Special Issue on Iterative Methods in Numerical Linear Algebra

More than 180 mathematicians from all corners of the world attended the First Copper Mountain Conference Devoted to Iterative Methods. The meeting, held April 1–5, 1990, took place at the Copper Mountain Resort, which is located 70 miles west of Denver. During the four days of the meeting, over 100 talks on current research were presented. Topics included nonsymmetric systems, preconditioning strategies, parallel implementations, applications, software, multigrid methods, domain decomposition, eigenvalue problems, integral equations, nonlinear systems, indefinite problems, discretization techniques, complex matrix problems and common software standards.

There are two special issues devoted to chronicling the presentations made at the Copper Mountain Conference, one in *SISSC* and the other in the *SIAM Journal on Matrix Analysis and Applications* (*SIMAX*). The review process followed the normal SIAM policies for selecting referees and making recommendations. This issue represents a rich mix of papers on a wide variety of topics related to iterative methods. There are two aspects of this collection that we would like to underscore. First, much of the research represented in these articles was motivated or influenced by the need to develop new algorithms for the growing variety of parallel processing computers. Second, the increasing interaction between the multigrid community and the iterative method community is reflected in the many articles that incorporate multigrid and multilevel ideas into the construction of preconditioners and domain decomposition strategies. The papers in this issue are representative of the lively and stimulating interaction that occurred at the meeting.

A special effort was made to bring students to the meeting. The vehicle for this effort was a Student Paper Competition, in which students were asked to submit an original research paper consisting primarily of their own work. Out of ten submissions, three winners were selected. First place went to Barry Smith of the Courant Institute at New York University. Second place was awarded to Doug James of North Carolina State University. Third place honors were shared by Sverker Holmgren and Kurt Otto from Uppsala University in Stockholm, Sweden. Barry Smith's paper appears in this issue; the other two winning papers will appear in the special issue of *SIMAX*, to be published in July 1992.

We would like to thank the members of the program committee for their help in organizing the meeting. They are: Seymour Parter (chair), Loyce Adams, Steve Ashby, Howard Elman, Roland Freund, Gene Golub, Anne Greenbaum, David Kincaid, Steve McCormick, Ahmed Sameh, Paul Saylor, Olof Widlund, and David Young. In particular, we would like to give special thanks to Parter, Elman, Greenbaum, McCormick, Sameh, and Widlund, who, in addition to helping organize the meeting, acted as special *SISSC* editors for this issue.

Through their efforts, the articles contained in this special issue were carefully refereed and brought into print on schedule. We would also like to thank the following persons for their generous support of this meeting: Fred Howes of the Applied Mathematics Program of the National Science Foundation, Don Austin from the Applied Mathematical Sciences Program of the Department of Energy, Andy White from the Advanced Computing Laboratory at Los Alamos National Laboratories, and Bob Huddleston of the Computing Division of Lawrence Livermore National Laboratories. Without their help, this meeting could not have taken place.

As this issue goes to press, planning for the next Copper Mountain Conference on Iterative Methods is in its final stages. It will be held April 9–16, 1992, in Copper Mountain, Colorado. Plans again include special journal issues in *SISSC* and *SIMAX*. It is our hope that the lively interaction and the fine quality of presentations and papers that marked the first meeting can be duplicated at the upcoming meeting.

A COMPARISON OF ADAPTIVE CHEBYSHEV AND LEAST SQUARES POLYNOMIAL PRECONDITIONING FOR HERMITIAN POSITIVE DEFINITE LINEAR SYSTEMS*

STEVEN F. ASHBY†, THOMAS A. MANTEUFFEL‡, AND JAMES S. OTTO‡

Abstract. This paper explores the use of adaptive polynomial preconditioning for Hermitian positive definite linear systems, $Ax = b$. Such preconditioners are easy to employ and well suited to vector and/or parallel machines. After examining the role of polynomial preconditioning in conjugate gradient methods, the least squares and Chebyshev preconditioning polynomials are discussed. Eigenvalue distributions for which each is well suited are then determined. An *adaptive procedure* for dynamically computing the best Chebyshev polynomial preconditioner is also described. Finally, the effectiveness of adaptive polynomial preconditioning is demonstrated in a variety of numerical experiments on a Cray X-MP/48 and Alliant FX/8. The results suggest that relatively low degree (2–16) polynomials are usually best.

Key words. conjugate gradient methods, polynomial preconditioning, Chebyshev polynomial, least squares polynomial, adaptive procedure

AMS(MOS) subject classifications. 65F10, 41A10

1. Introduction.

This paper examines polynomial preconditioning for Hermitian positive definite (hpd) linear systems of equations, $Ax = b$. Such systems arise in many scientific applications. For example, the matrix resulting from the seven-point finite difference approximation to a three-dimensional self-adjoint elliptic PDE is large, sparse, and hpd. The conjugate gradient (CG) method of Hestenes and Stiefel [22] is a popular and effective solution technique for these linear systems, especially when combined with a preconditioner. The incomplete Cholesky factorization of Meijerink and van der Vorst [26] is often an effective preconditioner for CG, but other choices include Jacobi and SSOR. In this paper, we will consider *polynomial preconditioning* for conjugate gradient methods. That is, we will solve

$$C(A)Ax = C(A)b \tag{1.1}$$

where $C(\lambda)$ is a *preconditioning polynomial* and $C(A)$ is the associated polynomial preconditioner. We will assume that $C(\lambda)$ has real coefficients, in which case both $C(A)$ and $C(A)A$ are Hermitian.

Polynomial preconditioning has several advantages, the first of which is simplicity. Since there are only two intrinsic operations, matrix-vector multiplication (*matvec*) and vector addition (*saxpy*), it is easy to implement. The user need only specify the polynomial degree and initialize a few parameters. Consequently, it is ideally suited to "matrix-free" computations [8] (in which the matrix is known only implicitly). Polynomial preconditioning is also versatile. As discussed in [3], polynomial preconditioners may be used in a variety of CG methods. The best known of these is the

PCG method of Concus, Golub, and O'Leary [13]. However, one may exploit the special properties of polynomial preconditioners to devise new CG methods [7]. The key here is commutativity: a polynomial in A commutes with A. In other words, the preconditioner C commutes with the matrix A, a property generally not shared by other preconditioners.

The main advantage of polynomial preconditioning is its suitability for vector and/or parallel architectures. If the matvec is vectorizable, as when A has a regular sparsity structure, polynomial preconditioning is effective on vector machines [3], [15], [24], [25]. In contrast, incomplete factorizations are difficult to vectorize, especially for the nonexpert. It is also possible to chain the matvecs implicit in the preconditioning, thereby enhancing data locality and reducing memory traffic [11], [12], [30], [31]. Polynomial preconditioning is also effective on parallel machines, especially those on which inner products are a bottleneck. This is so because polynomial preconditioned CG methods converge in fewer steps than unpreconditioned CG, and thus compute fewer inner products, albeit at the cost of several matvecs per step instead of one. However, in many applications the matvec is parallelizable, and so we can expect an overall reduction in CPU time on some architectures by substituting matvecs for inner products. The effectiveness of polynomial preconditioning has been demonstrated on an Alliant FX/8 [27] and on a Connection Machine [9].

A common complaint about polynomial preconditioning is that, unlike incomplete Cholesky (ICCG), it is only marginally better than unpreconditioned CG, which we will call CGHS. This criticism is somewhat misleading, however, because it is based on the number of iterations required for convergence rather than the CPU time. Although ICCG may take fewer iterations than polynomial preconditioned CG, the latter may take less time [15], [25]. Moreover, even when incomplete Cholesky is more effective, it can be further accelerated by using a polynomial preconditioner. Specifically, one applies CG to

$$C(M^{-1}A)M^{-1}Ax = C(M^{-1}A)M^{-1}b \tag{1.2}$$

where M is the matrix representation of the incomplete factorization. If M and A are Hermitian, then so is the preconditioner $C(M^{-1}A)M^{-1}$, and several CG methods are applicable [1], [2], [7]. Finally, we remark that polynomial preconditioning can be implemented automatically, and so it is as easy to use as CGHS.

1.1. Outline of paper.

In the next section we review preconditioned CG methods and discuss the various ways in which a polynomial preconditioner can be used. In § 3 we examine polynomial preconditioning. In particular, we discuss the least squares and Chebyshev preconditioning polynomials, study them in the context of CG methods, and show that the latter minimizes a bound on the condition number of the preconditioned matrix. We compare the two polynomials in § 4. In a variety of numerical experiments we determine those eigenvalue distributions for which each is well suited. In § 5 we describe an *adaptive procedure* for dynamically computing the extreme eigenvalues of A, which are used to determine the optimum endpoints on which to base the Chebyshev preconditioning polynomial. We also present numerical results demonstrating the accuracy, efficiency, and competitiveness of the resulting adaptive algorithm. Finally, in § 6, we summarize some numerical experiments that demonstrate the effectiveness of polynomial preconditioning on a variety of test problems. Our results suggest that relatively low degree (2–16) polynomials are usually best.

2. Preconditioned CG methods. In this section we examine the use of polynomial preconditioners in CG methods. To do this it is useful to first characterize CG methods. In [7], it is shown that any CG method is characterized by three matrices: an hpd inner product matrix B, a left preconditioning matrix C, and the original system matrix A. The resulting method, $CG(B, C, A)$, minimizes $||e_i||_B = \langle Be_i, e_i\rangle^{1/2}$ over $V_i(CA, Cr_0)$, where

$$V_i(CA, Cr_0) = \text{span}\{Cr_0, (CA)Cr_0, (CA)^2Cr_0, ..., (CA)^{i-1}Cr_0\} \tag{2.1}$$

is a Krylov subspace of dimension at most i, e_i is the error in the current iterate, r_0 is the initial residual, and $\langle\cdot,\cdot\rangle$ denotes the usual Euclidean inner product. By specifying the inner product matrix B, we obtain a particular CG method. For example, when A is hpd, one may take $B = A$ and $C = I$, which yields CGHS, the original method of Hestenes and Stiefel [22]. If one takes $B = A^2$ and $C = I$, the conjugate residual (CR) method results. Of course, one must chose B and C so that the method is computable [7].

The most robust implementation of a CG method is the so-called Odir algorithm [33], in which a three-term recursion is used to generate a set of direction vectors that form a B-orthogonal basis for V_i. This algorithm converges to the solution of $Ax = b$ whenever BCA is Hermitian. (For necessary and sufficient conditions, see [7] and [16].) If BCA is hpd, the cheaper and more familiar Omin algorithm [33] is applicable. Instead of using a three-term recursion for the direction vectors, Omin uses a two-term recursion involving the preconditioned residuals. Unfortunately, Omin may "stall" when BCA is indefinite, in which case the more expensive Odir, or an Odir/Omin hybrid, algorithm should be used [7], [10].

When A is hpd and $C = C(A)$, there are several choices for the inner product matrix B. A few of the resulting CG methods are listed in Table 2.1. (See [3] and [7] for a thorough discussion.) Notice that BCA is Hermitian in all cases, and so Odir converges. The Odir restrictions in Table 2.1 are sufficient to insure that B is hpd. The Omin restrictions are sufficient to guarantee that both B and BCA are hpd. The first method is PCG. Like CGHS, it minimizes the A-norm of the error, but does so over a preconditioned Krylov subspace. Although the matrix A must be hpd to define a norm, the preconditioner $C(A)$ only needs to be Hermitian for Odir. If $C(A)$ is hpd, one may use the more efficient Omin algorithm. The method GCGHS, which is CGHS on CA, minimizes in the $B = C(A)A$ norm, and so $C(\lambda)$ must be chosen so that the preconditioned matrix is hpd. As we will see, this is possible. The advantage of GCGHS is this: if $C(A)$ is a good preconditioner, then $C(A)A \approx I$, and so the method more nearly minimizes the Euclidean norm of the error. The next method, PCR, requires that $C(A)$ be hpd, in which case $C(A)A$ is hpd because A is hpd. The last two methods, GPCR and GCR, employ $B = A^2$ and $B = (C(A)A)^2$, respectively. The Odir algorithm will converge for either method; Omin is applicable if $C(A)A$ is hpd. Note that GPCR is possible because $CA = AC$ (which implies that BCA is Hermitian), an advantage of C being a polynomial in A. The last method, GCR, is simply CR applied to the preconditioned matrix, CA. We remark that each method except PCG is applicable to Hermitian indefinite A [6].

Finally, we note that the spectral and B condition numbers of CA are identical for each of the methods in Table 2.1. That is, $\kappa_I(CA) = \kappa_B(CA)$, where $\kappa_B(G) = ||G||_B||G^{-1}||_B$. Thus, estimates for the extreme eigenvalues of CA yield a bound on $\kappa_I(CA)$, which may be used to implement a stopping criterion based on the true

TABLE 2.1
Polynomial preconditioned CG methods for hpd A.

Method	B	CA	Odir Restrictions	Omin Restrictions
PCG	A	$C(A)A$	A hpd	A hpd, $C(A)$ hpd
GCGHS	$C(A)A$	$C(A)A$	$C(A)A$ hpd	C(A)A hpd
PCR	$AC(A)A$	$C(A)A$	A herm, $C(A)$ hpd	A hpd, $C(A)$ hpd
GPCR	A^2	$C(A)A$	A herm	C(A)A hpd
GCR	$(C(A)A)^2$	$C(A)A$	A herm	C(A)A hpd

error, rather than the more usual residual error. Eigenvalue estimates for CA are easily obtained from the CG iteration parameters [7], [13]. This is also the basis for the adaptive procedure discussed in § 5.

3. Polynomial preconditioning.

In this section we examine several choices for $C(\lambda)$. We wish to choose C to accelerate convergence of the CG iteration. One usually chooses C to approximate A^{-1} in some sense, for example, by choosing $C(\lambda) \approx \lambda^{-1}$. Of course, there are several ways of doing this. As we will see, there is no single "best" polynomial; the proper choice of $C(\lambda)$ depends on the eigenvalue distribution of A, which is seldom known a priori.

A simple choice for $C(\lambda)$ is based on the Neumann series. Let $A = M - N$ and consider

$$A^{-1} = (M-N)^{-1} = (I + G + G^2 + G^3 + \cdots)M^{-1} \tag{3.1}$$

where $G = M^{-1}N$. If the spectral radius of G is less than one, the series converges. We obtain our polynomial approximation to A^{-1} by truncating the Neumann series [2], [9], [15], [25]. The advantage of this polynomial is its simplicity: there are no parameters to estimate. Unfortunately, it may yield a poor preconditioner. If one desires a polynomial preconditioner of degree $m-1$, one can do much better than the Neumann series polynomial. For example, Jordan [25] has shown that the Chebyshev polynomial (§ 3.2) is superior. Experiments also suggest that the optimum degree for the Neumann series polynomial is two [2], [15], [25], whereas the optimum Chebyshev or least squares polynomial degree is often higher [3], [27], [30].

To obtain a better preconditioner, recall that $C(A)$ should approximate A^{-1} in some sense. That is, $C(\lambda)$ should be the "best" polynomial approximation to λ^{-1} on some set S containing the spectrum of A, $\sigma(A)$. Since A is hpd, we will take $S = [c, d]$, where $0 \leq c \leq d$. Ideally, $c = \lambda_c$ and $d = \lambda_d$, the smallest and largest eigenvalues of A. We next define the "best" polynomial to be that one which solves the following approximation problem:

$$\min_{C \in \pi_{m-1}} \|1 - C(\lambda)\lambda\| \tag{3.2}$$

where π_{m-1} is the set of polynomials of degree at most $m-1$. All that remains is to specify the norm.

3.1. The least squares polynomial preconditioner.

Let us define the inner product

$$\langle f, g \rangle = \int_c^d f(\lambda)\overline{g(\lambda)}\omega(\lambda)d\lambda \tag{3.3}$$

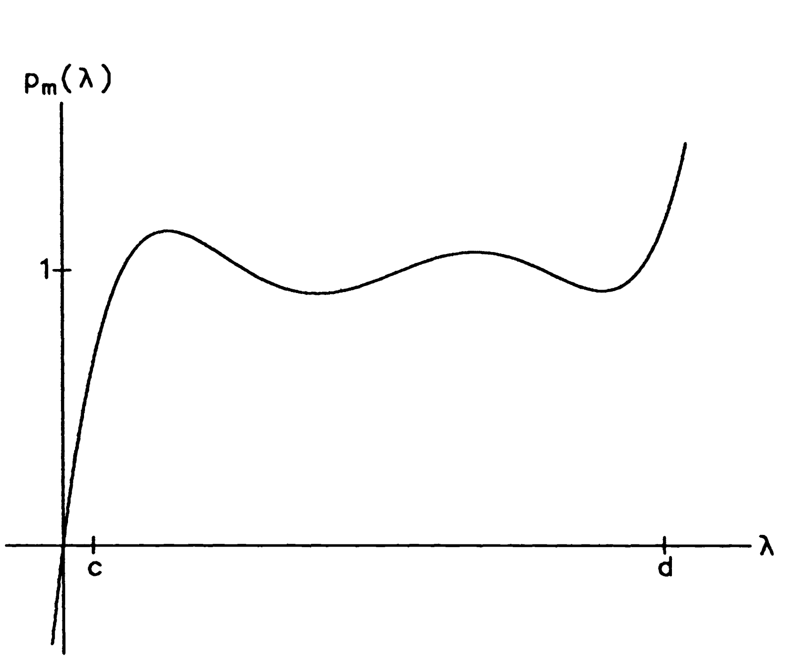

FIG. 3.1. *Least squares preconditioned polynomial* $(m = 5)$ *for* $S = [0, 20]$.

where $\omega(\lambda)$ is a positive weight function on $S = [c, d]$. It induces the following norm:

$$\|f\|_\omega^2 = \int_c^d |f(\lambda)|^2 \omega(\lambda) d\lambda. \tag{3.4}$$

The solution to (3.2) in this norm is called the weighted *least squares* polynomial. The associated *preconditioned* polynomial, $p_m(\lambda) = C(\lambda)\lambda$, is illustrated in Fig. 3.1. (We call $p_m(\lambda)$ the preconditioned polynomial because $p_m(A)$ is the preconditioned matrix.)

The related *residual* polynomials, $r_m(\lambda) = 1 - C(\lambda)\lambda$, are orthogonal with respect to the weight function $\lambda\omega(\lambda)$. This is so because the error in (3.2) is orthogonal to $\lambda\pi_{m-1}$, the subspace from which the best polynomial approximation to 1 is taken. Consequently,

$$\int_c^d r_m(\lambda) r_j(\lambda) \lambda \omega(\lambda) d\lambda = \int_c^d r_m(\lambda) q(\lambda) \omega(\lambda) d\lambda = 0, \qquad j \leq m - 1,$$

where $q(\lambda) = \lambda r_j(\lambda) \in \lambda\pi_{m-1}$. Thus, the least squares residual polynomials are orthogonal in the λ-inner product, $\langle f, g\rangle_\lambda = \langle \lambda f, g\rangle$, and hence satisfy a three-term recursion, which is computationally convenient (§ 3.3). See also [24] and [30].

Unlike the Chebyshev polynomial described below, the least squares polynomial is biased in its suppression of the eigenvalues of A. For example, when $\omega \equiv 1$, the eigenvalues of larger modulus are mapped closer to 1 than those of smaller modulus. If the eigenvalue distribution of A were known, one could choose ω to exploit this bias. In particular, one might consider a *Jacobi* weight function,

$$\omega(\alpha, \beta; \lambda) = (d - \lambda)^\alpha (\lambda - c)^\beta, \qquad \alpha, \beta > -1. \tag{3.5}$$

By appropriately choosing α and β, one portion of $\sigma(A)$ could be emphasized over another.

Saad [30] has noted that the least squares polynomial is relatively insensitive to c, and so one may take $c = 0$. Then, if a Jacobi weight function is used, the least squares polynomial is given by

$$C(\lambda)\lambda = 1 - \frac{P_m(\frac{d+2\lambda}{d})}{P_m(1)} \tag{3.6}$$

where $P_m(x)$ is the Jacobi polynomial [14] on $[-1,1]$ with respect to $\omega(\alpha+1, \beta; \lambda)$. This follows from the λ-orthogonality of the residual polynomials. If it is known that $\sigma(A)$ is clustered near some point $\lambda_0 \in [0,d]$, one might wish to choose α and β with the following result in mind.

THEOREM 3.1. *Let $r(\lambda)$ be the least squares residual polynomial for $[0,d]$ with respect to $\omega(\alpha,\beta;\lambda)$, where $(\alpha,\beta) \in W_1 = \{(\alpha,\beta) : \alpha > -1,\ \beta \geq -\frac{1}{2}\}$. Then the relative extrema of $r(\lambda)$ monotonically decrease in magnitude on $[0,\lambda_0]$ and monotonically increase in magnitude on $[\lambda_0, d]$, where*

$$\lambda_0 = \frac{d}{2}\left(1 - \frac{\beta-\alpha-1}{\beta+\alpha+2}\right) = \frac{d}{2}\left(\frac{2\alpha+3}{\beta+\alpha+2}\right). \tag{3.7}$$

Proof. The result follows from (3.6) and Theorem 7.32.1 of [32]. □

Of course, one should choose the weight function ω so that $p_m(\lambda) = C(\lambda)\lambda$ is positive on $[\lambda_c, \lambda_d]$. This guarantees that $p_m(A)$ is hpd, which makes practicable the Omin implementation of each method in Table 2.1. (Observe that PCG and PCR are applicable because $C(A)$ is hpd whenever $p_m(A) = C(A)A$ is hpd.) We note that $p_m(\lambda)$ may be indefinite if $\omega(\lambda)$ is biased toward the leftmost portion of $[c,d]$. However, if one employs a Jacobi weight function on $[c,d]$, one may show [24, p. 369] that $p_m(\lambda) > 0$ on $[c,d]$ if $(\alpha,\beta) \in W_2 = \{(\alpha,\beta) : \alpha \geq \beta \geq -\frac{1}{2}\}$, which includes the Legendre weight function $\omega \equiv 1$ ($\alpha = \beta = 0$). Moreover, if $c = 0$ and $\alpha = \beta$ in W_2, then $\lambda_0 = \lambda_0(\alpha) : [-\frac{1}{2}, \infty) \rightarrow (d/2, d]$. Thus, if $\sigma(A)$ is clustered near $\lambda_0 \in (d/2, d]$, one might employ the weight function $\omega(\alpha_0, \alpha_0; \lambda)$, where $\alpha_0 = -(\lambda_0 - 3d/4)/(\lambda_0 - d/2)$; cf. Theorem 3.1. Finally, if $(\alpha,\beta) \in W_3 = \{(\alpha,\beta) : \alpha > -1,\ -1 < \beta \leq -\frac{1}{2}\}$, it follows as in Theorem 3.1 that the relative extrema of the least squares polynomial decrease in magnitude on $(0,d]$. This property, which is in stark contrast to the equioscillation property of the Chebyshev preconditioned polynomial (see below), may be used to bias the preconditioner toward the large eigenvalues of A. This property also insures that $p_m(\lambda)$ is positive on $(0,d]$.

Because of its bias, the least squares polynomial yields an effective preconditioner in many cases [24], [30]. Since one may take $c = 0$, there is no need to estimate the smallest eigenvalue of A. The right endpoint is often taken to be the Gershgorin estimate for λ_d. However, the least squares polynomial is not always best. For example, if $\sigma(A)$ is dense near the origin, one should instead use the Chebyshev polynomial preconditioner, which we describe next.

3.2. The Chebyshev polynomial preconditioner.

Another interesting norm is the uniform norm:

$$\|f\|_\infty = \max_{\lambda \in S} |f(\lambda)|. \tag{3.8}$$

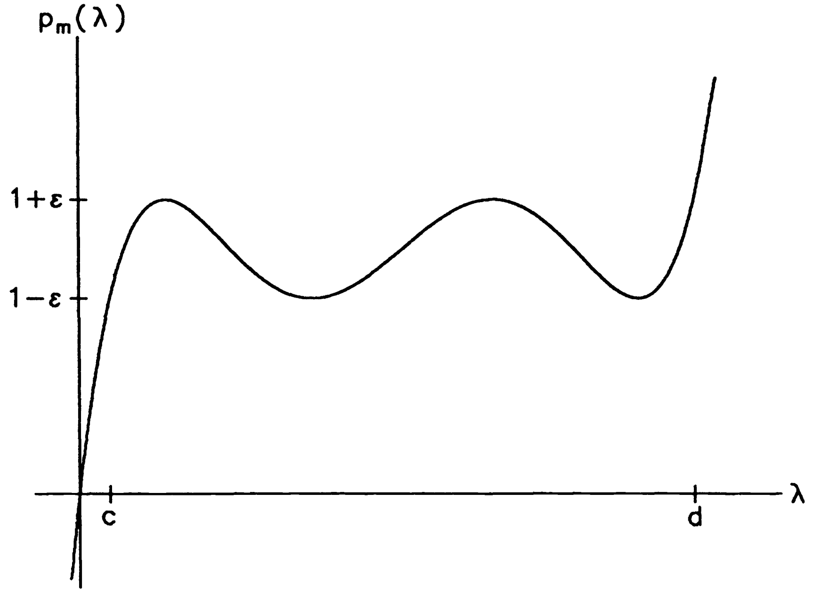

FIG. 3.2. *Chebyshev preconditioned polynomial* ($m = 5$) *for* $S = [1, 20]$.

The solution to (3.2) in this norm is obtained from a shifted and scaled Chebyshev polynomial:

$$C(\lambda)\lambda = 1 - \frac{T_m(\frac{d+c-2\lambda}{d-c})}{T_m(\frac{d+c}{d-c})} \tag{3.9}$$

where $T_m(x)$ is the mth Chebyshev polynomial of the first kind [28]. It is attractive for several reasons. First, like the least squares polynomial, it may be computed from a three-term recursion, which is computationally convenient. Second, since this polynomial is explicitly known, it is much easier to devise an adaptive procedure for dynamically computing the optimal endpoints c and d. Finally, this polynomial is unbiased in its suppression of those eigenvectors constituting the error. In other words, the Chebyshev preconditioning polynomial is well suited to those matrices whose eigenvalues are densely and nearly uniformly distributed throughout the interval $S = [c, d]$. See § 4.

This last fact follows from the Chebyshev minimax property, which states that the preconditioned polynomial, $p_m(\lambda) = C(\lambda)\lambda$, equioscillates about 1; see Fig. 3.2. This equioscillation property has several other implications. For example, if $\sigma(A) \subset [c, d]$, then $\sigma(p_m(A)) \subset [1-\epsilon_m, 1+\epsilon_m]$, where $\epsilon_m = \|1-p_m\|_\infty = |T_m^{-1}(\frac{d+c}{d-c})|$. Since $\epsilon_m < 1$, the preconditioned matrix, $p_m(A)$, is hpd. One may therefore apply CGHS to $p_m(A)$, yielding the method we call GCGHS. PCG is also applicable because $C(A)$ is hpd. Note that the spectral condition number of $p_m(A)$, $\kappa(p_m(A))$, satisfies

$$\kappa(p_m(A)) \leq \frac{1+\epsilon_m}{1-\epsilon_m} \tag{3.10}$$

when $\sigma(A) \subset [c,d]$. Since ϵ_m is a monotonically decreasing function of m, this bound may be made as small as desired by taking m large enough. Specifically, if

$$m \geq \frac{\cosh^{-1}(\frac{\delta+1}{\delta-1})}{\cosh^{-1}(\frac{\kappa(A)+1}{\kappa(A)-1})}, \tag{3.11}$$

then $\kappa(p_m(A)) < \delta$ for any $\delta > 1$. This follows from the definition of $T_m(\lambda)$ for $\lambda > 1$.

The bound (3.10) yields an estimate of the number of CG steps required for convergence. One needs approximately

$$\frac{\ln(\delta/2)}{\ln(cf)} \tag{3.12}$$

steps to reduce the error by an amount δ [21], where

$$cf = cf(p_m(A)) = \frac{\sqrt{\kappa(p_m(A))} - 1}{\sqrt{\kappa(p_m(A))} + 1} \tag{3.13}$$

is the *CG convergence factor* for the hpd matrix $p_m(A)$. If the eigenvalues of $p_m(A)$ are uniformly distributed throughout $[1-\epsilon_m, 1+\epsilon_m]$, then (3.12) is fairly accurate. Since $\kappa(p_m(A)) \leq \kappa(A)$ for $m > 1$, a Chebyshev polynomial preconditioned CG method will usually converge in fewer iterations than the unpreconditioned CGHS method. Of course, each iteration is more expensive, requiring m matvecs instead of one. We remark that $\kappa(p_m(A))$ is minimized when $c = \lambda_c$ and $d = \lambda_d$.

The Chebyshev polynomial preconditioner is also optimum in that it minimizes a bound on $\kappa(C(A)A)$. This is a consequence of the following result.

THEOREM 3.2. *A solution to*

$$\min_{C \in \pi_{m-1}} \frac{\max_{\lambda \in S} |C(\lambda)\lambda|}{\min_{\lambda \in S} |C(\lambda)\lambda|} \tag{3.14}$$

is given by the Chebyshev preconditioning polynomial.

Proof. First observe that (3.14) does not possess a unique solution. In particular, if Q solves (3.14), then so does γQ, where γ is any nonzero constant. We may assume $C(\lambda)\lambda > 0$ for $\lambda \in S$ without loss of generality. (If $C(\lambda)\lambda = 0$ for some $\lambda \in S$, then (3.14) is unbounded.) Thus, we may restrict ourselves to those polynomials $C(\lambda)$ for which

$$1 - \min_{\lambda \in S} (C(\lambda)\lambda) = \max_{\lambda \in S} (C(\lambda)\lambda) - 1 = \epsilon(C) = \epsilon. \tag{3.15}$$

The problem (3.14) is now equivalent to minimizing $\frac{1+\epsilon}{1-\epsilon}$. This is, in turn, equivalent to solving (3.2) in the uniform norm. □

Remark. If p_m is the Chebyshev preconditioned polynomial for S and $\sigma(A) \subset S$, the ratio in (3.14) gives a bound on the condition number of $p_m(A)$. Moreover, this bound is minimized with respect to S when $S = [\lambda_c, \lambda_d]$. The bound is attained when $S = [\lambda_c, \lambda_d]$ and m is odd.

This theorem is similar to Theorem 3 in [24], but our proof is different. It shows the equivalence of the minimax approximation problem (3.2) and the minimization problem (3.14). We also remark that Rutishauser [29] was the first to propose Chebyshev polynomial preconditioning for CGHS; his motive was to mitigate its rounding errors. We advocate polynomial preconditioning because it is well suited to vector and/or parallel architectures.

3.3. Implementation. To implement least squares or Chebyshev polynomial preconditioning, one neither explicitly forms the powers of A nor determines the coefficients of $C(\lambda)$. Instead, one may exploit the three-term recursion underlying the least squares and Chebyshev residual polynomials to effect the polynomial preconditioning. To see how, recall that both polynomials satisfy a recursion of the form

$$Q_{k+1}(\lambda) = (\phi_k \lambda + \psi_k) Q_k(\lambda) - \xi_k Q_{k-1}(\lambda) \tag{3.16}$$

where Q_k is the least squares or Chebyshev residual polynomial; cf. (3.6) and (3.9). The coefficients ϕ_k, ψ_k, and ξ_k may be generated recursively for the Jacobi-weighted least squares and Chebyshev polynomials. We may use (3.16) to formulate a second order Richardson iteration [21]:

$$r_0 = b - Ax_0 \tag{3.17}$$

$$\Delta_0 = -\phi_0 r_0 \tag{3.18}$$

$$x_{i+1} = x_i + \Delta_i \tag{3.19}$$

$$r_{i+1} = b - Ax_{i+1} \tag{3.20}$$

$$\Delta_{i+1} = \xi_{i+1}\Delta_i - \phi_{i+1} r_{i+1}. \tag{3.21}$$

Thus, to implement the polynomial preconditioning, one simply executes m steps of this nonstationary two-step iteration. (In the case of Chebyshev polynomial preconditioning, one uses the Chebyshev iteration [21].) Specifically, one applies the iteration to the linear system $Aw = v$ with $w_0 = 0$, where v is the vector to be preconditioned, usually the residual. One may show [4] that $w_m = C(A)v$. Note that we need only $m - 1$ matrix-vector multiplications because the final residual need not be computed. We also remark that the three-term recursion underlying the least squares and Chebyshev polynomials insures the stable evaluation of the preconditioning polynomial $C(\lambda)$. See also [24] and [30].

4. Chebyshev versus least squares. In this section we compare the least squares and Chebyshev preconditioning polynomials in a variety of numerical experiments. We will qualitatively describe those matrices for which the least squares polynomial yields a better preconditioner than the exact Chebyshev preconditioner. (The exact Chebyshev polynomial is the one based on $[\lambda_c, \lambda_d]$; recall that this polynomial minimizes a bound on the condition number of $C(A)A$.) Moreover, we will explain why this is so. The importance of the stopping criterion will also be discussed.

Let us begin by dispelling a common misconception: the least squares polynomial is *not* universally superior to the exact Chebyshev polynomial. This follows from a result of Greenbaum [20], who established a partial ordering on preconditioners. In brief, her result implies that the least squares preconditioner cannot be best for every initial guess, x_0. However, it is better in certain cases. For although the exact Chebyshev polynomial minimizes the condition number of $p_m(A)$, this does not alone determine the rate of convergence of the preconditioned CG method. The eigenvalue distribution of $p_m(A)$ is also important. Because of its equioscillation property, the Chebyshev polynomial tends to map $[c, d]$ uniformly into $[1-\epsilon_m, 1+\epsilon_m]$, obliterating any favorable clustering of the eigenvalues of A. The unweighted least squares polynomial ($\omega \equiv 1$) tends to map the larger eigenvalues of A most closely about 1, giving less weight to the smaller eigenvalues. This is due to the tendency of its relative extrema to decrease in magnitude on S. (This property can be made strict by an appropriate choice of weight function; see § 3.1.) Thus, if there are relatively few eigenvalues of A near c, these will become isolated eigenvalues of the least squares preconditioned matrix, the majority of whose eigenvalues will be clustered about 1. On the other hand, if the eigenvalues of A are dense near c, there will be no such clustering of eigenvalues. The proper choice of polynomial therefore depends on the spectrum of A. We will now explore this question numerically.

In the experiments below, the test matrices are diagonal with $N = 100,000$ eigenvalues between $\lambda_c = \delta$ and $\lambda_d = 1 + \delta$. The true solution is the vector having 1 in each of its components and $x_0 = 0$. Three eigenvalue distributions are considered. In the first, $\lambda_k = \delta + 1 - 1/k$, $k = 2, \ldots, N-1$, and so the eigenvalues are dense near the right endpoint d, such as with integral operators of the second kind. In the second, $\lambda_k = \delta + 1/(N - k + 1)$, and so the eigenvalues are dense near the left endpoint c, as with integral operators of the first kind. In the third, the eigenvalues are uniformly distributed, as is roughly the case for differential operators. In Figs. 4.1–4.4, we plot the PCG relative error, $\log_{10}(\|e_i\|_2/\|e_0\|_2)$, against i for three polynomials of degree $m = 9$. (Recall that PCG refers to the preconditioned CG method of Concus, Golub, and O'Leary [13].) The first is a least squares polynomial (with Legendre weight $\omega \equiv 1$) based on $[0, 1 + \delta]$; the second is the exact Chebyshev polynomial based on $[\delta, 1+\delta]$; and the third is a Chebyshev polynomial based on $[\zeta, 1+\delta]$, where ζ is chosen so that the related least squares and Chebyshev residual polynomials have the same first root. By choosing ζ in such a manner, we force this LS-Chebyshev polynomial to mimic the behavior of the least squares polynomial on $(0, \zeta)$. Consequently, the two preconditioning polynomials behave alike for matrices with eigenvalues in $(0, \zeta)$.

In Fig. 4.1, we have the dense-right eigenvalue distribution with $\delta = 10^{-3}$. Since the least squares polynomial is small on the large eigenvalues of A, the least squares PCG method converges much more rapidly than the exact Chebyshev PCG method. In Fig. 4.2, the eigenvalues are dense near the left endpoint, and the exact Chebyshev PCG method converges faster. Similar results were observed for other values of δ. In Figs. 4.3–4.4, we have the uniform eigenvalue distribution. When $\delta = 10^{-3}$, the gap between successive eigenvalues is $1/N$, which is smaller than λ_c, and the exact Chebyshev PCG method converges fastest. However, if $\delta = 10^{-5}$, the gap between successive eigenvalues is larger than λ_c, and the least squares PCG method converges faster. We have seen similar behavior in several other experiments. In short, the exact Chebyshev polynomial appears to be superior to the least squares polynomial when the gap between successive eigenvalues is small relative to the size of λ_c. The exact Chebyshev polynomial is also superior to the least squares polynomial when the eigenvalues of A are dense near both endpoints of S or throughout S. In the latter case, for instance, if we fix $\delta = 10^{-3}$ and increase N, the exact Chebyshev polynomial performs best for large N.

As claimed, the LS-Chebyshev polynomial behaves like the least squares polynomial and, depending on the eigenvalue distribution of A, may be superior to the exact Chebyshev polynomial. For example, if the eigenvalues of A are sparse near c and dense near d (recall Fig. 4.1), the LS-Chebyshev PCG method will usually converge in fewer iterations than the exact Chebyshev PCG method. The explanation is similar to that for the superiority of the least squares polynomial: The LS-Chebyshev polynomial maps those eigenvalues in $[\zeta, d]$ more tightly about 1 than does the exact Chebyshev polynomial. Of course, those eigenvalues in $[c, \zeta)$ are mapped further away from one. However, there are relatively few eigenvalues in $[c, \zeta)$; moreover, they be-

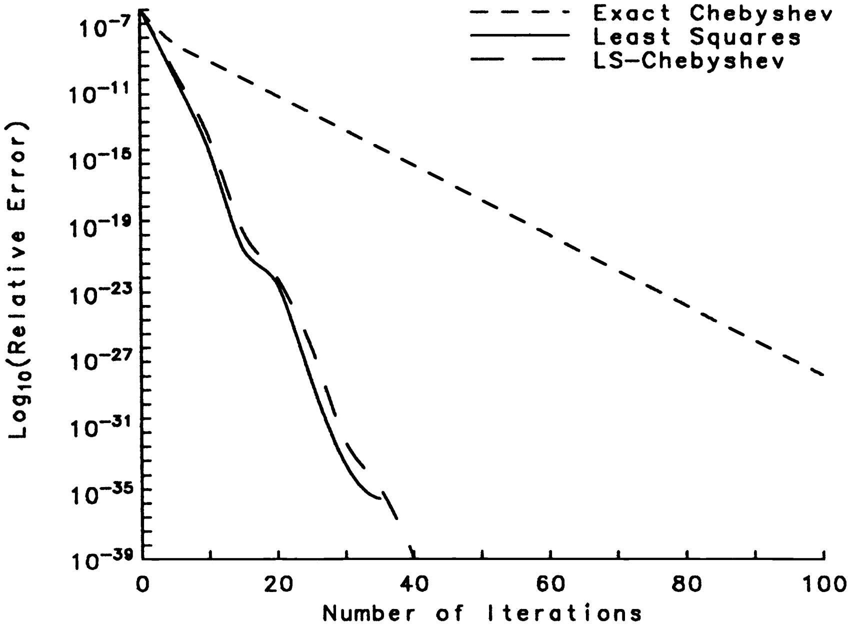

FIG. 4.1. *Dense-right eigenvalue distribution;* $\delta = 10^{-3}$.

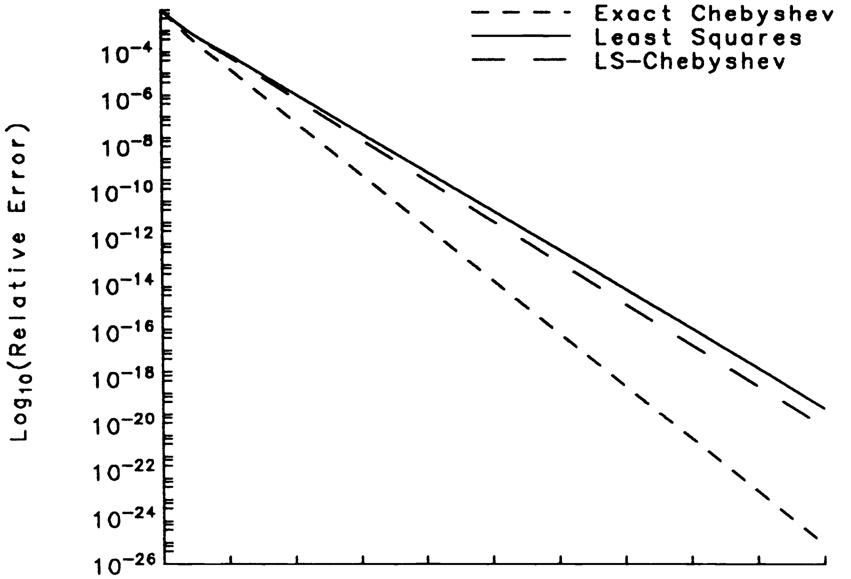

FIG. 4.2. *Dense-left eigenvalue distribution;* $\delta = 10^{-3}$.

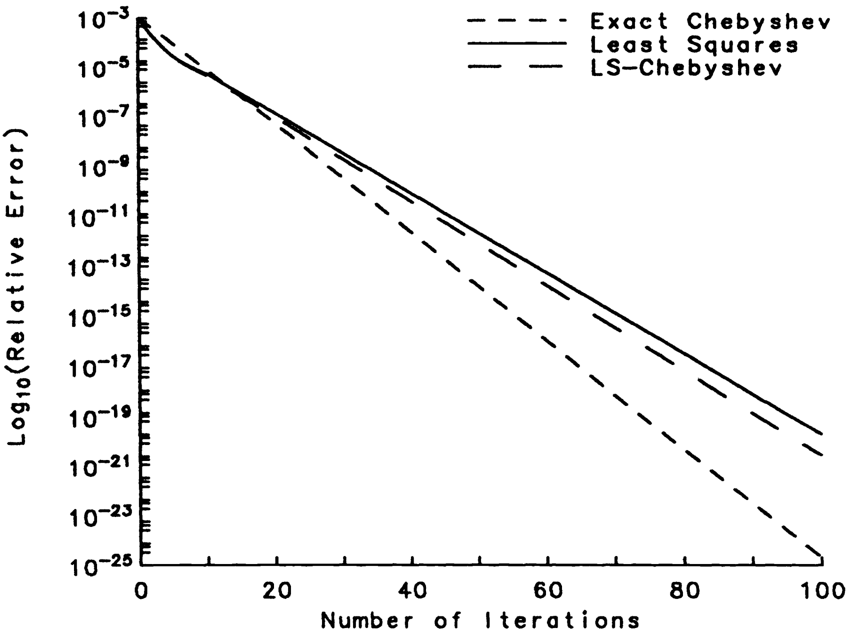

FIG. 4.3. *Uniform eigenvalue distribution;* $\delta = 10^{-3}$.

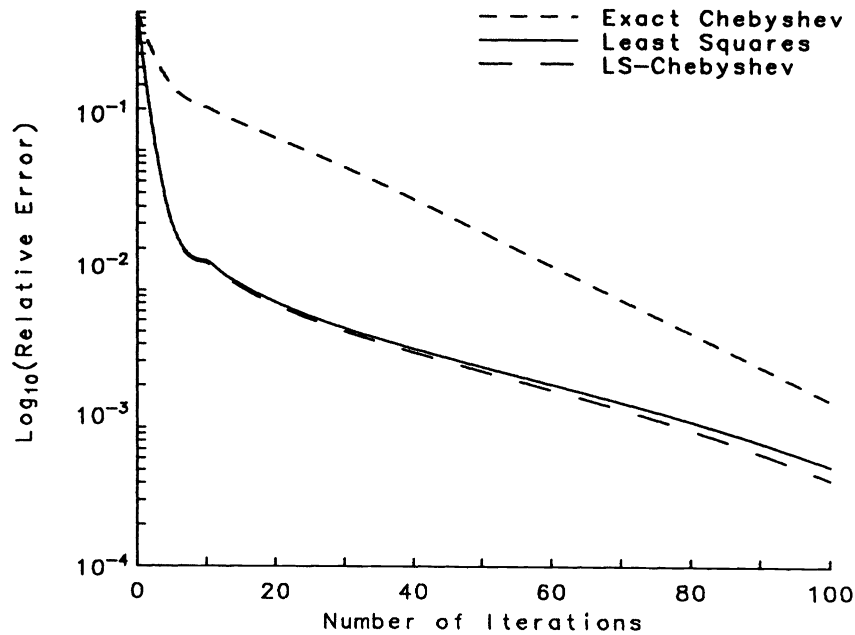

FIG. 4.4. *Uniform eigenvalue distribution;* $\delta = 10^{-5}$.

come isolated eigenvalues of $C(A)A$. It is well known that CG rapidly damps the error in the direction of the corresponding eigenvectors. After doing this, it is able to focus its effort on the dense part of the spectrum where the LS-Chebyshev polynomial does a better job of clustering the eigenvalues about 1. Since one seldom knows how the eigenvalues of A are distributed, one must rely on an adaptive procedure to find the optimum S. If one knew the eigenvalue distribution of A, an appropriately weighted Chebyshev or least squares polynomial could be used to achieve faster convergence. Freund [17] has recently proposed using the Lanczos eigenvalue estimates to obtain such a weight function, and his results are promising. In particular, he has shown that the resulting preconditioned CG method often converges faster than the method based on the exact Chebyshev polynomial. Unfortunately, there is no guarantee that the preconditioned matrix will be hpd for all S, and this can make difficult or impossible the robust implementation of some adaptive CG algorithms.

Finally, we note that the choice of stopping criterion can also affect the choice of polynomial. Since the least squares polynomial is small on the large eigenvalues of A, it is biased toward this part of the spectrum. Those eigenvectors associated with the large eigenvalues of A are consequently damped the most. If one bases the stopping criterion on the relative residual, the eigenvectors corresponding to these large eigenvalues are given greater weight. Thus, this stopping criterion is ideally suited to the least squares polynomial. The exact Chebyshev polynomial, on the other hand, is well suited for use in stopping criteria based on the true error. (Although the true error is unknown, it can be bounded [7].) The difference between these stopping criteria can be as large as $\kappa_B(A)$.

4.1. The need for an adaptive procedure. Recall that the weighted least squares and uniform norms are defined with respect to the positive interval S, which we have assumed contains the spectrum of A. That is, we have assumed that the smallest and largest eigenvalues of A, λ_c and λ_d, are given. Unfortunately, this is seldom true. In the case of the least squares polynomial, one may avoid this difficulty by choosing c and d to be the Gershgorin estimates for λ_c and λ_d. In particular, one may take $c = 0$. The resulting preconditioner is often effective, but there are eigenvalue distributions for which the exact Chebyshev polynomial is better. Here one needs accurate estimates for the extreme eigenvalues of A. Although this might be viewed as a reason for using the Neumann series or least squares polynomial, it is not. As we will see, one may dynamically estimate λ_c and λ_d from the CG iteration parameters. This is equivalent to dynamically determining the exact Chebyshev polynomial preconditioner. However, as we have seen, one can often do much better by basing the Chebyshev preconditioning polynomial on an interval $[c_{opt}, d_{opt}]$, where $\lambda_c \leq c_{opt} \leq d_{opt} \leq \lambda_d$. In the next section, we describe an *adaptive procedure* for finding these optimum endpoints.

5. Adaptive CG algorithms. In this section we discuss *adaptive* CG algorithms. In such an algorithm we apply a given CG method to the preconditioned linear system $C(A)Ax = C(A)b$, where $C(\lambda)$ is a Chebyshev preconditioning polynomial. Information about the spectrum of A is extracted from the CG iteration parameters and used to obtain a better preconditioner, $\tilde{C}(A)$. In this way the adaptive algorithm tries to determine the *optimum* Chebyshev polynomial preconditioner for A. Here the "optimum" polynomial is the one yielding the fastest convergence of the preconditioned CG algorithm. Although we consider only the Chebyshev polynomial, a similar procedure could be devised for the least squares polynomial.

In general, the interval on which the optimum polynomial is based, $[c_{opt}, d_{opt}]$, is a proper subset of $\Sigma(A) = [\lambda_c, \lambda_d]$. Our goal is to determine c_{opt} and d_{opt}. To do this, we start with an initial set $S_0 = [c_0, d_0]$ and expand it using information obtained from the CG iteration. Specifically, given an interval $S \subset \Sigma(A)$, and a Chebyshev preconditioning polynomial $C(\lambda)$ based on S, we apply a CG method to $C(A)Ax = C(A)b$. After a prescribed number of steps, say ℓ, the *adaptive procedure* is called:

(1) Compute eigenvalue estimates for $p_m(A) = C(A)A$.
(2) Extract eigenvalue estimates for A and update S.
(3) Determine the new preconditioning polynomial, $\tilde{C}(\lambda)$.
(4) Resume or restart the CG iteration, whichever is appropriate.

After another ℓ CG steps, the adaptive procedure is called again, and so on until convergence.

Eigenvalue estimates for $p_m(A)$ are easily obtained from the CG iteration parameters by exploiting the equivalence of the CG and Lanczos algorithms [7], [13], [19]. (See [18] for an alternative.) As we will see, it is easy to recover eigenvalue estimates for A when the degree m of the polynomial is odd. Once we have these estimates, we determine the new polynomial (i.e., the new endpoints on which to base it) by comparing several convergence factors. If a new polynomial results, we *restart* the CG iteration. By this we mean that the current iteration is abandoned and the CG method is applied to $\tilde{C}(A)Ax = \tilde{C}(A)b$. The new initial guess is the last iterate of the previous iteration or some linear combination of past iterates.

5.1. Estimating the extreme eigenvalues of A. Suppose we are executing a polynomial preconditioned CG iteration, where

$$p_m(\lambda) = C(\lambda)\lambda = 1 - \frac{T_m(\frac{d+c-2\lambda}{d-c})}{T_m(\frac{d+c}{d-c})} \tag{5.1}$$

is the Chebyshev preconditioned polynomial for $S = [c, d]$. Note that the image of S under p_m is $J_\epsilon = [1 - \epsilon, 1 + \epsilon]$, where $\epsilon = T_m^{-1}(\frac{d+c}{d-c})$; recall § 3.2. Next, assume the adaptive procedure has been called, and let μ be an eigenvalue estimate for $p_m(A)$ such that $\mu \in \Sigma(p_m(A))$, the convex hull of $\sigma(p_m(A))$. (This is true of the estimates we will obtain.) The desired eigenvalue estimate for A is one of the inverse images of μ; the task is to determine which one. It is important to choose an inverse image that lies in $\Sigma(A)$. Otherwise S might be improperly and irrevocably expanded, which would slow the convergence of subsequent CG iterations.

Suppose first that $\mu \in J_\epsilon$. Then there exists an inverse image of μ inside S. Since there is no justification for expanding S, this estimate may be discarded. If every eigenvalue estimate for $p_m(A)$ is in J_ϵ, there is no need to update S, and the CG iteration resumes. The adaptive procedure has yielded no new information.

Now suppose $\mu \notin J_\epsilon$. Since $\mu \in \Sigma(p_m(A))$, μ must have an inverse image in $\Sigma(A)\backslash S$, which means there is an eigenvalue of A outside S. If an estimate, λ, of this eigenvalue can be recovered, S can be expanded, and a new, better preconditioner computed. When m is odd, it is easy to extract λ from μ, as may be seen in Fig. 5.1. For example, let $\mu = \mu_1 < 1-\epsilon$. Since $p_m(\lambda)$ is monotonically increasing for $\lambda \in (0, c)$, there is a unique $\lambda_1 \in (0, c)$ such that $\mu_1 = p_m(\lambda_1)$. Moreover, since $\mu_1 \in \Sigma(p_m(A))$, λ_1 must lie in $\Sigma(A)$. Similarly, if $\mu = \mu_2 > 1+\epsilon$, then the unique inverse image of μ_2, λ_2, lies in $\Sigma(A)$. Note that estimates for only the smallest and largest eigenvalues of

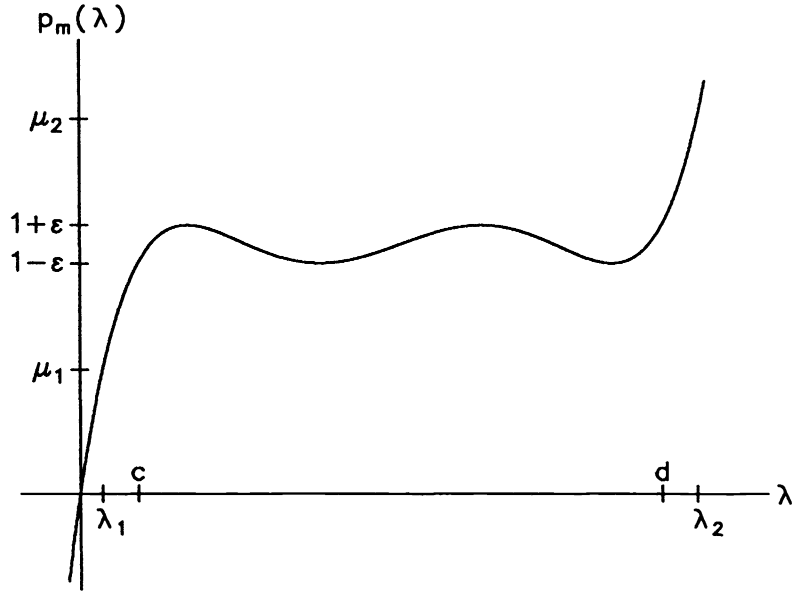

FIG. 5.1. *Chebyshev preconditioned polynomial* ($m = 5$) *for* $S = [1, 10]$.

$p_m(A)$ are needed, for these yield estimates, λ_1 and λ_2, for the extreme eigenvalues of A.

To compute the inverse images of μ_1 and μ_2, a rootfinder could be used, but this is unnecessary because $p_m(\lambda)$ is known explicitly. For m odd and $d \neq c$, one may show

$$\lambda_1 = \frac{1}{2}\left[(d+c) - (d-c)\cosh\left(\frac{1}{m}\cosh^{-1}\left(\frac{1-\mu_1}{\epsilon}\right)\right)\right] \tag{5.2}$$

and

$$\lambda_2 = \frac{1}{2}\left[(d+c) + (d-c)\cosh\left(\frac{1}{m}\cosh^{-1}\left(\frac{\mu_2-1}{\epsilon}\right)\right)\right]. \tag{5.3}$$

If $d = c$ (a common choice for the initial S), then

$$\lambda_1 = d\left(1 - (1-\mu_1)^{1/m}\right) \quad \text{and} \quad \lambda_2 = d\left(1 + (\mu_2 - 1)^{1/m}\right). \tag{5.4}$$

So far we have assumed that m is odd, which is important for two reasons. To see why, consider Fig. 5.2, in which m is even. As before, any eigenvalue estimates for $p_m(A)$ in J_ϵ are discarded. Since both tails of $p_m(\lambda)$ are negative, there can be no estimate $\mu > 1 + \epsilon$, so suppose $\mu < 1 - \epsilon$. There are now two inverse images, λ_1 and λ_2, at least one of which lies in $\Sigma(A)$. If the wrong one is chosen, the set S may be incorrectly enlarged, and the CG method will converge more slowly than necessary. To avoid this *ambiguity*, we shall always choose m odd.

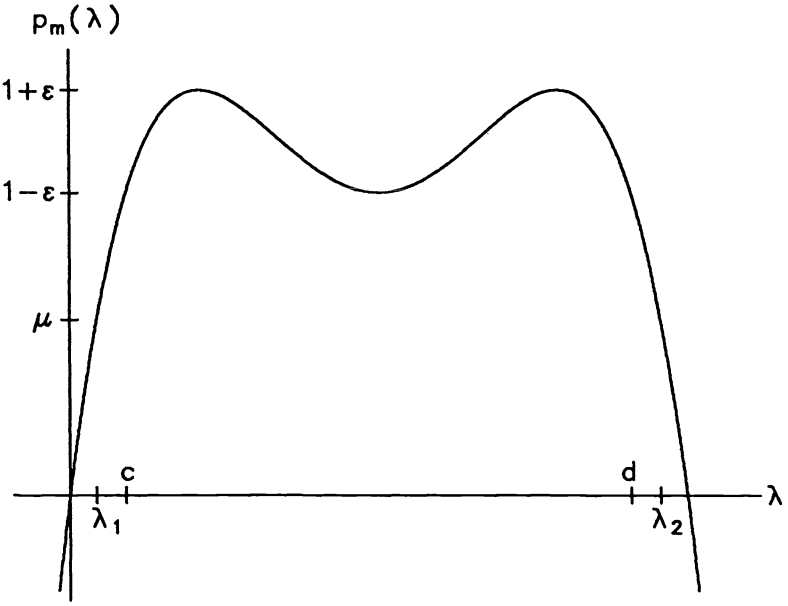

FIG. 5.2. *Chebyshev preconditioned polynomial* ($m = 4$) *for* $S = [1, 10]$.

Another advantage of choosing m odd is that it yields *robust* CG methods. By this we mean that $p_m(A)$ is hpd for any hpd A and for any set S. If this were not true, the CG method might not be defined in the early iterations. For example, if m were even and there were an eigenvalue of A greater than the largest root of $C(\lambda)\lambda$, $p_m(A)$ would be indefinite, in which case GCGHS and PCR are inappropriate, as are the Omin implementations of PCG, GPCR, and GCR. One would have to use the Odir or Odir/Omin implementation of PCG, GPCR, or GCR. When m is odd, on the other hand, $p_m(A)$ is hpd for any set S and the Omin implementation of each method in Table 2.1 is applicable.

5.2. Determining the new endpoints. After eigenvalue estimates for A are computed, we must determine the new endpoints on which to base the Chebyshev preconditioning polynomial. A simple choice is $c = \lambda_1$ and $d = \lambda_2$, which essentially gives the adaptive procedure in [3] and [5]. Since the Lanczos algorithm quickly determines the extreme eigenvalues of $C(A)A$, and hence of A, this procedure quickly finds the exact Chebyshev preconditioning polynomial. If this polynomial were used, $\kappa(C(A)A)$ would be minimized. However, this polynomial does not necessarily minimize the number of CG iterations required for convergence. It has been observed [24], [30] that one often obtains better performance by basing the Chebyshev preconditioning polynomial on some interval $[c_{opt}, d_{opt}]$, where $\lambda_c \leq c_{opt} \leq d_{opt} \leq \lambda_d$. The LS-Chebyshev polynomial (§ 4) is such an example. To understand why, recall that the true rate of convergence of a CG method depends on the distribution of the eigenvalues of A within $\Sigma(A)$. For instance, if λ_c is an isolated eigenvalue of A and $\sigma(A)\backslash\lambda_c \subset [\lambda_\nu, \lambda_d]$ for $\lambda_\nu \gg \lambda_c$, then $S = [\lambda_\nu, \lambda_d]$ is a better choice than $[\lambda_c, \lambda_d]$. The reason is that CG methods pick out isolated eigenvalues and rapidly suppress the error in the direction of corresponding eigenvectors. Unfortunately, one seldom knows such detailed information about $\sigma(A)$. Although the recent idea of Freund [17] to use the Lanczos eigenvalue estimates to approximate the eigenvalue distribution of A is appealing, it is unclear whether this can be done dynamically.

We will now describe an adaptive procedure for finding the optimal left endpoint, c_{opt}, on which to base the Chebyshev preconditioning polynomial. To ease the task, we will assume $d = \lambda_d$ (see below). Although there is a $d_{opt} \leq \lambda_d$, the CG iteration is less sensitive to changes in d than in c. This is so because $\epsilon = \epsilon(c, d)$ is most sensitive to changes in c. Ideally, the adaptive procedure will find $c_{opt} = \lambda_c$ when the exact Chebyshev preconditioning polynomial is best, and will find $c_{opt} = \zeta$ when the least squares polynomial is preferred. (Recall that the Chebyshev polynomial based on $[\zeta, \lambda_d]$ mimics the least squares polynomial.) In § 5.4 we will demonstrate the effectiveness of this adaptive procedure in a variety of numerical experiments.

Let $p_m(\lambda) = p_m(\lambda; c, d)$ be the Chebyshev preconditioned polynomial based on $[c, d]$, $0 < c \leq d$, m odd. Also let 2ϵ be the size of the oscillations in the Chebyshev polynomial, that is,

$$\epsilon = 1 - p_m(c) = p_m(d) - 1 = T_m^{-1}\left(\frac{d+c}{d-c}\right).$$

Since $d = \lambda_d$ is fixed, we will consider ϵ to be a function of c alone. As c increases from 0 to d, ϵ decreases from 1 to 0. If $\sigma(A) \subset [c, d]$, then $\kappa(p_m(A)) \leq \frac{1+\epsilon}{1-\epsilon}$. Suppose, however, that $\sigma(A) \subset [\lambda_o, d]$ for some $0 < \lambda_o \leq c$. That is, assume we have based the preconditioning polynomial on $[c, d]$, but there is an eigenvalue $\lambda_o \leq c$. Then $\kappa(p_m(A)) \leq \frac{1+\epsilon}{1-\delta}$, where $\delta = 1 - p_m(\lambda_o)$, and the associated *asymptotic convergence factor* is

$$cf(\lambda_o, c) = \frac{\sqrt{\frac{1+\epsilon}{1-\delta}} - 1}{\sqrt{\frac{1+\epsilon}{1-\delta}} + 1}. \tag{5.5}$$

(Note that $0 \leq \epsilon \leq \delta \leq 1$.) If $\sigma(A)$ is dense in $[\lambda_o, d]$, this convergence factor may be used to accurately predict the rate of convergence of the CG iteration.

Consider next Fig. 5.3, in which we plot $cf_c = cf(c, c)$ and $cf_o = cf(\lambda_o, c)$ as functions of c. The lower curve plots cf_c, the convergence factor when $\sigma(A) \subset [c, d]$ and $C(\lambda)$ is based on $p_m(\lambda; c, d)$. As c increases from 0 to d, cf_c decreases rapidly from 1 to 0. The upper curve plots cf_o, the convergence factor when $\sigma(A) \subset [\lambda_o, d]$, but $C(\lambda)$ is still based on $p_m(\lambda; c, d)$. Note that the curves intersect at λ_o and coincide for $c \leq \lambda_o$. Next let cf_e be the *empirical* convergence factor, which is given by

$$cf_e = \left(\frac{\|s_k\|}{\|s_0\|}\right)^{1/k} \tag{5.6}$$

if k is large enough. Here $s_k = C(A)r_k$ is the preconditioned residual, where $C(A)$ is the Chebyshev preconditioning polynomial for $[c, d]$. Note that cf_e may be monitored throughout the CG iteration. If $cf_e \leq cf_c$, the iteration is converging as it should, and there is no need to call the adaptive procedure. On the other hand, suppose $cf_e > cf_c$. Then the iteration is converging more slowly than it should because we have missed an eigenvalue of A, and so we need to compute eigenvalue estimates (§ 5.1). Since we have assumed $d = \lambda_d$, we will obtain only an estimate λ_1 for λ_c. Next let $cf_1 = cf(\lambda_1, c)$,

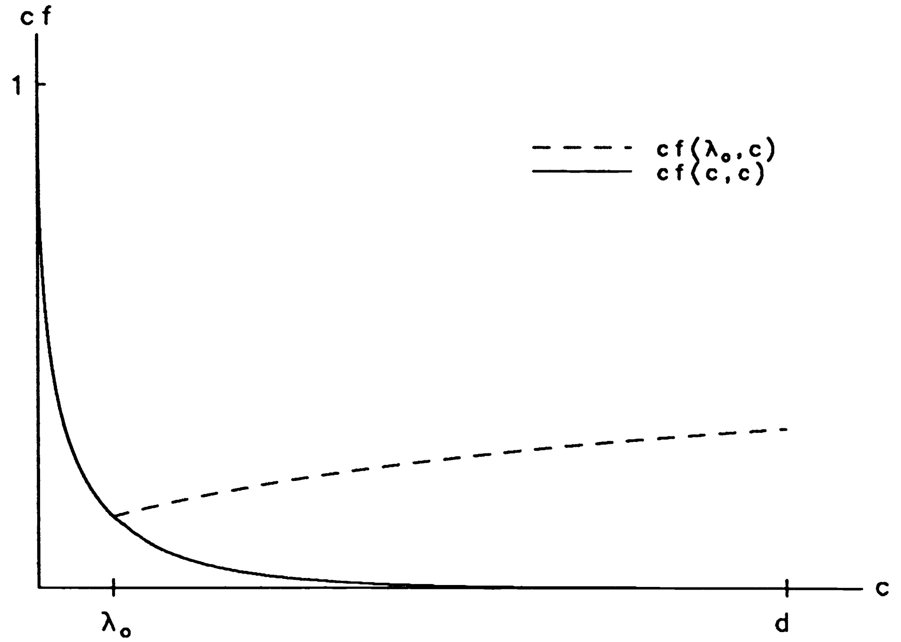

FIG. 5.3. *Convergence factors for $\sigma(A)$.*

which is the convergence factor for $\sigma(A) \subset [\lambda_1, d]$. If $cf_e > cf_1$, we will decrease c to λ_1, as in [3] and [5]. But suppose $cf_c < cf_e < cf_1$. This suggests that we should not decrease c to λ_1, but to λ_e, where $cf_e = cf(\lambda_e, c)$. As in (5.2), λ_e is given by

$$\lambda_e = \frac{1}{2}\left[(d+c) - (d-c)\cosh\left(\frac{1}{m}\cosh^{-1}\left(\frac{\delta}{\epsilon}\right)\right)\right] \tag{5.7}$$

where

$$\delta = 1 - (\epsilon - 1)\left(\frac{1+cf_e}{1-cf_e}\right)^2$$

from (5.5). By decreasing c to λ_e instead of λ_1, we are trying to minimize the *actual* convergence factor (see below). Note that this strategy guarantees that $c \in \Sigma(A)$.

5.3. Summary description. Given an interval $S \subset \Sigma(A)$, fix c and determine λ_d via the CG-Lanczos equivalence (§ 5.1). We will assume convergence when the relative difference in two successive estimates is less than some tolerance, say 10^{-2}. (Of course, if an a priori estimate of λ_d is available, it may be used.) After a prescribed number of steps, say ℓ, call the adaptive procedure:

(1) Compute eigenvalue estimates for $p_m(A) = C(A)A$.
(2) Extract an eigenvalue estimate λ_1 for λ_c.
(3) Compute cf_e, cf_c, and cf_1.
(4) Update c:
- If $cf_e \leq cf_c$, $c \leftarrow c$.
- If $cf_c < cf_e < cf_1$, $c \leftarrow \lambda_e$.

- If $cf_e \geq cf_1$, $c \leftarrow \lambda_1$.

(5) Restart the CG iteration if c has changed; resume if c is unchanged.

The key to this adaptive procedure is the comparison of cf_e with cf_c and cf_1. If $\sigma(A)$ is dense in $[\lambda_1, d]$, then cf_1 is an accurate indicator of the CG rate of convergence, and the comparison is well founded. Otherwise, it is simply an heuristic. If $\sigma(A)$ is not dense in $[\lambda_1, d]$, the adaptive procedure should detect this by computing $cf_e < cf_1$. In this case, the iteration is converging as if $\sigma(A)$ were dense in $[\lambda_e, d]$. However, we know that there is at least one eigenvalue to the left of λ_e because we computed $\lambda_1 \in \Sigma(A)\backslash[\lambda_e, d]$. Since the iteration is converging at a rate determined by cf_e, the dense portion of $\sigma(A)$ is no larger than $[\lambda_e, d]$. Thus, we assume that any eigenvalues to the left of λ_e are isolated, and we choose to base the Chebyshev preconditioning polynomial on $[\lambda_e, d]$. This heuristic is flawed because the dense portion of $\sigma(A)$ is actually some interval $[\lambda_\nu, d]$ for $\lambda_\nu > \lambda_e$. (The isolated eigenvalues gave rise to the convergence factor cf_e rather than cf_ν.) Unfortunately, there seems to be no way of determining λ_ν.

The difference between this adaptive procedure and the one described in [3] and [5] is essentially this: here we determine λ_d first and then refine c. (Of course, we can continue to refine d, but it seems to make little difference in practice.) In general, this new procedure will outperform the one in [3] and [5]. Of course, if the Chebyshev preconditioning polynomial is optimum, the other procedure will find it more quickly since c and d are adapted simultaneously.

Since S is either expanded or unchanged with each call to the adaptive procedure, it is important that the initial set, S_0, be such that $S_0 \subset \Sigma(A)$. If the $N \times N$ matrix A is scaled to have unit diagonal, one may take $S_0 = [1, 1]$. A more general choice is $S_0 = [\tau, \tau]$, where $\tau = \mathit{trace}(A)/N$ or $\tau = \langle Ab, b\rangle / \langle b, b\rangle$, both of which lie in $\Sigma(A)$. If one had an a priori estimate for λ_d, say from Gershgorin's theorem, one could take $c_0 = \zeta$ and $d_0 = \lambda_d$. As discussed in § 4, this would mimic the least squares polynomial initially, but retain the flexibility of the adaptive procedure. Although there is no guarantee that $\zeta \in \Sigma(A)$, this is often the case for moderate m and $\kappa(A) \gg 1$. In the next section we show that the polynomial found by this procedure usually bests the least squares polynomial.

5.4. Performance. Having introduced the theory behind the adaptive procedure, we now consider its performance in practice. We will first show that the adaptive procedure quickly and accurately determines λ_c and λ_d. We will then compare two adaptively determined Chebyshev preconditioning polynomials with the exact Chebyshev and least squares polynomials. We will see that the former are generally competitive with the latter. In § 6 we will demonstrate the effectiveness of adaptive polynomial preconditioned CG algorithms for some large matrices from hydrology.

The tables below summarize the behavior of the adaptive *procedure* for two simple test problems. The results are taken from [5], but the adaptive procedure described in this paper would give similar results. The matrices have order 2500 and result from a five-point and nine-point finite difference approximation to the two-dimensional Laplacian. Although PCG results are given only for a polynomial of degree 7, these results are typical. In each table we list the estimates for λ_c and λ_d computed by the adaptive procedure, which is called every five steps. The adaptive algorithm is initially given $c = d = 1$. In the last column we report the action taken by the adaptive procedure.

Consider Table 5.1. After five steps, the adaptive procedure found new estimates

TABLE 5.1

for λ_c and λ_d and decided to restart the iteration using a new preconditioning polynomial based on these estimates. After another five steps, the adaptive procedure refined its estimates for λ_c and λ_d and again restarted. From here on it continues to improve its estimates for λ_c and λ_d, but opts to resume the iteration using the polynomial determined at step 10. Similar behavior is seen in Table 5.2. We remark that λ_c and λ_d are found more quickly with higher degree polynomials.

The performance described here is typical. Although the estimates for λ_c and λ_d eventually converge to their true values, the adaptive procedure often finds satisfactory estimates early on in the iteration. In other words, the adaptive procedure is able to find a nearly optimum polynomial preconditioner within a few calls. This means that there is little overhead associated with the adaptive procedure. We remark that the resume versus restart decision is an important one: it can make a dramatic difference in the number of steps required for convergence to the solution of the linear system.

In Figs. 5.4–5.9 we compare the performance of four polynomial preconditioned CG (PPCG) algorithms on four eigenvalue distributions. (Here PPCG denotes PCG [13] with a polynomial preconditioner.) The algorithms are: (1) PPCG with the least squares preconditioning polynomial for $[0, \lambda_d]$; (2) PPCG with the exact Chebyshev preconditioning polynomial for $[\lambda_c, \lambda_d]$; (3) adaptive PPCG with $c_0 = \zeta$ and $d_0 = \lambda_d$; and (4) adaptive PPCG with $c_0 = d_0 = trace(A)/N$. We will abbreviate these algorithms LS, EC, AC(LS), and AC(TR), respectively. For these experiments, we employed the adaptive procedure described above. (Since the adaptive procedure in [3], [5] quickly finds λ_c and λ_d, it would behave like EC.) The algorithms AC(LS) and AC(TR) differ only in their initial intervals. The point of the former is to see how the adaptive algorithm compares with the least squares polynomial when given the same information, namely, λ_d. AC(TR) is, in a sense, the "black box" algorithm of choice since it requires no a priori knowledge of $\sigma(A)$.

The first three plots compare the four algorithms on the uniform, dense-left, and dense-right distributions described in § 4 ($\delta = 10^{-5}$, $N = 100,000$). In Fig. 5.4, the least squares polynomial outperforms the exact Chebyshev polynomial, but is inferior to AC(LS). The reason is this: Although AC(LS) initially behaves like the least squares polynomial, the adaptive procedure allows us to refine the left endpoint. In Fig. 5.5, the exact Chebyshev polynomial is best, but the two adaptive algorithms are competitive: Whereas EC starts off with the optimum left endpoint, they must determine it dynamically. Finally, in Fig. 5.6, all four algorithms converge quickly. AC(TR) beats AC(LS) because $c_0 = \zeta$ is already too small. AC(LS) is slightly worse than LS for this dense-right distribution because it erroneously adapts the left endpoint toward the origin.

In the last three plots, the eigenvalue distribution is that of the five-point Laplacian for a 400×400 grid. Since these eigenvalues are somewhat uniformly distributed in $(0, 8)$, Fig. 5.7 is nearly identical to Fig. 5.4, and the explanation for the algorithms' relative performance is the same. In Fig. 5.8, we consider the effect of overestimating λ_d, as is often the case with Gershgorin's theorem. Here LS, EC, and AC(LS) are all given $d_0 = 12$. Consequently, AC(TR) performs a bit better relative to the other three, but the difference is marginal. In Fig. 5.9, we underestimate λ_d with $d_0 = 6$. Note that LS and EC both suffer. The adaptive algorithms, however, are able to find λ_d quickly, before adapting the left endpoint. We remark that overestimating (underestimating) λ_d would have been much more troublesome for the dense-left (dense-right) distribution.

In summary, our results show that adaptive Chebyshev polynomial preconditioning is not only competitive with least squares and exact Chebyshev polynomial preconditioning, but usually beats them. In particular, AC(LS) was superior to the least squares polynomial for all but the dense-right distribution. This is so because, although it initially behaves like the least squares polynomial, it retains the option to adapt the left endpoint. Moreover, we have shown that the "black box" AC(TR) algorithm is always competitive. This is important because one seldom has any a priori knowledge of the eigenvalue distribution of A.

6. Numerical experiments.

In this section we demonstrate the effectiveness of adaptive polynomial preconditioning on a Cray X-MP/48 and Alliant FX/8 for some large matrices arising in hydrology. In particular, we show that polynomial preconditioned PCG (PPCG) can converge in less CPU time than the unpreconditioned CGHS method. Although we do not compare it with other preconditionings, we emphasize that polynomial preconditioning can be used to further accelerate any other preconditioning, for example, an incomplete factorization.

6.1. Description of experiments.

Our test matrices, which arise in the modeling of groundwater flow in a heterogeneous aquifer, result from the seven-point finite difference approximation to a three-dimensional elliptic PDE with variable coefficients. Although several parameters determine the difficulty of the problem, we isolate just two. In the first set of experiments, run on a Cray X-MP/48, the hydraulic conductivity field K is uncorrelated, which makes the problem difficult. In the second set of experiments, run on an Alliant FX/8, the field is correlated. For each machine we vary γ, the standard deviation of the $\ln K$ field. As γ increases, so does the condition number of A. See [27] for details.

In the tables below, m is the degree of the preconditioned polynomial, $p_m(\lambda)$.

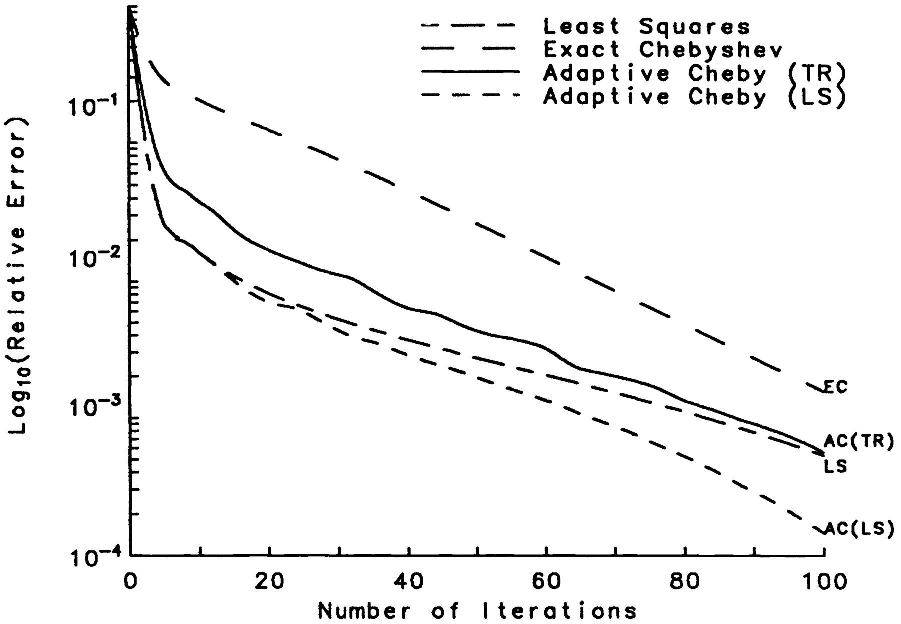

FIG. 5.4. *Uniform eigenvalue distribution;* $\delta = 10^{-5}$.

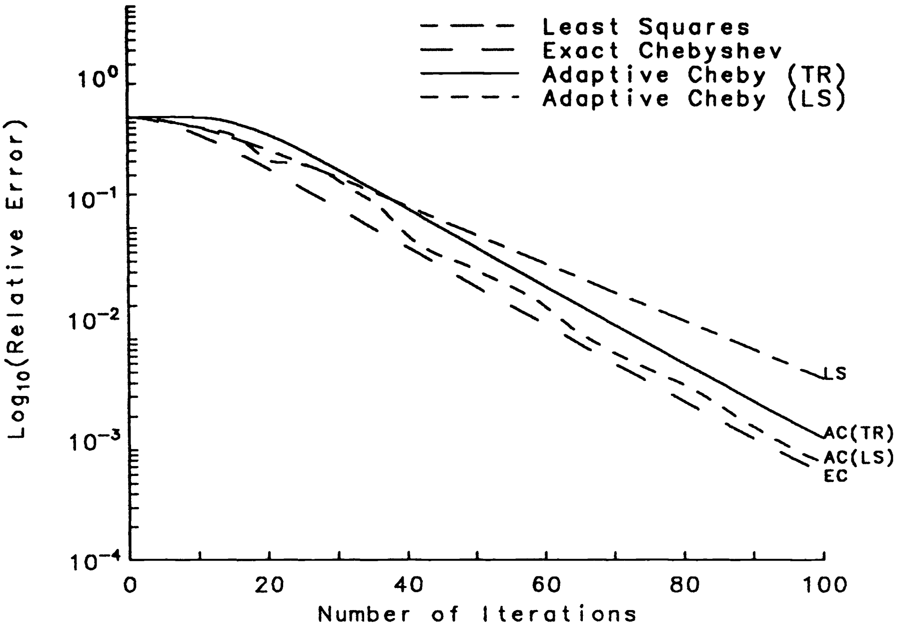

FIG. 5.5. *Dense-left eigenvalue distribution;* $\delta = 10^{-5}$.

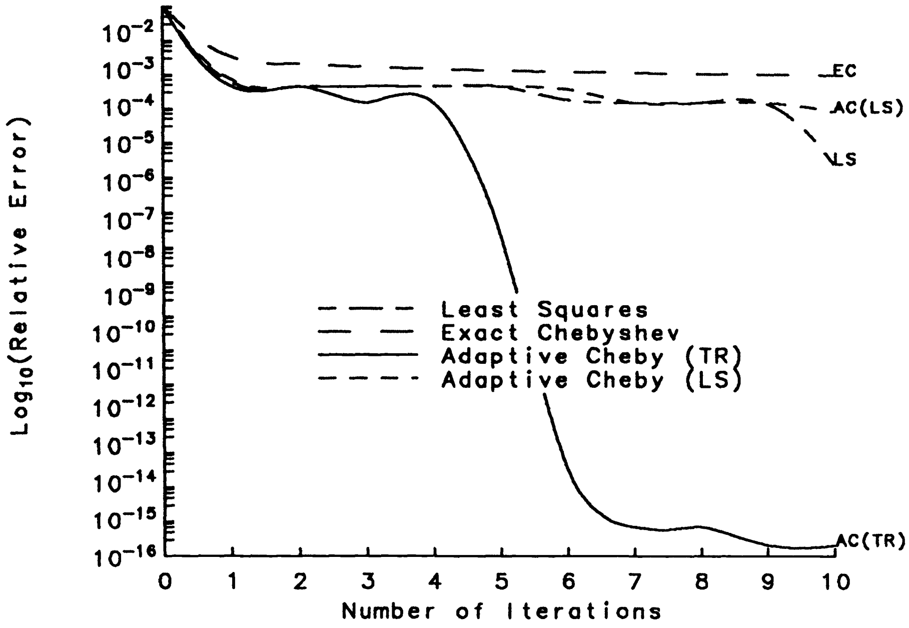

FIG. 5.6. *Dense-right eigenvalue distribution;* $\delta = 10^{-5}$.

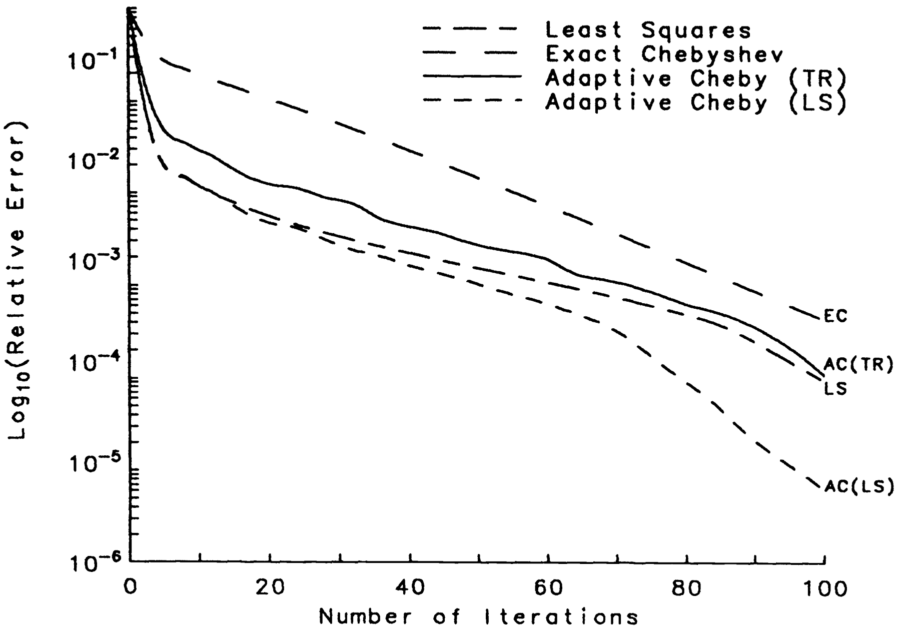

FIG. 5.7. *Laplacian distribution.*

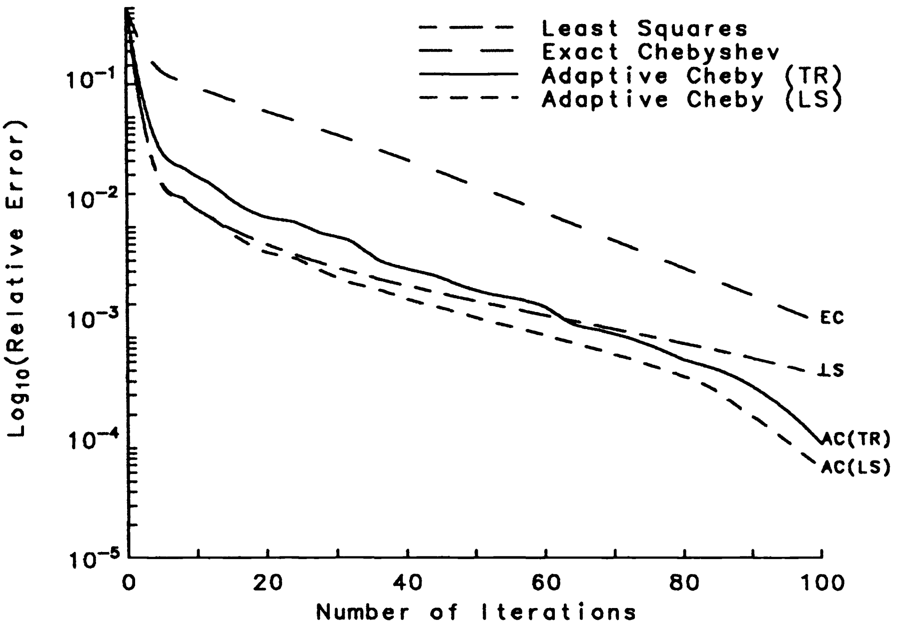

FIG. 5.8. *Overestimated Laplacian distribution.*

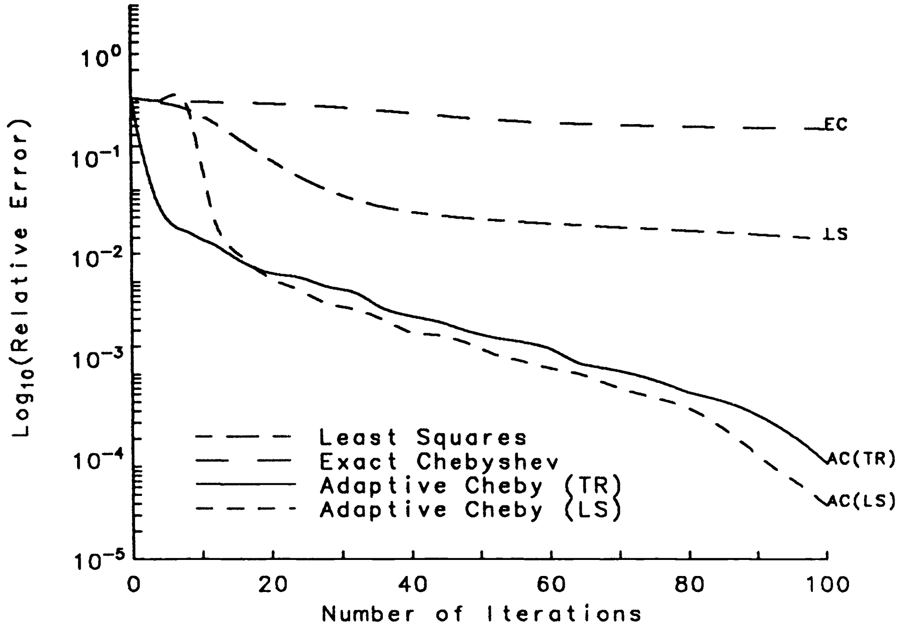

FIG. 5.9. *Underestimated Laplacian distribution.*

The first row of each table, $m = 1$, corresponds to the unpreconditioned CGHS method. We next give the number of CPU seconds required for convergence of the CG iteration, which includes the adaptive procedure. The iteration was halted once the relative error was brought below 10^{-8} on the Cray and 10^{-6} on the Alliant. In the last column of each table we list the ratio of CGHS time to PPCG time. If this ratio is greater than 1, we say that polynomial preconditioning is *effective*. In all the experiments, the right-hand-side vector b was chosen so that the true solution vector has 1 in each component, and the initial guess was the zero vector. The adaptive procedure used is the one described in [3] and [5]; the one presented in this paper would give even better performance. Since the matrix was symmetrically scaled to have unit diagonal, we set $c_0 = d_0 = 1$ in the adaptive procedure. New eigenvalue estimates were computed every ten steps with a maximum of ten calls to the adaptive procedure. Finally, we note that the results below were taken from [3] and [27].

6.2. Discussion of results. In Tables 6.1–6.3 we report results for a single vector processor of a Cray X-MP/48. In the first table, the condition number of A is about 60,000, as estimated by the adaptive procedure. Here we obtain a 15 percent improvement over CGHS with a polynomial of degree 5. In the next two tables, $\kappa(A)$ is 160,000 and 360,000, respectively, corresponding to $\gamma = 1.5$ and $\gamma = 1.75$. Notice that polynomial preconditioning is more effective here: it reduces the CPU time required to solve the problem by about 25 percent. Also observe that the optimum m is increasing with $\kappa(A)$.

TABLE 6.1
Cray X-MP/48 CPU times.

$N = 103,823$			$\gamma = 1.0$
m	Iterations	Seconds	CGHS/PPCG
1	1112	18.00	1.00

9	268	30.16	1.23
11	227	31.28	1.18
13	213	34.84	1.06

In Tables 6.4–6.6 we see similar qualitative results for the Alliant FX/8, which is an 8-vector-processor machine. Although the problems are much larger, they are not nearly as ill conditioned. (We estimate the condition numbers to be 8,400, 14,000, and 26,000.) We once again see the best performance on the hardest problem. Moreover,

TABLE 6.3

1	468	887.61	1.00
3	183	673.77	1.32
5	103	541.13	1.64
7	82	564.95	1.57
9	70	598.83	1.48
11	57	586.48	1.51

TABLE 6.5
Alliant FX/8 CPU times.

$N = 410,625$			$\gamma = 1.7$
m	Iterations	Seconds	CGHS/PPCG
1	607	1141.40	1.00
3	249	910.98	1.25
5	155	801.22	1.42
7	95	664.83	1.76
9	79	684.41	1.70
11	69	714.39	1.62

notice the much larger CGHS/PPCG ratios: the time required to solve the problem has been nearly cut in half. The computer architecture does indeed make a difference.

These results demonstrate the effectiveness of polynomial preconditioning on a Cray X-MP/48 and an Alliant FX/8. We have seen that polynomial preconditioning is most effective when the matrix A is ill conditioned. Moreover, as $\kappa(A)$ increases, so does the optimum degree m. In general, however, low degree (2–16) preconditioning polynomials are usually best. In contrast, high degree (20–50) polynomials are usually best for Hermitian indefinite matrices [3], [6]. Although we have presented results for only the hydrology problem, our conclusions are supported by a variety of other numerical experiments, including those in [3], [9], [15], [25], [27].

We emphasize that our adaptive CG algorithms are as easy to use as CGHS, yet can reduce the CPU time required to solve the linear system. The amount of reduction depends on the computer architecture. We note that Holst [23] has obtained results similar to those for the Alliant on a Cray 2. In particular, he has reported

TABLE 6.6
Alliant FX/8 CPU times.

$N = 410,625$			$\gamma = 2.3$
m	Iterations	Seconds	CGHS/PPCG
1	839	1584.50	1.00
3	308	1108.60	1.43
5	205	1057.20	1.50
7	134	913.34	1.73
9	103	869.94	1.82
11	88	889.15	1.78

CGHS/PPCG ratios of nearly 2 to 1, which is far better than those achieved on the X-MP. Chan, Kuo, and Tong [9] have shown that polynomial preconditioning is competitive with other preconditioners on the massively parallel CM-2.

7. Summary. In this paper we have explored the use of adaptive polynomial preconditioning for Hermitian positive definite linear systems. Such preconditioners are easy to employ and well suited to vector and/or parallel computer architectures. After reviewing preconditioned CG methods, we showed how one could use a polynomial preconditioner in a variety of different ways. We then discussed the least squares and Chebyshev preconditioning polynomials, studied them in the context of CG methods, and showed that the latter minimizes a bound on the condition number of the preconditioned matrix. We next compared the two polynomials in a variety of numerical experiments. In particular, we sought to determine those eigenvalue distributions for which each is well suited. The least squares polynomial is superior for those matrices whose eigenvalues are dense near the largest eigenvalue, λ_d. In contrast, the Chebyshev preconditioner is superior when the eigenvalues are dense throughout the interval or when the gap between successive eigenvalues is smaller than the smallest eigenvalue, λ_c. We next described an *adaptive procedure* for dynamically computing λ_c and λ_d, which are needed to determine the optimal Chebyshev polynomial preconditioner. Specifically, by comparing various convergence factors, we attempt to find the optimum endpoints on which to base the Chebyshev preconditioning polynomial. The accuracy and efficiency of this adaptive procedure was also demonstrated. In particular, we showed that our adaptive algorithm usually beats algorithms based on the least squares or exact Chebyshev polynomials. Finally, in the previous section, we presented some numerical results that demonstrate the effectiveness of adaptive polynomial preconditioning for some large matrices arising in hydrology. Our results suggest that relatively low degree (2–16) polynomials are usually best. Moreover, the optimum degree m of the polynomial tends to increase with the condition number of A, as does the effectiveness of polynomial preconditioning.

Acknowledgments. We wish to thank Professor Paul Saylor for his many helpful comments and thoughtful questions. We also thank Philip Meyer for providing the hydrology test problems and associated software.

PRECONDITIONED ITERATIVE METHODS FOR HOMOTOPY CURVE TRACKING*

COLIN DESA[†], KASHMIRA M. IRANI[†], CALVIN J. RIBBENS[†], LAYNE T. WATSON[†], AND HOMER F. WALKER[‡]

Abstract. Homotopy algorithms are a class of methods for solving systems of nonlinear equations that are globally convergent with probability one. All homotopy algorithms are based on the construction of an appropriate homotopy map and then the tracking of a curve in the zero set of this homotopy map. The fundamental linear algebra step in these algorithms is the computation of the kernel of the homotopy Jacobian matrix. Problems with large, sparse Jacobian matrices are considered. The curve-tracking algorithms used here require the solution of a series of very special systems. In particular, each $(n+1) \times (n+1)$ system is in general nonsymmetric but has a leading symmetric indefinite $n \times n$ submatrix (typical of large structural mechanics problems, for example). Furthermore, the last row of each system may by chosen (almost) arbitrarily. The authors seek to take advantage of these special properties. The iterative methods studied here include Craig's variant of the conjugate gradient algorithm and the SYMMLQ algorithm for symmetric indefinite problems. The effectiveness of various preconditioning strategies in this context are also investigated, and several choices for the last row of the systems to be solved are explored.

1. Introduction. The fundamental problem motivating this work is to solve a nonlinear system of equations $F(x) = 0$, where $F : E^n \to E^n$ is a C^2 map defined on real n-dimensional Euclidean space E^n. The homotopy approach to solving $F(x) = 0$ is to construct a continuous map $H(\lambda, x)$, the "homotopy," deforming a simple function $s(x)$ to the given function $F(x)$ as λ varies from 0 to 1. Starting from the easily obtained solution to $H(0,x) = s(x) = 0$, the essence of a homotopy algorithm is to track solutions of $H(\lambda, x) = 0$ until a solution of $H(1,x) = F(x) = 0$ is obtained. The theoretical and implementational details of such algorithms are nontrivial; see Rheinboldt and Burkardt [24] and Watson, Billups, and Morgan [36] for summaries of significant recent progress in this area.

Homotopies are a traditional part of topology and only recently have begun to be used for practical numerical computation. The homotopies considered here are sometimes called "artificial-parameter generic homotopies," in contrast to natural-parameter homotopies, where the homotopy variable is a physically meaningful parameter. In the latter case, the resulting homotopy zero curves must be dealt with as they are, bifurcations, ill-conditioning, and all. Therefore, curve tracking becomes the main focus of the problem-solving effort. Our artificial-parameter generic homotopies require that the homotopy zero curves obey strict smoothness conditions. These conditions generally will not hold if the homotopy parameter represents a physically meaningful quantity, but they can always be obtained via certain generic constructions using an artificial (i.e., nonphysical) homotopy parameter.

The objective is to solve a "parameter-free" system of equations, $F(x) = 0$. What this means is that one can design the homotopy to have paths with nice properties. Thus extra attention is devoted to constructing the homotopy, and the curve-tracking algorithm can be limited to a well-behaved class of curves. The goal of using these artificial-parameter homotopies is to solve fixed-point and zero-finding problems with homotopies whose zero curves do not have bifurcations or other singular or ill-conditioned behavior. The mathematical software package HOMPACK [36] used here for comparative purposes is designed for artificial-parameter generic homotopies.

The theory and algorithms for functions $F(x)$ with small, dense Jacobian matrices $DF(x)$ are well developed [33], [32]. In this paper we focus on large, sparse $DF(x)$, a class of problems about which much less is known. Solving large sparse nonlinear systems of equations via homotopy methods involves sparse rectangular linear systems of equations. The sparsity suggests the use of iterative solution methods. Preconditioning techniques are used to make the iterative methods more efficient. In this paper we are particularly interested in problems where the Jacobian matrix $DF(x)$ is symmetric. Such problems are common, for example, in structural mechanics, where the Jacobian matrix is often the Hessian of a potential energy function.

Section 2 describes the homotopy approach to zero-finding problems and outlines the curve-tracking algorithm used in this paper. Section 3 discusses the linear algebra details of homotopy curve tracking. Several algorithmic possibilities are presented. Section 4 presents numerical results from the application of the various algorithms to three test problems. Some general conclusions from these results are drawn in § 5.

2. Homotopy algorithm.

The philosophy of artificial-parameter homotopy algorithms is to create homotopies whose zero curves are well behaved, with Jacobian matrices that are well conditioned, and that reach a solution for almost all choices of a parameter. These homotopies may be used to solve fixed-point and zero-finding problems.

In this paper we concentrate on the zero-finding problem $F(x) = 0$, where $F : E^n \to E^n$ is a C^2 map. The theoretical basis for the homotopy algorithm can be summarized as follows (see [7] for details). Suppose there exists a C^2 map

$$\rho : E^m \times [0,1) \times E^n \to E^n$$

such that

(a) the $n \times (m + 1 + n)$ Jacobian matrix $D\rho(a, \lambda, x)$ has rank n on the set

$$\rho^{-1}(0) = \{\, (a, \lambda, x) \,|\, a \in E^m, 0 \le \lambda < 1, x \in E^n, \rho(a, \lambda, x) = 0 \,\},$$

and for any fixed $a \in E^m$, letting $\rho_a(\lambda, x) = \rho(a, \lambda, x)$,

(b) $\rho_a(0, x) = \rho(a, 0, x) = 0$ has a unique solution x_0,

(c) $\rho_a(1, x) = F(x)$,

(d) ${\rho_a}^{-1}(0)$ is bounded.

Then for almost all $a \in E^m$ there exists a zero curve γ of ρ_a along which the Jacobian matrix $D\rho_a$ has rank n, emanating from $(0, x_0)$ and reaching a zero $\bar{x}$ of F at $\lambda = 1$. Furthermore, γ does not intersect itself and is disjoint from any other zeros of ρ_a. Thus, with probability one, picking an $a \in E^m$ (which uniquely determines x_0), and following γ from $(0, x_0)$ to $(1, \bar{x})$, leads to a zero $\bar{x}$ of F.

There are many different algorithms for tracking the zero curve γ. HOMPACK supports three such algorithms: ordinary differential equation-based, "normal flow," and "augmented Jacobian matrix." We consider only the normal flow algorithm in this paper. A brief description of the normal flow algorithm is now given.

Consider the homotopy map

$$\rho_a(x,\lambda) = \lambda F(x) + (1-\lambda)(x-a).$$

The matrix $D_x\rho_a(x,\lambda) = \lambda DF(x) + (1-\lambda)I$ is symmetric and sparse. (For the problems of interest, $D_x\rho_a(x,\lambda)$ has a "skyline" structure, and is conveniently stored in a packed skyline format, in which the upper triangle is stored in a one-dimensional indexed array. An auxiliary array of diagonal indices is also required.) Assuming that $F(x)$ is C^2, a is such that the Jacobian matrix $D\rho_a(x,\lambda)$ has full rank along γ, and γ is bounded, the zero curve γ is C^1 and can be parameterized by arc length s. Thus $x = x(s), \lambda = \lambda(s)$ along γ, and

$$\rho_a(x(s),\lambda(s)) = 0$$

identically in s.

The zero curve γ given by $(x(s),\lambda(s))$ is the trajectory of the initial value problem

$$\text{(1)} \qquad \frac{d}{ds}\rho_a\Big(x(s),\lambda(s)\Big) = \Big[D_x\rho_a(x(s),\lambda(s)),\ D_\lambda\rho_a(x(s),\lambda(s))\Big]\begin{pmatrix}\frac{dx}{ds}\\ \frac{d\lambda}{ds}\end{pmatrix} = 0,$$

$$\text{(2)} \qquad \left\|\left(\frac{dx}{ds},\frac{d\lambda}{ds}\right)\right\|_2 = 1,$$

$$\text{(3)} \qquad x(0) = a, \qquad \lambda(0) = 0.$$

Since the Jacobian matrix has rank n along γ, the derivative $(dx/ds, d\lambda/ds)$ is uniquely determined by (1), (2), and continuity, and the initial value problem (1–3) can be solved for $x(s), \lambda(s)$. From (1) it can be seen that the unit tangent $(dx/ds, d\lambda/ds)$ to γ is in the one-dimensional kernel of $D\rho_a$.

The normal flow curve tracking algorithm has four phases: prediction, correction, step size estimation, and computation of the solution at $\lambda = 1$. For the prediction phase, assume that two points $(x(s_1),\lambda(s_1))$ and $(x(s_2),\lambda(s_2))$ on γ with corresponding tangent vectors $(dx/ds(s_1),\ d\lambda/ds(s_1))$, $(dx/ds(s_2),\ d\lambda/ds(s_2))$ have been found, and h is an estimate of the optimal step (in arc length) to take along γ. The prediction of the next point on γ is

$$Z^{(0)} = p(s_2 + h),$$

where $p(s)$ is the Hermite cubic interpolating $(x(s),\lambda(s))$ at s_1 and s_2. Precisely,

$$p(s_1) = (x(s_1),\lambda(s_1)), \qquad p'(s_1) = \left(\frac{dx}{ds}(s_1), \frac{d\lambda}{ds}(s_1)\right),$$

$$p(s_2) = (x(s_2),\lambda(s_2)), \qquad p'(s_2) = \left(\frac{dx}{ds}(s_2), \frac{d\lambda}{ds}(s_2)\right),$$

and each component of $p(s)$ is a polynomial in s of degree less than or equal to 3.

Starting at the predicted point $Z^{(0)}$, the corrector iteration is

$$\text{(4)} \qquad Z^{(k+1)} = Z^{(k)} - \Big[D\rho_a\big(Z^{(k)}\big)\Big]^+ \rho_a\big(Z^{(k)}\big), \qquad k = 0, 1, \cdots,$$

where $[D\rho_a(Z^{(k)})]^+$ is the Moore–Penrose pseudoinverse of the $n \times (n+1)$ Jacobian matrix $D\rho_a$. Small perturbations of a produce small changes in the trajectory γ, and the family of trajectories γ for varying a is known as the "Davidenko flow." Geometrically, the iterates given by (4) return to the zero curve along the flow normal to the Davidenko flow, hence the name "normal flow algorithm."

A corrector step ΔZ is the unique minimum norm solution of the equation

$$[D\rho_a]\Delta Z = -\rho_a. \tag{5}$$

Fortunately, ΔZ can be calculated at the same time as the kernel of $[D\rho_a]$, and with just a little more work. The numerical linear algebra details for solving (5), the optimal step size estimation, and the endgame to obtain the solution at $\lambda = 1$ are described by Watson [35], [34].

The calculation of the implicitly defined derivative $(dx/ds, d\lambda/ds)$ is done by computing the one-dimensional kernel of $D\rho_a$, i.e., by solving the $n \times (n+1)$ linear system

$$[D\rho_a]y = 0. \tag{6}$$

This can be elegantly and efficiently done for small dense matrices, but the large sparse Jacobian matrix presents special difficulties. The difficulty now is that the first n columns of the Jacobian matrix $D\rho_a(x,\lambda)$ involving $DF(x)$ are definitely special, and any attempt to treat all $n+1$ columns uniformly would be disastrous from the point of view of storage allocation. Hence, what is required is a good algorithm for solving nonsquare linear systems of equations (5) and (6), where the leading $n \times n$ submatrix of $D\rho_a$ is symmetric and sparse. This paper considers various iterative methods for solving such linear systems of equations.

3. Numerical linear algebra algorithms. As discussed in §2 for the normal flow curve-tracking algorithm, computing both the corrector step ΔZ and the tangent vector $(dx/ds, d\lambda/ds)$ requires the solution of a rectangular linear system involving the $n \times (n+1)$ matrix $[D\rho_a]$. This section describes various algorithms for the solution of such linear systems. In particular, we first consider various ways to construct an $(n+1) \times (n+1)$ invertible system $Ay = b$ whose solution yields a solution to the rectangular systems (5) and (6). We then describe two general approaches to solving systems involving this augmented matrix A, and within these approaches we consider various iterative solution methods. Finally, several preconditioners are suggested for improving the convergence of the iterative methods.

3.1. Defining an invertible system. Let $(\bar{x}, \bar{\lambda})$ be a point on the zero curve γ, and $\bar{y}$ the unit tangent vector to γ at $(\bar{x}, \bar{\lambda})$ in the direction of increasing arc length s. Then the matrix

$$A = \begin{pmatrix} D_x\rho_a(x,\lambda) & D_\lambda\rho_a(x,\lambda) \\ c^t & d \end{pmatrix},$$

where $(c^t \quad d)$ is any vector outside a set of measure zero (a hyperplane), is invertible at $(\bar{x}, \bar{\lambda})$ and in a neighborhood of $(\bar{x}, \bar{\lambda})$. Thus the kernel of $D\rho_a$ for (x, λ) near $(\bar{x}, \bar{\lambda})$ can be found by solving the linear system of equations

$$Ay = \alpha e_{n+1} = b, \tag{7}$$

where $(c^t \quad d)\bar{y} = \alpha$, and e_{n+1} is the $(n+1)$st standard basis vector. Similarly, the corrector step can be found by solving

$$A\Delta Z = \begin{bmatrix} -\rho_a \\ 0 \end{bmatrix}. \tag{8}$$

The coefficient matrix A in the linear systems of equations (7) and (8) has a very special structure, which can be exploited in several ways. Recall that the leading $n \times n$ submatrix of A is $D_x\rho_a$, which is symmetric and sparse, but possibly indefinite. We shall attempt to exploit this property below. The choice of the last row $(c^t \quad d)$ is considered first.

From an implementation point of view, the easiest choice for $(c^t \quad d)$ is probably the kth standard basis vector e_k^t, where the index k is defined by $|\bar{y}_k| = \max_i |\bar{y}_i|$. This is the choice made in HOMPACK. It is not difficult to show that with this choice for $(c^t \quad d)$, A is invertible, though clearly not symmetric.

A second choice for the last row of A considered here is $(c^t \quad d) = \bar{y}^t$. This choice would seem to be best from a conditioning standpoint, since $\bar{y}$ is orthogonal to the rows of $D\rho_a(\bar{x}, \bar{\lambda})$, and hence one expects $\bar{y}$ to be nearly orthogonal to the rows of $D\rho_a(x,\lambda)$ for (x,λ) near $(\bar{x},\bar{\lambda})$. It is clear that choosing $(c^t \quad d) = \bar{y}^t$ also makes A nonsymmetric, and in addition introduces a dense row into the otherwise sparse matrix A (the last column $D_\lambda\rho_a$ is also dense).

Since symmetry is advantageous for some algorithms, A can be made symmetric and invertible by a third choice $c = D_\lambda\rho_a$. The scalar d must still be chosen so that rank $A = n+1$. It is enough to consider two cases:

1. Suppose rank $D_x\rho_a = n-1$. Then $D_\lambda\rho_a$ is not a linear combination of the columns of $D_x\rho_a$, because rank $\left[D_x\rho_a \; D_\lambda\rho_a\right] = n$ by the homotopy theory. Thus $c^t = \left(D_\lambda\rho_a\right)^t$ is not a linear combination of the rows of the symmetric matrix $D_x\rho_a$, and we have
$$\text{row rank}\begin{bmatrix} D_x\rho_a \\ (D_\lambda\rho_a)^t \end{bmatrix} = n.$$
Finally, $(c^t \quad d)^t$ is not a linear combination of the first n columns of A, for *any* choice of d, so the column rank of A is $n+1$.
2. Now suppose that rank $D_x\rho_a = n$. Then
$$\text{rank}\begin{bmatrix} D_x\rho_a \\ \left(D_\lambda\rho_a\right)^t \end{bmatrix} = n,$$
and it suffices to choose d to make the last column of A independent from the first n columns. $D_\lambda\rho_a$ is a unique linear combination of the columns of $D_x\rho_a$, and any choice of d other than this combination of the components of $\left(D_\lambda\rho_a\right)^t$ will make the $(n+1)$st column independent. Let $\bar{A}$ denote A at $(\bar{x},\bar{\lambda})$. Since dim[ker$(\bar{A})$] ≤ 1, $\bar{A}y = 0$ implies $y = \alpha\bar{y}$, and thus with $\bar{y}^t = \left(\hat{y}^t, \bar{y}_{n+1}\right)$, $\left(D_\lambda\rho_a(\bar{x},\bar{\lambda})\right)^t\hat{y} + d\,\bar{y}_{n+1} = 0$. Choosing any $\beta \neq 0$ and solving $\left(D_\lambda\rho_a(\bar{x},\bar{\lambda})\right)^t\hat{y} + d\,\bar{y}_{n+1} = \beta$ for d ($\bar{y}_{n+1} \neq 0$ since rank $D_x\rho_a(\bar{x},\bar{\lambda}) = n$) gives a d such that rank $A = n+1$ for (x,λ) near $(\bar{x},\bar{\lambda})$.

Observe also that if $D_x\rho_a$ is positive definite, choosing $d > 0$ sufficiently large guarantees that

$$A = \begin{pmatrix} D_x\rho_a & D_\lambda\rho_a \\ \left(D_\lambda\rho_a\right)^t & d \end{pmatrix}$$

is also positive definite.

Proof. Since A is symmetric, by Sylvester's theorem A is positive definite if and only if all its leading principal minors are positive. Since $D_x\rho_a$ is positive definite, the first n leading principal minors are positive, and it suffices to show $\det A > 0$. Expanding $\det A$ along the last column,

$$\det A = d \cdot \det D_x\rho_a + \text{terms not involving } d > 0$$

for $d > 0$ sufficiently large. □

3.2. Splitting vs. direct approaches. Given a choice for the last row $(c^t \quad d)$, we now consider two general approaches to solving systems of the form (7) and (8). The first approach deals with the entire matrix A directly. As we have seen, depending on the choice of last row, it may be that A is nonsymmetric. This immediately eliminates several iterative solvers, at least for these cases. However, we do consider a few versions of this approach where possible in the experiments reported in § 4.

The second general approach is to attack (7) and (8) indirectly as follows. Split A into the sum of a symmetric matrix M and a low rank modification L:

$$A = M + L, \tag{9}$$

where

$$M = \begin{pmatrix} D_x\rho_a & c \\ c^t & d \end{pmatrix}, \tag{10}$$

$$L = ue_{n+1}^t, \qquad u = \begin{pmatrix} D_\lambda\rho_a - c \\ 0 \end{pmatrix}. \tag{11}$$

Observe that for almost all choices of $(c^t \quad d)$ the symmetric part M is also invertible. Then using the Sherman–Morrison formula, the solution y to the original system $Ay = b$ can be obtained from

$$y = \left[I - \frac{M^{-1}ue_{n+1}^t}{(M^{-1}u)^t e_{n+1} + 1} \right] M^{-1}b. \tag{12}$$

Equation (12) requires the solution of two linear systems involving the sparse (except possibly for c), symmetric, invertible matrix M. The scheme (9)–(12) was proposed by Kamat, Watson, and Junkins [20], and further investigated by Chan and Saad [6].

A third general approach, not considered here, would be a block-elimination approach that depends on solving systems involving the $n \times n$ matrix $D_x\rho_a$. Observe that block elimination will frequently fail in the homotopy context, because even though rank $A = n + 1$ and rank $(D_x\rho_a \quad D_\lambda\rho_a) =$ rank $D\rho_a = n$, it may very well happen that $D_x\rho_a$ is singular (i.e., rank $= n - 1$). Block-elimination strategies are considered by Chan [4], [3] and Chan and Resasco [5].

3.3. Iterative solution methods. In § 4 we report results from experiments using two iterative solution methods: Craig's method and SYMMLQ. Craig's method is nearly equivalent to the method of conjugate gradients (CG) [17] applied to the normal equations. (Technically, a different norm is minimized over a different Krylov space than if CG were applied directly to the normal equations.) It has long been known that one way to apply CG to nonsymmetric problems is to solve the normal equations instead of the original system. In particular, given any nonsingular matrix A, the system of linear equations $Ay = b$ can be solved by considering the linear system (normal equations)

$$A^t Ay = A^t b,$$

or the related system

$$AA^t z = b, \qquad y = A^t z.$$

Since the coefficient matrix for the latter system is both symmetric and positive definite, the system can be solved by the CG algorithm. Once a solution vector z is obtained, the vector y from the original system can be computed as $y = A^t z$. A major disadvantage of this technique is that the convergence rate depends on $\mathrm{cond}(AA^t) = (\mathrm{cond}(A))^2$ rather than $\mathrm{cond}(A)$. An implementation of the CG algorithm in which y is computed directly, without reference to z or AA^t, is due to Craig [9] and is described in [13] and [16]. Despite the efficiency of the implementation, the convergence rate still depends on $\mathrm{cond}(AA^T) = (\mathrm{cond}(A))^2$ in general. The cost per iteration of Craig's method is dominated by two matrix-vector products, one involving A and one involving A^t. Preconditioning (see § 3.4) increases the work per iteration substantially.

The second solution method considered here is the SYMMLQ algorithm described in Paige and Saunders [23]. SYMMLQ solves symmetric indefinite systems. It is based on a variant of the Lanczos procedure for tridiagonalizing a symmetric matrix. In [23] it is shown that for symmetric positive definite systems, SYMMLQ is mathematically equivalent to CG. However, unlike CG, which can break down when A is indefinite, SYMMLQ is well defined and numerically stable in this case. Like CG, the cost of one iteration of unpreconditioned SYMMLQ is primarily in a single matrix-vector multiplication.

There are many other CG-like methods (i.e., Krylov subspace methods) for solving nonsymmetric or indefinite problems, but most are not satisfactory in our context. The generalized conjugate gradient method of Concus and Golub [8] and Widlund [37] applies only to matrices with positive definite symmetric part (i.e., the matrix must be positive definite, but not necessarily symmetric), although with preconditioning it can sometimes be used to solve more general problems. The generalized conjugate residual method [12] and ORTHOMIN(k) [29] also may break down if the coefficient matrix is not positive definite. More general systems $Ax = b$, where A is not positive definite, can sometimes be solved by ORTHOMIN(k) if a nonsingular matrix Z is known such that ZA is positive definite. ORTHOMIN(k) is then applied to the transformed system $ZAx = Zb$. A related method known as ORTHODIR [38] does not break down in case A is indefinite, but it is observed to have stability problems [26]. ORTHORES is another method with similar properties. GMRES(k) [28], [31], like ORTHOMIN(k), is guaranteed to converge when the coefficient matrix is positive definite. However, for an indefinite coefficient matrix, GMRES(k), while it does not break down, may fail because the residual norms at each step, although nonincreasing, do not converge to zero. Other Krylov subspace methods are studied by Axelsson [1]; Dennis and Turner [10]; Eisenstat, Elman, and Schultz [11]; Jea [19]; Saad [25]; and Saad and Schultz [27].

Finally, there are other efficient iterative methods for solving sparse linear systems based on matrix splittings (see Hageman and Young [15]). Typical of these is the SSOR method, defined in terms of the splitting $A = D - L - U$, where D is the diagonal of A, L is the strict lower triangle of A, and U is the strict upper triangle of A. The method requires computations involving D^{-1}. In the homotopy context, D^{-1} frequently does not exist, and a diagonal matrix Σ such that $\left[\text{diag }(A+\Sigma)\right]^{-1}$ does exist may not be of low rank. Consequently SSOR and methods based on similar splittings are of limited utility in the present context.

3.4. Preconditioners. It is widely known that "preconditioning" can dramatically improve the performance of many iterative methods. For example, the solution to $Ax = b$ can also be obtained by solving the system

$$\tilde{A}x = (Q^{-1}A)x = Q^{-1}b = \tilde{b},$$

where Q is the so-called *preconditioner.* The goal of preconditioning is to decrease the computational effort required to solve systems of linear equations by increasing the rate of convergence of an iterative method. For preconditioning to be effective, faster convergence must outweigh the costs of applying the preconditioner, so that the total cost of solving the linear system is lower. The preconditioned coefficient matrix $\tilde{A}$ usually is not explicitly computed or stored, since although A is sparse, $\tilde{A}$ may not be. The extra work of preconditioning, then, occurs in solving systems involving the matrix Q. The main storage cost for preconditioning is usually for an extra array to hold a factorization of Q. In this paper we consider two preconditioners:

Gill–Murray (GM). The preconditioner is taken as the modified Choleksy factorization GG^t of a symmetric matrix A (see Gill and Murray [14]). In particular, if A is "sufficiently" positive definite, then $GG^t = A$. Otherwise $GG^t = A + \Sigma$, where Σ is diagonal with nonnegative diagonal entries. In the matrix splitting approach described in § 3.2, we apply GM preconditioning to the symmetric matrix M; in the direct approach we apply GM to the entire matrix A (necessitating the choice $c = D_\lambda \rho_a$ to make A symmetric). We apply the GM preconditioner on the left when Craig's method is used (i.e., if A is the original matrix, $(GG^t)^{-1}A$ is the preconditioned matrix). In the case of SYMMLQ, the preconditioned system is $G^{-1}A(G^t)^{-1}$, since SYMMLQ requires symmetry.

ILU. The incomplete LU factorization described in [22] computes a lower triangular matrix L and unit upper triangular matrix U satisfying

$$\begin{cases} L_{ij} = U_{ij} = 0, & (i,j) \in Z, \\ (LU)_{ij} = A_{ij}, & (i,j) \notin Z. \end{cases}$$

Here, Z is the set of indices where A is known to be zero off the diagonal. (This method is often referred to as ILU(0) to indicate that 0 fill-in is allowed.) It is possible that $L_{ii} = 0$ in this algorithm. In this case L_{ii} is set to a small positive number, in which case $(LU)_{ii} \neq A_{ii}$. The ILU factorization is modified slightly so that it may be used with SYMMLQ. In this case we compute an incomplete LDL^T factorization, and apply $LD^{1/2}$ symmetrically as a preconditioner as described above. If during the factorization procedure, an element of the diagonal matrix D is negative, we simply take its absolute value. This is very similar to the GM factorization, except with ILU we do no extra work to ensure that the factorization is well conditioned.

4. Numerical experiments. Of the various algorithmic possibilities mentioned in the previous section, we consider further 22 distinct combinations. Some possibilities do not make sense or are impractical in the homotopy context, and thus are not considered. Ignoring the choice for the last row of A, and also ignoring the question of

splitting, we have six basic methods: unpreconditioned Craig's method (CR), Craig's method with ILU preconditioning (CRILU), Craig's method with GM preconditioning (CRGM), unpreconditioned SYMMLQ (SY), SYMMLQ with ILU preconditioning (SYILU), and SYMMLQ with GM preconditioning (SYGM). Data for all of these methods, with both the splitting and direct approaches, and for various choices of the last row, are given in Tables 1–24. In the splitting cases, the method names have an -S appended (e.g., CR-S, SY-S, ...). We report results from all of these methods on three test problems, which are now briefly described.

Turning point problem. The turning point problem is a relatively simple (and artificial) example derived from the system of equations

$$F(\mathbf{x}) = \left(F_1(\mathbf{x}), F_2(\mathbf{x}), \cdots, F_N(\mathbf{x})\right)^t = 0$$

where

$$F_i(\mathbf{x}) = \tan^{-1}\left(\sin[x_i(i \bmod 100)]\right) - \frac{(x_{i-1} + x_i + x_{i+1})}{20}, \qquad i = 1, \cdots, N,$$

and $x_0 = x_{N+1} = 0$. The zero curve γ tracked from $\lambda = 0$ to $\lambda = 1$ corresponds to $\rho_a(x, \lambda) = (1 - .8\lambda)(x - a) + .8\lambda F(x)$, where a is chosen artificially to produce turning points in γ. The Jacobian matrix $D_x\rho_a$ for the turning point problem is tridiagonal. Tables 1–4 and 13–16 contain the data for this problem.

Shallow arch problem. This is a relatively small but quite difficult problem from structural mechanics. It results from solving the equilibrium equations for a discretization of a shallow arch under an externally applied load. See [21] and [18] for a more complete description. Although this problem is small, it is included in this study because it is a good test of the accuracy of our methods. To go through the limit point and along the unloading portion of the equilibrium curve requires very accurate Jacobian matrices and numerical linear algebra. In fact, the standard iterative linear equation solver used in HOMPACK is unable to go past the limit point without tweaking the HOMPACK step size control parameters. $D_x\rho_a$ for the

shallow arch problem has bandwidth 5. Tables 5–8 and 17–20 contain the data for this problem.

Shallow dome problem. This is another realistic problem from structural mechanics, in which the equations of equilibrium for a model of a shallow dome must be solved. See [18] for a more complete description. $D_x\rho_a$ for the shallow dome problem is block diagonal, with dense 21×21 blocks. Tables 9–12 and 21–24 contain the data for this problem.

The times reported in Tables 1–12 are for tracking the entire zero curve γ and thus represent the solution of many linear systems of varying degrees of difficulty. The average, maximum, and minimum number of iterations for each method (Craig's and SYMMLQ) are reported in Tables 13–24. The experiments are done in double precision using a single processor of a Sequent Symmetry S81 multiprocessor. The major headings are the acronyms for the algorithms, and the subheadings denote the choice $(c^t \quad d)$ for the last row of A. There is asymmetry in the tables because some possibilities do not make sense. For instance, there is no CRGM with e_k because the Gill–Murray preconditioner requires a symmetric matrix; and there are no methods based on splitting when $c = D_\lambda\rho_a$, since this choice makes A symmetric, so there is no need to split A into the sum of a symmetric matrix and a low rank modification.

5. Discussion and conclusions. Regarding the choice of last row $(c^t \quad d)$, Tables 1–12 show that there is no clear winner between e_k, $\bar{y}$, and $D_\lambda\rho_a$. Furthermore, there seems to be little correlation between the algorithm and the best choice for c. If anything, a weak conclusion—that all other things being equal, the best choice is e_k—seems to be indicated by the data. Apparently better conditioning (from $\bar{y}$) or symmetry (from $D_\lambda\rho_a$) does not compensate for the extra work involved in these choices compared with e_k.

A comparison of the direct with the splitting approach results in a slight preference for the direct approach. However, the advantage is not a strong one in most cases. In fact, there are cases where the splitting approach is better; and on the shallow arch problem there is virtually no difference. The average number of iterations is

considerably lower for many of the splitting cases than for the corresponding direct case. This helps explain why the direct methods are often not significantly faster, despite the fact that they solve half as many linear systems.

Regarding a comparison between the two basic iterative schemes, the data indicate that unpreconditioned SYMMLQ is faster than unpreconditioned Craig's method, often by a significant amount. The advantage of SYMMLQ seems to be both in fewer iterations and in less work per iteration (one less matrix-vector product). With GM preconditioning, SYMMLQ is still a bit faster than Craig's method for the turning point and shallow dome problems; on the shallow arch problem the two perform roughly the same. When ILU preconditioning is used, Craig's method appears to be superior. It performs slightly better on the turning point and shallow arch problems; and ILU preconditioning combined with SYMMLQ fails completely on the shallow dome problem (SYMMLQ is not converging to a solution of some of the linear systems, and consequently the curve-tracking algorithm does not make progress).

It is tempting to conclude from the data that the best method overall is CRILU. However, it must be pointed out that the ILU factorization fails to exist at turning points and is unstable whenever A is indefinite (as is illustrated by SYILU on the shallow dome problem). We encountered other homotopy curve-tracking runs, on slightly different problems, which failed because the ILU preconditioner failed to exist or generated an overflow, or because of the difficulty caused HOMPACK by inaccurate tangents resulting from ILU. Because of this potential catastrophic failure or instability, it is difficult to seriously consider the ILU preconditioner for use in robust homotopy software. Still, the data dó show why the concern of numerical analysts about unstable algorithms is not always shared by others.

The GM preconditioner, meanwhile, is fairly competitive with ILU on the turning point and shallow arch problems. Furthermore, it is more robust in the presence of turning points and when A becomes indefinite. However, the data for the shallow dome problem show that the GM preconditioner may do a very poor job indeed at a few points on the curve. Tables 21–24 indicate that while the average number of iterations is reduced by using the GM preconditioner, the maximum number can actually increase. Thus the net improvement in efficiency is not at all impressive.

The algorithms SSOR and ORTHOMIN(k), discussed earlier, are not shown in the tables because they totally fail at turning points and along unloading portions of equilibrium curves (for reasons stated in § 3). When these methods do work, they can be very efficient (e.g., ORTHOMIN(1) on A with $c = D_\lambda \rho_a$ took 443 (6092) seconds for the shallow arch problem with $n = 29$ (47)), but that is no consolation for homo-

topy curve tracking.

GMRES(k) has a solid theoretical justification and has been used very successfully in a variety of contexts [28], [2], [31], [30]. Nevertheless, GMRES(k) with $k < n$ performed unacceptably on the test problems here, at least without preconditioning. For the shallow arch problem with $n = 29$ and tol $= 10^{-12}$, GMRES(29) on A with $c = D_\lambda \rho_a$ took 591 seconds, comparable to CRGM and CRGM-S. For $k = 1$, 3, 25, GMRES(k) took over a day of CPU time. Relaxing the tolerance to 10^{-6}, GMRES(25) took 18,330 seconds. This is especially noteworthy because the A matrices are (theoretically) symmetric and positive definite. For the turning point problem with $n = 20$, tol $= 10^{-12}$, $c = D_\lambda \rho_a$, the performance degradation from the full GMRES to GMRES(k) was dramatic. With $k = 20$, 19, 18, 15, 10, 8, GMRES(k) took, respectively, 19, 117, 154, 375, 338, 420 seconds. Thus for these problems, without preconditioning, only the full GMRES method is competitive. Consequently GMRES(k) was not included in the tables.

There are some theoretical results concerning the convergence of GMRES(k) given in [28, §3.4]. These results give worst-case bounds on the rate of residual norm reduction which are determined by the distribution of eigenvalues of A. For the shallow arch and turning point problems, the eigenvalues of A were determined numerically along the homotopy curve, and the resulting bounds were often (although not in every case) found to guarantee only hopelessly slow residual norm reduction, indeed, often to guarantee no residual norm reduction at all even when $k = n$.

Actually, it is apparent from the data that a crucial advantage of Craig's method over methods such as GMRES(k) and ORTHOMIN(k) is that it can iterate indefinitely, if necessary long after the solution would have been reached in exact arithmetic, without incurring increasing costs per iteration and without restarting or otherwise losing information from earlier iterations. Furthermore, there are theoretical guarantees that Craig's method will make progress at each iteration, whereas GMRES(k) may fail to make any progress at all if A is indefinite. It is possible that if the number of iterations necessary to meet the stopping tolerance could be kept small through preconditioning, then GMRES(k) would be competitive for $k < n$. A complete study, similar to that done here for Craig's method, of GMRES(k) with preconditioning and polynomial acceleration would be interesting and will be the topic of a future paper.

Tables 13–24 show the average, maximum, and minimum number of iterations per linear system solution along the homotopy zero curve γ for the three problems, using the same algorithms as in Tables 1–12. Such iteration statistics give an intuitive feel for how the algorithms behave and are sometimes very revealing. For example, Tables 13 and 14 show that symmetry does improve the algorithms' efficiency (compare CR and CR-S with last row e_k^t), and that, all other things being equal, achieving symmetric coefficient matrices is worthwhile. (The algorithms based on splitting to achieve symmetry are not uniformly better, because all other things are not equal.) Note that in all cases (except for the shallow dome problem with GM preconditioning) the maximum number of iterations is less than or equal to four times the average, which says that the convergence behavior is fairly consistent. On the other hand the range between the minimum and maximum is as great as 3 to 536, showing that there is a wide variation in the difficulty of the linear systems encountered along γ.

A succinct, albeit oversimplified, summary of the discussion is that ILU preconditioning is the most efficient, but it may completely fail for some cases, while the Gill–Murray preconditioner rarely fails but may be considerably slower on extremely difficult problems.

A BLOCK PROJECTION METHOD FOR SPARSE MATRICES*

MARIO ARIOLI†¶, IAIN DUFF‡¶, JOSEPH NOAILLES§, AND DANIEL RUIZ¶

Abstract. A block version of Cimmino's algorithm for solving general sets of consistent sparse linear equations is described. The case of matrices in block tridiagonal form is emphasized because it is assumed that the general case can be reduced to this form by permutations. It is shown how the basic method can be accelerated by using the conjugate gradient (CG) algorithm. This acceleration is very dependent on a partitioning of the original system and several possible partitionings are discussed. Underdetermined systems corresponding to the subproblems of the partitioned system are solved using the Harwell sparse symmetric indefinite solver MA27 on an augmented system. These systems are independent and can be solved in parallel. An analysis of the iteration matrix for the conjugate gradient acceleration leads to the consideration of rather unusual and novel scalings of the matrix that alter the spectrum of the iteration matrix to reduce the number of CG iterations.

The various aspects of this algorithm have been tested by runs on an eight-processor Alliant FX/80 on four block tridiagonal systems, two from fluid dynamics simulations and two from the literature. The effect of partitioning and scaling on the number of iterations and overall elapsed time for solution is studied. In all cases, an accurate solution with rapid convergence can be obtained.

Key words. sparse matrices, block iterative methods, projection methods, partitioning, augmented systems, parallel processing, block Cimmino method, conjugate gradient preconditioning

AMS(MOS) subject classifications. 65F50, 65F10, 65F20, 65Y05

1. Introduction.

Consider the solution of the system

$$\mathbf{A}\mathbf{x}=\mathbf{b} \tag{1.1}$$

where $\mathbf{A}$ is an $m \times n$ sparse matrix, $\mathbf{x}$ is an n-vector, and $\mathbf{b}$ is an m-vector. Although the experiments will examine the case when m is equal to n, the method is applicable for any m and n. The analysis will be principally concerned with the case $m \leqq n$ where the system is consistent, that is, there exists a vector $\mathbf{x}$ satisfying (1.1). In the following, we assume for simplicity that $\mathbf{A}$ has full row rank, that is, $\dim(\mathbf{A}) = m$.

The general solution to (1.1) can be expressed as the sum

$$\xi+\eta \tag{1.2}$$

where ξ is in the range of $\mathbf{A}^T$ and η is in the nullspace of $\mathbf{A}$. Thus

$$\xi=\mathbf{A}^T\mathbf{z}$$

and, from (1.1), we have

$$\mathbf{A}\mathbf{A}^T\mathbf{z}=\mathbf{b}$$

so that ξ is given by

$$\mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{b} \tag{1.3}$$

or

$$\mathbf{A}^{+}\mathbf{b}$$

where $\mathbf{A}^{+}$ is the Moore-Penrose pseudoinverse of $\mathbf{A}$. Because, usually, the solution to (1.1) of minimum norm is required, the component η is taken to be zero, so the solution of (1.1) is given by (1.3).

Sometimes the solution needed is the one closest to a vector $\mathbf{y}$, that is, an $\mathbf{x}$ satisfying (1.1) such that

$$\|\mathbf{x}-\mathbf{y}\|_2 \tag{1.4}$$

is minimized. This is given by

$$\mathbf{x}=\mathbf{P}_{\mathcal{N}(\mathbf{A})}\mathbf{y}+\mathbf{A}^{+}\mathbf{b}$$

where $\mathbf{P}_{\mathcal{N}(\mathbf{A})}$ is the orthogonal projector onto the nullspace of $\mathbf{A}$ given by

$$\mathbf{I}-\mathbf{P}_{\mathcal{R}(\mathbf{A}^T)}$$

where $\mathbf{P}_{\mathcal{R}(\mathbf{A}^T)}$, the orthogonal projector on the range of $\mathbf{A}^T$, is given by

$$\mathbf{P}_{\mathcal{R}(\mathbf{A}^T)}=\mathbf{A}^{+}\mathbf{A}.$$

In this paper we will analyse parallel implementations of block iterative methods for solving (1.1) and (1.4). We describe the general framework in § 2, the extension to norms other than the Euclidean norm (1.4) in § 3. In § 4 we identify the iteration matrix associated with the algorithm and introduce in §§ 5 and 6 conjugate gradient acceleration and the augmented system, which is used in the implementation of the algorithm.

In § 7 the numerical properties of this algorithm will be studied, illustrating its performance on block tridiagonal matrices. We introduce in § 8 the block SSOR method of Kamath and Sameh (1988) and Bramley and Sameh (1990), which can be seen as an alternative to the block Cimmino algorithm. In § 9 some ellipsoidal norms, which will be used to improve the performance on some of our test problems, are introduced for block tridiagonal matrices.

In § 10 we then describe some numerical experiments performed on the Alliant FX/80, and we present some concluding remarks in § 11.

2. Block iterative methods. The method which will be introduced can be considered as a generalization of the method of Cimmino (see Sloboda (1988)), and will therefore be called the block Cimmino method.

The blocks are obtained by partitioning the system (1.1) as

$$\begin{pmatrix}\mathbf{A}^1\\ \mathbf{A}^2\\ \vdots\\ \mathbf{A}^p\end{pmatrix}\mathbf{x}=\begin{pmatrix}\mathbf{b}^1\\ \mathbf{b}^2\\ \vdots\\ \mathbf{b}^p\end{pmatrix} \tag{2.1}$$

where $1\leqq p\leqq m$.

If we define by $\mathbf{P}_{\mathcal{R}(\mathbf{A}^{i^T})}$ the projector onto the range of $\mathbf{A}^{i^T}$, and the pseudoinverse of $\mathbf{A}^i$ as $\mathbf{A}^{i^+}$, the block Cimmino algorithm can be described in the following way.

ALGORITHM 2.1 (block Cimmino method).

```
Choose $\mathbf{x}^{(0)}$, set $k=0$
repeat until convergence
    begin
        do in parallel $i=1,\cdots,p$
(2.2)           $\delta^{i^{(k)}} = \mathbf{A}^{i^+}\mathbf{b}^i - \mathbf{P}_{\mathcal{R}(\mathbf{A}^{i^T})}\mathbf{x}^{(k)}$
                $= \mathbf{A}^{i^+}(\mathbf{b}^i - \mathbf{A}^i\mathbf{x}^{(k)})$
        end parallel
        $\mathbf{x}^{(k+1)} = \mathbf{x}^{(k)} + \omega \sum_{i=1}^{p} \delta^{i^{(k)}}$
        set $k=k+1$
    end
```

This gives rise to a general purpose iterative solver well suited for both shared memory and distributed memory computers. If we take $p=m$, which means that each manifold from (2.1) is a hyperplane defined by one equation in (1.1), then Algorithm 2.1 becomes the algorithm of Cimmino (see Sloboda (1988)).

The iterative scheme (2.2) will converge for any pseudoinverse of $\mathbf{A}^i$ (see Campbell and Meyer (1979)) and, in particular, does not require $\mathbf{A}^i$ to be full rank. However, with the use of the explicit formulation of $\mathbf{A}^{i^+}$ introduced in (1.3), the partitioning of the system has to be chosen so that the rows in each $\mathbf{A}^i$ are linearly independent. This is possible even if $\mathbf{A}$ is not full rank.

A general study of this block-row method has been performed by Elfving (1980). In this paper, he calls this the "block-row Jacobi" method. He shows the effect of row and column partitioning, makes some comparisons with block SOR methods, and studies the effect of the parameter ω on the convergence of these methods.

First let us recall some results from Elfving (1980). Using the notation:

$$\mathbf{E}_{RJ} = \sum_{i=1}^{p} \mathbf{P}_{\mathcal{R}(\mathbf{A}^{i^T})} = \sum_{i=1}^{p} \mathbf{A}^{i^T}(\mathbf{A}^i\mathbf{A}^{i^T})^{-1}\mathbf{A}^i,$$

$$\mathbf{Q}_{RJ} = \mathbf{I} - \omega\mathbf{E}_{RJ}, \text{ for the iteration matrix,}$$

$$\rho(\mathbf{E}_{RJ}) = \text{the spectral radius of } \mathbf{E}_{\mathrm{RJ}}, \tag{2.3}$$

$$\mu_{\max} = \text{the largest nonzero eigenvalue of } \mathbf{E}_{RJ},$$

$$\mu_{\min} = \text{the smallest nonzero eigenvalue of } \mathbf{E}_{RJ},$$

we have the following:

(1) Suppose $\mathbf{b} \in \mathcal{R}(\mathbf{A})$ and $\mathbf{x}^{(0)} \in \mathcal{R}(\mathbf{A}^T)$, then the block-row method converges towards the minimum norm solution if and only if $0 < \omega < \min(2, (2/\rho(\mathbf{E}_{RJ})))$.

(2) The ω giving the optimal asymptotic rate of convergence is $\bar{\omega} = 2/(\mu_{\max} + \mu_{\min})$.

3. The use of other norms. The solution of (1.1), (1.4) can be determined in any ellipsoidal norm defined by

$$\|\mathbf{x}\|_{\mathrm{G}}^2 = \mathbf{x}^T\mathbf{G}\mathbf{x} \tag{3.1}$$

where $\mathbf{G}$ is an $n \times n$ symmetric positive definite (SPD) matrix.

When doing this, the arguments in § 1 still hold, except that a generalized pseudoinverse (see Rao and Mitra (1971))

$$\mathbf{A}_{\mathrm{G}^{-1}}^{-} = \mathbf{G}^{-1}\mathbf{A}^T(\mathbf{A}\mathbf{G}^{-1}\mathbf{A}^T)^{-1}, \tag{3.2}$$

must be defined in addition to corresponding oblique projectors

$$\mathbf{P}^{(\mathbf{G})}_{\mathcal{R}(\mathbf{G}^{-1}\mathbf{A}^T)} = \mathbf{A}^{-}_{\mathbf{G}^{-1}}\mathbf{A} \quad \text{and} \quad \mathbf{P}^{(\mathbf{G})}_{\mathcal{N}(\mathbf{A})} = \mathbf{I} - \mathbf{P}^{(\mathbf{G})}_{\mathcal{R}(\mathbf{G}^{-1}\mathbf{A}^T)}.$$

The solution to

$$\min_{\mathbf{x}} \|\mathbf{y}-\mathbf{x}\|_{\mathbf{G}} \quad \text{such that } \mathbf{x} \in \{\mathbf{x} \mid \|\mathbf{b}-\mathbf{A}\mathbf{x}\|_{\mathbf{G}} = \min\}$$

is then given by

$$\mathbf{x} = \mathbf{P}^{(\mathbf{G})}_{\mathcal{N}(\mathbf{A})}\mathbf{y} + \mathbf{A}^{-}_{\mathbf{G}^{-1}}\mathbf{b}. \tag{3.3}$$

The block Cimmino algorithm in § 2 can be defined in terms of this general norm.

We will now show that the use of $\mathbf{G} \neq \mathbf{I}$ can be viewed as a right-hand side preconditioning of the matrix **A**.

From (3.1), (3.2), and (3.3), and knowing that any SPD matrix **G** can be decomposed as $\mathbf{G}^{1/2}\mathbf{G}^{1/2}$, with $\mathbf{G}^{1/2}$ SPD, it follows that:

$$\begin{aligned}\mathbf{P}^{(\mathbf{G})}_{\mathcal{R}(\mathbf{G}^{-1}\mathbf{A}^{i^T})} &= \mathbf{G}^{-1/2}(\mathbf{G}^{-1/2}\mathbf{A}^{i^T})[(\mathbf{A}^i\mathbf{G}^{-1/2})(\mathbf{G}^{-1/2}\mathbf{A}^{i^T})]^{-1}(\mathbf{A}^i\mathbf{G}^{-1/2})\mathbf{G}^{1/2} \\ &= \mathbf{G}^{-1/2}\{(\mathbf{A}^i\mathbf{G}^{-1/2})^T[(\mathbf{A}^i\mathbf{G}^{-1/2})(\mathbf{A}^i\mathbf{G}^{-1/2})^T]^{-1}(\mathbf{A}^i\mathbf{G}^{-1/2})\}\mathbf{G}^{1/2} \\ &= \mathbf{G}^{-1/2}\mathbf{P}_{\mathcal{R}((\mathbf{A}^i\mathbf{G}^{-1/2})^T)}\mathbf{G}^{1/2}.\end{aligned} \tag{3.4}$$

Then the iteration matrix becomes:

$$\begin{aligned}\mathbf{Q}^{(\mathbf{G})}_{RJ} &= \mathbf{I} - \omega\mathbf{E}^{(\mathbf{G})}_{RJ} \\ &= \mathbf{I} - \omega\mathbf{G}^{-1/2}\sum_{i=1}^{p}\mathbf{P}_{\mathcal{R}((\mathbf{A}^i\mathbf{G}^{-1/2})^T)}\mathbf{G}^{1/2} \\ &= \mathbf{G}^{-1/2}\mathbf{Q}^*_{RJ}\mathbf{G}^{1/2}\end{aligned} \tag{3.5}$$

where

$$\mathbf{Q}^*_{RJ} = \mathbf{I} - \omega\mathbf{E}^*_{RJ} = \mathbf{I} - \omega\sum_{i=1}^{p}\mathbf{P}_{\mathcal{R}((\mathbf{A}^i\mathbf{G}^{-1/2})^T)}. \tag{3.6}$$

Thus the iteration matrix associated with the matrix **A** and using the ellipsoidal norm, and the one associated with the matrix $\mathbf{A}\mathbf{G}^{-1/2}$ and using the two-norm, are similar. However, in the case of the **G**-norm, all the convergence properties (which are determined only by the spectrum of the iteration matrix) can be written in a similar way to the previous ones (2.3), where block-rows $\mathbf{A}^i\mathbf{G}^{-1/2}$ are considered instead of block-rows $\mathbf{A}^i$.

So from now on, to simplify notation and formulae, we will, as in §§ 1 and 2, usually consider $\mathbf{G} = \mathbf{I}$, knowing that other choices for **G** can easily be incorporated.

4. The iteration matrix. Let the **QR** decomposition of the blocks $\mathbf{A}^{i^T}$ be given by

$\mathbf{A}^{i^T} = \mathbf{Q}^i\mathbf{R}^i$, $\quad i = 1, \cdots, p$ where $\mathbf{A}^i$ is an $m_i \times n$ matrix of full row rank,

$\mathbf{Q}^i$ $n \times m_i$, $\quad \mathbf{Q}^{i^T}\mathbf{Q}^i = \mathbf{I}_{m_i \times m_i}$,

$\mathbf{R}^i$ $m_i \times m_i$, $\quad \mathbf{R}^i$ nonsingular ''nper triangular matrix;

then:

$$
\begin{aligned}
\mathbf{E}_{RJ} &= \sum_{i=1}^{p} \mathbf{A}^{i^T}(\mathbf{A}^i\mathbf{A}^{i^T})^{-1}\mathbf{A}^i \\
&= \sum_{i=1}^{p} \mathbf{Q}^i\mathbf{R}^i(\mathbf{R}^{i^T}\mathbf{Q}^{i^T}\mathbf{Q}^i\mathbf{R}^i)^{-1}\mathbf{R}^{i^T}\mathbf{Q}^{i^T} \\
&= \sum_{i=1}^{p} \mathbf{Q}^i\mathbf{R}^i(\mathbf{R}^{i^T}\mathbf{R}^i)^{-1}\mathbf{R}^{i^T}\mathbf{Q}^{i^T} \qquad (4.1)\\
&= \sum_{i=1}^{p} \mathbf{Q}^i\mathbf{Q}^{i^T} \\
&= (\mathbf{Q}^1 \cdots \mathbf{Q}^p)(\mathbf{Q}^1 \cdots \mathbf{Q}^p)^T.
\end{aligned}
$$

But from the theory of the singular value decomposition (see Golub and Kahan (1965) and Golub and Van Loan (1989)), the nonzero eigenvalues of $(\mathbf{Q}^1 \cdots \mathbf{Q}^p)(\mathbf{Q}^1 \cdots \mathbf{Q}^p)^T$ are also the nonzero eigenvalues of $(\mathbf{Q}^1 \cdots \mathbf{Q}^p)^T(\mathbf{Q}^1 \cdots \mathbf{Q}^p)$.

Thus the spectrum of the matrix $\mathbf{E}_{RJ}$ is the same as that of the matrix

$$
(4.2) \qquad \begin{pmatrix}
\mathbf{I}_{m_1\times m_1} & \mathbf{Q}^{1^T}\mathbf{Q}^2 & \cdots & \cdots & \mathbf{Q}^{1^T}\mathbf{Q}^p \\
\mathbf{Q}^{2^T}\mathbf{Q}^1 & \mathbf{I}_{m_2\times m_2} & \mathbf{Q}^{2^T}\mathbf{Q}^3 & \cdots & \mathbf{Q}^{2^T}\mathbf{Q}^p \\
\vdots & & & & \vdots \\
\mathbf{Q}^{p^T}\mathbf{Q}^1 & & \cdots & & \mathbf{I}_{m_p\times m_p}
\end{pmatrix}
$$

where the $\mathbf{Q}^{i^T}\mathbf{Q}^j$ are matrices whose singular values represent the cosines of the principal angles between the subspaces $\mathcal{R}(\mathbf{A}^{i^T})$ and $\mathcal{R}(\mathbf{A}^{j^T})$ (see Björck and Golub (1973)). This implies that a preconditioner, to be successful, should modify the principal angles between the subspaces $\mathcal{R}(\mathbf{A}^{i^T})$, in order to make these subspaces as much orthogonal between each other as possible.

Another implication of the previous discussion concerns the choice of the partitioning (2.1). As stated in Bramley and Sameh (1990), an ill-conditioned matrix $\mathbf{A}$ has some linear combination of rows almost equal to the zero vector. After row partitioning, these may occur within the blocks or across the blocks. If, in the block Cimmino algorithm, we assume that we compute the projections on the subspaces exactly, the rate of convergence of the method will depend only on the conditioning across the blocks. However, if the method used for solving the subproblems is sensitive to ill-conditioning within the blocks, we can quickly converge to the wrong solution. Thus, for a robust algorithm, we must use the most stable algorithm for computing the projections combined with a partitioning that minimizes the ill-conditioning across the blocks.

5. Conjugate gradient acceleration. Even when using the optimal ω introduced before, the convergence can still be slow. Thus it is natural to try to accelerate the iterative scheme.

The equalities in (4.1) show that $(\mathbf{I}-\mathbf{Q}_{RJ})=\omega\mathbf{E}_{RJ}$ is symmetric positive semi-definite for any $\omega>0$, and is definite if and only if $\mathbf{A}$ is square and of full rank. Now, in the case of ellipsoidal norms as defined in § 3, (3.5) and (3.6) ensure that the matrix $\mathbf{G}^{1/2}(\mathbf{I}-\mathbf{Q}_{RJ}^{(\mathbf{G})})\mathbf{G}^{-1/2}$ will have these properties. Thus $\mathbf{G}^{1/2}$ can be seen as a symmetrization matrix for the block Cimmino method (see Hageman and Young (1981)), and so the CG acceleration procedure can be applied to the preconditioned case in the following manner:

ALGORITHM 5.1 (conjugate gradient acceleration).

$\mathbf{x}^{(0)}$ is arbitrary, $\mathbf{p}^{(0)} = \delta^{(0)}$,

and $\delta^{(k)}$ is the pseudoresidual vector defined, for $k = 0, 1, \cdots$, by

$$\delta^{(k)} = \mathbf{Q}_{RJ}^{(\mathbf{G})}\mathbf{x}^{(k)} - \mathbf{x}^{(k)} + \omega \sum_{i=1}^{p} \mathbf{A}^{i-}_{\mathbf{G}^{-1}}\mathbf{b}^i$$

$$= \omega\left(-\mathbf{E}_{RJ}^{(\mathbf{G})}\mathbf{x}^{(k)} + \sum_{i=1}^{p} \mathbf{A}^{i-}_{\mathbf{G}^{-1}}\mathbf{b}^i \right),$$

for $k = 1, 2, \cdots$, until convergence do:

$$\mathbf{x}^{(k)} = \mathbf{x}^{(k-1)} + \lambda_{k-1}\mathbf{p}^{(k-1)}$$

$$\mathbf{p}^{(k)} = \delta^{(k)} + \alpha_k \mathbf{p}^{(k-1)},$$

$$\alpha_k = \frac{(\mathbf{G}^{1/2}\delta^{(k)}, \mathbf{G}^{1/2}\delta^{(k)})}{(\mathbf{G}^{1/2}\delta^{(k-1)}, \mathbf{G}^{1/2}\delta^{(k-1)})}$$

$$= \frac{(\delta^{(k)}, \delta^{(k)})_{\mathbf{G}}}{(\delta^{(k-1)}, \delta^{(k-1)})_{\mathbf{G}}},$$

$$\lambda_{k-1} = \frac{(\mathbf{G}^{1/2}\delta^{(k-1)}, \mathbf{G}^{1/2}\delta^{(k-1)})}{(\mathbf{G}^{1/2}\mathbf{p}^{(k-1)}, \mathbf{G}^{1/2}(\mathbf{I} - \mathbf{Q}_{RJ}^{(\mathbf{G})})\mathbf{p}^{(k-1)})}$$

$$= \frac{(\delta^{(k-1)}, \delta^{(k-1)})_{\mathbf{G}}}{(\mathbf{p}^{(k-1)}, (\mathbf{I} - \mathbf{Q}_{RJ}^{(\mathbf{G})})\mathbf{p}^{(k-1)})_{\mathbf{G}}}$$

$$= \frac{(\delta^{(k-1)}, \delta^{(k-1)})_{\mathbf{G}}}{(\mathbf{p}^{(k-1)}, \omega\mathbf{E}_{RJ}^{(\mathbf{G})}\mathbf{p}^{(k-1)})_{\mathbf{G}}},$$

where $(\cdot, \cdot)_{\mathbf{G}}$ denotes the dot product in the **G** norm viz.

$$(\mathbf{x}, \mathbf{x})_{\mathbf{G}} = \mathbf{x}^T\mathbf{G}\mathbf{x}.$$

The two main reasons for our choice of CG acceleration are:

(1) It can be seen from the above equations that the CG acceleration is independent of the choice of the relaxation parameter ω, in the sense that the sequence of iterates $\mathbf{x}^{(k)}$ is the same for any nonzero ω (provided the starting point $\mathbf{x}^{(0)}$ is the same). This is the reason why we did not emphasize the use of ω too much in the previous sections.

(2) It is very simple to use ellipsoidal norms in the CG acceleration, because the only requirement is the ability to compute the matrix-vector product relevant to working with the dot product in the **G** norm. The matrix **G** can thus be generated implicitly or stored in any appropriate way.

6. Use of augmented systems in solving subproblems. When solving the subproblems (2.2), the use of the augmented system approach has been chosen for two main reasons. First, it is more stable than the normal equations approach (see Arioli, Duff, and de Rijk (1989)) because it avoids building and storing the normal equations for each block row $\mathbf{A}^i$. This can be useful for two reasons. It is less sensitive to ill-conditioning within the blocks caused by partitionings where rows within a block are nearly linearly dependent. Also, the kind of preconditioners (ellipsoidal norms) that will be used in the experiments introduce some ill-conditioning within the blocks. Second, the use of ellipsoidal norms and the computation of the corresponding oblique projectors can be trivially accommodated, as we will see in the following.

In the augmented system approach, the system

$$\begin{bmatrix} \mathbf{G} & \mathbf{A}^{i^T} \\ \mathbf{A}^i & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{u}^i \\ \mathbf{v}^i \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{b}^i - \mathbf{A}^i\mathbf{x} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{r}^i \end{bmatrix},$$

whose solution is

$$\mathbf{v}^i = -(\mathbf{A}^i\mathbf{G}^{-1}\mathbf{A}^{i^T})^{-1}\mathbf{r}^i$$

$$\mathbf{u}^i = \mathbf{G}^{-1}\mathbf{A}^{i^T}(\mathbf{A}^i\mathbf{G}^{-1}\mathbf{A}^{i^T})^{-1}\mathbf{r}^i,$$

is considered.

We solve the augmented systems with the sparse symmetric linear solver MA27 from the Harwell Subroutine Library (see Duff and Reid (1983)). The solver MA27 computes the $\mathbf{LDL}^T$ decomposition of a permutation of the augmented matrix, using a mixture of 1×1 or 2×2 pivots chosen during the numerical factorization. The resulting $\mathbf{L}$ and $\mathbf{D}$ factors are then used to solve the augmented systems by forward and backward substitution in the usual way.

It must be emphasized that the method (2.2) is totally independent of the choice of the solvers for the underdetermined subproblems. For instance, in some problems it may be preferable to use a solver adapted to the structure of the block $\mathbf{A}^i$. In special cases, several different solvers might be used, one for each different kind of block $\mathbf{A}^i$.

7. Effect of the partitioning. We will now focus on some particular partitionings of the system (1.1), and show how the algorithm can exploit them.

7.1. Two-block partitioning. Assume that the matrix $\mathbf{A}$ is partitioned in two blocks

$$\begin{pmatrix} \mathbf{A}^1 \\ \mathbf{A}^2 \end{pmatrix},$$

where $\mathbf{A}^1$ and $\mathbf{A}^2$ have m_1 and m_2 rows, respectively. Assume, without loss of generality, that $m_1 \geqq m_2$. With such a partitioning, the iteration matrix $\mathbf{Q}_{RJ}$ can be considered as $\mathbf{I} - \omega(\mathbf{P}_1 + \mathbf{P}_2)$, where $\mathbf{P}_1 = \mathbf{P}_{\mathcal{R}(\mathbf{A}^{1^T})}$ and $\mathbf{P}_2 = \mathbf{P}_{\mathcal{R}(\mathbf{A}^{2^T})}$. So, as in § 4, the matrix $\mathbf{E}_{RJ} = \mathbf{P}_1 + \mathbf{P}_2$ can be reduced to $(\mathbf{Q}^1\mathbf{Q}^2)(\mathbf{Q}^1\mathbf{Q}^2)^T$, and from (4.2), the spectrum of the iteration matrix $\mathbf{Q}_{RJ}$ is the same as that of the matrix

$$\begin{pmatrix} (1-\omega)\mathbf{I}_{m_1 \times m_1} & -\omega\mathbf{Q}^{1^T}\mathbf{Q}^2 \\ -\omega\mathbf{Q}^{2^T}\mathbf{Q}^1 & (1-\omega)\mathbf{I}_{m_2 \times m_2} \end{pmatrix}. \tag{7.1}$$

Since we know from § 5 that the block Cimmino algorithm with conjugate gradient acceleration is independent of ω, we can take $\omega = 1$, and matrix (7.1) becomes

$$\begin{pmatrix} \mathbf{0}_{m_1 \times m_1} & -\mathbf{Q}^{1^T}\mathbf{Q}^2 \\ -\mathbf{Q}^{2^T}\mathbf{Q}^1 & \mathbf{0}_{m_2 \times m_2} \end{pmatrix}. \tag{7.2}$$

Then, looking at the shape of the rectangular submatrix $\mathbf{Q}^{1^T}\mathbf{Q}^2$, which has m_1 rows and m_2 columns ($m_1 \geqq m_2$) and therefore a rank not greater than m_2, it follows that there are at most $2m_2$ nonzero eigenvalues.

The finite termination property of the conjugate gradient algorithm suggests that the block Cimmino algorithm with CG acceleration generally works better for small m_2, and in exact arithmetic takes not more than $2m_2$ steps for convergence. This is another reason for the choice of the conjugate gradient acceleration.

7.2. Block tridiagonal structures. We now concentrate on block tridiagonal matrices, which are quite general patterns very common in partial differential equation discretization, and are obtainable from general systems as a byproduct of bandwidth reduction (see, for example, Duff, Erisman, and Reid (1986, pp. 153-157)). For such structures, a partitioning equivalent to the two-block one can be introduced and used efficiently for obtaining fast convergence.

Consider, for instance, a block tridiagonal matrix **A** with blocks of size $l\times l$, partitioned as follows:

$$\left[\begin{array}{ccccccccccccc}
* & * & & & & & & & & & & & \\
* & * & * & & & & & & & & & & \\
& * & * & * & & & & & & & & & \\
\hline
& & * & * & * & & & & & & & & \\
& & & * & * & * & & & & & & & \\
\hline
& & & & * & * & * & & & & & & \\
& & & & & * & * & * & & & & & \\
& & & & & & * & * & * & & & & \\
\hline
& & & & & & & * & * & * & & & \\
& & & & & & & & * & * & * & & \\
\hline
& & & & & & & & & * & * & * & \\
& & & & & & & & & & * & * & * \\
& & & & & & & & & & & * & *
\end{array}\right]=\left[\begin{array}{c}\mathbf{A}^1\\ \mathbf{A}^2\\ \mathbf{A}^3\\ \mathbf{A}^4\\ \mathbf{A}^5\end{array}\right],$$

where $\mathbf{A}^i$ has $k_i\times l$ rows, $k_i\geqq 2$, $i=1,2,\cdots,5$. Then $\mathcal{R}(\mathbf{A}^{i^T})$ and $\mathcal{R}(\mathbf{A}^{i+2^T})$, $i=1,2,3$, represent orthogonal subspaces, so that

$$\mathbf{P}_{\mathcal{R}(\mathbf{A}^{i^T})}+\mathbf{P}_{\mathcal{R}(\mathbf{A}^{i+2^T})}=\mathbf{P}_{\mathcal{R}(\mathbf{A}^{i^T})\oplus\mathcal{R}(\mathbf{A}^{i+2^T})}.$$

On the one hand, matrices of this form can therefore be easily partitioned in sufficient blocks to utilize all the processors of the target machine (provided the matrix **A** is large enough in comparison with the size of the tridiagonal substructure). On the other hand, the problem being solved is equivalent, after permutation of the rows of the matrix **A**, to the one defined by taking only two blocks $\mathbf{B}^1$ and $\mathbf{B}^2$, where

$$\mathbf{B}^1=\left\{\bigcup_i \mathbf{A}^i/i\ odd\right\},\qquad \mathbf{B}^2=\left\{\bigcup_i \mathbf{A}^i/i\ even\right\};$$

thus

$$\left[\begin{array}{c}\mathbf{B}^1\\ \mathbf{B}^2\end{array}\right]=\left[\begin{array}{c}\mathbf{A}^1\\ \mathbf{A}^3\\ \mathbf{A}^5\\ \mathbf{A}^2\\ \mathbf{A}^4\end{array}\right]=\left[\begin{array}{ccccccccccccc}
* & * & & & & & & & & & & & \\
* & * & * & & & & & & & & & & \\
& * & * & * & & & & & & & & & \\
& & & & * & * & * & & & & & & \\
& & & & & * & * & * & & & & & \\
& & & & & & * & * & * & & & & \\
& & & & & & & & & * & * & * & \\
& & & & & & & & & & * & * & * \\
& & & & & & & & & & & * & * \\
& & * & * & * & & & & & & & & \\
& & & * & * & * & & & & & & & \\
& & & & & & & * & * & * & & & \\
& & & & & & & & * & * & * & &
\end{array}\right].$$

Then the nice property of the two-block partitioning discussed in the previous section is maintained while a good degree of parallelism is obtained.

If m_1 and m_2 denote the number of rows of $\mathbf{B}^1$ and $\mathbf{B}^2$, respectively, we observe that it is easy to vary the number of zero eigenvalues in the iteration matrix, setting it close to zero by taking the same size for the $\mathbf{A}^i$ in $\mathbf{B}^1$ as for the $\mathbf{A}^i$ in $\mathbf{B}^2$ $(m_1 \sim m_2)$, or setting it as big as possible $(m_1 \gg m_2)$ by taking large blocks $\mathbf{A}^i$ in $\mathbf{B}^1$, and defining small interface blocks in $\mathbf{B}^2$ of size $2 \times l$ (the minimum required for making the $\mathbf{A}^i$ in $\mathbf{B}^1$ structurally orthogonal).

A good partitioning strategy must compromise between reducing the size of the interface block $\mathbf{B}^2$, with the aim of reducing the number of CG iterations, and maintaining the degree of parallelism of the method. The degree of parallelism involves two things: first, the number of blocks in the partitioning compared to the number of processors of the target machine, and second, the size of these blocks compared to the amount of work the different processors will have to perform, which affects granularity and load balancing.

We remember from § 3 that we can easily incorporate ellipsoidal norms, replacing orthogonal projectors by oblique ones. But in this case, when looking for partitionings leading to a two-block partitioning, we must ensure that the right-hand side preconditioning matrix $\mathbf{G}^{-1/2}$ (see § 3) preserves the orthogonality between the subspaces $\mathscr{R}(\mathbf{A}^{i^T})$ in each of the two blocks $\mathbf{B}^1$ and $\mathbf{B}^2$ of the given two-block partitioning.

8. Block SSOR method. Kamath and Sameh (1988) use a block SSOR iterative scheme with a two-block partitioning for block tridiagonal structures. They consider, however, only the partitioning defined by taking equal-sized blocks of the smallest possible size for a matrix partitioned into two blocks (twice the number of rows of one block in the block tridiagonal structure). This leads to a high degree of parallelism, but also to the largest number of nonzero eigenvalues in the iteration matrix.

The block SSOR algorithm with two-block partitioning (as described in § 7.2) can be written in the following way:

```
ALGORITHM 8.1 (block SSOR method).
    Choose $\mathbf{x}^{(0)}$, set $k=0$
    repeat until convergence
        begin
                            $\mathbf{z}^1 = \mathbf{x}^{(k)}$
            Forward sweep   $\left[\begin{array}{l} \mathbf{z}^2 = \mathbf{z}^1 + \omega \mathbf{B}^{1^+}(\mathbf{b}^1 - \mathbf{B}^1\mathbf{z}^1) \\ \mathbf{z}^3 = \mathbf{z}^2 + \omega \mathbf{B}^{2^+}(\mathbf{b}^2 - \mathbf{B}^2\mathbf{z}^2) \end{array}\right.$
            Reverse sweep   $\left[\begin{array}{l} \mathbf{z}^4 = \mathbf{z}^3 + \omega \mathbf{B}^{2^+}(\mathbf{b}^2 - \mathbf{B}^2\mathbf{z}^3) \\ \mathbf{z}^5 = \mathbf{z}^4 + \omega \mathbf{B}^{1^+}(\mathbf{b}^1 - \mathbf{B}^1\mathbf{z}^4) \end{array}\right.$
                            $\mathbf{x}^{(k+1)} = \mathbf{z}^5$, set $k = k+1$
        end
```

where the current iterate is projected in sequence onto the different subspaces using the updated value each time.

The iteration matrix for this algorithm can be expressed as a product of projectors instead of a sum as in the block Cimmino algorithm, viz.,

$$\mathbf{Q}_{RS} = (\mathbf{I} - \omega \mathbf{P}_{\mathscr{R}(\mathbf{B}^{1^T})})(\mathbf{I} - \omega \mathbf{P}_{\mathscr{R}(\mathbf{B}^{2^T})})^2(\mathbf{I} - \omega \mathbf{P}_{\mathscr{R}(\mathbf{B}^{1^T})})$$

where one projection in the central part of the algorithm can be avoided, because of the idempotency of projectors.

A detailed study of the block SSOR algorithm and of its iteration matrix is performed by Bramley (1989) and by Bramley and Sameh (1990). They show that, even when conjugate gradient acceleration is used, the first projection can also be avoided, provided that $\omega = 1$ and that $\mathbf{x}^{(0)}$ is such that $\mathbf{B}^1\mathbf{x}^{(0)} = \mathbf{b}^1$. Therefore, with the two-block partitioning, one iteration of block SSOR has the same cost in number of flops as one iteration of block Cimmino.

It was shown by Elfving (1980) that, with $\omega = 1$, and the same kind of partitioning, the spectrum of the iteration matrices for the two algorithms are:

$$\text{for block Cimmino:}\quad \begin{array}{ll} \lambda_k = +\cos \Psi_k, & k = 1, \cdots, m_2, \\ \lambda_k = -\cos \Psi_{k-m_2}, & k = m_2 + 1, \cdots, 2m_2, \\ \lambda_k = 0, & k = 2m_2 + 1, \cdots, n; \end{array}$$

$$\text{for block SSOR:}\quad \begin{array}{ll} \lambda_k = \cos^2 \Psi_k, & k = 1, \cdots, m_2, \\ \lambda_k = 0, & k = m_2 + 1, \cdots, n \end{array}$$

where $\{\Psi_k\}_1^{m_2}$ are the principal angles between $\mathcal{R}(\mathbf{B}^{1^T})$ and $\mathcal{R}(\mathbf{B}^{2^T})$.

Thus, with two-block partitioning, the block SSOR algorithm with CG acceleration should converge in about half the number of iterations as the block Cimmino algorithm with CG acceleration.

Similar comparisons between block Cimmino and block SSOR can also be found in Bramley (1989) and in Bramley and Sameh (1990). They show that, in general, the block SSOR iteration matrix has more eigenvalues collapsed to zero than that of block Cimmino, which will benefit the convergence of block SSOR. But we must not forget that the degree of parallelism in the block Cimmino method is higher because all the projections can be performed in parallel. This is not the case for the block SSOR method where information must be updated from one subproblem to the next so that the subspaces must be orthogonal to permit parallelism.

However, when using two-block partitioning on shared memory machines, we have found experimentally that block SSOR is still faster because memory bank conflicts prevent block Cimmino from attaining twice the speedup of block SSOR. At any rate, in the following, results and comments on various two-block partitionings will be given for the CG accelerated block Cimmino scheme only, because the aim here is not to compare the two methods in terms of efficiency, but to emphasize our approach to the implementation of row projection methods, using block Cimmino by way of illustration. Different techniques have been introduced in the previous sections, e.g., the augmented system, the ellipsoidal norms that can easily be incorporated in the augmented system approach, and the varying of the relative sizes of the blocks in the two-block partitionings. The experiments are designed to emphasize these novel aspects.

The main reason why we have chosen block Cimmino is that its degree of parallelism depends only on the partitioning and not on special properties of structural orthogonality between sets of equations. Thus block Cimmino provides more degrees of freedom for the choice of any ellipsoidal norm as a preconditioner because it is not necessary to preserve the structure of the original matrix to maintain the degree of parallelism.

9. Use of ellipsoidal norms. In this section we introduce a particular kind of ellipsoidal norm associated with two-block partitioning. This will be used to improve the convergence on some of the test problems.

Consider a two-block partitioning as shown in Fig. 9.1. The aim is to make the two subspaces, generated by the two sets of rows, nearly orthogonal so that the

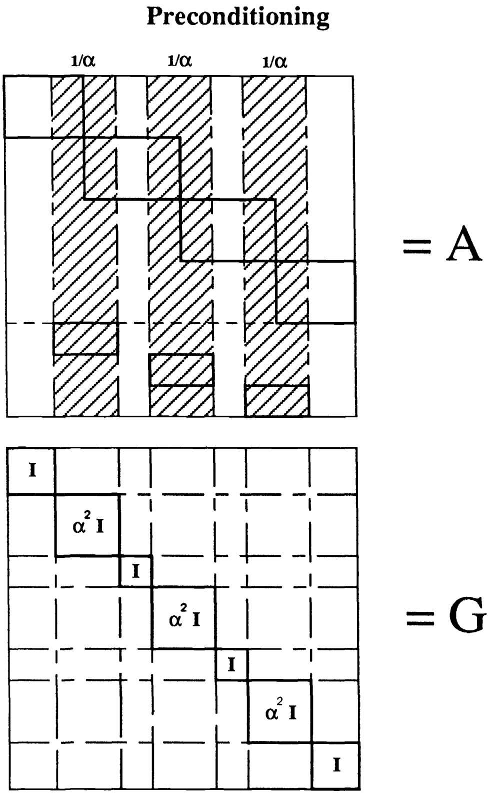

FIG. 9.1

eigenvalues of the iteration matrix (which are the cosines of the principal angles between the two subspaces, as shown in § 8) will all be small. The solution would then be obtained rapidly.

The simplest way to make two sets of rows in a matrix orthogonal is to multiply their overlapping part by zero. But obviously, if we do this, the resulting system can be rank deficient. In order to avoid this, we instead divide them by a large number α, as shown in Fig. 9.1. This leads to a diagonal matrix **G** with α^2 in positions corresponding to the overlapping columns and 1 elsewhere, remembering from § 3 that it is $\mathbf{G}^{-1/2}$ which preconditions the matrix **A**.

Of course, with such a preconditioner, some numerical instability in the factorization of the augmented systems can be expected if a very large value of α is used. We will see in § 10.4 that a value of $\alpha = 10$ gives the best compromise for our test problems and that much larger values for α introduce numerical instabilities without improving the rate of convergence. Also, the overlapping part must not involve all the columns of the matrix, because in that case the preconditioning would be equivalent to a scaling of the complete matrix, which would not modify the principal angles between the two spaces at all.

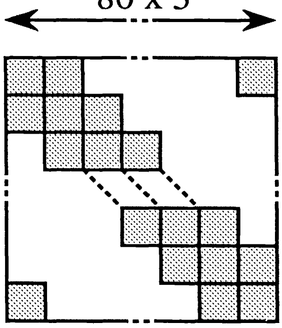
We note that this scaling preserves the block structure of the partitionings, as required in § 7.2, and thus can also be used with the block SSOR method of Kamath and Sameh (1988). However, it cannot be applied with their particular partitioning, because it involves a complete overlapping of the two blocks.

10. Numerical experiments. In this section we present some numerical experiments for testing the behaviour of our CG accelerated block Cimmino method. We first describe three different test problems and the particular points we wish to clarify by means of these tests. Then we analyse the results obtained on the eight-processor Alliant FX/80 at CERFACS, varying the two-block partitionings. Afterwards, we present results obtained using preconditioners of the kind discussed in § 9 and show how they decrease the number of iterations and the elapsed time for some of our test problems. Finally, we introduce a fourth test problem derived from Bramley (1989) and describe the results obtained using different kinds of partitioning from the two-block ones. These supplementary runs permit the comparison of our approach with the one of Bramley (1989) and Bramley and Sameh (1990) and an illustration of their differences.

10.1. The test problems. We will introduce the first three test problems. All are square problems, although we note that our algorithm does not require this. The first two problems come from simulation models of real flows developed at CERFACS in the fluid dynamics team.

The first model, developed by Perrel, concerns the study of a body entering the atmosphere at a high mach number. It is based on a finite-volume discretisation of the Navier–Stokes equations coupled with chemistry. For our test, we consider a two-dimensional problem which leads to three variables per mesh point (energy and two velocities), plus two species in the chemistry which lead to two density variables per mesh point, making a total of five variables. The discretization is performed using an implicit scheme on a curvilinear mesh of 69×60 points. This leads to block tridiagonal matrices of order $60 \times 69 \times 5 = 20{,}700$. The off-diagonal blocks are block diagonal with 69 blocks of 5×5 elements. The diagonal blocks have a block tridiagonal structure. The test problem solved is taken from the first time step in this time-dependent problem. The matrix is unsymmetric and nondiagonally dominant. The right-hand side is very large because the initial guess of the parameters is far from the steady-state solution. Therefore, a large correction to this guess is expected, and in this case, the solution need not be very accurate.

The second model, developed by Weinerfelt, is from the study of a two-dimensional wing profile at transonic flow (with no chemistry effects). It is still based on finite-volume discretisation, but this time, of the Euler equations. We are also looking for the steady-state solution, and the discretisation is performed using an upwind and implicit scheme on a curvilinear mesh of 80×32 points. This leads to unsymmetric but diagonally dominant block tridiagonal matrices of order $32 \times 80 \times 3 = 7{,}680$. The off-diagonal blocks are block diagonal with 80 blocks of 3×3 elements. The diagonal blocks are of the same order and have the following block triangular circulant structure:



This time the test problem solved is close to the steady-state solution, and a very accurate solution is required.

The other test problem comes from the paper by Kamath and Sameh (1988). It is obtained by application of the finite-difference method to a two-dimensional partial differential equation. The right-hand side is computed using a given solution

PROBLEM 3 (Kamath and Sameh (1988)).

$$-u_{xx}-u_{yy}+1000e^{xy}u_x-1000e^{xy}u_y=g, \qquad u=x+y,$$

on a 64×64 grid. We have selected this problem for the following reasons. First, as will be shown, it converges very slowly, but we will try to improve the situation using ellipsoidal norms. Second, this problem is the particular one for which Kamath and Sameh show that their block SSOR method converges while the iterative solver GMRES from the Yale package PCGPACK does not. By means of this test, we want to indicate that our method belongs to the same class of robust iterative solvers as the block SSOR method of Kamath and Sameh. This is also shown by Bramley and Sameh (1990), who compare different accelerated row projection methods, including the block Cimmino method with CG acceleration, with other iterative methods such as GMRES from PCGPACK, CG on the normal equations, and preconditioned versions of these two. They also use the previous equation and several other problems on three-dimensional grids.

10.2. Different partitionings. We now introduce the partitionings by which we hope to influence the number of iterations as indicated in the discussion in § 7. Since the tests are performed on an eight-processor Alliant, we consider the five following partitionings.

(1) A single block to provide a comparison with the direct solution of the augmented system on the overall matrix.

(2) Eight equal-sized blocks, in an attempt to balance the work on the eight processors of the Alliant FX/80. For this partitioning, however, the sizes of the two blocks in the equivalent two-block partitioning (after reordering the rows) are equal, so that the number of nonzero eigenvalues in the iteration matrix is expected to be maximum.

(3) Five large blocks in $\mathbf{B}^1$ and four minimum-sized blocks in $\mathbf{B}^2$. This partitioning should minimize the number of iterations, but gives a poor balancing of the work. It is then interesting to see if the gain in elapsed time due to the expected decrease in the number of iterations can overcome the loss of parallelism in the partitioning.

(4) A compromise between the size of the interface block and the degree of parallelism. For instance, if we consider a block tridiagonal structure with 32×32 blocks (which is the case for the problem given by Weinerfelt), we can partition by blocks of rows according to

$$\begin{array}{cccccccc} 4 & 4 & 4 & 4 & 4 & 1 & & (\mathbf{A}^i \text{ in } \mathbf{B}^1) \\ 1 & 2 & 2 & 2 & 2 & 2 & & (\mathbf{A}^i \text{ in } \mathbf{B}^2) \end{array}$$

where we give in sequence the number of block-rows for each partition. Here the size of the interface $\mathbf{B}^2$ is 11 block-rows, and the work is well balanced, with five processors handling blocks of size 4 (in number of block-rows) and the three remaining processors, each handling two blocks of size 2, or one block of size 2 plus two blocks of size 1. Of course, the number of rows in each block is only a rough heuristic for calculating the amount of work that will be performed by MA27 in the corresponding augmented systems. However, as we will see from the results, it gives a good estimate.

(5) The partitioning of Kamath and Sameh (1988), defined by taking equal-sized blocks of the smallest possible size for a matrix partitioned into two blocks (two times the number of rows in one block of the block tridiagonal structure). Although this partitioning also leads to a large interface block and to good load balancing, it has the added advantage that it minimizes the overall fill-in in the factorization of the different augmented systems because they are all of the smallest size. This leads to a smaller elapsed time for the factorization part, which can be of great benefit, especially in the case where the time for factorization is greater than the time for iterations.

10.3. Results. We will now present the results obtained on the Alliant FX/80. All the tests are performed in double precision (64 bit words) with machine precision $2.2\ 10^{-16}$.

For each test problem we give two figures, each with a histogram and a graph. In the first figure the histogram gives, for each partitioning, the number of floating-point operations for the factorization of all the augmented systems and the number of floating-point operations for the iterative part (computation of the minimum norm solutions and CG acceleration), and the graph in the same figure shows the number of iterations performed to reach the accuracy specified. With this histogram, we can see whether the factorization or the iteration is the more costly and also the effect of the partitionings on the number of iterations. The histogram in the second figure gives, for each partitioning, the total elapsed time for the solution (divided into the elapsed time for analysis and factorization of the augmented systems and the elapsed time for the iterative part), and the graph in the same figure gives the speedup of the method using the eight processors of the Alliant FX/80. The speedup measure used is the ratio between the elapsed time for execution on one processor and the elapsed time for execution on eight processors, using the same code. With this histogram, we can see which partitioning is the best, and also how well the work is balanced. We present, in tabular form in the Appendix, the results used in generating these figures.

For the stopping criterion of convergence, we use the scaled residual ω_k defined by

$$\omega_k = \frac{\|\mathbf{A}\mathbf{x}^{(k)} - \mathbf{b}\|_\infty}{\|\mathbf{A}\|_\infty \|\mathbf{x}^{(k)}\|_1 + \|\mathbf{b}\|_\infty}.$$

For an assigned value of *TOL*, if, at step k, $\omega_k \leqq TOL$, we stop the process. A small value for ω_k means that the algorithm is normwise backward stable (see Oettli and Prager (1964)) in the sense that the solution $\mathbf{x}^{(k)}$ is the exact solution of a perturbed problem where the max norm of the error matrix is less than or equal to ω_k. The bound

$$\frac{\|\mathbf{x}^{(k)} - \mathbf{x}\|_\infty}{\|\mathbf{x}\|_\infty} \leqq \omega_k (n+1) \|\mathbf{A}\|_\infty \|\mathbf{A}^{-1}\|_\infty + O(\omega_k^2)$$

also holds, which gives an estimate of the normwise relative error of the solution.

10.3.1. Problem given by Perrel. In the problem from Perrel, the iterations were stopped when $\omega_k \leqq TOL = 10^{-9}$ because, as we said in § 10.1, we do not need very high accuracy for this problem. Results for partitioning (1) are not given because the direct solution of the single augmented system produces too much fill-in for the memory of the Alliant. We present the results in Figs. 10.3.1 and 10.3.2 and, in tabular form, in Table A.1 in the Appendix.

The first remark is that the algorithm converges very quickly for this problem considering that the matrix is of order 20,700 and is not diagonally dominant. As expected from the discussion in § 10.2, the minimum number of iterations is attained

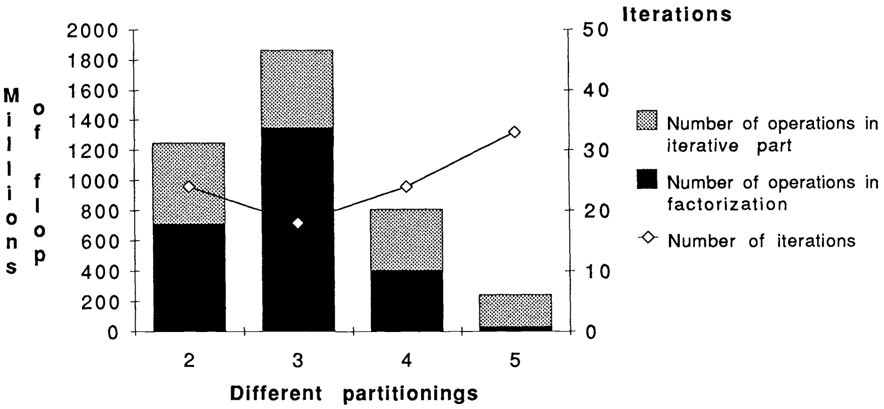


FIG. 10.3.1. *Perrel's test problem.* $\omega_k \leqq 10^{-9}$.

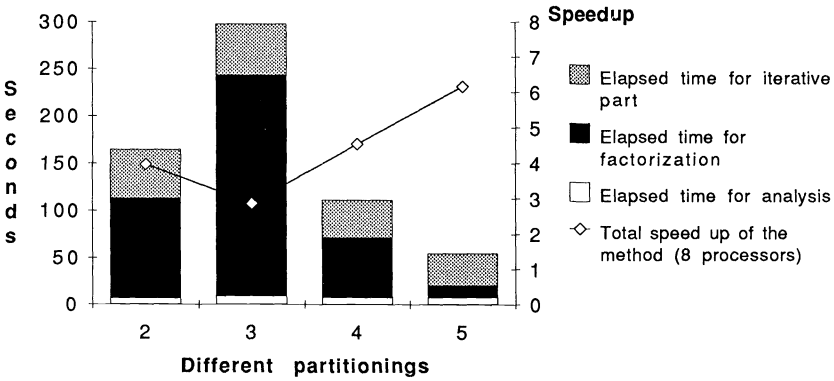

FIG. 10.3.2. *Perrel's test problem.* $\omega_k \leqq 10^{-9}$.

by partitioning (3), and partitioning (4) gives a good compromise between the number of iterations and the balancing of the work between factorization and iteration. In this problem, the fill-in in the direct solution of the subproblems is very significant and is more so when the subproblems are larger. Thus a partitioning with the smallest blocks possible should be the best even if this causes an increase in the number of iterations. This is illustrated by the results of partitioning (5), which has the least elapsed time although it has the greatest number of iterations. For such partitionings, we will also attain a higher speedup because, with the smaller blocks, there will be less cache conflict when solving the subsystems simultaneously on the different processors.

We also tried to obtain a more accurate solution with $\omega_k \leqq 10^{-14}$. The results are summarized in Table A.2 in the Appendix. All the partitionings achieved this accuracy with partitioning (5) again requiring the largest number of iterations but the least elapsed time because, even if the gap between the number of iterations for the different partitionings is increased for such an accuracy (it becomes roughly double that for the previous accuracy), the time and the amount of work performed during iterations still remains proportional to the fill-in produced during the factorization.

10.3.2. Problem given by Weinerfelt. In the problem from Weinerfelt, a very accurate solution is needed and so iterations are stopped when $\omega_k \leqq TOL = 10^{-14}$. We present

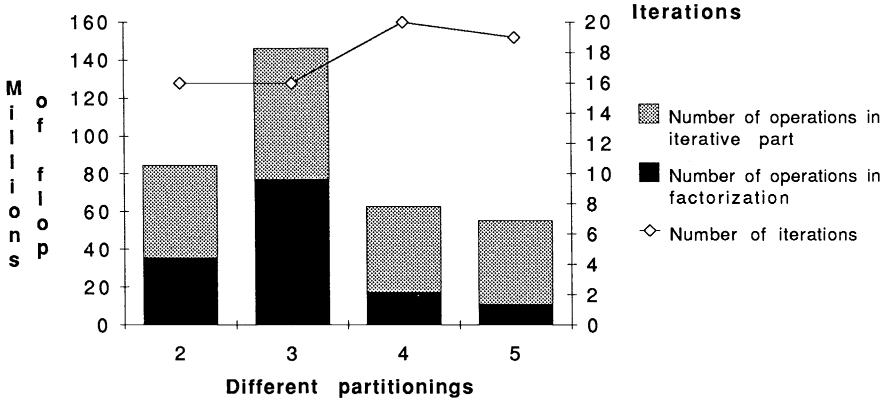

FIG. 10.3.3. *Weinerfelt's test problem.* $\omega_k \leqq 10^{-14}$.

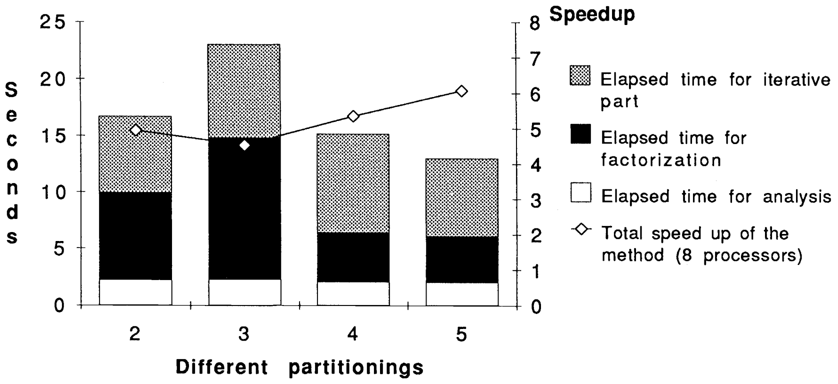

FIG. 10.3.4. *Weinerfelt's test problem.* $\omega_k \leqq 10^{-14}$.

the results in Figs. 10.3.3 and 10.3.4 and, in tabular form, in Table A.3 in the Appendix. Again, results for partitioning (1) are not shown in the figures, not because the direct solution of the augmented system with the original matrix does not fit in the memory of the Alliant, but because it takes so many operations and so much time that it would not make sense to display it on the same scales as for the other partitionings. However, the results from partitioning (1) can be found in Table A.3 in the Appendix.

Again, the algorithm converges very quickly. Additionally, the number of iterations is not very sensitive to the partitioning. We thus suspect a similar clustering of eigenvalues for the iteration matrices from the different partitionings, an effect which may be due to the diagonal dominance of the original matrix. Partitionings (4) and (5) give a good speedup. This supports what we have said in § 10.2, which is that the number of rows in the blocks is a reliable estimate for the amount of work that will be performed by MA27 in solving the augmented systems. In this case we cannot say that the factorization time dominates the time for iteration, but partitioning (5) still remains the best in terms of elapsed time, because now there is little difference in the number of iterations for the different partitionings and, of course, partitioning (5) still yields the least fill-in.

10.3.3. Problem 3 (two-dimensional PDE on a 64×64 grid). Problem 3 is the one on which Kamath and Sameh (1988) and Bramley and Sameh (1990) show that row projection methods are more robust than GMRES from the Yale package PCGPACK. The results, which are given in Figs. 10.3.5 and 10.3.6 and in Table A.4 in the Appendix, show that the block Cimmino method converges to high accuracy ($\omega_k \leqq TOL = 10^{-14}$), but the direct solution of the whole system is competitive, even though the solver MA27 does not exploit parallelism.

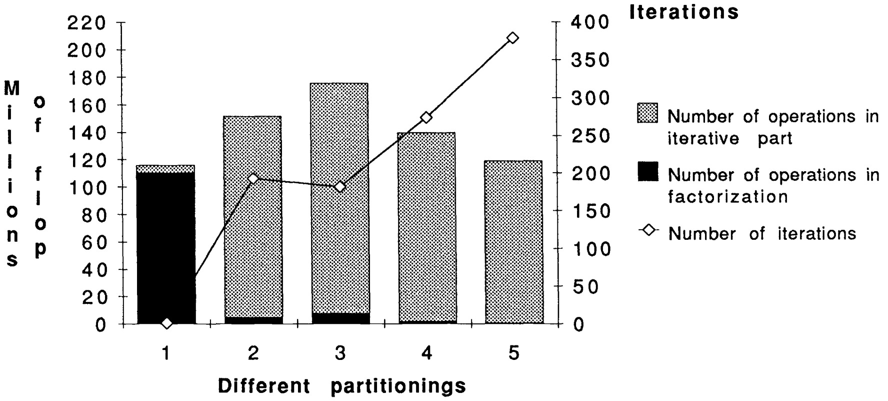

FIG. 10.3.5. *Problem* 3. $\omega_k \leqq 10^{-14}$.

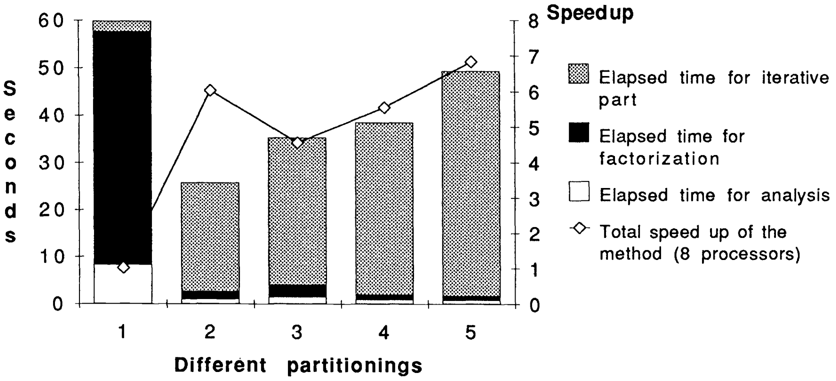

FIG. 10.3.6. *Problem* 3. $\omega_k \leqq 10^{-14}$.

The time for the iterations now completely dominates the time for factorization, and partitioning (3) requires the least number of iterations. Partitioning (2) with the eight equal-sized large blocks is the fastest. We remark that for partitionings (2), (4), and (5), the number of operations performed decreases and the speedup increases, respectively, but the elapsed time for reaching the solution increases gradually from partitioning (2) to (4) and (5). This effect, which is more deeply felt for smaller blocks, is due to a large number of delayed pivots and 2×2 pivots generated by MA27 during the factorization; the former increases the work involved while the latter disrupt the vectorization of the factorization and also of the forward and backward substitutions performed by MA27CD at each iteration.

10.4. Improvements with ellipsoidal norms. In this section we will show improvements to the previous results by using the ellipsoidal norms introduced in § 9.

A wide range of values for the parameter α in the matrix G (see § 9) were tried to improve the results on all of our test problems. This was not very helpful for the two problems coming from fluid dynamics simulations. For these, the convergence (as shown in § 10.3) was already very fast without the ellipsoidal norm. Thus, on the one hand, the number of iterations could be decreased by a small amount only and, on the other hand, more ill conditioned subsystems created more problems for the factorization. For this reason results are not given in this section for the two problems of Weinerfelt and Perrel. However, for the test coming from the set of Kamath and Sameh problems, and for which the convergence was quite slow, the use of ellipsoidal norms improved the results significantly.

For this test problem, better results, in terms of both accuracy and convergence, were obtained for all the partitionings on which we could apply this kind of ellipsoidal norm. These were partitionings (2), (3), and (4). Partitioning (1) is only one block, and partitioning (5), as we said in § 9, is one on which these ellipsoidal norms are equivalent to a complete scaling of the original matrix by a factor α.

Figure 10.4.1. shows, for Problem 3 with partitioning (4), the convergence for different values of the parameter α. The tests showed that it was not worth taking a very large α, but that the best improvements in convergence were obtained for α of order 10. Larger values for α introduce some oscillations in the convergence curve, as can be seen in Fig. 10.4.1. This phenomenon is due to the ill-conditioning of the subproblems when α increases. If iterative refinement (see Arioli, Duff, and de Rijk (1988)) is used in the computation on the subproblems, then the accuracy reached is the same, and the convergence behaviour for large α approaches that for α of order 10 but is never better than it.

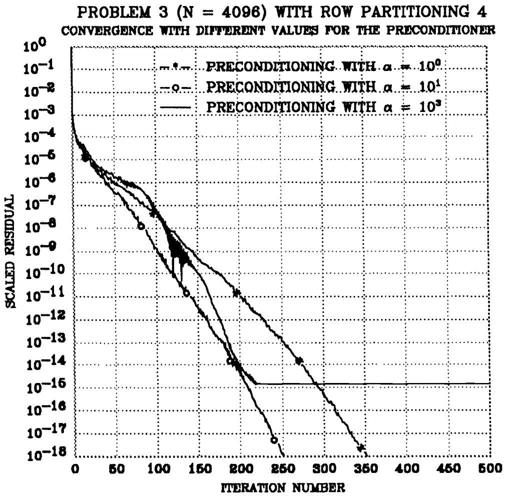

FIG. 10.4.1. *Effect of ellipsoidal norms. Two-dimensional* PDE *Problem* 3. *Partitioning* (4).

Table A.5 in the Appendix gives iteration counts, times, and flop counts obtained using ellipsoidal norms with $\alpha = 10$, on Problem 3 for partitionings (2), (3), and (4), and for a value of *TOL* equal to 10^{-14} in the stopping criterion.

The ratio between the number of flops for factorization before and after the preconditioning varies with the different partitionings. For example, in Problem 3, these ratios are 1.54 (partitioning (2)), 1.4 (partitioning (3)), and 1.47 (partitioning (4)).

10.5. Memory requirements. In this section we give the memory (integer and real) required by MA27 when solving the subproblems. These numbers do not take into account the arrays needed in the algorithm to perform all the other stages of the computations (conjugate gradient acceleration, etc.). These missing numbers can, however, be directly determined knowing the size of the original matrix and the partitioning in use.

It can be seen from Table 10.5.1 that the memory required decreases as the size of the blocks in the partitionings decreases.

TABLE 10.5.1
Memory requirements in thousands of words for handling the LU *factors of the different blocks.*

	Problem 1 $N = 20{,}700$ $NZ = 511{,}050$		Problem 2 $N = 7{,}680$ $NZ = 113{,}760$		Problem 3 $N = 4{,}096$ $NZ = 20{,}224$	
Part.	Int.	Real	Int.	Real	Int.	Real
1	—	—	123	4,328	65	697
2	368	4,881	171	611	50	167
3	400	6,328	142	907	55	207
4	430	3,539	187	429	48	103
5	676	1,067	172	375	60	56

We do not want, however, to focus too much on these numbers because the version of MA27 we are using does not perform well on augmented systems since the analysis phase assumes that the diagonal of the matrix is full. For instance, the ratio between the estimated amount of real storage (given by the analysis) and the actual amount of real storage used, can be as high as 2.5 for Problem 1 with partitioning (3) (the one with the largest blocks). A new version of MA27 that recognizes and exploits the zeros on the diagonal and behaves much better in terms of fill-in is being developed now at Rutherford Appleton Laboratory (Duff et al. (1991)).

Table 10.5.2 shows the memory required with and without the preconditioner, with $\alpha = 10$, for Problem 3. We see the bad effect on the fill-in due to the ill-conditioning that our scaling introduces in the augmented systems. In particular, partitioning (3) gives the least increase in memory requirement when going from the unpreconditioned

TABLE 10.5.2
Memory requirements in thousands of words for handling the LU *factors with and without preconditioning.*

	Problem 3 $N = 4{,}096$ $NZ = 20{,}224$				
	Unpreconditioned		Preconditioned

2	65	167	10	53	212
3	55	207	10	56	247
4	48	103	10	48	125

case to the preconditioned one (19 percent more). In this partitioning, the size of the interface is minimized; therefore, the size of the overlapping part (see § 9) is minimized and the augmented systems are not strongly affected by the scaling.

10.6. More experiments. Bramley (1989) and Bramley and Sameh (1990) describe implementations of the block Cimmino and block SSOR algorithms that are different from the ones illustrated here. They test the robustness of these row projection methods on a set of linear systems coming from the discretization of three-dimensional partial differential equations by the seven-point formula.

We will now present more tests related to one of their test problems in order to illustrate the difference between our approach and theirs. Consider the following three-dimensional partial differential equation defined on the unit cube

$$u_{xx}+u_{yy}+u_{zz}+100xu_z-yu_y+zu_z+\frac{100(x+y+z)u}{xyz}=\mathbf{F}$$

where the right-hand side **F** is computed using the solution

$$u=\exp(xyz)\sin(\pi x)\sin(\pi y)\sin(\pi z).$$

The test problem is obtained by discretizing the previous equation by the seven-point finite-difference formula on a 24×24×24 mesh. This problem is Problem 3 in Bramley and Sameh (1990) and Problem 5 in Bramley (1989).

Bramley and Sameh implement block Cimmino and block SSOR using the normal equations approach for computing the projections instead of the augmented system approach described in § 6. According to this choice, they analyse the most suitable row partitioning strategies, considering other partitionings than the two-block one. In fact, taking advantage of the nested level of tridiagonal structures in the seven-point finite-difference operator matrices, we can define the following row partitionings:

(1) A two-block partitioning of the kind (5) described in § 10.2, with 12 blocks of 2×24×24 rows each.

(2) A three-block partitioning (see Kamath and Sameh (1988)) with 24 blocks of 24×24 rows each.

(3) A six-block partitioning, with 24×8 blocks of 3×24 rows each.

(4) A nine-block partitioning, with 24×24 blocks of 24 rows each.

Partitioning (4) is reported by Bramley and Sameh (1990) as the one giving the best average performance.

In the runs, the value of *TOL* in the stopping criterion has been set to $TOL=10^{-11}$ because it was the value giving results similar to those provided in Bramley (1989, p. 158) and in Bramley and Sameh (1990) in terms of the residual ($\|\mathbf{Ax}^{(k)}-\mathbf{b}\|_\infty$) and the error ($\|\mathbf{x}^{(k)}-\mathbf{x}\|_\infty$). For ease of comparison, we give in Table 10.6.1 the values for

TABLE 10.6.1
Behaviour of the block Cimmino method on an Alliant FX/80 (eight processors). Three-dimensional partial differential equation. $\omega_k \leqq 10^{-11}$.

		Elapsed time (seconds)				
Part.	No. iter.	Analysis	Factorization	Iterations	$\|\mathbf{Ax}^{(k)}-\mathbf{b}\|_\infty$	$\|\mathbf{x}^{(k)}-\mathbf{x}\|_\infty$
1	128	6.6	13.8	103.9	1.34E−5	9.57E−4
2	127	4.7	6.7	83.8	1.25E−5	8.37E−4
3	383	7.9	17.3	548.8	1.35E−5	1.85E−3
4	205	14.1	20.5	705.4	1.27E−5	7.90E−4

the errors and the residuals reached in the tests. However, it must be observed that the value of ω_k does not decrease much after it has been reduced to 10^{-11}.

The experiments show that the behaviour of the number of iterations as a function of the partitioning is quite irregular. Moreover, for this problem and with the partitioning (4), Bramley and Sameh (1990) report that the block Cimmino algorithm converges in 572 iterations when the block SSOR algorithm converges in 666, with a final value for the residual of 10^{-5}. The considerable difference from our number of iterations of 205 for the block Cimmino algorithm can be explained by the difference in the two stopping criteria.

The augmented system approach performs very poorly in term of efficiency with blocks having a small number of rows, as illustrated in the elapsed time of partitioning (4). However, with bigger blocks, as for partitionings (1) and (2), it takes care of ill-conditioning within the subproblems and yields the fastest convergence. In particular, for the augmented system approach, partitioning (2) is the most efficient, whereas Bramley (1989, p. 69) rejects the same partitioning because of instability problems in solving the normal equations.

Finally, the elapsed times shown in Table 10.6.1 might be not very attractive compared to those shown in Bramley (1989, p. 158) where convergence is obtained in 76 seconds. However, the elapsed time obtained using partitioning (2) is only 1.3 times greater, and significant improvement can be expected from the use of a new version of MA27 specially tuned for augmented systems.

11. Conclusions. In this paper, we have introduced a method for the solution of large sparse linear systems. There are many different components to this method, most of which we have explored here, but some of which warrant further study. The main components are: the partitioning, the choice of the method for solving the subproblems, the iterative scheme used, and the scaling (ellipsoidal norm) employed. We have shown that we can, for block tridiagonal matrices, partition the system cleverly in order to reduce the number of conjugate gradient iterations, while maintaining a good degree of parallelism.

Our numerical experiments reinforce what we expect from the theory, showing that we can vary the number of iterations and tune the speedup, using simple heuristics like the size of the subblocks in the two-block partitioning.

There are, however, some problems still requiring further work or investigation. First, the method is very dependent on the behaviour of MA27, which can generate much fill-in, as in Problem 1, or induce many 2×2 pivots and delayed pivots and perform poorly, as in Problem 3. This is because MA27 considers all diagonal entries as nonzero, which is not the case for the augmented systems. It then picks a poor pivot order at the beginning and corrects it during the factorization. This situation is being improved at the moment at Rutherford Appleton Laboratory by Duff et al. (1991). We also need to study the phenomenon of clustering of the eigenvalues, which can be quite pronounced for some matrices (see Problem 2) and seems to be linked to the partitioning. We effectively saw in all our tests that partitioning (2) with eight equal-sized large blocks generally requires the least number of iterations, although the size of the interface block for this partitioning is the largest.

The results show that the block Cimmino method with conjugate gradient acceleration can be considered a robust iterative solver similar to the conjugate gradient accelerated block SSOR method of Kamath and Sameh (1988). In fact, since we use conjugate gradient acceleration, we know that we must converge in exact arithmetic within at most n iterations, n being the size of the system. Moreover, we know that we can estimate the number of nonzero eigenvalues by considering the size of the interface block. Then, knowing the influence of the spectrum of the iteration matrix on the conjugate gradient method, we can use this as an upper bound for the number of iterations in order to stop the iterative process if it will not reach the required accuracy.

It is also possible to interpret our method as a preconditioned conjugate gradient method, considering the block Cimmino scheme as an implicit preconditioner and the use of ellipsoidal norms as an explicit preconditioner. From the experiments, the block Cimmino method appears to be a good preconditioner for the CG scheme (with respect to robustness) and, when the convergence would be otherwise slow, the ellipsoidal norms appear to be good complementary preconditioners. From the behaviour of the method, we can, as a first conclusion, say that if the time for factorization is much larger than the time for the iterations, it is better to look for partitionings having small blocks to minimize the fill-in and increase the speedup. But if the time for iterations is the larger, then the use of ellipsoidal norms as preconditioners can help greatly. We still need, however, to study and better understand the effect of these ellipsoidal norms on the convergence of the method and, if possible, to determine when they work well.

Our iterative scheme appears to be reliable, at least for general block tridiagonal matrices and is rather friendly, since it is easy to tune the speedup and the number of iterations. For all the examples, we have separated the time for analysis and the time for factorization because, in a time-dependent problem, for instance, we can avoid the analysis after the first time step, setting the block tridiagonal structure and the partitioning at the beginning and performing the analysis only once.

A particular strength of our approach is that it is not necessary to have disjoint blocks in the partitions in order to exploit parallelism, thus widening the set of applicable partitions. We plan to investigate this further, extending the technique to more general systems. With these other partitionings, we hope to decrease the ratio of the number of iterations between block Cimmino and block SSOR, enlarging the range of applicability of block Cimmino compared to block SSOR. We also need to consider other kinds of ellipsoidal norms, for instance, for partitionings that involve a complete overlap of the columns.

Our final goal is to make the algorithm as complete and as friendly as possible, by designing heuristics for automatically choosing a good partitioning, a good ellipsoidal norm, or a combination of the two, and also a heuristic which can choose automatically between block Cimmino and block SSOR.

SPARSE APPROXIMATION FOR SOLVING INTEGRAL EQUATIONS WITH OSCILLATORY KERNELS*

FRANCIS X. CANNING†

Abstract. An integral equation formulation of Helmholtz's equation is considered as an example of a problem with an oscillatory kernel. For such a problem, the field due to a localized source contains a phase that is a function of position. This allows directional radiation patterns to be produced by using a phase cancellation when constructing "extended" sources. This directional property may be used in solving the integral equation. The region containing the sources is decomposed into subregions, each containing many such extended sources. The directional properties of these extended sources result in an $N \times N$ full matrix having many very small elements (which may be approximated by zero), and approximately Order $[N]$ large elements. A matrix defining the transformation between localized and extended source formulations in two dimensions is introduced, and its condition number is calculated. This transformation is effective whenever a large enough number of the unknowns correspond to "smooth" regions containing the sources. Numerical examples for a formulation of scattering of waves obeying Helmholtz's equation are considered in two dimensions. A sample calculation illustrates that the sparse matrix that results allows a solution with Order $[N]$ operations per iteration. A permutation of matrix rows and columns is introduced and an example is given in which it moves large matrix elements towards the diagonal. This suggests that incomplete LU preconditioning might be quite effective. Even without preconditioning, the resulting method is the most efficient available for general surface problems using the Helmholtz equation.

1. Introduction.

Integral equations with an oscillatory kernel arise from problems with a characteristic distance, i.e., a wavelength. Numerical solutions to these problems by either differential or integral equation approaches become computationally expensive for regions large compared to this wavelength. For example, consider two-dimensional problems involving "sources" on a surface with a characteristic size of L. For the exterior problem in an unbounded domain, a differential equation approach using a local radiation (i.e., absorbing) boundary condition typically requires the outer boundary to be at a distance away that scales as L [5]. Such a calculation requires a number of unknowns, N_d, and a storage, S_d, which scale with the wavenumber $k = 2\pi/\lambda$ as

$$N_d \sim (kL)^2, \qquad S_d \sim (kL)^2. \tag{1}$$

However, an integral equation only requires the surface to be discretized while the resulting matrix is full, so the resulting number of unknowns N and storage S scale as

$$N \sim kL, \qquad S \sim (kL)^2. \tag{2}$$

This paper gives a method for approximating the usual full matrix by a sparse one, thus reducing the storage required to be proportional to kL. When iterative techniques are used to solve the sparse equation, then each iteration for the integral equation method will only take a time proportional to kL, as opposed to proportional to $(kL)^2$ for the differential equation approach.

The above motivation suggests that we study the full matrix that results from discretizing an integral equation containing an oscillatory kernel. Consider the generic form

$$\mathbf{Zj}=\mathbf{e}, \tag{3}$$

where $\mathbf{Z}$ is a square $N \times N$ matrix of complex numbers, while $\mathbf{j}$ and $\mathbf{e}$ are N-dimensional vectors. This form is general enough to apply to both first and second kind Fredholm equations, etc. It is desired to find a square matrix $\mathbf{A}$ such that the new matrix $\mathbf{T}$ defined by

$$\mathbf{T}=\mathbf{AZA}^{*} \tag{4}$$

has of Order$[N]$ large elements and very many elements that are quite small in magnitude. The resulting matrix problem to solve is

$$\mathbf{Ti}=\mathbf{v}, \quad \text{where } \mathbf{j}=\mathbf{A}^{*}\mathbf{i} \quad \text{and} \quad \mathbf{v}=\mathbf{Ae}. \tag{5}$$

If $\mathbf{A}$ and $\mathbf{Z}$ are both well-conditioned matrices, then $\mathbf{T}$ may be approximated by a sparse matrix.

At this point some motivation will be given for the type of matrices $\mathbf{A}$ chosen below. Consider a problem involving sources on a one-dimensional surface in a two-dimensional space. The element (μ, ν) of the matrix $\mathbf{Z}$ may be found from

$$(\mathbf{Z})_{\mu,\nu}=\int g(s,s')\exp[ik(\alpha s-\alpha' s')]t_{\mu}(s)b_{\nu}(s')\,ds\,ds'. \tag{6}$$

The product of $g(s, s')$ with the exponential function gives the kernel of the integral equation to be approximated. The integral operator has an oscillatory kernel, by which we mean that for the appropriate choices of α and α', $g(s, s')$ will be slowly varying over distances of several wavelengths. The function $g(s, s')$ and the parameters α and α' may be (slowly varying) functions of μ and ν, though we do not explicitly show these subscripts. The functions $t_{\mu}(s)$ and $b_{\nu}(s')$ are used to form the discrete version of the integral equation. These functions of arc length are each assumed to be nonzero only for s (or s') in some interval shorter than a wavelength. If desired, one may let $t_{\mu}(s)$ (or $b_{\nu}(s')$) be a delta function (or a sum of delta functions) to achieve a discretization such as that in Nystrom's method.

The elements of the matrix $\mathbf{T}$ are given by an integral similar to that in (6), but with $t_{\mu}(s)$ replaced by $t'_{\mu}(s)$ and with $b_{\nu}(s')$ replaced by $b'_{\nu}(s')$. In each case the primed functions are the linear combination of the unprimed functions determined by the matrix $\mathbf{A}$. In order to motivate a choice for these primed functions (and for the corresponding $\mathbf{A}$), consider the approximation

$$(\mathbf{T})_{\mu,\nu}\approx g(s,s')\int \exp[ik(\alpha s-\alpha' s)]t'_{\mu}(s)b'_{\nu}(s')\,ds\,ds'. \tag{7}$$

Clearly, a phase cancellation for each integral may be achieved by letting both $t'_{\mu}(s)$ and $b'_{\nu}(s')$ be nonzero over some "extended" region, meaning a region of length several wavelengths or more. An earlier paper [7] contrasted two ill-conditioned choices for t' and b' with a well-conditioned choice. For the ill-conditioned choices, $t'_{\mu}(s)$ and $b'_{\nu}(s')$ had an approximately constant phase. They resulted in a $\mathbf{T}$ with all of the matrix elements between two different "extended" regions of the "body" being very small. However, it is known that these regions do interact, so we might hope that the condition number would be reduced by allowing this interaction to occur through one or more large matrix elements between these regions. This suggested constructing an $\mathbf{A}$ for which a small number of extended sources on each region gives rise to (a small number of) large matrix elements. This is accomplished by allowing the functions $t'_\mu(s)$ and $b'_\nu(s')$ to have a variety of rates of phase evolution as a function of s or s'. A simple implementation of this idea gives the unitary **A** described in [7] and [4]. Since the important interactions are localized to a small (i.e., Order$[N]$) number of elements of **T**, this method might be called the "interaction matrix localization" method.

The physical principle involved is quite simple to state. The scattering body is (conceptually) broken into many regions, and on each region there are many sources $b'_\nu(s')$. The subscript ν determines both the region where that source is centered and the rate of its linear phase evolution. The rate of phase evolution determines the narrow range of directions in which it radiates strongly. The resulting matrix element connecting such a source with the radiated field as observed by some "testing" function $t'_\mu(s)$ in another region will be large or small depending on whether that region is located within this range of directions. This effect is increased by similarly choosing the "testing" functions to give them the same directional dependence.

In order to understand the largeness and the smallness of the matrix elements resulting from this approach, note that for a specific value of the pair (μ, ν), the parameters α, α', γ, γ' may be chosen so that integral is in terms of three exponential functions and the three slowly varying functions $g(s, s')$, $t''_\mu(s)$, and $b''_\nu(s')$. The calculation now is in the form

$$(8) \qquad (\mathbf{T})_{\mu,\nu} = \int g(s, s') \exp[ik(\alpha s - \alpha' s')] \exp[i\gamma s] t''_\mu(s) \exp[i\gamma' s'] b''_\nu(s')\, ds\, ds'.$$

These integrals are over the regions where $b'_\nu(s)$ and $t'_\mu(s')$ are nonzero. Clearly, when the net rate of phase evolution as a function of s or s' is approximately zero (e.g., $k\alpha + \gamma \approx 0$), then the corresponding integral will give a large answer that may be found by approximating the integrand by a constant. When this condition is not met, an approximation to the integral may be found by repeated integration by parts, where the product of the three exponential functions is integrated at each step. For the integral involving s, the first integrated part will be zero, provided $t''_\mu(s)$ is zero at both endpoints of the integration. Furthermore, if the first derivative of $t''_\mu(s)$ is also zero at these endpoints, then the next integrated part will also be zero, and so on. Thus, requiring $t''_\mu(s)$ to go to zero smoothly may increase the smallness of many matrix elements [7]. These conclusions and many further details are well known to antenna designers. Indeed, what is being done might be thought of as thinking of the scattering surface as a collection of antennas where many modes are considered on each antenna. For our purposes we note that a magnitude taper going smoothly to zero at the edges of an antenna produces a more distinct beam. Both the form of **A** and its condition number depend on this taper. A larger class of candidates for **A** is introduced in the next section, and their condition numbers are explicitly evaluated in terms of the taper used.

If one is dealing with a second kind Fredholm equation, then the matrix **Z** involves the sum of a multiple of the identity matrix and a matrix resulting from an operator with an oscillatory kernel. For various preconditioning strategies, such as incomplete LU (ILU) decomposition, it is desirable to be able to transform all of **Z** in the same way. Fortunately, it can be shown that as long as the functions $b'_\nu(s)$ and $t'_\mu(s')$ are very smooth (i.e., their Fourier series contain only low frequencies), then the matrix $\mathbf{AA}^*$ will have Order$[N]$ large elements. However, that issue will not be further discussed in this paper. The discussion given here is intended only to outline the motivation for the choice of matrix **A**. A more extensive discussion, in the context of a more restrictive class of matrices, was given in [7]. It was predicted there that, for the two-dimensional case, the number of large matrix elements is Order $[N]$ for an $N \times N$ matrix. The generalization to the matrices $\mathbf{A}$ described below is confirmed by the numerical study presented in § 3.

The present method may be contrasted with other fast solution methods for integral equations. The multilevel scheme of Beylkin, Coifman, and Rokhlin [1] using wavelet transforms does not apply to problems with an oscillatory kernel (i.e., their coarsest level must have at least two points per wavelength). The more standard multilevel methods (e.g., [2]) also have this two points per wavelength limitation. An earlier method by Rokhlin [12], [13] does apply to the oscillatory kernels of scattering theory and has an advantage over the present approach in that it does not require any smoothness property of the scatterer. Rokhlin's method allows the matrix $\mathbf{Z}$ to be applied to a trial solution $\mathbf{j}$ in Order $[N \log N]$ operations, by expressing $\mathbf{Z}$ in terms of blocks of convolutions, etc. The present method generates a truly sparse matrix that may allow efficient preconditioning, which is important since scattering by nonpenetrable bodies generally results in a $\mathbf{Z}$ with a condition number not very different from N (assuming that the number of points per wavelength is fixed at a small constant as N varies, which is the standard practice). Thus, although integral equations often result in better condition numbers than differential equations, the number of iterations required is still somewhat large. This observation is all the more significant when problems with multiple right-hand sides ($\mathbf{e}$) are considered (the number of right-hand sides is proportional to N for some cases of interest). Some iterative results are given in § 4, where a permutation of rows and columns is introduced that may allow effective preconditioning by ILU decomposition. As will be seen below, an additional advantage of the present approach is its simplicity, both in itself and as an addition to existing computer programs.

2. A class of matrices. In this section, transformation matrices $\mathbf{A}$ having a general form are considered. These matrices should be sparse, and the elements of the resulting $\mathbf{T}$ should be easily computed. This leads us to consider matrices where the sources implicit in the resulting $\mathbf{T}$ [7] have linear progressive phase (as a function of arc length along the surface), since multiplication by the corresponding $\mathbf{A}$ may then be accomplished using fast Fourier transforms, as described below. $\mathbf{A}$, $\mathbf{T}$, and $\mathbf{Z}$ are $N \times N$ matrices of complex numbers, and we choose N to be the product of integers m and n. The matrix $\mathbf{A}$ will be constructed from n blocks by n blocks, where each block is an $m \times m$ matrix.

To construct $\mathbf{A}$, we consider an $m \times m$ unitary matrix $\mathbf{U}$ and $m \times m$ real diagonal matrices $\mathbf{C}$, $\mathbf{D}$, and $\mathbf{E}$, which are defined in terms of their elements in row α and column β as

$$(\mathbf{U})_{\alpha,\beta} = m^{-1/2} \exp\{2\pi i[\alpha-(m+1)/2][\beta-(m+1)/2]/m\}, \tag{9}$$

$$(\mathbf{C})_{\alpha,\beta} = \delta_{\alpha,\beta} c_\alpha, \qquad (\mathbf{D})_{\alpha,\beta} = \delta_{\alpha,\beta} d_\alpha, \qquad (\mathbf{E})_{\alpha,\beta} = \delta_{\alpha,\beta} e_\alpha. \tag{10}$$

One possible form for $\mathbf{A}$ is the block circulant matrix whose (j, k) submatrix is given by

$$(\mathbf{A})_{(j,k)} = \delta_{j,k+1}\mathbf{UC} + \delta_{j,k}\mathbf{UD} + \delta_{j,k-1}\mathbf{UE}, \tag{11}$$

where the indices on the delta functions are to be taken mod n, e.g.,

$$\delta_{0,n} = \delta_{0,0} = 1, \qquad \delta_{1,n+1} = \delta_{1,1} = 1. \tag{12}$$

In this paper, only $\mathbf{A}$ in the form given above is considered. Clearly, additional diagonal subblocks could be added to (11), and many of the results in this paper immediately generalize to that case. If **C** and **E** are taken to be zero matrices and **D** is taken to be the identity matrix, then the resulting matrix, which we call **A**′, is a block diagonal matrix, where each block describes a discrete Fourier transform of order m. That is, we define **A**′ by

$$(\mathbf{A}')_{(j,k)} = \delta_{j,k}\mathbf{U}. \tag{13}$$

Thus **A**′ is unitary, and when using it for **A** the 2-norm condition number of the resulting matrix **T** is the same as that of the **Z** it was derived from. Some numerical results using this matrix were given in [7] and [4].

To find the condition number of **A** having the general form (11), note that it can be factored as

$$\mathbf{A} = \mathbf{A}'\mathbf{W}, \tag{14}$$

where **W** is defined to have a submatrix at (j, k) given by

$$(\mathbf{W})_{(j,k)} = \delta_{j,k+1}\mathbf{C} + \delta_{j,k}\mathbf{D} + \delta_{j,k-1}\mathbf{E}. \tag{15}$$

Again, here and throughout the rest of this paper, the indices of the delta functions are to be taken mod n. This makes **W** block circulant. Since **A**′ is unitary, the 2-norm condition number of **A** is equal to that of **W**. Forming the product of **W** with its transpose,

$$\begin{aligned}(\mathbf{W}\mathbf{W}^t)_{(j,k)} = \{&\delta_{j,k}[\mathbf{C}^2+\mathbf{D}^2+\mathbf{E}^2] + \delta_{j,k+1}[\mathbf{DC}+\mathbf{ED}] + \delta_{j,k-1}[\mathbf{CD}+\mathbf{DE}]\\ &+ \delta_{j,k+2}[\mathbf{EC}] + \delta_{j,k-2}[\mathbf{CE}]\}.\end{aligned} \tag{16}$$

Transposing **W** is equivalent to interchanging **C** and **E**, so $\mathbf{W}^t\mathbf{W}$ may be found from the above equation by interchanging **C** and **E**. Doing so, and using that **C**, **D**, and **E** are diagonal and thus commute,

$$\mathbf{W}\mathbf{W}^t = \mathbf{W}^t\mathbf{W}, \tag{17}$$

proving that **W** is normal. This allows the singular values of **W** to be calculated as the absolute values of its eigenvalues.

The factorization of **A** given in (14) allows an efficient method for multiplying **A** by an arbitrary $N \times N$ matrix. Rather than taking Order $[N^3]$ operations as for general matrices, multiplying separately by **W** and **A**′ takes Order $[N^2]$ operations for **W** (which has three or fewer nonzero elements per row) plus Order $[N^2 \log N]$ for **A**′, since fast Fourier transforms may be used. It is also important to notice that each $m \times m$ block of **T** may be calculated from a slightly larger block of **Z** by using (4) and (14). Thus if one wants to calculate the elements of **T** with magnitude larger than some value, this can be done one block at a time where only the larger elements are saved from block to block. This implies the total memory required is not that for N^2 matrix elements, but rather only for a small constant times m^2 elements (e.g., for a block of **Z** and of **T**) plus the number of large elements saved. We will see in the next section that typically one chooses m so that $m^2 \approx N$, giving each block about N elements. Since the number of large elements saved will also be linear in N, so will the total memory required in a computer program, even though all N^2 of the elements of **T** were calculated.

A trial form for the eigenvectors of **W** is the vector of length N whose jth segment is given by $(\mathbf{e})_j = \mathbf{v}z^{jl}$, where $\mathbf{v}$ is a vector of length m and the complex number z is defined by

$$z = \exp[2\pi i/n]. \tag{18}$$

Forming the product **We**, we find that its jth segment is given by

(19) $$(\mathbf{We})_j = \sum_k \{[\delta_{j,k+1}\mathbf{C} + \delta_{j,k}\mathbf{D} + \delta_{j,k-1}\mathbf{E}]\mathbf{v}z^{kl}\}.$$

For any (integer) value of l, z^{jl} is periodic in j with period n, so the eigenvalue equation will be satisfied whenever

(20) $$(\mathbf{C}z^{-l} + \mathbf{D} + \mathbf{E}z^{l})\mathbf{v} = \lambda\mathbf{v}.$$

This shows that the trial form does indeed generate all N of the eigenvectors of **W**. The matrix above operating on **v** is diagonal, allowing a trivial solution for the eigenvectors and eigenvalues. The N eigenvalues of **W** are

(21) $$\lambda_{l,s} = c_s z^{-l} + d_s + e_s z^{l} \qquad \text{for } l = 0, \cdots, n-1, \quad s = 1, \cdots, m.$$

The (2-norm) condition number of **A** is thus given by

(22) $$\kappa(\mathbf{A}) = \left\{\max_{l,s} \operatorname{Abs}(\lambda_{l,s})\right\} \Big/ \left\{\min_{l,s} \operatorname{Abs}(\lambda_{l,s})\right\}.$$

An alternate method for calculating $\kappa(\mathbf{A})$ would be to notice that the sth column of **W** is the pth column of the kth column of blocks, where

(23) $$s = p + (k-1)m.$$

If one symmetrically permutes the rows and columns of **W** so that the sth column of the permuted matrix is related to the original p and k by

(24) $$s' = k + (p-1)n,$$

then the resulting matrix is block diagonal and the blocks are circulant and are essentially tridiagonal (but with an upper right and lower left element included). This resulting matrix thus is normal and the elements of its sth block (i.e., c_s, d_s, e_s) immediately give (21). If (11) were generalized to allow additional blocks, then after the permutation just described the blocks would still be circulant but would then have more than three nonzero elements per row, so the generalization of (21) would have more than three terms.

The coefficients c_s for $s = 1, \cdots, m$, d_s for $s = 1, \cdots, m$, and e_s for $s = 1, \cdots, m$ taken collectively in this order correspond to the discretely sampled version of the taper function used on an antenna [7]. Use will now be made of our assumption that these coefficients are real numbers. One particular case of interest is for

(25) $$c_s, e_s \geqq 0 \quad \text{and} \quad d_s > c_s + e_s \qquad \text{for } s = 1 \cdots m, \quad \text{where } n \text{ is even,}$$

in which case

(26) $$\kappa(\mathbf{A}) = \left\{\max_s [d_s + c_s + e_s]\right\} \Big/ \left\{\min_s [d_s - (c_s + e_s)]\right\}.$$

The example that will be considered in our numerical calculations is motivated by a weighting function well known in antenna theory:

(27) $$f(r) = 1 + \cos[\pi r/m] = 2\cos^2[\pi r/2m], \qquad -m < r < m,$$

(28) $$f(r) = 0 \quad \text{otherwise.}$$

This function will be sampled at discrete, uniformly spaced points. When m is odd, a symmetric choice of sampling points gives

(29) $$c_s = f(s - 1.5m - 0.5) \quad \text{for } s = 1, \cdots, m,$$

(30) $$d_s = f(s - 0.5m - 0.5) \quad \text{for } s = 1, \cdots, m,$$

(31) $$e_s = f(s + 0.5m - 0.5) \quad \text{for } s = 1, \cdots, m.$$

Sample numerical calculations using this particular form of **A** were given in [8]. Comparing this with (21) and assuming that n is even we find that

$$\lambda_{\max} = d_{(m+1)/2} = 2, \tag{32}$$

$$\lambda_{\min} = d_1 - e_1 = \cos[\pi(-0.5+0.5/m)] - \cos[\pi(0.5+0.5/m)] \approx \pi/m. \tag{33}$$

Since **W** is normal, this gives a 2-norm condition number

$$\kappa(\mathbf{A}) \approx 2m/\pi. \tag{34}$$

If n is not even, this is an upper bound on the condition number, as follows from Gersgorin's theorem. The result of a numerical calculation of $\kappa(\mathbf{A})$ as a function of n for several block sizes m is given in Fig. 1. As n increases through odd integers, $\kappa(\mathbf{A})$ slowly approaches the upper bound of (34).

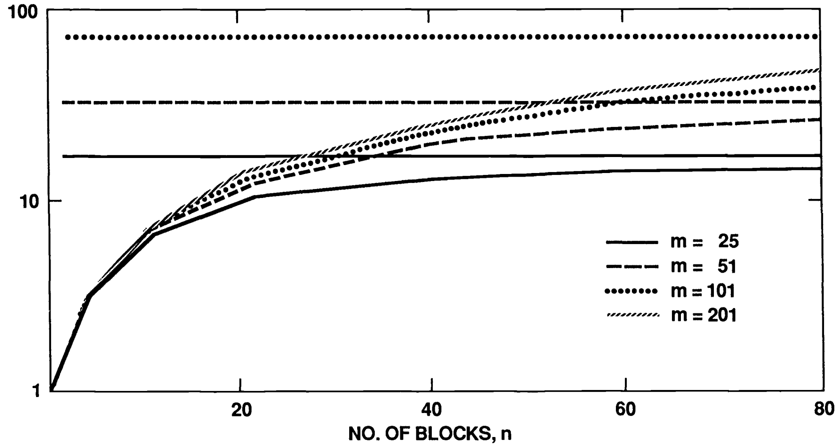

FIG. 1. *The 2-norm condition number, $\kappa(\mathbf{A})$, for $\mathbf{A}$ using (27)-(31) is plotted as a function of the number of blocks n, for several block sizes m. The results of calculations for even values of n are joined together, giving the horizontal lines. The results of calculations for odd values of n are similarly joined together, giving the curves that increase with n.*

The linear dependence of $\kappa(\mathbf{A})$ on m in (34) results from the linear behavior of $f(r)$ in (27) about $r = m/2$. Since it is theoretically interesting to find transformations with small κ, we consider modifying (27) so that $f(r)$ is still monotonically decreasing for Abs (r) increasing and Abs $(r) < m$, but so that for small Δr,

$$f(m/2+\Delta r) \approx \text{const.} + (\Delta r)^{1/\alpha}, \qquad \alpha > 1. \tag{35}$$

One can easily check that κ then satisfies

$$\kappa \sim m^{1/\alpha}. \tag{36}$$

While theoretically interesting, this result may not be especially useful in practice, since $\kappa(\mathbf{A})$ along with $\kappa(\mathbf{Z})$ gives only an upper bound on $\kappa(\mathbf{T})$, and that bound has been found to be quite pessimistic in several specific examples.

The conclusion that we have just reached is that in practice, the matrix **A** will be well conditioned enough so that **T** will be nearly as well conditioned as **Z**. It is important to stress the context in which this conclusion was reached. This paper describes a method for easing the severe limitations on problem size for computer solutions due to the storage and execution time restrictions of present and even near future computers.

For this reason, all methods used must be designed to work with the fewest possible unknowns (e.g., per wavelength) to reduce the order of the matrix to be solved. Thus, we should not be troubled that the method described here would not work in the limit that the number of points per wavelength used in the discretization approaches infinity (in that limit m approaches infinity and so does κ due to (34) or (36)).

3. Matrix element size. To give some numerical examples, we now specialize the discussion to consider the Helmholtz equation in an unbounded region in two dimensions with Dirichlet boundary conditions on a region Γ with boundary $\partial\Gamma$. When the field satisfying the Helmholtz equation in the exterior obeys an outgoing radiation condition and its (one-sided) normal derivative on the boundary exists, an integral equation for the "single layer source," $J(\rho)$, producing the field $E_i(\rho)$ on $\partial\Gamma$ is

$$E_i(\rho)=\int_{\partial\Gamma} H_0^{(2)}(k|\rho-\rho'|)J(\rho')\,ds' \tag{37}$$

where ρ is any vector on the boundary of the scatterer and ρ' is treated as a function of the arc length s' along the scatterer [9, § 3.5]. The scattered field external to Γ and on $\partial\Gamma$ due to the source J is found from

$$E_s(\rho)=-\int_{\partial\Gamma} H_0^{(2)}(k|\rho-\rho'|)J(\rho')\,ds'. \tag{38}$$

The sum E_i+E_s evaluated on $\partial\Gamma$ is clearly zero. If $E_i(\rho)$ is the value of an incident electric field at position ρ, then the total electric field, E_i+E_s, is zero on $\partial\Gamma$. This equation would then describe, for example, the scattering of an electric field aligned in the z-direction by a perfect electrical conductor which is in the shape of a cylinder, infinite (and uniform) in the z-direction [10]. The cross-section of this cylinder would be given by $\partial\Gamma$, which would lie in the x-y plane. The wavenumber k is defined as $2\pi/\lambda$, and $H_0^{(2)}$ is a Hankel function of zero order.

Although (37) is ill posed, that fact has not prevented the widespread practical use of matrix equations based on it in a variety of applications. This situation may seem strange, since it is well known that second kind integral equations may be discretized to matrix problems having condition numbers that are independent of N. At the same time, a first kind equation such as the one above is ill posed, and discretizations generally have condition numbers that grow with N. However, for the problem described above with a characteristic dimension L, the number of unknowns used in practice is nearly always a small constant times kL as kL varies. Thus, the relevant comparison in practice involves the condition numbers obtained with each method for the actual numbers of unknowns used.

To further illustrate this point, let the scatterer be a circle of radius a. For one choice of first and second kind equations the eigenvalues (and hence singular values since this geometry produces a circulant and therefore normal matrix) are

$$J_s(ka)H_s^{(2)}(ka)\to 1/s \quad \text{as } s\to\infty, \tag{39}$$

$$J_s(ka)H_s^{(2)\prime}(ka)\to 1/(\pi ka) \quad \text{as } s\to\infty. \tag{40}$$

In practice N and therefore the largest s used is proportional to ka; both approaches give matrices with similar condition numbers. A detailed discussion of the advantages of each approach including a justification for the discretization step for a first kind equation is beyond the scope of this paper. However, we do mention that there are some reasons for using a first kind equation, such as its applicability to both open and closed structures, its symmetry and the resulting savings in computer memory required and operation count [6], and the nonradiating character of the source associated with the resonant (interior) mode [3] at discrete values of k. While the numerical results presented here use (37), the method described for generating a sparse matrix is very general and also applies to second kind equations, etc.

For our calculations we will use a simple though quite crude discretization of (37), since the goal of this paper is to illustrate how our transformation and subsequent approximation *changes* an answer calculated by well-known techniques. This discretization may be described as Nystrom's method with a one-point rectangle rule, except for the diagonal elements where the asymptotic form of the Hankel function is used for the singular part. In the "moment method" context this is [10, § 3.2] delta function testing with pulse basis functions, with the same approximations to the integrals as above. Without examining under what conditions this (admittedly crude) method converges to the solution of the integral equation (37) as more sample points are taken, we observe that it has often been used with success at typical sampling densities. The form of **A** considered in § 2 is appropriate when the sampling density used to generate **Z** is kept constant, and the calculations that follow all have this property. Also, for this form of **A**, **Z** should be the discretization of the integral equation in terms of local unknowns. Using Nystrom's method, that means the quadrature formulas should involve only local points; using the moment method, it means the basis and testing functions (as in (6)) should be nonzero only in a local region, say, smaller than a wavelength or so. Using a variable sampling density for **Z** would require that **A** be modified so that the **T** created is the discretization of the integral equation in terms of expansion functions that have a phase evolution that is approximately linear with arc length along $\partial\Gamma$.

It was noted in [7] that the matrix **T** resulting from **A**′ may be thought of as giving the discretization of (37) in terms of an expansion of the sources $J(\rho')$ in the following functions. The scatterer is broken into blocks; each function has a magnitude of one throughout a given block, and is zero elsewhere. The βth function on a given block (for $\beta = 1, \cdots, m$) is nonzero only on that block and has a uniform phase progression at a rate determined by β. Since the above description allows one to think of each block as an antenna, each of the basis functions with support on a given block radiates most strongly (i.e., has a main beam) in a different direction. Let D be the size of this "antenna." For such beams nearly perpendicular to the surface, it is well known in antenna theory [15, Table 6.1] that the width of the main beam (i.e., the angle between the two relative minima enclosing it) is approximately $2\lambda/D$ and the first relative maximum past the main beam has a relative height (i.e., "sidelobe level") of about $10^{-1.32}$ (or -13.2 dB). The sidelobe level may be further reduced by tapering the current to decrease its discontinuity at the edges of the "antenna," although doing so increases the angular width of the beam. Note, however, that while nonoverlapping antennas with untapered currents describe **A**′, the **A** described by (27)-(31) corresponds to antennas twice as wide and overlapping. For this taper function, the width of the main beam is 4λ divided by the width of the antenna [15, Table 6.1], which is now $2D$, giving a width of $2\lambda/D$ as before, while the sidelobe level is now $10^{-3.2}$. Since **A** is applied to both sides of **Z**, the typical reduction in matrix element size is expected to be at least $10^{-6.4}$. Numerical results will now be presented that illustrate this reduction and confirm that it is quite an improvement over that for **A**′ as found in [7] and [4]. Although the taper function we have used as given by (27) and (28) gives impressive results, it was chosen in [7] because its analytical form allowed a quick estimation of matrix element size [7, Appendix]. As described in [14, § 9.1.1.1], the taper function of (27) was popular for antennas before computers were available, while more efficient functions are now in use. The general framework presented here should aid in the evaluation and use of such functions.

Before concluding this discussion of expected matrix element sizes, it is useful to note what would change if a double layer source had been used, as occurs in many second kind integral equations. A single layer (point) source radiates isotropically, while a double layer source in two dimensions radiates as sin (θ), where θ is the angle from tangential to the surface. The angular dependence resulting from an array of identical sources is the product of the angular dependences of the array and of the sources. Since the double layer source has a minimum along the tangent to the surface, the "resulting" part of **Z** and **T** would generally have smaller elements near the diagonal when using a double layer source. (There may be an additional part of **Z**, e.g., a multiple of the identity matrix.)

Numerical scattering calculations were performed for Γ consisting of a (two-dimensional) ogive with a blade at its end. The shape of $\partial\Gamma$ may be described by joining two circular arcs with a radius of curvature of 4.25 at their ends to give a chord length of 4 and a full width of 1. A blade of length 1 is then attached radially to one end. The total distance between the ends of Γ will be denoted L/λ, and several such sizes will be considered. The largest magnitude of an element of the resulting matrix **T** (using (29)-(31)) will be denoted γ, and τ will be used to denote a "relative drop tolerance." The matrix $\mathbf{T}'(\tau)$ may be defined by

$$(41)\qquad (\mathbf{T}'(\tau))_{\alpha,\beta} = (\mathbf{T})_{\alpha,\beta} \quad \text{if Abs}\,[(\mathbf{T}'(\tau))_{\alpha,\beta}] \geqq \tau\gamma,$$

$$(42)\qquad (\mathbf{T}'(\tau))_{\alpha,\beta} = 0 \quad \text{otherwise.}$$

The number of nonzero elements of **T** divided by that of $\mathbf{T}'(\tau)$ is plotted on Fig. 2 as the "sparseness factor." This sparseness factor is given for the ogive with blade of length $L/\lambda = 90$ using $N = 1701$ as a function of τ for various values of m. When $m = 1$, the corresponding matrix **A** is the identity, so in this case $\mathbf{T} = \mathbf{Z}$. This matrix does not have any elements smaller in magnitude than 0.02γ. Therefore, on Fig. 2, the $m = 1$ curve indicates a sparseness factor of 1 for $\tau < 0.02$. However, the situation changes dramatically as m increases. When $m = 63$ the sparseness factors for $\tau = 0.0005$ and

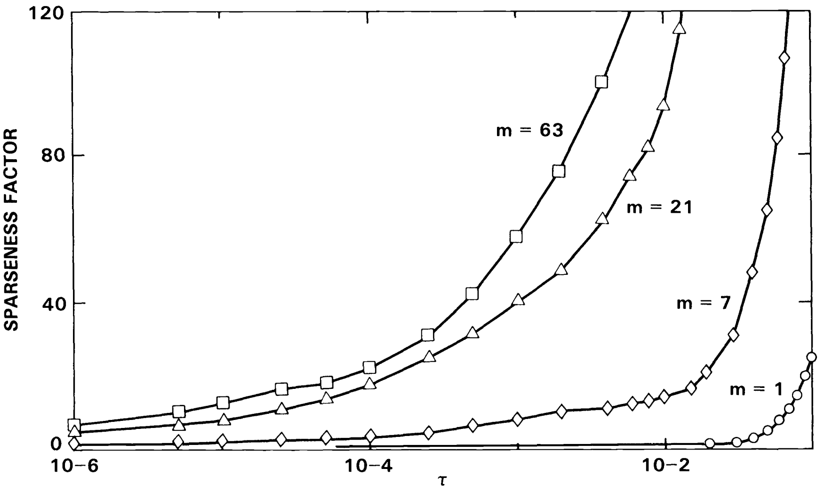

FIG. 2. *The sparseness factor for* $\mathbf{T}'(\tau)$ *as a function of relative drop tolerance* τ *for the ogive with blade described in the text and a chord length L of* 90 *wavelengths. Results are shown for* 1701 *unknowns and several block sizes m.*

0.0001 are 42 and 22, respectively. This transformation is much more effective than that involving $\mathbf{A}'$, as described in [7] and [4].

An earlier paper [7] argued that for a given (reasonably small) value of τ and for $N/(kL)$ fixed, the number of nonzero elements in $\mathbf{T}'(\tau)$ would be at most linear in N provided that N/m^2 is also constant. This scaling of the number of elements per block allows the main beam of each "antenna" to decrease in angular extent with increasing N proportionally to how the angle subtended by the "receiving" block (antenna) decreases. The discussions above about beamwidths, etc., assume that the receiving block is in the far field of the antenna (roughly speaking, the far field is where the approximation of (7) is valid). For an antenna of length D, the distance to the far field region is a constant times D^2/λ [15, § 6.9]. By varying N with both $N/(kL)$ and N/m^2 fixed, one can see that whether the far field condition is satisfied is independent of N but depends only on which parts of $\partial\Gamma$ are interacting (i.e., where the blocks are located). Rather than forming analytical estimates of the number of nonzero elements in $\mathbf{T}'(\tau)$, we now give some numerical results.

Figure 2 gave results for the ogive with blade using $m=63$ and $L/\lambda=90$ with $N=1701$. Keeping $N/(kL)$ constant at $1701/(2\pi 90)$, we now vary N from 21 to 15,309 by factors of three, and plot the resulting "sparseness factors" on Fig. 3. While in the previous figure we had $N/m^2=3/7$, in Fig. 3 the calculations for m satisfying this are plotted directly above the corresponding value of N; smaller and larger values of m (in factor of three increments) are plotted to the left and right, respectively. For example, the calculation for $N=1701$ and $m=63$ is given directly above $N=1701$, while the results for $m=21$ and $m=189$ are immediately to the left and right, respectively. For the values of τ of most interest (i.e., all $\tau<0.01$), this choice for m appears to be the best available (out of the discrete set plotted).

Having verified that $N/m^2=3/7$ is a good choice for m for this problem, the sparseness factor for only this value of m is now plotted as a function of N in Fig. 4.

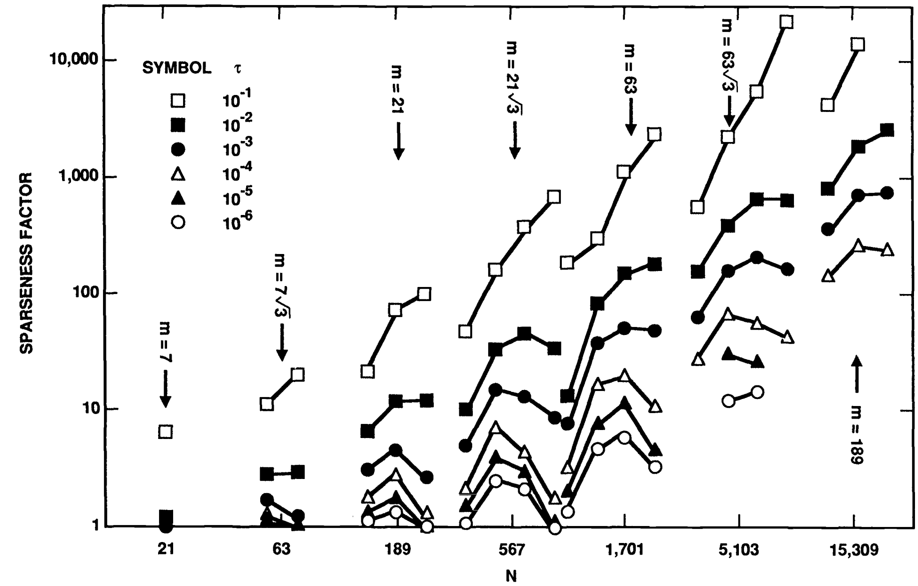

FIG. 3. *Sparseness factors for* $\mathbf{T}'(\tau)$ *as a function of m for m varying about* $m=[7N/3]^{0.5}$. *Calculations are shown for* $N=21$ *to* 15,309 *in factors of three and for* $\tau=10^{-6}$ *to* 10^{-1} *in factors of ten. The same ogive with blade is used as in Fig. 2, and its chord length L is given by* $L=N\lambda/18.9$.

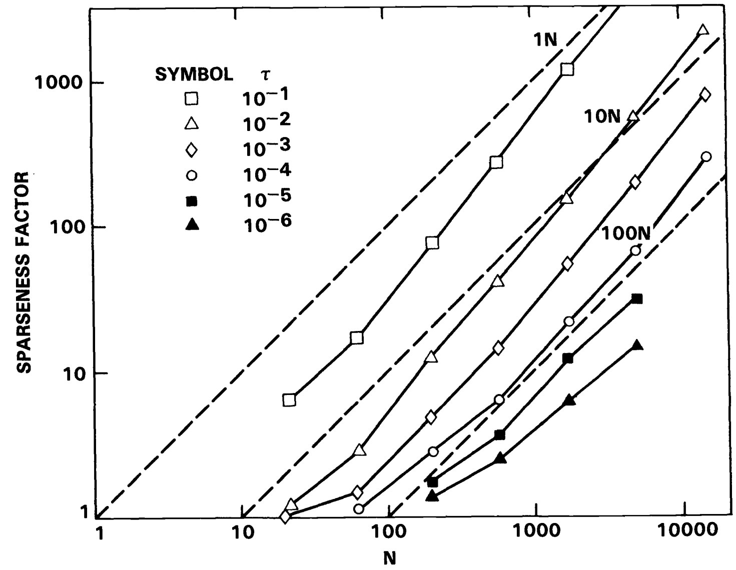

FIG. 4. *Sparseness factors for $m = [7N/3]^{0.5}$ from Fig. 3 are plotted as a function of N to illustrate how the storage required for a given value of τ scales with N. The dashed lines indicate a linear in N scaling of storage. The numerical results are steeper than these dashed curves, indicating the required storage is possibly even less than linear in N.*

When m from this equation would be some integer I times $\sqrt{3}$, the average of the sparseness factors for $m = I$ and $m = 3I$ is used. The dashed lines at 45 degrees on Fig. 4 indicate storage linear in N. The numerical results shown are asymptotically at least this steep, showing that for fixed τ, the storage required scales better than linear in N. Indeed, for $\tau = 10^{-4}$, the storage required is less than $100N$.

Since $\tau = 10^{-4}$ produces a sparse matrix, we now examine whether it produces accurate scattered fields. Fixing $N = 1701$, $m = 63$, and $L/\lambda = 90$, the cross-section for backward scattering of incident plane waves as a function of incidence angle is calculated and plotted in Fig. 5. Three curves are given, for $\tau = 0.0$, 0.0005, and 0.0001. The $\tau = 0.0001$ curve is nearly indistinguishable from the usual answer (i.e., for $\tau = 0.0$), while the $\tau = 0.0005$ curve is more than accurate enough for most practical applications. The condition numbers $\kappa[\mathbf{T}]$ for $m = 1$ and $m = 63$, respectively, were 2100 and 9400, while for $m = 63$, $\kappa[\mathbf{T}'(0.0001)]$ was 9700. Based on the condition number alone, we cannot say that $\tau = 0.0001$ will produce accurate scattering results. However, we have performed similar calculations for scatterers of several shapes and found accurate scattered fields in all cases examined. Note also that $\kappa[\mathbf{T}]/\kappa[\mathbf{Z}] < 5$, while the bound on this ratio is $\kappa^2[\mathbf{A}]$ which is over 100 (see Fig. 1).

4. Iterative results. In this section, first the results of standard iterative methods are given and then the possibility of preconditioning by incomplete LU (ILU) decomposition or one of its variants is discussed. The calculation of Fig. 5 will be used as an example, with a right-hand side given by a plane wave incident from $\theta = 0$. Using $\tau = 0.0001$ the iteration uses $\mathbf{T}'(0.0001)$. It was observed that $\mathbf{Z}$ is better conditioned than $\mathbf{T}$ for this problem, so it is likely that $\mathbf{A}^{-1}\mathbf{T}'(\tau)\mathbf{A}^{-*}$ would be a better matrix to use than $\mathbf{T}'(\tau)$. The factorization of $\mathbf{A}$ given by (14) into the product of matrices involving Fourier transforms and circulant matrices immediately shows how $\mathbf{A}^{-1}$ and $\mathbf{A}^{-*}$ may be applied in a sparse and efficient way. Although this approach is viable we will instead consider ILU preconditioning below.

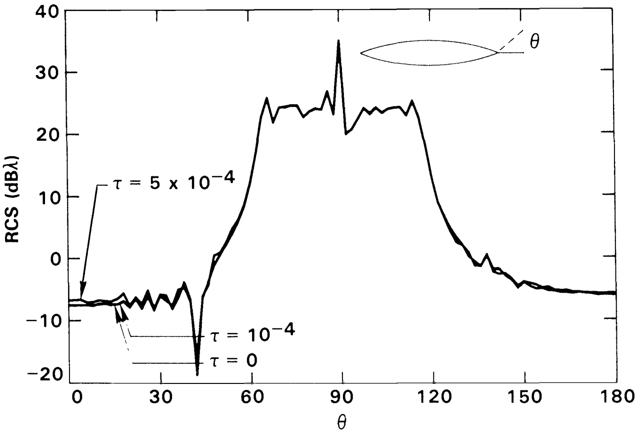

FIG. 5. *The backward scattering cross-section for the ogive with blade, as a function of the angle of incidence θ of an incident plane wave. The curves plotted for a standard calculation ($\tau = 0$) and for the approximation $\tau = 10^{-4}$ are indistinguishable, while the $\tau = 5 \times 10^{-4}$ curve differs only slightly. The two approximations that both used $m = 63$ gave sparseness factors of* 22 *and* 42, *respectively.*

The integral equation (37) is complex symmetric, and its eigenvalues all have a real part greater than or equal to zero [11]. When $\partial\Gamma$ encloses one or more regions, the interior Helmholtz problem(s) is known to have solutions at discrete values of k. Away from these values, the real part of the eigenvalues of the operator in (37) is positive. Since **Z** is fairly well conditioned, we might for the moment assume that it also has this property. The transformation to **T** given by (4) and the fact that **A** is nonsingular immediately imply that the eigenvalues of **T** would also lie in the right half plane. It is not completely clear if passing from **T** to **T**′(0.0001) would preserve this property, although the modest change in condition number between these two matrices is certainly encouraging. While this argument does not prove that the eigenvalues of **T**′(0.0001) lie in the right half plane, it certainly suggests trying an iterative method such as Orthomin.

The integral equation (37) and our symmetric discretization of it resulted in a complex symmetric **Z**. While that symmetry may be used to reduce the required storage for **Z**, the transformation (4) resulted in a nonsymmetric **T**. If the Hermitian conjugate indicated by * in (4) is replaced by simply a transpose, then the resulting matrix would still be complex symmetric. This complex symmetric form was used in [4], [7] and [8]. The two matrices (resulting from Hermitian conjugate and transpose) are simply related to each other by a permutation of columns, and they have the same condition numbers. However, as Fig. 6 shows, iteration using Orthomin [20] on these two matrices gives very different results. On the other hand, when using conjugate gradient on the normal equations the iteration matrix is **T*T** in one case and **PT*TP** in the other, where **P** gives the permutation of the columns of **T** mentioned above. These iteration matrices have identical eigenvalues, their eigenvectors are related by **P**, and each step of the iteration corresponds. The results of using (4) and conjugate gradient on the normal equations are shown on Fig. 6.

These iterative results show that an efficient solution has been demonstrated compared to other methods when one must solve for only one or a few right-hand sides. The sparseness of **T**′(0.0001) allows each iteration to be nearly 22 times quicker than it would be using **Z**. For example, on our Vax 6000 the matrix was generated in six minutes, and 300 iterations of conjugate gradient on the normal equations took an

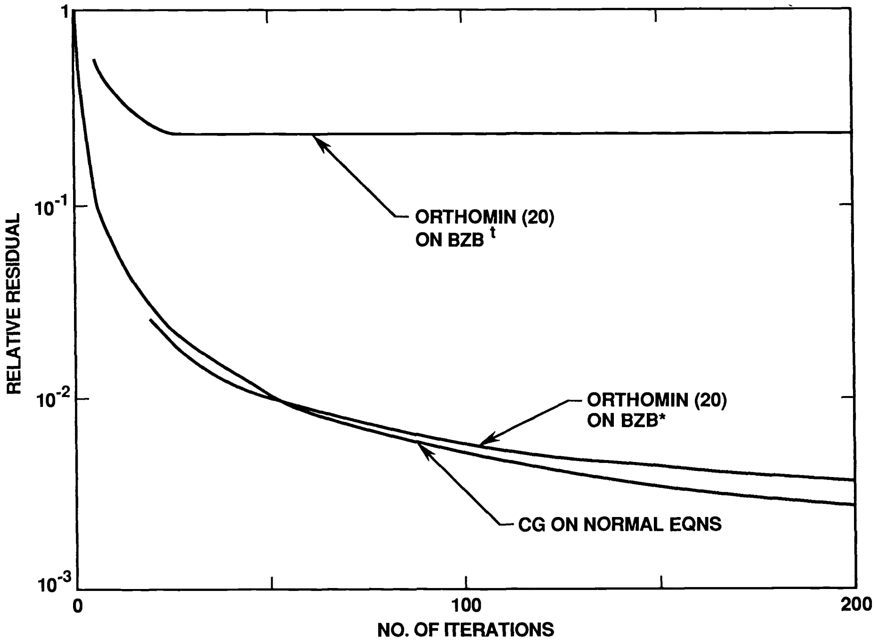

FIG. 6. *Reduction in residual as a function of the number of iterations for the ogive with blade of length* $L=90\lambda$ *using* $N=1701$. *Using the matrix* T′(0.0001) *the conjugate gradient applied to the normal equations and Orthomin* (20) *are used. Results also are shown using the corresponding matrix that results from replacing the Hermitian conjugate* (*indicated by* *) *in* (4) *and* (5) *by a transpose, and then using Orthomin* (20).

additional ten minutes. If enough memory had been available to store **Z**, then its full LU decomposition would have taken several hours. In contrast, the ILU decomposition of **T**′(0.0001) would take only two minutes.

ILU will be an effective preconditioner only if the large elements of **T** (or of a permutation of its rows and columns) tend to be near the diagonal. A discussion of the structure of the large elements of **T** is easier with an example to look at. A clear plot may be generated using $N=100$ and the scatterer given by a well-known airfoil shape, an NACA 0012 airfoil. A slight modification (to give a closed body) results in the shape defined by

$$(43)\qquad y=\pm 0.6\,[0.2969x^{1/2}-0.1281x-0.3516x^2+0.2843x^3-0.1015x^4].$$

T is calculated using $m=25$, $n=4$, and the **A** defined by (27)-(31), where this airfoil shape is scaled to have a chord length (tip to tail, in a straight line) of 5λ. Figure 7 gives a three-dimensional plot of the magnitudes of the elements of **T**. The block structure that appears is not very different from that found for this geometry using **A**′ to generate $\mathbf{A}'\mathbf{Z}\mathbf{A}'^{tr}$ as shown in [7, Fig. 5]. Unfortunately, in both cases the large elements in **T** occur successively further and further away from the diagonal. Fortunately, the spacing is somewhat regular, as we shall see below.

Column c of **T** may alternatively be identified as element a of block b, where $a=1,\cdots,m$, and $b=1,\cdots,n$. A permutation of the columns of **T** may be defined by relating the resulting column index c' to the old index c by

$$(44)\qquad c=a+(b-1)m,\qquad c'=b+(a-1)n.$$

In Fig. 7 large elements occur near the center of each block (i.e., for $a\approx(m+1)/2$ for $b=1,\cdots,n$) so we might expect that applying this permutation to both the rows and

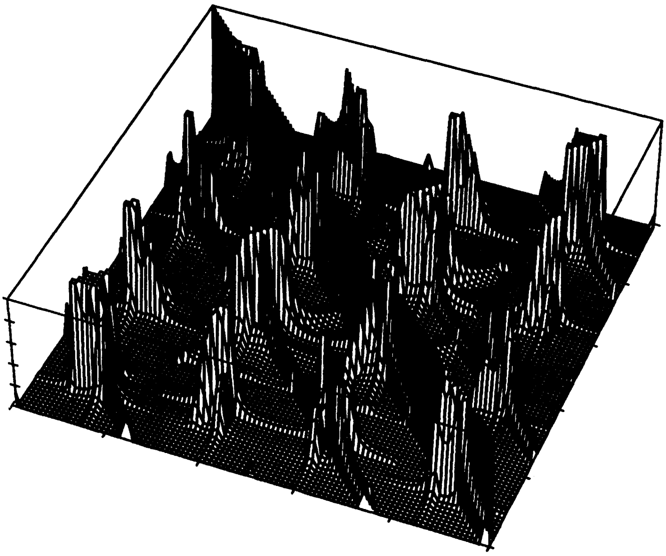

FIG. 7. *Three-dimensional plot of the magnitudes of the matrix elements for* **T** *using* (27)–(31) *for the modified* NACA 0012 *airfoil of* (43) *with a chord length of* 5λ. 100 *unknowns are used with* $m=25$ *and* $n=4$.

columns of **T** would group these large elements together. Figure 8 contains a three-dimensional plot of the permuted **T** and verifies that this is the case for all of these peaks. In addition, the large elements that had been on the diagonal are still on it since the permutation was done symmetrically. Although we do not yet have numerical results using ILU preconditioning, Fig. 8 strongly suggests that either it or a closely related method is likely to be highly effective.

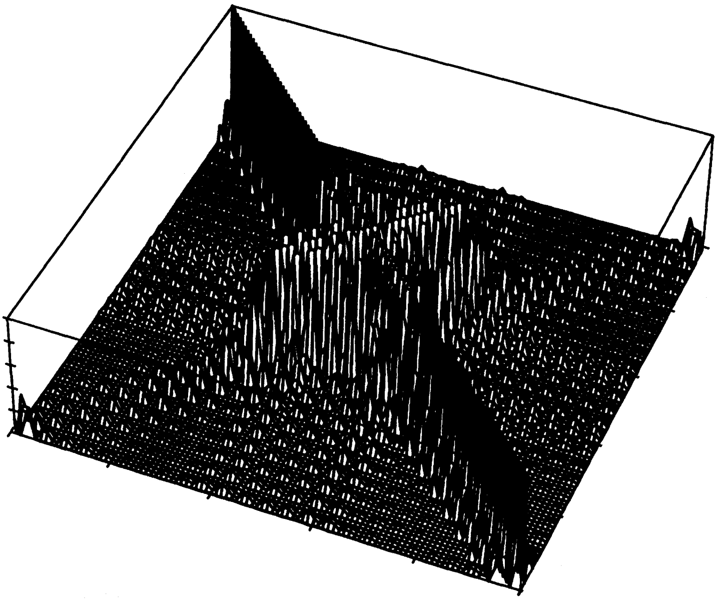

FIG. 8. *Three-dimensional plot of the magnitudes of the matrix elements of the permutation of the* **T** *of Fig.* 7 *as described by* (44) *and the associated text.*

The reason for the block structure in Fig. 7 and the size of the bandwidth in Fig. 8 are easy to find. The matrix $\mathbf{A}'$ contains $m \times m$ blocks of Fourier transforms and the mode with highest spatial frequency oscillates about $m/2$ times in m points (the spatial frequency in $\mathbf{A}$ is the same as that in $\mathbf{A}'$). If the discretization in $\mathbf{Z}$ used p points per wavelength of arc length, then m points correspond to a distance of m/p wavelengths. Thus, the rate of oscillation of this mode is $p/2$ times per wavelength, resulting in tangential propagation described by an effective wavenumber

$$k_t \approx (p/2)k. \tag{45}$$

The wavenumber describing the propagation of this mode perpendicular to the surface k_p satisfies

$$k_p = [k^2 - k_t^2]^{0.5} \approx k[1-(p/2)^2]^{0.5}. \tag{46}$$

Propagating modes require real k_p, so in these terms the sampling criterion of two points per wavelength (i.e., $p=2$) includes exactly the propagating modes. Since Figs. 7 and 8 used $p=10$, we would expect that only 2/10, or 20 percent, of the modes are propagating. That is, for $p=10$ and for "a" within a peak an approximation is

$$(m+1)/2 - 0.1m \leqq a \leqq (m+1)/2 + 0.1m. \tag{47}$$

The finite width of the "beams" causes some spillover from this region, which may be observed in Fig. 8.

Equation (47) has a remarkable consequence on the structure of the permutation of $\mathbf{T}$ and on our ability to solve it quickly. If N unknowns are used with p points per wavelength, then the permutation of $\mathbf{T}'(\tau)$ for some appropriate τ contains nonzero elements only in a central block of size $2N/p \times 2N/p$, or on or very near the diagonal. If this central block is treated as a full matrix, then the time for a direct solution would be nearly $(p/2)^3$ times faster than for the usual LU decomposition for large N. However, as N increases, the total number of elements in this block grows as N^2, while the number of nonzero elements is linear in N. Thus, for very large N, this block itself becomes sparse, and iterative methods preconditioned by ILU decomposition or related approaches are likely to be even more effective.

5. Conclusions. A class of transformations of the usual matrix formulations of integral equations involving oscillatory kernels was presented with the goal of generating a sparse $N \times N$ matrix from a full $N \times N$ matrix. In § 2 the basic properties of these transformations, such as their condition numbers, were calculated and the motivation for the transformations was developed. In § 3 the explanation of this transformation as one that generated a matrix whose elements each represented extended directional sources in a region interacting with similarly directional receiving elements was further developed. Numerical calculations based on an integral formulation of the Helmholtz equation in two dimensions showed that for a given smallness tolerance only a linear in N number of matrix elements need be kept after this transformation. This allows one to store profoundly larger physical problems with correspondingly larger numbers of unknowns in existing computers than has previously been possible. Sample calculations showed that the approximation of setting small elements of the transformed matrix $\mathbf{T}$ to zero allows good accuracy to be maintained. A permutation of the elements of $\mathbf{T}$ was introduced, which put it in a form allowing solution by banded matrix techniques orders of magnitude faster than by standard techniques. Some possible further increases in efficiency for very large N by the use of preconditioned iteration were also suggested.

The method described here should work for other integral equations where the fractional change in the magnitude of the kernel is small over one wavelength and the kernel's behavior is generally smooth. Such kernels may be described as oscillatory. The numerical results presented here were for a one-dimensional surface in two dimensions. Similarly, if the sources are spread over a two- or three-dimensional surface, the additionl integrals might serve to give further reductions in the magnitudes of the resulting matrix elements. Thus, there is reason to believe that this method will be useful for a variety of integral equations involving oscillatory kernels both in two and three dimensions.

The method described here reduces the storage requirements for a computer program based on an integral equation with oscillatory kernel with N unknowns from N^2 to Order $[N]$. The number of operations used to generate the matrix from the usual matrix is Order $[N^2 \log N]$. Directly generating this matrix can significantly reduce this operation count. The number of operations per iteration is similarly reduced from N^2 to Order $[N]$, allowing the most efficient method found to date storagewise, and also in terms of execution time, at least when a limited number of incident fields are considered.

A HIGHLY PARALLEL MULTIGRID-LIKE METHOD FOR THE SOLUTION OF THE EULER EQUATIONS*

RAY S. TUMINARO†

Abstract. A highly parallel multigrid-like method for the solution of the two-dimensional steady Euler equations is considered. The new method, introduced in [T. Chan and R. Tuminaro, in *Proc. Third Copper Mountain Conference on Multigrid Methods*, 1987, pp. 101-115] as a "filtering" multigrid, is similar to a standard multigrid scheme in that convergence on the finest grid is accelerated by iterations on coarser grids. In the filtering method, however, additional fine grid subproblems are processed concurrently with coarse grid computations to further accelerate convergence. These additional problems are obtained by splitting the residual into a smooth and an oscillatory component. The smooth component is then used to form a coarse grid problem (similar to standard multigrid) while the oscillatory component is used for a fine grid subproblem. The primary advantage in the filtering approach is that fewer iterations are required and that most of the additional work per iteration can be performed in parallel with the standard coarse grid computations.

In this paper, the filtering algorithm is generalized to a version suitable for nonlinear problems. It is emphasized that this generalization is conceptually straightforward and relatively easy to implement. In particular, no explicit linearization (e.g., formation of Jacobians) needs to be performed (similar to the FAS multigrid approach). The nonlinear version is illustrated by applying it to the Euler equations and presenting numerical results. Finally, a performance evaluation is made based on execution time models and convergence information obtained from numerical experiments.

1. Introduction. Multigrid methods are among the fastest algorithms for a wide variety of problems and are now used in many scientific disciplines. Structurally, the algorithm iterates on a hierarchy of consecutively coarser and coarser grids until convergence is reached. While critical to its rapid convergence, the coarse grid computations are more difficult to parallelize efficiently due to the presence of fewer grid points (and hence less parallelizable work). We therefore consider a highly parallel multigrid-like method (see [6], [7], and [8] for other types of highly parallel multigrid-like methods). This new algorithm, "filtering" (proposed in [4]), uses additional fine grid subproblems to accelerate the convergence of the overall process. More specifically, these fine grid problems are created by splitting the residual into a smooth and an oscillatory component. The smooth component is used to form a coarse grid problem (similar to standard multigrid) while the oscillatory component is used for the fine grid subproblem. The primary benefit to this approach is that while more work per iteration is necessary, fewer iterations are required and more of the work within an iteration is parallelizable. In fact, if the additional work can be performed concurrently with coarse grid computations, the CPU time per iteration need not rise significantly.

In this paper we generalize the filtering algorithm into a version suitable for nonlinear problems. This new algorithm is conceptually straightforward and relatively easy to implement. In particular, no explicit linearization (e.g., formation of Jacobians)

needs to be performed (similar to the FAS multigrid approach). We apply the nonlinear version to the solution of the Euler equations (see [4] and [11] for convergence analysis of the filtering algorithm for linear model problems). Specifically, we consider the filtering approach applied to the FLO52 algorithm. FLO52, written by Jameson [9], is a well-known multigrid code for the solution of the Euler equations describing transonic flow past an airfoil. The corresponding FLO52-filtering algorithm is similar to the ORIGINAL FLO52 with the exception of the additional subproblems. We begin our description of the algorithm with discussions of both the standard and filtering multigrid methods applied to linear problems in §§ 2 and 3. The generalization of both the standard multigrid and the filtering approach to nonlinear problems is then discussed in §§ 4 and 5. We conclude by comparing the convergence of the filtering and standard FLO52 algorithms on a fluid calculation. Based on these numerical experiments, as well as a mathematical execution time model, we make some predictions on the performance of the FLO52-filtering algorithm on massively parallel computers.

2. Standard multigrid algorithm. We begin our discussion with a brief sketch of the standard multigrid algorithm applied to linear elliptic partial differential equations (PDEs). More complete introductory material on multigrid methods can be found in [3] and [10].

Assume that a given elliptic partial differential equation is approximated by a discrete set of equations (finite differences or finite elements):

$$A_1 u = b, \tag{1}$$

where A_1 is a matrix, b is a vector, and u is a vector of unknowns for which we seek the solution. One iteration of a simple multigrid ("V" cycle) method consists of the following steps:

- relaxation iterations (e.g., Jacobi or SOR methods);
- formation of a correction equation for the error in the current approximation;
- projection of correction equation onto a coarser grid;
- "solution" of a coarse grid system;
- interpolation and addition of correction to previous approximation.

A key feature of this procedure is that the solution to the coarse grid equations can be approximated using the multigrid idea recursively. Thus the general algorithm consists of processing on a hierarchy of coarser grids (each processed in turn). We summarize this multigrid algorithm with a pseudocode fragment in Fig. 1.

For the most part, analysis of the two-level multigrid method reveals the general behavior of the multiple grid version. If we denote the projection operator by R_1, the

```
Proc Multigrid($A_i$, $b$, $u$, level)
{
    if (level = CoarsestLevel) then $u = A_i^{-1}b$
    else
        PreRelax($A_i$, $b$, $u$, level)
        ComputeResidual($b$, $u$, level, residual)
        ProjectResidual(level, residual, coarse_residual)
        Multigrid($A_{i+1}$, coarse_residual, v, level + 1)
        Interpolate(level, v, correction)
        $u = u +$ correction
    endif
}
```

FIG. 1. *Simple "V" cycle multigrid algorithm.*

interpolation operator by P_1, the relaxation iteration operator by G, and the coarse grid difference operator by A_2, we can express the two-grid iteration operator

$$e^{(k+1)} = Te^{(k)} \tag{2}$$

by

$$T = (A_1^{-1} - P_1 A_2^{-1} R_1) A_1 G, \tag{3}$$

where $e^{(k)}$ denotes the error after k iterations. In the next section, we will contrast this two-grid operator with that of the two-level filtering method.

3. Filtering algorithm. Conceptually, the filtering algorithm is similar to the standard multigrid method, the primary difference being that two correction equations are formed after the relaxation iterations. Specifically, let u_1 denote an approximate solution to the linear equation

$$A_1 u = b. \tag{4}$$

Within a standard multigrid method, a correction equation is usually formed by computing the residual $(r = b - A_1 u_1)$ and using this as the right-hand side to a new equation. Within the filtering algorithm, however, two subproblems are created by splitting the residual into the two components:

$$r_1 = Zr \quad \text{and} \quad r_2 = r - r_1, \tag{5}$$

which are then used as right-hand sides in

$$A_1 c^{(1)} = r_1 \quad \text{and} \quad A_1 c^{(2)} = r_2. \tag{6}$$

To approximate the solution of the first subproblem, the equation is projected onto a coarser grid, as within a standard multigrid method. The error associated with this approximation (solving the coarse problem exactly) is

$$e_1 = (A_1^{-1} - P_1 A_2^{-1} R_1) r_1, \tag{7}$$

where A_2 is the coarse grid operator. To approximate the solution of the second problem, q relaxation sweeps are performed on the fine grid. The error for this second approximation is given by

$$e_2 = S^q A_1^{-1} r_2, \tag{8}$$

where S is the iteration operator of the concurrent relaxation method, and we have assumed that the initial guess is zero. Thus the two-level algorithm generates one coarse grid correction (as in the standard multigrid method) and one additional fine grid problem to be processed by relaxation iterations. Once again, a multiple grid version of the method can be defined by recursively using the filtering procedure to "solve" the coarse grid subproblems. This multilevel version is summarized in Fig. 2, where the "FilterMultigrid ( )" and "ConcurrentRelax ( )" steps can occur in parallel.

```
Proc FilterMultigrid($A_i$, $b$, $u$, level)
  if (level = CoarsestLevel) then $u = A_i^{-1} b$;
  else
    PreRelax($b$, $u$, level);
    ComputeResidual($A_i$, $u$, $b$, level, res);
    SplitResidual(res, $r_1$, $r_2$);
    ProjRes($r_1$, $\hat{r}_1$);
    FilterMultigrid($A_{i+1}$, $\hat{r}_1$, $\hat{u}_1$, level + 1);
    ConcurrentRelax($A_i$, $r_2$, $u_2$, level + 1);
    Interpolate_and_add($\hat{u}_1$, $u_2$, level, $u$);
  endif
```

FIG. 2. *V cycle version of the filtering algorithm.*

Finally, an iteration operator for the two-level version of this algorithm is obtained by combining (7) and (8):

$$e^{(k+1)} = [(A_1^{-1} - P_1 A_2^{-1} R_1)Z + S^q A_1^{-1}(I - Z)]A_1 G e^{(k)}, \tag{9}$$

where we have included the possibility of performing one prerelaxation sweep with iteration operator G. That is,

$$r = A_1 G e^{(k)}. \tag{10}$$

Note that when the operator Z is the identity matrix, (9) is identical to (3).

Intuitively, the S^q term in (9) damps the high frequencies while the coarse grid correction damps the low frequencies. A critical element affecting the convergence behavior of the filtering algorithm is the properties of the splitting operator Z, used for computing r_1 and r_2. For the most part, this operator should decompose the residual so that high frequency errors remain on the fine grid while low frequency errors are projected onto the coarse grid subproblem. This can be accomplished by choosing an operator that filters out high frequencies in the residual. Many choices are possible. In this paper we consider only the operator

$$Z = P_1 R_1. \tag{11}$$

This corresponds to first projecting the residual onto the coarse grid and then interpolating back to the fine grid. See [4] for an alternative filter.

A detailed convergence analysis (via Fourier transform on the iteration operator) of a two-level filtering algorithm applied to the Poisson equation can be found in [4] and [11]. Using this analysis, it is possible to determine convergence rates for the filtering method. Table 1 lists the spectral radius of the two-grid iteration operator as a function of q when the algorithm is applied to the Poisson equation:

$$u_{xx} + u_{yy} = f. \tag{12}$$

The algorithm depicted uses full-weighted restriction, given by the stencil

$$\frac{1}{16}\begin{pmatrix} 1 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 1 \end{pmatrix}, \tag{13}$$

bilinear interpolation; one Jacobi prerelaxation sweep; q concurrent relaxation iterations of damped Jacobi with damping parameter equal to $\frac{4}{5}$; and the exact solution of the coarse grid equations. Finally, discretization is obtained via central differences on both the fine grid (32 × 32) and the coarse grid (16 × 16). We note that by comparison, the corresponding standard multigrid method using one damped Jacobi relaxation sweep (with optimal damping parameter) has a spectral radius of 0.570. Thus even with only one concurrent relaxation sweep, the convergence rate is accelerated.

4. FAS-multigrid method. To apply the multigrid method to a nonlinear problem, the simple scheme described in § 2 must be modified to implement the FAS algorithm. For the most part these modifications ensure that the correction equations correspond to physically meaningful subproblems. To describe the algorithm, we consider the nonlinear systems

$$A_k(u) = f_k, \tag{14}$$

arising from discretization of a partial differential equation on grid $\mathcal{G}_k$ (where $k = 0$ corresponds to the finest grid). We write one iteration of the relaxation scheme as

$$u_k \leftarrow Relax(u_k, f_k). \tag{15}$$

Once again, let R_k denote projection from grid k to grid $k+1$. Similarly, let P_k denote interpolation from grid k to grid $k-1$. Then the coarse grid subproblem is defined as follows. Let the initial guess on the coarse grid be given by

$$u_{k+1} \leftarrow R_k u_k. \tag{16}$$

On the finest grid, f_0 corresponds to the discretization of the continuous right-hand side. The right-hand sides on the coarser meshes are recursively defined by

$$f_{k+1} \leftarrow A_{k+1}(u_{k+1}) - R_k r_k, \tag{17}$$

where

$$r_k \leftarrow f_k - A_k(u_k). \tag{18}$$

Finally, after the solution on the coarse grid is improved (either by relaxation or recursively applying the multigrid procedure), the solution on the fine grid is corrected by

$$u_k \leftarrow u_k + P_{k+1}(u_{k+1} - R_k u_k). \tag{19}$$

Below we summarize a two-grid version of the algorithm using one relaxation sweep on each grid level:

$$\begin{aligned}
&u_0 \leftarrow Relax(u_0, f_0)\\
&u_1 \leftarrow R_0 u_0\\
&r_0 \leftarrow f_1 - A_1(u_1)\\
&f_1 \leftarrow A_1(u_1) - R_0 r_0\\
&u_1 \leftarrow Relax(u_1, f_1)\\
&u_0 \leftarrow u_0 + P_1(u_1 - R_0 u_0).
\end{aligned}$$

For more than two grids, the algorithm is recursively defined by replacing

$$u_1 \leftarrow Relax(u_1, f_1)$$

with

$$u_1 = \text{result of FAS algorithm starting on } \mathcal{G}_1.$$

Note that when this method is applied to a linear problem, it is mathematically identical to the method described in § 2. See [2] for more on the FAS procedure.

5. FAS-filtering algorithm. Similar to the FAS algorithm, the filtering algorithm must be modified so that all the subproblems are physically meaningful. To describe the method, we consider the discrete nonlinear systems defined by (14):

$$A_k(u) = f_k. \tag{20}$$

As with the FAS scheme, a coarse grid subproblem is created after relaxation on $\mathcal{G}_k$ by first computing the residual on that level. However, in the filtering version this residual is further split into two components and then the smooth component is used in forming the coarse grid subproblem. That is,

$$r_k = f_k - A_k(u_k), \quad \hat{r}_k = Zr_k, \quad \text{and} \quad \tilde{r}_k = r_k - \hat{r}_k. \tag{21}$$

The formation of the coarse grid subproblem proceeds in a simlar fashion to that of a standard FAS algorithm with the exception that $\hat{r}_k$ is used instead of r_k. That is, the initial guess on $\mathcal{G}_{k+1}$ is

$$u_{k+1} = R_k u_k, \tag{22}$$

and the right-hand side of the coarse grid equations are recursively defined by

$$f_{k+1} = A_{k+1}(u_{k+1}) - R_k \hat{r}_k. \tag{23}$$

In addition to the coarse grid subproblem, a fine grid problem is created

$$A_k(\tilde{u}_k) = \tilde{f}_k, \tag{24}$$

which can be processed concurrently with the coarse grid problem. The right-hand side of this fine grid subproblem is defined by

$$\tilde{f}_k = A_k(u_k) + \tilde{r}_k, \tag{25}$$

and the initial guess to this system is taken to be u_k. Similar to the filtering algorithm described in § 3, a relaxation scheme is used to improve the approximation to (24). Finally, after the approximations to the coarse grid and fine grid subproblems have been improved, the solution of the original problem is corrected by

$$u_k \leftarrow u_k + P_{k+1}(u_{k+1} - R_k u_k) + (\tilde{u}_k - u_k). \tag{26}$$

Below we summarize the two-grid version of the algorithm using one prerelaxation sweep, one concurrent relaxation sweep on the fine grid, and one relaxation sweep on the coarse grid:

```
              $u_0 \leftarrow Relax(u_0, f_0)$
              $r_0 \leftarrow f_0 - A_0(u_0)$
$\hat{r}_0 \leftarrow Zr_0$                          $\tilde{u}_0 \leftarrow u_0$
$u_1 \leftarrow R_0 u_0$                          $\tilde{r}_0 \leftarrow r_0 - \hat{r}_0$
$f_1 \leftarrow A_1(u_1) - R_0 \hat{r}_0$          $\tilde{f}_0 \leftarrow A_0(\tilde{u}_0) + \tilde{r}_0$
$u_1 \leftarrow Relax(u_1, f_1)$              $\tilde{u}_0 \leftarrow Relax(\tilde{u}_0, \tilde{f}_0)$
```

In the above pseudocode fragment, independent parts of the two subproblems appear in separate columns. A multilevel version of the above algorithm can be obtained by replacing

$$u_1 \leftarrow Relax(u_1, f_1)$$

with

$$u_1 = \text{result of FAS-filtering algorithm starting on } \mathcal{G}_1.$$

We can easily verify that when the operators A_i are linear, the FAS-filtering method is mathematically identical to that described in § 3.

It is important to realize the relative simplicity of modifying an FAS method to implement the FAS-filtering algorithm. One advantage is that no linearization is needed. Only the splitting operator and the concurrent relaxation operator must now be developed. For the concurrent relaxation we can use the same (or a similar) routine as for the prerelaxation. Additionally, no additional work is required to implement the splitting operator if

$$Z = P_k R_k$$

is used as these operators are already defined for the interpolation and restriction. In fact the only aspects of the filtering algorithm that requires nontrivial modification are the routines necessary for the allocation of subproblems to different processors.

6. FLO52 and the Euler equations. We consider both the FAS and the filtering schemes applied to the Euler equations. We begin by describing the Euler equations and the FLO52 code.

The FLO52 algorithm written by Jameson solves the two-dimensional steady Euler equations describing flow around an airfoil. It is widely used in research and industrial applications throughout the world. It produces good results for problems in its domain of application (steady inviscid flow around a two-dimensional body), and converges rapidly.

We briefly describe the Euler equations and the FLO52 scheme (see [9] for more on FLO52). We begin with the unsteady time-dependent two-dimensional equations written in conservation integral form as

$$\frac{d}{dt}\iint w + \oint \mathbf{n}\cdot\mathbf{F} = 0, \tag{27}$$

where **n** is the outward-pointing normal on the boundary of the region. The variable w is the vector of unknowns

$$w = (\rho, \rho u, \rho v, \rho E)^T, \tag{28}$$

where ρ is density, u and v are velocity components directed along the x and y-axes, respectively, and E is total energy per unit mass. The function **F** is given by

$$\mathbf{F}(w) \leftarrow (E(w), F(w)), \tag{29}$$

where

$$E(w) = (\rho u, \rho u^2 + p, \rho uv, \rho uH)^T,$$
$$F(w) = (\rho v, \rho uv, \rho v^2 + p, \rho vH)^T.$$

Here p is pressure and H is enthalpy. These are defined by

$$p = (\gamma - 1)\rho[E - (u^2 + v^2)/2],$$
$$H = E + p/\rho,$$

where γ is the ratio of specific heats. The integral relation given by (27) expresses conservation of mass, momentum, and energy which is to hold for any region in the flow domain.

To produce a numerical method based on (27), the flow domain is divided into quadrilaterals. On each quadrilateral of the domain, the double integral in (27) is approximated by the centroid rule and the line integral is approximated by the midpoint rule. For numerical stability, a dissipation term that is a blend of second- and fourth-order differences is added.

A simple iterative method (such as the Jacobi algorithm) for the steady-state problem can be viewed as a time-marching method for the time-dependent equations (27). After spatial discretization, the equations form a system of ordinary differential equations

$$\frac{dw}{dt}+A_1(w)=0, \tag{30}$$

where $A_1(\,)$ denotes the nonlinear finite-difference operator corresponding to differencing of spatial derivatives. Thus for the steady-state solution, we are interested in solving

$$A_1(w)=0. \tag{31}$$

The application of both the FAS-multigrid and -filtering algorithms to this problem is relatively straightforward. We conclude this section with a description of the relaxation method used within the algorithm. Specifically, it is a general multistage Runge-Kutta-like method. Such a procedure can be written in the form

$$\begin{aligned} &w^{(0)}=w_n,\\ &w^{(k)}=w^{(0)}-\Delta t\sum_{j=0}^{k-1}\alpha_{kj}A_i(w^{(j)}), \quad \text{for } k=1 \quad \text{to} \quad m,\\ &w_{n+1}=w^{(m)}, \end{aligned} \tag{32}$$

where Δt, the time step, and α_{kj} are chosen so that the multigrid procedure converges rapidly (and not necessarily to maintain time accuracy). In our experiments we always use $m=4$ for both the concurrent relaxation and the prerelaxation. The only nonzero parameters for the α_{kj}'s are given by $\alpha_{10}=\frac{1}{4}$, $\alpha_{21}=\frac{1}{3}$, $\alpha_{32}=\frac{1}{2}$, and $\alpha_{43}=1$.[1] Finally, we mention that a few other acceleration techniques are employed. These include local time-stepping and a residual smoothing technique (see [1] and [9] for more details).

7. Algorithmic choices and operation counts. To compare the performance of the filtering approach to the standard FAS multigrid, we modified the FLO52 algorithm to implement the procedure described in the previous section (denoted FLO52-filtering) on a serial machine. Using these codes, we compare the number of iterations required for convergence. Since the code was not implemented on a parallel machine, operation counts are made for both algorithms to compare the time per iteration. Additionally, the operation counts are used to determine the number of concurrent iterations that can be performed in parallel with the coarse grid correction. In this section, we describe the algorithmic choices and briefly discuss the corresponding floating point operation counts for each of the FLO52 algorithms.

The operators used in our experiments are the same as those typically used within the FLO52 code. Specifically, the Runge-Kutta relaxation scheme is used for prerelaxation and concurrent relaxation. Bilinear interpolation and full-weighted restriction are used to transfer values between grids. The coarse grid contains one-fourth as many points as the fine mesh. Coarse grid operators are defined using the same discretization scheme as on the fine grid. Finally, the operator Z, which splits the residual in the filtering algorithm, is given by

$$Z=(P_kR_k)^q, \tag{33}$$

where q is an algorithm parameter.

[1] We note that this choice corresponds to the standard Runge-Kutta scheme used in the FLO52 code, which is probably not the best choice for the FLO52-filtering procedure.

In estimating the time per iteration of both algorithms, we make a number of assumptions on the implementation and the architecture of the parallel machine. In particular, we assume that a hypercube multiprocessor is used and that each processor is assigned to one of the fine grid points using a binary reflected Gray code (see [5]). This implies that many processors are inactive when processing coarser meshes in the FLO52 procedure. In particular, each successively coarser grid contains one-fourth as many points as the previous grid. Thus the number of idle processors when computing on $\mathcal{G}_k$ is given by

$$P(1-(.25)^k), \tag{34}$$

where P is the total number of processors. For the FLO52-filtering algorithm, we assume that these inactive processors are used for the concurrent iterations. Specifically, the following sequence is proposed for a two-level FLO52-filtering algorithm.

(1) Prerelaxation is performed and the residual is computed using the full hypercube.

(2) The residual is split into two components using the full hypercube.

(3) The coarse grid right-hand side and initial guess are computed.

(4) The right-hand side corresponding to the fine grid subproblem is computed.

(5) The coarse grid right-hand side and initial guess are sent to a processor subcube ($\frac{1}{4}$ the size of the original hypercube) according to an algorithm of Chan and Saad (see [5]). At the same time, the right-hand side and initial guess for the fine grid subproblem are sent to a processor subcube ($\frac{1}{2}$ the size of the original hypercube).

(6) Initiate processing on both the coarse grid and fine grid subproblems.

(7) Fine grid processing terminates and the correction from this subproblem is added to the previous fine grid approximation.

(8) The coarse grid processing terminates and the correction is interpolated and added to the fine grid approximation.

The corresponding FAS method is identical except that steps 2, 4, and 7 are omitted and that no fine grid computations are necessary in steps 5 and 6. It should be noted that the communication necessary for initiating the subproblems on the subcubes is local in nature. Furthermore, contention between the subproblems on the communication network is avoided (since each is in a different subcube).

By way of example, Fig. 3 illustrates the different subproblems in a FLO52-filtering algorithm using five grid levels. In the figure, the darker boxes correspond to

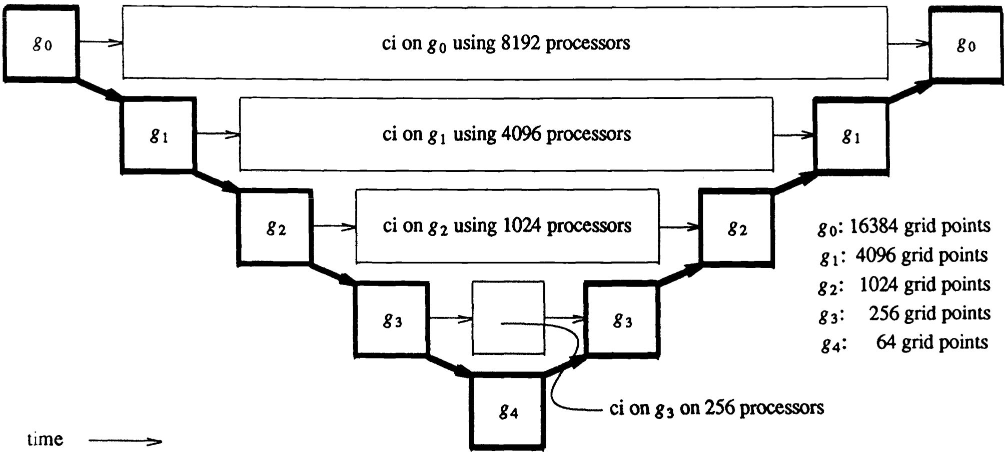

FIG. 3. *Illustration of the subproblems (and processor allocation) for a five-level filtering method.*

the standard multigrid "V" cycle. Within each box comprising the "V" cycle, the grid on which processing occurs is indicated. Each element of the first half of the "V" cycle (except for the coarsest grid) spawns a concurrent iteration problem. This is indicated by the lighter boxes, which are labeled "ci." Finally, we assume that for each element of the "V" cycle calculation, one grid point is assigned to each processor. The processors assigned to each concurrent relaxation subproblem are indicated on the figure.[2]

The operations per iteration of each algorithm are estimated using a timing model developed for an actual hypercube implementation of FLO52 (see [1]). In Table 2, we give the operation counts (not including communication operations) corresponding to a five-grid version of the two methods as a function of the number of prerelaxation sweeps μ and residual splitting cost q. Note that the filtering algorithm is only slightly more expensive. This additional cost is primarily due to the residual splitting computations. Of course, the numbers in Table 2 ignore communication. However, it can be argued that the additional cost of communication for both algorithms would scale in a similar fashion. That is, the amount of communication is proportional to the amount of computation.[3]

TABLE 2
A comparison of the maximum number of floating point operations performed by any processor as a function of prerelaxation sweeps μ and residual splitting costs q.

		FLO52-Filtering		
μ	FLO52	$q=1$	$q=2$	$q=3$
1	309	316	323	330
2	526	533	540	547
3	742	749	756	763

In addition to computing the time per iteration, we use the operation counts to determine the number of concurrent relaxation iterations that can be performed in parallel with the coarse grid correction. That is, the maximum number of concurrent relaxations that can be completed during the coarse grid correction is given by:

$$\begin{aligned}&\#\text{ concurrent iterations on } \mathcal{G}_k\\ &\quad= \text{floor}\left[\frac{\text{time for coarse grid correction for } \mathcal{G}_k}{\text{time for one fine grid relaxation on } \mathcal{G}_k}\right].\end{aligned} \tag{35}$$

In this way, we ensure that the concurrent iterations do not increase the overall time per iteration of the algorithm. In Table 3 we give the number of concurrent iterations that can be performed for each subproblem in Fig. 3 as a function of the number of prerelaxations used, μ.

8. Performance comparisons. A series of convergence experiments were run on a serial machine to evaluate the numerical properties of both the FLO52 and the FLO52-filtering code. For the most part, the relative performance of the two algorithms

[2] Note that for the concurrent iteration problem on grid $\mathcal{G}_0$, each processor contains two grid points. This is because there are not enough processors available to assign one processor for each grid point.

[3] This makes the assumption that the additional communication required for sending the fine grid information to a subcube can be overlapped with the communication necessary to set up the coarse grid correction.

TABLE 3
Number of concurrent iterations performed for each subproblem in Fig. 3 as a function of the number of Runge-Kutta prerelaxation sweeps, μ.

μ/grid	$\mathcal{G}_0$	$\mathcal{G}_1$	$\mathcal{G}_2$	$\mathcal{G}_3$
1	2	3	2	1
2	4	6	4	2
3	6	9	6	3

was fairly consistent for different grids and over a range of MACH numbers. In this paper we present results obtained from runs on a 256×64 grid. For these experiments an angle of attack of 1.25 degrees and a MACH number of 0.8 was chosen. As previously mentioned, a five-level multigrid scheme is used. The computation starts on the coarsest level, $\mathcal{G}_4$, using just relaxation until the norm of the residual is reduced below 10^{-2}. This solution is interpolated to $\mathcal{G}_3$ where a multigrid procedure is used to reduce the norm of the residual to 10^{-4}. The process is repeated for grids $\mathcal{G}_2$, $\mathcal{G}_1$, and $\mathcal{G}_0$, reducing the residual norm to 10^{-5}, 10^{-6}, and 10^{-9}, respectively.

Before proceeding with convergence results, we briefly comment on the serial run time of the filtering algorithm. In particular, we consider the FLO52 algorithm (using three prerelaxation iterations) and the FLO52-filtering algorithms (using two prerelaxation iterations, one concurrent iteration, and $q = 1$ for the residual splitting) on a serial machine. Since prerelaxation is more efficient than concurrent relaxation, it is not surprising to find that the FLO52 algorithm requires less time than the FLO52-filtering method (1568 seconds versus 1815 seconds). This inefficiency within the concurrent relaxation is a consequence of the fact that only the error associated with the fine grid suproblem is reduced (as opposed to prerelaxation, which reduces the entire error). Note that while the FLO52-filtering method is slower on serial machines, it is still competitive.

Of course the motivation for the filtering method is that more of the work is parallelizable. More specifically, we have argued that the cost per iteration of FLO52-filtering is not significantly greater than that of the corresponding FLO52 method when both are implemented on a massively parallel machine. Therefore, we can obtain a rough measure of the relative parallel performance of these two algorithms by comparing the number of iterations required for convergence. In Table 4, we present our results using different numbers of prerelaxation sweeps μ and splitting operators q.[4]

TABLE 4
Comparisons of multigrid iterations for the FLO52 *and* FLO52-*filtering algorithms where iterations correspond to the total (including one-, two-, and three-, four-, five-level multigrid iterations).*

		FLO52-Filtering	
μ	FLO52	$q = 1$	$q = 2$
2	90	78	64
3	53	44	39
4	48	35	33

[4] These results are representative of a number of different runs using different grid sizes, Mach number, and angle of attack.

As the table illustrates, the number of iterations required for the filtering algorithm is significantly less than the number of iterations for the standard method. Furthermore, the use of the more expensive filter, $q = 2$, yields somewhat better convergence results than the simpler filter. Additionally, it should be noted that the savings in using the filtering approach over the standard method is reduced when more prerelaxation is used: $\mu > 4$. This is to be expected, since the primary function of the new subproblems is to reduce high frequency errors in parallel with the coarse grid correction. However, when many prerelaxation sweeps are performed (before forming the new subproblem), the high frequency error is significantly reduced before the coarse grid correction begins.[5] Finally, we remark that it may be possible to boost the performance of the filtering method further by the use of more sophisticated operators. For example, the prerelaxation and concurrent relaxation operators use the identical Runge-Kutta coefficients that are used within the standard FLO52 scheme. These coefficients were specially chosen for the FLO52 method. Thus improvements may be possible if a new set of coefficients is chosen for the new method. Likewise, a more carefully chosen splitting operator Z may also yield significant improvements.

9. Conclusion. We have presented an FAS version of the filtering method. The principle idea is to use processors that could otherwise be idle in a standard multigrid method to perform relaxation iterations. These additional iterations are performed on subproblems that are created by splitting the residual into "smooth" and "oscillatory" components. The "smooth" component is used for the coarse grid correction, while the "oscillatory" component is used for the new subproblem. By using these otherwise idle processors, a filtering iteration need not cost significantly more than standard multigrid iterations. Additionally, we remark that the modifications necessary to implement a filtering algorithm from an FAS algorithm are relatively straightforward. This is primarily because no linearization of the operator is necessary.

We have applied the filtering approach to the FLO52 algorithm for solving the steady two-dimensional Euler equations. Based on numerical experimentation, it has been determined that this filtering method requires fewer iterations than the standard method, and consequently, it is an attractive alternative on parallel computers.

FAST PARALLEL ITERATIVE SOLUTION OF POISSON'S AND THE BIHARMONIC EQUATIONS ON IRREGULAR REGIONS*

A. MAYO† AND A. GREENBAUM‡

Abstract. In [*SIAM J. Numer. Anal.*, 21 (1984), pp. 285-299], a method was introduced for solving Poisson's or the biharmonic equation on an irregular region by making use of an integral equation formulation. Because fast solvers were used to extend the solution to an enclosing rectangle, this method avoided many of the standard problems associated with integral equations. The equations that arose were Fredholm integral equations of the second kind with bounded kernels. In this paper iterative methods are used to solve the dense nonsymmetric linear systems arising from the integral equations. Because the matrices are very well conditioned, conjugate gradient-like methods can be used and will converge very rapidly. The methods are very amenable to vectorization and parallelization, and parallel and vector implementations are described on shared memory multiprocessors. Numerical experiments are described and results presented for a three-dimensional interface problem for the Laplacian on a recording head geometry.

1. Introduction.

In this paper we present efficient parallel numerical methods for solving Poisson's and the biharmonic equations on general regions. Aside from being parallel, these methods also vectorize very well. This is in contrast to other methods for solving these equations on general irregular regions, notably finite element methods. Finite element methods may require use of a fast scatter/gather operation in order to efficiently perform a matrix-vector multiply for the large sparse matrix that arises. In addition, many of the standard preconditioners used in the iterative solution of such equations require inherently sequential operations (e.g., backsolving with the incomplete Cholesky decomposition [12]). This is especially true in the case of the biharmonic equation, and we know of no other effective parallel and vectorizable methods for solving it.

The methods presented here combine integral equation formulations of the problems with rapid finite difference methods on a larger rectangular region in which the irregular region is embedded. Both the integral equation method and the finite difference method parallelize and vectorize well. By using well-conditioned integral equation formulations and iterative methods for solving them, the main part of the computation is reduced to the iterative solution of a dense nonsymmetric matrix equation, instead of a (much larger) sparse (although symmetric) system of equations with an irregular pattern of nonzero elements.

The method used is very similar to the method developed in [10]. The main idea is to use the integral equation formulation to define a discontinuous extension of the solution to the remainder of the embedding region. All the discontinuities between the original function and its extension can be expressed in terms of the solution of the integral equation. These discontinuities are used to compute an approximation to the discrete Laplacian of the combined function at mesh points near the

original boundary. Fast Poisson solvers are then used to compute the extended function. This method can also be used to solve directly for the derivatives of the solution, which are usually the physically meaningful quantities.

This combination of integral equation formulations with finite difference methods on a larger rectangular region overcomes two of the standard problems usually associated with integral equation methods. First, because the solution is actually computed using a fast Poisson solver, it is not necessary to compute a costly integral in order to evaluate the solution at many points. Second, although the kernel of the integral is singular, and hence difficult to evaluate accurately by quadrature near the boundary, the solution can be computed very accurately using the fast Poisson solver. In addition, since the methods make use of integral equation formulations, they are very well suited to problems on exterior regions. A future aim is to use these methods for solving nonlinear magnetostatic problems in unbounded domains.

Work described in the current paper differs from that in [10] in several important respects. One difference is that we use a different integral equation formulation of the biharmonic equation, which has probably not been applied before in numerical computations. The other primary difference is the way in which the integral equations are solved. Conjugate gradient type iterative methods (i.e., the biconjugate gradient/conjugate gradient squared method [5], [18]; GMRES [16]; and the conjugate gradient method applied to the normal equations [6]), with simple diagonal preconditioners, are used to solve both Laplace's and the biharmonic equations. Since most of the operations in these methods consist of matrix-vector products, and since the matrices are dense, it is easy to see how the calculations can be performed in parallel and each of the parallel sections can be vectorized. The matrix can be divided into blocks, and each processor can handle multiplication by that block, while vectorization can be performed over the rows within the block. This can actually be accomplished using a level-2 Blas routine [4], and these routines have already been optimized on many parallel/vector supercomputers.

We also note that the integral equations used for solving both of these problems are well-conditioned Fredholm integral equations of the second kind, and so the matrices have eigenvalues and singular values that are bounded independent of the number of discretization points. Therefore we were able to achieve convergence in a small number of iterations. In particular, we were able to solve the biharmonic equation on general nonconvex regions, and, except on very eccentric ellipses, all of the iterative methods tested converged in fewer than 30 iterations. To solve the biharmonic equation on an ellipse with eccentricity 10 or 20, required no more than 32 GMRES iterations, provided enough direction vectors were saved.

In addition to using iterative methods to solve the integral equations, we also solved equations with different types of boundary conditions than before. Specifically, we solved a three-dimensional exterior interface problem in magnetostatics that arises from modeling a recording head, and a two-dimensional Dirichlet problem for Laplace's equation on a doubly connected region.

We note that fast Poisson solvers have also been used for solving Poisson's equation on irregular regions through the use of capacitance matrix methods [2], [14]. Our method is, however, better suited to problems on exterior regions. Although, by using a trick due to Hockney [7] and improved by James [8], it is possible to use capacitance matrix methods to solve exterior problems, both the operation count and the storage requirements for the fast solver are significantly increased. More important, capacitance matrix methods do not allow one to solve for derivatives directly. Moreover, we know of no implementation of a capacitance matrix method for solving the biharmonic equation on an irregular region or for solving interface problems.

The organization of the paper is as follows. Section 2 presents the integral equation formulations, and § 3 the method used for obtaining solutions to the differential equations, given the solutions of the integral equations. Section 4 describes results of numerical experiments carried out on the 8-processor New York University ultracomputer prototype, on the Cray X-MP and on the IBM 3090.

2. Integral equations.

2.1. Laplace's equation. Laplace's equation in two dimensions with Dirichlet boundary data $g(t)$ prescribed on the boundary curve $(x(s), y(s))$ is solved in terms of a double layer density function. In this formulation, the solution $u(z)$ is expressed as the integral over the boundary of the region of the product of an unknown density function μ with the normal derivative of the Green's function in the plane:

$$u(z)=\frac{1}{2\pi}\int_{\partial D}\frac{\partial \log r(s,z)}{\partial n_s}\mu(s)\,ds, \qquad z\in D, \tag{1}$$

where

$$r(s,z)=|s-z|.$$

If the region is simply connected, the density function μ satisfies

$$\mu(t)+\frac{1}{\pi}\int_{\partial D}\frac{\partial \log r(s,t)}{\partial n_s}\mu(s)\,ds=2g(t).$$

If the region is doubly connected, with boundary curves L_0 and L_1, then the boundary values can only be prescribed up to an additive constant. In this case $u(z)$ is the real part of a *single valued* analytic function, and the density function satisfies the following equation [13]:

$$\mu(t)+\frac{1}{\pi}\int_{\partial D}\left(\frac{\partial \log r(s,t)}{\partial n_s}+a(s,t)\right)\mu(s)\,ds=2g(t), \tag{2}$$

where

$$a(s,t)=\begin{cases}1 & \text{if } s \text{ and } t \text{ both lie on } L_1,\\ 0 & \text{otherwise.}\end{cases}$$

These are Fredholm integral equations of the second kind and, if the boundary ∂D is smooth enough, they can be solved very accurately numerically.

Outside D, (1) defines another harmonic function $\tilde{u}(z)$:

$$\tilde{u}(z)=\frac{1}{2\pi}\int_{\partial D}\frac{\partial \log r(s,z)}{\partial n_s}\mu(s)\,ds. \tag{3}$$

The function $\tilde{u}$ is, of course, a discontinuous extension of the function u. However, all the discontinuities between u and $\tilde{u}$ can be expressed in terms of the density μ and the boundary curve. In § 3 we show how to determine the discontinuities and how to use them to rapidly compute an approximation to the combined function $U(z)$, which is equal to $u(z)$ inside D, and $\tilde{u}(z)$ outside D.

We can also use (1) to express the conjugate function $v(z)$ to $u(z)$ in terms of the density μ. Since the conjugate harmonic function of $\partial \log r(s,z)/\partial n_s$ is $\partial \log r(s,z)/\partial s$, we have

$$v(z)=\frac{1}{2\pi}\int_{\partial D}\frac{\partial \log r(s,z)}{\partial s}\mu(s)\,ds. \tag{4}$$

2.2. Interface problems. A similar formulation can be used to solve certain interface problems. In linear magnetostatics, for example, the following problem arises. One seeks to find a function $u(z)$ defined on a magnetizable region D and on the infinite exterior region outside D such that

$$\nabla \cdot a\nabla u(z) = \phi(z),$$

where $\phi(z)$ is the given potential function for the applied field, a is the magnetic permeability of the region, and $u(z)$ is the unknown potential function for the H field (i.e., the function satisfying $\nabla u = -H$). In typical linear problems, a is equal to a large constant a_1 inside the magnetizable region D, and equal to a small constant a_0 in the exterior region. Continuity of the H field and the normal component of the B field imply that $u(z)$ and $au_n(z)$ are continuous across the boundary of D.

It turns out that both inside and outside D, the potential u can be expressed as the sum of a term involving the applied potential and the integral of a double layer density function, where the density is the value of the potential on the boundary:

$$(5) \qquad u(z) = \frac{\tilde{a}+1}{\tilde{a}} \int_{\partial D} \frac{\partial G(s,z)}{\partial n} u(s)\,ds + \frac{\phi(z)}{\tilde{a}}, \qquad z \in D$$

$$(6) \qquad u(z) = (\tilde{a}+1) \int_{\partial D} \frac{\partial G(s,z)}{\partial n} u(s)\,ds + \phi(z), \qquad z \in D^c,$$

where $\tilde{a} = a_1/a_0$ is the relative permeability. See [9]. On the boundary of the region, the potential $u(t)$ satisfies

$$(7) \qquad u(t) - \frac{\tilde{a}-1}{\tilde{a}+1} \int_{\partial D} \frac{\partial G(s,t)}{\partial n} u(s)\,ds = 2\phi(t).$$

In two dimensions, the kernel (Green's function) is $(1/2\pi)\log r(s,z)$, while in three dimensions it is $1/4\pi r(s,z)$. We have solved this integral equation in three dimensions, in which case the kernel, while in $L^2(\partial D)$, is unbounded.

2.3. The biharmonic equation. The integral equation formulation used for the biharmonic equation relies on the representation of a biharmonic function in terms of Goursat functions. Any two-dimensional biharmonic function $W(z)$ can be expressed as

$$(8) \qquad W(z) = \operatorname{Re}(\bar{z}\phi(z) + \chi(z)),$$

where $\phi(z)$ and $\chi(z)$ are analytic functions. The functions $\phi(z)$ and $\psi(z) = \chi'(z)$ are known as the Goursat functions. For a given biharmonic function $W(z)$, the Goursat functions are not uniquely determined. More precisely, $\phi'(z)$ is determined to within a purely imaginary additive constant, and so $\phi(z)$ is determined to within an additive term of the form

$$i\alpha z + \beta,$$

where α is real and β is complex. Similarly, $\psi(z)$ is not uniquely determined. However, all the *physically meaningful quantities*, such as velocities in fluid mechanics or stresses and displacements in elasticity can be expressed in terms of certain derivatives of the Goursat functions, which are uniquely determined. Therefore, it suffices to compute these two functions, and not the biharmonic function itself. Both of these functions can be expressed as Cauchy integrals:

$$(9) \qquad \phi(z) = \frac{1}{2\pi i} \int_{\partial D} \frac{\omega(s)}{s-z}\,ds, \qquad \psi(z) = \frac{1}{2\pi i} \int_{\partial D} \frac{\bar{\omega}(s) - \bar{s}\phi'(s)}{s-z}\,ds.$$

The integral equation one uses to determine the density function $\omega(t)$ depends on the boundary conditions. We have considered the case in which W_x and W_y (or, equivalently, W and W_n) are prescribed. In previous work [10], the following integral equation, originally developed by Sherman [17], was used:

$$\begin{aligned}\omega(t)+\frac{1}{\pi}\int_{\partial D}\omega(s)\,d\theta-\frac{1}{\pi}\int_{\partial D}\bar{\omega}(s)\,e^{2i\theta}\,d\theta\\ +\frac{b}{\pi i}\operatorname{Re}\left(\int_{\partial D}\frac{\omega(s)}{(s-c)^2}\,ds\right)=f(t),\end{aligned}\tag{10}$$

where

$$f(t)=W_x(t)+iW_y(t),$$

$$\theta(s,t)=\arctan\left(\frac{y(s)-y(t)}{x(s)-x(t)}\right),\qquad b=\frac{1}{t-c}-\frac{1}{(\bar{t}-\bar{c})^2}+\frac{t-c}{(\bar{t}-\bar{c})^2},$$

and c is any point inside the region D. It is important to note that the kernel of this equation is always bounded.

It is known [13] that if a function $\omega(t)$ satisfies this equation, then the third integral in the equation is zero, provided $f(t)$ satisfies the natural compatibility condition $\operatorname{Re}\left(\int_{\partial D}\bar{f}(t)\,dt\right)=0$. Thus (10) can be replaced by

$$\omega(t)+\frac{1}{\pi}\int_{\partial D}\omega(s)\,d\theta-\frac{1}{\pi}\int_{\partial D}\bar{\omega}(s)\,e^{2i\theta}\,d\theta=f(t).\tag{11}$$

We chose to solve this integral equation instead of (10), despite the fact that this equation need not have a unique solution. This is acceptable for the following reason. Any solution $\omega_0(t)$ of the homogeneous equation

$$\omega_0(t)+\frac{1}{\pi}\int_{\partial D}\omega_0(s)\,d\theta-\frac{1}{\pi}\int_{\partial D}\bar{\omega}_0(s)\,e^{2i\theta}\,d\theta=0$$

corresponds to the Goursat functions $\phi_0(z)=i\alpha z$ and $\psi_0(z)=0$, where α is real [13]. Since $\phi(z)$ is only determined up to terms of this form, and since the physically meaningful quantities are not changed by adding terms of this type to $\phi(z)$, any solution of the modified equation will provide a physically correct solution. Existence of multiple solutions is not a problem for the iterative methods we used, as will be explained in § 4. Furthermore, it is easy to show that whenever the kernel $\partial\theta/\partial s$ is symmetric, the kernel of (11) will be symmetric. This is true, for example, when the region is an ellipse. A symmetric kernel is an advantage, since in this case the minimum residual variant of the conjugate gradient algorithm can be used to solve the problem (and, in fact, the biconjugate gradient method and the (unrestarted) GMRES method reduce to the minimum residual conjugate gradient algorithm). Conjugacy of direction vectors is maintained without having to save vectors and explicitly orthogonalize. In addition, even when the kernel is not symmetric, we found that the kernel of (11) is closer to being normal than that of (10). Experimental evidence indicated that convergence was always more rapid with (11) than with (10), so it was decided to use this modified equation.

3. Solving the differential equations. After solving the integral equations of § 2 for the density function μ, we are then able to compute the solution $u(z)$, at points z within the region D, in the following manner. Discontinuous extensions of the solutions to the differential equations are defined throughout a larger embedding rectangular region. Specifically, (1) defines the extension of the solution of Laplace's equation, and (9) defines the extensions of the real and imaginary parts of the Goursat functions for the biharmonic equation. These functions are all harmonic, except at the boundary of the original region. Therefore, their discrete Laplacians are all zero, up to truncation error, except at mesh points near the boundary. We compute approximations to the discrete Laplacians at these points near the boundary and approximations to the extended function at the edge of the embedding region. Then we apply fast Poisson solvers to obtain approximate solutions to the differential equations, throughout the domain D.

3.1. Solution of Laplace's equation. The integral equation (1) can be used with the second-order accurate five-point discrete operator Δ_h^5 to compute a second-order accurate solution to $\Delta u = 0$ on an irregular region D with smooth boundary $\partial D = (x(s), y(s))$ on which smooth Dirichlet boundary data $u(s) = g(s)$ is prescribed. The procedure is as follows.

First embed D in some regular region R, such as a square with a uniform mesh of width h in the x and y directions. Define a discontinuous extension $\tilde{u}$ of u throughout the region R, using (3). As noted previously, all the jump discontinuities in the derivatives of u and $\tilde{u}$ can be expressed in terms of the density function and the derivatives of the boundary curve. Once the discontinuities in the derivatives of the combined function are known and the distances from the boundary curve to the neighboring mesh points are computed, it is easy to compute the discrete Laplacian of the combined function. Knowing an approximation to the discrete Laplacian throughout the regular region R, a fast Poisson solver can then be used to obtain an approximation to the solution u.

Define $U(z)$ to be combined function,

$$U(z) = \begin{cases} u(z) & z + D, \\ \tilde{u}(z) & z \in D^c. \end{cases}$$

The discontinuity between u and $\tilde{u}$ at a point on the boundary of D is equal to the value of the density at that point [13]. Therefore, the discontinuity between their tangential derivatives is equal to the derivative of the density,

$$u_s - \tilde{u}_s = \frac{d\mu}{ds}.$$

There is no discontinuity between their normal derivatives:

$$u_n = \tilde{u}_n.$$

Using these two facts and the direction of the curve, we can compute the discontinuities between u_x and $\tilde{u}_x$ and between u_y and $\tilde{u}_y$:

$$(12) \qquad u_x(s) - \tilde{u}_x(s) = \frac{\mu'(s)x'(s)}{x'(s)^2 + y'(s)^2}, \qquad u_y(s) - \tilde{u}_y(s) = \frac{\mu'(s)y'(s)}{x'(s)^2 + y'(s)^2}.$$

Discontinuities in higher-order derivatives of U can be obtained by differentiating these expressions.

In two dimensions it is also possible to compute these discontinuities by using the fact that $U(z)$ is the real part of a Cauchy integral with density function μ. Let

$$f(z) = \frac{1}{2\pi i} \int_{\partial D} \frac{\mu(\zeta)}{\zeta - z} \, d\zeta.$$

The kernel in (1) is the real part of the Cauchy kernel:

$$\operatorname{Re}\left(\frac{1}{2\pi i}\,\frac{d\zeta/ds}{\zeta-z}\,ds\right)=\frac{1}{2\pi}\,\frac{y'(s)[x(s)-x(t)]-x'(s)[y(s)-y(t)]}{(x(s)-x(t))^2+(y(s)-y(t))^2}\,ds$$
$$(13)\qquad =\frac{1}{2\pi}\,\frac{\partial \log r(s,z)}{\partial n_s}\,ds,$$

where

$$\zeta(s)=x(s)+iy(s), \qquad z(t)=x(t)+iy(t).$$

Therefore $u(z)=\operatorname{Re}(f(z))$ for z in D, and $\tilde{u}(z)=\operatorname{Re}(f(z))$ for z outside D. To find the discontinuities between u and $\tilde{u}$, we use the known discontinuities of Cauchy integrals across the boundary curve and the fact that Cauchy integrals are analytic functions. For details see [10].

These discontinuities are then used to compute approximations to the discrete Laplacian at mesh points near the boundary of D. Define the mesh function $U_{i,j}$ by

$$U_{i,j}=\begin{cases} u(x_i,y_j) & (x_i,y_j)\in D,\\ \tilde{u}(x_i,y_j) & (x_i,y_j)\in D^c.\end{cases}$$

An approximation to $\Delta_h^5 U_{i,j}$ at all mesh points of R can be computed as follows. At mesh points (i,j) of R, which have all four of their neighboring mesh points $(i+1,j)$, $(i-1,j)$, $(i,j+1)$, and $(i,j-1)$ on the same side of ∂D, set $\Delta_h^5 U_{i,j}=0$, since u and $\tilde{u}$ are harmonic. Consider the set B^+ of mesh points that have neighboring mesh points on both sides of ∂D. This set consists of two rings of mesh points, one inside and one outside D. Let p, for example, be a mesh point that is in D but whose neighbor to the right, p_E, is not. Let p^* be the point on ∂D on the line between p and p_E, let h_1 be the distance between p and p^*, and let $h_2=h-h_1$.

By manipulating the Taylor series at p and p_E, both evaluated at p^*, one can derive the following expression for $\tilde{u}(p_E)-u(p)$. (For details see [10].)

$$\begin{aligned}(14)\qquad \tilde{u}(p_E)-u(p)&=[\tilde{u}(p^*)-u(p^*)]+h_2[\tilde{u}_x(p^*)-u_x(p^*)]\\ &\quad+\tfrac{1}{2}h_2^2[\tilde{u}_{xx}(p^*)-u_{xx}(p^*)]+\tfrac{1}{6}h_2^3[\tilde{u}_{xxx}(p^*)-u_{xxx}(p^*)]\\ &\quad+\tfrac{1}{24}h_2^4[\tilde{u}_{xxxx}(p^*)-u_{xxxx}(p^*)]\\ &\quad+\tfrac{1}{120}h_2^5[\tilde{u}_{xxxxx}(p^*)-u_{xxxxx}(p^*)]\\ &\quad+hu_x(p)+\tfrac{1}{2}h^2u_{xx}(p)+\tfrac{1}{6}h^3u_{xxx}(p)+\tfrac{1}{24}h^4u_{xxxx}(p)\\ &\quad+\tfrac{1}{120}h^5u_{xxxxx}(p)+O(h^6).\end{aligned}$$

Note that the first six terms depend on the discontinuities between u and $\tilde{u}$ and their derivatives at the boundary. The other terms are the usual Taylor series terms. Therefore, once these discontinuities are known, the right-hand side of (14) is just the sum of known quantities and Taylor series terms.

Now let p_W be the point to the left of p. Then we have

$$\begin{aligned}U(p_W)-U(p)&=\{\text{known quantities}\}-hu_x(p)+\tfrac{1}{2}h^2u_{xx}(p)-\tfrac{1}{6}h^3u_{xxx}(p)\\ &\quad+\tfrac{1}{24}h^4u_{xxxx}(p)-\tfrac{1}{120}h^5u_{xxxxx}(p)+O(h^6),\end{aligned}$$

where the quantities in braces are zero if p_W is in D. In any case, we have

$$\begin{aligned}(15)\qquad U(p_W)+U(p_E)-2U(p)&=\{\text{known quantities}\}+h^2u_{xx}(p)\\ &\quad+\tfrac{1}{12}h^4u_{xxxx}(p)+O(h^6).\end{aligned}$$

If p_N is the point above p and p_S is the point below p, then by the same arguments we have

$$\begin{aligned}U(p_N)+U(p_S)-2U(p) &= \{\text{known quantities}\}+h^2u_{yy}(p)\\ &\quad +\tfrac{1}{12}h^4u_{yyyy}(p)+O(h^6).\end{aligned} \tag{16}$$

Let $g^+_{i,j}$ denote the sum of the quantities in braces in (15) and (16). Adding (15) and (16) and using the fact that $u_{xx}(p)+u_{yy}(p)=0$, we obtain

$$h^2\Delta^5_h U(p)=g^+_{i,j}+\frac{h^4}{12}[u_{xxxx}(p)+u_{yyyy}(p)]+O(h^6). \tag{17}$$

The same equation holds with u replaced by $\tilde{u}$ if p is a point outside D since $\tilde{u}$ is then harmonic at p. (It is important to notice that it is *not* assumed that either of the harmonic functions u or $\tilde{u}$ can be extended beyond ∂D. If, however, they could both be extended one mesh width, then the formulas we would obtain for the discrete Laplacian clearly agree with those we have derived.)

Therefore, if the integral equation can be solved accurately enough, one can obtain a fourth-order accurate approximation to $h^2\Delta^5_h U(p)$ at points of B^+. This guarantees the accuracy of the solution obtained after applying a fast solver. Define U^h_1 to be the solution of the following set of equations

$$\begin{aligned}(\Delta^5_h U^h_1)_{i,j} &= 0 & (x_i,y_j)&\in R-B^+\\ (\Delta^5_h U^h_1)_{i,j} &= g^+_{i,j} & (x_i,y_j)&\in B^+\\ (U^h_1)_{i,j} &= U_{i,j} & (x_i,y_j)&\in \partial R\end{aligned} \tag{18}$$

where the boundary values $U_{i,j}$ on ∂R are computed by evaluating the integral (3) using the computed density μ. In practice, we have used the trapezoid rule as the quadrature formula for two-dimensional problems.

If the values of $g^+_{i,j}$ and $U_{i,j}$ are sufficiently accurate, then U^h_1 will be a second-order accurate approximation to U. For a proof see [10]. By using a higher-order accurate approximation to the Laplacian and retaining more terms in the Taylor series, a higher-order accurate solution can be obtained.

3.1.1. Computation of the conjugate function. The conjugate of a harmonic function can also be computed at small additional cost. Using the Cauchy-Riemann equations, the discontinuities in the conjugate function v can be expressed in terms of the discontinuities in u. For example,

$$v_y-\tilde{v}_y=-(u_y-\tilde{u}_y)=\frac{\mu'(s)y'(s)}{x'(s)^2+y'(s)^2}.$$

These discontinuities could also be computed using the fact that v is the imaginary part of the same Cauchy integral that u determines:

$$v(z)=\text{Im}\left(\frac{1}{2\pi}\int_{\partial D}\frac{\mu(\zeta)}{\zeta-z}\,d\zeta\right)=\frac{1}{2\pi}\int_{\partial D}\frac{\partial \log r(s,z)}{\partial s}\mu(s)\,ds.$$

Knowing these discontinuities, we can, in the same way as before, compute an approximation to the discrete Laplacian of v, and then apply a fast Poisson solver to obtain an approximation to v.

3.1.2. Computation of derivatives. An important property of these methods is that one can easily compute the derivative of a harmonic function directly, without having to compute the function itself. This follows because all the derivatives of a harmonic function are themselves harmonic and because one can compute the discontinuities in all these derivatives.

3.2. Solution of interface problems. Since the integrals in (6) and (7) are also integrals of double layer density functions, the same method can be used to solve interface problems.

3.3 Solution of the biharmonic equation. As noted in § 2, the solution of the biharmonic equation can be reduced to the evaluation of two analytic functions that satisfy (9) and the prescribed boundary conditions. More precisely, the evaluation of the physically meaningful quantities reduces to the evaluation of the Goursat functions (8).

Both of the Goursat functions can be expressed as Cauchy integrals whose densities are given in terms of the solution of the integral equation (11). Therefore, it suffices to be able to evaluate a Cauchy integral $g(z)=\int_{\partial D}(f(t)/z-t)\,dt$ with prescribed density function $f(t)$. Suppose $f(t)=p(x,y)+iq(x,y)$. The integral $g(z)$ can be expressed in terms of certain integrals of double layer density functions and their conjugates:

$$g(z)=\frac{1}{2\pi i}\int_{\partial D}p(s)\left(\frac{\partial \log r}{\partial n_s}+i\frac{\partial \log r}{\partial s}\right)ds+\frac{1}{2\pi}\int_{\partial D}q(s)\left(\frac{\partial \log r}{\partial n_s}-i\frac{\partial \log r}{\partial s}\right)ds.$$

Therefore, the same methods can be used to evaluate the Goursat functions.

4. Numerical experiments. In this section we report on calculations we have performed. Parallel implementation of the method is discussed, and details are given on the performance of the iterative methods used for solving the integral equations. Accuracy of the method was discussed in detail in [10] and will not be repeated here.

The complete solution method consists of the following steps:

1. The irregular region D is embedded in a rectangle R with a uniform mesh, and distances from neighboring mesh points to the boundary are computed.

2. The boundary(ies) of the region D are discretized, and the integral operators are replaced by quadrature formulae. Since the kernels are bounded for the two-dimensional problems, we used the trapezoid rule, since it is extremely accurate on periodic regions. For the three-dimensional interface problem, a different procedure was used since the kernel is unbounded. We triangulated the surface of the region, which was flat. We assumed a continuous, piecewise linear density function and integrated the product of the kernel function with the piecewise linear basis functions exactly. Explicit quadrature formulae can be found in [9]. (These formulae require the surface to be flat.)

3. Having formed the dense, nonsymmetric matrix arising from the integral equation, the appropriate linear system is then solved for the density μ using an iterative method. Methods that we experimented with include the biconjugate gradient/conjugate gradient squared method [5], [18], GMRES [16], and the conjugate gradient method applied to the normal equations [6]. In each case, the diagonal of the matrix was used as a preconditioner.

4. Approximations to the discrete Laplacian are computed near the boundary ∂D, and approximations to the extended function are computed along the boundaries of R.

5. A fast Poisson solver is applied to obtain an approximate solution to the differential equation.

4.1. Test problems and performance of iterative methods. Although the matrices that arise from the integral equations of § 2 are dense and nonsymmetric, they are also well conditioned and, in most cases, have tightly clustered eigenvalues and singular values. For this reason, all of the nonsymmetric conjugate gradient-type iterative methods that we have tried have performed well. In each case, the diagonal of the matrix was used as the preconditioner. Results are presented primarily for the biconjugate gradient (BCG) method, but some of the problems were also solved using GMRES [16], conjugate gradients on the normal equations (CGNR) [6], and the conjugate gradient squared (CGS) method [18].

The effectiveness of these iterative methods for solving the double layer integral equation for Laplace's equation on simply connected regions is well documented. (See, for example, [11].) We have performed calculations on doubly connected regions and have found the results to be similar. In particular, we have tested the biconjugate gradient method on a region bounded by two nonconcentric ellipses. The outer ellipse had semiaxes .35 and .40, the inner ellipse had semiaxes .08 and .10, and the center of the inner ellipse was offset .14 from the center of the outer ellipse along the major axis. Starting with zero as an initial guess, we iterated until the relative size of the pseudo-residual was reduced below 10^{-6}:

$$\frac{\|M^{-1}r^k\|}{\|M^{-1}f\|}<10^{-6}.$$

Here M is the diagonal of the matrix, r^k is the residual at step k, and f is the right-hand side of the matrix equation. In all cases, the true residual, $f-Ax^k$ was computed, since, for some problems this may differ from the vector r^k generated by the biconjugate gradient algorithm.

Table 1 shows the number of iterations required to satisfy this convergence criterion, for different values of n, the number of boundary discretization points. Table 2 shows results for a slightly different region. Now the outer ellipse has semiaxes .35 and .15.

The biconjugate gradient method was also used to solve the three-dimensional integral equation (7) for an interface problem in magnetics. The region D, shown in Fig. 1, is shaped like a U-shaped recording head, with equal pole tips of width 5

meters, gap 1 meter, height 30 meters, and uniform depth 10 meters. The function $\phi(z)$ was the applied field due to an infinitely long straight wire with 100 amps of current, and the relative permeability was set to 1000. In one case we used 361 boundary elements and in another case we used 1086 elements. In both cases our initial guess for the potential at a point on the boundry was the value of the applied field at that point. The biconjugate gradient method required 28 iterations to achieve convergence for the smaller problem, 31 iterations for the larger problem.

What is perhaps more interesting is that good results were also obtained using iterative methods to solve the integral equation for the biharmonic equation. Table 3 shows the number of iterations required by various iterative methods to satisfy the convergence criterion on several different regions. We always placed 256 points on the boundary of the region, so the matrix was of order 512. The crescents mentioned in the table are nonconvex and are pictured in Fig. 2 and Fig. 3. They are given parametrically by

$$x(t) = \cos t + .15 \sin^2 t, \qquad y(t) = .5 \sin t + d \cos^2 t.$$

In crescent 1, $d = .4$, and in crescent 2, $d = .7$.

Most of the numbers in the table were obtained by taking the right-hand side of the equation to correspond to the biharmonic function $W(x, y) = x^2 + y^2 + x$, and using

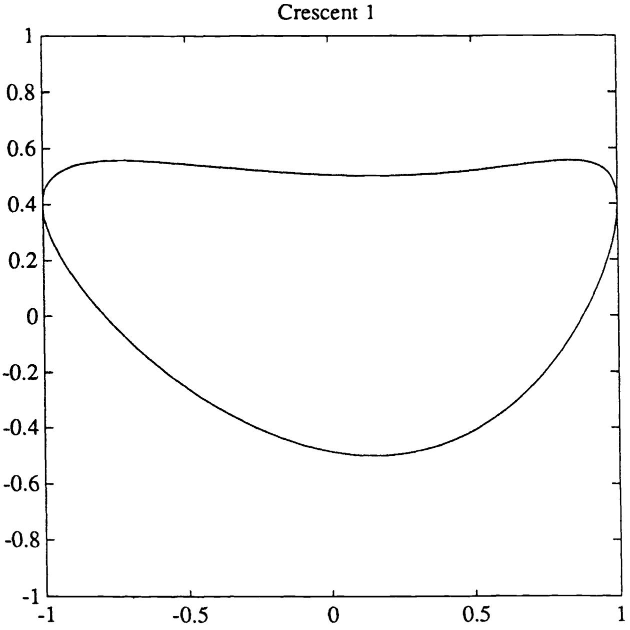

FIG. 2

a *random* initial guess. In practice, however, it is usually advantageous to use a smooth initial guess, such as zero or the right-hand side, since the true solution will be similarly smooth. To determine whether a reasonably chosen initial guess could significantly reduce the number of iterations, we solved the biharmonic problem for several more complicated right-hand sides, using a zero initial guess. The results did not differ significantly from those obtained previously, except on the highly eccentric ellipses. The numbers in parentheses in Table 3 are iteration counts using an initial guess of zero, when the biharmonic function $W(z)$ is given by

$$W(z) = \text{Re}\,(\bar{z}\phi(z) + \chi(z)), \quad \text{where}$$

$$\phi(z) = \sum_{k=0}^{5} (-1)^k \frac{z^k}{k+1} + e^z, \qquad \chi(z) = \sum_{k=0}^{5} \frac{z^k}{k+1} - 2e^z.$$

We believe that these convergence rates may be more realistic than those obtained with a random initial guess, for most applications.

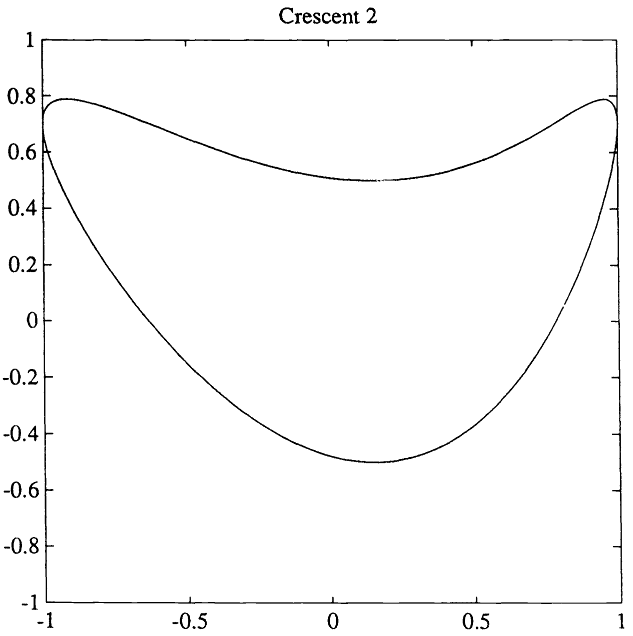

FIG. 3

Note that the most difficult problems for the iterative methods (with either initial guess) were those defined on highly eccentric ellipses. For problems 3 and 4, the GMRES method converged in 32 iterations (for the random initial guess), provided all direction vectors were saved (GMRES (40)), but required significantly more iterations when only five direction vectors were saved (GMRES (5)). Similarly, the other iterative methods were slower to converge on these regions.

It should be noted that some of these iterative methods require more work per iteration than others. Since the bulk of the work at each iteration is in applying the dense matrix to a vector, the BCG, CGS, and CGNR methods require almost twice as much work per iteration as the GMRES method, even when 40 direction vectors are saved and orthogonalized against at each step. (This is because the matrix is dense and so a standard matrix-vector multiply requires n^2 operations, compared to about $40n$ for orthogonalizing. In future work, it is planned to replace this standard matrix-vector multiply routine by an $O(n)$ method [3]. Still, the matrix-vector multiply will require significantly more than $40n$ operations, so the comparison of operation counts per iteration for the various iterative methods probably will not change.) Thus, to compare the methods according to total work performed, the iteration counts for BCG, CGS, and CGNR should be multiplied by two and compared with that of GMRES (5) and GMRES (40). It can then be seen that the GMRES (40) method is the most efficient, with CGS or GMRES (5) second. In addition, it may be necessary to compute the residual directly (as we have done) at each step of the CGS algorithm, since the vector r^k computed by updating may not resemble the true residual. If this is done, then the number of matrix-vector multiplies per CGS iteration is three instead of two, and the GMRES methods look even better in comparison. Of course, GMRES (40) requires almost 40 vectors more in storage than these other methods, and it is difficult to predict just how many vectors will be needed in order to obtain rapid convergence with GMRES. The least efficient iterative method for these problems is CGNR.

To understand why the iteration counts are as described, we computed the eigenvalues and singular values for these problems. The 512 singular values for each region are plotted in decreasing order of magnitude in Fig. 4. The eigenvalues were very close to the singular values (almost indistinguishable on graphs such as Fig. 4) and had tiny imaginary parts and nonnegative real parts. This tends to be an advantage for the GMRES method over, say, CGNR, because the convergence rate of GMRES is governed by the eigenvalues while that of CGNR is determined by the *squared* singular values. We note that in all cases, the eigenvalues and singular values cluster around 1. For the eccentric ellipses, more eigenvalues and singular values appear near the ends of the spectrum, causing some difficulty for the iterative methods. The ratio of the largest to the second smallest singular value for each of the six regions is 2.0, 5.2, 265, 2031, 8.5, and 22.3, respectively.

The presence of a zero singular value does not adversely affect the convergence rate of the iterative methods. The reason for this is as follows. For each of these

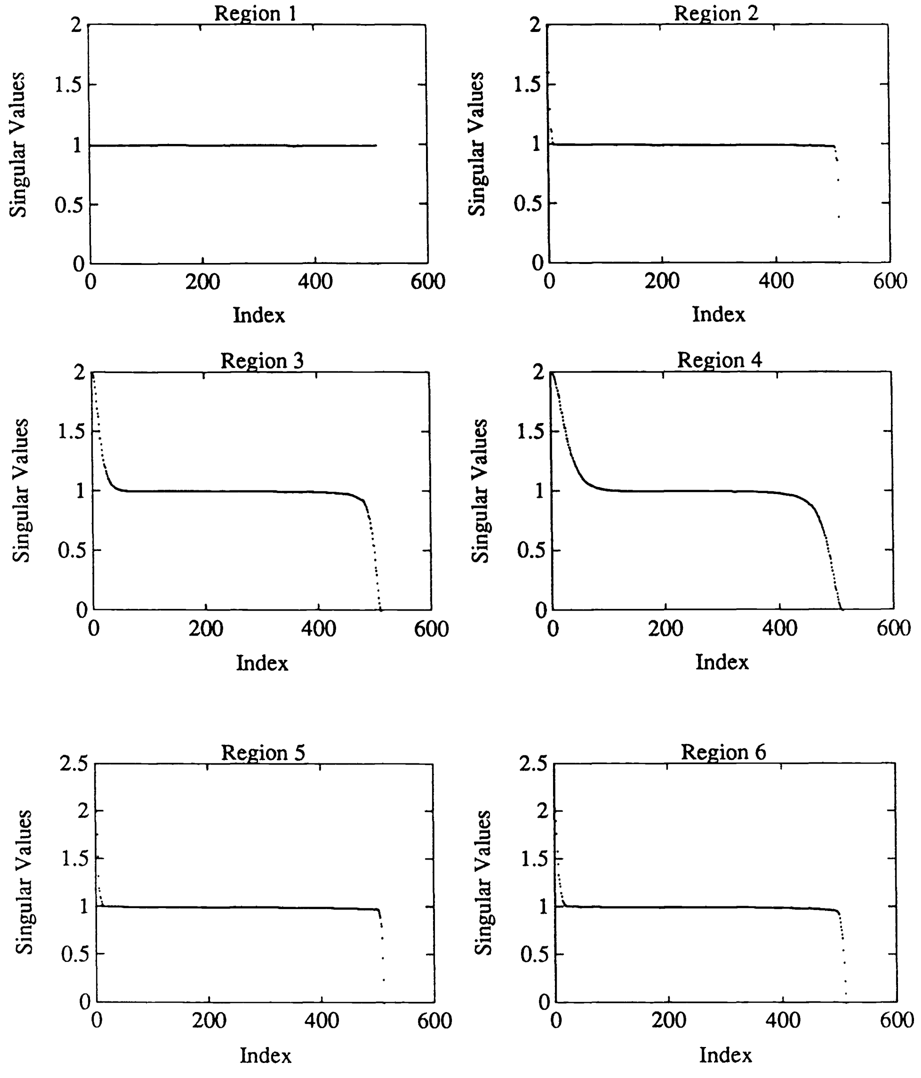

FIG. 4

iterative methods, the residual r^k satisfies

$$r^k = P_k(B)r^0,$$

where P_k is a kth or $2k$th for (CGS) degree polynomial with value one at the origin and $B = A$ for the GMRES, BCG, and CGS methods (actually, $M^{-1}A$, where M is the diagonal of A), $B = AA^T$ for CG on the normal equations. Assuming B has a complete set of eigenvectors V (which it does for each of these problems), we can write $B = V\Lambda V^{-1}$ and

$$V^{-1}r^k = P_k(\Lambda)V^{-1}r^0. \tag{19}$$

Now suppose some eigenvalue λ_i is zero. Since the equations are consistent, the ith component of V^{-1} times the right-hand side f of the equation $Bx = f$ must also be zero; for we have

$$\lambda_i(V^{-1}x)_i = (V^{-1}f)_i.$$

It also follows that the ith component of V^{-1} times the initial residual $r^0 = f - Bx^0$ is zero:

$$(V^{-1}r^0)_i = (V^{-1}f)_i - \lambda_i(V^{-1}x^0)_i.$$

It then follows from (19) that the ith component of $V^{-1}r^k$ is zero for all steps k, and it is easy to check that the coefficients computed by each of these iterative methods are the same as those that would be computed if this zero eigenvalue were not present. Thus, these methods converge to *a* solution of the singular linear system at the same rate as they would converge to *the* solution of a nonsingular linear system having only the nonzero eigenvalues.

Table 4 shows the number of iterations needed to satisfy the same convergence criterion, when we discretized (10) instead of (11). Note that the number of iterations required was significantly greater for each of the iterative methods. The GMRES (5) method failed on the crescent problems, stagnating (ceasing to reduce the error) well before it reached the desired level of accuracy.

4.2. Parallel and vector implementation of the method. The major part of the work at each iteration of the biconjugate gradient algorithm is in multiplying the matrix and its transpose by an arbitrary vector. This operation is easily vectorized and/or parallelized, as are the other operations (dot products, saxpy's, etc.) required for an iteration. On a machine with both vector and parallel capabilities, different blocks of the matrix can be assigned to different processors and vectorization can be performed over the rows within each block. This can actually be accomplished using a level-2 Blas routine

[4], and these routines have already been optimized on many parallel/vector supercomputers. Another significant part of the work is in applying the fast Poisson solver after the integral equations have been solved. This is also easily parallelized, with different processors computing FFTs simultaneously, while the individual FFTs may be vectorized.

We implemented the entire algorithm for computing a harmonic function, its conjugate, and its first derivatives on an 8-processor shared memory MIMD machine—the NYU Ultracomputer prototype—and obtained good speedup over the serial code. The region was the first doubly connected region bounded by two ellipses described above. We again placed 200 points on the boundary and used a 33 by 33 rectangular mesh on the rectangle in which the region was embedded.

In this case the biconjugate gradient routine accounted for about 40 per cent of the time required by the serial code. To obtain good speedup of the entire code, it was also necessary to parallelize the other sections of the code—generating the matrix, computing the Laplacian at irregular mesh points, and applying the fast Poisson solver. These sections were also easily parallelized, and the use of a parallel DO loop facility, called DOALL, on the ultracomputer allowed efficient parallelization of the entire code with only minor modifications to the original serial code. DOALL prespawns tasks and assigns loop indices to processors dynamically [1]. Different elements of the matrix were generated in parallel and the Laplacian was computed at irregular mesh points in parallel. The two-dimensional fast Poisson solver consists of one-dimensional FFTs, which were also executed in parallel.

Figure 5 shows the time and speedup on one to eight processors for the above problem. Using eight processors, an overall speedup of about a factor of 6 was obtained, with the biconjugate gradient routine obtaining about a factor of 7 speedup over its time on one processor. The time for the parallel code run on one processor was about 5 percent slower than the time for the serial code. A factor of seven speedup on the ultracomputer appears to be near the best attainable, due to bus traffic.

On the Cray X-MP, we measured the difference between the time required for the matrix generation only, when vectorized and unvectorized. For this section of the code, vectorization resulted in a factor of 9 speedup, and its effect on the other sections appears to be similar.

Acknowledgment. The authors thank the referees for many helpful comments.

COMPACT MULTIGRID*

VICTOR PAN† AND JOHN REIF‡

Abstract. The bit-complexity is a realistic complexity measure for computations on parallel computers such as the CONNECTION MACHINE (CM1) and the MASPAR. For a large class of linear PDEs satisfying some routine assumptions of the multigrid methods, the N point discretization of their solution is compressed to a constant number of bits per discretization point with no loss of information and without introducing errors beyond the order of the discretization error. Namely, it is shown that the bit-complexity of the compressed solution is $O(N)$ for the storage space and, if the PDE has (piecewise) constant coefficients, then also for the total number of bit-parallel operations. The compressed solution is also computed by using time $O(\log N)$ and $N/\log N$ bit-serial processors. The known bounds on the bit-complexity (for both sequential time and storage space) were at least $N \log N$; moreover, the order of $N \log N$ bit-serial processors was required to support the $O(\log N)$ parallel time in the known algorithms. It is believed that this is the first time when the solution to a linear system has been provably compressed (i.e., the bit-complexity of storage of the compressed solution is less than the solution size) and also the first case where the use of data compression provably speeds up the time to solve the system (in the compressed form).

1. Introduction.

1.1. Motivation and limitations.

Approximate solution of partial differential equations (PDEs) is usually obtained by means of their discrete approximation and by solving a sparse linear algebraic system of equations. Of course, the amount of the discretization affects the accuracy of the approximation. If N discrete approximation points have been chosen over a regular (two- or three-dimensional) grid, then for a very large and important class of linear PDEs, which we will call *weakly smooth*, the solution to the linear algebraic systems approximates to the solution of the PDE with an error of the order of N^{-g}, for some constant $g > 0$. Such discretization errors have been well studied by numerical analysts from the 1920s [CFL], [BR], [BS], [FW], [SF].

Thus the approximation gives us, at each discretization point, the first $O(\log N)$ bits of the actual value of the solution to the PDE, and the high accuracy solution of two- and three-dimensional PDEs requires in particular that the number of discretization points N grows very large. The computation is often more limited by the storage constraints than by the time constraints (particularly if it is desired to store the solution in the primary storage memory without the use of the much slower secondary storage of the conventional machines). It is therefore important to investigate methods that substantially reduce this storage by compressing the data in the solution. As we will see, this is indeed possible in some important cases and is a surprisingly fundamental

property of PDEs, which will also lead us to a substantial economization of bit-operations and (in parallel implementation) of bit-serial or nibble-serial processors involved. In this paper we will demonstrate the power of our new techniques in the simplest cases, that is, under the limitations of the linearity of a PDE and of the choice of simple lattice grids for its discretization; furthermore, to save bit-operations and bit-processors, we will assume that the PDE has piecewise constant coefficients and reduces to linear systems that we may solve by using linearly convergent iterations. Moreover, our present paper addresses special purpose hardware, rather than most of the existing computers. We believe that all these limitations will be at least partially relaxed in our further work, and substantial progress will be reported in our next publication.

1.2. The bit-complexity model. Certain sequential machines (such as the CRAY) were specifically designed to solve these large linear systems: their processor has the ability to do sequential arithmetic operations very quickly and also has a relatively large amount of primary storage. For such a machine, the arithmetic complexity model has generally been considered appropriate. However, a machine such as the CRAY is capable of performing a bit-vector operation in one parallel step (for example, it may perform AND, OR, or NOT operations on hundreds of bits), so that the parallel bit-complexity of such machines can also be of interest.

On the other hand, fine grained massively parallel machines (such as the MASPAR and the CONNECTION MACHINE, CM1) have been designed with large numbers of bit-serial or nibble-serial (4-bit-serial) processors (requiring a relatively long time to execute an arithmetic operation) and with a very limited memory, which is generally accessed bit- (or 4-bit-) serially. A complexity model for parallel algorithms must take into account both the bit-serial nature of the processors and the limited memory constraints; in particular, we feel that the parallel complexity of computing on such machines is most reasonably measured by the bit-complexity. In this model, we assume that each memory cell holds only one bit, and each processor can do a single bit-operation per step.

1.3. Previous solutions of PDEs. The solution of the linear algebraic systems approximating PDEs can be computed by means of a number of well-known and now classical algorithms. For example, for a large class of PDEs, we may apply the standard linearly convergent iterative solution algorithms, such as Gauss and Siedel's, and find the solutions to the auxiliary linear systems up to the maximum accuracy of $O(\log N)$ bits at N points in $O(\log N)$ iterations, using N processors. However, each such iteration generally involves arithmetic operations over the $O(\log N)$-bit numbers and hence requires at least $O(\log N)$ bit-operations per point. Thus the total work is $O(N \log N)$ arithmetic operations or $O(N \log N)$ bit-operations.

Various multigrid methods were first proposed by Fedorenko and Bakhvalov in the 1960s, and then by Astrakhantzev and Brandt in the early 1970s for the solution of these linear systems approximating PDEs (see [Ast], [Bak], [Fed], and [Bran2, 3, 4]). In [Bran2], it was claimed that these multigrid methods required only $O(N)$ arithmetic operations; this was rigorously proved for a large class of PDEs in [BD] (also see [Hack1, 2, 3], [HT], [McCor2], and [McT]). (Actually, the multigrid methods are effective even in many cases where the classical iterative algorithms converge too slowly.) The works of [Bran1], [FMc], [CSS], and [McV1, 2] all describe parallel algorithms that take $O(\log N)$ arithmetic steps using N processors, and thus use the order of $N \log N$ arithmetic operations, which is off by the factor of $\log N$ from the optimum. Even if the order of s bit-operations sufficed to add and to multiply two integers modulo 2^s, which is actually a lower estimate, whereas the current record upper bound is only $O(s \log s \log \log s)$ [AHU], it would follow that the known multigrid methods require a total of at least the order of $N \log N$ bit-operations, and at least the order of $N \log N$ bit-serial processors to support the order of $\log N$ time. The bit-operation bound appears to be unbeatable since the binary representation of the solution occupies a total of the order of $N \log N$ bits.

1.4. Our results. Our main goal is a rigorous study of the bit-complexity of these linear algebraic systems approximating linear PDEs. In spite of the lack of theoretical investigation into this area, we feel that the problems are fundamental in nature. In this paper we will show some surprising properties of the linear algebraic systems approximating to linear PDEs under some mild assumptions specified below and in § 2:

(1) The *weakly smooth* solutions to PDEs can be significantly compressed to $O(1)$ bits per solution point (which, by the factor of $\log N$, improves the previous storage requirements), by using a data structure that we call the *Compact Multigrid Data Structure.* (We do not know of any previous provable results for data compression of the solutions to any class of linear systems.)

(2) For a large class of linear PDEs with constant coefficients, their compressed solutions can be very efficiently computed (both sequentially and in parallel) by an algorithm that we also call *Compact Multigrid* and that only uses $O(\log N)$ time, $N/\log N$ bit-serial processors, and a total of $O(N)$ bit-operations, which is optimum since the size of the compressed solution is of the order of N. This improves by the factor of $\log N$ the bounds on both sequential time and storage space of the known algorithms and decreases by the factor of $\log^2 N$ the number of bit-serial processors supporting $O(\log N)$ time.

Note that already the $\log N$ factor is significant for even relatively small problems; for example, this factor is 10 or more for problems of size $N > 1000$, such as the three-dimensional grid of size $10 \times 10 \times 10$.

A bit-serial data communication required by our compact multigrid algorithm happens to be what is known as a pyramid network, consisting of a sequence of grids, $G_0, G_1, \cdots, G_k$, where the grid G_i has about 2^{di} points and where each nonboundary node of the ith grid is connected to $2d$, its neighbors in this grid, and also to the corresponding nodes of the $(i+1)$th and $(i-1)$th grids.

The weak smoothness assumption, sufficient for property (1) to hold, is just the very mild and customary bound $O(1/N^c)$, for a constant c, on the discretization errors (see (2.3) below), but even the assumptions required for the property (2) to hold are still satisfied for a large class of (piecewise) constant coefficient linear PDEs. Specifically, besides the weak smoothness, for a given linear (piecewise) constant coefficient PDE, we essentially need only an iterative algorithm (such as multigrid or SSOR) for solving the auxiliary linear systems over all the grids that use not more than a fixed constant number of steps on each grid in order to decrease the approximation error norms by a fixed constant factor—the same for all the grids. This is in fact a *routine assumption* of the multigrid methods (cf. [McCor1]).

We may compress a given N point uncompressed solution by using $O(\log N)$ time and N bit-serial processors, for a total of $O(N \log N)$ amount of work, which is optimal since the input solution is of size $O(N \log N)$. A very simple decompression algorithm requires only $O(\log N)$ sequential bit-operations to access the full precision (of $O(\log N)$ bits) solution value at any discretization point.

The compressed solution can be stored, and it can be decompressed only when its values need to be output. In many practical applications the solutions need not be decompressed. For example, in the solution of the time-dependent PDEs, the most customary solution methods perform at a discrete sequence of, say, T time steps. In each time step, a PDE is approximately solved, by using an N point discretization of the PDE fixed at that time value and by using the approximate solution obtained (in the compressed form) at the previous time step as an initial approximation to the current solution. Thus the solutions at these time steps need not be decompressed, except for the solution at the final time step. The total bit-complexity estimate for this computation, including decompression of the final solution and T calls for compact multigrid, would be $O(N(T+\log N))$ bit-operations (requiring $O(T \log N+\log^2 N)$ time and using $N/\log N$ bit-serial processors). Here we need, in particular, the linear convergence assumption; if it holds initially, we will preserve it by using sufficiently small time steps.

1.5. Organization of the paper. We will specify our compression techniques for PDEs in §§ 2–5. We will simplify our presentation, assuming, in particular, the simple lattice grids, although our results hold for more general discretization sets. In § 6 we will indicate some further extensions of our results, in particular, to more general discretization sets. We include Appendix A, where we bound interpolation errors in terms of discretization errors.

2. Definitions and assumptions. Let a linear PDE on the unit d-dimensional cube be discretized over a family of d-dimensional grids $G_0, G_1, \cdots, G_k$, having the distance $h_j=2^{-j}$ between each point of G_j and $2d$, its nearest neighbors, so that there are $|G_j|=N_j(1+o(1))$, $N_j=2^{dj}$, points in G_j, for $j=0, 1, \cdots, k$, and $N_k=N=2^{dk}$, where $k=(\log_2 N)/d$. Hereafter, for simplicity, we will ignore the smaller order terms $o(1)$, corresponding to the "extra" boundary points of the grids.

Let $u(x)$, a function in the d-dimensional vector, denote the solution to a PDE, let

$$D_j u_j = b_j, \tag{2.1}$$

denote the linear system of the difference equations generated by the discretization of the PDE over the grid G_j, and let $u_j(x)$ for a fixed $x \in G_j$ denote the respective component of the $|G_j|$-dimensional vector u_j representing the solution to this linear system, so that $\Delta_j(x)=u(x)-u_j(x)$ denote the discretization error functions on G_j, for $x \in G_j$ and $j=1, \cdots, k$.

Surely, discretization of the linear PDE gives matrices D_j with $O(1)$ nonzero coefficients per row as $j \to \infty$. Let $u_0(x)=0$ for $x \in G_0$, and let $\hat{u}_{j-1}(x)$, $j=1, 2, \cdots, k$, denote the prolongation of $u_{j-1}(x)$ from G_{j-1} to G_j, obtained by the interpolation (which usually means just the averaging) of the values of $u_{j-1}(x)$ at the appropriate subarray of points of G_{j-1} lying near x. Then

$$u_j(x)=\hat{u}_{j-1}(x)+e_j(x), \qquad x \in G_j, \qquad j=1, \cdots, k, \tag{2.2}$$

where $e_j(x)$ denotes the interpolation error on G_j.

We will assume that the discretization and interpolation errors satisfy the two following bounds, which we will call *the weak smoothness assumption* for the PDE:

$$|\Delta_j(x)| \leqq 2^{c-\alpha j}, \tag{2.3}$$

$$|e_j(x)| \leqq 2^{c-\alpha j} \tag{2.4}$$

for all $x \in G_j$, $j=1, \cdots, k$, and for fixed $c \geqq 0$ and $\alpha \geqq 1$. In the Appendix, we will deduce (2.4) from (2.3), whereas the assumption (2.3) holds for a wide class of PDEs (see, for instance, [Ame, p. 29], [LP]), including the well-posed linear PDEs, as well as many nonlinear PDEs. Such an assumption is routinely made in the analysis of the multigrid methods (e.g., [Bran2, 3, 4], [BD]); in particular, the auxiliary grid problems are said to be "solved to the level of truncation" defined by (2.3) (see [McCor1, p. 26]).

As a part of the weak smoothness assumption, let us further assume that $u(x)$ has been scaled so that $|u_j(x)| \leqq 1$ for $x \in G_j$ and for all j and that every $e_j(x)$ is represented with (that is, rounded off to) α binary bits (digits).

Remark. We may replace the bounds (2.3), (2.4), and $|u_j(x)| \leqq 1$ by the bounds

$$\|\Delta_j\| \leqq 2^{c-\alpha j} \|u_j\|,$$
$$\|e_j\| \leqq 2^{c-\alpha j} \|u_j\|,$$

for a fixed vector norm, provided that Δ_j, e_j, and u_j are considered as $|G_j|$-dimensional vectors with the components $\Delta_j(x)$, $e_j(x)$, and $u_j(x)$ for $x \in G_j$. This modification would not change our resulting estimates for the complexity of the Compact Multigrid.

In § 4, we will assume (in addition to weak smoothness) *interpolation regularity*, which means that the prolongation from G_{j-1} to G_j only requires $O(1)$ time using N_j bit-serial processors (which is surely the case for the interpolation by averaging).

In § 5, in addition to weak smoothness and interpolation regularity, we will assume the following:

(1) A fixed iterative algorithm (such as SSOR or a multigrid algorithm) applied to linear systems with matrices D_j uses $O(1)$ multiplications of submatrices of D_j by vectors for every j, in order to decrease, by the factor independent of j and N, the norm of the error of the approximation to the solution $u_j(x)$ of the system (2.1) (*linear convergence assumption*).

(2) The entries of the matrices D_j for all j, as well as the components of b_j, are integers having magnitudes $O(1)$ or turn into such integers after the scaling and truncation of the entries of the system (2.1) (*bounded coefficient assumption*, which holds for the constant coefficient PDEs).

Finally, for convenience, we will assume the fixed point binary representation, although shifting to the floating point representation would not actually lead to any substantial changes in our estimates.

3. Compression of the output. In this section, we will assume the weak smoothness relations and will compress approximations to all the values of $u_k(x)$ on G_k within absolute errors of at most $2^{c-\alpha k}$, so as to decrease the storage space required.

For the straightforward fixed point binary representation of these values of $u_k(x)$, we generally need $N\lceil \alpha k - c\rceil$ binary bits.

Alternatively, let us store $u_k(x)$ on G_k in the compressed form by recursively approximating within $2^{c-\alpha j-\alpha}$ to the fixed point binary values $e_j(x)$ for $x \in G_j$, $j = 1, \cdots, k$. The storage space of $2^d\lceil \alpha - c\rceil + \alpha(N_2 + N_3 + \cdots + N_k) < 2^d\lceil \alpha - c\rceil + 2\alpha N = O(N)$ binary bits suffices for this compressed information, which means saving roughly the factor of $0.5k = 0.5 \log_2 N$ binary bits against the straightforward representation.

4. Recovery of the solution values from the compressed data. In this section, we will assume the weak smoothness and the interpolation regularity. To recover $u_k(x)$ on G_k from the compressed information given by $e_j(x)$ on G_j for $j = 1, \cdots, k$, we start with $u_0(x) = 0$ for $x \in G_0$ and recursively, for $j = 1, \cdots, k$, compute the values

(a) $\hat{u}_{j-1}(x)$ on G_j, by prolongation of $u_{j-1}(x)$ from G_{j-1} to G_j, and then

(b) $u_j(x)$ on G_j, by applying (2.2).

Both stages (a) and (b) are performed with precision $2^{c-\alpha j-\alpha}$, so that stage (b) amounts to appending α binary bits of $e_j(x)$ to the available string of binary bits in the fixed point binary representation of $\hat{u}_{j-1}(x)$ for each $x \in G_j$, and stage (a) amounts to scanning the values of $u_{j-1}(x)$ on G_{j-1} and to the summation of few β-bit binary numbers (where, say, $\beta = O(\alpha)$) defined by the β least significant binary bits in the representation of $u_{j-1}(x)$ for appropriate x from G_{j-1}. Since $\sum_j N_j = O(N)$, the computational complexity estimates for stages (a) and (b) stay within the bounds stated in the Introduction.

5. Computing the compressed solution by compact multigrid. In this section, we will use all the assumptions of § 2, that is, the weak smoothness, interpolation regularity, linear convergence, and bounded coefficient assumptions. The time complexity of computing the compressed data structure is dominated by the time required to obtain the solution vectors e_j for the linear systems of equations over G_j for $j = 1, \cdots, k$:

$$D_j e_j = r_j, \tag{5.1}$$

where

$$r_j = b_j - D_j \hat{u}_{j-1}, \tag{5.2}$$

the matrices D_j and the vectors b_j are from the linear systems (2.1), and the vectors e_j and $\hat{u}_{j-1}$ have components $e_j(x)$ and $\hat{u}_{j-1}(x)$ for $x \in G_j$, defined by (2.1) and (2.2), respectively.

We will follow the routine of the V-cycle multigrid methods (cf. [McCor1] and [FMc]), and will recursively evaluate the vectors e_j for $j = 1, \cdots, k$. Initially, we will let $u_0(x) = 0$ for $x \in G_0$, and at stage j, we will successively compute for all $x \in G_j$:

(a) $\hat{u}_{j-1}(x)$ (by prolongation of $u_{j-1}(x)$ from G_{j-1} to G_j);

(b) $r_j(x)$ (by using (5.2));

(c) $e_j(x)$ (by solving the linear system (5.1) "to the level of truncation");

(d) $u_j(x)$ in the compressed form (by using (2.2), as in § 4).

We may then restrict $u_{j+1}(x)$ to $u_j(x)$ for $j = k-1, \ldots, 0$ (as in some customary multigrid algorithms) and then recursively repeat such a V-cycle.

The linear convergence assumption means that the errors of the approximations to $u_j(x)$ decrease by a constant factor independent of j and N when stages (a)-(d) are repeated once for all j, even if only $O(1)$ iteration steps are used at stage (c) for solving linear systems (5.1) for every j. Such convergence results have been proven for the customary multigrid algorithms applied to a wide class of PDEs (see [BD], [Hack2, 3], [HT], [McCor2], [McCT], and [FMc2]).

Let us estimate the time complexity of these computations, dominated by the time needed for solving the linear systems (5.1).

The size $N_j = 2^{dj}$ (within $O(N_j^{1/d})$) of the linear system (5.1) increases by 2^d times as j grows by 1. Even if we assume that the solution time for the system (5.1) is linear in $|G_j|$, the overall solution time for all the k such systems in terms of the number of arithmetic operations involved is less than $1/(1-2^{-d})$ times the solution time for the single system (2.1) for $j = k$, which gives us the uncompressed output values $u_k(x)$ for $x \in G_k$. The bit-operation count is even more favorable to the solution of the systems (5.1) for all j, as opposed to the single system (2.1) for $j = k$, because the output values $e_j(x)$, satisfying the systems (5.1), are sought with the lower precision of α binary bits.

Furthermore, we solve the linear systems (5.1) by iterative methods where each step is essentially reduced to a constant number (say, one or two) multiplications of a matrix D_j or its submatrices by vectors. Due to the linear convergence assumption we made, a constant number of iterations suffices at each step j in order to compute the α desired binary bits of $e_j(x)$.

The computational cost of multiplication of D_j by a vector is $O(N_j)$ arithmetic operations for a sparse and structured discretization matrix D_j (having $O(1)$ nonzero entries in each row). Furthermore, a parallel acceleration to the parallel time bound

$O(1)$ is possible by using N_j processors (for we multiply a vector by a matrix having $O(1)$ nonzero entries per row). Thus we arrive at Proposition 1, whose processor bound follows similarly to the proof of Proposition 2 below.

PROPOSITION 1. *$O(\log N)$ parallel arithmetic steps and $N/\log N$ processors suffice to compute the vectors e_j for all j, that is, to compute the smooth compressed solution to a* PDE *discretized over the grid G_k, under all the assumptions of* § 2.

Furthermore, we only need $O(1)$ binary bits in order to represent $e_j(x)$ for every $x \in G_j$ and every j. Since D_j has only $O(1)$ nonzero entries per row and since these entries are integers having magnitudes $O(1)$ (due to the bounded coefficients assumption), it suffices to use $O(1)$ bits to represent $r_j(x)$ (see (5.1)). (These bits may occupy not all the positions where the corresponding components of b_j have nonzero bits, for the most significant binary digits of these components may be canceled in subtracting $D_j\hat{u}_{j-1}$.) Thus, we will perform all the arithmetic operations with $O(1)$-bit operands and will arrive at Proposition 2.

PROPOSITION 2. *Under all the assumptions of* § 2, *$O(\log N)$ steps, $N/\log N$ bit-serial processors, and $O(N)$ storage space under the Boolean model of computation suffice in order to compute the compressed solution to a* PDE *by using the Compact Multigrid algorithm.*

Proof. As described above, our algorithm has stages $j=1,\cdots,k=(\log N)/d$, where at stage j we require $O(1)$ time for each of the $N_j=2^{dj}$ bit-serial processors. Thus our parallel algorithm (if naively implemented) appears to take $O(\log N)$ time using N bit-serial processors. However, the first $(\log N)/d$-$\log\log N$ stages only require $N/\log N$ bit-serial processors. Thus, at each of the last $\log\log N$ stages $j, j=(\log N)/d$-$\log\log N+1,\cdots,(\log N)/d$, we will slow down the computation to the time $O(2^{dj}\log N/N)$, and then we only need $N/\log N$ bit-serial processors. The overall time of our resulting parallel algorithm is then still $O(\log N)$.

6. Extensions of the results. Our results can be immediately extended to the case of more general sequences of the sets $S_0, S_1, \cdots, S_k$ of the discretization of the PDEs, provided that each set S_j consists of $c_j\sigma^j$ points where $0<c<c_j<c^*$, $\sigma>1$, c, c^*, and σ are constants (this includes the grids with step sizes that vary depending on the direction of the steps), and that the required assumptions of § 2 are, respectively, extended to the case of the sets S_j. We also need to assume that each discretization point of S_j has at most $O(d)$ neighbors: this will imply that each equation of the associated linear algebraic system has at most $O(d)$ nonzero coefficients.

Finally, the presented approach can be further extended to some nonlinear PDEs, as long as our assumptions (such as (2.3) and (2.4)) hold and as long as dealing with nonlinear systems of difference equations replacing the linear systems (2.1) remains relatively inexpensive.

Appendix A. Let us show that the bound (2.3) implies the bound (2.4) assuming that $\hat{u}_{j-1}(x_{j-1})=u_{j-1}(x_{j-1})$ for $x_{j-1}\in G_{j-1}$ and that $\hat{u}_{j-1}(x_j)$ has been defined on G_j-G_{j-1}, say, as the average value $u_{j-1}(x)$ at all the points x_{j-1} of G_{j-1} such that $|x_{j-1}-x_j|=gh_j$, for the minimum g. Then $|e_j(x_j)|\leqq|u_j(x_j)-u_{j-1}(x)|$ for at least one of these points. First rewrite the bound (2.3) as follows:

$$|\Delta_j(x_j)|\leqq ah_j^\gamma,\qquad x_j\in G_j, \tag{A.1}$$

where a and γ are positive constants, and h_j is the length of a side of the mesh G_j, so that $h_{j-1}=2h_j$ for the lattices G_j that we have chosen. Let $\gamma<1$, $x_{j-1}\in G_{j-1}$, $x_j\in G_j$, $|x_j-x_{j-1}|=h_j$, and $|e_j(x_j)|\leqq|u_j(x_j)-u_{j-1}(x_{j-1})|$. Then deduce from (A.1) that for some Θ, $0\leqq\Theta\leqq1$, $|e_j(x_j)|\leqq|u_j(x_j)-u_{j-1}(x_{j-1})|\leqq|u(x_j)-u_j(x_j)|+|u(x_{j-1})-u_{j-1}(x_{j-1})|+$

$|u(x_j)-u(x_{j-1})|\leqq a^*h_j^\gamma$, that is,

$$|e_j(x_j)|\leqq a^*h_j^\gamma, \tag{A.2}$$

$a^*=a(1+(h_{j-1}/h_j)^\gamma)+g|u'(x_j+\Theta h_j)|h_j^{1-\gamma}\leqq(1+2^\gamma)a+g\max|u'(x)|h_j^{1-\gamma}$. The bounds (A.1) and (A.2) turn into the bounds (2.3) and (2.4) for $c=\log_2 a^*$, $\alpha=-\gamma(\log_2 h_j)/j$, and $x=x_j$. If $x_j\in G_{j-1}$, then we just replace x_{j-1} by x_j above and cancel the term $|u(x_j)-u(x_{j-1})|$.

Acknowledgments. The authors thank the referee and the editor for helpful comments.

PARALLEL PERFORMANCE OF DOMAIN-DECOMPOSED PRECONDITIONED KRYLOV METHODS FOR PDEs WITH LOCALLY UNIFORM REFINEMENT*

WILLIAM D. GROPP† AND DAVID E. KEYES‡

Abstract. Preconditioners based on domain decomposition appear natural for the Krylov solution of implicitly discretized partial differential equations (PDEs) on parallel computers. Two-scale preconditioners (involving a global coarse-grid solve, independent solves over interfaces connecting the coarse-grid points, and independent subdomain solves) have been known since the early 1980s to be "near optimal" in the sense of ensuring a bounded, or at most logarithmically growing, iteration count as the mesh is refined. As a result, the refinement of the mesh can be chosen locally on the basis of truncation error, and the granularity of the domain decomposition can be chosen globally on the basis of parallel computing considerations with only mild effects on the convergence rate of the algorithm. However, overall computational complexity depends not only on the algebraic convergence rate, but also on the operation counts of the components of the preconditioner that must be applied at each iteration. The costs of solving the subdomain systems and the crosspoint system show superlinear growth in their respective (and inversely related) sizes. On the subdomains, the superlinear terms arise from arithmetic only; in the crosspoint system the cost of nonlocal data exchange is also superlinear. These factors make the preconditioner granularity and the choice of its components problem- and machine-dependent compromises.

The tradeoffs involved are illustrated through numerical experiments on both shared- and distributed-memory computers for convection-diffusion problems. Because of the development of boundary layers, these problems benefit from local mesh refinement, which is straightforward to accommodate within the domain decomposition framework in a locally uniform sense, but which introduces load balancing as a further consideration in selecting the granularity of the preconditioner. In spite of the tradeoffs, cumulative speedups are obtainable out to at least medium-scale granularity (up to 64 processors in our tests). The largest problems involve $\mathcal{O}(10^5)$ unknowns partitioned into $\mathcal{O}(10^3)$ subdomains and converge in $\mathcal{O}(10)$ iterations requiring $\mathcal{O}(1)$ seconds on the Intel iPSC/860.

Key words. domain decomposition, elliptic problems, parallel algorithms, mesh refinement

1. Introduction.

Several tributaries of applied mathematics and computer science meet at large-scale PDE-based scientific computing applications on parallel computers, where feasibility and efficiency rank alongside existence, uniqueness, and conditioning as essential considerations.

Iterative methods based on choosing the best solution in incrementally expandable subspaces have proved effective in many contexts and have been generalized to nonsymmetric operators in such archetypal forms as conjugate gradient squared (CGS) and generalized minimal residual (GMRES). For computational economy, these methods allow different representations of the underlying operator to be used, ultimately converging to a "high quality" representation, through a series of applications of the inverse of a "lower quality" representation, called a preconditioner. Though

already advantageous in linear problems and on serial computers, the ability to operate with multiple representations of the operator proves even more significant in nonlinear problems and in parallel.

Adaptive discretizations determine the feasibility boundary for many scientific computing applications. Unfortunately, the irregularity of adaptivity can complicate the management of parallel resources, a situation that has led to various compromises of adaptivity with quasi uniformity. Generally, the use of highly structured discretizations in a modular way at different scales has been favored.

Distributed computation puts a premium on the exchange of information between cooperating processors, since such operations are generally slower than local operations. The fact that nearby points usually interact more strongly than distant points motivates decomposition by domain and allows for a "nearly" local algorithm. Nevertheless, the physics intrinsic to many PDE-based problems, expressible in the form of Green's functions with global support, requires global sharing of information. Function-space decompositions based on coarsening processes, which propagate information on multiple scales simultaneously and even asynchronously, have evolved as another active research tributary.

This contribution does not push the frontier of any particular one of the methodologies mentioned above, but lies in their intersection. An implementation in software of a particular domain-decomposed locally uniform mesh refinement (LUMR) GMRES method with a two-scale preconditioner is offered as an effective prototype, which brings various tradeoffs to light. These include adaptivity and convergence rate, adaptivity and truncation error, and adaptivity and parallel load-balance. Except for details at the highest and lowest levels, the same code has been successfully ported from its serial incarnation to both shared- and distributed-memory computers with little sacrifice on any one machine, relative to a custom implementation for that machine alone. Our performance results on these machines allow comparisons with other parallel PDE algorithms, not based on a priori domain decomposition.

The mathematical framework of our domain-decomposed linear solver is described in § 2, followed by a discussion in § 3 of the shared and distributed parallel implementations. Section 4 contains selected performance measurements in the form of tabular cross-sections of a rather large parameter space. Finally, in § 5 we draw some conclusions and comment on bottlenecks and desired extensions.

2. GMRES, LUMR, and domain decomposition.

The generalized minimal residual method [21] is the most economical of the Krylov algorithms to which it is equivalent in the absence of round-off (including GCR [8] and ORTHODIR [25]) and is proposed for retention in [20] (along with CGNR [12] and CGS [23]) in any systematic comparative study of the performance of nonsymmetric Krylov methods. For the purpose of this study it is sufficient to recall the following salient features of GMRES, when used to solve $Ax=b$ in the right-preconditioned form $(AB^{-1})y=b$, $Bx=y$: (1) its implementation requires the ability to evaluate the action of the preconditioned operator (AB^{-1}), but not A^{-1}; (2) it converges monotonically in a number of iterations related to the number of separated clusters of eigenvalues in the spectrum (or the pseudo-spectrum; see, e.g., [24]) of the preconditioned operator; (3) its work and storage estimates are quadratic and linear in iteration count, respectively, because of the construction and retention of an orthonormalized basis for the Krylov subspace based on AB^{-1}; and (4) storage estimates and (sometimes) work estimates can be decreased for many problems by a restarted version of GMRES, which periodically accumulates the solution updates, discards the Krylov subspace, and starts anew.

The application of A is usually an easily parallelized operation, requiring only local communication for local discretization schemes (finite differences, finite elements, finite volumes, etc.). Good choices for B^{-1}, in the sense of producing the clustering mentioned in (2) above, will generally involve some nonlocal communication, but less than in parallel direct algorithms for forming the action of A^{-1}. Domain decomposition is one means of deriving efficient parallel preconditioners for elliptic operators, as well as other operator types.

Locally uniform mesh refinement is a means of resolving multiple spatial scales in PDE problems based on local discretizations. LUMR lies in between the extremes of excess mesh points/low overhead per point, on the one hand, and minimum mesh points/high overhead per point, on the other. It is motivated by the observation that threshold levels of certain continuous function(al)s are often good indicators for enhanced resolution requirements. Hence, adaptively inserted mesh points can be allocated in *quanta* of a convenient size and structure without a serious loss of efficiency through overresolution. In this paper, we assume that the refinement requirements are specifiable a priori, but this is not an inherent limitation of the technique. Serial demonstrations of the LUMR concept have been provided by many investigators; see, e.g., [1], [11] and references therein. In our implementation for a parallel port we are somewhat more restrictive than is serially natural in basing our quanta on initial coarse-grid subdivisions called "tiles." Tiles have standard data interfaces with each other but may support different discretizations and preconditioner modules internally. They are software analogs of the geometry defining processors (GDPs) of [5] and lead to a code that is object-oriented in concept, but not competely so in implementation. By requiring that corners of tiles meet other tiles at corners only (and thus that tiles are elements of a logically tensor product structure) we greatly simplify the portion of the code that performs interdomain information exchange, with dividends for parallel efficiency. For standardized "docking," tiles are tensor products of half-open intervals. On average, in two dimensions, each tile "owns" one of its corners, two of its sides, and all of its interior. At physical boundaries, a tile may "own" additional pieces of its border.

The term "domain decomposition" spans many approaches based on a geometric partitioning of the domain of a PDE, which thus also impose a partitioning on the matrix representations of A and B^{-1}. In this contribution, we discuss nonoverlapping partitionings of a two-dimensional region into subdomain interiors, subdomain interfaces, and crosspoints at interface intersections. A sample decomposition of an L-shaped region into many square subdomains is pictured in Fig. 1.

We write A as

$$A=\begin{pmatrix} A_I & A_{IB} & 0 \\ A_{BI} & A_B & A_{BC} \\ 0 & A_{CB} & A_C \end{pmatrix},$$

where the submatrices arise from a simple permutation of a naturally ordered local discrete operator as follows. A_I is a block diagonal matrix representing the discretization of all of the independent subdomain interior problems, also including physical boundary points other than crosspoints. (The boundary points are retained as degrees of freedom in order to accommodate general boundary conditions, including spatial coupling and also intercomponent coupling in multicomponent problems.) In a standard five-point finite difference (FD) discretization of a single two-dimensional PDE, for instance, the blocks of A_I (one for each domain) are each smaller five-point operators with the discrete subdomain diameter as the maximum bandwidth. A_B is a block diagonal matrix representing the discrete coupling *along* the artificial internal boundaries induced by the decomposition. In our five-point FD examples, each block of A_B is tridiagonal. The crosspoint matrix A_C is purely diagonal in the case of a local discretization of a single PDE. (This is based on the design assumption that the subdomains are too large to be completely spanned by a single discretization stencil, whatever its order.) The doubly subscripted blocks of A contain the coupling between the respective different categories of points. When neighboring subdomains are discretized at the same resolution, the appropriate coefficients are unambiguous. When resolution changes, the finite element method remains unambiguous, and a version of the finite volume method has been likewise rendered in [18], but special provisions are required for FD discretizations. In this paper, we use a biquadratic interpolation scheme (consistent with the best accuracy to be expected from the use of a five-point FD discretization) in the subdomain interiors, when constructing a fine stencil with data requirements from a coarse region. When constructing a coarse stencil with data requirements from a fine region, we employ unweighted injection. This is a consistent discretization, but not a conservative one.

As a preconditioner, we consider

$$B=\begin{pmatrix} \tilde{A}_I & \tilde{A}_{IB} & 0 \\ 0 & B_B & \tilde{A}_{BC} \\ 0 & 0 & B_C \end{pmatrix},$$

where the tilde quantities are related to the correspondingly subscripted blocks of A according to a variety of prescriptions. A key property of B is its block triangularity, which represents a compromise between a perfectly parallel block diagonality on one hand and the structurally symmetric form of A itself on the other. The formal inverse of B is, of course, also block triangular. The block B_C, solved first, is based on a coarse-grid discretization of the original PDE. This step requires the exchange of data between tiles. The resulting solution provides Dirichlet endpoint conditions, through $\tilde{A}_{BC}$ $(=A_{BC}$ in our examples), for the solution of the independent interface blocks which together constitute B_B. We use for B_B a discretization of the tangential part of the operator, defined as those terms that remain when the derivatives in directions normal to the interface in the local coordinate system are set to zero. Dense but FFT-implementable interfacial blocks have also been incorporated into B_B [3]. Finally, the blocks of $\tilde{A}_I$ are solved independently by using Dirichlet data at all artificial boundary points, through $\tilde{A}_{IB}$ $(=A_{IB})$, and actual boundary conditions at physical boundary points. In this paper, $\tilde{A}_I=A_I$, although other less expensive approximate replacements (such as fast solvers) can (and often should) be employed. Our choices for the components of B lead to good convergence results but are not the most convenient ones for convergence proofs of Krylov iteration based on AB^{-1}. A proof of near-optimality has been given [3] for the case where the blocks of B_B consist of the square root of the corresponding one-dimensional discrete Laplacian operator, but there is no known proof for the case employed herein, where the blocks of B_B derive directly from the tangential terms of the overall operator.

A discussion of the utility of the block triangular form of B (as opposed to a structurally symmetric B) in the case where A is already nonsymmetric is given in [4], and a detailed discussion of the preconditioner of this paper is given in [11]. In the opposite direction, the alternative of a purely block diagonal B is discussed in [10] and [15] and references therein. It may often, but not always, be dismissed as requiring too many extra iterations to justify the savings per iteration. Multicomponent problems in which source terms dominate provide examples in which a block diagonal preconditioning can outperform the coupled alternatives in overall wall-clock time.

3. Shared- and distributed-memory implementations. The tile-based decomposition described above is motivated partly by its yield of a suitably convergent preconditioned iterative method and partly by its control of overhead in a LUMR context, but our main interest in this contribution is its straightforward adaptation to parallel processing. There are a variety of ways to find independent threads of computation of commensurate size in the tile-based decomposition described above. Indivisible tiles can be parceled out over an MIMD processor array, or a collection of identical tiles can be broken up over a vector or SIMD processor array, to be operated on in lockstep. In between these extremes, an MIMD array can be subpartitioned into SIMD- or vector-like clusters and different sets of identical tiles allocated to each cluster for lockstep processing within each. Thus, a workload consisting of a large number of tiles in at most a moderate number of distinct sizes maps well onto a variety of parallel machines and hybridizes well on a hierarchical MIMD/SIMD machine. Our implementations to date are confined to the first type: tiles are not divided over processors, but processors may be responsible for more than one tile each. The number of processors in simultaneous use is therefore bounded below by the number of tiles, but is otherwise independent of it. In our current implementation, it is determined towards the outset of execution and held fixed throughout.

In the serial implementation, work arrays for the data structures associated with each tile are allocated separately, and the tiles are placed on a list that is traversed in an arbitrary order each time a grid-oriented operation (such as forming the action of A or B^{-1}, performing a DAXPY, or taking a residual norm) is required. A highly modular approach is adopted in which each tile has its own local coordinate system and its own subroutines for problem definition, preprocessing, application of an iteration step, exchange of data with neighbors, and (as a consequence of all this flexibility) its own workload estimates for each major iterative phase. The most complex of these phases is usually B^{-1}. In the examples of this paper, the only aspect of this modularity that we exploit nontrivially is the data exchange, in which different interface handling routines mediate the changes in mesh refinement across subdomain boundaries. However, we anticipate applying the same code to nonlinear problems such as reacting or high Reynolds number flows, in which every aspect of this modularity can purchase a significant work advantage. For instance, fast or frozen kinetics, or Euler or Navier–Stokes fluid mechanics, could be adaptively selected on each subdomain.

Code development on a serial workstation offers the obvious advantages of uncontested resources, high graphical display bandwidth, and ease of tracebacks in debugging. Furthermore, it allows the performance testing of algorithmic options apart from communication considerations. We mention that iteration-by-iteration contour plots of solution, error (when knowable), and residual were instrumental in shortening development time.

3.1. Shared-memory implementation. The port to a shared-memory machine (the Encore Multimax 320, equipped with 18 processors) required attention to three issues beyond the serial version: data access, load balance, and work-to-processor mapping. The Multimax offers its global address space to each processor; thus, when the traversal of the single sequential tile list is broken up into several simultaneous traversals of smaller tile lists, access to shared data must be controlled by locks and barriers. In anticipation of a further distributed-memory port, and in keeping with a structured, minimal side-effect programming paradigm, we restricted the use of data sharing to synchronization variables, accumulation registers (for inner products or max/min reductions), work arrays for the global crosspoint system, and data buffers at the artificial interfaces of the decomposition. A list of all tiles allowing neighbor inference is also shared.

In an earlier shared-memory code series for stripwise domain decompositions of tensor-product grids (see, e.g., [14], [15]), we shared substantially more data, including entire unknown fields. In earlier codes, data belonging to neighboring tiles was accessed by simply supplying an absolute index into the global array. In the current code, a buffer is maintained around the perimeter of each tile of a width corresponding to the semibandwidth of the difference stencil in use of that tile. These buffers are refreshed (by injection or interpolation) at appropriate synchronization points. The miserliness of the current code in allowing shared access only to interfacial buffers obviously incurs some unproductive time and space overhead, relative to the earlier versions. It is therefore natural to question whether this is an optimal shared-memory code or just a distributed-memory code implemented on a shared-memory processor, and to assess the impact of the extra overhead on parallel performance.

To quantify the cost of this overhead, we repeatedly executed on the Multimax a loop consisting of a MATVEC (an application of A to a vector), a vector DAXPY, and a vector inner product under both globally shared and buffered versions of the stripped-down code. A five-point FD stencil with hard-coded coefficients was used for A. This is a very conservative comparison, from the point of view of establishing the validity of the buffered version as a·reasonable shared-memory implementation for domain-decomposed elliptic PDE problems, because it includes all but one of the required forms of nonlocal data access per iterative cycle, together with the minimum amount of local arithmetic per access. Almost any mix of operations in a typical preconditioned iteration, except for the solution of the crosspoint system (considered separately below), will enjoy a better computation to "communication" ratio than these loops. Nevertheless, the penalty in wall-clock time for the buffered version was less than 10 percent of the globally shared version. In our judgment, this is a small penalty for the convenience of a code that is readily ported to distributed-memory configurations. Of course, this is a machine-dependent conclusion. However, we note further that many current and anticipated "shared-memory" multiprocessor designs have memory hierarchies that put an execution efficiency premium on global sharing. Fast global shared memory is destined to be a scarce resource on loaded multiprocessors. The Multimax 320 enjoys the evanescent luxury of a bus that is very fast relative to the data-sharing requirements of 16 processors cooperating on an elliptic PDE.

Banded Gaussian elimination, used in the inversion of B_C, does not map as gracefully onto multiprocessors as do the rest of the algorithmic modules. Its parallel performance (both factorization and backsolve) has been evaluated separately from the basic loops above for a five-point stencil Dirichlet problem on the Multimax. The problem sizes varied from 16 (which corresponds to the crosspoint system of a 3×3 grid of tiles) to 4,096 (a 63×63 grid of tiles), and the processing force from 1 to 16. For problem sizes up to 1,024 (bandwidth 32) there is speed*down* at 16 processors, and the case of dimension 4,096 is only 45 percent efficient at 16 processors. For our PDE examples (which employ a maximum of 1,024 tiles), we therefore factor and solve the crosspoint system with single-threaded code, letting other processors remain idle. For a sufficiently high tile-to-processor ratio, it will become more important to parallelize the crosspoint solve itself.

Our load balancing strategy is a primitive and static one that relies on asymptotic order estimates for the largest complexity terms in both the preprocessing and iteration phases of the computation. To be specific, to an $n \times n$ tile we assign the work estimate

$$W = n^2(I^2 + I(1+n) + n^2),$$

where I is an estimate for the number of (nonrestarted) Krylov iterations that will be necessary for convergence. The term in I^2 represents the cumulative orthogonalization work of GMRES; the two terms in I the applications of A and B^{-1}, respectively; and the remaining n^4 term the factorization preprocessing of the subdomain interior matrices of $\tilde{A}_I$ when a bandsolver is employed. Though this primitive estimate contains asymptotic leading terms only, for reasons of granularity we rarely work with asymptotically large tiles and would switch to sparse subdomain solvers if we did. In [11] it is shown, however, that a bandsolver outperforms a sparse direct solver based on nested dissection for sufficiently small n, such as 8 or 16.

Though I can be estimated more carefully on the basis of experience (§ 4), we simply set it to 20 in all examples herein. There is obviously considerable room for refinement of the per-tile work estimate on the basis of a priori or evolving information about the tile and the overall problem. For sufficiently large tile-to-processor ratios, very balanced load distributions become possible in spite of the tile-based quantization of work, and greater effort in work estimation pays dividends.

The question of work-to-processor mapping goes beyond load balancing in the sense that the objective of load balancing is finding simultaneous executable threads of execution of comparable durations, while mapping is further concerned with the data requirements of these threads in relation to the network and memory hierarchies of the machine. From the viewpoint of overall performance, these considerations are rarely independent, of course. We chose a fixed allocation of subdomains to processors based on either of two strategies. The first is tied to the work estimates of the preceding paragraphs. Tiles are ranked in order of decreasing W and parceled out to processors without regard to spatial proximity. While tiles remain, the tile with the largest W is assigned to the processor with the least amount of work, with ties broken by a fixed but arbitrary enumeration ordering.

The second strategy, called "wrap mapping," is based on the heuristic argument of § 2 that led initially to LUMR, namely, that regions requiring refinement tend to occur in contiguous clumps in elliptic PDE discretizations. Therefore, the assignment of tiles based on some regular lexicographic labeling is likely to be as good as a work estimate-based assignment in the limit of large tile-to-processor ratios. The two strategies are compared in § 4.2. Obviously, the ability to dynamically remap will be important to either mapping strategy once dynamic levels of refinement are implemented and should be pursued at the next level of coding sophistication.

3.2. Distributed-memory implementation. The tile-based domain decomposition code has also been tested on the Intel iPSC/860 in a 64-processor hypercube configuration with 8 Mb of memory per node. The port from shared to distributed memory was relatively straightforward because of the miserly use of shared memory in the Multimax version. The sharing of data is accomplished by explicit calls to message-passing subroutines. Since we make no assumptions about the locality in the processor domain of tiles sharing data, all intertile messages are routed via calls to the send/receive ethernet subroutines. For small numbers of processors, and hence strong locality of cooperating tiles, this approach is clearly suboptimal. However, our design is motivated primarily for extension to large numbers of processors, where going off-board is a reasonable default.

The distinctions, rooted in hardware, between "shared" and "distributed" memory are blurred by software. These should not be regarded as distinct opposites, but as different extremes on a continuum of memory hierarchies, with various cached memory designs as intermediates. At one end is the idealized model of a flat time cost for accessing different pieces of data, and at the other, a (usually nonlinear) time cost variation based on distance and packet size. The synchronized tile-interface buffering discussed above is well suited for the distributed-memory model. In order to minimize redundant storage, data areas used exclusively in a small number of processors should not be replicated on all processors. This procedure leads to a custom paring on each processor of the master tile data structure to the minimum size required for neighbor identification and cooperation in the global crosspoint solves and inner products. Without such storage optimizations, distributed-memory processors waste significant memory.

On the iPSC it is even less inviting than on the Multimax to perform the crosspoint solve in parallel. Experiments (see, e.g., [9], since updated in unpublished form for new hardware) show that a problem of size 1,024 (bandwidth 32) can be speeded up slightly by parallelization on up to 32 processors, but at very small efficiency. On the other hand, the single-threaded execution used on the Multimax is also unattractive, since it would have to be preceded and followed by significant global communication to gather the right-hand side and scatter the solution. Our compromise, which dates back to our earliest hypercube domain decomposition code series [13], is to broadcast the data required for the right-hand side to each processor, then to solve the crosspoint system redundantly on each processor. A future optimization for large numbers of tiles on either shared- or distributed-memory computers is cooperative solution of the crosspoint system within subclusters of processors. The crosspoint problem is sufficiently different from the balance of the code in its computation-to-communication ratio that either extreme of employing one or all processors in it is too restrictive. Like the coarse-grid solution in multigrid, it can be regarded as a black box which, though extremely important, is somewhat detachable. Many parallel algorithm designers concern themselves with this black box, and good solutions in the point-per-processor regime are readily incorporated.

4. Performance on model problems. We select for parallel study two-dimensional model problems from the suite of ten studied in serial in [11]. The examples are obtained by taking three different values of the convection, namely, $c=0$, $c=-1$, and $c=10$, in the cylindrically separable reentrant corner convection-diffusion problem:

$$-\nabla^2 u+\frac{c}{r}\frac{\partial u}{\partial r}=0,$$

$$u(x,y)=r^{\alpha}\sin\left(\frac{2}{3}\left(\theta-\frac{\pi}{2}\right)\right),$$

$$\text{where}\quad r=\sqrt{(x-1)^2+(y-1)^2}\quad\text{and}$$

$$\theta=\arg\left((x-1)+i(y-1)\right),\qquad 0\leqq\theta<2\pi,$$

$$\text{Dirichlet data on } \partial\Omega,$$

$$\Omega=L\text{-shaped region.}$$

The domain Ω is shown in Fig. 1.

The first of these corresponds to pure diffusion, and the second and third correspond to convection towards the reentrant corner and away from it, respectively, at a

FIG. 1. *The domain* Ω *and sample tessellations for* (a) *diffusion and inflow problems and* (b) *outflow problem. The integer labels in each tile give the logarithm of the maximum refinement ratio employed in that tile, over all the tests. For the (indicated) second level of refinement, the finest tiles are* 16×16 *subintervals, while the coarsest ones are* 4×4. *Some of the test runs are performed at smaller refinement ratios. In first-level tests, all tiles showing* "2" *are set to* "1" (8×8). *In zeroth-level refinement,* all *tiles are set to* "0".

rate inversely proportional to the radius (thus satisfying mass conservation). We refer to them as the *diffusion*, the *inflow*, and the *outflow* problems, respectively. The respective values of the radial eigenfunction exponent α are $\frac{2}{3}, \frac{1}{3}$, and approximately 10.0442. Figure 2 displays $u(x, y)$ for the three problems. The first two solutions lack derivatives at the reentrant corner. The last is everywhere twice differentiable, but the solution is characterized by steep variation in three of the *non-reentrant* corner regions, where $r>1$. Some form of local mesh refinement is critical to improving the accuracy of a finite difference solution. *Uniform* refinement is somewhat of a brute-force approach to a problem in which the strength of the singularity is known analytically. Instead of uniform refinement, or in conjunction with it, a simple change to the finite difference scheme in the vicinity of the reentrant corner can substantially improve the accuracy of the solution, as noted below.

4.1. The effect of adaptivity on convergence rate and truncation error. Tables 1 through 3 provide a purely serial demonstration of the value of local uniform mesh refinement: comparable accuracy in considerably fewer operations, compared with global uniform refinement. We solve these problems at effective refinement levels of $h^{-1}=32$, 64, and 128, where h^{-1} refers to the number of equal subintervals along one of the long edges of Ω. The computations are carried out to a reduction in the residual of 10^{-8}, so our report of the truncation error is not contaminated by incomplete

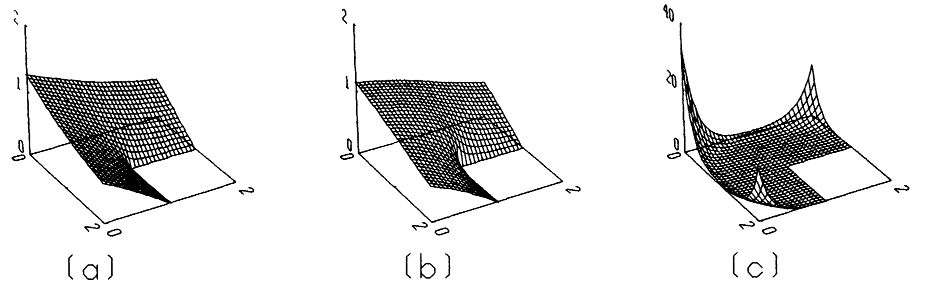

FIG 2. *Surface plots of* $u(x, y)$ *for* (a) *the diffusion problem, nondifferentiable at* $r=0$, (b) *the inflow problem, the singularity strengthened, and* (c) *the outflow problem, the singularity eliminated (note the change of vertical scale).*

algebraic convergence. Global refinement results are on the left, and local on the right. Each of these columns lists the number of unknowns, the sup-norm of the error, the number of iterations, and the total execution time on a SPARCstation-1. The rightmost column gives the global-to-local execution time ratios for each refinement level.

Though the particular refinement strategy illustrated in Fig. 1 is by no means considered optimal, appreciable sixfold improvements in computational work are available in the first two problems. In the third problem, the number of tiles refined to a high degree is a substantial fraction of the total, resulting in only a nearly threefold gain.

The roughly linear behavior of iteration count with each doubling a global refinement in Tables 1 through 3 is consistent with the logarithmic growth in conditioning with h^{-1} derived in [3].

Case-by-case comparisons between the globally and locally refined results show that correctly placed local refinement can replace global refinement in representative problems with essentially no loss in accuracy and with gains in both storage and iteration count. The gain in iteration count is modest; it may be better to simply summarize with the observation that iteration count is not significantly affected in the context of the two-level preconditioner. This result is expected on the basis of theory: the condition number of the overall system is bounded by the condition number of the worst-conditioned subdomain, not by the details of the distribution of subdomain problems. The gain in storage, on the other hand, is potentially very significant and shows up both in a lower cost per iteration in already feasible problems and in an enlargement of the class of feasible problems, given a fixed-size memory. These conclusions are not new; they are stated here to provide self-contained motivation for the parallel results below, where the tradeoffs between adaptivity and parallel load balance are addressed.

Before leaving this section, we comment briefly on two means other than ordinary h-type refinement for improving the truncation error of either the global or the local discretizations compared above: singularity fitted discretizations and higher-order upwind discretizations.

As expected in cases where the exact solution is nondifferentiable at the reentrant corner (Tables 1 and 2), the sup-norm of the truncation error (which is determined by the data at the corner) shows slow improvement in h when ordinary finite differences based on Taylor series expansions are employed. As was demonstrated nearly half a century ago [19], the error can be improved by making a local rediscretization in the neighborhood of the corner based on an expansion of the solution in most singular modes of the known local series representation. For this purpose, three special-purpose tiles (simple rotations of each other) are employed at the reentrant corner, and the remainder of the discretization is unchanged. A standard Cartesian grid is employed, but the operator coefficients near the corner are derived from a cylindrical coordinate analysis. The results are shown in Table 4, the Taylor part of which is repeated from Table 1 for convenient comparison.

TABLE 4

Number of unknowns N, sup-norm of the error e, iteration count I, and execution time T (sec) for the diffusion problem, for ordinary Taylor series-based finite differences and for a discretization fitted to the singularity at the reentrant corner.

		Ordinary Taylor			Singularity fitted		
h^{-1}	N	e	I	T	e	I	T
32	833	1.30 (−2)	18	1.1	1.63 (−3)	17	1.1
64	3201	8.30 (−3)	22	4.0	1.04 (−3)	22	4.0
128	12545	5.25 (−3)	26	24.4	6.54 (−4)	26	24.3

We observe that the alternative discretization leaves the convergence rate of the preconditioned Krylov method and the execution time virtually unchanged, while the error at each resolution of the grid is a constant eightfold factor better than the corresponding error of the ordinary discretization. (The error improves with h at the same rate.)

The first-order accurate upwind treatment of convection leaves its signature in the truncation error of the outflow problem (Table 3). As was demonstrated in [16], second-order convergence can be recovered in the overall method by improving A to second order while leaving the preconditioner B unchanged. This is a very convenient compromise from the point of view of practical computing, since the preconditioner is more complex to code and the application of its inverse consumes a higher proportion of the execution time than does the forward application of the original operator. The results are shown in Table 5, the first-order part of which is repeated from Table 3 for convenient comparison.

We observe that the higher-order discretization of A is not "free," in that both the iteration count and the cost per iteration are increased. However, the truncation accuracy increases more rapidly, so that the computational cost to achieve a given accuracy is less with the higher-order method. Fortuitously, a direct example of this advantage is obtained by comparing the second row of the first-order method with the first row of the second-order method. In both cases, $\|e\|_\infty$ is 4.15×10^{-1} (approximately 1.2 percent of $\|u\|_\infty$), and the number of iterations is nearly identical as well. The second-order method achieves this result with one-quarter of the gridpoints and one-half of the execution time, however. Second-order convergence of the sup-norm in h is clearly visible in the right-hand set of columns.

TABLE 5

Number of unknowns N, sup-norm of the error e, iteration count I, and execution time T (sec) for the outflow problem, for first-order and second-order upwind finite differences.

		First-order upwind			Second-order upwind		
h^{-1}	N	e	I	T	e	I	T
32	833	7.35 (−1)	19	1.2	4.15 (−1)	24	2.1
64	3201	4.15 (−1)	23	4.2	9.59 (−2)	29	9.0
128	12545	2.19 (−1)	29	27.0	2.10 (−2)	34	53.0

These examples show that global h-type refinement can be synergistically combined with singularity fitted and mixed-order discretizations of A and B. Local h-type refinement can also be so combined; however, full exploitation of discretization improvements places a greater burden on automatic refinement algorithms.

4.2. Adaptivity and parallel load balance. To prevent the parameter space from growing unwieldy as multiple processors are added and parallel performance is studied, we focus on the diffusion problem ($c = 0$) alone. Overall conclusions based on studies of the inflow and outflow problems are similar, however. Since our attention is not on truncation error in these tests, we relax our convergence tolerance to a level more typical of an intermediate step in a sequence of nonlinear iterations: we enforce a relative reduction of 10^{-5} in the residual.

In the first set of tests we fix the number of tiles and vary the maximum level of refinement, h^{-1}, and the number of processors, p ($= 2^k$). In Tables 6 and 7, we present separately the time spent on preprocessing ("factor," predominantly factorizing the interior $\tilde{A}_I$ and crosspoint B_C blocks) and the time spent on the GMRES iteration ("solve," which includes the application of the preconditioner in factored form). Actual times are shown for $p = 1$; for $p > 1$ we show T_1/T_p, where T_p is the maximum time reported by any of the p processors. For the Encore Multimax, efficiencies (namely, the tabulated speedups divided by the number of processors) at $p = 16$ range from 21 percent to 48 percent in the preprocessing, and from 33 percent to 51 percent in the solution. For the Intel iPSC/860, efficiencies at $p = 16$ are worse: from 24 percent to 34 percent in the preprocessing, and from 15 percent to 21 percent in the solution. With its large ratio of communication to computation rates, the Intel iPSC/860 is not a very well balanced machine for problems with relatively small tiles. On the earlier Intel iPSC/2-SX, efficiencies of up to 50 percent, comparable to the shared-memory Multimax, were achieved.

TABLE 6

16	4.20	2.38	5.44	3.34	3.76	3.16

The tests used eight tiles along one of the long edges of Ω (as in Fig. 1) and a "level 0" global resolution of $h^{-1} = 32$ (as in the first rows of Tables 1 through 3). The unrefined cases therefore employ 48 tiles, each 4×4. The uniformity at level 0 makes load balancing trivial (modulo boundary effects) for $p = 1, 2, 4, 8$, and 16, all of which evenly divide 48. However, the small size of each tile means short threads between synchronization points and intrinsic parallel inefficiency resulting from data exchanges and sequential data dependencies in the crosspoint equation solution are revealed. At level 1, there are 20 tiles of size 8×8 and 28 of size 4×4. The relatively better utilization of multiple processors at this level is due to the longer purely arithmetic threads of computation on the 8×8 tiles, which overcome a modest degree of load imbalance. At level 2, 3 of the 20 refined tiles at the previous stage are further refined to 16×16. Since there are few of these largest problems, load balance is much more distorted, but speedups still occur up to 16 processors. Load imbalance shrinks the "paydirt" region of parameter space for local uniform refinement in the parallel setting. For a problem in the small tile-to-processor ratio regime, which would otherwise lead to a lumpy work distribution, a certain amount of extra (numerically unnecessary) refinement, padding out the work distribution, is "free." The extra storage it requires is presumed available on a homogeneous distributed-memory array, the extra data movement is likely to be masked by comparably sized messages, the solution of the crosspoint system is independent of the degree of refinement, and the algebraic convergence rate is likewise unaffected.

The parallel efficiencies quoted above are not impressive, but the usual motivation for large-scale algorithm design is rapid solution, not linear speedup. Tables 8 and 9 pertain to the same diffusion problem at a finer resolution ($h^{-1}=128$) for a variety of tile sizes and processor numbers. In these tables, we show in three-column groups the speedups for the factorization and solution phases of the algorithm and the absolute execution times for the total run. In Table 8 all tiles are uniform, while in Table 9, the tiles near the corner of the L-shaped domain are refined to level 1. Note that all five sets of columns in both tables solve the original PDE to nearly identical levels of truncation error; therefore, the total execution times can be compared directly to determine the best "bottom line" discretization/decomposition/parallelization combination. To facilitate such comparisons, we present the unreduced "Total" timings alongside the speedups for each phase.

The best speedups in both tables are for the coarsest tessellations (48 tiles). These have the sparsest crosspoint systems and the largest tiles, and hence the smallest

TABLE 8

communication-to-computation ratios. However, among the cases in Table 8, the most parallel-efficient is not the fastest, at any number of processors. The intermediate tessellation in Table 8 gives the best wall-clock times, in spite of mediocre efficiency. The last set uses tiles that are too small, and it is choked by the large crosspoint system. In terms of total execution time, this is the worst case. Similar findings were made in [11] for a variety of convection-diffusion problems solved on a uniprocessor: the optimum granularity of tessellation (for a two-scale preconditioner with exact subdomain solves) occurs between the extremes of many small tiles (dominated by the crosspoint system) and few large tiles (dominated by the interior systems).

Among the locally refined cases in Table 9, the preferred tessellation is different at different numbers of processors, as a result of the interaction of load imbalance with communication-to-computation ratio. It is interesting to observe that the best time for this problem, 0.34*s*, is within 15 percent of the best time on the globally refined problem of the same effective resolution, though the number of unknowns involved is over 40 percent less. Load imbalance resulting from a small tile-to-processor ratio takes away from the advantage of local refinement in parallel.

Finally, we investigate differences between the work estimate and the wrap mappings of tiles to processors. This study is presented for a level-1 refinement at the upper end of the problem sizes we have tested in two dimensions. In Tables 10 and 11 we consider the L-shaped diffusion problem on the iPSC/860 for effective resolutions of $h^{-1} = 256$ and $h^{-1} = 512$ on 768 tiles with up to 64 processors. Since the largest problem does not fit onto a single processor, absolute speedup data are not available, and we report relative speedups with each doubling of processors ($T_p/T_{p/2}$) under the "Factor" and "Solve" headings.

TABLE 10

Number of unknowns N, iteration counts I, execution times (italic), and relative parallel speedups for the tile algorithm based on the work-estimated tile-to-processor mapping.

	768 tiles 4×4 or 8×8			768 tiles 8×8 or 16×16		
N	25,969			103,201		
I	10			12		
p	Factor	Solve	Total	Factor	Solve	Total
1	*0.90s*	*5.76s*	*6.66s*	—	—	—
2	1.44	1.16	*5.61s*	—	—	—
4	1.30	1.75	*3.32s*	*1.74s*	*7.87s*	*9.60s*
8	1.15	1.51	*2.29s*	1.67	1.74	*5.57s*
16	1.11	1.44	*1.67s*	1.47	1.65	*3.44s*
32	1.05	1.29	*1.36s*	1.36	1.49	*2.36s*
64	1.03	1.17	*1.21s*	1.18	1.31	*1.84s*

We observe that neither the work estimate nor the wrap mapping is systematically better than the other. It is noteworthy that as simple a scheme as wrap mapping competes as well as it does with a first attempt at a work estimation scheme. Both schemes suffer from an interesting nonmonotonicity in relative speedup versus *p* in going from one to two processors. We attribute this to poor tile-processor locality; that is, tiles have neighbors in different processors in numbers substantially greater

TABLE 11

64	1.04	1.12	*1.16s*	1.21	1.33	*1.81s*

than an optimal decomposition would require. As the number of processors increases, the amount of off-processor intertile data traffic does not decrease, but more of it can be overlapped in the larger number of communication channels available.

Finally, we report breakdowns of the factorization and solution times. For the factorization phase of the largest problem on 64 processors under the work estimate-based mapping, 79 percent was devoted to factoring the crosspoint system, 20 percent to the subdomain interior systems, and 1 percent to the interface systems. Of the time required to iterate it to convergence, 49 percent was spent solving the crosspoint system, 15 percent solving the interior systems, and 1 percent solving the interface systems. The remaining solution time went into the work of the GMRES algorithm apart from the inner products (23 percent), the inner products themselves (8 percent), and the application of A to a vector (4 percent). Execution rates are of interest as measures of compatibility of the software and the machine hardware and architecture, though they reveal little about the appropriateness of the algorithm itself. On the 64 processor run, 362 Mflops (5.7 Mflops per node) were achieved in the interior block factorization step, 271 Mflops in the interior solution steps, and 210 Mflops in the matrix-vector multiply with the A matrix. At the other end of the performance spectrum, the crosspoint factorization garnered only an aggregate 5.3 Mflops and the crosspoint system solution only 2.0 Mflops. The crosspoint system contributes to a substantial per-tile communication overhead, the penalty of which we look forward to reducing through faster communication and perhaps better algorithms. So-called asynchronous algorithms, allowing simultaneous solution of crosspoint and interior systems *within a single iteration step* represent one possibility. The high quality preconditioning resulting in only 12 iterations to solve an elliptic problem with 103,201 unknowns depends crucially on the crosspoint system.

5. Summary and shopping list. We conclude with some brief assessments of the state of parallel domain decomposition algorithms.

The potential advantages of domain-decomposed preconditioned iterative methods for PDE problems with complex geometry, adaptive refinement requirements, and vast numbers of unknowns are clear. A two-level preconditioner that includes a global crosspoint solve is capable of maintaining good conditioning, thus providing good algebraic convergence and preserving the usefulness of double-precision computer arithmetic in the context of very large problems. The key features to be addressed in a parallel implementation are the inefficiency of the crosspoint solve itself and load imbalance and data locality in tile-to-processor mapping.

The communication-intensive crosspoint system is the single largest consumer of time in both the preprocessing and iteration phases, when the number of tiles is sufficiently large; and a large number of tiles is often required to realize the advantages of the method in complex geometry and adaptive refinement contexts. Thus, the distributed solution of sparse matrix problems should remain the focal point of research that it is today. It is the importance of having a conveniently structured crosspoint system that keeps us from a much looser framework for our tessellations. This issue is described in greater detail in [11]. A preconditioner based only on nearest neighbor interactions would impose almost no rules on the topology of the decomposition, but the deterioration in convergence rate in the many tile limit would eventually become unacceptable, and no further useful parallelism could be found without subdividing the tile.

It is important to gain experience with domain decomposition algorithms in three-dimensional problems, since this is the true province of promise for parallel computing. Motivated by the fact that a two-level hierarchical preconditioner with crosspoint basis functions that are merely coarsened versions of the fine-grid basis functions cannot lead to (near) optimal convergence in three dimensions as it does in two, pioneering works [2], [6], [17] (see also [7]) considered preconditioners with greater coarse-grid implicitness requiring sequential computations on data associated with the full "wire basket" of the decomposition. A recent theoretical work written with an eye toward parallelism in three-dimensional applications is the doctoral thesis of Smith [22]. In it Smith presents an algorithm valid in two or three dimensions in which the coarse and multiple fine-grid problems can be attacked simultaneously.

Load imbalance can seriously detract from the parallel performance of an adaptive algorithm. It is desirable to have mapping algorithms that are superior to the simple ones employed herein, but they obviously must not be so complex as to begin to dominate the total execution time themselves. Attention to the processor locality of frequently cooperating (i.e., neighboring) tiles could also yield important dividends, depending on the architecture.

Tile subdivision and the clustering of homogeneously refined tiles into larger rectangular patches (meta-tiles) break the connection between the parallel data structure granularity and the crosspoint system dimension. These are two extensions that we have only begun to investigate, although their promise is considerable. Neither would necessarily replace the indivisible heterogeneous tile algorithm evaluated herein; rather, they would generalize it to move into parallel realms beyond moderate granularity MIMD. Tile subdivision accommodates numbers of processors larger than the maximum useful size of the crosspoint system. Homogeneous tile clustering for all algorithmic phases other than the multilevel preconditioning accommodates vector nodes in an MIMD array or in vector-like SIMD clusters within an MIMD array, the latter hybrid architectures being likely for massively parallel supercomputers because of their cost-effective use of the silicon.

OPTIMAL MULTILEVEL ITERATIVE METHODS FOR ADAPTIVE GRIDS*

WILLIAM F. MITCHELL†

Abstract. Many elliptic partial differential equations can be solved numerically with near optimal efficiency through the uses of adaptive refinement and multigrid solution techniques. This paper presents a more unified approach to the combined process of adaptive refinement and multigrid solution which can be used with high order finite elements. Refinement is achieved by the bisection of pairs of triangles, corresponding to the addition of one or more basis functions to the approximation space. An approximation of the resulting change in the solution is used as an error indicator. The multigrid iteration uses red-black Gauss-Seidel relaxation with local black relaxations. The grid transfers use the change between the nodal and hierarchical bases. This multigrid iteration requires only $O(N)$ operations, even for highly nonuniform grids, and is defined for any finite element space. The full multigrid method is an optimal blending of the processes of adaptive refinement and multigrid iteration. To minimize the number of operations required, the duration of the refinement phase is based on increasing the dimension of the approximation space by the largest possible factor, given the error reduction of the multigrid iteration. The algorithm (i) uses only $O(N)$ operations, (ii) solves the discrete system to the accuracy of the discretization error, and (iii) achieves optimal convergence of the discretization error in the presence of singularities. Numerical experiments confirm this for linear, quadratic, and cubic elements.

1. Introduction. The efficient numerical solution of elliptic partial differential equations (PDEs) has been an important area of research in numerical analysis for several decades. Over the years, many new methods have been discovered in the areas both of discretizing the differential equation and of solving the discrete problem. While every method has restrictions on the subclass of problems to which it is applicable, the efficiency of the methods has increased manyfold since even the best solvers of 25 years ago. A thorough presentation of most practical methods is provided by Birkhoff and Lynch [7]. Additionally, the ELLPACK project [22] has provided us with robust software for many of these methods and a sound environment in which to perform numerical experiments to determine the relative merits of each method.

Today, we are at a point where many problems can be solved with near optimal efficiency. Many of the recent improvements have occurred through the uses of adaptive refinement, multigrid solution techniques, and parallelism. We will not consider parallelism here but concentrate on adaptive refinement and full multigrid solution. At first glance, the two concepts seem almost meant for each other. Each is a process that alternately performs phases of refinement and solution, with one concentrating on refinement and the other on solution. Yet, when examined more deeply, subtle difficulties arise in combining them. Most researchers who have attempted to join the two have maintained the individual structures of the two phases and then developed strategies to overcome the problems that emerge. It is our goal to develop a more unified approach to the combined processes of adaptive refinement and multigrid solution that is so natural that it becomes obvious how to extend these important

techniques to more complicated situations, such as with high order methods and for three-dimensional problems. This unification and extendability is achieved by interpreting the parts of the method from the viewpoint of the hierarchical basis, in which successive coefficients represent a change in the solution rather than the value of the solution. In particular,

(i) adaptive refinement is considered to be the selective enrichment of the approximation space by adding new basis functions, rather than the division of triangles or rectangles. Local relaxations that are identical to those of the multigrid iteration are performed with the addition of each new basis function. The choice of which basis functions to add is based on how much each potential new basis function will reduce the error and is determined by approximating the hierarchical coefficients. This computation uses the equations that will be added to the linear system when the space is enriched by this function, and is the same as the local relaxation.

(ii) the multigrid iteration is defined strictly in terms of the hierarchical basis and is not restricted to the approximation spaces we consider. Grid transfers are achieved through the change between nodal and hierarchical bases. Relaxations are performed in both the nodal and hierarchical bases, essentially supersaturating the approximation space with an excessive number of directions in which to minimize the error.

(iii) the full multigrid method is a very natural, optimal blending of adaptive refinement with multigrid iterations. The approximation space is enriched with as many new basis functions as is possible with respect to the error-reducing power of the multigrid iteration. This minimizes the number of operations used to obtain a solution whose accuracy is comparable with the discretization error.

The method is presented in the context of the second order selfadjoint elliptic problem

$$\begin{aligned} Lu &= (pu_x)_x + (qu_y)_y + ru = f \quad \text{in } \Omega \\ u &= g \quad \text{on } \partial\Omega \end{aligned} \tag{1.1}$$

where Ω is a polygonal domain in $\mathbf{R}^2$ and p, q, r, f, and g are functions of x and y. The Galerkin finite element method is used to discretize the problem over a triangular mesh which covers Ω exactly. The method will be developed for the higher order spaces of C^0 pth degree piecewise polynomials over triangles, where p is any given positive integer, but the usual space of continuous piecewise linear functions over the triangles will frequently be used for illustration purposes.

In § 2, the adaptive refinement aspect of the method is presented. Triangles are divided by bisection, similar to the bisection method of Rivara [24], [25] and identical to that of Sewell [27], [28], the difference between the two being in the method for determining which side of the triangle is to be bisected, the longest edge or the side opposite the newest vertex, respectively. Compatibility of the triangulation is maintained during the refinement process, rather than before, as in Sewell [27], [28], or after as in Rivara [24], [25] and Bank and Sherman [3], [4]. The error indicator uses the hierarchical basis to estimate the norm of the change in the solution invoked by dividing the triangle, similar to that proposed by Zienkiewicz et al. [32] for bilinear elements. The overall structure of the adaptive refinement algorithm is based on the division of a small number of triangles, rather than local refinement of the entire grid, to provide more control over how often multigrid iterations occur.

Section 3 presents and analyzes the multigrid iteration used to solve the linear system of equations. This multigrid uses a V-cycle, a restricted form of red-black Gauss-Seidel relaxation, and restriction and prolongation operators which arise naturally from the hierarchical basis. In the case of uniform grids the method is equivalent to that studied by Braess [8], [9], [10] and is related to the MGR methods [16], [23]. It is also very closely related to the hierarchical basis multigrid method recently developed by Bank, Dupont, and Yserentant [6], and to the composite grid methods of McCormick.

In § 4 a full multigrid method is presented to combine the adaptive refinement procedure with the multigrid iteration into a very efficient unified solution method that is easily extended to high order finite element spaces. The full multigrid method consists of alternately performing refinement and solution phases. Properties of the convergence of the discretization error are used to justify basing the frequency of solution phases, not on the levels of refinement, but on the increase in the number of nodes. Thus, the refinement phase continues until the number of nodes has been increased by some given factor. A formula is derived to determine how large this factor can be in terms of the error reduction factor of the multigrid iteration and the convergence rate of the discretization error for the finite element space being used.

In § 5, the results of numerical experiments are presented to demonstrate the performance of the method.

2. Adaptive refinement. The use of adaptive refinement to obtain a grid for the discretization of a partial differential equation has been the subject of much research in the past decade [2], [3], [14], [17], [18], [20], [25], [27], [32]. The idea is to automatically construct a grid that is coarse where the solution is well behaved, fine near singularities, boundary layers, etc., and has a smooth transition between the coarse and fine parts. Such a grid can dramatically reduce the number of nodes needed to obtain an accurate solution for marginally smooth problems, and can recover the optimal order of convergence for nonsmooth problems.

Triangle division. Central to any adaptive refinement algorithm for a finite element grid is a method for dividing (refining) the elements, triangles in our case. There are two major methods for dividing triangles in adaptive refinement algorithms. Regular division divides a triangle into four similar triangles by connecting the midpoints of the sides. Bank and Sherman [3], [4] show how to use a regular division in an adaptive refinement algorithm. Bisection division connects one of the vertices of the triangle to the midpoint of the opposite side. Two approaches are in use regarding the selection of the vertex to be divided. Rivara [24], [25] chooses the vertex opposite the longest edge. Sewell [27], [28] chooses the "newest" vertex. The method presented here, *newest vertex bisection*, is nearly identical to the method presented by Sewell. Much of the terminology of this section is due to Sewell.

In bisection division a triangle is divided to form two new triangles by connecting one of the vertices, called the *peak*, to the midpoint of the opposite side, called the *base*, as in Fig. 2.1. The original triangle is called the *parent*, and the two new triangles are called the *children*. The children are said to have *generation* $i+1$ where i is the generation of the parent. The initial triangle is assigned generation 1. The new vertex

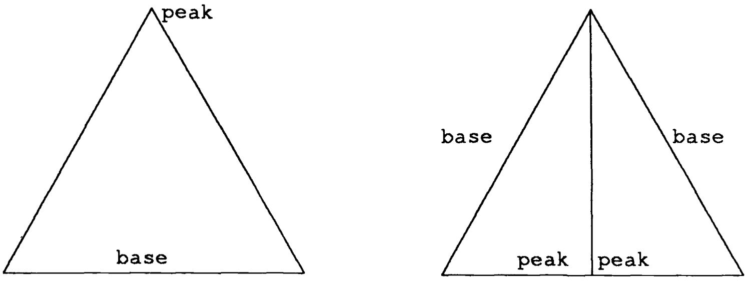

FIG. 2.1. *Propagation of the peak with newest node bisection.*

created at the midpoint of the base is assigned to be the peak of the children, hence the name *newest vertex bisection.*

It is easily shown that only four similarity classes of triangles [27] and only eight distinct angles [19] are created by this method, so the angles satisfy the important condition of being bounded away from 0 and π [1], [15].

Compatibility. One of the difficulties in adaptive refinement is that of maintaining compatibility of the triangulation. A triangulation is said to be *compatible* if for any two triangles t_i and t_j, $t_i \cap t_j$ is either empty, a common vertex, or a common side. In other approaches, some set of triangles with large error indicators is divided, producing an incompatible triangulation, and then a second process is performed to regain compatibility by dividing more triangles. In the approach that follows, compatibility is maintained *during* the refinement process, by dividing *pairs* of triangles rather than individual triangles, eliminating the need for a separate follow-up process to recover compatibility.

A triangle is said to be *compatibly divisible* if its base is either the base of the triangle that shares that side or part of the boundary of the domain. If a triangle is compatibly divisible, then divide the triangle and the neighbor opposite the peak (if such a neighbor exists) simultaneously as a pair. If a triangle is not compatibly divisible, then after a single bisection of the neighbor opposite the peak, it will be. So in this case, first divide the neighbor by the same process, and then divide the triangle and neighbor opposite the peak simultaneously. This is illustrated in Fig. 2.2. This leads to the recursive Algorithm 2.1, which is easily implemented in FORTRAN by constructing a stack of the triangles that need to be divided. It is easily seen that the length of the recursion is bounded by the generation of the triangle, since the generation of the triangles decrease with each recursive call. It can be shown [19] that it is always possible to assign peaks to the initial triangulation so that every triangle is compatibly divisible.

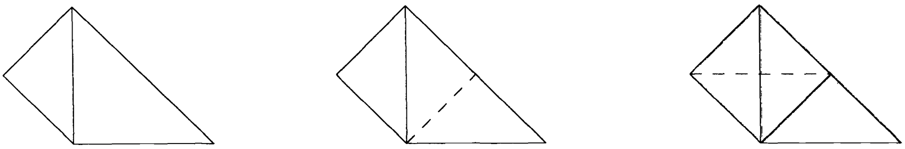

FIG. 2.2. *Maintaining compatibility during refinement.*

```
ALGORITHM 2.1. divide_triangle($t$)
  if $t$ is not compatibly divisible then
    divide_triangle(neighbor of $t$ opposite peak)
  endif
  divide the triangle pair $t$ and the neighbor opposite the peak of $t$
  return
```

Error indicator. Another critical element of any adaptive refinement algorithm is the error indicator, which is used to determine which triangles should be divided. Several good error indicators have been proposed [2], [3], [5], [23], [32]. Most of these are based on estimating the discretization error over each triangle. A slightly different approach is obtained by attempting to determine which admissible basis functions would reduce the discretization error the most. This becomes a type of error indicator for *pairs* of triangles. Mitchell [18] surveyed several error indicators and triangle division methods and compared them in a numerical experiment. He found that, among the methods considered, there is no universally "best" adaptive refinement method, and that most of the methods performed approximately the same. The method described here performed well in that experiment. This method is similar to that proposed by Zienkiewicz et al. [32] for bilinear rectangular elements. Interpretation in terms of hierarchical bases makes it possible to define this error indicator for any finite element space. It will be presented for the spaces of C^0 pth degree polynomials over bisected triangles, considering first linear elements, and then extending to arbitrary degree.

Instead of attempting to divide the triangles over which the error is the largest, attempt to divide the triangles whose division makes the greatest change in the solution. Since this change in the solution reduces the error, it is an attempt to divide the triangles that make the greatest reduction in the error, i.e., reduce the error the fastest for the number of divisions performed.

To approximate how much of a change in the solution will occur, use the hierarchical basis, defined in § 3. For what follows it suffices to know that when a function is expanded using the hierarchical basis, the coefficients represent displacements rather than nodal values as with the usual nodal basis, i.e., the coefficient of a hierarchical basis represents how much change occurs in the approximating function when the grid is refined by adding the new node.

The division of a pair of triangles, as in Fig. 2.3, by newest vertex bisection corresponds to the addition of one new basis function. Let v_i and ϕ_i, $i=1$, 2, 3, and 4 be the vertices of the triangles and corresponding hierarchical basis functions, and v_5 and ϕ_5 be the new vertex and basis function. To approximate how much change would occur if this division were to be performed, approximate the coefficient of ϕ_5, α_5, by assuming that α_i, the coefficients of ϕ_i, remain unchanged for $i=1$, 2, 3 and 4. Then

$$\alpha_5=\left((f,\phi_5)-\sum_{i=1}^{4}\alpha_i\langle\phi_i,\phi_5\rangle\right)\Big/\langle\phi_5,\phi_5\rangle \tag{2.1}$$

where $\langle\cdot,\cdot\rangle$ and $(\cdot,\cdot)$ are the usual inner products used to obtain the stiffness matrix and load vector, respectively, and f is the right-hand side of the differential equation. If $\|\cdot\|$ is the energy norm defined by $\|u\|^2=\langle u,u\rangle$, $\|\alpha_5\phi_5\|^2$ is the amount by which the square of the energy norm of the error is reduced by adding $\alpha_5\phi_5$ to the approximate solution. $\|\alpha_5\phi_5\|$ is the error indicator for this pair of triangles.

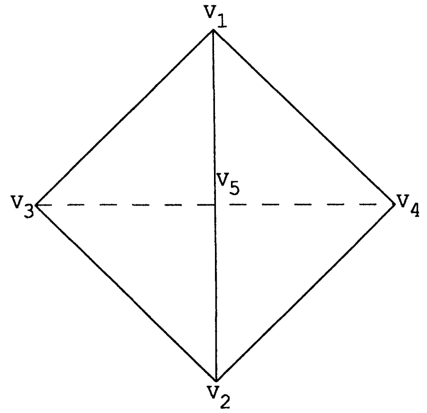

FIG. 2.3. *Triangle pair for error indicator.*

The extension of this error indicator to C^0 pth degree polynomials is straightforward. The only difference is that there are p^2 new basis functions rather than just one, so the amount of change depends on more than one basis function. Equation (2.1) is replaced by a linear system of p^2 equations in p^2 unknowns. This system can be solved by Cholesky decomposition in an acceptable number of operations, and one can compute $\|\sum \alpha_i\phi_i\|$, where the sum is over the p^2 new nodes associated with the prospective new vertex. Clearly this error indicator can be further extended to any finite element space with a hierarchical basis.

Refinement process. Given the error indicators for every triangle (or pairs of compatibly divisible triangles), one would ideally want to select the next triangle to divide by choosing the triangle with the largest error indicator. However, for an algorithm to use only $O(N)$ operations it is imperative that the selection of the next triangle to divide requires only $O(1)$ operations. This means that there is not enough time to search every triangle to find one with the largest error indicator. Instead, a triangle whose error indicator is close to the largest will be selected.

Let e be the largest error indicator at the beginning of the refinement phase. Partition the triangles (only including one triangle from each pair of compatibly divisible triangles) into Q sets such that each set contains all the triangles whose error indicators fall in a certain range. Specifically, for a given $0<c<1$, a triangle is in the qth set if and only if its error indicator is between $c^{q-1}e$ and $c^q e$ for $1 \leqq q \leqq Q-1$ and is in the Qth set if its error indicator is less than $c^{Q-1} e$. The first set contains all the triangles whose error indicator is larger than ce, and any one of these triangles can be selected as the next triangle to be divided. The selection of c and Q will determine the precision with which the correct triangles are selected. Mitchell [19] recommends $Q=4$ and $c=f^{-\alpha-1/2}$, where f is the factor by which the number of nodes is increased during the refinement phase, and α is the rate of convergence of the energy norm of the discretization error.

Combining the material presented in this section into an adaptive refinement algorithm results in the rather simple looking Algorithm 2.2. What is meant by "enough refinement" will be discussed in § 4. The actual process of dividing a triangle involves several steps which redefine the grid, change the linear system, provide a first approximation to the solution and update error indicators. The details of these steps are presented in [19]. Algorithm 2.3 summarizes the process.

```
ALGORITHM 2.2. Adaptive refinement
  repeat
    determine which triangle to divide
    divide the triangle
  until enough refinement has occurred
```

```
ALGORITHM 2.3. Divide triangle pair
  change grid specification
  add new equation(s) to the linear system
  change other affected equations
  block relaxation for new nodes
  Gauss-Seidel point relaxation for neighboring old nodes
  compute error indicators for new triangles and neighboring triangles
```

3. Multigrid solution. The multigrid method [11], [12], [29] has recently been established as perhaps the most efficient method for solving the linear systems that arise from the discretization of differential equations. The popularity of this method can be attributed to the fact that it is optimal in the sense that one multigrid iteration can reduce the norm of the error of the approximate solution of the linear system by a factor that is bounded away from 1 independent of N, the size of the linear system, while using only $O(N)$ operations. This section presents and analyzes a multigrid iteration suitable for the linear systems that arise from using the finite element method with low or high order bases on the triangulations generated by the adaptive refinement algorithm of § 2. In the special case of linear elements, uniform grids and certain domains, the method is equivalent to that studied by Braess [8], [9], [10] and the MGR methods [16], [23]. The method will be developed in terms of hierarchical bases from which it will be easy to extend the method to nonuniform grids, more general domains and high order bases.

Hierarchical bases. The use of hierarchical bases for finite elements has been considered by Zienkiewicz et al. [32]; Yserentant [30], [31]; Craig and Zienkiewicz [13]; and Bank, Dupont, and Yserentant [6]. The usual nodal basis, $\{\phi_i\}_{i=1}^N$, for a space of piecewise polynomials can be defined on a given grid by

$$\phi_i=\begin{cases}1 & \text{at node } i\\ 0 & \text{at all other nodes.}\end{cases}$$

In contrast, the hierarchical basis is defined using the family of nested grids, $\{T_i\}_{i=1}^L$, from the refinement process. The hierarchical basis begins with the nodal basis on the initial grid, T_1. As refinement proceeds, with each division one or more new nodes are added, and for each node a new basis function is defined so that it has the value 1 at the new node and 0 at all other nodes, *but the existing basis functions remain unchanged.* The *level* of a basis function is the same as the generation of the elements created when the basis function is added, i.e., higher level basis functions refer to those associated with smaller elements.

A *2-level hierarchical basis* can also be defined by starting with the nodal basis for the grid T_{L-1} and defining the higher level basis functions as above. The superscripts (N), (H), and (2) are used to indicate which basis is in use. Thus, $\phi_i^{(\mathrm{N})}$, $\phi_i^{(\mathrm{H})}$, and $\phi_i^{(2)}$ represent basis functions from the nodal, hierarchical, and 2-level bases, respectively.

Any function f that lies in the space of piecewise polynomial functions on T_L has an expansion in terms of any of the bases. Forms of α are used to denote the coefficients in this expansion. Thus

$$f=\sum_{i=1}^{N}\alpha_i^{(\mathrm{N})}\phi_i^{(\mathrm{N})}=\sum_{i=1}^{N}\alpha_i^{(\mathrm{H})}\phi_i^{(\mathrm{H})}=\sum_{i=1}^{N}\alpha_i^{(2)}\phi_i^{(2)}.$$

Conversion between bases is a linear process. S denotes the matrix that converts the coefficient vector of the hierarchical basis to the nodal basis, thus $\alpha^{(\mathrm{N})}=S\alpha^{(\mathrm{H})}$ and $\alpha^{(\mathrm{H})}=S^{-1}\alpha^{(\mathrm{N})}$. S_l denotes the conversion from the 2-level basis to the nodal basis on an l level grid. If the rows and columns of S_l are ordered such that rows corresponding to nodes of the same level are grouped together with lower level rows first, and S_l is partitioned into two parts corresponding to levels 1 through $l-1$ and level l, then S_l has the form

$$S_l=\begin{bmatrix}\mathrm{I} & 0\\ s & \mathrm{I}\end{bmatrix}$$

and

$$S_l^{-1}=\begin{bmatrix}\mathrm{I} & 0\\ -s & \mathrm{I}\end{bmatrix}$$

where $s_{ij}=\phi_j^{(2)}(x_i, y_i)$ and x_i and y_i are the coordinates of the ith node. Conversion between bases amounts to multiplying a vector by S_l or S_l^{-1}. If N_{l-1} is the number of nodes in the first $l-1$ levels

$$\alpha_i^{(\mathrm{N})}=\begin{cases}\alpha_i^{(2)} & \text{if node } i \text{ does not have level } l\\ \alpha_i^{(2)}+\sum\limits_{j=1}^{N_{l-1}}\phi_j^{(2)}(x_i, y_i)\alpha_j^{(2)} & \text{if node } i \text{ has level } l.\end{cases}$$

With newest vertex bisection refinement and pth degree piecewise polynomials, there are at most $(p+1)^2$ nonzeros in the sum. Moreover, the value of $\phi_j^{(2)}(x_i, y_i)$ depends only on p and the relative placements of nodes i and j in the same triangle, and is independent of the triangle shapes and sizes, problem being solved, etc. Thus a small $((p+1)^2\times p^2)$ table of these values can be constructed to be used whenever a basis change is desired.

To multiply a vector by S_l^{T} and $S_l^{-\mathrm{T}}$ the value of $\alpha_i^{(2)}$ is distributed over neighboring nodes when node i has level l, rather than collecting values from the neighboring nodes. The process of multiplying by S_l and S_l^{T} is summarized in Algorithm 3.1 and Algorithm 3.2. Here s_{ij} represents $\phi_j^{(2)}(x_i, y_i)$. Multiplication by S_l^{-1} and $S_l^{-\mathrm{T}}$ are the same but with $+s_{ij}$ changed to $-s_{ij}$.

```
ALGORITHM 3.1. Multiply $\alpha$ by $S_l$
  for each node $i$ with level $l$
    for each neighbor $j$ of $i$ with level $<l$
      $\alpha_i \leftarrow \alpha_i + s_{ij}\alpha_j$
    next $j$
  next $i$
```

```
ALGORITHM 3.2. Multiply $\alpha$ by $S_l^{\mathrm{T}}$
  for each node $i$ with level $l$
    for each neighbor $j$ of $i$ with level $<l$
      $\alpha_j \leftarrow \alpha_j + s_{ij}\alpha_i$
    next $j$
  next $i$
```

As with S, the rows and columns of the stiffness matrix, A, are ordered so that rows corresponding to nodes of the same level are grouped together, and smaller levels come first. The stiffness matrix will be called the *nodal matrix* or *hierarchical matrix* when we need to indicate which basis is in use. Yserentant [31] showed that the hierarchical matrix can be obtained from the nodal matrix by $A^{(\mathrm{H})}=S^{\mathrm{T}}A^{(\mathrm{N})}S$. Algorithm 3.3 shows how to change the basis of the matrix from nodal to 2-level.

```
ALGORITHM 3.3. Replace $A$ by $S_l^{\mathrm{T}}AS_l$
  for each node $i$ with level $l$
    for each neighbor $j$ of $i$ with level $<l$
      row $j \leftarrow$ row $j + s_{ij}$ * row $i$
      column $j \leftarrow$ column $j + s_{ij}$ * column $i$
    next $j$
  next $i$
```

Relaxation operator. The basis of the relaxation operator is the red-black Gauss-Seidel iteration. The red phase is done first, where the red nodes are those that are in the current grid, but not in the next coarser grid. ν_1 iterations of the relaxation operator are performed before coarse grid correction and ν_2 iterations after, allowing ν_1 and ν_2 to be multiples of $\frac{1}{2}$, where half an iteration means only the red phase. Bank, Dupont, and Yserentant [6] use $\nu_1=\nu_2=\frac{1}{2}$, i.e., they perform relaxations at the red nodes only. This V-cycle is equivalent to a symmetric Gauss-Seidel iteration using the hierarchical matrix. The condition number of the hierarchical matrix is $O(L^2)$, where L is the number of refinement levels [30], [31]. Since $L \geqq \log N$ and the number of Gauss-Seidel iterations depends on the condition number, their method requires at least $O(\log N)$ iterations to reduce the error by a given factor. To overcome this difficulty, use $\nu_1=\frac{1}{2}$ and $\nu_2=1$ by adding in relaxation at the black nodes after the coarse grid correction. This is a special case of the values of ν_1 and ν_2 considered by Braess [10]. He uses $\nu_1=\nu_2-\frac{1}{2}$, but performs the black phase first if ν_1 is an integer. Braess shows that by using $\nu_1=\frac{1}{2}$ and $\nu_2=1$, the V-cycle reduces the error by at least a factor of .5 independent of N for certain convex polygonal domains. Strong evidence is provided later in this section that for a square domain and uniform grid, the error is reduced by a factor of at least .125.

While the use of red-black Gauss-Seidel with $\nu_1=\frac{1}{2}$ and $\nu_2=1$ is an effective relaxation operator for uniform grids, it presents a problem with nonuniform grids, because the number of nodes might not grow exponentially with the number of levels. Suppose that the number of new nodes in each level, n_l, grows polynomially, i.e., $n_l=O(l^{p-1})$ for some power $p \geqq 1$. Then the total number of nodes in each level, N_l, satisfies $N_l=O(l^p)$. The number of operations used for relaxation with $\nu_1=\frac{1}{2}$ and $\nu_2=1$ is

$$\sum_{l=1}^{L} O(l^{p-1})+\sum_{l=1}^{L} O(l^p)=O(L^{p+1})=O(N_L^{1+1/p}).$$

This can be as bad as $O(N_L^2)$, which is unacceptable. To overcome this problem, the amount of relaxation performed must be restricted so that the number of operations used for the relaxation on one grid is proportional to the number of red nodes in that grid, not the total number of nodes. To achieve this, Bank, Dupont, and Yserentant perform the relaxation only at the red nodes. However, as noted earlier, this restriction is too strong and destroys the N-independence of the convergence. We propose the weaker restriction of performing the black phase only at black nodes that are immediate neighbors of red nodes. We call this *local black relaxation.* Since each red node has at most four black neighbors, the number of operations in the relaxation is proportional to the number of red nodes.

The relaxation operator is easily extended to higher order finite elements with only one minor change. To be specific, consider the spaces of C^0 pth degree polynomials over triangles. The difference for the higher order spaces is that the basis functions of the same level are not mutually orthogonal, as with the linear basis, so a simple red phase of red-black Gauss-Seidel does not solve the subsystem exactly. However, for the spaces considered, the submatrix is block diagonal with blocks of size p^2, so the subsystem can still be solved exactly by solving many small systems. For high order finite elements the bisection of a pair of triangles adds one new vertex, p^2 new nodes and p^2 new basis functions. These new nodes are the red nodes in the relaxation. Note that there are $(p+1)^2$ black nodes associated with each group of p^2 red nodes as illustrated in Fig. 3.1. The p^2 basis functions associated with the new vertex are not orthogonal to each other, but are orthogonal to all other basis functions of the same level, hence the block diagonal structure of the submatrix. Since the size of the symmetric positive definite diagonal blocks depends only on p, these small subsystems can be solved using Cholesky decomposition in a constant (with respect to N) number of operations and the $O(N)$ operation count for relaxation is maintained. Algorithms 3.4 and 3.5 give the red and black relaxation algorithms, respectively.

Transfer operators. The other main parts of a multigrid algorithm are the two transfer operators, which are used to move between fine grids and coarse grids. The restriction operator $\mathrm{I}_{\mathrm{f}}^{\mathrm{c}}$ transfers the problem from the fine grid to the coarse grid and the prolongation operator $\mathrm{I}_{\mathrm{c}}^{\mathrm{f}}$ transfers the problem from the coarse grid to the fine grid. The transfer operators proposed turn out to be those of the Galerkin approach [29]. In this approach the restriction and prolongation operators are adjoint and the coarse grid operator, A_{c}, is related to the fine grid operator, A_{f}, by $A_{\mathrm{c}}=\mathrm{I}_{\mathrm{f}}^{\mathrm{c}}A_{\mathrm{f}}\mathrm{I}_{\mathrm{c}}^{\mathrm{f}}$. In this presentation the change between the nodal and 2-level hierarchical bases is used to describe the transfer processes. Since the definition of the transfers depends only upon the basis change, this method applies to any finite element space with a hierarchical basis. The resulting operators are very natural and of the correct order of accuracy for the approximation space being used.

Let the nodal matrix for the linear system be

$$A=\begin{bmatrix} A_{11} & A_{12}^{\mathrm{T}} \\ A_{12} & A_{22} \end{bmatrix}$$

and the nodal solution vector and right side be $x=[x_1\ \ x_2]^{\mathrm{T}}$ and $b=[b_1\ \ b_2]^{\mathrm{T}}$, where the partition is such that the second part contains values corresponding to basis functions of the highest level. Let $\tilde{A}$, etc., be the corresponding entities using the 2-level basis, S be the matrix that converts from the 2-level basis to the nodal basis, and s be the lower left submatrix of S. From $\tilde{A}=S^{\mathrm{T}}AS$ and the equivalence of $Ax=b$ and $S^{\mathrm{T}}ASS^{-1}x=S^{\mathrm{T}}b$, it follows that $\tilde{x}=S^{-1}x$ and $\tilde{b}=S^{\mathrm{T}}b$. Since the lower level of the 2-level basis is the nodal basis of the coarse grid, $\tilde{A}_{11}$ is the nodal matrix for the coarse grid. To obtain the coarse grid problem, use the lower level part of the 2-level basis fine grid problem, i.e., extract the equations corresponding to the coarse grid nodes. This is

$$[\tilde{A}_{11}\ \ \tilde{A}_{12}^{\mathrm{T}}]\begin{bmatrix}\tilde{x}_1\\ \tilde{x}_2\end{bmatrix}=[\tilde{b}_1].$$

So the problem to be solved on the coarse grid is

$$\tilde{A}_{11}\tilde{x}_1=\tilde{b}_1-\tilde{A}_{12}^{\mathrm{T}}\tilde{x}_2.$$

This process is summarized in Algorithm 3.6. Recall that the algorithms for the basis changes were given earlier.

Algorithm 3.6. Restriction

```
$A \leftarrow S^{\mathrm{T}}AS$
$x \leftarrow S^{-1}x$
$b \leftarrow S^{\mathrm{T}}b$
$b_1 \leftarrow b_1 - A_{12}^{\mathrm{T}}x_2$
```

coarse grid problem is $A_{11}x_1=b_1$

From this derivation, it is not clear that this coarse grid problem is equivalent to the standard multigrid coarse grid problem, nor is it clear what the transfer operators are. In [19], an alternate derivation of this method is provided by using the Galerkin approach

$$(\mathrm{I}_{\mathrm{f}}^{\mathrm{c}}A_{\mathrm{f}}\mathrm{I}_{\mathrm{c}}^{\mathrm{f}})(\tilde{x}_1^{\mathrm{new}}-\tilde{x}_1^{\mathrm{old}})=\mathrm{I}_{\mathrm{f}}^{\mathrm{c}}(b-A_{\mathrm{f}}x^{\mathrm{old}})$$

with the transfer operators

$$\mathrm{I}_{\mathrm{f}}^{\mathrm{c}}=[\mathrm{I}\quad s^{\mathrm{T}}]\quad\text{and}\quad \mathrm{I}_{\mathrm{c}}^{\mathrm{f}}=\begin{bmatrix}\mathrm{I}\\ s\end{bmatrix}.$$

The prolongation process is simply to restore the part of the solution due to the high level basis functions and return the system back to the nodal basis. The changes made in x_1 by solving the coarse grid problem are carried into x_2 as corrections during the basis change $x\leftarrow S\tilde{x}$. The prolongation process is given in Algorithm 3.7.

Algorithm 3.7. Prolongation

```
$b_1 \leftarrow b_1 + A_{12}^{\mathrm{T}}x_2$
$b \leftarrow S^{-\mathrm{T}}b$
$x \leftarrow Sx$
$A \leftarrow S^{-\mathrm{T}}AS^{-1}$
```

This provides all the necessary components for a multigrid iteration. Algorithm 3.8 performs one V-cycle using $\nu_1=\frac{1}{2}$ and $\nu_2=1$. L is the number of levels in the grid. The exact solve on level 1 can be performed by Cholesky decomposition or a sufficient number of Gauss-Seidel iterations.

```

```

It is not sufficient to just know that a method requires only $O(N)$ operations; if the constant of proportionality is extremely large, the method is useless. Table 3.1 contains the asymptotic constants of proportionality for one multigrid iteration. It contains the constants for each part of the method, and for the complete V-cycle. In addition to the counts of the number of multiplications (equal to the number of additions) for each of linear, quadratic, and cubic elements, the count of the number of multiplications and additions for a specialized implementation of linear elements for Poisson's equation are provided, where one can take advantage of properties of the discrete operator.

Convergence of the multigrid iteration. In order to determine how many V-cycles are required to keep the *solution error* (the difference between the current solution vector and the exact solution of the discrete problem) of the same order as the *discretization error* (the difference between the exact solution of the discrete problem and the true solution of the continuous problem), it is necessary to know the factor by which one iteration reduces the error. In particular, the worst case reduction of the error in the energy norm is of interest, because the energy norm relates the error-reducing power of the multigrid iteration to the convergence of the discretization error through the orthogonality of the discretization error to the approximation space. This will be used in § 4.

Let V be the iteration operator for an l-level V-cycle, i.e., $e_{\text{new}} = Ve_{\text{old}}$, where e_{old} and e_{new} are the solution errors before and after the V-cycle, respectively. Let $\|\cdot\|$ be the energy norm defined by $\|x\|^2 = x^{\mathrm{T}}Ax$, where A is the stiffness matrix. Also let $\|\cdot\|$ denote the subordinate matrix norm. Define σ_l to be $\|V\|$, and σ, the *rate of convergence of the multigrid iteration*, to be $\sigma = \sup_{l \geqq 1} \sigma_l$. σ is a bound on the amount by which the energy norm of the error will be reduced by one V-cycle. The following proposition is proven in [19].

TABLE 3.1
Number of multiplications per node for the multigrid iteration.

	Poisson		Linear	Quadratic	Cubic
	mults	adds	elements	elements	elements
red relaxation	1	4	5	18	37 5/9

PROPOSITION 3.1. *Let x_0 not be orthogonal to the dominant eigenspace of $V^{\mathrm{T}}AVA^{-1}$, and $x_{i+1} = V^{\mathrm{T}}AVA^{-1}x_i$ for $i \geqq 0$. Then*

$$\lim_{i\to\infty} \frac{x_{i+1}^{\mathrm{T}}x_i}{x_i^{\mathrm{T}}x_i} = \|V\|^2.$$

As a consequence, σ_l can be computed numerically using the power method. The matrix V in Proposition 3.1 can be any linear operator, so this procedure can be used to compute the rate of convergence of both the V-cycle and the 2-grid iteration, which can be compared to the known theoretical 2-grid error reduction. Table 3.2 presents the theoretical and computed 2-grid iteration error reductions and the computed V-cycle error reduction. The computed 2-grid values agree with the theoretical values, and the V-cycle also appears to be bounded by $\frac{1}{8}$. Table 3.3 shows the reduction of the energy norm of the error by one V-cycle for linear, quadratic, and cubic elements. The rate of convergence slows as the order of the elements is increased, and σ is approximately .31 for quadratics and .38 for cubics.

4. Full multigrid with adaptive refinement. The multigrid iteration provides a method for reducing the error between the approximate solution and the exact solution of the discrete problem by a factor which is bounded away from 1 independent of N using $O(N)$ operations. From an arbitrary initial guess, however, it would take

TABLE 3.2

$O(\log N)$ iterations to reduce this error to the order of the discretization error. The *full multigrid method* provides a means to keep the solution error on the same order as the discretization error with $O(N)$ total operations. The basic idea of the full multigrid method [29] is to begin with a very coarse grid and alternately perform refinement and solution phases. At the end of each solution phase the solution error should be less than the discretization error.

For uniform grids, full multigrid is now a well-established method. The refinement phase consists of one uniform refinement of the grid (divide each triangle once) to obtain a grid of one level higher. This reduces the grid spacing h by a factor of $\sqrt{2}$ or 2, depending on the type of refinement used, and increases the number of nodes by about a factor of 2 or 4, respectively. Using linear elements and a refinement that cuts h in half as an example, the discretization error is cut in half. The solution phase must then perform enough cycles to cut the solution error at least in half, which can be done by a fixed number of cycles of the multigrid iterations. Since the number of nodes grows like 4^l where l is the number of levels, the total amount of work for this is about $\frac{4}{3}$ the amount of work done on the final grid, which is $O(N)$.

For adaptive grids, the number of nodes need not grow geometrically with the number of levels. If one used the full multigrid method the way it is used for uniform grids, the number of operations can be larger than $O(N)$. In the worst case where the number of nodes is proportional to the number of levels, the operation count is $O(N^2)$. In the usual approach used to overcome this [4], [26], the grid is refined to get one level higher, but if the number of nodes has not been increased by a factor of 2 or 4 (depending on the type of refinement used) the refinement is repeated rather than moving on to the solution phase. While this approach does result in an $O(N)$ algorithm, it does not flow smoothly, has unnecessary overhead in starting and ending refinements, and may overshoot the target increase factor of 2 or 4.

Since the basic step of the refinement of § 2 is the division of one pair of triangles and compatibility is always present, a more elegant approach to the full multigrid method can be taken. The refinement phase proceeds until the number of nodes has been increased by exactly some given factor f. Moreover, there is no reason for f to be the factor 2 or 4 from uniform refinement, so f can be any real number larger than 1. The solution phase consists of performing v V-cycles (multigrid iterations) where v is large enough to keep the solution error smaller than the discretization error.

The crucial missing element of the algorithm is a method for determining when to switch from one phase to the other, i.e., a way of determining reasonable values for f and v. The most efficient values of f and v in terms of α, the rate of convergence of the discretization error, and σ, the rate of convergence of the multigrid iteration, are determined in this section.

For uniform grids, the rate of convergence of the discretization error is usually given in terms of h, a measure of the size of the triangles. A method is said to have order 2α if the energy norm of the error decreases like $O(h^{2\alpha})$ as h gets small. For adaptively refined grids, h is not such a meaningful entity, but N can be used to measure the rate of convergence of the discretization error. For a uniform grid, $N = O(h^{-2})$ so the error decreases like $O(N^{-\alpha})$ as N gets large. Thus, α is said to be the *rate of convergence of the discretization error* if α is the largest value such that the discretization error is $O(N^{-\alpha})$, i.e., $\|u - u_N\| \sim cN^{-\alpha}$ for some constant c, where u is the true solution of the differential equation, u_N is the exact solution of the discrete problem with N nodes, and $\|\cdot\|$ is the energy norm. Normally, $\alpha = \frac{1}{2}$, 1, and $\frac{3}{2}$ for linear, quadratic, and cubic elements, respectively. Recall that σ is the rate of convergence of the multigrid iteration defined to be a bound on the factor by which the energy norm of the solution error is reduced in one V-cycle of the multigrid iteration, where the solution error is $\tilde{u}_N - u_N$ and $\tilde{u}_N$ is the approximate solution.

THEOREM 4.1. *Let α be the rate of convergence of the discretization error and f be the factor by which the refinement phase increases the number of nodes. Then, asymptotically, the solution error will remain less than the discretization error if the solution phase reduces the solution error by a factor of at least* $(2f^{2\alpha}-1)^{-1/2}$.

Proof. The true solution of the partial differential equation, u, lies in a Hilbert space $\mathbf{H}$ endowed with the energy inner product $\langle\cdot,\cdot\rangle$ and the subordinate energy norm $\|\cdot\|$. Let $\mathbf{S}_N \subseteq \mathbf{H}$ be the space of C^0 piecewise pth degree polynomials over the triangulation with N nodes, and $\mathbf{S}_{fN}$ be the space associated with the refined triangulation with fN nodes. $\mathbf{S}_N \subseteq \mathbf{S}_{fN}$ since the triangulation with fN nodes is a refinement of the triangulation with N nodes. Let u_N be the exact solution of the discrete problem in $\mathbf{S}_N$, i.e., u_N is the unique function in $\mathbf{S}_N$ such that $\langle u-u_N, w\rangle = 0\ \forall w \in \mathbf{S}_N$, and let u_{fN} be the exact solution of the discrete problem in $\mathbf{S}_{fN}$. Let $\tilde{u}_N$ be the approximate solution in $\mathbf{S}_N$. We assume that $\|\tilde{u}_N - u_N\| \leqq \|u-u_N\|$. We then wish to find a $\tilde{u}_{fN} \in \mathbf{S}_{fN}$ such that $\|\tilde{u}_{fN} - u_{fN}\| \leqq \|u - u_{fN}\|$ so that the solution phase will keep the solution error smaller than the discretization error.

From the definition of α, we obtain

$$\frac{\|u-u_{fN}\|}{\|u-u_N\|} \sim \frac{c(fN)^{-\alpha}}{cN^{-\alpha}} = f^{-\alpha}.$$

Thus $\|u-u_N\| \sim f^{\alpha}\|u-u_{fN}\|$.

Since $\tilde{u}_N \in \mathbf{S}_N$ and $\tilde{u}_N \in \mathbf{S}_{fN}$, we have the Pythagorean identities

$$\|\tilde{u}_N - u_N\|^2 + \|u-u_N\|^2 = \|\tilde{u}_N - u\|^2$$

and

$$\|\tilde{u}_N - u_{fN}\|^2 + \|u-u_{fN}\|^2 = \|\tilde{u}_N - u\|^2$$

and thus, using $\|\tilde{u}_N - u_N\| \leqq \|u-u_N\|$

$$\begin{aligned}\|\tilde{u}_N - u_{fN}\|^2 &= \|\tilde{u}_N - u_N\|^2 + \|u-u_N\|^2 - \|u-u_{fN}\|^2\\ &\leqq 2\|u-u_N\|^2 - \|u-u_{fN}\|^2\\ &\sim 2f^{2\alpha}\|u-u_{fN}\|^2 - \|u-u_{fN}\|^2\\ &= (2f^{2\alpha}-1)\|u-u_{fN}\|^2.\end{aligned}$$

Therefore, to insure that $\|\tilde{u}_{fN} - u_{fN}\| \leqq \|u-u_{fN}\|$ we must reduce the error $\|\tilde{u}_N - u_{fN}\|$ by a factor of $(2f^{2\alpha}-1)^{-1/2}$. □

COROLLARY. *For given α, σ and number of* V*-cycles v, f must be bounded by*

$$f \leqq \left(\frac{\sigma^{-2v}+1}{2}\right)^{1/2\alpha}.$$

Let $N_r = c_1 f^r$ be the number of nodes in the triangulation after r refinement phases, $c_2 N_r$ be the (asymptotic) number of operations used by one V-cycle on a triangulation with N_r nodes and the final triangulation be the result of R refinement phases. Then, the number of operations used by the full multigrid solution is

$$\sum_{r=1}^{R} vc_2N_r = \sum_{r=1}^{R} vc_2c_1f^r = vc_2c_1\frac{f(f^R-1)}{f-1} \sim v\frac{f}{f-1}c_2c_1f^R = v\frac{f}{f-1}c_2N_R.$$

For given v, the operation count is minimized by using the largest possible f. Thus one should choose $f = ((\sigma^{-2v}+1)/2)^{1/2\alpha}$. The most efficient choice of v is then given by the v that minimizes $v(f/(f-1))$ with this choice of f. Clearly, this is an increasing function of v when v is sufficiently large. Thus, for given α and σ, one can compute $v(f/(f-1))$ for a few small positive integer values of v to determine the most efficient choice for f and v. Usually, $v=1$ is best. Table 4.1 gives these values for linear, quadratic, and cubic elements. The last column contains the value of $v(f/(f-1))$. This represents the amount of work required with respect to one V-cycle on the finest grid, e.g., with quadratic elements the full multigrid is slightly faster than two V-cycles.

5. Numerical results. The method described in this paper has been implemented in a FORTRAN program to solve (1.1). Computations were performed on a Pyramid 90x with a floating point accelerator operating under the Pyramid Technology OSx 3.1 Operating System, which is a dual port of AT&T Bell Laboratories' System V Release 2.0 and the University of California, Berkeley's 4.2BSD. The Pyramid Technology Optimizing FORTRAN 77 compiler was used with single precision, which has about seven decimal digits.

Three sample problems were solved to demonstrate the method. The first two problems contain a singularity in the solution; the third problem illustrates a complicated differential operator.

Problem 1. Laplace's equation on the L-shaped domain of Figure 5.1(a) with the Dirichlet boundary conditions chosen so that the true solution is $r^{2/3}\sin(2\theta/3)$. Both x and y range from -1 to 1 and the reentrant corner is located at the origin. Figure 5.1(a) shows a sample adaptively refined grid with the initial six triangles in bold. The solution exhibits the leading term of the singularity due to the 270° reentrant corner.

Problem 2. Laplace's equation on the hexagonal domain of Fig. 5.1(b). The domain has a slit along the positive x axis. x ranges from -1 to 1 and y from $-\sqrt{3}/2$ to $\sqrt{3}/2$. The Dirichlet boundary conditions are chosen so that the true solution is $r^{1/2}\sin(\theta/2)$. The reentrant corner is located at the origin. Figure 5.1(b) shows a sample adaptively refined grid with the initial six triangles in bold. The solution exhibits the leading term of the singularity due to the 360° reentrant corner.

Problem 3. This is Problem 54 in the elliptic PDE population of Rice et al. [21], [22]. The differential equation is

$$((1+x^2)u_x)_x+((1+A^2)u_y)_y-(1+(8y-x-4)^2)u=f$$

on the unit square, where $A=4y^2+.9$. The right-hand side and Dirichlet boundary conditions are chosen so that the exact solution is

$$2.25x(x-A)^2(1-D)/A^3+1/(1+(8y-x-4)^2)$$

where

$$B=\max\{0,(3-x/A)^3\}$$
$$C=\max\{0,x-A\}$$
$$D=\begin{cases}0 & \text{if } C<.02\\ e^{-B/C} & \text{if } C\geqq .02.\end{cases}$$

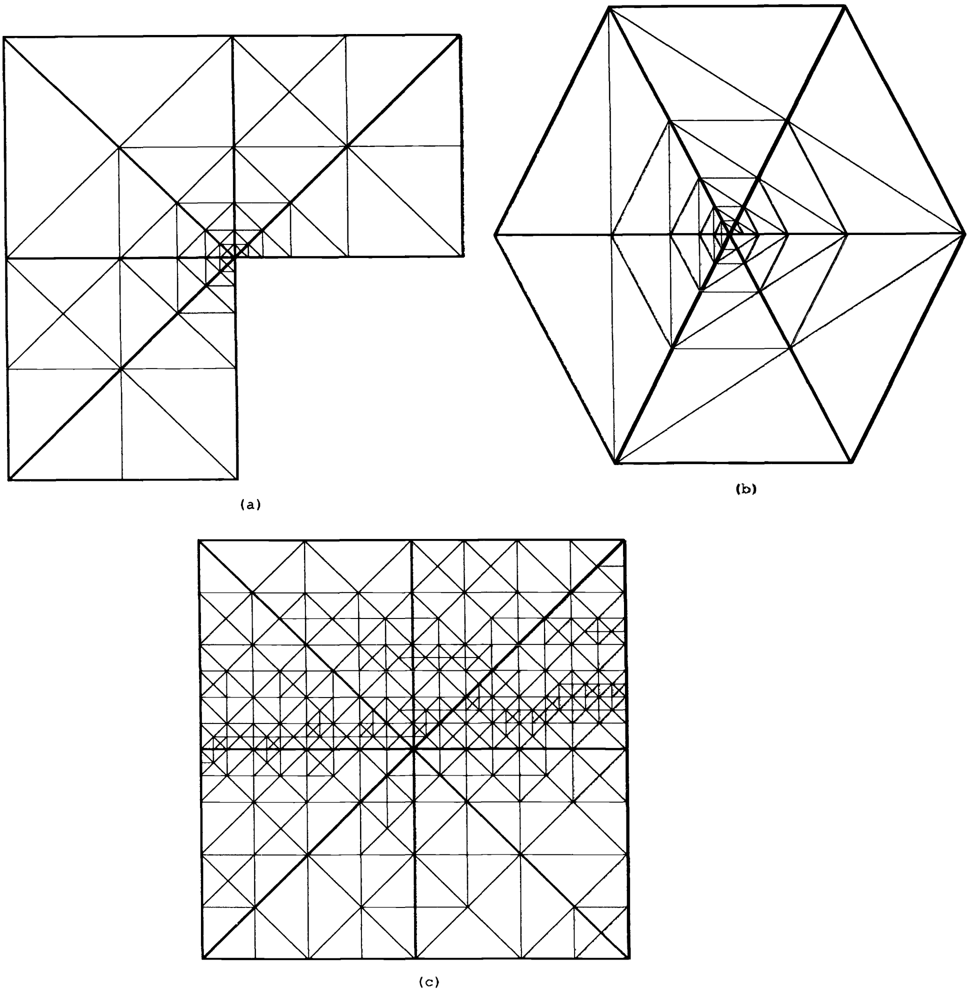

FIG. 5.1. *Domains and sample grids for* (a) *Problem* 1, (b) *Problem* 2, (c) *Problem* 3.

Figure 5.1(c) shows a sample adaptively refined grid with the initial eight triangles in bold. A contour plot of the solution can be found in [21] or [22]. The solution has a ridge in the vicinity of $y \approx .6-.7$.

Convergence of the discretization error. With uniform refinement, the rate of convergence of the discretization error depends on the smoothness of the solution. For Problems 1 and 2, the best one can hope for is $\alpha = \frac{1}{2}$ and $\frac{1}{4}$, respectively, no matter what degree polynomials are used. It is possible for adaptive refinement to recover the optimal rate of convergence. Problems 1 and 2 were solved using linear, quadratic, and cubic elements with both uniform and adaptively refined grids. For these solutions, one V-cycle was used for the solution phase, and the number of vertices was increased by the factor $f = 4$, 2.39, and 1.58 for linear, quadratic, and cubic elements, respectively, except for Problem 2, where $f = 2$ was used for quadratics. $f = 4$ was used instead of 32.5 for linear elements to give a sufficient number of data points for the graphs. The results are presented in Figs. 5.2, 5.3, and 5.4 for Problems 1, 2, and 3, respectively.

The data points on the graphs are labeled with A, B, and C for linear, quadratic, and cubic elements, respectively, for the uniform grids, and 1, 2, and 3 for linear, quadratic, and cubic elements, respectively, for the adaptive grids. The observed rate of convergence is given by the slope of a linear least squares fit of the data. When appropriate, some of the first data points were discarded in determining the slope. These slopes are given in Tables 5.1 and 5.2.

For uniform grids, the rate of convergence is about $\frac{1}{3}$ and $\frac{1}{4}$ for Problems 1 and 2, respectively, for all three polynomial degrees. For adaptive grids, the rate of convergence is about $\frac{1}{2}$, 1, and $\frac{3}{2}$ for linear, quadratic, and cubic elements, respectively, for both problems. For Problem 3 the rate of convergence is slightly larger than $\frac{1}{2}$, 1, and $\frac{3}{2}$ for linear, quadratic, and cubic elements, respectively, for both uniform and adaptive grids. Although the uniform grids achieve the optimal order of convergence for Problem 3, the adaptive grids have a smaller constant of proportionality. The convergence of

the error with CPU time is also of optimal order for the adaptive grids, illustrating the optimality of the full multigrid method.

In numerical experiments that compare low and high order methods with uniform grids for problems with well-behaved solutions (e.g., [22]) it is usually observed that for very low accuracy it is more efficient to use linear elements, but for moderate and high accuracy the high order elements are more efficient. The same result is observed when using adaptively refined grids for Problems 1 and 2.

Convergence of the multigrid iteration. The effect of several factors on the rate of convergence of the multigrid iteration was also considered. Proposition 3.1 was used to determine the rate of convergence for the L-shaped domain of Problem 1 with linear elements. This was computed using both a uniform grid and an adaptively refined grid. For the adaptive grid three forms of relaxation are compared:

(i) full black, in which relaxtion is at all the black nodes after solving the coarse grid problem ($\nu_1 = \frac{1}{2}, \nu_2 = 1$);

(ii) local black, in which relaxation is at the black nodes that are neighbors of red nodes as discussed in § 3;

(iii) no black relaxation ($\nu_1 = \frac{1}{2}, \nu_2 = \frac{1}{2}$).

The results of these computations are presented in Table 5.3.

Note first that the reentrant corner has a pronounced effect on the rate of convergence. The only difference between the uniform grid here and the V-cycle in Table 3.2 is the shape of the domain, yet the rate of convergence has slowed from 0.125 to about 0.2. The use of a nonuniform grid has almost no effect on the asymptotic rate of convergence. Using local black relaxation slows the rate of convergence very slightly. The difference is small enough to ignore, especially when one considers that the full black relaxation requires more than $O(N)$ operations for a highly nonuniform grid. When no black relaxation is performed, the rate of convergence deteriorates rapidly. The experiments show that the rate of convergence behaves like $1 - O(1/\log N)$, so it is not bounded away from 1, and, in fact, $O(\log N)$ iterations are required to reduce the error by a given constant.

6. Conclusion. In this paper, we presented a unified multilevel adaptive refinement method for elliptic PDEs. The adaptive refinement is done by bisecting pairs of triangles, corresponding to the addition of a hierarchical basis function. An estimate of the coefficient of the new basis function is used as an error indicator to select triangle pairs for division. The multigrid iteration uses the change between the nodal basis and 2-level hierarchical basis for the grid transfers. Red-black Gauss-Seidel relaxations are used, with local black relaxations performed only at black nodes that neighbor red nodes, to keep the operation count at $O(N)$. The full multigrid alternately performs refinement and multigrid iterations, with the amount of refinement and number of iterations determined to be optimal while keeping the solution error smaller than the

discretization error. The method was developed for the high order finite element spaces of C^0pth degree piecewise polynomials. Numerical computations were performed with linear, quadratic, and cubic elements to demonstrate the optimality of the adaptive grids in the presence of singularities, and the optimality of the full multigrid solution method.

ROW PROJECTION METHODS FOR LARGE NONSYMMETRIC LINEAR SYSTEMS*

R. BRAMLEY† AND A. SAMEH†

Abstract. Three conjugate gradient accelerated row projection (RP) methods for nonsymmetric linear systems are presented and their properties described. One method is based on Kaczmarz's method and has an iteration matrix that is the product of orthogonal projectors; another is based on Cimmino's method and has an iteration matrix that is the sum of orthogonal projectors. A new RP method, which requires fewer matrix-vector operations, explicitly reduces the problem size, is error reducing in the two-norm, and consistently produces better solutions than other RP algorithms, is also introduced. Using comparisons with the method of conjugate gradient applied to the normal equations, the properties of RP methods are explained.

A row partitioning approach is described that yields parallel implementations suitable for a wide range of computer architectures, requires only a few vectors of extra storage, and allows computing the necessary projections with small errors. Numerical testing verifies the robustness of this approach and shows that the resulting algorithms are competitive with other nonsymmetric solvers in speed and efficiency.

1. Introduction.

Over the last few years much research effort has been invested in developing iterative solvers for nonsymmetric linear systems $Ax = b$, where A is large, sparse, and nonsingular. These solvers can be grouped roughly into the four categories of *matrix splitting*, *CG-like*, *residual polynomial*, and *symmetrization* methods.

Matrix splitting methods and their acceleration via CG include the earliest iterative techniques for solving linear systems, and are based on splitting the coefficient matrix as $A = M - N$. This category includes the Jacobi, Gauss–Seidel, and successive overrelaxation methods, and convergence is assured if the spectral radius $\rho(M^{-1}N)$ is less than 1. This condition can often be shown to hold if, e.g., A is irreducible and diagonally dominant. Hageman and Young [18] describe many of these splitting techniques and provide other conditions on A that imply convergence.

The second category, CG-like methods, was motivated by the success of the conjugate gradient (CG) method for symmetric positive definite systems. Generalized conjugate residuals (GCR), Orthomin, generalized minimum residual (GMRES), Axelsson's method, and Orthodir are included in this category (see Saad and Schultz [31] for a summary of these methods). Like CG, these solvers generate a Krylov subspace K using only matrix-vector products with A and then enforce some minimization or orthogonality property on K; they differ primarily in how the basis of K is formed and which inner product is used to define orthogonality or minimality. Since computation and storage grow with the iteration number for these methods, they are most often used in a truncated or restarted form. In 1982, Elman [14] proved that restarted versions of many of these methods converge provided that the symmetric part $(A + A^T)/2$ of A is positive definite. In spite of this restriction, the restarted

GMRES(k) algorithm in particular is currently one of the more popular nonsymmetric solvers.

The second category generates residuals $r_k = b - Ax_k$ that satisfy

$$r_k = p_k(A)r_0, \tag{1}$$

where r_0 is the initial (restarted) residual and $p_k(\lambda)$ is a residual polynomial, i.e., $p_k(0) = 1$. A third category, residual polynomial methods, directly uses this idea by finding a convex region in the complex plane containing the eigenvalues of A. Iterates are then formed that satisfy (1) for some class of polynomials. Chebyshev polynomials [3], [27], [28] use ellipses for the convex region and Chebyshev polynomials to define $p_k(\lambda)$. Least squares polynomial methods [32] use an approximation of the convex hull cvx $(\sigma(A))$ of the extremal eigenvalues of A for the enclosing region and polynomials $p_k(\lambda)$ that minimize a weighted sum of squares on the boundary of cvx $(\sigma(A))$. Because of the restriction $p_k(0) = 1$, residual polynomial methods fail when the origin is in cvx $(\sigma(A))$.

All three categories above are thus restricted in applicability, requiring, e.g., $A + A^T$ to be positive definite or the spectrum of A to lie on one side of the imaginary axis. Symmetrization methods, the fourth category, implicitly or explicitly create a related symmetric positive definite system and then use one of the powerful iterative methods applicable to such systems. The most popular such approach is to use CG on the normal equations $A^TAx = A^Tb$. Actually forming A^TA can cause a loss of information and entail a large preprocessing cost as well as increased storage. Even if this is not done, a more serious problem is that the condition number $\kappa(A^TA)$ is the square of $\kappa(A)$. This can lead to outright failure of the solver.

In general, most nonsymmetric solvers either require storage and computation that grow excessively with the iteration number, special spectral properties of A to assure convergence, or a symmetrization process with potentially disastrous effects on the coefficient matrix. One group of methods that avoids these difficulties is that of accelerated row projection (RP) algorithms. Partition $A \in \Re^{N\times N}$ into m block rows:

$$A^T = [A_1, A_2, \cdots, A_m], \tag{2}$$

and partition the vector b conformally. A *row projection* (RP) method is any algorithm that requires the computation of the orthogonal projections $P_ix = A_i(A_i^TA_i)^{-1}A_i^Tx$ of a vector x onto range(A_i), $i = 1, 2, \cdots, m$. Note that the nonsingularity of A implies that A_i has full rank and so $(A_i^TA_i)^{-1}$ exists.

This paper presents three such methods and describes their properties. The first (KACZ) has an iteration matrix formed from the product of orthogonal projectors. A new method (V-RP) is derived from KACZ to reduce the number of matrix-vector operations needed and to reduce the problem size explicitly. The third RP method (CIMM) uses the sum of orthogonal projectors. Conjugate gradient (CG) acceleration is used on all three, and for KACZ this is shown to allow a reduction in the amount of work needed per iteration, while for V-RP an error-reducing algorithm results. Most importantly, the underlying relationship between RP methods and CG applied to the normal equations is shown. This provides an explanation for the behavior of RP methods, a basis for comparing them, and a guide for their effective use.

Possibly the most important implementation issue for RP methods is that of choosing the row partitioning that defines the projectors. An approach is shown for three-dimensional elliptic partial differential equations that yields algorithms with large scale parallelism, requires only a few extra vectors of storage, and allows the computation of the necessary projections with small errors. Numerical testing shows that the algorithms have superior robustness and can be competitive with other nonsymmetric solvers in speed and efficiency.

2. Three row projection methods.

2.1. Row projection method KACZ. The simplest RP method can be derived geometrically. Let $H_i = \{x : A_i^T x = b_i\}$ be the affine set of solutions to the ith block row of equations. The solution x^* to $Ax = b$ is the unique intersection point of those affine sets, and the method of successive projections gives the iteration

$$x_{k+1} = Q_u x_k + b_u = (I - P_m)(I - P_{m-1}) \cdots (I - P_1)x_k + b_u, \tag{3}$$

where

$$\begin{aligned} b_u = \hat{b}_m + (I - P_m)\hat{b}_{m-1} + (I - P_m)(I - P_{m-1})\hat{b}_{m-2} + \cdots \\ +(I - P_m) \cdots (I - P_2)\hat{b}_1, \end{aligned}$$

and $\hat{b}_i = A_i(A_i^T A_i)^{-1} b_i$.

In 1939 Kaczmarz [20] proposed iteration (3) and proved convergence for the $m = N$ case where each block row A_i^T consists of a single row of A. Since then many authors [10], [11], [19], [29], [30], [37] have examined the convergence of related iterative methods. The theoretical robustness of (3) is remarkable and the iteration converges even when A is singular or rectangular. However, as with any linear stationary process, the rate of convergence is determined by the spectral radius of Q_u and can be arbitrarily slow. For this reason Elfving [12] and Björck and Elfving [4] proposed symmetrizing Q_u by following a forward sweep through the rows with a backward sweep, and introduced an iteration parameter to get

$$x_{k+1} = Q(\omega)x_k + T(\omega)b, \tag{4}$$

$$Q(\omega) = (I - \omega P_1)(I - \omega P_2) \cdots (I - \omega P_m)^2 \cdots (I - \omega P_2)(I - \omega P_1), \tag{5}$$

with $T(\omega)$ defined by (8). When A is nonsingular and $0 < \omega < 2$, the spectrum $\sigma(I - Q(\omega))$ lies in the interval $(0, 1]$ and so the CG method can be applied to solve

$$(I - Q(\omega))x = T(\omega)b. \tag{6}$$

Also, (4) is equivalent to applying block SSOR to

$$\left\{ \begin{array}{rcl} AA^T y & = & b \\ x & = & A^T y \end{array} \right. \tag{7}$$

where the blocking is that induced by the row partitioning of A [12]. This gives a simple expression for $T(\omega)$:

$$T(\omega) = A^T(D + \omega L)^{-T} D (D + \omega L)^{-1}, \tag{8}$$

where $AA^T = L + D + L^T$ is the usual splitting into block lower triangular, diagonal, and upper triangular parts. This also shows that solving (6) using the CG algorithm can be placed in the category of symmetrization methods.

Although Björck and Elfving tested an accelerated RP algorithm, their work concentrated on the single row ($m = N$) case applied to weighted least squares problems.

Previous work dealing with the use of block forms is given by Kamath and Sameh [21], [22]. Using sample problems drawn from two-dimensional nonselfadjoint elliptic partial differential equations, they numerically examined the issues of suitable row partitionings and methods for the numerical solution of the induced projections, primarily for the $m = 2$ or 3 case. By comparisons with CG-like methods and preconditioned CG applied to the normal equations, they showed that the RP algorithm solved selected problems for which most of the other methods failed.

The first implementation issue is the choice of ω in (6). Normally the "optimal" ω is defined as the $\omega_{\min}$ that minimizes the spectral radius of $Q(\omega)$. In [22] $\omega_{\min} = 1$ is proven for the case where A is partitioned into two block rows, i.e., $m = 2$. This is no longer true for $m > 3$, as can be seen by considering

$$A = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{bmatrix} = \begin{bmatrix} A_1^T \\ A_2^T \\ A_3^T \end{bmatrix}.$$

For $Q(\omega)$ defined in (4) it can be proven that

$$\begin{aligned} \rho(Q(1)) &= (7+\sqrt{17})/16 = 0.69519 \pm 10^{-5}, \\ \rho(Q(0.9)) &\leq 0.68611 \pm 10^{-5} < \rho(Q(1)), \end{aligned}$$

and so $\omega_{\min} \neq 1$.

Throughout this paper, however, $\omega = 1$ will be used for three reasons. Because CG acceleration is to be applied, the entire distribution of the spectrum must be considered, not simply the spectral radius. When $\omega = 1$, many of the eigenvalues of the system matrix in (6) are exactly 1:

FACT 2.1. *At least* $\operatorname{rank}(A_1)$ *of the eigenvalues of* $Q(1)$ *are zero.*

Proof. $(I - P_1)x = 0$ for $x \in \operatorname{range}(P_1) = \operatorname{range}(A_1)$. From the definition of $Q(\omega)$, $\operatorname{null}(I - P_1) \subseteq \operatorname{null}(Q(1))$. □

Since CG acceleration requires in exact arithmetic a number of iterations equal to the number of distinct eigenvalues, this suggests that numerically fewer iterations are needed as compared to when $\omega \neq 1$. A second reason is that numerical experience shows $\rho(Q(\omega))$ is not sensitive to changes in ω. This matches classical results for SSOR iterations, which are not as sensitive to ω as the corresponding SOR methods. The small improvement that does result from choosing $\omega_{\min}$ is more than offset by the introduction of extra nonzero eigenvalues. The third reason for using $\omega = 1$ is given by Fact 2.2.

FACT 2.2. *When* $\omega = 1$ *and* $x_0 = 0$, $A_1^T x_k = b_1$ *holds in exact arithmetic on every iteration of* (4).

Proof. Using the definition $P_i = A_i(A_i^T A_i)^{-1} A_i^T$, (8) can be expanded to show that the ith block column of $T(1)$ is given by

$$\prod_{j=1}^{i-1}(I - P_j) \left[I + \prod_{j=i}^{m}(I - P_j) \prod_{j=m-1}^{i+1}(I - P_j) \right] (A_i^T)^{\dagger}. \tag{9}$$

The first product above should be interpreted as I when $i = 1$ and the third product should be interpreted as I when $i = m - 1$ and 0 when $i = m$, so that the first summand in forming $T(1)b$ is $[I + (I - P_1) \cdots (I - P_m) \cdots (I - P_2)](A_1^T)^{\dagger} b_1$. Since $A_1^T(I - P_1) = 0$, $A_1^T x_1 = A_1^T (A_1^T)^{\dagger} b_1 = b_1$. The succeeding iterates x_k are obtained by adding elements in $\operatorname{range}(Q(1)) \subseteq \operatorname{range}(I - P_1) = \operatorname{null}(A_1^T)$ to x_1. □

Later we show that this continues to hold when CG acceleration is used. This feature means that when $\omega = 1$ equations deemed more important than the others can be put into the first block and kept satisfied to machine precision.

The most important reason for choosing $\omega = 1$ is an a posteriori one; the resulting algorithm works well. For the remainder of the paper $Q = Q(1)$ and $T = T(1)$ will be used. The resulting system,

$$(I - Q)x = \tilde{b}, \tag{10}$$

$$Q = (I - P_1)(I - P_2)\cdots(I - P_m)\cdots(I - P_2)(I - P_1), \tag{11}$$

$$\tilde{b} = Tb, \tag{12}$$

will be called the KACZ system.

2.2. Row projection method V-RP. A new RP iteration with computational and theoretical advantages over (11) is now introduced. Let $A_i = Q_iU_i$ be the QR decomposition of A_i for $i = 1, 2, \cdots, m$. Note that $P_i = Q_iQ_i^T$ in this case. Let $AA^T = L + D + L^T$ be the decomposition of AA^T into the strictly lower block triangular, block diagonal, and strictly upper block triangular parts induced by the block row partitioning. As shown in [18, p. 31], the block SSOR iteration for $AA^Ty = b$ can be written as

$$\begin{aligned} y_{k+1} &= [I - \omega(2-\omega)(D+\omega L)^{-T}D(D+\omega L)^{-1}AA^T]y_k \\ &+ \omega(2-\omega)(D+\omega L)^{-T}D(D+\omega L)^{-1}b. \end{aligned}$$

For $\omega = 1$ this can be viewed as an iteration to solve the system

$$[(D+L)^{-T}D(D+L)^{-1}AA^T]y = (D+L)^{-T}D(D+L)^{-1}b. \tag{13}$$

The KACZ system is obtained by replacing A^Ty with x and premultiplying by A^T, or equivalently applying a similarity transformation with $W = A^T$ to the coefficient matrix in (13) to yield

$$[A^T(D+L)^{-T}D(D+L)^{-1}A]x = A^T(D+L)^{-T}D(D+L)^{-1}b. \tag{14}$$

In [4], applying a similarity transformation using $W = D^{-1/2}(D+L)^T$ was proposed; when CG acceleration is used this has the desirable property of being an error reducing process in the two-norm, instead of reducing the error in an elliptic norm. Unfortunately, computing $D^{-1/2}$ is only practical in the $m = N$ case where each A_i^T is a single row of A.

However, the triangular factors U_i can be found in the block case either from an orthogonal decomposition of A_i or a Cholesky factorization of $A_i^TA_i$. Let

$$Z = \operatorname{diag}(U_1, U_2, \cdots, U_m) \in \Re^{N\times N}$$

and consider applying a similarity transformation using $W = Z^{-T}(D+L)^T$ to (13). The resulting system is

$$Z(D+L)^{-1}AA^T(D+L)^{-T}Z^Tz = Z(D+L)^{-1}b \tag{15}$$

with $z = Z^{-T}(D+L)^Ty$ and

$$x = A^Ty = A^T(D+\omega L)^{-T}Z^Tz. \tag{16}$$

The motivation for proposing this new system follows. Suppose for convenience that each A_i^T contains the same number N/m of rows of A; in this case the KACZ system has at least $1/m$ of its eigenvalues equal to 1. When CG is applied to $I - Q$, implicitly a system only $(m-1)/m$ the size of the original system is being solved. Can this reduction in problem size be made explicit? Using (15) and some algebraic manipulation, the coefficient matrix can be written as $V = S_V^T S_V$, where

$$\begin{aligned} S_V &= A^T(D+L)^{-T}Z^T \\ &= [Q_1, (I-P_1)Q_2, \cdots, (I-P_1)\cdots(I-P_{m-1})Q_m]. \end{aligned} \tag{17}$$

Since Q_1 has orthonormal columns, the (1,1) block entry of $S_V^T S_V$ is $Q_1^T Q_1 = I$, and the (1,i) block is

$$Q_1^T(I-P_1)\left(\prod_{j=2}^{i-1}(I-P_j)\right)Q_i.$$

Since $Q_1^T(I-P_1) = Q_1^T - Q_1^T Q_1 Q_1^T = 0$, and $S_V^T S_V$ is symmetric, the first row and column are zero except for the (1,1) block entry. For the case $m = 3$, e.g., this implies that $I - V$ has the form

$$\begin{bmatrix} I & 0 & 0 \\ 0 & {Q_2}^T(I-P_1)Q_2 & {Q_2}^T(I-P_1)(I-P_2)Q_3 \\ 0 & {Q_3}^T(I-P_2)(I-P_1)Q_2 & {Q_3}^T(I-P_2)(I-P_1)(I-P_2)Q_3 \end{bmatrix}. \tag{18}$$

Clearly, the first block of unknowns requires no iterations to find, and so the CG algorithm only need be applied to a reduced system. An important point is that this reduction has no detrimental effect on the spectrum of the iteration matrix. This is because (11) and (15) have matrices with identical eigenvalues since they are similar to the system matrix in (13). The resulting system,

$$\begin{aligned} (I-V)z &= b_V, \\ V &= I - Z(D+L)^{-1}AA^T(D+L)^{-T}Z^T, \\ x &= A^T(D+L)^{-T}Z^T z, \end{aligned} \tag{19}$$

$$b_V = Z(D+L)^{-1}b, \tag{20}$$

will be called the the V-RP system.

Similar to KACZ, V-RP keeps the first block of equations exactly satisfied when used as a linear stationary iteration, but without requiring $x_0 = 0$.

THEOREM 2.1. *For any starting vector z_0, the iteration $z_{k+1} = Vz_k + Z(D+L)^{-1}b$ yields iterates x_k that satisfy $A_1^T x_k = b_1$, where x_k satisfies* (16).

Proof. Let the vector $z_k = (z_k^{(1)}, \cdots, z_k^{(m)})$ be partitioned conformally with the row partitioning of A. Referring to the system matrix shown in (18), note that $z_k^{(1)}$ is simply the first block of the modified right-hand side $Z(D+L)^{-1}b$. $(D+L)$ is block lower triangular with its (1,1) block equal to $A_1^T A_1$, so the first block of $Z(D+L)^{-1}b$ is $z_k^{(1)} = U_1(A_1^T A_1)^{-1}b_1 = U_1(U_1^T U_1)^{-1}b_1 = U_1^{-T}b_1$. From (17), (16), $A_1 = Q_1 U_1$, and $Q_1^T(I-P_1) = 0$,

$$\begin{aligned} A_1^T x_k &= U_1^T Q_1^T [Q_1, (I-P_1)Q_2, \cdots, (I-P_1)\cdots(I-P_{m-1})Q_m]\, z_k \\ &= U_1^T z_k^{(1)} = U_1^T U_1^{-T} b_1 = b_1. \end{aligned} \qquad \square$$

TABLE 1
Comparison of system matrices for four methods.

Method	W^T
CGNE	$[A_1,\ A_2,\ \cdots\ ,A_m]$
CIMM	$[Q_1,\ Q_2,\ \cdots\ ,Q_m]$
KACZ	$\left[P_1,\ (I-P_1)P_2,\ (I-P_1)(I-P_2)P_3,\ \cdots\ ,\prod_{i=1}^{m-1}(I-P_i)P_m\right]$
V-RP	$\left[Q_1,\ (I-P_1)Q_2,\ (I-P_1)(I-P_2)Q_3,\ \cdots\ ,\prod_{i=1}^{m-1}(I-P_i)Q_m\right]$

2.3. Row projection method CIMM. The third RP method can be derived as a preconditioner for the CG algorithm. Premultiply the system $Ax = b$ by $\tilde{A} = [A_1(A_1^TA_1)^{-1}, A_2(A_2^TA_2)^{-1}, \cdots, A_m(A_m^TA_m)^{-1}]$ to obtain

$$(P_1 + P_2 + \cdots + P_m)x = \tilde{A}b. \tag{21}$$

This system can also be derived as a block Jacobi method applied to the system (7); see [11]. For nonsingular A this system is symmetric positive definite and the CG algorithm can be applied. The advantage of this approach is that the projections can be computed in parallel and then added. In 1939 Cimmino [9] first proposed an iteration related to (21), and since then it has been examined by several others [1], [11], [12], [15], [25], [26], [38]. Later we will show how the individual projections can, for a wide class of problems, be computed with parallelism. In this case, the Cimmino method allows computations to proceed with two levels of parallelism, making it especially suitable for hierarchical memory machines such as Cedar [24].

2.4. Connection between RP systems and the normal equations. Although KACZ and V-RP can be derived as a block SSOR, and CIMM as a block Jacobi, method for (7), a more instructive comparison can be made with CGNE, conjugate gradients applied to the normal equations $A^TAx = A^Tb$. All four methods consist of CG applied to a system with coefficient matrix W^TW, where W^T is shown for the four methods in Table 1. Intuitively, an ill-conditioned matrix A has some linear combination of rows approximately equal to the zero vector. For a row partitioned matrix, near linear dependence may occur *within* the blocks, that is, some linear combination of the rows within a particular block is approximately zero, or *across* the blocks, that is, the linear combination must draw from more than one block row A_i^T. Now let $A_i = Q_iU_i$ be the orthogonal decomposition of A_i, and note that both Q_i and $P_i = Q_iQ_i^T$ have the perfect condition number of 1. Examining the matrices W shows that CGNE works on A^TA, and the ability to form a near linear dependence from both within and across blocks enters into the system matrix. CIMM replaces each A_i with Q_i, which has orthonormal columns. Hence CIMM removes the ability to form linear dependence within the blocks, but has no effect on that between the blocks. V-RP also replaces each A_i with the perfectly conditioned Q_i and then goes a step further by recursively orthogonalizing between blocks in the following way: The first block column of W^T is orthogonal to the others since $Q_1(I - P_1) = 0$. If the orthogonalizing $I - P_1$ factor is removed from the other block columns of W^T, then the second block column is orthogonal to the remaining ones since $Q_2(I - P_2) = 0$. This process continues until the last block is reached. The recursive nature of this partial orthogonalization can be seen by rewriting W^T for V-RP as

$$W^T = [Q_1,\ \ (I-P_1)[Q_2,\ \ (I-P_2)[Q_3,\ \ (I-P_3)\cdots[Q_{m-1},\ \ (I-P_{m-1})Q_m]\cdots]]].$$

KACZ has the same effect as V-RP, since $P_i^T(I - P_i) = 0$ in the same way that $Q_i(I - P_i) = 0$.

Several implications follow from this heuristic argument. First, the system matrix spectrum for KACZ and V-RP should be better than that of CIMM, which in turn should be better than that of CGNE, where "better" means having fewer small eigenvalues and many more eigenvalues near the maximal one. Section 4 will show that for $m = 2$ the first comparison is true, and the second comparison holds if condition numbers are used to measure "better." Furthermore, by computing the spectra for small grid sizes we have found these comparisons are valid for the problems in §6, where $m = 9$.

A second implication of this argument is that RP methods will require fewer iterations for matrices A where the near linear dependence comes primarily from within a block row rather than between block rows. A third implication of the heuristic argument for the relative performance of RP methods is that the number of block rows should be kept as small as possible. The reason is that the partial orthogonalization between blocks in the W of Table 1 becomes less effective as more block rows appear. In terms of the heuristic, progressively more orthogonalizing factors $I - P_i$ must be stripped away before the orthogonalization effect between block row i and the succeeding block rows is felt. Keeping the number of block rows small can also be seen to be important because, e.g., for the $m = N$ case all of the ability to form a near linear dependency between rows of the system matrix occurs between the block rows, where the outer CG acceleration method must deal with it.

3. CG acceleration. Although the CG algorithm can be applied directly to the row projection systems, special properties allow a reduction in the amount of work required by KACZ and provide another advantage of V-RP. CG acceleration for RP methods was proposed in [4] and tested in [7], [21], [22]. The reason that a reduction in work is possible and $A_1^T x_k = b_1$ on every iteration of CG applied to KACZ follows from Theorem 3.1.

THEOREM 3.1. *Suppose that the* CG *algorithm is applied to the* KACZ *system and let $r_k = \tilde{b} - (I - Q)x_k$ be the residual and d_k be the search direction. If $x_0 = \tilde{b}$ is chosen as the starting vector, then r_k, $d_k \in$* range$(I - P_1)$ *for all k.*

Proof.

$$\begin{aligned} r_0 &= \tilde{b} - (I - Q)\tilde{b} = Q\tilde{b} \\ &= (I - P_1)(I - P_2)\cdots(I - P_m)\cdots(I - P_2)(I - P_1)\tilde{b} \in \text{range}(I - P_1). \end{aligned}$$

Since $d_0 = r_0$, the same is true for d_0. Suppose the theorem holds for $k - 1$. Then $d_{k-1} = (I - P_1)d_{k-1}$ and so

$$\begin{aligned} w_k &\equiv (I - Q)d_{k-1} \\ &= (I - P_1)d_{k-1} - (I - P_1)(I - P_2)\cdots(I - P_m)\cdots(I - P_2)(I - P_1)d_{k-1} \\ &\in \ \text{range}(I - P_1). \end{aligned}$$

Since r_k is a linear combination of r_{k-1} and w_k, $r_k \in$ range$(I - P_1)$. Since d_k is a linear combination of d_{k-1} and r_k, $d_k \in$ range$(I - P_1)$. The result follows by induction. □

This reduces the requisite number of projections from $2m - 1$ to $2m - 2$ because the first multiplication by $(I - P_1)$ when forming $(I - Q)d_k$ can be omitted. For V-RP, the next section will show that the algorithm can be implemented so that effectively only $2m - 2$ projections are required on each iteration, for any starting vector. Using $x_0 = \tilde{b}$ for KACZ also keeps the first block of equations satisfied in exact arithmetic.

COROLLARY 3.2. *If* $x_0 = \tilde{b}$ *is chosen in the* CG *algorithm applied to the* KACZ *system, then* $A_1^T x_k = b_1$ *for all* $k \geq 0$.

Proof. The proof of Fact 2.2 shows that $\tilde{b} \in (A_1^T)^\dagger b_1 + \text{range}(I - P_1)$. Since $A_1^T(I - P_1) = A_1^T(I - A_1 A_1^\dagger) = 0$, $A_1^T x_0 = A_1^T(A_1^T)^\dagger b_1 = b_1$ because A_1 has full column rank. For $k > 0$, $d_{k-1} \in \text{range}(I - P_1)$, so

$$A_1^T x_k = A_1^T(x_{k-1} + \alpha_k d_{k-1}) = A_1^T x_{k-1} = \cdots = A_1^T x_0 = b_1. \qquad \square$$

V-RP has already been shown to allow an explicit reduction of the problem size. Its second major advantage is that when accelerated by CG, the resulting algorithm is error-minimizing in the two-norm.

THEOREM 3.3. *Suppose* CG *acceleration is applied to the* V-RP *system and let* x^* *be the solution to* $Ax = b$. *Then the kth iteration minimizes* $\| x - x^* \|$ *over all* $x \in S_V^T * \text{span}[x_0 - x^*, \cdots, x_{k-1} - x^*]$, *where* S_V *is defined by* (17).

Proof. Recall that $x_k = A^T(D + L)^{-T} Z^T z_k = S_V z_k$, where $V = I - S_V^T S_V$. The CG algorithm minimizes the quadratic form [16]

$$\begin{aligned} z^T(I - V)z - 2z^T b_V &= z^T S_V^T S_V z - 2z^T S_V^T A^{-1} b \\ &= x^T x - 2x^T x^* = \| x - x^* \|^2 - \| x^* \|^2 . \end{aligned}$$

Since $\| x^* \|^2$ is a constant, this is equivalent to minimizing $\| x - x^* \|^2$. The subspace over which this minimization occurs is

$$\begin{aligned} \text{span}[r_0, \cdots, r_{k-1}] &= \text{span}[S_V^T A^{-1} b - S_V^T S_V z_0, \cdots, S_V^T A^{-1} b - S_V^T S_V z_{k-1}] \\ &= S_V^T * \text{span}[x^* - x_0, \cdots, x^* - x_{k-1}]. \qquad \square \end{aligned}$$

In contrast, CG acceleration in the KACZ system minimizes $\| S_V^T(x_k - x^*) \|$ over the subspace $S_V S_V^T * \text{span}[x_0 - x^*, \cdots, x_{k-1} - x^*]$, a result established in [4].

In summary, CG acceleration for KACZ allows one projection per iteration to be omitted and one block of equations to be kept exactly satisfied, provided that $x_0 = \tilde{b}$ is used. CG acceleration for V-RP minimizes the two-norm rather than the A-norm of the error.

4. The $m = 2$ case. When $m = 2$ is chosen, the matrix A is partitioned into two block rows, and a complete eigenanalysis of RP methods is possible using the concept of the angles θ_k between the two subspaces $L_i = \text{range}(A_i)$, $i = 1, 2$. The definition presented here follows that of Björck and Golub in [5], but for convenience, L_1 and L_2 are assumed to have the same dimension. The smallest angle $\theta_1 \in [0, \pi/2]$ between L_1 and L_2 is defined by

$$\begin{aligned} \cos\theta_1 &= \max_{u \in L_1} \max_{v \in L_2} u^T v \\ &\text{subject to } \| u \| = \| v \| = 1. \end{aligned}$$

Let u_1 and v_1 be the attainment vectors; then for $k = 2, 3, \cdots, N/2$ the remaining angles between the two subspaces are defined as

$$\begin{aligned} \cos\theta_k &= \max_{u \in L_1} \max_{v \in L_2} u^T v \\ &\text{subject to} \begin{cases} \| u \| = \| v \| = 1 \\ u_i^T u = v_i^T v = 0, \quad i = 1, 2, \cdots, k - 1. \end{cases} \end{aligned}$$

Furthermore, when u_i and v_j are defined as above, $u_i^T v_j = 0$, $i \neq j$ also holds. From this one can obtain the CS decomposition [16], [36], which is stated below in terms of the projectors P_i.

THEOREM 4.1 (CS Decomposition). *Let $P_i \in \Re^{N \times N}$ be the orthogonal projectors onto the subspaces L_i, for $i = 1, 2$. Then there are orthogonal matrices U_1 and U_2 such that*

$$P_1 = U_1 \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} U_1^T, \quad P_2 = U_2 \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} U_2^T, \quad U_1^T U_2 = \begin{bmatrix} C & -S \\ S & C \end{bmatrix},$$

$$\begin{aligned} C &= \operatorname{diag}(c_1, c_2, \cdots, c_{N/2}), \\ S &= \operatorname{diag}(s_1, s_2, \cdots, s_{N/2}), \\ I &= C^2 + S^2, \\ 1 &\geq c_1 \geq c_2 \geq \cdots \geq c_{N/2} \geq 0. \end{aligned} \tag{22}$$

In the theorem $c_k = \cos\theta_k$ and $s_k = \sin\theta_k$, where the angles θ_k are defined above. Now consider the nonsymmetric RP iteration matrix $Q_u = (I - \omega P_1)(I - \omega P_2)$. Letting $\alpha = 1 - \omega$, and substituting in the expressions for P_1 and P_2 from the CS decomposition gives

$$Q_u = U_1 \begin{bmatrix} \alpha^2 C & -\alpha S \\ \alpha S & C \end{bmatrix} U_2^T.$$

Applying a similarity transformation using the matrix U_2^T gives

$$U_2^T Q_u U_2 = \begin{bmatrix} \alpha^2 C^2 + \alpha S^2 & (1-\alpha) CS \\ \alpha(1-\alpha) CS & C^2 + \alpha S^2 \end{bmatrix}. \tag{23}$$

Since each block in the above 2×2 matrix is diagonal, $U_2^T Q_u U_2$ has the same eigenvalues as its scalar 2×2 principal submatrices. These eigenvalues are given by

$$(1-\alpha)^2 c_i^2 + 2\alpha \pm |1-\alpha| c_i \sqrt{(1-\alpha)^2 c_i^2 + 4\alpha} \tag{24}$$

for $i = 1, 2, \cdots, N/2$. For a given α the modulus of this expression is a maximum when c_i is largest, i.e., when $c_i = c_1$. The spectral radius of Q_u can then be found by taking $c_i = c_1$ and the positive sign in (24). Doing so and minimizing with respect to α gives $\omega_{\min} = 1 - \alpha_{\min} = 2/(1 + s_1)$ and a spectral radius of $(1 - s_1)/(1 + s_1)$. The same result was derived in [12] using classical SOR theory. The benefit of the CS decomposition is that the full spectrum of Q_u is given and not simply the eigenvalue of largest modulus. In particular, when $\omega = 1$ the eigenvalues of the nonsymmetric RP iteration matrix Q_u become $\left\{c_1^2, c_2^2, \cdots, c_{N/2}^2, 0\right\}$ with 0 repeated $N/2$ times. Now applying the CS decomposition to the symmetrized RP iteration matrix $Q(\omega)$ gives

$$\begin{aligned} Q(\omega) &= (I - \omega P_1)(I - \omega P_2)(I - \omega P_1) \\ &= U_1 \begin{bmatrix} \alpha^2(\alpha C^2 + S^2) & \alpha(\alpha - 1) CS \\ \alpha(\alpha-1) CS & \alpha S^2 + C^2 \end{bmatrix} U_1^T, \end{aligned} \tag{25}$$

where again $\alpha = 1 - \omega$. When $\omega = 1$, the eigenvalues of the symmetrized matrix are identical to those of the unsymmetrized matrix Q_u. One objection to the symmetrization process is that $Q(\omega)$ requires three projections while Q_u only needs two. The previous section, however, showed that when $\omega = 1$, KACZ can be implemented with only two projections per iteration.

When $m = 2$ the value $\omega = 1$ minimizes the spectral radius of $Q(\omega)$, as was shown in [22]. This result can be obtained from the representation (25) in the same way as (23) was obtained.

The CS decomposition also allows the construction of an example showing that no direct relationship need exist between the singular value distribution of A and its related RP matrices. Define

$$A = \begin{bmatrix} A_1^T \\ A_2^T \end{bmatrix} = \begin{bmatrix} 0 & D \\ S & C \end{bmatrix}, \tag{26}$$

where each block is $N/2 \times N/2$, C and S satisfy (22), and $D = \mathrm{diag}(d_1, d_2, \cdots, d_{N/2})$. The projectors become

$$P_1 = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad P_2 = \begin{bmatrix} C \\ S \end{bmatrix} \begin{bmatrix} C & S \end{bmatrix},$$

and the eigenvalues of $I - Q(1)$ are $\{s_1^2, s_2^2, \cdots, s_{N/2}^2, 1\}$, while those of A are $\left[c_i \pm (c_i^2 + 4s_id_i)^{1/2}\right]/2$. A is nonsingular if and only if each s_i and d_i is nonzero. If the s_i's are chosen to be close to 1 while the d_i's are chosen to be close to 0, $I - Q(1)$ has eigenvalues clustered near 1 while A has singular values close to both 0 and 1. Hence A is badly conditioned while $I - Q(1)$ is very well conditioned. Conversely, if the d_i's are chosen to be large while the s_i's are close to 0 in such a way that d_is_i is near 1, then A is well conditioned while $I - Q(1)$ is badly conditioned. Hence the conditioning of A and its induced RP system matrix may differ greatly. Although this example is contrived, §7 presents two PDEs with induced matrices A that have identical singular values but drastically differing spectra for the corresponding RP matrices.

In §2.4 a heuristic argument was given implying that the eigenvalue distribution for the KACZ and V-RP systems is better for CG acceleration than that of CIMM, which in turn is better than that of CGNE, CG applied to $A^TAx = A^Tb$. For $m = 2$, the eigenvalues of KACZ and V-RP are $\{s_1^2, s_2^2, \cdots, s_{N/2}^2, 1\}$ while those of CIMM are easily seen to be $\{1 - c_1, \cdots, 1 - c_{N/2}, 1 + c_{N/2}, \cdots, 1 + c_1\}$, verifying that KACZ and V-RP have better spectral distribution than CIMM. The next theorem shows that in terms of condition numbers the heuristic argument is valid when $m = 2$.

THEOREM 4.2. *When* $m = 2$, $\kappa(A^TA) \geq \kappa(P_1 + P_2) \geq \kappa(I - (I - P_1)(I - P_2)(I - P_1))$. *Furthermore, let* $c_1 = \cos\theta_1$ *be the canonical cosine corresponding to the smallest angle between* range(A_1) *and* range(A_2). *Then* $\kappa(P_1 + P_2) = (1 + c_1)^2\kappa(I - (I - P_1)(I - P_2)(I - P_1))$.

Proof. Without loss of generality, suppose that range(A_1) and range(A_2) have dimension $N/2$. Let $U_1 = [G_1, G_2]$ and $U_2 = [H_1, H_2]$ be the matrices defined in Theorem 4.1 so that $P_1 = G_1G_1^T$, $P_2 = H_1H_1^T$, and $G_1^TH_1 = C$. Set $X = G_1^TA_1$ and $Y = H_1^TA_2$ so that $A_1 = P_1A_1 = G_1G_1^TA_1 = G_1X$ and $A_2 = H_1Y$. It is easily verified that the eigenvalues of $P_1 + P_2$ are $1 \pm c_i$, corresponding to the eigenvectors $g_i \pm h_i$ where $G_1 = [g_1, g_2, \cdots, g_{N/2}]$ and $H_1 = [h_1, h_2, \cdots, h_{N/2}]$. Furthermore, $G_1g_1 = H_1h_1 = e_1$ and $G_1h_1 = H_1g_1 = c_1e_1$, where e_1 is the first unit vector. Then $A^TA = A_1A_1^T + A_2A_2^T = G_1XX^TG_1^T + H_1YY^TH_1^T$, so $(g_1 + h_1)^T(A^TA)(g_1 + h_1) = (1 + c_1)^2e_1^T(A^TA)e_1$ and $(g_1 - h_1)^T(A^TA)(g_1 - h_1) = (1 - c_1)^2e_1^T(A^TA)e_1$. The minimax characterization of eigenvalues gives

$$\begin{aligned} \lambda_{\max}(A^TA) &\geq (1 + c_1)^2e_1^T(A^TA)e_1/(g_1 + h_1)^T(g_1 + h_1) \\ &= (1 + c_1)^2e_1^T(A^TA)e_1/2(1 + c_1) = (1 + c_1)e_1^T(A^TA)e_1/2 \end{aligned}$$

and $\lambda_{\min}(A^TA) \leq (1 - c_1)e_1^T(A^TA)e_1/2$. Hence $\kappa(A^TA) \geq (1 + c_1)/(1 - c_1) = \kappa(P_1 + P_2)$, proving the first inequality. For the second, from the CS decomposition the eigenvalues of $(I-(I-P_1)(I-P_2)(I-P_1))$ are $\{s_1^2, s_2^2, \cdots, s_{N/2}^2, 1\}$, where $s_i^2 = 1-c_i^2$ are the canonical sines and 1 is of multiplicity $N/2$. Then

$$\frac{\kappa(P_1+P_2)}{\kappa(I-(I-P_1)(I-P_2)(I-P_1))} = \frac{1+c_1}{1-c_1} \div \frac{1}{s_1^2} = (1+c_1)^2. \qquad \square$$

Note that $(1+c_1)^2$ is a measure of the lack of orthogonality between range(A_1) and range(A_2), and so measures the partial orthogonalization effect described in §2.4.

5. Implementation for three-dimensional elliptic PDEs. The primary implementation issue for RP methods is how to partition the rows of A. Since any row partitioning gives a convergent algorithm, the criteria for choosing one can be based on computational considerations. This section describes the set of test problems, outlines the row partitioning criteria, and presents the row partitioning used in the testing.

5.1. Test problems. Test problems are obtained from the seven-point centered difference operator [35] for elliptic partial differential equations

$$(27) \qquad a u_{xx} + b u_{yy} + c u_{zz} + d u_x + e u_y + f u_z + g u = F$$

where $a - g$ are functions of (x, y, z) and the domain is the unit cube $[0,1] \times [0,1] \times [0,1]$. Dirichlet boundary conditions are imposed in a manner described later. When discretized using n grid points in each direction the resulting system is of order $N = n^3$.

This class of test problems is chosen for four reasons. First, it includes important applications such as computational fluid dynamics and structural mechanics. Second, by refining the mesh the problem size grows rapidly with n, allowing test problems that can be scaled up to realistic sizes. Results are shown for problems of order 216000, corresponding to a 60 × 60 × 60 mesh. Third, by selecting the coefficient functions of the partial differential equation, matrices A can be created with or without properties such as diagonal dominance, definite symmetric part, eigenvalues on both sides of the imaginary axis, or extreme ill-conditioning. Fourth, the problems provide a specific example on how to select m, partition the rows into blocks, and analyze the subproblems that define the projectors.

The collection of test problems and their predetermined solutions follows. These are generalized versions of two-dimensional problems from a variety of sources [13], [22], [23], [34]. Each test problem has boundary conditions chosen to give a predetermined solution to the partial differential equation, so that the norm of the error vector as well as that of the residual vector can be checked.

PROBLEM 1. $\Delta u + 1000 u_x = F$.

PROBLEM 2. $\Delta u + 1000 \exp(xyz)(u_x + u_y - u_z) = F$.

PROBLEM 3. $\Delta u + 100 x u_x - y u_y + z u_z + 100(x+y+z)u/xyz = F$.

PROBLEM 4. $\Delta u - 10^5 x^2 (u_x + u_y + u_z) = F$.

PROBLEM 5. $\Delta u - 1000(1+x^2)u_x + 100(u_y + u_z) = F$.

PROBLEM 6. $\Delta u - 1000\left[(1-2x)u_x + (1-2y)u_y + (1-2z)u_z\right] = F$.

Problem 1 has the preassigned solution $u = xyz(1-x)(1-y)(1-z)$, Problem 2 has $u = x+y+z$, and Problems 3–6 have $u = \exp(xyz)\sin(\pi x)\sin(\pi y)\sin(\pi z)$. These test problems exhibit properties that cause difficulties for nonsymmetric iterative solvers, as summarized in Table 2 for a 12 × 12 × 12 grid. "Re $(\lambda) > 0$" indicates whether or not the eigenvalues lie in the right half plane of the complex plane; if this does not

TABLE 2
Properties of A for $N = 1728$

Problem	1	2	3	4	5	6
$\text{Re}(\lambda) > 0$	Yes	Yes	No	Yes	Yes	Yes
$A + A^T$ Definite	Yes	No	No	No	No	No
Estimated $\kappa(A)$	9	57	40000	4786	36	77

hold, then residual polynomial methods will fail. "$A + A^T$ definite" indicates whether or not the symmetric part of A is definite; if the answer is yes, then the sufficient conditions for GMRES(k) to converge hold. $\kappa(A)$ is an estimate of the condition number obtained by applying the LINPACK routine DPOCO to A^TA.

5.2. Row partitioning goals. The first criterion for a row partitioning is that the projections $P_ix = A_i(A_i^TA_i)^{-1}A_i^Tx$ must be efficiently computable. One way to achieve this is through parallelism: if A_i^T is the direct sum of blocks C_j for $j \in S_i$, then P_i is block diagonal [22]. The computation of P_ix can then be done by assigning each block of P_i to a different processor on a multiprocessor machine, or by vectorizing the computations across the blocks on a vector machine. The second criterion is storage efficiency. The additional storage should be $\mathcal{O}(N)$, that is, a few extra vectors, the number of which must not grow with increasing problem size N. The third criterion is that some bound on the condition number of the subproblems induced by the projections should be provided. The need for this is clear when $m = 1$ and A is partitioned into a single block of rows; in this case KACZ simply solves the normal equations $A^TAx = A^Tb$, an approach that can fail if $\kappa(A)$ is large. More generally, when $m > 1$, computing $y = P_ix$ requires solving a system of the form $A_i^TA_iv = w$. Hence the accuracy with which P_i can be computed depends on $\kappa(A_i^TA_i)$, and potentially large errors might occur in the projections if that condition number is large. A practical and cheap numerical way of bounding $\kappa(A_i^TA_i)$ for a given problem should be available. The fourth criterion is that the number m of projectors should be kept as small as possible, and should not depend on N. One reason was presented in Fact 2.1: when the block rows have equal numbers of rows of A, $1/m$ of the eigenvalues of the system matrix are exactly 1. For V-RP the possible reduction in problem size also decreases with increasing m.

In summary, the row partitioning should allow parallelism in the computations, require at most $\mathcal{O}(N)$ storage, give well-conditioned subproblems, and have m a small constant. One of the more useful results of this paper is that all four goals can be achieved simultaneously for important classes of problems.

5.3. Row partitioning of test problems. Row partitioning schemes ranging from $m = 4$ up to $m = 27$ have been tested on the test problems. For brevity, only one, an $m = 9$ partitioning generalized from a scheme in [22], is presented. Consider an $n \times n \times n$ mesh, and for convenience assume that n is a multiple of 3 and that lines in the mesh are numbered within each plane in the natural order. Place equations corresponding to nodes on lines $1, 4, 7, \cdots, n-2$ on the planes numbered $1, 4, 7, \cdots, n-2$ into the first block row A_1^T. Then assign those on lines $2, 5, 8, \cdots, n-1$ on the planes numbered $1, 4, 7, \cdots, n-2$ into the second block row A_2^T. In general, A_i^T consists of nodes on lines $l, l+3, l+6, \cdots$, on planes $p, p+3, p+6, \cdots$, where $l = (i+2) \bmod 3 + 1$ and $p = \lfloor \frac{i-1}{3} \rfloor + 1$. Figure 1 shows this scheme for a $6 \times 6 \times 6$ grid, with each node marked by the number i of its assigned block row A_i^T.

Because each line of nodes assigned to A_i^T is separated from the others by at least

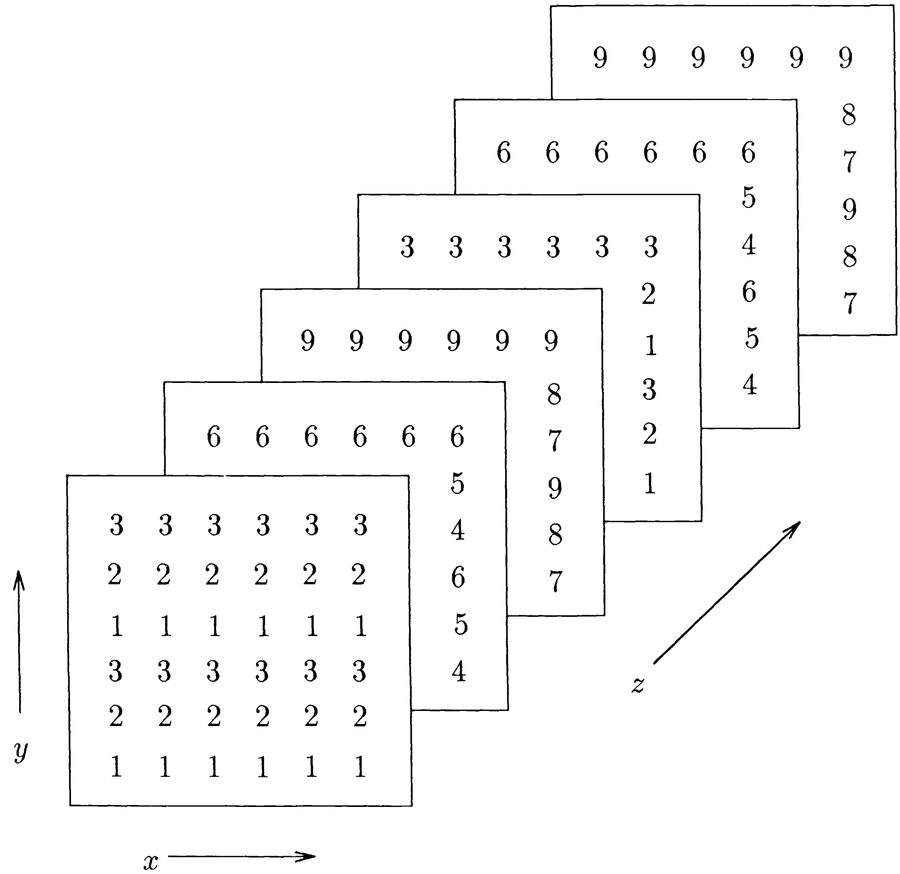

FIG. 1. *Row partitioning for $m = 9$.*

two other lines or planes, their seven point difference stars do not intersect and so A_i^T consists of $n^2/9$ separate subblocks of n coupled equations each. Each projector P_i can then be computed with a parallelism of $n^2/9$. What of the other row partitioning criteria? Let the subblocks of A_i^T be denoted C_j^T, for $j \in S_i$, where S_i is an index set of cardinality $n^2/9$. Dropping the subscripts temporarily, a typical C_j^T has the form

$$C^T = [0, D_1, 0, D_2, T, D_3, 0, D_4, 0] \tag{28}$$

with D_i a diagonal and T a tridiagonal matrix. The matrix C^TC is positive definite because when A is nonsingular each subblock is necessarily of full rank n. More importantly, C^TC is pentadiagonal and so its Cholesky factor R consists of three diagonals, and the Cholesky factors for all of the subblocks for all of the block rows A_i^T can be stored using only three additional vectors.

Surprisingly, the third requirement that each subproblem be well conditioned also is generally satisfied by the $m = 9$ partitioning. The details can be found in [6], but this can be seen intuitively because C^TC consists of the normal equations of T in (28), with the squares of the diagonal blocks D_i added to the main diagonal of T^TT, making it strongly diagonally dominant. This suggests that good bounds for the extremal eigenvalues of C^TC can be obtained from Gerschgorin estimates. However, for some

TABLE 3
$\max_j \kappa(C_j)$ *for* $n = 48$.

Problem	1	2	3	4	5	6
Estimated	7.94	1.92	74.9	1608	12.9	2.19
Actual	4.93	1.87	61.2	518	8.56	2.13

problems the Gerschgorin Disk Theorem provides an estimate $\lambda_{\min}(C^TC) \leq 0$. In these cases a better bound on the smallest eigenvalue comes from an application of the minimax characterization of singular values.

THEOREM 5.1. *Suppose that* $C^T = [D_1\ 0\ D_2\ T\ D_3\ 0\ D_4]$, *where each* $D_i \in \Re^{n\times n}$ *is diagonal, and let* $\delta_i = \min_k |D_i|_{kk}$. *Then*

$$\sigma^2_{\min}(C) = \lambda_{\min}(C^TC) \geq \delta_1^2 + \delta_2^2 + \delta_3^2 + \delta_4^2.$$

Proof. Let $z \in \mathcal{R}^n$, $\| z \| = 1$. Then

$$\begin{aligned} \| Cz \|^2 &= \| D_1z \|^2 + \| D_2z \|^2 + \| Tz \|^2 + \| D_3z \|^2 + \| D_4z \|^2 \\ &\geq \| D_1z \|^2 + \| D_2z \|^2 + \| D_3z \|^2 + \| D_4z \|^2 \geq \delta_1^2 + \delta_2^2 + \delta_3^2 + \delta_4^2. \end{aligned} \tag{29}$$

Minimizing $\| Cz \|$ over all such z gives the stated result. □

When C corresponds to a line of nodes at the top or bottom of a plane, or is within the first or last plane of the grid, one or more of the δ_i's is zero but the theorem is still valid. Table 3 shows results for the test problems on a 48 × 48 × 48 grid with the Gerschgorin estimate of the smallest singular value replaced by that of Theorem 5.1 when it is larger. The actual condition numbers are calculated using routines from Eispack. Clearly the subproblems are well conditioned, so the row partitioning with $m = 9$ satisfies all of the criteria for a suitable row partitioning.

The testing results show that the approach taken here for partitioning A is extremely effective. However, it is of limited use if applicable only to seven-point difference operator matrices. The reasoning for selecting the partitioning is based on a natural decoupling induced by the computational molecule used. This decoupling still occurs if, e.g., the domain is irregular or a 27-point difference operator is applied. Extensions to Neumann or periodic boundary conditions are also possible, again by considering the decoupling available on the mesh. Although more complicated, such a decoupling occurs with finite element methods applied to partial differential equations since usually the elements are chosen to have common support with only a few other elements. What determines the storage requirements of $3N$ for all of the Cholesky factors is that the longest line in the computational star contains three nodes. More generally, if the longest line in the computational star has l nodes, the Cholesky factors require only lN storage. The scheme used here for row partitioning can thus be extended to other, less simple, problems.

5.4. Other approaches. Recently, Arioli, Duff, Noailles, and Ruiz [2] experimented with a block Cimmino method for more general sparse systems. Their approach is to reorder the matrix into a block tridiagonal form, and then to use a row partitioning into two block rows. In this case the goal is not to have equal-sized blocks for load balancing, but rather to have few nonzero columns in the blocks of A_1^T shared with the nonzero columns in the blocks of A_2^T. This allows the use of a novel block diagonal right preconditioner that damps out the overlap between the shared nonzero columns and thereby increases the angles between the range of A_1 and A_2.

This reduces the number of CG iterations (cf. §2.4) but at the cost of making the subproblems more ill conditioned. Arioli et al. then handle this by using a direct method applied to an augmented system for solving the subproblems.

5.5. Implementation details. The crucial operations in the RP algorithms are the preprocessing stage, computation of the modified right-hand side vectors, and forming the matrix-vector products needed for the acceleration schemes. V-RP also requires a postprocessing stage to recover the solution x from the auxiliary unknown z. For convenience, an $n \times n \times n$ grid is used, with n a multiple of 3.

Preprocessing for RP methods consists of computing the necessary Cholesky factors R_j. As §5.3 showed, each C_j is well conditioned, so the procedure is to explicitly form the normal equations and then perform an LDL$^{\mathrm{T}}$ factorization. Recalling that S_i is the set of indices j for which C_j is a subblock of A_i, this stage consists of $n^2/9$ parallel tasks.

Cholesky Factorization:

```
For $i = 1, 2, \cdots, 9$ and $j \in S_i$ (in parallel)
    Form $R_j = (C_j)^T(C_j)$ (vectorized)
    Perform LDL$^{\mathrm{T}}$ factorization on $R_j$, overwriting $R_j$ with the result (sequential)
End For
```

R_j is stored as three vectors, and the diagonal is stored as $(D_j)^{-1}$ so that the backsolves can be performed using multiplication rather than division. The LDL$^{\mathrm{T}}$ factorization is an inherently sequential process, unsuitable for vector machines. For those computers the order of the loops is reversed, that is, the operations are vectorized *across* the blocks C_j rather than parallelized between the blocks.

To compute the KACZ modified right-hand side $\tilde{b}$, let $U_i = \mathrm{diag}(R_{j_1}, R_{j_2}, \cdots, R_{j_{n^2/9}})$, for $j_k \in S_i$. By overwriting, $\tilde{b}$ can be found using a temporary vector $w^T = (w_1^T, w_2^T, \cdots, w_m^T)$ of length N and $4m-2$ triangular solves with U_i or U_i^T, $2m-2$ multiplications by U_i or U_i^T, $3m$ multiplications by A_i, and $m^2 - m$ by A_i^T. The predominant expense is the triangular solves. Furthermore, each of the matrix-vector operations is implemented with $n^2/9$ parallelism.

Computation of $\tilde{b}$ from b for RP-m:

```
$w = b$
For $i = 1, 2, \cdots, m$
    $w_i = (U_i^T U_i)^{-1} w_i$
    $\tilde{b} = A_i w_i$
    For $j = i+1, i+2, \cdots, m$
        $w_j = w_j - A_j^T \tilde{b}$
    End For
End For
For $i = 1, 2, \cdots, m-1$
    $w_i = U_i^T U_i w_i$
End For
For $i = m, m-1, \cdots, 1$
    $\tilde{b} = A_i w_i$
    For $j = 1, 2, \cdots, i-1$
        $w_j = w_j - A_j^T \tilde{b}$
    End For
    If $i > 1$, $w_{i-1} = (U_{i-1}^T U_{i-1})^{-1} w_{i-1}$
```

```
End For
$\tilde{b} = A_1 w_1$
For $i = 2, 3, \cdots, m$
    $\tilde{b} = \tilde{b} + A_i w_i$
End For
```

The V-RP modified right-hand side b_V can be computed at a slightly lower cost, requiring $3m - 2$ triangular backsolves by U_i^T or U_i.

Computation of b_V from b for V-RP:

```
For $i = 1, 2, \cdots, m$
    $(b_V)_i = U_i^{-T} b_i$
End For
$w = A_m U_m^{-1} (b_V)_m$
For $i = m - 1, m - 2, \cdots, 2$
    $(b_V)_i = (b_V)_i - U_i^{-T} A_i^T w$
    $w = w + A_i U_i^{-1} (b_V)_i$
End For
$(b_V)_1 = (b_V)_1 - U_1^{-T} A_1^T w$
```

For KACZ the matrix-vector products needed by CG cost $4m-2$ triangular solves with U_i or U_i^T and $4m-2$ multiplications by A_i or A_i^T. For CIMM, this number is $2m$. V-RP can be implemented with $4m - 5$ of each operation, if the following algorithm is used.

Computation of $v = (I - V)d$ for V-RP:

```
$w = A_m U_m^{-1} d_m$
For $i = m - 1, \cdots, 3, 2$
    $w = w + A_i U_i^{-1} (d_i - U_i^{-T} A_i^T w)$
End For
$w = w - A_1 (U_1^T U_1)^{-1} A_1^T w$
For $i = 2, \cdots, m - 1$
    $v_i = U_i^{-T} A_i^T w$
    $w = w - A_i U_i^{-1} v_i$
End For
$v_m = U_m^{-T} A_m^T w$
```

Note that this only uses the block components numbered from 2 to m of the vectors d and v, reflecting the explicit reduction in the problem size allowed by V-RP. V-RP must also retrieve x from the auxiliary vector z, and this requires $2m - 1$ triangular solves and $2m - 2$ multiplications by A_i or A_i^T.

6. Testing results. Tests were run on three machines to examine different aspects of the algorithms. First, problems of order $N = 13824$ were run on one processor of the University of Illinois' National Center for Supercomputing Application's Cray X-MP in order to test the robustness and vectorization of the methods. Then problems of order $N = 216000$ were tested on one processor of the NCSA Cray-2 to verify that the results are valid for larger problem sizes. Finally the RP methods were tested on an eight-processor Alliant FX/8 at the Center for Supercomputing Research and Development to demonstrate that the algorithms can be implemented efficiently on a shared-memory multiprocessor. This section describes the other nonsymmetric solvers to which the RP methods are compared and the stopping tests used, and briefly summarizes the results comparing the methods. Fuller details of the results, including tables showing numbers of iterations, times, and residual and error norms are provided in [6].

6.1. Description of other methods tested. The RP algorithms are compared to two other basic methods, GMRES(10) (see [31] for references to this and the other Krylov subspace methods of this section) and CGNE, CG applied to $A^TAx = A^Tb$. GMRES(10) is from the PCGPAK library and has been optimized for the Cray-X/MP by Scientific Computing Associates [33], with portions written in Cray Assembly Language. The fixed value of $k = 10$ is chosen because larger values do not improve the robustness of GMRES(k) until k becomes a significant fraction of the problem size, and because iterative algorithms with $\mathcal{O}(N)$ additional storage are of primary interest in this paper. Whenever GMRES is referred to without an argument, GMRES(10) is understood. The reasons for selecting GMRES instead of another Krylov subspace method are the popularity of GMRES, and that Orthomin and GCR give similar results.

GMRES is also implemented with ILU and MILU preconditioners [17]. Because only GMRES is implemented with these preconditioners, the combination of GMRES with ILU preconditioning is abbreviated ILU, and similarly for MILU. PCGPAK allows the user to pass a shift parameter η to the preconditioning routine that helps guard against failure of the preconditioner by factoring $A + \eta I$ instead of A. This parameter is set to 0 in the experiments because in practice several tries at the incomplete factorization may be necessary to find a workable value for the parameter.

CGNE is also implemented with a preconditioner, found by performing an ILU* factorization on A to get $A \approx LU$. Then CG is applied to the normal equations of the left-preconditioned system $(LU)^{-1}Ax = (LU)^{-1}b$. When combined with this preconditioner, CGNE is denoted as ILCG. This is not the same as forming the normal equations A^TA and then performing an incomplete Cholesky factorization of A^TA; earlier work [7] with such a preconditioner for CGNE applied to two-dimensional problems showed that it also suffered robustness problems.

6.2. Stopping tests. The primary stopping test used is

$$\| Ax_k - b \|^2 \leq 10^{-9}. \tag{30}$$

For KACZ, the algorithm checks the *pseudoresidual* $\tilde{b} - (I - Q)x_k$. When it is less than ϵ_ρ, the *true residual* $b - Ax_k$ is checked. If the true residual is small enough, the algorithm stops. Otherwise the CG tolerance is adjusted by the assignment $\epsilon_\rho \leftarrow (0.7\epsilon_\rho / \| Ax_k - b \|^2)\epsilon$. Initially the tolerance for the pseudoresidual is equal to that on the true residual, i.e., $\epsilon_\rho = 10^{-9}$. Thus if the pseudoresidual's norm is 10 times smaller than the true residual's norm, the tolerance is decreased by 0.07, where the additional factor 0.7 is present to prevent the adjustment being made too often. Once this is done, the CG iteration resumes. The same procedure is used for CIMM and V-RP. However, since V-RP works on an auxiliary vector z_k, the corresponding x_k must be retrieved each time the true residual is computed. The preconditioned PCGPAK routines use the residual of the preconditioned system as the stopping test, so the same tolerance adjustment procedure is used with them. When resumed this way, the preconditioner is not recomputed.

Additional stopping tests, corresponding to failure conditions, are also imposed. A maximum number of iterations is set to 4001, except for CGNE which is allowed 8001 iterations. These limits are generous and when a method fails because the maximum allowed iterations are reached, iterating further has little effect.

TABLE 4
Failures among methods.

	$N = 13824$						$N = 216000$					
Method	1	2	3	4	5	6	1	2	3	4	5	6
KACZ												
V-RP			MX						MX			
CIMM									MX			
GMRES			RS	RS					RS	TM		
ILU		RS	RS	RS		RS		UP	UP	UP		
MILU	RS	RS	RS		RS	RS	RS	UP	RS		RS	UP
CGNE			MX	MX					MX	MX		
ILCG		UP	MX	MX		MX		UP	TM	UP		TM

For the test problems there is no guarantee that the preconditioners will exist or provide a better system. The preconditioner is called *unstable* if a zero pivot occurs during the factorization, or if the iterations experience overflow because of the use of a preconditioner.

The PCGPAK routines have one more stopping criterion. If the residual does not change by a difference of at least 10^{-6} over the course of ten successive iterations, the residual is said to *stagnate*. Omitting or relaxing this test simply changes the reason for failure from stagnated residual to maximum iterations reached.

Finally, for the problems with $N = 216000$ a maximum CPU time limit of 20 minutes is set for all of the methods. This is done for budgetary reasons. These error conditions are summarized and given the following codes in the tables of results:

- MX: Maximum iterations reached,
- UP: Unstable preconditioner,
- RS: Residual stagnates,
- TM: Maximum allowed CPU time reached.

6.3. Comparison of RP methods with other methods.

6.3.1. Robustness. Robustness results are shown in Table 4. KACZ is the only algorithm tested that succeeds in all cases, while CIMM and V-RP follow with only one and two failures, respectively. All the other methods fail at least in four cases. Furthermore, KACZ is the only method that solves Problem 3 for $N = 216000$.

Problems with large off-diagonal elements were the source of most of the failures of the preconditioned methods. A possible explanation is that ILU and ILCG ignore fillin positions when forming the incomplete factors and for matrices with large entries far from the central dense band of A, those positions can be large. MILU accounts for the fillin positions by moving their contributions to the main diagonal, but it failed in ten cases. For the test problems MILU still provides incomplete factors that are not good approximations to the factors of A, which is revealed by noting that the initial residual of the preconditioned system often is many orders of magnitude larger than that of the unpreconditioned system. Unpreconditioned GMRES fails on Problems 3 and 4, for which A has an indefinite symmetric part, but it succeeds on Problems 2, 5, and 6, which also have indefinite symmetric parts. This confirms that positive definiteness of $A + A^T$ is sufficient but not necessary for convergence. Unpreconditioned CGNE fails on Problems 3 and 4, which have a poor distribution of eigenvalues for the conjugate gradient algorithm, viz., they have many small eigenvalues.

Can the robustness of the GMRES(k)-based methods be improved by increasing the number k of vectors stored? To answer this, these algorithms were run again on the test problems of size $N = 13824$, for which they failed. Values of k up to 40 give no improvement in the robustness. Furthermore, since for some problems the GMRES(k)-based methods report a stalled residual after only a few iterations, those problems were also tested again by letting them run for as long a time as consumed by the successful RP methods. This resulted in no significant change in the error or residual norms, even when several hundred additional iterations were performed.

Why are RP methods more robust than GMRES algorithms? Each iteration of GMRES(k) minimizes the components of the residual contributed by the eigenvectors of A restricted to a Krylov subspace. If the residual is orthogonal to that subspace, the method stalls. Even when the residual is not orthogonal to the Krylov subspace, the minimization is over a subspace of dimension k, which becomes negligible for large N. However, every projection of KACZ and V-RP minimizes the residual on a subspace of dimension $N/9$, a fixed fraction of the problem size. Although each iteration requires more work than one iteration of GMRES(k), a more robust method results.

It should be noted that the test problems were chosen partly to be difficult for Krylov subspace methods and may not represent a fair mix of problems normally encountered. It should also be noted that some of the problems with robustness could possibly be obviated by using modified upwind differencing. However, the results show that such a change is unnecessary if RP methods are used. Furthermore, if a nonlinear PDE is being solved and a problem similar to the test problems is generated in the nonlinear iteration, it may not be easy or practical to change the differencing scheme adaptively.

6.3.2. Accuracy. The final residual and error norms are shown in Figs. 2 and 3, respectively, where for each problem the three points plotted are the smallest norm from the RP methods, the smallest from the GMRES-based methods, and the smallest from CGNE or ILCG. No point is plotted for the GMRES methods for Problem 3 or for CGNE or ILCG for Problem 4, because the final norms produced are $\mathcal{O}(1)$ or larger. CGNE produces the smallest residual norm on 8 of the 12 cases, while KACZ does so in two cases and CIMM and MILU in one each. V-RP and CGNE produce the smallest error norm in four cases, GMRES in one case, and ILU in three cases. Although V-RP fails on Problem 3 for both problem sizes by using the full number of iterations allowed, it produces a smaller error norm than all of the other methods, even though its residual norm is larger than that of the successful solvers. An explanation of this behavior lies in Theorem 3.3, which states that V-RP minimizes the error, while KACZ minimizes the error in an elliptic norm.

6.3.3. Speed and efficiency. The robustness property is expected, since RP methods were designed to achieve it. The pleasing result is that in spite of the greater amount of work done per iteration, RP methods are the fastest of the solvers tested on 8 of the 12 experiments with the $N = 13824$ problems run on the Cray X-MP and the $N = 216000$ problems run on the Cray-2. In the other four experiments, an RP method is still competitive with the fastest solver. Figure 4 shows the execution times for problems of size $N = 13824$, where for each problem the three points plotted are the fastest of the RP methods, the fastest of the GMRES-based methods, and the fastest of CGNE or ILCG. Since no Krylov method solved problem 3 and CGNE and ILCG failed on both Problems 3 and 4, those data points are omitted.

The speed of RP methods is caused by their parallelism. Roughly 85 percent of the computation time of KACZ is consumed in computing the matrix-vector products needed for the CG acceleration, and this has a natural parallelism or vector length

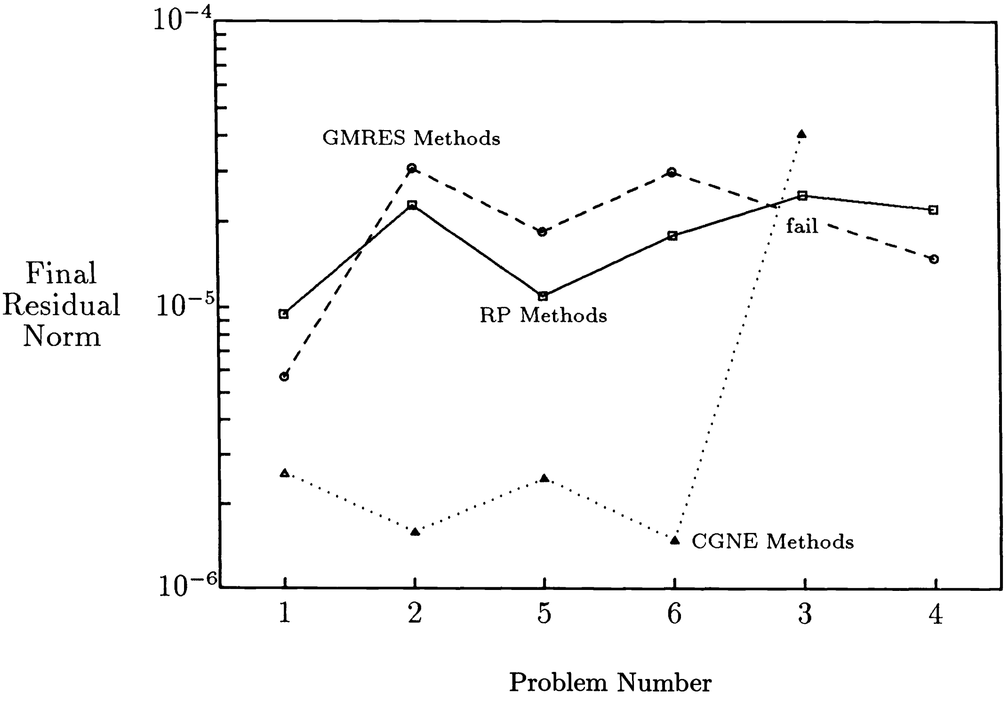

FIG. 2. *Best residual norms for* $N = 13824$.

of $n^2/9$, where $N = n^3$. GMRES computes the matrix-vector product with a vector length of only 7. Even though more parallelism is available for GMRES, since each row can be handled separately, the parallel tasks are small. This is partly because of the data structure that PCGPAK uses to store A, and GMRES can run faster if the matrix-vector product is performed by diagonals rather than rows. However, GMRES benefits by having crucial parts written in Cray Assembly Language, while the RP methods are written exclusively in Fortran. For CGNE, relatively poor performance results primarily from the large number of iterations it requires.

6.3.4. Multiprocessor results. The preceding results were obtained on single processors of Crays using vectorization across the $n^2/9$ block rows C_j^T that comprise a block row A_i^T. The algorithms can also be implemented on a shared-memory multiprocessor by treating the $n^2/9$ subproblems defined by a projector as separate tasks to be assigned to different processors, with vectorizaton available in each subtask from the matrix-vector multiplications. The RP methods were implemented this way on an eight-processor Alliant FX/8. Figure 5 shows the ratio of execution time on one processor of the Alliant FX/8 to that on p processors for KACZ, averaged over all six problems. For comparison, a dashed line with slope 1 is included showing the ratio corresponding to ideal parallelism. On eight processors KACZ runs between five and six times faster, and the efficiency is 63 percent–75 percent.

7. Discussion and summary. Section 2.4 presented an explanation for the properties of RP methods in terms of the ill-conditioning of a matrix arising from

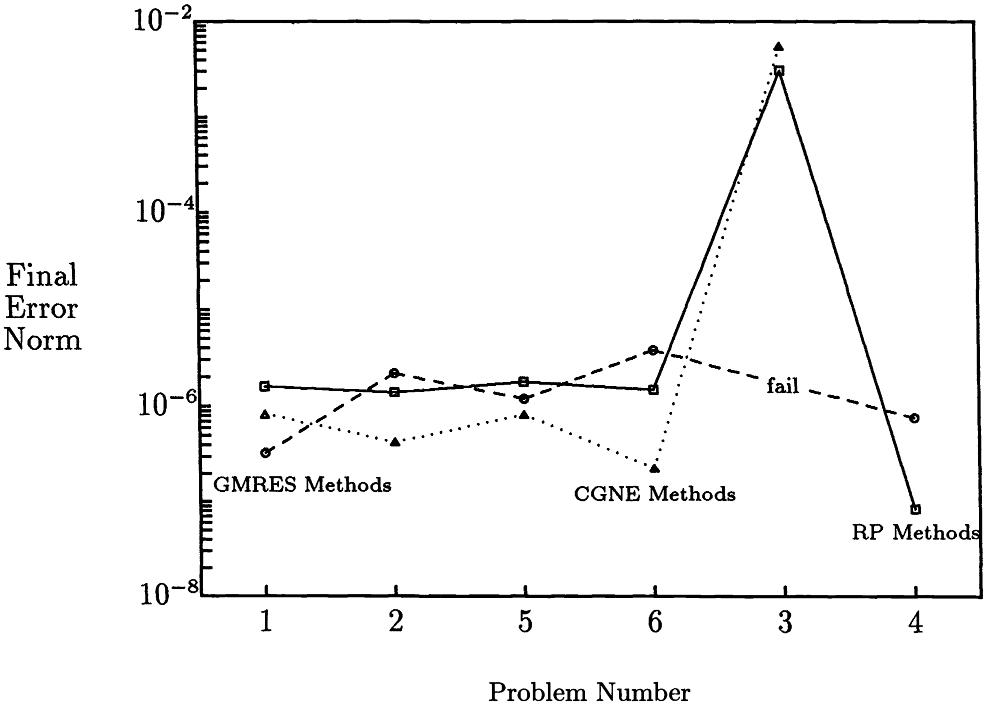

FIG. 3. *Best error norms for* $N = 13824$.

TABLE 5
Number of iterations required for $N = 13824$.

Method	1	2	3	4	5	6
KACZ	8	109	666	715	20	33
V-RP	9	113	4001	813	20	33
CIMM	17	343	572	2000	51	92
CGNE	90	682	8001	8001	325	114

within and across block rows A_i^T. One implication of that argument is proven for the two block row case by Theorem 4.2, which says that KACZ should require fewer CG iterations than CIMM, which in turn should require fewer than CGNE. Table 5 shows that this relationship also holds for the $m = 9$ case tested here; the only exception is that CIMM required fewer iterations than KACZ on Problem 3 with $N = 13824$. Generally, CIMM requires two to three times as many iterations as KACZ, while CGNE requires so many iterations on some problems that it uses the maximum number allowed.

Another implication of the heuristic explanation of RP properties is that fewer iterations are needed for a given RP method when rows that make small angles with each other are placed in the same block row instead of in different block rows. This is confirmed by considering the following problem.

PROBLEM 1′. $\Delta u + 1000 u_y = F$.

This is the same as Problem 1 but with the first derivative term u_y instead of

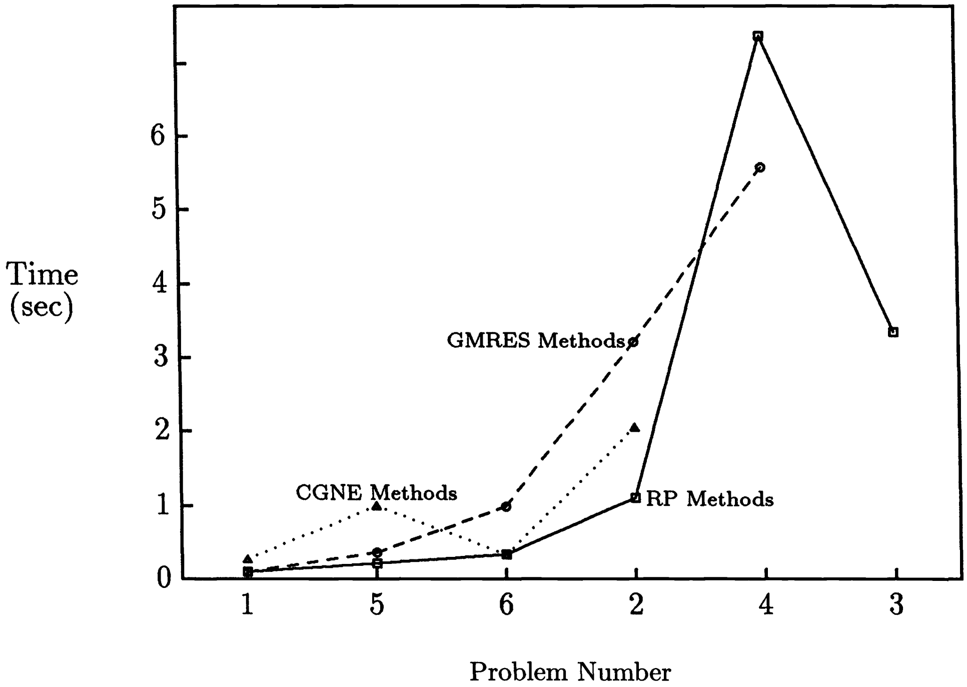

FIG. 4. *Fastest times for $N = 13824$.*

1′	35	36	73	269	90

u_x. The resulting matrix A has the same spectrum as that of Problem 1, but the number of iterations required increases for the RP methods while remaining constant for GMRES and CGNE, as shown in Table 6 for $N = 13824$. For both Problems 1 and 1′ it can be shown that each row a_i of A makes a small angle with at most two other rows. For Problem 1 these other two rows are located in the same block row as a_i, while for 1′ they are located in different block rows. For Problem 1 the RP methods remove this near linear dependence by implicitly replacing A_i with Q_i, an orthonormal basis matrix for range(A_i). For Problem 1′, the near linear dependence is across block rows and must be handled by the outer CG iteration.

The usefulness of this explanation of RP properties is that it indicates how one should partition the matrix and number the nodes for a given problem. For example, the grid for CFD problems should be arranged so that the lines of nodes that form the block rows A_i^T are aligned in the direction of predominant flow; this occurs in Problem 1 but not in Problem 1′. Furthermore, RP methods like other iterative solvers work well if the system is diagonally dominant. If there are large off-diagonal elements in the diagonal closest to the main diagonal, RP algorithms can still work

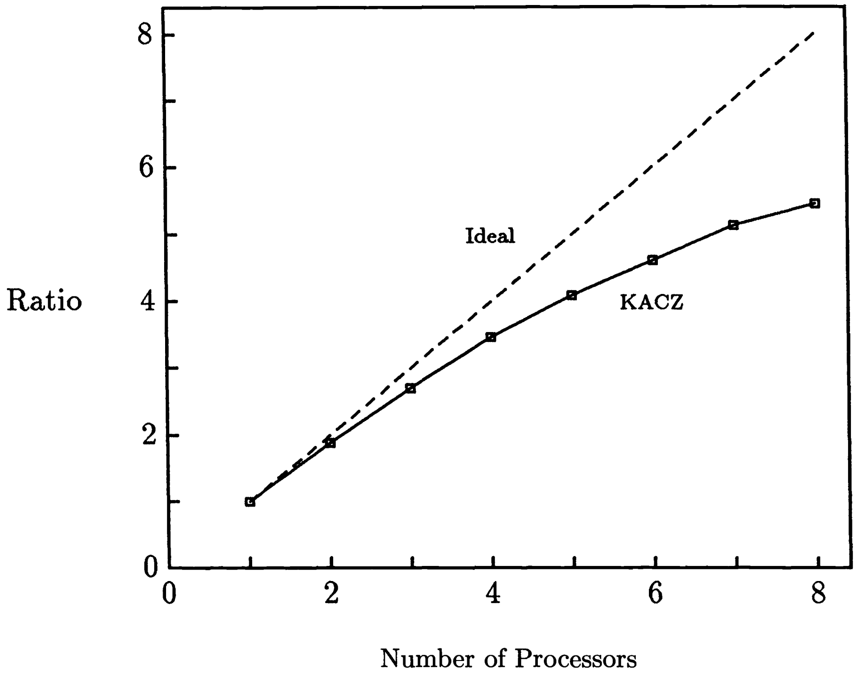

FIG. 5. *Ratio of times for p processors on Alliant FX/8.*

well. Although every worker in the field of RP methods has recognized the importance of having the angles between the block rows large, this seems to be the first guideline on how to achieve it for practical problems without having to actually compute the angles involved.

Although the testing results of this paper are for the structured sparse systems arising from seven-point centered differences, Arioli, Duff, Noailles, and Ruiz [2] have recently applied block Cimmino to more general sparse systems and introduced an innovative preconditioner with good results. In [2] they report on this approach and include tests on some of the problems from this paper.

In summary, CG accelerated row projection methods can have a robustness unmatched by other nonsymmetric solvers, and successfully solve large systems with indefinite real parts and eigenvalues arbitrarily distributed in the complex plane. The row partitioning scheme described here allows large scale parallelism suitable for both vector and multiprocessor machines and yields algorithms competitive in speed with other solvers. The new method V-RP is error minimizing and gives better solutions than the other methods, as well as explicitly reducing the problem size. Finally, the relationship with conjugate gradients applied to the normal equations is shown and an explanation for the behavior of RP algorithms is provided. This explanation is verified both theoretically and numerically.

A SET OF NEW MAPPING AND COLORING HEURISTICS FOR DISTRIBUTED-MEMORY PARALLEL PROCESSORS*

CLAUDE POMMERELL†, MARCO ANNARATONE†, AND WOLFGANG FICHTNER†

Abstract. New mapping and coloring heuristics are developed to parallelize preconditioned conjugate-gradient-like methods on distributed-memory parallel processors (DMPPs). All these heuristics are fast, with a "quasi" linear time complexity. These schemes are evaluated by solving several systems of linear equations from two-dimensional and three-dimensional semiconductor device simulation on irregular finite-element grids. The benchmarks have been carried out on a simulated 64-processor DMPP with fast communication channels that is under development at the Integrated Systems Laboratory of the Swiss Federal Institute of Technology. The linear systems involved had between 2000 and 75000 unknowns. Depending on the problem under consideration, speedups between 42 and 54 were obtained. Mapping heuristics that use geometric information given by the embedding of the problem graph into physical space were found to be superior to heuristics based solely on the topological information of adjacency structure. Coloring heuristics for vector computers or shared-memory parallel computers were not sufficient for effective parallelization on DMPPs. Coloring strategies for DMPPs had to balance the load for each color, taking into account the mapping and exploiting the locality corresponding to it.

Key words. preconditioned iterative methods, mapping, coloring, distributed-memory parallel processors, finite elements, semiconductor device simulation

1. Introduction.

The efficient solution of large sparse linear systems lies at the heart of many scientific computing problems. Such solutions usually account for the major part of the computing resources needed, both in CPU cycles and memory. The systems themselves arise from the application of appropriate discretization schemes (e.g., finite elements) to partial differential equations, and may exhibit rather irregular sparsity patterns.

While direct solution techniques based on Gaussian elimination have proved to be extremely robust and stable, they are no longer competitive with iterative methods for problems with large numbers of unknowns, as in three-dimensional (3-D) applications [30]. Apart from these reasons, iterative schemes offer unique opportunities to better exploit advanced computer architectures such as parallel and vector machines. Among the wide variety of methods published, preconditioned conjugate-gradient schemes [52], [16] have become popular in recent years.

The vectorization and parallelization of iterative methods applied to irregular problems are more difficult than similar program transformations on dense or regularly structured matrices. While some work on efficient parallelization of these irregular problems has been carried out for shared-memory multiprocessors and for vector processors [54], a similar effort for distributed-memory parallel processors (DMPPs) is still lacking. Moreover, as we shall show in this work, new methodologies are needed when the implementation on DMPPs is considered. The problem grid has to be *mapped* onto the DMPP's interconnection topology to lower the interprocessor communication overhead. As for shared-memory machines, *coloring* allows parallelization of preconditioning and/or vectorization of operations running on one processor.

The paper focuses on aspects of mapping and coloring as they might apply to implementations of iterative methods on DMPPs. First, we present a short overview

* Received by the editors April 5, 1990; accepted for publication (in revised form) July 20, 1990.

† Integrated Systems Laboratory, Swiss Federal Institute of Technology, CH-8092 Zürich, Switzerland.

of the implementation details of sparse matrix solvers; this will allow us to introduce the notation used throughout the study. Second, related results are discussed to review the current state-of-the-art. Third, and before going into the implementation details, we summarize the most important contributions our work gives to the research in this field. Then, the mapping and coloring schemes we developed will be presented, discussed, and analyzed. Finally, we evaluate the efficiency of the methods we devised by applying them to realistic problems stemming from two- and three-dimensional simulation of semiconductor structures.

2. Problem statement.

2.1. Sparse systems of linear equations. A system of N linear equations $Ax = b$ in N unknowns x is called *sparse* if most of the entries a_{ij} of the (square) matrix A are zero. We call M the total number of nonzeros in A, and $D = M/N$ the average number of nonzeros per row in A.

A symmetric or structurally symmetric sparse matrix is often represented as an undirected graph [23]. Each pair of off-diagonal nonzero entries a_{ij} and a_{ji} of the matrix A corresponds to an edge between the vertex i and the vertex j in the graph. There are N vertices and $(M - N)/2$ edges in the graph, and the average degree of a vertex is equal to $D - 1$.

In many applications with sparse systems this graph corresponds to a spatial discretization. Two vertices in the physical discretization that are close to each other are more likely to be connected by an edge than vertices that are physically far apart. The matrices are not always symmetric, but usually structurally symmetric, that is, a_{ij} is nonzero if and only if a_{ji} is nonzero. Graphs derived from finite-element discretizations can be quite irregular, featuring a much finer discretization in some regions than in others. A consequence of Euler's polyhedron formula [29] is that $D < 7$ in two-dimensional triangular grids. Values of D between 7 and 27 are typical for three-dimensional finite-element grids.

2.2. Direct solution methods. A sparse system can be solved by *direct* methods such as Gaussian elimination where A is decomposed into the product of the triangular matrices L and U. The lower and upper triangular matrices L and U are generally much denser than A [23], [49]. This fact is known as the problem of "fill" or "fill-in." Fill causes severe storage requirements that are difficult to estimate because of their strong dependence on the sparsity structure of A. The execution time of a direct solver also depends strongly on this unpredictable fill. Ordering techniques (such as the minimum degree algorithm [51], [25], [41], [24]) have been developed to reduce the fill on sequential computers. However, for very large problems (with several hundreds of thousands of unknowns) the storage requirements make the use of direct methods prohibitive [10], [30].

2.3. Iterative solution methods. Iterative solvers have a known storage overhead (generally, fewer than ten N-vectors and one matrix with the sparsity structure of A). The execution time depends on and can be controlled by the accuracy requirements imposed.

While there is a wide range of iterative methods reported in the literature [28], we focus our results on preconditioned conjugate gradient methods. These schemes are derived from the basic *Conjugate-Gradients algorithm* [31], [26], [27] for symmetric positive-definite systems. Several variants have been developed for nonsymmetric systems, such as Biconjugate Gradients [18], Conjugate Gradients Squared (CGS) [58], ORTHOMIN [60], ORTHODIR [61], GMRES [55], etc.

All the above methods share the same basic operations. Each iteration involves multiplications of the sparse matrix A by a vector, linear operations on vectors (scaling and addition of vectors), vector dot products, scalar divisions, and a test for convergence. The Biconjugate Gradients method requires also a multiplication of the transposed matrix A^T by a vector in each iteration.

2.4. Preconditioning for iterative solvers. *Preconditioning* improves stability and accelerates convergence [27]. A preconditioner Q is an approximation of A, such that $Q^{-1}A \approx I$. In addition to the operations mentioned in the previous section, a system $Qz = r$ must be solved in each preconditioned iteration. Therefore, the preconditioner Q must be easy to invert. Figure 1 shows one way of writing the preconditioned conjugate gradients algorithm [27].

```
$r_0 := b - Ax_0;$
$z_0 := Q^{-1}r_0;$
$k := 0;$
while no convergence loop
    if $k = 0$ then
        $p_0 := z_0;$
    else
        $\beta_k := \frac{z_k^T r_k}{z_{k-1}^T r_{k-1}};$
        $p_k := z_k + \beta_k p_{k-1};$
    end if;
    $\alpha_k := \frac{z_k^T r_k}{p_k^T A p_k};$
    $x_{k+1} := x_k + \alpha_k p_k;$
    $r_{k+1} := r_k - \alpha_k A p_k;$
    $z_{k+1} := Q^{-1} r_{k+1};$
    $k := k + 1;$
end loop;
```

FIG. 1. *The preconditioned conjugate gradient method.*

Incomplete factorizations are often used as preconditioning methods; here, Q is the product of two *sparse* triangular matrices L and U. The sparsity structure of $L + U$ is generally chosen to be identical to that of A. Solving a system with Q then reduces to one forward and one backward substitution step, with the same amount of computation as a sparse matrix-vector product. L and U must be set up before the first iteration starts. ILU, MILU, SSOR, ICCG(0) are examples of such schemes [17], [21].

3. Parallelization and vectorization of preconditioned conjugates-gradient-like methods. An efficient implementation of these methods must focus on the four basic operations mentioned above [54]. Both the sparse matrix-vector products and the substitution steps in the incomplete factorization preconditioner require $O(M)$ operations. The linear operations on vectors and the vector dot products require $O(N)$ operations each.

We summarize below the state-of-the-art in this field.

3.1. Vector and shared-memory parallel computers. Linear operations on vectors and vector dot products can be efficiently implemented on these machines. Sparse matrix-vector multiplication is also efficient on vector computers if gather and scatter hardware supports the execution of vector operations with irregular address patterns [7], [38].

Vectorization of the solution of sparse triangular systems with incomplete factorization preconditioners is more difficult. Figure 2 shows the forward substitution to solve the system $Lx = b$, where L is a sparse lower triangular matrix. The inner loop (the summation) can be vectorized, but it requires on average only $D/2$ multiplications and additions. The outer loop features a data dependence on x: the value of x_i depends on some x_j with $j < i$.

```
$i := 1$;
while $i \leq N$ loop
    $x_i := \frac{1}{\ell_{ii}} \left( b_i - \sum_{j<i,\, \ell_{ij} \neq 0} \ell_{ij} x_j \right)$;
    $i := i + 1$;
end loop;
```

FIG. 2. *Sparse forward substitution.*

The outer loop can only be vectorized if the sparsity structure of L is exploited. A set of contiguous values x_s to x_t can be computed in parallel if they are mutually independent in $Lx = b$, that is, the submatrix

$$\begin{pmatrix} \ell_{ss} & \cdots & \ell_{st} \\ \vdots & \ddots & \vdots \\ \ell_{ts} & \cdots & \ell_{tt} \end{pmatrix}$$

must be diagonal.

In the associated graph the vertices in the set $c = \{s, \cdots, t\}$ must be independent. There is no edge connecting any vertex in c to another vertex in c. In graph theory a *partitioning* of the vertices of a graph into sets of independent vertices is called *coloring.*

After coloring, the outer loop of the substitution can be vectorized *color by color.* The achievable performance depends on the relationship between the size of the color sets and the startup latency of the hardware vector pipeline(s). In general, vector processors benefit from color sets that are as large as possible. Finally, note that finding a coloring scheme that provides minimum number of colors in an arbitrary graph is an NP-complete problem [22].

Similar considerations apply also when parallelizing incomplete factorization preconditioners on shared-memory multiprocessors.

The coloring approach suggested by Schreiber and Tang in 1982 [57] has been used by several researchers to vectorize and parallelize the solution of triangular systems resulting from regular grids, like 5-point or 9-point stencil meshes [34], [1], [45], [50], [6], [10]. Red/black coloring is a well-known technique to create sets of independent vertices in finite difference meshes using a 5-point stencil [28].

Poole and Ortega [50] compare several patterns for 4-coloring regular 9-point stencil meshes. They define a *continuous coloring rule* to obtain maximum vector lengths for a given number of colors on a two- and three-dimensional rectangular grid.

Melhem and Ramarao [47] describe a technique to color irregular meshes of triangular elements. The algorithm proceeds by constructing a *level structure* [23] of the graph. Each level is an outerplanar graph (a planar graph that can be embedded in a plane such that all the vertices lie on a contour and all the edges lie inside this contour) and can be 3-colored. If two sets of three colors are used for all the odd and even levels, a 6-coloring is obtained. The coloring algorithm can be extended by a more extensive backtracking scheme to obtain a 4-coloring.

Bank et al. [10] use a simple greedy algorithm [2] to color irregular finite-element meshes, using at most one color more than the maximum vertex degree in the graph.

Lichnewsky [40], [39] uses ν steps of nested dissection [23] to split the graph into 2^ν subdomains that can be processed in parallel on 2^ν processors. The vertices on the separators are handled serially at the end.

Several of the above authors report a degradation in the convergence rate of multicolor preconditioned iterative methods. However, we are not aware of any generalizable results concerning systems with irregular sparsity patterns. In [30], we give some preliminary results on the influence of coloring and ordering on the convergence rate for problems in semiconductor device simulations.

3.2. Distributed-memory parallel processors. The following aspects arise in the parallelization of preconditioned conjugate-gradient-like methods on distributed-memory parallel processors.

3.2.1. Data distribution. Linear operations on vectors (multiplication of a vector by a scalar and addition of vectors) can be executed without any communication if for each component of the result vector computed on processor P, the corresponding components of the operand vectors are also available on P. It is therefore convenient to partition the components of all vectors in the same way. In terms of graphs, each vertex holds one component of each vector. We can assign at most $\lceil N/P \rceil$ vertices to each of the P processors in order to achieve the optimum load balance for the linear operations.

The vector dot product is computed as follows: First, the processors compute in parallel the dot product on their local vectors. This part of the computation is again load balanced with the vector partitioning above. Then, the partial results are added up globally. Finally, the result is made available to all the processors.

The sparse matrix A, as well as the sparse factors of the preconditioner, should be distributed to parallelize the matrix-vector multiplication and the substitutions. The rows or the columns of the matrices can be partitioned the same way as the vector components. In graph terms, row partitioning corresponds to storing each arc together with its source vertex, and column partitioning corresponds to storing each arc together with its destination vertex. The computational load for the two $O(M)$ operations is balanced if the number of arcs is also distributed equally among the processors.

Because global communication and processor synchronization is required, the vector dot product is dominating the execution time on message-passing DMPPs that feature relatively large message startup time, like the iPSC [8], [42]. Aykanat and Özygüner [8], and Aykanat, Özgüner, Ercal, and Sadayappan [9] propose to overcome this bottleneck by modifying the basic conjugate-gradient algorithm. Their "coarse grain" algorithms require fewer vector dot products, at the expense of some overhead in the local computation. Annaratone, Pommerell, and Rühl [5] showed that the synchronization overhead of the vector dot product can be neglected in DMPPs with low latency communication channels, such as those used in systolic communication.

3.2.2. Mapping. When performing a matrix-vector multiplication, the processors must access some nonlocal components of the operand vector, depending on the sparsity pattern of the local rows. In terms of graphs, the computation for one vertex requires data from all its adjacent vertices.

If the matrix is partitioned row-wise as described above, the whole communication can be performed before the actual computation starts. The processors send the components of their local vectors to all the processors that need them, that is, to those processors with nonzero entries in the corresponding columns of their local sparse matrix. After having received the missing parts of the vectors, a processor can multiply its local matrix by the extended vector (local vector and received nonlocal parts), yielding the local part of the resulting vector.

The assignment of adjacent vertices to processors determines the communication requirements:

1. If both vertices v_1 and v_2 incident to an edge are allocated to the same processor P_1 (Fig. 3), no communication is required by the data dependence represented by this edge.

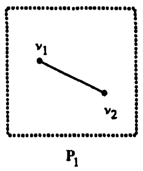

FIG. 3. *Two adjacent vertices on the same processor.*

2. If two adjacent vertices v_1 and v_2 are located on neighboring processors P_1 and P_2 (Fig. 4), their values have to be exchanged through the channel connecting P_1 and P_2.

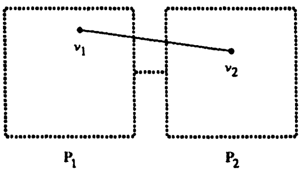

FIG. 4. *Two adjacent vertices on neighboring processors.*

3. If two adjacent vertices v_1 and v_2 are located on non-neighboring processors P_1 and P_3 (Fig. 5), the communication overhead to exchange their respective values increases with the number of hops separating the two processors. The two vertices should therefore be allocated onto neighboring or close processors.
4. The value of a vertex v_1 (located on processor P_1) that is needed by two or more vertices v_2, v_3, ... on the same other processor P_2 (Fig. 6) has to be sent only once to P_2.
5. The value of a vertex v_1 (located on processor P_1) that is needed by two or more vertices v_2, v_3, ... on different processors P_2, P_3, ... (Fig. 7) need

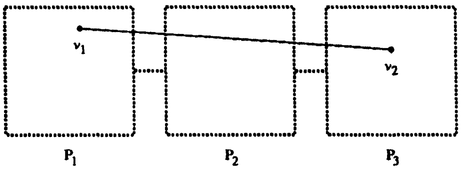

FIG. 5. *Two adjacent vertices on non-neighboring processors.*

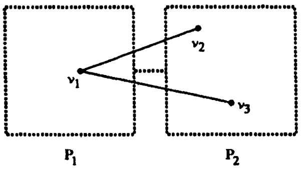

FIG. 6. *Two adjacent vertices to a vertex that are assigned to another processor.*

not be sent directly to all these processors, but can be forwarded by those processors on the shortest path.

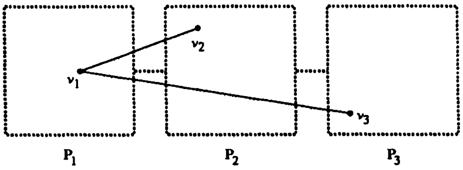

FIG. 7. *Two adjacent vertices to a vertex that are assigned to two other processors.*

6. A set of values to be sent from one processor P_1 to another processor P_2 (Fig. 8) can be packed together into a larger message. This is particularly important on message-passing architectures (e.g., hypercubes) where the overhead for message creation is large.

The problem graph has to be *mapped* onto the interconnection topology to minimize the communication overhead. This mapping still needs to ensure equal load balance as specified above. While this is easy to accomplish for finite-difference graphs, finding an optimal mapping of a complex structure—like a finite-element graph—is NP-complete [22].

The graph is often not mapped onto the full interconnection topology offered by the parallel architecture, but onto a linear array or onto a regular two-dimensional (2-D) mesh (hypercubes or tori contain these topologies). One reason is that the problem domain (the physical space that is discretized by the graph) is usually only two- or three-dimensional.

Sadayappan and Ercal [56] describe a heuristic technique to map square meshes and irregular graphs into a one-dimensional (1-D) array of processors. Vertices are assigned to processors in the order they appear in a level structure partitioning the graph. Load balance is assured, and only local communication is necessary. By using the intersections of two 1-D mappings starting from sets of vertices on orthogonal boundaries of the problem domain, they obtain an unbalanced mapping onto a 2-D mesh of processors. The latter is then rebalanced by local refinement. Aykanat, Ögüner, Ercal, and Sadayappan [9] evaluated these mapping strategies on 1-D and

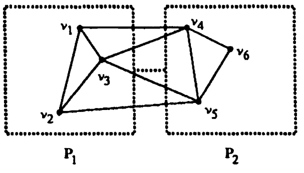

FIG. 8. *Multiple edges between the vertices of two processors.*

2-D topologies embedded into an Intel iPSC/2 hypercube. More values have to be exchanged in 1-D mappings, but they are packed into a smaller number of messages. Because of the large overhead in message creation, the 1-D mappings are preferred for realistic problem sizes.

Fox [20], [19] describes several mapping strategies that use only the topological information given by the graph adjacencies, and no geometric information on the embedding of the graph in the physical problem domain. Simulated annealing and an approach based on neural networks yield the best mappings at the expense of execution time for the mapping heuristic itself. Orthogonal recursive bisection (ORB) recursively cuts the graph into two subgraphs by ordering the vertices according to the difference of their distance to two sets of vertices. The quality of the mapping depends to a large degree on heuristics to obtain orthogonal cuts.

Other strategies have been proposed and tested on small graphs by Bokhari [13], Lee and Aggarwal [37], and Berger and Bokhari [12].

3.2.3. Coloring. The total amount of computation in the two substitution steps for incomplete factorization preconditioning is similar to the matrix-vector product. The total communication requirements are of the same order of magnitude. However, there is much more synchronization required to solve sparse triangular systems.

If two vertices i and j are allocated on two different processors P_i and P_j, and if x_j depends on x_i (that is, if $\ell_{ji} \neq 0$ or $u_{ji} \neq 0$), the processor P_j has to wait until it receives the new value x_i from P_i before it can update x_j. There are up to $2N$ such synchronization points required to perform both forward and backward substitution.

These synchronization points must be grouped together to reduce this unacceptable synchronization overhead. The way to achieve this is again through *coloring.* Each color is distributed to all the processors. Processors handle the same color concurrently. Between the processing of two colors, the needed values from the latest colors are exchanged. If C is the number of colors, a total of $(2C - 2)$ such synchronization points are required to perform the two substitution steps.

Coloring on DMPPs differs from coloring for shared-memory parallelization or vectorization in the following aspects:

1. Dependent vertices allocated on the same processor can be processed in the same color since no communication is required. The edges between local vertices need not be considered for the coloring of the graph. [1]
2. The vertices of each color have to be *distributed* equally onto the processors, in addition to the distribution requirements mentioned in §3.2.1.
3. The number of colors must be as small as possible to reduce the synchronization overhead.

[1] This is not true, however, if the nodes of the DMPP are vector processors and if we want to exploit the vector capabilities of each single node.

4. Coloring *and mapping* (§3.2.2) should be combined to ease the coloring task and to potentially reduce the number of colors that are required.

Because of this, the coloring strategies for shared-memory parallelization and vectorization described in §3.1 can only be partially applied to DMPPs.

Coloring for regular 5-point or 9-point stencil meshes has been described by several researchers, for instance by Saad [53], O'Leary [48], and Lai and Liddell [36].

Tseng [59] used maximum color renumbering to parallelize sparse substitution on a systolic computer. Melhem [43], [46] defines a systolic network for triangular system solution where the sparse matrix is *striped* [44], and each cell handles one stripe. Both these approaches can be applied to irregular sparse systems, and both schemes pass a whole vector through all processors (and through the host in the Warp implementation [3]), so that the communication overhead for each processor is $O(N)$.

4. Mapping and coloring schemes for DMPPs. In this section we describe the mapping and coloring schemes we use to solve sparse systems of equations on a DMPP. The quality of the various schemes for real problems will be compared in §5. In the description of each heuristic we put a shorthand name as (HEUR), which will be used to refer to this method in the tables.

Note that most of the heuristics described in this section are novel approaches for mapping and coloring on DMPPs. Only TOP1-1, GEO2-R, and GREEDY have been used before, albeit in another context.

We are mainly interested in mapping and coloring *irregular* graphs used in 2-D or 3-D finite-element analysis. Besides the requirements developed in §3.2, we want our mapping and coloring heuristics to be *fast*; all our schemes must execute in "almost" linear time, i.e., their time complexity must be smaller than $O(N^{1+\epsilon})$ for any $\epsilon > 0$. In fact, all our heuristics have a time complexity of

$$O(DN + N \log N + N \log P + CN), \tag{1}$$

where N is the number of vertices in the graph, D the average degree of the vertices, P the number of processors, and C the number of colors in the coloring.[2]

4.1. Mapping heuristics. Our mapping heuristics can be classified by the following criteria:

1. The type of information used. The heuristic can be based either only on *topological* information as given by the adjacency structure of the graph, or it can use *geometric* information given by the embedding of the graph into physical space. The latter is available, for instance, in a finite-element graph, where the physical position of the vertices (which are the corner points of elements) is already required to assemble the matrices.
2. The target topology. 1-D mappings map the graph onto a linear array of P processors, while 2-D mappings map it onto a $P_h \times P_v$-mesh of processors. The mappings can be compared for $P = P_h P_v$.

We write a mapping $\mathcal{A}$ as an ordered list of sets $\mathcal{A}_p$, where each $\mathcal{A}_p$ denotes the set of vertices assigned to the processor p. In particular,

$$\mathcal{A} = (\mathcal{A}_0, \mathcal{A}_1, \cdots, \mathcal{A}_{P-1})$$

is a partitioning of the set of vertices of the graph $V(G)$. We define the (*absolute*) *imbalance* $\mathcal{I}(\mathcal{A})$ of a mapping as the maximum number of vertices assigned to a

[2] There is one exception to this rule. If P is not a power of two, one of the heuristics executes in $O(N \log N \log P)$ time. See §4.3.1 for more details.

processor minus the average number of vertices assigned to processors:

$$\mathcal{I}(\mathcal{A}) = \max_p \{|\mathcal{A}_p|\} - \frac{N}{P}.$$

$\mathcal{I}(\mathcal{A})$ corresponds to *load imbalance* in any kind of operation where the amount of computation required for each vertex is the same. If the vertices can be treated independently from each other—e.g., no communication is required—the imbalance can be used to estimate the speedup:

$$S = \frac{N}{\mathcal{I}(\mathcal{A}) + \frac{N}{P}}. \tag{2}$$

Equation (2) gives an estimation for the speedup of linear operations on vectors assigned to the processors of a DMPP according to $\mathcal{A}$. If we assume, moreover, that all rows of the sparse matrix have about the same number of nonzeros, (2) can also be used to estimate the speedup of a matrix-vector product.

A necessary condition for $\mathcal{I}(\mathcal{A})$ to be zero is that the number of processors P divides the number of vertices N. In the general case, we say that a mapping is *perfectly balanced* if its imbalance is smaller or equal to 1:

$$\mathcal{I}(\mathcal{A}) \leq 1.$$

Theorem 4.1 follows immediately.

THEOREM 4.1. *A mapping is perfectly balanced if no processor is assigned more than* $\lceil \frac{N}{P} \rceil$ *vertices.*

All our mapping heuristics try to find a perfectly balanced mapping with minimal communication overhead. In the following, we give a short discussion of the various mapping schemes investigated in this study.

4.1.1. 1-D geometric mapping (GEO1). Geometric mapping onto a linear array of processors is straightforward. We sort the vertices by their x-coordinate and assign the first N/P vertices of the sorted list to the first (leftmost) processor, the next N/P vertices to the second processor, and so on. Instead of sorting according to the x-coordinate, we can choose any direction vector in physical space and sort the vertices according to their projection on this direction.

4.1.2. 2-D geometric mapping (GEO2-S, GEO2-R). We have implemented two schemes to map a graph onto a $P_h \times P_v$-mesh using geometric information.

The first method works on the two dimensions separately (GEO2-S). First, the vertices are sorted according to their x-coordinate. This sorted list of vertices is partitioned by $P_v - 1$ vertical cut lines into P_v sets of N/P_v vertices each, and each of these sets is assigned to one row of the mesh of processors. Then each set is sorted again according to the y-coordinate and partitioned by $P_h - 1$ horizontal cut lines into P_h sets, and each of these sets is assigned to one processor of this row.

The second method proceeds by recursively splitting the graph with dimensions alternating (GEO2-R). Let us assume for a moment that the target mesh is square and the number of processors is a power of two: $P_h = P_v = 2^\nu$. The vertices are first split into two sets by one vertical cut line. Then each of these two sets is split by one horizontal cut line, so that we have now four sets of vertices. Each of these four sets is again partitioned by a vertical cut line and then by horizontal cut lines. This procedure is executed recursively ν times, so that at the end there are P sets of vertices to be assigned to the P processors.

The latter approach is similar to the one that Berger and Bokhari [12] described and tested on some very small graphs. For convenience, we extended it also to the case where the processor mesh is not square and where the number of processors is not a power of two.

Note also that instead of using the x- and the y-coordinate, we can use the projection of the vertex onto any pair of independent vectors in the physical space as partitioning criteria for both our schemes.

4.1.3. 1-D topological mapping (TOP1-1, TOP1-2). If geometric information from the physical embedding of the problem graph is not available, we need another way to extract the concepts of position and distance in the graph.

The *(graphical) distance between a vertex v and a vertex w* is usually defined as the length of the shortest path from v to w [29]. Let S be a (nonempty) subset of the vertices of G. We define the *distance of a vertex v from the set S* as the minimum distance of v to any vertex in S:

$$d(v, S) = \min_{w \in S}\{d(v, w)\}.$$

We can now sort the vertices by their graphical distance from the set S. Then we can map this sorted list of vertices onto a linear array of processors in the way discussed §4.1.1, assigning the first N/P vertices of the sorted list to the first (leftmost) processor, the next N/P vertices to the second processor, and so on (TOP1-1).

This type of 1-D *topological mapping* has been used by Sadayappan and Ercal [56] and by Fox [19] to map sparse graphs onto a ring embedded in a hypercube.

Several vertices will have the same graphical distance from the set S. For a 2-D finite-element graph the number of vertices having the same distance from a small set S is $O(\sqrt{N})$. For a 3-D finite-element graph this number is $O(N^{2/3})$. Thus a variant of the 1-D topological mapping is to use the distance from a second subset of vertices T as a second sorting criterion for all the vertices having the same distance from the first set S (TOP1-2).

4.1.4. 2-D topological mapping (TOP2). The idea of using the distance of each vertex from two starting sets S and T can be used to derive a 2-D mapping of the graph onto a $P_h \times P_v$-mesh. The distances from the two sets S and T form a two-dimensional coordinate system in the graph, attributing to each vertex v its *position* relative to S and T by the pair $(d(v, S), d(v, T))$. Note that different vertices can have the same position.

The same procedure as in 2-D geometric mapping can thus be applied. We first sort the vertices according to their distance to S. We partition this sorted list into P_v sets of N/P_v vertices each and assign each of these sets to one row of the mesh of processors. The vertices of each set are then sorted according to their distance to T, and they are mapped to the row of processors in a similar way to the one shown in §4.1.3.

4.2. Coloring heuristics. Coloring is used to partition the vertices into sets (*colors*) of independent vertices. As pointed out in §3.2.3, local dependences need not be considered, that is, vertices assigned to the same processor of a DMPP can have the same color. We can define three categories of coloring strategies, depending on their relationship with the mapping strategy:

1. Mapping and coloring are done *independently* of each other. In this case, the above property is not exploited, and all vertices in one color must be

independent of each other regardless of their assignment to processors. We can thus use the mapping heuristics that have been developed for vector processors and shared-memory multiprocessors described in §3.1.

2. Coloring is done *after* mapping. After the mapping heuristic has assigned processors to vertices, the edges between vertices mapped on the same processor can be identified and ignored in the coloring heuristic. The first requirement for mapping strategies mentioned in §3.2.2 ensures that as many edges as possible can be deleted this way.
3. Coloring is done *before* mapping. Pairs of adjacent vertices that have received the same color must be assigned to the same processor in the later mapping stage. The mapping scheme has to be adapted to satisfy this additional requirement.

We have implemented the five following coloring heuristics.

4.2.1. Greedy coloring (GREEDY). This scheme colors the graph independently of the assignment of vertices to processors. The algorithm has been described by Aho, Hopcroft, and Ullman [2]. For each color it sweeps once through the whole set of vertices (in the order they are numbered). If a vertex is not yet colored and is not adjacent to any vertex having this color, it is assigned this color. The maximum number of colors is equal to one plus the maximum degree of any vertex, but usually fewer colors are needed to color all the vertices of the graph. Greedy coloring has been used by Bank et al. [10] to color irregular finite-element meshes for vectorization and shared-memory parallelization.

4.2.2. Greedy coloring after mapping (GRAFT). We now map first, then remove all edges between vertices assigned to the same processor, and apply greedy coloring to this reduced graph. As fewer edges restrict the coloring sweeps, possibly fewer colors are needed than in independent greedy coloring.

4.2.3. Balanced greedy coloring (BALANCED1, BALANCED2, BALANCED3). The previous scheme addresses the first and the third points we made about coloring on DMPPs in §3.2.3, ignoring local dependences and reducing the number of colors. The present scheme now addresses point 2 by trying to balance the distribution of the vertices of each color, even if this increases the number of colors.

In extension to the notation introduced in §4.1, let $\mathcal{C}^c$ be the set of vertices colored with the cth color. Let $\mathcal{A}_p^c$ be the set of vertices of color c assigned to processor p: $\mathcal{A}_p^c = \mathcal{A}_p \cap \mathcal{C}^c$. The *coloring imbalance of color* c, $\mathcal{I}^c(\mathcal{A},\mathcal{C})$, is defined as the maximum number of vertices of color c assigned to a processor minus the average number of vertices of color c assigned to processors:

$$\mathcal{I}^c(\mathcal{A},\mathcal{C}) = \max_p \left\{ |\mathcal{A}_p^c| \right\} - \frac{|\mathcal{C}^c|}{P}.$$

In a *balanced coloring scheme*, we put an upper bound $\mathcal{I}_{\max}$ on the coloring imbalance, forcing

$$\forall c : \mathcal{I}^c(\mathcal{A},\mathcal{C}) \leq \mathcal{I}_{\max}.$$

The resulting number of colors might be larger than in a coloring where the coloring imbalance is not limited.

Our balanced greedy coloring is implemented as follows: for each color, we try to color at each stage one vertex of each processor. We accept at most $\mathcal{I}_{\max}$ stages where we could not color vertices from all processors before passing to the next color. This coloring has to be performed after the mapping anyway, so we disregard local dependences in the mapping (BALANCED1 with $\mathcal{I}_{\max} = 1$, BALANCED2 with $\mathcal{I}_{\max} = 2$, and BALANCED3 with $\mathcal{I}_{\max} = 3$).

4.2.4. Level coloring (LEVEL). This and the following coloring schemes are performed before a suitable mapping scheme is carried out.

Let $S = L_0(S)$ be a (nonempty) subset of the vertices of the graph G. For each $k \geq 1$, the set $L_k(S)$ is called *kth level around S*, defined recursively as being the set of all vertices of G that are adjacent to a vertex in previous level $L_{k-1}(S)$, but do not belong to any of the levels $L_0(S), \cdots, L_{k-1}(S)$.
The collection of sets

$$\mathcal{L}(S) = (L_0(S), L_1(S), \cdots, L_{e(S)}(S))$$

is a *level structure around S* of G. S is called the *starting set* of the level structure. See Appendix A for a more rigorous derivation of the properties of level structures.

Level coloring colors all the vertices of the even-numbered levels with a first color and all the vertices of the odd-numbered levels with a second color. Isochromatic vertices in different levels are not connected because of Theorem A.2. Two vertices inside the same level, however, may be connected by an edge. This is why we have to map *whole levels together* so that these dependences inside a level are local to a processor.

A 1-D mapping heuristic on a level colored graph can be derived from our first 1-D topological mapping scheme TOP1-1 described in §4.1.3. We need to assign all the vertices having the same distance from the set S together. Each level that was partitioned on more than one processor in the original mapping is now entirely assigned to the processor that had the most of the vertices of this level (TOP1-1*).

The resulting mapping may not be perfectly balanced, but its imbalance cannot be larger than the largest level of the level structure:

$$\mathcal{I}(\mathcal{A}) \leq \max_i \{|L_i(S)|\}.$$

4.2.5. Level intersection coloring (INODE). Two level structures of the same graph can be combined into a *double level structure* $\mathcal{L}(S,T)$, defined as being the collection of the sets formed by the intersections of the levels of $\mathcal{L}(S)$ and $\mathcal{L}(T)$. The intersections $L_{ij}(S,T) = L_i(S) \cap L_j(T)$ are called *I-nodes.*

Level intersection coloring colors all the vertices that belong to the same I-node (that is, that have the same distances to the sets S and T) with the same color. Two I-nodes that are included into adjacent levels of either $\mathcal{L}(S)$ or $\mathcal{L}(T)$ are colored differently. In Appendix B we show how four colors can be used to obtain this coloring. As all the vertices of an I-node have the same color, we have to assign *whole I-nodes together* to the same processor when mapping the intersection level colored graph to a DMPP.

We can derive 1-D and 2-D mappings for intersection level colored graphs from all our three topological mapping heuristics in §§4.1.3 and 4.1.4. For our first 1-D topological mapping scheme TOP1-1, we can proceed as in §4.2.4, assigning whole levels together, so that I-nodes will certainly not be split (TOP1-1*). For the two schemes based on the graphical distance to two sets TOP1-2 and TOP2, each I-node will now be assigned to the processor that had most of the vertices of this I-node in the original topological mapping (TOP1-2* and TOP2*).

Again, we do not necessarily obtain a perfectly balanced mapping. The imbalance of the mapping based on I-nodes cannot be larger than the size of the largest I-node:

$$\mathcal{I}(\mathcal{A}) \leq \max_{i,j} \{|L_{ij}(S)|\}.$$

Note that no I-node can be larger than any level of the two level structures $\mathcal{L}(S)$ and $\mathcal{L}(T)$ it is derived from. Therefore, this upper bound on the imbalance of the mapping of the intersection level colored graph is certainly less than or equal to the smallest bound on the imbalance of the mappings of the graph level colored by any of these level structures.

4.3. Implementation. We will show now how all the heuristics presented above can be implemented with the complexity bound (1) fixed at the beginning of this section. The construction of data structures that support the data exchange during the parallel execution of the algorithms with fixed mapping and coloring requires an even harder implementation effort than these mapping and coloring heuristics. However, we will not go into these implementation details.

4.3.1. Geometric mappings. The 1-D geometric mapping heuristic (GEO1) only needs to *sort* all the N vertices according to a direction. To achieve this, standard sorting algorithms like *Quicksort* or *Heapsort*, which have a time complexity of $O(N \log N)$ [35], can be used.

The first 2-D geometric mapping heuristic (GEO2-S) also starts by sorting the N vertices according to the first dimension. In a second step, it has to sort P_v arrays of N/P_v vertices each according to the second dimension. The overall time complexity is still $O(N \log N)$.

Calculating the complexity of the second 2-D geometric mapping heuristic, recursive splitting (GEO2-R), is a bit more complicated. Assume that, in the first stage, we split the graph into P_1 subsets of equal size. We can again do this by sorting the N vertices and cutting the sorted array into P_1 pieces. In the second stage, we split each of these P_1 subsets into P_2 subsets, and we do this by sorting P_1 arrays of size N/P_1. This procedure is repeated recursively until we have P sets of vertices that can be assigned to the processors. Let us assume it takes r recursive stages, and we split into $P_1, P_2, P_3, \cdots, P_r$ pieces at each stage. The total number of operations will be a constant multiple of

$$\begin{aligned} n_{\text{oper}} &= N \log N + P_1 \frac{N}{P_1} \log \frac{N}{P_1} + \cdots + P_1 P_2 \cdots P_{r-1} \frac{N}{P_1 P_2 \cdots P_{r-1}} \log \frac{N}{P_1 P_2 \cdots P_{r-1}} \\ &= N(r \log N - (r-1) \log P_1 - (r-2) \log P_2 - \cdots - \log P_{r-1}). \end{aligned}$$

The product of the number of subsets P_k generated at each stage k must be equal to P:

$$P_1 P_2 \cdots P_r = P.$$

The P_k's are integers, and none of them can be smaller than 2. The number of stages can therefore not be larger than the logarithm base two of the number of processors:

$$r \leq \log_2 P.$$

This implies a bound on the complexity of the implementation:

$$n_{\text{oper}} \leq N \log P \log N.$$

This is the case mentioned in footnote 2 in the introduction of §4, and it does not satisfy the bound (1). If P is a power of 2, however, we need not sort the array completely at each stage: We rather use the *find* algorithm [32] to find the median element of the array. This algorithm, which uses the same divide-and-conquer strategy as Quicksort, executes in linear time and has the side effect that it reorders the array such that all the keys that are smaller than the median precede the median, and all the keys that are larger than the median succeed it. The bound then becomes

$$n_{\text{oper}} \leq N \log P,$$

which satisfies (1).

4.3.2. Topological mappings and level structures. The construction of a level structure can be derived directly from Corollary A.5 in Appendix A, as depicted in Fig. 9.

```
$L_0(S) := S$;
$R := V(G) - S$;
$k := 0$;
while $R \neq \emptyset$ loop
    $k := k + 1$;
    $L_k(S) := \emptyset$;
    for each vertex $v \in L_{k-1}(S)$ loop
        for each vertex $w \in Adj(v)$ loop
            if $w \in R$ then
                $L_k := L_k \cup \{w\}$;
                $R := R - \{w\}$;
            end if;
        end loop;
    end loop;
end loop;
$e(S) := k$;
```

FIG. 9. *Construction of a level structure.*

The algorithm in Fig. 9 takes $O(DN)$ time, as the inner loop is executed (on the whole) at most DN times, once for each edge.

If we put the vertices of G into a list in the order we remove them from the set of remaining vertices R, this list can be used directly for both *level coloring* and our first 1-D topological mapping scheme.

The distances to the two starting sets S and T, as they can be read from the two level structures $\mathcal{L}(S)$ and $\mathcal{L}(T)$, form a discrete two-dimensional "coordinate system" in the graph. In this coordinate system we can again use the same 2-D geometric mapping schemes to generate our second 1-D and our 2-D topological mapping scheme as well as our level intersection coloring scheme.

4.3.3. Greedy-type coloring schemes. Figure 10 shows a possible implementation of the greedy coloring algorithm described by Aho, Hopcroft, and Ullman [2]. After execution, the integer C holds the number of colors needed, and the sets C_c hold the vertices for each color c.

```
$R := V(G)$;
$c := 0$;
while $R \neq \emptyset$ loop
    $C_c := \emptyset$;
    $I := R$;
    while $I \neq \emptyset$ loop
        select a vertex $v \in I$
        $C_c := C_c \cup \{v\}$;
        $I := I - \{v\}$;
        $R := R - \{v\}$;
        for each vertex $w \in Adj(v)$ loop
            if $w \in I$ then
                $I := I - \{w\}$;
            end if;
        end loop;
    end loop;
    $c := c + 1$;
end loop;
$C := c$;
```

FIG. 10. *The greedy coloring algorithm.*

The outer loop in Fig. 10 is executed C times (where C is the number of colors), the second loop is executed N times on the whole, and the inner loop is executed DN times on the whole. The set assignment inside the outer loop takes at most $O(N)$ time, so the complexity of the basic greedy algorithm is $O(DN + CN)$.

The algorithm for greedy coloring after mapping is very similar to the simple greedy coloring algorithm, one just has to put an additional guard in the inner condition statement.

Figure 11 shows an implementation of the balanced greedy algorithm with a given mapping $\mathcal{A}$. The complexity analysis is the same as for the simple greedy algorithm, except that the innermost loop on the processors may execute up to $CP\mathcal{I}_{\max}$ times more. We ignored this term in our upper bound on the complexity (1), assuming that it is smaller than the other terms in (1).

5. Evaluation.

5.1. Description of the experiments.

We will now quantify the quality of the different mapping and coloring schemes by comparing the speedups obtained on conjugate-gradients-like methods applied to a set of test problems. The following parameters characterize our experimental environment:

- In each experiment, we applied all possible combinations of our mapping and our coloring schemes and then ran the same *number of iterations* of the same CG-like *algorithm* on the same *DMPP* (same *topology* and same *architecture*) to solve the same *problem.* Speedup comparisons are relative to the same algorithm without coloring on a single processor with the same architecture.
- All our examples are systems of linear equations used for 2-D or 3-D semiconductor device simulation with irregular finite-element grids. We used *conjugate gradients* (CG) to solve the symmetric (not necessarily positive-definite)

```
for each processor $p$ loop
    $R_p := \mathcal{A}_p$;
end loop;
$c := 0$;
while $R_0 \cup R_1 \cup \cdots \cup R_{P-1} \neq \emptyset$ loop
    $C_c := \emptyset$;
    for each processor $p$ loop
        $I_p := R_p$;
    end loop;
    $flag := false$;
    while $I_{\mathrm{curr}} < I_{\max}$ loop
        for each processor $p$ loop
            if $I_p = \emptyset$ then
                $flag := true$;
            else
                select a vertex $v \in I_p$
                $C_c := C_c \cup \{v\}$;
                $I_p := I_p - \{v\}$;
                $R_p := R_p - \{v\}$;
                for each vertex $w \in Adj(v)$ loop
                    find $p_w$ such that $w \in \mathcal{A}_{p_w}$
                    if $p_w \neq p$ AND $w \in I_{p_w}$ then
                        $I_{p_w} := I_{p_w} - \{w\}$;
                    end if;
                end loop;
            end if;
        end loop;
        if $flag = true$ then
            $I_{\mathrm{curr}} := I_{\mathrm{curr}} + 1$;
        end if;
    end loop;
    $c := c + 1$;
end loop;
$C := c$;
```

FIG. 11. *The balanced greedy coloring algorithm.*

systems for the solution of the Poisson equation for the electrostatic potential, and *biconjugate gradients* (BiCG), *conjugate gradients squared* (CGS), or ORTHOMIN(1), all with ILU or MILU preconditioning, to solve the nonsymmetric systems for the solution of the continuity equations for the carrier concentrations. We used the right preconditioned versions of all the algorithms. The preconditioner was ILU. For symmetric positive definite matrices, ILU preconditioning is equivalent to incomplete Cholesky preconditioning, so our CG algorithm is nothing but ICCG(0).

- We measured the execution time for *ten iterations* of the respective algorithm, regardless of the accuracy achieved. We will explain in §5.5 why we selected this standard of comparison rather than comparing the execution times to achieve a given accuracy.

- The topology we used is a 2-D *mesh* of 8 *rows by* 8 *columns of processors.* Each processor communicates with its four neighbors in the mesh via *send* and *receive* statements. Sending or receiving one number to or from a neighbor processor takes half the time of one multiply-add operation on one processor. The processors are AMD 29000 microprocessors with floating-point coprocessor. These numbers reflect the hardware of a DMPP currently under development at our Laboratory [4]. The choice of the topology is justified by the results from the works of Dally [15] and Johnsson [33], who show that a two-dimensional topology represents a natural choice for a DMPP with 64 processors.
- Our experiments were carried out on the *K9 simulator* [11]. Besides reproducible timing measurements, it delivers detailed information about the processor utilization and the communication volume. Although the K9 timing model for the hardware under development is accurate within ±8 percent, we will present here only relative results.

  We are aware of the risks associated with the use of simulators to predict speedup results. Note, however, that DMPPs supporting systolic communication tend to be easier to model than those employing message-passing. This is typically due to the former's high degree of synchronism in the communication and deterministic latency in information transfer.

Section 5.2 presents in detail the results obtained on one particular 2-D problem. Execution times will be broken down into the time required for the different kinds of operations, and also in the contributions of computation, communication, and idle time due to synchronization. Section 5.3 shows in a similar way the results for one particular 3-D problem. Section 5.4 summarizes the results obtained on other experiments.

5.2. A 2-D problem.

5.2.1. The problem. The problem we used in this experiment arises in the two-dimensional simulation of the electrical behavior of a short-channel MOSFET. The system of linear equations (whose sparsity structure is reflected by a rather irregular grid) has $N = 2674$ unknowns and $M = 18404$ nonzeros in the sparse matrix, with an average of 6.88 nonzero elements per row.

5.2.2. Obtained speedups. As an example, Table 1 shows the speedups obtained for preconditioned BiCG using different pairs of a mapping and a coloring. Each column of a table lists the values for the same mapping scheme, and each row lists the values for the same coloring scheme.

The first observation we can make concerns the type of information used for the mapping heuristic. Our geometric mapping strategies achieve significantly better results than our topological ones. The choice of the target topology, that is, whether the graph is mapped onto a 1-D array of 64 processors or onto an 2-D mesh of 8 by 8 processors, influences the speedup only marginally. The same holds true for the two variants for 2-D geometric and 1-D topological mapping. The effort of balancing the coloring pays off, and the improvement in speedup is noticeable. The level and level intersection coloring heuristics deliver some speedup, but are outperformed by the other schemes.

5.2.3. Analysis of relative contributions. We will now justify the speedup results by a detailed analysis. As we stated in §§2.3 and 2.4, the basic operations used

TABLE 1

Speedup obtained on a 64-processor torus for 10 iterations of preconditioned BiCG on a 2-D problem. With the exception of the numbers in italics, *all the results refer to the novel mapping and/or coloring techniques presented in this study.*

Coloring	*Mapping*					
	GEO1	GEO2-S	GEO2-R	TOP1-1	TOP1-2	TOP2
GREEDY	41.04	36.02	*35.99*	*21.00*	21.44	25.39
GRAFT	40.74	35.16	33.40	20.69	21.90	26.02
BALANCED1	44.74	44.68	43.37	22.34	23.11	26.87
BALANCED2	44.63	44.90	43.61	22.66	23.32	27.14
BALANCED3	44.03	44.10	43.45	22.93	23.58	27.14
LEVEL				8.92		
INODE				10.64	16.97	16.12

in all these methods are linear operations on vectors, vector dot products, multiplications of the sparse matrix A or its transpose A^T by a vector, and solutions of systems of the type $Qz = r$ with the preconditioner Q. Table 2 shows the relative percentages of the execution time of the serial implementation of the different algorithms taken by the different types of operations.

TABLE 2

Decomposition of the execution time of the serial algorithms (2-D *problem*) *into linear operations* ($\alpha v + w$)*, vector dot products* ($v^T w$)*, matrix-vector products* (Av)*, transposed matrix-vector products* ($A^T v$)*, and preconditioning operations* ($Q^{-1} v$).

Type of operation	*Contribution to*			
	CG	CGS	BiCG	ORTHOMIN(1)
$\alpha v + w$	13.16%	14.06%	16.72%	16.00%
$v^T w$	8.19%	5.95%	5.99%	13.91%
Av	35.14%	35.74%	17.99%	31.32%
$A^T v$	—	—	16.97%	—
$Q^{-1} v$	43.50%	44.24%	42.32%	38.77%

We will now examine the speedups that can be obtained on each of these basic operations.

5.2.4. Linear operations and vector dot products. For linear operations on vectors and vector dot products, we stated above that the achievable speedup depends only on a single parameter of the mapping, which is the imbalance $\mathcal{I}(\mathcal{A})$ defined in §4.1. Almost all our mappings are perfectly balanced. The only exceptions are the specialized variants of topological mappings used for level and level intersection coloring. Table 3 shows the speedups obtained for a linear operation (the SAXPY operation $v = v + \alpha w$) and for the vector dot product and compares them to the theoretical speedup computed from (2).

Besides confirming our estimation for the speedup of linear operations, Table 2 reinforces the assertion made by Annaratone, Pommerell, and Rühl [5] mentioned in §3.2.1 that the vector dot product does *not* hamper the parallelization of CG-like algorithms on a DMPP with fast interprocessor communication channels.

5.2.5. Sparse matrix-vector products. The efficiency of sparse matrix-vector products and transposed matrix-vector products depends only on the mapping. Table 4 lists the speedup of the matrix-vector product as well as the overhead caused by communication and load imbalance. The communication overhead is expressed by the average percentage of the total execution time that the processors spend actively

TABLE 3

Estimated and obtained speedup of linear operations on vector and vector dot products for balanced mappings and for specialized non-balanced mappings (2-D *problem*).

Mapping	$\mathcal{I}(\mathcal{A})$	*Theoretical speedup*	*Obtained speedup*	
			$v = v + \alpha w$	$v^T w$
(balanced)	0.2	63.67	63.24	49.79
TOP1-1*	120.2	16.51	16.48	15.55
TOP1-2*	22.2	41.78	41.60	36.56
TOP2*	20.2	43.13	42.94	37.14

communicating. The load imbalance overhead is expressed by the average percentage idle time of the processors. Such idle times occur in part during the data exchange if the communication is not perfectly synchronous, and are in part due to the unequal distribution of nonzeros, even if the unknowns are equally distributed.

TABLE 4

Speedup, communication time, and synchronization overhead (*idle time*) *for sparse matrix-vector product* (2-D *problem*).

Mapping	*Speedup*	*Communication*	*Idle*
GEO1	47.57	6.1%	5.3%
GEO2-S	47.06	5.1%	9.6%
GEO2-R	45.37	5.0%	12.7%
TOP1-1	24.07	12.7%	23.2%
TOP1-2	24.49	12.5%	23.1%
TOP2	28.36	8.0%	30.4%
TOP1-1*	12.14	2.3%	73.9%
TOP1-2*	21.77	10.9%	32.4%
TOP2*	24.59	6.8%	40.2%

Here we see the reason for the bad performance of the topological mappings compared to the geometric mappings. The pure communication time is not the only factor that limits the speedup, but the synchronization overhead due to idle time in the communication pattern is substantial. Had we used a DMPP architecture with slower communication and large setup times for message creation, our results would show a clearer advantage in using 1-D mappings, the increase in communication volume being more than compensated for by decomposition of the communication into fewer pieces. Note that these considerations are independent from whether or not the DMPP permits the overlap of communication with computation, as some message-passing architectures do.

The implementation of the transposed matrix-vector products involves the same amount of communication, but some additional arithmetic operations between the different communication steps are required. This increases the synchronization overhead slightly, so that transposed matrix-vector multiplication is slower than the nontransposed version. This explains why the speedup for biconjugate gradients, the only algorithm that requires transposed matrix-vector products, is slightly smaller than that of the other algorithms.

5.2.6. Preconditioning operators. The operator for incomplete factorization preconditioners involves one forward and one backward substitution step to solve sparse triangular systems of linear equations. The parallelization depends both on the mapping and on the coloring. Table 5 shows the speedups obtained for each viable combination of a mapping and a coloring.

TABLE 5
Speedups for the preconditioning operator ($Q^{-1}v$) (2-D *problem*).

Coloring	*Mapping*					
	GEO1	GEO2-S	GEO2-R	TOP1-1	TOP1-2	TOP2
GREEDY	35.16	28.88	28.97	18.40	18.81	22.65
GRAFT	34.78	27.71	25.61	17.69	19.70	23.31
BALANCED1	42.25	42.75	41.67	20.91	21.82	25.48
BALANCED2	42.03	43.33	41.89	21.37	22.17	26.15

LEVEL				6.80		
INODE				8.84	13.11	10.76

The parallelization of the preconditioning operator turns out to be the least efficient part of the algorithms, thus dominating their total efficiency. Comparing Tables 4 and 5, we see that the quality of the mapping gives a major contribution to the speedup of the preconditioning.

During the execution of the substitution steps, one color is processed after the other, and data have to be exchanged between two colors. Table 6 shows the number of colors obtained for each coloring heuristic.

TABLE 6
Number of colors (2-D *problem*).

Coloring	*Mapping*					
	GEO1	GEO2-S	GEO2-R	TOP1-1	TOP1-2	TOP2

BALANCED2	6	6	6	7	7	7
BALANCED3	6	5	5	6	5	6
LEVEL				2		
INODE				4	4	4

From the number of colors, we see that the communication inside the preconditioning operator is very fine-grained. On the average, only one to two numbers are exchanged with each neighbor between two colors. The number of colors alone does not explain the impact of the coloring on the performance of the preconditioning. Table 7 shows the total coloring imbalance, which is the sum of the coloring imbalances $\mathcal{I}^c(\mathcal{A},\mathcal{C})$ of all the colors, as defined in §4.2.3.

TABLE 7
Total coloring imbalance $\mathcal{I}(\mathcal{A},\mathcal{C}) = \sum_c \mathcal{I}^c(\mathcal{A},\mathcal{C})$ (2-D *problem*).

Coloring	*Mapping*					
	GEO1	GEO2-S	GEO2-R	TOP1-1	TOP1-2	TOP2

BALANCED3	6.2	3.2	4.2	5.2	4.2	4.2
LEVEL				278.2		
INODE				229.2	116.2	138.2

The total coloring imbalance is the final parameter that controls the quality of a coloring with a given mapping. Our balanced greedy coloring scheme (and any other balanced scheme based on another basic coloring heuristic) achieves the best results by minimizing this parameter. The number of colors is a smaller issue. As long as it is chosen small, the parameter $\mathcal{I}_{\max}$ of the heuristic does not influence the efficiency significantly.

5.3. A 3-D problem.

5.3.1. The problem. This sparse system arises in the 3-D simulation of a bipolar transistor. The transistor is discretized using bricks, tetrahedra, pyramids, and prisms [14]. The sparse matrix involved has $N = 20412$ rows and $M = 252074$ nonzeros, or, on the average, 12.35 nonzeros per row.

We will limit the discussion here to the presentation of only those results that may add new insight to the problems discussed so far.

5.3.2. Obtained speedups. Table 8 shows the speedups obtained for CGS with ILU preconditioning (the tables for other algorithms are similar).

TABLE 8

Speedup obtained on a 64-processor torus for 10 *iterations of preconditioned* CGS *on a* 3-D *problem. With the exception of the numbers in* italics, *all the results refer to the novel mapping and/or coloring techniques presented in this study.*

LEVEL				7.68		
INODE				9.16	15.92	17.95

While for the 2-D example, 1-D mappings were almost as successful as 2-D mappings, this is not true anymore for this 3-D example. 1-D mappings are now significantly worse than 2-D mappings. Also, the performance gap between topological and geometric mappings is here reduced. Level and level intersection colorings still perform poorly.

5.3.3. Analysis of relative contributions. The relative contributions of the matrix-vector products and the preconditioning operations to the total execution time of the algorithms are 2 to 5 percent higher than for the 2-D problem. This is due to the higher number of nonzeros per row.

5.3.4. Linear operations and vector dot products. The speedups and speedup predictions for the linear operations on vectors are about the same as in Table 3. As the problem size has increased, the vector dot product suffers even less from communication and synchronization overhead and shows a speedup of 61.72 on balanced mappings.

5.3.5. Sparse matrix-vector products. Table 9 shows the speedup of the matrix-vector product and the overhead caused by communication and synchronization in a similar manner as in Table 4.

The reason for the relatively poor performance of 1-D geometric mapping is that each of the 64 "slices" is not dense enough to separate the graph. The values of

BP25C	76926	20.1	3-D	43.80	GEO1	BALANCED2

Two-dimensional geometric mapping together with balanced greedy coloring with coloring imbalance 1 or 2 turned out to give best speedups in most cases. On the DRAM1 experiment, greedy coloring performed slightly (less than 1 percent) better than the balanced variant. This experiment was carried out on a regular 7-point stencil grid, where the greedy heuristic was the only one to find the optimal 2-coloring. The BP25C experiment involved three unknowns per grid point on a 3-D grid.

5.5. A note on convergence. Our speedup figures above are computed by running exactly 10 iterations of each method on the problem, regardless of the accuracy achieved. As coloring reorders the rows of the matrix, it modifies the fill of a complete factorization and thus modifies the quality of the incomplete factorization preconditioner. As a consequence, the convergence properties of the preconditioned algorithms change with coloring.

In normal application a user is not interested in how long it takes to perform a certain number of iterations of an iterative solver, but how long it takes to achieve a certain accuracy in the result. Since coloring modifies the convergence behavior of the preconditioned iterative method, the number of iterations to achieve a given accuracy will differ from one coloring scheme to another or to a sequential implementation, so that the user sees a different speedup value than the speedup over a fixed number of iterations.

At first glance, one should assume that we should give speedup results that compare the time to achieve a given accuracy in the result, rather than just comparing a fixed number of iterations. However, what accuracy should be selected?

In (transient) semiconductor device simulation, the application our examples come from, a great number of linear systems with the same sparsity structure have to be solved. These systems fall into four classes: the three types of systems derived from the three semiconductor drift-diffusion equations, and the coupled systems involving the three equations. The first three types of systems involve one unknown per discretization grid point. The latter type involves three unknowns per grid point. Its matrix is written as a block matrix with the same sparsity structure as the matrices of the single systems, but with blocks of size 3×3. The matrices of one of the first three classes are symmetric positive definite and can be solved using Conjugate Gradients, all the other systems are nonsymmetric, and CGS is the fastest solution method (see Heiser, Pommerell, Weis, and Fichtner [30] for details).

In Fig. 12 we plotted the speedup as a function of the desired accuracy. The accuracy is expressed as the relative reduction of the norm of the residual, and is varied from 1 to 10 digits of precision. The speedup is computed by dividing the time required to achieve this reduction of the error norm on a single processor by the time required on 64 processors. The sequential implementation uses the initial ordering of the unknowns produced by our grid generator [14], the parallel implementation uses GEO2 mapping and BALANCED1 coloring. The four curves represent one system out of each of the four classes mentioned above. All these systems stem from the same simulation of a trench DRAM cell on an irregular 3-D grid with 15564 unknowns, and thus all have the same sparsity structure.

The strong variations in the curves of Fig. 12 show the difficulties if we base our speedup calculations on the time to achieve a given accuracy. If we want three digits of precision in the residual for the fourth (coupled) system in Fig. 12, our 64-processor implementation shows a speedup of 130 over the 1-processor implementation. If we want one digit more, the speedup drops to less than 12. Note also how the speedup figure varies as we choose a different system with the same sparsity structure. For very high accuracies (higher than required for the surrounding nonlinear solver), these

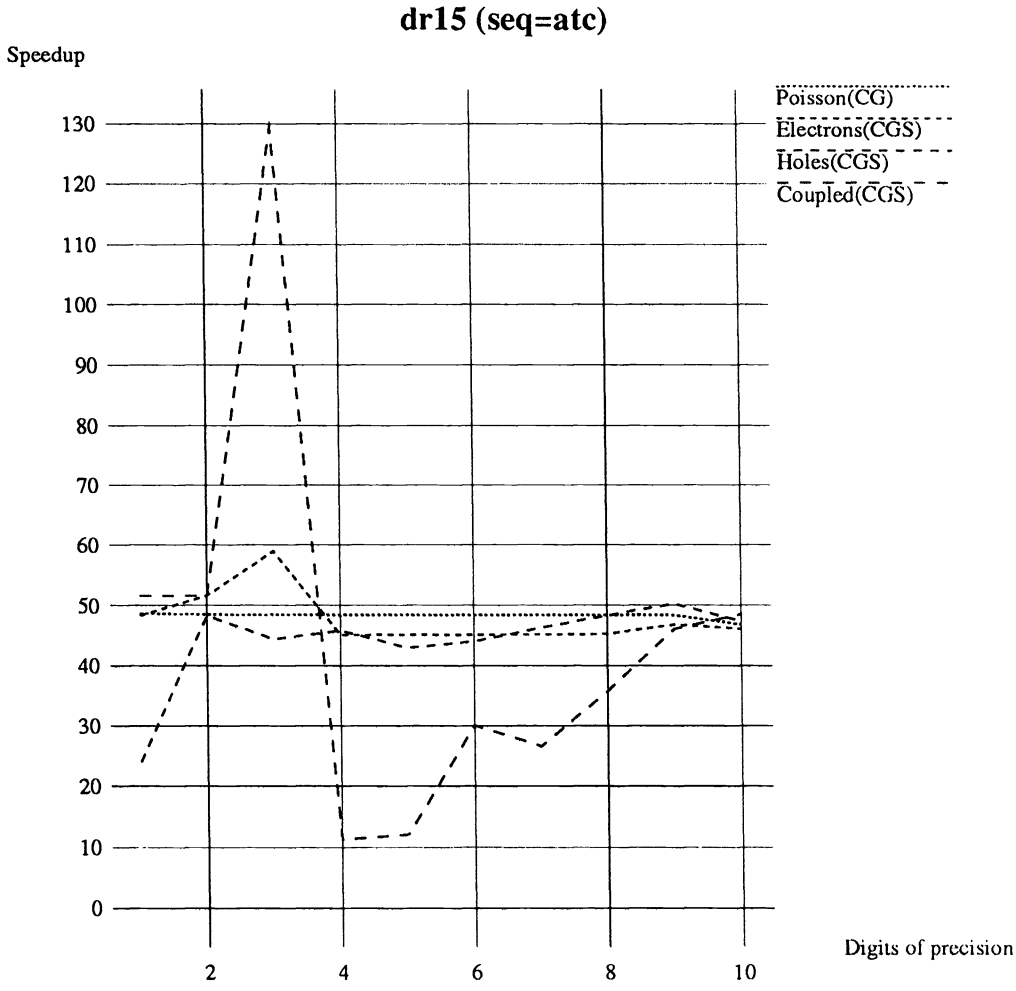

FIG. 12. *Speedup as a function of the desired accuracy, for four different matrices with the same sparsity structure. The sequential implementation uses the ordering as produced by the grid generator.*

speedups approach the value of 49, as predicted from the speedup on 10 iterations.

The fact that sometimes the parallel implementation requires fewer iterations should not lead to precipitate hopes, however. The convergence of the sequential implementation can be improved by other reordering techniques. For instance, using a natural ordering on the grid points (i.e., sorting the grid points by one of their coordinates) can reduce the number of iterations. Figure 13 shows the speedup as a function of the desired accuracy, as in Fig. 12, but uses the sequential implementation with natural ordering as the basis for comparison.

6. Summary of the findings derived from the experiments presented. The findings of the detailed analysis presented in §5 are summarized below:

1. The mapping should be kept perfectly balanced.
2. Geometric mappings perform better than topological mappings.

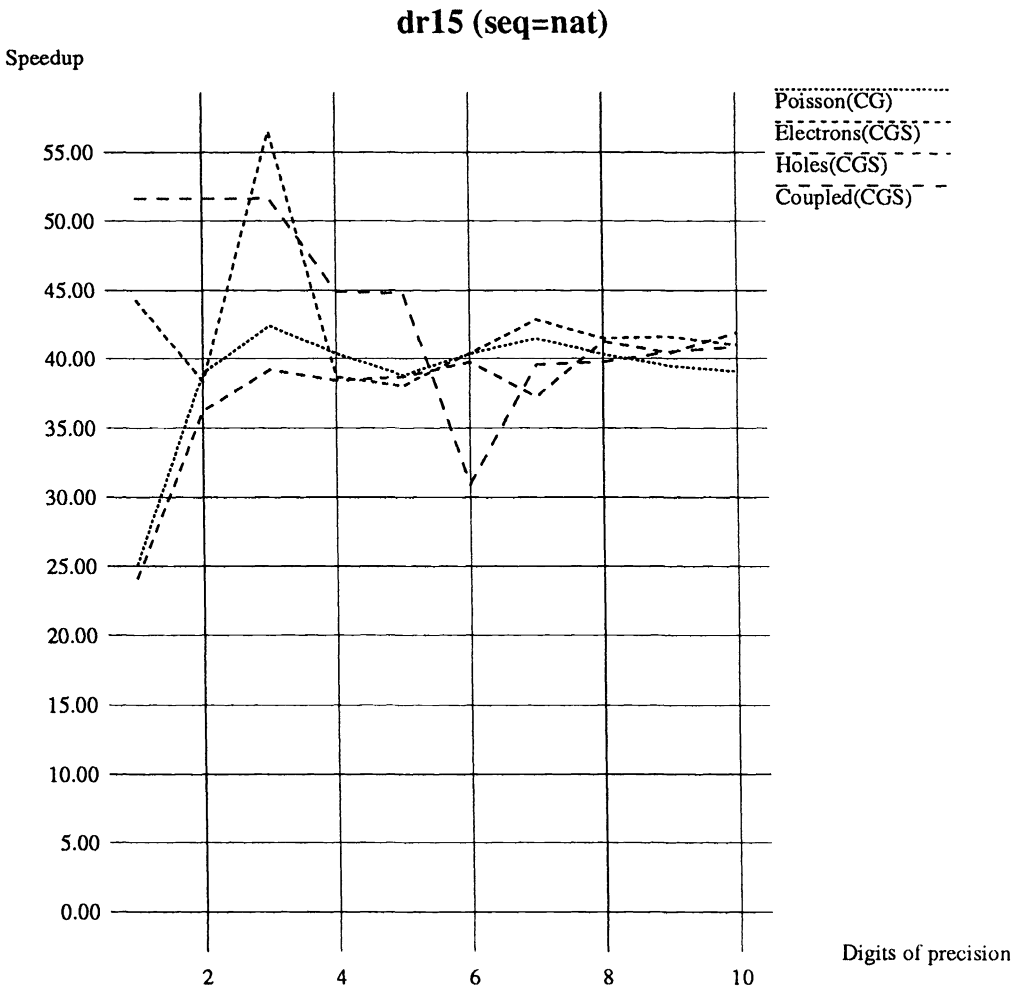

FIG. 13. *Speedup as a function of the desired accuracy, for four different matrices with the same sparsity structure. The sequential implementation uses a natural reordering of the grid points.*

3. For problems on 2-D meshes, 2-D geometric mappings do not bring much improvement over 1-D geometric mappings. On 3-D meshes, however, the improvement is significant.
4. The difference between the two variants for 2-D geometric and for 1-D topological mapping is small.
5. Level coloring and level intersection coloring perform generally much worse than the various greedy schemes.
6. Coloring can speed up the preconditioning operator almost up to the speedup of the matrix-vector multiplication, as long as each color is distributed equally to the processors.

We think that, whenever possible, geometric information on the physical location of a vertex of the sparse graph should be exploited in the mapping heuristic. Extracting good mappings from the adjacency structure only is much more expensive. 2-D mappings are never worse than 1-D mappings.

Load balancing is the most important aspect in parallelizing this type of operation on a DMPP. A good approximation to this is to balance carefully the data involved in each computation step. Balanced coloring schemes are the answer to obtain high speedups on distributed incomplete factorization preconditioning.

We cannot make any statement about the impact of the coloring on convergence. In some of our experiments, some colorings degraded seriously the convergence of the algorithms, while in other experiments, some colorings even improved it. These effects will be the topic of a future study.

7. Further improvements.

7.1. Topological mappings and level structures. Our current heuristic for choosing the starting sets for the level structures is quite simple. The first starting set S simply contains a single vertex at a corner of the problem domain. The second starting set T is then a single vertex lying in the middle level of $\mathcal{L}(S)$.

Further refinement would improve the quality of the topological mappings as well as of the level-based colorings:

- More edges local to the same level, thus reducing the communication volume.
- Smaller maximum size of a level or of an I-node, thus reducing the mapping and the coloring imbalances. For I-nodes this means that the two level structures should be more or less *orthogonal* to each other.

It is not clear whether these refinements can be easily implemented, and more experimentation is therefore necessary.

Sadayappan and Ercal [56] propose to use the vertices of orthogonal boundaries of the problem as starting sets to obtain orthogonal level structures, but this strategy failed on our case studies.

Some of the ideas presented by Fox [19] could be used to achieve these refinements. His ORB scheme could also extend our set of 2-D topological mapping heuristics.

7.2. Geometric mappings. In the experiments we only used the projections of the vertices onto the x- and y-axes as partitioning criteria. We could vary the projection vectors to obtain a slightly better mapping.

7.3. Mappings in general. Our current geometric mapping schemes use *only* geometric information and ignore the adjacency structure of the graph. We could experiment with mixed heuristics that use both topological and geometric sources of information.

We define the imbalance only by looking at the number of vertices assigned to each processor. However, vertices with many neighbors require more computation than vertices with few neighbors. We can include the degree of each vertex into our definition of imbalance.

7.4. Coloring after mapping. We derived our balanced coloring schemes from the greedy coloring algorithm. The ideas we presented here could be included into other general coloring algorithms, like the one proposed by Melhem and Ramarao [47].

8. Conclusions. We proposed and evaluated a set of fast mapping and coloring heuristics for the implementation of preconditioned conjugate-gradients-like methods on a DMPP. Most of these heuristics were new approaches to the problem. We evaluated the quality of the generated mappings and colorings using systems of linear equations stemming from semiconductor device simulation. Depending on the problem under consideration, we achieved speedups between 42 and 54 on the simulator of a 64-processor DMPP currently under development.

We found that mapping heuristics that use geometric information given by the embedding of the problem graph into physical space were superior to heuristics relying only on the topological information given by the nonzero structure of the system matrix. Coloring heuristics devised for vector computers or shared-memory parallel computers were not sufficient for the efficient implementation on a DMPP. Mapping and coloring had to be combined to yield best performance. The best approach was to map first and then to use a coloring heuristic that balances the number of vertices per processor for each color.

A. Level structures. Most of the theory in this section is well known [23]. We included it here as an introduction to the new notions presented in Appendix B.

Recall the notion of distance of a vertex from a set of vertices introduced in §4.1.3. The *eccentricity* of a vertex $v \in V(G)$ is the maximum distance of v from any vertex of G. We call the maximum distance of any vertex of G to S *eccentricity of the set* S:

$$e(S) = \max_{v \in V(G)} \{d(v, S)\}.$$

We call *kth level around* S the set $L_k(S)$ of vertices whose distance to any vertex in S is k:

$$L_k(S) = \{v \in V(G) : d(v, S) = k\}.$$

The following properties derive immediately:

$$L_0(S) = S, \tag{3}$$

$$L_k(S) \neq \emptyset \Leftrightarrow 0 \leq k \leq e(S), \tag{4}$$

$$i \neq j \Rightarrow L_i(S) \cap L_j(S) = \emptyset, \tag{5}$$

$$L_0(S) \cup L_1(S) \cup \cdots \cup L_{e(S)}(S) = V(G). \tag{6}$$

The collection of sets

$$\mathcal{L}(S) = (L_0(S), L_1(S), \cdots, L_{e(S)}(S))$$

is a *level structure around* S of G. It follows from (4), (5), and (6) that $\mathcal{L}(S)$ is a *partitioning* of $V(G)$. S is called the *starting set* of the level structure.

LEMMA A.1. *Any vertex adjacent to a level lies either in the preceding or in the succeeding level:*

$$\forall k : \mathrm{Adj}(L_k(S)) \subset L_{k-1}(S) \cup L_{k+1}(S).$$

Proof. Let $v \in L_i(S)$ and $w \in L_k(S)$ be adjacent to each other. Then we know that $d(v, S) = i$ and $d(w, S) = k$.

- If $i = k$, then $v \in L_k(S)$, so $v \notin \mathrm{Adj}(L_k(S))$ (by definition).
- If $i < k - 1$, there is a path of length $i + 1$ from a vertex in S to w going through v. This leads to a contradiction:

$$d(w, S) \leq (i + 1) < k.$$

- If $i > k+1$, there is a path of length $k+1$ from a vertex in S to v going through w. This also leads to a contradiction:

$$d(v,S) \leq (k+1) < i.$$

It follows that if $v \in \mathrm{Adj}(L_k(S))$, i can only be equal to $k-1$ or $k+1$. □

Theorem A.2 states a fundamental property of level structures, which follows immediately from Lemma A.1.

THEOREM A.2. *Two distinct nonsubsequent levels are not adjacent:*

$$\forall i,j : |i-j| > 1 \Rightarrow \mathrm{Adj}(L_i(S)) \cap L_j(S) = L_i(S) \cap \mathrm{Adj}(L_j(S)) = \emptyset.$$

The level $L_k(S)$ can be viewed as the vertices of the *quotient graph* $G/\mathcal{L}(S)$, where $L_i(S)$ is adjacent to $L_j(S)$ only if some vertex of $L_i(S)$ is adjacent to some vertex of $L_j(S)$ in G [23]. Theorem A.2 can be formulated as the following corollary.

COROLLARY A.3. *$G/\mathcal{L}(S)$ is a path.*

Finally, Theorem A.4 and Corollary A.5 give hints on how to construct a level structure.

THEOREM A.4. *$L_{k+1}(S)$ is the set of vertices adjacent to $L_k(S)$ that are not in $L_{k-1}(S)$.*

$$\forall k : L_{k+1}(S) = \mathrm{Adj}(L_k(S)) - L_{k-1}(S).$$

Proof.

- Subtracting $L_{k-1}(S)$ on both sides of the set inequality in Lemma A.1 leads to

$$\mathrm{Adj}(L_k(S)) - L_{k-1}(S) \subset L_{k+1}(S).$$

- Let $v \in L_{k+1}(S)$. There is a shortest path from v to S of distance $k+1$. The first internal vertex on this path is at distance k from S, thus v is adjacent to $L_k(S)$: $L_{k+1}(S) \subset Adj(L_k(S))$. As L_{k-1} and L_{k+1} are disjunct (5), we can write

$$L_{k+1}(S) \subset \mathrm{Adj}(L_k(S)) - L_{k-1}(S). \qquad \square$$

The same proof applies to Corollary A.5.

COROLLARY A.5. *$L_{k+1}(S)$ is the set of vertices adjacent to $L_k(S)$ that are not in a former level $L_i(S)$ with $i < k$:*

$$\forall k : L_{k+1}(S) = \mathrm{Adj}(L_k(S)) - (L_0(S) \cup L_1(S) \cup \cdots \cup L_k(S)).$$

Theorems A.2 and A.4 justify the term *adjacent levels* for two subsequent levels $L_k(S)$ and $L_{k+1}(S)$. Furthermore, we will call nonadjacent levels *independent.*

The quotient graph $G/\mathcal{L}(S)$ has the interesting property that it is 2*-colorable.* The vertices are assigned the two colors alternatively, as shown in Fig. 14.

B. Double level structures. Two level structures of the same graph can be combined into a *double level structure* $\mathcal{L}(S,T)$, defined as being the collection of the sets formed by the intersections of the levels of $\mathcal{L}(S)$ and $\mathcal{L}(T)$:

$$\mathcal{L}(S,T) = \{L_{ij}(S,T) : 0 \leq i \leq e(S), 0 \leq j \leq e(T)\},$$

FIG. 14. *2-coloring of a path.*

where $L_{ij}(S,T)$ (hereafter abbreviated L_{ij}) is defined as

$$L_{ij} = L_i(S) \cap L_j(T).$$

As levels are disjunct (5), so are their intersections:

$$(i,j) \neq (k,\ell) \Rightarrow L_{ij} \cap L_{k\ell} = \emptyset. \tag{7}$$

The following property follows from the construction and from (6):

$$L_{00} \cup L_{01} \cup \cdots \cup L_{10} \cup \cdots \cup L_{e(S)e(T)} = V(G). \tag{8}$$

Some intersections in $\mathcal{L}(S,T)$ may be empty, but the set of nonempty intersections in $\mathcal{L}(S,T)$ is a *partitioning* of $V(G)$. The concept of independent levels from Theorem A.2 extends to *independent intersections.*

THEOREM B.1. *Two intersections from independent levels in $\mathcal{L}(S)$ or in $\mathcal{L}(T)$ are independent:*

$$\forall i,j,k,\ell : |i-j| > 1 \vee |k-\ell| > 1 \Rightarrow \text{Adj}(L_{ij}) \cap L_{k\ell} = L_{ij} \cap \text{Adj}(L_{k\ell}) = \emptyset.$$

The intersections L_{ij} can be viewed as vertices (called from now on *I-nodes*) of the quotient graph $G/\mathcal{L}(S,T)$. Theorem B.1 can then be formulated as the following corollary.

COROLLARY B.2. *$G/\mathcal{L}(S,T)$ is a subgraph of a 9-point stencil mesh.*

We define a *9-point stencil mesh* with r rows and c columns $\mathcal{N}_{rc}$ as a graph with the following properties:

- $V(\mathcal{N}_{rc})$ contains rc vertices numbered v_{ij}, with $0 \leq i < r$ and $0 \leq j < c$.
- A pair of distinct vertices v_{ij} and $v_{k\ell}$ is connected by an edge only if

$$(|i-k| \leq 1) \quad \text{and} \quad (|j-\ell| \leq 1).$$

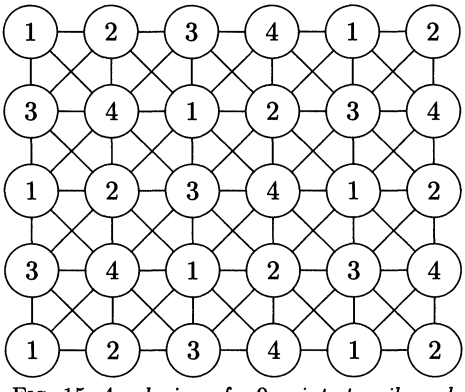

FIG. 15. *4-coloring of a 9-point stencil mesh.*

A 9-*point stencil mesh* is 4-colorable. Figure 15 gives one of the possible color assignments. Of course, any subgraph of such a graph, like the quotient graph $G/\mathcal{L}(S,T)$, is also 4-colorable and can be colored similarly.

Acknowledgments. We thank Josef Bürgler, Paolo Conti, and Gernot Heiser for providing us with the real data used in semiconductor device simulators. Stefan Ludwig implemented one of the mapping heuristics.

MULTILEVEL FILTERING PRECONDITIONERS: EXTENSIONS TO MORE GENERAL ELLIPTIC PROBLEMS*

CHARLES H. TONG[†], TONY F. CHAN[‡], AND C. C. JAY KUO[§]

Abstract. The concept of multilevel filtering (MF) preconditioning applied to second-order selfadjoint elliptic problems is briefly reviewed. It is then shown how to effectively apply this concept to other elliptic problems such as the second-order anisotropic problem, biharmonic equation, equations on locally refined grids and interface operators arising from domain decomposition methods. Numerical results are given to show the effectiveness of the MF preconditioners on these problems.

Key words. multilevel preconditioners, elliptic problems, conjugate gradient method, domain decomposition

1. Introduction.

Preconditioned conjugate gradient (PCG) methods have been a very popular and successful class of methods for solving large systems of equations arising from discretizations of elliptic partial differential equations. With the advent of parallel computers in recent years, there has been increased research into effective implementation of these methods on various parallel computers. Since effective preconditioning plays a critical role in the competitiveness of the PCG methods, many classical preconditioners have been proposed and studied, especially for second-order elliptic problems. Among these are the Jacobi preconditioner (diagonal scaling), the SSOR preconditioner, the incomplete factorization preconditioners (ILU and MILU), and polynomial preconditioners. Many such preconditioners have been very successful in giving high performance, especially when implemented on sequential computers.

In the parallel implementation of PCG methods, the major bottleneck is often the parallelization of the preconditioner. The rest of the PCG methods can usually be parallelized in a straightforward way (the inner product computation is also considered a bottleneck but its wide applicability in other methods has prompted many parallel computer manufacturers to develop a highly optimized and efficient code for it). Unfortunately, for many of the classical preconditioners, there is a fundamental trade-off in the ease of parallelization and the rate of convergence. A principal obstacle to parallelization of many preconditioners that are effective in improving the convergence rate (e.g., SSOR, ILU, and MILU) is the sequential manner these preconditioners use in traversing the computational grid—the data dependence implicitly prescribed by the method limits the amount of parallelism available. Reordering the grid traversal (e.g., from natural to red-black ordering) or inventing new methods

(e.g., polynomial preconditioners) to improve the parallelization alone often has an adverse effect on the rate of convergence [8].

The fundamental difficulty can be traced to the global dependence of elliptic problems. An effective preconditioner must account for the global coupling inherent in the original elliptic problem. Preconditioners that use purely local information (such as red-black orderings and polynomial preconditioners) are limited in their ability to improve the convergence rate. On the other hand, global coupling through a naturally ordered grid traversal is not highly parallelizable. The challenge is therefore to construct effective global coupling that is highly parallelizable. We are thus led to the consideration of preconditioners that share global information through a multilevel grid structure (ensuring a good convergence rate) but perform only local operations on each grid level (and are hence highly parallelizable). Preconditioners of the multilevel type for second-order selfadjoint operators have been proposed recently by several researchers, including Bramble, Pasciak, and Xu [6]; Axelsson [1]; Vassilevski [25]; Axelsson and Vassilevski [2]; [3]; Kuo, Chan, and Tong [13]; and Kuznetsov [14].

The main goal of our paper is to employ the main ideas in [6] and [13] to develop algorithms for more general problems, such as second-order anisotropic problems, the biharmonic equation, problems on locally refined grids, and interface operators for domain decomposition methods. Our approach can be viewed as adapting the projection operators and eigenvalue estimates in [6] to more general problems. On the other hand, the filtering framework of [13] offers the flexibility in designing the filters (or projection operators), which improves the performance substantially in several cases (e.g., the anisotropic case). In particular, the second-order anisotropic problems and problems on locally refined grids can be solved more efficiently by using different types of filters, while the the biharmonic equation and interface operator can be solved efficiently by using different eigenvalue estimates. To the best of our knowledge, two of these extensions (i.e., the biharmonic and the domain decomposition applications) are novel. While a general theory is lacking at this point, we demonstrate numerically that these algorithms perform very well, at least for model problems.

The multilevel preconditioners mentioned above are similar in spirit to the classical multigrid method. They are designed to capture the mesh-dependent spectral property of a discretized elliptic operator. The variations in the coefficients are handled in most cases by the conjugate gradient method, which also makes the iteration more robust. In [13], we presented some experimental results comparing several multilevel preconditioners with a multigrid cycle as a preconditioner. However, further tests are needed to decide whether this new class of multilevel preconditioners offers practical advantages over the classical multigrid methods.

2. The concept of MF preconditioners. We shall motivate the construction of the MF preconditioner by first considering the following one-dimensional Poisson equation on $\Omega = [0, 1]$:

$$-\triangle u = f(x) \tag{1}$$

subject to zero Dirichlet boundary conditions. A standard second-order discretization of the above equation on a uniform grid with grid size $h = 1/(n+1)$ gives rise to a linear system of equations denoted by $Au = f$, where A, u, and f correspond to the discrete Laplacian, the solution and the forcing functions, respectively, and A is a tridiagonal matrix with diagonal elements $-1/h^2$, $2/h^2$, $-1/h^2$. It is well known that the matrix A can be diagonalized as

$$A = W \Lambda W^T$$

where W is an orthogonal matrix with elements

$$(W)_{ij} = 2\sqrt{h}\sin ij\pi h,$$

and

$$\Lambda = diag(\lambda_k), \qquad \lambda_k = \frac{4}{h^2}\sin^2\frac{k\pi h}{2}.$$

The main idea of the MF preconditioning is to approximate this eigendecomposition of A. First, the eigenfunctions of A are grouped into subsets corresponding to different frequency bands. In matrix form, for $n = 2^L - 1$, we partition W into L bands so that

$$W = [W_1, W_2, \cdots, W_L].$$

where

$$W_l = [w_{2^{l-1}}, \cdots, w_{2^l-1}],$$

with w_j being the jth column of the matrix W. Thus, for example, W_1 and W_L correspond to the lowest and highest frequency bands, respectively.

Using the notations introduced above, we can rewrite

$$A = \sum_{l=1}^{L} W_l \Lambda_l W_l^T$$

where

$$\Lambda = diag(\Lambda_l), \Lambda_i = diag(\lambda_{2^{l-1}}, \cdots, \lambda_{2^l-1}).$$

The first approximation comes in when we replace all the eigenvalues (Λ_l) within each band by a constant c_l. Thus, we have a preconditioner $\hat{M}$ such that

$$\hat{M}^{-1}v = \sum_{l=1}^{L} \frac{B_l v}{c_l}$$

where

$$B_l = W_l W_l^T.$$

Note that we have the following property for B_l :

$$B_l v = \begin{cases} v & \text{if } v \in range\{W_l\} \\ 0 & \text{if } v \in range\{W_l\}^{\perp}. \end{cases}$$

Hence, B_l can be considered as an ideal spatial bandpass filter. Thus, applying the preconditioner $\hat{M}$ to a vector (i.e., $M^{-1}v$) consists of three phases : projection of v into the subspace corresponding to each band (operator B_l), scaling by the corresponding approximate eigenvalues c_l, and synthesizing the scaled components (summation).

Since the implementation of ideal filters is computationally expensive, requiring many global operations (e.g., sine transforms), we seek the approximation of ideal filters with nonideal ones that are computationally more efficient. For the construction of efficient nonideal filters, we borrow ideas from standard digital filtering theory [13]. Typically, a bandpass filter is constructed by taking the difference of two lowpass filters, one that filters out all frequencies higher than the highest ones in the band and the other one that lets through all frequencies lower than all frequencies in the band. In turn, the lowpass filters can be approximated by cascading a sequence of elementary filters H_l's, which are simple averaging operators over a small fixed number of grid points separated by spacing proportional to the wavelength of the band W_l.

Mathematically, the effect of using nonideal filters can be summarized by replacing B_l with approximations $\tilde{B}_l$ in the definition of $\hat{M}$ to get our final preconditioner M :

$$M^{-1}v = \sum_{l=1}^{L} \frac{\tilde{B}_l v}{c_l}.$$

In the rest of the paper, we use the following two filters :

- The first order filter defined by

$$(H_{l,1})_j = \frac{1}{4}(v_{j-2^{L-l}} + 2v_j + v_{j+2^{L-l}})$$

where $(\cdot)_j$ denotes the jth element of the argument, and v is extended periodically by

$$v_{-j} = -v_j, \quad \text{and} \quad v_{n+j} = -v_{n+2-j}.$$

- The filter $H_{l,2}$ obtained by applying $H_{l,1}$ twice :

$$(H_{l,2})_j = \frac{1}{16}(v_{j-2^{L-l+1}} + 4v_{j-2^{L-l}} + 6v_j + 4v_{j+2^{L-l}} + v_{j+2^{L-l+1}}).$$

We call the method introduced above the single grid multilevel filtering (SGMF) preconditioner, which involves computation on the same number of grid points n at all levels (corresponding to the frequency bands). Since there are $L = \log_2(n+1)$ levels and $O(n)$ operations are required per level, the total number of operations required per iteration is thus $O(nL)$.

To further improve the efficiency, we introduce a multigrid version of our preconditioner, which we called the multigrid multilevel filtering (MGMF) preconditioner. This is motivated by the fact that waveforms consisting only of low wavenumber components can be well represented on coarser grids. To incorporate the multigrid structure, the operators I_{l+1}^{l} and I_{l-1}^{l}, which are the down-sampling and up-sampling operators, respectively, are introduced. Note that in the multigrid literatures these operators are commonly known as restriction and interpolation operators. Using the concept of MGMF, we construct a sequence of grids Ω_l of sizes $h_l = O(2^{L-l}h), 1 \le l \le L$, to represent the decomposed components. With MGMF, the total number of operations per iteration is $O(n)$, a reduction by a factor of $\log_2 n$ compared to SGMF.

We allow variations in designing the filtering scheme. Several preconditioners, which will be used in the later sections, are defined specifically as follows:

MGMF1, the MGMF preconditioner with 9-point (27-point) filter for two-dimensional (three-dimensional) problems (i.e., $H_{l,1}$).

MGMF2, a modified version of MGMF in which the 9-point (27-point) filter is applied twice (i.e., $H_{l,2}$).

MGMF3, another modified version of MGMF in which the 9-point (27-point) filter is applied once at the finest grid level (to give a smaller amount of work compared to MGMF2) and twice at other grid levels (to achieve a convergence rate between MGMF1 and MGMF2 but close to MGMF2).

We summarize the MGMF1 preconditioning algorithm as follows:

```
Algorithm MGMF1 : input = $r$, output = $z = M^{-1}r$
Decomposition :
          $v_L := r$
          for $l = L-1, \cdots, 1$
                    $v_l := I_{l+1}^{l} H_{l+1,1} v_{l+1}$
          end for
Scaling :
          for $l = 1, \cdots, L$
                    $w_l := v_l \div c_l$
          end for
Synthesis :
          $z_1 := w_1$
          for $l = 2, \cdots, L$
                    $z_l := w_l + H_{l,1} I_{l-1}^{l} z_{l-1}$
          end for
          $z = z_L$
end MGMF1
```

As it stands, this definition of the preconditioner can be extended to higher dimensions, more general elliptic operators and finite element meshes, as long as we have appropriate definitions for the elementary filters H_l's, the restriction and interpolation operators I_{l+1}^{l} and I_{l}^{l+1}, and the c_l's. For example, filters for the high dimensional cases can be constructed from the tensor product of one-dimensional filters. Moreover, it is well known that the eigenvalues λ_k in the wavenumber band B_l behave like $O(h_l^{-2})$ for general second-order elliptic problems, where h_l denotes the grid spacing for level l [21]. Therefore, a general rule for selecting the scaling constant c_l at grid level l is $c_l = O(h_l^{-2})$. For quasiuniform meshes with a refinement factor of 2 (so that $h_l \approx 2h_{l+1}$), this leads to the recurrence relation $c_{l+1} = 4c_l$.

By appealing to the framework in [6], it is also possible to construct filters for quasi-uniform structured finite element meshes. This relationship was briefly discussed in [13]. Basically, the projection operator from the fine grid onto a coarser grid used in [6] can be interpreted as a low-pass filter on the fine grid. Therefore, on the one hand the elementary filters H_l's can be derived from the basis functions on the grid hierarchy. On the other hand, the projection operators in [6] can be adapted to special features of a particular problem, with the insight provided by the filtering framework (e.g., for anisotropic problems).

The MF preconditioner is designed to capture the mesh-dependent spectral property of a discretized elliptic operator, but not the variation of its coefficients. In order to take badly scaled variable coefficients into account, we use diagonal scaling [10]. Suppose that the coefficient matrix can be written as

$$A = D^{1/2} \tilde{A} D^{1/2}$$

where we choose D to be a diagonal matrix with positive elements in such a way that the diagonal elements of $\tilde{A}$ are of the same order. Then in order to solve $Au = f$, we can solve an equivalent problem $\tilde{A}\tilde{u} = \tilde{f}$, where $\tilde{u} = D^{1/2}u$ and $\tilde{f} = D^{-1/2}f$, with the MF preconditioner.

The SGMF preconditioner on uniform meshes can be easily analyzed exactly using Fourier analysis, and the predictions agree quite well with experimental results [13], [23]. However, the Fourier analysis is only meant to be used as a tool for deriving and gaining insights into the algorithms and cannnot be extended as a basis for a general convergence theory. While the Fourier analysis is rigorously applicable only for model problems, the derived algorithms are applicable in a more general setting. Fourier analysis does provide precise convergence rate estimates and eigenvalue distributions, which supplements the more general theory. For this reason, it has been used by many authors in studying iterative methods [27], [11], [26]. The MGMF preconditioner on uniform and quasi-uniform grids can be analyzed using the same finite element analysis framework used in [6], although we will not pursue that in this paper.

On a uniform mesh there is an obvious connection between our multilevel filtering idea and wavelets [20], [12]. Wavelets are orthonormal basis functions for square-integrable functions and are defined on a multilevel structure. These basis functions have compact support in space and almost compact support in the Fourier domain. Thus, wavelets can be considered as efficient bandpass filters. We are currently exploring the use of wavelets in our multilevel filtering preconditioner framework.

3. MF preconditioners for anisotropic problems. In this section, we extend the concept of multilevel filtering to the second-order anisotropic problems. To achieve a high degree of efficiency, the preconditioning step requires some modifications in the design of filters (or the use of a different multilevel nodal basis). We first provide justification for such modifications and then show the condition number as computed by Fourier analysis. Numerical experiments are also included.

Consider the following two-dimensional second-order anisotropic problem:

$$-\alpha u_{xx} - u_{yy} = f(x,y) \text{ in } \Omega = [0,1]^2, \tag{2}$$

where $\alpha > 1$, with zero Dirichlet boundary conditions. The discretization of the equation using a uniform square mesh with $h = 1/(n+1)$ gives a block-tridiagonal matrix A with an equation of the form $Au = f$. In the Fourier domain, we can express this as

$$\hat{A}(j,k)\hat{u}_{j,k} = \hat{f}_{j,k}, \qquad j,k = 1,2,\cdots,n-1 \tag{3}$$

where

$$\hat{u}_{j,k} = \frac{\sqrt{2}}{n}\sum_{l=1}^{n}\sum_{m=1}^{n} u_{l,m}\sin(j\pi lh)\sin(k\pi mh) \tag{4}$$

and

$$\hat{f}_{j,k} = \frac{\sqrt{2}}{n}\sum_{l=1}^{n}\sum_{m=1}^{n} f_{l,m}\sin(j\pi lh)\sin(k\pi mh) \tag{5}$$

such that

$$\hat{A}(j,k) = (2+2\alpha) - 2(\alpha\cos j\pi h + \cos k\pi h). \tag{6}$$

We can observe from the eigenvalue spectrum of $\hat{A}$ that for $\alpha \gg 1$ the variation in magnitudes of the eigenvalues in the k-direction is relatively small compared to that in the j-direction. To maintain uniform variation of eigenvalues within each band, we divide more wavenumber bands in the j-direction than in the k-direction. We call this technique *directionally adaptive filtering.* This can be done in practice by first performing one-dimensional filtering in the j-direction for a number of levels (say, the number of levels $= \gamma$), then resuming two dimensional filtering. This is in contrast to performing two-dimensional filtering for all the levels for the nearly isotropic problems described in the last section. Here γ depends on α as well as the problem to be solved. For second-order elliptic problems with quasi-uniform grid and $h_l \approx 2h_{l+1}$, it is sufficient to use $\gamma = round(\log_4 \alpha)$. Suppose $\alpha = 4$. Then $\gamma = 1$ and the modified $H_{l,1}$ for the finest grid level takes the following stencil form :

$$\frac{1}{4} \left| \begin{array}{ccc} 1 & 2 & 1 \end{array} \right|$$

while the filters for the other coarse grid levels have a two-dimensional stencil (tensor product of one-dimensional filter, i.e., $H_{l,1} \times H_{l,1}$).

Note that if the finest level is defined on a $(n+2) \times (n+2)$ grid, then for $\gamma \geq 1$ the next coarse level is defined on a $((n+1)/2+1) \times (n+2)$ grid instead of a $((n+1)/2+1) \times ((n+1)/2+1)$ grid for $\gamma = 0$. It should also be noted that this modified filtering scheme is analogous to the idea of semi coarsening in the multigrid literature.

We performed Fourier analysis of the single grid version of this scheme (called SGMF1a) on the two-dimensional anisotropic problem with different α and h. The condition numbers of the preconditioned system are given in Table 1. For comparison purposes, the condition numbers of the preconditioned system using the unmodified SGMF1 preconditioner are also included. Table 1 shows that this modified scheme is quite effective. For example, for $\alpha = 1000$ the condition number grows slowly with n, while this is not true for the unmodified SGMF1 preconditioner.

TABLE 1
Condition number for different α and n.

	$\alpha = 10$			$\alpha = 100$			$\alpha = 1000$		
n	A	SGMF1a	SGMF1	A	SGMF1a	SGMF1	A	SGMF1a	SGMF1
7	25	3.8	13	25	3.8	38	25	3.8	47
15	103	4.3	21	103	4.7	117	103	4.7	216
31	414	5.4	28	414	5.8	233	414	5.9	849
63	1659	6.6	34	1659	6.8	328	1659	6.9	2142
127	6639	8.2	40	6639	7.9	395	6639	8.0	3480
255	26560	9.7	46	26560	9.0	454	26560	9.0	4396

The MGMF1 preconditioning algorithm for the above anisotropic problems can be summarized as follows:

```
**Algorithm** MGMF1a : input = $r$, output = $z = M^{-1}r$
    $v_L := r$
Decomposition :
        $count = \gamma$
        **for** $l = L-1, \cdots, 1$
            **if** ($count = 0$) then
                $t_l :=$ x-filter1($v_{l+1}$)
                $v_l :=$ y-filter1($t_l$)
            **else**
                $count = count - 1$
                $v_l :=$ x-filter1($v_{l+1}$)
            **end if**
        **end for**
Scaling :
        **for** $l = 1, \cdots, L$
            $v_l := v_l \div c_l$
        **end for**
Synthesis :
        $t_1 := v_1$
        **for** $l = 2, \cdots, L$
            $t_l := v_l + H_{l,1} I^l_{l-1} t_{l-1}$
        **end for**
        $z := t_L$
**end** MGMF1a
```

Next we show numerical results using the multigrid MF (MGMF1a) preconditioner in conjunction with the conjugate gradient method. Again, we use the standard 5-point discretization on a uniform square mesh with $h = 1/(n+1)$ and the forcing function $f(x,y)$ is such that the solution is $u = x(x-1)y(y-1)e^{xy}$. The stopping criterion used is $\| r^k \| / \| r^0 \| \leq 10^{-5}$ and the initial guess is 0. The iteration counts for different h and α are shown in Table 2.

TABLE 2
Iteration counts for different α and n

	$\alpha = 10$			$\alpha = 100$			$\alpha = 1000$		
n	A	MGMF1a	MGMF1	A	MGMF1a	MGMF1	A	MGMF1a	MGMF1
7	23	11	18	17	7	19	13	6	20
15	48	13	26	41	10	41	27	9	44
31	97	15	32	90	12	64	63	12	84
63	197	16	36	187	13	83	126	13	140
127	405	19	41	388	15	95	258	15	193
255	839	20	45	812	17	106	608	17	224

The numerical results show that this scheme works very well for a wide range of α. A similar scheme can be applied to the case when $\alpha < 1$. It should be noted that the algorithm can also be applied to more general anisotropic problems (e.g., variable coefficients) in the same way that the semicoarsening technique in MG is used (e.g., by averaging coefficients) [18].

4. MF preconditioners for the biharmonic equation. Consider the following biharmonic equation in two dimensions:

$$-\Delta^2 u = f \quad \text{in } \Omega = [0,1]^2 \tag{7}$$

with first boundary conditions:

$$u(x,y)|_\Gamma = g(x,y) \tag{8}$$

and

$$\frac{\partial u}{\partial n} = b(x,y). \tag{9}$$

We discretize this equation using a 13-point second-order centered finite difference approximation with $h = 1/(n+1)$:

$$\begin{aligned} 20u_{i,j} &- 8(u_{i+1,j} + u_{i-1,j} + u_{i,j+1} + u_{i,j-1}) \\ &+ 2(u_{i+1,j+1} + u_{i-1,j+1} + u_{i+1,j-1} + u_{i-1,j-1}) \\ &+ u_{i+2,j} + u_{i-2,j} + u_{i,j+2} + u_{i,j-2} = h^4 f_i, j \end{aligned}$$

for $i, j = 2, n-1$. The difference equation for $i = 1$, and $j = 3, \cdots, n-2$ is:

$$\begin{aligned} 21u_{1,j} &- 8(u_{2,j} + u_{1,j+1} + u_{1,j-1}) + 2(u_{2,j+1} + u_{2,j-1}) + u_{3,j} + u_{1,j+2} + u_{1,j-2} \\ &= h^4(f_i, j + 8g_{0,j} - 2(g_{0,j+1} + g_{0,j-1}) - 2hb_{0,j}) \end{aligned}$$

since

$$\frac{\partial u}{\partial n} = -\frac{\partial u}{\partial x} \quad \text{on } x = 0.$$

Using central differencing, we get

$$-\frac{(u_{1,j} - u_{-1,j})}{2h} = b_{0,j}.$$

Also, at $i = j = 1$, we have

$$\begin{aligned} 22u_{1,1} &- 8(u_{2,1} + u_{1,2}) + 2(u_{2,2}) + u_{3,j} + u_{1,3} \\ &= h^4(f_i, j + 8(g_{0,j} + g_{1,0}) - 2(g_{0,j+1} + g_{0,j-1} + g_{2,0}) - 2h(b_{0,1} + b_{1,0})). \end{aligned}$$

The difference equations for other near boundary grid points can be derived similarly.

To derive MF preconditioners, we have to estimate the eigenvalues of the biharmonic operator. To do so, we apply Fourier analysis to the operator with modified boundary conditions, namely,

$$u(x,y)|_\Gamma = 0 \quad \text{and} \quad \frac{\partial^2 u}{\partial n^2} = 0.$$

Based on analyzing this problem, we can estimate the eigenvalues of $\hat{A}$ by

$$\hat{A}(j,k) \approx 4 - 2(\cos(i\pi h) + \cos(j\pi h))^2 \tag{10}$$

which is the square of that for the Poisson equation.

TABLE 3
Condition number for SGMF *preconditioning for the biharmonic equation.*

n	No preconditioning	SGMF1b	SGMF2b	SGMF3b
7	690	25	5.3	17
15	1.1×10^4	108	5.6	66
31	1.7×10^5	438	7.2	256
63	2.8×10^6	1814	8.7	1017
127	4.4×10^7	7367	10.2	4061
255	7.0×10^8	29705	11.7	16238

Since the eigenvalues in B_l for this equation behave like $O(h_l^{-4})$, a natural extension of the MF preconditioner involves changing the scaling recurrence $c_{l+1} = 4c_l$ to $c_{l+1} = 16c_l$ (again, $h_l \approx 2h_{l+1}$ is assumed). In Table 3, we show the result of the Fourier analysis on the MF-preconditioned biharmonic equation. In the table, SGMF1b, SGMF2b, and SGMF3b represent the original SGMF1, SGMF2, and SGMF3 preconditioners with the new scaling.

We see that the condition number of A grows about 16 times with each halving of h. The use of SGMF1b has effectively helped to reduce the condition number. Nevertheless, SGMF2b helps to reduce the condition number even more dramatically.

To verify the Fourier results, we implement the SGMF1b, SGMF2b and SGMF3b preconditioners for the biharmonic equation where the $f(x,y)$, $g(x,y)$ and $b(x,y)$ are such that the solution is $u = x(x-1)y(y-1)\sin(\pi x)\sin(\pi y)$. The stopping criterion is $\| r^k \| / \| r^0 \| \leq 10^{-6}$ and the initial guess is zero. The iteration counts are shown in Table 4.

TABLE 4
Iteration counts for SGMF*-preconditioned* PCG *for the biharmonic equation.*

n	No preconditioning	SGMF1b	SGMF2b	SGMF3b
7	10	9	10	9
15	42	17	12	16
31	160	36	14	30
63	586	82	17	57
127	2218	177	23	113
255	8587	366	33	220

Next we show (in Table 5) the iteration counts when the multigrid formulation of SGMF1b, SGMF2b, and SGMF3b (i.e., MGMF1b, MGMF2b, and MGMF3b) are applied to the same problem.

TABLE 5
Iteration counts for MGMF*-preconditioned* PCG *for the biharmonic equation.*

n	No preconditioning	MGMF1b	MGMF2b	MGMF3b
7	10	10	10	10
15	42	27	22	24
31	160	40	29	32
63	586	56	30	37
127	2218	80	35	40
255	8587	120	43	48

We observe a close correlation between the numerical and Fourier results for the SGMF preconditioners. Indeed, SGMF2b improves significantly over SGMF1b with only a little increase in cost per iteration. SGMF3b improves somewhat over SGMF1b but is still not good enough compared to SGMF2b. Therefore, SGMF2b requires the fewest operation counts out of the three. Looking into the numerical results for the MGMF preconditioners, we first observe that both MGMF1b and MGMF3b give better convergence rates than their SGMF counterparts. We cannot explain why this is the case, nor can we explain why MGMF3b performs much better than predicted by the corresponding Fourier results. Finally, with a little arithmetic, it is not difficult to show that MGMF3b gives the fewest overall operation counts.

5. MF preconditioners for problems with locally refined grids. In this section, we shall consider the application of the MF preconditioners to second-order elliptic problems with local mesh refinement. Such mesh refinements are necessary for accurate modeling of problems with various types of singular behavior. We consider the discretization scheme for locally mesh refined grids by McCormick and Thomas [16]. This discretization scheme was motivated by the desire to preserve the highly regular grid structure (to maintain efficiency on parallel computer architectures), as well as to satisfy the need for local resolution in many physical models. For example, the mesh in Fig. 1 would be effective if the forcing function $f(x,y)$ behaves like a δ function distribution at the points $(1,1)$ and (n,n) (both lower left and upper right corners).

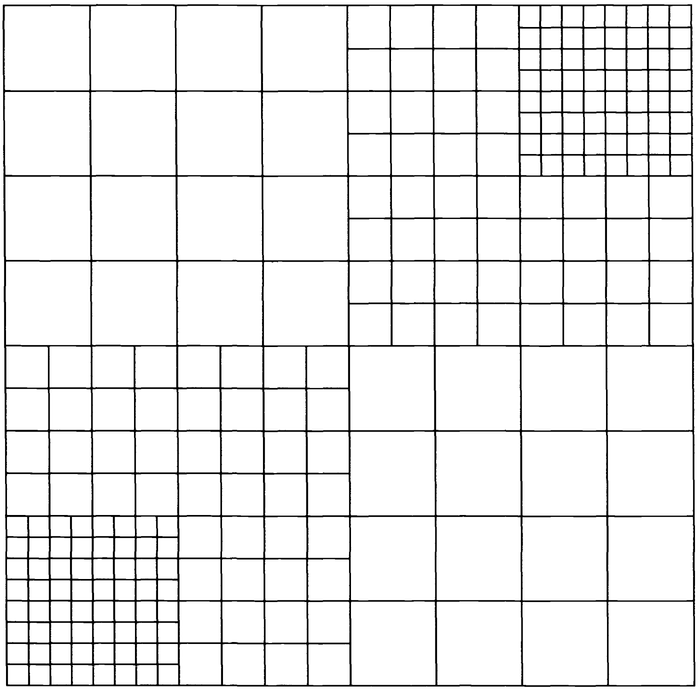

FIG. 1. *Locally refined grids—an example.*

The Fourier analysis cannot be applied here because of the presence of nonuniform grids. However, as was shown in our previous paper [13], the parallel multilevel preconditioner proposed by Bramble, Pasciak, and Xu [6] can be considered as a special case of MF preconditioners with appropriately chosen filters. We can borrow the finite element analysis result from them and we would expect the MGMF preconditioners to be effective also for meshes with local refinement. Below we show the MGMF algorithm for this problem. Here $\hat{I}_i^j$ and $\hat{H}_l$ are restriction (or interpolation) and elementary filtering operators restricted to the locally refined grids only. Moreover, we can use the same recurrence relation $c_l = 4c_{l+1}$ and we have the following algorithm:

```
**Algorithm** MGMF1c : input = $r$, output = $z = M^{-1}r$
Decomposition :
        $v_L := r$
        (* filtering at refined levels *)
        **for** $l = L - 1, \cdots, J - k$
                $v_l := \hat{I}_{l+1}^l \hat{H}_{l+1,1} v_{l+1}$
        **end for**
        (* filtering on uniform grid levels *)
        **for** $l = L - k - 1, \cdots, 1$
                $v_l := I_{l+1}^l H_{l+1,1} v_{l+1}$
        **end for**
Scaling :
        **for** $l = 1, \cdots, L$
                $v_l := v_l \div c_l$
        **end for**
Synthesis :
        $z_1 := v_1$
        **for** $l = 2, \cdots, L - k$
                $z_l := v_l + H_{l,1} I_{l-1}^l z_{l-1}$
        **end for**
        **for** $l = L - k + 1, \cdots, L$
                $z_l := v_l + \hat{H}_{l,1} \hat{I}_{l-1}^l z_{l-1}$
        **end for**
        $z = z_L$
**end** MGMF1c
```

We solve a Poisson equation on the grid

- shown in Fig. 1 but with refinement only at the upper right corner and the forcing function is $f(x,y) = 2^{-l}\delta(1-h, 1-h)$, and
- shown in Fig. 1 and the forcing function $f(x,y) = 2^{-l}(\delta(h,h)+\delta(1-h,1-h))$, where l is the number of level of refinements used and h is the grid size for the nonrefined grid.

We use the discretization scheme for the domain and the interfaces proposed by McCormick and Thomas [16] for aligned grids. The stopping criterion and initial guess are the same as before. The iteration counts for different number of levels and different h are given in Tables 6 and 7. The iteration counts for the unpreconditioned conjugate-gradient (CG) method and the parallel multilevel preconditioner (BPX) [6] are also included for comparison purposes.

The tables show the effectiveness of the MF preconditioner compared to the unpreconditioned CG method and the PCG method with parallel multilevel preconditioner (BPX). The convergence rates seem to be quite insensitive to the number of refinement levels used.

6. MF preconditioners for Schur complement systems. Consider solving a two-dimensional second-order elliptic problem on a domain divided into two subdomains by an interface. If we use a 5-point discretization and order unknowns in the subdomains Ω_1 and Ω_2 first followed by those on the interface Γ_3, we obtain the following linear system:

$$Au = \begin{bmatrix} A_1 & 0 & A_{13} \\ 0 & A_2 & A_{23} \\ A_{31} & A_{32} & A_3 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \\ f_3 \end{bmatrix}.$$

By applying block Gaussian elimination to eliminate the unknowns u_1 and u_2, we obtain the following system for the interface unknowns u_3:

$$Su_3 = \tilde{f}_3$$

where

$$S = A_3 - A_{31}A_1^{-1}A_{13} - A_{32}A_2^{-1}A_{23}$$

and

$$\tilde{f}_3 = f_3 - A_{31}A_1^{-1}f_1 - A_{32}A_2^{-1}f_2.$$

A standard approach in domain decomposition methods is to solve the Schur complement system $Su_3 = \tilde{f}_3$ with the preconditioned conjugate gradient method. Many preconditioners have been proposed in the literature [7]. A typical one is Dryja's preconditioner [9], which is defined to be the square root of the negative one-dimensional Laplacian and which can be inverted by the use of FFTs in $O(n \log n)$ time, where n is the number of unknowns on the interface. Recently, Smith and Widlund [19] proposed a hierarchical basis preconditioner for S which is cheaper than Dryja's preconditioner, requiring only $O(n)$ work per iteration. Here we propose to use the MF preconditioner for S. To do this, we can retain the multilevel filtering framework and we only need to modify the scaling constants c_l's. We know that the eigenvalues for the Schur complement in the frequency band B_l behaves like $O(h_l^{-1})$ [9]. Therefore, it is sufficient to use the recurrence $c_{l+1} = 2c_l$. In Table 8 we compare the number of iterations to obtain convergence for different n for the Poisson equation on a rectangular $2n \times n$ grid decomposed into two equal subdomains.

TABLE 8
Iteration count versus n.

n	No precond.	Dryja	MGMF1	MGMF2	HB
7	4	4	4	4	4
15	8	6	7	6	7
31	16	6	9	7	8
63	27	6	9	7	10
127	39	6	9	7	12

We observe that MGMF2 performs better than MGMF1 and the hierarchical basis (HB) preconditioner. All but the HB preconditioner seem to show convergence rates independent of n. Although we cannot prove spectral equivalence for the MGMF preconditioners, an $O(\log n)$ upper bound for the condition number for the MGMF1 preconditioned system can be proved and details of such a proof can be found in [24]. We also observe that the MGMF2 preconditioner performs almost as well as Dryja's preconditioner. The MGMF appears to offer convergence rates comparable to Dryja's preconditioner and at the same time is relatively easy to use and costs about the same as the HB preconditioner.

7. Conclusion. In our previous paper [13] and the first part of the present paper we show the competitiveness of the MF preconditioners compared with some other preconditioners such as the hierarchical basis preconditioner, multigrid preconditioner and others. In this paper we have further demonstrated the ease with which we can extend the MF preconditioners to effectively solve other more general elliptic problems. The flexibility of filter and scaling block design offers different ways of achieving a high degree of efficiency for these problems.

DOMAIN DECOMPOSITION ALGORITHMS FOR INDEFINITE ELLIPTIC PROBLEMS*

XIAO-CHUAN CAI† AND OLOF B. WIDLUND‡

Abstract. Iterative methods for linear systems of algebraic equations arising from the finite element discretization of nonsymmetric and indefinite elliptic problems are considered. Methods previously known to work well for positive definite, symmetric problems are extended to certain nonsymmetric problems, which can also have some eigenvalues in the left half plane.

This paper presents an additive Schwarz method applied to linear, second order, symmetric or nonsymmetric, indefinite elliptic boundary value problems in two and three dimensions. An alternative linear system, which has the same solution as the original problem, is derived and this system is then solved by using GMRES, an iterative method of conjugate gradient type. In each iteration step, a coarse mesh finite element problem and a number of local problems are solved on small, overlapping subregions into which the original region is subdivided. The rate of convergence is shown to be independent of the number of degrees of freedom and the number of local problems if the coarse mesh is fine enough. The performance of the method in two dimensions is illustrated by results of several numerical experiments.

Two other iterative methods for solving the same class of elliptic problems in two dimensions is also considered. Using an observation of Dryja and Widlund, it is shown that the rate of convergence of certain iterative substructuring methods deteriorates only quite slowly when the local problems increase in size. A similar result is established for Yserentant's hierarchical basis method.

1. Introduction.

Domain decomposition techniques are powerful iterative methods for solving linear systems of equations that arise from finite element problems. In each iteration step, a coarse mesh finite element problem and a number of smaller linear systems, which correspond to the restriction of the original problem to subregions, are solved instead of the large original system. These algorithms can be regarded as divide-and-conquer methods. The number of subproblems can be large and these methods are therefore promising for parallel computation. The central mathematical question is to obtain estimates on the rate of convergence of the iteration by deriving bounds on the spectrum of the iteration operator. We are able to establish quite satisfactory bounds if the coarse mesh is fine enough.

We work with two triangulations of the region: (1) partitioning the region into subregions, also called substructures, which define a coarse, global model; (2) partitioning the region into elements of a finite element model. As in the positive definite case considered previously (see Cai [3], [4]; Dryja [6]; and Dryja and Widlund [7], [8]), the coarse problem provides interchange of information among the different parts of the region. It is known that without such a coarse subproblem the rate of convergence is considerably slower, cf. [24]. This part of the approximate solver plays an additional role in the indefinite case. We can interpret the main results of this paper by saying that if the eigenfunctions corresponding to the eigenvalues in the left half

plane are approximated well enough on the coarse mesh, then the spectrum of the preconditioned linear system of equations lies in a fixed bounded subset of the right half plane. This is important for the rate of convergence of the iterative method. The least favorable situation for iterative methods of conjugate gradient type is the case where the origin of the complex plane is surrounded by eigenvalues of the iteration operator. Here we are able to avoid such a situation.

The additive Schwarz algorithms, introduced in [7], cf. also [6], [8], [9], [18], provide a means of constructing preconditioners for many problems in terms of a partition of a given finite element space into a sum of subspaces. The use of such a preconditioner involves solving, exactly or approximately, the restriction of the original problem to the different subspaces. The residual, which plays a central role in the iteration, is computed as a sum of terms from the different subspaces. These terms can be computed in parallel. We note that it has been shown in Dryja and Widlund [9] that many domain decomposition methods can be viewed as additive Schwarz methods. For recent work on the case of more than two levels of triangulation, see Dryja and Widlund [10] and Xu [25].

In the symmetric, positive definite case, the iterative method most commonly used to solve the transformed (preconditioned) equations is the conjugate gradient method. For the cases considered here symmetry is always lost. In our experiments, we have used a generalized conjugate residual method GMRES; see [22]. Since the spectrum of the operator is confined to the right half plane, Manteuffel's Chebyshev algorithm would also be successful, cf. [17]. Since we can show that the symmetric part of the operator is uniformly positive definite, with respect to a suitable inner product, and that the spectrum is uniformly bounded, we can guarantee a rate of convergence that is independent of the mesh size and the number of subregions.

Other methods for indefinite, elliptic problems are discussed in [2], [14], [16], [27], [28].

The paper is organized as follows. In §2, we introduce a class of indefinite, elliptic boundary value problem, the two triangulations of the domain, and a Galerkin finite element method. We briefly review the GMRES method in §3. In §4, we present two variants of the additive Schwarz method and a detailed analysis of their rates of convergence. Our analysis is based on previous work on the positive definite case, see [3], [4], [6], [7], [8], and a result due to Schatz [23]. Schatz's work, in turn, is based on Gårding's inequality and the Aubin–Nitsche trick, see Ciarlet [5] or Nitsche [21]. In §5, we discuss some numerical results. Finally, in §6, we show that, for problems in the plane, our result can be extended to iterative substructuring and hierarchical basis algorithms discussed in Dryja and Widlund [8], [9] and Yserentant [26], respectively.

2. The elliptic problems.

Let Ω be an open, bounded polygonal region in $R^d, d = 2$ or 3, with boundary $\partial\Omega$. Consider the homogeneous Dirichlet boundary value problem:

$$\left\{ \begin{array}{rcll} Lu & = & f & \text{in} \quad \Omega, \\ u & = & 0 & \text{on} \quad \partial\Omega. \end{array} \right. \tag{1}$$

The elliptic operator L has the form

$$Lu(x) = -\sum_{i,j=1}^{d} \frac{\partial}{\partial x_i}\left(a_{ij}(x)\frac{\partial u(x)}{\partial x_j}\right) + 2\sum_{i=1}^{d} b_i(x)\frac{\partial u(x)}{\partial x_i} + c(x)u(x).$$

All the coefficients are, by assumption, sufficiently smooth and the matrix $\{a_{ij}(x)\}$ is symmetric and uniformly positive definite for all $x \in \Omega$. The right-hand side $f \in L^2(\Omega)$. We also assume that the equation has a unique solution in $H_0^1(\Omega)$.

Let $(\cdot,\cdot)$ denote the usual L^2 inner product and $\|\cdot\|$ or $\|\cdot\|_{L^2}$ the corresponding norm. The weak form of (1) is: Find $u \in H_0^1(\Omega)$ such that

$$B(u,v) = (f,v), \qquad \forall v \in H_0^1(\Omega). \tag{2}$$

The bilinear form $B(u,v)$ is defined by

$$B(u,v) \;=\; \sum_{i,j=1}^{d} \int_{\Omega} a_{ij}\frac{\partial u}{\partial x_j}\frac{\partial v}{\partial x_i}dx + \sum_{i=1}^{d} 2\int_{\Omega} b_i \frac{\partial u}{\partial x_i} v dx + \int_{\Omega} cuvdx$$

or

$$B(u,v) \;=\; \sum_{i,j=1}^{d} \int_{\Omega} a_{ij}\frac{\partial u}{\partial x_j}\frac{\partial v}{\partial x_i}dx + \sum_{i=1}^{d} \int_{\Omega} b_i \frac{\partial u}{\partial x_i} v + \frac{\partial (b_i u)}{\partial x_i} v dx \;+ \int_{\Omega} \tilde{c}uvdx.$$

Here, $\tilde{c}(x) = c(x) - \sum_{i=1}^{d} \partial b_i(x)/\partial x_i$.

We also use two other bilinear forms

$$A(u,v) \;=\; \sum_{i,j=1}^{d} \int_{\Omega} a_{ij}\frac{\partial u}{\partial x_j}\frac{\partial v}{\partial x_i}dx$$

and

$$S(u,v) \;=\; \sum_{i=1}^{d} \int_{\Omega} b_i \frac{\partial u}{\partial x_i} v + \frac{\partial (b_i u)}{\partial x_i} v dx \;,$$

which correspond to the second-order terms and the skew-symmetric part of L, respectively. The bilinear form A defines a norm, which we denote by $\|\cdot\|_A$. Under the assumptions on the coefficients a_{ij}, this norm is equivalent to the H_0^1 norm. It is also easy to verify that

$$S(u,v) \;=\; -S(v,u), \;\; \forall u,v \in H_0^1(\Omega).$$

Throughout this paper, c and C, with or without subscripts, denote generic, strictly positive constants. They are independent of the mesh parameters h and H, which will be introduced later in this section.

Using elementary, standard tools, it is easy to establish the following inequalities:

(i) $\mid B(u,v) \mid \leq C\|u\|_A\|v\|_A, \;\; \forall u,v \in H_0^1(\Omega)$.

(ii) Gårding's inequality: There exists a constant C, such that

$$\|u\|_A^2 - C\|u\|_{L^2(\Omega)}^2 \leq B(u,u), \;\; \forall u \in H_0^1(\Omega) \;.$$

(iii) There exists a constant C, such that

$$\mid S(u,v) \mid \leq C\|u\|_A\|v\|_{L^2(\Omega)}, \;\; \forall u,v \in H_0^1(\Omega),$$

$$\mid S(u,v) \mid \leq C\|v\|_A\|u\|_{L^2(\Omega)}, \;\; \forall u,v \in H_0^1(\Omega).$$

We note that the bounds for $B(\cdot,\cdot)$ and $S(\cdot,\cdot)$ are different, since each of the terms in $S(\cdot,\cdot)$ contains a factor that is of zero order. This enables us to control the skew-symmetric term and makes our analysis possible.

We also use the following regularity result, cf. Grisvard [13] and Nečas [19].

(iv) The solution w of the adjoint equation

$$B(\phi, w) \;=\; (g, \phi), \;\; \forall \phi \in H_0^1(\Omega)$$

satisfies

$$\|w\|_{H^{1+\gamma}(\Omega)} \le C\|g\|_{L^2(\Omega)} \;,$$

where γ depends on the interior angles of $\partial\Omega$, is independent of g, and is at least 1/2.

We approximate (2) by a Galerkin conforming finite element method. For simplicity, we consider only continuous, piecewise linear, triangular elements in R^2 and tetrahedral elements in R^3.

To define the additive Schwarz algorithms, we need two levels of triangulation that have already been introduced in [3], [4], [6], [7], [8], and [9]. We first partition Ω into substructures $\{\Omega_i\}, i = 1, \cdots, N$, which provide a regular finite element triangulation of Ω. The Ω_i are nonoverlapping, d-dimensional simplices. They satisfy all the standard rules of finite elements, cf. Ciarlet [5]. This is the coarse mesh and it defines a mesh parameter $H \;=\; \max\{H_1, \cdots, H_N\}$. The triangulation is assumed to be shape regular, i.e., H_i, the diameter of Ω_i is bounded uniformly in terms of the diameter of the largest inscribed ball in Ω_i.

In a second step, we divide each substructure Ω_i into smaller simplices, denoted by $\{\; \tau_i^j, \; j = 1, \cdots \;\}$. They form a shape regular, fine mesh (h-level) finite element triangulation of Ω with the mesh parameter $h \;=\; \max_{i,j}\{h_i^j\}$. Here h_i^j is the diameter of τ_i^j.

We can now define the piecewise linear finite element spaces over the H-level and the h-level triangulations of Ω.

$$V^H = \{v^H \mid \text{ continuous on } \Omega,\; v^H|_{\Omega_i} \text{ linear },\; v^H = 0 \text{ on } \partial\Omega\}$$

and

$$V^h = \{v^h \mid \text{ continuous on } \Omega,\; v^h|_{\tau_i^j} \text{ linear },\; v^h = 0 \text{ on } \partial\Omega\}\;.$$

The Galerkin approximation of (2) is defined by: Find $u^h \in V^h$ such that

$$B(u^h, v^h) \;=\; (f, v^h), \qquad \forall v^h \in V^h. \tag{3}$$

If the mesh size h is small enough, it follows from a result by Schatz [23] that this problem has a unique solution. By using nodal basis functions to span the finite element space, (3) is transformed into a linear system of algebraic equations that is large, sparse, nonsymmetric, indefinite, and relatively ill-conditioned.

3. A brief discussion of the GMRES method.

Among the possible iterative methods to solve the linear system, we have only used one, the GMRES method, cf. Saad and Schultz [22] and Eisenstat, Elman, and Schultz [11]. This is a generalized minimum residual method, which in practice has proven quite powerful for a large class of nonsymmetric problems. The GMRES method is described in [22] and the theory developed in $L^2(\Omega)$ can be found in [11]. Both the algorithm and the theory can easily be extended to an arbitrary Hilbert space, see Cai [3]. In developing our theory and in the numerical results that are discussed in §5, we have exclusively used the A-norm introduced in §2. Here we briefly describe the GMRES algorithm and state a theorem without proof.

Let P be a linear operator in the finite dimensional space R^n with an inner product $[\cdot,\cdot]$, and a corresponding norm $\|\cdot\|$, chosen to take advantage of the special properties of P. (In our applications, P is the preconditioned stiffness matrix and the A-norm is used.) P is not symmetric but is positive definite with respect to $[\cdot,\cdot]$. The GMRES method is used to solve the linear system of equations

$$Px = b,$$

where $b \in R^n$ is given. We begin from an initial approximation $x_0 \in R^n$ and the initial residual $r_0 = b - Px_0$. In the mth iteration, a correction vector z_m is computed from the Krylov subspace

$$\mathcal{K}_m(r_0) = \text{span}\{r_0, Pr_0, \cdots, P^{m-1}r_0\},$$

which minimizes the norm of the residual. In other words, z_m solves

$$\min_{z \in \mathcal{K}_m(r_0)} \|b - P(x_0 + z)\| .$$

The mth iterate is $x_m = x_0 + z_m$.

The exact solution would be reached in no more than n iterations if we use exact arithmetic.

Following Eisenstat, Elman, and Schultz [11], the rate of convergence of the GMRES method can be characterized in terms of the minimal eigenvalue of the symmetric part of the operator and the norm of the operator. They are defined by

$$c_p = \inf_{x \neq 0} \frac{[x, Px]}{[x, x]} \quad \text{and} \quad C_p = \sup_{x \neq 0} \frac{\|Px\|}{\|x\|}.$$

By considering the decrease of the norm of the residual in a single step, the following theorem can be established.

THEOREM (Eisenstat, Elman, and Schultz). *If $c_p > 0$, then the* GMRES *method converges and after m steps, the norm of the residual is bounded by*

$$\|r_m\| \leq \left(1 - \frac{c_p^2}{C_p^2}\right)^{m/2} \|r_0\|.$$

4. Algorithms on overlapping subregions. In this section, we introduce two variants of an additive Schwarz algorithm and provide bounds on their convergence rates, see Theorem 1 in the following discussion. The analysis is valid for both two and three dimensions.

We first form a basic decomposition of the domain Ω into overlapping subregions and then introduce the projections that define our algorithms.

We use the H-level subdivision $\{\Omega_i\}$ of Ω. Each subregion Ω_i is extended to a larger region Ω_i', i.e., $\Omega_i \subset \Omega_i'$. The overlap is generous in the sense that there exists a constant $\alpha > 0$, such that

$$\text{distance}(\partial\Omega_i' \cap \Omega, \partial\Omega_i \cap \Omega) \geq \alpha H_i, \quad \forall i.$$

We assume that $\partial\Omega_i^{'}$ does not cut through any h-level elements. We use the same construction for the subregions that intersect the boundary $\partial\Omega$ except that we cut off the part that is outside Ω.

We also use the notation $\Omega_0^{'} = \Omega$.

We note that the larger α is, the fewer iterations can be expected. However, if we increase the overlap, the size and hence the cost of the subproblems increases. It is an important practical issue to balance the total number of iterations and the cost of solving the subproblems.

For each $\Omega_i^{'}, i > 0$, a regular finite element subdivision is inherited from the h-level subdivision of Ω. The corresponding finite element space is defined by

$$V_i^h = H_0^1(\Omega_i^{'}) \cap V^h.$$

The elements of this subspace of V^h can be extended continuously by zero to the complement of $\Omega_i^{'}$. We also use the subspace

$$V_0^h = V^H.$$

It is easy to see that our finite element function space V^h can be represented as the sum of the $N+1$ subspaces,

$$V^h = V_0^h + V_1^h + \cdots + V_N^h.$$

We can now define the projection operators, which are the main building blocks of our algorithms. These operators map the finite element space V^h onto the subspaces V_i^h and are defined in terms of the bilinear forms $B(\cdot,\cdot)$ and $A(\cdot,\cdot)$.

DEFINITION. For $i = 0, \cdots, N$:
For any $w^h \in V^h$, $Q_i w^h \in V_i^h$ is the solution of the finite element equation

$$B(Q_i w^h, v_i^h) = B(w^h, v_i^h), \quad \forall v_i^h \in V_i^h.$$

For any $w^h \in V^h$, $P_i w^h \in V_i^h$ is the solution of the finite element equation

$$A(P_i w^h, v_i^h) = B(w^h, v_i^h), \quad \forall v_i^h \in V_i^h.$$

We now introduce the two operators that define our transformed equations

$$Q^{(1)} = Q_0 + Q_1 + \cdots + Q_N$$

and

$$Q^{(2)} = Q_0 + P_1 + \cdots + P_N.$$

Our main effort goes into the study of the spectra of these two operators. The only difference between $Q^{(1)}$ and $Q^{(2)}$ is that, for $i > 0$, we replace the projection Q_i, corresponding to $\Omega_i^{'}$, by P_i. The coarse mesh projection is not changed.

The computation of $Q_i w^h$ or $P_i w^h$, for $i > 0$ and for an arbitrary function $w^h \in V^h$, involves the solution of a standard finite element linear system of algebraic equations on the small subregion $\Omega_i^{'}$. The former gives rise to a nonsymmetric linear system of equations and the latter to a positive definite, symmetric problem. For $i = 0$, the problem is a standard finite element equation on the H-level, coarse space. One can view P_i as a preconditioner of Q_i in the subspace V_i^h; cf. the discussion in Dryja and Widlund [8], [9]. The cost of the computation can often be decreased by simplifying the local problems further. We can replace the given second-order elliptic operator by the Laplacian. If it is possible to choose some of the Ω_i' to be rectangular and the corresponding mesh to be uniform, a Fast Poisson solver can then be used to compute the contribution from V_i^h. It is an easy exercise to modify our theory to cover such a case.

We will consider two additive Schwarz algorithms:

ALGORITHM 1. *Obtain the solution of* (3) *by solving the equation*

$$Q^{(1)}u^h = b^{(1)}, \tag{4}$$

and

ALGORITHM 2. *Obtain the solution of* (3) *by solving the equation*

$$Q^{(2)}u^h = b^{(2)}. \tag{5}$$

In order for (4) and (5) to have unique solutions, the operators $Q^{(1)}$ and $Q^{(2)}$ must be invertible. This follows from Theorem 1 given in the following discussion. To obtain the same solution as (3), the right-hand sides $b^{(1)}$ and $b^{(2)}$ must be chosen correctly. The crucial observation is that these right-hand sides can be computed without knowledge of the solution of (3). The following formulas are valid:

$$b^{(1)} = Q^{(1)}u^h = \sum_{i=0}^{N} Q_i u^h$$

and

$$b^{(2)} = Q^{(2)}u^h = Q_0 u^h + \sum_{i=1}^{N} P_i u^h.$$

Each of these terms can be computed by solving a problem in a subspace since, by (3) and the definitions of Q_i and P_i,

$$B(Q_i u^h, v_i^h) = B(u^h, v_i^h) = (f, v_i^h), \quad \forall v_i^h \in V_i^h$$

and

$$A(P_i u^h, v_i^h) = B(u^h, v_i^h) = (f, v_i^h), \quad \forall v_i^h \in V_i^h.$$

The main result of this study is Theorem 1. By combining it with the theorem given in §3, we establish that the two algorithms converge at a rate that is independent of the mesh parameters h and H, if the coarse mesh is fine enough.

THEOREM 1. *There exist constants* $H_0 > 0$, $c(H_0) > 0$ *and* $C(H_0) > 0$, *such that if* $H \le H_0$, *then, for* $i = 1, 2$,

$$c(H_0)C_0^{-2}A(u^h, u^h) \le A(u^h, Q^{(i)}u^h)$$

and

$$A(Q^{(i)}u^h, Q^{(i)}u^h) \le C(H_0)A(u^h, u^h).$$

The special constant C_0 is introduced in Lemma 1.

Remarks. (a) The operator Q_0 is very important, since it provides global transportation of information. All the other projections are local mappings. Without using Q_0, information would travel only from one subregion to its neighbors in each iteration and it would take $O(1/H)$ iterations for the information to propagate across the region. For further details, see [24].

Without such a global mechanism, it would also be impossible to confine the spectrum to the right half plane. To see this, we consider a symmetric, indefinite case. If the subregions are small enough, all the local elliptic problems are positive definite, symmetric and, in the absence of a global part, the preconditioner defined by the Schwarz algorithm is positive definite symmetric. Therefore, by the inertia theorem, the operator P has as many negative eigenvalues as the original discrete elliptic problem.

(b) The constant H_0 determines the minimal size of the coarse mesh problem and it depends on the operator L. In general, H_0 decreases if we increase the coefficients of the skew-symmetric terms, it decreases with $\tilde{c}$, while it increases if we increase the overlap. H_0 also depends on the shape of the domain Ω. If the domain is not convex, the estimate of H_0, implicit in our proof of Lemma 5, depends on the parameter γ in (iv). We do not have an explicit formula for H_0 but we know from experience that it can be determined by numerical experiments.

If the operator L is positive definite, symmetric, there is no restriction on the coarse mesh size H, i.e., $H_0 = \infty$.

The proof of Theorem 1 is based on the following results.

LEMMA 1. *There exists a constant C_0, which is independent of h and H, such that, for all $u^h \in V^h$, there exist $u_i^h \in V_i^h$ with*

$$u^h = \sum_{i=0}^{N} u_i^h$$

and

$$\sum_{i=0}^{N} A(u_i^h, u_i^h) \leq C_0^2 A(u^h, u^h).$$

This lemma is also central in the theory previously developed for positive definite, symmetric problems. For a proof see Dryja and Widlund [8]; cf. also Lions [15] or Nepomnyaschikh [20]. Note that this lemma is independent of the skew-symmetric and zero-order terms of the elliptic operator. In the symmetric, positive definite case, Lemma 1 is combined with an abstract argument to give a lower bound for the spectrum of the iteration operator.

The next lemma is a variation of a result by Schatz, cf. [23]. In his proof, Gårding's inequality, (ii), and the regularity result, (iv), are used. The proof of Lemma 2 follows directly from Schatz's work by replacing the approximate solution by the coarse mesh solution and the exact solution of the continuous problem by the finite element solution in V^h.

LEMMA 2. *There exist constants $H_0 > 0$ and $C(H_0) > 0$ such that if $H \leq H_0$, then,*

$$\|Q_0 u^h\|_A \leq C(H_0)\|u^h\|_A$$

and

$$\|Q_0 u^h - u^h\|_{L^2} \leq C(H_0) H^{\gamma} \|Q_0 u^h - u^h\|_A.$$

LEMMA 3. *The restriction of the quadratic form $B(\cdot,\cdot)$ to the subspaces V_i^h, $i > 0$, is strictly positive definite for H sufficiently small, i.e., there exists a constant $c > 0$ such that*

$$cA(u^h,u^h) \leq B(u^h,u^h), \quad \forall u^h \in V_i^h .$$

Proof of Lemma 3. We have to prove that the second order terms dominate the other symmetric term; the contribution from the skew-symmetric term vanishes. This follows from the fact that the smallest eigenvalue for the Dirichlet problem for $-\triangle$ on the region $\Omega_i^{'}$ is on the order of H_i^{-2}.

LEMMA 4. *Let $v^h = \sum v_i^h$, where $v_i^h \in V_i^h$. Then there exists a constant $C > 0$, such that*

$$\|\sum v_i^h\|_A^2 \leq C \sum \|v_i^h\|_A^2.$$

Proof of Lemma 4. The proof follows from the observation that for each $x \in \Omega$, the number of terms in the sum that differ from zero is uniformly bounded.

LEMMA 5. *There exist constants $H_0 > 0$, $c(H_0) > 0$, and $C(H_0) > 0$ such that if $H \leq H_0$, then,*

$$c(H_0)C_0^{-2}A(u^h,u^h) \leq \sum_{i=0}^{N} A(Q_iu^h,Q_iu^h) \leq C(H_0)A(u^h,u^h)$$

and

$$\begin{aligned} c(H_0)C_0^{-2}A(u^h,u^h) &\leq A(Q_0u^h,Q_0u^h) + \sum_{i=1}^{N} A(P_iu^h,P_iu^h) \\ &\leq C(H_0)A(u^h,u^h). \end{aligned}$$

Proof of Lemma 5. An upper bound for $A(Q_0u^h,Q_0u^h)$ is given in Lemma 2. To obtain an upper bound for the sum of the other terms, we use Lemma 3 and the formula

$$B(Q_iu^h,Q_iu^h) = B(u^h,Q_iu^h)$$

to show that

$$c\sum_{i=1}^{N} A(Q_iu^h,Q_iu^h) \leq B\left(u^h, \sum_{i=1}^{N} Q_iu^h\right).$$

The right-hand side can be estimated by using inequality (i) and Lemma 4. The other upper bound is established in a similar way.

To prove the lower bounds, we begin by using Lemma 2 and the triangle inequality to obtain

$$\|u^h\|_{L^2}^2 \leq C(H^{2\gamma}A(u^h,u^h) + \|Q_0u^h\|_{L^2}^2).$$

Since the eigenvalues of the Dirichlet problem for $-\triangle$ are bounded from below and Lemma 2 holds, the last term can be replaced by $C\|Q_0u^h\|_A\|u^h\|_A$. By using Gårding's inequality, (ii), it follows that

$$(1 - CH^{2\gamma})A(u^h,u^h) \leq B(u^h,u^h) + C\|Q_0u^h\|_A\|u^h\|_A .$$

By the definition of the operators Q_i and Lemma 1, we find that

$$B(u^h, u^h) = \sum_{i=0}^{N} B(u^h, u_i^h) = \sum_{i=0}^{N} B(Q_i u^h, u_i^h).$$

The boundedness of $B(\cdot, \cdot)$, (i), can now be used to obtain

$$\sum_{i=0}^{N} B(Q_i u^h, u_i^h) \le C \sum_{i=0}^{N} \|Q_i u^h\|_A \|u_i^h\|_A,$$

which by Lemma 1 and the Cauchy–Schwarz inequality can be bounded above by

$$CC_0 \left(\sum_{i=0}^{N} \|Q_i u^h\|_A^2 \right)^{1/2} \|u^h\|_A.$$

We finally obtain

$$A(u^h, u^h) \le CC_0^2 \sum_{i=0}^{N} A(Q_i u^h, Q_i u^h),$$

for sufficiently small H.

The proof of the other lower bound is quite similar.

Proof of Theorem 1. The upper bounds on the norms of the operators follow immediately from Lemmas 4 and 5.

To obtain the lower bounds, we first consider

$$A(u^h, Q^{(1)} u^h) = \sum_{i=0}^{N} A(u^h, Q_i u^h).$$

Using Lemma 5, we see that it suffices to show that

$$\left| \sum_{i=0}^{N} \left(A(u^h, Q_i u^h) - A(Q_i u^h, Q_i u^h) \right) \right|$$

can be bounded from above by

$$CHA(u^h, u^h).$$

By the definition of the quadratic forms

$$A(u^h - Q_i u^h, Q_i u^h) = B(u^h - Q_i u^h, Q_i u^h) - S(u^h - Q_i u^h, Q_i u^h) - (\tilde{c}(u^h - Q_i u^h), Q_i u^h).$$

By using the definition of Q_i, the first term of the right-hand side is seen to vanish.

For $i = 0$, the absolute value of the second term can be bounded above by $CH^\gamma A(u^h, u^h)$ using inequality (iii) and Lemma 2. We note that $S(Q_i u^h, Q_i u^h) = 0$. There remains to consider $S(u^h, \sum_1^N Q_i u^h)$. By using the inequality (iii),

$$\left| \sum_{i=1}^{N} S(u^h - Q_i u^h, Q_i u^h) \right| \le C \|u^h\|_A \left\| \sum_{i=1}^{N} Q_i u^h \right\|_{L^2}.$$

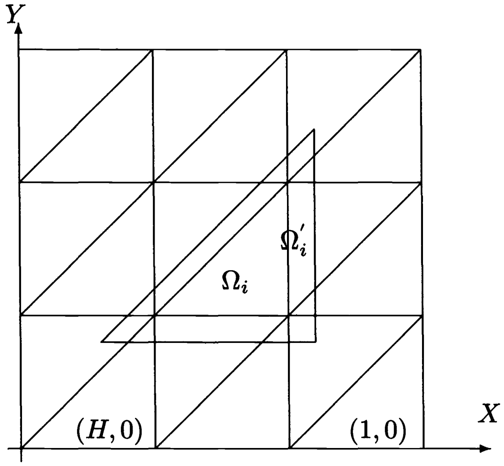

FIG. 1. *An extended subregion.*

Since, for each $x \in \Omega$, the number of terms $Q_i u^h$ that differ from zero is uniformly bounded, the second factor on the right-hand side can be bounded by $C(\sum_{i=1}^{N} \|Q_i u^h\|_{L^2}^2)^{1/2}$. By an elementary estimate, which shows that the smallest eigenvalue of the Dirichlet problem for $-\triangle$ on Ω_i' is on the order of H_i^{-2}, and Lemma 5, the required inequality is established.

The third term is written as the difference of two expressions, which can be handled by exactly the same tools.

The estimate for the operator $Q^{(2)}$ is obtained similarly.

5. Numerical results. In this section, we present some numerical results to demonstrate the behavior of our additive Schwarz algorithms for both symmetric and nonsymmetric indefinite boundary value problems in R^2. Numerical results for positive definite problems, both symmetric and nonsymmetric, have previously been given in [3], [4], [12].

We consider the problem

$$\begin{cases} Lu = f & \text{in } \Omega = [0,1] \times [0,1], \\ u = 0 & \text{on } \partial\Omega. \end{cases}$$

The coefficients of L are specified later for each problem. The right-hand side f is always chosen so that the exact solution is $u = xe^{xy}\sin(\pi x)\sin(\pi y)$.

We use a two-level subdivision of Ω as described in §2. The subregion Ω_i' is obtained by enlarging the triangle Ω_i as in Fig. 1. In this extension, the same number **ovlp** of h-level triangles are added in all directions.

In our experiments all the subproblems are solved exactly by using a band solver from LINPACK. We stop the GMRES method as soon as $\|r_i\|_A/\|r_0\|_A \leq 10^{-3}$. We work with the A-norm, since our theory so far has not been developed for any other norms. However, in our experience, the performance of the algorithm is quite comparable if we replace that norm with the 2-norm. We have found that the overall error is not substantially reduced by a more stringent stopping criterion. In our tables, the **error** denotes the difference between the computed solution and the exact solution of

the continuous problem measured in the norms indicated. The programs have been run in single precision on the Multiflow computer at Yale University.

EXAMPLE 1. We consider the symmetric and indefinite Helmholtz equation

$$\left\{ \begin{array}{rl} -\triangle u - \delta u = f & \text{in} \quad \Omega, \\ u = 0 & \text{on} \quad \partial\Omega. \end{array} \right. \tag{6}$$

δ is a constant. The eigenvalues of the operator in (6) are $(i^2 + j^2)\pi^2 - \delta$, where i, j are positive integers. The numerical results are given in Tables 1 and 2. Algorithms 1 and 2, given in (4) and (5), respectively, are used.

EXAMPLE 2. We consider a nonsymmetric and indefinite problem

$$\left\{ \begin{array}{rl} -\triangle u - \eta(\partial u/\partial x + \partial u/\partial y) - \delta u = f & \text{in} \quad \Omega \\ u = 0 & \text{on} \quad \partial\Omega. \end{array} \right. \tag{7}$$

The numerical results are given in Tables 3 and 4.

We note that in a few of the experiments, the rate of convergence is unsatisfactory but that the rate of convergence improves considerably by decreasing H. The rate of convergence varies only marginally with the parameter **ovlp**. Normally, the overall

cost of the computation is smallest if **ovlp** $= 1$. We also note that, as expected, a smaller H is required when the parameters δ and η are increased to increase the terms that make the operators skew-symmetric and indefinite.

6. Two other methods. We conclude by outlining how some other results, previously analyzed for the positive definite symmetric case, can be extended to the class of elliptic problems described in §2. We confine our discussion to problems in the plane; both of the algorithms considered here need to be modified considerably in order to obtain fast methods for problems in three dimensions.

We first consider a basic iterative substructuring method for problems in two dimensions, cf. Dryja and Widlund [8], [9]. For problems that are nonsymmetric but positive definite, the result to be formulated has previously been obtained by Cai [3], [4].

When iterative substructuring methods are used, the region is divided into substructures and elements as in §2. Though originally derived differently, it has been demonstrated by Dryja and Widlund [8] that these methods can be viewed as additive Schwarz methods. Our work depends heavily on this reinterpretation of the algorithms, see [8] for detailed arguments.

In defining the partition of the finite element space into subspaces, we use the coarse space V^H introduced in §4. We also use subspaces corresponding to the subregions $\Omega_{ij} = \Omega_i \bigcup \Gamma_{ij} \bigcup \Omega_j$. These subregions play the same role as the Ω_i' in §4. Here Ω_i and Ω_j are adjacent substructures with the common edge Γ_{ij}. We note that an interior substructure is covered by three such regions. The local subspaces are $V_{ij}^h = H_0^1(\Omega_{ij}) \cap V^h$.

Compared with the case considered previously, we use less overlap in the sense that only the elements of V^H can differ from zero at the vertices of the substructures. This is reflected in a poorer bound for the constant of Lemma 1,

$$C_0^2 \leq \text{const.}(1+\log(H/h))^2,$$

cf. Dryja and Widlund [8]. Lemma 1 is modified accordingly. The rest of the proof carries over without change. In Theorem 2, we use the notation $\tilde{Q} = Q_0 + \sum Q_{ij}$.

THEOREM 2. *For the iterative substructuring method, introduced as an additive Schwarz method with the subspaces V^H and V_{ij}^h, there exist constants $H_0 > 0$, $c(H_0) > 0$, and $C(H_0) > 0$, such that if $H \leq H_0$,*

$$c(H_0)(1+\log(H/h))^{-2} A(u^h, u^h) \leq A(u^h, \tilde{Q}u^h)$$

and

$$A(\tilde{Q}u^h, \tilde{Q}u^h) \leq C(H_0) A(u^h, u^h).$$

We finally show that the result, obtained by Yserentant [26] for positive definite symmetric problems, can be extended in the same way. We note that Bank and Yserentant [1] have already reported on successful numerical experiments with an accelerated variant of this algorithm for the class of elliptic problems introduced in §2. We also note that our algorithm is different from those proposed by Yserentant [27], [28] for indefinite and nonsymmetric problems. Thus in [27] a reduced system obtained by implicitly eliminating the nodes of the coarsest mesh is solved by an iterative method.

We assume that the region Ω is a plane polygon. A coarse triangulation is introduced as before. Its triangles are recursively subdivided into four congruent triangles a total of j times. The characteristic mesh size for the level k triangulation is h_k. As demonstrated in Yserentant [28], more complicated situations can also be considered where the final triangulation is highly nonuniform, but to simplify our discussion, we only consider the regular case in this paper.

As shown in Dryja and Widlund [10], Yserentant's method can also be viewed as an additive Schwarz method defined by a set of subspaces. Let $I_k v \equiv I_{h_k} v$ be the linear interpolant of $v \in V^h$ onto the space of finite elements on the level k triangulation. The following identity holds

$$v = I_0 v + (I_1 v - I_0 v) + \cdots + (I_j v - I_{j-1} v) \ , \ \forall v \in V^h \ .$$

We represent V^h as

$$V^h = V_0 \oplus V_1 \oplus \cdots \oplus V_j ,$$

where $V_0 = V^H$, and, for $k > 0$, $V_k = R(I_k - I_{k-1})$ is the range of the operator $(I_k - I_{k-1})$. An additive Schwarz method is defined for this set of subspaces. We obtain Yserentant's method by replacing, for $k > 0$, the resulting problems on the subspaces by suitable preconditioners.

The following result holds for the family of elliptic problems introduced in §2. Here $\hat{Q}$ denotes the operator of the transformed equation, which corresponds to Yserentant's method.

THEOREM 3. *For Yserentant's method there exist constants $H_0 > 0$, $c(H_0) > 0$, and $C(H_0) > 0$, such that if $H \leq H_0$,*

$$c(H_0)j^{-2}A(u^h, u^h) \leq A(u^h, \hat{Q}u^h)$$

and

$$A(\hat{Q}u^h, \hat{Q}u^h) \leq C(H_0)A(u^h, u^h).$$

We will only outline how this result can be established. We model our proof on that of Theorem 1. We have to show that the different lemmas hold for the spaces just introduced. It is shown in Yserentant [26] that Lemma 1 holds with $C_0 \leq Cj^2$, cf. [26, Lems. 2.4 and 2.5]. Lemma 2 is still valid since the same coarse operator is used in all the methods considered in this paper. A counterpart of Lemma 3 can be obtained as well, by using [26, Lem. 2.4]. Lemma 4 is modified by using [26, Lem. 2.7], a result that makes it possible to obtain a sharp upper bound in Yserentant's main theorem. Lemma 5 can be modified in a straightforward manner. One change is required in the proof of the theorem. The factor $\| \sum_{i=1}^{N} \hat{Q}_i u^h \|_{L^2}$ must be estimated differently, since, typically, all these terms differ from zero everywhere. By using Yserentant's tools, it is however possible to show that

$$\|\hat{Q}_i u^h\|_{L^2} \ \leq \ Ch_i \|\hat{Q}_i u^h\|_A \ .$$

Since the h_i decay geometrically, the triangle and Cauchy–Schwarz inequalities give

$$\| \sum_{i=1}^{N} \hat{Q}_i u^h \|_{L^2}^2 \ \leq \ CH^2 \sum_{i=1}^{N} \|\hat{Q}_i u^h\|_A^2 \ ,$$

and the proof can be completed.

PRECONDITIONING SECOND-ORDER ELLIPTIC OPERATORS: EXPERIMENT AND THEORY*

WAYNE JOUBERT†, THOMAS A. MANTEUFFEL‡, SEYMOUR PARTER¶, AND SZE-PING WONG§

Abstract. In an earlier work Manteuffel and Parter discussed the role of boundary conditions in obtaining elliptic operators B so that the preconditioned operators $B_h^{-1}A_h$ or $A_hB_h^{-1}$ have uniformly bounded L_2 condition number. Here A is the original elliptic operator and A_h and B_h are discretizations. Certain computations, mostly one-dimensional, were undertaken to illustrate and understand these results. These computational experiments provided several surprises. This current work describes those experiments and some subsequent experiments together with theoretical explanations of these surprising results. One of the main points of this report is the discussion of interaction of experimental results with the ensuing development of the theory.

Key words. preconditioning, boundary conditions, conjugate gradient, experiment

AMS(MOS) subject classifications. 65N, 65F

1. Introduction.

In [MP] Manteuffel and Parter studied the effect of boundary conditions on the preconditioning of an invertible nonsymmetric discrete second-order elliptic operator A_h (i.e., the discretization of an invertible second-order elliptic operator A) by B_h^{-1}, the inverse of another such discrete elliptic operator in the presence of H_2 regularity. They discussed L_2, H_1, and H_2 estimates on $B_h^{-1}A_h$ and L_2 estimates on $A_hB_h^{-1}$. Roughly speaking, the L_2 condition of $A_hB_h^{-1}$ is bounded independent of h if and only if A and B have the same boundary conditions, while the L_2 condition of $B_h^{-1}A_h$ is bounded independent of h if and only if A^* and B^* have the same boundary conditions. Further, the H_1 condition of $B_h^{-1}A_h$ is bounded independent of h if and only if A and B have Dirichlet boundary conditions on the same portion of the boundary. Finally, the H_2 condition number of $B_h^{-1}A_h$ is always bounded independent of h if A and B have H_2 regularity. In order to gain further insight and understanding, we undertook a number of computational experiments. At first, some of the numerical results seemed somewhat puzzling. The purpose of this report is to (i) describe and report on those experiments, (ii) explain their interesting results, and (iii) remark on several related ideas.

In §2 we present one-dimensional computational results. These results show that the condition number associated with various preconditioning strategies is either bounded or grows as the mesh size decreases, as predicted in [MP]. However, the conjugate gradient method applied to these problems converges much faster than bounds based upon the condition number would suggest. In the case where the condition number is growing, we discover in §3 that all but two singular values are bounded

above and below. This fact allows us to produce bounds that more accurately predict the performance of the conjugate gradient method. In §4, computational results reveal the structure of the bounded, as well as the unbounded, singular values. These results lead to a theory in §5 that explains the behavior of the conjugate gradient method when the condition is bounded.

In §6, two-dimensional computational results are presented. Here again, the various condition numbers behave as predicted in [MP]. Again, the conjugate gradient method behaves better than bounds based upon the condition number would suggest, but not as strikingly as in the one-dimensional case. Now, the rank of the growing part is low but is much greater than 2. In §7, an analysis of a separable problem shows that the number of unbounded singular values grows like the square root of the number of mesh points in the boundary segment where "incorrect" boundary conditions are used for the preconditioning.

2. One-dimensional computational results. In this section, the computational experiments involve simple one-dimensional operators. Let

$$Au = -(a_2(x)u')' + a_1(x)u' + a_0(x)u, \qquad 0 < x < 1, \tag{2.1a}$$

with boundary conditions

$$u(0) = 0, \qquad u'(1) + \alpha u(1) = 0, \tag{2.1b}$$

while

$$Bu = -(b_2(x)u')' + b_1(x)u' + b_0(x)u, \qquad 0 < x < 1, \tag{2.2a}$$

with boundary conditions

$$u(0) = 0, \qquad u'(1) + \beta u(1) = 0. \tag{2.2b}$$

We assume that $a_2(x), b_2(x)$ are smooth bounded positive functions bounded away from zero. That is, there are constraints $0 < \Delta_0 < \Delta_1$ such that

$$0 < \Delta_0 \le a_2(x), b_2(x) \le \Delta_1.$$

The discrete operators are obtained by simple central differences. For example, let $N > 1$ be an integer and let

$$h = \frac{1}{N+1}, \tag{2.3}$$

$$x_j = jh, \qquad j = 0, 1, \cdots, N+1, \tag{2.4}$$

and let $U = \{U_j, j = 0, 1, \cdots, N+1\}$ be a grid vector. Then A_h, the discretization of A, is given by

$$[A_h U]_j = -d_j U_{j-1} + e_j U_j - f_j U_{j+1}, \qquad j = 1, 2, \cdots, N, \tag{2.5a}$$

where

$$d_j = \left[a_2\left(x_j - \frac{1}{2}h\right) - \frac{h}{2}a_1(x_j)\right] h^{-2}, \tag{2.5b}$$

$$e_j = \left[a_2\left(x_j - \frac{1}{2}h\right) + a_2\left(x_j + \frac{1}{2}h\right) + h^2 a_0(x_j)\right] h^{-2}, \tag{2.5c}$$

$$f_j = \left[a_2\left(x_j + \frac{1}{2}h\right) + \frac{h}{2}a_1(x_j)\right] h^{-2}, \tag{2.5d}$$

with the additional (boundary) conditions

$$U_o = 0, \tag{2.6a}$$

$$(U_{N+1} - U_N) + \frac{h}{2}\alpha(U_{N+1} + U_N) = 0. \tag{2.6b}$$

The L_2 adjoint A^* of A is given by

$$A^*u = -(a_2(x)u')' - (a_1u)' + a_ou, \qquad 0 < x < 1, \tag{2.7a}$$

with boundary conditions

$$u(0) = 0, \qquad u'(1) + \alpha^* u(1) = 0, \tag{2.7b}$$

where

$$\alpha^* = \left[\alpha + \frac{a_1(1)}{a_2(1)}\right]. \tag{2.7c}$$

Let

$$\|U\|_h = \left\{h\sum_{j=1}^{N} U_j^2\right\}^{1/2}. \tag{2.8}$$

The theory developed in [MP] asserts: there is a constant $K_L > 0$, independent of h, such that

$$C_h(B_h^{-1}A_h) = \|B_h^{-1}A_h\|_h \cdot \|A_h^{-1}B_h\|_h \leq K_L, \tag{2.9a}$$

if and only if

$$\beta^* = \left[\beta + \frac{b_1(1)}{b_2(1)}\right] = \left[\alpha + \frac{a_1(1)}{a_2(1)}\right] = \alpha^* \tag{2.9b}$$

and there is a constant K_R independent of h, such that

$$C_h(A_hB_h^{-1}) = \|A_hB_h^{-1}\|_h \cdot \|B_hA_h^{-1}\|_h \leq K_R, \tag{2.10a}$$

if and only if

$$\alpha = \beta. \tag{2.10b}$$

Moreover, if these conditions are violated, the corresponding condition number is proportional to h^{-1}.

Numerical experiments were performed to verify the theoretical results. Two approaches were used. In the first, the operators $A_h B_h^{-1}$ and $B_h^{-1} A_h$ were constructed as full matrices and a singular value decomposition was used to determine the appropriate condition numbers. Memory constraints limited this approach to systems of 1024 unknowns.

The second approach was to exploit the relationship between the conjugate gradient method and the Lanczos algorithm. For left preconditioning, the normal equations of the preconditioned system were formed and the conjugate gradient method PCGNE (cf. [AMS]) was performed on the preconditioned system

$$(B_h^{-1}A_h)^*(B_h^{-1}A_h)U = (B_h^{-1}A_h)^* B_h^{-1}F. \tag{2.11}$$

The tridiagonal B_h was factored once and backsolution was used to compute $B_h^{-1}V$ for a given vector V. The PCGNE method is optimal in the ℓ_2-norm of the error, $E_j = U - U_j$, at each step of the iteration. The parameters generated by this iteration can be used to get eigenvalue estimates of the operator $A_h^* B_h^{-*} B_h^{-1} A_h$ and thus estimates of $C_h(B_h^{-1}A_h)$ (cf. [CGO], [AMS]).

For right preconditioning, the preconditioned conjugate gradient (PCG) method was applied to the normal equations. Consider the system

$$A_h B_h^{-1} V = F, \tag{2.12a}$$

$$B_h U = V. \tag{2.12b}$$

The normal equations associated with (2.12a) are

$$(A_h B_h^{-1})^*(A_h B_h^{-1})V = (A_h B_h^{-1})^* F. \tag{2.13}$$

The standard conjugate gradient algorithm (CGHS) may be performed on (2.13) and (2.12b) may be used to find the solution U. However, this process is computationally equivalent to performing the PCG algorithm on

$$(B_h^* B_h)^{-1} A_h^* A_h U = (B_h^* B_h)^{-1} A_h^* F \tag{2.14}$$

and avoids the auxiliary equation (2.12b). This method, known as PCGNR, minimizes the ℓ_2-norm of the residual, $R_i = A_h E_i = A_h(U - U_i)$, at each step of the iteration and yields estimates of the eigenvalues of $(B_h^* B_h)^{-1} A_h^* A_h$, which is similar to $B_h^{-*} A_h^* A_h B_h^{-1}$. Thus estimates of $C_h(A_h B_h^{-1})$ are available.

With this approach, systems of 262,144 unknowns were viable in a convenient amount of time and storage on Cray XMP 4/16. Remarkably, the iterative method gave the same results up to three digits of accuracy as the direct method on the smaller problems. For that reason, only the iterative results are displayed below.

The test problems were given a random starting guess and a zero right-hand side, $F \equiv 0$, so that the error could be easily computed. The algorithms were altered so that direct calculation of the residual replaced the recursive formula. This avoids the stalling that may occur when the residual and direction vector become disassociated due to round-off when the residual is driven to small values. For left preconditioning, the PCGNE iteration was terminated when the ℓ_2-norm of the error, $\| E_i \|_h$, was reduced by a factor of 10^{-9}. For the right preconditioning, the PCGNR iteration was terminated when the ℓ_2-norm of the residual, $\| R_i \|_h$, was reduced by a factor of 10^{-9}. Notice that the stopping criteria were based upon the measure of the error that was optimized by the respective algorithms.

Case (i). $D(A) = D(B)$. In the first set of experiments we consider operators with the same boundary conditions. We denote this by saying the domain of $A, D(A)$, equals the domain of $B, D(B)$. Let

$$A = -u'' + a_1u,' \quad u(0) = 0, \quad u'(1) = 0, \tag{2.15a}$$

$$B = -u'' + cu, \quad u(0) = 0, \quad u'(1) = 0. \tag{2.15b}$$

Table 2.1 shows the results for $a_1 = 10.0$, $c = 0$. The estimate of $C_h(B_h^{-1}A_h)$ grows while the estimate of $C_h(A_hB_h^{-1})$ does not. The rate of growth was measured by assuming that

$$C_h(B_h^{-1}A_h) = K\left(\frac{1}{h}\right)^P, \tag{2.16}$$

where K is independent of h. This yields

$$C_h(B_h^{-1}A_h)/C_{2h}(B_{2h}^{-1}A_{2h}) = 2^P. \tag{2.17}$$

The exponent P was calculated for each successive pair of values of h and appears in the column labeled "Growth Rate."

Finally, the number of iterations required to reduce the error for left preconditioning and the residual for right preconditioning by a factor of 10^{-9} appears in the column labeled "Its."

Numerical experiments were performed with various values of a_1 and c. The complete results appear in [JMPW], where it is shown that $C_h(A_h B_h^{-1})$ grows with a_1. The theory in [MP] predicts that $C_h(A_h B_h^{-1})$ should grow as $a_1^{3/2}$ and the constant K in (2.16) should also grow as $a_1^{3/2}$.

The behavior with respect to c is more complicated. It is possible to choose c so as to tightly cluster the spectrum of $A_h B_h^{-1}$, but the relation to the condition $C_h(A_h B_h^{-1})$ is more complicated. It is true, in any case, that for $a_1 \neq 0$ the optimal choice is not $c = 0$. These issues are explored in [MO], where it is shown that for a class of two-dimensional operators the optimal value of c grows as $(a_1 h)^2$.

Case (ii). $D(A^*) = D(B^*)$. In the next set of experiments we consider operators whose adjoints have the same boundary conditions. We have

$$A = -u'' + a_1 u \quad u(0) = 0, \quad u'(1) = 0, \tag{2.18a}$$

$$B = -u'' + cu \quad u(0) = 0, \quad u'(1) + a_1 u(1) = 0. \tag{2.18b}$$

Table 2.2 shows the results with $a_1 = 10$ and $c = 0$. We see that it is $C_h(B_h^{-1} A_h)$ that remains bounded while $C_h(A_h B_h^{-1})$ grows with h. Again, see [JMPW] for results for other values of a_1 and c.

TABLE 2.2
$D(A^*) = D(B^*)$, $a_1 = 10$, $c = 0$.

8192	.8397+01	.1540−02	13	.3969+04	.9981+00	23
16384	.8402+01	.7702−03	14	.7933+04	.9990+00	26
32768	.8404+01	.3845−03	14	.1585+05	.9991+00	26
65536	.8405+01	.1897−03	14	.3163+05	.9963+00	26
131072	.8405+01	.8317−04	14	.4970+04	−.2670+01	31
262144	.8406+01	.2272−04	14	.1268+06	.4673+01	62

Case (iii). A and B selfadjoint, $D(A) \neq D(B)$. In this set of experiments we let

$$A = -u'' \quad u(0) = 0, \quad u'(1) = 0, \tag{2.19a}$$

$$B = -u'' \quad u(0) = 0, \quad u'(1) + \alpha u(1) = 0. \tag{2.19b}$$

Since $D(A) \neq D(B)$ and $D(A^*) \neq D(B^*)$ neither $C_h(B_h^{-1} A_h)$ nor $C_h(A_h B_h^{-1})$ will be bounded independent of h. On the other hand, since A and B are selfadjoint and positive definite and have Dirichlet boundary conditions on the same portion of the boundary the results of [MP] tell us that A and B are spectrally equivalent. In other words, the spectrum of $B_h^{-1}A_h$ is bounded while $\| B_h^{-1}A_h \|_h$ is unbounded.

We again use PCGNE to yield estimates of $C_h(B_h^{-1}A_h)$. To get estimates of the spectrum of $B_h^{-1}A_h$ (which is the same as the spectrum of $B_h^{-1/2}A_hB_h^{-1/2}$) we use the PCG algorithm, which is optimal in the A_h-norm: $(\langle A_h\cdot,\cdot\rangle_h)^{1/2}$.

Table 2.3 shows the results for $\alpha = 2.0$ in (2.19b). Notice that $C_h(B_h^{-1}A_h)$ grows while $C_h(B_h^{-1/2}\ A_h\ B_h^{-1/2})$ remains bounded. The number of iterations for the symmetric preconditioning reflects the number required to reduce the A_h-norm of the error by a factor of 10^{-9}. Numerical results with $\alpha = 20.0$ in (2.19b) can be found in [JMPW]. The results in [MP] show that, in fact, $B_h^{-1}A_h$ has two eigenvalues:

$$\lambda_1 = 1, \qquad \lambda_2 = 1 + \frac{\alpha}{(1+\frac{\alpha h}{2})(1+h)}.$$

TABLE 2.3
A and B selfadjoint, $D(A) \neq D(B)$, $\alpha = 2.0$, $c = 0$.

3. Analysis of the one-dimensional computations. All conjugate gradient methods are polynomial methods and, thus, yield iterates that obey the equation

$$E_j = p_j(CA)E_0, \tag{3.1}$$

where CA is the preconditioned system and $p_j(z)$ is a polynomial of degree j such that $p_j(0) = 1$ (cf. [AMS]). In fact, if the particular conjugate gradient method is optimal in the $M_h - norm$, $(\langle M_h\cdot,\cdot\rangle_h)^{1/2}$, then we know

$$\| E_i \|_{M_h} = \min_{p_j \in P_j^0} \| p_j(CA)E_0 \|_{M_h} \leq \min_{p_j \in P_j^0} \| p_j(CA) \|_{M_h} \| E_0 \|_{M_h}, \tag{3.2}$$

where $P_j^0 = \{\text{polynomials of degree} \leq j,\ p(0) = 1\}$. If CA is M_h selfadjoint, which is the case in our experiments, then

$$\min_{p_j \in P_j^0} \| p_j(CA) \|_{M_h} = \min_{p_j \in P_j^0} \max_{\lambda \in \Sigma(CA)} | p_j(\lambda) |, \tag{3.3}$$

where $\Sigma(CA)$ is the spectrum of CA. If $\Sigma(CA)$ is assumed to fill the interval $[\lambda_{\min}, \lambda_{\max}]$, then p_j can be replaced in (3.3) by the scaled and translated Chebyshev polynomial based upon $[\lambda_{\min}, \lambda_{\max}]$ to yield the well-known bound

$$(3.4) \qquad \frac{\| E_j \|_{M_h}}{\| E_o \|_{M_h}} \leq 2\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)^j ,$$

where $\kappa = (\lambda_{\max}/\lambda_{\min}) = C_{M_h}(CA)$.

In the experiments in §2 we have $M_h = I$ for left preconditioning and

$$(3.5) \qquad \kappa_\ell = C_h((B_h^{-1}A_h)^*(B_h^{-1}A_h)) = [C_h(B_h^{-1}A_h)]^2,$$

while for right preconditioning we have $M_h = A_h^*A_h$ and

$$(3.6) \qquad \kappa_r = C_{A_h^*A_h}((B_h^*B_h)^{-1}(A_h^*A_h)) = [C_h(A_hB_h^{-1})]^2.$$

When the "wrong" boundary conditions are used we have $\kappa = 0(h^{-2})$ for either left and right preconditioning. For κ large, the number of iterations required to reduce the *bound* in (3.4) by a factor of ϵ is approximately

$$(3.7) \qquad j \cong \frac{\log(2) - \log(\epsilon)}{2}\sqrt{\kappa} \ .$$

For $\epsilon = 10^{-9}$ this yields

$$(3.8) \qquad j \cong 10.7\sqrt{\kappa}.$$

A quick glance at Table 2.1 reveals that the required number of iterations is a small fraction of the number suggested by (3.8). Note that the estimated condition number is equal to $\sqrt{\kappa}$ (see (3.5), (3.6)). Clearly, the behavior of the conjugate gradient method is not determined by the worst case analysis but is determined by the distribution of the eigenvalues of the preconditioned matrix CA. For the left preconditioned normal equations these are squares of the singular values of $B_h^{-1}A_h$ while for the right preconditioned normal equation these are the squares of the singular values of $A_hB_h^{-1}$.

We will analyze the behavior of these singular values. Given the differential operator A suppose we choose $B^{(1)}$ and $B^{(2)}$ to be two operators that differ only in the boundary conditions at $x = 1$. Suppose

$$(3.9) \qquad (\beta^{(1)})^* = \alpha^*,$$

while

$$(3.10) \qquad \beta^{(2)} = \alpha.$$

Let us analyze the singular values of $(B_h^{(2)})^{-1}A_h$ in terms of the singular values of $(B_h^{(1)})^{-1}A_h$. The theory of [MP] asserts that there are two positive constants $0 < \Lambda_0 < \Lambda_1$ such that

$$(3.11) \qquad 0 < \Lambda_0 \leq \sigma_j \leq \Lambda_1, \qquad j = 1, 2, \cdots, N,$$

where the σ_j are the singular values of

$$(B_h^{(1)})^{-1}A_h.$$

Observe that

$$B_h^{(2)} = B_h^{(1)} + R_1, \tag{3.12}$$

where R_1 is an operator of rank 1. In the generic case, the Sherman–Morrison formula yields

$$(B_h^{(2)})^{-1} = (B_h^{(1)})^{-1} + T_1, \tag{3.13}$$

where T_1 is an operator of rank 1. Hence

$$(B_h^{(2)})^{-1}A_h = (B_h^{(1)})^{-1}A_h + T_1A_h \quad , \tag{3.14}$$

where T_1A_h is an operator of rank 1. Therefore

$$((B_h^2)^{-1}A_h)^*((B_h^{(2)})^{-1}A_h) = ((B_h^{(1)})^{-1}A_h)^*((B_h^{(1)})^{-1}A_h) + S_2, \tag{3.15}$$

where S_2 is an Hermitian operator of rank 2. Hence we have the following result.

LEMMA 3.1. *Let $\hat{\sigma}_1 \geq \hat{\sigma}_2 \geq, \cdots, \geq \hat{\sigma}_N > 0$ be the singular values of $(B_h^{(2)})^{-1}A_h$. Then, for $j \neq 1$ and $j \neq N$ we have*

$$0 < \Lambda_0 \leq \hat{\sigma}_j \leq \Lambda_1, \qquad j = 2, 3, \cdots, N-1. \tag{3.16}$$

And, while it is possible that for some fixed $h > 0$, $\hat{\sigma}_1$ and/or $\hat{\sigma}_N$ also satisfies (3.16), *there are constants $C_1, C_2, C_3, C_4 > 0$ such that*

$$C_1h^{-1/2} \leq \sigma_1 \leq C_2h^{-1/2}, \tag{3.17a}$$

$$C_3h^{1/2} \leq \sigma_N \leq C_4h^{1/2}. \tag{3.17b}$$

Proof. The inequalities (3.16) follow from the remarks above and (3.11). The estimates (3.17) follow from the results of [MP]. □

Suppose h is fixed and the conjugate gradient method PCGNE applied to

$$Q_h^{(1)} = ((B_h^{(1)})^{-1}A_h)^*((B_h^{(1)})^{-1}A_h) \tag{3.18}$$

requires n_1 iterations to reduce the ℓ_2-norm of the error by a factor of ϵ. (PCGNE is optimal in the ℓ_2-norm.) Let $p_{n_1}(\lambda)$ be the optimal polynomial generated by the iteration. Assume

$$\max_{\lambda\in[\Lambda_0^2,\Lambda_1^2]} \mid p_{n_1}(\lambda) \mid < \epsilon. \tag{3.19}$$

Of course, this need not be true, but if either $\Lambda_1^2 - \Lambda_0^2$ is small or the eigenvalues of $Q_h^{(1)}$ fill the interval $[\Lambda_0^2, \Lambda_1^2]$, then (3.19) will be approximately correct. Consider the polynomial

$$q_{n_1+2}(\lambda) = \frac{(\lambda - \hat{\sigma}_1^2)(\lambda - \hat{\sigma}_N^2)}{\hat{\sigma}_1^2\hat{\sigma}_N^2}p_{n_1}(\lambda). \tag{3.20}$$

Clearly,

$$q_{n_1+2}(0) = 1, \tag{3.21a}$$

$$q_{n_1+2}(\hat{\sigma}_1^2) = q_{n_1+2}(\hat{\sigma}_N^2) = 0, \tag{3.21b}$$

$$\max_{\lambda \in [\Lambda_0^2, \Lambda_1^2]} | \, q_{n_1+2}(\lambda) \, | \leq \epsilon \frac{\Lambda_1^2}{\hat{\sigma}_N^2}. \tag{3.21c}$$

Thus, $n_1 + 2$ iterations of PCGNE applied to

$$Q_h^{(2)} = ((B_h^{(2)})^{-1} A_h)^* ((B_h^{(2)})^{-1} A_h) \tag{3.22}$$

yields

$$\| \, E_{n_1+2}^{(2)} \, \|_h \leq \| \, q_{n_1+2}(Q_h^{(2)}) \, \|_h \leq \epsilon \frac{\Lambda_1^2}{\hat{\sigma}_N^2} \leq \epsilon \frac{\Lambda_1^2}{C_3^2} h^{-1}. \tag{3.23}$$

Now, let r be an integer and observe that

$$\frac{\| \, E_{r(n_1+2)}^{(2)} \, \|_h}{\| \, E_0^{(2)} \, \|_h} \leq \left[\epsilon \frac{\Lambda_1^2}{C_3^2} h^{-1} \right]^r. \tag{3.24}$$

Thus, the number of steps of PCGNE required to reduce the ℓ_2-norm of the error, $\| \, E_i^{(2)} \, \|_h$, by a factor of ϵ can be approximated by setting

$$\left[\epsilon \frac{\Lambda_1^2}{C_3^2} h^{-1} \right]^r = \epsilon, \tag{3.25}$$

and solving for r. This yields

$$r = \frac{\log(\epsilon)}{\log(\epsilon) + 2\log(\Lambda_1) - 2\log(C_3) - \log(h)}. \tag{3.26}$$

In our experiments in §2 we have $\Lambda_1 / C_3 \cong (1 + a_1)/\sqrt{a_1}$, $\epsilon = 10^{-9}$, $h = 2^{-k}$. For $a_1 = 10$ this yields

$$r = \frac{1}{.88 - (.033)k}. \tag{3.27}$$

Table 3.1 displays the actual number of iterations and the number predicted by (3.27) for $h = 2^{-k}, k = 15 - 18$. The results for the "correct" preconditioning, $B_h^{(1)}$, are taken from the left preconditioning of Table 2.2, while the results for the "wrong" preconditioning, $B_h^{(2)}$, are taken from left preconditioning of Table 2.1. The actual numbers are surprisingly close to the predicted numbers.

TABLE 3.1
Predicted number of iterations.

1/h	Its(1)	Actual Its(2)	Predicted Its(2)
$2^{15} = 32768$	14	31	41
$2^{16} = 65536$	14	34	45
$2^{17} = 131072$	14	38	50
$2^{18} = 262144$	14	54	56

Similar arguments can be made for the right preconditioning using the "wrong" boundary conditions. The only difference is that, in this case, the M-norm is optimized where $M = A_h^* A_h$ and the roles of $B_h^{(1)}$ and $B_h^{(2)}$ are reversed, with $B_h^{(2)}$ being the "correct" preconditioning.

4. Further computational results. The analysis of §3 explains why the results of the one-dimensional experiments with the "wrong" boundary conditions are "not so bad" relative to the results for the cases where the "correct" boundary conditions were used. However, it is not yet clear why the results are so good in the case when the "correct" boundary condition is used. For this reason further computational experiments were undertaken. Section 5 will provide an analysis of these results. Recall that the operator A is given by

$$Au = -(a_2(x)u')' + a_1 u' + a_0 u, \tag{4.1a}$$

$$u(0) = 0, \qquad u'(1) = 0, \tag{4.1b}$$

where a_1 and a_0 are constants and $a_2(x)$ may be constant or may be variable. The preconditioners were

$$B^{(1)}v = -v'' + b_0 v, \tag{4.2a}$$

$$v(0) = 0, \qquad v'(1) = -\frac{a_1}{a_2(1)} v(1), \tag{4.2b}$$

and

$$B^{(2)}v = -v'' + b_0 v, \tag{4.3a}$$

$$v(0) = 0, \qquad v'(1) = 0. \tag{4.3b}$$

Here the discretization, A_h, was obtained essentially as the discretization described in §2 with one small change. The boundary condition at $x = 1$ was treated a bit more accurately by choosing

$$h = \frac{2}{(2N+1)}. \tag{4.4a}$$

Then

$$Nh = \frac{2N}{2N+1} = 1 - \frac{1}{2}h, \tag{4.4b}$$

$$(N+1)h = \frac{2(N+1)}{2N+1} = 1 + \frac{1}{2}h. \tag{4.4c}$$

The boundary condition is then expressed as (2.6b), as before.

The operators $(B_h^{(j)})^{-1}$ were given by one cycle multigrid iterations for the solution of

$$B_h^{(j)} V = f.$$

For technical reasons, the choice of (4.4) rather than (2.3) suggested that the multigrid coarsening factor be 3 rather than 2.

While we have done many experiments, for our present purposes we will limit ourselves to three particular operators A.

Case 1.

$$Au = -u'' + 8u' \tag{4.5a}$$

with boundary conditions

$$u(0) = 0, \qquad u'(1) = 0. \tag{4.5b}$$

In this case *all the eigenvalues of A are real and positive.*

The preconditioners chosen are given by

$$B^{(1)}v = -v'' \tag{4.6a}$$

with boundary conditions

$$v(0) = 0, \qquad v'(1) = -8v(1), \tag{4.6b}$$

and

$$B^{(2)}v = -v'' \tag{4.7a}$$

with boundary conditions

$$v(0) = 0, \qquad v'(1) = 0. \tag{4.7b}$$

The theory of [MP] asserts that

$$\|(B_h^{(1)})^{-1}A_h\|_h \le C, \qquad \|A_h^{-1}B_h^{(1)}\|_h \le C \tag{4.8a}$$

and

$$\|(B_h^{(2)})^{-1}A_h\|_h \sim Ch^{-1/2}, \qquad \|A_h^{-1}B_h^{(2)}\|_h \sim Ch^{-1/2}. \tag{4.8b}$$

The results for this case are summarized in Tables 4.1 and 4.2 and Figs. 4.3 and 4.4.

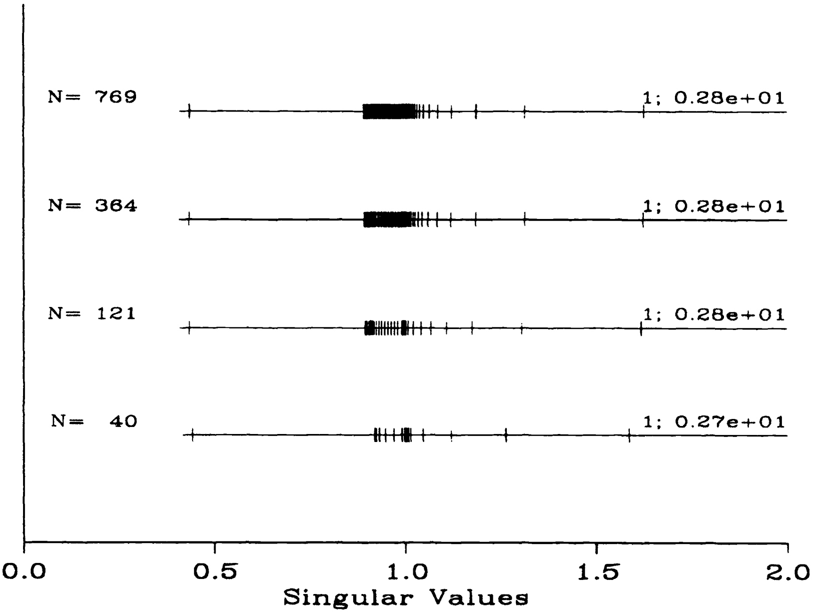

FIG. 4.3. *Singular value distribution of* $(B_h^{(1)})^{-1}A_h$.

In all the figures of this section, the numbers "$j; num$" on the right of the lines are to be read as follows:

$$j = \text{number of singular values larger than 2;}$$
$$num = \text{the largest singular value.}$$

We see that $\sigma^{(1)}(N)$ and $\sigma^{(1)}(1)$ remained fixed as N increases, while $\sigma^{(2)}(N)$ decreases and $\sigma^{(2)}(1)$ increases as N increases. The interior singular values for both preconditionings cluster about 1.0.

Case 2. In this case we introduce a nonconstant $a_2(x)$. Let

$$Au = -(a_2(x)u')' + 8u' \tag{4.9a}$$

with boundary conditions

$$u(0) = 0, \qquad u'(1) = 0, \tag{4.9b}$$

where

$$a_2(x) = 1 + \frac{1}{2}\sin 3\pi x. \tag{4.9c}$$

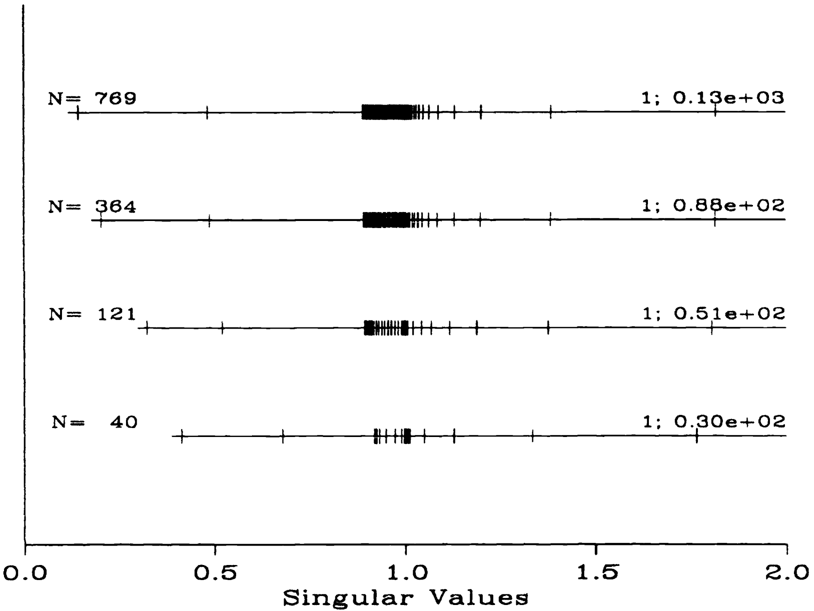

FIG. 4.4. *Singular value distribution of* $(B_h^{(2)})^{-1}A_h$.

As in Case 1, *all the eigenvalues of A are real and positive.* The preconditioners are again $B^{(1)}$ and $B^{(2)}$ as described by (4.6) and (4.7), respectively. Again the theory of [MP] yields (4.8a) and (4.8b). The results for this case are summarized in Tables 4.5 and 4.6 and Figs. 4.7 and 4.8.

TABLE 4.5

769	994.98	0.1289	0.4476	128.29

The extreme singular values behave as in Case 1. Here, however, the interior singular values become dense in the interval $[.5, 1.5]$.

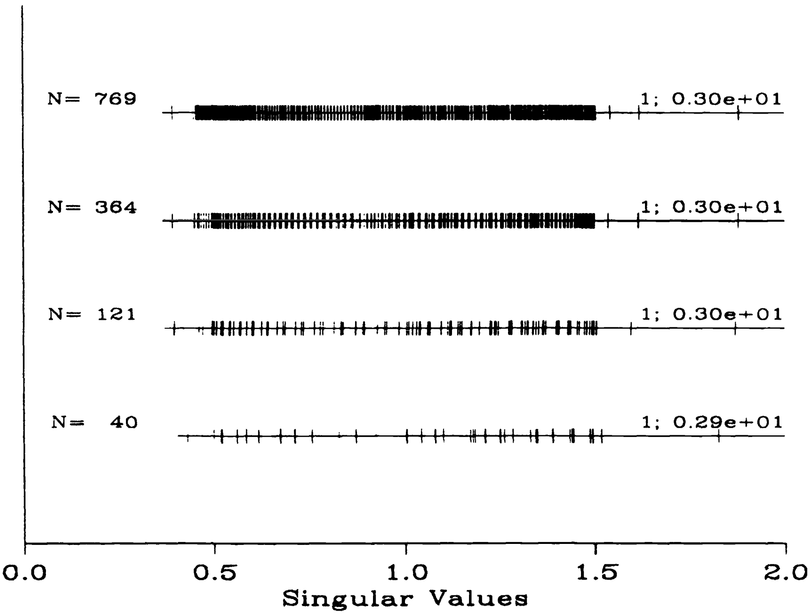

FIG. 4.7. *Singular value distribution of* $(B_h^{(1)})^{-1}A_h$.

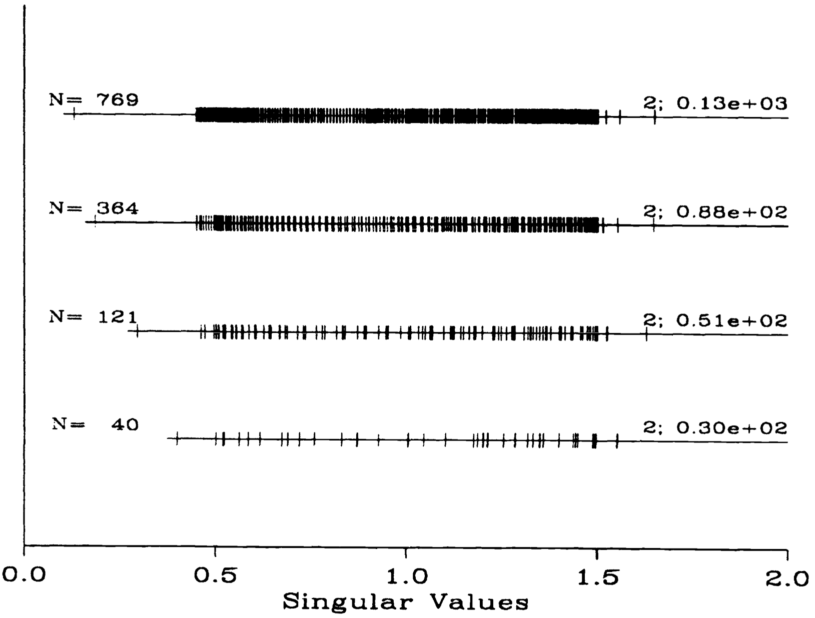

FIG. 4.8. *Singular value distribution of* $(B_h^{(2)})^{-1}A_h$.

Case 3. In this case we examine an indefinite operator. Let

$$Au = -u'' + 8u' - (6.5)\pi^2 u, \tag{4.10a}$$

with boundary conditions

$$u(0) = 0, \qquad u'(1) = 0. \tag{4.10b}$$

Two eigenvalues of A are negative, while all the others are positive. The preconditioners are again $B^{(1)}$ and $B^{(2)}$ as described by (4.6) and (4.7), respectively. Once more, the theory of [MP] yields (4.8a) and (4.8b). The results for this case are summarized in Tables 4.9 and 4.10 and Figs. 4.11 and 4.12.

TABLE 4.9
Singular values of $(B_h^{(1)})^{-1}A_h$.

769	6209.3	0.0209	0.2016	129.99

Observe that

$$\sigma^{(1)}(N) \approx \sigma^{(2)}(N) = \text{constant}$$

but $\sigma^{(2)}(N-1) << \sigma^{(1)}(N-1)$ and is steadily decreasing as a function of N. (This is easily seen from Fig. 4.11.) So, one would expect that for N large enough

$$\sigma^{(2)}(N) < \sigma^{(1)}(N)$$

and $\sigma^{(2)}(N)$ would continue to decrease as a function of N, while $\sigma^{(1)}(N)$ remains constant. Indeed, this is the result predicted by [MP]. Here, as in Case 1, the remaining singular values cluster about 1.0.

5. Distribution of the singular values.

In this section we assume that

$$\alpha^* = \beta^* \tag{5.1}$$

and consider the distribution of the singular values $0 < \sigma_N \leq \sigma_{N-1} \leq, \cdots, \leq \sigma_1$ of $B_h^{-1}A_h$. The theory developed in [MP] asserts only that there exists a pair of fixed numbers $0 < \Lambda_0(L) < \Lambda_0(U)$, independent of h such that

$$0 < \Lambda_0(L) \leq \sigma_N \leq \sigma_j \leq \sigma_1 \leq \Lambda_0(U). \tag{5.2}$$

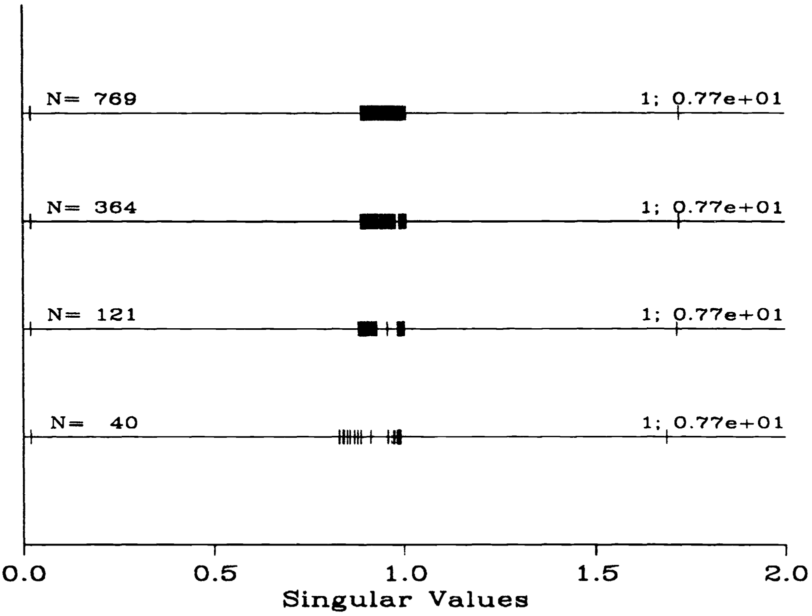

FIG. 4.11. *Singular value distribution of* $(B_h^{(1)})^{-1}A_h$.

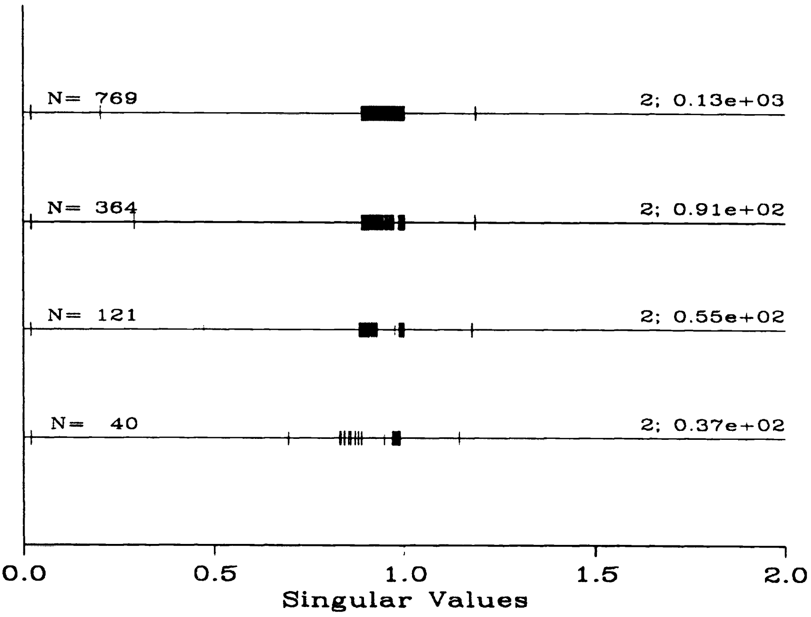

FIG. 4.12. *Singular value distribution of* $(B_h^{(2)})^{-1}A_h$.

The development in this section gives a qualitative explanation of the detailed results on the σ_j seen in §4.

Let A and B be the operators described by (2.1) and (2.2) subject to (5.1). Let u, v satisfy

$$B^{-1}Au = v, \tag{5.3a}$$

that is

$$Au = Bv. \tag{5.3b}$$

We show that

$$v(x) = \frac{a_2(x)}{b_2(x)}u(x) + Ku \tag{5.4a}$$

and the operator K is a linear compact operator. That is,

$$B^{-1}A = \frac{a_2(x)}{b_2(x)}I + K$$

and

$$Q = (B^{-1}A)^*B^{-1}A = \left[\frac{a_2(x)}{b_2(x)}\right]^2 I + \tilde{K}_1, \tag{5.4b}$$

where $\tilde{K}_1$ is another compact operator.

Next, we show that

$$Q_h = (B_h^{-1}A_h)^*(B_h^{-1}A_h) \tag{5.5}$$

is a consistent and convergent approximation to Q. Once this has been done it is an easy matter to prove the main result of this section.

THEOREM 5.1. *Let A, B be given by* (2.1) *and* (2.2), *respectively. Assume that* (5.1) *holds. Let A_h and B_h be constructed as in* (2.5). *Let*

$$m = \min \frac{a_2(x)}{b_2(x)}, \tag{5.6a}$$

$$M = \max \frac{a_2(x)}{b_2(x)}. \tag{5.6b}$$

Let $\epsilon > 0$ be given ($\epsilon < \frac{1}{2}m^2$ is not essential, but is a reasonable additional condition). Then there is an $h_0 > 0$ and an integer $\tilde{n} = \tilde{n}(\epsilon)$ such that for all $h \leq h_0$ at most $\tilde{n}$ of the squared singular values σ_j^2 are outside the interval $[m^2 - \epsilon, M^2 + \epsilon]$.

We return to the proof of (5.4a). From (5.3b) we have

$$-(a_2u')' + a_1u' + a_0u = -(b_2v')' + b_1v' + b_0v. \tag{5.7}$$

We remind the reader that the results of [MP] assert that there is a constant, say, C_0, such that

$$\|v\|_{L_2} \leq C_0\|u\|_{L_2}. \tag{5.8}$$

From (5.7) we obtain

$$(5.9)\qquad -a_2u' + \int_0^x a_1u'dt + \int_0^x a_0udt = (-b_2v') + \int_0^x b_1v'dt + \int_0^x b_0vdt + C_1,$$

where C_1 is a constant depending on u (since we are assuming that u is given and v is determined from (5.3a)).

Integration by parts yields

$$(5.10)\qquad -a_2u' + a_1u + \int_0^x (a_0 - a_1')udt = -b_2v' + b_1v + \int_0^x (b_0 - b_1')vdt + C_1.$$

We observe that the two integrals in (5.10) are compact linear operators applied to u. This is immediately apparent for the integral on the left-hand side of (5.10). However, it is also true of the integral on the right-hand side of (5.10) because (i) (5.3a) shows that v is a linear function of u, and (ii) (5.8) shows that v is a bounded function of u. We shall use the symbol $I(u)$ to denote any such term that is a compact linear operator applied to u. With this understanding, (5.10) can be rewritten as

$$(5.11)\qquad -a_2u' + a_1u + b_2v' - b_1v + I(u) = C_1.$$

Integration and integration by parts now yield

$$-a_2u + b_2v + \int_0^x [(a_2' + a_1)u - (b_2' + b_1)v]dt + \int_0^x I(u)dt = C_1x.$$

That is,

$$(5.12)\qquad v = \frac{a_2}{b_2}u + I(u) + \frac{1}{b_2}C_1x.$$

Since (5.8) must be true, we see that C_1 must be a bounded functional of u. Indeed, a bounded linear functional of u. Hence, $C_1(u)$ is also a compact linear operator. Therefore, we have

$$(5.13)\qquad v = \frac{a_2}{b_2}u + I(u).$$

This is the first goal enunciated at the beginning of this section.

Remark. In the special case where

$$b_1 = b_0 = 0$$

it is easy to obtain an explicit representation of $C_1(u)$.

Consider the difference equations

$$(5.14a)\qquad B_h^{-1}A_hU = V,$$

$$(5.14b)\qquad A_hU = B_hV.$$

A similar computation, based on summation by parts rather than integration by parts, yields

$$V_j = \frac{a_2(x_j - \frac{h}{2})}{b_2(x_j - \frac{h}{2})} U_j + K_h U, \tag{5.15}$$

where $K_h U$ is a discrete analog of the compact operator $K(u)$.

In addition to being a discretization of $K(u)$, these discrete operators are also uniformly compact in the sense that there is a constant C independent of h such that if U is a grid vector and $U(x,h)$ is the associated piecewise linear function, and if

$$K_h U = W, \tag{5.16a}$$

then

$$\|W(\cdot,h)\|_{H_1} \leq C\|U(\cdot,h)\|_{L_2}. \tag{5.16b}$$

Under these circumstances it is very easy to prove Lemma 5.1.

LEMMA 5.1. *Consider the operator*

$$(B^{-1}A)^*(B^{-1}A) = \left(\frac{a_2}{b_2}\right)^2 I + K^* \left(\frac{a_2}{b_2}\right) + \left(\frac{a_2}{b_2}\right) K + K^*K, \tag{5.17}$$

where K *is the operator of* (5.4a), *or, using the notation of* (5.13),

$$Ku = I(u).$$

Then

$$\tilde{K} = K^* \left(\frac{a_2}{b_2}\right) + \left(\frac{a_2}{b_2}\right) K + K^*K \tag{5.18a}$$

is a compact operator. Moreover, the discrete operators

$$\tilde{K}_h = K_h^* \left(\frac{a_2}{b_2}\right)_{j-1/2} + \left(\frac{a_2}{b_2}\right)_{j-1/2} K_h + K_h^* K_h \tag{5.18b}$$

are uniformly compact and

$$\tilde{K}_h \to \tilde{K}. \tag{5.19}$$

In particular, let λ_j *be the eigenvalues of* $\tilde{K}$ *arranged so that*

$$|\lambda_1| \geq |\lambda_2| \geq \cdots \tag{5.20a}$$

and let $\mu_j(h)$ *be the eigenvalues of* $\tilde{K}_h$ *arranged so that*

$$|\mu_1(h)| \geq |\mu_2(h)| \geq \cdots |\mu_k(h)| \geq 0. \tag{5.20b}$$

Then, given a fixed J *and an* ϵ, *there is an* $h_0 > 0$ *such that, for all* $h \leq h_0$, *we have*

$$|\lambda_j - \mu_j(h)| \leq \epsilon, \qquad j = 1, 2, \cdots, J. \tag{5.21}$$

Proof. We omit the proof, which is a standard compactness argument. □

We are now able to prove our main result.

Proof of Theorem 5.1. Let $\epsilon > 0$ be given. Choose J so large that $|\lambda_J| < \frac{\epsilon}{2}$. Choose h_0 so small that

$$|\lambda_j - \mu_j(h)| \le \frac{\epsilon}{4}, \qquad j = 1, 2, \cdots, J; \qquad h \le h_0. \tag{5.22}$$

Then the eigenvalue values $q_j(h)$ of Q_h are characterized by

$$q_j(h) = \max_{S_j} \min_{U \neq 0} \left\{ \frac{U^* Q_h U}{U^* U}, \quad U \in S_j \right\}, \tag{5.23}$$

where dim $S_j = j$. Hence, see [ST, Thm. 5.10],

$$m^2 - \mu_j \le \sigma_j^2 \le M^2 + \mu_j. \tag{5.24}$$

Hence, for $j > J$ we have

$$m^2 - \left(\frac{\epsilon}{2} + \frac{\epsilon}{4}\right) \le \sigma_j^2 \le M^2 + \left(\frac{\epsilon}{2} + \frac{\epsilon}{4}\right).$$

Thus, the theorem is proven. □

With Theorem 5.1 in hand, consider the numerical results of §4. In Case 1 and Case 3 we have $a_2(x) = b_2(x) = 1$. Thus,

$$((B^{(1)})^{-1}A)^*((B^{(1)})^{-1}A) = I + \tilde{K}. \tag{5.25}$$

Figures 4.1 and 4.5 show that the singular values of the discrete operators cluster about 1.0. In Case 2, we have $a_2(x) = 1 + \frac{1}{2}\sin(3\pi x)$ and $b_2(x) = 1$, which yields

$$((B^{(1)})^{-1}A)^*((B^{(1)})^{-1}A) = a_2(x)I + \tilde{K}. \tag{5.26}$$

The spectrum of the multiplication operator $a_2(x)I$ fills the interval $[.5, 1.5]$. In Fig. 4.3 we see that the singular values of the discrete operators fill the interval $[.5, 1.5]$ plus a few isolated values as the theory predicts.

6. Two-dimensional computational results. In this section, we describe computational results on two-dimensional problems. An analysis of these results will appear in §7. Our experiments use centered difference approximations to the operators

$$Au = -\Delta u + a_{11}u_x + a_{12}u_y, \tag{6.1}$$

$$Bu = -\Delta u, \tag{6.2}$$

for $(x, y) \in [0, 1] \times [0, 1]$. To make notation easier we will denote the boundary conditions schematically. For example, the boundary conditions

(6.3)

$u_y(x, 1) = 0$

$u(0, y) = 0, \qquad u_x(1, y) + a_{11}u(1, y) = 0$ become 
$u(x, 0) = 0$

Again, the conjugate gradient method PCGNE was used on the left preconditioned normal equations with iteration matrix

$$Q_h = (B_h^{-1}A_h)^*(B_h^{-1}A_h). \tag{6.4}$$

For right preconditioning, the conjugate gradient method PCGNR was applied to the iteration matrix

$$\tilde{Q}_h = (B_h^*B_h)^{-1}(A_h^*A_h). \tag{6.5}$$

For A and B selfadjoint, symmetric preconditioning was implemented by using PCG on the iteration matrix

$$G_h = B_h^{-1}A_h. \tag{6.6}$$

Inversion of B_h was accomplished by using a Fast Poisson solver.

Case (i). $D(A) = D(B)$. Let

(6.7a) $Au = -\Delta u + a_{11}u_x + a_{12}u_y,$ 
(6.7b) $Bu = -\Delta u,$ 
Table 6.1 shows the results for $a_{11} = a_{12} = 1$, while Table 6.2 shows the results for $a_{11} = a_{12} = 10$. Notice that $C_h(B_h^{-1}A_h)$ grows like $0(h^{-1})$, while $C_h(A_hB_h^{-1})$ is independent of h. Also, notice that this rate is only achieved for the smallest values of h that we were able to compute.

Here "Its" reflects the number of iterations to reduce the ℓ_2-norm of the error for left preconditioning and the ℓ_2-norm of the residual for right preconditioning by a factor of 10^{-6}.

TABLE 6.1

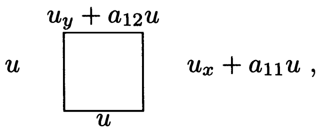
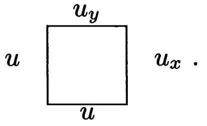
Case (ii). $D(A^*) = D(B^*)$. Let

(6.8a) $$Au = -\Delta u - a_{11}u_x - a_{12}u_y,$$



(6.8b) $$Bu = -\Delta u,$$



Notice that the A here is the adjoint of the A in Case (i). The operator A was changed rather than B so as to retain the easy-inversion of B_h by a Fast Poisson Solver. Table 6.3 shows the results for $a_{11} = a_{12} = 1$, while Table 6.4 shows the results for $a_{11} = a_{12} = 10$. Now, $C_h(B_h^{-1}A_h)$ is bounded, while $C_h(A_hB_h^{-1})$ grows like h^{-1}. Again, notice that the number of iterations using the "wrong" preconditioning grows very slowly.

TABLE 6.3

Case (iii). A and B selfadjoint, $D(A) \neq D(B)$. Let

(6.9a) $Au = -\Delta u,$ 
(6.9b) $B^{(1)}u = -\Delta u,$ 
(6.9c) $B^{(2)}u = -\Delta u,$ 
(6.9d) $B^{(3)}u = -\Delta u,$ 
Table 6.5 shows the results for both left and symmetric preconditioning with $(B_h^{(1)})^{-1}$. Although $D(A) \neq D(B)$, both A and $B^{(1)}$ have Dirichlet boundary conditions on the same portion of the boundary. The theory in [MP] says $C_h(B_h^{-1}A_h)$ should be $0(h^{-1})$, while $C_h(B_h^{-1/2}A_hB_h^{-1/2})$ should be bounded. These bounds are supported by the results in Table 6.5.

TABLE 6.5
$2-D$, A and B selfadjoint, $D(A) \neq D(B)$, same Dirichlet part.

	Left preconditioning			Symmetric preconditioning		
$1/h$	$C_h(B_h^{-1}A_h)$	Growth rate	Its	$C_h(B_h^{-1/2}A_hB_h^{-1/2})$	Growth rate	Its
4	.1141+01	.0000+00	5	.1135+01	.0000+00	4
8	.1245+01	.1260+00	5	.1204+01	.8431−01	4
16	.1455+01	.2246+00	5	.1255+01	.5975−01	4
32	.1782+01	.2926+00	7	.1286+01	.3609−01	4
64	.2282+01	.3569+00	7	.1297+01	.1159−01	4
128	.3090+01	.4369+00	8	.1301+01	.4966−02	4
256	.4796+01	.6341+00	9	.1113+01	−.2250+00	3
512	.7924+01	.7242+00	11	.1249+01	.1657+00	3

In Table 6.6 the same results are presented for preconditioning with $(B_h^{(2)})^{-1}$. In this case A has Dirichlet boundary conditions on the top, while $B^{(2)}$ does not. Thus, as predicted, $C_h(B_h^{-1}A_h) = 0(h^{-2})$, while $C_h(B_h^{-1/2}A_hB_h^{-1/2}) = 0(h^{-1})$. The blank line for left preconditioning and $h = 2^{-9}$ indicates that the iteration did not converge in 3000 iterations.

TABLE 6.6
$2-D$, A and B selfadjoint, $D(A) \neq D(B)$, Dirichlet part of A includes Dirichlet part of B.

	Left preconditioning			Symmetric preconditioning		
$1/h$	$C_h(B_h^{-1}A_h)$	Growth rate	Its	$C_h(B_h^{-1/2}A_hB_h^{-1/2})$	Growth rate	Its

512	—	—	—	.5970+03	.1002+01	43

Finally, Table 6.7 shows the results for preconditioning with $B^{(3)}$. Here A has Dirichlet boundary conditions where $B^{(3)}$ does not, and $B^{(3)}$ has Dirichlet boundary conditions where A does not. As predicted,

$$C_h(B_h^{-1}A_h) = 0(h^{-3}) \quad \text{while} \quad C_h(B_h^{-1/2}A_hB_h^{-1/2}) = 0(h^{-2}).$$

TABLE 6.7

7. Analysis of the two-dimensional computations. As we have seen, in the one-dimensional computational experiments described in §2, the conjugate gradient algorithm works better than might be expected even in those cases where the "wrong" boundary conditions are used. The reason for this is contained in the analysis of §3 and essentially comes about because

$$B_h^{(1)} = B_h^{(2)} + R_1, \tag{7.1}$$

where R_1 is an operator of rank one. In this section, we turn our attention to the two-dimensional computations and seek to explain their "not so bad" behavior.

The basic reasons for the efficiency of the two-dimensional examples in the cases where $D(A^*) = D(B^*)$, i.e., those cases where $C_{L_2}(B_h^{-1}A_h)$ is bounded independent of h, is essentially explained by the computations of §4 and the analysis of §5, see [GMP] for the two-dimensional extension of the results of §5. As for the case with "wrong" boundary conditions in two-dimensions, we consider a problem with $D((B^{(2)})^*) = D(A^*)$, $D(B^{(1)}) = D(A)$. And, as in all the examples of §6, we may analyze the problems by the method of "separation of variables." We have

$$B_h^{(1)} = B_h^{(2)} + R_t, \tag{7.2}$$

where we might expect R_t to be of rank $t = 0(1/h)$, the number of points next to the boundary. But, as we shall see, in fact the number, T, of unbounded singular values is (at most)

$$T = O\left(\frac{1}{h^{1/2}}\right),$$

a significantly smaller number.

Consider the problem with

$$\Omega = \{(x,y) \mid 0 < x, y < 1\}, \tag{7.3a}$$

$$Au = u_{xx} + u_{yy} + au_x, \tag{7.3b}$$

$$u = 0 \text{ on } x = 0, \quad y = 0, \quad y = 1, \tag{7.3c}$$

$$\frac{\partial u}{\partial x} = 0 \quad \text{on } x = 1. \tag{7.3d}$$

Let the preconditioner be

$$Bv = v_{xx} + v_{yy} \tag{7.4}$$

subject to the same boundary conditions as A. The discretizations A_h and B_h are obtained by straightforward central differences.

We turn immediately to the discrete problem

$$B_h^{-1} A_h U = V, \tag{7.5a}$$

$$A_h U = B_h V. \tag{7.5b}$$

We now apply an argument based on "separation of variables." Let

$$U = \sum_{j=1}^{N} \phi_j(x) \sin \pi j y, \tag{7.6a}$$

$$V = \sum_{j=1}^{N} \psi_j(x) \sin \pi j y, \tag{7.6b}$$

where

$$N = \frac{1}{h}. \tag{7.6c}$$

We find that the functions $\phi_j(x)$ and $\psi_j(x)$ are related by the equations (we drop the subscript j where possible)

$$\begin{gathered} \phi_{x\bar{x}} + a\phi_{\hat{x}} - \mu_j \phi = \psi_{x\bar{x}} - \mu_j \psi, \\ \phi(0) = 0, \qquad (\phi_x)_N = 0, \end{gathered} \tag{7.7a}$$

where

$$\mu_j = \frac{4 \sin^2(\pi j h/2)}{h^2}. \tag{7.7b}$$

The symbols ϕ_x,ψ_x are forward differences. That is,

$$(\phi_x)_k = \frac{\phi_{k+1} - \phi_k}{h}. \tag{7.7c}$$

The symbols $\phi_{x\bar{x}}$, $\psi_{x\bar{x}}$, $\phi_{\hat{x}}$, $\psi_{\hat{x}}$ are defined as central differences. That is,

$$(\phi_{x\bar{x}})_k = \frac{\phi_{k+1} - 2\phi_k + \phi_{k-1}}{h^2}, \tag{7.7d}$$

$$(\phi_{\hat{x}})_k = \frac{\phi_{k+1} - \phi_{k-1}}{2h}. \tag{7.7e}$$

Since

$$\frac{2}{\pi} \le \frac{\sin\theta}{\theta} \le 1, \qquad 0 \le \theta \le \frac{\pi}{2}$$

we have

$$4j^2 \le \mu_j \le \pi^2 j^2. \tag{7.8}$$

Our main results now follow easily.

LEMMA 7.1. *Let ϕ and ψ be connected by* (7.7). *Then*

$$\|\phi - \psi\|_h \le \frac{\|a\|_\infty}{2j^2 h}\|\phi\|_h. \tag{7.9}$$

Proof. We first observe that

$$\|\phi_{\hat{x}}\|_h \le \frac{2}{h}\|\phi\|_h. \tag{7.10}$$

Let $W = \psi - \phi$. Then W satisfies the equation

$$W_{x\bar{x}} - \mu_j W = a\phi_{\hat{x}}. \tag{7.11}$$

Multiplication by W and summation, together with a standard summation by parts argument, yields

$$\left|(-\|W_x\|_h^2 - \mu_j\|W\|_h^2)\right| \le \|a\|_\infty \frac{2}{h}\|\phi\|_h \cdot \|W\|_h, \tag{7.12}$$

thus,

$$4j^2\|W\|_h \le \frac{2\|a\|_\infty}{h}\|\phi\|_h,$$

which implies the lemma. □

LEMMA 7.2. *Let ϕ and ψ be connected by* (7.7). *Then*

$$\|\phi - \psi\|_h \le \frac{\|a\|_\infty}{4j^2}\left[\frac{2}{h}\|\psi\|_h + \frac{\|a\|_\infty}{4}\|\phi - \psi\|_h\right]. \tag{7.13}$$

Proof. Let

$$W = \phi - \psi.$$

Then W satisfies

$$W_{x\bar{x}} + aW_{\hat{x}} - \mu_j W = -a\psi_{\hat{x}}.$$

The summation by parts argument now yields

$$\|W_x\|_h^2 + \mu_j\|W\|_h^2 \le \|a\|_\infty\|W\|_h\left[\|\psi_{\hat{x}}\|_h + \|W_{\hat{x}}\|_h\right].$$

We apply the inequality

$$\|W\|_h \cdot \|W_{\hat{x}}\|_h \le \frac{1}{2}\left[\theta\|W_{\hat{x}}\|_h^2 + \frac{1}{\theta}\|W\|_h^2\right]$$

with $\theta = 2/\|a\|_\infty$. Then

$$\mu_j \|W\|_h^2 \le \|a\|_\infty \|\psi_{\bar{x}}\|_h \cdot \|W\|_h + \frac{\|a\|^2}{4}\|W\|_h^2, \tag{7.14}$$

which implies the lemma. □

This estimate contains $\|\phi - \psi\|_h$ on both sides of the inequality. However, the following corollary is immediate.

COROLLARY. *Suppose*

$$\frac{\|a\|_\infty^2}{8} \le j^2. \tag{7.15a}$$

Then

$$\|\phi - \psi\|_h \le \frac{\|a\|_\infty}{j^2 h}\|\psi\|_h. \tag{7.15b}$$

THEOREM 7.1. *Suppose ϕ and ψ are connected by (7.7). Suppose j is so large that*

$$\frac{\|a\|_\infty^2}{8} \le j^2 \quad \textit{and} \quad j \ge \sqrt{N}. \tag{7.16}$$

Then

$$\|\phi\|_h \le (1 + \|a\|_\infty)\|\psi\|_h, \tag{7.17a}$$

$$\|\psi\|_h \le (1 + \|a\|_\infty)\|\phi\|_h. \tag{7.17b}$$

Proof. Under these hypotheses we have both

$$\|\phi - \psi\|_h \le \frac{\|a\|_\infty}{j^2 h}\|\phi\|_h \le \|a\|_\infty \|\phi\|_h,$$

$$\|\phi - \psi\|_h \le \frac{\|a\|_\infty}{j^2 h}\|\psi\|_h \le \|a\|_\infty \|\psi\|_h.$$

Then the theorem follows from the triangle inequality, e.g.,

$$\|\psi\|_h = \|\psi - \phi + \phi\|_h \le \|\phi\|_h + \|\psi - \phi\|_h. \qquad \square$$

Consider the meaning of this theorem. For each j, $j = 1, 2, \cdots, N$ the separation of variables provides N singular values. However, if $j > \sqrt{N}$ those singular values are all bounded between

$$(1 + \|a\|_\infty)^{-1} \quad \text{and} \quad (1 + \|a\|_\infty).$$

Hence, there are *at most* $\sqrt{N}$ j's which can contribute singular values that tend toward ∞ or tend toward zero. As these are all one-dimensional problems, the analysis of §3 shows that for each such j there is exactly one singular value tending toward ∞ and exactly one singular value tending toward zero. In the worst case one singular value tends toward ∞ as $h^{-1/2}$ and one singular value tends toward zero as $h^{1/2}$. However, in this context many of the "bad" j's may produce singular values that approach 0 and

∞ at slower rates. Hence, the number of "bad" singular values is, at worst, $O(1/\sqrt{h})$ not $O(1/h)$, and the worst of these approach ∞ as $h^{-1/2}$ or 0 as $h^{1/2}$.

FAST ITERATIVE SOLUTION OF CARRIER CONTINUITY EQUATIONS FOR THREE-DIMENSIONAL DEVICE SIMULATION*

O. HEINREICHSBERGER†, S. SELBERHERR†, M. STIFTINGER†, AND K.P. TRAAR‡

Abstract. In this paper the use of iterative methods for the solution of the carrier continuity equations in three-dimensional semiconductor device simulators is summarized. An overview of the derivation of the linear systems from the basic stationary semiconductor device equations is given and the algebraic properties of the nonsymmetric coefficient matrices are discussed. Results from the following classes of iterative methods are presented: The classical conjugate gradient (CG), the symmetrized conjugate gradient (SCG), the generalized minimum residual (GMRES), and the conjugate gradient squared (CGS) method. Preconditioners of incomplete factorization type with partial fill-in are considered. High performance implementations for these algorithms on vector, concurrent, and vector–concurrent computers are presented.

Key words. semiconductor equations, nonsymmetric systems, preconditioned iterative methods, vector computers

1. Introduction.

The three-dimensional numerical analysis of semiconductor devices by device simulators is increasingly becoming an indispensable tool in design and optimization of micro-miniaturized devices. Such simulators compute the discrete self-consistent solution of the semiconductor device partial differential equations. We restrict ourselves to the decoupled solution method of the three nonlinear device equations on a three-dimensional nonuniform tensor product grid [15]. In this case each single nonlinear (outer) iteration consists of the solution of the Poisson equation for the electrostatic potential ψ and of two carrier continuity equations for the electron and hole concentrations, respectively. The coefficient matrices of the discrete continuity equations in the most practical variable set n (electrons) and p (holes) are nonsymmetric. In this contribution we consider preconditioned iterative methods for the solution of these nonsymmetric linear systems. Related work is found in [12], [19], [21], [28], and [32].

Iterative methods applied to the discrete continuity equations have to cope with high condition numbers of the coefficient matrices [1]. Another problem is the enormous numerical range of the solution vector that has to be computed accurately both in the depletion zones of the device under consideration as well as in high injection regimes. Contrary to the Poisson equation, the discrete continuity equations have to be evaluated much more accurately to guarantee the stability of the nonlinear iteration. This results in substantially higher iteration counts compared to the Poisson equation, and therefore the linear nonsymmetric solvers dominate in the solution process.

We have performed a comparative study of various preconditioned conjugate gradient type solvers of which the conjugate gradient squared (CGS) method [14], [26] was identified as the fastest and most economical. The success of this method (and related ones) depends quite critically on robust preconditioning. We have concentrated on incomplete factorizations of the coefficient matrix. Partial fill-in substantially reduces the iteration count at the expense of more arithmetic work per iteration.

Multiple solutions of linear systems of rank $\mathcal{O}(10^5)$ or even larger on vector or vector–concurrent computers with large main memory requires vectorized and/or parallelized iterative procedures. Our implementation has therefore been concentrated on an efficient vectorizable ILU preconditioner. We show how high performance is achieved on supercomputers such as the CRAY 2 (one vector unit), Fujitsu VP200, and on superminicomputers such as the Alliant FX40 (two vector CEs) and a Digital VAX 6260 (one to six scalar processors).

The outline of this paper is as follows. In §2 the semiconductor partial differential equations and the nonlinear expressions for the physical quantities within these equations are summarized, the discretization of which is discussed in §3. The brief consideration of the algebraic matrix properties in §4 provides the preliminaries for the iterative procedures outlined in §5. Robust preconditioning is vital for the iterative solution of the carrier continuity equations. We consider incomplete factorization preconditioners in §6 and their implementation on vector and parallel computers in §7. Numerical experiments and conclusive remarks are found in §8.

2. The semiconductor partial differential equations. We consider the time-invariant case on a three-dimensional rectangular spatial domain using finite difference discretization. The semiconductor equations for the variables (ψ, n, p) consist of the Poisson equation and the carrier continuity equations. Poisson's equation for the electrostatic potential ψ reads

$$\operatorname{div}(\epsilon \cdot \operatorname{grad}\psi) = -\rho \tag{1}$$

with the space charge $\rho = q \cdot (p - n + C)$, where C denotes the net doping density, n the hole, p the electron concentrations, and q the elementary charge. The carrier continuity equations for the electron and hole current densities $\vec{J}_{n,p}$ read

$$\operatorname{div}\vec{J}_n = q \cdot R, \tag{2}$$

$$\operatorname{div}\vec{J}_p = -q \cdot R, \tag{3}$$

where R denotes the carrier generation and recombination rate.

The current densities $\vec{J}_{n,p}$,

$$\vec{J}_n = \mu_n^{LISF} \cdot n \cdot \vec{F}_n, \tag{4}$$

$$\vec{J}_p = \mu_p^{LISF} \cdot p \cdot \vec{F}_p, \tag{5}$$

are assumed to be proportional to the driving forces $\vec{F}_{n,p}$. An extended drift–diffusion approach allows the treatment of hot electron effects in one-band semiconductors such as silicon. This approach for the driving forces reads [13]

$$\vec{F}_n = -q\left(\operatorname{grad}\psi - \frac{1}{n} \cdot \operatorname{grad}\left(\frac{k \cdot T_n}{q} \cdot n\right)\right), \tag{6}$$

$$\vec{F}_p = -q\left(\operatorname{grad}\psi + \frac{1}{p} \cdot \operatorname{grad}\left(\frac{k \cdot T_p}{q} \cdot p\right)\right), \tag{7}$$

where carrier heating is modeled by carrier temperatures $T_{n,p}$. For the mobilities $\mu_{n,p}^{LISF}$ the effect of carrier heating is modeled by a nonlinear dependence on the magnitude of the driving forces $F_{n,p}$:

$$\mu_{n,p}^{LISF} = \frac{2\mu_{n,p}^{LIS}}{1 + \left(1 + \left(2\mu_{n,p}^{LIS} \cdot |\vec{F}_{n,p}|/(q \cdot v_{n,p}^{sat})\right)^{\alpha_{n,p}}\right)^{1/\alpha_{n,p}}} \tag{8}$$

with $\alpha_n = 2$, $\alpha_p = 1$. $\mu_{n,p}^{LIS}$ denotes the zero-field mobility due to lattice (L), impurity (I), and surface (S) scattering mechanisms and $v_{n,p}^{sat}$ the saturation velocity.

Approximations for the carrier temperatures $T_{n,p}$ can be derived by a series expansion of the energy conservation equations

$$(9) \qquad T_{n,p} = T_0 + \frac{2}{3} \cdot \frac{q}{k} \cdot \tau_{n,p}^{\epsilon} \cdot \left(v_{n,p}^{sat}\right)^2 \cdot \left(\frac{1}{\mu_{n,p}^{LISF}} - \frac{1}{\mu_{n,p}^{LIS}}\right)$$

with the Boltzmann constant k, the ambient temperature T_0 and the energy relaxation times $\tau_{n,p}^{\epsilon}$.

The carrier generation and recombination rate R on the right-hand side of the carrier continuity equations represents the sum of the impact ionization rate R^{II}, the Shockley–Read–Hall recombination rate R^{SRH}, and the Auger recombination rate R^{AU}:

$$(10) \qquad R = R^{II} + R^{SRH} + R^{AU}.$$

The impact ionization rate is modeled by the Chynoweth formulae

$$(11) \qquad R^{II} = -\alpha_n \cdot \frac{\left|\vec{J}_n\right|}{q} - \alpha_p \cdot \frac{\left|\vec{J}_p\right|}{q},$$

in which the $\alpha_{n,p}$ depend exponentially on the local electric field:

$$(12) \qquad \alpha_{n,p} = \hat{\alpha}_{n,p} \cdot \exp\left(\frac{-\beta_{n,p}}{\left(\vec{J}_{n,p}/|\vec{J}_{n,p}|\right) \cdot \mathrm{grad}\psi}\right).$$

The SRH recombination rate is expressed by

$$(13) \qquad R^{SRH} = \frac{\left(n \cdot p - n_i^2\right)}{\tau_p\left(n + n_1\right) + \tau_n\left(p + p_1\right)}$$

with positive constants n_1,p_1,$\tau_{n,p}$. Last, the Auger recombination rate is given by

$$(14) \qquad R^{AU} = \left(C_n \cdot n + C_p \cdot p\right) \cdot \left(n \cdot p - n_i^2\right)$$

with $C_{n,p} \geq 0$.

3. Discretization of the nonlinear system of equations. The nonlinear system of equations can be solved either by a full Newton iteration or by decoupling the three partial differential equations (Gummel's algorithm [8]). We restrict ourselves to the latter option. In that case, a nonlinear Gauss–Seidel block iterative scheme is obtained neglecting the nonlinearities in the carrier mobilities and temperatures:

$$(15) \qquad \mathrm{div}\,\mathrm{grad}\psi^{k+1} = -\frac{q}{\epsilon}\left(\frac{\partial\left(p - n + C\right)^k}{\partial\psi}\left(\psi^{k+1} - \psi^k\right) + p^k - n^k + C\right),$$

$$(16) \qquad \mathrm{div}\vec{J}_p\left(\psi^{k+1}, p^{k+1}\right) = -q\left(R\left(\psi^{k+1}, n^k, p^k\right) + \frac{\partial R}{\partial p}\left(p^{k+1} - p^k\right)\right),$$

$$(17) \qquad \mathrm{div}\vec{J}_n\left(\psi^{k+1}, n^{k+1}\right) = q\left(R\left(\psi^{k+1}, n^k, p^{k+1}\right) + \frac{\partial R}{\partial n}\left(n^{k+1} - n^k\right)\right).$$

The set of equations is now discretized on a three-dimensional domain. The boundary value problem is of mixed Dirichlet–Neumann type. For the idealized ohmic contacts, Dirichlet boundary conditions hold. For the artificial interfaces in the deep semiconductor bulk, homogenous Neumann boundary conditions have to be applied. Nonhomogenous Neumann boundary conditions for the electrostatic potential are valid in case of interface charges, e.g., at semiconductor–oxide interfaces. Nonvanishing interface recombination velocities at Schottky contacts yield nonhomogenous Neumann boundary conditions for the carrier concentrations.

The nonlinearities in R have to be treated carefully. The derivatives of R^{II} with respect to the carrier concentrations can be neglected if the carrier generation rate is not updated at every nonlinear iteration but in a superimposed generation *supercycle*. For the recombination rates R^{SRH}, however, the derivatives with respect to n or p are computed, because these contributions increase the diagonal dominance in the resulting linear system. Such a stabilizing effect is not necessarily true for R^{AU}, therefore, negative contributions of the derivatives of R^{AU} to the main diagonal of the coefficient matrix are discarded.

For the finite difference discretization of the carrier continuity equations an exponential interpolation scheme for the carrier concentrations n and p must be used [3], [24]. This is due to an exponential dependence of the carrier concentrations on the electrostatic potential (Scharfetter–Gummel interpolation). Herein the quantities ψ, $\mu_{n,p}$, and $T_{n,p}$ are interpolated linearly. For a one-dimensional nonuniform discretization with mesh spacings h_i, neglecting the derivatives of R and assuming constant carrier temperatures $T_{n,p}$, one obtains for the three-point stencil

$$\begin{aligned} &n_{i-1} D_{n,i-1/2} \frac{\mathcal{B}(-\Delta_{i-1})}{2h_{i-1}} + n_{i+1} D_{n,i+1/2} \frac{\mathcal{B}(\Delta_i)}{2h_i} \\ &-n_i \left(D_{n,i-1/2} \frac{\mathcal{B}(\Delta_{i-1})}{2h_{i-1}} + D_{n,i+1/2} \frac{\mathcal{B}(-\Delta_i)}{2h_i} \right) = R_i \frac{h_{i-1} + h_i}{2}, \end{aligned} \tag{18}$$

$$\begin{aligned} &p_{i-1} D_{p,i-1/2} \frac{\mathcal{B}(\Delta_{i-1})}{2h_{i-1}} + p_{i+1} D_{p,i+1/2} \frac{\mathcal{B}(-\Delta_i)}{2h_i} - \\ &p_i \left(D_{p,i-1/2} \frac{\mathcal{B}(-\Delta_{i-1})}{2h_{i-1}} + D_{p,i+1/2} \frac{\mathcal{B}(\Delta_i)}{2h_i} \right) = R_i \frac{h_{i-1} + h_i}{2}. \end{aligned} \tag{19}$$

In these formulae the diffusivities obey the Einstein relation $D_{n,p} = \mu_{n,p} \cdot Ut$, where $Ut = \frac{k \cdot T_0}{q}$ denotes the thermal voltage. $\mathcal{B}$ is the Bernoulli function

$$\mathcal{B}(x) = \frac{x}{\exp(x) - 1}. \tag{20}$$

The arguments of the Bernoulli function are $\Delta_i = \frac{\psi_{i+1} - \psi_i}{Ut}$.

For nonconstant carrier temperatures $T_{n,p}$, the above expressions are generalized as follows [27]. Let

$$Ut_{(n,p),i} = \frac{k \cdot T_{(n,p),i}}{q} \tag{21}$$

denote the so-called local "electronic voltages" at the meshpoint i. Assume further that the electronic voltages $Ut_{(n,p),i}$ vary linearly between the meshpoints as is the assumption for the electrostatic potential. Then a local one-dimensional continuity equation is solved for the current densities $J_{n,p}$ between neighboring meshpoints.

Assuming constant current densities, the following midpoint interpolation formula replaces the diffusivities

$$(22)\quad D_{(n,p),i+1/2} = \mu_{(n,p),i+1/2} \cdot \left(Ut_{(n,p),i+1} - Ut_{(n,p),i}\right) \cdot \left[\ln\left(\frac{Ut_{(n,p),i+1}}{Ut_{(n,p),i}}\right)\right]^{-1}.$$

The midpoint values for the mobilities $\mu_{(n,p),i+1/2}$ are approximated by linear interpolation. The Bernoulli function argument evaluates to

$$(23)\qquad \Delta_{(n,p),i} = \frac{(\psi_{i+1} - \psi_i) - \left(Ut_{(n,p),i+1} - Ut_{(n,p),i}\right)}{\left(Ut_{(n,p),i+1} - Ut_{(n,p),i}\right)} \cdot \ln\left(\frac{Ut_{(n,p),i+1}}{Ut_{(n,p),i}}\right).$$

4. Algebraic properties of the coefficient matrices. The exponential interpolation scheme outlined in the last section produces a nonsymmetric, diagonally dominant, two-cyclic, seven-band coefficient matrix A.

Nonsymmetry is caused by the inequality $\mathcal{B}(-x) \neq \mathcal{B}(x)$. Diagonal dominance is due to the fact that each negative column sum of the offdiagonal elements is less than (for nonvanishing R) or equal (for vanishing R) to the main diagonal pivot. This implies at least semidefiniteness of A. Consider the case of constant carrier temperatures $T = T_n = T_p$. The equality

$$(24)\qquad \mathcal{B}(-x) = \exp(x) \cdot \mathcal{B}(x)$$

and the fact that the exponentially scaled potential increments can be factored yields that A can be transformed to a symmetric, positive definite matrix $\bar{A}$,

$$(25)\qquad \bar{A} = W^{-1} \cdot A \cdot W,$$

by a diagonal similarity transformation. The diagonal matrix W is positive definite and the elements $w_{(n,p),i}$ are given by $\exp(+\psi_i/2Ut)$ for electrons and $\exp(-\psi_i/2Ut)$ for holes. Since a similarity transformation leaves the spectrum of the matrix A unchanged, we have a nonsymmetric system of linear equations, in which A has a positive real spectrum. For local carrier temperature we are not aware of such a transformation, hence we cannot make statements of the spectrum of A in this case.

We note the enormous numerical range of the W matrices. For a maximum electrostatic potential of 100 Volts and liquid nitrogen temperature (77 K) we may expect exponents of the order $\log_{10}(w_{i,\max}) = 3275$. These numbers make the explicit transformation of the linear system undesirable on standard, double precision computer arithmetics. The very large rank of A gives preference to iterative methods over sparse Gaussian elimination.

5. Selected iterative methods for the linear systems. In this section we discuss the iterative procedures that were used in our computations. In the case of symmetrizability these are the classical conjugate gradient (CG) algorithm, then a variant of CG that circumvents the explicit symmetrization (SCG), and the conjugate gradient squared (CGS) procedure. For the nonsymmetrizable case we consider the generalized minimum residual algorithm (GMRES) and again CGS.

The numerical condition of the discrete carrier continuity equations can be rather poor [1], therefore efficient preconditioning is important. Incomplete (left or split) LU factorizations are used for preconditioning together with (left or symmetric) scaling by the main diagonal pivots $\tilde{D}$ of the preconditioner, and the Eisenstat procedure [7] is used to compute the preconditioned matrix-vector multiply. In §8, where various

```

numerical experiments will be presented, estimates for the extremal eigenvalues of the preconditioned matrix, obtained by the conjugate gradient method, illustrate that the preconditioned problem is well conditioned. We use the following notational conventions: The index s denotes the scaled matrix A_s and its strictly triangular parts L_s and U_s. Angle brackets denote the dot-product. Quantities with a hat ($\hat{\ }$) refer to the preconditioned system.

In this section we shall make explicit use of the similarity property, which was derived in the last section. In case of knowledge of the diagonal transformation matrices W, an explicit transformation (e.g., during the sparse matrix assembly) of the linear system into symmetric form is the most straightforward approach provided that the computer arithmetic is sufficiently accurate for the numbers generated by the similarity transformation. This transformation saves matrix storage and the classical preconditioned conjugate gradient algorithm (CG) is the optimal iterative method.

The very large number range in the iterates can be circumvented by a variant of the conjugate gradient algorithm, e.g., proposed in [11]. In this case the diagonal transformation matrices are confined to the inner products in the variant of the CG algorithm given in Table 1. An appropriate scaling can be employed for the inner products, thus avoiding restrictions on computer arithmetics. A three-term recursion is used with left preconditioning. The $W^T W Q^{-1} A$ norm of the solution error is minimized at each iteration step.

If the linear systems are not symmetrizable one must choose from a more general class of iterative methods for nonsymmetric linear systems. We concentrate on two methods: The generalized minimum residual method GMRES, an orthogonalization method, and the conjugate gradient squared method CGS, which has no (known) minimization property. Algorithms that were not considered are methods that require (e.g., dynamically computed) eigenvalue estimates, such as the Manteuffel algorithm, and the more recent hybrid methods, which adaptively switch between different acceleration schemes [6], [16].

The GMRES algorithm minimizes the two-norm of the residual at each iteration

step. An orthonormal basis is built by an Arnoldi process, and the Hessenberg least squares problem can be solved, e.g., by Householder transformations. See Table 2. The monotonic convergence of GMRES has to be paid for. Full orthogonalization at iteration step n, which yields optimum convergence speed, requires storage of n vectors. This is prohibitive for large, three-dimensional problems and makes restarting of the iteration necessary, thus abandoning optimality. Nevertheless, the convergence of the restarted GMRES(m) is certainly monotonic. Values for the restarting frequency m less than, say, 6 have been found acceptable. Although the solution vector is updated every m iterations, the residual norm is available at each iteration step at no extra cost. This is a by-product of the QR decomposition for the solution of the least squares problem, if the Q and R matrices are updated at each iteration step.

A way of decreasing storage and arithmetic requirements is the use of Lanczos methods, such as the biconjugate gradient (BiCG) algorithm or the biconjugate gradient squared (CGS) algorithm [26] given in Table 3. Both algorithms construct approximations to the solution in the same Krylov subspace as GMRES, but a biorthogonality condition to the transposed system is used rather than an orthogonality condition to

construct the direction vectors. The residual does not decrease monotonically, hence the stopping procedure is more difficult compared to GMRES. The initial vector $\hat{y}_0$ may be chosen arbitrarily such that $\langle \hat{y}_0, \hat{r}_0 \rangle \neq 0$. We conform to the common practice to set this vector equal to the initial residual vector $\hat{r}_0$. A well-known property of this algorithm is the possibility of breakdown by vanishing of certain inner products. This phenomenon, which cannot be excluded a priori, is certainly a reason for worry. It is an experimental observation that effective preconditioning makes the event of (near) breakdown unlikely. We have observed that a sufficiently high machine precision can avoid breakdown occurring when the iteration is near the true solution.

Related squared Lanczos algorithms [10] (BIORES^2 and BIODIR^2) exist due to the analogy to the Lanczos-ORTHORES and Lanczos-ORTHODIR algorithms. These algorithms can be implemented to generate the same iterates for the solution vector (in exact arithmetic) if identical vectors x_0 and $\hat{y}_0$ are chosen. Though mathematically equivalent, unavoidable roundoff errors cause the iterates of the three biorthogonalization algorithms to drive apart in the course of the iteration. BIOMIN^2, i.e., CGS, not only proved to perform best under presence of roundoff, but could also be implemented most economically concerning storage.

In Table 4 the arithmetic work of the iterative procedures is listed. These figures refer to one linear iteration. For the restarted GMRES(m) method the iteration counter is incremented after the computation of one new orthogonal basis vector.

TABLE 4
Comparison of arithmetic work/iteration.

Solver	Ax	$\langle x,y\rangle$	$x+y$	αx
CG	1	2	4	10
SCG	1	3	4	10
CGS	2	2	7	6
GMR	1	$\frac{m}{2}+1$	$\frac{m}{2}$	$\frac{m}{2}+1$

6. Efficient preconditioning. We start with a comparison of two preconditioners that have been examined intensively: Block Jacobi preconditioning $P_J = D$, where D is the tridiagonal part of A, and incomplete factorization preconditioning [17], where

$$P_{ILU} = \left(L + \tilde{D}\right)\tilde{D}^{-1}\left(U + \tilde{D}\right) \tag{26}$$

with L the strictly lower and U the strictly upper triangular part of A and $\tilde{D}$ computed such that

$$diag\,(P_{ILU}) = diag\,(A)\,. \tag{27}$$

It is trivial to see that for the matrices under consideration the nonzero pattern of the LU factors of P_J is a proper subset of the nonzero pattern of the factors of P_{ILU}. It can be proven that in this case the ILU preconditioner is superior to the Jacobi preconditioner in the sense that if $A = P_J - R_J$ and $A = P_{ILU} - R_{ILU}$, then

$$\rho\left(P_{ILU}^{-1}R_{ILU}\right) \le \rho\left(P_J^{-1}R_J\right) \tag{28}$$

where ρ denotes the spectral radius. Thus, a stationary iterative method based on the ILU splitting will converge at least as fast as a method based on a Jacobi splitting. Accelerated methods (see §5) will be influenced in a similar way. On the other hand, the arithmetic work for the Jacobi preconditioner compared with the ILU preconditioner is smaller and involves only first order recurrences, which can be vectorized more easily. Summarizing our experimental work, we state that the use of the Jacobi preconditioner seems to be limited to low bias voltage applications, i.e., examples where the diffusion term dominates in the current relations (4)–(6). For higher bias voltages unpleasant numerical effects have been observed (especially with the Lanczos methods), such as convergence stagnation or near breakdown in the Lanczos process at the beginning of the iteration. Another disadvantage is the orientation sensitivity due to the line elimination that forces the swapping of the matrix and vector elements to the most favorable direction, thus causing inconvenient computational overhead. A really clear relationship for both the minority and majority carrier continuity equations and the direction of the main current flow that would facilitate a detection of a favorable preconditioning orientation, however, could not be established. Therefore we cannot recommend this type of preconditioner for general use.

An incomplete factorization preconditioner of alternating direction type, P_T, with tridiagonal matrix factors, has been proposed in [5]. The basic idea is to use tridiagonal factors that lend themselves more to parallelization, rather than triangular factors as with ILU, at the same time maintaining the ILU sparsity pattern. For a seven-point stencil such a factorization would read

$$P_T = T_1 D^{-1} T_2 D^{-1} T_3, \tag{29}$$

where D is the main diagonal of A, and the T_i, $i = 1, 2, 3$, are tridiagonal matrices such that

$$T_1 + T_2 + T_3 = A + 2D. \tag{30}$$

The elements in the factors of P_T are altogether equal to the corresponding elements in A, hence there is no need to compute diagonal pivots $\tilde{D}$ as with ILU. However, there are more error terms outside the nonzero pattern in P_T; therefore it is no surprise that the iteration count in the iterative solver is higher compared with the ILU preconditioner. Computing $y = P_T^{-1}x$ involves the backsolves of the LU factors of three tridiagonal matrices. Since each tridiagonal matrix consists itself of many independent tridiagonal systems this work can be parallelized easily (e.g., by the partitioning method, cyclic reduction, etc.).

Let NX, NY, and NZ denote the number of gridlines in the respective directions. The inversion of T_1, which is assumed to contain the innermost diagonals of A, consists of $NY \cdot NZ$ independent tasks and has stride NX. T_3, which is assumed to contain the outermost diagonals of A, has $NX \cdot NY$ independent tasks and stride 1. For T_2 the situation is different because the stride is constant for NZ data sets only. The authors in [5] have reported that one preconditioning step with P_T can be performed up to three times as fast as one step in the hyperplane-ILU preconditioner on vector-supercomputers. Our numerical experiments, however, indicate that the convergence decrease with respect to ILU(0) is often larger than three even for simple examples. We refrained from an implementation on a supercomputer.

The most commonly used and probably most efficient preconditioner, at least on scalar computers, is incomplete LU factorization with allowable fill-in denoted by ILU(k), see, e.g., [2], [4], [12]. The index k denotes a controllable sparsity pattern along the matrix diagonals, $k = 0$ denoting no fill-in, $k = 1$ denoting fill-in caused by the original nonzero pattern but no further, and so on. As expected, a higher degree of fill-in reduces the iteration count. However, the number of operations for the factorization and for each iteration as well as the memory requirements increase considerably. For example, the ILU(1) preconditioner needs four extra diagonals within the original seven-diagonal nonzero pattern. For the fill-in ILU preconditioners we are not aware of a comparably efficient implementation to compute the preconditioned matrix vector multiply as proposed by Eisenstat for the ILU(0) [7], [29].

The two ILU(0) factorization variants under consideration are split ILU

$$\hat{A}_1\hat{x} \equiv \tilde{D}^{1/2}\left(\tilde{D}+L\right)^{-1}A\left(\tilde{D}+U\right)^{-1}\tilde{D}^{1/2}\hat{x} = \tilde{D}^{1/2}\left(\tilde{D}+L\right)^{-1}b \equiv \hat{b} \tag{31}$$

$$\hat{x} \equiv \tilde{D}^{-1/2}\left(\tilde{D}+U\right)^{-1}x \tag{32}$$

and left ILU

$$\hat{A}_2 x \equiv \left(\tilde{D}+U\right)^{-1}\tilde{D}\left(\tilde{D}+L\right)^{-1}Ax = \left(\tilde{D}+U\right)^{-1}\tilde{D}\left(\tilde{D}+L\right)^{-1}b \equiv \hat{b}. \tag{33}$$

The preconditioned matrix-vector multiply $\hat{A}_{1,2}\hat{p}$ can be simplified in the following manner. For the split ILU(0) one obtains, after having scaled the matrix symmetrically by $\tilde{D}$,

$$A_s = \tilde{D}^{-1/2}A\tilde{D}^{-1/2} \equiv diag\,(A_s) + L_s + U_s, \tag{34}$$

TABLE 5
Hyperplane-ILU(k) *on vectorcomputers.*

	VP-200			Cray-2			Alliant FX40		
k	B	Speedup	MFlop	B	Speedup	MFlop	B	Speedup	MFlop
0	4	13.75	96	14	4.30	27	212	1.34	1.8
1	8	12.12	96	26	4.76	30	327	1.51	2.3
2	8	12.62	128	30	5.93	34	410	1.64	2.5

$$\hat{A}_1\hat{p} = \left[\hat{t} + (I + L_s)^{-1}\left(\hat{p} - (2I - diag\,(A_s))\,\hat{t}\right)\right] \tag{35}$$

with

$$\hat{t} = (I + U_s)^{-1}\hat{p}, \tag{36}$$

and for the left ILU(0) together with left scaling

$$\hat{A}_2\hat{p} = (I + U_s)^{-1}\left[\hat{p} + (I + L_s)^{-1}\left(diag\,(A_s) - I + U_s\right)\hat{p}\right]. \tag{37}$$

In our implementation the split ILU(0) requires two additional scratch vectors and N square-roots, whereas the left ILU(0) requires no extra storage but a triangular matrix vector multiply.

Computing the diagonal pivots of the incomplete factorization such that $P_{ILU} - A$ has zero *column* sums (or row sums in the symmetric case) leads to modified incomplete factorization-type preconditioners (MILU) originated by [9]. A modification factor α in the interval $[0, 1]$ is usually introduced to smoothly sweep between pure ILU and full MILU factorization. Our results concerning the choice of such a modification factor do not admit a clear statement. It seems that $\alpha = 1$ always decreases the performance with respect to $\alpha = 0$ slightly. We found a number of device examples where a choice of $\alpha = 0.5$ yields a performance enhancement of about 10 percent to 30 percent concerning the iteration count. However, this gain is partly compensated by the higher arithmetic work for the factorization.

Parallelizable variants of ILU such as the Neumann polynomial preconditioner [31] were investigated as well. Numerical experiments carried out with the NSPCG (Non-Symmetric Preconditioned Conjugate Gradient) code [18] identified none of them competitive with ILU.

7. Implementation notes for parallel and vector computers. Vectorizing and parallelizing the backsolves of triangular or tridiagonal systems is a good exercise to explore computer architecture. We concentrate on vectorization techniques that are unlikely to degrade the performance of the incomplete factorization preconditioners; hence we do not consider multicolor orderings [20]. We further exclude computers that permit only unity-stride vector operations such as the CYBER 205 and disregard optimization measurements possibly required by memory bank and related conflicts. We aim at a production code that is as generally applicable as possible. This can be achieved by a reordering technique that does not change the preconditioner and produces long vector lengths. The *hyperplane* method, which is a plane-diagonalwise reordering, excellently reported in [2], [29], achieves this goal. The price for the rather general implementation we are aiming at is indirect addressing by list vectors.

If the unknowns as well as the matrix elements are indexed by $(i1, i2, i3)$ in the three spatial directions, then hyperplanes H_m (or "computational wavefronts") are defined by the set of all mesh points in the simulation domain that satisfy the equation

$$i1 + (k+1)(i2 + i3) = m, \tag{38}$$

where m is constant. k denotes the level of fill-in. Obviously the computation of the unknowns in H_m can be carried out in parallel (and hence is a vector operation) since they depend only on the unknowns in H_{m-1} for the lower triangular or H_{m+1} for the upper triangular system, respectively.

For an implementation of the hyperplane method it is desirable to form a unique vector of the unknowns in a particular H_m. This is achieved by initially computing the addresses of the unknowns to be processed in an integer list vector $LIST$ and marking the beginning of each hyperplane by an additional list vector $LPTR$. The vectorlengths increase from 1 to $\mathcal{O}(NX \cdot NY \cdot NZ)^{2/3}$.

Special attention has to be paid to the meshpoints at the simulation boundary. Addressing (nonexisting) elements at the boundary points can be prevented by proper IF statements in the code or by computing the unknowns at the boundary outside the loop. We decided to extend the array of the unknowns such that unallowed addressing at the boundaries cannot happen. This is done by allocating an array of size $NX \cdot NY \cdot (NZ + 2)$ for the vector of the unknowns $X(I)$ and filling the front and back plane of this vector with zeros. Then the code for the solution of the lower triangular system for $k = 0$ is surprisingly simple:

```
      DO 1 L=2,NX+NY+NZ-2
      DO 1 M=LPTR(L-1)+1,LPTR(L)
      I=LIST(M)
1     X(I)=R(I)-B(I)*X(I-1)-D(I)*X(I-NX)-F(I)*X(I-NX*NY).
```

R denotes the right-hand side and B, D, F the strictly lower triangular part of A_s. The inner loop is vectorizable. The implementation for the upper triangular system and the higher order recurrences ($k = 1, 2$) is straightforward. The approach sketched above is used in a similar manner to vectorize the ILU factorization at the beginning of the iteration.

Using the computational front approach, additional parallelism can be achieved by twisting the incomplete factorization in one specific direction [29], [30]. Then the factorization and the backsubstitutions can be performed concurrently from both ends to the center and from the center to both ends. Since such a twisting splits the domains into two equal halves, the mean hyperplane vectorlength in each half is decreased unless the number of meshpoints in the direction of splitting is significantly larger than the number of meshpoints in the remaining directions. It has been reported in [29] that the twisted hyperplane approach tends to decrease the iteration count in the linear solver, however, such an effect could not be verified with our type of equations. We think that the twisted hyperplane method is not advantageous, at least on a two-processor machine. To qualify the performance of the hyperplane-ILU(k) implementation, tests have been carried out on a Fujitsu VP200, a Cray-2, an Alliant FX40, and a Digital VAX 6260 computer. In Table 5 the CPU time for one triangular backsubstitution (B) in milliseconds (ms), the overall achieved speedup over the autovectorized code megaflop (MFlop) rate for this operation is given. This test example uses a 40 × 40 × 40 grid and the measured numbers are mean values for 100 solves. For a larger number of meshpoints the values are even more favorable.

The values in Table 6 show the convergence speed improvement factors the level 1, 2 preconditioners must reach to beat the ILU(0) preconditioner. As can be seen,

TABLE 6
ILU-*level* 1, 2 *preconditioner break-even points.*

k	VP-200	Cray-2	Alliant FX-40
1	1.56	1.4	1.44
2	2.15	2.0	1.58

TABLE 7
Parallel hyperplane ILU(0) *on the VAX* 6260.

# Processors	1	2	3	4	5	6
MFlop	0.58	1.15	1.64	2.06	2.41	2.65
Speedup	1.00	1.98	2.82	3.54	4.14	4.56

these values tend to favour ILU(1), since practical values for the convergence speedups against ILU(0) are about 2. Thus, if memory usage is not too restrictive, ILU(1) is to be preferred to ILU(0).

In Table 7 the performance of ILU(0) on a Digital VAX 6260 with six scalar processors is presented. The megaflop rates and the speedup over one processor for the above test example are shown.

8. Numerical results. In this section the effectiveness of the preconditioned iterative methods outlined in the previous chapters will be demonstrated. We chose two simulations of silicon MOS-transistors. The finite-difference grids of both simulations are comparatively small, thus the "true" solution $\bar{x}$ of the linear systems were obtained by a sparse direct solver and the 2-norm of the relative solution error

$$e_n = \frac{\|\bar{x} - x_n\|}{\|\bar{x}\|} \tag{39}$$

was evaluated. A (heuristic) error threshold of $\zeta = 10^{-8}$ for e_n was found satisfactory in practical simulations. The computations with the CG and the SCG were performed with quad precision, the CGS and GMRES(5) iterations in double precision. These tests were carried out on a Digital VAX 8800, the precision of 1.0 is $1.387 \cdot 10^{-17}$ for double precision and $9.629 \cdot 10^{-35}$ for quad precision arithmetic. All data presented in the following have been extracted from version 5 of the device simulator MINIMOS [25].

Example 1 is a moderately nonplanar N-channel MOSFET with a channel length of 1.5 microns. The gate voltage is $U_g = 0.5$ Volts, the drain voltage is $U_d = 1.0$ Volt, all other terminal voltages are zero. The finite-difference grid is built self-adaptively and is small due to the low biasing: $23 \times 27 \times 16$ in x- (channel length), y- (pointing into the substrate), and z- (channel width) direction. Gummel's decoupling algorithm converges in five iterations. The terminal currents are small: $5.30 \cdot 10^{-9}$ Amperes for the drain current (I_D), and $-1.20 \cdot 10^{-13}$ Amperes for the bulk current (I_B). Carrier temperatures are judiciously neglected in this simulation, hence the nonsymmetric linear equations can conveniently be symmetrized and solved by the classical CG algorithm. The convergence of CG is compared with the symmetrized variant of the CG algorithm (SCG) and the (CGS) method. ILU(0) and ILU(1) are used as preconditioners. The CG algorithm provides cheap estimates of the extremal eigenvalues of the preconditioned matrix and hence for the spectral condition number $\kappa = \lambda_{\max}/\lambda_{\min}$.

TABLE 8
Example 1 : Majority carrier continuity equation.

	ILU(0) $\kappa = 35$			ILU(1) $\kappa = 10$		
N	I-CG	I-SCG	I-CGS	I-CG	I-SCG	I-CGS
1	17	32	25	9	22	12
2	34	29	24	20	22	11
3	29	29	22	18	21	11
4	33	29	24	20	21	11
5	21	41	21	15	26	11

TABLE 9
Example 1 : Minority carrier continuity equation.

	ILU(0) $\kappa = 102$			ILU(1) $\kappa = 70$		
N	I-CG	I-SCG	I-CGS	I-CG	I-SCG	I-CGS
1	50	84	48	41	45	35
2	54	78	43	43	40	32
3	53	78	39	42	39	30
4	54	68	42	42	37	27
5	51	86	47	40	46	35

In Table 8 the iteration history of the majority carriers (holes) are listed, in Table 9 the minorities (electrons) are listed. The spectral condition number estimate κ varies only marginally during the nonlinear iterations.

As can be seen from the tables, the iteration counts of the CG algorithm correspond nicely to the bounds suggested by the spectral condition number. The CGS algorithm converges twice as fast as the CG method for the best conditioned problem (majorities with ILU(1)).

Convergence curves for the three iterative methods with the matrices from the first nonlinear iteration are given in Figs. 1 and 2.

The second example is a P-channel MOSFET with bias voltages of $U_s = 0.0$ Volt, $U_g = -4.0$ Volts, $U_d = -1.0$ Volt, and $U_b = 2.0$ Volts. The drain current is $I_d = -6.3 \cdot 10^{-5}$ Amperes and the bulk current is $I_b = -1.7 \cdot 10^{-9}$ Amperes. This time electron and hole carrier temperatures are simulated self-consistently. First an initial solution is computed, which satisfies the classical semiconductor equations for constant carrier (i.e., ambient) temperature. This requires ten Gummel iterations. Subsequently the solution of the semiconductor equations with the extended drift-diffusion transport equations (see §2) is found by relaxation with respect to the local carrier temperatures. This requires seven further nonlinear iterations.

Within this second relaxation scheme, the linear systems are no longer diagonally similar to a symmetric matrix, hence CG and SCG are no longer applicable, but CGS and GMRES are. The restarting frequency m for GMRES is chosen to be 5 and the results are in columns $GMR(5)$. In Table 10 the iteration counts for the carrier relaxation cycles are given. Convergence curves for the three iterative methods with the matrices from the first nonlinear iteration (for locally varying carrier temperatures) are given in Figs. 3 and 4, respectively.

We report some timing results using ILU(0)-CGS. Both small examples execute quickly on supercomputers: Less than 30 seconds on the Fujitsu VP and slightly more than a minute on the Cray-2. This timing ratio is in good accordance with the megaflop counts (see §7) of the forward and backsolves of the triangular systems on these machines. A computationally complex example requires substantially more time, e.g., on the Fujitsu VP computer: A nonplanar N-channel MOSFET with $U_d =$ 5.0 Volts, $U_g = 1.0$ Volt, requires a grid of 55 x 48 x 30 points. The grid loop and the computation of the initial solution requires 150 seconds. The subsequent nonlinear solution pass takes 80 Gummel iterations and a total of 1500 CPU seconds. The linear systems derived from the majority carrier continuity equation converge in roughly 70, from the minority carrier continuity equation 140 iterations (mean values). The same example computed on a fast scalar computer (NAS XL/80) takes approximately ten times more CPU time. The total time, however, is then increased substantially by references to secondary storage.

TABLE 10

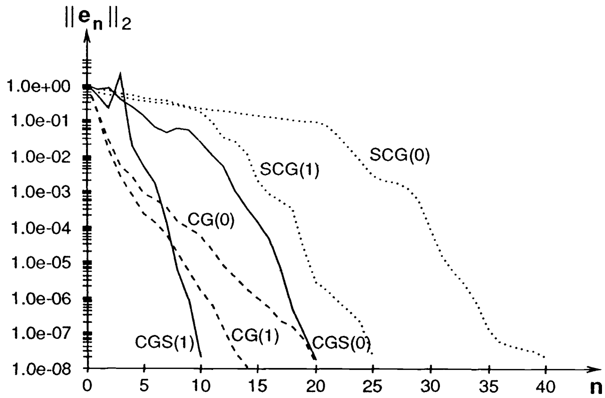

FIG. 1. *Convergence curves for the discrete majority continuity equation of Example* 1.

9. Conclusions. In this paper preconditioned iterative methods for the carrier continuity equations in three-dimensional device simulators have been studied and the performance of these algorithms on various high performance computing systems has been evaluated.

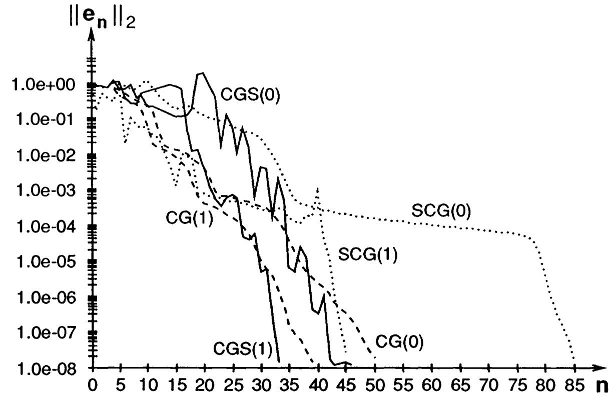

FIG. 2. *Convergence curves for the discrete minority continuity equation of Example* 1.

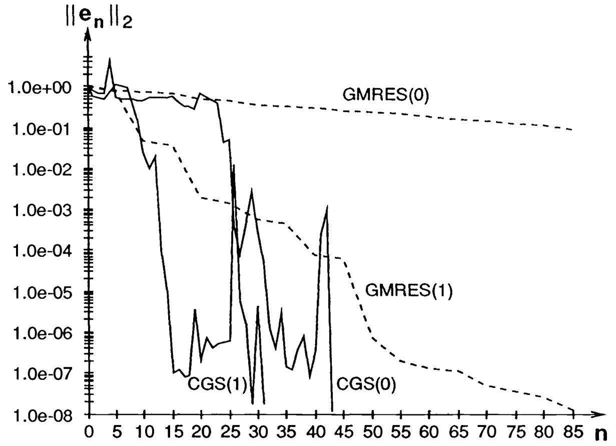

FIG. 3. *Convergence curves for the discrete majority continuity equation of Example* 2.

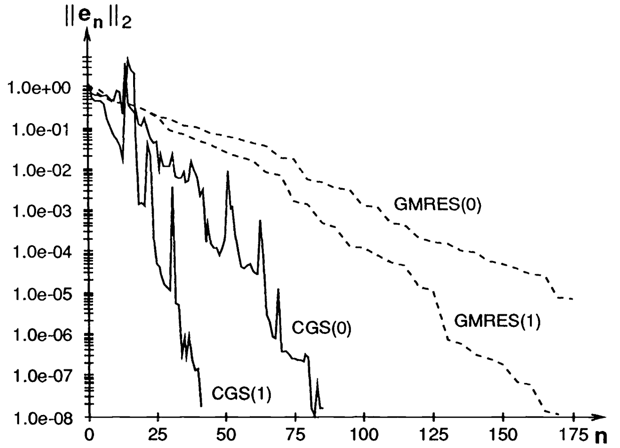

FIG. 4. *Convergence curves for the discrete minority continuity equation of Example* 2.

Among the iterative procedures we feel that the CGS method is the most versatile. It avoids possible numerical problems with the symmetrization matrices and is applicable to "real" nonsymmetric problems. Regarding convergence speed the GMRES(5) algorithm is clearly exceeded.

More decisive than the iterative (acceleration) procedures is the choice of a robust parallelizable preconditioner. We have investigated incomplete LU factorization of levels 0–2 and we have shown that quite a high performance (exceeding 100 megaflops on the Fujitsu VP200 computer) is reachable for the preconditioned matrix-vector multiply.

THE HIERARCHICAL BASIS EXTRAPOLATION METHOD*

U. RÜDE[†]

Abstract. Traditional extrapolation methods, like Richardson's extrapolation, are based on asymptotic error expansions of the solution, and thus depend on the use of uniform grids. Within the hierarchical basis framework for the finite element method it is natural to consider an extrapolation of the *energy functional.* This idea is based on a purely local element-by-element analysis and is applicable to irregular and unstructured meshes. It will be demonstrated that *higher order* discretization can be obtained by this type of extrapolation without imposing any additional restrictions on the finite element mesh. This method is especially well suited for use in combination with local refinement strategies. If combined with a multilevel solution procedure, the algorithm is closely related to multigrid *tau-extrapolation.* This paper will present the theoretical background and experimental results for the energy extrapolation method in hierarchical basis formulation.

Key words. elliptic partial differential equations, finite element method, hierarchical basis, extrapolation

1. Introduction.

For truly efficient elliptic solvers four conceptual components will be necessary:

1. adaptive refinement,
2. higher order discretization,
3. multilevel solvers,
4. advanced software techniques.

It is now widely acknowledged that for the effective solution of most *real-life* applications some form of adaptive discretization is needed. Different meshsizes in different parts of the solution domain are necessary to model the locally varying features of the solution effectively.

The need for higher order discretization has been less apparent. However, when high accuracy is desired, then by exploiting the smoothness of the solution in certain regions of the domain with higher order approximations, much better efficiency can be obtained. In most practical applications nonsmooth behavior in elliptic problems occurs at isolated points, typically singularities introduced by source terms, corners in the boundary, or discontinuities in the coefficients. Away from those points, the solutions of elliptic problems are smooth, typically even C^∞. In these parts of the domain higher order should be used.

Even with higher order schemes, the discretization will lead to systems with many unknowns. For these large scale applications we believe that only multilevel techniques can provide satisfactory efficiency.

Finally, the resulting complexity of the software must not be underestimated. We believe that the present software techniques are not powerful enough to provide a sufficient basis for implementing these algorithms effectively.

This paper will describe an extrapolation-based approach to obtain higher order finite element discretizations that is especially well suited to be integrated with adaptive techniques and multilevel solution strategies.

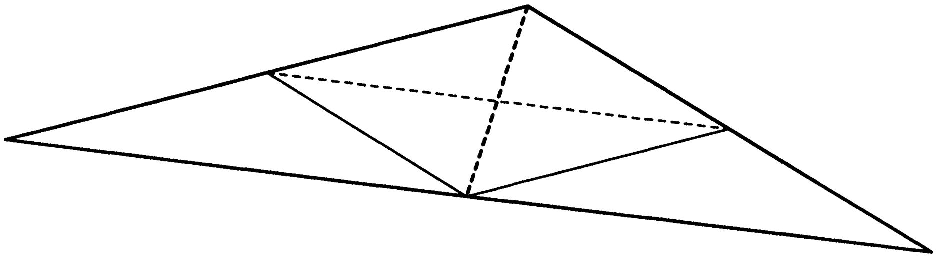

FIG. 1. *Modified refinement in triangles with an obtuse angle.*

After briefly introducing our overall concept, we will derive the *energy extrapolation*, a technique based on purely local elementwise analysis and therefore applicable to all irregular and unstructured meshes. This technique will be shown to be equivalent to the use of higher order finite elements.

2. The adaptive hierarchical algorithm. Our refinement strategy is essentially based on the ideas implemented in Bank's PLTMG [1]. It has been adapted such that the finite element spaces constructed during refinement are truly nested. This supports the multilevel solution procedure on the one side and the energy extrapolation on the other side.

Starting from a user-supplied primary triangulation, finer levels are constructed by partial refinement. Using error estimation techniques, (or a priori knowledge about local meshsizes) certain elements or edges are flagged for refinement.

Next, care must be taken that the new triangulation becomes consistent. This is implemented by a (recursive) procedure, imposing the following rules:

1. If the shortest side of a triangle is flagged for refinement, then all other edges will also be marked.
2. If two edges of a triangle are marked for refinement, the third will also be marked.

Now, a *solution space* with more degrees of freedom than the previous one is created by halving all flagged edges.

In case all three sides of a triangle are flagged, the midpoints of these sides are connected, creating four congruent new triangles. This is called regular refinement.

In case only one side is flagged, the midpoint of the edge is connected to the opposite vertex. It is this step that may cause trouble by creating triangles with large obtuse angles that in turn have unfavorable properties in the finite element solution. Rule 1 above alleviates this problem, but cannot guarantee a limit on the angles that occur. Additionally, it must be assumed that the error indicator behaves reasonably. Furthermore, as a user-selectable option, the regular refinement may be replaced by the refinement shown in Fig. 1 for triangles with an obtuse angle.

In our experiments this refinement strategy has worked well. It is simpler than the refinement algorithms used in Bank's PLTMG, and, in particular, it avoids the complication introduced by temporary edges that must be removed before further refinement levels are created. Our approach has the further advantage that the finite element spaces of coarse levels are true subspaces of finer levels—a feature that is frequently used in theoretical studies of multilevel solution methods.

We assume that the domain and its internal interfaces can be modeled with relatively few (curvilinear) elements, which make up the primary mesh, and that the number of elements necessary to obtain final accuracy is much larger. If the primary mesh contains very few degrees of freedom, direct solvers are feasible, and it can become the coarsest level of a multilevel solver.

If this is not the case, sparse solvers or multileveling "below" the primary triangulation is needed and we suggest using algebraic multigrid (AMG) (see Ruge and Stüben [10]) as a convenient way to construct "coarser" levels relative to the primary mesh. In the following we will assume that the solution on the primary triangulation can be efficiently obtained by some unspecified method and that the amount of work is negligible compared to the work required for the final solution.

Thus we now focus on how to obtain solutions on the increasingly finer meshes. First we notice that coarse grid solutions may be simply interpolated to finer grids, providing good guesses for starting an iterative solver.

To our knowledge two iterative solution techniques are the most promising: the hierarchical basis technique that, together with conjugate gradient acceleration, promises an $O(n \log(n))$ work estimate for n degrees of freedom, see Yserentant [11]. The alternative is a true multigrid-like solution technique, as proposed, e.g., in Brandt [3], or by McCormick [6].

The hierarchical basis technique has the advantage of using smoothing only on the nodes that are *newly added* in each particular step of refinement, which clearly limits the work to $O(n)$ per cycle, no matter how the points are distributed across different levels. The price for this nice feature is a slowly deteriorating convergence rate when the levels get finer—$O(\log(n))$ iterations are necessary to reduce the error by a prescribed factor (in two dimensions).

A multigrid-like approach (cf. MLAT, Brandt [3], or FAC, McCormick [6]) differs from the hierarchical basis algorithm by smoothing not only the newly added points but also the coarse grid points between them. For regular problems this will provide convergence rates independent of the number of levels. Recent results show (see Leinen [12]) that even without regularity assumptions a local refinement algorithm with multigrid-like processing will obtain convergence rates that are at least as good as hierarchical basis rates with conjugate gradient acceleration, and are superior in three dimensions, where the hierarchical basis algorithm's complexity further deteriorates.

Finally, we remark that in contrast to McCormick's FAC method, where processing is based on subgrids, the processing in our algorithms will be based on *global grids*, corresponding to the *composite grids* in FAC. In the most straightforward implementation we thus smooth in the whole domain including subdomains where no refinement has taken place. This is not optimal, because too much smoothing will be applied to points that have not been refined. Such points are smoothed on several levels. For these points coarsening and interpolation become just trivial copying operations for the residuals and solution values, respectively.

But, if the number of *gridpoints* grows geometrically with a factor larger than 1.0 between any two levels, this very simple strategy combined with a V-cycle will already have asymptotically optimal complexity. Furthermore, it of course makes the algorithm a special case of a regular, variational multigrid algorithm on global grids so that the theoretical results for this case become applicable.

3. The energy extrapolation. A multilevel algorithm generates an unusual wealth of information about the solution. Obviously, monitoring the change in the approximate solution from one level to the next provides insight about the local errors that may be used for simple error estimation techniques. On the other hand, an estimate of the local error for any given approximation may be used to improve the accuracy of this approximation. Thus it is quite natural that one attempts to use

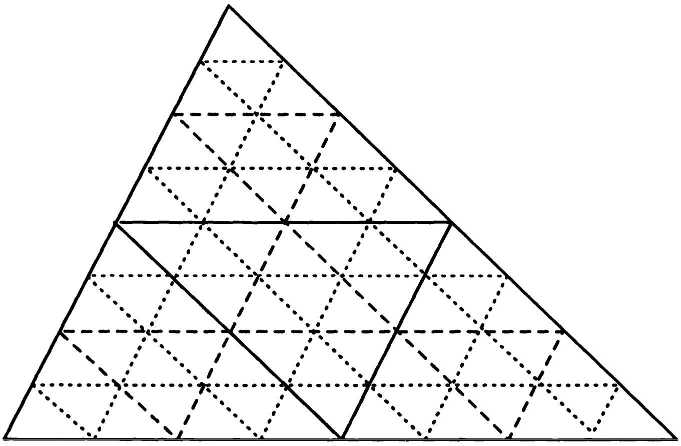

FIG. 2. *Regular refinement of a triangle.*

the extra information provided by multileveling to improve the accuracy. This is the basic idea of extrapolation.

The theoretical foundation of classical extrapolation is based on asymptotic error expansions, which, however, are a feature of using regular grids. The straightforward application of Richardson's extrapolation to the solution does not seem possible on unstructured finite element meshes. General finite element meshes as used in our approach typically only provide *error bounds*, not *error expansions*, as required for extrapolation.

The key for developing a suitable extrapolation technique is based on the variational principle. In a variational setting, the problem is to find a function that minimizes an expression like

$$\min_{u \in H}(E_\Omega[u] - (u, f)) \tag{1}$$

in some function space H. $E_\Omega[u]$ often has a physical interpretation as an energy. In this paper we are concerned with second order linear elliptic selfadjoint problems in two space dimensions, so that we can assume that E_Ω is of the form

$$E_\Omega[f] = \int\int_\Omega a(x,y)(\nabla f(x,y))^2 dxdy. \tag{2}$$

The numerical solution of (1) with finite elements is now closely related to finding numerical approximations for $E_\Omega[u]$.

Consider a single triangle $K = K^0$ of the mesh and a sequence of regular refinements $K^n, n = 1, 2, \cdots$, of this particular triangle, see Fig. 2. For any function $f(x, y)$ on the triangle, a numerical method to evaluate its energy can be defined by projecting f to the space of piecewise linears on K^n (by taking the interpolant), and calculating the energy of the projection. (This can be done exactly.) Thus we define a sequence of numerical methods $E_K^h[f]$ for calculating the energy $E_K[f]$. Note, that E_K^h gives the exact energy if f is piecewise linear (on the corresponding triangulation), and thus the integration method implicitly defines the finite element method (for linear elements).

Next, it can be shown that this sequence of approximations to the energy has an h^2-expansion in the following sense: If $f \in C^{2N+3}(K)$ and $a(x,y) \in C^{2N+2}(K)$, then

$$E_K^h[f] - E_K[f] = h^2 e_1 + h^4 e_2 + \cdots + h^{2N} e_N + h^{2N+2} R_{N+1},$$

where $h = 2^{-n} h_0$, h_0 the diameter of K^0, e_k are constants independent of h, and R_{N+1} a remainder term that satisfies $|R_{N+1}| \leq c$, where c is a constant independent of h. This is related to the fact that the integration rule resembles the trapezoidal rule. Using extrapolation (for h^2-expansions), we can thus calculate the energy of any sufficiently smooth function to $O(h^4)$ by one step of extrapolation, to $O(h^6)$ by two steps, etc. The existence of such an expansion has been proved in Rüde [9].

The remainder term depends on f and a. More precisely, for constant a, it depends on the derivatives of f in such a way that it vanishes if the derivatives of f of order $N+2$ vanish. In particular, if f is a polynomial of degree 1, (linear), then R_1 vanishes, which means that the error expansion degenerates: linear functions are represented correctly on all refinement levels.

Similarly, when f is polynomial of degree 2, then R_2 vanishes, so that the expansion has exactly one term. This means we can integrate quadratics correctly by using one step of extrapolation:

$$E_K[f] = 4/3 E_K^{h/2}[f] - 1/3 E_K^h[f].$$

These results have also been proved in Rüde [9].

Observe now that the extrapolated value is calculated by a linear combination of two bilinear forms based on the nodal values. The linear combination of bilinear forms is a bilinear form.

Considering the refined triangle as a new macro element, we see that the above constructed bilinear form must correspond to the element stiffness matrix for piecewise quadratics on the macro element. This stiffness matrix is uniquely defined for a given finite element space and basis.

Next, this carries over to the collection of all elements, providing us with an alternative method to generate a stiffness matrix for quadratic elements by taking a linear combination of the stiffness matrices for linear elements. In this process it is only required that each element be refined regularly.

This argument is still element by element. The error terms of the expansion are canceled within each element. The higher order terms and remainder terms that are not canceled by the extrapolation are then accumulated with possibly many different values of h and thus cause a perturbation to the solution. This perturbation in general does not have an asymptotic expansion, however, because the low order terms have been canceled elementwise, the perturbation must be of higher order.

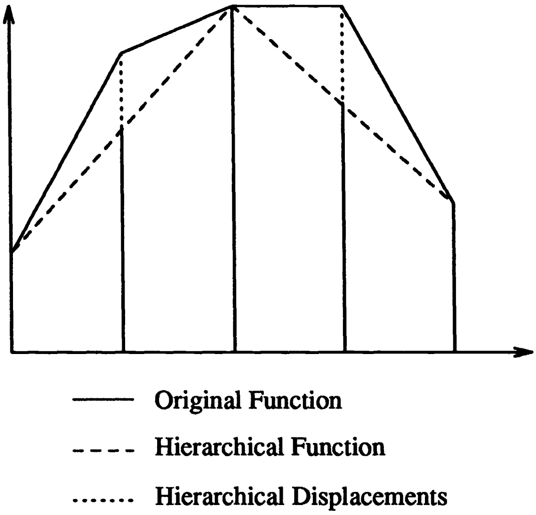
To exploit this idea algorithmically we must now look at the algebraic structure of the problem. Assume that we have a nested sequence of triangulations

$$T^1 \subseteq T^2 \subseteq T^3 \cdots, \tag{3}$$

and a corresponding sequence of nested, linear finite element spaces

$$V^1 \subseteq V^2 \subseteq V^3 \cdots. \tag{4}$$

An element $v^k \in V^k$ will interchangeably be interpreted as a piecewise linear finite element function or as a vector of nodal values on T^k. The nesting of meshes induces



—— Original Function
---- Hierarchical Function
.... Hierarchical Displacements

FIG. 3. *Hierarchical decomposition.*

a partitioning of v^k, $k > 1$:

$$v^k = \begin{bmatrix} v_C^k \\ v_F^k \end{bmatrix}, \tag{5}$$

where v_C^k is associated with the nodes on $T^{k-1} \subseteq T^k$ and v_F^k is associated with the nodes that are in T^k but not in T^{k-1}. Next, define $\bar{P}_{k-1}^k : V^{k-1} \longrightarrow V^k$ as the natural prolongation (linear interpolation). In nodal representation and following the partitioning in (5)

$$\bar{P}_{k-1}^k = \begin{bmatrix} I \\ P_{k-1}^k \end{bmatrix}. \tag{6}$$

P_{k-1}^k is the operator forming the arithmetic average of two values at vertices connected by an edge of the coarse triangulation.

Using this mapping, the *hierarchical transform* $\hat{v}^k$ of $v^k \in V^k$ is defined by

$$v^k = \begin{bmatrix} v_C^k \\ v_F^k \end{bmatrix} \xrightarrow{H_k^{k-1}} \hat{v}^k = \begin{bmatrix} v_C^k \\ \hat{v}_F^k \end{bmatrix} = H_k^{k-1} \begin{bmatrix} v_C^k \\ v_F^k \end{bmatrix} = \begin{bmatrix} I & 0 \\ -P_{k-1}^k & I \end{bmatrix} \begin{bmatrix} v_C^k \\ v_F^k \end{bmatrix}. \tag{7}$$

A one-dimensional example is shown in Fig. 3. Note that the inverse transform reads

$$(H_k^{k-1})^{-1} = \begin{bmatrix} I & 0 \\ P_{k-1}^k & I \end{bmatrix}. \tag{8}$$

A symmetric bilinear form $L^k : V^k \times V^k \longrightarrow \mathcal{R}$ can be partitioned in a compatible way

$$L^k = \begin{bmatrix} C^k & X^k \\ (X^k)^T & F^k \end{bmatrix}, \tag{9}$$

and be transformed to

$$\hat{L}^k = \begin{bmatrix} I & (P_{k-1}^k)^T \\ 0 & I \end{bmatrix} L^k \begin{bmatrix} I & 0 \\ P_{k-1}^k & I \end{bmatrix} = \begin{bmatrix} \hat{C}^k & \hat{X}^k \\ (\hat{X}^k)^T & F^k \end{bmatrix}, \tag{10}$$

where

$$\hat{C}^k = C^k + (P_{k-1}^k)^T (X^k)^T + X^k P_{k-1}^k + (P_{k-1}^k)^T F^k P_{k-1}^k, \tag{11}$$

$$\hat{X}^k = X + (P_{k-1}^k)^T F. \tag{12}$$

Now observe that solving

$$\min_{v^k \in V^k} \left\{ (v^k)^T L^k v^k - 2(v^k)^T f^k \right\} \tag{13}$$

is equivalent to solving the transformed minimization problem

$$\min_{\hat{v}^k \in V^k} \left\{ (\hat{v}^k)^T \hat{L}^k \hat{v}^k - 2(\hat{v}^k)^T \begin{bmatrix} I & (P_{k-1}^k)^T \\ 0 & I \end{bmatrix} f^k \right\}. \tag{14}$$

The *coarse grid block* $\hat{C}^k$ in the transformed matrix is L^{k-1}, that is, the finite element stiffness matrix for a coarser problem. This can be seen by interpreting the coarse grid part of (14) as the problem of minimizing the energy in the coarse grid finite element space.

Based on this formalism, a two-level hierarchical basis algorithm consists of the alternating solution (minimization) for v_C^k (keeping $\hat{v}_F^k$ frozen) and for $\hat{v}_F^k$ (keeping v_C^k frozen). Another interpretation for this is a block Gauss–Seidel procedure.

In this setting, the minimization for v_C is fully equivalent to a multigrid coarse grid correction (for variational multigrid). A good approximate solve for $\hat{v}_F^k$ can be implemented by a few relaxation steps for the corresponding unknowns. This is the form of a hierarchical basis multigrid algorithm as it has been suggested by Bank, Dupont, and Yserentant [2]. Except that smoothing is restricted to the F-unknowns, the hierarchical basis algorithm is a usual multigrid algorithm.

We will go a step further and reintroduce full smoothing making the method fully equivalent to a variational multigrid algorithm. This so-called *hierarchical transformation* multigrid algorithm (HTMG) has been introduced by Griebel [4], see also McCormick and Rüde [7].

A two-level variant of this algorithm is shown in Fig. 4. When step 4 is replaced by a recursive application of the same algorithm we get a V-cycle HTMG method. As mentioned before, it is fully equivalent to a regular (variational) multigrid algorithm. It provides a particularly efficient implementation of a *full approximation storage* (FAS) scheme. In some cases the HTMG implementation is even cheaper than classical *correction storage* schemes. For the details see Griebel [4].

Assume L^{k-1} is the stiffness matrix for a triangulation with linear elements, and L^k is the stiffness matrix for an associated regular (full) refinement. An approximation for the energy of any smooth function u represented by the nodal values $\left[\begin{smallmatrix} u_C \\ u_F \end{smallmatrix}\right]$ is given by $u_C^T L^{k-1} u_C$ and $[u_C^T u_F^T]\, L^k \left[\begin{smallmatrix} u_C \\ u_F \end{smallmatrix}\right]$, respectively. In this notation our results on asymptotic expansions of the energy become

$$[u_C^T u_F^T]\, L^k \begin{bmatrix} u_C \\ u_F \end{bmatrix} = E_\Omega[u] + h^2 e,$$

1. Perform ν_1 relaxations on $L^k v^k = f^k$.
2. Perform the hierarchical transform $v^k \to \hat{v}^k$ (7).
3. Calculate the coarse grid right-hand side $f^{k-1} = f_C^k + (P_{k-1}^k)^T f_F - \hat{X}^k \hat{v}^k$.
4. Solve the coarse grid system $L^{k-1} v^{k-1} = f^{k-1}$.
5. Calculate the corrected fine grid values by reversing (7):
$$v^k = \begin{bmatrix} v_C^k \\ v_F^k \end{bmatrix} \longleftarrow \begin{bmatrix} v^{k-1} \\ P_{k-1}^k v^{k-1} + \hat{v}_F^k \end{bmatrix}.$$
6. Perform ν_2 relaxations on $L^k v^k = f^k$.

FIG. 4. *Basic two-level solution algorithm.*

provided u_C are the nodal values of a function that is piecewise quadratic on the triangulation. Under the same assumptions

$$u_C^T L^{k-1} u_C = E_\Omega[u] + 4h^2 e,$$

such that the usual extrapolation gives

$$\frac{4}{3} \left[u_C^T u_F^T\right] L^k \begin{bmatrix} u_C \\ u_F \end{bmatrix} - \frac{1}{3} u_C^T L^{k-1} u_C = E_\Omega[u]. \tag{15}$$

This is now an *exact* representation of the energy for quadratics based on the energy for linear functions. The formula further simplifies when hierarchically transformed systems are used. Equation (15) is equivalent to

$$\frac{4}{3} \left[u_C^T u_F^T\right] L^k \begin{bmatrix} u_C \\ u_F \end{bmatrix} - \frac{1}{3} u_C^T L^{k-1} u_C = \left[u_C^T \hat{u}_F^T\right] \begin{bmatrix} L^{k-1} & \frac{4}{3}\hat{X}^k \\ \frac{4}{3}(\hat{X}^k)^T & \frac{4}{3}F \end{bmatrix} \begin{bmatrix} u_C \\ \hat{u}_F \end{bmatrix}. \tag{16}$$

In the hierarchical basis representation higher order is simply obtained by multiplying certain matrix entries by the extrapolation factor 4/3.

Finally, we must apply an analogous extrapolation for the inner product

$$(f, u) = \int\int_\Omega f(x, y) u(x, y)\, dxdy$$

to get better representations of the right-hand side. In the basic (linear element) algorithm the inner product is approximated by

$$\int\int_K u(x, y) f(x, y)\, dxdy \approx 1/3\, \text{area}(K)(u(a)f(a) + u(b)f(b) + u(c)f(c)),$$

where a, b, c are the corners of K. Thus in the basic system, the right-hand side value for node i is given by

$$f_i = 1/3 f(x_i, y_i) \sum_{(x_i, y_i) \text{vertex of } K} \text{area}(K).$$

This integration rule can also be shown to have an h^2-expansion, so that the extrapolated system genuinely provides higher order accuracy. The extrapolated equations can be written as

$$\begin{bmatrix} L^{k-1} & \frac{4}{3}\hat{X}^k \\ \frac{4}{3}(\hat{X}^k)^T & \frac{4}{3}F \end{bmatrix} \begin{bmatrix} u_C \\ \hat{u}_F \end{bmatrix} = \begin{bmatrix} \frac{4}{3}(P_{k-1}^k)^T f_F \\ \frac{4}{3} f_F \end{bmatrix}. \tag{17}$$

Note that in the extrapolation of the right-hand side the scaling of the equations has to be taken into account.

This system can now be solved by a standard hierarchical basis procedure. However, when we wish to improve the HB-performance by introducing full grid smoothing, a slight problem occurs. Such a smoothing on the untransformed system is incompatible with the higher order accuracy of the extrapolated system. There are two possible solutions:

- Ignore the problem and smooth anyway. In McCormick and Rüde [7] it has been shown that the resulting method is equivalent to a regular multigrid algorithm using τ-extrapolation. For this case theoretical results have been proven (see Hackbusch [5] or Rüde [8]) that show that the loss in accuracy due to the wrong smoother is not worse than the discretization error itself. This is based on the fact that smoothing affects mainly only high frequency solution components that are not important for the approximation accuracy. If this approach is chosen, the extrapolation only affects step 3 in the basic algorithm of Fig. 4 that must be changed to $f^{k-1} = 4/3(P^k_{k-1})^T f_F - 4/3\hat{X}^k\hat{v}^k$.
- It is also possible to design smoothers fully compatible with the modified system. For this we use a two-level smoothing technique. Here step 1 and step 6 of Fig. 4 are each replaced by a two-level algorithm that has the same basic structure as the basic two-level algorithm itself:

  S1. Perform ν_1 relaxations on the F-nodes of $L^k v^k = f^k$.
  S2. Perform the hierarchical transform $v^k \rightarrow \hat{v}^k$.
  S3. Calculate the coarse grid right-hand side $f^{k-1} = 4/3(P^k_{k-1})^T f_F - 4/3\hat{X}^k\hat{v}^k$ with the extrapolated equations.
  S4. Relax the coarse grid system $L^{k-1}v^{k-1} = f^{k-1}$ using v^k_C as a starting guess.
  S5. Calculate the corrected fine grid values by

$$v^k = \begin{bmatrix} v^k_C \\ v^k_F \end{bmatrix} \longleftarrow \begin{bmatrix} v^{k-1} \\ P^k_{k-1}v^{k-1} + \hat{v}^k_F \end{bmatrix}.$$

  S6. Perform ν_2 relaxations on $L^k v^k = f^k$.

  An algorithm involving this smoother then looks like a hierarchical basis algorithm (with fine point smoothing only) and a nonstandard cycling strategy that involves *short* visits to the coarser levels without full recursion. This more complicated strategy is of course only necessary on the finest level, where the extrapolation applies. On all other levels a standard smoother may be used.

4. Numerical experiments. Our example problem is

$$\begin{aligned} \Delta u &= 0 \text{ on } (0,1)^2, \\ u &= \frac{\cos(4\pi(x-y))\sinh(4\pi(2-x-y))}{\sinh(8\pi)} \quad \text{on } \partial[0,1]^2. \end{aligned} \tag{18}$$

The boundary function also describes the true solution. This function has value 1 at $(0,0)$ and decays exponentially to 0 in the solution domain. Though there is increased activity in the southwest corner of the domain we start out by solving on a regular *square mesh triangulation.* The first of these triangulations is obtained by halving the square with the southwest to northeast diagonal. Then full refinement steps are used to construct a sequence of uniform triangulations. For linear elements this discretization is equivalent to a 5-point difference stencil. In Table 1 the straightforward

full multigrid algorithm is compared to a version where extrapolation is applied every time on the finest grid. We further distinguish between a variant using a regular smoother and one that uses the two-level smoothing technique (see the discussion at the end of the previous section). In order to keep algebraic errors low, two V-cycles are used on each level. We are mainly interested in *differential* errors, that is, errors of the discrete solution with respect to the analytic solution. We display discrete Euclidean and discrete energy-norm error estimates. Note that the superiority of the higher order schemes only shows for finer meshes but that the extrapolation saves at least one level of refinement, when we need high accuracy. Further note that both algorithms with extrapolation behave about the same; the algorithm with regular smoothing seems to provide even somewhat lower energy errors. The experimentally determined convergence rates of the Euclidean norm indicate $O(h^2)$ convergence for the linear algorithm and $O(h^4)$ accuracy for the two extrapolated algorithms. In the energy norm the extrapolated algorithms exhibit $O(h^3)$ behavior.

The next example will apply adaptive refinement to the same problem. The algorithm has the structure of a nested iteration starting on the coarsest level.

On any level:

1. Perform a full (regular) refinement step.
2. Interpolate the solution to the new nodes, and perform a few relaxations on the new nodes to dampen high frequency interpolation errors.
3. Using the extrapolated stiffness matrix, calculate the solution with quadratic order accuracy using an extrapolation-V-cycle. (The results of Table 2 refer to regular smoothing. Using the more complicated two-level smoothing technique did not yield significantly better results.)
4. Compare with the coarser level solution to decide which of the new nodes are relevant for the improvement in accuracy.
5. Delete the fine grid nodes that (presumably) have not improved the accuracy.
6. If final accuracy has not been obtained yet, make this level the current level and go to step 1.

Remark. After deleting the extra nodes of a full refinement, there is no new solution phase, assuming that we have only deleted nodes that would cause negligible changes to the solution (relative to the accuracy on that level).

To this end note that asymptotically the exact solution behaves like $u = e^{4\pi(1-r)}$, where r is the distance from $(x, y) = (0, 0)$ and when we only consider the radial dependence. Thus (for a second order discretization) the truncation error asymptotically behaves like $e_t = h^2(4\pi)^4 e^{4\pi(1-r)}$. In order to achieve equally distributed truncation errors, we introduce variable meshsizes in the form

$$h(r) = He^{-4\pi(1-r)/2},$$

TABLE 2

rate		1.99	1.80		3.88	2.98

where H is a *global* meshsize parameter. For the higher order discretization we use accordingly

$$h(r) = He^{-4\pi(1-r)/4}.$$

We use these relationships to guide the local refinement: The edges of a node are refined, when they are longer than the h associated with the position of that node. The rules of §2 are used to complete the creation of a consistent new level. The results are displayed in Table 2.

It is also instructive to compare Tables 1 and 2. Note that the local refinement algorithm obtains almost the same accuracy on each refinement level as the global refinement algorithm, however with a much reduced number of nodes. This shows that we have really only omitted nodes that are irrelevant for obtaining the solution accuracy.

5. Conclusions. We have introduced the energy extrapolation technique, a method that obtains higher order based on a local extrapolation that can be used on unstructured finite element meshes. This approach is especially well suited for a combination with adaptive refinement and multilevel solution. For model problems we demonstrate the superiority of the integrated algorithm.

FOURIER ANALYSIS OF INCOMPLETE FACTORIZATION PRECONDITIONERS FOR THREE-DIMENSIONAL ANISOTROPIC PROBLEMS*

JUNE M. DONATO[†] [‡] AND TONY F. CHAN[†]

Abstract. To solve three-dimensional elliptic problems using preconditioned conjugate gradient, it is crucial to make a good choice of preconditioner. To facilitate this choice, a Fourier analysis technique has been used by Chan and Elman [*SIAM Rev.*, 31 (1989), pp. 20–49.] and others to study preconditioned systems arising from the discretization of the two-dimensional model elliptic equation. In this paper the same technique is used to analyze relaxed-modified incomplete factorization preconditioned systems that arise from the discretization of a three-dimensional anisotropic elliptic problem. Expressions for the "Fourier eigenvalues" of the preconditioned three-dimensional systems are presented along with estimates of the condition numbers. For MILU, an optimal value for the parameter c is derived. The correlation between the distribution of the eigenvalues and the Fourier results for the preconditioned systems is remarkable. From the expressions for the eigenvalues we prove that $\kappa(M^{-1}A)$ is order h^{-2} for ILU and order h^{-1} for MILU$(c \neq 0)$. Then by examining the distribution of Fourier eigenvalues, the dependence of PCG convergence rate on the clustering of the eigenvalues of an operator, as well as its condition number, can be exemplified. The PCG experiments were performed on an Alliant FX/80.

1. Introduction.

While *preconditioned conjugate gradient* (PCG) is a widely used method of solving systems arising from the discretization of elliptic partial differential equations (PDEs), its performance is highly dependent upon the preconditioner chosen. For two-dimensional discretized elliptic PDEs, much theory and experimental background exists for the use of *incomplete LU* (ILU) and *modified incomplete LU* (MILU) preconditioned systems [3], [4], [6], [12], [13]. However for three-dimensional problems there is considerably less knowledge [1], [2], [14], [15]. Experimental difficulties arise because the discretization of three-dimensional problems leads to extremely large systems. Even though these systems are typically sparse, the space and time requirements are still daunting on most sequential machines. Hence, we see the move to parallel computers. But the choice of a "good" preconditioner still remains.

To facilitate this choice, a Fourier analysis technique has been used by Chan and Elman [7] and by Chan and Meurant [8] to study preconditioned systems arising from the discretization of the two-dimensional model elliptic equation. In this paper we use the same technique to analyze relaxed-modified incomplete factorization preconditioned systems that arise from the discretization of a three-dimensional anisotropic elliptic problem.

Begin by considering the matrix A arising from the discretization of three-dimensional anisotropic elliptic problems. For the preconditioner M we will examine (point) relaxed-modified incomplete LU factorizations. (For experiments using point and block methods, see [2], [15].) Using the Fourier technique of [7], the resulting

preconditioned systems $M^{-1}A$ are analyzed. Expressions for the "Fourier eigenvalues" are given and from these expressions we derive bounds on the condition numbers. For the isotropic problem we find, as in the two-dimensional case [7], that $\kappa(M^{-1}A)$ is order h^{-2} for ILU and h^{-1} for MILU ($c \neq 0$). For MILU, an optimal value of c_{opt} is derived.

To examine the usefulness of these Fourier derivations and calculations, we present the results of a PCG implementation for comparison. Because of the inherent large size of these three-dimensional problems, the PCG algorithm was coded on an Alliant FX/80 using FX/FORTRAN. We examine various grid spacings and their effect upon condition numbers and iterations required for convergence. We find the dependence on h of the preconditioned Dirichlet and periodic operators to be in remarkable agreement. For the anisotropic problem we illustrate the dependence of PCG convergence on the distribution of eigenvalues [3], [4] and show that the clustering of the Fourier eigenvalues mimics that of the Dirichlet eigenvalues.

For many of the experiments, the distribution of the eigenvalues is given for both the preconditioned Dirichlet and the related periodic systems. While true Fourier analysis is not directly applicable to these problems, it is obvious from our numerical results that the Fourier technique is an extremely valuable heuristic method for examining the behavior of these preconditioned systems. The method is easy to apply and can save considerable time by determining initial approximations to optimal parameters. It is worth noting that the use of Fourier methods is a long-standing technique for the analysis of multigrid. A notable example is Brandt's "local mode analysis" [5].

The rest of this paper is outlined as follows. In §2 the stencil and recurrence relation are given for the general relaxed-(M)ILU preconditioner. In §3 the Fourier eigenvalues are derived for the related periodic preconditioned operator for the general anisotropic problem, and theorems for the isotropic problem are stated for ILU and MILU preconditioned systems. In §4 we give background information on the codes used. We also present various experimental results and we compare predicted results to the actual numerical results from the PCG implementation. Section 5 contains a summary of conclusions. Finally, the Appendix contains the proofs of the Fourier theorems and the derivation of c_{opt}.

2. The preconditioner.

We start by considering the following three-dimensional anisotropic equation as our expanded model problem

$$-\left(a_1 u_{xx} + a_2 u_{yy} + a_3 u_{zz}\right) = r \tag{1}$$

posed on the unit cube $\Omega = \{0 \leq x, y, z \leq 1\}$ with $a_1, a_2, a_3 \geq 0$ and Dirichlet boundary conditions

$$u(x, y, z) = 0 \qquad \text{on } \partial\Omega. \tag{2}$$

The problem is then discretized on the interior of the unit cube by the standard second-order finite differences using a uniform $n \times n \times n$ mesh with mesh size $h = \frac{1}{n+1}$. We get a matrix system $Au = b$, where A is represented by a seven-point stencil. The general seven-point stencil for the Dirichlet problem yields a linear equation of the form

$$\begin{aligned} &a_{i,j,k}u_{i,j,k} + b_{i,j,k}u_{i+1,j,k} + c_{i,j,k}u_{i,j+1,k} + d_{i,j,k}u_{i-1,j,k} + e_{i,j,k}u_{i,j-1,k} \\ &\qquad + f_{i,j,k}u_{i,j,k+1} + g_{i,j,k}u_{i,j,k-1} = h^2 r_{i,j,k} \end{aligned} \tag{3}$$

where $1 \leq i, j, k \leq n$ and

$$
\begin{aligned}
b_{i,j,k} &= 0, & i &= n, \\
c_{i,j,k} &= 0, & j &= n, \\
f_{i,j,k} &= 0, & k &= n, \\
d_{i,j,k} &= 0, & i &= 1, \\
e_{i,j,k} &= 0, & j &= 1, \\
g_{i,j,k} &= 0, & k &= 1.
\end{aligned} \tag{4}
$$

Note that the subscripts (i, j, k) correspond to the grid location (ih, jh, kh). For example, the entry $b_{i,j,k}$ represents the coupling between $u_{i,j,k}$ and its neighbor $u_{i+1,j,k}$. Writing the left hand side in stencil form (expanding by planes) we have

$k-1$ plane			k plane			$k+1$ plane		
·	·	·	·	$c_{i,j,k}$	·	·	·	·
·	$g_{i,j,k}$	·	$d_{i,j,k}$	$a_{i,j,k}$	$b_{i,j,k}$	·	$f_{i,j,k}$	·
·	·	·	·	$e_{i,j,k}$	·	·	·	·

Referring back to the anisotropic problem we have the assignments

$$
\begin{aligned}
a_{i,j,k} &= 2(a_1 + a_2 + a_3), \\
b_{i,j,k} &= -a_1, \\
c_{i,j,k} &= -a_2, \\
d_{i,j,k} &= -a_1, \\
e_{i,j,k} &= -a_2, \\
f_{i,j,k} &= -a_3, \\
g_{i,j,k} &= -a_3.
\end{aligned} \tag{5}
$$

A relaxed-modified ILU factorization is an approximate LU factorization M of A based on Gaussian elimination in which nonzero entries (fill-ins) of L and U are dropped (set to zero) if they correspond to a zero element in A (i.e., the sparsity patterns for L and U are the same as for A). Further, the nonzero entries of the resulting matrix $M = LU$ are required to equal the corresponding nonzero entries of A except possibly for those entries along the diagonal. For example, for ILU it is required that $\text{diag}(M) = \text{diag}(A)$. For MILU($c$), the diagonal of M is modified to ensure the condition $rowsum(M) = rowsum(A) + ch^2$. Hence, in MILU a fill-in in a row of M is added onto the diagonal element of that row of M along with the perturbation ch^2. For RILU(w), only a fraction w of the fill-ins are added back onto the diagonal of M. In this paper, we further restrict U to be unit diagonal.

Using the stencil viewpoint, the (relaxed-modified) LU factorization of A has the following structure where L is the lower triangular matrix

$k-1$ plane			k plane			$k+1$ plane		
·	·	·	·	·	·	·	·	·
·	$g_{i,j,k}$	·	$d_{i,j,k}$	$\alpha_{i,j,k}$	·	·	·	·
·	·	·	·	$e_{i,j,k}$	·	·	·	·

and U is the unit upper triangular matrix given by

$k-1$ plane			k plane			$k+1$ plane		
•	•	•	•	$\frac{c_{i,j,k}}{\alpha_{i,j,k}}$	•	•	•	•
•	•	•	•	1	$\frac{b_{i,j,k}}{\alpha_{i,j,k}}$	•	$\frac{f_{i,j,k}}{\alpha_{i,j,k}}$	•
•	•	•	•	•	•	•	•	•

The resulting preconditioner $M = LU$ is then represented by

$k-1$ plane			k plane			$k+1$ plane		
•	$m_{i+1,j,k-1}$	•	$m_{i-1,j+1,k}$	$c_{i,j,k}$	•	•	•	•
•	$g_{i,j,k}$	$m_{i,j+1,k-1}$	$d_{i,j,k}$	$m_{i,j,k}$	$b_{i,j,k}$	$m_{i-1,j,k+1}$	$f_{i,j,k}$	•
•	•	•	•	$e_{i,j,k}$	$m_{i+1,j-1,k}$	•	$m_{i,j-1,k+1}$	•

The center (diagonal) entries $m_{i,j,k}$ of M are given by

$$m_{i,j,k} = \alpha_{i,j,k} + d_{i,j,k}\frac{b_{i-1,j,k}}{\alpha_{i-1,j,k}} + e_{i,j,k}\frac{c_{i,j-1,k}}{\alpha_{i,j-1,k}} + g_{i,j,k}\frac{f_{i,j,k-1}}{\alpha_{i,j,k-1}}.$$

The other six entries of M that correspond to zero elements in A are called the "fill-ins." They are given by

$$\begin{aligned}
m_{i+1,j,k-1} &= g_{i,j,k}\frac{b_{i,j,k-1}}{\alpha_{i,j,k-1}},\\
m_{i,j+1,k-1} &= g_{i,j,k}\frac{c_{i,j,k-1}}{\alpha_{i,j,k-1}},\\
m_{i-1,j+1,k} &= d_{i,j,k}\frac{c_{i-1,j,k}}{\alpha_{i-1,j,k}},\\
m_{i+1,j-1,k} &= e_{i,j,k}\frac{b_{i,j-1,k}}{\alpha_{i,j-1,k}},\\
m_{i-1,j,k+1} &= d_{i,j,k}\frac{f_{i-1,j,k}}{\alpha_{i-1,j,k}},\\
m_{i,j-1,k+1} &= e_{i,j,k}\frac{f_{i,j-1,k}}{\alpha_{i,j-1,k}}.
\end{aligned}\tag{6}$$

To determine the $\alpha_{i,j,k}$ values, the relaxed modified LU factorization is typically augmented by the rowsum condition

$$rowsum(M) = rowsum(A) + ch^2 + (1-w) * (\text{fill-ins in } M).$$

The above formulation includes both the parameter $\delta = ch^2$ of Gustafsson [12], which is added to the main diagonal, and a relaxation parameter w of Axelsson and Lindskog [3]. (See also [1].) This condition yields the ILU factorization for $c = w = 0$ and MILU(c) for $w = 1$. For $c = 0, w \,\epsilon\, (0,1)$ we get RILU(w) [6], [10].

Given that six of the entries in any given row are common to both A and M, the rowsum condition yields a second expression for the diagonal entries of M

$$m_{i,j,k} = a_{i,j,k} + ch^2 - w(\text{fill-ins in } M).$$

Substituting in the expressions for the fill-ins and for $m_{i,j,k}$, the following recurrence for $\alpha_{i,j,k}$ results in

$$\begin{aligned}\alpha_{i,j,k} = a_{i,j,k} + ch^2 - d_{i,j,k}(b_{i-1,j,k} + w(c_{i-1,j,k} + f_{i-1,j,k}))/\alpha_{i-1,j,k} \\ - e_{i,j,k}(c_{i,j-1,k} + w(b_{i,j-1,k} + f_{i,j-1,k}))/\alpha_{i,j-1,k} \\ - g_{i,j,k}(f_{i,j,k-1} + w(b_{i,j,k-1} + c_{i,j,k-1}))/\alpha_{i,j,k-1},\end{aligned} \tag{7}$$

where (4) applies and a term is ignored if it involves an $\alpha_{i,j,k}$ having any of its indices equal to 0 or $n+1$.

3. Fourier analysis. A method of exact analysis of $M^{-1}A$ has not yet presented itself. Yet it is critical to be able to compare the distribution of the resulting eigenvalues and their clustering traits for different preconditioners M. These clustering traits, along with the condition number $\kappa(M^{-1}A)$, affect the convergence rate of a PCG method [3], [4]. So our basic approach here, while not exact, is to find the Fourier transform of $M^{-1}A$. We do this by applying $M^{-1}A$ to the eigenvectors $u^{(s,t,r)}$ composed of Fourier exponential modes. The (i,j,k)th grid component of $u^{(s,t,r)}$ is given by

$$u_{ijk}^{(s,t,r)} = e^{\iota i\theta_s} e^{\iota j\phi_t} e^{\iota k\xi_r}$$

where $\iota = \sqrt{-1}$, $\theta_s = (2\pi/(n+1))s, \phi_t = (2\pi/(n+1))t, \xi_r = (2\pi/(n+1))r$, for $r,s,t = 1,\cdots,n$.

However, this technique is theoretically exact only for constant coefficient problems with periodic boundary conditions [7]. In other words, the $u^{(s,t,r)}$ are not eigenvectors of the matrix $M^{-1}A$ that results from the discretization of the Dirichlet problem. To use the technique, we make the following extensions [7]:

(a) Treat the matrices M and A as if they were periodic. Enforce (5) for $0 \leq i,j,k \leq n+1$ and ignore the Dirichlet constraints (4).

(b) Force M to be a constant diagonal system by treating the $\alpha_{i,j,k}$ as the constant α arising as the asymptotic solution of the recurrence equation (7). So $\alpha_{i,j,k} = \alpha$ is then given by

$$\begin{aligned}\alpha = &\left((a_1+a_2+a_3) + \frac{ch^2}{2}\right) \\ &+\sqrt{\left((a_1+a_2+a_3) + \frac{ch^2}{2}\right)^2 - (a_1^2+a_2^2+a_3^2) - 2w(a_1a_2+a_1a_3+a_2a_3)},\end{aligned} \tag{8}$$

where the positive root has been chosen to agree in magnitude with the Dirichlet values. In the case of very large n, this is the value the $\alpha_{i,j,k}$ would tend toward for those (i,j,k) corresponding to grid points far from the boundaries of Ω. The proof that $\alpha_{i,i,i} \searrow \alpha$ follows analogously to the two-dimensional situation given in [16].

(c) From the theory developed in [7], we then use the formula $h_d = 2h_p$ to relate the mesh sizes used for the Dirichlet problem to that of the corresponding Fourier method (periodic) result.

With the above extensions, we have obtained a periodic constant coefficient ILU factorization preconditioner for which exact Fourier analysis can be used. Note that this related periodic ILU factorization is not the ILU factorization for the periodic version of the Dirichlet problem. It is an artificial operator that we analyze in the hope that the results will apply to the ILU preconditioned Dirichlet system.

Now applying these related periodic extensions of A and M to $u^{(s,t,r)}$ yields

$$\begin{aligned} Au^{(s,t,r)} &= \lambda_{str} u^{(s,t,r)}, \\ Mu^{(s,t,r)} &= \psi_{str} u^{(s,t,r)}, \end{aligned}$$

where

$$\lambda_{str} = \lambda_{str}(A) = 4\left(a_1 \sin^2\left(\frac{\theta_s}{2}\right) + a_2 \sin^2\left(\frac{\phi_t}{2}\right) + a_3 \sin^2\left(\frac{\xi_r}{2}\right)\right) \tag{9}$$

and

$$\begin{aligned} \psi_{str} &= \psi_{str}(M) \\ &= \lambda_{str} + \frac{2}{\alpha}(a_1a_2\cos(\theta_s - \phi_t) + a_1a_3\cos(\xi_r - \theta_s) + a_2a_3\cos(\phi_t - \xi_r)) \\ &\quad - 2w(a_1a_2 + a_1a_3 + a_2a_3)/\alpha + ch^2. \end{aligned} \tag{10}$$

Thus the Fourier transform of $M^{-1}A$ is

$$\mu_{str}(M^{-1}A) = \frac{\lambda_{str}(A)}{\psi_{str}(M)} \tag{11}$$

and the condition number of the preconditioned system is given by

$$\kappa = \kappa(M^{-1}A) = \frac{\max_{str} \mu_{str}}{\min_{str} \mu_{str}}.$$

From (9) and (10) this can be easily computed for a given mesh size h. The n^3 values μ_{str} are also called the Fourier eigenvalues of $M^{-1}A$.

Consider for now the isotropic problem ($a_1 = a_2 = a_3 = 1$). Using the above we get the following results whose proofs are presented in the Appendix.

THEOREM 3.1. *For the* ILU *preconditioned isotropic operator* ($w = 0, c = 0$),

$$\kappa^{(I)} = O(h^{-2}).$$

THEOREM 3.2. *For the* MILU *preconditioned isotropic operator* ($w = 1$),

$$\kappa^{(M)} = \begin{cases} O(h^{-1}), & \textit{if } c > 0; \\ O(h^{-2}), & c = 0. \end{cases}$$

Result 3.1. The optimal value of c occurs near $c_p = 12\pi^2$ for the periodic problem and $c_d = 3\pi^2$ for the Dirichlet problem.

It appears from numerical calculations below that the above results also hold for the Dirichlet ILU and MILU preconditioned systems except for MILU when c is near zero. And in the anisotropic cases, although generalizing these theorems poses some difficulties, we are able to show that the Fourier results are still excellent predictors of the Dirichlet results in terms of dependence on h and c.

4. Numerical results. In order to verify the preceding Fourier results, a PCG routine was implemented on an Alliant FX/80 to solve the system $Au = b$ using equations (3), (4), and (5) where the true solution was chosen to be

$$u(x, y, z) = x(1-x)y(1-y)z(1-z).$$

Except where noted, uniformly distributed random initial data* was used for u on the interior of the unit cube.

In order to compare condition numbers for small h we approximated the extreme eigenvalues of the (M)ILU preconditioned systems from PCG-generated values as outlined in [11]. From values generated during the PCG iterations, a symmetric tridiagonal matrix associated with the Lanczos vectors is generated. An EISPACK routine is then called to determine the eigenvalues of the tridiagonal matrix which will in turn approximate the extreme eigenvalues of the preconditioned system. All computations were done in double precision except for the EISPACK routine. The stopping criterion for the PCG iteration required the following three conditions to be satisfied concurrently

$$\frac{\|r^{(k)}\|}{\|r^{(0)}\|} < 10^{-14}, \quad |\mu_{\min}^{(k)} - \mu_{\min}^{(k-1)}| < 10^{-3}, \quad |\mu_{\max}^{(k)} - \mu_{\max}^{(k-1)}| < 10^{-3}.$$

For some experimental results the full set of eigenvalues was needed for the preconditioned operator. A full set of eigenvalues could only be generated in reasonable time for large h (small n). For this a separate program was implemented wherein the M and A matrices were generated and then a call to another EISPACK routine was made to solve the general eigenvalue problem $Ax = \mu Mx$.

A routine to generate the Fourier eigenvalues and condition numbers via equations (8), (9), and (10) was implemented on a Sun 3/150 workstation. The computations were performed in double precision.

4.1. ILU results ($c = w = 0$)**.** First, we show that the Fourier technique predicts the distribution of the eigenvalues for the ILU preconditioned Dirichlet operator. Figure 1 shows the distribution of the eigenvalues of the preconditioned Dirichlet and periodic operators for $h_d = \frac{1}{8}$ ($h_p = \frac{1}{16}$). The range and clustering of the Dirichlet ILU and the Fourier ILU eigenvalues are extremely close. Table 1 shows the results for various values of h for the ILU preconditioned Dirichlet problem. As h decreases, the Fourier results (Table 2) for the minimum and maximum eigenvalue (and hence condition number) are closer to those for the preconditioned Dirichlet system. As predicted, $\kappa(M^{-1}A) = O(h^{-2})$ in each case.

4.2. MILU results for $w = 1$**.** In Fig. 2 the minimum and maximum eigenvalues and the condition numbers are plotted as a function of c for $h_d = \frac{1}{8}$ for the Dirichlet operator and $h_p = \frac{1}{16}$ for the Periodic MILU results.

For large c, the maximum eigenvalues are indistinguishable. For the minimum eigenvalues (and hence the condition numbers) the values are different, but the trend in the values as functions of increasing c are similar. Also we see from Fig. 2 that the optimal c value for the MILU preconditioned Dirichlet operator does occur at c slightly less than the value $c_d = 3\pi^2$ predicted by Result 3.1.

* Experiments were also performed with zero initial data and normally distributed random initial data. Qualitatively, the results did not depend on the choice of these initial data.

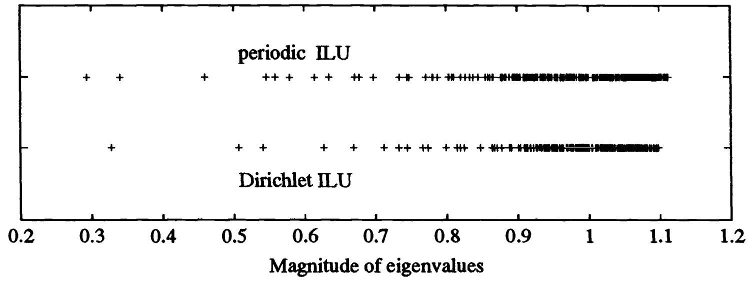

FIG. 1. *Eigenvalues of the isotropic* ILU *preconditioned system,* $h_d = \frac{1}{8}$ $(h_p = \frac{1}{16})$.

TABLE 1
Dirichlet ILU *results for various* h_d *values.*

Tables 3 and 4 contain the results for various values of h_d for $c_d = 3\pi^2$. We see that the Periodic values for MILU are not as close to the Dirichlet values as they were for the ILU case. But we do see that the periodic results display the $O(h^{-1})$ behavior that occurs for the MILU operator for $c_d = 3\pi^2$.

Tables 5 and 6 show the corresponding results for $c = 0$. The periodic MILU condition number displays $O(h^{-2})$ behavior rather than the $O(h^{-1})$ behavior of the Dirichlet MILU operator. This is the same situation that arises for the two-dimensional case [7]. For $c = 0$, it takes a very delicate cancellation to yield the $O(h^{-2})$ results for the Fourier condition number. Away from $c = 0$ the calculations are not as delicate and the Fourier prediction is very good.

Figure 3 plots the condition number of the MILU preconditioned Dirichlet problem and the Fourier condition number results for $h_d = \frac{1}{16}$ (the lower two curves) and for $h_d = \frac{1}{64}$ (the upper two curves). Again we see that, away from $c = 0$, the dependence of conditioning on the parameter c clearly follows the same general pattern for the preconditioned Dirichlet operator (a given h_d) and its corresponding Fourier results $(h_p = h_d/2)$.

4.3. Anisotropic results. To examine results from anisotropic problems we pick the following three sets of data:

Data Set 1: $a_1 = a_2 = a_3 = 1$.

Data Set 2: $a_1 = 1, a_2 = 1, a_3 = 0.01$.

$\frac{1}{64}$	0.500	10.429	20.859

Data Set 3: $a_1 = 1, a_2 = 0.01, a_3 = 0.01$.

These three data sets are a subset of those used in [2], and to allow us to compare results to [2] we use an initial guess for $u(x, y, z)$ that is zero on the interior of the unit cube.

Tables 7, 8, and 9 present the results for $h = 1/21$ for the ILU preconditioned operators. For each of the three data sets the periodic ILU results are in close approximation to the Dirichlet ILU values. In particular, the behavior of the Dirichlet ILU condition numbers is captured by the periodic ILU condition numbers. What is

TABLE 5

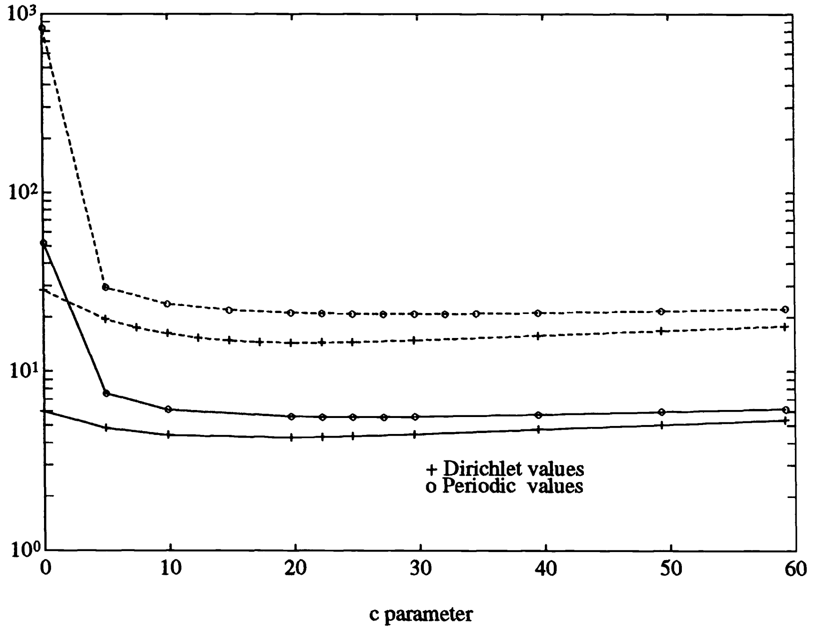

FIG. 3. MILU *condition numbers for* $h_d = \frac{1}{16}$ *(solid lines) and* $h_d = \frac{1}{64}$ *(dashed lines).*

of further interest is the comparison of condition numbers and PCG iteration counts for the Dirichlet ILU operator across the three data sets. $\kappa(M^{-1}A)$ for Data Set 1 is greater than κ for Data Set 2. Yet Data Set 1 requires significantly fewer PCG iterations to converge than Data Set 2. This iteration count variation is also seen in the data presented in [2].

To study this more closely, we redo the calculations for $h_d = \frac{1}{8}$ so that the full set of eigenvalues can be plotted. Tables 10, 11, and 12 present the minimum, maximum, and condition number results for the three data sets and we see that the same situation occurs as for $h_d = \frac{1}{21}$. In Fig. 4, the eigenvalues of the Dirichlet ILU operator are plotted in sorted order for Data Sets 2 and 3 with $h_d = \frac{1}{8}$. These figures also include

the Fourier eigenvalues for $h_p = \frac{1}{16}$.

For the corresponding figure for Data Set 1, refer back to Fig. 1.

First we notice the extreme similarity of the Dirichlet and Fourier eigenvalues. For each data set the behavior of the Fourier eigenvalues corresponds to that of the preconditioned Dirichlet system. And we can see using either the Dirichlet or Fourier spectra that it is the clustering [3], [4] of the eigenvalues that becomes the dominant factor in the number of iterations required.

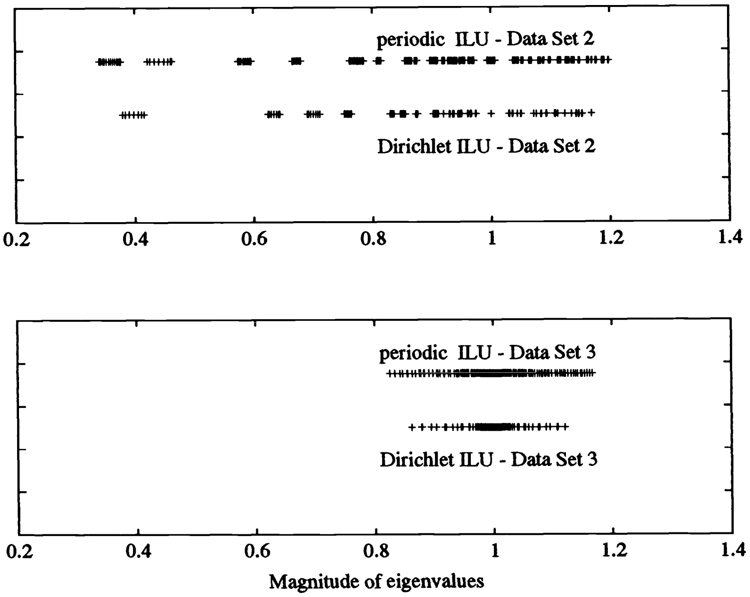

FIG. 4. *Eigenvalues for the anisotropic* ILU *preconditioned systems,* $h_d = \frac{1}{8}$ $(h_p = \frac{1}{16})$.

Data Set 1 yields a larger condition number than Data Set 2 because (in part) of its much smaller minimum eigenvalue. But Data Set 1 has only a few well-isolated minimum eigenvalues, whereas there is a clustering of eigenvalues near the minimum for Data Set 2. The eigenvalues for Data Set 1 have more clustering about 1 than those for Data Set 2. Hence, the systems from Data Set 1 converge more quickly via PCG than those from Data Set 2.

$\frac{1}{16}$	2.369	2.546
$\frac{1}{32}$	6.667	6.857

We see the remarkable agreement of the ILU and Fourier results that occurred in the isotropic case for ILU. Hence, the Fourier results remain a good predictor of the dependence of $\kappa(M^{-1}A)$ on h.

We also analyze the MILU preconditioned operators for the anisotropic data sets. Tables 15, 16, and 17 list the condition numbers for each of the three data sets using the MILU preconditioner with $c_d = 2\pi^2$. Each table includes both the Dirichlet MILU and the calculated Fourier condition number for various values of h_d. Again, the similarity in the dependence of $\kappa(M^{-1}A)$ is noticeable. For all three data sets and for both the Dirichlet and Fourier results, $\kappa(M^{-1}A)$ demonstrates $O(h^{-1})$ behavior.

In Figs. 5 and 6 we have plotted $\kappa(M^{-1}A)$ as a function of c for MILU for the anisotropic Data Sets 2 and 3, respectively. The upper two curves of each figure correspond to $h_d = \frac{1}{32}$ and the lower two curves to $h_d = \frac{1}{16}$. Again, as in the isotropic MILU results, except when c is near zero, the Fourier curves mimic the dependence on c demonstrated by the Dirichlet MILU preconditioned system.

From Figs. 5 and 6, we can see a difficulty in determining c_{opt} in anisotropic situations. The Dirichlet curves for $\kappa(M^{-1}A)$ are visually flat near the optimal value of c_d. This flatness may indicate that finding c_{opt} is a poorly conditioned numerical task. However, the optimal value for c in the Fourier curves certainly corresponds to a good initial approximation of c_{opt} in the Dirichlet case. By this we mean that by choosing c_d to be the value corresponding to the optimal c determined from the Fourier values, the behavior of $\kappa(M^{-1}A)$ in the Dirichlet problem will be $O(h^{-1})$ rather than $O(h^{-2})$.

5. Conclusions. We note that the Fourier technique used here and in [7] is not exact, but it has been shown to be a powerful tool in the analysis of preconditioned systems. Although the Fourier and Dirichlet condition numbers are not identical, the Fourier method is still capable of predicting the dependence of the Dirichlet condition number on the parameters h and c. In the case of an MILU preconditioner, the Fourier method provides a simple and fast technique to find a first approximation to the optimal c parameter. This makes the method very worthwhile, since there are currently no other "easy" methods to apply that give better results. And this is further emphasized by its easy application to anisotropic problems.

Appendix. In this section, we provide the details of proofs and derivations omitted from the main text: we prove Theorems 3.1 and 3.2 and derive Result 3.1.

THEOREM 3.1. *For the* ILU *preconditioned isotropic operator* $(w = 0, c = 0)$,

$$\kappa^{(I)} = O(h^{-2}).$$

Proof. For the isotropic problem $(a_1 = a_2 = a_3 = 1)$ with ILU preconditioner $(w = 0, c = 0)$ we get the recurrence (7) the expression $6 = \alpha + \frac{3}{\alpha}$ whose solution is $\alpha = 3 + \sqrt{6}$ and we have

$$\begin{aligned}\lambda_{str} &= 4\left(\sin^2\left(\frac{\theta_s}{2}\right) + \sin^2\left(\frac{\phi_t}{2}\right) + \sin^2\left(\frac{\xi_r}{2}\right)\right),\\ \psi_{str} &= \lambda_{str} + \frac{2}{\alpha}(\cos(\theta_s - \phi_t) + \cos(\xi_r - \theta_s) + \cos(\phi_t - \xi_r)).\end{aligned}$$

It holds immediately that

$$\begin{aligned}\lambda_{\min} &\geq \lambda_{l.b.} = 12\sin^2(\pi h) \approx 12(\pi h)^2 + O(h^4),\\ \lambda_{\max} &\leq \lambda_{u.b.} = 12,\\ \psi_{\max} &\leq \psi_{u.b.} = 12 + \frac{6}{\alpha}.\end{aligned}$$

Now, for the lower bound on ψ_{str}: Set $x = \sin\frac{\theta_s}{2}, y = \sin\frac{\phi_t}{2}, z = \sin\frac{\xi_r}{2}$ and use

$$\begin{aligned}\cos(\theta_s - \phi_t) &= 1 - 2(x^2 + y^2) + 4x^2y^2 \pm 4xy\sqrt{(1 - x^2)(1 - y^2)}\\ &> 1 - 2(x^2 + y^2) - 4|xy|,\end{aligned}$$

$$\begin{aligned}\psi_{str} &= \lambda_{str} + \frac{2}{\alpha}(\cos(\theta_s - \phi_t) + \cos(\phi_t - \xi_r) + \cos(\xi_r - \theta_s))\\ &\geq \lambda_{str} + \frac{2}{\alpha}(3 - 2(x^2 + y^2) - 4|xy| - 2(y^2 + z^2) - 4|yz| - 2(x^2 + z^2) - 4|xz|)\\ &= 4(x^2 + y^2 + z^2) + \frac{2}{\alpha}(3 - 4(x^2 + y^2 + z^2) - 4(|xy| + |yz| + |xy|))\\ &= \frac{4}{\alpha}((\alpha - 2)(x^2 + y^2 + z^2) - 2(|xy| + |yz| + |xy|)) + \frac{6}{\alpha}\\ &= \frac{4}{\alpha}((1 + \sqrt{6})(x^2 + y^2 + z^2) - 2(|xy| + |yz| + |xy|)) + \frac{6}{\alpha}\\ &> \frac{4}{\alpha}(2(x^2 + y^2 + z^2) - 2(|xy| + |yz| + |xy|)) + \frac{6}{\alpha}\\ &= \frac{4}{\alpha}((|x| - |y|)^2 + (|y| - |z|)^2 + (|x| - |z|)^2) + \frac{6}{\alpha}\\ &\geq \frac{6}{\alpha}.\end{aligned}$$

In other words,

$$\psi_{\min} \geq \psi_{l.b.} = \frac{6}{\alpha}.$$

So, we can now finally get bounds on the condition number via

$$\begin{aligned}
\mu_{\min}^{(I)} &\geq \frac{\lambda_{\min}}{\psi_{\max}} \geq \frac{12\sin^2(\pi h)}{12+\frac{6}{\alpha}} = \frac{2\sin^2(\pi h)}{2+\frac{1}{\alpha}} \\
\mu_{\max}^{(I)} &\leq \frac{\lambda_{\max}}{\psi_{\min}} \leq \frac{12}{\frac{6}{\alpha}} = 2\alpha \\
\kappa^{(I)} &= \frac{\mu_{\max}^{(I)}}{\mu_{\min}^{(I)}} \leq \frac{2\alpha}{\frac{2\sin^2(\pi h)}{2+1/a}} \\
&= \frac{\alpha(2+\frac{1}{\alpha})}{\sin^2(\pi h)} \approx \frac{\alpha(2+\frac{1}{\alpha})}{(\pi h)^2} \approx 1.2h^{-2}.
\end{aligned}$$

Now we will see that this $O(h^{-2})$ bound is tight.

Let $\theta_s = \phi_t = \xi_r = \pi$, $(r = s = t = (n+1)/2)$, to get $\lambda = 12, \psi = 12 + \frac{6}{\alpha}$. From these we have

$$\mu^{(1)} = \frac{\lambda}{\psi} = \frac{12}{12+\frac{6}{\alpha}} \approx 0.916 = O(1).$$

On the other end, letting $\theta_s = \phi_t = \xi_r = \theta_1 = 2\pi h$, we get for small enough h

$$\begin{aligned}
\lambda &= 12\sin^2(\pi h) \\
\psi &= 12\sin^2(\pi h) + \frac{6}{\alpha} \\
\mu^{(2)} &= \frac{\lambda}{\psi} = \frac{2\sin^2(\pi h)}{2\sin^2(\pi h)+\frac{1}{\alpha}} \approx \frac{2(\pi h)^2 + O(h^4)}{\frac{1}{\alpha} + 2(\pi h)^2 + O(h^4)} \\
&\approx 2\alpha(\pi h)^2 + O(h^4).
\end{aligned}$$

Finally, combining the above, we get

$$\begin{aligned}
\frac{\mu^{(1)}}{\mu^{(2)}} &\approx \frac{1}{(2\alpha+1)\pi^2h^2 + O(h^4)} \\
&= O(h^{-2})
\end{aligned}$$

and so we have that the bound of $O(h^{-2})$ on $\kappa^{(I)}$ is tight. □

THEOREM 3.2. *For the* MILU *preconditioned isotropic operator* $(w = 1)$,

$$\kappa^{(M)} = \begin{cases} O(h^{-1}), & \text{if } c > 0; \\ O(h^{-2}), & c = 0. \end{cases}$$

Proof. For the isotropic problem $(a_1 = a_2 = a_3 = 1)$ with MILU preconditioner $(w = 1, c \neq 0)$ we get for the recurrence (7) the expression $6 + ch^2 = \alpha + \frac{9}{\alpha}$ whose solution is

$$\alpha = 3 + \frac{ch^2}{2} + h\sqrt{3c}\sqrt{1+\frac{ch^2}{12}}.$$

So we have

$$\lambda_{str} = 4\left(\sin^2\left(\frac{\theta_s}{2}\right) + \sin^2\left(\frac{\phi_t}{2}\right) + \sin^2\left(\frac{\xi_r}{2}\right)\right),$$

$$\begin{aligned}\psi_{str} &= \lambda_{str} + \frac{2}{\alpha}(\cos(\theta_s - \phi_t) + \cos(\xi_r - \theta_s) + \cos(\phi_t - \xi_r)) - \frac{6}{\alpha} + ch^2 \\ &= \lambda_{str} - \frac{2}{\alpha}(3 - \cos(\theta_s - \phi_t) - \cos(\xi_r - \theta_s) - \cos(\phi_t - \xi_r)) + ch^2.\end{aligned}$$

We first derive a lower bound on $\mu^{(M)}$. Observe that $\psi_{str} \le \lambda_{str} + ch^2$. Also, for h small enough, there exists $\tilde{c}$ such that $\sin(\pi h) \ge \tilde{c}h$, which yields $\lambda_{str} \ge 12(\tilde{c}h)^2$. Thus we get the lower bound

$$\begin{aligned}\mu_{str}^{(M)} &\ge \frac{\lambda_{str}}{\lambda_{str} + ch^2} = \frac{1}{1 + \frac{ch^2}{\lambda_{str}}} \\ &\ge \frac{1}{1 + \frac{c}{12\tilde{c}^2}} \equiv \mu_{l.b.}.\end{aligned}$$

Next we derive the upper bound on $\mu^{(M)}$. We use that $\lambda_{str} \le 12$. With the aid of the symbolic manipulator Maple [9] we get

$$\frac{3 - \cos(\theta_s - \phi_t) - \cos(\xi_r - \theta_s) - \cos(\phi_t - \xi_r)}{\sin^2\left(\frac{\theta_s}{2}\right) + \sin^2\left(\frac{\phi_t}{2}\right) + \sin^2\left(\frac{\xi_r}{2}\right)} \le 6.$$

Hence,

$$\begin{aligned}\mu_{str} &= \frac{\lambda_{str}}{\lambda_{str} - \frac{2}{\alpha}(3 - \cos(\theta_s - \phi_t) - \cos(\xi_r - \theta_s) - \cos(\phi_t - \xi_r)) + ch^2} \\ &= \frac{1}{1 - \left(\frac{2}{\alpha}\right)\frac{3 - \cos(\theta_s - \phi_t) - \cos(\xi_r - \theta_s) - \cos(\phi_t - \xi_r)}{4(\sin(\theta_s/2) + \sin(\phi_t/2) + \sin(\xi_r/2))} + \frac{ch^2}{\lambda_{str}}} \\ &= \frac{1}{1 - \left(\frac{1}{2\alpha}\right)\frac{3 - \cos(\theta_s - \phi_t) - \cos(\xi_r - \theta_s) - \cos(\phi_t - \xi_r)}{\sin(\theta_s/2) + \sin(\phi_t/2) + \sin(\xi_r/2)} + \frac{ch^2}{\lambda_{str}}} \\ &\le \frac{1}{1 - \frac{1}{2\alpha}(6) + \frac{ch^2}{12}}.\end{aligned}$$

Now we use the approximation $\alpha \approx 3(1 + \frac{1}{3}h\sqrt{3c} + O(ch^2))$ to get for small enough h that $\frac{1}{\alpha} \approx \frac{1}{3}(1 - \frac{1}{3}h\sqrt{3c} + O(ch^2))$, which yields

$$\mu_{str} \le \frac{1}{\frac{1}{3}h\sqrt{3c} + O(h^2)} \equiv \mu_{u.b.}.$$

So, finally,

$$\begin{aligned}\kappa^{(M)} &= \frac{\max \mu_{str}}{\min \mu_{str}} \le \frac{\mu_{u.b.}}{\mu_{l.b.}} = \frac{1 + \frac{c}{12\tilde{c}^2}}{\frac{1}{3}h\sqrt{3c} + O(h^2)} \\ &= \begin{cases} O(h^{-1}), & \text{if } c \ne 0; \\ O(h^{-2}), & c = 0. \end{cases}\end{aligned}$$

Next it is shown that the above bounds are tight.

First consider $\theta_s = \phi_t = \xi_r = \theta_1 = 2\pi h$.

$$
\begin{aligned}
\lambda_{111} &= 12\sin^2(\pi h),\\
\psi_{111} &= 12\sin^2(\pi h) + \frac{2}{\alpha}(3) - \frac{6}{\alpha} + ch^2 = 12\sin^2(\pi h) + ch^2,\\
\mu^{(M)}_{111} &= \frac{\lambda_{111}}{\psi_{111}} = \frac{12\sin^2(\pi h)}{12\sin^2(\pi h) + ch^2} = \frac{1}{1 + (ch^2/12\sin^2(\pi h))} \approx \frac{1}{1 + (ch^2/12(\pi h)^2)}\\
&= \frac{1}{1 + (c/12\pi^2)} = O(1).
\end{aligned}
$$

Now consider $\theta_s = \xi_r = \theta$, and $\phi_t = 2\pi - 2\theta$. Then $\sin(\phi_t/2) = \sin\theta = 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}$ and $\cos(\phi_t - \theta_s) = \cos(\xi_r - \phi_t) = \cos(3\theta_s)$, $\cos(\xi_r - \theta_s) = 1$. In the expression for ψ we will also use the following

$$
\cos(3\theta) = 1 - 18\sin^2\frac{\theta}{2} + 48\sin^4\frac{\theta}{2} - 32\sin^6\frac{\theta}{2}.
$$

$$
\begin{aligned}
\lambda &= 4\left(2\sin^2\left(\frac{\theta}{2}\right) + 4\sin^2\left(\frac{\theta}{2}\right)\cos^2\left(\frac{\theta}{2}\right)\right) = 8\sin^2\left(\frac{\theta}{2}\right)\left(1 + 2\cos^2\left(\frac{\theta}{2}\right)\right)\\
&= 24\sin^2\left(\frac{\theta}{2}\right)\left(1 - \frac{2}{3}\sin^2\left(\frac{\theta}{2}\right)\right),\\
\psi &= \lambda - \frac{4}{\alpha}(1 - \cos(3\theta)) + ch^2\\
&= \lambda - \frac{4}{\alpha}\left(18\sin^2\frac{\theta}{2} - 48\sin^4\frac{\theta}{2} + 32\sin^6\frac{\theta}{2}\right) + ch^2\\
&= 24\sin^2\left(\frac{\theta}{2}\right)\left(1 - \frac{2}{3}\sin^2\left(\frac{\theta}{2}\right)\right)\\
&\quad - \frac{4}{3}\left(1 - \frac{1}{3}h\sqrt{3c} + O(ch^2)\right)\left(18\sin^2\frac{\theta}{2} - 48\sin^4\frac{\theta}{2} + 32\sin^6\frac{\theta}{2}\right) + ch^2\\
&\approx 48\sin^4\frac{\theta}{2} + \frac{4}{9}h\sqrt{3c}\left(18\sin^2\frac{\theta}{2} - 48\sin^4\frac{\theta}{2}\right) + O(ch^2),\\
\mu^{(M)} &= \frac{\lambda}{\psi} \approx \frac{24\sin^2(\frac{\theta}{2})(1 - \frac{2}{3}\sin^2(\frac{\theta}{2}))}{48\sin^4\frac{\theta}{2} + \frac{4}{9}h\sqrt{3c}(18\sin^2\frac{\theta}{2} - 48\sin^4\frac{\theta}{2}) + O(ch^2)}.
\end{aligned}
$$

If $c = 0$, this simplifies to $\mu^{(M)} \approx \frac{1}{2\sin^2(\frac{\theta}{2})}$. Setting $\theta = \theta_1 = 2\pi h$ leads to $\mu^{(M)} = O(h^{-2})$. If $c > 0$, setting $\theta \approx 2\sqrt{h}$ (i.e., $s \approx \sqrt{n+1}/\pi$) leads to $\mu^{(M)} = O(h^{-1})$. Hence, we have the exact bounds

$$
\kappa^{(M)} = \begin{cases} O(h^{-1}), & \text{if } c > 0;\\ O(h^{-2}), & c = 0. \end{cases} \qquad \square
$$

Result 3.1. For the MILU preconditioned isotropic operator, the optimal value of c (the one that minimizes $\kappa^{(M)}$) occurs near $c_p = 12\pi^2$ for the periodic problem and $c_d = 3\pi^2$ for the Dirichlet problem.

In the derivation of this result, we make use of the following empirical results: the maximum value of μ occurs on the plane $\theta + \phi + \xi = 2\pi$ (and symmetric planes) where $\theta = \phi$ is small.

So, as in the latter part of the proof of Theorem 3.2, we have

$$\mu_{str}^{(M)} \approx \frac{24\sin^2(\frac{\theta}{2})(1-\frac{2}{3}\sin^2(\frac{\theta}{2}))}{48\sin^4\frac{\theta}{2}+\frac{4}{9}h\sqrt{3c}(18\sin^2\frac{\theta}{2}-48\sin^4\frac{\theta}{2})+O(h^2)}.$$

Let $x \equiv \sin^2\left(\frac{\theta_s}{2}\right)$.

$$\begin{aligned}\mu_{str}^{(M)} &\approx \frac{24x(1-\frac{2}{3}x)}{48x^2+\frac{4}{9}h\sqrt{3c}(18x-48x^2)+O(h^2)}\\ &= \frac{24(1-\frac{2}{3}x)}{48x+\frac{4}{9}h\sqrt{3c}(18-48x)+\frac{O(h^2)}{x}}\\ &\approx \frac{24}{48x+\frac{4}{9}h\sqrt{3c}(18-48x)+\frac{O(h^2)}{x}}.\end{aligned}$$

In the above and in the rest of the derivation we use that $x << 1$ and hence $x^2 << x$, which can be verified a posteriori from the derivation.

Setting $0 = \partial\mu/\partial x$ we get $x^2 \approx ch^2/48$, which implies $\sin^2\left(\frac{\theta_s}{2}\right) \approx \sqrt{c/48}h$. Substituting this result back into the equation for $\mu_{\max}^{(M)}$ yields

$$\mu_{str}^{(M)} \approx \frac{3}{2\sqrt{3c}h}.$$

For the minimum we use $\theta = \phi = \xi = 2\pi h$ and get

$$\mu_{\min}^{(M)} = \frac{12\sin^2(\pi h)}{12\sin^2(\pi h)+ch^2} = \frac{1}{1+\frac{c}{12\pi^2}}.$$

Thus as a function of c,

$$\kappa^{(M)}(c) = \frac{\mu_{\max}}{\mu_{\min}} = \frac{1+(c/12\pi^2)}{(2\sqrt{3c}h/3)}.$$

We want the c value that yields the minimum $\kappa^{(M)}$, hence we set $0 = (\partial\kappa/\partial c)$ to get $c_p \approx 12\pi^2$.

But this is the parameter c for the periodic approximation. To predict the optimal c_d value for the Dirichlet problem, we use $\delta_p = c_p{h_p}^2 = \delta_d = c_d{h_d}^2$ as in [7], where $h_p = \frac{h_d}{2}$ and find that

$$c_d \approx \frac{1}{4}c_p = 3\pi^2.$$

Acknowledgment. The first author would like to acknowledge the helpful discussions with Rosa Donat on the use of Maple in the proof of Theorem 3.2 and to Richard E. Little for general encouragement. Also, many thanks to the reviewers of this paper. Their comments, large and small, were greatly appreciated.

LINE ITERATIVE METHODS FOR CYCLICALLY REDUCED DISCRETE CONVECTION-DIFFUSION PROBLEMS*

HOWARD C. ELMAN† AND GENE H. GOLUB‡

Abstract. An analytic and empirical study of line iterative methods for solving the discrete convection-diffusion equation is performed. The methodology consists of performing one step of the cyclic reduction method, followed by iteration on the resulting reduced system using line orderings of the reduced grid. Two classes of iterative methods are considered: block stationary methods, such as the block Gauss–Seidel and SOR methods, and preconditioned generalized minimum residual methods with incomplete LU preconditioners. New analysis extends convergence bounds for constant coefficient problems to problems with separable variable coefficients. In addition, analytic results show that iterative methods based on incomplete LU preconditioners have faster convergence rates than block Jacobi relaxation methods. Numerical experiments examine additional properties of the two classes of methods, including the effects of direction of flow, discretization, and grid ordering on performance.

Key words. iterative methods, line orderings, reduced system, convection-diffusion, elliptic operators

1. Introduction.

Consider the convection-diffusion equation

$$-\,[(pu_x)_x + (qu_y)_y] + ru_x + su_y = f \quad \text{on } \Omega \tag{1.1a}$$

$$\alpha u + \beta u_n = g \quad \text{on } \partial\Omega, \tag{1.1b}$$

where Ω is a smooth domain in $\mathbf{R}^2$ and $p > 0$, $q > 0$ on Ω. Discretization of (1.1) produces a linear system of equations

$$Au = f, \tag{1.2}$$

where u and f are now vectors in a finite-dimensional space, and A is a nonsymmetric matrix when r and s are nonzero. We are concerned with discretizations (principally, finite difference methods) for which each equation in (1.2) is centered at some mesh point (x_i, y_j), and the associated unknown u_{ij} depends only on its neighbors in the horizontal and vertical directions. That is, the equation centered at (x_i, y_j) has the form

$$a_{ij}u_{ij} = f_{ij} - b_{ij}u_{i,j-1} - c_{ij}u_{i-1,j} - d_{ij}u_{i+1,j} - e_{ij}u_{i,j+1}. \tag{1.3}$$

In this case, we say that (1.2) has a *computational molecule* of the form

$$\begin{array}{ccccc} & & e_{ij} & & \\ & & | & & \\ c_{ij} & \text{——} & a_{ij} & \text{——} & d_{ij}. \\ & & | & & \\ & & b_{ij} & & \end{array}$$

FIG. 1.1. *A* 6×5 *grid and a red-black ordering. Grid indices are shown on the left, and vector indices for a red-black ordering are shown on the right. Red points are denoted by "*$\otimes$*" and black points by "*$\times$*."*

When the system (1.2) has this property, the mesh points $\{(x_i, y_j)\}$ and unknowns $\{u_{ij}\}$ can be ordered with a red-black ordering so that every equation centered at a "red" point depends only on "black" unknowns, and every equation centered at a "black" point depends only on "red" unknowns. An example of a red-black ordering of a 6×5 grid is shown in Fig. 1.1. If u_{ij} is a black unknown, then by adding appropriate linear combinations of the equations for $u_{i\pm1,j}$ and $u_{i,j\pm1}$ to the equation for u_{ij}, we can eliminate the dependence of u_{ij} on its red neighbors. When this is done for every black equation, the result is a smaller linear system

$$A^{(b)}u^{(b)} = g^{(b)}, \tag{1.4}$$

where $u^{(b)}$ is the set of unknowns associated with black mesh points. In matrix notation, this process corresponds to ordering the rows and columns of A so that (1.2) has the form

$$\begin{pmatrix} D & C \\ E & F \end{pmatrix} \begin{pmatrix} u^{(r)} \\ u^{(b)} \end{pmatrix} = \begin{pmatrix} f^{(r)} \\ f^{(b)} \end{pmatrix},$$

where D and F are nonsingular diagonal matrices. Decoupling of the red points $u^{(r)}$ is equivalent to producing the system (1.4), where $A^{(b)} = F - ED^{-1}C$ and $g^{(b)} = f^{(b)} - ED^{-1}f^{(r)}$.

In [7], [8], we analyzed the convergence behavior of block iterative methods for solving the reduced system (1.4) derived from discretizations of (1.1). We considered block Jacobi, Gauss–Seidel, and successive overrelaxation (SOR) methods [25], [28], where the blockings (of the rows and columns of $A^{(b)}$) are derived from certain *line orderings* of the underlying reduced (black) grid. In particular, the unknown grid values $u^{(b)}$ can be grouped together either by individual lines of the grid, producing a class of *one-line* orderings, or by pairs of lines, producing *two-line* orderings (see §2). These orderings produce matrices with block Property A, so that the classical analysis of Gauss–Seidel and SOR methods [25], [28] can be used. The results of [7], [8] apply to problems with the constant coefficients $p(x, y) = q(x, y) = 1$, $r(x, y) = \sigma$, $s(x, y) = \tau$. They show that convergence is often very fast; in particular, for nonselfadjoint problems (σ or τ nonzero), convergence is typically faster than for selfadjoint problems. They also show that convergence rates for solving the reduced system are often faster than for solving the full system (1.2) by analogous line methods. These observations are in agreement with asymptotic results in [20] and the algebraic analysis of [13]. Related results for point iterative methods are given in [18].

In this paper, we extend the analysis of [7], [8] to separable problems, and we also use it to derive bounds on convergence behavior for stationary methods based on incomplete factorizations [17]. In addition, in a series of numerical experiments, we examine the effect of physically significant properties of the problem (1.1) on the performance of iterative methods applied to (1.4). Here, we consider both block relaxation methods and the preconditioned generalized minimum residual method (GMRES) [23], with preconditioning by incomplete factorizations [17]. We focus on the following issues:

1. For constant coefficient problems, the effect of the signs and magnitudes of r and s in (1.1). These quantities determine the direction and rate of flow associated with the convection in the model. The analysis of [7], [8] is sensitive to magnitudes but not to signs.
2. The effect of variable coefficients r and s. We consider problems both with and without turning points.
3. The effects of the choice of discretization on performance; we consider centered and upwind finite difference discretizations.
4. The first three issues do not address the issue of accuracy of the discrete solution. We also examine the effect of methods designed to improve accuracy in the presence of boundary layers, in particular, local mesh refinement and defect correction methods [12], [15].

An outline of the paper is as follows. In §2, we describe the reduced matrix $A^{(b)}$, and we present the ordering strategies and iterative methods used to solve (1.4), including some block red-black strategies of use for vector and parallel computations. In §3, we extend the analysis of [7], [8] to separable problems and incomplete factorizations. In §4, we describe the results of numerical experiments with constant coefficient problems. For several ordering strategies, we examine how performances of block stationary methods and preconditioned GMRES are affected by direction and rate of flow, choice of difference scheme, and use of local mesh refinement to resolve boundary layers. In §5, we compare experimental results with analytic bounds on convergence, for separable problems. In §6, we consider performance for some problems with nonseparable variable coefficients, i.e., where the flow varies in both direction and magnitude in Ω. Here we consider both centered and upwind finite differences, as well as a difference scheme used to implement defect correction methods. Finally, in §7 we make some concluding remarks.

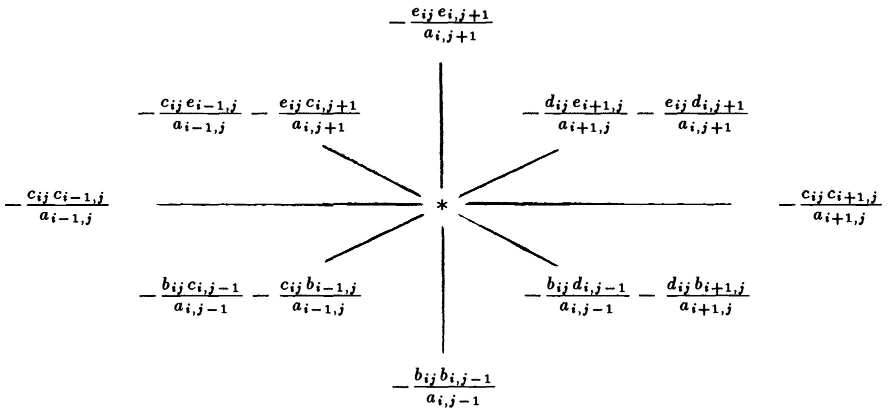
2. The reduced system and line iterative methods. Let u_{ij} be a black point not next to the boundary $\partial\Omega$. Elimination of the unknowns $u_{i\pm1,j}$ and $u_{i,j\pm1}$ from (1.3) produces an equation in the reduced system with the computational molecule shown in Fig. 2.1. The value "*" in the center is

$$a_{ij} - \frac{b_{ij}e_{i,j-1}}{a_{i,j-1}} - \frac{c_{ij}d_{i-1,j}}{a_{i-1,j}} - \frac{d_{ij}c_{i+1,j}}{a_{i+1,j}} - \frac{e_{ij}b_{i,j+1}}{a_{i,j+1}},$$

and the right-hand side is perturbed by an average of neighboring values,

$$g_{ij}^{(b)} = f_{ij} - \frac{b_{ij}f_{i,j-1}}{a_{i,j-1}} - \frac{c_{ij}f_{i-1,j}}{a_{i-1,j}} - \frac{d_{ij}f_{i+1,j}}{a_{i+1,j}} - \frac{e_{ij}f_{i,j+1}}{a_{i,j+1}}.$$

The line ordering strategies for the reduced grid are outlined as follows (see [7], [8] for further details). In the *natural one-line* ordering, points of the reduced grid are grouped together by diagonal lines, e.g., oriented in the NW–SE direction. The left side of Fig. 2.2 shows an example for a 6 × 5 grid. Here, the kth line consists of all points with grid indices (i, j) such that $i + j = 2k + 1$. (Compare with the left side of Fig. 1.1.) Thus, in Fig. 2.2, the first line consists of the points $\{1, 2\}$, the second line consists of the points $\{3, 4, 5, 6\}$, etc. In the *natural two-line* ordering, points



$-\frac{e_{ij}e_{i,j+1}}{a_{i,j+1}}$
$-\frac{c_{ij}e_{i-1,j}}{a_{i-1,j}}$
$-\frac{e_{ij}c_{i,j+1}}{a_{i,j+1}}$
$-\frac{d_{ij}e_{i+1,j}}{a_{i+1,j}}$
$-\frac{e_{ij}d_{i,j+1}}{a_{i,j+1}}$
$-\frac{c_{ij}c_{i-1,j}}{a_{i-1,j}}$
$*$
$-\frac{c_{ij}c_{i+1,j}}{a_{i+1,j}}$
$-\frac{b_{ij}c_{i,j-1}}{a_{i,j-1}}$
$-\frac{c_{ij}b_{i-1,j}}{a_{i-1,j}}$
$-\frac{b_{ij}d_{i,j-1}}{a_{i,j-1}}$
$-\frac{d_{ij}b_{i+1,j}}{a_{i+1,j}}$
$-\frac{b_{ij}b_{i,j-1}}{a_{i,j-1}}$

FIG. 2.2. *Natural one-line (left) and two-line (right) orderings of the reduced* 6×5 *grid.*

are grouped together by pairs of either horizontal or vertical lines. The right side of Fig. 2.2 shows an example of a horizontal grouping for a 6 × 5 grid. The points in the kth group are those with grid indices (i,j) such that $k-1 < j/2 \le k$. If the number of lines is odd, the last group consists of a single line, as in the group $\{13,14,15\}$. For both these strategies, $A^{(b)}$ is a block tridiagonal matrix; let D denote its block diagonal. For the one-line ordering, each block of D is a tridiagonal matrix, and for the two-line ordering, each block of D is a pentadiagonal matrix (except possibly the last block, which may be tridiagonal). It is also useful (e.g., for parallel computations, see [8]) to define *line red-black* variants of these orderings, in which alternating lines (or line pairs) are assigned opposite colors. For example, for the one-line version, let the sets $\{1,2\}$, $\{7,8,9,10,11\}$, and $\{15\}$ be denoted as "red" lines, and the others as "black" lines. Then every equation centered at a point in a red line depends only on that red line and the neighboring black lines; an analogous statement holds for equations centered on black lines. For the red-black one-line ordering, all red lines are ordered first, followed by all black lines. The red-black two-line ordering is defined in similar fashion.

For any of these line orderings, let

$$A^{(b)} = D - C = (D - L) - U, \tag{2.1}$$

where D is the block diagonal part of $A^{(b)}$ and L and U are the lower and upper triangular parts, respectively, of the block off-diagonal part of $A^{(b)}$. We consider several block stationary methods based on the splittings (2.1). The block Jacobi iteration is given by

$$u_{k+1}^{(b)} = D^{-1}Cu_k^{(b)} + D^{-1}g^{(b)},$$

and the block SOR iteration is

$$u_{k+1}^{(b)} = (D - \omega L)^{-1}[(1-\omega)D + \omega U]u_k^{(b)} + \omega(D - \omega L)^{-1}g^{(b)}. \tag{2.2}$$

The block Gauss–Seidel iteration corresponds to the case $\omega = 1$ in 2.2. In all cases, $A^{(b)}$ is block consistently ordered, so that [28]

$$\rho((D-L)^{-1}U) = [\rho(D^{-1}C)]^2, \tag{2.3}$$

where $\rho(X)$ denotes the spectral radius of a matrix X.

In addition, we consider the use of the ILU(0) incomplete factorization [17] applied to $A^{(b)}$ for each of the orderings. This factorization is defined as

$$M = (\hat{D} - \hat{L})\hat{D}^{-1}(\hat{D} - \hat{U}), \tag{2.4}$$

where $\hat{D}$ is a diagonal matrix; $\hat{L}$ and $\hat{U}$ are strictly lower triangular and upper triangular, respectively; the nonzero structure of $\hat{D} - \hat{L} - \hat{U}$ is the same as that of $A^{(b)}$; and the entries of M are the same as the corresponding entries of $A^{(b)}$ wherever the latter are nonzero. We will examine the use of this factorization as a preconditioner for GMRES.

3. Analysis of separable problems and the ILU(0) factorization. We will be concerned with finite difference discretizations of (1.1). For example, on a uniform grid with mesh size h, let standard second order differences [11] be used for the second derivative terms. If centered differences are used for the first derivative terms, then after scaling by h^2, the values in the computational molecule are given by

$$\begin{aligned} a_{ij} &= p(x_{i+1/2}, y_j) + p(x_{i-1/2}, y_j) + q(x_i, y_{j+1/2}) + q(x_i, y_{j-1/2}), \\ b_{ij} &= -(q(x_i, y_{j-1/2}) + s(x_i, y_j)h/2), \qquad d_{ij} = -(p(x_{i+1/2}, y_j) - r(x_i, y_j)h/2), \\ c_{ij} &= -(p(x_{i-1/2}, y_j) + r(x_i, y_j)h/2), \qquad e_{ij} = -(q(x_i, y_{j+1/2}) - s(x_i, y_j)h/2). \end{aligned}$$

If upwind differencing is used for the first derivatives, then (for the case $r(x_i, y_j) > 0$, $s(x_i, y_j) > 0$) the values are

$$\begin{aligned} a_{ij} &= p(x_{i+1/2}, y_j) + p(x_{i-1/2}, y_j) + q(x_i, y_{j+1/2}) + q(x_i, y_{j-1/2}) \\ &\quad + r(x_i, y_j)h + s(x_i, y_j)h, \\ b_{ij} &= -(q(x_i, y_{j-1/2}) + s(x_i, y_j)h), \qquad d_{ij} = -p(x_{i+1/2}, y_j), \\ c_{ij} &= -(p(x_{i-1/2}, y_j) + r(x_i, y_j)h), \qquad e_{ij} = -q(x_i, y_{j+1/2}). \end{aligned}$$

If instead, $s(x_i, y_j) < 0$, then $b_{ij} = -q(x_i, y_{j-1/2})$, $e_{ij} = -(q(x_i, y_{j+1/2}) - s(x_i, y_j)h)$, and $s(x_i, y_j)h$ is replaced by $-s(x_i, y_j)h$ in the expression for a_{ij}. The case $r(x_i, y_j) < 0$ is handled in an analogous manner.

If Ω is a rectangular domain and the coefficients of (1.1a) satisfy

$$p = p(x), \quad q = q(y), \quad r = r(x), \quad s = s(y),$$

then the differential operator of (1.1) is *separable* [26]. In this case, the discrete coefficients of (1.3) satisfy

$$\begin{aligned} &a_{ij} = a_i^{(x)} + a_j^{(y)} \\ &b_{ij} = b_j, \quad c_{ij} = c_i, \quad d_{ij} = d_i, \quad e_{ij} = e_j. \end{aligned} \tag{3.1}$$

Our convergence analysis is based on symmetrizing the reduced matrix $A^{(b)}$ by a diagonal similarity transformation. The following result gives circumstances under which $A^{(b)}$ can be symmetrized when it comes from a separable operator. In the analysis, matrix entries are referenced using indices from the underlying reduced grid, as shown in Fig. 2.1. That is, every nonzero entry of the row of $A^{(b)}$ associated with the (i, j) grid point is referenced using subscripts i and j. For example, the entry corresponding to the point southwest of the center of the computational molecule (see Fig. 2.1) is denoted by

$$-b_j c_i \left(\frac{1}{a_{i,j-1}} + \frac{1}{a_{i-1,j}} \right),$$

where the numerator is expressed using the notation of (3.1).

THEOREM 1. *If the operator of* (1.1) *is separable and* $c_i d_{i-1}$ *and* $b_j e_{j-1}$ *have the same sign for all* i *and* j, *then the reduced matrix* $A^{(b)}$ *can be symmetrized with a real diagonal similarity transformation.*

Proof. We seek a diagonal matrix Q such that $Q^{-1}A^{(b)}Q$ is symmetric. Let $A^{(b)}$ be ordered by the natural one-line ordering, so that its rows and columns are grouped into l blocks corresponding to l individual lines. Let Q be ordered the same way.

First consider the block diagonal D, which is a tridiagonal matrix. Any two successive rows of a block of D, corresponding to the (i, j) and $(i-1, j+1)$ mesh points, contain the 2×2 sub-block

$$\begin{pmatrix} * & -c_i e_j \left(\frac{1}{a_{i-1,j}} + \frac{1}{a_{i,j+1}}\right) \\ -b_{j+1} d_{i-1} \left(\frac{1}{a_{i-1,j}} + \frac{1}{a_{i,j+1}}\right) & * \end{pmatrix},$$

where "*" denotes a diagonal entry. If q_{ij} is known, then $q_{i-1,j+1}$ must be chosen so that

$$q_{i-1,j+1}^{-1} b_{j+1} d_{i-1} \left(\frac{1}{a_{i-1,j}} + \frac{1}{a_{i,j+1}} \right) q_{ij} = q_{ij}^{-1} c_i e_j \left(\frac{1}{a_{i-1,j}} + \frac{1}{a_{i,j+1}} \right) q_{i-1,j+1}.$$

Thus, within the blocks of Q, successive entries must satisfy

$$q_{i-1,j+1} = \left(\frac{b_{j+1} d_{i-1}}{c_i e_j} \right)^{1/2} q_{ij}. \tag{3.2}$$

For symmetrizing D, the first entry of each block of Q may be arbitrary.

To symmetrize the off-diagonal blocks of $A^{(b)}$, we require

$$Q_k^{-1} A_{k,k-1}^{(b)} Q_{k-1} = (Q_{k-1}^{-1} A_{k-1,k}^{(b)} Q_k)^T, \tag{3.3}$$

where k is a block (or line) index, $2 \le k \le l$. As in [7], there are three cases, corresponding to $2 \le k < l/2 + 1$, $k = l/2 + 1$ (l even), and $l/2 + 1 < k$. In the case $2 \le k \le l/2 + 1$, a careful specification of the entries of Q and $A^{(b)}$ shows that (3.3) is equivalent to the following three scalar relations:

$$q_{ij} = \left(\frac{c_i c_{i-1}}{d_{i-1} d_{i-2}} \right)^{1/2} q_{i-2,j}, \tag{3.4}$$

$$q_{i-1,j+1} = \left(\frac{b_{j+1} c_{i-1}}{d_{i-2} e_j} \right)^{1/2} q_{i-2,j}, \tag{3.5}$$

$$q_{i-2,j+2} = \left(\frac{b_{j+1}b_{j+2}}{e_j e_{j+1}}\right)^{1/2} q_{i-2,j}. \tag{3.6}$$

These relations specify three successive entries of Q_k in terms of a single entry of Q_{k-1} (where $k = (i+j-1)/2$). Since the first entry of Q_k is arbitrary, (3.4) can be used to define it. However, once this entry is defined, all subsequent entries are determined by (3.2). Thus, it is necessary to show that (3.4)–(3.6) are consistent with (3.2). But application of (3.2) and (3.4) in either order results in (3.5), showing that both (3.4) and (3.5) are consistent with (3.2). Similarly, (3.6) follows directly from (3.2) and (3.5).

The arguments for the cases $k = l/2+1$ (l even) and $l/2+1 < k$ are essentially the same and we omit the details. A sufficient condition to guarantee that all the required square roots are well defined is that $c_i d_{i-1}$ and $b_j e_{j-1}$ have the same sign for all i and j.

Finally, note that this analysis is not restricted to the natural one-line ordering. If $A^{(b)}$ is symmetrically permuted into some other order, giving the permuted matrix $\tilde{A}^{(b)}$, then for an analogous permutation of Q to $\tilde{Q}$, $\tilde{Q}^{-1}\tilde{A}^{(b)}\tilde{Q}$ is also symmetric. □

Remark 1. For the centered difference discretization, necessary and sufficient conditions to ensure that all $c_i d_{i-1}$ and $b_j e_{j-1}$ have the same sign are that either

$$\max_i \left[\max\left(\left|\frac{r(x_i)h}{2p(x_{i-1/2})}\right|, \left|\frac{r(x_{i-1})h}{2p(x_{i-1/2})}\right|\right)\right] < 1 \tag{3.7}$$

and

$$\max_j \left[\max\left(\left|\frac{s(y_j)h}{2q(y_{j-1/2})}\right|, \left|\frac{s(y_{j-1})h}{2q(y_{j-1/2})}\right|\right)\right] < 1;$$

or

$$\min_i \left[\min\left(\left|\frac{r(x_i)h}{2p(x_{i-1/2})}\right| \left|\frac{r(x_{i-1})h}{2p(x_{i-1/2})}\right|\right)\right] > 1$$

and

$$\min_j \left[\min\left(\left|\frac{s(y_j)h}{2q(y_{j-1/2})}\right|, \left|\frac{s(y_{j-1})h}{2q(y_{j-1/2})}\right|\right)\right] > 1.$$

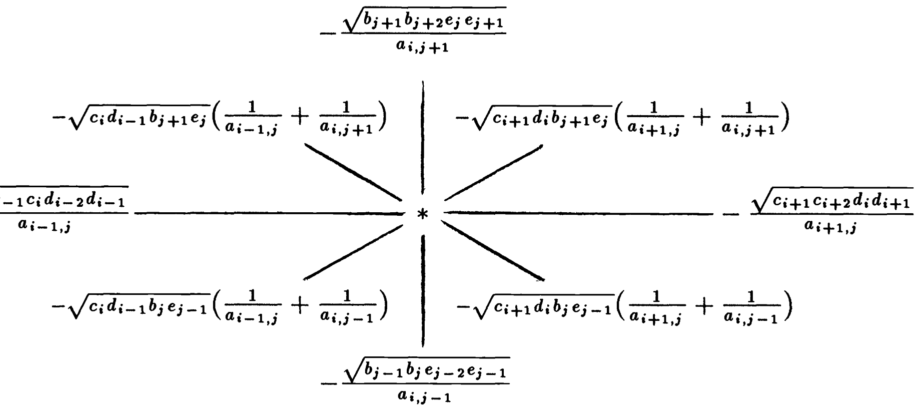
In contrast, the full system (1.2) can be symmetrized by a diagonal similarity transformation if and only if the conditions (3.7) hold. For upwind differences, it is always the case that $c_i d_{i-1} > 0$ and $b_j e_{j-1} > 0$ for all i, j.

Let $\hat{A}^{(b)} = Q^{-1}A^{(b)}Q$ denote the symmetrized reduced matrix, when it exists, for any of the strategies under consideration. Fig. 3.1 shows the resulting computational molecule. Let

$$\hat{A}^{(b)} = \hat{D} - \hat{C}$$

denote the block Jacobi splitting, where $\hat{D} = Q^{-1}DQ$, $\hat{C} = Q^{-1}CQ$. Note that $\hat{D}^{-1}\hat{C} = Q^{-1}D^{-1}CQ$, so that the eigenvalues of $D^{-1}C$ are the same as those of $\hat{D}^{-1}\hat{C}$, and in particular they are real. Let $\mathcal{L}_\omega = (D-\omega L)^{-1}[(1-\omega)D + \omega U]$ denote the block SOR iteration matrix. The following result is then a straightforward application of the analysis of the block SOR method [28].

COROLLARY 1. *If $A^{(b)}$ is the reduced matrix derived from a separable operator, and $c_i d_{i-1}$ and $b_j e_{j-1}$ have the same sign for all i and j, then $\rho(D^{-1}C) = \rho(\hat{D}^{-1}\hat{C})$. If $\rho(D^{-1}C) < 1$, then $\rho(\mathcal{L}_{\omega^*}) = \omega^* - 1$, where $\omega^* = 2/(1+\sqrt{1+[\rho(D^{-1}C)]^2})$ minimizes $\rho(\mathcal{L}_\omega)$.*



$-\frac{\sqrt{b_{j+1}b_{j+2}e_je_{j+1}}}{a_{i,j+1}}$
$-\sqrt{c_id_{i-1}b_{j+1}e_j}\left(\frac{1}{a_{i-1,j}}+\frac{1}{a_{i,j+1}}\right)$
$-\sqrt{c_{i+1}d_ib_{j+1}e_j}\left(\frac{1}{a_{i+1,j}}+\frac{1}{a_{i,j+1}}\right)$
$-\frac{\sqrt{c_{i-1}c_id_{i-2}d_{i-1}}}{a_{i-1,j}}$
$*$
$-\frac{\sqrt{c_{i+1}c_{i+2}d_id_{i+1}}}{a_{i+1,j}}$
$-\sqrt{c_id_{i-1}b_je_{j-1}}\left(\frac{1}{a_{i-1,j}}+\frac{1}{a_{i,j-1}}\right)$
$-\sqrt{c_{i+1}d_ib_je_{j-1}}\left(\frac{1}{a_{i+1,j}}+\frac{1}{a_{i,j-1}}\right)$
$-\frac{\sqrt{b_{j-1}b_je_{j-2}e_{j-1}}}{a_{i,j-1}}$

FIG. 3.1. *The computational molecule for the symmetrized reduced system in the separable case.*

Remark 2. It may be possible to establish the requirements of Corollary 1 a priori. Sufficient conditions to guarantee that $\rho(D^{-1}C) < 1$ are that the original matrix A be a diagonally dominant M-matrix,[1] which is always the case for upwind differences, and is also true for centered differences for small enough h. (In addition, if A is an M-matrix, then so is $A^{(b)}$ [10].) Even if Corollary 1 cannot be invoked from an a priori examination of matrix entries, it may still be useful as a guideline for practical computation. For example, for constant coefficient problems, empirical evidence and Fourier analysis suggest that $\rho(D^{-1}C) < 1$ in cases where c_id_{i-1} and b_je_{j-1} are both negative but A is not a diagonally dominant M-matrix. A good value for the SOR parameter could be computed from a dynamic estimation of $\rho(D^{-1}C)$, e.g., using the methods of [14, §9]. In addition, note that it is not necessary to compute Q or $\hat{A}^{(b)}$ in order to apply this result, see [7].

The following result contains upper bounds on $\rho(D^{-1}C)$ (for both one-line and two-line splittings), for separable problems.

COROLLARY 2. *Let $A^{(b)}$ come from a separable operator discretized on a uniform square grid of mesh width h, and assume that*

$$a_i^{(x)} \geq \alpha^{(x)}, \quad a_j^{(y)} \geq \alpha^{(y)}, \quad 0 < c_{i+1}d_i \leq \xi, \quad 0 < b_{j+1}e_j \leq \eta, \tag{3.8}$$

for all i, j. If $A^{(b)} = D - C$ is a one-line Jacobi splitting and

$$\alpha^{(x)} + \alpha^{(y)} \geq \sqrt{2}\,(\sqrt{\xi} + \sqrt{\eta}), \tag{3.9}$$

then

$$\rho(D^{-1}C) \leq \frac{2(\sqrt{\xi} + \sqrt{\eta})^2}{(\alpha^{(x)} + \alpha^{(y)})^2 - 2(\sqrt{\xi} + \sqrt{\eta})^2 + 4\sqrt{\xi\eta}\,(1 - \cos \pi h)}. \tag{3.10}$$

If $A^{(b)} = D - C$ is a two-line Jacobi splitting and

$$(\alpha^{(x)} + \alpha^{(y)})^2 \geq 2(\sqrt{\xi} + \sqrt{\eta})^2 + 2\xi, \tag{3.11}$$

[1] A nonsingular matrix X is an M-matrix if $X_{ij} \leq 0$ for $i \neq j$ and $X^{-1} \geq 0$.

then

$$(3.12)\qquad \rho(D^{-1}C) \leq \frac{2\,\eta\,\cos 2\pi h + 4\sqrt{\xi\eta}\cos\pi h}{(\alpha^{(x)}+\alpha^{(y)})^2 - 2(\sqrt{\xi}+\sqrt{\eta})^2 - 2\xi + 4\sqrt{\xi\eta}\,(1-\cos\pi h) + 4\xi\,(1-\cos^2\pi h)} + o(h^2).$$

Proof. Using Corollary 1, we have (for any ordering)

$$\rho(D^{-1}C) = \rho(\hat{D}^{-1}\hat{C}) \leq \|\hat{D}^{-1}\|_2\|\hat{C}\|_2 = \rho(\hat{D})\rho(\hat{C}).$$

Consider the one-line orderings. By (3.8), all nonzero off-diagonal entries of $\hat{D}$ are bounded below by $-2\sqrt{\xi\eta}/(\alpha^{(x)}+\alpha^{(y)})$, and all diagonal entries of $\hat{D}$ are bounded below by

$$\alpha^{(x)}+\alpha^{(y)} - 2\xi/(\alpha^{(x)}+\alpha^{(y)}) - 2\eta/(\alpha^{(x)}+\alpha^{(y)}).$$

Thus, $\hat{D} \geq \widetilde{D}$, where each block of $\widetilde{D}$ is a constant coefficient tridiagonal matrix

$$(3.13)\, tri\left[-\frac{2\sqrt{\xi\eta}}{\alpha^{(x)}+\alpha^{(y)}},\ \alpha^{(x)}+\alpha^{(y)} - \frac{2\xi}{\alpha^{(x)}+\alpha^{(y)}} - \frac{2\eta}{\alpha^{(x)}+\alpha^{(y)}},\ -\frac{2\sqrt{\xi\eta}}{\alpha^{(x)}+\alpha^{(y)}}\right].$$

The size of this block depends on the line from which it is derived. Assumption (3.9) implies that each block (3.13) and, therefore, each corresponding block of $\hat{D}$, is an irreducibly diagonally dominant M-matrix. Hence, the Perron–Frobenius theory implies $\rho(\hat{D}^{-1}) \leq \rho(\widetilde{D}^{-1})$. Similarly, by (3.8), $0 \leq \hat{C} \leq \widetilde{C}$, where $\widetilde{C}$ is a matrix with the same nonzero structure as that of $\hat{C}$ in which all occurences of $c_i d_{i-1}$, $b_j e_{j-1}$, and a_{ij} are replaced by ξ, η, and $\alpha^{(x)}+\alpha^{(y)}$, respectively. Consequently, $\rho(\hat{C}) \leq \rho(\widetilde{C})$, and we have

$$(3.14)\qquad \rho(\hat{D}^{-1})\rho(\hat{C}) \leq \rho(\widetilde{D}^{-1})\rho(\widetilde{C}),$$

where the right side of the inequality contains constant coefficient matrices. The bound (3.10) is determined from the maximum eigenvalue of $\widetilde{D}^{-1}$ and use of Gerschgorin's theorem for $\widetilde{C}$. (See [7, Thm. 4])

For the two-line ordering, the blocks of D and $\hat{D}$ are pentadiagonal matrices, and $\hat{D} \geq \widetilde{D}$, where each block of $\widetilde{D}$ is a constant coefficient pentadiagonal matrix,

$$penta\left[-\frac{\xi}{\alpha^{(x)}+\alpha^{(y)}},\ -\frac{2\sqrt{\xi\eta}}{\alpha^{(x)}+\alpha^{(y)}},\ \alpha^{(x)}+\alpha^{(y)} - \frac{2\xi}{\alpha^{(x)}+\alpha^{(y)}} - \frac{2\eta}{\alpha^{(x)}+\alpha^{(y)}},\right.$$
$$\left.-\frac{2\sqrt{\xi\eta}}{\alpha^{(x)}+\alpha^{(y)}},\ -\frac{\xi}{\alpha^{(x)}+\alpha^{(y)}}\right],$$

which is assumed in (3.11) to be diagonally dominant. In addition, exactly as above, $0 \leq \hat{C} \leq \widetilde{C}$, where $\widetilde{C}$ has the same nonzero structure as $\hat{C}$. The bound (3.12) then follows from [8, Thm. 5]. □

We will examine the use of this result in §5.

Remark 3. In the interest of brevity, we have limited our attention to the natural and red-black variants of the one-line orderings. Other variants, called "torus" one-line orderings, collect some individual lines together into sets of equal sizes; this is useful for parallel and vector computations. (See [8], [16].) All of the analysis of this section also applies to the torus orderings.

We now turn our attention to incomplete LU (ILU) factorizations. Let B be an M-matrix of order N, and let $\mathcal{N} \subseteq \{(i,j)\,|\,1 \le i,j \le N\}$ be an index set containing all diagonal indices (i,i). It is shown in [17] that there is a unique ILU factorization LU such that L is unit lower triangular, U is upper triangular, $l_{ij} = 0$ and $u_{ij} = 0$ for $(i,j) \notin \mathcal{N}$, and $[LU - B]_{ij} = 0$ for $(i,j) \in \mathcal{N}$. The ILU(0) factorization of (2.4) is a particular example. The following result of Beauwens ([2, Thm. 4.4]) can be used to compare the ILU(0) splitting to the block Jacobi splitting.

THEOREM 2. *Let B be a nonsingular M-matrix, and let*

$$B = M_1 - R_1 = M_2 - R_2, \tag{3.15}$$

where $M_1 = L_1U_1$ and $M_2 = L_2U_2$ are incomplete factorizations of B such that the set of matrix indices for which $L_1 + U_1$ is permitted to be nonzero is contained in the set of indices for which $L_2 + U_2$ is permitted to be nonzero. Then

$$\rho(M_2^{-1}R_2) \le \rho(M_1^{-1}R_1). \tag{3.16}$$

The analysis in [2] actually applies to a more general class of factorizations than the standard ILU factorization. Theorem 2 can be proved using the result of Woźnicki [27], that if (3.15) represents two regular splittings of a matrix B for which $B^{-1} \ge 0$, then

$$M_2^{-1} \ge M_1^{-1} \tag{3.17}$$

implies the conclusion (3.16). It is straightforward to establish (3.17) for ILU factorizations.

COROLLARY 3. *Suppose $A^{(b)}$ is an M-matrix, ordered using any of the orderings under consideration. Let $A^{(b)} = M - R$ where M is the* ILU(0) *factorization of $A^{(b)}$, and let $A^{(b)} = D - C$ denote the block Jacobi splitting. Then $\rho(M^{-1}R) \le \rho(D^{-1}C)$.*

Proof. The index set of nonzeros of the block diagonal D is a proper subset of the nonzero index set for the ILU(0) factorization. The result then follows from Theorem 2, where (the factorization of) D is viewed as an incomplete factorization of $A^{(b)}$. □

Thus, we expect convergence of a stationary method based on the ILU(0) splitting to be at least as fast as that for the block Jacobi method, for any ordering. (The work per step for the Jacobi method will be smaller, though.) In particular, as observed in [7], [8], convergence should be faster for mildly nonsymmetric problems arising from nonselfadjoint operators than for symmetric ones derived from selfadjoint operators. Combining the ILU(0) factorization with an acceleration scheme such as GMRES (i.e., using M as a preconditioner) should further improve convergence. Numerical experiments with the ILU(0) preconditioner that support this statement are presented in the following sections.

4. Experimental results: Constant coefficient problems.

In this section, we examine the numerical performance of the block Gauss–Seidel and SOR stationary methods, and GMRES(5) with the ILU(0) preconditioner, for solving the constant coefficient model problem

$$-\Delta u + \sigma u_x + \tau u_y = 0 \tag{4.1}$$

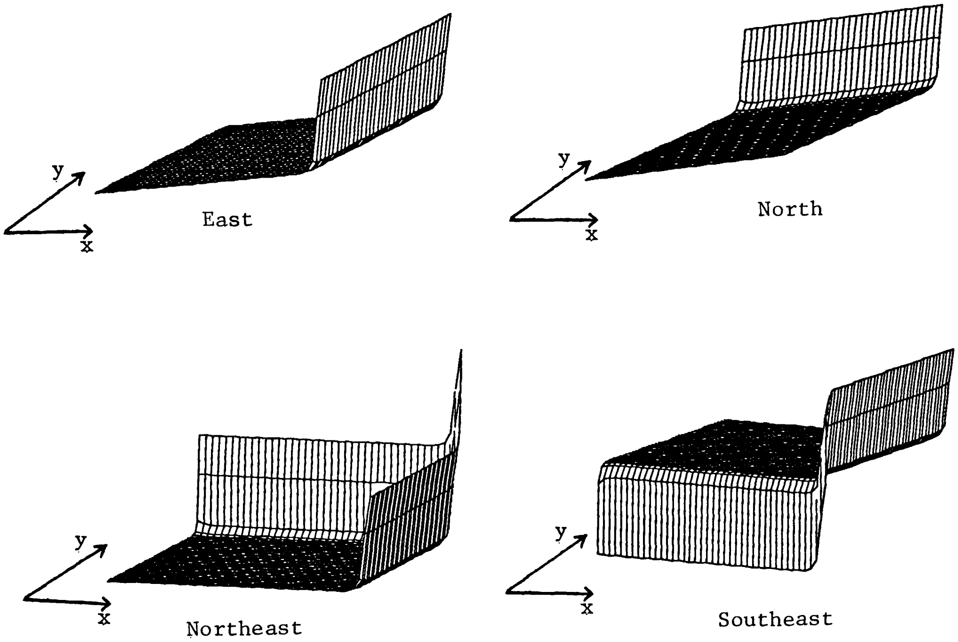


FIG. 4.1. *Plots of the constant coefficient solution for four different directions of flow.*

on $\Omega = (0,1) \times (0,1)$. Dirichlet boundary conditions on $\partial\Omega$ are determined from the exact solution

$$u(x,y) = \frac{e^{\sigma x}-1}{e^{\sigma}-1} + \frac{e^{\tau y}-1}{e^{\tau}-1} \tag{4.2}$$

on $\overline{\Omega}$. The vector (σ, τ) represents a velocity field with the signs of σ or τ determining the direction of flow. We consider eight types of velocity fields, corresponding to eight flow directions in the (x, y)-plane:

East (E):	$\sigma > 0, \tau = 0,$	Northeast (NE):	$\sigma = \tau > 0,$
West (W):	$\sigma < 0, \tau = 0,$	Southeast (SE):	$\sigma = -\tau > 0,$
North (N):	$\sigma = 0, \tau > 0,$	Northwest (NW):	$\sigma = -\tau < 0,$
South (S):	$\sigma = 0, \tau < 0,$	Southwest (SW):	$\sigma = \tau < 0.$

(For $\sigma = 0$ or $\tau = 0$, (4.2) is defined using the limit, i.e., $\lim_{\sigma \to 0}(e^{\sigma x}-1)/(e^{\sigma}-1) = x$.) In addition, the solution (4.2) has a boundary layer at any outflow boundary, i.e., near $x = 1$ for positive σ and $x = 0$ for negative σ, and similarly for y and τ. Plots of the solution for four such (σ, τ) combinations, corresponding to flows in the east, north, northeast, and southeast directions, are shown in Fig. 4.1. Our concern is to determine the effects of direction and magnitude of flow, ordering of unknowns, discretization scheme, and use of local mesh refinement on the performance of reduced system iterative methods.

Details of the numerical experiments are as follows. The experiments were performed on a VAX-8600 in double precision Fortran. Reported iteration counts are averages over three initial guesses consisting of vectors of random numbers in $[-1, 1]$. The stopping criterion for all methods was $\|r_i\|_2/\|r_0\|_2 \leq 10^{-6}$. A maximum of 150 iterations was permitted; an asterisk "*" in any table entry below indicates that for at least one initial guess, the stopping criterion was not met after 150 steps. (We remark that when the block stationary methods failed to meet the stopping criterion, they never "stagnated," i.e., they appeared to be converging.) For red-black SOR, the first iteration was performed with $\omega = 1$, as in [24]. Preconditioned GMRES was performed with right-oriented preconditioning, i.e., GMRES was applied to the preconditioned problem $A^{(b)}M^{-1}\hat{u}^{(b)} = g^{(b)}$, where M is the preconditioning matrix and $u^{(b)} = M^{-1}\hat{u}^{(b)}$. The construction of the reduced matrices and the experiments with GMRES were performed with PCGPAK [21].

The orientation of line orderings was as in §2. That is, for the one-line orderings, lines were oriented in the NW–SE direction, and the natural ordering arranged the lines starting from the SW corner; and for the two-line orderings, line pairs were grouped by horizontal lines and the natural listing is from bottom (south) to top (north). Note that the lines associated with ordering strategies have a relationship with the direction of flow (see also [4]). For example, for the natural one-line ordering, when the flow direction is NE, the lines are perpendicular to the direction of flow, and the Gauss–Seidel and SOR sweeps follow the flow. When the flow direction is SW, the lines are perpendicular to flow, but the sweeps are in the opposite direction of the flow. On the other hand, the sweeps for the red-black orderings do not have a clear relationship to the direction of flow (although the line orientations still do). The ILU(0) preconditioning entails lower and upper triangular solves, so that, for the natural line orderings, the preconditioning operation can be thought of as a pair of bidirectional sweeps.

Tables 4.1–4.4 contain results for centered difference discretizations on a uniform mesh of width $h = 1/32$. For this class of problems, the analysis of §3 is applicable when $|\sigma h/2|$ and $|\tau h/2|$ are both less than one, i.e., when σ or τ are 10 or 50 in the problems considered. In these cases, Corollary 1 is used to choose the SOR parameter ω, where $\rho(D^{-1}C)$ is approximated using the bounds (3.10) and 3.12; here

$$(4.3)\quad a_i^{(x)} = \alpha^{(x)} = a_j^{(y)} = \alpha^{(y)} = 2, \qquad \xi = 1 - (\sigma h/2)^2, \qquad \eta = 1 - (\tau h/2)^2.$$

For the one-line orderings, when both $|\sigma h/2|$ and $|\tau h/2|$ are greater than one, the Fourier analysis of [7] can be used to estimate $\rho(D^{-1}C)$, from which good values of ω are also obtained (i.e., using the formula for ω^* in Corollary 1). These values were also used for the two-line orderings when $|\sigma h/2| > 1$ and $|\tau h/2| > 1$, although there is no theoretical justification for this. We did not examine SOR when one of $|\sigma h/2|$, $|\tau h/2|$ is greater than one and the other is less than one. Table 4.5 shows the choices of ω used for Tables 4.1–4.4. Note that the analysis of §3 and [7], [8], does not distinguish between natural and red-black orderings, or between problems where the magnitudes of σ (or τ) are the same but the signs differ.

500		1.60			1.60
1000		1.77			1.77

We make the following observations on the data of Tables 4.1–4.4:

1. For the stationary methods (Gauss–Seidel and SOR), performance depends on the relationship between flow direction and sweep direction, but the effects vary depending on the magnitudes of the velocity vectors. For example, for the natural one-line orderings, when the convection terms are small or moderate in size, the best performance of the Gauss-Seidel and SOR methods occurs when the sweeps follow the flow (i.e., when the flow direction is NE). When the convection terms dominate, the stationary methods perform better when the flow direction forms a nonzero acute angle with the sweep direction (flow is N or E), than when the sweeps follow the flow. For the natural two-line ordering, performance for moderate sized convection terms is best when the flow direction forms an acute angle with the sweep direction (i.e., when flow is N, NE, or NW); for convection-dominated systems, performance is best when the sweep is perpendicular to the flow. It is always the case that sweeping in the opposite direction of the flow is a bad choice.

2. Performance of stationary methods for the red-black orderings is much less sensitive to flow directions. In particular, the average iteration counts (over the eight flow directions) are essentially the same for the natural and red-black orderings.

This is significant on parallel architectures, where the red-black orderings can be implemented more efficiently [8]. The minimum iteration counts are typically lower for the natural orderings than for the red-black orderings.

3. Somewhat different conclusions apply for GMRES/ILU. There is no clear correlation between direction of flow and performance, except that for convection-dominated problems, performance for both natural orderings degrades when the directions of flow are not parallel to one of the grid coordinates. We have no simple explanation for this. The average iteration counts for GMRES/ILU are typically higher for the red-black orderings than for the natural orderings. Similar results have been obtained for symmetric problems, with point red-black and natural orderings, e.g., in [1].

4. One step of the block SOR method is approximately as expensive as one matrix-vector product and one scalar-vector product [8]. Thus, its cost per step is approximately $10N_b$ multiply-adds, where N_b is the order of $A^{(b)}$. One step of GMRES(5) with ILU(0) preconditioning entails a preconditioning solve, a matrix-vector product, and approximately $8N_b$ vector operations [23], for a total cost of $26N_b$ multiply-adds. That is, one GMRES/ILU step is about 2.5 times as expensive as one SOR step. Consequently, the performances of the stationary methods and GMRES/ILU are comparable for problems with small and moderate-sized convection terms (where for problems with small convection terms, it is necessary to use a good SOR parameter to achieve good performance). GMRES/ILU is somewhat more effective for convection-dominated systems, especially when there is no simple way of choosing a relaxation parameter. GMRES(5) requires $7N_b$ storage locations [23], plus approximately $9N_b$ for the factors of M. SOR requires essentially one vector of storage for the solution iterates $\{u_b^{(k)}\}$, plus storage for the factors of the block diagonal D. If no pivoting is required, these factors could overwrite the analogous locations of $A^{(b)}$.

Table 4.6 shows the performance of the block Gauss–Seidel method for solving the same set of problems using the upwind difference scheme for the first derivative terms. The main difference from the results for centered differences is that performance improves as σ or τ increases. This is because $A^{(b)}$ (as well as A) becomes more diagonally dominant in these cases. In addition, for the natural one-line ordering, performance is consistently best when the flow is in the same direction as the sweep (NE), and good performance is achieved when the sweep and flow directions make an acute angle. Similar observations apply for the natural two-line ordering, except that sweeping in the direction of flow (N) is not best when the convection terms are small. As above, the red-black orderings tend to be less sensitive than the natural orderings to flow directions.

The results above do not address the issue of accuracy of the discrete solution. If $|\sigma h/2|$ or $|\tau h/2|$ is greater than one and boundary layers are present in the continuous solution, then the discrete solution tends to be inaccurate near the boundary layers, and it is oscillatory when centered differences are used [22]. If the boundary layer can be located, then one possible remedy is to use local mesh refinement. For the solution (4.2), for nonzero σ or τ, there are boundary layers of width $O(1/\sigma)$ (or $O(1/\tau)$) near the outflow boundary. We consider one local refinement strategy, which we describe in terms of the "horizontal" parameters x and σ. In the interval of width $2/\sqrt{\sigma}$ containing the boundary layer (at either $x = 0$ or $x = 1$), we use a mesh of size $\tilde{h}$ such that $|\sigma\tilde{h}/2| = .75$; away from that interval, we use $h = 1/32$.[2] It was shown in [6] that this strategy does a good job of resolving the boundary layer with the addition

[2] Grid points are distributed from left to right within each of these subintervals, so that the rightmost mesh width of either interval may differ from h and $\tilde{h}$.

of a relatively small number of additional mesh points. For example, in the present set of experiments, when $\sigma = 100$ there are 25 coarse grid points and 14 fine grid points in the horizontal direction; when $\sigma = 1000$, there are 29 coarse and 43 fine grid points. (The unrefined mesh contains 31 points in each direction.) Table 4.7 shows the performance of the Gauss–Seidel and GMRES/ILU methods for four problems where mesh refinement is used, for the natural one-line ordering. Comparison with Table 4.1 shows that the behavior of the two iterative methods is essentially the same as that for uniform meshes. Similar conclusions apply for the three other ordering strategies. Thus, we conclude that the behavior on uniform meshes is indicative of behavior where mesh refinement is used to resolve boundary layers. (Experiments with the Gauss–Seidel method for $|\sigma| = |\tau| = 1000$ were not performed because of storage constraints in our implementation.)

5. Experimental results: Separable variable coefficient problems. In this section, we examine the use of Corollary 2 to derive bounds on $\rho(D^{-1}C)$ when $A^{(b)}$ comes from a separable operator. We consider three model problems taken from [3]. Other experiments with these problems are described in [7].

PROBLEM 5.1.

$$\begin{aligned} -\Delta u + \frac{\sigma}{2}\left(1+x^2\right) u_x + \tau u_y &= 0 \quad \text{on } \Omega = (0,1)\times(0,1) \\ u &= 0 \quad \text{on } \partial\Omega. \end{aligned}$$

Discretization by centered differences gives, after scaling by h^2,

$$\begin{aligned} a_i^{(x)} &= \alpha^{(x)} = a_j^{(y)} = \alpha^{(y)} = 2, \\ c_{i+1}d_i &= \left(1 + \frac{\sigma h}{4}(1+x_{i+1}^2)\right)\left(1 - \frac{\sigma h}{4}(1+x_i^2)\right) \\ &\le 1 - \frac{1}{4}\left(\frac{\sigma h}{2}\right)^2 + \sigma h^2 = \xi, \\ b_{j+1}e_j &= 1 - \left(\frac{\tau h}{2}\right)^2 = \eta. \end{aligned} \tag{5.1}$$

For $\sigma \ge 0$ and $\tau \ge 0$, upwind discretization gives

$$\begin{aligned} a_i &= 2 + \frac{\sigma h}{2}\left(1 + x_i^2\right) \ge 2 + \frac{\sigma h}{2} = \alpha^{(x)}, \\ a_j &= 2 + \tau h = \alpha^{(y)}, \\ c_{i+1}d_i &= 1 + \frac{\sigma h}{2}\left(1 + x_{i+1}^2\right) \le 1 + \sigma h = \xi, \\ b_{j+1}e_j &= 1 + \tau h = \eta. \end{aligned}$$

TABLE 5.1

Comparison of computed spectral radii and bounds for the block Gauss–Seidel iteration matrices, for Problem 5.1 *with* $h = 1/32$.

	Centered differences				Upwind differences			
	One-line		Two-line		One-line		Two-line	
$\sigma = \tau$	Computed	Bound	Computed	Bound	Computed	Bound	Computed	Bound
20	.741	.809	.674	.731	.817	1.298	.772	1.379
40	.323	.385	.236	.275	.611	1.182	.544	1.212
60	.047	.062	.015	.018	.455	.961	.386	.985

Table 5.1 compares the bounds for $\rho(\mathcal{L}_1) = \rho(D^{-1}C)^2$ obtained from Corollary 2 with the corresponding computed values of $\rho(\mathcal{L}_1)$, for $h = 1/32$. For this problem, as well as the others considered below, we examine several choices of σ and τ where for the largest such choice, $\max_{x_i} |r(x_i)h/2|$ and $\max_{y_j} |s(y_j)h/2|$ are both close to one.

PROBLEM 5.2.

$$\begin{aligned} -\Delta u + \sigma x^2 u_x &= 0 \quad \text{on } \Omega = (0,1) \times (0,1), \\ u &= 0 \quad \text{on } \partial\Omega. \end{aligned}$$

Centered difference discretization gives

$$\begin{aligned} a_i^{(x)} &= \alpha^{(x)} = a_j^{(y)} = \alpha^{(y)} = 2, \\ c_{i+1}d_i &= \left(1 + \frac{\sigma h}{2} x_{i+1}^2\right)\left(1 - \frac{\sigma h}{2} x_i^2\right) \le 1 + \frac{\sigma h^2}{2} - \frac{\sigma^2 h^4}{2} = \xi, \\ b_{j+1}e_j &= 1 = \eta. \end{aligned}$$

Upwind difference discretization gives

$$\begin{aligned} a_i &= 2 + \sigma x_i^2 h \ge 2 + \sigma h^3 = \alpha^{(x)}, \\ a_j &= 2 = \alpha^{(y)}, \\ c_{i+1}d_i &= 1 + \sigma x_{i+1}^2 h \le 1 + \sigma h = \xi, \\ b_{j+1}e_j &= 1 = \eta. \end{aligned}$$

Table 5.2 compares bounds for $\rho(\mathcal{L}_1)$ with corresponding computed values for Problem 5.2. An entry "–" means that the analysis is not applicable because (3.11) is not satisfied.

TABLE 5.2

Comparison of computed spectral radii and bounds for the block Gauss–Seidel iteration matrices, for Problem 5.2 *with* $h = 1/32$.

	Centered differences				Upwind differences			
	One-line		Two-line		One-line		Two-line	
$\sigma = \tau$	Computed	Bound	Computed	Bound	Computed	Bound	Computed	Bound
20	.963	1.014	.951	.987	.964	3.077	.951	6.630
40	.953	1.033	.939	1.011	.955	10.37	.939	–
60	.945	1.051	.928	1.035	.947	56.22	.928	–

PROBLEM 5.3.

$$\begin{aligned} -\Delta u + \sigma(1 - 2x)u_x + \tau(1 - 2y)u_y &= 0 \quad \text{on } \Omega = (0,1) \times (0,1), \\ u &= 0 \quad \text{on } \partial\Omega. \end{aligned}$$

Centered difference discretization gives

$$\begin{aligned}
a_i^{(x)} &= \alpha^{(x)} = a_j^{(y)} = \alpha^{(y)} = 2, \\
c_{i+1}d_i &= \left(1 + \frac{\sigma h}{2}(1 - 2x_{i+1})\right)\left(1 - \frac{\sigma h}{2}(1 - 2x_i)\right) \\
&= 1 - 2h\left(\frac{\sigma h}{2}\right) - \left(\frac{\sigma h}{2}\right)^2 (1 - 2x_i)(1 - 2x_{i+1}) \\
&\leq 1 - \sigma h^2 + \left(\frac{\sigma h}{2}\right)^2 (2h^3 - h^4) = \xi, \\
b_{j+1}e_j &= \left(1 + \frac{\tau h}{2}(1 - 2y_{j+1})\right)\left(1 - \frac{\tau h}{2}(1 - 2y_j)\right) \\
&\leq 1 - \tau h^2 + \left(\frac{\tau h}{2}\right)^2 (2h^3 - h^4) = \eta.
\end{aligned}$$

For $\sigma \geq 0$ and $\tau \geq 0$, upwind discretization gives

$$\begin{aligned}
a_i &= 2 + \sigma|1 - 2x_i|h \geq 2 = \alpha^{(x)}, \\
a_j &= 2 + \tau|1 - 2y_j|h \geq 2 = \alpha^{(y)}, \\
c_{i+1}d_i &= 1 + \sigma|1 - 2x_{i+1}|h \leq 1 + \sigma h = \xi, \\
b_{j+1}e_j &= 1 + \tau|1 - 2y_{j+1}|h \leq 1 + \tau h = \eta.
\end{aligned}$$

Table 5.3 compares bounds and computed values of $\rho(\mathcal{L}_1)$ for Problem 5.3; the entry "–" indicates that either (3.9) or (3.11) is not satisfied.

TABLE 5.3
Comparison of computed spectral radii and bounds for the block Gauss–Seidel iteration matrices, for Problem 5.3 with $h = 1/32$.

	Centered differences				Upwind differences			
	One-line		Two-line		One-line		Two-line	
$\sigma = \tau$	Computed	Bound	Computed	Bound	Computed	Bound	Computed	Bound
20	.854	.921	.813	.869	.871	3.611	.833	6.986
40	.733	.852	.669	.785	.780	–	.723	–
60	.629	.788	.553	.710	.703	–	.634	–

To understand these results, it is useful to recall the constant coefficient problem (4.1). For that problem, the parameters associated with centered differences are given by (4.3). As shown in [7], [8], if both $\sigma h/2 < 1$ and $\tau h/2 < 1$, then the bounds from Corollary 2 essentially have the form $1 - O(\sigma^2 h^2) - O(\tau^2 h^2)$. In particular, if either $\sigma h/2$ or $\tau h/2$ are near 1, then ξ or η are close to 0, and the bounds from Corollary 2 are very small. For Problem 5.1, $r(x)$ (the coefficient of u_x) is bounded below away from 0, so that for large σ, the contribution $hr(x_i)/2$ cannot be small for any x_i. Consequently, the bounding value ξ is qualitatively like its constant coefficient counterpart (compare (5.1) and (4.3)). Moreover, $\alpha^{(x)}$, $\alpha^{(y)}$ and η have the same values as in the constant coefficient case. (This is true for $\alpha^{(x)}$ and $\alpha^{(y)}$ with all three problems considered here.) Thus, the bounds from Corollary 2 behave like their constant coefficient analogues. For Problem 5.2, the upper bound ξ corresponds to a value for $x_i(= h)$ for which the differential operator is locally nearly selfadjoint; the resulting bounds typically do not even guarantee convergence, and they are larger than what would be obtained in the selfadjoint case. For Problem 5.3, $\xi = 1 - O(\sigma h^2)$ and $\eta = 1 - O(\sigma h^2)$, which lead to asymptotic bounds of the form $1 - O(\sigma h^2) - O(\tau h^2)$; these are larger than those occurring for Problem 5.1 but smaller than for Problem 5.2. Note that for all three problems, the bounding values are qualitatively similar to the behavior of $\mathcal{L}_1$.

The parameters for upwind differences applied to the constant coefficient problem are

$$a_i^{(x)} = \alpha^{(x)} = 2 + \sigma h, \quad a_j^{(y)} = \alpha^{(y)} = 2 + \tau h, \quad \xi = 1 + \sigma h, \quad \eta = 1 + \tau h.$$

In this case, the bounds on $\rho(D^{-1}C)$ from Corollary 2 are less than one, and they decrease with increasing σ or τ (see [7], [8]). However, the extra inequalities required to define $\alpha^{(x)}$ and $\alpha^{(y)}$ decrease the size of the denominators in (3.10) and (3.12) and limit the usefulness of the corollary. For Problem 5.1, σh is replaced by $\sigma h/2$ in $\alpha^{(x)}$, and the bounds on $\rho(D^{-1}C)$ are less than one only when σh is large. The bounds for Problems 5.2 and 5.3, where they are defined, do not provide any useful information.

6. Experimental results: Nonseparable variable coefficient problems. We now examine the performance of the iterative methods for solving some nonseparable problems. Our goals are to examine the effectiveness of the block Gauss–Seidel and SOR methods, and ILU-preconditioned GMRES, for solving such problems; and to determine whether the analytic results of [7], [8], and §3 are of use in predicting behavior.

The following problem, from [19], models the circular flow of a cold fluid with a hot wall at the right boundary.

PROBLEM 6.1.

$$\begin{aligned} -\epsilon\Delta u + 2y(1-x^2)u_x - 2x(1-y^2)u_y &= 0 && \text{on } \Omega = (-1,1)\times(0,1),\\ u &= 0 && \text{on } 0 \le y \le 1, x = -1,\\ u &= 100 && \text{on } 0 \le y \le 1, x = 1,\\ u &= 0 && \text{on } -1 \le x < 0, y = 0,\\ u_n &= 0 && \text{on } 0 \le x \le 1, y = 0,\\ u &= 0 && \text{on } -1 \le x \le 1, y = 1. \end{aligned}$$

The velocity vectors have turning points in the vertical component, and their magnitudes vary throughout the domain of definition. The solution contains a boundary layer at $x = 1$. Figure 6.1 shows the boundary conditions and streamlines, and the general shape of the solution, for $\epsilon = 1/100$.[3] A related problem, differing from Problem 6.1 only in the boundary conditions, was also considered in [9]; experimental results were qualitatively similar to those presented below.

As above, we consider both centered difference and upwind difference discretizations. At the outflow boundary $x \ge 0$, $y = 0$, we used first order upwind differences

$$0 = u_n(x_i, 0) = u_y(x_i, y_0) \approx \frac{u(x_i, y_1) - u(x_i, y_0)}{h},$$

i.e., $u(x_i, 0) = u(x_i, y_1)$. For the centered difference scheme, we consider both a square 31×31 mesh, and a uniform mesh of width $h = 1/32$. The first choice

[3] The discrete solution was computed using centered differences with 31 interior grid points in each direction; the figure includes the exact solution values at $x = \pm 1$ and $y = 1$, but not at $y = 0$.

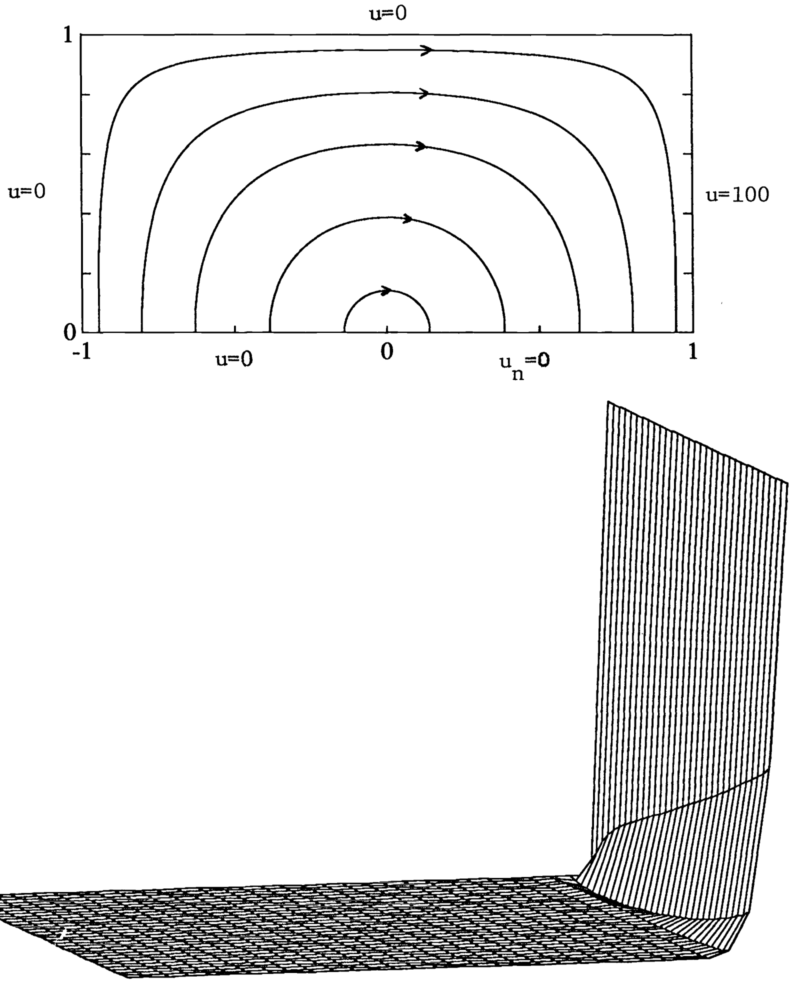

FIG. 6.1. *Boundary conditions and solution for Problem* 6.1.

produces matrices with the same algebraic structure as those considered in §§4–5, but the horizontal mesh width is twice that of the vertical width; the second choice leads to lines of different length in the grid. We also consider a strategy for improving the accuracy of the solution, based on defect correction methods. For all tests, the initial guesses and stopping criteria are as in §4.

Table 6.1 shows average iteration counts for solving the reduced system derived when centered differences are applied on a square 31 × 31 grid. Here, the grid sizes for the full system are uniform in each of the x and y coordinates, with $h_x = 1/16$ and $h_y = 1/32$. As in the constant coefficient case (§4), block relaxation is most effective for intermediate values of ϵ^{-1}, where it is competitive with GMRES/ILU. The latter method is more effective when ϵ^{-1} is either small or large. The performance of the stationary methods is fairly insensitive to the choice of ordering. This is consistent with the fact that, because of variable directions of flow, there is no clear correspondence between lines and flow direction. On the other hand, as in §4, the performance of GMRES/ILU is typically better with the natural orderings than with the red-black orderings. We remark that in a few experiments with Orthomin [5], we

Table 6.2 shows iteration counts for solving the reduced system derived from an underlying uniform mesh of width $h = 1/32$, for block Gauss–Seidel and GMRES/ILU, with the two natural line orderings. The lines are oriented as in Fig. 2.2. These results are similar to those of Table 6.1, except that GMRES/ILU has trouble with one problem class ($\epsilon = 1/1000$ with the natural one-line ordering). In this case, the iteration "stagnates," in the sense that the residual norm $\|g^{(b)} - A^{(b)}u_i^{(b)}\|_2$ remains constant over many iterations.[4] In contrast, whenever the block relaxation methods fail to meet the stopping criterion, they appear to be converging.

TABLE 6.3

Table 6.3 shows average iteration counts for solving the reduced system derived when upwind differences are applied to Problem 6.1. Note that the mesh points used

[4] Stagnation of this type also occurs for GMRES(10) and GMRES(15).

for discretization depend on the direction of flow (see §2), and the reduced matrices $A^{(b)}$ are always diagonally dominant. The results of Table 6.3 (for the stationary methods) are consistent with those for constant coefficient problems.

A methodology for improving accuracy that does not require a priori knowledge about the solution is the class of defect correction methods. A description of this approach can be found in [12], which contains several other references. For the operator $L_\epsilon u \equiv -\epsilon\Delta u + ru_x + su_y$, let $A_{\epsilon,h}$ denote the matrix associated with the (second order) centered difference discretization on a uniform mesh of width h. For $\hat{\epsilon} > \epsilon$, let $A_{\hat{\epsilon},h}$ denote the analogous matrix derived from $L_{\hat{\epsilon}}$. In its simplest form, the defect correction iteration consists of the following steps, where f is the discrete right-hand side.

```
Solve $A_{\hat{\epsilon},h}u^{(m)} = f$.
For $m = 0, 1, \cdots$, Do
    $r^{(m)} = f - A_{\epsilon,h}u^{(m)}$
    Solve $A_{\hat{\epsilon},h}d^{(m)} = r^{(m)}$
    $u^{(m+1)} = u^{(m)} + d^{(m)}$
End
```

The idea is to compensate for instabilities associated with high order operators using lower order operators. For the choice $\hat{\epsilon} = \epsilon + ch$ where $c > 0$ is a fixed constant, $A_{\hat{\epsilon},h}$ is a first order discretization. At every step of the iteration, $A_{\epsilon,h}$ is used only to calculate the residual, and a linear system with coefficient matrix $A_{\hat{\epsilon},h}$ must be solved. Thus, the cost of this method is highly dependent on the cost of solving the linear system.

Any $c > 0$ prevents the convection terms from dominating the discrete problem, for arbitrarily small ϵ. For $c \geq \max\{|r(x,y)|/2, |s(x,y)|/2\}$, $A_{\hat{\epsilon},h}$ and the resulting reduced matrix $A^{(b)}_{\hat{\epsilon},h}$ are diagonally dominant M-matrices. For Problem 6.1, this gives $c = 1$. However, Hemker [15] has observed that (using a variant of the algorithm above) better accuracy is obtained with smaller c. Following [15], we use $c = \frac{1}{2}$. The differential operator $L_{\hat{\epsilon}}$ for Problem 6.1 is then equivalent to

$$-\Delta u + \frac{2y(1-x^2)}{\epsilon + h/2}u_x - \frac{2x(1-y^2)}{\epsilon + h/2}u_y.$$

We refer to the discretization of this operator by centered difference as the "defect correction discretization." Table 6.4 shows the performance of the various iterative methods for solving the resulting reduced linear systems. (See [15] for a discussion of the overall iteration.) These results are qualitatively similar to performance for upwind differences.

7. Concluding remarks. In this paper, we have continued the study of line iterative methods for solving reduced systems begun in [7], [8]. We have extended the analysis in two ways. First, for matrices that arise from variable coefficient separable differential operators, we derived conditions under which the reduced matrices can be symmetrized via diagonal similarity transformations; previous results applied only to constant coefficient problems. Symmetrization is the key to the analysis of convergence behavior for the constant coefficient case. In the present analysis, it determines conditions under which the classical analysis of SOR applies, from which the optimal SOR parameter can be expressed as a simple function of the maximum eigenvalue of the line Jacobi iteration matrix, and it leads to some analytic bounds on performance for separable problems. In addition, we used regular splitting results to show that the

TABLE 6.4

analysis of line Jacobi splittings can be extended to splittings based on incomplete LU factorizations, for various line orderings of the reduced grid. The results help explain the good performance of IC preconditioners applied to the nonsymmetric matrix problems arising from the convection-diffusion equation.

We have also performed an extensive set of numerical experiments that examine the effects of direction of flow, discretization, and grid ordering on performance of the line iterative methods. For constant coefficient problems, the results reveal correlations between relaxation sweep direction and direction of flow that are not displayed by any analytic results. They also show that for block relaxation methods, red-black orderings are less sensitive to flow directions than natural orderings, whereas for IC-preconditioned GMRES, convergence is faster for natural orderings than for red-black orderings. In addition, both block relaxation and IC preconditioned GMRES are effective for many problems where the analysis does not apply. In general, IC-preconditioned GMRES is more robust than block relaxation. Finally, experimental results for problems with variable coefficients or locally refined grids are largely consistent with analysis and experiments for constant coefficients and uniform grids.

AN OPTIMAL DOMAIN DECOMPOSITION PRECONDITIONER FOR THE FINITE ELEMENT SOLUTION OF LINEAR ELASTICITY PROBLEMS*

BARRY F. SMITH†

Abstract. For linear elasticity problems the finite element method is an extremely successful method to model complicated structures. The successful implementation requires the solution of very large, sparse, positive definite linear systems of algebraic equations. A new technique for solving these systems using the preconditioned conjugate gradient method is proposed. Using ideas from both additive Schwarz methods and iterative substructuring methods, it is proven that the condition number of the resulting system does not grow as the substructures are made smaller and the mesh is refined. This result holds for two and three dimensions. Numerical experiments have been performed to demonstrate the power of this method. For linear elasticity problems in two dimensions the condition numbers are observed numerically to be less than four when using a regular mesh.

Key words. additive Schwarz methods, domain decomposition, elliptic equations, finite elements, iterative substructuring, linear elasticity, preconditioned conjugate gradient, Schur complement

1. Introduction.

We introduce a new domain decomposition method of solving the linear systems arising from the finite element discretization of coupled elliptic systems using a preconditioned conjugate gradient method. The method incorporates certain features of both additive Schwarz methods and iterative substructuring methods. We prove that for second-order, selfadjoint, uniformly elliptic systems the condition number of the resulting preconditioned linear system is bounded independently of the number of substructures and the mesh refinement. The method is highly parallelizable.

Very early, Sobolev [31] showed that the Schwarz alternating method converges for the equations of linear elasticity. More recent work using the Neumann–Dirichlet algorithm was done by Bjørstad and Hvidsten [4]. De Roeck [15] has implemented an iterative substructuring type algorithm for elasticity problems. Hughes and others have been using element-by-element preconditioning [21], [33], on large structural problems. The preconditioned problems for these latter two algorithms still can require hundreds of conjugate gradient iterations.

For the p-version finite elements Mandel has analyzed iterative substructuring type algorithms for elasticity [23], [24], [25], [26]. Other work using the p-version finite elements has been done by Babuška, Craig, Mandel, and Pitkäranta [1] and Babuška, Griebel, and Pitkäranta [2].

Much work using domain decomposition has focused on the scalar elliptic problem, including Bjørstad and Widlund [5], [6]; Bramble, Pasciak, and Schatz [7], [9], [10]; Chan and Resasco [11], [12]; Dryja [16], [17]; Dryja and Widlund [18], [19]; and Widlund [34]. The work by Matsokin and Nepomnyaschikh [27] discusses a Schwarz alternating algorithm that has some similarities to that presented in this paper.

2. The discrete problem. We consider a second order, symmetric, coercive, bilinear form $a_\Omega(u,v)$ on a bounded polyhedral (polygonal) domain Ω and, for simplicity, impose a homogeneous Dirichlet condition on $\partial\Omega$. The variational problem is then to find $u \in (H_0^1(\Omega))^q$, such that,

$$a_\Omega(u,v) = f(v), \qquad \forall v \in (H_0^1(\Omega))^q.$$

Our specific applications are various linear elasticity models, where q is from 2 to 6, cf. [14]. Our results also hold for the scalar case $q=1$.

We perform two levels of triangulations into substructures Ω_i and then triangulate the substructures into elements, and assume shape regularity and that the substructures and elements satisfy the usual rules of finite element triangulations; see, e.g., Ciarlet [13]. $V^H(\Omega) \subset (H_0^1(\Omega))^q$ and $V^h(\Omega) \subset (H_0^1(\Omega))^q$ are the spaces of continuous, piecewise linear functions, on the two triangulations, which vanish on the boundary $\partial\Omega$. We will be working only with piecewise linear finite elements but note that the theory may also hold for higher order elements.

The discrete variational problem is then of the form, find $u_h \in V^h(\Omega)$, such that,

$$a_\Omega(u_h,v_h) = f(v_h), \qquad \forall v_h \in V^h(\Omega). \tag{1}$$

This finite dimensional variational problem is turned into a linear system of equations by introducing a basis $\{\phi_i\}$ for the space V^h. We use the standard nodal basis functions in V^h. If we express the solution as $u_h = \sum x_i\phi_i$, we obtain the linear system

$$Kx = f.$$

Here x is the vector of unknowns x_i, f the vector of components $f(\phi_i)$, and K the stiffness matrix $K_{ij} = a_\Omega(\phi_i,\phi_j)$.

Using subscript notation explained below, for any block matrix

$$K = \begin{pmatrix} K_{II} & K_{IB} \\ K_{BI} & K_{BB} \end{pmatrix},$$

with K_{II} nonsingular, the Schur complement of K is given by

$$S = K_{BB} - K_{BI}K_{II}^{-1}K_{IB}.$$

This is the block that remains after the variables associated with K_{II} have been eliminated by Gaussian elimination. We give, without proof, the important lemma.

LEMMA 2.1. *If K is symmetric, positive definite and if x is partitioned in the same manner as $K, x = (x_I, x_B)^T$, then for any given x_B,*

$$x_B^T S x_B = \min_{x_I} x^T K x.$$

The minimizing extension x_I is referred to as the discrete harmonic extension. This is a direct analogy to the continuous case for the Laplacian. The discrete harmonic extension satisfies the relation $K_{II}x_I + K_{IB}x_B = 0$.

With each substructure Ω_k, we can associate the portion of the stiffness matrix K arising from the integration over that substructure,

$$K_{ij}^{(k)} = a_{\Omega_k}(\phi_i,\phi_j).$$

Similarly, the subvector of unknowns associated with this substructure is called $x^{(k)}$. Since we are working with nodal basis functions the support of ϕ_i associated with any node in the interior of a substructure lies completely in that substructure. Therefore there are no couplings between unknowns associated with the interiors of two different substructures. For each substructure, we partition the variables into those associated with a node in the interior of the substructure, $x_I^{(k)}$, and those on the boundary of the substructure, $x_B^{(k)}$. To simplify notation, we pad the subvectors $x^{(k)}$ and submatrices $K^{(k)}$ by zeros so that the following equation makes sense. This is called the subassembly process; cf. [19].

$$\begin{pmatrix} K_{II} & K_{IB} \\ K_{IB}^T & K_{BB} \end{pmatrix} \begin{pmatrix} x_I \\ x_B \end{pmatrix} = \sum_k \begin{pmatrix} K_{II}^{(k)} & K_{IB}^{(k)} \\ K_{IB}^{(k)^T} & K_{BB}^{(k)} \end{pmatrix} \begin{pmatrix} x_I^{(k)} \\ x_B^{(k)} \end{pmatrix}.$$

The Schur complement of the global stiffness matrix K is then given by

$$\begin{aligned} Sx_B &= \sum_k (K_{BB}^{(k)} - K_{IB}^{(k)^T} K_{II}^{(k)^{-1}} K_{IB}^{(k)}) x_B^{(k)} \\ &= \sum_k S^{(k)} x_B^{(k)}. \end{aligned}$$

Each of the Schur complements, $S^{(k)}$, can be formed independently and in parallel. We are now left with the still large linear system

$$Sx_B = g.$$

This system will be solved using the preconditioned conjugate gradient method. The preconditioner is constructed using the ideas developed in the theory of additive Schwarz methods.

3. Schwarz methods: An abstract framework. Suppose that we wish to solve the following finite dimensional variational problem. Find $u \in V$, such that,

$$a(u,v) = f(v), \qquad \forall v \in V. \tag{2}$$

Here $a(\cdot,\cdot)$ is a symmetric, positive definite bilinear form. For our purposes $a(\cdot,\cdot)$ will be the bilinear form induced by the matrix S. Let V_i be a set of subspaces of V so that $V = V_1 + \cdots + V_N$. With each subspace there is a corresponding projection operator P_i, which is the projection in the $a(u,v)$ inner product onto the subspace V_i, i.e.,

$$a(P_i u, w) = a(u,w) = f(w), \qquad \forall w \in V_i, \qquad P_i u \in V_i. \tag{3}$$

$P_i u$ can be determined by introducing a basis $\{\psi_j^{(i)}\}$ for V_i and expanding $P_i u$ in that basis, $P_i u = \sum_j \alpha_j^{(i)} \psi_j^{(i)}$. This results in the linear system

$$\tilde{K}^{(i)} \alpha^{(i)} = f^{(i)},$$

where $\tilde{K}_{jl}^{(i)} = a(\psi_j^{(i)}, \psi_l^{(i)})$, and $f^{(i)}$ is the vector defined by $f(\psi_j^{(i)})$.

The additive Schwarz method, see Dryja and Widlund [19], of solving (2) is to introduce an auxiliary problem

$$Pu = \sum_i P_i u = \hat{f}, \tag{4}$$

which has the same solution as (2). Since $P_i u$ can be found by (3) without knowing the solution of (2), we first compute $\hat{f}$ and then solve (4) using the conjugate gradient method.

The conjugate gradient method can be an effective method for the solution of a symmetric (in any inner product) positive definite linear system. The decrease in the energy norm of the error after m steps can be bounded by

$$2\left(\frac{\sqrt{\kappa(P)}-1}{\sqrt{\kappa(P)}+1}\right)^m,$$

where $\kappa(P)$ is the condition number of the matrix P, see, e.g., Golub and Van Loan [20].

The reason for going from problem (2) to problem (4) is that by a suitable choice of the subspaces V_i we can turn a large ill-conditioned system into a very well conditioned problem at the expense of solving many small independent linear systems. The following two lemmas allow us to develop bounds on the condition number of P.

LEMMA 3.1. *Consider the undirected graph with a node for each subspace V_i, and an edge between node i and node j if and only if $V_i \cap V_j \neq 0$. Let p be the number of colors needed to color the graph so that no two nodes connected by an edge have the same color. Then*

$$\lambda_{\max}(P) \leq p.$$

Proof. All the subspaces for a particular color are disjoint, hence their corresponding projection operators are mutually orthogonal. Therefore the sum of the projection operators of a particular color is itself a projection operator. P then consists of p of these composite projection operators each with a maximum eigenvalue of one; thus $\lambda_{\max}(P) \leq p$. □

LEMMA 3.2 ([18], [22], [28]). *Assume that for all $u \in V$, there exists a representation $u = \sum_i u_i$ with $u_i \in V_i$ such that*

$$\sum_i a(u_i, u_i) \leq C_0^2 a(u, u),$$

then

$$\lambda_{\min}(P) \geq C_0^{-2}.$$

Throughout this paper c, C, and C_0 represent generic constants independent of h and H.

Proof.

$$|u|_a^2 = \sum_i a(u, u_i) = \sum_i a(u, P_i u_i) = \sum_i a(P_i u, u_i).$$

Therefore,

$$|u|_a^2 \leq \left(\sum_i |P_i u|_a^2\right)^{1/2} \left(\sum_i |u_i|_a^2\right)^{1/2}.$$

By the assumption of the lemma and a property of projections,

$$|u|_a^2 \leq C_0^2 \sum_i |P_i u|_a^2 = C_0^2 \sum_i a(P_i u, u) = C_0^2 a(Pu, u). \qquad □$$

4. The new algorithm. The variational problem we are solving, after the unknowns in the interior of the substructures have been eliminated, is to find $\tilde{u}_h \in \tilde{V}^h$, such that,

$$a_\Omega(\tilde{v}_h, \tilde{u}_h) = f(\tilde{v}_h), \qquad \forall\, \tilde{v}_h \in \tilde{V}^h,$$

where $\tilde{V}^h$ is the subspace of V^h of discrete harmonic functions. The matrix formulation of the problem is to find x_B, such that,

$$y_B^T S x_B = y_B^T g, \qquad \forall y_B.$$

The vectors y_B and x_B are, as in §2, the coefficients of the finite element functions restricted to Γ.

For our algorithm we use the following subspaces: a global coarse space, and spaces associated with overlapping regions of Γ. We can regard the boundaries of the substructures as consisting of three pieces: the substructure vertices, the edges between substructure vertices, and the faces of the substructures. In two dimensions there are no faces, only vertices and edges. To obtain the overlapping regions for the Schwarz method we introduce the faces Γ^{F_i}. We choose Γ^{E_j} to be regions consisting of an edge and an overlap onto the adjacent faces to a distance of order H from the edge. The Γ^{V_k} are regions consisting of a vertex and an overlap onto all adjacent faces and edges to a distance of order H from the vertex. We constrain the overlap so that no portion of Γ is covered more than four times.

The subspaces of $\tilde{V}^h$ are given by,

$$V^H,$$

$$\tilde{V}^h_{F_i} = \{\phi \in \tilde{V}^h : \mathrm{supp}(\phi|_\Gamma) \subseteq \Gamma^{F_i}\},$$

$$\tilde{V}^h_{E_i} = \{\phi \in \tilde{V}^h : \mathrm{supp}(\phi|_\Gamma) \subseteq \Gamma^{E_i}\},$$

and

$$\tilde{V}^h_{V_i} = \{\phi \in \tilde{V}^h : \mathrm{supp}(\phi|_\Gamma) \subseteq \Gamma^{V_i}\}.$$

It is easy to see that each of these spaces is a subspace of $\tilde{V}^h$ and that

$$\tilde{V}^h = \left(\sum_i \tilde{V}^h_{F_i}\right) + \left(\sum_j \tilde{V}^h_{E_j}\right) + \left(\sum_k \tilde{V}^h_{V_k}\right).$$

The matrix projection onto the coefficients of each "face" subspace is given by

$$P_{F_i} = R^T_{F_i} S^{-1}_{F_i} R_{F_i} S,$$

where R_{F_i} is the restriction operator that returns only those coefficients associated with Γ^{F_i}, and S_{F_i} is the principal minor of the Schur complement S that is associated with that same set of coefficients. Note that P_{F_i} is a matrix projection acting on the coefficient vector x_B. Corresponding to each P_{F_i} is a projection in the space $\tilde{V}^h$. The projections onto "edge" and "vertex" subspaces are formed in the same manner.

Naturally the restriction operators R need never be explicitly represented, instead we would use something like hardware scatter-gather.

For the coarse space V^H, the projection operator is

$$P_H = R_H^T S_H^{-1} R_H S.$$

The operator R_H^T maps the coefficients of V^H to the coefficients of $\tilde{V}^h$ and represents linear interpolation from V^H to $\tilde{V}^h$. S_H is defined as $R_H S R_H^T$. This results in P_H being a projection matrix in the S inner product. The matrix $R_H S R_H^T$ may be regarded as a submatrix of the Schur complement after a partial change to hierarchical basis has been made, see Smith and Widlund [30]. In Smith [29] it is shown how this calculation may be made one subdomain at a time.

The preconditioned problem, corresponding to the abstract theory in §2, is given by

$$Px_B = \hat{S}^{-1} S x_B = \hat{S}^{-1} g.$$

The explicit form of the preconditioner is given by

$$\hat{S}^{-1} = R_H^T S_H^{-1} R_H + \sum_i R_{F_i}^T S_{F_i}^{-1} R_{F_i} + \sum_j R_{E_j}^T S_{E_j}^{-1} R_{E_j} + \sum_k R_{V_k}^T S_{V_k}^{-1} R_{V_k}.$$

We now present a detailed description of the algorithm. We note that many opportunities exist for parallelism between and within each step. Naturally, in each step we would take advantage of the band and sparse structures of the matrices.

Iterative substructuring/additive Schwarz algorithm

1. Form the stiffness matrices

$$K^{(j)} = \begin{pmatrix} K_{II}^{(j)} & K_{IB}^{(j)} \\ K_{IB}^{(j)^T} & K_{BB}^{(j)} \end{pmatrix}$$

for each substructure by integration.
2. Factor $K_{II}^{(j)}$ for each substructure.
3. Form the Schur complements $S^{(j)} = K_{BB}^{(j)} - K_{IB}^{(j)^T} K_{II}^{(j)^{-1}} K_{IB}^{(j)}$.
4. Form and factor the coarse stiffness matrix S_H.
5. Form, by subassembly, S_{F_i}, S_{E_i}, and S_{V_i}.
6. Factor S_{F_i}, S_{E_i}, and S_{V_i}.
7. Form the right-hand sides $b^{(j)}$ for each substructure by integration.
8. Modify the right-hand sides; $b_B^{(j)} = b_B^{(j)} - K_{IB}^{(j)^T} K_{II}^{(j)^{-1}} b_I^{(j)}$.
9. Solve $Sx_B = b_B$ using a preconditioned conjugate gradient method with the preconditioner

$$\hat{S}^{-1} = R_H^T S_H^{-1} R_H + \sum_i R_{F_i}^T S_{F_i}^{-1} R_{F_i} + \sum_j R_{E_j}^T S_{E_j}^{-1} R_{E_j} + \sum_k R_{V_k}^T S_{V_k}^{-1} R_{V_k}.$$

10. Form the right-hand sides for the problems on the interiors of the subdomains

$$b_I^{(j)} = b_I^{(j)} - K_{II}^{(j)^{-1}} K_{IB}^{(j)} x_B^{(j)}.$$

11. Solve for the interior unknowns $x_I^{(j)} = K_{II}^{(j)^{-1}} b_I^{(j)}$.

Steps 1 though 6 can be regarded as a preprocessing stage independent of the particular loads; they need not be repeated for different loads.

The main result of this paper is now given in Theorem 4.1.

THEOREM 4.1. *The condition number of the preconditioned linear system is bounded independently of the size of the substructures H and the size of the elements h, i.e.,*

$$\kappa(P) = \kappa(\hat{S}^{-1}S) \leq C.$$

Proof. We note that no node on Γ is contained in more than four of the regions Γ^{F_i}, Γ^{E_j}, and Γ^{V_k}. Therefore the graph as described in Lemma 3.1 can be colored by a fixed finite number of colors. Hence by Lemma 3.1 we have $\lambda_{\max}(P) \leq C$.

We first use the coerciveness of our bilinear form $a_\Omega(u,u)$,

$$c||u||^2_{H^1(\Omega)} \leq a_\Omega(u,u) \leq C||u||^2_{H^1(\Omega)},$$

to make it possible to work in the $(H^1(\Omega))^q$ norm instead of the equivalent norm induced by $a_\Omega(u,u)$. To obtain a lower bound, we must demonstrate that for all $\tilde{u}^h \in \tilde{V}^h$, there exists a representation

$$\tilde{u}^h = \tilde{u}^H + \sum_i \tilde{u}^h_{E_i} + \sum_j \tilde{u}^h_{F_j} + \sum_k \tilde{u}^h_{V_k},$$

with $\tilde{u}^h_{F_i} \in \tilde{V}^h_{F_i}$, $\tilde{u}^h_{E_i} \in \tilde{V}^h_{E_i}$, $\tilde{u}^h_{V_i} \in \tilde{V}^h_{V_i}$, and $\tilde{u}^H \in V^H$, such that,

$$\begin{aligned}(5)\qquad ||\tilde{u}^H||^2_{H^1(\Omega)} + \textstyle\sum_i ||\tilde{u}^h_{E_i}||^2_{H^1(\Omega)} + \sum_j ||\tilde{u}^h_{F_j}||^2_{H^1(\Omega)} + \sum_k ||\tilde{u}^h_{V_k}||^2_{H^1(\Omega)} \\ \leq C_0^2||\tilde{u}^h||^2_{H^1(\Omega)},\end{aligned}$$

where C_0 is independent of $\tilde{u}^h$, h, and H.

We construct this representation as follows. We extend the boundary regions $\Gamma^{E_i}, \Gamma^{F_j}, \Gamma^{V_k}$ into the neighboring substructures. That is, define the following domains, $\Omega^{E_j} = \Gamma^{E_j} \cup_i \Omega_i$ for all Ω_i that satisfy $\bar{\Omega}_i \cap \Gamma^{E_j} \neq \emptyset$. Define similar domains for the face regions, Γ_{F_j}, and vertex regions Γ_{V_j}. This results in a large collection of overlapping domains. Now apply the result of Appendix A to each component of the vector-valued function $\tilde{u}^h$ separately to obtain a representation of $\tilde{u}^h$,

$$\tilde{u}^h = u^H + \sum_i u^h_{E_i} + \sum_j u^h_{F_j} + \sum_k u^h_{V_k},$$

which satisfies

$$||u^H||^2_{H^1(\Omega)} + \sum_i ||u^h_{E_i}||^2_{H^1(\Omega)} + \sum_j ||u^h_{F_j}||^2_{H^1(\Omega)} + \sum_k ||u^h_{V_k}||^2_{H^1(\Omega)} \leq C_0^2||\tilde{u}^h||^2_{H^1(\Omega)}.$$

The equivalence of the $H^1(\Omega)$ norm and seminorm on V^h follows from Friedrichs' inequality and allows us to apply the result in Appendix A. The continuous, piecewise linear functions $u^h_{F_j}$, $u^h_{E_j}$, $u^h_{V_j}$, and u^H are in the spaces $V^h(\Omega) \cap H^1_0(\Omega^{F_j})$, $V^h(\Omega) \cap H^1_0(\Omega^{E_j})$, $V^h(\Omega) \cap H^1_0(\Omega^{V_j})$, and V^H, respectively.

We now define our representation by taking the restrictions of these new functions to Γ and then extending them as discrete harmonic.

$$\tilde{u}^H|_\Gamma = u^H|_\Gamma, \qquad \tilde{u}^h_{F_i}|_\Gamma = u^h_{F_i}|_\Gamma,$$

$$\tilde{u}^h_{E_j}|_\Gamma = u^h_{E_j}|_\Gamma, \qquad \tilde{u}^h_{V_k}|_\Gamma = u^h_{V_k}|_\Gamma.$$

The resulting discrete harmonic, continous piecewise linear functions

$$\tilde{u}^h_{F_i}, \tilde{u}^h_{E_j}, \tilde{u}^h_{V_k}, \text{and } u^H$$

are in the spaces $\tilde{V}^h_{F_j}$, $\tilde{V}^h_{E_j}$, $\tilde{V}^h_{V_j}$, and V^H, respectively. The definition of discrete harmonic then gives us the needed bound in (5). We then apply Lemma 3.2 to conclude the proof of the theorem. □

If we exclude from the algorithm all of the overlap and the "vertex" spaces, we obtain the iterative substructuring algorithm presented in Dryja and Widlund [19]. That is, in the definition of $\hat{S}^{-1}$, we drop the terms

$$\sum_k R^T_{V_k} S^{-1}_{V_k} R_{V_k}$$

and restrict Γ_{E_j} to be the edge extended out to but not including the first nodes on the adjacent faces, i.e., this implies that the restriction operator R_{E_j} retrieves only those coefficients associated with the nodes along the edge. Previously it would also retrieve some coefficients associated with nodes on the adjacent faces. The iterative substructuring algorithm is also very similar to that introduced by Bramble, Pasciak, and Schatz [7]. In two dimensions these algorithms have condition numbers that grow like $(1 + \log(H/h))^2$. In three dimensions the condition numbers for these algorithms grow faster than (H/h) [8], [16].

The algorithm considered here is not intended for the same class of problems as the algorithm presented in Bramble, Pasciak, and Schatz [7]. It is intended for elliptic systems, generally in three dimensions, which result in extremely ill-conditioned linear systems. The construction of the preconditioner, specifically step 3 in the algorithm, is expensive. However, for this more difficult class of problems, we believe the additional expense is needed to produce a well-conditioned problem.

5. Numerical results. We have performed numerous experiments with problems in two dimensions. The problems considered are

- The Laplacian using the usual five-point stencil.
- The equations of linear elasticity using four node square membrane elements with two degrees of freedom per node; cf. [3];
- The equations of linear elasticity using four node square shell elements with three degrees of freedom per node; cf. [3].

Experiments have been performed on square and L-shaped regions; since there was no appreciable difference between the two cases, results are only given for the square regions. The substructures are squares. For the elasticity problems the stiffness matrices were generated using the SESAM code [3], a large, reliable commercial structural analysis code, using a Poisson ratio of .3.

The experiments were run twice, once using all the subspaces as indicated in the algorithm and once excluding the "vertex" spaces. That is, we drop the terms $\sum_k R^T_{V_k} S^{-1}_{V_k} R_{V_k}$ from the preconditioner $\hat{S}^{-1}$. As expected the condition number remains bounded by a constant independent of H and h when all the spaces were included. When the "vertex" spaces were excluded the condition number appears to grow like $(1 + \log(H/h))^2$, as expected.

The selection of an appropriate stopping condition for the preconditioned conjugate gradient method is crucial. A stopping criteria based only on a norm of the

residual can make comparisons between preconditioned and unpreconditioned results misleading since the eigenvalues of the two operators can be of completely different orders of magnitude. For instance, for elasticity problems the eigenvalues of the original stiffness matrices can be of order 10^{12}, while the eigenvalues of the preconditioned problems generally are of order 1. We have therefore chosen to use the stopping condition

$$||\text{residual}||_{L^2} \leq \epsilon||\text{approx. solution}||_{L^2}\lambda_{\min}(\hat{S}^{-1}S).$$

$\lambda_{\min}(\hat{S}^{-1}S)$ is calculated using the Lanczos method at very little extra expense. We have chosen to use $\epsilon = 10^{-5}$; this assures that roughly five digits of the solution are correct and not many more, regardless of the preconditioner used.

In Table 1 the experiments are conducted for the Laplacian. The overlap of the "vertex" spaces onto the "edge" spaces is chosen to be $H/4$. In Table 2, we examine the effect of varying the amount of overlap of the "vertex" spaces onto the "edge" spaces for the case with 64 substructures and 31 nodes along the edge of each substructure. We see that the overlap is very important but a small overlap has almost as much effect as a larger overlap. We give a sample of the convergence behavior in Table 3, showing the discrete L^2 norm of the error as a function of the number of iterations. This is again for the case of 64 substructures and 31 nodes along the edge of each substructure. The linear elasticity problems are considered in Tables 4–9.

A. Appendix: A partitioning result. For two or three dimensions let Ω be a polyhedral (polygonal) domain that has been triangulated into substructures that are shape regular, with diameter $O(H)$. Continue the triangulation to obtain a triangulation with elements of diameter $O(h)$. Furthermore assume that Ω has been covered with N shape regular overlapping regions Ω_i (not necessarily related to the coarse triangulation above), each with a diameter $O(H)$, each of which overlaps all its neighbors with an overlap of $O(H)$. We require that the domains Ω_i be aligned with the fine triangulation. Let $V^H(\Omega) \subset H_0^1(\Omega)$ and $V^h(\Omega) \subset H_0^1(\Omega)$ be the spaces of continuous, piecewise linear functions, on the two triangulations, which vanish on the boundary $\partial\Omega$. We then construct the following spaces

$$V_0^h = V^H, \qquad V_i^h = V^h \cap H_0^1(\Omega_i).$$

The following theorem is a variation of a result given in Dryja and Widlund [19].

THEOREM A.1. *For all $u^h \in V^h$ there exists $u_i^h \in V_i^h$ with $u^h = \sum_{i=0}^N u_i^h$ such that*

$$\sum_{i=0}^{N} |u_i^h|^2_{H^1(\Omega)} \leq C_0^2 |u^h|^2_{H^1(\Omega)},$$

where C_0 is independent of $u^h, h,$ and H.

Proof. From Strang [32], we know that there exists a linear map $\hat{I}_H : V^h \rightarrow V^H$ that satisfies

$$||u^h - \hat{I}_H u^h||^2_{L_2(\Omega)} \leq CH^2 |u^h|^2_{H^1(\Omega)} \tag{6}$$

and

$$|u^h - \hat{I}_H u^h|^2_{H^1(\Omega)} \leq C|u^h|^2_{H^1(\Omega)}. \tag{7}$$

We then define

$$u_0^h = \hat{I}_H u^h, \qquad w^h = u^h - u_0^h$$

and

$$u_i^h = I_h(\theta_i w^h).$$

I_h is the linear interpolation operator onto the space V^h, and the θ_i form a partition of unity with $\theta_i \in C_0^\infty(\Omega_i), 0 \leq \theta_i \leq 1$, and $\sum_{i=1}^N \theta_i = 1$. Since I_h is a linear operator, it is immediate that

$$u^h = \sum_{i=0}^{N} u_i^h.$$

Because of the generous overlap between subregions, we can ensure that the gradients of θ_i are well behaved. That is, θ_i can be constructed so that its gradients never grow faster than $|\nabla\theta_i|^2_{L^\infty} \leq C/H^2$. If we let K represent any single element in the triangulation, this can be expressed as

$$||\theta_i - \bar{\theta}_i||^2_{L^\infty(K)} \leq C(h/H)^2. \tag{8}$$

7	*	*	1.9×10^{-3}	.41	1.4×10^{-4}	.28
8	*	*	1.4×10^{-3}	.44	3.9×10^{-5}	.28
9	*	*	5.5×10^{-4}	.43	1.6×10^{-5}	.29
10	*	*	3.3×10^{-4}	.45	4.9×10^{-6}	.29
11	*	*	2.5×10^{-4}	.47	1.3×10^{-6}	.29
12	*	*	2.5×10^{-4}	.50	4.6×10^{-7}	.30
13	*	*	2.4×10^{-4}	.53	1.5×10^{-7}	.30

Here $\bar{\theta}_i$ is the average of θ_i on element K.

We now estimate the H^1 norm of u_i^h over a single element.

$$\begin{aligned} |u_i^h|^2_{H^1(K)} &= |I_h(\bar{\theta}_i w^h + (\theta_i - \bar{\theta}_i)w^h)|^2_{H^1(K)} \\ &\leq 2|\bar{\theta}_i w^h|^2_{H^1(K)} + 2|I_h(\theta_i - \bar{\theta}_i)w^h|^2_{H^1(K)}, \end{aligned}$$

which can be bounded using an inverse inequality by

$$|u_i^h|^2_{H^1(K)} \leq 2|\bar{\theta}_i w^h|^2_{H^1(K)} + Ch^{-2}||I_h(\theta_i - \bar{\theta}_i)w^h||^2_{L^2(K)}.$$

We now use (8) and the trivial inequality $||\bar{\theta}_i||_{L^\infty} \leq 1$ to obtain

$$|u_i^h|^2_{H^1(K)} \leq 2|w^h|^2_{H^1(K)} + CH^{-2}||w^h||^2_{L^2(K)}.$$

Since a finite bounded number of u_i^h are nonzero for any element K, we obtain, when summing over i,

$$\sum_{i=1}^{N} |u_i^h|^2_{H^1(K)} \leq C|w^h|^2_{H^1(K)} + CH^{-2}||w^h||^2_{L^2(K)}.$$

Next sum over the elements K,

$$\sum_{i=1}^{N} |u_i^h|^2_{H^1(\Omega)} \leq C|w^h|^2_{H^1(\Omega)} + CH^{-2}||w^h||^2_{L^2(\Omega)}.$$

To finish the argument, we use (6) and (7) to obtain

$$\sum_{i=0}^{N} |u_i^h|^2_{H^1(\Omega)} \leq C_0^2|u^h|^2_{H^1(\Omega)}. \qquad \square$$

Acknowledgments. I would like to thank Petter Bjørstad and Anders Hvidsten for their assistance in using the SESAM code and for many useful discussions. I would also like to thank VERITAS SESAM SYSTEMS, Høvik, Norway, for the use and access to SESAM for the generation of test stiffness matrices which were used in the numerical experiments reported in this paper.

AN UNCONVENTIONAL DOMAIN DECOMPOSITION METHOD FOR AN EFFICIENT PARALLEL SOLUTION OF LARGE-SCALE FINITE ELEMENT SYSTEMS*

CHARBEL FARHAT† AND FRANCOIS-XAVIER ROUX‡

Abstract. A domain decomposition algorithm based on a hybrid variational principle is developed for the parallel finite element solution of selfadjoint elliptic partial differential equations. The spatial domain is partitioned into a set of totally disconnected subdomains, each assigned to an individual processor. Lagrange multipliers are introduced to enforce compatibility at the interface points. Within each subdomain, the singularity due to the disconnection is resolved in a two-step procedure. First, the null space component of each local operator is eliminated from the local problem. Next, its contribution to the local solution is related to the Lagrange multipliers through an orthogonality condition. Finally, a conjugate *projected* gradient algorithm is developed for the solution of the coupled system of local null space components and Lagrange multipliers. When implemented on local memory multiprocessors, the proposed hybrid method requires fewer interprocessor communications than conventional Schur methods. It is also suitable for parallel/vector computers with shared memory. Moreover, unlike parallel direct solvers, it exhibits a degree of parallelism that is not limited by the bandwidth of the finite element system of equations. In this paper, it is applied to the solution of large-scale structural and solid mechanics problems.

1. Introduction.

In this paper, we present a parallel finite element subdomain-based computational method for the solution of selfadjoint elliptic partial differential equations. The method blends direct and iterative solution schemes. Its unique feature is that it requires fewer interprocessor communications than conventional domain decomposition algorithms, while still offering the same amount of parallelism. Roux [9], [10] has presented an early version of this work that is limited to a very special class of problems where a finite element domain can be partitioned into a set of disconnected but nonfloating (nonsingular) subdomains. Here, we generalize the method for arbitrary finite element problems and arbitrary mesh partitions.

In §2, we partition the finite element domain into a set of totally disconnected subdomains and derive a computational strategy from a hybrid variational principle where the intersubdomain continuity constraint is removed by the introduction of a Lagrange multiplier. An arbitrary mesh partition typically contains a set of floating subdomains that induce local singularities. The handling of these singularities is treated in §3. First, the null space components are eliminated in parallel from each local problem and a direct scheme is applied concurrently to all subdomains in order to recover each partial local solution. Next, the contributions of these null space components are related to the Lagrange multipliers through an orthogonality condition.

A parallel preconditioned conjugate *projected* gradient algorithm is developed in §4 for the solution of the coupled system of local zero energy modes and Lagrange multipliers, which completes the solution of the problem. Section 5 emphasizes the parallel characteristics of the proposed method and contrasts it with conventional Schur methods. Section 6 illustrates the method with the parallel solution of structural examples on the iPSC/1 hypercube. Finally, §7 concludes this paper.

2. A hybrid variational principle. For the sake of clarity, we consider first the case of two subdomains, then generalize the method for an arbitrary number of subdomains.

The variational form of the three-dimensional boundary-value problem to be solved goes as follows. Given f and h, find the function u that is a stationary point of the functional:

$$J(v) = \tfrac{1}{2}a(v,v) - (v,f) - (v,h)_\Gamma$$

where

$$\begin{aligned} a(v,w) &= \int_\Omega v_{(i,j)} c_{ijkl} w_{(k,l)}\, d\Omega \\ (v,f) &= \int_\Omega v_i f_i\, d\Omega \\ (v,h)_\Gamma &= \int_{\Gamma_h} v_i h_i\, d\Gamma. \end{aligned} \tag{2.1}$$

In the above, the indices i, j, k take the values 1 to 3, $v_{(i,j)} = (v_{i,j} + v_{j,i})/2$ and $v_{i,j}$ denotes the partial derivative of the ith component of v with respect to the jth spatial variable, c_{ijkl} are tensorial coefficients defining a symmetric positive definite operator, Ω denotes the volume of the body, Γ its piecewise smooth boundary, and Γ_h the piece of Γ where the functions h_i are prescribed.

If Ω is subdivided into two regions Ω_1 and Ω_2 (Fig. 1), solving the above problem is equivalent to finding the two functions u_1 and u_2 that are stationary points of the functionals:

$$\begin{aligned} J_1(v_1) &= \tfrac{1}{2}a(v_1,v_1)_{\Omega_1} - (v_1,f)_{\Omega_1} - (v_1,h)_{\Gamma_1} \\ J_2(v_2) &= \tfrac{1}{2}a(v_2,v_2)_{\Omega_2} - (v_2,f)_{\Omega_2} - (v_2,h)_{\Gamma_2} \end{aligned}$$

where

$$\begin{aligned} a(v_1,w_1)_{\Omega_1} &= \int_{\Omega_1} v_{1(i,j)} c_{ijkl} w_{1(k,l)}\, d\Omega \\ a(v_2,w_2)_{\Omega_2} &= \int_{\Omega_2} v_{2(i,j)} c_{ijkl} w_{2(k,l)}\, d\Omega \\ (v_1,f)_{\Omega_1} &= \int_{\Omega_1} v_{1i} f_i\, d\Omega \\ (v_2,f)_{\Omega_2} &= \int_{\Omega_2} v_{2i} f_i\, d\Omega \\ (v_1,h)_{\Gamma_1} &= \int_{\Gamma_{h1}} v_{1i} h_i\, d\Gamma \\ (v_2,h)_{\Gamma_2} &= \int_{\Gamma_{h2}} v_{2i} h_i\, d\Gamma \end{aligned} \tag{2.2}$$

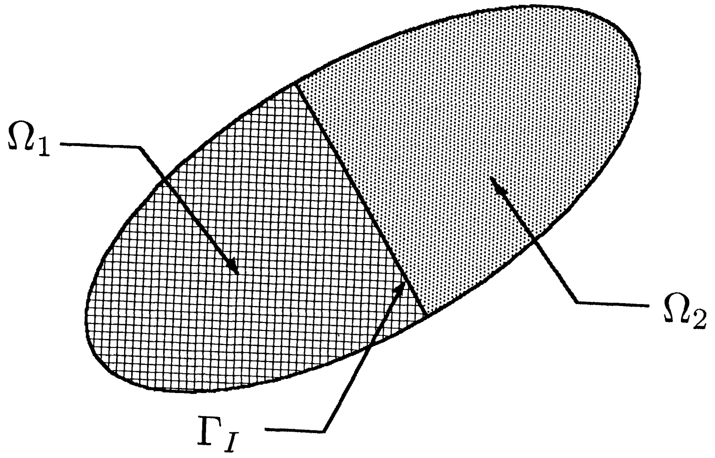

FIG. 1. *A two-subdomain decomposition.*

and that satisfy on the interface boundary Γ_I the continuity constraint:

$$u_1 = u_2 \quad \text{on } \Gamma_I. \tag{2.3}$$

Solving the two above variational problems (2.2) with the subsidiary continuity condition (2.3) is equivalent to finding the saddle point of the Lagrangian:

$$\begin{aligned} J^*(v_1, v_2, \mu) &= J_1(v_1) + J_2(v_1) + (v_1 - v_2, \mu)_{\Gamma_I}, \quad \text{where} \\ (v_1 - v_2, \mu)_{\Gamma_I} &= \int_{\Gamma_I} \mu(v_1 - v_2)\, d\Gamma, \end{aligned} \tag{2.4}$$

that is, finding the two displacement fields u_1 and u_2 and the Lagrange multiplier λ that satisfy

$$J^*(u_1, u_2, \mu) \leq J^*(u_1, u_2, \lambda) \leq J^*(v_1, v_2, \lambda) \tag{2.5}$$

for any admissible v_1, v_2, and μ. Clearly, the left inequality in (2.5) implies that $(u_1 - u_2, \mu)_{\Gamma_I} \leq (u_1 - u_2, \lambda)_{\Gamma_I}$, which imposes that $(u_1 - u_2, \mu)_{\Gamma_I} = 0$ for any admissible μ and therefore $u_1 = u_2$ on Γ_I. The right inequality in (2.5) imposes that $J_1(u_1) + J_2(u_2) \leq J_1(v_1) + J_2(v_2)$ for any pair of admissible functions (v_1, v_2). This implies that among all admissible pairs (v_1, v_2) that satisfy the continuity condition (2.3), the pair (u_1, u_2) minimizes the sum of the functionals J_1 and J_2 defined, respectively, on Ω_1 and Ω_2. Therefore, u_1 and u_2 are the restriction of the solution u of the nonpartitioned problem (2.1) to, respectively, Ω_1 and Ω_2. Indeed, (2.4) and (2.5) correspond to a hybrid variational principle where the intersubdomain continuity constraint (2.3) is removed by the introduction of a Lagrange multiplier (see, for example, Pian [8]).

If now the functions u_1 and u_2 are expressed by suitable shape functions as:

$$u_1 = \mathbf{Nu}_1 \quad \text{and} \quad u_2 = \mathbf{Nu}_2$$

and the continuity equation is enforced for the discrete problem, a standard Galerkin procedure transforms the hybrid variational principle (2.4) in the following algebraic system:

$$\begin{aligned} \mathbf{K}_1\mathbf{u}_1 &= \mathbf{f}_1 + \mathbf{B}_1^T\boldsymbol{\lambda} \\ \mathbf{K}_2\mathbf{u}_2 &= \mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda} \\ \mathbf{B}_1\mathbf{u}_1 &= \mathbf{B}_2\mathbf{u}_2 \end{aligned} \tag{2.6}$$

where $\mathbf{K}_j$, $\mathbf{u}_j$, and $\mathbf{f}_j$, $j = 1, 2$, are, respectively, the generalized stiffness symmetric matrix, the generalized displacement vector, and the prescribed generalized force vector associated with the finite element discretization of Ω_j. The vector of Lagrange multipliers $\boldsymbol{\lambda}$ represents the generalized interaction forces between the two subdomains Ω_1 and Ω_2 along their common boundary Γ_I. Within each subdomain Ω_j, we denote the number of interior nodal unknowns by n_j^s and the number of interface nodal unknowns by n_j^I. The total number of interface nodal unknowns is denoted by n_I. Note that $n_I = n_1^I = n_2^I$ in the particular case of two subdomains. If the interior degrees of freedom are numbered first and the interface ones are numbered last, each of the two connectivity matrices $\mathbf{B}_1$ and $\mathbf{B}_2$ takes the form

$$\mathbf{B}_j = [\,\mathbf{O}_j \quad \mathbf{I}_j\,], \qquad j = 1, 2,$$

where $\mathbf{O}_j$ is an $n_j^I \times n_j^s$ null matrix and $\mathbf{I}_j$ is the $n_j^I \times n_j^I$ identity matrix. The vector of Lagrange multipliers $\boldsymbol{\lambda}$ is n_I long.

If both $\mathbf{K}_1$ and $\mathbf{K}_2$ are nonsingular, (2.6) can be written as

$$\begin{aligned} (\mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{B}_1^T + \mathbf{B}_2\mathbf{K}_2^{-1}\mathbf{B}_2^T)\boldsymbol{\lambda} &= \mathbf{B}_2\mathbf{K}_2^{-1}\mathbf{f}_2 - \mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1 \\ \mathbf{u}_1 &= \mathbf{K}_1^{-1}(\mathbf{f}_1 + \mathbf{B}_1^T\boldsymbol{\lambda}) \\ \mathbf{u}_2 &= \mathbf{K}_2^{-1}(\mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda}) \end{aligned} \tag{2.7}$$

and the solution of (2.6) is obtained by solving the first of equations (2.7) for the Lagrange multipliers $\boldsymbol{\lambda}$, then substituting these in the second of (2.7) and backsolving for $\mathbf{u}_1$ and $\mathbf{u}_2$.

For an arbitrary number of subdomains Ω_j, the method goes as follows. First, the finite element mesh is decomposed into a set of totally disconnected meshes (Fig. 2). For each submesh, the matrix $\mathbf{K}_j$ and the vector $\mathbf{f}_j$ are formed. If a_j and N_s denote, respectively, the number of subdomains Ω_k that are adjacent to Ω_j and the total number of subdomains, the finite element variational interpretation of the saddle-point problem (2.4) generates the following algebraic system:

$$\begin{aligned} \mathbf{K}_j\mathbf{u}_j &= \mathbf{f}_j + \sum_{k=1}^{k=a_j} \mathbf{B}_{jk}{}^T\boldsymbol{\lambda} \qquad j = 1, N_s \\ \mathbf{B}_{jk}\mathbf{u}_j &= \mathbf{B}_{kj}\mathbf{u}_k \qquad\qquad\quad j = 1, N_s \text{ and } \Omega_k \text{ connected to } \Omega_j \end{aligned} \tag{2.8}$$

where $\mathbf{B}_{jk}$ is a boolean matrix that interconnects Ω_j with its neighbors Ω_k. In general, $\mathbf{B}_{jk}$ is $n_I \times (n_j^s + n_j^I)$ and has the following pattern:

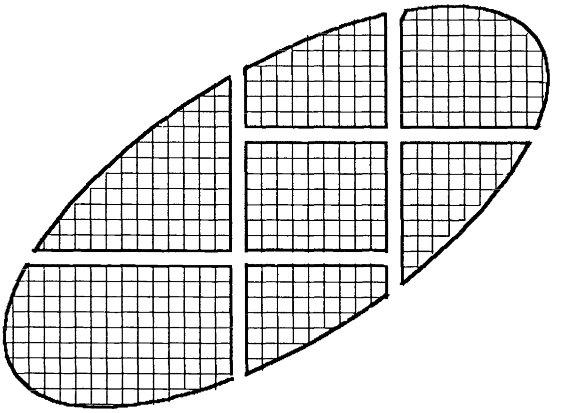

FIG. 2. *A multiple subdomain decomposition.*

$$\mathbf{B}_{jk} = \begin{bmatrix} \mathbf{O}_1(j,k) \\ \mathbf{C}_{jk} \\ \mathbf{O}_2(j,k) \end{bmatrix}$$

where $\mathbf{O}_1(j,k)$ is an $m_1(j,k) \times (n_j^s + n_j^I)$ zero matrix, $\mathbf{O}_2(j,k)$ is another $m_2(j,k) \times (n_j^s + n_j^I)$ zero matrix and $\mathbf{C}_{jk}$ is an $m_c(j,k) \times (n_j^s + n_j^I)$ connectivity matrix, $m_c(j,k)$ is the number of Lagrange multipliers that interconnect Ω_j with its neighbor Ω_k, and $m_1(j,k)$ and $m_2(j,k)$ are two nonnegative integers that satisfy $m_1(j,k) + m_c(j,k) + m_2(j,k) = n_I$. The connectivity matrix $\mathbf{C}_{jk}$ can be written as

$$\mathbf{C}_{jk} = \mathbf{O}_3(j,k) \quad \mathbf{I}_{jk} \quad \mathbf{O}_4(j,k)$$

where $\mathbf{O}_3(j,k)$ is an $m_c(j,k) \times m_3(j,k)$ zero matrix, $\mathbf{I}_{jk}$ is the $m_c(j,k) \times m_c(j,k)$ identity matrix, $\mathbf{O}_4(j,k)$ is another $m_c(j,k) \times m_4(j,k)$ zero matrix, and $m_3(j,k)$ and $m_4(j,k)$ are two nonnegative integers that verify $m_3(j,k) + m_c(j,k) + m_4(j,k) = n_j^s + n_j^I$.

If $\mathbf{K}_j$ is nonsingular for all $j = 1, N_s$, the solution procedure (2.7) can be extended to the case of an arbitrary number of subdomains. However, the finite element tearing process described in this section may produce some "floating" subdomains Ω_f that are characterized by a singular matrix $\mathbf{K}_f$. When this happens, the above solution algorithm (2.7) breaks down and a special computational strategy is required to handle the local singularities.

At this point, we note that the utility of Lagrange multipliers specifically for domain decomposition has also been previously recognized by other investigators (Dihn, Glowinski, and Periaux [2]; Dorr [3]).

3. Removing local singularities.

Again, we focus on the two-subdomain decomposition. The extrapolation to $N_s > 2$ is straightforward. For example, consider the elastostatic problem and suppose that Ω corresponds to a cantilever beam and that Ω_1 and Ω_2 are the result of a vertical partitioning (Fig. 3).

In this case, $\mathbf{K}_1$ is positive definite and $\mathbf{K}_2$ is positive semidefinite, since no boundary condition is specified over Ω_2. Therefore, the second of equations (2.6)

$$\mathbf{K}_2\mathbf{u}_2 = \mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda} \tag{3.1}$$

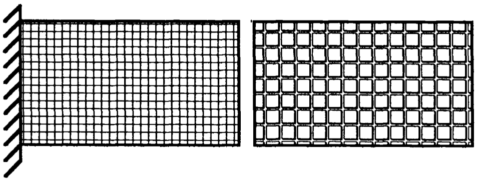

FIG. 3. *Decomposition resulting in a singular subdomain.*

requires special attention. If the singular system (3.1) is consistent, a generalized inverse of $\mathbf{K}_2$ can be found, that is, a matrix $\mathbf{K}_2^+$ that verifies $\mathbf{K}_2\mathbf{K}_2^+\mathbf{K}_2 = \mathbf{K}_2$, and the general solution of (3.1) is given by

$$\mathbf{u}_2 = \mathbf{K}_2^+(\mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda}) + \mathbf{R}_2\boldsymbol{\alpha} \tag{3.2}$$

where $\mathbf{R}_2$ is an $(n_2^s + n_2^I) \times n_2^r$ rectangular matrix whose columns form a basis of the null space of $\mathbf{K}_2$, and $\boldsymbol{\alpha}$ is a vector of length n_2^r. Physically, $\mathbf{R}_2$ represents the rigid body modes (zero energy modes) of Ω_2 and $\boldsymbol{\alpha}$ specifies a linear combination of these. Consequently, we have $n_2^r \leq 6$ for three-dimensional problems, and $n_2^r \leq 3$ for two-dimensional problems. Substituting (3.2) into (2.7) leads to

$$\begin{aligned}(\mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{B}_1^T + \mathbf{B}_2\mathbf{K}_2^+\mathbf{B}_2^T)\boldsymbol{\lambda} &= -\mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1 + \mathbf{B}_2(\mathbf{K}_2^+\mathbf{f}_2 + \mathbf{R}_2\boldsymbol{\alpha})\\ \mathbf{u}_1 &= \mathbf{K}_1^{-1}(\mathbf{f}_1 + \mathbf{B}_1^T\boldsymbol{\lambda})\\ \mathbf{u}_2 &= \mathbf{K}_2^+(\mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda}) + \mathbf{R}_2\boldsymbol{\alpha}.\end{aligned} \tag{3.3}$$

The following points should be noted.

1. Because $\mathbf{B}_j$ is a boolean operator, the result of its application to a matrix or vector quantity should be interpreted as an extraction process rather than a matrix-matrix or matrix-vector product. For example, $\mathbf{B}_2\mathbf{R}_2$ is the restriction of the null space basis $\mathbf{R}_2$ of $\mathbf{K}_2$ to the interface unknowns. In the sequel we adopt the notation:

$$\mathbf{R}_2^I = \mathbf{B}_2\mathbf{R}_2.$$

2. The generalized inverse $\mathbf{K}_2^+$ does not need to be explicitly computed. For a given input vector $\mathbf{v}$, the output vector $\mathbf{K}_2^+\mathbf{v}$ and the null space basis $\mathbf{R}_2$ can be obtained at almost the same computational cost as the response vector $\mathbf{K}_1^{-1}\mathbf{v}$, where $\mathbf{K}_1$ is nonsingular (See Appendix A).
3. System (3.3) is underdetermined. Both $\boldsymbol{\lambda}$ and $\boldsymbol{\alpha}$ need to be determined before $\mathbf{u}_1$ and $\mathbf{u}_2$ can be found, but only three equations are available so far.

Since $\mathbf{K}_2$ is symmetric, the singular equation (3.1) admits at least one solution if and only if the right-hand side $(\mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda})$ has no component in the null space of $\mathbf{K}_2$. This can be expressed as

$$\mathbf{R}_2^T(\mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda}) = 0. \tag{3.4}$$

The above orthogonality condition provides the missing equation for the complete solution of (3.3). Combining (3.3) and (3.4) yields after some algebraic manipulations:

$$
\begin{aligned}
\begin{bmatrix} \mathbf{F}_I & -\mathbf{R}_2^I \\ -\mathbf{R}_2^{I^T} & \mathbf{O} \end{bmatrix} \begin{bmatrix} \boldsymbol{\lambda} \\ \boldsymbol{\alpha} \end{bmatrix} &= \begin{bmatrix} \mathbf{B}_2\mathbf{K}_2^+\mathbf{f}_2 - \mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1 \\ -\mathbf{R}_2^T\mathbf{f}_2 \end{bmatrix} \\
\mathbf{u}_1 &= \mathbf{K}_1^{-1}(\mathbf{f}_1 + \mathbf{B}_1^T\boldsymbol{\lambda}) \\
\mathbf{u}_2 &= \mathbf{K}_2^+(\mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda}) + \mathbf{R}_2\boldsymbol{\alpha}, \quad \text{where} \\
\mathbf{F}_I &= (\mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{B}_1^T + \mathbf{B}_2\mathbf{K}_2^+\mathbf{B}_2^T)
\end{aligned}
\tag{3.5}
$$

Clearly, $\mathbf{F}_I$ is symmetric positive and $\mathbf{R}_2^I$ has full column rank. Therefore, the system of equations in $(\boldsymbol{\lambda}, \boldsymbol{\alpha})$ is symmetric and nonsingular. It admits a unique solution $(\boldsymbol{\lambda}, \boldsymbol{\alpha})$ which uniquely determines $\mathbf{u}_1$ and $\mathbf{u}_2$.

It is important to note that since $n_2^r \leq 6$, systems (3.5) and (2.7) have almost the same size. For an arbitrary number of subdomains N_s, of which N_f are floating, the additional number of equations introduced by the handling of local singularities is bounded by $6N_f$. For large-scale problems and relatively coarse mesh partitions, this number is a very small fraction of the size of the global system. On the other hand, if a given tearing process does not result in any floating subdomain, $\boldsymbol{\alpha}$ is zero and the systems of equations (3.5) and (2.7) are identical.

Next, we present a numerical algorithm for the solution of (3.5).

4. A preconditioned conjugate projected gradient algorithm. Here we focus on the solution of the nonsingular system of equations:

$$
\begin{aligned}
\begin{bmatrix} \mathbf{F}_I & -\mathbf{R}_2^I \\ -\mathbf{R}_2^{I^T} & \mathbf{O} \end{bmatrix} \begin{bmatrix} \boldsymbol{\lambda} \\ \boldsymbol{\alpha} \end{bmatrix} &= \begin{bmatrix} \mathbf{B}_2\mathbf{K}_2^+\mathbf{f}_2 - \mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1 \\ -\mathbf{R}_2^T\mathbf{f}_2 \end{bmatrix}, \quad \text{where} \\
\mathbf{F}_I &= \mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{B}_1^T + \mathbf{B}_2\mathbf{K}_2^+\mathbf{B}_2^T.
\end{aligned}
\tag{4.1}
$$

We seek an efficient solution algorithm that does not require the explicit assembly of $\mathbf{F}_I$.

Clearly, the nature of $\mathbf{F}_I$ makes the solution of (4.1) inadequate by any technique that requires this submatrix explicitly. This implies that a direct method or an iterative method of the SOR type cannot be used. The only efficient method of solving (4.1) in the general sparse case is that of conjugate gradients, because once $\mathbf{K}_1$ and $\mathbf{K}_2$ have been factorized, matrix-vector products of the form $\mathbf{F}_I\mathbf{v}$ can be performed very efficiently using only forward and backward substitutions. Unfortunately, the Lagrangian matrix

$$
\mathbf{L} = \begin{bmatrix} \mathbf{F}_I & -\mathbf{R}_2^I \\ -\mathbf{R}_2^{I^T} & \mathbf{O} \end{bmatrix}
$$

is indefinite so that a straightforward conjugate gradient algorithm cannot be directly applied to the solution of (4.1). However, the conjugate gradient iteration with the *projected* gradient (see, for example, Gill and Murray [7]) can be used to obtain the sought-after solution. In order to introduce the latter solution algorithm, we first note that solving (4.1) is equivalent to solving the equality constraint problem:

$$
\begin{aligned}
&\text{minimize} \quad \Phi(\boldsymbol{\lambda}) = \tfrac{1}{2}\boldsymbol{\lambda}^T\mathbf{F}_I\boldsymbol{\lambda} + (\mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1 - \mathbf{B}_2\mathbf{K}_2^+\mathbf{f}_2)^T\boldsymbol{\lambda} \\
&\text{subject to} \quad \mathbf{R}_2^{I^T}\boldsymbol{\lambda} = \mathbf{R}_2^T\mathbf{f}_2.
\end{aligned}
\tag{4.2}
$$

Since $\mathbf{F}_I$ is symmetric positive, a conjugate gradient algorithm is most suitable for computing the unique solution to the unconstrained problem. Therefore, this algorithm will converge to the solution to (4.1) if and only if it can be modified so that the constraint $\mathbf{R}_2^{I^T}\boldsymbol{\lambda} = \mathbf{R}_2^T\mathbf{f}_2$ is satisfied at each iteration. This can be achieved by projecting all the search directions onto the null space of $\mathbf{R}_2^{I^T}$.

The result is a conjugate gradient algorithm with the projected gradient. It is of the form:

Initialize

Pick $\boldsymbol{\lambda}^{(0)}$ such that $\mathbf{R}_2^{I^T}\boldsymbol{\lambda}^{(0)} \;=\; \mathbf{R}_2^T\mathbf{f}_2$

$$\mathbf{r}^{(0)} \;=\; [\mathbf{I} - \mathbf{R}_2^I(\mathbf{R}_2^{I^T}\mathbf{R}_2^I)^{-1}\mathbf{R}_2^{I^T}]\;(\mathbf{B}_2\mathbf{K}_2^{+}\mathbf{f}_2 - \mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1) \tag{4.3}$$

Iterate $k = 1, 2, \cdots$ until convergence

$$\begin{aligned}
\beta^{(k)} &= \mathbf{r}^{(k-1)^T}\mathbf{r}^{(k-1)}/\mathbf{r}^{(k-2)^T}\mathbf{r}^{(k-2)} \quad (\beta^{(1)} = 0)\\
\mathbf{s}^{(k)} &= \mathbf{r}^{(k-1)} + \beta^{(k)}\mathbf{s}^{(k-1)} \quad (\mathbf{s}^{(1)} = \mathbf{r}^{(0)})\\
\gamma^{(k)} &= \mathbf{r}^{(k-1)^T}\mathbf{r}^{(k-1)}/\mathbf{s}^{(k)^T}\mathbf{F}_I\mathbf{s}^{(k)}\\
\boldsymbol{\lambda}^{(k)} &= \boldsymbol{\lambda}^{(k-1)} + \gamma^{(k)}\mathbf{s}^{(k)}\\
\mathbf{r}^{(k)} &= \mathbf{r}^{(k-1)} - \gamma^{(k)}[\mathbf{I} - \mathbf{R}_2^I(\mathbf{R}_2^{I^T}\mathbf{R}_2^I)^{-1}\mathbf{R}_2^{I^T}]\;\mathbf{F}_I\mathbf{s}^{(k)}.
\end{aligned} \tag{4.4}$$

Given the projection operator $[\mathbf{I} - \mathbf{R}_2^I(\mathbf{R}_2^{I^T}\mathbf{R}_2^I)^{-1}\mathbf{R}_2^{I^T}]$, it is easily checked that the projected residual vector $\mathbf{r}^{(k)}$ is parallel to the null space of $\mathbf{R}_2^{I^T}$ at each iteration k, and that $\mathbf{R}_2^{I^T}\mathbf{s}^{(k)} = 0$ for all $k \geq 1$. Therefore, $\mathbf{R}_2^{I^T}\boldsymbol{\lambda}^{(k)} = \mathbf{R}_2^{I^T}\boldsymbol{\lambda}^{(0)}$, which indicates that the approximate solution $\boldsymbol{\lambda}^{(k)}$ satisfies the linear equality constraint of problem (4.1) at each iteration k. It is also important to note that within each iteration, only one projection is performed. This projection is relatively inexpensive since the only implicit computations that are involved are associated with the matrix $\mathbf{R}_2^{I^T}\mathbf{R}_2^I$, which is at most 6×6. This matrix is factored once, before the first iteration begins. Except for this small overhead, algorithm (4.4) above has the same computational cost as the regular conjugate gradient method. After $\boldsymbol{\lambda}$ is found, $\boldsymbol{\alpha}$ is computed as

$$\boldsymbol{\alpha} \;=\; (\mathbf{R}_2^{I^T}\mathbf{R}_2^I)^{-1}(\mathbf{F}_I\boldsymbol{\lambda} - \mathbf{B}_2\mathbf{K}_2^{+}\mathbf{f}_2 + \mathbf{B}_1\mathbf{K}_1^{-1}\mathbf{f}_1).$$

As in the case of the conjugate gradient method, the conjugate projected gradient algorithm is most effective when applied to the preconditioned system of equations. It should be noted that even in the presence of floating subdomains, only $\mathbf{F}_I$ needs to be preconditioned and not the global Lagrangian matrix $\mathbf{L}$. In the case of two subdomains, $\mathbf{F}_I$ can be written in matrix form as

$$\mathbf{F}_I \;=\; [\mathbf{B}_1 \quad \mathbf{B}_2]\begin{bmatrix}\mathbf{K}_1^{-1} & \mathbf{O}\\ \mathbf{O} & \mathbf{K}_2^{-1}\end{bmatrix}\begin{bmatrix}\mathbf{B}_1^T\\ \mathbf{B}_2^T\end{bmatrix} \tag{4.5}$$

where $\mathbf{K}_j^{-1}$, $j = 1, 2$, is replaced by $\mathbf{K}_j^{+}$ if Ω_j is a floating subdomain. The objective is to find an approximate inverse $\mathbf{P}_I^{-1}$ of $\mathbf{F}_I$ that (a) does not need to be explicitly assembled (especially since $\mathbf{F}_I$ is not explicitly assembled), and (b) is amenable to parallel computations. The matrix $\mathbf{P}$ is then the preconditioner. Equation (4.5) above suggests the following choice for $\mathbf{P}_I^{-1}$:

$$\mathbf{P}_I^{-1} = [\mathbf{B}_1 \quad \mathbf{B}_2] \begin{bmatrix} \mathbf{K}_1 & \mathbf{O} \\ \mathbf{O} & \mathbf{K}_2 \end{bmatrix} \begin{bmatrix} \mathbf{B}_1^T \\ \mathbf{B}_2^T \end{bmatrix}. \tag{4.6}$$

At each iteration k, the preconditioned conjugate projected gradient algorithm involves the solution of an auxiliary system of the form

$$\mathbf{P}_I \mathbf{z}^{(k)} = \mathbf{r}^{(k)} \tag{4.7}$$

where $\mathbf{r}^{(k)}$ is the residual at the kth iteration. The particular choice of $\mathbf{P}_I^{-1}$ given in (4.6) offers the advantage of solving (4.7) explicitly without the need for any intermediate factorization. For computational efficiency, $\mathbf{P}_I^{-1}$ is implemented as

$$\mathbf{P}_I^{-1} = \mathbf{K}_1^I + \mathbf{K}_2^I \tag{4.8}$$

where $\mathbf{K}_1^I$ and $\mathbf{K}_2^I$ are the traces of $\mathbf{K}_1$ and $\mathbf{K}_2$ on Γ_I. Clearly, with this choice for the preconditioner, the auxiliary system (4.7) is "cheap," easy to solve, and perfectly parallelizable on both local and shared-memory parallel architectures.

5. Parallel characteristics of the proposed method. Like most domain decomposition-based algorithms, the proposed method is perfectly suitable for parallel processing. If every subdomain Ω_j is assigned to an individual processor p_j, all local finite element computations can be performed in parallel. These include forming and assembling the matrix $\mathbf{K}_j$ and the vector $\mathbf{f}_j$, factoring $\mathbf{K}_j$ and eventually computing the null space basis $\mathbf{R}_j$, as well as backsolving for $\mathbf{u}_j$ after $\boldsymbol{\lambda}$ and $\boldsymbol{\alpha}$ have been determined. The conjugate projected gradient algorithm described in §4 is also amenable to parallel processing. For example, the matrix-vector product $\mathbf{F}_I\mathbf{s}^{(k)}$ can be computed in parallel by assigning to each processor p_j the task of evaluating

$$\mathbf{y}_j^{(k)} = \mathbf{B}_j^k \mathbf{K}_j^{-1} \mathbf{B}_j^{k^T} \mathbf{s}_j^{(k)},$$

and exchanging $\mathbf{y}_j^{(k)}$ with the processors assigned to neighboring subdomains in order to assemble the global result. Interprocessor communication is required only during the solution of the interface problem (4.1) and takes place exclusively among neighboring processors during the assembly of the subdomain results.

At this point, we stress that the parallel solution method developed herein requires inherently less interprocessor communication than other domain decomposition-based parallel algorithms. As mentioned earlier, interprocessor communication within the proposed method occurs only during the solution of the interface problem (4.1). The reader should trace back this problem as well as the presence of the Lagrange multipliers to the integral quantity

$$(v_i - v_j, \lambda)_{\Gamma_{I_{ij}}} = \int_{\Gamma_{I_{ij}}} \lambda(v_i - v_j)\, d\Gamma \tag{5.1}$$

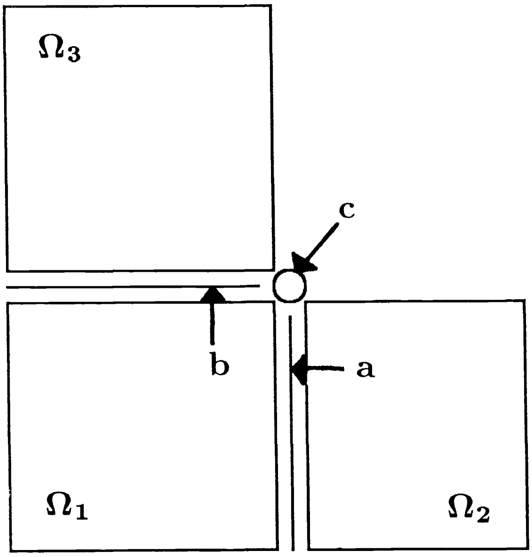

FIG. 4. *An L-shaped three-subdomain problem with a crosspoint.*

where $\Gamma_{I_{ij}}$ is the interface between subdomains Ω_i and Ω_j. If $\Gamma_{I_{ij}}$ has a zero measure, then $(v_i - v_j, \lambda)_{\Gamma_{I_{ij}}} = 0$ and no exchange of information is needed between Ω_i and Ω_j. Therefore the subdomains that interconnect along one edge in three-dimensional problems and those that interconnect along one vertex in both two- and three-dimensional problems do not require any interprocessor communication. This is unlike conventional domain decomposition methods (Schur-related methods), where assembly is required at any intersection point between two subdomains. This result can also be derived from a mechanical interpretation of relation (5.1), as demonstrated by the following example. Consider the case of an L-shaped domain uniformly partitioned into three subdomains Ω_1, Ω_2, and Ω_3 meeting at a "crosspoint" (Fig. 4). For the sake of clarity, in the following analysis the crosspoint c of interfaces a and b is treated as a separate entity. In the practical implementation of the method, it is integrated with every interface to which it belongs. Three discrete forces λ_i corresponding to the three subdomains meeting at the crosspoint c are introduced at each of its degrees of freedom. For simplicity, it is assumed that the elements across the interfaces are compatible so that the forces from both sides of an interface are equal in magnitude and opposite in direction. Moreover, for this problem, if $\mathbf{B}^k_{ij}$ denotes the boolean matrix that identifies the nodes which are shared by Ω_i and Ω_j along the interface k, the decomposition shown in Fig. 4 is such that $\mathbf{B}^k_{ij} = \mathbf{B}^k_{ji}$, and $\mathbf{B}^c_{12} = \mathbf{B}^c_{23} = \mathbf{B}^c_{13}$. Therefore if every subdomain is "glued" to every one of its neighbors, the subdomain equations of equilibrium for this problem can be written as

$$\begin{aligned}
\mathbf{K}_1\mathbf{u}_1 &= \mathbf{f}_1 + {\mathbf{B}^a_{12}}^T\boldsymbol{\lambda}^a_{12} + {\mathbf{B}^c_{12}}^T\boldsymbol{\lambda}^c_{12} + {\mathbf{B}^b_{13}}^T\boldsymbol{\lambda}^b_{12} + {\mathbf{B}^c_{13}}^T\boldsymbol{\lambda}^c_{13} \\
\mathbf{K}_2\mathbf{u}_2 &= \mathbf{f}_2 - {\mathbf{B}^a_{12}}^T\boldsymbol{\lambda}^a_{12} - {\mathbf{B}^c_{12}}^T\boldsymbol{\lambda}^c_{12} + {\mathbf{B}^c_{23}}^T\boldsymbol{\lambda}^c_{23} \qquad (5.2) \\
\mathbf{K}_3\mathbf{u}_3 &= \mathbf{f}_3 - {\mathbf{B}^b_{13}}^T\boldsymbol{\lambda}^b_{13} - {\mathbf{B}^c_{13}}^T\boldsymbol{\lambda}^c_{13} - {\mathbf{B}^c_{23}}^T\boldsymbol{\lambda}^c_{23}.
\end{aligned}$$

However, it can be argued that since Ω_2 and Ω_3 intersect at a single point, whenever Ω_1 is glued to Ω_2 and Ω_3, then Ω_2 is automatically glued to Ω_3. This holds only if there exist a set of discrete interface forces $\boldsymbol{\mu}_{ij}^k$ such that the subdomain equations of equilibrium can be simplified to

$$\begin{aligned}\mathbf{K}_1\mathbf{u}_1 &= \mathbf{f}_1 + \mathbf{B}_{12}^{a\ T}\boldsymbol{\mu}_{12}^a + \mathbf{B}_{12}^{c\ T}\boldsymbol{\mu}_{12}^c + \mathbf{B}_{13}^{b\ T}\boldsymbol{\mu}_{12}^b + \mathbf{B}_{13}^{c\ T}\boldsymbol{\mu}_{13}^c \\ \mathbf{K}_2\mathbf{u}_2 &= \mathbf{f}_2 - \mathbf{B}_{12}^{a\ T}\boldsymbol{\mu}_{12}^a - \mathbf{B}_{12}^{c\ T}\boldsymbol{\mu}_{12}^c \\ \mathbf{K}_3\mathbf{u}_3 &= \mathbf{f}_3 - \mathbf{B}_{13}^{b\ T}\boldsymbol{\mu}_{13}^b - \mathbf{B}_{13}^{c\ T}\boldsymbol{\mu}_{13}^c.\end{aligned} \tag{5.3}$$

Comparing equations (5.2) and (5.3) reveals that:

$$\begin{aligned}\boldsymbol{\mu}_{12}^a &= \boldsymbol{\lambda}_{12}^a \\ \boldsymbol{\mu}_{12}^c &= \boldsymbol{\lambda}_{12}^c \\ \boldsymbol{\mu}_{13}^c &= \boldsymbol{\lambda}_{13}^c \\ \boldsymbol{\mu}_{13}^c &= \boldsymbol{\lambda}_{13}^c + \boldsymbol{\lambda}_{23}^c \\ \boldsymbol{\mu}_{12}^c &= \boldsymbol{\lambda}_{12}^c - \boldsymbol{\lambda}_{23}^c\end{aligned} \tag{5.4}$$

which clearly demonstrates that any two subdomains that intersect at a single node do not need to be explicitly assembled.

Therefore, for a three-dimensional regular mesh that is partitioned into subcubes, the proposed method requires that each subdomain communicate with at most six neighboring subdomains (since a cube has only six faces), while the parallel Schur methods necessitate that each subdomain communicate with up to 26 neighbors (Fig. 5). For the latter method, one could of course group vertex- and edge-associated messages with the face-associated ones and perform some type of fast communication sweeps as described in [11]. However, that option creates an additional burden for the computer implementation and may not be feasible for arbitrary subdomain interconnections. Clearly, this communication characteristic makes the proposed parallel solution method very attractive for a multiprocessor with a distributed memory such as a hypercube. Indeed, the advantages of the method for this family of parallel processors are twofold: (a) the number of message-passing is dramatically reduced, which reduces the overhead due to communication start-up, and (b) the complexity of the communication requirements is improved so that an optimal mapping of the processors onto the subdomains can be reached (Bokhari [1], Farhat [4]); therefore the elapsed time for a given message is improved. Both enhancements (a) and (b) reduce the communication overhead of the parallel solution algorithm in a synergistic manner. This algorithmic feature of the proposed method is still desirable for shared-memory multiprocessors because it eases the assembly process during the interface solution and makes the latter more manageable. It is not, however, as critical for the performance as it is for local memory multiprocessors.

Finally, it should be noted that domain decomposition methods in general exhibit a larger degree of parallelism than parallel direct solvers. The efficiency of the latter is governed by the bandwidth of the given finite element system of equations. If the bandwidth is not large enough, interprocessor communication and/or process synchronization can dominate the work done in parallel by each processor. This is true not only for multiprocessors with a message-passing system, but also for supervector multiprocessors with a shared memory such as the CRAY systems, where synchronization

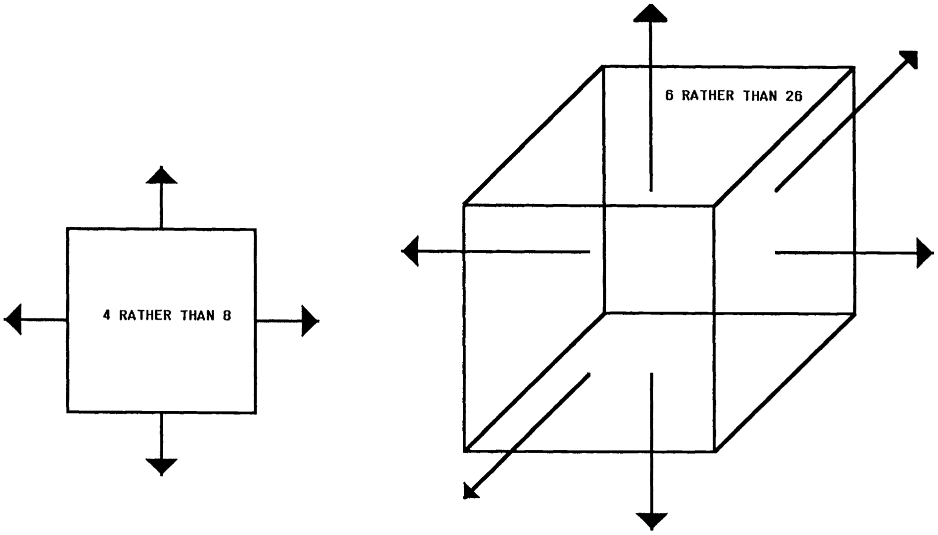

FIG. 5. *Reduced interprocessor communication patterns for two- and three-dimensional regular mesh partitions.*

primitives are rather expensive. Therefore, the computational method described in this paper should be seriously considered for large-scale problems with a relatively small or medium bandwidth. These problems are typically encountered in the finite element analysis of large space structures that are often elongated and include only a few elements along one or two directions (Farhat [5]). The method is also recommended for problems where the storage requirements of direct solvers cannot be met.

6. Applications and performance assessment. For conventional domain decomposition methods, the interface problem can be written as

$$[(\mathbf{K}_{II}^{(1)} - \mathbf{K}_{1I}^T\mathbf{K}_{11}^{-1}\mathbf{K}_{1I}) + (\mathbf{K}_{II}^{(2)} - \mathbf{K}_{2I}^T\mathbf{K}_{22}^{-1}\mathbf{K}_{2I})]\mathbf{u}_I = \mathbf{f}_{II} - \mathbf{K}_{1I}^T\mathbf{K}_{11}^{-1}\mathbf{f}_{11} - \mathbf{K}_{2I}^T\mathbf{K}_{22}^{-1}\mathbf{f}_{22} \tag{6.1}$$

where $\mathbf{K}_{II}^{(1)}$, $\mathbf{K}_{II}^{(2)}$, $\mathbf{K}_{11}$, and $\mathbf{K}_{22}$ are the stiffness matrices associated, respectively, with the interface nodes and the interior nodes of subdomains Ω_1 and Ω_2, and $\mathbf{K}_{1I}$ and $\mathbf{K}_{2I}$ are the coupling stiffnesses between, respectively, Ω_1 and Γ_I, and Ω_2 and Γ_I (see, for example, [6] for further details). Because the left-hand side of (6.1) is known as Schur's complement, we have been referring to these subdomain-based algorithms as Schur methods. A standard conjugate gradient algorithm may be used for solving (6.1). Here we compare for performance the above subdomain-based Schur method with the hybrid algorithm developed in this paper. While the preconditioner (4.8) is selected for the hybrid version, two different preconditioners are considered for Schur's method:

(a) diagonal scaling, and (b) subdomain scaling, that is,

$$\mathbf{P}^{-1} = (\mathbf{K}_{II}^{(1)} - \mathbf{K}_{1I}^T\mathbf{K}_{11}^{-1}\mathbf{K}_{1I})^{-1} + (\mathbf{K}_{II}^{(2)} - \mathbf{K}_{2I}^T\mathbf{K}_{22}^{-1}\mathbf{K}_{2I})^{-1}.$$

We focus on the static analysis on a 32-processor iPSC hypercube of a three-dimensional mechanical joint subjected to internal pressure loading. The finite element discretization of this mechanical joint using eight node brick elements is shown in Fig. 6. The mesh has 9912 elements and 29,654 degrees of freedom. Figure 7 displays its decomposition in 32 subdomains. For the hybrid formulation, most of these subdomains are floating and therefore induce each a singular local operator.

The obtained numerical results are reported in Figs. 8–10. For each algorithm, three curves are reported, which correspond to monitoring convergence with three different measures: (A) the global force relative residual, (B) the displacement relative variation, and (C) the interface relative residual.

It is interesting to note that for both algorithms, convergence using the relative global residual is harder to achieve than convergence using the relative variation of the solution. This is because the problem is ill conditioned. The interface residual is closer to the global solution variation in the hybrid method, while it is closer to the global residual in the Schur method. This is because in the former case, the interface problem is formulated in the functional space of the problem's solution derivative, while in the latter case, it is formulated in the same functional space as the problem's solution. Clearly, a stopping criterion should be based on the global relative residual. For a tolerance of 10^{-3} (typical for nonlinear problems), the preconditioned hybrid method requires fewer iterations for convergence than the diagonally preconditioned Schur method. On the other hand, the subdomain preconditioned Schur method converges faster than the other algorithms. However, it is still slower than the preconditioned hybrid method, as reported in Table 1, where $T_{msg}/itr.$, T_p, and SP denote, respectively, the time elapsed in message-passing per iteration, the total parallel time, and the overall parallel speedup. Here, the parallel speedup SP is defined as the ratio between the total time using one processor and the total time using p processors, for the same number of subdomains. It is computed as

$$SP = \frac{p}{1 + p\frac{T_{cmn}}{T_{cmp}}}$$

where p denotes the number of processors, and T_{cmn} and T_{cmp} denote, respectively, the total communication time and total computation time associated with the algorithm. Basically, SP measures how well the algorithm parallelizes on a message passing multiprocessor. It does not however reflect the intrinsic computational performance of the algorithm; the total parallel time does. Note also that the above expression of SP overcomes the practical difficulties associated with running a large problem on a single node of a hypercube.

speedup than the conventional Schur algorithms, for which the time elapsed in interprocessor communication is 3.31 times higher. Again, because it avoids interprocessor communication along the edges and corners of the subdomains, the hybrid algorithm requires fewer message-passing startups which, in the case of short messages, are known to account for the largest portion of the time elapsed in interprocessor communication on the iPSC.

7. Conclusion. A novel subdomain-based algorithm for the parallel finite element solution of selfadjoint elliptic partial differential equations is presented. The spatial domain is partitioned into a set of totally disconnected subdomains, each assigned to an individual processor. Lagrange multipliers are introduced to enforce compatibility at the interface nodes. In the static case, each floating subdomain induces a local singularity that is resolved in two phases. First, the null space components are eliminated in parallel from each local problem and a direct scheme is applied concurrently to all subdomains in order to recover each partial local solution. Next, the contributions of these components are related to the Lagrange multipliers through an orthogonality condition. A parallel conjugate *projected* gradient algorithm is developed for the solution of the coupled system of local null space components and Lagrange multipliers, which completes the solution of the problem. When implemented on local memory multiprocessors, this proposed method requires less interprocessor communication than other conventional domain decomposition methods. It is also suitable for parallel/vector computers with shared memory. Example applications from structural mechanics are reported on the iPSC hypercube. Measured performance results illustrate the advantages of the proposed method.

Appendix A. Solving a consistent singular system $\mathbf{K}_j\mathbf{u}_j = \mathbf{f}_j$. For completeness, we include in this appendix a derivation of the solution of a consistent singular system of equations. In this work, such a system arises in every floating subdomain Ω_j and takes the form

$$\mathbf{K}_j \mathbf{u}_j = \mathbf{f}_j \tag{A.1}$$

where $\mathbf{K}_j$ is the $(n_j^s + n_j^I) \times (n_j^s + n_j^I)$ stiffness matrix associated with Ω_j, and $\mathbf{u}_j$ and $\mathbf{f}_j$ are the corresponding displacement and forcing vectors. If Ω_j has n_j^r rigid body modes, $\mathbf{K}_j$ is rank n_j^r deficient. Provided that $\mathbf{f}_j$ is orthogonal to the null space of $\mathbf{K}_j$, the singular system (A.1) is consistent and admits a general solution of the form

$$\mathbf{u}_j = \mathbf{K}_j^+ \mathbf{f}_j + \mathbf{R}_j \boldsymbol{\alpha} \tag{A.2}$$

where $\mathbf{K}_j^+$ is a generalized inverse of $\mathbf{K}_j$ — that is, $\mathbf{K}_j^+$ verifies $\mathbf{K}_j \mathbf{K}_j^+ \mathbf{K}_j = \mathbf{K}_j$, $\mathbf{R}_j$ is a basis of the null space of $\mathbf{K}_j$ — that is, $\mathbf{R}_j$ stores the n_j^r rigid body modes of Ω_j, and $\boldsymbol{\alpha}$ is a vector of length n_j^r containing arbitrary real coefficients.

Computing the rigid body modes. Let the superscripts p and r denote, respectively, a principal and a redundant quantity. The singular stiffness matrix $\mathbf{K}_j$ is partitioned as

$$\mathbf{K}_j = \begin{bmatrix} \mathbf{K}_j^{pp} & \mathbf{K}_j^{pr} \\ \mathbf{K}_j^{pr^T} & \mathbf{K}_j^{rr} \end{bmatrix} \tag{A.3}$$

where $\mathbf{K}_j^{pp}$ has full rank equal to $n_j^s + n_j^I - n_j^r$. If $\mathbf{R}_j$ is defined as

$$\mathbf{R}_j = \begin{bmatrix} -[\mathbf{K}_j^{pp}]^{-1} \mathbf{K}_j^{pr} \\ \mathbf{I}_{n_j^r} \end{bmatrix} \tag{A.4}$$

where $\mathbf{I}_{n_j^r}$ is the $n_j^r \times n_j^r$ identity matrix, then $\mathbf{R}_j$ satisfies

$$\mathbf{K}_j \mathbf{R}_j = 0.$$

Moreover, $\mathbf{I}_{n_j^r}$ has full column rank and so does $\mathbf{R}_j$. Therefore, the n_j^r columns of $\mathbf{R}_j$ as defined in (A.4) form a basis of the null space of $\mathbf{K}_j$.

Computing $\mathbf{K}_j^+ \mathbf{f}_j$. The partitioning of the singular matrix $\mathbf{K}_j$ defined in (A.3) implies that

$$\mathbf{K}_j^{rr} = \mathbf{K}_j^{pr^T} [\mathbf{K}_j^{pp}]^{-1} \mathbf{K}_j^{pr}. \tag{A.5}$$

Using the above identity, it can be easily checked that the matrix $\mathbf{K}_j^+$ defined as

$$\mathbf{K}_j^+ = \begin{bmatrix} [\mathbf{K}_j^{pp}]^{-1} & \mathbf{O} \\ \mathbf{O} & \mathbf{O} \end{bmatrix}$$

is a generalized inverse of $\mathbf{K}_j$. Therefore, a solution of the form $\mathbf{K}_j^+ \mathbf{f}_j$ can be also written as

$$\mathbf{u}_j = \mathbf{K}_j^+ \mathbf{f}_j = \begin{bmatrix} [\mathbf{K}_j^{pp}]^{-1} \mathbf{f}_j^p \\ \mathbf{O} \end{bmatrix}.$$

In practice, $\mathbf{K}_j$ cannot be explicitly rearranged as in (A.3). Rather, the following should be implemented when $\mathbf{K}_j$ is stored in skyline form. A zero pivot that is encountered during the factorization process of $\mathbf{K}_j$ corresponds to a redundant equation which needs to be labeled and removed from the system. The zero pivot is set to one, the reduced column above it is copied into an extra right-hand side — this corresponds to a forward reduction with $\mathbf{K}_j^{pr}\mathbf{u}_j^r$ as right-hand side, and the coefficients in the skyline corresponding to that pivotal equation are set to zero. At the end of the factorization process, the nonlabeled equations define the full rank matrix $\mathbf{K}_j^{pp}$. The backward substitution is modified to operate also on the n_j^r extra right-hand sides in order to recover $\mathbf{u}_j^p = -[\mathbf{K}_j^{pp}]^{-1}\mathbf{K}_j^{pr}\mathbf{u}_j^r$.

The above procedure for solving a consistent singular system of equations has almost the same computational complexity as the solution of a nonsingular one.

DOMAIN DECOMPOSITION METHODS FOR PROBLEMS WITH PARTIAL REFINEMENT*

JAMES H. BRAMBLE[†], RICHARD E. EWING[‡], ROSSEN R. PARASHKEVOV[‡], AND JOSEPH E. PASCIAK[§]

Abstract. In this paper, a flexible mesh refinement strategy for the approximation of solutions of elliptic boundary value problems is considered. The main purpose of the paper is the development of preconditioners for the resulting discrete system of algebraic equations. These techniques lead to efficient computational procedures in serial as well as parallel computing environments. The preconditioners are based on overlapping domain decomposition and involve solving (or preconditioning) subproblems on regular subregions. It is proven that the iteration schemes converge to the discrete solution at a rate which is independent of the mesh parameters in the case of two spatial dimensions. The estimates proved for the iterative convergence rate in three dimensions are somewhat weaker. The results of numerical experiments illustrating the theory are also presented.

Key words. second-order elliptic equation, domain decomposition, overlapping domain decomposition, local mesh refinement, partial refinement, overlapping Schwarz methods, preconditioners

1. Introduction.

To provide the required accuracy in many applications involving large scale scientific computation, it becomes necessary to use local mesh refinement techniques. These techniques allow the use of finer meshes in regions of the computational domain where the solution exhibits large gradients. This remains practical only if efficient techniques for the solution of the resulting discrete systems are available. It is the purpose of this paper to provide such techniques. We will give a flexible scheme for refinement as well as develop and analyze effective iterative methods for the solution of the resulting systems of discrete equations.

In this paper, we shall be interested in techniques for problems with refinements which are not quite local. As an example, one might consider a front passing through a two-dimensional domain. In this case, it might be necessary to refine in the neighborhood of the front.

There are a number of ways of developing preconditioned iterative schemes for the discrete systems resulting from local mesh refinement in the literature. Techniques based on nested multilevel spaces are given in [1], [7], [8], [12]. Techniques based on domain decomposition are given in [2], [10], [13], [14]. The analysis presented there implicitly depends on the shape of the the refinement domain, and hence the resulting algorithms may not be as effective with irregularly shaped refinement regions.

These algorithms also require the solution of a subproblem or preconditioner on the refinement regions. We shall provide alternative preconditioned iterative techniques for these problems based on overlapping domain decomposition. Our algorithms are simpler and possibly more effective when implemented since they often lead to preconditioning subproblems defined on either regular subregions or topologically "nice" meshes. The refinement region is the union of the subregions and may be irregularly shaped.

The proposed mesh refinement strategy is important in that it provides a basic approach for implementing dynamic local grid refinement. An example of a refinement strategy involves starting with a uniform coarse grid and refining in small subregions associated with a selected set of coarse-grid vertices. These subregions are allowed to overlap and there are no theoretical restrictions on the resulting refinement region (the union of the subregions). Dynamic refinement is achieved by simply dynamically changing the selected set of coarse-grid vertices.

In addition, the technique can be integrated into existing large scale simulators without a complete redesign of the code. This is because most of the computation involves tasks on either the global coarse grid or the refinement grids associated with the refinement subregions. Choosing the coarse and refinement grid structure to be that already used in the code saves considerable development costs. For example, if one uses regularly structured meshes in the coarse and refinement grids, a substantial part of the resulting algorithm only requires operations on regular grids even though the resulting final approximation space is not regular.

The outline of the remainder of the paper is as follows. In §2, we define some preliminaries and describe the second-order elliptic problems that will be considered. The overlapping domain decomposition algorithms for grids with partial refinement are given in §3. An analysis of the resulting preconditioned algorithms is given in §4. It is shown that the condition number of the preconditioned systems is bounded independently of the mesh parameters for many two-dimensional applications. The results for three dimensions are somewhat weaker and involve logarithms of the mesh parameters. Finally, the results of numerical experiments using these preconditioning techniques are given in §5.

2. The elliptic problem and preliminaries. We shall be concerned with the efficient solution of discrete equations resulting from approximation of second-order elliptic boundary value problems in a polygonal or polyhedral domain Ω contained in Euclidean space R^d, for $d = 2, 3$. We consider the problem of approximating the solution u of

$$\begin{aligned} Lu &= f \qquad \text{in } \Omega, \\ u &= 0 \qquad \text{on } \partial\Omega. \end{aligned} \tag{2.1}$$

Here L is given by

$$Lv = -\sum_{i,j=1}^{d} \frac{\partial}{\partial x_i} a_{ij} \frac{\partial v}{\partial x_j},$$

and $\{a_{ij}(x)\}$ is a uniformly positive definite, bounded, piecewise smooth coefficient matrix on Ω. The corresponding bilinear form is denoted by $A(\cdot,\cdot)$ and is given by

$$A(v,w) = \sum_{i,j=1}^{d} \int_{\Omega} a_{ij} \frac{\partial v}{\partial x_i} \frac{\partial w}{\partial x_j}\, dx, \tag{2.2}$$

and is defined for functions $v,w \in H^1(\Omega)$. Here $H^1(\Omega)$ is the Sobolev space of order one on Ω. We denote the $L^2(\Omega)$ inner product by $(\cdot,\cdot)$. The weak solution u of (2.1) is the function $u \in H_0^1(\Omega)$ satisfying

$$A(u,\varphi) = (f,\varphi) \quad \text{for all } \varphi \in H_0^1(\Omega).$$

Here, $H_0^1(\Omega)$ is the subspace of functions in $H^1(\Omega)$ whose trace vanishes on $\partial\Omega$.

We consider the above model problem for convenience. Many extensions of the techniques to be presented are possible; for example, one could consider equations with lower-order terms and different boundary conditions.

In this paper, we shall deal with various domains. These domains will always be open. The closure of a domain θ will be denoted $\bar{\theta}$. In addition, we shall use various positive constants. These will be denoted by the character C, which will take on different values in different places. However, this constant shall always be independent of the mesh parameters in the approximation schemes.

3. The overlapping algorithms. In this section, we shall define iterative methods for problems with partial refinement based on overlapping domain decomposition. Our goal is to illustrate the technique and analysis and hence, for simplicity, we shall not attempt to provide the most general theorems. Many extensions are possible and can be inferred from the analysis presented.

The analysis given in the following section requires the application of techniques from both the theory of overlapping domain decomposition [9], [11] as well as the standard domain decomposition theory [4], [5]. We first give the setup in the two-dimensional case. We start with a coarse mesh $\cup\tau_H^i$ consisting of triangles of quasi-uniform size H. The associated finite element space M_0 is defined to be the set of those continuous piecewise linear functions on the coarse mesh that vanish on $\partial\Omega$. The mesh refinement is defined in terms of a number of coarse grid subdomains $\{\Omega_i\}$, for $i = 1,\cdots,K$. By convention, Ω_i is defined to be the interior of the union of the closures of the coarse grid triangles. The refinement regions will also be referred to as "the subdomains." We assume that they have limited overlap in that any point of Ω is contained in at most a fixed number (not depending on H) of the subdomains. We define the domain of refinement Ω^r to be the union of the subdomains, $\Omega^r = \cup_{1=1}^K \Omega_i$ There are no theoretical restrictions concerning the definition of the refinement subregions except that they are defined in terms of the coarse-grid triangles and satisfy the overlap property as described above.

We provide two examples of the construction in the two-dimensional case. For both examples, the subregions are associated with coarse-grid nodes. The interior and boundary nodes of this mesh will be denoted $\{x_i\}$, for $i = 1,\cdots,N_c$. For the first example, we define the region associated with a coarse-grid node x_i as the subdomain Ω_i that contains the coarse-grid triangles having x_i as a vertex. For the second example, we consider a mesh that is topologically equivalent to a regular rectangular mesh (see Fig. 3.1). In this case, we define Ω_i to be the four quadrilaterals that share the vertex x_i. Some reasons for such a choice will be explained later. In either case, an index set $I \subseteq [1,\cdots,N_c]$ is selected and only those subdomains $\{\Omega_i\}$ with $i \in I$ are used to define the refinement region. By possibly changing the numbering of the coarse-grid nodes, we assume, without loss of generality, that $I = 1,2,\cdots,K$. There are no additional restrictions concerning this set I and hence rather complex refinement regions are possible.

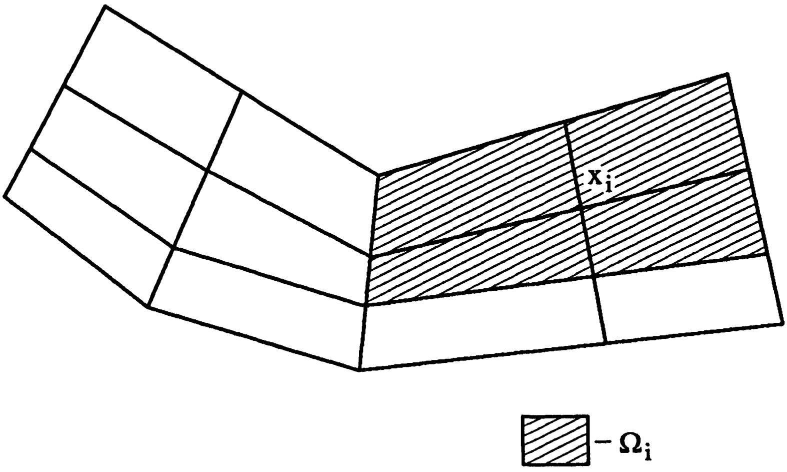

FIG. 3.1. *A distorted rectangular mesh.*

The composite space is defined in terms of a quasi-uniform mesh $\{\tau_h^i\}$ on Ω of size $h < H$ that satisfies

$$\cup_i \partial\tau_H^i \subseteq \cup_i \partial\tau_h^i.$$

The space of continuous piecewise linear functions with respect to this triangulation (which vanish on $\partial\Omega$) will be denoted by $\tilde{M}$. Note that this space is introduced for the construction and analysis of the composite grid space. It is not used in actual computation since it has too many degrees of freedom in Ω/Ω^r. The subspace M_i associated with the subdomain Ω_i is defined by

$$M_i = \{\phi \in \tilde{M} \,|\, \operatorname{supp}\phi \subseteq \Omega_i\}. \tag{3.1}$$

The composite finite element space is then defined to be

$$M = \sum_{i=0}^{K} M_i.$$

Note that the space M provides finer grid approximation in the refinement region Ω^r. An illustrative example of a mesh so generated is given in Fig. 3.2. The nodes on the boundary of the refinement region that are not coarse-grid nodes are slave nodes since, by continuity, the values of functions in M on these points are completely determined by their values on neighboring coarse-grid nodes. The operator $A_i : M_i \mapsto M_i$ is defined for $v \in M_i$ by

$$(A_i v, \phi) = A(v, \phi) \quad \text{for all } \phi \in M_i.$$

Our goal is to efficiently solve the composite grid problem: Given a function $f \in L^2(\Omega)$, find $U \in M$ satisfying

$$A(U, \phi) = (f, \phi) \quad \text{for all } \phi \in M. \tag{3.2}$$

As above, we define $A : M \mapsto M$ by

$$(Av, \phi) = A(v, \phi) \quad \text{for all } \phi \in M.$$

Problem (3.2) can then be rewritten as

$$AU = F, \tag{3.3}$$

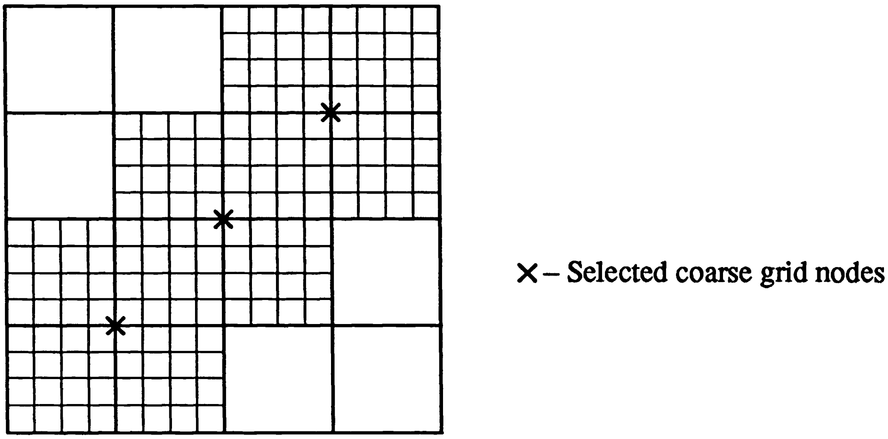

FIG. 3.2. *A composite grid.*

for appropriate $F \in M$. We will develop preconditioners for (3.3) by using overlapping domain decomposition.

There are basically two classes of these preconditioners, the additive and the multiplicative. The additive version defines the preconditioner B_a for A of (3.3) by

$$B_a = \sum_{i=0}^{K} R_i Q_i.$$

Here, Q_i denotes the $L^2(\Omega)$ projection operator onto M_i and R_i is a symmetric positive definite operator on M_i. Explicit choices for R_i will be discussed later; however, we note that it suffices to take R_i to be a preconditioner for A_i.

The multiplicative version is defined by applying the R_i consecutively. The multiplicative preconditioner B_m applied to a function $W \in M$ is defined as follows:

(1) Set $Y_0 = 0$.

(2) For $i = 1, \cdots, K+1$, define Y_i by

$$Y_i = Y_{i-1} + R_{i-1} Q_{i-1}(W - AY_{i-1}). \tag{3.4}$$

(3) For $i = K+2, \cdots, 2K+2$, define Y_i by

$$Y_i = Y_{i-1} + R_{2K+2-i} Q_{2K+2-i}(W - AY_{i-1}). \tag{3.5}$$

(4) Set $B_m W = Y_{2K+2}$.

It is not difficult to see that B_m is a symmetric linear operator on M.

The operators B_a and B_m defined above will be effective as preconditioners A if they satisfy the following:

(1) They are relatively inexpensive to evaluate.

(2) They lead to well-conditioned linear systems.

The first criterion involves implementation issues. The second criterion requires that the condition numbers $K(B_a A)$ and $K(B_m A)$ be small. In the case of the additive algorithms, this is equivalent to the existence of positive constants c_0, c_1 satisfying

$$c_0 A(v,v) \leq A(B_a Av, v) \leq c_1 A(v,v) \quad \text{for all } v \in M, \tag{3.6}$$

with c_1/c_0 small. A similar statement holds for the product algorithm. The goal of the analysis to be presented is to provide estimates for c_0 and c_1.

We note that the subdomains have limited overlap. This immediately implies that $c_1 \le CN_0$, where C depends only on the preconditioning properties of R_i, and N_0 is the maximum number of subdomains overlapping any point $x \in \Omega$. Thus, to analyze the additive algorithm, we are left to estimate the size of c_0. This will be done in the following section.

To analyze the product algorithm, we apply Theorem 2.2 of [6]. Assume that R_i is scaled so that for a fixed $\omega \in (0,2)$,

$$A(R_iA_iv, v) \le \omega A(v,v) \quad \text{for all } v \in M_i. \tag{3.7}$$

Then the product operator defined above satisfies

$$c_2A(v,v) \le A(B_mAv, v) \le A(v,v) \quad \text{for all } v \in M \tag{3.8}$$

where $c_2 \ge Cc_0$. Here c_0 is the constant in (3.6) and C is a positive constant which depends on N_0 and the preconditioning properties of R_i but not on h or H. Thus, to analyze the product algorithm, we are once again left to estimate the size of c_0 in (3.6).

Remark 3.1. It is easy to extend the above ideas to three-dimensional calculations. We consider the case where Ω is the union of rectangular parallelopipeds and the coarse-grid functions are piecewise trilinear on the rectangular parallelopipeds. The refinement subregions are defined to be the interior of the closures of coarse grid parallelopipeds. The composite mesh is defined in terms of a quasi-uniform mesh of parallelopipeds of size $h < H$. This mesh is assumed to be a refinement of the coarse-grid mesh. The space $\tilde{M}$ is defined to be the set of functions which are continuous on Ω, are trilinear with respect to the finer mesh, and vanish on $\partial\Omega$. The construction then proceeds exactly as described above for the two-dimensional case.

4. Convergence analysis. In this section, we provide an analysis for the overlapping domain decomposition preconditioners described in the previous section. As discussed earlier, we are to provide estimates for the constant c_0 appearing in (3.6). The analysis to be presented uses tools from both the theory of overlapping domain decomposition and the standard domain decomposition theory. We shall prove that under suitable hypotheses, the condition numbers $K(B_aA)$ and $K(B_mA)$ remain bounded independently of h and H in the two-dimensional case. The theorem for three dimensions guarantees that the condition numbers grow at most proportional to $(1 + \ln^2(H/h))$.

The first hypothesis for the theorems of this section provides control of the condition number $K(R_iA_i)$. Specifically, we assume that

$$C_0A(w,w) \le A(R_iA_iw, w) \le \omega A(w,w) \quad \text{for all } w \in M_i, \tag{4.1}$$

where the constants C_0 and ω remain fixed independent of h and H. For the product algorithm, we also assume that $0 < \omega < 2$. We have the following theorem.

THEOREM 4.1. *Let $d = 2$ and assume that there are no isolated points on the boundary of Ω^r. Then the condition numbers $K(B_aA)$ and $K(B_mA)$ remain bounded independently of h, H and the choice of subdomains $\{\Omega_i\}$.*

Before proving Theorem 4.1, we review some results from the theory of overlapping and nonoverlapping domain decomposition. These results will play a major role in the subsequent proof.

Let P_i denote the elliptic projection into the subspace M_i, i.e., $P_i v = w$ where w is the unique function in M_i satisfying

$$A(w, \phi) = A(v, \phi) \quad \text{for all } \phi \in M_i.$$

It immediately follows from the definitions that $Q_i A = A_i P_i$ and hence (4.1) implies that, for $v \in M$,

$$\begin{aligned} A(BAv, v) &= \sum_{i=0}^{K} A(R_i Q_i A v, v) \\ &= \sum_{i=0}^{K} A(R_i A_i P_i v, P_i v) \geq C_0 \sum_{i=0}^{K} A(P_i v, v). \end{aligned}$$

Thus, $c_0 \geq \tilde{c}_0 C_0$ for any constant $\tilde{c}_0$ satisfying the inequality

$$\tilde{c}_0 A(v, v) \leq \sum_{i=0}^{K} A(P_i v, v) \quad \text{for all } v \in M. \tag{4.2}$$

It is known (cf. [11]) that (4.2) follows provided that $\tilde{c}_0$ is a constant such that for any $v \in M$ there is a decomposition $v = \sum_{i=0}^{K} v_i$, with $v_i \in M_i$, satisfying

$$\sum_{i=0}^{K} A(v_i, v_i) \leq \tilde{c}_0^{-1} A(v, v). \tag{4.3}$$

We remark that it is easy to prove that statements (4.2) and (4.3) are equivalent.

We shall require a known result concerning overlapping domain decomposition [9], [11]. For each coarse-grid node x_i, we let $\tilde{\Omega}_i$ denote the interior of the union of the closures of the coarse-grid triangles that have x_i as a vertex. We define $\tilde{M}_i$ in terms of $\tilde{\Omega}_i$ as in (3.1). Given $w \in \tilde{M}$, there exists a decomposition $w = \sum_{i=1}^{N_c} \tilde{w}_i$, with $\tilde{w}_i \in \tilde{M}_i$, satisfying

$$\sum_{i=1}^{N_c} A(\tilde{w}_i, \tilde{w}_i) \leq C \left(A(w, w) + H^{-2} \|w\|^2 \right). \tag{4.4}$$

Here C is a constant not depending on h or H. The functions $\{\tilde{w}_i\}$ are defined in terms of a partition of unity with respect to the subdomains $\{\tilde{\Omega}_i\}$. An explicit partition can be defined from the coarse-grid nodal basis functions. These decompositions preserve support in the sense that if w vanishes at a node then every $\tilde{w}_i$ vanishes there also.

We will also need results from the standard domain decomposition theory which we introduce as the following lemma. The proof of this lemma is essentially given in [4].

LEMMA 4.1. *Let $y \in M \cap \tilde{M}_i$ be discrete harmonic on each coarse grid triangle. By this we mean that*

$$A(y, \phi) = 0$$

for all functions $\phi \in M$ which vanish on the coarse-grid mesh. Assume that y vanishes on at least one coarse-grid edge connecting $\partial\tilde{\Omega}_i$ and x_i. Let $\{\Gamma_j\}$ denote the remaining coarse-grid edges connecting $\partial\tilde{\Omega}_i$ and x_i and define y_j to be the function which is *discrete harmonic on the coarse-grid triangles, equals y on $\tilde{\Gamma}_j$ and vanishes on the remaining coarse-grid edges. Then $y = \sum_j y_j$ and*

$$\sum_j A(y_j, y_j) \le CA(y, y). \tag{4.5}$$

Remark 4.1. If the function y in Lemma 4.1 vanishes only on the point x_i (instead of a line from $\partial\tilde{\Omega}_i$ to x_i), then the above decomposition is still defined. However, in such cases, (4.5) only holds with the constant C replaced by $c\ln^2(H/h)$.

Proof of Theorem 4.1. As discussed in the previous section, it suffices to estimate the constant c_0 in (3.6). This in turn follows from the construction of a decomposition $v = \sum_{i=0}^K v_i$ with $v_i \in M_i$ satisfying (4.3).

Let Q denote the $L^2(\Omega)$ projection operator onto the subspace M_0.

We note that

$$\|(I - Q)w\|^2 \le CH^2 A(w, w) \tag{4.6}$$

and

$$A(Qw, Qw) \le CA(w, w) \tag{4.7}$$

hold for all $w \in H_0^1(\Omega)$.

We define v_0 in terms of Q by

$$v_0(x_i) = \begin{cases} v(x_i) & \text{for coarse-grid nodes } x_i \notin \Omega^r, \\ Qv(x_i) & \text{for coarse-grid nodes } x_i \in \Omega^r. \end{cases}$$

Clearly, we have that

$$\begin{aligned} A(v - v_0, v - v_0) &= A_r(v - v_0, v - v_0) \\ &\le 2[A((I - Q)v, (I - Q)v) + A_r(Qv - v_0, Qv - v_0)]. \end{aligned} \tag{4.8}$$

Here $A_r(\cdot,\cdot)$ is given by (2.2) but with integration only over the domain Ω^r. Note that $Qv - v_0$ is a function in M_0 which vanishes at all coarse-grid nodes in Ω^r and is equal to $Qv - v$ on the remaining coarse-grid nodes. Consequently,

$$A_r(Qv - v_0, Qv - v_0) \le C \sum_{x_i \in \partial\Omega^r} |(Qv - v)(x_i)|^2 . \tag{4.9}$$

Here, the sum is taken over coarse grid nodes $x_i \in \partial\Omega^r$. There are no isolated points on $\partial\Omega^r$ and hence for each $x_i \in \partial\Omega^r$, there is a coarse grid edge Γ_i contained in $\partial\Omega^r$ ending at x_i. Both functions Qv and v are linear on Γ_i and hence

$$\begin{aligned} |(Qv - v)(x_i)|^2 &\le cH^{-1} \|(Qv - v)\|_{\Gamma_i}^2 \\ &\le C[H^{-2} \|Qv - v\|_{\tau_H^i}^2 + A_{\tau_H^i}(Qv - v, Qv - v)]. \end{aligned} \tag{4.10}$$

Here τ_H^i denotes a coarse-grid triangle containing the edge Γ_i and $A_{\tau_H^i}$ denotes the form defined by (2.2) but with integration only over the region τ_H^i. The last inequality in (4.10) is a simple consequence of the divergence theorem and is well known. Combining (4.6)–(4.10) proves that

$$A(v - v_0, v - v_0) \le CA(v, v). \tag{4.11}$$

A similar argument gives that

$$\|v - v_0\|^2 \le CH^2 A(v, v). \tag{4.12}$$

We next apply the overlapping domain decomposition result to $w = v - v_0$. Specifically, we decompose $w = \sum_{i=1}^{N_c} \tilde{w}_i$, with $\tilde{w}_i \in \tilde{M}_i$ and satisfying (4.4). Note that this is clearly not the desired decomposition into the refinement subspaces $\{M_i\}$. We will distribute the functions $\tilde{w}_j$, $j = 1, \cdots, N_c$, into these subspaces. We start assigning each coarse grid-node $x_j \in \Omega^r$ to a unique subdomain $\Omega_{J(j)}$ which contains x_j. We then define

$$w_i = \sum_{J(j)=i} \tilde{w}_j.$$

We need to decompose the remaining functions $\tilde{w}_i$ for $x_i \notin \Omega^r$. Note that by the support property, $\tilde{w}_i$ vanishes unless $x_i \in \partial\Omega^r$. Consider a fixed function $\tilde{w}_i$ with $x_i \in \partial\Omega^r$. We write $\tilde{w}_i = y + y_i^0$ where $y = \tilde{w}_i$ on the boundaries of the coarse-grid triangulation and is discrete harmonic on the coarse-grid triangles (as in Lemma 4.1). The function y_i^0 vanishes on the boundaries of the coarse-grid triangulation and is orthogonal (in $A(\cdot,\cdot)$) to y. Note that the function y_i^0 is nonzero only on triangles contained in the refinement region. Thus, we can assign each of these triangles uniquely to a subdomain Ω_j and add the restriction of y_i^0 to the corresponding function w_j. The result of these modifications will still be denoted $\{w_j\}$.

We finally distribute the function y. There are no isolated points in $\partial\Omega^r$ and hence there must be a coarse-grid edge ending at x_i contained in $\partial\Omega^r$. Note, in addition, that both $\tilde{w}_i$ and y vanish on this edge. Thus, by Lemma 4.1,

$$\sum_j A(y_j, y_j) \leq CA(y, y). \tag{4.13}$$

The functions y_j are defined in Lemma 4.1 and the sum over j is taken over the coarse-grid indices corresponding to coarse-grid neighbors of x_i in Ω^r. The functions y_j are assigned to subdomains Ω_k which contain the corresponding edge (where y_j is nonzero) and the functions y_j are added into the corresponding w_k, producing a result which is still denoted w_k. It follows immediately that $w = \sum_{i=1}^K w_i$ and

$$\sum_{i=1}^K A(w_i, w_i) \leq C(A(w, w) + H^{-2} \|w\|^2). \tag{4.14}$$

Combining (4.11), (4.12), and (4.14) shows that the decomposition $v = \sum_{i=0}^K v_i$ with $v_i = w_i$ for $i = 1, \cdots, K$ satisfies (4.3). This completes the proof of the theorem. □

Remark 4.2. The hypothesis concerning isolated points on the boundary of Ω^r is included to provide a uniform bound for c_0. It is possible to show (using of [4], Thm. 1) that the constant c_0 only deteriorates like $C/\ln^2(H/h)$ if the isolated point hypothesis is not satisfied. This sort of decay is actually seen in the last numerical example in §5 where this assumption is violated.

Remark 4.3. There is very little restriction concerning the way that the domains Ω_i are defined. Note that if only one refinement domain is used, then Theorem 4.1 provides a result for the imbedded space case proposed in [2]. Alternatively, one can consider the case where Ω^r is all of Ω and hence $M = \tilde{M}$. In this case, Theorem 4.1 guarantees uniform bounds for the condition numbers without putting restrictions on the shapes of the subdomains $\{\Omega_i\}$. Thus, for example, the subdomains can be taken to be strips as long as the coarse problem is included.

Remark 4.4. There are numerous ways of modifying the above algorithm. One possibility is to include additional subspaces corresponding to the coarse-grid nodes on $\partial\Omega^r$. For such a node x_k, the space M_k would be defined to be the functions in M^r

with support in Ω_k. The same result holds with a somewhat simpler analysis since the standard domain decomposition theory is avoided. However, this algorithm has some practical disadvantages. There are more subproblems and many of them correspond to grids on irregularly shaped domains.

We next provide the result for three-dimensional applications.

THEOREM 4.2. *Let Ω be a domain in R^3 and let the mesh and approximation space be as discussed in Remark* 3.1. *Assume that the hypotheses preceding Theorem* 4.1 *hold and that Ω^r is the interior of its closure. Then*

$$K(B_aA) \le C(1+\ln^2(H/h))$$

and

$$K(B_mA) \le C(1+\ln^2(H/h)).$$

The constant C above does not depend on H or h.

Proof. The major part of the proof follows the proof of Theorem 4.1. We seek a decomposition of $v \in M$ satisfying (4.3) with $\tilde{c}_0^{-1} \le C(1+\ln^2(H/h))$. The construction of v_0 is exactly the same as in Theorem 4.1 and still satisfies (4.11) and (4.12). Here we used the assumption that Ω^r was the interior of its closure.

The overlapping domain decomposition $w = \sum_{i=1}^{N_c} \tilde{w}_i$ satisfying (4.4) is also valid in three dimensions. Once again we reduce to the problem of decomposing functions $\tilde{w}_k$ corresponding to coarse-grid nodes $x_k \in \partial\Omega^r$. As in the proof of Theorem 4.1, we write $\tilde{w}_k = y + y_k^0$, where y is discrete harmonic (with respect to the refined mesh) in the interior of the coarse parallelopipeds. The y_k^0 part is added into $\{w_i\}_{i=1}^K$.

Finally, we must take care of the function y. We write

$$y = \sum \bar{y}_{ij} + \sum \tilde{y}_l, \tag{4.15}$$

where:

(1) The functions $\{\bar{y}_{ij}\}$ are discrete harmonic (with respect to the refined mesh) in the interior of the coarse parallelopipeds.

(2) $\bar{y}_{ij} = y$ on the interior nodes on the face between coarse regions τ_H^i and τ_H^j and vanishes on the remaining nodes of $\cup\partial\tau_H^l$.

(3) $\tilde{y}_l$ equals y on the nodes of an edge of $\{\tau_H^l\}$ which is in $\tilde{\Omega}_k \cap \Omega_l$ and vanishes on all of the remaining nodes of the composite grid.

(4) The sums in (4.15) are taken over the appropriate faces and edges.

Applying Lemma 4.3 of [5] gives that

$$A(\bar{y}_{ij}, \bar{y}_{ij}) \le C(1+\ln^2(H/h))\{|\tilde{w}_k|^2_{1/2,\partial\tau_H^i} + H^{-1}|\tilde{w}_k|^2_{\tau_H^i}\}.$$

Here $|\cdot|_{1/2,\partial\tau_H^i}$ denotes the Sobolev seminorm of order 1/2 on $\partial\tau_H^i$. We clearly have

$$A(\bar{y}_{ij}, \bar{y}_{ij}) \le C(1+\ln^2(H/h))(A(w_k,w_k) + H^{-2}\|w_k\|^2).$$

Similar arguments using Lemmas 4.1–4.2 of [5] give

$$A(\tilde{y}_l, \tilde{y}_l) \le C(1+\ln^2(H/h))(A(w_k,w_k) + H^{-2}\|w_k\|^2).$$

The desired bound for $\tilde{c}_0^{-1}$ follows as in the proof of Theorem 4.1.

5. Numerical results. In this section, we provide the results of numerical examples illustrating the theory developed earlier. We shall consider the model problem

$$\begin{aligned} -\Delta u &= f \quad \text{in } \Omega, \\ u &= 0 \quad \text{on } \partial\Omega, \end{aligned} \tag{5.1}$$

where Δ denotes the Laplacian and Ω is the unit square $[0,1] \times [0,1]$. To define the coarse mesh, the domain Ω is first partitioned into $m \times m$ square subdomains of side length $H = 1/m$. Each smaller square is then divided into two triangles by one of the diagonals (e.g., the diagonal which goes from the bottom left to the upper right-hand corner of the square). The coarse-grid approximation space M_0 is defined to be the set of functions which are continuous on Ω, are piecewise linear with respect to the triangulation, and vanish on $\partial\Omega$. The space $\tilde{M}$ is defined from a similar finer mesh of size $h = H/l$ for some integer $l > 1$.

For our first two examples, we consider an application where it is required to refine along the diagonal connecting the origin with the point $(1,1)$. Such a refinement might be necessary if the function f has large gradients near this diagonal but is well behaved in the remainder of Ω. Accordingly, we select the coarse-grid nodes on the diagonal for refinement. We define the refinement region associated with a refinement node to be the four coarse mesh squares which have that node as a corner.

Note that the refinement region is highly irregular even though the coarse problem and the refinement subproblems involve regular rectangular meshes.

We will illustrate the rate of convergence of preconditioned algorithms for solving (3.2) where $A(\cdot,\cdot)$ is given by the Dirichlet form. To do this, we shall numerically compute the largest and smallest eigenvalue (λ_1 and λ_0, respectively) of the preconditioned operator $B_a A$. As is well known, the rate of convergence of the resulting preconditioned algorithms can be bounded in terms of the condition number $K(B_a A) = \lambda_1/\lambda_0$. We shall not report results for preconditioning with the product operator B_m, although our previous experience [6] suggests that the product version will converge somewhat faster than the additive.

Table 5.1 gives the largest and smallest eigenvalue and the condition number of the system $B_a A$ as a function of h. In this example, we took $R_i = A_i^{-1}$; i.e., we solved exactly on the subspaces $\{M_i\}$. For Table 5.1, $m = 4$, and there are three refinement subdomains $(0,1/2) \times (0,1/2)$, $(1/4,3/4) \times (1/4,3/4)$, and $(1/2,1) \times (1/2,1)$. Note that both the upper and lower eigenvalues appear to be tending to a limit as the ratio $h/H \mapsto 0$. Similar behavior is seen in Table 5.2, which corresponds to $m = 8$ and uses seven smaller refinement subregions.

TABLE 5.1
Condition numbers for 3 overlapping subregions.

h	λ_1	λ_0	$K(B_a A)$
1/8	2.44	0.50	4.9
1/16	2.50	0.41	6.1
1/32	2.51	0.38	6.6
1/64	2.52	0.36	6.9
1/128	2.52	0.35	7.1

In almost all realistic applications, the direct solution of subproblems is much more expensive than the evaluation of a suitable preconditioner. To illustrate the effect on the convergence rate of the preconditioned iteration, we next consider the previous example but with the direct solves on the subspaces replaced by multigrid preconditioners. Specifically, we employ the V-cycle multigrid algorithm (cf. [3]) using one pre- and post-smoothing Jacobi iteration on each grid level. This leads to

TABLE 5.2
Condition numbers for 7 overlapping subregions.

h	λ_1	λ_0	$K(B_aA)$
1/16	2.46	0.47	5.2

1/64	2.54	0.35	7.2
1/128	2.54	0.34	7.5

a preconditioning operator $R_i : M_i \mapsto M_i$, which satisfies

$$0.4A(v, v) \leq A(R_iA_iv, v) \leq A(v, v) \quad \text{for all } v \in M_i. \tag{5.2}$$

The constant 0.4 above was computed numerically and holds for all of the subspace problems that are required for this application, including M_0.

Tables 5.3 and 5.4 provide the eigenvalues and condition numbers for the above examples when direct solves were replaced by multigrid preconditioners. Note that in all of the reported runs, the condition number with multigrid preconditioners was at most 5/4 times as large as that corresponding to exact solves. Such an increase in condition number is negligible in a preconditioned iteration. In contrast, the computational time required for the multigrid sweep is considerably less than that needed for a direct solve (especially in more general problems with variable coefficients).

TABLE 5.3
Preconditioned subproblems, 3 overlapping subregions.

h	λ_1	λ_0	$K(B_aA)$
1/8	2.37	0.53	4.5
1/16	2.12	0.33	6.4
1/32	2.07	0.27	7.6
1/64	2.04	0.25	8.2
1/128	2.02	0.24	8.4

TABLE 5.4

h	λ_1	λ_0	$K(B_aA)$
1/16	2.36	0.40	5.9
1/32	2.11	0.28	7.5
1/64	2.06	0.24	8.8
1/128	2.03	0.22	9.4

As a final example, we consider a case where the isolated point hypothesis of Theorem 4.1 is not satisfied. Specifically, we consider a coarse mesh of size $H = 1/4$ and select the four nodes with (x, y) values (1/4,1/2), (3/4,1/2), (1/2,1/4), and

(1/2,3/4). The refinement region is everything but the subsquares $[0,1/4] \times [0,1/4]$, $[0,1/4] \times [3/4,1]$, $[3/4,1] \times [0,1/4]$, and $[3/4,1] \times [3/4,1]$. Note that, to satisfy the hypotheses of the theorem, it would be necessary to include a refinement region centered at the coarse-grid node $(1/2,1/2)$. Table 5.5 gives the smallest eigenvalue for the operator $B_a A$ as a function of h. The function $(.32+.36\log_2(h^{-1}))^{-2}$ is also provided for comparison. These results suggest that smallest eigenvalue λ_0 decays as predicted by the theoretical bound $C/\ln(H/h)^2$ (see Remark 4.2).

TABLE 5.5
A "bad" example in two dimensions.

A LARGE, SPARSE, AND INDEFINITE GENERALIZED EIGENVALUE PROBLEM FROM FLUID MECHANICS*

HANS D. MITTELMANN†, CINDY C. LAW‡, DANIEL F. JANKOWSKI‡, AND G. PAUL NEITZEL‡

Abstract. A numerical method for calculating the minimum positive eigenvalue of a sparse, indefinite, Hermitian algebraic problem has been developed. The method is based on inverse iteration and is a generalization of a procedure previously employed for the simpler problem of finding the smallest eigenvalue of a positive-definite matrix. Motivation was provided by a three-dimensional research problem from hydrodynamic stability. Stability limits obtained from the application of the method to a previously studied problem are compared to independently determined results.

Key words. eigenvalue problem, thermocapillary convection, energy stability, inverse iteration

AMS(MOS) subject classifications. 76E15, 76D99, 65F15

1. Background and motivation.

Hydrodynamic stability theory is concerned with determining the conditions under which a certain flow, called the *basic state*, will remain stable or become unstable due to the inevitable presence of unknown perturbations (see Joseph (1976)). In general, these perturbations are governed by nonlinear partial differential equations. Linear-stability theory assumes the perturbations to be infinitesimally small and neglects the nonlinear terms in comparison with their linear counterparts. This theory is local in nature and results in a criterion that guarantees growth of these small disturbances. Typically, an externally controllable dimensionless parameter, say, R, is selected and linear theory yields a value R_L such that $R > R_L$ is a sufficient condition for instability.

Energy stability theory, on the other hand, adopts a global approach by examining the behavior of a generalized integral disturbance energy. Unlike linear stability theory, energy-stability theory provides a value R_E such that $R < R_E$ is a sufficient condition for stability of a given basic state to disturbances of *arbitrary amplitude.* This technique is equivalent to a stability analysis utilizing a Lyapunov function (see Sinha and Carmi (1976) and the literature cited there). The application of either theory gives rise, in general, to an eigenvalue problem.

If R_E and R_L should coincide, a rigorous stability bound is obtained. However, this is usually not the case and the proximity of R_E to R_L is a function of the physical mechanism which gives rise to the instability (see Davis (1971)). Two such mechanisms for which R_E and R_L may be expected to be relatively close to each other are buoyancy and thermocapillarity. The former is responsible for the onset of convection in an initially quiescent fluid layer that is heated from below (cooled from above) under certain conditions. This is the classically termed *Bénard convection.* Thermocapillarity, which is the variation of a liquid's surface tension with temperature, can

*Received by the editors April 5, 1990; accepted for publication (in revised form) December 5, 1990. also result in the instability of a quiescent liquid layer with a free surface (liquid-gas interface) when heated from below. This is known as *Marangoni convection.*

Buoyancy and thermocapillarity are also mechanisms that can drive *dynamic* basic states, which themselves can become unstable; for instance, the buoyancy boundary layer adjacent to a vertical heated surface and *thermocapillary convection*, which results when a temperature gradient exists *along* a free surface. Problems of technological interest in which both of these mechanisms play an important role may be found in the field of materials processing. One problem in particular that has received a considerable amount of attention is the stability of thermocapillary convection associated with the *float-zone crystal-growth process.* This process has been identified as one that may benefit from a microgravity environment. Although buoyancy forces will be significantly reduced in such an environment, thermocapillary convection will persist. Since it has been conjectured that the instability of thermocapillary convection may be responsible for undesirable striations observed in material grown by this process, the stability properties of this basic state are of interest for both terrestrial and microgravity conditions.

Recent work on the stability of thermocapillary convection has been done by Shen, Neitzel, Jankowski, and Mittelmann (1990). They employed energy stability theory to obtain sufficient conditions for stability against *axisymmetric* disturbances. Comparisons with the experimental results of Preisser, Schwabe, and Scharmann (1983) have identified a need for corresponding results for nonaxisymmetric disturbances. The present work is motivated by the need for obtaining such stability information.

The earlier work of Shen et al. (1990) required the calculation of the smallest positive eigenvalue of a generalized eigenvalue problem of the form $\mathbf{A}x = \rho\mathbf{B}x$. Energy theory, since it has its basis in a variational problem, results in a differential eigenvalue problem that is selfadjoint. The direct discretization of the variational problem employed by Shen et al. preserved this character and thus resulted in *real symmetric* matrices $\mathbf{A}$ and $\mathbf{B}$. There are several complicating features: (i) both matrices are indefinite; (ii) the basic-state quantities in $\mathbf{B}$ depend on the stability parameter; and (iii) both $\mathbf{A}$ and $\mathbf{B}$ depend on a free coupling parameter λ. The latter two complications are easily dealt with by iteration processes, once a reliable procedure for calculating the eigenvalue of interest has been developed.

The standard algorithm for the solution of eigenvalue problems of the form $\mathbf{A}x = \rho\mathbf{B}x$, for general real or complex matrices $\mathbf{A}$ and $\mathbf{B}$, is the QZ algorithm. This method computes *all* of the eigenvalues of the system by means of orthogonal transformations. However, since it does not exploit either the sparsity or symmetry of $\mathbf{A}$ and $\mathbf{B}$, and only a single eigenvalue is desired, its use in the application of interest, where the system order is typically quite large, is extremely inefficient in terms of computer resources. In addition, it is possible that the calculation of the *single* eigenvalue of interest, which does not occur at any particular stage of the overall solution process, can be contaminated by earlier calculations. These factors motivated the development of the method that was successfully used by Shen et al. (1990). The QZ algorithm was used solely to obtain some insight into the distribution of the complete family of eigenvalues for coarse discretizations (i.e., low system order) of the variational problem.

Theoretically, the inclusion of nonaxisymmetric disturbances into the discretized functional is straightforward, involving only a normal-mode decomposition in the azimuthal coordinate (cf. (2.9)). However, the corresponding computational problem is more difficult because the matrices in the algebraic eigenvalue problem become *complex* and *Hermitian.* The numerical procedure of Shen, Neitzel, Jankowski, and

Mittelmann (1990) is unable to handle this case and some modification is necessary. Basically, their procedure is a form of inverse iteration. The modification to handle complex Hermitian matrices uses a residual-based inverse iteration, which, in each step, computes an increment of the last iterate and employs additional orthogonal projections. Both of these modifications were made, since standard inverse iteration computes nearly parallel vectors and the loss of significance in the correction to the previous vector leads to slow or no convergence. The complex case is reduced to a real case of twice the dimension, which is also symmetric. This permits a relatively efficient solution of this indefinite system using preconditioned conjugate-gradient methods. So far our emphasis has been on developing a working algorithm and obtaining solutions to these yet unsolved stability problems. An analysis of the method employed may be given in future work. It must be stressed, however, that the indefiniteness of both A and B makes this eigenvalue problem more general than is usually considered in the literature for large sparse eigenproblems from the applications. The recent survey article by Kerner (1989), for example, addresses only the case in which B is definite. Nevertheless, it may be that suitable generalizations of existing algorithms, for example, of generalized Davidson's method (see Morgan and Scott (1986)) to the present case may provide alternative approaches. This method, if applicable, would allow indefinite preconditioners.

In order to test this new numerical approach, we choose to examine in this paper a related stability problem for which results are available. As in Shen et al. (1990), we consider the onset of buoyant convection in a fluid-filled cylinder heated from below with either a conducting or insulating sidewall boundary. Linear-stability limits have been computed by Charlson and Sani (1970), (1971) for both axisymmetric and nonaxisymmetric disturbances. These linear-theory results can be compared directly with those of energy theory since it can be shown for this problem that both limits coincide (see Joseph (1976)). Although the heated-cylinder problem is somewhat simpler than the float-zone problem for which results will ultimately be computed, it nevertheless serves as an excellent test problem for the numerical procedure. For the first results on the float-zone problem, see Mittelmann, Law, Jankowski, and Neitzel (1991).

In the following section the application of energy-stability theory to the heated-cylinder problem will be described. Subsequently, the new version of the inverse iteration procedure for the computation of the stability bounds will be presented. Results for the heated-cylinder problem will be compared to those of Charlson and Sani (1970) and (1971), followed by a discussion on the generalization of the method to the problem of thermocapillary convection in a model of the float-zone crystal-growth process.

2. Energy-stability analysis of the heated-cylinder problem.

Consider a right circular cylinder of height H and radius R that is filled with a Boussinesq fluid of kinematic viscosity ν and thermal diffusivity κ, and oriented with its axis of symmetry in the direction of the gravitational acceleration of magnitude g. The top and bottom surfaces of the cylinder are maintained at temperatures T_C and $T_H > T_C$, respectively, and the sidewall may be either perfectly conducting or perfectly insulating. The dimensionless Boussinesq equations that govern the temperature $T(r,\theta,z,t)$, pressure $p(r,\theta,z,t)$, and velocity $\mathbf{v}(r,\theta,z,t)$ fields are

$$\mathbf{v}_t + Ra^{1/2}\mathbf{v}\cdot\nabla\mathbf{v} = -Pr\nabla p + Pr\nabla^2\mathbf{v} + Ra^{1/2}PrT\mathbf{e}_z, \tag{2.1}$$

$$T_t + Ra^{1/2}\mathbf{v}\cdot\nabla T = \nabla^2 T, \tag{2.2}$$

$$\nabla \cdot \mathbf{v} = 0, \tag{2.3}$$

where H, $kRa^{1/2}/H$, $\rho\nu\kappa Ra^{1/2}/H^2$, H^2/κ have been used to scale lengths, velocity, pressure, and time, respectively. The dimensionless temperature is defined to be

$$T = (T' - T_m)/\Delta T,$$

where T' is the dimensional temperature, $T_m = (T_H + T_C)/2$ is the mean temperature, and $\Delta T = T_H - T_C$. The dimensionless parameters appearing in (2.1) are the Rayleigh and Prandtl numbers, which are defined as

$$Ra = \beta g H^3 \Delta T/\kappa\nu$$

and

$$Pr = \nu/\kappa,$$

where β is the coefficient of thermal expansion.

The boundary conditions to be applied require no penetration and no slip at solid boundaries, constant temperatures at the planar endwalls, conducting or insulating conditions at the sidewall, and boundedness of all quantities on the axis of symmetry. Equations (2.1)–(2.3), along with the appropriate boundary conditions, permit a solution that is motionless ($\mathbf{v} = 0$), with the linear (pure conduction) temperature profile

$$\Theta(z) = 1/2 - z \tag{2.4}$$

and corresponding pressure distribution

$$P(z) = 1/2Ra^{1/2}z(1 - z) \tag{2.5}$$

where the arbitrary constant of integration in (2.5) has been chosen to be zero. This is the *basic state* of interest in the present paper.

We begin the energy-theory analysis of the basic state in the usual fashion by deriving the energy identity. We assume there exists a solution $[\mathbf{u}, p, T]$ to the governing equations ((2.1)–(2.3)) that is a perturbation to the motionless conducting basic state, i.e.,

$$\begin{aligned}[\mathbf{u}, p, T] =& [0, P(z), \Theta(z)] \\ &+ [u'(r,z,\theta,t), v'(r,z,\theta,t), w'(r,z,\theta,t), p'(r,z,\theta,t), T'(r,z,\theta,t)].\end{aligned} \tag{2.6}$$

In our earlier work (see Shen et al. (1990)) on the float-zone problem, we had restricted consideration to axisymmetric disturbances, i.e., the disturbance had no θ-component of velocity and no θ-dependence.

Substitution of (2.6) into the governing equations and the appropriate boundary conditions leads to a system of equations and boundary conditions for the disturbance quantities. We then take the inner product of the disturbance momentum equation with $\mathbf{u}'$, add to this the disturbance energy equation multiplied by $\lambda Pr T'$, and integrate over the volume

$$V = \{(r, \theta, z) \mid 0 \le r \le A,\ 0 \le \theta \le 2\pi,\ 0 \le z \le 1\}$$

of the cylinder, using the disturbance boundary conditions. The parameter $A = R/H$ is the aspect ratio of the cylinder. The result is the exact disturbance-energy evolution equation, which may be written (see Davis and von Kerczek (1973)),

$$\frac{1}{E}\frac{dE}{dt} = \frac{1}{E}\left(-PrD - Ra^{1/2}PrI\right), \tag{2.7}$$

where

$$E = \frac{1}{2}\int_V (\mathbf{u}' \cdot \mathbf{u}' + \lambda Pr T'^2)\, dV, \quad D = \int_V (\nabla \mathbf{u}' \cdot \nabla \mathbf{u}' + \lambda \nabla T' \cdot \nabla T')\, dV,$$

$$I = -\int_V (1+\lambda) w' T' dV.$$

The velocity and temperature disturbances have been joined by a positive *coupling parameter* λ (see Joseph (1976)) to form a generalized disturbance energy, E. An upper bound is constructed for the resulting right-hand side of this equation,

$$\nu = \max_H \left(\frac{-PrD - PrRa^{1/2} I}{E} \right), \tag{2.8}$$

where the maximum is taken over the space of kinematically admissible functions,

$$H = \{\mathbf{u}', T' \mid \mathbf{u}' = T' = 0 \text{ at } z = 0, 1; \text{ boundedness at } r = 0;$$
$$\mathbf{u}' = 0 \text{ and appropriate, homogeneous thermal conditions at } r = A; \nabla \cdot \mathbf{u}' = 0\}.$$

We choose to formulate the problem so that the Rayleigh number is the stability parameter. For fixed values of the other parameters associated with the problem, the smallest value of Ra that corresponds to the condition $\nu = 0$ will be called Ra^*.

The cylindrical geometry allows a Fourier decomposition in the azimuthal coordinate of the form

$$u'(r, \theta, z, t) \rightarrow \mathbf{u}(r, z, t) e^{in\theta} + \bar{\mathbf{u}}(r, z, t) e^{-in\theta}, \tag{2.9}$$

where n is the azimuthal (integer) wave number and "$^-$" denotes complex conjugation. Since λ is a free parameter, the maximum value of Ra^* for positive values of λ is sought (see Joseph (1976)), while a minimization has to be carried out with respect to n. The resulting value is the energy-stability limit, Ra_E, defined as

$$Ra_E = \min_n \max_{\lambda > 0} Ra^*. \tag{2.10}$$

It can be shown that $Ra < Ra_E$ is a sufficient condition for stability against disturbances of arbitrary amplitude belonging to the class H. For the problem of interest here, the search for the maximizing λ can be done analytically with the result that $\lambda = 1$ is the optimal choice.

It is convenient to consider a slightly different functional than ν in (2.8) that incorporates the divergence constraint by means of a Lagrange multiplier. Hence, the maximum problem to be solved is expressed as

$$\max_h \left[-PrD - PrRa^{1/2} I + 2\int_V \pi \nabla \cdot \mathbf{u}'\, dV + \bar{\nu}(E-1) \right] = 0, \tag{2.11}$$

where $\bar{\nu}$ is a Lagrange multiplier expressing the arbitrary normalization $E = 1$, $\pi(r, z)$ is a Lagrange multiplier, and h is the extension of H obtained by removing the divergence constraint. It is easy to show that $\nu = \bar{\nu}$. Following Shen et al. (1990), we consider the variation of a discretized version F_D of the *quadratic* functional

$$F = -PrD - PrRa^{1/2} I + 2\int_V \pi \nabla \cdot \mathbf{u}'\, dV.$$

The explicit homogeneous boundary conditions that arise following normal-mode decomposition and that are applied during the discretization process are dependent upon the azimuthal wave number n (see Batchelor and Gill (1962)). The same discretization procedure employed by Shen et al. (1990) is used, but there are probably opportunities available for further study of this topic.

A stationary value of F_D is located by differentiating it with respect to each unknown and setting each of these derivatives to zero, i.e.,

$$\frac{\partial F_D}{\partial q} = 0 \qquad q = u_{i,j}, v_{i,j}, w_{i,j}, \phi_{i,j} \quad \text{or } \pi_{k,l}; \tag{2.12}$$

here the indices correspond to a nodal numbering, see Shen et al. (1990). This process yields a *generalized algebraic eigenvalue* problem. We seek its minimum positive eigenvalue as the approximate (subject to discretization error) value of Ra^*. Calling the vector consisting of the unknowns on all grid points $\overline{\mathbf{X}}$, we rewrite (2.12) in the matrix form

$$\bar{\mathbf{A}}\overline{\mathbf{X}} = \rho\overline{\mathbf{B}}\,\overline{\mathbf{X}}, \tag{2.13}$$

where $\bar{\mathbf{A}}$ and $\overline{\mathbf{B}}$ are *indefinite, Hermitian* matrices with $\bar{\mathbf{A}}$ having a banded structure. More precisely, $\bar{A}$ and $\bar{B}$ have the following block structure

$$\bar{A} = \begin{pmatrix} A_{11} & A_{12} \\ \bar{A}_{12}^T & 0 \end{pmatrix}, \qquad \bar{B} = \begin{pmatrix} B_{11} & 0 \\ 0 & 0 \end{pmatrix},$$

where the upper left submatrices arise from the above functionals, while A_{12} results from the incompressibility condition. $\bar{B}$ has null vectors associated with its lower blocks, but B_{11} in general may yield additional null vectors.

3. Numerical procedure for finding Ra_E.

Equation (2.13) represents a generalized eigenvalue problem. The matrices $\bar{\mathbf{A}}$ and $\overline{\mathbf{B}}$ are Hermitian and sparse, but, in general, indefinite. For the ultimate problem of interest, in addition to the basic-state dependence of $\overline{\mathbf{B}}$ mentioned above, $\bar{\mathbf{A}}$ and $\overline{\mathbf{B}}$ depend nonlinearly on the other parameters of the problem, namely, Pr and the coupling parameter, λ. Due to the fact that we report here on the heated cylinder problem as a test for both the discretization procedure and the eigenproblem solver, we need to consider only fixed values of these parameters, reducing (2.13) to the generalized eigenvalue problem

$$\bar{\mathbf{A}}\overline{\mathbf{X}} = \rho\overline{\mathbf{B}}\,\overline{\mathbf{X}}, \qquad \|\overline{\mathbf{X}}\| = 1, \tag{3.1}$$

where $\|\cdot\|$ denotes the Euclidean norm.

The eigenvalues ρ of (3.1) are, in general, complex since in the case of at least one of the matrices being regular the problem is equivalent to the eigenvalue problem for a non-Hermitian complex matrix. Null vectors of $\bar{\mathbf{A}}$ and $\overline{\mathbf{B}}$ correspond to zero and "infinite" eigenvalues, respectively. The method developed for the present computations makes use of the sparseness of $\bar{\mathbf{A}}$ and $\overline{\mathbf{B}}$, the fact that they are Hermitian, and computes only the eigenvalue of interest.

Since a real eigenvalue of (3.1) has to be computed, it is convenient to transform the problem so that only real arithmetic is needed. Let

$$\mathbf{A} = \begin{bmatrix} \mathrm{Re}(\bar{\mathbf{A}}) & -\mathrm{Im}(\bar{\mathbf{A}}) \\ \mathrm{Im}(\bar{\mathbf{A}}) & \mathrm{Re}(\bar{\mathbf{A}}) \end{bmatrix},$$

where $\mathrm{Re}(\cdot)$, $\mathrm{Im}(\cdot)$ denote real and imaginary parts, and let $\mathbf{B}$ be defined in a similar way. A straightforward calculation shows that the eigenvalue problem

$$\mathbf{A}X = \rho\mathbf{B}X, \qquad \mathbf{X} \neq 0 \tag{3.2}$$

has the eigenpairs $\rho, (\overline{\mathbf{X}}, -i\overline{\mathbf{X}})^T$, $\overline{\rho}, (\overline{\overline{\mathbf{X}}}, i\overline{\overline{\mathbf{X}}})^T$, where $\rho, \overline{\mathbf{X}}$ are the eigenpairs of (3.1) and $i = \sqrt{-1}$ is the imaginary unit. Thus, each eigenvalue of (3.1) corresponds to a pair of complex-conjugate eigenvalues of (3.2).

It is important to note that all eigenvalues of (3.2) have the same modulus as the corresponding eigenvalues of (3.1) and that a simple real eigenvalue of (3.1) corresponds to a double eigenvalue of (3.2), but that (3.2) has no other eigenvalue of the same modulus. Apart from the multiplicity of the eigenvalues, (3.2) is an eigenvalue problem of the form considered in Shen et al. (1990).

The stability theory requires the computation of but a single eigenvalue of the problem (3.2), namely, ρ^*, the smallest positive one. The following observations from computations of the entire spectrum using the complex QZ algorithm led to the choice of a suitable form of inverse iteration for the solution of this problem. The problem specified in (3.2) has a spectrum that is roughly symmetrically distributed in the complex plane with respect to both the real and the imaginary axis. There are a number of *infinite* eigenvalues corresponding to null vectors of $\mathbf{B}$. The smallest positive eigenvalue ρ^* was, in general, also the smallest one in modulus. There were, however, several eigenvalues both in the negative and the positive halfplane that were not much greater in modulus than ρ^*. The nullspaces of $\mathbf{A}$ and $\mathbf{B}$ did not appear to have a nontrivial intersection. Thus, inverse iteration with an appropriately chosen shift of origin was selected for the solution of (3.2).

When the matrix $\mathbf{B}$ in (3.2) is positive definite, *Rayleigh quotient* iteration, i.e., inverse iteration with a shift computed in each step from the Rayleigh quotient of the current eigenvector approximation, is known to exhibit very rapid convergence. This procedure cannot be applied here. The technique developed for the present case is a generalization of that employed by Bank and Mittelmann (1986) in the program PLTMG for the simpler problem of finding the smallest eigenvalue of a positive-definite matrix. It cannot be expected to solve for any desired eigenvalue of (3.2) without having a rather good initial approximation for this eigenvalue, but the observations mentioned above justified the application of a suitably implemented version for the computation of ρ^*. The process is started with a random normalized vector $\mathbf{X}_0$ that is such that its Rayleigh quotient

$$\rho_0 = \mathbf{X}_0\mathbf{A}X_0/\mathbf{X}_0^T\mathbf{B}X_0 \tag{3.3}$$

is well defined. Given this initial pair $\rho_0, \mathbf{X}_0$, the inverse iteration procedure is performed as follows:

1. Solve $(\mathbf{A} - s\mathbf{B})\overline{\mathbf{Y}} = (\rho_k\mathbf{B} - \mathbf{A})\mathbf{X}_k$ and define

$$\mathbf{Y} = \frac{\overline{\mathbf{Y}} - \mathbf{X}_k^T\overline{\mathbf{Y}}\mathbf{X}_k}{\|\overline{\mathbf{Y}} - \mathbf{X}_k^T\overline{\mathbf{Y}}\mathbf{X}_k\|}.$$

2. Form $\mathbf{Q} = [\mathbf{X}_k|\mathbf{Y}]$ and solve the 2×2 problem

$$\mathbf{Q}^T\mathbf{A}\mathbf{Q}\mathbf{Z} = \tau\mathbf{Q}^T\mathbf{B}\mathbf{Q}\mathbf{Z}$$

for the eigenvalues τ_1, τ_2 and associated normalized eigenvectors $\mathbf{Z}_1, \mathbf{Z}_2$. Without loss of generality, let τ_1 be the *smallest positive* eigenvalue.

3. Set $\rho_{k+1} = \tau_1$, $\mathbf{X}_{k+1} = \mathbf{Q}\mathbf{Z}_1$, and check for convergence. If not converged, increment iteration index k and repeat.

While no analysis of this algorithm will be given here, a few remarks are in order. The shift s is chosen as a positive real number. From the well-known theory of inverse iteration s has to be closer to ρ^* than to any other eigenvalue of (3.2). Since ρ^* is unknown, this may require some adjustment of s during the iteration. Experience has shown, however, that a rough knowledge of the expected ρ^* and the facts observed above on the distribution of the other eigenvalues permitted the determination of a reasonable value for the shift.

The eigenvalue problem in step 2 is basically an orthogonal projection of the original problem into the subspace spanned by the columns of $\mathbf{Q}$. Since only one eigenvalue is needed, no attempt was made to save more than one vector and solve a larger auxiliary eigenvalue problem. Simpler inverse iteration algorithms are indeed available; however, their application to the present problem did not yield satisfactory results. In general, of course, this 2×2 eigenvalue problem may have complex eigenvalues as well as real ones. While several precautions for this and other cases were put into the program, they will not be described here, being a rather technical detail. Eventually, τ_1 will be positive and approximate ρ^* while $\mathbf{QZ}_1$ approximates the associated eigenvector. The quantities $\mathbf{X}_{k+1}$ and ρ_{k+1} are related through the Rayleigh quotient (3.3).

Due to the properties of $\mathbf{A}$ and $\mathbf{B}$, the matrix on the left-hand side of the linear system in step 1 is highly indefinite but symmetric. The latest version of the program SYMMLQ (see Paige and Saunders (1975)) was used for the solution of this system. It applies a conjugate-gradient method and provides for preconditioning by a positive-definite matrix. There is no complete theory available for the preconditioning of indefinite systems. The standard diagonal preconditioning for the associated normal equations led to the choice of the diagonal matrix with its ith element equal to the Euclidean norm of the ith column of the matrix $\mathbf{A} - s\mathbf{B}$.

The convergence of the above inverse iteration procedure is, in general, linear with a factor asymptotically equal to

$$\left| \frac{s - \rho^*}{s - \rho_n} \right| < 1,$$

where ρ_n is the next nearest eigenvalue of (3.2) to s and different from ρ^*. Choosing s close to ρ^* will thus speed up convergence of the inverse iteration while generally requiring more conjugate-gradient iterations for the nearly singular system matrix. The essential computational requirement per conjugate-gradient iteration is one matrix-vector multiplication with the system matrix. Since ρ^* is, in general, a double eigenvalue of (3.2), it is also important to note that inverse iteration exhibits the same convergence behavior for eigenvalues that are equal as opposed to those that are equal in modulus but different. Again, the observations on the distribution of the spectrum and the properties of (3.2) as a transformation of (3.1) are of relevance.

Finally, as a stopping criterion, a test on the relative decrease of the residual combined with one on the convergence of subsequent eigenvalue approximations was used. The resulting code never failed to solve the above eigenvalue problem and some information on its performance will be given in the following section.

4. Results and discussion. The algorithm described in the preceding section has been implemented in a FORTRAN code and executed on an Ardent Titan Mini-supercomputer in the Advanced Research Computing Facility of the Department of Mathematics at Arizona State University. The main storage requirement was for the Hermitian matrices $\overline{\mathbf{A}}$ and $\overline{\mathbf{B}}$. Only the nonzero elements of the upper halves of the real and imaginary parts of these matrices need to be stored. Indirect addressing prevents a full vectorization of the matrix-vector multiplication executed in each step of SYMMLQ. Experiments with, for example, storage of the matrices by diagonals permitted full vectorization, but yielded no gain in performance due to the relative sparseness of the diagonals caused by a staggered-grid discretization (see Shen et al. (1990) for details). For example, for the case of aspect ratio $A = 0.2$ with $\Delta r = 0.0052$ and $\Delta z = 0.0065$, the order of the matrices is 29022; the number of nonzero elements that must be stored are

$$\begin{aligned} 157946 &\quad \text{for} \quad \text{Re}\,(\overline{\mathbf{A}}), \\ 73168 &\quad \text{for} \quad \text{Im}\,(\overline{\mathbf{A}}), \\ 50396 &\quad \text{for} \quad \text{Re}\,(\overline{\mathbf{B}}). \end{aligned}$$

The inverse iteration was started with a random vector; a shift of 80 percent of a rough guess of the expected eigenvalue was used for all calculations.

The algorithm described in the previous section was used to compute the eigenvalues Ra^* of the heated-cylinder problem described in §2. Values were calculated for various azimuthal wave numbers, aspect ratios, and discretizations. The number of iterations required for convergence ranged between 4 and 16. Future theoretical investigation is needed to explain the causes of the larger iteration counts; one possibility may be the existence of closely spaced eigenvalues. The overall cost of solving the eigenvalue problem was not very sensitive with respect to the choice of the shift s in a relatively wide range of $0 < s < \rho^*$. The above preconditioning technique resulted in a number of *cg*-iterations within SYMMLQ equivalent to a few percent of the order of the linear system *if* s was not too close to ρ^*. When s approached ρ^* the faster convergence of the inverse iteration was, in general, more than offset by the increased *cg*-iterations. For the example whose dimensions were listed above, the number of *cg*-iterations with the simple and cheap diagonal preconditioning was on the order of 1000 for an order of $\mathbf{A}$ in (3.2) of 58044.

Since the results of Charlson and Sani (1971) are presented in the form Ra^* versus aspect ratio for integer values of the azimuthal wave number n, the minimization implied in (2.10) was not carried out. These values are denoted by Ra_n in the accompanying figures. In addition to performing calculations for nonaxisymmetric disturbances, cases for axisymmetric ($n = 0$) disturbances were computed and compared with earlier results of Charlson and Sani (1970). For axisymmetric disturbances, the complex Hermitian system (2.13) simplifies to a real, symmetric one, thus providing a means for testing the algorithm's ability to reproduce the results obtained with its predecessor (see Shen et al. (1990)). As an additional check, calculations of Ra_{-n} were in complete agreement with corresponding values of Ra_n, thereby indicating the expected indifference to the sense of the azimuthal coordinate.

The convergence of the inverse-iteration procedure was addressed earlier. Also of interest is the convergence behavior of the discretization scheme. Figure 1 illustrates this for a case with $A = 2$ and $n = 1$ for a conducting sidewall. For moderate values of stepsize $h = (\Delta r^2 + \Delta z^2)^{1/2}$, convergence is $O(h^2)$, but for smaller h, this appears to accelerate.

Figures 2 through 5 show a comparison between selected energy-stability results obtained with the present algorithm and linear-stability results, which are equal to those obtained from energy theory for this problem. Since our interest was in verifying the reliability of the new inverse-iteration algorithm for indefinite, Hermitian eigenvalue problems, we did not attempt to reproduce all available results. The $n = 1$ results reported by Charlson and Sani (1971), which were obtained with a Galerkin approach, were apparently not converged (R. L. Sani, private communication); recent

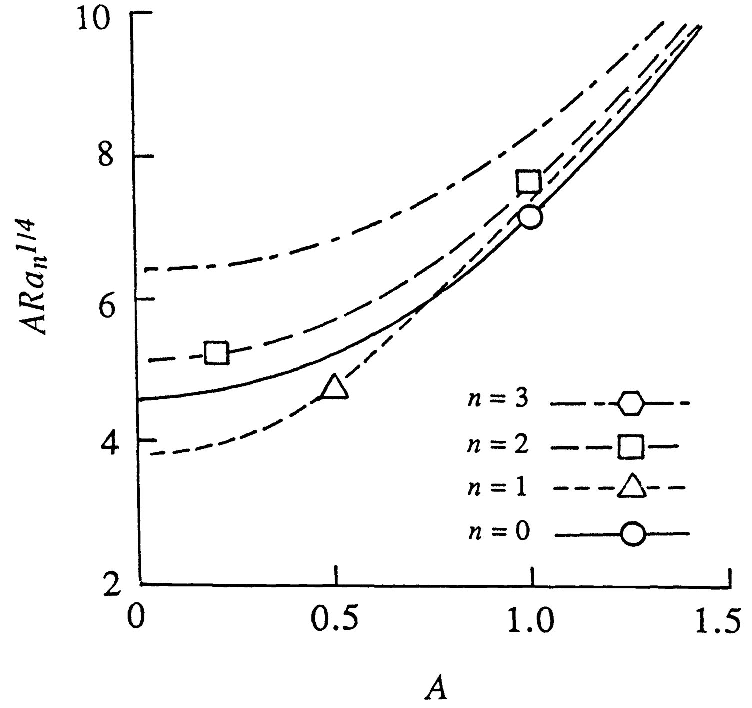

FIG. 4. *Comparison of selected results from the present computations (symbols) with those of Hardin et al.* (1990) *(curves) for $A < 1.5$ with a conducting sidewall.*

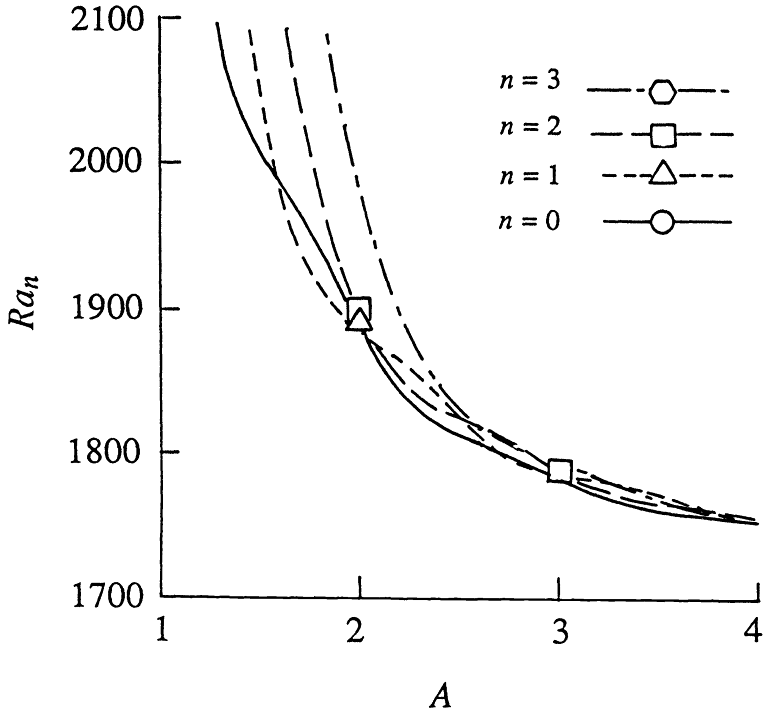

FIG. 5. *Comparison of selected results from the present computations (symbols) with those of Hardin* et al. (1990) *(curves) for $1 < A < 4$ with a conducting sidewall.*

Galerkin computations of Hardin, Sani, Henry, and Roux (1990) have obtained revised values of Ra_n; these are presented in the figures. Agreement is satisfactory in all cases, leading to the conclusion that the algorithm is implemented properly and is capable of performing such computations.

The confidence gained from the successful tests for the heated cylinder provides a basis for the extension of these ideas to the more difficult three-dimensional problem associated with the stability of thermocapillary convection in a model of the float-zone crystal-growth process. This problem will require, for fixed n, two additional outer iterations to find the energy-stability limit Ma_E (Ma denotes the dimensionless Marangoni number). First, as in (2.10), both matrices will depend on the coupling parameter $\lambda > 0$ requiring maximization with respect to this parameter. Second, the matrix $\overline{\mathbf{B}}$ will depend on the basic state and, in particular, on its Marangoni number Ma_{BS}. An accelerated fixed-point iteration method can be used to enforce the required condition $Ma^* = Ma_{BS}$. These two iterations form an intermediate level of the solution procedure with the inverse iteration being the inner, and a final minimization of the Ma_n with respect to the discrete wave number being the outer, iteration level.

A technologically significant problem associated with materials processing has driven the creation of a new numerical algorithm for finding the smallest positive eigenvalue of a sparse, indefinite, Hermitian system. Early attempts by Shen et al. (1990) to employ the QZ algorithm for the simpler problem of a real, symmetric system were only partially successful because of an inability to obtain adequate resolution due to restrictions on system order imposed by available computational resources. This difficulty was only resolved with the development of the new algorithm. The three-dimensional stability calculations that are now underway are necessary, both to obtain a complete stability picture for the problem, and also because laboratory experiments indicate that nonaxisymmetric modes are actually those responsible for causing instability in some cases. The algorithm has been successful in solving these technologically related problems; these, in turn, have provided motivation for further research in numerical analysis.

Acknowledgment. The authors thank the referees for their helpful comments.

CONJUGATE GRADIENT-TYPE METHODS FOR LINEAR SYSTEMS WITH COMPLEX SYMMETRIC COEFFICIENT MATRICES*

ROLAND W. FREUND†

Abstract. Conjugate gradient-type methods for the solution of large sparse linear systems $Ax = b$ with complex symmetric coefficient matrices $A = A^T$ are considered. Such linear systems arise in important applications, such as the numerical solution of the complex Helmholtz equation. Furthermore, most complex non-Hermitian linear systems which occur in practice are actually complex symmetric. Conjugate gradient-type iterations which are based on a variant of the nonsymmetric Lanczos algorithm for complex symmetric matrices are investigated. In particular, a new approach with iterates defined by a quasi-minimal residual property is proposed. The resulting algorithm presents several advantages over the standard biconjugate gradient method. Some remarks are also included on the obvious approach to general complex linear systems by solving equivalent real linear systems for the real and imaginary parts of x. Finally, numerical experiments for linear systems arising from the complex Helmholtz equation are reported.

Key words. complex symmetric matrices, nonsymmetric Lanczos algorithm, biconjugate gradients, minimal residual property

AMS(MOS) subject classifications. 65F10, 65N20

1. Introduction. Conjugate gradient-type methods—used in combination with preconditioning—are among the most effective iterative procedures for solving large sparse nonsingular systems of linear equations

$$Ax = b. \tag{1.1}$$

The archetype of these schemes is the classical conjugate gradient algorithm (CG hereafter) of Hestenes and Stiefel [24] for Hermitian positive definite matrices A.

While most linear systems that arise in practice have real coefficient matrices A and real right-hand sides b, there are some important applications (see [16] and the references therein) that lead to complex linear systems. Partial differential equations that model dissipative processes usually involve complex coefficient functions and/or complex boundary conditions (see, e.g., [29]), and discretizing them yields linear systems with complex matrices A. A typical example for this category is the complex Helmholtz equation

$$-\Delta u - \sigma_1 u + i\sigma_2 u = f, \tag{1.2}$$

where σ_1, σ_2 are real coefficient functions, which describes the propagation of damped time-harmonic waves as, e.g., electromagnetic waves in conducting media. Further applications, which give rise to complex linear systems, include discretizations of the time-dependent Schrödinger equation using implicit difference schemes, inverse

scattering problems, underwater acoustics, eddy current computations [2], numerical computations in quantum chromodynamics, and numerical conformal mapping.

In all these examples, the resulting coefficient matrices A are non-Hermitian. However, they still exhibit special structures. Often, A differs from a Hermitian matrix only by a shift and a rotation:

$$A = e^{i\theta}(T + i\sigma I), \quad T = T^H \quad \text{Hermitian}, \quad \sigma \in \mathbb{C},\ \theta \in \mathbb{R}, \quad i := \sqrt{-1}. \tag{1.3}$$

In almost all other cases, which lead to complex systems, the coefficient matrix is symmetric:

$$A = A^T \quad \text{is complex symmetric.} \tag{1.4}$$

Note that the two families (1.3) and (1.4) overlap. The matrix (1.3) is complex symmetric if and only if T is real.

Surprisingly, when complex linear systems (1.1) are solved in practice, usually no attempt is made to exploit the special structures (1.3) or (1.4). Indeed, there are two popular approaches. The first one (see, e.g., [1]) is to apply preconditioned CG to the Hermitian positive definite normal equations

$$A^H A x = A^H b. \tag{1.5}$$

Of course, complex numbers can always be avoided by rewriting (1.1) as a real linear system for the real and imaginary parts of x. The second popular approach is to solve this real and, in general, nonsymmetric linear system by one of the generalized CG methods such as GMRES [40]. It turns out that in both cases the resulting iterative schemes tend to converge slowly. As a consequence, complex linear systems have the bad reputation of being difficult to solve by CG-type methods. On the other hand, for the class of shifted Hermitian matrices (1.3), there are efficient CG-type algorithms [10], [11], [28], [16] for complex linear systems in their original form (1.1). We refer the reader to [16] for a detailed study and practical aspects of these schemes. In [16] it is also shown how the special structure (1.3) can be preserved by using polynomial preconditioning.

In this paper, we are mainly concerned with CG-type methods for linear systems (1.1) with coefficient matrices of the second class (1.4). In particular, we consider approaches based on a variant of the nonsymmetric Lanczos algorithm, which was successfully used for computing eigenvalues of complex symmetric matrices (see [35] and [6, Chap. 6]). This Lanczos recursion generates basis vectors for the Krylov subspace induced by A that are orthogonal with respect to a certain indefinite inner product. The standard way to obtain from this basis iterates, which approximate the exact solution of (1.1), is to enforce a biconjugate gradient (BCG hereafter) condition. Here, we propose a new approach that generates iterates via a quasi-minimal residual property. On typical examples, the resulting algorithm displays better convergence properties than the BCG approach. In particular, it produces residuals whose norms are almost monotonically decreasing, in contrast to the erratic convergence behavior that is typical for BCG. Moreover, the new technique eliminates one of the two sources of possible breakdown in the BCG approach.

The outline of the paper is as follows. In §2, we review the Lanczos recursion and related algorithms for complex symmetric matrices. Also, some theoretical properties which will be needed later on are listed. In §3, we propose the quasi-minimal residual approach for complex symmetric matrices. Section 4 contains some remarks on the problem of breakdown of the complex symmetric Lanczos recursion. In §5, we are concerned with the issue of "complex versus equivalent real linear systems."In particular, some results are presented which indicate that for Krylov subspace methods, such as CG-type algorithms, it is always preferable to solve the original complex system rather than equivalent real ones. In §6, some typical results of numerical experiments for linear systems arising from finite difference approximations to the complex Helmholtz equation (1.2) are given. Finally, in §7, we make some concluding remarks.

Throughout the paper, all vectors and matrices, unless stated otherwise, are assumed to be complex. As usual, $\overline{M} = [\overline{m_{jk}}]$, $M^T = [m_{kj}]$, and $M^H = \overline{M}^T$ denote the complex conjugate, transpose, and Hermitian matrix, respectively, corresponding to the matrix $M = [m_{jk}]$. Moreover, we set $\operatorname{Re} M = (M + \overline{M})/2$ and $\operatorname{Im} M = (M - \overline{M})/(2i)$ for its real and imaginary part, respectively. The notation

$$K_k(c, B) := \operatorname{span}\{c, Bc, \cdots, B^{k-1}c\}$$

is used for the kth Krylov subspace of $\mathbb{C}^n$ generated by $c \in \mathbb{C}^n$ and the $n \times n$ matrix B. Furthermore, $\sigma(B)$ denotes the spectrum of B. The vector norm $\|x\| = \sqrt{x^H x}$ is always the Euclidean norm. The set of all complex polynomials of degree at most k is denoted by

$$\Pi_k := \{p(\lambda) \equiv \gamma_0 + \gamma_1\lambda + \cdots + \gamma_k\lambda^k \mid \gamma_0, \gamma_1, \cdots, \gamma_k \in \mathbb{C}\}.$$

Moreover, the coefficient matrix A of (1.1) is always $n \times n$ and, unless stated otherwise, assumed to be complex symmetric. Generally, $x_k \in \mathbb{C}^n$, $k = 0, 1, \cdots$, denote iterates for (1.1) with corresponding residual vectors $r_k := b - Ax_k$. If necessary, quantities of different algorithms will be distinguished by superscripts, e.g., x_k^{BCG} and x_k^{QMR}. Finally, an iterative scheme for solving (1.1) is called a Krylov subspace method if its iterates are of the form

$$x_k \in x_0 + K_k(r_0, A) \quad \text{or, equivalently,} \quad x_k = x_0 + P(A)r_0, \; P \in \Pi_{k-1}. \tag{1.6}$$

Note that, in particular, CG-type algorithms for (1.1) fall into this category.

2. The Lanczos recursion and related algorithms for complex symmetric matrices.

The Lanczos procedure [31] for general complex $n \times n$ matrices A consists of two three-term recurrences (see, e.g., [43, pp. 388–394]). As Lanczos pointed out [33, p. 176], the general method reduces to only one recursion if A is Hermitian, respectively, complex symmetric. In particular, for these two special cases, work and storage of the general Lanczos method are halved. The resulting Hermitian Lanczos recursion has been studied extensively (see [20, Chap. 9] and the references therein). In contrast, the literature on the complex symmetric variant is scarce and restricted to the application of the algorithm to computing eigenvalues of complex symmetric matrices (see Moro and Freed [35] and Cullum and Willoughby [6, Chap. 6]). Here we hope to convince the reader that the complex symmetric Lanczos algorithm is also very useful for solving linear systems.

2.1. The Lanczos recursion.

The basic method is as follows:

ALGORITHM 2.1 (LANCZOS METHOD FOR $A = A^T$).

```
(1) Start:
    • Choose $r_0 \in \mathbb{C}^n$, $r_0 \neq 0$;
    • Set $\tilde{v}_1 = r_0$ and $v_0 = 0$.

(2) For $k = 1, 2, \cdots$ do:
    • Compute $\beta_k = (\tilde{v}_k^T \tilde{v}_k)^{1/2}$;
```

- *If* $\beta_k = 0$*: Set* $m_0 = k - 1$*, and stop;*
- *Otherwise, set* $v_k = \tilde{v}_k / \beta_k$*;*
- *Compute* $\alpha_k = v_k^T A v_k$*;*
- *Set* $\tilde{v}_{k+1} = Av_k - \alpha_k v_k - \beta_k v_{k-1}$.

In the following proposition, some elementary properties of Algorithm 2.1 are listed; proofs can be found in [5, Chap. 6]. We set

$$(2.1) \qquad V_k := [\, v_1 \quad v_2 \quad \dots \quad v_k \,] \quad \text{and} \quad T_k := \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \dots & 0 \\ \beta_2 & \alpha_2 & \beta_3 & \ddots & \vdots \\ 0 & \beta_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_k \\ 0 & \dots & 0 & \beta_k & \alpha_k \end{bmatrix}.$$

Moreover, $m_\star = m_\star(r_0, A) := \dim K_n(r_0, A)$ denotes the *grade* of r_0 with respect to A (cf. [43, p. 37]). We remark that $m_\star \geq 1$ is the smallest integer such that $K_{m_\star}$ is an A-invariant subspace of $\mathbb{C}^n$. Equivalently, if A is nonsingular and $r_0 = b - Ax_0$, $m_\star \geq 1$ is the smallest integer such that

$$(2.2) \qquad A^{-1}b \in x_0 + K_{m_\star}(r_0, A).$$

PROPOSITION 2.2. (a) *In exact arithmetic, Algorithm* 2.1 *stops after a finite number of steps* $k = m_0 + 1$ *and* $0 \leq m_0 \leq m_\star$*. Furthermore,* $\tilde{v}_{m_0+1} = 0$ *if* $m_0 = m_\star$ *("regular termination"), and* $\tilde{v}_{m_0+1} \neq 0$ *if* $m_0 < m_\star$ *("breakdown").*

(b) *For* $k = 1, 2, \cdots, m_0$*:*

$$(2.3) \qquad v_k^T v_j = \begin{cases} 0, & \text{if } k \neq j \\ 1, & \text{if } k = j \end{cases}, \quad j = 1, 2, \cdots, m_0,$$

$$(2.4) \qquad K_k(r_0, A) = \operatorname{span}\{v_1, v_2, \cdots, v_k\},$$

$$(2.5) \qquad AV_k = V_k T_k + [\, 0 \quad 0 \quad \cdots \quad 0 \quad \tilde{v}_{k+1} \,].$$

Notice that, by (2.3)–(2.4), the Lanczos vectors $v_1, \cdots, v_k$ form an orthonormal basis for $K_k(r_0, A)$ with respect to the indefinite bilinear form

$$(2.6) \qquad (x, y) := y^T x, \quad x, y \in \mathbb{C}^n.$$

In particular, if Algorithm 2.1 terminates regularly, it generates a basis of the affine space $x_0 + K_{m_\star}(r_0, A)$, which, in view of (2.2), contains the exact solution of $Ax = b$.

Note that the indefinite bilinear form (2.6) is the proper (cf. Craven [5]) "inner product" for complex symmetric matrices. Unfortunately, it has the defect that there exist vectors $v \in \mathbb{C}^n$ which are *quasi-null* [5], i.e., $(v, v) = 0$, but $v \neq 0$. Consequently, it cannot be excluded that Algorithm 2.1 actually breaks down. Indeed, in view of part (a) of Proposition 2.2, a breakdown occurs if we encounter a quasi-null vector $\tilde{v}_k$. The phenomenon of breakdown will be discussed further in §4.

Finally, we remark that there is a close connection (see Theorem 2.4 in [15]) of the complex symmetric variant 2.1 with the Lanczos algorithm for general matrices. Unlike Hermitian matrices, complex symmetric matrices do not have any special spectral properties. Indeed (see, e.g., [25, Thm. 4.4.9]), any complex $n \times n$ matrix is similar to a complex symmetric matrix. This result entails that the general nonsymmetric Lanczos method differs from the complex symmetric Algorithm 2.1 only in an additional starting vector s_0, which can be chosen independently of r_0 in 2.1.

After these preliminaries, we now turn to linear systems (1.1). In the sequel, it is always assumed that A is nonsingular.

2.2. Related algorithms. In his celebrated papers [31], [32], Lanczos also proposed a scheme, closely related to the nonsymmetric Lanczos process, for solving general non-Hermitian linear systems, namely, the biconjugate gradient algorithm (BCG). We refer the reader to [12], [39], [26] for a detailed discussion of the BCG approach.

Like the nonsymmetric Lanczos method, BCG for general linear systems is started with two vectors: the residual $r_0 = b - Ax_0$ of the initial guess x_0 and a second vector $s_0 \neq 0$. We remark that s_0 is still unspecified. Due to the lack of a criterion for the choice of s_0, we usually set $s_0 = r_0$ in practice. For the case of complex symmetric matrices A, it is straightforward to show that, in analogy to the complex symmetric variant 2.1 of the general Lanczos process, the choice $s_0 = r_0$ results in a scheme which requires only half the work and storage of general BCG. The resulting procedure is as follows:

ALGORITHM 2.3. (BCG *for* $A = A^T$)

```
(1) Start:
    • Choose $x_0 \in \mathbb{C}^n$;
    • Set $p_0 = r_0 = b - Ax_0$ and compute $r_0^T r_0$.

(2) For $k = 1, 2, \cdots$ do:
    • Compute $Ap_{k-1}$ and $p_{k-1}^T A p_{k-1}$;
    • If $p_{k-1}^T A p_{k-1} = 0$ or $r_{k-1}^T r_{k-1} = 0$: Set $m_1 = k - 1$, and stop;
    • Otherwise, set $\delta_k = r_{k-1}^T r_{k-1} / p_{k-1}^T A p_{k-1}$;
    • Compute $x_k = x_{k-1} + \delta_k p_{k-1}$ and $r_k = r_{k-1} - \delta_k A p_{k-1}$;
    • Compute $r_k^T r_k$ and set $\rho_k = r_k^T r_k / r_{k-1}^T r_{k-1}$;
    • Compute $p_k = r_k + \rho_k p_{k-1}$.
```

Note that the *transpose* in all dot products in Algorithm 2.3 is essential. In particular, Algorithm 2.3 is different from the classical CG method for positive definite matrices $A = A^H$.

In the sequel, BCG always refers to the complex symmetric Algorithm 2.3. Next, we list some basic properties of BCG that will be needed in subsequent sections. These results are immediate consequences of results (e.g., Jacobs [26]) for the general biconjugate gradient method.

PROPOSITION 2.4. (a) *In exact arithmetic, Algorithm* 2.3 *stops after a finite number of steps* $k = m_1 + 1$ *and* $0 \leq m_1 \leq m_\star$. *Furthermore,* $x_{m_1} = A^{-1}b$ *if* $m_1 = m_\star$ (*"regular termination"*), *and* $x_{m_1} \neq A^{-1}b$ *if* $m_1 < m_\star$ (*"breakdown"*).

(b) *For* $k = 1, 2, \cdots, m_1$:

$$r_{k-1}^T r_{j-1} = 0, \qquad k \neq j, \quad j = 1, 2, \cdots, m_1, \tag{2.7}$$

$$K_k(r_0, A) = \operatorname{span}\{r_0, r_1, \cdots, r_{k-1}\}. \tag{2.8}$$

(c) *Let* $k \in \{1, 2, \cdots, m_1\}$. *Then,* x_k *is uniquely determined by the Galerkin condition*

$$(b - Ax_k)^T y = 0 \quad \textit{for all} \quad y \in K_k(r_0, A), \qquad x_k \in x_0 + K_k(r_0, A), \tag{2.9}$$

with respect to the inner product (2.6).

By comparing (2.7)–(2.8) with (2.3)–(2.4), we conclude that r_{k-1} is parallel to the Lanczos vector v_k generated by Algorithm 2.1. More precisely, we easily verify that

$$r_{k-1} = (-1)^{k-1}\delta_1 \cdots \delta_{k-1}\beta_1 \cdots \beta_{k-1}\beta_k v_k, \quad k = 1, 2, \cdots, m_1. \tag{2.10}$$

Notice that there are two different causes for breakdown of Algorithm 2.3. The first one, namely, the occurrence of a quasi-null residual vector r_{k-1}, is, in view of (2.10), equivalent to the breakdown of the complex symmetric Lanczos Algorithm 2.1. In addition, Algorithm 2.3 breaks down if we encounter a search direction $p_{k-1} \neq 0$ with $p_{k-1}^T A p_{k-1} = 0$. This second cause of breakdown is more severe than the first one. As we will see in §3, it occurs if no Galerkin iterate (2.9) exists.

Closely related to the biconjugate gradient method for general linear systems (1.1) is the conjugate gradients squared algorithm (CGS hereafter) that was recently proposed by Sonneveld [41].

ALGORITHM 2.5. (CGS *for general* A)

```
(1) Start:
    • Choose $x_0 \in \mathbb{C}^n$ and $s_0 \in \mathbb{C}^n$, $s_0 \neq 0$;
    • Set $p_0 = u_0 = r_0 = b - Ax_0$ and compute $s_0^T r_0$.

(2) For $k = 1, 2, \cdots$ do:
    • Compute $Ap_{k-1}$ and $s_0{}^T Ap_{k-1}$;
    • If $s_0{}^T Ap_{k-1} = 0$ or $s_0{}^T r_{k-1} = 0$: Stop;
    • Otherwise, set $\alpha_k = s_0^T r_{k-1} / s_0^T Ap_{k-1}$;
    • Compute $q_k = u_{k-1} - \alpha_k Ap_{k-1}$;
    • Compute $x_k = x_{k-1} + \alpha_k(u_{k-1} + q_k)$ and $r_k = r_{k-1} - \alpha_k A(u_{k-1} + q_k)$;
    • Compute $s_0^T r_k$ and set $\beta_k = s_0^T r_k / s_0^T r_{k-1}$;
    • Compute $u_k = r_k + \beta_k q_k$ and $p_k = u_k + \beta_k(q_k + \beta_k p_{k-1})$.
```

Notice that, like general BCG, CGS has a second unspecified starting vector s_0. However, unlike BCG, even with the special choice $s_0 = r_0$, CGS cannot exploit the complex symmetry of A. In particular, for $A = A^T$, Algorithm 2.5 requires per iteration about twice as much work as the BCG Algorithm 2.3.

Finally, as a special case of the general connection [41] between the CGS and BCG approaches, we have the following result.

PROPOSITION 2.6. *Let* $A = A^T$, $r_0 = r_0^{\mathrm{BCG}} = r_0^{CGS}$, *and, in Algorithm* 2.5, $s_0 = r_0$. *Then, for* $k = 0, 1, \cdots, m_1$,

$$r_k^{\mathrm{BCG}} = p_k(A) r_0 \quad \text{and} \quad r_k^{CGS} = \big(p_k(A)\big)^2 r_0$$

for some $p_k \in \Pi_k$ *with* $p_k(0) = 1$.

3. A quasi-minimal residual algorithm for complex symmetric matrices.

In this section, we propose a new approach for solving complex symmetric linear systems. The method is based on the complex symmetric Lanczos Algorithm 2.1. For simplicity, we assume throughout this section that, in exact arithmetic, Algorithm 2.1 terminates regularly, i.e.,

$$\beta_k \neq 0 \quad \text{for} \quad k = 1, 2, \cdots, m_\star, \quad \beta_{m_\star + 1} = 0. \tag{3.1}$$

Moreover, always let $k \in \{1, 2, \cdots, m_\star\}$ in the following.

3.1. Basic approach. Let x_k be the kth iterate of any Krylov subspace method (1.6). Then, by (2.4) and with V_k as defined in (2.1), we have

$$x_k = x_0 + V_k z_k \quad \text{where} \quad z_k \in \mathbb{C}^k. \tag{3.2}$$

Using (2.5) and $r_0 = \beta_1 v_1$, it follows from (3.2) that

$$r_k = b - Ax_k = r_0 - AV_k z = \beta_1 v_1 - V_{k+1}\tilde{T}_k z_k = V_{k+1}\big(\beta_1 e_1 - \tilde{T}_k z_k\big). \tag{3.3}$$

Here, $e_1 := [1 \quad 0 \quad \cdots \quad 0]^T$ denotes the first unit vector,

$$\tilde{T}_k := \begin{bmatrix} T_k \\ \beta_{k+1} e_k^T \end{bmatrix} \quad \text{with} \quad e_k^T := [0 \quad \cdots \quad 0 \quad 1], \tag{3.4}$$

and, if $k = m_*$, $v_{m_*+1} := 0$. Recall that T_k was defined in (2.1).

Clearly, the aim is to choose z_k in (3.2)–(3.3) such that $r_k \approx 0$ as good as possible. In the BCG approach, this is attempted by enforcing the Galerkin condition (2.9). Using (2.3)–(2.4) and (3.3), we easily verify that (2.9) holds if and only if r_k and v_{k+1} are parallel or, equivalently, z_k is a solution of the linear system

$$T_k z = \beta_1 e_1. \tag{3.5}$$

Note that, by (3.1), (3.5) is inconsistent if T_k is singular. Thus we have the following result.

PROPOSITION 3.1. *A* BCG *iterate x_k^{BCG} satisfying the Galerkin condition* (2.9) *exists if and only if T_k is nonsingular. Moreover, if it exists, it is unique and given by*

$$x_k^{\text{BCG}} = x_0 + V_k z_k \quad \textit{and} \quad r_k = -\beta_{k+1}(z_k)_k v_{k+1} \tag{3.6}$$

where z_k is the solution of (3.5) *and $(z_k)_k$ denotes its kth component.*

Proposition 3.1 demonstrates the defects of the BCG approach. Simple examples show that singular T_k may indeed occur, and then, in view of Proposition 2.4, the BCG Algorithm 2.3 would break down in exact arithmetic. In floating-point arithmetic, such a breakdown is unlikely to happen. However, T_k may still be close to singular and then the Galerkin condition (2.9) defines a poor approximation to the true solution of (1.1). This is the reason for the typical erratic convergence behavior with wildly oscillating residual norms.

Obviously, the question arises as to whether there is a better strategy than (2.9) for choosing z_k in (3.2)–(3.3). Ideally, we would like to have the minimal residual (MR) property

$$\|b - Ax_k\| = \min_{x \in x_0 + K_k(r_0, A)} \|b - Ax\| = \min_{z \in \mathbb{C}^k} \|V_{k+1}\big(\beta_1 e_1 - \tilde{T}_k z_k\big)\|. \tag{3.7}$$

However, by (2.3), in general (see Theorem 3.4 for an exception) the columns of V_{k+1} are orthonormal only with respect to (2.6) rather than the Euclidean inner product $(x, y) = y^H x$. Consequently, solving the least-squares problem on the right-hand side of (3.7) results in an algorithm for which work and storage per iteration step k grows linearly with k. Hence, if we insist on a "true" iterative scheme with constant work and storage per iteration, this excludes the MR method.

Here, we propose the *quasi-minimal residual* (QMR) approach as a substitute for (3.7). Let

$$\Omega_{k+1} = \operatorname{diag}(\omega_1, \omega_2, \cdots, \omega_{k+1}) \quad \text{with} \quad \omega_j > 0 \quad \text{for all} \quad j$$

be a given positive diagonal weight matrix and rewrite (3.3) in the form

$$r_k = \big(V_{k+1}\Omega_{k+1}^{-1}\big)\big(\omega_1 \beta_1 e_1 - \Omega_{k+1}\tilde{T}_k z_k\big). \tag{3.8}$$

Instead of $\|r_k\|$ as in (3.7), we may at least minimize the vector of components in the representation (3.8) of r_k:

$$\min_{z\in\mathbb{C}^k} \|\omega_1\beta_1 e_1 - \Omega_{k+1}\tilde{T}_k z\|. \tag{3.9}$$

Hence, we define the iterates of the QMR method as follows:

$$x_k = x_k^{\mathrm{QMR}} = x_0 + V_k z_k \quad \text{where } z_k \in \mathbb{C}^k \text{ is the solution of (3.9).} \tag{3.10}$$

Notice that $\Omega_{k+1}\tilde{T}_k$ is a $(k+1)\times k$ matrix which, by (3.4) and (3.1), has full rank. Thus, the least squares problem (3.9) always has a unique solution z_k.

Clearly, the QMR approach still depends on the weights ω_j. A natural choice is

$$\omega_j = \|v_j\|, \quad j = 1, 2, \cdots, k+1, \tag{3.11}$$

so that all basis vectors v_j/ω_j in the representation (3.8) of r_k have Euclidean length 1. Our numerical tests (cf. §6) also confirmed (3.11) as the best strategy.

3.2. Practical implementation. Next we present an algorithm for the actual computation of the QMR iterates (3.10). The derivation is similar to that of Paige and Saunders' SYMMLQ and MINRES algorithms [36] for real symmetric matrices.

By (3.4), (2.1), and (3.1), $\Omega_{k+1}\tilde{T}_k$ is a tridiagonal $(k+1)\times k$ matrix with full column rank. Hence it admits a QR factorization of the type

$$Q_{k+1}\Omega_{k+1}\tilde{T}_k = \begin{bmatrix} R_k \\ 0 \end{bmatrix} \tag{3.12}$$

where Q_{k+1} is a unitary $(k+1)\times(k+1)$ matrix and R_k a nonsingular matrix of the form

$$R_k := \begin{bmatrix} \zeta_1 & \eta_2 & \theta_3 & 0 & \dots & 0 \\ 0 & \zeta_2 & \eta_3 & \ddots & \ddots & \vdots \\ 0 & \ddots & \zeta_3 & \ddots & \ddots & 0 \\ \vdots & & \ddots & \ddots & \ddots & \theta_k \\ \vdots & & & \ddots & \ddots & \eta_k \\ 0 & \dots & \dots & \dots & 0 & \zeta_k \end{bmatrix}. \tag{3.13}$$

The decomposition (3.12) can be generated by means of a series of k complex Givens rotations (e.g., [20, p. 47])

$$Q(c_j, s_j) = \begin{bmatrix} c_j & \overline{s_j} \\ -s_j & c_j \end{bmatrix}, \quad c_j \in \mathbb{R}, s_j \in \mathbb{C}, \quad c_j^2 + |s_j|^2 = 1, \quad j = 1, \cdots, k.$$

In particular, (3.12) is easily updated from the factorization $Q_k\Omega_k\tilde{T}_{k-1} = R_{k-1}$ of the previous step by setting

$$Q_{k+1} = \begin{bmatrix} I_{k-1} & 0 \\ 0 & Q(c_k, s_k) \end{bmatrix} \begin{bmatrix} Q_k & 0 \\ 0 & 1 \end{bmatrix} \tag{3.14}$$

and computing c_k, s_k and the new elements θ_k, η_k, ζ_k of R_k as follows:

$$\begin{aligned} &\theta_k = \overline{s_{k-2}}\omega_{k-1}\beta_k, \qquad \eta_k = c_{k-1}c_{k-2}\omega_{k-1}\beta_k + \overline{s_{k-1}}\omega_k\alpha_k, \\ &\tilde{\zeta}_k = c_{k-1}\omega_k\alpha_k - s_{k-1}c_{k-2}\omega_{k-1}\beta_k, \qquad |\zeta_k| = \left(|\tilde{\zeta}_k|^2 + \omega_{k+1}^2|\beta_{k+1}|^2\right)^{1/2}, \\ &\zeta_k = \begin{cases} |\zeta_k|\tilde{\zeta}_k/|\tilde{\zeta}_k|, & \text{if } \tilde{\zeta}_k \neq 0, \\ |\zeta_k|, & \text{if } \tilde{\zeta}_k = 0, \end{cases} \qquad c_k = \tilde{\zeta}_k/\zeta_k, \quad s_k = \omega_{k+1}\beta_{k+1}/\zeta_k. \end{aligned} \tag{3.15}$$

By (3.12) and since Q_{k+1} is unitary, (3.9) is equivalent to

$$\min_{z\in\mathbb{C}^k} \left\| \omega_1\beta_1 Q_{k+1}e_1 - \begin{bmatrix} R_k \\ 0 \end{bmatrix} z \right\|. \tag{3.16}$$

From (3.10) and (3.16) it follows that

$$x_k = x_0 + V_k z_k \quad \text{where} \quad z_k := R_k^{-1}t_k, \quad \begin{bmatrix} t_k \\ \tilde{\tau}_{k+1} \end{bmatrix} = \tilde{t}_{k+1} := \omega_1\beta_1 Q_{k+1}e_1. \tag{3.17}$$

Notice that, in view of (3.14), t_k differs from the previous vector t_{k-1} only by its kth component $\tau_k := (t_k)_k = c_k\tilde{\tau}_k$. Next, we define vectors p_j via

$$[p_1 \quad p_2 \quad \cdots \quad p_k] := V_k R_k^{-1}. \tag{3.18}$$

Finally, using (3.17)–(3.18) and (3.13), we obtain the recursion

$$x_k = x_{k-1} + \tau_k p_k, \quad \text{where} \quad p_k = \frac{1}{\zeta_k}\Big(v_k - \eta_k p_{k-1} - \theta_k p_{k-2}\Big),$$

for the QMR iterates. In combination with Algorithm 2.1, the following implementation results:

ALGORITHM 3.2 (QMR METHOD).

```
(1) Start:
    • Choose $x_0 \in \mathbb{C}^n$;
    • Set $\tilde{v}_1 = b - Ax_0$, $v_0 = p_0 = p_{-1} = 0$;
    • Set $\beta_1 = \left(\tilde{v}_1^T\tilde{v}_1\right)^{1/2}$, $\tilde{\tau}_1 = \omega_1\beta_1$, $c_0 = c_{-1} = 1$, and $s_0 = s_{-1} = 0$.

(2) For $k = 1, 2, \cdots$ do:
    • If $\beta_k = 0$, stop: $x_{k-1}$ solves $Ax = b$.
    • Otherwise, compute $v_k = \tilde{v}_k/\beta_k$ and $\alpha_k = v_k^T A v_k$;
    • Set $\tilde{v}_{k+1} = Av_k - \alpha_k v_k - \beta_k v_{k-1}$, $\beta_{k+1} = \left(\tilde{v}_{k+1}^T\tilde{v}_{k+1}\right)^{1/2}$;
    • Compute $\theta_k$, $\eta_k$, $\zeta_k$, $c_k$, and $s_k$, using formulas (3.15);
    • Set $p_k = (v_k - \eta_k p_{k-1} - \theta_k p_{k-2})/\zeta_k$;
    • Set $\tau_k = c_k\tilde{\tau}_k$, $\tilde{\tau}_{k+1} = -s_k\tilde{\tau}_k$;
    • Compute $x_k = x_{k-1} + \tau_k p_k$.
```

The assumption (3.1) guarantees that, in exact arithmetic, Algorithm 3.2 stops for $k = m_\star + 1$ and, by (2.2), x_{k-1} is indeed the solution of (1.1) then. However, in floating-point arithmetic, this finite termination property of the Lanczos recursion is no longer valid, and the stopping criterion stated in Algorithm 3.2 is not useful in practice. Instead, we should terminate the iteration as soon as $\|r_k\|$ is sufficiently reduced. We remark that r_k is not directly available in Algorithm 3.2. However, in view of (3.19), if we update one additional auxiliary vector, namely,

$$h_k = h_{k-1} + \frac{c_k\tilde{\tau}_{k+1}}{|s_1s_2\cdots s_k|^2\omega_{k+1}}v_{k+1}, \quad h_0 := r_0,$$

then $\|r_k\|$ can be computed via

$$\|r_k\| = |s_1s_2\cdots s_k|^2 \cdot \|h_k\|.$$

Finally, notice that, for the weighting strategy (3.11),

$$\|v_k\| = \frac{\sqrt{f^Tf + g^Tg}}{|\beta_k|}, \quad f := \operatorname{Re}\tilde{v}_k, \ g := \operatorname{Im}\tilde{v}_k,$$

can be obtained without extra cost during the computation of $\tilde{v}_k^T\tilde{v}_k = f^Tf - g^Tg + 2if^Tg$.

3.3. Properties. In this subsection, we list some further properties of the QMR approach.

PROPOSITION 3.3. *For* $k = 1, 2, \cdots, m_\star$:

(a)

$$r_k^{\mathrm{QMR}} = |s_k|^2 r_{k-1}^{\mathrm{QMR}} + (c_k\tilde{\tau}_{k+1}/\omega_{k+1})v_{k+1}; \tag{3.19}$$

(b) *The* BCG *iterate* x_k^{BCG} *defined by* (2.9) *exists if and only if* $c_k \neq 0$. *Moreover, if* $c_k \neq 0$, *then*

$$x_k^{\mathrm{BCG}} = x_{k-1}^{\mathrm{QMR}} + (\tilde{\tau}_k/c_k)p_k, \tag{3.20}$$

$$\|r_k^{\mathrm{BCG}}\| = |\omega_1\beta_1 s_1 s_2 \cdots s_{k-1}s_k| \cdot \|v_{k+1}\|/(\omega_{k+1}|c_k|). \tag{3.21}$$

Proof. (a) By (3.17), (3.12), and (3.8), we have

$$r_k^{\mathrm{QMR}} = \tilde{\tau}_{k+1}\tilde{w}_{k+1} \quad \text{where} \quad \tilde{w}_{k+1} := V_{k+1}\Omega_{k+1}^{-1}Q_{k+1}^H \begin{bmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}. \tag{3.22}$$

With (3.14), it follows that successive vectors $\tilde{w}_{k+1}$ and $\tilde{w}_k$ are connected by

$$\tilde{w}_{k+1} = -\overline{s_k}\tilde{w}_k + (c_k/\omega_{k+1})v_{k+1}. \tag{3.23}$$

Finally, by combining (3.23) and (3.22) and using $\tilde{\tau}_{k+1} = -s_k\tilde{\tau}_k$, we obtain (3.19).

(b) First we note that (3.12), (3.4), and (3.14) imply

$$Q_k\Omega_kT_k = \begin{bmatrix} I_{k-1} & 0 \\ 0 & c_k \end{bmatrix} R_k. \tag{3.24}$$

Thus, by Proposition 3.1, x_k^{BCG} exists if and only if $c_k \neq 0$. Now assume $c_k \neq 0$. Using (3.5)–(3.6), (3.24), and (3.17), we get

$$x_k^{\mathrm{BCG}} = x_0 + V_kz_k^{\mathrm{BCG}} \quad \text{where} \quad z_k^{\mathrm{BCG}} = R_k^{-1}\begin{bmatrix} t_{k-1} \\ \tilde{\tau}_k/c_k \end{bmatrix}. \tag{3.25}$$

By comparing (3.25) with (3.17), (3.20) follows. For the proof of (3.21), notice that, by (3.25), (3.13) , and the formula for s_k in (3.15),

$$\beta_{k+1}(z_k^{\mathrm{BCG}})_k = \beta_{k+1}\tilde{\tau}_k/(\zeta_kc_k) = \tilde{\tau}_ks_k/(\omega_{k+1}c_k). \tag{3.26}$$

Furthermore, Algorithm 3.2 shows that

$$|\tilde{\tau}_k| = |\omega_1\beta_1s_1s_2\cdots s_{k-1}|. \tag{3.27}$$

Finally, by inserting (3.26)–(3.27) into the formula (3.6) for r_k^{BCG}, we arrive at (3.21). □

In view of part (b) of Proposition 3.3, the QMR method has the additional feature that it also yields *all* existing BCG iterates. This is in contrast to the BCG Algorithm 2.3, which breaks down as soon as the *first* nonexisting BCG iterate is encountered. We remark that, by (3.21), $\|r_k^{\mathrm{BCG}}\|$ can be computed without extra cost from quantities which are generated in Algorithm 3.2 anyway. In particular, we may monitor $\|r_k^{\mathrm{BCG}}\|$ during the course of the QMR algorithm, and, whenever the actual BCG iterate is desired, compute x_k^{BCG} via (3.20).

There is an important special case for which the QMR method (with weighting strategy (3.11)) is even equivalent to the MR approach (3.7). Consider the subclass of (1.3) of complex symmetric matrices of the form

$$A = T + i\sigma I, \quad T = T^T \quad \text{real symmetric}, \quad \sigma > 0. \tag{3.28}$$

Assume that $r_0 \in \mathbb{R}^n$ (this can always be achieved by a proper choice of x_0). Then it is easily verified that the Lanczos vectors v_k generated by Algorithm 2.1 are all real and therefore, by (2.3), orthonormal with respect to the usual Euclidean inner product. In particular, by (3.11), $\omega_j \equiv 1$, and the least squares problem (3.9) is equivalent to the one on the right-hand side of (3.7). Hence we have the following result.

THEOREM 3.4. *Let A be of the form* (3.28) *and $r_0 \in \mathbb{R}^n$. Then, the iterates x_k generated by Algorithm* 3.2 (*with $\omega_j \equiv 1$*) *satisfy the minimal residual property* (3.7).

4. On the breakdown of the complex symmetric Lanczos algorithm. In the general nonsymmetric Lanczos process a breakdown—more precisely, division by 0—may occur, before an invariant subspace has been found (see, e.g., [43, p. 389]). Although this happens very rarely in practice, the possibility of such breakdowns has brought the nonsymmetric Lanczos method into discredit and has certainly kept many people from actually using the algorithm. On the other hand, it is possible to devise so-called *look-ahead* [42], [38], [27], [3] modifications of the Lanczos algorithm which allow it to skip—except in the very special case of an incurable breakdown [42], [37]—over those iterations in which the standard algorithm would break down. Note that this was already observed by Gragg [21, pp. 222–223] and, in the context of the partial realization problem, by Kung [30, Chap. IV] and Gragg and Lindquist [22]. However, a complete treatment of the modified Lanczos method and its intimate connection with orthogonal polynomials and Padé approximation was presented only recently by Gutknecht [23].

Like for the general nonsymmetric Lanczos process, the complex symmetric Algorithm 2.1 may break down, i.e., stop with $v^T v = 0$ and $v \neq 0$. Recall that, throughout §3, possible breakdowns of the complex symmetric Lanczos recursion were explicitly excluded by assuming (3.1). In this section we briefly sketch the basic idea of the look-ahead procedure for the special case of the complex symmetric Lanczos recursion and derive a new theoretical result concerning so-called incurable breakdowns for complex symmetric matrices.

Assume that a breakdown occurs in Algorithm 2.1. In view of Proposition 2.2, this happens if and only if there is no complete set of $m_\star$ Lanczos vectors $v_k \in K_k(r_0, A)$, $k = 1, \cdots, m_\star$, which are orthonormal (cf. (2.3)) with respect to the indefinite inner product (2.6). Clearly, there exists a maximal subset

$$\{k_1, k_2, \cdots, k_J\} \subsetneqq \{1, 2, \cdots, m_\star\}, \quad 1 \leq k_1 < k_2 < \cdots < k_J \leq m_\star, \tag{4.1}$$

such that for each $j = 1, 2, \cdots, J$ there exists a vector $v_{k_j} \in K_{k_j}(r_0, A)$ satisfying the orthonormality relations

$$v_{k_j}^T v = 0 \quad \text{for all } v \in K_{k_j - 1}(r_0, A) \quad \text{and} \quad v_{k_j}^T v_{k_j} = 1. \tag{4.2}$$

By the definition of Krylov subspaces, $K_k(r_0, A) = \{P(A) r_0 \mid P \in \Pi_{k-1}\}$, and especially

$$v_{k_j} = P_{k_j - 1}(A) r_0 \quad \text{with} \quad P_{k_j - 1} \in \Pi_{k_j - 1}. \tag{4.3}$$

Therefore, we can rewrite (4.2) in terms of polynomials:

$$(P_{k_j - 1}, P) = 0 \quad \text{for all } P \in \Pi_{k_j - 2}, \quad (P_{k_j - 1}, P_{k_j - 1}) \neq 0, \tag{4.4}$$

with the indefinite inner product

$$(P,Q) := r_0^T P(A)Q(A)r_0. \tag{4.5}$$

A polynomial $P_{k_j-1} \in \Pi_{k_j-1}$ that fulfills (4.4) is called a regular orthogonal (with respect to (4.5)) polynomial of degree $k_j - 1$. It is well known [7], [23] that three successive regular orthogonal polynomials are connected via a three-term recurrence. By (4.3), it follows that there is a corresponding three-term recurrence relating the vectors v_{k_j-1}, v_{k_j}, and v_{k_j+1}. The look-ahead Lanczos procedure is a modification of Algorithm 2.1 which—based on this three-term relation—generates the vectors v_{k_j}, $j = 1, 2, \cdots, J$. These vectors can then be completed to a basis of K_{k_J} by setting, e.g.,

$$v_k = A^{k-k_j} v_{k_j} \quad \text{for} \quad k = k_j+1, k_j+2, \cdots, k_{j+1}-1, \quad j = 0, 1, \cdots, J-1,$$

(cf. [19]). Here, for $j = 0$, we set $k_0 := 1$. We remark that the resulting look-ahead Lanczos algorithm produces block tridiagonal matrices T_{k_j}, $j = 1, \cdots, J$, of the type (2.1) with $(k_j - k_{j-1}) \times (k_j - k_{j-1})$ matrices α_{k_j} on the block diagonal.

In exact arithmetic, the outlined algorithm terminates with the block tridiagonal T_{k_J}. Suppose that $k_J = m_\star$ in (4.1). Then T_{k_J} represents the restriction of the matrix A to the A-invariant subspace $K_{m_\star}(r_0, A)$. Obviously, in view of (2.2), the solution of (1.1) can then be computed from the quantities generated by the look-ahead Lanczos procedure. On the other hand, if $k_J < m_\star$ in (4.1), it is not possible to obtain the solution of (1.1) by means of the Lanczos process. For this reason, the case $k_J < m_\star$ is called incurable breakdown.

Next, we derive a criterion for the occurrence of incurable breakdown in the complex symmetric Lanczos algorithm. In the following, it is assumed that A is diagonalizable. Then (e.g., [25, Thm. 3.4.13]), A has a complete set of orthonormal (with respect to (2.6)) eigenvectors. In particular, r_0 can be expanded into eigenvectors of A. More precisely, by collecting components corresponding to identical eigenvalues, we get

$$r_0 = \sum_{l=1}^{m_\star} \rho_l u_l \tag{4.6}$$

$$\text{where } \rho_l \neq 0, \quad Au_l = \lambda_l u_l, \quad \text{and, if } l \neq j, \quad \lambda_l \neq \lambda_j, \quad u_l^T u_j = 0.$$

Notice that, unless all eigenvalues of A are distinct, quasi-null vectors u_l may occur in (4.6). In view of the following theorem, this is equivalent to incurable breakdown.

THEOREM 4.1. *Let $A = A^T$ be a diagonalizable $n \times n$ matrix and $r_0 \in \mathbb{C}^n$. Then in* (4.1), *$k_J = m_\star$ if and only if the eigenvectors in the expansion* (4.6) *of r_0 satisfy*

$$u_l^T u_l \neq 0 \quad \textit{for all} \quad l = 1, \cdots, m_\star. \tag{4.7}$$

Proof. We need to show that (4.7) is equivalent to the existence of a regular orthogonal polynomial of degree $m_\star - 1$ with respect to the inner product (4.5). From the general theory of orthogonal polynomials, it is well known (e.g., [4, pp. 11–12]) that regular orthogonal polynomials of degree k exist if and only if the corresponding moment matrix $M_k := (\mu_{j+l})_{j,l=0,\cdots,k}$ is nonsingular. For the case of (4.5), by (4.6), we have

$$\mu_j := r_0^T A^j r_0 = \sum_{l=1}^{m_\star} \rho_l^2 \lambda_l^j u_l^T u_l, \quad j = 0, 1, \cdots. \tag{4.8}$$

Note that moment matrices are, in particular, Hankel matrices. By applying Kronecker's theorem on the rank of infinite Hankel matrices [18, pp. 204–207] to $M_\infty := (\mu_{j+l})_{j,l=0,1,\cdots}$, it follows that

$$\operatorname{rank} M_\infty = \operatorname{rank} M_k = \operatorname{rank} M_{m-1} = m \quad \text{for all} \quad k \geq m-1, \tag{4.9}$$

where m is the number of poles of the rational function

$$f(z) := \sum_{j=0}^{\infty} \frac{\mu_j}{z^{j+1}}.$$

Using (4.8) and $\sum_{j=0}^{\infty} \lambda_l^j / z^{j+1} \equiv 1/(z-\lambda_l)$, we obtain the following expansion of f:

$$f(z) = \sum_{l=1}^{m_\star} \frac{\rho_l^2 u_l^T u_l}{z - \lambda_l} \quad \text{for all} \quad |z| > \max_{l=1,\cdots,m_\star} |\lambda_l|. \tag{4.10}$$

In particular, by (4.10), $m \leq m_\star$ with equality holding if and only if (4.7) holds true. Hence, in view of (4.9), $M_{m_\star - 1}$ is nonsingular if and only if (4.7) is fulfilled. This concludes the proof. □

As mentioned, (4.7) is guaranteed if A has only simple eigenvalues. Thus we have the following corollary.

COROLLARY 4.2. *If $A = A^T$ is an $n \times n$ matrix with n distinct eigenvalues, then incurable breakdowns cannot occur in the complex symmetric Lanczos Algorithm* 2.1.

5. Complex versus equivalent real linear systems.

In this section, we study connections between (1.1) and its equivalent real versions. Unless stated otherwise, A is now assumed to be a general complex $n \times n$ matrix.

5.1. Equivalent real linear systems.

By taking real and imaginary parts in (1.1), we can rewrite (1.1) as the real linear system

$$A_\star \begin{bmatrix} \operatorname{Re} x \\ \operatorname{Im} x \end{bmatrix} = \begin{bmatrix} \operatorname{Re} b \\ \operatorname{Im} b \end{bmatrix}, \quad A_\star := \begin{bmatrix} \operatorname{Re} A & -\operatorname{Im} A \\ \operatorname{Im} A & \operatorname{Re} A \end{bmatrix}. \tag{5.1}$$

A second real version of (1.1) is

$$A_{\star\star} \begin{bmatrix} \operatorname{Re} x \\ -\operatorname{Im} x \end{bmatrix} = \begin{bmatrix} \operatorname{Re} b \\ \operatorname{Im} b \end{bmatrix}, \quad A_{\star\star} := \begin{bmatrix} \operatorname{Re} A & \operatorname{Im} A \\ \operatorname{Im} A & -\operatorname{Re} A \end{bmatrix}. \tag{5.2}$$

Obviously, (5.1) and (5.2) are the only essentially different possibilities of rewriting (1.1) as a real $2n \times 2n$ system. Furthermore, note that $A_\star$ is nonsymmetric if and only if $A \neq A^H$ is non-Hermitian, whereas $A_{\star\star}$ is symmetric if and only if $A = A^T$. Hence, for complex symmetric linear systems the approach (5.2) appears to be especially attractive since it permits the use of simple CG-type methods such as SYMMLQ and MINRES [36] for real symmetric matrices.

In the following proposition, we collect some simple spectral properties of $A_\star$ and $A_{\star\star}$.

PROPOSITION 5.1. (a) *Let $J = X^{-1}AX$ be the Jordan normal form of A. Then $A_\star$ has the Jordan normal form*

$$\begin{bmatrix} J & 0 \\ 0 & \overline{J} \end{bmatrix} = X_\star^{-1} A_\star X_\star \quad \textit{where} \quad X_\star := \frac{1}{\sqrt{2}} \begin{bmatrix} X & -i\overline{X} \\ -iX & \overline{X} \end{bmatrix}. \tag{5.3}$$

In particular,

$$\sigma(A_\star) = \sigma(A) \cup \overline{\sigma(A)}. \tag{5.4}$$

(b) *The matrices $A_{\star\star}$ and $-A_{\star\star}$ are similar. In particular,*

$$-\lambda, \overline{\lambda}, -\overline{\lambda} \in \sigma(A_{\star\star}) \quad \textit{for all} \quad \lambda \in \sigma(A_{\star\star}). \tag{5.5}$$

Moreover,

$$\sigma(A_{\star\star}) = \{\lambda \in \mathbb{C} \mid \lambda^2 \in \sigma(\overline{A}A)\}.$$

(c) *Let $A = A^T$ be complex symmetric. Then, there exists a singular value decomposition (the so-called Takagi* SVD) *of A of the form*

$$A = U\Sigma U^T, \quad \textit{U unitary}, \quad \Sigma = \operatorname{diag}(\sigma_1, \sigma_2, \cdots, \sigma_n) \geq 0. \tag{5.6}$$

Moreover, $A_{\star\star}$ is a real symmetric matrix with spectral decomposition

$$A_{\star\star} = \begin{bmatrix} Y & -Z \\ Z & Y \end{bmatrix} \begin{bmatrix} \Sigma & 0 \\ 0 & -\Sigma \end{bmatrix} \begin{bmatrix} Y & -Z \\ Z & Y \end{bmatrix}^T \quad \textit{where} \quad Y = \operatorname{Re} U, \; Z = \operatorname{Im} U. \tag{5.7}$$

Proof. (a) First, note that

$$X_\star = S \begin{bmatrix} X & 0 \\ 0 & \overline{X} \end{bmatrix} \quad \text{where} \quad S := \frac{1}{\sqrt{2}} \begin{bmatrix} I_n & -iI_n \\ -iI_n & I_n \end{bmatrix} \quad \text{is unitary.} \tag{5.8}$$

In particular, (5.8) shows that with X also $X_\star$ is nonsingular. We readily verify that

$$S^H A_\star S = \begin{bmatrix} A & 0 \\ 0 & \overline{A} \end{bmatrix},$$

and, in view of (5.8), this implies (5.3). Equation (5.4) is an obvious consequence of (5.3).

(b) Since

$$\begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix}^{-1} A_{\star\star} \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix} = -A_{\star\star},$$

the real matrices $A_{\star\star}$ and $-A_{\star\star}$ are similar. Hence, (5.5) holds true. The relation between $\sigma(A_{\star\star})$ and $\sigma(\overline{A}A)$ is known (see [25, p. 214] for a proof).

(c) Equation (5.6) is the well-known Takagi singular value decomposition for symmetric matrices (e.g., [25, Cor. 3.4.4]). By rewriting (5.6) in terms of the real and imaginary parts of A and U, we obtain (5.7) (cf. [25, pp. 212–213]). □

Roughly speaking, Krylov subspace methods are most effective for coefficient matrices A whose spectrum, except for possibly a few isolated eigenvalues, is contained in a half-plane which excludes the origin of the complex plane. On the other hand, if this half-plane condition is not satisfied and if a large number of eigenvalues of A straddle the origin, usually the convergence of CG-type algorithms is prohibitively slow. Typically, in these situations (see [8], [13], [14] for examples), iterations based on Krylov subspaces generated by A offer no advantage over solving the normal equations (1.5) by standard CG. See Theorem 5.4 for a theoretical result along these lines.

For complex linear systems that arise in practice the half-plane condition is usually satisfied. Indeed, mostly

$$\sigma(A) \subset \{\lambda \in \mathbb{C} \mid \operatorname{Im} \lambda \geq 0\}. \tag{5.9}$$

However, by rewriting (1.1) as real linear systems (5.1), respectively, (5.2), we deliberately create coefficient matrices whose spectra are most unfavorable for Krylov subspace methods. The case (5.2) is especially bad since, in view of (5.5), $\sigma(A_{\star\star})$ is symmetric with respect to real and imaginary axis and hence the eigenvalues always embrace the origin. Similarly, by (5.4), the coefficient matrix $A_\star$ of (5.1) in general has eigenvalues in the upper as well as in the lower half-plane. In particular, if (5.9) holds and, as in most applications, the Hermitian part $(A + A^H)/2$ of A is indefinite, the spectrum of $A_\star$ straddles the origin and the half-plane condition is not satisfied for $A_\star$. The following example illustrates this behavior.

Example 5.2. Consider the class (3.28) of complex symmetric matrices $A = T + i\sigma I$, where $T = T^T$ is real and $\sigma > 0$. Obviously,

$$\begin{aligned}\sigma(A) &= \{\lambda = \mu + i\sigma \mid \mu \in \sigma(T)\} \\ &\subset S := \big[\mu_m + i\sigma, \mu_M + i\sigma\big].\end{aligned} \tag{5.10}$$

Here μ_m and μ_M denote the smallest and largest eigenvalue of T, respectively. Note that the complex line segment S is parallel to the real axis and always contained in the upper half of the complex plane. In view of (5.4), (5.10) implies

$$\sigma(A_\star) = \{\lambda = \mu \pm i\sigma \mid \mu \in \sigma(T)\} \subset S \cup \overline{S}.$$

We remark that $S \cup \overline{S}$ is a tandem slit consisting of the two complex intervals S and $\overline{S}$, which are parallel and symmetric to each other with respect to the real axis. Moreover, the eigenvalues of $A_\star$ straddle the origin if the Hermitian part T of A is indefinite. Finally, using (3.28) and part (b) of Proposition 5.1, we obtain

$$\begin{aligned}\sigma(A_{\star\star}) &= \{\lambda = \pm\sqrt{\mu^2 + \sigma^2} \mid \mu \in \sigma(T)\} \\ &\subset \Big[-\sqrt{\mu_M^2 + \sigma^2}, -\sigma\Big] \cup \Big[\sigma, \sqrt{\mu_M^2 + \sigma^2}\Big].\end{aligned}$$

Note that the class (3.28) is closely related to shifted skewsymmetric matrices. Indeed, if, instead of $Ax = b$, we rewrite $-iAx = -ib$ as a real system (5.1), we obtain

$$(-iA)_\star = \begin{bmatrix} \sigma I_n & T \\ -T & \sigma I_n \end{bmatrix} = \sigma I_{2n} - N, \quad N := \begin{bmatrix} 0 & -T \\ T & 0 \end{bmatrix} \quad \Big(= -N^T\Big). \tag{5.11}$$

Then the eigenvalues are contained in a line segment which is parallel to the imaginary axis and symmetric with respect to the real axis:

$$\sigma\big((-iA)_\star\big) = \{\lambda = \sigma \pm i\mu \mid \mu \in \sigma(T)\} \subset [\sigma - i\rho, \sigma + i\rho], \qquad \rho = \max\{|\mu_m|, |\mu_M|\}.$$

5.2. Correspondence of Krylov subspace methods. In analogy to (1.6) for complex linear systems (1.1), a Krylov subspace method for the solution of the equivalent real systems (5.1), respectively, (5.2) generates iterates

$$\begin{bmatrix} \operatorname{Re} x_k \\ \operatorname{Im} x_k \end{bmatrix} = \begin{bmatrix} \operatorname{Re} x_0 \\ \operatorname{Im} x_0 \end{bmatrix} + P(A_\star) \begin{bmatrix} \operatorname{Re} r_0 \\ \operatorname{Im} r_0 \end{bmatrix}, \qquad P \in \Pi_{k-1}^{(r)}, \tag{5.12}$$

respectively,

$$\begin{bmatrix} \operatorname{Re} x_k \\ -\operatorname{Im} x_k \end{bmatrix} = \begin{bmatrix} \operatorname{Re} x_0 \\ -\operatorname{Im} x_0 \end{bmatrix} + P(A_{\star\star}) \begin{bmatrix} \operatorname{Re} r_0 \\ \operatorname{Im} r_0 \end{bmatrix}, \qquad P \in \Pi_{k-1}^{(r)}. \tag{5.13}$$

Here and in the sequel, $\Pi_{k-1}^{(r)}$ denotes the subset of Π_{k-1} of polynomials with real coefficients. Furthermore, the notation

$$K_k^{(r)}(c, B) := \{P(B)c \mid P \in \Pi_{k-1}^{(r)}\} \quad \Big(\subset K_k(c, B)\Big)$$

will be used.

At first glance it might appear that Krylov subspace iterations (1.6), respectively, (5.12)–(5.13) for the original complex systems, respectively, its equivalent real versions correspond to each other. However, as the following proposition shows, this is not the case in general.

PROPOSITION 5.3. *Let $k \in \mathbb{N}$.*

(a) *Let $P \in \Pi_{k-1}$. Then, $x_k = x_0 + P(A)r_0$ is equivalent to*

$$(5.14)\qquad \begin{bmatrix}\operatorname{Re} x_k\\ \operatorname{Im} x_k\end{bmatrix} = \begin{bmatrix}\operatorname{Re} x_0\\ \operatorname{Im} x_0\end{bmatrix} + P_1(A_\star)\begin{bmatrix}\operatorname{Re} r_0\\ \operatorname{Im} r_0\end{bmatrix} + P_2(A_\star)\begin{bmatrix}\operatorname{Im} r_0\\ -\operatorname{Re} r_0\end{bmatrix}$$

where $P = P_1 + iP_2$, $P_1, P_2 \in \Pi_{k-1}^{(r)}$.

(b) *Let $P \in \Pi_{k-1}^{(r)}$. Then,* (5.13) *is equivalent to*

$$(5.15)\qquad x_k = \operatorname{Re} x_k + i \operatorname{Im} x_k = x_0 + R(\overline{A}A)\overline{r_0} + S(\overline{A}A)\overline{A}r_0$$

where $R \in \Pi_{\lfloor (k-1)/2 \rfloor}^{(r)}$ and $S \in \Pi_{\lfloor (k-2)/2 \rfloor}^{(r)}$ are defined by $P(\lambda) \equiv R(\lambda^2) + \lambda S(\lambda^2)$.

Proof. First we note that, for $j = 0, 1, \cdots$,

$$(5.16)\quad (A_\star)^j = \begin{bmatrix}\operatorname{Re} A^j & -\operatorname{Im} A^j\\ \operatorname{Im} A^j & \operatorname{Re} A^j\end{bmatrix} \quad\text{and}\quad (A_{\star\star})^{2j} = \begin{bmatrix}\operatorname{Re}(\overline{A}A)^j & \operatorname{Im}(\overline{A}A)^j\\ -\operatorname{Im}(\overline{A}A)^j & \operatorname{Re}(\overline{A}A)^j\end{bmatrix},$$

as is easily verified by induction on j.

(a) Let γ_j and δ_j be the coefficients of the real polynomials P_1 and P_2, respectively. Then

$$(5.17)\qquad \begin{aligned}\operatorname{Re} P(A) &= \sum_{j=0}^{k-1}\left(\gamma_j \operatorname{Re} A^j - \delta_j \operatorname{Im} A^j\right),\\ \operatorname{Im} P(A) &= \sum_{j=0}^{k-1}\left(\gamma_j \operatorname{Im} A^j + \delta_j \operatorname{Re} A^j\right).\end{aligned}$$

By reformulating $x_k = x_0 + P(A)r_0$, by means of (5.17) and the first relation in (5.16), in terms of real and imaginary parts, we immediately obtain (5.14).

(b) A routine calculation, using the second identity in (5.16), shows that (5.13) can be rewritten as

$$\begin{bmatrix}\operatorname{Re} x_k\\ -\operatorname{Im} x_k\end{bmatrix} = \begin{bmatrix}\operatorname{Re} x_0\\ -\operatorname{Im} x_0\end{bmatrix} + \begin{bmatrix}\operatorname{Re}\{R(\overline{A}A)\overline{r}_0 + S(\overline{A}A)\overline{A}r_0\}\\ -\operatorname{Im}\{R(\overline{A}A)\overline{r}_0 + S(\overline{A}A)\overline{A}r_0\}\end{bmatrix}.$$

Hence (5.13) and (5.15) are equivalent. □

In view of part (a) of Proposition 5.3, the corresponding real equivalent of complex Krylov schemes (1.6) are iterations of the type (5.14) and not the obvious real Krylov subspace methods (5.12). Clearly, the actual choice of the polynomials in (1.6), respectively, (5.12)–(5.13) is aimed at obtaining iterates which are—in a certain sense—best possible approximations to the exact solution of the corresponding linear system. By using schemes of the type (5.12), from the first, we give up k of the $2k$ real parameters which are available for optimizing complex Krylov subspace methods (1.6). Consequently, it is always preferable to solve the complex system (1.1) rather than the real version (5.1) by Krylov subspace methods. Furthermore, numerical tests reveal that the convergence behavior of the two approaches can be drastically different (see § 6).

5.3. A connection between MR and CGNR for complex symmetric matrices. Now assume that A is a complex symmetric $n \times n$ matrix. Then, in view of part (c) of Proposition 5.1, $A_{\star\star}$ is a real symmetric indefinite matrix whose spectrum is given by

$$(5.18)\qquad \sigma(A_{\star\star}) = \{\pm\sigma_j \mid j = 1, \cdots, n\}.$$

Here $\sigma_j = \sigma_j(A) \geq 0$, $j = 1, \cdots, n$, denote the singular values of A.

Since there are simple extensions [36] of classical CG to real symmetric indefinite matrices, it is especially tempting to solve (5.2) by one of these methods. The iterates of these algorithms are defined either via a Galerkin condition or a minimal residual (MR) property. Here we consider the MR approach. Applied to (5.2) it generates a sequence of iterates z_k, $k = 1, 2, \cdots$, which are characterized by

$$\|b_{\star\star} - A_{\star\star} z_k\| = \min_{z \in z_0 + K_k^{(r)}(r_0^{\star\star}, A_{\star\star})} \|b_{\star\star} - A_{\star\star} z\|, \quad z_k \in z_0 + K_k^{(r)}(r_0^{\star\star}, A_{\star\star}). \tag{5.19}$$

Here we have set

$$b_{\star\star} := \begin{bmatrix} \operatorname{Re} b \\ \operatorname{Im} b \end{bmatrix}, \quad z_k := \begin{bmatrix} \operatorname{Re} x_k \\ -\operatorname{Im} x_k \end{bmatrix} \text{ for } k = 0, 1, \cdots, \quad r_0^{\star\star} := b_{\star\star} - A_{\star\star} z_0. \tag{5.20}$$

Roughly speaking, CG-type algorithms for real symmetric indefinite systems converge slowly if the coefficient matrix is strongly indefinite in the sense that it has many positive as well as many negative eigenvalues. Unfortunately, since by (5.18), $\sigma(A_{\star\star})$ is even symmetric to the origin, $A_{\star\star}$ exhibits this undesirable property. Indeed, numerical tests show that the convergence behavior of the MR method (5.19) is practically identical to that of the tabooed approach to (1.1) via solving the normal equations (1.5) by standard CG [24]. In the sequel, we refer to this latter method as CGNR. Notice that the iterates x_k of CGNR are defined by the minimization property

$$\|b - Ax_l\| = \min_{x \in x_0 + K_l(A^H r_0, A^H A)} \|b - Ax\|, \quad x_l \in x_0 + K_l(A^H r_0, A^H A). \tag{5.21}$$

Next we prove that MR and CGNR are even equivalent if the starting residual $r_0^{\star\star}$ satisfies a certain symmetry condition. Note that, corresponding to the spectral decomposition (5.7), $r_0^{\star\star}$ can be expanded into eigenvectors of $A_{\star\star}$ as follows:

$$r_0^{\star\star} = \begin{bmatrix} Y & -Z \\ Z & Y \end{bmatrix} c \quad \text{with} \quad c = \begin{bmatrix} c_1 \\ \vdots \\ c_{2n} \end{bmatrix} \in \mathbb{R}^{2n}. \tag{5.22}$$

THEOREM 5.4. *Let x_k^{MR}, respectively, x_l^{CGNR} denote the iterates generated by* (5.19)–(5.20), *respectively,* (5.21) *starting with the same initial guess $x_0 \in \mathbb{C}^n$. Assume that c in the expansion* (5.22) *of $r_0^{\star\star}$ satisfies*

$$|c_j| = |c_{n+j}|, \qquad j = 1, 2, \cdots, n. \tag{5.23}$$

Then,

$$x_l^{\mathrm{CGNR}} = x_{2l}^{MR} = x_{2l+1}^{\mathrm{MR}}, \qquad l = 0, 1, \cdots . \tag{5.24}$$

Proof. First note that, in view of (5.7) and (5.22), c_j and c_{n+j} are components corresponding to a pair of symmetric eigenvalues $\pm\sigma_j$ of $A_{\star\star}$. However, for any real symmetric linear system $A_{\star\star} z = b_{\star\star}$ with "symmetric" eigenvalues and "symmetric" starting residual $r_0^{\star\star}$ in the sense of (5.18) and (5.23), respectively, the MR method generates iterates with $z_k \in z_0 + K_{\lfloor k/2 \rfloor}^{(r)}(A_{\star\star} r_0^{\star\star}, A_{\star\star}^2)$ (see, e.g., [14]). Consequently the iterates defined by (5.19) satisfy

$$z_{2l} = z_{2l+1} \in z_0 + K_l^{(r)}(A_{\star\star} r_0^{\star\star}, A_{\star\star}^2). \tag{5.25}$$

In particular, by (5.20), (5.25) shows that $x_{2l}^{\mathrm{MR}} = x_{2l+1}^{\mathrm{MR}}$.

It remains to prove the first relation in (5.24). To this end, we remark that

$$(5.26)\qquad \|b_{\star\star}-A_{\star\star}z\|=\|b-Ax\| \quad\text{for all}\quad z=\begin{bmatrix}\operatorname{Re}x\\-\operatorname{Im}x\end{bmatrix},\quad x\in\mathbb{C}^n.$$

Moreover, by using (5.20) and part (b) of Proposition 5.3 (applied to polynomials $P(\lambda)\equiv\lambda S(\lambda^2)$), we deduce

$$(5.27)\qquad z_0+K_l^{(r)}(A_{\star\star}r_0^{\star\star},(A_{\star\star})^2)=\left\{\begin{bmatrix}\operatorname{Re}x\\-\operatorname{Im}x\end{bmatrix}\;\middle|\; x\in x_0+K_l^{(r)}(A^Hr_0,A^HA)\right\}$$

(notice that $\overline{A}=A^H$ in (5.15)!). In view of (5.25)–(5.27), (5.19) (for $k=2l$) can be rewritten in the form

$$(5.28)\quad \|b-Ax_{2l}^{MR}\|=\min_{x\in x_0+K_l^{(r)}(A^Hr_0,A^HA)}\|b-Ax\|,\quad x_{2l}^{\mathrm{MR}}\in x_0+K_l^{(r)}(A^Hr_0,A^HA).$$

Finally, note that the iterates of CGNR always correspond to real polynomials, i.e., $x_l^{\mathrm{CGNR}}\in x_0+K_l^{(r)}(A^Hr_0,A^HA)$. Hence, by comparing (5.21) with (5.28), we conclude that $x_l^{\mathrm{CGNR}}=x_{2l}^{\mathrm{MR}}$. □

Clearly, the special symmetry condition (5.23) will not be satisfied in general. Nevertheless, all our numerical experiments showed (cf. § 6) that (5.24) is still fulfilled approximately, i.e.,

$$(5.29)\qquad x_l^{\mathrm{CGNR}}\approx x_{2l}^{\mathrm{MR}}\approx x_{2l+1}^{\mathrm{MR}},\qquad l=0,1,\cdots.$$

6. Numerical examples. We have performed numerical experiments with all algorithms considered in this paper in numerous cases. In this section, we present a few typical results of these experiments.

Consider (1.2) on the unit square $G:=(0,1)\times(0,1)$ with $\sigma_1\in\mathbb{R}$ a constant and σ_2 a real coefficient function. First assume that u satisfies Dirichlet boundary conditions. Then, approximating (1.2) by finite differences on a uniform $m\times m$ grid with mesh size $h:=1/(m+1)$ yields a linear system (1.1) with A an $n\times n$, $n:=m^2$, matrix of the form

$$(6.1)\qquad A=T+ih^2D,\quad T:=A_0-\sigma_1h^2I,\quad D=\operatorname{diag}(d_1,d_2,\cdots,d_n).$$

Here A_0 is the symmetric positive definite matrix arising from the usual five-point discretization of $-\Delta$ and the diagonal elements of D are just the values of σ_2 at the grid points.

Similarly, if we consider the real Helmholtz equation (1.2), i.e., $\sigma_2\equiv 0$, but now with a typical complex boundary condition such as

$$\frac{\partial u}{\partial n}=i\alpha u\quad\text{on}\quad\{(1,y)\mid -1<y<1\}$$

(which is discretized using forward differences) and Dirichlet boundary conditions on the other three sides of the boundary of G, we again arrive at (6.1), where

$$(6.2)\qquad d_j=\begin{cases}\alpha/h, & \text{if } j=lm,\ l=1,\cdots,m,\\ 0, & \text{otherwise.}\end{cases}$$

The test problems presented in this section are all linear systems $Ax=b$ with complex symmetric coefficient matrices of the type (6.1). For Example 6.1, the mesh size $h=1/64$ was chosen resulting in a 3969×3969 matrix A. In Examples 6.2–6.4, $h=1/32$ and thus A is a 961×961 matrix. The right-hand side b was chosen to be a vector with random components in $[-1,1]+i[-1,1]$, with the exception of Example 6.2 where b had constant components $1+i$. As starting vector, $x_0 = 0$ was chosen.

As stopping criterion, we used

$$R_k := \frac{\|b - Ax_k\|}{\|b - Ax_0\|} \leq 10^{-6}. \tag{6.3}$$

In Figs. 6.1–6.4, the relative residual norm (6.3), R_k, is plotted versus the number N_k of matrix-vector products with A, $A_\star$, or $A_{\star\star}$. Note that $N_k = k$ is identical to the iteration number, except for CGS, respectively, CGNR, which both require two matrix-vector products $A \cdot v$, respectively, $A \cdot v$, $\overline{A} \cdot v$ per iteration and for which $N_k = 2k$. For GMRES [40], work and storage per iteration step k grows linearly with k and in practice it is necessary to use restarts. In the sequel, GMRES(k_0) and GMRES$_\star$(k_0) refer to complex and real versions—restarted after every k_0 iterations—of the GMRES method applied to (1.1) and (5.1), respectively.

In a first series of experiments, QMR (with different weighting strategies) and BCG were compared. The natural choice (3.11) turned out to be the best strategy in all cases. In the following, QMR always refers to Algorithm 3.2 with weights (3.11). Then QMR produces residual vectors whose norms are almost monotonically decreasing and generally smaller than those of the BCG residuals. However, convergence of QMR and BCG typically occurred after a comparable number of iterations. The following example is typical.

Example 6.1. Here (6.1) is a 3969 × 3969 matrix with $\sigma_1 = 200$, and the diagonal elements of D are given by (6.2) with $\alpha = 10$. In Fig. 6.1, the convergence behavior of BCG, QMR, and of the unweighted version ($\omega_j \equiv 1$) of the QMR Algorithm 3.2 is displayed.

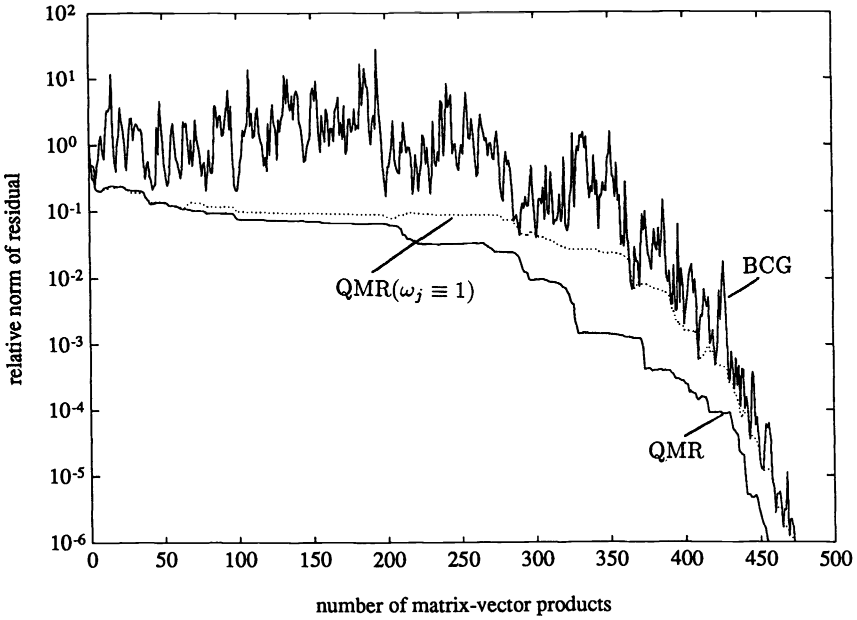

FIG. 6.1

Next we compared the CGS Algorithm 2.5 and complex GMRES with QMR and BCG. Typically, CGS needed slightly fewer iterations than QMR and BCG to reach (6.3). However, per iteration, QMR and BCG require only about half as much work and storage and thus CGS is more expensive than QMR or BCG for complex symmetric matrices. Due to the necessary restarts, GMRES was never competitive with QMR, BCG, or CGS.

Example 6.2. In (6.1) we set $n = 961$, $\sigma_1 = 100$, and d_j; $j = 1, \cdots, n$, are chosen as random numbers in $[0, 10]$. Figure 6.2 shows the convergence behavior of GMRES(20), QMR, BCG, and two runs of CGS with different starting vectors s_0, namely, $s_0 = r_0$, respectively, s_0 with random components in $[-1,1]+i[-1,1]$. Notice the extremely large residual norms in the early stage of the CGS iteration.

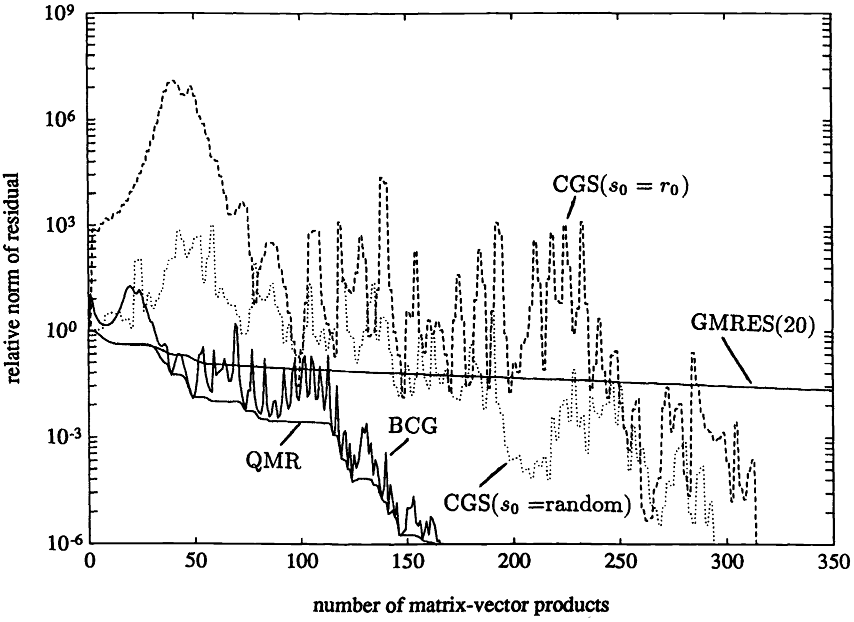

FIG. 6.2

In the following two examples we compared CG-type methods for $Ax = b$ with real schemes for the equivalent real systems (5.1), respectively, (5.2).

MR($A_{\star\star}$) denotes the minimal residual method (5.19) applied to the real symmetric system (5.2).

Example 6.3. Here, in (6.1), $n = 961$, $\sigma_1 = 100$, and d_j are given by (6.2) with $\alpha = 100$. In Fig. 6.3, the convergence behavior of QMR, MR($A_{\star\star}$), GMRES(20), GMRES(5), GMRES$_\star$(5), and CGNR is shown. Notice that, although the symmetry condition (5.23) is not fulfilled, the curves for CGNR and MR($A_{\star\star}$) are almost identical. This confirms (5.29). Finally, we tried GMRES(k_0) and GMRES$_\star$(k_0) also with other restart parameters k_0. For this example, both methods never did converge.

Example 6.4. Let A be the 961×961 matrix (6.1) with $\sigma_1 = 1000$, $D = \sigma_2 I$, $\sigma_2 = 100$, and set $\sigma := \sigma_2 h^2$. Note that A is a shifted Hermitian matrix of the form (3.28) (cf. Example 5.2). In particular, A belongs to the class of matrices (1.3) for which efficient true minimal residual algorithms for solving $Ax = b$ exist. Here we used the particular implementation, MR(A), derived in [16, Algorithm 2]. Recall that, by rewriting $-iAx = -ib$ as a real system (5.1), we obtain a shifted skewsymmetric matrix (5.11), $(-iA)_\star$. Again, for such matrices an efficient true minimal residual algorithm, denoted by MR($(-iA)_\star$), exists [9], [13]. Figure 6.4 shows the convergence behavior of MR(A), MR($A_{\star\star}$), MR($(-iA)_\star$),CGNR, and GMRES(20). Notice that MR($(-iA)_\star$) and CGNR are nearly identical. This is typical for the case in which σ is small compared to the spectral radius of T. Furthermore, if $\sigma = 0$, i.e., $(-iA)_\star$ in (5.11) is skewsymmetric, CGNR and MR($(-iA)_\star$) are even equivalent [13].

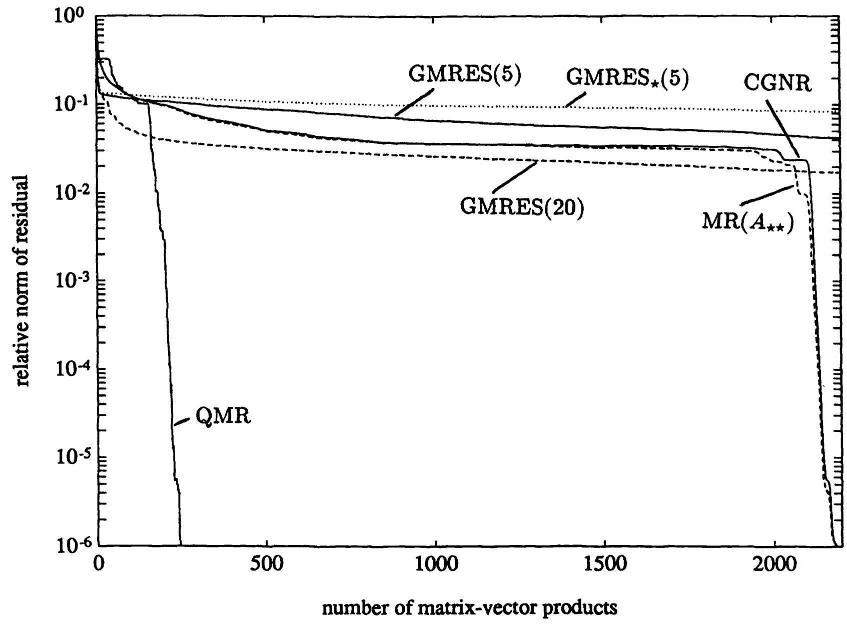

FIG. 6.3

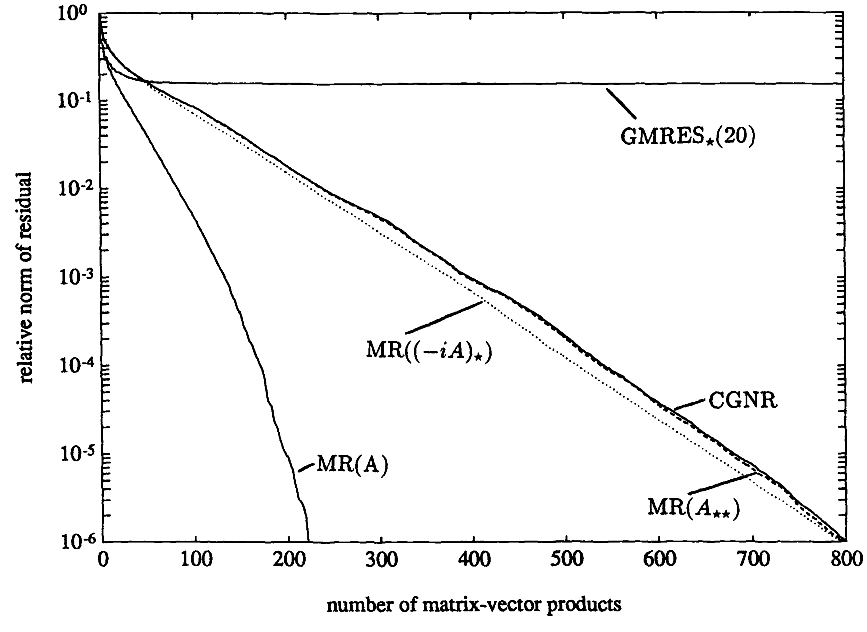

FIG. 6.4

7. Concluding remarks. Complex linear systems $Ax = b$, which arise in practice, often have complex symmetric coefficient matrices A. In this paper we have explored the use of a variant of the nonsymmetric Lanczos process for complex symmetric matrices for the solution of such linear systems. In particular, we have proposed a new method of defining approximate solutions of $Ax = b$ via a quasi-minimal residual (QMR) property. In contrast to the biconjugate gradient (BCG) approach, the QMR iterates are well defined as long as the basic Lanczos recursion does not break down. Moreover, unlike the wildly oscillating BCG residuals, the QMR residuals converge almost monotonically. Also, existing BCG iterates can be easily computed from the quantities generated during the QMR iteration. Finally, possible breakdowns—except incurable ones—of the complex symmetric Lanczos recursion can be overcome by using a look-ahead version of the Lanczos process. Incurable breakdowns occur only in very special situations. For example, they cannot occur if all eigenvalues of A are distinct.

It is very tempting (and often done in practice!) to avoid complex linear systems by solving equivalent real systems instead. We have presented some theoretical and numerical results which show that this—at least for Krylov subspace methods—is a fatal approach. Typically, the resulting real systems are unequally harder to solve by conjugate gradient-type algorithms than the original complex ones.

In this paper we have not addressed the question of how to choose preconditioners M for complex symmetric linear systems. This will be the subject of a forthcoming report. Here, we remark only that complex symmetry is preserved under preconditioning as long as M is complex symmetric. In particular, all algorithms for $A = A^T$ that we have considered can be used in conjunction with a complex symmetric preconditioner M. Note that the standard techniques, such as incomplete factorization [34], applied to $A = A^T$ generate complex symmetric preconditioners M.

Finally, we would like to mention that the quasi-minimal residual approach can also be used to stabilize the general nonsymmetric biconjugate gradient algorithm [17].

A SCHEME FOR PARALLELIZING CERTAIN ALGORITHMS FOR THE LINEAR INHOMOGENEOUS HEAT EQUATION*

STEVEN M. SERBIN†

Abstract. This paper proposes a technique for parallelizing some algorithms for the inhomogeneous heat equation developed by Brenner, Crouzeix, and Thomée. It is known that "reduction of order" may occur unless special treatment is afforded the inhomogeneity; their schemes do so without imposing "unsatisfactory" conditions on the forcing term. Certain distinct pole rational functions with matrix argument are expanded into partial fraction form and instructions are given on how this can be used to apportion the work of solving the corresponding linear algebraic systems to processors operating concurrently; this will allow for the implementation of a high-order scheme in essentially the same time as that of a less powerful lower-order scheme such as implicit Euler. Some numerical results for the implementation are presented, which is compared to a sequential implementation for the same scheme and a similar one which is based on a rational function with a multiple pole.

Key words. parallel methods, inhomogeneous heat equation, order reduction, partial fractions

AMS(MOS) subject classifications. 65M05, 65M20

1. Introduction. The purpose of this note is to synthesize two basic ideas to produce an implementation strategy for the approximate solution of the linear inhomogeneous heat equation. It has been observed by Crouzeix [3] and also by Verwer [14] and Sanz-Serna, Verwer, and Hunsdorfer [10] (in the context of implicit Runge-Kutta methods) that the order achieved in fully discrete schemes for such problems may fail to meet that which is expected from the usual ordinary differential equation (ODE) analysis for the corresponding semidiscrete equations. Numerical examples of this "order reduction" may be found, for instance, in the report of Verwer [14], and so the issue of avoiding this reduction is quite real. The approach we wish to follow here is specific to the linear inhomogeneous heat equation and thus is based upon the analysis of Brenner, Crouzeix, and Thomée. They describe in [2] (and summarize in [13]) a class of fully discrete schemes which achieve optimal (unreduced) order of convergence while avoiding the imposition of "unsatisfactory" boundary conditions on the forcing term and certain of its derivatives.

To accomplish the time-stepping procedures which constitute these implicit algorithms, certain systems of linear algebraic equations must be solved at each time step. The second basic component of our strategy is the decomposition of certain rational functions with matrix argument into partial fraction form. Of itself, this approach is, to some extent, known. Swayne [11] used such a decomposition for a class of low-order schemes for systems of ODEs. Recently, Sweet [12] exhibited the utility of the partial fraction approach to obtain parallelism in cyclic reduction methods for solving certain block tridiagonal linear algebraic systems. Also, it was brought to our attention by one of the referees that Gallopoulos and Saad [4] had undertaken independently a similar study. Their approach, as ours, involves the partial fraction expansion of rational matrix functions, but applies essentially only to the *homogeneous* semidiscrete problem (the forcing term being constant). While illuminating and important computational studies and numerical experiments performed on a true parallel system may be found in their work and associated references cited therein, our results reported here aim specifically at the issue of the inhomogeneity and thus complement their work.

Similar to the approach utilized by Gallopoulos and Saad for their problem, we shall note how the partial fraction approach allows, within each time step, the creation of subtasks which will be able to be accomplished concurrently; the resulting solutions will then be combined to produce the approximate solution of the heat equation at the next time level. One feature of our approach will be the ability to create the appropriate rational functions directly in partial fraction form, rather than having to use the more traditional expansions as intermediaries.

We will begin by presenting the problem and describing the Brenner-Crouzeix-Thomée algorithms. We will show the role of the partial fraction approach and elaborate on the conditions required and their fulfillment. We will show in general how these schemes can be implemented employing concurrency, and then demonstrate our approach with a particular fourth-order scheme. We will conclude with numerical examples which have been constructed to compare the partial fraction approach to a traditional computational scheme, as well as to investigate the order reduction question.

2. The inhomogeneous heat equation and some fully discrete numerical schemes. The problem described by Brenner, Crouzeix and Thomée is as follows. Let Ω be a bounded domain in R^d with smooth boundary; we wish to determine a function $u(x, t)$ satisfying

$$\begin{aligned} u_t - \Delta u &= f \quad \text{in } \Omega \times [0, \infty), \\ u &= 0 \quad \text{on } \partial\Omega \times [0, \infty), \\ u(\cdot, 0) &= 0 \quad \text{in } \Omega. \end{aligned} \tag{2.1}$$

Here, Δ is, as usual, the Laplace operator. In this section, we shall not attempt to present all of the stages leading to the fully discrete algorithms developed in [13]. To establish notation, though, we recount that (2.1) is first approximated by the semidiscrete problem

$$\begin{aligned} u_{h,t} - \Delta_h u_h &= f_h = P_0 f \quad \text{for } t \geqq 0, \\ u_h(0) &= 0, \end{aligned} \tag{2.2}$$

where Δ_h is the "semidiscrete" Laplacian defined on an appropriate finite-dimensional subspace S_h of $L_2(\Omega)$, $u_h : [0, \infty) \to S_h$ is the semidiscrete approximation to u, and P_0 denotes the L_2 projection operator from Ω to S_h. In turn, (2.2) will then be discretized in time to yield a scheme of the form

$$\begin{aligned} U^{n+1} &= r(k\Delta_h)U^n + k \sum_{i=1}^{m} q_i(k\Delta_h)P_0 f(t_n + \tau_i k), \qquad n = 0, 1, 2, \cdots \\ U^0 &= 0 \end{aligned} \tag{2.3}$$

where k is the time step, $t_n = nk$, $r(\lambda)$ and $q_i(\lambda)$, $i = 1, \cdots, m$ are rational functions bounded on the spectrum of $k\Delta_h$ uniformly in k and h and the quadrature nodes τ_i, $i = 1, \cdots, m$ are distinct real numbers (which are taken to be in $[0, 1]$). Each $U^n \in S_h$ is then an approximation to $u_h(t_n)$.

The aim of any such scheme (2.3) is to produce an efficient procedure which admits an "optimal" error estimate of the form $\|U^n - u_h(t_n)\| = \mathcal{O}(h^\beta + k^p)$, where h represents an appropriate spatial discretization parameter and the exponent β reflects the approximation property of the subspace S_h, while the exponent p is determined by the properties of the rational function r and $q_i(\lambda)$, $i = 1, \cdots, m$.

Certain conditions obtained by Brenner, Crouzeix, and Thomée are imperative. They first require the time discretization (2.3) to be "accurate of order p" (in a sense defined by applying the scheme to a scalar analogue), and establish the equivalence of the condition to the requirements

$$r(\lambda)=e^{\lambda}+\mathcal{O}(\lambda^{p+1}) \quad \text{as } \lambda\to 0 \tag{2.4}$$

and

$$\sum_{i=1}^{m} \tau_i^l q_i(\lambda)=\frac{l!}{\lambda^{l+1}}\left(e^{\lambda}-\sum_{j=0}^{l}\frac{\lambda^j}{j!}\right)+\mathcal{O}(\lambda^{p-l}) \quad \text{as } \lambda\to 0, \qquad 0\leqq l\leqq p. \tag{2.5}$$

To promote computational efficiency, an additional constraint on the schemes is that $r(\lambda)$ and all $q_i(\lambda)$ share the same denominator. With this choice, we shall discuss the usual implementation of (2.3), as well as our approach affording parallelism, in § 4.

When $m=p$, it turns out that (2.4)-(2.5) are easily satisfied (with the aid of a Vandermonde system to fix the $q_i(\lambda)$). However, a reduction of m at no loss in order of accuracy would lead to a more efficient scheme, so that possibility should be admitted.

Even when schemes are restricted to satisfy (2.4), (2.5), and, in addition, a certain stability condition imposed on $r(\lambda)$ for λ in the spectrum of $k\Delta_h$, a further objection is registered. Namely, the analysis is performed in certain Sobolev spaces $H^s(\Omega)$, and conditions requiring $f^{(l)}(t)$ to lie in certain of these spaces ($s=\max(\beta, 2p)-2l$, $l<p$) in order to obtain desired estimates force "unsatisfactory" boundary conditions on f and its derivatives, conditions that "are not necessary to ensure existence and uniqueness of the exact solution" of (2.1).

Strides are then taken to remove these objections. In doing so, it is necessary to reformulate the accuracy condition. Defining (with a slight notational deviation from [13])

$$\rho_l(\lambda)=\frac{l!}{\lambda^{l+1}}\left(r(\lambda)-\sum_{j=0}^{l}\frac{\lambda^j}{j!}\right)-\sum_{i=1}^{m}\tau_i^l q_i(\lambda), \qquad l=0,\cdots,p-1 \tag{2.6}$$

and

$$\rho_p(\lambda)=\frac{p!}{\lambda^{p+1}}\left(r(\lambda)-\sum_{j=0}^{p}\frac{\lambda^j}{j!}\right) \tag{2.7}$$

then accuracy of order p is equivalent to

$$\rho_l(\lambda)=\mathcal{O}(\lambda^{p-l}), \qquad \lambda\to 0, \qquad l=0,\cdots,p. \tag{2.8}$$

In addition, strict accuracy of order $p_0\leqq p$ is defined to be

$$\rho_l(\lambda)=0, \qquad l=0,\cdots,p_0-1. \tag{2.9}$$

After they perform further analysis, including the introduction of certain functions $h_l(\lambda)$, and in particular,

$$h_{p-1}(\lambda)=1-(p-1)\sum_{i=1}^{m}\tau_i^{p-2}q_i(\lambda)+\lambda\sum_{i=1}^{m}\tau_i^{p-1}q_i(\lambda) \tag{2.10}$$

the goal of the paper is achieved. Namely, by requiring (2.8), (2.9) with $p_0=p-1$, the stability condition $|r(\lambda)|\leqq 1$ for λ in the spectrum of $k\Delta_h$, *and* the condition that

$$\sigma(\lambda)\equiv h_{p-1}(\lambda)/(\lambda(1-r(\lambda))) \tag{2.11}$$

be bounded on the spectrum of $k\Delta_h$ *uniformly* in k and h, the optimal estimates are obtained, requiring appropriate regularity in the solution of (2.1), but not the objectionable boundary conditions on f.

Finally, for purposes of construction of the schemes for $m<p$, it is shown that the accuracy conditions needed should be (2.4), and, additionally,

$$\rho_l(\lambda)=\mathcal{O}(\lambda^{p-l}) \qquad \lambda\to 0, \qquad l=0,\cdots,m-1 \tag{2.12}$$

and a moment condition on the quadrature nodes,

$$\int_0^1 \omega(\tau)\tau^j\,d\tau=0, \qquad j=0,\cdots,p-m-1 \tag{2.13}$$

where $\omega(\tau)\equiv\prod_{i=1}^m(\tau-\tau_i)$.

3. Rational approximation via partial fractions: Selection of schemes. We suppose that

$$e^z\approx\sum_{j=0}^{\mu}\frac{a_j^{(\mu)}}{1-\gamma_j z}\equiv r(z) \tag{3.1}$$

where $\{\gamma_i\}_{i=0}^{\mu}$ is some specified collection of distinct real numbers, with $\gamma_0=0$. Thus, we are dealing here only with the case of rational approximation with real poles; the inclusion of complex poles indeed appears to be very interesting, and has been discussed for the homogeneous problem by Gallopoulos and Saad. For our problem, though, a general theory linking the optimal order of the scheme to the minimal number of quadrature nodes is unknown (to our knowledge) and so the case of complex poles will be deferred to a later study.

The approximation (3.1) will be of order at least ν (in the usual algebraic sense) if, letting $E(z)=e^z-r(z)$, it occurs that $E^{(j)}(0)=0, j=0,\cdots,\nu$. But, since differentiation of the individual terms in (3.1) and their subsequent evaluation at $z=0$ is trivial, the condition for order ν becomes simply

$$1=j!\left\{\sum_{i=0}^{\mu}\gamma_i^j a_i^{(\mu)}\right\}, \qquad j=0,\cdots,\nu. \tag{3.2}$$

In the case that $\nu=\mu$, (3.2) is then a Vandermonde system of order $\mu+1$:

$$\begin{bmatrix}1 & 1 & \cdots & 1\\ \gamma_0 & \gamma_1 & \cdots & \gamma_\mu\\ \vdots & \vdots & & \vdots\\ \gamma_0^\mu & \gamma_1^\mu & \cdots & \gamma_\mu^\mu\end{bmatrix}\begin{bmatrix}a_0^{(\mu)}\\ a_1^{(\mu)}\\ \vdots\\ a_\mu^{(\mu)}\end{bmatrix}=\begin{bmatrix}1/0!\\ 1/1!\\ \vdots\\ 1/\mu!\end{bmatrix} \tag{3.3}$$

which we shall abbreviate as $\mathrm{V}^{(\mu)}a^{(\mu)}=\Psi^{(\mu)}$.

It is well known that this system has a unique solution, which can be described as follows. Define

$$g_i(x)=\frac{\prod_{j=0,j\neq i}^{\mu}(x-\gamma_j)}{\prod_{j=0,j\neq i}^{\mu}(\gamma_i-\gamma_j)}. \tag{3.4}$$

If the coefficients of a matrix $C^{(\mu)}$, $\{c_{ij}\}$, $i,j=0,\cdots,\mu$ are defined via the expansion

$$g_i(x)=\sum_{j=0}^{\mu}c_{ij}x^j \tag{3.5}$$

then it follows easily that $[\mathrm{V}^{(\mu)}]^{-1}=C^{(\mu)}$, so that

$$a^{(\mu)}=C^{(\mu)}\Psi^{(\mu)}. \tag{3.6}$$

We can express the coefficients of $C^{(\mu)}$ in terms of elementary symmetric polynomials as follows. The elementary symmetric polynomial of degree κ on μ arguments is

$$S_\kappa(\alpha_1,\cdots,\alpha_\mu)=\sum_{j_1<j_2<\cdots<j_\kappa}\alpha_{j_1}\alpha_{j_2}\cdots\alpha_{j_\kappa}. \tag{3.7}$$

Denote

$$d_i^{(\mu)}=\prod_{j=0,j\neq i}^{\mu}(\gamma_i-\gamma_j)^{-1}. \tag{3.8}$$

It follows by expanding out (3.4) that

$$c_{ij}=(-1)^{\mu-j}S_{\mu-j}(\gamma_0,\gamma_1,\cdots,\gamma_{i-1},\gamma_{i+1},\cdots,\gamma_\mu)\cdot d_i^{(\mu)}, \tag{3.9}$$

so by (3.6),

$$a_i^{(\mu)}=\sum_{j=0}^{\mu}\frac{c_{ij}}{j!}. \tag{3.10}$$

(Alternatively, Golub and Van Loan [5] describe a recursive way to generate the solution of a Vandermonde system.)

We now undertake the task of selecting the reciprocal poles $\{\gamma_i\}$, determining the $q_i(\lambda)$, the quadrature nodes $\{\tau_i\}$, and fulfilling the conditions of § 2 under which the optimal estimates are obtained. In light of the decision to restrict our attention to real poles, we recall the result of Wanner, Hairer, and Norsett [15] that confines the maximal order of approximation in (3.1) to be $p=\mu+1$. Moreover, using the nomenclature of [8], the N-polynomial is defined to be

$$N(t)=\sum_{i=0}^{\mu}(-1)^iS_i\frac{t^{\mu-i}}{(\mu-i)!} \tag{3.11}$$

(where S_i without any arguments is taken to mean $S_i(\gamma_1,\cdots,\gamma_\mu)$), and the surfaces (sheets) on which the maximal order $p=\mu+1$ is actually achieved are characterized as

$$M=\left\{\gamma=(\gamma_1,\gamma_2,\cdots,\gamma_\mu)\,\middle|\,\int_0^1 N(t)\,dt=0\right\}. \tag{3.12}$$

This will provide us guidance in our choice of parameters.

Since the operator Δ_h will have its spectrum on the negative real axis, we wish to choose the poles $\gamma_1^{-1},\cdots,\gamma_\mu^{-1}$ so that the required order is obtained and that $r(\lambda)$ is A_0-acceptable. We have shown in [1] that it suffices that each $\gamma_i\geqq\frac{1}{2}$ for the desired stability to occur. Next, Brenner, Crouzeix, and Thomée instruct us to satisfy (2.13) if strict accuracy of order m is to be obtained; in this case, $m=p-1=\mu$ is desired. Then, it is possible to specify the rational functions $q_i(\lambda)$ from

$$\sum_{i=1}^{m}\tau_i^l q_i(\lambda)=\frac{l!}{\lambda^{l+1}}\left(r(\lambda)-\sum_{j=0}^{l}\frac{\lambda^j}{j!}\right)\equiv b_{l+1}(\lambda),\qquad l=0,\cdots,m-1. \tag{3.13}$$

Once again, we have a Vandermonde system, with solution

$$q_i(\lambda)=\frac{\sum_{j=1}^{m}(-1)^{m-j}S_{m-j}(\tau_1,\cdots,\tau_{i-1},\tau_{i+1},\cdots,\tau_m)}{\prod_{\kappa=1,\kappa\neq i}^{m}(\tau_i-\tau_\kappa)}\cdot b_j(\lambda). \tag{3.14}$$

While this is not delivered to us in partial fraction form, we will indicate such an expansion momentarily.

For, we will show that each $b_{l+1}(\lambda)$, $l=0,\cdots,\mu-1$ can be expressed as the rational function $\Phi_{l+1}(\lambda)/Q(\lambda)$, with $\deg \Phi_{l+1}<\mu$, and $\deg Q=\mu$. From (3.14), it then follows that each $q_i(\lambda)\to 0$ as $\lambda\to-\infty$, so it has the partial fraction expansion

$$q_i(\lambda)=\sum_{j=1}^{m}\frac{\delta_j^{(i)}}{1-\gamma_j\lambda}. \tag{3.15}$$

The assertion about $b_{l+1}(\lambda)$ follows easily from the results of [8]: under the assumption that $r(\lambda)\equiv P(\lambda)/Q(\lambda)$ approximates e^{λ} to order at least μ then

$$Q(\lambda)=\sum_{i=0}^{\mu}S_i(-\lambda)^i \tag{3.16}$$

and

$$P(\lambda)=\sum_{j=0}^{\mu}\lambda^j\sum_{i=0}^{j}S_i\frac{(-1)^i}{(j-i)!}. \tag{3.17}$$

Clearly, then

$$r(\lambda)-\sum_{j=0}^{l}\frac{\lambda^j}{j!}=\frac{P(\lambda)-Q(\lambda)\sum_{j=0}^{l}\lambda^j/j!}{Q(\lambda)}; \tag{3.18}$$

upon expansion of the numerator, a polynomial of degree $l+\mu$, the coefficients of λ^i, $i=0,\cdots,l$ vanish. Thence,

$$\frac{l!}{\lambda^{l+1}}\left\{P(\lambda)-Q(\lambda)\sum_{j=0}^{l}\frac{\lambda_j}{j!}\right\}$$

is indeed a polynomial of degree $(l+\mu)-(l+1)=\mu-1$, as promised.

The coefficients in (3.15) will be found, for any particular scheme, in the usual way:

$$\delta_j^{(i)}=\lim_{\lambda\to 1/\gamma_j}(1-\gamma_j\lambda)q_i(\lambda). \tag{3.19}$$

We shall show below a particular expansion of the form (3.15) for our model scheme. Finally, we must address the condition (2.11). By virtue of the choices made in (3.13), a simple computation shows that $h_{p-1}(\lambda)=-\lambda\rho_{p-1}(\lambda)$, so the condition (2.11) can be rephrased as follows: $\sigma(\lambda)=-\rho_{p-1}(\lambda)/(1-r(\lambda))$ must be bounded uniformly in k and h on the negative real axis. From (2.8), we know that $\rho_{p-1}(\lambda)=\mathcal{O}(\lambda)$, and, similarly, from (3.16) and (3.17), $P(\lambda)-Q(\lambda)=\lambda+\mathcal{O}(\lambda^2)$, $Q(\lambda)=\mathcal{O}(1)$ so $\sigma(\lambda)=\mathcal{O}(1)$ as $\lambda\to 0^-$. That $\sigma(\lambda)$ is bounded as $\lambda\to-\infty$ follows from our assertions following (3.17) with $l=\mu=p-1$, as well as the already discussed behavior of the $\{q_i(\lambda)\}$. So $\sigma(\lambda)$ is bounded for all $\lambda\leqq 0$.

4. Implementation: Parallelism. By virtue of the fact that $r(\lambda)$ and all $q_i(\lambda)$ share the same denominator $Q(\lambda)$, the "usual" implementation of (2.3) involves solution of problems of the form $Q(k\Delta_h)U^{n+1}=v^n$. Since $Q(k\Delta_h)=\prod_{j=1}^{\mu}(I-\gamma_jk\Delta_h)$, this results in a sequential algorithm requiring the solution of μ subproblems of the form $(I-\gamma_jk\Delta_h)U^{n+1,j}=U^{n+1,j-1}$ with $U^{n+1,0}=v^n$ and $U^{n+1,\mu}=U^{n+1}$. We note that in this instance, the poles need not all differ. By contrast, our computational approach is as follows. Inserting the partial fraction forms for $r(k\Delta_h)$ and $q_i(k\Delta_h)$, i.e., (3.1) and (3.15), into the fully discrete scheme (2.3), we find that

$$U^{n+1}=a_0^{(\mu)}U^n+\sum_{j=1}^{\mu}a_j^{(\mu)}(I-\gamma_jk\Delta_h)^{-1}U^n+k\sum_{i=1}^{m}\sum_{j=1}^{\mu}\delta_j^{(i)}(I-\gamma_jk\Delta_h)^{-1}P_0f(t_n+\tau_ik). \tag{4.1}$$

A simple rearrangement yields the following equation (since we have set $\mu = m$):

$$(4.2) \qquad U^{n+1} = a_0^{(\mu)} U^n + \sum_{j=1}^{\mu} (I - \gamma_j k \Delta_h)^{-1} \left\{ a_j^{(\mu)} U^n + k \sum_{i=1}^{\mu} \delta_j^{(i)} P_0 f(t_n + \tau_i k) \right\}$$

and therein lies the opportunity for parallelism. We define $W^{n,j} \in S_h$ by

$$(4.3) \qquad (I - \gamma_j k \Delta_h) W^{n,j} = a_j^{(\mu)} U^n + k \sum_{i=1}^{\mu} \delta_j^{(i)} P_0 f(t_n + \tau_i k), \qquad j = 1, \cdots, \mu$$

and then assemble

$$(4.4) \qquad U^{n+1} = a_0^{(\mu)} U^n + \sum_{j=1}^{\mu} W^{n,j}.$$

Indeed, (4.3) is normally manifested in a collection of large, sparse systems of linear algebraic equations, which can be solved concurrently on μ processors, one for each index j. Further, in a usual implementation, each processor would perform at the outset of the computation the appropriate matrix factorization, which is then available for the back substitutions performed at each time step. This approach then appears to be most suitable for a shared memory architecture with a relatively small number of processors. We mention, though, that a further opportunity for parallelism in the solution of each system corresponding to index j of (4.3) could also be explored.

5. A sample method: Numerical results. We elect to present as an example of our approach a fourth-order ($p = 4$) scheme with $\mu = m = 3$. Choosing $\tau_1 = 0$, $\tau_2 = .5$, and $\tau_3 = 1$, the moment condition (2.13), $j = 0$, is obviously met, and this selection of τ's clearly saves one evaluation of $P_0 f$ at each time step. With the specification of the γ_i's deferred, we shall proceed under the assumption that (3.9)-(3.10) will provide us with the necessary set of coefficients $\{a_i^{(\mu)}\}$. The other collection of required coefficients, the $\{\delta_j^{(i)}\}$, require elaboration for the case at hand. One can first invoke (3.13) to produce, with $Q(\lambda) = \prod_{j=1}^{3} (1 - \gamma_j \lambda)$, the formulae $q_i(\lambda) = J_i(\lambda)/Q(\lambda)$ with

$$(5.1) \qquad \begin{aligned} J_1(\lambda) &= [\tfrac{1}{6} + (\tfrac{1}{2}S_1 - 2S_2 + 4S_3)\lambda + (\tfrac{1}{6} - \tfrac{1}{2}S_1 + S_2 - S_3)\lambda^2], \\ J_2(\lambda) &= [\tfrac{2}{3} + (\tfrac{2}{3} - 2S_1 + 4S_2 - 8S_3)\lambda] \end{aligned}$$

and

$$J_3(\lambda) = [\tfrac{1}{6} + (-\tfrac{1}{6} + \tfrac{1}{2}S_1 - 2S_2 + 4S_3)\lambda + S_3\lambda^2].$$

Then, performing the operations indicated in (3.19), we determine that

$$(5.2) \qquad \delta_j^{(i)} = \gamma_j^2 J_i(\gamma_j^{-1}) \Big/ \prod_{\kappa \neq j} (\gamma_j - \gamma_\kappa), \qquad i, j = 1, \cdots, 3.$$

We present a numerical example utilizing this scheme with the following purpose in mind. We wish to explore how the partial fraction approach compares to the usual sequential implementation for the approximate solution of the semidiscrete problem. We also wish to produce evidence that order reduction does not occur when the schemes investigated here are applied to an example of a problem obtained from semidiscretization of an inhomogeneous heat equation with homogeneous Dirichlet boundary conditions. So, we have chosen a class of test problems similar to that employed by Verwer [14] in his study.

Namely, we semidiscretize the problem (2.1) in one space dimension with $\Omega = [0, 1]$ by applying a uniform grid second-order finite difference approximation in the spatial variable, so that we consider the standard system $U_t + AU = F(t)$ with A the usual symmetric $N \times N$ tridiagonal finite difference matrix with $A_{i,i+1} = -h^{-2}$ and $A_{ii} = 2h^{-2}$, with $h = 1/(N+1)$. With exact solution chosen to be $u(x, t) = t^\alpha x(1-x)$, we have $F_i(t) = t^{\alpha-1}[\alpha x_i(1-x_i) + 2t]$. One result of this choice is that as the solution to the partial differential equation (PDE) problem is quadratic in x, the spatial error vanishes (in theory), and thus the global error is totally controlled by the time step. This in no way obscures the issue of order reduction. Indeed, Verwer does report the occurrence of order reduction when this test problem is treated by the use of a standard diagonally implicit Runge-Kutta scheme. He has investigated the test problem described here using the exponent $\alpha = 2$. We cannot make use of this choice; having chosen a fourth-order scheme of the form (4.1), in fact the semidiscrete solution turns out to coincide (up to roundoff) on the spatial grid with the exact solution of the PDE. Hence, we report here results of experiments using exponents $\alpha = 3$ and 4.

It is known (cf. [9]) that among all choices of the $\{\gamma_i\}$ on a sheet of M described by (3.12), the smallest error constant results when the poles coalesce into a single pole of multiplicity μ. For the fourth-order case at hand, enforcing the A_0-stability condition restricts attention to one sheet of M on which the pertinent root of $\gamma^3 - \frac{3}{2}\gamma^2 + \frac{1}{2}\gamma - \frac{1}{24} = 0$ is $\gamma = 1.068579021301629$. However, we obviously cannot choose the multiple pole and still obtain the partial fraction decompositions desired. One objective of our numerical example, then, is to demonstrate (at least for this case) that we can move along this sheet of M to a nearby position where the poles are distinct and not effect a significant change in the quality of the scheme. This will be evidenced in two ways. We have at first the comparison between the triple pole scheme and the distinct pole algorithm. Further, we have the options of the sequential versus the partial fraction implementation of the distinct pole algorithm to consider. We note that we have not attempted here a study of the partial fraction version of the algorithm on actual parallel hardware, as in the spirit of [4]; our computations have been performed in double precision on a SUN SPARC 1+ workstation. We remark that as observed also by Gallopoulos and Saad in their context, even when implemented on a serial machine, the partial fraction version affords a significant saving in operations, in that the matrix multiplications by the numerators of $r(k\Delta_h)$ and $\{q_i(k\Delta_h)\}$ in (2.3) are eliminated, at the expense only of the linear combinations in (4.3) and (4.4).

This, in fact, defines our algorithm. Given a choice of poles, we determine $\{a_j^{(\mu)}\}$ from (3.7)-(3.10) and $\{\delta_j^{(i)}\}$ from (5.1)-(5.2), and then in each time step, we solve (4.3) for $W^{n,j}$ for $j = 1, \cdots, \mu$ and then form U^{n+1} from (4.4).

We see no obvious way to pick the distinct poles from the sheet of M. Perhaps stretching the point, we have chosen somewhat arbitrarily $\gamma_1 = 1.06$, and $\gamma_2 = 1.07$, as perturbations of the triple pole above, and then have determined $\gamma_3 = 1.07589033521764$ to satisfy (3.12). In terms of the error constant, a brief computation shows that it suffers a magnification of only 1.000095 from the minimal value at the triple pole. The resulting coefficients are $a_0 = -.6304261005497924$, $a_1 = 1{,}454.094874359267$, $a_2 = -3{,}794.673554929712$, $a_3 = 2{,}342.209106670995$, $\delta_1^{(1)} = 3{,}567.278607850113$, $\delta_2^{(1)} = -9{,}621.288547664747$, $\delta_3^{(1)} = 6{,}054.176606481301$, $\gamma_1^{(2)} = -7{,}319.518083718724$, $\delta_2^{(2)} = 19{,}811.01919385797$, $\delta_3^{(2)} = -12{,}490.83444347257$, $\delta_1^{(3)} = 5{,}293.580042689434$, $\delta_2^{(3)} = -14{,}250.03134996801$, and $\delta_3^{(3)} = 8{,}956.617973945243$. It is arguable whether or not these particular coefficients may be termed "of moderate size," but the numerical results in columns one and two of Tables 1 and 2 indicate that for this example the sequential and partial fraction versions produce nearly identical results, with agreement to about the tenth decimal place. We have recorded here the error at $t = T = 1$ with step $k = 1/K$ measured in the norm $\|\mathscr{E}\|_\infty \equiv \max_{1 \leqq i \leqq N} |u(x_i, T) - U_i^K|$; the same trends

TABLE 1
Maximum norm of error at $t = 1$; $\alpha = 3$.

are present if we use an l_2 error. For our other objective, comparing columns one and three of both tables, we see that the effect of moving away from the triple pole is almost negligible in the sequential implementation, and then, of course, only very slight when the distinct pole partial fraction form is compared with the triple pole case. Finally, we have shown in Table 1 results for $\alpha = 3$ both with h fixed and k decreasing, to exemplify the usual ODE order, but also in additional runs we have simultaneously reduced both h and k (making $h = k$) to examine the order *uniform in h*. Table 2 contains results for $\alpha = 4$ and only the uniform order is investigated. Using adjacent entries in the tables, we estimate the order as $\hat{p} = \ln[\mathscr{E}(k_i)/\mathscr{E}(k_j)]/\ln[k_i/k_j]$. It is quite clear that fourth-order accuracy is being approached in both manners, and that order reduction does not occur.

We hesitate to claim that these very small differences in results between the sequential and partial fraction versions would appear all the time (i.e., larger problems, higher-order algorithms), but the results do encourage us to believe that the approach is valid and to continue similar investigations concerning different choices for the poles and to other possible situations, such as the study of second-order systems arising from the forced wave equation.

We close with the acknowledgment that there is a definite relationship between the methods here and certain implicit Runge-Kutta methods being studied, for a broader range of problems, for example, by Keeling [7] and Karakashian and Rust [6]. We believe that the approach here is particularly germane to the problem at hand, in that Brenner, Crouzeix, and Thomée have pursued the study of this particular linear problem and their results are couched in that framework. In fact, we are indebted to Professor Thomée for the insistence that we attach our interest to the PDE problem, rather than just looking at ODE systems, so that we accomplish our computational objective while satisfying the special needs of the inhomogeneous PDE system.

COMPARING ALGORITHMS FOR SOLVING SPARSE NONLINEAR SYSTEMS OF EQUATIONS*

MÁRCIA A. GOMES-RUGGIERO†, JOSÉ MARIO MARTÍNEZ†, AND ANTONIO CARLOS MORETTI†

Abstract. This paper describes implementations of eight algorithms of Newton and quasi-Newton type for solving large sparse systems of nonlinear equations. For linear algebra calculations, a symbolic manipulation is used, as well as a static data structure introduced recently by George and Ng, which allows a partial pivoting strategy for solving linear systems. A numerical comparison of the implemented methods is presented.

Key words. nonlinear systems of equations, sparse matrices, LU factorizations, Newton's method, quasi-Newton methods

AMS(MOS) subject classification. 65H10

1. Introduction. Many real-life problems require the solution of large systems of nonlinear equations:

$$F(x)=0, \qquad F=(f_1,\cdots,f_n)^T, \tag{1.1}$$

where $F:\mathbb{R}^n\rightarrow\mathbb{R}^n$ is a nonlinear C^1-function, and its Jacobian matrix $J(x)$ is sparse (see [15], [41], [46]). The best-known method for solving this type of problem is Newton's method. This is an iterative method, where the successive approximations to the solution of (1.1) are calculated according to the following formula:

$$x_{k+1}=x_k-J(x_k)^{-1}F(x_k). \tag{1.2}$$

Hence, in most cases, at each iteration of Newton's method, the derivatives $\partial f_i/\partial x_j$ must be calculated, and the linear $n\times n$ system

$$J(x_k)s=-F(x_k) \tag{1.3}$$

must be solved, in order to obtain x_{k+1}. When analytic derivatives are not available, they may be estimated using finite differences (see [7]).

Quasi-Newton methods [2]-[5], [12]-[15], [19], [22], [23], [27]-[29], [34]-[38], [40], [42], [44], [48] were also introduced to deal with situations where analytic derivatives are not available or are very expensive to calculate. They obey the formulae

$$B_k s_k=-F(x_k), \tag{1.4}$$

$$x_{k+1}=x_k+s_k. \tag{1.5}$$

At each iteration of a quasi-Newton method, only the function values $F(x_k)$ are calculated and the linear system (1.4) is solved. The new matrix B_{k+1} is obtained from B_k using recurrence relations which only involve x_k, x_{k+1}, $F(x_k)$, and $F(x_{k+1})$. Usually, B_{k+1} is chosen as one of the matrices which satisfy the "secant equation"

$$B_{k+1}s_k=y_k\equiv F(x_{k+1})-F(x_k). \tag{1.6}$$

The best-known quasi-Newton method for small dense problems is Broyden's first method [2], [14], [15]. This method uses a rank-one correction matrix to obtain B_{k+1}

from B_k:

$$B_{k+1} = B_k + \frac{(y_k - B_k s_k) s_k^T}{s_k^T s_k}. \tag{1.7}$$

Using (1.7) and the Sherman-Morrison formula [21, p. 3], B_{k+1}^{-1} may be obtained from B_k^{-1} using $O(n^2)$ flops. Moreover, a QR factorization of B_{k+1} may be obtained from a QR factorization of B_k using $O(n^2)$ flops (see [40]). Hence, if (1.4), (1.5), and (1.7) are used, not only is the time for computing derivatives saved, but also the computational work for solving linear systems may be considerably reduced in relation to the computational work needed to solve (1.3) ($O(n^3)$ flops). For this reason, in many cases, Broyden's first method may be more efficient than Newton's method, even when derivatives are easily available, in spite of its lower speed of convergence.

The situation in the large sparse case is somewhat different. In fact, if B_k is a sparse matrix, and (1.7) is used, B_{k+1} generally turns out to be a dense matrix, which may have little relation to true Jacobian matrices. Broyden [3] and Schubert [37], [44] developed a variant of Broyden's first method where matrices B_k keep the same pattern of sparsity as $J(x^k)$, satisfying the secant equation (1.6), and using a minimum variation principle. However, the difference $B_{k+1} - B_k$ is no longer a rank-one matrix as in Broyden's first method, and so no easy relationship between factorizations of B_k and B_{k+1} seems to be possible. Therefore, when Schubert's method is used to generate the B_k's, the resolution of (1.4) is as expensive as the resolution of (1.3).

These observations motivated Dennis and Marwil [12] to develop the first quasi-Newton method where an LU factorization of B_{k+1} is obtained directly from an LU factorization of B_k, giving a substantially lower cost in the resolution of (1.4) in relation to the resolution of (1.3). Basically, the Dennis-Marwil method keeps the L-factor fixed and modifies the U-factor from one iteration to the following, preserving the sparsity pattern of U and using a Schubert-type formula. Unhappily, convergence properties of the Dennis-Marwil method are not quite satisfactory. In fact, local convergence is only obtained if the algorithm is restarted with $B_k = J(x_k)$ when k is a multiple of a fixed integer q. Martínez [34] introduced a method where the LDM^T factorization of B_k (see [21]) is stored and only the factor D is modified from one iteration to another, in order to obtain the factorization of B_{k+1}. This method belongs to a larger family introduced later in [35]. Unlike the Dennis-Marwil method, the methods in this family have local convergence properties without restarts, but superlinear convergence is only obtained using restart procedures. Chadee [5], generalizing a method of Johnson and Austria [28], introduced a locally superlinear method where the LU factorization of B_{k+1} is obtained simultaneously modifying the LU factors of B_k. Unfortunately, the inverses of the triangular matrices L must have a definite sparsity pattern for Chadee's method to be useful, and so its applicability seems to be limited to special structures of the Jacobian matrices. Martínez [36] introduced a very large family which includes most superlinearly convergent methods for solving systems of nonlinear equations. The Dennis-Marwil method does not belong to this family, but it may be interpreted as a limit case ($\theta \to 1$) of a parametric subfamily where the case $\theta = \frac{1}{2}$ is Chadee's method.

In this paper, we compare Newton's method, the modified Newton method, Schubert's method, the Dennis-Marwil method, three methods in the Martínez family [35], and the first method of Broyden.

As we mentioned above, sparsity of the Jacobian matrix is not preserved by Broyden approximations generated by (1.7). Therefore, as recommended in [38], we do not store B_k in our implementation of Broyden's method but instead the vectors which define the successive rank-one corrections. Both storage and computer time increase at each iteration and hence the process must be restarted when the iteration becomes excessively expensive. Storage and computer time economy is also obtained using a strategy of dropping old updates, but higher speed of convergence is achieved using Newton restarted iterations.

The implementation of methods for solving sparse nonlinear systems of equations requires a decision about the algorithm that is going to be used for linear algebra calculations. Lopes [30], [31] called our attention to some ill-conditioned banded linear systems, derived from approximation of diffusion problems using variational principles (see [30], [52]). According to [30], the resolution of these systems using the general purpose sparse linear system solver MA28 [16] with a default tolerance parameter $\alpha = 0.1$ was completely unreliable, but good results were obtained using a very strict tolerance $\alpha = 0.999$. This choice is very similar to the use of LU factorizations with partial pivoting (see [17], [18], [21]) which is one of the most stable ways of solving linear systems using LU factorizations. These very impressive experiments motivated us to privilege numerical stability over economy of storage in our implementations of nonlinear equations solvers. So we decide to use LU factorizations with partial pivoting.

Another reason of a more theoretical nature led us to the decision of using LU factorizations with partial pivoting. Namely, the local convergence theorems for the methods introduced in [12], [35] impose that the same pivoting rule which allows the LU factorization of $J(x_0)$ will also allow the LU factorization of $J(x_*)$, the Jacobian matrix at the solution. This objective is most likely attained if the partial pivoting rule is used, since it is intuitively evident that the larger the chosen pivots are for the factorization of a given matrix, the greater is the distance between that matrix and the set of matrices for which a zero pivot appears using the same permutation rule. According to these observations, we decided to use the George–Ng [20] factorization algorithm for all the linear algebra manipulations of our algorithms, an algorithm which uses partial pivoting, a static data structure, and a symbolic factorization scheme to predict fill-in in calculations.

The use of the George–Ng scheme has some additional advantages as a subroutine of a code for solving nonlinear systems. Since all Jacobian matrices $J(x_k)$ have the same structure, it is interesting to perform symbolic manipulations before the first iteration of the algorithm so that linear algebraic calculations at each iteration are exclusively numeric (not symbolic). Clearly, it is impossible to avoid nonnumeric manipulations when using a general sparse matrix package, such as MA28, unless we decide to use the same pivoting sequence at every iteration. However, this decision may be disastrous from the numerical stability point of view.

We would like to mention that Zambaldi [53] reported many experiments showing that the George–Ng method uses less CPU time (and, of course, is more stable) than MA28 (with the default parameter 0.1) for solving sparse linear systems with certain structures which appear frequently in applications. Of course, there exist structures for which the George–Ng scheme produces an excessive amount of fill-in, even after application of some minimum degree-type preprocessing scheme (see [17]), but we feel that in most of these cases iterative linear methods are more adequate than any direct linear equation algorithm, especially if we are dealing with the systems of linear equations which arise when solving nonlinear systems. In those cases, which certainly include discretizations of three-dimensional operators, inexact Newton methods are the best alternative (see [10]).

The efficiency of the George–Ng method is not restricted to systems with band structure. In fact, roughly speaking, the fill-in predicted by the George–Ng scheme is the same as the fill-in produced by the QR factorization of the matrix (see [21]) when Q is calculated using Householder transformations stored in product form. Therefore, the class of matrices for which the George–Ng scheme does not produce much fill-in is much larger than the class of band matrices, but even for band structures we found that the possibility of permuting rows to preserve stability is a positive advantage over band solvers (see [17, Chap. 8]), when numerical stability is critical.

This paper is organized as follows. In § 2 we describe the "local versions" of the algorithms used for our comparisons. That is, according to the descriptions in this section, the approximation x_{k+1} is always computed using (1.3) or (1.4) and (1.5) ignoring increases of the norm of F. These methods have local convergence properties, which are surveyed in § 3. In § 4 we describe our test functions and we present a numerical comparison of the local methods. In § 5 we discuss "global modifications" of the local methods and we present numerical experiments concerning the methods described in § 2 with a particular global modification. Finally, in § 6 we state some conclusions and we suggest some lines for future research.

2. The local algorithms. As we mentioned in § 1, we selected eight algorithms for our comparison: Newton's method, the modified Newton method, Broyden's first method, Schubert's method, the Dennis–Marwil method, and three methods of Martínez's family [34], [35]. We call the latter the diagonal-scaling method, the row-scaling method and the column-scaling method. All these methods use a small tolerance parameter $TOL > 0$, to detect and modify singularity of the matrices involved, and a step control Δ, to inhibit very large steps $x_{k+1} - x_k$. Moreover, a symbolic phase precedes the first iteration of all the algorithms, and even the first iteration is common to all of them. The symbolic phase corresponds to the symbolic manipulation of the George–Ng algorithm [20], and the first iteration corresponds to the following algorithm with $k = 0$.

ALGORITHM 2.1. NEWTON ITERATION.

Step 1. Compute $F(x_k)$, $J(x_k)$. Set $B_k = J(x_k)$.

Step 2. Compute a permutation P, a lower-triangular matrix $L = (l_{ij})$, an upper-triangular matrix $U = (u_{ij})$, and $2n$ sets I_i^L, I_i^U, $i = 1, \cdots, n$ such that

$$PB_k = LU, \tag{2.1}$$

$$l_{ii} = 1, \qquad i = 1, \cdots, n, \tag{2.2}$$

$$|l_{ij}| \leqq 1 \quad \text{for all } j = 1, \cdots, i, \qquad i = 1, \cdots, n, \tag{2.3}$$

$$\begin{gathered} I_i^L \subset \{1, \cdots, n\}, \\ I_i^U \subset \{1, \cdots, n\}, \qquad i = 1, \cdots, n, \end{gathered} \tag{2.4}$$

$$l_{ij} = 0 \quad \text{for all } j \notin I_i^L, \qquad j \neq i, \qquad i = 1, \cdots, n, \tag{2.5}$$

$$u_{ij} = 0 \quad \text{for all } j \notin I_i^U, \qquad j \neq i, \qquad i = 1, \cdots, n. \tag{2.6}$$

Step 3. If $|u_{ii}| < TOLB \equiv TOL \max_{i,j} |(B_k)_{ij}|$, replace u_{ii} by

$$sg(u_{ii})TOLB, \qquad i = 1, \cdots, n.$$

Step 4. Solve

$$Lw = -PF(x_k), \tag{2.7}$$

and

$$Us = w. \tag{2.8}$$

Step 5. If $\|s_k\|_\infty > \Delta$, replace s_k by $s_k \Delta / \|s_k\|_\infty$.

Step 6. $x_{k+1} = x_k + s_k$.

Matrices L, U, and the sets I_i^L, I_i^U which satisfy (2.1)-(2.6) are computed using the George-Ng algorithm. l_{ij} may be equal to zero for some $j<i$, $j \in I_i^L$, and u_{ij} may be equal to zero for some $j>i$, $j \in I_i^U$. In fact, the sets I_i^L, I_i^U represent the structural nonzero elements of any pair of matrices L, U when the partial pivoting algorithm is performed on a matrix with the nonzero structure of PB_k.

Algorithm 2.1 is a Newton iteration, with the safeguards against singularity and large steps given by Steps 3 and 5. Therefore, our Newton method may be described by the following algorithm.

ALGORITHM 2.2. NEWTON'S METHOD. Given an arbitrary initial point x_0, compute x_{k+1}, $k=0,1,2,\cdots$, using Algorithm 2.1.

The modified Newton method is described by the following algorithm.

ALGORITHM 2.3. MODIFIED NEWTON METHOD. Given x_0, compute x_1 using Algorithm 2.1. For $k=1,2,\cdots$, compute x_{k+1} performing Steps 4-6 of Algorithm 2.1.

Our implementation of Schubert's method requires the definition of n additional sets of indexes $I_i \subset \{1,\cdots,n\}$, $i=1,\cdots,n$. We define

$$I_i=\left\{j\in\{1,\cdots,n\} \,\middle|\, \frac{\partial f_i}{\partial x_j}(x)\neq 0 \text{ for some } x \text{ in the domain of } F\right\}. \tag{2.9}$$

With this definition, Schubert's method is described by Algorithm 2.4.

ALGORITHM 2.4. SCHUBERT'S METHOD. Given x_0, compute x_1 using Algorithm 2.1. For $k=1,2,\cdots$, compute x_{k+1} performing the following steps:

Step 1. Compute $y_{k-1}=F(x_k)-F(x_{k-1})$.
Step 2. Solve the optimization problem

$$\begin{gathered}\text{Minimize } \|B-B_{k-1}\|_F^2 \quad \text{s.t.}\\ B=(b_{ij}),\quad b_{ij}=0 \quad \text{if } j\notin I_i, \quad i=1,\cdots,n,\\ Bs_{k-1}=y_{k-1}.\end{gathered} \tag{2.10}$$

(Problem (2.10) always has a solution, the Frobenius projection of B_{k-1} on the feasible set, which is a linear manifold. Compact formulae for finding B_k, the unique solution of (2.10), are given in [37], [44].)
Step 3. Perform Steps 2-6 of Algorithm 2.1.

Algorithms 2.5-2.8 describe the Dennis-Marwil method, the diagonal-scaling method, the row-scaling method, and the column-scaling method, respectively. In the description of these methods, we denote $\{e_1,\cdots,e_n\}$, the canonical basis of $\mathbb{R}^n$.

ALGORITHM 2.5. DENNIS-MARWIL METHOD. Given x_0, compute x_1 using Algorithm 2.1. For $k=1,2,\cdots$, compute x_{k+1} performing the following steps:

Step 1. Compute $y_{k-1}=F(x_k)-F(x_{k-1})$.
Step 2. Solve $Lw=Py_{k-1}$.
Step 3. Define $v=Us_{k-1}$.
Step 4. For $i=1,\cdots,n$ perform Step 5.
Step 5. If

$$\left(\sum_{j\in I_i^U}(e_j^T s_{k-1})^2\right)^{1/2} \geqq 10^{-4}\cdot\|s_{k-1}\|_\infty$$

perform Step 5.1. Otherwise, increment i and repeat Step 5.

Step 5.1. For each j such that $u_{ij} \neq 0$, compute

$$u_{ij} \leftarrow u_{ij} + e_j^T s_{k-1} \cdot [e_i^T w - e_i^T v] \Big/ \sum_{j \in I_i^U} (e_j^T s_{k-1})^2.$$

Step 6. Perform Steps 3-6 of Algorithm 2.1.

The diagonal-scaling method [34], [35], the row-scaling method, and the column-scaling method belong to the family introduced by Martínez in [35].

As suggested by one of the referees of the first version of this paper, the diagonal-scaling method may be interpreted as follows. Given the factorization $PJ(x_0) = LU$, consider the function $\Phi(z)$ defined by

$$\Phi(z) = L^{-1} PF(U^{-1} z).$$

Define $z_k = Ux_k$ for all $k \geqq 0$. Clearly, $\Phi'(z_0) = I$. So, the diagonal-scaling method reduces to an iteration of the form

$$z_{k+1} = z_k - B_k^{-1} \Phi(z_k),$$

where the matrices B_k are chosen to be diagonal and to satisfy (if possible) the secant equation

$$B_{k+1}(z_{k+1} - z_k) = \Phi(z_{k+1}) - \Phi(z_k).$$

If some entry of B_{k+1} exceeds some a priori bound, it is left unchanged.

Similarly, the row-scaling method and the column-scaling method may be deduced by considering $\Phi(z) = U^{-1} L^{-1} PF(z)$ (with $z_k = x_k$) and $\Phi(z) = F(U^{-1} L^{-1} Pz)$ (with $z_k = P^{-1} LUx_k$), respectively.

ALGORITHM 2.6. DIAGONAL-SCALING METHOD. Given x_0, compute x_1 using Algorithm 2.1. Set $D = \text{Diag}\,(d_{ii}) = \text{Diag}\,(u_{ii})$ and replace U by $D^{-1} U$. For $k = 1, 2, \cdots$, compute x_{k+1} performing the following steps:

Step 1. Compute $y_{k-1} = F(x_k) - F(x_{k-1})$.
Step 2. Solve

$$Lw = Py_{k-1}.$$

Step 3. Define

$$v = Us_{k-1}. \tag{2.11}$$

Step 4. For $i = 1, \cdots, n$, execute Step 5.
Step 5. If

$$|e_i^T v| \geqq 10^{-4} \|s_{k-1}\|_\infty,$$

set $d_{ii} = e_i^T w / e_i^T v$; otherwise increment i and repeat this step.
Step 6. For $i = 1, \cdots, n$, if $|d_{ii}| < TOLB$, replace

$$d_{ii} \leftarrow sg(d_{ii})\, TOLB.$$

Step 7. Solve

$$LDUs_k = -PF(x_k).$$

Step 8. Perform Steps 5 and 6 of Algorithm 2.1.

ALGORITHM 2.7. ROW-SCALING METHOD. Given x_0, compute x_1 using Algorithm 2.1. Define $D = \mathrm{Diag}\,(d_{ii})$, $d_{ii} = 1$, $i = 1, \cdots, n$. Compute x_{k+1} performing the following steps:

Step 1. Compute $y_{k-1} = F(x_k) - F(x_{k-1})$.
Step 2. Define

$$v = LUs_{k-1}. \tag{2.12}$$

Step 3. Define $w = Py_{k-1}$.
Step 4. For $i = 1, \cdots, n$, execute Step 5.
Step 5. If

$$|e_i^T v| \geqq 10^{-4} \|F(x_k)\|_\infty,$$

set $d_{ii} = e_i^T w / e_i^T v$; otherwise increment i and repeat Step 5.
Step 6. For $i = 1, \cdots, n$, if $|d_{ii}| < TOLB$, replace

$$d_{ii} \leftarrow sg(d_{ii})\, TOLB.$$

Step 7. Solve

$$LDUs_k = -PF(x_k).$$

Step 8. Perform Steps 5 and 6 of Algorithm 2.1.

ALGORITHM 2.8. COLUMN-SCALING METHOD. Given x_0, compute x_1 using Algorithm 2.1. Define $D = \mathrm{Diag}\,(d_{ii})$, $d_{ii} = 1$, $i = 1, \cdots, n$. For $k = 1, 2, \cdots$, compute x_{k+1} performing the following steps:

Step 1. Define z as the solution of

$$LUz = PF(x_{k-1}). \tag{2.14}$$

Step 2. Solve

$$LUw = PF(x_k). \tag{2.15}$$

Step 3. Set

$$v = w - z.$$

Step 4. For $i = 1, \cdots, n$, execute Step 5.
Step 5. If

$$|e_i^T s_{k-1}| \geqq 10^{-4} \|s_{k-1}\|_\infty,$$

set $d_{ii} = e_i^T v / e_i^T s_{k-1}$; otherwise increment i and repeat Step 5.
Step 6. For $i = 1, \cdots, n$, if $|d_{ii}| < TOLB$, replace

$$d_{ii} \leftarrow sg(d_{ii})\, TOLB.$$

Step 7. Solve

$$\mathrm{Ds_k} = -\mathrm{w}.$$

Step 8. Execute Steps 5 and 6 of Algorithm 2.1.

Clearly, the row-scaling method and the column-scaling method may also be viewed as the methods which iterate according to (1.4) and (1.5), with $B_{k+1} = D_{k+1} J(x_0)$ or $B_{k+1} = J(x_0) D_{k+1}$, respectively, when the diagonal matrices D_{k+1} are chosen so as to satisfy the secant equation, if this is possible. Therefore, they may be interpreted as improvements (or variants) of the modified Newton method, and their implementation is hardly more expensive than the implementation of Algorithm 2.3. The expectation that the incorporation of secant information may consistently improve the performance of the modified Newton method motivated us to include Algorithms 2.7 and 2.8 in our comparative study. At Step 5 of Algorithms 2.5–2.8, we essentially test if it is possible to satisfy the secant equation for the ith component, with some relative tolerance. Later, we will comment on the relationship of this test to the overall performance of these algorithms.

Let us now describe our implementation of the first method of Broyden. As we mentioned in § 1, we used the inverse formula

$$B_{k+1}^{-1} = B_k^{-1} + \frac{(s_k - B_k^{-1}y_k)s_k^TB_k^{-1}}{s_k^TB_k^{-1}y_k}$$

storing at each iteration the vectors s_k and $s_k - B_k^{-1}y_k$. Hence we have the following product form for B_{k+1}^{-1}:

$$B_{k+1}^{-1} = \left[I + \frac{(s_k - B_k^{-1}y_k)s_k^T}{s_k^TB_k^{-1}y_k}\right] \cdots \left[I + \frac{(s_0 - B_0^{-1}y_0)s_0^T}{s_0^TB_0^{-1}y_0}\right]B_0^{-1}$$

or

$$B_{k+1}^{-1} = [I + u_ks_k^T] \cdots [I + u_0s_0^T]B_0^{-1}, \tag{2.16}$$

where

$$u_l = \frac{s_l - B_l^{-1}y_l}{s_l^TB_l^{-1}y_l}, \qquad l = 0, 1, \cdots, k. \tag{2.17}$$

Using (2.16) and (2.17), we may describe Broyden's method as follows.

ALGORITHM 2.9. BROYDEN'S METHOD. Given x_0, compute x_{k+1}, $k = 0, 1, 2, \cdots$ performing the following steps:

```
Step 1. If $k = 0$ execute Steps 1–4 of Algorithm 2.1. Go to Step 3.
Step 2. (Complete the computation of $s_k$.)
Compute
        $s_k = (I + u_{k-1}s_{k-1}^T)\tilde{s}_{k-1}$.
Step 3. (Normalize and compute the new point.)
        $\bar{s}_k \leftarrow s_k$,
        $s_k \leftarrow \lambda_k s_k$   where $\lambda_k = \min\left\{1, \frac{\Delta}{\|s_k\|_\infty}\right\}$,
        $x_{k+1} = x_k + s_k$.
Step 4. (Compute $u_k$.)
    Execute Steps 4.1–4.3.
        Step 4.1 (Compute $\tilde{s}_k = -B_k^{-1}F(x_{k+1})$.)
        Execute Steps 4.1.1–4.1.2.
            Step 4.1.1 (Compute $\tilde{s} = -B_0^{-1}F(x_{k+1})$.)
            Solve $LU\tilde{s} = -PF(x_{k+1})$.
            If $k = 0$ set $\tilde{s}_k = \tilde{s}$ and go to Step 4.2.
            Step 4.1.2
            Compute
            $\tilde{s}_k = (I + u_{k-1}s_{k-1}^T) \cdots (I + u_0s_0^T)\tilde{s}$.
    Step 4.2 (Compute $v_k = B_k^{-1}y_k \equiv B_k^{-1}F(x_{k+1}) - B_k^{-1}F(x_k)$.)
    $v_k = \bar{s}_k - \tilde{s}_k$.
    Step 4.3
    Compute $u_k = (s_k - v_k)/(s_k^T v_k)$.
Step 5. $k \leftarrow k+1$.
```

The computational cost of one iteration of Broyden's method, as described above, is $2nk+2n$ flops plus the resolution of two sparse triangular systems. Griewank [23] proposed an alternative implementation which has the same complexity as the one proposed here.

Of course, since both the memory and time of one iteration of Algorithm 2.9 tend to infinity with k, this algorithm must be restarted, say, when k is a multiple of some fixed integer q.

Remark. We used the words "solve" or "compute" to indicate that some calculation must effectively be performed, and the word "define" to indicate that the result of the calculation may be obtained from previous computations.

2.1. Singularity and step control. Step 3 of Algorithm 2.1 and Step 6 of Algorithms 2.6–2.8 correct the LU factorization when a nearly singular matrix B_k appears. However, a very ill conditioned B_k may still occur, provoking very large steps $-B_k^{-1}F(x_k)$. Therefore, in practical implementation of methods for solving nonlinear systems of equations, some control in the size of increments $x_{k+1}-x_k$ is recommended (see [20], [25]). In our codes, we adopted a very simple way of controlling the stepsize. Assuming that Δ is given by the user as an estimate of the distance between the initial guess and the solution, we simply test if $\|s_k\|_\infty = \|-B_k^{-1}F(x_k)\|_\infty$ is less than Δ or not. If it is, then the increment s_k is accepted. Otherwise, it is replaced by $s_k\Delta/\|s_k\|_\infty$. This is done at Steps 5 and 6 of Algorithm 2.1 and at Step 3 of Algorithm 2.9.

In Algorithm 2.9, the singularity of B_{k+1} is represented by the annihilation of the denominator $s_k^T v_k$ when computing u_k at Step 4. Consequently, in this algorithm, we decided to declare B_{k+1} singular if

$$|s_k^T v_k| \leqq SQMAP \|s_k\|_2 \|v_k\|_2$$

where $SQMAP$ is the square root of the machine precision. When this "quasi singularity" is detected, we reset $B_{k+1} = B_k$.

2.2. Stopping criteria. A natural stopping criterion for algorithms which solve nonlinear systems is

$$\|F(x_k)\|_\infty \leqq \varepsilon_1, \tag{2.18}$$

where ε_1 is a small positive number given by the user. When (2.18) occurs, we declare "convergence of type 0."

In production codes, (2.18) is generally replaced by a relative convergence criterion

$$\|F(x_k)\|_\infty \leqq \varepsilon_1 \|F(x_0)\|_\infty$$

(see [15]), but for comparative studies (2.18) is adequate.

However, sometimes criterion (2.18) is very difficult or impossible to achieve, maybe because of a large Jacobian at the solution. So we incorporate another convergence test:

$$\|s_k\|_\infty < \varepsilon_2 \|x^{k+1}\|_\infty + 10^{-25}. \tag{2.19}$$

When (2.19) holds, we declare "convergence of type 1."

Algorithms like Algorithms 2.2–2.9 are local in nature, and, therefore, divergence may occur for arbitrary nonlinear systems if x_0 is far from the solution. We declare "divergence" when, for some large positive number *BIG*, given by the user, the following inequality holds:

$$\|F(x_k)\|_\infty > BIG. \tag{2.20}$$

As in the case of the first convergence criterion, this "divergence criterion" is used only for comparison purposes. In production codes, we prefer to use criteria based on "lack of enough progress" as recommended, for example, in [39], [33]. We will return to this discussion in § 5.

Finally, the execution of the programs is interrupted when either a previously defined computer time or some large number of iterations is exceeded.

2.3. Restarting criteria. Sometimes, rather than executing Algorithms 2.3-2.9 in their original version, it is more efficient to restart the iterative process, performing a Newton iteration (Algorithm 2.1) instead of the original iteration, at certain steps k. The most natural restarting criterion is to execute Algorithm 2.1 for obtaining x_{k+1} when k is a multiple of a fixed integer q. For the modified Newton method, in absence of sparsity, an optimal q may be determined using Ostrowski's efficiency index (see [1], [32], [47]). However, the optimization of Ostrowski's efficiency proposed by Brent [1] is based on the theoretical asymptotic behavior of the algorithms and so it may not be very useful far from the solution of the system. So, we decided to develop a local efficiency restarting criterion (LERC) based on the following arguments.

Let us call t_k the computer time used by some algorithm at iteration k. Assume, further, that

$$\|F(x_{k+1})\| = \theta_k \|F(x_k)\|. \tag{2.21}$$

Therefore, if relation (2.21) is maintained throughout the calculation with $\theta_k < 1$ and the same type of iteration is used, the computer time to achieve (2.18) should be proportional to $-t_k/\log \theta_k$. This justifies the definition of E_k, the efficiency of iteration k, as

$$\begin{aligned} E_k &= \frac{-\log \theta_k}{t_k} \quad \text{if } \theta_k < 1, \\ E_k &= 0 \qquad\qquad \text{otherwise.} \end{aligned} \tag{2.22}$$

Assume now that l is the last index of a Newton iteration previous to iteration k. We adopt the following criterion for deciding whether to use a "normal" iteration or a Newton-type one at iteration $k+1$. If $\theta_k > 1$ or $E_l \geqq E_k$, iteration $k+1$ must be a Newton iteration. Otherwise, iteration $k+1$ must be a "normal" iteration.

A similar criterion is used in [11] for minimization problems, with good numerical results.

3. Theoretical properties. Let us assume that $F: \Omega \subset \mathbb{R}^n \to \mathbb{R}^n$, Ω an open and convex set, $F \in C^1(\Omega)$, $F(x_*) = 0$, $J(x_*)$ nonsingular, and, for all $x \in \Omega$,

$$\|J(x) - J(x_*)\| \leqq L\|x - x_*\|^p$$

for some L, $p > 0$.

For a local convergence analysis, consider the algorithms described in § 2, without correction of singularity and with no control of the stepsize. That is, eliminate Steps 3 and 5 of Algorithm 2.1, Step 4 of Algorithm 2.5, Step 6 of Algorithms 2.6-2.8, and the correction of s_k at Step 3 of Algorithm 2.9. In fact, local convergence theorems show that these steps are not necessary with the hypotheses above, if x_0 is near enough x_*. Let us survey here the convergence results related to Algorithms 2.2-2.9. The first one concerns local convergence of Newton's method and the modified Newton method.

THEOREM 3.1. *Given $r \in (0, 1)$, there exists $\varepsilon = \varepsilon(r) > 0$ such that if $\|x_0 - x_*\| \leqq \varepsilon$, the sequences (x_k) generated by Algorithm 2.2 or 2.3 converge to x_* and satisfy*

$$\|x_{k+1} - x_*\| \leqq r\|x_k - x_*\| \tag{3.1}$$

for all $k = 0, 1, 2, \cdots$. Moreover, for Algorithm 2.2 (Newton's method), there exists $c > 0$ such that

$$\|x_{k+1} - x_*\| \leqq c\|x_k - x_*\|^{p+1} \tag{3.2}$$

for all $k = 0, 1, 2, \cdots$.

Proof. See [15], [41], [46].

Like many quasi-Newton algorithms, Broyden's method and Schubert's method satisfy not only the linear convergence result (3.1), but a stronger (superlinear) convergence result which, on the other hand, is weaker than (3.2).

THEOREM 3.2. *Given $r \in (0, 1)$, there exists $\varepsilon = \varepsilon(r) > 0$ such that if $\|x_0 - x_*\| \leqq \varepsilon$, the sequence (x_k) generated by Algorithm 2.4 (Algorithm 2.9) converges to x_* and satisfies* (3.1). *Moreover, the speed of convergence is Q-superlinear, that is,*

$$\lim_{k\to\infty} \|x_{k+1} - x_*\| / \|x_k - x_*\| = 0. \tag{3.3}$$

Proof. See [15].

Algorithms 2.6–2.8 have the same type of convergence result as the modified Newton method.

THEOREM 3.3. *Given $r \in (0, 1)$, there exists $\varepsilon = \varepsilon(r) > 0$ such that if $\|x_0 - x_*\| \leqq \varepsilon$, the sequences (x_k) generated by Algorithm 2.6, 2.7, or 2.8 converge to x_* and satisfy* (3.1).

Proof. See [34] for the convergence of Algorithm 2.6. For proving the convergence of Algorithms 2.7 and 2.8, we need to interpret them as particular cases of the family introduced in [35]. This may be easily done: for Algorithm 2.7, $C(B) = I$, $D(B) = I$, $E(B) = B$, and for Algorithm 2.8, $C(B) = B$, $D(B) = I$, $E(B) = I$. Since these functions are trivially continuous, Theorem 2.1 of [35] may be applied. □

We are almost sure that the Dennis-Marwil method, without restarts, is not locally convergent. However, the members of a closely related family of methods introduced recently in [36] have local and superlinear convergence. We call the members of this family "quasi-Dennis-Marwil" methods. Given $\alpha \in (0, 1)$, the quasi-Dennis-Marwil method defined by α may be described by the following algorithm.

ALGORITHM 3.1. Given x_0, obtain x_1 using Algorithm 2.1. For computing x_k, $k = 1, 2, \cdots$, use the recurrence

$$x_{k+1} = x_k - (L_k U_k)^{-1} P F(x_k), \tag{3.4}$$

computing, at each iteration, L_{k+1}^{-1}, U_{k+1} as the solution of the following optimization problem:

$$\begin{aligned} &\text{Minimize}_{M,U}\ \alpha\|M - L_K^{-1}\|_F^2 + (1-\alpha)\|U - U_k\|_F^2 \quad \text{s.t.} \\ &U s_k = M y_k, \\ &s_k = x_{k+1} - x_k, \\ &y_k = P[F(x_{k+1}) - F(x_k)], \\ &U = (u_{ij}) | u_{ij} = 0 \quad \text{if } j \notin I_i^U. \end{aligned} \tag{3.5}$$

The relation between the Dennis-Marwil method and the method described above is given in the following theorem.

THEOREM 3.4. *Suppose x_k, L_k, U_k are given, and let us call L_{k+1}, U_{k+1} the matrices obtained using the Dennis-Marwil method. Of course, $L_{k+1}=L_k$. Let us call $L_{k+1}(\alpha)$, $U_{k+1}(\alpha)$ the ones obtained using Algorithm* 3.1. *Then,*

$$\lim_{\alpha\to 1} L_{k+1}(\alpha)=L_{k+1}, \tag{3.6}$$

$$\lim_{\alpha\to 1} U_{k+1}(\alpha)=U_{k+1}. \tag{3.7}$$

Proof. See [36].

The quasi-Dennis-Marwil methods are not practical for solving sparse nonlinear systems because sparsity of L_k is not preserved from one iteration to another. However, they have the same local convergence properties as Schubert's method (see [36]). Therefore, although the Dennis-Marwil method seems to have the poorest convergence properties among the algorithms described in § 2, the fact that "very analogous" methods in the sense of (3.6) and (3.7) have good local convergence properties makes us feel that "some part" of these properties is inherited by the Dennis-Marwil method.

Up to now, we have considered the convergence properties of the "pure" algorithms of § 2. If restarts are incorporated, the convergence results for quasi-Newton methods look very similar. In the following theorems, we consider the "restarted" versions of Algorithms 2.3 and 2.5-2.8. This means that for infinitely many iterations, x_{k+1} is computed using Algorithm 2.1, which involves a complete resetting of the LU factorization.

THEOREM 3.5. *Assume that (x_k) is obtained using Algorithm* 2.3, 2.6, 2.7, *or* 2.8, *except that for $k\in K_0$, an infinite set of indexes, the* LU *factorization of $J(x_k)$ is computed and x_{k+1} is calculated using Algorithm* 2.1. *Then there exists $\varepsilon>0$ such that if $\|x_0-x_*\|\leqq\varepsilon$, (x_k) converges Q-superlinearly to x_*.*

Proof. See [35] or use Theorems 3.1 and 3.3.

For the Dennis-Marwil method, the following slightly weaker result holds.

THEOREM 3.6. *Assume that (x_k) is obtained using Algorithm* 2.5, *except that for $k\in K_0$, an infinite set of indexes, the* LU *factorization of $J(x_k)$ is calculated and x_{k+1} is computed using Algorithm* 2.1. *Assume further that the difference between any pair of consecutive indexes of K_0 is never greater than a fixed integer q. Then the thesis of Theorem* 3.5 *holds for the sequence (x_k).*

Proof. See [12].

Remark. As a final remark in this section, let us stress the relationship between local convergence results of Algorithms 2.5 and 2.6. As we mentioned in § 1, the convergence results for these algorithms impose that the pivoting rule P which is used to factorize $J(x_0)$ will also allow the factorization of $J(x_*)$. This property will be satisfied by any pivoting rule which uses a threshold strategy like the one described by Dennis and Marwil in [12]. Now the partial pivoting strategy is just the strongest threshold strategy, since it uses the larger tolerance parameter $\mu=1$. Therefore, it is adequate for use in this type of algorithm. Moreover, if we use the partial pivoting strategy at $J(x_0)$, it is more likely that the same permutation matrix P allows the factorization of $J(x_*)$ than if we use less strict strategies, since the coefficients of the LU factorization (given P) are continuous functions of x. Therefore, the size of the neighborhoods of Theorems 3.5 and 3.6 is expected to be greater when we use partial pivoting than when we use any other threshold strategy.

4. Numerical experiments with the local algorithms. We wrote a FORTRAN code which implements the methods described in § 2. All the reported tests were run on a

VAX11/785 at the State University at Campinas, using the FORTRAN 77 compiler and the VMS Operational System. Single precision was used for real variables in all our tests. A compatible IBM-PC version of the code was also written using a Microsoft Fortran compiler. The results for this version were consistent with the results of the VAX version of the code.

We use the following notation:

N: Newton's method (Algorithm 2.2),
MN: Modified Newton method (Algorithm 2.3),
S: Schubert's method (Algorithm 2.4),
DM: Dennis-Marwil method (Algorithm 2.5),
DS: Diagonal-scaling method (Algorithm 2.6),
RS: Row-scaling method (Algorithm 2.7),
CS: Column-scaling method (Algorithm 2.8),
B: Broyden's method (Algorithm 2.9).

The numerical performance of the algorithms is described in Tables 1 and 2. In Table 1 we report the number of iterations used for an algorithm on each particular problem. The exit condition is represented by an output parameter IER. IER may assume five values: 0 for convergence of type 0, 1 for convergence of type 1, 2 for divergence, 3 for exceeded number of iterations and 4 for exceeded CPU time. In Table 2 we report the respective CPU times.

Each algorithm was run without restarts and with restarts based on the efficiency criterion described in § 3.

Let us describe the functions used in our numerical study.

Function 1. Broyden Tridiagonal. See [2], [3].

$$f_n(x)=(3-hx_n)x_n-x_{n-1}+1,$$
$$x_0=(-1,\cdots,-1)^T.$$

Algorithmic parameters: $\varepsilon_1=\varepsilon_2=10^{-4}$, $TOL=10^{-7}$, $\Delta=10$, $BIG=10^{10}$.

We ran this test with $h=0.5$ and $h=2$ and for $n=1000$, 2000, 3000, 4000, and 5000. Since no qualitative differences were detected, we report the results in Table 1 only for $h=2$ and $n=5000$. The computer CPU time of the symbolic phase of the methods (previous to the first iteration) obeys approximately the law

$$\text{time}=0.33n \text{ milliseconds.}$$

Now we give the observed relationships between n and CPU time of a typical iteration of the Algorithms 2.2-2.9:

N:	time $=0.25\ n$ milliseconds,
MN:	time $=0.09\ n$ milliseconds,
S:	time $=0.29\ n$ milliseconds,
DM:	time $=0.17\ n$ milliseconds,
DS, RS, and CS:	time $=0.11\ n$ milliseconds,
B:	time $=(0.13+0.005k)\ n$ milliseconds.

Function 2. Band Broyden [3].

$$f_i(x)=(3+5x_i^2)x_i+1-\sum_{j\in I_i}(x_j+x_j^2), \qquad i=1,\cdots,n,$$

where

$$I_i = \{i_1, \cdots, i_2\} - \{i\},$$

$$i_1 = \max\{1, i-5\}, \qquad i_2 = \min\{n, i+5\},$$

$$x_0 = (-1, \cdots, -1)^T, \quad \varepsilon_1 = \varepsilon_2 = 10^{-4}, \quad TOL = 10^{-7}, \quad \Delta = 10, \quad BIG = 10^{10}.$$

We ran this test for $n = 1000$, 2000, 3000, 4000, and 5000. For the same reasons as in Problem 1, we report in Table 1 the results only for $n = 5000$.

The CPU time of the symbolic phase of the George-Ng algorithm is approximately $1.22n$ milliseconds.

The CPU time of a typical iteration of each of the implemented methods obeys the following relationships:

N:	time $= 1.02\ n$ milliseconds,
MN:	time $= 0.22\ n$ milliseconds,
S:	time $= 1.15\ n$ milliseconds,
DM:	time $= 0.39\ n$ milliseconds,
DS, RS, and CS:	time $= 0.24\ n$ milliseconds,
B:	time $= (0.24 + 0.015\ k)\ n$ milliseconds.

Function 3. Trigexp [48].

$$f_1(x) = 3x_1^3 + 2x_2 - 5 + \sin(x_1 - x_2)\sin(x_1 + x_2),$$

$$f_i(x) = -x_{i-1}\, e^{(x_{i-1} - x_i)} + x_i(4 + 3x_i^2) + 2x_{i+1}$$
$$+ \sin(x_i - x_{i+1})\sin(x_i + x_{i+1}) - 8, \qquad i = 2, \cdots, n-1,$$

$$f_n(x) = -x_{n-1}\, e^{(x_{n-1} - x_n)} + 4x_n - 3.$$

Initial points: $(0, \cdots, 0)^T$ and $(0.3, \cdots, 0.3)^T$.

Algorithmic parameters: $\varepsilon_1 = \varepsilon_2 = 10^{-4}$, $TOL = 10^{-7}$, $\Delta = 10$, $BIG = 10^{10}$.

The Jacobian matrix of this system is tridiagonal, as in Problem 1. Therefore, the CPU time of the symbolic factorization is the same as in Problem 1. But the function is far more expensive to evaluate in this case. The CPU times of typical iterations of the algorithms, as functions of n, obey approximately the following laws:

N:	time $= 0.39\ n$ milliseconds,
MN:	time $= 0.15\ n$ milliseconds,
S:	time $= 0.34\ n$ milliseconds,
DM:	time $= 0.22\ n$ milliseconds,
DS, RS, and CS:	time $= 0.17\ n$ milliseconds,
B:	time $= (0.17 + 0.02\ k)\ n$ milliseconds.

As in the previous cases, we ran this problem for $n = 1000, 2000, \cdots, 5000$, but we report the results only for $n = 5000$.

Function 4. Poisson Problem [45]. This problem is the nonlinear system of equations arising from finite difference discretization of the Poisson boundary value problem

$$\Delta u = \frac{u^3}{1 + s^2 + t^2}, \qquad 0 \leqq s \leqq 1, \qquad 0 \leqq t \leqq 1,$$

$$u(0, t) = 1, \qquad u(1, t) = 2 - e^t, \qquad t \in [0, 1],$$

$$u(s, 0) = 1, \qquad u(s, 1) = 2 - e^s, \qquad s \in [0, 1].$$

We use an L^2 grid with $L = 15$ and $L = 31$. Therefore $n = 225$ and $n = 961$, respectively.

We ran the algorithms with $x_0 = (-1, \cdots, -1)^T$, $\varepsilon_1 = \varepsilon_2 = 10^{-4}$, $BIG = 10^{10}$, $\Delta = 5$.

The CPU times of the symbolic phase of the method of George and Ng for $L = 15$ and $L = 31$ were 1.31 seconds and 16.63 seconds, respectively. The CPU times of one ordinary iteration of the algorithms (in seconds) are shown in Table 3.

TABLE 3

Algorithm	$L=15$	$L=31$
N:	0.66	10.2
MN:	0.10	0.67
S:	0.68	10.3
DM:	0.17	1.23
DS:	0.13	0.74
RS:	0.10	0.53
CS:	0.11	0.88
$B(k=1)$:	0.15	0.89

As expected, the CPU times of Newton's and Schubert's iterations are roughly proportional to $L^4(=L^2n)$ while the CPU times of the other iterations are proportional to $L^3(=Ln)$.

Function 5.

$$f_1(x)=-2x_1^2+3x_1-2x_2+0.5x_{\alpha_1}+1.0,$$

$$f_i(x)=-2x_i^2+3x_i-x_{i-1}-2x_{i+1}+0.5x_{\alpha_i}+1.0, \qquad i=2,\cdots,n-1,$$

$$f_n(x)=-2x_n^2+3x_n-x_{n-1}+0.5x_{\alpha_n}+1.0$$

for α_i, $i=1,2,\cdots,n$, randomly chosen in the intervals: $\alpha_i\in\{\alpha_{i\,\min},\alpha_{i\,\max}\}$, where $\alpha_{i\,\min}=\max\{1,i-b\}$ and $\alpha_{i\,\max}=\min\{n,i+b\}$ for a parameter b which defines the bandwidth.

We used $(-1,\cdots,-1)^T$ as an initial point and, as in previous tests, $\varepsilon_1=\varepsilon_2=10^{-4}$, $TOL=10^{-7}$, $\Delta=10$, $BIG=10^{10}$. The structure of some typical Jacobian matrices with $n=40$, for different bandwidths and their correspondent data structures for LU factorizations, are given in Figs. 1 and 2.

The CPU time of the symbolic phase of the algorithm (with $b=100$ and $n=1000$) was 12.37 seconds.

The CPU time of typical iterations of the implemented methods for $b=100$, $n=1000$, was the following:

N: 9.7 seconds,

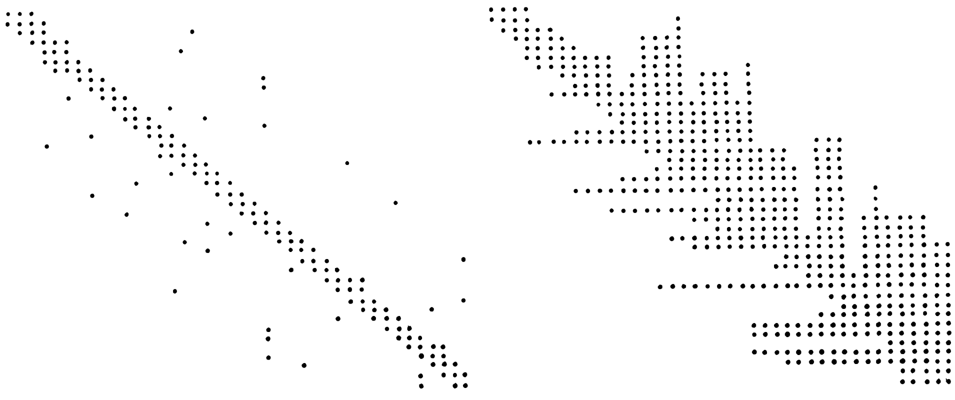

FIG. 1. *Structure of the Jacobian matrix and data structure for the* LU *factorization of Function* 5 ($b=15$).

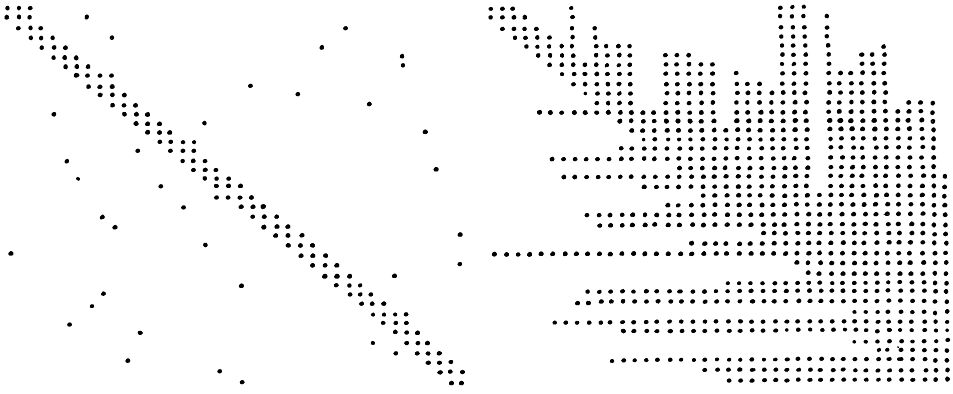

FIG. 2. *Structure of the Jacobian matrix and data structure for the* LU *factorization of Function* 5 ($b=30$).

MN: 0.67 seconds,
S: 9.68 seconds,
DM: 1.23 seconds,
DS: 0.78 seconds,
RS: 0.66 seconds,
CS: 0.64 seconds,
B: 0.68 seconds.

Function 6.

$$f_1(x)=-2x_1^2+3x_1+3x_{n-4}-x_{n-3}-x_{n-2}+0.5x_{n-1}-x_n+1,$$

$$f_i(x)=-2x_i^2+3x_i-x_{i-1}-2x_{i+1}+3x_{n-4}-x_{n-3}-x_{n-2}+0.5x_{n-1}-x_n+1, \qquad i=2,\cdots,n-1,$$

$$f_n(x)=-2x_n^2+3x_n-x_{n-1}+3x_{n-4}-x_{n-3}-x_{n-2}+0.5x_{n-1}-x_n+1.$$

We used $(-1,\cdots,-1)^T$ as initial point and the algorithmic parameters $\varepsilon_1=\varepsilon_2=10^{-4}$, $TOL=10^{-7}$, $\Delta=10$, $BIG=10^{10}$.

The structure of the Jacobian matrix and the correspondent data structure for the LU factorization produced by the symbolic phase of the George–Ng algorithm for $n=40$ is given in Fig. 3. The CPU time of the symbolic phase was $0.69n$ milliseconds. The CPU times of typical iterations of the implemented methods obey approximately the following laws:

N: time $=0.51\ n$ milliseconds,
MN: time $=0.12\ n$ milliseconds,
S: time $=0.68\ n$ milliseconds,
DM: time $=0.31\ n$ milliseconds,
DS, RS, and CS: time $=0.18\ n$ milliseconds,
B: time $=(0.16+0.008\ k)\ n$ milliseconds.

Function 7. Singular Broyden.

$$f_1(x)=((3-hx_1)x_1-2x_2+1)^2,$$

$$f_i(x)=((3-hx_i)x_i-x_{i-1}-2x_{i+1}+1)^2, \qquad i=2,\cdots,n-1,$$

$$f_n(x)=((3-hx_n)x_n-x_{n-1}+1)^2.$$

Initial point $=(-1,\cdots,-1)^T$.

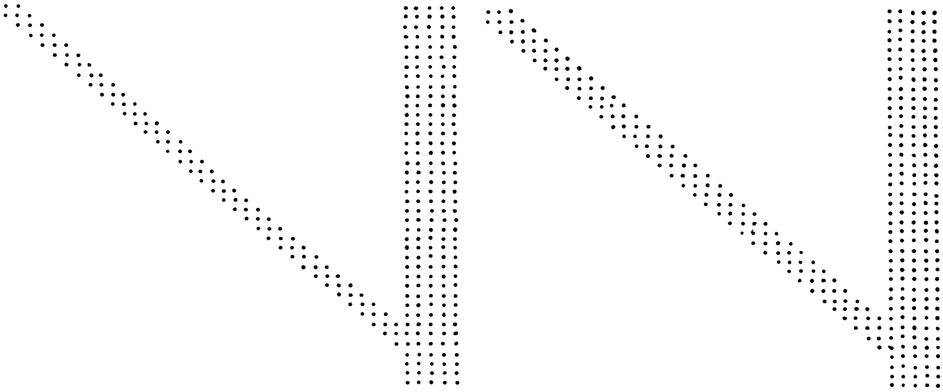

FIG. 3. *Structure of the Jacobian matrix and data structure for the* LU *factorization of Function* 6.

Algorithmic parameters: $\varepsilon_1 = \varepsilon_2 = 10^{-4}$, $TOL = 10^{-7}$, $\Delta = 10$, $BIG = 10^{10}$.

Clearly, this problem is equivalent to Problem 1, but its Jacobian matrix is singular at the solution. It was concluded in our comparative study to investigate the behavior of different algorithms in the presence of singular Jacobians. The computer CPU times of individual iterations are very similar to those of Function 1. As in Function 1, we will report the results only for $h = 2$ and $n = 5000$.

5. Global implementations. Many researchers and users of nonlinear equations codes think that too much consideration is given in the literature to local convergence properties of algorithms without regard to the possibility of developing global convergent methods derived from the local convergent ones.

However, there are a number of good reasons for that detected "deviation."

(a) Many practical problems have natural initial points which are not very far from the solution or, at least, are near enough to ensure a good behavior of purely local algorithms. This is the case of many boundary value problems and of the methods based on restoration of nonlinear feasibility in nonlinear programming.

(b) The most natural objective function which is associated to problem (1.1) is the sum of squares:

$$f(x) = \tfrac{1}{2}\|F(x)\|_2^2. \tag{5.1}$$

"Globally convergent" algorithms are ensured to converge to a stationary point of $f(x)$, possibly a local minimizer of f. Unhappily, $\nabla f(x)$ may be zero at a point where $F(x) \neq 0$ if $J(x)$ is singular. Clearly, a local minimizer of f is not a good answer to problem (1.1), if $F(x) \neq 0$. Many times, globally convergent implementations converge to undesirable local minimizers of f, while local methods (with a suitable control of steplength) converge to solutions of (1.1).

(c) Frequently, a sequence (x_k) generated by a particular local method converges to a solution x_* of (1.1) but $\|F(x_k)\|_2$ is not monotonically decreasing. In these cases a "global modification" of the sequence produces decrease of $\|F(x_k)\|$ at each iteration but at a cost of a lower speed of convergence. Sometimes, as was mentioned in [6], the new sequence converges to an undesirable local minimizer of f.

(d) Many times quasi-Newton methods exhibit a "jumping behavior," that is, while the modified Newton method usually converges in a monotone way (say, with $\|x_{k+1} - x_*\|_\infty \leqq \|x_k - x_*\|_\infty$ for all k), many quasi-Newton algorithms fail to exhibit that monotonical behavior but, finally, they converge much more quickly than the modified Newton method. For instance, when Broyden's method is applied to a linear system of equations (with $B_0 = I$), it is common to detect a number of apparently chaotic iterations before finite convergence occurs when $k = 2n$, according to Gay's theorem [19]. So, imposing norm decreasing in these cases destroys, in some sense, accumulated information of the sequence and slows down speed of convergence.

(e) When local algorithms do not converge at all, one of the most effective ways of solving problems is the "continuation strategy" (see [9], [41], [43], [49]-[51], etc.). This strategy essentially consists in replacing (1.1) by a family of problems $h(x, t) = 0$, $t \in [0, 1]$, such that $F(x) \equiv h(x, 1)$ and the solution of $h(x, 0) = 0$ is known. Sometimes the choice of h is suggested by the physical nature of the problem, but some standard mathematical choices are known to be effective (see [50]). The central idea is that one solves a sequence of problems $h(x, t_k) = 0$ so that problem $k+1$ is easy to solve using a local algorithm if the solution of problem k is known. Therefore the global continuation (or homotic) strategy essentially needs good local algorithms to be successful.

(f) Due to the numerical studies of Cosnard [8] and Moré and Cosnard [39], we know that trust region-like modifications of local algorithms (like the dogleg strategy of Powell [42]) may not be entirely satisfactory to ensure robustness of methods to solving nonlinear equations. After many numerical experiments, those authors found that the purely local Brent's method (see [1], [32]) was surprisingly effective when compared with the hybrid method of Powell [42], which is a global modification of Broyden's method. Of course, they also detected some cases where Powell's method converged while the local method did not. Due to the difficulty of incorporating global strategies based on the norm of F to Brent's method (the whole vector $F(x_k)$ is not calculated at any point in this method), Moré and Cosnard developed some step control procedures which turned to be very useful to add robustness to local methods and which, certainly, must be incorporated to production codes.

(g) Strategies for minimization of $f(x)(\equiv \frac{1}{2}\|F(x)\|_2^2)$ use $\nabla f(x)(\equiv J(x)^T F(x))$ and, thus, the Jacobian matrix of F or some difference approximation. An exception is the global strategy for Broyden's method introduced by Griewank [22], but his strategy requires additional hypotheses on F. In fact, quasi-Newton directions of the type produced by Algorithms 2.2–2.9 are not necessarily descent directions for f. Some authors (for instance, Toint in his implementation of partitioned quasi-Newton methods [48]) choose x_{k+1} as some point in the line defined by x_k and the direct prediction point such that $f(x_{k+1})$ is "sufficiently smaller" than $f(x_k)$ (see [15, p. 179]). However, it may be impossible to find that point if the line is orthogonal to $\nabla f(x_k)$, so the effectiveness of this strategy seems to be confined to practical situations where "quasi orthogonality" is unlikely to occur.

In spite of the considerations above, we decided, for completeness of our study, to implement global modifications of Algorithms 2.2–2.9.

The considerations on the nonmonotone behavior of quasi-Newton methods inspired in us a "tolerant global strategy" which essentially consists in imposing decrease of $\|F\|$ only (say) every q iterations where q is a user-supplied parameter. Clearly, this "tolerant strategy" is in the spirit of the watchdog technique for avoiding the Maratos effect in nonlinear programming (see [6]) and it is also related to the nonmonotone line search technique of Grippo, Lampariello, and Lucidi [26].

Given $x_0, x_1, \cdots, x_k$ (and $f(x)$ defined by (5.1)), we define

$$a_k = \text{Argmin}\,\{f(x_0), f(x_1), \cdots, f(x_k)\} \qquad (5.2)$$

for all $k = 0, 1, 2, \cdots$.

Assume that $q \geqq 0$ is a given integer, and $\theta \in (0, 1)$. At some stages, the global tolerant strategy will use "special iterations," which are defined by the following algorithm.

ALGORITHM 5.1. SPECIAL ITERATION. Given x_k, compute x_{k+1} performing the following steps:

Step 1. Compute the LU decomposition of $J(x_k)$ (Steps 2 and 3 of Algorithm 2.1). If, for all $i = 1, \cdots, n|u_{ii}| > TOLB$ (so that no replacement occurred at Step 3 of Algorithm 2.1), perform also Step 4 of Algorithm 2.1, defining the Newton step s_k. Else, define $s_k = -J(x_k)^T F(x_k)(\equiv \nabla f(x_k))$.
Step 2. If $\|s_k\|_\infty > \Delta$, replace $s_k \leftarrow s_k \Delta / \|s_k\|_\infty$.
Step 3. Using a safeguarded quadratic-cubic interpolation strategy (see [15, p. 126–129]) compute $\lambda_k \in (0, 1]$ such that

$$f(x_k + \lambda_k s_k) \leqq f(x_k) + 10^{-4} \lambda_k \nabla f(x_k)^T s_k.$$

Step 4. Define $x^{k+1} = x^k + \lambda_k s_k$.

Special iterations are combined with "ordinary iterations," which are the ones defined by the "local" algorithms described in § 2, according to the following "master subroutine."

ALGORITHM 5.2.
Initialization: $k \leftarrow 0$, $FLAG \leftarrow 1$.
Given x_k, execute Steps 1–4.

Step 1. If $FLAG = 1$, obtain x_{k+1} using an ordinary iteration. Else, compute x_{k+1} using a special iteration.
Step 2. If $k \not\equiv 0 (\text{mod } q)$ and $FLAG = 1$, increment $k \leftarrow k+1$. Return to Step 1.
Step 3. If $f(x_{k+1}) \leqq \theta f(a_k)$ (see definition (5.2)), set $FLAG \leftarrow 1$, $k \leftarrow k+1$ and return to Step 1.
Step 4. Redefine $x_{k+1} \leftarrow a_k$. Set $FLAG \leftarrow -1$, $k \leftarrow k+1$ and return to Step 1.

As we mentioned above, the tolerant strategy consists in iterating using a standard quasi-Newton algorithm testing every q iterations if the norm of the best point decreased enough (Algorithm 5.2, Step 3). If the sufficient decrease condition does not hold, we turn to a minimization algorithm based on Newton (or gradient) directions, which are guaranteed to be descent directions. We continue with these special iterations as long as the sufficient decrease condition of Step 3 is not satisfied. Clearly, if this condition is satisfied an infinite number of times, we will have that $\liminf_{k \to \infty} \|F(x_k)\| = 0$. Conversely, if after some finite k_0, all iterates are special, we will have, under mild conditions, that $\lim_{k \to \infty} \|\nabla f(x_k)\| = 0$ (see [15]).

There may be many other possible global strategies. Here we want to show how the algorithms presented in § 2 adapt to this global modification, and we leave the comparison between different global strategies to forthcoming works.

For comparison of Algorithms 2.2–2.9 with global strategy, we selected some problems of the set presented in § 4, with nonclassical initial points from which Newton's method had difficulties converging, or did not converge at all. We used $\theta = 0.9$. The problems were the following.

Problem 1. Function 1 with $x_0 = (10^{-3}, \cdots, 10^{-3})^T$ and $\Delta = 5000$.
Problem 2. Function 2 with $x_0 = (0, \cdots, 0)^T$ and $\Delta = 10$.
Problem 3. Function 3 with $x_0 = (-1, \cdots, -1)^T$ and $\Delta = 10$.
Problem 4. Function 4, $L = 15$, $x_0 = (-3, \cdots, -3)^T$, $\Delta = 100$.
Problem 5. Function 5, $x_0 = (-0.0008, \cdots, -0.0008)^T$, $\Delta = 10^4$, $n = 100$, $b = 100$.

Problem 6. Function 6, $x_0=(0.8,\cdots,0.8)^T$, $\Delta=10$, $n=100$.

Problem 7. Function 7, $x_0=(5,\cdots,5)^T$, $\Delta=20$, $n=100$.

The results of these experiments are reported in Table 4. For each method, we report the performance of the local version without restarts, and the performance of the "global" version, with $q=3$.

6. Conclusions. Considering the results of our "local" experiments presented in § 4, we may draw the following conclusions.

TABLE 4
Numerical results for the global algorithms.

Problem	n	Version	N	MN	S	DM	DS	RS	CS	B

† NC = nonconvergence.

‡ The superscript 1 indicates "convergence of type 1." Absence of superscript indicates "convergence of type 0."

§ * = overflow.

(a) There are no important differences between the secant Algorithms 2.4–2.9 in terms of robustness or number of iterations. Clearly, Algorithm 2.3 (modified Newton) behaves worse than all the secant methods. Since superlinear convergence (without restarts) is only proved for Broyden's method and Schubert's method, while DS, CS, and RS have only linear local convergence properties and DM has an even weaker convergence theorem (see § 2), we conclude that additional theory is necessary to explain the clear superiority of Algorithms 2.5–2.8 over MN, and the very analogous behavior of these algorithms in relation to Broyden and Schubert.

The relation between the effectiveness of DM, DS, CS, and RS and the number of iterations where the "secant stability test" at Step 5 of Algorithms 2.5–2.9 is satisfied, was studied by us, and the results were very impressive. In fact, we verified that good performances of these algorithms are associated with situations where the test was always satisfied, that is, the secant equation held at all iterations. Conversely, in the cases where Algorithms 2.5–2.9 had a poor behavior, we detected many iterations (from 20–90 percent in some cases) where the test of Step 5 failed.

(b) Schubert's method is not useful for problems where derivatives are not difficult to calculate. This is not surprising since in those cases the computational work involved in one Schubert iteration is essentially the work involved in a Newton iteration. However, since in terms of robustness and number of iterations Schubert's method did not perform better than the other tested secant methods, we may conclude that Schubert's method is not a reliable alternative to other secant methods, even if derivatives were difficult to obtain. There exist secant methods which solve a linear system of equations at each iteration but incorporate information about the problem in a more clever way than Schubert's method does. These are the pointwise family of quasi-Newton methods [27], [29] for boundary value problems, and partitioned quasi-Newton methods [48] for finite element problems. The first family may be defined in the original infinite-dimensional space where the boundary value problem takes place, and thus exhibits mesh independence properties, that is, its behavior does not depend on the discretization. Partitioned quasi-Newton methods seem to exhibit mesh independence in practice (see [23], [24]) but a theoretical justification is due. Both pointwise methods and partitioned quasi-Newton methods are more efficient than Schubert's method for the particular problems to which they are applied, but we do not know if this efficiency compensates the disadvantage of solving a linear system per iteration for comparison with other secant methods.

(c) Secant methods (except Schubert) outperformed Newton's method in "not difficult" problems where the Jacobian matrix has a "bad" structure for the application of the George–Ng algorithm, notably Problems 4 and 5. However, only Newton's method did not present any failure (nonconvergence) in this set of experiments. Of course, none of these facts is surprising since it is well known that the region of convergence of local versions of Newton's method is larger than that of quasi-Newton methods.

(d) Except for Problem 4, the "diagonal methods" DS, RS, and CS were slightly better than Broyden's method, on the average, both in terms of number of iterations and CPU time. Problem 4 (Poisson) deserves more careful analysis. In fact, this was the only problem where DM, DS, RS, and CS were not better than the modified Newton method, that is, in this case, the derivative information provided by the secant equation did not add any improvement to the convergence properties of MN. On the other hand, Broyden was the best method in this case. Griewank observed that since Broyden's method is invariant for regular linear changes in the range of F, the application of this method to $F(x)=0$ (with $B_0=J(x_0)$) is equivalent to its application to $G(x)\equiv J(x_0)^{-1}F(x)=0$ using $B_0=I$. Then, using the LU factorization of $J(x_0)$, one essentially preconditions the system by the inverse of the Laplacian and thus obtains conceptually a Fredholm integral equation of the second kind, for which Q-superlinear convergence of Broyden's method on the underlying infinite-dimensional problem has been proved [25].

(e) Nonconvergence only occurred in some nonrestarted executions of quasi-Newton methods. The main contribution of restarts was to correct with opportunistic Newton iterations a "wrong trajectory" of some quasi-Newton methods. In the cases where this correction was needed, the final performance of the restarted quasi-Newton was very similar to the performance of Newton.

(f) In contrast to modified Newton, Schubert, Dennis–Marwil, and Broyden, the methods DS, RS, and CS behaved surprisingly well in the singular Problem 7. Some research is needed to detect if there exist theoretical properties behind this empirical fact.

Before commenting on the results of the "global" algorithms, some explanation is necessary. We performed many experiments besides the ones reported in Table 4. We ran many problems where Newton's method did not converge, and its global modification or the global modifications of quasi-Newton methods, even with $q=1$, did not converge either, or most frequently converged to undesirable local minimizers of $\|F(x)\|$. In the problems reported in Table 2, the global version of Newton behaved better than the local version. We selected these problems with the aim of testing the behavior of the quasi-Newton algorithms in those situations.

Our main observations concerning the global implementations are:

(a) Unlike the local cases, there are no meaningful differences between the modified Newton method and the secant Algorithms 2.4–2.9. In fact the global MN was better than the global Newton four times, while RS, CS, and Broyden outperformed Newton in three cases (the Schubert, DM, and DS did it only in two cases).

(b) Only in Problem 6 did all the global methods fail to find a solution of the system and converge to the same local minimizer of $\|F(x)\|$. In Problem 7 most methods converged to (different) local minimizers of $\|F(x)\|$ and only RS and CS found a solution of the system.

(c) The tolerant strategy was successful for improving the performance of quasi-Newton methods in the following sense: in many cases where the performance of the local quasi-Newton was very poor, the global quasi-Newton with tolerant strategy succeeded in finding the solution and it was more efficient than "global Newton" in about 50 percent of the experiments. Generally, only a few special iterations are necessary for putting the quasi-Newton method on a "right trajectory."

The implementation and testing of a global strategy led us to discover many "very difficult problems," where even Newton's method with a global strategy which imposes sufficient decrease at each iteration failed to find a solution of the system. The present challenge is to implement new global strategies which will "jump" over local minimizers to solutions of $F(x)=0$ (which are, of course, global minimizers of the norm).

A production code, which, instead of the risky divergence criteria adopted in this comparative study, uses the steplength controls and stopping criteria given by Moré and Cosnard [39], is being elaborated.

Acknowledgments. The authors acknowledge A. Griewank and two referees for very helpful suggestions.

KNOT SELECTION FOR LEAST SQUARES THIN PLATE SPLINES*

JOHN R. McMAHON† AND RICHARD FRANKE‡

Abstract. An algorithm for the selection of knot point locations for approximation of functions from large sets of scattered data by least squares thin plate splines is given. The algorithm is based on the idea that each data point is equally important in defining the surface, which allows the knot selection process to be decoupled from the least squares. Properties of the algorithm are investigated, and examples demonstrating it are given. Results of some least squares approximations are given and compared with other approximation methods.

Key words. knot selection, least squares, thin plate splines, Dirichlet tessellation, scattered data

AMS(MOS) subject classification. 65D10

1. Introduction.

The problem of fitting a surface to small sets of given data has been addressed in many different ways, and several computer programs are currently available which enable one to deal with the problem effectively. Many of the methods available involve a global interpolation or approximation scheme and often involve solving a system of equations with an equivalent number of unknowns. For very large sets of data, the problem is computationally intractable. This consideration provides the motivation behind the development of a way to pare the problem down to a more manageable size.

We wish to construct a function F which approximately fits the data, since we assume the data collection is subject to measurement error. We propose to use approximation by least squares thin plate splines (TPS), where the surface function is constructed so as to minimize an error function subject to certain constraints. Solving the approximation problem will also involve as many equations as there are data points, but the number of unknowns will be significantly fewer. Part of the appeal of TPS approximation lies in the fact that it minimizes a certain linear functional and involves a linear combination of functions with no greater complexity than the natural logarithm of the distance function.

Interpolation of scattered data by the method of TPS was developed from engineering considerations by Harder and Desmarais [6]. It can be thought of as a two-dimensional generalization of the cubic spline, which models a thin beam under point loads subject to equilibrium constraints. The TPS function is derived from a differential equation which gives the deformation of an infinite, thin plate under the influence of point loads. A point load is applied at each data point so that the interpolating surface can be constructed as a sum of fundamental solutions of the TPS equation.

In using the least squares TPS approximation method to fit the surface, a fewer number of basis functions than the number of given data points is employed. These basis functions are centered at a different, smaller set of points, which, in analogy with the univariate case, we call the knots. Therefore, the problem at hand is one of selecting the knot points, and hence the basis functions. This approach differs from the use of smoothing splines, which were introduced by Wahba and Wendelberger [13] in the multidimensional case, and called Laplacian smoothing splines (LSS). LSS minimize

a certain functional which is a linear combination of a term measuring fidelity to the data and one measuring smoothness of the function (a generalization of the usual TPS functional). In this case there is still one basis function for each data point, but the interpolation condition is relaxed.

Given a "large" set of data points, (x_i, y_i, f_i), $i = 1, \cdots, N$, we wish to find a smaller set of knot points, $(\hat{x}_j, \hat{y}_j)$, $j = 1, \cdots, K$, which will "represent" the former reasonably well. This could be accomplished by choosing a subset of the original set or by some process which produces a representative set. The ultimate goal is to approximate the surface from which the original data arose using the representative set. Hence, a surface fit to the large set and one fit to the representative set should be essentially the same.

Approximation by least squares TPS is straightforward once the knot points are known. We construct the TPS function

$$F(x, y) = \sum_{j=1}^{K} A_j d_j^2 \log(d_j) + ax + by + c,$$

where $d_j^2 = (x - \hat{x}_j)^2 + (y - \hat{y}_j)^2$, and the coefficients A_j, a, b, and c are chosen to minimize the error function

$$E = \sum_{i=1}^{N} \{[F(x_i, y_i) - f_i]/s_i\}^2.$$

The ordinates, f_i, may be subject to random errors, say, with standard deviation s_i at the ith data point. We model the plate under the point loads at the knot points (as opposed to the data points); therefore, the constraint equations for the least squares TPS method, which may be thought of as "equilibrium conditions" on the plate, should be satisfied. Thus the error function is minimized subject to the following constraint equations:

$$\sum_{j=1}^{K} A_j = 0, \qquad \sum_{j=1}^{K} A_j \hat{x}_j = 0, \qquad \sum_{j=1}^{K} A_j \hat{y}_j = 0.$$

We use LINPACK [1] subroutines to do the actual calculations.

Previous attempts have been made to minimize the error function by considering it to be a function of the knot point locations as well as the coefficients, wherein a total of $3K$ parameters are involved. As reported on by Schmidt [11], the initial knot configuration was taken to be of tensor product form. The overall minimization process is a large nonlinear one, and is complicated by possible coalescence of knots as well as nonunique solutions (as indicated by consideration of one-dimensional cases). Also, the objective function may have many local minima so that avoiding poor local minima or searching for better local minima may be necessary. Because of these kinds of problems, our goal is to decouple the knot selection process from the least squares process.

When data are somewhat uniformly distributed, methods involving tensor product cubic splines may be desirable. Tensor product methods place knot locations on a grid, which may not reflect the actual disposition of the data points; in fact, there could be no data nearby. Even though these problems are surmountable, they could lead to nonuniqueness of the solution. The minimum norm solution that is often used may not be aesthetically appealing. We will say more about this later.

A different point of view is considered here wherein the knot point locations are predetermined based on two criteria. These criteria evolve from considerations relating the density of data to the dependent variable and mandating the importance of each individual data point. The solution of the overdetermined system of equations follows the knot point selection. A summary of the approach and results will be presented. Examples are given which illustrate rather well the ability of the scheme to select knot locations which reflect the underlying density of the data. We also report on actual surface fitting and comparison with two other methods, the LSS of Wahba and Wendelberger [13] and the tensor product bicubic Hermite method due to Foley [4]. We point out, however, that each of these approaches is geared toward a different problem than ours and thus it is difficult to compare them in a meaningful way.

We also point out three related ideas which are attempts to decrease the number of basis functions to be considered. Each is an attempt to choose a subset of points to be used to construct the approximation. Schiro and Williams [10] used an adaptive process for subset selection and overlapping regions to construct underwater topographic maps. Bozzini, diTisi, and Lenarduzzi [2] gave an algorithm for selecting a subset of points which were important to proper definition of the surface. Both of these methods made no assumptions about the density of the data points relative to the behavior of the surface, and both required consideration of the ordinate values. Another approach is an adaptive procedure suggested by LeMéhauté and Lafranche [7]. The underlying approximation is a piecewise polynomial over a triangulation; it is assumed that all derivative data necessary to construct the smooth approximation is available. Points are removed from the set as long as the approximation from the remaining set of points is accurate to within a specified tolerance.

2. The knot selection process. Given a priori flexibility in knot placement, the problem becomes the selection of knot locations, followed by solution of the system by least squares. Since the selection of knot locations is to be decoupled from the solution of the least squares problem, we establish a connection between these aspects of the problem by making two somewhat vague assumptions. First, we assume that the independent variables of the data indicate something about the behavior of the dependent variable. For example, the density of the data points may be dependent on the curvature of the surface. Hence, where relatively many data points are found, the function is assumed to be changing behavior rapidly, whereas a low density of data indicates slowly changing behavior. Although this assumption is not universally satisfied in practice, it does not seem to be an unreasonable one.

The second assumption is that each data point is equally important in defining the underlying surface. Therefore the number of data points represented by each knot should be the same or nearly the same. This leads to "equal representation" of the data points by the knot points where each data point is "close" to a knot point. A key advantage achieved in pursuing this approach is the existence of a natural heuristic for moving the knots around the plane in searching for a good knot configuration. This point will be elaborated later in the paper.

2.1. A local minimum property. We want each data point to be close to a knot point, so we try to minimize the sum of the distances squared from each data point to the nearest knot point, that is, minimize the "global" value,

$$GN^2 = \sum_{i=1}^{N} \min_j \left[(x_i - \hat{x}_j)^2 + (y_i - \hat{y}_j)^2\right].$$

This function is continuous and piecewise quadratic in $2K$ variables. The expression leads naturally to a "default" Dirichlet tessellation, a partitioning of the plane with respect to the knot points (see Fig. 1). Thus we say each data point belongs to some knot point according to the Dirichlet tile in which it lies. Data points on any of the

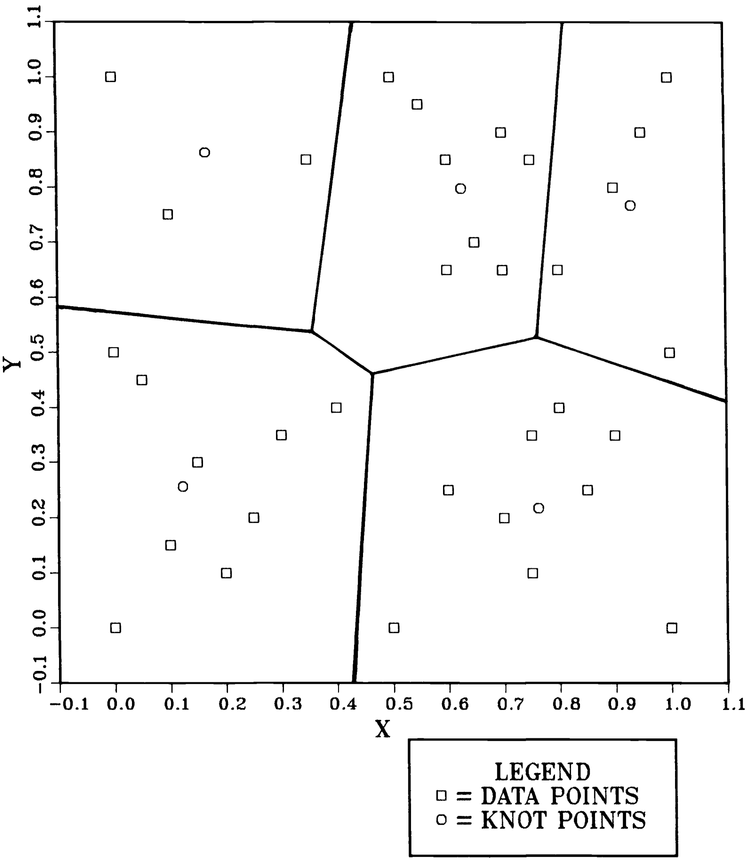

FIG. 1. *A Dirichlet tessellation with five tiles. It is constructed by connecting the perpendicular bisectors of the lines joining each of the knot points.*

tile boundaries (ties) must be resolved by a determination of to which tile they belong or some sharing mechanism. Our initial guess at the knot point configuration was taken to be quasi-gridded.

Differentiation of GN^2 with respect to the $\hat{x}_j$ and $\hat{y}_j$ show that at the minimum, each knot point will occupy the centroid with respect to the data points inside that tile. Given the initial configuration of knot points with its Dirichlet tessellation, the following algorithm for iteration to a local minimum GN^2 value is employed.

ALGORITHM 2.1. (a) Compute the centroid of each tile with respect to the data points contained within each tile.

(b) Move the knots to the corresponding centroids, which results in a new Dirichlet tessellation and a new set of knot point–data point associations; this is the configuration for the next iteration.

(c) Quit when two successive iterations yield the same knot locations, which means that a local minimum value of GN^2 has been found.

This algorithm was formulated in discussions at the Istituto per le Applicazioni della Matematica e dell'Informatica in 1983 [9], after the problem was posed by Nielson and Franke. The algorithm is known in clustering analysis as the method of k-means [12].

We note that the value of GN^2 will necessarily decrease as the iterations continue until two successive iterations yield the same configuration; this will be proven below. In the case where no data points lie in a tile for some knot point, the knot point is moved to the nearest data point. This mechanism avoids knots without data points. Furthermore, if a data point lies on a tile boundary, it is assigned to the knot with the smallest subscript (amongst the appropriate choices of knot points). Employment of a different criterion for the resolution of ties may yield different results. We note that knots cannot coalesce.

The following theorem is pertinent to this algorithm.

THEOREM 2.1. *The function GN^2 decreases with each iteration which involves movement of a knot point.*

Proof. Write GN^2 in the more convenient form

$$GN^2 = \sum_{j=1}^{K} \sum_{i \in I_j} [(x_i - \hat{x}_j)^2 + (y_i - \hat{y}_j)^2], \tag{1}$$

where $I_j = \{i\colon (x_i, y_i)$ in the tile for $(\hat{x}_j, \hat{y}_j)\}$. In (1), the interior sum is the sum of the distances squared from the data points in a tile to the knot point in that tile, and the exterior sum is over all K of the tiles. Let a prime denote the new knot points and index sets. This form leads to the expressions

$$(\hat{x}_j', \hat{y}_j') = \left(\sum_{i \in I_j} x_i / n_j, \sum_{i \in I_j} y_i / n_j \right),$$

where n_j is the number of indices in the set I_j. The new knot points will lead to a new tessellation, followed by the new index sets I_j'. Then the expression (1) is greater than or equal to

$$\sum_{j=1}^{K} \sum_{i \in I_j} [(x_i - \hat{x}_j')^2 + (y_i - \hat{y}_j')^2] \tag{2}$$

because the new knot point locations minimize the contribution of the interior sums. This expression (2), in turn, is greater than or equal to

$$\sum_{j=1}^{K} \sum_{i \in I_j'} [(x_i - \hat{x}_j')^2 + (y_i - \hat{y}_j')^2] \tag{3}$$

since an index i moves to another set only in the case wherein the corresponding data point is now closer to a different knot point, thus decreasing its contribution to the global GN^2 value. □

Finding a local minimum of GN^2 is well served by Algorithm 2.1; however, as demonstrated in a one-dimensional example [8], the function GN^2 is rife with local minima, and the local minimum value found depends on the initial configuration of knots used. We can draw similar conclusions for the multidimensional case based on the one-dimensional analogy.

The process of locating each knot occurs in two distinct steps: first, each data point is assigned to the closest knot and second, a determination is made within each tile as to the location of the centroid of its data points. The minimum distance in the expression for the GN^2 function causes it to be piecewise and it is quadratic. The minimization of GN^2 corresponds to locating each of the knots at the centroids of their respective Dirichlet tiles. As a direct result of the centroid requirement, the GN^2 function will stabilize at a local minimum value of the particular quadratic piece defined by stable knot locations.

The local minimum value of GN^2 will frequently occur out of the domain of one or more of the corresponding quadratic pieces. This leads to a "cascading" phenomenon which continues until a local minimum value occurs within the domain defined by the current set of knots. However, the global minimum value will not necessarily be attained.

2.2. The objective function. This inconsistent performance of Algorithm 2.1 in finding the global minimum value of GN^2 leads to consideration of a somewhat different criterion for locating a good configuration of knot points. We wish to exploit the second assumption specified at the end of § 2.1, while taking advantage of the minimization of the GN^2 function. Since each data point is assumed to be equally important, the Dirichlet tile for each knot should contain about the same number of data points. Thus we wish to minimize the sum of the squares of the differences between the number of knots in each tile and the average number of data points that should belong to each tile, that is, minimize the quantity

$$D=\sum_{j=1}^{K}(n_j-N/K)^2.$$

The new algorithm for determining knot locations is based on the minimization of D, subject to the constraint that each knot be located at the centroid of its tile.

This optimization leads to a natural heuristic for moving knots from a stable configuration to a possibly better configuration. We call the current configuration of knots a "base" configuration, and iterate through the algorithm as follows.

ALGORITHM 2.2. (a) Generate a new guess for the knot locations by moving the knot(s) with the smallest number of data points in their tile(s) toward the knot(s) with the largest number of knot(s) in their tile(s); the distance moved is initially a large fraction of the total distance between the knots.

(b) Iterate to a stable configuration using the first algorithm, compute the values of GN^2 and D, and compare D to the smallest value achieved to date, as represented by that of the base configuration.

(c) Repeat the process above when a smaller value of D is obtained, with the present configuration as the base configuration.

(d) When a smaller value of D is not found, take a shorter step in the movement of the knot(s) and repeat the process above.

(e) Continue with smaller and smaller steps until a smaller value of D is found (or an equal value of D with a smaller GN^2 value) or until the knot locations return to the base configuration.

(f) Perform the search in the symmetrical way when the base configuration is returned to, that is, move the knot(s) with the largest number of data points in their tiles toward the knot(s) with the smallest number of points in their tile.

(g) Quit when no smaller value of D is found.

The movement of the knots is justified by the rationale that a more equitable distribution of data points can be found by moving the tile boundaries across data points. Note that the algorithm for computing a local minimum of the GN^2 function value is embedded in Algorithm 2.2.

3. Results and examples. Using Algorithm 2.1 for the a priori selection of the knot point locations, experiments were conducted to test the scheme using different sets of test data. This was followed by verification of the scheme on two sets of real data. Results from two sets of the test data are presented here, one consisting of 200 data points called "cliff," and one consisting of 500 data points called "humps and dips."

Both sets of data were generated using known functions (see Franke [5]) in a way that forced the density of points to be approximately proportional to the curvature of the sampled function.

Figures 2 and 3 show these two test data sets graphically and illustrate the optimized knot point configurations found using Algorithm 2.1.

We also investigated how closely the constructed surface F and the "true" surface resemble one another for the cases where the data was generated from a known function. This comparison is made in the context of the root-mean-squared error (RMS) of the residuals (at the data points) and on a rectangular grid of locations in the plane. The two data sets constructed above, and one other which was generated in a similar manner, were used to compare RMS errors for the least squares Algorithm 2.1 developed here with the LSS method of Wahba and Wendelberger and the bicubic tensor product Hermite method of Foley.

The comparisons made here should be viewed in the proper perspective since the use of TPS (or other radial basis function methods) is not efficient in the construction of surfaces when compared with tensor product methods such as Foley's. This is true even apart from cost of the knot selection process, which may be significant. Thus it makes little sense to compare them on the basis of cost alone. The situation in which we envision the use of our method to be viable is one in which we expect difficulties (amounting to failure) with tensor product methods, such as those that may occur with greatly varying density of data. Such a case is mentioned in [3], and a solution within the context of least squares tensor product splines proposed. It is probable that there are situations in which the proposed solution would also fail, although we have not attempted to find any. In the case of such failures, one may be willing to make significant expenditures of computational effort to obtain a viable approximation. We believe our scheme is capable of being successful in many cases, and should be one of those available to users. No doubt the knot selection process should often be implemented as a preprocessing phase.

The dependent variable values of the experimental data sets were generated in two ways: (1) using a known function, and (2) contaminating the known function by the injection of independent, identically distributed normal random errors with a composite standard deviation of 0.05. In the first case, we would expect the RMS error on the data points and on the grid to be about the same, and to decrease as the number of knot points used to represent the data is increased.

In the contaminated case, the dependent variable at each data point is the sum of the unknown underlying function value and the error function value so that the difference between the constructed surface and the "true" surface is mainly attributable to the presence of error in the data. In the best situation, we expect the RMS error in the residuals to match the composite standard deviation of the random error injected to obtain the contaminated data. At the grid points, we expect the RMS error to be smaller than the composite standard deviation, since the grid sample is larger (33×33) and the errors are distributed more evenly throughout the entire region of interest.

Some observations can be made regarding Tables 1–3. The general trend of the RMS error on both the data points and the grid is to diminish as the number of knot points is increased. As expected with the exact data, the RMS error of the residuals and the RMS error on the grid are roughly equivalent. For the contaminated data, the RMS error of the residuals roughly matches the composite standard deviation of the data, and the RMS error on the grid is smaller than the RMS error of the residuals, as expected. In Table 1, the errors over the grid increase as the number of knot points is increased, and that of the residuals' RMS is less than the RMS of the injected errors.

In this case, undersmoothing has occurred, and the surface is "drawing" toward the error.

In comparing least squares TPS to the smoothing spline method in the exact data case, we note that the smoothing spline method yields a residual RMS error of zero. This could be expected, since there is no error in the data and the spline of interpolation is chosen. On the grid, the RMS error is small. When the data is not contaminated, the RMS error of least squares algorithm only begins to become as small as that of the smoothing splines method when the number of knots used becomes large. We also note that in the 500 data point set, no comparison is made since a potential limit for computing smoothing splines is 200–300 data points.

Foley's method for the contaminated case gives errors nearly equal to the composite standard deviation injected into the data. However, on the grid, the least squares method does better, an indication that smoothing is occurring, as expected. We also note that an increase in the number of grid points does not significantly improve the RMS error in Foley's method, even though an increase in the number of knots in the least squares method usually yields improved results. We used the default local approximations in Foley's method, and we note that performance of the method may be improved by using lower degree local approximations to estimate the grid values to be used.

Figure 4 depicts hydrographic data collected in Monterey Bay, consisting of 1669 points with greatly varying density. Figure 4(b) shows the results of applying Algorithm 2.1 with 100 knots, and is particularly interesting because the density of the data is faithfully replicated by the knots. We note, however, that the assumption regarding the density of the data points being indicative of the dependent variable is not necessarily a viable one in this particular application of the algorithm. These results demonstrate the ability of Algorithm 2.1 to produce reasonably representative sets of knots.

We discuss one further example arising from a practical problem. The general problem occurs with some frequency in practice, and it is not clear what the best method is for handling such data. The data consists of digitized height contours of a glacier. The contours were very densely sampled, with a total of 8345 points available. The contours were thinned by taking every third point, since this resulted in almost uniform density over part of the region while still leaving evidence of the contours. Those within a certain square were then retained, giving the total of 873 points shown in Fig. 5(a). In order to obtain an example which is not unreasonable, and under which our procedure can be expected to give reasonable results while other methods may encounter difficulties, a number of contours were stripped out of the data to leave the set of 678 points shown in Fig. 5(b). Admittedly this is a contrived example and one made to illustrate difficulties that tensor product methods can have when there are voids in the data. It is a situation which may occur in practical problems, however, and the missing data gives an opportunity to validate behaviors. The knot selection process applied to the data of Fig. 5(b) with 100 knots then gave the results shown in Fig. 5(c).

Figures 6(a) and (b) show the results when Foley's method (a 10×10 grid was used) is applied to the data of Figs. 5(a) and (b), and Fig. 6(c) shows the least squares TPS using the knots in Fig. 5(c). Figure 6(b) shows the potential misbehavior of tensor product methods in voids, while the TPS in Fig. 6(c) is well behaved. Outside of these regions the behavior of the methods is quite similar, although both Figs. 6(b) and (c) show that the details at the rear edge of the surface are incorrect because of the missing data. The RMS value of the residuals is comparable in the three cases: 5.2, 5.1, and 5.7, respectively (the contour interval is 25).

4. Conclusions. Again, we emphasize that we envision this scheme to be a useful one when other less costly schemes perform poorly or cannot be used because of the large systems of equations that must be solved. In particular, our scheme does not place knots in data deserts, avoiding the necessity of providing special handling for such cases. We caution that the search for a best knot configuration can be rather

expensive. For a large number of data points with a moderately large number of knot points, such as our last two examples, the computations took up to an hour on an IBM 3033 computer. We are investigating ways of speeding up Algorithm 2.1. One idea we are pursuing is to use a method of simulated annealing along with a simpler search process. Again, the results are dependent on the initial guess, although they generally look quite good for any reasonable initial guess. It may be viable to incorporate a divide and conquer scheme such as that suggested in [14] for clustering problems using k-means. In our situation, only a good set of knots is needed, and it is unclear whether great efforts will be worthwhile since the criteria are only based on reasonable, and not rigidly correct, assumptions.

NUMERICAL APPROXIMATION OF PARAMETRIC ORIENTED AREA-MINIMIZING HYPERSURFACES*

HAROLD R. PARKS†

Abstract. A numerical method for finding a function nearly minimizing the gradient integral among functions having given boundary data is described. Such functions can be used to approximate parametric oriented area-minimizing hypersurfaces. Results of using this method are presented.

Key words. least gradient method, area-minimizing surfaces, area-minimizing currents, functions of least gradient

AMS(MOS) subject classifications. 65N99, 49Q05, 49-04

1. Introduction. This paper presents the results of what we believe to be the first successful implementation of a numerical method for finding the solution to the least area problem without restricting the topological type of the surfaces considered.

The problem of finding a surface of least area with given boundary was first investigated by Lagrange [L] in the mid-eighteenth century. Since that time, the least area problem and the related study of minimal surfaces and their generalizations have captured the interest of many mathematicians. Often the attention given to the subject is motivated solely by its beauty; however, there are connections to physical problems, and practical applications have arisen. Soap films provide the most well known physical realization of the least area problem, but other related physical problems are Tschaplygin gas flows and nonlinear elasticity theory. The reader should consult the introduction of Nitsche's book [NJ] and the references mentioned there for a more complete discussion.

Only in very special circumstances can one analytically compute the area-minimizing surface which spans a given boundary. Thus for many years, going back at least to 1928 when Jesse Douglas published a paper on the subject [DJ], there has been interest in numerical methods for approximating area-minimzing surfaces. In case the area-minimizing surface being sought is not the graph of a function, i.e., is parametric, there is no analytical method to determine in advance even such a gross characteristic of the surface to be approximated as its topological type. This can be a significant difficulty, because it seems to be more natural for a numerical method to lessen the topological complexity of a surface as the method proceeds than it is to increase the complexity. In [PH1] and [PH2], the author has developed the theoretical basis for a method for numerically approximating parametric oriented area-minimizing hypersurfaces which can be applied without prior knowledge of the topological type (or, for higher dimensions, the singularity structure) of the minimizing surface. Indeed, the applications described in this paper show that the method will, in practice as well as in theory, produce surfaces with the needed topological complexity even if the starting data consists of only topologically trivial surfaces.

The method from [PH1] and [PH2], which we will refer to as the *least gradient method*, is applicable in Euclidean space of any dimension, and it allows the approximation of a parametric oriented area-minimizing hypersurface spanning a given boundary,

provided that the given boundary is extreme in the sense that it lies on the bounding surface of a convex domain. The least gradient method is based on the fact that any level set of a function which minimizes the integral of the norm of its gradient is an area-minimizing hypersurface. This is a nontrivial theorem of Bombieri, De Giorgi, and Giusti [BDG, Thm. 1]. Underlying this result is the coarea formula [FH, 3.2.11], which, as a special case, states that the three-dimensional gradient integral is equal to the integral of the areas of the level sets,

$$\int_\Omega |Du| \, d\mathscr{L}^3 = \int \mathscr{H}^2[\Omega \cap u^{-1}(r)] \, dr,$$

where Ω is a domain in $\mathbb{R}^3$, $|Du|$ denotes the Euclidean norm of the gradient of u, $\mathscr{L}^3$ denotes Lebesgue measure, and $\mathscr{H}^2$ denotes two-dimensional Hausdorff measure. In particular, the least gradient integral is equal to the integral of the areas of the minimal surfaces with the appropriate boundary values. It turns out, as was shown in [PH1] and [PH2], that if a function only nearly minimizes the integral of the norm of its gradient, then its level sets can be used to approximate area-minimizing hypersurfaces.

This paper reports on the implementation of the least gradient method in the approximation of two-dimensional oriented parametric area-minimizing hypersurfaces in $\mathbb{R}^3$. To implement the least gradient method, the problem which must be solved numerically is a discrete approximation to the following.

$$\text{(1a)} \qquad \text{Minimize} \int_\Omega |Du| \, d\mathscr{L}^3$$

subject to the Dirichlet boundary condition

$$\text{(1b)} \qquad u = \varphi \text{ on } \partial\Omega,$$

where Ω is a bounded convex domain in $\mathbb{R}^3$. The boundary data φ in (1b) is chosen so that the one-dimensional system of curves we wish to span with an area-minimizing surface occurs as a level set of φ. The appropriate level set of the discrete approximation to the solution to (1a) and (1b) is then used as the approximation to the desired area-minimizing surface. We will apply the least gradient method to three examples.

(i) The surface to be approximated can be found analytically and is actually a graph, namely, a portion of Enneper's surface.

(ii) The surface to be approximated can be found analytically and is either two discs or a catenoid depending on the exact choice of boundary conditions.

(iii) The surface to be approximated cannot be obtained analytically (at least as far as we know) and the topological type is either that of two discs or an annulus depending on the exact choice of boundary conditions.

We remark here that in [PH1] and [PH2] certain strict assumptions were made about Ω in order to prove theorems of general applicability. One such theorem concerned the existence of a Lipschitzian function of least gradient satisfying the Dirichlet boundary condition. Here we will be solving specific problems. In each case we can easily give a proof of the existence of a Lipschitzian function of least gradient, so it is not significant that we have not worked precisely in the settings of the theorems in [PH1] and [PH2].

Various methods can be used to solve the numerical problem described above; one of the more promising methods has been investigated by Overton in [OM1] and [OM2]. In [OM1], Overton has proved the quadratic convergence of a method for minimizing a sum of Euclidean norms which, at each iteration, computes a direction of search by solving the Newton system of equations, projected, if necessary, into a linear submanifold. In [OM2], Overton has applied the method from [OM1] to the problem consisting of (1a), (1b), and an additional constraint, but with Ω a domain in $\mathbb{R}^2$; in that case, the minimization problem arose from collapse load analysis (see [SG]). While it was noted in [OM2] that the hypotheses required for the theorems in [OM1] were not satisfied, the numerical results obtained were nonetheless in close agreement with known exact solutions. We have set up our discretization so that Overton's method can be applied; however, our experience in applying Overton's method to our problem has been less sanguine than in [OM2]. Indeed it has proved essential to use search directions other than those arising from the Newton system. The difficulties here are still not fully understood.

To apply Overton's method in [OM2] without making prohibitive demands on the machine memory certain technical details were essential. (Specifically, in the notation of [OM2], the problem is storing and factoring $\tilde{A}$.) The same difficulty arises here. A major portion of the exposition in this paper deals with this. It is most efficient to assume the reader is familiar with [OM2] and limit ourselves to discussing the modifications needed.

2. Discretization. The domain Ω will be an open subset of the unit cube in $\mathbb{R}^3$. The unit cube, denoted by C, will be tessellated by subdividing the cube into $(k-1)^3$ congruent subcubes and then dividing each such subcube into six quadrirectangular tetrahedra. (In Fig. 1, the six tetrahedra are illustrated.) The fact that each tetrahedron has three mutually orthogonal edges turns out to be crucial. In that sense this subdivision of the cube, which was well known to many (see for example [TG]), is the generalization of the subdivision of the square into two right triangles; once this three-dimensional subdivision has been done, it is fairly easy to see that this construction can be continued to any dimension.

The total number of mesh points will be

$$n = k^3. \tag{2}$$

Note that k is the number of mesh points which lie on the x axis, and

$$h = 1/(k-1) \tag{3}$$

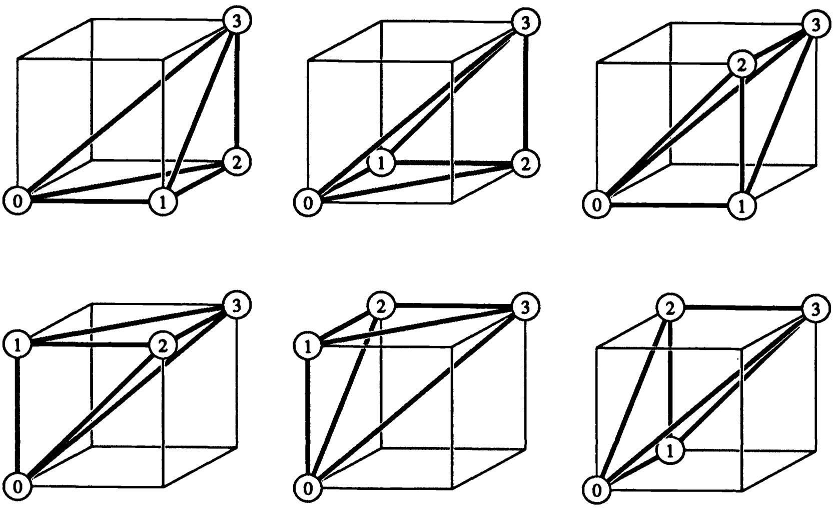

FIG. 1. *Decomposition of the cube.*

is the edge length of the subcubes, or mesh size. We will denote the mesh points by $X_1, X_2, \cdots, X_n$. The function φ will be assumed extended to $C \sim \Omega$. The function u in (1) will be replaced by a piecewise linear finite element approximation $\mathfrak{v}$, which is to agree with φ at mesh points in $C \sim \Omega$. Thus we obtain a finite-dimensional optimization problem for which the variables are the function values $\mathfrak{v}(X_i)$ at the given mesh points lying in Ω.

There are

$$m = 6(k-1)^3$$

tetrahedra in this tessellation of the unit cube. We will denote the tetrahedra by $T_1, T_2, \cdots, T_m$. The vertices of T_i will be denoted by

$$X_{\gamma(0,i)}, X_{\gamma(1,i)}, X_{\gamma(2,i)}, X_{\gamma(3,i)}.$$

We will assume that (as illustrated in Fig. 1), for each i, the vectors from $X_{\gamma(0,i)}$ to $X_{\gamma(1,i)}$, from $X_{\gamma(1,i)}$ to $X_{\gamma(2,i)}$, and from $X_{\gamma(2,i)}$ to $X_{\gamma(3,i)}$ are pairwise orthogonal and are, in fact, simply nonzero multiples of the standard basis vectors. Since $\mathfrak{v}$ is piecewise linear over this tessellation, the components of its gradient on T_i multiplied by the volume of T_i (i.e., $h^3/6$) are, possibly in some other order,

$$(\mathfrak{v}(X_{\gamma(1,i)}) - \mathfrak{v}(X_{\gamma(0,i)}))(h^2/6),$$
$$(\mathfrak{v}(X_{\gamma(2,i)}) - \mathfrak{v}(X_{\gamma(1,i)}))(h^2/6),$$
$$(\mathfrak{v}(X_{\gamma(3,i)}) - \mathfrak{v}(X_{\gamma(2,i)}))(h^2/6).$$

We now define a vector $v \in \mathbb{R}^n$ by setting $v_i = \mathfrak{v}(X_i)$, and we form a matrix A_i of dimension $n \times 3$ with

$$A_{i,\gamma(1,i),1} = A_{i,\gamma(2,i),2} = A_{i,\gamma(3,i),3} = h^2/6,$$
$$A_{i,\gamma(0,i),1} = A_{i,\gamma(1,i),2} = A_{i,\gamma(2,i),3} = -h^2/6,$$

and all other entries equal to zero. Note that the matrix A_i has only two nonzero entries in each column and those entries add to zero; this is a consequence of the fact that each tetrahedron in the tessellation has a set of three mutually perpendicular edges. This special structure of A_i turns out, as will be seen later, to be crucial to solving the problem economically. (It is also an economy that A_i need not be saved separately for each i, since it is readily constructed from γ.) Using the matrix A_i, we see that

$$\int_{T_i} |D\mathfrak{v}| \, d\mathscr{L}^3 = |A_i^T v|,$$

so that minimizing the integral of the gradient of $\mathfrak{v}$ over Ω is equivalent to the following problem:

$$\text{(4a)} \qquad \text{Minimize } F(v) = \textstyle\sum_i |A_i^T v|$$

over vectors $v \in \mathbb{R}^n$ which satisfy the boundary conditions

$$\text{(4b)} \qquad v_i = \varphi(X_i) \text{ if } X_i \text{ is not an interior point of } \Omega.$$

3. Adapting the algorithm. In solving the problem (4a), (4b), we will be following the procedure described in [OM2] which was, in turn, an adaptation of the algorithm proposed in [OM1]. As in [OM2] we set

$r_i(v) = A_i^T v$, the *residuals*,

$J(v) = \{i : |r_i(v)| = 0\}$, the *active set*,

$\hat{A}(v) = [A_{i_1}, A_{i_2}, \cdots]$, where $J(v) = \{i_1, i_2, \cdots\}$.

The problem (4a), (4b) is difficult because the gradient of the objective function, F, becomes discontinuous and the Hessian becomes unbounded whenever a residual vanishes. The idea of the algorithm is to project the objective function into the linear submanifold where zero residuals remain unchanged and where the boundary conditions (4b) are satisfied. In that space F is locally continuously differentiable. To accomplish this projection, we will construct a matrix Z consisting of a maximal set of independent n-dimensional columns such that

$$r_i(v+p)=r_i(v)=0 \quad \text{if } i\in J(v) \quad \text{and} \quad p\in \mathcal{R}(Z), \tag{5}$$

where $\mathcal{R}(Z)$ is the span of the columns of Z (i.e., the range space of Z). The requirement (5) of maintaining zero residuals is expressed by

$$\hat{A}^TZ=0,$$

but to incorporate the boundary conditions we must add columns to $\hat{A}$. For each boundary vertex X_r we add a column which has a one in the rth row and has zeros for all its other entries; this matrix is denoted by $\tilde{A}$. To maintain the zero residuals and satisfy the boundary conditions we require

$$\tilde{A}^TZ=0. \tag{6}$$

In [OM1], the matrix $\tilde{A}$ was assumed to be of full rank and the required Z was to be found by QR factorization. In our situation, as in [OM2], $\tilde{A}$ may quite well be rank deficient, and, in any case, n will surely be too large for storing and factoring $\tilde{A}$ to be practical. It is in getting around this difficulty that the special form of $\tilde{A}$ comes into play.

Definition. (i) Denote by $\mathfrak{A}=\mathfrak{A}_{n,l}$ the collection of $n\times l$ matrices such that each column contains at most two nonzero entries, and if a column does contain two nonzero entries, then they add to zero.

(ii) For $A\in\mathfrak{A}$, we define an equivalence relation, $\stackrel{A}{\sim}$, on $\{1,2,\cdots,n\}$ by setting

$i\stackrel{A}{\sim}j$ if and only if there exists a sequence i_1,
$i_2,\cdots,i_r$, with $i=i_1, j=i_r$, such that the i_lth row and the i_{l+1}st row each
have a nonzero entry in the same column, for $l=1,2,\cdots,r-1$.

The equivalence class of i will be denoted $\{i\}$.

(iii) An equivalence class $\{i\}$ will be called *null* if there is $j\in\{i\}$ such that the jth row of A contains a nonzero entry which is the only nonzero entry in its column.

(iv) Given $A\in\mathfrak{A}$ we construct $Z=Z_A$ as follows:

For each equivalence class $\{i\}$ which is not null include in Z a column which has a one in the jth row if and only if $j\in\{i\}$ and for which all other entries of the column are zeros.

With these definitions made, the following lemma should be obvious.

Lemma. *If $A\in\mathfrak{A}$, then $Z=Z_A$ is a maximal rank matrix such that $A^TZ=0$.* The main consequence of this lemma is that if we apply it to $\tilde{A}$, then the required maximal rank Z satisfying (6) is easily constructed. In fact, $\tilde{A}$ and Z can be represented as linked lists as was done in [OM2]. The remaining discussion of the adaptation of the algorithm from [OM1] is exactly as in [OM2].

4. Degeneracy. It was indicated in [OM2] that the most difficult step in adapting the algorithm from [OM1] to the problem (1a), (1b) was the check on optimality. The difficulty is referred to as *degeneracy*. A vector v that is optimal on the restricting submanifold may not be optimal in the whole space. This seems to occur in our applications in which a nonunique solution to the area-minimization problem leads to a so-called *lens*: the region in between two area-minimizing surfaces on which the function of least gradient is constant.

Since we must obtain a global optimal solution we have employed a *relaxation* method to reduce the objective function further once the optimality condition holds on the restricted manifold. We do a simple minimization varying each component of v separately. Since there are many components this is obviously slow. One efficiency is that any specific mesh point is a vertex of only 24 tetrahedra, so it is only necessary to compute a small part of the objective function. We have used the Golden Section Search [NR, 10.1] to accomplish the one-dimensional minimization.

In § 4.6 of [OM1], Overton comments that it is unlikely that a residual will be mistakenly set to zero. Essentially, this is because a set of codimension two or higher does not disconnect space. Apparently this intuition is misleading, because it has been necessary, in the problems involving a change in topological structure from initial data to optimal data, to apply the relaxation method to get off the restricted manifold.

5. Numerical results. There are situations in which it is possible to calculate analytically the exact solution to a least gradient problem. The simplest such situation is when the boundary data is the restriction of a linear function. This trivial case was useful for debugging.

5.1 As our first nontrivial test, we have used our method to approximate a portion of Enneper's surface. Since an exact parametrization is available (see [BC]) we can readily estimate the accuracy of our approximation. Specifically, we use the portion of the surface parametrized by

$$\begin{aligned} x &= 3(u - \tfrac{1}{3}u^3 + uv^2),\\ y &= \tfrac{1}{4} + 3(-v + \tfrac{1}{3}v^3 - u^2 v),\\ z &= .43 + 3(u^2 - v^2), \end{aligned}$$

which lies in the unit cube; the surface has purposely been positioned so as not to be symmetric. Supposing the part of the above surface which lies in the unit cube is given nonparametrically by

$$z = \psi(x, y),$$

we can easily and rapidly determine $\psi(x, y)$ numerically by solving for (u, v) through the iteration

$$\begin{aligned} u_0 &= 0, \qquad v_0 = 0\\ u_{n+1} &= \tfrac{1}{3}x + \tfrac{1}{3}(u_n)^3 - (u_n)(v_n)^2,\\ v_{n+1} &= -\tfrac{1}{3}(y - \tfrac{1}{4}) + \tfrac{1}{3}(v_n)^3 - (u_n)^2(v_n). \end{aligned}$$

One can then verify that the height of the surface varies from about .2 to about .8.

TABLE 1
Approximation to Enneper's surface.

k	n	Initial F	Final F	Error	Ratio of error to mesh size
7	343	1.1029466511	1.0746701779	.0045223315	.0271340

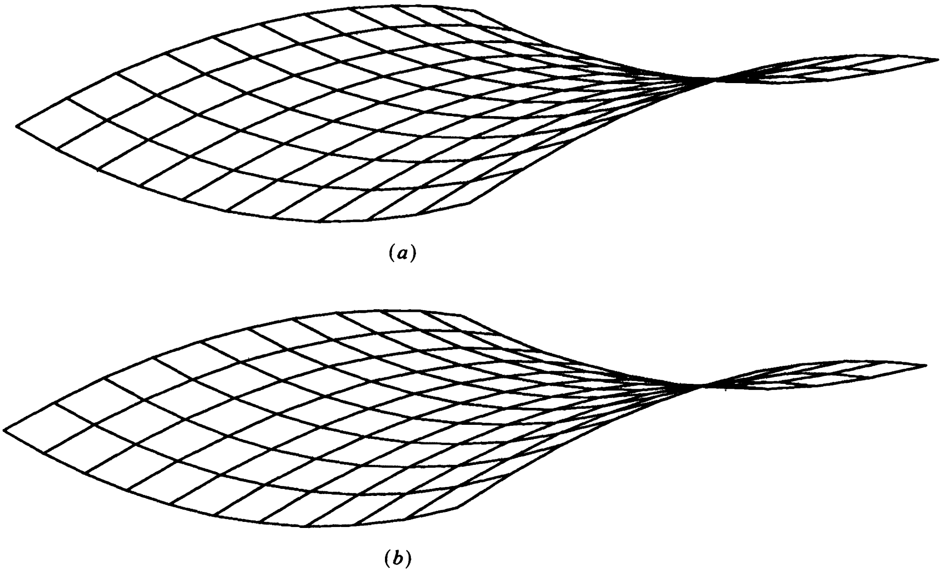

FIG. 2. (a) *Enneper's surface by the usual formulas*; (b) *Enneper's surface by the least gradient method.*

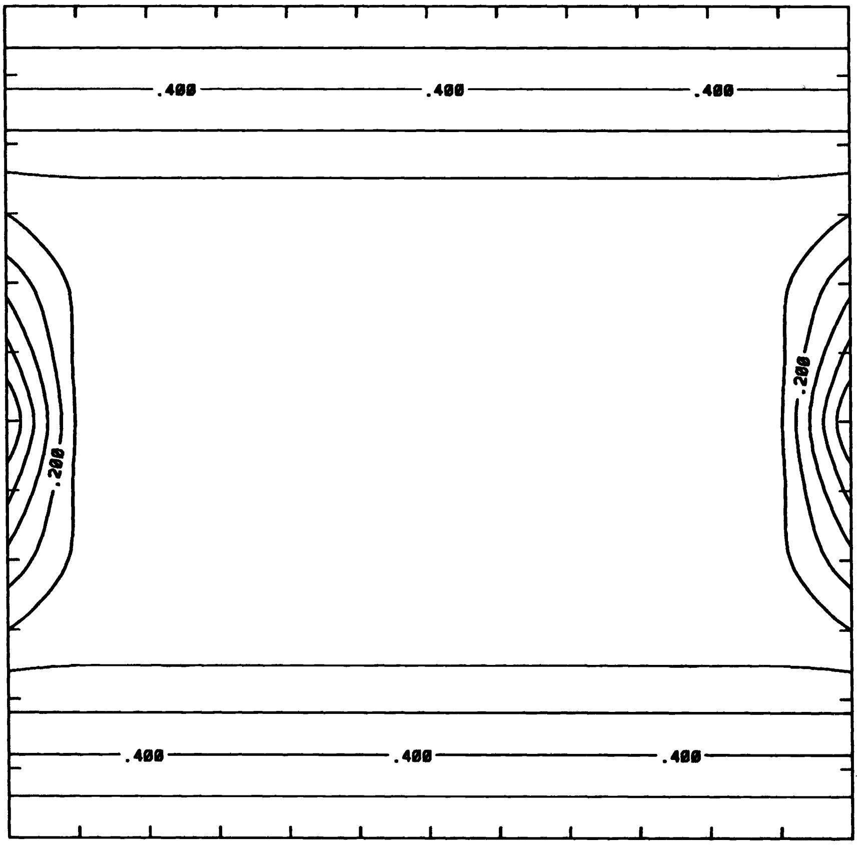

FIG. 3. *Level curves for cross section of exact solution to the catenoid problem.*

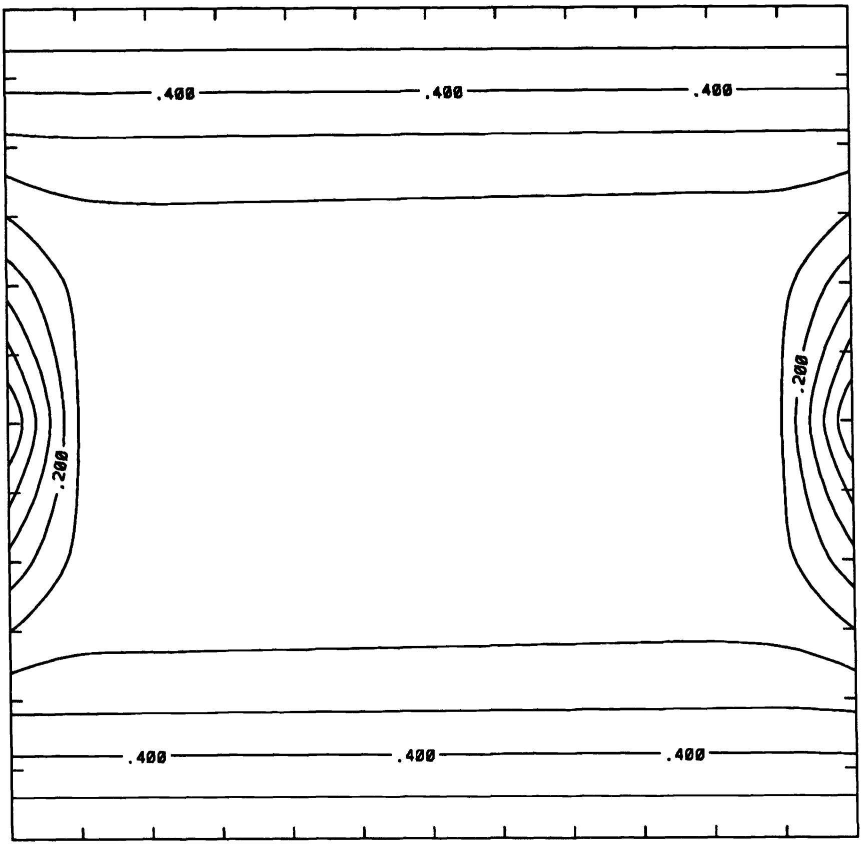

FIG. 4. *Level curves for cross section of approximate solution to the catenoid problem.*

The Dirichlet data imposed on the unit cube for the least gradient problem were chosen to be zero on the base of the unit cube, one on the top of the unit cube, and one-half on

$$\{(x, y, \psi(x, y)): xy(1-x)(1-y) = 0\}.$$

The values at the remaining boundary points were smoothly interpolated in such a way as to be increasing in the z-direction. The solution to the least gradient problem with such boundary values would necessarily be increasing in the z-direction, but we know of no method for obtaining the solution analytically. The starting data was the extension of the boundary data construction, but with a random term added.

The results of this test are summarized in Table 1. In that table, k is the number of grid points on each axis, n is the total number of grid points as in (2), and F is as in (4a). In each case the computed approximation to u was increasing in the z-direction. Linearly interpolating between grid points along lines parallel to the z-axis, we located the level where the function had the value $\frac{1}{2}$. That defines our computed approximation to ψ. The error is the maximum of the absolute value of the difference between ψ and the computed approximation to ψ, the maximum being taken over all grid points in the unit square in the x,y-plane. As a measure of the accuracy, we have compared the error with the mesh size, h.

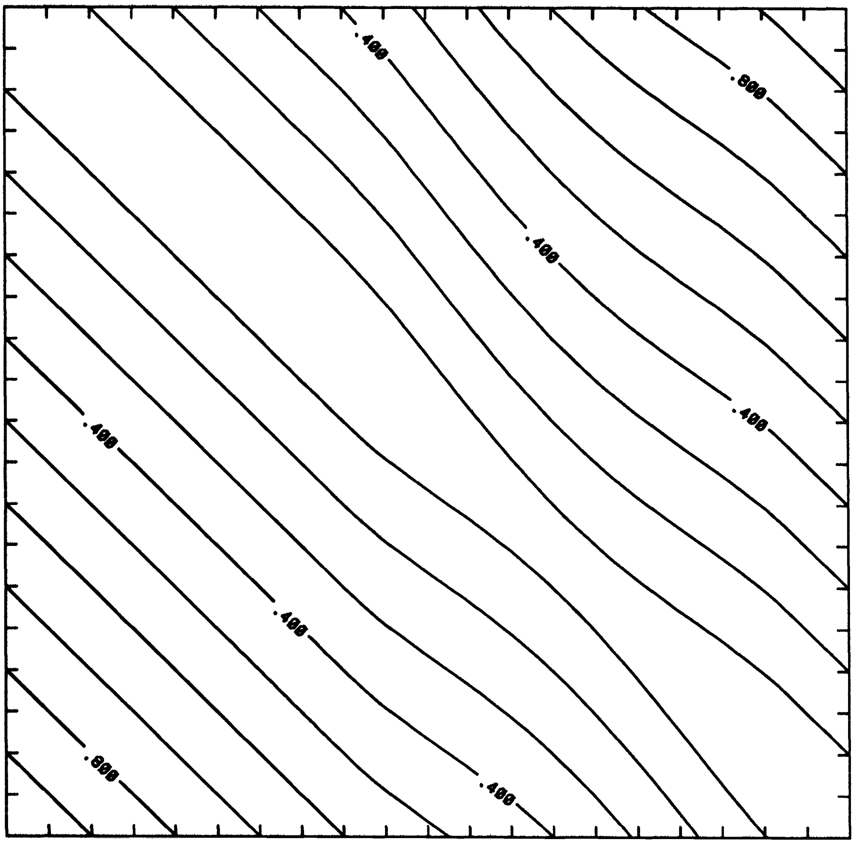

FIG. 5. *Level curves for cross section of initial guess for the problem which is not analytically solvable.*

In Fig. 2, we have used the NCAR Graphics routine EZSRFC to illustrate the portion of Enneper's surface and the approximation obtained by our method; they are visually indistinguishable.

5.2. Of course, for a nonparametric problem such as that illustrated in § 5.1, a numerical method was developed over sixty years ago by Douglas [DJ] which might well be just as fast and accurate and is certainly much faster and easier to program, but the most important attribute of our method is that it does not require a priori knowledge of the topological type of the solution. To illustrate and test this our second nontrivial problem involved the transition from two discs to the catenoid. In this case, all mesh points (x, y, z) at distance greater than or equal to one-half from the line $\{(\frac{1}{2}, \frac{1}{2}, t) : t \in \mathbb{R}\}$ will be assigned a fixed value, namely, $|z-\frac{1}{2}|$. The transition from catenoid to plane solution should occur at $|z-\frac{1}{2}|$ approximately equal to .264 (a better estimate of this is .2638987).

The function, u, of least gradient with the values $|z-\frac{1}{2}|$ on the boundary of the cylinder

$$\Omega = \{(x, y, z) : (x-\tfrac{1}{2})^2 + (y-\tfrac{1}{2})^2 < \tfrac{1}{4}, 0 < z < 1\}$$

can be directly evaluated at each point by solving a few analytic equations. To each

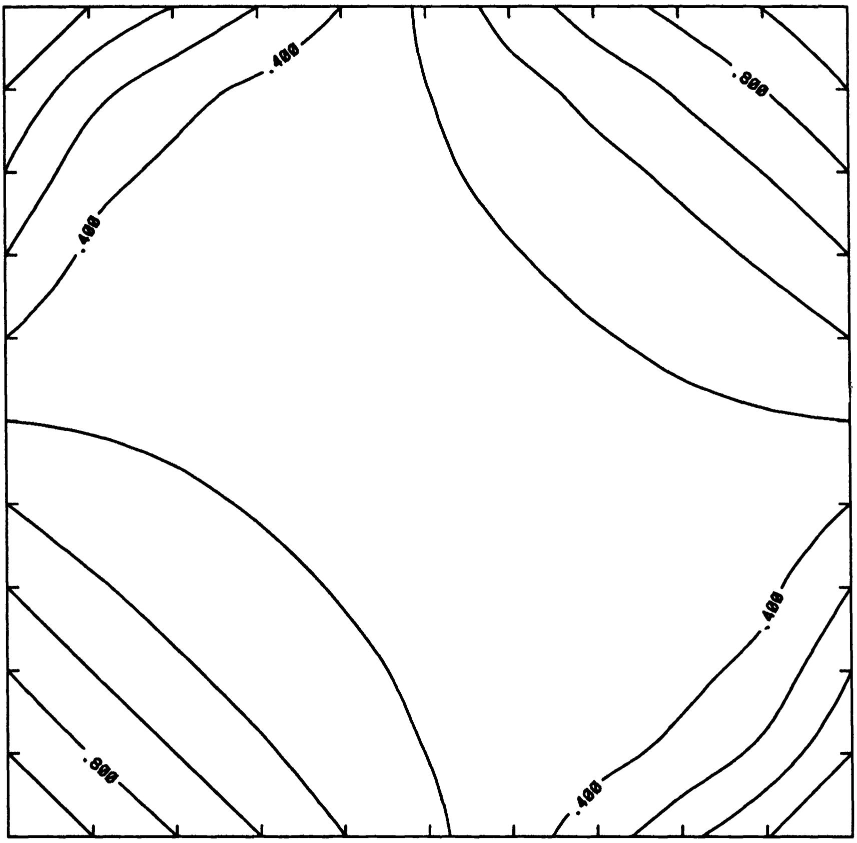

FIG. 6. *Level curves for cross section of approximate solution to the problem which is not analytically solvable.*

point (x, y, z) we associate

$$r=[(x-\tfrac{1}{2})^2+(y-\tfrac{1}{2})^2]^{1/2}$$

and

$$h=z-\tfrac{1}{2}.$$

Recall that the equation of a catenoid is

$$\lambda r=\cosh(\lambda h),$$

where λ is a parameter that we can choose. We find the transition from discs to catenoid by finding λ^* and $h^*>0$ such that

$$\lambda^*\tfrac{1}{2}=\cosh(\lambda^* h^*)$$

and the area of the catenoid, with parameter λ^*, between $h=-h^*$ and $h=h^*$ is equal to the area of two discs of radius $\frac{1}{2}$. Given any $(x, y, z)\in\Omega$, we evaluate u as follows. (i) If $|h|\geqq h^*$, then $u(x, y, z)=|z-\frac{1}{2}|$, (ii) if $|h|<h^*$, then we let r^* be the solution of

$$\lambda^* r^*=\cosh(\lambda^* h),$$

and in case $r\leqq r^*$ we have $u(x, y, z)=h^*$, while in the case $r>r^*$ we solve for λ in $\lambda r=\cosh(\lambda h)$ and set $u(x, y, z)$ equal to the solution of $\lambda\frac{1}{2}=\cosh(\lambda u)$.

In Fig. 3, we have sketched, using the NCAR Graphics routine CONREC, the level sets of $u(x, \frac{1}{2}, z)$ in the plane $\{(x, \frac{1}{2}, z) : x, z \in \mathbb{R}\}$. The presence of the lens does tend to confuse the level set routine, so we have chosen parameters for the routine which give a nice looking diagram for the known analytic solution; we have continued to use the same parameters in diagramming the approximation. The starting data we have used is equal to $|z - \frac{1}{2}|$ at (x, y, z); with that data the level sets are all discs. In this test the use of the relaxation method to get off the restricting manifold was essential. In Fig. 4, we show the contour lines from the approximate solution. Note that the topological type has become more complex, as it should.

5.3. In this case, we have taken Ω to be the entire unit cube and the boundary data is given by

$$\varphi(x, y, z) = |x + y + z - \tfrac{3}{2}| + \varepsilon(x, y),$$

where

$$\varepsilon(x, y) = \exp\left[-1/\left(\tfrac{1}{3} - 3(x-\tfrac{2}{3})^2 - 4(y-\tfrac{1}{2})^2\right)\right], \qquad \text{if } \tfrac{1}{3} - 3(x-\tfrac{2}{3})^2 - 4(y-\tfrac{1}{2})^2 > 0,$$

$$\varepsilon(x, y) = 0, \text{ otherwise.}$$

We would suspect that there must be a transition from the topological type of the disc to the topological type of the catenoid; however, there does not seem to be any analytic method to determine exactly where it occurs or to find the catenoid type solutions. (We would have used simply $|x+y+z-\frac{3}{2}|$ for the Dirichlet data, but it is conceivable that the function of least gradient could have been obtained analytically, since the minimal surfaces involved would all have polygonal boundaries. Of course, such a computation would be very difficult.) We have used our approximation method to approximate $u(x, y, z)$. The contours of the cross section $u(x, \frac{1}{2}, z)$ are sketched for the initial guess in Fig. 5 and for the function approximately of least gradient in Fig.

6. Figures 7 and 8 illustrate the level sets with value .25 and .30, respectively, from the same point of view. We emphasize that the topological type was not provided as part of the initial information, but is rather a result obtained from the computation.

Since in this final case, the exact solution is not known, the accuracy, as approximations of minimal surfaces, of the final surfaces pictured is also not known. In [PH1] and [PH2] it was proved that between two appropriate level sets there is a minimal surface, but the estimates from those papers are for the worst case and would require too large a value of k (recall k is the number of mesh points on each axis). Computations were terminated when the decrease in the gradient integral, especially as compared to the change in v, became sufficiently small. (In calling the subroutine that implements Overton's method for minimizing the sum of norms, we used the tolerance $\varepsilon_{PG} = 10^{-8}$ for the norm of the projected gradient.) The value of k was started at 7 and increased by interpolating from the results of the previous run. Final termination occurred when an adequate value of k was reached. Typically, $k = 11$ was enough to produce a smooth appearing contour plot for a cross section, while $k = 15$ was enough to produce a smooth appearing level set. For all practical purposes, our system limited us to $k \leqq 25$.

Acknowledgments. The author would like to thank Michael Overton for his generous assistance, including giving the author access to the FORTRAN code used to produce the numerical results presented in [OM1] and [OM2]. Further, the author would like to thank Jon Pitts and David Hendricks for their assistance with the computational work. The referee also deserves thanks for his or her careful work and helpful comments. Finally, the author would like to thank Frederick Almgren for applying gentle, but continual, pressure.

NONLINEAR MULTIGRID APPLIED TO A ONE-DIMENSIONAL STATIONARY SEMICONDUCTOR MODEL*

P. M. DE ZEEUW†

Abstract. The nonlinear multigrid method is applied to a transistor problem in one dimension. A weak spot in the linearization of the well-known Scharfetter-Gummel discretization scheme is reported. Further, it is shown that both the residual transfer and the solution transfer from a fine to a coarse grid need special requirements due to the rapidly varying problem coefficients. Some modifications are proposed which make the multigrid algorithm perform well for the hard example problem.

Key words. semiconductor equations, multigrid methods

AMS(MOS) subject classifications. 65N20, 65H10

1. Introduction. There is a great demand for a proper numerical simulation of semiconductors in order to reduce the costs of constructing expensive prototypes. The search for a fast and robust algorithm has proven to be a challenge. So far only a few papers have considered the multigrid solution of the discrete semiconductor equations (e.g., see [1], [2], [6], [9], [13]) and therefore extensive further research is required.

In this paper we restrict ourselves on purpose to one space dimension as a preparatory study for the case of more space dimensions. We study a particular example problem which has been put forward by Schilders (Philips, the Netherlands). This problem models a transistor and turns out to be much harder to solve than the forward or reversed biased diode problem. We apply the nonlinear multigrid method and encounter a serious difficulty due to the nonlinearity of the problem. Some modifications are proposed which significantly increase the robustness of the nonlinear multigrid method and which look promising also for the higher-dimensional case.

2. The problem. The behavior of a steady semiconductor device can be described by the following set of equations (cf. [10]):

$$\nabla(-\varepsilon\nabla\psi)=q(p-n+D), \tag{2.1a}$$

$$\nabla J_n=+qR, \tag{2.1b}$$

$$\nabla J_p=-qR, \tag{2.1c}$$

where J_n and J_p are defined by

$$J_n=q\mu_n\left(\frac{1}{\alpha}\nabla n-n\nabla\psi\right), \tag{2.2a}$$

$$J_p=-q\mu_p\left(\frac{1}{\alpha}\nabla p+p\nabla\psi\right). \tag{2.2b}$$

Substitution of (2.2) into (2.1) results in a system of three nonlinear partial differential equations for ψ, n, and p. In (2.1) ψ represents the electrostatic potential, p and n describe the concentration of holes and electrons, respectively. Equations (2.1b) and (2.1c) are called the continuity equations, J_n is the electron current density, J_p is the hole current density, and R is the recombination-generation rate, a function of n and p. The doping profile D is a function of the space variable x. The quantities ε, q, α,

* Received by the editors June 21, 1989; accepted for publication (in revised form) November 14, 1990.

† Centre for Mathematics and Computer Science, P.O. Box 4079, 1009 AB Amsterdam, the Netherlands.

μ_n, μ_p represent the permittivity, the elementary charge, the inverse of the thermal voltage, and the electron and hole mobility, respectively.

In this paper we consider the case of only one space dimension and assume ε, α, μ_n and μ_p to be constant. It is common practice to replace the variables n and p by the hole and electron quasi-Fermi potentials ϕ_n and ϕ_p defined by the relations

$$\text{(2.3a)} \qquad n = n_i\, e^{\alpha(\psi-\phi_n)},$$

$$\text{(2.3b)} \qquad p = n_i\, e^{\alpha(\phi_p-\psi)}.$$

On the one hand, by this change of variables, the nonlinearity of the problem is strongly increased, on the other hand the values assumed by (ψ, ϕ_n, ϕ_p) are in a much more moderate range. For extensive discussions on the choice of variables see [9], [10]. Using (2.3) the equations (2.1) are transformed into

$$\text{(2.4a)} \qquad -\nabla J_\psi = n_i q(e^{\alpha(\phi_p-\psi)} - e^{\alpha(\psi-\phi_n)}) + qD,$$

$$\text{(2.4b)} \qquad -\nabla J_n = +qR,$$

$$\text{(2.4c)} \qquad -\nabla J_p = -qR,$$

where J_ψ is defined by

$$\text{(2.5a)} \qquad J_\psi = \varepsilon \nabla \psi,$$

and J_n, J_p are now defined by

$$\text{(2.5b)} \qquad J_n = \bar{\mu}_n\, e^{\alpha(\psi-\phi_n)} \nabla(\alpha\phi_n),$$

$$\text{(2.5c)} \qquad J_p = \bar{\mu}_p\, e^{\alpha(\phi_p-\psi)} \nabla(\alpha\phi_p),$$

with

$$\text{(2.5d)} \qquad \bar{\mu}_n = \frac{n_i q \mu_n}{\alpha}, \qquad \bar{\mu}_p = \frac{n_i q \mu_p}{\alpha}.$$

In this paper we adhere to the formulation (2.4)-(2.5).

2.1. A particular one-dimensional model problem. We will focus our attention to a particular (hard) one-dimensional model problem which has been supplied by Schilders [14]. Here the problem constants are

$$\text{(2.6)} \qquad \begin{array}{lll} \varepsilon = 1.035918_{10}^{-12}\ \text{As V}^{-1}\,\text{cm}^{-1}, & q = 1.6021_{10}^{-19}\ \text{As}, & \\ \mu_n = \mu_p = 500\ \text{V}^{-1}\,\text{s}^{-1}\,\text{cm}^2, & n_i = 1.22_{10}{}^{10}\ \text{cm}^{-3}, & \\ k = 1.38054_{10}^{-23}\ \text{V As K}^{-1}, & T = 300\ \text{K}, & \alpha = q/kT. \end{array}$$

The function R is given by

$$R = \frac{pn - n_i^2}{\tau(p+n+2n_i)}, \qquad \tau = 10^{-6}\ s.$$

The doping function D (in cm^{-3}) is given by

$$D(x) = 6_{10}{}^{15} + 6_{10}{}^{19} \exp(-(x/7.1_{10}^{-5})^2) - 2.15_{10}{}^{18} \exp(-(x/1.15_{10}^{-4})^2) + 1.1_{10}{}^{19} \exp(-((x-8_{10}^{-4})/1.3_{10}^{-4})^2).$$

The equations (2.4) are defined on the domain $\Omega = [0, 8_{10}^{-4}]$(cm). We have three contacts to our semiconductor device (the one-dimensional model of a transistor): the emitter (E), the basis (B) and the collector (C) (see Fig. 1).

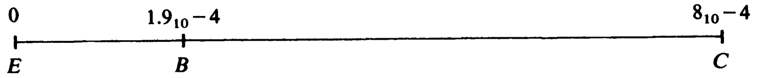

FIG. 1. *The contacts in the one-dimensional transistor problem.*

In Fig. 2 the doping function $D(x)$ is shown after the transformation $D \to sign(D)^{10}\log(1+|D|)$. Boundary conditions at the emitter E are:

(2.7a) $p-n+D=0$ (i.e., vanishing space charge),

(2.7b) $\phi_n = V_E$,

(2.7c) $J_p = 0$.

Boundary conditions at the basis B:

(2.8) $\phi_p = V_B = 0$.

Boundary conditions at the collector C:

(2.9a) $p-n+D=0$,

(2.9b) $\phi_n = V_C$,

(2.9c) $\phi_p = V_C$.

For fifteen different cases, each characterized by a pair of voltages (V_E, V_C), the solution is required (see Table 4.1). Figure 8 shows the solution-component ψ for the subsequent cases.

3. Discretization. At the outset of this section we give a short preview of its contents.

In order to abide by the law of conservation we use a finite volume technique based on the piecewise constant approximation of J_ψ, J_n, and J_p. As a consequence we arrive at a cell-centered version of the well-known Scharfetter-Gummel scheme [4], [9], [11]. We examine how the nonlinear discrete operator depends on the discrete solution.

3.1. Box integration. The interval $\Omega=(x_0, x_N)$ is split up into disjoint *boxes* $B_j=(x_{j-1}, x_j)$, $j=1\,(1)N$. A point x_j is called a *wall*, a point $x_{j-1/2}=(x_{j-1}+x_j)/2$ is called a *center*. The basis B is at the partition-wall between two boxes. Another set of

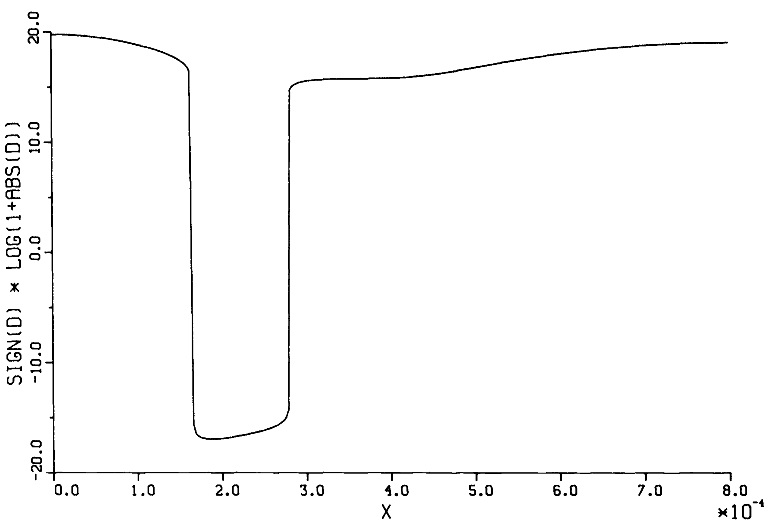

FIG. 2. *The doping profile.*

subintervals $\{D_j\}$ is defined by

$$\begin{aligned} D_0 &= (x_0, x_{1/2}), \\ D_j &= (x_{j-1/2}, x_{j+1/2}), \quad j = 1\,(1)N-1, \\ D_N &= (x_{N-1/2}, x_N). \end{aligned}$$

This set is called the set of *dual boxes.*

Now, by applying the Gauss divergence theorem in one dimension to (2.4) on the domains B_j we find

$$\begin{aligned} &-J_\psi\Big|_{x_{j-1}}^{x_j} - n_i q \int_{B_j} (e^{\alpha(\phi_p-\psi)} - e^{\alpha(\psi-\phi_n)})\, d\Omega = q \int_{B_j} D\, d\Omega, \\ (3.1)\qquad &-J_n\Big|_{x_{j-1}}^{x_j} - q \int_{B_j} R\, d\Omega = 0, \\ &-J_p\Big|_{x_{j-1}}^{x_j} + q \int_{B_j} R\, d\Omega = 0, \quad j = 1\,(1)N. \end{aligned}$$

We can write (3.1) in symbolic form as

$$(3.2)\qquad \mathcal{M}(\boldsymbol{q}) = f$$

where $\boldsymbol{q}$ denotes the vector $(\psi, \phi_n, \phi_p)^T$, $\mathcal{M}$ the nonlinear operator in the left-hand side of (3.1) and f the right-hand side of (3.1).

3.2. Box discretization. We introduce the variables $(\psi_j, \phi_{n,j}, \phi_{p,j})^T$, $j = 1\,(1)N$, which are associated with the centers $x_{j-1/2}$ of the boxes B_j. Let $\approx$ denote approximation by midpoint quadrature. We then define

$$\begin{aligned} &S_j \approx n_i q \int_{B_j} (\exp(\alpha(\phi_p - \psi)) - \exp(\alpha(\psi - \phi_n)))\, d\Omega, \\ &F_j \approx q \int_{B_j} D\, d\Omega, \\ (3.3)\qquad &R_j \approx q \int_{B_j} R\, d\Omega, \\ &j = 1\,(1)N. \end{aligned}$$

We make the assumption that J_ψ, J_n and J_p are piecewise constant on the dual set $\{D_j\}$ (see [4], [9], [11]) and correspondingly we use the notation $J_{\psi,j}$, $J_{n,j}$, $J_{p,j}$. By this assumption and applying (3.3) we arrive at the following discrete equations:

$$(3.4a)\qquad -J_{\psi,j} + J_{\psi,j-1} - S_j = F_j,$$

$$(3.4b)\qquad -J_{n,j} + J_{n,j-1} - R_j = 0,$$

$$(3.4c)\qquad -J_{p,j} + J_{p,j-1} + R_j = 0,$$

with

$$(3.5a)\qquad J_{\psi,j} = \varepsilon \frac{\psi_{j+1} - \psi_j}{x_{j+1/2} - x_{j-1/2}},$$

$$(3.5b)\qquad J_{n,j} = \bar{\mu}_n \frac{\exp(-\alpha\phi_{n,j+1}) - \exp(-\alpha\phi_{n,j})}{\exp(-\alpha\psi_{j+1}) - \exp(-\alpha\psi_j)} \cdot \frac{\alpha\psi_{j+1} - \alpha\psi_j}{x_{j+1/2} - x_{j-1/2}},$$

$$(3.5c)\qquad J_{p,j} = \bar{\mu}_p \frac{\exp(\alpha\phi_{p,j+1}) - \exp(\alpha\phi_{p,j})}{\exp(\alpha\psi_{j+1}) - \exp(\alpha\psi_j)} \cdot \frac{\alpha\psi_{j+1} - \alpha\psi_j}{x_{j+1/2} - x_{j-1/2}}.$$

At the emitter E, basis B, and collector C similar equations are obtained; for full details see [16]. Thus we have obtained the cell-centered version of the well-known Scharfetter-Gummel scheme (see [4], [9], [11]). Summarizing, we have discretized (2.4), together with the boundary conditions (2.7)-(2.9), into a set of $3N$ nonlinear equations (3.4) with the $3N$ variables ψ_j, $\phi_{n,j}$, $\phi_{p,j}$; $j=1\,(1)N$. We can write (3.4) in symbolic form as

$$\mathcal{M}_h(q_h)=f_h \tag{3.6}$$

where $\mathcal{M}_h$ denotes the nonlinear difference operator and f_h the right-hand side.

3.3. Properties of the discretized operator. In this subsection we study how the Jacobian of the nonlinear discrete operator $\mathcal{M}_h$ depends on the discrete solution. We assume the recombination term to be zero and confine ourselves to the dependency on ϕ_p. Results for ϕ_n can be derived analogously. We freeze the solution components ψ and ϕ_n and consider the ϕ_p-stencil, at box B_j, defined by the triplet

$$[stp(j,-1), stp(j,0), stp(j,+1)] \tag{3.7a}$$

with

$$stp(j,k)=\frac{\partial(-J_{p,j}+J_{p,j-1})}{\partial\phi_{p,j+k}}, \qquad k=-1,0,1. \tag{3.7b}$$

We introduce the notation

$$\Delta_j x \equiv x_{j+1/2}-x_{j-1/2},$$
$$\Delta_j\psi \equiv \psi_{j+1}-\psi_j$$

and the function $s(z):\mathbb{R}\to\mathbb{R}$ by

$$s(z)\equiv\frac{z}{e^z-1}. \tag{3.8}$$

By straightforward computation it can be verified that the following equalities hold:

$$stp(j,-1)=-\alpha\bar{\mu}_p \exp(\alpha(\phi_{p,j-1}-\psi_j))\frac{s(-\alpha\Delta_{j-1}\psi)}{\Delta_{j-1}x}, \tag{3.9a}$$

$$stp(j,0)=\alpha\bar{\mu}_p \exp(\alpha(\phi_{p,j}-\psi_j))\left\{\frac{s(-\alpha\Delta_{j-1}\psi)}{\Delta_{j-1}x}+\frac{s(\alpha\Delta_j\psi)}{\Delta_j x}\right\}, \tag{3.9b}$$

$$stp(j,+1)=-\alpha\bar{\mu}_p \exp(\alpha(\phi_{p,j+1}-\psi_j))\frac{s(\alpha\Delta_j\psi)}{\Delta_j x}, \tag{3.9c}$$

and

$$stp(j,0)=-(stp(j,-1)+stp(j,+1))+\alpha(-J_{p,j}+J_{p,j-1}). \tag{3.9d}$$

Because $s(z)>0$ for all z, it follows that

$$stp(j,-1)<0, \qquad stp(j,0)>0, \qquad stp(j,+1)<0, \tag{3.10}$$

so the ϕ_p-stencils correspond with an $\mathcal{L}$-matrix. Further, at the exact discrete solution, i.e., when $-J_{p,j}+J_{p,j-1}=0$ is satisfied, it follows from (3.9d) that

$$stp(j,0)=-(stp(j,-1)+stp(j,+1)),$$

so then the $\mathscr{L}$-matrix also possesses weak diagonal dominance (provided there is at least one stencil corresponding with a Dirichlet boundary condition, see [15]). However, in the middle of some iterative process to determine the solution, we may well have negative residuals so that (3.9d) implies the loss of diagonal dominance. Therefore ill-conditioning and numerical difficulties can be expected.

4. The Newton method and expedients. An obvious way of solving the set of nonlinear equations (3.6) is application of the Newton method. Because the Newton method is not globally convergent and the operator $\mathcal{M}_h$ is strongly nonlinear in the variables (ψ, ϕ_n, ϕ_p) we use two additional tools which are considered subsequently in this section:

(1) Correction transformation.

(2) Smoothing of the Newton-iterates.

It turns out that these expedients make the Newton method well applicable. Other modifications of the Newton method including inexact line searches and related techniques have been found to be reliable elsewhere (see [4]).

In two or more space dimensions direct application of the Newton method to (3.6) would involve large storage requirements and the solution of large linear systems. If well designed, a nonlinear multigrid algorithm holds out a prospect of both a computational complexity which is linear in the number of gridpoints and low storage requirements even for the case of two or more space dimensions. Therefore we want to apply the Newton method only for very coarse grids and we restrict the use of the Newton method as a *coarsest grid solver* for multigrid methods (§ 5).

4.1. Correction transformation. The correction transformation introduced by Schilders [10] is a device to transform the Newton-correction $(d\psi, d\phi_n, d\phi_p)$, computed by linearisation with respect to (ψ, ϕ_n, ϕ_p), into the correction for these very variables that would be obtained if linearisation were applied with respect to (ψ, n, p). Because the system in terms of (ψ, n, p) is much less nonlinear, a much better convergence behavior of the Newton method can be expected. By performing the calculations in terms of (ψ, ϕ_n, ϕ_p) and applying a transformation afterwards, we avoid complications due to the extremely wide range of values of n and p. In this way we take advantage of the benefits of both variable sets [9], [10], [14].

4.2. Smoothing. In § 4.1 we pointed out a technique to improve the global convergence behavior of the Newton method. Even yet difficulties are encountered when we apply the improved Newton method. As an example consider Fig. 3 which shows subsequent Newton iterates for case 12 starting from the solution for case 11.

The dips in the iterates are attended with very small pivot numbers while solving the linear systems. Section 3.3 explains the ill-conditioning whenever there is a large residual somewhere. Artificially increasing the main diagonal of the Jacobian turned out to be not efficient. Simply cutting off the correction at certain points is hardly justifiable because of lack of a more or less general criterion to do so. A more appropriate way of handling the phenomenon sketched above is to apply relaxation or smoothing sweeps at the beginning of the Newton process [9]. As a smoother the collective symmetric Gauss–Seidel relaxation (CSGS) can be used. It is called collective because at each box we solve collectively the three nonlinear equations which arise (employing Newton's method).

We will present here some numerical results to show the effect of smoothing. The grid is more or less uniform and satisfies $x_{N/4} = B$. The set of voltages $\{(V_E, V_C)\}$ for which a solution is required is defined in Table 4.1. For each case > 0 the solution of the previous case serves as a starting solution; in case 0 we start with $\phi_{n,j} = \phi_{p,j} = 0$,

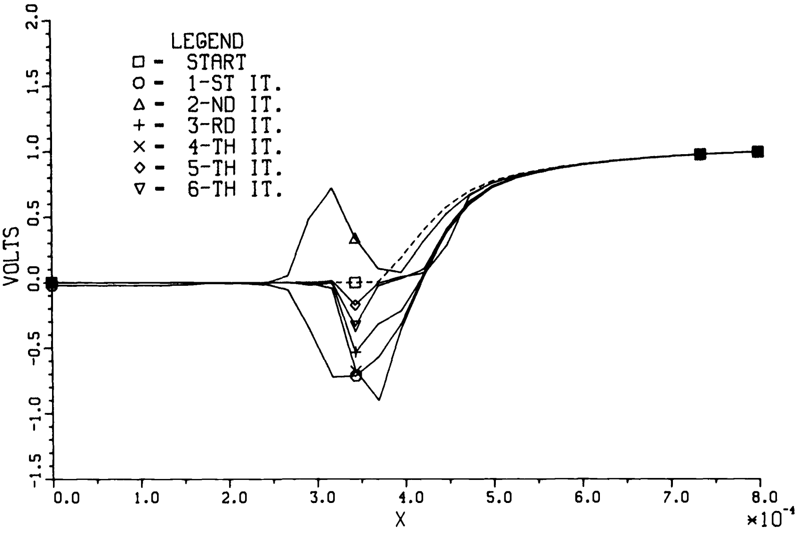

FIG. 3. *Subsequent Newton iterates of* ϕ_p.

13	−0.95	1
14	−1	1

for all j, and ψ is determined by assuming space charge neutrality. We use the correction transformation. For the solution of the linear systems we apply rowscaling followed by rowpivotting. Table 4.2 shows the number of Newton sweeps required to reach a correction with absnorm$<10^{-12}$, and the smallest pivot number encountered during the solution process. Table 4.2 also contains the results for the case when in addition a CSGS sweep is applied each time after a Newton-correction for which the infinity norm of the correction was larger than 0.1. This method will henceforth be referred to as Newton-CSGS. We observe that in the difficult cases 11–14 the application of smoothing sweeps has a positive effect on the efficiency and robustness of the Newton method. When smoothing is applied the smallest pivot numbers encountered keep a substantial distance from zero which shows that then the Jacobians generated within

TABLE 4.2

the Newton method are far from being singular (e.g., compare to case 12 in Table 4.2) and therefore no large dips in the Newton-corrections do occur. Experiments for $N=16$, 64, 128 show results similar to Table 4.2.

5. The multigrid method. More advanced ways of solving a set of nonlinear equations are the full approximation scheme (FAS) [5], and the nonlinear multigrid method (NMGM) [7]. Both *multigrid methods* are very similar although the NMGM is more general. The multigrid method has already found many specific applications in the fields of elliptic, parabolic, and hyperbolic equations and integral equations as well. Recently, also in the field of semiconductor equations research on multigrid methods has been initiated ([1], [2], [6], [9], [13]). If well applied, a multigrid method can be optimal in the sense that the rate of convergence is independent of the meshsize. An important advantage of the FAS/NMGM method is that no large linear systems need to be stored and solved. The subsequent stages of a usual FAS method, applied to (3.6), are

(1) Apply p nonlinear relaxation sweeps; thus we get an approximation q_h of the solution which has a *smooth* residual $d_h \equiv f_h - \mathcal{M}_h(q_h)$.

(2) Transfer q_h and d_h from Ω_h to a coarser grid Ω_H by means of the respective restriction operators R_H and $\bar{R}_H$.

(3) Solve (approximately) on Ω_H the equation $\mathcal{M}_H(q_H) = \mathcal{M}_H(R_H q_h) + \bar{R}_H d_h$.

(4) Interpolate the correction, computed on Ω_H, onto Ω_h and add the correction to q_h.

(5) Apply q nonlinear relaxation sweeps.

The combination of stages 2, 3, and 4 is called the coarse grid correction (CGC). Stage 3 may be obtained by applying a number of σ FAS cycles on the coarser grid. In this way a recursive procedure is obtained in which a sequence of increasingly coarser grids is used. In this paper we use $p=q=\sigma=1$ throughout. In the subsections to come we will define precisely the coarse grid correction and the grid transfer operators involved. In § 6 a significant improvement of the CGC will be introduced. It consists of a solution-dependent adjustment of the restriction of the residual d_h.

5.1. Nested boxes. Let a coarse grid Ω_H, a discretization of Ω, be given by the set of boxes $\{B_{H,j}\}_{j=1(1)N}$. From Ω_H we construct the next finer grid $\Omega_h=\{B_{h,j}\}_{j=1(1)2N}$ by division of each $B_{H,j}$ into two disjoint boxes $B_{h,2j-1}$ and $B_{h,2j}$. By repetition we obtain thus a sequence of increasingly finer grids. By definition all boxes are nested. Of course, the corresponding dual boxes are not nested. For all our numerical experiments in this paper we assume in addition that $B_{h,2j-1}$ and $B_{h,2j}$ have equal size.

5.2. Restriction operators. For the problem (3.2) on Ω, let S denote the domain and V the range of nonlinear operator $\mathcal{M}$. For each discretization on Ω_h, we have the spaces S_h and V_h, the discrete analogues of S and V.

Let the restriction operator for right-hand side functions

$$\bar{R}_h : V \to V_h \tag{5.1a}$$

be defined by

$$\bar{R}_h f = f_h, \tag{5.1b}$$

$$f_{h,j}=\int_{B_{h,j}} f\,d\Omega, \qquad \forall j \text{ at } \Omega_h. \tag{5.1c}$$

It follows for the next coarser grid that

$$(\bar{R}_H f)_j=(\bar{R}_h f)_{2j-1}+(\bar{R}_h f)_{2j}, \qquad \forall j \text{ at } \Omega_H. \tag{5.2}$$

By this equality, $\bar{R}_H$ can be defined also on V_h:

$$\bar{R}_H : V_h \to V_H, \tag{5.3a}$$

$$(\bar{R}_H f_h)_j = f_{h,2j-1}+f_{h,2j}, \qquad \forall j \text{ at } \Omega_H. \tag{5.3b}$$

The restriction operator for solutions

$$R_h : S \to S_h \tag{5.4}$$

may be defined by the well-known full weighting operator [5].

5.3. Prolongation/interpolation. A prolongation transfers a solution from a coarse grid to a finer one:

$$P_h : S_H \to S_h. \tag{5.5}$$

A common and simple choice for the prolongation should be linear interpolation. However, two objections against this choice do arise. Firstly, by the use of linear interpolation it is implicitly assumed that the solution behaves like a smooth function on Ω_H. Because of the exponential behavior of the solution in some areas, this is only true on an unfeasibly fine grid. Secondly, linear interpolation does not satisfy here the so-called Galerkin condition

$$\bar{R}_H \mathcal{M}_h(P_h s_H)=\mathcal{M}_H(s_H), \tag{5.6}$$

which is a condition that ascertains the reduction of low frequency components in the residual after a CGC. Hemker [9] has introduced a prolongation which is based on the assumption of smoothness of fluxes, and which satisfies (5.6) for the simplified case that all S_j and R_j are zero, see (3.4). Here, we use the same assumption but we choose a short and convenient formulation in order to handle also the situation near the inner boundary point B. Figure 4 depicts how the dual box $[L, R]$ is divided into the boxes $[L, M]$ and $[M, R]$.

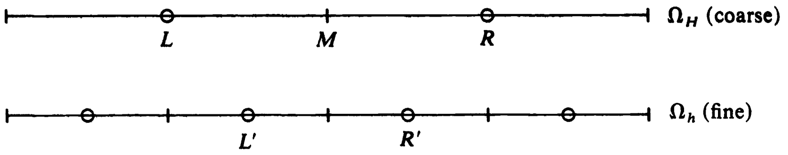

FIG. 4. *Staggering of a coarse and fine grid.*

The assumption reads that J_ψ, J_n, J_p are constant on $[L, R]$. Given the values of the variables (ψ, ϕ_n, ϕ_p) at L and R we wish to compute the values at L' and R'. From (3.5a) it follows that $\psi|_{L'}$ and $\psi|_{R'}$ can be computed by linear interpolation. For ϕ_p we first determine the value at the wall M. If we write

$$\Delta\psi = \psi|_R - \psi|_L, \qquad \Delta\phi_p = \phi_p|_R - \phi_p|_L \tag{5.7}$$

then we derive that

```
$\phi_p|_M =$
    if $\Delta\psi < 0$
    then if $\frac{\Delta\psi}{2} - \Delta\phi_p < 0$
            then $\phi_p|_R + z\left(\frac{\Delta\psi}{2}, \frac{\Delta\psi}{2} - \Delta\phi_p\right)$
            else $\phi_p|_L + \frac{\Delta\psi}{2} + z\left(\frac{\Delta\psi}{2}, -\frac{\Delta\psi}{2} + \Delta\phi_p\right)$
(5.8)       end if
    else if $\frac{\Delta\psi}{2} - \Delta\phi_p < 0$
            then $\phi_p|_R - \frac{\Delta\psi}{2} + z\left(-\frac{\Delta\psi}{2}, \frac{\Delta\psi}{2} - \Delta\phi_p\right)$
            else $\phi_p|_L + z\left(-\frac{\Delta\psi}{2}, -\frac{\Delta\psi}{2} + \Delta\phi_p\right)$
            end if
    end if
```

where the function $z: \mathbb{R}^2 \to \mathbb{R}$ is defined by

$$z(u, v) = \frac{1}{\alpha} \log\left(\frac{\exp(\alpha v) + 1}{\exp(\alpha u) + 1}\right). \tag{5.9}$$

Note that in (5.8) the function z is used with only nonpositive arguments and

$$|z(u, v)| \leqq \frac{\log(2)}{\alpha} \quad \text{for } u \leqq 0, v \leqq 0. \tag{5.10}$$

By repeating the interpolation procedure, we can compute $\phi_p|_{L'}$ from $\phi_p|_L$ and $\phi_p|_M$, and $\phi_p|_{R'}$ from $\phi_p|_M$ and $\phi_p|_R$. In the particular case that the wall M is the basis B, we do not first determine $\phi_p|_M$ by interpolation, but simply state that

$$\phi_p|_M \equiv \phi_p|_B = V_B. \tag{5.11}$$

Analogously, we can derive a formula for $\phi_n|_M$.

5.4. Coarse grid correction. Let q_h^{old} and q_H^{old} be given approximations to the solution on Ω_h and Ω_H, respectively. The CGC is defined by

$$\text{(5.12a)} \qquad \textit{compute } d_H = \bar{R}_H(f_h - \mathcal{M}_h(q_h^{old})),$$

$$\text{(5.12b)} \qquad \textit{solve } \mathcal{M}_H(q_H^{new}) = \mathcal{M}_H(q_H^{old}) + d_H,$$

$$\text{(5.12c)} \qquad \textit{compute } q_h^{new} = q_h^{old} + (P_h q_H^{new} - P_h q_H^{old}),$$

where $\bar{R}_H$ and P_h are the grid transfer operators defined in the previous subsections. Note that q_H^{new} in (5.12b) may be approximated by applying a number of σ FAS cycles on the grid Ω_H with q_H^{old} as an initial approximation. The approximation q_H^{old} may be given by means of full weighting:

$$\text{(5.13a)} \qquad q_H^{old} = R_H q_h^{old},$$

$$\text{(5.13b)} \qquad q_{H,j}^{old} = \tfrac{1}{2} q_{h,2j-1}^{old} + \tfrac{1}{2} q_{h,2j}^{old}, \qquad \forall j \text{ at } \Omega_H.$$

Another possibility is to take q_H^{old} equal to q_H^{new} obtained from the last of previous CGCs. The solution efficiency of many nonlinear problems is not influenced by either choice of q_H^{old}. In our case however it is (see § 7).

5.5. Full multigrid. The full multigrid (FMG) algorithm provides the efficient construction of an initial approximation to the solution on a fine grid, once a solution on a coarse grid has been computed [5], [7]. Let Ω_{coarse} be the coarsest grid and Ω_{fine} be the finest one. Intermediate grids are denoted by $l \in \mathbb{N}$. Operators and grid functions now have l as a subscript instead of h or H. Here we introduce an improvement of the usual FMG in a quasi-Algol description.

```
        procedure BOX-FMG ($'\mathcal{M}_{fine}(q_{fine}) = f_{fine}'$, input: $f_{fine}$, output: $q_{fine}$)
        begin
        (1)  for $l$ from fine − 1 by −1 to coarse
        (2)  do $f_l = \bar{R}_l f_{l+1}$
        (3)  end do
        (4)  SOLVE ($'\mathcal{M}_{coarse}(q_{coarse}) = f_{coarse}'$, input: $f_{coarse}$, output: $q_{coarse}$)
(5.14)  (5)  for $l$ from coarse + 1 to fine
        (6)  do $q_l = P_l q_{-1}$
        (7)     to $\gamma$
        (8)     do FAS ($'\mathcal{M}_l(q_l) = f_l'$, input: $f_l$, in/output: $q_l$)
        (9)     end do
        (10) end do
        end procedure
```

where $\bar{R}_l$ is defined by (5.3). The improvement is in the lines (1)-(3) of the procedure. The grid function f_l is independent of q_l; the components represent

$$\text{(5.15)} \qquad f_{l,j} = \int_{B_j} D \, d\Omega,$$

i.e., the dope function integrated over box B_j. By means of (1)-(3) we compute the integral as a Riemann sum over a larger number of subintervals. This is more accurate because D is a rapidly varying function. In the numerical experiments to come we use $\gamma = 1$ throughout. For SOLVE ( ) we use the techniques of § 4.

6. Adaptation of the coarse grid correction. Hemker [9] successfully applied box centered multigrid FAS iteration to the forward and the reverse biased diode problem. A key feature in his application is the prolongation based on locally constant fluxes.

This prolongation has been reformulated and made suitable for the transistor problem in § 5. Application of the same MG algorithm to the transistor problem gives rise to a complication in the CGC due to drastically varying problem coefficients. This complication and possible remedies are the topics of this section.

6.1. Improper solution transfer. The first attempt of applying multigrid to our specific problem was done by employing BOX-FMG with only two grids. The coarse grid problem (5.12b), within the CGC of FAS, was to be solved up to machine accuracy by means of Newton-CSGS. For several cases of our test problem it turned out that the two-grid algorithm gets stuck precisely at stage (5.12b) of the CGC. This is remarkable because Newton-CSGS was shown in § 4.2 to be successful for $\mathcal{M}_H(q_H)=f_H$ even for rather coarse grids. Apparently f_H is within an appropriate range of $\mathcal{M}_H$ while the right-hand side of (5.12b) may be outside such a proper range of $\mathcal{M}_H$. The computational difficulty occurs in CSGS on the coarse grid exactly where one or more of the three solution components depicts a steep gradient. Consider two adjacent boxes B_L^h and B_R^h on the fine grid which together constitute a box B^H on the coarse grid. Because of the steep gradient it may well occur that the problem coefficients, i.e., the entries of the Jacobian of $\mathcal{M}_h$, show a quite different order of magnitude on B_L^h and B_R^h, respectively. Grid function d_H, the restriction of the residual, is dominated by the fine grid box with the large coefficients. On the other hand, the operator $\mathcal{M}_H$ is generated by the particular choice of q_H^{old}. This particular choice may be full weighting applied to q_h^{old}, or the last q_H available, etc. Because of the steep gradient in q_h^{old} there is a large range of possible values for q_H^{old} at B^H. Depending on the choice of q_H^{old} the operator $\mathcal{M}_H$ may have either large or small coefficients at box B^H due to the exponential behavior of the entries in the Jacobian as a function of the solution. In the case of small coefficients, the right-hand side of (5.12b) may become out of the appropriate range for $\mathcal{M}_H$ (d_H does not depend on the particular choice of q_H^{old}) and the two-grid algorithm gets stuck.

We will now confirm the foregoing by considering our discretized problem in more detail. Consider the center of the ϕ_p-stencil given by (3.9b) and let us suppose that ψ is monotonous on $[x_{j-3/2}, x_{j-1/2}]$; then either $s(-\alpha\Delta_{j-1}\psi)\geqq 1$ or $s(\alpha\Delta_j\psi)\geqq 1$. If both $|\Delta_{j-1}\psi|$ and $|\Delta_j\psi|$ are sufficiently small then $stp(j,0)$ is approximated by

$$stp(j,0)\approx \alpha\bar{\mu}_p \exp\left(\alpha(\phi_{p,j}-\psi_j)\right)\cdot\left(\frac{1}{\Delta_{j-1}x}+\frac{1}{\Delta_j x}\right).$$

If both $|\Delta_{j-1}\psi|$ and $|\Delta_j\psi|$ are sufficiently large then $stp(j,0)$ is approximated by

$$stp(j,0)\approx \alpha\bar{\mu}_p \exp\left(\alpha(\phi_{p,j}-\psi_j)\right)\cdot\begin{cases}\alpha\dfrac{\Delta_{j-1}\psi}{\Delta_{j-1}x} & \text{if} \quad \Delta_{j-1}\psi\geqq 0,\\ -\alpha\dfrac{\Delta_j\psi}{\Delta_j x} & \text{if} \quad \Delta_j\psi\leqq 0.\end{cases}$$

These approximations show that indeed the ϕ_p-stencil is extremely sensitive to the difference $(\phi_{p,j}-\psi_j)$. Hence the ϕ_p-stencil on the coarse grid is sensitive to how $\phi_{p,j}$ and ψ_j on the coarse grid are determined from their counterparts on the fine grid. If q_H^{old} is determined by applying full weighting (linear interpolation) to q_h^{old} then

$$stp(j/2,0)\approx \exp\left(-\frac{\alpha}{2}|\Delta_j(\phi_p-\psi)|\right)\cdot\max\{stp(j-1,0), stp(j,0)\}$$

where $stp(j-1,0)$, $stp(j,0)$ (j even) are defined at the fine grid Ω_h and $stp(j/2)$ at the coarse grid Ω_H. If $(\phi_p-\psi)$ shows a steep gradient then indeed

$$stp(j/2)\ll \max\{stp(j-1,0), stp(j,0)\}.$$

Note. The possible occurrence of the above sketched phenomenon has already been noted (for general nonlinear problems) by Brandt [5, p. 279], where he discusses how the transferred solution (i.e., q_H^{old}) implicitly determines the problem coefficients on the coarse grid.

6.2. Possible remedies. Let L and R be the centers of the two adjacent boxes B_L^h and B_R^h on the fine grid Ω_h which together constitute a coarse grid box B_M^H with center M on the coarse grid Ω_H (see Fig. 5).

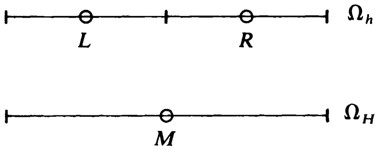

FIG. 5. *Nested boxes.*

Let us assume that $\partial\psi/\partial x = c$ is constant on $B_L^h \cup B_R^h$. The centers of the ϕ_p-stencils at L, R are then determined by the coefficients $a_L^h \equiv \exp(\alpha(\phi_p - \psi)|_L)\bar{c}$, $a_R^h \equiv \exp(\alpha(\phi_p - \psi)|_R)\bar{c}$, respectively, and the center of the ϕ_p-stencil at M by $a_M^H \equiv \exp(\alpha(\phi_p - \psi)|_M)\bar{c}$ with $\bar{c} = \alpha^2\bar{\mu}_p|c|$ (see § 6.1). Let $\Delta_M(\phi_p - \psi)$ denote the variation $\Delta_M(\phi_p - \psi) = (\phi_p - \psi)|_R - (\phi_p - \psi)|_L$. The solution at M on the coarse grid somehow relates to the solution at L and R on the fine grid (for instance by means of the full weighting restriction). If $\Delta_M(\phi_p - \psi)$ is small (a smooth solution) then obviously a_M^H does not differ much from either a_L^h or a_R^h. If $\Delta_M(\phi_p - \psi)$ is large (a steep gradient in the solution) then a_M^H may differ orders of magnitude from both a_L^h and a_R^h, and therefore the MG algorithm may get stuck as was pointed out in the previous subsection. A radical remedy to meet this situation is to prevent $\Delta_M(\phi_p - \psi)$ from getting large, i.e., to introduce local refinement of the mesh just where the solution has a large variation $\Delta_M(\phi_p - \psi)$, e.g., by means of equidistributing the variation. However, we want to be able to find solutions without much refinement, in order to apply coarse grids in our MG algorithm. Besides, a solution without much resolution can serve as a guide for where a local mesh refinement should take place. For these reasons we resort to another remedy. Let us consider the CGC (5.12). Let $d_h(L)$, $d_h(R)$ be the residuals at L, R (e.g., for the third equation (3.4c) only). At M the difference between q_H^{new} and q_H^{old} may have the order of magnitude $d_H(M)/a_M^H$ with $d_H(M) = d_h(L) + d_h(R)$. Because of (5.12c) at either L, R, or both L and R a correction with order of magnitude $d_H(M)/a_M^H$ is added to the solution q_h^{old}. Assume that (because of a steep gradient in the solution) the inequality

$$a_M^H \ll \max\{a_L^h, a_R^h\}$$

holds. Therefore

$$d_H(M)/a_M^H \gg (d_h(L) + d_h(R))/\max\{a_L^h, a_R^h\},$$

which implies that the correction that will be transferred to the fine grid becomes far too large and the solution q_h^{old} gets spoiled. A way to prevent this situation is to multiply the restricted residual d_H with

$$\theta_M^H \equiv \frac{a_M^H}{\max\{a_L^h, a_R^h\}}, \qquad 0 < \theta_M^H \leqq 1, \tag{6.1}$$

at each center M. For a smooth part of the solution this fraction will be near one, for a rapidly varying part of the solution it will be near zero, so that the solution q_h^{old} will be preserved. The foregoing is the motivation for the following modification of the FAS algorithm (MFAS) using the notation of § 5.5:

```
       Procedure MFAS ($'\mathcal{M}_l(q_l)=f_l'$, input: $f_l$, in/output: $q_l$)
       begin
       (1)  If $l=$coarse
       (2)  then SOLVE ($'\mathcal{M}_{coarse}(q_{coarse})=f_{coarse}'$, input : $f_{coarse}$, in/output: $q_{coarse}$)
       (3)  else RELAX ($'\mathcal{M}_l(q_l)=f_l'$, input: $f_l$, in/output: $q_l$)
       (4)       $d_{l-1}:=\bar{R}_{l-1}(f_l-\mathcal{M}_l(q_l))$
       (5)       $q_{l-1}:=R_{l-1}q_l$   (optional !)
       (6)       $d_{l-1}:=\Theta_{l-1}(\mathcal{M}_{l-1},\mathcal{M}_l)d_{l-1}$
(6.2)  (7)       $d_{l-1}:=d_{l-1}+\mathcal{M}_{l-1}(q_{l-1})$
       (8)       $s_{l-1}:=q_{l-1}$
       (9)       to $\sigma$
       (10)      do MFAS ($'\mathcal{M}_{l-1}(q_{l-1})=d_{l-1}'$, input: $d_{l-1}$, in/output: $q_{l-1}$)
       (11)      end do
       (12)      $q_l:=q_l+P_lq_{l-1}-P_ls_{l-1}$
       (13)      RELAX ($'\mathcal{M}_l(q_l)=f_l'$, input: $f_l$, in/output: $q_l$)
       (14) end if
       end procedure
```

The modification is in line (6). Here Θ_{l-1} represents a diagonal matrix $\mathbb{R}^{3N(\Omega_{l-1})}\rightarrow\mathbb{R}^{3N(\Omega_{l-1})}$ ($N(\Omega_{l-1})$ denotes the number of boxes at Ω_{l-1}). It is defined by

$$\Theta_{l-1}d_{l-1}=(\boldsymbol{\theta}_{l-1,1}d_{l-1,1},\cdots,\boldsymbol{\theta}_{l-1,j}d_{l-1,j},\cdots,\boldsymbol{\theta}_{l-1,N(\Omega_{l-1})}d_{l-1,N(\Omega_{l-1})})^T$$

with $d_{l-1,j}\in\mathbb{R}^3$, $\theta_{l-1,j}:\mathbb{R}^3\rightarrow\mathbb{R}^3$ and

$$\boldsymbol{\theta}_{l-1,j}\equiv\begin{pmatrix}\theta_{l-1,j,1} & 0 & 0\\ 0 & \theta_{l-1,j,2} & 0\\ 0 & 0 & \theta_{l-1,j,3}\end{pmatrix}$$

$$(\theta_{l-1,j,k}\in\mathbb{R},\ k=1,2,3).$$

For our particular semiconductor problem the $\theta_{l-1,j,k}$ are defined by:

(6.3a1) $$\theta_{l-1,j,1}=1,$$

(6.3a2) $$\theta_{l-1,j,2}=\min\{2\eta_{l-1,j},1\},\qquad \eta_{l-1,j}\in\mathbb{R},$$

(6.3a3) $$\theta_{l-1,j,3}=\min\{2\xi_{l-1,j},1\},\qquad \xi_{l-1,j}\in\mathbb{R},$$

where

(6.3b) $$\begin{aligned}\eta_{l-1,j}&\equiv\exp(\alpha(\psi_j^{l-1}-\phi_{n,j}^{l-1}))\Big/\max_{i=0,-1}\exp(\alpha(\psi_{2j+i}^{l}-\phi_{n,2j+i}^{l})),\\ \xi_{l-1,j}&\equiv\exp(\alpha(\phi_{p,j}^{l-1}-\psi_j^{l-1}))\Big/\max_{i=0,-1}\exp(\alpha(\phi_{p,2j+i}^{l}-\psi_{2j+i}^{l})).\end{aligned}$$

The superscripts $l-1, l$ refer to Ω_{l-1}, Ω_l, respectively.

The first component of the restricted residual does not need to be adjusted. The definition originates from the evaluation of expression (6.1). By means of (6.3a2)-(6.3a3) the numbers $\theta_{l-1,j,2}$ and $\theta_{l-1,j,3}$ are rounded off upwards to 1 when $\eta_{l-1,j}$, $\xi_{l-1,j}$ are $\geqq\frac{1}{2}$. Summarizing, we observe the following from (6.2)-(6.3):

(i) Where q_l is smooth, d_{l-1} will not be suppressed.

(ii) Where q_l depicts a steep gradient, d_{l-1} may be strongly suppressed.

(iii) Let Ω_0 be some fixed grid, then, for $l\rightarrow\infty$, the matrix Θ_{l-1} becomes asymptotically the identity matrix.

(iv) By a proper local mesh refinement the suppression of d_{l-1} will decrease. The performance of the modified FAS algorithm will be shown and discussed in § 7.

In the nonlinear multigrid algorithm as proposed by Hackbusch [7, p. 187], the restricted residual d_{l-1} is divided by a global parameter $s \geqq 1$ and the resulting coarse grid correction is multiplied by s. The division by an appropiate s ensures that the right-hand side of the coarse grid equation is within an appropriate range of the coarse grid operator $\mathcal{M}_{l-1}$. There are two main differences with our approach. First, the same number s is used at each different box. Second, within our class of problems we have to omit the multiplication of the correction by s. Such a multiplication would result in a far too large correction and thereby a dip or peak in the fine grid solution. In recent work of Hackbusch and Reusken [8] a global parameter ψ is proposed by which the coarse grid correction should be damped. For a limited class of problems an appropriate ψ can be computed. Important differences with our approach are the following:

(i) ψ is a damping parameter for the correction, instead of the residual.

(ii) ψ is a global parameter, i.e., the same ψ is used at each different box.

(iii) After sufficient FAS sweeps the damping parameter ψ converges to 1, the parameters $\theta_{l-1,j,2}$, $\theta_{l-1,j,3}$ do not and should not converge to 1.

(iv) The ψ parameter is meant to enlarge the domain of guaranteed convergence on the analogy of the damping parameter in the Newton method; the Θ_{l-1} operator is meant to deal with discrepancies between the operators $\mathcal{M}_{l-1}$ and $\mathcal{M}_l$ due to rapidly varying problem coefficients.

7. Numerical results. In this section we investigate the performance of our nonlinear multigrid algorithm. We focus our attention on the effects of local suppressing of the restricted residual and the choice of the coarse grid solution. The residual norm ($\|\cdot\|_{res}$) that we use is the maximum norm of the scaled residual. At level l the said scaling is done by multiplying the residual at each box with the inverse of the 3 × 3-matrix

$$\left(\frac{\partial \mathcal{M}_l|_{x_{j-1/2}}}{\partial(\psi_j^l, \phi_{n,j}^l, \phi_{p,j}^l)^T}\right).$$

The performance of the MFAS algorithm is shown in Table 7.1. In the heading of the table we use the following abbreviations:

case: see Table 4.1.

q_H^{old}: defined by . . . : see § 5.4.

without Θ: No local suppression of the restricted residual is applied.

with Θ: Local suppression of the restricted residual is applied on all coarser grids.

#MFAS, 10^{-1} red: The average number of MFAS sweeps necessary to obtain an additional reduction factor 10^{-1} of the residual norm after the application of BOX-FMG.

after FMG: The last column shows the scaled norm of the residual, after application of BOX-FMG (see (5.14), $\gamma = 1$). In each case > 0 we obtain a starting approximation of the solution on the coarsest grid by means of continuation and application of Newton-CSGS (see § 4.2).

For Table 7.1 the multigrid procedures are applied with 3 grids, with $N = 16$, 32, 64, respectively. In the event of no convergence the symbol * is written.

We observe that the use of the Θ operator, combined with a proper choice of the coarse grid solution, gives convergence for all cases. In the cases 3-6 the use of the Θ operator is essential for convergence. The use of the Θ operator does not slow down

convergence in the cases where it is not needed (cases 0–2 and 7–14). We observe further that apparently the full weighting approximation of the fine grid solution on the coarse grid may be a poor one. Experiments for more and finer grids showed almost identical results for Table 7.1. Further we observe that mere application of BOX-FMG, without further MFAS sweeps, already gives fairly accurate results which may be good enough for practical purposes.

For two typical cases, case 4 and case 12, we investigate the grid-dependence of the multigrid convergence. In Fig. 6 we show the 10-logarithm of the scaled residual norms after subsequent FAS sweeps, starting from the result obtained by BOX-FMG. The coarsest grid contains 16 boxes; for the finest grid we take 32, 64, 128, and 256 boxes, respectively; Θ is applied (without application of Θ case 4 persistently depicts divergence). We observe that the multigrid convergence becomes grid-independent when the meshsize of the finest grid decreases. This indicates that the semiconductor problem has been treated correctly at each multigrid stage. Hereby it is shown that even for the strongly nonlinear (and particularly hard) problem it is possible to compose a multigrid method with optimal multigrid efficiency. Of course, considered in one space dimension only, competitive methods are available. However, the multigrid method as developed in this paper offers several clues for the foundation of an MG algorithm which solves the semiconductor problem also in more space dimensions with a computational complexity that is linear in the number of gridpoints.

In order to give some insight into the behavior of the Θ operator, we show in Fig. 7 the solution components ψ and ϕ_n for case 4 on a 64-grid and a graph of $\theta_{2,j,2}$ (see (6.3a2)).

We observe the typical behavior that $\theta_{2,j,2}$ equals 1 almost everywhere, except for some isolated points.

8. Conclusions. We find, by deriving explicit expressions for the entries of the Jacobian, that the linearization of the Scharfetter-Gummel discretization scheme contains a weak spot. When applying full multigrid followed by FAS/NMGM-iterations to our one-dimensional transistor problem, we find a serious lack of robustness which is explained by the strong nonlinearity of the discretized problem. This difficulty is met by adaptation of the coarse grid correction, which looks to be equally applicable for the higher-dimensional case. A proper choice of the coarse grid solutions is of importance too, e.g., the full weighting approximation is not satisfactory. Furnished with the improvements as proposed, we obtain a robust multigrid algorithm with a convergence which is independent of the meshsize.

Acknowledgements. The author wishes to thank Prof. Dr. P. W. Hemker and Prof. Dr. P. Wesseling for their useful comments and Ms. M. Middelberg for typing the manuscript.

AN ITERATIVE METHOD FOR MATRIX SPECTRAL FACTORIZATION*

T. J. HARRIS† AND J. H. DAVIS‡

Abstract. A computationally efficient algorithm is implemented to factorize a multivariate spectrum at a discrete number of frequencies. This method uses an iterative causal projection procedure to factorize the spectrum. The causal projection is computed using fast Fourier transforms.

Key words. multivariable spectral factorization, Ricatti equation, conjugate periodic function, discrete Hilbert transform, optimal control, attenuation factors

AMS(MOS) subject classifications. 15A09, 49D40, 62M10, 65F05

1. Introduction. The spectral factorization of para-Hermitian matrices arises in prediction theory [20], [24], [25]; linear optimal control theory [6], [13], [19]; and in the construction of approximate inverses for multivariable control [18]. Numerous computational procedures have been proposed. Generally, these may be classified as either parametric or nonparametric methods. In the parametric approach, the matrix to be factored is expressed explicitly in terms of the Laplace or z-transform operator. Constructive methods for factorization may employ (i) symmetric factor extraction [4], [22]; (ii) construction of a state space realization and solution via the Ricatti equation [1], [2], [9], [23]; (iii) an iterative Newton-Raphson solution to a set of bilinear equations [16], [24]; or (iv) decomposition of block Hankel and Toeplitz matrices [19], [21], [26]. In the nonparametric approach, the matricial spectrum at a discrete number of frequencies is factored using a Newton-Raphson iteration as in [24], [25] or an optimal gain iteration as in [6]. These techniques involve a causal projection operator in the iteration, and hence rely on the properties of functions which are analytic and harmonic in and upon the unit disk.

In this paper a computationally efficient algorithm is implemented to factorize the matricial spectrum at a discrete number of frequencies. This method uses an iterative causal projection procedure to factorize the spectrum. To calculate the causal projection in each iteration, it is necessary to numerically approximate a discrete Hilbert transform. This is accomplished with a fast Fourier transform. The use of attenuation factors [12] is investigated to reduce the computational requirements. A benchmark example and an application arising in the control of a pilot scale packed bed reactor are used to illustrate the methodology. The proposed method is also compared to the parametric method proposed in [26] with respect to computation time and solution accuracy.

2. Preliminaries. Consider an $m \times m$ matrix function $H(e^{j\theta})$ defined on the interval $[-\pi, \pi]$ which has the following properties:

(P)
(1) $H(e^{j\theta})$ is Hermitian, i.e., $H(e^{j\theta}) = H^T(e^{-j\theta})$, where ^{T} denotes transpose,
(2) $H(e^{j\theta})$ is positive definite on the interval, i.e., $H(e^{j\theta}) > 0$,
(3) $H(e^{j\theta})$ is in the ring of absolutely convergent Fourier series.

$H(e^{j\theta})$ thus admits a Fourier series expansion of the form

$$H(e^{j\theta}) = \sum_{k=-\infty}^{\infty} H_k e^{j\theta k}. \tag{1}$$

Since $H(e^{j\theta})$ is Hermitian, the coefficients H_k are real and $H_{-k}=H_k^T$.

A fundamental result is that a function $H(e^{j\theta})$ having properties (P) can be factorized as [10]:

$$H(e^{j\theta})=F(e^{j\theta})WF^*(e^{j\theta}). \tag{2}$$

$F(e^{j\theta})$, known as the left factor, is an $m\times m$ matrix function having a Fourier expansion in nonnegative powers of $e^{j\theta}$,

$$F(e^{j\theta})=\sum_{k=0}^{\infty}F_k e^{j\theta k} \tag{3}$$

with $F_0=I$. Furthermore, the coefficients $\langle F_k\rangle$ are real valued. $F^*(e^{j\theta})$ denotes the conjugate transpose of $F(e^{j\theta})$. W is a positive definite matrix.

$F(e^{j\theta})$ admits an extension to the interior of the unit disk such that

$$F(z)=\sum_{k=0}^{\infty}F_k z^k \tag{4}$$

is analytic in the region $|z|<1$. The generating function $F(z)$ is invertible in the sense that $F(z)$ has all its zeros in z, outside the unit circle. In the case of the convolution algebra approach to the factorization problem, the condition is invertibility in the convolution algebra [10]. Properties (P) are sufficient for $H(e^{j\theta})$ to be characterized as a full rank spectral density function [20]. The factorization of $H(e^{j\theta})$ via equation (2) is commonly known as spectral factorization.

Wilson [24] has developed two iterative procedures for spectral factorization. Both methods are based on a second order Taylor series expansion and subsequent Newton-Raphson iteration. In the first, the coefficients $\langle F_k\rangle$ are determined directly from the coefficients $\langle H_k\rangle$. This algorithm can be applied when the Fourier expansion of $H(z)$ can be represented by truncated series of degree L. F_0 is constrained to be upper triangular, and W is taken as the identity matrix. The method requires the solution of a bilateral polynomial equation. This equation can be transformed to a system of linear equations which require inversion of a matrix of dimension $(Lm^2\times Lm^2)$. Jezek and Kucera [16] demonstrated that a Shur reduction can be used to solve the bilateral polynomial equations. This eliminates the need to invert the aforementioned matrix. Their approach requires the calculation of a determinant of an $m\times m$ polynomial matrix of degree L.

The second approach of Wilson is an iteration for $F(e^{j\theta})$, where θ is evaluated at a number of equispaced points on the unit circle. The coefficients of the generating function are then determined by taking the inverse Fourier transform of $F(e^{j\theta})$. A much more streamlined algorithm than the one proposed by Wilson is obtained, however, by insisting upon the normalized factorization described above. The following iterative procedure is arrived at [6].

Define the sequence of iterates, $F_{n+1}(e^{j\theta})$, $F_n(e^{j\theta})$ via

$$F_{n+1}(e^{j\theta})=W_n^{-1}[F_n^*(e^{j\theta})^{-1}H(e^{j\theta})F_n(e^{j\theta})^{-1}]^+(e^{j\theta})F_n(e^{j\theta}) \tag{5}$$

for $\theta\in[0,2\pi]$. W_n is the constant coefficient in the Laurent expansion of the power series for $F_n^*(e^{j\theta})^{-1}$ $H(e^{j\theta})$ $F_n(e^{j\theta})^{-1}$. The projection operator $[\ ]^+$ of a function $G(z)$ in terms of the Fourier expansion

$$G(z)=\sum_{k=-\infty}^{\infty}G_k z^k,\qquad |z|=1 \tag{6}$$

is

$$[G(z)]^+ = \sum_{k=0}^{\infty} G_k z^k, \qquad |z| \leqq 1. \tag{7}$$

The proposed factorization involves an iteration for $F_n(e^{j\theta})$ and an iteration for W_n. The iteration (5) is initialized with $F_0(e^{j\theta}) = I$. The origin and properties of the iteration (5) are discussed in [6, Appendix A].

The iteration (5) requires calculation of W_n, which is the mean value of the function $G(e^{j\theta}) = F_n^*(e^{j\theta})^{-1} H(e^{j\theta}) F_n(e^{j\theta})^{-1}$. W_n is given by

$$W_n = \frac{1}{2\pi} \oint_0^{2\pi} G(e^{j\theta})\, d\theta. \tag{8}$$

The projection operator must be calculated on $|z| = 1$. $[G(e^{j\theta})]^+(e^{j\theta})$ can be calculated from the formulas of Sokhotskyi [15]

$$[G(e^{j\theta})]^+(e^{j\theta}) = \tfrac{1}{2}[W_n + G(e^{j\theta}) + j\mathbb{H}[G(e^{j\theta})](e^{j\theta})], \tag{9}$$

where $\mathbb{H}[G(e^{j\theta})](e^{j\theta})$ is the Hilbert transform of $G(e^{j\theta})$ and is given by

$$\mathbb{H}[G(e^{j\theta})](e^{j\theta}) = 1/(2\pi j)\mathrm{PV} \oint G(e^{j\theta})(e^{j\tau} + e^{j\theta})/(e^{j\tau} - e^{j\theta})\, d\tau. \tag{10}$$

PV denotes that the integral is to be interpreted in the principal value sense. Equation (10) is recognized as the Cauchy principal value integral of the function $G(z)$, for $|z| = 1$.

The form of the iteration and restrictions on $H(e^{j\theta})$ guarantee that the elements of $G(e^{j\theta})$ are representable by Fourier series. Therefore the (p, q)th element, denoted by $g_{pq}(e^{j\theta})$ admits a Fourier series expansion of the form

$$g_{pq}(e^{j\theta}) = \sum_{k=-\infty}^{\infty} a_{pqk}\, e^{jk\theta}. \tag{11}$$

The representation of the Hilbert transform of $g_{pq}(e^{j\theta})$ in terms of the Fourier expansion for $g_{pq}(e^{j\theta})$ is [8]

$$\mathbb{H}[G(e^{j\theta})](e^{j\theta}) = -j \sum_{k=-\infty}^{\infty} \varepsilon_k a_{pqk}\, e^{jk\theta}, \qquad \varepsilon_k = \begin{cases} 1, & k > 0, \\ 0, & k = 0, \\ -1, & k < 0. \end{cases} \tag{12}$$

3. Numerical procedure. In the frequency domain calculation (8)-(12) are evaluated at $N = 2^s + 1$ equispaced points on the half circle between $[0, \pi]$. These points on the half circle are denoted by θ_r, $r = 0, 1, \cdots, N$. It is not necessary to evaluate $H(e^{j\theta})$ for negative θ since $H(e^{j\theta})$ is Hermitian. The values of $G(e^{j\theta})$ for negative θ are simply the conjugate of those for positive θ.

The function $g_{pq}(e^{j\theta})$ is approximated by the truncated series

$$\tilde{g}_{pq}(e^{j\theta}) = \sum_{k=-N}^{N}{}' \tilde{a}_{pqk}\, e^{jk\theta}. \tag{13}$$

The $'$ denotes that the summation is to be taken with the factor $\frac{1}{2}$ when $k = +/-N$. The circumflex $\sim$ denotes that the quantity is associated with the truncated expansion. $\tilde{a}_{pqk}$ is the approximated Fourier coefficients of $g_{pq}(e^{j\theta})$ [8]. The approximate Hilbert transform, denoted by $\mathbb{H}[\tilde{g}_{pq}(e^{j\theta})](e^{j\theta})$, is given by

$$\mathbb{H}[\tilde{g}_{pq}(e^{j\theta})](e^{j\theta}) = -j \sum_{k=-N}^{N}{}' \varepsilon_k \tilde{a}_{pqk}\, e^{jk\theta}, \qquad \varepsilon_k = \begin{cases} 1, & k > 0, \\ 0, & k = 0, \\ -1, & k < 0. \end{cases} \tag{14}$$

A fast Fourier transform (FFT) can be used to evaluate the Fourier coefficients $\langle \tilde{a}_{pqk} \rangle$, and an inverse transform can be used to evaluate $\tilde{g}_{pq}(e^{j\theta})$ at θ_r, $r = 0, 1, 2, \cdots, N$ [11]. Since $G(e^{j\theta})$ is an even function, the coefficients $\langle \tilde{a}_{pqk} \rangle$ are real valued. It is also straightforward to verify that $\mathbb{H}[\tilde{g}_{qp}(e^{j\theta})](e^{j\theta}) = -[\mathbb{H}[\tilde{g}_{pq}(e^{j\theta})](e^{j\theta})]^*$ for $p \neq q$. This latter identity reduces the computational requirements of the algorithm since it is only necessary to evaluate $m(m+1)/2$ FFTs in each iteration. The proposed FFT solution method is computationally more efficient than the method of Wilson [24] where the principal value integral in (10) is evaluated as an ordinary improper integral using Simpson's rule integration formula.

Remarks. (1) To obtain a factorization of the form $H(e^{j\theta}) = E^*(e^{j\theta}) WE(e^{j\theta})$, the algorithm is applied to $H^*(e^{j\theta})$. $E(e^{j\theta})$, known as the right factor, is calculated as $E(e^{j\theta}) = F^*(e^{j\theta})$.

(2) The algorithm is terminated whenever

$$\max_{\theta} \frac{1}{m} |I - H(e^{j\theta})^{-1}[F_n(e^{j\theta}) W_n F_n^*(e^{j\theta})]|_\infty < \varepsilon \qquad \text{for } \theta = \theta_r = r\pi/2^s, \ r = 0, 1, \cdots, 2^s.$$

(3) A bound on the achievable accuracy is

$$\max_{\theta} \frac{1}{m} |I - H(e^{j\theta})^{-1} H(e^{j\theta})|_\infty \qquad \text{for } \theta = \theta_r = r\pi/2^s, \ r = 0, 1, \cdots, 2^s.$$

(4) Frequently one wants to obtain the spectral factor of $H(z)$, where the solution is given in terms of the generating function. To employ the above procedure, the spectrum $H(e^{j\theta})$ is obtained by evaluating $H(z)$ at $N = 2^s + 1$ points on the unit circle, i.e., $z = \exp(jr\pi/N)$, $r = 0, 1, 2, \cdots, N$. The algorithm described above is implemented. The coefficients of the generating function $\langle F_k \rangle$ are obtained by taking the inverse Fourier transform of $F(e^{j\theta})$.

(5) As indicated in [6, Appendix A], (5) can be used instead of a parametric method to obtain the steady state gain for the Kalman-Bucy filtering problem in state variable form.

4. Error analysis. The primary source of errors in the algorithm arises from truncating the Fourier expansion (14) approximating the Hilbert transform with (12). An estimate of the error in evaluating the Hilbert transform arising from truncation of the Fourier series is [8]

$$(15) \qquad |\mathbb{H}[g_{pq}(e^{j\theta})](e^{j\theta}) - \mathbb{H}[\tilde{g}_{pq}(e^{j\theta})](e^{j\theta})| \leqq 2 \sum_{|k| \geqq N}' |a_{pqk}|.$$

The $'$ denotes that the term with $k = N$ is to be taken with the factor $\frac{1}{2}$. A tighter estimate has been developed in [14]. The truncation error is zero when $g_{pq}(e^{j\theta})$ has a Fourier expansion in fewer than N terms. The truncation error can be reduced by increasing the number of terms used to approximate $g_{pq}(e^{j\theta})$. This increases the computational overhead in the algorithm. An alternate approach is to use the theory of attenuation factors [3], [7], [12]. This approach is equivalent to using either a windowed or smoothed estimate for the Fourier coefficients or a periodic spline to approximate $g_{pq}(e^{j\theta})$. In either case, the result is that ε_k in (14) is a function of frequency and independent of the projected function $G(e^{j\theta})$. For an Euler spline of order σ, ε_k is [3]

$$(16) \qquad \varepsilon_k = \begin{cases} (1 - (k/N)^\sigma), & k > 0, \\ 0, & k = 0, \\ -(1 - (k/N)^\sigma), & k < 0. \end{cases}$$

Error estimates for the conjugate function have been developed in [3], [12]. The error estimates of [3] require that the norm of the derivative of $g_{pq}(e^{j\theta})$ be less than one in magnitude. Gutknecht [12] has shown that attentuation factors based on spline interpolants have certain optimality properties in the sense of minimizing a norm of $\mathbb{H}[g_{pq}(e^{j\theta})](e^{j\theta})-\mathbb{H}[\tilde{g}_{pq}(e^{j\theta})](e^{j\theta})$. However, the optimality of the attenuation factors based on spline interpolants does not ensure that the error is minimized at the interpolation points. The effectiveness of attenuation factors is examined in the next section.

Chawla and Ramakrishnan [5] developed an N point quadrature formula for approximating Hilbert transforms that is exact if the Fourier expansion for $g(e^{j\theta})$ has fewer than $2N$ terms. It is straightforward to show that their procedure is equivalent to calculating the approximated Hilbert transform using an Euler spline of order one, and correcting the expression in (12) by adding the term $-[dg(e^{j\theta})/d\theta]/N$. The derivative of $g(e^{j\theta})$ is not known. It may be approximated by a central difference formula. Alternatively, this derivative can be approximated from the Fourier expansion for $g(e^{j\theta})$. If the latter approach is taken, it can be shown that the approximate Hilbert transform is given by (13).

5. Numerical examples. The first example is taken from [24]. The dimension is $m=2$. The calculations are performed at $N=1+2^s$ points between $[0, \pi]$ with s taking on values between 3 and 7. Attenuation factors were calculated using linear interpolation and a cubic interpolation polynomial [12]. These attenuation factors are shown in Fig. 1. The quadrature procedure of [5] was also implemented with a central difference approximation for the derivative.

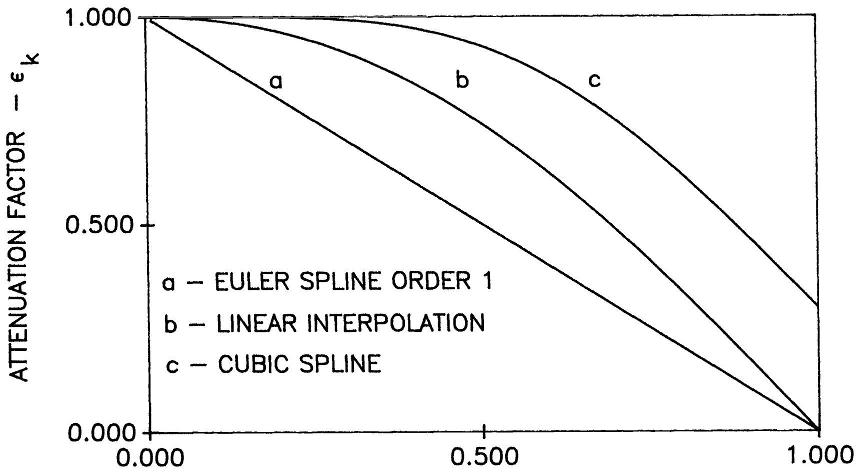

FIG. 1. *Attenuation factors. Example* 1.

To investigate the effectiveness of attenuation factors, the maximum infinity norm of $\frac{1}{2}|I-H(e^{j\theta})^{-1}[F_n(e^{j\theta})W_nF_n^*(e^{j\theta})]|$ was calculated after six iterations of the algorithm for increasing values of N. The infinity norm was calculated using 129 equispaced points on the interval $[0, \pi]$. These results are summarized in Table 1. Included in this table are the CPU times, and a bound on the achievable accuracy. The calculations were performed on an IBM 3081. From this table, we note that the use of attenuation

TABLE 1
Error norm and computation time for example 1.

	Attenuation Method				
s	Equation (14)	Linear interpolation	Cubic spline	Euler spline $\sigma=1$, derivative approximation	Relative time
3	0.46	0.12	0.78	0.12	1.00
4	0.18	0.60	0.28	0.42	1.15
5	0.41E−02	0.12	0.21E−01	0.59E−01	1.42
6	0.22E−03	0.30E−01	0.17E−02	0.22E−03	2.09
7	0.45E−04	0.45E−03	0.30E−04	0.40E−03	3.21

Notes. (1) The error norm is defined as

$$\max_\theta \tfrac{1}{2}|I-H(e^{j\theta})^{-1}[F_n(e^{j\theta})W_nF_n^*(e^{j\theta})]|_\infty, \qquad \theta=\theta_r=r\pi/128, \qquad r=0,1,\cdots,128.$$

(2) The achievable error bound

$$\max_\theta \tfrac{1}{2}|I-H(e^{j\theta})^{-1}H(e^{j\theta})|_\infty, \qquad \theta=\theta_r=r\pi/128, \qquad r=0,1,\cdots,128$$

was calculated as 0.81E−5.

(3) The calculations were performed on an IBM 3081. The computation time is relative to the time taken to solve the problem from the first line of this table, which was 0.47 seconds. The computation time was essentially independent of the method used to calculate the attenuation factors.

factors can reduce the accuracy. Of the methods examined, no single method consistently gave more accurate results than using no attenuation factors.

Based on these results, one would conclude that the use of attenuation factors may not be desirable. An effective strategy is to use as many equispaced points as possible, without using attenuation factors. A heuristic approach was adopted to select the number of points on the unit circle. The algorithm is implemented as described with 2^s+1 points, with s typically 4 or 5. s was increased by 1 whenever

$$(17) \qquad \sum_{k=N/4}^{N/2}\{|\tilde{a}_{pqk}|+|\tilde{a}_{pq-k}|\}\geqq .001\sum_{k=1}^{N/2}\{|\tilde{a}_{pqk}|+|\tilde{a}_{pq-k}|\}, \qquad p,q=1,2,\cdots,m.$$

This procedure was continued until some upper limit on s was reached. For many examples studied, $s=7$ was found to be adequate. The computation time is typically reduced by forty percent compared to using a fixed value of $s=7$.

The second example is taken from [17]. In designing a controller to regulate the exit concentrations from a pilot scale chemical reactor, it is necessary to compute the left spectral factor of the matrix polynomial $H(z)=M^T(z)M(z^{-1})$, where $M(z^{-1})$ is given by

$$M(z^{-1})=\begin{bmatrix} 1.8-6.64z^{-1}+5.158z^{-2} & 0.5384z^{-1}-0.3307z^{-2} \\ -0.7498-2.62z^{-1}-2.266z^{-2} & 0.1592z^{-2}-0.0866z^{-3} \\ -0.1069z^{-3}-0.3453z^{-4} & -0.0614z^{-4}-0.0594z^{-5} \end{bmatrix}.$$

The determinant of $M(z^{-1})$ has a zero located at infinity and zeros located at $z=-5.3514$, $z=-.5791$, $z=.4735\pm.5145j$, $z=.6701\pm.2291j$. To compute the spectral factor, the spectrum of $H(z)$ is evaluated at 129 points between 0 and π by letting $z=\exp(\pi jr/N)$, $r=0,1,\cdots,128$. $H(e^{j\theta})$ satisfies properties (P). The condition number of $H(e^{j\theta})$ is shown in Fig. 2.

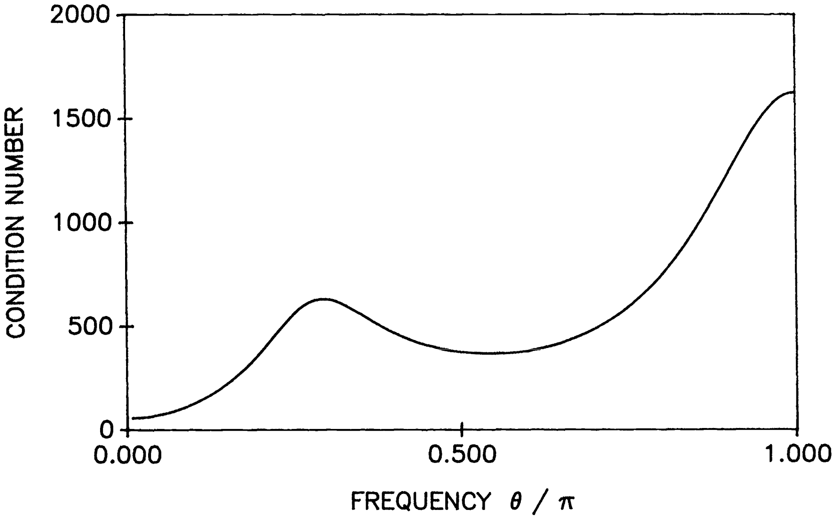

FIG. 2. *Condition number of spectrum. Example* 2.

The iteration described above was employed. The initial value for s was 4. The final value was 7. The iteration was terminated when the $\max \frac{1}{2}|I - H(e^{j\theta})^{-1}[F_n(e^{j\theta}) W_n F_n^*(e^{j\theta})]|_\infty < .001$. Six iterations and 0.69 seconds of CPU time were required. The maximum infinity norm upon termination was 0.12E − 4. The bound on the achievable performance was 0.76E − 5. The coefficients $\langle F_k \rangle$ were determined by taking the Fourier transform of $F(e^{j\theta})$. The final values for $F_{ij}(z^{-1})$ are

$$F_{11}(z^{-1}) = 1.000 - 1.192z^{-1} + 0.497z^{-2} + 0.080z^{-3} + 0.0167z^{-4},$$

$$F_{12}(z^{-1}) = 0.029z^{-1} - 0.032z^{-2} + 0.020z^{-4} + 0.001z^{-5},$$

$$F_{21}(z^{-1}) = -2.076z^{-1} + 4.115z^{-2} + 0.683z^{-4} + 0.148z^{-5},$$

$$F_{22}(z^{-1}) = 1.000 - 0.329z^{-1} - 0.333z^{-2} + 0.221z^{-3} - 0.083z^{-4} - 0.025z^{-5}.$$

6. Comparison with a parametric method. In this section, we compare the computation time and solution accuracy of the proposed algorithm to the parametric method proposed in [26] which involves a Bauer-type factorization. The iteration proposed in [26] involves the Cholesky factorization of an $m \times m$ matrix in each iteration. The computations can be carried out in place, in a vector of length $m^2 \times (L+1)(L+2)$, where L is the degree of the polynomial to be factored. That algorithm exhibits both geometric and monotone convergence [19]. Unlike the nonparametric method proposed in this paper, the algorithm in [26] is capable of factorizing a spectrum whose determinant has zeros on $|z| = 1$.

We want to find the left spectral factor of the $m \times m$ matrix polynomial $H(z) = M^T(z)M(z^{-1})$, where $M(z^{-1})$ is of the form

$$M(z^{-1}) = M_0 + M_1 z^{-1} + \cdots + M_L z^{-L}. \tag{18}$$

A comparative study is influenced by the dimension m and L, the location of the zeros of the determinant of $M(z^{-1})$, the condition number of the spectrum, and the desired accuracy. To provide a manageable basis for comparison between these two methods, the matrix M_k was chosen to be lower diagonal with common elements $k+1$. The

Notes. (1) The error norm and norm bound are defined in the notes attached to Table 1.

(2) The solution time is the computation time relative to the time taken to solve the factorization with $m=2$ and $L=2$ using the nonparametric method, which was 0.26 seconds.

zeros of the determinant of $M(z^{-1})$, in the z-plane, are given by the roots of the equation

$$(z^L+2z^{L-1}+\cdots+Lz+(L+1))^m=0. \tag{19}$$

All of the zeros of this polynomial are greater than one in magnitude.

We seek a solution of the form

$$H(z)=F^T(z)WF(z^{-1}), \tag{20}$$

where $F(z^{-1})$ is an $m\times m$ matrix polynomial of degree L. It is readily verified that the solution is given by

$$R^{1/2}F_k=M_{L-k}, \qquad k=0,\cdots,L \tag{21}$$

where R is the lower diagonal Cholesky factor of W.

The common feature to both algorithms is that an estimate of W is produced in each iteration. Both algorithms were terminated using the criterion suggested in [26], that is, when $1/m$ trace $(I-W_{n+1}W_n^{-1})<.0001$. The infinity norm error discussed in the previous sections was calculated for each method after termination at 129 equispaced points on the interval $[0, \pi]$. An estimate of the achievable accuracy was also calculated.

The results of this numerical simulation are summarized in Table 2 for $L=2$, 5, 10, 20, 25, 30, 40, and 50 and $m=2$, 5, and 10. The computation time is that required to perform the factorization and to calculate the infinity norm error. No more than seven iterations were required to satisfy the termination criterion using the nonparametric method. The parametric method requires that at least L iterations be performed. On average, $L+5$ iterations were required to terminate the algorithm. Several conclusions are apparent from the data in Table 2. First, the time to compute the nonparametric solution is much less sensitive to the degree of the matrix polynomial than is the solution time for the parametric method. Second, there is a crossover point at which the solution time for the parametric method increases very rapidly. Third, with the exception of the case where $m=10$ and $L=2$, the frequency-dependent error norm was less for the nonparametric method than for the parametric method, even though both methods employed the same termination criterion.

7. Summary. A computationally attractive algorithm has been developed for the spectral factorization of a multivariable spectrum using fast Fourier transforms. In the examples studied, it was found that attenuation factors do not ensure that a more accurate solution is obtained. An area of future work is to develop the algorithm to enable a factorization when the determinant of $H(z)$ has zeros on $|z|=1$, and to investigate how readily the algorithm can be vectorized.

ON THE STRUCTURE OF JACOBIANS FOR SPECTRAL METHODS FOR NONLINEAR PARTIAL DIFFERENTIAL EQUATIONS*

ROBERT D. RUSSELL†, DAVID M. SLOAN‡, AND MANFRED R. TRUMMER§

Abstract. When solving nonlinear partial differential equations with periodic boundary conditions, one frequently uses spectral methods. Implicit time-stepping, the computation of steady-state solutions, or the approximation of inertial manifolds lead to nonlinear equations which can be solved by Newton's method. In this note the structure of the Jacobian matrix is described for typical nonlinearities, namely, those involving products of the unknown function and its derivatives.

Key words. spectral methods, Galerkin methods, nonlinear PDEs, convolutions

AMS(MOS) subject classifications. 65P05, 42A10, 65J15, 65N30, 35K55, 42A85

1. Introduction. There is a growing interest in computing solutions of evolutionary partial differential equations (PDEs), and highly accurate discretisation in space is often achieved using spectral methods. Two of the most commonly used spectral methods are the standard spectral Galerkin method and the pseudospectral method [1], [5]. The latter, which is algebraically equivalent to a collocation method, differs from a Galerkin method in its treatment of nonlinear terms. Convolution sums are evaluated in a way that introduces aliasing errors. These errors arise due to the inability of a discrete grid to distinguish between large classes of periodic functions. There is ample evidence to suggest that for many problems—particularly nonevolutionary problems with smooth solutions—aliasing errors have little influence on accuracy once sufficient resolution has been obtained. However, in long-time integrations of nonlinear evolutionary problems, the presence of aliasing errors can influence the onset of nonlinear instabilities (see [12], [13]). The aliased pseudospectral method is less likely than the alias-free Galerkin method to yield semidiscrete equations which satisfy appropriate conservation properties. Since lack of conservation can have a deleterious effect on stability, it follows that Galerkin methods have some advantages in such circumstances. There are techniques which may be used to remove aliasing errors from pseudospectral computations (see [2]), and the de-aliased method is then algebraically equivalent to the Galerkin method. However, the removal of aliasing adds to the computational cost and reduces the efficiency relative to the Galerkin method.

Here we describe a technique which simplifies the treatment of certain nonlinearities by the alias-free Galerkin method. When solving nonlinear evolutionary equations using the Galerkin method with implicit time-stepping techniques, one can face the problem of evaluating Jacobian matrices in terms of the expansion coefficients. In this paper we expose the structure of Jacobians arising from a variety of nonlinearities in Fourier spectral methods, and we suggest efficient ways to compute the Jacobian

and to evaluate nonlinearities. An important application for which this structure has been exploited successfully is the computation of approximate inertial manifolds for dissipative equations (see [11]).

This note was originally motivated by the study of the Kuramoto-Sivashinsky equation [8]

$$\text{(KS)}\qquad u_t + 4u_{xxxx} + \theta[u_{xx} + uu_x] = 0, \quad u(x,t) = u(x+2\pi, t), \quad (x,t) \in \mathbb{R}\times\mathbb{R}.$$

If one discretises in space using a spectral method, the PDE is transformed into a system of ordinary differential equations (ODEs). For instance, if we try to find an odd solution of (KS) of the form

$$u(x,t) = \sum_{k=1}^{n} b_k(t) \sin kx, \tag{1}$$

then the Galerkin approach yields the following system of nonlinear ODEs for the Fourier coefficients $\mathbf{b} := (b_1, \cdots, b_n)^T$:

$$\frac{d}{dt} b_k(t) + 4k^4 b_k(t) + \theta[-k^2 b_k(t) + h_k(\mathbf{b})] = 0, \qquad k = 1, \cdots, n, \tag{2}$$

where

$$h_k(\mathbf{b}) = \frac{1}{2}\left\{ -k \sum_{j=1}^{n-k} b_j b_{j+k} + \sum_{j=1}^{k-1} j b_j b_{k-j} \right\}. \tag{3}$$

Let $\Lambda \in \mathbb{R}^{n\times n}$ denote the diagonal matrix with kth entry $\Lambda_{kk} := 4k^4 - \theta k^2$, and let $\mathbf{h}(\mathbf{b}) := (h_1(\mathbf{b}), \cdots, h_n(\mathbf{b}))^T$. We may rewrite system (2) in vector form

$$\dot{\mathbf{b}}(t) + \Lambda \mathbf{b}(t) + \theta \mathbf{h}(\mathbf{b}(t)) = 0. \tag{4}$$

Whether we integrate (4) with an implicit time-stepping scheme or compute steady-state solutions directly by setting $\dot{\mathbf{b}} = 0$ in (4), we are faced with solving a nonlinear system of algebraic equations for $\mathbf{b}$, with the essential nonlinearity $\mathbf{h}(\mathbf{b})$.

For general nonlinear PDEs, the resulting nonlinear algebraic equations are frequently solved by ordinary fixed-point iteration. However, it turns out that for many nonlinearities the Jacobian matrix $(\partial h_j(\mathbf{b})/\partial b_k)$ has a fairly simple structure and can be computed rather efficiently. Therefore, Newton's method becomes a viable alternative to ordinary iteration procedures. Higher accuracy in time can be achieved more efficiently, commensurate with spectral accuracy in space.

2. Complex and real Fourier series. In §3 we compute Jacobian matrices of special nonlinearities, using complex Fourier series for u and the convolution theorem. While one can instead use a (truncated) cosine/sine series for the unknown real-valued 2π-periodic function u, this often tends to obscure the underlying simple structure of the Jacobian. To see this consider both representations, namely truncated series of complex exponentials,

$$u(x) = \sum_{k=-n}^{+n} c_k e^{ikx}, \tag{5}$$

where $i^2 = -1$, and trigonometric polynomials

$$u(x) = \frac{a_0}{2} + \sum_{k=1}^{n} a_k \cos kx + \sum_{k=1}^{n} b_k \sin kx. \tag{6}$$

The relation between the complex Fourier coefficients c_k and the real cosine/sine coefficients a_k, b_k is given by

$$\begin{aligned} a_k &= c_k + c_{-k}, & c_k &= \tfrac{1}{2}(a_k - ib_k), \\ b_k &= i(c_k - c_{-k}), & c_{-k} &= \tfrac{1}{2}(a_k + ib_k). \end{aligned} \tag{7}$$

Let $F(u)$ be a (nonlinear) function. Restricting F to the finite-dimensional subspaces spanned by complex exponentials or trigonometric polynomials as in (5) or (6), respectively, we write

$$u \to PF(u(x)) = \sum_{k=-n}^{+n} f_k e^{ikx} = \frac{g_0}{2} + \sum_{k=1}^{n} g_k \cos kx + \sum_{k=1}^{n} h_k \sin kx, \tag{8}$$

where the g_k, h_k, and f_k are related in the same way as the a_k, b_k, and c_k in (7). P denotes the orthogonal projection onto the space containing functions of the form (5) or (6), respectively. Equation (8) gives rise to two related mappings on finite-dimensional vector spaces, namely,

$$\mathbf{c} \to \mathbf{f} \tag{9C}$$

on the complex vector space C^{2n+1}, and

$$(\mathbf{a}, \mathbf{b}) \to (\mathbf{g}, \mathbf{h}) \tag{9R}$$

on the real vector space $\mathbb{R}^{2n+1}$. (If u and $F(u)$ are not real-valued, there is no need to avoid the complex Fourier series.)

For many types of nonlinearities, it is fairly straightforward to compute the Jacobian matrix $\partial \mathbf{f}/\partial \mathbf{c}$ of (9C), as we see below. The Jacobian matrix of the mapping in (9R) can then be obtained easily using $g_k = f_k + f_{-k}$, $h_k = i(f_k - f_{-k})$. Letting $J_{j,k} := \partial f_j/\partial c_k$, the chain rule gives

$$\frac{\partial f_j}{\partial a_k} = \frac{1}{2}\{J_{j,k} + J_{j,-k}\}, \qquad \frac{\partial f_j}{\partial b_k} = \frac{i}{2}\{-J_{j,k} + J_{j,-k}\}. \tag{10}$$

The formulas relating the Jacobian J of (9C) and the Jacobian of (9R) can be written in compact form as a unitary transformation

$$\begin{bmatrix} \partial g_j/\partial a_k \\ \partial g_j/\partial b_k \\ \partial h_j/\partial a_k \\ \partial h_j/\partial b_k \end{bmatrix} = \frac{1}{2} \begin{bmatrix} 1 & 1 & 1 & 1 \\ -i & i & -i & i \\ i & i & -i & -i \\ 1 & -1 & -1 & 1 \end{bmatrix} \begin{bmatrix} J_{j,k} \\ J_{j,-k} \\ J_{-j,k} \\ J_{-j,-k} \end{bmatrix}. \tag{11}$$

3. Jacobian of "monomials." We now return to the problem of computing the matrix $J = \partial \mathbf{f}/\partial \mathbf{c}$ and present an algorithm for the case where $F(u)$ involves products of powers of the unknown function u and its space derivatives u_x, u_{xx}, etc. Our basic tool is the convolution theorem of Fourier analysis (see, e.g., [7]). Note that we write the unknown function u as a sum of complex exponentials in (5), even though u is usually real-valued.

The convolution of two sequences $\mathbf{x} = (x_j)$ and $\mathbf{y} = (y_j)$ is the new sequence $\mathbf{x}^*\mathbf{y}$ given by

$$(\mathbf{x}^*\mathbf{y})_k := \sum_j x_j y_{k-j}. \tag{12}$$

The identity element for convolution is the sequence $\mathbf{e} = (e_j)$, with $e_0 := 1$, and $e_j := 0$ for $j \neq 0$. The convolution of two sequences is well defined if both sequences $\mathbf{x}$, $\mathbf{y}$ are square summable. For the new sequence $\mathbf{x}^*\mathbf{y}$ to be square summable, it is sufficient that, in addition, one of the sequences has compact support. In our applications, all sequences involved have compact support, and all subsequent results hold without any further technical assumptions. However, it is important to bear in mind that all these results hold for *bi-infinite* sequences and *bi-infinite* matrices only, although in practical terms one just needs to use sufficiently large vectors and/or matrices. See also the comments on bandwidth below.

We remark that sequences and convolution form a semigroup. Since convolution is commutative and since there is an identity element, this semigroup is a commutative monoid (all properties of an Abelian group except for the existence of an inverse element).

For simplicity, we start with powers of u only. If u has Fourier coefficients $\mathbf{c}$, then u^2 has Fourier coefficients $\mathbf{c}^*\mathbf{c}$. The Fourier coefficients of u^m are the elements of the sequence $\mathbf{c}^{*m} := \mathbf{c}^* \cdots {}^*\mathbf{c}$, the m-fold convolution of $\mathbf{c}$ with itself. This definition extends to the case $m = 0$, with $\mathbf{c}^{*0} := \mathbf{e}$.

Convolutions can also be expressed in terms of matrices and matrix multiplications.

DEFINITION 1. Let $\mathbf{c} = (c_j)$ be a sequence. We define the (bi-infinite) complex Toeplitz matrix $\Gamma(\mathbf{c})$ by

$$\Gamma(\mathbf{c}) = (\gamma(\mathbf{c})_{jk}), \qquad \gamma_{jk} := c_{j-k}. \tag{13}$$

Then $\mathbf{c}$ is the zeroth column of the matrix $\Gamma(\mathbf{c})$, $\mathbf{c}^*\mathbf{c}$ is the zeroth column of the matrix $\Gamma(\mathbf{c})^2$, and $\mathbf{c}^{*m}$ is the zeroth column of the matrix $\Gamma(\mathbf{c})^m$, for every nonnegative integer m.

It is straightforward to prove the following proposition by induction.

PROPOSITION 1. *Let $m \geqq 1$, and $F(u) = u^m$. The Jacobian matrix of the induced mapping $\mathbf{c} \to \mathbf{f}(\mathbf{c}) = \mathbf{c}^{*m}$ is given by*

$$\frac{\partial f_j}{\partial c_k} = m(\mathbf{c}^{*m-1})_{j-k}. \tag{14}$$

With the matrix interpretation above, this can also be simply expressed as

$$J = \frac{\partial \mathbf{c}^{*m}}{\partial \mathbf{c}} = m\Gamma(\mathbf{c})^{m-1}. \tag{15}$$

Proposition 1 is the analogue to differentiating powers in calculus. Note that if $c_j = 0$ for $|j| > n$, then $\Gamma(\mathbf{c})$ has bandwidth n, and $\Gamma(\mathbf{c})^m$ has bandwidth mn. Even if in the end we only look at Fourier modes with frequencies not larger than n, we still must allow the intermediate bandwidth to grow in order to capture all nonlinear interactions.

We proceed to state the product rule for differentiating convolutions. Notice that, unlike a scalar product, the convolution of two sequences is yet another sequence. We therefore extend the definition of the convolution operation to a convolution product of a sequence with a (bi-infinite) matrix. Doing this in a "natural" way results in a matrix as the product.

DEFINITION 2. Let $A = (a_{jk})$ be a bi-infinite matrix, and $\mathbf{x} = (x_k)$ be a sequence. We further denote by $\mathbf{e}^{(j)}$ the jth standard basis sequence, i.e., the sequence consisting of all zeros, except for the jth component which equals 1 (convolution $\mathbf{x}^*\mathbf{e}^{(j)}$ corresponds to shifting the sequence $\mathbf{x}$ by j). Then $B := \mathbf{x}^*A$ is the bi-infinite matrix whose jth column is the (ordinary) convolution of the jth column of A with the sequence $\mathbf{x}$:

$$(\mathbf{x}^*A)\mathbf{e}^{(j)} := \mathbf{x}^*(A\mathbf{e}^{(j}). \tag{16}$$

The reason for writing $\mathbf{x}^*A$ rather than $A^*\mathbf{x}$ lies in the way this convolution corresponds to ordinary matrix multiplication and the Toeplitz matrices defined in (13).

PROPOSITION 2. *Let I be the identity matrix, let S be a diagonal matrix, and let $\mathbf{x}=(x_j)$ be a sequence. Then*

$$\mathbf{x}^*I=\Gamma(\mathbf{x}), \qquad \mathbf{x}^*S=\Gamma(\mathbf{x})S, \tag{17}$$

where Γ is defined in (13).

PROPOSITION 3. *Γ as defined in* (13) *is a homomorphism between the commutative monoid (semigroup) of sequences with the convolution operation, and the commutative monoid (semigroup) of Toeplitz matrices with matrix multiplication. If $\mathbf{x}=(x_j)$ and $\mathbf{y}=(y_j)$ are sequences, then*

$$\Gamma(\mathbf{x}^*\mathbf{y})=\Gamma(\mathbf{x})\Gamma(\mathbf{y}). \tag{18}$$

Furthermore, this homomorphism is consistent with the definition of the convolution of a sequence with a matrix in the following sense:

$$\mathbf{x}^*\Gamma(\mathbf{y})=\Gamma(\mathbf{x}^*\mathbf{y})=\Gamma(\mathbf{x})\Gamma(\mathbf{y}). \tag{19}$$

Proof. We compute the (j, k)-element of the matrices in (18),

$$\Gamma(\mathbf{x}^*\mathbf{y})_{jk}=\sum_p x_p y_{j-k-p}=\sum_q x_{j-q}y_{q-k}=\sum_q \Gamma(\mathbf{x})_{jq}\Gamma(\mathbf{y})_{qk}=(\Gamma(\mathbf{x})\Gamma(\mathbf{y}))_{jk}.$$

To prove (19), we use Proposition 2 and the associative law:

$$\mathbf{x}^*\Gamma(\mathbf{y})=\mathbf{x}^*(\mathbf{y}^*I)=(\mathbf{x}^*\mathbf{y})^*I=\Gamma(\mathbf{x}^*\mathbf{y}). \qquad \square$$

PROPOSITION 4 (PRODUCT RULE). *Let $\mathbf{x}=(x_j)$ and $\mathbf{y}=(y_j)$ be sequences depending on the sequence $\boldsymbol{\alpha}=(\alpha_k)$. Denote the Jacobians of $\mathbf{x}(\boldsymbol{\alpha})$ and $\mathbf{y}(\boldsymbol{\alpha})$ by $J^{\mathbf{x}}:=\partial\mathbf{x}/\partial\boldsymbol{\alpha}$ and $J^{\mathbf{y}}:=\partial\mathbf{y}/\partial\boldsymbol{\alpha}$, respectively. Then the Jacobian of $\mathbf{z}:=\mathbf{x}^*\mathbf{y}$ is*

$$J^{\mathbf{z}}:=\frac{\partial\mathbf{z}}{\partial\boldsymbol{\alpha}}=\mathbf{y}^*J^{\mathbf{x}}+\mathbf{x}^*J^{\mathbf{y}}. \tag{20}$$

The proof is straightforward, using commutativity of (ordinary) convolution.

Proposition 1 allows us to compute Jacobians of positive integral powers of u. To find the Jacobian of a product involving u and its space derivatives u_x, u_{xx}, etc., we need to employ the Fourier spectral derivative matrix

$$D:=\operatorname{diag}(\cdots, -in, -i(n-1), \cdots, -2i, -i, 0, i, 2i, \cdots, i(n-1), in, \cdots). \tag{21}$$

The pth derivative of u has Fourier coefficients $D^p\mathbf{c}$.

There is an interesting relationship between D and the matrix Γ defined in (13), which allows us to write $\Gamma(D^p\mathbf{c})$ in terms of products of $\Gamma(\mathbf{c})$ and D.

PROPOSITION 5. *Let $\mathbf{c}=(c_j)$ be a sequence, and D the Fourier spectral derivative matrix defined in* (21). *Then*

$$\Gamma(D\mathbf{c})=[D,\Gamma\mathbf{c}]:=D\Gamma(\mathbf{c})-\Gamma(\mathbf{c})D. \tag{22}$$

$\Gamma(D\mathbf{c})$ is the commutator of D and $\Gamma(\mathbf{c})$, and (22) *can be used recursively to express $\Gamma(D^p\mathbf{c})$ in terms of $\Gamma(\mathbf{c})$ and D only.*[1]

This result can be shown by direct calculation, or, more elegantly, by comparing the Jacobians of uu_x and $\frac{1}{2}(u^2)_x$ (see Example 1 below).

[1] $\Gamma(D^p\mathbf{c})=\sum_{k=0}^{p}(-1)^{p-k}\binom{p}{k}D^k\Gamma(\mathbf{c})D^{p-k}$, as has been kindly pointed out by one of the referees.

We now give a few examples which show how products of u, u_x, u_{xx}, etc., can be handled.

Example 1. $F(u)=u^m u_x$, $m \geqq 0$. Noting that $u^m u_x = (1/(m+1))(u^{m+1})_x$, we obtain from (15) the Jacobian as

$$J = D\Gamma(\mathbf{c})^m. \tag{23}$$

Let us have a closer look at the case $m=1$, i.e., $F(u)=uu_x$. This is the Burgers' nonlinearity arising in the Kuramoto-Sivashinsky equation, or in the nonlocal Burgers' equation (e.g., [4]). The product rule gives

$$J = D\mathbf{c} * I + \mathbf{c} * D = \Gamma(D\mathbf{c}) + \Gamma(\mathbf{c})D, \tag{24}$$

which equals $D\Gamma(\mathbf{c})$ because of (22).

Example 2. $F(u)=uu_{xx}$. Using the product rule and Proposition 3, we can express the result as

$$J = D^2\mathbf{c} * I + \mathbf{c} * D^2 = \Gamma(D^2\mathbf{c}) + \Gamma(\mathbf{c})D^2. \tag{25}$$

Noting that $uu_{xx} = \frac{1}{2}(u^2)_{xx} - u_x^2$, the Jacobian can also be written as

$$J = D^2\Gamma(\mathbf{c}) - 2\Gamma(D\mathbf{c})D. \tag{26}$$

The expressions (25) and (26) are equal, because from (22)

$$\Gamma(D^2\mathbf{c}) = D\Gamma(D\mathbf{c}) - \Gamma(D\mathbf{c})D = D^2\Gamma(\mathbf{c}) - 2D\Gamma(\mathbf{c})D + \Gamma(\mathbf{c})D^2,$$

so

$$\Gamma(D^2\mathbf{c}) + \Gamma(\mathbf{c})D^2 = D^2\Gamma(\mathbf{c}) - 2(D\Gamma(\mathbf{c}) - \Gamma(\mathbf{c})D)D = D^2\Gamma(\mathbf{c}) - 2\Gamma(D\mathbf{c})D.$$

Example 3. $F(u)=u_x^2$. The product rule applied to $D\mathbf{c} * D\mathbf{c}$ gives

$$J = 2D\mathbf{c} * D = 2\Gamma(D\mathbf{c})D, \tag{27}$$

which can also be found using the chain rule for mappings between vector spaces. For example, the Kolmogorov-Sivashinsky-Spiegel equation (KSS) (see, e.g. [3]) has a term u_x^2. The same equation features the term treated in the next example.

Example 4. $F(u)=(u_x^3)_x$. First we compute the Jacobian K of u_x^3. From Example 3 and the product rule, we get (note that we compute the Jacobian of $D\mathbf{c} * D\mathbf{c} * D\mathbf{c}$)

$$K = D\mathbf{c} * 2\Gamma(D\mathbf{c})D + (D\mathbf{c} * D\mathbf{c}) * D.$$

From Propositions 2 and 3 we finally obtain

$$K = 2\Gamma(D\mathbf{c} * D\mathbf{c})D + \Gamma(D\mathbf{c} * D\mathbf{c})D = 3\Gamma(D\mathbf{c})^2 D. \tag{28}$$

By induction we can also show that the Jacobian of u_x^m is $m\Gamma(D\mathbf{c})^{m-1}D$.

The function $F(u)$ has an outer derivative, which corresponds to a diagonal scaling by D from the left to yield the Jacobian

$$J = 3D\Gamma(D\mathbf{c})^2 D. \tag{29}$$

Example 5. $F(u)=(u^m)_{xx}$. This nonlinearity occurs in the one-dimensional Cahn-Hilliard equation [4]. Applying our convolution calculus we obtain

$$J = mD^2\Gamma(\mathbf{c})^{m-1}. \tag{30}$$

For $m=2$ we can also write $(u^2)_{xx} = 2(u_x^2 + uu_{xx})$. The Jacobians of each of the two terms are in Examples 2 and 3:

$$J = 2\{2\Gamma(D\mathbf{c})D + \Gamma(D^2\mathbf{c}) + \Gamma(\mathbf{c})D^2\}. \tag{31}$$

Equivalently, if we use (26) instead of (25), we obtain

$$J=2\{2\Gamma(D\mathbf{c})D+D^2\Gamma(\mathbf{c})-2\Gamma(D\mathbf{c})D\}=2D^2\Gamma(\mathbf{c}), \tag{32}$$

which agrees with (30).

As long as we compute with sufficient bandwidth, we can use any form of the function F to compute the Jacobians. However, if we compute with a fixed bandwidth (i.e., $2n+1$ by $2n+1$ matrices), different ways of writing F may lead to different results.

4. Application to the Kuramoto–Sivashinsky equation. One important application for which the structure of the Jacobian matrix is of special interest is the computation of approximate inertial manifolds for dissipative PDEs [11], [9]. This problem motivated the study of the structure of the Jacobians presented in this paper. While skipping many details, we give a brief account of the method. We consider the evolution equation

$$u_t+Au+F(u)=0, \tag{33}$$

where A is a self-adjoint positive operator defined on a Hilbert space H, and F is the nonlinear part defined on the domain of A. Let $w_1, w_2, \cdots$ be orthogonal eigenfunctions of the operator A with corresponding eigenvalues $0<\lambda_1\leqq\lambda_2\leqq\cdots$. P denotes the usual (orthogonal) spectral projection onto the subspace spanned by the first m eigenfunctions, and Q is the spectral projection onto the subspace spanned by $w_{m+1}, \cdots, w_n$. We also set $p:=Pu$ and $q:=Qu$. An *approximate inertial manifold* (AIM) $q=\phi(p)$ for (33) can then be constructed by solving the differential algebraic equations

$$\dot{p}+Ap+PF(p+q)=0, \tag{34a}$$

$$Aq+QF(p+q)=0 \tag{34b}$$

(see [11], [14]). This AIM is referred to as the *steady* AIM, and has many nice properties. The relationship $q=\phi(p)$ can be determined by solving (34b); substituting $q=\phi(p)$ into (34a) yields an *approximate inertial form* of (33), and the resulting finite-dimensional ODE system has, under certain assumptions, many of the long-term dynamics features of the original equation (33).

To solve (34b) accurately, we use Newton's method. Here p is fixed, and we need the Jacobian matrix of $QF(p+q)$ with respect to the "high frequency modes" q. We are therefore only interested in the $(n-m)\times(n-m)$ trailing principal submatrix of the full Jacobian matrix $\partial F/\partial u$ corresponding to the partial derivatives of the high frequency modes of $F(u)$ with respect to the high frequency modes of u. It is easy to see that in the common case $n=2m$ the Jacobian only depends on the low frequency modes for *quadratic* nonlinearities like u^2, uu_x, u_x^2, uu_{xx}, etc. Therefore, the relation between the high frequency spectrum and the low frequency spectrum is a *linear* one and Newton's method for solving (34b) converges in one step (see [11]). For cubic or higher order terms this dependence is no longer linear.

We illustrate this for the Jacobian of uu_x (the essential nonlinearity of equation (KS)) in the odd case, i.e., on the subspace spanned by the first n sine functions $\sin x, \cdots, \sin nx$. From Example 1 the Jacobian matrix is

$$J=\partial\mathbf{f}/\partial\mathbf{c}=D\Gamma(\mathbf{c}). \tag{35}$$

Using (7), we express J in terms of the b_k by substituting $c_k=-\frac{1}{2}\operatorname{sign}(k)ib_{|k|}$. Finally, from (11) we obtain

$$\begin{aligned}\frac{\partial h_j}{\partial b_k}&=\tfrac{1}{2}\{ijc_{j-k}-ijc_{j+k}+ijc_{-j-k}-ijc_{-j+k}\}\\&=\tfrac{1}{2}j\{\operatorname{sign}(j-k)b_{|j-k|}-b_{j+k}\}.\end{aligned} \tag{36}$$

Any b_k with an index falling out of the range $1 \leqq k \leqq n$ is set to zero. Thus, the Jacobian $\partial \mathbf{h}/\partial \mathbf{b}$ is the sum of a skew-symmetric Toeplitz matrix and a Hankel matrix, with a diagonal scaling from the left. If $S = \operatorname{diag}(1, 2, 3, \cdots, n)$, and

$$(37) \qquad T := \begin{bmatrix} 0 & -b_1 & -b_2 & \cdots & -b_{n-1} \\ b_1 & 0 & -b_1 & \cdots & -b_{n-2} \\ b_2 & b_1 & 0 & \cdots & -b_{n-3} \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ b_{n-1} & b_{n-2} & b_{n-3} & \cdots & 0 \end{bmatrix}, \qquad H := \begin{bmatrix} b_2 & b_3 & b_4 & b_5 & \cdots & 0 \\ b_3 & b_4 & b_5 & \cdot & \cdots & 0 \\ b_4 & b_5 & b_6 & \cdot & \cdots & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdots & \cdot \\ b_n & 0 & 0 & \cdot & \cdots & 0 \\ 0 & 0 & 0 & \cdot & \cdots & 0 \end{bmatrix},$$

then

$$(38) \qquad \frac{\partial \mathbf{h}}{\partial \mathbf{b}} = \tfrac{1}{2} S(T - H).$$

In inertial manifold computations, when $n = 2m$, we are only interested in $\partial h_j / \partial b_k$ for $j, k = m+1, \cdots, 2m = n$, i.e., in the lower right-hand submatrix of (38). With $\hat{T}$ the trailing principal m by m submatrix of T ($\hat{T}$ is skew symmetric and Toeplitz, with $(0, b_1, b_2, \cdots, b_{m-1})^T$ as its first column), and $\hat{S} = \operatorname{diag}(m+1, m+2, \cdots, 2m)$, the Jacobian of the Fourier coefficients h_k of the last m modes of uu_x with respect to the Fourier coefficients $b_{m+1}, \cdots, b_{2m}$ is simply $\frac{1}{2}\hat{S}\hat{T}$. Clearly, this matrix is independent of $b_{m+1}, \cdots, b_{2m}$.

5. Conclusions. We presented an algorithm to compute Jacobians of nonlinear functions arising in the application of (Fourier) spectral methods to dissipative PDEs. We believe that this algorithm is an excellent way to derive the form of these Jacobians analytically. Note that the nonlinear function itself could also be computed via convolutions. Our method applies to the Fourier spectral method in general, not only to computing inertial manifolds (where we used it).

One could use the procedure outlined above to numerically evaluate Jacobians. In this case, one would not perform the matrix multiplications, but rather compute via convolutions, in particular, compute $\Gamma(\mathbf{c})^m$ as $\Gamma(\mathbf{c}^{*m})$. If $\mathbf{c}$ has compact support with $c_j = 0$ for $|j| > n$, one chooses the length of the sequence to be at least $2mn+1$, i.e., pad the sequence $\mathbf{c}$ with $(m-1)n$ extra zeros on either side. The convolutions can then be performed via (discrete) fast Fourier transforms (FFT) (see, e.g., [6], [7]) in $O(mn \log(mn))$ operations. Expressions like $\Gamma(\mathbf{c})^2\Gamma(D\mathbf{c})D$ can be evaluated as efficiently, with a bandwidth of n times the degree of the expression; in this case we have three Γ-matrices, hence the degree is 3 and the required bandwidth is $3n$. Again, the nonlinear function $\mathbf{c} \to \mathbf{f}$ (cf. (9C)) can also be evaluated via convolutions and FFT, provided there is sufficient padding of the sequences. Even though all these Jacobians can be expressed in terms of D and $\Gamma(\mathbf{c})$ only, for practical computations there is often no advantage in doing so. It is just as economical to perform convolutions with $\mathbf{c}$ and $D^p\mathbf{c}$ as with $\mathbf{c}$ alone. One should simply aim to keep the number of terms as small as possible. The convolution approach using FFTs will be faster only for a fairly large number of modes—experiments indicate a threshold of 64 to 128 modes. However, similar thresholds for efficiency are observed for Fourier spectral methods in general.

A wide variety of (dissipative) PDEs arising in physical applications has nonlinearities of the types discussed in this note. Among these equations are equation (KS); the Cahn-Hilliard equation (e.g., [10]),

$$(\mathrm{CH}) \qquad u_t + u_{xxxx} + (\alpha u - \beta u^2 - \gamma u^3)_{xx} = 0;$$

Burgers' equation,

$$\text{(B)} \qquad u_t - \nu u_{xx} + u u_x = 0;$$

the Kolmogorov-Sivashinsky-Spiegel equation [3],

$$\text{(KSS)} \qquad u_t + u_{xxxx} + ((2 - \theta u_x^2) u_x)_x + u_x^2 + \alpha u = 0;$$

and the Chafee-Infante reaction-diffusion equation (see, e.g., [4]),

$$\text{(CI-RD)} \qquad u_t - \nu u_{xx} + u^3 - u = 0.$$

IMPROVING THE ACCURACY OF INVERSE ITERATION*

ELIZABETH R. JESSUP† AND ILSE C. F. IPSEN‡

Abstract. The EISPACK routine TINVIT is an implementation of inverse iteration for computing eigenvectors of real symmetric tridiagonal matrices. Experiments have shown that the eigenvectors computed with TINVIT are numerically less accurate than those from implementations of Cuppen's divide-and-conquer method (TREEQL) and of the QL method (TQL2). The loss of accuracy can be attributed to TINVIT's choice of starting vectors and to its iteration stopping criterion.

This paper introduces a new implementation of TINVIT that computes each eigenvector from a different random starting vector and performs an additional iteration after the stopping criterion is satisfied. A statistical analysis and the results of numerical experiments with matrices of order up to 525 are presented to show that the numerical accuracy of this new implementation is competitive with that of the implementations of the divide-and-conquer and QL methods. The extension of this implementation to larger order matrices is discussed, albeit in less detail.

Key words. symmetric tridiagonal eigenvalue problem, inverse iteration, EISPACK

AMS(MOS) subject classification. 65F15

1. Introduction. Our goal is to determine an accurate method for computing all eigenvalues and eigenvectors of real symmetric tridiagonal matrices that is efficient both sequentially and in parallel. Experimental results in [16], [17] indicate that bisection with inverse iteration is generally the fastest and most efficient parallel eigensolver on a distributed-memory hypercube multiprocessor such as the Intel iPSC and that it is also the fastest sequential method for many problems. The computed eigendecompositions, however, are less accurate than those computed by existing implementations of Cuppen's divide-and-conquer method (TREEQL) [5], [12] or the QL method (TQL2) [3], [22]. The tested implementations of bisection are the EISPACK routines BISECT and TSTURM [22], both of which produce eigenvalues to high *absolute* accuracy [22]. With minor modification, each of these routines would produce eigenvalues to high *relative* accuracy when small relative changes in the matrix lead to small relative changes in the eigenvalues [7]. The loss of accuracy can thus be attributed to the tested implementation of inverse iteration (EISPACK's TINVIT). In this paper, we identify the factors influencing the accuracy of inverse iteration and present a new serial implementation of inverse iteration that computes eigenvectors to high absolute accuracy.

Suppose that T is an $n \times n$ real symmetric tridiagonal matrix with eigendecomposition

$$T = U\Lambda U^T, \qquad \Lambda = \begin{pmatrix} \lambda_1 & & \\ & \ddots & \\ & & \lambda_n \end{pmatrix}, \qquad U = (u_1 \cdots u_n),$$

where the diagonal elements Λ are the eigenvalues of T and the column u_i of the orthogonal matrix U is the eigenvector associated with eigenvalue λ_i. Given an

Select a starting vector $y^{(0)}$.
For $k = 1, 2, \cdots$ until convergence:
    Solve $(T-\hat{\lambda}_jI)y^{(k)} = y^{(k-1)}$ for $y^{(k)}$.
$\hat{u}_j = y^{(k)}/\|y^{(k)}\|_2$.
```

Representing the starting vector $y^{(0)}$ as a linear combination of the eigenvectors $y^{(0)} = \sum_{i=1}^{n} \eta_i u_i$ gives for the first iterate

$$y^{(1)} = \sum_{i=1}^{n} \frac{\eta_i}{\lambda_i - \hat{\lambda}_j} u_i.$$

If the contribution η_j of u_j in $y^{(0)}$ is not too small, and if $\hat{\lambda}_j$ is close to λ_j, the contribution $\eta_j/(\lambda_j - \hat{\lambda}_j)$ of u_j in the next iterate $y^{(1)}$ is large, and $y^{(1)}$ is a better approximation to u_j than is $y^{(0)}$ [24, p. 321]. Likewise, in the next iteration, the contribution of u_j in $y^{(2)}$ increases to $\eta_j/(\lambda_j - \hat{\lambda}_j)^2$ and so on for subsequent iterations. Thus, the iterates $y^{(k)}$ usually converge to u_j in only a few iterations.

If all eigenvalues are well separated, and if the starting vector in each eigenvector computation contains a large enough component η_i, inverse iteration using shifts $\hat{\lambda}_1, \cdots, \hat{\lambda}_n$ in turn computes an orthogonal set of eigenvectors. However, if some eigenvalues are close together, inverse iteration as outlined in Algorithm 1.1 produces eigenvectors that are not orthogonal. An additional step to orthogonalize iterates associated with close eigenvalues is necessary.

This discussion of the inverse iteration algorithm shows that if the eigenvalues $\hat{\lambda}_i$ are determined to working precision (which is true for BISECT) and if the linear system solution and the orthogonalization of iterates corresponding to close eigenvalues are carried out accurately (which is true for TINVIT), the overall accuracy of inverse iteration is determined by

(1) the choice of starting vector,
(2) the reorthogonalization criterion,
(3) the iteration stopping criterion.

We will examine the EISPACK routine TINVIT with regard to each factor in turn and gradually improve its accuracy to that of the implementations of the QL and Cuppen's divide-and-conquer methods. The numerical experiments presented involve matrix orders up to $n = 525$. We also discuss in less detail the extension of the implementation to larger order problems.

This paper is organized as follows: A simple perturbation result is presented in § 2 to define measures of high absolute accuracy for the computed eigenvalue decomposition. The EISPACK implementation TINVIT is described in § 3, and its lack of numerical accuracy explored in § 4. A new implementation of inverse iteration based on the experiments in § 4 is presented in § 5. The numerical accuracy of this improved implementation is compared to implementations of Cuppen's divide-and-conquer method and of the QL method in § 6. The use of random starting vectors in the new implementation of inverse iteration is justified by a statistical analysis in § 7. The most important points of this paper are summarized in § 8.

2. The computed eigendecomposition. This section shows that the computed eigendecomposition has high absolute accuracy if its residual and the deviation of the eigenvectors from orthogonality are small.

Suppose that the diagonal elements of Λ are the eigenvalues of $T = U\Lambda U^T$ in descending order

$$\lambda_1 \geqq \cdots \geqq \lambda_n,$$

and that the column u_i of the orthogonal matrix U is the eigenvector associated with λ_i satisfying $\|u_i\|_2 = 1$. The spectral radius of T is denoted by

$$|\lambda|_{\max} \equiv \max\{|\lambda_1|, |\lambda_n|\}.$$

It is further assumed throughout the paper that the matrix T is unreduced, that is, that none of the immediate sub- or superdiagonal elements of T is zero. Otherwise, the matrix would consist of a direct product of disjoint, lower order matrices whose eigendecompositions can be computed independently [24, p. 315]. Although an unreduced tridiagonal matrix has distinct eigenvalues in exact arithmetic, it may still have computationally coincident ones in finite precision.

Number the computed eigenvalues so that they satisfy the same order as the corresponding exact eigenvalues, i.e.,

$$\hat{\lambda}_1 \geqq \cdots \geqq \hat{\lambda}_n.$$

The accuracy of the computed eigendecomposition $\hat{U}\hat{\Lambda}\hat{U}^{-1}$ of T is then determined by the largest residual error $\mathcal{R}$ of any computed eigenpair and by the deviation from orthogonality $\mathcal{O}$ of the computed eigenvectors:

$$\mathcal{R} = \frac{1}{|\hat{\lambda}|_{\max}} \max_{1 \leqq i \leqq n} \|T\hat{u}_i - \hat{\lambda}_i \hat{u}_i\|_2, \qquad \mathcal{O} = \|\hat{U}^T\hat{U} - I\|_\infty,$$

where $|\hat{\lambda}|_{\max} = \max\{|\hat{\lambda}_1|, |\hat{\lambda}_n|\}$. The particular norms for $\mathcal{R}$ and $\mathcal{O}$ were chosen because they are convenient to analyze and to compute. The outcome of the numerical experiments in the later sections does not change if the matrix norm $\mathcal{O}$ is replaced by the vector norm $\max_{1 \leqq i \leqq n} \|(\hat{U}^T\hat{U} - I)e_i\|_\infty$. Our analysis is restricted to the above norm-based criteria; other quality measures that are applicable when T is known to very high accuracy are discussed in [2], [6]-[8].

Theorem 2.1 below shows that the computed eigendecomposition $\hat{U}\hat{\Lambda}\hat{U}^{-1}$ is the exact eigendecomposition of a matrix $T + E$ close to T if residuals and deviation from orthogonality are small. The error matrix E is in general neither symmetric nor tridiagonal; hence, $\hat{U}$ is not in general exactly orthogonal.

THEOREM 2.1. *Let $\hat{U}\hat{\Lambda}\hat{U}^{-1}$ be the computed eigendecomposition of a symmetric tridiagonal matrix T and let*

$$\mathcal{R} = \frac{1}{|\hat{\lambda}|_{\max}} \max_{1 \leqq i \leqq n} \|T\hat{u}_i - \hat{\lambda}_i \hat{u}_i\|_2, \qquad \mathcal{O} = \|\hat{U}^T\hat{U} - I\|_\infty.$$

Then there exists a matrix E such that

$$T + E = \hat{U}\hat{\Lambda}\hat{U}^{-1}, \qquad \|E\|_2 \leqq \frac{|\hat{\lambda}|_{\max}\sqrt{n}\,\mathcal{R}}{\sqrt{1 - \sqrt{n}\,\mathcal{O}}}.$$

Proof. Let

$$E_1 = \frac{1}{|\hat{\lambda}|_{\max}}(T\hat{U} - \hat{U}\hat{\Lambda}), \qquad E_2 = \hat{U}^T\hat{U} - I.$$

Because for any $n \times n$ matrix A, $\|A\|_2 \leqq \sqrt{n} \max_{1 \leqq i \leqq n} \|Ae_i\|_2$, where e_i is the ith canonical vector,

$$\|E_1\|_2 \leqq \sqrt{n} \max_{1 \leqq i \leqq n} \|E_1 e_i\|_2 = \sqrt{n}\,\mathcal{R}, \qquad \|E_2\|_2 \leqq \sqrt{n}\,\|E_2\|_\infty = \sqrt{n}\,\mathcal{O}.$$

From the definition of E_1,

$$T\hat{U}\hat{U}^{-1} - \hat{U}\hat{\Lambda}\hat{U}^{-1} = |\hat{\lambda}|_{\max} E_1 \hat{U}^{-1},$$

so that

$$\hat{U}\hat{\Lambda}\hat{U}^{-1} = T\hat{U}\hat{U}^{-1} - |\hat{\lambda}|_{\max} E_1 \hat{U}^{-1} = T + E,$$

where $E = -|\hat{\lambda}|_{\max} E_1 \hat{U}^{-1}$, and

$$\|E\|_2 = \| |\hat{\lambda}|_{\max} E_1 \hat{U}^{-1} \|_2 \leqq |\hat{\lambda}|_{\max} \|E_1\|_2 \|\hat{U}^{-1}\|_2 \leqq |\hat{\lambda}|_{\max} \sqrt{n}\, \mathcal{R} \|\hat{U}^{-1}\|_2.$$

We use the Neumann lemma [14, p. 59] to bound $\|\hat{U}^{-1}\|_2$:

$$\|\hat{U}^{-1}\|_2^2 = \|(\hat{U}^T\hat{U})^{-1}\|_2 = \|(I + (I - \hat{U}^T\hat{U}))^{-1}\|_2$$

$$\leqq \frac{1}{1 - \|I - \hat{U}^T\hat{U}\|_2} \leqq \frac{1}{1 - \sqrt{n}\, \mathcal{O}}.$$

Thus,

$$\|E\|_2 \leqq \frac{|\lambda|_{\max} \sqrt{n}\, \mathcal{R}}{\sqrt{1 - \sqrt{n}\, \mathcal{O}}}. \qquad \square$$

Under the assumptions

$$\|T\hat{U} - \hat{U}\hat{\Lambda}\|_2 \leqq \varepsilon_1, \qquad \|\hat{U}^T\hat{U} - I\|_2 \leqq \varepsilon_2,$$

the error matrix is bounded above by

$$\|E\|_2 \leqq \frac{|\hat{\lambda}|_{\max} \mathcal{R}}{\sqrt{1 - \mathcal{O}}},$$

which is independent of the matrix order. A related result is proven in [14, p. 416].

3. The EISPACK routine TINVIT. The steps for computing all eigenvectors of an unreduced symmetric tridiagonal matrix T by inverse iteration are given in Algorithm 3.1.

ALGORITHM 3.1 (Basic Implementation of Inverse Iteration)

```
For $j = n, n-1, \cdots, 1$:
    1. Choose a starting vector $y_j$.
    2. Solve $(T - \hat{\lambda}_j I) z_j = y_j$ for $z_j$.
    3. If the reorthogonalization criterion is satisfied, orthogonalize $z_j$ against
       iterates associated with computed eigenvalues close to $\hat{\lambda}_j$.
    4. If the stopping criterion is not satisfied, set $y_j = z_j / \|z_j\|_\infty$ and go to step 2.
    5. The computed eigenvector is $\hat{u}_j = z_j / \|z_j\|_2$.
```

As suggested in [23, p. 143] and [24, p. 329], the EISPACK implementation TINVIT performs the linear system solution in step 2 by Gaussian elimination with partial pivoting and the orthogonalizations in step 3 by the modified Gram–Schmidt algorithm. Because TINVIT yields less accurate eigenvectors than do existing implementations of the QL method (TQL2) [3], [22] or Cuppen's divide-and-conquer method (TREEQL) [5], [12], the loss in accuracy must be due to one or more of the following three factors: the choice of starting vector, the reorthogonalization criterion, and the stopping criterion. TINVIT deals with these issues as follows.

3.1. The starting vector. As argued in § 1, a good starting vector y_j has a large enough contribution of an eigenvector associated with the current eigenvalue λ_j to yield an iterate with dominant components in the eigenspace associated with λ_j.

Without advance knowledge of the eigenvectors, however, it is difficult to ensure a high quality starting vector. For instance, the canonical basis vectors e_1 and e_n should not be used as starting vectors because they are often nearly orthogonal to some eigenvectors of a symmetric tridiagonal matrix T [23, p. 147]. The vector of all ones is also a poor choice as it is orthogonal to half of the eigenvectors of a symmetric tridiagonal Toeplitz matrix [15].

Analytic determination of a good starting vector is complicated by the role of roundoff error in inverse iteration. As shown in [21], [23]-[25], one or two iterations in finite precision arithmetic are generally sufficient to produce a significant iterate component in the correct direction unless the starting vector is exactly orthogonal to that direction.

In agreement with [23, p. 147], TINVIT avoids explicit formation of the starting vector y_j as follows. The tridiagonal system $(T-\hat{\lambda}_j I)z_j = y_j$ is solved by using Gaussian elimination with partial pivoting to factor the matrix $T-\hat{\lambda}_j I = L_j U_j$. (Throughout this paper, we disregard the permutation matrix for simplicity.) The vector y_j is chosen so that the result of the forward substitution equals e, the vector of all ones. That is, the computation $L_j e = y_j$ need never be carried out, and the solution of the first linear system in each eigenvector computation amounts to solving only the second of the two triangular systems $U_j z_j = e$.

When computationally coincident eigenvalues (i.e., eigenvalues that are identical to working precision) are used as shifts, their iterates converge to a single eigenvector and fail to span the whole eigenspace. However, these iterates are very sensitive to the value of $\hat{\lambda}_j$ [24, p. 329]. Wilkinson suggests that the computationally coincident eigenvalues be slightly perturbed so as to make them distinct and that inverse iteration be used with the perturbed eigenvalues to produce iterates that are linearly independent. The increased distance of $\hat{\lambda}_{i+1}, \cdots, \hat{\lambda}_{i+k}$ from $\hat{\lambda}_i$ should affect only the speed of convergence and not the accuracy of inverse iteration [24, p. 329].

TINVIT replaces computationally coincident eigenvalues $\hat{\lambda}_i = \hat{\lambda}_{i-1} = \cdots = \hat{\lambda}_{i-k}$ by

$$\hat{\lambda}_i < \hat{\lambda}_i + \varepsilon_M \|T\|_R < \cdots < \hat{\lambda}_i + (k-1)\varepsilon_M \|T\|_R,$$

where ε_M is machine epsilon, and

$$\|T\|_R \equiv \max_{1 \leqq j \leqq n} \{|\alpha_j| + |\beta_j|\}$$

for a matrix T with diagonal elements $\alpha_1, \cdots, \alpha_n$ and off-diagonal elements $\beta_2, \cdots, \beta_n$, and $\beta_1 \equiv 0$. Note that $\|T\|_R$ does not satisfy the definition of a matrix norm but that an unreduced tridiagonal matrix T satisfies $\|T\|_R \leqq \|T\|_\infty$.

3.2. The reorthogonalization criterion. The above strategy for perturbing computationally coincident eigenvalues is intended to produce computed eigenvectors that are linearly independent. To assure orthogonal computed eigenvectors, the iterates associated with close eigenvalues are reorthogonalized against each other. In TINVIT, two adjacent eigenvalues $\hat{\lambda}_j$ and $\hat{\lambda}_{j+1}$ are considered close if

$$\hat{\lambda}_j - \hat{\lambda}_{j+1} < 10^{-3} \|T\|_R.$$

Note that eigenvalues *close* enough for reorthogonalization may or may not be *computationally coincident.* The process of reorthogonalizing the iterates proceeds as follows.

The eigenvectors are computed successively, according to the ascending order of the eigenvalues. That is, at the time of computation of $\hat{u}_j$, the computation of the eigenvectors $\hat{u}_{j+1}, \cdots, \hat{u}_n$ has already been completed. If a computed eigenvalue $\hat{\lambda}_j$ is close to the computed eigenvalue $\hat{\lambda}_{j+1}$, then the iterate z_j is reorthogonalized against $\hat{u}_{j+1}$ and against all eigenvectors against which $\hat{u}_{j+1}$ was orthogonalized. In the outline of TINVIT in § 3.4, the data structure CLUSTER(i) contains the indices $i+1, \cdots, i+k$ of all those vectors, against which z_i must be orthogonalized.

3.3. The stopping criterion. In [23, p. 145], Wilkinson shows that if an iterate z_j has a large norm after reorthogonalization but before normalization, the eigenpair $(\hat{\lambda}_j, z_j)$ has a small residual error. Specifically, the large iterate norm $\varepsilon_M \|z_j\|_2 = \Omega(n^{-1/2})$ leads to the small residual $\|(T-\hat{\lambda}_j I)z_j\|_2 = O(\varepsilon_M n^{1/2})$ [23, p. 145]. Furthermore, the large norm of z_j (after reorthogonalization) indicates that the iterates associated with $\hat{\lambda}_{j+1}, \cdots, \hat{\lambda}_n$ were linearly independent (before reorthogonalization) so that the computed eigenvector $\hat{u}_j = z_j/\|z_j\|_2$ is orthogonal to $\hat{u}_{j+1}, \cdots, \hat{u}_n$. (The connection between large iterate norm and successful orthogonalization by the modified Gram-Schmidt procedure is demonstrated in § 4.1.)

From the perturbation result in § 2 we can then conclude that $(\hat{\lambda}_j, z_j)$ is an eigenpair of a matrix close to T and hence that z_j is an accurate eigenvector. Because $\|z_j\|_2 \geqq \|z_j\|_\infty$, the two-norm can be replaced by the cheaper infinity norm for convergence testing. Thus, if $\|y_j\|_\infty = 1$ and $\varepsilon_M \|z_j\|_\infty > 1$, then z_j is a good eigenvector approximation. The difficulty lies in determining just how large $\|z_j\|_\infty$ should be. TINVIT stops iteration if $\varepsilon_M \|z\|_\infty \geqq 1$ (ignoring scaling factors).

3.4. Implementation of inverse iteration. A sketch of the EISPACK routine TINVIT is given as Algorithm 3.2 below. Numerical details such as scaling factors used to prevent overflow are not included. The computed eigenvalues are in descending order $\hat{\lambda}_1 \geqq \cdots \geqq \hat{\lambda}_n$, and ε_M is machine epsilon.

ALGORITHM 3.2 (Outline of TINVIT)

```
For $j = n, n-1, \cdots, 1$
    0. Perturb computationally coincident eigenvalues: if $j < n$ and $\hat{\lambda}_j - \hat{\lambda}_{j+1} \leqq 0$, then replace $\hat{\lambda}_j$ with $\hat{\lambda}_{j+1} + \varepsilon_M \|T\|_R$.
    1. Initialize the set of eigenvalues close to $\hat{\lambda}_j$: $CLUSTER(j) = \emptyset$. If $j < n$ and $\hat{\lambda}_j - \hat{\lambda}_{j+1} < 10^{-3}\|T\|_R$, then $CLUSTER(j) = CLUSTER(j+1) \cup \{j+1\}$.
    2. Initialize the iterate norm $\sigma_j \equiv 0$.
    3. Factor $T - \hat{\lambda}_j I = L_j U_j$.
    4. Loop until $\varepsilon_M \sigma_j \geqq 1$ (error exit after 5 iterations).
        4.a. If this is the first iteration, solve $U_j z_j = e$, otherwise solve $L_j U_j z_j = y_j$.
        4.b. Reorthogonalize $z_j$ against all $\hat{u}_i$ with $i \in CLUSTER(j)$.
        4.c. Set $\sigma_j = \|z_j\|_\infty$ and $y_j = z_j/\sigma_j$.
    5. The computed eigenvector is $\hat{u}_j = y_j/\|y_j\|_2$.
```

4. Experimental results. The experimental results in [17] show that TQL2 or TREEQL generally yield residuals $\mathcal{R} = (1/|\hat{\lambda}|_{\max}) \max_i \|T\hat{u}_i - \hat{\lambda}_i \hat{u}_i\|_2$ less than 10^{-14} for matrix orders $n \leqq 525$; and deviations from orthogonality $\mathcal{O} = \|\hat{U}^T\hat{U} - I\|_\infty$ less than 10^{-14} for $n \approx 32$, less than 10^{-13} for $n \approx 100$, and less than 10^{-12} for $n \approx 512$. (A similar dependence on the matrix order occurs when the deviation from orthogonality is instead measured by $\mathcal{O} = \max_i \|(\hat{U}^T\hat{U} - I)e_i\|_2$.) The EISPACK routine TSTURM (a combination of BISECT and TINVIT) yields respective residuals $\mathcal{R}$ less than 10^{-14}, 10^{-13}, and 10^{-12} and orthogonality measures $\mathcal{O}$ less than 10^{-12}, 10^{-11}, and 10^{-10} for matrix orders 32, 100, and 512, respectively.

The numerical experiments in this section were designed to determine which features of TINVIT need to be modified so that it is at least as accurate in practice as the QL routine TQL2 [22] and the divide-and-conquer routine TREEQL [12]. All experiments were performed in double precision on a single Sequent Symmetry S81 processor using the Weitek 1167 floating-point accelerator. The eigenvalues were computed with the EISPACK routine BISECT to working precision. On this machine, machine epsilon $\varepsilon_M = 2.22 \times 10^{-16}$.

This paper presents representative results selected from the ones in [17]. The first test matrix [1, 2, 1] illustrates the case of matrices without close eigenvalues. The matrix [1, 2, 1] is a symmetric tridiagonal Toeplitz matrix of order n having twos on the diagonal and ones on the first sub- and superdiagonals. Its exact eigenvalues are well separated and given by [15]

$$\lambda_j = 2\left(1 + \cos \frac{j\pi}{n+1}\right), \qquad 1 \leqq j \leqq n.$$

For matrix orders $n \leqq 525$, the computed eigenvalues $\hat{\lambda}_i$ are also well separated.

The second test matrix is the "glued Wilkinson matrix" W_g^+ and represents one of the most difficult test cases for dealing with groups of close eigenvalues. It is constructed as follows: The "Wilkinson matrix" W_{21}^+ of order $n = 21$ has diagonal elements $10, 9, \cdots, 1, 0, 1, \cdots, 9, 10$ and immediate off-diagonal elements equal to one. It possesses pairs of eigenvalues that are very close [24, p. 309]. The spacing between eigenvalues in a pair decreases with increasing magnitude of the eigenvalues, and the eigenvalues in the largest pairs are computationally coincident with regard to double precision. The glued Wilkinson matrix W_g^+ of order $21j$ is formed by placing j copies of W_{21}^+ along the diagonal of the matrix and setting off-diagonal elements equal to 10^{-14} at the positions $\beta_{21}, \beta_{42}, \cdots$ where the submatrices join. For matrix orders $n > 200$, W_g^+ has clusters of eigenvalues near the integers $1, 2, \cdots, \lfloor n/2 \rfloor$ [20].

The conclusions drawn from numerical experiments with these two matrix types are supported by tests on random matrices in [17].

4.1. Starting vectors. In this section, we examine the influence of the starting vector on the accuracy of inverse iteration and on the number of iterations performed. To this end, we use the following vectors as starting vectors for the computation of $\hat{u}_j$.

1. The "correct" eigenvector $\hat{u}_j$: This starting vector is the eigenvector $\hat{u}_j$ computed by inverse iteration with a random starting vector. Each starting vector $\hat{u}_1, \cdots, \hat{u}_n$ has residuals $\mathcal{R} < 10^{-14}$ for all orders and orthogonalities $\mathcal{O} < 10^{-14}$ for $n \leqq 42$, $\mathcal{O} < 10^{-13}$ for $n \leqq 105$, and $\mathcal{O} < 10^{-12}$ for $n \leqq 525$.

2. $\hat{u}_n + \tau \hat{u}_j$: This linear combination of $\hat{u}_n$ and $\hat{u}_j$ is used as the starting vector to compute $\hat{u}_j$ for $1 \leqq j \leqq n-1$, and a random starting vector is used to compute $\hat{u}_n$. When $\tau = 0$ and $\hat{\lambda}_{n-1} > \hat{\lambda}_n$, $\hat{u}_n + \tau \hat{u}_j$ is roughly orthogonal to the eigenvectors associated with $\lambda_1, \cdots, \lambda_{n-1}$. Increasing the value of τ amounts to increasing the contribution of the desired eigendirection in the starting vector and thus determines the minimal size of the contribution that is sufficient for convergence.

3. Random vectors: These vectors have uniformly distributed pseudorandom components between -1 and 1 generated with the linear congruential random number generator from NETLIB [11]. For each matrix order n, a single $n \times n$ random matrix is generated. In one set of experiments, we use the first column of this matrix as the starting vector for *all* eigenvectors. In the second set of experiments, we use column j of the matrix as the starting vector for the jth eigenvector.

4. The TINVIT starting vector y_j: This starting vector is not computed explicitly. Instead it is assumed to be the right-hand side of the lower triangular system $L_j e = y_j$, where e is the vector of all ones, and $T - \hat{\lambda}_j I = L_j U_j$ is the LU decomposition (disregarding the permutation matrix).

For the purposes of this section, TINVIT was modified to perform the same number of iterations for all eigenvectors (the number of iterations is determined by the required accuracy but does not exceed five). Computationally coincident eigenvalues were perturbed as in step 0 of Algorithm 3.2 except when different starting vectors were used for each shift. For different random starting vectors, the rate of convergence and accuracy of inverse iteration are preserved even if computationally coincident eigenvalues are not perturbed, that is, even if step 0 of TINVIT is omitted. The following two sections distinguish between the experimental results for the cases of well separated and close eigenvalues.

4.1.1. Starting vectors for matrices with well-separated eigenvalues. Table 1 shows the number of iterations required by inverse iteration to compute the eigenvectors to the same accuracy as TQL2 or TREEQL for each type of starting vector.

TABLE 1
Number of inverse iterations to compute eigenvector $\hat{u}_j$ for matrix $[1, 2, 1]$ *of order n. The same number of iterations is performed for each $\hat{u}_j$.*

Starting vector	$n=32$ Number of iterations for $\mathcal{R}<10^{-14}$ $\mathcal{O}<10^{-14}$	$n=100$ Number of iterations for $\mathcal{R}<10^{-14}$ $\mathcal{O}<10^{-13}$	$n=512$ Number of iterations for $\mathcal{R}<10^{-14}$ $\mathcal{O}<10^{-12}$
$\hat{u}_j$	1	1	1
$\hat{u}_n$	2	2	4
$\hat{u}_n+10^{-16}\hat{u}_j$	2	2	3
$\hat{u}_n+10^{-8}\hat{u}_j$	2	2	2
$\hat{u}_n+10^{-2}\hat{u}_j$	2	2	2
same random	2	2	2
different random	2	2	2
TINVIT	2	2	2

High accuracy is achieved in one iteration only when accurately computed eigenvectors $\hat{u}_j$ are the starting vectors. More than two iterations are needed only for larger n and only when the starting vector is orthogonal or nearly orthogonal to the computed eigenvector ($\tau \leqq 10^{-16}$). All other starting vectors require two iterations.

Thus, for matrices $[1, 2, 1]$ of order $n \leqq 512$, a starting vector component η_j of magnitude 10^{-8} in the desired direction u_j suffices for rapid convergence, i.e., two iterations. Performing more iterations than listed in Table 1 does not significantly change the accuracy. These results are supported by numerical experiments on random matrices with minimal eigenvalue spacing of 10^{-4} [17].

In summary, when all eigenvalues are well separated the performance of inverse iteration does not strongly depend on the starting vector: random starting vectors and the TINVIT starting vector provide a large enough component in the desired direction for fast convergence.

4.1.2. Starting vectors for matrices with groups of close eigenvalues. Table 2 shows the number of iterations for the glued Wilkinson matrix W_g^+ with $n=42$, 105, and 525 for the different starting vectors. As for matrix $[1, 2, 1]$, accurate eigenvectors are produced in one iteration only when the starting vector is the eigenvector. Two iterations suffice when the starting vector has a correct component of size at least 10^{-8} or when a different random starting vector is used for each eigenvector. The remaining starting

TABLE 2

Number of inverse iterations to compute eigenvector $\hat{u}_j$ for the glued Wilkinson matrix W_g^+ of order n. The same number of iterations is performed for each $\hat{u}_j$.

Starting vector	$n=42$ Number of iterations for $\mathcal{R}<10^{-14}$ $\mathcal{O}<10^{-14}$	$n=105$ Number of iterations for $\mathcal{R}<10^{-14}$ $\mathcal{O}<10^{-13}$	$n=525$ Number of iterations for $\mathcal{R}<10^{-14}$ $\mathcal{O}<10^{-12}$
$\hat{u}_j$	1	1	1
$\hat{u}_n$	3	3	>5
$\hat{u}_n+10^{-16}\hat{u}_j$	3	3	>5
$\hat{u}_n+10^{-8}\hat{u}_j$	2	2	2
$\hat{u}_n+10^{-2}\hat{u}_j$	2	2	2
same random	2	3	3
different random	2	2	2
TINVIT	2	3	>5

vectors require more than two iterations. For $n = 525$, inverse iteration does not converge in five iterations when the iterations are started with $\hat{u}_n$, $\hat{u}_n+10^{-16}\hat{u}_j$ or with the TINVIT starting vector.

Table 3 illustrates the connection between the convergence rate of the iterates and their linear dependence for different types of starting vectors and the matrix W_g^+. The numbers in Table 3 were obtained as follows: The iterates z_j, $1 \leqq j \leqq n$, before the reorthogonalization step 4.b in the *first* iteration of Algorithm 3.2 compose the columns of an $n \times n$ matrix. The smallest singular value of this matrix is listed in the first column of numbers, and the smallest norm σ_j attained by the z_j, $1 \leqq j \leqq n$, after reorthogonalizing in step 4.b is listed in the second column of numbers. The same information is given for z_j in the second iteration of Algorithm 3.2 in the last two columns. These data show that except in the case of different random starting vectors, the iterates after the first iteration are linearly dependent. Thus, the modified Gram-Schmidt procedure breaks down and produces vectors that are almost zero. Likewise, the second iteration fails to produce linearly independent iterates for all but the different random starting vectors. (The singular value for the matrix of iterates from the same random starting vector is so small, 10^{-18}, that the iterates can be considered numerically linearly dependent.)

TABLE 3

Singular values of the matrix of iterates and the smallest iterate norm for the glued Wilkinson matrix W_g^+ of order $n=525$ after one and after two iterations of TINVIT.

Starting vector	Smallest singular value of first iterates	Minimal iterate norm $\min_j \|z_j\|_\infty$ after one iteration	Smallest singular value of second iterates	Minimal iterate norm $\min_j \|z_j\|_\infty$ after two iterations
$\hat{u}_n$	0	0	0	$1.24d-13$
same random vector	0	$4.69d-12$	10^{-18}	$7.04d-04$
different random vector	0.02	$4.94d-04$	0.08	>1.00
TINVIT	0	$4.94d-12$	0	$1.06d-12$

While the TINVIT starting vectors are difficult to analyze, the other choices suggest a possible correlation between linearly dependent starting vectors and iterates: linearly dependent starting vectors lead to linearly dependent iterates in the case of computationally coincident eigenvalues. Table 4 shows that the smallest singular value for a matrix composed of n different random starting vectors is much larger than zero; the only exception is $n=512$, where the 512th column is linearly dependent on the first 479. Because none of the test matrices has a group of eigenvalues including both the 479th and the 512th eigenvalues, inverse iteration starts out with linearly independent random starting vectors for all iterates associated with the same group of close eigenvalues.

TABLE 4
The smallest singular value for a matrix of different random starting vectors.

Matrix order	Smallest singular value
42	0.0362
100	0.0341
105	0.0198
512	$1.d-229$
525	0.0128

In summary, when a different random starting vector is used to compute each eigenvector of the glued Wilkinson matrix, both the starting vectors and the iterates are highly likely to be linearly independent. This correlation between linear dependence of starting vectors and number of iterations can be observed to a lesser degree for other large matrices with groups of close eigenvalues [17].

4.2. Stopping criterion. The experimental results in this section show that TINVIT's choice of stopping criterion causes inverse iteration to stop before highest accuracy is attained. We will examine an alternative that consistently improves the accuracy. For the experiments in this section, TINVIT was modified to compute each eigenvector from a different random starting vector and to use unperturbed computed eigenvalues as shifts.

For matrices $[1,2,1]$ and W_g^+, Table 5 shows how the accuracy of the computed eigendecomposition depends on the norm of the computed iterates (after reorthogonalization in step 4.b of Algorithm 3.2). The TINVIT stopping criterion works correctly for both orders of the glued Wilkinson matrix W_g^+: unit iterate norm and full accuracy are both attained on the second iteration. It fails, however, on the matrix $[1,2,1]$, where all iterates have greater than unit norm but less than full accuracy on the first iteration. The same conclusions can be drawn from experiments with random matrices in [17]. It seems, therefore, that at least two iterations should always be performed regardless of iterate norm when different random starting vectors are used. In other words, after the iterate norm is large enough and the loop in step 4 of Algorithm 3.2 is exited, the algorithm should perform one more iteration. The additional iteration was already suggested in [24, p. 324], but was not implemented in TINVIT.

We have not found a simple correlation between size of the iterate norms and the number or size of the groups of close eigenvalues.

4.3. Reorthogonalization. For the purpose of this section, TINVIT was modified to compute each eigenvector from a different random starting vector and to perform

TABLE 5

Iterate norm, residual, and orthogonality for matrices [1, 2, 1] *and* W_g^+ *after one and after two inverse iterations. A different random starting vector is used for each eigenvector computation.*

Matrix	Iteration	Minimal iterate norm $\min_j \|z_j\|_\infty$	Maximal residual $\mathscr{R}$	Deviation from orthogonality $\mathscr{O}$
$[1, 2, 1](n = 100)$	1	>1.00	$3.18d-14$	$3.05d-12$
	2	>1.00	$1.58d-16$	$3.20d-14$
$W_g^+(n = 105)$	1	0.14	$1.47d-13$	$1.68d-11$
	2	>1.00	$8.70d-16$	$3.85-15$
$[1, 2, 1](n = 512)$	1	>1.00	$1.60d-11$	$4.62d-09$
	2	>1.00	$3.93d-16$	$1.57d-13$
$W_g^+(n = 525)$	1	$4.94d-04$	$3.42d-09$	$6.02d-07$
	2	>1.00	$5.99d-15$	$1.98d-14$

one more iteration after the iterate norm becomes large enough, i.e., one more iteration after exiting the loop in step 4 of Algorithm 3.2. In the numerical experiments below, we vary the distance at which adjacent eigenvalues are considered to be so close as to require orthogonalization of the associated iterates.

Table 6 shows the residuals $\mathscr{R}$ and deviations from orthogonality $\mathscr{O}$ for matrix [1, 2, 1] of order $n = 100$ as the reorthogonalization criterion is varied from 0 to $10^{10}\|T\|_R$ after one and after two inverse iterations. These data confirm that more orthogonalization is not a substitute for extra iterations because small residuals are not attained until the second iteration even with reorthogonalization of all eigenvectors. Table 7 shows the same situation for W_g^+ when $n = 105$ and $n = 525$, as well as the fraction of inverse iteration time spent in the modified Gram-Schmidt procedure.

Increasing the reorthogonalization criterion beyond that of TINVIT does not significantly improve the accuracy for matrices [1, 2, 1] and W_g^+. It can, however, substantially increase the computation time. With the TINVIT criterion $10^{-3}\|T\|_R$, most of the eigenvectors of W_g^+ are reorthogonalized (80 percent when $n = 105$ and 96 percent when $n = 525$), but reorthogonalization occurs in many small groups. In contrast, with the criterion $10^{10}\|T\|_R$ all eigenvectors are reorthogonalized as one group, and the cost rises markedly although the accuracy hardly changes.

TABLE 6

Accuracy for matrix [1, 2, 1] *with different reorthogonalization criteria when* $n = 100$.

Criterion	Number of vectors orthogonalized	One iteration		Two iterations	
		$\mathscr{R}$	$\mathscr{O}$	$\mathscr{R}$	$\mathscr{O}$
$10^{10}\|T\|_R$ (all)	99	$6.09d-13$	$6.41d-15$	$2.12d-16$	$5.75d-15$
$10^{-1}\|T\|_R$	97	$1.87d-12$	$7.40d-15$	$2.13d-16$	$6.12d-15$
$10^{-2}\|T\|_R$	33	$7.69d-14$	$4.97d-12$	$1.67d-16$	$1.82d-15$
$10^{-3}\|T\|_R$	2	$3.18d-13$	$3.05d-12$	$1.58d-16$	$3.20d-14$
$10^{-5}\|T\|_R$	1	$1.10d-13$	$2.75d-11$	$1.90d-16$	$4.28d-14$
0	0	$2.28d-13$	$2.68d-11$	$1.61d-16$	$4.68d-14$

TABLE 7

Accuracy and computation time for W_g^+ after two inverse iterations with different reorthogonalization criteria when $n = 100$ and $n = 525$. The last column shows the fraction of reorthogonalization (MGS) *time in inverse iteration.*

Order	Criterion	$\mathcal{R}$	$\mathcal{O}$	Number of vectors	Time for inverse iteration	Fraction MGS time
$n = 105$	$10^{10}\|T\|_R$ (all)	$1.97d-16$	$4.57d-15$	104	30.6	0.67
	$10^{-1}\|T\|_R$	$1.60d-16$	$3.14d-15$	88	27.7	0.10
	$10^{-3}\|T\|_R$	$8.70d-16$	$3.85d-15$	84	1.4	0.07
	$10^{-5}\|T\|_R$	$2.09d-16$	$2.52d-13$	78	1.4	0.05
	0	$1.85d-16$	2.05	0	0	0
$n = 525$	$10^{10}\|T\|_R$ (all)	$7.58d-15$	$1.53d-14$	524	5807.1	0.98
	$10^{-1}\|T\|_R$	$4.69d-15$	$3.51d-14$	523	5287.6	0.73
	$10^{-3}\|T\|_R$	$5.99d-15$	$1.98d-14$	504	338.1	0.15
	$10^{-5}\|T\|_R$	$3.46d-15$	$6.24d-13$	498	253.1	0.12
	0	$2.04d-16$	6.38	0	0	0

These experiments show that the best possible orthogonality can generally be attained only by the time-consuming process of reorthogonalizing all eigenvectors. The accuracy desired here, however, can usually be achieved by means of the TINVIT reorthogonalization criterion along with different random starting vectors and the improved stopping criterion of § 4.2.

5. A new implementation of inverse iteration. The improvements to inverse iteration developed in § 4 are incorporated into the following algorithm. These changes are based on experiments in § 4 with matrix orders $n \leqq 525$ and may not apply to much larger matrix orders. Some comments on solving larger order problems conclude this section.

ALGORITHM 5.1 (Improved Inverse Iteration Algorithm (III))

```
For $j = n, n-1, \cdots, 1$
    1. Initialize the set of eigenvalues close to $\hat{\lambda}_j$: $CLUSTER(j) = \emptyset$.
       If $j < n$ and $\hat{\lambda}_j - \hat{\lambda}_{j+1} < 10^{-3}\|T\|_R$, then
       $CLUSTER(j) = CLUSTER(j+1) \cup \{j+1\}$.
    2. Generate a random vector $x_j$ with uniformly distributed components in
       the interval $[-1, 1]$, and form the starting vector $y_j = x_j / \|x_j\|_2$.
    3. Initialize the iterate norm $\sigma_j \equiv 0$.
    4. Factor $T - \hat{\lambda}_j I = L_j U_j$.
    5. Loop until $\varepsilon_M \sigma_j \geqq 1$ (error exit after 5 iterations).
       5.a. Solve $L_j U_j z_j = y_j$.
       5.b. Reorthogonalize $z_j$ against all $\hat{u}_i$ with $i \in CLUSTER(j)$.
       5.c. Set $\sigma_j = \|z_j\|_\infty$ and $y_j = z_j / \sigma_j$.
    6. Repeat step 5 once.
    7. The computed eigenvector is $\hat{u}_j = y_j / \|y_j\|_2$.
```

Tables 8 and 9 compare the computation time of the EISPACK routine TSTURM with that of the EISPACK routine BISECT combined with Algorithm III (B/III). Because of the additional iterations performed, the computation time of III is substantially higher than that of TINVIT. For matrix $[1, 2, 1]$ of order $n = 512$, however, very

TABLE 8

42	1.6	0.4	4.25d − 15	2.3d − 13	0.6	1.61d − 16	2.61d − 15
105	4.72	3.0	5.11d − 14	2.36d − 12	4.8	6.98d − 16	4.43d − 15
525	23.3	171.1	1.14d − 13	4.08d − 11	333.4	5.55d − 15	1.69d − 14

little orthogonalization of eigenvectors takes place (see Table 6), and eigenvector computation is cheap compared to eigenvalue computation. The longer time of Algorithm III represents only a 13 percent increase in total computation time for B/III over TSTURM.

The storage requirements for Algorithm III are the same as for TINVIT. The time for generation of random starting vectors in Algorithm III is small compared to the total computation time. It constitutes less than 4 percent of the total eigenvector computation time for matrix [1, 2, 1] of order $n \leqq 512$ and for W_g^+ of order $n \leqq 525$. A 1000×1000 matrix of random elements can be generated in 14.00 seconds.

Algorithm III allows accurate solution of problems up to about order 525. It thus gives a roughly four-fold increase of the order solved accurately (or at all) by TINVIT. It also provides guidelines for solving problems of larger order. Experiments performed on an IBM RS6000/520 after the compilation of data for this paper show that with minor modification, the new implementation allows accurate solution of all tested problems up to order 2000. (No larger orders were tried.) To achieve this accuracy, it is necessary to perform two (rather than one) extra iterations after the iterate norm grows sufficiently large. It is also necessary to separate computationally coincident eigenvalues by a perturbation that is small relative to the magnitude of the eigenvalues. Because the longer vectors are likely to have smaller infinity norms, it is also possible to decrease the stopping criterion. If the maximum number of iterations is reached without sufficient norm growth, it is advisable to compute the residual of the computed vector before accepting it as a computed eigenvector. Even with a small residual, the computed vector may not be fully orthogonal to the other computed eigenvectors. A complete version of this code is available as routine DSTEIN in LAPACK [1].

6. Comparison with other methods. This section offers an experimental comparison of Cuppen's divide-and-conquer method, the QL method, and bisection with inverse iteration. The respective implementations are TREEQL [12], TQL2 [22], and B/III. TREEQL switches from divide and conquer to TQL2 for subproblems of order $n \leqq 50$. For a given problem, the relative speeds of the three methods depend on the degree of deflation in TREEQL, the amount of matrix splitting in TQL2, and the clustering of eigenvalues for B/III. Because they illustrate the range of results for all matrices from [17], we use the three test matrices $[1, 2, 1]$, W_g^+, and $[1, u, 1]$ as a basis for comparison. The matrix $[1, u, 1]$ has ones in its first subdiagonal and superdiagonal and the value $i \times 10^{-6}$ in the ith diagonal position. It undergoes little deflation when its eigendecomposition is computed by TREEQL. As none of these test matrices contains row sums of widely differing magnitudes, we exclude IMTQL2 from the comparison: the performance and accuracy of TQL2 and IMTQL2 are nearly identical for these test matrices [17].

Table 10 shows that the maximal residual $\mathcal{R} = (1/|\hat{\lambda}|_{\max}) \max_{1 \leqq i \leqq n} \|T\hat{u}_i - \hat{\lambda}_i \hat{u}_i\|_2$ and deviation from orthogonality $\mathcal{O} = \|\hat{U}^T\hat{U} - I\|_\infty$ of the eigendecompositions computed by the three methods do not differ significantly.

TABLE 10
Maximal residual and deviation from orthogonality of eigendecompositions computed by B/III, TREEQL, *and* TQL2 *for matrices* $[1, 2, 1]$, W_g^+, $[1, u, 1]$.

Matrix order	Method	Maximal residual $\mathcal{R}$	Deviation from orthogonality $\mathcal{O}$
$n = 32$ or 42			
	TREEQL	$3.26d-15$	$5.59d-15$
	TQL2	$1.52d-15$	$1.30d-14$
	B/III	$1.80d-16$	$6.20d-15$
$n = 100$ or 105			
	TREEQL	$6.07d-14$	$2.75d-15$
	TQL2	$2.39d-15$	$1.06d-14$
	B/III	$3.67d-15$	$8.52d-14$
$n = 512$ or 525			
	TREEQL	$3.96d-15$	$1.67d-13$
	TQL2	$1.66d-14$	$2.50d-13$
	B/III	$6.05d-15$	$7.92d-13$

As shown in Figs. 1-3, however, the computation times for the problems can differ significantly. The top graphs in these figures show the different computation times for matrix orders $n \leqq 60$. B/III is slowest for matrices $[1, 2, 1]$ and $[1, u, 1]$ of order $n \leqq 20$. TQL2 is fastest for $[1, 2, 1]$ and $[1, u, 1]$ of order $n \leqq 20$ and slowest for all matrices of order $50 \leqq n \leqq 525$. TREEQL is fastest for W_g^+ of all orders and for $[1, 2, 1]$ of order $20 \leqq n \leqq 60$ due to moderate ($[1, 2, 1]$) and heavy (W_g^+) deflation. The bottom graphs in Figs. 1-3 show the different computation times for matrix orders $60 \leqq n \leqq 512$. For $n = 512$, TREEQL is about 2 to 40 times faster than TQL2, and B/III is about eight times faster than TQL2.

Because the degree of deflation and the grouping of eigenvalues are rarely known in advance, it is generally not possible to select the fastest serial method for a given

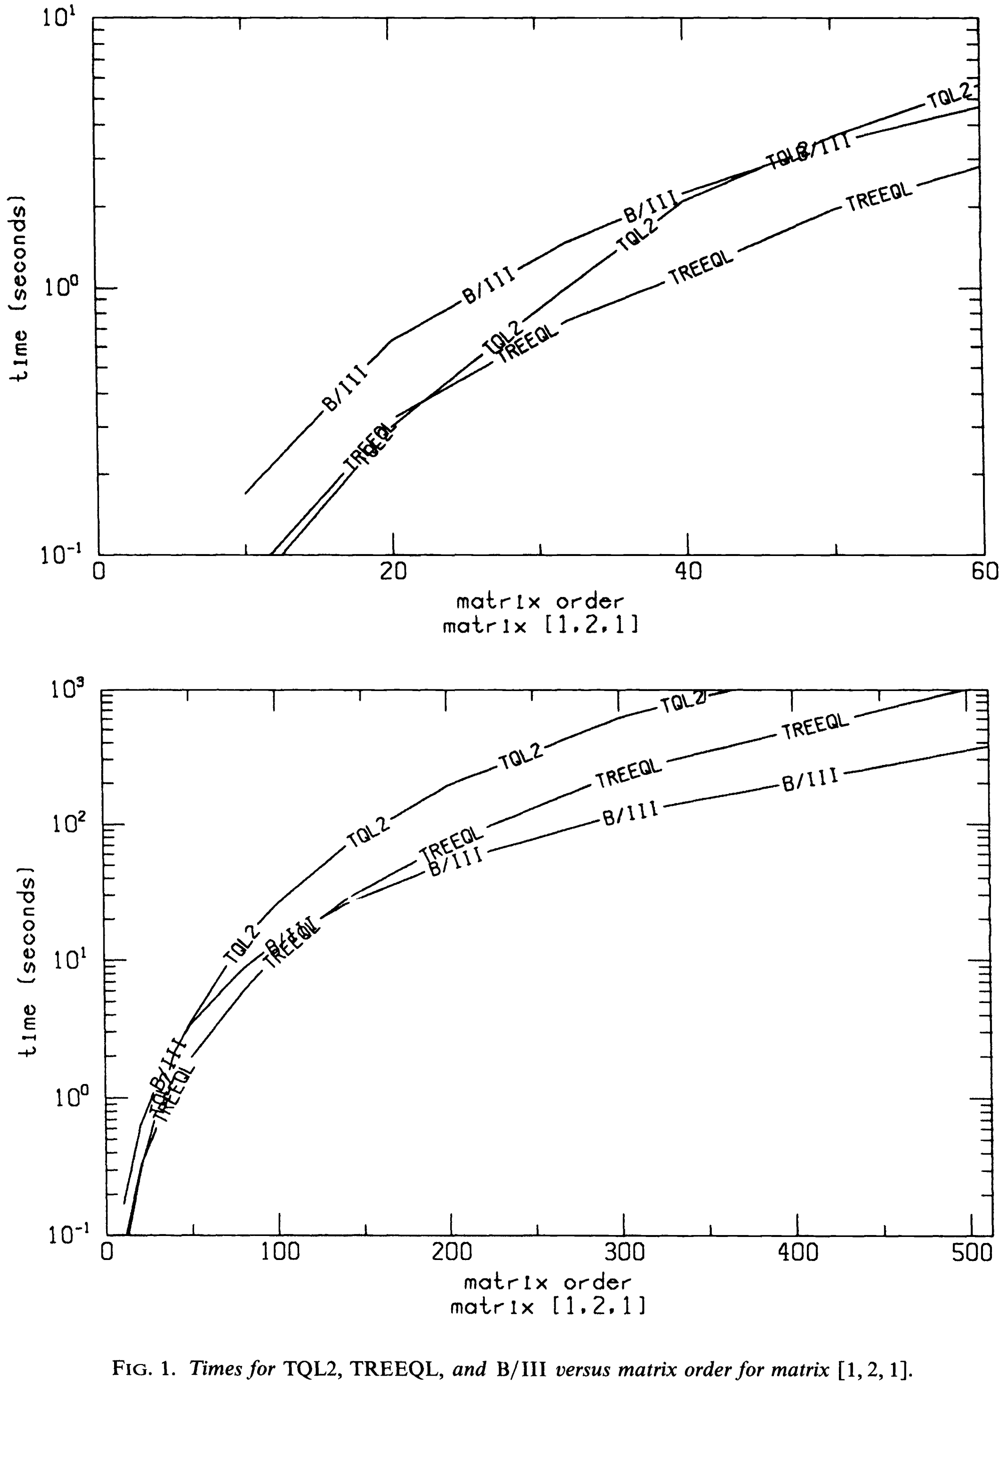

FIG. 1. *Times for* TQL2, TREEQL, *and* B/III *versus matrix order for matrix* [1, 2, 1].

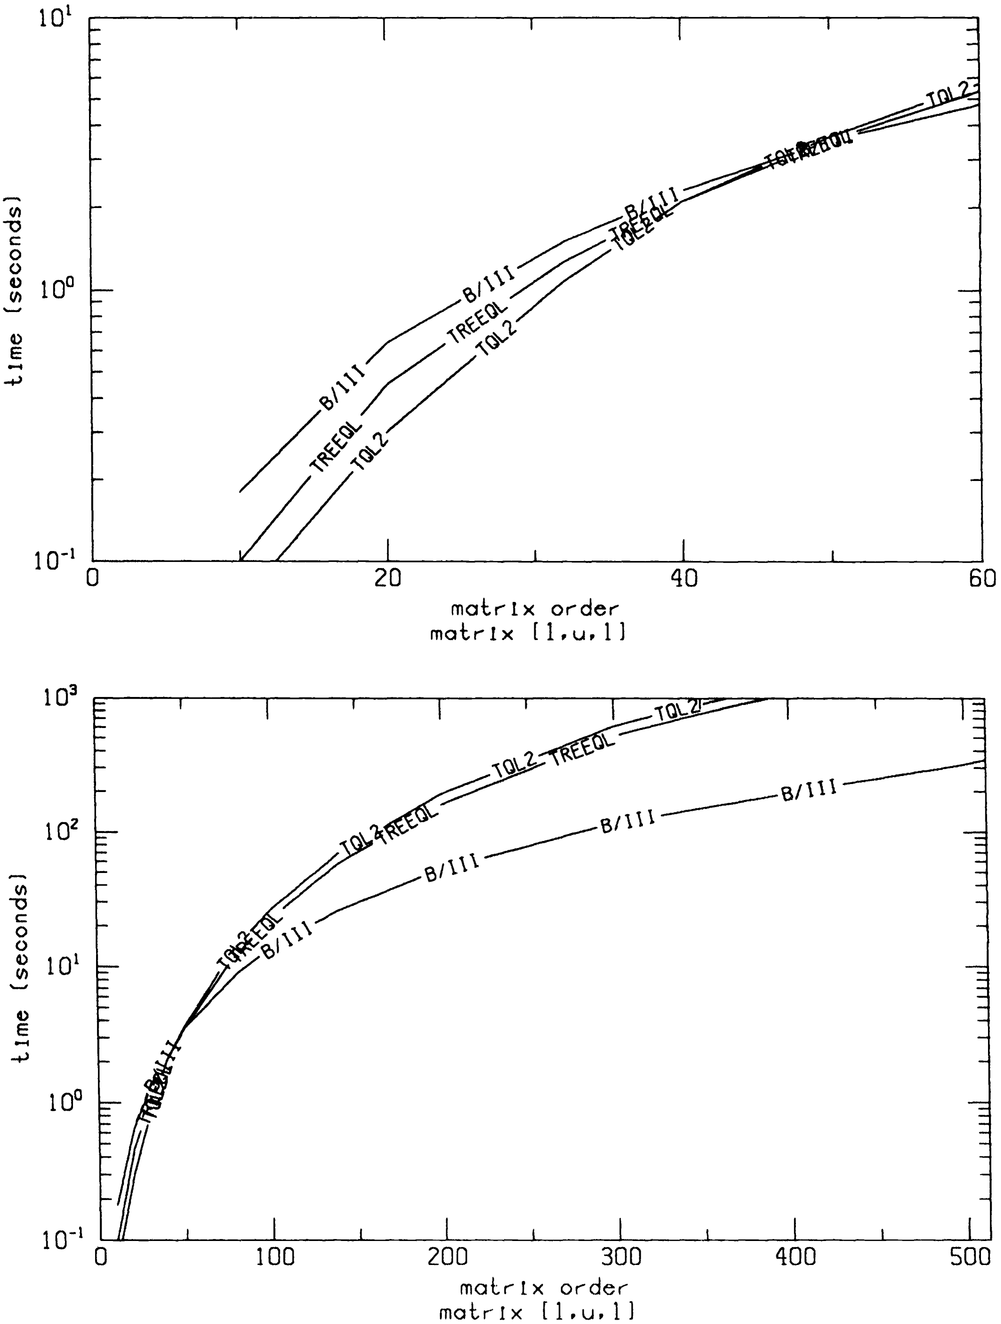

FIG. 3. *Times for* TQL2, TREEQL, *and* B/III *versus matrix order for matrix* [1, *u*, 1].

problem. In all of our experiments, however, B/III is much faster than TQL2 and equally accurate. For larger matrix orders, B/III is fastest for light to medium deflation, while TREEQL is fastest for heavy deflation.

7. A statistical analysis of inverse iteration. The preceding sections establish experimentally the design choices for an accurate implementation of inverse iteration. Because they rely on the use of starting vectors with randomly distributed components, we now give a statistical analysis to explain some of the experimental observations. Section 7.1 states our assumptions, § 7.2 defines a good eigenvector approximation, § 7.3 determines the expected quality of a random starting vector and briefly discusses the limitations of the analysis, and § 7.4 estimates the error in applying the analysis based on starting vectors with normally distributed components to starting vectors with uniformly distributed components. Statistical analyses of methods for computing *eigenvalues* can be found, for example, in [10], [19].

7.1. Assumptions. A unit-norm starting vector $y = x/\|x\|_2$ is computed from a vector x with independent random components, each of which has a normal distribution with mean 0 and variance 1 (normal (0, 1)). Such vectors y are uniformly distributed on the unit n-sphere [9]. Because the distribution of their components is invariant under orthogonal transformations, these vectors can be represented in terms of the orthonormal basis of eigenvectors $\{u_1, u_2, \cdots, u_n\}$ of the symmetric tridiagonal matrix T:

$$y = (\eta_1, \eta_2, \cdots, \eta_n)^T, \qquad \text{where } y = \sum_{i=1}^{n} \eta_i u_i, \qquad \|u_i\|_2 = 1, \qquad \sum_{i=1}^{n} \eta_i^2 = 1.$$

7.2. The quality of an approximate eigenvector. A vector y as defined above is a good approximation to u_i if η_i is much larger than any other component, i.e., if $\eta_i^2 \geqq 1 - \varepsilon^2$ for some error tolerance $0 \leqq \varepsilon \leqq 1$. Geometrically, the angle θ_i between y and u_i satisfies $\cos \theta_i \geqq \sqrt{1 - \varepsilon^2}$. Similarly, y is a good approximation to a linear combination of eigenvectors $u_1, \cdots, u_d$ if $\sum_{i=1}^{d} \eta_i^2 \geqq 1 - \varepsilon^2$. Because random vectors are uniformly distributed on the sphere, the probability that y is a good approximation to the linear combination is just the fraction of the surface area of the sphere defined by all vectors whose components $\xi_1, \cdots, \xi_d$ satisfy $\sum_{i=1}^{d} \xi_i^2 \geqq 1 - \varepsilon^2$.

The probability that $\sum_{i=1}^{d} \eta_i^2 \geqq 1 - \varepsilon^2$ is determined by integrating the probability density function of the sum $\sum_{i=1}^{d} \eta_i^2$ between $1 - \varepsilon^2$ and 1. If the component ξ_i has a normal (0, 1) distribution, then $\eta_i^2 = \xi_i^2 / \sum_{j=1}^{n} \xi_j^2$ has the beta distribution $B(\frac{1}{2}, \frac{n-1}{2})$, and the sum $\sum_{i=1}^{d} \eta_i^2$ has a $B(\frac{d}{2}, \frac{n-d}{2})$ distribution [9] with probability density function $t^{(d/2)-1/2}(1-t)^{((n-d)/2)-1}$. The probability that y is a good approximation to a linear combination of eigenvectors $u_1, \cdots, u_d$ is thus given in the following theorem.

THEOREM 7.1. *Let x have independent random components, each with a normal* (0, 1) *distribution, and let $y = x/\|x\|_2 = (\eta_1, \cdots, \eta_n)^T$. Given $0 \leqq \varepsilon \leqq 1$, the probability that $\sum_{i=1}^{d} \eta_i^2 \geqq 1 - \varepsilon^2$ is*

$$(1) \qquad P\left(\sum_{i=1}^{d} \eta_i^2 \geqq 1 - \varepsilon^2\right) = 1 - \alpha \int_0^{1-\varepsilon^2} t^{\frac{d}{2}-1}(1-t)^{\frac{n-d-2}{2}}\, dt \equiv 1 - \alpha I$$

with

$$\alpha = \frac{\gamma(\frac{n}{2})}{\gamma(\frac{d}{2})\gamma(\frac{n-d}{2})},$$

where $\gamma(\omega)$ is the gamma function with argument ω.

7.3. The quality of the starting vectors. The experiments in § 4 show that random vectors make good starting vectors for inverse iteration. It turns out that the random starting vectors used were linearly independent and not orthogonal to the eigenvectors being computed. In this section, we demonstrate the practical usefulness of Theorem 7.1 and establish the number of times a random starting vector can be reused for computing eigenvectors associated with well-separated eigenvalues.

For rapid convergence of an iterate to an eigenvector u_i, it is essential that the starting vector y have a large enough component in the u_i direction. The probability that a component η_i is of size at least $\sqrt{1-\varepsilon^2}$ is given in Theorem 7.1 with $d=1$. Table 11 gives these probabilities for matrix orders $n=100$, 1000, and 10,000 for a range of $1-\varepsilon^2$ values. The integral in Theorem 7.1 was computed by Gauss-Legendre quadrature with 100 nodes. For $n \leqq 10{,}000$, the probability that any one component of y is at least 0.0001 is no smaller than $1-10^{-16}$, while the probability that any one component is at least 0.001 is no smaller than 0.9. The unit two-norm of the starting vector guarantees that not all components are very small. Recall from Table 2 that a component of size 10^{-8} is sufficient for fast convergence. For a given tolerance $1-\varepsilon^2$, the probability bounds decrease as n increases: as the number of components in a vector increases, the probability that any one component is large decreases.

TABLE 11
Lower bounds on the probability that $\eta_i^2 \geqq 1-\varepsilon^2$. Numbers in parentheses indicate the number of zero decimal places.

$\sqrt{1-\varepsilon^2}$	For $n=100$ $P(\lvert\eta_i\rvert \geqq \sqrt{1-\varepsilon^2})$	For $n=1000$ $P(\lvert\eta_i\rvert \geqq \sqrt{1-\varepsilon^2})$	For $n=10{,}000$ $P(\lvert\eta_i\rvert \geqq \sqrt{1-\varepsilon^2})$
$<10^{-4}$	1.00 (16)	1.00 (16)	1.00 (16)
10^{-3}	0.99	0.97	0.90
10^{-2}	0.92	0.76	0.34
10^{-1}	0.34	0 (2)	0 (16)
>0.7	0 (16)	0 (16)	0 (16)

Table 4 shows that sets of n randomly generated starting n-vectors tend to be linearly independent. This observation is supported statistically by the result from [13] restated here as Lemma 7.1.

LEMMA 7.1. *Assume that the vectors x_i have independent random components with normal $(0,1)$ distributions. Let $\sigma_{\min}$ denote the smallest singular value of $X=(x_1, \cdots, x_n)$. Then, as $\sigma \rightarrow 0$, the probability that $\sigma_{\min}^2 < \sigma^2$ is*

$$P(\sigma_{\min}^2 < \sigma^2) \sim \sigma\sqrt{n}.$$

Thus, the probability of a nearly singular matrix of starting vectors X is small but grows with increasing number of columns of X. For example, the probability of $\sigma_{\min} < 10^{-16}$ is on the order of 10^{-7} when $n=512$.

For the computation of eigenvectors associated with well-separated eigenvalues, linear independence of the starting vectors seems less important, and one could try to use the same random starting vector for all of them. Given $\varepsilon > 0$, the same starting vector y can be used to compute eigenvectors $u_1, \cdots, u_d$ if $\eta_i^2 \geqq 1-\varepsilon^2$ for $1 \leqq i \leqq d$. The following theorem shows how the number d of eigenvectors for which y can be used depends on the probability ρ with which each of the d eigenvectors provides a significant contribution of y.

THEOREM 7.2. (Reuse of starting vectors.) *Assume that x has independent random components with normal $(0,1)$ distributions and that $y=x/\|x\|_2$. If $d \leqq \lfloor \frac{1-\rho}{\alpha\mathcal{I}} \rfloor$, then $\eta_i^2 \geqq 1-\varepsilon^2$ for $1 \leqq i \leqq d$ with probability at least ρ.*

Proof. Let $y = x/\|x\|_2 = (\eta_1, \cdots, \eta_n)^T$. Then

$$P(\eta_i^2 \geqq 1-\varepsilon^2, 1 \leqq i \leqq d) = 1 - P(\eta_i^2 < 1-\varepsilon^2, 1 \leqq i \leqq d)$$

$$\geqq 1 - \sum_{i=1}^{d} P(\eta_i^2 \leqq 1-\varepsilon^2) = 1 - d\alpha\mathcal{J},$$

where the last equality comes from Theorem 7.1. Setting $\rho = 1 - d\alpha\mathcal{J}$ gives $d \leqq \lfloor \frac{1-\rho}{\alpha\mathcal{J}} \rfloor$. □

Table 12 shows values of d for several choices of $\sqrt{1-\varepsilon^2}$ when $n = 100$, 1000, 10,000: the number of times y can be reused decreases with increasing matrix order n, for fixed ρ and ε. This echoes the trend observed in Table 11: a long vector of norm one is less likely to have large components and so is less acceptable for reuse. From the numerical experiments, we know that a component of size 10^{-8} suffices for rapid convergence. According to Table 12 all components are of size 10^{-4} for random vectors up to length 1000 with probability 0.99 so that the same starting vector can be used to compute all eigenvectors for matrices of order up to $n = 10{,}000$ with probability 0.99.

TABLE 12

The number of times d a starting vector can be used, when $\eta_i^2 \geqq 1-\varepsilon^2$ for $1 \leqq i \leqq d$ with probability ρ.

ρ	$\sqrt{1-\varepsilon^2}$	For $n = 100$ d	For $n = 1000$ d	For $n = 10{,}000$ d
0.5	$<10^{-4}$	100	1000	10,000
	10^{-3}	50	16	5
	10^{-2}	6	2	<1
	10^{-1}	<1	<1	<1
0.9	$<10^{-4}$	100	1000	10,000
	10^{-3}	10	3	1
	10^{-2}	1	<1	<1
	10^{-1}	<1	<1	<1
0.99	$<10^{-4}$	100	1000	10,000
	10^{-3}	1	<1	<1
	10^{-2}	<1	<1	<1
	10^{-1}	<1	<1	<1

The main significance of the statistical analysis is in justifying the choice of random starting vector. The analysis can be applied to the results of inverse iteration in only a limited way. If $z = (T - \hat{\lambda}_j I)^{-k} y = (\zeta_1, \cdots, \zeta_n)^T$ is the unnormalized kth iterate, and no reorthogonalization has taken place, the probability that any one component ζ_j is larger in magnitude than $\sqrt{1-\varepsilon^2}$ is [17]

$$P(\zeta_j^2 \geqq 1-\varepsilon^2) \geqq 1 - \alpha \int_0^{(\lambda_j - \hat{\lambda}_j)^{2k}(1-\varepsilon^2)} t^{-1/2}(1-t)^{(n-3/2)}\, dt.$$

According to the mean value theorem for definite integrals, the integral $\mathcal{J}$ is bounded above by $(\lambda_j - \hat{\lambda}_j)^{2k}(1-\varepsilon^2)$. Thus, if $\hat{\lambda}_j$ is a good approximation to λ_j, then $\mathcal{J}$ is small and the probability that z_j approximates u_j is close to one. If $\lambda_j - \hat{\lambda}_j = \lambda_{j+1} - \hat{\lambda}_j$, then z_j approximates u_j and u_{j+1} with equal probability. When λ_j and λ_{j+1} are close but not equal, one of the two eigenvectors u_j and u_{j+1} will be approximated better than the other only if $(1-\varepsilon^2)(\lambda_j-\hat{\lambda}_j)$ and $(1-\varepsilon^2)(\lambda_{j+1}-\hat{\lambda}_j)$ lie where the integrand $f(t)=t^{-1/2}(1-t)^{(n-3)/2}$ has a large derivative. Hence, although the effects of additional iterations on the accuracy can be assessed in terms of the integral $\mathcal{I}$, a qualitative interpretation seems difficult.

Just as the statistical analysis falls short in determining the preferred number of iterations, it fails regarding stopping and reorthogonalization criteria: even the simplest approximations of distributions become unwieldy [4], [17], [18], and probability density functions become dependent on the exact eigenvalues and on other assumptions that are difficult to verify [17]. Therefore, we did not extend the statistical analysis to the iterates.

7.4. Practical considerations. The preceding statistical analysis qualitatively confirms the experimental observations regarding the starting vectors in § 4. However, the analysis is based on starting vectors with independent, normally distributed components, while the experiments were performed with uniformly distributed components in $[-1, 1]$ having some degree of dependence. Thus, the experimental starting vectors of length n are not uniformly distributed on the unit n-sphere but rather on an n-cube of height 2. Although normally distributed pseudorandom numbers can be generated at a higher cost than uniform ones [9], we will now show that uniform random numbers are acceptable substitutes.

The error in applying the analysis to uniformly distributed starting vectors may be estimated by circumscribing an n-sphere of radius $\sqrt{n}$ about the hypercube. A vector $y=(\eta_1,\cdots,\eta_n)^T=\sum_{i=1}^n \eta_i u_i$ on this sphere is a good approximation to a multiple $\sqrt{n}u_i$ of the eigenvector u_i if $|\eta_i|\geqq\sqrt{n(1-\varepsilon^2)}$. Following the derivation in § 7.2, the probability of this occurrence is

$$P(\eta_i^2\geqq n(1-\varepsilon^2))=1-\alpha\int_0^{n(1-\varepsilon^2)} t^{-1/2}(1-t)^{(n-3)/2}\,dt.$$

Lower bounds for this probability computed by Gauss-Legendre quadrature are given in Table 13.

TABLE 13

Lower bounds on the probability that $\eta_i^2\geqq n(1-\varepsilon^2)$. Numbers in parentheses indicate the number of zero decimal places.

$\sqrt{1-\varepsilon^2}$	For $n=100$ $P(\eta_i^2\geqq n(1-\varepsilon^2))$	For $n=1000$ $P(\eta_i^2\geqq n(1-\varepsilon^2))$	For $n=10{,}000$ $P(\eta_i^2\geqq n(1-\varepsilon^2))$
$\leqq 10^{-6}$	1.00 (16)	1.00 (16)	1.00 (16)
10^{-5}	1.00 (16)	0.99	0.90
10^{-4}	0.99	0.36	0.34
10^{-3}	0.92	0.33	0 (16)
10^{-2}	0.34	0 (2)	0 (16)
$\geqq 10^{-1}$	0 (16)	0 (16)	0 (16)

The probability of a large component η_i in the uniform case is not as high as in the normally distributed case, but components with magnitude 10^{-6} can be expected with near certainty, and this value still suffices for fast convergence. The linear independence of the pseudorandom starting vectors is demonstrated in Table 4.

8. Conclusions. Algorithm III presented in § 5 of this paper replaces the EISPACK routine TINVIT for computing the eigenvectors of a symmetric tridiagonal matrix by inverse iteration. Algorithm III both provides more accurate eigenvectors and allows solution of larger problems than does TINVIT. These improvements follow from a new iteration stopping criterion and the use of random starting vectors. The latter allow us to formalize a portion of the algorithm formerly based solely on heuristics. Namely, the statistical analysis in § 7 proves that random vectors are usually linearly independent and have sufficient components in the directions of the eigenvectors being computed. The first property leads to linearly independent iterates, the second to fast convergence.

9. Acknowledgment. The authors thank Stan Eisenstat and Jim Demmel for many helpful discussions and the reviewers for their instructive comments.

GENERALIZED SCHWARZ SPLITTINGS*

WEI PAI TANG†

Abstract. A classic mathematical technique, the Schwarz Alternating Method (SAM), has recently attracted much attention from researchers in the field of parallel computations, as well as theoreticians. Its advantages in parallelism, wide applicability and great flexibility in implementation make SAM a competitive choice in parallel computations. However, the computational performance of the classical SAM and its modern extensions strongly depend on the amount of overlap between the neighboring subregions. Introducing a large overlap has changed the image of SAM from an impractical theoretical technique to a rewarding numerical approach. However, the duplication of work in these overlapped regions is undesirable. Reducing the amount of overlap without affecting the speed of convergence has become an important performance issue.

Schwarz Splitting (SS) has been proposed as an extension of SAM in numerical linear algebra, and a generalized SS is presented in this paper. The new approach allows utilization of the flexibility of the splitting to further improve convergence speed and complexity. A fast convergence is obtained by choosing a good splitting instead of increasing the overlap. The best performance of our generalized SS is much better than that of a previously recommended SS, in which a large overlap is used. Both convergence analysis and numerical results are presented here.

1. Introduction.

Experience with the new generation of parallel computers has promoted efforts to search for *truly* parallel algorithms rather than parallelizing the existing sequential algorithms. For coarse grain parallelism, domain decomposition has become an increasingly important focus of research for the numerical solution of partial differential equations.

A classic mathematical approach, the Schwarz Alternating Method (SAM) (1869), [16] appears to offer promise for the parallel solution of the very large systems of linear or nonlinear algebraic equations that arise when elliptic problems in elasticity, fluid dynamics, or other important areas are discretized by finite elements or finite differences. With this approach, a large problem is decomposed into several coupled subproblems. If a proper ordering is used, these subproblems can be solved independently. Starting from a given initial guess, the solution is iterated in each subregion and new values are exchanged on these coupled artificial boundaries. This process will converge to the solution for the entire region. Flexibility in mapping these subproblems into different parallel computer topologies and the advantageous ratio between communication and computation make SAM a tempting choice in parallel processing. It is also crucial for some complex fluid flow calculations that different modelings or grids be applied to different subdomains of the flow. For example, in many applications we need to merge Euler's equation, the Navier–Stokes equations, potential flow, and other models in suitable subregions for a single large problem. There are also applications where composite meshes in regions with complicated boundaries are needed. SAM can provide a natural framework within which all these requirements are met.

The recognition of SAM's potential in numerical computations was a rather recent event [2], [14], [11], [12], [5], [17], [4], [10], [3]. This delay may have been caused by

† Department of Computer Science, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.

some disappointing experiments with earlier implementations of SAM [15]. During the past several years, understanding of SAM's computational behavior has become clearer. If the area of the overlap regions is a constant fraction of the subregions, it has been shown that the convergence of SAM is independent of the mesh [12], [3].

Several *modern extensions* of SAM have been proposed. For example, a generalization of SAM in linear algebra—Schwarz splittings—was introduced in [14], [17], and an additive version of SAM is being investigated [4], [3]. It is now known that the convergence of the classical SAM and most of its extensions strongly depend on the amount of overlap between subregions. Introducing a larger overlap does considerably improve the performance of SAM [12], [8]. In conjunction with other acceleration techniques, such as multilevel techniques, preconditioning or SOR accelerations, SAM has proven to be a useful method in large scale scientific computations. However, one undesirable feature of SAM is the duplication of work on the overlapped regions at each iteration. Reducing the amount of overlap without affecting speed of convergence has become an important performance issue.

Schwarz originally proposed a coupling between subregions which requires only the continuity of the unknown. Kantorovich and Krylov ([9, pp. 617–626]) presented a rather general convergence result of SAM for a second order partial differential equation of the form

$$L(u) = F\left(x, y, u, \frac{\partial u}{\partial x}, \frac{\partial u}{\partial y}, \frac{\partial^2 u}{\partial x^2}, \frac{\partial^2 u}{\partial y^2}\right) = 0,$$

with Dirichlet boundary condition. They also used Dirichlet boundary condition on the artificial boundaries. It is not difficult to observe that we can replace the continuity of the unknown on these artificial boundaries by other couplings, for example, the continuity of the unknown's derivative. Several attempts to use different boundary conditions on these overlapped regions were not very successful [17], [13], leading us to conjecture a few years ago that "For different problems the best choice of the type of boundary conditions may vary. It is a very interesting open problem for future research." For the model problem, it was shown that the Dirichlet boundary condition has a better convergence rate than the Neumann boundary condition [17].

In this paper, a new coupling between the overlap subregions is identified. If a successful coupling is chosen, a fast convergence of the alternating process can be achieved without a large overlap.

Before proceeding, let us introduce a generalized version of SAM. We consider the Dirichlet problem for a second order elliptic operator L

$$\begin{aligned} &L(u(\mathbf{x})) = 0, && \mathbf{x} \in \Omega, \\ &u(\mathbf{x})\,|_{\Gamma_\Omega} = \psi(\mathbf{x}), && \mathbf{x} \in \Gamma_\Omega, \end{aligned} \tag{1}$$

where Ω is a bounded region in k-dimensional space, Γ_Ω is the boundary of Ω, and $\mathbf{x} = \{x_1, x_2, \cdots, x_k\}$ is the independent variable (Fig. 1 shows an example of the two-dimensional case). To simplify the discussion, we consider a case for two subregions, although direct generalization can be made to more subregions. We also assume that the solution to this problem exists and is unique.

Split the solution domain Ω into two overlapping subdomains Ω_1 and Ω_2 (see Fig. 1), provided $\Omega_{12} = \Omega_1 \cap \Omega_2 \neq \emptyset$. Denote Γ_{Ω_1}, Γ_{Ω_2}, $\Gamma_{\Omega_{12}}$ the boundaries of Ω_1, Ω_2, and Ω_{12}, respectively. We denote Γ_i, $i = 1, 2$, the part of boundary which belongs to

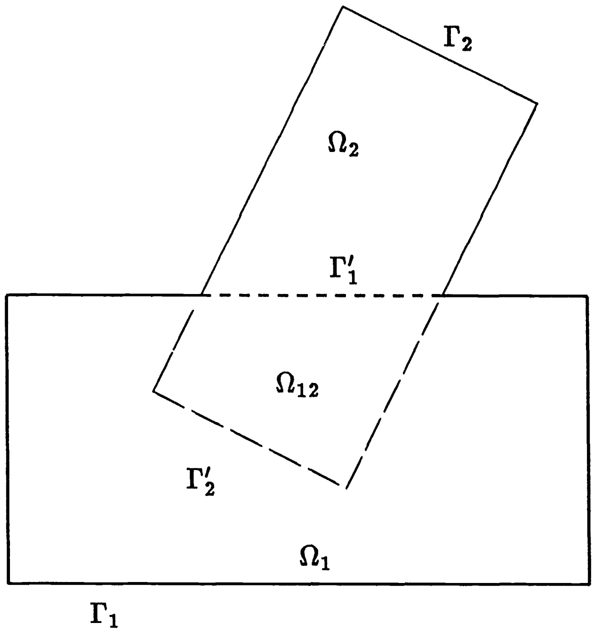

FIG. 1. *Two overlapping subregions.*

Γ_{Ω_i}. Let Γ_i' , $i = 1, 2$, be the part of the artificial boundary in Ω_i. We have

$$\Gamma_{\Omega_1} = \Gamma_1 \cup \Gamma_1',$$
$$\Gamma_{\Omega_2} = \Gamma_2 \cup \Gamma_2'.$$

Denote u_1 and u_2 as the solutions on subdomain Ω_1 and Ω_2, respectively. Then, the following couplings

$$g_1(u_1) \mid_{\Gamma_1'} = g_1(u_2) \mid_{\Gamma_1'}, \tag{2}$$

$$g_2(u_2) \mid_{\Gamma_2'} = g_2(u_1) \mid_{\Gamma_2'}, \tag{3}$$

are true on the artificial boundaries Γ_1' and Γ_2', where

$$g_i(u) = \omega_i u + (1 - \omega_i)\frac{\partial u}{\partial n}, \qquad i = 1, 2. \tag{4}$$

With these new couplings we can formulate two coupled subproblems

$$\begin{aligned} &L(u_1(\mathbf{x})) = 0, \qquad \mathbf{x} \in \Omega_1, \\ &u_1(\mathbf{x}) \mid_{\Gamma_1} = \psi(\mathbf{x}), \\ &g_1(u_1(\mathbf{x})) \mid_{\Gamma_1'} = g_1(u_2(\mathbf{x})) \mid_{\Gamma_1'}, \end{aligned} \tag{5}$$

$$\begin{aligned} &L(u_2(\mathbf{x})) = 0, \qquad \mathbf{x} \in \Omega_2, \\ &u_2(\mathbf{x}) \mid_{\Gamma_2} = \psi(\mathbf{x}), \\ &g_2(u_2(\mathbf{x})) \mid_{\Gamma_2'} = g_2(u_1(\mathbf{x})) \mid_{\Gamma_2'} . \end{aligned} \tag{6}$$

We have the following result.

THEOREM 1. *If the boundary value problem*

$$\begin{aligned} &L(w(\mathbf{x})) = 0, \qquad \mathbf{x} \in \Omega_{12}, \\ &g_1(w(\mathbf{x}))\,|_{\Gamma_1'} = 0, \\ &g_2(w(\mathbf{x}))\,|_{\Gamma_2'} = 0, \end{aligned} \tag{7}$$

has only trivial solution and the solutions u_1, u_2 of (5) *and* (6) *exist, then*

1. $u_1(\mathbf{x}) = u_2(\mathbf{x})$, $\mathbf{x} \in \Omega_{12}$.
2. $u(\mathbf{x}) = u_1(\mathbf{x})$, $\mathbf{x} \in \Omega_1$ *and* $u(\mathbf{x}) = u_2(\mathbf{x})$, $\mathbf{x} \in \Omega_2$,

where u, and u_1, u_2 are the solutions of (1) *and, respectively,* (5) *and* (6).

The proof of this theorem is straightforward and a direct generalization of this result to a finite number of overlapping subregions can be made. However, the same proof can work only for the case in which no three subregions have a common overlap region. We say that problem (1) is *equivalent* to (5) and (6), if 1 and 2 in Theorem 1 are true. A version of this result in linear algebra will be shown in the next section. Following Theorem 1, we can replace problem (1) by (5) and (6).

Since there are unknowns which are coupled in the boundary conditions of (5) and (6), we cannot solve the two problems independently. Given an initial guess $u_2^{(0)}\,|_{\Gamma_1'} = \psi_0$, we will then be able to construct a sequence $\{u_1^{(i)}, u_2^{(i)}\}$ as follows:

$$\begin{aligned} &L(u_1^{(i)}) = 0, \qquad \mathbf{x} \in \Omega_1, \\ &u_1^{(i)}\,|_{\Gamma_1} = \psi, \\ &g_1(u_1^{(i)})\,|_{\Gamma_1'} = g_1(u_2^{(i-1)})\,|_{\Gamma_1'}, \end{aligned} \tag{8}$$

$$\begin{aligned} &L(u_2^{(i)}) = 0, \qquad \mathbf{x} \in \Omega_2, \\ &u_2^{(i)}\,|_{\Gamma_2} = \psi, \\ &g_2(u_2^{(i)})\,|_{\Gamma_2'} = g_2(u_1^{(i)})\,|_{\Gamma_2'}, \qquad i = 1, 2, \cdots. \end{aligned} \tag{9}$$

A key question to ask is "Under what conditions will the sequence $\{u_1^{(i)}, u_2^{(i)}\}$ converge to the solutions $\{u_1, u_2\}$ of (5) and (6)?" If it converges, then the solution of (1) can be constructed from the solution of (5) and (6). An analysis for the model problem will be given in §3.

The generalized SAM provides us with a general framework. Several questions of implementation which affect efficiency are left open. We can effectively tailor this approach to different problems or a different computer architecture. In particular, the following issues have an important impact on performance in real applications.

- The choice of the couplings $g_i(u)$. A better choice of g_i can yield substantial improvement in the convergence rate (see numerical results in §3).
- The decomposition of the solution domain. The flexibility in decomposition makes it possible to choose the geometry of most of the subregions to meet the requirements imposed by fast solvers or by grids. A fast biharmonic solver on irregular domains using generalized SAM is studied in [1].
- The selection of the individual solution technique for each subdomain. We are able to use different solution techniques for different subproblems. It is also

possible to use different ways to obtain the solution of the same subproblem in the different stages of the computation, allowing us to use an optimal approach at any particular moment and in any particular location. Hierarchical grid and inexact solution strategies are typical examples here [18], [7].

- Numerical model for each subproblem. Special boundary shapes or local behavior of the solution may require different models in different subregions. The decoupled subproblems allow us to localize the special treatment to the place where it is needed. Composite grids are a good example of this case.

A particularly important application of SAM is for parallel computations. In the previous description of generalized SAM, the parallelism is not very obvious. When the number of the subregions is greater than or equal to the number of processors, we can color the subregions such that subregions with the same color can be solved independently. There are many issues which need to be considered in practical parallel implementation such as load balancing, communication, synchronization, and ordering of the solution of the subproblems. These are very important in terms of parallel efficiency; however, we shall not study them in depth here.

In the next section, a generalized Schwarz Splitting (generalized SS) and an equivalence theorem are presented. This generalization is an analogy of the generalization from SAM to Schwarz Splitting. Then, an application of this generalized SS to the solution of elliptic equations is shown in §3. The convergence analysis of the strip case and our numerical results indicate that the performance of a proposed generalized SS depends mostly on a coupling parameter α. A fast convergence rate based on a proper choice of α can be obtained with very little overlap, thus the concern about the duplication of computation in the traditional SAM can be alleviated.

2. Generalized Schwarz Splittings. In this section we present an extension of the generalized SAM to numerical linear algebra. For a matrix equation $Ax = f$, we first introduce a Schwarz enhanced equation $\widetilde{A}\widetilde{x} = \widetilde{f}$. The corresponding matrix $\widetilde{A}$ is called a Schwarz enhanced matrix. A necessary and sufficient condition for the equivalence of the original equation and the Schwarz enhanced equation is shown. The analogy of applying generalized SAM to the matrix equation is equivalent to applying a particular block Gauss–Seidel scheme to the Schwarz enhanced matrix. The corresponding splitting of the Schwarz enhanced matrix is called generalized Schwarz Splitting (generalized SS). With this extension, many classical results in numerical linear algebra can be applied to this problem.

2.1. Definitions. As we mentioned in the introduction, the approach of the generalized SAM to a problem is to create an equivalent problem which consists of several loosely coupled subproblems, then to solve the subproblems iteratively. It is not necessary to view SAM only as a way of solving elliptic partial differential equations, as it can also be viewed as a general method for problem solving. Here the generalized SAM is discussed in terms of matrix theory. This approach provides new opportunities for generalizing and improving the original SAM.

Consider a matrix problem:

$$Ax = f, \tag{10}$$

where A is an $N \times N$ nonsingular matrix, f and x are N vectors. A partitioned form of (10) will be used in the rest of this paper. A partition is defined by the integers $n_1, n_2, \cdots, n_{2k+1}$ such that

$$n_1 + n_2 + \cdots + n_{2k+1} = N, \tag{11}$$

$$n_{2i} > 0, \qquad n_{2i+1} \geq 0, \qquad i = 1, \cdots, k. \tag{12}$$

Given a set $\{n_i\}_{i=1}^{2k+1}$ which satisfies (11) and (12), the $(2k+1) \times (2k+1)$ partitioned form of the matrix A is then given by

$$A = \begin{bmatrix} A_{1\ 1} & A_{1\ 2} & \cdots & A_{1\ 2k+1} \\ A_{2\ 1} & A_{2\ 2} & \cdots & A_{2\ 2k+1} \\ \vdots & \vdots & \ddots & \vdots \\ A_{2k+1\ 1} & A_{2k+1\ 2} & \cdots & A_{2k+1\ 2k+1} \end{bmatrix}, \tag{13}$$

where $A_{i\ j}$ is an $n_i \times n_j$ submatrix. We always assume that the unknown vector x and the known vector f in the matrix equation $Ax = f$ are partitioned in a form consistent with A. Thus, if A is given by (13), then x is assumed to be partitioned as

$$x = [x_1, x_2, \cdots, x_{2k+1}]^T, \tag{14}$$

where x_i is an $n_i \times 1$ matrix (column vector). An *augmented vector* of x

$$\tilde{x} = [x_1, x_2, x_2, x_3, x_4, x_4, x_5, \cdots, x_{2k}, x_{2k}, x_{2k+1}]^T \tag{15}$$

is defined such that all even subvectors x_{2i}, $i = 1, \cdots, k$ are duplicated once in their places, and all odd subvectors remain the same.

We present the cases for $N = 3$ and 5 here for readability. The generalization to a large N is direct. A dense 3×3 partitioned matrix can be written as

$$A = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix}.$$

If the operator $L(u)$ in (1) is a linear second order elliptic operator, then the discretized problem can be written as a matrix equation:

$$Ax = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ A_{31} & A_{32} & A_{33} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \\ f_3 \end{bmatrix} = f. \tag{16}$$

The order of the unknowns is arranged so that $[x_1, x_2]$ corresponds to the unknowns in Ω_1, $[x_2, x_3]$ corresponds to the unknowns in Ω_2, and $[x_2]$ corresponds to the unknowns in Ω_{12}, which is the overlapped region. The numerical generalized SAM for the above problem solves the following subproblems alternately:

$$\begin{aligned} \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & B_2 \end{bmatrix} \begin{bmatrix} x_1^{(i)} \\ x_2^{(i-1/2)} \end{bmatrix} &= \begin{bmatrix} f_1 \\ f_2 \end{bmatrix} + \begin{bmatrix} 0 & A_{13} \\ C_2 & A_{23} \end{bmatrix} \begin{bmatrix} x_2^{(i-1)} \\ x_3^{(i-1)} \end{bmatrix}, \\ \begin{bmatrix} B_2' & A_{23} \\ A_{32} & A_{33} \end{bmatrix} \begin{bmatrix} x_2^{(i)} \\ x_3^{(i)} \end{bmatrix} &= \begin{bmatrix} f_2 \\ f_3 \end{bmatrix} + \begin{bmatrix} A_{21} & C_2' \\ A_{31} & 0 \end{bmatrix} \begin{bmatrix} x_1^{(i)} \\ x_2^{(i-1/2)} \end{bmatrix}, \end{aligned} \tag{17}$$

where

$$A_{22} = B_2 + C_2 = B_2' + C_2'. \tag{18}$$

The splittings in (18) correspond to the couplings in (2) and (3). In the next section we will show that a good choice of the splitting of A_{22} can significantly affect the convergence of SAM. It is therefore a very interesting research problem for further improvement of SAM.

It is not difficult to observe that this procedure is equivalent to a 2 × 2 block Gauss–Seidel iteration for the following matrix equation:

$$\text{(19)} \qquad \widetilde{A}\widetilde{x} = \left[\begin{array}{cc|cc} A_{11} & A_{12} & 0 & A_{13} \\ A_{21} & B_2 & C_2 & A_{23} \\ \hline A_{21} & C_2' & B_2' & A_{23} \\ A_{31} & 0 & A_{32} & A_{33} \end{array}\right] \begin{bmatrix} \widetilde{x}_1 \\ \widetilde{x}_2 \\ \widetilde{x}_2' \\ \widetilde{x}_3 \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \\ f_2 \\ f_3 \end{bmatrix} = \widetilde{f}.$$

Under certain conditions [14], [17], we know that the procedure (17) will converge, the solution of (19) satisfies $\widetilde{x}_2 = \widetilde{x}_2'$, and $[\widetilde{x}_1, \widetilde{x}_2, \widetilde{x}_3]^T$ is a solution of (16). This is to say, the augmented vector of the solution of (16) is the solution of (19) and vice versa. Later we will prove that this conclusion can be true only when $(B_2 - C_2')^{-1}$ exists. For most approximations of an elliptic partial differential equation, this restriction is not very difficult to satisfy. We shall call (19) the generalized Schwarz enhanced equation of (16), and the corresponding matrix $\widetilde{A}$ in (19) the generalized Schwarz enhanced matrix of the matrix A.

It may be observed that the second equation in (16) becomes a pair of dual equations in (19):

$$A_{21}\widetilde{x}_1 + B_2\widetilde{x}_2 + C_2\widetilde{x}_2' + A_{23}\widetilde{x}_3 = f_2,$$

$$A_{21}\widetilde{x}_1 + C_2'\widetilde{x}_2 + B_2'\widetilde{x}_2' + A_{23}\widetilde{x}_3 = f_2.$$

They are almost identical, except the term $A_{22}x_2$ of the second equation in (16) is split in two different ways:

$$\begin{aligned} A_{22}x_2 &\implies B_2\widetilde{x}_2 + C_2\widetilde{x}_2', \\ A_{22}x_2 &\implies C_2'\widetilde{x}_2 + B_2'\widetilde{x}_2'. \end{aligned}$$

Here is another example of a 5 × 5 block matrix equation and its generalized Schwarz enhanced equation:

$$Ax = \begin{bmatrix} A_{11} & A_{12} & A_{13} & A_{14} & A_{15} \\ A_{21} & A_{22} & A_{23} & A_{24} & A_{25} \\ A_{31} & A_{32} & A_{33} & A_{34} & A_{35} \\ A_{41} & A_{42} & A_{43} & A_{44} & A_{45} \\ A_{51} & A_{52} & A_{53} & A_{54} & A_{55} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \\ f_3 \\ f_4 \\ f_5 \end{bmatrix} = f,$$

$$\widetilde{A}\widetilde{x} = \left[\begin{array}{cc|ccc|cc} A_{11} & A_{12} & 0 & A_{13} & A_{14} & 0 & A_{15} \\ A_{21} & B_2 & C_2 & A_{23} & A_{24} & 0 & A_{25} \\ \hline A_{21} & C_2' & B_2' & A_{23} & A_{24} & 0 & A_{25} \\ A_{31} & 0 & A_{32} & A_{33} & A_{34} & 0 & A_{35} \\ A_{41} & 0 & A_{42} & A_{43} & B_4 & C_4 & A_{45} \\ \hline A_{41} & 0 & A_{42} & A_{43} & C_4' & B_4' & A_{45} \\ A_{51} & 0 & A_{52} & A_{53} & 0 & A_{54} & A_{55} \end{array}\right] \begin{bmatrix} x_1 \\ x_2 \\ x_2' \\ x_3 \\ x_4 \\ x_4' \\ x_5 \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \\ f_2 \\ f_3 \\ f_4 \\ f_4 \\ f_5 \end{bmatrix} = \widetilde{f},$$

where

$$A_{22} = B_2 + C_2 = B_2' + C_2',$$
$$A_{44} = B_4 + C_4 = B_4' + C_4'.$$

For a general partitioned matrix (13), the splittings of the submatrices $A_{2i\ 2i}$ are

$$A_{2i\ 2i} = B_{2i} + C_{2i} = B_{2i}' + C_{2i}'.$$

From these examples, we can summarize the following rules for constructing the Schwarz enhanced equation. The odd-numbered equations in $Ax = f$ are changed to

$$\sum_{j=1}^{2k+1} A_{1\ j}x_j = f_1,$$

$$\sum_{j=1}^{i} A_{2i-1\ 2j-1}x_{2j-1} + \sum_{j=1}^{i-1} A_{2i-1\ 2j}x_{2j}' + \sum_{j=2i}^{2k+1} A_{2i-1\ j}x_j = f_{2i-1}, \quad 1 < i \le k, \quad k \ne 1,$$

$$\sum_{j=1}^{k+1} A_{2k+1\ 2j-1}x_{2j-1} + \sum_{j=1}^{k} A_{2k+1\ 2j}x_{2j}' = f_{2k+1},$$

while the even-numbered equations become a pair of dual equations in the generalized Schwarz enhanced equation:

$$\begin{aligned} &\sum_{j=1}^{i} A_{2i\ 2j-1}x_{2j-1} + \sum_{j=1}^{i-1} A_{2i\ 2j}x_{2j}' + B_{2i}x_{2i} + C_{2i}x_{2i}' + \sum_{j=2i+1}^{2k+1} A_{2i\ j}x_j = f_{2i},\\ &\sum_{j=1}^{i} A_{2i\ 2j-1}x_{2j-1} + \sum_{j=1}^{i-1} A_{2i\ 2j}x_{2j}' + C_{2i}'x_{2i} + B_{2i}'x_{2i}' + \sum_{j=2i+1}^{2k+1} A_{2i\ j}x_j = f_{2i},\\ &\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad i = 1, \cdots, k. \end{aligned} \tag{20}$$

Only two terms are different in the two dual equations. We will not describe the details of how to form the generalized Schwarz enhanced matrix in general cases, as it is similar to the Schwarz enhanced matrix described in [17]. From the construction of the generalized Schwarz enhanced equation, it is easy to see the following result.

LEMMA 1. *If the vector* $x = (x_1, x_2, \cdots, x_{2k+1})^T$ *is the solution of* (10), *then its augmented vector* $\tilde{x}$ *is the solution of the generalized Schwarz enhanced equation* $\tilde{A}\tilde{x} = \tilde{f}$, *where* $\tilde{f}$ *is the augmented vector of* f.

The matrices $A_{2i\ 2i}$, $i = 1, \cdots, k$, are also called overlapped blocks. Let two matrices $\tilde{B}$ and $\tilde{C}$ be the Schwarz enhanced matrices of the same matrix A and their overlapped blocks are $B_{2i\ 2i}$ and $C_{2i\ 2i}, i = 1, \cdots, k$, respectively. If $B_{2i\ 2i}$ and $C_{2i\ 2i}$ have a relationship such that each $B_{2i\ 2i}$ is a submatrix of the corresponding $C_{2i\ 2i}$, we then say $\tilde{C}$ has *more overlap* than $\tilde{B}$. This overlap is closely related to the overlap area of the solution regions for the subregions mentioned in the introduction. As we have shown in [17], for the continuous model problem, if the amount of overlap increases, then the convergence rate will increase if a traditional SAM is applied. For the matrix model we have a similar result [12].

2.2. Equivalence theorem. A necessary and sufficient condition for the equivalence of (10) and its Schwarz enhanced equation (19) is given in this section. Let A be the same partitioned matrix in (13) and $\widetilde{A}$ be its Schwarz enhanced matrix.

THEOREM 2. *Let $\lambda(A)$, $\lambda(\widetilde{A})$, and $\lambda(B_{2i} - C'_{2i})$, $i = 1, \cdots, k$, be the sets of eigenvalues of $A, \widetilde{A}$, and $(B_{2i} - C'_{2i})$, $i = 1, \cdots, k$, respectively. Then $\lambda(\widetilde{A}) \subset \lambda(A) \cup (\bigcup_{i=1}^{k} \lambda(B_{2i} - C'_{2i}))$.*

Proof. Let λ be an eigenvalue of $\widetilde{A}$ and

$$\tilde{x} = (\tilde{x}_1, \tilde{x}_2, \tilde{x}'_2, \cdots, \tilde{x}_{2k+1})$$

be the corresponding eigenvector. Substituting $\tilde{x}$ into the equation $2i$ and its dual equation, we have

$$\sum_{j=1}^{i} A_{2i\ 2j-1}\tilde{x}_{2j-1} + \sum_{j=1}^{i-1} A_{2i\ 2j}\tilde{x}'_{2j} + B_{2i}\tilde{x}_{2i} + C_{2i}\tilde{x}'_{2i} + \sum_{j=2i+1}^{2k+1} A_{2i\ j}\tilde{x}_j = \lambda\tilde{x}_{2i},$$

$$\sum_{j=1}^{i} A_{2i\ 2j-1}\tilde{x}_{2j-1} + \sum_{j=1}^{i-1} A_{2i\ 2j}\tilde{x}'_{2j} + C'_{2i}\tilde{x}_{2i} + B'_{2i}\tilde{x}'_{2i} + \sum_{j=2i+1}^{2k+1} A_{2i\ j}\tilde{x}_j = \lambda\tilde{x}'_{2i}.$$

As we mentioned in the last section, only two terms are different in the left-hand sides of the two equations. Subtracting the first equation from the second, we have

$$(B_{2i} - C'_{2i})(\tilde{x}_{2i} - \tilde{x}'_{2i}) = \lambda(\tilde{x}_{2i} - \tilde{x}'_{2i}), \qquad i = 1, \cdots, k.$$

If $\tilde{x}_{2i} - \tilde{x}'_{2i} \neq 0$ for some i, then we have $\lambda \in \bigcup_{i=1}^{k} \lambda(B_{2i} - C'_{2i})$. If $\lambda \notin \bigcup_{i=1}^{k} \lambda(B_{2i} - C'_{2i})$, then $\tilde{x}_{2i}$ has to be equal to $\tilde{x}'_{2i}$ for $i = 1, \cdots, k$. Therefore, $\tilde{x}$ is an augmented vector of $x = (\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, \cdots, \tilde{x}_{2k+1})^T$, which will satisfy equation

$$Ax = \lambda x.$$

Thus $\lambda \in \lambda(A)$, which concludes the proof. □

Define the Schwarz enhanced equation (19) as *equivalent* to (10) if $\widetilde{A}^{-1}$ exists and the solution vector $\tilde{x}$ is an augmented vector of the solution x of (10). Similarly, we say that the Schwarz enhanced matrix $\widetilde{A}$ is *equivalent* to matrix A if $\widetilde{A}^{-1}$ exists. With this definition and the result from Theorem 2 we have the following theorem.

THEOREM 3. *If a matrix $\widetilde{A}$ is a Schwarz enhanced matrix of the nonsingular matrix A, then the following conditions are equivalent:*

1. *Matrix $\widetilde{A}$ is equivalent to matrix A.*
2. $0 \notin \bigcup_{i=1}^{k} \lambda(B_{2i} - C'_{2i})$.

Proof. If $0 \notin \bigcup_{i=1}^{k} \lambda(B_{2i} - C'_{2i})$, then from Theorem 2 we know $\widetilde{A}^{-1}$ exists. Applying the same strategy used in the previous proof, we can show that the solution $\tilde{x}$ of $\widetilde{A}\tilde{x} = \tilde{f}$ is an augmented vector of the solution x of $Ax = f$.

Now we show that $0 \notin \bigcup_{i=1}^{k} \lambda(B_{2i} - C'_{2i})$ is also a necessary condition. Suppose there is a j such that $0 \in \lambda(B_{2j} - C'_{2j})$. We know that $(B_{2j} - C'_{2j})$ is singular, hence so is $(B'_{2j} - C_{2j})$, since $(B_{2j} - C'_{2j}) = (B'_{2j} - C_{2j})$. Now, if we subtract row $2j$ from $2j'$ in matrix $\widetilde{A}$, we will have

$$0, \cdots, 0, (B_{2j} - C'_{2j}), -(B'_{2j} - C_{2j}), 0, \cdots, 0. \tag{21}$$

This means that $\widetilde{A}$ is singular. The proof is complete. □

If a matrix is a positive definite matrix or an M-matrix,[1] any principal minor of this matrix is also a positive definite matrix or an M-matrix, respectively. Thus, if we choose $C_{2i} = 0$ and $C'_{2i} = 0$,[2] we immediately have the following corollaries.

COROLLARY 1. *Any Schwarz enhanced matrix of a positive definite matrix A is equivalent to A if $C_{2i} = 0$ and $C'_{2i} = 0, i = 1, \cdots, k$.*

COROLLARY 2. *Any Schwarz enhanced matrix of an M-matrix A is equivalent to A if $C_{2i} = 0$ and $C'_{2i} = 0, i = 1, \cdots, k$.*

3. A parameterized generalized Schwarz Splitting. The general framework of a generalized SS is given in the last section. Here, the convergence behavior of a particular generalized SS for the elliptic equation, namely, parameterized generalized SS, is studied. In a traditional approach to SS, we choose $C_{2i} \equiv 0$. In this case, it is well understood that the amount of overlap is a key factor which affects the convergence rate. Even though a larger overlap means more duplication of work on these overlapping regions, the overall complexity is still better than with a smaller overlap. However, a natural question is raised: is a larger overlap the ultimate choice? The generalized Schwarz Splitting discussed in the previous section provides a way to explore possibilities of further improving the performance of SAM. In particular, we will examine the importance of splitting

$$A_{2i\ 2i} = B_{2i} + C_{2i} = B'_{2i} + C'_{2i}.$$

First, an application of generalized SS to a two-point boundary value problem is investigated. A similar approach can also be applied to two-dimensional problems.

Consider a two-point boundary value problem

$$\begin{aligned} U''(x) + qU(x) &= f(x), & x &\in (0,1), \\ U(0) &= a_0, & U(1) &= a_1, \end{aligned}$$

where $q \leq 0$. After discretization using a centered finite difference, the resulting linear system is

$$T_n(\beta)x = b, \tag{22}$$

where

$$T_n(\beta) = Tridiagonal\{-1, \quad \beta, \quad -1\}_{n \times n}$$

and $\beta \geq 2$. If there is no ambiguity, it will be abbreviated as T_n. Denote

$$T_n(x_1, x_2, x_3)$$

as the same $n \times n$ tridiagonal matrix $T_n(x_2)$, except the first diagonal element is x_1 and the last is x_3.

The generalized SAM for solving this problem divides the region into k overlapping subregions Ω_i $i = 1, \cdots, k$ as shown in Fig. 2. (To simplify the analysis we assume the overlap pattern is uniform). Let h be the grid size, ℓ the length of the overlap and η

[1] Any $n \times n$ matrix $A = (a_{ij})$ with $a_{ij} \leq 0$ for all $i \neq j$ is an M-matrix if A is nonsingular, and $A^{-1} \geq 0$.

[2] In the traditional approach of SAM, we always choose $C_{2i} = 0$ and $C'_{2i} = 0$.

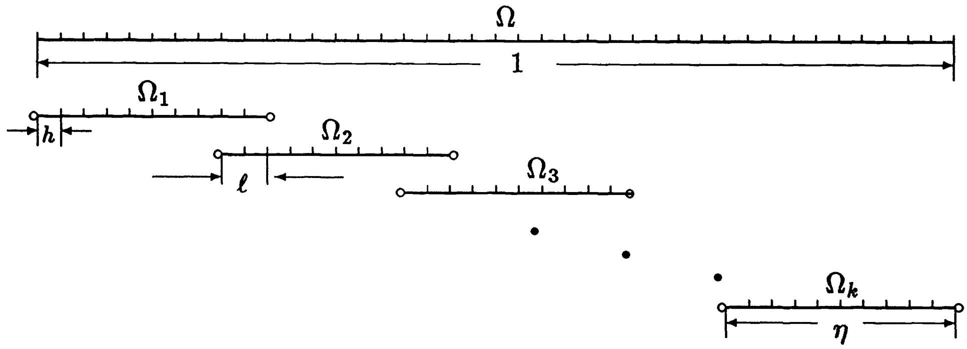

FIG. 2. *One-dimensional overlapping grid.*

the length of every subregion. Then let $n+1 = 1/h$, $l = \ell/h$ and $m+1 = \eta/h$. Here we assume

$$l < m/2,$$

which means no three subregions have a common overlap part. The open circle points in Fig. 2 are the boundaries of the subregions.

We display the case of $k = 3$ for readability. The general case can be easily extended from this case. The partitioned form of (22) is now

$$T_n x = \begin{bmatrix} T_{m-l} & -F_1 & 0 & 0 & 0 \\ -E_2 & T_l & -F_2 & 0 & 0 \\ 0 & -E_3 & T_{m-2l} & -F_3 & 0 \\ 0 & 0 & -E_4 & T_l & -F_4 \\ 0 & 0 & 0 & -E_5 & T_{m-l} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ b_4 \\ b_5 \end{bmatrix} = b.$$

Its corresponding Schwarz enhanced equation is

$$\widetilde{T}_n \widetilde{x} = \begin{bmatrix} T_{m-l} & -F_1 & 0 & 0 & 0 & 0 & 0 \\ -E_2 & B_2 & C_2 & -F_2 & 0 & 0 & 0 \\ -E_2 & C_2' & B_2' & -F_2 & 0 & 0 & 0 \\ 0 & 0 & -E_3 & T_{m-2l} & -F_3 & 0 & 0 \\ 0 & 0 & 0 & -E_4 & B_4 & C_4 & -F_4 \\ 0 & 0 & 0 & -E_4 & C_4' & B_4' & -F_4 \\ 0 & 0 & 0 & 0 & 0 & -E_5 & T_{m-l} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_2' \\ x_3 \\ x_4 \\ x_4' \\ x_5 \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ b_2 \\ b_3 \\ b_4 \\ b_4 \\ b_5 \end{bmatrix} = \widetilde{b}.$$

The quantities above are defined as

- F_1: an $(m-l) \times l$ matrix with zero elements everywhere except for a 1 in position $(m-l, 1)$.
- F_2: an $l \times (m-2l)$ matrix with zero elements everywhere except for a 1 in position $(m-2l, 1)$.
- F_3: an $(m-2l) \times l$ matrix with zero elements everywhere except for a 1 in position $(m-2l, 1)$.

- F_4: an $l \times (m-l)$ matrix with zero elements everywhere except for a 1 in position $(m-l, 1)$.
- E_2: an $l \times (m-l)$ matrix with zero elements everywhere except for a 1 in position $(1, m-l)$.
- E_3: an $(m-2l) \times l$ matrix with zero elements everywhere except for a 1 in position $(1, l)$.
- E_4: an $l \times (m-2l)$ matrix with zero elements everywhere except for a 1 in position $(1, m-2l)$.
- E_5: an $(m-l) \times l$ matrix with zero elements everywhere except for a 1 in position $(1, l)$.

There are many ways to split the matrix T_l. We will introduce a parameterized generalized SS for this problem below. Let

- F be an $l \times l$ matrix with zero elements everywhere except for a 1 in position (l, l) and
$$C = C_2 = C_4 = \alpha F, \qquad B = B_2 = B_4 = T_l - C.$$
- E be an $l \times l$ matrix with zero elements everywhere except for a 1 in position $(1, 1)$ and
$$C' = C_2' = C_4' = \alpha E, \qquad B' = B_2' = B_4' = T_l - C',$$

where $0 \le \alpha < 1$. It is not difficult to show that

$$\det(B - C') = \det(T_l(\beta - \alpha, \beta, \beta - \alpha)) \neq 0,$$

provided $\beta \ge 2$. The resulting Schwarz enhanced equation is equivalent to (22). Then the parameterized generalized SS of (22) is defined as

$$\begin{aligned}\widetilde{T}_n &= M(\alpha) - N(\alpha)\\ &= \begin{bmatrix} T_1 & 0 & 0 \\ 0 & T_2 & 0 \\ 0 & 0 & T_3 \end{bmatrix} - \begin{bmatrix} 0 & U_1 & 0 \\ L_2 & 0 & U_2 \\ 0 & L_3 & 0 \end{bmatrix},\end{aligned}$$

where

$$T_1 = T_m(\beta, \beta, \beta - \alpha), \quad T_2 = T_m(\beta - \alpha, \beta, \beta - \alpha), \quad T_3 = T_m(\beta - \alpha, \beta, \beta),$$
$$L_2 = \begin{bmatrix} E_2 & \alpha E \\ 0 & 0 \\ 0 & 0 \end{bmatrix}, \qquad L_3 = \begin{bmatrix} 0 & E_4 & \alpha E \\ 0 & 0 & 0 \end{bmatrix},$$
$$U_1 = \begin{bmatrix} 0 & 0 & 0 \\ \alpha F & F_2 & 0 \end{bmatrix}, \qquad U_2 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ \alpha F & F_4 \end{bmatrix}.$$

A simple calculation can show that the relationship between α and ω in (4) is

$$\omega = \frac{1-\alpha}{1-\alpha+h\alpha}.$$

When $\alpha = 0$, we have $\omega = 1$. Thus, this parameterized generalized SS reduced to the traditional SS, namely, a Dirichlet boundary condition, is used on these artificial boundaries. If $\beta > 2$ and $\alpha = 1$, we have $\omega = 0$. It is equivalent to using a Neumann condition on the artificial boundaries. (If $\beta = 2$, we can use a Neumann condition on only one of the boundaries for interior subregions. Otherwise, the resulting Schwarz enhanced matrix is singular. For two-dimensional problems, if a strip decomposition is employed, then a Neumann boundary condition can be used for both artificial boundaries.) For $0 < \alpha < 1$, this generalized SS corresponds to

$$g_1(u) = g_2(u) = \omega u + (1-\omega)\frac{\partial u}{\partial n}.$$

The convergence analysis of this parameterized generalized SS is therefore reduced to calculating the spectral radius of the block Jacobi matrix $J = M^{-1}N$. Notice that the matrix $N(\alpha)$ has only eight nonzero elements. So the matrix $J = M^{-1}N$ has only eight nonzero columns, provided $l < m/2$. They are related only to the elements in the last or first columns of the matrices T_1^{-1}, T_2^{-1}, and T_3^{-1}. Let $t_{i,j}$ be the elements of the matrix $T_n^{-1}(\beta)$ and $D_i(\beta) = \det T_i(\beta)$. We have the following results (see [6]):

$$D_k(\beta) = \begin{cases} \sinh(n+1)\theta/\sinh\theta, & \beta > 2, \quad 2\cosh\theta = \beta, \\ n+1, & \beta = 2, \\ \sin(n+1)\theta/\sinh\theta, & \beta < 2, \quad 2\cos\theta = \beta, \end{cases}$$

$$t_{i,j} = \begin{cases} D_{j-1}(\beta)D_{n-i}(\beta)/D_n(\beta), & i \geq j, \\ D_{i-1}(\beta)D_{n-j}(\beta)/D_n(\beta), & i < j. \end{cases}$$

Based on this result, the elements of T_1^{-1} and T_2^{-1} can be easily derived from the Sherman–Morrison formula. We will not elaborate on the detailed derivation here.

Denote the last columns of the matrices T_1^{-1} and T_2^{-1} by $t^{(1)}$ and $t^{(2)}$, respectively:

$$t^{(1)} = (t_1^{(1)}, t_2^{(1)}, \cdots, t_m^{(1)}),$$
$$t^{(2)} = (t_1^{(2)}, t_2^{(2)}, \cdots, t_m^{(2)}).$$

Note that elements $t_i^{(j)}$ are functions of α. Since matrix T_3^{-1} is a permuted matrix of T_1^{-1}, the first column of the inverse T_3^{-1} can be derived from the last column of T_1^{-1} by a simple permutation. Let P^T be a permutation matrix; permute columns $m-l$, $m-l+1$; $m+l$, $m+l+1$; $2m-l$, $2m-l+1$; $2m+l$, $2m+l+1$ to $3m-k+1$, $k = 8, 7, \cdots, 1$, respectively. J can be similarly transformed to $\tilde{J}$:

$$\tilde{J} = PJP^T = \begin{bmatrix} 0 & K \\ 0 & G \end{bmatrix},$$

where

$$G = \begin{pmatrix} 0 & 0 & -\alpha t_{m-l}^{(1)} & t_{m-l}^{(1)} & 0 & 0 & 0 & 0 \\ 0 & 0 & -\alpha t_{m-l+1}^{(1)} & t_{m-l+1}^{(1)} & 0 & 0 & 0 & 0 \\ t_{m-l+1}^{(2)} & -\alpha t_{m-l+1}^{(2)} & 0 & 0 & 0 & 0 & -\alpha t_{l-1}^{(2)} & t_{l-1}^{(2)} \\ t_{m-l}^{(2)} & -\alpha t_{m-l}^{(2)} & 0 & 0 & 0 & 0 & -\alpha t_l^{(2)} & t_l^{(2)} \\ t_l^{(2)} & -\alpha t_l^{(2)} & 0 & 0 & 0 & 0 & -\alpha t_{m-l}^{(2)} & t_{m-l}^{(2)} \\ t_{l-1}^{(2)} & -\alpha t_{l-1}^{(2)} & 0 & 0 & 0 & 0 & -\alpha t_{m-l+1}^{(2)} & t_{m-l+1}^{(2)} \\ 0 & 0 & 0 & 0 & t_{m-l+1}^{(1)} & -\alpha t_{m-l+1}^{(1)} & 0 & 0 \\ 0 & 0 & 0 & 0 & t_{m-l}^{(1)} & -\alpha t_{m-l}^{(1)} & 0 & 0 \end{pmatrix}.$$

Note that matrix G has only four independent columns. After a simple reduction, we know the following matrix includes four nonzero eigenvalues of G:

$$G' = \begin{bmatrix} 0 & t^{(1)}_{m-l} - \alpha t^{(1)}_{m-l+1} & 0 & 0 \\ t^{(2)}_{m-l} - \alpha t^{(2)}_{m-l+1} & 0 & 0 & t^{(2)}_{l} - \alpha t^{(2)}_{l-1} \\ t^{(2)}_{l} - \alpha t^{(2)}_{l-1} & 0 & 0 & t^{(2)}_{m-l} - \alpha t^{(2)}_{m-l+1} \\ 0 & 0 & t^{(1)}_{m-l} - \alpha t^{(1)}_{m-l+1} & 0 \end{bmatrix}$$

$$= \begin{bmatrix} 0 & g_1 & 0 & 0 \\ g_2 & 0 & 0 & g_3 \\ g_3 & 0 & 0 & g_2 \\ 0 & 0 & g_1 & 0 \end{bmatrix}.$$

Let

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{bmatrix}.$$

We have

$$HG'H = \begin{bmatrix} 0 & g_1 & 0 & 0 \\ g_2 + g_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & g_2 - g_3 \\ 0 & 0 & g_1 & 0 \end{bmatrix}.$$

Thus, the four eigenvalues of G' are:

$$\lambda_{1,2} = \pm\sqrt{g_1(g_2 + g_3)},$$
$$\lambda_{3,4} = \pm\sqrt{g_1(g_2 - g_3)}.$$

Here we present two figures to show the relationship between the spectral radius and the parameter α. For both cases, the size of each subproblem is $m = 10$ and $\beta = 2$. When $\beta > 2$, the generalized SS has a faster convergence rate. Figures 6 and 7 will show the results for the latter case. The x-axis is the parameter α, while the y-axis is the spectral radius of the Jacobi matrix for the generalized SS. The top figure shows the case of one overlapping node while the lower one demonstrates the case of overlapping half the subregion. In Fig. 3, we can see that the traditional SS (when $\alpha = 0$) has a very poor convergence rate, since the overlap is so small. The convergence factor is 0.9. To reduce l_2 norm of the residual by a factor of 10^6 requires more than 60 iterations. When the parameter α approaches 1, an amazing improvement of the convergence rate appears. For $\alpha = 0.9$, the convergence factor is less than 10^{-4}. That is to say, only very few iterations are needed for any particular computation. From the second picture, we can observe when $\alpha = 0.85$ the convergence rate of the generalized SS approaches the optimum. But the optimal convergence rate in this case is even worse than having minimum overlap, and the only positive point here is the sensitivity of the convergence rate with the parameter α.

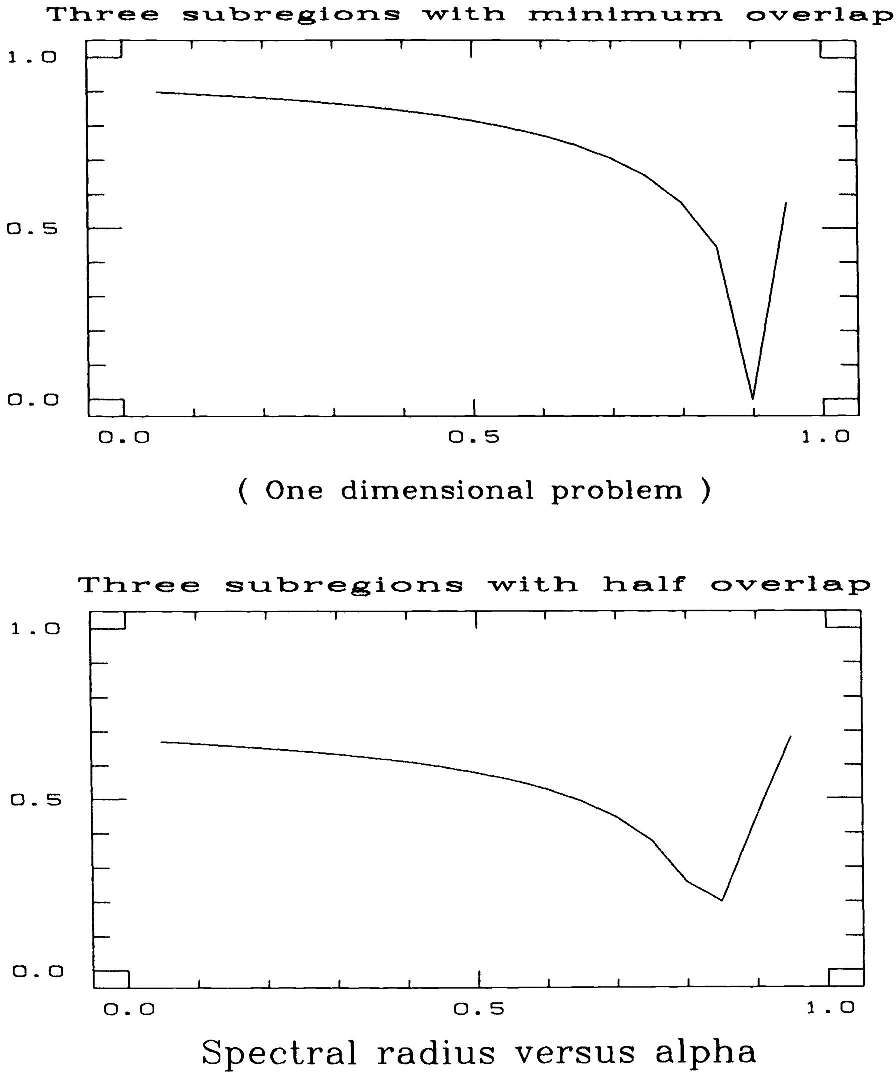

FIG. 3.

A numerical test has verified this analysis. The problem we are testing is

$$y''(x) = 2e^x \cos x, \qquad x \in (0,1),$$
$$y(0) = 0, \qquad y(1) = e\sin(1),$$

which has a solution $y(x) = e^x \sin(x)$. The solution region is covered by three overlap subregions with m unknowns each. Two neighboring subregions have one overlapping grid node. A random initial guess is used when the iteration starts and the l_2 norm is used to measure convergence. For $\alpha = 0.948, m = 20$, and $l = 2$, the residual is reduced by a factor of 10^{14} after three iterations. The results are the same for different mesh sizes. For $\alpha = 0.9, m = 10$, and $l = 2$, the residual is reduced by a factor of 10^{15} after three iterations. By comparison, the traditional SS with the same overlap will take 60 iterations to reduce the residual by only a factor of 10^5.

We apply the traditional SS to the same problem with an overlap of half of the subregion. Numerical testing shows that 11 iterations are needed to achieve a reduction of the initial residual by a factor of 10^5. If an optimal α is used, 4 iterations are needed. This again verifies the analysis shown in Fig. 3. The above results are summarized in Table 1.

TABLE 1

	Minimum overlap		Half overlap	
	Convergence factor	Number of iterations	Convergence factor	Number of iterations
Classical SAM	0.91	60	0.68	11
Generalized SAM	10^{-4}	3	0.06	4

In general, for k overlapping subregions, the nonzero eigenvalues of the Jacobi matrix are included in those of the following $(k-1) \times (k-1)$ block matrix:

$$G_k = \begin{bmatrix} D_1 & L & 0 & \cdot & \cdot & \cdot & 0 & 0 \\ U & D_2 & L & 0 & \cdot & \cdot & 0 & 0 \\ & & \ddots & \ddots & & & & \\ & & & \ddots & \ddots & & & \\ 0 & 0 & \cdot & \cdot & \cdot & U & D_2 & L \\ 0 & 0 & \cdot & \cdot & & 0 & U & D_3 \end{bmatrix}.$$

There will not be a closed form for the eigenvalues of G_k when $k > 4$. In Fig. 4 we present a numerical result for the spectral radius of J where five overlapping subregions exist. The first picture is for the minimum overlap case, while the second is for the overlapping half of the subregions. Again, a significant improvement can be obtained by choosing a good parameter α.

For the two-dimensional problem

$$\Delta U(x,y) - qU(x,y) = f(x,y), \qquad (x,y) \in (0,1) \times (0,1),$$
$$U(x,y)\,|_\Gamma = g(x,y),$$

where $q < 0$, a matrix equation

$$Ax = b$$

can be derived using the centered finite difference. Given grid size $h = 1/(n+1)$, A can be written as

$$A = T_n(\beta) \otimes I_n + I_n \otimes T_n(2),$$

where $\beta > 2$. Decompose the solution region into three overlapping subregions (in strip). The overlap pattern in the x-direction is exactly the same as in the one-dimensional case. The corresponding Schwarz enhanced matrix is

$$\widetilde{A} = \begin{bmatrix} A_1 & -F_1 & 0 \\ -E_1 & A_2 & -F_1 \\ 0 & -E_1 & A_3 \end{bmatrix},$$

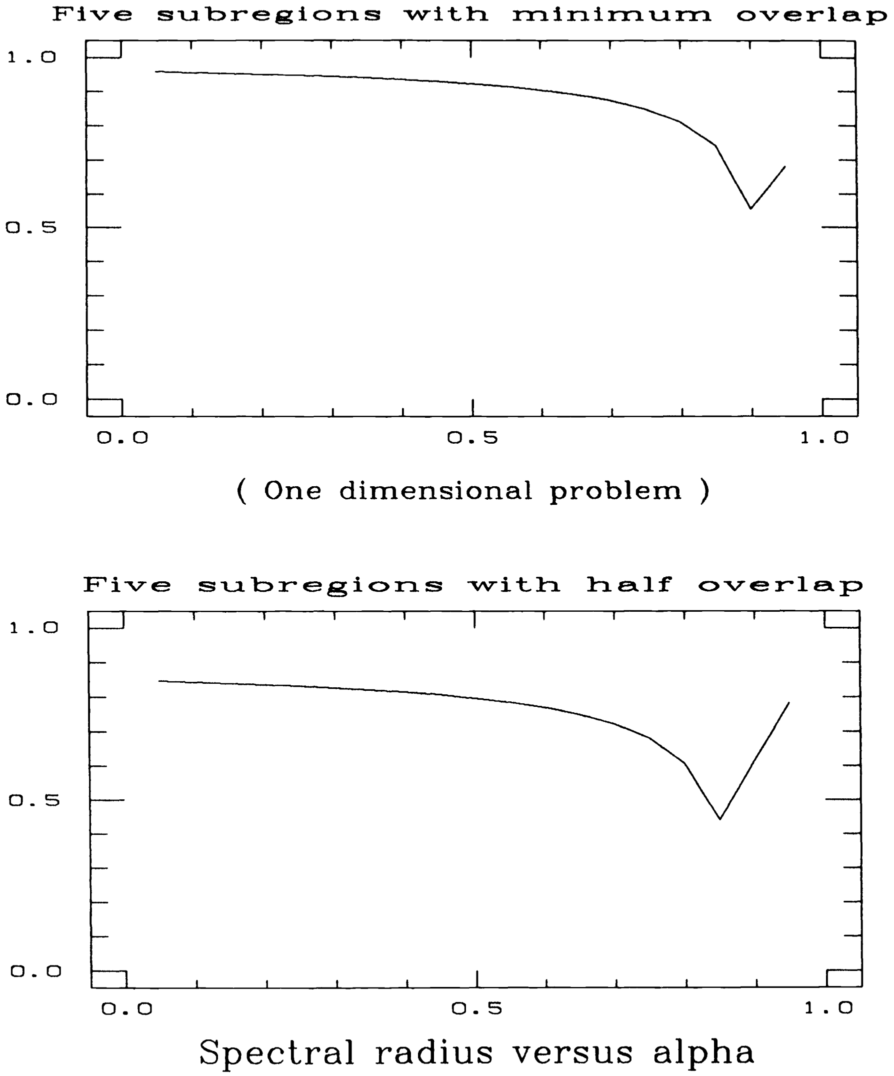

FIG. 4.

where

$$
\begin{aligned}
A_1 &= T_1 \otimes I_n + I_m \otimes T_n(2), \\
A_2 &= T_2 \otimes I_n + I_m \otimes T_n(2), \\
A_3 &= T_3 \otimes I_n + I_m \otimes T_n(2), \\
E_1 &= E_m \otimes I_n, \\
F_1 &= F_m \otimes I_n,
\end{aligned}
$$

and

- E_m is an $m \times m$ matrix with zero elements everywhere except for a 1 in position $(1, m-l)$ and α in position $(1, m-l+1)$.

- F_m is an $m \times m$ matrix with zero elements everywhere except for an α in position $(m, m-l)$ and 1 in position $(m, l-1)$.

The Jacobi iterative matrix for the generalized Schwarz splitting is

$$\begin{aligned} J &= \begin{bmatrix} A_1^{-1} & 0 & 0 \\ 0 & A_2^{-1} & 0 \\ 0 & 0 & A_3^{-1} \end{bmatrix} \begin{bmatrix} 0 & F_1 & 0 \\ E_1 & 0 & F_1 \\ 0 & E_1 & 0 \end{bmatrix} \\ &= M^{-1}N. \end{aligned}$$

Let

$$U = \begin{bmatrix} I_m \otimes X_n & 0 & 0 \\ 0 & I_m \otimes X_n & 0 \\ 0 & 0 & I_m \otimes X_n \end{bmatrix},$$

where X_n is an orthogonal matrix. Each column in X_n corresponds to an eigenvector of matrix $T_n(2)$ and $X_n T_n(2) X_n = D_n =$ diag $\{d_i\}$, $d_i = 2 + 2\cos(i\pi/(n+1))$, $i = 1, \cdots, n$. Note that U is orthogonal and $UNU = N$. So

$$\begin{aligned} J' &= UJU^T \\ &= (UMU^T)^{-1}N \\ &= \widetilde{M}N \end{aligned}$$

where

$$\begin{aligned} \widetilde{M} &= \begin{bmatrix} \widetilde{A}_1 & 0 & 0 \\ 0 & \widetilde{A}_2 & 0 \\ 0 & 0 & \widetilde{A}_3 \end{bmatrix}, \\ \widetilde{A}_i &= (I_m \otimes X_n) A_i (I_m \otimes X_n)^T \\ &= T_i \otimes I_n + I_m \otimes D_n. \end{aligned}$$

Let P be the permutation matrix which permutes row $(k-1)n+i$ to $(i-1)3m+k$, $k = 1, \cdots, 3m$, $i = 1, \cdots, n$. Then

$$PJ'P^T = \begin{bmatrix} J(d_1) & & & \\ & J(d_2) & & \\ & & \ddots & \\ & & & J(d_n) \end{bmatrix},$$

where each $J(d_i)$ is the Jacobi iterative matrix of the generalized SAM for matrix $T_n(d_i)$ in the one-dimensional case. Similar to the traditional SAM, we found that the convergence of the lower frequency components are slower than that of higher frequencies. We present two pictures in Fig. 5 to show how $\rho_{J(d_i)}$ changes when d_i changes. The first represents three subregions with minimum overlap, while the second shows the same number of subregions with half overlap.

Another two sets of figures (Figs. 6 and 7) present the relations between the spectral radius $\rho_{J(d_i)}$ and the parameter α. The first set is for $J(2.01)$ and the other is

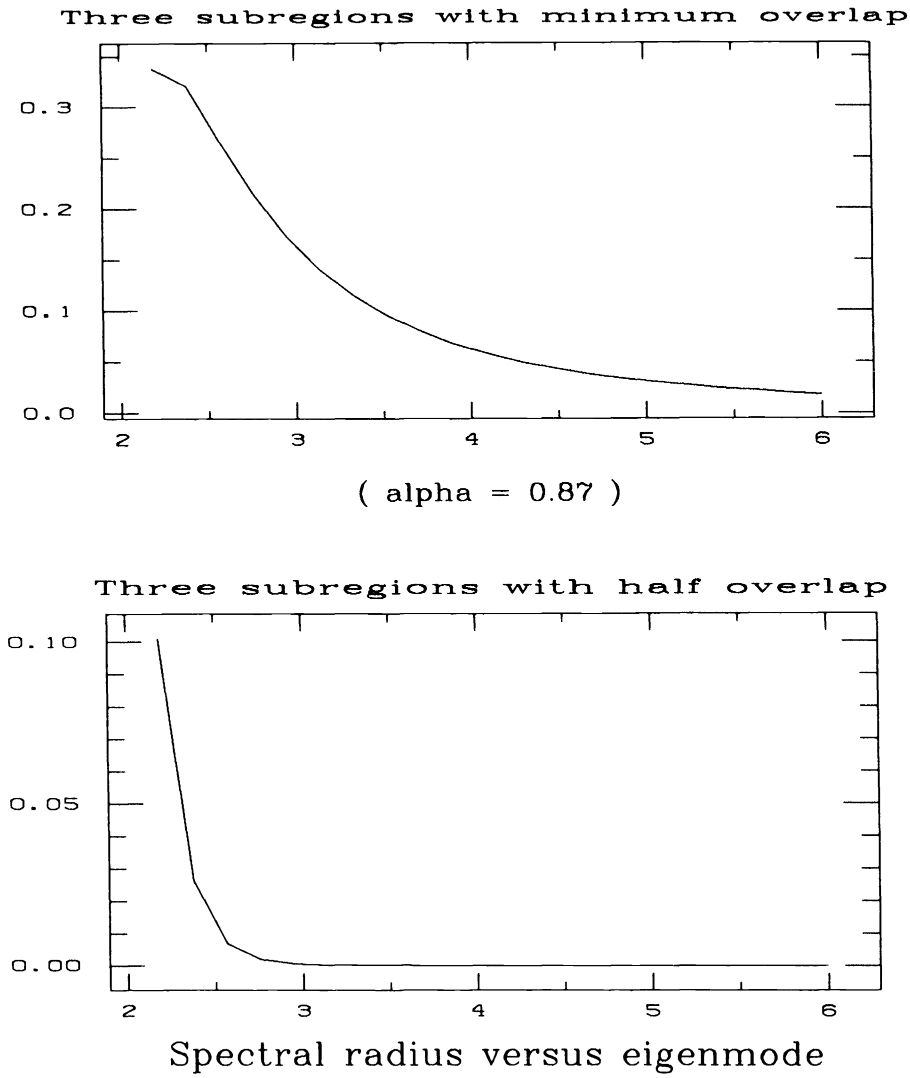

FIG. 5.

for $J(5.99)$, which represent the lowest and the highest frequencies of the eigenmodes, respectively. Both sets have one figure for minimum overlapping (one grid line) and another for overlapping half of the subregion. We can see that the sensitivity of the convergence rate with the parameter α is better in a two-dimensional problem. It is also noticeable that the convergence of the higher frequency mode is very fast for all α.

Numerical testing results for the model problem

$$\begin{aligned}&\Delta U(x,y) = -2x(1-x) - 2y(1-y), \qquad (x,y) \in (0,1) \times (0,1),\\ &U(x,y)\mid_\Gamma = 0\end{aligned}$$

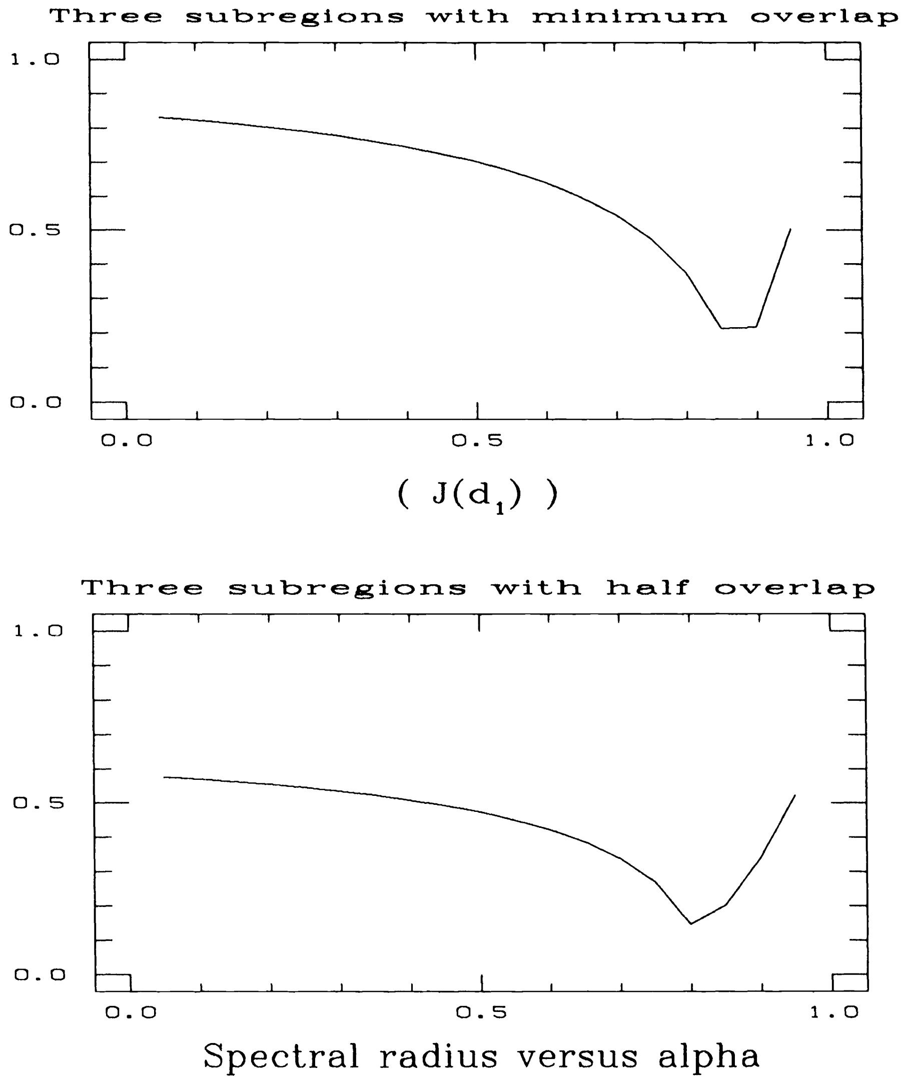

FIG. 6.

are given in Fig. 8. We present the relations between the number of iterations and the parameter α in these figures. Testing is carried out for three and five subregion cases, and for each decomposition, both minimum overlap and half overlap are tested. The initial guess is randomly generated. To make the programming easier, the grid size is slightly different for each case. h is between 1/40 and 1/50. The results plainly verify our analysis. The x-axis is the parameter α while the y-axis is the number of iterations needed for reducing the initial error by a factor of 10^5.

4. Conclusion. From the above analysis, a generalization of the traditional SAM is presented and the improvement of its performance is significant. The results of this study suggest that there may be other interesting splittings or couplings with good or even better performance characteristics. So far, our analysis has been

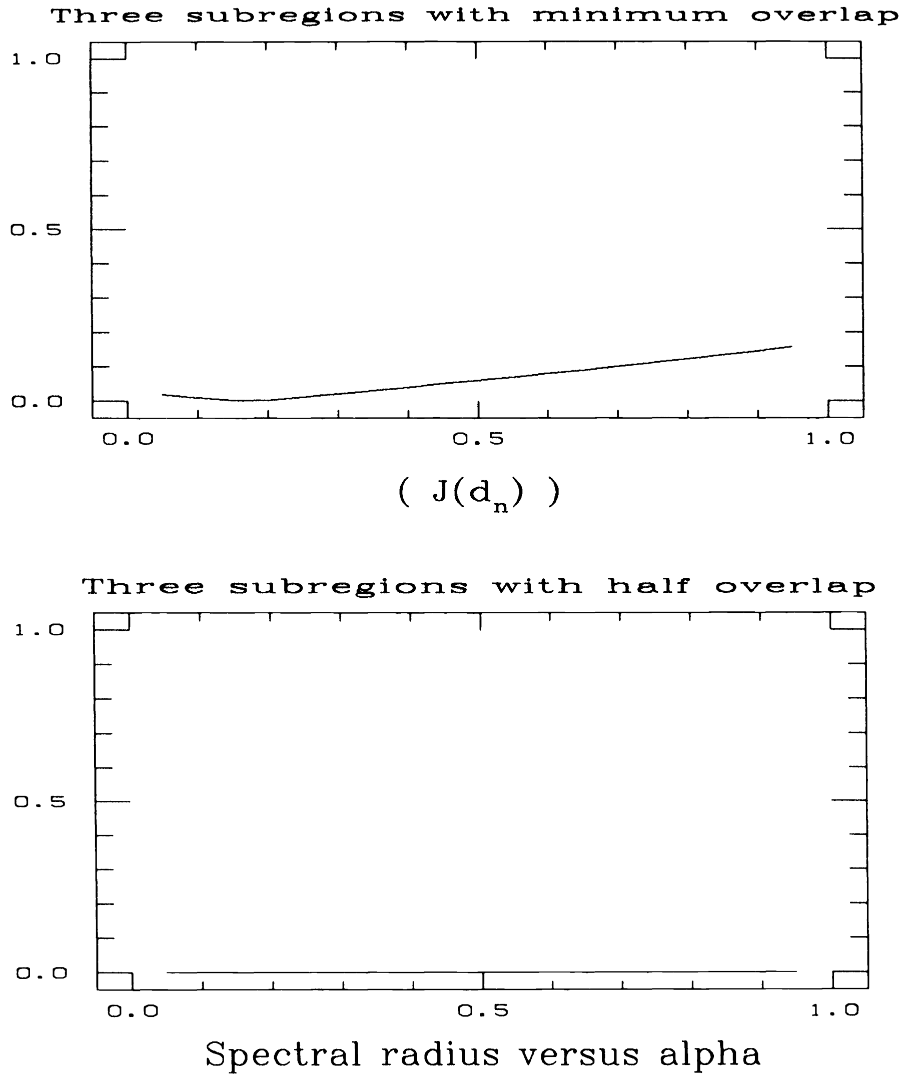

FIG. 7.

restricted to a simple case, namely, the strip decomposition. In particular, the close form of the spectral radius did not provide us with an insight of how the convergence is related to the decomposition and the parameter α. We do not have the same intuitive understanding we had for the classical SAM. More interesting problems remain to be studied. The effects of different couplings on the convergence of SAM have also been observed in a study for the fourth order equation [1].

We should also indicate that there is an extreme sensitivity between the parameter α and the convergence rate of generalized SS. A better understanding of this sensitivity is needed to make this generalized SS a practical technique.

Acknowledgment. The author would like to thank Gérard Meurant and referees for their valuable comments on this paper.

FOURIER ANALYSIS OF FINITE ELEMENT PRECONDITIONED COLLOCATION SCHEMES*

MICHEL O. DEVILLE† AND ERNEST H. MUND ‡

Abstract. This paper investigates the spectrum of the iteration operator of some finite element preconditioned Fourier collocation schemes. The first part of the paper analyses one-dimensional elliptic and hyperbolic model problems and the advection-diffusion equation. Analytical expressions of the eigenvalues are obtained with use of symbolic computation. The second part of the paper considers the set of one-dimensional differential equations resulting from Fourier analysis (in the transverse direction) of the two-dimensional Stokes problem. All results agree with previous conclusions on the numerical efficiency of finite element preconditioning schemes.

Key words. finite element, collocation method, eigenvalue analysis

AMS(MOS) subject classifications. 65N30, 65N35

1. Introduction.

In the recent past, Chebyshev collocation schemes have been applied extensively to the numerical integration of the Navier–Stokes equations [1], [3], [4]. For scalar elliptic problems, it is well known that the condition number of the matrix system of discrete algebraic equations increases rapidly with N, the number of degrees of freedom of the problem at hand. Therefore, the preconditioning technique seems to be the only adequate tool in order to overcome this numerical burden. The present authors [5], [6] demonstrated that finite elements (FE) constitute powerful preconditioners for general second-order elliptic equations. In [3], several fluid flow elements in velocity-pressure formulation were investigated. From the analysis of the eigenspectrum of the iteration operator, it was shown that the Q2–Q1 element is the best choice for the steady Stokes problem. As all the previous analyses on finite element preconditioning were carried out numerically, the present note aims at analytical results through use of symbolic manipulation languages (cf. [10]).

For the sake of simplicity, we will restrict ourselves to the study of a finite element preconditioned Fourier collocation scheme. Although the Fourier collocation scheme has a condition number of the same order of magnitude as finite element methods and therefore does not require preconditioning per se, the Fourier case provides uniform mesh and a much simpler algebraic treatment; moreover, there is numerical evidence that the Fourier results extend to the more difficult cases like Chebyshev or Legendre collocation [1]. In §2, a one-dimensional elliptic model is considered. The collocation process is preconditioned by Lagrangian linear, quadratic, cubic, and Hermite cubic elements, respectively. The Richardson iteration method is set up with these FE preconditioners as approximate operators and algebraic solvers. Using the spatial structure of the eigenvectors of the Fourier solutions, one may perform a full analysis of the eigenvalues of the iteration operator. This theoretical investigation corroborates

the previous numerical analyses [6]. In §3, a one-dimensional hyperbolic model is investigated using linear and quadratic FE preconditioning. The upwinding technique is also examined. A further model consists in an advection-diffusion equation. In §4, the Stokes problem is reduced to a one-dimensional incompressible flow model amenable to Fourier discretization. The Q2-Q1 and Q1-P0 elements are candidates as preconditioners. A similar Fourier analysis is done. The results corroborate numerical experiments carried out in the framework of Chebyshev collocation [3].

2. Elliptic model. Let us first consider the simple elliptic problem:

$$-u_{xx} = f, \qquad 0 \le x \le 2\pi, \tag{2.1}$$

with periodic boundary conditions. The subscript indicates partial derivative. The Fourier approximation of the dependent variable u is

$$u_N = \sum_{p=-N/2}^{(N/2)-1} \hat{u}_p e^{ipx_j}, \qquad 0 \le j < N, \tag{2.2}$$

where $\hat{u}_p$ are the discrete Fourier coefficients and x_j the collocation points defined by

$$x_j = \frac{2\pi j}{N}, \qquad j \in [0, N[. \tag{2.3}$$

The linear system corresponding to (2.1) may be found in [1] and will be denoted by L_c. The eigenfunctions of (2.1) are

$$\xi_j(p) = e^{ipx_j}, \qquad 0 \le j < N, \tag{2.4}$$

with the corresponding eigenvalues

$$\lambda(p) = p^2, \qquad p \in \left[-\frac{N}{2}, \frac{N}{2} - 1\right]. \tag{2.5}$$

The collocation problem will be preconditioned by finite elements. Introducing the approximate FE operator $\hat{L}$, the preconditioned Richardson iteration is written as

$$\bar{u}^{k+1} = \bar{u}^k - \alpha_k \hat{L}^{-1}(L_c \bar{u}^k - \bar{f}), \tag{2.6}$$

where k is an iteration index; α_k a relaxation factor; and $\bar{u}, \bar{f}$ the vectors corresponding to the unknowns and source terms at the collocation points. The convergence of (2.6) is governed by the spectral radius $\rho(A)$ of the iteration operator defined by $A = I - \alpha_k \hat{L}^{-1} L_c$. The optimal value of the relaxation factor is

$$\alpha_{\text{opt}} = \frac{2}{\lambda_{\min} + \lambda_{\max}}, \tag{2.7}$$

where $\lambda_{\min}$ and $\lambda_{\max}$ are the minimum and maximum eigenvalues of $\hat{L}^{-1} L_c$. An approximate estimate of the number of iterations n needed to reduce the error norm by a factor ζ is given by

$$n = -\log \zeta / R_\infty(A), \tag{2.8}$$

where $R_\infty(A) = -\log \rho(A)$ is the asymptotic rate of convergence of the iteration matrix. The spectral radius $\rho(A)$, which is involved in the error reduction process with the use of α_{opt} (2.7), is given by

$$\rho(A) = \frac{\lambda_{\max} - \lambda_{\min}}{\lambda_{\max} + \lambda_{\min}}. \tag{2.9}$$

In order to investigate this quantity for various preconditioners, we have to define the finite element problem more precisely.

Lagrangian linear elements, Hermite cubic elements (i.e., Q1, P3 in Ciarlet's notations [2]) as well as higher-order Lagrangian interpolants have their vertices at the Fourier collocation grid (2.3). However, for Lagrangian quadratics (Q2), midpoints are added at

$$x_{j+\frac{1}{2}} = \frac{2\pi}{N}\left(j + \frac{1}{2}\right), \qquad j \in [0, N[, \tag{2.10}$$

while for Lagrangian cubics (Q3), we have additional grid nodes located at

$$x_{j+1/3}, x_{j+2/3}, \quad j \in [0, N[, \tag{2.11}$$

with obvious definitions. For the Lagrangian case, the FE unknowns are the nodal values, while for the Hermite case, the unknowns are u_j and u'_j , the prime denoting the first-order derivative of u. In [5], the iteration operator is written as

$$A \equiv I - S_h^{-1} M_h I_h L_c, \tag{2.12}$$

where S_h is the stiffness matrix, M_h the mass matrix, and I_h an interpolation matrix evaluating the Fourier interpolant of the collocation operator at the FE nodes. The mesh size of the FE grid is defined by

$$h = 2\pi/N.$$

For Q1 elements, I_h reduces to the unit matrix; for higher-order interpolants, however, the structure of this matrix is more complicated. In order to avoid writing the details of I_h, we will systematically assume the use of static condensation. Consequently, the iteration operator may be written as follows:

$$A = I - \hat{S}_h^{-1} \hat{M}_h L_c, \tag{2.13}$$

where $\hat{S}_h$ and $\hat{M}_h$ refer to stiffness and mass matrices after static condensation.

2.1. Linear Lagrangian elements. For an interior node, the expressions for the stiffness and mass matrices are well known:

$$S_h u_j = \frac{1}{h}(-u_{j-1} + 2u_j - u_{j+1}), \tag{2.14}$$

$$M_h f_j = \frac{h}{6}(f_{j-1} + 4f_j + f_{j+1}). \tag{2.15}$$

Fourier analysis of (2.14), (2.15) with the eigenfunction (2.4) leads to the expression of the eigenspectrum of $S_h^{-1} M_h L_c$, denoted by $\sigma(p)$,

$$\sigma(p) = \frac{(ph/2)^2}{\sin^2 ph/2}\frac{(2 + \cos ph)}{3}, \qquad -\frac{N}{2} \le p \le \frac{N}{2} - 1. \tag{2.16}$$

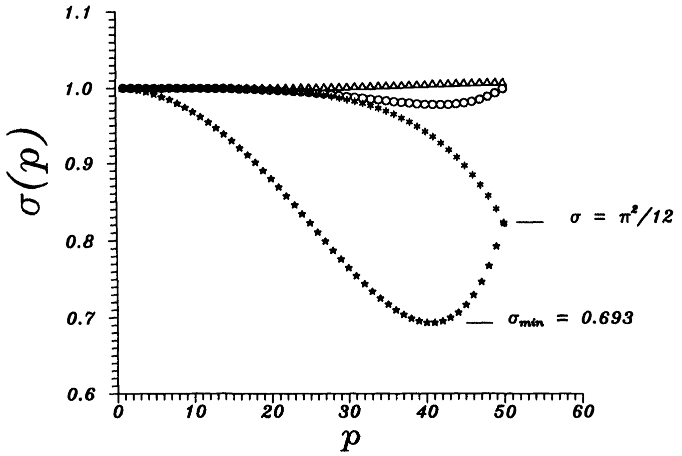

FIG. 1. *Eigenspectrum of* $\hat{S}_h^{-1}\hat{M}_h L_c$ *for an elliptic model. Preconditioners:* Q1 (★); Q2 (∗); Q3 (△); *Cubic Hermite* (○).

Typically, the second factor in the right-hand side of (2.16) comes from the contribution of the mass matrix. In the case of finite difference (FD) preconditioning, this factor is one. For $p = 0$, $\sigma(p) = 1$, while for $p = -N/2, \sigma(p) = \pi^2/12$. This last value should be compared to the FD equivalent, which is $\sigma(p) = \pi^2/4$ [7]. The eigenvalue spectrum of the FE preconditioning is reduced because of the beneficial presence of the mass matrix. Figure 1 shows the behaviour of $\sigma(p)$ with respect to p for $h = 2\pi/100$. The function has a minimum value equal to 0.693. Therefore, the optimum value for α is

$$\alpha_{\text{opt}} \simeq 1.18, \tag{2.17}$$

and overrelaxation is possible for FE preconditioning unlike the FD preconditioning where underrelaxation is required to converge. In practice, the Q1 preconditioning with a spectral radius of 0.18 converges twice as fast as the FD preconditioner whose spectral radius is of the order of 0.42.

2.2. Quadratic Lagrangian elements. The equations related to nodes j and $j \pm \frac{1}{2}$ may be cast in the following matrix form:

$$\frac{1}{3h}\begin{pmatrix} -8 & 16 & -8 & 0 & 0 \\ 1 & -8 & 14 & -8 & 1 \\ 0 & 0 & -8 & 16 & -8 \end{pmatrix}\begin{pmatrix} u_{j-1} \\ u_{j-1/2} \\ u_j \\ u_{j+1/2} \\ u_{j+1} \end{pmatrix} = \frac{h}{15}\begin{pmatrix} 1 & 8 & 1 & 0 & 0 \\ -\frac{1}{2} & 1 & 4 & 1 & -\frac{1}{2} \\ 0 & 0 & 1 & 8 & 1 \end{pmatrix}\begin{pmatrix} f_{j-1} \\ f_{j-1/2} \\ f_j \\ f_{j+1/2} \\ f_{j+1} \end{pmatrix}. \tag{2.18}$$

The use of static condensation eliminates the contribution of $u_{j-1/2}$ and $u_{j+1/2}$ and (2.18) reduces to only one relationship for node j on the collocation grid

$$\frac{1}{h}(-u_{j-1} + 2u_j - u_{j+1}) = \frac{h}{3}(f_{j-1/2} + f_j + f_{j+1/2}). \tag{2.19}$$

Note that for $\hat{S}_h$ on the left-hand side of (2.19), we recover the stiffness matrix S_h associated to Q1 elements, whereas in the right-hand side, $\hat{M}_h$ corresponds to a different quadrature rule. Carrying out the Fourier analysis of (2.19), we obtain

$$\sigma(p) = \frac{(ph/2)^2}{\sin^2(ph/2)}\frac{1}{3}(1 + 2\cos(ph/2)), \qquad -\frac{N}{2} \leq p \leq \frac{N}{2} - 1. \tag{2.20}$$

For the particular values $p = 0$ and $p = -N/2$, $\sigma(p)$ is equal to 1 and $\pi^2/12$, respectively. As $\sigma(p)$ is a monotically decreasing function with respect to p (Fig. 1), the optimum value of α is

$$\alpha_{\text{opt}} = 2/(1+\pi^2/12) = 1.0974, \tag{2.21}$$

and the corresponding spectral radius $\rho(A)$ is equal to 0.0974.

2.3. Cubic Lagrangian elements. For the sake of compactness, we give the local stiffness and mass matrices over the uniform mesh:

$$S_h = \frac{2}{h}\begin{pmatrix} 37/20 & -189/80 & 27/40 & -13/80 \\ -189/80 & 27/5 & -297/80 & 27/40 \\ 27/40 & -297/80 & 27/5 & -189/80 \\ -13/80 & 27/40 & -189/80 & 37/20 \end{pmatrix}. \tag{2.22}$$

$$M_h = \frac{h}{2}\begin{pmatrix} 16/105 & 33/280 & -3/70 & 19/840 \\ 33/280 & 27/35 & -27/280 & -3/70 \\ -3/70 & -27/280 & 27/35 & 33/280 \\ 19/840 & -3/70 & 33/280 & 16/105 \end{pmatrix}. \tag{2.23}$$

Assembling the matrices of (2.22), (2.23) over two adjacent elements and eliminating the four unknowns attached to the interior nodes $u_{j\pm1/3}$, $u_{j\pm2/3}$, we are left with the relation:

$$\begin{aligned} \frac{1}{h}(-u_{j-1}+2u_j-u_{j+1}) = \frac{h}{10}\Bigg(&\frac{f_{j-1}}{6}+\frac{3}{4}f_{j-2/3}+3f_{j-1/3} \\ &+\frac{13}{6}f_j+3f_{j+1/3}+\frac{3}{4}f_{j+2/3}+\frac{f_{j+1}}{6}\Bigg). \end{aligned} \tag{2.24}$$

Here again, as in the previous case, we recover in the left-hand side of (2.24) the stiffness matrix of Q1 elements. Fourier analysis of (2.24) leads to the eigenvalue spectrum $\sigma(p)$:

$$\begin{aligned} &\sigma(p) = \frac{(ph/2)^2}{\sin^2(ph/2)}\frac{1}{10}\left(\frac{4}{3}\cos^3\frac{ph}{3}+3\cos^2\frac{ph}{3}+5\cos\frac{ph}{3}+\frac{2}{3}\right), \\ &-\frac{N}{2}\le p\le\frac{N}{2}-1. \end{aligned} \tag{2.25}$$

The particular values of $\sigma(p)$ corresponding to $p = 0$ and $p = -N/2$ are $\sigma(p) = 1$ and $49\pi^2/480 \simeq 1.007522$. The optimal value of the relaxation factor is given by $2/(1+49\pi^2/480) \simeq 0.9963$ and the corresponding spectral radius $\rho(A)$ is equal to 0.00375.

Looking back at the results in the previous subsections, one observes that the spectral radius $\rho(A)$ diminishes with increasing polynomial degrees. This does not mean, however, that one should use higher-order elements in the preconditioning because they involve more computational work as the bandwidth of the algebraic system increases.

2.4. Cubic Hermite elements. At node j, the discrete equations are

$$\begin{aligned} &-\frac{6}{5h}(u_{j-1}-2u_j+u_{j+1})-\frac{1}{10}(u'_{j-1}-u'_{j+1}) \\ &\quad=\frac{13h^2}{420}(f'_{j-1}-f'_{j+1})+\frac{h}{7}\left(\frac{9}{10}f_{j-1}+\frac{26}{5}f_j+\frac{9}{10}f_{j+1}\right), \end{aligned} \tag{2.26}$$

$$\begin{aligned}(2.27)\qquad &\frac{1}{10}(u_{j-1} - u_{j+1}) - \frac{h}{30}(u'_{j-1} - 8u'_j + u'_{j+1}) \\ &= -\frac{13}{420}h^2(f_{j-1} - f_{j+1}) - \frac{h^3}{140}\left(f'_{j-1} - \frac{8}{3}f'_j + f'_{j+1}\right).\end{aligned}$$

Fourier analyzing (2.26), one gets the spectrum
(2.28)

$$\sigma(p) = \frac{(ph/2)^2}{6\sin^2(ph/2) - (ph/2)\sin(ph/2)\cos(ph/2)}\frac{1}{7}\left(26 + 9\cos ph + \frac{13}{6}ph\sin ph\right), \qquad |ph| \in [0, \pi].$$

For $p = 0$ and $-N/2$, $\sigma(p) = 1$ and $17\pi^2/168 \simeq 0.9987$, respectively. Figure 1 displays the behaviour of $\sigma(p)$, which is first slightly decreasing with respect to p, achieving its minimum value 0.97722 and then increasing to 1. The optimal value of α is 1.01152 and the corresponding spectral radius 0.0115, an intermediate value between those of Q2 and Q3 preconditioning.

3. Hyperbolic problems.

We now turn our attention to the first-order differential equation

$$(3.1)\qquad u_x = f,$$

in the periodic case. The eigenfunctions of (3.1) are again (2.4) with the eigenvalues

$$\lambda(p) = ip, \qquad p \in \left[-\frac{N}{2}, \frac{N}{2} - 1\right].$$

3.1. Linear Lagrangian elements.

Using the standard Galerkin approach, a centered scheme is produced and yields the discrete equation

$$(3.2)\qquad \frac{u_{j+1} - u_{j-1}}{2} = \frac{h}{6}(f_{j-1} + 4f_j + f_{j+1}).$$

By Fourier analysis, we obtain

$$(3.3)\qquad \sigma(p) = \frac{ph}{\sin ph}\frac{2 + \cos ph}{3}, \qquad |ph| \in [0, \pi].$$

For $p = 0$, $\sigma(p) = 1$, while $\sigma(-N/2)$ is obviously unbounded as in the FD case. The presence of the mass matrix does not help to circumvent the difficulty.

One may proceed, however, using an upwinding technique. This has been a key step in treating hyperbolic problems. In finite elements, the method uses separate test and trial function spaces, i.e., the Petrov–Galerkin method. There are several ways to implement upwinding. Let us introduce the weight functions $w^i(r)$, $(i = 1, 2)$, defined on the reference interval $[-1, +1]$ by Heinrich and Zienkiewicz [8]:

$$(3.4)\qquad w^i(r) = \varphi^i(r) + (-1)^i\epsilon F(r), \qquad -1 \le r \le 1,$$

where $\varphi^i(r)$ are the linear Lagrangian trial functions, $F(r)$ an auxiliary quadratic element vanishing at both end points

$$(3.5)\qquad F(r) = \frac{3}{4}(1 - r^2),$$

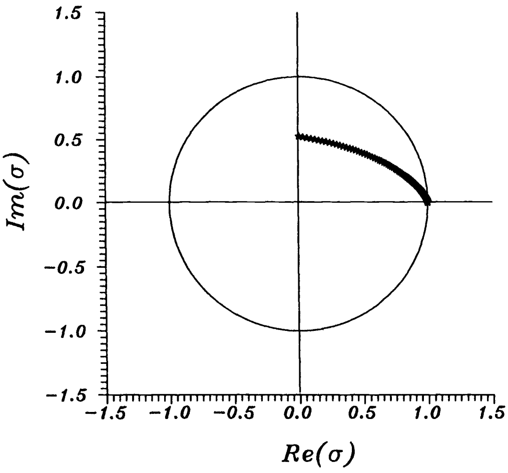

FIG. 2. *Eigenspectrum of $\hat{S}_h^{-1}\hat{M}_h L_c$ for a first-order operator. Upwinding with a parameter $\epsilon = 1$ is used.*

and ϵ the upwinding parameter to be given independently. Using φ^i and w^i as trial and test functions, respectively, one gets

$$(3.6) \qquad -\frac{1+\epsilon}{2h}u_{j-1} + \frac{\epsilon}{h}u_j + \frac{1-\epsilon}{2h}u_{j+1} = \frac{2+3\epsilon}{12}f_{j-1} + \frac{2}{3}f_j + \frac{2-3\epsilon}{12}f_{j+1}.$$

This equation reduces to (3.2) when $\epsilon = 0$ (no upwinding). With a value of ϵ as yet undefined, the Fourier analysis of (3.6) leads to complex eigenvalues given by

$$(3.7) \qquad \begin{aligned} &\sigma(p) = \frac{1}{6}\frac{1}{\epsilon(1-\cos ph) + i\sin ph}(3\epsilon ph \sin ph + 2iph(2+\cos ph)), \\ &|ph| \in [0, \pi]. \end{aligned}$$

For $p = 0, \sigma(p) = 1$, while for $p = -N/2, \sigma(p) = -i\pi/6\epsilon$. Upwinding forces the spectrum of $S_h^{-1}M_hL_c$ almost entirely inside the unit circle, as shown in Fig. 2, where the eigenvalues (3.7) have been plotted for $\epsilon = 1$ and positive values of ph. The spectral radius of the matrix A in this case is approximately equal to $\sqrt{5}/2$ and underrelaxation is required in order to ensure convergence of the preconditioning iterations. The eigenvalues (3.7) being complex, the evaluations of α_{opt} and the spectral radius $\rho(A)$ are no longer given by (2.7) and (2.9).

3.2. Quadratic Lagrangian elements. Another way to solve (3.1) consists of using a FE preconditioner based on quadratic Lagrangian elements. Applying the Galerkin approach and assembling the contributions of two adjacent elements at node j, one obtains a set of three equations related to nodes j and $j \pm \frac{1}{2}$ similar to (2.18), which are cast in matrix form:

(3.8)

$$\begin{pmatrix} -\frac{2}{3} & 0 & \frac{2}{3} & 0 & 0 \\ \frac{1}{6} & -\frac{2}{3} & 0 & \frac{2}{3} & -\frac{1}{6} \\ 0 & 0 & -\frac{2}{3} & 0 & \frac{2}{3} \end{pmatrix} \begin{pmatrix} u_{j-1} \\ u_{j-1/2} \\ u_j \\ u_{j+1/2} \\ u_{j+1} \end{pmatrix} = \frac{h}{30}\begin{pmatrix} 2 & 16 & 2 & 0 & 0 \\ -1 & 2 & 8 & 2 & -1 \\ 0 & 0 & 2 & 16 & 2 \end{pmatrix} \begin{pmatrix} f_{j-1} \\ f_{j-1/2} \\ f_j \\ f_{j+1/2} \\ f_{j+1} \end{pmatrix}.$$

If static condensation is carried out through Gaussian elimination, the contribution of the exterior nodes u_{j-1}, u_{j+1} disappears and one is left with a staggered scheme:

$$(3.9) \qquad \frac{2}{3}(u_{j-1/2} - u_{j+1/2}) = \frac{h}{60}(-f_{j-1} + 12f_{j-1/2} + 18f_j + 12f_{j+1/2} - f_{j+1}),$$

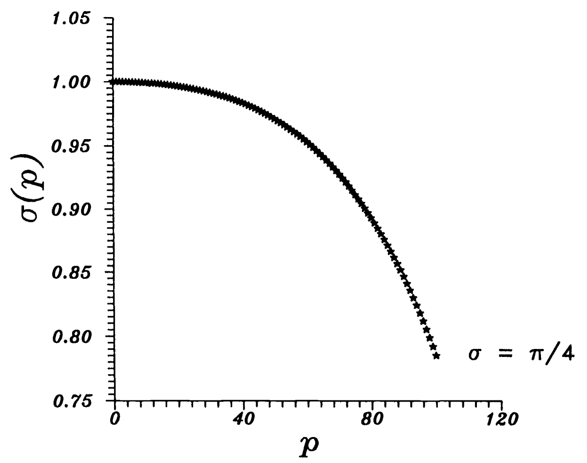

FIG. 3. *Eigenspectrum of a first-order operator preconditioned by* Q2 *elements.*

suitable for Fourier analysis. Its spectrum is given by

$$\sigma(p) = \frac{\frac{ph}{2}}{\sin\frac{ph}{2}} \frac{9 + 12\cos\frac{ph}{2} - \cos ph}{20}, \qquad |ph| \in [0, \pi]. \tag{3.10}$$

It is monotonically decreasing and bounded by $\sigma(0) = 1$ and $\sigma(-N/2) = \pi/4$ as shown in Fig. 3. Note that the first factor in the right-hand side of (3.10) is identical to the spectrum obtained in the FD case where the function is computed on the main grid while the derivative is evaluated by first-order differences on a staggered grid. The second factor whose maximum value is equal to one is induced by the presence of the mass matrix and reduces to unity in the FD case. The optimal value of α is equal to

$$\alpha_{\text{opt}} = 2/(1 + \pi/4) = 1.1202,$$

and the corresponding spectral radius $\rho(A)$ is equal to 0.1202. This staggered scheme generated by Q2 elements is the key to success for FE preconditioning of Navier–Stokes problems. This excellent behaviour explains the reason why in Demaret and Deville [4], the relaxation parameter was almost independent of the Reynolds number.

3.3. Advection-diffusion model. The last scalar model analyzed in this paper is the one-dimensional advection-diffusion problem. The differential equation writes

$$-\kappa u_{xx} + c u_x = f(x), \tag{3.11}$$

where κ is the diffusion coefficient and c the constant advection velocity. Of particular interest are advection-dominated problems, which impose severe conditions on the element mesh size (cf. [9]). With the eigenvectors (2.4), the eigenvalues of (3.11) are

$$\lambda(p) = p^2 + \frac{i\gamma p}{h}, \qquad p \in \left[-\frac{N}{2}, \frac{N}{2} - 1\right],$$

where γ is the cell Reynolds number defined by $\gamma = ch/\kappa$.

Using the linear FE basis and upwinding introduced in the previous section, one gets the discrete equations

$$\begin{aligned} &-\left(1 + \gamma\frac{1+\epsilon}{2}\right)u_{j-1} + (2 + \gamma\epsilon)u_j - \left(1 - \gamma\frac{1-\epsilon}{2}\right)u_{j+1} \\ &= \frac{h^2}{12}\left[(2 + 3\epsilon)f_{j-1} + 8f_j + (2 - 3\epsilon)f_{j+1}\right], \end{aligned} \tag{3.12}$$

where ϵ is the upwinding parameter of (3.4). With no upwinding (i.e., $\epsilon = 0$), stability requirements of FD and FE schemes restrict γ to values ≤ 2 [9]. The Fourier analysis of (3.12) is straightforward. The eigenvalues of (3.12) are complex and given by

$$(3.13) \qquad \sigma(p) = \frac{\frac{(ph)^2}{3}(2+\cos ph) + \epsilon\gamma\frac{ph}{2}\sin ph + i[\gamma\frac{ph}{3}(2+\cos ph) - \epsilon\frac{(ph)^2}{2}\sin ph]}{2(2+\epsilon\gamma)\sin^2\frac{ph}{2} + i\gamma\sin ph}, \quad |ph| \in [0,\pi].$$

In absence of upwinding, (3.13) reduces to an analytical expression whose real and imaginary parts may be written in compact form:

$$(3.14) \qquad \begin{aligned} \mathrm{Re}(\sigma(p)) &= ph\frac{4ph\sin^2\frac{ph}{2} + \gamma^2\sin ph}{16\sin^4\frac{ph}{2} + \gamma^2\sin ph}\frac{2+\cos ph}{3}, \\ \mathrm{Im}(\sigma(p)) &= \gamma ph\frac{4\sin^2\frac{ph}{2} - ph\sin ph}{16\sin^4\frac{ph}{2} + \gamma^2\sin ph}\frac{2+\cos ph}{3}. \end{aligned}$$

The factor $(2+\cos ph)/3$ in the right-hand side of (3.14) is another example of the contribution of the mass matrix in FE preconditioning. As in (2.16), this factor reduces to unity in the expression of the eigenvalues corresponding to FD preconditioning. One can draw similar conclusions to the diffusion problem, except for the complex nature of the eigenvalues. Introducing $ph = 0$ and $ph = \pi$ into the eigenvalues of the FD case gives the bounds of the spectrum:

$$(3.15) \qquad 1 \leq \mathrm{Re}(\sigma^{FD}) \leq \frac{\pi^2}{4}, \quad 0 \leq \mathrm{Im}(\sigma^{FD}) \leq \frac{\gamma\pi}{4}.$$

In the FE case, the upper bounds are reduced by a factor of 3 because of the presence of the mass matrix. Figure 4 displays the result (3.14) for both FD and FE preconditionings and for two different values of γ: 0.2 and 2. Provided the value of γ is less than the stability limit, the spectrum of A for FE preconditioning lies inside the unit circle. Reducing the value of the cell Reynolds number brings the eigenvalues closer to the real axis. Figure 5 exhibits the spectrum (3.13) for FE preconditioning and for γ exceeding the stability limit: 5 and 10. Without upwinding in this case, the spectrum lies outside the unit circle and blows up linearly with the value of γ. This is to be expected on the grounds that we approach a true hyperbolic problem (3.1). Introducing upwinding brings the spectrum inside the unit circle. For increasing values of γ one gets back the results displayed on Fig. 2, since in the limit where γ goes to infinity, (3.13) reduces to (3.7).

4. Stokes equations. Let us write the Stokes equations in stress formulation:

$$(4.1) \qquad div\underline{\underline{\sigma}} + \rho\underline{f} = 0,$$

$$(4.2) \qquad div\underline{v} = 0.$$

The symbol $\underline{\underline{\sigma}}$ denotes the stress tensor, ρ is the density, $\underline{f}$ the body force term and $\underline{v}$ is the velocity field. Equation (4.1) is the momentum equation and (4.2) enforces the continuity constraint. The two-dimensional Stokes problem may be reduced to a one-dimensional problem if the solution of (4.1), (4.2) is sought as a Fourier mode:

$$(4.3) \qquad \underline{v} = \underline{v}(x)e^{iky}, p = p(x)e^{iky}.$$

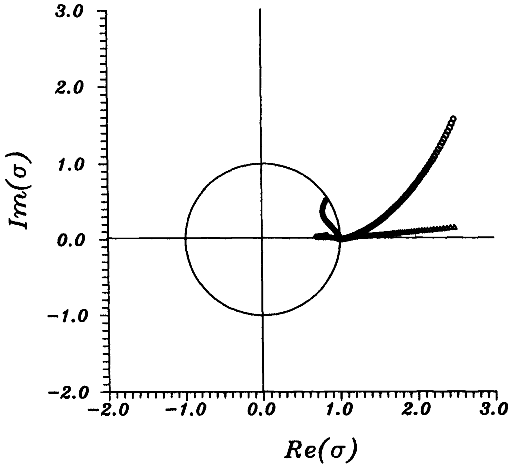

FIG. 4. *Eigenspectrum of an advection-diffusion problem. The curves outside the unit circle are concerned with* FD *preconditioning, while the inside curves are related to* FE *preconditioning. Both top curves are obtained for the cell Reynolds number* $\gamma = 2$. *The bottom curves are gotten for* $\gamma = 0.2$

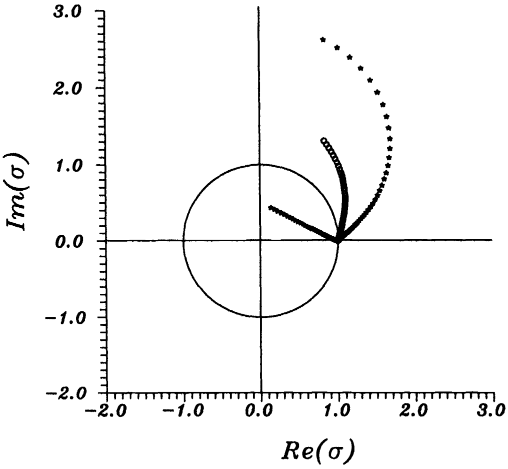

FIG. 5. *Eigenspectrum of an advection-diffusion problem preconditioned by* Q1 *elements for* $\gamma = 5(\bigcirc)$ *and* 10★. *Without upwinding* ($\epsilon = 0$), *the spectrum lies outside the unit circle. Upwinding* ($\epsilon = 1$) *brings the spectrum inside the unit circle.*

Introducing (4.3) in (4.1), (4.2), we get:

$$-\frac{\partial p}{\partial x} + 2\mu\frac{\partial^2 u}{\partial x^2} + ik\mu\left(iku + \frac{\partial v}{\partial x}\right) + \rho f_x = 0, \tag{4.4}$$

$$\mu\frac{\partial}{\partial x}\left(iku + \frac{\partial v}{\partial x}\right) - ikp - 2\mu k^2 v + \rho f_y = 0, \tag{4.5}$$

$$\frac{\partial u}{\partial x} + ikv = 0, \qquad 0 \le x \le 2\pi. \tag{4.6}$$

The velocity and pressure fields are assumed to be 2π-periodic. This one-dimensional problem is discretized in the x direction using Fourier series of type (2.2) for each variable. The discrete collocation equations are preconditioned by finite elements such as the Q2-Q1 and Q1-P0 elements. The FE equations come from Galerkin projection. Introducing ψ_l and φ_l, the trial functions for the FE approximations of the velocity and pressure fields, respectively, such that

$$\underline{v}(x) = \sum_{l=1}^{M} \underline{v}_l \psi_l, \qquad p(x) = \sum_{l=1}^{N} p_l \varphi_l, \tag{4.7}$$

the discrete FE equations are obtained by use of the divergence theorem as a tool for the integration by parts with the notation $f_x = f$, $f_y = g$:

$$\sum_l [2\mu A_{jl} + \mu k^2 B_{jl}] u_l - ik\mu \sum_l C_{jl} v_l - \sum_l D_{jl} p_l = \sum_l B_{jl} f_l, \qquad 0 \le j \le M, \tag{4.8}$$

$$ik\mu \sum_l C_{jl}^T u_l + \sum_l [2\mu k^2 B_{jl} + \mu A_{jl}] v_l + ik \sum_l E_{jl} p_l = \sum_l B_{jl} g_l, \qquad 0 \le j \le M, \tag{4.9}$$

$$-\sum_l D_{jl}^T u_l - ik \sum_l E_{jl}^T v_l = 0, \qquad 0 \le j \le N. \tag{4.10}$$

In (4.8)–(4.10), the various matrices are defined by the relationships:

$$\begin{gathered} A_{jl} = \int \frac{\partial \psi_j}{\partial x} \frac{\partial \psi_l}{\partial x} dx, \qquad B_{jl} = \int \psi_j \psi_l dx, \qquad C_{jl} = \int \psi_j \frac{\partial \psi_l}{\partial x} dx, \\ D_{jl} = \int \frac{\partial \psi_j}{\partial x} \varphi_l dx, \quad E_{jl} = \int \varphi_j \psi_l dx. \end{gathered} \tag{4.11}$$

4.1. Q2-Q1 elements. For this element, $M = 2N$. Carrying through the algebra involved by the quadratures (4.11) and assembling by direct stiffness the contributions of the two elements connected to node j, we obtain

$$\begin{aligned} &\frac{2\mu}{3h}(u_{j-1} - 8u_{j-1/2} + 14u_j - 8u_{j+1/2} + u_{j+1}) \\ &\quad + \frac{\mu k^2 h}{30}(-u_{j-1} + 2u_{j-1/2} + 8u_j + 2u_{j+1/2} - u_{j+1}) \\ &\quad - \frac{ik\mu}{6}(v_{j-1} - 4v_{j-1/2} + 4v_{j+1/2} - v_{j+1}) \\ &\quad - \frac{1}{6}(p_{j-1} - p_{j+1}) = \frac{h}{30}(-f_{j-1} + 2f_{j-1/2} + 8f_j + 2f_{j+1/2} - f_{j+1}), \end{aligned} \tag{4.12}$$

$$\begin{aligned} &\frac{4\mu}{3h}(-4u_j + 8u_{j+1/2} - 4u_{j+1}) + \frac{\mu k^2 h}{30}(2u_j + 16u_{j+1/2} + 2u_{j+1}) \\ &\quad - \frac{2ik\mu}{3}(-v_j + v_{j+1}) - \frac{2}{3}(p_j - p_{j+1}) = \frac{h}{30}(2f_j + 16f_{j+1/2} + 2f_{j+1}), \end{aligned} \tag{4.13}$$

$$
\begin{aligned}
&\frac{ik\mu}{6}(-u_{j-1}+4u_{j-1/2}-4u_{j+1/2}+u_{j+1})\\
&\quad-\frac{\mu k^2h}{15}(-v_{j-1}+2v_{j-1/2}+8v_j+2v_{j+1/2}-v_{j+1})\\
&\quad+\frac{2\mu}{6}(v_{j-1}-8v_{j-1/2}+14v_j-8v_{j+1/2}+v_{j+1})-\frac{ikh}{3}p_j\\
&=\frac{h}{30}(-g_{j-1}+2g_{j-1/2}+8g_j+2g_{j+1/2}-g_{j+1}),
\end{aligned}
\tag{4.14}
$$

$$
\begin{aligned}
&\frac{2ik\mu}{3}(u_j-u_{j+1})+\frac{8\mu}{3h}(-v_j+2v_{j+1/2}-v_{j+1})-\frac{2\mu k^2h}{15}(v_j+8v_{j+1/2}+v_{j+1})\\
&\quad-\frac{ikh}{3}(p_j+p_{j+1})=\frac{h}{15}(f_j+8f_{j+1/2}+f_{j+1}),
\end{aligned}
\tag{4.15}
$$

$$
\frac{1}{6}(-u_{j-1}-4u_{j-1/2}+4u_{j+1/2}+u_{j+1})+\frac{2ik}{3}(v_{j-1/2}+v_j+v_{j+1/2})=0.
\tag{4.16}
$$

Equations (4.12), (4.14), and (4.16) correspond to momentum and incompressibility relations, while (4.13) and (4.15) are the momentum equations associated to mid-node $x_{j+1/2}$. Similar expressions hold for mid-node $x_{j-1/2}$ with appropriate shifts for the indices.

Now, static condensation represents a formidable task and is greatly helped by the symbolic manipulation program. Elimination of $u_{j\pm1/2}, v_{j\pm1/2}$ leads to a matrix system of order three.

The full Fourier solution gives the collocation matrix L_c:

$$
L_c=\begin{pmatrix}-2\mu l^2-k^2\mu & -\mu kl & -il\\ -\mu kl & -\mu l^2-2\mu k^2 & -ik\\ -il & -ik & 0\end{pmatrix},
\tag{4.17}
$$

where l is the wavenumber in the x direction.

The analytical computation of $\hat{S}_h^{-1}\hat{M}_hL_c$ is performed as far as the symbolic program can handle tractable expressions. Then numerical evaluation of the eigenspectrum is done. Because of the divergence-free constraint, a zero eigenvalue is systematically obtained. In Figs. 6 and 7, the eigenspectrum of $\hat{S}_h^{-1}\hat{M}_hL_c$ is plotted for two cases $k=1$ and $k=10$, respectively. In these two figures, the lower curve shows the same behaviour as the eigenspectrum of the elliptic problem solved by Q2 elements. For $l=-N/2$, $\sigma(l)$ is equal to $\pi^2/12$. For the other curve, $\sigma(0)=1$ and $\sigma(-N/2)$ is close to 2.08. Therefore, the optimal α value is given by

$$
\alpha_{\text{opt}}=2/(2.08+\pi^2/12)\simeq 0.69,
$$

a value close to $\frac{2}{3}$ obtained by Demaret and Deville [3] for a two-dimensional Chebyshev collocation discretization of the Stokes problem preconditioned by Q2-Q1 elements.

4.2. Q1-P0 element. The quadratures (4.11) provide less complicated discrete equations in this case:

$$
\begin{aligned}
&\frac{2\mu}{h}(-u_{j-1}+2u_j-u_{j+1})-\frac{\mu hk^2}{6}(u_{j-1}+4u_j+u_{j+1})+\frac{ik\mu}{2}(v_{j+1}-v_{j-1})\\
&\quad-p_j+p_{j+1}=\frac{h}{6}(f_{j-1}+4f_j+f_{j+1}),
\end{aligned}
\tag{4.18}
$$

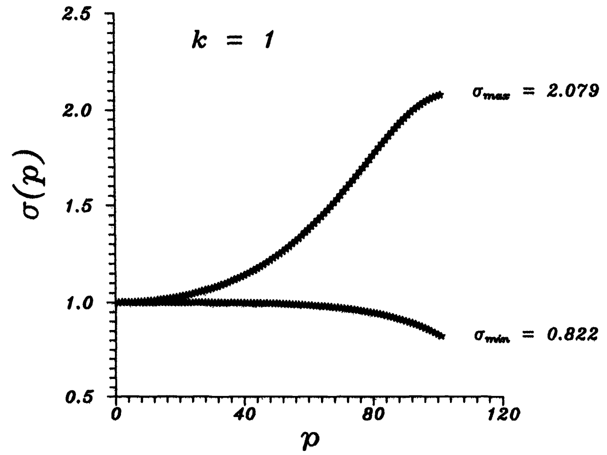

FIG. 6. *Eigenspectrum of the Stokes problem preconditioned by* Q2-Q1 *element. Here* $k = 1$.

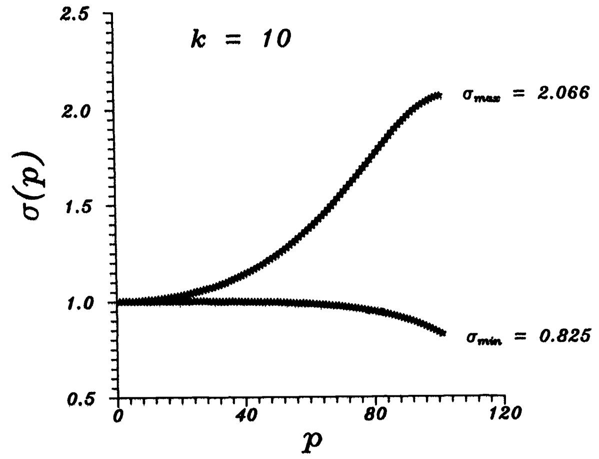

FIG. 7. *Eigenspectrum of the Stokes problem preconditioned by* Q2-Q1 *element. Here* $k = 10$.

$$\begin{aligned}(4.19)\qquad &\frac{ik\mu}{2}(u_{j-1}-u_{j+1})-\frac{\mu k^2 h}{3}(v_{j-1}+4v_j+v_{j+1})+\frac{\mu}{h}(-v_{j-1}+2v_j-v_{j+1})\\ &\quad-\frac{ikh}{2}(p_j+p_{j+1})=\frac{h}{6}(g_{j-1}+4g_j+g_{j+1}),\end{aligned}$$

$$(4.20)\qquad -u_{j-1}+u_{j+1}+\frac{ikh}{2}(v_{j-1}+2v_j+v_{j+1})=0.$$

Obviously, this element generates second-order differences for partial derivatives. When the mass matrix is involved, the standard weighted mean between three adjacent nodes appears in the expressions. No static condensation is needed in this case. Fourier analyzing (4.18)–(4.20), the stiffness and mass matrices are now

$$S_h=\begin{pmatrix} 8\frac{\mu}{h}\sin^2(\frac{hl}{2})+\frac{hk^2\mu}{3}(2+\cos hl) & \mu k\sin hl & 2i\sin(\frac{hl}{2})\\ \mu k\sin hl & 4\frac{\mu}{h}\sin^2(\frac{hl}{2})+\frac{2\mu k^2 h}{3}(2+\cos hl) & ikh\cos(\frac{hl}{2})\\ 2i\sin hl & ikh(1+\cos hl) & 0\end{pmatrix},$$

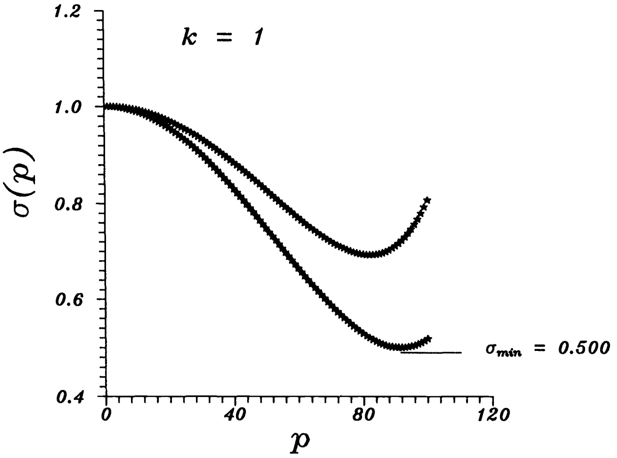

FIG. 8. *Eigenspectrum of the Stokes problem preconditioned by* Q1-P0 *element. Here* $k = 1$.

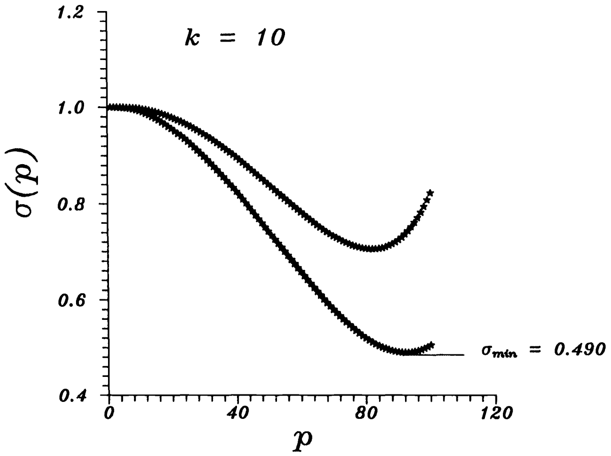

FIG. 9. *Eigenspectrum of the Stokes problem preconditioned by* Q1-P0 *element. Here* $k = 10$.

$$M_h = \operatorname{diag}\left(\frac{h}{3}(2+\cos hl), \frac{h}{3}(2+\cos hl), 0\right). \tag{4.21}$$

In Figs. 8 and 9, the eigenspectrums of $S_h^{-1}M_hL_c$ are displayed for $k = 1$ and 10, respectively. In these two figures, the top curve is that of the elliptic model preconditioned by the Q1 element. The bottom curve starts from 1 for $l = 0$, decreases till a minimum value close to 0.49 and then increases to reach $\sigma(-N/2) = 0.5$. The optimum value is

$$\alpha_{\text{opt}} = 2/(1+0.5) = \tfrac{4}{3}.$$

5. Conclusions. In this paper, we have Fourier analyzed the eigenspectrum of the iteration operator for finite element preconditioning of Fourier collocation applied to one-dimensional problems. For elliptic models, this theoretical analysis confirms previous numerical findings, especially the beneficial presence of the mass matrix which reduces the bounds of the eigenspectrum. For first-order problems, linear elements without and with upwinding are considered. With quadratic elements, a staggered scheme is produced. Its eigenspectrum is bounded and ranges between 1 and $\pi/4$. Finally, a Stokes problem is reduced to a one-dimensional approach. Two types of elements are examined. The Q2-Q1 element leads to an optimum value of the relaxation parameter close to the value obtained by numerical analysis of preconditioned Chebyshev collocation. For Q1-P0 element, the method can be overrelaxed.

SONIC FLUX FORMULAE*

P. L. ROE†

Abstract. The numerical solution of hyperbolic partial differential equations is studied, with special reference given to behaviour near a sonic point. A thorough treatment of the scalar case generalises to yield a satisfactory modification of upwind schemes for systems of equations.

Key words. initial-value problems, sonic points, upwind differencing

AMS(MOS) subject classifications. 65M05, 76N15

1. Introduction. This paper deals with the calculation of numerical solutions to hyperbolic differential equations. Initially, it concentrates on the scalar conservation law

$$u_t + f_x = 0, \tag{1.1}$$

where $f(u)$ is some nonlinear function. The particular aspect of interest is the behaviour of the solution near sonic points ($u \simeq \bar{u}, f'(\bar{u}) = 0$). It is well known that details of the numerical flux calculation under these conditions are very critical. If a wrong choice is made, the algorithm may not converge (under mesh refinement, or as time increases) to the correct (entropy-satisfying) weak solution. "Sonic flux formulae" that do guarantee such convergence are developed in [11], [5]. Even when convergence does take place, it may be very slow, and the choice of flux formula has a pronounced effect [8], [9].

Also, even though the local errors may be small, they tend to accumulate into some kind of local pathology (variously named "glitches" or "doglegs") as noted in [14], for example. It will be explained in §2 that such glitches are to be expected from *any* first-order upwind method in which only the sonic flux (the flux at the interface across which the characteristic speed changes sign) is modified. This is because the various design criteria that might be used to obtain a sonic flux formula cannot all be satisfied simultaneously. In §3, a more accurate treatment is presented that involves modifying the sonic flux and both its neighbours. Section 4 reports some numerical experiments. Section 5 demonstrates that the analysis is actually simpler for second-order schemes, and §6 contains the generalisation to systems of equations. The one-dimensional Euler equations are investigated in §7, and §8 gives the numerical results. Section 9 comments briefly on the behaviour of schemes designed using the MUSCL approach.

The emphasis throughout is on the accuracy of the approximation. Nevertheless, convergence to the correct entropy solution follows, at least for convex problems, because we are able to show that sonic gradients always decay [3]. The fact that they decay at the correct rate may be expected to accelerate convergence also. We do not, at this stage, attempt to relate this work to the more empirical "entropy fixes" that are found necessary in many practical calculations, both to smooth the solution and to enable the application of Newton-like iterations in seeking a steady state. For these purposes, the entropy modification due to Harten [4] has proved popular.

2. The origin of glitches. Consider (1.1) rewritten as

$$u_t + a(u)u_x = 0, \tag{2.1}$$

where $a(u) = f'(u)$. To solve (1.1) or (2.1) to first order on a mesh $(j\Delta x, n\Delta t)$, the generic conservative method is

$$u_j^{n+1} = u_j^n - \lambda \left[F_{j+\frac{1}{2}}^{n+\frac{1}{2}} - F_{j-\frac{1}{2}}^{n+\frac{1}{2}} \right], \tag{2.2}$$

where $\lambda = \Delta t/\Delta x$. For an upwind scheme away from shock or sonic points, the interface flux is defined by

$$F_{j+\frac{1}{2}}^{n+\frac{1}{2}} = \begin{cases} f(u_j^n) & \text{if } a_j^n, a_{j+1}^n > 0, \\ f(u_{j+1}^n) & \text{if } a_j^n, a_{j+1}^n < 0. \end{cases} \tag{2.3}$$

If

$$a(u_j^n) \geq 0 \geq a(u_{j+1}^n)$$

we have a *shock point*, and if

$$a(u_j^n) \leq 0 \leq a(u_{j+1}^n)$$

we have a *sonic point*. In these two cases, various upwind schemes offer various prescriptions for calculating the flux $F_{j+(1/2)}^{n+(1/2)}$. We are concerned here with the sonic case, illustrated diagrammatically in Fig. 1. Henceforward, subscripts $(\cdot)_L$ and $(\cdot)_R$ will denote quantities in two consecutive cells for which $a_L \leq 0 \leq a_R$. The fluxes across the three interfaces involved in updating u_L, u_R will be labelled F_L, F_S, F_R. Conventional upwind practice will always take

$$\begin{aligned} F_L &= f(u_L), \\ F_R &= f(u_R) \end{aligned} \tag{2.4}$$

and the question will simply be the choice of F_S. To make this choice, we can attempt to enforce either of two properties characteristic of sonic points.

For any sonic point $\bar{x}$ such that $u(\bar{x}) = \bar{u}$, we have from (2.1) that $u_t(\bar{x}) = 0$. Thus $x = \bar{x}$ remains a sonic point for all time (or at least until the arrival of a shockwave). To implement this first sonic point property as a design criterion, we may note that both a and u_t are, to first order, proportional to the distance from the (fixed) sonic point. Hence

$$\frac{u_R^{n+1} - u_R^n}{u_L^{n+1} - u_L^n} = \frac{a_R}{a_L} \tag{2.5}$$

or

$$\frac{F_R - F_S}{F_S - F_L} = \frac{a_R}{a_L},$$

so that

$$F_S = \frac{1}{2}\left[f(u_L) + f(u_R)\right] - \frac{a_R - a_L}{a_R + a_L}\left[f(u_R) - f(u_L)\right].$$

FIG. 1. *Sketch used to define notation near a sonic point.*

If we approximate

$$\frac{1}{2}(a_R + a_L) = \frac{f(u_R) - f(u_L)}{u_R - u_L}, \tag{2.6}$$

we arrive at

$$F_S = \frac{1}{2}[f(u_L) + f(u_R)] - \frac{1}{4}(a_R - a_L)(u_R - u_L). \tag{2.7}$$

Comparing this with the standard "viscosity form" for a flux formula

$$F^{n+\frac{1}{2}}_{j+\frac{1}{2}} = \frac{1}{2}\left[f(u^n_j) + f(u^n_{j+1})\right] - \frac{q}{2}\left[u^n_{j+1} - u^n_j\right] \tag{2.8}$$

we see that to enforce the first sonic point property, we should choose

$$q_S = \frac{1}{2}\Delta a.$$

The second property comes from differentiating (2.1) with respect to x:

$$u_{xt} + a_x u_x + a u_{xx} = 0. \tag{2.9}$$

Let $s = u_x(\bar{x})$. Then

$$s_t + a_u s^2 = 0, \tag{2.10}$$

where $a_u = f_{uu}(u)$ is evaluated at $u = \bar{u}$. Thus we know the rate at which the solution gradient decays near sonic points. Indeed, we can integrate (2.10) to obtain

$$\frac{1}{s(t)} - \frac{1}{s(0)} = a_u t. \tag{2.11}$$

Discretising in time, we have the *exact* result

$$s^{n+1} - s^n = -\Delta t\, a_u s^n s^{n+1}. \tag{2.12}$$

To implement a design based on the second sonic property, we note that

$$(u_R - u_L)^{n+1} - (u_R - u_L)^n = -\lambda\left[F_R + F_L - 2F_S\right]. \tag{2.13}$$

The left-hand side (LHS) can be approximated (see (2.12)) as

$$-\lambda(a_R - a_L)^n(u_R - u_L)^n$$

which leads to

$$F_S = \frac{1}{2}\left[f(u_L) + f(u_R)\right] - \frac{1}{2}(a_R - a_L)(u_R - u_L). \tag{2.14}$$

Therefore we now have

$$q_S = \Delta a,$$

exactly twice the previous value.

The formulae (2.7), (2.14) are due to this author [13] and Goodman and Leveque [3], respectively. Specialised to Burgers' equation $f(u) = \frac{1}{2}u^2$ they yield

$$F_S = \frac{1}{2}u_L u_R$$

and

$$F_S = u_L u_R - \frac{1}{4}(u_L^2 + u_R^2).$$

To ask which of these two formulae is correct is to miss the point; both are wrong! The reason can be traced back to the use of the basic upwind formulae (2.4) for F_L and F_R. This results in the solution inside the pair of cells concerned being updated according to

$$\frac{(u_L + u_R)^{n+1} - (u_L + u_R)^n}{\Delta t} = \frac{f(u_L) - f(u_R)}{\Delta x}.$$

The LHS is an approximation to *twice* u_t; the right-hand side (RHS) is an approximation to $-f_x$. Displacing the fluxes from the cell centres to the cell interfaces creates only a first-order error if done consistently. Here the displacements are in opposite directions, which means that locally we are solving

$$u_t + \frac{1}{2}f(u)_x = 0. \tag{2.15}$$

Alternatively, we can say that although the flux still has only a first-order error in its absolute value, there is a zero-order relative error. It is because of this inconsistency that we cannot enforce both of the properties that ought to hold, so that a glitch of some kind is inevitable. This simple trap built into first-order upwinding seems so far to have gone unobserved.

Before giving the correct treatment, this may be a convenient place to insert the observation that according to (2.13) the sonic gradient $u_R - u_L$ will always diminish in magnitude, provided

$$\frac{f(u_R) + f(u_L) - 2F_S}{u_R - u_L} > 0.$$

Now for a convex (concave) flux function, u_R is greater than (less than) u_L, so that F_S must be less than (greater than) the average of $f(u_L), f(u_R)$. For such flux functions, this is enough to guarantee convergence to the entropy-satisfying weak solution [3]. This may be compared with Osher's [11] definition of an E-scheme as one for which F_S, whenever u_R is greater than (less than) u_L, is less than (greater than) the minimum (maximum) value of f in the interval $u \in [u_L, u_R]$. This condition ensures, for any flux function, that any value of u that should appear in the solution will eventually do so. Taking F_S actually to be the minimum (maximum) value is, as Osher observes, equivalent to Godunov's technique of obtaining interface fluxes from the exact solution to the Riemann problem $[u_L, u_R]$. It is possible that there exist entropy-satisfying schemes that are not E-schemes, since Osher proved sufficiency, but not necessity, of his condition. The present technique does not, however, yield such a scheme for nonconvex flux functions. Basically, this is because it is designed around sonic points; it successfully breaks up stationary rarefaction shocks, but can be fooled by ones that move.

3. A consistent sonic point treatment. A scheme will be devised that both satisfies a consistent conservation equation, and also yields the correct decay rate. Both conditions are met to second order. The conservation equation will be

$$\frac{\delta u_L + \delta u_R}{2} = -\lambda \left[f(u_R) + \frac{1}{2} a_R \delta u_R - f(u_L) - \frac{1}{2} a_L \delta u_L \right] \tag{3.1}$$

which is obtained by integrating around the control volume ABCD in Fig. 2, and approximating the flux values by Taylor expansions. The notation $\delta u_L = u_L^{n+1} - u_L^n$ has been used and variables without superscripts (like u_R) are at time level n. The decay equation will be (see (2.12))

$$\delta u_R - \delta u_L = -\lambda(a_R - a_L)\left[u_R + \delta u_R - u_L - \delta u_L\right]. \tag{3.2}$$

This can be written as

$$(\delta u_R - \delta u_L)(1 + \Delta\nu) = -(u_R - u_L)\Delta\nu, \tag{3.3}$$

where the difference of Courant numbers is

$$\Delta\nu = \lambda(a_R - a_L). \tag{3.4}$$

Now (3.1) can be rearranged, using Δf for $f(u_R^n) - f(u_L^n)$, as

$$\delta u_L + \delta u_R = -2\lambda\Delta f - \frac{1}{2}\lambda(\delta u_L + \delta u_R)(a_R - a_L) - \frac{1}{2}\lambda(\delta u_R - \delta u_L)(a_R + a_L). \tag{3.5}$$

Combining (3.3) and (3.5) leads to

$$(\delta u_L + \delta u_R)\left(1 + \frac{1}{2}\Delta\nu\right) = -\lambda\left[2\Delta f - \frac{(a_L + a_R)(u_R - u_L)\Delta\nu}{2(1 + \Delta\nu)}\right].$$

Using the approximation (2.6), the RHS of this expression simplifies, and a factor $(1 + \frac{1}{2}\Delta\nu)$ cancels, leaving

$$\delta u_L + \delta u_R = \frac{-\lambda}{1 + \Delta\nu}(a_L + a_R)(u_R - u_L). \tag{3.6}$$

Combining this with (3.3) leads to the simple results

$$\delta u_L = -\frac{\lambda a_L (u_R - u_L)}{1 + \Delta\nu}, \tag{3.7}$$

$$\delta u_R = -\frac{\lambda a_R(u_R - u_L)}{1+\Delta\nu}. \tag{3.8}$$

Note that by specifying *consistent* conservation and decay equations we have achieved as a free bonus the condition (2.5) requiring sonic points not to move. However, when stationarity was the only criterion the changes obtained differed from those above by a factor $(1+\Delta\nu)/2$.

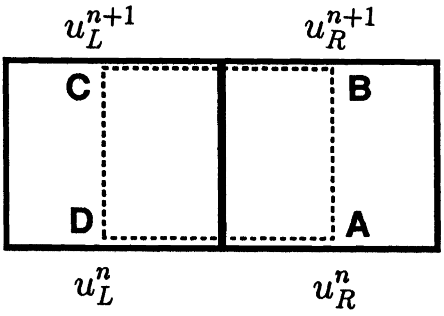

FIG. 2. *The control volume used to define equations* (3.1), (3.2).

Next, the interface fluxes that bring about these changes will be found. We must have

$$-\lambda^{-1}\,\delta u_L = \frac{a_L(u_R - u_L)}{1+\Delta\nu} = F_S - F_L, \tag{3.9}$$

$$-\lambda^{-1}\,\delta u_R = \frac{a_R(u_R - u_L)}{1+\Delta\nu} = F_R - F_S. \tag{3.10}$$

Clearly there is no unique solution to these equations, because the same constant could be added to each flux, but a particular solution having more symmetry than the alternatives is

$$F_L = \frac{f(u_L) - \frac{1}{8}(5a_L - a_R)(u_R - u_L)}{1+\Delta\nu}, \tag{3.11}$$

$$F_S = \frac{\frac{1}{2}[f(u_L) + f(u_R)] - \frac{1}{8}(a_R - a_L)(u_R - u_L)}{1+\Delta\nu}, \tag{3.12}$$

$$F_L = \frac{f(u_R) - \frac{1}{8}(5a_R - a_L)(u_R - u_L)}{1+\Delta\nu}. \tag{3.13}$$

In this case, the semidiscrete fluxes ($\Delta\nu = 0$) can be obtained by the sort of geometrical argument typically used to construct second-order schemes. Assume that a and u both vary linearly over the interval $[j-\frac{1}{2}, j+\frac{3}{2}]$, where the sonic interface is at $j+\frac{1}{2}$. Then the average value of a in the interval $[j+1, j+\frac{3}{2}]$ is $(5a_R - a_L)/4$. Extrapolating f from $j+1$ to $j+\frac{3}{2}$ using $df = a\,du$ now gives (3.11) and similar arguments give (3.13). The same technique applied to the intervals $[j, j+\frac{1}{2}]$ and $[j+\frac{1}{2}, j+1]$ gives two alternative formulae for F_S,

$$F_S = f(u_L) + \frac{3a_L + a_R}{8}(u_R - u_L),$$

$$F_S = f(u_R) - \frac{3a_R + a_L}{8}(u_R - u_L).$$

Approximate equality of these expressions follows from (2.6), and taking the average gives (3.12). Note that this formula, even without the factor $(1+\Delta\nu)^{-1}$, is different from both (2.7) and (2.14).

4. Numerical experiments. The test problem chosen in this section is the inviscid Burgers' equation

$$u_t + \left(\frac{1}{2}u^2\right)_x = 0,$$

with initial data (see Fig. 3)

$$\begin{aligned} u &= -1, && 0 \le x \le 2.9, \\ u &= 1 - \frac{(x-4.1)^2}{0.72}, && 2.9 \le x \le 4.1, \\ u &= 1, && 4.1 \le x \le 7. \end{aligned}$$

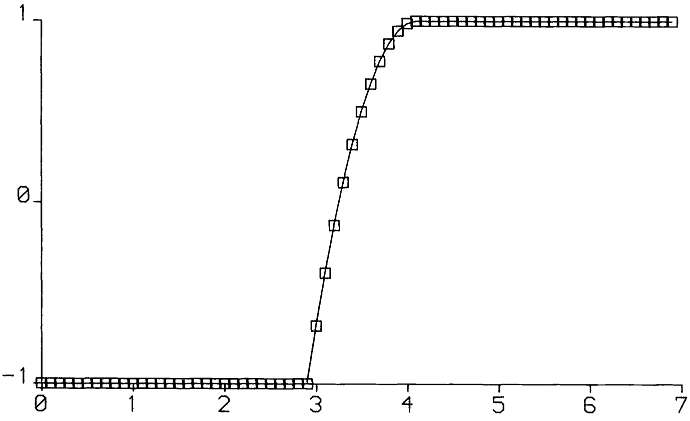

FIG. 3. *Data at $t=0$ for the test problem using Burgers' equation.*

It was thought that a nonuniform gradient might make a more demanding task than the usual ramp test. The numbers were juggled to produce a sonic point roughly halfway between mesh points; this appears to be the hardest case. The problem above has an analytical solution, the nontrivial part of which is

$$u = \frac{4xt - 1 + (8t^2 - 8xt + 1)^{\frac{1}{2}}}{4t^2}, \qquad -(1+t) \le x \le t,$$

where x has been scaled to place the initial data on $[-1, 1]$.

Solutions were obtained at t=2.25, by taking 45 timesteps with $\Delta t = 0.05$. Figures 4(a)–(d) show results from various first-order methods. Figure 4(a) uses the simple version of the author's flux formula,

$$F_S = \frac{1}{2}[f(u_L) + f(u_R)] - \frac{1}{2}\left|\frac{f(u_R) - f(u_L)}{u_R - u_L}\right|(u_R - u_L) \tag{4.1}$$

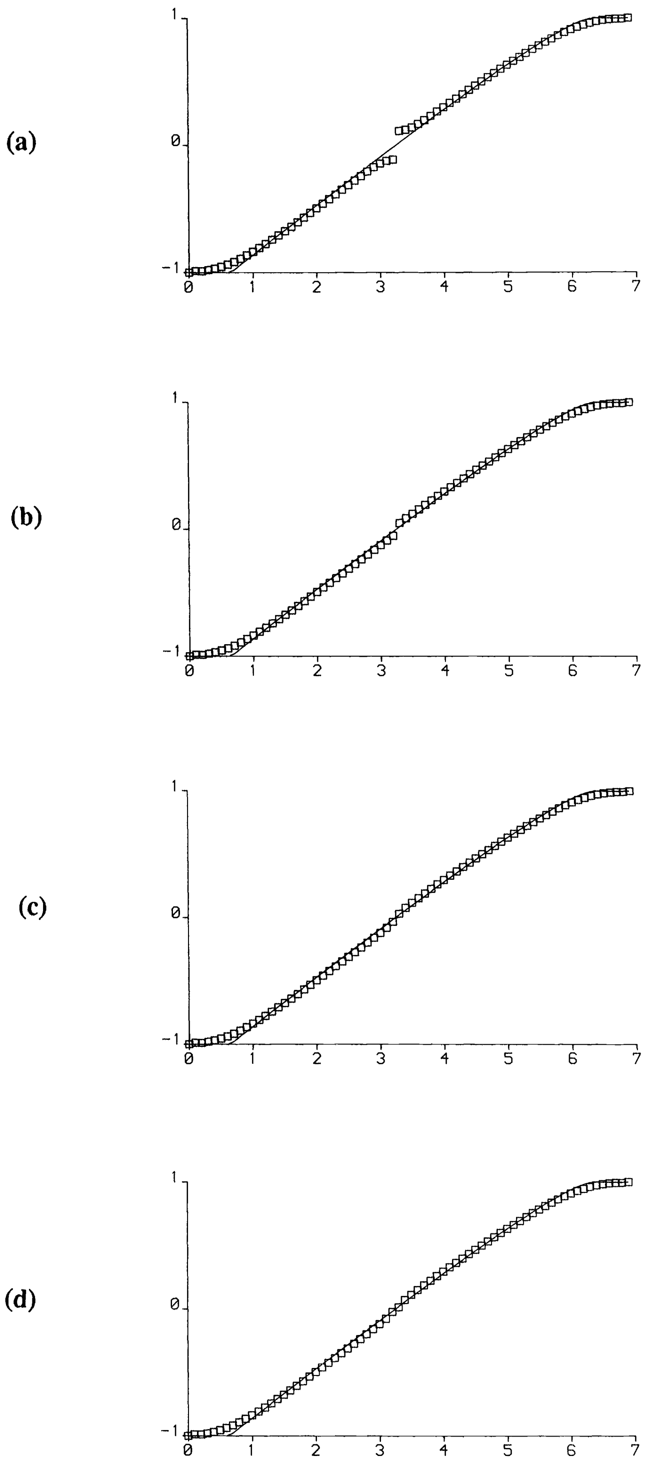

FIG. 4. *Results at* $t = 2.25$ *for the Burgers' equation test problem from four first-order schemes.* (a) *The flux formula* (4.1), *used everywhere, gives these results.* (b) *At the sonic interface,* (4.1) *is replaced by the sonic flux* $f = 0$. (c) *At the sonic interface,* (4.1) *is replaced by* (2.7). (d) *At the sonic interface,* (4.1) *is replaced by* (2.14).

and clearly shows an entropy-violating shockwave. This will not decay if the solution is continued to later time. Figure 4(b) shows the results from Godunov's method (for Burgers' equation this means taking $F_S = 0$). The central gradient does decay, but far too slowly. Figure 4(c) shows the result of keeping the sonic point stationary, (2.7). The solution no longer appears discontinuous, but still suffers a marked inflection. In fact it is easy to show that, at the sonic point, Godunov's flux causes the slope to decay too slowly by a factor of four, and (2.7) by a factor of two. The flux (2.14), due to Goodman and Leveque [3], produces the results in Fig. 4(d). The two symbols straddling the sonic point are now almost exact because the true decay rate is guaranteed, but on either side there are noticeable errors. These are due to using the locally inconsistent upwind values of F_L and F_R, which provide poor boundary conditions for the solution away from the sonic point. However, this is the best of the first-order methods.

Some second-order results are shown in Figs. 5 (a)–(c). The solution has been noticeably improved, compared to the first-order solutions, in its outer parts (it seems that this problem is sufficiently smooth that no overshoots are created in the solution), but there is still a rather irregular passage through the sonic point. The code was then amended so that the fluxes $F_S, F_{S\pm 1}$ were overwritten with the formulae (3.11)–(3.13). This produced the results shown in Fig. 5(b). The sonic region is now very smooth and accurate. Finally, in Fig. 5(c), we see the results of modifying the Lax–Wendroff scheme with the Superbee flux limiter [13]. The antidiffusive effects of the limiter produce a further marked improvement in the outer regions, and close examination of the computer printout reveals that there is even a consequent slight improvement near the sonic point.

5. Simplified second-order schemes. Although the flux formulae (3.11)–(3.13) give excellent results, they are rather complex, especially for systems of equations, so a simplified strategy was sought. Recall that for first-order schemes a major source of error was the fluxes on either side of the sonic flux; when these were made more accurate the discrepancies of §2 disappeared.

If we assume that in a second-order scheme these neighbouring fluxes are sufficiently accurate anyway, then only the sonic flux has to be chosen. It now does make sense to ask which of the two sonic properties should be enforced, because choosing either of them can be shown to imply the other with second-order accuracy. However, there are numerical reasons to prefer one over the other, and other reasons too, as will emerge.

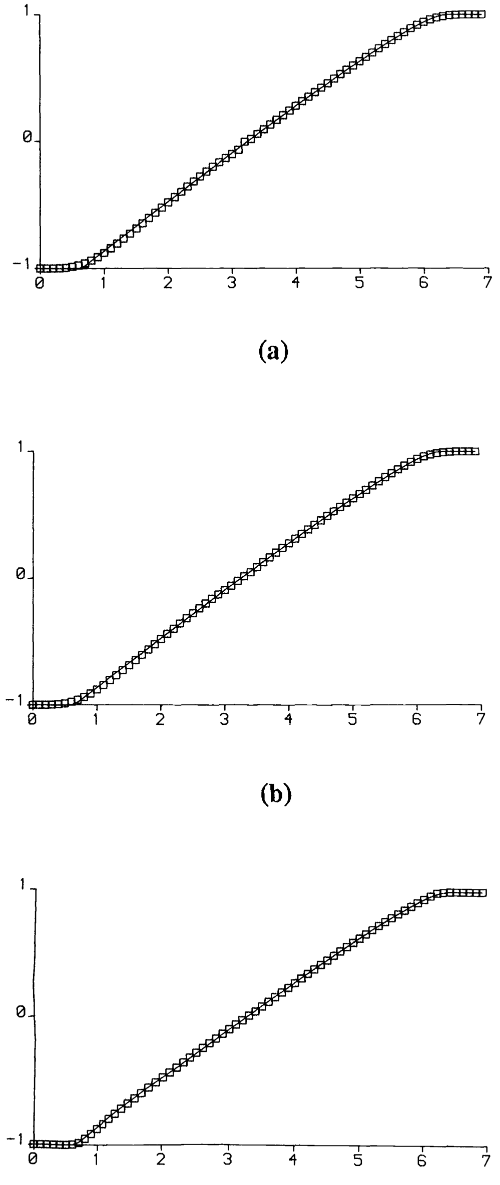
To keep the sonic point stationary, we should impose

$$\frac{F_R - F_S}{F_S - F_L} = \frac{a_R}{a_L},$$

where F_L, F_R are assumed given by some regular second-order scheme. Then

$$F_S = \frac{F_L a_R + F_R a_L}{a_R + a_L}. \tag{5.1}$$

This is an ill-formed expression, since near a sonic point both the numerator and denominator will be small.



(a)

(b)

(c)

FIG. 5. *Results at $t = 2.25$ for the Burgers' equation test problem from three second-order schemes.* (a) *Results from the unmodified Lax–Wendroff scheme.* (b) *For F_L, F_S, F_R the Lax–Wendroff flux is overwritten with* (3.11)–(3.13). (c) *As* (b), *but the Superbee limiter is added to the Lax–Wendroff scheme.*

To ensure the correct decay rate, we should return to (3.12) to obtain

$$F_S = \frac{1}{2}\left[F_L + F_R - \frac{\Delta a \Delta u}{1 + \Delta \nu}\right] \tag{5.2}$$

which will not cause any numerical problems.

As an experimental confirmation, the flux limited solution was rerun, using (5.2) to overwrite the sonic flux F_S only. To graphical accuracy the results were identical with those in Fig. 5(c). In fact, the numbers were even a little better. However, using (5.1) instead produced the results in Fig. 6 with a small but noticeable reduction of slope near the sonic point. In other runs, with different timesteps, the slope obtained from (5.1) was too large. This might be anticipated, since no control is being exerted over the slope, and it is open to accidental causes of any kind.

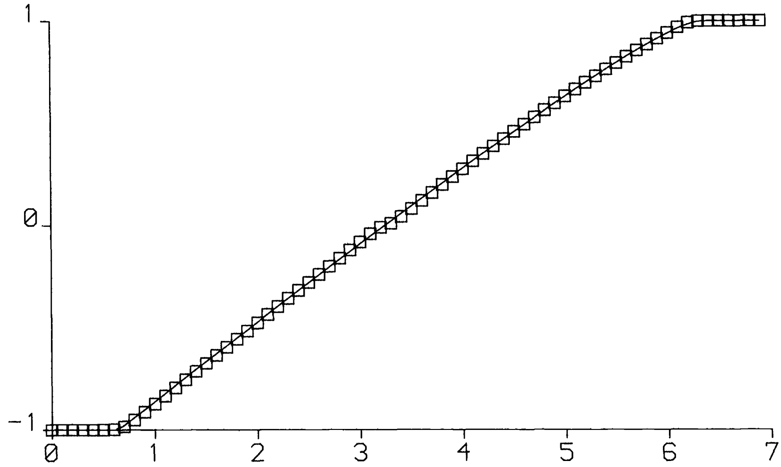


FIG. 6. *Results at $t = 2.25$ for Burgers' equation test problem from a simplified second-order scheme.*

Experiments were also made on the celebrated test case due to Harten, Hyman, and Lax [6]. Here the flux function is

$$f(u) = u - 3\sqrt{3}u^2(u-1)^2,$$

which is illustrated in Fig. 7. The solution with Riemann data $u = 1, x < 0; u = 0, x > 0$ has the entropy-satisfying solution denoted by the tangent OI, which represents a single jump moving to the right with unit speed. Harten, Hyman, and Lax [6] demonstrated that the Lax–Wendroff scheme admits entropy-violating solutions. The oscillations created by the Lax–Wendroff scheme send u outside the range $[0, 1]$ into regions where $f'(u)$ is negative. A stable numerical solution forms, represented by the path OABI. Here, OA is a weak, entropy-satisfying, right-moving shock; BI is a strong, entropy-satisfying, left-moving shock; and AB is a strong, entropy-violating, stationary shock. Overwriting the sonic flux values with (5.1) did nothing to cure the problem, but using (5.2) had a dramatic effect, producing the solution OPI. This time, OP is a right-moving, entropy-violating shock that nevertheless closely approximates the true solution, whereas PI is a weak, right-moving, entropy-satisfying shock. Although not completely successful, this was a big step in the right direction. But, clearly, at least one more chapter of this story remains to be written.

6. Extension to systems. We consider now the solution of a one-dimensional system of conservation laws written in the form

$$\mathbf{u}_t + \mathbf{f}(\mathbf{u})_x = 0, \tag{6.1}$$

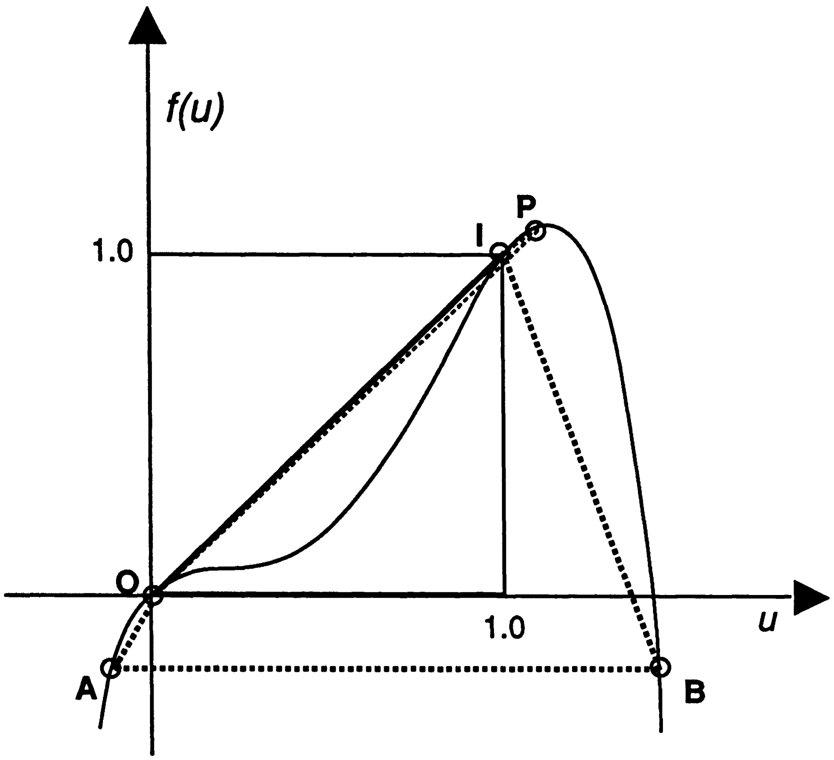

FIG. 7. *Diagram to illustrate solution to the Harten, Hyman, and Lax* [6] *test problem.*

or, more conveniently here, in matrix form

$$\mathbf{u}_t + A(\mathbf{u})\mathbf{u}_x = 0. \tag{6.2}$$

The question now is what statements can be made analogous to the two properties of sonic points given in the scalar case. In fact, we can make *no* general statements about sonic points remaining stationary. For a system of equations, sonic points in general move, unless they occur within simple waves. Thus, all we have to work with is the decay rate, but since this proved the more reliable criterion in the scalar case, this is not too distressing. A result corresponding to (2.10) can be found by differentiating (6.2) with respect to x, and premultiplying with ℓ, where $\ell(\mathbf{u})$ is a left eigenvector of $A(\mathbf{u})$. The result is

$$\ell \cdot [\mathbf{u}_{xt} + A_x\mathbf{u}_x + A\mathbf{u}_{xx}] = 0. \tag{6.3}$$

Let λ be the eigenvalue associated with ℓ. Since $\ell A = \lambda A$, we can write, at a sonic point where λ vanishes,

$$\ell \cdot [\mathbf{u}_{xt} + A_x\mathbf{u}_x] = 0, \tag{6.4}$$

and we have a prediction for the scalar quantity $\ell \cdot \mathbf{u}_{xt}$. This quantity is only in some loose sense a measure of the rate at which the wave of this particular family is decaying. For that we would need something like $(\ell \cdot \mathbf{u_x})_\mathbf{t}$, with a careful normalisation of ℓ. However, it is (6.4) that is the computationally useful result, although there seems to be no simple rule that transforms it from one set of unknowns to another. Therefore, we evaluate (6.4) for a particular case, that of the Euler equations in conservation form, $\mathbf{w} = (\rho, m, E)^T$, for which the matrix $A(\mathbf{u})$ is

$$\begin{vmatrix} 0 & 1 & 0 \\ \frac{1}{2}(\gamma-3)u^2 & -(\gamma-3)u & (\gamma-1) \\ -\frac{uc^2}{\gamma-1} + \frac{\gamma-2}{2}u^3 & \frac{c^2}{\gamma-1} + \frac{3-2\gamma}{2}u^2 & \gamma u \end{vmatrix}, \tag{6.5}$$

of which the left and right eigenvectors are contained in the rows of L and the columns of R, respectively, where

$$L = \frac{1}{2c^2}\begin{vmatrix} \frac{\gamma-1}{2}u^2 + uc & -(\gamma-1)u - c & \gamma-1 \\ 2c^2 - (\gamma-1)u^2 & 2(\gamma-1)u & -2(\gamma-1) \\ \frac{\gamma-1}{2}u^2 - uc & -(\gamma-1)u + c & \gamma-1 \end{vmatrix}, \tag{6.6}$$

$$R = \begin{vmatrix} 1 & 1 & 1 \\ u-c & u & u+c \\ \frac{1}{2}u^2 - uc + \frac{c^2}{\gamma-1} & \frac{1}{2}u^2 & \frac{1}{2}u^2 + uc + \frac{c^2}{\gamma-1} \end{vmatrix}. \tag{6.7}$$

Note that A, L, R can be written entirely in terms of the fluid velocity $u = m/\rho$ and the sound speed c given by $c^2 = \gamma(\gamma-1)[E/\rho - \frac{1}{2}m^2/\rho^2]$. L and R are given here in a normalised form such that $LR = RL = I$. From the above we can evaluate

$$A_x\mathbf{u}_x = \begin{bmatrix} 0 \\ (3-\gamma)\rho u_x^2 \\ \frac{4}{\gamma-1}\rho c u_x c_x + (3-\gamma)\rho u u_x^2 \end{bmatrix}. \tag{6.8}$$

By taking the inner product of this with each left eigenvector of A in turn, we find the astonishingly simple results,

$$\ell \cdot \mathbf{u}_{xt} = \frac{u_x}{2\rho c}[(3-\gamma)u_x - 4c_x], \tag{6.9}$$

$$\ell \cdot \mathbf{u}_{xt} = \frac{4u_x c_x}{\rho c}, \tag{6.10}$$

$$\ell \cdot \mathbf{u}_{xt} = \frac{u_x}{2\rho c}[(3-\gamma)u_x + 4c_x], \tag{6.11}$$

for sonic points associated with waves of the families $(u-c), u, (u+c)$, respectively.

For the special case of a simple wave, these results take interesting special forms. Inside a simple wave of the (u-c) family we have

$$u_x = -\frac{2}{\gamma-1}c_x = -\frac{1}{\rho c}p_x.$$

Under these circumstances, (6.7) can be written

$$\ell \cdot \mathbf{u}_{xt} = \frac{1}{2\rho c}\left(u_x - \frac{1}{\rho c}p_x\right)(u_x - c_x). \tag{6.12}$$

Strikingly, the brackets here do represent wavestrength and the gradient of wavespeed, directly analogous to the $\Delta u \Delta a$ term in the scalar case. For a simple $(u+c)$-wave we have

$$\ell \cdot \mathbf{u}_{xt} = -\frac{1}{2\rho c}\left(u_x + \frac{1}{\rho c}p_x\right)(u_x + c_x), \tag{6.13}$$

and for a simple u-wave, since $u_x = 0$, we have

$$\ell \cdot \mathbf{u}_{xt} = 0. \tag{6.14}$$

Actually, for a simple wave of any family, we can write, obtaining brevity at the expense of physical interpretation,

$$\ell \cdot \mathbf{u}_{xt} = -\frac{\gamma+1}{\gamma-1}\frac{c_x u_x}{\rho c}. \tag{6.15}$$

However, the fact that for nonsimple waves the equations (6.9)–(6.11) are not of the form $\Delta u \Delta a$ does seem to indicate that the sonic flux problem cannot be dealt with field by field. Despite this, we find experimentally that a field-by-field treatment is very successful.

7. Implementation for systems. Implementing these ideas in a code is straightforward. In the course of each timestep any sonic interface can be flagged, and the neighbouring cells corrected at the end without destroying the flow of any vectorisation. Let $\delta \mathbf{u}_L$ be the change brought about in the left cell by whatever preferred method is being used, and $\delta \mathbf{u}_R$ the change in the right cell. Let $\delta^* \mathbf{u}_L, \delta^* \mathbf{u}_R$ be changes that will bring about the proper decay. Then

$$\ell \cdot [\delta^* \mathbf{u}_R - \delta^* \mathbf{u}_L] = \ell \cdot \mathbf{u_{xt} \Delta x \Delta t}. \tag{7.1}$$

Since the neighbouring fluxes are not going to be altered (in a second-order scheme), we have

$$\delta^* \mathbf{u}_R + \delta^* \mathbf{u}_L = \delta \mathbf{u}_R + \delta \mathbf{u}_L. \tag{7.2}$$

Combining these gives

$$\ell \cdot (\delta \mathbf{u}_L^* - \delta \mathbf{u}_L) \;=\; \frac{1}{2}\left[\delta \mathbf{u}_R - \delta \mathbf{u}_L - \mathbf{u}_{xt} \Delta x \Delta t\right], \tag{7.3}$$

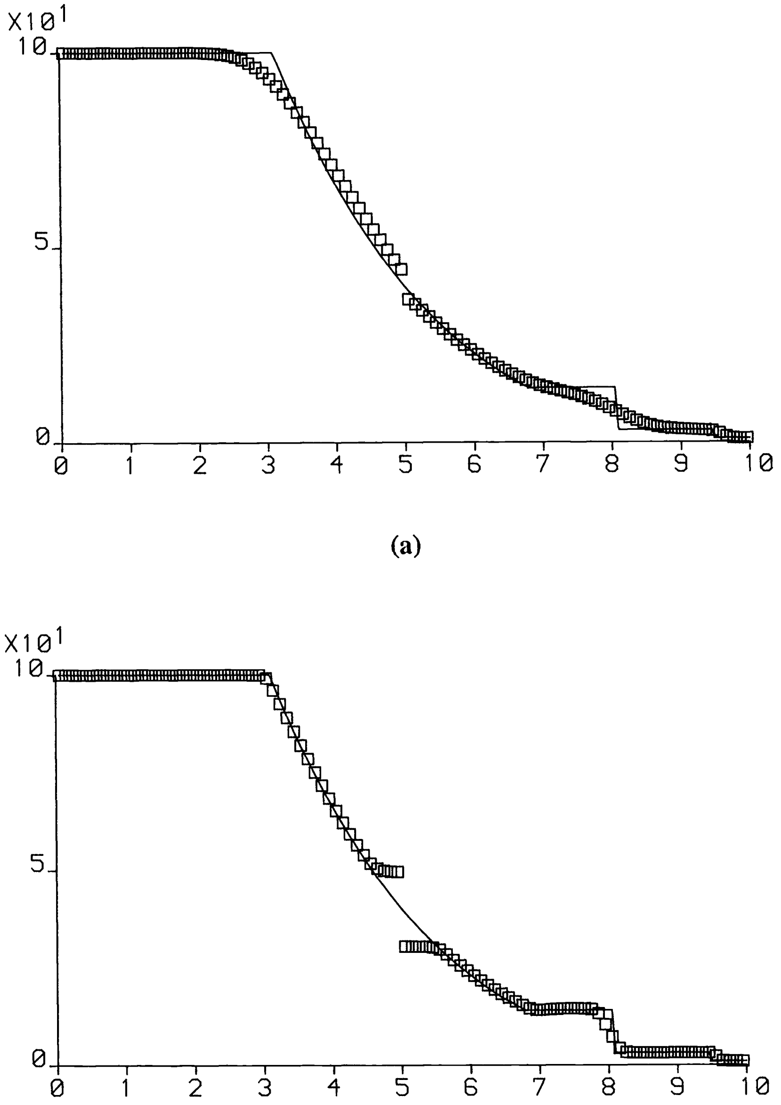
$$\ell \cdot (\delta \mathbf{u}_R^* - \delta \mathbf{u}_R) \;=\; -\frac{1}{2}\left[\delta \mathbf{u}_R - \delta \mathbf{u}_L - \mathbf{u}_{xt} \Delta x \Delta t\right]. \tag{7.4}$$

These conditions can be met, and conservation retained, if certain conserved quantities are transferred from the left cell to the right cell. It is natural to suppose that these should be proportional to $\mathbf{r}$, the right eigenvector corresponding to the sonic field, evaluated at the sonic interface. If they are taken to be $\alpha \mathbf{r}$, then by orthogonality of the left and right eigenvectors, and the normalisation used in (6.6), (6.7),

$$\alpha = \frac{1}{2}\ell \cdot \mathbf{u}_{xt} \Delta x \Delta t - \frac{1}{2}\ell \cdot \left[\delta \mathbf{u}_R - \delta \mathbf{u}_L\right], \tag{7.5}$$

where the first term is obtained from the appropriate equation of (6.9)–(6.11), or one of its simplifications.

8. Experiments with the Euler equations. As a first test for the Euler equations, the shock tube problem $\rho_L = 100$, $\rho_R = 1.0$; $p_L = 100, p_R = 1.0$; $u_L = u_R = 0$ was chosen. Figure 8(a) shows the solution to this problem on a mesh of 100 points using the author's upwind scheme [12] with no special treatment of the sonic point; 80 timesteps have been taken with $\Delta t / \Delta x = 0.20$. Apart from the usual defects of a first-order method, there is a very noticeable expansion shock. Figure 8(b) shows a



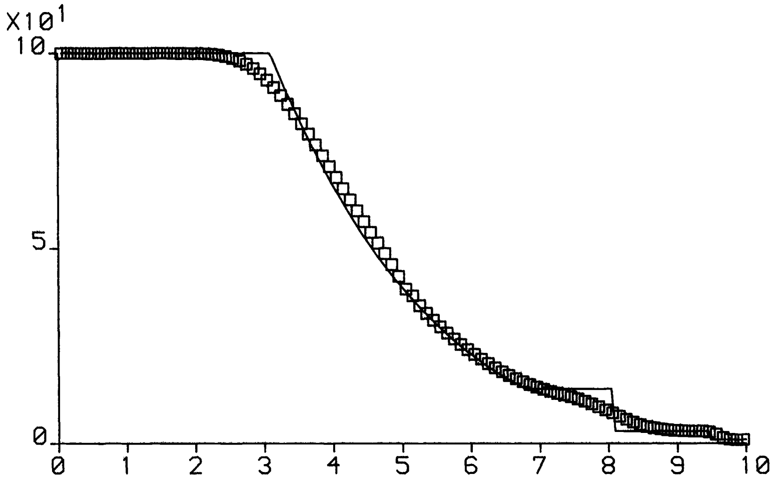
(a)

(b)

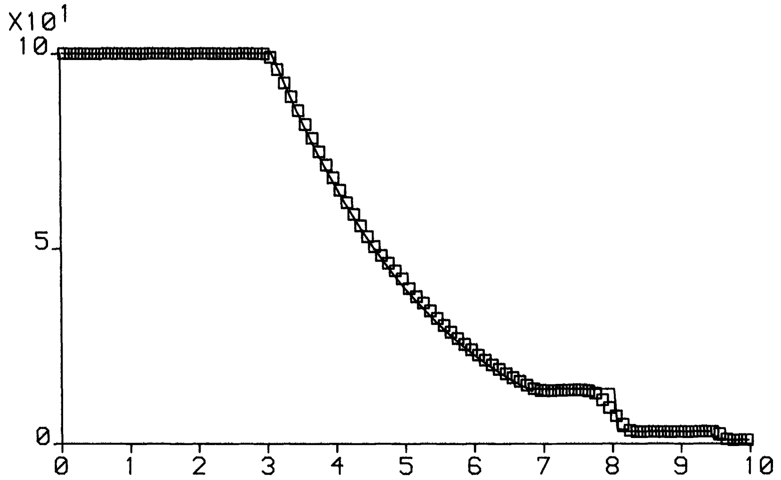
FIG. 8. *Results for a shock tube problem with no special treatment of the sonic point.* (a) *The basic first-order scheme.* (b) *The second-order scheme with Superbee limiter.*

second-order solution featuring the Superbee limiter. All the discontinuities are very much better resolved, including, unfortunately, the expansion shock. Clearly, this is an excellent solution to the wrong problem.

In Fig. 9(a) the first-order algorithm has been supplemented with the correction (7.5) evaluating the spreading rate to first order from (6.12). A very small disturbance can be observed near the sonic point, but this is by now the least of the errors. To have removed this completely we should have, as in the scalar case, modified the neighbouring fluxes as well. Figure 9(b) shows the second-order results, again with



(a)



(b)

FIG. 9. *As Fig.* 8 *but with the sonic cells modified according to* (7.3)–(7.4). (a) *The first-order scheme.* (b) *The second-order scheme with Superbee limiter.*

the spreading rate evaluated to the first order. The results are nearly as good as in the scalar case. For this test, no discernible change to the graphical results followed from using the more complicated evaluation of the spreading rate (6.9)–(6.11), or the simplified version (6.15). Indeed, since the flow is actually a simple wave, there should be no difference.

To investigate a more complex situation, the penetration of two rarefactions was considered. This is a classical problem solved by Riemann. A very full account of it is given by von Mises [10] and the main results are quoted in [2, pp. 191–196]. Unfortunately, the solution is inverse giving x and t in terms of u and c. Instead, accurate results were found from a numerical characteristics solution for data

$$u = 0, \qquad c = 1.2, \qquad |x| < 1, \tag{8.1}$$

$$u = 1.5\text{sgn}(x), \qquad c = 0.9, \quad 1 \leq |x| \leq 5. \tag{8.2}$$

The pattern of characteristics in Fig. 10 was produced. In this figure, the limiting characteristics of each expansion intersect at $t = 12.31$, which compares well with the exact value of $295/24 = 12.29$. The two lines marked by small symbols are the loci of the sonic points $|u| = c$. Initially these are fixed at $x = \pm 1$, but move outward as the waves penetrate. Figures 11(a), (b) show the distribution of a Mach number at $t = 3.0$. In the exact solution, the gradients are different (but not quite piecewise constant) in the central interaction region, and in the simple wave regions outside. In the unmodified second-order solution (Fig. 11(a)), the sonic points have remained in their original positions, and all parts of the solution are badly in error. Figure 11(b) shows that the modification (7.5) produces good results.

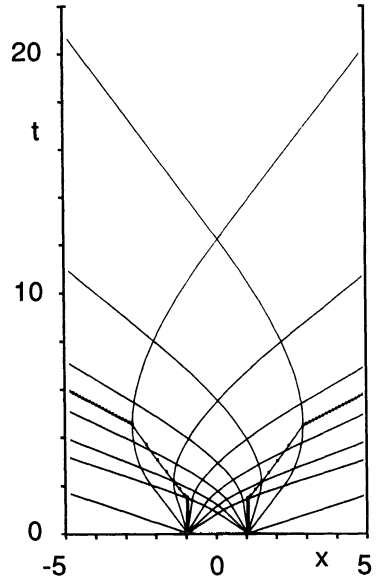


FIG. 10. *Wave diagram for two interpenetrating rarefactions.*

It had been intended to try and use the double expansion test as a way of discriminating between the various formulae (6.9)–(6.15). Since only (6.9)–(6.11) are derived without assuming simple waves, it was anticipated that they would do much better on this test than their simplified rivals. Surprisingly, very little difference was observed, and the following explanation(s) are advanced. The errors committed at a sonic point are usually very small. They become significant only by accumulation. However, in a compound wave the sonic points move and the errors do not accumulate at one point. Following this line of reasoning, the sonic modification was turned off entirely for $t > 1.2$ (when the sonic points first begin to move), and little change was seen. Thus moving sonic points seem able to take care of themselves, and it only seems necessary to modify the sonic behaviour for simple, and hence stationary, waves. Another possibility is that a completely correct treatment of the interaction would require modification of waves belonging to the nonstationary families. This would presumably be a second-order effect, but would need to be included before the

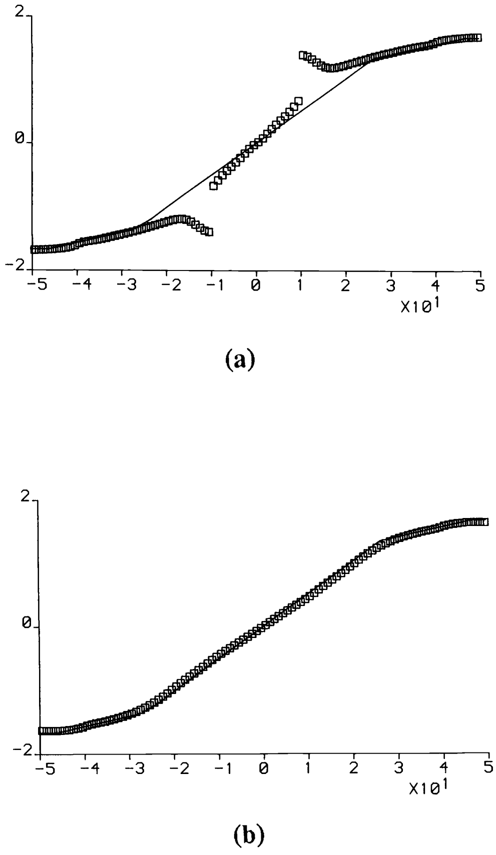

FIG. 11. *Two numerical solutions at* $t = 3$. (a) *No special treatment of the sonic points.* (b) *Sonic points treated according to* (7.3)–(7.4).

benefit of other second-order terms could be felt. In fact, an attempt was made to work out a second-order estimate for $\ell \cdot \mathbf{u}_{xt}$ along the lines adopted for the scalar problem in §3. However, the resulting formulae were very complicated, and resulted in no improvement. The conclusion is, therefore, that the very simple estimate (6.15) is satisfactory for practical application, and leads to excellent results.

9. Remarks on MUSCL-type schemes. It has often been noted that schemes using the MUSCL formulation [7], its higher order extensions [1], and to a lesser extent higher order schemes generally, have fewer difficulties near sonic points. Compare, for example, [15, Fig. 7a], which shows a near-discontinuous rarefaction wave in a solution generated using Godunov's method, with [15, Fig. 7e] where a MUSCL-type scheme generates a satisfyingly smooth solution to the same problem. This is because, in a region of fairly continuous expansion, the second-order fluxes at the interfaces either side of the sonic interface will avoid the errors discussed in connection with first-order upwind schemes, leading to equation (2.15).

If the data are not smooth, and limiters are called into play, the reconstructed data may be only first-order accurate, and the problem will recur. Recovery from this situation will eventually take place (provided the Riemann problems are solved using an entropy-satisfying scheme) in the sense that the solution will begin to decay, and may even come to decay at the correct rate. However the scheme cannot "know" at later times that its data derives from earlier errors, so some local distortion will persist. Whenever this happens, the present technique of enforcing the correct decay rate at all times should cure the problem.

10. Concluding remarks. The proper treatment of sonic regions in the context of upwind differencing has been the source of much confusion. This seems to be because all existing theory (which is limited to scalar problems) is based on the assumption that each interface flux away from the sonic interface will be computed by simple first-order upwinding. It is pointed out here that this necessarily creates errors at those interfaces next to the sonic interface, and that tinkering with the sonic interface alone cannot cure all the problems. For a first-order method to meet all of the natural design criteria, the adjacent fluxes must also be modified. For second-order schemes there is a choice between "fixing" the stationary characteristic, or forcing the proper decay of the stationary wave. The second choice is numerically better posed, gave better results, and is also the only one that can be generalised to systems of equations. The algebra for the one-dimensional Euler equations leads to fairly simple conditions that are straightforward to implement to first order. Although there is some indication that a field-by-field treatment is not valid to second order, the first-order implementation gives excellent practical results.

Acknowledgment. The shock tube data used for the first Euler test case were suggested by Dr. E.F. Toro, of the College of Aeronautics, Cranfield. For this, and for interesting discussions, I am most grateful.

BI-CGSTAB: A FAST AND SMOOTHLY CONVERGING VARIANT OF BI-CG FOR THE SOLUTION OF NONSYMMETRIC LINEAR SYSTEMS*

H. A. VAN DER VORST†

Abstract. Recently the Conjugate Gradients-Squared (CG-S) method has been proposed as an attractive variant of the Bi-Conjugate Gradients (Bi-CG) method. However, it has been observed that CG-S may lead to a rather irregular convergence behaviour, so that in some cases rounding errors can even result in severe cancellation effects in the solution. In this paper, another variant of Bi-CG is proposed which does not seem to suffer from these negative effects. Numerical experiments indicate also that the new variant, named Bi-CGSTAB, is often much more efficient than CG-S.

Key words. Bi-CG, CG-S, nonsymmetric linear systems, iterative solver, preconditioning

AMS(MOS) subject classification. 65F10

1. Introduction.

In recent years the Conjugate Gradients-Squared (CG-S) method [8] has been recognized as an attractive variant of the Bi-Conjugate Gradient (Bi-CG) iterative method for the solution of certain classes of nonsymmetric linear systems. Recent studies indicate that the method is often competitive with other established methods, such as GMRES [7]. For such comparative studies see, e.g., [1], [2], [6].

In many situations, however, one is faced with a quite irregular convergence behaviour of CG-S, in particular in situations when starting the iteration close to the solution. This is a common situation in, e.g., the final stages of some nonlinear solvers and in time dependent problems. The then often occurring irregularities in the iteration process may even lead to severe cancellation, spoiling the solution delivered by the process.

This motivated our search for a more smoothly converging variant of Bi-CG, without giving up the attractive speed of convergence of CG-S. It appeared that an early predecessor of CG-S, named IDR [10], could be reformulated to a method that shows the desired properties (at least for a large number of test cases).

In this paper we give some relevant background for the CG-S method in §2, which provides a suitable framework for the presentation of the new variant Bi-CGSTAB in §3. The various ways in which preconditioning can be incorporated in the algorithm are discussed in §4. In §5 we show, by suitable examples, that Bi-CGSTAB may be very attractive in comparison with CG-S in many situations.

2. Conjugate gradients-squared (CG-S).

The residual vectors r_i, generated by the CG method, satisfy a 3-term recurrence relation. This 3-term recurrence relation is not used explicitly in CG, but it is fundamental for the efficiency of the method. When A is not symmetric we lose this property for the r_i's. Moreover, when A is not positive definite, then $\| \; \|_A$ does not define a norm, so that it does not make sense to minimize $\| x - x_i \|_A$.

In the Bi-CG method [3], the approximations are constructed in such a way that the residual r_j is orthogonal with respect to another row of vectors $\hat{r}_0, \hat{r}_1, \cdots, \hat{r}_{j-1}$,

* Received by the editors May 21, 1990; accepted for publication (in revised form) February 18, 1991.

† Mathematical Institute, University of Utrecht, Budapestlaan 6, NL-3584 CD Utrecht, the Netherlands (vorst@math.ruu.nl).

and, vice versa, $\hat{r}_j$ is orthogonal with respect to $r_0, r_1, \cdots, r_{j-1}$. This can be accomplished by two 3-term recurrence relations for the rows $\{r_j\}$ and $\{\hat{r}_j\}$. The Bi-CG method also terminates within n steps at most (when A is an n by n matrix), but there is no minimization property as in CG for the intermediate steps.

Sonneveld [8] made the observation that, in the case of convergence, both the rows $\{r_j\}$ and $\{\hat{r}_j\}$ converge towards zero, but that only the convergence of the $\{r_j\}$ is exploited. He proposes the following modification to Bi-CG by which all the convergence effort is concentrated in the r_i vectors. For the Bi-CG vectors it is well known that they can be written as $r_j = P_j(A)r_0$ and $\hat{r}_j = P_j(A^T)\hat{r}_0$, and because of the bi-orthogonality relation we have that

$$\begin{aligned}(r_j, \hat{r}_i) &= (P_j(A)r_0, P_i(A^T)\hat{r}_0)\\ &= (P_i(A)P_j(A)r_0, \hat{r}_0) = 0 \quad \text{for } i < j.\end{aligned}$$

The iteration parameters for Bi-CG are computed from innerproducts like the above. Sonneveld observed that we can also construct the vectors $\tilde{r}_j = P_j^2(A)r_0$, using only the latter form of the innerproduct for recovering the Bi-CG parameters (which implicitly define the polynomial P_j). By doing so, it can be avoided that the vectors $\hat{r}_j$ have to be formed, nor is there any multiplication with the matrix A^T.

The resulting algorithm can be represented by the following scheme.

Unpreconditioned CG-S Algorithm.

```
$x_0$ is an initial guess; $r_0 = b - Ax_0$;
$\hat{r}_0$ is an arbitrary vector, such that $(r_0, \hat{r}_0) \neq 0$,
    e.g., $\hat{r}_0 = r_0$;
$\rho_0 = 1; p_0 = q_0 = 0$;
for $i = 1, 2, 3, \cdots$,
    $\rho_i = (\hat{r}_0, r_{i-1})$;
    $\beta = \rho_i / \rho_{i-1}$;
    $u = r_{i-1} + \beta q_{i-1}$;
    $p_i = u + \beta(q_{i-1} + \beta p_{i-1})$;
    $v = Ap_i$;
    $\alpha = \rho_i / (\hat{r}_0, v)$;
    $q_i = u - \alpha v$;
    $\hat{u} = u + q_i$;
    $x_i = x_{i-1} + \alpha w$;
    if $x_i$ is accurate enough then quit;
    $r_i = r_{i-1} - \alpha Aw$;
end
```

One iteration step of CG-S involves about as many arithmetical operations as one step of Bi-CG.

The last line of the Unpreconditioned CG-S Algorithm could be replaced by the computation of the true residual vector $r_i = b - Ax_i$. However, in many of the experiments, especially those with the typical jumping convergence behaviour of CG-S, it has been seen that this has a negative effect on the iteration process, i.e., it may take many more iteration steps for this *true residual* process to get at an x_i of similar accuracy as in the CG-S algorithm in its form described above. In some cases the *true residual* process did even not converge whereas CG-S did.

An example of such a situation is discussed in §5.4. A possible explanation might be that locally large variations in a current update direction overshadow variations in other almost converged directions, so that the true residual vector does not necessarily satisfy the underlying orthogonality relations for the updated vectors $P_i(A)r_0$. This aspect needs further research.

If the Bi-CG polynomial $P_i(A)$ is viewed as a reductor working on r_0, then this reductor is now applied twice in the new method and this explains the name *conjugate gradients-squared.*

The weak point in this way of reasoning is that the reduction operator $P_i(A)$ in Bi-CG is very dependent on the starting initial residual r_0, and that it is not likely to be a reduction operator for any other vector, not even for the particular vector $P_i(A)r_0$ itself. Indeed, it is not very difficult to construct examples for which $P_i(A)r_0$ is small in norm and for which ${P^2}_i(A)r_0$ is even much bigger in norm then r_0 is.

Such a phenomenon may happen in the following situation. Suppose that r_0 has small coordinates in some eigenvector directions of the matrix A. Then $P_i(\lambda)$ may take very large values in the corresponding eigenvalues, in particular when these eigenvalues are more or less isolated from the others, without leading to a significant contribution of that eigenvector direction to the norm of r_i in Bi-CG. However, the value of ${P^2}_i(\lambda)$ may be so large that the contribution of the corresponding eigenvector direction even dominates in the residual r_i of CG-S.

These situations occur quite often, and even during one convergence history we may observe many local peaks in the convergence curve for CG-S (see, e.g., the examples in §5). These peaks do not seem to delay the convergence of CG-S. However, in practical situations they may have quite adverse effects, since they may be so large that the local corresponding corrections to the current iterate result in cancellation. As a result, the final solution may have little significance, which can be checked by computing the real residual (instead of the updated residual as is done usually in these processes). This is a very serious problem with CG-S and in our examples in §5 we will encounter significant losses in accuracy.

For a more detailed discussion on the convergence behaviour of CG-S, see [9].

3. A more smoothly converging variant of CG-S. We have mentioned that the residuals r_i in CG-S satisfy the relation $r_i = P_i(A)^2r_0$, in which $P_i(A)r_0$ just defines the residual $r_{bi-CG,i}$ in the Bi-CG method:

$$r_{bi-CG,i} = P_i(A)r_0.$$

By construction we have that $(P_i(A)r_0, P_j(A^T)\hat{r}_0) = 0$ for $j < i$, which expresses the fact that $P_i(A)r_0$ is perpendicular to the subspace $K^i(A^T; \hat{r}_0)$, spanned by the vectors

$$\hat{r}_0, A^T\hat{r}_0, \cdots, (A^T)^{i-1}\hat{r}_0.$$

This implies that, in principle, we can also recover the Bi-CG iteration parameters by requiring that, e.g., r_i is perpendicular to $\tilde{P}_j(A^T)\hat{r}_0$, or, equivalently, that $(\tilde{P}_j(A)P_i(A)r_0, \hat{r}_0) = 0$, for another suitable set of polynomials $\tilde{P}_j$ of degree j. In Bi-CG one takes $\tilde{P}_j = P_j$, namely, $\hat{r}_j = P_j(A^T)\hat{r}_0$. This is exploited in CG-S, as we have indicated before, since recursion relations for the vectors $P_j^2(A)r_0$ can be derived from those for $P_j(A)r_0$.

Of course, we can construct other iteration methods, by which x_i are generated so that $r_i = \tilde{P}_i(A)P_i(A)r_0$ with other ith degree polynomials, like, e.g., Chebychev polynomials, which might be more suitable. Unfortunately, the optimal parameters for the Chebychev polynomials are in general not easily obtainable and also the recurrence relations for the resulting method are more complicated than for CG-S. Another possibility is to take for $\tilde{P}_j$ a polynomial of the form

$$(1) \qquad Q_i(x) = (1-\omega_1 x)(1-\omega_2 x)\cdots(1-\omega_i x),$$

and to select suitable constants ω_j. This expression leads to an almost trivial recurrence relation for the Q_i.

An obvious possibility to select ω_j in the jth iteration step is to minimize r_j, with respect to ω_j, for residuals that can be written as $r_j = Q_j(A)P_j(A)r_0$. This leads to a method which is mathematically equivalent with the IDR method described in [10]. IDR, however, in the form as it is described in [10] may also suffer from severe cancellation and can therefore lead to unreliable results. These effects can be even much worse than in CG-S. In fact, the CG-S method has been derived as an improvement to IDR and the IDR method was not given further attention.

However, it is possible to rewrite the scheme, in which the residuals $Q_i(A)P_i(A)r_0$ are generated, to an apparently rather stable and more efficient one. Because of its similarity to CG-S, its favourable stability properties, and its relation with Bi-CG, we have named the method Bi-CGSTAB.

We will now derive the (unpreconditioned) Bi-CGSTAB Algorithm. This will be done in a similar way as followed in [8] for the derivation of CG-S.

The polynomial P_i and related polynomials are implicitly defined by the Bi-CG scheme.

Unpreconditioned Bi-CG Algorithm.

```
$x_0$ is an initial guess; $r_0 = b - Ax_0$;
$\hat{r}_0$ is an arbitrary vector, such that
    $(\hat{r}_0, r_0) \neq 0$, e.g., $\hat{r}_0 = r_0$;
$\rho_0 = 1$;
$\hat{p}_0 = p_0 = 0$;
for $i = 1, 2, 3, \cdots$,
    $\rho_i = (\hat{r}_{i-1}, r_{i-1}); \beta_i = (\rho_i/\rho_{i-1})$;
    $p_i = r_{i-1} + \beta_i p_{i-1}$;
    $\hat{p}_i = \hat{r}_{i-1} + \beta_i \hat{p}_{i-1}$;
    $v_i = Ap_i$;
    $\alpha_i = \rho_i/(\hat{p}_i, v_i)$;
    $x_i = x_{i-1} + \alpha_i p_i$;
    if $x_i$ is accurate enough then quit;
    $r_i = r_{i-1} - \alpha_i v_i$;
    $\hat{r}_i = \hat{r}_{i-1} - \alpha_i A^T \hat{p}_i$;
end
```

From this scheme it is straightforward to show that $r_i = P_i(A)r_0$ and $p_{i+1} = T_i(A)r_0$, in which $P_i(A)$ and $T_i(A)$ are ith degree polynomials in A. The Bi-CG Algorithm then defines the relations between these polynomials:

$$T_i(A)r_0 = (P_i(A) + \beta_{i+1}T_{i-1}(A))r_0,$$

and

$$P_i(A)r_0 = (P_{i-1}(A) - \alpha_i A T_{i-1}(A))r_0.$$

In the Bi-CGSTAB Algorithm we wish to have recurrence relations for

$$r_i = Q_i(A)P_i(A)r_0.$$

With Q_i as in (1) and the Bi-CG relation for the factor P_i and T_i, it then follows that

$$\begin{aligned}Q_i(A)P_i(A)r_0 &= (1-\omega_i A)Q_{i-1}(A)(P_{i-1}(A)-\alpha_i AT_{i-1}(A))r_0\\ &= \{Q_{i-1}(A)P_{i-1}(A)-\alpha_i AQ_{i-1}(A)T_{i-1}(A)\}r_0\\ &\quad -\omega_i A\{(Q_{i-1}(A)P_{i-1}(A)-\alpha_i AQ_{i-1}(A)T_{i-1}(A))\}r_0.\end{aligned}$$

Clearly, we also need a relation for the product $Q_i(A)T_i(A)r_0$. This can also be obtained from the Bi-CG relations:

$$\begin{aligned}Q_i(A)T_i(A)r_0 &= Q_i(A)(P_i(A)+\beta_{i+1}T_{i-1}(A))r_0\\ &= Q_i(A)P_i(A)r_0+\beta_{i+1}(1-\omega_i A)Q_{i-1}(A)T_{i-1}(A)r_0\\ &= Q_i(A)P_i(A)r_0+\beta_{i+1}Q_{i-1}(A)T_{i-1}(A)r_0\\ &\quad -\beta_{i+1}\omega_i AQ_{i-1}(A)T_{i-1}(A)r_0.\end{aligned}$$

Finally we have to recover the Bi-CG constants ρ_i, β_i, and α_i by innerproducts in terms of the new vectors that we now have generated. For example, β_i can be computed as follows. First we compute

$$\tilde{\rho}_{i+1} = (\hat{r}_0, Q_i(A)P_i(A)r_0) = (Q_i(A^T)\hat{r}_0, P_i(A)r_0).$$

By construction, $P_i(A)r_0$ is orthogonal with respect to all vectors $U_{i-1}(A^T)\hat{r}_0$, where U_{i-1} is an arbitrary polynomial of degree $i-1$ at most. This means that we have to consider only the highest order term of $Q_i(A^T)$ when computing $\tilde{\rho}_{i+1}$. This term is given by $(-1)^i\omega_1\omega_2\cdots\omega_i(A^T)^i$. We actually wish to compute

$$\rho_{i+1} = (P_i(A^T)\hat{r}_0, P_i(A)r_0),$$

and since the highest order term of $P_i(A^T)$ is given by $(-1)^i\alpha_1\alpha_2\cdots\alpha_i(A^T)^i$, it follows that

$$\beta_i = (\tilde{\rho}_i/\tilde{\rho}_{i-1})(\alpha_{i-1}/\omega_{i-1}).$$

The other constants can be derived similarly.

Note that in our discussion we have focused on the recurrence relations for the vectors r_i and p_i, while in fact our main goal is to determine x_i. As in all CG-type methods, x_i itself is not required for continuing the iteration, but it can easily be determined as a "sideproduct" by realizing that an update of the form $r_i = r_{i-1} - \gamma Ay$ corresponds to an update $x_i = x_{i-1} + \gamma y$ for the current approximated solution.

By writing r_i for $Q_i(A)P_i(A)r_0$ and p_i for $Q_{i-1}(A)T_{i-1}(A)r_0$, we obtain the following scheme for Bi-CGSTAB (we trust that, with the foregoing observations, the reader will now be able to verify the relations in Bi-CGSTAB). In this scheme we have computed the ω_i so that $r_i = Q_i(A)P_i(A)r_0$ is minimized in 2-norm as a function of ω_i.

UNPRECONDITIONED BI-CGSTAB ALGORITHM.

```
$x_0$ is an initial guess; $r_0 = b - Ax_0$;
$\hat{r}_0$ is an arbitrary vector, such that
    $(\hat{r}_0, r_0) \neq 0$, e.g., $\hat{r}_0 = r_0$;
$\rho_0 = \alpha = \omega_0 = 1$;
```

```
$v_0 = p_0 = 0$;
for $i = 1, 2, 3, \cdots$,
    $\rho_i = (\hat{r}_0, r_{i-1}); \beta = (\rho_i/\rho_{i-1})(\alpha/\omega_{i-1})$;
    $p_i = r_{i-1} + \beta(p_{i-1} - \omega_{i-1}v_{i-1})$;
    $v_i = Ap_i$;
    $\alpha = \rho_i/(\hat{r}_0, v_i)$;
    $s = r_{i-1} - \alpha v_i$;
    $t = As$;
    $\omega_i = (t, s)/(t, t)$;
    $x_i = x_{i-1} + \alpha p_i + \omega_i s$;
    if $x_i$ is accurate enough then quit;
    $r_i = s - \omega_i t$;
end
```

In order to restrict on memory traffic, we have carried out both updates to the current solution x in one single step, while the updates to the residual r had to be done separately ($s = r_{i-1} - \alpha v_i$ and $r_i = s - \omega_i t$). So s represents the residual after a "Bi-CG step" and one might terminate the iteration as soon as $\|s\|$ is small enough, but in that case, before stopping the algorithm, the current solution has to be updated appropriately as $x_i = x_{i-1} + \alpha p_i$ in order to be compatible with the current residual s (and the computation of t, ω_i, as well as the second update $\omega_i s$ should be skipped).

From the orthogonality property $(P_i(A)r_0, Q_j(A^T)\hat{r}_0) = 0$, for $j < i$, it follows that Bi-CGSTAB is also a finite method, i.e., in exact arithmetic it will terminate after $m \leq n$ iteration steps. In this case we get $s = 0$ at iteration step m and ω_m is then not defined. This represents a lucky breakdown of the algorithm and the process should be terminated as indicated in the previous paragraph.

In the above form Bi-CGSTAB requires, for the solution of an N by N system $Ax = b$, evaluation of two matrix vector products with A, $12N$ flops for vector updates, and four innerproducts. This has to be compared with (unpreconditioned) CG-S which requires also two matrix vector products with A, and $13N$ flops, but only two innerproducts. In practical situations, however, the two additional innerproducts lead to only a small increase in computational work per iteration step and this is readily undone by almost any reduction in the number of iteration steps (especially on vector computers on which innerproducts are usually fast operations).

Except for memory locations for x, b, r, and A, we need for Bi-CGSTAB memory space for four additional N-vectors $\hat{r}_0, p, v$, and t (note that r may be overwritten by s). This is the same as for CG-S.

In §5 we will see, for some examples, the more smooth convergence properties of Bi-CGSTAB in comparison with CG-S. We will also see that, at least for our experiments, the new method is often more efficient than CG-S, in terms of the amount of computational work necessary to achieve a specified accuracy in the final result.

We have not discussed convergence problems that one can encounter with Bi-CG, and, hence, with CG-S and Bi-CGSTAB. These problems stem basically from the fact that for general matrices the bilinear form

$$[x, y] \equiv (P(A^T)x, P(A)y),$$

which is used to form the bi-orthogonality, does not define an innerproduct. In particular, it may occur that, by an unfavourable choice for $\hat{r}_0$, an iteration parameter ρ_i or $(\hat{r}_0, v_i)$ is zero (or very small), without convergence having taken place. In an actual code, one should test for such situations and take appropriate measures, e.g., restart with a different $\hat{r}_0$ or switch to another method (for example, GMRES [7]).

Moreover, one should keep in mind that Bi-CGSTAB, in the form as presented, is one out of many possible variants, which are all equivalent in exact arithmetic but which may have different behaviour in finite precision arithmetic. One such variant, which is less straightforward than the presented one, is obtained by the following changes to the scheme:

- include $\rho_1 = (\hat{r}_0, r_0)$ in the initialization part of the scheme;
- skip the computation of ρ_i in the first line of the iteration part;
- add the computation of $\rho_{i+1} = -\omega_i(\hat{r}_0, t)$ immediately after the computation of ω_i.

We have seen, in some of our experiments, a markedly better convergence behaviour for this variant, but further research is necessary in order to determine the most satisfying variant.

4. Preconditioning. If we want to use preconditioning with a suitable preconditioning matrix K, i.e., $K \approx A$, then we write $K = K_1K_2$ and we may apply any of the previously discussed iteration schemes to the explicitly preconditioned system

$$\tilde{A}\tilde{x} = \tilde{b}, \tag{2}$$

with $\tilde{A} = K_1{}^{-1}AK_2{}^{-1}, x = K_2{}^{-1}\tilde{x}$, and $\tilde{b} = K_1{}^{-1}b$. For example, for $K_1 = I$ we have preconditioning from the right (or postconditioning), for $K_2 = I$ we have preconditioning from the left, and for $K_1 = L, K_2 = U$, we have the well-known preconditioning from both sides.

Now we write the CG-S scheme (§2) for (2), and denote all the occurring vectors by $\tilde{}$, e.g., $\tilde{p}_i$. With the change of variables:

$$\begin{aligned}
&\tilde{p}_i \Rightarrow K_1{}^{-1}p_i, \tilde{q}_i \Rightarrow K_1{}^{-1}q_i, \tilde{v}_i \Rightarrow K_1{}^{-1}v_i,\\
&\tilde{r}_i \Rightarrow K_1{}^{-1}r_i, \tilde{u}_i \Rightarrow K_1{}^{-1}u_i, \tilde{x}_i \Rightarrow K_2x_i,\\
&\hat{r}_0 \Rightarrow K_1{}^T\bar{r}_0,
\end{aligned}$$

this leads to the following scheme for *preconditioned CG-S*.

PRECONDITIONED CG-S ALGORITHM.

```
$x_0$ is an initial guess; $r_0 = b - Ax_0$;
$\bar{r}_0$ is an arbitrary vector, such that $(r_0, \bar{r}_0) \neq 0$,
    e.g., $\bar{r}_0 = r_0$;
$\rho_0 = 1; p_0 = q_0 = 0$;
for $i = 1, 2, 3, \cdots$,
    $\rho_i = (\bar{r}_0, r_{i-1})$;
    $\beta = \rho_i/\rho_{i-1}$;
    $u = r_{i-1} + \beta q_{i-1}$;
    $p_i = u + \beta(q_{i-1} + \beta p_{i-1})$;
    Solve $y$ from $Ky = p_i$;
    $v = Ay$;
    $\alpha = \rho_i/(\bar{r}_0, v)$;
    $q_i = u - \alpha v$;
    Solve $z$ from $Kz = u + q_i$
    $x_i = x_{i-1} + \alpha z$;
```

```
        if $x_i$ is accurate enough then quit;
        $r_i = r_{i-1} - \alpha Az$;
    end
```

Note that this scheme delivers the variables x_i and r_i corresponding to the original system $Ax = b$, i.e., $r_i = b - Ax_i$.

A remarkable observation is that K_1 and K_2 play no explicit role in the scheme, and that any of the forms of preconditioning (i.e., any of the choices for K_1 and K_2) *correspond only with a different choice for* $\hat{r}_0$ in the original, explicitly preconditioned scheme. Hence, if one of the forms of explicit preconditioning in the original scheme might lead to an advantage, then the same advantage can be obtained by the above scheme through an appropriate choice of $\bar{r}_0$. Or, in still other words, instead of studying the effect of the different forms of applying the preconditioner, one may as well study the effect of the choice for $\bar{r}_0$.

When we rewrite the Bi-CGSTAB scheme for equation (2), similarly as previously for CG-S, then with the change of variables:

$$\tilde{p}_i \Rightarrow {K_1}^{-1}p_i, \tilde{v}_i \Rightarrow {K_1}^{-1}v_i, \tilde{r}_i \Rightarrow {K_1}^{-1}r_i,$$
$$\tilde{s} \Rightarrow {K_1}^{-1}s, \tilde{t} \Rightarrow {K_1}^{-1}t, \tilde{x}_i \Rightarrow K_2 x_i,$$
$$\hat{r}_0 \Rightarrow {K_1}^T \bar{r}_0,$$

we obtain the following scheme for *preconditioned Bi-CGSTAB*.

PRECONDITIONED BI-CGSTAB ALGORITHM.

```
    $x_0$ is an initial guess; $r_0 = b - Ax_0$;
    $\bar{r}_0$ is an arbitrary vector, such that
        $(\bar{r}_0, r_0) \neq 0$, e.g., $\bar{r}_0 = r_0$;
    $\rho_0 = \alpha = \omega_0 = 1$;
    $v_0 = p_0 = 0$;
    for $i = 1, 2, 3, \cdots$,
        $\rho_i = (\bar{r}_0, r_{i-1}); \beta = (\rho_i/\rho_{i-1})(\alpha/\omega_{i-1})$;
        $p_i = r_{i-1} + \beta(p_{i-1} - \omega_{i-1}v_{i-1})$;
        Solve $y$ from $Ky = p_i$;
        $v_i = Ay$;
        $\alpha = \rho_i/(\bar{r}_0, v_i)$;
        $s = r_{i-1} - \alpha v_i$;
        Solve $z$ from $Kz = s$;
        $t = Az$;
        $\omega_i = ({K_1}^{-1}t, {K_1}^{-1}s)/({K_1}^{-1}t, {K_1}^{-1}t)$;
        $x_i = x_{i-1} + \alpha y + \omega_i z$;
        if $x_i$ is accurate enough then quit;
        $r_i = s - \omega_i t$;
    end
```

This scheme too delivers the variables x_i and r_i corresponding to the original system $Ax = b$.

For preconditioned CG-S we have seen that any of the forms of preconditioning can be regarded as a suitable choice for $\bar{r}_0$. However, for Bi-CGSTAB there is an explicit difference between the different forms, which cannot be attributed to a suitable choice for $\bar{r}_0$, because of the expression for ω_i. This expression does not seem to make the preconditioned scheme very attractive, but we might as well compute another value for ω_i:

$$\omega_i = (t, s)/(t, t). \tag{3}$$

When computing ω_i as in (3), we are minimizing the current residual for the original system rather than the preconditioned one. In this case we have in fact the same effect as by explicit postconditioning in the original scheme (though for a different $\bar{r}_0$), and hence we lose potential (near-)symmetry of the preconditioned operator. In such a case we might prefer to apply the Unpreconditioned Bi-CGSTAB Algorithm, as in §3, to the explicitly preconditioned system $K_1^{-1}AK_2^{-1}\tilde{x} = K_1^{-1}b$. However, this has the obvious disadvantage that we have to construct a (near-)symmetric splitting of the preconditioner K.

We will refer to the scheme with expression (3) for the ω_i as Bi-CGSTAB-P.

Hence, if one compares Bi-CGSTAB-P with preconditioned CG-S then one can view this as a comparison between the two explicitly postconditioned schemes in §§2 and 3 (each with a different $\hat{r}_0$).

5. Numerical results. In our experiments we consider four different, but representative situations. These experiments have been carried out in double precision floating point arithmetic (about 15 decimal places) on a CONVEX C-240 computer. In order to avoid all confusion about the definition of $\bar{r}_0$ (see §4), all experiments have been carried out with CG-S and Bi-CGSTAB applied to the explicitly preconditioned system $L^{-1}AU^{-1}\tilde{x} = L^{-1}b$. However, based upon our experiments so far, our conclusions would be about the same when we compare the preconditioned CG-S scheme with Bi-CGSTAB-P (§4).

In all cases the iteration was started with $x_0 = 0$.

5.1. Example 1. The first situation is one in which Bi-CG converges quite smoothly and in which it was, apparently, a good idea to square the Bi-CG polynomial. This happens sometimes in the early phases of the iteration process or in situations where the eigenvalue distribution is quite uniform.

As an example we show in Fig. 1 the convergence behaviour for the discretized Poisson equation in two dimensions over a 150 × 150 grid (leading to a symmetric positive definite system), preconditioned by Modified Incomplete Choleski decomposition [4]. In this case CG-S converged about twice as fast as Bi-CG, as we might expect from heuristic arguments.

We see that in this case, though Bi-CGSTAB converges more smoothly, it does not improve the iteration process with respect to efficiency. In similar experiments Bi-CGSTAB requires roughly the same number of iteration steps as CG-S, sometimes slightly more and sometimes slightly less.

5.2. Example 2. Our second example is a preconditioned symmetric positive definite system for which Bi-CG (=Conjugate Gradients in this case) loses orthogonality among the residuals in a very early phase. For a discussion on this effect and its consequences, see [9]. In such a case one would expect some strong effects when squaring the Bi-CG polynomial, as is done in CG-S.

The linear system comes from a 5-point finite difference discretization of the partial differential equation

$$-(Du_x)_x - (Du_y)_y = 1$$

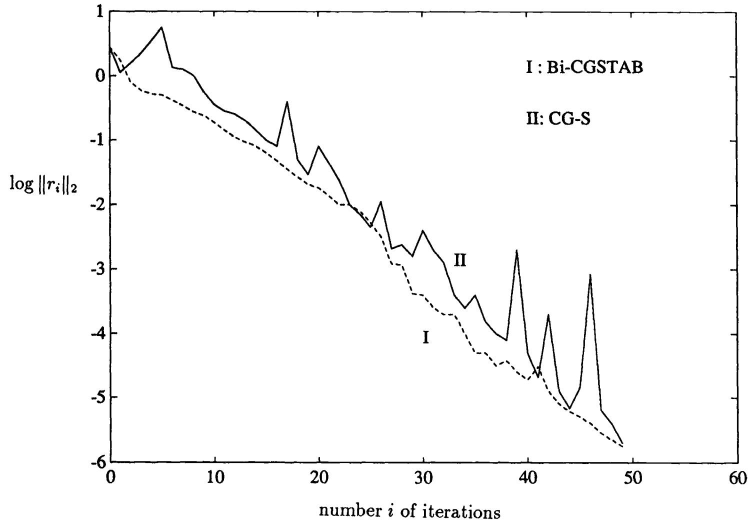

FIG. 1. *CG-S and Bi-CGSTAB for an ideal CG-S situation.*

over the unit square, with Dirichlet boundary conditions along $y = 0$ and Neumann conditions along the other parts of the boundary. Meshsizes have been chosen so that the resulting linear system has $150 \times 150 = 22,500$ unknowns.

The function D is defined as

$$D = 1000 \quad \text{for } 0.1 \leq x, y \leq 0.9, \quad \text{and } D = 1 \quad \text{elsewhere.}$$

Modified Incomplete Choleski Decomposition [4] was used as preconditioner.

In Fig. 2 we see the loss of orthogonality reflected in the convergence behaviour of Bi-CG by small irregularities and by the fact that superlinear convergence does not take place. CG-S converges faster eventually, but we see that the local effects in this method are much more violent.

Bi-CGSTAB seems to have about the same "asymptotical" speed of convergence as CG-S (if we discard the peaks in the CG-S curve), but its convergence behaviour is definitely smoother. In situations like these, we often see that the updated residual in Bi-CGSTAB has more significance than the one in CG-S. See also the discussion of example 4 (§5.4) for this effect.

5.3. Example 3. In our third example the nonsymmetric linear system comes from discretization of the partial differential equation

$$-u_{xx} - u_{yy} + ((au)_x + au_x)/2 = 1$$

over the unit square, with $a = 20 \exp(3.5(x^2 + y^2))$. Along the boundaries we have Dirichlet conditions (this equation was taken from [11]). The equation was discretized over a rectangular grid, with central differences for the first order terms, with stepsize $1/201$ in each direction, leading to a system with $40,000$ unknowns. The linear system was preconditioned by a standard incomplete LU factorization [5].

In Fig. 3 we have displayed the norms of the iterated vectors r_i for both CG-S and Bi-CGSTAB, and again we note the much smoother convergence behaviour of

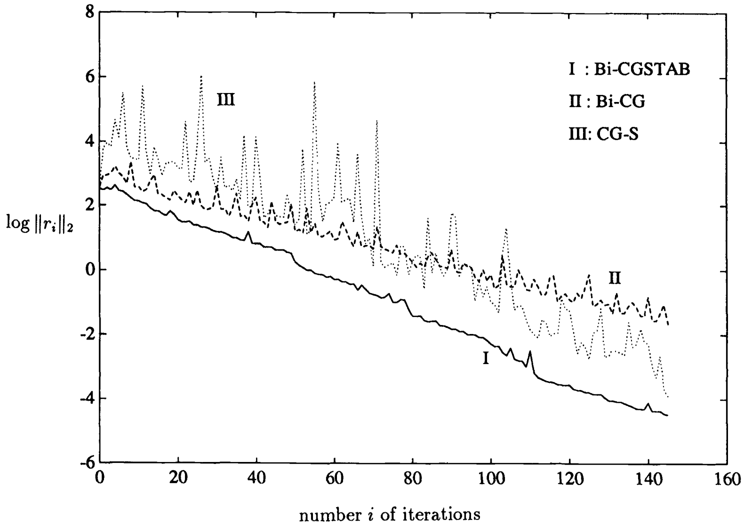

FIG. 2. *Less smooth convergence behaviour of Bi-CG and CG-S.*

Bi-CGSTAB. Also note that some residuals in CG-S may be quite large as compared with the starting residual. Since the updates to the corresponding iterate vectors x_i must have been large too, we may expect cancellation effects in the iterated vector. Indeed, after 200 CG-S iterations, the explicitly computed residual (using the delivered iteration vector x_i) was larger (in norm) than the updated residual vector r_i by three orders of magnitude. This implies that the approximated solution had an error which was about 1000 times as large as we might have thought. For Bi-CGSTAB both residuals were virtually equal to each other.

Finally note that in this case Bi-CGSTAB, apart from being more stable, also converges faster than CG-S. This was true for most of our test cases. We have also tested Bi-CG for this problem, but this method showed hardly any progress within 450 iteration steps.

5.4. Example 4. The fourth example is typical for a situation in which Bi-CGSTAB is much more efficient than CG-S. The nonsymmetric linear system comes from discretization of the partial differential equation

$$-(Au_x)_x - (Au_y)_y + B(x,y)u_x = F$$

over the unit square, with $B(x,y) = 2\exp(2(x^2+y^2))$. Along the boundaries we have Dirichlet conditions: $u = 1$, for $y = 0, x = 0$ and $x = 1$, and $u = 0$ for $y = 1$.

The function A is defined as shown in Fig. 4; $F = 0$ everywhere, except for the small subsquare in the centre where $F = 100$.

The equation was discretized over a rectangular grid, with central differences for the first order term, with stepsize $1/128$ in each direction, leading to a system with 127^2 unknowns. The linear system was preconditioned by an incomplete LU factorization [5].

Figure 5 shows the norms of the iteration vectors r_i and we observe similar effects as in example 3. At the 151st iteration Bi-CGSTAB was terminated with $\|r_i\|_2 \approx 10^{-8}$; at that point the true residual $\|b - Ax_i\|_2$ is virtually the same.

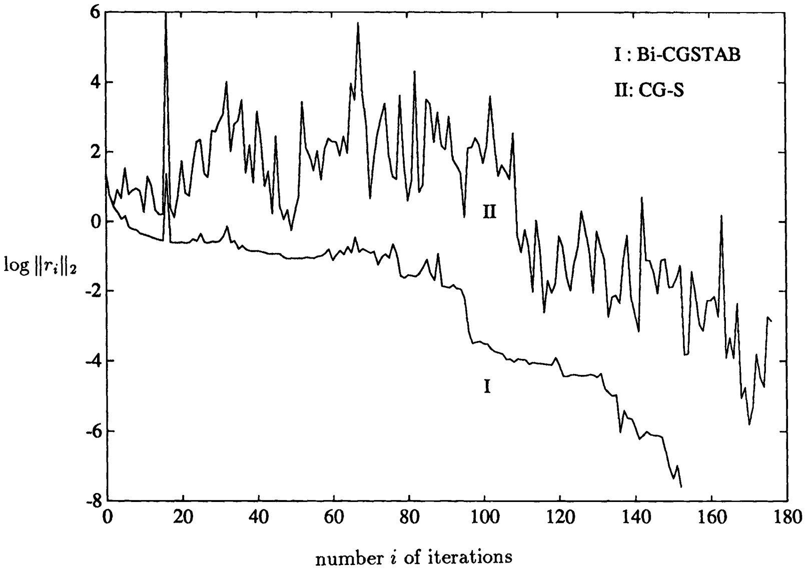

FIG. 3. *CG-S and Bi-CGSTAB for a nonsymmetric problem (example* 3).

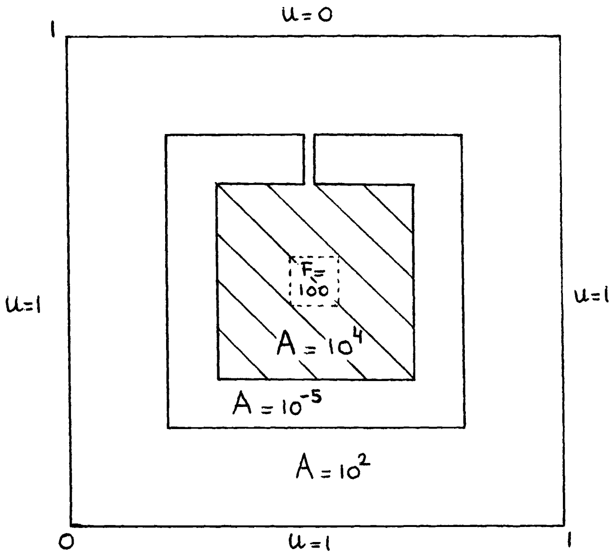

FIG. 4. *The coefficients for example* 4.

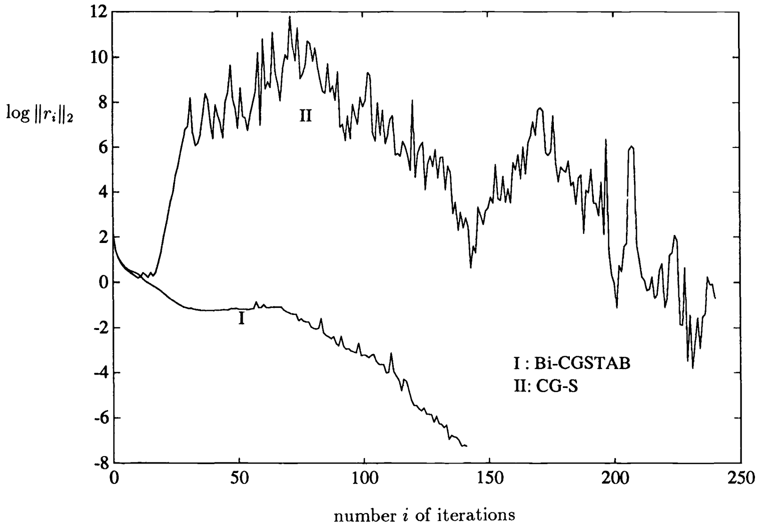

FIG. 5. *CG-S and Bi-CGSTAB for a nonsymmetric problem (example* 4).

It takes CG-S 382 iteration steps to obtain $\|r_i\|_2 \approx 10^{-8}$, but at that point the true residual $\|b - Ax_i\|_2$ is only about 10^{-4}. This means that in this case we have to iterate even further with CG-S, possibly after restarting the process, in order to get a result similar to that with Bi-CGSTAB.

For CG-S we have also checked what happens if we replace the *updated* vector r_i in the process by $r_i = b - Ax_i$ (see §2). It then turns out that both CG-S processes produce about the same residual vectors up to the 70th iteration step. But from then on the *updated* r_i process and the *true residual* process produce r_i vectors that differ more and more. After a while the *true residual* process delivers even much less accurate x_i vectors than Bi-CGSTAB. For example, at the 382nd iteration step the norm of the true residual $b - Ax_i$ in the *updated* r_i process is, as has been mentioned before, about 10^{-4}, whereas $\|b - Ax_i\|_2$ in the *true residual* process is about 10^2 for $i = 382$.

For this problem Bi-CG required 282 iteration steps to get the residual in norm below 10^{-8}. This example represents one of those rare examples in which CG-S does much worse than Bi-CG.

6. Conclusions. From many experiments we have learned that Bi-CGSTAB (and Bi-CGSTAB-P) is an attractive alternative for CG-S. Its convergence behaviour is much smoother so that it often produces much more accurate residual vectors (and, hence, more accurate solutions), and in most cases it converges considerably faster than CG-S.

The method has recently been tested for problems coming from semi-conductor device simulation and oil reservoir simulation and also in these circumstances our earlier findings have been confirmed (for many of these problems CG-S was the method of choice so far).

Therefore, we conclude that Bi-CGSTAB (with preconditioning, of course) is a very competitive method for solving relevant classes of nonsymmetric linear systems.

Acknowledgements. Peter Sonneveld (TU-Delft) suggested that I reconsider his old method IDR again, which turned out to be the key for Bi-CGSTAB, and I learned a lot from discussions with him.

I wish to thank Wolfgang Fichtner (ETH-Zürich), Koos Meijerink (Shell-Rijswijk), Marjan Driessen (Philips-Eindhoven), and Shun Doi (NEC-Kawasaki) for testing Bi-CGSTAB extensively on industrial problems and for reporting their results to me.

The referees have helped me to improve the presentation of this paper.

I further wish to express my thanks to Philips-Eindhoven for kindly permitting me access to their IBM 3090 system. Most of the numerical experiments, leading to understanding CG-S and to learning about the advantages of Bi-CGSTAB, have been carried out on that computer.

A FAST REORDERING ALGORITHM FOR PARALLEL SPARSE TRIANGULAR SOLUTION*

ALEX POTHEN† AND FERNANDO L. ALVARADO‡

Abstract. A space-efficient partitioned representation of the inverse of a unit lower triangular matrix L may be used for efficiently solving sparse triangular systems on massively parallel computers. The number of steps required in the parallel triangular solution is equal to the number of subsets of elementary triangular matrices in the partitioned representation of the inverse. Alvarado and Schreiber have recently described two partitioning algorithms that compute the minimum number of subsets in the partition over all permutations of L which preserve the lower triangular structure of the matrix. Their algorithms require space linear and time nonlinear in the number of nonzeros in L. This paper describes a partitioning algorithm that requires only $\mathcal{O}(n)$ time and space for computing an optimal partition, when L is restricted to be a Cholesky factor. (Here n is the order of L.) The savings result from the observation that instead of working with the structure of L, it is sufficient to work with its transitive reduction, the elimination tree of L. Experimentally the new partitioning algorithm requires negligible time in comparison to the previous partitioning algorithms and to the Multiple-Minimum-Degree ordering algorithm.

1. The problem.

A unit lower triangular matrix L of order n can be expressed as a product of elementary lower triangular matrices $L = \prod_{i=1}^{n-1} L_i$, where $L_i = I + \underline{m}_i \, \underline{e}_i^{\,T}$, $\underline{m}_i$ has its first i components equal to zero, and $\underline{e}_i$ is the ith coordinate vector. Assume that L is sparse. Consider a representation of L in which the elementary lower triangular matrices are grouped together to form m unit lower triangular factors $L = \prod_{i=1}^{m} P_i$, where each factor P_i has the property that P_i^{-1} can be represented in the same space as P_i. We say that P_i is invertible in place. Here each $P_i = \prod_{k=e_i}^{e_{i+1}-1} L_k$, with $e_1 \equiv 1 < e_2 < \cdots < e_m < e_{m+1} \equiv n$. This leads to a partitioned representation of the inverse of L of the form $L^{-1} = \prod_{i=m}^{1} P_i^{-1}$, that can be stored in just the space required for L. This partitioned inverse representation is advantageous when a triangular system $L\underline{y} = \underline{b}$ must be solved repeatedly with different right-hand-side vectors $\underline{b}$ on a massively parallel computer such as the Connection Machine; on such a machine, the solution $\underline{y}$ can be computed as $\underline{y} := \prod_{i=m}^{1} P_i^{-1}\underline{b}$ in m steps. This representation has been considered by Alvarado et al. in the Power Engineering literature [4], [8], and by Alvarado and Schreiber [3]. It has been observed that a

reduction in the number of factors m is advantageous, and that this number can be reduced by permuting L into a new lower triangular matrix L_Π, and determining the partitioned representation of L_Π^{-1}.

Henceforth, without loss of generality, we will assume that L is irreducible. Alvarado and Schreiber [3] considered the following problem:

(P1) Given a unit lower triangular matrix $L = \prod_{i=1}^{n-1} L_i$, find a permutation $L_\Pi = \Pi L \Pi^T$ and a representation $L_\Pi = \prod_{i=1}^{m} P_i$, where

(1) each $P_i = \prod_{k=e_i}^{e_{i+1}-1} L_k$, with $e_1 = 1 < e_2 < \cdots e_m < e_{m+1} = n$,

(2) each P_i is invertible in place, and

(3) m is minimum over all permutations Π such that L_Π is lower triangular.

They designed two algorithms to solve (P1), which they called RP1 and RP2 in their paper. Both algorithms require time nonlinear in the number of nonzeros in L, and space proportional to the number of nonzeros in L.

In this paper, we consider the restriction of (P1) to unit lower triangular matrices, which arise in the LDL^T factorization of symmetric, positive definite matrices. (Henceforth we call this the Cholesky factorization.) Several applications of this problem in Power Engineering are described in [8]. We describe an $\mathcal{O}(n)$-time algorithm to compute the minimum number of factors in the partitioned inverse representation of L. The algorithm requires only the elimination tree and the number of nonzeros in each column of L as input, and *not* the nonzero structure of L. Thus the space requirement of the proposed algorithm is $\mathcal{O}(n)$. Further, since the elimination tree and the nonzero counts of the columns of L may be computed directly from the original matrix A, the space requirement of the overall algorithm to compute the factors in the partitioned inverse representation from A is $\mathcal{O}(n + \tau(A))$, where $\tau(A)$ is the number of nonzeros in the strict lower triangle of A.

In (P1), the action of the permutation Π on L is to reorder the elementary matrices whose product is L; however, these elementary matrices cannot be arbitrarily reordered, since we require the resulting matrix L_Π to be lower triangular. From the equation $L_i = I + \underline{m}_i \, \underline{e}_i{}^T$, it can be verified that the elementary matrices L_i and L_{i+1} can be permuted if and only if $l_{i+1,i} = 0$. These precedence constraints on the order in which the elementary matrices may appear is captured in a graph model of the problem.

2. A graph model.

Let $G(L) = (V, E)$ denote the directed graph with vertex set V equal to the set of columns of L, and an edge $(j, i) \in E$ (with $i > j$) if and only if $l_{i,j} \neq 0$. The edge (j, i) is directed from the lower-numbered vertex j to the higher-numbered vertex i. Hence $G(L)$ is a directed acyclic graph (DAG). Since we have assumed that L is irreducible, $G(L)$ is weakly connected, i.e., there is a path joining every pair of vertices in $G(L)$ when $G(L)$ is viewed as an undirected graph. If there is a directed path from a vertex j to a vertex i in $G(L)$, we will say that j is a *predecessor* of i, and that i is a *successor* of j. In particular, if $(j, i) \in E$, then j is a predecessor of i and i is a successor of j.

Given a subset P of the columns of L, the concept of the subgraph corresponding to the nonzeros in P will be useful in the remainder of this paper. Accordingly, we define the *subgraph of* $G(L)$ *induced by a set of vertices* P as the graph that contains all edges directed from vertices in P to all vertices in $G(L)$, and all the vertices that are the endpoints of such edges.

A *topological ordering* of $G(L)$ is an ordering of its vertices in which predecessors are numbered lower than successors; i.e., for every edge $(j, i) \in E$, $i > j$. By construction, the original vertex numbering of $G(L)$ is a topological ordering. A permutation

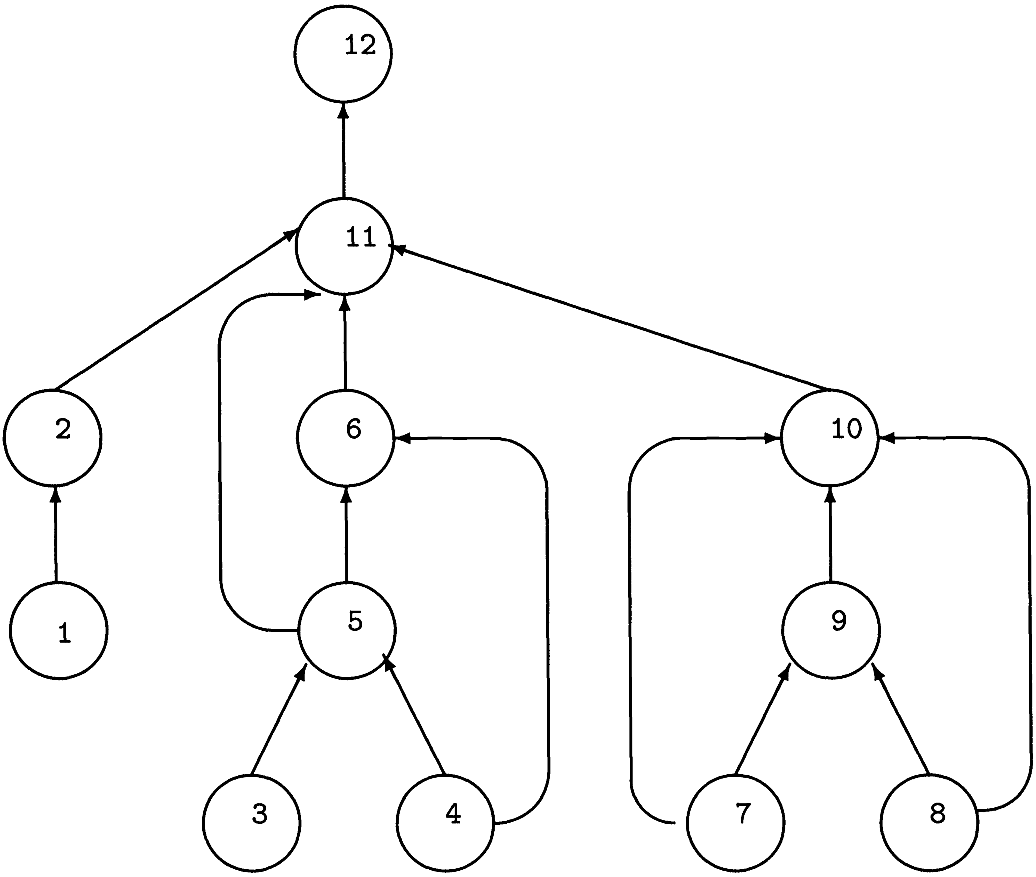

FIG. 1. *A directed acyclic graph $G(L)$ corresponding to a Cholesky factor L.*

Π that leaves L_{Π} lower triangular corresponds to a topological reordering of the vertices of $G(L)$. A topologically ordered DAG corresponding to a Cholesky factor L is shown in Fig. 1.

In what follows, we identify a subset of columns P with the factor formed by multiplying, in order of increasing column number, the elementary matrices corresponding to columns in P. The condition that the nonzero structure of a factor P should be the same as the structure of its inverse corresponds in the graph model to the requirement that the subgraph induced by P should be transitively closed [3], [9]. (A DAG G is *transitively closed* if for every pair of vertices j and i such that there is a directed path in G from j to i, the edge (j, i) is present in G.)

A graph model of (P1) is provided in the following problem:

(P2) Find an ordered partition $P_1 \prec P_2 \prec \cdots \prec P_m$ of the vertices $\{1, 2, \cdots, n-1\}$ of a topological ordering of $G(L)$ such that
(1) for every $v \in \{1, 2, \cdots, n-1\}$, if $v \in P_i$ then all predecessors of v belong to $P_1, \cdots, P_i$,
(2) the subgraph induced by each P_i is transitively closed, and
(3) m is minimum subject to the two conditions above.

The permutation Π in (P1) can be obtained by renumbering the vertices in the ordered partition P_1 to P_m in increasing order. The first condition follows from the fact that the factors are formed by grouping the elementary matrices of L_Π in order from lowest-numbered to highest-numbered. The other conditions follow from the discussion in the preceding paragraphs. The graph model (P2) is not explicitly stated in Alvarado and Schreiber [3], although it is implicit in the description of their algorithm RP1.

3. Cholesky factorization. Now we consider the restriction of (P1) to Cholesky factors. Then the graph $G(L)$, viewed as an undirected graph, is a chordal graph. The gist of this section is that the chordality of $G(L)$ simplifies the problem a great deal, and enables the design of an $\mathcal{O}(n)$ algorithm for computing the partition, whereas previous algorithms [3] required time nonlinear in the number of edges of $G(L)$. The savings result from the fact that it suffices to consider the transitive reduction of $G(L)$, the elimination tree of L, instead of all the edges in $G(L)$.

The *elimination tree* of L is a directed tree $T = (V, E_T)$, whose vertices are the columns of L, with a directed edge $(j,i) \in E_T$ if and only if the lowest-numbered row index of a subdiagonal nonzero in the jth column of L is i. (The edge is directed from j to i.) The vertex i is the *parent* of j, and j is a *child* of i.

We define the *higher adjacency set* $hadj(j)$ to be the set of all vertices k adjacent to j in $G(L)$ such that k is numbered higher than j. If (j,i) is an edge in the elimination tree, the lowest-numbered vertex in $hadj(j)$ is i. The reader can verify that the elimination tree of the graph $G(L)$ in Fig. 1 is obtained by omitting the edges $(4,6)$, $(5,11)$, $(7,10)$, and $(8,10)$ from the graph.

A comprehensive survey of the role of elimination trees in sparse Cholesky factorization has been provided by Liu [13]. We will assume some knowledge of the properties of elimination trees, and in particular, the following result will be useful.

LEMMA 3.1. *If v is the parent of a vertex u in the elimination tree T, then* $hadj(u) \subseteq \{v\} \cup hadj(v)$. □

Our partitioning algorithm will require as input the elimination tree with vertices numbered in a topological ordering. It also requires the subdiagonal nonzero counts of each column of L, stored in an array $hd(v)$. The algorithm uses a variable *level* to partition the vertices; $level(v) = l$ implies that v belongs to the set P_l.

The idea of the algorithm is as follows. It examines the vertices of the elimination tree in increasing order. If a vertex v is a leaf of the tree, then it is included in the first *level*, which constitutes the vertices in P_1. Otherwise, it divides the children of v into two sets: C_1 is the subset of the children u such that the subgraph of $G(L)$ induced by u and v is transitively closed, and C_2 denotes the subset of the remaining children. Let l_1 denote the maximum *level* of a child in C_1 and l_2 denote the maximum *level* of a child in C_2. Set $l_i = 0$ if $C_i = \emptyset$. If C_1 is empty, or if $l_1 \leq l_2$, then v cannot be included in the same *level* as any of its children, and hence begins a new *level* $(l_2 + 1)$. Otherwise, $l_1 > l_2$, and v can be included together with some child $u \in C_1$ such that $level(u) = l_1$.

We now describe the details of an implementation. The vertices of the elimination tree are numbered in a topological ordering from 1 to n. The descendant relationships in the elimination tree are represented by two arrays of length n, *child* and *sibling*. $child(v)$ represents the first child of v, and $sibling(v)$ represents the right sibling of v, where the children of each vertex are ordered arbitrarily. If $child(v) = 0$, then v has no child and is a leaf of the elimination tree; if $sibling(v) = 0$, then v has no right sibling. The array $hd(.)$, also of length n, contains the *higher degree* of a vertex v (equal to $|hadj(v)|$). Our partitioning algorithm, Algorithm RPtree, is shown in Fig. 2. The reader can verify that $P_1 = \{1,3,4,7,8,9\}$, $P_2 = \{2,5,6,10\}$, and $P_3 = \{11\}$ for the

FIG. 2. *Algorithm RPtree.*

graph in Fig. 1.

The complexity of the algorithm is easily analyzed. For a given vertex v, we examine all of its children, and the operations associated with examining a child u can be performed in constant time. If we charge the cost of examining a child u of v to u, then each vertex in the elimination tree is charged at most once, since each child has a unique parent. Thus the time complexity of the algorithm is $\mathcal{O}(n)$. The space complexity is also $\mathcal{O}(n)$, since the elimination tree, the higher degrees, and the *level* information are all stored using arrays of length n.

4. Correctness of the algorithm.

We now prove that Algorithm RPtree correctly solves (P1).

THEOREM 4.1. *Algorithm RPtree correctly solves* (P1) *when L is the unit lower triangular matrix in the LDL^T factorization of a symmetric, positive definite matrix.*

Proof. We consider problem (P2), the graph model of (P1), and the DAG $G(L)$, which viewed as an undirected graph is chordal. We will show that the ordered partition obtained by the algorithm satisfies the three conditions in (P2).

First we show that a vertex $v \in P_i$ only if all predecessors of v belong to $P_1, \cdots, P_i$. Since the elimination tree T is the transitive reduction of $G(L)$, any predecessor of v in the latter graph is a predecessor of v in T as well. Thus it suffices to consider the descendants of v in the elimination tree. Further, since the vertices in the elimination tree are topologically ordered, and the algorithm assigns *level* values to the vertices in increasing order, it suffices to consider the children of v in T. Finally, since the algorithm assigns *level* values to a vertex v such that

$$level(v) \geq \max\{level(u) : u \text{ is a child of } v\},$$

the result is true.

Second, we show that the subgraph induced by the vertices in a *level* is transitively closed. In the preceding paragraph, it was seen that *level* values are nondecreasing along any path from a leaf to the root on the elimination tree. Hence it follows that the vertices included in a *level* l by Algorithm RPtree can be expressed as the union (not necessarily disjoint) of certain paths in the elimination tree, where vertices on a path are constrained to have *level* values equal to l. Let u_0, u_1, $\cdots$, u_p be such a path, which is maximal with respect to the property of having the same *level* value; then since the algorithm includes all these vertices in a single *level*,

$$hd(u_0) = 1 + hd(u_1) = 2 + hd(u_2) = \cdots = p + hd(u_p).$$

It follows from Lemma 3.1 that

$$hadj(u_0) = \{u_1\} \cup hadj(u_1) = \cdots = \{u_1, \ldots, u_p\} \cup hadj(u_p).$$

Hence the subgraph induced by the vertices in this path is transitively closed. Since the set of vertices in a *level* is the union of such paths, the result now follows.

It remains to show that m is the minimum number of ordered sets in the partition of $G(L)$ subject to the above conditions. We prove the result by induction on $(n-1)$, the number of vertices to be partitioned. The base case when this number is one is trivial. Assume inductively that Algorithm RPtree optimally partitions all chordal graphs with at most $n-1$ vertices (hence there are at most $n-2$ vertices to be partitioned).

Consider the partition $P_1 \prec P_2 \prec \cdots \prec P_m$ with m levels obtained by the algorithm on a chordal graph $G(L)$ with n vertices. Let T denote the elimination tree of $G(L)$ with vertices in a topological ordering. As shown in the proof of the second condition, P_1 consists of the union of vertices on certain paths on the elimination tree T, each path beginning from a leaf and ending at a vertex w such that *level*(w) is one, and *parent*(w) has *level* greater than one. (Thus these paths are maximal with respect to the condition that their *level* values are equal to one.) Let $u_0 < u_1 \ldots < u_p$ be such a path, and denote by u_{p+1} the *parent* of u_p in T.

The fact that the algorithm did not include u_{p+1} in P_1 together with u_p could be due to one of two reasons. If u_{p+1} has some child x with $level(x) > level(u_p) = 1$, then the inclusion of u_{p+1} in P_1 would destroy the first condition of problem (P2). Otherwise, all the children of u_{p+1} belong to P_1. Now the algorithm would not include u_{p+1} in P_1 only if some child x satisfied $hd(x) < 1 + hd(u_{p+1})$. If this were the case, there is some vertex $w \in hadj(u_{p+1}) \setminus hadj(x)$. Thus the inclusion of u_{p+1} into P_1 would destroy the property that the subgraph induced by P_1 is transitively closed. Thus P_1 contains the maximum number of vertices possible from the vertices in $G(L)$.

Now consider the set of vertices Q which consists of those vertices of $G(L)$ not included in P_1. Then the induced subgraph $G(Q)$ has fewer than $n-1$ vertices, and by the inductive hypothesis, is partitioned optimally by Algorithm RPtree into $m-1$ ordered sets. Let T_Q denote the elimination tree of the subgraph $G(Q)$ obtained by removing vertices in P_1 from the elimination tree T of $G(L)$. From the preceding paragraph, since vertices in P_1 cannot be included in a *level* which contains the leaf vertices of T_Q, it follows that any partition of $G(L)$ requires at least $(m-1)+1 = m$ levels. This completes the proof. □

5. Experimental results. We implemented Algorithm RPtree and compared its performance with the RP1 and RP2 algorithms of Alvarado and Schreiber on eleven problems from the Boeing–Harwell collection [6]. All the algorithms were implemented in C, within Alvarado's Sparse Matrix Manipulation System [1]. Each problem was initially ordered using the Multiple-Minimum-Degree ordering of Liu [12], and the structure of the resulting lower triangular factor L was computed. We call this the primary ordering step. Then Algorithms RP1, RP2, or RPtree were used in a secondary ordering step to reorder the structure of L to obtain the minimum number of partitions over reorderings that preserve the DAG $G(L)$. All three algorithms lead to the same number of levels in the partition since they solve the same problem.

The experiments were performed on a Sun SPARCstation IPC with 24 Mbytes of main memory and a 100 Mbyte swap space running SunOS 4.1 version of the Unix operating system. The unoptimized standard system compiler was used to compile the code. Recall that $\tau(A)$ is the number of nonzeros in the strict lower triangle of A; $\tau(L)$ is similarly defined. We scale these numbers by a thousand for convenience. In Table 1, we report the scaled values of $\tau(A)$ and $\tau(L)$, the CPU times taken by the primary and secondary ordering algorithms (in seconds), and the height of the elimination tree obtained from the primary ordering. (The fill and the etree height reported here are somewhat different from previously published values for the MMD ordering because of our use of SMMS. In SMMS, the problem datum is first converted to an element list from the Boeing–Harwell format before it is stored using sparse matrix data structures. This changes the initial matrix ordering which is input to the MMD algorithm, with the consequent change in the fill and etree height.)

Table 1 also reports the number of factors in the partitioned inverse of L. The number in the column "levels(new)" corresponds to the number of factors in the solution of the problem (P1), i.e., in the partition of the permuted matrix L_Π. The number in the column "levels(orig)" indicates the number of factors obtained when the unpermuted Cholesky factor L is partitioned. In the graph model (P2), this corresponds to replacing the first condition with the stricter condition:

For every $v \in \{1, \cdots, n-1\}$, if $v \in P_i$, then all vertices numbered lower than v belong to $P_1, \cdots, P_i$.

Alvarado and Schreiber [2] have shown that when the partitioned inverse is employed on a massively parallel computer such as the CM-2, the number of levels in the partitioned inverse representation determines the complexity of parallel triangular solution. On the other hand, the complexity of a conventional triangular solution algorithm is governed by the height of the elimination tree. Table 1 shows both these quantities, and it is seen that the number of levels in the partitioned inverse is many times smaller (by a factor of sixteen on the average) than the elimination tree height. Hence the use of the partitioned inverse leads to much faster parallel triangular system solution on massively parallel computers.

An interesting feature in these results is that the number of levels seems to be only weakly dependent on the problem, the order of A, or the number of nonzeros in A or L. This number is between ten and forty and is significantly smaller than the order of the matrix A for most of these problems. If this observation holds true for larger instances of a wide collection of problems, then it will have a significant impact on the application of the ideas in this paper to parallel computing. For the $k \times k$ model grid problem ordered by the optimal nested dissection ordering, the height of the elimination tree is $3k + \Theta(1)$, while the number of levels is $2 \log_2 k + \Theta(1)$.

Algorithm RPtree has $\mathcal{O}(n)$ time complexity while RP1 and RP2 are both nonlinear in the number of nonzeros in L. This is confirmed by the experiments: on the average problem in this test set, RPtree is more than *a hundred* times faster than RP1 or RP2, and the advantage increases with increasing problem size. From a practical perspective, the time needed by Algorithm RPtree is quite small when compared to the cost of computing the initial MMD ordering. This is not true of either the RP1 or the RP2 algorithm. An equally important advantage of Algorithm RPtree is that it requires only $\mathcal{O}(n)$ additional space, whereas both RP1 and RP2 require $\mathcal{O}(\tau(L))$ additional space.

We have also experimented with a variant of the Minimum-Length-Minimum-Degree (MLMD) ordering [5] as the primary ordering, but we do not report detailed results because Timely Communications are by definition brief. The MLMD ordering incurs a great deal more fill in L than the MMD algorithm, and its current, fairly straightforward implementation is quite slow compared to the MMD algorithm. We believe an implementation comparable in sophistication to the MMD algorithm should not be significantly slower than MMD, and may also reduce the number of fills. In spite of the larger number of fills, the MLMD ordering is more effective in almost all cases than MMD in reducing the number of levels in the partition of both L and L_{Π}. In some cases, the initial number of levels obtained when MLMD is used as the primary ordering is lower than the final number of levels obtained with MMD after the secondary reordering.

When the MLMD ordering is used, Algorithm RPtree has an even greater time advantage over the RP1 and RP2 algorithms, since the former works with the elimination tree, while the latter algorithms require the structure of the Cholesky factor. For instance, on BCSSTK13, RP2 takes 461 seconds, while RPtree requires only 0.07 seconds.

6. Extensions.

There are two directions in which the results in this paper may be extended.

Given the factorization $A = LDL^T$ of a symmetric, positive definite matrix, consider the filled matrix $F = L + L^T$ and the corresponding chordal undirected graph $G_u(F)$. In problem (P3) we ask for the minimum number of factors m in the partitioned inverse representation of L over all vertex orderings that preserve the structure of the filled graph $G_u(F)$ (rather than the DAG $G(L)$ and the corresponding elimination tree of L as (P2) does). A solution to this problem would reduce the number of factors in the partitioned inverse over the number required in (P2). Such an ordering would have to be applied to the original matrix A, *before* the computation of the factorization. This problem turns out to be much harder than (P2), and many subtle issues are involved in the solution of this problem. It can be solved by a *generalization* of the Jess and Kees ordering [11]. (However, the Jess and Kees ordering by itself will not work.) An efficient algorithm to solve (P3) that makes use of the clique tree data structure will be reported in [14]. It is heartening that the above ordering is also appropriate for efficiently computing the factorization in parallel on massively parallel machines.

The ideas in this paper can also be applied to the general unsymmetric problem to obtain a more efficient partitioning algorithm than RP2. It turns out that the transitive reduction of the directed graph $G(L)$ could be used instead of $G(L)$ at several places in the RP2 algorithm. It is necessary to implement this idea to see the net computational savings the use of transitive reduction may bring in this context. Other applications of transitive reduction in unsymmetric sparse factorizations have been recently considered by Eisenstat, Gilbert, and Liu [7], [10].

COMPUTATION OF CONSTANTS IN THE STRENGTHENED CAUCHY INEQUALITY FOR ELLIPTIC BILINEAR FORMS WITH ANISOTROPY*

PANAYOT S. VASSILEVSKI† AND MAYA H. ETOVA‡

Abstract. Numerical results are presented that give dependence of the constants in the strengthened Cauchy inequality, which is a basic tool for constructing two-level and multilevel preconditioning matrices on the anisotropy of second-order elliptic bilinear forms for a number of finite element piecewise polynomial spaces over triangular and rectangular elements.

Key words. strengthened Cauchy inequality, second-order elliptic problems, anisotropy, finite elements

AMS(MOS) subject classifications. 65N20, 65N30

1. Introduction. Consider the following elliptic bilinear form:

$$a(u, \phi) = \int_\Omega (\nabla u)^T \begin{pmatrix} \varepsilon & \delta \\ \delta & 1 \end{pmatrix} (\nabla \phi),$$

where $\varepsilon > 0$ and $\delta \geqq 0$ are parameters, $\varepsilon > \delta^2$, and Ω is, say, a two-dimensional polygon. By ∇u we denote $(\partial u/\partial x, \partial u/\partial y)^T$.

We consider two nested piecewise polynomial finite element spaces

$$\tilde{\mathbf{V}} \subset \mathbf{V}.$$

Let the corresponding triangulations of Ω be $\tilde{\tau}$ and τ, with τ obtained from $\tilde{\tau}$ by uniform refinement; that is, the elements of τ are obtained by dividing the elements of $\tilde{\tau}$ into a fixed number of congruent parts. We denote the nodes in $\tilde{\tau}$ and τ by $\tilde{N}$ and N, respectively. We have by construction that $\tilde{N} \subset N$.

It is well known (cf. Bank and Dupont [5]; Axelsson and Gustafsson [2]; Axelsson [1]; Braess [6], [7]; and Maitre and Musy [9]) that the following strengthened Cauchy (or Cauchy-Bunyakowskii-Schwarz) inequality is valid: There exists a constant $\gamma \in (0, 1)$ independent of the mesh parameter $\tilde{h}$ of $\tilde{\tau}$, such that

$$a(\phi, \tilde{\phi}) \leqq \gamma (a(\phi, \phi))^{1/2} (a(\tilde{\phi}, \tilde{\phi}))^{1/2} \quad \text{for all } \tilde{\phi} \in \tilde{\mathbf{V}}, \tag{1.1}$$
$$\text{and } \phi \in \mathbf{V}, \quad \phi(x) = 0, \quad x \in \tilde{N}.$$

As shown in Maitre and Musy [9] (see also Axelsson [1] or Eijkhout and Vassilevski [8]), this inequality can be verified element by element by first deriving inequalities of the form

$$a_{\tilde{E}}(\phi, \tilde{\phi}) \leqq \gamma_{\tilde{E}} (a_{\tilde{E}}(\phi, \phi))^{1/2} (a_{\tilde{E}}(\tilde{\phi}, \tilde{\phi}))^{1/2} \quad \text{for all } \tilde{\phi} \in \tilde{\mathbf{V}},$$
$$\text{and } \phi \in \mathbf{V}, \quad \phi(x) = 0, \quad x \in \tilde{N} \cap \tilde{E},$$

for each element $\tilde{E} \in \tilde{\tau}$. Here

$$a_{\tilde{E}}(\phi, \tilde{\phi}) = \int_{\tilde{E}} (\nabla \phi)^T \begin{pmatrix} \varepsilon & \delta \\ \delta & 1 \end{pmatrix} (\nabla \tilde{\phi})\, dx. \tag{1.2}$$

Then γ is defined as

$$\gamma = \max_{\tilde{E} \in \tilde{\tau}} \gamma_{\tilde{E}}.$$

It is clear then that γ is independent of the grid parameter $\tilde{h}$ and on possible jumps of the coefficients, in the case of more general elliptic form

$$a(u, \phi) = \int_{\Omega} (\nabla u)^T \begin{pmatrix} a_{11}(x) & a_{12}(x) \\ a_{21}(x) & a_{22}(x) \end{pmatrix} (\nabla \phi)\, dx,$$

if they are continuous or, say, constants within each element from the initial triangulation $\tilde{\tau}$. In this case, when we have piecewise constant coefficients, the constant γ can be shown to be independent of the number of refinement levels, since by construction we have that γ depends on the form of the element $\tilde{E}$ but not on its size. In other words, if we keep the elements at every discretization level geometrically similar to a fixed set of elements and the piecewise polynomials are of fixed degree throughout the refinement, it is clear that γ will remain bounded away from unity uniformly with respect to the number of discretization levels used (cf. Maitre and Musy [9], Eijkhout and Vassilevski [8]).

The purpose of this communication is to supply some computational information about the dependence of γ on possible anisotropy and mixed derivatives in the considered second-order elliptic bilinear form. Such information is useful since the above-defined constant γ is needed explicitly for the construction of the recently proposed algebraic multilevel iterative methods in Axelsson and Vassilevski [3], [4]. For the case of coefficient matrix

$$\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

that is, for diffusion problems, it has been demonstrated in [9] that for arbitrary initial triangles and piecewise linear polynomials the above constant γ is strictly less than $\frac{3}{4}$ and tends to $\frac{3}{4}$ if some of the triangles degenerate. For the algebraic multilevel methods proposed in [3], [4], there is an important inequality upon which the optimality of the methods are valid: $\nu > 1/\sqrt{1-\gamma^2}$, where ν is the degree of a properly scaled and shifted Chebyshev polynomial involved in the construction of the multilevel preconditioning matrices. For details, see [3], [4]. We see that for the above-mentioned example of diffusion problems, this inequality is satisfied with $\nu = 2$. We cannot choose ν, the degree of the Chebyshev polynomials, very large since this causes the computational labor per iteration, that is, solving a system of equations defined by the multilevel preconditioning matrix becomes too costly. For two-dimensional problems, we consider uniform refinement, that is, when we partition the elements at a given discretization level into four congruent ones we have the restriction $\nu < 4$ in order to ensure that the arithmetic operations needed for solving a system with the multilevel preconditioning matrix are proportional to the number of unknowns on the finest discretization level. In other words, we have to satisfy the following inequalities:

$$4 > \nu > 1/\sqrt{1-\gamma^2},$$

or since ν can be 2 or 3, the inequalities:

$$\begin{aligned} &\text{for } \nu=2, \quad \gamma<\gamma^{(2)}=\sqrt{3}/2=0.8660\cdots, \\ &\text{for } \nu=3, \quad \gamma<\gamma^{(3)}=2\sqrt{2}/3=0.9428\cdots. \end{aligned} \tag{1.3}$$

The remainder of the paper is organized as follows. In the next section we briefly describe the algorithm for the computation of local γ-constants. In § 3 the computed constants γ for linear and quadratic piecewise polynomials on triangular elements and for bilinear, quadratic, and cubic serendipity piecewise polynomials on square elements are shown. Finally some conclusions are drawn.

A main observation from the presented numerical results is that increasing the degree of the piecewise polynomials used can cause severe deterioration of γ constants in certain cases of anisotropy, especially in the presence of mixed derivatives in the considered elliptic bilinear form. However, in most of the cases we have constants γ that satisfy the required inequality at least for $\nu=3$.

2. Computation of γ-constants. Consider the local bilinear form (1.2). In Figs. 1(a) and 1(b) a refined triangular element with linear and quadratic piecewise polynomials, respectively, are shown.

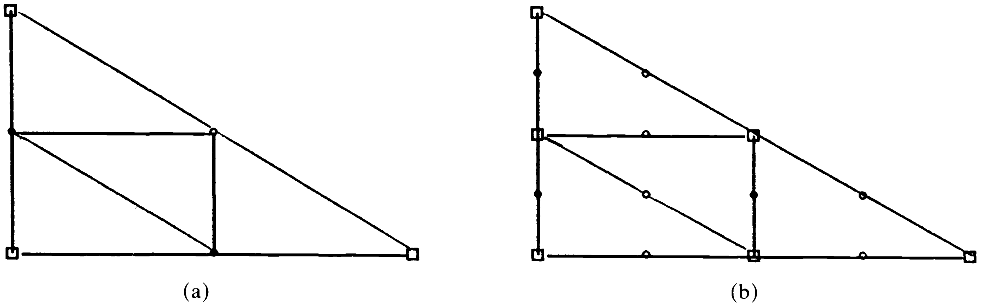

FIG. 1. *A refined triangular element.* (a) *Piecewise linear polynomials.* (b) *Piecewise quadratic polynomials.*

The nodes (degrees of freedom) are denoted by $\tilde{N}$ and N_1, where $\tilde{N}$ are the nodes from the coarser triangulation and N_1 the nodes added after the refinement. In Figs. 1(a) and (b) the $\tilde{N}$ nodes are denoted by "□," whereas the N_1 nodes are denoted by "○." Similarly, in Figs. 2(a)-(c) refined rectangular elements with piecewise bilinear polynomials (Fig. 2(a)), piecewise quadratic serendipity polynomials (Fig. 2(b)), and piecewise cubic serendipity polynomials (Fig. 2(c)) are shown. Here the splitting of the nodes (degrees of freedom) into two sets $\tilde{N}$ (the nodes from the coarser grid) and N_1 (those added in the refinement nodes) is also denoted by "□" and "○," respectively.

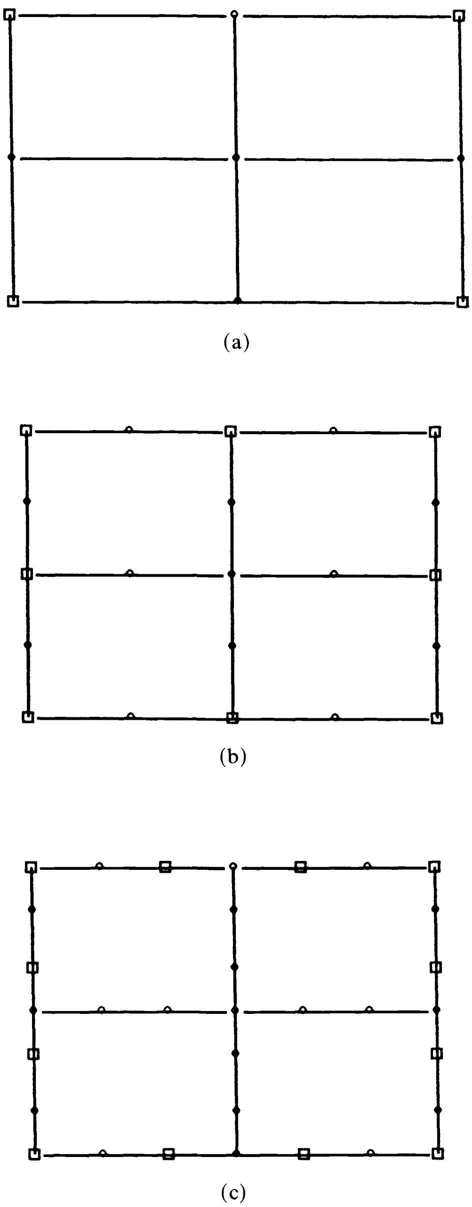
Below we list the nodal basis functions for a reference element $\hat{E}$: a triangle with baricentric coordinate functions λ_1, λ_2, and λ_3, and the square $(-1,1)\times(-1,1)$.

Consider first the triangular element $\hat{E}$ with vertices $A_1=(0,0)$, $A_2=(1,0)$, and $A_3=(X, Y)$, and angles α and β. We have

$$X=\cot\alpha/(\cot\alpha+\cot\beta), \qquad Y=1/(\cot\alpha+\cot\beta).$$

Linear polynomials:

$$\phi_i=\lambda_1, \qquad i=1,2,3,$$



(a)

(b)

(c)

FIG. 2. (a) *Refined rectangular element with piecewise bilinear polynomials.* (b) *Refined rectangular element with piecewise quadratic serendipity polynomials.* (c) *Refined rectangular element with piecewise cubic serendipity polynomials.*

where

$$\lambda_i = (a_i + b_i x + c_i y)/(2S).$$

S is the area of $\hat{E}$, that is, $S = \sin\alpha \sin\beta/(2\sin(\alpha+\beta))$. If we denote the coordinates of the vertices A_i by (x_i, y_i), the coefficients of the baricentric functions λ_i are given by

$$a_i = x_j y_k - x_k y_j, \quad b_i = y_j - y_k, \quad c_i = x_k - x_j,$$

where the triple (i, j, k) is the corresponding transposition of $(1, 2, 3)$. In our case we obtain

$$\begin{array}{lll} a_1 = 1/(a+b), & b_1 = -1/(a+b), & c_1 = -b/(a+b), \\ a_2 = 0, & b_2 = 1/(a+b), & c_2 = -a/(a+b), \\ a_3 = 0, & b_3 = 0, & c_3 = 1, \end{array}$$

with $a = \cot\alpha$, $b = \cot\beta$.

Quadratic polynomials are

$$\begin{aligned} \phi_1 &= \lambda_1(2\lambda_1 - 1), \\ \phi_2 &= 4\lambda_1\lambda_2, \\ \phi_3 &= \lambda_2(2\lambda_2 - 1), \\ \phi_4 &= 4\lambda_2\lambda_3, \\ \phi_5 &= \lambda_3(2\lambda_3 - 1), \\ \phi_6 &= 4\lambda_1\lambda_3. \end{aligned}$$

Consider now the rectangular element $\tilde{E} = (-1, 1) \times (-1, 1)$.

Bilinear polynomials:

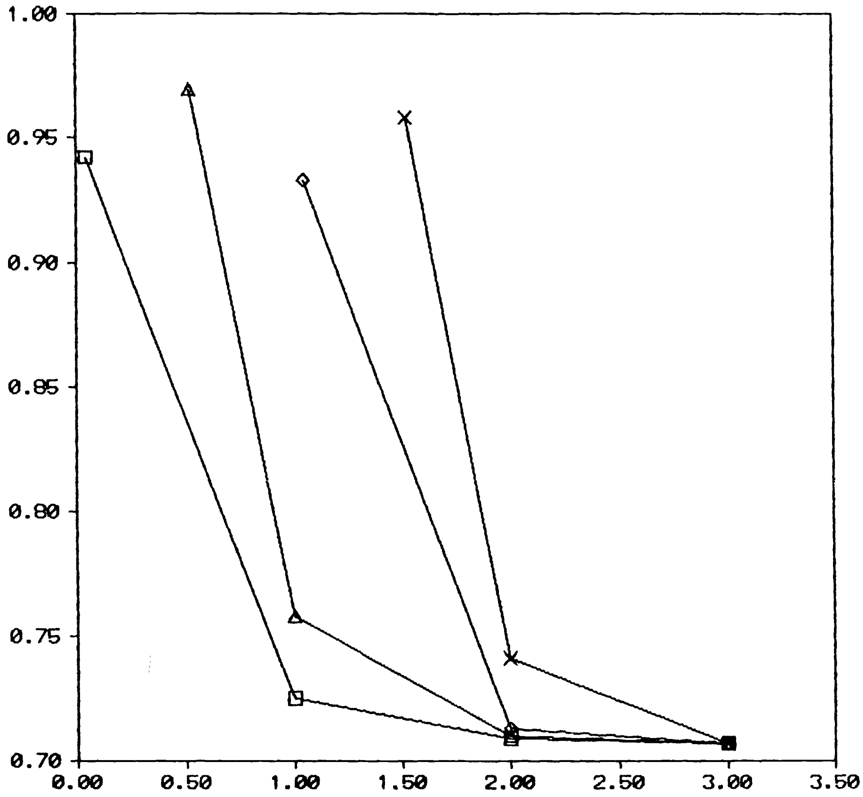
$$\begin{aligned} \phi_1 &= \tfrac{1}{4}(1-x)(1-y), \\ \phi_2 &= \tfrac{1}{4}(1+x)(1-y), \\ \phi_3 &= \tfrac{1}{4}(1+x)(1+y), \\ \phi_5 &= \tfrac{1}{4}(1-x)(1+y). \end{aligned}$$

Quadratic serendipity polynomials:

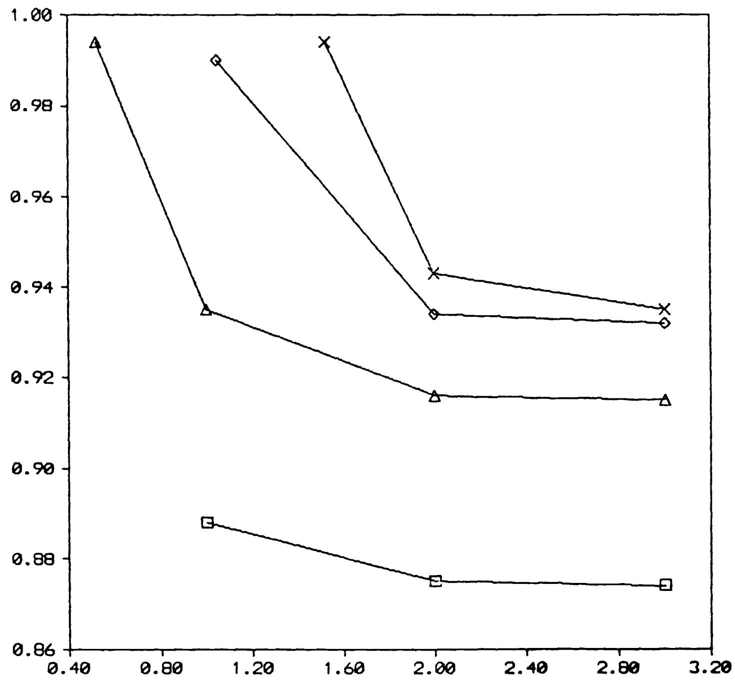
$$\begin{aligned} \phi_1 &= -\tfrac{1}{4}(1-x)(1-y)(1+x+y), \\ \phi_2 &= \tfrac{1}{2}(1-x^2)(1-y), \\ \phi_3 &= \tfrac{1}{4}(1+x)(1-y)(x-y-1), \\ \phi_4 &= \tfrac{1}{2}(1+x)(1-y^2), \\ \phi_5 &= \tfrac{1}{4}(1+x)(1+y)(x+y-1), \\ \phi_6 &= \tfrac{1}{2}(1-x^2)(1+y), \\ \phi_7 &= -\tfrac{1}{4}(1-x)(1+y)(x-y+1), \\ \phi_8 &= \tfrac{1}{2}(1-x)(1-y^2). \end{aligned}$$

Cubic serendipity polynomials:

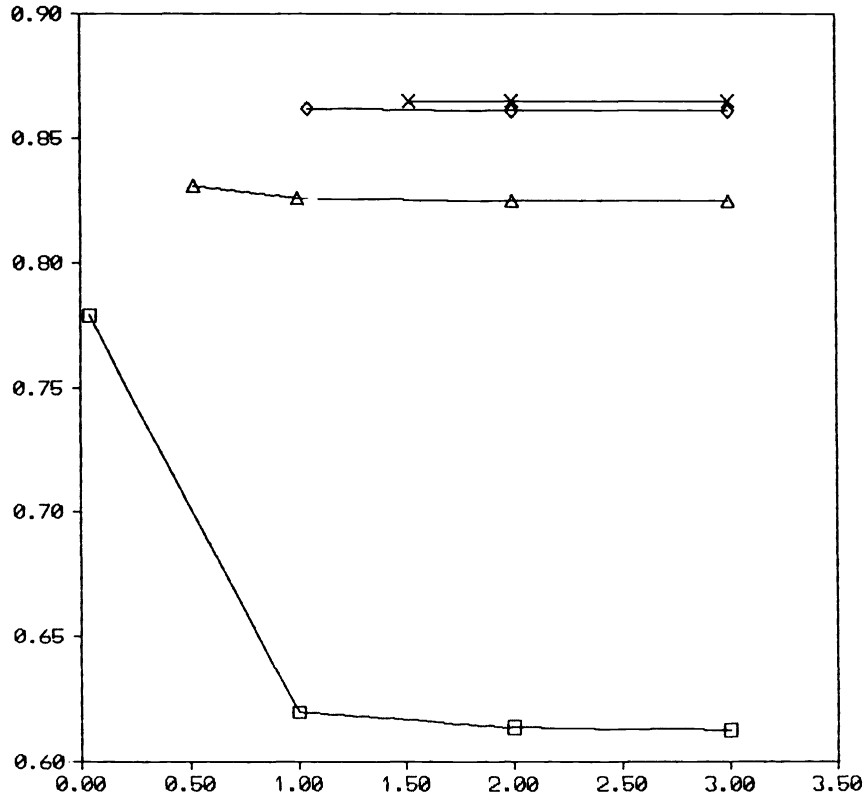
$$\begin{aligned} \phi_1 &= \tfrac{1}{32}(1-x)(1-y)(-10+9x^2+9y^2), \\ \phi_2 &= \tfrac{9}{32}(1-x^2)(1-y)(1-3x), \\ \phi_3 &= \tfrac{9}{32}(1-x^2)(1+3x)(1-y), \\ \phi_4 &= \tfrac{1}{32}(1+x)(1-y)(-10+9x^2+9y^2), \\ \phi_5 &= \tfrac{9}{32}(1+x)(1-y^2)(1-3y), \\ \phi_6 &= \tfrac{9}{32}(1+x)(1-y^2)(1+3y), \\ \phi_7 &= \tfrac{1}{32}(1+x)(1+y)(-10+9x^2+9y^2), \\ \phi_8 &= \tfrac{9}{32}(1-x^2)(1+3x)(1+y), \\ \phi_9 &= \tfrac{9}{32}(1-x^2)(1-3x)(1+y), \\ \phi_{10} &= \tfrac{1}{32}(1-x)(1+y)(-10+9x^2+9y^2), \\ \phi_{11} &= \tfrac{9}{32}(1-x)(1+3y)(1-y^2), \\ \phi_{12} &= \tfrac{9}{32}(1-x)(1-3y)(1-y^2). \end{aligned}$$



GRAPH 1. *Triangular elements*: $\alpha = \beta = \pi/4$; *piecewise linear polynomials*.



GRAPH 2. *Triangular elements*: $\alpha = \beta = \pi/4$; *piecewise quadratic polynomials*.



GRAPH 3. *Rectangular elements: piecewise bilinear polynomials.*

The bilinear form $a_{\tilde{E}}(\cdot,\cdot)$ generates the assembled stiffness matrix $A_{\tilde{E}}$ obtained by assembling the corresponding element stiffness matrices for all four finer elements contained in $\tilde{E}$ (see Figs. 1(a), (b) and Figs. 2(a)-(c)). Using the partitioning of the nodes into $\tilde{N}$ and N_1 as described above, the assembled stiffness matrix admits the following two-level block form:

$$A_{\tilde{E}}=\begin{pmatrix} A_{\tilde{E};1,1} & A_{\tilde{E};1,2} \\ A_{\tilde{E};2,1} & A_{\tilde{E};2,2}\end{pmatrix}\begin{matrix}\}N_1 \\ \}\tilde{N}\end{matrix},$$

that is, first are ordered the nodes from N_1 and then the nodes from $\tilde{N}$. We will need the element Schur complement

$$S_{\tilde{E}}=A_{\tilde{E};2,2}-A_{\tilde{E};2,1}(A_{\tilde{E};1,1})^{-1}A_{\tilde{E};1,2}.$$

We also consider the coarse grid element stiffness matrix $\tilde{A}_{\tilde{E}}$.

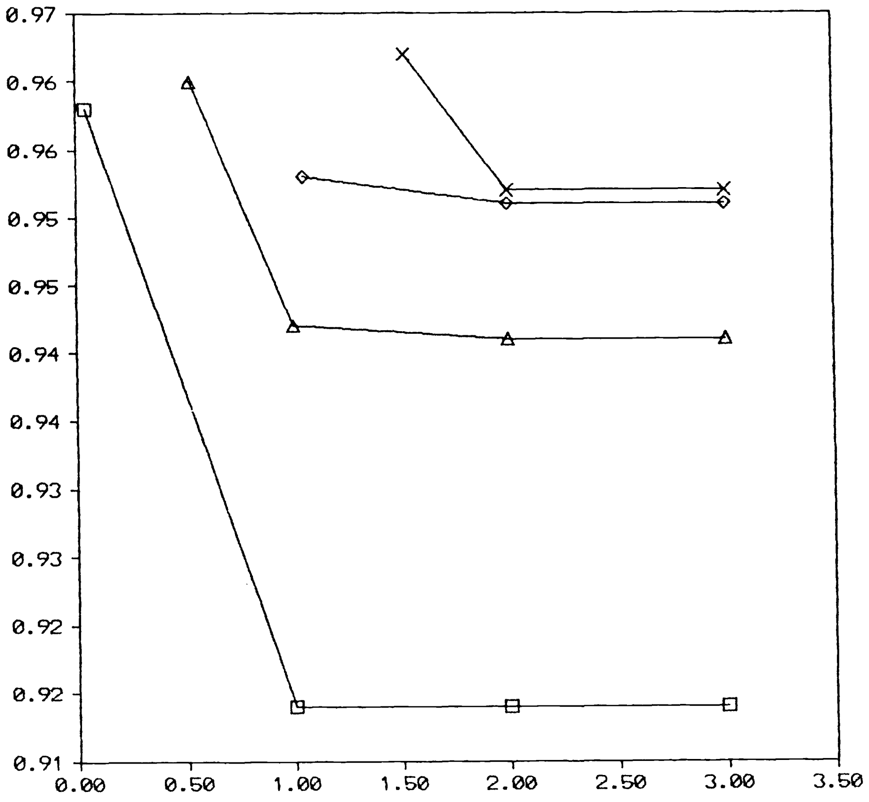
It has been demonstrated (e.g., in [8]) that the local γ-constant, $\gamma_{\tilde{E}}$, and the minimal eigenvalue, $\lambda_{\tilde{E},\min}$, of the generalized eigenvalue problem

$$\lambda_{\tilde{E}}\tilde{A}_{\tilde{E}}\mathbf{q}=S_{\tilde{E}}\mathbf{q}, \tag{2.1}$$

are related as follows:

$$\lambda_{\tilde{E},\min}=1-\gamma_{\tilde{E}}^2.$$

Note that $\tilde{A}_{\tilde{E}}$ and $S_{\tilde{E}}$ have the same nullspace $\{C(1,1,\cdots,1)^T\}$, that is, the constant vectors.



GRAPH 4. *Rectangular elements: piecewise quadratic serendipity polynomials.*

For the actual computation of $\lambda_{\tilde{E},\min}$ we use matrices obtained from $\tilde{A}_{\tilde{E}}$ and $S_{\tilde{E}}$ by deleting, say, the last row and the last column of both matrices. This is readily seen (cf. [8]) since (2.1) implies for $\mathbf{e}=(1,\cdots,1)^{\mathrm{T}}$

$$\lambda_{\tilde{E}}\tilde{A}_{\tilde{E}}(\mathbf{q}-q_{i_0}\mathbf{e})=S_{\tilde{E}}(\mathbf{q}-q_{i_0}\mathbf{e}), \tag{2.2}$$

where q_{i_0} is the i_0th component of $\mathbf{q}$ for arbitrary i_0.

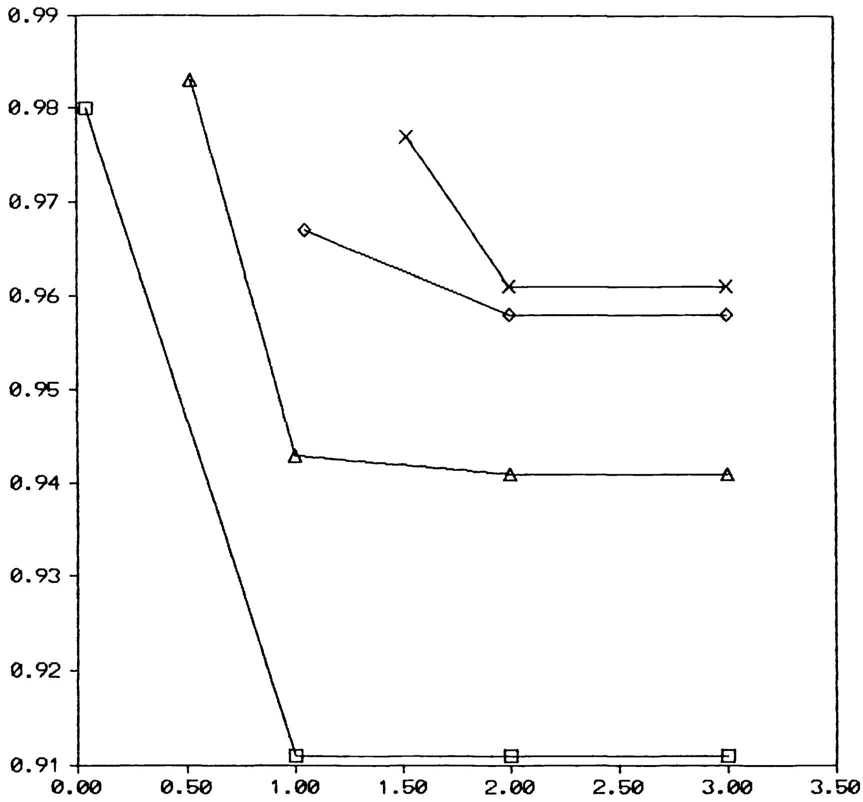
Now by leaving out the i_0th equation of (2.2) we obtain

$$\lambda_{\tilde{E}}\tilde{A}'_{\tilde{E}}\mathbf{q}'=S'_{\tilde{E}}\mathbf{q}', \tag{2.3}$$

where by "′" we denote the matrices and vectors obtained by deleting the i_0th column and the i_0th row of the matrices and by deleting the i_0th component of the corresponding vectors.

Now $\tilde{A}'_{\tilde{E}}$ and $S'_{\tilde{E}}$ are nonsingular, hence positive definite (and symmetric) and any algorithm for computing the minimal eigenvalue of (2.3) can be applied. We have chosen the simple bisection algorithm.

3. Numerical results. The numerical results are collected in Graphs 1-5. The results are listed for $\varepsilon=1$, 0.1, 0.01, and 0.001 for the cases of triangular elements: linear and quadratic piecewise polynomials, Graphs 1 and 2, respectively. Results are also listed for rectangular elements: piecewise bilinear, piecewise quadratic serendipity, and piecewise cubic serendipity polynomials on Graphs 3, 4, and 5, respectively. Recall that $\gamma^{(2)}$ and $\gamma^{(3)}$ are defined by (1.3).



GRAPH 5. *Rectangular elements*: *piecewise cubic serendipity polynomials.*

For all the graphs we have used the following notation:

□ $\varepsilon = 1$,

△ $\varepsilon = 0.1$,

◇ $\varepsilon = 0.01$,

× $\varepsilon = 0.001$,

x-axis: $\log_{10} 1/\delta$,

y-axis: γ.

The actual computed values of the γ-constants are shown in Tables 1-5, corresponding to Graphs 1-5.

4. Conclusion. It is clearly demonstrated by our numerical test that for problems without mixed derivatives ($\delta = 0$) all the computed γ-constants are less than the critical value $\gamma^{(2)}$ (see (1.3)) in the case of piecewise linear or bilinear polynomials. This is also the case for the same piecewise polynomials in the presence of mixed derivatives for all tested values δ such that δ^2 is not very close to ε, that is, when the bilinear form is clear of indefiniteness. However, increasing δ and the degree of the piecewise polynomials lead to deterioration in γ and in some specific cases (piecewise cubic serendipity polynomials, Graph 5 or Table 5) γ becomes larger than the critical $\gamma^{(3)}$. Note that the most stable results are obtained for piecewise bilinear polynomials (Table 3). We have in this case that all the computed values of γ are less than $\gamma^{(2)}$.

We can draw the conclusion that for problems with anisotropy, mixed derivatives, and piecewise polynomials of high degree, the straightforward application of the algebraic multi-level iterative (AMLI) methods from Axelsson and Vassilevski [3], [4] can be troublesome. A remedy has been suggested in Vassilevski [10] by allowing the polynomials involved in the construction of the AMLI preconditioning matrices to have degrees that vary with the discretization levels, that is, to have $\nu=\nu_k$, $k=1,2,\cdots,l$, where l is the number of discretization levels used. It was demonstrated in [10] that at most of the levels one can use polynomials of first degree, which leads to a hybrid V-cycle multilevel iteration. This latter approach does not impose such strong restriction on the degree $\nu=\nu_k$ of the Chebyshev polynomials involved in the construction of the AMLI preconditioning matrices, and it preserves their asymptotic optimality (when l, the number of discretization levels used, is sufficiently large). For details, see [10].

APPROXIMATION OF THE INVARIANT MANIFOLD IN THE JOSEPHSON EQUATION*

M. VAN VELDHUIZEN†

Abstract. This paper considers the application of the algorithm described in [M. van Veldhuizen, *Math. Comp.*, 51 (1988), pp. 677-697] to approximate the average slope of solutions of the Josephson equation. The potential for parallelism of this algorithm has been a motivation for its study. In this work this potential is realized by presenting results obtained on a multiprocessor environment.

Key words. invariant curve, parallel computation

AMS(MOS) subject classifications. primary 65L99; secondary 65H10, 34C40

1. Introduction. Recently there has been some interest in numerical algorithms for the approximation of an invariant curve (cf. Chan [2]; Kevrekidis et al. [9]; Kaas-Peterson [6]-[8]; van Veldhuizen [16], [18]; Dieci, Lorenz, and Russell [4] and the references therein). In this paper we concentrate on collocation-type methods for the Josephson equation

$$\beta\ddot{\phi}+(1+\gamma\cos\phi)\dot{\phi}+\sin\phi=p(t), \tag{1.1}$$

where $\beta>0$ and γ are parameters, and $p(t)$ is periodic of period $T=2\pi/\omega$. This equation is sometimes used as a model for the Kamper-Soulen resistively shunted Josephson thermometer (cf. [14], [15]). The quantity of interest is the average slope of the solution $\langle\dot{\phi}\rangle=\lim(\phi(t)/t)$, $t\to\infty$. It can be measured, since it is proportional to the voltage over the junction. A straightforward computation of this quantity leads to a sequential algorithm. In this paper we describe a parallel algorithm based on the invariant curve of the Josephson equation and its properties.

It is convenient to rewrite this second-order differential equation as a system of two first-order differential equations

$$\beta\dot{\phi}=\psi-\phi-\gamma\sin\phi, \tag{1.2a}$$

$$\psi=-\sin\phi+p(t). \tag{1.2b}$$

Define the Poincaré map P as the period map taking $x=(\phi(0),\psi(0))$ into Px defined as the solution of (1.2a,b) at $t=T=2\pi/\omega$ with initial vector x at $t=0$. Since (1.2a,b) are essentially defined on the cylinder obtained by identifying each point (ϕ,ψ) with its 2π translates $(\phi+2\pi j,\psi+2\pi j)$, so is the Poincaré map P. The following characterization is due to Levi [10].

THEOREM 1.1. *For all T-periodic functions $p(t)$ and all parameters β and γ satisfying*

$$0\leqq\gamma\leqq 1,\qquad 0<\beta<\tfrac{1}{4}(1-\gamma)^2, \tag{1.3}$$

the Poincaré map P possesses a globally attracting invariant circle Γ given by $\psi=f(\phi)$, where $f(\phi)$ tends to $\phi+\gamma\sin\phi$ for $\beta\to 0$. Also, f is strictly increasing.

Observe that f is invertible. Thus, the invariant manifold may also be written as $\phi=f^{-1}(\psi)$. This simplifying observation is used in the algorithm described below.

The Poincaré map P induces a circle map P_Γ on the invariant circle Γ. It is easily seen that $\langle\dot{\phi}\rangle = \omega\rho$, where ρ is the rotation number of the circle map induced by P on Γ. In particular, $\langle\dot{\phi}\rangle$ exists. See Levi [10]. For the definition of the rotation number ρ of a circle map, see Guckenheimer and Holmes [5] or Coddington and Levinson [3].

The restrictions (1.3) are discussed in Levi [10]. In particular, the constraint $\beta < 1/4$ for $\gamma = 0$ has a physical interpretation.

Computationally we have two ways of approximating the average slope $\langle\dot{\phi}\rangle$. First, we may approximate the limit by the quotient $\phi(t)/t$ for large t. For a slightly more sophisticated way of doing this, see van Veldhuizen and Fowler [15]. These processes are purely sequential in nature. Second, we might approximate the invariant manifold Γ and the circle map P_Γ induced on it by P (see Algorithm 1.2 below), followed by the numerical approximation of the rotation number; see [17]. We shall see that the computation of the approximate invariant manifold can be done in parallel. Hence, the larger part of the work involving the integration of the differential equations (1.2a,b) can be done in parallel. This is advantageous on a multiprocessor machine (cf. § 3).

We shall now describe a numerical algorithm for the approximation of Γ and the circle map P_Γ. This algorithm is very much in the spirit of Kevrekidis et al. [9], and has been investigated in [18].

ALGORITHM 1.2. Let Δ be a partitioning of the circle $[0, 2\pi)$, consisting of the N points

$$0 = \psi_0 < \psi_1 < \cdots < \psi_{N-1} < 2\pi. \tag{1.4}$$

Approximate Γ by a polygon Γ_Δ described by $\phi = g_\Delta(\psi)$, where g_Δ is a piecewise linear (with respect to Δ) continuous function. Determine g_Δ, i.e., determine the $g_\Delta(\psi_i)$, by the equations, $i = 0, 1, \cdots, N-1$,

$$(g_\Delta(\psi_i), \psi_i) \in \bar{\Gamma}_\Delta, \tag{1.5}$$

where $\bar{\Gamma}_\Delta$ is the polygon on the cylinder with vertices $P(g_\Delta(\psi_i), \psi_i)$. The circle map P_Γ is approximated by the piecewise linear continuous function induced by $\psi_i \to \bar{\psi}_i$, $\bar{\psi}_i$ the ψ-coordinate of $P(g_\Delta(\psi_i), \psi_i)$, $i = 0, 1, \cdots, N-1$.

The set of equations is solved by successive substitution, as in [18]. In order to clarify the programming of this algorithm, let us describe the iterative process separately. For all i, let $\phi_i^{(k)}$ denote the actual approximation to $g_\Delta(\psi_i)$. First, one integrates the ordinary differential equations (1.2a,b) with initial vector $(\phi_i^{(k)}, \psi_i)$ from $t = 0$ to $t = 2\pi/\omega$, $i = 0, 1, \cdots, N-1$. Or, in a formal notation,

$$P: \quad (\phi_i^{(k)}, \psi_i) \to (\bar{\phi}_i^{(k)}, \bar{\psi}_i^{(k)}).$$

After the integration step comes the interpolation step. For all i separately determine the index l (depending on i) such that $\psi_i \in I_l = [\bar{\psi}_l^{(k)}, \bar{\psi}_{l+1}^{(k)}]$ on the circle $[0, 2\pi)$. Then $\phi_i^{(k+1)}$ is obtained by linear interpolation on the segment I_l in the point ψ_i. The process stops if the norm of the difference between two successive vectors of iterates is smaller than a prescribed tolerance.

Observe the parallel nature of this algorithm; the images under the Poincaré map P can be computed in parallel. This computation can be done by a high quality numerical code for the integration of ordinary differential equations.

2. Summary of results.

In this section we summarize the results obtained by Levi [10] for the Josephson equation. In addition, we summarize the results from the convergence analysis in [18]. We omit the details, since no essentially new arguments are used in deriving the results.

A remarkable feature of the global existence result by Levi [10] (cf. Theorem 1.1 above) is the explicit estimate for the domain in parameter space for which the result holds true. In fact, by carefully redoing Levi's proof, one can extend this domain in parameter space somewhat. Instead of restricting β and γ by (1.3), it suffices to restrict β and γ to the union of the regions I, II, and III in Fig. 1, a somewhat larger domain. Nevertheless, even this larger domain still belongs to the strip $0 \leqq \gamma < 1$. On the other hand, numerical evidence suggests that the properties of the Josephson equation do not dramatically change at $\gamma = 1$, although the character of the solution followed in time may do so (internal layers for $\gamma > 1$). An existence result for $\gamma > 1$ in an open neighborhood of the line $\beta = \gamma$ in parameter space follows from the following simple observation.

PROPOSITION 2.1. *If $\beta = \gamma$, then for all T-periodic functions $p(t)$ and all values of $\beta > 0$, the Poincaré map P possesses an invariant circle Γ given by*

$$\psi - \phi = \bar{p} = \int_{-\infty}^{0} e^{s/\beta} p(s)\, ds. \tag{2.1}$$

Thus Γ is a straight line parallel to the line $\psi = \phi$.

Proof. If $\beta = \gamma$ one easily obtains from (1.2a,b) the differential equation

$$\beta(\dot{\psi} - \dot{\phi}) = \phi - \psi + \beta p(t). \tag{2.2}$$

If $\psi(0) - \phi(0) = \bar{p}$, then so is $\psi(T) - \phi(T)$. This proves the assertion. □

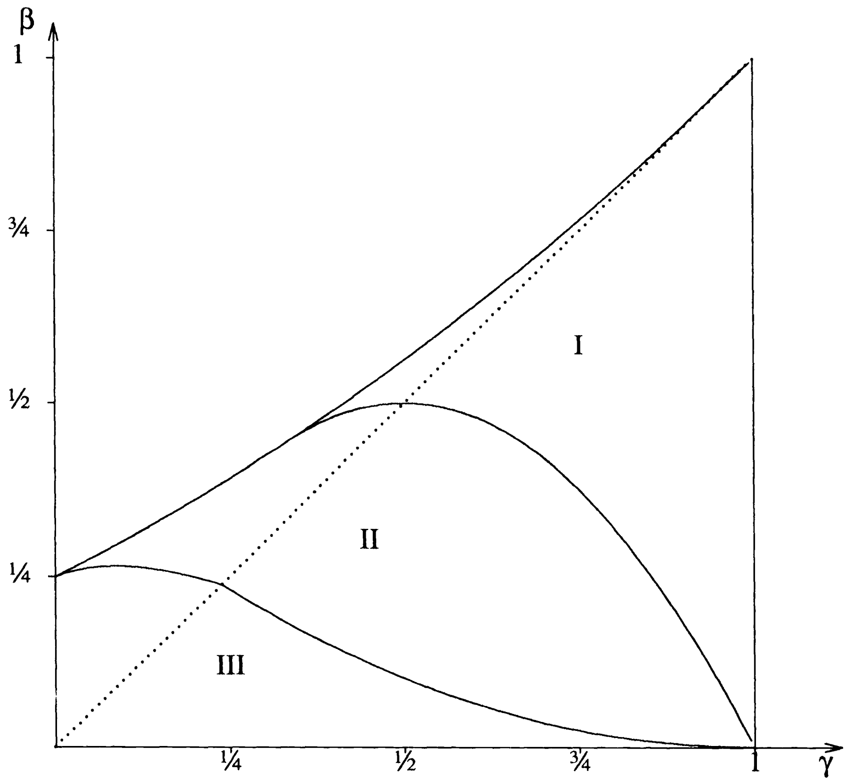

FIG. 1. *Regions in parameter space where Theorem* 1.1 *is valid* (I + II + III), *and where convergence results for Algorithm* 1.2 *are available* (II + III).

If $\beta=\gamma$ we may compute the restriction of P to Γ, the circle map corresponding to the invariant manifold. Let Δ denote the unique periodic solution of (2.2), which satisfies (2.1) in the points jT, $j \in \mathbb{N}$. Let ϕ solve

$$\beta\dot{\phi}=\Delta-\beta \sin \phi. \tag{2.3}$$

Then $\sigma: \phi(0) \rightarrow \phi(T)$ describes the circle map σ on Γ.

One might ask for the existence of an invariant manifold in the neighborhood of the line $\beta=\gamma$ in the (β, γ)-plane. Typical perturbation results for invariant manifolds require that the action on the manifold is small in relation to the attraction to the manifold. See Sacker [12] for typical results and nice counterexamples. In the language of Sacker [12] (we use his symbols on the left of the equality sign), one has

$$\bar{\beta}=1, \qquad \underline{\lambda}=\beta.$$

An invariant manifold exists in an open neighborhood of the point (β, β) in the (β, γ)-plane if $\bar{\beta}<\underline{\lambda}$ (cf. Sacker [12]). This condition is satisfied for all $\beta>1$. Hence, *the invariant manifold exists in an open neighborhood of the line* $\beta=\gamma$, $\beta>1$.

The convergence of Algorithm 1.2 follows from the results in [18], at least if some conditions are fulfilled. Actually, the convergence theory in [18] contains two related criteria. We give the interpretation adapted to Algorithm 1.2.

The first criterion given in [18] is based on the following idea. The Poincaré map P cannot be a contraction, but its restriction to lines parallel to the ϕ-axis might be a contraction. The first criterion of [18] is based on this possibility in combination with the linear interpolation process of Algorithm 1.2. For the Josephson equation, it is possible to estimate the region in parameter space for which this criterion assures convergence of the algorithm: just adapt the proofs in [18] to this differential equation. Of course, the estimates give part of the region. The region of convergence in parameter space obtained in this way is shown as region III in Fig. 1. Observe that this criterion requires no assumption about the mesh.

The second criterion given in [18] requires that the Poincaré map reduces the horizontal distance to the invariant curve. Here, the horizontal distance of $x=(\phi, \psi)$ to Γ is defined by $|f^{-1}(\psi)-\phi|$ (cf. Theorem 1.1). If the Poincaré map reduces the horizontal distance to Γ, then Algorithm 1.2 converges for a sufficiently fine mesh in a sufficiently narrow tube along the invariant curve. In regions III and II in Fig. 1, convergence can be proved in view of this criterion. Again, this region is obtained by carefully redoing the estimates given in the convergence proofs in [18].

These criteria, when satisfied, result in convergence by a contraction principle. In actual computations, the iterative process for solving the nonlinear equations is based on this contracting map. Hence, if the contraction factor is sufficiently small, say $<\frac{1}{2}$, the algorithm is stable with respect to small perturbations. This is important, since small perturbations are to be expected. Rounding errors cause small perturbations, but we also have the errors caused by numerical integration of the initial value problems. In actual computations the contraction factor is easily estimated, and often as small as $\frac{1}{10}$. For large values of ω the contraction factor tends to unity. This is easily avoided by using an mth iterate of the Poincaré map instead of the Poincaré map itself.

3. Numerical experiments. In this section we mention a few numerical results obtained by Algorithm 1.2. We compare the results with earlier ones. Also, we shortly discuss the parallel nature of Algorithm 1.2, and we give some examples.

In actual computations, Algorithm 1.2 performs much better than suggested by the theory of [18]. For instance, the algorithm converges rapidly in the union of the regions I, II, and III in Fig. 1, not only in the regions II and III. Also, the algorithm converges for $\gamma > 1$, and small $\beta > 0$. In addition, one may even interchange the role of ψ and ϕ in Algorithm 1.2, and this new algorithm behaves very much like Algorithm 1.2. Results for γ as large as 3.0 have been obtained, for both algorithms.

The algorithm uses linear interpolation, a rather crude type of interpolation. However, higher-order interpolation may cause problems. From the explicit description in § 1, it is obvious that the ordering of the ψ-coordinate of the images plays an important part. With linear interpolation no problems have been observed, due to the shape-preserving properties of linear interpolation and the existence of a global P-invariant foliation of the plane (cf. Levi [11]). With piecewise quadratic or cubic interpolation the images may get out of order, making the computation worthless. For the moment, linear interpolation seems a reasonable choice.

As mentioned in § 1, one is interested in the numerical values of $\langle\dot{\phi}\rangle = \omega\rho$, where ρ is the rotation number of the circle map, i.e., the restriction of P to Γ. In [15] results have been reported in which $\langle\dot{\phi}\rangle$ is approximated directly. This requires the integration of the differential equations (1.2a,b) over large intervals, say $2000T$ or even larger. This is a sequential process, and there is a real danger of accumulation of integration errors.

Some idea about the loss of accuracy is obtained by considering an artificial example. By Proposition 2.1 we may construct an example in which the invariant curve Γ is known. Choose $\beta = \gamma = 0.1$, and choose $\phi(t) = \omega t + A \sin(\Omega t)$, Ω an integer multiple of $\omega \sim 1$. Consequently, the function $\Delta(t) = \beta(\dot{\phi} + \sin\phi)$ (cf. (2.3)) is ω-periodic. Since Δ is the periodic solution of (2.2), we obtain $p(t)$ from (2.2). Hence $p(t)$ is ω-periodic. However, in a numerical experiment designed to estimate the accumulation of truncation errors, the problem behaves rather like a Ω-periodic function. Therefore, we use $T = 2\pi/\Omega$. In using this smaller value, we can be sure not to exaggerate. Typically, $\Omega = 100\,\omega$. Even with $T = 2\pi/\Omega$, there is a significant loss in accuracy after integration over 2000 periods. Using the multistep code from Shampine and Gordon [13] with initial values on Γ the errors in ϕ are of the order 10^3 TOL, where TOL is the tolerance used, $\text{TOL} < 1.0\text{E}-06$ (equal absolute and relative error tolerance). The deviation from the stable manifold Γ is much smaller, say in the order of 10 TOL. This is what one would expect. The relation between the error in the solution ϕ and the average slope $\langle\dot{\phi}\rangle$ is a complicated one. For tolerances as small as $1.0\text{E}-08$, the effect of the accumulation of errors really shows in the obtained approximation. However, for a tolerance like $1.0\text{E}-11$ the accumulation of errors is hardly noticeable. In one typical example, the error in the approximation for $\langle\dot{\phi}\rangle$ increases by $4\text{E}-12$ in every 500 periods, with integration by the Shampine–Gordon code and tolerances $1.0\text{E}-11$. In this particular example we had $\gamma = 1.5$, $\beta = 0.05$, $\omega = 38.0$. Clearly, direct approximation of ρ is possible, but only with limited accuracy due to accumulation of errors, unless very small tolerances are being used. For instance, the results reported in [15, Fig. 2] have an error of up to 0.1 percent. A better accuracy, if possible, would increase the computing time considerably.

As an alternative, one might compute an approximation to the circle map by Algorithm 1.2, and compute the rotation number of this approximate circle map. In this way, one also integrates the differential equations (1.2a,b), many times over short intervals typically of length T and there is hardly any serious accumulation of rounding errors and local errors. Afterwards, one approximates ρ by means of [17, Algorithm 3.2], an algorithm for the numerical approximation of the rotation number. In the invariant manifold approach, there are two main error sources: the approximation error in the approximate invariant manifold and the truncation error in the approximate rotation number. This latter error is hard to assess theoretically (cf. the discussion in

[17]). Practical experience indicates the reliability of the algorithm used, with truncation errors less than 1.0E − 07. It is much harder to estimate the error in the approximate invariant manifold. Typically, with $N \sim 100$, i.e., a step size of $2\pi/N$, the invariant manifold approach results in approximations with an error of about 1.0E − 05 in the rotation number (comparison with results for $N = 800$). In resonance regions the method performs even better, sometimes giving the exact result with $N = 50$. In many instances the invariant manifold approach is highly competitive with direct integration over extremely long intervals.

As an example, consider Fig. 2. We have shown the rotation number computed from the approximate circle map obtained by Algorithm 1.2, with $N = 100$, $p(t) = 11 + 0.9\,\omega \cos(\omega t)$, $\beta = 0.01$, $\gamma = 3/2$. Results are shown for $\omega = 37.853\ (0.01)\ 40.653$. The results show the familiar devil's staircase picture. In the upper part of Fig. 2 we show the difference between the results from Algorithm 1.2 and direct integration (data from [15]). The maximal error is 3.6E − 04 on a rotation number $\rho \sim 2/7$. The upper graph shows larger errors at the borders of the steps. Actually, a step in the devil's staircase is just a resonance region, and the difference between the two results tends to be larger at the borders of these regions. These places correspond to places where

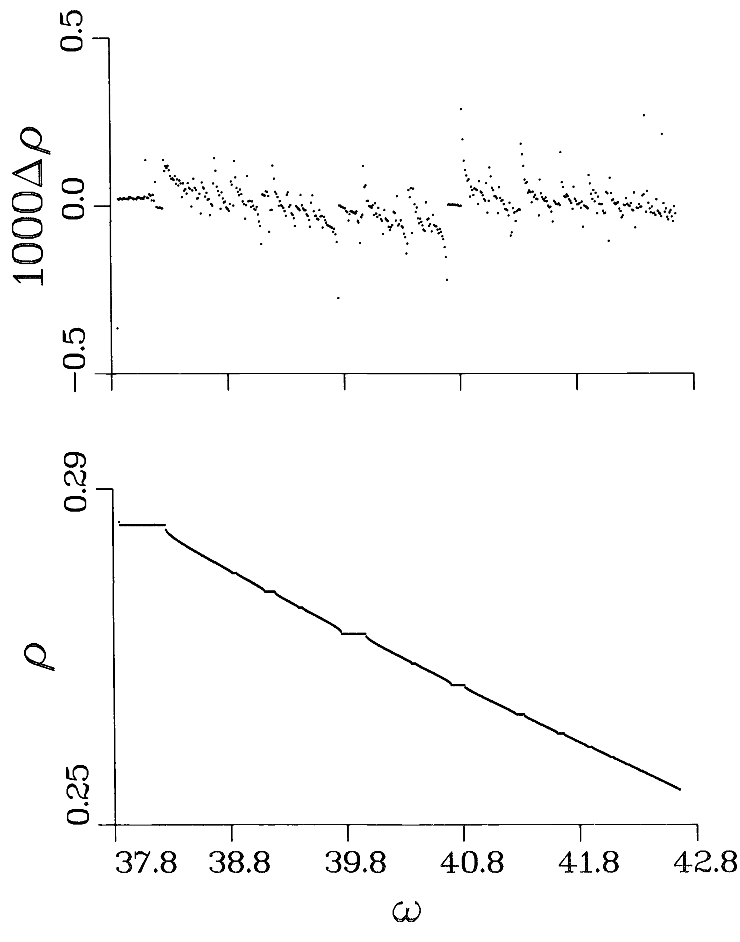

FIG. 2. *The rotation number of the circle map of the Josephson equation as computed with Algorithm* 1.2 *and* [17, *Algorithm* 3.2]. *The upper part shows the difference between these values and the values obtained in* [15]. *For the parameter values, see text.*

ρ has a square root behavior. One might also say that the different methods result in slightly different resonance regions. Relatively large errors at the borders of the resonance regions are then to be expected. For this specific example the computation based on Algorithm 1.2 is approximately twice as fast as a comparable (in tolerances) direct computation. In order to get comparable timings, all computations have been done on one mainframe computer (CDC Cyber 990), with recomputation of the results reported in [15].

A further speed-up is to be expected if one exploits the parallel nature of Algorithm 1.2. To that end we have implemented this algorithm on the department's shared memory machine, best described as a set of 16 boards, each of them with 4Mbyte local memory, an M68030 CPU and an M68882 FPU, and mutually connected by a VME-bus. The programming language implemented on this system is Orca (cf. Bal and Tanenbaum [1]). Orca is based on Modula-2, with a fork statement for the creation of new asynchronous processes, and a guard mechanism for synchronizing these processes. Both the hardware and the software are still in an experimental stage, mainly used for research in distributed systems.

The parallelism in Algorithm 1.2 comes from the parallel computation of the images under the Poincaré map P. So let us consider this computation in some detail. In one mode, whether in parallel or not, one computes many evaluations of P simultaneously by integrating one big system of differential equations. In this way one distributes the overhead of the code over many evaluations. This works well if the step sizes in the integration do not vary that much. This is typically the case for $0 < \gamma < 1$. However, if γ is significantly larger than 1, the solution contains small areas with internal layers along the t-axis. These areas require small steps in the integration routine. The position of the internal layer strongly depends on the initial condition. Thus, if one would combine the computation of many images under P in one integration, one would be forced at some point in time to use small internal layer steps for all equations together, while only a few equations require them. Hence, combination of differential equations into one larger set may not be economical for large values of γ. For $\gamma = 1.5$ both processes require about the same amount of time.

We have implemented Algorithm 1.2 in many ways on the multiprocessor. In the first implementation, all processors, the master and the slave processors, did their share in the computation of images under the Poincaré map. This turned out to be inefficient, resulting in a lot of idle time and bad load balancing. Therefore, we changed the strategy. The master now distributes the tasks and performs the interpolation required for the computation of new iterates. The slave processors do the actual integration and report to the master. For small p, $p = 1, 2, 3$, one wastes some time on the master. For larger values of p, this process is by far superior to a process in which the master does some integration as well. Of course, in all implementations one should carefully minimize the number of bus accesses. Also, one should minimize the amount of data shared between master and slave. This is partly due to the hardware, partly to the software overhead caused by Orca.

Many implementations with a master processor have been tried. Two implementations of Algorithm 1.2 capture the whole range of possibilities. In the implementation A-1, the master assigns the computation of just one image of P to an idle processor, until all evaluations have been done. The master then does the interpolation, and goes on with the next step. Actually, part of the interpolation is done in parallel. If there are p slaves, the master does the interpolation for the first p assignments. Then, while the slaves are at work, the master does the next p interpolations, and so on. At the other end of the spectrum, in implementation A-2, we compute as many images as are feasible together on a slave processor. Suppose one wants to compute N evaluations of the Poincaré map P on $p+1$ processors, p slaves, and 1 master. Divide the N evaluations in p sets of $N \operatorname{div} p$ and $(N \operatorname{div} p)+1$ equations. Integrate these equations together, each of them on one slave processor. Of course, the equations are collected in such a way that the variation in the initial values is as small as possible. This implies that the initial value problems are as similar as possible. Thus, if internal layers are present, there is as much overlap of these layers on the t-axis as possible.

In Table 1 we give results for the problem with equidistant mesh, and

$$(3.1) \qquad N=128, \quad \beta=0.25, \quad \gamma=0.7, \quad \omega=19.0, \quad \alpha=5, \quad \kappa=0.$$

The total number of processors, p slaves plus 1 master, is mentioned under NCPU. A Runge-Kutta code with variable step size is used as integrator, tolerance 1.0E−07. The invariant curve algorithm uses 12 iteration steps. The efficiency "eff" in Table 1 is defined as follows. On one processor the best time obtained is 293 seconds (same compiler, identical CPU plus FPU). The efficiency is defined by

$$(3.2) \qquad \text{eff} = \frac{\text{time one processor}}{\text{NCPU} * \text{time}}$$

expressed as a percentage. Note that implementation A-2 is very much superior to implementation A-1 (both implementations of Algorithm 1.2, and mathematically equivalent).

In a second example we choose

$$(3.3) \qquad N=128, \quad \beta=0.02, \quad \gamma=2.5, \quad \omega=19.0, \quad \alpha=2, \quad \kappa=5.$$

Now we have a large value of γ and a small β. Algorithm 1.2 converges in six steps, starting from the straight line $\phi=\psi$ as an initial guess. Again we look at the parallel implementations, implementation A-1 and implementation A-2. Since γ is quite large, we expect implementation A-1 to outperform implementation A-2. The results confirm this for a small number of processors. Indeed, with a few processors implementation

TABLE 1
Results for (3.1).

	Implementation A-1		Implementation A-2	
NCPU	Time in seconds	eff	Time in seconds	eff
2	440.0	33%	282.0	52%
3	220.0	44%	149.5	65%
4	148.0	49%	101.0	73%
5	111.3	53%	78.2	75%

10	52.4	56%	38.0	77%
11	45.6	58%	35.1	76%
12	42.5	57%	31.9	77%
13	39.3	57%	30.0	75%
14	35.8	58%	28.6	73%
15	34.9	56%	27.0	72%
16	34.6	53%	25.0	73%

A-2 lumps many equations together into one rather large differential equation; this is inefficient for large γ as outlined above. However, the number of differential equations lumped together decreases if the number of processors increases. Hence, in implementation A-2 the bad effects of large γ diminish for larger p. In order to show this effect as clearly as possible, we have added a few additional columns in Table 2. Under the heading "size" we give the maximal number of equations lumped together. The minimal number equals the maximal number if p divides 128, else the minimal number equals the maximal number minus 1. Under the heading "time/eq" we give the time per equation, i.e., the time divided by the maximal number of lumped equations. These results of Table 2 strongly indicate the extra cost of lumping together too many equations. The table also shows that implementation A-2 outperforms implementation A-1 for many slave processors. Because of the internal layers we solve this problem with a tolerance of 1.0E−10.

TABLE 2
Results for (3.3).

	Implementation A-1	Implementation A-2		
NCPU	Time in seconds	Time in seconds	Size	Time/eq
2	810.0	1376.5	128	10.7
3	406.0	641.3	64	10.0
4	272.7	359.0	43	8.3
5	205.8	242.2	32	7.6
6	164.8	187.5	26	7.2
7	138.5	147.7	22	6.7
8	118.9	122.3	19	6.4
9	105.0	102.6	16	6.4
10	94.7	90.5	15	6.0
11	83.9	83.1	13	6.4
12	76.6	74.1	12	6.2
13	69.8	67.5	11	6.1
14	64.8	61.5	10	6.2
15	62.4	55.1	10	5.5
16	57.6	54.7	9	6.1

The results in Table 2 for 14 and 15 processors reflect the programming of the master. The maximum size of a job is ten equations in each case. By a job we mean the task assigned to a slave processor, which consists of the integration of a number of differential equations lumped together. With 14 processors, there are 11 jobs consisting of ten equations, and two jobs consisting of nine equations. The master assigns the larger jobs first, then the smaller ones. In the case of 15 processors two jobs of ten equations and 12 jobs of nine equations result. The maximum job consists of ten differential equations, as in the previous case. But the total time spent is more reminiscent of jobs of nine equations, as with 16 processors. The explanation seems to be the overlap caused by distributing the larger jobs first.

4. Conclusion. The results of § 3 show the reliability of Algorithm 1.2. The algorithm performs well, even far outside the domain in parameter space in which convergence can be proved. Second, Algorithm 1.2 may serve as the basis for the approximation of rotation numbers. As such, the approach via Algorithm 1.2 is at least competitive with a direct approach. In addition, Algorithm 1.2 can be implemented efficiently on parallel architectures.

Acknowledgments. I am indebted to M. F. Kaashoek, H. E. Bal and C. J. H. Jacobs for implementing the floating point hardware, and for help with Amoeba, Orca, and the use of C functions in Orca.

A GENERALIZED PRIME FACTOR FFT ALGORITHM FOR ANY $N = 2^p 3^q 5^r$ *

CLIVE TEMPERTON†

Abstract. Prime factor fast Fourier transform (FFT) algorithms have two important advantages: they can be simultaneously self-sorting and in-place, and they have a lower operation count than conventional FFT algorithms. The major disadvantage of the prime factor FFT has been that it was only applicable to a limited set of values of the transform length N. This paper presents a generalized prime factor FFT, which is applicable for any $N = 2^p 3^q 5^r$, while maintaining both the self-sorting in-place capability and the lower operation count. Timing experiments on the Cray Y-MP demonstrate the advantages of the new algorithm.

Key words. fast Fourier transform (FFT), prime factor algorithm (PFA), self-sorting FFT, in-place FFT

AMS(MOS) subject classification. 65T05

1. Introduction. Fast Fourier transform (FFT) algorithms can be defined whenever the transform length N can be factorized as $N = N_1 N_2 \cdots N_k$, where the factors N_i are integers. Though there are many variants of these algorithms, they fall into two basic categories: those based on the prime factor algorithm (PFA) of Good [5], which are only applicable if the factors N_i are mutually prime, and those descended from the algorithm of Cooley and Tukey [3], for which there is no such restriction (indeed the most familiar case is $N_i = 2$ for all i).

The prime factor algorithms have two important advantages. For a given value of N, the operation count is lower than that for the corresponding Cooley–Tukey algorithm. Moreover, the PFA can be made both self-sorting (input and output both naturally ordered) and in-place (requiring no work space) [2], [10], [14]. Their principal disadvantage is that in order to achieve this, a program to implement the PFA requires an explicit section of code (a "discrete Fourier transform (DFT) module") which performs a self-sorting in-place transform of length N_i for each of the factors. (The DFT module is the radix-N_i generalization of the familiar radix-2 "butterfly.") In most implementations of the PFA, the factors N_i are thus assumed to be members of the set $\{2, 3, 4, 5, 7, 8, 9, 16\}$. Coupled with the requirement that the factors be mutually prime, this severely limits the set of practicable transform lengths N.

Johnson and Burrus [7] demonstrated that the radix-2 Cooley–Tukey algorithm could also be made self-sorting and in-place, and in [18] the principle was extended to radix-3, radix-4, and radix-5 transforms, and finally to the mixed-radix case. However, as hinted in [18] the operation count for the resulting algorithm can be improved if N contains a mixture of factors.

In this paper we combine ideas from the PFA and from the self-sorting in-place form of the Cooley–Tukey algorithm, to derive a new generalized prime factor FFT algorithm with the following nice properties:

(1) It works for any transform length of the form $N = 2^p 3^q 5^r$;

(2) It is always self-sorting and in-place (the only work space required is for an optional list of precomputed twiddle factors);

* Received by the editors April 30, 1990; accepted for publication (in revised form) March 19, 1991. Much of this work was done at Recherche en Prévision Numérique, Atmospheric Environment Service, Canada.

† European Centre for Medium Range Weather Forecasts, Shinfield Park, Reading, Berkshire RG2 9AX, United Kingdom.

(3) For values of N suitable for the PFA, the new algorithm reduces to the PFA and has the same operation count;

(4) For $N=2^p$, 3^q, or 5^r, the new algorithm reduces to that described in [18], and has the same operation count;

(5) If N contains a mixture of factors but is unsuitable for the PFA, the new algorithm has a lower operation count than for the Cooley-Tukey algorithm.

Section 2 of this paper reviews the essentials of the prime factor algorithm. In § 3 we show how the PFA can be generalized to yield the new algorithm, removing the restriction on the transform lengths. Section 4 describes the implementation on a Cray Y-MP, and includes timing results to illustrate the properties of the new algorithm. In § 5, we describe a refinement of the algorithm which gives an even lower operation count for suitable values of N. Finally, § 6 includes a brief summary and discussion.

2. Prime factor algorithms. A thorough derivation of the family of prime factor FFT algorithms has been given by Burrus [1], [2]. Briefly, the DFT of length N is defined by

$$x(n)=\sum_{k=0}^{N-1} z(k)\omega_N^{kn}, \qquad 0\leqq n\leqq N-1, \tag{2.1}$$

where $x(n)$ and $z(k)$ are complex, and we use the notation

$$\omega_N=\exp(\pm 2i\pi/N). \tag{2.2}$$

Either sign may be taken in the definition (2.2).

We illustrate the derivation of the PFA by means of an example. Suppose that $N=N_1N_2$, where N_1 and N_2 are mutually prime. In this case [8, p. 250] we can find integers p, q, r, s $(0<p<N_1,\ 0<q<N_2,\ 0<r<N_2,\ 0<s<N_1)$ such that

$$pN_2=rN_1+1,\ qN_1=sN_2+1. \tag{2.3}$$

We use this "Chinese Remainder Theorem" (CRT) to define a mapping between the integers n, k $(0\leqq n\leqq N-1,\ 0\leqq k\leqq N-1)$ and the corresponding integer pairs (n_1, n_2) and (k_1, k_2) where $0\leqq n_1<N_1$, $0\leqq n_2<N_2$, $0\leqq k_1<N_1$, $0\leqq k_2<N_2$. As described in [14], we have a choice of two such mappings, the CRT map itself and the "Ruritanian" map [6]. In [14] the CRT map was chosen; this time we choose the Ruritanian map, for reasons which will become clear later.

Thus, the mapping is defined by

$$n_1=(pn) \bmod N_1, \quad n_2=(qn) \bmod N_2; \tag{2.4}$$

$$k_1=(pk) \bmod N_1, \quad k_2=(qk) \bmod N_2, \tag{2.5}$$

where p, q are defined in (2.3).

The inverse map is given by

$$n=(N_2n_1+N_1n_2) \bmod N; \tag{2.6}$$

$$k=(N_2k_1+N_1k_2) \bmod N. \tag{2.7}$$

An example for $N=40$ $(N_1=8,\ N_2=5)$ is shown in Table 1. The integer solutions of (2.3) are $p=5$, $q=2$, $r=3$, $s=3$. In fact, it is easy to construct the mapping in the form of a table without having to find these solutions. The entries in the first column increase from 0 in steps of $N/N_1(=N_2)$, while those in the first row increase from 0 in steps of $N/N_2(=N_1)$. The remaining columns (or rows) can then be filled in by using the same increment as in the first column (or row), and taking the results modulo N. We will use this technique later for indexing in the transform algorithm.

TABLE 1
The Ruritanian map for $N_1=8$, $N_2=5$.

			n_2		
n_1	0	1	2	3	4
0	0	8	16	24	32
1	5	13	21	29	37
2	10	18	26	34	2
3	15	23	31	39	7
4	20	28	36	4	12
5	25	33	1	9	17
6	30	38	6	14	22
7	35	3	11	19	27

As shown in [14], if we substitute (2.6) and (2.7) into (2.1), we obtain

$$x(n_1, n_2) = \sum_{k_2=0}^{N_2-1} \left[\sum_{k_1=0}^{N_1-1} z(k_1, k_2)\omega_{N_1}^{N_2 k_1 n_1} \right] \omega_{N_2}^{N_1 k_2 n_2}. \tag{2.8}$$

If it were not for the appearance of N_2 and N_1 multiplying the exponents, (2.8) would be exactly in the form of a two-dimensional DFT of dimension $N_1 \times N_2$, and the transform could be computed simply by performing N_2 DFTs of length N_1 in one dimension, followed by N_2 DFTs of length N_1 in the other (or vice versa, without changing the results). There are no "twiddle factors" between the two stages (hence the lower operation count than for the Cooley-Tukey algorithm). The output of each of the short one-dimensional transforms can overwrite the corresponding input, and the whole computation can thus be done in place. (Here we assume that N_1 and N_2 are "small" so that explicit DFT modules can be coded for these transform lengths.)

As further shown in [14], the appearance of N_2 and N_1 in the exponents simply *rotates* the transforms (applying a rotation r to a transform of length N_i means that instead of appearing in the original order $0, 1, 2, \cdots, N_i - 1$, the same results appear in the order $0, r, 2r, \cdots, (N_i - 1)r$, where these indices are to be interpreted modulo N_i). Moreover, these rotations can be incorporated by modifying certain constants which appear in the definitions of the short DFT algorithms of length N_1 and N_2. Detailed algorithms for rotated "small-n" DFTs are given in [14], [16].

The generalization to the case $N = N_1 N_2 \cdots N_k$, where all the factors are mutually prime, is straightforward; the one-dimensional transform of length N is equivalent to a k-dimensional transform in which the DFTs in each dimension are rotated as appropriate.

For future reference, it will be helpful to express these results in matrix form. We define W_N to be the DFT matrix of order N; thus element (j, k) of W_N is ω_N^{jk} (rows and columns of W_N are indexed from 0 to $N-1$), and (2.1) can be rewritten as $\underset{\sim}{x} = W_N \underset{\sim}{z}$. Further, we define $W_N^{[r]}$ to be the matrix W_N with all its elements raised to the power r. Then (2.8) corresponds to the factorization

$$W_N = R^{-1}(W_{N_2}^{[N_1]} \times W_{N_1}^{[N_2]})R \tag{2.9}$$

where × denotes the Kronecker (tensor) product and R is the permutation matrix which maps the integers $0 \leqq n \leqq N-1$ to the corresponding integer pairs (n_1, n_2) via the Ruritanian map (2.4). In general, if $N = N_1 N_2 \cdots N_k$, where all the N_i's are mutually prime, then the factorization is

$$W_N = R^{-1}(W_{N_k}^{[N/N_k]} \times \cdots \times W_{N_2}^{[N/N_2]} \times W_{N_1}^{[N/N_1]})R \tag{2.10}$$

where R now maps the array $x(n)$ to the corresponding k-dimensional array $x(n_1, n_2, \cdots, n_k)$ via the appropriate Ruritanian mapping. Notice that, to compute the transform, it is not necessary to reorder the input (or output) physically; the required mapping can be implemented implicitly via the indexing logic.

3. The generalized PFA. Using the results of the previous section, we can derive self-sorting in-place PFAs for certain values of N. For example, if $N = 60 = 3.4.5$, (2.10) becomes

$$W_{60} = R^{-1}(W_5^{[12]} \times W_4^{[15]} \times W_3^{[20]})R. \tag{3.1}$$

Since the rotation $[r]$ in $W_{N_i}^{[r]}$ can be taken modulo N_i, (3.1) simplifies to

$$W_{60} = R^{-1}(W_5^{[2]} \times W_4^{[3]} \times W_3^{[2]})R. \tag{3.2}$$

Algorithms are available for each of the short transforms W_5, W_4, W_3, including the rotations [14], [16], and these short transforms can be self-sorting and in-place.

Suppose now that $N = 129600 = 3^4 \times 4^3 \times 5^2$. If we arrange the factors in the form of a palindrome, for example

$$N = 3 \times 3 \times 4 \times 5 \times 4 \times 5 \times 4 \times 3 \times 3,$$

then we can use the results of [18, § 5] to obtain a self-sorting in-place algorithm for a transform of this length. However, the operation count would be the same as that for the corresponding mixed-radix Cooley–Tukey algorithm.

Alternatively, by (2.10) we have

$$W_{129600} = R^{-1}(W_{25}^{[5184]} \times W_{64}^{[2025]} \times W_{81}^{[1600]})R, \tag{3.3}$$

which, on reducing the rotations modulo N_i, becomes

$$W_{129600} = R^{-1}(W_{25}^{[9]} \times W_{64}^{[41]} \times W_{81}^{[61]})R. \tag{3.4}$$

In previous work on the PFA, it appeared that a self-sorting in-place implementation of (3.4) was not possible, since there was no way to perform self-sorting in-place transforms of lengths 25, 64, and 81. This is no longer true, thanks to the Johnson–Burrus self-sorting in-place radix-2 algorithm [7] and its generalization to other radices [18]. We need one final ingredient, so that the necessary rotations can be incorporated.

The required lemma was given in [14], in connection with deriving a rotated DFT module for $N_i = 9$. It can be stated as follows: if we have a radix-p algorithm for a transform of length $N = p^m$, then we can apply a rotation r by the following:

(1) Applying the rotation r (modulo p) to each radix-p module (e.g., by changing the multiplier constants); and

(2) raising all the twiddle factors to the power r.

For example, $W_{25}^{[9]}$ in (3.4) can be implemented by rotating each radix-5 module by $r' = 4$ ($=9$ modulo 5), and by raising all the twiddle factors to the power 9 (note that if the twiddle factors are stored in a precomputed list, this simply reorders them).

Thus, the generalized self-sorting in-place prime factor FFT algorithm (GPFA) for any $N = 2^p 3^q 5^r$ is constructed as follows:

(1) Use the Ruritanian mapping to convert to a three-dimensional transform of size $2^p \times 3^q \times 5^r$;

(2) Do the component one-dimensional transforms of length 2^p, 3^q, and 5^r using the generalized Johnson–Burrus scheme [18] with rotations incorporated as described above.

If the factors 2^p, 3^q, and 5^r are all "small," then the above algorithm is equivalent to the original PFA. If $N=2^p$, 3^q, or 5^r (i.e., only one of p, q, r is nonzero), then the transform remains one-dimensional and the above algorithm is equivalent to that in [18], with the same operation count as the Cooley-Tukey algorithm. In other cases, we have a new self-sorting in-place algorithm which takes advantage of the splitting of N into its mutually prime factors to reduce the operation count.

3.1. Operation counts. In [13], it was shown how to compute the operation counts for the mixed-radix Cooley-Tukey FFT algorithm. Here we adapt the formulae given in [13] to the case $N=2^p3^q5^r$, where the factors of 2 are treated in pairs (i.e., using a radix-4 algorithm). As in [13], the formulae assume that redundant multiplications are avoided when the twiddle factor is 1, but that there is no special treatment of other "simple" twiddle factors. The number of real additions is then given by

$$\mathcal{A}(N)=2N(1.375p+2.67q+4r-1)+2, \tag{3.5}$$

while the number of real multiplications is

$$\mathcal{M}(N)=2N(0.75p+2q+2.8r-2)+4. \tag{3.6}$$

In the case of the GPFA, we sum the operation counts from the transforms in each of the three dimensions: if $N=N_1N_2N_3$, where $N_1=2^p$, $N_2=3^q$, $N_3=5^r$, then the numbers of real additions and multiplications are given, respectively, by

$$\mathcal{A}(N)=\sum_{i=1}^{3}(N/N_i)\mathcal{A}(N_i), \tag{3.7}$$

$$\mathcal{M}(N)=\sum_{i=1}^{3}(N/N_i)\mathcal{M}(N_i), \tag{3.8}$$

where $\mathcal{A}(N_i)$ and $\mathcal{M}(N_i)$ are obtained from (3.5) and (3.6).

Examples for $N=3600=3^2\cdot 4^2\cdot 5^2$ are given in Table 2. In comparison with the Cooley-Tukey algorithm, the GPFA saves 10 percent of the additions and 33 percent of the multiplications. Thus, besides being both self-sorting and in-place, the GPFA has a significantly lower operation count than the conventional FFT when N contains a mixture of factors. Further examples of operation counts will be given in § 4. (The GPFA+algorithm is described in § 5.)

As an additional bonus, there is a useful saving in the storage required for tables of precalculated twiddle factors. Since a separate table is now used for the transforms in each of the three dimensions, the storage required becomes $2^p+3^q+5^r$ rather than $2^p\times 3^q\times 5^r$. For example, in the case $N=216000=3^3\times 4^3\times 5^3$ the twiddle factor storage requirement falls from 216000 to 216.

3.2. Indexing. To illustrate the indexing logic, we present a section of Fortran code which implements the first half of the radix-2 part of the algorithm for general

TABLE 2
Real operation counts for $N=3600$.

	+	*
Cooley-Tukey	128402	76324
GPFA	115538	50596
GPFA+	110250	40020

$N = 2^p 3^q 5^r$. Set $NI = 2^p$, $IP = p$. We first compute the required rotation and set up the table of twiddle factors:

```
   COMPLEX TRIGS(NI)
   DEL=4.0*ASIN(1.0)/FLOAT(NI)
   IROT=MOD((N/NI),NI)
   KK=0
   DO 10 K=1, NI
   ANGLE=FLOAT(KK)*DEL
   TRIGS(K)=CMPLX(COS(ANGLE),SIN(ANGLE))
   KK=KK+IROT
   IF (KK.GT.NI) KK=KK-NI
10 CONTINUE
```

The first $(p+1)/2$ radix-2 passes are then performed by the following code:

```
   COMPLEX X(N), W, Z
   NH=N/2
   INC=N/NI
   DO 50 L=1, (IP+1)/2
   LA=2**(L-1)
   JA=0
   JB=NH/LA
   KK=1
   DO 40 K=0, JB-1, INC
   W=TRIGS(KK)
   DO 30 J=K+1, N, N/LA
   IA=JA+J
   IB=JB+J
   DO 20 I=1, INC
   Z=W*(X(IA)-X(IB))
   X(IA)=X(IA)+X(IB)
   X(IB)=Z
   IA=IA+NI
   IF (IA.GT.N) IA=IA-N
   IB=IB+NI
   IF (IB.GT.N) IB=IB-N
20 CONTINUE
30 CONTINUE
   KK=KK+LA
40 CONTINUE
50 CONTINUE
```

The details of the indexing may be understood by comparing this code with Table 1 ($N=40$, $NI=8$). The three outer loops are very similar to the three loops of the code presented in [18], which performed the first half of a self-sorting in-place radix-2 algorithm. In the present case these loops set up base addresses in the first column of Table 1. The advantage of the Ruritanian map is that the entries in the first column (or row) increase monotonically in steps of N/NI; there is no need to compute these addresses modulo N. The innermost loop (DO 20) then steps *across* the table, performing one "butterfly" from each of the N/NI transforms of length NI. Only in this innermost loop is it necessary to update the addresses modulo N.

The code for the second half of the radix-2 part of the algorithm for general $N = 2^p 3^q 5^r$ may be obtained by similarly adapting the corresponding code given in [18], again inserting a new innermost loop which "traverses" the table. Notice that the indexing for the radix-2 part of the algorithm depends only on NI and N/NI; it is immaterial whether the Ruritanian map is one-, two- or three-dimensional. The same is true of the corresponding radix-3 and radix-5 parts.

4. Implementation on Cray Y-MP. The three Cray Assembly Language (CAL) routines described in [18], which implemented multiple self-sorting in-place complex FFTs for $N = 2^p$, 3^q and 5^r, have been generalized to implement the GPFA. The input parameter list for the modified version of each of the three routines now includes both $N = 2^p 3^q 5^r$ and the appropriate $NI = 2^p$, 3^q, or 5^r. The sequences of floating-point vector instructions are essentially unchanged, but the addressing and loop control now have to "navigate" the Ruritanian map as described in § 3.2, and are more complicated. However, this extra complexity has no impact on the vectorization, since the innermost loops (within the individual vector instructions) still step across the M simultaneous transforms being performed, with constant stride. For general $N = 2^p 3^q 5^r$, each of the three routines is now called in turn to implement the complete transform algorithm.

For the timing experiments presented below, 64 transforms were performed simultaneously. The experiments were run using a single processor of a Cray Y-MP with clock cycle 6.4 nsec. The new algorithm was compared with three other FFT routines, all CAL-coded and vectorized in the same way. In Tables 3-5, CFFT refers to the "old

routine" used as a standard of comparison in [18]; this was originally coded for the Cray-1 and implements the self-sorting form of the Cooley-Tukey algorithm by alternating between the original data array and a work array of the same size. PFA refers to the implementation of the prime factor algorithm described in [15]. SSIP refers to the self-sorting in-place routines presented in [18], and GPFA is the new algorithm. Operation counts given in the tables were computed via (3.5)-(3.8), with appropriate modifications when p is odd (as in [18], the $N_i = 2^p$ part of the computation is done using a radix-4 algorithm with an extra radix-2 or radix-8 section called once if p is odd).

Table 3 presents timing comparisons for values of N suitable for the PFA. Operation counts for the PFA routine are in principle the same as those for GPFA. In practice they are slightly smaller in some cases, since the special DFT modules used in PFA for $N_i = 9$ and $N_i = 16$ include some economies which are not available to the general-purpose radix-3 and radix-4 DFT modules in GPFA. As shown in Table 3, the times for GPFA are almost exactly the same as those for PFA, and represent savings of 20-25 percent over CFFT. The last column of Table 3 gives a measure of the efficiency of GPFA, defined as in [18] as

$$\frac{\text{Minimum possible time}}{\text{Measured time}} \times 100 \text{ percent.}$$

The minimum possible time is computed on the basis of the number of real additions in the algorithm, and the efficiency is equivalent to the percentage of CPU time during which the floating-point addition unit is active. As demonstrated in Table 3, optimum use of the hardware is very nearly achieved. In particular, the rather complicated indexing is successfully hidden behind the floating-point arithmetic.

Table 4 presents timings for values of N suitable for the self-sorting in-place routines described in [18], i.e., of the form $2^p, 3^q$, or 5^r. The operation counts for the three routines are the same. The times for GPFA are almost exactly the same as those for SSIP (despite the more complicated indexing, which is redundant in this case as the Ruritanian map is now one-dimensional), representing savings of 10-15 percent over CFFT.

Table 5 presents timings for values of N which contain a mixture of factors but are unsuitable for the PFA because at least one of the mutually prime factors is too large. The times for GPFA represent savings of 18–24 percent over CFFT, demonstrating that the two major advantages of the prime factor algorithm (self-sorting in-place capability and reduced operation count) have been extended to general values of $N=2^p3^q5^r$.

The results presented in this section show that in GPFA we have a self-sorting in-place FFT algorithm which works for any $N=2^p3^q5^r$. If the transform length N is suitable for the PFA, then GPFA is essentially equivalent to it and runs just as fast. If $N=2^p, 3^q$, or 5^r, then GPFA is equivalent to the self-sorting in-place algorithms in [18], and runs just as fast. If N contains a mixture of factors but the PFA is not applicable, then GPFA has a lower operation count than the conventional FFT, and runs faster.

5. A further refinement. For suitable values of the transform length N, a refinement is possible which leads to a further reduction in the operation count. We illustrate the procedure by way of an example, for $N=3600=3^2\cdot 4^2\cdot 5^2$. From (2.10), we have

$$W_{3600}=R^{-1}(W_{25}^{[9]}\times W_{16}\times W_9^{[4]})R. \tag{5.1}$$

The heart of the algorithm is a three-dimensional transform; the Ruritanian mapping and the rotations are not germane to the present discussion, and the same procedure could be used with any multidimensional transform.

In § 3, (5.1) was implemented by performing transforms of length 9 along the first dimension, then transforms of length 16 along the second dimension, and finally transforms of length 25 along the third dimension. The transform of length 9 is a two-stage procedure using a radix-3 algorithm; it can be written

$$W_9^{[4]}=U_9(D_9T_9). \tag{5.2}$$

The first stage (D_9T_9) consists of three radix-3 "butterflies" (T_9) followed by multiplication by a diagonal matrix (D_9) of twiddle factors. The second stage (U_9) consists of another three radix-3 butterflies (since we are using a self-sorting in-place algorithm here, the butterflies in U_9 are coupled and some results are interchanged [18], but again this does not affect the argument). Similarly, we can write the transforms of length 16 and 25 as two-stage procedures using radix-4 and radix-5 algorithms, respectively:

$$W_{16}=U_{16}(D_{16}T_{16}), \tag{5.3}$$

$$W_{25}^{[9]}=U_{25}(D_{25}T_{25}), \tag{5.4}$$

where D_{16} and D_{25} are diagonal matrices of twiddle factors.

Substituting (5.2)–(5.4) into (5.1),

$$W_{3600}=R^{-1}((U_{25}D_{25}T_{25})\times(U_{16}D_{16}T_{16})\times(U_9D_9T_9))R. \tag{5.5}$$

Using the algebra of Kronecker (tensor) products, (5.5) becomes

$$W_{3600}=R^{-1}((U_{25}\times U_{16}\times U_9)(D_{25}\times D_{16}\times D_9)(T_{25}\times T_{16}\times T_9))R. \tag{5.6}$$

The interpretation of (5.6) is as follows. We can perform the first stage (T_9) of the radix-3 algorithm along the first dimension, without the twiddle factors, and follow it immediately by the first stage (T_{16}) of the radix-4 algorithm along the second dimension, and the first stage (T_{25}) of the radix-5 algorithm along the third dimension. Next, we apply the "delayed" twiddle factors, contained in the matrix $(D_{25}\times D_{16}\times D_9)$.

Finally, we perform the second stages (U_9, U_{16}, U_{25}) of the radix-3, radix-4, and radix-5 algorithms along the three dimensions in turn. The important point about this reordering of the calculation is that ($D_{25} \times D_{16} \times D_9$) is a single diagonal matrix (of order N) of twiddle factors; thus, the twiddle factors in the original algorithm (5.1) have been nested together. Each of these combined twiddle factors can be found somewhere in the precomputed list of length N as used for the Cooley-Tukey algorithm (unfortunately the reduction to a table of length $2^p + 3^q + 5^r$ is now lost). This nesting of the twiddle factors is analogous to that proposed for two-dimensional transforms in [13].

The number of twiddle factors in ($D_{25} \times D_{16} \times D_9$) that have the value 1 is given by the product of the numbers of 1's in the three matrices D_{25}, D_{16}, D_9, respectively. Assuming we can still pick these out and avoid redundant twiddle factor multiplications, the operation count for this refined algorithm (GPFA+), for $N = 3600$, is given in Table 2. Compared with GPFA, the new algorithm saves a further 5 percent of the additions and 20 percent of the multiplications.

For $N = 2^p 3^q 5^r$, nesting the twiddle factors in this fashion can be done whenever at least two of p, q, r are greater than one (so the Ruritanian map is at least two-dimensional, and the transforms in at least two of the dimensions consist of at least two stages with intervening twiddle factors). The practical aspects of indexing the refined algorithm in the general case have not yet been addressed.

6. Summary and discussion. In this paper we have developed a new FFT algorithm which works for any transform length of the form $N = 2^p 3^q 5^r$, and is always self-sorting and in-place. It includes the prime factor algorithm [14] and the self-sorting in-place version of the fixed-radix Cooley-Tukey algorithm [18] as special cases, and is always at least as fast as previously available algorithms.

A refinement, applicable for certain values of N, has already been proposed in § 5; it is natural to ask whether further refinements are possible. Promising directions include replacing the radix-2 part of the procedure by the split-radix algorithm [4], [11], and the radix-3 part by the algorithm of Suzuki, Sone, and Kido [12]; but in both cases it remains to be shown whether these algorithms can be made self-sorting and in-place, and generalized to include rotations. These refinements would reduce the multiplication count to a greater extent than the addition count—which is unfortunate from the viewpoint of implementation on Cray-like machines, where the multiplications are effectively already free of charge.

Another topic worth pursuing is the analogous generalization to any $N = 2^p 3^q 5^r$ of the self-sorting in-place real/half-complex prime factor FFT [17] and the corresponding fast sine and cosine transform algorithms [9].

Acknowledgments. The author wishes to thank Dr. Deborah Salmond of Cray Research Inc. for her help in running the timing experiments on the Cray Y-MP.

A METHOD OF SMOOTH BIVARIATE INTERPOLATION FOR DATA GIVEN ON A GENERALIZED CURVILINEAR GRID*

DAVID W. ZINGG† AND MAURICE YARROW‡

Abstract. A method of locally bicubic interpolation is presented for data given at the nodes of a two-dimensional generalized curvilinear grid. The physical domain is transformed to a computational domain in which the grid is uniform and rectangular by a generalized curvilinear coordinate transformation. The metrics of the transformation are obtained by finite differences in the computational domain. Metric derivatives are determined by repeated application of the chain rule for partial differentiation. Given the metrics and the metric derivatives, the partial derivatives required to determine a locally bicubic interpolant can be estimated at each data point using finite differences in the computational domain. A bilinear transformation is used to analytically transform the individual quadrilateral cells in the physical domain into unit squares, thus allowing the use of simple formulas for bicubic interpolation.

Key words. interpolation, generalized curvilinear coordinates

AMS(MOS) subject classification. 65D05

1. Introduction. When function values are known at rectangular grid points in a plane, smooth bivariate interpolation can be efficiently performed using a method such as that presented by Akima [1]. However, when function values are given at irregularly distributed points in a plane, considerably more time-consuming methods are required. For example, the method developed by Akima [2] involves the following procedures: (1) triangulation, (2) determination of suitable nearest neighbors for each data point, (3) determination of the triangle in which each output point lies, (4) estimation of partial derivatives at each data point, and (5) calculation of the value of the interpolant at each output point. When the data points are given at rectangular grid points, the time-consuming procedures for triangulation and nearest-neighbor determination are not required. Furthermore, the procedures for determining the rectangle in which the output lies and for estimating partial derivatives are simplified.

In this paper, we develop a method of smooth bivariate interpolation for data given at the nodes of a generalized curvilinear grid. This problem is intermediate in complexity between the two problems above. Procedures for triangulation and nearest neighbor determination are not required, since the grid connectivity is implied by the data structure. In the present work, we assume that the cell in which a given output point lies is known. Procedures are described for estimation of partial derivatives and calculation of the value of the interpolant at the output points.

Generalized curvilinear grids are in common use in computational fluid dynamics. The grids are usually numerically generated using algebraic or partial differential equation techniques. Thompson, Warsi, and Mastin [7] give an excellent review of numerical grid generation techniques. Curvilinear grids are structured in that the grid nodes are aligned along curvilinear coordinate lines. Consequently, the grid can be mapped to an equispaced rectangular grid by a generalized curvilinear coordinate transformation. This facilitates the application of finite-difference methods for estimating partial derivatives. The physical coordinates are stored in two-dimensional arrays such that the curvilinear coordinates at each node are given by the array indices. Hence the grid connectivity is implied by the array indices.

There are numerous applications for interpolation on curvilinear grids, including transferring data from one grid to another in embedded or overlapping grid schemes and graphical output. While linear interpolants are sometimes used [4], a smooth interpolant may be required for some applications. Yarrow and Mehta [8] found that a cubic interpolant increases the accuracy of the coupling between overlapping grids. They used an iterative method for interpolation on curvilinear grids. The method presented here avoids iteration and associated difficulties with convergence. The bicubic interpolant does not ensure monotonicity. Bilinear interpolation can be used in regions where this is an important consideration.

2. Generalized curvilinear coordinate transformation. The generalized curvilinear coordinate transformation maps a nonuniform, nonrectangular grid in the physical domain to a uniform, rectangular grid in the computational domain [3], as shown in Fig. 1. The physical coordinates (x, y) are mapped to the curvilinear coordinates (ξ, η) by the following general transformation:

$$\xi=\xi(x, y), \qquad \eta=\eta(x, y), \tag{1}$$

where we consider two space dimensions only. Note that the physical coordinates of the grid nodes are normally determined by a numerical grid-generation procedure. Consequently, no analytical mapping of the above form is defined. The mapping is defined at the grid nodes by assigning curvilinear coordinate values to each grid node. The mapping is chosen such that the resulting grid in the computational domain is uniform, rectangular, and of unit length, i.e.,

$$\Delta\xi=\Delta\eta=1. \tag{2}$$

Hence finite-difference representations of ∂_ξ and ∂_η are easily formulated. Each physical point is mapped to one point in the computational domain and vice versa except at topological singularities or cuts, where one physical point may be mapped to many computational points.

The chain rule for partial differentiation gives, in matrix form,

$$\begin{bmatrix}\partial_x\\ \partial_y\end{bmatrix}=\begin{bmatrix}\xi_x & \eta_x\\ \xi_y & \eta_y\end{bmatrix}\begin{bmatrix}\partial_\xi\\ \partial_\eta\end{bmatrix}. \tag{3}$$

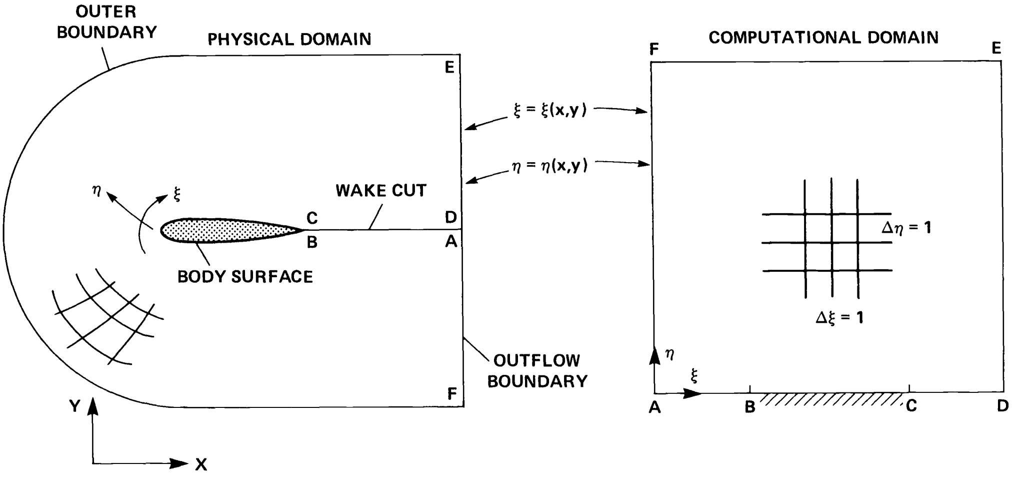

FIG. 1

Therefore, given the values of the elements of the above matrix, which are known as the metrics of the transformation, at each grid node, estimates of the partial derivatives with respect to the physical coordinates can be obtained from the simple finite-difference expressions for ∂_ξ and ∂_η. However, since the coordinate transformation is generally not known analytically, the metrics of the transformation must be determined using finite differences. Reversing the roles of the coordinate systems in (3), the chain rule also gives

$$(4)\qquad \begin{bmatrix} \partial_\xi \\ \partial_\eta \end{bmatrix} = \begin{bmatrix} x_\xi & y_\xi \\ x_\eta & y_\eta \end{bmatrix} \begin{bmatrix} \partial_x \\ \partial_y \end{bmatrix}.$$

Therefore, we must have

$$(5)\qquad \begin{bmatrix} \xi_x & \eta_x \\ \xi_y & \eta_y \end{bmatrix} = \begin{bmatrix} x_\xi & y_\xi \\ x_\eta & y_\eta \end{bmatrix}^{-1}$$

$$(6)\qquad = J \begin{bmatrix} y_\eta & -y_\xi \\ -x_\eta & x_\xi \end{bmatrix},$$

where

$$J^{-1} = x_\xi y_\eta - x_\eta y_\xi.$$

Equation (6) is the matrix form of the metric relations. All of the terms involving ∂_ξ and ∂_η are evaluated as finite differences. In the interior of the domain, standard three-point centered difference expressions are used. At boundaries, one-sided expressions must be used.

3. Interpolation method. Our objective is to smoothly interpolate a function $f(x, y)$ using values given at the nodes of a generalized curvilinear grid. The method proceeds in three steps. First, the required partial derivative information in the physical domain is determined using finite-difference approximations to the partial derivatives in the computational domain. The individual cells are then analytically transformed into unit squares by a bilinear transformation. Finally, a bicubic spline interpolant is determined within each unit square.

For locally bicubic interpolation, we require f_x, f_y, f_{xx}, f_{xy}, f_{yy}, as will be shown below. Using finite differences in computational space, we can determine f_ξ, f_η, $f_{\xi\xi}$, $f_{\xi\eta}$, $f_{\eta\eta}$. Applying the chain rule to (3) yields

$$(7)\qquad \begin{aligned} \partial_{xx} &= \xi_{xx}\partial_\xi + \eta_{xx}\partial_\eta + \xi_x^2\partial_{\xi\xi} + 2\xi_x\eta_x\partial_{\xi\eta} + \eta_x^2\partial_{\eta\eta}, \\ \partial_{xy} &= \xi_{xy}\partial_\xi + \eta_{xy}\partial_\eta + \xi_x\xi_y\partial_{\xi\xi} + (\xi_x\eta_y + \eta_x\xi_y)\partial_{\xi\eta} + \eta_x\eta_y\partial_{\eta\eta}, \\ \partial_{yy} &= \xi_{yy}\partial_\xi + \eta_{yy}\partial_\eta + \xi_y^2\partial_{\xi\xi} + 2\xi_y\eta_y\partial_{\xi\eta} + \eta_y^2\partial_{\eta\eta}. \end{aligned}$$

Equations (3) and (7) may be assembled as

$$(8)\qquad \boldsymbol{\partial}_{xy} = \boldsymbol{B}\boldsymbol{\partial}_{\xi\eta},$$

where

$$B = \begin{bmatrix} \xi_x & \eta_x & 0 & 0 & 0 \\ \xi_y & \eta_y & 0 & 0 & 0 \\ \xi_{xx} & \eta_{xx} & \xi_x^2 & 2\xi_x\eta_x & \eta_x^2 \\ \xi_{xy} & \eta_{xy} & \xi_x\xi_y & \xi_x\eta_y + \eta_x\xi_y & \eta_x\eta_y \\ \xi_{yy} & \eta_{yy} & \xi_y^2 & 2\xi_y\eta_y & \eta_y \end{bmatrix},$$

$$\boldsymbol{\partial}_{xy}=\begin{bmatrix}\partial_x\\ \partial_y\\ \partial_{xx}\\ \partial_{xy}\\ \partial_{yy}\end{bmatrix}, \quad\text{and}\quad \boldsymbol{\partial}_{\xi\eta}=\begin{bmatrix}\partial_\xi\\ \partial_\eta\\ \partial_{\xi\xi}\\ \partial_{\xi\eta}\\ \partial_{\eta\eta}\end{bmatrix}.$$

Similarly,

(9) $$\boldsymbol{\partial}_{\xi\eta}=C\boldsymbol{\partial}_{xy},$$

where

$$C=\begin{bmatrix} x_\xi & y_\xi & 0 & 0 & 0\\ x_\eta & y_\eta & 0 & 0 & 0\\ x_{\xi\xi} & y_{\xi\xi} & x_\xi^2 & 2x_\xi y_\xi & y_\xi^2\\ x_{\xi\eta} & y_{\xi\eta} & x_\xi x_\eta & x_\xi y_\eta+y_\xi x_\eta & y_\xi y_\eta\\ x_{\eta\eta} & y_{\eta\eta} & x_\eta^2 & 2x_\eta y_\eta & y_\eta^2\end{bmatrix}.$$

Therefore, $B=C^{-1}$.

In block matrix form, B can be written as

(10) $$B=\begin{bmatrix}B_1 & 0\\ B_2 & B_3\end{bmatrix},$$

where

$$B_1=\begin{bmatrix}\xi_x & \eta_x\\ \xi_y & \eta_y\end{bmatrix},\qquad B_2=\begin{bmatrix}\xi_{xx} & \eta_{xx}\\ \xi_{xy} & \eta_{xy}\\ \xi_{yy} & \eta_{yy}\end{bmatrix},$$

and

$$B_3=\begin{bmatrix}\xi_x^2 & 2\xi_x\eta_x & \eta_x^2\\ \xi_x\xi_y & \xi_x\eta_y+\eta_x\xi_y & \eta_x\eta_y\\ \xi_y^2 & 2\xi_y\eta_y & \eta_y^2\end{bmatrix}.$$

Similarly,

(11) $$C=\begin{bmatrix}C_1 & 0\\ C_2 & C_3\end{bmatrix},$$

where

$$C_1=\begin{bmatrix}x_\xi & y_\xi\\ x_\eta & y_\eta\end{bmatrix},\qquad C_2=\begin{bmatrix}x_{\xi\xi} & y_{\xi\xi}\\ x_{\xi\eta} & y_{\xi\eta}\\ x_{\eta\eta} & y_{\eta\eta}\end{bmatrix},$$

and

$$C_3=\begin{bmatrix}x_\xi^2 & 2x_\xi y_\xi & y_\xi^2\\ x_\xi x_\eta & x_\xi y_\eta+y_\xi x_\eta & y_\xi y_\eta\\ x_\eta^2 & 2x_\eta y_\eta & y_\eta^2\end{bmatrix}.$$

Now $B=C^{-1}$ gives

(12) $B_1=C_1^{-1}$ (the metric relations),

(13) $B_3=C_3^{-1}$,

and

$$B_2 = -C_3^{-1} C_2 C_1^{-1}. \tag{14}$$

Substituting (12) and (13) into equation (14) gives

$$B_2 = -B_3 C_2 B_1. \tag{15}$$

Finally, employing the metric relations gives

$$\begin{aligned}
\xi_{xx} &= -\frac{1}{J^3}[y_\eta^3 x_{\xi\xi} - 2y_\eta^2 y_\xi x_{\xi\eta} + y_\eta y_\xi^2 x_{\eta\eta} - x_\eta y_\eta^2 y_{\xi\xi} \\
&\qquad +2x_\eta y_\eta y_\xi y_{\xi\eta} - x_\xi y_\xi^2 y_{\eta\eta}], \\
\eta_{xx} &= -\frac{1}{J^3}[-y_\xi y_\eta^2 x_{\xi\xi} + 2y_\xi^2 y_\eta - y_\xi^3 x_{\eta\eta} + x_\xi y_\eta^2 y_{\xi\xi} \\
&\qquad -2x_\xi y_\eta y_\xi y_{\xi\eta} + x_\xi y_\xi^2 y_{\eta\eta}], \\
\xi_{xy} &= -\frac{1}{J^3}[-y_\eta^2 x_\eta x_{\xi\xi} + y_\eta(y_\eta x_\xi + x_\eta y_\xi) x_{\xi\eta} - y_\eta y_\xi x_\xi x_{\eta\eta} + x_\eta^2 y_\eta y_{\xi\xi} \\
&\qquad -x_\eta(y_\eta x_\xi + x_\eta y_\xi) y_{\xi\eta} + x_\eta y_\xi x_\xi y_{\eta\eta}], \\
\eta_{xy} &= -\frac{1}{J^3}[y_\xi y_\eta x_\eta x_{\xi\xi} - y_\xi(y_\eta x_\xi + x_\eta y_\xi) x_{\xi\eta} + y_\xi^2 x_\xi x_{\eta\eta} - x_\xi y_\eta x_\eta y_{\xi\xi} \\
&\qquad +x_\xi(y_\eta x_\xi + x_\eta y_\xi) y_{\xi\eta} - x_\xi^3 y_\xi y_{\eta\eta}], \\
\xi_{yy} &= -\frac{1}{J^3}[y_\eta x_\eta^2 x_{\xi\xi} - 2y_\eta x_\eta x_\xi x_{\xi\eta} + y_\eta x_\xi^2 x_{\eta\eta} - x_\eta^3 y_{\xi\xi} \\
&\qquad +2x_\eta^2 x_\xi y_{\xi\eta} - x_\eta x_\xi^2 y_{\eta\eta}], \\
\eta_{yy} &= -\frac{1}{J^3}[-y_\xi x_\eta^2 x_{\xi\xi} + 2y_\xi x_\eta x_\xi x_{\xi\eta} - y_\xi x_\xi^2 x_{\eta\eta} + x_\xi x_\eta^2 y_{\xi\xi} \\
&\qquad -2x_\eta x_\xi^2 y_{\xi\eta} + x_\xi^3 y_{\eta\eta}].
\end{aligned} \tag{16}$$

Therefore, all of the elements of matrix B can be expressed in terms of the elements of matrix C. As a result, $\partial_{xy} f$ can be determined given $\partial_{\xi\eta} f$. The elements of C and $\partial_{\xi\eta} f$ are approximated using three-point centered finite-difference formulas. At boundaries, one-sided formulas must be used.

Given f_x, f_y, f_{xx}, f_{xy}, f_{yy} at the corners of a given cell, the problem remains to interpolate f on an arbitrary quadrilateral. We now consider the new two-dimensional space given by (p, q) shown in Fig. 2 below. The quadrilateral in physical space is

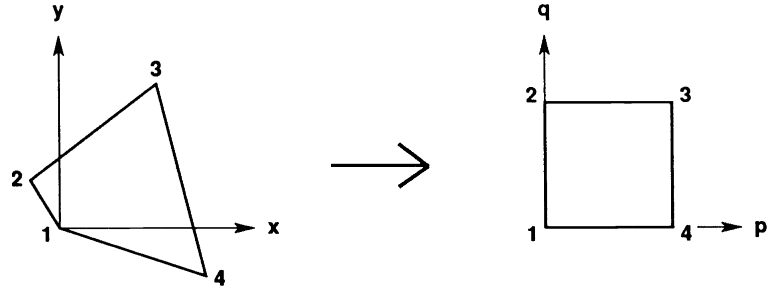

FIG. 2. *Two-dimensional space given by* (p, q).

related to a unit square in (p, q) space by a bilinear mapping, as follows. (Without loss of generality, we will assume the lower left-hand corner to be at $(0, 0)$.)

$$x = ap + bq + cpq, \tag{17a}$$

$$y = dp + eq + fpq. \tag{17b}$$

Note that a different mapping is used for each quadrilateral, or cell, in the grid. This contrasts with the generalized curvilinear coordinate transformation, in which a single smooth numerically generated mapping is applied to the entire grid. Consequently, analytical mappings can be utilized.

The coefficients of the bilinear mapping are given by

$$\begin{aligned} a &= x_4, \quad & b &= x_2, \quad & c &= x_3 - x_4 - x_2, \\ d &= y_4, \quad & e &= y_2, \quad & f &= y_3 - y_4 - y_2. \end{aligned} \tag{18}$$

The required derivatives in (p, q) space are given (as in (8)) by

$$\begin{aligned} \partial_p &= x_p \partial_x + y_p \partial_y, \\ \partial_q &= x_q \partial_x + y_q \partial_y, \\ \partial_{pq} &= x_{pq} \partial_x + y_{pq} \partial_y + x_p x_q \partial_{xx} + (x_p y_q + x_q y_p) \partial_{xy} + y_p y_q \partial_{yy}, \end{aligned} \tag{19}$$

where

$$x_p = a + cq, \quad y_p = d + fq, \quad x_q = b + cp, \quad y_q = e + fp, \quad x_{pq} = c, \quad y_{pq} = f,$$

and we have used $x_{pp} = x_{qq} = y_{pp} = y_{qq} = 0$.

Given a location in physical space (x_0, y_0), we must find the corresponding (p_0, q_0). From (17b), we have

$$q_0 = \frac{y_0 - dp_0}{e + fp_0}. \tag{20}$$

Substituting this into (17a) as follows:

$$x_0 = ap_0 + (b + cp_0)\left(\frac{y_0 - dp_0}{e + fp_0}\right) \tag{21}$$

gives the following quadratic for p_0:

$$p_0^2(cd - af) + p_0(-cy_0 + bd + x_0 f - ae) + (-y_0 b + ex_0) = 0. \tag{22}$$

Solution of (22) gives two values of p_0. The corresponding values of q_0 are determined from (20). One location (p_0, q_0) will not lie within the unit square and hence can be discarded.

Using f_x, f_y, f_{xx}, f_{xy}, f_{yy} as calculated from (8), we can determine f_p, f_q, and f_{pq} from (19) at each corner of the unit square in (p, q) space. We then employ the standard formula for bicubic interpolation within a unit square (see Appendix). The bicubic is finally evaluated at (p_0, q_0), as calculated from (22) and (20), respectively.

4. Conclusions. A method has been presented for smooth bivariate interpolation on a two-dimensional generalized curvilinear grid. Such grids are commonly used in computational fluid dynamics. Applications of the interpolation method include graphical output and problems in which data must be transferred from one grid to another. The method avoids any iterative procedures. Consequently, no difficulties with stability or convergence can occur in the application of the method.

Appendix: Locally bicubic interpolation on a unit square. In this appendix, we give a piecewise bicubic formulation for interpolation within a unit square. De Boor [5] presents a technique for determining the required partial derivatives at the corners of each cell in a rectangular grid such that C^2 continuity is obtained for the domain. In the formulation used here, the required partial derivatives at the corners of the unit square are given by centered difference formulas, leading to C^1 continuity, analogous to the univariate cubic Bessel spline given by de Boor [6]. This formulation has the advantage of producing a local interpolant.

The bicubic interpolant on a unit (p, q) square can be written as

$$f(p,q) \simeq \sum_{m,n=0}^{3} \gamma_{mn} p^m q^n, \qquad 0 \le p, q \le 1, \tag{A-1}$$

where

$$[\gamma_{mn}] = AKA^t,$$

$$A = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -3 & -2 & 3 & -1 \\ 2 & 1 & -2 & 1 \end{bmatrix},$$

and

$$K = \begin{bmatrix} f(0,0) & f_q(0,0) & f(0,1) & f_q(0,1) \\ f_p(0,0) & f_{pq}(0,0) & f_p(0,1) & f_{pq}(0,1) \\ f(1,0) & f_q(1,0) & f(1,1) & f_q(1,1) \\ f_p(1,0) & f_{pq}(1,0) & f_p(1,1) & f_{pq}(1,1) \end{bmatrix}.$$

ITERATIVE SOLUTION OF LINEAR SYSTEMS ARISING FROM THE BOUNDARY INTEGRAL METHOD*

KENDALL E. ATKINSON† AND IVAN G. GRAHAM‡

Abstract. In this paper the behavior of some standard two-grid iterative schemes for the solution of linear systems arising from discretizations of second-kind boundary integral equations of potential theory is studied. When the boundary of the domain has corners, these schemes converge slowly, and in some cases even diverge. New iterative schemes are derived which always converge, and estimates for the accuracy of the solution to which they converge are given. Extensive numerical experiments are reported and discussed.

Key words. boundary integral equation, linear systems, iteration methods

1. Introduction. When the interior Dirichlet problem for Laplace's equation is solved by the indirect approach using a double layer potential representation, a second-kind integral equation results. If the boundary of the domain is smooth, this integral equation has an operator with a smooth kernel. The classical Nyström method (where the integral operator is approximated by a quadrature rule, and the resulting approximate equation collocated at the quadrature points) may be used to solve this equation. This Nyström method is fully discrete, and in fact can be shown to be equivalent to either a collocation or Galerkin method, with the necessary integrals done by an appropriate quadrature rule. Moreover, two-grid (or more generally multigrid) schemes for the iterative solution of the resulting linear equations always converge, providing the coarse grid is sufficiently fine.

When the boundary has corners, the situation is much less pleasant. However it has recently been shown in Graham and Chandler (1988), henceforth referred to as GC, that a (slightly modified) Nyström method (based on a composite quadrature rule) may still be applied to solve the integral equation, and that optimal uniform convergence is obtained when the mesh is graded near each corner.

This paper examines the performance of two-grid iterative schemes for the solution of the linear systems arising from the Nyström method of GC. We show that unless proper care is taken these iterative schemes may perform very poorly. Then we go on to propose and study three improved iterative schemes. In the process we extend the analysis of GC to a piecewise C^∞ boundary with any finite number of noncuspoidal corners. To simplify notation and to make the paper easier to read, however, we will limit our presentation here to the single-corner case.

In this section we introduce the integral equation, the Nyström method, and the standard two-grid scheme. Let Ω be a bounded simply connected planar domain, and let Γ denote its boundary. Introduce the *double layer potential*

$$Wu(\mathbf{x}) = \int_\Gamma G'(\mathbf{x}, \xi) u(\xi)\, d\Gamma(\xi), \qquad \mathbf{x} \in \Gamma. \tag{1.1}$$

In this formula,

$$G(\mathbf{x}, \xi) = -\frac{1}{2\pi} \log |\mathbf{x} - \xi|,$$

$$G'(\mathbf{x}, \xi) = \frac{\partial}{\partial \mathbf{n}(\xi)} G(\mathbf{x}, \xi), \quad \mathbf{x} \in \mathbb{R}^2, \quad \xi \in \Gamma,$$

with $\partial/\partial\mathbf{n}(\xi)$ denoting the outward normal derivative at $\xi \in \Gamma$. The function u is called a density function.

We are interested in solving the integral equation

$$(1.2) \qquad u(\mathbf{x}) - 2Wu(\mathbf{x}) + \chi(\mathbf{x})u(\mathbf{x}) = -2g(\mathbf{x}), \qquad \mathbf{x} \in \Gamma.$$

In it, $\chi(\mathbf{x}) \in (-1, 1)$ and $[1 + \chi(\mathbf{x})]\pi$ is the exterior angle between the tangents to Γ at $\mathbf{y}$ as $\mathbf{y} \to \pm\mathbf{x}$. (Thus $\chi(\mathbf{x}) = 0$ except at corners of Γ.) This integral equation arises in solving Laplace's equation, in several ways.

For example, if u satisfies (1.2), then the function Wu of (1.1) solves the interior Dirichlet problem for Laplace's equation, with the given Dirichlet data $g(\mathbf{x})$. Alternatively, (1.2) arises in solving the exterior Neumann problem: find U satisfying

$$(1.3) \qquad \begin{aligned} &\Delta U(\mathbf{x}) = 0, \qquad \mathbf{x} \in \Omega_e = \mathbb{R}^2 \backslash \bar{\Omega}, \\ &\frac{\partial U(\mathbf{x})}{\partial \mathbf{n}} = h(\mathbf{x}), \qquad \mathbf{x} \in \Gamma, \\ &U(\mathbf{x}) = O(\log |\mathbf{x}|) \quad \text{as } |\mathbf{x}| \to \infty. \end{aligned}$$

Green's representation formula

$$(1.4) \qquad U(\mathbf{x}) = \int_\Gamma [u(\xi)G'(\mathbf{x}, \xi) - h(\xi)G(\mathbf{x}, \xi)] \, d\Gamma(\xi), \qquad \mathbf{x} \in \Omega_e$$

gives a solution to (1.3), provided $u(\mathbf{x})$ satisfies (1.2) with

$$g(\mathbf{x}) = \int_\Gamma h(\xi)G(\mathbf{x}, \xi) \, d\Gamma(\xi).$$

Let Γ be parameterized by $\mathbf{x}(s)$, $s \in [-1, 1]$, and for notational convenience extend $\mathbf{x}(s)$ to a 2-periodic function on all of $\mathbb{R}$. Assume $x \in C^\infty[-1, 1]\backslash\{0\}$, but allow Γ to have a single corner at $\mathbf{0} = \mathbf{x}_0 = \mathbf{x}(0)$. We shall assume throughout that s is proportional to the arc length along Γ, so that $|\mathbf{x}'(s)| = |\Gamma|/2$, where $|\Gamma|$ = length of Γ. It is straightforward to extend the results to any parameterization $\mathbf{x} \in C^\infty([-1, 1]\backslash\{0\})$ satisfying $|\mathbf{x}'(s)| > 0$, $s \in [-1, 1]\backslash\{0\}$.

For any integer $n \geqq 1$ and real number $q \geqq 1$, introduce the following graded mesh for $[-1, 1]$ and Γ:

$$(1.5) \qquad \begin{aligned} &s_j^{(n)} = \left(\frac{j}{n}\right)^q, \quad s_{2n-j}^{(n)} = -s_j^{(n)}, \quad j = 0, 1, \cdots, n, \\ &\mathbf{x}_j^{(n)} = \mathbf{x}(s_j^{(n)}), \qquad j = 0, 1, \cdots, 2n. \end{aligned}$$

Extend these points periodically with

$$s_{j+2n}^{(n)} = s_j^{(n)}, \quad x_{j+2n}^{(n)} = x_j^{(n)}, \quad -\infty < j < \infty.$$

Let

$$(1.6) \qquad \int_0^1 \varphi(\eta) \, d\eta \doteq \sum_{j=1}^r \omega_j \varphi(\eta_j)$$

be an interpolatory quadrature rule of order R, where $r \leqq R \leqq 2r$, with weights $\{\omega_j\}$ and nodes

$$0 \leqq \eta_1 < \eta_2 < \cdots < \eta_r \leqq 1.$$

Throughout we assume the weights $\{\omega_j\}$ are positive. This is the case with almost all practical interpolatory rules.

The Nyström approximation W_n to the operator W of (1.2) is obtained by applying (1.6) to each of the subintervals of Γ with breakpoints (1.5), that is,

$$W_n\phi(\mathbf{x}) = \sum_{i=1}^{2n} \sum_{j=1}^{r} \omega_{ij} G'(\mathbf{x}, \mathbf{x}_{ij}^{(n)}) \phi(\mathbf{x}_{ij}^{(n)}), \tag{1.7}$$

where the *quadrature points* on Γ are

$$\mathbf{x}_{ij}^{(n)} = \mathbf{x}(s_{ij}^{(n)}) \quad \text{with } s_{ij}^{(n)} = (1-\eta_j)s_{i-1}^{(n)} + \eta_j s_i^{(n)},$$

and the weights are

$$\omega_{ij} = \omega_j (s_i^{(n)} - s_{i-1}^{(n)}) \frac{|\Gamma|}{2}.$$

Rather than approximating W by W_n directly in (1.2), we first rearrange (1.2) slightly. As we shall see later, this rearrangement ensures a uniformly convergent approximate solution. Let

$$\tilde{u}(\mathbf{x}) = u(\mathbf{x}) - u(\mathbf{0}), \qquad \mathbf{x} \in \Gamma. \tag{1.8}$$

Substituting into (1.2) gives

$$(1+\chi)\tilde{u} - 2W\tilde{u} + ((1+\chi) - 2W1)u(\mathbf{0}) = -2g, \tag{1.9}$$

where 1 denotes the unit functions. Now it is well known (e.g., Jaswon and Symm (1977)) that $2W1 = -(1-\chi)$ on Γ, so (1.9) reduces to

$$(1+\chi)\tilde{u} - 2W\tilde{u} + 2u(\mathbf{0}) = -2g$$

or equivalently (since $\tilde{u}(\mathbf{0}) = 0$, and $\chi(\mathbf{x}) = 0$ when $\mathbf{x} \neq \mathbf{0}$)

$$\tilde{u} - 2W\tilde{u} + 2u(\mathbf{0}) = -2g. \tag{1.10}$$

Our numerical method for (1.10) (or equivalently (1.2)) is to seek u_n such that $u_n(\mathbf{0})$ and $\tilde{u}_n := u_n - u_n(\mathbf{0})$ satisfy

$$\tilde{u}_n - 2W_n\tilde{u}_n + 2u_n(\mathbf{0}) = -2g. \tag{1.11}$$

Observe that $\tilde{u}_n(\mathbf{0}) = 0$, so even if $\mathbf{0}$ is a quadrature point, the sum $W_n\tilde{u}_n$ contains no term in $G'(\mathbf{x}, 0)$ and hence is continuous on Γ. Thus, collocation at the points $\{x_{ij}^{(n)}\} \cup \{\mathbf{0}\}$ reduces (1.11) to a linear system for the unknowns $\{\tilde{u}_n(\mathbf{x}_{ij}^{(n)})\} \cup \{u_n(\mathbf{0})\}$. Once this is solved, (1.11) gives a formula for $\tilde{u}_n(\mathbf{x})$ at any $\mathbf{x} \in \Gamma$; this is the *Nyström interpolation formula.* Having found $\tilde{u}_n$ and $u_n(\mathbf{0})$, the approximation u_n to the exact solution u of (1.2) is then recovered by $u_n = \tilde{u}_n + u_n(\mathbf{0})$.

We analyze (1.11) in § 2. To prove stability, we need the following slight modification of the method. For some integer $i^* \geqq 0$ define W_n not by (1.7), but rather by

$$W_n\phi(\mathbf{x}) = \sum_{i=i^*+1}^{2n-i^*} \sum_{j=1}^{r} \omega_{ij} G'(\mathbf{x}, \mathbf{x}_{ij}^{(n)}) \phi(\mathbf{x}_{ij}^{(n)}).$$

Thus if $i^*=0$, W_n is unchanged. Then we shall show in § 2 that there is an $i^* \geqq 0$ and a $q>1$ such that (1.11) defines u_n uniquely for n sufficiently large, and u_n converges optimally, i.e.,

$$\|u-u_n\|_\infty = O\left(\frac{1}{n^R}\right) \quad \text{as } n \to \infty. \tag{1.12}$$

The introduction of i^* is an artifact of the stability proof of CG, and has no effect on the practical direct solution of (1.11). In fact, (1.12) has been observed to hold with $i^*=0$ in all practical computations. However, as we shall see in § 3, i^* turns out to be useful in a different context: as a parameter for the acceleration of the convergence of iterative schemes for solving (1.11).

To analyze (1.11) and to discuss its iterative solution, it is convenient to rearrange (1.10) into a 2×2 system for the unknown $(\tilde{u}, u(\mathbf{0}))$, and to think of (1.11) as a corresponding approximate system for $(\tilde{u}_n, u_n(\mathbf{0}))$. To do this, evaluate (1.10) at $\mathbf{0}$, and subtract the result from (1.10) to obtain the system (which is equivalent to (1.2))

$$(I-\mathscr{L})\begin{bmatrix}\tilde{u}\\ u(\mathbf{0})\end{bmatrix} = \begin{bmatrix}-2\tilde{g}\\ -2g(\mathbf{0})\end{bmatrix}, \tag{1.13}$$

where $\tilde{g}=g-g(\mathbf{0})$ and $\mathscr{L}$ is the operator

$$\mathscr{L}\begin{bmatrix}\tilde{u}\\ u(\mathbf{0})\end{bmatrix} = \begin{bmatrix}2W\tilde{u}-2(W\tilde{u})(\mathbf{0})\\ 2(W\tilde{u})(\mathbf{0})-u(\mathbf{0})\end{bmatrix}.$$

Carry out the same process on (1.11) to obtain

$$(I-\mathscr{L}_n)\begin{bmatrix}\tilde{u}_n\\ u_n(\mathbf{0})\end{bmatrix} = \begin{bmatrix}-2\tilde{g}\\ -2g(\mathbf{0})\end{bmatrix}, \tag{1.14}$$

where $\mathscr{L}_n$ is defined by replacing W by W_n in $\mathscr{L}$.

System (1.14) is in an appropriate form for solution by two-grid (or more generally multigrid) iterative solution procedures. In this paper we discuss some two-grid schemes which are closely related to a method studied in Atkinson (1973). As a motivation, we first describe this latter method.

We first write (1.13) and (1.14) (with n replaced by m) as

$$(I-\mathscr{L})v=z, \tag{1.15}$$

$$(I-\mathscr{L}_m)v_m=z, \tag{1.16}$$

with $v=(\tilde{u}, u(\mathbf{0}))^T$, etc. In § 2 we cast these equations in a Banach space $\mathscr{B}$, with norm $\|\cdot\|$ designed so that $\|v\|=\|(\tilde{u}, u(\mathbf{0}))^T\|=\|u\|_\infty$. Suppose that m is the discretization level of the system we wish to solve iteratively. Assume that we can solve exactly an equation of smaller level n, $(I-\mathscr{L}_n)v_n=y$, for any right-hand side y. Let $v_m^{(0)}$ be an initial guess for the solution v_m of (1.16). Calculate the *residual* or *defect*

$$d_m = z-(1-\mathscr{L}_m)v_m^{(0)}.$$

Then the error $e_m=v_m-v_m^{(0)}$ satisfies

$$(I-\mathscr{L}_m)e_m=d_m.$$

Write this as $e_m=d_m+\delta_m$, with $\delta_m=\mathscr{L}_m d_m$. Then δ_m satisfies the equation

$$(I-\mathscr{L}_m)\delta_m=\mathscr{L}_m d_m.$$

Approximate this with the equation

$$(I-\mathscr{L}_n)\delta_n=\mathscr{L}_m d_m,$$

which is solved directly for δ_n. The improved approximation to v_m is then given by

$$v_m^{(1)}=v_m^{(0)}+d_m+\delta_n.$$

Continuing iteratively, we obtain the following algorithm, which is easily recognizable as a simple multigrid scheme (using only two grids).

ALGORITHM 1.

(1.17a)	Input:	$v_m^{(j)}$
(1.17b)	Compute residual:	$d_m^{(j)}=z-(I-\mathscr{L}_m)v_m^{(j)}$
(1.17c)	Smoothing step:	Find $\mathscr{L}_m d_m^{(j)}$
(1.17d)	Coarse-grid correction:	$\delta_n^{(j)}=(I-\mathscr{L}_n)^{-1}\mathscr{L}_m d_m^{(j)}$
(1.17e)	Output:	$v_m^{(j+1)}=v_m^{(j)}+d_m^{(j)}+\delta_n^{(j)}.$

This scheme can be put into the form of the two-grid algorithm of Hackbusch (1985, p. 309). Some simple manipulations on (1.17a–e) lead to the well-known error expression

$$(v_m-v_m^{(j+1)})=(I-\mathscr{L}_n)^{-1}(\mathscr{L}_m-\mathscr{L}_n)\mathscr{L}_m(v_m-v_m^{(j)}). \tag{1.18}$$

Suppose Γ is smooth. Write the direct Nyström approximation of (1.2) as

$$(I-\mathscr{L}_m)u_m=-2g, \tag{1.19}$$

and apply Algorithm 1 to solve (1.19). Then (1.18) can be used to show

$$\|u_m-u_m^{(j+1)}\|_\infty \leqq C_{m,n}\|u_m-u_m^{(j)}\|_\infty \tag{1.20}$$

with $C_{m,n}<1$, for all $m>n$, provided n is sufficiently large (Atkinson (1973)). However, such estimates cannot be obtained for (1.17a–e) applied to (1.16). Indeed, in § 3 we give an example where the presence of a sharp corner diminishes the smoothing property of the operator $\mathscr{L}_m$ to such an extent that (1.17a–e) diverge. This paper describes some new two-grid methods for (1.16), which converge even in the presence of corners. This convergence will not be so interesting unless it is achieved without too much degradation in the accuracy of v_m, and without substantial escalation of the operation count of the iteration. Thus, we distinguish three properties which we would like an "ideal" iterative scheme to possess:

(P1) Convergence in the presence of any corners.

(P2) Convergence to solutions $v_m=(\tilde{u}_m, u_m(\mathbf{0}))^T$ which satisfy the (optimal) order of accuracy estimate (1.12).

(P3) Convergence achieved with an operation count comparable to that of the basic scheme (1.17).

As we shall see in §§ 3 and 4, there is a certain amount of "trade-off" between these three properties.

There is a large literature on the multigrid (or multilevel) solution of equations such as (1.2), particularly when Γ is smooth. For extensive surveys, see Hackbusch (1985) and references therein, and also Mandel (1985). A fast Fourier method is given in Reichel (1988). There are also several papers discussing the case of nonsmooth Γ, but using methods different from those proposed in the present paper. In particular, we mention Hebeker (1986), (1988) and Schippers (1982), (1985), (1987). We compare these with our own work later in the paper, but we remark here that previously most discretizations of (1.2) (when Γ has corners) were obtained by Galerkin or collocation schemes. These latter schemes generally necessitate further (numerical) integration. With an appropriate choice of quadrature rules, these can be shown to be equivalent to Nyström schemes (see Atkinson and Bogomolony (1987)). Thus this present work covers many common discretization strategies for (1.2), with the extra novelty here being that the preliminary rearrangement (1.10) is being used to improve the accuracy of the integration around the corner.

At this stage it seems important to justify why our main interest here is in two-grid schemes rather than in the more general multigrid method. Recall that we are interested, in the long run, in good approximations to the solution u of (1.2), or in quantities derived from u by postprocessing (potentials in the interior, stress intensity factors, etc.). It is not known a priori what value of m is needed in (1.16) to obtain these quantities within a prescribed tolerance. So in practice the problem would first be solved for a (moderate) value (or values) of m, the error would be estimated by some a posteriori technique (extrapolation or something more sophisticated), and then m would be increased if necessary.

The two-grid iteration (1.17a–e) fits in very nicely with this philosophy. A possible implementation is to first solve (1.16) directly for some moderate sized $m = n = n_0$, say, and then apply (1.17a–e) recursively with $m := 2n$ each time. This yields solutions on a sequence of *increasing* levels $\{2^j n_0 : j = 0, 1, 2, \cdots\}$, with termination when a prescribed accuracy is achieved.

The multigrid technique (e.g., Hackbusch (1985, § 16.5)), on the other hand, would solve (1.16) at level m by recursively applying the two-grid scheme on a nested sequence of *decreasing* levels. This yields a more complicated code, but achieves a better rate of convergence. Specifically it may be shown that when applied to (1.19), the multigrid method yields a sequence $u_m^{(j)}$ with property

$$(1.21) \qquad \|u_m - u_m^{(j+1)}\|_\infty \leqq C'_m \|u_m - u_m^{(j)}\|_\infty,$$

where, in contrast with (1.20), $C'_m \to 0$ as $m \to \infty$. Again this result does not apply for the iterative solution of (1.16), but we would argue that, even in the case of smooth Γ, the power of the full multigrid scheme may be unnecessary. To see this, consider (1.17a–e) applied to (1.19) with $u_m^{(0)} = u_{m/2}$, and suppose estimate (1.12) is sharp, i.e., for suitable constants C_1 and C_2,

$$C_1(1/m^R) \leqq \|u - u_m\|_\infty \leqq C_2(1/m^R),$$

and

$$C_1 2^R(1/m^R) \leqq \|u - u_{m/2}\|_\infty \leqq C_2 2^R(1/m^R).$$

Then

$$\begin{aligned}\|u - u_m\|_\infty &\geqq C_1 C_2^{-1} 2^{-R} \|u - u_{m/2}\|_\infty \\ &\geqq C_1 C_2^{-1} 2^{-R} (\|u_m - u_{m/2}\|_\infty - \|u - u_m\|_\infty),\end{aligned}$$

so that

$$(1 + C_1 C_2^{-1} 2^{-R}) \|u - u_m\|_\infty \geqq C_1 C_2^{-1} 2^{-R} \|u_m - u_{m/2}\|_\infty.$$

But, for sufficiently large values of n, (1.20) implies

$$\begin{aligned}\|u_m - u_m^{(j)}\|_\infty &\leqq (C_{m,n})^j \|u_m - u_m^{(0)}\|_\infty \\ &= (C_{m,n})^j \|u_m - u_{m/2}\|_\infty \\ &\leqq (C_{m,n})^j (C_1^{-1} C_2 2^R + 1) \|u - u_m\|_\infty.\end{aligned}$$

Clearly the iteration should be stopped when $\|u_m - u_m^{(j)}\|_\infty$ is less significant than $\|u-u_m\|_\infty$, i.e., when

$$(1.22) \qquad (C_{m,n})^j < (C_1^{-1}C_2 2^R + 1)^{-1}.$$

Suppose (as seems reasonable for smooth implementations) $C_{m,m/2} = 0.1$, $C_2 C_1^{-1} = 10$ (conservatively large), and the trapezoidal rule ($R = 2$) is used. Then (1.22) requires only $j = 2$. In this context, the significantly greater programming complexity needed to achieve (1.21) seems unnecessary, and so we concentrate our attention in this paper on two-grid methods.

Finally we remark that in (1.17d) it is implicitly assumed that Nyström interpolation is used to transform back and forth between coarse and fine grids. This is not necessary; prolongation and restriction operators may be used, and we shall discuss these in § 4. We remark that Hebeker (1986), (1988) has shown how a judicious choice of such prolongations and restrictions can lead to an accelerated two-grid scheme, satisfying (1.21) with $C'_m \to 0$ as $m \to \infty$.

2. Theory of the Nyström method. The discussion here mirrors that of GC, where the Nyström solution of (1.2) when Γ is polygonal was analyzed. Here we have only one corner, but extra work is necessary to deal with the curved boundary. Our exposition could be extended in a straightforward (but tedious) manner to a piecewise C^∞ boundary with a finite number of corners.

For the rest of the paper, D denotes differentiation, and C denotes a generic constant. Let $C(\Gamma)$ denote the space of continuous real-valued functions on Γ with the uniform norm, and let $C_0(\Gamma)$ denote the subspace $\{v \in C(\Gamma)\colon v(\mathbf{0}) = 0\}$, normed again with $\|\cdot\|_\infty$. We also use $\|\cdot\|_\infty$ to denote the norm of any bounded linear operator on $C(\Gamma)$.

The first step in the analysis is to introduce an operator $\mathcal{K}$ which contains a simpler form of the nonsmooth part of the operator $2W$ of (1.2). To this end, define the function $\mathbf{y}:[-1,1]\to\mathbb{R}^2$ by

$$(2.1) \qquad y(s) = \begin{cases} \left(-\dfrac{s|\Gamma|}{2}\cos(1-\chi_0)\pi,\ -\dfrac{s|\Gamma|}{2}\sin(1-\chi_0)\pi\right), & s\in[-1,0], \\ \left(\dfrac{s|\Gamma|}{2}, 0\right), & s \in [0,1]. \end{cases}$$

Thus $\mathbf{y}(s)$ is a parameterization of the open "wedge" $\tilde{\Gamma}$ consisting of two straight lines, each of length $|\Gamma|/2$, meeting at an exterior angle $(1+\chi_0)\pi$ at $\mathbf{0}$. Then for $v:\Gamma\to\mathbb{R}$, define $\mathcal{K}v:\Gamma\to\mathbb{R}$ by

$$(2.2) \qquad \mathcal{K}v(\mathbf{x}(s)) = 2\int_{\tilde{\Gamma}} G'(\mathbf{y}(s),\mathbf{y}(\sigma))v(\mathbf{x}(\sigma))\,d\Gamma(\mathbf{x}(\sigma)), \qquad s\in[-1,1].$$

Since the relationship between $\mathbf{x}(s)$ and $\mathbf{y}(s)$ is bijective, $\mathcal{K}v:\Gamma\to R$ is a well-defined function. The kernel $G'(\mathbf{y}(s),\mathbf{y}(\sigma))$ may be computed easily (e.g., see Atkinson and deHoog (1984)):

$$(2.3) \qquad \mathcal{K}v(\mathbf{x}(s)) = \begin{cases} \displaystyle\int_0^1 K\left(\frac{s}{\sigma}\right)v(\mathbf{x}(\sigma))\frac{d\sigma}{\sigma}, & s\in[-1,0], \\ \displaystyle -\int_{-1}^0 K\left(\frac{s}{\sigma}\right)v(\mathbf{x}(\sigma))\frac{d\sigma}{\sigma}, & s\in[0,1], \end{cases}$$

where

$$K(\sigma)=\frac{\sin(\chi_0\pi)}{\pi}\left[\frac{\sigma}{1-2\sigma\cos(\chi_0\pi)+\sigma^2}\right].$$

The properties of $\mathcal{K}$ are well understood. In particular,

$$\lim_{s\to 0\pm}\mathcal{K}v(\mathbf{x}(s))=-\chi_0 v(\mathbf{0}). \tag{2.4}$$

Using this limit to define $\mathcal{K}v(\mathbf{0})$, $\mathcal{K}$ is a bounded linear operator on $C(\Gamma)$ to $C(\Gamma)$, with

$$\|\mathcal{K}\|_\infty=|\chi_0|<1. \tag{2.5}$$

By (2.4), $\mathcal{K}$ is also bounded on $C_0(\Gamma)$ with a norm as in (2.5). It was shown by Atkinson and de Hoog (1984) that $\mathcal{N}:=2W-\mathcal{K}$ is compact on $C(\Gamma)$.

We study systems (1.13), (1.14) in the Banach space $\mathcal{B}=C_0(\Gamma)\times\mathbb{R}$, with the norm

$$\left\|\begin{bmatrix} v\\ \nu\end{bmatrix}\right\|=\|v+\nu\|_\infty.$$

Recall the definition of $\mathcal{L}$ following (1.13). Using the decomposition $2W=\mathcal{K}+\mathcal{N}$ and (2.4), we have $\mathcal{L}=\mathcal{S}+\mathcal{M}$, where

$$\mathcal{S}\begin{bmatrix}\tilde u\\ u(\mathbf{0})\end{bmatrix}=\begin{bmatrix}\mathcal{K}\tilde u\\ 0\end{bmatrix},$$

$$\mathcal{M}\begin{bmatrix}\tilde u\\ u(\mathbf{0})\end{bmatrix}=\begin{bmatrix}\mathcal{N}\tilde u-(\mathcal{N}\tilde u)(\mathbf{0})\\ (\mathcal{N}\tilde u)(\mathbf{0})-u(\mathbf{0})\end{bmatrix}.$$

The operator $\mathcal{M}$ is a finite rank-bounded perturbation of the compact operator

$$\begin{bmatrix}\tilde u\\ u(\mathbf{0})\end{bmatrix}\to\begin{bmatrix}\mathcal{N}\tilde u\\ 0\end{bmatrix},$$

and thus $\mathcal{M}$ is compact from $\mathcal{B}$ into $\mathcal{B}$. The operator $\mathcal{S}$ is a contraction, with norm as in (2.5); thus

$$\|(I-\mathcal{S})^{-1}\|\leqq\frac{1}{1-|\chi_0|}. \tag{2.6}$$

Combining these results, the Fredholm Alternative Theorem can be applied to (1.13). Using the equivalence of (1.13) and (1.2), we can show that the only solution of the homogeneous form of (1.13) is the zero solution. That then implies the existence and boundedness of the inverse of $(I-\mathcal{L})$ from $\mathcal{B}$ onto $\mathcal{B}$.

Now we discuss the stability and convergence of a (slightly modified) version of method (1.11), obtaining the result (1.12) described in § 1. Define

$$K(s,\sigma)=\begin{Bmatrix}0 & \sigma\in[-1,0]\\ K(s/\sigma)1/\sigma & \sigma\in[0,1]\end{Bmatrix},\qquad s\in[-1,0],$$

$$K(s,\sigma)=\begin{Bmatrix}-K(s/\sigma)1/\sigma & \sigma\in[-1,0]\\ 0 & \sigma\in[0,1]\end{Bmatrix},\qquad s\in[0,1],$$

so that

$$\mathcal{K}v(\mathbf{x}(\mathrm{s}))=\int_{-1}^{1}K(s,\sigma)v(\mathbf{x}(\sigma))\,d\sigma, \tag{2.7}$$

and introduce $N(s,\sigma)$ as the kernel function of $\mathcal{N}$, i.e.,

$$\mathcal{N}v(\mathbf{x}(s))=\int_{-1}^{1} N(s,\sigma)v(\mathbf{x}(\sigma))\,d\sigma. \tag{2.8}$$

To describe the modified Nyström method, choose $\beta\in[0,1]$, and define the truncated operator $\mathcal{K}_\beta$ by replacing the domain of integration $[-1,1]$ in (2.7) by $[-1,\beta]\cup[\beta,1]$. Define $\mathcal{N}_\beta$ from $\mathcal{N}$ analogously and use these to define $\mathcal{S}_\beta$, $\mathcal{M}_\beta$, and $\mathcal{L}_\beta$ in an obvious way. When $\beta=s_{i^*}^{(n)}$ for some $0\leqq i^*\leqq n$ (i.e., $\pm\beta$ are mesh points in $[-1,1]$), we define $\mathcal{K}_{i^*,n}$, $\mathcal{N}_{i^*,n}$ to be the Nyström approximations to $\mathcal{K}_{s(i^*,n)}$, $\mathcal{N}_{s(i^*,n)}$. (For typesetting purposes, we substitute $s(i^*,n)$ for $s_{i^*}^{(n)}$.) Replacing $\mathcal{K},\mathcal{N}$ by $\mathcal{K}_{s(i^*,n)}$, $\mathcal{N}_{s(i^*,n)}$ or $\mathcal{K}_{i^*,n}$, $\mathcal{N}_{i^*,n}$ in an obvious way, we define operators $\mathcal{S}_{s(i^*,n)}$, $\mathcal{M}_{s(i^*,n)}$, $\mathcal{L}_{s(i^*,n)}$, $\mathcal{S}_{i^*,n}$, $\mathcal{M}_{i^*,n}$, and $\mathcal{L}_{i^*,n}$ on $\mathcal{B}$. The *modified Nyström method* then consists of choosing some $i^*\geqq 0$ and solving

$$(I-\mathcal{L}_{i^*,n})\begin{bmatrix}\tilde{u}_n\\ u_n(\mathbf{0})\end{bmatrix}=\begin{bmatrix}-2\tilde{g}\\ -2g(\mathbf{0})\end{bmatrix} \tag{2.9}$$

for $n\geqq i^*$. When $i^*=0$, (2.9) coincides with (1.14).

We shall analyze (2.9) by appealing to some of the results of GC, and adding some perturbation arguments to cope with the curved boundary Γ. The following lemma summarizes some required results which follow trivially from Theorems 3 and 4 of Graham and Chandler.

LEMMA 1. (i) *For each $\varepsilon>0$ there exists i^*, such that*

$$\|(\mathcal{K}_{s(i^*,n)}-\mathcal{K}_{i^*,n})\mathcal{K}_{i^*,m}\|_\infty<\varepsilon \quad \textit{for all } m,n\geqq i^*.$$

(ii) *If u satisfies the estimate*

$$\sup\{|s|^{k-\alpha}|D_s^R u(\mathbf{x}(s))|: s\in[-1,1]\backslash\{0\}\}\leqq C_k, \tag{2.10}$$

with $1>\alpha>0$, for all $k\geqq 0$, for some constants C_k, then for each fixed $i^*\geqq 0$, we have

$$\|(\mathcal{K}-\mathcal{K}_{i^*,n})\tilde{u}\|_\infty=O\left(\frac{1}{n^R}\right) \quad \textit{as } n\to\infty, \tag{2.11}$$

provided $q>R/\alpha$. (Recall that R is the order of the quadrature rule (1.6).)

A careful examination of GC shows that the proof of Lemma 1 depends on the operator $\mathcal{K}$ only through the estimates

$$|s^kD^k(\mathcal{K}_{i^*,n}v)(\mathbf{x}(s))|\leqq A_k\|v\|_\infty, \qquad s\in[-1,1]\backslash\{0\}, \tag{2.12}$$

$$|\sigma^{k+1}D_\sigma^k(K(s,\sigma))|\leqq B_k, \qquad s,\sigma\in[-1,1]\backslash\{0\}, \tag{2.13}$$

for all $k\geqq 0$, which are easy generalizations of Graham and Chandler's Lemma 2(ii), (iii).

We shall prove the following technical generalization of Lemma 1.

LEMMA 2. (i) *For each $\varepsilon>0$ there exists i^* such that*

$$\|(\mathcal{L}_{s(i^*,n)}-\mathcal{L}_{i^*,n})\mathcal{L}_{i^*,m}\|<\varepsilon \quad \textit{for all } m,n\geqq i^*.$$

(ii) *For each $i^*\geqq 0$ fixed independently of n,*

$$\left\|(\mathcal{L}-\mathcal{L}_{i^*,n})\begin{bmatrix}\tilde{u}\\ u(\mathbf{0})\end{bmatrix}\right\|_\infty=O\left(\frac{1}{n^R}\right) \quad \textit{as } n\to\infty,$$

provided $q>R(1+|\chi_0|)$, where $u=\tilde{u}+u(\mathbf{0})$ is the exact solution of (1.2).

Proof. In the Appendix we demonstrate that (2.12) holds with $\mathcal{K}_{i^*,n}$ replaced by $\mathcal{N}_{i^*,n}$ and (2.13) holds with K replaced by N (where N is defined by (2.8)). Then, by

Lemma 1(i), each of the quantities $\|(\mathcal{K}_{s(i^*,n)}-\mathcal{K}_{i^*,n})\mathcal{N}_{i^*,m}\|$, $\|(\mathcal{N}_{s(i^*,n)}-N_{i^*,n})\mathcal{K}_{i^*,m}\|$, and $\|(\mathcal{N}_{s(i^*,n)}-\mathcal{N}_{i^*,n})\mathcal{N}_{i^*,m}\|$ may be made arbitrarily small, for all $m, n \geqq i^*$, by an appropriate choice of i^*. Writing

$$(\mathcal{L}_{s(i^*,n)}-\mathcal{L}_{i^*,n})\mathcal{L}_{i^*,m}=(\mathcal{S}_{s(i^*,n)}-\mathcal{S}_{i^*,n})\mathcal{S}_{i^*,m}+(\mathcal{S}_{s(i^*,n)}-\mathcal{S}_{i^*,n})\mathcal{M}_{i^*,m}$$
$$+(\mathcal{M}_{s(i^*,n)}-\mathcal{M}_{i^*,n})\mathcal{S}_{i^*,m}+(\mathcal{M}_{s(i^*,n)}-\mathcal{M}_{i^*,n})\mathcal{M}_{i^*,m},$$

and using the above facts yields the proof of Lemma 2(i).

For Lemma 2(ii) we first observe that for the solution u of (1.2), the condition (2.10) is true for all $0<\alpha<(1+|\chi_0|)^{-1}$. This is shown by Costabel and Stephan (1983), who applied a perturbation argument to the usual regularity analysis of (1.2) for polygonal boundaries. Hence (2.11) holds provided $q>R(1+|\chi_0|)$. By the Appendix, the result (2.11) (with $\mathcal{K}$ replaced by $\mathcal{N}$) also holds for the same range of q. Writing

$$(\mathcal{L}-\mathcal{L}_{i^*,n})\begin{bmatrix}\tilde{u}\\ u(\mathbf{0})\end{bmatrix}=(\mathcal{S}-\mathcal{S}_{i^*,n})\begin{bmatrix}\tilde{u}\\ u(\mathbf{0})\end{bmatrix}+(\mathcal{M}-\mathcal{M}_{i^*,n})\begin{bmatrix}\tilde{u}\\ u(\mathbf{0})\end{bmatrix},$$

and using the above facts yields the proof of Lemma 2(ii). □

The following theorem proves the optimal convergence estimate (1.12) provided the mesh grading exponent q is sufficiently large.

THEOREM 3. *There exists i^* fixed independently of n such that for all sufficiently large $n \geqq i^*$, $I-\mathcal{L}_{i^*,n}$ has a uniformly bounded inverse on $\mathcal{B}$. In this case* (2.9) *defines* $(\tilde{u}_n, u_n(\mathbf{0}))^T$ *uniquely in $\mathcal{B}$ and*

$$\|u-u_n\|_\infty=\|(\tilde{u}, u(\mathbf{0}))^T-(\tilde{u}_n, u_n(\mathbf{0}))^T\|=O\left(\frac{1}{n^R}\right) \quad \text{as } n\to\infty,$$

provided $q>R(1+|\chi_0|)$.

Proof. Our first step is to show that

$$\|\mathcal{N}-\mathcal{N}_\beta\|_\infty\to 0 \quad \text{as } \beta\to 0. \tag{2.14}$$

To prove this, let $v\in C(\Gamma)$ with $\|v\|_\infty \leqq 1$. In Atkinson and deHoog (1984), it is shown that N (the kernel of $\mathcal{N}$) is bounded on $[-1,1]\times[-1,1]$. Thus

$$|(\mathcal{N}-\mathcal{N}_\beta)v(\mathbf{x}(s))|\leqq \int_{-\beta}^{\beta}|N(s,\sigma)|\,d\sigma\to 0 \quad \text{as } \beta\to 0,$$

uniformly in s, v, which proves (2.14). It follows directly from (2.14) that

$$\|\mathcal{M}-\mathcal{M}_\beta\|\to 0 \quad \text{as } \beta\to 0. \tag{2.15}$$

We next show that

$$\mathcal{S}_\beta\to\mathcal{S} \quad \text{as } \beta\to 0, \quad \text{pointwise on } \mathcal{B}. \tag{2.16}$$

Clearly (2.16) is true provided $\mathcal{K}_\beta\to\mathcal{K}$, pointwise on $C_0(\Gamma)$ as $\beta\to 0$. Thus let $v\in C_0(\Gamma)$. Then, using (2.5),

$$\begin{aligned}|(\mathcal{K}_\beta-\mathcal{K})v(\mathbf{x}(s))|&=\left|\int_{-\beta}^{\beta}K(s,\sigma)v(\mathbf{x}(\sigma))\right|d\sigma\\ &\leqq|\chi_0|\sup\{|v(\mathbf{x}(\sigma))|:\sigma\in[-\beta,\beta]\}\\ &\to|\chi_0|v(\mathbf{x}(0))=0 \quad \text{as } \beta\to 0,\end{aligned}$$

and (2.16) follows.

Now observe that $\|\mathcal{S}_\beta\| = \|\mathcal{K}_\beta\|_\infty \leqq \|\mathcal{K}\|_\infty = |\chi_0| < 1$, so that $(I - \mathcal{S}_\beta)^{-1}$ exists on $\mathcal{B}$ and is bounded as in (2.6), independently of β. Our next step is to show

$$\|(I - \mathcal{S}_\beta)^{-1}\mathcal{M}_\beta - (I - \mathcal{S})^{-1}\mathcal{M}\| \to 0 \quad \text{as } \beta \to 0. \tag{2.17}$$

To obtain (2.17), simply write

$$(I - \mathcal{S}_\beta)^{-1}\mathcal{M}_\beta - (I - \mathcal{S})^{-1}\mathcal{M} = (I - \mathcal{S}_\beta)^{-1}(\mathcal{S}_\beta - \mathcal{S})(I - \mathcal{S})^{-1}\mathcal{M} + (I - \mathcal{S}_\beta)^{-1}(\mathcal{M}_\beta - \mathcal{M}).$$

Since $\mathcal{M}$ is compact on $\mathcal{B}$, the first term goes to 0 in norm as $\beta \to 0$, by (2.16). Also by (2.15), the second term goes to 0 in norm, proving (2.17).

Now recall that $I - \mathcal{L}$ and $I - \mathcal{S}$ are invertible on $\mathcal{B}$, so that (2.17) ensures $I - (I - \mathcal{S}_\beta)^{-1}\mathcal{M}_\beta$ is invertible for sufficiently small β, with uniformly bounded inverse. The identity $(I - \mathcal{L}_\beta)^{-1} = (I - (I - \mathcal{S}_\beta)^{-1}\mathcal{M}_\beta)^{-1}(I - \mathcal{S}_\beta)^{-1}$ then ensures the existence of constants $\bar{\beta} > 0$, and $\bar{C} > 0$ such that,

$$\|(I - \mathcal{L}_\beta)^{-1}\| \leqq \bar{C} \quad \text{for all } 0 \leqq \beta \leqq \bar{\beta}. \tag{2.18}$$

Now by Lemma 2(i), we can choose i^* so that

$$\|(\mathcal{L}_{s(i^*,n)} - \mathcal{L}_{i^*,n})\mathcal{L}_{i^*,n}\| \leqq \bar{C}^{-1} \leqq \|(I - \mathcal{L}_{s(i^*,n)})^{-1}\|^{-1},$$

for all n sufficiently large. This shows (Atkinson (1976, p. 15)) that

$$\mathcal{R}_n := (I - \mathcal{L}_{s(i^*,n)}) + (\mathcal{L}_{s(i^*,n)} - \mathcal{L}_{i^*,n})\mathcal{L}_{i^*,n}$$

has a uniformly bounded inverse for all sufficiently large $n \geqq i^*$. Then

$$(I - \mathcal{L}_{i^*,n})^{-1} = \mathcal{R}_n^{-1}(I - \mathcal{L}_{s(i^*,n)} + \mathcal{L}_{i^*,n}).$$

Since $\|\mathcal{L}_{s(i^*,n)}\| \leqq \|\mathcal{L}\|$, and (by (2.12) and (A.1) of the Appendix),

$$\|\mathcal{L}_{i^*,n}\| \text{ is bounded independently of } i^*, n, \tag{2.19}$$

it follows that for some $i^* \geqq 0$, $(I - \mathcal{L}_{i^*,n})^{-1}$ exists and is uniformly bounded, for all sufficiently large $n \geqq i^*$. For such i^* and n, (2.9) defines $(\tilde{u}_n, u_n(\mathbf{0}))^T$ uniquely, and Lemma 2(ii) yields

$$\begin{aligned}\|u_n - u\|_\infty &= \|(\tilde{u}_n, u_n(\mathbf{0}))^T - (\tilde{u}, u(\mathbf{0}))^T\| \\ &= \left\|(I - \mathcal{L}_{i^*,n})^{-1}(\mathcal{L}_{i^*,n} - \mathcal{L})\begin{bmatrix}\tilde{u} \\ u(\mathbf{0})\end{bmatrix}\right\| \\ &= O\left(\frac{1}{n^R}\right),\end{aligned}$$

provided $q > R(1 + |\chi_0|)$, as required. □

2.1. Numerical Experiment 1. The above results generalize to regions with any number of corners. As an illustration, we solve the interior Dirichlet problem

$$\Delta U = 0 \quad \text{in } \Omega, \qquad U = g \quad \text{on } \Gamma = \partial\Omega, \tag{2.20}$$

where Ω is the "pie-shaped" region composed of a segment of the unit disk, as depicted in Fig. 1. The exterior angles at corners P_1, P_2 are always $3\pi/2$, while the exterior angle at corner P_3 is $(1+\chi)\pi$ with $\chi < 0$, χ variable. To try the method out on a realistic singularity, we solve (2.20) with the known solution $U(\mathbf{x}) = r^\alpha \cos(\alpha\tilde{\theta})$, where $-\pi < \tilde{\theta} \leqq \pi$ is the polar angle of $\mathbf{x}$ after it has been rotated through $\pi/2$ anticlockwise about the origin, and $\alpha = 1/(1-\chi)$. This U is then harmonic in Ω and has the worst singularity which can be expected at the origin for a solution of (2.20) with smooth g. As described in § 1, (2.20) can be solved by solving (1.2) on Γ.

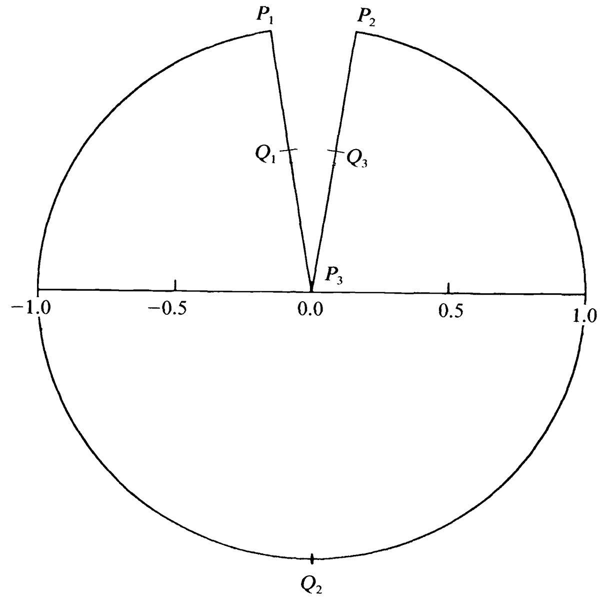

FIG. 1. *Pie-shaped domain,* $\chi = -0.9$.

Let Q_1, Q_2, Q_3 be the midpoints of P_3P_1, P_1P_2, and P_2P_3, respectively, and let Γ_l for $l = 1, 2, 3$ denote the portion of Γ joining Q_l to Q_{l+1} (with $Q_4 = Q_1$). Then the numerical method for (1.2) is to first rearrange it as

$$(1+\chi)u - 2\sum_{l=1}^{3} W\tilde{u}^l - 2\sum_{l=1}^{3} u(P_l)W1^l = -2g,$$

where $\tilde{u}^l$ denotes $u - u(P_l)$ restricted to Γ_l and 1^l denotes the constant function 1 on Γ_l. Discretize this by replacing W in the first sum on the left-hand side by W_n, and collocate at the quadrature points and the corner points. This determines the numerical solution at the collocation points. The solution U_n to (2.20) is then recovered by the approximate potential

$$U_n(x) = \sum_{l=1}^{3} W_n\tilde{u}_n^l(x) + \sum_{l=1}^{3} u_n(P_l)W1^l(x).$$

For more detail see Graham and Chandler (1988), or Atkinson and Graham (1988).

In the experiments reported here, we have chosen in (1.6) the two-point Gauss-Legendre rule (so that $R = 4$). For each n there were n subintervals on each of P_3Q_1, Q_1P_1, P_2Q_3, and Q_3P_3, and $2n$ subintervals on each of P_1Q_2 and Q_2P_2. We have graded the mesh near each of the corners P_l with a grading exponent q_l. Thus, for example, the mesh points on each side of P_3 are a distance $(i/2n)^{q_3}$ from P_3 for $i = 0, \cdots, n$. In Fig. 2 we plot the error $|U(\mathbf{x}) - U_n(\mathbf{x})|$, for $\mathbf{x} = r(\cos(-\chi\pi/4), \sin(-\chi\pi/4))$, $r \in (0, 1)$, with $\mathbf{q} = (q_1, q_2, q_3) = (3, 3, 4)$, $\chi = -0.9$, $i^* = 0$, and various n. The error decreases like $O(n^{-4})$ and becomes more evenly distributed as n increases. Figure 3 shows the effect of varying the grading exponents $\mathbf{q}$. Here we

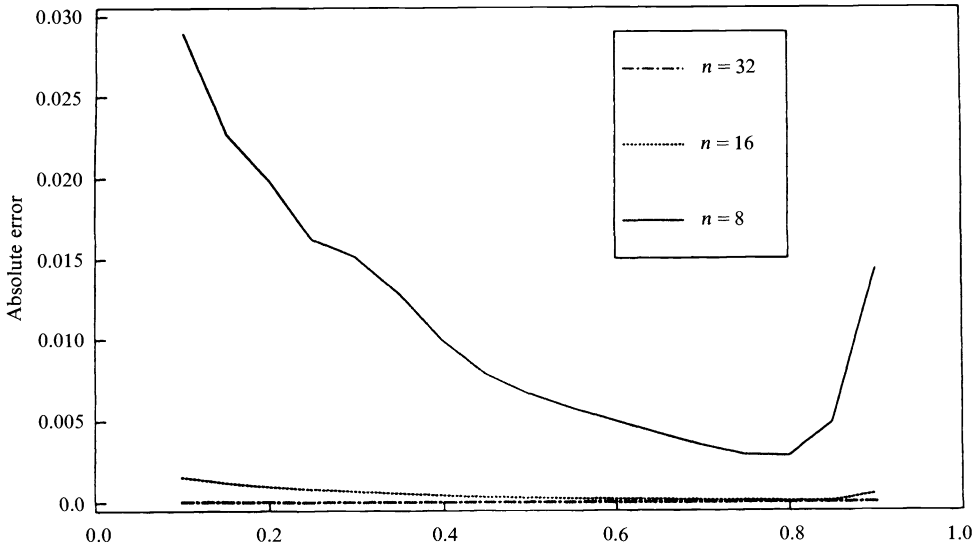

FIG. 2. $\chi=-0.9$, $q=(3,3,4)$, $i^*=0$.

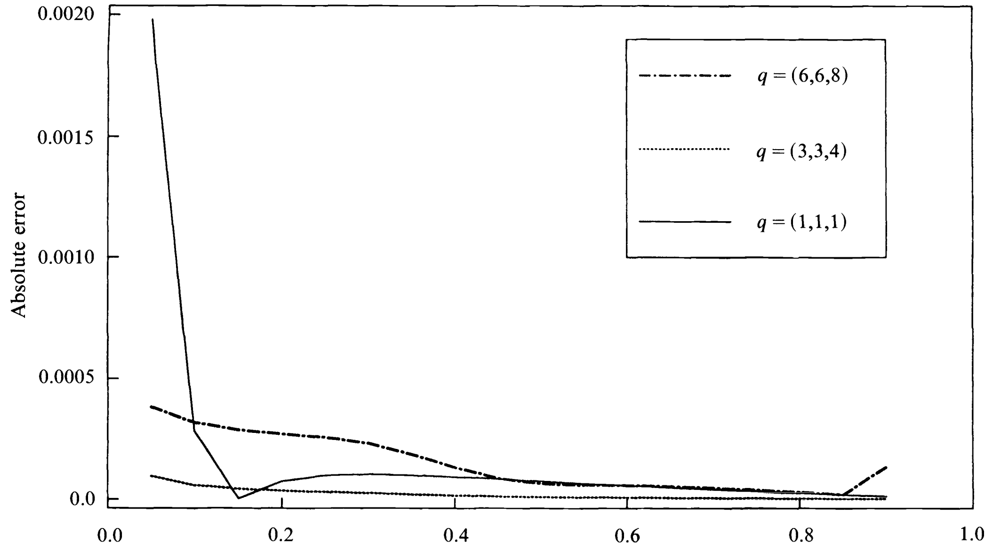

FIG. 3. $\chi=-0.9$, $n=32$, $i^*=0$.

plot the same error with $\chi=-0.9$, $n=32$, and $i^*=0$, but for various $\mathbf{q}$. Note that the analogue of Theorem 3 for the three-cornered case would imply that $\mathbf{q}>(6,6,7.6)$ is needed for optimal convergence of the boundary distribution u. However, U is calculated from u by integration against a smooth function, so we might expect that a smaller $\mathbf{q}$ would achieve optimal results for U. This is borne out in Fig. 3, where $\mathbf{q}=(3,3,4)$ is seen to be optimal. Finally note that in all these experiments, $i^*=0$ is sufficient for stability. Nevertheless, small $i^*>0$ does not affect the accuracy very much. In Table 1 we show the value of the boundary distribution u_n at $\boldsymbol{B}_3$ for $n=32$, $\mathbf{q}=(3,3,4)$, and various i^*.

3. Basic iteration schemes. In this section we discuss the convergence of appropriately modified versions of (1.17a–e).

Modification 1. The modification which is the simplest to analyze is obtained by setting

$$\mathscr{L}_m = \mathscr{L}_{i^*(m),m}, \tag{3.1}$$

$$\mathscr{L}_n = \mathscr{L}_{i^*(n),n} \tag{3.2}$$

in (1.17a–e), where $i^*(n)$, $i^*(m)$ are chosen so that

$$\beta := s(i^*(n),n) = s(i^*(m),m),$$

that is, the cutoff points of the coarse and fine meshes coincide and are independent of m, n. This can easily be arranged, for example, by choosing $m=kn$, $i^*(n)=n/r$, $i^*(m)=kn/r$, where r is any divisor of n.

Then $\{\mathscr{L}_m\}$, $\{\mathscr{L}_n\}$ given by (3.1) and (3.2) are collectively compact approximations to $\mathscr{L}_\beta$. For sufficiently small β, $(I-\mathscr{L}_\beta)^{-1}$ satisfies (2.18) and the standard results of Atkinson (1976) then show that (1.17a–e) converge linearly for all $m>n$, provided n is sufficiently large. This algorithm clearly has properties (P1) and (P3) described in § 1. However (P2) is lost. This is because the limit of $v_m^{(j)}$ as $j\to\infty$ is the numerical solution of (1.15), with $\mathscr{L}$ replaced by $\mathscr{L}_\beta$, where $\beta>0$ is independent of m. (However, the error induced by small β may not be very significant.) To preserve (P2), we need to do something more sophisticated.

Modification 2. To best describe the modification, assume

$$m = kn.$$

Then for any i^*, in (1.17a–e), choose the fine-grid operator

$$\mathscr{L}_m = \mathscr{L}_{i^*,m}. \tag{3.3}$$

If we chose, as the coarse-grid operator, $\mathscr{L}_n=\mathscr{L}_{i^*,n}$, then it is not possible to use (1.18) to show that (1.17a–e) converge for all $m \geqq n$.

This is because the distance between the cutoff points of the coarse and fine meshes $|s(i^*,n)-s(i^*,m)| \not\to 0$ as $m\to\infty$, for fixed n. To overcome this problem, we allow the coarse mesh to be augmented with the subintervals of the fine mesh contained within the troublesome region

$$[-s(i^*,n), -s(i^*,m)] \cup [s(i^*,m), s(i^*,n)], \tag{3.4}$$

that is, we choose as our coarse-grid operator in (1.17a–e)

$$\mathscr{L}_n = \tilde{\mathscr{L}}_{i^*,n}, \tag{3.5}$$

where $\tilde{\mathscr{L}}_{i^*,n}$ is the quadrature approximation to $\mathscr{L}_{s(i^*,m)}$ obtained by using the m level mesh in the region (3.4) and the n level mesh in the region $[-1, -s(i^*,n)] \cup [s(i^*,n), 1]$.

TABLE 1
Numerical values at corner P_3.

i^*	0	2	4
$u_n(P_3)$	14.025602	14.025575	14.025243

This means that the dimension of the n level system is now $O(n+m/n)$ which is increasing with m, so property (P3) is lost. However, (P2) is gained and (P1) remains, as we shall see in the following result which uses (1.18) to estimate the convergence of (1.17a–e).

THEOREM 4. *Suppose* $\mathscr{L}_m$, $\mathscr{L}_n$ *are given by* (3.3), (3.5), *and define*

$$C_{m,n,i^*} = \|(I-\mathscr{L}_n)^{-1}(\mathscr{L}_m-\mathscr{L}_n)\mathscr{L}_m\|. \tag{3.6}$$

Then there exists i^* *fixed independently of* n *such that for all* n *sufficiently large and all* $m=kn$, $k \geqq 1$ *we have* $C_{m,n,i^*}<1$.

Proof. The details are technical but not difficult, so we shall only sketch the proof. First we observe

$$\begin{aligned}\mathscr{L}_m-\mathscr{L}_n &= \mathscr{L}_{i^*,m}-\tilde{\mathscr{L}}_{i^*,n}\\ &= (\mathscr{L}_{i^*,m}-\mathscr{L}_{s(i^*,m)})+(\mathscr{L}_{s(i^*,n)}-\mathscr{L}_{i^*,n})+(\mathscr{L}_{s(i^*,m)}-\mathscr{L}_{s(i^*,n)}-\tilde{\mathscr{L}}_{i^*,n}+\mathscr{L}_{i^*,n}).\end{aligned}$$

The operator in the final term is really just $\mathscr{L}_{s(i^*,m)}-\mathscr{L}_{i^*,m}$ restricted to functions which are zero in $[-1,1]\backslash[-s(i^*,n), s(i^*,n)]$. Thus, by Lemma 2 (or a slight variation of it), we can show that for each $\varepsilon>0$, there exists i^* independent of n, such that for all $n\geqq i^*$ and $m=kn$, $k\geqq 1$,

$$\|(\mathscr{L}_m-\mathscr{L}_n)\mathscr{L}_m\|<\varepsilon, \tag{3.7}$$

$$\|(\mathscr{L}_m-\mathscr{L}_n)\mathscr{L}_n\|<\varepsilon. \tag{3.8}$$

Now recall the identity

$$(I-\mathscr{L}_n)^{-1}=\mathscr{R}^{-1}(I-\mathscr{L}_m+\mathscr{L}_n),$$

where $\mathscr{R}=(I-\mathscr{L}_m)+(\mathscr{L}_m-\mathscr{L}_n)\mathscr{L}_n$. By Theorem 3 and (3.8), $\mathscr{R}^{-1}$ has a uniformly bounded inverse for appropriate fixed i^*, and for all n sufficiently large and $m=kn$. Under these conditions, $\|(I-\mathscr{L}_n)^{-1}\|$ is uniformly bounded; combined with (3.7), we obtain the required result. □

Remark. Theorem 4 corrects an incorrect sentence in the last paragraph of § 2 of Atkinson and Graham (1988).

DISCUSSION. A strict reading of Modification 2 will lead to a modification which is unpleasantly complicated. To speed up the convergence, not only would it be necessary to increase i^*, but also one would be expected to add m level points to the n level grid. It was observed in Atkinson and Graham (1988) that the following simpler algorithm worked well in several cases where a direct application of Algorithm 1 did not.

ALGORITHM 2.

(3.9a) Perform steps: (1.17a)–(1.17e)

(3.9b) Compute: $e_m^{(j+1)}=\|v_m^{(j+1)}-v_m^{(j)}\|$

(3.9c) If $e_m^{(j+1)}<$required tolerance: stop.

(3.9d) Compute: $\Delta_m^{(j+1)}=e_m^{(j+1)}/e_m^{(j)}$

(3.9e) If $\Delta_m^{(j+1)}>1$: Increase i^*, and go to (3.9a).

In the following experiment we study the performance of (3.9).

3.1. Numerical Experiment 2. We discretized (1.2) on the boundary Γ of the pie-shaped region, exactly as described in Numerical Experiment 1. For a given i^*, we removed from W_n contributions from i^* subintervals on each side of each of the three corners of Γ. We show in Table 2 how the convergence of (3.9a–e) is affected by the choice of χ, $\mathbf{q}$, n, m, and i^*. Remarkable points are the following: The iteration works well unmodified (i.e., with $i^*=0$) when all the angles are right angles, a frequently occurring practical situation. As $\chi \to -1$ the iteration slows down and diverges for $\chi \leqq -0.75$, unless a modification is made. The modification i^* needed to restore convergence as $\chi \to -0.9$ increases to the extent that the coarse-grid operator on the "wedge" portion of Γ must be almost removed entirely. There is strong evidence to suggest that the convergence rate remains fixed for a given i^* and $m=2n$, for a range of values of n.

If m were allowed to increase indefinitely compared to n, the distance between the cutoff points $s(i^*, m)$ and $s(i^*, n)$ would grow and may pollute the estimate of C_{m,n,i^*} given in Theorem 4. This could be alleviated by cautiously adding m level points to the coarse grid. (This would mean that extra rows and columns would be added to the coarse-grid matrix, a process which could be done efficiently using block elimination techniques (e.g., Chan (1984)).) We see from Numerical Experiment 2 that if $m \approx 2n$ (again a practically relevant choice—see § 1), then such cautious updating may not be necessary.

In the next section we describe another technique for obtaining a two-grid algorithm with arbitrarily fast convergence for (1.16). This technique also requires that the dimension of the coarse level should be allowed to increase with m, but in a different and more deliberate way than that suggested by Modification 2.

4. An alternative iteration scheme. Recall the system (1.13). We define an iteration method for the first equation in (1.14), finding $\tilde{u}_m$; then the second equation in (1.14) is used to calculate $u_m(\mathbf{0})$. Begin by defining

$$\begin{aligned}(V\tilde{v})(\mathbf{x}) &= 2[(W\tilde{v})(\mathbf{x})-(W\tilde{v})(\mathbf{0})]\\ &= 2\int_\Gamma [G'(\mathbf{x},\xi)-G'(0,\xi)]\tilde{v}(\xi)\,d\Gamma, \qquad \mathbf{x}\in\Gamma,\\ (V_m\tilde{v})(\mathbf{x}) &= 2[(W_m\tilde{v})(\mathbf{x})-(W_m\tilde{v})(\mathbf{0})]\end{aligned}$$

TABLE 2
Iteration results for (3.9).

for all $\tilde{v} \in C_0(\Gamma)$. We iteratively solve

$$\tilde{u}_m - V_m \tilde{u}_m = -2\tilde{g}, \tag{4.1}$$

which is the Nyström discretization of

$$\tilde{u} - V\tilde{u} = -2\tilde{g}. \tag{4.2}$$

By a simple extension of the proof of Theorem 3, we have the existence and uniform boundedness of $(I - V_m)^{-1}$ on $C_0(\Gamma)$. This assumes that the quantity i^* of Theorem 3 is chosen sufficiently large, which we assume throughout this section.

Consider applying the iteration method (1.17a–e) to (4.1), with the role of $\mathcal{L}_m$ replaced by V_m and $v_m^{(j)} = u_m^{(j)}$. The resulting iteration will often converge, but at a slow rate. The problem lies in the lack of smoothing by the operator V; the function $(V\tilde{v})(\mathbf{x})$ need be no smoother than $\tilde{v}(\mathbf{x})$ for $\mathbf{x}$ near $\mathbf{0}$. To deal with this, we break Γ into two parts: $\Gamma = \Gamma_1 \cup \Gamma_2$. The portion Γ_1 will contain the corner $\mathbf{0}$, and the remaining boundary Γ_2 will be bounded away from $\mathbf{0}$. The discretization of the equation (4.2) on Γ_1 is solved exactly, and then the iteration method of (1.17a–e) is applied to the corner-modified version of (4.1).

The idea of inverting directly that portion of the operator in a small neighborhood of the corner, in order to improve the performance of iteration methods, has been used previously by other authors. It is used in Schippers (1985) to solve a discretization based on Galerkin's method with piecewise constant functions on a uniform grid. Hebeker (1988) uses it to solve boundary integral equations from fluid mechanics for discretizations based on the collocation method with bilinear trial functions. The idea also existed in the work of Radon (1919) who used it in developing a theory for (1.2) generalizing the work of Fredholm. Also, Bruhn and Wendland (1967) used it in the analysis of numerical methods for (1.2).

Let $0 < \delta < 1$, and restrict the values of m to those integers for which

$$\delta = \left(\frac{j^*(m)}{m}\right)^q \tag{4.3}$$

for some $1 \leqq j^*(m) < m$. Define Γ_1 to be the portion of Γ joining $\mathbf{x}(-\delta)$ and $\mathbf{x}(\delta)$, containing the corner $\mathbf{0}$; let Γ_2 be the closure of the remainder of Γ. For $\tilde{v} \in C_0(\Gamma)$, let

$$v^{(1)} = \tilde{v}|_{\Gamma_1}, \qquad v^{(2)} = \tilde{v}|_{\Gamma_2}.$$

Let $\mathscr{X} = C_0(\Gamma_1) \oplus C(\Gamma_2)$. Define $\mathscr{V}: \mathscr{X} \to \mathscr{X}$ by

$$\mathscr{V}\begin{bmatrix} v^{(1)} \\ v^{(2)} \end{bmatrix} = \begin{bmatrix} V^{(1,1)} & V^{(1,2)} \\ V^{(2,1)} & V^{(2,2)} \end{bmatrix} \begin{bmatrix} v^{(1)} \\ v^{(2)} \end{bmatrix}, \tag{4.4}$$

$$V^{(i,j)} v^{(j)}(\mathbf{x}) = 2 \int_{\Gamma_j} [G'(\mathbf{x}, \xi) - G'(\mathbf{0}, \xi)] v^{(j)}(\xi)\, d\Gamma, \qquad \mathbf{x} \in \Gamma_i \tag{4.5}$$

for $i, j = 1, 2$, with $v^{(1)} \in C_0(\Gamma_1)$ and $v^{(2)} \in C(\Gamma_2)$. It is straightforward to extend the unique solvability of (4.2) on $C_0(\Gamma)$ to that of

$$(I - \mathscr{V})\mathbf{u} = \mathbf{f}, \qquad \mathbf{u}, \mathbf{f} \in \mathscr{X}. \tag{4.6}$$

(Note that $C_0(\Gamma)$ is isomorphic to a closed subspace of $\mathscr{X}$ of codimension two.) For notational simplicity, we have let $\tilde{f} = -2\tilde{g}$ in going from (4.2) to (4.6).

Extend the above reformulation to the discretized equation (4.1):

$$\mathcal{V}_m\begin{bmatrix} v^{(1)} \\ v^{(2)} \end{bmatrix}=\begin{bmatrix} V_m^{(1,1)} & V_m^{(1,2)} \\ V_m^{(2,1)} & V_m^{(2,2)} \end{bmatrix}\begin{bmatrix} v^{(1)} \\ v^{(2)} \end{bmatrix}, \qquad \mathbf{v}\in\mathscr{X}, \tag{4.7}$$

$$(I-\mathcal{V}_m)\mathbf{u}_m=\mathbf{f}, \qquad \mathbf{u}_m, \mathbf{f}\in\mathscr{X}.$$

The operators $V^{(i,j)}, (i,j)\neq(1,1)$, are compact; their approximations $\{v_m^{(i,j)}\}, (i,j)\neq(1,1)$, are collectively compact and pointwise convergent. This follows from (a) the continuity of the kernel function $[G'(\mathbf{x},\xi)-G'(\mathbf{0},\xi)]$ for $\mathbf{x}\in\Gamma_i$, $\xi\in\Gamma_j$, $(i,j)\neq(1,1)$, and (b) the convergence for all continuous integrands of the integration scheme used in (1.7).

The equation

$$[I-V^{(1,1)}]u^{(1)}=f^{(1)}, \qquad f^{(1)}\in C_0(\Gamma_1)$$

is defined on a "wedge boundary," and it has a theory completely analogous to that of $(I-\mathscr{K})\tilde{u}=f$. The use of a wedge boundary is investigated in Atkinson and deHoog (1984); the arguments leading to Theorem 3 are easily extended to the wedge equation with operator $I-V^{(1,1)}$. The above equation is uniquely solvable for all $f^{(1)}\in C_0(\Gamma_1)$. For its discretization, we have that $[I-V_m^{(1,1)}]^{-1}$ exists and is uniformly bounded on $C_0(\Gamma_1)$ for all sufficiently large m.

Apply these results to equations (4.6) and (4.7) to obtain the equivalent equations

$$\begin{bmatrix} I & -[I-V^{(1,1)}]^{-1}V^{(1,2)} \\ -V^{(2,1)} & I-V^{(2,2)} \end{bmatrix}\begin{bmatrix} u^{(1)} \\ u^{(2)} \end{bmatrix}=\begin{bmatrix} [I-V^{(1,1)}]^{-1}f^{(1)} \\ f^{(2)} \end{bmatrix}, \tag{4.8}$$

$$\begin{bmatrix} I & -[I-V_m^{(1,1)}]^{-1}V_m^{(1,2)} \\ -V_m^{(2,1)} & I-V_m^{(2,2)} \end{bmatrix}\begin{bmatrix} u_m^{(1)} \\ u_m^{(2)} \end{bmatrix}=\begin{bmatrix} [I-V_m^{(1,1)}]^{-1}f^{(1)} \\ f^{(2)} \end{bmatrix}. \tag{4.9}$$

Denote these symbolically by

$$(I-\mathscr{L})\mathbf{u}=\mathbf{z}, \tag{4.10}$$

$$(I-\mathscr{L}_m)\mathbf{u}_m=\mathbf{z}_m, \tag{4.11}$$

respectively. (Note: This $\mathscr{L}$ is not the same as that used in (1.13) of § 1 nor in §§ 2 and 3.) Using the uniform boundedness of $[I-V_m^{(1,1)}]^{-1}$, together with Theorem 3 for the original equation (4.1), we have that $(I-\mathscr{L}_m)^{-1}$ is uniformly bounded for all sufficiently large m.

Apply the iteration method (1.17a-e) to (4.9). The steps for solving (4.1) are as follows: (1) Calculate the matrix associated with $I-\mathscr{L}_n$ and its LU factorization, for some $n<m$. (2) Calculate the matrix associated with $I-V_m^{(1,1)}$ and its LU factorization; modify the right-hand side to form $z_m^{(1)}=[I-V_m^{(1,1)}]^{-1}f^{(1)}$. (3) Given an initial guess $\mathbf{u}_m^{(0)}$ for the solution to (4.9), perform the following iteration:

$$\begin{gathered} \mathbf{d}_m^{(j)}=\mathbf{z}_m-(I-\mathscr{L}_m)\mathbf{u}_m^{(j)}, \\ \delta_n^{(j)}=(I-\mathscr{L}_n)^{-1}\mathscr{L}_m\mathbf{d}_m^{(j)}, \\ \mathbf{u}_m^{(j+1)}=\mathbf{u}_m^{(j)}+\mathbf{d}_m^{(j)}+\delta_n^{(j)} \end{gathered} \tag{4.12}$$

for $j=0,1,\cdots$. The calculation of $\mathbf{d}_m^{(j)}$ and $\mathscr{L}_m\mathbf{d}_m^{(j)}$ uses the LU factorization of $I-V_m^{(1,1)}$ obtained earlier.

THEOREM 5. *Assume the existence and uniform boundedness of* $[I-\mathscr{L}_m]^{-1}$ *for all sufficiently large* m, *say,* $m \geqq N$. *Then the iteration method* (4.12) *will converge if* n *is chosen sufficiently large, uniformly for* $m>n$. *Moreover,*

$$\|\mathbf{u}_m-\mathbf{u}_m^{(j+1)}\| \leqq c\lambda_n \|\mathbf{u}_m-\mathbf{u}_m^{(j)}\|, \qquad j \geqq 0, \tag{4.13}$$

where λ_n *is defined below in* (4.15) *and*

$$c=\operatorname*{Sup}_{m \geqq N} \|[I-\mathscr{L}_m]^{-1}\|.$$

Proof. As in (1.18), we have the identity

$$\begin{aligned} \mathbf{u}_m-\mathbf{u}_m^{(j+1)} &= M_{n,m}[\mathbf{u}_m-\mathbf{u}_m^{(j)}], \qquad j \geqq 0, \\ M_{n,m} &= [I-\mathscr{L}_m]^{-1}[\mathscr{L}_m-\mathscr{L}_n]\mathscr{L}_m. \end{aligned} \tag{4.14}$$

To obtain convergence of $\{\mathbf{u}_m^{(j)} \mid j \geqq 0\}$, we show

$$\lambda_n \equiv \operatorname*{Sup}_{m>n} \|[\mathscr{L}_m-\mathscr{L}_n]\mathscr{L}_m\| \to 0 \tag{4.15}$$

as $n \to \infty$.

We begin by showing that the set $\{\mathscr{L}_m\}$ is collectively compact on the Banach space $\mathscr{X}$. To prove this is relatively straightforward. First, the families of operators $\{V_m^{(i,j)} \mid m \geqq 1\}$ are collectively compact for $(i,j) \neq (1,1)$. Second, the operators $[I-V_m^{(1,1)}]^{-1}$ are uniformly bounded on $C_0(\Gamma_1)$, for all large m. If these results are combined with the definition of $\mathscr{L}_m$ given in (4.9), then the desired collective compactness of $\{\mathscr{L}_m\}$ follows.

Next we show that $[\mathscr{L}_m-\mathscr{L}_n]\mathbf{v} \to 0$ as $m, n \to \infty$, for all $\mathbf{v} \in \mathscr{X}$. From the definition in (4.9),

$$\mathscr{L}_m-\mathscr{L}_n=\begin{bmatrix} 0 & [I-V_m^{(1,1)}]^{-1}V^{(1,2)}-[I-V_n^{(1,1)}]^{-1}V_n^{(1,2)} \\ -V_m^{(2,1)}+V_n^{(2,1)} & -V_m^{(2,2)}+V_n^{(2,2)} \end{bmatrix}.$$

The uniform convergence of

$$[-V_m^{(2,j)}+V_n^{(2,j)}]v^{(j)} \to 0 \quad \text{as } n, m \to \infty, \qquad j=1,2, \tag{4.16}$$

is straightforward based on the convergence of the quadrature method in (1.7) for all continuous integrands. For the remaining element, in the $(1,2)$ position of $\mathscr{L}_m-\mathscr{L}_n$, write

$$\begin{aligned} &\{[I-V_m^{(1,1)}]^{-1}V_m^{(1,2)}-[I-V_n^{(1,1)}]^{-1}V_n^{(1,2)}\}v^{(2)} \\ &\quad=\{[I-V_m^{(1,1)}]^{-1}V_m^{(1,2)}-[I-V^{(1,1)}]^{-1}V^{(1,2)}\}v^{(2)} \\ &\qquad+\{[I-V^{(1,1)}]^{-1}V^{(1,2)}-[I-V_n^{(1,1)}]^{-1}V_n^{(1,2)}\}v^{(2)}. \end{aligned} \tag{4.17}$$

For either of these expressions, say the one depending on m, we further decompose it as

$$\begin{aligned} &[I-V_m^{(1,1)}]^{-1}[V_m^{(1,1)}-V^{(1,1)}][I-V^{(1,1)}]^{-1}V^{(1,2)}v^{(2)} \\ &\quad+[I-V_m^{(1,1)}]^{-1}\{V_m^{(1,2)}-V^{(1,2)}\}v^{(2)}. \end{aligned} \tag{4.18}$$

For the first term, note that $V^{(1,2)}v^{(2)}$ is in $C_0(\Gamma_1)$; consequently, the term $[I-V^{(1,1)}]^{-1}V^{(1,2)}v^{(2)}$ can be shown to satisfy the estimate (2.10) near the corner. Then following Lemma 1(ii), the first term in (4.18) converges to zero as $n \to \infty$. The second term converges to zero since $V_m^{(1,2)}$, converges pointwise to the smoothing compact operator $V^{(1,2)}$. Combining with (4.16), we have $[\mathscr{L}_m-\mathscr{L}_n]\mathbf{v} \to 0$ as $m, n \to \infty$, for all $\mathbf{v} \in \mathscr{X}$.

To show (4.15) follows by standard arguments from the theory of collectively compact operator approximations. For example, see Atkinson (1976, p. 97). Combining this with (4.14) shows (4.13). □

We have actually implemented a variation on the above iteration, using the framework of prolongation and restriction operators to define the passage between functions defined on the coarse grid and on the fine grid. Collocate (4.7) at all nonzero points $\mathbf{x}_{ij}$. This yields the linear system

$$(4.19) \qquad (I-\hat{\mathscr{V}}_m)\hat{\mathbf{u}}_m=\hat{\mathbf{f}}, \qquad \hat{\mathbf{u}}_m, \hat{\mathbf{f}}\in\mathbb{R}^D$$

with $D=D_m$ the number of nonzero quadrature points. The matrix equation is

$$(4.20) \qquad \begin{bmatrix} I-\hat{V}_m^{(1,1)} & -\hat{V}_m^{(1,2)} \\ -\hat{V}_m^{(2,1)} & I-\hat{V}_m^{(2,2)} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}^{(1)} \\ \hat{\mathbf{u}}^{(2)} \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{f}}^{(1)} \\ \hat{\mathbf{f}}^{(2)} \end{bmatrix}.$$

Here

$$\hat{\mathbf{f}}=\begin{bmatrix} \hat{\mathbf{f}}^{(1)} \\ \hat{\mathbf{f}}^{(1)} \end{bmatrix}$$

denotes the values of f at the quadrature points. Similarly, $\hat{\mathscr{V}}_m$ is the matrix based on regarding $\mathscr{V}_m$ as an operator from $\mathbb{R}^D$ to $\mathbb{R}^D$. Let $\hat{\mathbf{f}}^{(1)}$ denote the restriction to $x_{ij}\in\Gamma_1$ of the function $\mathbf{f}^{(1)}$, and similarly for $\hat{\mathbf{f}}^{(2)}$. Let $D^{(1)}$ and $D^{(2)}$ denote the respective orders of the vectors $\hat{\mathbf{f}}^{(1)}$ and $\hat{\mathbf{f}}^{(2)}$. If in (1.6) the points η_j all lie in $0<\eta<1$, then $D^{(1)}=2j^*(m)r$, $D^{(2)}=2(m-j^*(m))r$, and $D=D^{(1)}+D^{(2)}$.

Define the *prolongation* operator $P_{nm}:\mathbb{R}^{D_n}\to\mathbb{R}^{D_m}$ by using piecewise polynomial interpolation of degree $2r-1$. For $\mathbf{v}\in\mathbb{R}^{D_n}$, let $P_{nm}\mathbf{v}$ be the values at $\{\mathbf{x}_{ij}^{(m)}\}$ of the piecewise polynomial interpolate of degree $2r-1$, interpolating the given values in $\mathbf{v}$ at the abscissae $\{\mathbf{x}_{ij}^{(n)}\}$. Define the *restriction* operator $R_{mn}:\mathbb{R}^{D_m}\to\mathbb{R}^{D_n}$ similarly. For $\mathbf{v}\in\mathbb{R}^{D_m}$, let $R_{mn}\mathbf{v}$ be the values at $\{\mathbf{x}_{ij}^{(n)}\}$ of the piecewise polynomial interpolate of degree $2r-1$, interpolating the given values in $\mathbf{v}$ at the abscissae $\{\mathbf{x}_{ij}^{(m)}\}$. In the case $\{\mathbf{x}_{ij}^{(n)}\}\subset\{\mathbf{x}_{ij}^{(m)}\}$, $R_{mn}\mathbf{v}$ is simply the restriction of $\mathbf{v}$ to those components corresponding to nodes $\mathbf{x}_{ij}^{(n)}$.

In analogy with (4.9), transform (4.20) to the equivalent equation

$$(4.21) \qquad \begin{bmatrix} I & -[I-\hat{V}_m^{(1,1)}]^{-1}\hat{V}_m^{(1,2)} \\ -\hat{V}_m^{(2,1)} & I-\hat{V}_m^{(2,2)} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}_m^{(1)} \\ \hat{\mathbf{u}}_m^{(2)} \end{bmatrix} = \begin{bmatrix} [I-\hat{V}_m^{(1,1)}]^{-1}\hat{\mathbf{f}}^{(1)} \\ \hat{\mathbf{f}}^{(2)} \end{bmatrix}$$

which contains the exact solution of the discrete equation in a neighborhood of the corner. Denote this equation by

$$(4.22) \qquad (I-\hat{\mathscr{L}}_m)\hat{\mathbf{u}}_m=\hat{\mathbf{z}}_m.$$

We define the iteration in analogy with (4.12), but we use the prolongation-restriction operator framework to move between the coarse and fine grids, rather than the Nyström interpolation used in (4.12). Define

$$(4.23) \qquad \begin{aligned} \hat{\mathbf{d}}_m^{(j)} &= \hat{\mathbf{z}}_m-(I-\hat{\mathscr{L}}_m)\hat{\mathbf{u}}_m^{(j)}, \\ \hat{\delta}_n^{(j)} &= P_{nm}(I-\hat{\mathscr{L}}_n)^{-1}R_{mn}\hat{\mathscr{L}}_m\hat{\mathbf{d}}_m^{(j)}, \\ \hat{\mathbf{u}}_m^{(j+1)} &= \hat{\mathbf{u}}_m^{(j)}+\hat{\mathbf{d}}_m^{(j)}+\hat{\delta}_n^{(j)} \end{aligned}$$

for $j=0, 1, \cdots$. This requires the exact solution of the linear systems with coefficient matrices $I-\hat{\mathscr{L}}_n$ and $I-\hat{V}_m^{(1,1)}$, of orders D_n and $D_m^{(1)}$, respectively.

For convergence, we use

$$\hat{\mathbf{u}}_m - \hat{\mathbf{u}}_m^{(j+1)} = \hat{M}_{nm}[\hat{\mathbf{u}}_m - \hat{\mathbf{u}}_m^{(j)}], \qquad j \geqq 0,$$
$$\hat{M}_{nm} = [I - P_{nm}(I - \hat{\mathscr{L}}_n)^{-1} R_{mn}(I - \hat{\mathscr{L}}_m)]\hat{\mathscr{L}}_m.$$

Then by an argument similar to that of Theorem 5,

$$\operatorname*{Sup}_{m>n} \|\hat{M}_{nm}\| \to 0 \quad \text{as } n \to \infty.$$

The matrix norm is the row norm, the operator norm induced by $\|\cdot\|_\infty$ on $\mathbb{R}^D$.

4.1. Numerical Experiment 3. Let Γ be the curve

$$\mathbf{x}(s) = \sin\left(\frac{\pi s}{\theta}\right)(\cos s, \sin s), \qquad 0 \leqq s \leqq \theta,$$

with $0 < \theta < \pi$ given. Then Γ has an interior angle of θ at the corner $\mathbf{0}$, and $\chi_0 = 1 - (\theta/\pi)$. (We refer to Γ as having a "teardrop" shape.) As earlier in Numerical Experiment 1, consider solving the interior Dirichlet problem

$$\begin{aligned} &\Delta U(\mathbf{x}) = 0, \qquad \mathbf{x} \in D, \\ &U(\mathbf{x}) = r^\beta \cos(\beta s), \qquad \mathbf{x} \in \Gamma = \partial D \end{aligned} \tag{4.24}$$

with $\mathbf{x} = (r \cos s,\ r \sin s)$ and $\beta = 2/\pi$. This is chosen to exhibit the behavior of the method of GC and the iteration method for a fairly ill behaved problem.

As before, we use the double layer representation

$$U(\mathbf{x}) = \int_\Gamma G'(\mathbf{x}, \xi) u(\xi)\, d\Gamma, \qquad \mathbf{x} \in D$$

with u found by solving (1.2). Having found $u_m \doteq u$, we evaluate the resulting potential $U_m \doteq U$ in the equivalent form

$$U_m(\mathbf{x}) = \int_\Gamma G'(\mathbf{x}, \xi)\tilde{u}_m(\xi)\, d\Gamma - u_m(\mathbf{0}). \tag{4.25}$$

Because the region D is convex, we can show the potential U_m satisfies the error bound

$$|U(\mathbf{x}) - U_m(\mathbf{x})| \leqq \|u - u_m\|_\infty, \qquad \mathbf{x} \in D. \tag{4.26}$$

The quantity $\|u - u_m\|_\infty$ can usually be estimated while solving for u_m, for example, by using Richardson's error estimation formula.

To solve the integral equation (1.2), we use the two-point Gauss-Legendre formula in (1.6), with $r = 2$. Then the number of integration nodes $\{\mathbf{x}_{ij}^{(n)}\}$ is $4n$, and we use these nodes in defining the numerical integral operator W_n in (1.7). We also take $i^* = 0$ in all cases, because empirically this has been completely satisfactory for all angles considered. (There are integration formulas (1.7) for which there are angles θ where $i^* > 0$ is necessary.)

To evaluate $U_m(\mathbf{x})$, we must use an additional numerical integration. Let $U_{m,r}(\mathbf{x})$ denote the numerical evaluation of $U_m(\mathbf{x})$ using an r-point Gauss-Legendre quadrature formula on each $[\mathbf{x}_{j-1}, \mathbf{x}_j]$ of Γ (or, more precisely, on each subinterval $[s_{j-1}, s_j]$ of $[0, 1]$). When $r = 2$, we use the density $\tilde{u}_m(\mathbf{x})$ at the integration nodes $\{\mathbf{x}_{ij}^{(m)}\}$, and these were the values of $\tilde{u}_m$ obtained in solving (4.1). For $r > 2$, we obtain the needed new integration node points by using Nyström interpolation, namely,

$$\tilde{u}_m(\mathbf{x}) = -2g(\mathbf{x}) + V_m\tilde{u}_m(\mathbf{x}). \tag{4.27}$$

The total error in approximating $U(\mathbf{x})$ is given by

$$(4.28)\qquad \begin{aligned} |U(\mathbf{x})-U_{m,r}(\mathbf{x})| &\leqq |U(\mathbf{x})-U_m(\mathbf{x})|+|U_m(\mathbf{x})-U_{m,r}(\mathbf{x})| \\ &\leqq \|u-u_m\|_\infty+|U_m(\mathbf{x})-U_{m,r}(\mathbf{x})|. \end{aligned}$$

As $r\to\infty$, $U_{m,r}(\mathbf{x})\to U_m(\mathbf{x})$. But for $\mathbf{x}$ near to Γ, the integrand $G'(\mathbf{x},\xi)$ in (4.25) is very peaked, and thus r will probably need to be quite large to make $|U_m(\mathbf{x})-U_{m,r}(\mathbf{x})|$ less significant than $\|u-u_m\|_\infty$.

Using the convergence theory from GC and that given earlier in Theorem 3, we have that

$$\|u-u_m\|_\infty=O(m^{-4}),$$

provided

$$(4.29)\qquad q>\frac{4}{\alpha},\qquad \alpha=\operatorname{Min}\{\beta,1/(1+\chi_0)\}.$$

As was noted earlier in Numerical Experiment 1, we obtain the order of convergence $O(m^{-4})$ with smaller values of q. We give results for several values of q. Rather than study the speed of convergence of $\{u_m\}$, we use points chosen along the axis of symmetry of D; in particular, take

$$\mathbf{x}=\mathbf{z}_j=\gamma_j\mathbf{x}(\theta/2),$$
$$\gamma_j=0.001,0.01,0.1,0.5,0.75,0.9,0.99$$

for $j=1,\cdots,7$. $\mathbf{z}_1$ is very close to the corner Γ at $\mathbf{0}$, and $\mathbf{z}_7$ is close to the part of Γ furthest from $\mathbf{0}$.

Tables 3, 4, and 5 show the errors in $U_{m,2}$ for $\theta=\pi/5$, for increasing values of m. (Recall that the number of equations being solved is $4m$.) Condition (4.29) says that

$q>7.2$ will yield $O(m^{-4})$ convergence in approximating $U(\mathbf{x})$ with $U_{m,2}(\mathbf{x})$. Empirically, much smaller values of q are sufficient. In the tables,

$$E_m \equiv U(\mathbf{z}_j) - U_{m,r}(\mathbf{z}_j).$$

All of the numerical calculations of this section were carried out on a microcomputer with an 80286/287 microprocessor and a standard sized memory of 640K bytes.

To show the effect of using a more accurate integration in evaluating the potential U_m of (4.25), we calculate $U_{m,10}(\mathbf{x})$ for $q=2$. The results are shown in Table 5. For points $\mathbf{z}_j$ away from the boundary Γ, the error $|U_m(\mathbf{z}_j) - U_{m,10}(\mathbf{z}_j)|$ is less than $|U(\mathbf{z}_j) - U_m(\mathbf{z}_j)|$; thus the ratios in Table 5 are indicative of the rate of convergence of $U_m(\mathbf{z}_j)$ to $U(\mathbf{z}_j)$. Empirically, this rate is about $O(m^{-3.3})$. More importantly, considerable additional accuracy in the approximation of $U(\mathbf{x})$ is obtained by simply using a more accurate integration formula. Comparing Tables 3 and 5, we have obtained much more accuracy at most points in D without needing to solve a larger linear system of equations. The results in Table 5 also show that a larger grading parameter q is needed to increase the accuracy of the approximate solution $U_m(\mathbf{x})$ for $\mathbf{x}$ near $\mathbf{0}$. In fact, $q=4$ gives much better results around $\mathbf{0}$, while slightly increasing the error around $\mathbf{z}_7$ at the portion of Γ opposite the corner $\mathbf{0}$.

We study the iteration method (4.23) for solving the linear system (4.19) arising in solving (4.24). Results have been obtained for a variety of values of q, (n, m), θ, and Dirichlet data g. The results given here illustrate that for fixed cutoff parameter δ, the iteration method converges geometrically and

$$\operatorname*{Limit}_{m,n\to\infty} \|\hat{M}_{n,m}\| = 0.$$

In Tables 6 and 7, we give the empirical rate of convergence

$$\Delta_{n,m} \equiv \operatorname*{Limit}_{j\to\infty} \frac{\|\hat{\mathbf{u}}_m^{(j)} - \hat{\mathbf{u}}_m^{(j-1)}\|_\infty}{\|\hat{\mathbf{u}}_m^{(j-1)} - \hat{\mathbf{u}}_m^{(j-2)}\|_\infty}, \tag{4.30}$$

if it exists. For cases where this limit was not evident after $\hat{\mathbf{u}}_m$ was obtained to machine precision (about 16 decimal digits), we give the geometric mean of the last several ratios in (4.30), indicating such entries in the table by *. For the corner portion Γ_1 of Γ, we give $j^*(m)$; also given is $2\delta/\theta$, the fraction of the parameterization interval $[0, \theta]$ that is associated with Γ_1. The order of the linear systems associated with $n, m, j^*(m)$ are, respectively, $4n$, $4m$, and $4j^*(m)$.

As shown in Tables 6 and 7, the rate of convergence can be improved by increasing n while keeping δ fixed (e.g., in Table 7, see $(n, m, j^*(m)) = (8, 32, 4)$ and $(16, 32, 4)$ for $q=3$). The results in both tables illustrate that the size of δ can be quite small

* Geometric mean of the last several ratios in (4.30).

while still obtaining an acceptable rate of convergence $\Delta_{n,m}$. This is important from a practical view, to keep down the order $4j^*(m)$ of the "corner matrix" $I-\hat{V}_m^{(1,1}$, since linear systems with this matrix must be solved exactly, twice in every iteration of (4.23). The rates for $\theta=\pi/5$ are worse than for $\theta=\pi/2$, but are still generally acceptable.

4.2. Storage considerations. In carrying out the iteration (4.23), many evaluations of the kernel of the double layer integral operator W are needed. For example, with $m=128$, the linear system (4.1) being solved is of order 512. Thus there are 512^2 kernel evaluations needed to define the matrix of coefficients. These kernel evaluations should be calculated during only the first loop in (4.23) and then re-used in subsequent loops. With many machines, there is insufficient main memory to store these coefficients, and thus they must be stored on disk.

To avoid having a complicated algorithm to remember the origin of the various quantities that are loop independent, we have created two simple Fortran subroutines STORE and LOAD to use in storing these quantities onto a disk and then retrieving them. A buffer is set up in STORE. In the main iteration program, each time in loop 1 that a quantity is calculated that is loop independent, we call STORE to save it. In subsequent loops, we use LOAD to retrieve these quantities in the same order that they were stored, again using a buffer. In the subroutine STORE, as soon as the buffer fills, it is dumped in "free format" to a disk and the buffer is initialized to being empty again. The main program need not have knowledge of the size of the buffer nor of when the subroutines STORE and LOAD are using the disk. We have found that the cost in time of the first loop is from 10 to 20 times that of subsequent loops, and the savings after the first loop are due entirely to the storing of the quantities that are loop independent.

Appendix. We sketch proofs of the inequalities (2.12) and (2.13), with $\mathscr{K}$ replaced by $\mathscr{N}$. Recall that the double layer integral operator $2W$ can be decomposed as

$$2W=\mathscr{K}+\mathscr{N},$$

where $\mathscr{K}$ is the double layer operator on an open wedge and N is a compact remainder. The operator $\mathscr{K}$ is defined in (2.2) and in the following. Let $K(s,\sigma)$ and $N(s,\sigma)$ denote the kernel functions of $\mathscr{K}$ and $\mathscr{N}$, respectively. We must show that for $k\geqq 0$,

$$|s^kD_s^k(\mathscr{N}_{i^*,n}v)(\mathbf{x}(s))|\leqq A_k'\|v\|_\infty,\qquad s\in[-1,1]\backslash\{0\},\tag{A.1}$$

$$|\sigma^{k+1}D_\sigma^k(N(s,\sigma))|\leqq B_k',\qquad s,\sigma\in[-1,1]\backslash\{0\},\tag{A.2}$$

for some constants A_k', B_k'.

We first note that if $-1\leqq s$, $\sigma<0$ (or $0<s$, $\sigma\leqq 1$), then the function $K(s,\sigma)\equiv 0$ and the function $N(s,\sigma)$ are the standard double layer potential functions one obtains for a smooth boundary. Thus the above inequalities are satisfied easily. From here on, we are interested in the case $-1\leqq s<0<\sigma\leqq 1$ (and the analogous case $-1\leqq\sigma<0<s\leqq 1$). We assume $-2W$ is defined on an open curved wedge Γ of the type pictured in Fig. 4. For simplicity, we assume Γ has a C^∞ parameterization on both arms of the wedge, with the origin $\mathbf{0}$ the sole point at which the tangent does not exist. (For the case of Γ a closed contour, the operator $-2W$ can be decomposed as two operators, as in § 4, with one operator the double layer integral operator on an open wedge and the second operator a smoothing compact integral operator.) Let Γ be as pictured in Fig. 4, with one arm tangent to the positive x-axis, the vertex of Γ at the origin, and the second arm making an angle of $\theta=(1-\chi)\pi$ with the positive x-axis. We let Γ' denote the wedge with linear arms, tangent to Γ; the lengths of the arms of Γ' are to

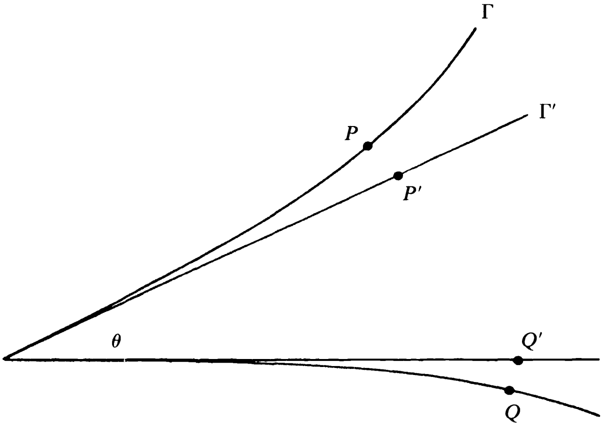

FIG. 4. *Corner region with tangent wedge.*

be the same as the corresponding arms of Γ. We are interested in the double layer integral operator defined on Γ with the kernel function

$$V(P, Q) = \frac{1}{\pi}\mathbf{n}_Q \cdot \frac{Q-P}{|Q-P|^2}. \tag{A.3}$$

In line with the earlier restriction $-1 \leqq s < 0 < \sigma \leqq 1$, the points P and Q are to be on different arms of the wedge Γ, as pictured in Fig. 4.

To obtain $N(s, \sigma)$, we need the parametric representation of Γ in terms of arc length. The lower and upper arms of the tangent wedge Γ′ are given by

$$Q' = (\sigma, 0), \qquad 0 \leqq \sigma \leqq 1,$$
$$P' = (s \cos\theta, s \sin\theta), \qquad 0 \leqq s \leqq 1.$$

Here σ and s denote arc length along Γ′, measured from (0, 0); for convenience, we let σ and s both vary over [0, 1]. For the parameterization of Γ, the use of arc length σ and s leads to

$$\begin{aligned} Q &= (\sigma + \sigma^3 c(\sigma), \sigma^2 b(\sigma)), && 0 \leqq \sigma \leqq 1, \\ P &= (s\cos\theta + s^2 a(s), s\sin\theta + s^2 d(s)), && 0 \leqq s \leqq 1 \end{aligned} \tag{A.4}$$

with $a, b, c, d \in C^\infty[0, 1]$. The arc length parameterization also imposes other consistency restrictions on these functions, for example,

$$6c(0) + 4b(0)^2 = 0.$$

But such conditions are not needed in our derivations. The normal to Γ at Q is given by

$$\mathbf{n}_Q = (2\sigma b + \sigma^2 b', -1 - 3t^2 c - t^3 c').$$

We can now give an explicit formula for the function $V(s, \sigma) \equiv V(P, Q)$ of (A.3). The formula is algebraically complicated, and for that reason we consider here only the right angle case $\theta = \pi/2$. The techniques used and results obtained will generalize to the case of a general angle θ, $0 < \theta < 2\pi$.

With $\theta = \pi/2$, the kernel function V of (A.3) becomes

$$V(s, \sigma) = \frac{1}{\pi}\frac{(2b\sigma + \sigma^2 b')(\sigma + \sigma^3 c - s^2 a) - (1 + 3c\sigma^2 + \sigma^3 c')(\sigma^2 b - s - s^2 d)}{[\sigma + \sigma^3 c - s^2 a]^2 + [s + s^2 d - \sigma^2 b]^2}. \tag{A.5}$$

Note that from the definition (A.3), the denominator of (A.5) is zero if and only if $P=Q=0$, or equivalently, $s=\sigma=0$. Also, from (2.3),

$$K(s,\sigma)=\frac{1}{\pi}\frac{s}{s^2+\sigma^2}.$$

Subtracting $N=V-K$, we obtain

$$\text{(A.6)} \qquad N(s,\sigma)=\frac{\alpha(s,\sigma)}{\beta(s,\sigma)}=\frac{\alpha(s,\sigma)}{|P'-Q'|^2|P-Q|^2}.$$

The denominator

$$\beta(s,\sigma)=\{[\sigma+\sigma^3c-s^2a]^2+[s+s^2d-\sigma^2b]^2\}\{s^2+\sigma^2\}$$

is a "polynomial" in s,σ of degree 4 exactly, and it is zero if and only if $P=Q=0$. The numerator $\alpha(s,\sigma)$ is a "polynomial" in s,σ and all of its terms are of degree $\geqq 4$. Both of these polynomials have coefficients that contain the C^∞ functions a, b, c, d, c', d', but their presence will not affect the validity of the following arguments, since we will be assuming s and σ are sufficiently close to zero. Then, for example,

$$\beta \doteq [s^2+\sigma^2]^2.$$

Because the numerator and denominator are C^∞ functions for $0<s,\sigma\leqq 1$, and because the denominator is zero only when $s=\sigma=0$, we can check the boundedness of $N(s,\sigma)$ and its derivatives by considering only a neighborhood in (s,σ) about $(0,0)$. For example, $N(s,\sigma)$ is easily shown to be bounded for (s,σ) near $(0,0)$ by using Taylor's theorem and the inequalities

$$\text{(A.7)} \qquad \frac{s^2}{s^2+\sigma^2}\leqq 1, \quad \frac{\sigma^2}{s^2+\sigma^2}\leqq 1, \quad \frac{s\sigma}{s^2+\sigma^2}\leqq\frac{1}{2}.$$

We first show (A.2). Introduce

$$N^{(k)}(s,\sigma)=\sigma D_\sigma N^{(k-1)}(s,\sigma), \qquad k\geqq 1,$$
$$N^{(0)}(s,\sigma)=\sigma N(s,\sigma).$$

The proof of (A.2) is equivalent to showing

$$\text{(A.8)} \qquad |N^{(k)}(s,\sigma)|\leqq c_k, \quad 0<s,\sigma\leqq 1, \quad k\geqq 0.$$

The proof for $k=0$ was described in the preceding paragraph; we can write

$$N^{(0)}(s,\sigma)=\frac{\sigma\alpha(s,\sigma)}{\beta(s,\sigma)}\equiv\frac{\gamma(s,\sigma)}{\beta(s,\sigma)}.$$

All terms in the numerator γ have degree $\geqq 5$. For $k=1$,

$$N^{(1)}(s,\sigma)=\sigma D_\sigma(\gamma/\beta)=\frac{\sigma[\gamma'\beta-\gamma\beta']}{\beta^2}.$$

This fraction has the same form as previously, but now the denominator is β^2 rather than β. All terms in the numerator have degree one greater (or more) than that of the denominator. As a consequence, we can again easily show $N^{(1)}(s,\sigma)$ is uniformly bounded for (s,σ) near $(0,0)$. This form of argument can be continued inductively to show (A.8) for all k.

For showing (A.1), we first refer the reader to the corresponding proof of (2.12) in (GC, Lemma 2(ii)). Using that proof to show (A.1), it is sufficient to show

$$\text{(A.9)} \qquad |s^k D_s^k N(s,\sigma)| \leqq c_k, \qquad 0 < s, \sigma \leqq 1, k \geqq 0.$$

Equivalently, show

$$\text{(A.10)} \qquad |N_k(s,\sigma)| \leqq d_k, \qquad 0 < s, \sigma \leqq 1, \quad k \geqq 0,$$

where

$$N_0(s,\sigma) = N(s,\sigma), \qquad N_k(s,\sigma) = sD_s N_{k-1}(s,\sigma), \quad k \geqq 1.$$

The proof of (A.10) when $k = 0$ has been given previously. The cases $k \geqq 1$ are essentially the same as for (A.8). The only major difference is that all terms in the numerator will have degree greater than or equal to the degree of the denominator, but this is still sufficient for the proof of boundedness. This completes the proof.

Acknowledgments. We wish to thank everyone at the Department of Mathematics, University of Queensland, Queensland, Australia, for their hospitality during our visit, especially Graeme Chandler.

MODIFICATION OF THE HOUSEHOLDER METHOD BASED ON THE COMPACT WY REPRESENTATION*

CHIARA PUGLISI†

Abstract. This paper presents a modification of the block Householder method based on the compact **WY** representation [R. Schreiber and C. Van Loan, *SIAM J. Sci. Statist. Comput.*, 10 (1989), pp. 52-57]. It is modified in order to introduce more matrix-matrix operations.

Key words. Householder method, compact **WY** representation, matrix-matrix multiplication, Level 3 BLAS

AMS(MOS) subject classification. 65F

1. Introduction. The Householder method for factorizing an $m \times n$ matrix $\mathbf{A}$, $n \leqq m$, consists of building n Householder matrices $\mathbf{H}_i = (\mathbf{I} - (2/\mathbf{u}_i^T\mathbf{u}_i)\mathbf{u}_i\mathbf{u}_i^T)$ so that if

$$\mathbf{Q} = \mathbf{H}_n\mathbf{H}_{n-1} \cdots \mathbf{H}_1, \tag{1.1}$$

and $\mathbf{QA} = \mathbf{R}$, then $\mathbf{R}$ is upper triangular. The Householder matrices are orthogonal and so it follows that $\mathbf{Q}$ is orthogonal. We are interested in "Householder methods" using as many matrix-matrix operations as possible in order to increase the efficiency of the algorithm on vector and parallel machines (see [2]). Some block techniques have been studied by Schreiber and Van Loan [3], all of them using a block representation of the matrix $\mathbf{Q}$. We study one of them, the so-called compact **WY** representation (also used in the new LAPACK [1]) and modify it to introduce more matrix-matrix operations. We describe the **WY** representation in § 2 and our modified version in § 3. We show the results of some numerical experiments in § 4.

2. The compact WY representation. A generic Householder matrix $\mathbf{H}_i = (\mathbf{I} - (2/\mathbf{u}_i^T\mathbf{u}_i)\mathbf{u}_i\mathbf{u}_i^T)$ can also be written as

$$\mathbf{H}_i = \mathbf{I} - \mathbf{w}_i\mathbf{w}_i^T, \tag{2.1}$$

where

$$\|\mathbf{w}_i\|_2 = \sqrt{2}. \tag{2.2}$$

In the compact **WY** representation $\mathbf{Q}$ is written as

$$\mathbf{Q} = \mathbf{I} - \mathbf{YTY}^T, \tag{2.3}$$

where $\mathbf{Y}$ is a rectangular $m \times n$ matrix, and each of its columns is a Householder vector $\mathbf{w}_i$, and $\mathbf{T}$ is a lower unit triangular matrix. For the proof, we refer to Schreiber and Van Loan [3] noticing that they proved (2.3) for $\mathbf{Q}^T$ using Householder matrices of the type $\mathbf{I} - 2\mathbf{v}_i\mathbf{v}_i^T(\|\mathbf{v}_i\|_2 = 1)$.

The algorithm for computing $\mathbf{T}$ is the following:

$$\mathbf{T}_1 = 1, \qquad \mathbf{T}_i = \begin{bmatrix} \mathbf{T}_{i-1} & 0 \\ \mathbf{z}_i & 1 \end{bmatrix}, \tag{2.4}$$

where $\mathbf{z}_i = \mathbf{w}_i^T\mathbf{Y}_{i-1}\mathbf{T}_{i-1}$.

Suppose $n = rN$; then, using the compact **WY** representation, we have the following block algorithm (these are the basic steps of the algorithm of the new LAPACK).

```
ALGORITHM 1.
for $k = 1, N$
  for $s = 1, r$
    1. $i = (k-1)r + s$
    2. compute $\mathbf{w}_i$
    3. if $s = 1$ then $\mathbf{Y}_i = \mathbf{w}_i$
         else $\mathbf{Y}_i = [\mathbf{Y}_{i-1}\mathbf{w}_i]$
       endif
    4. $\mathbf{A}(i\colon m;\ i+1\colon kr) = (\mathbf{I} - \mathbf{w}_i\mathbf{w}_i^T)\mathbf{A}(i\colon m;\ i+1\colon kr)$
  endfor
  if $k < N$ then
    5. compute $\mathbf{T}_k$
    6. $j = kr+1$; $\mathbf{A}((k-1)r+1\colon m; j\colon n) = (\mathbf{I} - \mathbf{Y}_{kr}\mathbf{T}_k\mathbf{Y}_{kr}^T)\mathbf{A}((k-1)r+1\colon m; j\colon n)$
  endif
endfor
```

$\mathbf{A}(a\colon b;\ c\colon d)$ means the block of $\mathbf{A}$ with rows from a to b and columns from c to d.

Step 5 of the algorithm involves a for-loop over i, $i = (k-1)r + 1, kr$, and each iteration in the loop involves two matrix-vector operations:

$$\mathbf{x}_i^T = \mathbf{w}_i^T\mathbf{Y}_{i-1} \qquad \text{(DGEMV)},$$

$$\mathbf{z}_i = -\mathbf{x}_i^T\mathbf{T}_{i-1} \qquad \text{(DTRMV)}.$$

Step 6 involves three matrix-matrix operations:

$$\mathbf{B} = \mathbf{Y}_{kr}^T\mathbf{A} \qquad \text{(DGEMM)},$$

$$\mathbf{B} = \mathbf{T}_k\mathbf{B} \qquad \text{(DTRMM)},$$

$$\mathbf{A} = \mathbf{A} - \mathbf{Y}_{kr}\mathbf{B} \qquad \text{(DGEMM)}.$$
