y_n}{2} \\ & \qquad = a\left(\nu-\frac{1}{2}\right)(x_{n+1}-x_n) + b\left(\tau-\frac{1}{2}\right)(y_{n+1}-y_n), \end{aligned}$$

that is,

$$\begin{aligned} & a\frac{x_{n+1}+x_n}{2} + b\frac{y_{n+1}+y_n}{2} \\ & \qquad = -[1+b(\tau-1/2)](y_{n+1}-y_n) - a(\nu-1/2)(x_{n+1}-x_n) \\ & \qquad = -C_2(y_{n+1}-y_n) - C_1(x_{n+1}-x_n), \end{aligned}$$

where $C_2 := [1 + b\,(\tau - 1/2)]$ and $C_1 := a\,(\nu - 1/2)$, which by (3.3) entails

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) - \delta(\phi(x_{n+1}) - \phi(x_n)) + 2\delta\epsilon_n \\ &= \left\langle a(x_{n+1} - x_n) + b(y_{n+1} - y_n), a\frac{x_{n+1} + x_n}{2} + b\frac{y_{n+1} + y_n}{2} \right\rangle \\ &= -C_2\langle a(x_{n+1} - x_n) + b(y_{n+1} - y_n), y_{n+1} - y_n\rangle \\ &\quad - C_1\langle a(x_{n+1} - x_n) + b(y_{n+1} - y_n), x_{n+1} - x_n\rangle \\ &= -bC_2|y_{n+1} - y_n|^2 - aC_1|x_{n+1} - x_n|^2 \\ &\quad - (aC_2 + bC_1)\langle x_{n+1} - x_n, y_{n+1} - y_n\rangle. \end{aligned} \tag{3.4}$$

As a result we equivalently get

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) = \delta(\phi(x_{n+1}) - \phi(x_n)) - 2\delta\epsilon_n \\ - (aC_2 + bC_1)\langle x_{n+1} - x_n, y_{n+1} - y_n\rangle \\ - bC_2|y_{n+1} - y_n|^2 - aC_1|x_{n+1} - x_n|^2. \end{aligned} \tag{3.5}$$

As $(q_n, p_{n+1}) \in \partial_{\epsilon_n} h(x_n) \times \partial_{\epsilon_n} g(x_{n+1})$ and remembering that $\phi = \psi + g - h$, from Lemma 2.1 we obtain

$$\begin{aligned} \phi(x_{n+1}) - \phi(x_n) \\ \le \langle p_{n+1} + \nabla\psi(x_n) - q_n, x_{n+1} - x_n\rangle + L|x_{n+1} - x_n|^2 + 2\epsilon_n. \end{aligned} \tag{3.6}$$

Combining (3.5) and (3.6), we consequently obtain

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) \le \delta\langle p_{n+1} + \nabla\psi(x_n) - q_n, x_{n+1} - x_n\rangle \\ - (aC_2 + bC_1)\langle x_{n+1} - x_n, y_{n+1} - y_n\rangle \\ - bC_2|y_{n+1} - y_n|^2 + (\delta L - aC_1)|x_{n+1} - x_n|^2, \end{aligned} \tag{3.7}$$

which along with (3.2) yields

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) \le \delta\frac{\mu k}{\lambda}\left(-\frac{1 - \mu\nu\alpha}{\mu k}|x_{n+1} - x_n|^2 + \langle y_{n+1} - y_n, x_{n+1} - x_n\rangle\right) \\ - (aC_2 + bC_1)\langle x_{n+1} - x_n, y_{n+1} - y_n\rangle \\ - bC_2|y_{n+1} - y_n|^2 + (\delta L - aC_1)|x_{n+1} - x_n|^2, \end{aligned} \tag{3.8}$$

which is the desired result. □

Now, let us establish the main result of this section.

THEOREM 3.2. *Assume that the following conditions are satisfied:*

$$\gamma > 0, \quad \alpha + \gamma > 0, \quad \tau > -\frac{2 + \alpha}{2\gamma}, \quad \nu \ge 1/2, \tag{3.9}$$

$$\sum_{n\ge 0} \epsilon_n < \infty. \tag{3.10}$$

Suppose also that $f, g \in \Gamma_0(\mathcal{H})$ and ψ is a differentiable function on $\mathcal{H}$ with an L-Lipschitz continuous gradient for some $L \in]0, +\infty[$, and set $\phi := \psi + g - h$ and $k := (1 + \tau\gamma + \frac{(\alpha+\gamma)}{2})$. If in addition ϕ is bounded from below and $\mu, \lambda > 0$ verify

$$\lambda L + \mu(\nu\alpha + k) \le 1, \tag{3.11}$$

then the sequences (x_n) *and* (y_n) *generated by scheme* (1.4) *satisfy the following properties:*

(i) *For* $\delta \in [\beta(\sqrt{b_2} - \sqrt{a_2+b_2})^2, \beta(\sqrt{b_2} + \sqrt{a_2+b_2})^2]$, *where* $\beta = \lambda/(k\mu)$, $a_2 := a[1+2b(\nu-1/2)]$, $b_2 := b[1+b(\tau-1/2)]$ ($a := \frac{2\alpha}{2+\alpha+\gamma}$ *and* $b := \frac{2\gamma}{2+\alpha+\gamma}$), *the energy* $(E_n(\delta))$ *is a decreasing and converging sequence.*

(ii) $\lim_{n\to+\infty} \phi(x_n)$ *exists.*

(iii) $\lim_{n\to+\infty} |x_{n+1} - x_n| = \lim_{n\to+\infty} |y_{n+1} - y_n| = 0$.

(iv) $\lim_{n\to+\infty} |\alpha x_n + \gamma y_n| = 0$.

(v) *There exists a sequence* $p_{n+1} \in \partial_{\epsilon_n} g(x_{n+1})$ *such that*

$$\lim_{n\to+\infty} |p_{n+1} + \nabla\psi(x_n) - q_n| = 0.$$

(vi) *If* $\mathcal{H}$ *is a finite dimensional space and if the sequences* (x_n) *and* (q_n) *are bounded, then every cluster-point* x_∞ *of the sequences* (x_n) *is a critical point of the function* $\psi + g - h$.

Proof. To begin, regarding the parameters involving in this theorem, we wish to emphasize that the conditions given in (3.9) ensure that

$$a > 0, \quad a+b > 0, \quad k > 0, \quad \beta > 0.$$

Furthermore, setting $\beta = \lambda/(k\mu)$ (hence $\lambda = k\mu\beta$), we have

$$-\frac{1-\mu\nu\alpha}{\lambda} + L = -\frac{1}{\beta}\left(\frac{1}{k\mu}(1-L\lambda) - \frac{\nu\alpha}{k}\right),$$

which by (3.1) yields

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) \le{}& \left(-\frac{\delta}{\beta}\left(\frac{1}{k\mu}(1-L\lambda) - \frac{\nu\alpha}{k}\right) - aC_1\right)|x_{n+1}-x_n|^2 \\ &- bC_2|y_{n+1}-y_n|^2 \\ &+ \left(\frac{\delta}{\beta} - (aC_2+bC_1)\right)\langle x_{n+1}-x_n, y_{n+1}-y_n\rangle, \end{aligned} \tag{3.12}$$

where $C_2 := [1 + b\,(\tau - 1/2)]$ and $C_1 := a\,(\nu - 1/2)$. Clearly, we have

$$aC_1 = a^2\,(\nu - 1/2) \ge 0 \quad \text{for} \quad \nu \ge 1/2,$$

while it is immediate that $\frac{1}{k\mu}(1-L\lambda) - \frac{\nu\alpha}{k} \ge 1$ when (3.11) is satisfied.

As a consequence, by (3.12) we have

$$\begin{aligned} E_{n+1}(\delta) - E_n(\delta) \le{}& -\frac{\delta}{\beta}|x_{n+1}-x_n|^2 - bC_2|y_{n+1}-y_n|^2 \\ &+ \left(\frac{\delta}{\beta} - (aC_2+bC_1)\right)\langle x_{n+1}-x_n, y_{n+1}-y_n\rangle. \end{aligned} \tag{3.13}$$

Let us denote $a_2 := (aC_2 + bC_1)$ and $b_2 := bC_2$, so that the previous inequality becomes

$$E_{n+1}(\delta) - E_n(\delta) \le q_n(\delta), \tag{3.14}$$

where $q_n(\delta)$ is defined by

$$q_n(\delta) := -\frac{\delta}{\beta}|x_{n+1}-x_n|^2 - b_2|y_{n+1}-y_n|^2 + \left(\frac{\delta}{\beta}-a_2\right)\langle x_{n+1}-x_n, y_{n+1}-y_n\rangle. \tag{3.15}$$

Observe that $q_n(\delta)$ is an affine function with respect to δ, since the sequences (x_n) and (y_n) are independent of δ.

Moreover, for $\tau > 1/2 - 1/b$ (hence $1 + b\,(\tau - 1/2) > 0$), we obviously have

$$b_2 = bC_2 = b[1 + b\,(\tau - 1/2)] > 0 \quad (\text{since } b > 0)$$

and

$$a_2 + b_2 = (a+b)C_2 + bC_1 > 0, \quad \text{because } a+b>0,\ C_2>0,\ b>0, \text{ and } C_1 \geq 0.$$

It is also easily checked that for

$$\delta_1 := \beta(\sqrt{b_2} - \sqrt{a_2+b_2})^2, \quad \delta_2 := \beta(\sqrt{b_2} + \sqrt{a_2+b_2})^2, \tag{3.16}$$

we obtain

$$\begin{aligned} q_n(\delta_1) &= -|(\sqrt{b_2} - \sqrt{a_2+b_2})(x_{n+1}-x_n) + \sqrt{b_2}(y_{n+1}-y_n)|^2, \\ q_n(\delta_2) &= -|(\sqrt{b_2} + \sqrt{a_2+b_2})(x_{n+1}-x_n) - \sqrt{b_2}(y_{n+1}-y_n)|^2. \end{aligned} \tag{3.17}$$

Therefore, for $\delta \in [\delta_1, \delta_2]$, we deduce that

$$q_n(\delta) \leq \max\{q_n(\delta_1), \quad q_n(\delta_2)\} \leq 0, \tag{3.18}$$

which by (3.14) yields

$$E_{n+1}(\delta) - E_n(\delta) \leq 0,$$

so that $(E_n(\delta))$ is a decreasing sequence. As a consequence, $(E_n(\delta))$ is a converging and bounded sequence, provided that $\sum_{j\geq 0}\epsilon_j < \infty$ and ϕ is bounded from below. On the other hand, taking into account the identity

$$\begin{aligned} \langle x_{n+1}-x_n, y_{n+1}-y_n\rangle = &-\frac{1}{2}|(x_{n+1}-x_n)-(y_{n+1}-y_n)|^2 \\ &+\frac{1}{2}|x_{n+1}-x_n|^2 + \frac{1}{2}|y_{n+1}-y_n|^2, \end{aligned} \tag{3.19}$$

inequality (3.14) can be rewritten as

$$\begin{aligned} &E_{n+1}(\delta) - E_n(\delta) \\ &+\frac{1}{2}\left(a_2 + \frac{\delta}{\beta}\right)|x_{n+1}-x_n|^2 + \left(b_2 + \frac{a_2}{2} - \frac{\delta}{2\beta}\right)|y_{n+1}-y_n|^2 \\ &+\frac{1}{2}\left(\frac{\delta}{\beta} - a_2\right)|(x_{n+1}-x_n)-(y_{n+1}-y_n)|^2 \leq 0. \end{aligned}$$

In the particular case when $\delta = \delta_3 := \beta(a_2 + 2b_2)$, this inequality becomes

$$E_{n+1}(\delta_3) - E_n(\delta_3) + (a_2+b_2)\,|x_{n+1}-x_n|^2 + b_2|(x_{n+1}-x_n)-(y_{n+1}-y_n)|^2 \leq 0;$$

hence

$$E_{n+1}(\delta_3) - E_0(\delta_3) + (a_2+b_2)\sum_{j=1}^{n}|x_{j+1}-x_j|^2 + b_2\sum_{j=1}^{n}|(x_{j+1}-x_j)-(y_{j+1}-y_j)|^2 \le 0. \tag{3.20}$$

Consequently, by the boundedness of $E_n(\delta_3)$ and remembering that $b_2>0$, $a_2+b_2>0$, we deduce that $\sum_{j\ge1}|(x_{j+1}-x_j)-(y_{j+1}-y_j)|^2<\infty$ and $\sum_{j\ge1}|x_{j+1}-x_j|^2<\infty$, which leads to

$$\lim_{n\to+\infty}|x_{n+1}-x_n| = \lim_{n\to+\infty}|y_{n+1}-y_n| = 0. \tag{3.21}$$

This combined with (2.1)(i) yields $\lim_{n\to+\infty}(ax_n+by_n)=0$, and (2.3) ensures then the existence of $p_{n+1}\in\partial_{\epsilon_n}g(x_{n+1})$ satisfying $\lim_{n\to+\infty}|p_{n+1}+\nabla\psi(x_n)-q_n|=0$.

Taking μ_1, μ_2 in $[\beta(\sqrt{b_2}-\sqrt{a_2+b_2})^2, \beta(\sqrt{b_2}+\sqrt{a_2+b_2})^2]$ such that $\mu_1\neq\mu_2$, we have

$$\phi(x_n) = \frac{1}{\mu_1-\mu_2}(E_n(\mu_1)-E_n(\mu_2)),$$

so that $\lim_{n\to+\infty}\phi(x_n)$ exists, because both $(E_n(\mu_1))$ and $(E_n(\mu_2))$ are converging sequences.

Now let us consider two subsequences (x_{n_ν}) and (q_{n_ν}) of (x_n) and (q_n) (we will use the same notation for the index even if this requires extracting other subsequences) converging, respectively, to x_∞ and q_∞. By passing to the limit in (2.5) and in the relation $q_{k_\nu}\in\partial_{\varepsilon_{k_\nu}}h(x_{k_\nu})$ and taking into account the fact that the multivalued maps $\partial_{(\cdot)}f(\cdot)$ and $\partial_{(\cdot)}h(\cdot)$ are closed on $\mathbb{R}_+\times\mathbb{R}^n$ and that $\nabla\psi$ is Lipschitz continuous, we obtain

$$q_\infty\in\partial g(x_\infty)+\nabla\psi(x_\infty) \quad\text{and}\quad q_\infty\in\partial h(x_\infty),$$

from which we infer that $(\partial g(x_\infty)+\nabla\psi(x_\infty))\cap\partial h(x_\infty)\neq\emptyset$; in other words, x_∞ is a critical point of $\psi+g-h$.

Remark 3.1. By virtue of [5, Proposition 6.1.1], minimizing ϕ is equivalent to minimizing the functional $E(\frac{1}{b^2})$ defined by (2.7); thus our result could also be considered as a discrete version of Theorem 6.1.1. by Attouch, Bolte, and Redont [5].

4. Convex minimization case. In this section, we will focus on the case where the objective function is convex. Our interest is in solving the convex minimization problem $\min_{x\in\mathcal{H}}g(x)$ or, equivalently,

$$\text{find } \bar{x}\in\mathcal{H} \text{ such that } 0\in\partial g(\bar{x}). \tag{4.1}$$

In this context, (1.4) is nothing else than the following algorithm:

$$\left[\begin{array}{l}\text{Initialization: } (x_0,y_0) \text{ in } \mathcal{H}\times\mathcal{H}.\\[2ex] \text{Step 1: Compute}\\ \quad x_{n+1}\in J_\lambda^{\partial_{\epsilon_n}g}[x_n-\mu(\alpha x_n+\gamma y_n)].\\[2ex] \text{Step 2: Compute}\\ \quad y_{n+1}=y_n-\dfrac{1}{k}[\alpha x_n+\gamma y_n+\nu\alpha(x_{n+1}-x_n)],\\ \quad \text{where } k:=\left(1+\tau\gamma+\frac{(\alpha+\gamma)}{2}\right).\end{array}\right. \tag{4.2}$$

We are going to prove, under adequate conditions, the weak convergence of the sequence (x_n) to a minimizer of the function g. This result is the discrete version of the main result in [3]. However, the proof is much more technical than in the continuous case and will be obtained by verifying that conditions of Opial's lemma are fulfilled.

LEMMA 4.1. *Let $\mathcal{H}$ be a Hilbert space and (x_n) a sequence in $\mathcal{H}$ such that there exists a nonempty set $C \subset \mathcal{H}$ satisfying the following:*

(i) *For every $\tilde{x} \in C$, $\lim_n |x_n - \tilde{x}|$ exists.*

(ii) *Any weak-cluster point of the sequence (x_n) belongs in C.*

Then, there exists $\bar{x} \in C$ such that (x_n) weakly converges to $\bar{x}$.

Now, we are in a position to present the main convergence result of this section.

THEOREM 4.2. *Assume that the following conditions are satisfied:*

$$\gamma > 0,\ \alpha + \gamma > 0, \tag{4.3}$$

$$\tau > -\tfrac{2+\alpha}{2\gamma},\ \nu \geq 1/2, \tag{4.4}$$

$$\textstyle\sum_{n\geq 0} \epsilon_n < \infty. \tag{4.5}$$

Suppose also that a function $g \in \Gamma_0(\mathcal{H})$ is bounded from below and such that Argmin *g, the set of minimizers of g on $\mathcal{H}$, is nonempty. Then for any $\lambda > 0$ and $\mu > 0$ verifying*

$$\begin{aligned} &\mu(\nu\alpha + k) \leq 1, \\ &\text{where } k := \Big(1 + \tau\gamma + \tfrac{(\alpha+\gamma)}{2}\Big), \end{aligned} \tag{4.6}$$

the sequences (x_n) and (y_n) generated by scheme (4.2) satisfy the following properties:

(i) $\sum |x_{n+1} - x_n|^2 < \infty$, $\sum |y_{n+1} - y_n|^2 < \infty$,

(ii) $\lim_{n\to+\infty} |\alpha x_n + \gamma y_n| = 0$, *and*

(iii) *(x_n) weakly converges to a minimizer of the function g on $\mathcal{H}$.*

Proof. Let $\tilde{x}$ be a minimizer of g, set $c_\mu := \frac{(1-\mu\nu\alpha)}{\mu k}$, and introduce the energy-like sequence U_n defined by

$$U_n = \langle \tilde{x} - x_n, ax_n + by_n \rangle + \frac{1}{2}(a + bc_\mu)|\tilde{x} - x_n|^2 + b\beta g(x_n), \tag{4.7}$$

where $\beta = \lambda/(k\mu)$, $a := \frac{2\alpha}{2+\alpha+\gamma}$, and $b := \frac{2\gamma}{2+\alpha+\gamma}$.

It should be noticed that (4.7) can be viewed as a discrete version of a slight modification of the Lyapunov functional used in [3]. Moreover, under the assumptions of the present theorem, Theorem 3.2 clearly holds true. Furthermore, it is easily observed that

$$\begin{aligned} U_{n+1} - U_n - \beta b(g(x_{n+1}) - g(x_n)) &= \langle \tilde{x} - x_{n+1}, ax_{n+1} + by_{n+1} \rangle - \langle \tilde{x} - x_n, ax_n + by_n \rangle \\ &\quad + \frac{1}{2}(a + bc_\mu)\left(|\tilde{x} - x_{n+1}|^2 - |\tilde{x} - x_n|^2\right) \\ &= \langle \tilde{x} - x_{n+1}, a(x_{n+1} - x_n) + b(y_{n+1} - y_n) \rangle + \langle x_n - x_{n+1}, ax_n + by_n \rangle \\ &\quad + (a + bc_\mu)\left\langle x_n - x_{n+1}, \tilde{x} - \frac{x_{n+1} + x_n}{2} \right\rangle, \end{aligned}$$

that is,

$$\begin{aligned}U_{n+1}-U_n-\beta b(g(x_{n+1})-g(x_n))&\\ =a\langle\tilde{x}-x_{n+1},x_{n+1}-x_n\rangle+b\langle\tilde{x}-x_{n+1},y_{n+1}-y_n\rangle&\\ +\langle x_n-x_{n+1},ax_n+by_n\rangle&\\ +(a+bc_\mu)\langle x_n-x_{n+1},\tilde{x}-x_{n+1}\rangle+(a+bc_\mu)\left\langle x_n-x_{n+1},\frac{x_{n+1}-x_n}{2}\right\rangle;&\end{aligned}$$

hence

$$\begin{aligned}U_{n+1}-U_n&=\beta b(g(x_{n+1})-g(x_n))\\ &\quad+b\langle\tilde{x}-x_{n+1},y_{n+1}-y_n-c_\mu(x_{n+1}-x_n)\rangle\\ &\quad+\langle x_n-x_{n+1},ax_n+by_n\rangle-\frac{a+bc_\mu}{2}|x_{n+1}-x_n|^2.\end{aligned}\tag{4.8}$$

Let us estimate the first term and the third term in the right-hand side of the previous equality. By (2.1)(ii), we also have

$$\begin{aligned}y_n-y_{n+1}&=a[\nu x_{n+1}+(1-\nu)x_n]+b[\tau y_{n+1}+(1-\tau)y_n]\\ &=a\nu(x_{n+1}-x_n)+b\tau(y_{n+1}-y_n)+(ax_n+by_n),\end{aligned}$$

that is,

$$ax_n+by_n=-(1+b\tau)(y_{n+1}-y_n)-a\nu(x_{n+1}-x_n).\tag{4.9}$$

Referring to (3.6), for any $p_{n+1}\in\partial_{\epsilon_n}g(x_{n+1})$ we additionally get

$$g(x_{n+1})-g(x_n)\le\langle p_{n+1},x_{n+1}-x_n\rangle+\epsilon_n.\tag{4.10}$$

Combining (4.8), (4.9), and (4.10), we deduce

$$\begin{aligned}U_{n+1}-U_n&\le\beta b(\langle p_{n+1},x_{n+1}-x_n\rangle+\epsilon_n)\\ &\quad+b\langle\tilde{x}-x_{n+1},y_{n+1}-y_n-c_\mu(x_{n+1}-x_n)\rangle\\ &\quad+\langle x_n-x_{n+1},-(1+b\tau)(y_{n+1}-y_n)-a\nu(x_{n+1}-x_n)\rangle\\ &\quad-\frac{a+bc_\mu}{2}|x_{n+1}-x_n|^2,\end{aligned}\tag{4.11}$$

namely,

$$\begin{aligned}U_{n+1}-U_n&\le b\left(\beta\langle p_{n+1},x_{n+1}-x_n\rangle+\langle\tilde{x}-x_{n+1},y_{n+1}-y_n-c_\mu(x_{n+1}-x_n)\rangle\right)\\ &\quad+b\beta\epsilon_n+(1+\tau b)\langle x_{n+1}-x_n,y_{n+1}-y_n\rangle\\ &\quad-[bc_\mu/2-a(\nu-1/2)]|x_{n+1}-x_n|^2.\end{aligned}\tag{4.12}$$

In addition, by (2.3) with $\psi=h\equiv 0$ and taking into account the fact that $\beta=\frac{\lambda}{\mu k}$, we have

$$c_\mu(x_{n+1}-x_n)+\beta[\partial_{\epsilon_n}g(x_{n+1})]-(y_{n+1}-y_n)\ni 0,\tag{4.13}$$

so that there exists $p_{n+1} \in \partial_{\epsilon_n} g(x_{n+1})$ such that

$$\beta p_{n+1} = (y_{n+1} - y_n) - c_\mu(x_{n+1} - x_n); \tag{4.14}$$

hence

$$\begin{aligned} &\beta\langle p_{n+1}, x_{n+1} - \tilde{x}\rangle + \beta\langle p_{n+1}, x_{n+1} - x_n\rangle \\ &\quad = \langle (y_{n+1} - y_n) - c_\mu(x_{n+1} - x_n), (x_{n+1} - \tilde{x}) + (x_{n+1} - x_n)\rangle. \end{aligned} \tag{4.15}$$

As $p_{n+1} \in \partial_{\epsilon_n} g(x_{n+1})$ and $0 \in \partial g(\tilde{x})$, from the definitions of ∂g and $\partial_{\epsilon_n} g$, we additionally have

$$\langle p_{n+1}, x_{n+1} - \tilde{x}\rangle \geq -\epsilon_n,$$

so that

$$\begin{aligned} &\beta\langle p_{n+1}, x_{n+1} - x_n\rangle \\ &\quad \leq \langle (y_{n+1} - y_n) - c_\mu(x_{n+1} - x_n), (x_{n+1} - \tilde{x}) + (x_{n+1} - x_n)\rangle + \beta\epsilon_n. \end{aligned} \tag{4.16}$$

This can be equivalently rewritten as

$$\begin{aligned} &\beta\langle p_{n+1}, x_{n+1} - x_n\rangle + \langle \tilde{x} - x_{n+1}, y_{n+1} - y_n - c_\mu(x_{n+1} - x_n)\rangle \\ &\quad \leq \langle (y_{n+1} - y_n) - c_\mu(x_{n+1} - x_n), x_{n+1} - x_n\rangle + \beta\epsilon_n, \end{aligned} \tag{4.17}$$

which along with (4.12) leads to

$$\begin{aligned} U_{n+1} - U_n \leq\ & b\langle (y_{n+1} - y_n) - c_\mu(x_{n+1} - x_n), x_{n+1} - x_n\rangle \\ & + 2b\beta\epsilon_n + (1 + \tau b)\langle x_{n+1} - x_n, y_{n+1} - y_n\rangle \\ & - [bc_\mu/2 - a(\nu - 1/2)]|x_{n+1} - x_n|^2, \end{aligned}$$

that is,

$$\begin{aligned} U_{n+1} - U_n \leq\ & [1 + (\tau + 1)b]\langle y_{n+1} - y_n, x_{n+1} - x_n\rangle \quad + 2b\beta\epsilon_n \\ & - \left(\frac{3}{2}bc_\mu - a\left(\nu - \frac{1}{2}\right)\right)|x_{n+1} - x_n|^2. \end{aligned} \tag{4.18}$$

This last inequality can be obviously written as

$$U_{n+1} - U_n \leq S_n, \tag{4.19}$$

where

$$\begin{aligned} S_n := \ & 2b\beta\epsilon_n + [1 + (\tau + 1)b]\langle x_{n+1} - x_n, y_{n+1} - y_n\rangle \\ & -[\tfrac{3}{2}bc_\mu - a(\nu - \tfrac{1}{2})]|x_{n+1} - x_n|^2. \end{aligned} \tag{4.20}$$

It is then immediate that $U_n - \sum_{k=0}^{n-1} S_k$ is a nonincreasing sequence. Furthermore, we obviously observe that $\sum_{n\geq 0} S_n$ is bounded, because $\sum_{n\geq 0} \epsilon_n < \infty$ and, by Theorem 3.2, the two sums $\sum_{n\geq 0} |x_{n+1} - x_n|^2$ and $\sum_{n\geq 0} |x_{n+1} - x_n|^2$ are finite. It turns out that U_n is bounded from above, and by (4.7) we have

$$-|\tilde{x} - x_n| \times |ax_n + by_n| + \frac{1}{2}(bc_\mu + a)|\tilde{x} - x_n|^2 + b\beta g(x_n) \leq U_n; \tag{4.21}$$

from (4.9) and Theorem 3.2, we also note that the quantity $|ax_n + by_n|$ is bounded since it converges to zero. By an easy computation, we also have

$$\frac{(2+\alpha+\gamma)(a+bc_\mu)}{2} = \alpha + \gamma\frac{1-\mu\nu\alpha}{k\mu} = (\alpha+\gamma) + \gamma\frac{1-\mu(\nu\alpha+k)}{k\mu},$$

so that $a + bc_\mu > 0$, since $\alpha + \gamma > 0$, $\gamma > 0$, $\mu > 0$, $k > 0$, and $1 - \mu(\nu\alpha + k) \geq 0$.

Consequently, we deduce that $|\tilde{x} - x_n|$ is bounded; hence U_n is bounded from below and is convergent. On the other hand, by Theorem 3.2, we know that $g(x_n)$ also converges. As a consequence, observing that

$$|\tilde{x} - x_n|^2 = \frac{2}{a+bc_\mu}\left(U_n - \langle \tilde{x} - x_n, ax_n + by_n\rangle - b\beta g(x_n)\right)$$

and since $\langle \tilde{x}-x_n, ax_n+by_n\rangle \to 0$, we deduce the convergence of the sequence $(|\tilde{x}-x_n|)$. Taking into account (4.13), we can easily check that any weak-cluster point of (x_n) is in Argmin g, because $|x_{n+1} - x_n| \to 0$, $|y_{n+1} - y_n| \to 0$, and the graph of ∂g is weakly-strongly closed. Applying Opial's lemma with $C = \text{Argmin } g$, we conclude that the sequence (x_n) weakly converges to a minimizer of g. This completes the proof. □

Finally, we would like to emphasize again that in the case where $\psi = h \equiv 0$, $\alpha > 0, \gamma > 0$, and the parameters τ and ν satisfy (1.5), DPM is nothing but the inertial proximal method. Moreover, $k = \gamma$, and thus condition (4.6) can be rewritten as $\mu < \frac{1}{\alpha+\gamma+1}$. This ensures that $\mu \in (0,1)$, and we recover Theorem 3.1 by Alvarez [1].

Conclusion. The main purpose of this article is to establish the asymptotic convergence of some new implicit iterative methods for solving a nonconvex minimization problem which is a natural extension of differentiable, convex, and DC programming. These algorithms, which generalize Sun, Sampaio, and Candido's scheme [27], the classical proximal algorithm [25], the inertial proximal method [1], and the gradient algorithm [15], are obtained by a discretization of a first order dissipative dynamical system. Particular attention to the convex case is also given, and the results obtained are nothing but discrete versions of those proposed in the continuous case by Alvarez, Attouch, Bolte, and Redont [3] and [5]. We think that the results obtained in this paper may inspire and pave the way for future research in this field, especially in developing new hybrid algorithms which admit less stringent requirements on solving proximal subproblems in the spirit of Solodov and Svaiter [26], who showed that the tolerance requirements for solving subproblems can be significantly relaxed if the solving of each subproblem is followed by a projection onto a certain hyperplane which separates the current iterate from the solution set of the problem.

Acknowledgments. The authors would like to thank the anonymous referees and Professor Adrian Lewis for their careful reading of the paper and for their comments and suggestions which permitted us to improve the presentation.

RECURSIVE TRUST-REGION METHODS FOR MULTISCALE NONLINEAR OPTIMIZATION*

SERGE GRATTON†, ANNICK SARTENAER‡, AND PHILIPPE L. TOINT‡

Abstract. A class of trust-region methods is presented for solving unconstrained nonlinear and possibly nonconvex discretized optimization problems, like those arising in systems governed by partial differential equations. The algorithms in this class make use of the discretization level as a means of speeding up the computation of the step. This use is recursive, leading to true multilevel/multiscale optimization methods reminiscent of multigrid methods in linear algebra and the solution of partial differential equations. A simple algorithm of the class is then described and its numerical performance is shown to be numerically promising. This observation then motivates a proof of global convergence to first-order stationary points on the fine grid that is valid for all algorithms in the class.

1. Introduction.

Large-scale finite-dimensional optimization problems often arise from the discretization of infinite-dimensional problems, a primary example being optimal control problems defined in terms of either ordinary or partial differential equations [8]. While the direct solution of such problems for a discretization level is often possible using existing packages for large-scale numerical optimization, this technique typically makes very little use of the fact that the underlying infinite-dimensional problem may be described at several discretization levels; the approach thus rapidly becomes cumbersome. Motivated by this observation, we explore here a class of algorithms which makes explicit use of this fact.

Using the different levels of discretization for an infinite-dimensional problem is not a new idea. A simple first approach is to use coarser grids in order to compute approximate solutions which can then be used as starting points for the optimization problem on a finer grid (see [5, 6, 7, 22], for instance). Other efficient techniques are inspired from the multigrid paradigm in the solution of partial differential equations and associated systems of linear algebraic equations (see, for example, [10, 11, 12, 23, 41, 43] for descriptions and references).

The purpose of our paper is threefold. We first introduce a new extension of the full approximation scheme (FAS) (see, for instance, Chapter 3 of [12] or [25]), an existing multigrid-type method, to a class of trust-region based optimization algorithms. We then indicate that this class contains numerically efficient members, thereby motivating further analysis. We finally provide a global convergence proof for all members of the class, which gives a robustness guarantee typical in optimization but, to the authors' knowledge, uncommon in multigrid approaches. Significantly, this guarantee holds even for nonconvex (nonelliptic) problems.

The work presented here was in particular motivated by the paper by Gelman and Mandel [16], the "generalized truncated Newton algorithm" presented in Fisher [15], a talk by Moré [28], and the contributions by Nash and coauthors [26, 27, 30]. These latter three papers present the description of MG/OPT, a linesearch-based recursive algorithm, an outline of its convergence properties, and impressive numerical results. The generalized truncated Newton algorithm and MG/OPT are very similar and, like many linesearch methods, naturally suited to convex problems, although their generalization to the nonconvex case is possible. An older contribution for convex problems is the damped nonlinear multilevel method by Hackbusch and Reusken [24], where convergence is analyzed for a variant of the FAS under the condition that a Lipschitz constant for the problem Hessian is explicitly known or can be numerically estimated. In the same spirit, the very recent contribution by Yavneh and Dardyk [45] considers a linesearch to improve the radius of local convergence of a nonlinear equations solver. Further motivation to consider the more general nonconvex problem is also provided by the computational success of the low/high-fidelity model management techniques of Alexandrov, Lewis, and coauthors [2, 3] and a paper by Borzi and Kunisch [9] on multigrid globalization.

The class of algorithms discussed in this note can be viewed as an alternative where one uses the trust-region technology whose efficiency and reliability in the solution of nonconvex problems is well known (we refer the reader to [13] for more complete coverage of this subject). Our developments are organized as follows. We first describe our class of multiscale trust-region algorithms in section 2 and show in section 3 that it can be specialized to a multigrid method that performs well on examples. This observation then motivates the proof of global convergence to first-order critical points presented in section 4. The main results of this section are Theorem 4.10, which establishes a level-independent complexity bound for general trust-region algorithms, and Theorem 4.13, which is the desired convergence property. Some conclusions and perspectives are presented in section 5.

2. Recursive multiscale trust-region algorithms. We start by considering the solution of the unconstrained optimization problem

$$\min_{x\in\Re^n} f(x), \tag{2.1}$$

where f is a twice-continuously differentiable objective function which maps $\Re^n$ into $\Re$ and is bounded below. The trust-region methods which we investigate are iterative: given an initial point x_0, they produce a sequence $\{x_k\}$ of iterates (hopefully) converging to a first-order critical point for the problem, i.e., to a point where $g(x) \stackrel{\text{def}}{=} \nabla f(x) = 0$. At each iterate x_k, trust-region methods build a model $m_k(x)$ of $f(x)$ around x_k. This model is then assumed to be adequate in a "trust region," defined as a sphere of radius $\Delta_k > 0$ centered at x_k, and a step s_k is then computed such that the trial point $x_k + s_k$ sufficiently reduces this model in the region. The objective function is computed at $x_k + s_k$ and the trial point is accepted as the next iterate if the ratio of achieved to predicted reduction is larger than a small positive constant. The value of the radius is finally updated to ensure that it is decreased when the trial point cannot be accepted as the next iterate and is increased or unchanged otherwise. In many practical trust-region algorithms, the model m_k is quadratic, and obtaining sufficient decrease then amounts to (approximately) solving

$$\min_{\|s\|\le\Delta_k} m_k(x_k+s) = \min_{\|s\|\le\Delta_k} f(x_k) + \langle g_k, s\rangle + \tfrac{1}{2}\langle s, H_k s\rangle \tag{2.2}$$

for s, where $g_k \stackrel{\rm def}{=} \nabla f(x_k)$, H_k is a symmetric $n \times n$ approximation of $\nabla^2 f(x_k)$, $\langle \cdot, \cdot \rangle$ is the Euclidean inner product, and $\| \cdot \|$ is the Euclidean norm.

Such methods are efficient and reliable and provably converge to first-order critical points whenever the sequence $\{\|H_k\|\}$ is uniformly bounded. Besides computing the value $f(x_k + s_k)$, their work per iteration is dominated by the numerical solution of the subproblem (2.2), which crucially depends on the dimension n of the problem. When (2.1) results from the discretization of some infinite-dimensional problem on a relatively fine grid, the solution cost is therefore often significant.

In what follows, we investigate what can be done to reduce this cost by exploiting the knowledge of alternative simplified expressions of the objective function, when available. More specifically, we assume that we know a collection of functions $\{f_i\}_{i=0}^r$ such that each f_i is a twice-continuously differentiable function from $\Re^{n_i}$ to $\Re$ (with $n_i \geq n_{i-1}$), the connection with our original problem being that $n_r = n$ and $f_r(x) = f(x)$ for all $x \in \Re^n$. We will also assume that, for each $i = 1, \ldots, r$, f_i is "more costly" to minimize than f_{i-1}. This may be because f_i has more variables than f_{i-1} (as would typically be the case if the f_i represent increasingly finer discretizations of the same infinite-dimensional objective), or because the structure (in terms of partial separability, sparsity, or eigenstructure) of f_i is more complex than that of f_{i-1}, or for any other reason. To fix terminology, we will refer to a particular i as a *level*.

Of course, for f_{i-1} to be useful at all in minimizing f_i, there should be some relation between the variables of these two functions. We henceforth assume that, for each $i = 1, \ldots, r$, there exist a full-rank linear operator R_i from $\Re^{n_i}$ into $\Re^{n_{i-1}}$ (the restriction) and another full-rank operator P_i from $\Re^{n_{i-1}}$ into $\Re^{n_i}$ (the prolongation) such that

$$\sigma_i P_i = R_i^T \tag{2.3}$$

for some known constant $\sigma_i > 0$. In the context of multigrid algorithms, P_i and R_i are interpreted as restriction and prolongation between a fine and a coarse grid (see [12], for instance). This assumption is also used in Nash [30].

The main idea is then to use f_{r-1} to construct an alternative model h_{r-1} for $f_r = f$ in the neighborhood of the current iterate that is cheaper than the quadratic model at level r, and to use this alternative model, whenever suitable, to define the step in the trust-region algorithm. If more than two levels are available ($r > 1$), this can be done recursively, the approximation process stopping at level 0, where the quadratic model is always used. In what follows, we use a simple notation where quantities of interest have a double subscript i, k. The first, i ($0 \leq i \leq r$), is the level index (meaning, in particular, if applied to a vector, that this vector belongs to $\Re^{n_i}$), and the second, k, is the index of the current iteration *within level* i and is *reset to 0 each time level* i *is entered*.[1]

Consider now some iteration k at level i (with current iterate $x_{i,k}$) and suppose that one decides to use the lower level model h_{i-1} based on f_{i-1} to compute a step. The first task is to restrict $x_{i,k}$ to create the starting iterate $x_{i-1,0}$ at level $i-1$, that is, $x_{i-1,0} = R_i x_{i,k}$. We then define the lower level model by

$$h_{i-1}(x_{i-1,0} + s_{i-1}) \stackrel{\rm def}{=} f_{i-1}(x_{i-1,0} + s_{i-1}) + \langle v_{i-1}, s_{i-1} \rangle, \tag{2.4}$$

[1] We are well aware that this creates some ambiguities, since a sequence of indices i, k can occur more than once if level i ($i < r$) is used more than once, implying the existence of more than one starting iterate at this level. This ambiguity is resolved by the context.

where $v_{i-1} = R_i g_{i,k} - \nabla f_{i-1}(x_{i-1,0})$ with $g_{i,k} \stackrel{\text{def}}{=} \nabla h_i(x_{i,k})$. By convention, we set $v_r = 0$ such that, for all s_r,

$$h_r(x_{r,0} + s_r) = f_r(x_{r,0} + s_r) = f(x_{r,0} + s_r) \text{ and } g_{r,k} = \nabla h_r(x_{r,k}) = \nabla f(x_{r,k}).$$

The function h_i therefore corresponds to a modification of f_i by a linear term that enforces the relation

$$g_{i-1,0} = \nabla h_{i-1}(x_{i-1,0}) = R_i g_{i,k}. \tag{2.5}$$

The first-order modification (2.4) is not unusual in multigrid applications in the context of the FAS and is also used by Fisher [15] and Nash [30]. It crucially ensures that the first-order behaviors of h_i and h_{i-1} are coherent in a neighborhood of $x_{i,k}$ and $x_{i-1,0}$, respectively: indeed, one verifies that, if s_i and s_{i-1} satisfy $s_i = P_i s_{i-1}$, then

$$\langle g_{i,k}, s_i\rangle = \langle g_{i,k}, P_i s_{i-1}\rangle = \frac{1}{\sigma_i}\langle R_i g_{i,k}, s_{i-1}\rangle = \frac{1}{\sigma_i}\langle g_{i-1,0}, s_{i-1}\rangle, \tag{2.6}$$

where we have also used (2.3) and (2.5). This coherence was independently imposed in [26] and, in a slightly different context, in [2] and other papers on first-order model management.

Our task, when entering level $i = 0, \ldots, r$, is then to (locally) minimize h_i starting from $x_{i,0}$. At iteration k of this minimization, we first choose, at iterate $x_{i,k}$, either the model $h_{i-1}(x_{i-1,0} + s_{i-1})$ (given by (2.4)) or

$$m_{i,k}(x_{i,k} + s_i) = h_i(x_{i,k}) + \langle g_{i,k}, s_i\rangle + \tfrac{1}{2}\langle s_i, H_{i,k} s_i\rangle, \tag{2.7}$$

where the latter is the usual truncated Taylor series in which $H_{i,k}$ is a symmetric $n_i \times n_i$ approximation to the second derivatives of h_i (which are also the second derivatives of f_i) at $x_{i,k}$. Once the model is chosen (we will return to the conditions of this choice below), we then compute a step $s_{i,k}$ that generates a decrease on this model within a trust region $\{s_i \mid \|s_i\|_i \le \Delta_{i,k}\}$ for some trust-region radius $\Delta_{i,k} > 0$. The norm $\|\cdot\|_i$ in this last expression is level-dependent and defined, for some symmetric positive-definite matrix M_i, by

$$\|s_i\|_i \stackrel{\text{def}}{=} \sqrt{\langle s_i, M_i s_i\rangle} \stackrel{\text{def}}{=} \|s_i\|_{M_i}. \tag{2.8}$$

If the model (2.7) is chosen,[2] this is nothing but a usual ellipsoidal trust-region subproblem solution yielding a step $s_{i,k}$. The decrease of the model $m_{i,k}$ is then understood in its usual meaning for trust-region methods, which is to say that $s_{i,k}$ is such that

$$m_{i,k}(x_{i,k}) - m_{i,k}(x_{i,k} + s_{i,k}) \ge \kappa_{\text{red}} \|g_{i,k}\| \min\left[\frac{\|g_{i,k}\|}{1 + \|H_{i,k}\|}, \Delta_{i,k}\right] \tag{2.9}$$

for some constant $\kappa_{\text{red}} \in (0, 1)$. This condition is known as the "sufficient decrease" or "Cauchy point" condition. Chapter 7 of [13] reviews several techniques that enforce it, including the exact minimization of $m_{i,k}$ within the trust region or an approximate minimization using (possibly preconditioned) Krylov space methods. On the other

[2] Observe that this is the only possible choice for $i = 0$.

hand, if the model h_{i-1} is chosen, minimization of this latter model (hopefully) produces a new point $x_{i-1,*}$ such that $h_{i-1}(x_{i-1,*}) < h_{i-1}(x_{i-1,0})$ and a corresponding step $x_{i-1,*} - x_{i-1,0}$ which must then be brought back to level i by the prolongation P_i. Since

$$\|s_i\|_i = \|s_i\|_{M_i} = \|P_i s_{i-1}\|_{M_i} = \|s_{i-1}\|_{P_i^T M_i P_i} \stackrel{\text{def}}{=} \|s_{i-1}\|_{M_{i-1}} = \|s_{i-1}\|_{i-1} \tag{2.10}$$

(which is well defined since P_i is full-rank), the trust-region constraint at level $i-1$ then becomes

$$\|x_{i-1,*} - x_{i-1,0}\|_{i-1} \leq \Delta_{i,k}. \tag{2.11}$$

The lower level subproblem consists in (possibly approximately) solving

$$\min_{\|s_{i-1}\|_{i-1} \leq \Delta_{i,k}} h_{i-1}(x_{i-1,0} + s_{i-1}). \tag{2.12}$$

The relation (2.10) also implies that, for $i = 0 \ldots, r-1$,

$$M_i = Q_i^T Q_i, \ \text{ where } \ Q_i = P_r \ldots P_{i+2} P_{i+1}, \tag{2.13}$$

while we define $M_r = I$ for consistency. Preconditioning can also be accommodated by choosing M_r more elaborately.

Is the cheaper model h_{i-1} always useful? Obviously not, as it may happen, for instance, that $g_{i,k}$ lies in the nullspace of R_i and thus that $R_i g_{i,k}$ is zero while $g_{i,k}$ is not. In this case, the current iterate appears to be first-order critical for h_{i-1} in $\Re^{n_{i-1}}$ while it is not for h_i in $\Re^{n_i}$. Using the model h_{i-1} is hence potentially useful only if $\|g_{i-1,0}\| = \|R_i g_{i,k}\|$ is large enough compared to $\|g_{i,k}\|$. We therefore restrict the use of the model h_{i-1} to iterations where

$$\|R_i g_{i,k}\| \geq \kappa_{\text{g}} \|g_{i,k}\| \ \text{ and } \ \|R_i g_{i,k}\| > \epsilon_{i-1}^{\text{g}} \tag{2.14}$$

for some constant $\kappa_{\text{g}} \in (0, \min[1, \min_i \|R_i\|])$ and where $\epsilon_{i-1}^{\text{g}} \in (0,1)$ is a measure of the first-order criticality for h_{i-1} that is judged sufficient at level $i-1$. Note that, given $g_{i,k}$ and R_i, this condition is easy to check before even attempting to compute a step at level $i-1$.

We are now in a position to describe our recursive multiscale trust-region (RMTR) algorithm more formally as Algorithm 2.1.

In this description, we use the constants η_1, η_2, γ_1, and γ_2 satisfying the conditions $0 < \eta_1 \leq \eta_2 < 1$ and $0 < \gamma_1 \leq \gamma_2 < 1$. It is assumed that the prolongations/restrictions P_i and R_i are known, as are the description of the levels $i = 0, \ldots, r$. An initial trust-region radius for each level $\Delta_i^{\text{s}} > 0$ is also defined, as well as level-dependent gradient norm tolerances $\epsilon_i^{\text{g}} \in (0,1)$ and trust-region tolerances $\epsilon_i^{\Delta} \in (0,1)$ for $i = 0, \ldots, r$. The algorithm's initial data consists of the level index i ($0 \leq i \leq r$), a starting point $x_{i,0}$, the gradient $g_{i,0}$ at this point, the radius Δ_{i+1} of the level-$(i+1)$ trust region, and the tolerances ϵ_i^{g} and ϵ_i^{Δ}. The original task of minimizing $f(x) = f_r(x_r) = h_r(x_r)$ (up to the gradient norm tolerance $\epsilon_r^{\text{g}} < \|\nabla f_r(x_{r,0})\|$) is achieved by calling RMTR(r, $x_{r,0}$, $\nabla f_r(x_{r,0})$, $\Delta_{r+1,0}$, ϵ_r^{g}, ϵ_r^{Δ}, Δ_r^{s}) for some starting point $x_{r,0}$ and initial trust-region radius Δ_r^{s}, and where we define $\Delta_{r+1,0} = \infty$. For coherence of notation, we thus view this call as being made with an infinite radius from some (virtual) iteration 0 at level $r+1$. The motivation for (2.17) in Step 6 of the algorithm and the termination test $\|x_{i,k+1} - x_{i,0}\|_i > (1 - \epsilon_i^{\Delta})\Delta_{i+1}$ in Step 5 are

Algorithm 2.1: RMTR(i, $x_{i,0}$, $g_{i,0}$, Δ_{i+1}, ϵ_i^{g}, ϵ_i^{Δ}, Δ_i^{s})

Step 0: Initialization. Compute $v_i = g_{i,0} - \nabla f_i(x_{i,0})$ and $h_i(x_{i,0})$. Set $\Delta_{i,0} = \min[\Delta_i^{\mathrm{s}}, \Delta_{i+1}]$ and $k = 0$.

Step 1: Model choice. If $i = 0$ or if (2.14) fails, go to Step 3. Otherwise, choose to go to Step 2 (recursive step) or to Step 3 (Taylor step).

Step 2: Recursive step computation.
Call Algorithm RMTR($i-1$, $R_i x_{i,k}$, $R_i g_{i,k}$, $\Delta_{i,k}$, $\epsilon_{i-1}^{\mathrm{g}}$, ϵ_{i-1}^{Δ}, $\Delta_{i-1}^{\mathrm{s}}$), yielding an approximate solution $x_{i-1,*}$ of (2.12). Then define $s_{i,k} = P_i(x_{i-1,*} - R_i x_{i,k})$, set $\delta_{i,k} = h_{i-1}(R_i x_{i,k}) - h_{i-1}(x_{i-1,*})$, and go to Step 4.

Step 3: Taylor step computation. Choose $H_{i,k}$ and compute a step $s_{i,k} \in \Re^{n_i}$ that sufficiently reduces the model $m_{i,k}$ (given by (2.7)) in the sense of (2.9) and such that $\|s_{i,k}\|_i \le \Delta_{i,k}$. Set $\delta_{i,k} = m_{i,k}(x_{i,k}) - m_{i,k}(x_{i,k}+s_{i,k})$.

Step 4: Acceptance of the trial point. Compute $h_i(x_{i,k} + s_{i,k})$ and define

$$\rho_{i,k} = (h_i(x_{i,k}) - h_i(x_{i,k} + s_{i,k}))/\delta_{i,k}. \tag{2.15}$$

If $\rho_{i,k} \ge \eta_1$, then define $x_{i,k+1} = x_{i,k}+s_{i,k}$; otherwise define $x_{i,k+1} = x_{i,k}$.

Step 5: Termination. Compute $g_{i,k+1}$. If $\|g_{i,k+1}\|_\infty \le \epsilon_i^{\mathrm{g}}$ or $\|x_{i,k+1} - x_{i,0}\|_i > (1 - \epsilon_i^{\Delta})\Delta_{i+1}$, then return with the approximate solution $x_{i,*} = x_{i,k+1}$.

Step 6: Trust-region radius update. Set

$$\Delta_{i,k}^{+} \in \begin{cases} [\Delta_{i,k}, +\infty) & \text{if } \rho_{i,k} \ge \eta_2, \\ [\gamma_2 \Delta_{i,k}, \Delta_{i,k}] & \text{if } \rho_{i,k} \in [\eta_1, \eta_2), \\ [\gamma_1 \Delta_{i,k}, \gamma_2 \Delta_{i,k}] & \text{if } \rho_{i,k} < \eta_1, \end{cases} \tag{2.16}$$

and

$$\Delta_{i,k+1} = \min\left[\Delta_{i,k}^{+}, \Delta_{i+1} - \|x_{i,k+1} - x_{i,0}\|_i\right]. \tag{2.17}$$

Increment k by one and go to Step 1.

to guarantee that iterates at a lower level in a recursion remain in the trust region defined at the calling level, as verified below in Lemma 4.1.

Iteration k at level i, associated with the computation of the step $s_{i,k}$, will be referred to as iteration (i, k). It will be called a *Taylor iteration* if Step 3 is used (that is, if Taylor's model $m_{i,k}(x_{i,k} + s_i)$ is chosen at Step 1). If Step 2 is used instead, iteration (i, k) will then be called a *recursive iteration*. We emphasize that we expect the most efficient algorithms in our class to make use of a combination of both iteration types, which means, in particular, that recursive iterations should not be automatic if (2.14) holds. As is usual for trust-region methods, iteration (i, k) is said to be *successful* if $\rho_{i,k} \ge \eta_1$, that is, if the trial point $x_{i,k} + s_{i,k}$ is accepted as the next iterate $x_{i,k+1}$. It is said to be *very successful* if $\rho_{i,k} \ge \eta_2$, implying that $\Delta_{i,k}^{+} \ge \Delta_{i,k}$.

In the case where $r = 0$, that is, if there is only one level in the problem, the algorithm reduces to the well-known usual trust-region method (see p. 116 of [13]) and enjoys all the desirable properties of this method. If $r > 0$, the recursive nature

of Algorithm RMTR is clear from Step 2. It is, in that sense, reminiscent of multigrid methods for linear systems [23] and is close in spirit to the MG/OPT method [30]. However, this latter method differs from ours in two main respects: Algorithm RMTR is of trust-region type, and its global convergence properties considered in this paper do not rely on performing Taylor iterations before or after a recursive one. Algorithm RMTR can also be viewed as an extension of the low-/high-fidelity model management method of [2] and [3]. The main differences are that our framework explicitly uses prolongation and restriction operators between possibly different variable spaces, allows more than two nested levels of fidelity, and, maybe less importantly, does not require coherence of low-fidelity model values with the high-fidelity objective function (zeroth-order model management). On the other hand, Algorithm RMTR does not fit in the framework of [16] because this latter formalism considers only "memoryless" iterations and therefore does not cover adaptive algorithmic features such as the trust-region radius. Moreover, the convergence results analyzed in this reference require nonlocal properties on the involved functions and the limit points are proved only to belong to a set containing the problem's critical points and the iteration fixed points. Finally, the proposal by Borzi and Kunisch [9] differs from ours in that it emphasizes convergence to minimizers on the coarsest grid but does not directly consider globalization on finer ones.

3. A practical algorithm and some numerical motivation. Clearly, our algorithmic description so far leaves a number of practical choices unspecified and is best viewed at this stage as a theoretical shell which potentially contains both efficient and inefficient algorithms. Can efficient algorithms be found in this shell? It is the purpose of this section to show that this is indeed the case. Instead of considering the RMTR class in its full generality, we will therefore focus on a simple implementation of our framework, and then show that the resulting method is, in our view, numerically promising.

3.1. Algorithm definition.

Smoothing and Taylor iterations. The most important of the open algorithmic questions is how one enforces sufficient decrease at Taylor iterations. A first answer is provided by existing algorithms for large-scale optimization, such as truncated conjugate-gradient (TCG) [37, 38] or generalized Lanczos trust-region (GLTR) [19] methods, in which the problem of minimizing (2.7) is solved in successive embedded Krylov subspaces (see also section 7.5 in [13]). This method is known to ensure (2.9). While it can be viewed as a Ritz procedure where solutions of subproblems of increasing sizes approach the desired high-dimensional one, the definition of these embedded subspaces does not exploit the explicit knowledge of discretization grids. We are thus interested in alternatives that exploit this knowledge.

If the model (2.7) is strictly convex and the trust-region radius Δ_k sufficiently large, minimizing (2.7) amounts to an (approximate) solution of the classical Newton equations $H_{i,k}s_i = -g_{i,k}$. If the problem additionally results from discretizing a convex operator on successively finer grids, then multigrid solvers constitute a most interesting alternative. Our intention is not to review this vast class of numerical algorithms here (we refer the reader to [12] for an excellent introduction to the field), but we briefly outline their main characteristics. Multigrid algorithms are based on three complementary observations. The first is that some algorithms, called *smoothers*, are very efficient at selectively reducing the high-frequency components of the error on a grid, that is (in most cases), components whose "wavelength" is comparable to the grid's mesh-size. The second is that a low-frequency error component on a fine grid

appears more oscillatory on a coarse grid and may thus be viewed as a high-frequency component on this grid. The third is that computations on coarse grids are typically much cheaper than on finer grids. These observations may be exploited by a two-grid procedure, as follows. A few iterations of a smoother are first applied on the fine grid, reducing the error's high frequencies. The residual is then projected on the coarse grid where the low frequencies are more oscillatory and thus efficiently and cheaply reduced by the smoother applied on the coarse grid. The remaining error on the coarse grid is then prolongated back to the fine grid, which reintroduces a small amount of high-frequency error. A few more steps of the fine-grid smoother are finally applied to eliminate it. The multigrid algorithm is obtained by recursively replacing the error smoothing on the coarse grid by another two-grid procedure. Multigrid methods for positive-definite systems of equations typically result in remarkably efficient linearly convergent processes. Our intention here is to exploit the same features in minimizing (2.7), although it is expected only to reduce to a positive-definite system of linear equations asymptotically, when a minimizer of the problem is approached.

At the coarsest level, where further recursion is impossible, the cost of exactly minimizing (2.7) within the trust region remains small, because of the low dimensionality of the subproblem. Our strategy is thus to solve it using the method by Moré and Sorensen [29] (see also section 7.3 in [13]), whose very acceptable cost is then dominated by that of a small number of small-scale Cholesky factorizations. At finer levels, we have the choice of using the TCG or GLTR algorithms mentioned above, or an adaptation of the multigrid smoothing techniques that guarantees sufficient descent inside the trust region and also handles the possible nonconvexity of the model. The remainder of this section is devoted to describing this last option.

A very well-known multigrid smoother for systems of equations is the Gauss–Seidel method, in which every individual equation of the Newton system is solved in succession.[3] This procedure can be extended to optimization without major difficulty as follows: instead of successively solving equations, we may perform cyclic successive one-dimensional minimizations along the coordinate axes of the model (2.7), provided the curvature of this model along each axis is positive. Thus, if j is an index such that the jth diagonal entry of $H_{i,k}$ is strictly positive, the updates

$$\alpha_j = -[g]_j/[H_{i,k}]_{jj}, \quad [s]_j \leftarrow [s]_j + \alpha_j, \quad \text{and} \quad g \leftarrow g + \alpha_j H_{i,k} e_{i,j}$$

are performed for the minimization along the jth axis (starting each cycle from s such that $\nabla m_{i,k}(x_{i,k} + s) = g$), where we denote by $[v]_j$ the jth component of the vector v and by $[M]_{ij}$ the (i,j)th entry of the matrix M, and where $e_{i,j}$ is the jth vector of the canonical basis of $\Re^{n_i}$. This is nothing but the well-known (and widely ill-considered) sequential coordinate minimization (see, for instance, [33, section 14.6]), which we abbreviate as SCM. In order to enforce convergence on nonconvex problems to first-order points, we still have to ensure sufficient model decrease (2.9) while keeping the step in the trust region. This can be achieved in various ways, but we choose here to start the SCM cycle by initiating the cycle with the axis corresponding to the largest component of the gradient $g_{i,k}$ in absolute value. Indeed, if this component is the ℓth one and if $d_\ell = -\text{sign}([g_{i,k}]_\ell)e_{i,\ell}$, then minimization of the model $m_{i,k}$ along d_ℓ within the trust region is guaranteed to yield a *Cauchy step* $\alpha_\ell d_\ell$ such that the inequality

$$m_{i,k}(x_{i,k}) - m_{i,k}(x_{i,k} + \alpha_\ell d_\ell) \geq \tfrac{1}{2}|[g_{i,k}]_\ell| \min\left[\frac{|[g_{i,k}]_\ell|}{1 + |[H_{i,k}]_{\ell\ell}|}, \Delta_{i,k}\right] \tag{3.1}$$

[3] See [12, p. 10], or [18, p. 510], or [33, p. 214] amongst many others.

holds. But

$$|[g_{i,k}]_\ell| = \max_j |\,[g_{i,k}]_j| \geq \frac{1}{\sqrt{n}}\|g_{i,k}\|, \quad \text{and} \quad |[H_{i,k}]_{\ell\ell}| \leq \|H_{i,k}\|,$$

and (2.9) then follows from these inequalities and (3.1) since the remaining SCM operations only reduce the value of the model $m_{i,k}$ further. If, after completing one SCM cycle, one then notices that the overall step s lies outside of the trust region, we then apply a variant of the *dogleg* strategy (see [35], or [13, section 7.5.3]) to the step, by minimizing $m_{i,k}$ along the segment $[\alpha_\ell d_\ell, s]$ *restricted to the trust region*. The final step is then given by $\alpha_\ell d_\ell + \alpha_s(s - \alpha_\ell d_\ell)$, where α_s is the multiple of $s - \alpha_\ell d_\ell$ where the minimizer is achieved.

Our description of the smoothing method is complete if we finally specify what is done when negative curvature is encountered along one of the coordinate axes, the jth one, say, during the SCM cycles. In this case, the model minimizer along $e_{i,j}$ lies on the boundary of the trust region, and it is very easy to compute the associated model reduction. The largest of these reductions is remembered (along with the corresponding step) if negative curvature is met along more than one axis. It is then compared to the reduction obtained by minimizing along the axes with positive curvature, and the step is finally chosen as that giving the maximum reduction.

The V-cycles. One of the flexible features of our RMTR framework is that the minimization at lower levels ($i = 1, \ldots, r-1$) can be stopped after the first successful iteration without affecting convergence properties (as will become clear in section 4). This therefore opens the possibility of considering *fixed form* recursion patterns and *free form* ones. A free form pattern is obtained when Algorithm RMTR is run without using the premature termination option, in which case minimization is carried out at each level until the gradient becomes small enough or the relevant trust-region boundary is approached sufficiently (see Step 5 of Algorithm RMTR). The actual recursion pattern is then uniquely determined by the progress of minimization at each level and may be difficult to forecast. By contrast, the fixed form recursion patterns are obtained by specifying a maximum number of successful iterations at each level, a technique directly inspired from the definitions of V- and W-cycles in multigrid algorithms (see [12, p. 40], for instance).

In this section, we consider only V-cycle iterations, where minimization at lower levels (above the coarsest) consists in, at most, one successful smoothing iteration followed by either a successful TCG Taylor iteration (if (2.14) fails) or a recursive iteration (if (2.14) holds), itself followed by a second successful smoothing iteration. The lower iteration is however terminated if the boundary of the upper-level trust region is met, which typically occurs only far from a solution, or if the gradient becomes sufficiently small.

Second-order and Galerkin models. The definition of the gradient correction v_{i-1} in (2.4) is engineered to ensure (2.6), which is to say that h_i and h_{i-1} coincide at first order (up to the constant σ_i) in the range of the prolongation operator. But coherence of the models can also be achieved at second order: if we choose

$$h_{i-1}(x_{i-1,0} + s_{i-1}) = f_{i-1}(x_{i-1,0} + s_{i-1}) + \langle v_{i-1}, s_{i-1}\rangle + \tfrac{1}{2}\langle s_{i-1}, W_{i-1}s_{i-1}\rangle, \tag{3.2}$$

where $W_{i-1} = R_i H_{i,k} P_i - \nabla^2 f_{i-1}(x_{i-1,0})$, then we also have that

$$\langle P_i s_{i-1}, H_{i,k} P_i s_{i-1,}\rangle = \frac{1}{\sigma_i}\langle s_{i-1}, \nabla^2 h_{i-1}(x_{i-1,0}) s_{i-1}\rangle,$$

as desired. An even more radical strategy is to choose $f_{i-1}(x_{i-1,0} + s_{i-1}) = 0$ for all s_{i-1} in (3.2), which amounts to choosing the lower-level objective function as the "restricted" version of the quadratic model at the upper level, also known as the "Galerkin approximation." This technique is known to improve performance for difficult cases involving an underlying infinite-dimensional problem with discontinuous coefficients (see, in particular, the recent analysis in [45]). This is also the option considered in this section. In the case where this model is strictly convex and the trust-region radius is large enough, an iteration of the algorithm reduces to the solution of a positive-definite linear system; multigrid algorithms for solving this system, such as the multigrid V-Cycle scheme of [12, p. 44], can then be viewed as instances of Algorithm RMTR.

Computing the starting point at successively finer levels. It is clear that, if the multilevel recursion idea has any power within an iteration from the finest level down and back, it must also be advantageous to use the lower-level problems for computing the starting point $x_{r,0}$. In our motivating application, we have chosen to compute $x_{r,0}$ by successively minimizing at levels 0 up to $r-1$ starting from the lowest one, where an initial starting point is assumed to be supplied by the user. (Note that, in general, the starting point can be supplied at any discretization level and transferred to other levels by using the prolongations or restrictions.) At level $i < r$, the accuracy on the gradient infinity norm that is required for termination is given by

$$\epsilon_i^{\mathrm{g}} = \min(0.01, \epsilon_{i+1}^{\mathrm{g}}/\nu_i^{\psi}), \tag{3.3}$$

where ψ is the dimension of the underlying continuous problem, ν_i is the discretization mesh-size along one of these dimensions, and ϵ_r^{g} is the user-supplied gradient accuracy requirement for the topmost level. Once computed at level i, the solution is prolongated to level $i+1$ using cubic interpolation.

3.2. Two test examples.

A simple quadratic example. We consider here the two-dimensional model problem for multigrid solvers in the unit square domain S_2,

$$-\Delta u(x,y) = f \quad \text{in } S_2, \qquad\qquad u(x,y) = 0 \quad \text{on } \partial S_2,$$

where f is such that the analytical solution to this problem is

$$u(x,y) = \sin[2\pi x(1-x)]\sin[2\pi y(1-y)].$$

This problem is discretized using a five-point finite-difference scheme, giving a linear system $A_i x = b_i$ at level i, where A_i is a symmetric positive-definite matrix. Algorithm RMTR is used on the variational minimization problem

$$\min_{x \in \Re^{n_r}} \tfrac{1}{2} x^T A_r x - x^T b_r,$$

which is equivalent to the linear system $A_r x = b_r$. The starting point for the values of u not on the boundary is chosen as a random perturbation (of amplitude 10^{-5}) of the vector of all ones. This example illustrates that RMTR exhibits performance similar to traditional linear multigrid solvers on a model problem.

A nonconvex example. We introduce the nonlinear least-squares problem

$$\min_{u,\gamma} \quad \tfrac{1}{1000} \int_{S_2} \gamma(x,y)^2 + \int_{S_2} [u(x,y) - u_0(x,y)]^2 + \int_{S_2} [\Delta u(x,y) - \gamma(x,y) u(x,y)]^2,$$

where the unknown functions $u(x,y)$ and $\gamma(x,y)$ are defined on the unit square S_2 and the function $u_0(x,y)$ is defined on S_2 by $u_0(x,y) = \sin(6\pi x)\sin(2\pi y)$. This problem is again discretized using five-point finite differences, but the square in the last term makes the Hessian denser than for the pure Laplacian. The starting values for u and γ are random perturbations (of amplitude 100) of u_0 and zero, respectively. The nonconvexity of the resulting discretized problem on the fine grid has been assessed by a direct eigenvalue computation on the Hessian of the problem.

Prolongations and restrictions. In both examples, we have defined the prolongation to be the linear interpolation operator and the restriction to be its transpose normalized to ensure that $\|R_i\| = 1$. These operators are never assembled but are applied locally for improved efficiency.

3.3. Numerical results. The algorithm described above has been coded in MATLAB (Release 7.0.0) and the experiments below were run on a Dell Precision M70 laptop computer with 2MBytes of RAM. The test problems are solved with $\epsilon_r^g = 0.5\times10^{-9}$. Smoothing iterations use a single SCM cycle, and we choose $\eta_1 = 0.01$, $\eta_2 = 0.95$, $\gamma_1 = 0.05$, $\gamma_2 = 0.25$, $\kappa_g = 0.5$, and $\epsilon_i^\Delta = 0.001$ for all i. The choice of Δ_r^s, the initial trust-region radius at level r, is slightly more difficult (see, for instance, [34, 36] for suggested strategies), but here we choose to use $\Delta_r^s = 1$. The gradient thresholds ϵ_i^g are chosen according to the rule (3.3).

We consider the simple quadratic example first. In this example, recursive iterations were always accepted by the test (2.14). As a result, the work consisted only in exactly minimizing (2.7) in the trust region at the coarsest level and SCM smoothing at higher levels. Table 3.1 gives the problem dimension (n) for each level and the number of smoothing SCM cycles (# fine SCM) at the finest level required to solve the complete problem from scratch. This is, by far, the dominant linear algebra cost. For completeness, we also report the solution time in seconds (as reported by MATLAB) in the line "CPU(s)" of the same table.

For comparison, we also tested an efficient classical trust-region method using mesh-refinement with cubic interpolation and a TCG solver, where the conjugate-gradient minimization at iteration (i,k) is terminated as soon as the model gradient falls under the threshold

$$\max\left[\min\left(0.1, \sqrt{\|g_{i,k}\|}\right)\|g_{i,k}\|, 0.95\,\epsilon_r^g\right]$$

(see section 7.5.1 of [13], for instance). This algorithm solved the level-7 problem ($n = 261,121$) with 657 conjugate-gradient iterations at the finest level in 190.54 seconds, and solved the level-8 problem ($n = 1,046,529$) with 1,307 conjugate-gradient iterations at the finest level in 2,463.33 seconds. (Note that this TCG solver can also be obtained as a special case of our framework by replacing smoothing iterations by TCG ones and disabling the recursive calls to RMTR.) As expected for a typical multigrid algorithm for linear equations, we observe that the number of smoothing cycles is fairly independent of the mesh size and dimension, which indicates that the trust-region machinery does not alter this property.

TABLE 3.1
Performance on the simple quadratic example.

Level	0	1	2	3	4	5	6	7	8
n	9	49	225	961	3,969	16,129	65,025	261,121	1,046,529
# fine SCM	-	11	11	11	9	8	6	5	3
CPU(s)	-	0.05	0.14	0.37	0.97	2.84	9.4	38.4	150.88

TABLE 3.2
Performance on the nonconvex example.

Level	0	1	2	3	4	5	6	7
n	18	98	450	1,922	7,938	32,258	130,050	522,242
# fine SCM	-	21	19	21	28	32	14	9
CPU(s)	-	0.43	1.05	3.60	14.90	73.63	151.53	560.26

We now consider our nonconvex test problem, for which the same statistics are given in Table 3.2. As for the quadratic example, the test (2.14) was always satisfied and the algorithm thus never had to use TCG iterations for levels above the coarsest.

On this example, the mesh-refinement algorithm using the TCG solver solved the level-6 problem ($n = 130,050$) with 33,033 conjugate-gradient iterations at level 6 in 3,262.06 seconds, and solved the level-7 problem ($n = 522,242$) with 3,926 conjugate-gradient iterations at level 7 in 6,154.96 seconds.

Even if these results were obtained by a very simple implementation of our framework, they are nevertheless highly encouraging, as they suggest that speed-ups of one order of magnitude or more could be obtained over (good) contending methods. Moreover, the statistics presented here also suggest that, at least for not too nonlinear problems, performance in CPU time can be essentially proportional to problem size, a very desirable property. The authors are of course aware that only continued experience with more advanced implementations will vindicate those preliminary tests (this work is currently under way) but consider that the potential numerical benefits justify a sound convergence analysis of the algorithm, which is best carried out considering the general RMTR class. This is the purpose of the next section.

4. Global convergence. Our exposition of the global convergence properties of our general class of recursive multiscale algorithms starts with the analysis of properties that are specific to our class. The main concepts and developments of section 6.4 in [13] are subsequently revisited to conclude the case of the multiscale algorithm. Interestingly, the techniques of proof are different and lead to a new complexity result (Theorem 4.10) that is also valid in the classical single-level case.

We first complete our assumptions by supposing that the Hessians of each h_i and their approximations are bounded above by the constant $\kappa_{\text{H}} \geq 1$, i.e., more formally, that, for $i = 0, \ldots, r$,

$$1 + \|\nabla^2 h_i(x_i)\| \leq \kappa_{\text{H}} \tag{4.1}$$

for all $x_i \in \Re^{n_i}$, and

$$1 + \|H_{i,k}\| \leq \kappa_{\text{H}} \tag{4.2}$$

for all k. In order to keep our notation simple, we also assume, without loss of generality, that

$$\sigma_i = 1 \tag{4.3}$$

in (2.3) for $i = 0, \ldots, r$ (this can be directly obtained from the original form by scaling P_i and/or R_i). We also define the constants

$$\kappa_{\text{PR}} \stackrel{\text{def}}{=} \max\left[1, \max_{i=1,\ldots,r} \|P_i\|\right] = \max\left[1, \max_{i=1,\ldots,r} \|R_i\|\right] \tag{4.4}$$

(where we used (2.3) and (4.3) to deduce the second equality) and

$$\kappa_\sigma \stackrel{\rm def}{=} \min\left[1, \min_{i=0,\ldots,r} \sigma_{\min}(M_i)\right] > 0, \tag{4.5}$$

where $\sigma_{\min}(A)$ denotes the smallest singular value of the matrix A. We finally define

$$\Delta^{\rm s}_{\min} = \min_{i=0,\ldots,r} \Delta^{\rm s}_i, \qquad \epsilon^{\rm g}_{\min} = \min_{i=0,\ldots,r} \epsilon^{\rm g}_i, \ \text{ and } \ \epsilon^{\Delta}_{\min} = \min_{i=0,\ldots,r} \epsilon^{\Delta}_i. \tag{4.6}$$

We also introduce some additional concepts and notation.

1. If iteration (i,k) is recursive, we say that this iteration initiates a *minimization sequence* at level $i-1$, which consists of all successive iterations *at this level* (starting from the point $x_{i-1,0} = R_i x_{i,k}$) until a return is made to level i within iteration (i,k). In this case, we also say that iteration (i,k) is the *predecessor* of the minimization sequence at level $i-1$. If $(i-1,\ell)$ belongs to this minimization sequence, this is written as $(i,k) = \pi(i-1,\ell)$.
2. To a given iteration (i,k), we associate the set

$$\mathcal{R}(i,k) \stackrel{\rm def}{=} \{(j,\ell) \mid \text{iteration } (j,\ell) \text{ occurs within iteration } (i,k)\}. \tag{4.7}$$

   The set $\mathcal{R}(i,k)$ always contains the pair (i,k) and contains only that pair if Step 3 is used at iteration (i,k). If Step 2 is used instead of Step 3, then it additionally contains the pairs of level and iteration numbers of all iterations that occur in the potential recursion started in Step 2 and terminating on return within iteration (i,k). Because $\mathcal{R}(i,k)$ is defined in terms of iterations, it does *not* contain the pairs of indices corresponding to the terminating iterates $(j,*)$ of its (internal) minimization sequences. One easily verifies that $j \le i$ for every j such that $(j,\ell) \in \mathcal{R}(i,k)$ for some nonnegative k and ℓ. The mechanism of the algorithm also ensures that

$$\Delta_{j,\ell} \le \Delta_{i,k} \ \text{ whenever } \ (j,\ell) \in \mathcal{R}(i,k), \tag{4.8}$$

   because of the choice of $\Delta_{j,0}$ in Step 0 and (2.17). Note that $\mathcal{R}(i,k)$ contains at most one minimization sequence at level $i-1$ but may contain more than one at level $i-2$, since each iteration at level $i-1$ may generate its own.
3. For any iteration $(j,\ell) \in \mathcal{R}(i,k)$, there exists a unique *path* from (j,ℓ) to (i,k) defined by taking the predecessor of iteration (j,ℓ), say, $(j+1,q) = \pi(j,\ell)$, and then the predecessor of $(j+1,q)$ and so on until iteration (i,k). We also define

$$d(i,k) = \min_{(j,\ell)\in\mathcal{R}(i,k)} j, \tag{4.9}$$

   which is the index of the deepest level reached by the potential recursion of iteration (i,k). The path from $(d(i,k),\ell)$ to (i,k) is the longest in $\mathcal{R}(i,k)$.
4. We use the symbol

$$\mathcal{T}(i,k) \stackrel{\rm def}{=} \{(j,\ell) \in \mathcal{R}(i,k) \mid \text{iteration } (j,\ell) \text{ uses Step 3}\}$$

   to denote the subset of Taylor iterations in $\mathcal{R}(i,k)$, that is, iterations at which Taylor's model $m_{j,\ell}(x_{j,\ell} + s_j)$ is chosen.

We start the analysis of Algorithm RMTR by proving that it has a central property of trust-region methods, namely, that the steps remain in the trust region.

LEMMA 4.1. *For each iteration (i,k), we have that*

$$\|s_{i,k}\|_i \leq \Delta_{i,k}. \tag{4.10}$$

Moreover, if $\Delta_{j+1,q}$ is the trust-region radius of iteration $(j+1,q) = \pi(j,\ell)$, we have that, for each $(j,\ell) \in \mathcal{R}(i,k)$,

$$\|x_{j,\ell} - x_{j,0}\|_j \leq \Delta_{j+1,q} \quad \textit{and} \quad \|x_{j,*} - x_{j,0}\|_j \leq \Delta_{j+1,q}. \tag{4.11}$$

Proof. The constraint (4.10) is explicit for Taylor iterations. We therefore have to verify that it holds only if Step 2 is chosen at iteration (i,k). If this is the case, consider $j = d(i,k)$, and consider the first time it occurs in $\mathcal{R}(i,k)$. Assume, furthermore, that $x_{j,*} = x_{j,p}$. Because no recursion occurs to a level lower than j, one must have (from Step 3) that

$$\|s_{j,\ell}\|_j \leq \Delta_{j,\ell} \quad (\ell = 0, \ldots, p-1). \tag{4.12}$$

Then we obtain, for $\ell = 1, \ldots, p$, that, if iteration $(j,\ell-1)$ is successful,

$$\|x_{j,\ell} - x_{j,0}\|_j = \|x_{j,\ell-1} - x_{j,0} + s_{j,\ell-1}\|_j \leq \|x_{j,\ell-1} - x_{j,0}\|_j + \|s_{j,\ell-1}\|_j$$

because of the triangle inequality, while

$$\|x_{j,\ell} - x_{j,0}\|_j = \|x_{j,\ell-1} - x_{j,0}\|_j \leq \|x_{j,\ell-1} - x_{j,0}\|_j + \|s_{j,\ell-1}\|_j$$

if it is unsuccessful. Combining these two bounds and (4.12), we have that

$$\begin{aligned} \|x_{j,\ell} - x_{j,0}\|_j &\leq \|x_{j,\ell-1} - x_{j,0}\|_j + \Delta_{j,\ell-1} \\ &\leq \|x_{j,\ell-1} - x_{j,0}\|_j + \Delta_{j+1,q} - \|x_{j,\ell-1} - x_{j,0}\|_j \\ &= \Delta_{j+1,q} \end{aligned} \tag{4.13}$$

for $\ell = 2, \ldots, p$, where the last inequality results from (2.17). The same result also holds for $\ell = 1$, since $\|x_{j,1} - x_{j,0}\|_j \leq \Delta_{j,0} \leq \Delta_{j+1,q}$ because of Step 0 in the algorithm. We then verify, using (2.10), that

$$\|s_{j+1,q}\|_{j+1} = \|P_{j+1}\,(x_{j,*} - x_{j,0})\,\|_{j+1} = \|x_{j,*} - x_{j,0}\|_j = \|x_{j,p} - x_{j,0}\|_j \leq \Delta_{j+1,q},$$

which is nothing but inequality (4.12) at iteration $(j+1,q)$. The same reasoning may then be applied to each iteration at level $j+1$ that uses Step 2. Since inequality (4.12) is guaranteed for all other iterations of that level by Step 3, we obtain that (4.12) also holds with j replaced by $j+1$. The same must therefore be true for (4.13). The induction can then be continued up to level i, yielding both (4.10) and (4.11) (for which the case $\ell = 0$ is obvious). ∎

In the same vein, the algorithm also ensures the following two properties.

LEMMA 4.2. *The mechanism of Algorithm RMTR guarantees that, for each iterate of index (j,ℓ) such that $(j,\ell) \neq (j,*)$ (i.e., for all iterates at level j but the last one),*

$$\|g_{j,\ell}\| > \epsilon_j^g \tag{4.14}$$

and

$$\|x_{j,\ell} - x_{j,0}\|_j \leq (1 - \epsilon_j^{\Delta})\Delta_{j+1,q}, \tag{4.15}$$

where $\Delta_{j+1,q}$ *is the trust-region radius of iteration* $(j+1,q) = \pi(j,\ell)$.

Proof. These bounds directly follow from the stopping criteria for minimization at level j, in Step 5 of the algorithm. ∎

We now prove some useful bounds on the gradient norms for all iterates that belong to a recursion process initiated within a sufficiently small trust region.

LEMMA 4.3. *Assume that, for some iteration* (i,k),

$$\Delta_{i,k} \leq \frac{\sqrt{\kappa_\sigma}\kappa_{\rm g}^r}{2r\kappa_{\rm H}}\|g_{i,k}\| \stackrel{\rm def}{=} \kappa_1\|g_{i,k}\|, \tag{4.16}$$

where $\kappa_1 \in (0,1)$. *Then one has that, for all* $(j,\ell) \in \mathcal{R}(i,k)$,

$$\tfrac{1}{2}\kappa_{\rm g}^r\|g_{i,k}\| \leq \|g_{j,\ell}\| \leq \kappa_{\rm PR}^r(1 + \tfrac{1}{2}\kappa_{\rm g}^r)\|g_{i,k}\|. \tag{4.17}$$

Proof. The result is obvious for $(j,\ell) = (i,k)$ since, by definition, $\kappa_{\rm g} < 1$ and $\kappa_{\rm PR} \geq 1$. Let us now consider some iteration $(j,\ell) \in \mathcal{R}(i,k)$ with $j < i$. From the mean-value theorem, we know that, for any iteration (j,ℓ),

$$g_{j,\ell} = g_{j,0} + G_{j,\ell}(x_{j,\ell} - x_{j,0}), \tag{4.18}$$

where

$$G_{j,\ell} = \int_0^1 \nabla^2 h_j(x_{j,0} + t(x_{j,\ell} - x_{j,0}))\, dt. \tag{4.19}$$

But

$$\|G_{j,\ell}\| \leq \max_{t\in[0,1]} \|\nabla^2 h_j(x_{j,0} + t(x_{j,\ell} - x_{j,0}))\| \leq \kappa_{\rm H}, \tag{4.20}$$

and hence, by definition of the norms and (4.5),

$$\|g_{j,\ell}\| \geq \|g_{j,0}\| - \kappa_{\rm H}\|x_{j,\ell} - x_{j,0}\| \geq \|g_{j,0}\| - \frac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\|x_{j,\ell} - x_{j,0}\|_j \tag{4.21}$$

for all (j,ℓ). On the other hand, if $(j+1,q) = \pi(j,\ell)$, we have also that, for all $(j,\ell) \in \mathcal{R}(i,k)$,

$$\|x_{j,\ell} - x_{j,0}\|_j \leq \Delta_{j+1,q} \leq \Delta_{i,k} \tag{4.22}$$

because of (4.11) and (4.8) (as $(j+1,q) \in \mathcal{R}(i,k)$). Combining (4.21) and (4.22), we obtain that, for all $(j,\ell) \in \mathcal{R}(i,k)$,

$$\|g_{j,\ell}\| \geq \|g_{j,0}\| - \frac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k}. \tag{4.23}$$

Consider now the path from (j,ℓ) to (i,k) in $\mathcal{R}(i,k)$. Let this path consist of the iterations (j,ℓ), $(j+u,t_{j+u})$ for $u = 1,\ldots,i-j-1$, and (i,k). We then have that

$$\begin{aligned}
\|g_{j,\ell}\| &\geq \|g_{j,0}\| - \tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \geq \kappa_{\rm g}\|g_{j+1,t_{j+1}}\| - \tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \\
&\geq \kappa_{\rm g}\|g_{j+1,0}\| - 2\tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \geq \kappa_{\rm g}^2\|g_{j+2,t_{j+2}}\| - 2\tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \\
&\geq \kappa_{\rm g}^r\|g_{i,k}\| - r\tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k},
\end{aligned}$$

where we successively used (4.23), (2.5), the first part of (2.14), and the inequality $\kappa_{\rm g} < 1$. We then deduce the first inequality of (4.17) from (4.16).

To prove the second, we reuse (4.18)–(4.20) to obtain that

$$\|g_{j,\ell}\| \le \|g_{j,0}\| + \kappa_{\rm H}\|x_{j,\ell} - x_{j,0}\| \le \|g_{j,0}\| + \frac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\|x_{j,\ell} - x_{j,0}\|_j. \tag{4.24}$$

Combining this with (4.22), we conclude that

$$\|g_{j,\ell}\| \le \|g_{j,0}\| + \frac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k}. \tag{4.25}$$

We now retrack the iteration path from (j,ℓ) back to (i,k) as above and successively deduce from (4.25), (2.5), and (4.4) that

$$\begin{aligned}
\|g_{j,\ell}\| &\le \|g_{j,0}\| + \tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \le \kappa_{\rm PR}\|g_{j+1,t_{j+1}}\| + \tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \\
&\le \kappa_{\rm PR}\|g_{j+1,0}\| + (\kappa_{\rm PR}+1)\tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \le \kappa_{\rm PR}^2\|g_{j+2,t_{j+2}}\| + 2\tfrac{\kappa_{\rm PR}\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \\
&\le \kappa_{\rm PR}^r\|g_{i,k}\| + r\tfrac{\kappa_{\rm PR}^{r-1}\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k} \le \kappa_{\rm PR}^r\left[\|g_{i,k}\| + r\tfrac{\kappa_{\rm H}}{\sqrt{\kappa_\sigma}}\Delta_{i,k}\right],
\end{aligned}$$

using $\kappa_{\rm PR} \ge 1$. We may now use the bound (4.16) to conclude that the second inequality of (4.17) must hold. ∎

We now investigate what happens at noncritical points if the trust-region radius $\Delta_{i,k}$ is small enough. This investigation is conducted by considering the subset $\mathcal{V}(i,k)$ of $\mathcal{R}(i,k)$ defined by

$$\mathcal{V}(i,k) = \left\{(j,\ell) \in \mathcal{R}(i,k) \mid \delta_{j,\ell} \ge \tfrac{1}{2}\kappa_{\rm red}\kappa_{\rm g}^r\kappa_\epsilon^{j-d(i,k)}\|g_{i,k}\|\Delta_{j,\ell}\right\}, \tag{4.26}$$

where

$$\kappa_\epsilon \stackrel{\rm def}{=} \eta_2\epsilon_{\rm min}^{\Delta} < 1. \tag{4.27}$$

$\mathcal{V}(i,k)$ is the subset of iterations within the recursion at iteration (i,k) for which the model decrease is bounded below by a (level-dependent) factor times the product of the gradient norm $\|g_{i,k}\|$ and the trust-region radius $\Delta_{j,\ell}$. Note that, if iteration (j,ℓ) belongs to $\mathcal{V}(i,k)$, this implies that $\delta_{j,\ell}$ can be computed in a finite number of iterations, and thus that $\mathcal{R}(j,\ell)$ is finite. The idea of the next two results is to show that $\mathcal{V}(i,k)$ and $\mathcal{R}(i,k)$ coincide for a sufficiently small radius $\Delta_{i,k}$.

THEOREM 4.4. *Consider an iteration (i,k) for which $\|g_{i,k}\| > 0$ and*

$$\begin{aligned}
\Delta_{i,k} &\le \min\left[\Delta_{\rm min}^s, \min\left(\kappa_1, \frac{\kappa_{\rm red}\kappa_\sigma\kappa_{\rm g}^r\kappa_\epsilon^r(1-\eta_2)}{2\kappa_{\rm H}}\right)\|g_{i,k}\|\right] \\
&\stackrel{\rm def}{=} \min[\Delta_{\rm min}^s, \kappa_2\|g_{i,k}\|],
\end{aligned} \tag{4.28}$$

where $\kappa_2 \in (0,1)$. Then the following conclusions hold:

1. *every iteration using Taylor's model belongs to* (4.26)*, that is,*

$$\mathcal{T}(i,k) \subseteq \mathcal{V}(i,k), \text{ and} \tag{4.29}$$

2. *iteration (j,ℓ) is very successful for every $(j,\ell) \in \mathcal{V}(i,k)$.*

Moreover, if all iterations (j,ℓ) of a minimization sequence at level $j < i$ belong to $\mathcal{V}(i,k)$ and if $\pi(j,\ell) = (j+1,q)$, then

3. *the decrease in the objective function at level j satisfies, for each $\ell > 0$,*

$$h_j(x_{j,0}) - h_j(x_{j,\ell}) \geq \tfrac{1}{2}\kappa_{\rm red}\kappa_{\rm g}^r\kappa_\epsilon^{j-d(i,k)+1}\ell\,\|g_{i,k}\|\Delta_{j+1,q}, \tag{4.30}$$

4. *there are at most*

$$p_* \stackrel{\rm def}{=} \left\lceil \frac{\kappa_{\rm PR}^r\sqrt{\kappa_\sigma}(2+\kappa_{\rm g}^r)+\kappa_2\kappa_{\rm H}}{\kappa_{\rm red}\kappa_\sigma\kappa_{\rm g}^r\kappa_\epsilon^r} \right\rceil \tag{4.31}$$

iterations in the minimization sequence at level j, and

5. *we have that*

$$(j+1,q) \in \mathcal{V}(i,k). \tag{4.32}$$

Proof. 1. We start by proving (4.29). Note that, for $(j,\ell) \in \mathcal{R}(i,k)$, (4.8), the fact that the positive constants $\kappa_{\rm red}$, κ_σ, κ_ϵ, and η_2 are all bounded above by one, (4.28), the left inequality in (4.17), and (4.2) allow us to conclude that

$$\Delta_{j,\ell} \leq \Delta_{i,k} \leq \frac{\kappa_{\rm g}^r}{2\kappa_{\rm H}}\|g_{i,k}\| \leq \frac{\|g_{j,\ell}\|}{1+\|H_{j,\ell}\|}. \tag{4.33}$$

If we now assume that $(j,\ell) \in \mathcal{T}(i,k)$, the decrease condition (2.9) must hold at this iteration, which, together with the left part of (4.17) and (4.33), gives that

$$\delta_{j,\ell} = m_{j,\ell}(x_{j,\ell}) - m_{j,\ell}(x_{j,\ell}+s_{j,\ell}) \geq \kappa_{\rm red}\|g_{j,\ell}\|\Delta_{j,\ell} \geq \tfrac{1}{2}\kappa_{\rm red}\kappa_{\rm g}^r\|g_{i,k}\|\Delta_{j,\ell}, \tag{4.34}$$

which then implies (4.29) since $\kappa_\epsilon < 1$.

2. We prove item 2 separately for $(j,\ell) \in \mathcal{T}(i,k)$ and for $(j,\ell) \in \mathcal{V}(i,k) \setminus \mathcal{T}(i,k)$. Consider the case where $(j,\ell) \in \mathcal{T}(i,k)$ first. We deduce from Taylor's theorem that, for $(j,\ell) \in \mathcal{T}(i,k)$,

$$|h_j(x_{j,\ell}+s_{j,\ell}) - m_{j,\ell}(x_{j,\ell}+s_{j,\ell})| \leq \kappa_{\rm H}\left(\frac{\|s_{j,\ell}\|}{\|s_{j,\ell}\|_j}\right)^2\Delta_{j,\ell}^2 \tag{4.35}$$

(see, for instance, Theorem 6.4.1 on p. 133 of [13]). But, by definition of the norms and (4.5), we know that $\|s_{j,\ell}\|_j \geq \sqrt{\kappa_\sigma}\|s_{j,\ell}\|$. Hence, (4.35) becomes

$$|h_j(x_{j,\ell}+s_{j,\ell}) - m_{j,\ell}(x_{j,\ell}+s_{j,\ell})| \leq \frac{\kappa_{\rm H}}{\kappa_\sigma}\Delta_{j,\ell}^2.$$

Combining this last bound with (4.34), we obtain from (2.15) that

$$|\rho_{j,\ell}-1| \leq \left|\frac{h_j(x_{j,\ell}+s_{j,\ell}) - m_{j,\ell}(x_{j,\ell}+s_{j,\ell})}{m_{j,\ell}(x_{j,\ell}) - m_{j,\ell}(x_{j,\ell}+s_{j,\ell})}\right| \leq \frac{2\kappa_{\rm H}}{\kappa_{\rm red}\kappa_\sigma\kappa_{\rm g}^r\|g_{i,k}\|}\Delta_{j,\ell} \leq 1-\eta_2,$$

where the last inequality is deduced from (4.8) and the fact that (4.28) implies the bound

$$\Delta_{i,k} \leq \kappa_{\rm red}\kappa_\sigma\kappa_{\rm g}^r\|g_{i,k}\|(1-\eta_2)/2\kappa_{\rm H}$$

since $\kappa_\epsilon < 1$. Hence $\rho_{j,\ell} \geq \eta_2$ and iteration $(j,\ell) \in \mathcal{T}(i,k)$ is very successful, as requested in item 2.

We next prove item 2 for $(j,\ell) \in \mathcal{V}(i,k) \setminus \mathcal{T}(i,k)$, which implies, in particular, that $\mathcal{R}(j,\ell)$ is finite and $x_{j-1,*}$ is well defined. If we consider iteration (j,ℓ), we may still deduce from the mean-value theorem that

$$h_j(x_{j,\ell}) - h_j(x_{j,\ell} + s_{j,\ell}) = -\langle g_{j,\ell}, s_{j,\ell}\rangle - \tfrac{1}{2}\langle s_{j,\ell}, \nabla^2 h_j(\xi_j)\, s_{j,\ell}\rangle$$

for some $\xi_j \in [x_{j,\ell}, x_{j,\ell} + s_{j,\ell}]$ and also that

$$h_{j-1}(x_{j-1,0}) - h_{j-1}(x_{j-1,*}) = -\langle g_{j-1,0}, z_{j-1}\rangle - \tfrac{1}{2}\langle z_{j-1}, \nabla^2 h_{j-1}(\xi_{j-1})\, z_{j-1}\rangle$$

for some $\xi_{j-1} \in [x_{j-1,0}, x_{j-1,0} + z_{j-1}]$, where $z_{j-1} = x_{j-1,*} - x_{j-1,0} = x_{j-1,*} - R_j x_{j,\ell}$. Now, because $s_{j,\ell} = P_j z_{j-1}$, we deduce from (2.6) and (4.3) that $\langle g_{j,\ell}, s_{j,\ell}\rangle = \langle g_{j-1,0}, z_{j-1}\rangle$ and therefore that

$$\begin{aligned} h_j(x_{j,\ell}) - h_j(x_{j,\ell} + s_{j,\ell}) &= h_{j-1}(x_{j-1,0}) - h_{j-1}(x_{j-1,*}) \\ &\quad - \tfrac{1}{2}\langle s_{j,\ell}, \nabla^2 h_j(\xi_j)\, s_{j,\ell}\rangle \\ &\quad + \tfrac{1}{2}\langle z_{j-1}, \nabla^2 h_{j-1}(\xi_{j-1})\, z_{j-1}\rangle. \end{aligned} \tag{4.36}$$

But Lemma 4.1 implies that $\|s_{j,\ell}\|_j \le \Delta_{j,\ell}$ and $\|z_{j-1}\|_{j-1} \le \Delta_{j,\ell}$, which, in turn with the Cauchy–Schwarz inequality, gives that

$$|\langle s_{j,\ell}, \nabla^2 h_j(\xi_j)\, s_{j,\ell}\rangle| \le \kappa_{\mathrm{H}} \|s_{j,\ell}\|^2 \le \kappa_{\mathrm{H}} \left(\frac{\|s_{j,\ell}\|}{\|s_{j,\ell}\|_j}\right)^2 \Delta_{j,\ell}^2 \le \frac{\kappa_{\mathrm{H}}}{\kappa_\sigma} \Delta_{j,\ell}^2. \tag{4.37}$$

Similarly,

$$|\langle z_{j-1}, \nabla^2 h_{j-1}(\xi_{j-1})\, z_{j-1}\rangle| \le \frac{\kappa_{\mathrm{H}}}{\kappa_\sigma} \Delta_{j,\ell}^2. \tag{4.38}$$

Combining (4.36), (4.37), (4.38), and the definition of $\delta_{j,\ell}$, we obtain that

$$h_j(x_{j,\ell}) - h_j(x_{j,\ell} + s_{j,\ell}) \ge \delta_{j,\ell} - \frac{\kappa_{\mathrm{H}}}{\kappa_\sigma} \Delta_{j,\ell}^2. \tag{4.39}$$

But since $(j,\ell) \in \mathcal{V}(i,k)$ and $\kappa_\epsilon < 1$, we have that

$$\delta_{j,\ell} \ge \tfrac{1}{2}\kappa_{\mathrm{red}} \kappa_{\mathrm{g}}^r \kappa_\epsilon^{j-d(i,k)} \|g_{i,k}\| \Delta_{j,\ell} \ge \tfrac{1}{2}\kappa_{\mathrm{red}} \kappa_{\mathrm{g}}^r \kappa_\epsilon^r \|g_{i,k}\| \Delta_{j,\ell} > 0,$$

and we conclude from (4.39), the definition of $\rho_{j,\ell}$, and this last bound that

$$\rho_{j,\ell} = \frac{h_j(x_{j,\ell}) - h_j(x_{j,\ell} + s_{j,\ell})}{\delta_{j,\ell}} \ge 1 - \frac{\kappa_{\mathrm{H}} \Delta_{j,\ell}^2}{\kappa_\sigma \delta_{j,\ell}} \ge 1 - \frac{2\kappa_{\mathrm{H}} \Delta_{j,\ell}}{\kappa_{\mathrm{red}} \kappa_\sigma \kappa_{\mathrm{g}}^r \kappa_\epsilon^r \|g_{i,k}\|}.$$

Noting now that (4.28) implies the inequality

$$\Delta_{i,k} \le \tfrac{1}{2}\kappa_{\mathrm{red}} \kappa_\sigma \kappa_{\mathrm{g}}^r \kappa_\epsilon^r \|g_{i,k}\| (1 - \eta_2)$$

and using the bound (4.8), we obtain that $\rho_{j,\ell} \ge \eta_2$. Iteration (j,ℓ) is thus very successful, which completes the proof of item 2.

3. We now assume that all iterations (j,ℓ) of a minimization sequence at level $j < i$ belong to $\mathcal{V}(i,k)$ with $(j+1,q) = \pi(j,\ell)$. We first notice that $(j+1,q) \in \mathcal{R}(i,k)$, (4.8), (4.28), and (4.6) imply that $\Delta_{j+1,q} \le \Delta_{i,k} \le \Delta_{\min}^{\mathrm{s}} \le \Delta_j^{\mathrm{s}}$. Hence Step 0 gives

that $\Delta_{j,0} = \Delta_{j+1,q}$, and since all iterations at level j are very successful because of item 2, we have from Step 6 that, for all (j,ℓ) with $\ell > 0$,

$$\begin{aligned}
\Delta_{j,\ell} &= \min\left[\Delta^+_{j,\ell-1},\, \Delta_{j+1,q} - \|x_{j,\ell} - x_{j,0}\|_j\right] \\
&\geq \min\left[\Delta_{j,\ell-1},\, \Delta_{j+1,q} - \|x_{j,\ell} - x_{j,0}\|_j\right] \\
&= \min\left[\min[\Delta^+_{j,\ell-2}, \Delta_{j+1,q} - \|x_{j,\ell-1} - x_{j,0}\|_j],\, \Delta_{j+1,q} - \|x_{j,\ell} - x_{j,0}\|_j\right] \\
&\geq \min\left[\Delta_{j,\ell-2},\, \Delta_{j+1,q} - \max_{p=\ell-1,\ell} \|x_{j,p} - x_{j,0}\|_j\right] \\
&\geq \min\left[\Delta_{j,0},\, \Delta_{j+1,q} - \max_{p=1,\ldots,\ell} \|x_{j,p} - x_{j,0}\|_j\right] \\
&= \Delta_{j+1,q} - \max_{p=1,\ldots,\ell} \|x_{j,p} - x_{j,0}\|_j \\
&\geq \epsilon^{\Delta}_j \Delta_{j+1,q},
\end{aligned}$$

where we used (4.15) to deduce the last inequality. Note that $\Delta_{j,0} = \Delta_{j+1,q} > \epsilon^{\Delta}_j \Delta_{j+1,q}$, covering the case where $\ell = 0$. Combining these bounds with the very successful nature of each iteration at level j, we obtain that, for each (j,p) with $p = 0, \ldots, \ell - 1$,

$$\begin{aligned}
h_j(x_{j,p}) - h_j(x_{j,p} + s_{j,p}) &\geq \eta_2 \delta_{j,p} \\
&\geq \tfrac{1}{2}\eta_2 \kappa_{\rm red} \kappa_{\rm g}^r \kappa_\epsilon^{j-d(i,k)} \|g_{i,k}\| \Delta_{j,p} \\
&\geq \tfrac{1}{2}\kappa_{\rm red} \kappa_{\rm g}^r \kappa_\epsilon^{j-d(i,k)} \eta_2 \epsilon^{\Delta}_j \|g_{i,k}\| \Delta_{j+1,q} \\
&\geq \tfrac{1}{2}\kappa_{\rm red} \kappa_{\rm g}^r \kappa_\epsilon^{j-d(i,k)+1} \|g_{i,k}\| \Delta_{j+1,q},
\end{aligned}$$

where we used (4.6) and (4.27) to obtain the last inequality. Summing now over iterations $p = 0, \ldots, \ell - 1$ at level j, we obtain that

$$\begin{aligned}
h_j(x_{j,0}) - h_j(x_{j,\ell}) &= \sum_{p=0}^{\ell-1} [h_j(x_{j,p}) - h_j(x_{j,p} + s_{j,p})] \\
&\geq \tfrac{1}{2}\kappa_{\rm red} \kappa_{\rm g}^r \kappa_\epsilon^{j-d(i,k)+1} \ell \, \|g_{i,k}\| \Delta_{j+1,q},
\end{aligned}$$

yielding (4.30).

4. In order to prove item 4, we start by proving that the total decrease in h_j (the objective function for the considered minimization sequence at the jth level) is bounded above by some multiple of $\|g_{i,k}\|$ and $\Delta_{j+1,q}$. We first note that the mean-value theorem gives that

$$h_j(x_{j,0} + s_{j,\min}) = h_j(x_{j,0}) + \langle g_{j,0}, s_{j,\min}\rangle + \tfrac{1}{2}\langle s_{j,\min}, \nabla^2 h_j(\xi_j)\, s_{j,\min}\rangle$$

for some $\xi_j \in [x_{j,0}, x_{j,0} + s_{j,\min}]$, where we have defined

$$s_{j,\min} = \arg \min_{\|s_j\|_j \leq \Delta_{j+1,q}} h_j(x_{j,0} + s_j).$$

Hence, we obtain that, for all s_j such that $\|s_j\|_j \leq \Delta_{j+1,q}$,

$$h_j(x_{j,0}) - h_j(x_{j,0} + s_j) \leq h_j(x_{j,0}) - h_j(x_{j,0} + s_{j,\min}) \leq \frac{\|g_{j,0}\|}{\sqrt{\kappa_\sigma}} \Delta_{j+1,q} + \frac{\kappa_{\rm H}}{2\kappa_\sigma} \Delta^2_{j+1,q}.$$

But we have that $\|x_{j,\ell} - x_{j,0}\|_j \leq \Delta_{j+1,q}$ because of (4.11), and therefore the right inequalities of (4.17), (4.8), and (4.28) now give that

$$h_j(x_{j,0}) - h_j(x_{j,\ell}) \leq \left[\frac{\kappa_{\rm PR}^r + \frac{1}{2}\kappa_{\rm PR}^r \kappa_{\rm g}^r}{\sqrt{\kappa_\sigma}} + \frac{\kappa_2 \kappa_{\rm H}}{2\kappa_\sigma} \right] \|g_{i,k}\| \Delta_{j+1,q} \tag{4.40}$$

for all (j,ℓ) with $\ell \geq 0$. Combining now this bound with (4.30) and remembering that $\kappa_\epsilon < 1$, we deduce that item 4 must hold with (4.31).

5. Finally, since the minimization sequence at level j is guaranteed to terminate after a finite number of iterations $1 \leq \ell \leq p_*$, we deduce from (4.30) and the definition of $\delta_{j+1,q}$ that

$$\delta_{j+1,q} \geq \tfrac{1}{2}\kappa_{\rm red}\kappa_{\rm g}^r \kappa_\epsilon^{j+1-d(i,k)} \|g_{i,k}\| \Delta_{j+1,q},$$

and (4.32) then immediately follows. ∎

We may deduce the following important corollary from this theorem.

COROLLARY 4.5. *Assume* (4.28) *holds for some iteration* (i,k) *for which* $\|g_{i,k}\| > 0$. *Then all iterations* $(j,\ell) \in \mathcal{R}(i,k)$ *are very successful. Moreover, the total number of iterations in* $\mathcal{R}(i,k)$ *is finite and* $\Delta_{i,k}^+ \geq \Delta_{i,k}$.

Proof. As suggested above, we proceed by showing that $\mathcal{V}(i,k) = \mathcal{R}(i,k)$, working from the deepest recursion level upward. Thus consider level $j = d(i,k)$ first. At this level, all iterations (j,ℓ) belong to $\mathcal{T}(i,k)$ and thus, by (4.29), to $\mathcal{V}(i,k)$. If $j = i$, we have achieved our objective. Assume, therefore, that $j < i$ and consider level $j+1$. Using (4.32), we see that all iterations involving a recursion to level j must belong to $\mathcal{V}(i,k)$, while the other (Taylor) iterations again belong to $\mathcal{V}(i,k)$ by (4.29). If $j+1 = i$, we have thus proved that $\mathcal{V}(i,k) = \mathcal{R}(i,k)$. If $j+1 < i$, we may then apply the same reasoning to level $j+2$, and so on, until level i is reached. We may thus conclude that $\mathcal{V}(i,k)$ and $\mathcal{R}(i,k)$ always coincide and, because of item 2 of Theorem 4.4, contain only very successful iterations. Furthermore, using item 4 of Theorem 4.4, we see that the total number of iterations in $\mathcal{R}(i,k)$ is bounded above by

$$\sum_{l=0}^{r} p_*^\ell \leq r p_*^r + 1.$$

Finally, the fact that $\Delta_{i,k}^+ \geq \Delta_{i,k}$ then results from the mechanism of Step 6 of the algorithm and the very successful nature of iteration $(i,k) \in \mathcal{R}(i,k)$. ∎

This last result guarantees the finiteness of the recursion at iteration (i,k) (and thus the finiteness of the computation of $s_{i,k}$) if $\Delta_{i,k}$ is small enough. It also ensures the following useful consequence.

LEMMA 4.6. *Each minimization sequence contains at least one successful iteration.*

Proof. This follows from the fact that unsuccessful iterations cause the trust-region radius to decrease, until (4.28) is eventually satisfied and a (very) successful iteration occurs because of Corollary 4.5. ∎

We now investigate the consequence of the above results on the trust-region radius at each minimization level.

LEMMA 4.7. *For every iteration* (j,ℓ), *with* $j = 0, \ldots, r$ *and* $\ell \geq 0$, *we have that*

$$\Delta_{j,\ell} \geq \gamma_1 \min\left[\Delta_{\min}^s,\, \kappa_2 \epsilon_j^g,\, \epsilon_j^\Delta \Delta_{j+1,q}\right], \tag{4.41}$$

where $(j+1,q) = \pi(j,\ell)$.

Proof. Consider the minimization sequence at level $j \leq r$ initiated from iteration $(j+1, q)$, and assume, for the purpose of obtaining a contradiction, that iteration (j, ℓ) is the first such that

$$\Delta_{j,\ell} < \gamma_1 \min\left[\Delta^{\rm s}_{\rm min},\, \kappa_2 \epsilon^{\rm g}_j,\, \epsilon^{\Delta}_j \Delta_{j+1,q}\right]. \tag{4.42}$$

Note that, because $\epsilon^{\Delta}_j < 1$ and $\gamma_1 < 1$,

$$\Delta_{j,0} = \min[\Delta^{\rm s}_j,\, \Delta_{j+1,q}] \geq \min[\Delta^{\rm s}_{\rm min},\, \epsilon^{\Delta}_j \Delta_{j+1,q}] > \gamma_1 \min\left[\Delta^{\rm s}_{\rm min},\, \kappa_2 \epsilon^{\rm g}_j,\, \epsilon^{\Delta}_j \Delta_{j+1,q}\right],$$

which ensures that $\ell > 0$ and hence that $\Delta_{j,\ell}$ is computed by applying Step 6 of the algorithm at iteration $(j, \ell-1)$. Suppose now that

$$\Delta_{j,\ell} = \Delta_{j+1,q} - \|x_{j,\ell} - x_{j,0}\|_j; \tag{4.43}$$

i.e., the second term is active in (2.17). Our definition of $\Delta_{r+1,0} = \infty$ and (4.42) then ensure that $j < r$. Then, using (4.15), the definition of γ_1, and (4.42), we deduce that, for $j < r$,

$$\Delta_{j,\ell} \geq \Delta_{j+1,q} - (1 - \epsilon^{\Delta}_j)\Delta_{j+1,q} = \epsilon^{\Delta}_j \Delta_{j+1,q} > \gamma_1 \epsilon^{\Delta}_j \Delta_{j+1,q} > \Delta_{j,\ell},$$

which is impossible. Hence (4.43) cannot hold, and we obtain from (2.17) that $\Delta_{j,\ell} = \Delta^+_{j,\ell-1} \geq \gamma_1 \Delta_{j,\ell-1}$, where the last inequality results from (2.16). Combining this bound with (4.42) and (4.14), we deduce that

$$\Delta_{j,\ell-1} \leq \min\left[\Delta^{\rm s}_{\rm min},\, \kappa_2 \epsilon^{\rm g}_j,\, \epsilon^{\Delta}_j \Delta_{j+1,q}\right] \leq \min\left[\Delta^{\rm s}_{\rm min},\, \kappa_2 \|g_{j,\ell-1}\|\right].$$

Hence we may apply Corollary 4.5 and conclude that iteration $(j, \ell-1)$ is very successful and that $\Delta_{j,\ell-1} \leq \Delta^+_{j,\ell-1} = \Delta_{j,\ell}$. As a consequence, iteration (j, ℓ) cannot be the first such that (4.42) holds. This contradiction now implies that (4.42) is impossible, which completes the proof. ∎

Thus trust-region radii are bounded away from zero by a level-dependent factor. We now verify that this factor may be made independent of the level.

THEOREM 4.8. *There exists a constant* $\Delta_{\rm min} \in (0, \min[\Delta^s_{\rm min}, 1])$ *such that*

$$\Delta_{j,\ell} \geq \Delta_{\rm min} \tag{4.44}$$

for every iteration (j, ℓ).

Proof. Observe first that Lemma 4.7 ensures the bound

$$\Delta_{r,k} \geq \gamma_1 \min[\Delta^{\rm s}_{\rm min},\, \kappa_2 \epsilon^{\rm g}_r] \stackrel{\rm def}{=} \gamma_1 \mu \tag{4.45}$$

for all $k \geq 0$, because we have assumed that the call to the uppermost level is made with an infinite trust-region radius. Note that $\mu \in (0, 1)$ because κ_2 and $\epsilon^{\rm g}_r$ both belong to $(0, 1)$. Suppose now that, for some iteration (j, ℓ),

$$\Delta_{j,\ell} < \gamma_1^{r+2} (\epsilon^{\Delta}_{\rm min})^r \mu. \tag{4.46}$$

If $j = r$, this contradicts (4.45); hence $0 \leq j < r$. Lemma 4.7 and the definition of μ in (4.45) then imply that

$$\min[\mu,\, \epsilon^{\Delta}_j \Delta_{j+1,q}] < \gamma_1^{r+1} (\epsilon^{\Delta}_{\rm min})^r \mu,$$

where, as above, iteration $(j+1,q) = \pi(j,\ell)$. If $\min[\mu,\, \epsilon_j^{\Delta}\Delta_{j+1,q}] = \mu$, then $\mu < \gamma_1^{r+1}(\epsilon_{\min}^{\Delta})^r\mu$, which is impossible because $\gamma_1^{r+1}(\epsilon_{\min}^{\Delta})^r < 1$. As a consequence,

$$\epsilon_j^{\Delta}\Delta_{j+1,q} = \min[\mu,\, \epsilon_j^{\Delta}\Delta_{j+1,q}] < \gamma_1^{r+1}(\epsilon_{\min}^{\Delta})^r\mu \le \gamma_1^{r+1}(\epsilon_{\min}^{\Delta})^{r-1}\epsilon_j^{\Delta}\mu,$$

because of (4.6), and hence

$$\Delta_{j+1,q} < \gamma_1^{r+1}(\epsilon_{\min}^{\Delta})^{r-1}\mu.$$

This condition is entirely similar to (4.46) but one level higher. We may therefore repeat the reasoning at levels $j+1,\ldots,r-1$, yielding the bound

$$\Delta_{r,k} < \gamma_1^{r+2-(r-j)}(\epsilon_{\min}^{\Delta})^{r-(r-j)}\mu = \gamma_1^{j+2}(\epsilon_{\min}^{\Delta})^{j}\mu < \gamma_1\mu.$$

But this last inequality contradicts (4.45), and we therefore deduce that (4.46) never holds. This proves (4.44) with

$$\Delta_{\min} \stackrel{\text{def}}{=} \gamma_1^{r+2}(\epsilon_{\min}^{\Delta})^r \min[\Delta_{\min}^{\text{s}},\, \kappa_2\epsilon_r^{\text{g}}], \tag{4.47}$$

and the bounds $\gamma_1 \in (0,1)$, $\epsilon_{\min}^{\Delta} \in (0,1)$, $\kappa_2 \in (0,1)$, and $\epsilon_r^{\text{g}} \in (0,1)$ together imply that $\Delta_{\min} \in (0, \min[\Delta_{\min}^{\text{s}},\, 1])$, as requested. ∎

This result must be compared to Theorem 6.4.3 on p. 135 of [13], keeping (4.14) in mind along with the fact that we have called the uppermost minimization level with some nonzero tolerance ϵ_r^{g}. Also note in (4.47) that $\Delta_{\min}$ is linearly proportional to ϵ_r^{g} for small enough values of this threshold. The next crucial step of our analysis is to show that the algorithm is well defined in that all the recursions are finite.

THEOREM 4.9. *The number of iterations at each level is finite. Moreover, there exists $\kappa_h \in (0,1)$ such that, for every minimization sequence at level $i = 0,\ldots,r$,*

$$h_i(x_{i,0}) - h_i(x_{i,p+1}) \ge \tau_{i,p}\,\eta_1^{i+1}\kappa_h,$$

where $\tau_{i,p}$ is the total number of successful iterations in $\bigcup_{\ell=0}^{p}\mathcal{T}(i,\ell)$.

Proof. We prove the desired result by induction on higher and higher levels from 0 to r. We start by defining $\omega_{i,\ell}$ to be the number of successful iterations in $\mathcal{T}(i,\ell)$, as well as the number of successful iterations in the set $\bigcup_{\ell=0}^{p}\mathcal{T}(i,\ell)$:

$$\tau_{i,p} = \sum_{\ell=0}^{p}\omega_{i,\ell}. \tag{4.48}$$

Note that $\omega_{i,\ell} \ge 1$ if iteration (i,ℓ) is successful.

Consider first an arbitrary minimization sequence at level 0 (if any), and assume, without loss of generality, that it belongs to $\mathcal{R}(r,k)$ for some $k \ge 0$. Every iteration in this minimization sequence must be a Taylor iteration, which means that every successful iteration in the sequence satisfies

$$\begin{aligned} h_0(x_{0,\ell}) - h_0(x_{0,\ell+1}) &\ge \eta_1\kappa_{\text{red}}\epsilon_0^{\text{g}}\min\left[\frac{\epsilon_0^{\text{g}}}{\kappa_{\text{H}}},\, \Delta_{\min}\right] \\ &\ge \omega_{0,\ell}\,\eta_1\kappa_{\text{red}}\epsilon_{\min}^{\text{g}}\min\left[\frac{\epsilon_{\min}^{\text{g}}}{\kappa_{\text{H}}},\, \Delta_{\min}\right], \end{aligned} \tag{4.49}$$

where we have used (2.9), (4.14), (4.2), Theorem 4.8, (4.6), and the fact that $\omega_{0,\ell} = 1$ for every successful iteration $(0,\ell)$ because $\mathcal{T}(0,\ell) = \{(0,\ell)\}$. Since we know from

Lemma 4.6 that there is at least one such iteration for every minimization sequence, we may sum the objective decreases at level 0 and obtain from (4.49) that

$$h_0(x_{0,0}) - h_0(x_{0,p+1}) = \sum_{\ell=0}^{p} {}^{(\mathrm{S})}[h_0(x_{0,\ell}) - h_0(x_{0,\ell+1})] \geq \tau_{0,p}\eta_1\kappa_h, \tag{4.50}$$

where the sum with superscript (S) is restricted to successful iterations and where

$$\kappa_h \stackrel{\mathrm{def}}{=} \kappa_{\mathrm{red}}\epsilon_{\mathrm{min}}^{\mathrm{g}} \min\left[\frac{\epsilon_{\mathrm{min}}^{\mathrm{g}}}{\kappa_{\mathrm{H}}}, \Delta_{\mathrm{min}}\right] \in (0,1). \tag{4.51}$$

If $r = 0$, we know that $h_0 = f$ is bounded below by assumption, and (4.50) implies that $\tau_{0,p}$ must be finite. If $r > 0$, our assumption that f_0 is continuous implies that h_0 is also continuous and hence bounded below on the set $\{x \in \Re^{n_0} \mid \|x - x_{0,0}\|_0 \leq \Delta_{r,k}\}$. The relation (4.50), Lemma 4.1, and (4.8) therefore again impose the finiteness of $\tau_{0,p}$. Since $\tau_{0,p}$ accounts for all successful iterations in the minimization sequence, we obtain that there must be a last finite successful iteration $(0, \ell_0)$. If the sequence were nevertheless infinite, this would mean that every iteration $(0, \ell)$ is unsuccessful for all $\ell > \ell_0$, causing $\Delta_{j,\ell}$ to converge to zero, which is impossible in view of Theorem 4.8. Hence the minimization sequence is finite. The same reasoning may be applied to every such sequence at level 0.

Now consider an arbitrary minimization sequence at level i (again, without loss of generality, within $\mathcal{R}(r,k)$ for some $k \geq 0$) and assume that each minimization sequence at level $i-1$ is finite and also that each successful iteration $(i-1,u)$ in every minimization sequence at this lower level satisfies

$$h_{i-1}(x_{i-1,u}) - h_{i-1}(x_{i-1,u+1}) \geq \omega_{i-1,u}\,\eta_1^i\kappa_h, \tag{4.52}$$

which is the direct generalization of (4.49) at level $i-1$. Consider a successful iteration (i,ℓ), whose existence is ensured by Lemma 4.6. If it is a Taylor iteration (i.e., if $(i,\ell) \in \mathcal{T}(i,\ell)$), we obtain as above that

$$h_i(x_{i,\ell}) - h_i(x_{i,\ell+1}) \geq \eta_1\kappa_h \geq \eta_1^{i+1}\kappa_h = \omega_{i,\ell}\,\eta_1^{i+1}\kappa_h \tag{4.53}$$

since $\eta_1 \in (0,1)$ and $\omega_{i,\ell} = 1$ for every successful Taylor iteration. If, on the other hand, iteration (i,ℓ) uses Step 2, then, assuming $x_{i-1,*} = x_{i-1,t+1}$, we obtain that

$$\begin{aligned} h_i(x_{i,\ell}) - h_i(x_{i,\ell+1}) &\geq \eta_1[h_{i-1}(x_{i-1,0}) - h_{i-1}(x_{i-1,*})] \\ &= \eta_1 \sum_{u=0}^{t} {}^{(\mathrm{S})}[h_{i-1}(x_{i-1,u}) - h_{i-1}(x_{i-1,u+1})]. \end{aligned}$$

Observing that $\omega_{i,\ell} = \tau_{i-1,t}$, (4.52) and (4.48) then give that

$$h_i(x_{i,\ell}) - h_i(x_{i,\ell+1}) \geq \eta_1^{i+1}\kappa_h \sum_{u=0}^{t} \omega_{i-1,u} = \tau_{i-1,t}\,\eta_1^{i+1}\kappa_h = \omega_{i,\ell}\,\eta_1^{i+1}\kappa_h. \tag{4.54}$$

Combining (4.53) and (4.54), we see that (4.52) again holds at level i instead of $i-1$. Moreover, as above,

$$h_i(x_{i,0}) - h_i(x_{i,p+1}) = \sum_{\ell=0}^{p} {}^{(\mathrm{S})}[h_i(x_{i,\ell}) - h_i(x_{i,\ell+1})] \geq \tau_{i,p}\,\eta_1^{i+1}\kappa_h \tag{4.55}$$

for the minimization sequence including iteration (i, ℓ). If $i = r$, $h_i = f$ is bounded below by assumption and (4.55) imposes that the number of successful iterations in this sequence must again be finite. The same conclusion holds if $i < r$, since h_i is continuous and hence bounded below on the set $\{x \in \Re^{n_i} \mid \|x - x_{i,0}\|_i \leq \Delta_{r,k}\}$, which contains $x_{i,p+1}$ because of Lemma 4.1 and (4.8). As for level 0, we may then conclude that the number of iterations (both successful and unsuccessful) in the minimization sequence is finite. Moreover, the same reasoning holds for every minimization sequence at level i, and the induction is complete. ∎

A first remarkable consequence of this theorem is an upper bound on the number of iterations needed by the trust-region algorithm to reduce the gradient norm at level r below a given threshold value.

THEOREM 4.10. *Assume that one knows a constant $f_{\rm low}$ such that $h_r(x_r) = f(x) \geq f_{\rm low}$ for every $x \in \Re^n$. Then Algorithm RMTR needs at most*

$$\left\lceil \frac{f(x_{r,0}) - f_{\rm low}}{\theta(\epsilon^g_{\rm min})} \right\rceil$$

successful Taylor iterations at any level to obtain an iterate $x_{r,k}$ such that $\|g_{r,k}\| \leq \epsilon^g_r$, where

$$\theta(\epsilon) = \eta_1^{r+1} \kappa_{\rm red} \epsilon \min\left[\frac{\epsilon}{\kappa_{\rm H}}, \gamma_1^{r+2} (\epsilon^{\Delta}_{\rm min})^r \min[\Delta^s_{\rm min}, \kappa_2 \epsilon] \right].$$

Proof. The desired bound directly follows from Theorem 4.9, (4.51), (4.47), and the definition of $\epsilon^{\rm g}_{\rm min}$. (To keep the expression manageable, we have refrained from substituting the value of κ_2 from (4.28) and, in this value, that of κ_1 from (4.16), all these values being independent of ϵ.) ∎

Of course, the bound provided by this theorem may be very pessimistic and not all the constants in the definition of $\theta(\epsilon)$ may be known in practice, but this loose complexity result is nevertheless theoretically interesting as it applies to general nonconvex problems. One should note that the bound is in terms of iteration numbers, and implicitly accounts only for the cost of computing a Taylor step satisfying (2.9). Theorem 4.10 suggests several comments.

1. The bound involves the number of successful Taylor iterations, that is, successful iterations where the trial step is computed without resorting to further recursion. This provides an adequate measure of the linear algebra effort for all successful iterations, since successful iterations using the recursion of Step 2 cost little beyond the evaluation of the level-dependent objective function and its gradient. Moreover, the number of such iterations is, by construction, at most equal to r times that of Taylor iterations (in the worst case, where each iteration at level r includes a full recursion to level 0 with a single successful iteration at each level $j > 0$). Hence the result shows that the number of necessary successful iterations, all levels included, is of order $1/\epsilon^2$ for small values of ϵ. This order is not qualitatively altered by the inclusion of unsuccessful iterations either, provided we replace the very successful trust-region radius update (top case in (2.16)) by

$$\Delta^+_{i,k} \in [\Delta_{i,k}, \gamma_3 \Delta_{i,k}] \quad \text{if } \rho_{i,k} \geq \eta_2$$

for some $\gamma_3 > 1$. Indeed, Theorem 4.8 imposes that the decrease in radius caused by unsuccessful iterations must asymptotically be compensated for by

an increase at successful iterations, irrespective of the fact that $\Delta_{\min}$ depends on ϵ by (4.47). This is to say that, if α is the average number of unsuccessful iterations per successful one at any level, then one must have that $\gamma_3\gamma_2^{\alpha} \geq 1$ and therefore that $\alpha \leq -\log(\gamma_3)/\log(\gamma_2)$. Thus the complexity bound in $1/\epsilon^2$ for small ϵ is modified by a constant factor only if all iterations (successful and unsuccessful) are considered. This therefore also gives a worst-case upper bound on the number of function and gradient evaluations.

2. This complexity bound is of the same order as the corresponding bound for the pure gradient method (see [31, p. 29]). This is not surprising given that it is based on the Cauchy condition, which itself results from a step in the steepest-descent direction.
3. The bound involves the number of successful Taylor iterations *summed up on all levels* (as a result of Theorem 4.9). Thus successful such iterations at cheap low levels decrease the number of necessary expensive ones at higher levels, and the multiscale algorithm requires (at least in the theoretical worst case) fewer Taylor iterations at the upper level than the single-level variant. This provides theoretical backing for the practical observation that the structure of multiscale unconstrained optimization problems can be used to advantage.
4. The constants involved in the definition of $\theta(\epsilon)$ do not depend on the problem dimension but rather on the properties of the problem (r, $\kappa_{\rm H}$, κ_σ) or of the algorithm itself ($\kappa_{\rm red}$, $\kappa_{\rm g}$, γ_1, η_1, η_2, $\epsilon^{\Delta}_{\min}$, $\Delta^{\rm s}_{\min}$). If we consider the case where different levels correspond to different discretization meshes and make the mild assumption that r and $\kappa_{\rm H}$ are uniformly bounded above and that κ_σ is uniformly bounded below, we observe that our complexity bound is mesh-independent.

A second important consequence of Theorem 4.9 is that the algorithm is globally convergent in the sense that it generates a subsequence of iterates whose gradients converge to zero if run with $\epsilon^{\rm g}_r = 0$.

COROLLARY 4.11. *Assume that Algorithm RMTR is called at the uppermost level with $\epsilon^g_r = 0$. Then*

$$\liminf_{k\to\infty} \|g_{r,k}\| = 0. \tag{4.56}$$

Proof. We first observe that the sequence of iterates $\{x_{r,k}\}$ generated by the algorithm called with $\epsilon^{\rm g}_r = 0$ is identical to that generated as follows. We consider, at level r, a sequence of gradient tolerances $\{\epsilon^{\rm g}_{r,j}\} \in (0,1)$ monotonically converging to zero, start the algorithm with $\epsilon^{\rm g}_r = \epsilon^{\rm g}_{r,0}$, and slightly alter the mechanism of Step 5 (at level r only) to reduce $\epsilon^{\rm g}_r$ from $\epsilon^{\rm g}_{r,j}$ to $\epsilon^{\rm g}_{r,j+1}$ as soon as $\|g_{r,k+1}\| \leq \epsilon^{\rm g}_{r,j}$. The calculation is then continued with this more stringent threshold until it is also attained, $\epsilon^{\rm g}_r$ is then again reduced, and so on. Since $\Delta_{r+1,0} = \infty$, each successive minimization at level r can stop at iteration k only if

$$\|g_{r,k+1}\| \leq \epsilon^{\rm g}_{r,j}. \tag{4.57}$$

Theorem 4.9 then implies that there are only finitely many successful iterations between two reductions of $\epsilon^{\rm g}_r$. We therefore obtain that for each $\epsilon^{\rm g}_{r,j}$ there is an arbitrarily large k such that (4.57) holds. The desired result then follows immediately from our assumption that $\{\epsilon^{\rm g}_{r,j}\}$ converges to zero. ∎

The interest of this result is mostly theoretical, since most practical applications of Algorithm RMTR consider a nonzero gradient tolerance $\epsilon^{\rm g}_r$.

The reader may have noticed that our theory still applies when we modify the technique described at the start of Corollary 4.11 by allowing a reduction of all the $\epsilon_i^{\rm g}$ to zero at the same time,[4] instead of merely reducing the uppermost one. If this modified technique is used, and assuming the trust region becomes asymptotically inactive at every level (as is most often the case in practice), each minimization sequence in the algorithm becomes infinite (as if it were initiated with a zero gradient threshold and an infinite initial radius). Recursion to lower levels then remains possible for arbitrarily small gradients and may therefore occur arbitrarily far in the sequence of iterates. Moreover, we may still apply Corollary 4.11 at each level and deduce that, if the trust region becomes asymptotically inactive,

$$\liminf_{k\to\infty} \|g_{i,k}\| = 0 \tag{4.58}$$

for all $i = 0, \ldots, r$.

As is the case for single-level trust-region algorithms, we now would like to prove that the limit inferior in (4.56) (and possibly (4.58)) can be replaced by a true limit, while still allowing recursion for very small gradients. We start by deriving a variant of Theorem 4.9 that does not assume that *all* gradient norms remain above some threshold to obtain a measure of the predicted decrease at some iteration (i, k).

LEMMA 4.12. *There exists a constant $\kappa_3 \in (0, 1)$ such that, for all (i, k) such that $\|g_{i,k}\| > 0$,*

$$\delta_{i,k} \geq \kappa_{\rm red}\eta_1^r\gamma_1^r\kappa_{\rm g}^r\|g_{i,k}\| \min\left[\, \Delta_{\rm min}^s,\, \kappa_3\|g_{i,k}\|,\, \Delta_{i,k} \,\right]. \tag{4.59}$$

Proof. Consider iteration (i, k). If it is a Taylor iteration, then, if we set

$$\kappa_3 = \min\left[\frac{\kappa_{\rm g}^r}{\kappa_{\rm H}},\, \kappa_2\kappa_{\rm g}^r \right] = \kappa_2\kappa_{\rm g}^r \in (0, 1), \tag{4.60}$$

(4.59) immediately follows from (2.9), (4.2), and the bounds $\kappa_{\rm g} \in (0, 1)$, $\eta_1 \in (0, 1)$, and $\gamma_1 \in (0, 1)$. Otherwise, define the iteration (j, ℓ) (with $j < i$) to be the deepest successful iteration in $\mathcal{R}(i, k)$ such that $g_{j,0} = g_{j,1} = \cdots = g_{j,\ell} = R_{j+1} \ldots R_i\, g_{i,k}$ and such that all iterations $(j + 1, t_{j+1})$, $(j + 2, t_{j+2})$, $\ldots$, up to $(i - 1, t_{i-1})$ of the path from (j, ℓ) to (i, k), are successful (meaning that iterations (j, u) are unsuccessful for $u = 0, \ldots, \ell - 1$, if any, and that iterations (p, u) are also unsuccessful for $p = j + 1, \ldots, i - 1$ and $u = 0, \ldots, t_p - 1$, if any). Note that such a path is guaranteed to exist because of Lemma 4.6. Using the first part of (2.14), we then obtain that

$$\|g_{j,0}\| = \|g_{j,1}\| = \cdots = \|g_{j,\ell}\| = \|R_{j+1} \ldots R_i\, g_{i,k}\| \geq \kappa_{\rm g}^r\|g_{i,k}\| > 0. \tag{4.61}$$

If $\ell = 0$, then

$$\Delta_{j,\ell} = \min[\Delta_j^{\rm s},\, \Delta_{j+1,t_{j+1}}] \geq \min[\Delta_{\rm min}^{\rm s},\, \Delta_{j+1,t_{j+1}}]. \tag{4.62}$$

If, on the other hand, $\ell > 0$, we know that iterations $(j, 0)$ to $(j, \ell-1)$ are unsuccessful. Corollary 4.5 then implies that (4.28) cannot hold for iteration $(j, \ell - 1)$, and thus that

$$\Delta_{j,\ell-1} > \min[\, \Delta_{\rm min}^{\rm s},\, \kappa_2\|g_{j,\ell-1}\| \,] = \min[\, \Delta_{\rm min}^{\rm s},\, \kappa_2\|g_{j,0}\| \,].$$

[4] The ratios $\epsilon_i^{\rm g}/\epsilon_r^{\rm g}$ could, for instance, be fixed or kept within prescribed bounds.

But this inequality, (2.16), (2.17), the unsuccessful nature of the first ℓ iterations at level j, (4.61), and the bound $\gamma_1 < 1$ then yield that

$$\begin{aligned}\Delta_{j,\ell} &\geq \min[\,\gamma_1\Delta_{j,\ell-1},\, \Delta_{j+1,t_{j+1}} - \|x_{j,0} - x_{j,\ell}\|_j\,]\\ &= \min[\,\gamma_1\Delta_{j,\ell-1},\, \Delta_{j+1,t_{j+1}}\,]\\ &\geq \min[\,\gamma_1 \min(\Delta^{\rm s}_{\min},\, \kappa_2\|g_{j,0}\|),\, \Delta_{j+1,t_{j+1}}\,]\\ &\geq \min[\,\gamma_1 \min(\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|),\, \Delta_{j+1,t_{j+1}}\,]\\ &\geq \gamma_1 \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{j+1,t_{j+1}}\,].\end{aligned}$$

Combining this last inequality with (4.62), we conclude that, for $\ell \geq 0$,

$$\Delta_{j,\ell} \geq \gamma_1 \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{j+1,t_{j+1}}\,].$$

Our choice of iteration (j,ℓ) also ensures that the same reasoning can now be applied not only to iteration (j,ℓ) but also to every iteration in the path $(j+1,t_{j+1})$, $\ldots$, $(i-1,t_{i-1})$, because the first part of (2.14) implies that $\|g_{p,0}\| = \|R_{p+1}\ldots R_i\, g_{i,k}\| \geq \kappa_{\rm g}^r\|g_{i,k}\|$ for all $j \leq p < i$. Thus we obtain that

$$\Delta_{j+u,t_{j+u}} \geq \gamma_1 \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{j+u+1,t_{j+u+1}}\,]$$

for $u = 0,\ldots,i-j-1$ (where we identify $t_i = k$ for $u = i-j-1$). We may then use these bounds recursively level by level and deduce that

$$\begin{aligned}\Delta_{j,\ell} &\geq \gamma_1 \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{j,k}\|,\, \Delta_{j+1,t_{j+1}}\,]\\ &\geq \gamma_1 \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \gamma_1 \min(\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{j+2,t_{j+2}})\,]\\ &\geq \gamma_1^2 \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{j+2,t_{j+2}}\,]\\ &\geq \gamma_1^r \min[\,\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{i,k}\,]\end{aligned} \tag{4.63}$$

because $\gamma_1 < 1$. On the other hand, $(j,\ell) \in \mathcal{T}(i,k)$ by construction, and we therefore obtain from (2.9) and (4.2) that

$$\delta_{j,\ell} \geq \kappa_{\rm red}\|g_{j,\ell}\| \min\left[\,\frac{\|g_{j,\ell}\|}{\kappa_{\rm H}},\, \Delta_{j,\ell}\right]. \tag{4.64}$$

Gathering now (4.61), (4.63), and (4.64), we obtain that

$$\delta_{j,\ell} \geq \kappa_{\rm red}\kappa_{\rm g}^r\|g_{i,k}\| \min\left[\,\frac{\kappa_{\rm g}^r\|g_{i,k}\|}{\kappa_{\rm H}},\, \gamma_1^r \min[\Delta^{\rm s}_{\min},\, \kappa_2\kappa_{\rm g}^r\|g_{i,k}\|,\, \Delta_{i,k}]\right],$$

and thus, using (4.60), that

$$\delta_{j,\ell} \geq \kappa_{\rm red}\kappa_{\rm g}^r\gamma_1^r\|g_{i,k}\| \min\left[\,\Delta^{\rm s}_{\min},\, \kappa_3\|g_{i,k}\|,\, \Delta_{i,k}\,\right]. \tag{4.65}$$

But the fact that all iterations on the path from (j,ℓ) to (i,k) are successful also implies that

$$\begin{aligned}\delta_{i,k} &= h_{i-1}(x_{i-1,0}) - h_{i-1}(x_{i-1,*}) \geq h_{i-1}(x_{i-1,t_{i-1}}) - h_{i-1}(x_{i-1,t_{i-1}+1})\\ &\geq \eta_1\delta_{i-1,t_{i-1}} = \eta_1[h_{i-2}(x_{i-2,0}) - h_{i-2}(x_{i-2,*})]\\ &\geq \eta_1[h_{i-2}(x_{i-2,t_{i-2}}) - h_{i-2}(x_{i-2,t_{i-2}+1})] \geq \eta_1^2\delta_{i-2,t_{i-2}} \geq \eta_1^r\delta_{j,\ell}.\end{aligned}$$

The bound (4.59) then follows from this last inequality and (4.65). ∎

All the elements are now in place to show that, if the algorithm is run with $\epsilon_r^{\rm g} = 0$, then gradients at level r converge to zero.

THEOREM 4.13. *Assume that Algorithm RMTR is called at the uppermost level with $\epsilon_r^g = 0$. Then*

$$\lim_{k\to\infty} \|g_{r,k}\| = 0. \tag{4.66}$$

Proof. The proof is identical to that of Theorem 6.4.6 on p. 137 of [13], with (4.59) (with $i = r$) now playing the role of the sufficient model reduction condition AA.1 at level r. ∎

This last result implies, in particular, that any limit point of the infinite sequence $\{x_{r,k}\}$ is first-order critical for problem (2.1). But we may draw stronger conclusions. If we assume that the trust region becomes asymptotically inactive at all levels and that all $\epsilon_i^{\rm g}$ $(i = 0, \ldots, r-1)$ are driven down to zero together with $\epsilon_r^{\rm g}$ (thus allowing recursion even for very small gradients), then, as explained above, each minimization sequence in the algorithm becomes infinite, and we may apply Theorem 4.13 to each of them, concluding that, if the trust region becomes asymptotically inactive,

$$\lim_{k\to\infty} \|g_{i,k}\| = 0$$

for every level $i = 0, \ldots, r$. The behavior of Algorithm RMTR is therefore truly coherent with its multiscale formulation, since the same convergence results hold for each level.

The convergence results at the upper level are unaffected if minimization sequences at lower levels are "prematurely" terminated, provided each such sequence contains at least one successful iteration. Indeed, Lemmas 4.1 and 4.2 do not depend on the actual stopping criterion used, and all subsequent proofs do not depend on it either. Thus, one might think of stopping a minimization sequence after a preset number of successful iterations: in combination with the freedom left at Step 1 to choose the model whenever (2.14) holds, this strategy allows a straightforward implementation of fixed lower-iterations patterns, like the V or W cycles in multigrid methods. This is what we have done in section 3.

Our theory also remains essentially unchanged if we merely insist on first-order coherence (i.e., conditions (2.5) and (2.6)) to hold only for small enough trust-region radii $\Delta_{i,k}$, or only up to a perturbation of the order of $\Delta_{i,k}$ or $\|g_{i,k}\|\Delta_{i,k}$. Other generalizations may be possible. Similarly, although we have assumed for motivation purposes that each f_i is "more costly" to minimize that f_{i-1}, we have not used this feature in the theory presented above, nor have we used the form of the lower levels objective functions. In particular, our choice of section 3 to define f_i as identically zero for $i = 0, \ldots, r-1$ satisfies all our assumptions. Nonconstant prolongation and restriction operators of the form $P_i(x_{i,k})$ and $R_i(x_{i,k})$ may also be considered, provided the singular values of these operators remain uniformly bounded.

In its full generality, convergence to second-order critical points appears to be out of reach unless one is able to guarantee some "eigenpoint condition." Such a condition imposes that, if $\tau_{i,k}$, the smallest eigenvalue of $H_{i,k}$, is negative, then

$$m_{i,k}(x_{i,k}) - m_{i,k}(x_{i,k} + s_{i,k}) \geq \kappa_{\rm eip} |\tau_{i,k}| \min[\tau_{i,k}^2, \Delta_{i,k}^2]$$

for some constant $\kappa_{\rm eip} \in (0, \frac{1}{2})$ (see AA.2 in [13, p. 153]). This is easy to obtain at relatively coarse levels, where the cost of an eigenvalue computation or of a factorization remains acceptable. For instance, the algorithm considered in section 3 is convergent

to critical points that satisfy second-order optimality conditions *at the coarsest level*. This results from the application of the Moré–Sorensen exact trust-region subproblem solver at that level, for which this property is well known (see section 6.6 of [13], for instance). The idea of imposing an eigenpoint condition at the coarsest level to obtain second-order criticality at that level is also at the core of the globalization proposal in [9], but it can be verified [21] that this technique does not enforce second-order convergence at finer levels. However, imposing an eigenpoint condition at fine levels may be judged impractical: for instance, the SCM smoothing strategy described above does not guarantee such a condition but merely that

$$m_{i,k}(x_{i,k}) - m_{i,k}(x_{i,k} + s_{i,k}) \geq \tfrac{1}{2}|\mu_{i,k}|\Delta_{i,k}^2,$$

where $\mu_{i,k}$ is the most negative diagonal element of $H_{i,k}$. This weaker result is caused by the fact that SCM limits its exploration of the model's curvature to the coordinate axes, at variance with the TCG and GLTR methods, which implicitly construct Lanczos approximations to Hessian eigenvalues. Convergence to fine-level first-order critical points satisfying a weak version of second-order optimality can, however, be expected in this case. In particular, the diagonal elements of the objective function's Hessian have to be nonnegative at such limit points (see [21]).

5. Comments and perspectives. We have defined a class of recursive trust-region algorithms whose members are able to exploit cheap lower-level models in a multiscale optimization problem. This class has been proved to be well defined and globally convergent to first order; preliminary numerical experience suggests that it may have strong potential. We have also presented a theoretical complexity result giving a bound on the number of iterations that are required by the algorithms of our class to find an approximate critical point of the objective function within prescribed accuracy. This last result also shows that the total complexity of solving an unconstrained multiscale problem can be shared amongst the levels, exploiting the structure to advantage.

Although the example of discretized problems has been used as a major motivation for our work, this is not the only case where our theory can be applied. We think, in particular, of cases where different models of the true objective function might live in the same space but involve different levels of complexity and/or cost. This is of interest, for instance, in a number of problems arising from physics, like data assimilation in weather forecasting [15], where different models may involve different levels of sophistication in the physical modeling itself. More generally, the algorithms and theory presented here are relevant in most areas where simplified models are considered, such as multidisciplinary optimization [1, 2, 3] or PDE-constrained problems [4, 14].

We may also think of investigating even more efficient algorithms combining the trust-region framework developed here with other globalization techniques, like line-searches [17, 32, 39], nonmonotone techniques [40, 42, 44], or filter methods [20]. While this might add yet another level of technicality to the convergence proofs, we expect such extensions to be possible and the resulting algorithms to be of practical interest.

Another important research direction is to investigate what kinds of Hessian (and possibly gradient) approximations are practically efficient within our framework, especially at the fine levels. Various options are possible, ranging from specialized finite differences to secant approximations.

Applying recursive trust-region methods of the type discussed here to constrained problems is another obvious avenue of research. Although we anticipate the associated

convergence theory to be again more technically difficult, intuition and limited numerical experience suggest that the power of such methods should also be exploitable in this case.

A number of practical issues related to Algorithm RMTR (such as alternative gradient smoothing and choice of cycle patterns) have not been discussed, although they may be crucial in practice. We investigate these issues in a forthcoming paper describing (so far encouraging) numerical experience with Algorithm RMTR.

ON THE GLOBAL SOLUTION OF LINEAR PROGRAMS WITH LINEAR COMPLEMENTARITY CONSTRAINTS*

JING HU†, JOHN E. MITCHELL†, JONG-SHI PANG‡, KRISTIN P. BENNETT†, AND GAUTAM KUNAPULI†

Abstract. This paper presents a parameter-free integer-programming-based algorithm for the global resolution of a linear program with linear complementarity constraints (LPCCs). The cornerstone of the algorithm is a minimax integer program formulation that characterizes and provides certificates for the three outcomes—infeasibility, unboundedness, or solvability—of an LPCC. An extreme point/ray generation scheme in the spirit of Benders decomposition is developed, from which valid inequalities in the form of satisfiability constraints are obtained. The feasibility problem of these inequalities and the carefully guided linear-programming relaxations of the LPCC are the workhorses of the algorithm, which also employs a specialized procedure for the sparsification of the satifiability cuts. We establish the finite termination of the algorithm and report computational results using the algorithm for solving randomly generated LPCCs of reasonable sizes. The results establish that the algorithm can handle infeasible, unbounded, and solvable LPCCs effectively.

1. Introduction. Forming a subclass of the class of mathematical programs with equilibrium/complementarity constraints (MPECs/MPCCs) [37, 39, 11], linear programs with linear complementarity constraints (LPCCs) are disjunctive linear optimization problems that contain a set of complementarity conditions. In turn, a large subclass of LPCCs are bilevel linear/quadratic programs [10] that provide a broad modeling framework for parameter identification in convex quadratic programming; an example of such an application was proposed recently for the cross validation of a host of machine-learning problems [6, 33, 32]. While there have been significant recent advances on nonlinear-programming- (NLP-) based computational methods for solving MPECs and the closely related MPCCs [1, 2, 3, 8, 14, 15, 19, 20, 29, 30, 25, 35, 36, 42, 43], many of which have nevertheless focused on obtaining stationary solutions [12, 13, 37, 39, 38, 40, 42, 48, 47, 46], the global solution of an LPCC remains elusive. Particularly impressive among these advances is the suite of NLP solvers publicly available on the NEOS system [49]; many of them, such as FILTER and KNITRO, are capable of producing a solution of some sort to an LPCC very efficiently. Yet they are incapable of ascertaining the quality of the computed solution. This is the major deficiency of these numerical solvers. Continuing our foray into the subject of computing global solutions of LPCCs, which begins with the recent article [41] that pertains to a special problem arising from the optimization of the value at risk, the present

paper proposes a parameter-free integer-programming-based cutting-plane algorithm for globally resolving a general LPCC.

As a disjunctive linear optimization problem, the global solution of an LPCC has been the subject of sustained, but not particularly focused, investigation since the early work of Ibaraki [26, 27] and Jeroslow [28], who pioneered some cutting-plane methods for solving a "complementary program," which is a historical and not widely used name for an LPCC. Over the years, various integer-programming-based methods [4, 5, 21] and global-optimization-based methods [16, 17, 44, 45] have been developed that are applicable to an LPCC. In this paper, we present a new cutting-plane method that will successfully resolve a general LPCC in finite time; i.e., the method will terminate with one of the following three mutually exclusive conclusions: the LPCC is infeasible, the LPCC is feasible but has an unbounded objective, or the LPCC attains a finite optimal solution. We also leverage the advances of the NLP solvers and use two of them to benchmark our algorithm. In addition, we propose a simple linear-programming-based preprocessor whose effectiveness will be demonstrated via computational results.

The proposed method begins with an equivalent formulation of an LPCC as a 0-1 integer program (IP) involving a conceptually very large parameter, whose existence is not guaranteed unless a certain boundedness condition holds. Via dualization of the linear-programming relaxation of the IP, we obtain a minimax 0-1 integer program, which yields a certificate for the three states of the LPCC, without any a priori boundedness assumption. The original 0-1 IP with the conceptual parameter provides the formulation for the application of Benders decomposition [34], which we show can be implemented without involving the parameter in any way. Thus, the resulting algorithm is reminiscent of the well-known phase I implementation of the "big-M" method for solving linear programs, wherein the big-M formulation is only conceptual whose practical solution does not require the knowledge of the scalar M.

The implementation of our parameter-free algorithm is accomplished by solving integer subprograms defined solely by *satisfiability constraints* [7, 31]; in turn, each such constraint corresponds to a "piece" of the LPCC. By using this interpretation, the overall algorithm can be considered as solving the LPCC by searching on its (finitely many) linear-programming pieces, with the search guided by solving the satisfiability IPs. The implementation of the algorithm is aided by valid upper bounds on the LPCC optimal objective value that are being updated as the algorithm progresses, which also serve to provide the desired certificates at the termination of the algorithm.

Hooker [22, 23] and Hooker and Ottosson [24] have presented a general Benders decomposition framework for integer-programming problems, where the subproblems and the master problem may be solved by various techniques, for example, constraint programming. The constraints returned by the subproblems may well be satisfiability constraints similar to those we derive from solving a linear-programming subproblem, leading to a satisfiability master problem. Hooker develops a broad framework for integrating different solution methodologies, with the solution approaches driven by the types of constraints. Different decomposition methods are available depending on the particular mix of types of constraints. Codato and Fischetti [9] have specialized Hooker's approach to solve integer programs arising from linear programs with conditional constraints of the kind "if then," of which the complementarity condition is a special case. Such constraints are modeled with the introduction of integer variables together with big-M coefficients. The cited article presents computational results for feasible bounded problems where only the binary variables associated with the big-M coefficients appear in the objective function. In our problem (2.3), the objective func-

tion is a linear function of the continuous variables; the objective function could be regarded as a nonlinear function of the binary variables (see $\varphi(z)$ defined in (2.9)). Our algorithmic approach can successfully characterize infeasible and unbounded LPCC problems as well as solve problems with a finite optimal value. Hooker [23] states that "the success of a Benders method often rests on finding strong Benders cuts that rule out as many infeasible solutions as possible." The sparsification methodology we present in section 4 is an approach to generate strong Benders cuts.

The organization of the rest of the paper is as follows. Section 2 presents the formal statement of the LPCC, summarizes the three states of the LPCC, and introduces the new minimax IP formulation. Section 3 reformulates the minimax IP formulation in terms of the extreme points and rays of the key polyhedron Ξ (see (2.6)) and establishes the theoretical foundation for the cutting-plane algorithm to be presented in section 5. The key steps of the algorithm, which involve solving linear programs (LPs) to sparsify the satisfiability constraints, are explained in section 4. The sixth and last section reports the computational results and completes the paper with some concluding remarks.

2. Preliminary discussion. Let $c \in \Re^n$, $d \in \Re^m$, $f \in \Re^k$, $q \in \Re^m$, $A \in \Re^{k \times n}$, $B \in \Re^{k \times m}$, $M \in \Re^{m \times m}$, and $N \in \Re^{m \times n}$ be given. Consider the LPCC [18] of finding $(x, y) \in \Re^n \times \Re^m$ in order to

$$\begin{array}{ll} \underset{(x,y)}{\text{minimize}} & c^T x + d^T y \\ \text{subject to} & Ax + By \geq f \\ \text{and} & 0 \leq y \perp q + Nx + My \geq 0, \end{array} \tag{2.1}$$

where $a \perp b$ means that the two vectors are orthogonal; i.e., $a^T b = 0$. It is well known that the LPCC is equivalent to the minimization of a large number of linear programs, each defined on one *piece* of the feasible region of the LPCC. That is, for each subset α of $\{1, \ldots, m\}$ with complement $\bar{\alpha}$, we may consider the LP(α):

$$\begin{array}{ll} \underset{(x,y)}{\text{minimize}} & c^T x + d^T y \\ \text{subject to} & Ax + By \geq f, \\ & (\, q + Nx + My \,)_\alpha \geq 0 = y_\alpha, \\ \text{and} & (\, q + Nx + My \,)_{\bar{\alpha}} = 0 \leq y_{\bar{\alpha}}. \end{array} \tag{2.2}$$

The following facts are consequences of the disjunctive property of the complementarity condition:

(a) The LPCC (2.1) is infeasible if and only if the LP(α) is infeasible for *all* $\alpha \subseteq \{1, \ldots, m\}$;

(b) the LPCC (2.1) is feasible and has an unbounded objective if and only if the LP(α) is feasible and has an unbounded objective for *some* $\alpha \subseteq \{1, \ldots, m\}$;

(c) the LPCC (2.1) is feasible and attains a finite optimal objective value if and only if (i) a subset α of $\{1, \ldots, m\}$ exists such that the LP(α) is feasible and (ii) every such feasible LP(α) has a finite optimal objective value; in this case, the optimal objective value of the LPCC (2.1), denoted $\text{LPCC}_{\min}$, is the minimum of the optimal objective values of all such feasible LPs.

The first step in our development of an IP-based algorithm for solving the LPCC (2.1) without any a priori assumption is to derive results parallel to the above three

facts in terms of some parameter-free integer problems. For this purpose, we recall the standard approach of solving (2.1) as an IP containing a large parameter. This approach is based on the following "equivalent" IP formulation of (2.1) wherein the complementarity constraint is reformulated in terms of the binary vector $z \in \{0,1\}^m$ via a conceptually very large scalar $\theta > 0$:

$$
\begin{array}{lll}
\underset{(x,y,z)}{\text{minimize}} & & c^T x + d^T y \\
\text{subject to} & & Ax + By \geq f, \\
& \theta\, z \;\geq\; q + Nx + My \geq 0, & \\
& & \theta(\,\mathbf{1} - z\,)\, y \geq 0, \\
\text{and} & & z \in \{\,0,1\,\}^m,
\end{array}
\tag{2.3}
$$

where $\mathbf{1}$ is the m-vector of all ones. In the standard approach, we first derive a valid value on θ by solving LPs to obtain bounds on all of the variables and constraints of (2.1). We then solve the fixed IP (2.3) by using the so-obtained θ by, for example, the Benders approach. There are two drawbacks of such an approach: One is the limitation of the approach to problems with bounded feasible regions; the other drawback is the nontrivial computation to derive the required bounds even if they are known to exist implicitly. In contrast, our new approach removes such a theoretical restriction and eliminates the front-end computation of bounds. The price of the new approach is that it solves a (finite) family of IPs of a special type, each defined solely by constraints of the *satisfiability* type. The following discussion sets the stage for the approach. [A referee suggests that "another drawback of attacking the integer program (2.3) is the probably (very) weak LP relaxations (which will affect the convergence of branch and cut methods as well as approaches based on Benders decomposition)."]

For a given binary vector z and a positive scalar θ, we associate with (2.3) the linear program below, which we denote $\mathrm{LP}(\theta; z)$:

$$
\begin{array}{lll}
\underset{(x,y)}{\text{minimize}} & c^T x + d^T y & \\
\text{subject to} & Ax + By \geq f & (\,\lambda\,), \\
& Nx + My \geq -q & (\,u^-\,), \\
& -Nx - My \geq q - \theta\, z & (\,u^+\,), \\
& -y \geq -\theta\,(\,\mathbf{1} - z\,) & (\,v\,), \\
\text{and} & y \geq 0, &
\end{array}
\tag{2.4}
$$

where the dual variables of the respective constraints are given in the parentheses. The dual of (2.4), which we denote $\mathrm{DLP}(\theta, z)$, is

$$
\begin{array}{lll}
\underset{(\lambda,u^\pm,v)}{\text{maximize}} & f^T\lambda + q^T(\,u^+ - u^-\,) - \theta\,\left[\, z^T u^+ + (\,\mathbf{1} - z\,)^T v \,\right] \\
\text{subject to} & A^T\lambda - N^T(\,u^+ - u^-\,) \;=\; c, \\
& B^T\lambda - M^T(\,u^+ - u^-\,) - v \;\leq\; d, \\
\text{and} & (\,\lambda, u^\pm, v\,) \;\geq\; 0.
\end{array}
\tag{2.5}
$$

Let $\Xi \subseteq \Re^{k+3m}$ be the feasible region of the $\mathrm{DLP}(\theta, z)$; i.e.,

$$
\Xi \equiv \left\{ (\,\lambda, u^\pm, v\,) \;\geq\; 0 \;:\; \begin{array}{r} A^T\lambda - N^T(\,u^+ - u^-\,) \;=\; c \\ B^T\lambda - M^T(\,u^+ - u^-\,) - v \;\leq\; d \end{array} \right\}.
\tag{2.6}
$$

Note that Ξ is a fixed polyhedron independent of the pair (θ, z); Ξ has at least one extreme point if it is nonempty. Let $\mathrm{LP}_{\min}(\theta; z)$ and $d(\theta; z)$ denote the optimal objective value of (2.4) and (2.5), respectively. Throughout, we adopt the standard convention that the optimal objective value of an infeasible maximization (minimization) problem is defined to be $-\infty$ (∞). We summarize some basic relations between the above programs in the following result.

PROPOSITION 2.1. *The following three statements hold:*

(a) *Any feasible solution (x^0, y^0) of (2.1) induces a pair (θ_0, z^0), where $\theta_0 > 0$ and $z^0 \in \{0,1\}^m$, such that the tuple (x^0, y^0, z^0) is feasible to (2.3) for all $\theta \geq \theta_0$; such a z^0 has the property that*

$$\begin{aligned} (\, q + Nx^0 + My^0 \,)_i \, > \, 0 \Rightarrow z_i^0 \, = \, 1, \\ (\, y^0 \,)_i \, > \, 0 \Rightarrow z_i^0 \, = \, 0. \end{aligned} \tag{2.7}$$

(b) *Conversely, if (x^0, y^0, z^0) is feasible to (2.3) for some $\theta \geq 0$, then (x^0, y^0) is feasible to (2.1).*

(c) *If (x^0, y^0) is an optimal solution to (2.1), then it is optimal to the $\mathrm{LP}(\theta, z^0)$ for all pairs (θ, z^0) such that $\theta \geq \theta_0$ and z^0 satisfies (2.7); moreover, for each $\theta > \theta_0$, any optimal solution $(\widehat{\lambda}, \widehat{u}^{\pm}, \widehat{v})$ of the $\mathrm{DLP}(\theta, z^0)$ satisfies $(z^0)^T \widehat{u}^+ + (\, \mathbf{1} - z^0 \,)^T \widehat{v} = 0$.*

Proof. Only (c) requires a proof. Suppose that (x^0, y^0) is optimal to (2.1). Let (θ, z^0) be such that $\theta \geq \theta_0$ and $z^0 \in \{0,1\}^m$ satisfies (2.7). Then (x^0, y^0) is feasible to the $\mathrm{LP}(\theta, z^0)$; hence

$$c^T x^0 + d^T y^0 \, \geq \, \mathrm{LP}_{\min}(\theta, z^0). \tag{2.8}$$

But the reverse inequality must hold because of (b) and the optimality of (x^0, y^0) to (2.1). Consequently, equality holds in (2.8). For $\theta > \theta_0$, if i is such that $z_i^0 > 0$, then

$$(\, q + Nx^0 + My^0 \,) \, \leq \, \theta_0 \, z_i^0 \, < \theta \, z_i^0,$$

and complementary slackness implies that $(\widehat{u}^+)_i = 0$. Similarly, we can show that $z_i^0 = 0 \Rightarrow v_i = 0$. Hence (c) follows. ∎

2.1. The parameter-free dual programs. Property (c) of Proposition 2.1 suggests that the inequality constraint $z^T u^+ + (\mathbf{1} - z)^T v \leq 0$, or, equivalently, the equality constraint $z^T u^+ + (\mathbf{1} - z)^T v = 0$ (because all variables are nonnegative and $z \in \{0,1\}^m$), should have an important role to play in an IP approach to the LPCC. This motivates us to define two value functions on the binary vectors. Specifically, for any $z \in \{0,1\}^m$, define

$$\begin{aligned} \Re \cup \{ \pm\infty \} \ni \varphi(z) \equiv \quad & \underset{(\lambda, u^{\pm}, v)}{\text{maximum}} \quad f^T\lambda + q^T(\, u^+ - u^- \,) \\ & \text{subject to} \quad A^T\lambda - N^T(\, u^+ - u^- \,) \, = \, c, \\ & \qquad\qquad\quad B^T\lambda - M^T(\, u^+ - u^- \,) - v \, \leq \, d, \\ & \qquad\qquad\quad (\, \lambda, u^{\pm}, v \,) \, \geq \, 0, \\ & \text{and} \qquad\quad z^T u^+ + (\mathbf{1} - z)^T v \, \leq \, 0 \end{aligned} \tag{2.9}$$

and its homogenization:

$$
\begin{array}{rlll}
\{\,0,\infty\,\} \ni \varphi_0(z) \equiv & \underset{(\lambda,u^{\pm},v)}{\text{maximum}} & f^T\lambda + q^T(\,u^+ - u^-\,) \\
& \text{subject to} & A^T\lambda - N^T(\,u^+ - u^-\,) = 0, \\
& & B^T\lambda - M^T(\,u^+ - u^-\,) - v \le 0, \\
& & (\,\lambda, u^{\pm}, v\,) \ge 0, \\
& \text{and} & z^T u^+ + (\,\mathbf{1} - z\,)^T v \le 0.
\end{array} \tag{2.10}
$$

Clearly, (2.10) is always feasible, and $\varphi_0(z)$ takes on the values 0 or ∞ only. Unlike (2.10), which is independent of the pair (c,d), (2.9) depends on (c,d) and is not guaranteed to be feasible; thus $\varphi(z) \in \Re \cup \{\pm\infty\}$. For any pair (c,d) for which (2.9) is feasible, we have

$$\varphi(z) < \infty \;\Leftrightarrow\; \varphi_0(z) = 0.$$

To this equivalence we add the following proposition that describes a one-to-one correspondence between (2.10) and the feasible pieces of the LPCC. The *support* of a vector z, denoted $\mathrm{supp}(z)$, is the index set of the nonzero components of z.

PROPOSITION 2.2. *For any $z \in \{0,1\}^m$, $\varphi_0(z) = 0$ if and only if the* LP(α) *is feasible, where $\alpha \equiv \mathrm{supp}(z)$.*

Proof. The dual of (2.10) is

$$
\begin{array}{ll}
\underset{(x,y)}{\text{minimize}} & 0^T x + 0^T y \\
\text{subject to} & Ax + By \ge f, \\
& \theta\, z \ge q + Nx + My \ge 0, \\
\text{and} & \theta\,(\,\mathbf{1} - z\,) \ge y \ge 0.
\end{array} \tag{2.11}
$$

By LP duality, it follows that if $\varphi_0(z) = 0$, then (2.11) is feasible for any $\theta > 0$; conversely, if (2.11) is feasible for some $\theta > 0$, then $\varphi_0(z) = 0$. In turn, (2.11) is feasible for some $\theta > 0$ if and only if the LP(α) is feasible for $\alpha \equiv \mathrm{supp}(z)$. □

For subsequent purposes, it would be useful to record the following equivalence between the extreme points/rays of the feasible region of (2.9) and those of the feasible set Ξ.

PROPOSITION 2.3. *For any $z \in [0,1]^m$, a feasible solution $(\lambda^p, u^{\pm,p}, v^p)$ of* (2.9) *is an extreme point in this region if and only if it is extreme in Ξ; a feasible ray $(\lambda^r, u^{\pm,r}, v^r)$ of* (2.9) *is extreme in this region if and only if it is extreme in Ξ.*

Proof. We prove only the first assertion; that for the second is similar. The sufficiency holds because the feasible region of (2.9) is a subset of Ξ. To prove the converse, suppose that $(\lambda^p, u^{\pm,p}, v^p)$ is an extreme solution of (2.9). Then this triple must be an element of Ξ. If it lies on the line segment of two other feasible solutions of Ξ, then the latter two solutions must satisfy the additional constraint $z^T u^+ + (\mathbf{1} - z)^T v \le 0$. Therefore, $(\lambda^p, u^{\pm,p}, v^p)$ is also extreme in Ξ. □

2.2. The set $\mathcal{Z}$ and a minimax formulation. We now define the key set of binary vectors:

$$\mathcal{Z} \equiv \{\, z \in \{\,0,1\,\}^m : \varphi_0(z) = 0\,\},$$

which, by Proposition 2.2, is the feasibility descriptor of the feasible region of the LPCC (2.1). Note that $\mathcal{Z}$ is a finite set. We also define the minimax integer program:

$$\text{(2.12)}\qquad \underset{z\in\mathcal{Z}}{\text{minimize}}\ \varphi(z) \equiv \left[\begin{array}{ll} \underset{(\lambda,u^{\pm},v)}{\text{maximum}} & f^T\lambda + q^T(\,u^+ - u^-\,) \\ \text{subject to} & A^T\lambda - N^T(\,u^+ - u^-\,) \,=\, c, \\ & B^T\lambda - M^T(\,u^+ - u^-\,) - v \,\le\, d, \\ & (\,\lambda, u^{\pm}, v\,) \,\ge\, 0, \\ \text{and} & z^T u^+ + (\mathbf{1} - z)^T v \,\le\, 0 \end{array}\right].$$

Since $\mathcal{Z}$ is a finite set, and since $\varphi(z) \in \Re \cup \{-\infty\}$ for $z \in \mathcal{Z}$, it follows that $\operatorname{argmin}_{z\in\mathcal{Z}} \varphi(z) \neq \emptyset$ if and only if $\mathcal{Z} \neq \emptyset$. The following result rephrases the three basic facts connecting the LPCC (2.1) and its LP pieces in terms of the IP (2.12).

THEOREM 2.4. *The following three statements hold:*

(a) *The LPCC* (2.1) *is infeasible if and only if* $\min_{z\in\mathcal{Z}} \varphi(z) = \infty$ *(i.e.,* $\mathcal{Z} = \emptyset$*);*

(b) *the LPCC* (2.1) *is feasible and has an unbounded objective value if and only if* $\min_{z\in\mathcal{Z}} \varphi(z) = -\infty$ *(i.e.,* $z \in \mathcal{Z}$ *exists such that* $\varphi(z) = -\infty$*);*

(c) *the LPCC* (2.1) *attains a finite optimal objective value if and only if* $-\infty < \min_{z\in\mathcal{Z}} \varphi(z) < \infty$.

In all cases, $\text{LPCC}_{\min} = \min_{z\in\mathcal{Z}} \varphi(z)$*; moreover, for any* $z \in \{0,1\}^m$ *for which* $\varphi(z) > -\infty$, $\text{LPCC}_{\min} \le \varphi(z)$.

Proof. Statement (a) is an immediate consequence of Proposition 2.2. Statement (b) is equivalent to saying that the LPCC (2.1) is feasible and has an unbounded objective if and only if $z \in \{0,1\}^m$ exists such that $\varphi_0(z) = 0$ and $\varphi(z) = -\infty$. Suppose that the LPCC (2.1) is feasible and unbounded. Then an index set $\alpha \subseteq \{1,\ldots,m\}$ exists such that the LP(α) is feasible and unbounded. By letting $z \in \{0,1\}^m$ be such that $\operatorname{supp}(z) = \alpha$ and $\bar{\alpha}$ be the complement of α in $\{1,\ldots,m\}$, we have $\varphi_0(z) = 0$. Moreover, the dual of the (unbounded) LP(α) is

$$\text{(2.13)}\qquad \left[\begin{array}{ll} \underset{(\lambda,u_{\bar{\alpha}},u_{\alpha}^-)}{\text{maximize}} & f^T\lambda + (\,q_{\bar{\alpha}}\,)^T u_{\bar{\alpha}} - (\,q_{\alpha}\,)^T u_{\alpha}^- \\ \text{subject to} & A^T\lambda - (\,N_{\bar{\alpha}\bullet}\,)^T u_{\bar{\alpha}} + (\,N_{\alpha\bullet}\,)^T u_{\alpha}^- \,=\, c, \\ & (\,B_{\bullet\bar{\alpha}}\,)^T\lambda - (\,M_{\bar{\alpha}\bar{\alpha}}\,)^T u_{\bar{\alpha}} + (\,M_{\alpha\bar{\alpha}}\,)^T u_{\alpha}^- \,\le\, d_{\bar{\alpha}}, \\ \text{and} & (\,\lambda, u_{\alpha}^-\,) \,\ge\, 0, \end{array}\right.$$

which is equivalent to the problem (2.9) corresponding to the binary vector z defined here. (Note that the $\bullet$ in the subscripts is the standard notation in linear programming, denoting rows/columns of matrices.) Therefore, since (2.13) is infeasible, it follows that $\varphi(z) = -\infty$ by convention. Conversely, suppose that $z \in \{0,1\}^m$ exists such that $\varphi_0(z) = 0$ and $\varphi(z) = -\infty$. Let $\alpha \equiv \operatorname{supp}(z)$ and $\bar{\alpha} \equiv$ complement of α in $\{1,\ldots,m\}$. It then follows that (2.11), and thus the LP(α), is feasible. Moreover, since $\varphi(z) = -\infty$, it follows that (2.13), being equivalent to (2.9), is infeasible; thus the LP(α) is unbounded. Statement (c) follows readily from (a) and (b). The equality between $\text{LPCC}_{\min}$ and $\min_{z\in\mathcal{Z}} \varphi(z)$ is due to the fact that the maximizing LP defining $\varphi(z)$ is essentially the dual of the piece LP(α). To prove the last assertion of the theorem, let $z \in \{0,1\}^m$ be such that $\varphi(z) > -\infty$. Without loss of generality, we may assume that $\varphi(z) < \infty$. Thus the LP (2.9) attains a finite maximum; hence $\varphi_0(z) = 0$. Therefore $z \in \mathcal{Z}$, and the bound $\text{LPCC}_{\min} \le \varphi(z)$ holds readily. ∎

3. The Benders approach. In essence, our strategy for solving the LPCC (2.1) is to apply a Benders approach to the minimax IP (2.12). For this purpose, we let $\{(\lambda^{p,i}, u^{\pm,p,i}, v^{p,i})\}_{i=1}^{K}$ and $\{(\lambda^{r,j}, u^{\pm,r,j}, v^{r,j})\}_{j=1}^{L}$ be the finite set of extreme points and extreme rays of the polyhedron Ξ. Note that $K \geq 1$ if and only if $\Xi \neq \emptyset$. (These extreme points and rays will be generated as needed. For the discussion in this section, we take them as available.) In what follows, we derive a restatement of Theorem 2.4 in terms of these extreme points and rays.

The IP (2.12) can be written as

$$\underset{z \in \mathcal{Z}}{\text{minimize}} \left[\begin{array}{ll} \underset{(\rho^p, \rho^r) \geq 0}{\text{maximum}} & \displaystyle\sum_{i=1}^{K} \rho_i^p \left[f^T \lambda^{p,i} + q^T (u^{+,p,i} - u^{-,p,i}) \right] \\ & \qquad + \displaystyle\sum_{j=1}^{L} \rho_j^r \left[f^T \lambda^{r,j} + q^T (u^{+,r,j} - u^{-,r,j}) \right] \\ \text{subject to} & \displaystyle\sum_{i=1}^{K} \rho_i^p \left[z^T u^{+,p,i} + (\mathbf{1} - z)^T v^{p,i} \right] \\ & \qquad + \displaystyle\sum_{j=1}^{L} \rho_j^r \left[z^T u^{+,r,j} + (\mathbf{1} - z)^T v^{r,j} \right] \leq 0 \\ \text{and} & \displaystyle\sum_{i=1}^{K} \rho_i^p = 1 \end{array} \right], \tag{3.1}$$

which is the *master IP*. It turns out that the set $\mathcal{Z}$ can be completely described in terms of certain *ray cuts*, whose definition requires the index set:

$$\mathcal{L} \equiv \left\{ j \in \{1, \ldots, L\} : f^T \lambda^{r,j} + q^T (u^{+,r,j} - u^{-,r,j}) > 0 \right\}.$$

The following proposition shows that the set $\mathcal{Z}$ can be described in terms of satisfiability inequalities by using the extreme rays in $\mathcal{L}$.

PROPOSITION 3.1.

$$\mathcal{Z} = \left\{ z \in \{0,1\}^m : \sum_{\ell : u_\ell^{+,r,j} > 0} z_\ell + \sum_{\ell : v_\ell^{r,j} > 0} (1 - z_\ell) \geq 1 \ \ \forall j \in \mathcal{L} \right\}.$$

Proof. Since a tuple $(\lambda, u^{\pm}, v)$ is feasible to (2.10) if and only if it is a nonnegative combination of the extreme rays of (2.9), which are necessarily extreme rays of Ξ by Proposition 2.3, it follows that a tuple $(\lambda, u^{\pm}, v)$ is feasible to (2.10) if and only if there exist nonnegative coefficients $\{\rho_j^r\}_{j=1}^{L}$ such that

$$(\lambda, u^{\pm}, v) = \sum_{j=1}^{L} \rho_j^r (\lambda^{r,j}, u^{\pm,r,j}, v^{r,j})$$

and $\sum_{j=1}^{L} \rho_j^r [z^T u^{+,r,j} + (\mathbf{1} - z)^T v^{r,j}] \leq 0$. Therefore, $\varphi_0(z)$ is equal to

$$\begin{array}{ll} \underset{\rho^r \geq 0}{\text{maximize}} & \displaystyle\sum_{j=1}^{L} \rho_j^r \left[f^T \lambda^{r,j} + q^T (u^{+,r,j} - u^{-,r,j}) \right] \\ \text{subject to} & \displaystyle\sum_{j=1}^{L} \rho_j^r \left[z^T u^{+,r,j} + (\mathbf{1} - z)^T v^{r,j} \right] \leq 0, \end{array}$$

and the latter maximization problem has a finite optimal solution if and only if

$$f^T\lambda^{r,j} + q^T(\,u^{+,r,j} - u^{-,r,j}\,) \;>\; 0 \quad\Longrightarrow\quad z^T u^{+,r,j} + (\mathbf{1}-z)^T v^{r,j} \;>\; 0$$
$$\Longleftrightarrow\quad \sum_{\ell:u_\ell^{+,r,j}>0} z_\ell + \sum_{\ell:v_\ell^{r,j}>0} (\,1-z_\ell\,) \;\geq\; 1.$$

Therefore, the equality between $\mathcal{Z}$ and the right-hand set is immediate. □

An immediate corollary of Proposition 3.1 is that it provides a certificate of infeasibility for the LPCC.

COROLLARY 3.2. *If $\mathcal{R} \subseteq \mathcal{L}$ exists such that*

$$\left\{ z \in \{0,1\}^m \,:\, \sum_{\ell:u_\ell^{+,r,j}>0} z_\ell + \sum_{\ell:v_\ell^{r,j}>0} (\,1-z_\ell\,) \;\geq\; 1 \;\; \forall\, j \;\in\; \mathcal{R} \right\} = \emptyset,$$

then the LPCC (2.1) *is infeasible.*

Proof. The assumption implies that $\mathcal{Z} = \emptyset$. Thus the infeasibility of the LPCC follows from Theorem 2.4(a). □

In view of Proposition 3.1, (3.1) is equivalent to:

$$\underset{z\in\mathcal{Z}}{\text{minimize}} \left[\begin{array}{ll} \underset{\rho^p\geq 0}{\text{maximum}} & \displaystyle\sum_{i=1}^{K} \rho_i^p \left[f^T\lambda^{p,i} + q^T(u^{+,p,i} - u^{-,p,i}) \right] \\ \text{subject to} & \displaystyle\sum_{i=1}^{K} \rho_i^p \left[\, z^T u^{+,p,i} + (\mathbf{1}-z)^T v^{p,i} \,\right] \;\leq\; 0 \\ \text{and} & \displaystyle\sum_{i=1}^{K} \rho_i^p \;=\; 1 \end{array}\right]. \tag{3.2}$$

Note that the $\text{LPCC}_{\min}$ is equal to the minimum objective value of (3.2). Similar to the inequality

$$\sum_{\ell:u_\ell^{+,r,j}>0} z_\ell + \sum_{\ell:v_\ell^{r,j}>0} (\,1-z_\ell\,) \;\geq\; 1,$$

which we call a *ray cut* (because it is induced by an extreme ray), we will make use of a *point cut*

$$\sum_{\ell:u_\ell^{+,p,i}>0} z_\ell + \sum_{\ell:v_\ell^{p,i}>0} (\,1-z_\ell\,) \;\geq\; 1,$$

that is induced by an extreme point $(\lambda^{p,i}, u^{\pm,p,i}, v^{p,i})$ of Ξ chosen from the following collection:

$$\mathcal{K} \equiv \left\{\, i \;\in\; \{\,1,\ldots,K\,\} \,:\, f^T\lambda^{p,i} + q^T(\,u^{+,p,i} - u^{-,p,i}\,) \;=\; \varphi(z) \text{ for some } z \in \mathcal{Z} \,\right\}.$$

Note that $\mathcal{K} \neq \emptyset \Rightarrow \mathcal{Z} \neq \emptyset$, which in turn implies that the LPCC (2.1) is feasible. Moreover,

$$\min_{i\in\mathcal{K}} \left[\, f^T\lambda^{p,i} + q^T(\,u^{+,p,i} - u^{-,p,i}\,) \,\right] \;\geq\; \text{LPCC}_{\min}.$$

For a given pair of subsets $\mathcal{P} \times \mathcal{R} \subseteq \mathcal{K} \times \mathcal{L}$, let

$$\mathcal{Z}(\mathcal{P},\mathcal{R}) \equiv \left\{ z \in \{0,1\}^m : \begin{array}{c} \sum\limits_{\ell: u_\ell^{+,r,j}>0} z_\ell + \sum\limits_{\ell: v_\ell^{r,j}>0} (1-z_\ell) \geq 1 \ \forall j \in \mathcal{R} \\ \sum\limits_{\ell: u_\ell^{+,p,i}>0} z_\ell + \sum\limits_{\ell: v_\ell^{p,i}>0} (1-z_\ell) \geq 1 \ \forall i \in \mathcal{P} \end{array} \right\}.$$

We have the following result.

PROPOSITION 3.3. *If there exists $\mathcal{P} \times \mathcal{R} \subseteq \mathcal{K} \times \mathcal{L}$ such that*

$$\min_{i \in \mathcal{P}} \left[f^T \lambda^{p,i} + q^T (u^{+,p,i} - u^{-,p,i}) \right] > \mathrm{LPCC}_{\min},$$

then $\operatorname{argmin}_{z \in \mathcal{Z}} \varphi(z) \subseteq \mathcal{Z}(\mathcal{P},\mathcal{R})$.

Proof. Let $\widetilde{z} \in \mathcal{Z}$ be a minimizer of $\varphi(z)$ on $\mathcal{Z}$. (The proposition is clearly valid if no such minimizer exists.) If $\widetilde{z} \notin \mathcal{Z}(\mathcal{P},\mathcal{R})$, then there exists $i \in \mathcal{P}$ such that

$$\sum_{\ell: u_\ell^{+,p,i}>0} \widetilde{z}_\ell + \sum_{\ell: v_\ell^{p,i}>0} (1-\widetilde{z}_\ell) = 0.$$

Hence, $(\lambda^{p,i}, u^{\pm,p,i}, v^{p,i})$ is feasible to the LP (2.9) corresponding to $\varphi(\widetilde{z})$; thus

$$\mathrm{LPCC}_{\min} = \varphi(\widetilde{z}) \geq f^T \lambda^{p,i} + q^T (u^{+,p,i} - u^{-,p,i}) > \mathrm{LPCC}_{\min},$$

which is a contradiction. ∎

Analogous to Corollary 3.2, we have the following corollary of Proposition 3.3.

COROLLARY 3.4. *If there exists $\mathcal{P} \times \mathcal{R} \subseteq \mathcal{K} \times \mathcal{L}$, with $\mathcal{P} \neq \emptyset$, such that $\mathcal{Z}(\mathcal{P},\mathcal{R}) = \emptyset$, then*

$$\mathrm{LPCC}_{\min} = \min_{i \in \mathcal{P}} \left[f^T \lambda^{p,i} + q^T (u^{+,p,i} - u^{-,p,i}) \right] \in (-\infty, \infty). \tag{3.3}$$

Proof. Indeed, if the claimed equality does not hold, then $\operatorname{argmin}_{z \in \mathcal{Z}} \varphi(z) = \emptyset$. But this implies that $\mathcal{Z} = \emptyset$, which contradicts the assumption that $\mathcal{P} \neq \emptyset$. ∎

Combining Corollaries 3.2 and 3.4, we obtain the desired restatement of Theorem 2.4 in terms of the extreme points and rays of Ξ.

THEOREM 3.5. *The following three statements hold:*

(a) *The LPCC* (2.1) *is infeasible if and only if a subset $\mathcal{R} \subseteq \mathcal{L}$ exists such that $\mathcal{Z}(\emptyset,\mathcal{R}) = \emptyset$;*
(b) *the LPCC* (2.1) *is feasible and has an unbounded objective if and only if $\mathcal{Z}(\mathcal{K},\mathcal{L}) \neq \emptyset$;*
(c) *the LPCC* (2.1) *attains a finite optimal objective value if and only if a pair $\mathcal{P} \times \mathcal{R} \subseteq \mathcal{K} \times \mathcal{L}$ exists, with $\mathcal{P} \neq \emptyset$, such that $\mathcal{Z}(\mathcal{P},\mathcal{R}) = \emptyset$.*

Proof. Statement (a) follows from Corollary 3.2 by noting that a subset $\mathcal{R} \subseteq \mathcal{L}$ exists such that $\mathcal{Z}(\emptyset,\mathcal{R}) = \emptyset$ if and only if $\mathcal{Z} = \mathcal{Z}(\emptyset,\mathcal{L}) = \emptyset$. To prove (b), suppose first that $\mathcal{Z}(\mathcal{K},\mathcal{L}) \neq \emptyset$. Let $\widehat{z} \in \mathcal{Z}(\mathcal{K},\mathcal{L})$. Then $\widehat{z} \in \mathcal{Z}$. We claim that $\varphi(\widehat{z}) = -\infty$; i.e., the LP (2.9) corresponding to $\widehat{z}$ is infeasible. Assume otherwise, and then since $\varphi_0(\widehat{z}) = 0$, it follows that $\varphi(\widehat{z})$ is finite. Hence there exists an extreme point $(\lambda^{p,i}, u^{\pm,p,i}, v^{p,i})$ of the LP (2.9) corresponding to $\widehat{z}$ such that $f^T \lambda^{p,i} + q^T (u^{+,p,i} - u^{-,p,i}) = \varphi(\widehat{z})$; thus the index $i \in \mathcal{K}$, which implies that

$$\sum_{\ell: u_\ell^{+,p,i}>0} \widehat{z}_\ell + \sum_{\ell: v_\ell^{p,i}>0} (1-\widehat{z}_\ell) \geq 1,$$

because $\widehat{z} \in \mathcal{Z}(\mathcal{K}, \mathcal{L})$. But this contradicts the feasibility of $(\lambda^{p,i}, u^{\pm,p,i}, v^{p,i})$ to the LP (2.9) corresponding to $\widehat{z}$. Therefore, the LPCC (2.1) is feasible and has an unbounded objective value; thus, the "if" statement in (b) holds. Conversely, suppose that $\text{LPCC}_{\min} = -\infty$. By Theorem 2.4, it follows that $\widehat{z} \in \mathcal{Z}$ exists such that $\varphi(\widehat{z}) = -\infty$; i.e., the LP (2.9) corresponding to $\widehat{z}$ is infeasible. In turn, this means that

$$\widehat{z}^T u^{+,p,i} + (\mathbf{1} - \widehat{z})^T v^{p,i} > 0$$

for all $i = 1, \ldots, K$, or, equivalently,

$$\sum_{\ell : u_\ell^{+,p,i} > 0} \widehat{z}_\ell + \sum_{\ell : v_\ell^{p,i} > 0} (1 - \widehat{z}_\ell) \geq 1$$

for all $i = 1, \ldots, K$. Consequently, $\widehat{z} \in \mathcal{Z}(\mathcal{K}, \mathcal{L})$. Hence, statement (b) holds. Finally, the "if" statement in (c) follows from Corollary 3.4. Conversely, if the LPCC (2.1) has a finite optimal solution, then by (b), it follows that $\mathcal{Z}(\mathcal{K}, \mathcal{L}) = \emptyset$. Since the LPCC (2.1) is feasible, $\mathcal{K} \neq \emptyset$ by (a), establishing the "only if" statement in (c). □

Theorem 3.5 constitutes the theoretical basis for the algorithm to be presented in section 5 for resolving the LPCC. Through the successive generation of extreme points and rays of Ξ, the algorithm searches for a pair of subsets $\mathcal{P} \times \mathcal{R}$ such that $\mathcal{Z}(\mathcal{P}, \mathcal{R}) = \emptyset$. If such a pair can be successfully identified, then the LPCC is either infeasible ($\mathcal{P} = \emptyset$) or attains a finite optimal solution ($\mathcal{P} \neq \emptyset$). If no such pair is found, then the LPCC is unbounded. In the algorithm, the last case is identified with a binary vector $z \in \mathcal{Z}$, with $\varphi(z) = -\infty$; i.e., the LP (2.9) is infeasible. Based on the value function $\varphi(z)$ and the point/ray cuts, the algorithm will be shown to terminate in finite time.

4. Simple cuts and sparsification. In this section, we explain several key steps in the main algorithm to be presented in the next section. The first idea is a version of the well-known Gomory cut in integer programming specialized to the LPCC and which has previously been employed for bilevel LPs; see [5]. The second idea aims at "sparsifying" the ray/point cuts to facilitate the computation of elements of the working sets $\mathcal{Z}(\mathcal{P}, \mathcal{R})$. Specifically, a satisfiability constraint

$$\sum_{i \in \mathcal{I}'} z_i + \sum_{j \in \mathcal{J}'} (1 - z_j) \geq 1 \quad \text{is } \textit{sparser} \text{ than} \quad \sum_{i \in \mathcal{I}} z_i + \sum_{j \in \mathcal{J}} (1 - z_j) \geq 1$$

if $\mathcal{I}' \subseteq \mathcal{I}$ and $\mathcal{J}' \subseteq \mathcal{J}$. In general, a satisfiability inequality cuts off certain LP pieces of the LPCC; the sparser the inequality is, the more pieces it cuts off. Thus, it is desirable to sparsify a cut as much as possible. Nevertheless, sparsification requires the solution of linear subprograms; thus one needs to balance the work required with the benefit of the process.

4.1. Simple cuts. The following discussion is a minor variant of that presented in [5] for bilevel LPs. Consider the LP relaxation of the LPCC (2.1):

$$\begin{array}{lll} \underset{(x,y,w)}{\text{minimize}} & c^T x + d^T y & \\ \text{subject to} & Ax + By \geq f & \\ \text{and} & 0 \leq y, \quad w \equiv q + Nx + My \geq 0, & \end{array} \tag{4.1}$$

where the orthogonal condition $y^T w = 0$ is dropped. Assume that, by solving this LP, an optimal solution is obtained that fails the latter orthogonality condition, say,

$y_i w_i > 0$ in this solution. Thus, y_i and w_i must be basic variables in a basic optimal solution of the LP; in such a solution, w_i and y_i can be expressed in terms of the nonbasic variables, which we denote by the generic variables s_j, as follows: For some constants a_j and b_j,

$$w_i \;=\; w_{i0} - \sum_{s_j:\text{nonbasic}} a_j\, s_j \quad \text{and} \quad y_i \;=\; y_{i0} - \sum_{s_j:\text{nonbasic}} b_j\, s_j,$$

where w_{i0} and y_{i0} are the current values of the variables w_i and y_i, respectively, with $\min(w_{i0}, y_{i0}) > 0$. It is not difficult to show that the following inequality must be satisfied by all feasible solutions of the LPCC (2.1):

$$\sum_{\substack{s_j:\text{nonbasic} \\ \max(a_j,b_j)>0}} \max\left(\frac{a_j}{w_{i0}}, \frac{b_j}{y_{i0}}\right) s_j \;\geq\; 1. \tag{4.2}$$

Note that if $a_j \leq 0$ for all nonbasic j, then $w_i > 0 = y_i$ for every feasible solution of the LPCC (2.1). A similar remark can be made if $b_j \leq 0$ for all nonbasic j.

Following the terminology in [5], we call the inequality (4.2) a *simple cut*. Multiple such cuts can be added to the constraint $Ax + By \geq f$, resulting in a modified inequality $\widetilde{A}x + \widetilde{B}y \geq \widetilde{f}$. We can generate and add even more simple cuts by repeating the above step. This strategy turns out to be a very effective preprocessor for the algorithm to be described in the next section. At the end of this preprocessor, we obtain an optimal solution $(\bar{x}, \bar{y}, \bar{w})$ of (4.1) that remains infeasible to the LPCC (otherwise, this solution would be optimal for the LPCC); the optimal objective value $c^T\bar{x} + d^T\bar{y}$ provides a valid lower bound for $\text{LPCC}_{\min}$. (Note that if (4.1) is unbounded, then the preprocessor does not produce any cuts or a finite lower bound.)

LPCC feasibility recovery. Occurring in many applications of the LPCC, the special case $B = 0$ deserves a bit more discussion. First note that in this case the modified matrix $\widetilde{B}$ is not necessarily zero. Nevertheless, the solution $(\bar{x}, \bar{y}, \bar{w})$ obtained from the simple-cut preprocessor can be used to produce a feasible solution to the LPCC (2.1) by simply solving the linear complementarity problem (LCP): $0 \leq y \perp q + N\bar{x} + My \geq 0$ (assuming that the matrix M has favorable properties so that this step is effective). By letting $\bar{y}'$ be a solution to the latter LCP, the objective value $c^T\bar{x} + d^T\bar{y}'$ yields a valid upper bound to $\text{LPCC}_{\min}$. This recovery procedure of an LPCC feasible solution can be extended to the case where $B \neq 0$. (Incidentally, this class of LPCCs is generally "more difficult" than the class where $B = 0$, where the difficulty is determined by our empirical experience from the computational tests.) Indeed, from any feasible solution $(\bar{x}, \bar{y}, \bar{w})$ to the LP relaxation of the LPCC (2.1) but not to the LPCC itself, we could attempt to recover a feasible solution to the LPCC along with an element in $\mathcal{Z}$ either by solving the LP(α), where $\alpha \equiv \{i : \bar{y}_i \leq \bar{w}_i\}$, or by solving $\varphi(z)$, where $z_\alpha = 1$ and $z_{\bar{\alpha}} = 0$. A feasible solution to this LP piece yields a feasible solution to the LPCC and a finite upper bound. In general, there is no guarantee that this procedure will always be successful; nevertheless, it is very effective when it works.

4.2. Cut management. A key step in our algorithm involves the selection of elements in the sets $\mathcal{Z}(\mathcal{P}, \mathcal{R})$ for various index pairs $(\mathcal{P}, \mathcal{R})$. Generally speaking, this involves solving integer subprograms. By recognizing that the constraints in each $\mathcal{Z}(\mathcal{P}, \mathcal{R})$ are of the satisfiability type, we could in principle employ special algorithms

for implementing this step (see [7, 31], and the references therein for some such algorithms). To facilitate such a selection, we have developed a special heuristic that utilizes a valid upper bound of $\mathrm{LPCC}_{\min}$ to sparsify the terms in the ray/point cuts in a working set. In what follows, we describe how the algorithm manages these cuts.

There are three pools of cuts, labeled $\mathcal{Z}_{\mathrm{work}}$, the working pool, $\mathcal{Z}_{\mathrm{wait}}$, the wait pool, and $\mathcal{Z}_{\mathrm{cand}}$, the candidate pool. Inequalities in $\mathcal{Z}_{\mathrm{work}}$ are valid sparsifications of those in $\mathcal{Z}(\mathcal{P}, \mathcal{R})$ corresponding to a current pair $(\mathcal{P}, \mathcal{R})$. Thus, the set of binary vectors satisfying the inequalities in $\mathcal{Z}_{\mathrm{work}}$, which we denote $\widehat{\mathcal{Z}}_{\mathrm{work}}$, is a subset of $\mathcal{Z}(\mathcal{P}, \mathcal{R})$. Inequalities in $\mathcal{Z}_{\mathrm{cand}}$ are candidates for sparsification; the sparsification procedure described below always ends with this set empty. The decision of whether or not to sparsify a valid inequality is made according to a current LPCC upper bound and a small scalar $\delta > 0$. In essence, the sparsification is an effective way to facilitate the search for a feasible element in $\widehat{\mathcal{Z}}_{\mathrm{work}}$. At one extreme, a sparsest inequality with only one term in it automatically fixes one complementarity (e.g., $z_1 \geq 1$ fixes $w_1 = 0$); at another extreme, it is computationally more difficult to find feasible points satisfying many dense inequalities.

We sparsify an inequality

$$\sum_{i \in \mathcal{I}} z_i + \sum_{j \in \mathcal{J}} (\, 1 - z_j \,) \geq 1 \tag{4.3}$$

in the following way. Let $\mathcal{I} = \mathcal{I}_1 \cup \mathcal{I}_2$ be a partition of $\mathcal{I}$ into two disjoint subsets $\mathcal{I}_1$ and $\mathcal{I}_2$; similarly, let $\mathcal{J} = \mathcal{J}_1 \cup \mathcal{J}_2$. We split (4.3), which we call the *parent*, into two subinequalities:

$$\sum_{i \in \mathcal{I}_1} z_i + \sum_{j \in \mathcal{J}_1} (\, 1 - z_j \,) \geq 1 \quad \text{and} \quad \sum_{i \in \mathcal{I}_2} z_i + \sum_{j \in \mathcal{J}_2} (\, 1 - z_j \,) \geq 1 \tag{4.4}$$

and test both to see if they are valid for the LPCC. To test the left-hand inequality, we consider the LP relaxation (4.1) of the LPCC (2.1) with the additional constraints $w_i = (q + Nx + My)_i = 0$ for $i \in \mathcal{I}_1$ and $y_i = 0$ for $i \in \mathcal{J}_1$, which we call a *relaxed LP with restriction*. If this LP has an objective value greater than the current $\mathrm{LPCC}_{\mathrm{ub}}$, then we have successfully sparsified the inequality (4.3) into the sparser inequality:

$$\sum_{i \in \mathcal{I}_1} z_i + \sum_{j \in \mathcal{J}_1} (\, 1 - z_j \,) \geq 1, \tag{4.5}$$

which must be valid for the LPCC. (In this situation, any dual solution to the relaxed LP with restriction is feasible in the dual LP (2.9) for any binary vector z that violates (4.5). Hence, the value $\varphi(z)$ of the LPCC on this piece must be at least $\mathrm{LPCC}_{\mathrm{ub}}$, implying that such a piece cannot contain an optimal solution of the LPCC.) Otherwise, by using the feasible solution to the relaxed LP, we employ the LPCC feasibility recovery procedure to compute an LPCC feasible solution along with a binary $z \in \mathcal{Z}$. If successful, one of two cases happen: If $\varphi(z) \geq \mathrm{LPCC}_{\mathrm{ub}}$, then a new cut can be generated; otherwise, we have reduced the LPCC upper bound. In either case, we obtain positive progress in the algorithm. If no LPCC feasible solution is recovered, then we save the cut (4.5) in the wait pool $\mathcal{Z}_{\mathrm{wait}}$ for later consideration. In essence, cuts in the wait pool are not yet proven to be valid for the LPCC; they will be revisited when there is a reduction in $\mathrm{LPCC}_{\mathrm{ub}}$. Note that every inequality in $\mathcal{Z}_{\mathrm{wait}}$ has an LP optimal objective value associated with it that is less than the current LPCC upper bound.

In our experiment, we randomly divide the sets $\mathcal{I}$ and $\mathcal{J}$ roughly into two equal halves each and adopt a strategy that attempts to sparsify the *root inequality* (4.3) as much as possible via a random branching rule. The following illustrates one such division:

$$\begin{array}{ccc} & z_1 + z_3 + z_4 + (1 - z_2) + (1 - z_6) \geq 1 & \\ & \swarrow \qquad\qquad \searrow & \\ z_1 + z_3 + (1 - z_2) \geq 1 & & z_4 + (1 - z_6) \geq 1. \end{array}$$

We use a small scalar $\delta > 0$ to help decide on the subsequent branching. In essence, we branch only if the inequality appears strong. By solving LPs, the procedure below sparsifies a given valid inequality for the LPCC, called the *root* of the procedure.

SPARSIFICATION PROCEDURE. Let (4.3) be the root inequality to be sparsified, $\mathrm{LPCC}_{\mathrm{ub}}$ be the current LPCC upper bound, and $\delta > 0$ be a given scalar. Branch (4.3) into two subinequalities (4.4), both of which we put in the set $\mathcal{Z}_{\mathrm{cand}}$.

Main step. If $\mathcal{Z}_{\mathrm{cand}}$ is empty, terminate. Otherwise pick a *candidate* inequality in $\mathcal{Z}_{\mathrm{cand}}$, say, the left one in (4.4) with the corresponding pair of index sets $(\mathcal{I}_1, \mathcal{J}_1)$. Solve the LP relaxation (4.1) of the LPCC (2.1) with the additional constraints $w_i = (q + Nx + My)_i = 0$ for $i \in \mathcal{I}_1$ and $y_i = 0$ for $i \in \mathcal{J}_1$, obtaining an LP optimal objective value, say, $\mathrm{LP}_{\mathrm{rlx}} \in \Re \cup \{\pm\infty\}$. We have the following three cases:

- If $\mathrm{LP}_{\mathrm{rlx}} \in [\,\mathrm{LPCC}_{\mathrm{ub}}, \mathrm{LPCC}_{\mathrm{ub}} + \delta\,]$, move the candidate inequality from $\mathcal{Z}_{\mathrm{cand}}$ into $\mathcal{Z}_{\mathrm{work}}$ and remove its parent; return to the main step.
- If $\mathrm{LP}_{\mathrm{rlx}} < \mathrm{LPCC}_{\mathrm{ub}}$, apply the LPCC feasibility recovery procedure to the feasible solution at termination of the current relaxed LP with restriction. If the procedure is successful, return to the main step with either a new cut or a reduced $\mathrm{LPCC}_{\mathrm{ub}}$. Otherwise, move the incumbent candidate inequality from $\mathcal{Z}_{\mathrm{cand}}$ into $\mathcal{Z}_{\mathrm{wait}}$; return to the main step.
- If $\delta + \mathrm{LPCC}_{\mathrm{ub}} < \mathrm{LP}_{\mathrm{rlx}}$, move the candidate inequality from $\mathcal{Z}_{\mathrm{cand}}$ into $\mathcal{Z}_{\mathrm{work}}$ and remove its parent; further branch the candidate inequality into two subinequalities, both of which we put into the candidate pool $\mathcal{Z}_{\mathrm{cand}}$; return to the main step.

During the procedure, the set $\mathcal{Z}_{\mathrm{cand}}$ may grow from the initial size of 2 inequalities when the root of the procedure is first split. Nevertheless, by solving finitely many LPs, this set will eventually shrink to empty; when that happens, either we have successfully sparsified the root inequality and placed multiple sparser cuts into $\mathcal{Z}_{\mathrm{work}}$, or some sparser cuts are added to the pool $\mathcal{Z}_{\mathrm{wait}}$, waiting to be proven valid for the LPCC in subsequent iterations. Note that associated with each inequality in $\mathcal{Z}_{\mathrm{wait}}$ is the value $\mathrm{LP}_{\mathrm{rlx}}$.

5. The IP algorithm. We are now ready to present the parameter-free IP-based algorithm for resolving an arbitrary LPCC (2.1). Subsequently, we will establish that the algorithm will successfully terminate in a finite number of *iterations* with a definitive resolution of the LPCC in one of its three states. Referring to a return to Step 1, each iteration consists of solving one feasibility IP of the satisfiability kind, a couple of LPs to compute $\varphi(\widehat{z})$ and possibly $\varphi_0(\widehat{z})$ corresponding to a binary vector $\widehat{z}$ obtained from the IP, and multiple LPs within the sparsification procedure associated with an induced point/ray cut.

ALGORITHM.
Step 0 (preprocessing and initialization). Generate multiple simple cuts to tighten the complementarity constraints. If any of the LPs encountered in this step is infeasible, then so is the LPCC (2.1). In general, let LPCC_{lb} ($-\infty$ allowed) and LPCC_{ub} (∞ allowed) be valid lower and upper bounds of $\text{LPCC}_{\min}$, respectively. Let $\delta > 0$ be a small scalar. [A finite optimal solution to a relaxed LP provides a finite lower bound, and a feasible solution to the LPCC, which could be obtained by the LPCC feasibility recovery procedure, provides a finite upper bound.] Set $\mathcal{P} = \mathcal{R} = \emptyset$ and $\mathcal{Z}_{\text{work}} = \mathcal{Z}_{\text{wait}} = \emptyset$. (Thus, $\widehat{\mathcal{Z}}_{\text{work}} = \{0,1\}^m$.)
Step 1 (solving a satisfiability IP). Determine a vector $\widehat{z} \in \widehat{\mathcal{Z}}_{\text{work}}$. If this set is empty, go to Step 2. Otherwise go to Step 3.
Step 2 (termination: infeasibility or finite solvability). If $\mathcal{P} = \emptyset$, we have obtained a certificate of infeasibility for the LPCC (2.1); stop. If $\mathcal{P} \neq \emptyset$, we have obtained a certificate of global optimality for the LPCC (2.1) with $\text{LPCC}_{\min}$ given by (3.3); stop.
Step 3 (solving dual LP). Compute $\varphi(\widehat{z})$ by solving the LP (2.9). If $\varphi(\widehat{z}) \in (-\infty, \infty)$, go to Step 4a. If $\varphi(\widehat{z}) = \infty$, proceed to Step 4b. If $\varphi(\widehat{z}) = -\infty$, proceed to Step 4c.
Step 4a (adding an extreme point). Let $(\lambda^{p,i}, u^{\pm,p,i}, v^{p,i}) \in \mathcal{K}$ be an optimal extreme point of Ξ. There are 3 cases:

- If $\varphi(\widehat{z}) \in [\ \text{LPCC}_{\text{ub}},\ \text{LPCC}_{\text{ub}} + \delta]$, let $\mathcal{P} \leftarrow \mathcal{P} \cup \{i\}$, and add the corresponding point cut to $\mathcal{Z}_{\text{work}}$; return to Step 1.
- If $\varphi(\widehat{z}) > \text{LPCC}_{\text{ub}} + \delta$, let $\mathcal{P} \leftarrow \mathcal{P} \cup \{i\}$, and add the corresponding point cut to $\mathcal{Z}_{\text{work}}$. Apply the sparsification procedure to the new point cut, obtaining an updated $\mathcal{Z}_{\text{work}}$ and $\mathcal{Z}_{\text{wait}}$ and possibly a reduced LPCC_{ub}. If the LPCC upper bound is reduced during the sparsification procedure, go to Step 5 to activate some of the cuts in the wait pool; otherwise, return to Step 1.
- If $\varphi(\widehat{z}) < \text{LPCC}_{\text{ub}}$, let $\text{LPCC}_{\text{ub}} \leftarrow \varphi(\widehat{z})$, and go to Step 5.

Step 4b (adding an extreme ray). Let $(\lambda^{r,j}, u^{\pm,r,j}, v^{r,j}) \in \mathcal{L}$ be an extreme ray of Ξ. Set $\mathcal{R} \longleftarrow \mathcal{R} \cup \{j\}$, and add the corresponding ray cut to $\mathcal{Z}_{\text{work}}$. Apply the sparsification procedure to the new ray cut, obtaining an updated $\mathcal{Z}_{\text{work}}$ and $\mathcal{Z}_{\text{wait}}$ and possibly a reduced LPCC_{ub}. If the LPCC upper bound is reduced during the sparsification procedure, go to Step 5 to activate some of the cuts in the wait pool; otherwise, return to Step 1.
Step 4c (determining LPCC unboundedness). Solve the LP (2.10) to determine $\varphi_0(\widehat{z})$. If $\varphi_0(\widehat{z}) = 0$, then the vector $\widehat{z}$ and its support provide a certificate of unboundedness for the LPCC (2.1). Stop. If $\varphi_0(\widehat{z}) = \infty$, go to Step 4b.
Step 5 (LPCC_{ub} is reduced). Move all inequalities in $\mathcal{Z}_{\text{wait}}$ with values LP_{rlx} greater than (the just-reduced) LPCC_{ub} into $\mathcal{Z}_{\text{work}}$. Apply the sparsification procedure to each newly moved inequality with $\text{LP}_{\text{rlx}} > \text{LPCC}_{\text{ub}} + \delta$. Reapply this step to the cuts in $\mathcal{Z}_{\text{wait}}$ each time the LPCC upper bound is reduced from the sparsification procedure. Return to Step 1 when no more cuts in $\mathcal{Z}_{\text{wait}}$ are eligible for sparsification.

We have the following finiteness result.

THEOREM 5.1. *The algorithm terminates in a finite number of iterations.*

Proof. The finiteness is due to several observations: (a) The set of m-dimensional binary vectors is finite, (b) each iteration of the algorithm generates a new binary vector that is distinct from all of those previously generated, and (c) there are only

finitely many cuts, sparsified or not. In turn, (a) and (c) are obvious, and (b) follows from the operation of the algorithm: Whenever $\varphi(\widehat{z}) \geq \text{LPCC}_{\text{ub}}$, the new point cut or ray cut will cut off all binary vectors generated so far, including $\widehat{z}$; if $\varphi(\widehat{z}) < \text{LPCC}_{\text{ub}}$, then $\widehat{z}$ cannot be one of previously generated binary vectors because its φ-value is smaller than those of the other vectors. □

5.1. A numerical example. We use the following simple example to illustrate the algorithm:

$$
\begin{array}{ll}
\underset{(x,y)}{\text{minimize}} & x_1 + 2\,y_1 - y_3 \\
\text{subject to} & x_1 + x_2 \geq 5, \\
& x_1,\, x_2 \geq 0, \\
& 0 \leq y_1 \perp x_1 - y_3 + 1 \qquad \geq 0, \\
& 0 \leq y_2 \perp x_2 + y_1 + y_2 \qquad \geq 0, \\
& 0 \leq y_3 \perp x_1 + x_2 - y_2 + 2 \geq 0.
\end{array} \tag{5.1}
$$

Note that the LCP in the variable y is not derived from a convex quadratic program; in fact, the matrix

$$
M \equiv \begin{bmatrix} 0 & 0 & -1 \\ 1 & 1 & 0 \\ 0 & -1 & 0 \end{bmatrix}
$$

has all principal minors nonnegative, but the LCPs defined by this matrix may have zero or unbounded solutions.

Initialization: Set the upper bound as infinity: $\text{LPCC}_{\text{ub}} = \infty$. Set the working set $\mathcal{Z}_{\text{work}}$ and the waiting set $\mathcal{Z}_{\text{wait}}$ both equal to empty.

Iteration 1: Since $\widehat{\mathcal{Z}}_{\text{work}} = \{0,1\}^3$, we can pick an arbitrary binary vector z. We choose $z = (0,0,0)$ and solve the dual LP (2.9):

$$
\begin{array}{ll}
\underset{(\lambda,u^{\pm},v)}{\text{maximize}} & 5\,\lambda + u_1^+ + 2\,u_3^+ - u_1^- - 2\,u_3^- \\
\text{subject to} & \lambda - u_1^+ + u_1^- - u_3^+ + u_3^- \leq 1, \\
& \lambda - u_2^+ + u_2^- - u_3^+ + u_3^- \leq 0, \\
& -u_2^+ + u_2^- - v_1 \leq 2, \\
& -u_2^+ + u_2^- + u_3^+ - u_3^- - v_2 \leq 0, \\
& u_1^+ - u_1^- - v_3 \leq -1, \\
& v_1 + v_2 + v_3 \leq 0, \\
& (\,\lambda, u^{\pm}, v\,) \geq 0,
\end{array} \tag{5.2}
$$

which is unbounded, yielding an extreme ray with $u^+ = (0, 10/7, 10/7)$ and $v = (0,0,0)$ and a corresponding ray cut: $z_2 + z_3 \geq 1$. (Briefly, this cut is valid since $z_2 = z_3 = 0$ implies that both $x_2 + y_1 + y_2 = 0$ and $x_1 + x_2 - y_2 + 2 = 0$, which can't both hold for nonnegative x and y.) Add this cut to $\mathcal{Z}_{\text{work}}$, and initiate the sparsification procedure. This inequality $z_2 + z_3 \geq 1$ can be branched into $z_2 \geq 1$ or $z_3 \geq 1$. To test if $z_2 \geq 1$ is a valid cut, we form the following relaxed LP of (5.1) by

restricting $x_2 + y_1 + y_2 = 0$:

$$\begin{array}{lll} \underset{(x,y)}{\text{minimize}} & x_1 + 2\,y_1 - y_3 & \\ \text{subject to} & x_1 + x_2 & \geq 5, \\ & x_1 - y_3 + 1 & \geq 0, \\ & x_2 + y_1 + y_2 & = 0, \\ & x_1 + x_2 - y_2 + 2 & \geq 0, \\ & x,\, y \geq 0. & \end{array} \tag{5.3}$$

An optimal solution of the LP (5.3) is $(x_1, x_2, y_1, y_2, y_3) = (5, 0, 0, 0, 6)$ with the optimal objective value $\mathrm{LP}_{\mathrm{rlx}} = -1$. This is not a feasible solution of the LPCC (5.1) because the third complementarity is violated. The inequality $z_2 \geq 1$ is therefore placed in the waiting set $\mathcal{Z}_{\mathrm{wait}}$. We then use $(x_1, x_2) = (5, 0)$ to recover an LPCC feasible solution by solving the LCP in the variable y. This yields $y = (0, 0, 0)$, $w = (6, 0, 7)$, and hence a corresponding vector $z = (1, 0, 1)$. By using this z in (2.9), we get another dual problem:

$$\begin{array}{lr} \underset{(\lambda,u^{\pm},v)}{\text{maximize}} & 5\,\lambda + u_1^+ + 2\,u_3^+ - u_1^- - 2\,u_3^- \\ \text{subject to} & \lambda - u_1^+ + u_1^- - u_3^+ + u_3^- \leq 1, \\ & \lambda - u_2^+ + u_2^- - u_3^+ + u_3^- \leq 0, \\ & -u_2^+ + u_2^- - v_1 \leq 2, \\ & -u_2^+ + u_2^- + u_3^+ - u_3^- - v_2 \leq 0, \\ & u_1^+ - u_1^- - v_3 \leq -1, \\ & u_1^+ + v_2 + u_3^+ \leq 0, \\ & (\,\lambda, u^{\pm}, v\,) \geq 0, \end{array} \tag{5.4}$$

which has an optimal value 5 that is smaller than the current upper bound $\mathrm{LPCC}_{\mathrm{ub}}$. So we update the upper bound as $\mathrm{LPCC}_{\mathrm{ub}} = 5$. Note that this update occurs during the sparsification step. A corresponding optimal solution to (5.4) is $u^+ = (0, 1, 0)$ and $v = (0, 0, 1)$. Hence we can add the point cut $z_2 + (1 - z_3) \geq 1$ to $\mathcal{Z}_{\mathrm{work}}$.

When we next proceed to the other branch $z_3 \geq 1$, we have a relaxed LP:

$$\begin{array}{lll} \underset{(x,y)}{\text{minimize}} & x_1 + 2\,y_1 - y_3 & \\ \text{subject to} & x_1 + x_2 & \geq 5, \\ & x_1 - y_3 + 1 & \geq 0, \\ & x_2 + y_1 + y_2 & \geq 0, \\ & x_1 + x_2 - y_2 + 2 & = 0, \\ & x,\, y \geq 0. & \end{array} \tag{5.5}$$

Solving (5.5) gives an optimal value $\mathrm{LP}_{\mathrm{rlx}} = -1$, which is smaller than $\mathrm{LPCC}_{\mathrm{ub}}$, and a violated complementarity with $w_2 = 12$ and $y_2 = 7$. By adding $z_3 \geq 1$ to $\mathcal{Z}_{\mathrm{wait}}$, we apply the LPCC feasibility recovering procedure to $x = (0, 5)$ and get a new LPCC

feasible piece with $z = (1, 1, 1)$. By substituting z into (2.9), we get another LP:

$$
\begin{array}{lrcl}
\underset{(\lambda, u^{\pm}, v)}{\text{maximize}} & 5\,\lambda + u_1^+ + 2\,u_3^+ - u_1^- - 2\,u_3^- & & \\
\text{subject to} & \lambda - u_1^+ + u_1^- - u_3^+ + u_3^- & \le & 1, \\
& \lambda - u_2^+ + u_2^- - u_3^+ + u_3^- & \le & 0, \\
& -u_2^+ + u_2^- - v_1 & \le & 2, \\
& -u_2^+ + u_2^- + u_3^+ - u_3^- - v_2 & \le & 0, \\
& u_1^+ - u_1^- - v_3 & \le & -1, \\
& u_1^+ + u_2^+ + u_3^+ & \le & 0, \\
& (\lambda, u^{\pm}, v) & \ge & 0,
\end{array}
\tag{5.6}
$$

which has an optimal objective value 0. So a better upper bound is found; thus $\mathrm{LPCC}_{\mathrm{ub}} = 0$. A point cut $1 - z_3 \ge 1$ is derived from an optimal solution of (5.6). This cut obviously implies the previous cut $z_2 + (1 - z_3) \ge 1$. In order to reduce the work load of the IP solver, we can delete $z_2 + (1 - z_3) \ge 1$ from $\mathcal{Z}_{\mathrm{work}}$ and add in $1 - z_3 \ge 1$ instead. So far, we have the updated upper bound $\mathrm{LPCC}_{\mathrm{ub}} = 0$ and the working set $\mathcal{Z}_{\mathrm{work}}$ defined by the two inequalities:

$$
z_2 + z_3 \ge 1 \quad \text{and} \quad 1 - z_3 \ge 1. \tag{5.7}
$$

This completes iteration 1. During this iteration, we have solved 5 LPs, the $\mathrm{LPCC}_{\mathrm{ub}}$ has improved twice, and we have obtained 2 valid cuts.

Iteration 2: Solving a satisfiability IP yields a $z = (0, 1, 0) \in \widehat{\mathcal{Z}}_{\mathrm{work}}$. Indeed, any element in $\widehat{\mathcal{Z}}_{\mathrm{work}}$, which is defined by the two inequalities in (5.7), must have $z_2 = 1$ and $z_3 = 0$; thus it remains to determine z_1. As it turns out, z_1 is irrelevant. To see this, we substitute $z = (0, 1, 0)$ into (2.9), obtaining

$$
\begin{array}{lrcl}
\underset{(\lambda, u^{\pm}, v)}{\text{maximize}} & 5\,\lambda + u_1^+ + 2\,u_3^+ - u_1^- - 2\,u_3^- & & \\
\text{subject to} & \lambda - u_1^+ + u_1^- - u_3^+ + u_3^- & \le & 1, \\
& \lambda - u_2^+ + u_2^- - u_3^+ + u_3^- & \le & 0, \\
& -u_2^+ + u_2^- - v_1 & \le & 2, \\
& -u_2^+ + u_2^- + u_3^+ - u_3^- - v_2 & \le & 0, \\
& u_1^+ - u_1^- - v_3 & \le & -1, \\
& u_2^+ + v_1 + v_3 & \le & 0, \\
& (\lambda, u^{\pm}, v) & \ge & 0.
\end{array}
\tag{5.8}
$$

The LP (5.8) is unbounded and has an extreme ray where $u^+ = (0, 0, 10/7)$ and $v = (0, 10/7, 0)$. So we can add a valid ray cut $(1 - z_2) + z_3 \ge 1$ to $\mathcal{Z}_{\mathrm{work}}$.

Termination: The updated working set $\mathcal{Z}_{\mathrm{work}}$ consists of 3 inequalities:

$$
\left\{ \begin{array}{r} z_2 + z_3 \ge 1 \\ 1 - z_3 \ge 1 \\ (1 - z_2) + z_3 \ge 1 \end{array} \right\},
$$

which can be seen to be inconsistent. Hence we get a certificate of termination. Since there is one point cut in $\mathcal{Z}_{\rm work}$, the LPCC (5.1) has an optimal objective value 0, which happens on the piece $z = (1, 1, 1)$. (This termination can be expected from the fact that $z_2 = 1$ and $z_3 = 0$ for elements in the set $\widehat{\mathcal{Z}}_{\rm work}$ prior to the last ray cut; these values of z imply that $y_2 = w_3 = 0$, which is not consistent with the nonnegativity of x. This inconsistency is detected by the algorithm through the generation of a ray cut that leaves $\widehat{\mathcal{Z}}_{\rm work}$ empty.)

6. Computational results. To test the effectiveness of the algorithm, we have implemented and compared it with benchmark algorithms from NEOS, which for the purpose here were chosen to be the FILTER solver and the KNITRO solver. As expected, these two solvers consistently produce high-quality LPCC feasible solutions. For the test problems we used, both often found solutions that turned out to be globally optimal, as was proved by our algorithm. (The details can be seen in Tables 6.1, 6.2, and 6.3.) We coded our algorithm in MATLAB and used CPLEX 9.1 to solve the LPs and the satisfiability IPs. The experiments were run on a DELL desktop computer with 1.40 GHz Pentium 4 processor and 1.00 GB of RAM.

Our goal in this computational study is threefold: (A) to test the practical ability of the algorithm to provide a certificate of global optimality for LPCCs with finite optimal solutions; (B) to determine the quality of the solutions obtained by using the simple-cut preprocessor; and (C) to demonstrate that the algorithm is capable of detecting infeasibility and unboundedness for LPCCs of these kinds. All problems are randomly generated. One at a time, a total of $\lfloor m/3 \rfloor$ simple cuts are generated in the preprocessing step for each problem. To test (A) and (B), the problems are generated to have optimal solutions; for (C), the problems are generated to be either infeasible or have unbounded objective values. The algorithm does not make use of such information in any way; instead, it is up to the algorithm to verify the prescribed

TABLE 6.1

Special LPCCs with $B = 0$, $A \in \Re^{90\times 100}$, and 100 complementarities. Remark: The first column "#" is the problem counter; the second column "$\mathrm{LPCC}_{\rm lb}$" contains the objective values of LP relaxations before and after the preprocessing. The column "$\mathrm{LPCC}_{\rm ub}$" reports the objective values of the LPCC feasible solutions. The right subcolumn contains the verifiably optimal $\mathrm{LPCC}_{\rm min}$. The left subcolumn contains the values obtained after preprocessing with the LPCC feasibility recovery procedure. The objective values obtained from FILTER *and* KNITRO *are reported in the next columns. (Note that these values are very comparable and practically optimal in all problems except* 1 *and* 7 *for both and* 8 *for* KNITRO.*) The total number of LPs solved (excluding the $\lfloor m/3 \rfloor$ relaxed LPs in the preprocessing step) and the number of IPs solved in the run are reported in the last two columns. At the suggestion of a referee, we also reported the number of "major iterations" in the two* NEOS *solvers; these are placed as subscripts in the objective values of the respective solvers. It should be noted that such iterations refer to different procedures in the two solvers.*

problem status. In all of the experiments, optimality of the LPCC is declared if the difference between the lower and upper bounds is less than or equal to 1e-6; this tolerance is also employed to determine the LPCC feasibility of the relaxed LP solutions. The parameter δ for the sparsification step is selected to be 0.2.

All problems have the nonnegativity constraint $x \geq 0$. The computational results for the problems with finite optima are reported in Figures 6.1, 6.2, and 6.3 and Tables 6.1, 6.2, and 6.3. Each figure contains one set of ten randomly generated problems with the same characteristics. Figures 6.1, 6.2, and 6.3 correspond to problems with $[n, m, k] = [100, 100, 90]$, $[300, 300, 200]$, and $[50, 50, 55]$, respectively. These sizes and the data density are dictated by the limitations of MATLAB that is the environment where our experiments were performed. All data are randomly generated with uniform distributions. The objectives vectors c and d are generated from the intervals [0 1] and [1 3], respectively. For Figures 6.1 and 6.2, the matrix $B = 0$, and the matrix M is generated with up to 2000 nonzero entries and of the form:

$$M \equiv \begin{bmatrix} D_1 & E^T \\ -E & D_2 \end{bmatrix}, \tag{6.1}$$

where D_1 and D_2 are positive diagonal matrices of random order and with elements

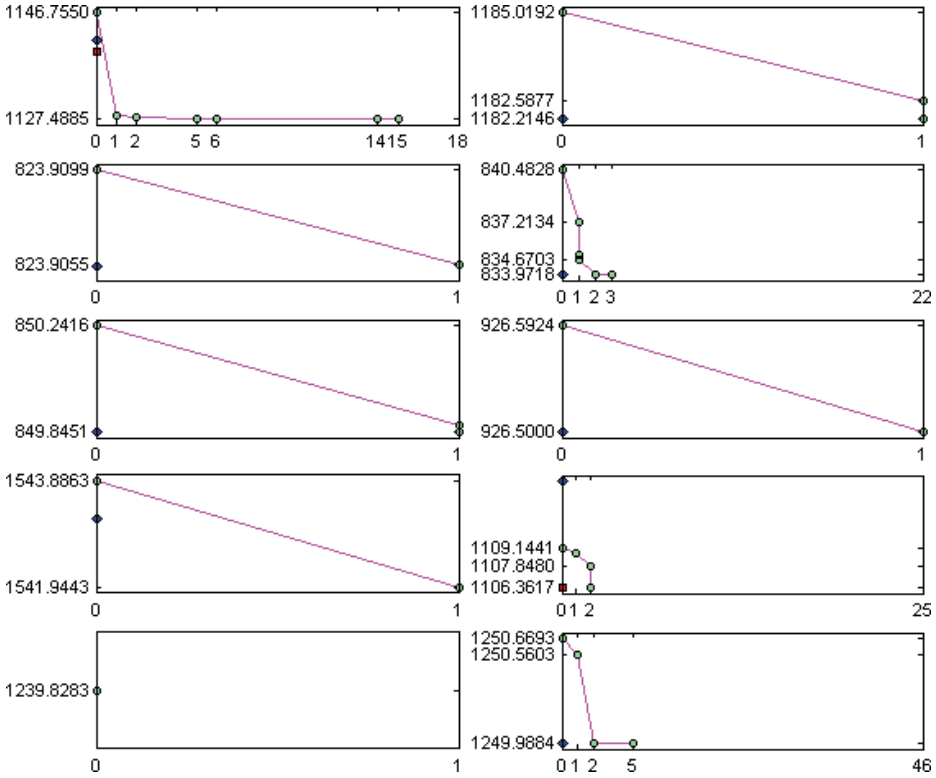

FIG. 6.1. *Special LPCCs with* $B = 0$, $A \in \Re^{90\times 100}$, *and* 100 *complementarities. Remark: Each circle signifies that a better feasible LPCC solution is found. The circle's horizontal coordinate indicates the iteration where* $\mathrm{LPCC}_{\mathrm{ub}}$ *is updated; its vertical coordinate gives the value of updated* $\mathrm{LPCC}_{\mathrm{ub}}$ *(we omitted some values if they are not significantly improved). Note that it is possible for* $\mathrm{LPCC}_{\mathrm{ub}}$ *to improve within one iteration by the sparsification step; see the example in subsection* 5.1 *and also the top run in the right column. In the fifth run in the left column, both of the* FILTER *and* KNITRO *results coincide with* $\mathrm{LPCC}_{\mathrm{min}}$*, which is obtained after preprocessing and verified to be optimal after one iteration.*

chosen from [0 2] and E is arbitrary with elements in $[-11]$. The vector q is randomly generated with elements in the interval $[-20 - 10]$. Note that M is positive definite, albeit not symmetric. This property of M and the choice of $B = 0$ ensure LPCC feasibility and thus optimality (because c and d are nonnegative and the variables are nonnegative). For Figure 6.3, $B \neq 0$, and the matrix M has no special structure but has only 10% density. The rest of the data A, f, q, and N are generated to ensure LPCC feasibility and thus optimality. Details of the data generation and the resulting data can be found in [50].

Figures 6.1, 6.2, and 6.3 detail the progress of the runs, showing in particular how $\mathrm{LPCC}_{\mathrm{ub}}$ decreases with the number of iterations. The vertical axis refers to the LPCC objective values, and the horizontal axis labels the number of iterations as defined in the opening paragraph of section 5. The top value on the vertical axis is the LPCC objective value obtained at termination of the preprocessor with the LPCC feasibility recovery step. The bottom value is verifiably $\mathrm{LPCC}_{\mathrm{min}}$. The vertical axis is scaled differently in each run with respect to the difference between the top and the bottom values. As comparison, the objective values obtained from FILTER (marked by the red square) and KNITRO (marked by the blue diamond) are also shown on the vertical axis;

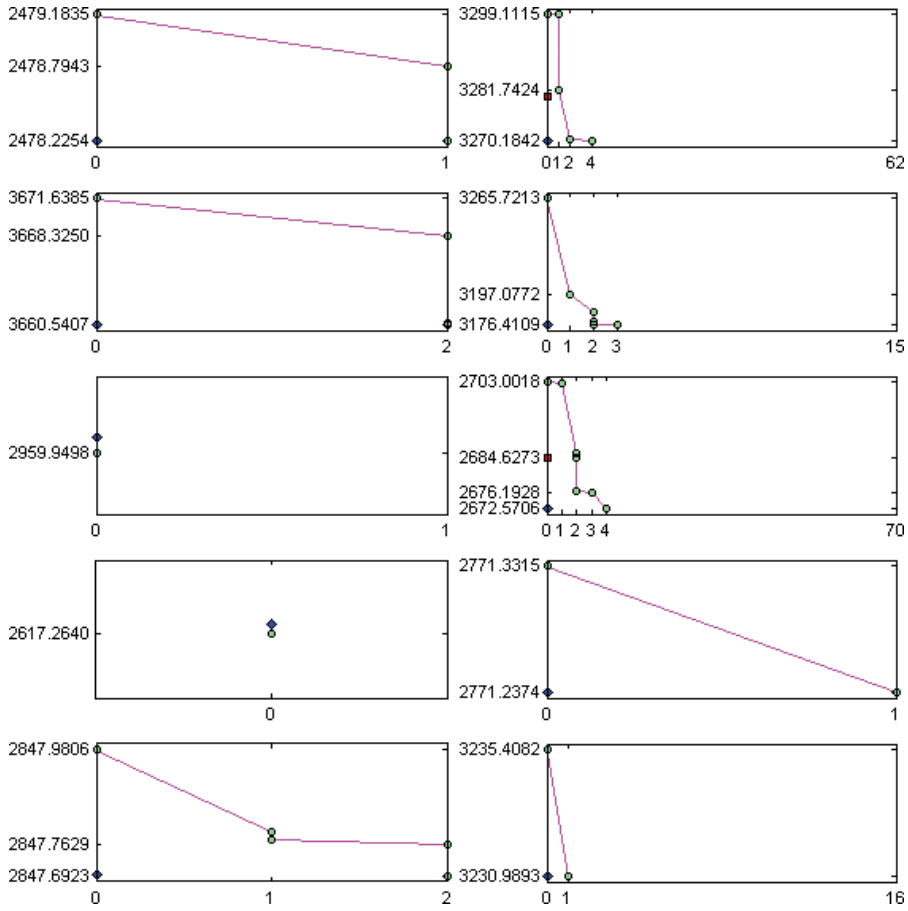

FIG. 6.2. *Special LPCCs with* $B = 0$, $A \in \Re^{200\times 300}$, *and* 300 *complementarities. Remark: The explanation for the figure is similar to that of Figure* 6.1. *Note that in the third and fourth runs in the left column* $\mathrm{LPCC}_{\mathrm{ub}}$ *is obtained right after preprocessing. In the third run, the solution's global optimality is verified after* 1 *iteration; while in the fourth run, the solution is immediately verified to be globally optimal (the difference between the upper and lower bounds of the LPCC is within* 1e-6*).*

if the difference between the FILTER and KNITRO values in a run is within 1e-3, we mark only the KNITRO result (the exact values from these two solvers can be found in Tables 6.1, 6.2, and 6.3). The upper limit of the horizontal axis indicates the number of IPs needed to be solved in each run. Note that in some runs a globally optimal solution might have been obtained in an earlier iteration without certification, and the algorithm needs more subsequent iterations to verify its global optimality. For example, in the fourth run of the right-hand column in Figure 6.1, a globally optimal solution is first obtained at iteration 2, but the certificate is established only after 23 more iterations. Other details about the figures are summarized in the remarks below the figures.

Corresponding to the problems in Figures 6.1, 6.2, and 6.3, respectively, Tables 6.1, 6.2, and 6.3 report more details about the runs, which are indexed by counting first rowwise and then columnwise in the figures (for example, the fourth run in Table 6.1 is the second row on the right column in Figure 6.1). In addition to the objective values obtained in our algorithm and from the NEOS solvers, these tables also

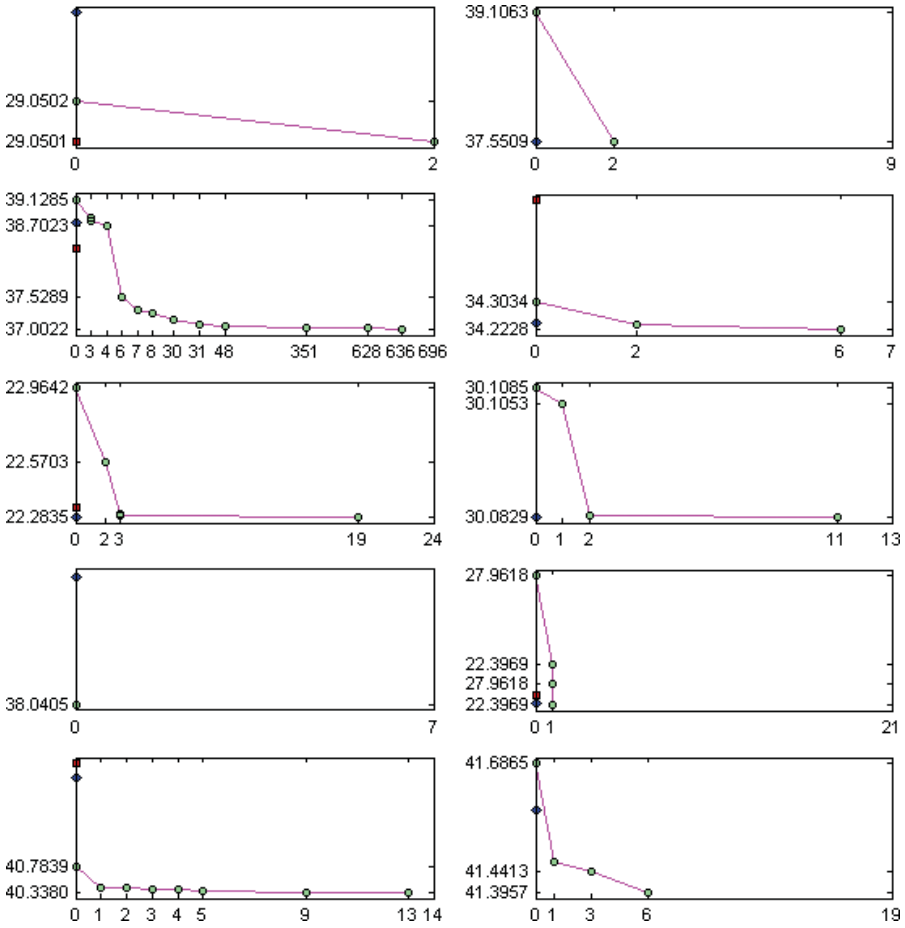

FIG. 6.3. *General LPCCs with* $B \neq 0$, $A \in \Re^{55\times 50}$, *and* 50 *complementarities.*

report the numbers of IPs and LPs (excluding the $\lfloor m/3 \rfloor$ relaxed LPs solved in the preprocessor), solved in the solution process. These numbers, which are independent of the computational platform and machine, provide a good indicator of the efforts required by the algorithm in processing the LPCCs. We did not report computational times for two reasons: (i) The MATLAB results are computer-dependent, and the runs involve interfaces between MATLAB and CPLEX, and (ii) our runs are experimental, and our coding is at an amateur level.

The computational results for the infeasible and unbounded LPCCs are reported in Table 6.4, which contains 3 subtables (a), (b), and (c). The first two subtables (a) and (b) pertain to feasible but unbounded LPCCs. For the unbounded problems, we set $B = 0$, q is arbitrary, and we generate A with a nonnegative column, M given by (6.1), and f such that $\{x \geq 0 : Ax \geq f\}$ is feasible. Problems in (a) and (b) have the same parameters except for the objective vectors c and d and matrix A. For the problems in (a), we simply maximize one single x-variable whose A column is nonnegative. For the problems in (b), the objective vectors c and d are both negative, and the matrix A is the same as it is in group (a) except that a small number 0.005 is added to its nonnegative column (see the discussion in the first conclusion below for why this is done). The third subtable (c) pertains to a class of infeasible LPCCs

TABLE 6.4

Infeasible and unbounded LPCCs with 50 complementarities. # iters = number of returns to Step 1 = number of IPs solved; # cuts = number of satisfiability constraints in $\mathcal{Z}_{work}$ at termination; # LPs = number of LPs solved, excluding the $\lfloor m/3 \rfloor$ relaxed LPs in the preprocessing step.

TABLE 6.5

General LPCCs with $B \neq 0$, $A \in \Re^{25\times 25}$, and 25 complementarities. Column A = number of IPs or LPs solved in the run without sparsification; column B = number of IPs or LPs solved in the run with sparsification. Remark: In column A, the number of IPs solved in the run is equal to the number of solved LPs. Except for problems 3, 9, and 10, the B approach (with the sparsification step implemented) is doing much better than the A approach. Especially for problems 1 and 5–8, the numbers of IPs and LPs are dramatically reduced. For the remaining problems, the computational effort with sparsification is at least comparable to, if not better than, the approach without sparsification. When the number of complementarities in the LPCCs grows, we expect more computational savings with the sparsification step implemented.

	A		B	
Prob	# LPs	# IPs	# LPs	# IPs
1	122	122	61	18
2	17	17	33	11
3	7	7	51	9
4	16	16	41	12
5	280	280	70	21
6	598	598	85	23
7	195	195	90	26
8	65	65	43	10
9	9	9	41	9
10	8	8	33	8

generated as follows: q, N, and M are all positive so that the only solution to the LCP $0 \leq y \perp q + Nx + My \geq 0$ for $x \geq 0$ is $y = 0$; $Ax + By \geq f$ is feasible for some $(x, y) \geq 0$, with $y \neq 0$, but $Ax \geq f$ has no solution in $x \geq 0$.

To illustrate the effectiveness of the sparsification step, we generated some LPCCs with $n = m = k = 25$ and the same characteristics as the problems in Figure 6.3. Table 6.5 reports the numbers of LPs and IPs that are needed to be solved in both runs with or without this step.

The main conclusions from the experiments are summarized below.

• The algorithm successfully terminates with the correct status of all of the LPCCs reported. In fact, we have tested many more problems than those reported and obtained similar success. There are, nevertheless, a few instances where the LPCCs are apparently unbounded but the algorithm fails to terminate after 6000 iterations without the definitive conclusion, even though the LPCC objective is noticeably tending to $-\infty$. We cannot explain these exceptional cases which we suspect are due to round-off errors in the computations. This suspicion led us to add the small 0.005

adjustment in the unbounded set of runs reported above; with this small adjustment, the algorithm successfully terminated with the desired certificate of unboundedness.

• For the special LPCCs with $B = 0$, the results from the 2 NEOS algorithms FILTER and KNITRO are proved to be suboptimal in 2 out of the 20 runs (the first and fourth runs on the left column in Figure 6.1). In the other 18 runs, our algorithm is able to obtain an optimal solution with little computational effort (within 5 iterations) but requires significant additional computations to produce the desired certificate of global optimality. For the general LPCCs with $B \neq 0$, the objective values obtained from FILTER and KNITRO are suboptimal in 6 out of 10 runs. In the other 4 runs, only 5 iterations are needed to derive either a globally optimal solution or an LPCC feasible solution whose objective value is within 3% of the optimal value. These results confirm that the verification of global optimality is generally much more demanding than the computation of the solution without proof of optimality.

• Except for one problem (problem 7 in Table 6.3), the solutions obtained by the simple-cut preprocessor for all LPCCs with finite optima are within 5% of the globally optimal solutions. In fact, some of the solutions obtained from the preprocessing are immediately verified to be optimal. This suggests that very high-quality LPCC feasible solutions can be produced efficiently by solving a reasonable number of LPs.

• The sparsification procedure is quite effective; so is the LPCC feasibility recovery step. Indeed without the latter, there is a significant percentage of problems where the algorithm fails to make progress after 3000 iterations. With this step installed, all problems are resolved satisfactorily.

• While the numbers of IPs solved are quite reasonable in most cases, there are several runs where the numbers of relaxed LPs solved are unusually large, especially when the problem size increases. This suggests that stronger cuts are needed for both general LPCCs and for specialized problems arising from large-scale applications. The implementation of a dedicated solver for satisfiability problems, such as those described in [7, 31], could considerably improve the overall solution times of the LPCC algorithm. These refinements of the algorithm are presently being investigated.

Concluding remarks. In this paper, we have presented a parameter-free IP-based algorithm for the global resolution of an LPCC and reported computational results with the application of the algorithm for solving a set of randomly generated LPCCs of moderate sizes. Continued research on refining the algorithm and applying it to realistic classes of LPCCs, such as the bilevel machine-learning problems described in [6, 32, 33] and other applied problems, is currently underway.

Acknowledgments. The authors are grateful to 2 referees for their constructive comments that have significantly improved the presentation of the paper. In particular, one of them alerted the authors to [9], which discusses Benders techniques for conditional linear constraints without requiring the big-M.

EMBEDDED IN THE SHADOW OF THE SEPARATOR*

FRANK GÖRING†, CHRISTOPH HELMBERG†, AND MARKUS WAPPLER†

Abstract. Eigenvectors to the second smallest eigenvalue of the Laplace matrix of a graph, also known as Fiedler vectors, are the basic ingredient in spectral graph partitioning heuristics. Maximizing this second smallest eigenvalue over all nonnegative edge weightings with bounded total weight yields the *absolute algebraic connectivity* introduced by Fiedler, who proved tight connections of this value to the connectivity of the graph. Our objective is to gain a better understanding of the connections between separators and the eigenspace of this eigenvalue by studying the dual semidefinite optimization problem to the absolute algebraic connectivity. By exploiting optimality conditions we show that this problem is equivalent to finding an embedding of the n nodes of the graph in n-space so that their barycenter is the origin, the distance between adjacent nodes is bounded by one, and the nodes are spread as much as possible (the sum of the squared norms is maximized). For connected graphs we prove that, for any separator in the graph, at least one of the two separated node sets is embedded in the shadow (with the origin being the light source) of the convex hull of the separator. Furthermore, we show that there always exists an optimal embedding whose dimension is bounded by the tree width of the graph plus one.

1. Introduction.

Let $G := (N, E)$ be an undirected graph with node set $N := \{1, \dots, n\}$ and edge set $E \subseteq \{\{i, j\} : i, j \in N, i \neq j\}$. Edge $\{i, j\}$ will be abbreviated by ij if there is no danger of confusion. The adjacency matrix $A \in \mathbb{R}^{n\times n}$ of the graph is defined as the (symmetric) matrix having $a_{ij} = 1$ if $ij \in E$ and 0 otherwise. The *Laplace matrix* or *Laplacian* of the graph is the matrix $L := \operatorname{diag}(Ae) - A$, where e denotes the vector of all ones of appropriate dimension and $\operatorname{diag}(v)$ denotes the diagonal matrix having v on its main diagonal. For symmetric matrices $H \in \mathbb{R}^{n\times n}$ we order the eigenvalues by $\lambda_1(H) \leq \lambda_2(H) \leq \cdots \leq \lambda_n(H)$. Because the Laplacian L is positive semidefinite and $Le = 0$, we have $\lambda_1(L) = 0$ with eigenvector e. Fiedler [6, 7] showed that the second smallest eigenvalue $\lambda_2(L)$ is tightly related to edge and vertex connectivity of the graph. In particular, $\lambda_2(G)$ is positive if and only if G is connected. Therefore, Fiedler called $\lambda_2(L)$ the *algebraic connectivity* of the graph. Eigenvectors to $\lambda_2(L)$, often referred to as Fiedler vectors, have been used quite successfully in heuristics for graph partitioning in parallel computing [20, 21, 14], in clustering of geometric objects [1] or hyperlinks in the World Wide Web [12], or even in computer vision [15]. The second smallest eigenvalue allows one to derive various bounds in graph partitioning or bandwidth optimization [13, 11]; further properties of the Laplacian spectrum are presented in [8, 9, 10, 2, 29], and [17, 18] give a survey on the Laplacian spectrum of graphs. See also [3, 19] for related applications of spectral graph theory in combinatorial optimization.

By the Courant–Fischer theorem, the eigenvalue $\lambda_2(L)$ and its eigenvectors may be characterized as optimal solutions to the optimization problem

$$\lambda_2(L) = \min_{v \in \mathbb{R}^n, v^T e = 0, \|v\| = 1} v^T L v.$$

The usefulness of λ_2 and its eigenvectors in graph partitioning should relate to this characterization in some way. In order to get a better understanding of these connections, it seems natural to study the eigenspace of λ_2 for weighted matrices on the same support (i.e., arc weighted graphs on the same edge set) that are extremal in the sense that, for their distribution of the weight, λ_2 is maximal. The optimal λ_2 with respect to the support of the graph was introduced by Fiedler [7] under the name "absolute algebraic connectivity." We study the semidefinite dual of this optimization problem. Due to complementarity, the optimal solutions of the dual are restricted to the eigenspace of the optimal λ_2, and so all properties of dual optimal solutions directly provide information on the structure of the eigenspace associated with the absolute algebraic connectivity. It turns out that the dual may be interpreted as an embedding problem of the nodes of G in $\mathbb{R}^n$; see (4). The same optimization problem appears in [24] in connection with finding the fastest mixing Markov process on a graph; this work also mentions interest in low-dimensional solutions of this problem within the field of maximum variance unfolding in machine learning [26, 27].

We show that optimal embeddings of (4) have structural properties tightly connected to the separator structure of the graph (Theorem 3). In particular, if a subset $S \subset N$ of nodes separates the graph into two separated node sets C_1, C_2 that form a partition of $N \setminus S$, then for one of the two sets, say, C_1, all nodes are in the "shadow" of the convex hull of the nodes in S as seen from the origin; i.e., the straight line segment between any node of C_1 and the origin intersects the convex hull of S. Since any nonzero projection of the embedding to a one-dimensional subspace yields an eigenvector to the optimal λ_2 (Remark 2), this offers good geometric insight into the usefulness of Fiedler vectors for graph partitioning.

The embedding may also be interpreted as a variant of vector labelings of graphs as introduced in [16]. On first sight, strong similarities exist with respect to the Colin de Verdière number $\mu(G)$; see the excellent survey [25]. But the strong Arnold property is not required in our context, so no direct connection to $\mu(G)$ should be expected. Yet, similar to maximizing the corank in the Colin de Verdière number, one may ask for an optimal embedding of minimal dimension. Besides general interest in the existence of low-dimensional optimal solutions of semidefinite programs [22], such solutions are also sought in the machine learning applications [26, 27] mentioned above. Even though we are still far from answering this question to our full satisfaction, we are able to exhibit an intriguing bound based on the tree width of the graph. Indeed, we show in the proof of Theorem 5 that there is always an optimal embedding whose dimension is bounded by the cardinality of a "central" node of an arbitrary tree decomposition of G. This bound is tight for some particular graph classes (see Example 8). Nonetheless, the bound seems to be far too pessimistic, e.g., for planar graphs. Therefore it is conceivable that significantly better bounds can be obtained by minor related approaches.

The paper is organized as follows. In section 2 we derive the embedding problem as the dual problem to the eigenvalue optimization problem of determining the absolute algebraic connectivity and present an overview of our main results on this embedding together with some examples. The proof of the first result (the separator-shadow theorem) is given in section 3. Section 4 is devoted to optimality-preserving manipu-

lations of optimal embeddings for reducing the dimension of embeddings. These are rotations and foldings around separators that contain the origin in their convex hull and allow us, in section 5, to design an algorithm that gives rise to the proof of the tree width bound on the minimal dimension of optimal solutions.

We use basic notions and notation from graph theory and semidefinite programming [28]. In particular, for symmetric $H \in \mathbb{R}^{n\times n}$, $H \succeq 0$ is used to denote positive semidefiniteness; for matrices $A, B \in \mathbb{R}^{m\times n}$, $\langle A, B\rangle := \sum_{ij} A_{ij}B_{ij}$ is the canonical inner product; in the case of vectors $a, b \in \mathbb{R}^n$ we will simply use a^Tb; $\|\cdot\|$ refers to the usual Euclidean norm; e denotes the vector of all ones of appropriate size; for a set $\mathcal{S} \subset \mathbb{R}^n$, $\operatorname{conv}\mathcal{S}$ refers to the convex hull of $\mathcal{S}$ and $\operatorname{cone}\mathcal{S} := \{\lambda x : x \in \operatorname{conv}\mathcal{S}, \lambda \geq 0\}$. The projection on a closed convex set C is denoted by $p_C(\cdot)$.

2. Optimal embeddings and main results. In the remainder of the paper we assume that the graph $G = (N, E)$ is connected and $|N| = n \geq 2$. Let

$$\mathcal{C} := \left\{ c \in \mathbb{R}^E_+ : \sum_{ij\in E} c_{ij} = |E| \right\}$$

denote the set of all possible nonnegative edge weightings that sum up to $|E|$. For a particular $c \in \mathcal{C}$, let A_c denote the weighted adjacency matrix, i.e., $A_{ij} = c_{ij}$ for $ij \in E$ and 0 otherwise, and $L_c := \operatorname{diag}(A_ce) - A_c$ the corresponding weighted Laplacian. For $i, j \in N$, $i \neq j$, define $E_{ij} \in \mathbb{R}^{n\times n}$ as the matrix having the two diagonal elements $(E_{ij})_{ii} = (E_{ij})_{jj} = 1$, the two off-diagonal elements $(E_{ij})_{ij} = (E_{ij})_{ji} = -1$, and all other elements equal to zero. Then we may rewrite the Laplacian as

$$L_c = \sum_{ij\in E} c_{ij}E_{ij}.$$

The matrix L_c is positive semidefinite (because E_{ij} is positive semidefinite and $c_{ij} \geq 0$ for all $ij \in E$) and has an eigenvalue zero with eigenvector e (because $E_{ij}e = 0$). Our basic optimization problem is to determine the absolute algebraic connectivity

$$\hat{a}(G) := \max_{c\in\mathcal{C}} \lambda_2(L_c), \tag{1}$$

where $\hat{a}(G)$ denotes the absolute algebraic connectivity introduced in [7]. The maximum is attained, because a continuous function is maximized over a compact set. Since G is assumed to be connected, the result of Fiedler [6] for $c = e$ asserts that $\lambda_2(L_c) = \lambda_2(L) > 0$, so the optimum value is strictly positive. In order to reformulate the optimization problem as a semidefinite program, it will be convenient to shift the smallest eigenvalue 0 to a sufficiently large value. Thus, (1) may be rewritten as the following semidefinite program:

$$\begin{aligned} \hat{a}(G) = \max \quad & \lambda \\ \text{such that (s.t.)} \quad & \sum_{ij\in E} c_{ij}E_{ij} + \rho ee^T - \lambda I \succeq 0, \\ & \sum_{ij\in E} c_{ij} = |E|, \\ & c \geq 0,\ \lambda, \rho \text{ free}. \end{aligned}$$

Because the optimal value is strictly greater than zero by the connectedness of G, we may rescale the problem by $1/\lambda$ and equivalently minimize the sum of the scaled

weights $w_{ij} := c_{ij}/\lambda$ instead. Together with the scaled $\mu := \rho/\lambda$ we obtain

$$\begin{aligned} \frac{|E|}{\hat{a}(G)} = \min \quad & \sum_{ij\in E} w_{ij} \\ \text{s.t.} \quad & \sum_{ij\in E} w_{ij}E_{ij} + \mu ee^T \succeq I, \\ & w \geq 0,\ \mu \text{ free.} \end{aligned} \tag{2}$$

Note that, by the considerations above, choosing $w = \frac{1+\varepsilon}{\lambda_2(L)}e$ and $\mu = 1+\varepsilon$ yields a strictly feasible solution for $\varepsilon > 0$. Therefore the program attains its optimal solution, and semidefinite duality theory together with strict feasibility asserts that the optimal value of its dual semidefinite program is also attained. The dual reads

$$\begin{aligned} \frac{|E|}{\hat{a}(G)} = \max \quad & \langle I, X\rangle \\ \text{s.t.} \quad & \left\langle ee^T, X\right\rangle = 0, \\ & \langle E_{ij}, X\rangle \leq 1 \qquad \text{for } ij \in E, \\ & X \succeq 0. \end{aligned} \tag{3}$$

Now consider a Gram representation of X via a matrix $V \in \mathbb{R}^{n\times n}$ with $X = V^TV$, and denote column i of V by v_i, i.e., $V = [v_1, \ldots, v_n]$. Then

$$X_{ij} = v_i^Tv_j \quad \text{and} \quad \langle E_{ij}, X\rangle = \|v_i\|^2 - 2v_i^Tv_j + \|v_j\|^2 = \|v_i - v_j\|^2.$$

Since $0 = \left\langle ee^T, X\right\rangle = e^TXe = e^TV^TVe$ and $Ve = \sum v_i$, the dual semidefinite program (3) translates directly to

$$\begin{aligned} \frac{|E|}{\hat{a}(G)} = \max \quad & \sum_{i\in N} \|v_i\|^2 \\ \text{s.t.} \quad & \left(\sum_{i\in N} v_i\right)^2 = 0, \\ & \|v_i - v_j\|^2 \leq 1 \qquad \text{for } ij \in E, \\ & v_i \in \mathbb{R}^n \text{ for } i \in N. \end{aligned} \tag{4}$$

Thus, the dual problem to (1) is equivalent to finding an embedding of the nodes of the graph in n-space so that their barycenter is at the origin (we will call this the *equilibrium constraint*), the distances of adjacent nodes are bounded by one (the *distance constraints*), and the sum of their squared norms is maximized.

Remark 1. Together with the KKT conditions (we do not list feasibility constraints again)

$$\begin{aligned} v_j + \sum_{ij\in E} w_{ij}(v_i - v_j) + \mu\sum_{i\in N} v_i = 0 \qquad & \forall j \in N, \\ w_{ij}(1 - \|v_i - v_j\|^2) = 0 \qquad & \forall ij \in E, \\ \mu\left(\sum_{i\in N} v_i\right)^2 = 0, & \end{aligned}$$

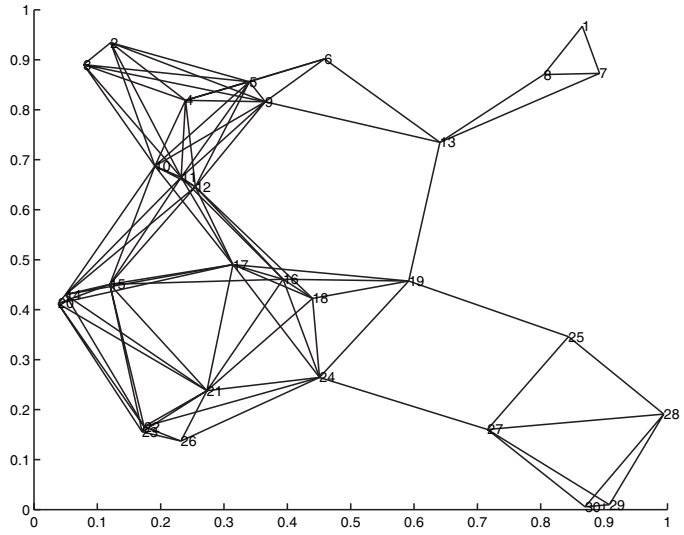

FIG. 1. *Original graph: The* 30 *vertices, picked randomly in* $[0,1]^2$*, are connected by an edge if the Euclidean distance is at most* 0.3.

the embedding problem suggests the following physical interpretation of optimal primal and dual solutions. Consider each node as having a point mass of unit size, and imagine each edge being a mass-free rope of length one that connects the points. Now the optimum solution of (4) corresponds to an equilibrium solution of this net spread within a force field that acts with force v on a point of mass one at position v. The w_{ij} are the forces acting along rope ij. Indeed, all $w_{ij} > 0$ are on the same scale as the force field, because $w_{ij} > 0$ only if $\|v_i - v_j\|^2 = 1$. So the first line of the KKT conditions asserts that these forces are in equilibrium in each point ($\mu \sum v_i = 0$ by feasibility, so this term does not enter). If an optimal two-dimensional embedding exists, such a physical situation is encountered when spreading the net on a disk rotating around its center (the centripetal force is $m\omega^2 r$, where m is the mass, ω the angular frequency, and r the radius). In [24] the same problem (and interpretation) was derived by starting from the problem of determining the fastest mixing Markov chain.

We illustrate this for an example graph on 30 vertices (see Figure 1) that was generated by picking the vertices randomly in the unit square and by connecting two points by an edge if their Euclidean distance is at most 0.3. The edge weights corresponding to an optimal solution of problem (2) are given in gray shades in Figure 2 (white is weight 0, black is maximum weight). The optimal embedding of (4) is displayed in Figure 3. It was computed by using SeDuMi [23] and is in fact two-dimensional in this case. The origin is indicated by the small circle in the center.

Remark 2. The projections of optimal embeddings onto one-dimensional subspaces yield eigenvectors to the algebraic connectivity. To see this, suppose that $V = [v_1, \ldots, v_n]$ is an optimal embedding of (4) and c are the corresponding optimal weights giving rise to the algebraic connectivity $\lambda_2(L_c)$ in (1). For any $p \in \mathbb{R}^n$, the vector $u := V^T p$ is an eigenvector of L_c for the eigenvalue $\lambda_2(L_c)$, i.e., $L_c u = \lambda_2(L_c)u$. Indeed, $X = V^T V$ is then an optimal solution of (3), $w = c/\lambda_2(L_c)$ together with some $\mu = 1$ is an optimal solution of (2), and by complementarity and $\langle ee^T, X \rangle = 0$

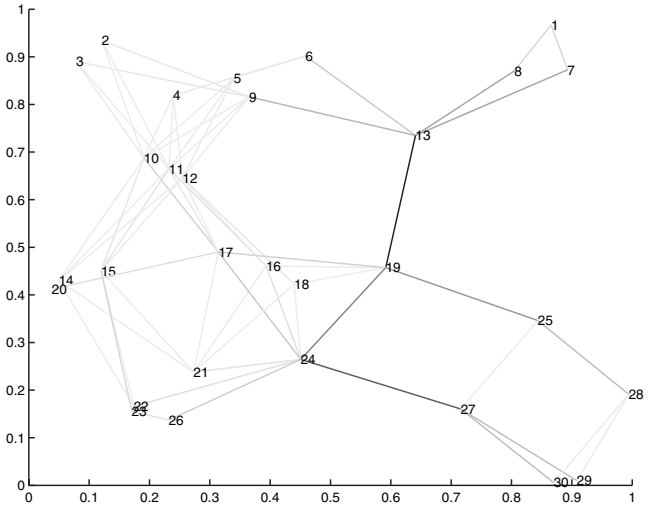

FIG. 2. *Graph with optimal edge weights.*

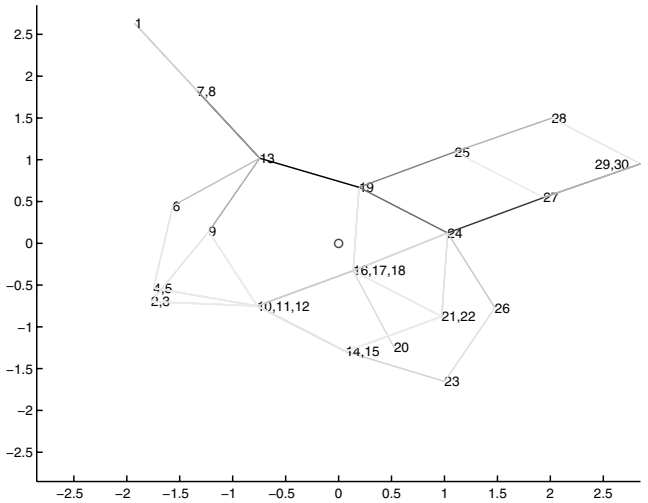

FIG. 3. *Optimal embedding (the central circle indicates the origin).*

we obtain

$$\begin{aligned} 0 &= \left\langle X, \sum_{ij\in E} w_{ij}E_{ij} + \mu ee^T - I \right\rangle \lambda_2(L_c) \\ &= \left\langle X, \sum_{ij\in E} \lambda_2(L_c) w_{ij}E_{ij} - \lambda_2(L_c)I \right\rangle \\ &= \left\langle V^TV, L_c - \lambda_2(L_c)I \right\rangle \\ &= \left\langle I, V(L_c - \lambda_2(L_c)I)V^T \right\rangle. \end{aligned}$$

So each column of V^T (and hence $u = V^Tp$) is in the eigenspace of L_c to eigenvalue $\lambda_2(L_c)$.

Our main results show that structural properties of optimal embeddings v_i, $i \in N$, of (4) are tightly linked to the separator structure of the underlying graph. Here a (node-)*separator* of G is a subset $S \subset N$ of nodes, whose removal disconnects the graph into at least two connected components. Often we will not discern every single component arising this way but simply speak of two or more separated sets of nodes. The first result states that for each separator S all but at most one of its components must be embedded so that any ray emanating from the origin first has to hit $\operatorname{conv}\{v_s : s \in S\}$ before it can reach a node of these components; i.e., by considering the origin as a light source and $\operatorname{conv}\{v_s : s \in S\}$ as a solid object, all but one of the components must be embedded in the shadow of the separator.

THEOREM 3 (separator-shadow). *Let $v_i \in \mathbb{R}^n$ ($i \in N$) be an optimal solution of (4) for a connected graph $G = (N, E)$. Let S be a separator in G giving rise to a partition $N = S \cup C_1 \cup C_2$ where there is no edge between C_1 and C_2. Then for at least one C_j*

$$\operatorname{conv}\{0, v_i\} \cap \operatorname{conv}\{v_s : s \in S\} \neq \emptyset \qquad \forall i \in C_j. \tag{5}$$

In words, the straight line segments $\operatorname{conv}\{0, v_i\}$ of all nodes $i \in C_j$ intersect the convex hull of the points in S.

We encourage the reader to check the separator-shadow property on some of the separators in Figure 3, e.g., for $S = \{13\}$ or $S = \{19, 24\}$.

Condition (5) holds trivially if $\operatorname{conv}\{v_s : s \in S\}$ contains the origin. Considering a separator S with the property $0 \notin \operatorname{conv}\{v_s : s \in S\}$, the separator-shadow theorem ensures that all but one of the components are embedded in the subspace spanned by the separator. Thus, if all minimal separators are small in size, there seems to be hope that there also exists an optimal embedding of small dimension. Our second main result confirms this expectation. In order to state it, we first recall the definitions of tree decomposition and tree width as given in [5].

DEFINITION 4. *For a graph $G = (N, E)$ a* tree decomposition *of G is a tree $(\mathcal{N}, \mathcal{E}) =: T$, with $\mathcal{N} \subseteq 2^N$ and $\mathcal{E} \subseteq \binom{\mathcal{N}}{2}$, satisfying the following requirements:*

(i) $N = \bigcup_{U \in \mathcal{N}} U$.

(ii) *For every $e \in E$ there is a $U \in \mathcal{N}$ with $e \subseteq U$.*

(iii) *If $U_1, U_2, U_3 \in \mathcal{N}$ with U_2 on the T-path from U_1 to U_3, then $U_1 \cap U_3 \subseteq U_2$.*

The width of T is the number $\max\{|U| - 1 : U \in \mathcal{N}\}$. The tree width *$tw(G)$ is the least width of any tree decomposition of G.*

For example, trees have tree width one (each edge forms one set U, so choose $\mathcal{N} = E$, and for $\mathcal{E}$ use the edge set of any spanning tree of the original tree's line graph). In general, it is NP-complete to determine the tree width, but any valid tree decomposition provides an upper bound.

THEOREM 5. *For each connected graph G there exists an optimal embedding of (4) of dimension at most $tw(G) + 1$.*

It is not difficult to devise examples where optimal embeddings of much higher dimensions exist, as well. A simple one, that will also be helpful in the remainder of the paper, is the star $K_{1,n}$.

Example 6. For a star $K_{1,n} := (\{0, 1, \ldots, n\}, \{\{0, i\} : i = 1, \ldots, n\})$, with $n \geq 2$, one optimal solution embeds the center node 0 in the origin and all other nodes in the vertices of a regular $n-1$-dimensional simplex with $\|v_i\| = 1$, $i = 1, \ldots, n$, for an objective value of n (optimality follows from choosing $w_{ij} = 1$ and $\mu = 1$ in (2)). For even $n \geq 2$, a one-dimensional optimal embedding is given by assigning the center node 0 to the origin, half of the outer nodes to $+1$, and the other half to -1. For odd $n \geq 3$, one possibility to find a two-dimensional optimal embedding is to put node 0

into the origin, node 1 to $(1,0)$ even nodes $i \geq 2$ to $(-\frac{1}{n-1}, \sqrt{1-(\frac{1}{n-1})^2})$, and the odd nodes $i \geq 3$ to $(-\frac{1}{n-1}, -\sqrt{1-(\frac{1}{n-1})^2})$.

Solving (3) by interior point methods will, in fact, always generate optimal embeddings of (4) of maximum dimension, because interior point methods generate maximally complementary solutions [4]. So the next question is whether it is difficult to find optimal embeddings satisfying the bound of Theorem 5. For general graphs there is little hope to find a tree decomposition giving the tree width of the graph, but for a given optimal embedding and some tree decomposition of width t our proof of Theorem 5 allows us to transform the embedding algorithmically by a sequence of optimality-preserving rotations and foldings into an optimal embedding of dimension at most $t+1$.

The bound of Theorem 5 on the minimum dimension of optimal embeddings is not tight for all graphs. Already in the example above, any star $K_{1,n}$ with even $n \geq 2$ has an optimal embedding in one dimension. For certain classes of graphs the bound of Theorem 5 on the minimum dimension of optimal embeddings is, in fact, far off (e.g., planar grid graphs have one-dimensional optimal embeddings), but in general the bound cannot be improved as is shown by the second of the following two examples.

Example 7 (complete graphs). For $K_n := (\{1,\ldots,n\}, \{\{i,j\} : 1 \leq i < j \leq n\})$ we show that the unique optimal embedding is the regular $n-1$-dimensional simplex with all points lying on the ball of radius $r_n := \sqrt{\frac{n-1}{2n}}$. The optimal X is given by $X_{ii} = r_n^2 = \frac{n-1}{2n}$ for $1 \leq i \leq n$ and $X_{ij} = X_{ji} = -\frac{r_n^2}{n-1} = -\frac{1}{2n}$ for $1 \leq i < j \leq n$, and the optimal weights are $w_{ij} = \frac{1}{n}$ for $1 \leq i < j \leq n$. By choosing $\mu = \frac{1}{n}$ we compute $L_w + \mu ee^T - I = 0$, so (w,μ) is feasible for (2) with objective $\frac{n-1}{2}$. Likewise, X is feasible for (3) and $\langle I, X\rangle = \frac{n-1}{2}$, so optimality is shown. Furthermore, since $w_{ij} > 0$ for all ij, the constraints $\langle E_{ij}, X\rangle = 1$ hold for all optimal X; i.e., the embedding must have all points pairwise at distance one. So the regular $n-1$-dimensional simplex is the only optimal embedding. Note that the tree width of K_n is $n-1$, and thus the complete graphs are not tight with respect to the bound of Theorem 5.

Example 8 (graphs with tight dimension bound). We append to K_n three independent vertices that are completely linked to K_n resulting in a graph $G(n) := (\{1,\ldots,n+3\}, \{\{i,j\} : 1 \leq i \leq n, i < j \leq n+3\})$. The tree width of $G(n)$ is n, and for $n \geq 4$ the minimal dimension of an optimal embedding of $G(n)$ is $n+1$. In fact, we show that, for $n \geq 4$, the vertices of K_n are again arranged as a centrally symmetric $n-1$-dimensional simplex with all points lying on a ball of radius $r_n := \sqrt{\frac{n-1}{2n}}$, and the three new points are arranged centrally symmetric on a circle orthogonal to this simplex with radius $\bar{r} := \sqrt{\frac{n+1}{2n}}$. The optimum of (3) is obtained by extending the optimum of Example 7 with $X_{ii} = \bar{r}^2 = \frac{n+1}{2n}$ for $n < i \leq n+3$, $X_{ij} = X_{ji} = -\frac{\bar{r}^2}{2} = -\frac{n+1}{4n}$ for $n < i < j \leq n+3$, and $X_{ij} = X_{ji} = 0$ for $1 \leq i \leq n$, $n < j \leq n+3$. The optimal weights are $w_{ij} = \frac{1}{n}$ for $1 \leq i \leq n$, $n < j \leq n+3$, and $w_{ij} = \frac{1}{n} - \frac{3}{n^2}$ for $1 \leq i < j \leq n$ (use Remark 1 and symmetry). By setting $\mu = \frac{1}{n}$ the slack matrix of (2) computes to

$$Z := L_w + \frac{1}{n} ee^T - I = \begin{bmatrix} \frac{3}{n^2} J_n & 0 \\ 0 & \frac{1}{n} J_3 \end{bmatrix} \succeq 0, \tag{6}$$

where J_k denotes the square matrix of all ones of order k. Therefore (w,μ) is feasible for (2), and the objective value is $3n\frac{1}{n} + \frac{n(n-1)}{2}(\frac{1}{n} - \frac{3}{n^2}) = 1 + \frac{n}{2} + \frac{3}{2n}$. Likewise, X is positive semidefinite because it is a Gram matrix. Furthermore, X satisfies all

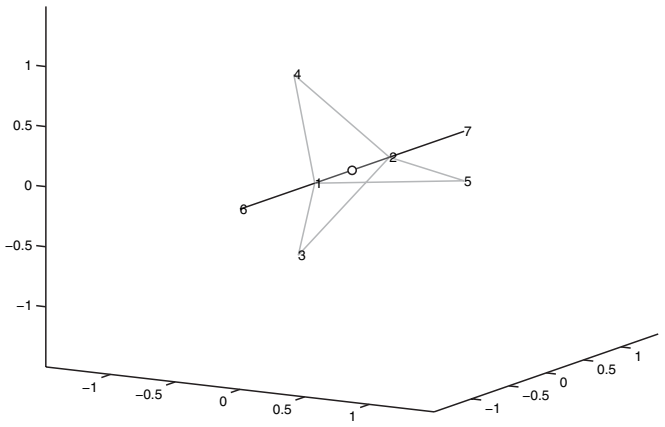

FIG. 4. *A graph with tree width* 2 *and optimal embedding of dimension at least three; see Example* 8 *(the central circle indicates the origin).*

distance constraints and has the same objective value. Hence the primal and the dual solution are optimal.

Now take any optimal embedding v_i, $i = 1, \ldots, n$, so $V = [v_1, \ldots, v_n]$. Since $w > 0$, all optimal embeddings must have all edge lengths equal to one: $\|v_i - v_j\| = 1$ for all $ij \in E(G(n))$. By (6) and semidefinite complementarity it holds that $\langle V^T V, Z \rangle = 0$; thus $\sum_{i=1}^{n} v_i = 0$ and $\sum_{i=n+1}^{n+3} v_i = 0$. So the embedding of K_n must be centrally symmetric like in Example 7, and by the distance constraints each of the three additional vertices must be embedded orthogonal to the embedding of K_n with distance $\bar{r}$ to the origin. As the three vectors have to sum up to zero, this can be done only in two additional dimensions. This completes the proof.

For $n = 1$ the construction yields a star with one central and three exterior nodes, and the bound is also tight. For $n = 2$ the embedding described above is not optimal (it would collapse to the image of the star), for $n = 3$ the embedding is optimal but not of minimal dimension. Without going into details, the cases $n = 2, 3$ can be extended to tight examples by appending to each node of K_n yet another node by a single edge; see Figure 4 for an illustration of the resulting embedding for $n = 2$.

3. The proof of the separator-shadow Theorem 3. Our proof of the separator-shadow theorem will be indirect. Given a feasible embedding that does not satisfy the statement of the theorem, we improve it by folding appropriate components out of the current space in opposite directions (see Figures 6 and 7 below). This requires some preparations. First note that a feasible embedding cannot be full-dimensional, and so there is always space for folding.

OBSERVATION 9. *Given $v_i \in \mathbb{R}^n$ $(i \in N)$ feasible for* (4)*, there is a vector $h \in \mathbb{R}^n$, $\|h\| = 1$, with $v_i \in \mathcal{H} := \{x \in \mathbb{R}^n : h^T x = 0\}$ for $i \in N$.*

Proof. The n vectors v_i satisfy $\sum_{i \in N} v_i = 0$, so they are linearly dependent, and therefore $\dim(\operatorname{span}\{v_1, \ldots, v_n\}) \leq n - 1$. ∎

Given the linear subspace $\mathcal{H} := \{x \in \mathbb{R}^n : h^T x = 0\}$, a normalized $b \in \mathcal{H}$, and some $\beta \in \mathbb{R}$, we next describe the operation of folding the flat half-space $\{x \in \mathcal{H} : b^T x < \beta\}$ along the affine subspace $\mathcal{B} := \{x \in \mathbb{R}^n : h^T x = 0, b^T x = \beta\}$ by rotating it around $\mathcal{B}$ into direction h by an angle γ and show that distances between folded points are not longer than before. The latter fact will help to ensure feasibility with respect to the distance constraints of (4). In stating this operation we make use of

the fact that, due to $\|h\| = \|b\| = 1$ and $h^T b = 0$, the projection of a point $x \in \mathbb{R}^n$ onto $\mathcal{B}$ is computed by

$$p_{\mathcal{B}}(x) = x + (\beta - b^T x)b - h^T x h. \tag{7}$$

Therefore the rotation of $x \in \mathcal{H}$ around $\mathcal{B}$ uses the radius $\|x - p_{\mathcal{B}}(x)\| = |\beta - b^T x|$.

OBSERVATION 10 (folding a flat half-space). *Given $h \in \mathbb{R}^n$, with $\|h\| = 1$, let $\mathcal{H} := \{x \in \mathbb{R}^n : h^T x = 0\}$, and given $b \in \mathcal{H}$, with $\|b\| = 1$, $\beta \in \mathbb{R}$, let $\mathcal{B} := \{x \in \mathcal{H} : b^T x = \beta\}$. Define the continuous map $\varphi : \mathcal{H} \times [-\pi, \pi] \to \mathbb{R}^n$ by*

$$\varphi(x, \gamma) := \begin{cases} p_{\mathcal{B}}(x) - (\beta - b^T x)[b \cos\gamma + h \sin\gamma] & \text{if } b^T x < \beta, \\ x & \text{if } b^T x \geq \beta. \end{cases}$$

For all $\gamma \in [-\pi, \pi]$ and all $x \in \mathcal{H}$,

(i) *$p_{\mathcal{B}}(x) = p_{\mathcal{B}}(\varphi(x, \gamma))$ and $\|x - p_{\mathcal{B}}(x)\| = \|\varphi(x, \gamma) - p_{\mathcal{B}}(x)\|$,*
(ii) *$\|\varphi(x, \gamma) - \varphi(y, \gamma)\| = \|x - y\|$ for all $y \in \mathcal{B}$,*
(iii) *$\|\varphi(x, \gamma) - \varphi(y, \gamma)\| \leq \|x - y\|$ for all $y \in \mathcal{H}$.*

Proof. (i) follows by direct calculation from (7).

If $b^T x \geq \beta$ and $b^T y \geq \beta$, the points are not transformed. If $b^T x < \beta$ and $b^T y \leq \beta$, both points are subject to the same orthogonal transformation which preserves distances. This implies (ii). If, without loss of generality (w.l.o.g.), $b^T x < \beta \leq b^T y$, the intersection of the line segment between x and y and $\mathcal{B}$ determines a unique point $z \in \mathcal{B} \cap \operatorname{conv}\{x, y\}$. The triangle inequality and (ii) yield $\|\varphi(x, \gamma) - y\| \leq \|\varphi(x, \gamma) - z\| + \|z - y\| = \|x - z\| + \|z - y\| = \|x - y\|$, so (iii) holds. ∎

Next, we need to trace the objective value as we fold a subset of nodes. Any such operation can be viewed as a combination of a rotation around the barycenter of the nodes and a uniform translation without rotation. The following two observations show that rotations around the barycenter do not affect the cost function, while the change induced by a translation is easily tracked via the barycenter alone.

OBSERVATION 11 (rotation around the barycenter). *Given $v_i \in \mathbb{R}^n$ ($i \in C \subseteq N$), let $\bar{v} := \frac{1}{|C|} \sum_{i \in C} v_i$, and set $v_i' := Q(v_i - \bar{v}) + \bar{v}$, where Q is an orthogonal matrix. Then*

$$\sum_{i \in C} \|v_i'\|^2 = \sum_{i \in C} \|v_i\|^2 .$$

Proof.

$$\begin{aligned} \sum_{i \in C} \|v_i'\|^2 &= \sum_{i \in C} \|Q(v_i - \bar{v})\|^2 + 2\bar{v}^T Q \underbrace{\sum_{i \in C} (v_i - \bar{v})}_{=0} + |C| \, \|\bar{v}\|^2 \\ &= \sum_{i \in C} \|v_i - \bar{v}\|^2 + 2\bar{v}^T \sum_{i \in C} (v_i - \bar{v}) + |C| \, \|\bar{v}\|^2 \\ &= \sum_{i \in C} \|v_i - \bar{v} + \bar{v}\|^2 \;\; = \;\; \sum_{i \in C} \|v_i\|^2 . \end{aligned}$$ ∎

OBSERVATION 12 (translation). *Given $d \in \mathbb{R}^n$ and $v_i \in \mathbb{R}^n$ ($i \in C \subseteq N$), let $v_i' := v_i + d$ ($i \in C \subseteq N$) and $\bar{v} := \frac{1}{|C|} \sum_{i \in C} v_i$. Then*

$$\sum_{i \in C} \|v_i'\|^2 = \sum_{i \in C} \|v_i\|^2 + |C|(2\bar{v} + d)^T d.$$

Proof. $\sum_{i \in C} \|v_i + d\|^2 = \sum_{i \in C} \|v_i\|^2 + 2|C|\bar{v}^T d + |C| d^T d.$ ∎

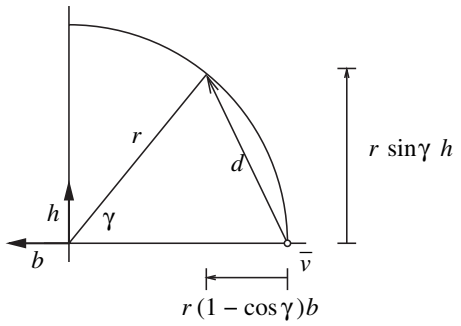

FIG. 5. *Rotation around an affine subspace.*

By putting these together, we now describe the cost change arising in folding a subset of the nodes.

OBSERVATION 13 (the cost of folding). *For h, b, $\beta > 0$, $\mathcal{H}$, $\mathcal{B}$, and φ as in Observation* 10 *and given $v_i \in \{x \in \mathcal{H} : b^T x < \beta\}$ $(i \in C \subseteq N)$, let $\bar{v} := \frac{1}{|C|}\sum_{i\in C} v_i$, $\gamma \in [-\pi, \pi]$, and set for $i \in C$*

$$v_i' := \varphi(v_i, \gamma).$$

Then

$$\sum_{i\in C} \|v_i'\|^2 = \sum_{i\in C} \|v_i\|^2 + 2|C|r(1-\cos\gamma)\beta, \qquad \text{where } r := \beta - b^T\bar{v} > 0.$$

Proof. The rotation around $\mathcal{B}$ may be split into a rotation of the points in C around their barycenter $\bar{v}$ as in Observation 11 and a translation as analyzed in Observation 12. The corresponding displacement for rotating $\bar{v}$ around $\mathcal{B}$ by angle γ is $d := r(\sin\gamma)h + r(1-\cos\gamma)b$, where $r = \beta - b^T\bar{v} > 0$ is the radius (see Figure 5). By $\bar{v}^T h = 0$, $b^T h = 0$, and Observation 12 the cost function changes by

$$\begin{aligned}
|C|(2\bar{v}^T d + d^T d) &= |C|\left(2r(1-\cos\gamma)\bar{v}^T b + r^2[\sin^2\gamma + (1-\cos\gamma)^2]\right)\\
&= |C|\left(2r(1-\cos\gamma)\bar{v}^T b + r^2[2 - 2\cos\gamma]\right)\\
&= 2|C|r(1-\cos\gamma)(\bar{v}^T b + r)\\
&= 2|C|r(1-\cos\gamma)\beta. \qquad \square
\end{aligned}$$

Proof of Theorem 3. Let $h \in \mathbb{R}^n$, with $\|h\| = 1$, satisfy $h^T v_i = 0$ for all $i \in N$ as in Observation 9, and let $\mathcal{S} := \operatorname{conv}\{v_s : s \in S\}$. Assume, for contradiction, that the theorem is not true. Then there is a node in C_1 (call it node 1) and a node in C_2 (call it node 2) embedded in v_1 and v_2, respectively, that satisfy $\operatorname{conv}\{0, v_1\} \cap \mathcal{S} = \operatorname{conv}\{0, v_2\} \cap \mathcal{S} = \emptyset$. By convex separation each set $\operatorname{conv}\{0, v_j\}$ can be separated from $\mathcal{S}$ by a separating hyperplane within the subspace $\operatorname{span}\{v_i : i \in N\}$. So for $j \in \{1, 2\}$ there are vectors $b_j \in \operatorname{span}\{v_i : i \in N\}$ (these satisfy $b_j^T h = 0$) and scalars $\beta_j > 0$ so that $b_j^T x \geq \beta_j$ for all $x \in \mathcal{S}$ and $b_j^T x < \beta_j$ for all $x \in \operatorname{conv}\{0, v_j\}$.

Next we show that we can find a convex combination of these two inequalities by choosing an appropriate $\alpha \in [0, 1]$ so that, for $b(\alpha) := (1-\alpha)b_1 + \alpha b_2$ and $\beta(\alpha) := (1-\alpha)\beta_1 + \alpha\beta_2$, the open half-space $\{x : b(\alpha)^T x < \beta(\alpha)\}$ contains points of both C_1 and C_2 (illustrated in Figure 6). Indeed, for $\alpha = 0$ the half-space contains v_1 and so a point of C_1, for $\alpha = 1$ it contains v_2 which belongs to C_2, and it contains the

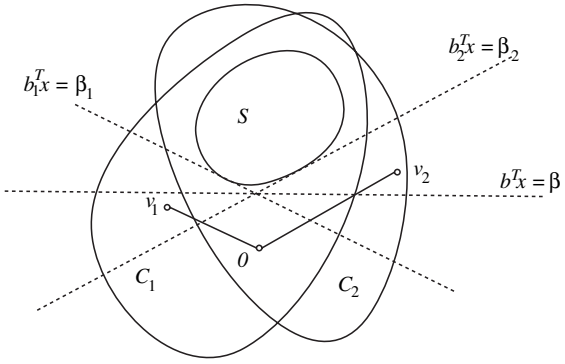

FIG. 6. *Initial setting in case* (i) *of the separator-shadow proof.*

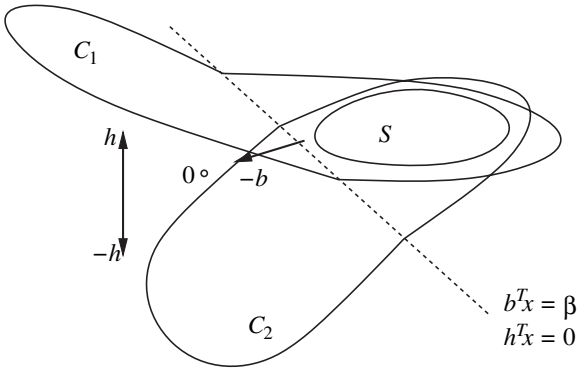

FIG. 7. *Improving movement in case* (i) *of the separator-shadow proof.*

origin for all $\alpha \in [0,1]$. Suppose, for contradiction, that in sweeping α through $[0,1]$ the half-space loses the last point of C_1 before it encounters the first point of C_2 at some particular $\bar{\alpha}$. Then the corresponding hyperplane defined by $b(\bar{\alpha})^T x = \beta(\bar{\alpha}) > 0$ would separate 0 strictly from $\text{conv}\{v_i : i \in N\}$, but this contradicts the feasibility of the v_i as the origin is a convex combination of the v_i by the equilibrium constraint $\frac{1}{n}\sum_{i\in N} v_i = 0$.

Thus we have found $b := b(\alpha)$ and $\beta := \beta(\alpha) > 0$ such that the open half-space $\{x : b^T x < \beta\}$ contains points from C_1 and C_2. Note that $b^T h = 0$ holds, and by scaling b and β we may assume w.l.o.g. that $\|b\| = 1$. Let, for $j \in \{1,2\}$, $M_j := \{i \in C_j : b^T v_i < \beta\}$, $m_j := |M_j| > 0$, and $\bar{v}_j := \frac{1}{m_j}\sum_{i\in M_j} v_i$. Next, consider rotating independently for each j the points in M_j around the affine subspace $\mathcal{B} = \{x \in \mathbb{R}^n : h^T x = 0, b^T x = \beta\}$ as specified in Observation 13. Because the points in M_1 and M_2 are not adjacent and distances to the remaining points are not increased by Observation 10(iii), the edge constraints in (4) remain satisfied. We show that rotating the points in M_1 in direction h and the points in M_2 against direction h by sufficiently small angles γ_1 and γ_2 improves the solution (see Figure 7). As in the proof of Observation 13, denote, for $j \in \{1,2\}$, the radius and displacement of $\bar{v}_j$ by

$$r_j := \beta - b^T \bar{v}_j > 0 \qquad \text{and} \qquad d_j := r_j[(\sin\gamma_j)h + (1-\cos\gamma_j)b],$$

respectively, yielding the improvement $2m_j r_j(1-\cos\gamma_j)\beta$. Rotation j adds $m_j d_j$ to

the barycenter of all points and has to be compensated in order to maintain feasibility with respect to the equilibrium constraint. Shifts of the global barycenter in the direction of h can be avoided by requiring $m_1 d_1^T h = -m_2 d_2^T h$; i.e., given γ_1, choose γ_2 in dependence of γ_1 so that $m_1 r_1 \sin\gamma_1 = -m_2 r_2 \sin\gamma_2$. After carrying out these rotations it therefore remains to shift all points by

$$d := -(m_1 d_1^T b + m_2 d_2^T b)b/n = -[m_1 r_1(1-\cos\gamma_1) + m_2 r_2(1-\cos\gamma_2)]b/n$$

for feasibility in (4). By using Observation 12, the total objective improvement is

$$\begin{aligned}&\sum_{j\in\{1,2\}} 2m_j r_j(1-\cos\gamma_j)\beta - nd^T d\\ &= \sum_{j\in\{1,2\}} 2m_j r_j(1-\cos\gamma_j)\beta - \frac{1}{n}[m_1 r_1(1-\cos\gamma_1) + m_2 r_2(1-\cos\gamma_2)]^2.\end{aligned}$$

This is positive for γ_1 and $\gamma_2(\gamma_1)$ close enough to zero, yielding a contradiction to the optimality of the embedding. ∎

4. Separators containing the origin. The freedom for squeezing optimal embeddings into lower dimensions that will be needed for the proof of Theorem 5 in section 5 is offered by separators that contain the origin in the convex hull of their embedded nodes. Example 6 of the star $K_{1,n}$ may help to illustrate the main idea of the transformations we employ. By alluding to the physical interpretation, we will proceed in two steps:

Step one: We rearrange the cumulated force vectors of the separated node sets so that they are balanced in just one or two additional dimensions with respect to this central separator.

Step two: We show how to combine this with reducing the dimension of each component.

The result will be that either we find a particularly large component that governs the dimension of the entire embedding or no such component exists and we succeed in flattening the embedding to a space exceeding the dimension of the separator by at most two.

We start with an optimal embedding v_i ($i \in N$) of G and, by using Observation 9, fix some $h \in \mathbb{R}^n$, $\|h\| = 1$, so that

$$\{v_i : i \in N\} \subset \mathcal{H} := \{x \in \mathbb{R}^n : h^T x = 0\}.$$

Throughout this section we assume that $S \subset N$ is a separator in G satisfying

$$0 \in \mathcal{S} := \operatorname{conv}\{v_i : i \in S\}$$

and separating G into m sets

$$C_j \subset N, \quad j \in M := \{1, \dots, m\}.$$

Together with S, they form a partition of N, and each edge of G is incident to at most one of the sets C_j. Sometimes we also use sets C_j that contain more than one of the separated connected components. For each $j \in M$, the *cumulated vector* is denoted by

$$\bar{v}_j := \sum_{i\in C_j} v_i.$$

We will not modify the embedding on the linear subspace

$$\mathcal{L} := \operatorname{span} \mathcal{S}$$

spanned by the vectors of the separator. Modifications will be restricted to its orthogonal complement $\mathcal{L}^\perp$, so mostly our illustrations are given with respect to the embedding obtained by projecting the v_i onto $\mathcal{L}^\perp$. In the projected embedding $p_{\mathcal{L}^\perp}(v_i)$ $(i \in N)$, all nodes $i \in S$ are embedded in the origin, and, like in the case of the star, the projected cumulated vectors $p_{\mathcal{L}^\perp}(\bar{v}_j)$, $j \in M$, pointing out of the origin in various directions, are in equilibrium, i.e., $\sum_{j\in M} p_{\mathcal{L}^\perp}(\bar{v}_j) = 0$ by feasibility. We note for later use that, in any such configuration, none of the vectors may be longer than the sum of the others. Indeed, set

$$\bar{\delta}_j := \|p_{\mathcal{L}^\perp}(\bar{v}_j)\| \quad \text{for } j \in M,$$

and then $\sum_{j\in M} p_{\mathcal{L}^\perp}(\bar{v}_j) = 0$ implies that

$$\sum_{j\in M\setminus\{\hat{\jmath}\}} \bar{\delta}_j \geq \bar{\delta}_{\hat{\jmath}} \quad \text{for all } \hat{\jmath} \in M. \tag{8}$$

The following fundamental fact will be used repeatedly (the equilibrium constraint may get violated initially, but this will be taken care of later). For each $j \in M$ the vector $p_{\mathcal{L}^\perp}(\bar{v}_j)$ can be rotated around the origin freely within $\mathcal{L}^\perp$ while preserving all distances between nodes in $C_j \cup S$ by applying to all $p_{\mathcal{L}^\perp}(v_i)$, $i \in C_j$, an orthogonal transformation Q_j with $\mathcal{L}$ contained in its invariant subspace (i.e., Q_j restricted to $\mathcal{L}$ is the identity). Furthermore, such transformations do not influence the objective value, as distances to $0 \in \mathcal{L}$ are preserved. We complete step one by showing that the vectors $p_{\mathcal{L}^\perp}(\bar{v}_j)$ with their lengths $\bar{\delta}_j$ can always be rotated into at most three normalized directions d_1, d_2, d_3 so that the equilibrium constraint holds again in $\mathcal{L}^\perp$ (by definition, the equilibrium constraint stays valid within $\mathcal{L}$).

OBSERVATION 14. *Given scalars $\bar{\delta}_j \geq 0$ for $j \in M = \{1, \dots, m\}$, $m \geq 2$, so that, for each $\hat{\jmath} \in M$, $\sum_{j\in M\setminus\{\hat{\jmath}\}} \bar{\delta}_j \geq \bar{\delta}_{\hat{\jmath}}$. There exist vectors $d_1, d_2, d_3 \in \mathbb{R}^2$ with $\|d_1\| = \|d_2\| = \|d_3\| = 1$ and an assignment $\kappa : M \to \{1, 2, 3\}$ so that $\sum_{j\in M} \bar{\delta}_j d_{\kappa(j)} = 0$. This also holds if in addition $|\{j \in M : \kappa(j) = 1\}| = 1$ is required.*

Proof. If $|M| = 2$, then $\bar{\delta}_1 = \bar{\delta}_2$, and the claim holds for $d_1 = -d_2$ and κ correspondingly. Otherwise let $\hat{\jmath} \in M$ be the smallest number so that $\sum_{j=1}^{\hat{\jmath}-1} \bar{\delta}_j < \frac{1}{2}\sum_{j\in M} \bar{\delta}_j \leq \sum_{j=1}^{\hat{\jmath}} \bar{\delta}_j$, and set $\kappa(\hat{\jmath}) = 1$, $\kappa(j) = 2$ for $\hat{\jmath} > j \in M$ and $\kappa(j) = 3$ for $\hat{\jmath} < j \in M$. Set $\check{\delta}_h := \sum_{j\in M,\kappa(j)=h} \bar{\delta}_j$, $h \in \{1, 2, 3\}$. Note that $\check{\delta}_1 \leq \check{\delta}_2 + \check{\delta}_3$, $\check{\delta}_2 \leq \check{\delta}_1 + \check{\delta}_3$, $\check{\delta}_3 \leq \check{\delta}_1 + \check{\delta}_2$. Assume, w.l.o.g., that $\check{\delta}_1 \leq \check{\delta}_2 \leq \check{\delta}_3$. Set $d_1(\alpha) := (\cos\alpha, -\sin\alpha)^T$ for $0 \leq \alpha \leq \pi$, $d_2(\alpha) := (\cos\gamma(\alpha), \sin\gamma(\alpha))^T$, where $\gamma(\alpha)$ is defined implicitly by $\check{\delta}_2 \sin\gamma(\alpha) = \check{\delta}_1 \sin\alpha$, and $d_3 = (-1, 0)^T$. Then $b(\alpha) := \check{\delta}_1 d_1(\alpha) + \check{\delta}_2 d_2(\alpha) + \check{\delta}_3 d_3$ satisfies $[b(\alpha)]_2 = 0$ for all $0 \leq \alpha \leq \pi$, $[b(0)]_1 \geq 0$, and $[b(\pi)]_1 \leq 0$, so by continuity of $b(\alpha)$ there is an $\hat{\alpha} \in [0, \pi]$ with $b(\hat{\alpha}) = 0$. ∎

Let us now turn towards step two and try to reduce the dimension of the node sets. If $\operatorname{span}\{v_i : i \in C_j\} \subseteq \mathcal{L}$ for $j \in M$, then the embedding is good enough for our purposes. Assume therefore that there is some $j \in M$ with $\operatorname{span}\{v_i : i \in C_j\} \not\subseteq \mathcal{L}$. In manipulating the embedding of C_j in Observations 15–19 we will again apply only orthogonal transformations (sometimes we will simultaneously use separate ones for each point in C_j) that contain $\mathcal{L}$ in their invariant subspace. Therefore all distances of points in C_j will preserve their distance to the origin and to the embedding of S. In

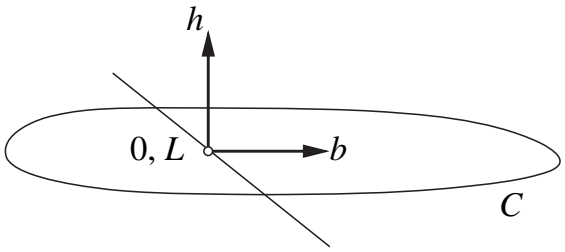

FIG. 8. *Initial setting before the transformation of C in Observations* 15–19.

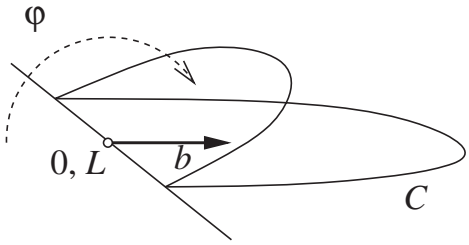

FIG. 9. *φ folds C into the half-space specified by b (Observation* 15*).*

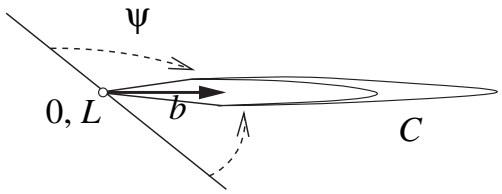

FIG. 10. *ψ collapses C into the flat half-space spanned by $\mathcal{L}$ and direction b (Observation* 17*).*

consequence, optimality is guaranteed if feasibility can be maintained. In particular, feasibility of the distance constraints is ensured whenever distances within C_j are not increased. Our manipulations may, however, increase the length of $p_{\mathcal{L}^\perp}(\bar{v}_j)$ and thus $\bar{\delta}_j$. But by Observation 14 it suffices that condition (8) is satisfied at the end in order to restore the equilibrium constraint, as well.

Before giving the transformations in detail, we outline the main idea by sketching the underlying geometric intuition. The goal is to squeeze the entire embedding of component C_j into the flat half-space spanned by $\mathcal{L}$ and one additional direction $b_j \in \mathcal{H} \cap \mathcal{L}^\perp$, with $\|b_j\| = 1$. This works as follows. The transformation of Observation 15 folds all nodes into the flat half-space $\{x \in \mathcal{H} : b^T x \geq 0\}$ via Observation 10 (put $b = b_j$ and $\beta = 0$)—see Figures 8 and 9; this leaves $\mathcal{L} \subseteq \mathcal{B}$ untouched as required. Then the transformation of Observation 17 collapses this flat half-space into the even flatter half-space cone$(\mathcal{L} \cup \{b_j\})$ as if collapsing an umbrella by rotating the ribs towards its handle (see Figure 10). In Observation 19 these two operations are concatenated to a continuous transformation $u_i(t)$ of the embedding for $t \in [0, 1]$, and we will see via Observations 16 and 18 that the norm $\|p_{\mathcal{L}^\perp}(\bar{u}_j(t))\|$ of the cumulated vector $\bar{u}_j(t) = \sum_{i \in C_j} u_i(t)$ is nondecreasing throughout, so that we can easily stop the transformation at an appropriate t to ensure condition (8). We start with the folding operation.

OBSERVATION 15 (transformation part 1, folding). *Given $j \in M$ and $b_j \in \mathcal{H} \cap \mathcal{L}^\perp$, with $\|b_j\| = 1$, define $\varphi_i : [0,1] \to \mathbb{R}^n$ for $i \in C_j$ by*

$$\varphi_i(t) := \begin{cases} v_i - (v_i^T b_j) b_j + (v_i^T b_j)[b_j \cos t\pi + h \sin t\pi] & \text{if } v_i^T b_j < 0, \\ v_i & \text{if } v_i^T b_j \geq 0. \end{cases}$$

Then, for $i \in C_j$,

(i) $\varphi_i(0) = v_i$,

(ii) $\varphi_i(1) \in \{x \in \mathcal{H} : b_j^T x \geq 0\}$,

and for all $t \in [0,1]$ it holds that

(iii) $p_{\mathcal{L}}(v_i) = p_{\mathcal{L}}(\varphi_i(t))$ *and* $\|p_{\mathcal{L}^\perp}(v_i)\| = \|p_{\mathcal{L}^\perp}(\varphi_i(t))\|$,

(iv) $\|\varphi_i(t) - v\| = \|v_i - v\|$ *for* $v \in \mathcal{L} \supseteq \{v_s : s \in S\}$,

(v) $\|\varphi_i(t) - \varphi_k(t)\| \leq \|v_i - v_k\|$ *for* $k \in C_j$.

Proof. (i) and (ii) follow from direct calculation and $v_i \in \mathcal{H}$; (iii)–(v) follow from Observation 10(i)–(iii) by using $b = b_j$, $\beta = 0$, $\varphi_i(t) = \varphi(v_i, t\pi)$, and the fact that $\mathcal{S} \subseteq \mathcal{L} \subseteq \mathcal{B}$. ∎

Next, we show that throughout this first transformation the length of the projected cumulated vector increases.

OBSERVATION 16. *For φ_i ($i \in C_j$) as defined in Observation 15, define $\bar{\varphi}_j : [0,1] \to \mathbb{R}^n$ by*

$$\bar{\varphi}_j(t) := \sum_{i \in C_j} \varphi_i(t).$$

The length $\|p_{\mathcal{L}^\perp}(\bar{\varphi}_j(t))\|$ is nondecreasing in $t \in [0,1]$.

Proof. The choice of b_j ensures that $\mathcal{B} := \{x \in \mathcal{H} : b_j^T x = 0\} \supseteq \mathcal{L}$ and $\mathcal{B}^\perp = \operatorname{span}\{h, b_j\}$. By definition of the φ_i in Observation 15 we obtain

$$\begin{aligned} \|p_{\mathcal{L}^\perp}(\bar{\varphi}_j(t))\|^2 &= \|p_{\mathcal{L}^\perp}(p_{\mathcal{B}}(\bar{\varphi}_j(0)))\|^2 + \|p_{\mathcal{B}^\perp}(\bar{\varphi}_j(t))\|^2 \\ &= \|p_{\mathcal{L}^\perp}(p_{\mathcal{B}}(\bar{\varphi}_j(0)))\|^2 \\ &\quad + \left\| \sum_{i \in C_j, v_i^T b_j < 0} (v_i^T b_j)[b_j \cos t\pi + h \sin t\pi] + \sum_{i \in C_j, v_i^T b_j \geq 0} (v_i^T b_j) b_j \right\|^2. \end{aligned}$$

As b_j and h are orthogonal it remains to study the monotonicity of

$$\begin{aligned} &\left[\sum_{i \in C_j, v_i^T b_j < 0} v_i^T b_j \cos t\pi + \sum_{i \in C_j, v_i^T b_j \geq 0} v_i^T b_j \right]^2 + \left[\sum_{i \in C_j, v_i^T b_j < 0} v_i^T b_j \sin t\pi \right]^2 \\ &= \left[\sum_{i \in C_j, v_i^T b_j < 0} v_i^T b_j \right]^2 (\cos^2 t\pi + \sin^2 t\pi) + \left[\sum_{i \in C_j, v_i^T b_j \geq 0} v_i^T b_j \right]^2 \\ &\quad + 2 \underbrace{\left[\sum_{i \in C_j, v_i^T b_j < 0} v_i^T b_j \right] \left[\sum_{i \in C_j, v_i^T b_j \geq 0} v_i^T b_j \right]}_{\leq 0} \cos t\pi. \end{aligned}$$

The last term is clearly nondecreasing. ∎

The collapsing transformation starts from the points $\varphi_i(1)$ and runs as follows.

OBSERVATION 17 (transformation part 2, collapsing). *Given the setting of Observation* 15, *for* $i \in C_j$, *set* $\delta_i := \|p_{\mathcal{L}^\perp}(\varphi_i(1))\|$, *determine* $0 \le \gamma_i \le \frac{\pi}{2}$ *and* $q_i \in \mathcal{L}^\perp$, $q_i^T b_j = 0$, $\|q_i\| = 1$ *so that* $p_{\mathcal{L}^\perp}(\varphi_i(1)) = \delta_i(q_i \cos\gamma_i + b_j \sin\gamma_i)$, *and define* $\psi_i : [0,1] \to \mathbb{R}^n$ *by*

$$\psi_i(t) := p_{\mathcal{L}}(\varphi_i(1)) + \delta_i \left[q_i \cos\left(\gamma_i + t\left[\frac{\pi}{2} - \gamma_i\right]\right) + b_j \sin\left(\gamma_i + t\left[\frac{\pi}{2} - \gamma_i\right]\right)\right].$$

Then, for $i \in C_j$,

(i) $\psi_i(0) = \varphi_i(1)$,

(ii) $\psi_i(1) = p_{\mathcal{L}}(v_i) + \|p_{\mathcal{L}^\perp}(v_i)\| b_j \in \mathcal{L} + \{\beta b_j : \beta \ge 0\}$,

and for all $t \in [0,1]$ *it holds that*

(iii) $p_{\mathcal{L}}(v_i) = p_{\mathcal{L}}(\psi_i(t))$ *and* $\|p_{\mathcal{L}^\perp}(v_i)\| = \|p_{\mathcal{L}^\perp}(\psi_i(t))\|$,

(iv) $\|\psi_i(t) - v\| = \|v_i - v\|$ *for* $v \in \mathcal{L} \supseteq \{v_s : s \in S\}$,

(v) $\|\psi_i(t) - \psi_k(t)\| \le \|v_i - v_k\|$ *for* $k \in C_j$.

Proof. First note that Observation 15(iii) implies that $p_{\mathcal{L}}(v_i) = p_{\mathcal{L}}(\varphi_i(1))$ and $\delta_i = \|p_{\mathcal{L}^\perp}(v_i)\|$. Now (i) and (ii) follow from direct calculation, and (iii) and (iv) are proved in the same way as (i) and (ii) of Observation 10. It remains to prove (v).

Because of Observation 15(v) it suffices to prove that $\|\psi_i(t) - \psi_k(t)\|^2 \le \|\varphi_i(1) - \varphi_k(1)\|^2$ for $i, k \in C_j$. For this we need to show that $\psi_i(t)^T \psi_k(t) \ge \varphi_i(1)^T \varphi_k(1)$, which leads to the condition

$$\begin{aligned} f_{ik}(t) &:= (q_i^T q_k)\left[\cos\left(\gamma_i + t\left[\frac{\pi}{2} - \gamma_i\right]\right)\cos\left(\gamma_k + t\left[\frac{\pi}{2} - \gamma_k\right]\right)\right] \\ &\quad + \sin\left(\gamma_i + t\left[\frac{\pi}{2} - \gamma_i\right]\right)\sin\left(\gamma_k + t\left[\frac{\pi}{2} - \gamma_k\right]\right) \\ &\ge (q_i^T q_k)[\cos\gamma_i \cos\gamma_k] + \sin\gamma_i \sin\gamma_k = f_{ik}(0). \end{aligned} \tag{9}$$

We prove that $f_{ik}(t)$ is nondecreasing in $t \in [0,1]$. In the case $q_i^T q_k < 0$, both cosine terms in $f_{ik}(t)$ are nonincreasing, and the sine terms are nondecreasing. In the remaining case we use the angle addition formulas to find

$$\begin{aligned} f_{ik}(t) &= q_i^T q_k \cos((1-t)[\gamma_i - \gamma_k]) \\ &\quad + (1 - q_i^T q_k)\sin\left(\gamma_i + t\left[\frac{\pi}{2} - \gamma_i\right]\right)\sin\left(\gamma_k + t\left[\frac{\pi}{2} - \gamma_k\right]\right). \end{aligned}$$

But $0 \le q_i^T q_k \le 1$, and so the cosine and sine terms are nondecreasing. ∎

Again, we continue with showing that during this transformation the length of the projected cumulated vector is nondecreasing.

OBSERVATION 18. *For* ψ_i $(i \in C_j)$ *as defined in Observation* 17, *define* $\bar{\psi}_j : [0,1] \to \mathbb{R}^n$ *by*

$$\bar{\psi}_j(t) := \sum_{i \in C_j} \psi_i(t).$$

The length $\|p_{\mathcal{L}^\perp}(\bar{\psi}_j(t))\|$ *is nondecreasing in* $t \in [0,1]$.

Proof. By using the functions f_{ik} introduced in (9) we may write

$$\begin{aligned} \left\| \sum_{i \in C_j} p_{\mathcal{L}^\perp}(\psi_i(t)) \right\|^2 &= \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(\psi_i(t))\|^2 + \sum_{i,k \in C_j, i<k} 2(p_{\mathcal{L}^\perp}(\psi_i(t)))^T (p_{\mathcal{L}^\perp}(\psi_k(t))) \\ &= \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(\psi_i(t))\|^2 + \sum_{i,k \in C_j, i<k} \delta_i \delta_k f_{ik}(t), \end{aligned}$$

and we have shown in the proof of Observation 17 that each $f_{ik}(t)$ is nondecreasing in $t \in [0,1]$. ∎

We concatenate both transformations into one and summarize our findings on this collapsing transformation.

OBSERVATION 19 (collapsing transformation). *Given $j \in M$ and $b_j \in \mathcal{H} \cap \mathcal{L}^\perp$, with $\|b_j\| = 1$, define $u_i : [0,1] \to \mathbb{R}^n$ for $i \in C_j$ by*

$$u_i(t) := \begin{cases} \varphi_i(2t) & \text{for } t \in [0, \frac{1}{2}], \\ \psi_i(2[t - \frac{1}{2}]) & \text{for } t \in (\frac{1}{2}, 1], \end{cases} \tag{10}$$

with φ_i and ψ_i as given in Observations 15 and 17. Then, for $i \in C_j$,

(i) $u_i(0) = v_i$,

(ii) $u_i(1) = p_{\mathcal{L}}(v_i) + \|p_{\mathcal{L}^\perp}(v_i)\| b_j \in \mathcal{L} + \{\beta b_j : \beta \geq 0\}$,

and for all $t \in [0,1]$ it holds that

(iii) $p_{\mathcal{L}}(v_i) = p_{\mathcal{L}}(u_i(t))$ *and* $\|p_{\mathcal{L}^\perp}(v_i)\| = \|p_{\mathcal{L}^\perp}(u_i(t))\|$,

(iv) $\|u_i(t) - v\| = \|v_i - v\|$ *for* $v \in \mathcal{L} \supseteq \{v_s : s \in S\}$,

(v) $\|u_i(t) - u_k(t)\| \leq \|v_i - v_k\|$ *for* $k \in C_j$.

Furthermore, for

$$\bar{u}_j(t) := \sum_{i \in C_j} u_i(t)$$

the length $\|p_{\mathcal{L}^\perp}(\bar{u}_j(t))\|$ is nondecreasing in $t \in [0,1]$ and

$$\|p_{\mathcal{L}^\perp}(\bar{u}_j(1))\| = \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(v_i)\|.$$

Proof. The result follows from Observations 15, 17, 16, and 18. ∎

Suppose that the lengths

$$\tilde{\delta}_j := \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(v_i)\| \qquad (j \in M)$$

of the collapsed sets satisfy the condition corresponding to (8). Then, in order to obtain an embedding that is also in equilibrium with respect to the subspace $\mathcal{L}^\perp$, we have to choose only the collapsing direction b_j of each component C_j according to the vectors d_k (embedded in $\mathcal{L}^\perp$) with the assignment κ of Observation 14, $b_j = d_{\kappa(j)}$. This will yield an optimal embedding of dimension at most $\dim \mathcal{L} + 2$ as described in the following lemma.

LEMMA 20. *Let $v_i \in \mathbb{R}^n$ for $i \in N$ be an optimal solution of (4) for a connected graph $G = (N, E)$, and let $S \subset N$, with $0 \in \mathcal{S} := \operatorname{conv}\{v_s : s \in S\}$, be a separator in G giving rise to separated sets $C_j \subset N$, $j \in M := \{1, \ldots, m\}$. Put $\mathcal{L} := \operatorname{span} \mathcal{S}$ and, for $j \in M$, $\tilde{\delta}_j := \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(v_i)\|$.*

If $\tilde{\delta}_{\hat{\jmath}} \leq \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$ for all $\hat{\jmath} \in M$, then there exist vectors $d_1, d_2, d_3 \in \mathcal{L}^\perp$, $\|d_1\| = \|d_2\| = \|d_3\| = 1$, with $\dim \operatorname{span}\{d_1, d_2, d_3\} \leq 2$, $b_j \in \{d_1, d_2, d_3\}$, $j \in M$, so that the embedding v'_i, $i \in N$, with

$$v'_i := \begin{cases} v_i & \text{for } \ i \in S, \\ p_{\mathcal{L}}(v_i) + \|p_{\mathcal{L}^\perp}(v_i)\| b_j & \text{for } \ i \in C_j, \end{cases}$$

is also an optimal embedding of (4). Furthermore, such an embedding exists with $b_j = d_1$ for at most one $j \in M$ and satisfies $\dim \operatorname{span}\{v'_i : i \in N\} \leq \dim \mathcal{L} + 2 \leq |S| + 1$.

Proof. Observe that $\dim \mathcal{L} \le |S| - 1$ because by $0 \in \mathcal{S}$ the v_i $(i \in S)$ are linearly dependent. Choose h, and define $\mathcal{H}$ as specified in Observation 9. If $\tilde{\delta}_j = 0$ for all $j \in M$, then the statement holds for $d_1 = d_2 = d_3 = h$ because $v'_i = v_i \in \mathcal{L}$ for $i \in N$. So we may assume that $\tilde{\delta}_j > 0$ for at least two $j \in M$. In the case $\dim(\mathcal{H} \cap \mathcal{L}^\perp) = 1$ we must have $|S| = n - 2$, $m = 2$, and $|C_1| = |C_2| = 1$, so $b_1 = d_1 = -b_2 = -d_2 = -d_3$, with $d_1 = p_{\mathcal{L}^\perp}(v_i)/\|p_{\mathcal{L}^\perp}(v_i)\|$, satisfies all requirements. It remains to consider the case $\dim(\mathcal{H} \cap \mathcal{L}^\perp) \ge 2$.

By Observation 14 we find three vectors $d_1, d_2, d_3 \in \mathcal{H} \cap \mathcal{L}^\perp$ of norm one and an assignment $\kappa : M \to \{1, 2, 3\}$ satisfying $\sum_{j \in M} \tilde{\delta}_j d_{\kappa(j)} = 0$ and $\{j \in M : \kappa(j) = 1\} = 1$. For $j \in M$ set $b_j = d_{\kappa(j)}$, and let $u_i(t)$, $i \in C_j$, be the transformations of Observation 19 for the respective b_j. Then $v'_i = u_i(1)$ for $i \in C_j$, $j \in M$ by Observation 19(ii). The distance constraints are satisfied for the new embedding because for $\{i, k\} \in E$

$$\begin{array}{ll} i, k \in S: & \|v'_i - v'_k\| = \|v_i - v_k\| \text{ by definition,} \\ i \in C_j \text{ for some } j \in M, k \in S: & \|v'_i - v'_k\| = \|v_i - v_k\| \text{ by Observation 19(iv),} \\ i, k \in C_j \text{ for some } j \in M: & \|v'_i - v'_k\| \le \|v_i - v_k\| \text{ by Observation 19(v).} \end{array}$$

The equilibrium constraint is satisfied on $\mathcal{L}$, because $p_{\mathcal{L}}(v_i) = p_{\mathcal{L}}(v'_i)$ for all $i \in N$ (by definition for $i \in S$ and by Observation 19(iii) otherwise). It is also satisfied on $\mathcal{L}^\perp$, because

$$\begin{aligned} \sum_{i \in N} p_{\mathcal{L}^\perp}(v'_i) &= \sum_{i \in S} \underbrace{p_{\mathcal{L}^\perp}(v'_i)}_{=0} + \sum_{j \in M} \sum_{i \in C_j} p_{\mathcal{L}^\perp}(v'_i) \\ &= \sum_{j \in M} \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(v_i)\| b_j = \sum_{j \in M} \tilde{\delta}_j d_{\kappa(j)} = 0 \end{aligned}$$

by construction of the d_j. Finally, the objective value has not changed because $\|v_i\| = \|v'_i\|$ for all $i \in N$ (by definition for $i \in S$ and by Observation 19(iii) otherwise). ∎

If one set $\hat{\jmath} \in M$ is "heavier" than the other sets, $\tilde{\delta}_{\hat{\jmath}} > \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$, the need to recover feasibility in the equilibrium constraint will not allow us to collapse $\hat{\jmath}$ in full. We can, however, collapse all other sets and compensate this by carrying through the transformation in $\hat{\jmath}$ up to the $t_{\hat{\jmath}} \in [0, 1]$ when $\|p_{\mathcal{L}^\perp}(\bar{u}_{\hat{\jmath}}(t_{\hat{\jmath}}))\| = \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$. Even though this may lead to a slight increase in the overall dimension if $t_{\hat{\jmath}} < \frac{1}{2}$, it will help later to reduce the number of components about which we have to worry.

LEMMA 21. *Given the setting of Lemma 20 assume that there is a $\hat{\jmath} \in M$ with $\tilde{\delta}_{\hat{\jmath}} > \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$. There exists an $h \in \operatorname{span}\{v_i : i \in N\}^\perp$ and an optimal embedding v'_i $(i \in N)$ of (4), with*

$$\begin{array}{ll} v'_i \in \operatorname{span}\{h, v_i : i \in C_{\hat{\jmath}}\} & \text{for } i \in C_{\hat{\jmath}}, \\ v'_i = v_i & \text{for } i \in S, \\ v'_i = p_{\mathcal{L}}(v_i) + \|p_{\mathcal{L}^\perp}(v_i)\| \bar{b} & \text{for } i \in C_j, \text{ with } j \in M \setminus \{\hat{\jmath}\}, \end{array}$$

where $\bar{b} := -\frac{p_{\mathcal{L}^\perp}(\bar{v}'_{\hat{\jmath}})}{\|p_{\mathcal{L}^\perp}(\bar{v}'_{\hat{\jmath}})\|}$ if $\bar{v}'_{\hat{\jmath}} = \sum_{i \in C_{\hat{\jmath}}} v'_i \notin \mathcal{L}$ and $\bar{b} := 0$ otherwise.

Furthermore, if there is some direction $\hat{b} \in \operatorname{span}\{v_i : i \in C_{\hat{\jmath}}\} \cap \mathcal{L}^\perp \setminus \{0\}$ with $\hat{b}^T v_i \ge 0$ for $i \in C_{\hat{\jmath}}$, then such an embedding exists with $v'_i \in \operatorname{span}\{v_i : i \in C_{\hat{\jmath}}\}$ for $i \in C_{\hat{\jmath}}$.

Proof. If $\sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j = 0$, then we may choose $h = \bar{b} = 0$ and not transform the embedding at all to obtain the result. Therefore assume that $\sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j \ne 0$.

Choose h, and define $\mathcal{H}$ as specified in Observation 9. Since $\tilde{\delta}_{\hat{\jmath}} > 0$, we can find a $b_{\hat{\jmath}} \in \mathcal{L}^{\perp} \cap \operatorname{span}\{v_i : i \in C_{\hat{\jmath}}\}$ with $\|b_{\hat{\jmath}}\| = 1$. Let $u_i(t)$ $(i \in C_{\hat{\jmath}})$ denote the transformations of Observation 19 for this $b_{\hat{\jmath}}$, and set $\bar{u}_{\hat{\jmath}}(t) := \sum_{i \in C_{\hat{\jmath}}} u_i(t)$. By Observation 19, the function $\|p_{\mathcal{L}^{\perp}}(\bar{u}_{\hat{\jmath}}(t))\|$ is continuous and nondecreasing. As the equilibrium constraint is satisfied for the v_i $(i \in N)$, we have

$$\begin{aligned}
\|p_{\mathcal{L}^{\perp}}(\bar{u}_{\hat{\jmath}}(0))\| &\overset{\text{Observation19(i)}}{=} \left\| \sum_{i \in C_{\hat{\jmath}}} p_{\mathcal{L}^{\perp}}(v_i) \right\| \overset{\text{equilib.}}{=} \left\| \sum_{i \in N \setminus C_{\hat{\jmath}}} p_{\mathcal{L}^{\perp}}(v_i) \right\| \\
&\overset{p_{\mathcal{L}^{\perp}}(v_i)=0 \ (i \in S)}{=} \left\| \sum_{j \in M \setminus \{\hat{\jmath}\}} \sum_{i \in C_j} p_{\mathcal{L}^{\perp}}(v_i) \right\| \\
&\leq \sum_{j \in M \setminus \{\hat{\jmath}\}} \left\| \sum_{i \in C_j} p_{\mathcal{L}^{\perp}}(v_i) \right\| \overset{\text{(by def.)}}{=} \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j
\end{aligned}$$

and, by assumption, $\|p_{\mathcal{L}^{\perp}}(\bar{u}_{\hat{\jmath}}(1))\| = \tilde{\delta}_{\hat{\jmath}} > \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$. So there is a $t_{\hat{\jmath}} \in [0,1]$ with

$$\|p_{\mathcal{L}^{\perp}}(\bar{u}_{\hat{\jmath}}(t_{\hat{\jmath}}))\| = \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j. \tag{11}$$

Choose $v'_i = u_i(t_{\hat{\jmath}})$ for $i \in C_{\hat{\jmath}}$, and put

$$\bar{v}'_{\hat{\jmath}} = \sum_{i \in C_{\hat{\jmath}}} v'_i = \bar{u}_{\hat{\jmath}}(t_{\hat{\jmath}}) \quad \text{and} \quad \bar{b} = -p_{\mathcal{L}^{\perp}}(\bar{v}'_{\hat{\jmath}}) / \|p_{\mathcal{L}^{\perp}}(\bar{v}'_{\hat{\jmath}})\|. \tag{12}$$

For $j \in M \setminus \{\hat{\jmath}\}$ choose $b_j = \bar{b}$, and let $u_i(t)$, $i \in C_j$, be the transformations of Observation 19 for the respective b_j. Then, by Observation 19(ii), $v'_i = u_i(1)$ for $i \in C_j$, with $j \in M \setminus \{\hat{\jmath}\}$, satisfies the requirements of the lemma. The equilibrium constraint is satisfied for the embedding v'_i, $i \in N$, because it holds on $\mathcal{L}$ due to $p_{\mathcal{L}}(v_i) = p_{\mathcal{L}}(v'_i)$ for $i \in N$ by Observation 19(iii) and it holds on $\mathcal{L}^{\perp}$, because

$$\begin{aligned}
\sum_{i \in N} p_{\mathcal{L}^{\perp}}(v'_i) &= \sum_{i \in S} \underbrace{p_{\mathcal{L}^{\perp}}(v'_i)}_{=0} + \sum_{i \in C_{\hat{\jmath}}} p_{\mathcal{L}^{\perp}}(v'_i) + \sum_{j \in M \setminus \{\hat{\jmath}\}} \sum_{i \in C_j} p_{\mathcal{L}^{\perp}}(v'_i) \\
&\overset{\text{(by def.)}}{=} p_{\mathcal{L}^{\perp}}(\bar{v}'_{\hat{\jmath}}) + \sum_{j \in M \setminus \{\hat{\jmath}\}} \sum_{i \in C_j} \|p_{\mathcal{L}^{\perp}}(v_i)\| \bar{b} \\
&\overset{(12)}{=} \left(\|p_{\mathcal{L}^{\perp}}(\bar{v}'_{\hat{\jmath}})\| - \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j \right) \frac{p_{\mathcal{L}^{\perp}}(\bar{v}'_{\hat{\jmath}})}{\|p_{\mathcal{L}^{\perp}}(\bar{v}'_{\hat{\jmath}})\|} \overset{(11)}{=} 0.
\end{aligned}$$

The feasibility of v'_i, $i \in N$, with respect to the distance constraints and optimality follows from Observation 19(iv) and (v) as in the proof of Lemma 20.

Finally, suppose that $\hat{b}$ exists as described in the statement of the lemma. Then we may choose $b_{\hat{\jmath}} = \frac{\hat{b}}{\|\hat{b}\|}$ and, by construction (10) of the u_i $(i \in C_{\hat{\jmath}})$, $u_i(t) = v_i$ for $t \in [0, \frac{1}{2}]$ (see Observation 15 for φ_i) and $u_i(t) \in \mathcal{L} + \operatorname{span}\{\hat{b}, v_i\}$ for $t \in [\frac{1}{2}, 1]$ (see Observation 17 for ψ_i). This completes the proof. □

Remark 22. A solution corresponding to the modified solution of this lemma is not necessarily an optimal embedding of minimal dimension. Consider, e.g., the graph

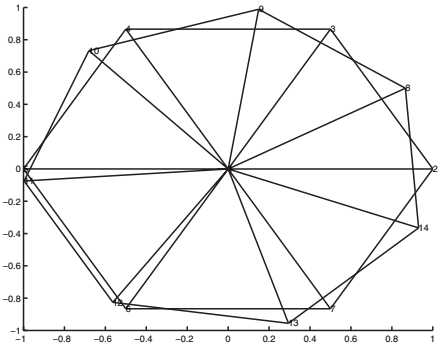

FIG. 11. *Optimal two-dimensional embedding of two wheels with identical hub; see Remark* 22. *The construction of the proof of Lemma* 21 *would yield a three-dimensional embedding.*

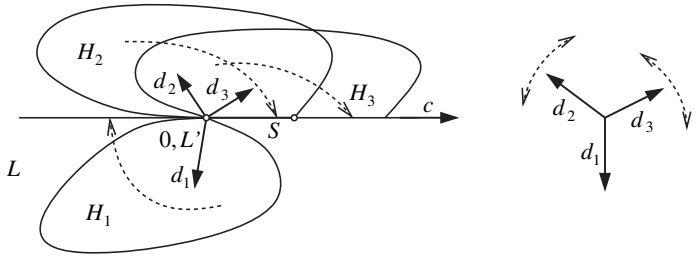

FIG. 12. *Transformation in the proof of Lemma* 25.

consisting of two wheels with identical hub, and rims of k and $k+1$ nodes with $k \geq 6$; see Figure 11.

Lemma 21 does not provide a bound on the dimension of the embedding but will tell us which component we have to think about next in order to get to such a bound. In order to arrive at the result of Theorem 5, we will need a further refinement of Lemma 20 in the case $\dim \mathcal{L} = |S| - 1$. In order to set up the scene, assume that the v_i $(i \in N)$ are already embedded in dimension $|S|+1$ as described in Lemma 20 with each node set C_j collapsed to some flat half-space $\mathcal{L} + \{\delta d_{\kappa(j)} : \delta \geq 0\}$, and denote by H_1 the set C_j that is the only one assigned to direction d_1. We are interested in the case that H_1 is not connected to some $\hat{s} \in S$, so $S' := S \backslash \{\hat{s}\}$ is a separator for H_1 in G. By Theorem 3 we must have $0 \in \mathcal{S}' := \operatorname{conv}\{v_i : i \in S'\}$, with $\mathcal{L}' := \operatorname{span} \mathcal{S}'$ a linear subspace of dimension $\dim(\mathcal{L}') = \dim(\mathcal{L}) - 1$ and $v_{\hat{s}} \neq 0$ (otherwise the dimension of the embedding would be $|S|$ already). Figure 12 depicts the situation when projected onto $\mathcal{L}'^{\perp}$ with $H_i := \bigcup_{j \in M:\kappa(j)=i} C_j$ the set of nodes which are embedded in direction d_i, $i = 2, 3$. It will turn out that the transformation indicated in this illustration will yield an optimal embedding of dimension at most $|S|$, so we can get rid of one more dimension. For this purpose we introduce yet another transformation comparable to closing a fan; see Figure 13. In the following observation think of vector g as spanning the missing direction $\pm p_{\mathcal{L}'^{\perp}}(v_{\hat{s}}) / \|p_{\mathcal{L}'^{\perp}}(v_{\hat{s}})\|$ in $\mathcal{L}$ and d as the additional direction d_j that spans the embedding of node set H_j.

OBSERVATION 23. *Given a linear subspace* $\mathcal{L}' \subset \mathbb{R}^n$, *vectors* $d, g \in \mathcal{L}'^{\perp}$, *with* $\|d\| = \|g\| = 1$, $d^T g = 0$, *and* $v_i \in \{x \in \mathcal{L}' + \operatorname{span}\{d, g\} : d^T x \geq 0\}$ *(*$i \in C \subseteq N$*). For* $i \in C$, *set* $\delta_i' := \|p_{\mathcal{L}'^{\perp}}(v_i)\|$, *determine* $\gamma_i \in [0, \pi]$ *so that* $p_{\mathcal{L}'^{\perp}}(v_i) = \delta_i'(g \cos \gamma_i +$

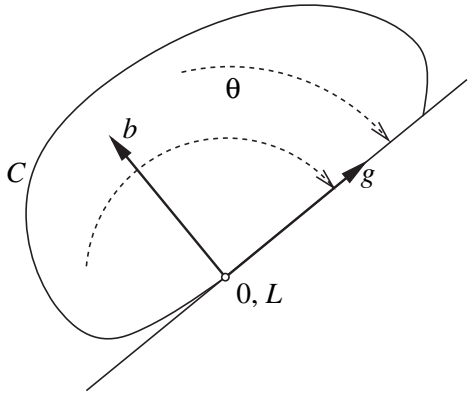

FIG. 13. *θ squeezes C spanned by $\mathcal{L}' + \operatorname{span}\{g\}$ and nonnegative d into the boundary half-space spanned by $\mathcal{L}$ and nonnegative g (Observation 23).*

$d \sin\gamma_i$), and define continuous maps $\theta_i : [0,1] \to \mathbb{R}^n$:

$$\theta_i(t) := p_{\mathcal{L}'}(v_i) + \delta_i' \left[g\cos(\gamma_i - t\gamma_i) + d\sin(\gamma_i - t\gamma_i) \right].$$

Then, for $i \in C$,

(i) $\theta_i(0) = v_i$,

(ii) $\theta_i(1) = p_{\mathcal{L}'}(v_i) + \|p_{\mathcal{L}'^{\perp}}(v_i)\| g$,

and for all $t \in [0,1]$ it holds that

(iii) $p_{\mathcal{L}'}(v_i) = p_{\mathcal{L}'}(\theta_i(t))$ *and* $\|p_{\mathcal{L}'^{\perp}}(v_i)\| = \|p_{\mathcal{L}'^{\perp}}(\theta_i(t))\|$,

(iv) $\|\theta_i(t) - v\| \le \|v_i - v\|$ *for* $v \in \mathcal{L}' + \{\beta g : \beta > 0\}$,

(v) $\|\theta_i(t) - \theta_k(t)\| \le \|v_i - v_k\|$ *for* $k \in C$.

Furthermore, for $\bar{\theta}_C(t) := \sum_{i \in C} \theta_i(t)$,

(vi) $p_{\mathcal{L}'^{\perp}}(\bar{\theta}_C(t)) \in \operatorname{span}\{g\} + \{\beta d : \beta \ge 0\}$ *for* $t \in [0,1]$,

(vii) $g^T \bar{\theta}_C(t)$ *is strictly increasing in* $t \in [0,1]$ *if* $\gamma_i \in (0,\pi]$ *and* $\delta_i' > 0$ *for some* $i \in C$,

(viii) $\bar{\theta}_C(1) = \sum_{i \in C} p_{\mathcal{L}'}(v_i) + g \sum_{i \in C} \delta_i'$.

Proof. (i)–(iii) follow from direct calculation and by exploiting the fact that $g, d \in \mathcal{L}'^{\perp}$ are orthonormal vectors. In order to prove (iv), apply the same arguments used in the proofs of Observation 10(ii) and (iii) to $v \in \mathcal{L}'$ and to $v \in \mathcal{L}' + \{\beta g : \beta \ge 0\}$, respectively.

For proving (v), i.e., $\|\theta_i(t) - \theta_k(t)\|^2 \le \|v_i - v_k\|^2$ for $i, k \in C$, it suffices to show that

$$f_{ik}(t) := \theta_i(t)^T \theta_k(t) \ge v_i^T v_k \overset{\text{(i)}}{=} \theta_i(0)^T \theta_k(0) = f_{ik}(0)$$

or, as $g, d \in \mathcal{L}'^{\perp}$ are orthonormal vectors, that the function

$$f_{ik}(t) = p_{\mathcal{L}'}(v_i)^T p_{\mathcal{L}'}(v_k) + \delta_i' \delta_k' [\cos(\gamma_i - t\gamma_i)\cos(\gamma_k - t\gamma_k) + \sin(\gamma_i - t\gamma_i)\sin(\gamma_k - t\gamma_k)]$$

is nondecreasing in $t \in [0,1]$. By the angle addition formulas and since the cosine is an even function,

$$\cos(\gamma_i - t\gamma_i)\cos(\gamma_k - t\gamma_k) + \sin(\gamma_i - t\gamma_i)\sin(\gamma_k - t\gamma_k) = \cos((1-t)|\gamma_i - \gamma_k|).$$

The right-hand side is nondecreasing, and, thus, f_{ik} is nondecreasing.

(vi) and (viii) follow from direct computation, and for (vii) it suffices to observe that

$$g^T \bar{\theta}_C(t) = \sum_{i \in C} \delta'_i \cos(\gamma_i - t\gamma_i)$$

is strictly increasing because $\delta'_i \geq 0$ for all $i \in C$ and $\cos(\gamma_i - t\gamma_i)$ is strictly increasing in $t \in [0,1]$ whenever $\gamma_i \in (0, \pi]$. ∎

The next observation will serve to find the correct balancing of the parameters for each H_j in order to guarantee the equilibrium constraint on the subspace spanned by g and appropriately chosen d_j.

OBSERVATION 24. *Given continuous functions $\lambda_j : [0,1] \to \mathbb{R}^2$ ($j \in \{1,2,3\}$) and $\sigma \in \mathbb{R}$, with*

(i) $[\lambda_1(t)]_1$ *is strictly decreasing,* $[\lambda_2(t)]_1$ *and* $[\lambda_3(t)]_1$ *are strictly increasing,*
(ii) $[\lambda_i(t)]_2 \geq 0$ *for* $t \in [0,1]$ *and* $i = 1,2,3$,
(iii) $[\lambda_1(0)]_1 + [\lambda_2(0)]_1 + [\lambda_3(0)]_1 + \sigma = 0$,
(iv) $[\lambda_i(0)]_2 < [\lambda_j(0)]_2 + [\lambda_k(0)]_2$ *for pairwise distinct* $i,j,k \in \{1,2,3\}$,
(v) $[\lambda_1(1)]_2 = [\lambda_2(1)]_2 = [\lambda_3(1)]_2 = 0$,

there exist $t_1, t_2, t_3 \in [0,1]$ *and pairwise distinct* $\hat{\imath}, \hat{\jmath}, \hat{k} \in \{1,2,3\}$ *satisfying*

(vi) $[\lambda_1(t_1)]_1 + [\lambda_2(t_2)]_1 + [\lambda_3(t_3)]_1 + \sigma = 0$,
(vii) $[\lambda_{\hat{\imath}}(t_{\hat{\imath}})]_2 = [\lambda_{\hat{\jmath}}(t_{\hat{\jmath}})]_2 + [\lambda_{\hat{k}}(t_{\hat{k}})]_2$.

Proof. Due to continuity, the monotonicity property (i), and the initial condition (iii), there exists a continuous nondecreasing function $\tau : [0, \bar{\tau}] \to [0,1]$ defined implicitly via

$$[\lambda_1(t)]_1 + [\lambda_2(\tau(t))]_1 + [\lambda_3(\tau(t))]_1 + \sigma = 0,$$

where

$$\bar{\tau} := \max\{t \in [0,1] : [\lambda_1(t)]_1 + [\lambda_2(t')]_1 + [\lambda_3(t')]_1 + \sigma = 0 \text{ for some } t' \in [0,1]\}.$$

By definition, $(t'_1, t'_2, t'_3) = (\bar{\tau}, \tau(\bar{\tau}), \tau(\bar{\tau}))$ satisfies (vi), and by monotonicity at least one of t'_1, t'_2, t'_3 is equal to one. Then (v) and (ii) imply that there are pairwise distinct $i,j,k \in \{1,2,3\}$ with $[\lambda_i(t_i)]_2 \geq [\lambda_j(t_j)]_2 + [\lambda_k(t_k)]_2$. By the initial condition (iv) and the continuity of the λ_j and τ, there must be a smallest $t_1 \in (0,1]$ so that $t_2 = t_3 = \tau(t_1)$ satisfy (vi) and (vii). ∎

LEMMA 25. *Given the setting of Lemma 20, assume that $\tilde{\delta}_{\hat{\jmath}} \leq \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$ holds for all $\hat{\jmath} \in M$, and let $\bar{\jmath} \in M$ be the only index with $b_{\bar{\jmath}} = d_1$ within the new embedding of Lemma 20. If at most $|S|-1$ nodes of S are adjacent to nodes in $C_{\bar{\jmath}}$, then there is an optimal embedding of dimension at most $|S|$.*

Proof. Let v_i, $i \in N$, be the optimal embedding resulting from Lemma 20 with normalized vectors $d_1, d_2, d_3 \in \mathcal{L}^\perp$ satisfying $\dim \operatorname{span}\{d_1, d_2, d_3\} \leq 2$ and an assignment $\kappa : M \to \{1,2,3\}$ with $b_j = d_{\kappa(j)}$ for $j \in M$. Choose $H_k := \bigcup_{j \in M : \kappa(j) = k} C_j$ for $k \in \{1,2,3\}$. Then

$$v_i \in \mathcal{L} + \{\beta d_j : \beta \geq 0\} \quad \text{for } i \in H_j,\ j \in \{1,2,3\}. \tag{13}$$

Together with $\mathcal{L} = \operatorname{span} \mathcal{S}$ and $0 \in \mathcal{S} = \operatorname{conv}\{v_s : s \in S\}$, the dimension of this embedding is bounded by $\dim \mathcal{L} + \dim \operatorname{span}\{d_1, d_2, d_3\}$ and $\dim \mathcal{L} \leq |S| - 1$. If $\dim \mathcal{L} < |S| - 1$ or $\dim \operatorname{span}\{d_1, d_2, d_3\} < 2$, then the statement holds, so we may assume that $\dim \mathcal{L} = |S| - 1$ and $\dim \operatorname{span}\{d_1, d_2, d_3\} = 2$. Next suppose that there

is a $j \in \{1,2,3\}$ with $v_i^T d_j = 0$ for all $i \in H_j$; w.l.o.g. assume this to hold for $j = 1$. Then the equilibrium constraint on $\mathcal{L}^\perp$ simplifies to $\sum_{i\in H_2} \|p_{\mathcal{L}^\perp}(v_i)\| d_2 = \sum_{i\in H_3} \|p_{\mathcal{L}^\perp}(v_i)\| d_3$. Thus, the embedding on $\mathcal{L}^\perp$ is restricted to a one-dimensional subspace, and the dimension of the embedding is again bounded by $|S|$. So it remains to consider the case

$$\text{for each } j \in \{1,2,3\}, \quad v_i^T d_j > 0 \text{ for some } i \in H_j. \tag{14}$$

By assumption there is a node $\hat{s} \in S$ not adjacent to any node in $H_1 = C_{\bar{\jmath}}$. Put $S' := S \setminus \{\hat{s}\}$. This set S' separates H_1 from G. We have $0 \in \mathcal{S}' := \operatorname{conv}\{v_s : s \in S'\}$, because otherwise the separator-shadow Theorem 3 would imply that $v_i \in \mathcal{L}' := \operatorname{span} \mathcal{S}'$ for $i \in H_1$, in contradiction to (14). Now $0 \in \mathcal{S}'$ yields $\dim \mathcal{L}' = |S'| - 1$, and as $\dim \mathcal{L} = |S| - 1$ we find a vector $\hat{g}$ with

$$0 \neq \hat{g} = \frac{p_{\mathcal{L}'^\perp}(v_{\hat{s}})}{\|p_{\mathcal{L}'^\perp}(v_{\hat{s}})\|} \in \mathcal{L} \cap \mathcal{L}'^\perp \quad \text{and} \quad \hat{g}^T v_s = 0 \text{ for } s \in S'. \tag{15}$$

Set $g_1 := -\hat{g}$ and $g_2 := g_3 := \hat{g}$, and then by (13)

$$\text{for each } j \in \{1,2,3\}, \quad v_i \in \{x \in \mathcal{L}' + \operatorname{span}\{d_j, g_j\} : d_j^T x \geq 0\} \text{ for all } i \in H_j.$$

Therefore we may use Observation 23 for $j \in \{1,2,3\}$ with $C = H_j$, $d = d_j$, $g = g_j$ to define transformations $\theta_i(t)$ for $i \in H_j$ and $\bar{\theta}_j(t) = \bar{\theta}_{H_j}(t)$. Observe that $\mathcal{S}' \subset \mathcal{L}'$ and $\mathcal{S} \subset \mathcal{L}' + \{\beta g_j : \beta \geq 0\}$ for $j \in \{2,3\}$, so Observation 23(iv) and (v) establish that for $j \in \{1,2,3\}$ and $t_j \in [0,1]$ the distance constraints of edges incident to nodes $i \in H_j$ remain satisfied for embedding $\theta_i(t_j)$, and the objective value remains unchanged due to Observation 23(iii) by $0 \in \mathcal{L}'$. Also note that replacing d_j by some other normalized $d_j' \in \mathcal{L}^\perp$ will not affect distance constraints but only the equilibrium constraint. So it remains to find appropriate $t_j \in [0,1]$ and normalized $d_j' \in \mathcal{L}^\perp$ so that the equilibrium constraint holds while the dimension of the embedding is reduced by at least one. For this purpose, define for $j \in \{1,2,3\}$ the function $\lambda_j : [0,1] \to \mathbb{R}^2$ by

$$\lambda_j(t) := \begin{pmatrix} \hat{g}^T \bar{\theta}_j(t) \\ d_j^T \bar{\theta}_j(t) \end{pmatrix} \qquad \text{for } t \in [0,1].$$

We show that the λ_j and $\sigma := \hat{g}^T v_{\hat{s}}$ satisfy the requirements of Observation 24. Observation 24(i) holds because of Observation 23(vii) and (14). Observation 24(ii) follows from Observation 23(vi). Observation 24(iii) is implied by the feasibility of equilibrium constraint on the linear subspace spanned by $\hat{g}$ for the embedding v_i, $i \in N$; for this, use Observation 23(i), (15), and the definition of σ. Suppose that Observation 24(iv) does not hold, and assume, w.l.o.g., that $\lambda_1(0) \geq \lambda_2(0) + \lambda_3(0)$; then by (13) and Observation 23(i) this is equivalent to

$$\sum_{i\in H_1} \|p_{\mathcal{L}^\perp}(v_i)\| \geq \sum_{i\in H_2 \cup H_3} \|p_{\mathcal{L}^\perp}(v_i)\|,$$

and together with the equilibrium constraint

$$\sum_{i\in H_1} \|p_{\mathcal{L}^\perp}(v_i)\| d_1 + \sum_{i\in H_2} \|p_{\mathcal{L}^\perp}(v_i)\| d_2 + \sum_{i\in H_2} \|p_{\mathcal{L}^\perp}(v_i)\| d_3 = 0$$

this implies that $d_1 = -d_2 = -d_3$ in contradiction to $\dim \operatorname{span}\{d_1, d_2, d_3\} = 2$. Thus, Observation 24(iv) holds. Finally, Observation 24(v) follows from Observation 23(viii). Hence, there exist $t_1, t_2, t_3 \in [0,1]$ and pairwise distinct $\hat{\imath}, \hat{\jmath}, \hat{k} \in \{1,2,3\}$ so that Observation 24(vi) and (vii) hold. Now

$$\text{choose } \hat{d} \in \mathcal{L}^\perp, \|\hat{d}\| = 1, \quad \text{set } d'_{\hat{\imath}} := -d'_{\hat{\jmath}} := -d'_{\hat{k}} := \hat{d}, \tag{16}$$

and

$$v'_i := \begin{cases} v_i & i \in S, \\ p_{\mathcal{L}'}(v_i) + \delta_i[g_j \cos(\gamma_i - t_j\gamma_i) + d'_j \sin(\gamma_i - t_j\gamma_i)] & i \in H_j, j \in \{1,2,3\}. \end{cases}$$

Since only the d_j have been replaced by d'_j, $j \in \{1,2,3\}$, the distance constraints are still valid for the new embedding v'_i, $i \in N$, and the objective value is unchanged. Furthermore, by setting

$$\bar{\theta}'_j(t) := \sum_{i \in H_j} p_{\mathcal{L}'}(v_i) + \delta_i[g_j \cos(\gamma_i - t\gamma_i) + d'_j \sin(\gamma_i - t\gamma_i)] \quad \text{for } j \in \{1,2,3\},$$

we see that the functions λ_j, $j \in \{1,2,3\}$, also satisfy

$$\lambda_j(t) = \begin{pmatrix} \hat{g}^T \bar{\theta}'_j(t) \\ d'^T_j \bar{\theta}'_j(t) \end{pmatrix} \qquad \text{for } t \in [0,1].$$

Therefore Observation 24(vi) and (vii) still hold for t_1, t_2, t_3 and $\hat{\imath}, \hat{\jmath}, \hat{k}$ yielding

$$0 = \sigma + \hat{g}^T(\bar{\theta}'_1(t_1) + \bar{\theta}'_2(t_2) + \bar{\theta}'_2(t_2)) = \hat{g}^T \left(v_{\hat{s}} + \sum_{j \in \{1,2,3\}} \sum_{i \in H_j} v'_i \right) \overset{(15)}{=} \hat{g}^T \left(\sum_{i \in N} v'_i \right),$$

$$0 = d'^T_{\hat{\imath}} \bar{\theta}'_{\hat{\imath}}(t_{\hat{\imath}}) - d'^T_{\hat{\jmath}} \bar{\theta}'_{\hat{\jmath}}(t_{\hat{\jmath}}) - d'^T_{\hat{k}} \bar{\theta}'_{\hat{k}}(t_{\hat{k}}) \overset{(16)}{=} \hat{d}^T \sum_{j \in \{1,2,3\}} \sum_{i \in H_j} v'_i \overset{\hat{d} \in \mathcal{L}^\perp}{=} \hat{d}^T \left(\sum_{i \in N} v'_i \right).$$

So the equilibrium constraint holds on the linear subspaces spanned by $\hat{g}$ and $\hat{d}$. It also holds on $\mathcal{L}'$ because $p_{\mathcal{L}'}(v_i) = p_{\mathcal{L}'}(v'_i)$ for $i \in N$ and the embedding v_i was feasible. Since $v'_i \in \mathcal{L}' + \operatorname{span}\{\hat{g}, \hat{d}\} = \mathcal{L} + \operatorname{span}\{\hat{d}\}$ for $i \in N$, the new embedding satisfies the equilibrium constraint on the entire space. Therefore it is an optimal embedding of dimension at most $\dim \mathcal{L} + 1 = |S|$. ∎

5. The proof of the tree-width Theorem 5. We will show that for any tree decomposition $T = (\mathcal{N}, \mathcal{E})$ of G (see Definition 4) there is always an optimal embedding of dimension at most $\max\{|U| : U \in \mathcal{N}\}$. As this also holds for a tree decomposition giving the tree width of G, this will prove the theorem.

Note that in a tree decomposition any $U \in \mathcal{N}$ and any $U \cap U'$ with $\{U, U'\} \in \mathcal{E}$ is a separator of G (see, e.g., Lemma 12.3.1 in [5]). In the proof we will show that by successively transforming the optimal embedding v_i, $i \in N$, we can find a separator of the form $U \in \mathcal{N}$ or $U \cap U'$ for some $\{U, U'\} \in \mathcal{E}$ containing 0 in the convex hull of its points so that either Lemma 20 or Lemma 25 yields an optimal embedding of appropriate dimension.

The first step asserts that for any optimal embedding any tree decomposition has "zero-nodes" containing the origin in their convex hull.

LEMMA 26. *Consider a tree decomposition $T = (\mathcal{N}, \mathcal{E})$ of a connected graph $G = (N, E)$ and an optimal embedding $v_i \in \mathbb{R}^n$ $(i \in N)$ of* (4). *There is a $U \in \mathcal{N}$ with $0 \in \operatorname{conv}\{v_u : u \in U\}$.*

Proof. Consider a subtree $(\mathcal{N}', \mathcal{E}') =: T'$ of T, with $|\mathcal{N}'|$ minimal so that $0 \in \operatorname{conv}\{v_i : i \in \bigcup_{U \in \mathcal{N}'} U\}$. Such a tree exists since the condition holds for $T' = T$ by the equilibrium constraint. Let the convex combination giving the origin be described by $C := \bigcup_{U \in \mathcal{N}'} U$ and $\alpha \in \mathbb{R}_+^C$, with $\alpha^T e = 1$, so that $\sum_{i \in C} \alpha_i v_i = 0$. If $|\mathcal{N}'| = 1$, we are done.

Assume, for contradiction, that $|\mathcal{N}'| > 1$. Then there is an edge $\{U, U'\} \in \mathcal{E}'$, and $S' := U \cap U'$ is a separator of G. Deleting edge $\{U, U'\}$ from T' splits T' into two nonempty subtrees $(\mathcal{N}'_j, \mathcal{E}'_j) =: T'_j$ for $j \in \{1, 2\}$ with $0 \notin \operatorname{conv}\{v_i : i \in \bigcup_{U \in \mathcal{N}'_j} U\}$ by assumption. Set $N'_j := \bigcup_{U \in \mathcal{N}'_j} U$. Because $S' \subseteq N'_j$ for $j \in \{1, 2\}$ we obtain $0 \notin \mathcal{S}' := \operatorname{conv}\{v_i : i \in S'\}$. Applying the separator-shadow Theorem 3 with respect to $S = S'$ and $C_j = N'_j \setminus S'$ $(j \in \{1, 2\})$ yields, w.l.o.g., $\operatorname{conv}\{v_i, 0\} \cap \mathcal{S}' \neq \emptyset$ for all $i \in C_1 = N'_1 \setminus S'$. But then the origin must be contained in the convex hull of subtree T'_2 as we show next. Put $C'_1 := N'_1 \setminus S'$, $C'_2 := N'_2$ and set, for $j \in \{1, 2\}$, $\bar{\alpha}_j := \sum_{i \in C'_j} \alpha_i$ and $\bar{v}_j := \frac{1}{\bar{\alpha}_j} \sum_{i \in C'_j} \alpha_i v_i \in \operatorname{conv}\{v_i : i \in N'_j\}$. Then $0 = \bar{\alpha}_1 \bar{v}_1 + \bar{\alpha}_2 \bar{v}_2 \in \operatorname{conv}\{\bar{v}_1, \bar{v}_2\}$ (by definition of the α_i) and $\emptyset \neq \mathcal{S}' \cap \operatorname{conv}\{\bar{v}_1, 0\} \subset \operatorname{conv}\{\bar{v}_1, \bar{v}_2\}$ (as the separator-shadow property holds for C'_1), so there is a $p \in \mathcal{S}' \subset \operatorname{conv}\{v_i : i \in N'_2\}$ with $0 \in \operatorname{conv}\{p, \bar{v}_2\} \subset \operatorname{conv}\{v_i : i \in N'_2\}$, a contradiction to the minimality of $|\mathcal{N}'|$. Hence, T' consists of only one node. ∎

We will call a node $U \in \mathcal{N}$ a *zero-node* (with respect to the embedding v_i, $i \in N$) if $0 \in \operatorname{conv}\{v_i : i \in U\}$ and an edge $\{U, U'\} \in \mathcal{E}$ a *zero-edge* (with respect to the embedding v_i, $i \in N$) if $0 \in \operatorname{conv}\{v_i : i \in U \cap U'\}$. Note that for a zero-edge both end points are zero-nodes.

OBSERVATION 27. *The subgraph $(\mathcal{N}', \mathcal{E}') =: T'$ of $T = (\mathcal{N}, \mathcal{E})$ induced by the zero-nodes of an optimal embedding v_i $(i \in N)$ of* (4) *is a tree, and $\mathcal{E}'$ is the set of zero-edges.*

Proof. Suppose that there are two zero-nodes U_1 and U_2 that are not connected in T' or that are connected in T' by an edge that is not a zero-edge. In both cases there is an edge $\{\bar{U}, \bar{U}'\} \in \mathcal{E}$ inducing a separator $S := \bar{U} \cap \bar{U}'$ in G with $0 \notin \mathcal{S} := \operatorname{conv}\{v_i : i \in S\}$ on the path connecting U_1 and U_2 in T. Deleting edge $\{\bar{U}, \bar{U}'\}$ from T splits T into two nonempty subtrees $(\mathcal{N}_j, \mathcal{E}_j) =: T_j$, with $U_j \in \mathcal{N}_j$ for $j \in \{1, 2\}$, so that the node sets $C_j := \bigcup_{U \in \mathcal{N}_j} U \setminus S$ have no common incident edge in G. For S, C_1, and C_2 the separator-shadow Theorem 3 implies, w.l.o.g., that $\operatorname{conv}\{v_i, 0\} \cap \mathcal{S} \neq \emptyset$ for all $i \in C_1$. Because $U_1 \subseteq C_1 \cup S$ we obtain $0 \notin \operatorname{conv}\{v_i : i \in U_1\}$, which contradicts the assumption that U_1 is a zero-node. ∎

Hence, for a given tree decomposition any optimal embedding induces a *zero-tree* (with respect to the embedding v_i, $i \in N$) consisting of the zero-nodes and zero-edges.

The algorithmic idea is to pick a zero-node U, transform the embedding for $S = U$ as suggested in Lemmas 20, 21, and 25, and check whether the resulting dimension is at most $|U|$. If it is not, it will turn out that, in the zero-tree of the new optimal embedding, U has a unique incident zero-edge $\{U, U'\}$ leading to that part of the graph whose embedding cannot yet be flattened out sufficiently with respect to U. We then go on transforming the new optimal embedding with respect to the separator $U \cap U'$ which may again lead to a sufficiently flat optimal embedding or, in failing to find one, lead on to U' via the part that is not flat enough. Now at some point this algorithm might turn back in U' and try to cross this last edge a second time.

Happily, this will immediately allow one to produce an optimal embedding that is sufficiently flat. As going on in one direction will be possible only for a finite number of times, this will complete the proof.

We start with the convenient case, where all parts can be flattened out sufficiently.

LEMMA 28. *Consider a tree decomposition $T = (\mathcal{N}, \mathcal{E})$ of a connected graph $G = (N, E)$, an optimal embedding $v_i \in \mathbb{R}^n$ $(i \in N)$ of (4), and a zero-node $S \in \mathcal{N}$ whose deletion splits T into m subtrees $(\mathcal{N}_j, \mathcal{E}_j) =: T_j$ $(j \in M := \{1, \dots, m\})$. Put*

$$\begin{aligned} \mathcal{L} &:= \operatorname{span}\{v_s : s \in S\}, \\ C_j &:= \bigcup_{U \in \mathcal{N}_j} U \setminus S, \\ \tilde{\delta}_j &:= \sum_{i \in C_j} \|p_{\mathcal{L}^\perp}(v_i)\| \quad (j \in M). \end{aligned}$$

If $\tilde{\delta}_{\hat{\jmath}} \le \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$ for all $\hat{\jmath} \in M$, then there is an optimal embedding v'_i $(i \in N)$ of dimension at most $|U'|$ for some $U' \in \{S, U : \{S, U\} \in \mathcal{E}\}$.

Proof. We distinguish two cases. In the first case assume that S has a neighbor U' in T, with $|U'| > |S|$, and apply Lemma 20 with respect to S and the C_j $(j \in M)$. The resulting optimal embedding v'_i has dimension at most $\dim \mathcal{L} + 2$, and since $\dim \mathcal{L} \le |S| - 1$ $(0 \in \operatorname{conv}\{v_s : s \in S\})$ the dimension is at most $|U'|$.

In the second case all neighbors U of S in T satisfy $|U| \le |S|$. By definition, no two nodes in $\mathcal{N}$ are identical, so each set C_j is separated from S by a subset $S_j := S \cap U_j$ induced by an edge $\{S, U_j\} \in \mathcal{E}$, with $|S_j| < |S|$. By applying Lemma 20 with respect to S and the C_j $(j \in M)$ we obtain the corresponding embedding v'_i $(i \in N)$ with a unique index $\bar{\jmath} \in M$ satisfying $b_{\bar{\jmath}} = d_1$. Because $S_{\bar{\jmath}} \subset S$ separates S and $C_{\bar{\jmath}}$, at most $|S| - 1$ nodes of S are incident to nodes in $C_{\bar{\jmath}}$. Therefore we may apply Lemma 25 with respect to S, the C_j $(j \in M)$, and the embedding v'_i $(i \in N)$ and obtain an optimal embedding v''_i $(i \in N)$ of dimension at most $|S|$. ∎

If, however, one of the sets is too big to be flattened out, we can find a unique edge that leads us towards a more balanced center in the big set.

LEMMA 29. *Given the setting of Lemma 28, assume that $\tilde{\delta}_{\hat{\jmath}} > \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$ for a $\hat{\jmath} \in M$. Let v'_i $(i \in N)$ be an optimal embedding arising from Lemma 21 for this S and the C_j $(j \in M)$. The (unique) edge $\{S, \widehat{U}\} \in \mathcal{E}$, with $\widehat{U} \in \mathcal{N}_{\hat{\jmath}}$, is a zero-edge with respect to this new optimal embedding.*

Proof. Since $\tilde{\delta}_{\hat{\jmath}} > 0$, neither the subtree $T_{\hat{\jmath}}$ nor $C_{\hat{\jmath}}$ are empty, so there is an edge $\{S, \widehat{U}\} \in \mathcal{E}$, with $\widehat{U} \in \mathcal{N}_{\hat{\jmath}}$. Suppose, for contradiction, that it is not a zero-edge with respect to the embedding v'_i $(i \in N)$. Then $S' := S \cap \widehat{U}$ separates G into $C_{\hat{\jmath}}$ and $N \setminus (S' \cup C_{\hat{\jmath}})$. By assumption, $0 \notin \operatorname{conv}\{v_s : s \in S'\}$ and $0 \in \operatorname{conv}\{v_s : s \in S\}$, so the separator-shadow Theorem 3 applied with respect to the separator S' implies that $v_i \in \operatorname{cone}\{v_s : s \in S'\} \subset \mathcal{L}$ for $i \in C_{\hat{\jmath}}$. But then $\tilde{\delta}_{\hat{\jmath}} = 0$. ∎

Note that $\widehat{U}$ is a zero-node of the embedding v'_i, and we could continue with transforming v'_i with respect to $\widehat{U}$ ending up in Lemma 28 or Lemma 29 again. However, in order to ensure that no edge is crossed twice, we need to look at the zero-edge itself first.

LEMMA 30. *Consider the setting of Lemma 29 with $\{S, \widehat{U}\} \in \mathcal{E}$ being the zero-edge with respect to embedding v'_i $(i \in N)$ satisfying $\widehat{U} \in \mathcal{N}_{\hat{\jmath}}$. Deleting this edge in T splits T into two subtrees $(\mathcal{N}'_j, \mathcal{E}'_j) =: T'_j$, with $j \in \{S, \widehat{U}\}$, so that $S \in \mathcal{N}'_S$ and*

$\widehat{U} \in \mathcal{N}'_{\widehat{U}}$. *Put*

$$\begin{aligned} S' &:= S \cap \widehat{U}, \\ \mathcal{L}' &:= \operatorname{span}\{v_s : s \in S'\}, \\ C'_j &:= \bigcup_{U \in \mathcal{N}'_j} U \setminus S', \\ \tilde{\delta}'_j &:= \sum_{i \in C_j} \|p_{\mathcal{L}'^{\perp}}(v'_i)\| \quad (j \in \{S, \widehat{U}\}). \end{aligned}$$

If $\tilde{\delta}'_S \geq \tilde{\delta}'_{\widehat{U}}$, *then there is an optimal embedding* v''_i $(i \in N)$ *of dimension at most* $|S|$.

Proof. If $\tilde{\delta}'_S = \tilde{\delta}'_{\widehat{U}}$, then Lemma 20 applied to embedding v'_i with respect to S' and C'_j for $j \in \{S, \widehat{U}\}$ yields an optimal embedding

$$v''_i := \begin{cases} v'_i & \text{for } \ i \in S', \\ p_{\mathcal{L}'}(v_i) + \|p_{\mathcal{L}'^{\perp}}(v_i)\| b & \text{for } \ i \in C'_S, \\ p_{\mathcal{L}'}(v_i) - \|p_{\mathcal{L}'^{\perp}}(v_i)\| b & \text{for } \ i \in C'_{\widehat{U}} \end{cases}$$

for some normalized $b \in \mathcal{L}'^{\perp}$, and the dimension is bounded by $\dim \mathcal{L}' + 1 \leq |S'| \leq |S|$.

For $\tilde{\delta}_S > \tilde{\delta}_{\widehat{U}}$ remember that the v'_i were constructed via Lemma 21. So with the definitions of $\bar{b}$ and the v'_i given there, we have

$$v'_i = p_{\mathcal{L}}(v_i) + \|p_{\mathcal{L}^{\perp}}(v_i)\| \bar{b} \quad \text{for } i \in C'_S = \bigcup_{j \in M \setminus \{\hat{\jmath}\}} C_j \cup S \setminus S'.$$

If $\bar{b} = 0$, then all of these v'_i lie in $\mathcal{L}$, and, by applying Lemma 21 to v'_i with respect to S' and C'_j for $j \in \{S, \widehat{U}\}$, the space of the new optimal embedding v''_i, $i \in N$, will be $\mathcal{L}$ enlarged by some direction h at most, so its dimension is bounded by $\dim \mathcal{L} + 1 \leq |S|$.

If $\bar{b} \neq 0$, then $p_{\mathcal{L}^{\perp}}(v_i) \neq 0$ for some $i \in C'_S$, and, by using $\bar{b} \in \mathcal{L}^{\perp}$, $\|\bar{b}\| = 1$, we get

$$\bar{b}^T v'_i = \bar{b}^T p_{\mathcal{L}}(v_i) + \|p_{\mathcal{L}^{\perp}}(v_i)\| \bar{b}^T \bar{b} = \|p_{\mathcal{L}^{\perp}}(v_i)\| \geq 0 \quad \text{for } i \in C'_S.$$

Since $\mathcal{L}' \subseteq \mathcal{L}$ we obtain $\bar{b} \in \operatorname{span}\{v'_i : i \in C'_S\} \cap \mathcal{L}'^{\perp} \setminus \{0\}$ and $\bar{b}^T v'_i \geq 0$ for $i \in C'_S$. So we are in the special case of Lemma 21. Thus, applying Lemma 21 to v'_i with respect to S' and C'_j for $j \in \{S, \widehat{U}\}$ yields a new optimal embedding v''_i, $i \in N$, with $v''_i \in \operatorname{span}\{v'_i : i \in C'_S\} \subseteq \mathcal{L} + \operatorname{span}\{\bar{b}\}$ for $i \in C'_S$, and therefore $v''_i \in \mathcal{L} + \operatorname{span}\{\bar{b}\}$ for all $i \in N$. The dimension of this new embedding is again bounded by $|S|$. □

In proving the finiteness of the algorithm below we will see that the values $\tilde{\delta}'_j$ of Lemma 30 do not change if the algorithm turns back in $\hat{U}$ to cross the same edge again, so that the condition $\tilde{\delta}'_S \geq \tilde{\delta}'_{\hat{U}}$ will be met the second time at the latest.

ALGORITHM 31.

Input*: A connected graph* $G = (N, E)$, *a tree decomposition* $T = (\mathcal{N}, \mathcal{E})$ *of* G, *an optimal embedding* v_i, $i \in N$, *of* (4).

Step* 0: Set* S *to a zero-vertex of* T *with respect to the embedding.*

Step* 1: By using the notation of Lemma* 28 *with respect to* S, *determine* $\tilde{\delta}_j$ *for* $j \in M$.

Step* 2: If* $\tilde{\delta}_{\hat{\jmath}} \leq \sum_{j \in M \setminus \{\hat{\jmath}\}} \tilde{\delta}_j$ *for all* $\hat{\jmath} \in M$, *apply the proof of Lemma* 28 *to find an optimal embedding of dimension at most the width of* T *plus one, and stop.*

Step 3*: Transform, as described in Lemma* 29*, the optimal embedding to* v'_i *(*$i \in N$*), and compute the corresponding zero-edge* $\{S, \widehat{U}\}$*. Determine* $\tilde{\delta}'_S$ *and* $\tilde{\delta}'_{\widehat{U}}$ *in the notation of Lemma* 30*.*

Step 4*: If* $\tilde{\delta}_S \geq \tilde{\delta}_{\widehat{U}}$*, apply the proof of Lemma* 30 *to find an optimal embedding of dimension at most the width of* T *plus one, and stop.*

Step 5*: Set* $S \leftarrow \widehat{U}$*,* $v_i \leftarrow v'_i$ *for* $i \in N$*, and goto Step* 1*.*

THEOREM 32. *Let* $G = (N, E)$ *be a connected graph and* $T = (\mathcal{N}, \mathcal{E})$ *a tree decomposition of* G*. Algorithm* 31 *is correct and stops with an optimal embedding for* (4) *of dimension at most width of* T *plus one in at most* $|\mathcal{N}|$ *iterations.*

Proof. Step 0 can be carried through by Lemma 26.

If in Step 1 the set M is empty ($\mathcal{N} = \{S\}$), then the condition in Step 2 is vacuously satisfied and the transformation of Lemma 28 is the identity. But in this case $S = |N|$ and any optimal embedding has dimension at most $|N| - 1$ by Observation 9, so the algorithm stops correctly.

We will prove that the algorithm steps over any edge at most once without stopping, and this will yield the iteration bound. Suppose that $\{S, \widehat{U}\}$ is the first edge of T to be considered a second time and that the algorithm just stepped from S to $\widehat{U}$ and now considers stepping back to S. Then $\widehat{U}$ transforms, by means of Lemma 29, the embedding v'_i that was generated by S via Lemma 29. By construction (see Lemma 21), both transformations have $\mathcal{L}' := \operatorname{span}\{v'_i : i \in S \cap \widehat{U}\}$ as an invariant subspace. Therefore the numbers $\tilde{\delta}'_S$ and $\tilde{\delta}'_{\widehat{U}}$ of Lemma 30 computed in Step 3 have identical values in both cases (but with names interchanged), so the condition of Step 4 is certainly satisfied the second time, and the algorithm stops.

The correctness of the statement regarding the dimension of the optimal embedding at termination is a consequence of the respective Lemmas 28 and 30. ∎

SEMIDEFINITE RELAXATION BOUNDS FOR INDEFINITE HOMOGENEOUS QUADRATIC OPTIMIZATION*

SIMAI HE†, ZHI-QUAN LUO‡, JIAWANG NIE§, AND SHUZHONG ZHANG†

Abstract. This paper studies the relationship between the optimal value of a homogeneous quadratic optimization problem and its semidefinite programming (SDP) relaxation. We consider two quadratic optimization models: (1) $\min\{x^*Cx \mid x^*A_kx \geq 1,\ k = 0, 1, \ldots, m,\ x \in \mathbb{F}^n\}$ and (2) $\max\{x^*Cx \mid x^*A_kx \leq 1,\ k = 0, 1, \ldots, m,\ x \in \mathbb{F}^n\}$, where $\mathbb{F}$ is either the real field $\mathbb{R}$ or the complex field $\mathbb{C}$, and A_k, C are symmetric matrices. For the minimization model (1), we prove that if the matrix C and all but *one* of the A_k's are positive semidefinite, then the ratio between the optimal value of (1) and its SDP relaxation is upper bounded by $O(m^2)$ when $\mathbb{F} = \mathbb{R}$, and by $O(m)$ when $\mathbb{F} = \mathbb{C}$. Moreover, when two or more of the A_k's are indefinite, this ratio can be arbitrarily large. For the maximization model (2), we show that if C and at most one of the A_k's are indefinite while other A_k's are positive semidefinite, then the ratio between the optimal value of (2) and its SDP relaxation is bounded from below by $O(1/\log m)$ for both the real and the complex case. This result improves the bound based on the so-called approximate S-Lemma of Ben-Tal, Nemirovski, and Roos [*SIAM J. Optim.*, 13 (2002), pp. 535–560]. When two or more of the A_k's in (2) are indefinite, we derive a general bound in terms of the problem data and the SDP solution. For both optimization models, we present examples to show that the derived approximation bounds are essentially tight.

Key words. quadratic optimization, SDP relaxation, approximation ratio, probabilistic solution

1. Introduction.

In this paper we study the relationship between the optimal values of a homogeneous quadratic optimization problem and its *semidefinite programming* (SDP) relaxation. Two specific optimization models are considered.

The minimization model. Let A_k $(k = 0, 1, \ldots, m)$ and C be $n \times n$ real symmetric or complex Hermitian matrices. Consider

$$\begin{aligned} \min \quad & x^*Cx \\ \text{s.t.} \quad & x^*A_kx \geq 1,\ k = 0, 1, \ldots, m \\ & x \in \mathbb{F}^n, \end{aligned} \tag{1.1}$$

where $\mathbb{F}$ can be either the field of real numbers $\mathbb{R}$ or the field of complex numbers $\mathbb{C}$, and the superscript * represents Hermitian transpose (or regular transpose in case of real matrices). The quadratic optimization problems of form (1.1) are NP-hard [14], even when all the data matrices, C and A_k, $k = 1, \ldots, m$, are positive semidefinite. Homogeneous quadratic optimization problems (1.1) arise naturally in telecommunications and robust control applications; see [22, 17, 14] and the references therein.

In these applications, the optimization variables are naturally complex since they represent the in-phase and quadrature components of a complex signal. A popular approach to approximately solving the NP-hard quadratic problem (1.1) is to use the following SDP relaxation:

$$\begin{aligned} \min \quad & \mathrm{Tr}\,(CX) \\ \text{s.t.} \quad & \mathrm{Tr}\,(A_k X) \geq 1,\ k = 0, 1, \ldots, m \\ & X \in \mathbb{SF}^n_+, \end{aligned}$$

where $\mathrm{Tr}\,(\cdot)$ represents the trace of a matrix, and $\mathbb{SF}^n_+$ denotes the convex cone of positive semidefinite matrices in the space of all (Hermitian) symmetric matrices $\mathbb{SF}^n$. The above SDP is convex and can be solved efficiently using interior point methods. After the SDP relaxation problems are solved, we can apply a *probabilistic method* to the corresponding optimal SDP solution to extract rank-one feasible solutions for (1.1). Theoretically, even though the probabilistic solutions obtained in this manner are not globally optimal for (1.1), they can be shown to be high quality approximate solutions; see, e.g., [3, 14]. Recently, Luo et al. [14] considered problem (1.1) and gave bounds for the SDP approximation ratio for (1.1). When all of the matrices A_k and C are positive semidefinite, Luo et al. [14] showed that the ratio between the original optimal value and the SDP relaxation optimal value is bounded above by $O(m^2)$ when $\mathbb{F} = \mathbb{R}$ and by $O(m)$ when $\mathbb{F} = \mathbb{C}$, where the factors in the big O notations are absolute constants and independent of data matrices A_k and C. All of these bounds are shown to be tight in the worst case. However, the average performance can be much better than the stated worst-case bounds for randomly generated instances. The simulation studies in [14] showed that the average ratios are typically close to 1.

Our contributions. In section 3, we analyze the approximation ratio of the SDP relaxation for the homogeneous quadratic optimization problem (1.1) when some of the constraint matrices A_k are *indefinite*. We show that, for problem (1.1), the same upper bounds for the SDP approximation ratios as given in [14] ($O(m^2)$ when $\mathbb{F} = \mathbb{R}$ and $O(m)$ when $\mathbb{F} = \mathbb{C}$) still hold true even when *one* of the constraint matrices is indefinite. If there are more than one indefinite quadratic constraints, then we show by an example that the SDP approximation ratio can be infinity. Therefore, our bounds are essentially the best possible.

The maximization model. We also consider the quadratic optimization problem of the form

$$\begin{aligned} \max \quad & x^* C x \\ \text{s.t.} \quad & x^* A_k x \leq 1,\ k = 0, 1, \ldots, m \\ & x \in \mathbb{F}^n. \end{aligned} \tag{1.2}$$

This quadratic optimization problem is still NP-hard [3, 18], even when all of the matrices C and A_k are positive semidefinite. Problem (1.2) arises naturally in telecommunications and robust control applications; see [22, 17, 3] and the references therein. The SDP relaxation for (1.2) can be written as follows:

$$\begin{aligned} \max \quad & \mathrm{Tr}\,(CX) \\ \text{s.t.} \quad & \mathrm{Tr}\,(A_k X) \leq 1,\ k = 0, 1, \ldots, m \\ & X \in \mathbb{SF}^n_+. \end{aligned}$$

As in the minimization case, after the SDP relaxation problem is solved, some probabilistic method can be applied to extract a high quality rank-one feasible solution for (1.2). Various estimates exist for the quality of approximate solutions; see, e.g., [3, 18]. Specifically, Nemirovski, Roos, and Terlaky [18] proved that if all A_k's are positive semidefinite, then the ratio between the optimal value of the SDP relaxation problem and that of the original quadratic problem is bounded above by $O(\log m)$. More generally, Ben-Tal, Nemirovski, and Roos [3] established a so-called *approximate S-Lemma* which shows that the approximation ratio for the SDP relaxation is at most $O(\log(n^2 m))$ when all but one of the matrices A_k, $k = 0, 1, \ldots, m$ are positive semidefinite.

Our contributions. In section 4, we study the SDP approximation ratio for the homogeneous quadratic maximization problem (1.2) when some of the constraint matrices $\{A_k\}$ are *indefinite*. Our results are as follows. We strengthen the approximate S-Lemma of Ben-Tal, Nemirovski, and Roos [3] by improving their upper bound on the SDP approximation ratio from $O(\log(n^2 m))$ to $O(\log m)$ when *one* quadratic inequality is indefinite. In the process of establishing this new bound, we give a universal lower bound of 0.03 on the probability that a homogeneous quadratic form of n binary i.i.d. Bernoulli random variables lies below its mean. The previous best known lower bound for this probability was $1/(8n^2)$ due to Ben-Tal, Nemirovski, and Roos [3]. In this reference, the authors also conjectured that the actual lower bound should be 0.25. We also present a new and unifying upper bound on the ratio of the optimal value of SDP relaxation over that of the original quadratic maximization problem (1.2) *without* any positive definiteness assumptions. This new general bound involves the problem data and the SDP optimal solution, which is computable in polynomial time. We also present an example showing that this bound is essentially the best possible.

Related literature. In addition to the work of Ben-Tal, Nemirovski, and Roos [3], Luo et al. [14], and Nemirovski, Roos, and Terlaky [18], there is a sizeable literature on the quality bounds of SDP relaxation for solving nonconvex quadratic optimization problems. For instance, for problem (1.2), when $m = n$, $A_i = e_i e_i^T$ (there is no A_0), and C is positive semidefinite with nonpositive nondiagonal entries and row sums 0 (which corresponds to the maximum cut problem), Goemans and Williamson [8] showed that the ratio of the optimal value of SDP relaxation over that of the original quadratic maximization problem (1.2) is bounded below by $0.87856\ldots$. Furthermore, if C is only positive semidefinite, Nesterov [19] showed the same ratio is bounded below by $0.6366\ldots$. For closely related results, see Ye [24] and Bertsimas and Ye [4]. Recently, So, Ye, and Zhang [23] developed SDP relaxation methods for finding approximate low rank solutions for linear matrix inequalities. Their results unify and extend the approximation bounds of Nemirovski, Roos, and Terlaky [18] and Luo et al. [14] for the case when all of the data matrices are positive semidefinite. Beck and Teboulle [2] discussed the nonconvex problem of minimizing the ratio of two nonconvex quadratic functions over a possibly degenerate ellipsoid, and showed that the SDP relaxation can return exact solutions under a certain condition. There is also some work on solving quadratic optimization problems using other methods, e.g., Hiriart-Urruty and Jean-Baptiste [10], Jeyakumar, Rubinov, and Wu [12], and Madsen, Nielsen, and Pinar [15, 16].

Outline of this paper. Section 2 is devoted to analyzing the probability of a general random variable to be above (or below) its mean value. Section 3 concentrates on the SDP approximation bound for the quadratic minimization problem (1.1), while section 4 studies the SDP approximation bound for quadratic maximization

problem (1.2). Some concluding remarks are given in the last section (section 5).

2. Estimating the asymmetry of a random variable. To facilitate the technical analysis in subsequent sections, we establish in this section a bound on the probability for a general random variable to be above (or symmetrically, below) its mean value, using only the high order moment information of the random variable. This problem on its own is of importance in statistics and probability theory. The following lemma is a generalization of Theorem 2.1 in [13].

LEMMA 2.1. *Suppose that a random variable* Φ *satisfies* $\mathsf{E}\Phi = 0$, $\mathrm{Var}(\Phi) = 1$, *and* $\mathsf{E}|\Phi|^t \le \tau$ *for some* $t > 2$ *and* $\tau > 0$. *Then* $\mathrm{Prob}\{\Phi \ge 0\} > 0.25\tau^{-\frac{2}{t-2}}$ *and* $\mathrm{Prob}\{\Phi \le 0\} > 0.25\tau^{-\frac{2}{t-2}}$.

Proof. Let $p_1 = \mathrm{Prob}\{\Phi \ge 0\}$ and $p_2 = \mathrm{Prob}\{\Phi \le 0\}$. Also, let $Y_1 = \max(\Phi, 0)$ and $Y_2 = -\min(\Phi, 0)$. Since $\mathsf{E}\Phi = 0$, we know that $\mathsf{E}Y_1 - \mathsf{E}Y_2 = 0$. Let $s := \mathsf{E}Y_1 = \mathsf{E}Y_2$. By Hölder's inequality it follows that $(\mathsf{E}Y_1^t)^{1/(t-1)}(\mathsf{E}Y_1)^{(t-2)/(t-1)} \ge \mathsf{E}Y_1^2$ and $(\mathsf{E}Y_2^t)^{1/(t-1)}(\mathsf{E}Y_2)^{(t-2)/(t-1)} \ge \mathsf{E}Y_2^2$. Since $\mathsf{E}Y_1^t + \mathsf{E}Y_2^t = \mathsf{E}|\Phi|^t$, we have

$$\tau \ge \mathsf{E}|\Phi|^t = \mathsf{E}Y_1^t + \mathsf{E}Y_2^t \ge \frac{(\mathsf{E}Y_1^2)^{t-1} + (\mathsf{E}Y_2^2)^{t-1}}{s^{t-2}}.$$

Let $u = \mathsf{E}Y_1^2 \in [0,1]$. Since $\mathsf{E}Y_1^2 + \mathsf{E}Y_2^2 = \mathsf{E}\Phi^2 = \mathrm{Var}(\Phi) = 1$, it follows that $s^{t-2} \ge \frac{u^{t-1}+(1-u)^{t-1}}{\tau}$. On the other hand, by the Cauchy–Schwartz inequality, we have

$$s^2 = (\mathsf{E}Y_1)^2 = (\mathsf{E}(\mathbf{1}_{\{Y_1 \ge 0\}} Y_1))^2 \le \mathsf{E}(\mathbf{1}^2_{\{Y_1 \ge 0\}})\mathsf{E}Y_1^2 \le p_1 u,$$

which implies that

$$\begin{aligned} p_1 &\ge u^{-1}\left[\frac{u^{t-1} + (1-u)^{t-1}}{\tau}\right]^{\frac{2}{t-2}} \\ &= \frac{\left(u^{t-1} + (1-u)^{t-1}\right)^{\frac{2}{t-2}}}{u}\,\tau^{-\frac{2}{t-2}} \\ &\ge \left(u^{t-1} + (1-u)^{t-1}\right)^{\frac{2}{t-2}}\tau^{-\frac{2}{t-2}} \\ &\ge \left(2\left(\frac{1}{2}\right)^{t-1}\right)^{\frac{2}{t-2}}\tau^{-\frac{2}{t-2}} \\ &= 0.25\tau^{-\frac{2}{t-2}}, \end{aligned}$$

where the third inequality follows from the convexity of the function u^{t-1} when $t > 2$. Obviously, the equality cannot hold throughout. Therefore, $p_1 > 0.25\tau^{-\frac{2}{t-2}}$. By symmetry, we also have $p_2 > 0.25\tau^{-\frac{2}{t-2}}$. □

In case $t = 4$, Lemma 2.1 asserts that $\mathrm{Prob}\{\Phi \ge 0\} \ge \frac{1}{4\tau}$ and $\mathrm{Prob}\{\Phi \le 0\} \ge \frac{1}{4\tau}$. However, in this particular case, this specific bound can in fact be further sharpened.

LEMMA 2.2. *Suppose that a random variable* Φ *satisfies* $\mathsf{E}\Phi = 0$, $\mathrm{Var}(\Phi) = 1$, *and* $\mathsf{E}\Phi^4 \le \tau$. *Then* $\mathrm{Prob}\{\Phi \ge 0\} \ge \frac{2\sqrt{3}-3}{\tau} > \frac{9}{20\tau}$ *and* $\mathrm{Prob}\{\Phi \le 0\} \ge \frac{2\sqrt{3}-3}{\tau} > \frac{9}{20\tau}$.

Proof. It follows from the proof of Lemma 2.1 that

$$p_1 \ge \frac{u^3 + (1-u)^3}{\tau u} = \left(\frac{1}{u} + 3u - 3\right)\frac{1}{\tau} \ge \frac{2\sqrt{3}-3}{\tau} > \frac{9}{20\tau}.$$

By symmetry, $p_2 > \frac{9}{20\tau}$ holds as well. □

3. SDP relaxation bounds for the quadratic minimization model. Consider the homogeneous quadratic optimization

$$\begin{aligned} v_{qp}^{\min} := \min \quad & x^* C x \\ \text{s.t.} \quad & x^* A_k x \geq 1,\ k = 0, 1, \ldots, m \\ & x \in \mathbb{F}^n, \end{aligned} \tag{3.1}$$

where $C, A_0, A_1, \ldots, A_m \in \mathbb{SF}^n$ are symmetric matrices. This problem is NP-hard [14]. A natural SDP relaxation to the above quadratic optimization problem is

$$\begin{aligned} v_{sdp}^{\min} := \min \quad & \mathrm{Tr}\,(CZ) \\ \text{s.t.} \quad & \mathrm{Tr}\,(A_k Z) \geq 1,\ k = 0, 1, \ldots, m \\ & Z \in \mathbb{SF}^n_+. \end{aligned} \tag{3.2}$$

Obviously, the SDP relaxation provides a lower bound, i.e., $v_{sdp}^{\min} \leq v_{qp}^{\min}$. In the case $C = I_n$ and $A_0, A_1, \ldots, A_m$ are all positive semidefinite, Luo et al. [14] proved that $v_{qp}^{\min}/v_{sdp}^{\min} \leq \frac{27(m+1)^2}{\pi}$ for $\mathbb{F} = \mathbb{R}$, and $v_{qp}^{\min}/v_{sdp}^{\min} \leq 8(m+1)$ for $\mathbb{F} = \mathbb{C}$. Moreover, when two or more of $A_0, A_1, \ldots, A_m$ are indefinite, there is in general no data-independent upper bound on $v_{qp}^{\min}/v_{sdp}^{\min}$, as shown by the following example [14]:

$$\begin{aligned} \min \quad & x_1^2 + x_2^2 \\ \text{s.t.} \quad & x_2^2 \geq 1 \\ & x_1^2 + M x_1 x_2 \geq 1 \\ & x_1^2 - M x_1 x_2 \geq 1, \end{aligned}$$

where $M > 0$ is a constant. In the above example, $v_{sdp}^{\min} = 1$ and the last two constraints imply $x_1^2 \geq M|x_1||x_2| + 1$ which, together with the first constraint $x_2^2 \geq 1$, yield $x_1^2 \geq M|x_1| + 1$ or, equivalently, $|x_1| \geq (M + \sqrt{M^2+4})/2$. Therefore, $v_{qp}^{\min} \geq 1 + \frac{1}{4}(M + \sqrt{M^2+4})^2$. That is, $v_{qp}^{\min}/v_{sdp}^{\min} \geq 1 + \frac{1}{4}(M + \sqrt{M^2+4})^2$, which can be arbitrarily large, depending on the problem data $M > 0$.

In this section, we consider the homogeneous quadratic optimization (3.1) under the assumption that $C, A_1, A_2, \ldots, A_m \in \mathbb{SF}^n_+$ are positive semidefinite while $A_0 \in \mathbb{SF}^n$ can be indefinite. Throughout this section, we assume that (3.1) is feasible, and that there is $\mu_k \geq 0$, $k = 0, 1, \ldots, m$, such that $\sum_{k=0}^m \mu_k A_k \prec C$. This assumption guarantees that the SDP relaxation is primal feasible while its dual problem satisfies the Slater condition. Hence the strong duality holds and the primal problem (3.2) has an optimal solution that attains its infimum.

Our analysis shall treat the cases $\mathbb{F} = \mathbb{R}$ and $\mathbb{F} = \mathbb{C}$ separately, leading to strikingly different bounds.

3.1. The real case. Let us start with a useful lemma regarding a lower bound on worst asymmetric mass distributions for a χ^2-distribution around its mean vector. In fact this result is interesting on its own right.

LEMMA 3.1. *Let τ_i be any real numbers, $i = 1, \ldots, n$, and let $\eta \sim N(0, I_n)$ be an n-dimensional normal distribution with zero mean and covariance matrix I_n. Then*

we have

$$\text{Prob}\left\{\sum_{i=1}^{n}\tau_i(\eta_i^2-1)\geq 0\right\}>\frac{3}{100},\quad \text{Prob}\left\{\sum_{i=1}^{n}\tau_i(\eta_i^2-1)\leq 0\right\}>\frac{3}{100}.$$

Proof. Note that $\mathsf{E}(\eta_i^2-1)^2=\mathsf{E}(\eta_i^4-2\eta_i^2+1)=3-2+1=2$. Let $\Psi=\sum_{i=1}^n\tau_i(\eta_i^2-1)$, and $\Phi=\frac{\Psi}{\sqrt{2\sum_{i=1}^n\tau_i^2}}$. Then $\mathsf{E}\Phi=0$ and $\text{Var}(\Phi)=1$. Since $\mathsf{E}(\eta_i^2-1)^2=2$, and $\mathsf{E}(\eta_i^2-1)^4=60$, direct calculation shows that

$$\mathsf{E}\Psi^4=48\sum_{i=1}^{n}\tau_i^4+12\left(\sum_{i=1}^{n}\tau_i^2\right)^2\leq 60\left(\sum_{i=1}^{n}\tau_i^2\right)^2.$$

Therefore, we have

$$\mathsf{E}\Phi^4=\frac{\mathsf{E}\Psi^4}{4(\sum_{i=1}^n\tau_i^2)^2}\leq 15.$$

It follows from Lemma 2.2 that $\text{Prob}\{\Phi\geq 0\}>\frac{3}{100}$. Similarly, we have $\text{Prob}\{\Phi\leq 0\}>\frac{3}{100}$ by symmetry. ∎

Using Hölder's inequality, we also have $\mathsf{E}|\Psi|^3\leq 60^{\frac{3}{4}}(\sum_{i=1}^n\tau_i^2)^{\frac{3}{2}}$ and $\mathsf{E}|\Phi|^3\leq 15^{\frac{3}{4}}$, which can be used to lower $\text{Prob}\{\Phi\geq 0\}$ (cf. Theorem 2.1 in [13]). However, in this particular case, the bound so obtained is slightly worse than the one that we derived in Lemma 3.1.

LEMMA 3.2. *Let A,Z be two real symmetric matrices with $Z\succeq 0$ and $\text{Tr}\,(AZ)\geq 0$. Let $\xi\in N(0,Z)$ be a normal random vector with zero mean and covariance matrix Z. Then for any $0\leq\gamma\leq 1$ we have*

$$\text{Prob}\{\xi^TA\xi<\gamma\mathsf{E}(\xi^TA\xi)\}<1-\frac{3}{100}.$$

Proof. Let $r=\text{rank}(AZ)$, and let $Q\in\mathbb{R}^{n\times n}$ be an orthogonal matrix such that

$$Q^T(Z^{\frac{1}{2}}AZ^{\frac{1}{2}})Q=\text{diag}(\lambda_1,\ldots,\lambda_r,0,\ldots,0).$$

Since $\text{Tr}\,(AZ)\geq 0$ we have $\sum_{i=1}^r\lambda_i\geq 0$. Let $\bar\xi\in N(0,I_n)$ and $\xi:=Z^{\frac{1}{2}}Q\bar\xi$. Then ξ follows a Gaussian distribution $N(0,Z)$. Moreover, we have $\xi^TA\xi=\sum_{i=1}^r\lambda_i\bar\xi_i^2$, where $\bar\xi_i$, $i=1,\ldots,r$, are independent and follow the normal distribution $N(0,1)$. Therefore, we have $\mathsf{E}(\xi^TA\xi)=\sum_{i=1}^r\lambda_i$ and

$$\begin{aligned}\text{Prob}\{\xi^TA\xi<\gamma\mathsf{E}(\xi^TA\xi)\}&=\text{Prob}\left\{\sum_{i=1}^{r}\lambda_i\bar\xi_i^2<\gamma\sum_{i=1}^{r}\lambda_i\right\}\\&=\text{Prob}\left\{\sum_{i=1}^{r}\lambda_i(\bar\xi_i^2-1)<(\gamma-1)\sum_{i=1}^{r}\lambda_i\right\}\\&\leq\text{Prob}\left\{\sum_{i=1}^{r}\lambda_i(\bar\xi_i^2-1)<0\right\}<1-\frac{3}{100},\end{aligned}$$

where the first inequality follows from $\gamma\in[0,1]$ and $\sum_{i=1}^r\lambda_i\geq 0$, and the last step is due to Lemma 3.1. ∎

Now we are ready to establish the following quality bound for the SDP relaxation. The argument follows closely to those of [14].

THEOREM 3.3. *Consider the real quadratic program* (3.1) *and its SDP relaxation* (3.2)*, where* $\mathbb{F} = \mathbb{R}$*. Then, there holds*

$$\frac{v_{qp}^{\min}}{v_{sdp}^{\min}} \leq \frac{10^6 m^2}{\pi}.$$

Proof. Let $\hat{Z}$ be an optimal solution of the SDP relaxation (3.2) with rank r satisfying $\frac{(r+1)r}{2} \leq m$. The existence of such a matrix solution is well known; cf. Pataki [20]. Moreover, this low rank matrix can be constructed in polynomial time; cf. [11]. Clearly, $r < \sqrt{2m}$. Since $\hat{Z}$ is feasible, $\mathrm{Tr}\,(A_0\hat{Z}) \geq 1$. Define random vector $\xi = \mathcal{N}(0, \hat{Z})$. For any $0 < \gamma \leq 1$ and $\mu > 0$ we have

$$\begin{aligned}
&\mathrm{Prob}\left\{\min_{0\leq k\leq m} \xi^T A_k \xi \geq \gamma,\, \xi^T C\xi \leq \mu\,\mathrm{Tr}\,(C\hat{Z})\right\}\\
&= \mathrm{Prob}\left\{\xi^T A_k\xi \geq \gamma\,\forall k = 0,1,\ldots,m,\ \text{and}\ \xi^T C\xi \leq \mu\,\mathrm{Tr}\,(C\hat{Z})\right\}\\
&\geq \mathrm{Prob}\left\{\xi^T A_k\xi \geq \gamma\,\mathrm{Tr}\,(A_k\hat{Z})\,\forall k = 0,1,\ldots,m,\ \text{and}\ \xi^T C\xi \leq \mu\,\mathrm{Tr}\,(C\hat{Z})\right\}\\
&= \mathrm{Prob}\left\{\xi^T A_k\xi \geq \gamma\,\mathsf{E}(\xi^T A_k\xi)\,\forall k = 0,1,\ldots,m,\ \text{and}\ \xi^T C\xi \leq \mu\,\mathsf{E}(\xi^T C\xi)\right\}\\
&\geq 1 - \sum_{k=0}^{m} \mathrm{Prob}\left\{\xi^T A_k\xi < \gamma\,\mathsf{E}(\xi^T A_k\xi)\right\} - \mathrm{Prob}\left\{\xi^T C\xi > \mu\,\mathsf{E}(\xi^T C\xi)\right\}.
\end{aligned}$$

Since $A_k \succeq 0$ for $k = 1,\ldots,m$, it follows from Lemma 3.1 of [14] that

$$\mathrm{Prob}\left\{\xi^T A_k\xi < \gamma\mathsf{E}(\xi^T A_k\xi)\right\} \leq \max\left\{\sqrt{\gamma}, \frac{2(r-1)\gamma}{\pi-2}\right\}.$$

Although A_0 is indefinite, we can use Lemma 3.2 to obtain

$$\mathrm{Prob}\left\{\xi^T A_0\xi < \gamma\mathsf{E}(\xi^T A_0\xi)\right\} < 1 - \frac{3}{100}.$$

Also, since $C \succeq 0$, we can apply the Markov inequality to obtain

$$\mathrm{Prob}\left\{\xi^T C\xi > \mu\,\mathsf{E}(\xi^T C\xi)\right\} \leq \frac{1}{\mu}.$$

Combining the above estimates yields

$$\mathrm{Prob}\left\{\min_{0\leq k\leq m} \xi^T A_k\xi \geq \gamma,\, \xi^T C\xi \leq \mu\,\mathrm{Tr}\,(C\hat{Z})\right\} > \frac{3}{100} - m\max\left\{\sqrt{\gamma}, \frac{2(r-1)\gamma}{\pi-2}\right\} - \frac{1}{\mu}.$$

Let $\hat{\mu} = 100$ and $\hat{\gamma} = \frac{\pi}{10^4 m^2}$. Since $r < \sqrt{2m}$, we have $\sqrt{\hat{\gamma}} \geq \frac{2(r-1)\hat{\gamma}}{\pi-2}$. Then we have

$$\frac{3}{100} - m\max\left\{\sqrt{\hat{\gamma}}, \frac{2(r-1)\hat{\gamma}}{\pi-2}\right\} - \frac{1}{\hat{\mu}} = \frac{3}{100} - m\frac{\sqrt{\pi}}{100m} - \frac{1}{100} > \frac{1}{500}.$$

Therefore, there exists a vector $\xi \in \mathbb{R}^n$ such that

$$\xi^T A_k \xi \geq \hat{\gamma}, \quad k = 0, 1, \ldots, m, \quad \text{and} \quad \xi^T C \xi \leq \hat{\mu} \mathrm{Tr}\,(C\hat{Z}).$$

Now let $x = \frac{1}{\sqrt{\hat{\gamma}}}\xi$. Then, $x^T A_k x \geq 1$, $k = 0, 1, \ldots, m$, and

$$v_{qp}^{\min} \leq x^T C x = \frac{1}{\hat{\gamma}} \xi^T C \xi \leq \frac{\hat{\mu}}{\hat{\gamma}} \mathrm{Tr}\,(C\hat{Z}) = \frac{10^6 m^2}{\pi}\, v_{sdp}^{\min},$$

which establishes the desired bound. □

3.2. The complex case. Recall that the density function of a complex-valued normal distribution[1] $\eta \sim N_c(0, 1)$ is

$$\frac{1}{\pi} e^{-|u|^2} \, \forall u \in \mathbb{C}.$$

In polar coordinates, the density function becomes

$$\frac{\rho}{\pi} e^{-\rho^2} \, \forall \, \rho \in [0, +\infty) \quad \theta \in [0, 2\pi).$$

The argument θ is uniformly distributed in $[0, 2\pi)$, and the modulus ρ has the distribution

$$f(\rho) = \begin{cases} 2\rho e^{-\rho^2} & \text{if } \rho \geq 0, \\ 0 & \text{if } \rho < 0. \end{cases}$$

Thus squared modulus $|\eta|^2$ has the exponential distribution

$$\mathrm{Prob}\,\{|\eta|^2 \leq \alpha\} \leq 1 - e^{-\alpha}.$$

LEMMA 3.4. *For any real numbers τ_i and i.i.d. exponential random variables η_i with unit variance, $i = 1, \ldots, n$, there holds*

$$\mathrm{Prob}\left\{\sum_{i=1}^n \tau_i(\eta_i - 1) \geq 0\right\} > \frac{1}{20}, \qquad \mathrm{Prob}\left\{\sum_{i=1}^n \tau_i(\eta_i - 1) \leq 0\right\} > \frac{1}{20}.$$

Proof. Note that $\mathsf{E}(\eta_i - 1)^2 = 1$. Let $\Psi = \sum_{i=1}^n \tau_i(\eta_i - 1)$ and $\Phi = \frac{\Psi}{\sqrt{\sum_{i=1}^n \tau_i^2}}$. Clearly, $\mathsf{E}\Phi = 0$ and $\mathrm{Var}(\Phi) = 1$. Since $\mathsf{E}(\eta_i - 1)^4 = 9$, direct calculation shows that

$$\mathsf{E}\Psi^4 = 6\sum_{i=1}^n \tau_i^4 + 3\left(\sum_{i=1}^n \tau_i^2\right)^2 \leq 9\left(\sum_{i=1}^n \tau_i^2\right)^2.$$

This further implies

$$\mathsf{E}\Phi^4 = \frac{\mathsf{E}\Psi^4}{(\sum_{i=1}^n \tau_i^2)^2} \leq 9.$$

Using Lemma 2.2 we have $\mathrm{Prob}\,\{\Phi \geq 0\} > \frac{1}{20}$. Similarly, $\mathrm{Prob}\,\{\Phi \leq 0\} > \frac{1}{20}$. □

[1]For a discussion on the complex normal distribution and the related references, see Zhang and Huang [26].

Interestingly, it is possible to find a closed formula (see, e.g., [7] and [1]) for the above probability. In particular, if all the τ_i's are distinctive, then

$$\text{Prob}\left\{\sum_{i=1}^{n}\tau_i(\eta_i-1)\geq 0\right\}=\sum_{i=1}^{n}\frac{e^{-\frac{1}{\tau_i}}}{\prod_{j\neq i}\left(1-\frac{\tau_j}{\tau_i}\right)}.$$

Therefore, we have

$$\frac{1}{20}<\sum_{i=1}^{n}\frac{e^{-\frac{1}{\tau_i}}}{\prod_{j\neq i}\left(1-\frac{\tau_j}{\tau_i}\right)}<\frac{19}{20}$$

for any distinctive real values τ_i, $i=1,\ldots,n$.

LEMMA 3.5. *Let A, Z be two Hermitian matrices satisfying $Z\succeq 0$ and $\text{Tr}\,(AZ)\geq 0$. Let $\xi\sim N_c(0,Z)$ be a complex normal random vector. Then, for any $0\leq\gamma\leq 1$, we have*

$$\text{Prob}\left\{\xi^*A\xi<\gamma\mathsf{E}(\xi^*A\xi)\right\}<1-\frac{1}{20}.$$

Proof. Let $Q\in\mathbb{C}^{n\times n}$ be a unitary matrix such that

$$Q^*(Z^{\frac{1}{2}}AZ^{\frac{1}{2}})Q=\text{diag}(\lambda_1,\ldots,\lambda_r,0,\ldots,0),$$

where $r=\text{rank}(AZ)$. Since $\text{Tr}\,(AZ)\geq 0$, it follows that $\sum_{i=1}^{r}\lambda_i\geq 0$. Let $\hat{\xi}\in\mathbb{C}^n$ be a random Gaussian vector drawn from the complex normal distribution $N_c(0,I_n)$. Then the random vector $\xi=Z^{\frac{1}{2}}Q\hat{\xi}$ follows the Gaussian distribution $N_c(0,Z)$. As a result, there holds

$$\begin{aligned}\text{Prob}\left\{\xi^*A\xi<\gamma\mathsf{E}(\xi^*A\xi)\right)&=\text{Prob}\left\{\sum_{i=1}^{r}\lambda_i|\hat{\xi}_i|^2<\gamma\sum_{i=1}^{n}\lambda_i\right\}\\&=\text{Prob}\left\{\sum_{i=1}^{n}\lambda_i(|\hat{\xi}_i|^2-1)<(\gamma-1)\sum_{i=1}^{n}\lambda_i\right\}\\&\leq\text{Prob}\left\{\sum_{i=1}^{n}\lambda_i(|\hat{\xi}_i|^2-1)<0\right\},\end{aligned}$$

where the last step follows from $\gamma\in[0,1]$ and $\sum_{i=1}^{r}\lambda_i\geq 0$. Since $|\xi_i|^2$ is exponentially distributed, by Lemma 3.4 we have

$$\text{Prob}\left\{\sum_{i=1}^{n}\lambda_i(|\hat{\xi}_i|^2-1)\geq 0\right\}>\frac{1}{20},$$

which proves the lemma. ∎

THEOREM 3.6. *Consider* (3.1) *and* (3.2)*, where $\mathbb{F}=\mathbb{C}$. Then*

$$\frac{v_{qp}^{\min}}{v_{sdp}^{\min}}\leq 2400m.$$

Proof. It is known that in this case, if $v_{sdp}^{\min}$ is finite and $m \le 3$, then $v_{qp}^{\min}/v_{sdp}^{\min} = 1$ (cf., e.g., [11] and [25]). Below we shall consider only the case where $m \ge 4$. Let $\hat{Z}$ be a low rank optimal solution of the SDP relaxation (3.2) such that $r = \mathrm{rank}(\hat{Z}) \le \sqrt{m}$ (see [11, section 5]). The feasibility of $\hat{Z}$ implies that $\mathrm{Tr}\,(A_0\hat{Z}) \ge 1$. Similar to Theorem 3.3, we can use the union bound to obtain the following inequality:

$$\begin{aligned}&\mathrm{Prob}\left\{\min_{0\le k\le m} \xi^* A_k\xi \ge \gamma,\, \xi^* C\xi \le \mu\,\mathrm{Tr}\,(C\hat{Z})\right\}\\ &\ge 1 - \sum_{k=0}^{m} \mathrm{Prob}\,\{\xi^* A_k\xi < \gamma\,\mathsf{E}(\xi^* A_k\xi)\} - \mathrm{Prob}\,\{\xi^* C\xi > \mu\,\mathsf{E}(\xi^* C\xi)\}.\end{aligned}$$

Since $A_k \succeq 0$, $k = 1, \ldots, m$, it follows from Lemma 3.4 in [14] that

$$\mathrm{Prob}\,\{\xi^* A_k\xi < \gamma\mathsf{E}(\xi^* A_k\xi)\} \le \max\left\{\frac{4}{3}\gamma, 16(r-1)^2\gamma^2\right\}.$$

Although A_0 is indefinite, Lemma 3.5 asserts that

$$\mathrm{Prob}\,\{\xi^* A_0\xi < \gamma\mathsf{E}(\xi^* A_0\xi)\} < 1 - \frac{1}{20}.$$

Therefore, combining these estimates and using the Markov inequality, we have

$$\begin{aligned}&\mathrm{Prob}\left\{\min_{0\le k\le m} \xi^* A_k\xi \ge \gamma, \xi^* C\xi \le \mu,\, \mathrm{Tr}\,(C\hat{Z})\right\}\\ &> \frac{1}{20} - m\max\left\{\frac{4}{3}\gamma, 16(r-1)^2\gamma^2\right\} - \frac{1}{\mu}.\end{aligned}$$

Now choose $\hat{\mu} = 60$ and $\hat{\gamma} = \frac{1}{40m}$. In this case, $\frac{4}{3}\hat{\gamma} \ge \hat{1}6(r-1)^2\hat{\gamma}^2$. We also have a strict lower bound of the above probability:

$$\mathrm{Prob}\left\{\min_{0\le k\le m} \xi^* A_k\xi \ge \hat{\gamma},\, \xi^* C\xi \le \hat{\mu}\,\mathrm{Tr}\,(C\hat{Z})\right\} > 0.$$

This implies that there exists $\xi \in \mathbb{C}^n$ such that

$$\xi^* A_k\xi \ge \hat{\gamma},\ k = 0, 1, \ldots, m; \quad \xi^* C\xi \le \hat{\mu}\mathrm{Tr}\,(C\hat{Z}).$$

Now let $x := \frac{1}{\sqrt{\hat{\gamma}}}\xi$. Then $x^* A_k x \ge 1$, $k = 0, 1, \ldots, m$, and so

$$v_{qp}^{\min} \le x^* C x \le \frac{\xi^* C\xi}{\hat{\gamma}} \le \frac{\hat{\mu}\mathrm{Tr}\,(C\hat{Z})}{\hat{\gamma}} = 2400m \cdot v_{sdp}^{\min}.$$

The theorem is proven. □

Notice that there are examples (see [14]) which show that the worst-case ratios of $v_{qp}^{\min}/v_{sdp}^{\min}$ are indeed $O(m^2)$ and $O(m)$ in the real and complex case, respectively, even in the absence of the indefinite constraint $x^* A_0 x \ge 1$. Thus, the bounds of Theorems 3.3 and 3.6 are essentially tight.

What happens if there is more than one indefinite quadratic constraint? The following example shows that in this case the SDP relaxation does not admit any *finite* quality bound.

Example 3.7.

$$\begin{aligned} \min \quad & x_4^2 \\ \text{s.t.} \quad & x_1x_2 + x_3^2 + x_4^2 \geq 1 \\ & -x_1x_2 + x_3^2 + x_4^2 \geq 1 \\ & \tfrac{1}{2}x_1^2 - x_3^2 \geq 1 \\ & \tfrac{1}{2}x_2^2 - x_3^2 \geq 1 \\ & x_1, x_2, x_3, x_4 \in \mathbb{R}. \end{aligned}$$

The first two constraints are equivalent to $|x_1x_2| \leq x_3^2 + x_4^2 - 1$. At the same time, the last two constraints imply $|x_1x_2| \geq 2(x_3^2 + 1)$. Combining these two inequalities yields

$$x_3^2 + x_4^2 - 1 \geq 2(x_3^2 + 1),$$

which further implies $x_4^2 \geq 3$. Therefore, we must have $v_{qp}^{\min} \geq 3$ in this case. However,

$$\begin{bmatrix} 4 & 0 & 0 & 0 \\ 0 & 4 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

is feasible for the corresponding SDP relaxation problem and attains an objective value of 0. Thus, it must be optimal, and thus $v_{sdp}^{\min} = 0$. Hence, $v_{qp}^{\min}/v_{sdp}^{\min} = \infty$ in this case.

4. SDP relaxation bounds for the quadratic maximization model. In this section, we discuss the approximation bound of SDP relaxation for the nonconvex homogeneous quadratic maximization problem (1.2). Subsection 4.1 considers the case that one constraint is indefinite, and subsection 4.2 considers the case that two or more constraints are indefinite.

4.1. One indefinite constraint. In this subsection, consider the quadratic maximization problem

$$\begin{aligned} v_{qp}^{\max} := \max \quad & x^*Cx \\ \text{s.t.} \quad & x^*A_kx \leq 1,\ k = 0, 1, \ldots, m \\ & x \in \mathbb{F}^n, \end{aligned} \tag{4.1}$$

where $A_k \in \mathbb{SF}_+^n$, $k = 1, \ldots, m$, are positive semidefinite, while $C, A_0 \in \mathbb{SF}^n$ may be indefinite. For convenience, from now on we shall focus on the case $\mathbb{F} = \mathbb{R}^n$. Unlike the case of minimization form, this choice does not significantly affect the quality of SDP approximation ratios, since in the complex case the bounds are of the same order of magnitude. We assume that there is $\mu_k \geq 0$, $k = 0, 1, \ldots, m$, such that

$$\sum_{k=0}^{m} \mu_k A_k \succ 0.$$

Under this condition, the SDP relaxation satisfies the dual Slater condition. Thus the primal-dual optimal solutions exist and the primal-dual optimal objective values are attainable. Let the SDP relaxation optimal value be

$$\begin{aligned} v_{sdp}^{\max} := \max \quad & \mathrm{Tr}\,(CX) \\ \text{s.t.} \quad & \mathrm{Tr}\,(A_k X) \le 1,\ k = 0, 1, \ldots, m \\ & X \succeq 0. \end{aligned} \tag{4.2}$$

Obviously $v_{qp}^{\max} \le v_{sdp}^{\max}$.

LEMMA 4.1. *Let w_{ij} $(1 \le i < j \le n)$ be any real numbers, and let ξ_i $(1 \le i \le n)$ be random variables such that* Prob $\{\xi_i = -1\}$ = Prob $\{\xi_i = 1\} = 0.5$. *Then there holds*

$$\text{Prob}\left\{\sum_{1\le i<j\le n} w_{ij}\xi_i\xi_j \le 0\right\} > \frac{3}{100}.$$

Proof. Let $\Psi = \sum_{1\le i<j\le n} w_{ij}\xi_i\xi_j$. Then $\mathsf{E}\Psi = 0$, $\mathsf{E}(\Psi^2) = \sum_{1\le i<j\le n} w_{ij}^2$ and

$$\mathsf{E}(\Psi^4) = \sum_{1\le i<j\le n} w_{ij}^4 + 6 \sum_{1\le i<j<k\le n} (w_{ij}^2 w_{ik}^2 + w_{ij}^2 w_{jk}^2 + w_{ik}^2 w_{jk}^2) + W,$$

where

$$\begin{aligned} W = {} & 24 \sum_{1\le i<j<k<\ell\le n} (w_{ij}w_{ik}w_{j\ell}w_{k\ell} + w_{ij}w_{i\ell}w_{jk}w_{k\ell} + w_{ik}w_{i\ell}w_{jk}w_{j\ell}) \\ & + 6 \sum_{1\le i<j<k<\ell\le n} \left(w_{ij}^2 w_{k\ell}^2 + w_{ik}^2 w_{j\ell}^2 + w_{i\ell}^2 w_{jk}^2\right) \\ & \le 30 \sum_{1\le i<j<k<\ell\le n} \left(w_{ij}^2 w_{k\ell}^2 + w_{ik}^2 w_{j\ell}^2 + w_{i\ell}^2 w_{jk}^2\right). \end{aligned}$$

Therefore, we have $\mathsf{E}(\Psi^4) \le 15(\sum_{1\le i<j\le n} w_{ij}^2)^2$. Now let $\Phi = \frac{\Psi}{\sqrt{\sum_{1\le i<j\le n} w_{ij}^2}}$. Then $\mathsf{E}(\Phi) = 0$, $\mathrm{Var}(\Phi) = 1$, and $\mathsf{E}(\Phi^4) \le 15$. By Lemma 2.2, we have

$$\text{Prob}\,\{\Phi \le 0\} > \frac{3}{100}.$$

The desired result follows. □

Lemma 4.1 represents a significant advancement in settling an open question of Ben-Tal, Nemirovski, and Roos [3, Conjecture A.5] who conjectured that

$$\text{Prob}\left\{\sum_{1\le i<j\le n} w_{ij}\xi_i\xi_j \le 0\right\} \ge \frac{1}{4} \qquad \forall\ w_{ij}.$$

We managed to show a smaller constant bound of 3/100, instead of 1/4. The above inequality was needed to establish the so called *approximate S-lemma*—an extension of the well-known S-lemma, which is important in the context of robust optimization and is closely related to our analysis in this section. In their work [18], Nemirovski,

Roos, and Terlaky derived a weaker lower bound of $1/8n^2$, which goes to zero as $n \to \infty$.

We can now use Lemma 4.1 to analyze the performance of SDP relaxation for (4.2). Let $\hat{X} = UU^T$ be one optimal solution of (4.2), where $U \in \mathbb{R}^{n\times r}$ and $r = \text{rank}(\hat{X})$. Suppose $Q \in \mathbb{R}^{n\times r}$ is the orthogonal matrix such that $\hat{C} := Q^T U^T C U Q$ is diagonal. Let ξ_k, $k = 1, \ldots, r$, be i.i.d. random variables taking values -1 or 1 with equal probabilities, and let

$$x(\xi) := \frac{1}{\sqrt{\max\limits_{0\le k\le m} \xi^T \hat{A}_k \xi}}\, UQ\xi,$$

where $\hat{A}_k = Q^T U^T A_k U Q$. Note that the above random vector $x(\xi)$ is always well-defined, since the assumption $\sum_{k=0}^m \mu_k A_k \succ 0$ implies

$$\max_{0\le k\le m} \xi^T \hat{A}_k \xi > 0 \text{ for any } \xi \neq 0.$$

Let $\mu = \min\{m, \max_i \text{rank}(A_i \hat{X})\}$. We have the following estimate of the SDP approximation ratio.

THEOREM 4.2. *It holds that*

$$v_{qp}^{\max} \le v_{sdp}^{\max} \le 2\log(67\, m\mu)\, v_{qp}^{\max}.$$

Proof. Notice that $\hat{C} = Q^T U^T C U Q$ is diagonal, and hence

$$x(\xi)^T C x(\xi) = \frac{1}{\max\limits_{0\le k\le m} \xi^T \hat{A}_k \xi}\, \xi^T Q^T U^T C U Q \xi = \frac{1}{\max\limits_{0\le k\le m} \xi^T \hat{A}_k \xi} \text{Tr}\,(CX).$$

Therefore, for any $\alpha > 1$ we have

$$\begin{aligned}
&\text{Prob}\left\{x(\xi)^T C x(\xi) \ge \frac{1}{\alpha}\,\text{Tr}\,(CX)\right\} \\
&= \text{Prob}\left\{\max_{0\le k\le m} \xi^T \hat{A}_k \xi \le \alpha\right\} \\
&= 1 - \text{Prob}\left\{\max_{0\le k\le m} \xi^T \hat{A}_k \xi > \alpha\right\} \\
&\ge 1 - \text{Prob}\left\{\max_{1\le k\le m} \xi^T \hat{A}_k \xi > \alpha\right\} - \text{Prob}\left\{\xi^T \hat{A}_0 \xi > \alpha\right\}.
\end{aligned}$$

Since $\text{Tr}\,(A_0) \le 1$ and so $\alpha - \text{Tr}\,(A_0) \ge 0$, it follows from Lemma 4.1 that

$$\text{Prob}\left\{\xi^T \hat{A}_0 \xi > \alpha\right\} \le \text{Prob}\left\{\sum_{1\le i<j\le m} (\hat{A}_0)_{ij}\xi_i\xi_j > 0\right\} < 1 - \frac{3}{100}.$$

Since $\hat{A}_k \succeq 0$ for $k = 1, \ldots, m$, and $\text{Tr}\,(\hat{A}_k) \le 1$, it follows from (12) in [18] that

$$\text{Prob}\left\{\max_{1\le k\le m} \xi^T \hat{A}_k \xi > \alpha\right\} < 2m\mu e^{-\frac{1}{2}\alpha}.$$

Hence we have

$$\text{Prob}\left\{x(\xi)^T C x(\xi) \geq \frac{1}{\alpha}\,\text{Tr}\,(CX)\right\} > \frac{3}{100} - 2m\mu e^{-\frac{1}{2}\alpha}.$$

Letting $\hat{\alpha} = 2\log(67\,m\mu)$ ensures the above probability will be positive. Therefore, there exists a random vector ξ such that $\text{Tr}\,(CX) \leq \hat{\alpha}\, x(\xi)^T C x(\xi)$, and the theorem is proven. □

We point out that Theorem 4.2 is an improvement of the so-called approximate S-lemma of Ben-Tal, Nemirovski, and Roos [3, Lemma A.6]. In particular, they showed that $\alpha \leq 2\log(16n^2\,m\mu)$, in contrast to our bound $\alpha \leq 2\log(67\,m\mu)$.

Notice that in (4.1) there is only one indefinite inequality. Can we allow more than one indefinite constraint? The following example shows that the answer is "no" if we wish to have a data-independent worst-case approximation ratio. (Data-dependent approximation ratio bounds will be discussed in section 4.2, where we do allow multiple indefinite constraints.)

Example 4.3. Consider

$$\begin{aligned} \max \quad & x_1^2 + \tfrac{1}{M}x_2^2 \\ \text{s.t.} \quad & Mx_1x_2 + x_2^2 \leq 1 \\ & -Mx_1x_2 + x_2^2 \leq 1 \\ & M(x_1^2 - x_2^2) \leq 1, \end{aligned}$$

where $M > 0$ is an arbitrarily large positive constant. Its SDP relaxation is

$$\begin{aligned} \max \quad & X_{11} + \tfrac{1}{M}X_{22} \\ \text{s.t.} \quad & MX_{12} + X_{22} \leq 1,\ -MX_{12} + X_{22} \leq 1,\ M(X_{11} - X_{22}) \leq 1 \\ & \begin{bmatrix} X_{11} & X_{12} \\ X_{21} & X_{22} \end{bmatrix} \succeq 0. \end{aligned}$$

For this quadratic program, the first two constraints imply that $|x_1x_2| \leq \frac{1-x_2^2}{M} \leq \frac{1}{M}$, and so $x_1^2 \leq \frac{1}{M^2x_2^2}$. The third inequality assures that $x_1^2 \leq \frac{1}{M} + x_2^2$. Therefore, $x_1^2 \leq \min\{\frac{1}{M^2x_2^2}, \frac{1}{M} + x_2^2\} \leq \frac{\sqrt{5}+1}{2M} \approx \frac{1.618}{M}$. Moreover, $x_2^2 \leq 1$, and so $v_{qp}^{\max} \leq \frac{2.618}{M}$.

The SDP relaxation satisfies both primal and dual Slater conditions, so the primal-dual optimal solutions exist. A feasible solution for the SDP relaxation (primal problem) is the 2 x 2 identity matrix, with the objective value being $1 + \frac{1}{M} > 1$. On the other hand, since $X_{22} \leq M|X_{12}| + X_{22} \leq 1$, and $X_{11} \leq X_{22} + \frac{1}{M}$, an upper bound for the SDP optimal value is $1 + \frac{2}{M}$. Therefore, for this example the ratio $\frac{v_{sdp}^{\max}}{v_{qp}^{\max}} \geq \frac{M}{2.618} \approx 0.382M$ can be arbitrarily large, depending on the size of M.

If there are at most two homogeneous quadratic constraints, and, moreover, if the SDP relaxation has a primal-dual complementary optimal solution, then the SDP optimal value will be equal to the optimal value of the quadratic model; see, e.g., Ye and Zhang [25, Corollary 2.6]. In other words, if there are no more than two inequality constraints, then under the primal-dual Slater condition, we will have $v_{sdp}^{\max}/v_{qp}^{\max} = 1$. In this sense, Example 4.3 is the smallest possible in size. By removing the requirement that the SDP relaxation has a finite optimal value, then it is possible to construct an example which involves only two inequality constraints.

Example 4.4. Consider

$$\begin{aligned} \max \quad & x_1x_2 + x_1^2 \\ \text{s.t.} \quad & x_1x_2 \le 1 \\ & x_1^2 - x_2^2 \le 1, \end{aligned}$$

with the SDP relaxation

$$\begin{aligned} \max \quad & X_{12} + X_{11} \\ \text{s.t.} \quad & X_{12} \le 1,\ X_{11} - X_{22} \le 1, \\ & \begin{bmatrix} X_{11} & X_{12} \\ X_{21} & X_{22} \end{bmatrix} \succeq 0. \end{aligned}$$

In terms of polar coordinates, $(x_1, x_2) \longrightarrow (r\cos\theta, r\sin\theta)$, the original quadratic problem can be turned into

$$\begin{aligned} \max \quad & r^2(\sin 2\theta + \cos 2\theta + 1)/2 \\ \text{s.t.} \quad & r^2 \sin 2\theta \le 2 \\ & r^2 \cos 2\theta \le 1. \end{aligned}$$

By a further change of variables $(r^2\cos 2\theta, r^2 \sin 2\theta) \longrightarrow (y_1, y_2)$, we can reformulate the original quadratic problem as

$$\begin{aligned} \max \quad & \tfrac{1}{2}\left(y_1 + y_2 + \sqrt{y_1^2 + y_2^2}\right) \\ \text{s.t.} \quad & y_1 \le 2 \\ & y_2 \le 1. \end{aligned}$$

This optimization problem has a unique optimal solution at $(y_1^*, y_2^*) = (2, 1)$ with the optimal value being $\frac{3+\sqrt{5}}{2} \approx 2.618$. The SDP relaxation problem is clearly unbounded, as any positive multiple of the identity matrix is feasible. Therefore, $v_{sdp}^{\max}/v_{qp}^{\max} = +\infty$. This example is possible because the dual of the SDP relaxation problem is infeasible.

4.2. Multiple indefinite constraints. Unlike the minimization form (1.1) for which the SDP approximation ratio can be infinite when there are more than one indefinite constraints (see Example 3.7), the maximization form (1.2) can still admit a finite SDP approximation ratio in this case. In particular, consider a general homogeneous quadratic maximization problem

$$\begin{aligned} \max \quad & x^T C x \\ \text{s.t.} \quad & x^T A_k x \le 1,\ k = 0, 1, \ldots, m \\ & x \in \mathbb{F}^n. \end{aligned} \tag{4.3}$$

Suppose that $\mathcal{I}, \mathcal{D}$ are two index sets, $\mathcal{I} \cup \mathcal{D} = \{0, 1, \ldots, m\}$ and $\mathcal{I} \cap \mathcal{D} = \emptyset$, such that $A_k \succeq 0$ for $k \in \mathcal{D}$ and A_k indefinite for $k \in \mathcal{I}$. The SDP relaxation for (4.3) is

$$\begin{aligned} \max \quad & \mathrm{Tr}\,(CX) \\ \text{s.t.} \quad & \mathrm{Tr}\,(A_k X) \le 1,\ k = 0, 1, \ldots, m \\ & X \succeq 0. \end{aligned} \tag{4.4}$$

We begin our analysis with a technical lemma which bounds the probability of an exponential tail. Similar bounds exist in the literature, e.g., [6]. However, the lemma below serves our needs exactly; for completeness we include a proof here.

LEMMA 4.5. *Let $\{\lambda_i\}_{i=1}^n$ be any given real numbers, and $\{\eta_i\}_{i=1}^n$ be i.i.d. random variables drawn from either the real or complex valued zero mean Gaussian distribution with unit variance. Let $\sigma = \sqrt{\sum_{i=1}^n \lambda_i^2}$ and $\delta = \max\{\max\{\lambda_i \mid 1 \le i \le n\}, 0\}$. Then, for any $\alpha > 0$ there holds*

$$\begin{aligned}&\text{Prob}\left\{\sum_{i=1}^n \lambda_i\eta_i^2 - \sum_{i=1}^n \lambda_i \ge \alpha\sigma\right\}\\ &\quad\le \begin{cases} \exp\left(-\min\left\{\alpha, \frac{\sigma}{\delta}\right\}\frac{\alpha}{8}\right) & \text{if } \eta_i \sim N(0,1) \text{ is real Gaussian,}\\ \exp\left(-\min\left\{\alpha, \frac{\sigma}{\delta}\right\}\frac{\alpha}{4}\right) & \text{if } \eta_i \sim N_c(0,1) \text{ is complex Gaussian.}\end{cases}\end{aligned}$$

Proof. We will prove only the real Gaussian case; the complex case is similar and therefore omitted. Let $\beta := \frac{1}{4}\min\{\frac{1}{\delta}, \frac{\alpha}{\sigma}\}$. Then, $2\beta\lambda_i \le 1/2$ for all $i = 1, \ldots, n$, and $\beta\sigma = \frac{1}{4}\min\{\frac{\sigma}{\delta}, \alpha\}$. Note that for any $t \le 1/2$ the following inequality holds:

$$\frac{1}{1-t} \le e^{t+t^2}. \tag{4.5}$$

Let $\zeta := e^{\beta\sum_{i=1}^n \lambda_i\eta_i^2}$. Since $\{\eta_i^2\}_{i=1}^n$ are standard i.i.d. χ^2 random variables, it follows that

$$\begin{aligned}\mathsf{E}(\zeta) &= \prod_{i=1}^n \mathsf{E}\left(e^{\beta\lambda_i\eta_i^2}\right) = \prod_{i=1}^n \frac{1}{\sqrt{1-2\beta\lambda_i}} = \left(\prod_{i=1}^n \frac{1}{1-2\beta\lambda_i}\right)^{\frac{1}{2}}\\ &\le \left(\prod_{i=1}^n e^{2\beta\lambda_i + 4\beta^2\lambda_i^2}\right)^{\frac{1}{2}} = e^{2\beta^2\sigma^2 + \beta\sum_{i=1}^n \lambda_i},\end{aligned}$$

where the inequality is due to (4.5). This together with the Markov inequality implies

$$\begin{aligned}\text{Prob}\left\{\sum_{i=1}^n \lambda_i\eta_i^2 - \sum_{i=1}^n \lambda_i \ge \alpha\sigma\right\} &= \text{Prob}\left\{\zeta \ge e^{\beta(\alpha\sigma + \sum_{i=1}^n \lambda_i)}\right\}\\ &\le \frac{\mathsf{E}(\zeta)}{e^{\beta(\alpha\sigma + \sum_{i=1}^n \lambda_i)}}\\ &\le e^{2\beta^2\sigma^2 - \beta\sigma\alpha} = e^{\beta\sigma(2\beta\sigma - \alpha)} \le e^{\beta\sigma(\frac{\alpha}{2} - \alpha)}\\ &= e^{-\min\left\{\alpha, \frac{\sigma}{\delta}\right\}\frac{\alpha}{8}}.\end{aligned}$$

The lemma is proven. ∎

We are now ready to pursue the performance analysis for the real case $\mathbb{F} = \mathbb{R}$. Assume that (4.4) has an optimal solution $\hat{X}$. Denote the set of (real) eigenvalues of $A_k\hat{X}$ as $\lambda_1^k, \ldots, \lambda_n^k$, $k = 0, 1, \ldots, m$. Since $\text{Tr}\,(A_k\hat{X}) \le 1$, it follows that $\sum_{i=1}^n \lambda_i^k \le 1$. Moreover, $\|A_k\hat{X}\|_F^2 \ge \sum_{i=1}^n (\lambda_i^k)^2$, $k = 0, 1, \ldots, m$, where $\|\cdot\|_F$ denotes the Frobenius norm of a matrix.

Let ξ be a random vector drawn from the Gaussian distribution $N(0, \hat{X})$. For any $\alpha > 1$ and $0 \le k \le m$, we consider the probability of the event $\text{Prob}\{\xi^T A_k\xi > \alpha\}$.

By diagonalization, we have $\text{Prob}\{\xi^T A_k \xi > \alpha\} = \text{Prob}\{\sum_{i=1}^n \lambda_i^k \eta_i^2 > \alpha\}$, where $\eta = (\eta_1, \ldots, \eta_n)^T$ is a random vector following the normal distribution $N(0, I_n)$.

If we let $\sigma^k := \sqrt{\sum_{i=1}^n (\lambda_i^k)^2} \le \|A_k \hat{X}\|_F$ and $\delta^k := \max\{0, \max\{\lambda_i^k \mid 1 \le i \le n\}\}$, then Lemma 4.5 leads to

$$\text{Prob}\{\xi^T A_k \xi > \alpha\} \tag{4.6}$$
$$\le \exp\left(-\min\left\{\frac{\alpha - \sum_{i=1}^n \lambda_i^k}{\sigma^k}, \frac{\sigma^k}{\delta^k}\right\} \frac{\alpha - \sum_{i=1}^n \lambda_i^k}{8\sigma^k}\right) \quad \forall\, 0 \le k \le m.$$

Alternatively, we can bound the tail probability using Chebyshev's inequality. In particular, since $\text{Var}(\sum_{i=1}^n \lambda_i^k \eta_i^2) = 2\sum_{i=1}^n (\lambda_i^k)^2 \le 2\|A_k \hat{X}\|_F^2$, it follows from Chebyshev's inequality that

$$\begin{aligned}
\text{Prob}\left\{\sum_{i=1}^n \lambda_i^k \eta_i^2 > \alpha\right\} &= \text{Prob}\left\{\sum_{i=1}^n \lambda_i^k \eta_i^2 - \sum_{i=1}^n \lambda_i^k > \alpha - \sum_{i=1}^n \lambda_i^k\right\} \\
&\le \text{Prob}\left\{\left|\sum_{i=1}^n \lambda_i^k \eta_i^2 - \sum_{i=1}^n \lambda_i^k\right| > \alpha - \sum_{i=1}^n \lambda_i^k\right\} \\
&\le \frac{\text{Var}(\sum_{i=1}^n \lambda_i^k \eta_i^2)}{\left(\alpha - \sum_{i=1}^n \lambda_i^k\right)^2} \le \frac{2\|A_k \hat{X}\|_F^2}{(\alpha - 1)^2} \quad \forall\, 0 \le k \le m, \qquad (4.7)
\end{aligned}$$

where we have used the fact $\alpha > 1 \ge \sum_{i=1}^n \lambda_i^k$. Applying Lemma 3.1 and using (4.6)–(4.7) gives

$$\begin{aligned}
&\text{Prob}\left\{\xi^T A_k \xi \le \alpha,\, k = 0, 1, \ldots, m;\, \xi^T C \xi \ge \text{Tr}\,(C\hat{X})\right\} \\
&\ge 1 - \text{Prob}\left\{\xi^T C \xi < \text{Tr}\,(C\hat{X})\right\} - \sum_{k=0}^m \text{Prob}\left\{\xi^T A_k \xi > \alpha\right\} \\
&\ge \frac{3}{100} - \sum_{k=0}^m \min\left\{\exp\left(-\min\left\{\frac{\alpha - \sum_{i=1}^n \lambda_i^k}{\sigma^k}, \frac{\sigma^k}{\delta^k}\right\} \frac{\alpha - \sum_{i=1}^n \lambda_i^k}{8\sigma^k}\right), \frac{2\|A_k \hat{X}\|_F^2}{(\alpha - 1)^2}\right\}.
\end{aligned}$$

Notice that $\delta^k \le \sigma^k$ and $\sum_{i=1}^n \lambda_i^k \le 1$ for any k. Therefore, we have, for any $\alpha > 1$,

$$\begin{aligned}
&\text{Prob}\left\{\xi^T A_k \xi \le \alpha,\, k = 0, 1, \ldots, m;\, \xi^T C \xi \ge \text{Tr}\,(C\hat{X})\right\} \\
&\ge \frac{3}{100} - \sum_{i \in \mathcal{D}} \exp\left(-\min\left\{\frac{\alpha - 1}{\sigma^k}, 1\right\} \frac{\alpha - 1}{8\sigma^k}\right) \\
&\quad - \sum_{i \in \mathcal{I}} \min\left\{\exp\left(-\min\left\{\frac{\alpha - 1}{\sigma^k}, 1\right\} \frac{\alpha - 1}{8\sigma^k}\right), \frac{2\|A_k \hat{X}\|_F^2}{(\alpha - 1)^2}\right\}.
\end{aligned}$$

Let us choose

$$\hat{\alpha} = 1 + \max\left\{20 + 8\log|\mathcal{D}|, \min\left\{(20 + 8\log|\mathcal{I}|) \max_{k \in \mathcal{I}} \|A_k \hat{X}\|_F, \sqrt{200 \sum_{k \in \mathcal{I}} \|A_k \hat{X}\|_F^2}\right\}\right\}.$$

Since $\sigma^k \le \sum_{i=1}^n \lambda_i^k \le 1$ for $k \in \mathcal{D}$, it follows from the choice of $\hat{\alpha}$ that

$$\exp\left(-\min\left\{\frac{\hat{\alpha}-1}{\sigma^k}, 1\right\}\frac{\hat{\alpha}-1}{8\sigma^k}\right)$$
$$= \exp\left(-\frac{\hat{\alpha}-1}{8\sigma^k}\right) \le \exp\left(-\frac{\hat{\alpha}-1}{8}\right) \le \frac{1}{100|\mathcal{D}|} \quad \forall\, k \in \mathcal{D}$$

and

$$\sum_{i\in\mathcal{I}} \min\left\{\exp\left(-\min\left\{\frac{\hat{\alpha}-1}{\sigma^k}, 1\right\}\frac{\hat{\alpha}-1}{8\sigma^k}\right), \frac{2\|A_k\hat{X}\|_F^2}{(\hat{\alpha}-1)^2}\right\} \le \frac{1}{100}.$$

This further implies that

$$\text{Prob}\left\{\xi^T A_k \xi \le \hat{\alpha},\, k = 0, 1, \ldots, m;\, \xi^T C \xi \ge \text{Tr}\,(C\hat{X})\right\} \ge \frac{1}{100}.$$

Summarizing, we obtain the following worst-case performance ratio bounds on the SDP relaxation for a real-valued homogeneous (indefinite) quadratic maximization problem. (We also state the complex case without proof.)

THEOREM 4.6. *For the quadratic optimization problem* (4.3) *with* $\mathbb{F} = \mathbb{R}$ *and its SDP relaxation* (4.4)*, suppose that an optimal solution, say* $\hat{X}$*, for* (4.4) *exists. Then,*

$$\frac{v_{sdp}^{\max}}{v_{qp}^{\max}} \le 1 + \max$$
$$\left\{20 + 8\log|\mathcal{D}|, \min\left\{(20 + 8\log|\mathcal{I}|)\max_{k\in\mathcal{I}}\|A_k\hat{X}\|_F, \sqrt{200\sum_{k\in\mathcal{I}}\|A_k\hat{X}\|_F^2}\right\}\right\}.$$

Similarly, for the complex case $\mathbb{F} = \mathbb{C}$*, we have*

$$\frac{v_{sdp}^{\max}}{v_{qp}^{\max}} \le 1 + \max$$
$$\left\{15 + 4\log|\mathcal{D}|, \min\left\{(15 + 4\log|\mathcal{I}|)\max_{k\in\mathcal{I}}\|A_k\hat{X}\|_F, \sqrt{40\sum_{k\in\mathcal{I}}\|A_k\hat{X}\|_F^2}\right\}\right\}.$$

Let us consider two special cases of Theorem 4.6. First, if $\mathcal{I} = \emptyset$, then Theorem 4.6 becomes $\frac{v_{sdp}^{\max}}{v_{qp}^{\max}} \le 20 + 8\log m$ (in the real case), which recovers the approximation result of Nemirovski, Roos, and Terlaky [18]. The second case is $\mathcal{D} = \emptyset$, where Theorem 4.6 becomes

$$\frac{v_{sdp}^{\max}}{v_{qp}^{\max}} \le 1 + \min\left\{(20 + 8\log(m+1))\max_{0\le k\le m}\|A_k\hat{X}\|_F, \sqrt{200\sum_{k=0}^{m}\|A_k\hat{X}\|_F^2}\right\}.$$

Below is an example showing that this bound is also tight (in the order of magnitude). Specifically, consider Example 4.3 again:

$$\begin{aligned} \max \quad & x_1^2 + \tfrac{1}{M}x_2^2 \\ \text{s.t.} \quad & Mx_1x_2 + x_2^2 \le 1 \\ & -Mx_1x_2 + x_2^2 \le 1 \\ & M(x_1^2 - x_2^2) \le 1. \end{aligned}$$

In this case we know that the SDP relaxation has an optimal solution $\hat{X} = \left[\begin{smallmatrix} 1+\frac{1}{M} & 0 \\ 0 & 1 \end{smallmatrix}\right]$, while the approximation ratio is $v_{sdp}^{\max}/v_{qp}^{\max} = O(M)$. There are three constraints, all indefinite, $\mathcal{I} = \{1, 2, 3\}$, with

$$A_1 = \begin{bmatrix} 0 & \frac{M}{2} \\ \frac{M}{2} & 1 \end{bmatrix}, \quad A_2 = \begin{bmatrix} 0 & -\frac{M}{2} \\ -\frac{M}{2} & 1 \end{bmatrix}, \quad A_3 = \begin{bmatrix} M & 0 \\ 0 & -M \end{bmatrix},$$

and so one may compute that

$$A_1\hat{X} = \begin{bmatrix} 0 & \frac{M}{2} \\ \frac{M}{2}+\frac{1}{2} & 1 \end{bmatrix}, \; A_2\hat{X} = \begin{bmatrix} 0 & -\frac{M}{2} \\ -\frac{M}{2}-\frac{1}{2} & 1 \end{bmatrix}, \; A_3\hat{X} = \begin{bmatrix} M+1 & 0 \\ 0 & -M \end{bmatrix}.$$

Thus, $\|A_k\hat{X}\|_F^2 = O(M^2)$, for $k = 1, 2, 3$. Theorem 4.6 predicts that $v_{sdp}^{\max}/v_{qp}^{\max} \leq O(M)$, and this upper bound is exactly attained in this example.

5. Discussions. This paper studies the quality bounds of SDP relaxations for some classes of nonconvex quadratic optimization problems. Our analysis reveals interesting differences in the quality bounds for the optimization models expressed in either maximization or minimization form, and for optimization variables defined over either the real or complex field. It provides a complete picture on the performance of the SDP relaxation techniques for quadratic optimization problems involving indefinite constraints.

Theoretically, the minimization model (1.1) and maximization model (1.2) are intrinsically different; they cannot be directly transformed from one to the other. In general, the feasible region of problem (1.1) can be nonconvex, unbounded, or even disconnected, while its objective function is usually assumed to be convex. In contrast, the maximization model (1.2) typically has a convex and bounded feasible region, but the nonconvexity of the objective function makes it difficult. These essential differences have led to the qualitatively different behaviors in the respective SDP approximation ratios.

It is equally interesting to note that the choice of field in which the optimization variables reside can also impact the quality of SDP relaxation. In a natural way, every complex quadratic program can be turned into an equivalent real quadratic program by doubling the dimension. Such a transformation will not affect the resulting approximation ratio. Since the SDP approximation ratio is weaker in the real case, we cannot derive the desired approximation ratio for the complex case by this simple reduction. It is worth noting that the tighter SDP approximation ratio for the complex case has been observed in digital communication applications [22, 17, 14], where the signals are naturally complex due to their in-phase and quadrature components.

An interesting byproduct of our work is a universal lower bound of Prob($\sum_{i=1}^n \tau_i (\eta_i - 1) \geq 0$) for the i.i.d. exponential random variables η_i (Lemma 4.1). The lower bounds of this type are interesting on their own and are related to the well-known inequality of Grünbaum [9] in convex analysis. In particular, by a different analytic argument, it is possible to further improve the universal lower bound obtained in this paper as follows:

$$\text{Prob}\left(\sum_{i=1}^n \tau_i(\eta_i - 1) \geq 0\right) = \sum_{i=1}^n \frac{e^{-\frac{1}{\tau_i}}}{\prod_{j\neq i}\left(1 - \frac{\tau_j}{\tau_i}\right)} > \frac{1}{e}, \tag{5.1}$$

where τ_i, $i = 1, \ldots, n$, are any real numbers. (The above equality can be derived by evaluating a multidimensional integral.) The inequality (5.1) admits a simple

geometric interpretation. For the joint standard exponential distribution on $\mathbb{R}^n_+$, the center of gravity of $\mathbb{R}^n_+$ is $x^c := \mathsf{E}(\eta) = (1, 1, \ldots, 1)^T$, and the inequality (5.1) can be interpreted as follows:

$$\text{Prob}(\mathbb{R}^n_+ \cap \mathcal{H}_+) \geq e^{-1} \quad \text{for any hyperplane } \mathcal{H} \text{ passing through } x^c. \tag{5.2}$$

Here $\mathcal{H}_+$ denotes the positive side of the hyperplane $\mathcal{H}$. The inequality (5.2) is an extension of the Grünbaum inequality [9]:

$$\text{Volume}\,(\mathcal{C} \cap \mathcal{H}_+) \geq e^{-1}\ \text{Volume}\,(\mathcal{C})$$

for any bounded convex set $\mathcal{C}$ in $\mathbb{R}^n$, and for any hyperplane $\mathcal{H}$ passing through the center of gravity of $\mathcal{C}$

$$x^c = \frac{1}{\text{Volume}(\mathcal{C})} \int_{\mathcal{C}} dx.$$

In particular, if we assign the uniform distribution to $\mathcal{C}$, then the mean vector of this distribution is given by the center of gravity x^c, and the probability in (5.2) can be expressed in terms of volume. In this way, Grünbaum's inequality can be equivalently written as (5.2). This shows that the inequality (5.2) generalizes Grünbaum's theorem [9] from the uniform distribution over a compact, convex set to the exponential distribution over $\mathbb{R}^n_+$. Interestingly, it is possible to establish the inequality (5.2) for any log-concave distributions defined over any (possibly unbounded) convex set in $\mathbb{R}^n$. The proof of this inequality relies on a result of Bobkov [5, Lemma 3.3] and a result of Prekopa [21] on the projection of any log-concave distribution. We plan to report the details of this proof in the future.

Acknowledgment. The authors wish to thank Yuval Peres for suggesting reference [13] to us.

ON RATES OF CONVERGENCE FOR STOCHASTIC OPTIMIZATION PROBLEMS UNDER NON–INDEPENDENT AND IDENTICALLY DISTRIBUTED SAMPLING*

TITO HOMEM-DE-MELLO†

Abstract. In this paper we discuss the issue of solving stochastic optimization problems by means of sample average approximations. Our focus is on rates of convergence of estimators of optimal solutions and optimal values with respect to the sample size. This is a well-studied problem in case the samples are independent and identically distributed (i.e., when standard Monte Carlo simulation is used); here we study the case where that assumption is dropped. Broadly speaking, our results show that, under appropriate assumptions, the rates of convergence for *pointwise estimators* under a sampling scheme carry over to the optimization case, in the sense that convergence of approximating optimal solutions and optimal values to their true counterparts has the same rates as in pointwise estimation. We apply our results to two well-established sampling schemes, namely, Latin hypercube sampling and randomized quasi-Monte Carlo (QMC). The novelty of our work arises from the fact that, while there has been some work on the use of variance reduction techniques and QMC methods in stochastic optimization, none of the existing work—to the best of our knowledge—has provided a theoretical study on the effect of these techniques on rates of convergence for the optimization problem. We present numerical results for some two-stage stochastic programs from the literature to illustrate the discussed ideas.

Key words. stochastic optimization, two-stage stochastic programming with recourse, sample average approximation, Monte Carlo simulation, quasi-Monte Carlo methods, Latin hypercube sampling, variance reduction techniques

1. Introduction.

In this paper we consider stochastic optimization problems of the form

$$\min_{x\in X} \{g(x) := \mathbb{E}[G(x,\boldsymbol{\xi})]\}, \tag{1.1}$$

where X is a subset of $\mathbb{R}^n$, $\boldsymbol{\xi}$ is a random vector in $\mathbb{R}^s$, and $G : \mathbb{R}^n \times \mathbb{R}^s \rightarrowtail \mathbb{R}$ is a real-valued measurable function. We refer to (1.1) as the "true" optimization problem. The class of problems falling into the framework of (1.1) is quite large and includes two-stage stochastic programs as a particular subclass.

Oftentimes the expectation in (1.1) cannot be calculated exactly, particularly when G does not have a closed form. In those cases, approximations based on sampling are usually the alternative. One such approximation can be constructed as follows. Consider a family $\{\hat{g}_N(\cdot)\}$ of random approximations of the function $g(\cdot)$, each $\hat{g}_N(\cdot)$ being defined as

$$\hat{g}_N(x) := \frac{1}{N}\sum_{j=1}^{N} G(x,\boldsymbol{\xi}^j), \tag{1.2}$$

where $\{\boldsymbol{\xi}^1,\ldots,\boldsymbol{\xi}^N\}$ is a sample from the distribution of $\boldsymbol{\xi}$. When $\boldsymbol{\xi}^1,\ldots,\boldsymbol{\xi}^N$—viewed as random variables—are independent and identically distributed (i.i.d.) the quantity $\hat{g}_N(x)$ is called a *(standard) Monte Carlo* estimator of $g(x)$.

Given the family of estimators $\{\hat{g}_N(\cdot)\}$ defined in (1.2), one can construct the corresponding approximating program

$$\min_{x \in X} \hat{g}_N(x). \tag{1.3}$$

Let $\hat{x}_N$ and $\hat{\nu}_N$ denote, respectively, an optimal solution and the optimal value of (1.3). Then $\hat{x}_N$ and $\hat{\nu}_N$ provide approximations, respectively, to an optimal solution x^* and the optimal value ν^* of the true problem (1.1). Note that the optimization in (1.3) is performed for a fixed sample; for that reason, this is called an *external sampling* approach. When $\hat{g}_N(\cdot)$ is a standard Monte Carlo estimator of $g(\cdot)$, such an approach is found in the literature under the names of sample average approximation method, stochastic counterpart, and sample-path optimization, among others.

The external sampling approach with standard Monte Carlo simulation has been implemented in various settings; see, for instance, [14, 23, 43]. One advantage of that approach lies in its nice convergence properties; for example, it is possible to show that, when x^* is the unique optimal solution, $\hat{x}_N \to x^*$ and $\hat{\nu}_N \to \nu^*$ under fairly general assumptions (see, e.g., [10, 22, 44, 48, 49]). Two properties have proven particulary useful in terms of establishing *rates of convergence*: The first establishes that, under proper conditions, $P(|g(\hat{x}_N) - g(x^*)| \leq \varepsilon)$ and $P(\|\hat{x}_N - x^*\| \leq \varepsilon)$ converge to one *exponentially fast* in the sample size N for any fixed $\varepsilon > 0$ (see [6, 21]). Under some further conditions one can say more, namely, that $P(\hat{x}_N = x^*)$ converges to one exponentially fast in the sample size N [53]. Exponential rates of convergence have interesting consequences in terms of complexity of the underlying problems; see [51] for a discussion.

Another useful property establishes that the sequence of optimal values $\{\hat{\nu}_N\}$ satisfies a certain kind of *central limit theorem* (CLT). More specifically, one has

$$N^{1/2}(\hat{\nu}_N - \nu^*) \xrightarrow{d} \text{Normal}(0, \sigma^*),$$

where "$\xrightarrow{d}$" denotes convergence in distribution and $\sigma^* := \text{Var}[G(x^*)]$ [48]. An immediate conclusion from the above result is that the rate of convergence of optimal values of (1.3) is of order $N^{-1/2}$. A compilation of these and other related results can be found in [50].

It is no surprise that the sequence of approximating optimal values converges at rate $N^{-1/2}$. Indeed, consider the estimator $\hat{g}_N$ defined in (1.2), and fix $x \in X$. Under mild conditions, it follows from the CLT that $\sqrt{N}[\hat{g}_N(x) - g(x)]/\sigma(x)$ converges in distribution to the standard Normal, where $\sigma^2(x)$ is the variance of $G(x)$. This implies that the error $\hat{g}_N(x) - g(x)$ converges to zero at the rate $N^{-1/2}$. That is, even the pointwise estimators converge at rate $N^{-1/2}$. In many practical cases, the value of N necessary to obtain a reasonably small error under this scheme becomes prohibitively large, especially if evaluation of $G(x, \boldsymbol{\xi})$ for a given $\boldsymbol{\xi}$ is computationally expensive. This motivates the use of *variance reduction techniques* that can yield estimators with smaller variance than the ones obtained with standard sampling. Consequently, the same error can be obtained with less computational effort, which is a crucial step for the use of sampling-based methods in large-scale problems.

Several variance reduction techniques have been developed in the simulation and statistics literature, notably importance sampling, control variates, stratified sampling, and others (see, e.g., [11, 25]). However, incorporation of these techniques into a stochastic optimization algorithm is still at an early stage. Existing work [1, 7,

16, 19, 26, 52] already shows that significant benefits can be gained by implementing some of these methods, but these papers provide only *empirical* evidence of the gain.

Another approach to obtain better pointwise estimators is to choose the sample points in an appropriate manner. Such is the case of *quasi-Monte Carlo methods* (QMC); see [32] for a comprehensive discussion. This class of methods has been gaining popularity in the past few years, as it has been observed that these techniques can provide rates of convergence for pointwise estimators superior to the $N^{-1/2}$ obtained with standard Monte Carlo methods. However, because estimating the actual error of a QMC estimator relative to the quantity being estimated can be difficult, some procedures to randomize a QMC sequence have been proposed in the literature. We provide a brief review of the basic ideas of QMC methods in section 3.2.

A few papers study the optimization problem $\min_{x\in X} \hat{g}_N(x)$ under QMC: In [20], empirical results are provided for the use of Hammersley sequences (one form of QMC) in stochastic optimization problems. In [39, 40], the authors use the fact that the empirical measure defined by a QMC sequence converges weakly to the uniform distribution to show that, under mild assumptions, the estimator function $\hat{g}_N$ constructed with QMC points *epiconverges* to the true function g, which guarantees convergence of optimal values and optimal solutions under appropriate further conditions; in [24] those results are applied to the case where the QMC sequence is randomized with the so-called Cranley–Patterson procedure. The numerical results in those papers also suggest considerable gains in terms of rates of convergence when using QMC methods. A different type of point sequences is studied in [41] whereby the sampling points are chosen in a way to minimize the Wasserstein distance between the original distribution and the empirical distribution generated by the points. A related approach is used in [15], which deals with the Fortet–Mourier metrics instead. Again, the numerical results presented in [42] suggest a considerable advantage of these techniques over standard Monte Carlo methods.

The above discussion shows that, while there has been some important work on the use of variance reduction techniques and QMC methods in stochastic optimization, none of these papers has provided a theoretical study on the effect of these techniques on *rates of convergence*. The reason is that, without the i.i.d. assumption, many of the classical results in probability theory cannot be applied. One exception is the work in [6], which provides results on the exponential rate of convergence of optimal solutions even without the i.i.d. assumption. However, that paper does not focus on any particular sampling technique; rather, they assume that certain conditions that allow for the application of the Gartner–Ellis theorem in large deviations theory (see, e.g., [8]) are satisfied.

Another potential way to study convergence rates in general settings (i.e., without the i.i.d. assumption) is by means of *stability* theory. Broadly speaking, stability theory in the context of stochastic optimization quantifies how much the optimal value and the optimal solutions of the problem change when the underlying probability measures are perturbed. For example, by writing the optimal values of (1.1) and (1.3), respectively, as $\nu(F)$ and $\nu(F_N)$—where F is the distribution of $\boldsymbol{\xi}$ and F_N is the empirical distribution defined by a sample—it is possible to show that, under certain assumptions, $|\nu(F) - \nu(F_N)|$ is bounded by an appropriately defined distance between F and F_N. In the particular case of i.i.d. sampling, one can write the latter distance in terms of the sample size N, which leads to a different way to view the $N^{-1/2}$ rate obtained via the CLT. We refer to [45] for a thorough exposition of stability results in stochastic programming.

In this paper we propose a study of rates of convergence for optimal solutions and optimal values of the approximating problem (1.3) *without imposing that the sample be independent or identically distributed*. More specifically, we show that, under certain conditions, if the proposed sampling scheme yields an exponential rate of convergence for pointwise estimators, then the convergence of optimal solutions will also have an exponential rate. Moreover, in case of discrete or piecewise linear problems, if the proposed sampling scheme yields a CLT for pointwise estimators, then the convergence of optimal values will obey the CLT as well. Unless stated otherwise the setting is fairly general—i.e., the decision space can be continuous or discrete, and the distributions of the underlying random variables can be continuous or discrete, although some of the results will not be valid in some of these cases.

We illustrate the ideas for the particular cases of Latin hypercube sampling (LHS) and a specific variation of randomized QMC called scrambled (t, m, s)-nets. We show that, for a particular class of functions, the exponential feature of the rate of convergence is preserved under LHS for pointwise estimators and therefore for estimators of optimal solutions. We also use CLT-type results available for LHS and randomized QMC to illustrate the convergence results for estimators of optimal values. In particular, we show that, under LHS, the estimators $\hat{\nu}_N$ of optimal values converge at a rate of order $N^{-1/2}$, the same as standard Monte Carlo methods; for QMC, under appropriate assumptions the sequence $\{\hat{\nu}_N\}$ converges at a rate of order $[(\log N)^{s-1}/N^3]^{1/2}$, which asymptotically is better than $N^{-1/2}$.

We then apply our results to two-stage stochastic linear programs and discuss the validity of our assumptions in that context. Numerical results are presented for two problems from the literature to illustrate the ideas.

The remainder of the paper is organized as follows: In section 2 we describe our main results for rates of convergence of estimators of optimal solutions and optimal values. In section 3 we apply these results to LHS and randomized QMC. We illustrate the ideas for two-stage stochastic programs in section 4 and present numerical results in section 5. Concluding remarks are presented in section 6.

2. Rates of convergence. We discuss separately the results on rates of convergence for optimal solutions and optimal values. Throughout this paper, S^* and S_N denote the set of optimal solutions of (1.1) and (1.3), respectively. Before we study the two cases, we shall make a general assumption.

Assumption A1. For each $x \in X$, $\hat{g}_N(x) \to g(x)$ with probability one (denoted w.p.1).

Assumption A1 is very natural, as it requires the estimators to be *consistent*. In the i.i.d. case, this is just the standard strong law of large numbers, which holds if $\mathbb{E}[|\hat{g}_N(x)|] < \infty$ for each $x \in X$.

2.1. Convergence of estimators of optimal solutions. We start by making the following probabilistic assumption on the estimators $\{\hat{g}_N(x)\}$.

Assumption B1. For each $x \in X$, there exist a number $C_x > 0$ and a function $\gamma_x(\cdot)$ such that $\gamma_x(0) = 0$, $\gamma_x(z) > 0$ if $z > 0$, and

$$P\left(|\hat{g}_N(x) - g(x)| \geq \delta\right) \leq C_x\, e^{-N\gamma_x(\delta)} \qquad \text{for all } N \geq 1 \text{ and all } \delta > 0. \tag{2.1}$$

That is, the probability that the deviation between $\hat{g}_N(x)$ and $g(x)$ is bigger than δ goes to zero exponentially fast with N. Notice that (2.1) implies that $\hat{g}_N(x)$ converges in probability to $g(x)$, which is also ensured by Assumption A1.

Instead of (2.1), we can impose the following weaker condition.

Assumption B1′. For each $x \in X$, there exists a function $\gamma_x(\cdot)$ such that $\gamma_x(0) = 0$, $\gamma_x(z) > 0$ if $z > 0$, and

$$\limsup_{N\to\infty} \frac{1}{N} \log P\left(|\hat{g}_N(x) - g(x)| \geq \delta\right) \leq -\gamma_x(\delta) \qquad \text{for all } \delta > 0. \tag{2.2}$$

Some of our results will be stated by assuming that B1 holds; alternatively, B1′ can be used, though in such cases the corresponding result will be stated in asymptotic form as well.

We study now a sufficient condition for Assumption B1 to hold. The main concept behind it arises from the theory of *large deviations*, a well-studied field. For a thorough exposition of the theory, we refer to any of the classical texts in the area, e.g., [8]. We present here a result from [9].

PROPOSITION 2.1. *Consider the sample $\boldsymbol{\xi}^1, \ldots, \boldsymbol{\xi}^N$ used in* (1.2)*, and define the extended real-valued function*

$$\phi_N(x,t) := \frac{1}{N} \log \mathbb{E}\left[e^{tN\hat{g}_N(x)}\right]. \tag{2.3}$$

Suppose that for each $x \in X$ there exists an extended real-valued function ϕ_x^* such that $\phi_N(x,\cdot) \leq \phi_x^*(\cdot)$ for all N, and assume that ϕ_x^* satisfies the following conditions: (i) $\phi_x^*(0) = 0$*;* (ii) $\phi_x^*(\cdot)$ *is continuously differentiable and strictly convex on a neighborhood of zero; and* (iii) $(\phi_x^*)'(0) = g(x)$*. Then, Assumption* B1 *holds, with the constants C_x all equal to 2 and the functions $\gamma_x(\cdot)$ given by $\gamma_x(\delta) := \min\{I_x(g(x)+\delta), I_x(g(x)-\delta)\}$, where $I_x(z) = \sup_{t\in\mathbb{R}}\{tz - \phi_x^*(t)\}$.*

A simple setting where the conditions of Proposition 2.1 are satisfied is when the functions $\phi_N(x,\cdot)$, $N = 1, 2, \ldots$, are bounded by the log-moment-generating function of some random variable W_x (i.e., $\phi_x^*(t) = \log \mathbb{E}[e^{tW_x}]$) such that $\mathbb{E}[W_x] = g(x)$. Clearly, condition (i) holds in that case. Moreover, if there exists an open neighborhood $\mathcal{N}$ of zero such that $\phi_x^*(\cdot)$ is finite on $\mathcal{N}$, then it is well known that ϕ_x^* is infinitely differentiable on $\mathcal{N}$ (see, e.g., p. 35 of [8]) and (iii) holds. In that case, Proposition 1 in [54] ensures that ϕ_x^* is strictly convex on $\mathcal{N}$.

Note that when the samples $\{\boldsymbol{\xi}^i\}$ are i.i.d. we have

$$\begin{aligned}\phi_N(x,t) &= \frac{1}{N}\log(\mathbb{E}[e^{tN\hat{g}_N(x)}]) = \frac{1}{N}\log(\{\mathbb{E}[e^{tG(x,\xi)}]\}^N) = \log(\mathbb{E}[e^{tG(x,\xi)}]) \\ &= \log M_x(t),\end{aligned}$$

where $M_x(t) := \mathbb{E}[e^{tG(x,\boldsymbol{\xi})}]$ is the moment-generating function of $G(x,\boldsymbol{\xi})$ evaluated at t. Hence, in that case we have $\phi_N(x,t) = \phi_x^*(t) := \log M_x(t)$ for all N, so the resulting function I_x in Proposition 2.1 is the rate function associated with $G(x,\boldsymbol{\xi})$. Inequality (2.1) then yields the well-known Chernoff upper bounds on the deviation probabilities. It is also well known (Cramér's theorem) that in that case $\gamma_x(\delta)$ in Proposition 2.1 is an *asymptotically exact* rate, in the sense that (2.2) holds with equality.

One important consequence of the above developments is the following: Suppose that the function ϕ_x^* in Proposition 2.1 is dominated by the log-moment-generating function of the random variable $G(x,\boldsymbol{\xi})$, i.e., $\phi_x^*(t) \leq \phi_x^{\mathrm{MC}}(t) := \log \mathbb{E}[e^{tG(x,\boldsymbol{\xi})}]$. This immediately implies that the rate function I_x dominates the rate function associated with the random variable $G(x,\boldsymbol{\xi})$, which as seen earlier is the asymptotically exact rate function obtained with i.i.d. (i.e., Monte Carlo) sampling. In other words, if one

uses a sampling technique that yields functions $\phi_N(x,\cdot)$ for which one can find ϕ_x^* in Proposition 2.1 such that $\phi_x^*(\cdot) \le \phi_x^{\mathrm{MC}}(\cdot)$, then *the pointwise convergence rate for this sampling technique—in the sense of* (2.1)*—is at least as good as the rate obtained with standard Monte Carlo methods.* We will use this basic argument repeatedly in the course of this paper.

In the subsections below we will study the convergence of optimal solutions in two different settings—one when the function $G(\cdot,\boldsymbol{\xi})$ is Lipschitz and the other when either $G(\cdot,\boldsymbol{\xi})$ is piecewise linear or the feasible set X is finite.

2.1.1. The Lipschitz case. We now make an assumption on the integrand G viewed as a function of its first argument.

Assumption A2. The feasibility set X is compact, and there exists an integrable function $L : \mathbb{R}^s \rightarrowtail \mathbb{R}$ such that, for almost every $\boldsymbol{\xi}$ and all $x, y \in X$,

$$|G(x,\boldsymbol{\xi}) - G(y,\boldsymbol{\xi})| \le L(\boldsymbol{\xi})\|x-y\|. \tag{2.4}$$

Clearly, Assumption A2 ensures that the function $G(\cdot,\boldsymbol{\xi})$ is continuous for almost every $\boldsymbol{\xi}$. Moreover, it implies that $\hat{g}_N(\cdot)$ and $g(\cdot)$ are also Lipschitz continuous with constants equal to $\hat{L}_N := N^{-1}\sum_{j=1}^N L(\boldsymbol{\xi}^j)$ and $\mathbb{E}[L(\boldsymbol{\xi})]$, respectively. From classical results in convex analysis (e.g., [18, Theorem IV.3.1.2]), we see that if (i) the feasibility set X is compact and contained in the relative interior of the domain of $G(\cdot,\boldsymbol{\xi})$ for almost every $\boldsymbol{\xi}$, and (ii) $G(\cdot,\boldsymbol{\xi})$ is *convex* for almost every $\boldsymbol{\xi}$, then the existence of $L(\boldsymbol{\xi})$ in (2.4) is assured, so in that case only integrability of $L(\boldsymbol{\xi})$ needs to be checked.

Recall that $\hat{x}_N$ is an optimal solution of (1.3) and S^* is the set of optimal solutions of (1.1). Below, $\mathrm{dist}(z,A)$ denotes the usual Euclidean distance function between a point z and a set A, i.e., $\mathrm{dist}(z,A) := \inf_{y\in A}\|z-y\|$. The following result is known (see, e.g., [46, pp. 67–70]), but we state it here for reference.

PROPOSITION 2.2. *Suppose that Assumptions* A1 *and* A2 *hold. Then*

(i) $\hat{g}_N(x) \to g(x)$ *uniformly on* X *w.p.*1*;*

(ii) $\hat{\nu}_N \to \nu^*$ *w.p.*1*;*

(iii) $\mathrm{dist}(\hat{x}_N, S^*) \to 0$ *w.p.*1.

Theorem 2.3 below shows a probabilistic rate of convergence of optimal solutions. In preparation for that result, we state the following assumption, which is similar to Assumption B1 but applied to the random variable $L(\boldsymbol{\xi})$ in Assumption A2. Conditions under which such an assumption holds are similar to those given in Proposition 2.1.

Assumption $\mathrm{B1}_L$. Let $\hat{L}_N$ be the estimator of $\mathbb{E}[L(\boldsymbol{\xi})]$ defined as $\hat{L}_N := N^{-1}\sum_{j=1}^N L(\boldsymbol{\xi}^j)$, where as before $\{\boldsymbol{\xi}^1,\dots,\boldsymbol{\xi}^N\}$ is a sample from the distribution of $\boldsymbol{\xi}$. There exist a number $C_L > 0$ and a function $\gamma_L(\cdot)$ such that $\gamma_L(0) = 0$, $\gamma_L(z) > 0$ if $z > 0$, and

$$P\left(|\hat{L}_N - \mathbb{E}[L(\boldsymbol{\xi})]| \ge \delta\right) \le C_L\, e^{-N\gamma_L(\delta)} \qquad \text{for all } N \ge 1 \text{ and all } \delta > 0. \tag{2.5}$$

THEOREM 2.3. *Consider problem* (1.3)*, and suppose that Assumptions* A2*,* B1*, and* $\mathrm{B1}_L$ *hold. Then, given* $\varepsilon > 0$*, there exist constants* $K > 0$ *and* $\alpha > 0$ *such that*

$$P\left(\mathrm{dist}(\hat{x}_N, S^*) \ge \varepsilon\right) \le Ke^{-\alpha N} \qquad \textit{for all } N \ge 1.$$

The constants K *and* α *depend on the families of estimators* $\{\hat{g}_N(\cdot)\}$ *and* $\{\hat{L}_N\}$ *only through, respectively, the constants* C_x *and* C_L *and the exponent functions* $\gamma_x(\cdot)$ *and*

$\gamma_L(\cdot)$ *in* (2.1) *and* (2.5). *More specifically,*

$$\alpha = \min\left(\min_{k=1,\ldots,r}\{\gamma_{x_k}(\delta/3)\},\ \gamma_L(\delta/3)\right),$$
$$K = (r+1)\max\left(\max_{k=1,\ldots,r}\{C_{x_k}\},\ C_L\right),$$

where $\delta > 0$, r *is a finite number, and* $x_1, \ldots, x_r$ *are points in* X.

The proof of Theorem 2.3 will be based on the following lemma.

LEMMA 2.4. *Suppose that Assumptions* A2, B1, *and* B1$_L$ *hold. Then, for any* $\delta > 0$, *there exist positive constants* $A = A(\delta)$ *and* $\alpha = \alpha(\delta)$ *such that*

$$P\left(|\hat{g}_N(x) - g(x)| \geq \delta\right) \leq Ae^{-\alpha N} \qquad \text{for all } x \in X \text{ and all } N \geq 1. \tag{2.6}$$

Moreover, there exists a positive constant K *(also dependent on* δ*) such that*

$$P\left(|\hat{g}_N(x) - g(x)| < \delta \text{ for all } x \in X\right) \geq 1 - Ke^{-\alpha N} \qquad \text{for all } N \geq 1. \tag{2.7}$$

Proof. Let $\eta := \delta/(3\mathbb{E}[L(\boldsymbol{\xi})] + \delta)$, and denote by $B(x, \eta)$ the open ball with center x and radius η. Let $\mathcal{X} = \{x_1, \ldots, x_r\}$ be a collection of points in X such that $X \subset \cup_{k=1}^r B(x_k, \eta)$. Notice that the existence of $\mathcal{X}$ is ensured by the compactness of X.

Consider now an arbitrary point $x \in X$. By construction, there exists some $x_k \in \mathcal{X}$ such that $\|x - x_k\| < \eta$. Thus, from (2.4) we have

$$|\hat{g}_N(x) - \hat{g}_N(x_k)| \leq \frac{1}{N}\sum_{j=1}^{N}\left|G(x, \boldsymbol{\xi}^j) - G(x_k, \boldsymbol{\xi}^j)\right| < \qquad \hat{L}_N\eta = \frac{\delta}{3}\,\frac{\hat{L}_N}{\mathbb{E}[L(\boldsymbol{\xi})] + \delta/3}, \tag{2.8}$$

$$|g(x) - g(x_k)| \leq \quad \mathbb{E}\left[|G(x, \boldsymbol{\xi}) - G(x_k, \boldsymbol{\xi})|\right] \quad < \mathbb{E}[L(\boldsymbol{\xi})]\eta < \ \delta/3. \tag{2.9}$$

Moreover, by Assumptions B1 and B1$_L$ we have

$$P\left(|\hat{g}_N(x_k) - g(x_k)| \geq \delta/3\right) \leq C_{x_k}\, e^{-N\gamma_{x_k}(\delta/3)}, \tag{2.10}$$
$$P(|\hat{L}_N - \mathbb{E}[L(\boldsymbol{\xi})]| \geq \delta/3) \leq C_L\, e^{-N\gamma_L(\delta/3)}. \tag{2.11}$$

Finally, since

$$|\hat{g}_N(x) - g(x)| \leq |\hat{g}_N(x) - \hat{g}_N(x_k)| + |\hat{g}_N(x_k) - g(x_k)| + |g(x) - g(x_k)|,$$

it follows that

$$\begin{aligned}\{|\hat{g}_N(x) - g(x)| < \delta\} \ &\supseteq\ \{|\hat{g}_N(x) - \hat{g}_N(x_k)| < \delta/3\} \cap \{|\hat{g}_N(x_k) - g(x_k)| < \delta/3\} \\ &\quad \cap \{|g(x_k) - g(x)| < \delta/3\} \\ &\supseteq \{|\hat{L}_N - \mathbb{E}[L(\boldsymbol{\xi})]| < \delta/3\} \cap \{|\hat{g}_N(x_k) - g(x_k)| < \delta/3\},\end{aligned} \tag{2.12}$$

and then from (2.10)–(2.11) we have

$$\begin{aligned}P\left(|\hat{g}_N(x) - g(x)| \geq \delta\right) &\leq P\left(|\hat{g}_N(x_k) - g(x_k)| \geq \delta/3\right) + P(|\hat{L}_N - \mathbb{E}[L(\boldsymbol{\xi})]| \geq \delta/3) \\ &\leq C_{x_k}\, e^{-N\gamma_{x_k}(\delta/3)} + C_L\, e^{-N\gamma_L(\delta/3)}.\end{aligned}$$

By taking

$$\alpha := \min\left(\min_{k=1,\ldots,r}\{\gamma_{x_k}(\delta/3)\},\ \gamma_L(\delta/3)\right), \tag{2.13}$$

$$A := 2\max\left(\max_{k=1,\ldots,r}\{C_{x_k}\},\ C_L\right), \tag{2.14}$$

inequality (2.6) follows.

To show (2.7), notice that from (2.12) we have

$$\begin{aligned} &P(|\hat{g}_N(x) - g(x)| < \delta \text{ for all } x \in X) \\ &\quad \geq P\left(\{|\hat{g}_N(x_k) - g(x_k)| < \delta/3, \quad k = 1,\ldots,r\} \cap \{|\hat{L}_N - \mathbb{E}[L(\boldsymbol{\xi})]| < \delta/3\}\right) \\ &\quad \geq 1 - \sum_{k=1}^{r} P\left(|\hat{g}_N(x_k) - g(x_k)| \geq \delta/3\right) - P(|\hat{L}_N - \mathbb{E}[L(\boldsymbol{\xi})]| \geq \delta/3), \end{aligned} \tag{2.15}$$

where the last inequality stems from a direct application of Bonferroni's inequality. It follows from (2.10), (2.11), and (2.15) that

$$P\left(|\hat{g}_N(x) - g(x)| < \delta \text{ for all } x \in X\right) \geq 1 - \frac{r+1}{2} A e^{-\alpha N},$$

so by taking

$$K := \frac{r+1}{2} A \tag{2.16}$$

we obtain (2.7). □

We return now to the proof of Theorem 2.3.

Proof. Let $\varepsilon > 0$ be given. Assumption A2 implies the existence of some $\delta > 0$ such that $\text{dist}(\hat{x}_N, S^*) < \varepsilon$ whenever $|\hat{g}_N(x) - g(x)| < \delta$ for all $x \in X$; see, e.g., [46, p. 69] for a proof. By Lemma 2.4, the event $\{|\hat{g}_N(x) - g(x)| < \delta \text{ for all } x \in X\}$ occurs with probability at least $1 - Ke^{-\alpha N}$ (where both K and α depend on δ). It follows that

$$P\left(\text{dist}(\hat{x}_N, S^*) \geq \varepsilon\right) \leq Ke^{-\alpha N}$$

as asserted. Notice that δ does not depend on the particular approximation $\hat{g}_N(\cdot)$; therefore, from (2.13), (2.14), and (2.16) we see that the constants K and α depend on $\{\hat{g}_N(\cdot)\}$ and $\{\hat{L}_N\}$ only through, respectively, the constants C_x and C_L and the exponent functions $\gamma_x(\cdot)$ and $\gamma_L(\cdot)$ in Assumptions B1 and B1$_L$. □

In essence, Theorem 2.3 says that the existence of an exponential rate of convergence for *pointwise estimators* is enough to ensure an exponential rate of convergence for *optimal solutions* of the corresponding approximating problems, regardless of the sampling scheme adopted. Although reasonably intuitive, such a result has not—to the best of our knowledge—been stated or proved anywhere in the literature.

It is important to remark that the second part of Theorem 2.3 suggests that a better pointwise convergence rate leads to a better rate of convergence of optimal solutions. Indeed, suppose that one has at hand two families of approximations, say, $\{\bar{g}_N(x)\}$ and $\{\tilde{g}_N(x)\}$, whose respective exponent functions $\bar{\gamma}_x(\cdot)$ and $\tilde{\gamma}_x(\cdot)$ in (2.1) are such that $\bar{\gamma}_x(\cdot) \geq \tilde{\gamma}_x(\cdot)$ for all $x \in X$. Then the corresponding constants $\bar{\alpha}$ and $\tilde{\alpha}$ will be such that $\bar{\alpha} \geq \tilde{\alpha}$, which suggests that the family $\{\bar{g}_N(\cdot)\}$ yields a better rate

of convergence of $\hat{x}_N$ to S^*. Of course, Theorem 2.3 gives only an *upper bound* on the deviation probability $P\left(\text{dist}(\hat{x}_N, S^*) \geq \varepsilon\right)$, so no definitive statements can be made.

Nevertheless, we shall see later specific situations where the pointwise rate of convergence yields an asymptotically exact rate of convergence for the optimization problem; in those cases, the superiority of one sampling scheme over another can be established.

2.1.2. The finite/piecewise linear case. We derive now results that parallel the ones in section 2.1.1 but with the following assumption in place of Assumption A2.

Assumption A3. Either (i) the feasibility set X is finite or (ii) X is compact, convex, and polyhedral, the function $G(\cdot, \boldsymbol{\xi})$ is convex piecewise linear for every value of $\boldsymbol{\xi}$, and the distribution of $\boldsymbol{\xi}$ has finite support.

Assumption A3 is useful in the context of discrete stochastic optimization (case (i)) or stochastic linear programs (case (ii)). The proposition below shows consistency of the estimators. In the proposition (and elsewhere in this paper), the statement "w.p.1 for N large enough" means that, with probability one, there exists an N_0 such that, on each sample path of the underlying process, the condition holds for all $N > N_0$. The value of such N_0 depends on the particular sample path. The proof of the proposition follows a similar argument to that of Theorem 2.6 below and is therefore omitted.

PROPOSITION 2.5. *Suppose that Assumptions* A1 *and* A3 *hold. Then*

(i) $\hat{g}_N(x) \to g(x)$ *uniformly on* X *w.p.*1*;*

(ii) $\hat{\nu}_N \to \nu^*$ *w.p.*1*;*

(iii) $\hat{x}_N \in S^*$ *w.p.*1 *for* N *large enough.*

THEOREM 2.6. *Consider problem* (1.3)*, and suppose that Assumptions* A3 *and* B1 *hold. Then there exist constants* $K > 0$ *and* $\alpha > 0$ *such that*

$$P\left(\hat{x}_N \notin S^*\right) \leq Ke^{-\alpha N} \qquad \text{for all } N \geq 1.$$

Moreover, the constants K *and* α *depend on the family of estimators* $\{\hat{g}_N(\cdot)\}$ *only through the constants* C_x *and the exponent functions* $\gamma_x(\cdot)$ *in* (2.1)*.*

The proof of Theorem 2.6 will be based on the following lemma.

LEMMA 2.7. *Suppose that Assumption* B1 *holds and that the set* X *is finite. Then, for any* $\delta > 0$*, there exist positive constants* $A = A(\delta)$ *and* $\alpha = \alpha(\delta)$ *such that*

$$P\left(|\hat{g}_N(x) - g(x)| \geq \delta\right) \leq Ae^{-\alpha N} \qquad \text{for all } x \in X \text{ and all } N \geq 1. \tag{2.17}$$

Moreover, there exists a positive constant K *(also dependent on* δ*) such that*

$$P\left(|\hat{g}_N(x) - g(x)| < \delta \text{ for all } x \in X\right) \geq 1 - Ke^{-\alpha N} \qquad \text{for all } N \geq 1. \tag{2.18}$$

Proof. By setting $\alpha := \min_{x \in X} \gamma_x(\delta)$ and $A := \max_{x \in X} C_x$ in (2.1), we immediately show (2.17). The proof of (2.18) follows a very similar argument to that in the proof of Lemma 2.4 and is therefore omitted. □

We return now to the proof of Theorem 2.6.

Proof. Suppose initially that X is finite. Let δ be defined as $(1/2)\min_{x \in X \setminus S^*} g(x) - \nu^*$. It is clear that, if $|\hat{g}_N(x) - g(x)| < \delta$ for all $x \in X$, we have $\hat{g}_N(x) < \hat{g}_N(y)$ for all $x \in S^*$ and all $y \in X \setminus S^*$, i.e., $\hat{x}_N \in S^*$. Now suppose that the conditions in part (ii) of Assumption A3 hold. Then, from Lemma 2.4 in [53], we know that there exists a finite set of points $\{x_1, \ldots, x_\ell\} \cup \{y_1, \ldots, y_q\}$ such that $x_i \in S^*$, $y_j \in X \setminus S^*$ and, if $\hat{g}_N(x_i) < \hat{g}_N(y_j)$ for all $i \in \{1, \ldots, \ell\}$ and all $j \in \{1, \ldots, q\}$, then $\hat{x}_N \in S^*$ (in fact, the set S_N forms a face of S^*). Therefore, we can use the same argument as in the

case where X is finite. We remark that similar results were derived in [23, 53] in the i.i.d. context.

Next, by Lemma 2.7, the event $\{|\hat{g}_N(x) - g(x)| < \delta \text{ for all } x \in X\}$ occurs with probability at least $1 - Ke^{-\alpha N}$ (where both K and α depend on δ). It follows that

$$P(\hat{x}_N \notin S^*) \leq Ke^{-\alpha N}$$

as asserted. As argued in the proof of Theorem 2.3, δ does not depend on the particular approximation $\hat{g}_N(\cdot)$, so the constants K and α depend on $\{\hat{g}_N(\cdot)\}$ only through the constants C_x and the exponent functions $\gamma_x(\cdot)$ in Assumption B1. □

We conclude this section by mentioning that an analogous form of Theorems 2.3 and 2.6 can be derived in case Assumption B1′ holds instead of B1. We state the result below for completeness; the proof follows very similar steps to the proofs of those theorems and is therefore omitted.

THEOREM 2.8. *Consider problem* (1.3)*, and suppose that Assumption* B1′ *holds.*

1. *Suppose that Assumptions* A2 *and* B1_L *hold. Then, given* $\varepsilon > 0$*, there exists a constant* $\alpha > 0$ *such that*

$$\limsup_{N\to\infty} \frac{1}{N} \log P(\text{dist}(\hat{x}_N, S^*) \geq \varepsilon) \leq -\alpha. \tag{2.19}$$

2. *Suppose that Assumption* A3 *holds. Then there exists a constant* $\alpha > 0$ *such that*

$$\limsup_{N\to\infty} \frac{1}{N} \log P(\hat{x}_N \notin S^*) \leq -\alpha. \tag{2.20}$$

2.2. Convergence of estimators of optimal values. We consider now the convergence of the optimal value of (1.3). In the previous section we showed that an exponential rate of convergence for pointwise estimators leads to an exponential rate of convergence for solutions of (1.3); here we will show that, in the context of Assumption A3, a CLT-type result for pointwise estimators leads to a CLT-type result for the optimal value of (1.3). Outside the context of A3, however, one needs more than CLT for pointwise estimators.

We start by making the following probabilistic assumptions on the estimators $\{\hat{g}_N(x)\}$.

Assumption B2. For each $x \in S^*$, the random variable $W_N(x)$ defined as

$$W_N(x) := \frac{\hat{g}_N(x) - g(x)}{\sigma_N(x)}, \tag{2.21}$$

where $\sigma_N^2(x) := \text{Var}[\hat{g}_N(x)]$, is such that $W_N(x)$ converges in distribution to a standard Normal (denoted $W_N(x) \xrightarrow{d} \text{Normal}(0,1)$).

Of course, Assumption B2 holds in case of i.i.d. sampling under very mild assumptions—in that case it corresponds to the classical CLT (with $\sigma_N(x) = \sqrt{\text{Var}[G(x,\boldsymbol{\xi})]/N}$). However, as we shall see later, B2 holds in other contexts as well. Note that we impose Assumption B2 only on the set S^* of optimal solutions to (1.1).

The lemma below states a property that will be used in what follows.

LEMMA 2.9. *Suppose that Assumptions* A1 *and* A3 *hold. Then*

$$\hat{g}_N(\hat{x}_N) - \min_{x^* \in S^*} \hat{g}_N(x^*) = 0 \quad \textit{w.p.1 for } N \textit{ large enough.}$$

Proof. We have already seen in Proposition 2.5 that, under Assumptions A1 and A3, we have $\hat{x}_N \in S^*$ w.p.1 for N large enough. Consider now an arbitrary sample

path where such a condition holds. Then there exists N_0 such that $\hat{x}_N \in S^*$ for all $N > N_0$. That is, for each $N > N_0$ there exists some point $x^*(N) \in S^*$ such that $\hat{x}_N = x^*(N)$. It follows that

$$\hat{g}_N(\hat{x}_N) - \hat{g}_N(x^*(N)) = 0 \quad \text{for all } N > N_0.$$

By definition, $\hat{x}_N$ minimizes $\hat{g}_N(\cdot)$ over X. Together with the above equality, this implies that

$$\hat{g}_N(\hat{x}_N) \leq \min_{x^* \in S^*} \hat{g}_N(x^*) \leq \hat{g}_N(x^*(N)) = \hat{g}_N(\hat{x}_N) \quad \text{for all } N > N_0$$

and hence

$$\hat{g}_N(\hat{x}_N) - \min_{x^* \in S^*} \hat{g}_N(x^*) = 0 \quad \text{for all } N > N_0. \qquad \square$$

We then have the following result for rates of convergence.

THEOREM 2.10. *Consider problem* (1.3)*, and suppose that Assumptions* A1 *and* A3 *hold. Suppose also that the estimators* $\hat{g}_N(x)$ *have the* same variance *on the set* S^* *of optimal solutions to* (1.1)*, i.e., the function* $\sigma_N^2(\cdot)$ *is constant on* S^**, and let* $(\sigma_N^*)^2$ *denote that common value. Then*

$$\frac{\hat{\nu}_N - \nu^*}{\sigma_N^*} - \min_{x^* \in S^*} W_N(x^*) \xrightarrow{d} 0. \tag{2.22}$$

If, in addition, Assumption B2 *holds and problem* (1.1) *has a* unique *optimal solution (call it* x^**), then*

$$\frac{\hat{\nu}_N - \nu^*}{\sigma_N(x^*)} \xrightarrow{d} \text{Normal}(0,1). \tag{2.23}$$

Proof. By Lemma 2.9 we have

$$\frac{\hat{g}_N(\hat{x}_N) - \nu^*}{\sigma_N^*} - \frac{\min_{x^* \in S^*} \hat{g}_N(x^*) - \nu^*}{\sigma_N^*} = 0 \quad \text{w.p.1 for } N \text{ large enough.}$$

Since convergence w.p.1 implies convergence in distribution, it follows that

$$\frac{\hat{g}_N(\hat{x}_N) - \nu^*}{\sigma_N^*} - \frac{\min_{x^* \in S^*} \hat{g}_N(x^*) - \nu^*}{\sigma_N^*} \xrightarrow{d} 0$$

and hence

$$\frac{\hat{g}_N(\hat{x}_N) - \nu^*}{\sigma_N^*} - \min_{x^* \in S^*} \frac{\hat{g}_N(x^*) - \nu^*}{\sigma_N^*} \xrightarrow{d} 0.$$

Note that the term inside the min operation is actually $W_N(x^*)$. Moreover, by definition $\hat{g}_N(\hat{x}_N) = \hat{\nu}_N$, which then shows (2.22).

Suppose now that B2 holds and that $S^* = \{x^*\}$. Then, since $W_N(x^*) \xrightarrow{d}$ Normal$(0,1)$, by using a classical result in convergence of distributions (see, e.g., [3, Theorem 3.1]), we conclude that

$$\frac{\hat{\nu}_N - \nu^*}{\sigma_N(x^*)} \xrightarrow{d} \text{Normal}(0,1). \qquad \square$$

The above result can be slightly strengthened in case the set S^* is finite (say, $S^* = \{x^1, \ldots, x^\ell\}$) and a multivariate version of Assumption B2 holds—namely, that for some deterministic sequence $\{\tau_N\}$ such that $\tau_N \to \infty$ the multivariate process $\tau_N(\hat{g}_N(x^1) - g(x^1), \ldots, \hat{g}_N(x^\ell) - g(x^\ell))$ converges in distribution to a random vector Y with Normal distribution with mean vector zero and covariance matrix Σ. In that case, by using a very similar argument to that used in [23], one can show directly that $\tau_N(\hat{\nu}_N - \nu^*)$ converges in distribution to $\min_{x^* \in S^*} Y(x^*)$. We chose to present our result in the above form because it requires only a univariate CLT.

As mentioned earlier, outside the context of Assumption A3 stronger conditions are required. One possibility is to assume that Assumption A2 holds and that a version of Assumption B2 for functional spaces holds for the space $C(X)$ of continuous functions defined on X. As discussed in [48], Assumption A2 suffices to ensure that each $G(\cdot, \boldsymbol{\xi})$ is a random element of the space $C(X)$, and hence $\hat{g}_N(\cdot) := N^{-1} \sum_{j=1}^N G(\cdot, \boldsymbol{\xi})$ is also a random element of $C(X)$. The validity of a CLT in that functional space, in turn, implies that a convergence result such as (2.23) holds. This approach works well in the i.i.d. context; see [48] for a discussion. However, we are not aware of other contexts where a CLT in a functional space exists, so we do not elaborate further on this topic.

3. Applications. We discuss now the application of the results developed in section 2 to two classes of non-i.i.d. sampling techniques—namely, LHS and randomized QMC methods. Note that these techniques are devised to sample s-dimensional random vectors U that are uniformly distributed on $[0,1]^s$ and have independent components. Given an s-dimensional random vector $\boldsymbol{\xi}$ with arbitrary distribution and not necessarily independent components, it is always possible to write $\boldsymbol{\xi} = \Psi(U)$ for some mapping $\Psi : [0,1]^s \mapsto \mathbb{R}^s$, which is constructed by inverting the conditional distribution of ξ_j, given $\xi_1, \ldots, \xi_{j-1}$, $j = 1, \ldots, s$; for details see, for example, [47]. In practice, it is difficult to generate Ψ for a general multivariate distribution, so such a method is typically used when either the distribution has a special form or the components of $\boldsymbol{\xi}$ are independent. In the latter case, $\Psi(u_1, \ldots, u_s) = (F_1^{-1}(u_1), \ldots, F_s^{-1}(u_s))$, where F_j^{-1} is the inverse of the cumulative distribution function F_j of ξ_j, defined as $F_j^{-1}(u) := \inf\{y \in \Xi_j : F_j(y) \geq u\}$, and Ξ_j denotes the support of the distribution F_j. For the remainder of this paper *we assume that the components of* $\boldsymbol{\xi}$ *are independent.* Moreover, since $G(x, \boldsymbol{\xi}) = G(x, \Psi(U))$, we will restrict the domain of $G(x, \cdot)$ to $\Xi_1 \times \ldots \Xi_s$. Sometimes we will refer to the function $G(x, \Psi(\cdot))$, which is defined on $[0,1]^s$.

3.1. Latin hypercube sampling. Stratified sampling techniques have been used in statistics and simulation for years (see, for instance, [11] and references therein). Generally speaking, the idea is to partition the sample space and fix the number of samples on each component of the partition, which should be proportional to the probability of that component. This way we ensure that the number of sampled points on each region will be approximately equal to the *expected* number of points to fall in that region. It is intuitive that such a procedure yields a smaller variance than crude Monte Carlo methods; for proofs see [11]. Notice, however, that, though theoretically appealing, implementing such a procedure is far from trivial, since the difficulty is to determine the partition as well as to compute the corresponding probabilities.

There are many variants of this basic method, one of the most well known being the so-called LHS, introduced in [31]. The LHS method operates as follows: Suppose that we want to draw N samples from a random vector $\boldsymbol{\xi}$ with s independent

components $\xi_1, \ldots, \xi_s$, each of which has a Uniform(0,1) distribution. The algorithm consists of repeating the two steps below for each dimension $j = 1, \ldots, s$:

1. Generate

$$Y^1 \sim U\left(0, \frac{1}{N}\right), \qquad Y^2 \sim U\left(\frac{1}{N}, \frac{2}{N}\right), \ldots, Y^N \sim U\left(\frac{N-1}{N}, 1\right);$$

2. let $\xi_j^i := Y^{\pi(i)}$, where π is a random permutation of $1, \ldots, N$.

In [31], it is shown that each sample ξ_j^i (viewed as a random variable) has *the same distribution* as ξ_j, which in turn implies that the estimators generated by the LHS method are unbiased. In case of arbitrary distributions, the above procedure is easily modified by drawing the sample as before and applying the inversion method discussed at the beginning of section 3 to generate the desired random variates.

It is also shown in [31] that, under some conditions, the LHS method does indeed reduce the variance compared to crude Monte Carlo methods. The papers [37, 55] show that, asymptotically (i.e., as the sample size N goes to infinity), LHS is never worse than crude Monte Carlo methods, even without the assumptions of [31]. More specifically, $V_{\text{LHS}} \leq N/(N-1)V_{\text{MC}}$, where V_{LHS} and V_{MC} are the variances under LHS and crude Monte Carlo methods, respectively.

3.1.1. Exponential rate of convergence. Suppose that the objective function $g(\cdot)$ in (1.1) is approximated by a sample average calculated by using the LHS method; i.e., for each $i = 1, \ldots, s$, $\xi_i^1, \ldots, \xi_i^N$ are samples of ξ_i (the ith component of $\boldsymbol{\xi}$) constructed by using the LHS method. Call the resulting estimator in (1.2) $\hat{g}_N^{\text{LHS}}(x)$. To study convergence properties of the approximating problem in (1.3), we shall use the tools of section 2. Our first goal is to show that the family $\{\hat{g}_N^{\text{LHS}}(\cdot)\}$ satisfies Assumption B1, so that we can apply Theorems 2.3 and 2.6 to ensure an exponential rate of convergence.

We shall restrict our attention to functions satisfying the following assumption.

Assumption C1. For each $x \in X$, the function $G(x, \cdot)$ is monotone in each component. That is, for each $i = 1, \ldots, s$ and each $\delta > 0$ we have

$$\text{either} \qquad G(x, z + \delta e_i) \geq G(x, z) \qquad \text{for all } z \in \mathbb{R}^s \tag{3.1}$$

$$\text{or} \qquad G(x, z + \delta e_i) \leq G(x, z) \qquad \text{for all } z \in \mathbb{R}^s, \tag{3.2}$$

where as customary e_i denotes the vector with 1 in the ith component and zeros otherwise.

An important case where such an assumption is satisfied is that of two-stage stochastic linear programs with fixed recourse. In section 4 we discuss that case in detail.

An alternative assumption is the following.

Assumption C1′. For each $x \in X$, the function $G(x, \cdot)$ is *additive*; i.e., there exist functions $G_1, \ldots, G_s$ (all of them mapping $\mathbb{R}^n \times \mathbb{R}$ to $\mathbb{R}$) such that $G(x, \boldsymbol{\xi}) = G_1(x, \xi_1) + \cdots + G_s(x, \xi_s)$. Moreover, $|\mathbb{E}[G_j(x, \xi_j)]| < \infty$, the functions $G_j(x, F_j^{-1}(\cdot))$ have at most a finite number of singularities (i.e., points where the function approaches $\pm\infty$), and the set of points at which $G_j(x, F_j^{-1}(\cdot))$ is discontinuous has Lebesgue measure zero.

The importance of Assumptions C1 and C1′ in the present context is given by the results below.

THEOREM 3.1. *Suppose that* (i) *Assumption* C1 *holds and* (ii) *for each $x \in X$, the moment-generating function of $G(x, \boldsymbol{\xi})$ (denoted $\phi_x^{\text{MC}}(t) := \mathbb{E}[e^{tG(x,\xi)}]$) is finite*

everywhere. Consider the LHS estimators $\hat{g}_N^{\mathrm{LHS}}(\cdot)$ *above defined and the corresponding problem* $\min_{x\in X} \hat{g}_N^{\mathrm{LHS}}(x)$. *Let* $\hat{x}_N^{\mathrm{LHS}}$ *denote an optimal solution of that problem. Then*

1. *if Assumption* A2 *holds with a uniform Lipschitz constant* L *(i.e.,* $L(\cdot) \equiv L$*), then given* $\varepsilon > 0$ *there exist constants* $\tilde{K} > 0$ *and* $\tilde{\alpha} > 0$ *such that*

$$P\left(\operatorname{dist}(\hat{x}_N^{\mathrm{LHS}}, S^*) \geq \varepsilon\right) \leq \tilde{K} e^{-\tilde{\alpha} N} \qquad \text{for all } N \geq 1; \tag{3.3}$$

2. *if Assumption* A3 *holds, then there exists a constant* $\tilde{\alpha} > 0$ *such that*

$$P\left(\hat{x}_N^{\mathrm{LHS}} \notin S^*\right) \leq \tilde{K} e^{-\tilde{\alpha} N} \qquad \text{for all } N \geq 1. \tag{3.4}$$

Moreover, in either case the exponent $\tilde{\alpha}$ *is at least as large as the corresponding exponent obtained for standard Monte Carlo methods.*

Proof. Let $\phi_N(x,t) := \frac{1}{N} \log \mathbb{E}[e^{tN\hat{g}_N^{\mathrm{LHS}}(x)}]$. If conditions (i) and (ii) above hold, then by Proposition 6 in [9] we have $\phi_N(x,t) \leq \phi_x^{\mathrm{MC}}(t)$ for all x and all t, and hence it follows from Proposition 2.1 that Assumption B1 holds for $\{\hat{g}_N^{\mathrm{LHS}}(\cdot)\}$. Moreover, in case 1 of the theorem (i.e., when Assumption A2 holds with $L(\cdot) \equiv L$) Assumption $\mathrm{B1}_L$ is trivially satisfied. The two cases of the theorem then parallel Theorems 2.3 and 2.6, which shows (3.3) and (3.4).

The last assertion of the theorem is a consequence of the remark following the proof of Theorem 2.3. Indeed, the arguments in the previous paragraph show that the constants C_x and the exponent functions $\gamma_x(\cdot)$ used to show (2.1) are the same for both LHS and standard Monte Carlo methods. □

Although Theorem 3.1 guarantees only the same bounds for both LHS and standard Monte Carlo methods, a closer look at the proof of the inequality $\phi_N(x,\cdot) \leq \phi_x^{\mathrm{MC}}(\cdot)$ in [9] shows that such an inequality is essentially a consequence of Jensen's inequality, which often holds strictly; hence, generally speaking, LHS tends to behave better than Monte Carlo methods.

In case Assumption C1′ holds instead of C1, we have the following stronger result.

THEOREM 3.2. *Suppose that the assumptions of Theorem* 3.1 *are satisfied, but Assumption* C1′ *holds instead of* C1. *Then the conclusions of Theorem* 3.1 *hold. In addition, we have the following:*

1. *If Assumption* A2 *holds with a uniform Lipschitz constant* L *(i.e.,* $L(\cdot) \equiv L$*), then*

$$\lim_{N\to\infty} \frac{1}{N} \log P\left(\operatorname{dist}(\hat{x}_N^{\mathrm{LHS}}, S^*) \geq \varepsilon\right) = -\infty. \tag{3.5}$$

2. *If Assumption* A3 *holds, then*

$$\lim_{N\to\infty} \frac{1}{N} \log P\left(\hat{x}_N^{\mathrm{LHS}} \notin S^*\right) = -\infty. \tag{3.6}$$

Proof. The proof of the first part of the theorem follows the same steps as the proof of Theorem 3.1 (except that Proposition 4 in [9] is invoked instead of Proposition 6).

To show the second part, by writing each random variable ξ_j as $F_j^{-1}(U_j)$ (where $U_j \sim U(0,1)$), we have that conditions (i) and (ii) of Theorem 3.1 ensure that the assumptions of Theorem 3 in [9] are satisfied. The latter result, in turn, ensures that Assumption B1′ holds with the function $\gamma_x = \infty$ everywhere except at zero, where it is equal to zero. Then (3.5) and (3.6) follow from (2.19) and (2.20) in Theorem 2.8. □

The strength of Theorem 3.2, of course, lies in the asymptotic results (3.5)–(3.6), which show that in the additive case the rate of convergence under LHS is *superexponential*.

3.1.2. Central limit theorem. We study now the convergence of optimal values of the approximating problem (1.3) under LHS. To do so we shall apply the results of section 2.2. Before that, however, we need to review some results related to the ANOVA decomposition of a function.

Let $U = (U_1, \ldots, U_s)$ be an s-dimensional random vector of independent components with uniform distribution on $[0,1]^s$ and $f : [0,1]^s \longrightarrow \mathbb{R}$ an arbitrary measurable function, and consider the problem of estimating $I := \mathbb{E}[f(U)]$. It is shown in [55] that, when $\mathbb{E}[f(U)^2] < \infty$, f can be decomposed as

$$f(u_1, \ldots, u_s) = \mathbb{E}[f(U)] + \sum_{k=1}^{s} f_k(u_k) + r(u_1, \ldots, u_s), \tag{3.7}$$

where $f_k(u_k) = \mathbb{E}[f(U) \,|\, U_k = u_k] - \mathbb{E}[f(U)]$ and $r(u)$ is the *residual* term, which satisfies $\mathbb{E}[r(U) \,|\, U_j = u_j] = 0$ for all j and all u_j. [55] also shows that the residual term can be viewed as a "residual from additivity" in the following sense. We say that a function $g : [0,1]^s \longrightarrow \mathbb{R}$ is *additive* if there exist unidimensional functions $g_1, \ldots, g_s$ and a constant C such that g can be written as $g(u_1, \ldots, u_s) = C + \sum_k g_k(u_k)$ for almost all $u \in [0,1]^s$ (where "almost all" refers to the Lebesgue measure). Then the additive function $f_a : [0,1]^s \longrightarrow \mathbb{R}$, defined as $f_a(u_1, \ldots, u_s) = \mathbb{E}[f(U)] + \sum_{k=1}^{s} f_k(u_k)$, is the best additive fit to f in the L^2-norm; i.e., it minimizes $\mathbb{E}[(f(U) - g(U))^2]$ over all additive functions g. Note that if f is itself additive, then the residual $r(u) = f(u) - f_a(u)$ will be equal to zero almost everywhere (a.e.); conversely, if $r(u) = 0$ a.e., then $f(u) = f_a(u)$ a.e., so in that case f is additive.

The variance of the estimator I_{LHS} (defined as $I_{\mathrm{LHS}} := N^{-1} \sum_{i=1}^{N} f(U^i)$, where $U^1, \ldots, U^N$ are samples drawn with LHS) satisfies

$$\sigma_N^2 := \mathrm{Var}[I_{\mathrm{LHS}}] = N^{-1} \mathbb{E}\left[(r(U))^2\right] + o(N^{-1}); \tag{3.8}$$

see [55]. By using (3.7) and (3.8), it is shown in [33] that, when f is bounded, a CLT holds for the estimator I_{LHS} under LHS. More specifically, it is shown that

$$N^{1/2}(I_{\mathrm{LHS}} - I) \;\xrightarrow{d}\; \mathrm{Normal}(0, \sigma^2), \quad \text{where } \sigma^2 := \mathbb{E}[(r(U))^2]. \tag{3.9}$$

Next, notice that from (3.8) we can write

$$\frac{I_{\mathrm{LHS}} - I}{\sigma_N} = \frac{N^{1/2}(I_{\mathrm{LHS}} - I)}{\left[\sigma^2 + \frac{o(N^{-1})}{N^{-1}}\right]^{1/2}}.$$

Since $N^{1/2}(I_{\mathrm{LHS}} - I) \xrightarrow{d} \mathrm{Normal}(0, \sigma^2)$ and the deterministic sequence $\{[\sigma^2 + \frac{o(N^{-1})}{N^{-1}}]^{1/2}\}$ converges to σ, it follows from a classical result in probability theory (see, e.g., [3, p. 29]) that, when $\sigma > 0$,

$$\frac{I_{\mathrm{LHS}} - I}{\sigma_N} \;\xrightarrow{d}\; \frac{1}{\sigma}\mathrm{Normal}(0, \sigma^2) = \mathrm{Normal}(0, 1). \tag{3.10}$$

Notice that the condition $\mathbb{E}[f(U)^2] < \infty$ also implies that a strong law of large numbers holds for LHS, i.e.,

$$|I_{\mathrm{LHS}} - I| \;\to\; 0 \quad \text{w.p.1}; \tag{3.11}$$

for a proof, see [27].

By applying (3.10) to our setting we see that Assumption B2 holds for LHS when, for every $x \in S^*$, the random variable $G(x, \boldsymbol{\xi})$ is bounded and the function $G(x, \Psi(\cdot))$ has a nonzero ANOVA residual. As seen above, the latter condition means that $G(x, \Psi(\cdot))$ is not additive; i.e., it cannot be written in the form $C + \sum_k g_k(u_k)$. It is easy to see that this is equivalent to saying that the function $G(x, \cdot)$ is not additive; note that here we extend the definition of additivity to the domain of $G(x, \cdot)$, which as discussed before is restricted to the support of $\boldsymbol{\xi}$.

On the other hand, if $\mathbb{E}[G(x, \boldsymbol{\xi})^2] < \infty$ for all $x \in X$, then (3.11) implies that Assumption A1 holds. Thus, under additional assumptions we can apply Theorem 2.10 and Propositions 2.2 and 2.5. We summarize the result in the theorem below.

THEOREM 3.3. *Consider the LHS estimators $\hat{g}_N^{\mathrm{LHS}}(\cdot)$ defined above and the corresponding problem $\min_{x \in X} \hat{g}_N^{\mathrm{LHS}}(x)$. Let $\hat{x}_N^{\mathrm{LHS}}$ and $\hat{\nu}_N^{\mathrm{LHS}}$ denote, respectively, an optimal solution and the optimal value of that problem. Suppose that $\mathbb{E}[G(x, \boldsymbol{\xi})^2] < \infty$ for all $x \in X$.*

1. *If Assumption* A2 *holds, then* $\operatorname{dist}(\hat{x}_N^{\mathrm{LHS}}, S^*) \to 0$ *w.p.*1 *and* $\hat{\nu}_N^{\mathrm{LHS}} \to \nu^*$ *w.p.*1.
2. *If Assumption* A3 *holds, then $\hat{x}_N^{\mathrm{LHS}} \in S^*$ w.p.*1 *for N large enough and $\hat{\nu}_N^{\mathrm{LHS}} \to \nu^*$ w.p.*1. *In addition, if problem* (1.1) *has a* unique *optimal solution (call it x^*), the random variable $G(x^*, \boldsymbol{\xi})$ is bounded, and the function $G(x^*, \cdot)$ is not additive, then*

$$\frac{\hat{\nu}_N^{\mathrm{LHS}} - \nu^*}{\sigma_N(x^*)} \xrightarrow{d} \mathrm{Normal}(0, 1),$$

where $\sigma_N^2(x^*)$ is the variance of $\hat{g}_N^{\mathrm{LHS}}(x^*)$. Moreover, there exists a positive constant C such that

$$\sigma_N^2(x^*) = N^{-1}C + o(N^{-1}). \tag{3.12}$$

Theorem 3.3 shows that the rate of convergence of optimal values under LHS (under the conditions of case 2 of the theorem) is $N^{-1/2}$. Thus, compared to standard Monte Carlo methods we can see that, although LHS will likely reduce the variance of pointwise estimators, it cannot improve the *rate* of convergence unless $G(x^*, \cdot)$ is additive; in that case, we expect the convergence rate to be much faster. Indeed, recall from Theorem 3.2 that, under the assumptions of that theorem (which include additivity), the convergence of optimal solutions is superexponential. Note also that, when S^* is finite (but not necessarily a singleton), $G(x^*, \boldsymbol{\xi})$ is bounded, and $G(x^*, \cdot)$ is not additive for all $x^* \in S^*$, the stronger result discussed in the paragraph following the proof of Theorem 2.10 applies with $\tau_N = N^{1/2}$, since the aforementioned CLT result proved in [33] is also valid in a multivariate context.

3.2. Randomized QMC. For completeness, we provide in this section a brief review of QMC techniques. We follow mostly [32], which we refer to for a comprehensive treatment of QMC concepts. Let U be an s-dimensional random vector with uniform distribution on $[0, 1]^s$ and $f : [0, 1]^s \longrightarrow \mathbb{R}$ an arbitrary function, and consider the problem of estimating $I := \mathbb{E}[f(U)]$.

The basic idea of QMC is to calculate a sample average estimate as in the standard Monte Carlo method, but, instead of drawing a random sample from the uniform distribution on $[0, 1]^s$, a certain set of points $u^1, \ldots, u^N$ on space $[0, 1]^s$ is carefully chosen. The deterministic estimate

$$I_{\mathrm{QMC}} := \frac{1}{N} \sum_{i=1}^{N} f(u^i) \tag{3.13}$$

is constructed. A key result is the so-called Koksma–Hlawka inequality, which, roughly speaking, states that the quality of the approximation given by I_{QMC} depends on the quality of the chosen points (measured by the difference between the corresponding empirical measure and the uniform distribution, which is quantified by the so-called *star discrepancy*) as well as on the nature of the function f (measured by its total variation). A great deal of the research on QMC methods aims at determining ways to construct *low-discrepancy sequences*, i.e., sequences of points $u^1, u^2, \ldots$ for which the star discrepancy is small for all N. A particular type of sequence that has proven valuable is defined in terms of (t, m, s)-nets. We need some definitions before delving into more details, which we do next.

Let $b \geq 2$ be an arbitrary integer called the base. An *elementary interval in base* b (in dimension s) is a subinterval E of $[0,1]^s$ of the form

$$E = \prod_{j=1}^{s} \left[\frac{a_j}{b^{d_j}}, \ \frac{a_j + 1}{b^{d_j}} \right]$$

for nonnegative integers $\{a_j\}$ and $\{d_j\}$ such that $a_j < b^{d_j}$ for all j. The volume of E is $b^{-\sum_j d_j}$. Next, let t and m be nonnegative integers such that $t \leq m$. A finite sequence of b^m points is a (t, m, s)-*net* in base b if every elementary interval in base b of volume b^{t-m} contains exactly b^t points of the sequence. A sequence of points $u^1, u^2, \ldots$ is a (t, s)-*sequence* in base b if, for all integers $k \geq 0$ and $m > t$, the set of points consisting of the u^n such that $kb^m \leq n < (k+1)b^m$ is a (t, m, s)-net in base b.

The advantage of (t, m, s)-nets becomes clear from a result due to Niederreiter [32, Theorems 4.10 and 4.17], who shows that the error $|I_{\mathrm{QMC}} - I|$ is (i) of order $(\log N)^{s-1}/N$ when I_{QMC} is computed from a (t, m, s)-net in base b with $m > 0$ and (ii) of order $(\log N)^s/N$ when I_{QMC} is computed from the first $N \geq 2$ terms of a (t, s)-sequence in base b. Note that in case (i) N must be equal to b^m, whereas in case (ii) N is arbitrary, which explains the weaker bound. In either case, it is clear that, asymptotically, the error is smaller than $N^{-1/2}$ given by standard Monte Carlo methods.

Despite the advantage of QMC with respect to error rates, the method has two major drawbacks:

(a) The bounds provided by the Koksma–Hlawka inequality involve difficult-to-compute quantities such as the total variation of f; i.e., they yield qualitative (rather than quantitative) results. Hence, obtaining an exact estimate of the error may be difficult.

(b) A comparison of the functions $(\log N)^s/N$ and $N^{-1/2}$ shows that, even though asymptotically the error from QMC is smaller than the error from standard Monte Carlo methods, such an advantage does not appear until N is very large, unless s is small.

These difficulties have long been realized by the QMC community, and various remedies have been proposed. A common way to overcome difficulty (a) above is to incorporate some randomness into the choice of QMC points. By doing so, errors can be estimated by using standard methods, e.g., via multiple independent replications. This is the main idea of *randomized* QMC methods (RQMC); see [12, 38] for detailed discussions.

One particular technique we are interested in using relies on "scrambling" the decimal digits of each point of a (t, s)-sequence in a proper way. This idea was proposed in [34] and has gained popularity due to the nice properties of the randomized sequence. We shall use these properties below.

3.2.1. Using QMC in optimization. Consider again the family of estimators defined in (1.2). Suppose that $\{\boldsymbol{\xi}^i\}$ is generated by a (t,s)-sequence, and call the resulting family $\{\hat{g}_N^{\mathrm{QMC}}(x)\}$.

Let us fix $x \in X$ for a moment. As argued by the authors of [40]—who in turn cite a result in [30]—the empirical measure defined by a QMC sequence converges weakly to the uniform distribution, provided that the star discrepancy of that sequence goes to zero, which is the case of (t,s)-sequences. It follows from [3, Theorem 2.7] that, if $G(x,\boldsymbol{\xi})$ is bounded, then $\hat{g}_N^{\mathrm{QMC}}(x) \to g(x)$ as $N \to \infty$. Now suppose that $\{\boldsymbol{\xi}^i\}$ is generated by a scrambled (t,s)-sequence, and call the corresponding estimator $\hat{g}_N^{\mathrm{RQMC}}$. In [35] it is shown that scrambled (t,s)-sequences are (t,s)-sequences with probability one, which then implies that

$$\hat{g}_N^{\mathrm{RQMC}}(x) \to g(x) \quad \text{w.p.1.} \tag{3.14}$$

Moreover, $\hat{g}_N^{\mathrm{RQMC}}(x)$ is an unbiased estimator of $g(x)$, i.e., $\mathbb{E}[\hat{g}_N^{\mathrm{RQMC}}(x)] = g(x)$. Notice that the term "with probability one" above refers to the probability space where the random variables defining the permutations that are part of the scrambling algorithm lie. We assume that this probability space is the same as the one where the random vectors $\boldsymbol{\xi}$ are defined.

For some of the results that follow we will need the following assumption.

Assumption D1. The following conditions hold for each $x \in S^*$:

$$\left| \frac{\partial^s}{\partial u_1 \dots \partial u_s} G(x, \Psi(u_1, \dots u_s)) - \frac{\partial^s}{\partial u_1 \dots \partial u_s} G(x, \Psi(v_1, \dots v_s)) \right| \le B\|u - v\|^\beta \tag{3.15}$$

(for some $B > 0$ and some $\beta \in (0,1]$), and

$$\int_{[0,1]^s} \left[\frac{\partial^s}{\partial u_1 \dots \partial u_s} G(x, \Psi(u_1, \dots u_s)) \right]^2 du \; > \; 0, \tag{3.16}$$

where $\Psi(u_1, \dots u_s) = (F_1^{-1}(u_1), \dots, F_s^{-1}(u_s))$.

A few remarks about cases where Assumption D1 is satisfied are now in order. Suppose momentarily that G is infinitely differentiable in the second argument and that each F_j^{-1} is differentiable as well. Then we have

$$\begin{aligned} &\frac{\partial}{\partial u_1} G(x, F_1^{-1}(u_1), \dots, F_s^{-1}(u_s)) \\ &\qquad = \frac{\partial}{\partial \xi_1} G(x, \xi_1, F_2^{-1}(u_2) \dots, F_s^{-1}(u_s)) \Big|_{\xi_1 = F_1^{-1}(u_1)} \frac{\partial}{\partial u_1} F_1^{-1}(u_1), \end{aligned}$$

so, by repeating the calculation for the higher-order mixed derivatives, we obtain

$$H(u_1, \dots, u_s) := \frac{\partial^s}{\partial u_1 \dots \partial u_s} G(x, F_1^{-1}(u_1), \dots, F_s^{-1}(u_s)) \tag{3.17}$$

$$= \frac{\partial^s}{\partial \xi_1 \dots \partial \xi_s} G(x, \xi_1, \dots, \xi_s) \Big|_{\substack{\xi_j = F_j^{-1}(u_j) \\ j=1,\dots,s}} \frac{\partial}{\partial u_1} F_1^{-1}(u_1) \dots \frac{\partial}{\partial u_s} F_s^{-1}(u_s). \tag{3.18}$$

It follows that, if the gradient of the function H defined in (3.17) is uniformly bounded for all $u \in [0,1]^s$, then H is Lipschitz (see, e.g, [2, Corollary 40.6]); i.e., (3.15) holds.

A sufficient condition for uniform boundedness of $\nabla H(u)$ on $[0,1]^s$ is its continuity on $[0,1]^s$. Equation (3.18) shows that continuous differentiability of G (up to order $s+1$) and F_j^{-1}, $j=1,\ldots,s$ (up to second order), on the closed set $[0,1]^s$ suffices for that. Of course, imposing a continuous differentiability assumption on F_j^{-1} restricts the type of distributions that can be used; we shall return to that issue shortly.

Condition (3.16) essentially says that interactions of order up to s are significant, at least on a set of positive probability. For example, (3.16) does not hold if $G(x,\cdot)$ is linear for $x \in S^*$, since the mixed derivatives of any order bigger than 1 are equal to zero. Situations like that suggest that the *effective dimension* (see [35]) of the problem is less than s—indeed, in the linear case the effective dimension is 1. In that case, one should apply QMC only to the most significant variables, for which mutual interaction is significant.

By applying the above results on RQMC to the general context of section 2.2, we obtain the following.

THEOREM 3.4. *Consider the RQMC estimators $\hat{g}_N^{\mathrm{RQMC}}(\cdot)$ above defined and the corresponding problem $\min_{x\in X} \hat{g}_N^{\mathrm{RQMC}}(x)$. Let $\hat{x}_N^{\mathrm{RQMC}}$ and $\hat{\nu}_N^{\mathrm{RQMC}}$ denote an optimal solution and the optimal value of that problem, respectively. Suppose that $G(x,\boldsymbol{\xi})$ is bounded for all $x \in X$.*

1. *If Assumption* A2 *holds, then* $\mathrm{dist}(\hat{x}_N^{\mathrm{RQMC}}, S^*) \to 0$ *w.p.*1 *and* $\hat{\nu}_N^{\mathrm{RQMC}} \to \nu^*$ *w.p.*1.
2. *If Assumption* A3 *holds, then $\hat{x}_N^{\mathrm{RQMC}} \in S^*$ w.p.*1 *for N large enough and $\hat{\nu}_N^{\mathrm{RQMC}} \to \nu^*$ w.p.*1. *If, in addition, Assumption* D1 *holds, problem* (1.1) *has a* unique *optimal solution (call it x^*), and the samples $\{\boldsymbol{\xi}^i\}$ are generated by a scrambled $(0,m,s)$-net (i.e., $t=0$), then*

$$\frac{\hat{\nu}_N^{\mathrm{RQMC}} - \nu^*}{\sigma_N(x^*)} \xrightarrow{d} \mathrm{Normal}(0,1), \tag{3.19}$$

where $\sigma_N^2(x^*)$ is the variance of $\hat{g}_N^{\mathrm{RQMC}}(x^*)$. Moreover, in the latter case there exist positive constants c and C such that

$$c\,\frac{(\log_b N)^{s-1}}{N^3} \le \sigma_N^2(x^*) \le C\,\frac{(\log_b N)^{s-1}}{N^3} \tag{3.20}$$

as $m \to \infty$.

Proof. Let us fix $x \in X$. The assertion in case 1 and the first assertion in case 2 follow directly from (3.14) (which implies that Assumption A1 holds) and Propositions 2.2 and 2.5.

Consider now the random variable $W(x)$ defined as

$$W(x) := \frac{\hat{g}_N^{\mathrm{RQMC}}(x) - g(x)}{\sigma_N(x)}, \tag{3.21}$$

where $\sigma_N^2(x) := \mathrm{Var}[\hat{g}_N^{\mathrm{RQMC}}(x)]$. Here we resort to a key result on scrambled (t,m,s)-nets proved in [28]—building upon previous results in [35, 36]—that says that a CLT holds for pointwise estimators constructed with a scrambled $(0,m,s)$-net. Assumption D1 translates the conditions in [28] into our notation. It follows that, under D1, $W(x)$ converges in distribution to the standard normal for each $x \in S^*$; i.e., Assumption B2 holds and hence the conclusion follows from Theorem 2.10. □

Theorem 3.4 shows the benefits of using RQMC methods in optimization. Essentially, it says that, in the setting of case 2 of the theorem, the convergence rate

of optimal values is of order $[(\log N)^{s-1}/N^3]^{1/2}$, which asymptotically is better than the $N^{-1/2}$ obtained with standard Monte Carlo methods. This suggests that RQMC methods can be very efficacious for stochastic optimization. Note, however, that, strictly speaking, (3.19) applies only to the case where X is finite, since the assumption of finite support of $\boldsymbol{\xi}$ in the second case of Assumption A3 conflicts with the smoothness condition in Assumption D1. We will discuss the smoothness issue in more detail later. Note also that (3.19) is valid only for scrambled $(0, m, s)$-nets, which restricts the choice of the base b—as shown in [32], when $m \geq 2$ a $(0, m, s)$-net in base b can exist only if $b \geq s - 1$.

4. Two-stage stochastic programs. In this section we discuss the application of the results outlined in the previous sections to two-stage stochastic linear programs (see, e.g., [4] for a comprehensive discussion of this class of problems). We consider problems of the form

$$\min_{x \in X} c^t x + \mathbb{E}[Q(x, \boldsymbol{\xi})], \tag{4.1}$$

where X is a convex polyhedral set,

$$Q(x, \boldsymbol{\xi}) = \inf \left\{ q^t y \,:\, Wy \leq h - Tx,\ y \geq 0 \right\}, \tag{4.2}$$

and $\boldsymbol{\xi} = (h, T)$. As before, $\boldsymbol{\xi}$ is an s-dimensional random vector with arbitrary distribution. Let $G(x, \boldsymbol{\xi})$ denote the function $c^t x + Q(x, \boldsymbol{\xi})$; then we see that the the above problem falls in the framework of (1.1).

The use of Monte Carlo sampling to solve two-stage problems has been extensively studied in the literature, from both algorithmic (e.g., [17, 19, 26, 52]) and theoretical perspectives (see, for instance, [50] for a compilation of results).

Note that the function $Q(x, \boldsymbol{\xi})$ can be written in the form $Q(x, \boldsymbol{\xi}) = \tilde{Q}(h - Tx)$, where

$$\tilde{Q}(z) = \inf \left\{ q^t y \,:\, Wy \leq z,\ y \geq 0 \right\}. \tag{4.3}$$

By duality, we see that the function $\tilde{Q}(\cdot)$ can be represented in the form

$$\tilde{Q}(z) = \sup\{u^t z : W^t u \leq q,\ u \leq 0\}. \tag{4.4}$$

For the sake of simplicity we assume that (i) for every vector z the system $Wy \leq z$, $y \geq 0$, has a solution (the recourse is complete) and (ii) the system $W^t u \leq q,\ u \leq 0$, has a solution (dual feasibility). Under these assumptions, $\tilde{Q}(\cdot)$ is a finite-valued, piecewise linear convex function. This in turn implies that the function $G(x, \boldsymbol{\xi})$ is also piecewise linear convex in each argument and can be written as

$$G(x, \boldsymbol{\xi}) = \max_{k=1,\ldots,r} c^t x + (v^k)^t (h - Tx), \tag{4.5}$$

where $v^1, \ldots, v^r$ are the vertices of the polyhedron $\{u \,:\, W^t u \leq q,\ u \leq 0\}$. Furthermore, by standard subdifferential calculus we have that the subdifferential set of $G(x, \boldsymbol{\xi})$ with respect to x is given by

$$\partial_x G(x, \boldsymbol{\xi}) = \operatorname{conv}\{c - T^t v^k \,:\, G(x, \boldsymbol{\xi}) = c^t x + (v^k)^t (h - Tx),\ k = 1, \ldots, r\}, \tag{4.6}$$

where "conv" denote the convex hull of the set.

In the discussion that follows we assume that the feasibility set X is compact.

4.1. LHS results. In order to apply the results for LHS discussed in section 3.1, we need to verify that the corresponding assumptions are satisfied.

Assume momentarily that the matrix T is deterministic, so that $\boldsymbol{\xi} = h$. Consider Assumption A2. It follows from (4.6) that $\partial_x G(x, \boldsymbol{\xi})$ is uniformly bounded for all x and all $\boldsymbol{\xi}$, and thus, by a version of the mean-value theorem for subdifferentiable functions (see, e.g., [18, Theorem VI.2.3.3]), we conclude that A2 holds with a constant L such that $L(\cdot) \equiv L$. Next, notice that from (4.3) we have $G(x, \boldsymbol{\xi}) = \min\{q^t y : Wy \le \boldsymbol{\xi} - Tx,\ y \ge 0\}$. Thus, for any $\delta > 0$ we have $G(x, \boldsymbol{\xi} + \delta e_i) \le G(x, \boldsymbol{\xi})$; i.e., Assumption C1 holds.

It follows from the above discussion and from Theorem 3.1 that, if the moment-generating function of $G(x, \boldsymbol{\xi})$ is finite everywhere for all x, then given $\varepsilon > 0$ there exist constants $\tilde{K} > 0$ and $\tilde{\alpha} > 0$ such that

$$P\left(\operatorname{dist}(\hat{x}_N^{\mathrm{LHS}}, S^*) \ge \varepsilon\right) \le \tilde{K} e^{-\tilde{\alpha} N} \qquad \text{for all } N \ge 1.$$

Moreover, the exponent $\tilde{\alpha}$ is at least as large as the corresponding exponent obtained for standard Monte Carlo methods. This suggests that convergence under LHS will indeed be faster than under standard Monte Carlo methods.

As mentioned earlier, $G(\cdot, \boldsymbol{\xi})$ is piecewise linear. Thus, if $\boldsymbol{\xi}$ has finite support, then Assumption A3 holds, so from Theorem 3.1 we have

$$P\left(\hat{x}_N^{\mathrm{LHS}} \notin S^*\right) \le \tilde{K} e^{-\tilde{\alpha} N} \qquad \text{for all } N \ge 1.$$

It is fruitful to compare the above result with the i.i.d. case derived in [53]. Indeed, when problem (4.1) has a unique solution x^*, a slightly modified proof of Theorem 3.2 in [53] shows that there exists $\beta > 0$ such that

$$\limsup_{N \to \infty} \frac{1}{N} \log P\left(\hat{x}_N \ne x^*\right) = -\beta, \tag{4.7}$$

where $\hat{x}_N$ is the solution obtained with standard Monte Carlo methods. Moreover, the constant β is given by the minimum of a number of pointwise rates $-\gamma_x(\delta_0)$ in (2.1) (for a fixed $\delta_0 > 0$) over a *finite* number of x's. Since finite support of $\boldsymbol{\xi}$ implies that the moment-generating function of $G(x, \boldsymbol{\xi})$ is finite everywhere for all x, it follows from Proposition 6 in [9] that the pointwise rates $-\gamma_x(\delta_0)$ under LHS are no worse than under Monte Carlo methods. It follows that, when LHS is applied, an equation similar to (4.7) holds and the resulting constant β is *no worse* than under Monte Carlo methods. Since the rate in (4.7) is exact, we conclude that LHS can only improve upon Monte Carlo methods in this setting.

Next, we apply Theorem 3.3 to the present context. As seen above, Assumption A2 holds if T is deterministic. Note that A2 holds even if we allow T to be random (i.e., $\boldsymbol{\xi} = (h, T)$), as long as the distribution of $\boldsymbol{\xi}$ has bounded support, since in that case $\partial_x G(x, \boldsymbol{\xi})$ in (4.6) is uniformly bounded for all x. Moreover, under such a condition (4.5) clearly implies that $G(x, \boldsymbol{\xi})$ is bounded for each x. Theorem 3.3 then ensures that $\operatorname{dist}(\hat{x}_N^{\mathrm{LHS}}, S^*) \to 0$ w.p.1 and $\hat{\nu}_N^{\mathrm{LHS}} \to \nu^*$ w.p.1. Now suppose again that the distribution of $\boldsymbol{\xi}$ has finite support, so Assumption A3 holds. Then $\hat{x}_N^{\mathrm{LHS}} \in S^*$ w.p.1 for N large enough and $\hat{\nu}_N^{\mathrm{LHS}} \to \nu^*$ w.p.1. It follows that, if problem (1.1) has a unique optimal solution x^* and $G(x^*, \cdot)$ is not additive, then

$$\frac{\hat{\nu}_N^{\mathrm{LHS}} - \nu^*}{\sigma_N(x^*)} \ \xrightarrow{d}\ \mathrm{Normal}(0, 1),$$

where $\sigma_N(x^*) := \mathrm{Var}[\hat{g}_N^{\mathrm{LHS}}(x^*)] = N^{-1}C + o(N^{-1})$ for some positive constant C. Note that the nonadditivity assumption is reasonable in this setting, since at the optimal solution x^* typically it happens that the maximum in (4.5) is achieved by more than one k, so $G(x^*, \cdot)$ is not linear.

4.2. QMC results. We now apply the results from section 3.2 to the two-stage stochastic programming model described above. As seen above, a sufficient condition for Assumption A2 to hold is that the distribution of $\boldsymbol{\xi}$ have bounded support. In that case, we have from Theorem 3.4 that $\mathrm{dist}(\hat{x}_N^{\mathrm{RQMC}}, S^*) \to 0$ w.p.1 and $\hat{\nu}_N^{\mathrm{RQMC}} \to \nu^*$ w.p.1. When $\boldsymbol{\xi}$ has finite support (i.e., Assumption A3 holds), we obtain a stronger result, namely, that $\hat{x}_N^{\mathrm{RQMC}} \in S^*$ w.p.1 for N large enough.

The second part of Theorem 3.4—which deals with convergence rates—unfortunately is not applicable in this context. The reason, as pointed out in the discussion following Theorem 3.4, is that the smoothness condition stated in Assumption D1 cannot hold in this case, since $G(x, \cdot)$ is nondifferentiable for each x. Moreover, the assumption that $\boldsymbol{\xi}$ has finite support causes the inverse cumulative distribution function (cdfs) F_j^{-1} to be discontinuous. Note, however, that, as recognized in [28], the smoothness condition in Assumption D1 is only *sufficient* for the proof of the CLT for scrambled $(0, m, s)$-nets. Indeed, as the numerical experiments in section 5 show, it appears that the rates obtained with Theorem 3.4 are sometimes valid in the stochastic programming context considered above even though the smoothness condition does not apply.

5. Numerical experiments. To illustrate the ideas set forth in the previous sections, we discuss now some numerical experiments conducted with two small problems available in the literature. The first problem is `APL1P`, a model for electric power capacity expansion on a transportation network that was first described in [19]. The second problem is `LandS`, a modification of a simple problem in electrical investment planning originally presented in [29]. The modified version we study is the one discussed in [26].

APL1P. `APL1P` has 2 decision variables with 2 constraints (plus lower bound constraints) on the first stage and 9 decision variables with 5 constraints (plus lower bound constraints) on the second stage. The random variables appear on both the right-hand side and the technology matrix of the second stage. There are $s = 5$ independent random variables. The number of realizations per random variable yields a total of $4{\times}5{\times}4{\times}4{\times}4 = 1280$ scenarios. With current computing power, this problem can be easily solved exactly; nevertheless, we present the results with sampling because from that perspective the problem is ill-conditioned (cf. [54]), which means that the approximating solutions $\hat{x}_N$ are likely to vary with replications. That, in turn, ensures that the objective value estimators $\hat{\nu}_N$ do not correspond to the same solution—if they did, the analysis of rate of convergence would reduce to that of pointwise estimation. Thus, we view this case as a good test for the theoretical results presented in the paper.

We adopted the following methodology. We solved the approximating problem (1.3) by using samples generated with standard Monte Carlo methods, LHS, and randomized (t, s)-sequences in base 5—which, as discussed in section 3.2, is a form of RQMC. For each sampling scheme, we solved the problem with sample sizes equal to successive powers of the base, ranging from 5^2 to 5^6. The choice for such sample sizes was driven by two factors: (i) the restriction on the choice of the base in order for a $(0, m, s)$-net to exist ($b \geq s - 1$; cf. the discussion following Theorem 3.4), and (ii) the restriction on sample sizes to be powers of the base in order for a sequence to be a (t, m, s)-net. We feel that the two restrictions together would be rather limiting

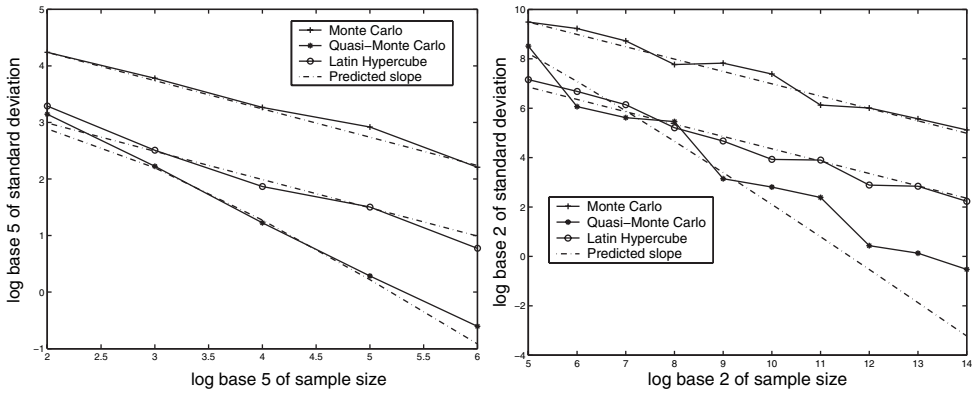

FIG. 5.1. *Rates of convergence for the APL1P problem using base* 5 *(left) and base* 2 *(right).*

in practice; thus, we also present results with base 2, which in addition yields faster generators [13].

For each sample size, twenty-five replications were run, and the standard deviation of the estimators $\hat{\nu}_N$ over these replications was calculated. All simulations used independent random streams. By plotting the logarithm of the standard deviation against the logarithm of the sample size, we can visualize the rate of convergence—for example, with standard Monte Carlo methods one expects to obtain a straight line with slope $-1/2$. We also calculated the *mean-squared error* of the estimators, but, since the results were very similar (in this problem, the bias was much smaller than the standard deviation), we chose not to display them.

The sampling approximation problems were solved in two steps: First, we used the SUTIL library [5] to generate the linear programs corresponding to each sampled problem. SUTIL can construct MPS files for Monte Carlo sampling approximations of two-stage stochastic linear programs; we modified the library slightly to incorporate LHS and randomized (t, s)-sequences, by using the publicly available routines developed in [13]. The resulting MPS files were fed into the software package Xpress–MP$^{\text{TM}}$ from Dash Optimization (available to us under the Academic Partnership Program).

Figure 5.1 shows the results. We can see that both Monte Carlo methods and LHS yield a convergence rate of $N^{-1/2}$, thus corroborating the results of [48] for Monte Carlo methods and of Theorem 3.3 for LHS. The rate for RQMC for both bases appears to be of order N^{-1} (although that is more evident with base 5), which is not as good as the rate in Theorem 3.4; a possible explanation is the absence of the smoothness assumed for that result. It is clear from the figure that the rate obtained with RQMC in either case is better than with both Monte Carlo methods and LHS. Note also that both LHS and RQMC yield estimators with smaller variance than Monte Carlo methods—even though the rate of convergence (in the case of LHS) is the same as that of Monte Carlo methods—and that the variance with RQMC is smaller than with LHS except for very small sample sizes.

LandS. The `LandS` problem has 4 decision variables on the first stage and 12 decision variables on the second stage. Randomness appears only on the right-hand side of the second stage, in the form of demand constraints. There are $s = 3$ independent random variables, each with 100 possible realizations. Thus, the total number of scenarios is 10^6.

The methodology we adopted was the same as in the `APL1P` case, except that used bases 3 and 2. Figure 5.2 shows the results. Again, we see that both Monte

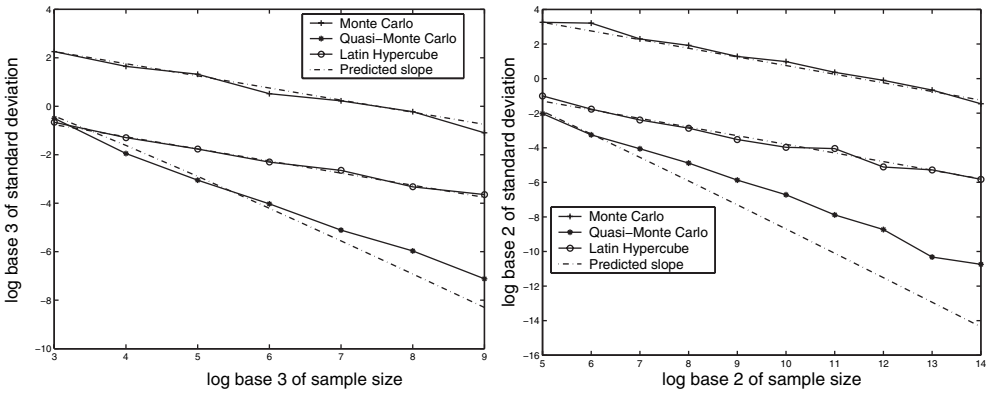

FIG. 5.2. *Rates of convergence for the* `LandS` *problem using base* 3 *(left) and base* 2 *(right).*

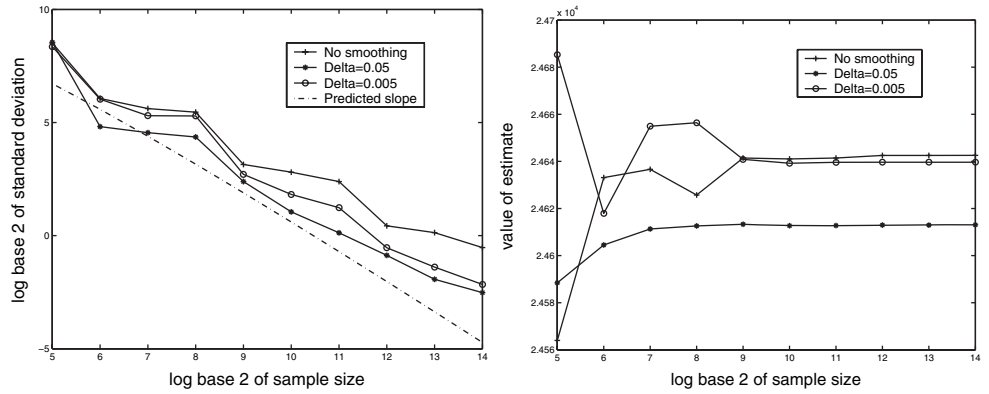

FIG. 5.3. *Rates of convergence (left) and values of the estimate* $\hat{\nu}_N$ *(right) for the APL1P problem under RQMC with smoothing, using base* 2.

Carlo methods and LHS yield a convergence rate of $N^{-1/2}$, and the rate for RQMC appears to be of order N^{-1}. As in the previous example, the RQMC rate is better than the Monte Carlo and LHS rates, both LHS and RQMC yield estimators with smaller variance than Monte Carlo methods, and the variance with RQMC is smaller than with LHS.

A brief study of smoothness. To check the role of the lack of smoothness in the convergence rates, we considered the effect of smoothing the inverse cdfs F_i^{-1}. This was accomplished by replacing F_i^{-1} with a smooth function F_i^{Δ} such that F_i^{-1} and F_i^{Δ} coincide everywhere except on a interval of size 2Δ around each discontinuity point.

Figures 5.3 and 5.4 depict the results. In general, such a smoothing procedure may introduce bias; this is clearly seen in case of the `APL1P` problem, where smoothing does not seem to help much, at least for base 2. With `LandS`, however, smoothing works perfectly—with $\Delta = 0.005$ we obtain the rate predicted by Theorem 3.4 without incurring virtually any bias, even though the theorem is not directly applicable in the absence of Assumption A3 (the smoothed distribution does not have finite support).

As another way to verify the effect of smoothness, we modified the `APL1P` problem by fitting continuous distributions to the discrete data. More precisely, we used Weibull distributions for each of the five random variables in the problem, in such a way that the mean and variance of the random variables were approximately the

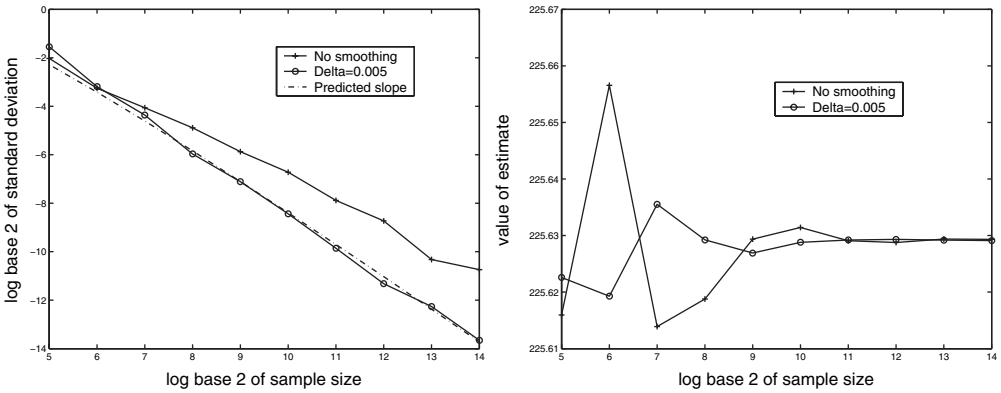

FIG. 5.4. *Rates of convergence (left) and values of the estimate $\hat{\nu}_N$ (right) for the* LandS *problem under RQMC with smoothing, using base* 2.

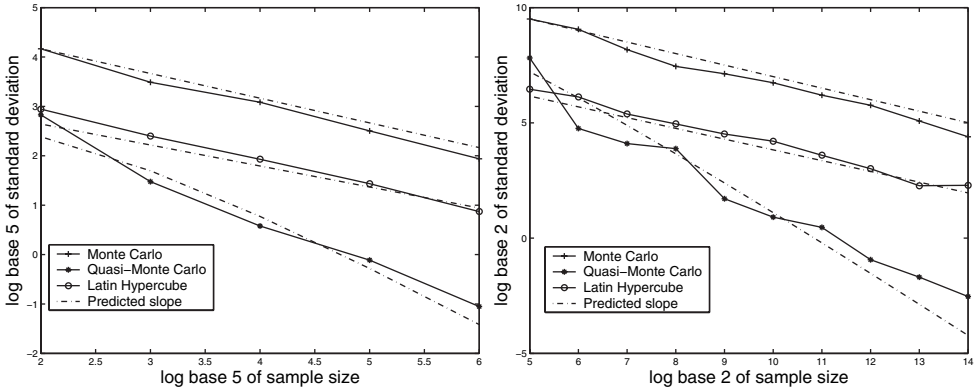

FIG. 5.5. *Rates of convergence for the modified APL1P problem with Weibull distributions, using base* 5 *(left) and base* 2 *(right).*

same as in the original data. Figure 5.5 depicts the results, again for bases 2 and 5. We see that the rates of convergence behave somewhat similarly to the discrete case, although the benefits of using RQMC seem slightly higher in the continuous case.

These results suggest that Theorem 3.4 may be valid under more general conditions than those we have used.

6. Conclusions. The theoretical and numerical results in this paper suggest that alternative sampling methods such as LHS and QMC can be very effective when solving stochastic optimization problems via sample average approximations. The effectiveness is measured in terms of rates of convergence of estimators of optimal solutions and of optimal values as functions of the sample size. The main contribution of the paper is establishing that rates of convergence for pointwise estimators (i.e., estimation of integrals) carry over to estimators of optimal values/solutions, which allows for the use of results for pointwise estimation available in the literature. In particular, the results in the paper show that, under appropriate conditions, it is possible to obtain a rate of convergence of order $[(\log N)^{s-1}/N^3]^{1/2}$ for the approximating optimal values $\hat{\nu}_N$, which asymptotically is much better than the $N^{-1/2}$ obtained with standard Monte Carlo methods.

Such results are very encouraging and at the same time raise some interesting issues for further investigation. One topic concerns the effect of smoothing on the rates of convergence when using RQMC—as discussed earlier, the "ideal" rate $[(\log N)^{s-1}/N^3]^{1/2}$ derived in Theorem 3.4 seems to require smoothness of the inverse cdf and of the objective function. However, our numerical results suggest that such conditions may not be necessary. Moreover, it is important to mention that Theorem 2.10 is valid regardless of any smoothness conditions. That is, if one shows that a CLT holds for RQMC under nonsmooth (or potentially discontinuous) functions with a certain rate, then Theorem 2.10 will ensure that under appropriate conditions the optimal value estimators $\hat{\nu}_N^{\mathrm{RQMC}}$ converge at the same rate. The result in [28] used in the proof of Theorem 3.4 is, however, the only CLT-type result available for RQMC, at least to the best of our knowledge.

On the other hand, our experiments also suggest that Theorem 3.4 is valid even when Assumption A3 does not hold. This is not surprising—as we mentioned earlier, it is possible that a functional version of Assumption B2 holds for the functional space $C(X)$ under RQMC, in which case the conditions of Assumption A3 would not be required; however, we are not aware of the existence of such a result.

It would also be interesting to study the precise effect of having multiple optimal solutions on the rates of convergence of optimal values—the main results we have obtained for that case under LHS and RQMC (Theorems 3.3 and 3.4) require uniqueness of the optimal solution. Such a task, however, is likely to require again a functional or at least multivariate version of Assumption B2 (we note that multivariate CLTs have been proved for LHS but not for RQMC).

Another important issue concerns the dimensionality of the problems. It is well known that the performance of RQMC methods worsens with the number of dimensions—indeed, it is easy to see that, when s is large, the term $[(\log_b N)^{s-1}/N^3]^{1/2}$ becomes smaller than $N^{-1/2}$ only for large N. For example, with $s = 30$ and $b = 2$ one needs $N \geq 2^{16}$ to get the benefits of the RQMC approach. This suggests that RQMC sampling should be used only with some of the random variables involved in the problem; however, determining which ones to select is a nontrivial issue. Research on this topic is underway.

Acknowledgments. We thank Shane Drew for help with the numerical experiments, Jeff Linderoth for assistance with the SUTIL library, and Mihai Anitescu and Alexander Shapiro for discussions on an early version of this paper. We also thank two anonymous referees and the associate editor for their comments.

STOCHASTIC PROGRAMS WITH FIRST-ORDER DOMINANCE CONSTRAINTS INDUCED BY MIXED-INTEGER LINEAR RECOURSE*

RALF GOLLMER†, FREDERIKE NEISE†, AND RÜDIGER SCHULTZ†

Abstract. We propose a new class of stochastic integer programs whose special features are dominance constraints induced by mixed-integer linear recourse. For these models, we establish closedness of the constraint set mapping with the underlying probability measure as a parameter. In the case of finite probability spaces, the models are shown to be equivalent to large-scale, block-structured, mixed-integer linear programs. We propose a decomposition algorithm for the latter and discuss computational results.

Key words. stochastic integer programming, stochastic dominance, mixed-integer optimization

1. Introduction.

Two-stage stochastic programming models are derived from random optimization problems with information constraints. In the present paper we start out from the following random mixed-integer linear program:

$$\min\{c^\top x + q^\top y \ : \ Tx + Wy = z(\omega),\ x \in X,\ y \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}\} \tag{1}$$

together with the information constraint that x must be selected without anticipation of $z(\omega)$. This leads to a two-stage scheme of alternating decision and observation: The decision on x is followed by observing $z(\omega)$, and then y is taken, thus depending on x and $z(\omega)$. Accordingly, x and y are called first- and second-stage decisions, respectively.

Assume that the ingredients of (1) have conformable dimensions, that W is a rational matrix, and that $X \subseteq \mathbb{R}^m$ is a nonempty polyhedron, possibly involving integer requirements to components of x.

The mentioned two-stage dynamics becomes explicit by the following reformulation of (1):

$$\begin{aligned} &\min_x \left\{ c^\top x + \min_y \{q^\top y \ : \ Wy = z(\omega) - Tx,\ y \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}\} \ : \ x \in X \right\} \\ &\qquad = \min_x \{c^\top x \ + \ \Phi(z(\omega) - Tx) \ : \ x \in X\}, \end{aligned} \tag{2}$$

where

$$\Phi(t) := \min\{q^\top y \ : \ Wy = t,\ y \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}\}. \tag{3}$$

The function Φ, called the value function of the mixed-integer linear program

$$\min\{q^\top y \ : \ Wy = t, \ y \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}\},$$

has been studied in parametric optimization. Under the assumptions

(A1) (complete recourse) $W(\mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}) = \mathbb{R}^s$,

(A2) (sufficiently expensive recourse) $\{u \in \mathbb{R}^s \ : \ W^\top u \leq q\} \neq \emptyset$,

it holds that Φ is real-valued and lower semicontinuous on $\mathbb{R}^s$, i.e., $\liminf_{t_n \to t} \Phi(t_n) \geq \Phi(t)$ for all $t \in \mathbb{R}^s$ [2, 7].

In view of (2), the random optimization problem (1) gives rise to the family of random variables

$$\Big(c^\top x + \Phi(z(\omega) - Tx)\Big)_{x \in X}. \tag{4}$$

Thus every first-stage decision $x \in X$ induces a random variable $f(x,z) := c^\top x + \Phi(z(\omega) - Tx)$. Traditional two-stage stochastic programming aims at optimizing nonanticipative decisions, i.e., finding a best x, or in other words a best member in the family (4) of random variables. For the specification of best, statistical parameters reflecting mean and/or risk are employed. Early approaches in the literature used the expectation, leading to optimization problems

$$\min\{\mathbb{E}[f(x,z)] \ : \ x \in X\}. \tag{5}$$

Employing the weighted sum of $\mathbb{E}$ and some risk measure $\mathcal{R}$ leads to mean-risk models

$$\min\{\mathbb{E}[f(x,z)] + \rho \cdot \mathcal{R}[f(x,z)] \ : \ x \in X\} \qquad (\rho > 0 \text{ fixed}). \tag{6}$$

There is an extensive literature on structural analysis and algorithm design for this class of stochastic programs; see, for instance, [1, 5, 13, 19, 20, 23, 27, 29, 31, 32].

Here we take an alternative view. Rather than heading for best members of (4), we want to identify "acceptable" members and optimize over them. This leads to a new class of stochastic integer programs (see (8) below), whose structural analysis and algorithmic treatment is the aim of the present paper.

Stochastic dominance, an established concept in decision theory [14, 22, 24], provides a possibility to formalize the above-mentioned acceptability. In the present paper we deal with first-order stochastic dominance. A (real-valued) random variable X is said to be stochastically smaller in first order than a random variable Y ($\mathsf{X} \preceq_1 \mathsf{Y}$) iff $\mathbb{E}h(\mathsf{X}) \leq \mathbb{E}h(\mathsf{Y})$ for all nondecreasing functions h for which both expectations exist. An equivalent formulation reads as follows (see, e.g., [24]):

$$\mathsf{X} \preceq_1 \mathsf{Y} \quad \text{iff} \quad \mathbb{P}[\{\omega : \mathsf{X}(\omega) \leq \eta\}] \ \geq \ \mathbb{P}[\{\omega : \mathsf{Y}(\omega) \leq \eta\}] \quad \forall \eta \in \mathbb{R}. \tag{7}$$

Coming back to our two-stage random optimization problem (1) and the related family (4), we assume that some (random) benchmark cost profile $d(\omega)$ is given. We consider only those $x \in X$ acceptable for which the corresponding $f(x,z)$ is stochastically smaller in first order than the benchmark profile $d(\omega)$. Over all acceptable $x \in X$ we optimize some function $g : \mathbb{R}^m \to \mathbb{R}$. This leads to the following stochastic program with first-order dominance constraints induced by mixed-integer linear recourse:

$$\min\{g(x) \ : \ f(x,z) \ \preceq_1 \ d, \ x \in X\}. \tag{8}$$

Stochastic optimization problems with dominance constraints involving general random variables were pioneered in [10, 11, 12, 25]. These papers address structure,

stability, and algorithms for (8) if general random variables, enjoying suitable continuity, smoothness, or linearity properties in x and/or z, are placed instead of $f(x,z)$. The random variables $f(x,z)$, on the one hand, are more specific, since they are essentially given by the mixed-integer value function in (3). On the other hand, the results from [10, 11, 12, 25] are not applicable to our setting due to lacking continuity of Φ; recall the above-mentioned lower semicontinuity.

Our paper is organized as follows. In section 2 we elaborate a basic structural property of the constraint sets of (8) and draw some conclusions, among others, on the stability behavior of (8). Section 3 is devoted to algorithmic aspects. We prove the equivalence of (8) with a structured mixed-integer linear program if the underlying probability spaces are finite. Then we propose a decomposition algorithm for these models. In section 4 we report computational results with this algorithm. The paper concludes with section 5, where a model involving a weaker stochastic order is put into perspective, both theoretically and numerically.

2. Structure and stability. The stochastic program (8) is essentially governed by its constraint set. In what follows we establish some results concerning the basic well posedness of this set.

Let $\mathcal{P}(\mathbb{R}^s)$ and $\mathcal{P}(\mathbb{R})$ be the sets of all Borel probability measures on $\mathbb{R}^s$ and $\mathbb{R}$, respectively. By $\mu \in \mathcal{P}(\mathbb{R}^s)$ and $\nu \in \mathcal{P}(\mathbb{R})$ we denote the probability measures induced by the random variables $z(\omega)$ and $d(\omega)$, respectively. We fix ν and consider the multifunction $C : \mathcal{P}(\mathbb{R}^s) \to 2^{\mathbb{R}^m}$, where

$$C(\mu) \;:=\; \{x \in \mathbb{R}^m \;:\; f(x,z) \preceq_1 d,\, x \in X\}.$$

Moreover, we equip $\mathcal{P}(\mathbb{R}^s)$ with weak convergence of probability measures [3]. A sequence $\{\mu_n\}$ in $\mathcal{P}(\mathbb{R}^s)$ is said to converge weakly to $\mu \in \mathcal{P}(\mathbb{R}^s)$, written $\mu_n \xrightarrow{w} \mu$, if for any bounded continuous function $h : \mathbb{R}^s \to \mathbb{R}$ it holds that $\int_{\mathbb{R}^s} h(z)\mu_n(dz) \to \int_{\mathbb{R}^s} h(z)\mu(dz)$ as $n \to \infty$.

PROPOSITION 2.1. *Assume* (A1) *and* (A2). *Then C is a closed multifunction on $\mathcal{P}(\mathbb{R}^s)$. This means that for arbitrary $\mu \in \mathcal{P}(\mathbb{R}^s)$ and sequences $\mu_n \in \mathcal{P}(\mathbb{R}^s), x_n \in C(\mu_n)$, with $\mu_n \xrightarrow{w} \mu$ and $x_n \to x$, it follows that $x \in C(\mu)$.*

Proof. In view of $x_n \in C(\mu_n)$ and (7) it holds for all n that

$$\nu[d \le \eta] \;\le\; \mu_n[f(x_n,z) \le \eta] \qquad \forall \eta \in \mathbb{R}. \tag{9}$$

(The shorthand notations $d \le \eta$ and $f(x_n,z) \le \eta$ refer to the sets $\{d \in \mathbb{R} : d \le \eta\}$ and $\{z \in \mathbb{R}^s : f(x_n,z) \le \eta\}$, respectively.)

Denote that $M_\eta(x) := \{z \in \mathbb{R}^s \;:\; f(x,z) > \eta\}$. By (A1) and (A2), the function Φ, and hence $f(\cdot,\cdot)$, is lower semicontinuous. Therefore, $M_\eta(x)$ is open for all $\eta \in \mathbb{R}$ and all $x \in \mathbb{R}^m$. With the new notation, (9) says that for all n

$$\nu[d \le \eta] \;+\; \mu_n[M_\eta(x_n)] \;\le\; 1 \qquad \forall \eta \in \mathbb{R}. \tag{10}$$

Since $M_\eta(x)$ is open, the Portmanteau theorem (see [3, Theorem 2.1, pp. 11–12]) implies that

$$\mu[M_\eta(x)] \;\le\; \liminf_n \mu_n[M_\eta(x)] \qquad \forall \eta \in \mathbb{R}. \tag{11}$$

The lower semicontinuity of Φ yields

$$M_\eta(x) \;\subseteq\; \liminf_n M_\eta(x_n) \qquad \forall \eta \in \mathbb{R}. \tag{12}$$

Here "$\liminf_n$" denotes the set-theoretic limits inferior, i.e., the set of all points belonging to all but a finite number of sets $M_\eta(x_n)$. For fixed n, (12) and the lower semicontinuity of the probability measure (see [4, Theorem 4.1, p. 48] now imply that

$$\mu_n[M_\eta(x)] \;\le\; \mu_n[\liminf_k M_\eta(x_k)] \;\le\; \liminf_k \mu_n[M_\eta(x_k)] \qquad \forall \eta \in \mathbb{R}.$$

By taking the limits inferior with respect to n, we obtain

$$\begin{aligned} \liminf_n \mu_n[M_\eta(x)] &\le \liminf_n \liminf_k \mu_n[M_\eta(x_k)] \\ &\le \liminf_n \mu_n[M_\eta(x_n)] \end{aligned} \qquad \forall \eta \in \mathbb{R}. \tag{13}$$

For the last inequality we have picked the diagonal subsequence where $n = k$. By putting together (11) and (13) we arrive at

$$\mu[M_\eta(x)] \;\le\; \liminf_n \mu_n[M_\eta(x_n)] \qquad \forall \eta \in \mathbb{R}. \tag{14}$$

Taking the limits inferior with respect to n in (10) and observing (14) leads to

$$\nu[d \le \eta] \;+\; \mu[M_\eta(x)] \;\le\; \nu[d \le \eta] \;+\; \liminf_n \mu_n[M_\eta(x_n)] \;\le\; 1 \qquad \forall \eta \in \mathbb{R}.$$

This implies (see (10), (9), and (7)) that $f(x, z) \preceq_1 d$. By the closedness of X, $x_n \to x$, and $x_n \in X$ (for all n), we have $x \in X$. Altogether it follows that $x \in C(\mu)$, and the proof is complete. □

Remark 2.2 (about variable ν). Equipping $\mathcal{P}(\mathbb{R})$ with uniform convergence of distribution functions (Kolmogorov–Smirnov convergence), as, for instance, in [10], allows us to extend Proposition 2.1 to the multifunction $\bar{C} : \mathcal{P}(\mathbb{R}^s) \times \mathcal{P}(\mathbb{R}) \to 2^{\mathbb{R}^m}$, where $\bar{C}(\mu, \nu) := \{x \in \mathbb{R}^m : f(x, z) \preceq_1 d,\, x \in X\}$. Indeed, if ν_n converge to ν in the Kolmogorov–Smirnov sense, then $\nu_n[d \le \eta] \to \nu[d \le \eta]$ for all $\eta \in \mathbb{R}$, and the above proof readily extends.

Remark 2.3 (about weak convergence on $\mathcal{P}(\mathbb{R}^s)$). For a different class of random variables, [10] has established a closedness result for a dominance constraint of first order, where convergence on the counterpart space to $\mathcal{P}(\mathbb{R}^s)$ is given by a suitable discrepancy. Compared with [10], Proposition 2.1 applies to a more focused family of random variables (even allowing for discontinuities) with a weaker convergence notion on $\mathcal{P}(\mathbb{R}^s)$, namely, weak convergence of probability measures instead of convergence induced by the discrepancy in [10].

Proposition 2.1 in particular implies that $C(\mu)$ is a closed set for any $\mu \in \mathcal{P}(\mathbb{R}^s)$.

COROLLARY 2.4. *Assume* (A1) *and* (A2). *Then* $C(\mu)$ *is a closed subset of* $\mathbb{R}^m$ *for any* $\mu \in \mathcal{P}(\mathbb{R}^s)$.

The optimization problem (8) thus is well-posed in the sense that for, e.g., lower semicontinuous g, bounded X, and nonempty $C(\mu)$, the infimum is finite and is attained.

It is well known that continuity properties of constraint set mappings, such as the one established in Proposition 2.1, allow for direct conclusions regarding the stability of the related optimization problems. We next turn to such a conclusion.

Consider (8) as a parametric program where the probability distribution μ of the random variable $z(\omega)$ enters as a parameter:

$$P(\mu) \qquad \min\{g(x) \;:\; x \in C(\mu)\}.$$

Studying the stability of stochastic programs with respect to perturbations of the underlying probability distributions is motivated by the incomplete information on these distributions that is often met and by approximation issues in the context of computations; see [28] for a recent overview on stability analysis in stochastic programming.

PROPOSITION 2.5. *Assume* (A1) *and* (A2)*, that X is nonempty and compact, and that g is lower semicontinuous. Let $\bar{\mu} \in \mathcal{P}(\mathbb{R}^s)$ be such that $P(\bar{\mu})$ has an optimal solution. Then the optimal value function $\varphi(\mu) := \inf\{g(x) : x \in C(\mu)\}$ is lower semicontinuous at $\bar{\mu}$.*

Proof. Let $\mu_n \xrightarrow{w} \bar{\mu}$, and assume without loss of generality that $C(\mu_n) \neq \emptyset$ for all n. Otherwise, we would have $\varphi(\mu_n) = +\infty$, which does not interfere with the validity of $\liminf_n \varphi(\mu_n) \geq \varphi(\bar{\mu})$.

Let $\varepsilon > 0$ be arbitrarily fixed. Then there exist $x_n \in C(\mu_n)$ such that $g(x_n) \leq \varphi(\mu_n) + \varepsilon$. By the compactness of X there exists an accumulation point $\bar{x}$ of the x_n. By the closedness of $C(.)$ (Proposition 2.1), it follows that $\bar{x} \in C(\bar{\mu})$. Together with the lower semicontinuity of g, this implies that

$$\varphi(\bar{\mu}) \;\leq\; g(\bar{x}) \;\leq\; \liminf_n g(x_n) \;\leq\; \liminf_n \varphi(\mu_n) + \varepsilon.$$

Since $\varepsilon > 0$ was arbitrary, the proof is complete. □

Remark 2.6 (about approximation schemes). It is well known that approximation schemes based on discretization via conditional expectations [6, 18] or on empirical estimation [26, 33] often produce weakly converging sequences of discrete probability measures. Stability results such as Propositions 2.1 and 2.5 thus enable justification of numerical procedures that rely on problem solution for discrete measures, possibly belonging to weakly converging sequences. This links our stability analysis to the solution procedure of the next section. From Proposition 2.1 it follows that accumulation points of feasible solutions to the approximates are feasible solutions to the original problem. Proposition 2.5 yields the fact that limits of optimal values of the approximates never drop below the optimal value of the original.

3. Algorithmic treatment. In the present section we deal with algorithmic possibilities for (8) in case $z(\omega)$ and $d(\omega)$ follow discrete probability distributions with finitely many realizations. We start with establishing an equivalence between (8) and a large-scale, but structured, mixed-integer linear program.

PROPOSITION 3.1. *Let $z(\omega)$ and $d(\omega)$ in* (8) *follow discrete distributions with realizations z_l, $l = 1, \ldots, L$, and d_k, $k = 1, \ldots, K$, as well as probabilities π_l, $l = 1, \ldots, L$, and p_k, $k = 1, \ldots, K$, respectively. Let further $g(x) := g^\top x$ be linear and X be bounded. Assume* (A1) *and* (A2)*. Then there exists a constant* M *such that* (8) *is equivalent to the mixed-integer linear program*

$$\min\Big\{ g^\top x : \begin{array}{lcll} c^\top x + q^\top y_{lk} - d_k & \leq & \mathsf{M}\theta_{lk} & \forall l\ \forall k \\ Tx + W y_{lk} & = & z_l & \forall l\ \forall k \\ \sum_{l=1}^{L} \pi_l \theta_{lk} & \leq & \bar{d}_k & \forall k \\ x \in X,\ y_{lk} \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'},\ \theta_{lk} \in \{0,1\} & & & \forall l\ \forall k \end{array} \Big\}, \tag{15}$$

where $\bar{d}_k := 1 - \nu[d \leq d_k]$, $k = 1, \ldots, K$.

Proof. By (7), the constraint $f(x,z) \preceq_1 d$ is equivalent to

$$\nu[d \leq \eta] \;\leq\; \mu[f(x,z) \leq \eta] \qquad \forall \eta \in \mathbb{R}.$$

As shown in [25] this is equivalent to

$$\nu[d \le d_k] \;\le\; \mu[f(x,z) \le d_k] \quad \text{for } k = 1, \dots, K. \tag{16}$$

The asserted constant M is put such that

$$\mathsf{M} \;>\; \sup\big\{c^\top x + \Phi(z_l - Tx) - d_k \;:\; x \in X,\, l \in \{1,\dots,L\},\, k \in \{1,\dots,K\}\big\}.$$

It has to be shown that the right-hand side above is finite. To this end, we employ the following growth property of Φ; see, [2, 7], for instance. Under (A1) and (A2) there exist constants $\alpha > 0, \beta > 0$ such that for all $t_1, t_2 \in \mathbb{R}^s$

$$|\Phi(t_1) - \Phi(t_2)| \;\le\; \alpha\|t_1 - t_2\| + \beta.$$

Moreover, (A2) implies that $\Phi(0) = 0$. This enables the following estimate:

$$\begin{aligned} |c^\top x + \Phi(z_l - Tx) - d_k| &\le |c^\top x| + |\Phi(z_l - Tx) - \Phi(0)| + |d_k| \\ &\le \|c\| \cdot \|x\| + \alpha\|z_l\| + \alpha\|T\| \cdot \|x\| + \beta + |d_k|. \end{aligned}$$

Since X is bounded, this verifies the finiteness of the above supremum.

By considering the complementary event on the right, we rewrite (16) as

$$\mu[f(x,z) > d_k] \;\le\; 1 - \nu[d \le d_k] \;=:\; \bar{d}_k \qquad \text{for } k = 1, \dots, K. \tag{17}$$

For any $k \in \{1, \dots, K\}$ we now consider the following sets:

$$S_1 \;:=\; \{x \in X \;:\; \mu[f(x,z) > d_k] \;\le\; \bar{d}_k\}$$

and

$$S_2 \;:=\; \left\{ x \in X : \begin{array}{ll} \exists \theta_l \in \{0,1\} & \\ \exists y_l \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'},\; l = 1, \dots, L, & \\ \text{such that:} & \\ c^\top x + q^\top y_l - d_k & \le\; \mathsf{M}\theta_l \\ Tx + W y_l & =\; z_l \\ \sum_{l=1}^{L} \pi_l \theta_l & \le\; \bar{d}_k \end{array} \right\}.$$

We complete the proof by showing that $S_1 = S_2$ and begin with the inclusion $S_1 \subseteq S_2$.

Let $x \in S_1$, and consider $I := \big\{l \in \{1,\dots,L\} \;:\; c^\top x + \Phi(z_l - Tx) > d_k\big\}$. Then $\sum_{l \in I} \pi_l \le \bar{d}_k$, by the definition of S_1. Put $\theta_l := 1$, for $l \in I$, and $\theta_l := 0$, otherwise. This gives

$$\sum_{l=1}^{L} \pi_l \theta_l \;=\; \sum_{l \in I} \pi_l \;\le\; \bar{d}_k.$$

For $l \notin I$ we have $c^\top x + \Phi(z_l - Tx) \le d_k$. Hence there exists $y_l \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}$ fulfilling

$$c^\top x + q^\top y_l - d_k \;\le\; 0 \;=\; \mathsf{M}\theta_l \qquad \text{and} \qquad Tx + W y_l \;=\; z_l.$$

For $l \in I$ take $y_l \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}$ such that $Tx + Wy_l = z_l$ and $q^\top y_l = \Phi(z_l - Tx)$. By the selection of M we then have

$$c^\top x + q^\top y_l - d_k \;\leq\; \mathsf{M} \;=\; \mathsf{M}\theta_l.$$

This implies that $x \in S_2$.

To show $S_2 \subseteq S_1$ let $x \in S_2$, and consider $I := \big\{l \in \{1, \ldots, L\} \,:\, \theta_l = 0\big\}$. For each $l \in I$, then there exists a $y_l \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'}$ such that

$$c^\top x + q^\top y_l - d_k \;\leq\; 0 \qquad \text{and} \qquad Tx + Wy_l \;=\; z_l.$$

Hence $c^\top x + \Phi(z_l - Tx) \;\leq\; d_k$ for all $l \in I$. Therefore

$$\big\{l \in \{1, \ldots, L\} \,:\, c^\top x + \Phi(z_l - Tx) > d_k\big\} \;\;\subseteq\;\; \big\{l \in \{1, \ldots, L\} \,:\, \theta_l = 1\big\}.$$

This yields

$$\mu[c^\top x + \Phi(z - Tx) \;>\; d_k] \;\;\leq\;\; \sum_{l \notin I} \pi_l \theta_l \;\;=\;\; \sum_{l=1}^{L} \pi_l \theta_l \;\;\leq\;\; \bar{d}_k.$$

Thus $x \in S_1$, and the proof is complete. □

As a mixed-integer linear program, the optimization problem from Proposition 3.1 clearly can be tackled by general-purpose mixed-integer linear programming software. With growing numbers L and K of scenarios of the data and the benchmark distributions, however, it can be expected that this approach will come to its limitations.

This motivates us to study decomposition of the model. By having in mind the L-shaped form of the constraint matrix that arises with discrete probability spaces in the traditional stochastic program (5) (see [5, 19, 27, 29]), similarities and differences come to the fore: The constraints

$$\begin{aligned} c^\top x + q^\top y_{lk} - d_k \;&\leq\; \mathsf{M}\theta_{lk} \quad \forall l\, \forall k, \\ Tx + Wy_{lk} \;&=\; z_l \qquad \forall l\, \forall k \end{aligned}$$

correspond to K blocks, each of them in L-shaped form. By the latter we mean that, for fixed k, there are no constraints explicitly interlinking variables y_{lk}, θ_{lk} belonging to different $l \in \{1, \ldots, L\}$. Linkage is established only by the omnipresent x-variables. These variables must not depend on l and must not depend on k. So they couple the K blocks above into a single L-shaped block. The constraints

$$\sum_{l=1}^{L} \pi_l \theta_{lk} \;\;\leq\;\; \bar{d}_k \qquad \forall k \tag{18}$$

provide linkage between variables belonging to different scenarios $l \in \{1, \ldots, L\}$ such that the full model no longer obeys the L-shaped structure.

Our basic algorithmic idea now is to generate lower bounds by a suitable relaxation, to generate upper bounds by a tailored feasibility heuristic, and to embed the two into a branch-and-bound scheme in the spirit of global optimization.

Lower bounds. Relaxation is carried out in a twofold manner: The nonanticipativity of x gets relaxed by introducing copies $x_l, l = 1, \ldots, L$, and the constraints (18) undergo Lagrangean relaxation. This is formalized as follows.

In the objective we put $x = \sum_{l=1}^{L} \pi_l x_l$, and for the constraints (18) we introduce Lagrangean multipliers $\lambda_k \geq 0$, $k = 1, \ldots, K$. The Lagrangean function then reads

$$\begin{aligned}\mathcal{L}(x, \theta, \lambda) &= \sum_{l=1}^{L} \pi_l \cdot g^\top x_l \ + \ \sum_{k=1}^{K} \lambda_k \left(\sum_{l=1}^{L} \pi_l \theta_{lk} - \bar{d}_k \right) \\ &= \sum_{l=1}^{L} \pi_l \cdot g^\top x_l \ + \ \sum_{l=1}^{L} \sum_{k=1}^{K} \lambda_k \cdot (\pi_l \theta_{lk} - \pi_l \bar{d}_k) \\ &= \sum_{l=1}^{L} \mathcal{L}_l(x_l, \theta_l, \lambda),\end{aligned}$$

where

$$\mathcal{L}_l(x_l, \theta_l, \lambda) \ := \ \pi_l \cdot g^\top x_l \ + \ \pi_l \sum_{k=1}^{K} \lambda_k \cdot (\theta_{lk} - \bar{d}_k).$$

This leads to the Lagrangean dual

$$\max\{D(\lambda) \ : \ \lambda \in \mathbb{R}^K_+\},$$

where

$$D(\lambda) \ = \ \min \left\{ \mathcal{L}(x, \theta, \lambda) : \begin{array}{lcll} c^\top x_l + q^\top y_{lk} - d_k & \leq & \mathsf{M}\theta_{lk} & \forall l \, \forall k \\ T x_l + W y_{lk} & = & z_l & \forall l \, \forall k \\ x_l \in X, \ y_{lk} \in \mathbb{Z}^{\bar{m}}_+ \times \mathbb{R}^{m'}_+, \ \theta_{lk} \in \{0,1\} & & & \forall l \, \forall k \end{array} \right\}.$$

The optimization problem behind $D(\lambda)$ now is separable in l, and we obtain

$$D(\lambda) \ = \ \sum_{l=1}^{L} \min \left\{ \mathcal{L}_l(x_l, \theta_l, \lambda) : \begin{array}{lcll} c^\top x_l + q^\top y_{lk} - d_k & \leq & \mathsf{M}\theta_{lk} & \forall k \\ T x_l + W y_{lk} & = & z_l & \forall k \\ x_l \in X, \ y_{lk} \in \mathbb{Z}^{\bar{m}}_+ \times \mathbb{R}^{m'}_+, \ \theta_{lk} \in \{0,1\} & & & \forall k \end{array} \right\}. \tag{19}$$

The Lagrangean dual is a nonsmooth concave maximization (or convex minimization) problem whose optimal value yields a lower bound to the optimal value of the mixed-integer linear program in Proposition 3.1. For solving the Lagrangean dual, bundle-trust algorithms from nonsmooth convex optimization, such as the conic bundle method [17], can be employed. Per iteration, these methods require the function value $D(\lambda)$ and one subgradient from $\partial D(\lambda)$. Here the above separability becomes essential, since it leads to a decomposition of the optimization problem behind $D(\lambda)$ into subproblems corresponding to the individual scenarios z_l, $l = 1, \ldots, L$.

In principle, the above lower bounding procedure can be improved by applying Lagrangean relaxation not only to (18) but also to the nonanticipativity of x that can be expressed by the system of identities $x_1 = x_2 = \cdots = x_L$. This, however, leads to a drastic increase of dimension in the Lagrangean dual, namely, from K to $K + m \cdot (L - 1)$. Recall that L is the number of data scenarios z_l, while K is the number of benchmark scenarios d_k. It is reasonable to assume that L, possibly stemming from past observations, is far bigger than K, possibly stemming from subjective

risk perception. Typically, L can be on the order of several hundreds or even thousands, while K is around 20 or even less. Compared with Lagrangean relaxation of nonanticipativity (see, for instance, [8]), the above dual bounding scheme thus has the advantage that the Lagrangean dual lives in a space of low dimension.

Upper bounds. An upper bound to the optimal value of (15) is computed by the following heuristic that aims at finding a feasible solution to (15). The input of the heuristic consists of the x_l-parts $\tilde{x}_l$ of optimal solutions to the single-scenario problems in (19) for optimal or nearly optimal λ.

ALGORITHM 3.2.

STEP 1:

Understand $\tilde{x}_l$, $l = 1, \ldots, L$, as proposals for x and pick a "reasonable candidate" $\bar{x}$, for instance, one arising most frequently or one with minimal $\mathcal{L}_l(x_l, \theta_l, \lambda)$, or average the $\tilde{x}_l$, $l = 1, \ldots, L$, and round to integers if necessary.

STEP 2:

Check whether the following problems are feasible for $l = 1, \ldots, L$:

$$\min \left\{ g^\top \bar{x} : \begin{array}{lll} c^\top \bar{x} + q^\top y_{lk} - d_k & \leq & \mathsf{M}\theta_{lk} \\ T\bar{x} + W y_{lk} & = & z_l \\ y_{lk} \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'},\ \theta_{lk} \in \{0,1\},\ k = 1, \ldots, K & & \end{array} \right\}. \tag{20}$$

As soon as one of them fails to be feasible, $\bar{x}$ cannot be feasible for (15)*, and the heuristic stops with assigning the formal upper bound $+\infty$. Otherwise, go to Step* 3*.*

STEP 3:

Check whether the θ_{lk} found in (20) *fulfill*

$$\sum_{l=1}^{L} \pi_l \theta_{lk} \ \leq \ \bar{d}_k, \qquad k = 1, \ldots, K.$$

If yes, then a feasible solution to (15) *is found. The heuristic stops with the upper bound $g^\top \bar{x}$. Otherwise, go to Step* 4*.*

STEP 4:

Solve for each $l = 1, \ldots, L$:

$$\min \left\{ \sum_{k=1}^{K} \theta_{lk} : \begin{array}{lll} c^\top \bar{x} + q^\top y_{lk} - d_k & \leq & \mathsf{M}\theta_{lk} \\ T\bar{x} + W y_{lk} & = & z_l \\ y_{lk} \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'},\ \theta_{lk} \in \{0,1\},\ k = 1, \ldots, K & & \end{array} \right\}.$$

Go to Step 5*.*

STEP 5:

Repeat the test from Step 3 *with the θ_{lk} found in Step* 4*. If the test is positive, then the heuristic stops with the upper bound $g^\top \bar{x}$. Otherwise, the heuristic stops without a feasible solution to* (15) *and assigns the formal upper bound $+\infty$.*

The purpose of Step 4 is to "push down" the θ_{lk} in order to fulfill (18). The implementation is such that Step 4 just continues with the feasible solution found in Step 2. The impact of Step 4 is particularly striking, if in Step 2 the θ_{lk} were "poorly" selected such that the test in Step 3 fails, although $\bar{x}$ is feasible for (15), with different θ_{lk}.

Branch-and-bound scheme. The bounding procedures developed above are integrated into a branch-and-bound scheme where branching is accomplished by partitioning the set X with increasing granularity. Linear inequalities are used for this purpose to maintain the mixed-integer linear description of problems.

This results in the following algorithm. By $\mathbf{P}$ we denote a list of problems, and $\varphi_{LB}(P)$ is a lower bound for the optimal value of $P \in \mathbf{P}$. Moreover, $\bar{\varphi}$ denotes the currently best upper bound to the optimal value of (15), and $X(P)$ is the element in the partition of X belonging to P.

ALGORITHM 3.3.

STEP 1 (INITIALIZATION):

Let $\mathbf{P} := \{(15)\}$ *and* $\bar{\varphi} := +\infty$.

STEP 2 (TERMINATION):

If $\mathbf{P} = \emptyset$, *then the* $\bar{x}$ *that yielded* $\bar{\varphi} = g^\top \bar{x}$ *is optimal.*

STEP 3 (BOUNDING):

Select and delete a problem P *from* $\mathbf{P}$. *Compute a lower bound* $\varphi_{LB}(P)$ *by the bounding procedure developed above, and apply Algorithm* 3.2 *to find a feasible point* $\bar{x}$ *of* P.

STEP 4 (PRUNING):

If $\varphi_{LB}(P) = +\infty$ *(infeasibility of a subproblem in* (19)*) or* $\varphi_{LB}(P) > \bar{\varphi}$ *(inferiority of* P*), then go to Step* 2.

If $\varphi_{LB}(P) = g^\top \bar{x}$ *(optimality for* P*), then check whether* $g^\top \bar{x} < \bar{\varphi}$. *If yes, then* $\bar{\varphi} := g^\top \bar{x}$. *Go to Step* 2.

If $g^\top \bar{x} < \bar{\varphi}$, *then* $\bar{\varphi} := g^\top \bar{x}$.

STEP 5 (BRANCHING):

Create two new subproblems by partitioning the set $X(P)$. *Add these subproblems to* $\mathbf{P}$, *and go to Step* 2.

Generally speaking, the branching in Step 5 is accomplished by applying linear inequalities to maintain representation of subproblems as mixed-integer linear programs. In practice, however, these inequalities usually correspond to ranges of components of variables. For continuous variables, tolerances are used to avoid endless branching with finer and finer granularity.

4. Computations. In the following we report computational results for Algorithm 3.3 applied to test instances from power planning. The first group of instances refers to the optimal management of a dispersed generation (DG) system run by a power utility in Germany; see [16] for a detailed model description. The instances of the second group are inspired by an early stochastic program from the literature, the investment planning problem for electricity generation of [21].

4.1. DG system. The system consists of five engine-based cogeneration (CG) stations, producing power and heat simultaneously, twelve wind turbines, and one hydroelectric power plant. The CG stations include eight gas boilers, nine gas motors, and one gas turbine, and each is equipped with a thermal storage and a cooling device. While the heat is distributed locally, the electricity is fed into the global distribution network. The cost minimal operation of this system with respect to relevant

TABLE 1
Dimensions of mixed-integer linear programming equivalents.

Number of	10 scenarios	20 scenarios	30 scenarios	50 scenarios
Boolean variables	299159	596799	894439	1489719
Continuous variables	283013	564613	846213	1409413
Constraints	742648	1481568	2220488	3698328

technical constraints and fulfillment of heat and power demand can be formulated as a mixed-integer linear program, with on-off decisions for the generation units as the source of integrality. With a planning horizon of 24 hours, divided into quarter-hourly subintervals, this (still deterministic) model has about 17500 variables (9000 Boolean and 8500 continuous) and 22000 constraints.

The optimization problem is influenced by stochasticity on the production side, where the in-feed from renewable resources is not known with certainty, as well as on the consumer side, where demand of electrical and thermal energy are uncertain. The problem turns into a random mixed-integer linear problem, a specification of (1).

Assuming that the uncertainty-prone data are known for the first four hours of the planning horizon leads to a two-stage stochastic program with the decisions belonging to these first four hours as the first stage. For a more detailed description of the arising stochastic program and results on purely expectation-based and mean-risk specifications of (6), see [16, 30].

To derive a benchmark profile d in (8) we first consider $f(\hat{x}, z)$, where $\hat{x}$ denotes an optimal solution to the expectation model (5). With heuristically selected benchmark values, the $f(\hat{x}, z)$ then are clustered around these values, and the probability of each benchmark value arises as the sum of the probabilities of the members in its cluster. Further problem instances were derived by fixing the probabilities and increasing the values of d successively.

A meaningful objective function g is to count the number of start-ups over all units and time steps in the first stage. This number serves as a measure for the abrasion of the DG units. Then the dominance-constrained model minimizes abrasion of units over all generation policies incurring costs that, in a stochastic sense, do not exceed the given benchmark profile.

We report results for instances with $K = 4$ benchmark scenarios and $L = 10$ up to 50 scenarios for heat and power demand. The deterministic equivalents according to Proposition 3.1 then finally are truly large-scale, as seen in Table 1, and can hardly be handled with mixed-integer solvers such as CPLEX [9].

In Tables 2–5 computations for these equivalents with CPLEX are compared to computations made with the implementation ddsip.vSD of Algorithm 3.3 derived in section 3. Problems were solved on a Linux PC with a 3.2 GHz Pentium processor and 2 GB RAM. As a stopping criterion we used a time limit of eight hours.

In all tables the benchmark costs increase successively from instance 1 to instance 5. This means that the dominance constraints get easier to fulfill. As one would expect, this affects the needed numbers of start-ups positively. They decrease with increasing reference values, which is reported in the column "Upper Bound," where the objective value of the current best solution is displayed. The corresponding best lower bound can be found in the column "Lower Bound."

In every table we show the status of the optimization for different points in time. Usually the first two points are the times where either the decomposition method or CPLEX finds the first feasible solution. Also for the time limit of eight hours the

objective values and the best bounds are given for each solver, unless optimality was proven earlier.

For test instances with 20 or 30 scenarios CPLEX sometimes stops before reaching a first feasible solution, because the available memory is exceeded (marked by "oom."). In these cases only the lower bounds already found before the memory error occurred are displayed.

With 50 data scenarios the deterministic equivalents become so large that the available memory is not sufficient to build up the model (lp-) file used by CPLEX, preventing optimization with CPLEX for these instances. Therefore the last table reports only best values and lower bounds calculated with the decomposition method ddsip.vSD.

Our computations show that for all instances the decomposition method reaches the first feasible solution faster then CPLEX does. In most cases this is already an optimal solution. In the computations dealing with 30 and 50 scenarios, the superiority of the decomposition method over general-purpose solvers becomes particularly evident. For 30 scenarios CPLEX can't provide any feasible solution and for 50 scenarios even no lower bound, while ddsip.vSD is able to solve almost all problems.

In reaching these results, proper branching strategies in Step 5 of Algorithm 3.3 turned out to be essential. In the above computations branching priority was given to Boolean variables arising in the objective of (15). As a comparison consider Table 6 reporting computations for the 10-scenario instances with an alternative, rather standard, branching strategy. Here a first-stage variable was selected for branching for which the optimal solutions to the single-scenario problems in (19), with optimal or nearly optimal λ, violated nonanticipativity the most, with violation measured by a suitable entity reflecting dispersion. The performance gains of the first branching strategy over the second are quite remarkable.

4.2. Investment planning. The investment planning problems for electricity generation that form our second group of test instances are inspired by [21]. We consider two-stage versions of the multistage model there and add integrality requirements to the first stage. This leads to a two-stage mixed-integer linear stochastic program where, in the first stage, decisions on capacity expansions for different generation technologies under budget constraints and supply guarantee are made. We assume that these decisions reflect indivisibilities (generation units) and hence are integer-valued. The second stage concerns the minimization of production costs for electricity under the constraints that electricity demand is met and the available capacity is not exceeded.

The electricity demand is captured by a load duration curve assigning to each duration $\tau \in \mathbb{R}_+$ the minimum load to be covered over time spans adding up to

TABLE 7
Dimensions of mixed-integer linear programming equivalents.

Number of	20 scenarios	50 scenarios	100 scenarios	500 scenarios
Boolean and integer variables	404	1004	2004	10004
Continuous variables	38400	96000	192000	960000
Constraints	11622	29022	58022	290022

τ. This is where uncertainty enters, since in practice load durations are typically available only stochastically. The model uses step function approximations for load duration curves. So each data scenario is represented by a (finite) step function.

The aim of the optimization is cost minimization where costs are incurred by the expansion decisions of the first stage and the production levels of the second stage. Together with the random load durations, this leads to a random optimization problem which is a specification of (1).

The benchmarks were constructed in a similar way as in subsection 4.1. With first-stage decisions x fixed to "reasonable" values, the $f(x, z)$ were clustered around heuristically selected benchmark values, whose probabilities were obtained as probabilities of the cluster sets.

As objective function g we considered the capacity expansion of one of the different technologies, possibly one least desired for environmental reasons. The dominance-constrained stochastic program then minimizes expansion of this capacity over all expansion policies whose costs do not exceed the benchmark profile in terms of first-order stochastic dominance.

We report results for instances with $K = 3$ up to 20 benchmark scenarios and $L = 20$ up to 500 scenarios for load duration. Deterministic equivalents according to Proposition 3.1 again become pretty large-scale. Table 7 shows dimensions for $K = 20$ and the different L.

Table 8 summarizes our computations for the investment planning instances. Again, a Linux PC with a 3.2 GHz Pentium processor and 2 GB RAM was used. The time limit was set to one hour.

The first column indicates three principal problem instances marked by their optimal values. (Let us remark that all test instances were constructed in such a way that their optimal values were known in advance.) The next two columns list the numbers K of benchmark and L of data scenarios. The remaining columns list lower and upper bounds obtained when applying CPLEX [9] and our implementation ddsip.vSD of Algorithm 3.3. Time entries deviating from the limit of 1 h indicate that the instance was solved to optimality within this span.

It becomes evident that, at the investment planning instances, Algorithm 3.3 is superior to applying a general-purpose solver such as CPLEX. Although we have experimented with various time limits and parameter settings in CPLEX, such as "emphasize integer feasibility," we were unable to improve the CPLEX results for upper bounds. The instance 0/3/100 (optimal-value/K/L), for example, was solved to optimality by CPLEX after more than three hours only. For the instance 0/10/100, as another example, CPLEX did not find a feasible solution even after four days of computing time.

5. Alternative lower bounding: Increasing convex order. Let X and Y be real-valued random variables. Then X is said to be stochastically smaller than Y in increasing convex order ($\mathsf{X} \preceq_{icx} \mathsf{Y}$) iff $\mathbb{E}h(\mathsf{X}) \leq \mathbb{E}h(\mathsf{Y})$ for all nondecreasing convex functions h for which both expectations exist (cf., e.g., [24]). This gives rise to the

following counterpart model to (8):

$$\min\{g(x) \ : \ f(x,z) \preceq_{icx} \ d, \ x \in X\}. \tag{21}$$

Since $f(x,z) \preceq_1 d$ implies $f(x,z) \preceq_{icx} d$ to hold, but not vice versa, problem (21) is a relaxation to (8), thus providing an alternative means for lower bounding of (8). In what follows we address this issue theoretically and numerically. We begin with reviewing some theoretical facts about (21) that are taken from [15], where structural properties and algorithmic aspects of (21) were explored in detail.

The constraint $f(x,z) \preceq_{icx} d$ can be equivalently expressed as

$$\mathbb{E}_z[f(x,z)-\eta]_+ \ \leq \ \mathbb{E}_d[d-\eta]_+ \quad \forall \eta \in \mathbb{R}. \tag{22}$$

This paves the way for an analogous result to Proposition 2.1: Assuming (A1), (A2), and finite first moments for z and d, the constraint set of (21) defines a closed multifunction in the probability measure underlying z. Moreover, finiteness of $\mathbb{E}_z$ in (22)

provided, (22) defines a convex set if $f(.,z)$ is convex, a situation encountered in two-stage stochastic programs with linear recourse. As soon as integrality requirements on y enter problem (1), however, the convexity of $f(.,z)$ is lost in general, and it has to be expected that (21) has nonconvex constraints. Since the constraint set mapping of (21) is a closed multifunction, a stability result for (21) in the spirit of Proposition 2.5 is valid. This justifies numerical treatment of (21) for finite probability spaces, tacitly assuming that, if necessary, continuous probability distributions of z (and d) are replaced by finite discrete ones that are "sufficiently close" in terms of suitable topologies on spaces of probability measures.

If z and d follow discrete distributions with realizations $z_l,\ l = 1,\dots,L$, and $d_k,\ k = 1,\dots,K$, as well as probabilities $\pi_l,\ l = 1,\dots,L$, and $p_k,\ k = 1,\dots,K$, respectively, and $g(x) := g^\top x$ is linear, then, under (A1) and (A2), problem (21) is equivalent to the mixed-integer linear program

$$\left.\begin{array}{lll} \min\Big\{ g^\top x : & c^\top x + q^\top y_{lk} - d_k \ \le\ v_{lk} & \forall l\ \forall k \\ & Tx + W y_{lk} \ =\ z_l & \forall l\ \forall k \\ & \sum_{l=1}^{L} \pi_l v_{lk} \ \le\ \bar{d}_k & \forall k \\ & x \in X,\ y_{lk} \in \mathbb{Z}_+^{\bar{m}} \times \mathbb{R}_+^{m'},\ v_{lk} \ge 0 & \forall l\ \forall k \end{array}\right\}, \tag{23}$$

where $\bar{d}_k := \mathbb{E}_d[d - d_k]_+,\ k = 1,\dots,K$. Clearly, the optimal value to (23) is a lower bound to the optimal value to (15). Compared to (15), problem (23) looks a little simpler since continuous variables v_{lk} instead of Boolean variables θ_{lk} can be employed for integrating the stochastic order. Nevertheless, (23) remains a mixed-integer model due to the integralities in the y_{lk}. Moreover, (23) bears the same internal coupling as (15): Beside nonanticipativity, the counterparts to (18) link subproblems belonging to the individual scenarios $l \in \{1,\dots,L\}$. Computational tests in [15] have confirmed that this linkage is critical when tackling (23) with mixed-integer linear program solvers such as CPLEX. Thus it seems that, although formally simpler than (15), problem (23) does not offer a "cheap" option for its direct solution.

In [15] a decomposition algorithm for (23) was developed that resembles Algorithm 3.3: Within a branch-and-bound framework, lower bounding is achieved by ignoring nonanticipativity and subjecting the counterparts to (18) to Lagrangean relaxation. Upper bounds are obtained by a feasibility heuristic. This algorithm proves superior to the solver CPLEX.

In our numerical experiments, reported in Tables 9 and 10, we have evaluated the potential of (23) to provide lower bounds to (15) that are tighter than the lower bounds generated via Algorithm 3.3. Table 9 shows the development over time of lower bounds for instance 4 from subsection 4.1 with 20, 30, and 50 data scenarios. Here the model (21) provides preferable lower bounds in early stages of the iteration. However, just the opposite occurs in Table 10 for instance 2 where Algorithm 3.3 yields the preferable lower bounds throughout the iteration.

Acknowledgments. We thank Christoph Helmberg (Technical University of Chemnitz) for giving us access to the implementation of his spectral bundle method. Moreover, we are grateful to Uwe Gotzes (University of Duisburg-Essen) for fruitful discussions and his support in running computational tests. Last but not least, we express our thanks to two anonymous referees and the associate editor for their suggestions improving earlier versions of this paper.

THE OPERATOR Ψ FOR THE CHROMATIC NUMBER OF A GRAPH*

NEBOJŠA GVOZDENOVIĆ† AND MONIQUE LAURENT†

Abstract. We investigate hierarchies of semidefinite approximations for the chromatic number $\chi(G)$ of a graph G. We introduce an operator Ψ mapping any graph parameter $\beta(G)$, nested between the stability number $\alpha(G)$ and $\chi(\overline{G})$, to a new graph parameter $\Psi_\beta(G)$, nested between $\alpha(\overline{G})$ and $\chi(G)$; $\Psi_\beta(G)$ is polynomial time computable if $\beta(G)$ is. As an application, there is no polynomial time computable graph parameter nested between the fractional chromatic number $\chi^*(\cdot)$ and $\chi(\cdot)$ unless P = NP. Moreover, based on the Motzkin–Straus formulation for $\alpha(G)$, we give (quadratically constrained) quadratic and copositive programming formulations for $\chi(G)$. Under some mild assumptions, $n/\beta(G) \leq \Psi_\beta(G)$, but, while $n/\beta(G)$ remains below $\chi^*(G)$, $\Psi_\beta(G)$ can reach $\chi(G)$ (e.g., for $\beta(\cdot) = \alpha(\cdot)$). We also define new polynomial time computable lower bounds for $\chi(G)$, improving the classic Lovász theta number (and its strengthenings obtained by adding nonnegativity and triangle inequalities); experimental results on Hamming graphs, Kneser graphs, and DIMACS benchmark graphs will be given in the follow-up paper [N. Gvozdenović and M. Laurent, *SIAM J. Optim.*, 19 (2008), pp. 592–615].

1. Introduction.

The chromatic number $\chi(G)$ of a graph $G = (V, E)$ is the minimum number of colors needed to color the nodes of G in such a way that adjacent nodes receive distinct colors. Computing $\chi(G)$ is an NP-hard problem [11], and it is also hard to approximate $\chi(G)$ within $|V(G)|^{1/14-\epsilon}$ for any $\epsilon > 0$ [1]. An obvious lower bound for $\chi(G)$ is the clique number $\omega(G)$, defined as the maximum size of a clique (i.e., a set of pairwise adjacent nodes) in G; computing $\omega(G)$ is also hard [11] as well as approximating $\omega(G)$ within $|V(G)|^{1/6-\epsilon}$ for any $\epsilon > 0$ [1]. A well-known stronger lower bound for $\chi(G)$ is $\overline{\vartheta}(G) := \vartheta\left(\overline{G}\right)$, the theta number of the complementary graph, introduced by Lovász [23] (see (2.3)). The theta number satisfies the "sandwich inequality":

$$\omega(G) \leq \overline{\vartheta}(G) \leq \chi(G),$$

and it can be computed to any arbitrary precision in polynomial time since it can be formulated via a semidefinite program. It can also be used for approximately coloring the graph (see [5, 8, 17]). Intensive research has been done for strengthening the bound $\overline{\vartheta}(G)$ towards $\omega(G)$ or, equivalently, $\vartheta(G)$ towards the stability number $\alpha(G)$; see, e.g., [6, 19, 20, 21, 24, 26, 30, 32, 34]. Here $\alpha(G) = \omega(\overline{G})$, the maximum size of a stable set (i.e., a set of pairwise nonadjacent nodes) in G. In particular, hierarchies of semidefinite (or linear) bounds were constructed that find $\alpha(G)$ in $\alpha(G)$ steps [19, 20, 24, 34]. As $\chi(G)$ can be formulated via a 0/1 linear program (see, e.g.,

†Centrum voor Wiskunde en Informatica, Kruislaan 413, 1098 SJ Amsterdam, The Netherlands (N.Gvozdenovic@cwi.nl, M.Laurent@cwi.nl).

[7]), the lift-and-project methods of [19, 24, 34] can in principle be applied to derive hierarchies of semidefinite approximations finding $\chi(G)$ in finitely many steps. To the best of our knowledge such hierarchies have not been investigated in detail so far.

In this paper we propose a systematic investigation of semidefinite approximations for $\chi(G)$. One of our main contributions is a simple construction permitting one to derive from any graph parameter $\beta(G)$ nested between $\alpha(G)$ and $\overline{\chi}(G)$ a new graph parameter $\Psi_\beta(G)$ nested between $\omega(G)$ and $\chi(G)$. For this, given an integer $t \geq 0$, let $K_t \Box G$ denote the Cartesian product of the two graphs G and K_t, with node set

$$V(K_t \Box G) := V(K_t) \times V(G) = \bigcup_{p=1}^{t} V_p, \quad \text{where } V_p := \{pi \mid i \in V(G)\}, \tag{1.1}$$

and having an edge (pi, qj) if $(p \neq q$ and $i = j)$ or if $(p = q$ and $ij \in E(G))$. Chvátal [4] observed the following useful reduction of the chromatic number to the stability number:

$$\chi(G) \leq t \Longleftrightarrow \alpha(K_t \Box G) = |V(G)|. \tag{1.2}$$

(Reverse reductions, from the stability number to the chromatic number, can be found in Poljak [31] and in Schrijver [33].) Given a graph parameter $\beta(\cdot)$ nested between $\alpha(\cdot)$ and $\overline{\chi}(\cdot)$, relation (1.2) motivates the introduction of the new graph parameter $\Psi_\beta(\cdot)$, defining $\Psi_\beta(G)$ as the smallest integer $t \geq 0$ for which $\beta(K_t \Box G) = |V(G)|$. Among other properties, $\Psi_\alpha(G) = \chi(G)$, $\Psi_{\overline{\chi}}(G) = \Psi_{\overline{\chi^*}}(G) = \omega(G)$, $\Psi_\vartheta(G) = \lceil \overline{\vartheta}(G) \rceil$, and $\Psi_{\vartheta'}(G) = \lceil \overline{\vartheta^+}(G) \rceil$. Here χ^* is the fractional chromatic number, and ϑ' and ϑ^+ are variations of ϑ obtained by adding certain nonnegativity conditions; see section 2.1. Moreover, the operator Ψ is monotone nonincreasing and, if $\beta(G)$ is polynomial time computable (resp., given by a semidefinite program), then the same holds for $\Psi_\beta(G)$. A somewhat surprising application is that there does *not* exist a polynomial time computable graph parameter nested between the fractional chromatic number and the chromatic number unless P = NP (see Theorem 2.6). As another application we can give (quadratically constrained) quadratic and copositive programming formulations for $\chi(G)$ based on the Motzkin–Straus formulation for $\alpha(G)$ (see section 2.5).

The operator Ψ permits one to transform any hierarchy of upper bounds for $\alpha(G)$ into a hierarchy of lower bounds for $\chi(G)$. In this paper we study in particular hierarchies of lower bounds for $\chi(G)$ related to the Lasserre hierarchy $\mathrm{las}^{(r)}(G)$ ($r \in \mathbb{N}$) for $\alpha(G)$ [19], which finds $\alpha(G)$ at order $r = \alpha(G)$ and refines several other known hierarchies for $\alpha(G)$. More precisely, we consider two hierarchies $\psi^{(r)}(G)$ and $\Psi_{\mathrm{las}^{(r)}}(G)$ of lower bounds for the chromatic number $\chi(G)$, which satisfy $\psi^{(1)}(G) = \overline{\vartheta}(G)$ and $\psi^{(2)}(G) \geq \overline{\vartheta^{+\triangle}}(G)$ (Meurdesoif strengthening—see section 2.1), and

$$\frac{|V(G)|}{\mathrm{las}^{(r)}(G)} \leq \psi^{(r)}(G) \leq \Psi_{\mathrm{las}^{(r)}}(G) \leq \chi(G).$$

The parameter $\psi^{(r)}(G)$ has the same computational cost as $\mathrm{las}^{(r)}(G)$, but it cannot go beyond the fractional chromatic number; in fact, $\psi^{(r)}(G) = \chi^*(G)$ for $r \geq \alpha(G)$. The parameter $\Psi_{\mathrm{las}^{(r)}}(G)$ has a higher computational cost than $\mathrm{las}^{(r)}(G)$ (one has to evaluate $\mathrm{las}^{(r)}(K_t \Box G)$ for $O(\log n)$ queries on $t \leq n$), but it finds $\chi(G)$ at step $r = n$. Dukanovic and Rendl [9] introduced recently another hierarchy for $\chi(G)$, which is related to the hierarchy of de Klerk and Pasechnik [6] for $\alpha(G)$, both being based on

copositive programming. The hierarchy of Dukanovic and Rendl remains, however, bounded by the fractional chromatic number; see section 3.5 for details.

Although polynomial time computable for any fixed r, the parameters $\psi^{(r)}(G)$ and $\Psi_{\mathrm{las}^{(r)}}(G)$ are yet too costly to compute for large values of n already for order $r = 2$. We propose some variations $\psi(G)$ and $\Psi_\ell(G)$ of the order 2 bounds, which are at least as good as $\overline{\vartheta^+}(G)$. As will be shown in the follow-up paper [14], for vertex-transitive graphs, the computation of $\psi(G)$ involves a semidefinite program with two matrices of sizes $n+1$ and n, while the computation of $\Psi_\ell(G)$ can be reduced to $O(\log n)$ semidefinite programs with matrices of sizes $2n+1, 2n, n$, and n; these formulations are obtained by exploiting symmetries in the structure of the semidefinite programs and symmetries arising from the permutation group $\mathrm{Sym}(t)$ acting on the complete graph K_t.

More details about the results of this paper can also be found in [12].

Contents of the paper. In section 2 we present the operator Ψ and its main properties, we discuss various ways for computing $\Psi_\beta(G)$, and we give (quadratically constrained) quadratic and copositive programming formulations for $\chi(G)$. In section 3 we investigate two hierarchies of lower bounds for $\chi(G)$ related to the hierarchy of Lasserre for $\alpha(G)$ and converging, respectively, to $\chi^*(G)$ and $\chi(G)$. This leads to two bounds $\psi(G)$ and $\Psi_\ell(G)$ formulated via semidefinite programs involving matrices of size $O(n)$. Finally we explore the link between our bounds and the copositive programming-based hierarchies of de Klerk and Pasechnik [6] for $\alpha(G)$ and of Dukanovic and Rendl [9] for $\chi(G)$.

Notation. Given a graph $G = (V, E)$, $\overline{G}$ denotes its complementary graph whose edges are the pairs $uv \notin E(G)$ $(u, v \in V(G),\ u \neq v)$. Throughout we set $V := V(G)$, $n = |V|$, and to avoid trivial technicalities we assume that $G \neq K_n$ and $G \neq \overline{K_n}$, where K_n denotes the complete graph on n nodes. For two graphs G and G', their Cartesian product $G \square G'$ has node set $V(G) \times V(G')$, with two nodes $uu', vv' \in V(G) \times V(G')$ being adjacent in $G \square G'$ if and only if ($u = v$ and $u'v' \in E(G')$) or ($uv \in E(G)$ and $u' = v'$). For an integer $t \geq 1$, we sometimes set $G_t = K_t \square G$ as a shorthand notation for the Cartesian product of G and K_t, whose node set is as in (1.1). Given a graph parameter $\beta(\cdot)$, $\overline{\beta}(\cdot)$ is the graph parameter defined by $\overline{\beta}(G) := \beta(\overline{G})$ for any graph G.

Throughout, the letters $\mathbf{I}, \mathbf{J}$, and e denote, respectively, the identity matrix, the all-ones matrix, and the all-ones vector (of the suitable size); $\mathbb{N}$ is the set of nonnegative integers. For $n \times n$ matrices A, B, $\mathrm{Tr}(A) = \sum_{i=1}^n A_{ii}$ and $\langle A, B \rangle = \mathrm{Tr}(A^T B) = \sum_{i,j=1}^n A_{ij} B_{ij}$. Moreover, the notation $A \succeq 0$ means that A is a symmetric positive semidefinite matrix.

Given a finite set V, $\mathcal{P}(V)$ denotes the collection of all subsets of V. Given an integer r, set $\mathcal{P}_r(V) := \{I \in \mathcal{P}(V) \mid |I| \leq r\}$. $\mathcal{P}_r(V)$ contains the empty subset of V which we will denote as $\mathbf{0}$; thus, for instance, $\mathcal{P}_1(V) = \{\mathbf{0}, \{i\}\ (i \in V)\}$. We sometimes identify $\mathcal{P}_1(V) \setminus \{\mathbf{0}\}$ with V; i.e., we write $\{i\}$ as i and $\{i, j\}$ as ij, and, given a vector $x \in \mathbb{R}^{\mathcal{P}(V)}$ we also set $x_i := x_{\{i\}}$, $x_{ij} := x_{\{i,j\}}$, $x_{ijk} := x_{\{i,j,k\}}$, etc.

Let V be a finite set, and let $\mathcal{G}$ be a subgroup of $\mathrm{Sym}(V)$, the group of permutations of V, also denoted as $\mathrm{Sym}(n)$ if $|V| = n$. $\mathcal{G}$ acts on $\mathcal{P}(V)$ by letting $\sigma(I) := \{\sigma(i) \mid i \in I\}$ for $I \subseteq V$, $\sigma \in \mathcal{G}$. Moreover, $\mathcal{G}$ acts on vectors and matrices indexed by V (and thus on vectors and matrices indexed by $\mathcal{P}(V)$). Namely, for $\sigma \in \mathcal{G}$, $x \in \mathbb{R}^V$, and $M \in \mathbb{R}^{V \times V}$, set $\sigma(x) := (x_{\sigma(i)})_{i \in V}$ and $\sigma(M) := (M_{\sigma(i),\sigma(j)})_{i,j \in V}$. One says that M is invariant under the action of $\mathcal{G}$ if $\sigma(M) = M$ for all $\sigma \in \mathcal{G}$: The matrix $\frac{1}{|\mathcal{G}|!} \sum_{\sigma \in \mathcal{G}} \sigma(M)$, the "symmetrization" of M obtained by applying the Reynolds

operator, is invariant under the action of $\mathcal{G}$. The same holds analogously for vectors. A semidefinite program is said to be invariant under action of $\mathcal{G}$ if, for any feasible matrix X and any $\sigma \in \mathcal{G}$, the matrix $\sigma(X)$ is again feasible with the same objective value; then the optimum value of the program remains unchanged if we restrict to invariant feasible solutions and, in particular, there is an invariant optimal solution.

The automorphism group $\mathrm{Aut}(G)$ of a graph $G = (V, E)$ consists of all $\sigma \in \mathrm{Sym}(V)$ preserving the set of edges. G is said to be vertex-transitive when, given any two nodes $i, j \in V$, there exists $\sigma \in \mathrm{Aut}(G)$, with $\sigma(i) = j$.

2. New parameters and formulations.

2.1. Some known graph parameters. We review here some classic bounds for the stability number $\alpha(G)$ and the chromatic number $\chi(G)$ of a graph $G = (V, E)$. We give some equivalent formulations for the bounds. Some work may be required to derive some of them; for details see, e.g., [22, 33].

• The *fractional clique cover number*, also known as the *fractional chromatic number of* $\overline{G}$:

$$\begin{array}{rlll} \overline{\chi^*}(G) := \max & e^T x & = \min & e^T \lambda \\ \text{s.t.} & \sum_{i \in C} x_i \le 1 \ (C \text{ clique}) & \text{s.t.} & \sum_{C \text{ clique}} \lambda_C \chi^C = e, \\ & x \in \mathbb{R}^V_+, & & \lambda \ge 0. \end{array} \tag{2.1}$$

It is well known (and easy to verify) that $\alpha(G) \le \overline{\chi^*}(G) \le \overline{\chi}(G)$, and

$$\omega(G)\overline{\chi^*}(G) \ge |V(G)|, \quad \text{with equality when } G \text{ is vertex-transitive.} \tag{2.2}$$

It is hard to compute the fractional chromatic number, and, for some $\epsilon > 0$, there is no polynomial time algorithm to approximate $\chi^*(G)$ within $|V(G)|^\epsilon$ unless P = NP [25].

• *Lovász's theta number* (introduced in [23]):

$$\begin{array}{rlll} \vartheta(G) := \max & \langle \mathbf{J}, X \rangle & = \min & t \\ \text{s.t.} & \mathrm{Tr}(X) = 1 & \text{s.t.} & U_{ii} = 1 \ (i \in V), \\ & X_{ij} = 0 \ \ (ij \in E(G)), & & U_{ij} = -\dfrac{1}{t-1} \ (ij \in E(\overline{G})), \\ & X \succeq 0, & & U \succeq 0, \ t \ge 2, \end{array} \tag{2.3}$$

where X and U are symmetric matrices indexed by V. The minimization program in the above definition of $\vartheta(G)$ is used, e.g., in [17] for constructing a vector k-coloring. We will also use the following equivalent formulation:

$$\begin{array}{rll} \vartheta(G) = \max & \sum_{i \in V} X_{ii} & \\ \text{s.t.} & X_{\mathbf{00}} = 1, \ X_{ij} = 0 \ (ij \in E), & \\ & X_{ii} = X_{\mathbf{0}i} \ (i \in V), \ X \succeq 0, & \end{array} \tag{2.4}$$

where the matrix variable X is indexed by the set $\mathcal{P}_1(V)$. Lovász [23] proved the following analogue of (2.2) for the pair $(\vartheta, \overline{\vartheta})$:

$$\vartheta(G)\overline{\vartheta}(G) \ge |V(G)|, \quad \text{with equality when } G \text{ is vertex-transitive.} \tag{2.5}$$

• The *strengthening of the theta number* of [26, 32]:

(2.6)
$$\begin{array}{rlll} \vartheta'(G) := \max & \langle \mathbf{J}, X\rangle & = \min & t \\ \text{s.t.} & \mathrm{Tr}(X) = 1 & \text{s.t.} & U_{ii} = 1 \ (i \in V), \\ & X_{ij} = 0 \ \ (ij \in E(G)), & & U_{ij} \le -\dfrac{1}{t-1} \ \ \left(ij \in E\left(\overline{G}\right)\right), \\ & X \succeq 0, \ X \ge 0, & & U \succeq 0, \ t \ge 2. \end{array}$$

• *Szegedy's number* [36]:

(2.7)
$$\begin{array}{rlll} \vartheta^+(G) := \max & \langle \mathbf{J}, X\rangle & = \min & t \\ \text{s.t.} & \mathrm{Tr}(X) = 1 & \text{s.t.} & U_{ii} = 1 \ (i \in V), \\ & X_{ij} \le 0 \ \ (ij \in E(G)), & & U_{ij} = -\dfrac{1}{t-1} \ \ \left(ij \in E\left(\overline{G}\right)\right), \\ & X \succeq 0, & & U_{ij} \ge -\dfrac{1}{t-1} \ \ (ij \in E(G)), \\ & & & U \succeq 0, \ t \ge 2. \end{array}$$

Szegedy [36] showed that the analogue of (2.2) and (2.5) also holds for the pair $(\vartheta', \overline{\vartheta^+})$:

$$\vartheta'(G)\overline{\vartheta^+}(G) \ge |V(G)|, \quad \text{with equality when } G \text{ is vertex-transitive.} \tag{2.8}$$

Thus one may see the pairs (α, χ^*), $(\vartheta, \overline{\vartheta})$, and $(\vartheta', \overline{\vartheta^+})$ as "reciprocal" pairs of graph parameters. We will see later in this paper (see Theorem 3.1(e)) that they are in fact part of a more general hierarchy of reciprocal pairs.

• Meurdesoif [27] defines *the bound* $\vartheta^{+\triangle}(G)$ obtained by adding the "triangle inequalities" $U_{ij} + U_{jk} - U_{ik} \le 1$ (for $ij, jk \in E$) to the minimization program defining $\vartheta^+(G)$ in (2.7).

The above parameters satisfy

$$\alpha(G) \le \vartheta'(G) \le \vartheta(G) \le \vartheta^+(G) \le \vartheta^{+\triangle}(G) \le \overline{\chi^*}(G) \le \overline{\chi}(G).$$

The inequality $\vartheta^{+\triangle}(G) \le \overline{\chi^*}(G)$ will follow from Theorem 3.1(c) and (d), and the other inequalities follow directly by using the definitions.

2.2. The operator Ψ. By using relation (1.2), we see that the chromatic number of a graph G can be defined as the optimum solution of the following program:

$$\chi(G) = \min_{t \in \mathbb{N}} \ t \ \text{ s.t. } \alpha(K_t \square G) = |V(G)|. \tag{2.9}$$

This fact motivates the following definition.

DEFINITION 2.1. *Given a graph parameter $\beta(\cdot)$ satisfying*

$$\min\left(\alpha(\cdot), \frac{|V(\cdot)|}{\omega(\cdot)}\right) \le \beta(\cdot) \le \overline{\chi}(\cdot), \tag{2.10}$$

define the graph parameter $\Psi_\beta(\cdot)$ by

$$\Psi_\beta(G) := \min_{t \in \mathbb{N}} \ t \ \ \textit{s.t. } \beta(K_t \square G) = |V(G)|. \tag{2.11}$$

Note added in proof. The operator Ψ applies in fact to the larger range of graph parameters $\beta(\cdot)$ satisfying $\frac{|V(\cdot)|}{\chi(\cdot)} \le \beta(\cdot) \le \bar{\chi}(\cdot)$, thus including graph parameters satisfying relation (2.10). See [12] for the details.

LEMMA 2.2.

(a) *The graph parameter* $\Psi_\beta(G)$ *is well defined if* $\beta(\cdot)$ *satisfies* (2.10).

(b) *The operator* Ψ *is monotone nonincreasing; that is,* $\Psi_{\beta_2}(\cdot) \le \Psi_{\beta_1}(\cdot)$ *if* $\beta_1(\cdot)$ *and* $\beta_2(.)$ *satisfy* (2.10) *and* $\beta_1(\cdot) \le \beta_2(\cdot)$.

(c) $\Psi_\alpha(G) = \chi(G)$.

(d) $\Psi_\beta(G) = \omega(G)$ *for* $\beta(\cdot) := \frac{|V(\cdot)|}{\omega(\cdot)}$.

(e) $\Psi_{\bar{\chi}}(G) = \omega(G)$.

(f) $\Psi_\beta(G) = \chi(G)$ *for* $\beta(\cdot) := \min(\alpha(\cdot), \frac{|V(\cdot)|}{\omega(\cdot)})$.

(g) *If* $\beta(\cdot)$ *satisfies* (2.10), *then*

$$\omega(\cdot) \le \Psi_\beta(\cdot) \le \chi(\cdot). \tag{2.12}$$

Proof. (a) Assume that $\beta(\cdot)$ satisfies (2.10), and let $1 \le t \le n := |V(G)|$. As $\omega(K_t \Box G) = \max(t, \omega(G))$, we have $\frac{|V(K_t \Box G)|}{\omega(K_t \Box G)} \ge t$; together with $\alpha(K_t \Box G) \ge t$, this implies that $\beta(K_t \Box G) \ge t$. On the other hand, $\beta(K_t \Box G) \le \overline{\chi}(K_t \Box G) \le n$. Therefore, $\beta(K_n \Box G) = n$, thus showing that $\Psi_\beta(G)$ is well-defined.

(b) If $\beta_1(\cdot) \le \beta_2(\cdot)$ satisfies (2.10), then $\beta_1(K_t \Box G) = n$ implies that $\beta_2(K_t \Box G) = n$, which gives $\Psi_{\beta_2}(G) \le \Psi_{\beta_1}(G)$.

(c) The identity $\Psi_\alpha(G) = \chi(G)$ follows directly from (2.9).

(d) For $\beta(\cdot) := \frac{|V(\cdot)|}{\omega(\cdot)}$, the identity $\Psi_\beta(G) = \omega(G)$ follows from the fact that $\omega(K_t \Box G) = \max(t, \omega(G))$.

(e) We verify that $\Psi_{\bar{\chi}}(G) = \omega(G)$. As $\overline{\chi}(\cdot) \ge \frac{|V(\cdot)|}{\omega(\cdot)}$, we deduce by using (b) and (d) that $\Psi_{\overline{\chi}}(G) \le \Psi_{|V|/\omega}(G) = \omega(G)$. To show the reverse inequality, consider a clique C in G of size $\omega(G)$, and let C_t be the subset of $V(K_t \Box G)$ consisting of all of the copies of the nodes in C. Thus C_t is covered by t cliques of $K_t \Box G$. As the remaining nodes of $K_t \Box G$ can be covered by $n - |C|$ cliques, we have $\overline{\chi}(K_t \Box G) \le t + n - |C|$. Therefore $\overline{\chi}(K_t \Box G) = n$ implies that $t \ge |C| = \omega(G)$, which shows that $\Psi_{\bar{\chi}}(G) \ge \omega(G)$.

(f) Consider now the parameter $\beta(\cdot) := \min(\alpha(\cdot), \frac{|V(\cdot)|}{\omega(\cdot)})$. As $\beta(\cdot) \le \alpha(\cdot)$, we deduce by using (b) that $\Psi_\beta(G) \ge \Psi_\alpha(G) = \chi(G)$, and equality holds since one can easily verify that $\beta(K_t \Box G) = n$ for $t := \chi(G)$.

(g) Relation (2.12) now follows directly by using again (b). □

COROLLARY 2.3. *If* $\beta(\cdot)$ *is a graph parameter satisfying* $\frac{|V(\cdot)|}{\omega(\cdot)} \le \beta(\cdot) \le \bar{\chi}(\cdot)$, *then* $\Psi_\beta = \omega$. *In particular,* $\Psi_{\overline{\chi^*}} = \omega$.

Proof. The proof follows directly from Lemma 2.2(b), (d), and (e) and (2.2). □

Therefore, the operator Ψ takes a graph parameter $\beta(G)$ (nested, e.g., between $\alpha(G)$ and $\overline{\chi}(G)$) and produces the integer lower bound $\Psi_\beta(G)$ (nested between $\omega(G)$ and $\chi(G)$) for the chromatic number $\chi(G)$; Figure 2.1 illustrates how the operator Ψ acts on various parameters. As $\alpha(G)\chi^*(G) \ge |V(G)|$,

$$\beta(G) \ge \alpha(G) \Longrightarrow \chi(G) \ge \chi^*(G) \ge \frac{|V(G)|}{\beta(G)}.$$

The next lemma shows that, under the mild assumption (2.13), $\Psi_\beta(G)$ is at least as good as the obvious lower bound $|V(G)|/\beta(G)$ for $\chi(G)$. However, $\Psi_\beta(G)$ may be equal to $\chi(G)$, while $\frac{|V(G)|}{\beta(G)}$ always remains below the fractional chromatic number $\chi^*(G)$. One can easily verify that condition (2.13) holds for the graph parameters

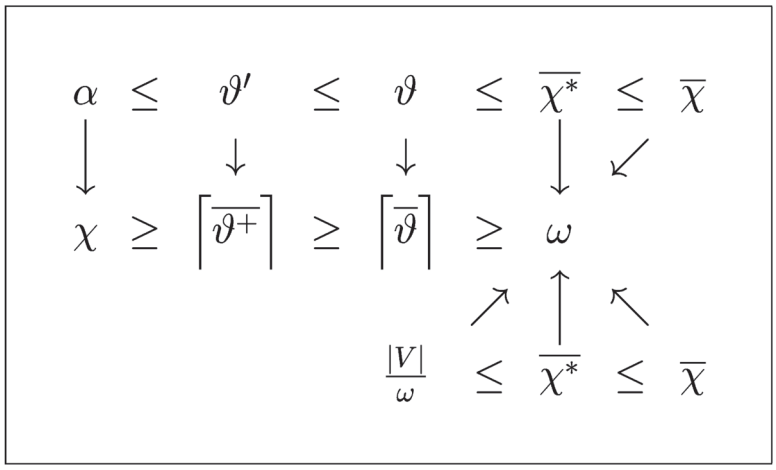

FIG. 2.1. *Converting graph parameters by the operator* Ψ.

considered in this paper, e.g., for $\beta(\cdot) = \alpha(\cdot)$, $\chi(\cdot)$, $\chi^*(\cdot)$, $\vartheta(\cdot)$, $\vartheta'(\cdot)$ and the parameter $\mathrm{las}^{(r)}(\cdot)$ defined later in (3.1) (see [12] for details).

LEMMA 2.4. *Assume that the graph parameter* $\beta(\cdot)$ *satisfies* $\alpha(\cdot) \le \beta(\cdot) \le \overline{\chi}(\cdot)$ *and*

$$\beta(K_t \Box G) \le t\beta(G) \quad \textit{for all } t \in \mathbb{N}. \tag{2.13}$$

Then $\Psi_\beta(G) \ge \frac{|V(G)|}{\beta(G)}$.

Proof. If $\beta(K_t \Box G) = |V(G)|$, then $|V(G)| \le t\beta(G)$, i.e., $t \ge \frac{|V(G)|}{\beta(G)}$. □

Remark 2.5. If $\beta(\cdot) \in [\alpha(\cdot), \overline{\chi}(\cdot)]$, then $\Psi_\beta(G) - \frac{|V(G)|}{\beta(G)} \le \chi(G) - \frac{|V(G)|}{\overline{\chi}(G)}$, with equality, e.g., when G is a perfect graph (since then $\alpha(G) = \overline{\chi}(G) = \beta(G)$ and $\omega(G) = \chi(G) = \Psi_\beta(G)$). Hence the gap $\Psi_\beta(G) - \frac{|V(G)|}{\beta(G)}$ can be made arbitrarily large. For instance, this gap is equal to $n - \frac{2n}{n+1} = n\frac{n-1}{n+1}$ when G is the disjoint union of a clique of size n and n isolated points.

We will investigate in the next section how the operator Ψ applies to the theta number $\vartheta(\cdot)$ and its strengthening $\vartheta'(\cdot)$. We now present an easy but quite surprising consequence of Lemma 2.2 concerning the complexity of graph parameters nested between the fractional chromatic and chromatic numbers or, more generally, in the interval $[|V(\cdot)|/\omega(\cdot), \overline{\chi}(\cdot)]$. The key observation is that the operator Ψ maps the whole interval $[|V(\cdot)|/\omega(\cdot), \overline{\chi}(\cdot)]$ to a single graph parameter (namely, the clique number $\omega(\cdot)$), which is hard to compute.

THEOREM 2.6. *If* $\beta(\cdot)$ *is a graph parameter satisfying* $\frac{|V(\cdot)|}{\omega(\cdot)} \le \beta(\cdot) \le \overline{\chi}(\cdot)$, *then there is no algorithm permitting one to compute* $\beta(G)$ *in time polynomial in* $|V(G)|$ *unless* $P = NP$. *As* $\frac{|V(\cdot)|}{\omega(\cdot)} \le \overline{\chi^*}(\cdot) \le \overline{\chi}(\cdot)$, *the same conclusion holds if* $\overline{\chi^*}(\cdot) \le \beta(\cdot) \le \overline{\chi}(\cdot)$.

Proof. By applying Lemma 2.2, we find that $\Psi_\beta(\cdot) = \omega(\cdot)$. Suppose that one can compute $\beta(G)$ in time $f(n)$, where f is a polynomial in $n = |V(G)|$. Then one can compute $\Psi_\beta(G) = \omega(G)$ in time $\sum_{l=1}^{n} f(ln)$, thus polynomial in n. As computing the clique number is an NP-hard problem [11], this implies that P = NP. □

Let us mention a few graph parameters that are known to lie within the "hard" interval $[\chi^*, \chi]$. Hence none of them can be computed in polynomial time unless

P = NP; such a result was known already, e.g., for the circular chromatic number $\chi_c(G)$ [3].

The *circular graph chromatic number* (or *star chromatic number*) $\chi_c(G)$, introduced by Vince [37] and further studied, e.g., in [3, 39], is defined as follows. Given $r \in \mathbb{R}$, $r \geq 2$, a function $f : V(G) \to [0, r)$ is said to be a r-coloring if $1 \leq |f(u)-f(v)| \leq r-1$ for all edges $uv \in E(G)$. Then $\chi_c(G)$ is defined as the infimum of all r for which G has a r-coloring. The following hold: $\chi(G) - 1 < \chi_c(G) \leq \chi(G)$ and $\chi^*(G) \leq \chi_c(G) \leq \chi(G)$ (see, e.g., [39]).

Another graph parameter lying in the hard interval $[\chi^*, \chi]$ is the *local chromatic number* $\chi_{\mathrm{loc}}(G)$, introduced in [10] as the minimum over all proper colorings of G of the largest number of colors used to color the neighborhood $N_G(v) = \{w \in V(G) \mid vw \in E(G)\}$ of any vertex $v \in V(G)$. Obviously, $\chi_{\mathrm{loc}}(G) \leq \chi(G)$ (the gap between the two parameters can in fact be arbitrarily large [10]), and Körner, Pilotto, and Simonyi [18] show that $\chi^*(G) \leq \chi_{\mathrm{loc}}(G)$.

The *independence ratio* of a graph G is $i(G) := \frac{\alpha(G)}{|V(G)|}$, and its *Hall ratio* is $\rho(G) := \max_{H \subseteq G} \frac{|V(H)|}{\alpha(H)}$, where the maximum is taken over all subgraphs of G. For an integer $k \geq 1$, let $G^{\Box k}$ denote the graph obtained by taking the Cartesian product of k copies of G. Then the *ultimate independence ratio* $I(G)$ and the *ultimate Hall ratio* $h_\Box(G)$ are defined, respectively, as $I(G) := \lim_{k\to\infty} i(G^{\Box k})$ and $h_\Box(G) := \lim_{k\to\infty} \rho(G^{\Box k})$. These graph parameters are studied, e.g., in [15, 16, 35]. In particular, the following relations with fractional and circular chromatic numbers are shown there:

$$\chi^*(G) \leq \frac{1}{I(G)} = h_\Box(G) \leq \chi_c(G) \leq \chi(G)$$

(see [39] for the inequality $1 \leq I(G)\chi_c(G)$).

2.3. Action of the operator Ψ on the theta number. The next theorem shows that the operator Ψ maps the theta number $\vartheta(\cdot)$ to $\lceil \overline{\vartheta}(\cdot) \rceil$ and its strengthening $\vartheta'(\cdot)$ to $\lceil \overline{\vartheta^+}(\cdot) \rceil$. De Klerk, Pasechnik, and Warners [5] consider a graph parameter closely related to Ψ_ϑ for which they can also show that it coincides with $\lceil \overline{\vartheta}(\cdot) \rceil$.

THEOREM 2.7. *For any graph G the following hold:*

(i) $\Psi_\vartheta(G) = \lceil \overline{\vartheta}(G) \rceil$,

(ii) $\Psi_{\vartheta'}(G) = \lceil \overline{\vartheta^+}(G) \rceil$.

We first state two lemmas that we need for the proof of Theorem 2.7.

LEMMA 2.8. *Let X be a $t \times t$ block matrix, having an $n \times n$ matrix A as its diagonal blocks and an $n \times n$ matrix B as nondiagonal blocks, i.e.,*

$$X = \underbrace{\begin{pmatrix} A & B & \dots & B \\ B & A & \dots & B \\ \vdots & \vdots & \ddots & \vdots \\ B & B & \dots & A \end{pmatrix}}_{t \text{ blocks}}. \tag{2.14}$$

Then $X \succeq 0 \iff A - B \succeq 0$ and $A + (t-1)B \succeq 0$.

Proof. We define a $t \times t$ block matrix U_t having the same block structure as the matrix X. For $p, q = 1, \dots, t$, let U_t^{pq} denote the (p, q)th block of U_t, defined by

$$U_t^{pq} := \begin{cases} \frac{1}{\sqrt{t}}\mathbf{I} & \text{if } p = 1 \text{ or } q = 1, \\ \left(\frac{1}{\sqrt{t}+t} - 1\right)\mathbf{I} & \text{if } p = q \geq 2, \\ \frac{1}{\sqrt{t}+t}\mathbf{I} & \text{otherwise.} \end{cases} \tag{2.15}$$

Here $\mathbf{I}$ stands for the identity matrix of order n. Notice that U_t is symmetric and orthogonal, i.e., $U_t(U_t)^T = \mathbf{I}$. Let $Y := (U_t)^T X U_t$. Then $Y \succeq 0$ if and only if $X \succeq 0$, and a simple calculation gives

$$Y = \begin{bmatrix} A+(t-1)B & 0 & \dots & 0 \\ 0 & A-B & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & A-B \end{bmatrix}, \tag{2.16}$$

which shows the lemma. □

LEMMA 2.9. *For a positive semidefinite $n \times n$ matrix X, $n\mathrm{Tr}(X) \geq \langle \mathbf{J}, X \rangle$, with equality if and only if $X = c\mathbf{J}$ for some nonnegative scalar c.*

Proof. As $X \succeq 0$, its entries satisfy $X_{ii} + X_{jj} \geq 2X_{ij}$ for all $i, j \in \{1, \dots, n\}$. Thus, $n \sum_{i=1}^n X_{ii} \geq \sum_{i,j=1}^n X_{ij}$. Equality holds if and only if $X_{ii} + X_{jj} = 2X_{ij}$ for all i, j, which gives $X_{ii} = X_{jj} = X_{ij}$ for all i, j. □

Proof of Theorem 2.7. (i) As G has at least one edge, $\vartheta(G) < n$ and thus $\Psi_\vartheta(G) \geq 2$. Let (t, X) be a feasible solution for the program defining $\Psi_\vartheta(G)$; that is,

$$X \succeq 0,\ X_{uv} = 0\ (uv \in E(K_t \square G)),\ \mathrm{Tr}(X) = 1,\ \langle \mathbf{J}, X \rangle = n. \tag{2.17}$$

Here the matrix X is indexed by $V(K_t \square G) = \cup_{p=1}^t V_p$ (recall (1.1)) and $t \in \mathbb{N}$, $t \geq 2$. As the program (2.17) is invariant under action of the group $\mathrm{Sym}(t)$, one may assume that X is invariant under action of $\mathrm{Sym}(t)$. Then X has the block form (2.14). By using Lemma 2.8, (2.17) can be rewritten as

$$\begin{gathered} A - B \succeq 0,\ A + (t-1)B \succeq 0,\ A_{ij} = 0\ (ij \in E(G)),\ \mathrm{diag}(B) = 0, \\ \mathrm{Tr}(A) = \frac{1}{t},\ \langle \mathbf{J}, A + (t-1)B \rangle = \frac{n}{t}. \end{gathered} \tag{2.18}$$

Lemma 2.9 implies that $A + (t-1)B = \frac{1}{nt}\mathbf{J}$. By setting $U := nt(A - B)$, we find that

$$U = \frac{1}{t-1}(nt^2 A - \mathbf{J}). \tag{2.19}$$

One can verify that (t, U) is feasible for the program

$$\min\ t\ \text{ s.t. } \mathrm{diag}(U) = e,\ U_{ij} = -\frac{1}{t-1}\ (ij \in E(G)),\ U \succeq 0,\ t \geq 2 \tag{2.20}$$

defining the parameter $\overline{\vartheta}(G)$ (see (2.3)). As $t \in \mathbb{N}$, this implies that $\Psi_\vartheta(G) \geq \lceil \overline{\vartheta}(G) \rceil$. Conversely, let (t, U) be feasible for (2.20), with t an integer. Define the matrices A and B via the equations

$$A - B = \frac{1}{nt}U \ \text{ and } A + (t-1)B = \frac{1}{nt}\mathbf{J}, \tag{2.21}$$

and let X be the corresponding block matrix as in (2.14). One can verify that (2.18) holds and thus (2.17) holds, too. That is, (t, X) is feasible for (2.17). Thus we have shown that

$$\Psi_\vartheta(G) = \min_{t \in \mathbb{N}}\ t\ \text{ s.t. } \mathrm{diag}(U) = e,\ U_{ij} = -\frac{1}{t-1}\ (ij \in E(G)),\ U \succeq 0,\ t \geq 2. \tag{2.22}$$

We now show that $\Psi_\vartheta(G) \le \lceil \overline{\vartheta}(G) \rceil$. For this, set $t := \overline{\vartheta}(G)$, and take an optimal solution U to the program (2.20). Then, by setting $Y := \frac{t-1}{\lceil t \rceil - 1} U + \frac{\lceil t \rceil - t}{\lceil t \rceil - 1} \mathbf{I}$, the pair $(\lceil t \rceil, Y)$ is feasible for (2.22) with objective value $\lceil t \rceil$, which implies that $\lceil t \rceil \ge \Psi_\vartheta(G)$. Thus equality $\lceil \overline{\vartheta}(G) \rceil = \Psi_\vartheta(G)$ holds.

The proof of (ii) is analogous to that of (i). Simply note that adding the condition $X \ge 0$ to (2.17) amounts to adding the condition $A, B \ge 0$ to (2.18) and thus, in view of (2.19), to adding the condition $U_{ij} \ge -\frac{1}{t-1}$ $(i, j \in V)$ to (2.22). □

2.4. Semidefinite programming formulation for the new bounds. We consider here issues related to the computation of $\Psi_\beta(G)$. We assume throughout that $\beta(\cdot)$ satisfies (2.10). There is an obvious way to find $\Psi_\beta(G)$, namely, by computing $\beta(K_t \Box G)$ for each $t = 1, \dots, n$. We now observe that, when $\beta(\cdot)$ is monotone nondecreasing (with respect to taking induced subgraphs), one can use binary search, and it suffices to compute $\beta(K_t \Box G)$ for $O(\log n)$ instances of t.

LEMMA 2.10. *Assume that*

$$\beta(K_t \Box G) \le \beta(K_{t+1} \Box G) \text{ for all } t \in \mathbb{N}. \tag{2.23}$$

Then $\beta(K_t \Box G) = n \Longleftrightarrow \Psi_\beta(G) \le t$.

Proof. The "only if" part follows from the definition of $\Psi_\beta(G)$. For the "if" part assume that $t_0 := \Psi_\beta(G) \le t$. Then $\beta(K_{t_0} \Box G) = n \le \beta(K_t \Box G)$ implies that $\beta(K_t \Box G) = n$, since $\beta(K_t \Box G) \le \overline{\chi}(G) \le n$. □

Under assumption (2.23) one can use binary search for computing $\Psi_\beta(G)$. Namely, given $t_0 \in [1, n]$, compute $\beta(K_{t_0} \Box G)$. There are two cases:

- $\beta(K_{t_0} \Box G) < n$. Then $\Psi_\beta(G) \ge t_0 + 1$ (by the above lemma), and we can now restrict the search to $t \in [t_0 + 1, n]$.
- Or $\beta(K_{t_0} \Box G) = n$. Then $\Psi_\beta(G) \le t_0$, and we can restrict the search to $t \in [1, t_0]$.

Therefore, one can find $\Psi_\beta(G)$ by computing $\beta(K_t \Box G)$ for $O(\log n)$ queries of t.

Observe that one may restrict the range of search for t. Suppose that we know a lower bound t_1 and an upper bound t_2 on $\chi(G)$; that is, $t_1 \le \chi(G) \le t_2$. Then we may assume that $t \le t_2$ in the definition of $\Psi_\beta(G)$, and if we add the condition $t \ge t_1$, then one still obtains a lower bound for $\chi(G)$. Therefore, we may restrict the binary search to $t \in [t_1, t_2]$. For instance, one can choose $t_1 = 3$ if G is not bipartite, or $t_1 = \omega(G)$, and $t_2 = \Delta(G) + 1$ (or even $\Delta(G)$ by Brook's theorem (see [33]) if G is not a clique or an odd circuit), $\Delta(G)$ being the maximum degree of G.

Next we show that $\Psi_\beta(G)$ can be formulated via a single semidefinite program when $\beta(\cdot)$ is given by a semidefinite program satisfying certain assumptions. Namely, our construction applies to the case when the semidefinite program defining $\beta(\cdot)$ involves at least one equality constraint of the form $\langle A, X \rangle = 1$, with $A \succeq 0$. Then one may assume without loss of generality (w.l.o.g.) that all other (in)equality constraints in the program are homogeneous, i.e., of the form $\langle B, X \rangle \ge 0$. (Write any equation $\langle B, X \rangle = 0$ as two opposite inequalities $\langle -B, X \rangle \ge 0$ and $\langle B, X \rangle \ge 0$.) So let us assume that, for an arbitrary graph H, we can express $\beta(H)$ as

$$\begin{aligned} \beta(H) = \max \langle C(H), X(H) \rangle \quad \text{s.t.} \quad & \langle A(H), X(H) \rangle = 1, \\ & \mathcal{B}(H)(X(H)) \ge 0, \\ & X(H) \succeq 0, \end{aligned} \tag{2.24}$$

where $C(H)$ and $A(H)$ are constant symmetric $n \times n$ matrices, $\mathcal{B}(H) : S_n \to \mathbb{R}^{d(H)}$ is a linear operator, and $X(H)$ is the matrix variable. Note that $d(\cdot)$ depends on H,

e.g., $d(H) = 2|E(H)|$ in the formulation of $\vartheta(H)$. Moreover we assume that

$$A(H) \succeq 0, \tag{2.25}$$

$$\langle A(H), X(H)\rangle = 0 \Longrightarrow \langle C(H), X(H)\rangle = 0. \tag{2.26}$$

Note that assumptions (2.23), (2.24), (2.25), and (2.26) hold, e.g., for $\vartheta(\cdot)$ or for the Lasserre hierarchy considered in section 3.1. Recall that our operator Ψ maps $\beta(\cdot)$ in the following way:

$$\begin{array}{rlll} \Psi_\beta(G) := \min t & = \min & t & \\ \text{s.t. } \beta(G_t) = n & \text{s.t.} & \langle C(G_t), X(G_t)\rangle = n, & \\ & & \langle A(G_t), X(G_t)\rangle = 1, & \\ & & \mathcal{B}(G_t)(X(G_t)) \geq 0, & \\ & & X(G_t) \succeq 0. & \end{array} \tag{2.27}$$

Here we use the more concise notation $G_t := K_t \square G$. Let us define

$$\begin{array}{rlll} \Phi_\beta(G) := \min \displaystyle\sum_{t=1}^n t\langle A(G_t), X(G_t)\rangle & \text{s.t.} & \displaystyle\sum_{t=1}^n \langle C(G_t), X(G_t)\rangle = n, & \\ & & \displaystyle\sum_{t=1}^n \langle A(G_t), X(G_t)\rangle = 1, & \\ & & \mathcal{B}(G_t)(X(G_t)) \geq 0 \ (t = 1, \ldots, n), & \\ & & X(G_t) \succeq 0 \ (t = 1, \ldots, n). & \end{array} \tag{2.28}$$

THEOREM 2.11. *Under assumptions* (2.24), (2.25), *and* (2.26), $\Phi_\beta(G) = \Psi_\beta(G)$.

Proof. Take a feasible solution $(t, X(G_t))$ for the program (2.27), and for $k \neq t$ set $X(G_k) := 0$. In this way one obtains a feasible solution for (2.28) with the same objective value as (2.27), which shows that $\Phi_\beta(G) \leq \Psi_\beta(G)$. Conversely, let $X(G_t)$ $(t = 1, \ldots, n)$ be a feasible solution for (2.28), and set $a_t := \langle A(G_t), X(G_t)\rangle$. Thus $a_t \geq 0$ since $A(G_t) \succeq 0$ (by assumption (2.25)) and $\sum_t a_t = 1$. Consider t for which $a_t > 0$. As $\langle A(G_t), \frac{X(G_t)}{a_t}\rangle = 1$, $\frac{X(G_t)}{a_t}$ is feasible for (2.24) (with $H = G_t$), which implies that $\langle C(G_t), \frac{X(G_t)}{a_t}\rangle \leq \beta(G_t) \leq n$; moreover, equality $\langle C(G_t), \frac{X(G_t)}{a_t}\rangle = n$ implies that $\beta(G_t) = n$ and thus $\Psi_\beta(G) \leq t$. Now we have

$$n = \sum_t \langle C(G_t), X(G_t)\rangle = \sum_{t|a_t>0} a_t \left\langle C(G_t), \frac{X(G_t)}{a_t}\right\rangle \leq \left(\sum_{t|a_t>0} a_t\right) n = n.$$

(Here we used assumption (2.26) for the second equality.) Therefore, equality holds throughout, which implies that $\Psi_\beta(G) \leq t$ whenever $a_t > 0$. Hence, $\sum_t t a_t = \sum_{t|a_t>0} t a_t \geq \Psi_\beta(G)(\sum_{t|a_t>0} a_t) = \Psi_\beta(G)$, which gives $\Phi_\beta(G) \geq \Psi_\beta(G)$. □

Hence, under the assumptions (2.24), (2.25), and (2.26), the parameter $\Psi_\beta(G)$ can be formulated via the semidefinite program (2.28), which involves a block-diagonal matrix with diagonal blocks $X(G_1), \ldots, X(G_n)$, each $X(G_t)$ being the matrix variable involved in the program (2.24) for the graph $H = G_t$. For instance, if (2.24) involves a matrix variable of order $f(V(H))$, then (2.28) involves a block-diagonal matrix with block sizes $f(n), f(2n), \ldots, f(n^2)$. As explained above one can reduce the size of the program (2.28) by restricting the range of t in program (2.28) to $t \in [t_1, t_2]$, where $t_1 \leq \chi(G) \leq t_2$.

2.5. Copositive programming formulation for the chromatic number. The technique used in section 2.4 can also be applied to derive (quadratically constrained) quadratic and copositive programming formulations for the chromatic number. Recall that a matrix X is *copositive* if $x^T X x \geq 0$ for all $x \geq 0$. A matrix X is *completely positive* if it belongs to the dual of the cone of copositive matrices, i.e., if it can be written as $X = \sum_i x_i x_i^T$ for some $x_i \geq 0$.

Our starting point is the theorem of Motzkin and Straus [28], which, for a graph G with adjacency matrix A_G, gives the following formulation for its stability number:

$$\frac{1}{\alpha(G)} = \min\ x^T(\mathbf{I} + A_G)x \ \text{ s.t. } x \in \mathbb{R}_+^{V(G)},\ e^T x = 1, \tag{2.29}$$

or, equivalently (see [6]),

$$\alpha(G) = \min\ t \ \text{ s.t. } t(\mathbf{I} + A_G) - \mathbf{J} \text{ is copositive.} \tag{2.30}$$

By using (2.29), we can rewrite the program (2.9) as

$$\chi(G) = \min\ t \text{ s.t. } x_t^T(\mathbf{I} + A_{G_t})x_t = \frac{1}{n},\ e_t^T x_t = 1,\ x_t \in \mathbb{R}_+^{V(G_t)}. \tag{2.31}$$

Here and below e_t denotes the all-ones vector in $\mathbb{R}^{V(G_t)}$. By using the idea from section 2.4 let us define

$$\begin{aligned} \Phi_1(G) := \min & \sum_{t=1}^n t(e_t^T x_t)^2 \\ \text{s.t. } & \sum_{t=1}^n (e_t^T x_t)^2 = 1, \\ & \sum_{t=1}^n x_t^T(\mathbf{I} + A_{G_t})x_t = \frac{1}{n}, \\ & x_t \in \mathbb{R}_+^{V(G_t)}\ (t = 1, \ldots, n). \end{aligned} \tag{2.32}$$

PROPOSITION 2.12. $\Phi_1(G) = \chi(G)$.

Proof. By taking a feasible solution (t, x_t) for the program (2.31) and setting $x_k = 0$ for $k \neq t$, we obtain a feasible solution for (2.32) with objective value t. Thus, $\Phi_1(G) \leq \chi(G)$. Conversely, let x_t $(t = 1, \ldots, n)$ be feasible for (2.32). Then

$$\frac{1}{n} = \sum_t x_t^T(\mathbf{I} + A_{G_t})x_t = \sum_{t|x_t \neq 0} \frac{x_t^T}{e_t^T x_t}(\mathbf{I} + A_{G_t})\frac{x_t}{e_t^T x_t}(e_t^T x_t)^2 \geq \frac{1}{n}\sum_{t|x_t \neq 0}(e_t^T x_t)^2 = \frac{1}{n}.$$

We have used $\frac{x_t^T}{e_t^T x_t}(\mathbf{I} + A_{G_t})\frac{x_t}{e_t^T x_t} \geq \frac{1}{\alpha(G_t)} \geq \frac{1}{n}$. Hence equality holds throughout, which implies that $\alpha(G_t) = n$ if $x_t \neq 0$ and thus $\chi(G) \leq t$ if $x_t \neq 0$. Therefore,

$$\sum_t t(e_t^T x_t)^2 = \sum_{t|x_t \neq 0} t(e_t^T x_t)^2 \geq \chi(G) \sum_{t|x_t \neq 0}(e_t^T x_t)^2 = \chi(G).$$

This shows that $\Phi_1(G) \geq \chi(G)$. ∎

Up to rescaling, we obtain the following formulation for $\chi(G)$ involving only quadratic constraints:

$$\begin{aligned} \chi(G) = \min \quad & \frac{1}{n^2}\sum_{t=1}^{n} t(e_t^T x_t)^2 \\ \text{s.t.} \quad & \sum_{t=1}^{n}(e_t^T x_t)^2 = n^2, \\ & \sum_{t=1}^{n} x_t^T(\mathbf{I}+A_{G_t})x_t = n, \\ & x_t \in \mathbb{R}_+^{V(G_t)} \ (t=1,\dots,n). \end{aligned} \tag{2.33}$$

It is not difficult to verify that the above program remains a formulation of $\chi(G)$ if we replace the condition $x_t \geq 0$ (for all t) by the condition that x_t is 0/1 valued (for all t). Therefore this gives a 0/1 (quadratically constrained) quadratic programming formulation for the chromatic number involving $O(n^3)$ variables.

By starting from (2.33), we can now derive a copositive programming formulation for $\chi(G)$. Namely, consider the program

$$\begin{aligned} \Phi_2(G) := \min \quad & \frac{1}{n^2}\sum_{t=1}^{n} t\langle \mathbf{J}, X_t\rangle \\ \text{s.t.} \quad & \sum_{t=1}^{n}\langle \mathbf{J}, X_t\rangle = n^2, \\ & \sum_{t=1}^{n}\langle \mathbf{I}+A_{G_t}, X_t\rangle = n, \\ & X_t \text{ completely positive } \ (t=1,\dots,n). \end{aligned} \tag{2.34}$$

PROPOSITION 2.13. $\Phi_2(G) = \chi(G)$.

Proof. The formulation (2.33) for $\chi(G)$ implies directly that $\Phi_2(G) \leq \chi(G)$. Conversely, let X_t $(1 \leq t \leq n)$ be a feasible solution for (2.34). Consider t for which $X_t \neq 0$. Say, $X_t = \sum_{i_t} x_{i_t} x_{i_t}^T$ where $x_{i_t} \geq 0$, $x_{i_t} \neq 0$ for all i_t. Thus $\lambda_{i_t} := \sqrt{\langle \mathbf{J}, x_{i_t} x_{i_t}^T\rangle} = e_t^T x_{i_t} > 0$. Set $y_{i_t} := \frac{x_{i_t}}{\lambda_{i_t}}$. By assumption, we have $\sum_t \langle n(\mathbf{I}+A_{G_t})-\mathbf{J}, X_t\rangle = 0$. By (2.30), each matrix $n(\mathbf{I}+A_{G_t})-\mathbf{J}$ is copositive, since $n \geq \alpha(G_t)$. This implies that $\langle n(\mathbf{I}+A_{G_t})-\mathbf{J}, X_t\rangle = 0$ and thus $\langle n(\mathbf{I}+A_{G_t})-\mathbf{J}, x_{i_t}x_{i_t}^T\rangle = 0$ for all i_t. From this follows that $\langle \mathbf{I}+A_{G_t}, y_{i_t}y_{i_t}^T\rangle = \frac{1}{n}$ for all i_t. As $e_t^T y_{i_t} = 1$, y_{i_t} is feasible for the program (2.31), implying that $\chi(G) \leq t$ whenever $X_t \neq 0$. Now $(1/n^2)\sum_t t\langle \mathbf{J}, X_t\rangle \geq (1/n^2)\chi(G)\sum_t \langle \mathbf{J}, X_t\rangle = \chi(G)$, giving $\Phi_2(G) \geq \chi(G)$. □

By rewriting the condition $\sum_t \langle \mathbf{I}+A_{G_t}, X_t\rangle = n$ as $\sum_t \langle n(\mathbf{I}+A_{G_t})-\mathbf{J}, X_t\rangle = 0$, the dual conic program of (2.34) reads:

$$\max_{y,z} \ y \text{ s.t. } \frac{1}{n^2}(t-y)\mathbf{J} + z(n(\mathbf{I}+A_{G_t})-\mathbf{J}) \text{ copositive for } 1 \leq t \leq n. \tag{2.35}$$

There is no duality gap since the program (2.35) is strictly feasible. Thus (2.35) is yet another formulation of $\chi(G)$. This opens the road to another type of hierarchy of relaxations for $\chi(G)$, obtained by approximating the copositive cone by tractable subcones as suggested by Parrilo [29]. This type of approach based on copositive programming has been studied, e.g., in [2] for standard quadratic optimization problems, in [6, 13, 30] for the stable set problem, and recently in [9] for the coloring problem. We will come back to it in section 3.5.

3. Semidefinite hierarchies for (fractional) chromatic numbers. We have seen in the previous section how to construct semidefinite programming lower bounds for the chromatic number of a graph from semidefinite programming upper bounds on the stability number. Several hierarchies of such upper bounds for the stability number have been proposed in the literature, in particular, in [6, 19, 24, 30, 34]. These hierarchies were further studied and compared, e.g., in [13, 20]. It turns out that Lasserre's hierarchy, proposed in [19], gives the tightest bounds. For this reason we focus in this section on this hierarchy, and we show how it can be used and transformed to produce hierarchies of lower bounds for the (fractional) chromatic number. We will also discuss the link with another hierarchy recently proposed by Dukanovic and Rendl [9] based on copositive programming.

3.1. Lasserre's hierarchy towards the stability number. For a subset $S \subseteq V$ and an integer $r \geq 1$, define the vectors $\chi^S \in \{0,1\}^V$ with ith entry 1 if and only if $i \in S$ (for $i \in V$) and $\chi^{S,r} \in \{0,1\}^{\mathcal{P}_r(V)}$ with Ith entry 1 if and only if $I \subseteq S$ (for $I \in \mathcal{P}_r(V)$). Given a vector $x = (x_I)_{I \in \mathcal{P}_{2r}(V)}$, consider the matrix:

$$M_r(x) := (x_{I \cup J})_{I,J \in \mathcal{P}_r(V)}$$

indexed by $\mathcal{P}_r(V)$, known as the *(combinatorial) moment matrix* of x of order r. Consider the program:[1]

$$\text{las}^{(r)}(G) := \max \sum_{i \in V} x_i \ \text{ s.t. } M_r(x) \succeq 0,\ x_{\mathbf{0}} = 1,\ x_{ij} = 0\ (ij \in E), \tag{3.1}$$

with variable $x \in \mathbb{R}^{\mathcal{P}_{2r}(V)}$. As the feasible region is bounded, the maximum is indeed attained in program (3.1). Obviously, $\text{las}^{(r+1)}(G) \leq \text{las}^{(r)}(G)$ (since $M_r(x)$ is a principal submatrix of $M_{r+1}(x)$) and, in view of (2.4), $\text{las}^{(1)}(G) = \vartheta(G)$. In this way one obtains a hierarchy of semidefinite programming bounds for the stability number, known as Lasserre's hierarchy [19, 20]. Indeed, if S is a stable set, the vector $x := \chi^{S,2r}$ is feasible for (3.1) with objective value $|S|$, showing that $\alpha(G) \leq \text{las}^{(r)}(G)$. For fixed r, the parameter $\text{las}^{(r)}(G)$ can be computed in polynomial time (to an arbitrary precision) since the semidefinite program (3.1) involves matrices of size $O(n^r)$ with $O(n^{2r})$ variables (see, e.g., [38] for details on semidefinite programming). It is shown in [20] that, for $r \geq \alpha(G)$,

$$x \text{ is feasible for (3.1)} \iff x = \sum_{S \text{ stable}} \lambda_S \chi^{S,2r},\ \text{for some } \lambda \geq 0,\ \sum_{S \text{ stable}} \lambda_S = 1. \tag{3.2}$$

This implies that

$$\alpha(G) = \text{las}^{(r)}(G) \text{ for } r \geq \alpha(G). \tag{3.3}$$

3.2. An analogous semidefinite programming hierarchy towards the fractional chromatic number. For an integer $r \geq 1$, define the parameter

$$\psi^{(r)}(G) := \min t \ \text{ s.t. } M_r(x) \succeq 0,\ x_{\mathbf{0}} = t,\ x_i = 1\ (i \in V),\ x_{ij} = 0\ (ij \in E), \tag{3.4}$$

where the variable x is indexed by $\mathcal{P}_{2r}(V)$. Note that one can avoid the variable t simply by replacing t by $x_{\mathbf{0}}$ in the objective function. We choose this formulation in

[1] One can easily verify that, under the condition $M_r(x) \succeq 0$, the edge condition $x_{ij} = 0$ for $ij \in E$ implies that $x_I = 0$ for any $I \in \mathcal{P}_{2r}(V)$ containing an edge.

order to have a unified presentation of the various bounds; compare, e.g., with (2.9), (2.11), (3.9), (3.12), and (3.14). Again the minimum is attained in program (3.4), and, for fixed r, one can compute $\psi^{(r)}(G)$ to any arbitrary precision in polynomial time.

THEOREM 3.1. *The parameters $\psi^{(r)}(G)$ satisfy:*

(a) $\psi^{(r)}(G) \le \psi^{(r+1)}(G)$,

(b) $\psi^{(1)}(G) = \overline{\vartheta}(G)$,

(c) $\overline{\vartheta^{+\triangle}}(G) \le \psi^{(2)}(G)$,

(d) $\psi^{(r)}(G) \le \chi^*(G)$, *with equality if $r \ge \alpha(G)$,*

(e) $\psi^{(r)}(G)\mathrm{las}^{(r)}(G) \ge |V(G)|$, *with equality if G is vertex-transitive.*

Proof. (a) is obvious. For (b), let $M_1(x) = \begin{pmatrix} t & e^T \\ e & M \end{pmatrix}$ be a matrix optimal for (3.4) with $r = 1$. Then $\psi^{(1)}(G) = t \ge 2$ (as G has an edge) and $M_1(x) \succeq 0$ or, equivalently, $M - \frac{1}{t}ee^T \succeq 0$. After setting $U := \frac{t}{t-1}(M - \frac{1}{t}ee^T) = \frac{t}{t-1}M - \frac{1}{t-1}ee^T$, we can rewrite the program for $\psi^{(1)}(G)$ in the following way:

$$\begin{aligned} \psi^{(1)}(G) = \min\ t\ \text{ s.t. }\quad & U_{ii} = 1, \\ & U_{ij} = -\frac{1}{t-1}\ (ij \in E), \\ & U \succeq 0,\ t \ge 2. \end{aligned}$$

Thus, in view of (2.3), $\psi^{(1)}(G) = \overline{\vartheta}(G)$.

(c) Assume that (t, x) is feasible for the program defining $\psi^{(2)}(G)$. Consider the principal submatrix X of $M_2(x)$ indexed by $\{k, ij, ik, jk\}$, where i, j, k are distinct elements of V and the vector $w := (1, 1, -1, -1)^T$. Then $w^T X w \ge 0$ gives $x_{ik} + x_{jk} - x_{ij} \le 1$. By setting $U := \frac{t}{t-1}((x_{ij})_{i,j=1}^n - \frac{1}{t}\mathbf{J})$, one can now verify that (t, U) is feasible for the program defining $\overline{\vartheta^{+\triangle}}(G)$, which shows the result.

(d) Let λ be an optimum solution for the minimization program defining $\chi^*(G)$ (recall (2.1)). That is, $e^T\lambda = \chi^*(G)$, $\sum_{S \text{ stable}} \lambda_S \chi^S = e$, and $\lambda \ge 0$. For $r \in \mathbb{N}$, the vector $x := \sum_{S \text{ stable}} \lambda_S \chi^{S,r}$ is feasible for (3.4) with objective value $\chi^*(G)$, which shows that $\psi^{(r)}(G) \le \chi^*(G)$. Assume now that $r \ge \alpha(G)$, and consider an optimum solution $M_r(x)$ for (3.4). By setting $y := \frac{1}{\psi^{(r)}(G)}x$, we have $M_r(y) \succeq 0$, $y_{\mathbf{0}} = 1$, and $y_{ij} = 0$ $(ij \in E)$. By using (3.2) we derive $y = \sum_{S \text{ stable}} \lambda_S \chi^{S,2r}$ for some $\lambda_S \ge 0$, with $\sum_S \lambda_S = 1$. By rescaling and taking the projection onto the subspace $\mathbb{R}^V$, we find a decomposition $e = \psi^{(r)}(G)\sum_{S \text{ stable}} \lambda_S \chi^S$, with $\sum_S \lambda_S \psi^{(r)}(G) = \psi^{(r)}(G)$, which shows that $\chi^*(G) \le \psi^{(r)}(G)$.

(e) Take again an optimum solution $M_r(x)$ for (3.4), and let $n = |V(G)|$. Since $M_r(\frac{1}{\psi^{(r)}(G)}x)$ is feasible for (3.1) with objective value $\frac{n}{\psi^{(r)}(G)}$, we get $\mathrm{las}^{(r)}(G) \ge \frac{n}{\psi^{(r)}(G)}$. Assume that G is vertex-transitive. Then there exists an optimum solution x for (3.1) which is invariant under the action of the automorphism group of G. In particular, $x_i = x_j$ for all $i, j \in V$ and thus $x_i = \frac{\mathrm{las}^{(r)}(G)}{n}$ for all $i \in V$. Then the matrix $\frac{n}{\mathrm{las}^{(r)}(G)}M_r(x)$ is feasible for (3.4), yielding $\psi^{(r)}(G) \le \frac{n}{\mathrm{las}^{(r)}(G)}$. ∎

Theorem 3.1 shows that the reciprocity relations (2.5) and (2.2) for the pairs $(\vartheta, \overline{\vartheta}) = (\mathrm{las}^{(1)}, \psi^{(1)})$ and $(\alpha, \chi^*) = (\mathrm{las}^{(r)}, \psi^{(r)})$ (for r large, $r \ge \alpha(G)$) extend to any order r pair $(\mathrm{las}^{(r)}, \psi^{(r)})$ in the hierarchy.

3.3. The hierarchy $\Psi_{\mathrm{las}^{(r)}}(G)$ $(r \ge 0)$ towards the chromatic number. By applying the operator Ψ to the hierarchy $\mathrm{las}^{(r)}(\cdot)$ introduced in section 3.1, we

obtain the following hierarchy of lower bounds for $\chi(G)$:

$$\begin{aligned}\Psi_{\mathrm{las}^{(r)}}(G) &= \min\ t \ \text{ s.t. } \quad \mathrm{las}^{(r)}(G_t) = n \\ &= \min\ t \ \text{ s.t. } \quad y_{\mathbf{0}} = 1,\ \sum_{u\in V(G_t)} y_u = n, \\ &\qquad\qquad\quad y_{uv} = 0\ (uv \in E(G_t)),\ M_r(y) \succeq 0,\end{aligned} \tag{3.5}$$

where the variable y is indexed by $\mathcal{P}_{2r}(V(G_t))$. As $\alpha(G_t) \le n$, we deduce by using (3.3) that $\mathrm{las}^{(n)}(G_t) = \alpha(G_t)$ for all $t \in \mathbb{N}$. Therefore, (1.2) implies the following.

PROPOSITION 3.2. $\Psi_{\mathrm{las}^{(n)}}(G) = \chi(G)$.

In fact, this new hierarchy $\Psi_{\mathrm{las}^{(r)}}$ refines the hierarchy $\psi^{(r)}$.

PROPOSITION 3.3. *For any integer $r \ge 1$, $\psi^{(r)}(G) \le \Psi_{\mathrm{las}^{(r)}}(G)$.*

Proof. Let (t, y) be feasible for the program defining the parameter $\Psi_{\mathrm{las}^{(r)}}(G)$; that is, $y \in \mathbb{R}^{\mathcal{P}_{2r}(V(G_t))}$ satisfies $y_{\mathbf{0}} = 1$, $y_{uv} = 0$ $(uv \in E(G_t))$, $\sum_{u\in V(G_t)} y_u = n$, and $M_r(y) \succeq 0$. We may assume w.l.o.g. that y is invariant under the action of the symmetric group $\mathrm{Sym}(t)$. The next claim determines y_u for $u \in V(G_t)$.

CLAIM 3.4. *$y_u = \frac{1}{t}$ for all $u \in V(G_t)$.*

Proof. Let X denote the principal submatrix of $M_r(y)$ indexed by $\mathcal{P}_1(V(G_t))$. With respect to the partition of $\mathcal{P}_1(V(G_t)) \sim \{\mathbf{0}\} \cup V(G_t)$ into $\{\mathbf{0}\} \cup V_1 \cup \cdots \cup V_t$ (recall (1.1)), the matrix X has the block form

$$\begin{pmatrix} 1 & a^T & a^T & \dots & a^T \\ a & A & B & \dots & B \\ a & B & A & \dots & B \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a & \underbrace{B}_{t \text{ blocks}} & B & \dots & A \end{pmatrix}, \tag{3.6}$$

where $a = \mathrm{diag}(A)$, $\mathrm{diag}(B) = 0$, $A_{ij} = 0$ for $ij \in E(G)$, and $e^T a = \frac{n}{t}$. By taking the Schur complement with respect to the left upper corner and using Lemma 2.8, we have $A + (t-1)B - taa^T \succeq 0$. This implies that $\langle \mathbf{J}, A + (t-1)B\rangle \ge t(e^T a)^2 = \frac{n^2}{t}$. On the other hand, by Lemma 2.9, $\langle \mathbf{J}, A + (t-1)B\rangle \le n\mathrm{Tr}(A + (t-1)B) = n\mathrm{Tr}(A) = \frac{n^2}{t}$. Hence equality holds, implying that $A + (t-1)B = \frac{1}{t}\mathbf{J}$ and thus $a = \frac{1}{t}e$. This shows that $y_u = \frac{1}{t}$ for all $u \in V(G_t)$. ∎

Define the vector $x \in \mathbb{R}^{\mathcal{P}_{2r}(V)}$ with Ith entry $x_I := t y_{\{pi \mid i\in I\}}$ for $I \in \mathcal{P}_{2r}(V) \setminus \{\mathbf{0}\}$ (where p is any fixed integer in $\{1, \dots, t\}$) and $x_{\mathbf{0}} = t$. Then $M_r(x) \succeq 0$, since it coincides with the principal submatrix of $M_r(ty)$ indexed by $\{\mathbf{0}\} \cup \{\{pi \mid i \in I\} \mid I \in \mathcal{P}_r(V)\setminus\{\mathbf{0}\}\}$. Moreover, $x_{\mathbf{0}} = t$ and $x_i = 1$ for $i \in V$. Thus, (t, x) is feasible for the program (3.4), which implies that $\psi^{(r)}(G) \le \Psi_{\mathrm{las}^{(r)}}(G)$. ∎

In summary, we have shown the following relations among the graph parameters $\mathrm{las}^{(r)}(G)$, $\psi^{(r)}(G)$, and $\Psi_{\mathrm{las}^{(r)}}(G)$:

$$\frac{|V(G)|}{\mathrm{las}^{(r)}(G)} \le \psi^{(r)}(G) \le \Psi_{\mathrm{las}^{(r)}}(G) \le \chi(G). \tag{3.7}$$

Let us point out again that, while $\psi^{(r)}(G)$ remains below the fractional chromatic number $\chi^*(G)$, $\Psi_{\mathrm{las}^{(r)}}(G)$ may reach the chromatic number $\chi(G)$.

3.4. Variations of the second order bounds. As observed in Theorem 3.1 and Proposition 3.3, we have

$$\overline{\vartheta^+}(G) \le \overline{\vartheta^{+\triangle}}(G) \le \psi^{(2)}(G) \le \Psi_{\mathrm{las}^{(2)}}(G).$$

To compute $\psi^{(2)}(G)$ one needs to solve a semidefinite program with matrix size $O(n^2)$ and with $O(n^4)$ variables. We now introduce some variations of the parameters $\psi^{(2)}(G)$ and $\Psi_{\mathrm{las}^{(2)}}(G)$ which are less costly to compute but still at least as good as $\overline{\vartheta^+}(G)$. The idea is to consider, instead of the full moment matrix of order 2, some principal submatrix of it. Namely, given $h \in V$, let $M_2(h;x)$ denote the principal submatrix of $M_2(x)$ indexed by the subset $\mathcal{P}_1(V) \cup \{\{h,i\} \mid i \in V\}$ of $\mathcal{P}_2(V)$. Thus in order to define the matrices $M_2(h;x)$ for all $h \in V$, one needs only the components of x indexed by $\mathcal{P}_3(V)$. By following [21], define the following upper bound for the stability number $\alpha(G)$:

$$\ell(G) := \max \sum_{i\in V} x_i \ \text{ s.t. } M_2(h;x) \succeq 0 \ (h \in V),\ x_{\mathbf{0}} = 1,\ x_{ij} = 0 \ (ij \in E(G)), \tag{3.8}$$

with variable $x \in \mathbb{R}^{\mathcal{P}_3(V)}$. Obviously,

$$\mathrm{las}^{(2)}(G) \le \ell(G) \le \mathrm{las}^{(1)}(G) = \vartheta(G).$$

Next, define the graph parameter

$$\begin{aligned} \psi(G) := \min\ t \ \text{ s.t. } \quad & M_2(h;x) \succeq 0 \ (h \in V),\ x_{ij} = 0 \ (ij \in E(G)), \\ & x_{\mathbf{0}} = t,\ x_i = 1 \ (i \in V), \end{aligned} \tag{3.9}$$

where the variable x is indexed by $\mathcal{P}_3(V)$. Again one can avoid variable t by replacing t by $x_{\mathbf{0}}$ in the objective function. We first observe that the pair (ℓ, ψ) satisfies the analogue of the reciprocity relation from Theorem 3.1(e) for the pairs $(\mathrm{las}^{(r)}, \psi^{(r)})$.

PROPOSITION 3.5. *We have*

$$\ell(G)\psi(G) \ge |V(G)|, \ \textit{with equality if } G \textit{ is vertex-transitive,} \tag{3.10}$$

$$\overline{\vartheta^+}(G) \le \psi(G) \le \psi^{(2)}(G). \tag{3.11}$$

Proof. The proof for (3.10) is analogous to that of Theorem 3.1(e), and the right inequality in (3.11) is obvious. For the left inequality, let (t,x) be feasible for (3.9). Observe first that $x_{hi} \ge 0$ for all $h,i \in V$, since x_{hi} is the diagonal entry of $M_2(h;x)$ at the $\{h,i\}$th position and $M_2(h;x) \succeq 0$. Let A denote the principal submatrix of $M_2(h;x)$ indexed by V. Then $A = (x_{ij})_{i,j\in V} \ge 0$ and $A - \frac{1}{t}\mathbf{J} \succeq 0$, which implies that $U := \frac{t}{t-1}(A - \frac{1}{t}\mathbf{J})$ is feasible for the program defining $\overline{\vartheta^+}(G)$ (recall (2.7)). □

By applying the operator Ψ to the parameter $\ell(\cdot)$ (introduced in (3.8)), one obtains the lower bound $\Psi_\ell(G)$ for $\chi(G)$, defined as

$$\begin{aligned} \Psi_\ell(G) &= \min_{t\in\mathbb{N}}\ t \ \text{ s.t. } \quad \ell(K_t \square G) = n \\ &= \min_{t\in\mathbb{N}}\ t \ \text{ s.t. } \quad \sum_{u\in V(G_t)} y_u = n,\ y_{uv} = 0 \ (uv \in E(G_t)), \\ &\qquad\qquad\qquad\quad y_{\mathbf{0}} = 1,\ M_2(u;y) \succeq 0 \ (u \in V(G_t)), \end{aligned} \tag{3.12}$$

where the variable y is indexed by $\mathcal{P}_3(V(G_t))$. (Recall that $G_t = K_t \square G$.)

PROPOSITION 3.6. $\psi(G) \le \Psi_\ell(G) \le \Psi_{las^{(2)}}(G)$.

Proof. The right inequality follows from Lemma 2.2(b), and the proof for the left inequality is analogous to that of Proposition 3.3. □

In summary, we have the following analogue of (3.7) about $\ell(G)$, $\psi(G)$, and $\Psi_\ell(G)$:

$$\frac{|V(G)|}{\ell(G)} \le \psi(G) \le \Psi_\ell(G) \le \chi(G). \tag{3.13}$$

Again, $\psi(G) \leq \chi^*(G)$ since $\psi^{(2)}(G) \leq \chi^*(G)$, but $\Psi_\ell(G)$ may sometimes reach $\chi(G)$. The bound $\Psi_\ell(G)$ can be especially useful when the gap between $\chi^*(G)$ and $\chi(G)$ is large, e.g., when $\chi^*(G) \sim \omega(G) < \chi(G)$. We refer to the follow-up paper [14], where such graph instances will be considered (e.g., Kneser graphs) with experimental results. One can easily verify that the graph parameter $\ell(\cdot)$ is monotone nondecreasing with respect to induced subgraphs. Therefore, as explained in section 2.4, one can compute $\Psi_\ell(G)$ by evaluating $\ell(G_t)$ for $O(\log n)$ queries of t. We will show in the follow-up paper [14] how to give a more compact reformulation for the program (3.12) when G is a vertex-transitive graph. Namely, we will show there that each $\ell(G_t)$ can be computed via a semidefinite program involving four matrices of size $2n+1$, $2n$, n, and n, respectively.

3.5. Link with copositive programming-based hierarchies. We have just seen one possible construction for hierarchies of bounds towards $\alpha(G)$ and $\chi^*(G)$, based on the method of Lasserre. As mentioned earlier in this section there are several other possible constructions for approximating the stable set problem. However, to the best of our knowledge, such constructions were much less investigated for the coloring problem. Recently Dukanovic and Rendl [9] investigated a hierarchy of lower bounds for $\chi^*(G)$, which is closely related to the hierarchy of de Klerk and Pasechnik [6] for $\alpha(G)$; both are based on copositive programming and some of its tractable relaxations in terms of sums of squares of polynomials, proposed by Parrilo [29]. Let $\mathcal{C}_n$ denote the cone of $n \times n$ copositive matrices and $\mathcal{C}_n^*$ its dual cone, consisting of the completely positive matrices. Thus $M \in \mathcal{C}_n$ if and only if $p_M(x) := \sum_{i,j=1}^n M_{ij} x_i^2 x_j^2 \geq 0$ for all $x \in \mathbb{R}^n$. Obviously if, for some $r \in \mathbb{N}$, the polynomial $p_M(x)(\sum_{i=1}^n x_i^2)^r$ can be written as a sum of squares of polynomials (s.o.s. for short), then $M \in \mathcal{C}_n$. By following Parrilo [29], for an integer $r \geq 0$, define the cone

$$K_n^{(r)} := \left\{ M \in \mathbb{R}^{n \times n} \mid p_M(x) \left(\sum_{i=1}^n x_i^2 \right)^r \text{ is s.o.s.} \right\}.$$

Thus, $K_n^{(r)} \subseteq K_n^{(r+1)} \subseteq \mathcal{C}_n$. By following [6], define the graph parameter

$$\vartheta^{(r)}(G) := \min\ t \ \text{ s.t. } t(\mathbf{I} + A_G) - \mathbf{J} \in K_n^{(r)}.$$

In view of (2.30), $\alpha(G) \leq \vartheta^{(r)}(G)$. Moreover, it is proved in [6] that $\vartheta^{(0)}(G) = \vartheta'(G)$ (defined in (2.6)) and $\lfloor \vartheta^{(r)}(G) \rfloor = \alpha(G)$ for $r \geq (\alpha(G))^2$. Dukanovic and Rendl [9] propose an analogous hierarchy toward the fractional chromatic number. To start with, they show the following copositive programming formulation for $\chi^*(G)$:

$$\chi^*(G) = \min\ t \ \text{ s.t. } \begin{array}{l} X_{ii} = t\ (i \in V),\ X_{ij} = 0\ (ij \in E(G)), \\ X \in \mathcal{C}_n^*,\ X - \mathbf{J} \succeq 0. \end{array} \tag{3.14}$$

For an integer $r \geq 0$, let $\kappa^{(r)}(G)$ denote the graph parameter obtained by replacing the cone $\mathcal{C}_n$ by its subcone $K_n^{(r)}$ in (3.14). Thus, $\kappa^{(r)}(G) \leq \kappa^{(r+1)}(G) \leq \chi^*(G)$. Moreover, it is proved in [9] that $\kappa^{(0)}(G) = \overline{\vartheta^+}(G)$ (defined in (2.7)) and that the pair $(\vartheta^{(r)}, \kappa^{(r)})$ satisfies the reciprocity relation:

$$\vartheta^{(r)}(G)\kappa^{(r)}(G) \geq |V(G)|, \text{ with equality if } G \text{ is vertex-transitive,} \tag{3.15}$$

thus extending (2.8) for the case $r = 0$.

Now one may wonder what the link is between the two hierarchies $\mathrm{las}^{(r)}$ and $\vartheta^{(r)}$ for α and between the two hierarchies $\psi^{(r)}$ and $\kappa^{(r)}$ for χ^*. Here is what we can say about this. In order to be able to compare the various bounds we have to add nonnegativity to the definition of $\mathrm{las}^{(r)}$ and $\psi^{(r)}$; namely, let $\mathrm{las}^{(r)}_{\geq 0}(G)$ (resp., $\psi^{(r)}_{\geq 0}(G)$, $\ell_{\geq 0}(G)$, and $\psi_{\geq 0}(G)$) denote the parameter obtained by adding the condition $x \geq 0$ to program (3.1) (resp., to (3.4), (3.8), and (3.9)). The analogue of Theorem 3.1(e) holds for the pairs $(\mathrm{las}^{(r)}_{\geq 0}, \psi^{(r)}_{\geq 0})$ and $(\ell_{\geq 0}, \psi_{\geq 0})$ as well, and we have $\mathrm{las}^{(1)}_{\geq 0}(G) = \vartheta'(G) = \vartheta^{(0)}(G)$ and $\psi^{(1)}_{\geq 0}(G) = \overline{\vartheta}^{+}(G) = \kappa^{(0)}(G)$. It is shown in [13] that, for any graph G,

$$\mathrm{las}^{(r)}_{\geq 0}(G) \leq \vartheta^{(r-1)}(G) \quad \text{for all } r \geq 1,$$

and the same proof technique also shows that $\ell_{\geq 0}(G) \leq \vartheta^{(1)}(G)$ (see [12] for details). In view of the reciprocity relations for the pairs $(\ell_{\geq 0}, \psi_{\geq 0})$, $(\mathrm{las}^{(r)}_{\geq 0}, \psi^{(r)}_{\geq 0})$, and $(\vartheta^{(r)}, \kappa^{(r)})$, this implies that

$$\kappa^{(1)}(G) \leq \psi_{\geq 0}(G),\ \kappa^{(r-1)}(G) \leq \psi^{(r)}_{\geq 0}(G)\ (r \geq 1), \quad \text{when } G \text{ is vertex-transitive.}$$

It is an open question to determine whether the above inequalities remain valid when G is not vertex-transitive. See [9, 14] for instances of Hamming graphs (which are indeed vertex-transitive) having a substantial gap between the two bounds $\kappa^{(1)}(G)$ and $\psi_{\geq 0}(G)$.

Acknowledgments. We are very grateful to two referees for their careful reading and for their useful suggestions, which helped improve the presentation of the paper. We also thank A. Schrijver for bringing the reduction relation (1.2) to our attention.

COMPUTING SEMIDEFINITE PROGRAMMING LOWER BOUNDS FOR THE (FRACTIONAL) CHROMATIC NUMBER VIA BLOCK-DIAGONALIZATION*

NEBOJŠA GVOZDENOVIĆ† AND MONIQUE LAURENT†

Abstract. Recently we investigated in [*SIAM J. Optim.*, 19 (2008), pp. 572–591] hierarchies of semidefinite approximations for the chromatic number $\chi(G)$ of a graph G. In particular, we introduced two hierarchies of lower bounds: the "ψ"-hierarchy converging to the fractional chromatic number and the "Ψ"-hierarchy converging to the chromatic number of a graph. In both hierarchies the first order bounds are related to the Lovász theta number, while the second order bounds would already be too costly to compute for large graphs. As an alternative, relaxations of the second order bounds are proposed in [*SIAM J. Optim.*, 19 (2008), pp. 572–591]. We present here our experimental results with these relaxed bounds for Hamming graphs, Kneser graphs, and DIMACS benchmark graphs. Symmetry reduction plays a crucial role as it permits us to compute the bounds by using more compact semidefinite programs. In particular, for Hamming and Kneser graphs, we use the explicit block-diagonalization of the Terwilliger algebra given by Schrijver [*IEEE Trans. Inform. Theory*, 51 (2005), pp. 2859–2866]. Our numerical results indicate that the new bounds can be much stronger than the Lovász theta number. For some of the DIMACS instances we improve the best known lower bounds significantly.

Key words. chromatic number, Lovász theta number, semidefinite programming, Terwilliger algebra, Hamming graph, Kneser graph

1. Introduction.

The chromatic number $\chi(G)$ of a graph G is the smallest number of colors needed to color the vertices of G so that no two adjacent vertices share the same color. Determining $\chi(G)$ is an NP-hard problem [14], and it is hard to approximate $\chi(G)$ within $|V(G)|^{1/14-\epsilon}$ for any $\epsilon > 0$ [1]. Finding a proper vertex coloring with a small number of colors is essential in many real-world applications. A lot of work has been done in order to develop efficient heuristics for this problem (see, e.g., [5]). Nevertheless, these methods can provide us only with upper bounds on the chromatic number. Lower bounds were mainly obtained by using linear programming [26, 27], critical subgraphs [8], and semidefinite programming (SDP) [9, 10, 11, 18, 28, 32]. The semidefinite approaches are based on computing (variations of) the well-known lower bound $\overline{\vartheta}(G) := \vartheta\left(\overline{G}\right)$, the theta number of the complementary graph, introduced by Lovász [24]. The theta number satisfies the "sandwich inequality":

$$\omega(G) \leq \overline{\vartheta}(G) \leq \chi(G),$$

and it can be computed to any arbitrary precision in polynomial time since it can be formulated via a semidefinite program of size $|V(G)|$. Here $\omega(G)$ is the clique number of G, defined as the maximum size of a clique (i.e., a set of pairwise adjacent nodes) in G, the stability number $\alpha(G) := \omega(\overline{G})$ of G being the maximum size of

a stable set (i.e., a set of pairwise nonadjacent nodes) in G. The theta number has been strengthened towards the chromatic number by using nonnegativity [32], triangle inequalities [28], or some lift-and-project methods [11]. Computational results were reported in [9, 10, 11]. A common feature shared by all of these bounds is that they remain below the fractional chromatic number $\chi^*(G)$. Thus they are of little use when $\chi^*(G)$ is close to the clique number $\omega(G)$. In [17] the authors investigated another type of lift-and-project approach leading to a hierarchy of bounds converging to the chromatic number $\chi(G)$. We explore in the present follow-up paper the behavior of these bounds through experimental results on several classes of graphs.

The approach in [17] is based on the following reduction of Chvátal [6] of the chromatic number to the stability number:

$$\chi(G) \leq t \Longleftrightarrow \alpha(K_t \Box G) = |V(G)|, \tag{1.1}$$

where $K_t \Box G$ denotes the Cartesian product of K_t, the complete graph on t nodes, and the graph G. For a given graph parameter $\beta(\cdot)$ satisfying $\alpha(\cdot) \leq \beta(\cdot) \leq \overline{\chi}(\cdot)$, define the new graph parameter $\Psi_\beta(\cdot)$ by

$$\Psi_\beta(G) := \min_{t \in \mathbb{N}} t \ \text{ s.t. } \beta(K_t \Box G) = |V(G)|. \tag{1.2}$$

As shown in [17], the operator Ψ is monotone nonincreasing and satisfies

$$\omega(G) = \Psi_{\overline{\chi}}(G) \leq \Psi_\beta(G) \leq \Psi_\alpha(G) = \chi(G) \text{ and } \Psi_\vartheta(G) = \left\lceil \overline{\vartheta}(G) \right\rceil. \tag{1.3}$$

In other words the operator Ψ transforms upper bounds for the stability number into lower bounds for the chromatic number. An interesting bound for $\alpha(\cdot)$ from the computational point of view is the graph parameter $\ell(\cdot)$ introduced by Laurent [21] as a relaxation of the second order bound in Lasserre's hierarchy for $\alpha(\cdot)$ (see [19, 21]). Two hierarchies for the chromatic number, related to Lasserre's hierarchy for $\alpha(\cdot)$, are studied in [17], as well as two bounds $\psi(\cdot)$ and $\Psi_\ell(\cdot)$ related to the parameter $\ell(\cdot)$. See section 2.2 for the precise definition of the parameters ℓ, ψ, and Ψ_ℓ.

In the present paper we investigate how to compute the bounds $\psi(\cdot)$ and $\Psi_\ell(\cdot)$ for Hamming graphs and for Kneser graphs. Coloring Hamming graphs is of interest, e.g., to the Borsuk problem (see [33]), and the chromatic number of Kneser graphs was computed in the celebrated paper [23] of Lovász by using topological methods; see, e.g., [25] for a study of topological lower bounds for the chromatic number. The Hamming graph $G = H(n, \mathcal{D})$ has node set $V(G) = \{0,1\}^n$, with an edge uv if the Hamming distance between u and v lies in the given set $\mathcal{D} \subseteq \{1, \ldots, n\}$. For $n \geq 2r$, the Kneser graph $K(n, r)$ is the subgraph of $H(n, \{2r\})$ induced by the set of words $u \in \{0,1\}^n$ with weight $\sum_{i=1}^n u_i = r$. The Hamming graph has a large automorphism group which enables us to block-diagonalize and reformulate the programs for $\psi(G)$ and $\Psi_\ell(G)$ in such a way that they involve $O(n)$ matrices of size $O(n)$ (instead of $2^n = |V(G)|$). As a crucial ingredient we use the block-diagonalization for the Terwilliger algebra given by Schrijver [31]. We also use this technique, which was extended to constant-weight codes in [31], for computing the bound $\Psi_\ell(\cdot)$ for Kneser graphs. For Kneser graphs, the bound $\psi(\cdot)$ coincides with the fractional chromatic number (see section 4), but, as will be seen in Table 2, $\Psi_\ell(K(n, r))$ can go beyond the fractional chromatic number. We report experimental results for Hamming and Kneser graphs in Tables 1 and 2. For some instances, the parameter $\psi(G)$ improves substantially the theta number $\bar{\vartheta}(G)$, and adding nonnegativity may also help; moreover, while $\Psi_\ell(G)$ hardly improves upon $\psi(G)$ for Hamming graphs, it does give an improvement for Kneser graphs.

Finally we introduce a further variation $\psi_K(G)$ of our bounds (where K is a clique in G), which can be especially useful for graphs without apparent symmetries. By using a simple block-diagonalization argument, $\psi_K(G)$ can be formulated via a semidefinite program involving $|K|$ matrices of size $|V(G)|$ and one matrix of size $|V(G)|+1$. The bound $\psi_K(G)$ is bounded above by the fractional chromatic number $\chi^*(G)$. We report experimental results on some DIMACS benchmark instances. To the best of our knowledge, our lower bound improves the best known lower bound in the literature for several instances of DSJC and DSJR graphs, sometimes substantially. Moreover, for the two instances $G =$ DSJC125.9 and DSJR500.1c, we can determine the exact value of the chromatic number $\chi(G)$, since our lower bound matches the known upper bound for $\chi(G)$. This indicates that the bound ψ_K can be quite strong for random graphs, despite the fact that it remains below the fractional chromatic number. Moreover, we observed experimentally that adding nonnegativity constraints to the formulation of ψ_K does not help for the DSJC instances, which is similar to the observation made in [9] that strengthening the theta number with nonnegativity does not help for random graphs.

More details about the results of this paper can also be found in [16].

Contents of the paper. In section 2 we recall the definitions of the graph parameters $\ell(\cdot)$, $\psi(\cdot)$, and $\Psi_\ell(\cdot)$ and their main properties; we show how symmetry in the semidefinite programming formulations and in the graph can be exploited to (sometimes dramatically) reduce the sizes of the semidefinite programs defining these bounds. Section 3 is devoted to the computation of the bounds for Hamming graphs; we describe how to block-diagonalize the matrices in the semidefinite programs and report computational experiments. In section 4 we focus on the graph parameter $\Psi_\ell(\cdot)$ for Kneser graphs; we present the block-diagonalization of the matrices and conclude the section with computational results. We describe in section 5 the new lower bound $\psi_K(\cdot)$, which we test on some DIMACS benchmark graphs.

Notation. Given a graph $G = (V, E)$, $\overline{G}$ denotes its complementary graph whose edges are the pairs $uv \notin E(G)$ $(u, v \in V(G),\ u \neq v)$. Given a graph parameter $\beta(\cdot)$, $\overline{\beta}(\cdot)$ is the graph parameter defined by $\overline{\beta}(G) := \beta(\overline{G})$ for any graph G. For two graphs G and G', their Cartesian product $G\square G'$ has node set $V(G) \times V(G')$, with two nodes uu', $vv' \in V(G) \times V(G')$ being adjacent in $G\square G'$ if and only if ($u = v$ and $u'v' \in E(G')$) or ($uv \in E(G)$ and $u' = v'$). For an integer $t \geq 1$, K_t is the complete graph on t nodes. We also set $G_t = K_t\square G$ as a shorthand notation for the Cartesian product of G and K_t.

Throughout, the letters $\mathbf{I}$, $\mathbf{J}$, and e denote, respectively, the identity matrix, the all-ones matrix, and the all-ones vector (of suitable size); $\mathbb{N}$ is the set of nonnegative integers. For matrices A and A' indexed, respectively, by $I \times J$ and $I' \times J'$, their tensor product $A \otimes A'$ is the matrix indexed by $(I \times I') \times (J \times J')$, with $(A \otimes A')_{(i,i'),(j,j')} := A_{i,j}B_{i',j'}$. Moreover, the notation $A \succeq 0$ means that A is a symmetric positive semidefinite matrix.

Given a finite set V, $\mathcal{P}(V)$ denotes the collection of all subsets of V. Given an integer r, set $\mathcal{P}_r(V) := \{I \in \mathcal{P}(V) \mid |I| \leq r\}$; in particular, $\mathcal{P}_1(V) = \{\emptyset, \{i\}\ (i \in V)\}$. Sometimes (e.g., when dealing with Hamming graphs) we deal with the collection $\mathcal{P}_1(V)$, where $V = \mathcal{P}(N)$, and $N = \{1, \ldots, n\}$; then $\mathcal{P}_1(V)$ contains $\emptyset$ (the empty subset of V) and $\{\emptyset\}$ (the singleton subset of V consisting of the empty subset of N). To avoid confusion we use the symbol $\mathbf{0}$ to denote the empty subset of V, so that $\mathcal{P}_1(V) = \{\mathbf{0}, \{i\}\ (i \in V)\}$. We sometimes identify $\mathcal{P}_1(V) \setminus \{\mathbf{0}\}$ with V; i.e., we

write $\{i\}$ as i and $\{i,j\}$ as ij, and, given a vector $x \in \mathbb{R}^{\mathcal{P}(V)}$, we also set $x_i := x_{\{i\}}$, $x_{ij} := x_{\{i,j\}}$, $x_{ijk} := x_{\{i,j,k\}}$ (for $i,j,k \in V$), etc.

Let V be a finite set, and let $\mathcal{G}$ be a subgroup of $\mathrm{Sym}(V)$, the group of permutations of V, also denoted as $\mathrm{Sym}(n)$ if $|V| = n$. Then $\mathcal{G}$ acts on $\mathcal{P}(V)$ by letting $\sigma(I) := \{\sigma(i) \mid i \in I\}$ for $I \subseteq V$, $\sigma \in \mathcal{G}$. Moreover, $\mathcal{G}$ acts on vectors and matrices indexed by $\mathcal{P}_r(V)$, by letting $\sigma(x) := (x_{\sigma(I)})_{I \in \mathcal{P}_r(V)}$, $\sigma(M) := (M_{\sigma(I),\sigma(J)})_{I,J \in \mathcal{P}_r(V)}$ for $x \in \mathbb{R}^{\mathcal{P}_r(V)}$, $M \in \mathbb{R}^{\mathcal{P}_r(V) \times \mathcal{P}_r(V)}$, and $\sigma \in \mathcal{G}$. One says that M is invariant under the action of $\mathcal{G}$ if $\sigma(M) = M$ for all $\sigma \in \mathcal{G}$; then the matrix $\frac{1}{|\mathcal{G}|!} \sum_{\sigma \in \mathcal{G}} \sigma(M)$, the "symmetrization" of M obtained by applying the Reynolds operator, is invariant under the action of $\mathcal{G}$. The analogue statement holds for vectors. A semidefinite program is said to be invariant under the action of $\mathcal{G}$ if, for any feasible matrix X and any $\sigma \in \mathcal{G}$, the matrix $\sigma(X)$ is again feasible with the same objective value; then the optimum value of the program remains unchanged if we restrict to invariant feasible solutions, and, in particular, there is an invariant optimal solution.

The automorphism group $\mathrm{Aut}(G)$ of a graph $G = (V,E)$ consists of all $\sigma \in \mathrm{Sym}(V)$ preserving the set of edges. G is said to be vertex-transitive when, given any two nodes $i,j \in V$, there exists $\sigma \in \mathrm{Aut}(G)$, for which $\sigma(i) = j$. For instance, for the graph $G_t = K_t \square G$, $\mathrm{Sym}(t) \times \mathrm{Aut}(G) \subseteq \mathrm{Aut}(G_t)$, where $(\tau,\sigma) \in \mathrm{Sym}(t) \times \mathrm{Aut}(G)$ acts on $V(G_t)$ (and thus on $\mathcal{P}_r(V(G_t))$ for $r \in \mathbb{N}$) by $(\tau,\sigma)(p,i) = (\tau(p),\sigma(i))$ for $(p,i) \in V(K_t) \times V(G)$. We will deal in this paper with semidefinite programs involving matrices indexed by $\mathcal{P}_r(V(G_t))$, which are invariant under this action of $\mathrm{Sym}(t) \times \mathrm{Aut}(G)$.

2. Graph parameters.

2.1. Classic bounds. We recall here some classic bounds for the chromatic number $\chi(G)$ of a graph $G = (V,E)$. Throughout section 2, $V = V(G)$ is the node set of graph G and $n := |V(G)|$. (For details see, e.g., [17, 22, 30].)

- The *fractional chromatic number of* G:

$$\chi^*(G) := \max\ e^T x \ \text{ s.t. } \sum_{i \in S} x_i \le 1 \ (S \text{ stable}), \quad x \in \mathbb{R}^V_+. \tag{2.1}$$

It is well known (and easy to verify) that $\omega(G) \le \chi^*(G) \le \chi(G)$, and

$$\alpha(G)\chi^*(G) \ge |V(G)| \ \text{ with equality when } G \text{ is vertex-transitive.} \tag{2.2}$$

- *Lovász's theta number* (introduced in [24]):

$$\begin{aligned} \overline{\vartheta}(G) = \vartheta(\overline{G}) := \quad & \max \quad e^T Y e \\ & \text{s.t.} \quad \sum_{i \in V} Y_{ii} = 1, \\ & \qquad Y_{ij} = 0 \ \ (ij \in E(\overline{G})), \\ & \qquad Y \succeq 0, \end{aligned} \tag{2.3}$$

where Y is a symmetric matrix indexed by V. For a later purpose we recall the following equivalent formulation (cf., e.g., [15, Theorem 9.3.12]):

$$\begin{aligned} \overline{\vartheta}(G) = \quad & \min \quad X_{\mathbf{00}} \\ & \text{s.t.} \quad X_{ii} = X_{\mathbf{0}i} \ (i \in V), \\ & \qquad X_{ij} = 0 \ (ij \in E(G)), \\ & \qquad X \succeq 0, \end{aligned} \tag{2.4}$$

where the matrix variable X is indexed by the set $\mathcal{P}_1(V) = V \cup \{\mathbf{0}\}$. Lovász [24] proved the following analogue of (2.2) for the pair $(\vartheta, \overline{\vartheta})$:

$$\vartheta(G)\overline{\vartheta}(G) \geq |V(G)| \text{ with equality when } G \text{ is vertex-transitive.} \tag{2.5}$$

• *Szegedy's number* was first defined in [32]. We present the following equivalent formulation from [17]:

$$\begin{array}{rlll} \overline{\vartheta^+}(G) = \vartheta^+(\overline{G}) = & \min & X_{\mathbf{00}} \\ & \text{s.t.} & X_{ii} = X_{\mathbf{0}i} \ (i \in V), \\ & & X_{ij} = 0 \ (ij \in E(G)), \\ & & X \geq 0, \ X \succeq 0. \end{array} \tag{2.6}$$

The above parameters satisfy

$$\omega(G) \leq \overline{\vartheta}(G) \leq \overline{\vartheta^+}(G) \leq \chi^*(G) \leq \chi(G).$$

2.2. The bounds ℓ, ψ, and Ψ_ℓ. We review here the graph parameters $\ell(\cdot)$ proposed in [21] and $\psi(\cdot)$ and $\Psi_\ell(\cdot)$ proposed in [17]; for details see also [16]. For a subset $S \subseteq V$ and an integer $r \geq 1$, define the vectors $\chi^S \in \{0,1\}^V$, with ith entry 1 if and only if $i \in S$ (for $i \in V$), and $\chi^{S,r} \in \{0,1\}^{\mathcal{P}_r(V)}$, with Ith entry 1 if and only if $I \subseteq S$ (for $I \in \mathcal{P}_r(V)$). Given a vector $x = (x_I)_{I \in \mathcal{P}_{2r}(V)}$, consider the matrix:

$$M_r(x) := (x_{I \cup J})_{I,J \in \mathcal{P}_r(V)}$$

known as the *(combinatorial) moment matrix* of x of order r. Consider the programs:

$$\text{las}^{(r)}(G) := \max \sum_{i \in V} x_i \ \text{ s.t. } M_r(x) \succeq 0, \ x_{\mathbf{0}} = 1, \ x_{ij} = 0 \ (ij \in E), \tag{2.7}$$

$$\psi^{(r)}(G) := \min \ t \ \text{ s.t. } M_r(x) \succeq 0, \ x_{\mathbf{0}} = t, \ x_i = 1 \, (i \in V), \ x_{ij} = 0 \ (ij \in E), \tag{2.8}$$

where the variable x is indexed by $\mathcal{P}_{2r}(V)$. Note that the variable t can be avoided in (2.8) by replacing t by $x_{\mathbf{0}}$ in the objective function. We choose this formulation to emphasize the analogy with the formulations (2.13), (2.17), and (5.1) below. The above two programs were studied, respectively, in [19, 20] and in [17]. In particular, the following holds:

$$\alpha(G) = \text{las}^{(\alpha(G))} \leq \cdots \leq \text{las}^{(r+1)}(G) \leq \text{las}^{(r)}(G) \leq \cdots \leq \text{las}^{(1)}(G) = \vartheta(G), \tag{2.9}$$

$$\vartheta(\overline{G}) = \psi^{(1)}(G) \leq \cdots \leq \psi^{(r)}(G) \leq \psi^{(r+1)}(G) \leq \cdots \leq \psi^{(\alpha(G))}(G) = \chi^*(G), \tag{2.10}$$

$$\psi^{(r)}(G)\text{las}^{(r)}(G) \geq |V(G)| \text{ with equality if } G \text{ is vertex-transitive.} \tag{2.11}$$

Thus the parameters $\text{las}^{(r)}(G)$ (for $r = 1, \ldots, \alpha(G)$) create a hierarchy of upper bounds for the stability number, while the parameters $\psi^{(r)}(G)$ create a hierarchy of lower bounds for the fractional coloring number. Theoretically, the parameters $\text{las}^{(r)}(G)$ and $\psi^{(r)}(G)$ can be computed to any precision in polynomial time for fixed r, since the semidefinite programs (2.7) and (2.8) involve matrices of size $O(n^r)$. On the other hand, in practice, we are not able to compute $\text{las}^{(2)}(G)$ or $\psi^{(2)}(G)$ for "interesting" graphs, that is, for graphs of reasonably large size. For this reason some variations of the parameters $\text{las}^{(2)}(G)$ and $\psi^{(2)}(G)$ were proposed in [17, 21]. The idea is to consider, instead of the full moment matrix of order 2, a number of principal submatrices of

it. Given $h \in V$, let $M_2(h;x)$ denote the principal submatrix of $M_2(x)$ indexed by the subset $\mathcal{P}_1(V) \cup \{\{h,i\} \mid i \in V\}$ of $\mathcal{P}_2(V)$. Thus in order to define the matrices $M_2(h;x)$ for all $h \in V$, one needs only the components of x indexed by $\mathcal{P}_3(V)$. Following [17, 21], define the upper bound for the stability number $\alpha(G)$:

$$\ell(G) := \max \sum_{i \in V} x_i \ \text{ s.t. } M_2(h;x) \succeq 0 \ (h \in V),\ x_{\mathbf{0}} = 1,\ x_{ij} = 0 \ (ij \in E(G)), \tag{2.12}$$

and the lower bound for the fractional coloring number $\chi^*(G)$:

$$\begin{aligned} \psi(G) := \min\ t \ \text{ s.t. } \quad & M_2(h;x) \succeq 0 \ (h \in V),\ x_{ij} = 0 \ (ij \in E(G)), \\ & x_{\mathbf{0}} = t,\ x_i = 1 \ (i \in V), \end{aligned} \tag{2.13}$$

where the variable x is indexed by $\mathcal{P}_3(V)$. For the parameter $\ell(G)$ we have (see [21])

$$\alpha(G) \le \mathrm{las}^{(2)}(G) \le \ell(G) \le \mathrm{las}^{(1)}(G) = \vartheta(G) \le \overline{\chi}(G), \tag{2.14}$$

while $\psi(G)$ satisfies (see [17])

$$\overline{\vartheta^+}(G) \le \psi(G) \le \psi^{(2)}(G). \tag{2.15}$$

They also satisfy an inequality similar to (2.11), namely,

$$\psi(G)\ell(G) \ge |V(G)| \text{ with equality if } G \text{ is vertex-transitive.} \tag{2.16}$$

As $\alpha(\cdot) \le \ell(\cdot) \le \overline{\chi}(\cdot)$ (by (2.14)), we can apply the operator Ψ from (1.2) to $\ell(\cdot)$ and obtain the lower bound $\Psi_\ell(G)$ for $\chi(G)$, defined as

$$\Psi_\ell(G) = \min_{t \in \mathbb{N}} t \ \text{ s.t. } \ell(G_t) = n. \tag{2.17}$$

The parameter $\ell(G_t)$ is defined via the program

$$\begin{aligned} \ell(G_t) = \max \sum_{u \in V(G_t)} y_u \ \text{ s.t. } \quad & M_2(u;y) \succeq 0 \ (u \in V(G_t)), \\ & y_{\mathbf{0}} = 1,\ y_{uv} = 0 \ (uv \in E(G_t)), \end{aligned} \tag{2.18}$$

where the variable y is indexed by $\mathcal{P}_3(V(G_t))$. (Recall that $G_t = K_t \square G$.) Finally, the two parameters $\psi(G)$ and $\Psi_\ell(G)$ were compared in [17], where the following relation is shown:

$$\overline{\vartheta}(G) \le \psi(G) \le \Psi_\ell(G) \le \chi(G). \tag{2.19}$$

Let us finally note that one can easily strengthen the bounds $\ell(G)$, $\psi(G)$, and $\Psi_\ell(G)$, e.g., by requiring nonnegativity[1] of the variables. Let $\ell_{\ge 0}(G)$ (resp., $\psi_{\ge 0}(G)$) denote the variation of $\ell(G)$ (resp., $\psi(G)$) obtained by adding the condition $x \ge 0$ to

[1]Note, however, that the condition $x_{ij} \ge 0 \ \ \forall i,j \in V$ already automatically holds in (2.12) and (2.13), since it is implied by $M_2(h;x) \succeq 0 \ \forall h \in V$ (as x_{hi} occurs as a diagonal entry of $M_2(h;x)$). Analogously, $y_{uv} \ge 0 \ \ \forall u,v \in V(G_t)$ automatically holds in (2.18).

(2.12) (resp., (2.13)); we have again $\psi_{\geq 0}(G)\ell_{\geq 0}(G) = |V(G)|$ when G is vertex-transitive. Define accordingly $\Psi_{\ell_{\geq 0}}(G)$, which amounts to requiring $y \geq 0$ in (2.18).

2.3. Exploiting symmetry to compute the bounds ℓ, ψ, and Ψ_ℓ. We group here some observations about the complexity of computing the graph parameters $\ell(\cdot)$, $\psi(\cdot)$, and $\Psi_\ell(\cdot)$. We show how one can exploit symmetry, present in the structure of the matrices involved in the programs defining the parameters or in the graph instance, in order to reduce the size of the programs. This symmetry reduction is a crucial step as it allows reformulating the parameters via more compact programs. In this way we will be able to compute the graph parameters for certain large graphs (with as many as 2^{20} nodes for certain Hamming graphs), a task that would obviously be out of reach without applying this symmetry reduction.

We begin with observing that the matrix $M_2(h;x)$, used in definitions (2.12) and (2.13), has a special block structure, whose symmetry can be exploited to "block-diagonalize" it. Recall that $M_2(h;x)$ is indexed by the set $\mathcal{P}_1(V) \cup \{\{h,i\} \mid i \in V\} = \{\mathbf{0}\} \cup \{\{i\} \mid i \in V\} \cup \{\{h,i\} \mid i \in V\}$. Here we keep the two occurrences of the singleton $\{h\}$ in the index set, occurring first as $\{i\}$ for $i = h$ and second as $\{i,h\}$ for $i = h$. Thus, the index set of $M_2(h;x)$ is partitioned into $\{\mathbf{0}\}$ and two copies of V.

LEMMA 2.1. *With respect to this partition of its index set, the matrix $M_2(h;x)$ has the block form:*

$$M_2(h;x) = \begin{pmatrix} a & c^T & d^T \\ c & C & D \\ d & D & D \end{pmatrix}, \tag{2.20}$$

where $a = x_{\mathbf{0}}$, $c_i = x_i$, $d_i = x_{hi}$ $(i \in V)$, $C_{ij} = x_{ij}$, and $D_{ij} = x_{hij}$ $(i,j \in V)$. Then

$$M_2(h;x) \succeq 0 \Longleftrightarrow \begin{pmatrix} a - c_h & c^T - d^T \\ c - d & C - D \end{pmatrix} \succeq 0 \quad \text{and} \quad D \succeq 0. \tag{2.21}$$

Proof. The form (2.20) follows directly from the definition of $M_2(h;x)$. To show (2.21), observe that the row of $M_2(h;x)$ indexed by $\{h\}$ has the form (c_h, d^T, d^T). Indeed, for $i,j \in V$, $C_{ij} = x_{\{i,j\}}$, $D_{ij} = x_{\{h,i,j\}}$, $c_j = x_j$, and $d_j = x_{\{h,j\}}$, implying that $C_{hj} = D_{hj} = d_j$. As in [21], we perform some row/column manipulation on $M_2(h;x)$ to show (2.21). Say the second row/column of $M_2(h;x)$ is indexed by $\{h\}$, i.e., h comes first when listing the elements of V. Then

$$U_1^T M_2(h;x) U_1 = \begin{pmatrix} a - c_h & c^T - d^T & 0 \\ c - d & C & D \\ 0 & D & D \end{pmatrix}, \quad \text{setting } U_1 := \begin{pmatrix} 1 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & \mathbf{I} \end{pmatrix},$$

where $\mathbf{I}$ is the identity matrix of order $2n-1$ ($n = |V|$). Next,

$$U_2^T (U_1^T M_2(h;x) U_1) U_2 = \begin{pmatrix} a - c_h & c^T - d^T & 0 \\ c - d & C - D & 0 \\ 0 & 0 & D \end{pmatrix}, \quad \text{setting } U_2 := \begin{pmatrix} 1 & 0 & 0 \\ 0 & \mathbf{I} & 0 \\ 0 & -\mathbf{I} & \mathbf{I} \end{pmatrix},$$

where $\mathbf{I}$ has order n. □

Hence, in (2.12) and (2.13), we may replace each constraint $M_2(h;x) \succeq 0$ (which involves a matrix of size $2n+1$) by two constraints involving matrices of sizes $n+1$ and n.

We now consider symmetries present in the graph instance G. Observe that the program (2.12) (or (2.13)) is invariant under the action of $\mathrm{Aut}(G)$. Hence one may assume that the variable x is invariant under the action of $\mathrm{Aut}(G)$. Therefore, when G is vertex-transitive, it suffices to require the condition $M_2(h;x) \succeq 0$ for *one* choice of $h \in V$ (instead of for *all* $h \in V$), and thus $\ell(G)$ and $\psi(G)$ can be computed via a semidefinite program involving two linear matrix inequality (LMIs) matrices of sizes $n+1$, n and with $O(n^2)$ variables.

We now turn to the graph parameter $\Psi_\ell(G)$. In order to determine $\Psi_\ell(G)$, we need to compute the parameter $\ell(G_t) = \ell(K_t \square G)$ from (2.18) (for several queries of $t \in \mathbb{N}$). As was just observed above, the program defining $\ell(G_t)$ is invariant under the action of $\mathrm{Aut}(G_t)$ thus in particular under the action of $\mathrm{Sym}(t) \times \mathrm{Aut}(G)$ or simply of $\mathrm{Sym}(t)$. In particular, in program (2.18), one may assume that y is invariant under the action of $\mathrm{Sym}(t)$. Moreover, it suffices to require the condition $M_2(u;y) \succeq 0$ for all $u \in V_1$ instead of for all $u \in V(G_t)$; here $V_1 = \{1i \mid i \in V\}$ denotes the "first layer" of the node set $V(G_t) = \{pi \mid p = 1, \ldots, t,\ i \in V\}$ of G_t. Furthermore, when G is vertex-transitive, it suffices to require $M_2(u;y) \succeq 0$ for *one* choice of $u \in V_1$ instead of for *all* $u \in V_1$.

We now show, by using the invariance of y under the action of $\mathrm{Sym}(t)$, that the matrix $M_2(u;y)$ has a special block structure, whose symmetry can be used to block-diagonalize it. To begin with, with respect to the partition $\{\mathbf{0}\} \cup \{\{v\} \mid v \in V(G_t)\} \cup \{\{u,v\} \mid v \in V(G_t)\}$ of its index set, the matrix $M_2(u;y)$ has the block form shown in (2.20) with a, c, d, C, and D being now defined in terms of y (instead of x). In view of (2.21), we have

$$M_2(u;y) \succeq 0 \Longleftrightarrow \begin{pmatrix} y_{\mathbf{0}} - y_u & c^T - d^T \\ c - d & C - D \end{pmatrix} \succeq 0 \ \text{ and } \ D \succeq 0. \tag{2.22}$$

Next we observe that the invariance of y under $\mathrm{Sym}(t)$ implies a special block structure for the matrices C and D.

LEMMA 2.2. *Consider the partition $V(G_t) = V_1 \cup \cdots \cup V_t$ of the node set of graph G_t, where $V_p := \{pi \mid i \in V\}$ for $p = 1, \ldots, t$. With respect to this partition, the matrices C and D have the block form:*

$$C = \begin{pmatrix} A^1 & A^2 & \cdots & A^2 \\ A^2 & A^1 & \cdots & A^2 \\ \vdots & \vdots & \ddots & \vdots \\ A^2 & \cdots & \cdots & A^1 \end{pmatrix}, \qquad D = \begin{pmatrix} B^1 & B^2 & B^2 & \cdots & B^2 \\ (B^2)^T & B^3 & B^4 & \cdots & B^4 \\ (B^2)^T & B^4 & B^3 & \cdots & B^4 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ (B^2)^T & B^4 & \cdots & \cdots & B^3 \end{pmatrix}, \tag{2.23}$$

where[2] *$A^1, \ldots, B^4 \in \mathbb{R}^{n \times n}$. Moreover, by setting $a_1 := \mathrm{diag}(A^1)$, $b_1 := \mathrm{diag}(B^1)$, and $b_3 := \mathrm{diag}(B^3)$, we have $c = [a_1^T, \ldots, a_1^T]^T$ and $d = [b_1^T\, b_3^T\, b_3^T, \ldots, b_3^T]^T$.*

Proof. Consider $i, j \in V$ and $p, q, p', q' \in \{1, \ldots, t\}$, with $p = q$ if and only if $p' = q'$. Then $C_{pi,qj} = y_{\{pi,qj\}} = y_{\{p'i,q'j\}} = C_{p'i,q'j}$; indeed, as there exists $\sigma \in \mathrm{Sym}(t)$ mapping $\{p,q\}$ to $\{p',q'\}$, the equality $y_{\{pi,qj\}} = y_{\{p'i,q'j\}}$ follows from the fact that y is invariant under the action of $\mathrm{Sym}(t)$. This shows that C has the form indicated in (2.23); the argument is analogous for matrix D. ∎

[2]Here A^i or B^i should not be interpreted as powers of A or B, as i is not an exponent but just an upper index.

To fix ideas, set $u = 1h \in V_1$ (where $h \in V$ is a given node of G). Then the entries of $A^1, \ldots, B^4$ are given by

$$\begin{aligned} A^1_{ij} = y_{\{1i,1j\}},\ A^2_{ij} = y_{\{1i,2j\}},\ B^1_{ij} = y_{\{1i,1h,1j\}},\\ B^2_{ij} = y_{\{1i,1h,2j\}},\ B^3_{ij} = y_{\{2i,1h,2j\}},\ B^4_{ij} = y_{\{2i,1h,3j\}} \end{aligned} \tag{2.24}$$

for $i, j \in V$. (Recall that $y_{\{1i,1j\}} = y_{\{pi,pj\}}$, $y_{\{1i,2j\}} = y_{\{pi,qj\}}$, and $y_{\{1i,2j,3h\}} = y_{\{pi,qj,rh\}}$ for any distinct $p, q, r \in \{1, \ldots, t\}$ since y is invariant under the action of $\mathrm{Sym}(t)$.) Moreover, the edge constraints $y_{uv} = 0$ (for $uv \in E(G_t)$) in (2.18) can be reformulated as

$$\begin{aligned} &A^1_{ij} = 0 \ \text{ if } \ ij \in E(G),\\ &B^1_{ij} = 0 \ \text{ if } \ \{i,j,h\} \text{ contains an edge of } G,\\ &B^2_{ij} = 0 \ \text{ if } \ hi \in E(G) \text{ or } j \in \{i,h\},\\ &B^3_{ij} = 0 \ \text{ if } \ ij \in E(G) \text{ or if } h \in \{i,j\},\\ &B^4_{ij} = 0 \ \text{ if } \ h \in \{i,j\},\\ &\mathrm{diag}(A^2) = \mathrm{diag}(B^2) = \mathrm{diag}(B^4) = 0 \end{aligned} \tag{2.25}$$

for distinct $i, j \in V$.

The next lemma indicates how one can further block-diagonalize the two matrices appearing at the right-hand side of the equivalence in (2.22).

LEMMA 2.3. *We have*

$$D \succeq 0 \Longleftrightarrow \begin{pmatrix} B^1 & (t-1)B^2 \\ (t-1)(B^2)^T & (t-1)B^3 + (t-1)(t-2)B^4 \end{pmatrix},\ B^3 - B^4 \succeq 0.$$

Moreover,

$$\begin{pmatrix} y_{\mathbf{0}} - y_u & c^T - d^T \\ c - d & C - D \end{pmatrix} \succeq 0 \Longleftrightarrow\ A^1 - B^3 - A^2 + B^4 \succeq 0 \ \ \textit{and}$$

$$\begin{pmatrix} y_{\mathbf{0}} - y_u & a_1^T - b_1^T & (t-1)(a_1^T - b_3^T) \\ & A^1 - B^1 & (t-1)(A^2 - B^2) \\ & & (t-1)(A^1 - B^3) + (t-1)(t-2)(A^2 - B^4) \end{pmatrix} \succeq 0.$$

(We wrote only the upper triangular part in the above (symmetric) matrix.)

Proof. Consider the orthogonal matrices

$$M := \begin{pmatrix} \mathbf{I} & 0 \\ 0 & U_{t-1} \end{pmatrix}, \qquad N := \begin{pmatrix} 1 & 0 \\ 0 & M \end{pmatrix},$$

where $\mathbf{I}$ is the identity matrix of order n and U_{t-1} is defined as follows. U_{t-1} is a $(t-1) \times (t-1)$ block matrix where, for $p, q = 1, \ldots, t-1$, its (p,q)th block U^{pq}_{t-1} is the $n \times n$ matrix defined as

$$U^{pq}_{t-1} := \begin{cases} \frac{1}{\sqrt{t-1}}\mathbf{I} & \text{if } p = 1 \text{ or } q = 1,\\ \left(\frac{1}{\sqrt{t-1}+t-1} - 1\right)\mathbf{I} & \text{if } p = q \geq 2,\\ \frac{1}{\sqrt{t-1}+t-1}\mathbf{I} & \text{otherwise.} \end{cases} \tag{2.26}$$

Notice that U_{t-1} is symmetric and orthogonal, i.e., $U_{t-1}(U_{t-1})^T = \mathbf{I}$. A simple calculation shows that

$$MDM = \begin{pmatrix} B^1 & \sqrt{t-1}B^2 & 0 & \dots & 0 \\ \sqrt{t-1}(B_2)^T & B^3 + (t-2)B^4 & 0 & \dots & 0 \\ 0 & 0 & B^3 - B^4 & & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & B^3 - B^4 \end{pmatrix}.$$

The first assertion of the lemma now follows after multiplying the second row/column block by $\sqrt{t-1}$. Next we have

$$N \begin{pmatrix} y_{\mathbf{0}} - y_u & c^T - d^T \\ c - d & C - D \end{pmatrix} N = \begin{pmatrix} y_{\mathbf{0}} - y_u & (c-d)^T M \\ M(c-d) & M(C-D)M \end{pmatrix}.$$

As the matrix $C - D$ has the same type of block shape as D, we deduce from the above that $M(C - D)M$ is block-diagonal. More precisely, the first diagonal block has the form

$$\begin{pmatrix} A^1 - B^1 & \sqrt{t-1}(A^2 - B^2) \\ \sqrt{t-1}(A^2 - B^2)^T & (A^1 - B^3) + (t-2)(A^2 - B^4) \end{pmatrix},$$

and the remaining $t - 2$ diagonal blocks are all equal to $A^1 - B^3 - A^2 + B^4$. One can moreover verify that $(c-d)^T M = \big(a_1^T - b_1^T, \sqrt{t-1}(a_1^T - b_3^T), 0 \dots 0\big)$. From this follows the second assertion of the lemma. □

In summary, we have obtained the following more compact semidefinite program for the parameter $\ell(G_t)$:

(2.27)

$$\begin{aligned} \ell(G_t) = \max\ & te^T a_1 \ \text{ s.t. } a_1 = \operatorname{diag}(A^1),\ b_1 = \operatorname{diag}(B^1),\ b_3 = \operatorname{diag}(B^3) \in \mathbb{R}^n, \\ & A^1, A^2, B^1, B^2, B^3, B^4 \in \mathbb{R}^{n \times n} \text{ satisfy (2.25) and} \\ & \begin{pmatrix} 1 - (a_1)_h & a_1^T - b_1^T & (t-1)(a_1^T - b_3^T) \\ & A^1 - B^1 & (t-1)(A^2 - B^2) \\ & & (t-1)(A^1 - B^3) + (t-1)(t-2)(A^2 - B^4) \end{pmatrix} \succeq 0, \\ & \begin{pmatrix} B^1 & (t-1)B^2 \\ & (t-1)B^3 + (t-1)(t-2)B^4 \end{pmatrix} \succeq 0, \\ & A^1 - A^2 - B^3 + B^4 \succeq 0, \\ & B^3 - B^4 \succeq 0. \end{aligned}$$

This formulation applies when G is vertex-transitive; here h is any fixed node of G. Hence $\Psi_\ell(G)$ can be obtained by computing $\ell(G_t)$ for $O(\log n)$ queries of the parameter t (see [17]) and the computation of each $\ell(G_t)$ is via an SDP involving four LMIs matrices of size $2n + 1$, $2n$, n, and n, respectively. The above reductions obviously apply to the stronger bound $\Psi_{\ell_{\geq 0}}$ obtained by adding nonnegativity, i.e., by adding the constraints $A^1, \dots, B^4 \geq 0$ in (2.27).

3. Bounds for Hamming graphs. We indicate here how to compute the parameters $\psi(G)$ and $\Psi_\ell(G)$ when G is a Hamming graph. Given an integer $n \geq 1$ and $\mathcal{D} \subseteq N := \{1, \dots, n\}$, G is the graph $H(n, \mathcal{D})$ with node set $V(G) := \mathcal{P}(N)$ and with an edge (I, J) if $|I \triangle J| \in \mathcal{D}$ (for $I, J \in \mathcal{P}(N)$). Thus we now have $|V(G)| = 2^n$.

As G is vertex-transitive, we can use the program (2.27). As the program (2.27) involves matrices of size $O(2^n)$, it cannot be solved directly for interesting values of n. However, one can use the fact that the Hamming graph $G = H(n, \mathcal{D})$ has a large automorphism group for reducing the size of the matrices $A^1, \dots, B^4$ involved in the program (2.27). Each permutation $\sigma \in \mathrm{Sym}(n)$ induces an automorphism of G by letting $\sigma(I) := \{\sigma(i) \mid i \in I\}$ for $I \in \mathcal{P}(N)$, and, for any $K \in \mathcal{P}(N)$, the *switching mapping* s_K defined by $s_K(I) := I \triangle K$ (for $I \in \mathcal{P}(N)$) is also an automorphism of G. Then $\mathrm{Aut}(G) = \{\sigma s_K \mid \sigma \in \mathrm{Sym}(n),\ K \in \mathcal{P}(N)\}$ and $|\mathrm{Aut}(G)| = n!2^n$.

It turns out that the matrices $A^1, \dots, B^4$ appearing in (2.27) belong to the Terwilliger algebra of the Hamming graph. By using the explicit block-diagonalization of the Terwilliger algebra, presented by Schrijver [31], we are able to block-diagonalize the matrices in (2.27) which enables the computation of $\Psi_\ell(G)$ for $G = H(n, \mathcal{D})$ for n up to 20. We recall the details needed for our treatment in the next subsection.

3.1. The Terwilliger algebra. For $i, j, p = 0, \dots, n$, let $M^{p,n}_{i,j}$ denote the 0/1 matrix indexed by $\mathcal{P}(N)$ whose (I, J)th entry is 1 if $|I| = i$, $|J| = j$, and $|I \cap J| = p$ and equal to 0 otherwise. The set

$$\mathcal{A}_n := \left\{ \sum_{i,j,p=0}^{n} x^p_{i,j} M^{p,n}_{i,j} \mid x^p_{i,j} \in \mathbb{R} \right\}$$

is an algebra, known as the *Terwilliger algebra* of the Hamming graph. For $k = 0, \dots, n$, let M^n_k be the matrix indexed by $\mathcal{P}(N)$ whose (I, J)th entry is 1 if $|I \triangle J| = k$ and 0 otherwise. The set

$$\mathcal{B}_n := \left\{ \sum_{k=0}^{n} x_k M^n_k \mid x_k \in \mathbb{R} \right\}$$

is an algebra, known as the *Bose–Mesner algebra* of the Hamming graph. Obviously, $\mathcal{B}_n \subseteq \mathcal{A}_n$, since $M^n_k = \sum_{i,j,p \mid i+j-2p=k} M^{p,n}_{i,j}$. As is well known, $\mathcal{B}_n$ is a commutative algebra, and thus all matrices in $\mathcal{B}_n$ can be simultaneously diagonalized (cf. Delsarte [7]). The Terwilliger algebra is not commutative, and thus it cannot be diagonalized; however, it can be block-diagonalized, as explained in [31]. We recall the main result below.

Given integers $i, j, k, p = 0, \dots, n$, set

$$\beta^{p,n}_{i,j,k} := \sum_{u=0}^{n} (-1)^{p-u} \binom{u}{p} \binom{n-2k}{n-k-u} \binom{n-k-u}{i-u} \binom{n-k-u}{j-u}, \tag{3.1}$$

$$\alpha^{p,n}_{i,j,k} := \beta^{p,n}_{i,j,k} \binom{n-2k}{i-k}^{-\frac{1}{2}} \binom{n-2k}{j-k}^{-\frac{1}{2}}. \tag{3.2}$$

THEOREM 3.1 (see [31]). *For a matrix $M = \sum_{i,j,p} M^{p,n}_{i,j} x^p_{i,j}$ in the Terwilliger algebra,*

$$M \succeq 0 \Longleftrightarrow M_k := \left(\sum_p \alpha^{p,n}_{i,j,k} x^p_{i,j} \right)_{i,j=k}^{n-k} \succeq 0 \quad \text{for } k = 0, 1, \dots, \left\lfloor \frac{n}{2} \right\rfloor. \tag{3.3}$$

To show this, Schrijver [31] constructs an orthogonal matrix U having the following property:

$$U^T M U = \begin{pmatrix} \widehat{M}_0 & 0 & \dots & 0 \\ 0 & \widehat{M}_1 & \dots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & \dots & \widehat{M}_{\lfloor n/2 \rfloor} \end{pmatrix}, \quad \text{where } \widehat{M}_k = \begin{pmatrix} M_k & 0 & \dots & 0 \\ 0 & M_k & \dots & 0 \\ \vdots & \vdots & \ddots & 0 \\ 0 & 0 & \dots & M_k \end{pmatrix},$$

with block M_k being repeated $\binom{n}{k} - \binom{n}{k-1}$ times, for $k = 0, \dots, \lfloor n/2 \rfloor$.

The result extends to a block matrix whose blocks all lie in the Terwilliger algebra and which has a border of a special form. We state Lemma 3.2 for a 2×2 block matrix, but the analogous result holds obviously for any number of blocks.

LEMMA 3.2. *Let $A, B, C \in \mathcal{A}_n$, say, $A = \sum_{i,j,p} a^p_{i,j} M^{p,n}_{i,j}$, $B = \sum_{i,j,p} b^p_{i,j} M^{p,n}_{i,j}$, and $C = \sum_{i,j,p} c^p_{i,j} M^{p,n}_{i,j}$, and define accordingly*

$$A_k = \left(\sum_p \alpha^{p,n}_{i,j,k} a^p_{i,j} \right)^{n-k}_{i,j=k}, \; B_k = \left(\sum_p \alpha^{p,n}_{i,j,k} b^p_{i,j} \right)^{n-k}_{i,j=k}, \; C_k = \left(\sum_p \alpha^{p,n}_{i,j,k} c^p_{i,j} \right)^{n-k}_{i,j=k}.$$

Then

$$\begin{pmatrix} A & B \\ B^T & C \end{pmatrix} \succeq 0 \iff \begin{pmatrix} A_k & B_k \\ B_k^T & C_k \end{pmatrix} \succeq 0 \; \forall k = 0, 1, \dots, \left\lfloor \frac{n}{2} \right\rfloor.$$

Proof. The proof follows directly from the above by using the orthogonal matrix $\left(\begin{smallmatrix} U & 0 \\ 0 & U \end{smallmatrix}\right)$. ∎

LEMMA 3.3 (see Lemma 1 in [21]). *Let $M = \sum_{i,j,p=0}^n x^p_{i,j} M^{p,n}_{i,j} \in \mathcal{A}_n$, $c = \sum_{i=0}^n c_i \chi^i$, where $\chi^i \in \{0,1\}^{\mathcal{P}(N)}$ with $\chi^i_I = 1$ if $|I| = i$ (for $I \in \mathcal{P}(N)$), and $d \in \mathbb{R}$. Then*

$$\begin{pmatrix} d & c^T \\ c & M \end{pmatrix} \succeq 0 \iff \begin{cases} M_k \succeq 0 \;\; \text{for } k = 1, \dots, \left\lfloor \frac{n}{2} \right\rfloor, \\ \tilde{M}_0 := \begin{pmatrix} d & \tilde{c}^T \\ \tilde{c} & M_0 \end{pmatrix} \succeq 0 \end{cases}$$

after setting $\tilde{c}^T := (c_i \sqrt{\binom{n}{i}})_{i=0}^n$.

3.2. Compact formulation for $\psi(G)$ for Hamming graphs. As the graph $G = H(n, \mathcal{D})$ is vertex-transitive, we have $\psi(G) = \frac{2^n}{\ell(G)}$ by (2.16). It is shown in [21] how to compute the parameter $\ell(G)$ (when $\mathcal{D}$ is an interval $[1, d]$, but the reasoning is the same for any $\mathcal{D}$). The basic idea is that the matrix $M_2(h; x)$ appearing in (2.12) is a block matrix whose blocks lie in the Terwilliger algebra, and thus it can be block-diagonalized. We recall the details, directly for the parameter $\psi(G)$ from (2.13), as they will be useful for our treatment of the parameter $\Psi_\ell(G)$ in the next section.

Let x be feasible for the program (2.13). As G is vertex-transitive it suffices to require the condition $M_2(h; x) \succeq 0$ in (2.13) for *one* choice of $h \in V(G)$. Moreover, we may assume that the variable x is invariant under the action of the automorphism group of G. To fix ideas, let us choose the node $h := \emptyset$ of G (the empty subset of N). The matrix $M_2(\emptyset; x)$ has the block form

$$M_2(\emptyset; x) = \begin{pmatrix} t & e^T & b^T \\ e & A & B \\ b & B & B \end{pmatrix}, \tag{3.4}$$

where A, B, e, and b are indexed by $V(G) = \mathcal{P}(N)$, $\mathrm{diag}(A) = e$, and $\mathrm{diag}(B) = b$. By Lemma 2.1, we have

$$M_2(\emptyset; x) \succeq 0 \Longleftrightarrow \begin{pmatrix} t-1 & e^T - b^T \\ e-b & A-B \end{pmatrix} \succeq 0 \text{ and } B \succeq 0. \tag{3.5}$$

As x is invariant under the action of $\mathrm{Aut}(G)$, it follows that $A_{I,J} = x_{\{I,J\}} = x_{\{I',J'\}} = A_{I',J'}$ if $|I \triangle J| = |I' \triangle J'|$. In other words, the matrix A lies in the Bose–Mesner algebra, say,

$$A = \sum_{k=0}^{n} x_k M_k^n = \sum_{i,j,p=0}^{n} x_{i+j-2p} M_{i,j}^{p,n} \tag{3.6}$$

for some reals x_k. Moreover, $B_{I,J} = x_{\{\emptyset,I,J\}} = x_{\{\emptyset,I',J'\}} = B_{I',J'}$ if $|I'| = |I|$, $|J'| = |J|$, and $|I' \cap J'| = |I \cap J|$. In other words, the matrix B lies in the Terwilliger algebra, say,

$$B = \sum_{i,j,p=0}^{n} x_{i,j}^p M_{i,j}^{p,n} \tag{3.7}$$

for some reals $x_{i,j}^p$. The following relations link the parameters x_i and $x_{i,j}^p$.

LEMMA 3.4. *For $i, j, p = 0, \ldots, n$,*

$$\begin{aligned} &x_i = x_{0,i}^0, \\ &x_{i,j}^p = x_{j,i}^p = x_{i+j-2p,j}^{j-p} = x_{i+j-2p,i}^{i-p}, \end{aligned} \tag{3.8}$$

and the edge equations read

$$x_{i,j}^p = 0 \quad \textit{if} \quad \{i, j, i+j-2p\} \cap \mathcal{D} \neq \emptyset. \tag{3.9}$$

Proof. If $|I| = i$, then $x_i = A_{\emptyset,I} = x_{\{\emptyset,I\}} = B_{\emptyset,I} = x_{0,i}^0$. Let $|I| = i$, $|J| = j$, and $|I \cap J| = p$. Then $x_{i,j}^p = B_{I,J} = B_{J,I} = x_{j,i}^p$. Moreover, $x_{i,j}^p = B_{I,J} = x_{\{\emptyset,I,J\}} = x_{\{I,\emptyset,I\triangle J\}} = B_{I,I\triangle J} = x_{i+j-2p,i}^{i-p}$. This shows (3.8). The edge conditions read $B_{I,J} = x_{\{I,\emptyset,J\}} = 0$ if $\{|I|, |J|, |I \triangle J|\} \cap \mathcal{D} \neq \emptyset$, giving (3.9). □

We can now use the results from the previous subsection (Theorem 3.1 and Lemma 3.3) for block-diagonalizing the matrices occurring in (3.5). For $k = 0, \ldots, \lfloor n/2 \rfloor$, define the matrices

$$A_k := \left(\sum_p \alpha_{i,j,k}^{p,n} x_{0,i+j-2p}^0 \right)_{i,j=k}^{n-k}, \qquad B_k := \left(\sum_p \alpha_{i,j,k}^{p,n} x_{i,j}^p \right)_{i,j=k}^{n-k} \tag{3.10}$$

corresponding, respectively, to the matrices A, and B in (3.6) and (3.7). Define the vector

$$\tilde{c} := \left(\sqrt{\binom{n}{i}} \left(1 - x_{0,i}^0\right) \right)_{i=0}^{n} \in \mathbb{R}^{n+1}. \tag{3.11}$$

Then the parameter $\psi(H(n, \mathcal{D}))$ can be reformulated in the following way:

$$\begin{aligned} \psi(H(n,\mathcal{D})) = \min\ t \ \text{ s.t.} \quad & x_{0,0}^0 = 1 \text{ and } x_{i,j}^p \text{ satisfy (3.8) and (3.9), and} \\ & A_k - B_k \succeq 0 \ \text{ for } k = 1, \ldots, \lfloor n/2 \rfloor, \\ & B_k \succeq 0 \ \text{ for } k = 0, 1, \ldots, \lfloor n/2 \rfloor, \\ & \begin{pmatrix} t-1 & \tilde{c}^T \\ \tilde{c} & A_0 - B_0 \end{pmatrix} \succeq 0, \end{aligned} \tag{3.12}$$

where A_k, B_k, and $\tilde{c}$ are as in (3.10) and (3.11). To compute $\psi_{\geq 0}(H(n,\mathcal{D}))$, simply add the nonnegativity condition $x^p_{i,j} \geq 0$ to (3.12).

3.3. Compact formulation for $\Psi_\ell(G)$ for Hamming graphs. We now give a more compact formulation for the parameter $\Psi_\ell(G)$ when $G = H(n,\mathcal{D})$. As mentioned above, one has to evaluate $\ell(G_t)$ for various choices of $t \in \mathbb{N}$, with $\ell(G_t)$ being given by (2.27). As for the parameter $\psi(H(n,\mathcal{D}))$, we now observe that $A^1,\dots,B^4$, and thus all blocks in the matrices in (2.27) lie in the Terwilliger algebra. (As in the previous section we fix $h := \emptyset$, the empty subset of N.)

LEMMA 3.5. *The matrices A^s ($s = 1,2$) belong to the Bose–Mesner algebra $\mathcal{B}_n$, and the matrices B^s ($s = 1,2,3,4$) belong to the Terwilliger algebra $\mathcal{A}_n$, say, $A^s = \sum_{i=0}^n x(s)_i M^n_i$ ($s = 1,2$) and $B^s = \sum_{i,j,p=0}^n y(s)^p_{i,j} M^{p,n}_{i,j}$ ($s = 1,2,3,4$). Then*

$$
\begin{aligned}
&x(s)_i = y(s)^0_{0,i} \quad \text{for } s = 1,2,\ i = 1,\dots,n,\\
&y(s)^p_{i,j} = y(s)^p_{j,i} = y(s)^{j-p}_{i+j-2p,j} = y(s)^{i-p}_{i+j-2p,i} \ (\text{for } s = 1,4),\\
&y(2)^p_{i,j} = y(2)^{i-p}_{i,i+j-2p}, \qquad y(3)^p_{i,j} = y(3)^p_{j,i},\\
&y(3)^p_{i,j} = y(2)^{i-p}_{i+j-2p,i} \quad \text{for } i,j,p = 0,\dots,n.
\end{aligned} \tag{3.13}
$$

Moreover, the edge conditions can be reformulated as

$$
\begin{aligned}
&y(1)^p_{i,j} = 0 && \text{if } \{i,j,i+j-2p\} \cap \mathcal{D} \neq \emptyset,\\
&y(2)^i_{i,i} = y(4)^i_{i,i} = 0 && \text{for } i = 0,\dots,n,\\
&y(2)^p_{i,j} = 0 && \text{if } i \in \mathcal{D} \text{ or } j = 0,\\
&y(3)^p_{i,j} = 0 && \text{if } i+j-2p \in \mathcal{D}, \text{ or } i = 0, \text{ or } j = 0,\\
&y(4)^p_{i,j} = 0 && \text{if } i = 0 \text{ or } j = 0
\end{aligned} \tag{3.14}
$$

for distinct $i,j \in \{0,1,\dots,n\}$.

Proof. We use the fact that $A^1,\dots,B^4$ satisfy (2.24) and (2.25) where the variable y is assumed to be invariant under the action of $\mathrm{Sym}(t) \times \mathrm{Aut}(G) \subseteq \mathrm{Aut}(G_t)$. We have $A^1, A^2 \in \mathcal{B}_n$, since the entries $A^1_{I,J} = y_{\{1I,1J\}}$ and $A^2_{I,J} = y_{\{1I,2J\}}$ depend only on $|I \triangle J|$. (Indeed, if $|I' \triangle J'| = |I \triangle J|$, then there exists $\sigma \in \mathrm{Aut}(G)$ mapping $\{I,J\}$ to $\{I',J'\}$, and thus, by the invariance of y under action of σ, $y_{\{1I,1J\}} = y_{\{1I',1J'\}}$ and $y_{\{1I,2J\}} = y_{\{1I',2J'\}}$.) Similarly, for $s = 1,\dots,4$, $B^s \in \mathcal{A}_n$ since the entry $B^s_{I,J}$ depends only on $|I|, |J|$ and $|I \cap J|$. The proof for the identities $x(s)_i = y(s)^0_{0,i}$ ($s = 1,2$) and $y(1)^p_{i,j} = \cdots = y(1)^{i-p}_{i+j-2p,i}$ is identical to the proof of (3.8). Let $I,J \in \mathcal{P}(N)$, with $|I| = i$, $|J| = j$, and $|I \cap J| = p$. Then $y(4)^p_{i,j} = B^4_{I,J} = y_{\{1\emptyset,2I,3J\}} = y_{\{1\emptyset,3I,2J\}}$ (use the invariance of y under the permutation $(2,3) \in \mathrm{Sym}(t)$) and thus is equal to $B^4_{J,I} = y(4)^p_{j,i}$. Moreover, $y(4)^p_{i,j} = y_{\{1\emptyset,2I,3J\}} = y_{\{1I,2\emptyset,3I\triangle J\}} = y_{\{2I,1\emptyset,3I\triangle J\}}$ (first apply the switching mapping by I and then permute the indices $1,2$) and thus is equal to $B^4_{I,I\triangle J} = y(4)^{i-p}_{i,i+j-2p}$. Next we have $y(2)^p_{i,j} = B^2_{I,J} = y_{\{1I,1\emptyset,2J\}} = y_{\{1\emptyset,1I,2I\triangle J\}}$ (apply the switching mapping by I) and thus is equal to $B^2_{I,I\triangle J} = y(2)^{i-p}_{i,i+j-2p}$. Finally, $y(3)^p_{i,j} = B^3_{I,J} = y_{\{2I,1\emptyset,2J\}} = B^3_{J,I} = y(3)^p_{j,i}$, and $y(3)^p_{i,j} = y_{\{2I,1\emptyset,2J\}} = y_{\{2\emptyset,1I,2I\triangle J\}} = y_{\{1\emptyset,2I,1I\triangle J\}}$ (first switch by I and then permute $1,2$) and thus is equal to $B^2_{I\triangle J,I} = y(2)^{i-p}_{i+j-2p,i}$. The identities (3.14) follow directly from (2.25). ∎

As the blocks of the matrices in the program (2.27) lie in the Terwilliger algebra, the matrices in (2.27) can be block-diagonalized, as explained in section 3.1. For this, define the matrices

$$A_k^s := \left(\sum_p \alpha_{i,j,k}^{p,n} y(s)_{i+j-2p,0}^0\right)_{i,j=k}^{n-k}, \qquad B_k^s := \left(\sum_p \alpha_{i,j,k}^{p,n} y(s)_{i,j}^p\right)_{i,j=k}^{n-k} \tag{3.15}$$

corresponding, respectively, to the matrices A^s $(s = 1, 2)$ and B^s $(s = 1, 2, 3, 4)$, and define the vectors

$$\tilde{a} := \left(\sqrt{\binom{n}{i}}\,(y(1)_{0,0}^0 - y(1)_{i,i}^i)\right)_{i=0}^{n}, \ \tilde{b} := \left(\sqrt{\binom{n}{i}}\,(y(1)_{i,i}^i - y(3)_{i,i}^i)\right)_{i=0}^{n} \in \mathbb{R}^{n+1}. \tag{3.16}$$

By using Lemmas 3.2 and 3.3, we obtain the following reformulation for the parameter $\ell(G_t)$ from (2.27):

$$\begin{aligned}
\ell(G_t) = \ \max\ & 2^n t y(1)_{0,0}^0 \ \text{ s.t. } y(s)_{i,j}^p \ (s = 1, \dots, 4) \text{ satisfy (3.13) and (3.14), and} \\
& \begin{pmatrix} 1 - y(1)_{0,0}^0 & \tilde{a}^T & (t-1)\tilde{b}^T \\ & A_0^1 - B_0^1 & (t-1)(A_0^2 - B_0^2) \\ & & (t-1)(A_0^1 - B_0^3) + (t-1)(t-2)(A_0^2 - B_0^4) \end{pmatrix} \succeq 0, \\
& \begin{pmatrix} A_k^1 - B_k^1 & (t-1)(A_k^2 - B_k^2) \\ & (t-1)(A_k^1 - B_k^3) + (t-1)(t-2)(A_k^2 - B_k^4) \end{pmatrix} \succeq 0 \text{ for } k = 1, \dots, \lfloor n/2 \rfloor, \\
& \begin{pmatrix} B_k^1 & (t-1)B_k^2 \\ & (t-1)B_k^3 + (t-1)(t-2)B_k^4 \end{pmatrix} \succeq 0 \text{ for } k = 0, \dots, \lfloor n/2 \rfloor, \\
& A_k^1 - A_k^2 - B_k^3 + B_k^4 \succeq 0 \ \text{ for } k = 0, \dots, \lfloor n/2 \rfloor, \\
& B_k^3 - B_k^4 \succeq 0 \ \text{ for } k = 0, \dots, \lfloor n/2 \rfloor,
\end{aligned} \tag{3.17}$$

where A_k^s, B_k^s, $\tilde{a}$, and $\tilde{b}$ are as in (3.15) and (3.16). To compute $\ell_{\geq 0}(G_t)$ simply add the nonnegativity condition $y(s)_{i,j}^p \geq 0$ on all variables.

3.4. Numerical results for Hamming graphs. We have tested the various bounds on some instances of Hamming graphs. In what follows we use the following convention: For an integer $1 \leq d \leq n$, $H(n, d)$ (resp., $H^-(n, d)$, $H^+(n, d)$) denotes the graph $H(n, \mathcal{D})$, with $\mathcal{D} = \{d\}$ (resp., $\mathcal{D} = \{1, \dots, d\}$, $\{d, \dots, n\}$). The papers [9, 10, 11] give numerical results for the parameters $\overline{\vartheta}(G)$ and $\overline{\vartheta^+}(G)$ for such instances. Moreover, a bound related to copositive programming is computed in [11] (called the $\mathcal{K}_1$-bound in [11] or the $\kappa^{(1)}$ bound in [17]); it is shown in [17] that this bound is dominated by our parameter $\psi_{\geq 0}$.

In Table 1, the symbol "*" indicates the strict inequality $\Psi_\ell(G) > \lceil \psi(G) \rceil$, which happens for $H(10, 8)$ and $H^+(10, 8)$, and we indicate in bold the values satisfying LB $= \chi(G)$ for the obtained lower bound (LB). (Indeed, in these instances, LB $= 2^{n-1}$, while $\mathcal{P}(V)$ can be covered by the 2^{n-1} distinct pairs $\{I, V \setminus I\}$ $(I \subseteq V)$ which are stable sets as $n \notin \mathcal{D}$.)

The results in Table 1 indicate that the parameters $\psi(G)$ and $\psi_{\geq 0}(G)$ give in some instances a major improvement on Szegedy's bound $\overline{\vartheta^+}(G)$. On the other hand,

TABLE 1
Bounds for the chromatic number of Hamming graphs.

in most cases, the parameter $\Psi_\ell(G)$ gives no improvement since $\Psi_\ell(G) = \lceil \psi(G) \rceil$. It could be that this feature is specific to Hamming graphs. As we will see in the next section, the bound $\Psi_\ell(G)$ does improve the bound $\lceil \psi(G) \rceil$ for Kneser graphs.

4. Bounds for Kneser graphs. We have seen that the parameter $\psi(G)$ is bounded by $\chi^*(G)$ and that, for vertex-transitive graphs, it coincides with the bound $|V(G)|/\ell(G)$. On the other hand, $\Psi_\ell(G)$ can sometimes be strictly greater than $\lceil \psi(G) \rceil$, e.g., for the Hamming graph $H(10,8)$ (recall Table 1). We present here some numerical results showing that $\Psi_\ell(G)$ can in fact be strictly greater than $\lceil \chi^*(G) \rceil$ for Kneser graphs.

Given integers $n \geq 2r$, the Kneser graph $K(n,r)$ is the graph whose vertices are the subsets of size r of a set N, with $|N| = n$, two vertices being adjacent if and only if they are disjoint. As shown in [24], $\alpha(K(n,r)) = \binom{n-1}{r-1}$, and thus $\chi^*(K(n,r)) = \frac{n}{r}$ in view of (2.2) as $K(n,r)$ is vertex-transitive. Lovász proved that $\chi(K(n,r)) = n-2r+2$ in his celebrated paper [23]. Thus the fractional chromatic number and the chromatic number of $K(n,r)$ can differ significantly, while the fractional chromatic number is close to the clique number $\omega(K(n,r)) = \lfloor \frac{n}{r} \rfloor$. Moreover, Lovász [24] proved that, for $G = K(n,r)$, $\alpha(G) = \vartheta(G)$. Hence, $\ell(G) = \alpha(G)$, implying that $\psi(G) = \frac{|V(G)|}{\ell(G)} = \chi^*(G) = n/r$. Therefore, $\Psi_\ell(G) \geq \lceil n/r \rceil$. We show in this section how to compute $\Psi_\ell(G)$.

The Kneser graph $K(n,r)$ coincides with the subgraph of the Hamming graph $H(n,\{2r\})$ induced by the subset $\mathcal{P}_{=r}(N) := \{I \in \mathcal{P}(N) \mid |I| = r\}$. It will be convenient to view the Kneser graph also in the following alternative way. Fix a set $T \subseteq N$, with $|T| = r$, and define

$$\mathcal{P}(N,T) := \{(I', I'') \in \mathcal{P}(T) \times \mathcal{P}(N \setminus T) \mid |I'| = |I''|\}.$$

The mapping

$$\begin{array}{ccc} \mathcal{P}_{=r}(N) & \longrightarrow & \mathcal{P}(N,T), \\ I & \mapsto & (T \setminus I, I \setminus T) \end{array} \tag{4.1}$$

is a bijection, and $|I \triangle J| = |(T \setminus I) \triangle (T \setminus J)| + |(I \setminus T) \triangle (J \setminus T)|$ holds for $I, J \in \mathcal{P}_{=r}(N)$. Hence $K(n,r)$ can also be viewed as the graph with node set $\mathcal{P}(N,T)$, with two nodes $(I', I''), (J', J'') \in \mathcal{P}(N,T)$ being adjacent if $|I' \triangle J'| + |I'' \triangle J''| = 2r$.

As we will see below, the matrices involved in the program (2.27) for the computation of $\Psi_\ell(K(n,r))$ lie in $\mathcal{B}_{r,r'}$ ($r' = n - r$), a subalgebra of a tensor product of two Terwilliger algebras, which has also been studied and block-diagonalized by Schrijver [31] (in connection with constant-weight codes). We follow the same steps as in section 3 for the computation of $\ell(G_t)$ for Hamming graphs, which we now carry out for Kneser graphs.

4.1. The subalgebra $\mathcal{B}_{r,r'}$. As above, $|N| = n$, and we fix a subset $T \subseteq N$, with $|T| = r$, and set $r' := n - r$. For $i, j, p = 0, 1, \ldots, r$ (resp., $i', j', q = 0, 1, \ldots, r'$), let $M^{p,r}_{i,j}$ (resp., $M^{q,r'}_{i',j'}$) be the matrices indexed by $\mathcal{P}(T)$ (resp., $\mathcal{P}(N \setminus T)$) defining the Terwilliger algebra $\mathcal{A}_r$ (resp., $\mathcal{A}_{r'}$) as in section 3.1. Let now $\mathcal{A}_{r,r'}$ be the algebra generated by the tensor products of matrices in $\mathcal{A}_r$ and $\mathcal{A}_{r'}$, that is,

$$\mathcal{A}_{r,r'} := \left\{ \sum_{i,j,p,i',j',q} x^{p,q}_{i,j,i',j'} M^{p,r}_{i,j} \otimes M^{q,r'}_{i',j'} \mid x^{p,q}_{i,j,i',j'} \in \mathbb{R} \right\}.$$

Matrices in $\mathcal{A}_{r,r'}$ are indexed by the set $\mathcal{P}(T) \times \mathcal{P}(N \setminus T)$. Consider the subalgebra

$$\mathcal{B}_{r,r'} := \left\{ \sum_{i,j,p,q} y^{p,q}_{i,j} M^{p,r}_{i,j} \otimes M^{q,r'}_{i,j} \mid y^{p,q}_{i,j} \in \mathbb{R} \right\}.$$

So $\mathcal{B}_{r,r'}$ consists of all matrices from $\mathcal{A}_{r,r'}$ satisfying $x^{p,q}_{i,j,i',j'} = 0$ if $i \neq i'$ or $j \neq j'$. Hence, for $M \in \mathcal{B}_{r,r'}$ and $(I, I'), (J, J') \in \mathcal{P}(T) \times \mathcal{P}(N \setminus T)$, $M_{(I,I'),(J,J')} = 0$ if $|I| \neq |I'|$ or if $|J| \neq |J'|$. Therefore any row/column of M indexed by $(I, I') \notin \mathcal{P}(N,T)$ is identically zero, and we may thus restrict matrices in $\mathcal{B}_{r,r'}$ to being indexed by the subset $\mathcal{P}(N,T)$ of $\mathcal{P}(T) \times \mathcal{P}(N \setminus T)$.

For $k \leq r$, let $M^{n,r}_k$ be the matrix indexed by $\mathcal{P}(N,T)$, whose $((I, I'), (J, J'))$th entry is equal to 1 if $|I \triangle J| + |I' \triangle J'| = 2k$ and to 0 otherwise. Thus $M^{n,r}_k$ corresponds to the principal submatrix of M^n_{2k} (in the Bose–Mesner algebra $\mathcal{B}_n$) indexed by the subset $\mathcal{P}_{=r}(N)$ and $M^{n,r}_k \in \mathcal{B}_{r,r'}$ as $M^{n,r}_k = \sum_{i,j,p,q \mid i+j-p-q=k} M^{p,r}_{i,j} \otimes M^{q,r'}_{i,j}$. Hence the set

$$\mathcal{B}^r_n := \left\{ \sum_{k=0}^{r} x_k M^{n,r}_k \mid x_k \in \mathbb{R} \right\}$$

is a subalgebra of $\mathcal{B}_{r,r'}$.

Schrijver [31] proved the following analogue of Theorem 3.1, giving the explicit block-diagonalization for matrices in $\mathcal{B}_{r,r'}$. For $k = 0, \ldots, \lfloor \frac{r}{2} \rfloor$, $l = 0, \ldots, \lfloor \frac{r'}{2} \rfloor$, set

$$W_{kl} := \{k, k+1, \ldots, r-k\} \cap \{l, l+1, \ldots, r'-l\}.$$

THEOREM 4.1 (see [31]). *For a matrix $M = \sum_{i,j,p,q} y^{p,q}_{i,j} M^{p,r}_{i,j} \otimes M^{q,r'}_{i,j}$ in $\mathcal{B}_{r,r'}$,*

$$M \succeq 0 \iff M_{k,l} := \left(\sum_{p,q} \alpha^{p,r}_{i,j,k} \alpha^{q,r'}_{i,j,l} y^{p,q}_{i,j} \right)_{i,j \in W_{kl}} \succeq 0 \tag{4.2}$$
$$\text{for each } k = 0, 1, \ldots, \lfloor \tfrac{r}{2} \rfloor \text{ and } l = 0, 1, \ldots, \left\lfloor \frac{r'}{2} \right\rfloor.$$

We have the following analogues of Lemmas 3.2 and 3.3.

LEMMA 4.2. *Let* $A = \sum_{i,j,p,q} a_{i,j}^{p,q} M_{i,j}^{p,r} \otimes M_{i,j}^{q,r'}$, $B = \sum_{i,j,p,q} b_{i,j}^{p,q} M_{i,j}^{p,r} \otimes M_{i,j}^{q,r'}$, *and* $C = \sum_{i,j,p,q} c_{i,j}^{p,q} M_{i,j}^{p,r} \otimes M_{i,j}^{q,r'}$ *be matrices in* $\mathcal{B}_{r,r'}$, *and define accordingly*

$$A_{kl} = \left(\sum_{p,q} \alpha_{i,j,k}^{p,r} \alpha_{i,j,l}^{q,r'} a_{i,j}^{p,q} \right)_{i,j \in W_{kl}}, \qquad B_{kl} = \left(\sum_{p,q} \alpha_{i,j,k}^{p,r} \alpha_{i,j,l}^{q,r'} b_{i,j}^{p,q} \right)_{i,j \in W_{kl}},$$
$$C_{kl} = \left(\sum_{p,q} \alpha_{i,j,k}^{p,r} \alpha_{i,j,l}^{q,r'} c_{i,j}^{p,q} \right)_{i,j \in W_{kl}}.$$

Then

$$\begin{pmatrix} A & B \\ B^T & C \end{pmatrix} \succeq 0 \Longleftrightarrow \begin{pmatrix} A_{kl} & B_{kl} \\ B_{kl}^T & C_{kl} \end{pmatrix} \succeq 0 \ \forall k = 0, 1, \ldots, \left\lfloor \frac{r}{2} \right\rfloor \text{ and } l = 0, 1, \ldots, \left\lfloor \frac{r'}{2} \right\rfloor.$$

LEMMA 4.3. *Let* $M = \sum_{i,j,p,q=0}^{n} x_{i,j}^{p,q} M_{i,j}^{p,r} \otimes M_{i,j}^{q,r'} \in \mathcal{B}_{r,r'}$ *and* $c = \sum_{i=0}^{n} c_i \chi^i$, *where* $\chi^i \in \{0,1\}^{\mathcal{P}(N,T)}$ *with* $\chi^i_{(I,I')} = 1$ *if* $|I| = i$ *(for* $(I, I') \in \mathcal{P}(N,T)$*) and* $d \in \mathbb{R}$. *Then*

$$\begin{pmatrix} d & c^T \\ c & M \end{pmatrix} \succeq 0 \Longleftrightarrow \begin{cases} M_{kl} \succeq 0 \ \text{ for } k = 0, \ldots, \left\lfloor \frac{r}{2} \right\rfloor, l = 0, \ \ldots, \left\lfloor \frac{r'}{2} \right\rfloor, \ k + l > 0; \\ \tilde{M}_{00} := \begin{pmatrix} d & \tilde{c}^T \\ \tilde{c} & M_{00} \end{pmatrix} \succeq 0 \end{cases}$$

after setting $\tilde{c}^T := (c_i \sqrt{\binom{r}{i}\binom{r'}{i}})_{i=0}^{r}$.

4.2. Compact formulation for $\Psi_\ell(G)$ for Kneser graphs. In order to compute $\Psi_\ell(G)$ for the Kneser graph $G = K(n,r)$, one has to evaluate $\ell(G_t)$ for various choices of t. As G is vertex-transitive, $\ell(G_t)$ can be computed by using the program (2.27). We now fix $h := T \in \mathcal{P}_{=r}(N)$ corresponding to $(\emptyset, \emptyset) \in \mathcal{P}(N,T)$ as a chosen node of G. We now show that the matrices $A^1, \ldots, B^4$ appearing in program (2.27) lie in the algebra $\mathcal{B}_{r,r'}$, and thus they can be block-diagonalized by using Theorem 4.1. The following lemma is the analogue of Lemma 3.5.

LEMMA 4.4. *The matrices* A^s $(s = 1,2)$ *belong to* $\mathcal{B}_n^r$, *and the matrices* B^s $(s = 1,2,3,4)$ *belong to* $\mathcal{B}_{r,r'}$, *say,* $A^s = \sum_{i=0}^{r} x(s)_i M_i^{n,r}$ $(s = 1,2)$ *and* $B^s = \sum_{i,j,p,q=0}^{r} y(s)_{i,j}^{p,q} M_{i,j}^{t,r} \otimes M_{i,j}^{q,r'}$ $(s = 1,2,3,4)$. *We have*

$$\begin{aligned} x(s)_i &= y(s)_{0,i}^{0,0} \ \text{ for } s = 1,2, \ i = 1, \ldots, r, \\ y(s)_{i,j}^{p,q} &= y(s)_{j,i}^{p,q} = y(s)_{i,i+j-p-q}^{i-q,i-p} = y_{j,i+j-p-q}^{j-q,j-p} \ \text{ for } s = 1,4, \\ y(2)_{i,j}^{p,q} &= y(2)_{i,i+j-p-q}^{i-q,i-p}, \qquad y(3)_{i,j}^{p,q} = y(3)_{j,i}^{p,q}, \\ y(3)_{i,j}^{p,q} &= y(2)_{i+j-p-q,i}^{i-q,i-p} \ \text{ for } i,j,p,q = 0, \ldots, r. \end{aligned} \tag{4.3}$$

Moreover, the edge conditions can be reformulated as

$$\begin{aligned} y(1)_{i,j}^{p,q} &= 0 \quad \text{if } \ i = r, \ \text{or } j = r, \ \text{or } i + j - p - q = r, \\ y(2)_{i,j}^{p,q} &= 0 \quad \text{if } i = r, \ \text{or } j = 0, \ \text{or } i + j - p - q = 0, \\ y(3)_{i,j}^{p,q} &= 0 \quad \text{if } i = 0, \ \text{or } j = 0, \ \text{or } i + j - p - q = r, \\ y(4)_{i,j}^{p,q} &= 0 \quad \text{if } i = 0, \ \text{or } j = 0, \ \text{or } i + j - p - q = 0. \end{aligned} \tag{4.4}$$

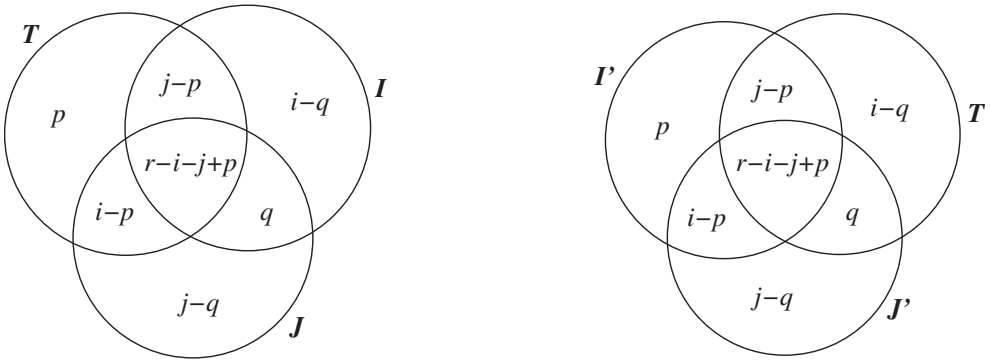

FIG. 4.1. *Venn diagrams.*

Proof. As in the proof of Lemma 3.5, the matrices $A^1, \dots, B^4$ satisfy (2.24) and (2.25), where the variable y is invariant under the action of $\mathrm{Sym}(t) \times \mathrm{Aut}(G)$. A main difference with the case of the Hamming graph is that, for the Kneser graph $G = K(n,r)$, $\mathrm{Aut}(G) \sim \mathrm{Sym}(n)$; i.e., the only automorphisms of G arise from the permutations of N. Recall that $\sigma \in \mathrm{Sym}(n)$ acts on $\mathcal{P}_{=r}(N)$ in the obvious way, by letting $\sigma(I) = \{\sigma(i) \mid i \in I\}$ for $I \in \mathcal{P}_{=r}(N)$.

Let us first show that $A^1 \in \mathcal{B}_n^r$; that is, $A^1_{I,J}$ depends only on $|I \triangle J|$ (for $I, J \in \mathcal{P}_{=r}(N)$). For this, let $I, J, I', J' \in \mathcal{P}_{=r}(N)$, with $|I \triangle J| = |I' \triangle J'|$. Then $|I \cap J| = |I' \cap J'|$, and thus there exists $\sigma \in \mathrm{Sym}(n)$ such that $\sigma(I) = I'$ and $\sigma(J) = J'$. Hence, $A^1_{I,J} = y_{\{1I,1J\}} = y_{\{1\sigma(I),1\sigma(J)\}} = A^1_{I',J'}$ since y is invariant under the action of σ. The proof for $A^2 \in \mathcal{B}_n^r$, $B^s \in \mathcal{B}_{r,r'}$, is along the same lines.

Let us now prove the identity $y(1)^{p,q}_{i,j} = y(1)^{i-q,i-p}_{i,i+j-p-q}$; the proofs for the remaining identities are along the same lines and thus are omitted. Say, $y(1)^{p,q}_{i,j} = B^1_{I,J}$, where $I, J \in \mathcal{P}_{=r}(N)$ with $|T \setminus I| = i$, $|T \setminus J| = j$, $|(T \setminus I) \cap (T \setminus J)| = p$, and $|(I \setminus T) \cap (J \setminus T)| = q$. See Figure 4.1 for the Venn diagram of the sets I, J, and T. Consider sets $I', J' \in \mathcal{P}_{=r}(N)$, which together with the set T have the Venn diagram shown in Figure 4.1. Then $B^1_{I',J'} = y(1)^{i-q,i-p}_{i,i+j-p-q}$, and there exists $\sigma \in \mathrm{Sym}(n)$ such that $\sigma(T) = I'$, $\sigma(I) = T$, and $\sigma(J) = J'$. Therefore, $y(1)^{p,q}_{i,j} = B^1_{I,J} = y_{\{1I,1J,1T\}} = y_{\{1\sigma(I),1\sigma(J),1\sigma(T)\}} = y_{\{1T,1J',1I'\}} = B^1_{I',J'} = y(1)^{i-q,i-p}_{i,i+j-p-q}$. ∎

For $k = 0, \dots, \lfloor r/2 \rfloor$, $l = 0, \dots, \lfloor r'/2 \rfloor$, define the matrices

(4.5)
$$A^s_{kl} = \left(\sum_{p,q} \alpha^{p,r}_{i,j,k} \alpha^{q,r'}_{i,j,l} y(s)^{0,0}_{0,i+j-p-q} \right)_{i,j \in W_{kl}}, \qquad B^s_{kl} = \left(\sum_{p,q} \alpha^{p,r}_{i,j,k} \alpha^{q,r'}_{i,j,l} y(s)^{p,q}_{i,j} \right)_{i,j \in W_{kl}}$$

corresponding, respectively, to the matrices A^s $(s = 1, 2)$ and B^s $(s = 1, 2, 3, 4)$, and define the vectors

(4.6)
$$\tilde{a} := \left(\sqrt{\tbinom{r}{i}\tbinom{r'}{i}} \left(y(1)^{0,0}_{0,0} - y(1)^{i,i}_{i,i} \right) \right)_{i=0}^{r}, \qquad \tilde{b} := \left(\sqrt{\tbinom{r}{i}\tbinom{r'}{i}} \left(y(1)^{i,i}_{i,i} - y(3)^{i,i}_{i,i} \right) \right)_{i=0}^{r}.$$

By using Lemmas 4.2 and 4.3, we obtain the following reformulation for the parameter

$\ell(G_t)$ from (2.27):

(4.7)

$$\ell(G_t) = \max \binom{n}{r} t y(1)_{0,0}^{0,0} \text{ s.t. } y(s)_{i,j}^{p,q},\ s = 1,\dots,4 \text{ satisfy (4.3) and (4.4), and}$$

$$\begin{pmatrix} 1 - y(1)_{0,0}^{0,0} & \tilde{a}^T & (t-1)\tilde{b}^T \\ & A_{00}^1 - B_{00}^1 & (t-1)(A_{00}^2 - B_{00}^2) \\ & & (t-1)(A_{00}^1 - B_{00}^3) + (t-1)(t-2)(A_{00}^2 - B_{00}^4) \end{pmatrix} \succeq 0;$$

$$\begin{pmatrix} A_{kl}^1 - B_{kl}^1 & (t-1)(A_{kl}^2 - B_{kl}^2) \\ & (t-1)(A_{kl}^1 - B_{kl}^3) + (t-1)(t-2)(A_{kl}^2 - B_{kl}^4) \end{pmatrix} \succeq 0$$
$$\text{for } k = 0,\dots,\lfloor r/2 \rfloor, l = 0,\dots,\lfloor r'/2 \rfloor,\ k + l > 0;$$

$$\begin{pmatrix} B_{kl}^1 & (t-1)B_{kl}^2 \\ & (t-1)B_{kl}^3 + (t-1)(t-2)B_{kl}^4 \end{pmatrix} \succeq 0 \text{ for } k = 0,\dots,\lfloor r/2 \rfloor, l = 0,\dots,\lfloor r'/2 \rfloor;$$

$$A_{kl}^1 - A_{kl}^2 - B_{kl}^3 + B_{kl}^4 \succeq 0 \text{ for } k = 0,\dots,\lfloor r/2 \rfloor, l = 0,\dots,\lfloor r'/2 \rfloor;$$

$$B_{kl}^3 - B_{kl}^4 \succeq 0 \text{ for } k = 0,\dots,\lfloor r/2 \rfloor, l = 0,\dots,\lfloor r'/2 \rfloor,$$

where A_{kl}^s, B_{kl}^s, $\tilde{a}$, and $\tilde{b}$ are as in (4.5) and (4.6). To compute $\ell_{\geq 0}(G_t)$ simply add the nonnegativity condition $y(s)_{i,j}^{p,q} \geq 0$ on all variables.

4.3. Numerical results for Kneser graphs. We show in Table 2 below our numerical results for the bounds $\Psi_\ell(G)$ and $\Psi_{\ell_{\geq 0}}(G)$ for several instances of Kneser graphs. We indicate in bold the values achieving the chromatic number.

5. Computing the new bound ψ_K for DIMACS benchmark graphs. So far we have been dealing with vertex-transitive graphs and with the bounds $\psi(\cdot)$ and $\Psi_\ell(\cdot)$. For the formulation of $\psi(G)$, it was observed in section 2 that, when G is vertex-transitive, it suffices to require in (2.13) positive semidefiniteness of $M_2(h,x)$ for *only one* $h \in V(G)$ instead of *for all* $h \in V(G)$. In the case of a nonsymmetric graph G one would need to require $M_2(h,x) \succeq 0$ for *all* $h \in V(G)$; therefore, with

TABLE 2
Bounds for the chromatic number of Kneser graphs.

Graph	$\lceil \chi^*(G) \rceil = \lceil n/r \rceil$	$\Psi_\ell(G)$	$\Psi_{\ell_{\geq 0}}(G)$	$\chi(G) = n - 2r + 2$
$K(6,2)$	3	**4**	**4**	**4**

$K(24,6)$	4	4	6	14
$K(25,5)$	5	6	7	17
$K(34,7)$	5	6	7	22
$K(36,6)$	6	7	9	26

$n := |V(G)|$, in order to compute $\psi(G)$ (resp., $\ell(G_t)$, and thus $\Psi_\ell(G)$), one would have to solve a semidefinite program with $2n$ (resp., $4n$) matrices of order $\leq n+1$ (resp., $\leq 2n+1$). For graphs that are of interest, e.g., with $n \geq 100$, this cannot be done with the currently available software for semidefinite programming.

For nonsymmetric graphs we propose another variant of the bound $\psi^{(2)}(G)$. Given a clique K in G, let $M_2(K;x)$ denote the principal submatrix of $M_2(x)$ indexed by the multiset $\mathcal{P}_1(V) \cup (\cup_{h\in K}\{\{h,i\} \mid i \in V\})$. Now define the parameter

$$\psi_K(G) := \min\ t \ \text{ s.t. } \quad \begin{array}{l} x_{\mathbf{0}} = t,\ x_i = 1\ (i \in V),\ M_2(K;x) \succeq 0, \\ x_I = 0 \text{ for all } I \text{ containing an edge.} \end{array} \tag{5.1}$$

Then $\overline{\vartheta}(G) \leq \psi_K(G) \leq \chi^*(G)$. (The left inequality follows by using (2.4), and the right inequality follows from $\psi_K(G) \leq \psi^{(2)}(G) \leq \chi^*(G)$ by using (2.8) and (2.10).) Set $k := |K|$, and assume without loss of generality that $K = \{1, 2, \ldots, k\}$. With respect to the partition of its index set as $\{\mathbf{0}\} \cup \{\{i\} \mid i \in V\} \cup \cup_{h=1}^k \{\{h,i\} \mid i \in V\}$, the matrix $M_2(K;x)$ has the block form

$$M_2(K;x) = \begin{pmatrix} t & a_0^T & a_1^T & a_2^T & \ldots & a_k^T \\ a_0 & A_0 & A_1 & A_2 & \ldots & A_k \\ a_1 & A_1 & A_1 & 0 & \ldots & 0 \\ a_2 & A_2 & 0 & A_2 & \ddots & \vdots \\ \vdots & \vdots & \vdots & \ddots & \ddots & 0 \\ a_k & A_k & 0 & \ldots & 0 & A_k \end{pmatrix},$$

where $a_0, \ldots, a_k, A_0, \ldots, A_k$ are indexed by V, $a_i = \mathrm{diag}(A_i)$ $(0 \leq i \leq k)$, $a_0 = e$, $(A_0)_{ij} = x_{ij}$, and $(A_h)_{ij} = x_{\{h,i,j\}}$ for $h \in K$, $i, j \in V$. Note that for $h \in V$ the columns of A_0 and A_h indexed by $\{h\}$ are both equal to a_h. Hence, as in the proof of Lemma 2.1, we can do some row/column manipulations and verify that

$$M_2(K;x) \succeq 0 \Longleftrightarrow \begin{pmatrix} t-k & e^T - (\sum_{h=1}^k a_h)^T \\ e - \sum_{h=1}^k a_h & A_0 - \sum_{h=1}^k A_h \end{pmatrix} \succeq 0, \quad A_1, \ldots, A_k \succeq 0.$$

Hence $\psi_K(G)$ can be computed via a semidefinite program involving $k+1$ matrices of sizes $n+1$ (once) and n (k times).

We have conducted experiments for some DIMACS benchmark graphs (studied, e.g., in [4, 5, 8, 9, 12, 26, 27]). In Table 3 we present our lower bounds for the chromatic number of the graphs DSJC$a.b$. Recall that DSJC$a.b$ are random graphs with a vertices, two vertices being adjacent with probability $10^{-1}b$. The graph DSJR500.1 is a geometric graph with 500 nodes randomly distributed in the unit square, with an edge between two nodes if their distance is less than 0.1. The graph DSJR500.1c is the complement of DSJR500.1. The graphs can be downloaded from [34].

In Table 3, the column "LB" contains the previously best known lower bounds taken from [8, 26, 27], and the values in parentheses come from [3]; the bound 82 for DSJR500.1c is the size of a clique obtained by using the heuristic of [2]. The column "UB" contains the best known upper bounds taken from [4, 12, 13], i.e., the number of colors in the best colorings found so far. The column "K" contains the size of the clique used for computing the parameter $\psi_K(G)$ (the clique is found by using the heuristic from [2]). We also indicate the value of the theta number $\bar{\vartheta}(G)$ (also computed in [9, 10] for some instances), which already improves the best lower bound

TABLE 3
Bounds for the chromatic number of DIMACS instances.

Graph	LB	$\overline{\vartheta}(G)$	$\lceil\overline{\vartheta}(G)\rceil$	K	$\psi_K(G)$	$\lceil\psi_K(G)\rceil$	UB
DSJC125.1	5	4.1062	5	4	4.337	**5**	5
DSJC125.5	14 (17)	11.7844	12	10	13.942	**14**	17
DSJC125.9	42	37.768	38	34	42.53	**43**	43
DSJC250.1	6 (8)	4.906	5	4	5.208	**6**	8

DSJC500.1	6	6.217	**7**	5	6.542	7	12
DSJC500.5	13 (16)	20.542	21	13	27.791	**28**	48
DSJC500.9	59	84.04	85	56	100.43	**101**	126
DSJC1000.1	6	8.307	**9**	5	-	-	20
DSJC1000.5	15 (17)	31.89	**32**	14	-	-	83
DSJC1000.9	66	122.67	**123**	65	-	-	224
DSJR500.1c	82 (83)	83.74	84	77	84.12	**85**	85

in several instances. We indicate in bold our best new lower bounds for the chromatic number. In several instances they give a significant improvement on the best known lower bound. Moreover, in two instances, we are able to close the gap as our lower bound matches the upper bound; indeed we find the exact value of the chromatic number for the graphs DSJC125.9 ($\chi(G) = 43$) and DSJR500.1c ($\chi(G) = 85$), which were not known before to the best of our knowledge. These results demonstrate that the bounds $\psi_K(G)$ can be quite strong.

One may wonder why we did not add nonnegativity constraints in the formulation for ψ_K. The reason is that for random graphs adding nonnegativity constraints gives only a negligible improvement. This fact was already observed for the Lovász theta number in [9].

Remarks about the computational results. The computational results reported in Tables 1 and 2 were carried out by using the open source codes for semidefinite programming CSDP 5.0 and DSDP 5.8 available, respectively, at [35] and [36].

For finding the large cliques reported in column "K" of Table 3, we used the heuristic Max-AO (based on [2]), available at [37]. The values in the columns "$\overline{\vartheta}(G)$" and "$\psi_K(G)$" of Table 3 were computed by using the boundary point method of Povh, Rendl, and Wiegele [29], whose code is available at [38].

The semidefinite program for the parameter ψ_K can indeed be quite large. For instance, for the graph DSJR500.1*c*, it contains one 501×501 block and 77 blocks of size at most 500×500, and such a big problem cannot be solved by using solvers based on interior point methods.

Experiments were conducted on a single machine with an AMD Athlon 64 3500 processor and 1024 MB RAM memory. Here is a rough indication of the times needed to compute the bounds in Tables 1–3. Each bound in Tables 1–2 could be computed in less than a minute, as it involves a relatively small SDP; for instance, computing $\Psi_\ell(H(20,6))$ is via an SDP with 1502 variables and 47 blocks with sizes ranging from 1 to 43. It was harder to compute the bounds ψ_K in Table 3. In fact, we had to rerun the boundary point code several times for each instance in order to tailor the parameters of the code and speed up the convergence to an optimal solution. The computation times for the parameter $\psi_K(G)$ vary from a few minutes (e.g., less than 3 minutes for DCJC125.5 and about 25 minutes for DCJC125.1) up to four days for the most demanding instance DSJR500.1c.

Acknowledgments. We are very grateful to two referees for their careful reading and their useful suggestions which helped improve the presentation of the paper. We also thank Marco Chiarandini and Michael Trick, for telling us about coloring results for DIMACS benchmark graphs, and Janez Povh, Franz Rendl, and Angelika Wiegele, for adapting their boundary point algorithm code in such a way that it now exploits the block-diagonal structure in semidefinite programs.

SUFFICIENT SECOND-ORDER OPTIMALITY CONDITIONS FOR SEMILINEAR CONTROL PROBLEMS WITH POINTWISE STATE CONSTRAINTS*

EDUARDO CASAS†, JUAN CARLOS DE LOS REYES‡, AND FREDI TRÖLTZSCH§

Abstract. Second-order sufficient optimality conditions are established for the optimal control of semilinear elliptic and parabolic equations with pointwise constraints on the control and the state. In contrast to former publications on this subject, the cone of critical directions is the smallest possible in the sense that the second-order sufficient conditions are the closest to the associated necessary ones. The theory is developed for elliptic distributed controls in domains up to dimension three. Moreover, problems of elliptic boundary control and parabolic distributed control are discussed in spatial domains of dimension two and one, respectively.

Key words. optimal control, elliptic equations, parabolic equations, pointwise state constraints, second-order necessary optimality conditions, second-order sufficient optimality conditions

1. Introduction.

In this paper, we essentially improve the theory of second-order sufficient optimality conditions for state-constrained optimal control problems of elliptic and parabolic type. We derive second-order sufficient conditions that are as close as possible to the associated necessary ones. In this way, we are able to complete the theory of second-order sufficient conditions for this class of problems, if the dimension of the spatial domain is sufficiently small.

For the theory of nonconvex differentiable mathematical programming in finite-dimensional spaces, second-order sufficient optimality conditions are indispensible both in the numerical analysis and for reliable numerical methods. If second-order information is not available, then local minima will not in general be stable and numerical methods will most likely not converge. For instance, the convergence analysis of SQP methods relies heavily on second-order conditions.

In the numerical analysis of nonlinear optimal control problems, second-order sufficient optimality conditions are even more important. If they are not satisfied, then the (strong) convergence of optimal controls or states and/or error estimates for numerical discretizations of the problems can hardly be shown. Also, other types of perturbations are difficult to handle without second-order conditions.

As is well known from the calculus of variations and the control theory for nonlinear ordinary differential equations, the theory of second-order conditions is more delicate and rich in function spaces. We mention, for instance, the work by Maurer [20] or Maurer and Zowe [21]. In particular, the well-known two-norm discrepancy occurs that essentially complicates the analysis; cf. the expositions in Ioffe [16] or
