We now modify the algorithm in order to substitute the for-loop with the matrix-vector operations in step 5 with a matrix-matrix operation.

3. The new algorithm. As we mentioned before, the **Q** matrix in (1.1) is orthogonal, that is,

$$\mathbf{Q}^{-1} = \mathbf{Q}^T.$$

In the case of **Q** in compact **WY** representation, this means that

$$\mathbf{Q}^{-1} = (\mathbf{I} - \mathbf{YTY}^T)^T = \mathbf{I} - \mathbf{YT}^T\mathbf{Y}^T. \tag{3.1}$$

Another way to compute the inverse of (2.3) is to use the Woodbury-Morrison formula, which can be expressed as the following: Given

$$\mathbf{A} = \mathbf{B} + \mathbf{UV}^T,$$

where $\mathbf{A}$, $\mathbf{B}$ are invertible $m \times m$ matrices, and $\mathbf{U}$, $\mathbf{V}$ are $m \times p$ matrices, $p < m$, we can compute its inverse by

$$\mathbf{A}^{-1} = \mathbf{B}^{-1} - \mathbf{B}^{-1}\mathbf{U}(\mathbf{I}_p + \mathbf{V}^T\mathbf{B}^{-1}\mathbf{U})^{-1}\mathbf{V}^T\mathbf{B}^{-1}. \tag{3.2}$$

Substituting in (3.2) $\mathbf{B} = \mathbf{I}$, $\mathbf{U} = -\mathbf{Y}$, and $\mathbf{V}^T = \mathbf{T}\mathbf{Y}^T$, we obtain

$$(\mathbf{I} - \mathbf{Y}\mathbf{T}\mathbf{Y}^T)^{-1} = \mathbf{I} + \mathbf{Y}(\mathbf{I}_p - \mathbf{T}\mathbf{Y}^T\mathbf{Y})^{-1}\mathbf{T}\mathbf{Y}^T. \tag{3.3}$$

Comparing (3.1) and (3.3) gives us

$$\mathbf{I} + \mathbf{Y}(\mathbf{I}_p - \mathbf{T}\mathbf{Y}^T\mathbf{Y})^{-1}\mathbf{T}\mathbf{Y}^T = \mathbf{I} - \mathbf{Y}\mathbf{T}^T\mathbf{Y}^T.$$

Postmultiplying by $\mathbf{Y}$ and premultiplying by $\mathbf{Y}^T$ gives us

$$\mathbf{Y}^T\mathbf{Y}(\mathbf{I}_p - \mathbf{T}\mathbf{Y}^T\mathbf{Y})^{-1}\mathbf{T}\mathbf{Y}^T\mathbf{Y} = -\mathbf{Y}^T\mathbf{Y}\mathbf{T}^T\mathbf{Y}^T\mathbf{Y}.$$

Because $\mathbf{Y}^T\mathbf{Y}$ is invertible,

$$\begin{aligned}(\mathbf{I}_p - \mathbf{T}\mathbf{Y}^T\mathbf{Y})^{-1}\mathbf{T} &= -\mathbf{T}^T,\\ (\mathbf{I}_p - \mathbf{T}\mathbf{Y}^T\mathbf{Y}) &= -\mathbf{T}\mathbf{T}^{-T},\\ \mathbf{I}_p &= \mathbf{T}(\mathbf{Y}^T\mathbf{Y} - \mathbf{T}^{-T}),\\ \mathbf{T}^{-1} + \mathbf{T}^{-T} &= \mathbf{Y}^T\mathbf{Y},\end{aligned}$$

so that

$$\mathbf{T}^{-1}(i, i) = \frac{\mathbf{w}_i^T\mathbf{w}_i}{2}, \quad \mathbf{T}^{-1}(i, j) = \mathbf{w}_i^T\mathbf{w}_j, \quad i > j. \tag{3.4}$$

Note also that $\mathbf{w}_i^T\mathbf{w}_i/2 = 1$, $i = 1, \cdots, n$, from (2.2).

Using (3.4), steps 5 and 6 of Algorithm 1 can be modified as follows.

```
5.
  $\mathbf{T}_k^{-1} = \mathbf{Y}_{kr}^T\mathbf{Y}_{kr}$          (DSYRK)
  for $i = 1, r$
    $\mathbf{T}_k^{-1}(i, i) = 1$
  endfor
6.
  $\mathbf{B} = \mathbf{Y}_{kr}^T\mathbf{A}$,            (DGEMM)
  $\mathbf{B} = (\mathbf{T}_k^{-1})^{-1}\mathbf{B}$,       (DTRSM)
  $\mathbf{A} = \mathbf{A} - \mathbf{Y}_{kr}\mathbf{B}$         (DGEMM)
```

Essentially, both algorithms compute the matrix $\mathbf{T}_k^{-1}$, but in the first one we invert the matrix $\mathbf{T}_k^{-1}$ explicitly and then perform a matrix-matrix multiplication; in the second one we solve several triangular systems with $\mathbf{T}_k^{-1}$ as the coefficient matrix. For factorizing an $m \times n$ matrix with blocks of size r, the modified LAPACK algorithm does $(n-r) \times (2m - \frac{3}{2}n + (n^2/3) + 2r - \frac{10}{3})$ operations more than the LAPACK algorithm.

4. Numerical results. We show in Table 1 the time to factorize three matrices with the same algorithm as in LAPACK and the modified LAPACK algorithm with different block sizes. All the experiments have been done on an Alliant FX/80.

As may be noticed, the modified LAPACK algorithm is better than the "LAPACK" algorithm, but not very much so. This reflects the poor performance of the subroutine DSYRK on the target machine.

TABLE 1
Execution time of the two algorithms with different block sizes. A; 1024 × 512, B: 512 × 512, C: 1024 × 1024.

Size of the blocks		LAPACK	Modified LAPACK
16	Matrix A	12.67	11.88
	Matrix B	6.09	5.48
	Matrix C	31.49	29.20
32	Matrix A	11.32	9.98
	Matrix B	5.12	4.62
	Matrix C	28.04	26.34
64	Matrix A	11.64	10.80
	Matrix B	5.02	4.66
	Matrix C	27.16	25.45
128	Matrix A	15.99	15.13
	Matrix B	5.92	5.34
	Matrix C	34.25	32.81

Finally, it can be shown that from the stability point of view, the new algorithm is as stable as the old one. The propagation of the error in the two algorithms is different because in the old one we compute $\mathbf{T}_k$ inverting in place $\mathbf{T}_k^{-1}$ and we successively update by multiplying by $\mathbf{T}_k$, whereas in the new one $\mathbf{T}_k^{-1}$ is stored and we update by solving lower triangular systems, but the final errors are of the same order.

Acknowledgments. I would like to thank Mario Arioli and Iain Duff for supporting me in writing this communication.

SOME APPLICATIONS OF THE RANK REVEALING QR FACTORIZATION*

TONY F. CHAN† AND PER CHRISTIAN HANSEN‡

Abstract. The rank revealing QR factorization of a rectangular matrix can sometimes be used as a reliable and efficient computational alternative to the singular value decomposition for problems that involve rank determination. This is illustrated by showing how the rank revealing QR factorization can be used to compute solutions to rank deficient least squares problems, to perform subset selection, to compute matrix approximations of given rank, and to solve total least squares problems.

Key words. rank revealing QR factorization, numerical rank, rank deficient problems, subset selection, matrix approximation, total least squares

AMS(MOS) subject classifications. 65F25, 65F20

1. Introduction. One of the more intricate problems in numerical linear algebra is to find the numerical rank of a matrix. This computational problem is the heart of many numerical methods, such as subset selection, total least squares, regularization, and matrix approximation. The *singular value decomposition* (SVD) is undoubtedly the most reliable method for computing the numerical rank. A big disadvantage of the SVD is, however, the high computational complexity of the standard SVD algorithm, as compared to a QR factorization, for example, [12, p. 248]. The same is true for SVD algorithms based on Jacobi iteration. SVD algorithms for sparse or structured matrices based on Lanczos iteration are faster, but they have problems with computation of the smallest singular values and, therefore, are not reliable for numerical rank determination.

A number of alternative, less computationally demanding, methods have been proposed. Most of these are based on a QR factorization with column pivoting [4], [18], [19], but the numerical rank computed by these methods is not entirely reliable (see [12, §5.5.7] and [1, §7]), and none of these methods are suited for sparse matrices because of the column pivoting. Similar QR-based methods specially designed for sparse matrices [16], [21], based solely on detecting small elements on the diagonal of the triangular matrix, are not reliable either. Another alternative method, the partial SVD (PSVD) [25], is as reliable as the SVD. However, a complete reduction to bidiagonal form is required, so its complexity is still higher than that of a QR factorization, and it is not well suited to general sparse matrices.

The most promising alternative to the SVD is the *rank revealing* QR *factorization* (RRQR factorization) defined by Chan [6], [7] (we note that similar ideas were proposed independently by Foster [10]). An important existence proof of RRQR factorizations is given in [17]. The RRQR factorization will reveal the numerical rank of any matrix, because it is guaranteed to capture all the small singular values of the matrix by producing reasonably tight upper and lower bounds for these singular

values. In addition, the RRQR algorithm produces a set of linearly independent vectors that span a good approximation to the numerical null-space of the matrix. This information is sufficient to solve many problems in numerical linear algebra.

The computational complexity of the RRQR algorithm is only slightly larger than that of the standard QR algorithm, as long as the nullity is small compared to the dimensions of the matrix. A Fortran implementation of the algorithm is now available from ACM TOMS [22]. Moreover, the RRQR factorization of a sparse matrix can be computed efficiently without destroying the sparsity pattern of the matrix, and Bischof and Hansen [1] have demonstrated how to implement the RRQR factorization algorithm with a minimum of column interchanges. Thus, we feel that the time is ripe for using the RRQR factorization in numerical linear algebra.

Chan and Hansen [8] showed how truncated SVD solutions can be computed efficiently by means of the RRQR factorization, and Hansen, Sekhii, and Shibahashi [15] use RRQR factorizations to regularize discrete ill-posed problems. Comon and Golub [9] use RRQR factorizations in conjunction with Lanczos block-bidiagonalization. Bischof and Shroff [2] have shown how to use the null-space information from an RRQR factorization in conjunction with the "signal subspace" approach to parameter estimation in signal processing. In this paper, we illustrate several other important applications of the RRQR factorization in numerical linear algebra.

Stewart [24] has recently proposed a related factorization, namely, a rank revealing complete orthogonal decomposition, which is particularly suited to "subspace tracking" in signal processing. This factorization is computationally more expensive than the RRQR factorization, but *updating of the null-space* from Stewart's factorization is cheaper than updating the null-space from an RRQR factorization.

Our paper is organized as follows. In §2, we summarize the most important properties of the RRQR factorization. Then, we show how the RRQR factorization can be used in rank deficient least squares problems (§3), in subset selection problems (§4), and in matrix approximations (§5). Finally, we demonstrate in §6 how the RRQR factorization can be used to solve total least squares problems with full rank as well as rank deficient coefficient matrices.

We shall use two-norms almost entirely, so we use the abbreviation $\|\cdot\|$ for $\|\cdot\|_2$. The range (column space) of a matrix is denoted by $\mathcal{R}(\cdot)$. Throughout this paper, in addition to our new results, we include a few results already published in other manuscripts. We feel that the present constellation of this material will provide new insight into the applications and practical use of the RRQR factorization.

2. RRQR factorizations.

Throughout the paper, we assume that the matrix A has been properly scaled, for example, such that the uncertainties in its elements are roughly of the same size [23]. The numerical rank, or *ϵ-rank*, of A with respect to the tolerance ϵ is defined by

$$k = k(A,\epsilon) \equiv \min_{\|A-B\|\leq\epsilon} \operatorname{rank}(B). \tag{1}$$

In other words, the ϵ-rank of A is equal to the number of columns in A that are guaranteed to be linearly independent for any perturbation of A with norm less than or equal to the tolerance ϵ. As a guide to choosing this tolerance, it is customary to let ϵ reflect the uncertainties in A [23]. See also [11] and [12, §2.5.4] for more details.

The most reliable way of computing the ϵ-rank of A is via its SVD. Assume for simplicity that $A \in \Re^{m\times n}$ with $m \geq n$. Then the SVD of A is

$$A = U\Sigma V^T = \sum_{i=1}^{n} \mathbf{u}_i\, \sigma_i\, \mathbf{v}_i^T, \tag{2}$$

where $U = [\mathbf{u}_1, \cdots, \mathbf{u}_n]$ and $V = [\mathbf{v}_1, \cdots, \mathbf{v}_n]$ are matrices with orthonormal columns, and $\Sigma = \mathrm{diag}(\sigma_1, \cdots, \sigma_n)$ is an $m \times n$ diagonal matrix whose diagonal entries, the *singular values* of A, are ordered such that $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq 0$. From the orthonormality of the columns of U and V it follows that $\|A\mathbf{v}_i\| = \sigma_i$, $i = 1, \cdots, n$. It is straightforward to show that if k is the number of singular values strictly greater than ϵ, i.e., $\sigma_k > \epsilon \geq \sigma_{k+1}$, then k is the ϵ-rank of A as defined in (1). For every singular value $\sigma_i < \epsilon$, the corresponding right singular vector $\mathbf{v}_i$ is a numerical null-vector of A in the sense that $\|A\,\mathbf{v}_i\| \leq \epsilon$. It is therefore natural to define the *numerical null-space* of A as the space spanned by the vectors $\mathbf{v}_{k+1}$ through $\mathbf{v}_n$:

$$\mathcal{N}_k(A) \equiv \mathrm{span}\{\mathbf{v}_{k+1}, \cdots, \mathbf{v}_n\}. \tag{3}$$

We can now define a rank revealing QR factorization of A as a special QR factorization $A\Pi = QR$, which is guaranteed to reveal the ϵ-rank k of A in displaying elements in the lower portion of R with magnitude of the order σ_{k+1} or less. An RRQR factorization thus has the form

$$A\Pi = QR = Q\begin{pmatrix} R_{11} & R_{12} \\ 0 & R_{22} \end{pmatrix}, \tag{4}$$

where Π is a permutation matrix, Q has orthonormal columns, R_{11} is a $k \times k$ matrix with condition number approximately equal to σ_1/σ_k, $\|R_{22}\|$ is of the order σ_{k+1}, and k is the ϵ-rank of A. Such an RRQR factorization of A is not unique, and different RRQR algorithms may produce different factorizations. The key idea in all RRQR algorithms is, however, the same: first compute any QR factorization of A and then construct Π and Q by building up R_{22} one row at a time, starting from the bottom. Assume that a trailing $(n-i) \times (n-i)$ submatrix with small norm has already been generated. In the next step, the RRQR algorithm then proceeds as follows:

1. Compute the smallest singular value δ_i and the corresponding right null-vector $\mathbf{w}^{(i)} \in \Re^i$ of the leading $i \times i$ submatrix $R^{(i)}$ of R, such that

$$\|\mathbf{w}^{(i)}\| = 1, \qquad \|R^{(i)}\mathbf{w}^{(i)}\| = \delta_i \leq \sigma_i. \tag{5}$$

   The inequality $\delta_i \leq \sigma_i$ follows immediately from the interlacing inequality for singular values [12, Cor. 8.3.3].
2. Find the permutation that permutes the largest element in absolute value of $\mathbf{w}^{(i)}$ to the bottom.
3. Apply this permutation to the columns of $R^{(i)}$ and compute a new QR factorization of this matrix.
4. The (i,i)-element of $R^{(i)}$ is now *guaranteed* to be of the order δ_i.

This process continues until $\delta_i > \epsilon$ and then the ϵ-rank k of A, given by (1), is equal to i. The vectors $\mathbf{w}^{(i)}$ are padded with zeros and gathered in a matrix

$$W = \begin{pmatrix} W_1 \\ W_2 \end{pmatrix}$$

in such a way that $W_2 \in \Re^{(n-k)\times(n-k)}$ is upper triangular. The resulting column permutation matrix Π seeks to make W_2, produced by the RRQR algorithm, as well conditioned as possible (a priori upper bounds for $\|W_2^{-1}\|$, which depend on the particular RRQR algorithm, can be found in [1], [8], [10]). It is very important that the submatrix W_2 be well conditioned, for then we are guaranteed to obtain tight bounds for the singular values of A due to the following theorem.

THEOREM 2.1. *Let $R_{22}^{(i)}$ and $W_2^{(i)}$ denote the lower right $(n-i+1)\times(n-i+1)$ submatrices of R_{22} and W_2, respectively. Also, let δ_i denote the smallest singular value of the leading principal $i \times i$ submatrices of R. Then for $i = k+1, \cdots, n$:*

$$\frac{\sigma_i}{\sqrt{n-i+1}\,\|(W_2^{(i)})^{-1}\|} \le \delta_i \le \sigma_i \le \|R_{22}^{(i)}\| \le \sigma_i\sqrt{n-i+1}\,\|(W_2^{(i)})^{-1}\|. \tag{6}$$

Proof. See [7, Cor. 4.1]. □

Theorem 2.1 shows that the quantities δ_i and $\|R_{22}^{(i)}\|$ provide easily computed lower and upper bounds for the singular values σ_i. Moreover, the outermost bounds in (6) show that if $\|(W_2^{(i)})^{-1}\|$ is not large, then δ_i and $\|R_{22}^{(i)}\|$ are guaranteed to be tight bounds for σ_i. Therefore, the ϵ-rank of A will always be revealed from inspection of the upper and lower bounds for σ_i produced by the RRQR algorithm. In addition, Theorem 2.1 guarantees that $\|R_{22}\|$ is indeed of the order σ_{k+1}.

The matrix W produced during the RRQR algorithm is such an integral part of the RRQR that one may almost consider it a part of the factorization, the reason being that $\mathcal{R}(\Pi W)$ is a good approximation to the numerical null-space $\mathcal{N}_k(A)$. In fact, as shown in [8, Thm. 4.1], the larger the gap between σ_k and σ_{k+1}, the smaller the subspace angle between $\mathcal{R}(\Pi W)$ and $\mathcal{N}_k(A)$, i.e., the better $\mathcal{R}(\Pi W)$ approximates the numerical null-space. If a more accurate basis for $\mathcal{N}_k(A)$ is required, the columns of W can always be improved by a few inverse iterations, as shown in [8].

3. Rank deficient least squares problems.

In this section we consider algorithms for solving the linear least squares problem

$$\min \|A\mathbf{x} - \mathbf{b}\|, \qquad A \in \Re^{m\times n}, \tag{7}$$

where the matrix A is very ill conditioned. The usual least squares solution, formally given by $\mathbf{x} = \Pi R^{-1}Q^T\mathbf{b}$, is then of no use because it is extremely sensitive to perturbations of $\mathbf{b}$ and it is usually dominated by highly oscillating contributions from the errors in the right-hand side $\mathbf{b}$. A standard approach to computing a least squares solution that is less sensitive to perturbations is to transform (7) into a nearby problem that is better conditioned. In practice, this process usually corresponds to damping or filtering the contributions to the least squares solution corresponding to the smallest singular values of A [13], [14]. One such approach is the *truncated* SVD (TSVD) method, in which one completely filters out all the small singular values below the ϵ-rank k. The TSVD solution $\mathbf{x}_{TSVD}$ is thus defined as

$$\mathbf{x}_{TSVD} \equiv \sum_{i=1}^{k} \frac{\mathbf{u}_i^T\mathbf{b}}{\sigma_i}\mathbf{v}_i, \qquad k = k(A,\epsilon). \tag{8}$$

The TSVD solution can always be computed from the complete SVD of A, but this is computationally expensive because a great deal of the information provided by the SVD is not used. In fact, only the ϵ-rank and information about the numerical

TABLE 1
Dominating terms of the computational effort.

	excl. RRQR factorization	incl. RRQR factorization
$\mathbf{x}_{TSVD}$	$(2q(n-k)+1)n^2$	$(2m-\frac{2}{3}n+(\frac{7}{2}+2q)(n-k)+1)n^2$
$\mathbf{x}_{TQR}$	$(2(n-k)+1)n^2$	$(2m-\frac{2}{3}n+\frac{11}{2}(n-k)+1)n^2$
$\mathbf{x}_B$	n^2	$(2m-\frac{2}{3}n+\frac{7}{2}(n-k)+1)n^2$

null-space is required. Therefore, the TSVD solution can be computed efficiently by means of the RRQR factorization of A, as shown in [8].

Instead of using the RRQR to compute $\mathbf{x}_{TSVD}$, one may define a least squares solution in terms of the RRQR factorization itself. Here, we shall analyze and compare this approach to the TSVD method. Let the RRQR factorization of A be given by (4). The standard approach [12, §5.5] is to neglect the submatrix R_{22} (which is guaranteed to have a norm of the order σ_{k+1} due to Theorem 2.1) and to then solve this modified problem. In analogy with the TSVD solution, it is natural to define the *truncated* QR (TQR) solution $\mathbf{x}_{TQR}$ as the minimum two-norm least squares solution to the modified problem. To compute $\mathbf{x}_{TQR}$, which involves the pseudoinverse of

$$\begin{pmatrix} R_{11} & R_{12} \\ 0 & 0 \end{pmatrix},$$

it is convenient to use a right orthogonal transformation P to annihilate R_{12} by means of R_{11}, i.e., $(R_{11}, R_{12})P = (\hat{R}_{11}, 0)$. Then the TQR solution is given by

$$\mathbf{x}_{TQR} \equiv \Pi P \begin{pmatrix} \hat{R}_{11}^{-1} & 0 \\ 0 & 0 \end{pmatrix} Q^T \mathbf{b}. \tag{9}$$

Alternatively, one can compute the *basic solution* $\mathbf{x}_B$, defined as the solution to another modified least squares problem where both submatrices R_{12} and R_{22} are neglected. The basic solution is given by

$$\mathbf{x}_B \equiv \Pi \begin{pmatrix} R_{11}^{-1} & 0 \\ 0 & 0 \end{pmatrix} Q^T \mathbf{b}. \tag{10}$$

We list in column one of Table 1 the dominating terms of the computational effort required to compute the three solutions $\mathbf{x}_{TSVD}$, $\mathbf{x}_{TQR}$, and $\mathbf{x}_B$, assuming that the RRQR factorization of A has been computed and that $Q^T\mathbf{b}$ is computed simultaneously with the factorization. The computational effort is measured in flops (a flop is either one addition or one multiplication). The quantity q is the number of inverse iterations used to compute accurate singular subspaces, and usually q is less than 4. The computational effort to compute the RRQR factorization itself depends on the column permutations needed during the computations, but it never exceeds $(2m - \frac{2}{3}n + \frac{7}{2}(n-k))n^2$ flops (provided that the Linpack condition estimator is used in each step). This leads to the total amount of computational effort given in column two. We note that more recent condition estimators, such as Incremental Condition Estimation and related algorithms, may be much more efficient in this context; see [1] for details.

In comparison, we can compute the complexity required by a similar technique for computing $\mathbf{x}_{TSVD}$ based on the PSVD algorithm [25] with accumulation of $Q^T\mathbf{b}$

(PSVD is not suited to computation of $\mathbf{x}_{TQR}$ or $\mathbf{x}_B$). The R-bidiagonalization of $A = U_B B V_B^T$ requires $2(m+n)n^2$ flops. Computation of the $n-k$ smallest singular values and the corresponding left and right singular vectors, using on average two "chases" per singular value, requires $24(n-k)n^2$ flops. Backsubstitution with B and orthogonalization with respect to the left and right null spaces requires $O(n)$ flops. Coordinate transformation with V_B requires $2n^2$ flops. Thus the total is $(2m+2n+24(n-k)+2)n^2$ flops. Therefore, the RRQR algorithm is always less computationally demanding than the PSVD-based algorithm.

For our numerical comparison, it is convenient to define the residual vectors corresponding to the three solutions:

$$\mathbf{r}_i = A\mathbf{x}_i - \mathbf{b}, \qquad i = TSVD, TQR, B. \tag{11}$$

Then we have the following results.

THEOREM 3.1. *The* TSVD *and* TQR *solutions are related by*

$$\|\mathbf{x}_{TSVD} - \mathbf{x}_{TQR}\| \le \|R_{22}\|\,\|R_{11}^{-1}\|\left(2\,\|\mathbf{x}_{TSVD}\| + \frac{\|\mathbf{r}_{TSVD}\|}{\sigma_k}\right) \tag{12}$$

and the TQR *and basic solutions are related by*

$$\|\mathbf{x}_{TQR} - \mathbf{x}_B\| \le \frac{1+\sqrt{5}}{2}\,\|R_{11}^{-1}\|^2\,\|R_{12}\|\,\|\mathbf{b}\|. \tag{13}$$

The three residual vectors satisfy

$$\|\mathbf{r}_{TSVD} - \mathbf{r}_{TQR}\| \le \|R_{22}\|\left(\|\mathbf{x}_{TSVD}\| + \frac{\|\mathbf{r}_{TSVD}\|}{\sigma_k}\right) \tag{14}$$

and

$$\|\mathbf{r}_{TQR} - \mathbf{r}_B\| \le \|R_{22}\|\,\|R_{11}^{-1}\|\,\|\mathbf{b}\|. \tag{15}$$

Proof. The TQR solution $\mathbf{x}_{TQR}$ is identical to a truncated SVD solution to the problem

$$\min\left\|Q\begin{pmatrix} R_{11} & R_{12} \\ 0 & 0 \end{pmatrix}\Pi^T\mathbf{x} - \mathbf{b}\right\| = \min\left\|\left(A - Q\begin{pmatrix} 0 & 0 \\ 0 & R_{22} \end{pmatrix}\Pi^T\right)\mathbf{x} - \mathbf{b}\right\|.$$

Thus, we can consider $\mathbf{x}_{TQR}$ a perturbation of $\mathbf{x}_{TSVD}$, with the perturbed matrix given by

$$\tilde{A} = Q\begin{pmatrix} R_{11} & R_{12} \\ 0 & 0 \end{pmatrix}\Pi^T$$

(which has rank k) and with the perturbation matrix given by

$$E = Q\begin{pmatrix} 0 & 0 \\ 0 & R_{22} \end{pmatrix}\Pi^T.$$

Note in particular that $\|E\| = \|R_{22}\|$, that $\|\tilde{A}^+\| = \|\hat{R}_{11}^{-1}\| \le \|R_{11}^{-1}\|$, and that the $(k+1)$th singular value of $\tilde{A}$ is zero. In [13, §3] Hansen derived general perturbation bounds for TSVD problems. For this special case, these bounds become somewhat simpler:

$$\|\mathbf{x}_{TSVD} - \mathbf{x}_{TQR}\| \le \|\tilde{A}^{+}\| \, (\|E\| \, \|\mathbf{x}_{TSVD}\| + \sin\theta_k \, \|\mathbf{r}_{TSVD}\|) + \sin\theta_k \, \|\mathbf{x}_{TSVD}\|,$$
$$\|\mathbf{r}_{TSVD} - \mathbf{r}_{TQR}\| \le \|E\| \, \|\mathbf{x}_{TSVD}\| + \sin\theta_k \, \|\mathbf{r}_{TSVD}\|,$$

where $\sin\theta_k \le \|E\|/\sigma_k$. Inserting this bound into the above expressions, and using the fact that $\sigma_k^{-1} \le \delta_k^{-1} = \|R_{11}^{-1}\|$, we obtain (12) and (14). The difference between $\mathbf{x}_{TQR}$ and $\mathbf{x}_B$ satisfies

$$\|\mathbf{x}_{TQR} - \mathbf{x}_B\| \le \left\| \begin{pmatrix} R_{11} & R_{12} \\ 0 & 0 \end{pmatrix}^{+} - \begin{pmatrix} R_{11} & 0 \\ 0 & 0 \end{pmatrix}^{+} \right\| \, \|\mathbf{b}\|.$$

Here, we can consider

$$\begin{pmatrix} 0 & R_{12} \\ 0 & 0 \end{pmatrix}$$

a perturbation of

$$\begin{pmatrix} R_{11} & 0 \\ 0 & 0 \end{pmatrix},$$

and a standard result for perturbed pseudoinverses [3, Thm. 5.3], $\|(A+E)^{+} - A^{+}\| \le \frac{1+\sqrt{5}}{2} \, \|A^{+}\| \, \|(A+E)^{+}\| \, \|E\|$, then yields (13). Finally, to prove (15), we have

$$\mathbf{r}_B - \mathbf{r}_{TQR} = A\,(\mathbf{x}_{TQR} - \mathbf{x}_B) = Q \begin{pmatrix} 0 & 0 \\ R_{22}P_{21}\hat{R}_{11}^{-1} & 0 \end{pmatrix} Q^T\mathbf{b},$$

where P_{21} is the bottom left $(n-k) \times k$ submatrix of the orthogonal matrix P. Taking norms and using $\|\hat{R}_{11}^{-1}\| \le \|R_{11}^{-1}\|$, we obtain (15). □

Due to Theorem 2.1 we are guaranteed that $\|R_{22}\| \le \sigma_{k+1}\sqrt{n-k}\,\|W_2^{-1}\|$ when R is computed via a RRQR factorization. Hence, as long as σ_{k+1} is small, Theorem 3.1 guarantees that TSVD and TQR will produce approximately the same solutions, as well as residuals. These two methods are therefore in many circumstances equally well suited for solving rank deficient least squares problems with well-determined ϵ-rank (unless, of course, the exact TSVD solution is required), and $\mathbf{x}_{TQR}$ is cheaper to compute than $\mathbf{x}_{TSVD}$.

The RRQR also leads to a basic solution $\mathbf{x}_B$ with approximately the same residual vector as both $\mathbf{r}_{TQR}$ and $\mathbf{r}_{TSVD}$, because R_{11} is guaranteed to be well conditioned. The basic solution itself, on the other hand, may be very different from both $\mathbf{x}_{TSVD}$ and $\mathbf{x}_{TQR}$. This is so because the basic solution $\mathbf{x}_B$ has a (possibly large) component in the numerical null-space of A.

To illustrate the different properties of all the above-mentioned solutions, we have carried out a series of experiments using Pro-Matlab [20]. The dimensions were $m = n = 100$, the ratio σ_1/σ_k (where k is the ϵ-rank) was 10^3 for all the matrices, and the right-hand side $\mathbf{b}$ was generated such that the TSVD residual vector satisfies $\|\mathbf{r}_{TSVD}\| = 10^{-3}\|A\,\mathbf{x}_{TSVD}\|$. Typical numerical results are shown in Table 2 for three different values of the ϵ-rank k and three different ratios σ_k/σ_{k+1}. These results clearly illustrate how the similarity of $\mathbf{x}_{TSVD}$ and $\mathbf{x}_{TQR}$, as well as the similarity of all the residual vectors, depends on the size of the gap between σ_k and σ_{k+1}, but not on the ϵ-rank k. Table 2 also illustrates that the solutions $\mathbf{x}_{TQR}$ and $\mathbf{x}_B$ generally are very different.

4. Subset selection problems. *Subset selection* is the problem of determining the most linearly independent columns of the matrix A. To be precise, if k is the ϵ-rank of A, then the aim is to find a column permutation Π such that the submatrix consisting of the first k columns of $A\,\Pi$ are as well conditioned as possible. The RRQR factorization of A obviously produces such a permutation Π. The basic solution $\mathbf{x}_B$ discussed in the previous section is in fact the least squares solution derived from this strategy by forcing to zero those elements of $\mathbf{x}_B$ that correspond to the linearly dependent columns of A. Such a solution may in some applications be preferred to the TSVD and TQR solutions. Subset selection is also interesting in its own right.

It is therefore interesting to compare the RRQR-based subset selection algorithm with the standard SVD-based algorithm proposed by Golub, Klema, and Stewart [11], [12, §12.2]. Their algorithm constructs a permutation matrix Π_{SVD} such that the bottom right $(n-k) \times (n-k)$ submatrix $\tilde{V}_{22}$ of $\Pi_{SVD}^T V$ is well conditioned, and then the first $n-k$ columns of $A\,\Pi_{SVD}$ are guaranteed to form a well-conditioned matrix. In other words, these columns form a linearly independent set of the columns of A.

The RRQR factorization also produces a permutation Π such that the first $n-k$ columns of $A\Pi$ are linearly independent, but this Π is constructed on the basis of information in the matrix W. The difference between these two methods therefore basically lies in the way that Π is computed. In general, we cannot guarantee that the two algorithms give identical permutations, and this makes a comparison of the two solutions difficult. On the other hand, it is more appropriate for subset selection problems to compare the subspaces spanned by the first $n-k$ columns of $A\,\Pi_{SVD}$ and $A\,\Pi$.

THEOREM 4.1. *Let* $\mathcal{R}(U_k)$ *denote the subspace* $\operatorname{span}\{\mathbf{u}_1, \cdots, \mathbf{u}_k\}$, *and let* B_{SVD} *and* B_{RRQR} *denote the submatrices consisting of the first* $n-k$ *columns of* $A\,\Pi_{SVD}$ *and* $A\,\Pi$, *respectively. Then*

$$\sin\theta(\mathcal{R}(U_k), \mathcal{R}(B_{SVD})) \le \sigma_{k+1}\|\tilde{V}_{22}^{-1}\|\,\sigma_k^{-1}, \tag{16}$$

$$\sin\theta(\mathcal{R}(U_k), \mathcal{R}(B_{RRQR})) \le \sigma_{k+1}\|R_{11}^{-1}\|. \tag{17}$$

Proof. Our proof follows that given by Golub and Van Loan for [12, Thm. 12.2.2]. In their proof, they derive the upper bound $\sin\theta(\mathcal{R}(U_k), \mathcal{R}(B_{SVD})) \le \sigma_{k+1}/\sigma_k(B_{SVD})$, where $\sigma_k(B_{SVD})$ denotes the smallest singular value of B_{SVD}. They also show in [12,

TABLE 3
Typical numerical results for the RRQR *subset selection algorithm. Each entry in the table shows the subspace angles* $\sin\theta(\mathcal{R}(U_k),\mathcal{R}(B_{RRQR}))$ *and* $\sin\theta(\mathcal{R}(B_{SVD}),\mathcal{R}(B_{RRQR}))$. *The dimensions are* $m = n = 100$.

$\frac{\sigma_k}{\sigma_{k+1}}$	$k = 50$		$k = 75$		$k = 90$	
10^6	$1.03\cdot10^{-6}$	$1.26\cdot10^{-6}$	$1.58\cdot10^{-6}$	$1.74\cdot10^{-6}$	$1.30\cdot10^{-6}$	$1.51\cdot10^{-6}$
10^3	$9.70\cdot10^{-4}$	$1.18\cdot10^{-3}$	$1.54\cdot10^{-3}$	$1.66\cdot10^{-3}$	$1.30\cdot10^{-3}$	$1.51\cdot10^{-3}$
10	$9.38\cdot10^{-2}$	$1.14\cdot10^{-1}$	$1.50\cdot10^{-3}$	$1.62\cdot10^{-1}$	$1.30\cdot10^{-7}$	$1.50\cdot10^{-1}$

Thm. 12.2.1] that $\sigma_k(B_{SVD}) \geq \sigma_k\,\|\tilde{V}_{22}^{-1}\|$, which yields (16). Similarly, since

$$B_{RRQR} = Q\begin{pmatrix} R_{11} \\ 0 \end{pmatrix},$$

we obtain that

$$\sin\theta(\mathcal{R}(U_k),\mathcal{R}(B_{RRQR})) \leq \frac{\sigma_{k+1}}{\sigma_k(B_{RRQR})} = \frac{\sigma_{k+1}}{\sigma_k(R_{11})},$$

which is (17). □

The submatrix R_{11} in the RRQR factorization of A is guaranteed to be well conditioned and $\|R_{11}^{-1}\|$ is of the order σ_k^{-1}. Theorem 4.1 therefore ensures that the sine of both subspace angles is of the same order as σ_{k+1}/σ_k. Moreover, if this ratio is small, then Theorem 4.1 ensures that both $\mathcal{R}(B_{SVD})$ and $\mathcal{R}(B_{RRQR})$ will be close to the subspace $\mathcal{R}(U_k)$, and the subspace angle between $\mathcal{R}(B_{SVD})$ and $\mathcal{R}(B_{RRQR})$ is therefore also bound to be small. Hence, if σ_{k+1}/σ_k is small, then SVD and RRQR yield approximately the same subspaces. We illustrate this in Table 3, where we show typical values of $\sin\theta(\mathcal{R}(U_k),\mathcal{R}(B_{RRQR}))$ and $\sin\theta(\mathcal{R}(B_{SVD}),\mathcal{R}(B_{RRQR}))$. We see that both subspace angles are indeed of the same order as the ratio σ_{k+1}/σ_k. The conclusion is that although the SVD and RRQR subset selection algorithms do not necessarily produce the same column permutations and thus the same subset of columns of A, the subspaces spanned by these two sets of columns are still almost identical whenever σ_{k+1}/σ_k is small.

5. Matrix approximation. It is well known that the best rank-k approximation A_k to the matrix A, in any unitarily invariant norm, is the matrix obtained by truncating the SVD expansion in (2) after the first k terms. That is, the matrix A_k given by

$$A_k = \sum_{i=1}^{k} \mathbf{u}_i\,\sigma_i\,\mathbf{v}_i^T, \qquad k \leq n \tag{18}$$

solves the problem $\min_{\mathrm{rank}(X)=k}\|A - X\|$ (this is the Eckart–Young–Mirsky Theorem [12, Thm. 2.5.2]). In particular, $\|A - A_k\| = \sigma_{k+1}$ and $\|A - A_k\|_F = (\sigma_{k+1}^2 + \cdots + \sigma_n^2)^{1/2}$. As we shall demonstrate in the following theorem, neglection of the submatrix R_{22} in a RRQR factorization also yields a good rank-k approximation, provided that W_2 is well conditioned.

THEOREM 5.1. *Let*

$$B_k = Q\begin{pmatrix} R_{11} & R_{12} \\ 0 & 0 \end{pmatrix}\Pi^T$$

TABLE 4
Typical numerical results for RRQR *matrix approximations. Each entry shows* $\|A - B_k\|$ *and* $\|A_k - B_k\|$ *for matrices with* $m = n = 100$, $\sigma_1 = 1$, *and* $\sigma_{k+1} = \|A - A_k\| = 10^{-7}$.

$\frac{\sigma_k}{\sigma_{k+1}}$	$k = 50$		$k = 75$		$k = 90$	
10^6	$3.05 \cdot 10^{-7}$	$2.90 \cdot 10^{-7}$	$2.55 \cdot 10^{-7}$	$2.48 \cdot 10^{-7}$	$2.63 \cdot 10^{-7}$	$2.51 \cdot 10^{-7}$
10^3	$2.39 \cdot 10^{-7}$	$2.17 \cdot 10^{-7}$	$2.51 \cdot 10^{-7}$	$2.31 \cdot 10^{-7}$	$5.68 \cdot 10^{-7}$	$5.60 \cdot 10^{-7}$
10	$4.20 \cdot 10^{-7}$	$4.08 \cdot 10^{-7}$	$5.02 \cdot 10^{-7}$	$4.92 \cdot 10^{-7}$	$6.98 \cdot 10^{-7}$	$6.91 \cdot 10^{-7}$

denote the matrix obtained from the RRQR *factorization* (4) *by neglecting the submatrix* R_{22}. *Then*

$$\|A - B_k\| \le \sqrt{n-k}\,\|W_2^{-1}\|\,\sigma_{k+1}, \tag{19}$$

$$\|A - B_k\|_F \le \sqrt{n-k}\,\|W_2^{-1}\|\,(\sigma_{k+1}^2 + \cdots + \sigma_n^2)^{1/2}, \tag{20}$$

where A_k *denotes the truncated* SVD *matrix* (18).

Proof. Obviously, $\|A - B_k\| = \|R_{22}\|$ and $\|A - B_k\|_F = \|R_{22}\|_F$, and (19) then follows from Theorem 2.1. To get an upper bound for $\|R_{22}\|_F$, we use the fact that $\|R_{22}\|_F \le \|R_{22}\,W_2\|_F\,\|W_2^{-1}\|_F \le \|A\Pi W\|_F\,\|W_2^{-1}\|_F$. Since each column vector $\mathbf{w}_i$ of W satisfies

$$\|A\Pi\mathbf{w}_i\| = \left\|QR\begin{pmatrix}\mathbf{w}^{(i)}\\ \mathbf{0}\end{pmatrix}\right\| = \|R^{(i)}\mathbf{w}^{(i)}\| = \delta_i \le \sigma_{k+i}$$

(cf. (5)), we obtain $\|A\Pi W\|_F^2 \le \sigma_{k+1}^2 + \cdots + \sigma_n^2$. This yields (20). □

Theorem 5.1 states that matrix approximations derived from RRQR factorizations are almost as good as those derived from truncated SVD approximations. Moreover, it is trivial from Theorem 5.1 that the difference between A_k and B_k satisfies $\|A_k - B_k\| \le (1 + \sqrt{n-k}\,\|W_2^{-1}\|)\,\sigma_{k+1}$. The interesting fact about the RRQR matrix approximations is that the bounds in (19) and (20) do not depend on the gap between σ_k and σ_{k+1}. The algorithm can therefore be applied to any matrix independently of its singular value spectrum and with potential application to digital image compression. We illustrate this in Table 4, which shows typical values of $\|A - B_k\|$ and $\|A_k - B_k\|$ for random matrices with $m = n = 100$, $\sigma_1 = 1$, $\sigma_{k+1} = \|A - A_k\| = 10^{-7}$, and different values of the ϵ-rank k and the ratio σ_k/σ_{k+1}. The table confirms that $\|A - B_k\|$ and $\|A_k - B_k\|$ are both of the order σ_{k+1}, as proved in the above theorem, and are independent of σ_k/σ_{k+1}.

6. Total least squares problems.

Another aspect of matrix approximation arises in connection with total least squares (TLS) problems [12, §12.3]. The key problem here is to find three matrices E, R, and X such that $\|(E, R)\|$ is small and such that $(A + E)X = B + R$, with $A \in \Re^{m\times n}$ and $B \in \Re^{m\times p}$ (the ordinary least squares problem corresponds to setting $E = 0$). Total least squares problems typically arise in applications where both the coefficient matrix A and the right-hand side B are contaminated with errors, in which case one can think of E and R as being residual matrices.

The classical approach to TLS is based on the SVD and is described in [12, §12.3]. Let

$$V = \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix}$$

be the matrix of right singular vectors in the SVD of the compound matrix (A, B), partitioned such that $V_{11} \in \Re^{n \times r}$, where r is the ϵ-rank of A. If A has full rank $(r = n)$, then the solution that minimizes the Frobenius norm of the compound residual matrix $\|(E, R)\|_F$ is given by $X_{SVD} = -V_{12}V_{22}^{-1}$ [12, Thm. 12.3.1]. When A is rank deficient $(r < n)$, the solution of the minimum Frobenius norm that minimizes $\|(E, R)\|_F$ is given by [27]

$$X_{SVD} = -V_{12}V_{22}^{+}. \tag{21}$$

Here, V_{22}^{+} is the pseudoinverse of the $p \times (n - r + p)$ submatrix V_{22}, and V_{22}^{+} is identical to V_{22}^{-1} when $r = n$. As long as $p \ll n$, V_{22}^{+} can easily be computed stably, e.g., by a QR factorization of V_{22}. Note that there is no guarantee that V_{22} is well conditioned. Also note that the numerical rank of the compound matrix (A, B) is not used in total least squares, only the ϵ-rank of A is required. We return to this aspect at the end of this section.

From (21) it is obvious that the complete SVD of (A, B) is not needed for computing X_{SVD}. Instead, only the right singular vectors corresponding to the smallest $n - r + p$ singular values are required. It is possible to modify the classical SVD algorithm by taking this into account. This is done in the PSVD algorithm [25], [26], developed for TLS problems, which requires $(2m + 2n + 14p + 2)(n + p)^2 + O(n)$ flops to compute X_{SVD} if the bidiagonalization part is preceded by a standard QR factorization, as described in [5].

Here we derive algorithms for TLS based on the RRQR factorization of (A, B). The key idea is to use the RRQR algorithm to compute approximate null-vectors corresponding to the $n-r+p$ smallest singular values of (A, B) (assume for the moment that r is known). We can then use the same approach as that used in [8] to compute TSVD solutions, namely, to use inverse subspace iterations to refine the numerical null-vectors in W. This approach yields the right singular vectors required to compute X_{SVD} by (21), and the accuracy of the solution depends primarily on the number of subspace iterations. Except for a single backsubstitution, which is not required to compute X_{SVD}, the dominating computational effort remains the same as that for computing $\mathbf{x}_{SVD}$; cf. §3. Hence, this approach requires $(2m - \frac{2}{3}n + (2q + 3))(n + p)^2$ flops (where q is the number of inverse iterations required to refine the null vectors), and it is actually less demanding than the PSVD approach, mainly because a reduction to bidiagonal form is avoided.

We shall now analyze an even simpler approach to TLS, based directly on the matrix W without performing any inverse iterations. Whenever the singular values σ_r and σ_{r+1} are well separated, it is shown in [8, Thm. 4.1] that the range of ΠW is a good approximation to $\mathcal{N}_r(A, B)$, in the sense that the subspace angle θ between $\mathcal{R}(\Pi W)$ and $\mathcal{N}_r(A, B)$ is small. Thus, it is natural to obtain an approximation to the last $n - r + p$ null vectors of (A, B) simply by orthonormalization of the columns of ΠW, e.g., by means of the modified Gram–Schmidt process, to obtain

$$\Pi W = \begin{pmatrix} \bar{V}_{12} \\ \bar{V}_{22} \end{pmatrix} \bar{R}, \qquad \bar{V}_{12}^T \bar{V}_{12} + \bar{V}_{22}^T \bar{V}_{22} = I_{n-r+p}, \tag{22}$$

and then define the alternative TLS solution by $X_{RRQR} = -\bar{V}_{12}\bar{V}_{22}^{-1}$ or, in the general case, by

$$X_{RRQR} = -\bar{V}_{12}\bar{V}_{22}^{+}. \tag{23}$$

As is the case in the SVD approach, we cannot guarantee that $\bar{V}_{22}$ is well conditioned. The question is then whether a small subspace angle θ ensures that X_{RRQR} is close to X_{SVD}. In Theorem 6.3 below we give a positive answer to this question for the full rank case $(r = n)$, but first we need the following two lemmas.

LEMMA 6.1. *If*

$$V = \begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix}$$

is orthogonal, then the norm of the Schur complement of V_{22} *satisfies*

$$\|V_{11} - V_{12}V_{22}^{-1}V_{21}\| = \|V_{22}^{-1}\|. \tag{24}$$

Proof. For simplicity, we assume $V_{11} \in \Re^{q\times q}$, $V_{22} \in \Re^{p\times p}$ with $q > p$. Then the CS decomposition [12, Thm. 2.6.1] of V is given by

$$\begin{pmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{pmatrix} = \begin{pmatrix} \hat{U}_1 & 0 \\ 0 & \hat{U}_2 \end{pmatrix} \begin{pmatrix} I_{q-p} & 0 & 0 \\ 0 & C & S \\ 0 & -S & C \end{pmatrix} \begin{pmatrix} \hat{V}_1^T & 0 \\ 0 & \hat{V}_2^T \end{pmatrix},$$

where $C^2 + S^2 = I_p$. It is straightforward to show that $V_{22}^{-1} = \hat{V}_2 C^{-1}\hat{U}_2^T \Rightarrow \|V_{22}^{-1}\| = \|C^{-1}\|$ and, by inserting the CS decomposition, that

$$V_{11} - V_{12}V_{22}^{-1}V_{21} = \hat{U}_1 \begin{pmatrix} I_{q-p} & 0 \\ 0 & C^{-1} \end{pmatrix} \hat{V}_1^T,$$

from which (24) immediately follows. □

LEMMA 6.2. *If* Q, V, *and* $\bar{V}$ *are orthogonal matrices such that*

$$\bar{V} = (\bar{V}_1, \bar{V}_2) = VQ = (V_1, V_2) \begin{pmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{pmatrix}, \tag{25}$$

then the subspace angle θ *between the subspaces* $\mathcal{R}(V_2)$ *and* $\mathcal{R}(\bar{V}_2)$ *satisfies*

$$\sin\theta = \|Q_{12}\|, \qquad \cos\theta = \|Q_{22}^{-1}\|^{-1}. \tag{26}$$

Proof. We have $\sin\theta = \|V_1^T\bar{V}_2\| = \|V_1^T(V_1Q_{12} + V_2Q_{22})\| = \|Q_{12}\|$. The relation for $\cos\theta$ follows from the CS decomposition of Q. □

THEOREM 6.3. *Let* X_{SVD} *and* X_{RRQR} *be given by* (21) *and* (23), *respectively, and assume that* A *has full rank. If* θ *denotes the subspace angle between* $\mathcal{N}_r(A,B)$ *and* $\mathcal{R}(\Pi W)$, *and if* $\tan\theta < \|V_{22}^{-1}\|^{-1}$, *then*

$$\|X_{SVD} - X_{RRQR}\| \le \tan\theta\, \|V_{22}^{-1}\|^2 \Big(1 + O(\tan\theta)\Big). \tag{27}$$

Proof. Using the notation from (25) with

$$V_2 = \begin{pmatrix} V_{12} \\ V_{22} \end{pmatrix} \quad \text{and} \quad \bar{V}_2 = \begin{pmatrix} \bar{V}_{12} \\ \bar{V}_{22} \end{pmatrix},$$

we obtain $\bar{V}_{12} = V_{11}Q_{12} + V_{12}Q_{22}$ and $\bar{V}_{22} = V_{21}Q_{12} + V_{22}Q_{22} = (V_{21}Q_{12}Q_{22}^{-1}V_{22}^{-1} + I_p)V_{22}Q_{22}$. If we define $\Delta = V_{21}Q_{12}Q_{22}^{-1}V_{22}^{-1}$, then $\bar{V}_{22} = (I_p + \Delta)V_{22}Q_{22}$. From

TABLE 5

Mean and maximum values for an experiment with 100 *matrices with dimensions* $m = 150$, $n = 100$, *and* $p = 5$. *The* ϵ*-rank of* A *is* $r = 90$.

	Mean	Maximum
$\tan\theta$	$1.92 \cdot 10^{-7}$	$1.92 \cdot 10^{-6}$
$\lVert\bar{V}_{22}^{+}\rVert$	1.20	1.30
$\tan\theta\,\lVert V_{22}^{+}\rVert^2/\lVert X_{SVD}\rVert$	$4.07 \cdot 10^{-7}$	$3.95 \cdot 10^{-6}$
$\lVert X_{SVD} - X_{RRQR}\rVert/\lVert X_{SVD}\rVert$	$5.06 \cdot 10^{-8}$	$5.27 \cdot 10^{-7}$

Lemma 6.2 we have $\|\Delta\| \leq \tan\theta\,\|V_{22}^{-1}\|$, and since we have assumed that $\tan\theta < \|V_{22}^{-1}\|^{-1}$ such that $\|\Delta\| < 1$, we have

$$\bar{V}_{22}^{-1} = Q_{22}^{-1}V_{22}^{-1}(I_p + \Delta)^{-1} = Q_{22}^{-1}V_{22}^{-1}(I_p - \Delta + O(\Delta^2)).$$

Thus, we obtain that

$$X_{RRQR} = -\bar{V}_{12}\bar{V}_{22}^{-1} = -V_{11}Q_{12}Q_{22}^{-1}V_{22}^{-1} - V_{12}V_{22}^{-1} + (V_{11}Q_{12}Q_{22}^{-1} + V_{12})V_{22}^{-1}\Delta + O(\Delta^2).$$

Inserting the expression for Δ and using the fact that $X_{SVD} = -V_{12}V_{22}^{-1}$, we then obtain

$$X_{RRQR} - X_{SVD} = -(V_{11} - V_{12}V_{22}^{-1}V_{21})\,Q_{12}Q_{22}^{-1}V_{22}^{-1} + V_{11}Q_{12}Q_{22}^{-1}V_{22}^{-1}\Delta + O(\Delta^2).$$

Taking norms on both sides of the above equation and using Lemmas 6.1 and 6.2, we then obtain (27). □

Theorem 6.3 states that if A has full rank, if the subspace angle θ is small, and if V_{22} is well conditioned, then the total least squares solution X_{RRQR} defined by (23) will be close to the ordinary total least squares solution X_{SVD} given by (21). Although we cannot ensure that the matrix V_{22} is well conditioned, it is our experience that it is very unlikely to be ill conditioned.

Unfortunately, we were not able to prove a similar result for the rank deficient case ($r < n$), the reason being the appearance of the pseudoinverse V_{22}^{+}, which severely complicates the relations. On the other hand, our experiments with Matlab strongly suggest that (27) holds in general: among 100 random matrices with dimensions $m = 150$, $n = 100$, and $p = 5$ and with A's ϵ-rank $r = 90$, the ratio between $\|X_{SVD} - X_{RRQR}\|$ and $\tan\theta\,\|V_{22}^{+}\|^2$ in (27) never exceeded 0.6. The results from this test are summarized in Table 5, where we list the mean and maximum values of $\tan\theta$, $\|\bar{V}_{22}^{+}\|$, $\tan\theta\,\|V_{22}^{+}\|^2/\|X_{SVD}\|$, and $\|X_{SVD} - X_{RRQR}\|/\|X_{SVD}\|$. This confirms the fact that $\bar{V}_{22}$ is in all likelihood a well-conditioned matrix and that the upper bound in (27) is not large. The conclusion is that X_{RRQR} is indeed a good TLS solution.

Besides being faster than both the traditional SVD algorithm and the PSVD algorithm, our approach to TLS based on RRQR has one more important advantage: if the ϵ-rank of A is unknown, then one can compute it during the RRQR factorization of (A, B) with very little overhead. First compute an RRQR factorization of A,

$$A\,\Pi^{(1)} = Q^{(1)}\begin{pmatrix} R^{(1)} \\ 0 \end{pmatrix} = Q^{(1)}\begin{pmatrix} R_{11}^{(1)} & R_{12}^{(1)} \\ 0 & R_{22}^{(1)} \\ 0 & 0 \end{pmatrix}, \tag{28}$$

revealing the ϵ-rank r of A. Then append

$$\begin{pmatrix} R^{(1)} \\ 0 \end{pmatrix}$$

with $(Q^{(1)})^T B$, to form

$$C = \begin{pmatrix} R_{11}^{(1)} & R_{12}^{(1)} & \hat{B}_1 \\ 0 & R_{22}^{(1)} & \hat{B}_2 \\ 0 & 0 & \hat{B}_3 \end{pmatrix}, \quad \begin{pmatrix} \hat{B}_1 \\ \hat{B}_2 \\ \hat{B}_3 \end{pmatrix} = (Q^{(1)})^T B$$

and compute the RRQR factorization of the lower right 2×2 block submatrix of C:

$$\begin{pmatrix} R_{22}^{(1)} & \hat{B}_2 \\ 0 & \hat{B}_3 \end{pmatrix} \Pi^{(2)} = Q^{(2)} \begin{pmatrix} R_{22}^{(2)} & R_{23}^{(2)} \\ 0 & R_{33}^{(2)} \end{pmatrix}. \tag{29}$$

Finally, apply the second set of permutations to $\begin{pmatrix} R_{12}^{(1)} & \hat{B}_2 \end{pmatrix}$ to obtain

$$\begin{pmatrix} R_{12}^{(2)} & R_{13}^{(2)} \end{pmatrix} = \begin{pmatrix} R_{12}^{(1)} & \hat{B}_1 \end{pmatrix} \Pi^{(2)}. \tag{30}$$

Then the resulting triangular factor of (A, B) is given by

$$R = \begin{pmatrix} R_{11}^{(1)} & R_{12}^{(2)} & R_{13}^{(2)} \\ 0 & R_{22}^{(2)} & R_{23}^{(2)} \\ 0 & 0 & R_{33}^{(2)} \end{pmatrix}.$$

During the second factorization (29), one can take advantage of the fact that the first $n - r$ columns are in all likelihood linear combinations within the tolerance ϵ of the remaining columns. Since $R_{11}^{(1)}$ is guaranteed to be well conditioned, the QR factorization resulting from (28)–(30) is close to being an RRQR factorization of (A, B), and the desired RRQR factorization can then be achieved by a few "backward passes" through R as described in [1, §5].

STABLE PARALLEL ALGORITHMS FOR TWO-POINT BOUNDARY VALUE PROBLEMS*

STEPHEN J. WRIGHT†

Abstract. Some of the most widely used algorithms for two-point boundary value ordinary differential equations, namely, finite-difference and collocation methods and standard multiple shooting, proceed by setting up and solving a structured system of linear equations. It is well known that the linear system can be set up efficiently in parallel; we show here that a structured orthogonal factorization technique can be used to solve this system, and hence the overall problem, in an efficient, parallel, and stable way.

Key words. parallel algorithms, two-point boundary value problems, error analysis, stability

AMS(MOS) subject classifications. 65F05, 65G05, 65L10, 65L20, 65W05

1. Introduction.

Many numerical algorithms for solving the linear two-point boundary value problem (BVP)

$$y' = M(t)y + q(t), \qquad t \in [a,b], \qquad y \in R^n, \tag{1}$$

$$B_a y(a) + B_b y(b) = d \tag{2}$$

have been proposed and studied over the last 30 years. Many of these methods require a structured linear algebraic system (for example, a block-tridiagonal or staircase system) to be solved as a "core" operation, and considerable effort has been devoted to minimizing the amount of computer time and storage required during the factorization of the coefficient matrix of this system. Efficient factorization schemes, based on structured Gaussian elimination, have been implemented and are widely available (see §2 and Varah [19]; Diaz, Fairweather, and Keast [7]; Lentini and Pereyra [13]; and Keller [9]).

During the last 10 years, the question of stability of algorithms for (1), (2) has received a great deal of attention (see, for example, Mattheij [15]). It has been recognized that in a well-conditioned problem (that is, one whose solution is not too sensitive to perturbations in M, q, or the boundary conditions (2)), the fundamental solution space generally contains both exponentially increasing and exponentially decreasing modes. The stability of a numerical method for (1), (2) depends on its ability to at some point perform a "decoupling" of these modes. For the standard multiple shooting and finite-difference algorithms, this decoupling is performed implicitly, during the factorization of the structured linear system, through the use of a pivoting strategy that prevents element growth in the factors. Unfortunately, parallel and vectorizable algorithms that have been proposed for solving the linear system invariably place some restriction on the choice of pivots. This can lead to undesirable element growth in the factors, and such methods are in fact similar to compactification algorithms for (1), (2), which are known to be unstable. In this paper, we use instead a structured orthogonal factorization technique that is stable, has an identical serial complexity to the best-known algorithms, and can be efficiently implemented

on a wide variety of parallel architectures. A variant of the algorithm vectorizes efficiently, in much the same way as cyclic reduction for block-tridiagonal linear systems. No separability of the boundary conditions is needed. Although we focus on matrices arising from multiple shooting and one-step differencing schemes, the technique can be applied equally well to the more general staircase matrix structures that arise in other numerical schemes, such as collocation.

We assume throughout that n is too small to allow efficient parallel or vector implementation of order-n matrix and vector operations. Instead, parallelism is sought by partitioning the domain $[a, b]$ of the independent variable.

The remainder of the paper is organized as follows: in §2 we review the multiple shooting and finite-difference algorithms, the structured linear systems that result from them, and the efficient Gaussian elimination techniques used to solve them on serial computers. In §3 we briefly review previous work on parallel and vectorizable algorithms. The new algorithm is presented in §4, together with a stability result and analysis of serial and parallel complexity. In §5 we describe parallel implementation of a standard technique for estimating the condition number of the coefficient matrix, which can be used for purposes of a posteriori error analysis. Finally, in §6 we describe the results of implementation of the scheme on shared-memory and vector architectures.

2. Serial algorithms. The "standard" multiple shooting technique for (1), (2) proceeds by defining a mesh

$$a = t_1 < t_2 < \cdots < t_{k+1} = b, \tag{3}$$

and finding a fundamental and particular solution on each interval of the mesh:

$$Y_i' = M(t)Y_i, \qquad Y_i(t) \in R^{n\times n}, \qquad t \in [t_i, t_{i+1}], \qquad Y_i(t_i) = I,$$

$$y_{pi}' = M(t)y_{pi} + q(t), \qquad y_{pi}(t) \in R^n, \qquad t \in [t_i, t_{i+1}], \qquad y_{pi}(t_i) = 0.$$

Then, we try to find $s_i \in R^n$, $i = 1, \cdots, k+1$, such that

$$y(t) = Y_i(t)s_i + y_{pi}(t), \qquad t \in [t_i, t_{i+1}], \quad i = 1, \cdots, k.$$

(Note in particular that $s_i = y(t_i)$, $i = 1, \cdots, k+1$.) By applying the boundary conditions (2), and continuity at the meshpoints, we obtain the following linear system in $s_1, \cdots, s_{k+1}$:

$$\begin{bmatrix} B_a & & & & B_b \\ Y_1(t_2) & -I & & & \\ & Y_2(t_3) & -I & & \\ & & \ddots & \ddots & \\ & & & Y_k(t_{k+1}) & -I \end{bmatrix} \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ \vdots \\ s_{k+1} \end{bmatrix} = \begin{bmatrix} d \\ -y_{p1}(t_2) \\ -y_{p2}(t_3) \\ \vdots \\ -y_{pk}(t_{k+1}) \end{bmatrix}. \tag{4}$$

In the (quite common) case in which the boundary conditions are separated, this system can be rearranged into a block-banded form. If p is the number of initial conditions and q is the number of final conditions ($p + q = n$), we can assume without loss of generality that the boundary data (2) can be partitioned as follows:

$$B_a = \begin{bmatrix} \bar{B}_a \\ 0 \end{bmatrix}, \quad B_b = \begin{bmatrix} 0 \\ \bar{B}_b \end{bmatrix}, \quad d = \begin{bmatrix} d_a \\ d_b \end{bmatrix}.$$

If the rows $p+1, \cdots, n$ of (4) are moved to the bottom, we obtain the form

$$\begin{bmatrix} \bar{B}_a & & & & & \\ Y_1(t_2) & -I & & & & \\ & Y_2(t_3) & -I & & & \\ & & \ddots & \ddots & & \\ & & & Y_k(t_{k+1}) & -I \\ & & & & \bar{B}_b \end{bmatrix} \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ \vdots \\ s_k \\ s_{k+1} \end{bmatrix} = \begin{bmatrix} d_a \\ -y_{p1}(t_2) \\ -y_{p2}(t_3) \\ \vdots \\ -y_{pk}(t_{k+1}) \\ d_b \end{bmatrix}. \tag{5}$$

One-step finite-difference methods proceed by again choosing a mesh of the form (3) and seeking $s_1, \cdots, s_{k+1}$ to approximate $y(t_1), \cdots, y(t_{k+1})$. On the interval $[t_i, t_{i+1}]$, (1) is approximated by the linear relationship

$$\frac{s_{i+1} - s_i}{h_i} = \bar{A}_i s_i + \bar{C}_i s_{i+1} + \bar{f}_i, \tag{6}$$

where $h_i = t_{i+1} - t_i$. Two schemes with a local truncation error of $O(h_i^2)$ are the "box scheme" ($\bar{A}_i = \bar{C}_i = \frac{1}{2}M(t_{i+1/2})$, $\bar{f}_i = q(t_{i+1/2})$) and the trapezoidal rule ($\bar{A}_i = \frac{1}{2}M(t_i)$, $\bar{C}_i = \frac{1}{2}M(t_{i+1})$, $\bar{f}_i = \frac{1}{2}(q(t_i) + q(t_{i+1}))$). By including (2), we obtain a linear system of the form

$$\begin{bmatrix} B_a & & & & B_b \\ A_1 & C_1 & & & \\ & A_2 & C_2 & & \\ & & \ddots & \ddots & \\ & & & A_k & C_k \end{bmatrix} \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ \vdots \\ s_{k+1} \end{bmatrix} = \begin{bmatrix} d \\ f_1 \\ f_2 \\ \vdots \\ f_k \end{bmatrix}, \tag{7}$$

where $A_i = -I - h_i \bar{A}_i$, $C_i = I - h_i \bar{C}_i$, and $f_i = h_i \bar{f}_i$. If the boundary conditions are separated, we obtain

$$\begin{bmatrix} \bar{B}_a & & & & \\ A_1 & C_1 & & & \\ & A_2 & C_2 & & \\ & & \ddots & \ddots & \\ & & & A_k & C_k \\ & & & & \bar{B}_b \end{bmatrix} \begin{bmatrix} s_1 \\ s_2 \\ s_3 \\ \vdots \\ s_k \\ s_{k+1} \end{bmatrix} = \begin{bmatrix} d_a \\ f_1 \\ f_2 \\ \vdots \\ f_k \\ d_b \end{bmatrix}. \tag{8}$$

The accuracy of finite-difference schemes is often enhanced by the use of deferred correction techniques (see, for example, Pereyra [18]).

As has been observed, the two algorithms are closely related, in the sense that for a reasonable choice of the approximation (6), $-C_i^{-1}A_i$ should be close to $Y_i(t_{i+1})$. Hence, the conditioning of the matrices in (4) and (7) is quite similar when the h_i are small. If we quantify the conditioning of the problem (1), (2) by a bound κ on its Green's function (see Ascher, Mattheij, and Russell [3, §3.2]), it has been shown by Osborne [16] (and also by Mattheij [14] and Lentini, Osborne, and Russell [12]) that the inverse of A_S from (4) satisfies the bound

$$\|A_S^{-1}\|_\infty \leq k\kappa.$$

Hence if we define γ by

$$\gamma = 1 + \max_{i=1,\cdots,k} \|Y_i(t_{i+1})\|_\infty$$

and assume that B_a and B_b are scaled such that $\|[B_a, B_b]\|_\infty = 1$, then from (4), (5),

$$\text{cond}_\infty(A_S) \leq \gamma k \kappa. \tag{9}$$

For the finite-difference coefficient matrix A_D in (7), a similar analysis applies if we note that $\gamma = 2 + O(\bar{h})$ for small $\bar{h} = \max_{i=1,\cdots,k} h_i$. We use this fact, together with $A_D = A_S + O(\bar{h})$, to derive the bound

$$\text{cond}_\infty(A_D) \leq (2 + O(\bar{h}))k\kappa. \tag{10}$$

The slightly different form of the bounds (9) and (10) is motivated by the fact that k is typically larger in a finite-difference algorithm than in a multiple shooting algorithm. Bounds for the coefficient matrices in (5) and (8) are, of course, identical to their nonseparated counterparts.

As stated earlier, Gaussian elimination algorithms with various forms of pivoting have been previously proposed for solving (4), (5), (7), and (8). The practical stability of such algorithms for general matrices is well known, but it is also well known that the worst-case behavior can be very bad, as a result of possible growth of elements in the factors, which is exponential in the dimension $(k+1)n$ of the system. It has been shown (see, for example, Mattheij [15]) that the presence of an exponential dichotomy in (1), (2) ensures that this worst-case behavior does not arise when elimination algorithms are applied to the matrices in (4), (5), (7), and (8). In the partially separated cases (5), (8), similar results can be proved, without referring to the dichotomy at all, by using the results of Bohte [4]. Bohte shows that for banded linear systems, the bound on element growth in partial pivoting algorithms is exponential only in the bandwidth.

In the simplest case of Gaussian elimination with row partial pivoting (with coefficient matrices and right-hand sides denoted by A_{SP} and f_{SP} in (5) and A_{DP} and f_{DP} in (8)), possible fill-in of kpn elements can occur in the upper triangular factor. Element growth is, however, bounded by 2^{2n-1}, and so we obtain the following theorem.

THEOREM 2.1. *Let $s = (s_1^T, \cdots, s_{k+1}^T)^T$ denote the true solution of the system (8), and suppose that $\hat{s}$ is the approximate solution obtained by Gaussian elimination with row partial pivoting. Then, provided that*

(i) *$\bar{h}$ is chosen small enough that* $\text{cond}_\infty(A_{DP}) \leq 4k\kappa$,

(ii) $8c_1\kappa\mathbf{u} \leq 1$, *where* $c_1 = (1.12)2^{2n}n^3k(k+1)(k+8) = O(k^3n^32^{2n})$ *and* $\mathbf{u}$ *is the unit roundoff error,*

the following relative error bound applies:

$$\frac{\|\hat{s} - s\|_\infty}{\|s\|_\infty} \leq 16c_1\kappa\mathbf{u}. \tag{11}$$

Suppose that the fundamental and particular solutions that are used to construct A_{SP} and f_{SP} in (5) are calculated to a tolerance of τ, that is,

$$\|A_{SP} - \bar{A}_{SP}\|_\infty \leq \tau\|A_{SP}\|_\infty, \qquad \|f_{SP} - \bar{f}_{SP}\|_\infty \leq \tau\|f_{SP}\|_\infty. \tag{12}$$

Let $\tilde{s}$ be the solution obtained by using Gaussian elimination with row partial pivoting. Then provided that

(iii) $\tau k\kappa\gamma \leq \frac{1}{2}$,

(iv) $6c_1\mathbf{u}\kappa\gamma \leq 1$, *we have*

$$\frac{\max_{i=1,\cdots,k+1}\|\tilde{s}_i - y(t_i)\|_\infty}{\max_{i=1,\cdots,k+1}\|y(t_i)\|_\infty} \le 4\gamma\kappa[k\tau + 3c_1\mathbf{u} + c_2\mathbf{u}\tau], \tag{13}$$

where $c_2 = 12c_1k\kappa\gamma$.

Proof. For the first part of the theorem, the proof follows from Theorem 2.7.2 in Golub and Van Loan [8] and §4 of Bohte [4]. The latter assumes that

$$\mathbf{u} \le .009 \qquad \text{and} \qquad (k+1)n\mathbf{u} \le 0.1,$$

which are clearly implied by assumption (ii), since $\kappa \ge 1$, $k \ge 1$, and $n \ge 1$. Bohte then shows that $\hat{s}$ solves the system

$$(A_{DP} + E)\hat{s} = f_{DP},$$

where E satisfies the bound

$$\|E\|_\infty \le \Lambda\mathbf{u}(0.56)(4n-1)n(k+1)(kn+7n+3),$$

and Λ is a bound on the maximal element that arises during the elimination. By simplifying this expression, and noting from the discussion above that

$$\Lambda \le 2^{2n-1}\max_{i,j}|(A_{DP})_{ij}| \le 2^{2n-1}\|A_{DP}\|_\infty,$$

we have that

$$\|E\|_\infty \le (c_1/k)\mathbf{u}\|A_{DP}\|_\infty.$$

The result now follows by setting $r = \frac{1}{2}$ in [8, Thm. 2.7.2].

For the second part, note first that

$$\|\bar{A}_{SP}\|_\infty \le (1+\tau)\|A_{SP}\|_\infty$$

and

$$\|\bar{A}_{SP}^{-1}\|_\infty \le \|[I + A_{SP}^{-1}(\bar{A}_{SP} - A_{SP})]^{-1}\|_\infty\|A_{SP}^{-1}\|_\infty.$$

Provided

$$\|A_{SP}^{-1}(\bar{A}_{SP} - A_{SP})\|_\infty \le 1, \tag{14}$$

we have from [8, Lemma 2.3.3] that

$$\|\bar{A}_{SP}^{-1}\|_\infty \le \frac{\|A_{SP}^{-1}\|_\infty}{1 - \|A_{SP}^{-1}\|_\infty\tau} \le \frac{k\kappa}{1 - \tau k\kappa} \le 2k\kappa.$$

The inequality (14) is implied by (iii). Since k, γ, and κ are all at least 1, assumption (iii) implies that $\tau \le \frac{1}{2}$, and so

$$\operatorname{cond}_\infty(\bar{A}_{SP}) \le 2(1+\tau)k\kappa\gamma \le 3k\kappa\gamma. \tag{15}$$

Now let $\bar{s}$ be the exact solution of $\bar{A}_{SP}\bar{s} = \bar{f}_{SP}$. Direct application of [8, Thm. 2.7.2] with $r = \frac{1}{2}$ shows, again using (iii), that

$$\frac{\max_{i=1,\cdots,k+1}\|\bar{s}_i - y(t_i)\|_\infty}{\max_{i=1,\cdots,k+1}\|y(t_i)\|_\infty} \le 4\operatorname{cond}_\infty(A_{SP})\tau \le 4k\kappa\gamma\tau. \tag{16}$$

Application of Bohte's results shows that the computed solution $\tilde{s}$ satisfies $(\bar{A}_{SP} + E)\tilde{s} = \bar{f}_{SP}$, where

$$\|E\|_\infty \le \frac{c_1}{k}\mathbf{u}\|\bar{A}_{SP}\|_\infty.$$

Assumption (iv) and (15) imply that

$$\frac{c_1}{k}\mathbf{u}\mathrm{cond}_\infty(\bar{A}_{SP}) \le \frac{1}{2},$$

and so

$$\frac{\|\tilde{s}-\bar{s}\|_\infty}{\|\bar{s}\|_\infty} \le \frac{4c_1\mathbf{u}}{k}\mathrm{cond}_\infty(\bar{A}_{SP}) \le 12c_1\mathbf{u}\kappa\gamma. \tag{17}$$

The result follows by combining (16) and (17) in an elementary way. □

A more economical scheme for solving (5) and (8), described by Varah [19] and implemented by Diaz, Fairweather, and Keast [7], is the method of alternate row and column elimination. For the first p stages of the process, we use *column* pivoting and elimination (involving columns 1 through n); this produces no fill-in. For stages $p+1$ through n we use *row* pivoting and elimination for the same reason. Column and row elimination alternate in this way until a factorization of the form

$$A_{DP} = PLBU\Pi \tag{18}$$

is produced, where P and Π are permutation matrices, L and U are lower and upper triangular matrices of multipliers, and B has the form

$$B = \begin{bmatrix}
L & & & & & & & & & \\
X & R & X & X & & & & & & \\
X & & L & & & & & & & \\
 & & X & R & X & X & & & & \\
 & & X & & L & & & & & \\
 & & & & \ddots & \ddots & \ddots & & & \\
 & & & & & & X & 0 & L & \\
 & & & & & & & & X & R
\end{bmatrix}.$$

(L denotes a lower triangular $p \times p$ block, R denotes an upper triangular $(n-p)\times(n-p)$ block, and X denotes a dense block.) It is easy to show that element growth in the B factor is bounded by 2^{n-1} and, hence, that the scheme is very stable. We can prove the following.

THEOREM 2.2. *Let $s = (s_1^T, \cdots, s_{k+1}^T)^T$ denote the true solution of the system (8), and let $\hat{s}$ be the approximate solution calculated by alternate row and column elimination. Suppose further that*

(i) *$\bar{h}$ is chosen small enough that* $\mathrm{cond}_\infty(A_{DP}) \le 4k\kappa$, *and*

(ii) $8c_4\kappa\mathbf{u} \le 1$,

where

$$c_4 = k(k+2)n(5+6n)(1+n^2 2^{n-1}) = O(k^2n^4 2^n).$$

Then

$$\frac{\|\hat{s}-s\|_\infty}{\|s\|_\infty} \le 16c_4\kappa\mathbf{u}.$$

Let $\tilde{s}$ be obtained by multiple shooting with alternate row and column elimination, and suppose that (12) *holds, with*

(iii) $\tau k\kappa\gamma \leq \frac{1}{2}$,

(iv) $6c_4\mathbf{u}\kappa\gamma \leq 1$.

Then

$$\frac{\max_{i=1,\cdots,k+1}\|\tilde{s}_i - y(t_i)\|_\infty}{\max_{i=1,\cdots,k+1}\|y(t_i)\|_\infty} \leq \gamma k\kappa[k\tau + 3c_4\mathbf{u} + c_5\mathbf{u}\tau],$$

where $c_5 = 12c_4k\kappa\gamma$.

Proof. The assumptions of Lemma A.1 are consequences of (ii) and (iv) above. The first part of the result follows directly from Lemma A.2 and [8, Thm. 2.7.2]. The second part is analogous to the second part of Theorem 2.1, with c_4 replacing c_1 and c_5 replacing c_2. □

3. Parallel elimination algorithms. Other parallel and vectorizable algorithms, based on Gaussian elimination, have recently been proposed for (4), (5), (7), and (8). In general, they suffer either from poor stability properties or from limitations in the amount of parallelism that is possible.

Wright and Pereyra [21] describe variants of a block factorization algorithm applied to (7). In the most highly vectorized variant, a factorization of the form

$$\begin{bmatrix} \tilde{A}_1 & & & & \\ & \tilde{A}_2 & & & \\ & & \ddots & & \\ & & & \tilde{A}_k & \\ Z_1 & Z_2 & \cdots & Z_k & \tilde{A}_{k+1} \end{bmatrix} \begin{bmatrix} I & W_1 & & & \\ & I & W_2 & & \\ & & \ddots & \ddots & \\ & & & I & W_k \\ & & & & I \end{bmatrix} = \begin{bmatrix} P_1 & & & & \\ & P_2 & & & \\ & & \ddots & & \\ & & & P_k & \\ & & & & P_{k+1} \end{bmatrix} \begin{bmatrix} A_1 & C_1 & & & \\ & A_2 & C_2 & & \\ & & \ddots & \ddots & \\ & & & A_k & C_k \\ B_a & & & & B_b \end{bmatrix}$$

(where the P_i are permutation matrices) is produced. It is easy to show that for h sufficiently small, this factorization exists. It is equivalent to compactification [3, p. 153] which, because of its similarity to single shooting, is known to be potentially unstable. However, this instability can usually be recognized by the presence of large elements in the Z_i blocks. The strategy described in [21, §5] is to use this factorization where possible, and discard it in favor of a more stable method if the $\|Z_i\|$ are too large. In many applications (such as the one described in [21]) the lack of stability is not a problem.

Paprzycki and Gladwell [17] describe a partitioned elimination algorithm in which (8) is torn into P submatrices, each of which has the same form as the original A_{DP}, and alternate row and column elimination is applied to each piece. This corresponds to partitioning the interval $[a, b]$ and solving a number of sub-BVPs, each of which has p initial and q final conditions. Although the number of initial and final conditions is correct, this alone is not enough to ensure well-conditioning of the sub-BVPs. In a linear algebra sense, well-conditioning of the whole matrix A_{DP} does not guarantee well-conditioning of each of the P submatrices. Ascher and Mattheij [2] develop a "theoretical multiple shooting" framework in which they show how boundary values for the sub-BVPs should be chosen to ensure well-conditioning. Ascher and Chan [1] suggest how to implement this in a parallel environment.

Another possibility, which leads to near-perfect speedup on two processors (but cannot be generalized to a higher order of parallelism) is the "burn at both ends" or "twisted" factorization. Here, some form of pivoted Gaussian elimination is applied simultaneously from both ends of the matrix (either A_{DP} or A_{SP}). When the factorizations meet in the center, a small reduced system is formed and factored. This is analogous to the approach of Lentini [11].

Finally, we mention the approach of Ascher and Chan [1], who form the normal equations for (5) and (8), and factorize the resulting symmetric, positive definite, block-tridiagonal system using cyclic reduction. In exact arithmetic, this scheme produces a triangular factor that is identical to that given by the "cyclic reduction" variant of the algorithm to be described in the next section. The difference lies in the fact that by explicitly forming the normal equations, the condition number of a linear system is squared, an effect that is avoided when the algorithm from §4 is used.

4. Structured orthogonal factorization. We now describe the structured QR factorization algorithm, as applied to the system (7). It can of course be applied equally well to the systems (8), (4), and (5), since it is indifferent to separability of the boundary conditions.

The first step is to partition the system into, say, P pieces of approximately equal size. We choose indices $k_1, k_2, \cdots, k_{P+1}$ to satisfy

$$0 = k_1 < k_2 < \cdots < k_{P+1} = k, \qquad k_{j+1} \geq k_j + 2, \quad j = 1, \cdots, P.$$

(P could, for instance, be the number of processors on the physical machine being used to solve the problem.) Partition j then consists of rows $(k_j+1)n+1, \cdots, (k_{j+1}+1)n$ of (7). Each partition is now processed independently; in effect, the variables s_i for $i \neq k_j + 1$, $j = 0, \cdots, P$, are eliminated from the problem.

We describe this process in detail for the first partition, which, if augmented with its right-hand side, has the form

$$\left[\begin{array}{ccccc|c} A_1 & C_1 & & & & f_1 \\ & A_2 & C_2 & & & f_2 \\ & & \ddots & \ddots & & \vdots \\ & & & A_{k_2} & C_{k_2} & f_{k_2} \end{array}\right]. \tag{19}$$

We first find an orthogonal matrix $Q_1 \in R^{2n \times 2n}$ such that

$$Q_1^T \begin{bmatrix} C_1 \\ A_2 \end{bmatrix} = \begin{bmatrix} R_1 \\ 0 \end{bmatrix},$$

where $R_1 \in R^{n \times n}$ is upper triangular. If we form Q_1 as a product of n Householder transformations, the information needed to reconstruct Q_1 could be stored in the space formerly occupied by the "zeroed" elements of $[C_1^T, A_2^T]^T$, plus an additional n locations. We also need to apply Q_1^T to the other columns of the matrix (19), and the overall effect is

$$\begin{bmatrix} Q_1^T & 0 \\ 0 & I \end{bmatrix} \left[\begin{array}{ccccc|c} A_1 & C_1 & & & & f_1 \\ & A_2 & C_2 & & & f_2 \\ & & \ddots & \ddots & & \vdots \\ & & & A_{k_2} & C_{k_2} & f_{k_2} \end{array}\right] \tag{20}$$

$$= \left[\begin{array}{cccccc|c} G_1 & R_1 & E_1 & & & & g_1 \\ \bar{G}_2 & 0 & \bar{C}_2 & & & & \bar{f}_2 \\ & & A_3 & C_3 & & & f_3 \\ & & & \ddots & \ddots & & \vdots \\ & & & & A_{k_2} & C_{k_2} & f_{k_2} \end{array}\right].$$

The next step is to find an orthogonal $Q_2 \in R^{2n \times 2n}$ such that

$$Q_2^T \begin{bmatrix} \bar{C}_2 \\ A_3 \end{bmatrix} = \begin{bmatrix} R_2 \\ 0 \end{bmatrix},$$

and to apply Q_2^T to rows $n+1, \cdots, 3n$ of the reduced system (20). This process is repeated a total of $k_2 - 1$ times, until finally we obtain a system equivalent to (19), which has the form

$$(21) \qquad \left[\begin{array}{cccccc|c} G_1 & R_1 & E_1 & & & & g_1 \\ G_2 & & R_2 & E_2 & & & g_2 \\ \vdots & & & \ddots & \ddots & & \vdots \\ G_{k_2-1} & & & & R_{k_2-1} & E_{k_2-1} & g_{k_2-1} \\ \tilde{A}_1 & & & & & \tilde{C}_1 & \tilde{f}_1 \end{array}\right].$$

Formally, the reduction process for partition j can be specified as follows:

$$\bar{C}_{k_j+1} = C_{k_j+1}, \quad \bar{G}_{k_j+1} = A_{k_j+1}, \quad \bar{f}_{k_j+1} = f_{k_j+1}$$

for $i = k_j + 1, \cdots, k_{j+1} - 1$.

Find orthogonal Q_i such that

$$(22) \qquad Q_i^T \begin{bmatrix} \bar{C}_i \\ A_{i+1} \end{bmatrix} = \begin{bmatrix} R_i \\ 0 \end{bmatrix},$$

where $R_i \in R^{n \times n}$ is upper triangular;

Set

$$\begin{bmatrix} E_i \\ \bar{C}_{i+1} \end{bmatrix} \leftarrow Q_i^T \begin{bmatrix} 0 \\ C_{i+1} \end{bmatrix}, \quad \begin{bmatrix} G_i \\ \bar{G}_{i+1} \end{bmatrix} \leftarrow Q_i^T \begin{bmatrix} \bar{G}_i \\ 0 \end{bmatrix}, \quad \begin{bmatrix} g_i \\ \bar{f}_{i+1} \end{bmatrix} \leftarrow Q_i^T \begin{bmatrix} \bar{f}_i \\ f_{i+1} \end{bmatrix}.$$

end (for)

$$\text{Set } \tilde{A}_j = \bar{G}_{k_{j+1}}, \qquad \tilde{C}_j = \bar{C}_{k_{j+1}}, \qquad \tilde{f}_j = \bar{f}_{k_{j+1}}.$$

Clearly, if we knew the values of s_{k_j+1} and $s_{k_{j+1}+1}$, the values of $s_{k_j+2}, \cdots, s_{k_{j+1}}$ could be recovered by the simple back-substitution:

for $i = k_{j+1} - 1, k_{j+1} - 2, \cdots, k_j + 1$

$$(23) \qquad \text{Solve } R_i s_{i+1} = g_i - G_i s_{k_j} - E_i s_{i+2}.$$

In fact, these "separator" variables can be found by forming and solving a reduced system by taking the last n rows of each (processed) partition, and the boundary conditions. This reduced system has the form

$$
\begin{bmatrix} B_a & & & & B_b \\ \tilde{A}_1 & \tilde{C}_1 & & & \\ & \tilde{A}_2 & \tilde{C}_2 & & \\ & & \ddots & \ddots & \\ & & & \tilde{A}_P & \tilde{C}_P \end{bmatrix} \begin{bmatrix} s_{k_1+1} \\ s_{k_2+1} \\ s_{k_3+1} \\ \vdots \\ s_{k_{P+1}+1} \end{bmatrix} = \begin{bmatrix} d \\ \tilde{f}_1 \\ \tilde{f}_2 \\ \vdots \\ \tilde{f}_P \end{bmatrix} . \tag{24}
$$

The form of (24) is obviously identical to the form of the original system (7), so this immediately suggests that it may be possible to apply the whole process recursively, that is, (24) could be partitioned into $P_2 \leq P/2$ pieces, and the algorithm described above could be applied to obtain a smaller reduced system. This process could be repeated for, say, L levels, so at the innermost level a $(P_L + 1)n$-dimensional system would remain.

In a parallel implementation of the algorithm, the number of levels L to be used and the number of processors to be used at each level depend on the number of available processors on the physical machine, and, on a distributed-memory machine, on the cost of interprocessor communication. The "extreme" cases are as follows:

- A one-level version ($P = 1, k_2 = k$), in which (7) is reduced to the $2n \times 2n$ system

$$
\begin{bmatrix} B_a & B_b \\ \tilde{A}_1 & \tilde{C}_1 \end{bmatrix} \begin{bmatrix} s_1 \\ s_{k+1} \end{bmatrix} = \begin{bmatrix} d \\ \tilde{f}_1 \end{bmatrix}, \tag{25}
$$

  which is then solved by QR factorization. This is the "serial" version of the algorithm.
- A two-level version, in which P processors are used to do the reduction and back-substitution (23), and the system (24) is solved by the one-level algorithm just described. It is easy to see that, assuming that each partition contains about k/P rows of blocks, the time required for the reduction phase is proportional to $(k/P - 1)n^3$. The time required to solve (24) on a single processor is proportional to $(P + 1)n^3$. The latter operation will not be a bottleneck for the whole process, provided that $k \gg P^2$.
- A "cyclic reduction" version, in which P is equal to the number of available processors (assuming that $P \leq k/2$), and then $P_2 = P/2$, $P_3 = P/4$, $\cdots$, $P_L = 1$. Here, clearly, $L = \log_2 P + 1$. The total computation time required will be proportional to $(k/P - 1 + \log_2 P)n^3$, while the communication time will be proportional to $n^2 \log_2 P$. With regard to complexity, the algorithm is optimal: when $k = P \log_2 P$, the execution time is $O(\log_2 P)$ on P processors, while the serial time is $O(P \log_2 P)$.

The cyclic reduction variant is also appropriate for implementation on a single *vector* processor. In this environment, we could choose $P = k/2, P_2 = k/4, P_3 = k/8, \cdots$, and so $L = \log_2 k + 1$. At level l, the reduction and back-substitution processes can be coded so that most of the arithmetic involves vectors of length $k/2^l$. At low levels, a reversal of the loop nesting can be used to ensure that vector lengths do not fall below n.

It is not difficult to see that the factorization and solution phases can be separated, provided that the Householder vectors are stored (in the locations vacated by the zeroed elements). This feature is useful when quasi linearization is used to solve a first-order nonlinear BVP. The same coefficient matrix (and its factorization) can be used for a number of consecutive iterations to produce "chord method" approximations to Newton steps.

It is important to note that the scheme proposed above is simply standard Householder QR factorization applied to an initial row- and column-permuted form of the original matrix. Thus, we can apply the standard stability analysis for $(k+1)n$-dimensional matrices from Lawson and Hanson [10] to obtain error bounds for the computed solutions. We have refined these bounds to take into account the structure of the matrix. In addition, to allay any possible concerns about instability at the level of the $O(\mathbf{u}^2)$ terms, we have removed these terms using the style of analysis in Wilkinson [20]. The relevant results are stated and proved in Appendix B. Here, we summarize the analysis in the following lemma and theorem.

LEMMA 4.1. *Let $s = (s_1^T, s_2^T, \cdots, s_{k+1}^T)^T$ denote the true solution of the system* (7), *and suppose that $\hat{s}$ is the approximate solution obtained by using the structured QR factorization and back-substitution. Suppose that the orthogonal matrices used in the factorization are all constructed from Householder reflectors, and that n, k, and $\mathbf{u}$ satisfy*

$$(12n+51)n(k+1)\mathbf{u} \le 0.1. \tag{26}$$

Then $\hat{s}$ is the exact solution of a perturbed system

$$(A_D + \delta A_D)\hat{s} = f_D + \delta f_D, \tag{27}$$

where

$$\|\delta A_D\|_F \le (1.106)(12n+51)(k+2)n\mathbf{u}\|A_D\|_F, \tag{28}$$

$$\|\delta f_D\|_2 \le (1.106)(12n+51)(k+1)n\mathbf{u}\|f_D\|_2. \tag{29}$$

Proof. See Appendix B. □

THEOREM 4.2. *Suppose that the conditions of Lemma* 4.1 *are satisfied. Then, provided that*

(i) *$\bar{h}$ is chosen small enough that* $\text{cond}_\infty(A_{DP}) \le 4k\kappa$,

(ii) $8c_6\kappa\mathbf{u} \le 1$, *where* $c_6 = (1.106)k(k+2)^2n^2(12n+51)$,

the following relative error bound applies:

$$\frac{\|\hat{s}-s\|_\infty}{\|s\|_\infty} \le 16c_6\kappa\mathbf{u}.$$

Suppose that the fundamental and particular solutions that are used to construct A_S and f_S in (4) *are calculated to a tolerance of τ, that is,*

$$\|A_S - \bar{A}_S\|_\infty \le \tau\|A_S\|_\infty, \qquad \|f_S - \bar{f}_S\|_\infty \le \tau\|f_S\|_\infty. \tag{30}$$

Let $\tilde{s}$ be the solution obtained by using a structured QR algorithm, where (26) *holds. Then, provided that*

(iii) $\tau k\kappa\gamma \le \frac{1}{2}$,

(iv) $6c_6\mathbf{u}\kappa\gamma \le 1$,

we have

$$\frac{\max_{i=1,\cdots,k+1}\|\tilde{s}_i - y(t_i)\|_\infty}{\max_{i=1,\cdots,k+1}\|y(t_i)\|_\infty} \le 4\gamma\kappa[k\tau + 3c_6\mathbf{u} + c_7\mathbf{u}\tau],$$

where $c_7 = 12c_6 k\kappa\gamma$.

Proof. The proof is identical to that of Theorem 2.1, once we convert the Frobenius norm bounds (28) and (29) into ∞-norm bounds. This is done by noting that for an $N \times N$ matrix A,

$$\frac{1}{N^{1/2}}\|A\|_\infty \leq \|A\|_F \leq N^{1/2}\|A\|_\infty.$$

Hence

$$\|\delta A_D\|_\infty \leq (1.106)(k+2)^2 n^2 (12n+51)\mathbf{u}\|A_D\|_\infty. \qquad \square$$

5. Condition estimation.

For purposes of assessing the reliability of the computed solution, it is useful to have an estimate of the conditioning of the discrete system. Such an estimate can be obtained, simultaneously with the factorization and solution process, by adapting the procedure described in Cline et al. [6] to our situation.

We aim to compute an estimate of the quantity

$$\hat{\kappa} = \|A\|_\infty \|R^{-1}\|_\infty,$$

where A is one of the coefficient matrices from (4), (7), (5), and (8), and R is the upper triangular factor produced by the procedure just described. It is easy to show that

$$\frac{1}{\sqrt{(k+1)n}}\hat{\kappa} \leq \mathrm{cond}_\infty(A) \leq \sqrt{(k+1)n}\hat{\kappa}.$$

$\|A\|_\infty$ can of course be calculated directly, and so computation of the estimate of $\|R^{-1}\|_\infty$ is the major part of the task of finding $\hat{\kappa}$. Following [6], we do this by first finding vectors z and v such that

$$R^T v = z,$$

where the components of z are all ± 1 and are chosen by a heuristic that attempts to maximize $\|v\|_\infty$. This is done during the factorization of A; as reduction of each partition into a single row of blocks is performed, the heuristic can be applied to finding the components of z and v corresponding to the rows and columns of the original system that are eliminated. Next, the solution of

$$Rw = v$$

is found concurrently with the solution of the original linear system $Rs = Q^T f$. We then use the estimate

$$\|R^{-1}\|_\infty \approx \frac{\|w\|_\infty}{\|v\|_\infty}.$$

The operation count for calculation of $\hat{\kappa}$ is approximately four times that of doing a single backsolve with R, and the parallel complexity is the same as that of the factorization and solution. Comparisons with the LINPACK condition number estimator of $\mathrm{cond}_1(A)$ (which is based on an LU factorization of A but uses similar heuristics) show that the two estimates are usually within a factor of 3 of each other.

TABLE 1

Operation counts and storage requirements for four algorithms, assuming separated end conditions. k = number of meshpoints, n = dimension of y, p = number of left-hand end conditions, R = number of right-hand sides.

Algorithm	Operation count	Storage
LU (row pivoting)	$k[\frac{5}{3}n^3 + 3pn^2 + R(4n^2 + 2pn)]$	$kn(2n + p)$
Structured QR	$k[\frac{46}{3}n^3 + (15R + 30)n^2]$	$4kn^2$
Normal equations	$k[\frac{38}{3}n^3 + 12Rn^2]$	$4kn^2$
DECOMP/SOLVE	$k[\frac{2}{3}n^3 + (4R + 5p)n^2 - 2np^2]$	$2kn^2$

TABLE 2

Operation counts and storage requirements for four algorithms, assuming nonseparated end conditions. k = number of meshpoints, n = dimension of y, R = number of right-hand sides.

Algorithm	Operation count	Storage
LU (row pivoting)	$k[\frac{23}{3}n^3 + 8Rn^2]$	$4kn^2$
Structured QR	$k[\frac{46}{3}n^3 + (15R + 30)n^2]$	$4kn^2$
Normal equations	$k[\frac{62}{3}n^3 + 12Rn^2]$	$5kn^2$
DECOMP/SOLVE	$k[\frac{14}{3}n^3 + 4Rn^2]$	$3kn^2$

6. Computational results. Versions of the structured QR algorithm have been implemented on the Alliant FX/8 vector multiprocessor at Argonne National Laboratory and on the CRAY Y-MP at the North Carolina Supercomputing Center. Performance comparisons were made with

- a row partial pivoting code (two versions, for separated and nonseparated boundary conditions), and
- the DECOMP and SOLVE routines from the PASVA codes [13]. The DECOMP routine uses alternate row and column pivoting (as does the algorithm described in Varah [19] and in §2) but always eliminates by rows.

Approximate operation counts and storage requirements for these algorithms and the normal equations method of Ascher and Chan [1] are given in Tables 1 and 2, for separated and nonseparated boundary conditions, respectively. In tabulating storage requirements, it has been assumed that intermediate information generated during the factorization—namely, the multipliers and Householder vectors—is stored for possible later use with a different right-hand side. In general, the structured QR algorithms require the most operations. This result is not surprising, since it is well known that orthogonal factorization of dense matrices requires about twice as much work as Gaussian elimination. Moreover, in the case of separated end conditions, structured QR generates fill-in that is avoided by the elimination-based methods, and this adds further to the operation count. On the other hand, the operation counts and storage requirements for structured QR are not affected if the end conditions are nonseparated rather than separated, while for the other methods, they increase substantially. The method based on normal equations requires about the same amount of work as structured QR; however, as we noted earlier, it is less stable. We add the caveat that operation counts are notoriously bad predictors of run time for factorizations of narrow-banded matrices. For small n, much of the CPU time is taken up with nonnumerical operations. This is borne out by our results, which show that the QR algorithm does not do as badly as predicted in serial mode.

TABLE 3
Box method, error in first component of computed solution for Problem 1 *for four different linear system solvers.*

	$k = 16$	$k = 64$	$k = 1024$
$\hat{\kappa}$	.17(+2)	.51(+1)	.21(+1)

DECOMP	.22(-2)	.10(-3)	.32(-6)
SQR-1	.21(-2)	.10(-3)	.32(-6)
COMPACT	.22(-2)	.93(+27)	.16(+72)

TABLE 4
Multiple shooting, error in first component of computed solution for Problem 1 *for four different linear system solvers.*

	$k = 16$	$k = 32$	$k = 128$
$\hat{\kappa}$	.85(+6)	.17(+4)	.13(+2)
ROWPP	.45(-3)	.67(-6)	.64(-7)
DECOMP	.45(-3)	.67(-6)	.64(-7)
SQR-1	.45(-3)	.67(-6)	.64(-7)
COMPACT	.51(+72)	.21(+72)	.11(+72)

The linear system solvers described above have been incorporated into both a multiple shooting and finite-difference (box method) framework. The `dverk` code from netlib was used to solve the initial value problems (IVPs) on each interval of multiple shooting, with the global error tolerance parameter set to 10^{-10}. A user-specified number k of equally spaced intervals is used for both methods. For practical codes, the choice of the number of intervals and their lengths (and efficient parallel implementation of this) are important issues, but we focus here on the linear algebra, which typically is the most computationally intensive part of a finite-difference–based code. In accord with the theoretical results of §§2 and 4, virtually no difference was noted between the stability properties of structured QR and row-pivoted LU. As evidence of this, we quote results for the following test problem.

PROBLEM 1 (Ascher and Chan [1]). $a = 0$, $b = 1$, $n = 2$,

$$y'(t) = \begin{bmatrix} -\lambda\cos 2\omega t & \omega + \lambda\sin 2\omega t \\ -\omega + \lambda\sin 2\omega t & \lambda\cos 2\omega t \end{bmatrix} y(t) + f(t),$$

$$B_a = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \qquad B_b = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix},$$

with $f(t)$ and d chosen so that $y(t) = e^t(1,1)^T$.

A fundamental solution is

$$Y(t) = \begin{bmatrix} \cos\omega t & \sin\omega t \\ -\sin\omega t & \cos\omega t \end{bmatrix} \begin{bmatrix} e^{-\lambda t} & 0 \\ 0 & e^{\lambda t} \end{bmatrix},$$

so clearly there exist one growing and one decaying mode. The problem was solved using both multiple shooting and the box method for $\lambda = 200$ and $\omega = 1$. Four different algorithms were used to solve the linear system, namely,

- SQR-1—one-level structured QR;
- ROWPP—LU factorization with row partial pivoting;
- DECOMP—the DECOMP and SOLVE routines from PASVA; and
- COMPACT—compactification, as implemented in the codes D4/S4 described in [21].

TABLE 5

Dimensions of the five test cases, and conditioning of the multiple shooting and finite-difference matrices.

Problem	n	k	ms conditioning	fd conditioning
1a	2	64	.41(+2)	.17(+2)
1b	2	1024	.30(+2)	.30(+2)
2a	4	64	.37(+9)	.83(+3)
2b	4	1024	.26(+2)	.17(+2)
3	3	1024	.20(+1)	.34(+1)

Tables 3 and 4 show the maximum error in the first component of the computed result. Because of its failure to decouple the fundamental solution modes, compactification performs poorly. The accuracy of box method solutions is limited by discretization error, while the multiple shooting solutions are accurate up to the conditioning of the discrete system and the tolerance imposed on the IVP solver. The DECOMP code gives accurate results here because the end conditions are separated. When this is not the case, as in Problem 3 below, DECOMP is known to be unstable.

To test the relative speed of the linear solvers, two further problems from the literature were used in addition to Problem 1.

PROBLEM 2 (Brown and Lorenz [5]). $a = -1$, $b = 1$, $n = 4$,

$$\begin{aligned} -\epsilon y'' - \frac{t}{2}y' + \frac{t}{2}z' + z &= \epsilon\pi^2 \cos \pi t \ + \frac{1}{2}\pi t \sin \pi t, \\ \epsilon z'' &= z, \\ y(-1) = -1 \quad & y(1) = e^{-2/\sqrt{\epsilon}}, \\ z(-1) = 1 \quad & z(1) = e^{-2/\sqrt{\epsilon}}. \end{aligned}$$

(We use $\epsilon = .001$.)

PROBLEM 3 (Mattheij [15]). $a = 0$, $b = \pi$, $n = 3$,

$$\begin{aligned} y'(t) = &\begin{bmatrix} 1 - 19\cos 2t & 0 & 1 + 19\sin 2t \\ 0 & 19 & 0 \\ -1 + 19\sin 2t & 0 & 1 + 19\cos 2t \end{bmatrix} y(t) \\ &+e^t \begin{bmatrix} -1 + 19(\cos 2t \ - \sin 2t) \\ -18 \\ 1 - 19(\cos 2t \ + \sin 2t) \end{bmatrix}, \end{aligned}$$

$$\begin{aligned} y_1(0) &= 1, \\ y_3(0) + y_3(\pi) &= 1 + e^{\pi}, \\ y_2(0) + y_2(\pi) &= 1 + e^{\pi}. \end{aligned}$$

The solution is $y(t) = e^t(1, 1, 1)^T$.

Problems 1 and 2 have separated end conditions, while two of the three end conditions for Problem 3 are nonseparated. We report on five cases (two different values of k were tried for Problems 1 and 2, and values of $\lambda = 1$ and $\omega = 50$ were used in Problem 1). Table 5 gives condition estimates for the multiple shooting and finite-difference matrices.

Results from "scalar" implementations on one processor of the Alliant FX/8 are shown in Table 6. We have tabulated the times required to solve the linear systems. The -Og compiler option was used with each code, so the vector processing capabilities of the Alliant were not used. In addition to the linear solvers already mentioned, we

1b	34.6	48.3	139.	10.9
2a	5.32	8.38	21.1	6.40
2b	84.4	133.	341.	51.6
3	136.	116.	232.	26.3

tested SQR-CR, which was the cyclic-reduction variant of structured QR. Note that the SQR codes typically take two to three times as long as ROWPP, though the penalty is much smaller when the end conditions are not separated (as in Problem 3). In either case, the overhead for using structured QR is not as great as the operation counts in Tables 1 and 2 would suggest.

Timings for a vectorized implementation on one processor of a CRAY Y-MP are shown in Table 7. In general, the SQR-CR code becomes very competitive, particularly when $n = 2$ or 3, k is large, and/or the end conditions are not separated. This code performs extremely well on Problems 1b and 3. When $n = 4$ (Problem 2), the small amount of vectorization that occurs in the other codes lessens the advantage of SQR-CR, while in Problems 1a and 2a the value of k makes the overall computational task too small to benefit from vectorization.

Table 8 gives results for an eight-processor parallel implementation on the Alliant FX/8. The -Ogc option was used during compilation. Here, SQR-2 refers to the two-level version of structured QR, in which the original system is broken into eight partitions of equal size, which are factorized concurrently. On the largest problem, the parallel efficiency of structured QR (measured by comparing serial SQR-1 to parallel SQR-2) is 87 percent—quite acceptable, given that the solution of the reduced system is an unavoidable bottleneck. The efficiency improves further for still larger problems. Defining speedup as the ratio of the one-processor time for the best serial algorithm to the eight-processor time for the best parallel algorithm, we see, from Table 9, that in three of the five cases good parallel efficiency is attained. The remaining two problems were too small for parallelism to have much effect.

Comparing Tables 6 and 8, it can be seen that ROWPP and DECOMP also speed up a little when extra processors are available. This is because the Alliant is a shared-memory machine. It is important to note that on the current generation of message-passing machines, these algorithms will *not* benefit from multiprocessing unless n is large enough that rows or columns *within each block* can profitably be distributed around the processor array. This is unlikely to happen until n is at least 50 or 100. On the other hand, efficient implementations of multilevel SQR on these machines will be possible for much more typical problem sizes.

To summarize, we conclude that the structured QR codes are useful in the following circumstances:

- when the computational task of solving the linear equations is substantial enough to benefit from vectorization or parallelism;
- especially, when the end conditions are not separated;
- on a vector processor, when the value of n is too small (say, only 2 or 3) to allow efficient vectorized factorization of $n \times n$ blocks;
- on the current generation of distributed-memory multiprocessors, unless n is very large and the number of processors is very small;
- on a shared-memory multiprocessor, unless n is quite large (say, greater than 8) and there are fewer than four processors.

A. Appendix A.

We start with a result which is similar to [8, Thm. 3.3.1].

LEMMA A.1. *Suppose that alternate row and column elimination, without pivoting, is applied to an $N \times N$ matrix A with bandwidth b_w to produce computed factors $\hat{L}$, $\hat{B}$, $\hat{U}$. Assume that N, b_w, and the unit roundoff error $\mathbf{u}$ satisfy*

$$N\mathbf{u} < 0.1, \tag{31}$$

$$N\mathbf{u}(2 + 1.06b_w + 2.12b_w\mathbf{u}) < 0.5. \tag{32}$$

Then

$$\hat{L}\hat{B}\hat{U} = A + H,$$

where

$$|H| \le c_3(N-1)\mathbf{u}\{|A| + |\hat{L}||\hat{B}||\hat{U}|\} \tag{33}$$

and

$$c_3 = 5 + 3b_w.$$

Proof. The result is trivially true for $N = 1$. Suppose for induction that (31) holds for matrices of size up to $N - 1$. Let

$$A = \begin{bmatrix} \alpha & w^T \\ v & A_1 \end{bmatrix},$$

where $\alpha \in R$, $A_1 \in R^{(N-1)\times(N-1)}$, etc., and suppose that row elimination will be used to eliminate v. We compute

$$\hat{z} = \frac{1}{\alpha}v + f, \qquad |f| \le \frac{|v|}{\alpha}\mathbf{u}, \tag{34}$$

$$\hat{A}_1 = A_1 - \hat{z}w^T + F, \qquad |F| \le 2\mathbf{u}(|A_1| + |\hat{z}||w|^T). \tag{35}$$

It follows immediately from (35) that

$$|\hat{A}_1| \le (1 + 2\mathbf{u})(|A_1| + |\hat{z}||w|^T). \tag{36}$$

An LBU factorization of $\hat{A}_1$ is then performed, yielding

$$\hat{L}_1\hat{B}_1\hat{U}_1 = \hat{A}_1 + H_1,$$

with

$$|H_1| \le c_3(N-2)\mathbf{u}\{|\hat{A}_1| + |\hat{L}_1||\hat{B}_1||\hat{U}_1|\}. \tag{37}$$

The calculated factors of A are therefore

$$\hat{L} = \begin{bmatrix} 1 & 0 \\ \hat{z} & \hat{L}_1 \end{bmatrix}, \qquad \hat{B} = \begin{bmatrix} \alpha & \hat{w}^T \\ 0 & \hat{B}_1 \end{bmatrix}, \qquad \hat{U} = \begin{bmatrix} 1 & 0 \\ 0 & \hat{U}_1 \end{bmatrix},$$

where $\hat{w}$ is the computed solution of the system $\hat{U}_1^T\tilde{w} = w$. Defining $\bar{b}_w = 1.06b_w$, and noting that $\hat{U}_1^T$ has lower bandwidth b_w, it is easy to show that $\hat{w}$ *exactly* solves

$$(\hat{U}_1^T + \delta_U)\hat{w} = w,$$

where

$$|\delta_U| \le \bar{b}_w\mathbf{u}|\hat{U}_1|^T.$$

Hence

$$|\hat{U}_1^T\hat{w} - w| = |\delta_U\hat{w}| \le |\delta_U||\hat{w}| \le \bar{b}_w\mathbf{u}|\hat{U}_1|^T|\hat{w}|, \tag{38}$$

and so

$$|w| \le (1 + \bar{b}_w\mathbf{u})|\hat{U}_1|^T|\hat{w}|. \tag{39}$$

Now

$$\begin{aligned} &\hat{A}_1 = A_1 - \hat{z}w^T + F, \\ \Rightarrow\ &\hat{z}\hat{w}^T\hat{U}_1 + \hat{L}_1\hat{B}_1\hat{U}_1 = A_1 + F + H_1 - \hat{z}[w - \hat{U}_1^T\hat{w}]^T. \end{aligned}$$

Combining this with (34),

$$\hat{L}\hat{B}\hat{U} = A + \begin{bmatrix} 0 & \hat{w}^T\hat{U}_1 - w^T \\ \alpha f & F + H_1 - \hat{z}[w - \hat{U}_1^T\hat{w}]^T \end{bmatrix}. \tag{40}$$

Now, combining (35), (36), (37), and (39), we find that

$$\begin{aligned} &|F + H_1 - \hat{z}[w - \hat{U}_1^T\hat{w}]^T| \\ &\quad \le |F| + |H_1| + |\hat{z}||w - \hat{U}_1^T\hat{w}|^T \\ &\quad \le [c_3(N-2)\mathbf{u}(1+2\mathbf{u}) + 2\mathbf{u}]|A_1| \\ &\qquad + [c_3(N-2)\mathbf{u}(1+2\mathbf{u})(1+\bar{b}_w\mathbf{u}) + 2\mathbf{u}(1+\bar{b}_w\mathbf{u}) + \bar{b}_w\mathbf{u}]|\hat{z}||\hat{w}|^T|\hat{U}_1| \\ &\qquad + c_3(N-2)\mathbf{u}|\hat{L}_1||\hat{B}_1||\hat{U}_1|. \end{aligned} \tag{41}$$

We now show that

$$c_3(N-2)\mathbf{u}(1+2\mathbf{u})(1+\bar{b}_w\mathbf{u})+2\mathbf{u}(1+\bar{b}_w\mathbf{u})+\bar{b}_w\mathbf{u}\le c_3(N-1)\mathbf{u}. \tag{42}$$

This is equivalent to

$$\begin{aligned}&c_3(N-2)\mathbf{u}(2\mathbf{u}+\bar{b}_w\mathbf{u}+2\bar{b}_w\mathbf{u}^2)+(2\mathbf{u}+\bar{b}_w\mathbf{u}+2\bar{b}_w\mathbf{u}^2)\le c_3\mathbf{u}\\ &\qquad\Leftrightarrow c_3[1-(N-2)\mathbf{u}(2+\bar{b}_w+2\bar{b}_w\mathbf{u})]\ge(2+\bar{b}_w+2\bar{b}_w\mathbf{u}).\end{aligned}$$

Since by assumption (32),

$$1-(N-2)\mathbf{u}(2+\bar{b}_w+2\bar{b}_w\mathbf{u})\ge\tfrac{1}{2},$$

inequality (42) will hold provided that

$$c_3\ge 2(2+\bar{b}_w+2\bar{b}_w\mathbf{u}). \tag{43}$$

From (31), and using $b_w<N$, it is clear that$2\bar{b}_w\mathbf{u}\le 0.5$, so (43) follows trivially.

Since the left-hand side of (42) is the largest of the three coefficients in (41), we can combine (41) and (42) to obtain

$$|F+H_1-\hat{z}[w-\hat{U}_1^T\hat{w}]^T|\le c_3(N-1)\mathbf{u}\{|A_1|+|\hat{z}||\hat{w}|^T|\hat{U}_1|+|\hat{L}_1||\hat{B}_1||\hat{U}_1|\}. \tag{44}$$

Combining (40), (34), (38), and (44), we therefore find that

$$\begin{aligned}&|A-\hat{L}\hat{B}\hat{U}|\\ &=\left|\begin{bmatrix}0 & \hat{w}^T\hat{U}_1-w^T\\ \alpha f & F+H_1-\hat{z}[w-\hat{U}_1^T\hat{w}]^T\end{bmatrix}\right|\\ &\le c_3(N-1)\mathbf{u}\left\{\begin{bmatrix}|\alpha| & |w|^T\\ |v| & |A_1|\end{bmatrix}+\begin{bmatrix}1 & 0\\ |\hat{z}| & |\hat{L}_1|\end{bmatrix}\begin{bmatrix}|\alpha| & |\hat{w}|^T\\ 0 & |\hat{B}_1|\end{bmatrix}\begin{bmatrix}1 & 0\\ 0 & |\hat{U}_1|\end{bmatrix}\right\}\\ &=c_3(N-1)\mathbf{u}\{|A|+|\hat{L}||\hat{B}||\hat{U}|\}.\end{aligned}$$

This proves the result for the case in which row elimination is used at stage N. When column elimination is used instead, the proof is analogous. □

LEMMA A.2. *If the alternate row and column elimination is used to solve* (5) *or* (8), *and the assumptions of Lemma* A.1 *hold, with* $N=(k+1)n$ *and* $b_w=2n$, *then the computed solution* $\hat{s}$ *is the exact solution of the perturbed system*

$$(A+E)\hat{s}=f,$$

where

$$\|E\|_\infty\le(k+2)n(5+6n)(1+n^2 2^{n-1})\|A_{DP}\|_\infty\mathbf{u}.$$

Proof. Note first that the pivoting does not alter the sparsity structure of A. We can, therefore, view alternate row and column elimination as being applied to $P^TA\Pi^T$ (where P and Π are permutation matrices) to produce a computed factorization

$$P^TA\Pi^T+H=\hat{L}\hat{B}\hat{U}.$$

It is easy to show that the procedure leading to $\hat{s}$ results in the following sequence of perturbed problems:

$$\begin{aligned} (\hat{L}+\delta_L)\hat{w} &= P^T f, & |\delta_L| &\le (1.06)n\mathbf{u}|\hat{L}|, \\ (\hat{B}+\delta_B)\hat{v} &= \hat{w}, & |\delta_B| &\le 2(1.06)n\mathbf{u}|\hat{B}|, \\ (\hat{U}+\delta_U)\hat{z} &= \hat{v}, & |\delta_U| &\le (1.06)n\mathbf{u}|\hat{U}|, \\ \hat{s} &= \Pi^T \hat{z}. \end{aligned}$$

(The bounds on $|\delta_L|$, $|\delta_B|$, $|\delta_U|$ are a consequence of the maximum number of nonzeros in each row of $\hat{L}$, $\hat{B}$, $\hat{U}$, respectively.) Hence

$$\begin{aligned} &P^T E \Pi^T = H + (\hat{L}+\delta_L)(\hat{B}+\delta_B)(\hat{U}+\delta_U) - \hat{L}\hat{B}\hat{U} \\ &\Rightarrow \|E\|_\infty \le \|H\|_\infty + [4(1.06)n\mathbf{u} + 5(1.06)^2 n^2\mathbf{u}^2 + 2(1.06)^3 n^3 \mathbf{u}^3]\|\hat{L}\|_\infty \|\hat{B}\|_\infty \|\hat{U}\|_\infty. \end{aligned}$$

It follows from (31) that $n\mathbf{u} \le 0.1$, so the coefficient of $\|\hat{L}\|_\infty \|\hat{B}\|_\infty \|\hat{U}\|_\infty$ can be bounded above by $5n\mathbf{u}$. Since element growth in B is bounded by 2^{n-1}, and since all entries in $\hat{L}$ and $\hat{U}$ are bounded by 1, we have

$$\|\hat{B}\|_\infty \le 2^{n-1}\|P^T A \Pi^T\|_\infty \le 2^{n-1}\|A\|_\infty, \qquad \|\hat{L}\|_\infty \le n, \qquad \|\hat{U}\|_\infty \le n.$$

Combining these observations with the result of Lemma A.1, we obtain

$$\begin{aligned} \|E\|_\infty &\le (5+6n)(k+1)n\mathbf{u}\{\|A\|_\infty + \|\hat{L}\|_\infty \|\hat{B}\|_\infty \|\hat{U}\|_\infty\} + 5n\mathbf{u}\|\hat{L}\|_\infty \|\hat{B}\|_\infty \|\hat{U}\|_\infty \\ &\le \{(5+6n)(k+1)n + [(5+6n)n(k+1) + 5n]n^2 2^{n-1}\}\|A\|_\infty \mathbf{u} \\ &\le (k+2)n(5+6n)(1+n^2 2^{n-1})\|A\|_\infty \mathbf{u}, \end{aligned}$$

as required. □

B. Appendix B. We start by stating two results on the rounding error due to Householder reduction. These results are similar to those in Lawson and Hanson [10, pp. 85–89] and Wilkinson [20, pp. 157–162]. They differ from Lawson and Hanson's results in that the $O(\mathbf{u}^2)$ term is explicitly accounted for at every stage, and from Wilkinson's in that we do not assume double-precision accumulation of inner products. Since the proofs are tedious and do not offer any new insight, they are omitted.

LEMMA B.1. *Suppose that an $m_1 \times m_2$ matrix X is multiplied by an $m_1 \times m_1$ Householder reflector Q. Then, provided that*

$$(6m_1 + 18)\mathbf{u} \le 0.1,$$

the computed result Y satisfies

$$Y = Q(X+E),$$

where

$$\|E\|_F \le (7m_1 + 42)\mathbf{u}\|X\|_F.$$

LEMMA B.2. *If Q is a product of r Householder reflectors whose effect is to introduce zeros into the subdiagonals in the first r columns of the $m_1 \times m_2$ matrix X, then provided that*

$$(7m_1 + 42)r\mathbf{u} \le 0.1,$$

the computed result Y satisfies

$$Y = Q(X + E),$$

where

$$\|E\|_F \leq (8m_1 - 4r + 51)r\mathbf{u}\|X\|_F.$$

For the purpose of this Appendix, it is simplest to view the structured factorization process as the application of $k - 1$ orthogonal transformation matrices $Q_1, Q_2, \cdots, Q_{k-1}$ to a row- and column-reordered version of A_D (and the right-hand side f_D), followed by the application of another two matrices Q_k and Q_{k+1} to effect the final reduction of (25). (Q_k and Q_{k+1} reduce the first and last n columns of the coefficient matrix in (25), respectively.) Each of the Q_j, $j = 1, \cdots, k-1$ are products of n Householder reflectors, and each operates on only a small part of the matrix that it multiplies: to be precise, a $2n \times 3n$ submatrix. Since we wish to reduce (7) to (25), it follows that exactly $k - 1$ such transformations are needed.

Proof (Lemma 4.1). Let $\hat{A}_{D,i+1}$ be the transformed version of A_D after i stages of the structured factorization, and $\hat{A}_{D,1} = A_D$. Let $X_{D,i}$ be the submatrix that is actually affected at stage i by the matrix Q_i from (22), and let $\hat{Q}_i$ be the orthogonal matrix that is obtained by embedding Q_i into a $(k+1)n$-dimensional identity matrix. For $i = 1, \cdots, k+1$, we have from Lemma B.2 that $\hat{A}_{D,i}$ and $\hat{A}_{D,i+1}$ are related by

$$\hat{A}_{D,i+1} = \hat{Q}_i(\hat{A}_{D,i} + E_i),$$

where E_i consists of the $2n \times 3n$ "error" submatrix corresponding to the factorization of $X_{D,i}$, padded out with zeros to dimension $(k+1)n$. Hence

$$\|E_i\|_F \leq (8(2n) - 4n + 51)n\mathbf{u}\|X_{D,i}\|_F \leq (12n + 51)n\mathbf{u}\|\hat{A}_{D,i}\|_F.$$

Hence

$$\|\hat{A}_{D,i+1}\|_F \leq [1 + (12n + 51)n\mathbf{u}]\|\hat{A}_{D,i}\|_F \leq [1 + (12n + 51)n\mathbf{u}]^i\|A_D\|_F.$$

The errors made in stages k and $k + 1$ are bounded in the same way, since the submatrices affected at these stages are no larger than those affected at the earlier stages. Under the assumption $(12n + 51)n(k + 1)\mathbf{u} \leq 0.1$, we therefore obtain

$$\|\hat{A}_{D,i+1}\|_F \leq [1 + (1.06)(12n + 51)n(k + 1)\mathbf{u}]\|A_D\|_F \leq (1.106)\|A_D\|_F,$$

for $i = 1, \cdots, k + 1$. Hence

$$\|E_i\|_F \leq (1.106)(12n + 51)n\mathbf{u}\|A_D\|_F.$$

The final (upper triangular) matrix is $\hat{A}_{D,k+2}$, which satisfies

$$\begin{aligned}\hat{A}_{D,k+2} &= \hat{Q}_{k+1}(\hat{A}_{D,k+1} + E_{k+1}) \\ &= \hat{Q}_{k+1}\hat{Q}_k(\hat{A}_{D,k} + E_k) + \hat{Q}_{k+1}E_{k+1} \\ &\vdots \\ &= \hat{Q}_{k+1}\cdots\hat{Q}_1 A_D + \hat{Q}_{k+1}\cdots\hat{Q}_1 E_1 + \hat{Q}_{k+1}\cdots\hat{Q}_2 E_2 + \cdots + \hat{Q}_{k+1}E_{k+1} \\ &= \hat{Q}[A_D + E_D].\end{aligned}$$

Here $\hat{Q} = \hat{Q}_{k+1}\hat{Q}_k \cdots \hat{Q}_1$ is orthogonal, and E_D satisfies the bound

$$\|E_D\|_F \le \sum_{i=1}^{k+1} \|E_i\|_F = (1.106)(12n + 51)n(k+1)\mathbf{u}\|A_D\|_F.$$

Similarly, application of $\hat{Q}$ to the right-hand side f_D, results in a computed vector $\hat{f}_D$, which satisfies

$$\hat{f}_D = \hat{Q}[f_D + \delta f_D],$$

where

$$\|\delta f_D\|_2 \le (1.106)(12n + 51)n(k+1)\mathbf{u}\|f_D\|_2$$

(since $\|v\|_F = \|v\|_2$ when v is a vector). Finally, back-substitution is used on the system with coefficient matrix $\hat{A}_{D,k+2}$ and right-hand side $\hat{f}_D$. The computed solution satisfies

$$(\hat{A}_{D,k+2} + E_S)\hat{s} = \hat{f}_D, \tag{45}$$

where, since $\hat{A}_{D,k+2}$ has at most $3n$ nonzeros per row,

$$\begin{aligned}\|E_S\|_F &\le 3(1.06)n\mathbf{u}\|\hat{A}_{D,k+2}\|_F \\ &\le 3(1.06)n\mathbf{u}[1 + (1.106)(12n+51)n(k+1)\mathbf{u}]\|A_D\|_F \\ &\le 3(1.06)(1.1106)n\mathbf{u}\|A_D\|_F.\end{aligned}$$

Substituting in (45),

$$\begin{aligned}\left[\hat{Q}[A_D + E_D] + E_S\right]\hat{s} &= \hat{Q}[f_D + \delta f_D] \\ \Rightarrow (A_D + E_D + \hat{Q}^T E_S)\hat{s} &= (f_D + \delta f_D).\end{aligned}$$

Defining

$$\delta A_D = E_D + \hat{Q}^T E_S,$$

we have

$$\begin{aligned}\|\delta A_D\|_F &\le \|E_D\|_F + \|E_S\|_F \\ &\le [(1.106)(12n+51)n(k+1) + 3(1.06)(1.1106)n]\,\mathbf{u}\|A_D\|_F \\ &\le (1.106)(12n+51)n(k+2)\mathbf{u}\|A_D\|_F,\end{aligned}$$

as required. □

THREE-DIMENSIONAL DELAUNAY TRIANGULATIONS FOR FINITE ELEMENT APPROXIMATIONS TO A SECOND-ORDER DIFFUSION OPERATOR*

FRANK W. LETNIOWSKI†

Abstract. The second-order diffusion operator given by $\mathcal{L}u = \nabla \cdot (\mathbf{K}\nabla u)$ is studied in terms of finite element numerical solutions. When a standard Galerkin finite element approximation of the operator is arranged in a specific manner, a condition of positive connection values is imposed that is necessary to produce an M-matrix in a linear system when boundary nodes are properly handled. In two dimensions, the condition is achieved when a Delaunay triangulation is imposed. However, it is shown that a three-dimensional Delaunay triangulation does not generally produce a discretisation satisfying the condition. Further, it is generally not possible to produce a three-dimensional triangulation that satisfies the positive interior connection condition.

Key words. finite element method, three-dimensional triangulation, Delaunay triangulation

AMS(MOS) subject classification. 65N30

1. Introduction.

Three-dimensional triangulations have been studied frequently in the context of finite element discretisations [1], [3], [12], [15]. A set of tetrahedra are selected to cover a polyhedron that approximates a region. A common triangulation approach is the three-dimensional Delaunay triangulation [8], [2], [14], where the tetrahedra satisfy a sphere criterion.

This paper considers the effect of triangulation on the finite element approximation of the second-order diffusion operator. Example areas of application include groundwater contamination problems, petroleum reservoir simulation, heat transfer, semiconductor device modelling, and Navier–Stokes fluid flow.

For a dependent variable u, the action of the diffusion operator, $\mathcal{L}$, is defined by

$$\mathcal{L}u = \nabla \cdot (\mathbf{K}\nabla u), \tag{1}$$

where in general $\mathbf{K}$ is possibly nonconstant and a tensor. The assumption in this paper is that $\mathbf{K}$ is symmetric positive definite with constant components.

2. Galerkin finite element discretisation.

The operator $\mathcal{L}$ is approximated using the Galerkin finite element method.

Let N_i be a $\mathcal{C}^0$ linear basis function for the ith node of the discretisation. In the usual way, the unknown u is approximated as

$$u \approx \sum_j u_j N_j := \hat{u}. \tag{2}$$

Define

$$v_i = \{j \text{ s.t. node } j \text{ is adjacent to node } i\}.$$

Consequently,

$$(\mathcal{L}\hat{u}, N_i) = \sum_{j \in v_i} \Gamma_{ij}(u_j - u_i), \tag{3}$$

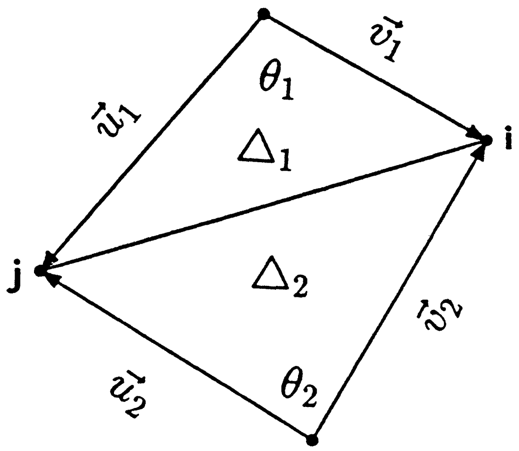

FIG. 1. *Interior connection for triangular elements.*

where

$$\Gamma_{ij} = -\int_R (\mathbf{K}\nabla N_j) \cdot \nabla N_i \, dV, \tag{4}$$

which will be called the *connection value* for the connection between nodes i and j. We have assumed either Dirichlet or Neumann boundary conditions on ∂R.

Define the matrix A such that

$$\begin{aligned} A_{ij} &= \Gamma_{ij}, \qquad i \neq j, \\ A_{ii} &= -\sum_{j \neq i} \Gamma_{ij}. \end{aligned} \tag{5}$$

When Γ_{ij} are positive, the matrix A is an M-matrix when there is at least one Dirichlet node. It is well known that with an M-matrix, the approximation to $\mathcal{L}$ satisfies a discrete maximum principle. An M-matrix is also desirable for iterative sparse matrix methods [11].

Without loss of generality, we perform a linear transformation and set $\mathbf{K}$ to the identity matrix for the remainder of this paper.

3. Two dimensions. In two dimensions, it is always possible to achieve positive interior connection values under the above assumptions. A connection between two nodes is called *interior* if the line segment joining the two nodes does not form part of the boundary.

For triangular elements, an interior connection is shared by exactly two triangles (see Fig. 1). The value of the connection Γ_{ij} is [5]

$$\Gamma_{ij} = \tfrac{1}{2}[\cot\theta_1 + \cot\theta_2]; \tag{6}$$

hence the requirement for positivity is

$$\theta_1 + \theta_2 \leq \pi. \tag{7}$$

A triangulation that satisfies condition (7) is the Delaunay triangulation [5], [7], [6], which satisfies the *circle criterion*: the circumcircle of each triangle in the triangulation contains no nodes of the discretisation in its interior.

Any valid triangulation of a two-dimensional convex region may be transformed into a Delaunay triangulation through a series of local transformations [7], [6]. This series of transformations must converge in a finite number of steps. The local transformation procedure is an *edge swap*, which is described in [9].

In summary, the following theorem holds.

THEOREM 3.1. *In the transformed region, a Delaunay triangulation of a two-dimensional convex region satisfies the positive interior connection value criterion.*

A connection that is situated along the boundary of the region is the edge of only one triangular element. In this case, if the connection value is negative, it may be necessary to add boundary nodes [4] to ensure that (3) produces an M-matrix.

4. Three dimensions. It is natural to speculate that a three-dimensional Delaunay triangulation satisfies the criterion of positive interior connection values; however, the theorem and corollary in this section demonstrate that this is not true in general.

It is well known that any polyhedron may be divided into a finite number of tetrahedra. Such a discretisation is called a three-dimensional triangulation.

One possible triangulation for a set of nodes is the three-dimensional Delaunay triangulation [8], which has been used for three-dimensional mesh generation [1], [3], [12], [15]. The tetrahedra in the discretisation satisfy the *sphere condition*: the circumsphere of the four vertices of any tetrahedron in the triangulation contains no vertices in its interior. The local transformation that changes a local triangulation into one satisfying the sphere condition is a face swap, which is described in [8].

THEOREM 4.1. *In general, a three-dimensional triangulation satisfying the positive interior connection criterion may not be constructed using strictly local transformations.*

Proof. Consider the local region defined by the six three-dimensional points:

$$\begin{aligned} \mathsf{A} &= (-2,-2,0.5),\\ \mathsf{B} &= (0,-2,0.1),\\ \mathsf{C} &= (-2,0,0.1),\\ \mathsf{D} &= (0,0.1,0),\\ \mathsf{E} &= (-2,-2,-0.25),\\ \mathsf{F} &= (-2,-2,1.5). \end{aligned}$$

Consider Figs. 2, 3, and 4, which are the only possible triangulations of the above six points from the transformations described in [8]. The triangulations in each figure produce the following tetrahedra:

Fig. 2: ABDE, ABDF, ACDE, and ACDF;
Fig. 3: ABCF, BCDF, ABCE, and BCDE;
Fig. 4: ABDF, ACDF, ABCE, BCDE, and ABCD.

Table 1 gives the values for the interior connections, AD and BC, for each of the figures. Each of the connection values is negative, which breaches the positive connection criterion. Note also that any tetrahedron that might exist exterior to this local region cannot have AD or BC as one of its edges; that is, all tetrahedra affecting the connection AD or BC are included in the figures. □

COROLLARY 4.2. *A three-dimensional Delaunay triangulation may not satisfy the condition of positive interior connections.*

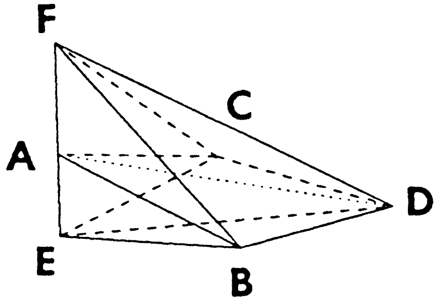

FIG. 2. *Sample triangulation with* AD *connection.*

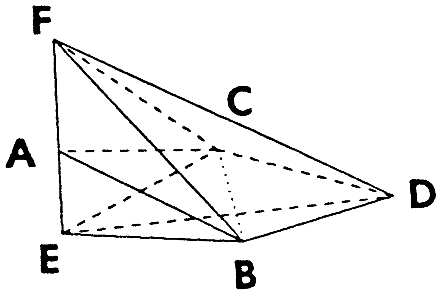

FIG. 3. *Sample triangulation with* BC *connection.*

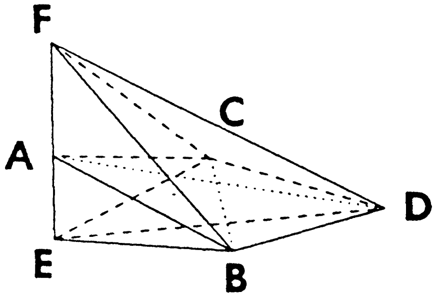

FIG. 4. *Sample Delaunay triangulation.*

TABLE 1
Interior connections for the triangulation example.

	Connection	Γ_{ij}

Fig. 4	AD	−2.208
	BC	−1.4694

TABLE 2
Circumcentres for the triangulation example.

Tetrahedron	Circumcentre	Sphere condition?
ABDE	$(-1.035, -0.9464, 0.125)$	no
ACDE	$(-0.942, -1.035, 0.125)$	no
ABDF	$(-0.86, -0.9048, 1.0)$	yes
ACDF	$(-0.907, -0.86, 1.0)$	yes
ABCD	$(-0.919, -0.919, 0.706)$	yes
ABCF	$(-0.86, -0.86, 1.0)$	no
DBCF	$(-0.908, -0.908, 0.931)$	no
ABCE	$(-1.035, -1.035, 0.125)$	yes
DBCE	$(-0.965, -0.965, -0.273)$	yes

Proof. Table 2 lists the nine tetrahedra in Figs. 2–4, gives the coordinates of their circumcentres, and indicates whether or not the tetrahedra satisfy the sphere condition. The table identifies Fig. 4 as the Delaunay triangulation; however, from Table 1 it is seen that the interior connections AD and BC of this triangulation are negative. □

Note that from Table 1, the sizes of the negative connections AD and BC of Figs. 3 and 4 are on the order of 100 times larger than the connection AD given in Fig. 2. In a specific example given in [10], it is determined that the size of negative connections may be more important than the number of negative connections. Thus, *the Delaunay triangulation is not, in general, the best triangulation for a three-dimensional finite element grid, in terms of the positive connection criterion.*

5. Conclusions. In this paper, a condition of positive connection values was imposed. This condition produces an M-matrix, and hence a discrete maximum principle, for a linear diffusion problem when there is at least one Dirichlet node. In two dimensions, this condition may be satisfied by selecting a Delaunay triangulation when boundary nodes are handled properly. It is shown by counterexample that a three-dimensional Delaunay triangulation does not, in general, satisfy the condition.

Moreover, this paper illustrates that, in three dimensions, a triangulation producing positive interior connections may not, in general, be obtained with strictly local transformations. This suggests that, in three dimensions, it may be very difficult to produce a triangulation that always gives an M-matrix, and hence a maximum principle, for a linear diffusion problem with at least one Dirichlet node.

A PARALLEL NONLINEAR LEAST-SQUARES SOLVER: THEORETICAL ANALYSIS AND NUMERICAL RESULTS*

THOMAS F. COLEMAN† AND PAUL E. PLASSMANN‡

Abstract. The authors recently proposed a new parallel algorithm, based on the sequential Levenberg–Marquardt method, for the nonlinear least-squares problem. The algorithm is suitable for message-passing multiprocessor computers.

In this paper a parallel efficiency analysis is provided and computational results are reported. The experiments were performed on an Intel iPSC/2 multiprocessor with 32 nodes: this paper presents experimental results comparing the given parallel algorithm with sequential MINPACK code executed on a single processor. These experimental results show that essentially full efficiency is obtained for problems where the row size is sufficiently larger than the number of processors.

Key words. hypercube computer, Levenberg–Marquardt, nonlinear least squares, message-passing multiprocessor, parallel algorithms, QR factorization, trust-region algorithms

AMS(MOS) subject classifications. 65H10, 65F05, 65K05, 65K10, 90C30

1. Introduction. Let $F : \mathbf{R}^n \mapsto \mathbf{R}^m$, with $m \geq n$, be a continuously differentiable function. The nonlinear least-squares problem is to find a local minimum of the function

$$\psi(x) = \frac{1}{2}\|F(x)\|_2^2 = \frac{1}{2}\sum_{i=1}^{m} f_i^2(x), \tag{1.1}$$

where f_i is the ith component of F. Recently, Coleman and Plassmann [CP89] proposed a parallel implementation of the well-known Levenberg–Marquardt algorithm [L44], [M63] for solving this problem when the Jacobian of $F(x)$ is dense.[1] In this paper we present a theoretical analysis of our parallel method, as well as experimental results obtained on an Intel iPSC/2 hypercube. The experimental results are obtained on a hypercube multiprocessor; however, we feel that the algorithm is not limited to this architecture. In fact, all that is required of the multiprocessor interconnection topology is support of a ring embedding and means for efficient gather and broadcast operations.

There are three main computational tasks that need to be addressed in a parallel implementation of the Levenberg–Marquardt algorithm [2]:

1. Evaluation or approximation of the Jacobian matrix $J(x)$.

[1] Plassmann [P90] considers the large sparse case.

[2] For a more detailed description of the Levenberg–Marquardt algorithm, including step acceptance and convergence criteria, we refer the interested reader to the excellent article by Moré [M78].

2. The QR factorization of $J(x)$,

$$J = Q\begin{bmatrix} R \\ 0 \end{bmatrix},$$

where Q is an orthogonal matrix and R is upper-triangular, in order to solve the least-squares problem

$$\begin{bmatrix} R \\ 0 \end{bmatrix} s \overset{\text{L.S.}}{=} -Q^T F. \tag{1.2}$$

3. The computation of the Levenberg–Marquardt parameter λ_*, and vector s_*, satisfying

$$(J^T J + \lambda_* D^T D)s_* = -J^T F, \tag{1.3}$$

such that $\|Ds_*\|_2 = \Delta$, where D is a diagonal scaling matrix and Δ is a positive scalar representing the "trust region" size. Computationally, this means solving least-squares systems of the form

$$\begin{bmatrix} R \\ 0 \\ \lambda^{1/2} D \end{bmatrix} s(\lambda) \overset{\text{L.S.}}{=} -\begin{bmatrix} Q^T F \\ 0 \end{bmatrix} \tag{1.4}$$

for different values of λ.

We address these computational issues in the remainder of the paper. In §2 we summarize the issues involved with respect to the parallel finite-difference approximation of the Jacobian matrix. In §3 we summarize the row-oriented parallel QR factorization proposed in [CP89], provide a new complexity analysis, and present numerical results. A theoretical analysis of the parallel algorithm for determining the Levenberg–Marquardt parameter is given in §4, along with numerical results. Finally, we present experimental results for the entire method and conclusions in §5.

2. Parallel approximation of the Jacobian. It is often the case that the number of rows of the Jacobian is much larger than the number of columns. For the QR factorization stage this suggests a row-oriented method, where the rows of the Jacobian are distributed to processors. This data distribution achieves a better load balancing than a column-oriented method, and results in an algorithm whose efficiency depends on the ratio m/p rather than n/p, where p is the number of processors. Experience has shown that computational costs involved in the QR factorization stage often dominate the Jacobian approximation stage. Thus, we have chosen to pursue a row-oriented QR factorization algorithm.[3] We would like to take advantage of this data distribution in approximating the Jacobian whenever possible. Let I_i, $i = 1, \cdots, p$, be a partition of the rows of J, where I_i is the set of row indices assigned to processor i and let $F_{I_i}(x) = \{f_j(x) \mid j \in I_i\}$ be the corresponding function blocks. We

[3] If a column-oriented Jacobian approximation scheme is used, one must convert this column-oriented data distribution into a row-oriented distribution for the QR factorization stage [JH88], [MVV87], [SS85]. Of course, for sufficiently large n this problem can be avoided by using a column-oriented QR factorization algorithm. We did not take such an approach because it is usually the case that $m \gg n$. However, there exist good column-oriented QR factorization algorithms [B88], [CG88], [M87], and in §4 we describe an efficient column-oriented algorithm for determining the Levenberg–Marquardt parameter.

say that the function F is *block separable* if there exists a partition of the rows such that the evaluation of each function block is computationally independent.

Suppose the function is block separable relative to the partition I_i, $i = 1, \cdots, p$ and let $J_{I_i}^T(x)$ be the set of the rows of the Jacobian estimated at the point x. The jth column of the Jacobian can be estimated in parallel by having each processor compute its block of row components according to the formula

$$J_{I_i}^T(x)e_j \cong \frac{F_{I_i}(x + \tau e_j) - F_{I_i}(x)}{\tau}. \tag{2.1}$$

However, often the evaluation of $F(x)$ is not completely separable; there may be some amount of redundant computation due to common factors that must be computed for each partition of the function $F_{I_i}(x)$, $i = 1, \cdots, p$. If this redundant computation is inexpensive relative to communication cost entailed by using a column-oriented scheme, then we consider this computational overhead tolerable. All of the test problems considered in the experimental section fall into this category. Otherwise, if the redundant computation required by such a partition of the rows is deemed too expensive, a column-oriented approach to approximating $J(x)$ must be adopted.

A subtle problem occurs when n/p is small, the evaluation of $F(x)$ is expensive and not separable, and therefore the estimation of the Jacobian is computationally expensive relative to the QR factorization. Suppose a step $s^{(k)}$ is to be considered at the kth iteration of the algorithm; $F(x^{(k)} + s^{(k)})$ must be evaluated to determine if it meets certain acceptance criteria. When this computation is relatively expensive and not separable, and therefore must be done on one processor, then the remainder of the processors will remain idle during this computation. This can result in detrimental effects on the efficiency of the entire implementation. Byrd, Schnabel, and Shultz [BSS88] and Coleman and Li [CL87] note that this problem can be alleviated somewhat by guessing, based on the previous iteration, whether the proposed point will be accepted. If acceptance is assumed, the Jacobian at $x^{(k)} + s^{(k)}$ can begin to be approximated by idle processors. If we guess that the proposed iterate will not be accepted, then idle processors could evaluate the function at some additional points that might fare better with the acceptance criteria. These ideas were not implemented in our code, but could easily be added. Nevertheless, for $n/p \gg 1$, the computation required to estimate the Jacobian will always dominate these isolated function evaluations.

3. A parallel row-oriented Householder QR algorithm.

In this section we analyze and experiment with the parallel row-oriented Householder QR factorization proposed in [CP89]. We show that this algorithm is more efficient than previous hybrid (Householder/Givens) factorization algorithms. The efficiency of the parallel QR factorization used to solve (1.2) is of paramount importance because a completely new approximation to the Jacobian is computed for each iteration. Consequently, a full QR factorization is also required. For the test problems considered in this paper, we find that the QR factorization is always a major (and sometimes the dominant) computational cost. An additional advantage of this algorithm is that, unlike the hybrid scheme, it produces the same Householder vectors that would be produced by a standard sequential Householder QR algorithm. This property is advantageous in situations where the same system must be solved for multiple right-hand sides. Finally, we show that column pivoting can be introduced into the algorithm with only a slight increase in the computation and communication complexity. In our implementation column pivoting is important because the QR factorization can then be used to estimate matrix rank.

Column-oriented methods have dominated the work on parallel QR algorithms; however, two row-oriented algorithms have been considered previously [CP86], [PR87]. These two algorithms are very similar: to reduce each column of the matrix a reduction involving only data local to each processor is performed, followed by a global reduction requiring communication between the processors. The reduction of rows local to a processor yields one row per processor with a nonzero in the column being reduced to upper-triangular form. This approach has the advantage that all these reductions and matrix updates will be local to the processors, and with the wrap mapping[4] of rows the computational load will be well balanced. Following this local stage is a global stage: a minimum-depth spanning tree is embedded in the hypercube, rooted at the processor where the nonzero for the column under consideration should reside. Rows are communicated up this tree and the leading nonzero is annihilated by a Givens rotation with respect to the parent's row. These rows are then updated with this rotation and the result communicated back to the child. The hypercube topology allows this global reduction process to take place in $\log(p)$ steps. Of these two algorithms, the one presented by Pothen and Raghavan [PR87] seems to be the most efficient, since Householder reductions, as opposed to Givens, are used in the local stage.

Our algorithm is computationally more efficient than the hybrid approach: the full Householder vector is calculated and the intermediate Givens reductions are avoided. However, our challenge is to obtain the same communication complexity as the hybrid approach. We meet this challenge by noticing that computation of the Householder vector and the subsequent rank-one update to the matrix can be combined to halve the number of messages that seem to be required at first glance.

To review the algorithm given in [CP89], consider the QR factorization of an $m \times n$ matrix A. At step j of the factorization, the first $j-1$ rows of R and the Householder vectors have been computed; we need only consider the $(m-j+1) \times (n-j+1)$ lower right submatrix of A, denoted by $A^{(j)}$, with columns $a_k^{(j)}$, $k = j, \cdots, n$. The Householder transformation, $P^{(j)}$, to reduce the first column of $A^{(j)}$, $a_j^{(j)}$, is

$$P^{(j)} = \left[I - 2\frac{v_{(j)} v_{(j)}^T}{v_{(j)}^T v_{(j)}} \right], \tag{3.1}$$

where $v_{(j)} = a_j^{(j)} \pm \|a_j^{(j)}\|_2 e_j$. To determine $a_k^{(j+1)}$, $k = j+1, \cdots, n$, we need to compute the corresponding rank-one update to $A^{(j)}$:

$$\begin{aligned} a_k^{(j+1)} &= a_k^{(j)} - \frac{2}{v_{(j)}^T v_{(j)}} v_{(j)}^T a_k^{(j)} v_{(j)} \\ &= a_k^{(j)} - \alpha_k^{(j)} v_{(j)}, \end{aligned} \tag{3.2}$$

with $\alpha_k^{(j)}$ defined as shown. Let *leader* designate the processor that holds row j. Note that $v_{(j)}$ agrees with $a^{(j)}$ except in the first component. Therefore, the portions of the inner product $v_{(j)}^T a_k^{(j)}$ local to each processor are just $a_j^{(j)T} a_k^{(j)}$ except on *leader*, where $a^{(j)}$ and $v_{(j)}$ differ in the first component. We can take advantage of this fact

[4] The specific row-oriented distribution we consider is a wrapping of rows onto processors. Thus, if the processors on the ring are numbered $0, 1, 2, \cdots, p-1$, then row k of the Jacobian is assigned to processor $(k-1) \mathrm{mod}(p)$.

and combine the communication to compute $v_{(j)}$ with the communication required for the rank-one update to the remainder of the matrix. An outline of the resulting algorithm is given as Algorithm 3.1. For this description we use the notation $[a_j^{(j)}]_{I_i}$ to represent the subvector of $a_j^{(j)}$ with components given by the index set I_i. The $\tilde{\alpha}$ vector is a work vector used in the computation of $\|a_j^{(j)}\|_2$ and the constants $\alpha_k^{(j)}$, $k = j+1, \cdots, n$.

```
Index Set: $I_i$ {set of row indices assigned to processor $i$}

Proc ($i$) : {program for processor $i$}
    For $j = 1, \cdots, n$ do
        If ($i$ =leader) Delete $\{j\}$ from $I_i$;
        Compute dot products for $k = j, \cdots, n$
            $\tilde{\alpha}_k = [a_j^{(j)}]_{I_i}^T [a_k^{(j)}]_{I_i}$;
        Combine $[\tilde{\alpha}_j, \cdots, \tilde{\alpha}_n]$ using gather-sum;
        If ($i$ = leader) then
            Compute first component of $v^{(j)}$ and the coefficients
                $[\alpha_{j+1}^{(j)}, \cdots, \alpha_n^{(j)}]$ and broadcast the result;
        endif
        Update columns, $k = j+1, \cdots, n$
            $[a_k^{(j+1)}]_{I_i} = [a_k^{(j)}]_{I_i} - \alpha_k^{(j)} [v^{(j)}]_{I_i}$;
    enddo
```

ALGORITHM 3.1. *A parallel row-oriented Householder* QR *algorithm.*

In Fig. 3.1 we exhibit the efficiencies of this algorithm compared to the hybrid algorithm described by Pothen and Raghavan in [PR87] as a function of the number of rows. (The data points in the figure are experimental results obtained on a 32 node iPSC/2 hypercube with 4.5 Mbytes of memory per node. All the experimental results presented in this paper are from implementations done on this machine.) The dotted lines in the figure are plots of a theoretical model of the efficiencies of the algorithms that will be presented later in this section. For this plot the number of columns is fixed at 100. The efficiencies shown were calculated by dividing the time taken by an efficient sequential implementation of the algorithm run on one processor by the product of the time taken by the parallel implementation and the number of processors used. In this case our parallel implementations were compared with the MINPACK QR factorization subroutine QRFAC executed on a single processor of the hypercube, and the efficiencies shown were computed from the execution times of these programs. In Table 3.1 we show some representative execution times for our implementations of the hybrid algorithm (Hybrid) and Algorithm 3.1, as compared to the sequential QR factorization program (Single processor).

There is a subtle point in solving (1.2): the orthogonal matrix Q does not need to be saved if the right-hand side of the equation is updated along with the rows of the Jacobian. To achieve this goal, the right-hand side is treated like an additional column to the matrix J, and is distributed across the processors in the same wrap mapping and updated along with the corresponding rows of the Jacobian.

Column pivoting can be added to Algorithm 3.1. The column norms of the

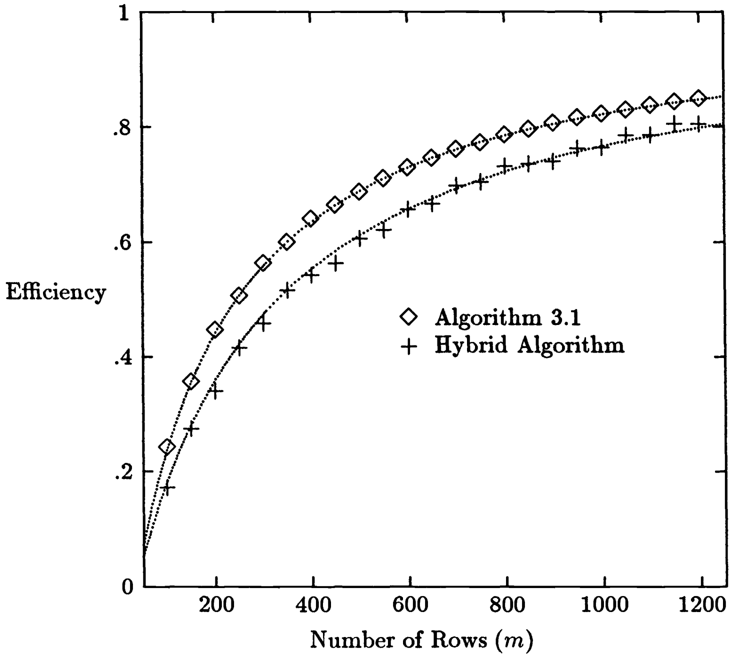

FIG. 3.1. *Efficiencies of Algorithm* 3.1 *and Hybrid on the iPSC/2* ($n = 100, p = 32$).

matrix A are initialized at the beginning. They are updated after each stage of the computation to obtain the column norms of $A^{(j)}$. For example, suppose at stage j the column norms $\|a_k^{(j)}\|_2$, $k = 1, \cdots, n$, are known by *leader*. The column of maximum norm, $k_{\max}$, is determined by *leader* and the result is broadcast. Columns j and $k_{\max}$ are then interchanged by all processors. After stage j of the algorithm the updated norms can be obtained from the formula

$$\|a_k^{(j+1)}\|_2 = \|a_k^{(j)}\|_2 \left(1 - \left(\frac{[a_k^{(j+1)}]_j}{\|a_k^{(j)}\|_2}\right)^2\right)^{1/2}, \tag{3.3}$$

for $k = j{+}1, \cdots, n$. The results are then sent to the next leader (i.e., the next processor on the ring) for stage $j + 1$ of the QR algorithm. Note that numerical cancellation is a potential problem in computing these norm updates. However, circumstances that would result in this problem can be monitored and the suspect column norm can be recomputed. A standard way to monitor for numerical cancellation is to keep track of the products of the multiplicative factors in (3.3) that have been obtained since the last explicit calculation of the column norm. When this product is sufficiently less than one, then there is the possibility of cancellation error, and the column norm is recomputed. In our implementation the recomputation is done by broadcasting a special notifier to the other processors instead of the column pivot. The required column norms are then recomputed and the result gathered at *leader*. Our observation has been that recomputation of the column norms is rarely required and therefore does not significantly affect the efficiency of the algorithm.

Another potential concern for numerical stability might be the possibility of overflow from the way the $\tilde{\alpha}_k$ are computed in Algorithm 3.1. We note that these partial sums can be scaled by the most recent approximation to the column norms available to all the processors. We did not find it necessary to include this scaling in our implementation.

Figure 3.2 exhibits a graph comparing the efficiencies of Algorithm 3.1 with and without pivoting. In Table 3.2 we include some representative times from these experiments. The efficiencies are again computed by comparing the running times of the parallel algorithms to running times of the MINPACK QR subroutine QRFAC on a single processor. As before, these results were obtained on a 32 node iPSC/2 hypercube with the number of columns fixed at 100. The data points are the experimental results and the dotted curves are theoretical approximations to these efficiencies, which we will now describe.

The efficiencies observed for the row-oriented Householder algorithm can be explained by a simple model for the communication overhead involved and consideration of computational imbalances between the processors. The efficiency is computed by the formula

$$\text{efficiency} = \frac{t_{\text{seq}}}{p\, t_{\text{parallel}}}, \tag{3.4}$$

where t_{seq} is the execution time of the sequential algorithm and t_{parallel} is the execution time of the parallel algorithm on p processors. The parallel execution time can be considered to consist of three parts: (1) the optimal time, t_{seq}/p, (2) the computational imbalance relative to the optimal distribution of work, t_{comp}, and (3) the communication overhead demanded by the parallel algorithm, t_{comm}. Hence, we have

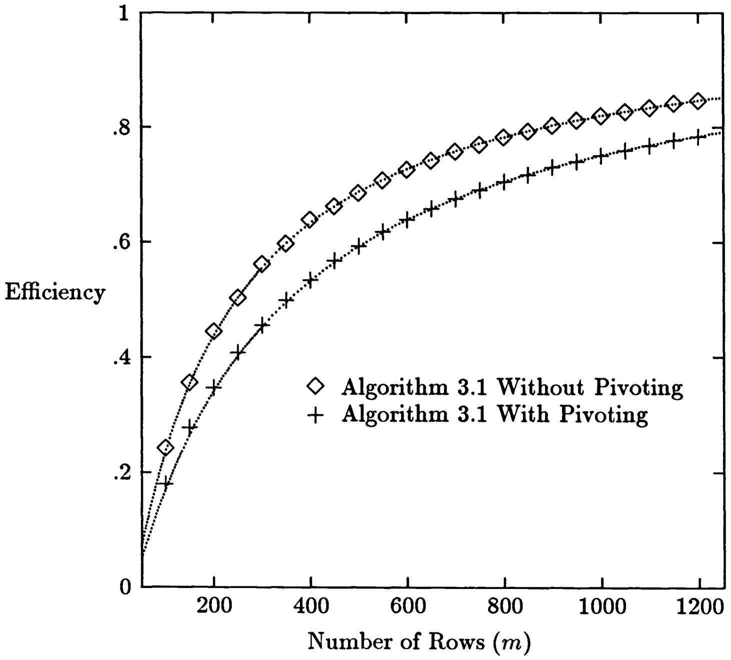

FIG. 3.2. *Efficiencies of Algorithm* 3.1 *with and without column pivoting* ($n = 100$, $p = 32$).

that

$$t_{\text{parallel}} = \frac{t_{\text{seq}}}{p} + t_{\text{comp}} + t_{\text{comm}} \tag{3.5}$$

and (3.4) can be rewritten as

$$\text{efficiency} = \frac{1}{1 + \frac{t_{\text{comm}} + t_{\text{comp}}}{t_{\text{seq}}} p}. \tag{3.6}$$

The sequential execution time of the Householder QR algorithm measured in old-style flops is

$$t_{\text{seq}} = n^2(m - n/3). \tag{3.7}$$

In the discussion that follows, we use (3.7) to define the length of time we consider to be one flop. On the iPSC/2 this time was experimentally determined to be 19.15μsec. However, this definition can be tricky since, for example, an add, multiply, or divide can take varying lengths of time to execute depending on how the code is written. Consequently, some of the coefficients in the following formulae had to be obtained experimentally and are not simple multiples of the above-defined flop.

To approximate the computational imbalance we consider two dominant terms. The first is due to the variation of the number of rows assigned to the processors, and the second term is due to the idle time of processors during the computation of the α's in Algorithm 3.1. Work is not quite equally distributed to the processors with the row wrapping. On the average, half the processors are assigned an

TABLE 3.2

			16	70.66
			32	47.52

extra row; hence, the remaining processors are idle during the portion of the Householder update corresponding to this extra row. The Householder update to a row of length k requires $2k$ flops, resulting in a computational imbalance over the entire factorization of $\frac{1}{2}\sum_{k=1}^{n} 2k = n^2/2$ flops. The total idle time of processors during the accumulations of sums in the computation of an $\tilde{\alpha}$-vector of length k is approximately $(\log(p) - 1)k\tau_{\text{add}}$, where τ_{add} is the time required for an add. Summing this expression from $k = 1$ to n yields $\frac{1}{2}(\log(p) - 1)n^2\tau_{\text{add}}$. Finally, the processor *leader* requires some length of time, say, β_1, to compute each element of the α-vector and time β_2 per element to update the column norms. These computations result in a total imbalance of $(\beta_1 + \beta_2)n^2/2$. Combining these contributions yields an approximation for t_{comp}, in flops, of

$$t_{\text{comp}} \approx (\beta_1 + \beta_2 + (\log(p) - 1)\tau_{\text{add}} + 1)n^2/2. \tag{3.8}$$

In our implementation, the times β_1 and β_2 were determined to be 22.4μsec and 110.6μsec and τ_{add} was found to be 11.2μsec.

The communication overhead for Algorithm 3.1 includes the time required for the accumulation and broadcast of the α-vectors. This overhead is $\sum_{k=1}^{n} 2\log(p)\tau(k)$, where $\tau(k)$ is the time required to send a double precision vector of length k between neighboring processors. An additional time of $n\log(p)\tau(1) + \sum_{k=1}^{n}\tau(k)$ is required to broadcast the pivot and transfer the column norms. Combining these two terms yields an approximation to the communication overhead of

$$t_{\text{comm}} \approx (2\log(p) + 1)T(n) + n\log(p)\tau(1), \tag{3.9}$$

where we define $T(n)$ to be $\sum_{k=1}^{n}\tau(k)$.

For the iPSC/2 the function $\tau(k)$ is, fortunately, empirically simple to describe; the cost function is essentially linear over large ranges of vector lengths k. Experimentally, we determined that a good approximation to this cost function is given by

$$\tau(k) \approx \tau_1 + \gamma_1 k, \qquad 1 \leq k \leq 12, \tag{3.10}$$
$$\tau(k) \approx \tau_2 + \gamma_2 k, \qquad 13 \leq k.$$

The startup times, τ_1 and τ_2, were determined to be 378μsec and 702μsec. The incremental costs, γ_1 and γ_2, are 1.19μsec/value and 2.87μsec/value. With these coefficients, the term $T(n)$ in (3.9) can be approximated, for $n \geq 13$, by

$$T(n) \approx \gamma_2 n^2/2 + \tau_2 n + 78(\gamma_1 - \gamma_2) + 12(\tau_1 - \tau_2). \tag{3.11}$$

After substituting these coefficients into the equations for t_{comp} and t_{comm}, (3.6) was plotted, along with the experimental results for Algorithm 3.1, in Figs. 3.1, 3.3, and 3.4. To model the efficiency of the row-oriented Householder algorithm without pivoting we need only eliminate the β_2 term from the equation for t_{comp} and also the communication overhead due to pivoting in the equation for t_{comm}. The resulting modeling function is plotted in Figs. 3.1 and 3.2.

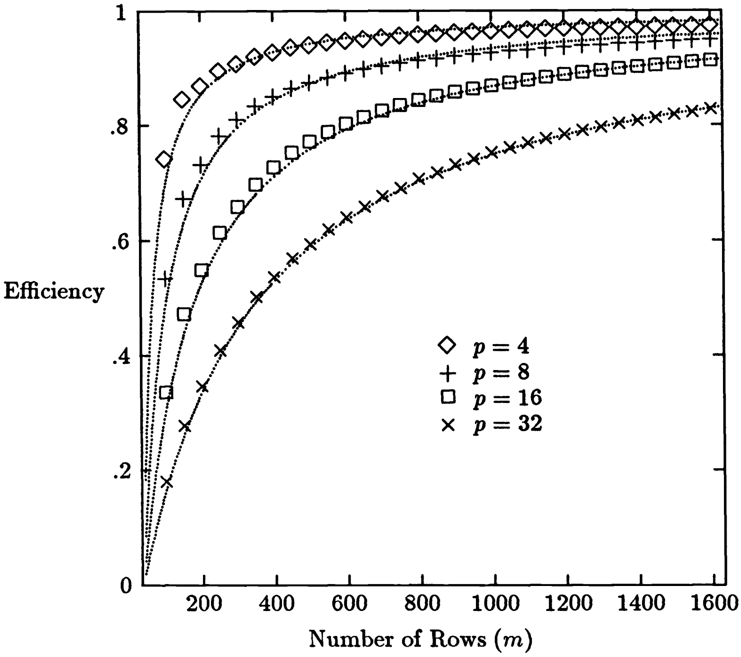

FIG. 3.3. *Efficiencies of Algorithm* 3.1 *with pivoting* ($m = 100$).

Finally, to model the hybrid algorithm we note that only t_{comp} must be modified from the analysis of the efficiency of Algorithm 3.1. Instead of accumulating sums as in Algorithm 3.1, the hybrid algorithm performs a nonlocal binary reduction of rows by Givens rotations. The binary reduction of rows of length k by Givens rotations

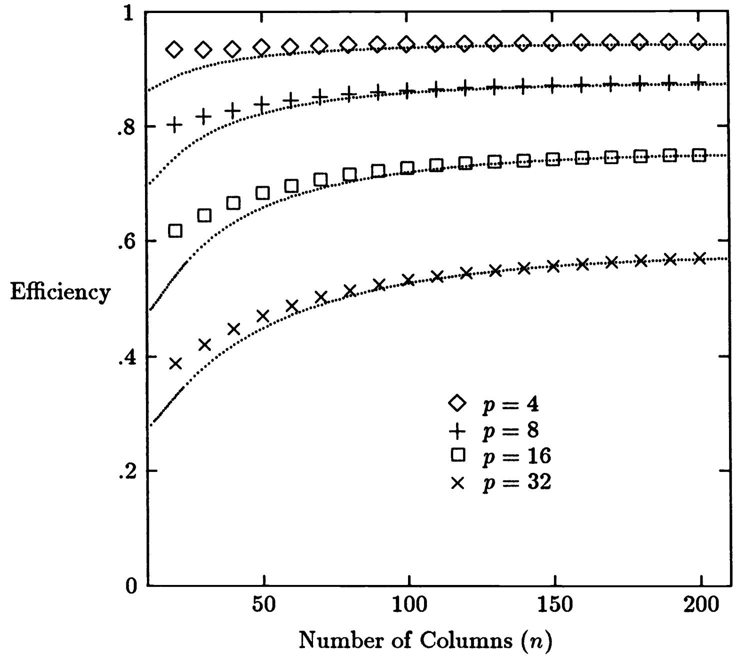

FIG. 3.4. *Efficiencies of Algorithm* 3.1 *with pivoting* ($m = 400$).

entails a total idle time for the processors of approximately $(\log(p) - 1)k\tau_{\text{Givens}}$, where τ_{Givens} is the time required to apply a Givens rotation to a 2-vector. For the iPSC/2, τ_{Givens} was measured to be approximately 37.3μsec. Summing this value from $k = 1$ to n yields total time $\frac{1}{2}(\log(p) - 1)n^2\tau_{\text{Givens}}$. Including the term for the differing number of rows assigned to processors we have that computational imbalance for the hybrid algorithm measured in flops is

$$t_{\text{comp}}^{(\text{hybrid})} \approx ((\log(p) - 1)\tau_{\text{Givens}} + 1)n^2/2. \tag{3.12}$$

Substituting this expression into (3.6) along with the expression for t_{comm} without pivoting we obtain the efficiency modeling function plotted in Fig. 3.1.

4. A parallel implementation of the Levenberg–Marquardt algorithm. To determine the Levenberg–Marquardt parameter, the matrix in (1.4) must be reduced to upper-triangular form. This reduction is computationally intensive: $n(n+1)/2$ Givens rotations and the corresponding row updates, or $O(n^3)$ flops. Note that the work required in this reduction is independent of m, the number of rows. Algorithm 4.1 details a parallel method to accomplish this reduction. In the algorithmic description let S represent storage for an upper-triangular matrix that is initially set equal to the matrix $\sqrt{\lambda}I$ in (1.4). Remember that the rows of R and S are wrapped onto an embedded ring of processors, as described in §1.

Algorithm 4.1 proceeds in n stages, which have been indexed by $j = 0, \cdots, n-1$ in the description. At stage j of Algorithm 4.1 the superdiagonal of S that is a distance j from the main diagonal is eliminated by Givens rotations. After n stages, the upper-triangular matrix S has been completely zeroed and the updated upper-triangular matrix R is still wrapped onto the processors in the same manner as at

```

Proc ($i$) : {program for processor $i$}
    For $j = 0, \cdots, n-1$ do
        If ($j \neq 0$) receive rows $S^T_{k-j}$, $k \in I_j$, from processor prev ($i$);
        For $k \in I_j$ do
            Compute Givens rotation to zero the bottom
                of the vector $(R_{k,k}, S_{k-j,k})^T$;
            Update rows $R^T_k$ and $S^T_{k-j}$ with above Givens rotation;
            If ($k = j+1$) Delete {$k$} from $I_i$;
        enddo
        Send rows $S^T_{k-j}$, $k \in I_j$, to processor next ($i$);
    enddo
```

ALGORITHM 4.1. *A parallel row-oriented* R-S *reduction.*

the start of the algorithm. As the leading nonzero of each row of S is eliminated and the corresponding rows updated, the rows of S move around the embedded ring in a systolic manner. Although the work at each stage is not completely balanced, the processor doing the most work rotates around the ring. This imbalance is somewhat offset by the required communication. Experimental results of the efficiency of this algorithm as a function of the number of columns are presented as data points in Fig. 4.1. Also plotted in the figure are the modeling functions for these efficiencies, which we will develop below.

Similar to the analysis of the QR factorization algorithms, we can model the observed efficiencies of Algorithm 4.1. First note that the total sequential work, measured in flops, is given by the formula

$$\begin{aligned} t_{\text{seq}} &\approx \sum_{k=1}^{n} 4\left(\frac{k^2}{2}\right) \\ &\approx \frac{2}{3}n^3, \end{aligned} \tag{4.1}$$

since the application of each Givens rotation to a 2-vector requires four flops. As before, we use the above equation to define the length of time we consider to be a flop. On the iPSC/2, this time was determined to be 10.9μsec.

At each step of the outer loop in Algorithm 4.1 there is a processor assigned the longest rows relative to other processors. Each of these rows differs from the average row length by $p/2$ elements. Since each processor has approximately k/p rows at step $n-k$, we have that the computational imbalance is bounded by

$$\begin{aligned} t^{(\text{row})}_{\text{comp}} &\approx \sum_{k=1}^{n} 4\left(\frac{k}{p}\right)\left(\frac{p}{2}\right) \\ &\approx n^2. \end{aligned} \tag{4.2}$$

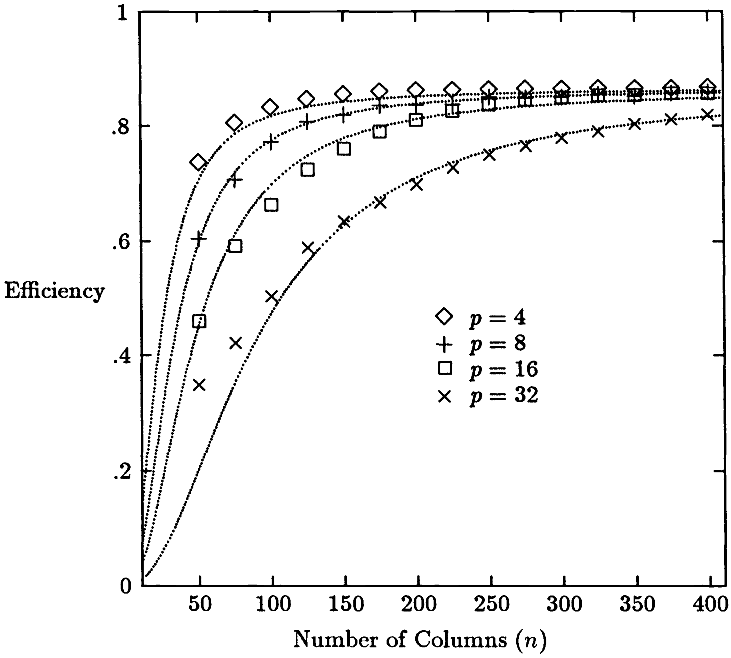

FIG. 4.1. *Efficiencies of Algorithm* 4.1 *on the iPSC/2.*

To compute the communication overhead we define the function $\rho(k)$ to be the length of time for all the processors on an embedded ring to send synchronously a double precision vector of length k to their neighbors. Experimentally, this function is essentially linear; hence, we introduce the approximation

$$\rho(k) \approx \rho_0 + \phi k. \tag{4.3}$$

For the iPSC/2 we determined values of 1105μsec for ρ_0 and 6.85μsec/value for ϕ.

At iteration $n-k$ of Algorithm 4.1 the message length is approximately $k^2/(2p)$; hence, we have that

$$\begin{aligned} t_{\text{comm}}^{(\text{row})} &\approx \sum_{k=1}^{n} \rho\left(\frac{k^2}{2p}\right) \\ &\approx \rho_0 n + \phi \frac{n^3}{6p}. \end{aligned} \tag{4.4}$$

Using (3.6), we obtain the following modeling function for the efficiency of Algorithm 4.1:

$$\text{efficiency}^{(\text{row})} \approx \frac{1}{1 + \phi/4 + \frac{3}{2}(p/n + \rho_0 p/n^2)}. \tag{4.5}$$

After substituting the necessary coefficients into (4.5), the resulting efficiency functions were plotted in Fig. 4.1. Note that for large n the efficiencies do not asymptotically approach 1, but rather approach the constant $1/(1+\phi/4)$, which is independent of the number of processors used.

```
Index Set: $K_i$ {set of column indices assigned to processor $i$}

Proc ($i$) : {program for processor $i$}
    For $j = 0, \cdots, n-1$ do
        If ($j \neq 0$) Receive Givens vector $g$ from processor prev ($i$);
        For $k \in K_j$ do
            For $l = \min(j, p-1), \cdots, 1$ do
                Update rows $R_{k-l}^T$ and $S_{k-j}^T$ with Givens rotation $g_{k-l}$;
            enddo
            Compute Givens rotation to zero the bottom
                of the vector $(R_{k,k}, S_{k-j,k})^T$;
            Update rows $R_k^T$ and $S_{k-j}^T$ with above Givens rotation;
            Update $g_k$ in Givens vector;
            If ($k = j + 1$) Delete {$k$} from $I_i$;
        enddo
        Send Givens vector $g$ to processor next ($i$);
    enddo
```

ALGORITHM 4.2. *A parallel column-oriented* R-S *reduction.*

A column-oriented approach is also possible and is presented as Algorithm 4.2. Experimental results for this algorithm are compared to those of Algorithm 4.1 in Table 4.1 and also plotted in Fig. 4.2. For Algorithm 4.2 the columns, as opposed to the rows, of R and S are wrapped onto the ring of processors. Rather than communicating rows of S between neighboring processors, the Givens rotations are stored in vectors g that rotate around the ring. Once the algorithm has been running for more than p steps, i.e., $j \geq p-1$, then the Givens vector g is completely filled with updates that need to be applied once received. The order in which these rotations are applied in the l loop is important. Since they operate on the same row of S, the rotations must be applied from the oldest to the most recent. Also, by row R_k^T we mean the nonzero components of row R_k^T that are local to processor i. These components are given by the index set K_i.

Even though Algorithm 4.2 is a bit more complicated, the total number of messages that have to be sent is the same as in Algorithm 4.1. However, for large n/p, the total number of values that have to communicated is actually less. For an average step j in Algorithm 4.2 we need only communicate the single Givens vector g of length $O(n)$ between neighboring processors. For the row-oriented version we need to communicate $O(n/p)$ rows of S of length $O(n)$ between processors. In practice, the rows of S are combined into one long message that results in the same number of communication startups as appear in Algorithm 4.2. The message startup cost, measured in equivalent flops, for the Intel iPSC hypercube is very expensive and is normally the dominant factor in the communication cost of an algorithm. For large n/p, however, the average message lengths are extremely different; hence, in comparing Figs. 4.1 and 4.2, it is apparent that the column-oriented version is asymptotically superior. By the same argument, for small n/p, the row-oriented version is superior. This crossover in the observed efficiencies of the two algorithms can be explained by also modeling the efficiency of Algorithm 4.2.

TABLE 4.1
Execution times of Algorithms 4.1 and 4.2 on the iPSC/2 hypercube.

Execution times (sec)				
n	Single processor	p	Algorithm 4.1	Algorithm 4.2
50	1.06	8	0.22	0.21
		16	0.15	0.15
		32	0.09	0.12
100	7.78	8	1.26	1.20
		16	0.74	0.72
		32	0.48	0.49

		16	2.11	2.01
		32	1.25	1.25
200	59.67	8	8.97	8.07
		16	4.63	4.37
		32	2.67	2.59
300	198.28	8	29.43	25.95
		16	14.66	13.68
		32	7.95	7.56
400	466.14	8	67.91	60.27
		16	34.24	31.28
		32	17.79	16.71

The computational imbalance of Algorithm 4.2 is the same as that for the row-oriented algorithm. Hence, we need only modify the expression for the communication overhead in the efficiency model. Since at iteration $n-k$ in the column-oriented algorithm, each processor sends k Givens rotations to its ring neighbor, we have that

$$t_{\mathrm{comm}}^{(\mathrm{col})} \approx \sum_{k=1}^{n} \rho(2k) \approx \rho_0 n + \phi n^2. \tag{4.6}$$

Combining this expression with the bound for the computational imbalance obtained earlier we obtain an approximation to the efficiency of Algorithm 4.2:

$$\text{efficiency}^{(\mathrm{col})} \approx \frac{1}{1+\frac{3}{2}((1+\phi)p/n + \rho_0 p/n^2)}. \tag{4.7}$$

Comparing (4.5) and (4.7) we note that they are equal for $n^* = 6p$. Experimentally, this crossover in the efficiencies of the two algorithms can be observed in Fig. 4.3. In this figure the crossover appears to occur near $n = 150$, close to the value of $n^* = 192$ predicted by the efficiency modeling functions.

Finally, we note that there are two possible ways to improve the asymptotic performance of the row-oriented algorithm. The first would be to wrap blocks of rows, say, b rows, onto the processors instead of single rows. This would decrease the length of messages sent at each iteration by a factor of $1/b$. Of course, this approach would also increase the computational imbalance by a factor of b. Following the analysis done above for the row-oriented algorithm we find that the optimum block size is $b^* = \sqrt{\phi n/(6p)}$. For this value of b, the asymptotic efficiency of the algorithm is improved to $1/(1+\sqrt{3\phi p/(2n)})$. However, note that for the value of ϕ determined above and for $p = 32$, n must be greater than 610 for the efficiency to improve when

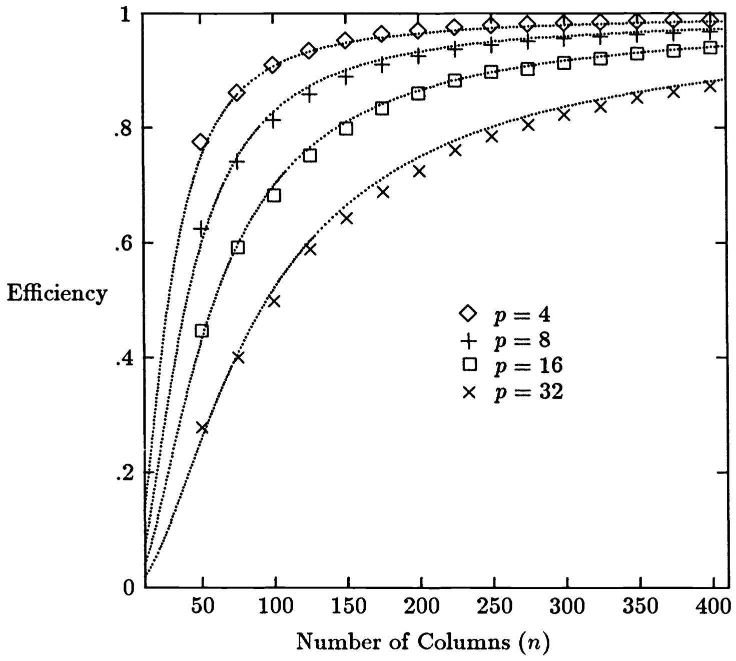

FIG. 4.2. *Efficiencies of Algorithm* 4.2 *on the iPSC/2.*

using block size $b = 2$ instead of block size $b = 1$. A second possible improvement would be to decrease the length of the messages sent in the row-oriented method by postponing the application of the Givens rotations. Unfortunately, both of these algorithms are very complicated and were not implemented.

The reduction of the matrix in (1.4) to upper-triangular form is the major task in a parallel algorithm for determining the Levenberg–Marquardt parameter λ_*, and we have shown that there exist effective algorithms to perform this reduction. However, efficient solution of triangular systems is also important in this context. In fact, for each iteration involving a solution of (1.4) there are two associated triangular solutions that are used to bracket the solution λ_* [M78]. Recently, much work has been done on the parallel solution of triangular systems [C86], [LC88], [LC89], [HR88]. We used the triangular solution algorithms developed by Li and Coleman in our implementations, but it should be noted that the efficiencies of these algorithms are not nearly as good as those of Algorithms 4.1 and 4.2. This difference is what accounts for the discrepancies between the efficiencies shown in Fig. 4.1 and the efficiencies reported in the next section for solving for the Levenberg–Marquardt parameter. This effect is apparent since even though there is an $O(n)$ difference between the amount of work required for Algorithm 4.1 and the corresponding triangular solutions, their communication costs are comparable. The importance of efficient parallel triangle system solvers has also been observed in the parallel solution of systems of nonlinear equations [CL87].

5. Experimental results and conclusions. These algorithms were implemented on a 32 node Intel iPSC/2 hypercube with 4.5 MBytes of memory per node in Green Hills Fortran-386 and run under version R3.2 of the iPSC operating system.

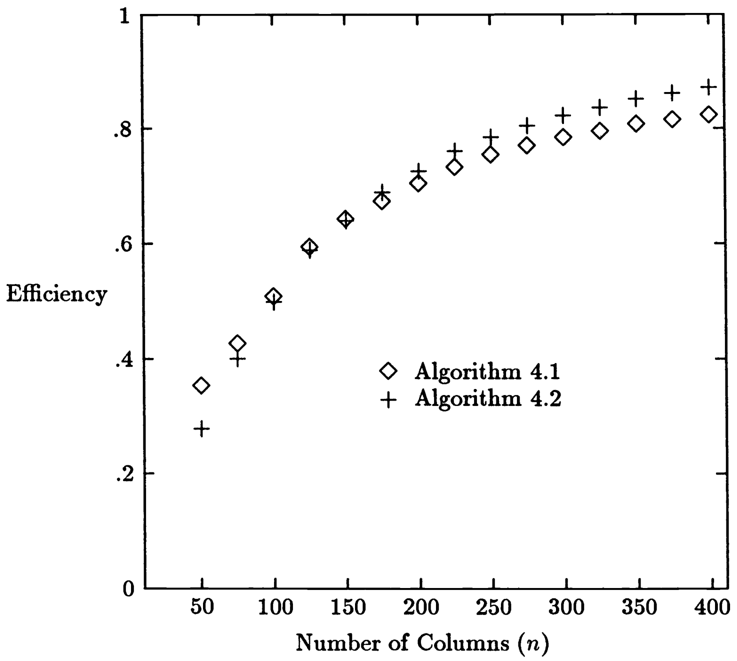

FIG. 4.3. *Efficiencies of Algorithms* 4.1 *and* 4.2 ($p = 32$).

The efficiencies shown below were calculated by dividing the running time of MINPACK [MGH80] code on a single processor by the number of processors used times the running times of the parallel algorithms. Therefore, a large number corresponds to greater efficiency. The comparison is fair, as both programs generate the same sequence of iterates and consequently do the same number of Jacobian approximations, QR factorizations, and Newton iterations in computing the Levenberg–Marquardt parameter.

TABLE 5.1
Description of test functions.

Problem number	Function form	Characteristics	F eval. cost	J approx. cost	F eval. separable?
1	$F = Ax - e$	$A \in \mathbf{R}^{m \times n}$, full rank, Ax easily evaluated, e an m-vector of ones	$O(m)$	cheap	no
2	$F = Ax - e$	$A \in \mathbf{R}^{m \times n}$, low rank, dense	$O(mn)$	expensive	yes
3	$f_i = \sum_{i,k} A_{ijk} x_j x_k - 1$	A sparse	$O(m)$	cheap	yes

Table 5.1. Shown is the functional form of the test problems, and the computational complexity of evaluating each function is given in the column labeled "F eval. cost." We also make a subjective determination as to whether estimation of the Jacobian is cheap or expensive relative to its QR factorization. To be more specific about the functions used for testing, problem 1 has an $O(m)$ evaluation cost because of a special form for the matrix A: $A_{ij} = -2/m$, $i \neq j$; $A_{ii} = 1-2/m$. The matrix A used in problem 2 is of low rank: $A_{ij} = ij + O(\epsilon)$ perturbations, where ϵ is the machine precision. For problem 3 the tensor A has a bandwidth of 2, allowing for function evaluation with $O(m)$ cost. The constants used for problem 4 were $\alpha_j = -j$ and $\tau_i = i/m$. In the final column of Table 5.1 we note whether we consider evaluation of these functions to be separable.

Tables 5.2–5.5 summarize the experimental results obtained by comparing our parallel algorithms with the MINPACK code running on a single processor for solving the test problems described in Table 5.1. The efficiencies and the fraction of the total parallel running time spent in each of six sections of the programs are detailed. The six sections refer to: QR, the QR factorization of the Jacobian approximation; L-M, computation of the Levenberg–Marquardt parameter; R-S, the R-S reduction

described in §5; Tri-s, the solution of triangular systems; and J-appr, the approximation of the Jacobian by forward differences. We include in J-appr the function evaluations necessary to estimate the Jacobian, but not the function evaluations done to test the step acceptance criteria. These function evaluations are included in the total time but not in one of the six sections. Their efficiency is comparable to that of the Jacobian approximation but their fraction of the total running time is much smaller.

These results were chosen to illustrate an average-case behavior of the parallel algorithms in solving nonlinear least-squares problems. For a particular problem the fraction of time spent in the different routines and the number of iterations required for convergence can vary dramatically for various choices of a starting point, initial trust region size, and termination tolerances. For the above problems the MINPACK tolerances were set to $\sqrt{\epsilon}$, where ϵ is the machine precision. The initial trust region size was given by $100\|\hat{x}_0\|_2$, where $\hat{x}_0$ is the starting point normalized by the 2-norms of the columns of the initial Jacobian approximation. For problems 1, 2, and 3, an n-vector of ones was used as the starting point, and for problem 4 the starting point $x_j = -(j + 0.1)$ was employed. For the problem sizes shown, problem 1 required 2 to 3 iterations (Jacobian approximations) for convergence; problem 2 used 10 to

12 iterations. Problem 3 required 7 to 8 iterations to converge and more than 10 iterations were required for problem 4 to converge; the results shown in Table 5.5 were taken from the first 10 iterations.

From these results it is apparent that either the QR factorization or the Jacobian approximation is the dominant computational cost for these problems. When the QR factorization cost dominates, the implementation is more efficient as m, the number of rows, increases. The cost of computing the Levenberg–Marquardt parameter can also be significant; this computation could dominate the QR factorization for problems that require a disproportionately large number of R-S reductions and for which the ratio m/n is close to one. This effect would occur in problems where the Jacobian is rank-deficient or the function is very nonlinear (which would require a small trust region in order to ensure an accurate quadratic model of the function). But again, for a fixed ratio m/n, the efficiency in solving for the Levenberg–Marquardt parameter increases as m increases. As expected, the parallel triangular system solutions are very inefficient when compared to the QR factorization and R-S reductions. However, the time required for these solutions composes only a small fraction of

the total computation time of the parallel implementation, and therefore it does not significantly decrease the overall efficiency. However, note that for fixed problem size the fraction of total time spent solving triangular systems does increase significantly as the number of processors is increased.

For functions whose evaluation is very expensive we observe that the computation required for the approximation of the Jacobian by forward differences can equal or exceed the computation required for these other tasks. For the expensive test functions we considered, the function evaluation was separable, and hence the row-oriented Jacobian approximation algorithm yielded efficiencies comparable to the QR factorization and Levenberg–Marquardt parameter solves. If the function evaluation were expensive and not separable, one would have to resort to a column-oriented Jacobian approximation algorithm, as described in §3. In this case the efficiency of the implementation would depend on the number of columns being sufficiently large. Another possibility would be to obtain an algebraic expression for the Jacobian and to evaluate the Jacobian directly rather than using forward differences; the algebraic evaluation of the Jacobian could be separable even when the function itself is not.

When the function evaluation is expensive and not separable, a column-oriented implementation suggests itself. In this context, the improved efficiency of using a pipelined, column-oriented QR factorization is tempting. However, complete pivoting destroys the pipelining aspect of these column-oriented algorithms. A local pivoting strategy is possible [B88], but the effect of a different pivoting strategy on the solution of these nonlinear problems would have to be tested.

In summary, we have observed good efficiencies when solving moderate-sized nonlinear least-squares problems on the Intel hypercube. For the test problems considered we noted that the efficiency of our parallel implementation improved as the ratio m/p increased, where m is the number of rows of the Jacobian and p is the number of processors. We also point out that it is possible to solve much larger problems than those we have described above (which had to be run on one processor for comparison). The efficiencies for such larger problems would be correspondingly better. A related topic is the solution of large sparse problems: Plassmann [P90] has considered the general case, and future consideration should be given to problems that have special structure. For example, the row-oriented approach could also be used if the Jacobian were banded and would be efficient in solving problems with a block structure.

WELL-CONDITIONED ITERATIVE SCHEMES FOR MIXED FINITE-ELEMENT MODELS OF POROUS-MEDIA FLOWS*

MYRON B. ALLEN†, RICHARD E. EWING†, AND PENG LU‡

Abstract. Mixed finite-element methods are attractive for modeling flows in porous media since they can yield pressures and velocities having comparable accuracy. In solving the resulting discrete equations, however, poor matrix conditioning can arise both from spatial heterogeneity in the medium and from the fine grids needed to resolve that heterogeneity. This paper presents two iterative schemes that overcome these sources of poor conditioning. The first scheme overcomes poor conditioning resulting from the use of fine grids. The idea behind the scheme is to use spectral information about the matrix associated with the discrete version of Darcy's law to precondition the velocity equations, employing a multigrid method to solve mass-balance equations for pressure or head. This scheme still exhibits slow convergence when the permeability or hydraulic conductivity is highly variable in space. The second scheme, based on the first, uses mass lumping to precondition the Darcy equations, thus requiring more work per iteration and minor modifications to the multigrid algorithm. However, the scheme is insensitive to heterogeneities. The overall approach should also be useful in such applications as electric field simulation and heat transfer modeling when the media in question have spatially variable material properties.

1. Introduction.

We consider methods for solving discrete approximations to the equations governing single-fluid flow in a porous medium. If the flow is steady and two-dimensional with no gravity drive, Darcy's law and the mass balance take the following forms:

$$\begin{aligned} \mathbf{u} &= -K \operatorname{grad} p \quad \text{in } \Omega, \\ \operatorname{div} \mathbf{u} &= f \quad \text{in } \Omega. \end{aligned} \tag{1.1}$$

Here $\mathbf{u}, p$, and f represent the Darcy velocity, pressure, and source term, respectively. For simplicity, we take the spatial domain to be a square, scaled so that $\Omega = (0,1) \times (0,1)$. The coefficient $K(x,y)$ is the *mobility*, defined as the ratio of the permeability of the porous medium to the dynamic viscosity of the fluid. In applications to underground flows, the structure of K may be quite complex, depending on the lithology of the porous medium and the composition of the fluid. We assume, however, that this ratio is bounded and integrable on $\bar{\Omega}$ and satisfies $K \geq K_{\text{inf}} > 0$. We impose the boundary condition $p = 0$ on $\partial\Omega$, so that p effectively represents the deviation in pressure from a reference value known along $\partial\Omega$.

Scientists modeling contaminant flows in groundwater or solvent flows in oil reservoirs often need accurate finite-element approximations of $\mathbf{u}$ and p simultaneously. For this reason, mixed finite-element methods for solving the system (1.1) are particularly attractive, since they can yield approximations to $\mathbf{u}$ and p that have comparable accuracy [1], [5], [9]. The key to achieving such approximations is the use of appropriate piecewise polynomial trial spaces, such as those proposed by

Raviart and Thomas [11]. As we review in §2, if we use the lowest-degree Raviart–Thomas spaces, the mixed formulation yields systems of discrete equations that have the form

$$\begin{aligned} AU + NP &= 0, \\ N^T U &= F. \end{aligned} \tag{1.2}$$

Here, U and P signify vectors containing nodal values of the trial functions for $\mathbf{u}$ and p, defined on a grid over Ω, and A and N are matrices. As we illustrate below, the matrix A contains information about the spatially varying material property K, while N and N^T are essentially finite-difference matrices.

Equations (1.2) can be quite difficult to solve efficiently, for the following reasons. When K varies over short distances, accurate finite-element approximations require fine grids on Ω. For example, one might choose grids fine enough to allow reasonable approximations of K by piecewise constant functions. Fine grids, however, typically yield poorly conditioned matrix equations. For classical stationary iterative schemes, this increase in the condition number of the system leads to slow convergence, no matter how "nice" K may be [2, §4.11]. The problem is compounded whenever K exhibits large spatial variations, as can occur near lithologic changes in the porous medium or sharp contacts between fluids of different viscosity. In such problems, as we shall demonstrate, the poor conditioning associated with spatial variability typically aggravates that associated with the fine grids needed to resolve the physics of the problem. Thus, in problems with significant material heterogeneity, methods that are relatively insensitive to these two sources of poor conditioning can have considerable utility.

In this paper we discuss two iterative schemes for the mixed-method equations (1.2). The first scheme possesses convergence rates that are independent of the fineness of the grid. The second scheme, derived from the first, also overcomes the sensitivity to the spatial structure of K, at the expense of somewhat more computation per iteration. Briefly, the first scheme proceeds as follows: Let $(U^{(0)}, P^{(0)})$ be initial guesses for the value of (U, P). Then the kth iterate for (U, P) is the solution of

$$\begin{pmatrix} \omega I & N \\ N^T & 0 \end{pmatrix} \begin{pmatrix} U^{(k)} \\ P^{(k)} \end{pmatrix} = \begin{pmatrix} 0 \\ F \end{pmatrix} + \begin{pmatrix} \omega I - A & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} U^{(k-1)} \\ P^{(k-1)} \end{pmatrix}, \tag{1.3}$$

where I stands for the identity matrix and ω signifies a parameter, discussed below, that is related to the spectral radius $\rho(A)$ of A. For each iteration level k, the main computational work in (1.3) is to solve a linear system of the form $(\omega^{-1} N^T N) P^{(k)} = G^{(k-1)}$. However, the matrix $\omega^{-1} N^T N$ remains vulnerable to the poor conditioning associated with fine grids. We overcome this difficulty by using a multigrid scheme to solve for $P^{(k)}$, thereby greatly reducing the computational work in each iteration.

An interesting feature of this approach is that $N^T N$ is essentially the matrix associated with the five-point difference approximation to the Laplace operator with Dirichlet boundary conditions. Hence, the multigrid portion of the scheme does not encounter the variable coefficient, and the algorithm is particularly simple. The price paid for this simplicity, as we shall see, is sensitivity to the poor conditioning associated with spatial variability.

To overcome this second source of trouble, we modify the first scheme to get new ones of the form

$$\begin{pmatrix} D & N \\ N^T & 0 \end{pmatrix} \begin{pmatrix} U^{(k)} \\ P^{(k)} \end{pmatrix} = \begin{pmatrix} 0 \\ F \end{pmatrix} + \begin{pmatrix} D - A & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} U^{(k-1)} \\ P^{(k-1)} \end{pmatrix}, \tag{1.4}$$

where D denotes a diagonal matrix that we compute from A. This new class of schemes requires us to invert N^TDN, which we again do using a multigrid method to preserve h-independence of the convergence rate. While the multigrid method must now accommodate spatially varying coefficients, the overall scheme possesses the advantage that its convergence rate is independent of the spatial structure of K, provided K is piecewise constant on the grids of interest.

Our paper has the following format. In §2 we review the mixed finite-element method that we use. Section 3 describes the first iterative scheme in more detail and analyzes its convergence. In §4 we discuss the application of multigrid ideas to the first scheme. Much of the motivation and groundwork for the second class of iterative schemes resides in §§3 and 4. In §5 we present some numerical results for this algorithm. Section 6 describes the modifications necessary to produce the second class of iterative schemes and presents numerical results illustrating good convergence rates even in the presence of heterogeneities.

2. A mixed finite-element method. We begin with a brief review of the mixed finite-element method, following the notation of Ewing and Wheeler [8]. Let $H(\text{div}, \Omega) = \{\mathbf{v} \in L^2(\Omega) \times L^2(\Omega) : \text{div } \mathbf{v} \in L^2(\Omega)\}$. The variational form for (1.1) is as follows: Find a pair $(\mathbf{u}, p) \in H(\text{div}, \Omega) \times L^2(\Omega)$ such that

$$\begin{aligned} &\int_\Omega \frac{\mathbf{u} \cdot \mathbf{v}}{K} dx\, dy - \int_\Omega p \text{ div } \mathbf{v}\, dx\, dy = 0 \quad \forall\, \mathbf{v} \in H(\text{div}, \Omega), \\ &\int_\Omega (\text{div } \mathbf{u} - f) q\, dx\, dy = 0 \quad \forall\, q \in L^2(\Omega). \end{aligned} \tag{2.1}$$

By our assumptions on K, there exist constants $K_{\text{inf}}, K_{\text{sup}}$ such that $0 < K_{\text{inf}} \le K \le K_{\text{sup}}$. Implicit in these equations is also the assumption that K^{-1} is integrable on $\bar{\Omega}$.

To discretize the system (2.1), let $\Delta_x = \{0 = x_0 < x_1 < \cdots < x_m = 1\}$ be a set of points on the x-axis and $\Delta_y = \{0 = y_0 < y_1 < \cdots < y_n = 1\}$ a set of points on the y-axis. Let $\Delta_h = \Delta_x \times \Delta_y$ be the rectangular grid on Ω with nodes $\{(x_i, y_j)\}_{i=0,j=0}^{m,n}$. The mesh of this grid is

$$h = \max_{i,j}\{x_i - x_{i-1},\, y_j - y_{j-1}\}.$$

We assume throughout the paper that Δ_x and Δ_y are quasi-uniform in the sense that $x_i - x_{i-1} \ge \alpha h$ and $y_j - y_{j-1} \ge \alpha h$ for some fixed $\alpha \in (0, 1)$. With Δ_h we associate a finite-element subspace $\mathbf{Q}_h \times V_h$ of $H(\text{div}, \Omega) \times L^2(\Omega)$. The "velocity space" is $\mathbf{Q}_h = Q_h^x \times Q_h^y$, where Q_h^x and Q_h^y are both tensor-product spaces of one-dimensional, finite-element spaces. In particular, we use the lowest-order Raviart–Thomas spaces in which Q_h^x contains functions that are piecewise linear and continuous on Δ_x and piecewise constant on Δ_y. Similarly, Q_h^y contains functions that are piecewise linear and continuous on Δ_y and piecewise constant on Δ_x. The "pressure space" V_h consists of functions that are piecewise constant on Δ_h.

Given these approximating spaces, the corresponding mixed finite-element method for solving (2.1) is as follows: Find a pair $(\mathbf{u}_h, p_h) \in \mathbf{Q}_h \times V_h$ such that

$$\begin{aligned} &\int_\Omega \frac{\mathbf{u}_h \cdot \mathbf{v}_h}{K} dx\, dy - \int_\Omega p_h \text{ div } \mathbf{v}_h dx\, dy = 0 \qquad \forall\, \mathbf{v}_h \in \mathbf{Q}_h, \\ &\int_\Omega (\text{div } \mathbf{u}_h - f) q_h dx\, dy = 0 \qquad \forall\, q_h \in V_h. \end{aligned} \tag{2.2}$$

This finite-element discretization yields approximations $\mathbf{u}_h$ and p_h whose global errors are both $O(h)$ in the norm $\|\cdot\|_{L^2(\Omega)}$. Ewing, Lazarov, and Wang [6] also prove superconvergence results that guarantee smaller errors at special points in Ω. This phenomenon appears in our numerical examples in §5. In contrast, standard approaches solve for approximations to p and then numerically differentiate to compute $\mathbf{u} = -K \operatorname{grad} p$, thereby losing an order of accuracy in the velocity field [1].

To see the linear algebraic equations implied by (2.2), suppose $\mathbf{u}_h$ and p_h have the expansions

$$\mathbf{u}_h(x,y) = \left(\sum_{i=0}^{m} \sum_{j=1}^{n} U^x_{i,j} \phi^x_{i,j}(x,y), \sum_{i=1}^{m} \sum_{j=0}^{n} U^y_{i,j} \phi^y_{i,j}(x,y) \right),$$

$$p_h(x,y) = \sum_{i=1}^{m} \sum_{j=1}^{n} P_{i,j} \psi_{i,j}(x,y).$$

Here, $\phi^x_{i,j}$, $\phi^y_{i,j}$, and $\psi_{i,j}$ signify elements in the standard nodal bases for Q^x_h, Q^y_h, and V_h. Define the column vectors $U \in \mathbb{R}^{2mn+m+n}$, $P \in \mathbb{R}^{mn}$ containing the nodal unknowns as follows:

$$\begin{aligned} U^T = (&U^x_{0,1}, U^x_{1,1}, \cdots, U^x_{m,1}, \cdots, U^x_{0,n}, U^x_{1,n}, \cdots, U^x_{m,n}, \\ &U^y_{1,0}, U^y_{1,1}, \cdots, U^y_{1,n}, \cdots, U^y_{m,0}, U^y_{m,1}, \cdots, U^y_{m,n}), \end{aligned} \tag{2.3}$$

$$P^T = (P_{1,1}, P_{2,1}, \cdots, P_{m,1}, \cdots, P_{1,n}, P_{2,n}, \cdots, P_{m,n}).$$

Figure 1 shows how to associate these coefficients with nodes on a spatial grid Δ_h with $m = 4$, $n = 3$.

With these bases, the problem (2.2) has a matrix representation of the form

$$\begin{pmatrix} A & N \\ N^T & 0 \end{pmatrix} \begin{pmatrix} U \\ P \end{pmatrix} = \begin{pmatrix} 0 \\ F \end{pmatrix}. \tag{2.4}$$

Here A is a symmetric, positive definite matrix having the block structure

$$A = \begin{pmatrix} A^x & 0 \\ 0 & A^y \end{pmatrix},$$

in which $A^x \in \mathbb{R}^{(m+1)n \times (m+1)n}$ and $A^y \in \mathbb{R}^{m(n+1)\times m(n+1)}$ have entries of the form

$$\int_\Omega \frac{\phi^x_{i,j}\phi^x_{k,\ell}}{K} dx\, dy, \qquad \int_\Omega \frac{\phi^y_{i,j}\phi^y_{k,\ell}}{K} dx\, dy,$$

respectively. Note that these entries contain information about the spatially varying coefficient K. The matrix N has the block structure

$$N = \begin{pmatrix} N^x \\ N^y \end{pmatrix},$$

where $N^x \in \mathbb{R}^{(m+1)n\times mn}$ and $N^y \in \mathbb{R}^{m(n+1)\times mn}$ have entries given, respectively, by

$$\int_\Omega \psi_{i,j} \frac{\partial \phi^x_{k,\ell}}{\partial x} dx\, dy, \qquad \int_\Omega \psi_{i,j} \frac{\partial \phi^y_{k,\ell}}{\partial y} dx\, dy.$$

By calculating these integrals, one readily confirms that N^x and N^y reduce to the usual difference approximations to $\partial/\partial x$ and $\partial/\partial y$. The vector $F \in \mathbb{R}^{mn}$ has entries given by the integrals $\int_\Omega f \psi_{i,j} dx\, dy$. The appendix to this paper gives more detail on the construction of A and N.

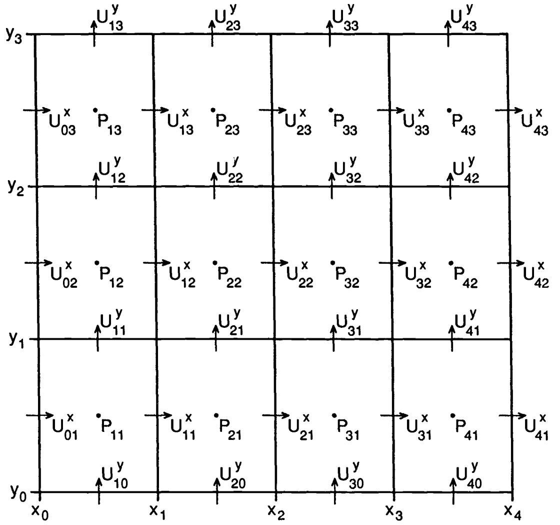

FIG. 1. *Sample* 4×3 *rectangular grid on* $\Omega = (0,1) \times (0,1)$, *showing locations of the nodal unknowns in the velocity and pressure trial functions.*

3. An h-independent iterative method.

Our first iterative scheme for solving the discrete system (2.4) is as follows.

ALGORITHM 1. Beginning with initial guess $\left(U^{(0)}, P^{(0)}\right)^T$ for (U, P), the kth iterate $\left(U^{(k)}, P^{(k)}\right)^T$ is the solution of

$$\begin{pmatrix} \omega I & N \\ N^T & 0 \end{pmatrix} \begin{pmatrix} U^{(k)} \\ P^{(k)} \end{pmatrix} = \begin{pmatrix} 0 \\ F \end{pmatrix} + \begin{pmatrix} \omega I - A & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} U^{(k-1)} \\ P^{(k-1)} \end{pmatrix}, \tag{3.1}$$

where $I \in \mathbb{R}^{(2mn+m+n)\times(2mn+m+n)}$ is the identity matrix and ω is a parameter chosen to satisfy $\omega \geq \rho(A)$.

Here, $\rho(A)$ denotes the spectral radius of the matrix A. Later in this section we discuss a practical way to pick ω that does not require detailed knowledge of the spectrum of A.

Computationally, Algorithm 1 has the following compact form: Given an initial guess $\left(U^{(0)}, P^{(0)}\right)^T$, compute $\left(U^{(k)}, P^{(k)}\right)^T$ by executing three steps:

$$\text{(i) } G^{(k-1)} \leftarrow -F + \omega^{-1} N^T (\omega I - A) U^{(k-1)}, \tag{3.2}$$

$$\text{(ii) Solve } \omega^{-1} N^T N P^{(k)} = G^{(k-1)}, \tag{3.3}$$

$$\text{(iii) } \omega U^{(k)} \leftarrow (\omega I - A) U^{(k-1)} - N P^{(k)}. \tag{3.4}$$

In each iteration, the main computational work is to solve for $P^{(k)} = \omega (N^T N)^{-1} G^{(k-1)}$. An easy calculation shows that the matrix $\omega^{-1}(N^T N)$ is positive definite, being proportional to the standard five-point, finite-difference Laplace operator applied to $P^{(k)}$. Therefore, we expect the numerical solution for $P^{(k)}$ using stationary iterative methods to be plagued by poor conditioning when the grid mesh h is small.

This observation leads us to use a multigrid scheme to get approximations to $P^{(k)}$. (In fact, any fast solver for the five-point discrete Laplacian operator would be appropriate here.) Such a device preserves the h-independence of the overall scheme's convergence rate. We discuss this facet of the algorithm in more detail in the next section. For now let us analyze the convergence properties of the overall iterative scheme, assuming an efficient "black-box" solver for $P^{(k)}$.

We begin by writing (3.1) as a stationary iterative scheme

$$\begin{pmatrix} U^{(k)} \\ P^{(k)} \end{pmatrix} = L + M \begin{pmatrix} U^{(k-1)} \\ P^{(k-1)} \end{pmatrix}, \tag{3.5}$$

where

$$L = \begin{pmatrix} \omega I & N \\ N^T & 0 \end{pmatrix}^{-1} \begin{pmatrix} 0 \\ F \end{pmatrix},$$

$$M = \begin{pmatrix} \omega I & N \\ N^T & 0 \end{pmatrix}^{-1} \begin{pmatrix} \omega I - A & 0 \\ 0 & 0 \end{pmatrix}.$$

The convergence of Algorithm 1 depends on the spectral radius of the matrix M, for which the following proposition gives a bound.

PROPOSITION 3.1. *Let*

$$0 < \lambda_{\min} \le \cdots \le \lambda_{\max} \tag{3.6}$$

be the eigenvalues of the matrix A, and let $\omega \ge \lambda_{\max}$. Then the spectral radius of M obeys the estimate

$$\rho(M) \le 1 - \frac{\lambda_{\min}}{\omega}. \tag{3.7}$$

Proof. Let $\lambda \neq 0$ be an eigenvalue of M with eigenvector $(U_\lambda, P_\lambda)^T$. Thus

$$M \begin{pmatrix} U_\lambda \\ P_\lambda \end{pmatrix} \equiv \begin{pmatrix} \omega I & N \\ N^T & 0 \end{pmatrix}^{-1} \begin{pmatrix} \omega I - A & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} U_\lambda \\ P_\lambda \end{pmatrix} = \lambda \begin{pmatrix} U_\lambda \\ P_\lambda \end{pmatrix}, \tag{3.8}$$

so

$$(\omega I - A) U_\lambda = \lambda(\omega U_\lambda + N P_\lambda), \tag{3.9a}$$

$$0 = \lambda N^T U_\lambda. \tag{3.9b}$$

Since $(U_\lambda, P_\lambda)^T \neq 0$, (3.9a) shows that $U_\lambda \neq 0$; however, U_λ may be complex. Let U_λ^H denote its Hermitian conjugate. If we multiply (3.9a) by U_λ^H, observe that N is a real matrix, and apply (3.9b), we obtain

$$\begin{aligned} U_\lambda^H (\omega I - A) U_\lambda &= \lambda \omega U_\lambda^H U_\lambda + \lambda (N^T U_\lambda)^H P_\lambda \\ &= \lambda \omega U_\lambda^H U_\lambda. \end{aligned}$$

This equation allows us to conclude that

$$0 < |\lambda| = \left| \frac{U_\lambda^H (I - \omega^{-1} A) U_\lambda}{U_\lambda^H U_\lambda} \right| \leq \rho(I - \omega^{-1} A),$$

which implies

$$\rho(M) \leq \rho(I - \omega^{-1} A). \tag{3.10}$$

Also, by (3.6) and the fact that $\omega \geq \lambda_{\max}$, we have

$$\rho(I - \omega^{-1} A) \leq 1 - \frac{\lambda_{\min}}{\omega}.$$

These last two inequalities imply the desired bound (3.7). □

If we choose $\omega = \lambda_{\max} = \rho(A)$, then the estimate (3.7) for the spectral radius of the iteration matrix M becomes

$$\rho(M) \leq 1 - \frac{\lambda_{\min}}{\lambda_{\max}}.$$

To estimate $\lambda_{\min}/\lambda_{\max}$, the following proposition is helpful.

PROPOSITION 3.2. *For the matrix A appearing in (2.4), there exist constants k_0 and k_1, independent of h, such that*

$$k_0 h^2 U^T U \leq U^T A U \leq k_1 h^2 U^T U. \tag{3.11}$$

Proof. The representation of $\mathbf{u}_h$ given in (2.3) leads to the identity

$$U^T A U = \int_\Omega \frac{1}{K} |\mathbf{u}_h|^2 dx\, dy = \sum_{i=1}^{m} \sum_{j=1}^{n} \int_{\Omega_{i,j}} \frac{1}{K} |\mathbf{u}_h|^2 dx\, dy,$$

where $\Omega_{i,j} = (x_{i-1}, x_i) \times (y_{j-1}, y_j)$. Since K is bounded and integrable on $\Omega_{i,j}$, the mean value theorem for integrals [10, pp. 184–185] guarantees the existence of a number $K_{i,j}$, satisfying $\inf_{\Omega_{i,j}} K \leq K_{i,j} \leq \sup_{\Omega_{i,j}} K$, such that

$$\int_{\Omega_{i,j}} \frac{1}{K} |\mathbf{u}_h|^2 dx\, dy = \frac{1}{K_{i,j}} \int_{\Omega_{i,j}} |\mathbf{u}_h|^2 dx\, dy.$$

(If K^{-1} is continuous on $\bar{\Omega}_{i,j}$, then K^{-1} actually assumes the value $K_{i,j}^{-1}$ somewhere on $\Omega_{i,j}$.) Calculating the last integral using our basis for $\mathbf{Q}_h$, we get

$$U^T A U = \sum_{i=1}^{m} \sum_{j=1}^{n} \frac{a_{ij}}{6K_{ij}} \left[\begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix}^T \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} \begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix} \right.$$
$$\left. + \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix}^T \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix} \right],$$

where a_{ij} signifies the area of $\Omega_{i,j}$. To simplify notation, we notice that the 2×2 matrix appearing in each term of this sum is positive definite. This observation allows us to define a new norm on $\mathbb{R}^2$ as follows:

$$\left\| \begin{pmatrix} U_1 \\ U_2 \end{pmatrix} \right\|_A^2 = \begin{pmatrix} U_1 \\ U_2 \end{pmatrix}^T \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix} \begin{pmatrix} U_1 \\ U_2 \end{pmatrix}.$$

If $\|\cdot\|_2$ denotes the usual Euclidean norm on $\mathbb{R}^2$, then it is easy to check that $\|\cdot\|_2^2 \le \|\cdot\|_A^2 \le 3\|\cdot\|_2^2$. In terms of the new norm,

$$U^TAU = \sum_{i=1}^{m}\sum_{j=1}^{n} \frac{a_{ij}}{6K_{ij}} \left[\left\| \begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix} \right\|_A^2 + \left\| \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix} \right\|_A^2 \right].$$

The quantity U^TU is easier to calculate:

$$U^TU = \sum_{i=0}^{m}\sum_{j=1}^{n} |U_{ij}^x|^2 + \sum_{i=1}^{m}\sum_{j=0}^{n} |U_{ij}^y|^2. \tag{3.12}$$

Now we use the bounds on K and the quasi uniformity of Δ_h to observe that

$$\begin{aligned} U^TAU &\ge \frac{\alpha^2h^2}{6K_{\sup}} \sum_{i=1}^{m}\sum_{j=1}^{n} \left[\left\| \begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix} \right\|_A^2 + \left\| \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix} \right\|_A^2 \right] \\ &\ge \frac{\alpha^2h^2}{6K_{\sup}} \sum_{i=1}^{m}\sum_{j=1}^{n} \left[\left\| \begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix} \right\|_2^2 + \left\| \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix} \right\|_2^2 \right] \\ &\ge \frac{\alpha^2h^2}{6K_{\sup}} \left[\sum_{i=0}^{m}\sum_{j=1}^{n} \left\| \begin{pmatrix} 0 \\ U_{i,j}^x \end{pmatrix} \right\|_2^2 + \sum_{i=1}^{m}\sum_{j=0}^{n} \left\| \begin{pmatrix} 0 \\ U_{i,j}^y \end{pmatrix} \right\|_2^2 \right] \\ &= \frac{\alpha^2h^2}{6K_{\sup}} U^TU. \end{aligned}$$

This observation establishes the first inequality in (3.11), since we can take $k_0 = \alpha^2/6K_{\sup}$. To prove the second inequality in (3.11), we rewrite (3.12) as follows:

$$\begin{aligned} U^TU = &\frac{1}{2}\sum_{i=0}^{m}\sum_{j=0}^{n} \left[\left\| \begin{pmatrix} 0 \\ U_{i,j}^x \end{pmatrix} \right\|_2^2 + \left\| \begin{pmatrix} 0 \\ U_{i,j}^y \end{pmatrix} \right\|_2^2 \right] \\ &+\frac{1}{2}\sum_{i=1}^{m+1}\sum_{j=1}^{n+1} \left[\left\| \begin{pmatrix} U_{i-1,j}^x \\ 0 \end{pmatrix} \right\|_2^2 + \left\| \begin{pmatrix} U_{i,j-1}^y \\ 0 \end{pmatrix} \right\|_2^2 \right], \end{aligned}$$

where we agree that $U_{ij}^x = 0$ if either $j = 0$ or $j = n + 1$, and $U_{ij}^y = 0$ if either $i = 0$ or $i = m + 1$. Hence,

$$\begin{aligned} U^TU &\ge \frac{1}{2}\sum_{i=1}^{m}\sum_{j=1}^{n} \left[\left\| \begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix} \right\|_2^2 + \left\| \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix} \right\|_2^2 \right] \\ &\ge \frac{1}{6}\sum_{i=1}^{m}\sum_{j=1}^{n} \left[\left\| \begin{pmatrix} U_{i-1,j}^x \\ U_{i,j}^x \end{pmatrix} \right\|_A^2 + \left\| \begin{pmatrix} U_{i,j-1}^y \\ U_{i,j}^y \end{pmatrix} \right\|_A^2 \right] \\ &\ge \frac{K_{\inf}}{h^2} U^TAU. \end{aligned}$$

We conclude that $U^TAU \le k_1h^2U^TU$, where $k_1 = 1/K_{\inf}$. □

If we apply Proposition 3.2 to the case when U is an eigenvector of A associated with the eigenvalue $\lambda_{\min}$ or $\lambda_{\max}$, respectively, we find that $\lambda_{\min} \geq \alpha^2 h^2/6K_{\sup}$ and $\lambda_{\max} \leq h^2/K_{\inf}$. Therefore, provided we choose $\omega \geq \lambda_{\max}$ in Algorithm 1, the spectral radius of our iteration matrix M obeys the bound

$$\rho(M) \leq 1 - \frac{\alpha^2 K_{\inf}}{6K_{\sup}}. \tag{3.13}$$

Notice that the right side of this inequality is a constant independent of h. This is the sense in which the convergence rate of Algorithm 1 is independent of h.

Two remarks about the practical implications of the estimate (3.13) are in order. First, the bound on $\rho(M)$ depends strongly on the nature of the coefficient $K(x, y)$. In particular, if $K_{\inf}/K_{\sup}$ is very small, reflecting a high degree of heterogeneity in the physical problem, then we can expect the actual convergence of the algorithm to be slow, albeit independent of grid mesh. Several examples in §5 confirm this expectation. Second, even though the bound (3.13) suggests choosing $\omega = \lambda_{\max}$ to accelerate iterative convergence, this choice is impractical owing to the expense of calculating $\lambda_{\max}$. In practice, we typically pick $\omega = \|A\|_\infty \geq \lambda_{\max}$. This choice is easily computable as the maximum row sum of A, and it preserves h-independence of convergence rate, even though it may be theoretically nonoptimal.

4. Application of a multigrid solver. As we have mentioned, the computation of the pressure iterate $P^{(k)}$ in step (ii) of Algorithm 1 is inefficient if we use direct schemes or classical stationary iterative methods on fine grids. However, the fact that $\omega^{-1}N^TN$ is essentially the finite-difference Laplacian operator motivates us to reduce the computational work for each iteration by calculating an approximation to the kth pressure iterate by using several cycles of a multigrid method on the system (3.3). We refer the reader to [3] for a discussion of the multigrid approach and for a Fortran code applicable in the context of our problem. The modified scheme is as follows.

ALGORITHM 2. Begin with an initial guess $\left(U^{(0)}, P^{(0)}\right)^T$, and suppose that we have computed $\left(U^{(k-1)}, P^{(k-1)}\right)^T$. Compute a new approximation $\left(U^{(k)}, P^{(k)}\right)^T$ using the following steps:

1. Compute the residual,

$$G^{(k-1)} \leftarrow -F + N^T(I - \omega^{-1}A)U^{(k-1)}. \tag{4.1}$$

2. Let $\hat{P}^{(k)}$ denote the exact solution of the problem

$$\omega^{-1}N^TN\hat{P}^{(k)} = G^{(k-1)}. \tag{4.2}$$

   Calculate an approximation $P^{(k)}$ of $\hat{P}^{(k)}$ by applying r cycles of the multigrid algorithm [3] to (4.2), using $P^{(k-1)}$ as initial guess. (We discuss the choice of r below.)

3. Compute $U^{(k)}$ as in Algorithm 1:

$$\omega U^{(k)} \leftarrow (\omega I - A)U^{(k-1)} - NP^{(k)}. \tag{4.3}$$

Multigrid methods for solving elliptic problems have an advantage that is quite relevant to the conditioning problems associated with fine grids: Each cycle has a convergence rate that is independent of h [4, Chap. 4]. Therefore, we need only show that we can choose a *fixed* number r of multigrid cycles such that each iteration of Algorithm 2 reduces the error norm by an appropriate factor close to $\rho(M)$. We do this in Proposition 4.1. Since the factor is independent of h, Algorithm 2 has convergence rate independent of h.

We begin by defining norms on the "pressure" and "velocity" spaces that will make the proof easier. Any $p_h \in V_h$ has a representation

$$p_h(x,y) = \sum_{i,j} P_{i,j}\psi_{i,j}(x,y).$$

Taking advantage of the fact that N^TN is positive definite, we compute a norm of the vector

$$P = (P_{1,1}, P_{2,1}, \cdots, P_{m,1}, \cdots, P_{1,n}, P_{2,n}, \cdots, P_{m,n})^T$$

by setting $||P||_h^2 = P^T(\omega^{-1}N^TN)P$. On the other hand, any $\mathbf{u}_h \in \mathbf{Q}_h$ has a representation

$$\mathbf{u}_h(x,y) = \left(\sum_{i,j} U^x_{i,j}\phi^x_{i,j}(x,y), \sum_{i,j} U^y_{i,j}\phi^y_{i,j}(x,y) \right).$$

We compute a norm of the vector

$$U = (U^x_{0,1}, U^x_{1,1}, \cdots, U^x_{m,1}, \cdots, U^x_{0,n}, U^x_{1,n}, \cdots, U^x_{m,n},$$

$$U^y_{1,0}, U^y_{1,1}, \cdots, U^y_{1,n}, \cdots, U^y_{m,0}, U^y_{m,1}, \cdots, U^y_{m,n})^T$$

by setting $||U||^2_\omega = \omega U^TU$.

The norm $||\cdot||_\omega$ is just a scalar multiple of the Euclidean distance function $||\cdot||_2$, and since ω is a constant related to $\rho(A)$, $||\cdot||_\omega$ is actually a discrete analog of the Euclidean norm $||\cdot||_{L^2(\Omega)\times L^2(\Omega)}$ on the velocity space by Proposition 3.2. This norm is appropriate for measuring the convergence of velocity iterates $U^{(k)}$ to the true discrete approximation U. Also, since N^TN is just the positive definite matrix associated with the five-point difference approximation to the Laplace operator, the norm $||\cdot||_h$ is appropriate for measuring the rapidity with which the pressure iterates satisfy the discrete pressure equation (3.3) as the iterations progress. Ultimately, we want to relate our results to more familiar norms such as $||\cdot||_2$ and $||\cdot||_\infty$; for this step we shall rely on the equivalence of norms for finite-dimensional Euclidean spaces.

In the following proposition, we assume $\nu = \rho(I - \omega^{-1}A) < 1$. Thus ν is an upper bound on $\rho(M)$. Suppose the multigrid iteration used to approximate $\hat{P}^{(k)}$ in step (ii) of Algorithm 1 has convergence rate $\mu \in (0,1)$. This implies that, after r multigrid cycles for $P^{(k)}$ using $P^{(k-1)}$ as initial guess,

$$\left|\left|\hat{P}^{(k)} - P^{(k)}\right|\right|_h \le \mu^r \left|\left|\hat{P}^{(k)} - P^{(k-1)}\right|\right|_h. \tag{4.4}$$

PROPOSITION 4.1. *For any $\nu' \in (\nu, 1)$, there exists a number r of multigrid cycles such that*

$$\left|\left|P - P^{(k)}\right|\right|_h + \left|\left|U - U^{(k)}\right|\right|_\omega \le \nu' \left(\left|\left|P - P^{(k-1)}\right|\right|_h + \left|\left|U - U^{(k-1)}\right|\right|_\omega \right),$$

where (P, U) is the solution of the problem (2.4) and $\left(P^{(k)}, U^{(k)}\right)$ is the approximation to (P, U) produced by the kth iteration of Algorithm 2.

Proof. Suppose we compute $\hat{U}^{(k)}$ according to (3.4) with the exact (nonmultigrid) pressure iterate $\hat{P}^{(k)}$. Thus,

$$\omega\hat{U}^{(k)} = (\omega I - A)U^{(k-1)} - N\hat{P}^{(k)}, \tag{4.5}$$

where $\hat{P}^{(k)}$ satisfies (4.2). Then from (2.4), (4.1), (4.2), and (4.5), we have

$$\omega\left(U - \hat{U}^{(k)}\right) + N\left(P - \hat{P}^{(k)}\right) = (\omega I - A)\left(U - U^{(k-1)}\right), \tag{4.6}$$

$$N^T\left(U - \hat{U}^{(k)}\right) = 0. \tag{4.7}$$

Multiplying (4.6) by $\left(U - \hat{U}^{(k)}\right)^T$ and using the identity (4.7), we get

$$\begin{aligned}\left|\left|U - \hat{U}^{(k)}\right|\right|_\omega^2 &= \left(U - \hat{U}^{(k)}\right)^T (\omega I - A)\left(U - U^{(k-1)}\right)\\ &\le \left|\left|U - \hat{U}^{(k)}\right|\right|_\omega \left|\left|(I - \omega^{-1}A)\left(U - U^{(k-1)}\right)\right|\right|_\omega\\ &\le \rho(I - \omega^{-1}A)\left|\left|U - \hat{U}^{(k)}\right|\right|_\omega \left|\left|U - U^{(k-1)}\right|\right|_\omega .\end{aligned}$$

Therefore, the velocity iterates obey the estimate

$$\left|\left|U - \hat{U}^{(k)}\right|\right|_\omega \le \nu\left|\left|U - U^{(k-1)}\right|\right|_\omega .$$

Similarly, multiplying (4.6) by $\left[\omega^{-1}N\left(P - \hat{P}^{(k)}\right)\right]^T$, we get

$$\begin{aligned}\left|\left|P - \hat{P}^{(k)}\right|\right|_h^2 &= \left(P - \hat{P}^{(k)}\right)^T N^T\omega^{-1}(\omega I - A)\left(U - U^{(k-1)}\right)\\ &\le \left|\left|\omega^{-1}N\left(P - \hat{P}^{(k)}\right)\right|\right|_\omega \left|\left|(I - \omega^{-1}A)\left(U - U^{(k-1)}\right)\right|\right|_\omega\\ &\le \left|\left|P - \hat{P}^{(k)}\right|\right|_h \rho(I - \omega^{-1}A)\left|\left|U - U^{(k-1)}\right|\right|_\omega .\end{aligned}$$

Hence, the pressure iterates obey the bound

$$\left|\left|P - \hat{P}^{(k)}\right|\right|_h \le \nu\left|\left|U - U^{(k-1)}\right|\right|_\omega .$$

Now we derive bounds on $\left|\left|P - P^{(k)}\right|\right|_h$ and $\left|\left|U - U^{(k)}\right|\right|_\omega$ in terms of their values at the previous iterative level. For $\left|\left|P - P^{(k)}\right|\right|_h$, we use the triangle equality and the multigrid estimate (4.4) to get

$$\begin{aligned}\left|\left|P - P^{(k)}\right|\right|_h &\le \left|\left|P - \hat{P}^{(k)}\right|\right|_h + \left|\left|\hat{P}^{(k)} - P^{(k)}\right|\right|_h\\ &\le \left|\left|P - \hat{P}^{(k)}\right|\right|_h + \mu^r\left|\left|\hat{P}^{(k)} - P^{(k-1)}\right|\right|_h \qquad (4.8)\\ &\le \left|\left|P - \hat{P}^{(k)}\right|\right|_h + \mu^r\left(\left|\left|P - \hat{P}^{(k)}\right|\right|_h + \left|\left|P - P^{(k-1)}\right|\right|_h\right).\end{aligned}$$

But the original iterative scheme (3.5) implies that

$$\begin{pmatrix} U - \hat{U}^{(k)} \\ P - \hat{P}^{(k)} \end{pmatrix} = M \begin{pmatrix} U - U^{(k-1)} \\ P - P^{(k-1)} \end{pmatrix}.$$

So, in light of the inequality (3.1) bounding $\rho(M)$ by ν, we have

$$\left|\left|\hat{P} - P^{(k)}\right|\right|_h \leq \rho(M) \left|\left|P - P^{(k-1)}\right|\right|_h \leq \nu \left|\left|P - P^{(k-1)}\right|\right|_h.$$

This inequality allows us to simplify (4.8), getting

$$\left|\left|P - P^{(k)}\right|\right|_h \leq (\nu + \mu^r + \nu\mu^r) \left|\left|P - P^{(k-1)}\right|\right|_h. \tag{4.9}$$

Turning to $\left|\left|U - U^{(k)}\right|\right|_\omega$, we use (4.3), multiplied by ω^{-1}, to write

$$\left(U - U^{(k)}\right) = (I - \omega^{-1}A)\left(U - U^{(k-1)}\right) + \omega^{-1}N\left(P - P^{(k)}\right).$$

This identity implies that

$$\begin{aligned} \left|\left|U - U^{(k)}\right|\right|_\omega &\leq \left|\left|(I - \omega^{-1}A)\left(U - U^{(k-1)}\right)\right|\right|_\omega + \left|\left|\omega^{-1}N\left(P - P^{(k)}\right)\right|\right|_\omega \\ &\leq \nu \left|\left|U - U^{(k-1)}\right|\right|_\omega + \left|\left|P - P^{(k)}\right|\right|_h \\ &\leq \nu \left|\left|U - U^{(k-1)}\right|\right|_\omega + (\nu + \mu^r + \nu\mu^r) \left|\left|P - P^{(k-1)}\right|\right|_h \\ &\leq (\nu + \mu^r + \nu\mu^r)\left(\left|\left|P - P^{(k-1)}\right|\right|_h + \left|\left|U - U^{(k-1)}\right|\right|_\omega\right). \end{aligned} \tag{4.10}$$

Combining the inequalities (4.9) and (4.10), we get

$$\begin{aligned} &\left|\left|P - P^{(k)}\right|\right|_h + \left|\left|U - U^{(k)}\right|\right|_\omega \\ &\qquad \leq (\nu + \mu^r + \nu\mu^r)\left(\left|\left|P - P^{(k-1)}\right|\right|_h + \left|\left|U - U^{(k-1)}\right|\right|_\omega\right). \end{aligned}$$

Since $\mu < 1$, $\mu^r + \nu\mu^r \to 0$ as $r \to \infty$. We can therefore choose r large enough so that $\nu + \mu^r + \nu\mu^r + \nu \leq \nu' < 1$. In this way,

$$\left|\left|P - P^{(k)}\right|\right|_h + \left|\left|U - U^{(k)}\right|\right|_\omega \leq \nu' \left(\left|\left|P - P^{(k-1)}\right|\right|_h + \left|\left|U - U^{(k-1)}\right|\right|_\omega\right). \qquad \square$$

In view of the norm equivalence mentioned earlier, Proposition 4.1 leads us to expect that, if we choose ω as prescribed in §3, then the computed convergence rate

$$\bar{\mu} = \lim_{k \to \infty} \left[\frac{\|P - P^{(k)}\|_\infty + \|U - U^{(k)}\|_\infty}{\|P - P^{(0)}\|_\infty + \|U - U^{(0)}\|_\infty}\right]^{1/k} \tag{4.11}$$

should be a constant independent of h as $h \to 0$. In fact, for "generic" initial guesses, the contribution from the eigenvector associated with the largest magnitude eigenvalue of M will eventually dominate the error. We therefore expect $\bar{\mu}$ to give good approximations to $\rho(M)$ in computational practice [2, p. 129].

5. Numerical examples of *h*-independence. To test our results, we apply Algorithm 2 to several versions of the following boundary-value problem:

$$\begin{aligned} -\operatorname{div}[K(x,y)\operatorname{grad} p(x,y)] &= f(x,y), && (x,y) \in \Omega, \\ p(x,y) &= 0, && (x,y) \in \partial\Omega. \end{aligned} \tag{5.1}$$

We use the lowest-order, mixed finite-element method on grids with $h = 2^{-\ell}$, where $\ell = 4, 5, 6, 7, 8$. Each iteration of the solution scheme includes $r = 2$ V-cycles of the multigrid algorithm described in [3], where the coarsest grid in each cycle has mesh 2^{-1}, and the finest has mesh $2^{-\ell}$. We use the following realizations of the coefficient $K(x,y)$:

$$\begin{aligned} K_{\text{I}}(x,y) &= 1, \\ K_{\text{II}}(x,y) &= e^{-x-y}, \\ K_{\text{III}}(x,y) &= \begin{cases} 1 & \text{if } x < y, \\ 0.1 & \text{if } x \geq y, \end{cases} \\ K_{\text{IV}}(x,y) &= K_{\text{II}}(x,y) \cdot K_{\text{III}}(x,y), \\ K_{\text{V}}(x,y) &= \begin{cases} 1 & \text{if } x < y, \\ 0.01 & \text{if } x \geq y. \end{cases} \end{aligned}$$

To confirm the convergence properties of the mixed finite-element method as $h \to 0$, we examine the exact and numerical solutions to (5.1) using $K = K_{\text{II}}$ and taking $f(x,y)$ to be the function that results when the solution is $p(x,y) = x(1-x)\sin(\pi y) + y(1-y)\sin(\pi x)$. We compute the nodal error indicators $\|U_{\text{exact}} - U\|_\infty$ and $\|P_{\text{exact}} - P\|_\infty$, where U_{exact} and P_{exact} stand for the vectors of nodal values of the exact solutions $\mathbf{u}$ and p, and U and P are vectors containing nodal values of the finite-element approximations on a uniform grid of mesh h. Figure 2 shows plots of $\log\|U_{\text{exact}} - U\|_\infty$ and $\log\|P_{\text{exact}} - P\|_\infty$ versus $\log h$ having least-squares slopes of 1.899 and 2.000, respectively. These results suggest that the nodal values of U and P are accurate to $O(h^2)$, corroborating the equal-order accuracy available in the Raviart–Thomas subspaces and indicating superconvergent nodal values in accordance with the work of Ewing, Lazarov, and Wang [6].

To check the convergence properties of the iterative scheme, we examine the behavior of the ratio $\bar{\mu}$, defined in (4.11), for each of the choices of K. Our results, shown in Fig. 3, support the expectation that, as $h \to 0$, the convergence rate of the scheme tends to a constant independent of h. Notice however that, as K exhibits more spatial variation, the convergence of the algorithm becomes slower. Any effects of variability in K on the conditioning of the discrete equations still influence this first algorithm; the only effects of poor conditioning that we have eliminated so far are those associated with grid refinement.

6. Modified schemes for heterogeneous media. To mitigate the difficulties associated with spatial variability, we modify the first iterative scheme (3.1) to get a class of new schemes having the following form.

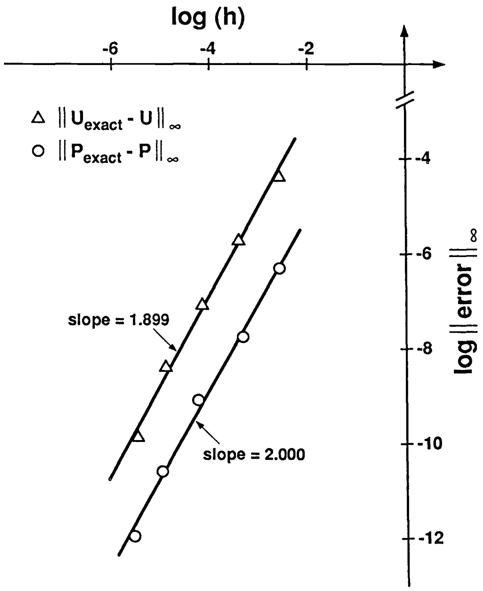

FIG. 2. *Convergence plot for the mixed finite-element scheme for Poisson's equation, using lowest-order Raviart–Thomas trial spaces. The plots demonstrate the rate of decrease in the nodal errors as* $h \to 0$.

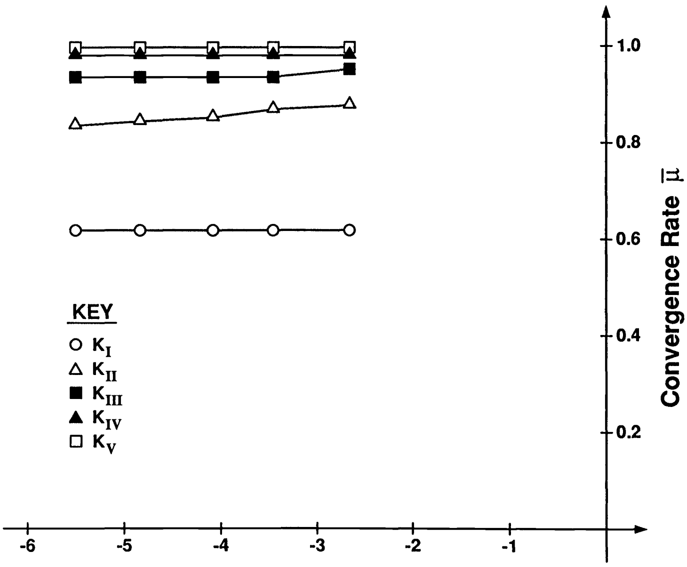

FIG. 3. *Rate of convergence* $\bar{\mu}$ *versus grid mesh* h *for Algorithm* 2, *using the various choices of coefficient* $K(x, y)$.

ALGORITHM 3. Given initial guess $\left(U^{(0)}, P^{(0)}\right)^T$, the kth iterate $\left(U^{(k)}, P^{(k)}\right)^T$ is the solution of

$$\begin{pmatrix} D & N \\ N^T & 0 \end{pmatrix} \begin{pmatrix} U^{(k)} \\ P^{(k)} \end{pmatrix} = \begin{pmatrix} 0 \\ F \end{pmatrix} + \begin{pmatrix} D-A & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} U^{(k-1)} \\ P^{(k-1)} \end{pmatrix}. \tag{6.1}$$

Here, the "preconditioning" matrix $D \in \mathbb{R}^{(2mn+m+n)\times(2mn+m+n)}$ is a diagonal matrix whose choice we discuss below.

When we construct D properly, the iteration matrix

$$M = \begin{pmatrix} D & N \\ N^T & 0 \end{pmatrix}^{-1} \begin{pmatrix} D-A & 0 \\ 0 & 0 \end{pmatrix} \tag{6.2}$$

has spectral radius that is independent of both h and the structure of K. The price we pay for this benefit is apparent in the computational form of the new algorithm:

$$\text{(i) } G^{(k-1)} \leftarrow -F + N^T D^{-1}(D-A)U^{(k-1)}, \tag{6.3}$$

$$\text{(ii) Solve } N^T D^{-1} N P^{(k)} = G^{(k-1)}, \tag{6.4}$$

$$\text{(iii) } U^{(k)} \leftarrow D^{-1}(D-A)U^{(k-1)} - D^{-1}NP^{(k)}. \tag{6.5}$$

In contrast to (3.3), solving for $P^{(k)}$ in the new scheme calls for the inversion of $N^T D^{-1} N$ instead of $N^T N$. Therefore, we must modify the multigrid segment of the algorithm to accommodate variable coefficients. As we discuss, this modification is fairly easy to make. This section establishes criteria for the construction of D, gives two examples that satisfy these criteria, comments on the multigrid solver used, and presents computational results.

As with the original scheme presented in §3, the key to the convergence of the new scheme is the spectral radius of the iteration matrix M defined in (6.2). The following proposition gives sufficient conditions under which $\rho(M) < 1$.

PROPOSITION 6.1. *Suppose D is a diagonal matrix with positive entries on the diagonal, and suppose there exist constants $b_1, b_2 \in (0,1)$ such that*

$$b_1 \le \frac{U^H A U}{U^H D U} \le 2 - b_2$$

for all vectors $U \in \mathbb{C}^{(m+1)n+m(n+1)}$. Then the iteration matrix M defined in (6.2) *satisfies*

$$0 < \rho(M) \le \max\{1-b_1, 1-b_2\} < 1. \tag{6.6}$$

Proof. Let $\lambda \neq 0$ be an eigenvalue of M with associated eigenvector $(U_\lambda, P_\lambda)^T$, as in Proposition 3.1. Then steps similar to those yielding (3.9) show that

$$\begin{aligned}(D-A)U_\lambda &= \lambda(DU_\lambda + NP_\lambda), \\ 0 &= \lambda N^T U_\lambda.\end{aligned}$$

Thus $U_\lambda^H(D-A)U_\lambda = \lambda U_\lambda^H D U_\lambda$, which is nonzero since D is positive definite. Therefore,

$$|\lambda| = \left| 1 - \frac{U_\lambda^H A U_\lambda}{U_\lambda^H D U_\lambda} \right|.$$

Hence, using the hypothesized bounds on $U_\lambda^H A U_\lambda / U_\lambda^H D U_\lambda$, we have the desired inequalities (6.6). □

To use this proposition, we need estimates on $U^H AU$. Given the structure of A as shown in the Appendix, one can calculate a useful expression for $U^H AU$, assuming $U \in \mathbb{C}^{(m+1)n+m(n+1)}$ has the form $(U^x, U^y)^T$ indicated in (2.3). In particular,

$$U^H AU = \frac{1}{3} S(U) + \frac{1}{6} R(U),$$

where, in the notation of the Appendix,

$$S(U) = \sum_{i=1}^{m} \sum_{j=1}^{n} \left(T^{\mathrm{I}}_{i,j} |U^x_{i-1,j}|^2 + T^{\mathrm{III}}_{i,j} |U^x_{i,j}|^2 + T^{\mathrm{IV}}_{i,j} |U^y_{i,j-1}|^2 + T^{\mathrm{VI}}_{i,j} |U^y_{i,j}|^2 \right),$$

$$R(U) = \sum_{i=1}^{m} \sum_{j=1}^{n} \left[T^{\mathrm{II}}_{i,j} \left(\bar{U}^x_{i,j} U^x_{i-1,j} + \bar{U}^x_{i-1,j} U^x_{i,j} \right) + T^{\mathrm{V}}_{i,j} \left(\bar{U}^y_{i,j} U^y_{i,j-1} + \bar{U}^y_{i,j-1} U^y_{i,j} \right) \right].$$

Here, $\bar{z}$ denotes the complex conjugate of z. The coefficients $T^{\mathrm{I}}_{i,j}, \cdots, T^{\mathrm{VI}}_{i,j}$ appearing in these expressions are values depending on $K(x,y)$ and arising from applications of the mean value theorem for integrals over each cell $\bar{\Omega}_{i,j}$ in the finite-element grid Δ_h. By using the inequality $|w|^2 + |z|^2 \geq -2|w||z|$, we can estimate $R(U)$ as follows:

$$\begin{aligned} -2 \sum_{i=1}^{m} \sum_{j=1}^{n} \left(T^{\mathrm{II}}_{i,j} |U^x_{i,j}| |U^x_{i-1,j}| + T^{\mathrm{V}}_{i,j} |U^y_{i,j}| |U^y_{i,j-1}| \right) &\leq R(U) \\ &\leq \sum_{i=1}^{m} \sum_{j=1}^{n} \left(T^{\mathrm{II}}_{i,j} |U^x_{i-1,j}|^2 + T^{\mathrm{II}}_{i,j} |U^x_{i,j}|^2 + T^{\mathrm{V}}_{i,j} |U^y_{i,j-1}|^2 + T^{\mathrm{V}}_{i,j} |U^y_{i,j}|^2 \right). \end{aligned} \tag{6.7}$$

In general, the estimates $0 < K_{\mathrm{inf}} \leq K \leq K_{\mathrm{sup}}$ may be too coarse to provide enough control on the coefficients $T^{\mathrm{I}}_{i,j}, \cdots, T^{\mathrm{VI}}_{i,j}$ for constructing a reasonable preconditioner D. Strictly speaking, the necessary level of control will be available only if we have information about the *local* variation of K on each cell $\bar{\Omega}_{i,j}$.

In practice, however, we rarely have such fine-scale knowledge of K, and even if we did we would not try to use it in calculating the Galerkin integrals $\int_\Omega K^{-1}\mathbf{u} \cdot \mathbf{v}\,dx\,dy$ exactly. Instead, most practical codes use approximate quadrature schemes that effectively treat K^{-1} as piecewise polynomial. In fact, as we suggested in §1, for sufficiently fine grids it is reasonable to treat K^{-1} as piecewise constant. In such applications, we can use the second inequality in (6.7), together with the identities $T^{\mathrm{II}}_{i,j} = T^{\mathrm{V}}_{i,j} = T_{i,j}$, to show that

$$U^H AU = \frac{1}{3} S(U) + \frac{1}{6} R(U) \leq \frac{1}{2} S(U).$$

Similarly, the first inequality in (6.7), together with the identities $T^{\mathrm{I}}_{i,j} = T^{\mathrm{III}}_{i,j} = T^{\mathrm{IV}}_{i,j} =$

$T^{\rm VI}_{i,j} = T_{i,j}$, shows that

$$\begin{aligned} U^H AU &= \frac{1}{6}S(U) + \frac{1}{6}[S(U) + R(U)] \\ &\geq \frac{1}{6}S(U) + \frac{1}{6}\sum_{i=1}^{m}\sum_{j=1}^{n} T_{i,j}\left[\left(|U^x_{i-1,j}| - |U^x_{i,j}|\right)^2 + \left(|U^y_{i,j-1}| - |U^y_{i,j}|\right)^2\right] \\ &\geq \frac{1}{6}S(U). \end{aligned}$$

In summary, $\frac{1}{6}S(U) \leq U^H AU \leq \frac{1}{2}S(U)$ whenever K is piecewise constant on the grid Δ_h.

Now consider the choice $D = \frac{2}{3}\text{lump}(A)$, where

$$[\text{lump}(A)]_{i,j} = \begin{cases} 0 & \text{if } i \neq j, \\ \sum\limits_j A_{i,j} & \text{if } i = j. \end{cases}$$

This is the matrix that results when we add entries along each row of A and assign the sum to the diagonal entry in that row. Gonzales and Wheeler [9] use this "mass lumping" idea to improve conditioning in mixed finite-element discretizations of petroleum reservoir problems. This choice of D is also a simple instance of a preconditioner developed in [7] for other iterative schemes. It is a straightforward matter to show that, when K is piecewise constant, $U^H\text{lump}(A)U = \frac{1}{2}S(U)$, so $U^H DU = \frac{1}{3}S(U)$. As a consequence,

$$b_1 = \frac{1}{2} \leq \frac{U^H AU}{U^H DU} \leq \frac{3}{2} = 2 - b_2.$$

Therefore, by Proposition 6.1, $\rho(M) \leq \frac{1}{2}$, and the iterative scheme converges with a rate independent of h and K. According to our remarks at the end of §4, we expect the ratio of error norms between successive iterates to approach $\frac{1}{2}$ as the iteration counter $k \to \infty$.

As an even simpler example, consider the choice $D = \text{diag}(A)$, where

$$[\text{diag}(A)]_{i,j} = \begin{cases} 0 & \text{if } i \neq j, \\ A_{i,i} & \text{if } i = j, \end{cases}$$

is the matrix A stripped of its off-diagonal entries. This choice has the attractive feature that it is trivial to compute from A. With D defined in this way, we once again find that $U^H DU = \frac{1}{3}S(U)$ when K is piecewise constant on Δ_h. Therefore, $\rho(M) \leq \frac{1}{2}$, and this iterative scheme also converges with a rate independent of h and K.

Either choice of D requires us to solve a matrix equation of the form

$$N^T D^{-1} N P^{(k)} = G^{(k-1)}$$

at each iteration. To do this, we use two cycles of a multigrid scheme in which the Jacobi iteration is the smoother, the coarse-to-fine interpolation is bilinear, and the fine-to-coarse restriction is accomplished using half-injection [4, p. 65]. This scheme preserves the h-independence of the overall algorithm's convergence rate and appears

TABLE 1
Convergence rates for various coefficients and grids.

	Grid Mesh h				
Coefficient	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}
K_{I}	0.4933	0.4988	0.4993	0.4995	0.4999
K_{II}	0.4966	0.4995	0.4988	0.4997	0.4999
K_{III}	0.4948	0.4982	0.4991	0.4998	0.4999
K_{IV}	0.4947	0.4980	0.4992	0.4998	0.4999
K_{V}	0.4939	0.4978	0.4989	0.4999	0.5000

to handle the variable coefficient K effectively. Alternative multigrid implementations are certainly possible here.

To test the convergence rate of Algorithm 3, we apply it to the boundary-value problems described in §5, using the preconditioner $D = \frac{2}{3}\text{lump}(A)$. Table 1 shows values of the convergence rate $\bar{\mu}$ computed for each choice of coefficient K, for each of five different values of the grid mesh h. All of the tabulated values are very close to the spectral radius estimate $\rho(M) \leq \frac{1}{2}$. We conclude that this scheme converges at a rate independent of both grid mesh h and the heterogeneity reflected in the mobility coefficient K.

7. Conclusions. Poor conditioning associated with heterogeneity and fine spatial grids is a common problem. While this paper focuses on steady flows in porous media, similar equations and results apply in other fields. Two obvious applications for (1.1) arise in heat transfer, where temperature plays the role of pressure and heat flux plays the role of the Darcy velocity, and in electrostatics, where the electric potential and the electric field serve as the analogs of pressure and Darcy velocity, respectively. In either case, mixed finite-element methods can give useful approximations. However, heterogeneity, either in the thermal diffusivity or in the dielectric coefficient, can lead to poor conditioning in precisely the same way as it does for porous media. One virtue of the mixed finite-element formulation is that it permits us to attack the two sources of poor conditioning separately, exploiting multigrid ideas to reduce the sensitivity to fine grids and using spectral information associated with the material coefficient to reduce the sensitivity to heterogeneity.

Appendix: Matrix structure of the finite-element equations. The mixed finite-element equations (2.2) give rise to integral equations having the following forms. For the x-velocity equation,

$$\int_{\Omega} \left(K^{-1} u_h^x \, \phi_{i,j}^{x} \; - \; p_h \, \frac{\partial \phi_{i,j}^{x}}{\partial x} \right) dx \, dy = 0, \quad i = 0, \cdots, m, \quad j = 1, \cdots, n.$$

For the y-velocity equation,

$$\int_{\Omega} \left(K^{-1} u_h^y \, \phi_{i,j}^{y} \; - \; p_h \, \frac{\partial \phi_{i,j}^{y}}{\partial y} \right) dx \, dy = 0, \quad i = 1, \cdots, m, \quad j = 0, \cdots, n.$$

For the mass balance,

$$\int_{\Omega} \left(\frac{\partial u_h^x}{\partial x} + \frac{\partial u_h^y}{\partial y} - f \right) \psi_{i,j} dx \, dy = 0, \quad i = 1, \cdots, m, \quad j = 1, \cdots, n.$$

The following integrals appearing in these expressions involve no spatially varying coefficients and hence are easy to compute using the bases for $\mathbf{Q}_h$ and V_h:

$$\int_\Omega p_h \frac{\partial \phi_{i,j}^x}{\partial x} dx\, dy, \quad \int_\Omega p_h \frac{\partial \phi_{i,j}^y}{\partial y} dx\, dy, \quad \int_\Omega \frac{\partial u_h^x}{\partial x} \psi_{i,j} dx\, dy, \quad \int_\Omega \frac{\partial u_h^y}{\partial y} \psi_{i,j} dx\, dy.$$

However, the remaining integrals involve the spatially varying functions $K^{-1}(x,y)$ and $f(x,y)$. We compute these integrals using the mean value theorem for integrals [10, pp. 184–185] as follows: Since K^{-1} is bounded and integrable on each cell $\overline{\Omega}_{i,j}$, there exist numbers $T^{\rm I}_{i,j}, T^{\rm II}_{i,j}, T^{\rm III}_{i,j}$ such that

$$\int_\Omega K^{-1}\, \phi_{s,t}^x\, \phi_{i,j}^x\, dx\, dy = \begin{cases} T^{\rm II}_{i,j}/6, & t=j, \quad s=i-1; \\ (T^{\rm I}_{i,j} + T^{\rm III}_{i+1,j})/3, & t=j, \quad s=i; \\ T^{\rm II}_{i+1,j}/6, & t=j, \quad s=i+1\,. \end{cases}$$

Here, $T^{\rm I}_{i,j}/[(x_i - x_{i-1})(y_j - y_{j-1})]$ is a number lying between the upper and lower bounds of K^{-1} on the cell $\overline{\Omega}_{i,j}$, and similarly for $T^{\rm II}_{i,j}$ and $T^{\rm III}_{i,j}$. Analogous calculations show that

$$\int_\Omega K^{-1}\, \phi_{s,t}^y\, \phi_{i,j}^y\, dx\, dy = \begin{cases} T^{\rm V}_{i,j}/6, & t=j-1, \quad s=i; \\ (T^{\rm IV}_{i,j} + T^{\rm VI}_{i,j+1})/3, & t=j, \quad s=i; \\ T^{\rm V}_{i,j+1}/6, & t=j+1, \quad s=i\,. \end{cases}$$

The calculations of $\int_\Omega f\, \psi_{i,j}\, dx\, dy$ can proceed similarly.

Now let us adopt the following orderings for the vectors of unknown nodal coefficients:

$$U^x = \begin{bmatrix} U_{0,1}^x \\ \vdots \\ U_{m,1}^x \\ \vdots \\ U_{0,n}^x \\ \vdots \\ U_{m,n}^x \end{bmatrix}, \quad U^y = \begin{bmatrix} U_{1,0}^y \\ \vdots \\ U_{1,n}^y \\ \vdots \\ U_{m,0}^y \\ \vdots \\ U_{m,n}^y \end{bmatrix}, \quad P = \begin{bmatrix} P_{1,1} \\ \vdots \\ P_{m,1} \\ \vdots \\ P_{1,n} \\ \vdots \\ P_{m,n} \end{bmatrix}.$$

Then the entire algebraic system arising from (2.2) has the structure

$$\begin{bmatrix} A^x & 0 & N^x \\ 0 & A^y & N^y \\ (N^x)^T & (N^y)^T & 0 \end{bmatrix} \begin{bmatrix} U^x \\ U^y \\ P \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ F \end{bmatrix}.$$

Here,

$$A^x = \begin{bmatrix} A_1^x & & \\ & \ddots & \\ & & A_n^x \end{bmatrix} \in \mathbb{R}^{(m+1)n \times (m+1)n}\,,$$

where each block $A_j^x \in \mathbb{R}^{(m+1)\times(m+1)}$ has the tridiagonal structure

$$A_j^x = \frac{1}{6}\begin{bmatrix} 2T_{1,j}^{\mathrm{III}} & T_{1,j}^{\mathrm{II}} & & & \\ T_{1,j}^{\mathrm{II}} & 2(T_{1,j}^{\mathrm{III}} + T_{2,j}^{\mathrm{I}}) & T_{2,j}^{\mathrm{II}} & & \\ & & \ddots & & \\ & & & T_{m,j}^{\mathrm{II}} & 2T_{m,j}^{\mathrm{III}} \end{bmatrix}.$$

Similarly,

$$A^y = \begin{bmatrix} A_1^y & & \\ & \ddots & \\ & & A_m^y \end{bmatrix} \in \mathbb{R}^{m(n+1)\times m(n+1)},$$

where each block $A_i^y \in \mathbb{R}^{(n+1)\times(n+1)}$ has the tridiagonal form

$$A_i^y = \frac{1}{6}\begin{bmatrix} 2T_{i,1}^{\mathrm{VI}} & T_{i,1}^{\mathrm{V}} & & & \\ T_{i,1}^{\mathrm{V}} & 2(T_{i,1}^{\mathrm{VI}} + T_{i,2}^{\mathrm{IV}}) & T_{i,2}^{\mathrm{V}} & & \\ & & \ddots & & \\ & & & T_{i,n}^{\mathrm{V}} & 2T_{i,n}^{\mathrm{VI}} \end{bmatrix}.$$

Finally, the two "difference" matrices N^x and N^y have the following structures:

$$N^x = \begin{bmatrix} N_1^x & & \\ & \ddots & \\ & & N_n^x \end{bmatrix} \in \mathbb{R}^{n(m+1)\times nm},$$

where

$$N_j^x = (y_j - y_{j-1})\begin{bmatrix} 1 & & & \\ -1 & 1 & & \\ & -1 & 1 & \\ & & \ddots & \ddots \\ & & & 1 \\ & & & -1 \end{bmatrix} \in \mathbb{R}^{(m+1)\times m},$$

while

$$N^y = \begin{bmatrix} N_{1,1}^y & \dots & N_{1,n}^y \\ \vdots & & \\ N_{m,1}^y & \dots & N_{m,n}^y \end{bmatrix} \in \mathbb{R}^{(n+1)m\times nm},$$

where

$$N_{i,j}^{y} = (x_i - x_{i-1}) \begin{array}{cc} \left[\begin{array}{ccc} & \vdots & \\ \cdots & 1 & \cdots \\ \cdots & -1 & \cdots \\ & \vdots & \end{array}\right] & \begin{array}{l} \\ \leftarrow \text{row } j \\ \leftarrow \text{row } j+1 \\ \\ \end{array} \\ \begin{array}{c} \uparrow \\ \text{column } i \end{array} & \end{array} \in \mathbb{R}^{(n+1)\times m} .$$

EFFICIENT HIGH ACCURACY SOLUTIONS WITH GMRES(m)*

KATHRYN TURNER† AND HOMER F. WALKER†

Abstract. Consideration of an abstract improvement algorithm leads to the following principle, which is similar to that underlying iterative refinement: By making judicious use of relatively few high accuracy computations, high accuracy solutions can be obtained very efficiently by the algorithm. This principle is applied specifically to GMRES(m) here; it can be similarly applied to a number of other "restarted" iterative linear methods as well. Results are given for numerical experiments in solving a discretized linear elliptic boundary value problem and in computing a step of an inexact Newton method using finite differences for a discretized nonlinear elliptic boundary value problem.

Key words. GMRES(m), "restarted" iterative linear methods, high accuracy solutions, iterative refinement, large-scale linear and nonlinear systems, elliptic boundary value problems

AMS(MOS) subject classifications. 65F10, 65H10

1. Introduction. Our specific objective is to outline efficient algorithms for obtaining high accuracy with GMRES(m), the restarted version of the generalized minimal residual (GMRES) method of Saad and Schultz [10] for numerically solving general nonsingular linear systems. These algorithms are based on general observations which have broader applicability and are of interest in their own right, and we begin with them.

We consider a very abstract *improvement algorithm* for a problem in which the solution $x^* \in \mathbb{R}^n$ is characterized as a zero of a *residual function* $r : \mathbb{R}^n \to \mathbb{R}^n$, i.e., $r(x^*) = 0$. The algorithm centers around an unspecified *correction process* which, given a current approximate solution x, computes a correction z such that $x + z$ is, one hopes, an improved approximation of x^*. Our presumption is that the accuracy in the computed value of z is limited by the accuracy in the computed value of $r(x)$. Therefore, we explicitly require in the algorithm that $r(x)$ be computed accurately, by which we mean as accurately as is reasonably possible or affordable, or in some sense especially accurately. For similar reasons, on which we expand in the following, we require $x + z$ to be computed accurately in the same sense.

Algorithm GI: General Improvement Algorithm

```
LET AN INITIAL $x$ BE GIVEN.
UNTIL TERMINATION, DO:
  COMPUTE $r(x)$ ACCURATELY.
  DETERMINE $z$ BY THE CORRECTION PROCESS.
  UPDATE $x \longleftarrow x + z$ ACCURATELY.
END DO.
```

The termination criterion may be based on the smallness of $\|r(x)\|$, or on some related but different feature, as in the iterative refinement example below.

Our interest is in the limits of accuracy which can be obtained by Algorithm GI. Since the actual error in x is unknown, we take "limits of accuracy" to mean limits of reduction of $\|r(x)\|$, where $\|\cdot\|$ is an appropriate norm on $\mathbb{R}^n$. If we assume that

the accuracy in the computed value of z is limited only by the relative error in the computed value of $r(x)$, and not by the smallness of $\|r(x)\|$ per se, then it is clear that accuracy is limited only by the accuracy which can be maintained in computing $r(x)$ and in updating $x \longleftarrow x + z$.

A familiar example of Algorithm GI is *iterative refinement* for improving approximate solutions of a system of linear equations. (See, e.g., Golub and Van Loan [7, §3.5.3] as a general reference.) Consider a linear problem written as follows:

$$\text{(1)} \qquad \text{Given } A \in \mathbb{R}^{n\times n} \text{ and } b \in \mathbb{R}^n, \quad \text{find } x^* \in \mathbb{R}^n \text{ such that } Ax^* = b.$$

Suppose that we have computed factors of A and have used them to compute an initial x. In iterative refinement, we take $r(x) \equiv b - Ax$ and, at each step, determine a correction z by solving $Az = r(x)$ using the previously computed factors of A. Iterative refinement is typically applied when we can afford to do most computing only in single precision, but full single precision accuracy is desired in the computed solution. Thus A, b, x, $r(x)$, and z are stored in single precision, and the factors of A are computed and stored in single precision. The accuracy in z depends on the relative error in the computed value of $r(x)$ and not on the smallness of $\|r(x)\|$, provided all computations remain within the floating point range of the machine. However, if $r(x)$ is small, then special care must be taken to compute it accurately. The usual prescription is to compute it in double precision in a well-known way. Unless A is very ill conditioned, this results in sufficient accuracy in $r(x)$ and z to provide improvement in x until z is so small that x and $x + z$ have the same single precision representation, i.e., the updating $x \longleftarrow x + z$ results in no change, at which point x is the single precision representation of the exact solution and the algorithm terminates. Since only single precision accuracy is desired in x, there is no need to form $x + z$ with more than single precision accuracy. If higher accuracy *were* desired in x, then it could be obtained by maintaining x in double precision and forming $x + z$ with z represented in double precision; however, this is unlikely to be of practical interest.

This discussion illustrates our guiding principle: By making judicious use of relatively few high accuracy calculations within Algorithm GI, specifically in computing $r(x)$ and in updating $x \longleftarrow x + z$, we can obtain essentially the accuracy that would be realized by using high accuracy calculations throughout, while maintaining storage requirements and execution times only modestly above those which would be required if only low accuracy calculations were used.

We now turn to the case of particular interest, viz., that of problem (1) in which $r(x) \equiv b - Ax$ and the correction process consists of one cycle of GMRES(m). Although we focus exclusively on GMRES(m), we emphasize that Algorithm GI and the guiding principle drawn from it are more broadly applicable. In particular, there are a number of other "restarted" iterative linear methods which could be used in place of GMRES(m) in the algorithms formulated below, e.g., a restarted version of a method of Axelsson [1], the iterative Arnoldi method of Saad [9, §3.2], and GCR(m) given by Elman [5] and Eisenstat, Elman, and Schultz [4].

For completeness, we give very brief descriptions of GMRES and GMRES(m) here; for more detailed descriptions, see Saad and Schultz [10] or Walker [12], [13]. The GMRES method begins with an initial approximate solution x and initial residual $r(x) = b - Ax$. At the kth iteration, a correction z is characterized as the solution of the least-squares problem

$$\text{(2)} \qquad \min_{\bar{z}\in\mathcal{K}_k} \|b - A(x + \bar{z})\|_2 = \min_{\bar{z}\in\mathcal{K}_k} \|r(x) - A(\bar{z})\|_2,$$

where $\mathcal{K}_k$ is the kth Krylov subspace generated by A and $r(x)$, defined by

$$\mathcal{K}_k \equiv \text{span}\{r(x), Ar(x), \cdots, A^{k-1}r(x)\}.$$

The correction z is not actually computed by the method unless a termination criterion is satisfied. If it is computed, then the least-squares problem (2) is solved by using a basis of $\mathcal{K}_k$ to reduce (2) to a k-dimensional least-squares problem for the coefficients of the basis elements. The basis used in practice is the orthonormal *Arnoldi basis*, generated inductively by

$$\begin{aligned} v_1 &= r(x)/\|r(x)\|_2, \\ v_{j+1} &= P^{\perp}_{\mathcal{K}_j} Av_j/\|P^{\perp}_{\mathcal{K}_j} Av_j\|_2 \quad \text{for } j = 1, \cdots, k-1. \end{aligned} \tag{3}$$

Here, $P^{\perp}_{\mathcal{K}_j} v$ denotes the orthogonal projection of a vector v onto the orthogonal complement of $\mathcal{K}_j$; it can be computed using either the modified Gram–Schmidt process [10] or Householder transformations [12]. We use the modified Gram–Schmidt process below since it is used more often in practice. Note that the process (3) fails for some $j < k$ if and only if $P^{\perp}_{\mathcal{K}_j} Av_j = 0$, i.e., $Av_j \in \mathcal{K}_j$, in which case it can be shown that GMRES produces $z \in \mathcal{K}_j$ such that $r(x + z) = 0$, i.e., $x + z = x^*$ (see [10, Prop. 2, p. 865]). The process (3) is implemented as the GMRES iterations proceed, i.e., v_1 is determined and stored initially and at the kth iteration, (only) v_{k+1} is generated and added to storage. At the kth iteration, $k + 1$ n-vectors must be stored, and orthogonalizing Av_k against $v_1, \cdots, v_k$ requires $O(kn)$ arithmetic operations.

Because storage and arithmetic costs increase as the GMRES iterations proceed, the algorithm usually implemented in practice is GMRES(m), where m is some maximum allowable number of iterations which is prescribed at the outset, typically much less than n. In one cycle of GMRES(m), beginning with a current approximate solution x, up to m GMRES iterations are performed; the iterations are terminated when either the residual norm has been reduced sufficiently or the full m iterations have been taken. The residual norm can be monitored during the iterations without actually computing the correction or the residual; see below. After the iterations have been performed, the cycle is concluded with the computation of the correction z. If $\|r(x + z)\|_2$ is not sufficiently small, then additional cycles may be performed as needed.

We give below a detailed outline of one cycle of GMRES(m) as used here. In it, for each i, J_i denotes a Givens rotation which "rotates" components i and $i + 1$ of vectors on which it acts; see, e.g., [7, §5.1] for definitions and properties of Givens rotations. Also, for each k, $(J_k\rho)_{k+1}$ denotes the $(k + 1)$st component of the vector $J_k\rho$ and $w_1, \cdots, w_{k+1}$ denote the first $k + 1$ components of the vector w.

Algorithm: One Cycle of GMRES(m)

```
LET $r(x) \neq 0$, $m$, AND TOL$> 0$ BE GIVEN.
INITIALIZE:
    SET $v_1 = r(x)/\|r(x)\|_2$ AND $w = (\|r(x)\|_2, 0, \cdots, 0)^T \in \mathbb{R}^{m+1}$.
ITERATE:
    FOR $k = 1, 2, \cdots, m$, DO:
        EVALUATE $v_{k+1} = Av_k$.
        FOR $i = 1, \cdots, k$, DO:
            SET $\rho_i = v_i^T v_{k+1}$.
            OVERWRITE $v_{k+1} \longleftarrow v_{k+1} - \rho_i v_i$.
        END DO.
```

```
            SET $\rho_{k+1} = \|v_{k+1}\|_2$.
            IF $\rho_{k+1} \neq 0$, OVERWRITE $v_{k+1} \longleftarrow v_{k+1}/\rho_{k+1}$.
            SET $\rho = (\rho_1, \cdots, \rho_{k+1}, 0, \cdots, 0)^T \in \mathbb{R}^{m+1}$.
            IF $k > 1$, OVERWRITE $\rho \longleftarrow J_{k-1} \cdots J_1 \rho$.
            FIND $J_k$ SUCH THAT $(J_k\rho)_{k+1} = 0$ AND OVERWRITE
              $\rho \longleftarrow J_k\rho$ AND $w \longleftarrow J_k w$.
            SET $R_k = [\rho]$ IF $k = 1$ AND $R_k = [R_{k-1}, \rho]$ IF $k > 1$.
            IF $|w_{k+1}|$ <TOL, THEN GO TO SOLVE.
        END DO.
    SOLVE:
        LET $k$ BE THE FINAL ITERATION NUMBER REACHED, LET
          $\bar{R}_k \in \mathbb{R}^{k\times k}$ BE THE UPPER TRIANGULAR MATRIX DETERMINED
          BY THE FIRST $k$ ROWS OF $R_k$, AND SET $\bar{w} = (w_1, \cdots, w_k)^T \in \mathbb{R}^k$.
        SOLVE $\bar{R}_k y = \bar{w}$ FOR $y$.
        FORM $z = [v_1, \cdots, v_k]y$.
```

The test $|w_{k+1}|$ <TOL at the final step of the iteration is explained by the fact that if the correction z were formed, then we would have $\|r(x+z)\|_2 = |w_{k+1}|$, at least in exact arithmetic; see [10, Prop. 1, p. 862]. Also, we note that $\bar{R}_k$ is always nonsingular.

Our general efficient high accuracy algorithm centering around GMRES(m) is the following adaptation of Algorithm GI.

Algorithm EHA: Efficient High Accuracy Algorithm

```
    LET AN INITIAL $x$ BE GIVEN. UNTIL TERMINATION, DO:
        COMPUTE $r(x)$ ACCURATELY.
        DETERMINE $z$ BY ONE CYCLE OF GMRES($m$).
        UPDATE $x \longleftarrow x + z$ ACCURATELY.
    END DO.
```

Algorithm EHA terminates when the residual norm becomes less than a given tolerance TOL> 0. If $\|r(x)\|_2$ <TOL prior to beginning a GMRES(m) cycle, then the algorithm terminates immediately; if this criterion is met during a GMRES(m) cycle, then the algorithm terminates as soon as the updating $x \longleftarrow x + z$ is done.

In the following, we explore applications of Algorithm EHA. In §2, we show how the steps in Algorithm EHA can be specified so that essentially all of the accuracy obtainable from a full double precision implementation of GMRES(m) can be obtained with storage requirements and arithmetic costs which, in a typical problem, are only a little greater than those of a single precision implementation. In §3, we consider the computation of inexact Newton steps for a nonlinear problem by means of Algorithm EHA, in which products of the Jacobian (matrix) with vectors are approximated by finite differences. We show that by using high-order finite difference approximations in the computation of each $r(x)$ and low-order finite difference approximations in each cycle of GMRES(m), we can obtain essentially the accuracy that could be obtained by using high-order finite difference approximations throughout, but at much less cost.

2. Obtaining double precision accuracy efficiently. Here we show how Algorithm EHA can be used to obtain essentially double precision accuracy efficiently in the solution of a linear problem (1). By double precision accuracy, we mean the accuracy which could be obtained by using double precision arithmetic throughout; we do not mean that the result will be the exact solution rounded to double precision.

In applying Algorithm EHA, we use three double precision vectors: one for the approximate solution x, one for the right-hand side b, and one for the matrix-vector product Ax. A subroutine to compute Ax in double precision is needed in addition to a subroutine that is used within GMRES(m) to compute products of A with other vectors in single precision. We apply Algorithm EHA as follows: Given a double precision approximate solution x, we first compute $r(x)$ by computing Ax in double precision, subtracting Ax from b in double precision, and then rounding the difference to single precision. A cycle of GMRES(m) is then carried out, entirely in single precision, producing a single precision correction z. The update of the approximate solution is $x \longleftarrow x + \text{dble}\,(z)$, where $\text{dble}\,(z)$ indicates that z is represented in double precision in the addition. This representation is done componentwise and does not require that z be converted in toto to a double precision vector.

2.1. Numerical experiments. We conducted numerical experiments on nonsymmetric linear systems arising from the discretization of the elliptic boundary value problem

$$\begin{aligned} \Delta w + cw + d\frac{\partial w}{\partial x} &= f \qquad \text{in } D, \\ w &= 0 \qquad \text{on } \partial D, \end{aligned} \tag{4}$$

where $D = [0,1] \times [0,1]$ and $c \geq 0$ and d are constants. In the experiments reported here, we took $f \equiv 1$ and used a 100×100 mesh of equally spaced discretization points in D, so that the resulting linear systems were of dimension $10,000$. Discretization was by the usual second-order centered differences.

We compared Algorithm EHA as specified above with methods which differed only in that either exclusively single or exclusively double precision arithmetic and storage were used throughout. We refer to the latter two methods as the full single precision (FSP) and full double precision (FDP) methods, respectively. We note that in the context of these experiments, Algorithm EHA requires only a little more storage than the FSP method, which requires about half that of the FDP method. The additional storage required by Algorithm EHA over the FSP method arises mainly from the double precision storage of b, x, and Ax. In the double precision computation of Ax, the simplicity of A in these experiments allows the nonzero entries of A to be represented by a few nonzero constants.

In GMRES(m), we used $m = 10$ in all of the experiments reported here because that seemed to be more effective than other choices we tried. All computing was done on a Sun Microsystems SPARCstation 1 using the SunOS FORTRAN compiler.

In our first set of experiments, we took $c = d = 10$ and used right preconditioning with a fast Poisson solver from FISHPACK [11], which is very effective for these fairly small values of c and d. We first started each method with zero as the initial approximate solution and allowed it to run for 40 GMRES(m) iterations, after which the limit of residual norm reduction had been reached. Figure 1 shows plots of the logarithm of the Euclidean norm of the residual versus the number of GMRES(m) iterations for the three methods. We note that in Fig. 1 and in all other figures below, the plotted residual norms were not the values maintained by GMRES(m), but rather were computed as accurately as possible "from scratch." That is, at each GMRES(m) iteration, the current approximate solution was formed and its product with the coefficient matrix was subtracted from the right-hand side, all in double precision. It was important to compute the residual norms in this way because the values maintained by GMRES(m) become increasingly untrustworthy as the limits of residual norm reduction are neared; see [12]. It is seen in Fig. 1 that Algorithm EHA achieved the same ultimate level of residual norm reduction as the FDP method and required only a few more GMRES(m) iterations to do so.

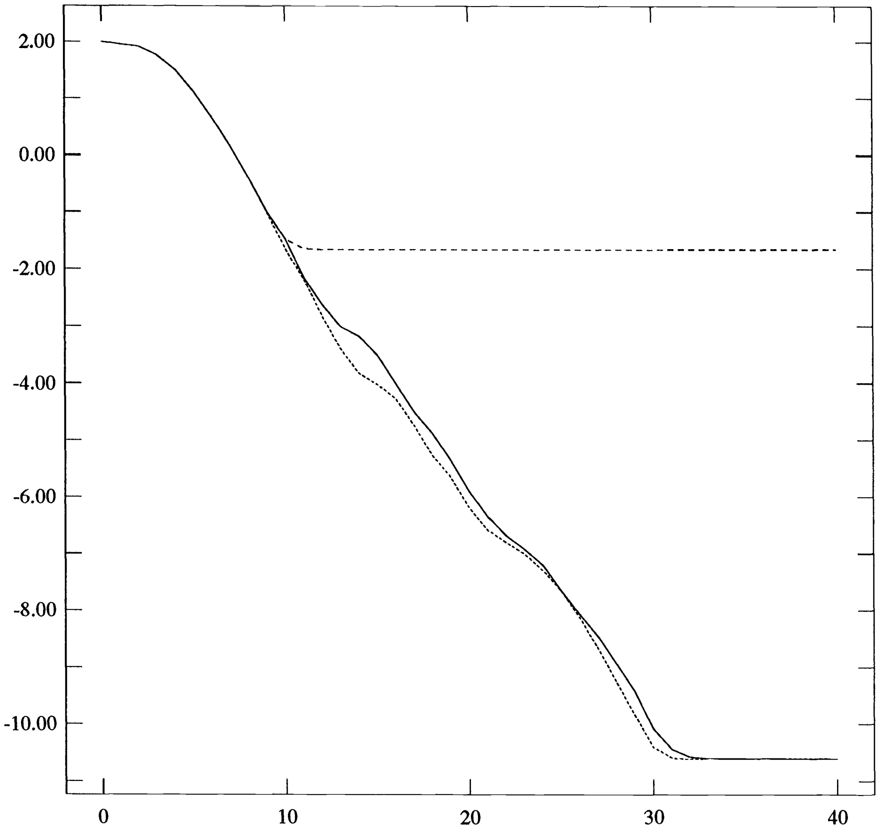

FIG. 1. Log$_{10}$ *of the residual norm versus the number of* GMRES(m) *iterations for* $c = d = 10$ *with fast Poisson preconditioning. Solid curve: Algorithm* EHA*; dotted curve:* FDP *method; dashed curve:* FSP *method.*

In order to assess the relative amount of computational work required by Algorithm EHA and the FDP method to reach comparable levels of residual norm reduction, we observed in each of 20 trials the GMRES(m) iteration numbers and run times required by each method to reduce the residual norm by a factor of 10^{-12}. Since timing was of major interest, the residual norms were not computed "from scratch" in these trials; instead, the values maintained by GMRES(m) were used. These values were trustworthy because 10^{-12} is significantly larger than the limiting residual norm reduction factor for these methods evident in Fig. 1. In each trial, the components of the initial approximate solution were obtained by generating uniformly distributed random numbers over $[-1, 1]$. The means and standard deviations of the run times are given in Table 1. Each method required exactly 30 GMRES(m) iterations to reach termination in every trial, which accounts for the small standard deviations.

In our second set of experiments, we took $c = d = 100$ and carried out trials analogous to those in the first set above. No preconditioning was used in these experiments, both because we wanted to compare the methods without preconditioning and because the fast Poisson preconditioning used in the first set of experiments is not

TABLE 1

Method	Mean Run Time (Seconds)	Standard Deviation
EHA	28.77	.03125
FDP	45.80	.06442

cost effective for these large values of c and d. We first allowed each method to run for 600 GMRES(m) iterations, starting with zero as the initial approximate solution, after which the limit of residual norm reduction had been reached. The results are shown in Fig. 2. We note that Algorithm EHA reached the same ultimate level of residual norm reduction as the FDP method but required about ten percent more GMRES(m) iterations to reach this level.

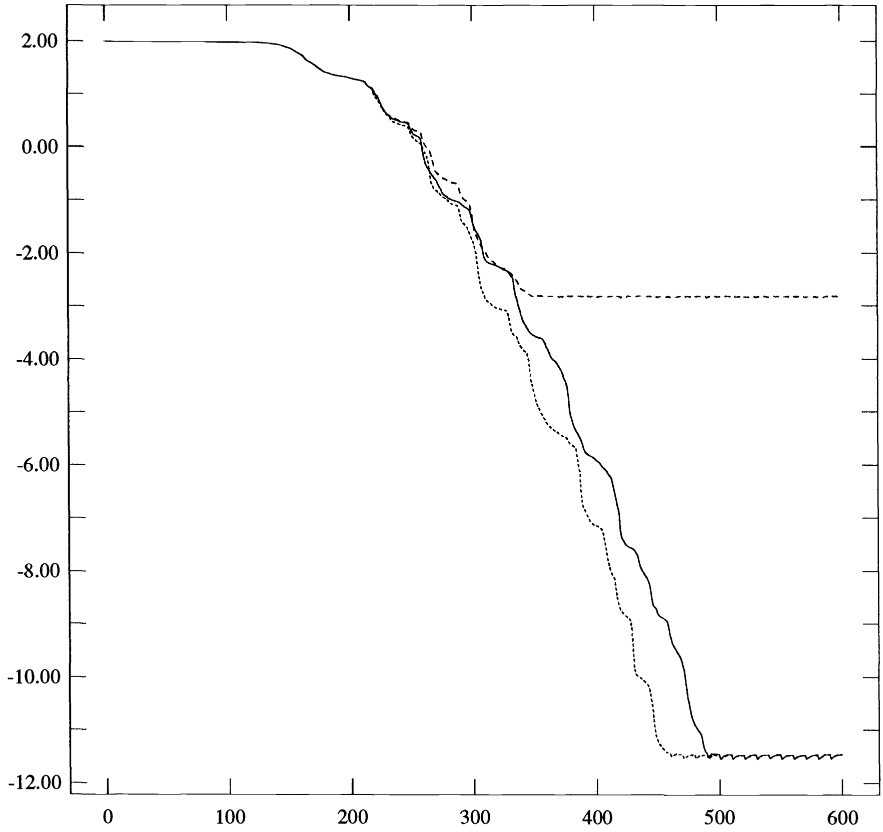

FIG. 2. Log$_{10}$ *of the residual norm versus the number of* GMRES(m) *iterations for* $c = d = 100$ *with no preconditioning. Solid curve: Algorithm* EHA; *dotted curve:* FDP *method; dashed curve:* FSP *method.*

We then observed in each of 20 trials the numbers of GMRES(m) iterations and run times required by Algorithm EHA and the FDP method to reduce the residual norm by a factor of 10^{-12}. In these trials, the initial approximate solutions were obtained by generating random components as in the previous such trials. In contrast

to the previous trials, there was in these trials significant variation in both the numbers of GMRES(m) iterations and the run times for each method. Consequently, the means and standard deviations of the GMRES(m) iteration counts as well as the run times are given in Table 2.

3. Computing inexact Newton steps using finite differences.

We now consider an inexact Newton method [3] for the solution of a nonlinear problem, written as follows:

$$\text{Given } F : \mathbb{R}^n \to \mathbb{R}^n, \quad \text{find } u^* \in \mathbb{R}^n \text{ such that } F(u^*) = 0. \tag{5}$$

Given an approximate solution u of (5), an inexact Newton method determines a step x such that $F'(u)x \approx -F(u)$ and updates $u \longleftarrow u + x$; such a method is of interest when computing the exact Newton step $-F'(u)^{-1}F(u)$ is infeasible. We shall apply Algorithm EHA to the computation of a single inexact Newton step, in which u remains fixed and $r(x) \equiv -F(u) - F'(u)x$.

We focus on the case in which $F'(u)$ cannot be used analytically. In this case, we might approximate $F'(u)$ using finite differences. However, with GMRES(m), $F'(u)$ or an approximation of it is not explicitly needed; we require only its action on vectors v, which can be approximated, e.g., to first, second, fourth, and sixth order, respectively, by

$$\frac{1}{\delta}[F(u+\delta v) - F(u)], \tag{6}$$

$$\frac{1}{2\delta}[F(u+\delta v) - F(u-\delta v)], \tag{7}$$

$$\frac{1}{6\delta}\left[8F\left(u+\frac{\delta}{2}v\right) - 8F\left(u-\frac{\delta}{2}v\right) - F(u+\delta v) + F(u-\delta v)\right], \tag{8}$$

$$\begin{aligned}\frac{1}{90\delta}\Bigg[256F\left(u+\frac{\delta}{4}v\right) - 256F\left(u-\frac{\delta}{4}v\right) - 40F\left(u+\frac{\delta}{2}v\right)\\ + 40F\left(u-\frac{\delta}{2}v\right) + F(u+\delta v) - F(u-\delta v)\Bigg].\end{aligned} \tag{9}$$

In an inexact Newton method, $F(u)$ is already available; therefore, each of (6)–(9) requires a number of new F-evaluations equal to its order.

We apply Algorithm EHA in this context by using a higher-order formula, e.g., one of (7)–(9), in the residual computation preceding each cycle of GMRES(m) and using a lower-order formula, e.g., the first-order formula (6), for matrix-vector products required within GMRES(m).

3.1. Numerical experiments. We conducted numerical experiments in computing inexact Newton steps for discretizations of a *modified Bratu problem*, given by

$$\begin{aligned} \Delta w + ce^{w} + d\frac{\partial w}{\partial x} &= f \qquad \text{in } D, \\ w &= 0 \qquad \text{on } \partial D, \end{aligned} \tag{10}$$

where c and d are constants. The actual Bratu problem has $d = 0$ and $f \equiv 0$. It provides a simplified model of nonlinear diffusion phenomena, e.g., in combustion and semiconductors, and has been considered by Glowinski, Keller, and Rheinhardt [6], as well as by a number of other investigators; see [6] and the references therein. See also problem 3 by Glowinski and Keller and problem 7 by Mittelmann in the collection of nonlinear model problems assembled by Moré [8]. The modified problem (10) has been used as a test problem for inexact Newton methods by Brown and Saad [2].

In our experiments, we took $D = [0,1] \times [0,1]$, $f \equiv 0$, $c = d = 10$, and discretized (10) using the usual second-order centered differences over a 100×100 mesh of equally spaced points in D. In GMRES(m), we took $m = 10$ and used fast Poisson right preconditioning as in the experiments in §2. The computing environment was as described in §2. All computing was done in double precision.

Letting F denote the nonlinear function obtained by discretizing (10) and letting u denote an approximate solution of the discretized problem, we used (6)–(9) in approximating Jacobian-vector products $F'(u)v$. The value of δ used for each formula was chosen according to the usual heuristic when F is evaluated to full machine precision: If p is the order of the formula, then $\delta = \mathbf{u}^{1/(p+1)}$, where $\mathbf{u}$ is unit roundoff (taken to be 10^{-16} here).

The methods we compared in our experiments are the following:

1. Four methods, each of which used one of (6), (7), (8), or (9) exclusively for all Jacobian-vector products. We refer to these below as FD1, FD2, FD4, and FD6, respectively.
2. Three versions of Algorithm EHA, each of which used one of (7), (8), or (9) exclusively in the accurate evaluation of initial residuals and then used (6) exclusively in the GMRES(m) cycles. We refer to these below as EHA2, EHA4, and EHA6, respectively.
3. A method in which all Jacobian-vector products were evaluated analytically. We refer to this as method A.

In the first set of experiments, we allowed each method to run for 40 GMRES(m) iterations, starting with zero as the initial approximate solution, after which the limit of residual norm reduction had been reached. The results are shown in Fig. 3. In Fig. 3, the top curve was produced by method FD1. The second curve from the top is actually a superposition of the curves produced by methods EHA2 and FD2; the two curves are visually indistinguishable. Similarly, the third curve from the top is a superposition of the curves produced by methods EHA4 and FD4, and the fourth curve from the top, which lies barely above the bottom curve, is a superposition of the curves produced by methods EHA6 and FD6. The bottom curve was produced by method A.

In the second set of experiments, our purpose was to assess the relative amount of computational work required by the methods which use higher-order differencing to reach comparable levels of residual norm reduction. We compared pairs of methods EHA2 and FD2, EHA4 and FD4, and EHA6 and FD6 by observing in each of 20

trials the number of GMRES(m) iterations, number of F-evaluations, and run time required by each method to reduce the residual norm by a factor of ϵ, where for each pair of methods ϵ was chosen to be somewhat greater than the limiting ratio of final to initial residual norms obtainable by the methods. In these trials, the initial approximate solutions were obtained by generating random components as in the similar experiments in §2. We note that for every method, the numbers of GMRES(m) iterations and F-evaluations required before termination did not vary at all over the 20 trials. The GMRES(m) iteration counts, numbers of F-evaluations, and means and standard deviations of the run times are given in Table 3.

Acknowledgments. We thank John Dennis and Gene Golub for stimulating conversations relating to this work.

A GRID-BASED SUBTREE-SUBCUBE ASSIGNMENT STRATEGY FOR SOLVING PARTIAL DIFFERENTIAL EQUATIONS ON HYPERCUBES*

MO MU† AND J. R. RICE†

Abstract. The authors propose a grid-based subtree-subcube assignment strategy for solving PDE problems on hypercubes. A complexity analysis of the communication is given for the proposed approach and the standard subtree-subcube assignment when applied to a variant of nested dissection indexing and a nonsymmetric sparse solver. The new assignment reduces communication cost using p processors by a factor of $O(\log\ p)$ in message startups and a factor of about two in traffic volume. Using a modified nested dissection indexing, the total effect on message startups is a reduction by a factor of $O(\log\ N)$ compared to previous approaches, where N is the number of unknowns. This grid-based assignment strategy achieves the optimal order in both traffic volume and startups; it provides good load balancing and as much parallelism as is inherent in the underlying algorithm. Some experimental results are presented which confirm the increased communication efficiency.

1. Introduction.

Parallel sparse solvers for elliptic partial differential equation (PDE) problems on a distributed memory, message passing (DMMP) multiprocessor can be generally divided into three major components: *assignment*, *indexing*, and *solution*. By assignment we mean that the discrete equations and the associated subtasks are assigned to processors. Indexing means that equations/unknowns are given an order, which establishes a system of linear algebraic equations. Solution means applying a numerical method to solve this linear system. Potentially, one can apply any algorithm to each of these three components. Various combinations of these algorithms will, of course, perform differently. Our Parallel Ellpack system provides a test bed for such performance experiments [11], [16].

Most parallel implementations of sparse solvers are based on elimination trees which represent the sparse structure of a linear system (e.g., [6], [13], [2]). A better shaped elimination tree (balanced, wide, and short) implies higher parallelism. The elimination tree shape is, in turn, determined by indexing because it determines the sparse structure. Indexings of the nested dissection type are appropriate for generating well-shaped elimination trees. See [13] and [3] for further references to earlier work in this area.

This paper mainly deals with one of the three components, the assignment issue, for a hypercube multiprocessor. An ideal assignment strategy should keep the load balanced, exploit fully the parallelism inherent in the problem, and minimize the communication requirement. For a nested dissection type indexing and a general purpose sparse solver, an attractive *subtree-subcube* approach is proposed by [7] which has the lowest order of traffic volume. However, for most current commercially available hypercube multiprocessors, both the traffic volume and the number of communication startups strongly affect efficiency. We observe that this assignment does

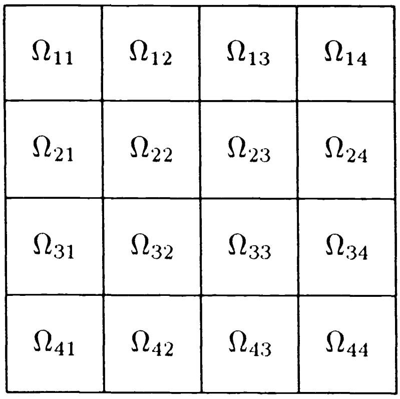
not achieve the lowest order of startups, and thus propose a new assignment strategy, *grid-based subtree-subcube*, which minimizes the startup cost while also retaining the other desirable properties.

A geometric (or physical) approach to develop parallel sparse solvers for solving PDE problems is suggested in [13], [16] which has several advantages over some standard algebraic approaches (e.g., [6], [2]). For example, it naturally allows nonsymmetric structure in the linear system, avoids symbolic factorization, leads to a well-shaped (block) elimination tree, and also allows flexible combinations of various techniques in different regions according to the local information about the geometry and physics of the PDE problem. Basically, the approach is based on a domain decomposition in a nested dissection manner. For indexing, we use *nested dissection* modified by locally using *minimum degree ordering* combined with an idea from the *multifrontal method.* This, together with the domain decomposition, implies a block elimination tree. Various parallel sparse solvers can then be devised based on this block elimination tree.

2. Background.

2.1. Domain decomposition and block elimination tree.

For the readers' convenience, this section briefly describes our geometric approach to developing a parallel sparse solver and the associated algorithms used in indexing and solution. For more details, see [13], [15]–[17]. For simplicity, we consider a PDE problem on a rectangular domain Ω. The approach can be extended easily to general domains. Suppose we have $p\,(= 2^{2d})$ processors available, 2^d in each direction. By domain decomposition Ω is divided into p subdomains Ω_{ij}, $i,\ j = 1,\ 2,\ \cdots, p^{1/2}$ as shown in Fig. 2.1. One puts a local grid on each subdomain Ω_{ij} and discretizes the local problem whose solution U_{ij} only depends on unknowns at grid points of $\partial\Omega_{ij}$, the boundary of Ω_{ij}.



Ω_{11}	Ω_{12}	Ω_{13}	Ω_{14}
Ω_{21}	Ω_{22}	Ω_{23}	Ω_{24}
Ω_{31}	Ω_{32}	Ω_{33}	Ω_{34}
Ω_{41}	Ω_{42}	Ω_{43}	Ω_{44}

FIG. 2.1. *Domain decomposition of a rectangle for $d = 2$.*

Initially, all interior unknowns U_{ij} are eliminated locally as in the standard domain decomposition approach. This step is obviously totally parallel. Then, all processors participate in eliminating interface unknowns. To exploit more parallelism, we use dissection in alternating directions to partition the interface set into several levels suitable for a hypercube machine. Each level consists of several *separators*, groups of unknowns which separate regions. The partition, which we call the *incomplete* *nested dissection decomposition* (borrowing the term used in [10]), is shown by Fig. 2.2 with circles representing the subdomain Ω_{ij}, and boxes representing the *separators.* For simplicity, these are all called *subdomains* of this domain decomposition and are numbered from top level to bottom level as shown in Fig. 2.2.

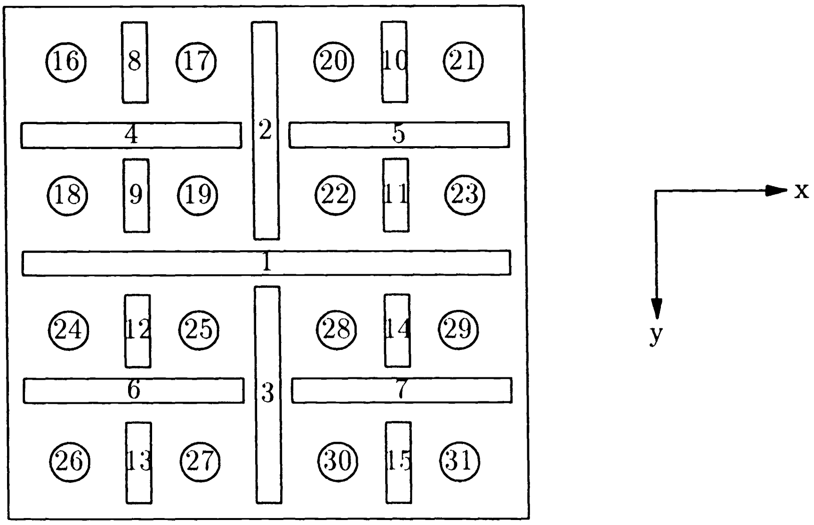


FIG. 2.2. *Partition of the subdomain interfaces in Fig.* 2.1 *using the incomplete nested dissection. The circles* (16–31) *represent the* 16 *groups of subdomain unknowns and the boxes represent groups of interface unknowns or separators. All boxes of the same size in each direction are on the same level of the elimination tree.*

This domain decomposition naturally inherits certain parallelism because the PDE discretization process leads to a local or boundary dependence property for interfaces. For example, if we consider the union of subdomains 16, 17, and 8 as a more general subdomain Ω'_8 then the local interior solution set U'_8 is uniquely determined by unknowns on $\partial\Omega'_8$. This relation holds similarly for groups at higher levels of the dissection decomposition for the unknowns arising in PDE applications. This local dependency can be described by a binary tree as shown in Fig. 2.3 with each tree node corresponding to a subdomain in the decomposition as shown in Fig. 2.2. We call it a *block elimination tree* because it plays a similar role as the standard *elimination tree* [2] does in exploiting parallelism. However, each node corresponds to, in the former case, a block of unknowns/equations, while in the latter case, a single unknown/equation. In other words, we are seeking the parallelism in the block sense no matter what local properties the linear system has within each subdomain locally. This block elimination tree has the following properties: (a) Each node corresponds to a set of unknowns from one location; local ordering and lack of symmetry in the linear system do not affect the tree structure. (b) Eliminating a node only has effects on its ancestors. (c) The eliminations of nodes that are not descendants/ancestors of one another are independent of one another. It thus implies several basic rules for assignment, indexing and solution, as in Fig. 2.3, to exploit the full parallelism inherent in the block elimination tree.

2.2. Indexing. It is natural to index the unknowns/equations globally according to the order of the dissection decomposition, i.e., if unknowns u and v are in nodes

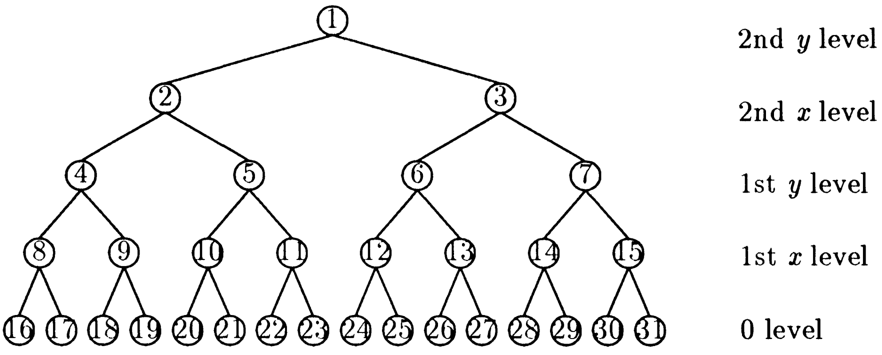

FIG. 2.3. *Block elimination tree produced by the incomplete nested dissection domain decomposition. The numbering of nodes corresponds to the groups of unknowns in Fig.* 2.2; *the* x, y *levels refer to the directions of the bisection.*

S and T, respectively, and S is on a higher level than T is, then the index of u is larger than that of v. This variation of nested dissection is incomplete in the sense that each separator is a line, instead of a cross as usual. It is also incomplete in the sense that we do not perform the dissection all the way until each node on the bottom level contains a single unknown/equation. Potentially, any linear system solver can be applied locally within each node without affecting the good shape of the block elimination tree. This allows us to choose appropriate local indexings in different regions for different purposes and thus to mix nested dissection with other indexings to improve performance without affecting the parallelism. For example, within each subdomain on the bottom level, elimination occurs sequentially in a single processor while the local problem is still sparse, so the fill-in issue here is a major concern. For example, the *minimum degree* ordering may have less fill-in than nested dissection does [12], especially for irregular domains. In the following, we will generically use *minimum degree* to mean whatever indexing gives the best performance on the sequential problems on the lowest level. The classic minimum degree ordering is just one reasonable choice here. Furthermore, if we keep the elimination front in Ω_{ij} as far as possible from $\partial\Omega_{ij}$, it helps to reduce the communication cost. Denote the boundary layer of grid points in Ω_{ij} (those next to $\partial\Omega_{ij}$) by B_{ij} as shown in Fig. 2.4. Without loss of generality *assume* that only unknowns on B_{ij} are related to those on $\partial\Omega_{ij}$ in the linear system, such as the *five-point star* discretization would generate. So we first eliminate the unknowns on $\Omega_{ij} - B_{ij}$ using the minimum degree ordering. There is no communication required at this stage. Then unknowns on B_{ij} are eliminated. Notice that the local indexing we use here is the minimum degree combined with the multifrontal method idea. We call the indexing described above the *modified nested dissection.*

Processing the boundary B_{ij} last in Ω_{ij} might increase the fill-in and computational cost. Application of the argument in [5] shows that the effects are very minor. And, as the size of the domains Ω_{ij} increases, this small effect becomes less important. More specifically, if one performs operation counts for nested dissection applied to all of Ω_{ij} and for nested dissection applied to $\Omega_{ij} - B_{ij}$ followed by B_{ij} elimination, one finds that not only is the order (in terms of k) the same, but the leading coefficients are the same. We have not experimentally measured this effect since we

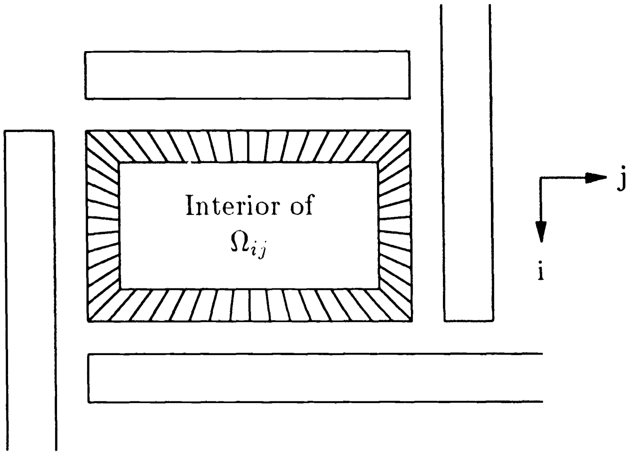

FIG. 2.4. *View of a typical subdomain Ω_{ij} of the* PDE *discretization. There are k^2 unknowns (grid points) in Ω_{ij}, $(k-2)^2$ in the interior and $n_0 = 4(k-1)$ in B_{ij}, the boundary layer (dashed area). The separators (shown as boxes) are lines of grid points separating the subdomains.*

expect it to be small or even totally absent. On the other hand, for existing and contemplated DMMP machines, these algorithms are usually communication bound, so that processing the boundary B_{ij} last appears to be the correct choice for algorithm designs.

As far as the nodes on higher levels (separator subdomains) are concerned, local indexing does not affect fill-in and communication significantly since the local systems are almost dense when the elimination front arrives. In the following, a *wrapping ordering* is assumed for each of these nodes locally.

No pivoting is assumed in the above discussion because we are mainly interested in solving elliptic PDEs where the matrix problems are usually numerically stable even though the matrices are often nonsymmetric. However, using this framework, one can still perform certain local pivoting within each $\Omega_{ij} - B_{ij}$ or within separators.

2.3. Solution. There are four kinds of potential parallelism here. First, elimination steps in independent nodes of the block elimination tree can execute simultaneously. We call this the *outer parallelism.* Second, if there are several processors available for a single node, we can also exploit *inner parallelism* within the node. This does not occur at leaf nodes if each leaf node has only one processor, as in usual cases, even though it represents a sparse subproblem. For the other nodes we apply various efficient parallel dense solvers to exploit the inner parallelism. Third, the task to modify an equation to eliminate an unknown (or simply, a *modification*) is independent for different equations just as for dense matrices. Finally, fourth, modifications, even on the same equation, due to independent descendant nodes can be performed in arbitrary order and hence in parallel. Further, modifications of one equation are vector operations whose components can be processed in parallel.

The potential parallelism inherent in the block elimination tree provides many ways to develop parallel algorithms for different matrix properties and machine architectures. Fan-in [1], multifrontal [2], and fan-out [8] organizations are commonly used in parallel sparse solvers. The fan-in scheme is currently known to be efficient in communication [1]. But it is strictly restricted to symmetric matrices when used on DMMP machines because forming the so-called aggregate update column (or row) needs the information from not only a set of columns (or rows), but also a row (or column) for the corresponding multipliers. This causes substantial communication expense for nonsymmetric matrices, even if they are structurally symmetric. We do not assume structural symmetry in our analysis. We believe that practical solvers will have the matrix distributed to the processors either by rows or by columns.

One can easily see that a realistic sparse solver essentially involves the following communication assumption for handling nonsymmetric linear systems on DMMP machines.

ASSUMPTION 3.1. *For Gauss elimination of nonsymmetric matrices on a DMMP machine, each pivot equation must be sent to those processors which hold equations related to the pivot equation.*

In other words, if $a_{mk} \neq 0$, $m > k$, then the processor holding the mth equation must receive the kth equation (after it becomes a pivot equation). This communication assumption is enough for the communication complexity analysis in §4 so that further details about a particular solution algorithm are not used. The multifrontal and fan-out schemes both satisfy this assumption. We recently presented a new organization of Gauss elimination for nonsymmetric problems in [17] which achieves much higher speedup than the fan-in, multifrontal, and fan-out methods do even for symmetric problems with comparable sizes. This very efficient algorithm (which is basically of fan-out type) still satisfies this assumption except for the bottom level in the elimination tree. That level, however, does not affect the analysis in §4. In summary, the analysis includes all potential solution algorithms for solving nonsymmetric problems on DMMP machines except the fan-in scheme which is not applicable here.

3. Assignment strategy.

By assigning an unknown to a processor we mean assigning both the problem data and the factorization subtask associated with this unknown. To achieve high parallelism, load balancing, and low communication costs based on the block elimination tree, we want to (a) avoid assigning independent nodes to the same processor, and (b) assign processors to a single node so as to have minimal communication connections. The standard wrapping assignment is not as effective here even though it achieves load balancing. Recall that the primary goal in parallel algorithms is efficiency and that load balancing is not a necessary condition to achieve maximum efficiency.

In [7] an attractive *subtree-subcube with local wrapping* assignment is proposed. We refer to it as the *standard* subtree-subcube assignment. It is a top to bottom process. First, the root node of the elimination tree is assigned to the whole hypercube and then the hypercube is split into two subcubes to which the two descendant subtrees are assigned. This process goes on recursively until all subtrees become assigned to single processors. The assignment within each node is simply in a wrapping manner. Note that: (a) eliminating an unknown in a node need not affect all of its ancestor nodes, and (b) even when effects occur in some ancestor nodes, they need not affect all equations in them. Geometrically, the effect of elimination spreads in a multifrontal manner with each processor starting with one subdomain and continuing to work on "merged" domains containing it as interface (separator) unknowns are eliminated. However, one cannot represent these properties completely by elimination trees even though they may affect the parallel efficiency very much. This suggests that unknown assignments be made in a multifrontal manner with a processor responsible only for those unknowns located at the fronts of some nodes to which the processor has been assigned. If several processors (usually a subcube) correspond to the same set of unknowns, then local wrapping can be applied within this set. We call this the *grid-based subtree-subcube* assignment which is defined more precisely as follows.

This is a bottom to top assignment process. Let us denote the levels in the block elimination tree from bottom to top by 0, 1st x, 1st y, 2nd x, 2nd y, $\cdots$, ith x, ith y, and so on. The x and y refer to the horizontal (j) and vertical (i) directions, respectively. The process is related to Fig. 2.2 where level zero consists of the leaves, 1st x consists of the eight separators 8–15, 1st y consists of the four separators 4–7, 2nd x consists of separators 2 and 3, and 2nd y consists of separator 1. The first step is to map the given hypercube to a two-dimensional grid (for domain decomposition) by the well-known *gray code* such that adjacent processors are directly connected and Ω_{ij} is assigned to proc.essor P_{ij}. This defines the assignment at the leaves of the block elimination tree, the 0 level. Next, we subdivide each separator on the ith x level and the ith y level into 2^{i-1} and 2^i *segments*, respectively. This subdivision of segments corresponds to the natural geometric segments along the separators of the domain decomposition. We take care of the intersection points of adjacent segments in each separator by adding an intersection point to its top (left) segment for the $x(y)$ direction. Then we assign each segment on the ith $x(y)$ level to the closest 2^i processors in the $x(y)$ direction. The assignment within each segment uses wrapping. This scheme is illustrated in Fig. 3.1. Thus, processors P_{11} and P_{12} are assigned to the interface unknowns of separator 8 (the upper left box in Fig. 3.1). For comparison, Fig. 3.2 illustrates the standard subtree-subcube assignment strategy.

The potential for reducing communication is seen by examining separator 4 which is the top, left horizontal box in Figs. 2.2 and 3.2. In Fig. 3.1 we see those unknowns divided into two separate groups (segments). In the grid-based subtree-subcube assignment (Fig. 3.1), the processors P_{11} and P_{21} only handle the interface between the two subdomains (16 and 18) they handled at the lower level. In the standard subtree-subcube assignment (Fig. 3.2), the processors P_{11} and P_{21} are part of a group of processors handling the four subdomains (16, 17, 18, and 19). Thus P_{11} and P_{21} must now obtain information about subdomains 17 and 19 at this step while this is not required in the grid-based subtree-subcube assignment. This reduction in the communication occurs in a similar manner for every separator.

4. Communication complexity analysis. Throughout this section, we use the communication Assumption 3.1. The communication complexity, of course, depends on indexing schemes, too. We will make it clear which indexing is used whenever necessary.

In [7] it is proved that the total amount (or volume) of communication for the standard subtree-subcube assignment is $O(pN)$. This order is optimal in the sense of minimizing traffic volume for nested dissection algorithms; the grid-based subtree-subcube assignment has this same optimal order, as the analysis in [7] applies to all types of subtree-subcube assignments. We give an analysis which provides estimates for the communication complexity of startups as well as of traffic volume for both assignments when applied to the modified nested dissection indexing and general nonsymmetric solution algorithms. The analysis does not apply to the fan-in scheme because the fan-in algorithm does not satisfy Assumption 3.1. But this algorithm is not applicable to nonsymmetric problems which we are considering here.

Suppose that a set of q processors composes a connected subgraph in the hypercube architecture and it is involved in communicating a piece of message. We assume that each nonroot processor receives the message exactly once from one of its direct neighbors. This occurs in most procedures for multicasting, i.e., sending a message

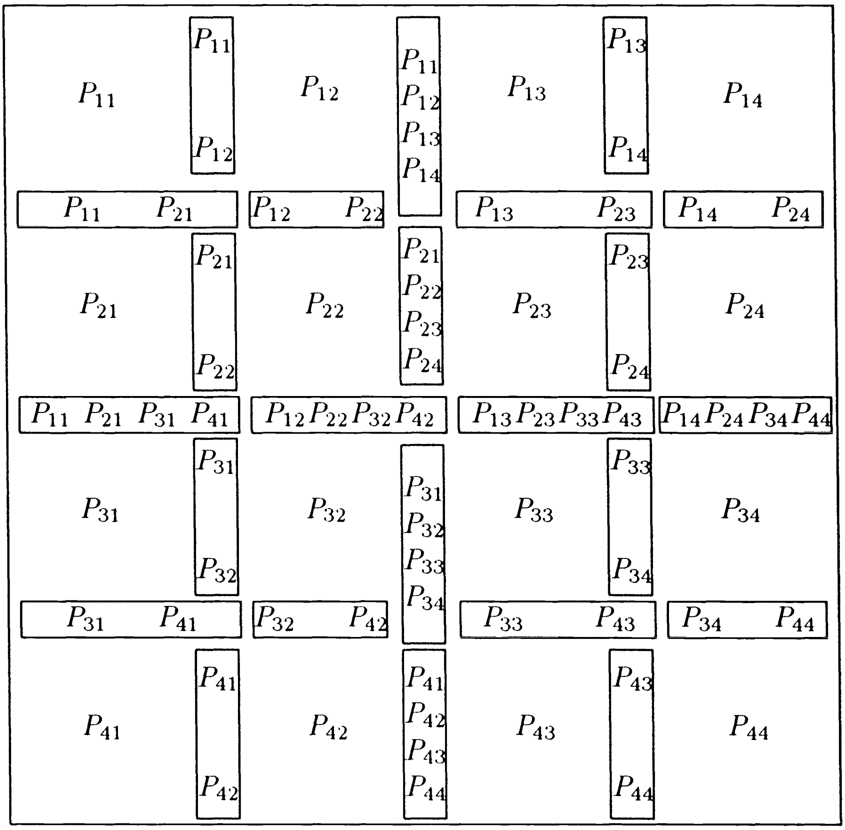

FIG. 3.1. *Grid-based subtree-subcube assignment for* 16 *processors. Within the subdomain interfaces we show how the processors are assigned to unknowns in parts of the separators.*

from one processor to a list of other processors. Therefore the total number of startups required in such a communication process is equal to $q - 1$. Putting a $k \times k$ grid on each subdomain Ω_{ij}, we have the total number of grid points on Ω equal to $N = n \times n$ with $n = p^{1/2}\ k\ +\ p^{1/2}\ -\ 1$. Without loss of generality assume that there is a correspondence between each unknown and a grid point, as in the *five-point star* discretization.

Let *startup*(n, p) denote the number of startups required for communication corresponding to the $n \times n$ grid and the p processors assigned to this grid. From Assumption 3.1, in eliminating a particular unknown we need to count the cost for communicating a piece of multiplier message (a vector) among those processors holding unknowns which are currently related to this unknown. First we estimate *startup*(n, p) for the grid-based subtree-subcube assignment and the modified nested dissection indexing using the recursive analysis similar to the argument used in [7].

THEOREM 4.1. *Suppose $d \geq 3$ and there are $N = n \times n$ unknowns and $p = 4^d$ processors. Assume that a nonsymmetric sparse solver uses the grid-based subtree-subcube assignment, the modified nest dissection indexing, and a solution algorithm which satisfies Assumption* 3.1. *Then, on a DMMP machine the number of startups satisfies*

FIG. 3.2. *Standard subtree-subcube assignment for* 16 *processors. Within each box unknowns are assigned in wrapping manner to processors shown in the box.*

$$startup(n,p) \le 10np \; + \; 80np^{1/2}. \tag{4.1}$$

Proof. Notice that the "cross" set on the top level consisting of two separators on the dth x level and one on the dth y level divides the $n \times n$ grid and the set of p processors into four $\frac{n}{2} \times \frac{n}{2}$ subgrids and four groups of $\frac{p}{4}$ processors. We introduce the function $f_2(m,\; q)$ as the number of startups required due to the outside processors on the subgrid border for eliminating unknowns in each $m \times m$ subgrid with two border sides on the top level "cross" set and each side having q processors assigned to it. So, $startup(n,p)$ is bounded by three terms:

$$startup(n,p) \le 4\; startup(\tfrac{n}{2},\; \tfrac{p}{4}) \; + \; 4f_2(\tfrac{n}{2},\; \tfrac{p}{2}) \; + \; \{2(\tfrac{n}{2}p) \; + \; n\, p\,\}, \tag{4.2}$$

The third term in (4.2) corresponds to the number of startups required for eliminating unknowns in three separators of the "cross" set.

To estimate $f_2(\frac{n}{2},\; \frac{p}{2})$, we examine one lower level by using the "cross" set in the $\frac{n}{2} \times \frac{n}{2}$ grid to further divide it into four $\frac{n}{4} \times \frac{n}{4}$ subgrids and we have

$$f_2(\tfrac{n}{2},\; \tfrac{p}{2}) \le f_2(\tfrac{n}{4},\; \tfrac{p}{4}) \; + \; 2f_1(\tfrac{n}{4},\; \tfrac{p}{4}) \; + \; \{[\tfrac{n}{4}(\tfrac{p}{4} \; + \; \tfrac{p}{8}) \; + \; \tfrac{n}{4}\tfrac{p}{8}] \; + \; \tfrac{n}{2}\,(\tfrac{p}{4} \; + \; \tfrac{p}{4})\} \tag{4.3}$$

where the function f_1 has a meaning similar to f_2, but with only one border side on the top level "cross" set. The third term in (4.3) comes from eliminating three separators in the "cross" set of this $\frac{n}{2} \times \frac{n}{2}$ grid.

Similarly, we go to the next lower level to estimate the function f_1 as follows:

$$f_1(\tfrac{n}{4},\ \tfrac{p}{4}) \leq 2f_1(\tfrac{n}{8},\ \tfrac{p}{8}) + \{\tfrac{n}{8} \cdot \tfrac{p}{8} + \tfrac{n}{4} \cdot \tfrac{p}{8}\}. \tag{4.4}$$

Notice that on the bottom level, i.e., the domain decomposition level, we have

$$f_1(\tfrac{n}{p^{1/2}},\ p^{1/2}) \leq (4 \cdot \tfrac{n}{p^{1/2}}) \cdot \tfrac{p^{1/2}}{2} \ = \ 2n. \tag{4.5}$$

By recursively using (4.4) till the bottom level, we get

$$\begin{aligned} f_1(\tfrac{n}{4},\tfrac{p}{4}) &\leq \tfrac{3}{64}np + 2f_1(\tfrac{n}{8},\tfrac{p}{8}) \\ &\leq \tfrac{3}{64}np(1 + \tfrac{1}{2} + \tfrac{1}{2^2} + \cdots) + 2f_1(\tfrac{n}{p^{1/2}},p^{1/2}) \\ &\leq \tfrac{3}{32}np + 4n. \end{aligned} \tag{4.6}$$

Similarly, on the bottom level we have

$$f_2(\tfrac{n}{p^{1/2}},\ p^{1/2}) \leq (4 \cdot \tfrac{n}{p^{1/2}}) \cdot p^{1/2} \ = \ 4n. \tag{4.7}$$

Substituting f_1 from (4.6) and recursively using (4.3) and then using (4.7), we obtain (4.8)

$$\begin{aligned} f_2(\tfrac{n}{2},\tfrac{p}{2}) &\leq \tfrac{9}{16}np + 8n + f_2(\tfrac{2}{4},\tfrac{p}{4}) \\ &\leq \tfrac{9}{16}np(1 + \tfrac{1}{4} + \tfrac{1}{4^2} + \cdots) + 8n(1 + \tfrac{1}{2} + \tfrac{1}{2^2} + \cdots) + f_2(\tfrac{n}{p^{1/2}},p^{1/2}) \\ &\leq \tfrac{3}{4}np + 16n + 4n \\ &= \tfrac{3}{4}np + 20n. \end{aligned}$$

We substitute (4.8) into (4.2) to obtain

$$startup(n,p) \leq 5np \ + \ 80n \ + \ 4startup(\tfrac{n}{2},\ \tfrac{p}{4}). \tag{4.9}$$

We observe that

$$startup(\tfrac{n}{p^{1/2}},1) \ = \ 0. \tag{4.10}$$

We apply (4.9) recursively and then use (4.10) to obtain

$$\begin{aligned} startup(n,p) &\leq 5np(1 \ + \ \tfrac{1}{2} \ + \ \tfrac{1}{2^2} \ + \ \cdots) \ + \ 80n(1 \ + \ 2 \ + \ 2^2 \ + \ \cdots \ + \ 2^{d-1}) \\ &\leq 10np \ + \ 80np^{1/2}. \end{aligned}$$

This completes the proof. □

This analysis gives an upper bound. We see that the bound is sharp in terms of the orders for n and p for a pipelined algorithm (one where a processor forwards information needed by another processor as soon as it becomes available). The final step (node 1 of the elimination tree) involves the n unknowns on the separator 1; see Fig. 2.2. This step involves a dense matrix where all p processors must exchange information with all other processors about all the remaining n equations. If we maintain pipelining, then each multiplier vector must be broadcast as soon as it is available. Thus np message startups are required. Thus we see that the grid-based subtree-subcube assignment is of optimal order with respect to startups; we thus have the following.

COROLLARY. *With $d \geq 3$, p processors, $n \times n$ unknowns, and a pipelined algorithm, we have*

$$\mathit{startup}(n,p) \;=\; O(pn).$$

One could consider a partially pipelined algorithm where several multiplier vectors are collected before being broadcast. This would be similar in philosophy to loop unrolling (see [4]); it has the disadvantage of delaying computations on other processors. While the optimal strategy will depend on the exact characteristics of the hypercube, we believe that the optimal strategy will usually involve only a small number of vectors to be collected together before broadcasting so the order will remain the same.

Changing the new assignment in Theorem 4.1 to the standard subtree-subcube one, we see that the functions f_1 and f_2 do not depend on the second argument, the number of processors. Therefore, an extra factor $\log_2 p$ is introduced into the estimate for $\mathit{startup}(n,p)$. Furthermore, if the indexing in Theorem 4.1 is also changed to the standard nested dissection, then the factor $\log_2 p$ will become $\log_2 n$ because the number of the dissection levels increases from $\log_2 p$ to $\log_2 n$. This is also pointed out in [19]. These two facts are stated as follows.

THEOREM 4.2. *Change the subtree-subcube assignment in Theorem* 4.1 *from grid-based to standard. Then we have*

$$\mathit{startup}(n,p) \;=\; O(pn \;\log_2 p).$$

Further, if the indexing is replaced by the standard nested dissection, then we have

$$\mathit{startup}(n,p) \;=\; O(pn \;\log_2 n).$$

We can also bound the traffic volume for both assignments. Specifically, let V_g and V_s denote the total communication volume for the grid-based subtree-subcube assignment and the standard subtree-subcube assignment, respectively.

THEOREM 4.3. *With the assumptions of Theorems* 4.1 *and* 4.2 *we have*

$$V_g \leq 14.4pN \;+\; O(\log_2 pN), \tag{4.11}$$

$$V_s \leq 31.85pN \;+\; O(\log_2 pN). \tag{4.12}$$

We do not give the proof for Theorem 4.3 here. It can be found in [14]. From Theorem 4.3 we see that the bound on V_s is about twice the bound on V_g. Both have the same optimal order $O(pN)$ as seen by examining the elimination at node 1. It is intuitively clear and not hard to show that both algorithms are load balanced, i.e., the volume of messages from each processor is $O(N)$.

5. Implementation and performance. Serious experimental studies are needed to measure the value of the many variations in sparse matrix algorithms for hypercubes. This is a difficult challenge because of the sheer number of variations and the difficulty is further compounded by (a) the lack of a stable architecture, and (b) the lack of good performance analysis tools for hypercubes. Thus, even if we knew everything now, the next generation of hypercubes is likely to have such a different balance of hardware capabilities that we would have to start over. Even now, we face the problem of whether poor performance observed is due to an inherent flaw in the algorithm/method or to a terrible implementation of some underlying system service. In view of this, we settle for performance comparison of these two assignment strategies, which are implemented as two *assignment* modules in our Parallel Ellpack and are combined with the *indexing* module MODIFIED NESTED DISSECTION and two *solution* modules PARALLEL SPARSE [15], which is basically a fan-out scheme, and NEW GAUSS ELIMINATION [17], on our two hypercubes (a first generation NCUBE with 128 processors and a second generation NCUBE with 64 processors).

We solve a *Poisson* equation with *Dirichlet* boundary condition on a rectangle domain using 16 processors by our geometric approach with *five-point star* discretization. We only consider the communication cost and timing of the *LU* factorization phase. While this problem is actually symmetric, we still treat it as a nonsymmetric one since we want to examine the effects of these two assignments on general problems. In the following, we use *standard* and *new* to briefly denote the *standard subtree-subcube* and the *grid-based subtree-subcube* assignments, respectively.

Figure 5.1 shows the number of messages versus $N^{1/2}$ for both *standard* and *new*. The total message volume versus N for both *standard* and *new* is shown in Fig. 5.2. PARALLEL SPARSE is used as the solution module for both of these figures. We observe a substantial reduction in communication requirements using the *new* assignment strategy. These data also firmly support the analysis in §4. If the standard nested dissection indexing is used with the "standard" curve, then the number of messages is increased.

Applying the new assignment and indexing strategies to the NEW GAUSS ELIMINATION module, we get a speedup of 4 for solving a 23 × 23 grid problem using four processors, and a speedup of 15.7 for solving a 61 × 61 grid problem using 16 processors. Notice that even for symmetric solvers, the best speedup reported previously for 16 processors is 10.62. This is for solving a 125 × 63 L-shaped grid problem with nine-point star by the fan-in scheme on an Intel iPSC/2 hypercube [1]. For more detailed performance data, see [18].

6. Conclusion.

We propose a grid-based subtree-subcube assignment strategy appropriate for sparse matrix algorithms to solve PDE problems on hypercubes. The change from the standard subtree-subcube assignment is motivated by the multifrontal method used in PDE solvers where interfaces between subdomains are handled by the processors assigned to the subdomains. For both assignments we give a complexity analysis of the communication costs of the elimination considering both the total traffic volume and the number of message startups. The analysis is given for a PDE problem on a rectangular domain but the arguments can be extended to more general domains. We show that our assignment has, theoretically, about half the total communication volume as the standard assignment and the number of communication startups is improved by a factor of $\log_2 p$. With the modified nested dissection indexing, the number of startups is then improved in total by a factor of $\log_2 n$. This approach achieves the optimal order in traffic volume and number of startups. Experimental measurements indicate that these theoretical improvements occur in practice. This assignment also provides load balancing and exploits fully the parallelism inherent in the problem. It is applied to nonsymmetric problems.

PARALLEL METHODS FOR SOLVING NONLINEAR BLOCK BORDERED SYSTEMS OF EQUATIONS*

XIAODONG ZHANG†, RICHARD H. BYRD‡, AND ROBERT B. SCHNABEL‡

Abstract. A group of parallel algorithms, and their implementation for solving a special class of nonlinear equations, are discussed. The type of sparsity occurring in these problems, which arise in VLSI design, structural engineering, and many other areas, is called a *block bordered* structure. The explicit method and several implicit methods are described, and the new *corrected implicit method* for solving block bordered nonlinear problems is presented. The relationship between the two types of methods is analyzed, and some computational comparisons are performed. Several variations and globally convergent modifications of the implicit method are also described. Parallel implementations of these algorithms for solving block bordered nonlinear equations are described, and experimental results on the Intel hypercube that show the effectiveness of the parallel implicit algorithms are presented. These experiments include a fairly large circuit simulation that leads to a multilevel block bordered system of nonlinear equations.

Key words. systems of nonlinear equations, parallel computation

AMS(MOS) subject classifications. 65H10, 65W05

1. Introduction.

1.1. Definition of block bordered nonlinear problems. In this paper we present a group of parallel algorithms and their implementations for solving a special class of nonlinear equations, instances of which occur in VLSI design, structural engineering, and many other areas. The class of sparsity occurring in these problems is called a block bordered structure. In such a problem the general system of n nonlinear equations in n unknowns may be grouped into $q+1$ subvectors $x_1, \cdots, x_{q+1}$ and $f_1, \cdots, f_{q+1}$ such that the nonlinear system of equations has the form

$$\begin{aligned} & f_i(x_i, x_{q+1}) = 0, \qquad i = 1, \cdots, q \\ & f_{q+1}(x_1, \cdots, x_{q+1}) = 0 \end{aligned} \tag{1.1}$$

where

$$x_i \in R^{n_i},$$
$$f_i \in R^{n_i}, \qquad i = 1, \cdots, q+1,$$
$$\sum_{i=1}^{q+1} n_i = n.$$

The block bordered Jacobian matrix of (1.1) is

$$\begin{pmatrix} A_1 & & & & B_1 \\ & A_2 & & & B_2 \\ & & \ddots & & \vdots \\ & & & A_q & B_q \\ C_1 & C_2 & \cdots & C_q & P \end{pmatrix}, \tag{1.2}$$

where

$$A_i = \frac{\partial f_i}{\partial x_i} \in R^{n_i \times n_i}, \quad i = 1, \cdots, q,$$

$$B_i = \frac{\partial f_i}{\partial x_{q+1}} \in R^{n_i \times n_{q+1}}, \qquad i = 1, \cdots, q,$$

$$C_i = \frac{\partial f_{q+1}}{\partial x_i} \in R^{n_{q+1} \times n_i}, \qquad i = 1, \cdots, q,$$

$$P = \frac{\partial f_{q+1}}{\partial x_{q+1}} \in R^{n_{q+1} \times n_{q+1}}.$$

Newton's method is the fundamental approach for solving a general nonlinear system of equations. Several parallel algorithms for solving general systems of nonlinear equations that are based upon Newton's method have been developed and implemented on various parallel computers. These parallel algorithms consist mainly of solving the linear Jacobian system in parallel. Many parallel algorithms have been developed for solving linear systems, such as as parallel factorizations, parallel SOR methods, parallel red-black methods, parallel multicolor, and others (see e.g., Ortega and Voigt [1985], O'Leary and White [1985], White [1986], Fontecilla [1987], and Coleman and Li [1990]).

In the case of very large nonlinear problems we cannot expect a single parallel algorithm to efficiently handle all the instances of the system of nonlinear equations problem, but rather the algorithm must take into account the sparsity structure and other special characteristics of the problem. In fact, many nonlinear problems arising in applications have their own special sparsity structure. Parallel algorithms taking advantage of this special structure may be much more efficient than the algorithms ignoring the special structure. This paper is an instance of developing special algorithms for a special, important structure.

1.2. Background on block bordered problems. Block bordered problems of the form (1.1) arise in many areas of science and engineering, and a few algorithms have been developed to efficiently solve linear block bordered systems of equations. In applications such as structural engineering, large spatial models may be divided into q regions such that each region only interacts directly with neighboring regions. The variables x_i for each region are chosen so that the model can determine their values, given the values of the linking variables (the x_{q+1}) at the boundaries of the regions. The linking variables are tied together by a $(q+1)$st set of equations representing the interactions between the regions. Thus the equilibrium equations for such a model will be of the form (1.1). In addition, the Jacobian matrix is symmetric. These problems, and parallel algorithms for solving the linear block bordered systems that arise from them, are discussed in Farhat and Wilson [1986] and Nour-Omid and Park [1986].

Mu and Rice [1989] study parallel Gaussian elimination for the block bordered matrices arising from the discretization of partial differential equations (PDEs). Christara and Houstis [1988], [1989] implement a domain decomposition spline collocation method and a preconditioned conjugate gradient (PCG) method for this linear block bordered system on both NCUBE/7 and Sequent multiprocessors.

All the work described above concerns parallel methods for solving linear block bordered equations. Our research is to develop, implement, and analyze parallel methods for solving nonlinear block bordered problems. To our knowledge, no one has done similar work.

Block bordered equations also arise in VLSI circuit design, where parts of the circuits may be divided into regions. The concept of macromodeling the circuit is to decompose the circuit into subcircuits and to analyze the subcircuits separately (see Rabbat, Sangiovanni-Vincentelli, and Hsieh [1979] and Rabbat and Sangiovanni-Vincentelli [1980]). Macromodeling of the circuit results in a system of nonlinear equations of form (1.1). A_i and B_i $(i=1, \cdots, q)$ in the Jacobian matrix are usually used to represent internal and input-output variables in each of the q independent subcircuits. The variables represent voltages and currents. The bottom block f_{q+1} represents the voltages or currents between subcircuits. Since each voltage or current is used only in one block of equations f_i plus possibly the bottom block f_{q+1}, the nonzero columns of the B_i's (and A_i) are disjoint, meaning that the matrices $B_i, \cdots B_q$ in (1.2) also follow a block diagonal pattern. In addition, since f_{q+1} describes the point-to-point connections of voltage and current, it is a linear function. The size of the function f_{q+1} depends on the number of connections among the subcircuits.

We have studied parallel methods for solving block bordered nonlinear equations extensively from both theoretical and practical viewpoints. Section 2 considers the explicit method and several implicit methods for solving block bordered nonlinear equations, and presents a new implicit approach—the corrected implicit method. A mathematical analysis of the two types of methods and a computational comparison in a sequential context is made. Section 3 briefly discusses techniques used to make these methods globally convergent. In § 4, we give a group of parallel algorithms for solving block bordered nonlinear systems of form (1.1), which may be implemented and distributed on both shared and distributed memory multiprocessors. The implementations and experimental results of these algorithms on the Intel hypercube, a distributed memory multiprocessor, are presented in § 5. Finally, our conclusions and some future research directions are summarized in § 6,

2. Explicit and implicit methods.

2.1. Introduction. There are two basic ways in which Newton's method can be applied to the nonlinear block bordered system of equations (1.1), which we refer to as the explicit and implicit approaches. The explicit approach is to simply apply Newton's method to (1.1). This involves iteratively solving the linear system

$$J(X^k)\Delta X^k = -F(X^k), \qquad k=0, 1, \cdots \tag{2.1}$$

for ΔX^k, where $J(X^k)$ is the Jacobian of F, which has the block bordered structure (1.2), and $X=(x_1, \cdots, x_q, x_{q+1})$.

The pure implicit approach is to use each of the q systems of nonlinear equations

$$f_i(x_i, x_{q+1})=0, \qquad i=1, \cdots, q \tag{2.2}$$

to solve for x_i, given a fixed value of x_{q+1}. This means that each of the x_i is implicitly given by a function of x_{q+1}. The whole problem (2.2) is then equivalent to solving

$$f_{q+1}(x_1(x_{q+1}), \cdots, x_q(x_{q+1}), x_{q+1})=0. \tag{2.3}$$

The Jacobian of this system is given by

$$\hat{J}=\frac{\partial f_{q+1}}{\partial x_{q+1}}-\sum_{i=1}^{q} \frac{\partial f_{q+1}}{\partial x_i}\left(\frac{\partial f_i}{\partial x_i}\right)^{-1} \frac{\partial f_i}{\partial x_{q+1}} \tag{2.4}$$

or

$$\hat{J}=P-\sum_{i=1}^{q} C_i A_i^{-1} B_i \tag{2.5}$$

and we may solve (2.3) by Newton's method. We will be considering practical variants of the implicit method that do not calculate $x_i(x_{q+1})$ exactly. We assume here and for the rest of § 2 that the matrices A_i and $\hat{J}$ are nonsingular. The situation where this does not hold will be discussed in § 3.

In this section we describe the explicit and implicit methods and their relations to each other, introduce the new corrected implicit method, and give some simple experimental results using these methods on a sequential computer.

2.2. Algorithms and analysis for the explicit and implicit methods. Newton's method applied to (1.1) in the explicit method consists of solving the following linear equations at iteration k $(k=0, 1, \cdots)$: from $f_i(x)=0$, $i=1, \cdots, q$,

$$A_i\Delta x_i^k + B_i\Delta x_{q+1}^k + f_i(x_i^k, x_{q+1}^k)=0, \tag{2.6}$$

and from $f_{q+1}(x_1^k, \cdots, x_q^k, x_{q+1}^k)=0$,

$$\sum_{i=1}^{q} C_i\Delta x_i^k + P\Delta x_{q+1}^k + f_{q+1}(x_1^k, \cdots, x_q^k, x_{q+1}^k)=0. \tag{2.7}$$

(For simplicity, we omit superscripts k on A_i, B_i, C_i, and P, but note that at least the A_i's and B_i's can change at each iteration.) Solving for Δx_i^k in (2.6) and substituting into (2.7), we obtain

$$\hat{J}\Delta x_{q+1}^k = -f_{q+1}(x_1^k, \cdots, x_q^k, x_{q+1}^k) + \sum_{i=1}^{q} C_iA_i^{-1}f_i(x_i^k, x_{q+1}^k) \tag{2.8}$$

where $\hat{J}$ is given by (2.5). So

$$x_{q+1}^{k+1} = x_{q+1}^k + \Delta x_{q+1}^k \tag{2.9}$$

can be determined from (2.8), and

$$x_i^{k+1} = x_i^k + \Delta x_i^k, \qquad i=1, \cdots, q \tag{2.10}$$

can be determined from (2.6).

In the pure implicit method, Newton's method is applied to (2.3) and gives

$$\hat{J}\Delta x_{q+1}^k + f_{q+1}(x_1(x_{q+1}^k), \cdots, x_q(x_{q+1}^k), x_{q+1}^k)=0, \tag{2.11}$$

where $x_i(x_{q+1}^k)$ $(i=1, \cdots, q)$ is implicitly determined by solving the nonlinear system

$$f_i(x_i, x_{q+1}^k)=0 \tag{2.12}$$

for x_i. To turn this into a practical computational procedure, we use a second (or inner) Newton process on (2.12) to calculate $x_i(x_{q+1}^k)$, which solves (2.12) approximately. For each $i=1, \cdots, q$, this yields the inner iteration

$$\hat{A}_i\Delta x_i^{k,j-1} + f_i(x_i^{k,j-1}, x_{q+1}^k)=0, \quad i=1, \cdots, q, \quad j=1, 2, \cdots, I_{in}. \tag{2.13}$$

Here $x_i^{k,0}=x_i^k$, I_{in} is the number of inner iterations, and $\hat{A}_i = A_i$ if it is only evaluated once at the beginning of each outer iteration; or, it may be evaluated up to I_{in} times. At the end of each inner iteration, we set

$$x_i^{k,j} = x_i^{k,j-1} + \Delta x_i^{k,j-1}, \qquad i=1, \cdots, q. \tag{2.14}$$

When we exit the inner iterations, we set

$$x_i(x_{q+1}^k) = x_i^{k+1} = x_i^{k,j}. \tag{2.15}$$

Then x_{q+1} is determined from (2.11) and

$$x_{q+1}^{k+1} = x_{q+1}^k + \Delta x_{q+1}^k. \tag{2.16}$$

The implicit Newton iteration (2.11) is also considered by Rabbat, Sangiovanni-Vincentelli, and Hsieh [1979], but instead of focusing on the number of inner iterations, they assume that (2.12) is solved to some tolerance. By considering a method with a fixed number of inner iterations, we are led to the following theorems, which show a close relationship between the explicit method and the implicit methods just described. We are also led to a new method—the corrected implicit method.

THEOREM 1. *If f_{q+1} is linear, the matrices A_i and $\hat{J}$ are nonsingular, and only one inner Newton iteration is applied to solve for $x_i^{k,j}$ $(i=1,\cdots,q)$ in the implicit method, i.e., $I_{in}=1$, then for a fixed k, the steps Δx_{q+1}^k are identical in both methods.*

Proof. In this case $x_i^{k+1}=x_i^k-A_i^{-1}f_i(x_i^k,x_{q+1}^k)$ and $f_{q+1}(x_1^{k+1},\cdots,x_q^{k+1},x_{q+1}^k)=f_{q+1}(x_1^k,\cdots,x_q^k,x_{q+1}^k)-\sum_{i=1}^q C_iA_i^{-1}f_i(x_i^k,x_{q+1}^k)$. Substituting this into (2.11) gives

$$\hat{J}\Delta x_{q+1}^k=-f_{q+1}(x_1^k,\cdots,x_q^k,x_{q+1}^k)+\sum_{i=0}^q C_iA_i^{-1}f_i(x_i^k,x_{q+1}^k), \tag{2.17}$$

which is identical to the explicit formula (2.8). □

The corrected implicit method. In the implicit method described above, the steps Δx_i for $i\leqq q$ do not involve any information about f_{q+1} or Δx_{q+1}, and are not the same as in the explicit method. If the value of $x_i^{k+1}(i\leqq q)$ calculated by the implicit method is corrected after each iteration to account for the change in x_{q+1}, however, the implicit method can be made closer to the explicit method and quadratically convergent. The problem may be defined to find a correction term δ such that

$$f_i(x_i^{k+1}+\delta,\ x_{q+1}^{k+1})\approx 0 \tag{2.18}$$

or

$$f_i(x_i^{k+1}+\delta,x_{q+1}^k+\Delta x_{q+1}^k)\approx 0. \tag{2.19}$$

Making a linear approximation to f_i in (2.19) yields the condition

$$f_i(x_i^{k+1},x_{q+1}^k)+A_i\delta+B_i\Delta x_{q+1}^k=0. \tag{2.20}$$

The correction term δ obtained from (2.20) would then be

$$\delta=-A_i^{-1}[f_i(x_i^{k+1},x_{q+1}^k)+B_i\Delta x_{q+1}^k]. \tag{2.21}$$

However, after I_{in} inner iterations of solving for x_i^{k+1}, $f_i(x_i^{k+1},x_{q+1}^k)\approx 0$. Thus we make a further approximation giving the correction term

$$\delta_i=-A_i^{-1}B_i\Delta x_{q+1}^k. \tag{2.22}$$

We call the new implicit method with this correction the *corrected implicit method.* The cost of the correction term (2.22) is small since the matrices $A_i^{-1}B_i$ $(i=1,\cdots,q)$ have been calculated already and in a parallel implementation, the matrix-vector products can be parallelized fully.

We can now see that when f_{q+1} is linear, the explicit method is a special case of the corrected implicit method.

THEOREM 2. *If f_{q+1} is linear, the matrices A_i and $\hat{J}$ are nonsingular, and only one Newton iteration is applied to solve for $x_i^{k,j}$ $(i=1,\cdots,q)$ in the implicit method, i.e., $I_{in}=1$, and the system is corrected by adding $-A_i^{-1}B_i\Delta x_{q+1}$ to $x_i^{k+1}(i\leqq q)$ after each iteration, then the explicit method and implicit method are identical.*

Proof. From Theorem 1, Δx_{q+1}^k is identical for the two methods. Combining (2.14) with $j=1$ and (2.22) gives

$$x_i^{k+1}=x_i^k-A_i^{-1}[f_i(x_i^k,,x_{q+1}^k)-B_i\Delta x_{q+1}^k] \tag{2.23}$$

which is identical to (2.6) in the explicit method. □

This equivalence, together with the standard convergence analysis for Newton's method, gives the following convergence result.

COROLLARY. *Suppose $J(X)$ is continuously differentiable near a solution X^*, the matrices $A_i(x^*)$ and $J(\hat{X}^*)$ are nonsingular, and f_{q+1} is linear. Then the corrected implicit method with $I_{in}=1$ inner iterations per outer iteration is locally quadratically convergent to the solution.*

Quadratic convergence can also be shown for $I_{in}>1$ and when f_{q+1} is nonlinear. The proof is given in Zhang [1989], and is based on the fact that the extra inner iterations tend to move X closer to the solution, and the nonlinearity in f_{q+1} at most adds a term of order $\|X^k - X^*\|^2$ to the error at X^{k+1}.

2.3. Some experiments on a sequential processor. The previous subsection shows that a variant of the implicit method is equivalent to the explicit method, but does not indicate why the implicit method might be preferred. The main reason is that, by using more than one inner iteration per outer iteration in the implicit method, the number of outer iterations can be reduced substantially, which is advantageous, especially for parallel computation. In this subsection we give a first indication of the sort of computational behavior that we have found.

We initially tested the methods discussed in this section on several artificial problems. Here we report results on a simple 20×20 nonlinear block bordered system of quadratic equations that has four 4×4 blocks, $A_1, \cdots, A_4$, and a 4×4 bottom block P, with f_{q+1} linear. In all cases, the starting value of x was close to the solution, and no global strategy (e.g., line search) was used. All these experiments were run on a Pyramid P90 computer.

First we compare the performance of the three methods when only one inner iteration ($I_{in}=1$) is used in the uncorrected implicit and corrected implicit methods (Table 2.1). The explicit method and the corrected implicit method with $I_{in}=1$ are identical in this case (see Theorem 2). Thus the same number of iterations is required to converge to the solutions. The computing times are slightly different since the implementations of the two methods are different. The uncorrected implicit method converges more slowly than the other two methods, which is reasonable since the correction step is needed to make it quadratically convergent.

TABLE 2.1
Experiments with the three methods.

($I_{in}=1$) Outer iterations (seconds)		
Explicit	Implicit	Corrected implicit
13 (0.44)	14 (0.40)	13 (0.40)

Next we increased the number of inner iterations in the uncorrected and corrected implicit methods. The experimental results (Tables 2.2 and 2.3) show that the number of outer iterations is sharply decreased when the number of inner iterations is two. However, the number of outer iterations decreases more slowly as I_{in} increases further. There exists an optimal value I_{in} for computing time in both the methods, but it is problem dependent. Our experiments also show that the corrected implicit method converges a little bit faster than the uncorrected implicit method when $I_{in}>1$, which is consistent with our convergence analysis. In § 5 we will see that for larger problems,

TABLE 2.2
Experiments with the (uncorrected) implicit method.

($I_{in} > 1$) Outer iterations (seconds)				
$I_{in} = 1$	$I_{in} = 2$	$I_{in} = 3$	$I_{in} = 4$	$I_{in} = 5$
14 (0.40)	8 (0.34)	7 (0.40)	6 (0.44)	6 (0.54)

TABLE 2.3
Experiments with the corrected implicit method.

($I_{in} > 1$) Outer iterations (seconds)				
$I_{in} = 1$	$I_{in} = 2$	$I_{in} = 3$	$I_{in} = 4$	$I_{in} = 5$
13 (0.40)	8 (0.38)	6 (0.36)	6 (0.50)	5 (0.54)

the improvements in time for the corrected implicit method with $I_{in} > 1$ can be considerably larger than those seen here. Also, we will see in §§ 4 and 5 that the decrease in iterations is advantageous for parallel computation.

3. Globally convergent modifications of the explicit and implicit methods. The explicit method and corrected implicit method are locally quadratically convergent to the solution. In other words, when the initial solution approximation is good enough, those methods are guaranteed to converge rapidly to a solution. However, it is often hard to find a good initial approximation for nonlinear problems in practice. In addition, many practical problems, such as the circuit equations, are highly nonlinear, and if the current solution approximation is not close enough, a Newton step may easily result in an increase in the function norm. For example, a small change in some voltage difference in a nonlinear circuit equation may result in a great change in an exponential term in a diode or transistor's function evaluation. Also, many block bordered equations result in nearly singular or singular Jacobians in the process of the iterations, for example, because a transistor with an exponential model is turned on at a nearly flat function curve (see Zhang, Byrd, and Schnabel [1989]). For these reasons, the methods need to be modified to handle unacceptable steps and singular Jacobian matrices in order to converge to a solution. In this section, we briefly describe the modifications we have used, which are motivated in part by their appropriateness for parallel distributed computation. They are described in more detail in Zhang [1989]. A global convergence analysis will be given in a forthcoming paper.

We achieve convergence from poor starting points by using a line search. The explicit method is just a standard Newton's method, so we can use a standard line search. That is, we calculate the overall step direction $d^k = (\Delta x_1^k \cdots \Delta x_q^k, \Delta x_{q+1}^k)$ as described in § 2.2, and then set

$$X^{k+1} = X^k + \lambda^k d^k,$$

where the steplength parameter $\lambda^k > 0$ is chosen by a line search procedure that assures sufficient descent on $\|F(X)\|_2$. Our line search is based upon Algorithm A6.3.1 in Dennis and Schnabel [1983].

The implicit method is more complicated since we have both inner and outer iterations. We need to choose the steps $\Delta x_i^{k,j} = (x_i^{k,j+1} - x_i^{k,j})$ in the inner iterations so that the overall step direction

$$d^k = \left(\sum_{j=0}^{I_{in}-1} \Delta x_1^{k,j} + \delta_1^k, \cdots, \sum_{j=0}^{I_{in}-1} \Delta x_q^{k,j} + \delta_q^k, \Delta_{q+1}^k \right), \tag{3.1}$$

where δ_i^k is the correction step (2.22), is a descent direction on $\|F(x)\|_2$. In addition, we would like the calculation of the steps $\Delta x_i^{k,j}$ for different values of i to be independent, so that the calculations of the inner iterations can be parallelized easily and efficiently.

Zhang [1989] shows that if each $\Delta x_i^{k,j}$ is calculated by

$$\Delta x_i^{k,j} = -\lambda_i^{k,j} A_i^{-1} f_i(x_i^{k,j}, x_{q+1}^k), \qquad i = 1, \cdots, q \tag{3.2}$$

(i.e., the step discussed in § 2.2 multiplied by a line search parameter $\lambda_i^{k,j} > 0$), the correction steps δ_i^k are calculated by (2.22), Δx_{q+1}^k is calculated by (2.11) as before, and f_{q+1} is linear, then d^k given by (3.1) satisfies

$$J(X^k)d^k$$

$$= -\left(\sum_{j=0}^{I_{in}-1} \lambda_1^{k,j} f_1(x_1^{k,j}, x_{q+1}^k), \cdots, \sum_{i=0}^{I_{in}-1} \lambda_q^{k,j} f_q(x_q^{k,j}, x_{q+1}^k), f_{q+1}(x_1^k, \cdots, x_q^k, x_{q+1}^k) \right).$$

Since the derivative of $\|F(X)\|_2^2$ in the direction d^k is equal to

$$F(X_k)^T J(X^k) d^k = -\sum_{i=0}^{q} \sum_{j=0}^{I_{in}-1} \lambda_i^{k,j} f_i(x_i^{k,j}, x_{q+1}^k)^T f_i(x_i^{k,0}, x_{q+1}^x) - \|f_{q+1}(X^k)\|^2,$$

it is clear that a sufficient condition for d^k given by (3.1) to be a descent direction on $\|f(X)\|_2$ is that for each $i = 1, \cdots, q$,

$$\sum_{j=0}^{I_{in}-1} \lambda_i^{k,j} f_i(x_i^{k,j}, x_{q+1}^k)^T f_i(x_i^{k,0}, x_{q+1}^k) > 0. \tag{3.3}$$

Note that (3.3) always holds for $I_{in} = 1$ (since each $\lambda_i^{k,1} > 0$), and that it is true for $I_{in} = 2$ if $\|f_i(x_i^{k,1}, x_{q+1}^k)\| < \|f_i(x_i^{k,0}, x_{q+1}^k)\|$ (which any line search will enforce) and $\lambda_i^{k,1} \leqq \lambda_i^{k,0}$. Thus we expect to get a descent direction most of the time. However, since (3.3) can be monitored independently for each i, the following parallel procedure could be used to guarantee that a descent direction is generated. For each j, the procedure calculates each $\Delta x_i^{k,j}$ by (3.2) using a standard line search as mentioned above, and then checks whether the corresponding partial sum of (3.3) is satisfied. If it is not, it sets $\Delta x_i^{k,l} = 0$ for $l = j, \cdots, I_{in} - 1$ and exits the inner iteration for x_i. The outer line search can be performed as in the explicit method.

Our approach for dealing with (nearly) singular Jacobians is based upon the Levenberg-Marquardt approach as described in Dennis and Schnabel [1983]. For a general system of nonlinear equations, if the current Jacobian matrix J is (nearly) singular, this approach modifies the search direction to be $-(J^TJ + \mu I)^{-1} J^T F$, where F is the current function value, and μ is a small positive number. This direction is a descent direction on $\|F(x)\|_2$ and is the solution to the trust region problem

$$\text{minimize}_d \ \|F + Jd\|_2 \quad \text{subject to } \|d\|_2 \leqq \Delta$$

for some $\Delta > 0$. In the limit as $\mu \to 0$, this direction equals $-J^+F$, where J^+ is the pseudoinverse of J.

In the explicit and implicit methods described in § 2, we need to solve systems of linear equations using the matrices $A_1, \cdots, A_q$ and the matrix $\hat{J} = P - \sum_{i=1}^{q} C_i A_i^{-1} B_i$. If any of these matrices, say, M, is nearly singular (i.e., either the factorization detects numerical singularity or the estimated condition number of M is greater than *macheps*$^{-1/2}$) we simply replace M^{-1} by $(M^T M + \mu I)^{-1} M^T$ in the formulas of § 2, where μ is chosen by the trust region strategy described by Dennis and Schnabel [1983], and is thus a function of M and the trust region size. These perturbations again have interpretations in terms of trust regions. Note also that the algorithms for deciding whether to perturb each $A_1, \cdots, A_q$, and for perturbing them if necessary, are totally independent so that they can be performed in parallel.

Combining these perturbation techniques with the inner line searches to assure descent at the outer iteration and global convergence is somewhat more complex, and will be addressed in a future paper. In our implementations, we have simply taken I_{in} inner iterations for each block i, $i = 1, \cdots, q$. We have used a standard line search to choose each $\lambda_i^{k,j}$ (requiring sufficient descent on f_i) but have not checked a condition like (3.3) that assures global descent, as this condition is more restrictive than necessary. To our knowledge, the algorithm has still always produced a descent direction.

The algorithm we implement is summarized below. If J or any A_i below is (nearly) singular, $\hat{J}^{-1}$ or A_i^{-1} is replaced by $(\hat{J}^T \hat{J} + \mu I)^{-1} J^T$ or $(A_i^T A_i + \mu_i I)^{-1} A_i^T$ for a small positive μ or μ_i, respectively. When f_{q+1} is linear, the explicit method is just a special case with $I_{in} = 1$ and each $\lambda_i^{k,1} = 1$.

IMPLICIT METHOD WITH GLOBAL MODIFICATION

1. For $j = 0, \cdots, I_{in} - 1$, calculate $x_i^{k,j+1} = x_i^{k,j} - \lambda_i^{k,j} A_i^{-1} f_i(x_i^{k,j}, x_{q+1}^k)$ where $\lambda_i^{k,j} \geqq 0$, $i = 1, \cdots, q$.
2. Form and factor $\hat{J} = P - \sum_{i=1}^{q} C_i A_i^{-1} B_i$.
3. Calculate $\Delta x_{q+1}^k = -\hat{J}^{-1} f_{q+1}(x_1^{k,I_{in}}, \cdots, x_q^{k,I_{in}}, x_{q+1}^k)$.
4. Calculate the corrections $\delta_i^k = -A_i^{-1} B_i \Delta x_{q+1}^k$ and set $\bar{x}_i^{k+1} = x_i^{k,I_{in}} + \delta_i^k$, $i = 1, \cdots, q$.
5. Calculate $X^{k+1} = X^k - \lambda^k d^k$ where $d^k = (\bar{x}_1^{k+1} - x_1^k, \cdots, \bar{x}_q^{k+1} - x_q^k, \Delta x_{q+1}^k)$.

4. Parallel explicit and implicit algorithms.

4.1. Motivation—LU factorization of block bordered linear equations.

Note that the LU factorization of the block bordered Jacobian matrix

$$\begin{pmatrix} A_1 & & & & B_1 \\ & A_2 & & & B_2 \\ & & \ddots & & \vdots \\ & & & A_q & B_q \\ C_1 & C_2 & \cdots & C_q & P \end{pmatrix}$$

is

$$\begin{pmatrix} L_1 & & & & \\ & L_2 & & & \\ & & \ddots & & \vdots \\ & & & L_q & \\ \hat{C}_1 & \hat{C}_2 & \cdots & \hat{C}_q & L_{q+1} \end{pmatrix} \begin{pmatrix} U_1 & & & & \hat{B}_1 \\ & U_2 & & & \hat{B}_2 \\ & & \ddots & & \vdots \\ & & & U_q & \hat{B}_q \\ & & \cdots & & U_{q+1} \end{pmatrix},$$

where for $i = 1, \cdots, q$,

$$A_i = L_i U_i,$$
$$\hat{B}_i = L_i^{-1} B_i,$$
$$\hat{C}_i = C_i U_i^{-1},$$

and

$$L_{q+1}U_{q+1}=\hat{J}=P-\sum_{i=1}^{q} C_iA_i^{-1}B_i=P-\sum_{i=1}^{q} \hat{C}_i\hat{B}_i,$$

provided that the matrices A_i are nonsingular. (This is the same matrix $\hat{J}$ as in § 2.) The calculations of L_i, U_i, $\hat{B}_i$, and $\hat{C}_i$ for each i are independent, and thus can be parallelized very efficiently. The factorization of $\hat{J}$ must follow these calculations and will not parallelize as efficiently, especially on distributed memory multiprocessors, because it will require considerable communication.

A parallel version of the explicit method essentially consists of performing the above factorization in parallel at each iteration. The parallel version of the implicit method that we discuss next will be seen to perform closely related operations. The major difference will be that, by performing more than one inner iteration per outer iteration, it will spend a larger portion of its time on the calculations that parallelize very efficiently (those for blocks $1, \cdots, q$) and a smaller portion of its time on the calculations that parallelize less well—the formation and factorization of $\hat{J}$ and the outer line search. Thus the implicit method can be expected to parallelize more effectively than the explicit method, especially on distributed memory computers. If the two methods require similar amounts of time on sequential computers, as indicated in § 2, then the implicit method can be expected to be faster on parallel computers.

4.2. Parallel algorithms. Below we give a general description of a parallel corrected implicit method that is based upon the sequential method presented in §§ 2 and 3. The parallelism comes mainly from executing all the operations on blocks 1 through q, which have been designed to be independent, concurrently. The parallel explicit method is just the special case with $I_{in}=1$ and no inner line search.

```
INNER ITERATIONS
1. For $i=1, q$, Do in parallel:
   1.1. Factor $A_i$ and estimate its condition number Cond $(A_i)$.
   1.2. If Cond $(A_i)\leqq Tol$ then set $M_i=A_i$, $N_i=I$.
        Else choose $\mu_i>0$, form and factor $M_i=A_i^TA_i+\mu_iI$, set $N_i=A_i^T$.
   1.3. For $j=0, I_{in}-1$, Do:
        Solve $M_i\Delta x_i^{k,j}=-N_if_i(x_i^{k,j}, x_{q+1}^k)$ for $\Delta x_i^{k,j}$.
        Inner line search: $x_i^{k,j+1}=x_i^{k,j}+\lambda_i^{k,j}\Delta x_i^{k,j}$ for some $\lambda_i^{k,j}>0$.
   1.4. Solve $M_iW_i=N_iB_i$ for $W_i$.
   1.5. Calculate $T_i=C_iW_i$.

OUTER ITERATION
*2. Form $\hat{J}=P-\sum_{i=1}^q T_i$.
*3. Factor $\hat{J}$ and estimate its condition number Cond $(\hat{J})$.
*4. If Cond $(\hat{J})\leqq Tol$ then set $M=\hat{J}$, $N=I$.
    Else choose $\mu>0$, form and factor $M=\hat{J}^T\hat{J}+\mu I$, set $N=\hat{J}^T$.
*5. Solve $M\Delta x_{q+1}^k=-Nf_{q+1}(x_1^{k,I_{in}}, \cdots, x_q^{k,I_{in}}, x_{q+1}^k)$ for $\Delta x_{q+1}^k$.
 6. For $i=1, q$, Do in parallel:
    Calculate corrections $\delta_i^k=-W_i\Delta x_{q+1}^k$ and set $\bar{x}_i^{k+1}=x_i^{k,I_{in}}+\delta_i^k$.
*7. Outer line search: $X^{k+1}=X^k+\lambda^k(\bar{x}_1^{k+1}-x_1^k, \cdots, \bar{x}_q^{k+1}-x_q^k, \Delta x_{q+1}^k)$ for some
    $\lambda^k>0$.
```

The steps marked with stars require synchronization (on a shared memory multiprocessor) or communication (on a distributed memory multiprocessor). Step 2 requires synchronization if the matrices T_i are full. In the VLSI problems, however, the nonzero columns of B_i, and hence T_i, are disjoint (see § 1.2) and hence step 2 can be performed in parallel.

On shared memory machines, steps 3-5 can be performed in parallel using standard parallel methods for solving linear equations. On a distributed memory machine, it will only be efficient to perform steps 3-5 in parallel if the dimension of $\hat{J}$ is rather large. In our test problems, $\hat{J}$ was fairly small, so we performed steps 3-5 on one processor, on which we kept P, $\hat{J}$, and x_{q+1}. The remaining data was distributed in the obvious way: A_i, B_i, C_i, and x_i were stored together on one processor that handled block i. Step 7 includes two main operations, the calculation of trial points $\bar{x}^{k+1}$ and the evaluations of F at the points, which are performed in parallel on a shared memory machine, and may be performed in parallel on a distributed memory machine depending on their costs relative to the cost of communication.

5. Experimental results on a hypercube multiprocessor.

5.1. The test problem: A nonlinear block bordered circuit equation. The nonlinear block bordered application we consider for testing is the VLSI circuit simulation problem. Standard circuit simulation methods consist of stiffly stable implicit integration formulae to discretize the differential equations, Newton's method to solve the resulting nonlinear algebraic equations

$$F(X)=0, \tag{5.1}$$

and sparse LU decomposition to solve the linear equations that arise at each iteration

$$J\Delta X=-F(X), \tag{5.2}$$

where $J \in R^{n\times n}$ is the Jacobian matrix of (5.1). Typically, less than 2 percent of the entries of J are nonzero for $n>500$ (see, e.g., Sangiovanni-Vincentelli and Webber [1986]). The Newton iteration is repeated until the solution converges or the upper bound on the number of iterations is reached. The program then decides whether to accept the solution, based on its estimate of local truncation error and the number of iterations required.

As mentioned in § 1.2, partitioning the circuit leads to a block bordered system of nonlinear equations of the form (1.1) (see, e.g., Rabbat, Sangiovanni-Vincentelli, and Hsieh [1979]). Given a circuit network Γ, a group of partitioned subnetworks γ_i, $i=1,\cdots,q$, and the connecting current and voltage equations, the block bordered nonlinear system of equations is defined as follows. Currents between two subnetworks and voltages at the boundary are each represented by two variables, one in each subnetwork, which are set equal to each other by equations of f_{q+1}. Variables x_i $(i=1,\cdots,q)$ are used to represent internal voltages and current variables in each of the q independent subnetworks. Some of these are the current connecting variables among the q subnetworks. The variables x_{q+1} are used to represent the voltage connecting variables among the q subnetworks. Here the equations for voltages and currents are standard current equations involving resistors, transistors, diodes, voltage sources, and other elements. Since the connecting equation f_{q+1} is linear, the coefficient matrices C_i, $i=1,\cdots,q$ for the current connecting functions are constant, and the coefficient matrix P for the voltage connecting function is also constant.

For a very large circuit, the network Γ may be divided into subnetworks recursively, which leads to a multilevel block bordered system of nonlinear equations. In such a case, the diagonal blocks A_i $(i=1,\cdots,q)$ are themselves block bordered matrices. The border elements of the multilevel system represent the connections of the highest level.

We applied our algorithm to a simulation of the 741 op-amp circuit (see, e.g., Sedra and Smith [1982]), which was introduced in 1966 and is currently produced by almost every analog semiconductor manufacturer. The circuit is partitioned into four parts with roughly equal nodes in each subcircuit. A transistor is viewed as a nonlinear three-terminal device in the circuit. Thus, applying the Ebers–Moll transistor model (see Ebers and Moll [1954]), 24, 27, 23, and 27 KCL functions are defined in the first, second, third, and fourth block, respectively. The seven connections among the four blocks result in 14 linear current and voltage connecting functions. The total number of variables is $24+27+23+27+14=115$.

We also used a large analog filter composed of three 741 op-amp circuits (see, e.g., Smith [1971] and Valkenburg [1982]) to construct a two-level block bordered nonlinear system. The analog filter is first partitioned into three parts, each of which contains one 741 op-amp circuit. The first-level block bordered structure is thus formed with three diagonal blocks and one connecting block. Each of the diagonal blocks is a 741 op-amp circuit that is partitioned into the second-level block bordered structure.

5.2. The 741 op-amp circuit simulation on the Intel Hypercube. The nonlinear block bordered equations of the 741 op-amp circuit were solved in parallel on an Intel iPSC1 hypercube using the algorithm of § 4.2. The four blocks of the circuit were distributed among four nodes of the hypercube. For convenience, the steps involving the connection function f_{q+1} (steps 3–5 of the parallel algorithm) were performed on a different node which plays the control role. They could just as well have been done on one of the four nodes. Identical initial values were used as the inputs for all the above experiments, and the convergence tolerances were also the same for those experiments. The solutions of the experiments were verified by comparing them to the solutions computed by the program SPICE, which is a general-purpose circuit simulation program for nonlinear dc, nonlinear transient, and linear ac analysis (see Newton, Pederson, and Sangiovanni-Vincentelli [1988]).

Tables 5.1 and 5.2 show the experimental results for the explicit method. Tables 5.3 and 5.4 list the experimental results for the corrected implicit method with one or more than one inner iterations per outer iteration and with inner line searches. Note that as long as the inner line search is applied, the corrected implicit method even with one inner iteration per outer iteration is not the same as the explicit method.

In Tables 5.1 and 5.3, T_i $(i=1,\cdots,4)$ is the total computing time for all computations for solving the ith diagonal block on node i, T_b is the total computing time for all computations for solving the bottom block on the control node, T_c is the total

communication time for the computation, N_{out} is the total number of outer iterations required to converge to the solution, and I_{in} in Table 5.3 is the number of inner iterations used in the corrected implicit method. In the performance Tables 5.2 and 5.4, T_s is the computing time for solving the same problem on one node:

$$T_s = \sum_{i=1}^{4} T_i + T_b,$$

T_p is the parallel computing time;

$$T_p = \max(T_i, \cdots, T_4) + T_b + T_c,$$

sp is the speedup of the parallel computation:

$$sp = \frac{T_s}{T_p},$$

and eff is the parallel efficiency defined by

$$eff = \frac{sp}{\text{number of processors}}.$$

Our experiments show that the inner line search and inner iterations indeed speed up the convergence to the solution. For example, the experiment with one inner iteration with inner line search used 18 iterations to converge to the solution. The same experiment without inner line search (explicit method) used 20 iterations. As the number of inner iterations I_{in} is increased, the total number of outer iterations N_{out} decreases from 18 to 11, and the speedup increases because the bottom block computations constitute a smaller percentage of the overall computation. However, the sequential computing time only decreases by a small amount for $I_{in} = 3$, and then increases dramatically because the cost of the extra inner iterations swamps the small savings from the further decrease in the number of outer iterations. Both the sequential and parallel computing times are minimized when the number of inner iterations is $I_{in}=3$, and the speedup in this case, 3.43, is good.

Our experiments also show that the bottleneck computing time T_b of the corrected implicit method is more than 50 percent lower than in the explicit method if more than one inner iteration is applied. The communication time is also lower since the total number of iterations, and hence the time to send the updated variables among the nodes, is less than for the explicit method. Consequently, the advantage of the implicit method over the explicit method should be greater in larger problems where the amount of communication and cost of solving the bottom block are larger.

5.3. Experiments for two-level block bordered circuit equations. We also solved in parallel the two-level system of nonlinear block bordered equations for an analog filter formed by connecting together three blocks of the 741 op-amp circuit. We again used the Intel iPSC1 hypercube multiprocessor. The linearization of these equations at each iteration has the form

$$J\Delta X=-F, \tag{5.3}$$

where J is the two-level block bordered matrix

$$\left(\begin{array}{ccccccccccccc}
A_1^1 & & & B_1^1 & & & & & & & & & \\
 & \ddots & & \vdots & & & & & & & & & \hat{B}_1 \\
 & & A_q^1 & B_q^1 & & & & & & & & & \\
C_1^1 & \cdot & C_q^1 & P^1 & & & & & & & & & \\
 & & & & A_1^2 & & & B_1^2 & & & & & \\
 & & & & & \ddots & & \vdots & & & & & \hat{B}_2 \\
 & & & & & & A_q^2 & B_q^2 & & & & & \\
 & & & & C_1^2 & \cdot & C_q^2 & P^2 & & & & & \\
 & & & & & & & & A_1^3 & & & B_1^3 & \\
 & & & & & & & & & \ddots & & \vdots & \hat{B}_3 \\
 & & & & & & & & & & A_q^3 & B_q^3 & \\
 & & & & & & & & C_1^3 & \cdot & C_q^3 & P^3 & \\
 & \hat{C}_1 & & & & \hat{C}_2 & & & & \hat{C}_3 & & & \hat{P}
\end{array}\right),$$

$$\Delta X=(\Delta x_1^1,\cdots,\Delta x_q^1,\Delta x_{q+1}^1,\Delta x_1^2,\cdots,\Delta x_q^2,\Delta x_{q+1}^2,\Delta x_1^3,\cdots,\Delta x_q^3,\Delta x_{q+1}^3,\Delta\hat{x}_{q+1})^T,$$

and

$$F=(f_1^1,\cdots,f_q^1,f_{q+1}^1,f_1^2,\cdots,f_q^2,f_{q+1}^2,f_1^3,\cdots,f_q^3,f_{q\times1}^3,\hat{f}_{q+1})^T.$$

The system (5.3) could be solved by applying the block bordered solver to each of the three block bordered submatrices, and then solving the whole system by applying the block bordered solver again. Alternatively, the block bordered Jacobian matrix may be reordered to

$$\begin{bmatrix}
A_1^1 & & & & & & & & & B_1^1 & & & \\
& \cdot & & & & & & & & \cdot & & & \hat{B}_1 \\
& & A_q^1 & & & & & & & B_q^1 & & & \\
& & & A_1^2 & & & & & & & B_1^2 & & \\
& & & & \cdot & & & & & & \cdot & & \hat{B}_2 \\
& & & & & A_q^2 & & & & & B_q^2 & & \\
& & & & & & A_1^3 & & & & & B_1^3 & \\
& & & & & & & \cdot & & & & \cdot & \hat{B}_3 \\
& & & & & & & & A_q^3 & & & B_q^3 & \\
C_1^1 & \cdot & C_q^1 & & & & & & & P^1 & & & \\
& & & C_1^2 & \cdot & C_q^2 & & & & & P^2 & & \\
& & & & & & C_1^3 & \cdot & C_q^3 & & & P^3 & \\
& \hat{C}_1 & & & \hat{C}_2 & & & \hat{C}_3 & & & & & \hat{P}
\end{bmatrix},$$

with ΔX reordered to

$$\Delta X = (\Delta x_1^1, \cdots, \Delta x_q^1, \Delta x_1^2, \cdots, \Delta x_q^2, \Delta x_1^3, \cdots, \Delta x_q^3, \Delta x_{q+1}^1, \Delta x_{q+1}^2, \Delta x_{q+1}^3, \Delta \hat{x}_{q+1})^T,$$

and F reordered to

$$F = (f_1^1, \cdots, f_q^1, f_1^2, \cdots, f_q^2, f_1^3, \cdots, f_q^3, f_{q+1}^1, f_{q+1}^2, f_{q+1}^3, \hat{f}_{q+1})^T.$$

In solving this block bordered system, two levels of parallelism can be exploited. Let m be the number of amplifiers in the analog filter and q the number of subcircuits inside each amplifier; here $m = 3$ and $q = 4$. First the $m \times q$ independent operations for solving the diagonal blocks can be performed in parallel. Second, the m independent operations for transforming the matrices P^j, $j = 1, \cdots, m$, and solving the resultant systems of equations can be performed in parallel. Finally, the very bottom block, with the matrix $\hat{P}$, must be transformed and solved.

In our test program, the 12 diagonal block equations of the analog filter were distributed among 12 nodes of the Intel hypercube. The first level of internal connection functions in each amplifier, f_{q+1}^j $(j = 1, \cdots, 3)$, was distributed to three of the 12 nodes, and the second level connection function among the three amplifiers in the analog filter, $\hat{f}_{q+1}$, was handled sequentially by one of the 12 nodes.

Tables 5.5 and 5.6 give the experimental results and the performance of the explicit method for solving the two-level analog filter equation. Tables 5.7-5.11 show the

experimental results and performance of the corrected implicit method for solving the two-level block bordered analog filter equations with one to four inner iterations. The symbols in the tables have the same meanings as in Tables 5.1–5.4, with the following exception: T_i, $i = 1, \cdots, 12$, is the total time for the 12 first-level blocks, while T^j, $j = 1, 2, 3$, is the time for the three second-level blocks.

Our experimental results show that the corrected implicit method is also more efficient than the explicit method on this larger block bordered system of equations. The total number of iterations N_{out} decreases from 18 to 11 as the number of inner iterations I_{in} is increased from 1 to 4, but the sequential computing time T_b only decreases from 157.19 to 148.68 for $I_{in} = 2$, then increases again. The high speedups for $I_{in} = 3$ and 4 in comparison to the same sequential method are not significant since the large number of inner iterations makes the algorithm inefficient, and the sequential time is suboptimal. For the optimal number of inner iterations, $I_{in} = 2$, the speedup is 10.01 out of 12 processors and the efficiency is 83.40 percent. The computation time improvement over the parallel explicit method is 28 percent, as compared to 19 percent in the sequential case. Our parallel analog filter simulation experiment indicates that applying the implicit method to solving large block bordered circuit equations on a distributed memory multiprocessor can result in high efficiency.

6. Summary and future research. We have introduced a corrected implicit method for solving block bordered systems of nonlinear equations. It allows multiple "inner" iterations, iterations on the variables, and equations of the q diagonal blocks, to be performed per each "outer" iteration, which involves all the variables and equations including the connecting bottom block. If only one inner iteration is performed per outer iteration, no line search is used, and the bottom connecting equations are linear, then the corrected implicit method is identical to the explicit method (Newton's method). When more than one inner iteration is performed per outer iteration, however, the methods are different, and in our experiments the corrected implicit method solves problems in somewhat less time than the explicit method on sequential computers. On parallel computers, the corrected implicit method has a larger advantage over the explicit method because it parallelizes more effectively, since the inner iterations constitute a larger percentage of the total computation and parallelize far better than the outer iterations. On one- and two-level block bordered problems from VLSI circuit design that we tested, the parallel efficiency of the fastest (sequential and parallel) corrected implicit method on an Intel iPSC1 hypercube was about 85 percent.

The methods presented in this paper all assume that the Jacobian matrix is available at each iteration, either analytically or by finite differences, and that it is not too expensive to evaluate. In some applications, however, the nonlinear equations are given by an expensive computational procedure, and analytic or finite difference Jacobians are very expensive to obtain. In such cases, for general systems of nonlinear equations, secant approximations to the Jacobian are used that are based entirely on function values at the iterates (see, e.g., Dennis and Schnabel [1983]). The development of related secant approximations to the Jacobian for block bordered nonlinear equations seems to be an attractive research topic, since it appears possible to construct approximations that retain the block bordered sparsity pattern of the Jacobian, and also allow the factorization of the Jacobian approximation to be updated efficiently.

AN EFFICIENT SCHEME FOR UNSTEADY FLOW PAST AN OBJECT WITH BOUNDARY CONFORMAL TO A CIRCLE*

MO-HONG CHOU†

Abstract. An efficient finite-difference method is presented for studying unsteady two-dimensional incompressible flow past an object with boundary conformal to a circle. At each time step the computations of vorticity transport and streamfunction are decoupled and based on a body-fitted, prowake, orthogonal grid. To handle the no-slip condition properly and efficiently, a new wall-vorticity conditioning algorithm is proposed and incorporated into the vorticity transport equation. When the object presents sharp edges, this algorithm performs particularly well in that it yields a significant increase in the time step increment that can be used in comparison to other known "decoupled" methods. In the method developed here the vorticity is advanced by an implicit scheme of Crank-Nicholson type, and the streamfunction equation is solved by a multigrid technique based on body-fitted coordinates. As an application, the experiment on flow past an inclined thin ellipse with angle of attack ranging from 5° to 85°, and at Reynolds number 200 and 400, is presented in detail. Depending on the angle of attack, the computed results present in the long run a quasi-steady or quasi-periodic feature, as demonstrated by the flow pattern and by the curves of drag, lift, and moment coefficients. Furthermore, the pivot point, with respect to which the thin ellipse exercises no torque, is also investigated and compared to the asymptotic result based on Kirchhoff theory. Such a result might be useful in modeling a pivoting prosthetic heart valve.

1. Introduction. In this paper we present a finite-difference method to tackle the problem of unsteady two-dimensional flow past an object with boundary conformal to a circle. Such a problem is encountered, for example, in the modeling of prosthetic heart valves [7]. The numerical simulation is based on the unsteady Navier-Stokes equations, which are written in terms of vorticity and streamfunction. Some important features in our scheme are stated as follows.

We propose a novel, body-fitted, orthogonal grid system which, in contrast to the standard radial coordinates, automatically provides a prowake computational domain. Such a setup facilitates long time computations in the wake region. At each time step, the computations of vorticity and streamfunction are decoupled. The vorticity transport equation is handled by a Crank-Nicholson-type scheme in which a new wall-vorticity algorithm is incorporated. This algorithm provides a mechanism to couple the interior vorticity and the wall vorticity in such a way that the no-slip condition is handled properly and efficiently. This idea of vorticity conditioning is similar to that of Quartapelle's [8] in that the Green's identity plays an important role in both cases. However, as seen in § 2, our implementation is quite different from [8]. Owing to such an approach, the stability of the proposed numerical scheme is increased, and hence we are able to employ a larger time increment than can be used with other known "decoupled" schemes (see [5], for example). The elliptic problem that determines the streamfunction is solved by a multigrid method. The rate of convergence of the iterative method is extremely fast, as compared, for example, to unigrid line SOR [5]. The accuracy of the whole scheme is approximately of the second order in space. The temporal accuracy of the proposed Crank-Nicholson-like scheme, strictly speaking,

† Institute of Mathematics, Academia Sinica, Nankang, Taipei, Taiwan 11529, Republic of China.

is of the first order, since there is a time lag in updating the streamfunction. However, the efficiency we have gained from this scheme is better than the backward Euler scheme. Finally, since the computation domain is doubly connected, the single-valuedness of the surface fluid pressure might be of great concern in the conventional approach to compute the fluid dynamic properties, such as drag and lift (see Wu [12]). We propose an alternative to circumvent this difficulty. The idea has the same spirit as our vorticity conditioning algorithm. Namely, the Green's identity is employed together with auxiliary functions in order to get an integral viewpoint of the desired data. Van Der Vegt [11] has also used such an alternative in conjunction with discrete vortex methods. For flow past an object with sharp edges, this alternative is important in our experience in that it generates much smoother data, especially when we use an unsteady approach to quasi-steady flow problems.

This paper is organized as follows. In § 2 we present the details of our approach for the problem of flow past an inclined thin ellipse. For other bodies, the only adaptation required is the change of the conformal mapping from a circle to the boundary of the object. As we check on the accuracy of our approach, we compare our results with an asymptotic result concerning the pivot point about which the ambient fluid exerts no torque on the ellipse. This asymptotic result is presented in § 3. This result is derived from the classical Kirchhoff–Rayleigh theory and provides elegant information on how this point varies with the angle of attack, which would be quite useful, for example, for designing a pivoting artificial heart valve whose maximum angle of opening (that is, 90° minus the torque-free angle of attack) matches the physiological conditions (see the work of Peskin and McQueen [7]).

The efficiency and accuracy of our approach is demonstrated in § 4 for flow past an inclined thin ellipse. The angle of attack ranges from 5° to 85°. The Reynolds number is taken to be between 200 and 400. Depending on the angle of attack, the computed results present, in the long run, a quasi-steady or quasi-periodic feature, as demonstrated by the flow pattern (streamlines, lines of equal vorticity) and by the curves of drag, lift, and moment coefficients. Among these computed results a particular case of 45° incidence is also compared with the work of Lugt and Haussling [5], where good agreement is shown. Furthermore, the aforementioned zero-torque pivot point is also investigated and compared with the Kirchhoff theory. The Strouhal number, regarded as a function of the angle of attack, is also compared with some relevant experiments [1], [2], [5], and it is shown that our result is within the correct range.

2. Numerical method for Navier–Stokes equations. As sketched in Fig. 1, we consider a uniform flow, with density $\rho \equiv 1$ and velocity $(U_\infty 0)$ at infinity, past a thin ellipse inclined at an angle of attack α measured clockwise from the negative x axis. The thinness of the ellipse is measured by the aspect ratio $\lambda \equiv l/L$, in which $l(L)$ denotes the length of the short(long) axis. In our consideration $\lambda = 0.1$ (or 10 percent) is taken in order to have the results directly compared with existing literature.

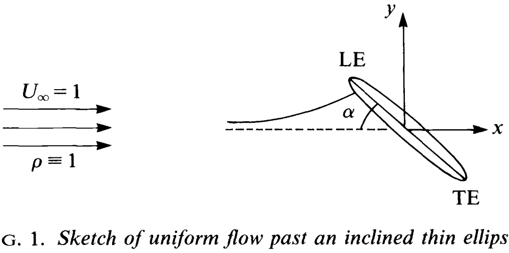

FIG. 1. *Sketch of uniform flow past an inclined thin ellipse.*

The flow is governed by unsteady Navier-Stokes equations, which we write in terms of vorticity(ω) and streamfunction(ψ) as follows.

$$\omega_t + \psi_y\omega_x - \psi_x\omega_y = \frac{2}{R}(\omega_{xx} + \omega_{yy}), \tag{2.1}$$
$$\psi_{xx} + \psi_{yy} = -\omega.$$

System (2.1) is supplemented by some initial and boundary conditions, which will be stated later. Note that in (2.1) the length scale is based on half long axis, i.e., $L/2$, while the Reynolds number R is defined as $R = (LU_\infty/\nu)$ (ν is the kinematic viscosity).

The proposed finite-difference scheme for solving (2.1) starts with the following generation of a body-fitted orthogonal coordinate system. This system is essentially composed of two conformal mappings. Let $z = x + iy$ denote the physical coordinates, and $\zeta = \xi + is$ the transformed coordinates (note that $i = \sqrt{-1}$). Then, the map $z = z(\mathfrak{z}(\zeta))$ is determined as follows.

$$z = \frac{\sqrt{1-\lambda^2}}{2}\left(\mathfrak{z} + \frac{e^{-2i\alpha}}{\mathfrak{z}}\right) \quad \text{for } |\mathfrak{z}| \geqq \sqrt{\frac{1+\lambda}{1-\lambda}} \equiv d; \tag{2.2a}$$

$$\zeta = \frac{-i}{2d}\left(\mathfrak{z} - \frac{d^2}{\mathfrak{z}}\right) + \frac{\Gamma}{\pi i}\operatorname{Log}(\mathfrak{z}/d) \quad \text{for } \zeta \text{ such that } -\Gamma \leqq \xi \leqq \Gamma,\ s \leqq 0. \tag{2.2b}$$

We note that (2.2a) provides desired high resolution in the vicinity of the edges (where $\mathfrak{z} = \pm de^{-i\alpha}$) of the ellipse, as is done in the standard elliptic coordinates. The novelty of our system is due to (2.2b), which generates a prowake computation domain (see Fig. 3) through the introduction of a strong circulation term with strength $2\Gamma \gg 0$. To increase the resolution in the proximity of the ellipse, a quadratic scaling in the s-direction is also introduced. Namely, let a, b be suitable positive constants; then

$$s = -(a\eta + b\eta^2) \equiv f(\eta) \quad \text{for } \eta \geqq 0. \tag{2.2c}$$

We also note that, in our scheme, (2.2a) is the only component that varies with the boundary of the object in consideration.

By virtue of (2.2), the Navier-Stokes equations (2.1) are transformed into the following. For $(\xi, \eta) \in [-\Gamma, \Gamma] \times [0, \eta_\infty]$,

$$(Jf'^2)\omega_t + f'(\psi_\eta\omega_\xi - \psi_\xi\omega_\eta) = \frac{2}{R}\left[\omega_{\eta\eta} - \frac{f''}{f'}\omega_\eta + f'^2\omega_{\xi\xi}\right], \tag{2.3a}$$

$$\psi_{\eta\eta} - \frac{f''}{f'}\psi_\eta + f'^2\psi_{\xi\xi} + (Jf'^2)\omega = 0. \tag{2.3b}$$

In (2.3), $J = |dz/d\zeta|^2$ is the Jacobian of the mapping composed of (2.2a) and (2.2b), and f', f'' denote the first and second derivatives of the function f defined in (2.2c). Note that, in the sequel, J is modified to denote the combined term Jf'^2.

The initial condition of (2.3) is specified by uniform potential flow past the given ellipse. We denote the initial streamfunction by ψ°. With the aid of Fig. 3, in which the mapping (2.2) is sketched, boundary conditions are specified as follows.

(2.4a) $\psi = \dfrac{\partial \psi}{\partial \eta} = 0$ for $\eta = 0$, $-\Gamma \leqq \xi \leqq \Gamma$;

(2.4b) $\psi(-\Gamma, \eta) = \psi(\Gamma, \eta)$, $\omega(-\Gamma, \eta) = \omega(\Gamma, \eta)$ for $0 \leqq \eta \leqq \eta^*$, where, associated with (2.2), $\zeta = \pm\Gamma + if(\eta^*)$ is the point(s) such that $|z'(\zeta)| = \infty$;

(2.4c) $\psi(\pm\Gamma, \eta) = \psi^\circ(\pm\Gamma, \eta)$, $\omega(\pm\Gamma, \eta) = 0$ for $\eta^* \leqq \eta \leqq \eta_\infty$,

(2.4d) $\dfrac{\partial \psi}{\partial \eta} = \dfrac{\partial \psi^\circ}{\partial \eta}$, and ω is updated through (2.3a) with $R = \infty$, for $\eta = \eta_\infty$, $-\Gamma \leqq \xi \leqq \Gamma$.

We note in passing that in our experiment the downstream boundary conditions for ψ, as proposed by Lugt and Haussling [5] and by Mehta and Lavan [6], will lead to abnormal vorticity accumulation along the downstream boundary for long-term computation, unless η_∞ is sufficiently large. To obtain comparable results, condition (2.4d), on the other hand, allows us to use smaller η_∞, which in turn leads to a smaller algebraic system to be solved.

In our computation, the vorticity and streamfunction are decoupled at each time step. According to such an approach the specification of wall vorticity plays a very important part in the stability consideration, especially in the presence of sharp edges. The standard method, which utilizes (2.3b) together with (2.4a), places a severe limitation on the time increment (see [5], for example). To relax this limitation, we propose a new approach, which is based on the following theorem.

THEOREM 1. (As shown in Fig. 2.) *Let Ω be a neighborhood of the ellipse. The boundary $\partial\Omega = B_0 \cup B_1$ with unit outer normal ν. If ω, ψ are such that $\Delta\psi = -\omega$ in Ω and $\psi \equiv$ constant on B_0, then the condition that $\partial\psi/\partial\nu = 0$ on B_0 is equivalent to the following*:

(2.5a) $$\int_\Omega \omega g_n\,dxdy + \oint_{B_1} \left[g_n \frac{\partial \psi}{\partial \nu} - \psi \frac{\partial}{\partial \nu}(g_n) \right] ds = 0 \quad \textit{for } n = 0, 1, 2, \cdots,$$

where, with the aid of (2.2), *the auxiliary functions g_n are given by*

(2.5b) $$g_n(z) \equiv g_n(z(\zeta)) = \exp(i\pi n(\bar{\zeta} + \Gamma)/\Gamma) \quad \textit{for } n = 0, 1, 2, \cdots.$$

The proof of Theorem 1 is a straightforward application of Green's theorem and Fourier analysis, and is therefore omitted.

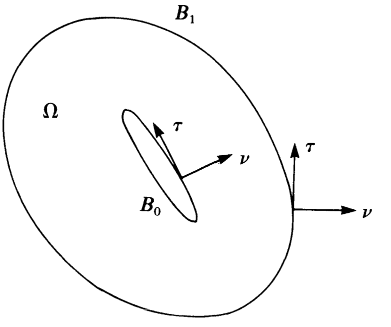

FIG. 2. *Illustration of Theorem* 1 *for wall-vorticity conditioning.*

This idea of replacing the no-slip condition by a set of integral constraints on ω has been used, for example, by Quartapelle [8]. As compared to [8], some major differences are noted below. First, the integration domain Ω is just a small portion of the whole computational domain. Thus, for each n, (2.5) contains a term involving ψ, which, though not known in advance, is assumed to have a smooth time-varying property provided that B_1 is chosen not too close to the ellipse B_0. Second, the test harmonic functions, i.e., $\{g_n\}$, are given analytically. However, the expression of ω in terms of $\{g_n\}$ is not pursued. Thus Theorem 1 is applied to vorticity conditioning in a way quite different from [8], as will be seen below.

The transformed Navier–Stokes equations (2.3) are discretized over a uniform grid. Centered differencing is used to approximate spatial differentiation except for the terms ω_ξ and ω_η. For these two terms, a third-order upwinding involving cubic interpolation [4] is used instead, in order to suppress spurious oscillations that occur as the Reynolds number R gets large, while the mesh is fixed. This type of upwinding, in our experience, is certainly superior to those hybrid schemes combining first-order upwinding and centered difference. In fact, this kind of hybrid scheme will introduce erroneous numerical diffusion around the sharp edges, which eventually destroys the accuracy of the whole computation.

To apply Theorem 1, we couple (2.5) with (2.3a). Before doing so, we assume they have the following discrete forms.

$$J\omega_t + G(\psi, \omega_0)\omega = 0 \quad \text{for (2.3a)}, \tag{2.6a}$$

$$A_0 \cdot \omega_0 + A \cdot \omega + g \cdot \psi = 0 \quad \text{for (2.5)}. \tag{2.6b}$$

The matrices A_0, A, and g in (2.6b), with A_0 invertible, are discrete integral operators corresponding to suitable quadrature formulas. Note that the wall vorticity ω_0 has been separated from the interior vorticity ω. In (2.6a) the convection and diffusion of ω is handled by the operator G, which is discretized according to the discussion of the last paragraph.

By virtue of (2.6), we can discuss the advancement of ω, ω_0 as follows. Let Δt denote the time increment and $(\omega^n, \omega_0^n, \psi^n)$ denote the quantities at the nth time step. Then, $(\omega^{n+1}, \omega_0^{n+1})$ are obtained as the asymptotic steady state of the following coupled ordinary differential equations:

$$\frac{d\omega}{d\tau} + \omega - \omega^n + \frac{\Delta t}{2}\{G(\psi^n, \omega_0)\omega + G(\psi^n, \omega_0^n)\omega^n\}/J = 0, \tag{2.7a}$$

$$\frac{d\omega_0}{d\tau} + \beta[\omega_0 + A_0^{-1}(A \cdot \omega + g \cdot \psi^n)] = 0 \quad \text{for } \tau > 0, \tag{2.7b}$$

$$\omega = \omega^n, \qquad \omega_0 = \omega_0^n \quad \text{at } \tau = 0. \tag{2.7c}$$

Note that the relaxation parameter $\beta > 0$ in (2.7b) is introduced to accelerate the convergence. Also note that (2.7a) presents an implicit scheme for the interior vorticity, which is of Crank-Nicholson type, when the τ-derivative term becomes negligible. Since there is a time lag in updating ψ, the temporal accuracy of this scheme, strictly speaking, is of the first order. However, it is more accurate than the backward Euler scheme.

The ODE (2.7) is solved over a sequence of discrete τ, namely, $\tau = k\Delta\tau$, $k \geqq 0$. Denote the result of the kth step by $(\omega^{n+1,k}, \omega_0^{n+1,k})$. Then $(\omega^{n+1,k+1}, \omega_0^{n+1,k+1})$ is obtained through the following algorithm.

ALGORITHM A.

(1) Defect-correction formula for (2.7a):

$$J\left(\frac{1}{\Delta\tau}+1\right)\delta^{k+1}+\frac{\Delta t}{2}F(\psi^n,\omega_0^{n+1,k})\delta^{k+1}$$

$$=-\left\{J(\omega^{n+1,k}-\omega^n)+\frac{\Delta t}{2}[G(\psi^n,\omega_0^{n+1,k})\omega^{n+1,k}+G(\psi^n,\omega_0^n)\omega^n]\right\}$$

$$\equiv H^k,$$

$$\omega^{n+1,k+1}=\omega^{n+1,k}+\delta^{k+1},$$

where F differs from G only in the convection part in which first-order upwinding is used instead.

(2) Obtain approximate δ^{k+1} for (1) through incomplete LU factorization (ILU).

(3) Substitute $\omega^{n+1,k+1}$ into (2.7b), and solve it for $\omega_0^{n+1,k+1}$ by forward Euler method.

(4) Go back to (1) and repeat the cycle until, for some prescribed tolerance ε, RMS $(H^k)<\varepsilon$ where RMS $(\cdot)$ means the root mean square over the whole computational grid.

Some remarks on the efficiency and accuracy of Algorithm A are made below. Associated with our choice of $\{g_n\}$ in (2.5), the matrix A_0 is the product of an orthogonal matrix and a diagonal one. So the additional effort to obtain A_0^{-1} is negligible. Furthermore, the computation of $A_0^{-1}(A\cdot\omega+g\cdot\psi)$ is fully vectorizable and hence the labor of updating ω_0 through (2.7b) can be largely saved on a vector computer. For fixed Δt, we can adjust $\Delta\tau$ and β such that ILU is an excellent preconditioner, and the stopping criterion can be met in just a few cycles. If the tolerance $\varepsilon=0$, our algorithm is of second-order accuracy in space. For small ε we expect that it is approximately of this order. Finally, the complexity of Algorithm A is well offset by its stability, which allows us to employ much larger Δt, as compared to other "decoupled" methods [5].

After obtaining ω^{n+1}, we must update ψ by solving the transformed Poisson equation (2.3b) together with the boundary conditions (2.4), in which we note that the condition $\partial\psi/\partial\eta=0$ along the ellipse has been dropped. To this end, a three-grid iterative method is adopted, which yields considerably fast convergence as compared, for example, to one-grid line SOR [5]. Such an approach is also more efficient than GMRES [9] in our experiment. The basic ingredients of this scheme are listed as follows. Namely, standard double coarsening strategy on the grid, five-point central difference formula for (2.3b), incomplete LU factorization as smoothing operator, and standard nine-point prolongation and restriction scheduled in a "saw-tooth" manner. For details of this framework, we refer to the work of Sonneveld, Wesseling, and de Zeeuw [10]. The overall efficiency of the proposed Navier–Stokes solver is evidenced in §4.

Finally, we discuss the computations of drag, lift, moment, and the pivot point of zero torque. As a rule, the surface pressure p is calculated through the expression

$$\frac{\partial p}{\partial\tau}=\frac{2}{R}\frac{\partial\omega}{\partial\nu}, \tag{2.8}$$

where τ, ν denote the counterclockwise tangential and outer normal components, respectively. Since the computational domain is doubly connected, the single-valuedness of this computed surface pressure might be of great concern. See, for example, the discussion of Wu [12]. In our experience in small angle-of-attack simulations, formula (2.8) leads to unpleasant fluctuations in determining the pivot point of zero torque, while the variation of this point is supposed to be quite small in these quasi-steady situations. To circumvent this difficulty, we propose the following alternative. The idea has the same spirit as our vorticity conditioning algorithm, Theorem 1, as will be seen in Theorem 2. Van der Vegt [11] has also used such an alternative in conjunction with discrete vortex methods.

THEOREM 2. *Let Ω, B_0, B_1 be as shown in Theorem* 1, *and ω, ψ denote the vorticity and streamfunction, respectively. Then, the drag, lift, and moment exerted by the nondimensionized surface pressure can be expressed as follows.*

$$\text{(2.9a)} \qquad -\frac{d}{dt}\oint_{B_1}\psi d\varphi+\int_{\Omega}\omega\nabla\psi\cdot\nabla\varphi dxdy-\frac{2}{R}\left[\oint_{B_1}\omega d\varphi-\oint_{B_0}\omega d\varphi\right]$$

where the auxiliary function φ satisfies the following partial differential equation (PDE):

$$\text{(2.9b)} \qquad \begin{aligned} &\Delta\varphi=0 \quad \text{in } \Omega,\\ &\frac{\partial\varphi}{\partial\nu}=0 \quad \text{on } B_1,\\ &\frac{\partial\varphi}{\partial\nu}=\frac{\partial g}{\partial\tau} \quad \text{on } B_0,\end{aligned}$$

where $g(x, y)=-y$ for drag; $=x$ *for lift*; $=(x^2+y^2)/2$ *for moment.*

The proof is sketched as follows. By definition, we have (drag, lift, moment)$_p=$ $\oint_{B_0}p(-dy, dx, xdx+ydy)$. Substitute the result of (2.9b) into the last integral. Then, (2.9a) follows from Green's theorem, momentum equation $(\vec{u}_t+(\vec{u}\cdot\nabla)\vec{u}+\nabla p=(2/R)\Delta\vec{u})$, the Gauss theorem, and the physical boundary conditions on the velocity.

The skin friction part is handled as usual, namely,

$$\text{(2.10)} \qquad (\text{drag, lift, moment})_s=\frac{2}{R}\oint_{B_0}\omega(dx, dy, x\,dy-y\,dx).$$

For large R, the contribution of (2.10) is minor, except for the drag component in those cases where α is small, as compared to the pressure part (2.9). The drag, lift, and moment coefficients are defined as

$$\text{(2.11)} \qquad (C_D, C_L)=(\text{drag, lift})/\tfrac{1}{2}\rho U_\infty^2 L \quad \text{and} \quad C_M=\text{moment}/\tfrac{1}{2}\rho U_\infty^2 L^2.$$

Along the long axis of the ellipse, there exists a pivot point with respect to which the ellipse experiences no torque. The signed distance, q, of this point from the ellipse center is given by

$$\text{(2.12)} \qquad q=[C_M/(C_D\cdot\sin\alpha+C_L\cdot\cos\alpha)]\cdot L.$$

If $q<0$ this point is closer to the leading edge than to the trailing edge, and conversely if $q>0$.

3. An asymptotic result for zero-torque pivoting. For studying high Reynolds number flow past a thin ellipse, the classical Kirchhoff-Rayleigh model [3, §§76–77] of steady inviscid flow past a flat plate can be used as a first approximation. Thus we consider a uniform potential flow past a flat plate inclined at an angle of attack α, $0<\alpha\leqq\pi/2$. Behind the plate the wake is occupied by dead fluid, which is bounded by two free streamlines emanating from the edges of the plate. Let the plate, of length L, be uniformly parametrized by q such that $-1\leqq q\leqq 1$, in which $q=-1$ and $+1$ correspond to the leading edge (LE) and the trailing edge (TE), respectively.

With respect to a pivot point q, the ambient fluid exerts a torque T on the plate, which, after being nondimensionized by $\frac{1}{2}\rho U_\infty^2 L^2$, has the following form:

$$T(\alpha, q) = -\frac{\pi \sin \alpha}{4+\pi \sin \alpha}\left[q+\frac{3 \cos \alpha}{2(4+\pi \sin \alpha)}\right]. \tag{3.1}$$

Formula (3.1) is derived by following the procedure as presented in [3]. From (3.1) it is easy to see that the pivot point of zero torque is

$$q(\alpha) = \frac{-3 \cos \alpha}{2(4+\pi \sin \alpha)} \quad \text{for } 0<\alpha \leqq \pi/2. \tag{3.2}$$

In view of (3.2), it is easy to check that: (1) The zero-torque pivot point is unique for each α with $0<\alpha \leqq \pi/2$; (2) The distance $1+q$ of this point from the leading edge of the plate is a smooth increasing function of α; (3) As $\alpha \to 0+$, $1+q \to \frac{5}{8} > 0$, however. This means that when the plate is placed parallel to the incoming flow, there exists, starting from the leading edge, a wide range for picking a torque-free pivot point.

4. Numerical results.

4.1. Computing facilities. The numeric computations were run on an ETA10-Q108 computer. We do take advantage of this machine's vector facilities. Associated with our program, the vector/scalar speed ratio is 8/1. The numerical results were then loaded down to a VAX8530 computer in which we used GKS to generate the graphic output.

4.2. Computational domain. Figure 3 sketches the result of (2.2). In the transformed $\xi\eta$-plane, we employ a 60×80 uniform grid. The corresponding physical domain

is outerscribed by the rectangle $[-7, 50]\times[-17, 17]$, and the downstream boundary is about 25 plate lengths from the ellipse center.

4.3. Vorticity transport with $R=200$ and 400. According to Algorithm A in §2, the interior and wall vorticity are advanced with time increment $\Delta t=0.04$, which is 8 times as large as that used by Lugt and Haussling [5]. To check the temporal accuracy, a comparative experiment with $\Delta t=0.02$ is also performed. For $\alpha\leqq 45°$ the difference is negligible. The cases with higher α will be discussed later in conjunction with the estimate of Strouhal number. A much smaller time increment, e.g., $\Delta t/20$, is used for the first few steps in order to make a smooth transition from the potential flow. In Algorithm A, the pseudo time increment $\Delta\tau$ is chosen as $\Delta\tau=1.5$ for $R=200$, and as $\Delta\tau=1.75$ for $R=400$. The relaxation parameter β for wall vorticity is chosen such that $\beta\cdot\Delta\tau=0.45$. Although such an arrangement of β and $\Delta\tau$ is not optimal, the average reduction rate $\mu\equiv \text{RMS}\,(H^k)/\text{RMS}\,(H^{k+1})$ reaches the value 2.4 for $R=200$, and 2.7 for $R=400$. With $\varepsilon=2\times10^{-5}$, Algorithm A takes few ($\leqq 6$) iterations to advance one time step for angle of attack α ranging from 5° to 85°. The long-term behavior of the vorticity transport presents either a quasi-steady or a quasi-periodic feature, depending on the angle of attack. Figures 4(a)–4(d) show several stages in one period of vortex shedding for $\alpha=60°$ and $R=200$. In our computations, the results for $R=200$ and for $R=400$ are quite similar.

4.4. Streamfunction calculation. As discussed in §2, the transformed Poisson equation (2.3b) was solved by a three-grid iterative method. The stopping criterion is that the RMS (see Algorithm A) of the left-hand side of (2.3b) is less than or equal to 2×10^{-5}. For each time step with $\Delta t=0.04$, the work done to meet this criterion is no more than two "saw-tooth" cycles in which the ILU smoothing is applied twice in each grid level. Such a convergence rate is certainly superior to one-grid line SOR [5], and is also better than GMRES [9] with ILU preconditioning. The streamlines during one period of vortex shedding are also shown in Figs. 4(a)–4(d).

4.5. Drag, lift, moment, and Strouhal number. Figures 5(a)–5(f) present the C_D, C_L, and C_M curves plotted against time. They also show a quasi-steady or quasi-periodic feature. In those quasi-periodic cases ($\alpha\geqq 30°$), we found that these curves reach their respective local extreme (maximum for C_D, C_L, and $-C_M$) around the time when the recirculatory region developed behind the leading edge reaches its maximum and is going to separate from this tip. With higher α, these curves also reach their respective local extreme (maximum for C_D, C_L, and C_M) around the time when the recirculatory region developed behind the trailing edge reaches the same situation as stated above for the leading edge. However, the local C_L-maximum corresponding to trailing-edge vortex shedding is illegible for $R=200$, and becomes appreciable for $R=400$. In view of these results, our work is in agreement with the observation of Lugt and Haussling [5] for $\alpha=45°$ and $R=200$ (note that as compared to (2.11), Lugt's definitions of C_D, C_L, and C_M have an amplification factor of 2, 2, 4, respectively).

In Fig. 6 the Strouhal number, as defined by $S=fL\sin\alpha/U_\infty$ where f is the frequency of vortex shedding, is plotted against α. This curve is expected to be nearly constant, as demonstrated by some relevant experiments [1]. It turns out that, with $\Delta t=0.04$, the computed curve increases slightly with α, and yields a mean 0.20. To improve the accuracy we try again with $\Delta t=0.02$; this curve becomes much flatter and yields a mean 0.18. To judge the correctness, we cite some relevant known results as follows. For an ellipse having the same aspect ratio as ours, the result of Lugt and Haussling [5] with $\alpha=45°$ and $R=200$ indicates that $S=0.16-0.18$; the wind tunnel experiment of Fage and Johansen [1] indicates that $S=0.15$ for inviscid flow past a

flat plate; an experiment on a 12 percent thick symmetric Joukowski airfoil with $\alpha = 15°$, $30°$, and $R = 1000$ as made by Ghia, Osswald, and Ghia [2] indicates that $S = 0.17 - 0.18$.

4.6. Pivot point of zero torque. The time history of this point is quite similar to a C_M-curve with largely reduced amplitude. In Fig. 7, the mean position of this point scaled by $L/2$ is plotted against α along with the result from Kirchhoff theory as presented in §3. We see that these results show agreement in qualitative behavior. In spite of its simplicity, the Kirchhoff-Rayleigh model also serves as an excellent approximation for high α for finding this zero-torque pivot point.

Abstract. Determination of the optimal design of a survey to measure minority voting participation can be posed as a very large number of highly structured geometric programming problems. The problem formulation is discussed, and an efficient special-purpose algorithm based on relaxation and duality is presented. The approach can also be applied to problems with similar structure.

Key words. stratified sampling, sample survey design, geometric programming, Lagrangian duality

AMS(MOS) subject classifications. 62D05, 90C28

1. Introduction.

Determination of the optimal design of a survey to measure minority voting participation can be posed as a very large number of highly structured geometric programming problems. A special heuristic algorithm was devised to exploit the structure of the thousands of geometric programs that needed to be solved. The heuristic procedure is exact for special cases. In the other cases, a methodology is developed for determining an a posteriori bound on the relative error of the solution obtained by the procedure. We discuss the model formulation, solution procedure, and its application to the survey design problem.

1.1. Survey background and requirements.

A 1978 survey of voting and registration statistics was designed by the U.S. Census Bureau to measure the difference in the voting participation rates between a given minority population and the (white) nonminority population in specified voting jurisdictions across the nation, but concentrated largely in the South. Congress, the Department of Justice, and the Census Bureau jointly identified 955 voting jurisdictions (mostly counties) to be surveyed. The minorities of interest, which varied by jurisdiction, included black, Spanish origin, American Indian, Japanese, Chinese, Filipino, Hawaiian, and Native Alaskan subgroups.

A design goal of the survey was to satisfy a given standard error of the estimated minority/nonminority voting rate differential within 718 jurisdictions. (The sampling procedure was specified a priori in the remaining 237 jurisdictions.) For each jurisdiction, all minorities that comprised three percent or more of the voting age population were considered to be minorities of interest. Frequently, there were two or more specified minorities in a jurisdiction, thereby requiring a sample design that reliably measured several voting rate differentials.

1.2. Efficient sample survey design. The estimated total cost of conducting the survey was large (approximately \$40,000,000). To keep the costs as low as possible, the survey design was chosen as follows. First, sixteen possible sampling schemes were considered for each jurisdiction. For every jurisdiction, the "optimum" implementation of a given scheme was determined as a solution to the optimization problem of finding the combination of sampling parameters that satisfied the specified error requirements at a minimum cost. Completion of this step required the solution of more than 11,000 such optimization problems. The "best" scheme for each jurisdiction was then taken as the least expensive of the sixteen optimized schemes.

In § 2 we describe how the specification of the optimum version of each scheme in a single jurisdiction can be formulated as an optimization problem, and in § 3 we derive a specialized algorithm for such a problem.

2. Development of a typical optimization problem. In demographic sample surveys, the Census Bureau typically selects populations from three frames (groups). These three frames are mutually exclusive and cover (virtually) all housing units in a typical jurisdiction.

(1) *Permit old construction* (POC) frame consists of all housing units which existed in permit-issuing areas (i.e., areas that issue building permits) at the time of the previous national census. Computer records of these housing units contain demographic information, and hence it is straightforward to perform a stratified sample.

(2) *Permit new construction* (PNC) frame consists of all housing units constructed in permit-issuing areas since the previous census. Within this frame, clusters of eight housing units were systematically selected from a sorted list of building permits.

(3) *Nonpermit area* (NPA) frame (old and new construction) consists of all housing units not in permit-issuing areas. Three basic sample designs were considered for use in this frame. Common to all three designs is the selection of a number of land areas with known boundaries. The selection of housing units within these land areas depends on parameters of the chosen sampling scheme.

We will describe only the first of the sixteen sampling schemes, which illustrates the optimization problem in its most general form. With scheme 1, free parameters are associated only with the first and third frames, and the scheme is defined as follows.

(a) The POC frame sample is divided into n_1 strata, where n_1 is known for each jurisdiction and can be as large as eight. One parameter is associated with each stratum; let $x_j, j=1, \cdots, n_1$, represent the number of housing units to be taken from stratum j.

(b) In the PNC frame, a systematic sample of clusters of housing units is selected, where the expected number of units in each cluster is predetermined to be eight.

(c) The NPA frame sample is selected in three stages and depends on two parameters. First, x_{n_1+1} enumeration districts (EDs) are selected, where an ED contains approximately 300 housing units. These EDs are then divided into segments whose average size is 30 housing units, and x_{n_1+2} segments are chosen from each ED. Finally, a sample of eight housing units is chosen from each of these segments.

To formulate an optimization problem whose solution gives the optimum implementation of this scheme, we must first define the objective function to be minimized with respect to the parameters $\{x_j\}$, $j=1, \cdots, n_1+2$. The cost function, expressed in dollars, is taken as (see [9]):

$$\text{cost} = 17.5 \sum_{j=1}^{n_1} x_j + 87.35 x_{n_1+1} + 89.87 x_{n_1+1} x_{n_1+2} + 17.5 N, \tag{1}$$

where the PNC frame sampling size of N housing units was predetermined for each jurisdiction, and the aim is to minimize (1).

The constraints on $\{x_j\}$ come in two forms. First, the variance associated with scheme 1 for the estimated difference between the nonminority voting rate and that of the ith minority is defined as (see [4], [6]):

$$(2) \qquad V_i = \sum_{j=1}^{n_1} \frac{a_{ij}}{x_j} + \frac{a_{i,n_1+1}}{x_{n_1+1}} + \frac{a_{i,n_1+2}}{x_{n_1+1}x_{n_1+2}} - (f_{1i} - f_{2i} + f_{3i}) \quad \text{for } i = 1, \cdots, m,$$

where m is the total number of minorities. In (2), the quantities $\{a_{ij}\}$ are nonnegative constants (see [9] for details and [4] for a simple example). The constants f_{1i} and f_{3i} reflect the finite population correction factors associated with the POC and NPA frames, respectively. The constant f_{2i} is equal to the variance component associated with PNC frame sampling. The x's are the unknown sample sizes. All of the constants vary by jurisdiction and minority. The reliability requirements for the survey impose m nonlinear constraints of the following form

$$(3) \qquad V_i \leqq \sigma_i^2, \qquad i = 1, \cdots, m,$$

where σ_i is the required standard error for the ith minority.

In addition to the m nonlinear constraints (3), upper and lower bounds are placed on each variable, so that we require

$$(4) \qquad 0 < x_j \leqq u_j, \qquad j = 1, \cdots, n_1 + 2.$$

For $i \leqq j \leqq n_1$, the upper bound u_j is the total number of housing units *available* to be in the sample from stratum j of the POC frame. (Frequently, u_j is much less than the total number of housing units in stratum j, since in some jurisdictions the sample was not chosen from the full census.) The upper bound u_{n_1+1} is the total number of the NPA frame EDs, and u_{n_1+2} is an estimate of the average number of segments per NPA frame ED. It is assumed that the average segment contains approximately 30 housing units, and $30u_{n_1+2}$ is the average number of housing units per NPA frame ED.

In summary, the optimization problem associated with sampling scheme 1 includes the objective function (2), and constraints (3) and (4). (In our work, we did not require that the sample sizes be integers for two reasons. The use of integer variables would substantially increase the algorithmic complexity, and the optimal values were typically very large.) To simplify the notation, let $n = n_1 + 2$, let c_j be the coefficient of the jth term in the objective function (1), and let $b_i = \sigma_i^2 + f_{1i} - f_{2i} + f_{3i}$. The optimization problem thus has the form

$$(\text{P1}) \qquad \begin{aligned} &\text{minimize} && \sum_{j=1}^{n-1} c_j x_j + c_n x_n x_{n-1} \\ &\text{subject to} && \sum_{j=1}^{n-1} \frac{a_{ij}}{x_j} + \frac{a_{in}}{x_n x_{n-1}} \leqq b_i, \qquad i = 1, \cdots, m, \\ &&& 0 < x_j \leqq u_j, \qquad j = 1, \cdots, n. \end{aligned}$$

3. A solution approach. To complete the survey design, approximately 11,000 problems of form similar to (P1) needed to be solved. Obviously, these problems could have been solved using general-purpose nonlinear programming methods. However, a crucial special feature of this application was that in more than 90 percent of the problems, $m \leqq 2$ and it was known a priori that only a single constraint would be satisfied exactly at the solution. We now describe how a special solution procedure was developed to exploit these properties.

A constrained optimization problem of the form

$$(\text{C1}) \qquad \begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && g_i(x) \leqq b_i, \qquad i = 1, \cdots, m, \end{aligned}$$

is called a *convex program* whenever f and each g_i are convex functions. (For a definition of convex functions and related properties, see, e.g., Rockafellar [8].) A function h of n real variables $\{x_i\}$, $i=1,\cdots,n$, is said to be a *posynomial* (i.e., a generalized polynomial with positive coefficients) if it can be written as

$$h(x)=\sum_{i=1}^{m} c_i \prod_{j=1}^{n} x_j^{a_{ij}},$$

where $c_i>0$ and a_{ij} are real constants. If f and each g_i are posynomials defined on the positive orthant, then (C1) restricted to the positive orthant becomes a *posynomial geometric program*, a class of problems that can be transformed into equivalent convex programs (see, for example, [1]).

The general approach, to be described in detail below, is to solve a sequence of (simpler) convex programs related to (P1). Consider the following two convex programs:

$$\text{(P2)}\qquad \begin{aligned} &\text{minimize} && \sum_{j=1}^{n} c_j x_j \\ &\text{subject to} && \sum_{j=1}^{n} \frac{a_{ij}}{x_j} \leqq b_i, \qquad i=1,\cdots,m, \\ & && x_j>0, \qquad j=1,\cdots,n, \end{aligned}$$

and

$$\text{(P3)}\qquad \begin{aligned} &\text{minimize} && \sum_{j=1}^{n} c_j x_j \\ &\text{subject to} && \sum_{j=1}^{n} \frac{a_{ij}}{x_j} \leqq b_i, \qquad i=1,\cdots,m, \\ & && 0<x_j\leqq u_j, \qquad j=1,\cdots,n. \end{aligned}$$

Note that (P3) is (P1) with the $x_n x_{n-1}$ term in the objective replaced by x_n, and that (P2) is (P3) without upper bounds on the variables.

The partial Lagrangian function (see, e.g., Bazaraa and Shetty [2, Chap. 6]) for (P2) is given by

$$\text{(5)}\qquad L(x,\lambda)=\sum_{j=1}^{n} c_j x_j+\sum_{i=1}^{m}\lambda_i\left[\sum_{j=1}^{n}\frac{a_{ij}}{x_j}-b_i\right],$$

where x is the n-vector of decision variables and λ is the m-vector of Lagrange multipliers for the general constraints. For fixed $\lambda\geqq 0$ ($\lambda\neq 0$), the function L is strictly convex in x for $x>0$. Its unique feasible minimizer (with respect to x) is given by

$$\text{(6)}\qquad x_j^*(\lambda)=\sqrt{\sum_{i=1}^{m}\frac{\lambda_i a_{ij}}{c_j}}, \qquad j=1,\cdots,n.$$

Substituting (6) into (5) and simplifying yields

$$\text{(7)}\qquad h(\lambda)=L(x^*(\lambda),\lambda)=2\sum_{j=1}^{n}\sqrt{c_j\sum_{i=1}^{m} a_{ij}\lambda_i}-\sum_{i=1}^{m}\lambda_i b_i.$$

It is not difficult to show that h is a concave function and its maximum for $\lambda\geqq 0$ coincides with the minimum value of the objective function in (P2). We thus have the dual of problem (P2)

$$\text{(D2)}\qquad \begin{aligned} &\text{maximize} && h(\lambda) \\ &\text{subject to} && \lambda\geqq 0, \end{aligned}$$

where λ is now called the dual vector. Problem (D2) is also a convex program, so let λ^* denote the unique optimal solution. It follows that the solution of (P2) is defined by $x_j^* = x_j^*(\lambda^*)$.

Problem (D2) can be solved using general methods for bound-constrained optimization (e.g., McCormick [7, Chap. 13]). However, if (P2) has only one constraint, then (D2) has only one variable and its solution is given in closed form as

$$\lambda_1^* = \left(\frac{1}{b_1}\sum_{j=1}^{n}\sqrt{c_j a_{1j}}\right)^2. \tag{8}$$

Thus, the solution to (P2) when $m=1$ is given by

$$x_j^* = x_j^*(\lambda_1^*) = \frac{1}{b_1}\sqrt{\frac{a_{1j}}{c_j}}\sum_{i=1}^{n}\sqrt{c_i a_{1i}}, \tag{9}$$

which corresponds to the well-known Neyman allocation [5]. In the next section, we consider how to use this result to solve (P3) when $m=1$.

3.1. The case $m=1$. When $m=1$, the single general constraint is always active at the optimal solution of (P3), assuming a nonempty feasible set. Let x^* and $\hat{x}$ denote the unique optimal solutions of (P2) and (P3), respectively. Standard optimality conditions then indicate that, for *each* component j for which $x_j^* \geqq u_j$, it holds that $\hat{x}_j = u_j$ (see, e.g., Rockafellar [8, § 28] or Bazaraa and Shetty [2, Chap. 4]). This observation is much stronger than the result for general convex programs (see, e.g., [2, Exercise 4.15]) which only guarantees the existence of a solution, say $\bar{x}$, to a convex program such that *at least* one constraint violated by the optimal solution of a relaxed problem (obtained by dropping that constraint along with, possibly, others) is active at $\bar{x}$. Moreover, in our situation, knowledge of an active (upper bound) constraint at the optimal solution automatically reduces the dimensionality of the problem. These observations suggest the following simple solution procedure for (P3) (assumed feasible), which is based on repeated solution of subproblems obtained from relaxations (P2) by fixing different sets of variables to the bound u.

ALGORITHM A.

Step 0. Set $k=1$, $\bar{b}_k = b_1$, and $J_k = \{1, 2, \cdots, n\}$. Problem (P2) with $m=1$ can be written as

$$\text{(P2M1(k))}\qquad \begin{aligned} &\text{minimize} && \sum_{j\in J_k} c_j x_j \\ &\text{subject to} && \sum_{j\in J_k}\frac{a_{1j}}{x_j} \leqq \bar{b}_k, \\ &&& x_j > 0, \qquad j \in J_k. \end{aligned}$$

Step 1. Let x^k solve problem P2M1(k). The solution is given by (7) as

$$x_j^k = \frac{1}{\bar{b}_k}\sqrt{\frac{a_{1j}}{c_j}}\sum_{i\in J_k}\sqrt{c_i a_{1i}} \quad \text{for } j \in J_k.$$

Step 2. If $x_j^k \leqq u_j$ for all $j \in J_k$, set $x_j^* = x_j^k$ for all $j \in J_k$; STOP, $x^* = \hat{x}$ solves (P3).

Step 3. If $x_j^k > u_j$ for some $j \in J_k$, set $x_j^* = u_j$ for all such j. Define

(a) $F_k = \{j: x_j^k > u_j, j \in J_k\}$

(b) $J_{k+1} = J_k \backslash F_k$

(c) $\bar{b}_{k+1} = \bar{b}_k - \sum_{j\in F_k}\frac{a_{1j}}{u_j}$.

Set $k = k+1$ and return to Step 1.

Remark. The algorithm clearly terminates since, at the unique solution $\hat{x}$ to (P3), we know that $\sum_j a_{1j}/\hat{x}_j = b_1$ and that reduction of problem dimensionality at each iteration does not change the implication on active upper bounds inferred by solving the relaxed problem (P2). The algorithm assumes the feasible set for (P3) to be nonempty. Infeasible problems can be detected by simply verifying $\sum_j a_{1j}/u_j > b_1$.

3.2. The case $m \geqq 2$. For $m \geqq 2$, it is no longer true, in general, that if $x_j^* > u_j$ in the optimal solution of (P2) then it follows that $\hat{x}_j = u_j$ in the optimal solution of (P3). However, the (heuristic) rule of fixing the jth variable to its upper bound whenever $x_j^* > u_j$, and repeatedly solving lower-dimensional relaxations (P2), leads to a feasible solution to (P3) whose closeness to $\hat{x}$ can be measured.

We next present a formal statement of this procedure for finding the solution x^* to (P3) obtained using the foregoing rule. In the next section, we present a method for computing a relative error bound on using x^* as an approximation to the true optimum solution $\hat{x}$ of (P3).

ALGORITHM B.

Step 0. Set $k=1$, $b_i^k = b_i$, and $J_k = \{1, 2, \cdots, n\}$. Problem (P2) can be written as

$$\text{(P2(k))}\qquad \begin{aligned} &\text{minimize} && \sum_{j \in J_k} c_j x_j \\ &\text{subject to} && \sum_{j \in J_k} \frac{a_{ij}}{x_j} \leqq b_i^k, \quad i = 1, \cdots, m, \\ &&& x_j > 0, \quad j \in J_k \end{aligned}$$

and its dual becomes

$$\text{(D2(k))}\qquad \begin{aligned} &\text{maximize} && 2 \sum_{j \in J_k} \sqrt{c_j \sum_{i=1}^m a_{ij} \lambda_i} - \sum_{i=1}^m \lambda_i b_i \\ &\text{subject to} && \lambda_i \geqq 0, \qquad i = 1, \cdots, m. \end{aligned}$$

Step 1. Solve (D2(k)) by any terminating procedure and let λ^k denote the solution. Then the solution to (P2(k)) is given by (4) as

$$x_j^k = \sqrt{\sum_{i=1}^m \frac{\lambda_i^k a_{ij}}{c_j}} \quad \text{for } j \in J_k.$$

Step 2. If $x_j^k \leqq u_j$ for all $j \in J_k$, set $x_j^* = x_j^k$ for all $j \in J_k$; STOP, x^* is an approximate solution for (P3).

Step 3. If $x_j^k > u_j$ for some $j \in J_k$, set $x_j^* = u_j$ for all such j. Define

(a) $F_k = \{j : x_j^k > u_j, j \in J_k\}$

(b) $J_{k+1} = J_k \backslash F_k$

(c) $b_i^{k+1} = b_i^k - \sum_{j \in F_k} \dfrac{a_{ij}}{u_j} \qquad i = 1, \cdots, m.$

Set $k = k+1$ and return to Step 1.

Remark. Here again, we assume that the feasible set of (P3) is nonempty; otherwise, $\sum_j a_{ij}/u_j > b_i$ for at least one i. Convergence of the algorithm depends on the procedure selected in Step 1 for solving (D2(k)). A general variable reduction algorithm (see, e.g., [7, Chap. 13]) such as the reduced gradient method can be used, or a specialized technique such as the projected Newton method using only the diagonal elements of the Hessian matrix and an Armijo-like inexact line search presented in [3]. Moreover, it is easy to show that if one and only one component of an optimal solution to (P2) exceeds its upper bound, then that variable is at its bound in the optimal solution of (P3). Hence, if the optimal solution x^k of problem (P2(k)) has at most one component exceeding its upper bound for *every* k, then the solution obtained by the preceding algorithm is optimal for (P3).

3.3. Bound on relative error. By expending a little more effort, the feasible point x^* can be checked to see if it is in fact optimal for (P3). Otherwise, an error bound can be calculated by just finding a point $\tilde{x}$ that satisfies

$$f(\tilde{x}) < f(\hat{x}) < f(x^*), \tag{10}$$

where the second inequality follows from feasibility of x^*, and then using $[f(x^*) - f(\tilde{x})]/f(\tilde{x})$ as an upper bound on the relative error $[f(x^*) - f(\hat{x})]/f(\hat{x})$ of using x^* to approximate $\hat{x}$. In this way, an a posteriori error bound on the optimal objective function value is available for purposes of assessing the goodness of the heuristic employed.

Suppose Algorithm B terminates in iteration k. Then x^* solves the problem

$$\begin{aligned} \text{minimize} \quad & \sum_{j \in N} c_j x_j \\ \text{subject to} \quad & \sum_{j \in N} \frac{a_{ij}}{x_j} \leqq b_i, \qquad i \in M, \\ & x_j = u_j, \qquad j \in F(k), \\ & x_j > 0, \qquad j \in N, \end{aligned} \tag{11}$$

where $M = \{1, 2, \cdots, m\}$, $N = \{1, 2, \cdots, n\}$, and $F(k) = \bigcup_{i=1}^{k} F_i$ is the index set of variables fixed to their upper bounds. Let v^* and w^* be the multiplier vectors such that (x^*, v^*, w^*) solves the following Karush-Kuhn-Tucker conditions (see, e.g., Bazaraa and Shetty [2, Chap. 4]):

$$\begin{aligned} & c_j = \sum_{i \in M} v_i a_{ij} / x_j^2 - w_j, \qquad j \in F(k), \\ & c_j = \sum_{i \in M} v_i a_{ij} / x_j^2, \qquad j \in N \backslash F(k), \\ & v_i \left[\sum_{j \in N} a_{ij} / x_j - b_i \right] = 0, \qquad i \in M, \\ & v_i \geqq 0, \qquad i \in M. \end{aligned} \tag{12}$$

Here w^* is the vector of multipliers for the active upper bounds. If $w_j^* \geqq 0$ for all $j \in F(k)$, then $x^* = \hat{x}$ is the unique solution of (P3). Otherwise, a point x satisfying (10) can be computed in the following way

The general idea for determining an appropriate error bound is to take $\tilde{x}$ as the optimal solution determined by an application of Algorithm A to the problem of minimizing $\sum_j c_j x_j$ subject to a single functional constraint, which is either chosen from the index set M or constructed as a convex combination of two constraints from M.

Assume $w_j^* < 0$ for at least one $j \in F(k)$. From (12) we have

$$x_j^* = \sqrt{\sum_{i \in M} v_i^* a_{ij} / (c_j + w_j^*)} \quad \text{for all } j \in F(k).$$

It follows that

$$\tilde{x}_j = \begin{cases} \sqrt{\sum_{i \in M} v_i^* a_{ij} / c_j} < x_j^* & \text{for } j \in F(k) \quad \text{such that } w_j^* < 0, \\ x_j^* & \text{otherwise} \end{cases} \tag{13}$$

is infeasible to (P3). We shall use the vector $\tilde{x}$ given by (13) to identify the single constraint to be passed to Algorithm A.

Two cases are distinguished depending on whether or not $\bar{x}$ violates all constraints in M.

Case 1. $\bar{x}$ satisfies at least one constraint.

Let $i \in M$ be the index of a satisfied constraint and $\nu \in M$ be the index of a violated constraint. Then, because of convexity, the convex combination of these two constraints that passes through $\bar{x}$ contains the feasible region; specifically,

$$\sum_{j \in N} \frac{\alpha a_{ij} + (1-\alpha) a_{\nu j}}{x_j} \leqq \alpha b_i + (1-\alpha) b_\nu, \tag{14}$$

where

$$\alpha = \frac{\varphi_\nu(\bar{x}) - b_\nu}{b_i - \varphi_i(\bar{x}) + \varphi_\nu(\bar{x}) - b_\nu}$$

and

$$\varphi_\nu(x) = \sum_{j \in N} \frac{a_{\nu j}}{x_j}.$$

In problem (P2M1(1)) of Algorithm A, take $a_{1j} = \alpha a_{ij} + (1-\alpha) a_{\nu j}$ and $\bar{b}_1 = \alpha b_i + (1-\alpha) b_\nu$ and let $\tilde{x}$ denote the solution obtained for this problem.

Case 2. $\bar{x}$ violates all constraints.

A simple procedure in this case is to choose, for Algorithm A, that violated constraint which is closest to $\bar{x}$ in the direction c. This constraint can be determined as the binding constraint of the easily solvable problem

$$\begin{aligned} &\text{maximize} && \alpha \\ &\text{subject to} && g_i(\alpha) \geqq b_i, \qquad i \in M, \\ & && \alpha \geqq 0, \end{aligned}$$

where

$$g_i(\alpha) = \sum_{j \in N} \frac{a_{ij}}{\bar{x}_j + \alpha c_j}.$$

For both cases above, more elaborate procedures are not difficult to devise, but our aim here is to keep the treatment simple, since a comparative experiment (or theoretical analysis) of different heuristics is not the focus of this study.

An example that illustrates Case 1 is presented next.

3.4. Example. The following example illustrates Case 1.

$$\begin{aligned} &\text{minimize} && 100x_1 + 5x_2 + x_3 \\ &\text{subject to} && \frac{1}{x_1} + \frac{5}{x_2} + \frac{1}{x_3} \leqq 1.6, \\ & && \frac{125}{x_1} + \frac{1}{x_2} + \frac{1200}{x_3} \leqq 252.75, \\ & && x_1, x_2, x_3 > 0, \\ & && x_1 \leqq 15,\ x_2 \leqq 4.5,\ x_3 \leqq 5. \end{aligned} \tag{15}$$

Algorithm B returns the point $x^* = (9.98, 4.5, 5)$ with $f(x^*) = 1025.5$, $k = 2$, and $F(2) = \{2, 3\}$. The triple (x^*, v^*, w^*) with $(v_1^*, v_2^*) = (0, 79.68)$ and $(w_2^*, w_3^*) = (-1.07, 3823.66)$

solves (12), and $\bar{x} = (9.98, 3.99, 5)$ is now available from (13); checking feasibility of $\bar{x}$ fixes $i = 1$ and $v = 2$.

Replace the two functional constraints in (15) by the convex combination determined by (14); namely,

$$\frac{77.88}{x_1} + \frac{2.52}{x_2} + \frac{744.38}{x_3} \leqq 157.31. \tag{16}$$

Algorithm A gives $\tilde{x} = (9.90, 4.5, 5)$, with $f(\tilde{x}) = 1017.08$, as the optimal solution for the problem with (16) as its single constraint, and all other data being the same as (15).

Since $[f(x^*) - f(\tilde{x})]/f(\tilde{x}) = 0.0083$, then $f(x^*)$ is within 0.83 percent of the true optimum value $f(\hat{x})$. Here, we know that the optimal solution is $\hat{x} = (10, 4, 5)$ with $f(\hat{x}) = 1025$, so that our heuristic solution is actually within 0.05 percent of optimality.

4. Solving the survey design model. In this section we describe a solution procedure for the survey design model (P1), which we stated earlier to be related to the simpler convex program (P3). We now make this relationship clear. It is easy to see that (P1) is equivalent to

$$\text{(P4)} \quad \begin{aligned} &\text{minimize} && \sum_{j=1}^{n} c_j y_j \\ &\text{subject to} && \sum_{j=1}^{n} \frac{a_{ij}}{y_j} \leqq b_i, \qquad i = 1, \cdots, m, \\ &&& y_n - u_n y_{n-1} \leqq 0, \\ &&& 0 < y_j \leqq \bar{u}_j, \qquad j = 1, \cdots, n, \end{aligned}$$

where $\bar{u}_j = u_j$ for all $1 \leqq j \leqq n-1$ and $\bar{u}_n = u_n u_{n-1}$. The equivalence follows immediately from the one-to-one correspondence between the feasible points under the transformation defined by $y_j = x_j$ $(1 \leqq j \leqq n-1)$ and $y_n = x_n x_{n-1}$. Note that (P3) is a relaxation of the above problem. For convenience, (P3) is rewritten here as

$$\text{(P5)} \quad \begin{aligned} &\text{minimize} && \sum_{j=1}^{n} c_j y_j \\ &\text{subject to} && \sum_{j=1}^{n} \frac{a_{ij}}{y_j} \leqq b_i, \qquad i = 1, \cdots, m, \\ &&& 0 < y_j \leqq \bar{u}_j, \qquad j = 1, \cdots, n, \end{aligned}$$

If $\hat{y}$ denotes the optimal solution of (P5) and $\tilde{y}$ is the optimal solution of (P4), it is straightforward to show that if $\hat{y}_n > u_n \hat{y}_{n-1}$, then $\tilde{y}_n = u_n \tilde{y}_{n-1}$. Hence, with $y_n = u_n y_{n-1}$, (P4) reduces to

$$\text{(P6)} \quad \begin{aligned} &\text{minimize} && \sum_{j=1}^{n-1} c'_j y_j \\ &\text{subject to} && \sum_{j=1}^{n-1} \frac{a'_{ij}}{y_j} \leqq b_i, \qquad i = 1, \cdots, m, \\ &&& 0 < y_j \leqq \bar{u}_j, \qquad j = 1, \cdots, n-1, \end{aligned}$$

where $c'_j = c_j$ and $a'_{ij} = a_{ij}$ for $1 \leqq j \leqq n-2$ and all i, and $c'_{n-1} = c_{n-1} + c_n u_n$ and $a'_{i,n-1} = a_{i,n-1} + a_{in}/u_n$. Since (P6) has the same form as (P3), then (P1) can be solved by solving at most two problems of the form (P3). The overall algorithm for (P1) is presented next, followed by a remark on bounding the relative error of the heuristic solution obtained.

ALGORITHM C.

Step 1. Solve (P5) and let $\hat{y}$ denote a solution. One of three alternative procedures may be used.

(1) If $m=1$, use Algorithm A, whereupon $\hat{y}$ is the solution to the problem.

(2) If $m \geqq 2$, apply Algorithm A for each of the m constraints and let $y^1, \cdots, y^m$ denote the solutions obtained. For any j, if y^j satisfies all m constraints then $\hat{y}=y^j$ solves (P5). If all m solutions are infeasible to (P5), then use Algorithm B, whereupon $\hat{y}$ is an approximate solution to the problem.

Step 2. If $\hat{y}_n \leqq u_n \hat{y}_{n-1}$, then

$$\hat{y}^* = (\hat{y}_1, \hat{y}_2, \cdots, \hat{y}_{n-1}, \hat{y}_n/\hat{y}_{n-1})$$

is an exact or approximate solution to (P1), depending on whether $\hat{y}$ is an exact or approximate solution to (P5). Otherwise, go to Step 3.

Step 3. Solve (P6) using one of the alternative procedures in Step 1. Let $(y_1^*, y_2^*, \cdots, y_{n-1}^*)$ denote a solution. Then

$$y^* = (y_1^*, y_2^*, \cdots, y_{n-1}^*, u_n y_{n-1}^*)$$

is an exact or approximate solution to (P1), depending on the method used to solve (P6).

Remark. The methodology for bounding the relative error of the heuristic solution (§ 3.3) can be applied to either (P5) or (P6), depending on whether the algorithm terminates in Step 2 or Step 3, respectively.

5. Concluding remarks. In the sample survey design application, sixteen sampling schemes were considered for each of the 718 jurisdictions. The optimum implementation of each scheme required the solution of an optimization problem to determine the least cost stratified sample sizes that met voting participation variance limits. Each problem was either of the form (P1) if both NPA and POC frames were used in the survey design, or of the form (P3) if only POC frames were used. For the 11,488 problems considered, the number of stratified sample sizes n did not exceed nine, and the number of minorities m was four or less. Moreover, experimentation with different stratifications and different techniques for estimating variance resulted in the need to solve these problems several times. Approximately 90 percent of the jurisdictions had only one or two minorities, and many of those had only POC frames. Thus, a substantial proportion of the problems that needed to be solved were of the form (P3) with $m \leqq 2$, for which the approach presented above is ideally suited. Available general optimization procedures could not satisfactorily process the large number of small problems in this application because they did not exploit the highly specialized nature of the survey design optimization problems.

One of the sixteen sampling schemes is a minor variation of the standard scheme that the Census Bureau usually uses for this type of survey. In each jurisdiction, the optimum scheme was compared to the optimized standard scheme (SC). For this purpose, 650 of the 718 jurisdictions were optimized. Schemes for the remaining jurisdictions were preselected. In 155 jurisdictions, the feasible region of SC was empty. That is, SC does not satisfy the variance constraints unless either the nonpermit area (NPA) frame cluster size or the permit new construction (PNC) frame sample size is increased.

For the 495 jurisdictions where SC was feasible, the cost of using SC in all jurisdictions was estimated to be \$15,400,000. In 118 jurisdictions, an optimum scheme different from SC was selected at an estimated savings of about \$400,000. In the 155 jurisdictions where SC was infeasible, the savings from selecting an optimum scheme was estimated to be about \$140,000. Therefore, a conservative estimate of the amount saved on the cost of conducting surveys in the 650 jurisdictions was \$540,000.

A jurisdiction is said to be undercovered if not all housing units have a chance to be surveyed, and in some jurisdictions such an occurrence was unacceptable. By listing the costs of the 16 different schemes, the optimization procedure allowed the analysts to weigh coverage against costs in a precise manner. In some jurisdictions, suboptimal survey designs were chosen to prevent either known or suspected undercoverage. These subjective choices resulted in an estimated \$260,000 loss of savings.

Without optimization, alternatives to the standard Census Bureau scheme could not have been considered while still conducting the survey on schedule. Unfortunately, for unrelated reasons the survey project was canceled at the last moment. However, the model and methodology have been successfully applied in subsequent studies by the bureau (see, e.g., Causey [4]).

Acknowledgments. The authors are grateful to the referees and to the Reviewing Editor, Margaret H. Wright, who provided many constructive comments.

BLOCK M-MATRICES AND COMPUTATION OF INVARIANT TORI*

LUCA DIECI[†] AND JENS LORENZ[‡]

Abstract. In this work a generalization of nonsingular M-matrices to block matrices is proposed, where positivity of numbers is replaced by positive definiteness of blocks. In addition, the outer diagonal blocks are multiples of the identity. This generalization is arrived at by studying the matrices that arise from discretizing linear first-order systems of partial differential equations (PDEs) where each equation has the same principal part. These PDEs occur in the study of invariant tori of dynamical systems. In this paper, a first-order discretization of these PDEs is investigated and block M-matrix properties are used to establish stability and error estimates. To obtain higher-order convergence, an error expansion is proved, which legitimates Richardson's extrapolation. Some of the numerical and algorithmic aspects of the proposed discretization are discussed and briefly contrasted to others. Some numerical examples to illustrate the theory and to highlight the interplay between attractivity and smoothness of the tori versus accuracy of the approximation are also presented.

Key words. invariant tori, numerical computation, PDEs with same principal part, upwinding, extrapolation

1. Introduction.

In [DLR], we considered the problem of computing invariant tori of dynamical systems numerically. Our approach required the solution of an associated system of partial differential equations (PDEs). We used the leap-frog discretization for this system, and proved stability and second-order convergence for linear constant coefficient problems. The extension to linear variable coefficients has been the main motivation for this paper. Here, we provide such an extension for an upwind scheme; under suitable assumptions, we prove stability and first-order convergence. To prove stability, we are led to define a class of block matrices that generalizes the usual class of nonsingular M-matrices. This generalization is necessary, because the PDE is not scalar. We prove that the *block M-matrices* are invertible, and we give explicit bounds on the norm of their inverse. This allows us to show stability.

An outline of the paper is as follows. In the remainder of the introduction we set some notation. In §2 we define block M-matrices and, extending a basic property of usual M-matrices, we obtain a bound on their inverse. In §3, we consider the application of block M-matrices to the computation of invariant tori. Under certain assumptions, an invariant torus can be parametrized by the solution of a system of first-order PDEs, where each equation of the system has the same principal part. For linear systems of PDEs of this type, we investigate a first-order upwind scheme. The discretization leads to a block M-matrix if the coefficient matrix of the zero-order term in the PDE system is positive definite. (Positive definiteness of this zero-order coefficient implies attractivity of the torus.) It is then possible to prove stability and

first-order convergence. Under smoothness assumptions, we show that the discretization error admits an expansion in terms of powers of the mesh sizes. This result can be used in conjunction with Richardson's extrapolation to obtain higher-order procedures. In §4, we present some of the implementation considerations, and two examples, to illustrate the theory and to stress the relation between smoothness and attractivity of the tori and accuracy of the computed approximations.

We consider block square matrices of the form

$$A = \begin{pmatrix} A_{11} & \cdots & A_{1n} \\ \vdots & & \vdots \\ A_{n1} & \cdots & A_{nn} \end{pmatrix}, \tag{1.1}$$

where each $A_{ij} \in \mathbb{R}^{m \times m}$. For matrices $B, C \in \mathbb{R}^{m \times m}$, possibly unsymmetric, we write

$$B \geq_q C$$

if and only if the quadratic form defined by $B - C$ is positive semidefinite, i.e.,

$$\mathbf{x}^T B \mathbf{x} \geq \mathbf{x}^T C \mathbf{x} \quad \forall \mathbf{x} \in \mathbb{R}^m.$$

For vectors $\mathbf{a},\mathbf{b} \in \mathbb{R}^n$, we write $\mathbf{a} \geq \mathbf{b}$ if and only if $a_i \geq b_i$, for all i. Also, for $\mathbf{e} \in \mathbb{R}^n$, we write $\mathbf{e} > \mathbf{0}$ if and only if all $e_i > 0$. A vector $\mathbf{e} > \mathbf{0}$ induces the scaled maximum norm for vectors in $\mathbb{R}^n$ ($|x_i|$ denotes absolute value):

$$\|\mathbf{x}\|_e := \max_{1 \leq i \leq n} \frac{|x_i|}{e_i}, \qquad \mathbf{x} \in \mathbb{R}^n.$$

For vectors $\mathbf{c},\mathbf{d} \in \mathbb{R}^m$ we denote the usual Euclidean scalar product and induced norm as

$$\langle \mathbf{c},\mathbf{d} \rangle := \sum_{i=1}^{m} c_i d_i, \qquad |\mathbf{c}| := \langle \mathbf{c},\mathbf{c} \rangle^{1/2}.$$

For vectors

$$\mathbf{x} = \begin{pmatrix} \mathbf{x}^1 \\ \vdots \\ \mathbf{x}^n \end{pmatrix} \in \mathbb{R}^{nm}, \quad \mathbf{x}^j \in \mathbb{R}^m, \quad \text{and} \quad \mathbf{e} \in \mathbb{R}^n, \quad \mathbf{e} > \mathbf{0},$$

we define the scaled maximum two-norm:

$$\|\mathbf{x}\|_e := \max_{1 \leq j \leq n} \frac{|\mathbf{x}^j|}{e_j},$$

and if $e_j = 1$, for all j, we denote this norm simply as $\|\mathbf{x}\|$. Induced matrix norms are defined in the usual way.

2. Block M-matrices.

Nonsingular M-matrices can be characterized in many ways. In [BP] and [P], 40 equivalent conditions are listed. Here, we will generalize the following *semipositivity* characterization (it is K33 or K35 of [P]).

DEFINITION 2.1. A matrix $B = (b_{ij}) \in \mathbb{R}^{n \times n}$ is an M-matrix if

$$b_{ij} \leq 0, \qquad i \neq j \tag{2.1a}$$

and if there exists a vector $\mathbf{e} \in \mathbb{R}^n$ such that

$$\text{(2.1b)} \qquad \mathbf{e} > 0 \quad \text{and} \quad B\mathbf{e} > \mathbf{0}.$$

Several properties/characterizations of M-matrices are well known. For example, if B is an M-matrix, then B^{-1} exists (and $B^{-1} \geq 0$). We will extend this invertibility result in the stronger form given by the following lemma, of which we provide a simple proof for completeness.

LEMMA 2.2. *Let $B \in \mathbb{R}^{n \times n}$ be an M-matrix, and let $\mathbf{e} \in \mathbb{R}^n$, $\mathbf{e} > \mathbf{0}$, and $B\mathbf{e} > \mathbf{0}$. Let $\eta \in \mathbb{R}$, $\eta > 0$, such that $B\mathbf{e} \geq \eta\mathbf{e}$. Then we have*

$$\text{(2.2)} \qquad \|\mathbf{x}\|_e \leq \frac{1}{\eta}\|B\mathbf{x}\|_e \quad \forall\, \mathbf{x} \in \mathbb{R}^n.$$

Proof. Clearly we have

$$\pm\mathbf{r} \leq \|\mathbf{r}\|_e\mathbf{e} \quad \forall\, \mathbf{r} \in \mathbb{R}^n.$$

Since $B^{-1} \geq 0$, if we set $B\mathbf{x} =: \mathbf{r}$ we have

$$\pm\mathbf{x} = \pm B^{-1}\mathbf{r} \leq \|\mathbf{r}\|_e B^{-1}\mathbf{e} \leq \|\mathbf{r}\|_e \frac{1}{\eta}\mathbf{e}.$$

This implies (2.2), because

$$\|\mathbf{x}\|_e \leq \frac{1}{\eta}\|\mathbf{r}\|_e = \frac{1}{\eta}\|B\mathbf{x}\|_e. \qquad \square$$

We are ready to define block M-matrices.

DEFINITION 2.3. A matrix A as in (1.1) is called a *block M-matrix* if

$$\text{(2.3)} \qquad A_{ij} = \sigma_{ij}I, \quad \sigma_{ij} \in \mathbb{R}, \quad \sigma_{ij} \leq 0, \quad i \neq j,$$

where I is the identity matrix, and if there exists a vector $\mathbf{e} \in \mathbb{R}^n$, $\mathbf{e} > \mathbf{0}$, and a scalar $\sigma \in \mathbb{R}$, $\sigma > 0$, such that

$$\text{(2.4)} \qquad \sum_{j=1}^{n} e_j A_{ij} \geq_q \sigma I, \qquad i = 1, \cdots, n.$$

Remarks. (1) Conditions (2.3) and (2.4) generalize (2.1a) and (2.1b), respectively. If the blocks are scalar ($m = 1$) we obtain Definition 2.1.

(2) Since $\mathbf{e} > \mathbf{0}$ in the above definition, an immediate consequence of (2.4) is the following: there is some $\eta \in \mathbb{R}$, $\eta > 0$ such that

$$\text{(2.5)} \qquad \sum_{j=1}^{n} e_j A_{ij} \geq_q \eta e_i I, \qquad i = 1, \cdots, n.$$

The conditions (2.4) and (2.5) express a "scaled diagonal dominance" property. If $e_j = 1$ in (2.4), for all j, we obtain a condition equivalent in this context to that of a strictly block diagonally dominant block matrix.

We can now prove the following theorem.

THEOREM 2.4. *Let A be a block M-matrix. Let $\eta \in \mathbb{R}$, $\eta > 0$, such that* (2.5) *is satisfied. Then we have*

$$\|\mathbf{x}\|_e \le \frac{1}{\eta}\|A\mathbf{x}\|_e \quad \forall\, \mathbf{x} \in \mathbb{R}^{nm}. \tag{2.6}$$

Proof. (i) Let us first assume that (2.4) is satisfied with $e_j = 1$, $j = 1, \cdots, n$. Let $\mathbf{x},\mathbf{r} \in \mathbb{R}^{nm}$ such that $A\mathbf{x} = \mathbf{r}$. Determine an index k so that

$$\|\mathbf{x}\| = |\mathbf{x}^k| \ge |\mathbf{x}^j|, \qquad j = 1, \cdots, n.$$

Taking the scalar product of $A_{kk}\mathbf{x}^k + \sum_{j\ne k} A_{kj}\mathbf{x}^j = \mathbf{r}^k$ with $\mathbf{x}^k$, and using (2.3), we obtain

$$(\mathbf{x}^k)^T A_{kk}\mathbf{x}^k + \sum_{j\ne k} \sigma_{kj}(\mathbf{x}^k)^T\mathbf{x}^j = (\mathbf{x}^k)^T\mathbf{r}^k.$$

Since $\sigma_{kj} \le 0$ and $(\mathbf{x}^k)^T\mathbf{x}^j \le (\mathbf{x}^k)^T\mathbf{x}^k$ we have

$$(\mathbf{x}^k)^T A_{kk}\mathbf{x}^k + \sum_{j\ne k}(\mathbf{x}^k)^T A_{kj}\mathbf{x}^k \le (\mathbf{x}^k)^T\mathbf{r}^k.$$

Then, (2.4) with $i = k$ gives us

$$\sigma|\mathbf{x}^k|^2 \le (\mathbf{x}^k)^T\mathbf{r}^k \le |\mathbf{x}^k| \cdot |\mathbf{r}^k|,$$

and therefore (2.6) follows in this case, because

$$\|\mathbf{x}\| = |\mathbf{x}^k| \le \frac{1}{\sigma}|\mathbf{r}^k| \le \frac{1}{\sigma}\|\mathbf{r}\|.$$

(ii) In the general case, where $\mathbf{e} > \mathbf{0}$ is arbitrary, we define the invertible $nm \times nm$ diagonal matrix

$$\Lambda = \begin{pmatrix} e_1 I & & 0 \\ & \ddots & \\ 0 & & e_n I \end{pmatrix},$$

and then $\Lambda^{-1}A\Lambda =: B$ is a block M-matrix to which the first part of the proof applies with $\sigma = \eta$. Now, $A\mathbf{x} = \mathbf{r}$ implies

$$B\Lambda^{-1}\mathbf{x} = \Lambda^{-1}\mathbf{r},$$

and therefore

$$\|\mathbf{x}\|_e = \|\Lambda^{-1}\mathbf{x}\| \le \frac{1}{\eta}\|\Lambda^{-1}\mathbf{r}\| = \frac{1}{\eta}\|\mathbf{r}\|_e$$

and the proof is completed. □

An immediate consequence of the theorem is Corollary 2.5.

COROLLARY 2.5. *Under the assumptions of Theorem* 2.4, *A is nonsingular and*

$$\|A^{-1}\|_e \le \frac{1}{\eta}. \tag{2.7}$$

□

Remark. It is possible to generalize other properties of standard M-matrices to block M-matrices. In this work we have only extended that property which is needed for the stability analysis in the next section. However, not all of the properties that characterize usual M-matrices can be extended to block M-matrices, as we have defined them. This aspect will be addressed in the future. Other extensions (not equivalent to ours) of standard M-matrices to the block case are in [EM] (and also here, not all standard M-matrix properties extend to the block case).

3. Computation of invariant tori.

3.1. Basic setting. In this paper, we restrict the setting to dynamical systems of the following form

$$\begin{aligned} \dot{\boldsymbol{\theta}} &= \mathbf{f}(\boldsymbol{\theta}), \\ \dot{\mathbf{r}} &= -C(\boldsymbol{\theta})\mathbf{r} + \mathbf{g}(\boldsymbol{\theta}), \end{aligned} \tag{3.1}$$

where $\boldsymbol{\theta}(t) \in T^p$ and $\mathbf{r}(t) \in \mathrm{I\!R}^q$; here $T^p = \mathrm{I\!R}^p(\bmod \mathbb{Z}^p)$ denotes the standard p-torus. The functions

$$\mathbf{f} : T^p \to \mathrm{I\!R}^p, \quad C : T^p \to \mathrm{I\!R}^{q\times q}, \quad \mathbf{g} : T^p \to \mathrm{I\!R}^q$$

are assumed to be in C^r, where $r \geq 1$ will be specified below. Then, for all initial data

$$(\boldsymbol{\theta}(0), \mathbf{r}(0)) = (\boldsymbol{\theta}_0, \mathbf{r}_0) \in T^p \times \mathrm{I\!R}^q, \tag{3.2}$$

the system (3.1) has a unique solution existing for all times. We are interested in determining a manifold $\mathcal{M}$, diffeomorphic to T^p, of the form

$$\mathcal{M} = \{(\boldsymbol{\theta}, \mathbf{R}(\boldsymbol{\theta})) : \boldsymbol{\theta} \in T^p\}, \qquad \mathbf{R} : T^p \to \mathrm{I\!R}^q, \tag{3.3}$$

which is invariant under the flow of (3.1). This means that if $(\boldsymbol{\theta}_0, \mathbf{r}_0) \in \mathcal{M}$, then the whole trajectory determined by the initial data (3.2) lies in $\mathcal{M}$.

The following well-known result (e.g., see [K]) is at the core of our computational technique.

LEMMA 3.1. *Suppose* $\mathbf{R} : T^p \to \mathrm{I\!R}^q$ *is a* C^1*-function. Then* $\mathcal{M}$ *in* (3.3) *is invariant under the flow of* (3.1) *if and only if* $\mathbf{R}$ *satisfies*

$$\sum_{\nu=1}^{p} f_\nu(\boldsymbol{\theta}) \frac{\partial \mathbf{R}}{\partial \theta_\nu}(\boldsymbol{\theta}) + C(\boldsymbol{\theta})\mathbf{R}(\boldsymbol{\theta}) = \mathbf{g}(\boldsymbol{\theta}), \qquad \boldsymbol{\theta} \in T^p, \tag{3.4}$$

where f_ν *and* θ_ν, $\nu = 1, \cdots, p$, *denote the components of* $\mathbf{f}$ *and* $\boldsymbol{\theta}$, *respectively.* □

Remark. Note that (3.4) is a vector equation for the q components of $\mathbf{R}$. The *principal part* of each equation reads

$$\sum_{\nu=1}^{p} f_\nu \frac{\partial R_\mu}{\partial \theta_\nu}, \qquad \mu = 1, \cdots, q,$$

i.e., the coefficients are the same for each $\mu = 1, \cdots, q$. This is why we can force the outer diagonal blocks of the discretization matrix to become multiples of the identity, and we are able to satisfy the condition (2.3).

To motivate condition (3.6) below, let us assume temporarily that the matrices $C(\boldsymbol{\theta})$ are all positive definite. Then we can expect that the influence of initial data $\mathbf{r}(0) = \mathbf{r}_0$ becomes negligible as $t \to \infty$, and the $\mathbf{r}$-vector becomes a function of $\boldsymbol{\theta}(t)$ only, $\mathbf{r}(t) \sim \mathbf{R}(\boldsymbol{\theta}(t))$. Thus we expect existence of an attracting manifold (3.3), which is positively invariant. (For the compact manifold $\mathcal{M}$, invariance for $t \to \infty$ implies invariance for $t \to -\infty$ as well.)

However, precise existence and smoothness statements are more involved. The basic difficulty is well understood, and it is given by the fact that (3.4) does not generally have a smooth solution $\mathbf{R}$ even if $\mathbf{f}(\boldsymbol{\theta})$, $C(\boldsymbol{\theta})$, and $\mathbf{g}(\boldsymbol{\theta})$ are in C^∞. General existence and smoothness results for invariant manifolds can be obtained from Fenichel [F]. For our purposes, Theorem 3.2 below suffices. To state the result, we need some further definitions.

Consider the two initial value problems

$$\dot{\boldsymbol{\theta}} = \mathbf{f}(\boldsymbol{\theta}),$$
$$\boldsymbol{\theta}(0) = \boldsymbol{\theta}_0,$$

with solution $\boldsymbol{\theta}(t) = S^t(\boldsymbol{\theta}_0)$, and

$$\dot{\mathbf{r}} = -C(S^t(\boldsymbol{\theta}_0))\mathbf{r},$$
$$\mathbf{r}(0) = \mathbf{r}_0,$$

with solution $\mathbf{r}(t) = M(t, \boldsymbol{\theta}_0)\mathbf{r}_0$, $M(t, \boldsymbol{\theta}_0) \in \mathbb{R}^{q \times q}$. We let $DS^t(\boldsymbol{\theta}_0) \in \mathbb{R}^{p \times p}$ denote the derivative of S^t with respect to $\boldsymbol{\theta}_0$. Then we define the generalized Lyapunov-type numbers (denoted by ν and σ, respectively, in [F])

$$\rho(\boldsymbol{\theta}_0) = \inf\{a \in (0, \infty) : |M(t, S^{-t}(\boldsymbol{\theta}_0))|/a^t \to 0, \text{ as } t \to \infty\}, \tag{3.5a}$$

$$\mu(\boldsymbol{\theta}_0) = \inf\{s \in (0, \infty) : |DS^{-t}(\boldsymbol{\theta}_0)| \cdot |M(t, S^{-t}(\boldsymbol{\theta}_0))|^s \to 0, \text{ as } t \to \infty\}. \tag{3.5b}$$

(The expressions do not depend on the chosen matrix norm $|\cdot|$, but in our discussion below we shall assume that $|\cdot|$ corresponds to the Euclidean vector norm.)

THEOREM 3.2. *Let* $\mathbf{f}, C, \mathbf{g} \in C^r$, $r \in \mathbb{N}$, *in* (3.4). *Let* $\rho(\boldsymbol{\theta}_0) < 1$, $\mu(\boldsymbol{\theta}_0) < 1/r$, *for all* $\boldsymbol{\theta}_0 \in T^p$. *Then* (3.4) *has a solution* $\mathbf{R} \in C^r(T^p, \mathbb{R}^q)$. *The solution is unique in* $C^1(T^p, \mathbb{R}^q)$.

Remark. The existence result follows from Theorem 1 of [F] if we consider (3.1) with $\mathbf{g} \equiv \mathbf{0}$ as the unperturbed case with the invariant torus

$$\mathcal{M}_0 = \{(\boldsymbol{\theta}, 0) \ : \ \boldsymbol{\theta} \in T^p\}.$$

Then a perturbation $\epsilon\mathbf{g}(\boldsymbol{\theta})$ is introduced and the result of [F] applied; because of the linearity of the equation, the size of ϵ is irrelevant. Uniqueness of $\mathbf{R}$ follows from the proof in [F], which is based on a contraction argument.

To illustrate Theorem 3.2, let us assume:

(3.6) There exists a $\sigma \in \mathbb{R}$, $\sigma > 0$ such that $C(\boldsymbol{\theta}) \geq_q \sigma I \quad \forall\, \boldsymbol{\theta} \in T^p$.

Then we obtain $|M(t, \boldsymbol{\theta})| \leq e^{-\sigma t}$ for all $t \geq 0$ and all $\boldsymbol{\theta} \in T^p$, and therefore

$$\rho(\boldsymbol{\theta}_0) \leq e^{-\sigma} < 1 \quad \text{for all } \boldsymbol{\theta}_0 \in T^p.$$

Thus, if $\mathbf{g} \equiv \mathbf{0}$ in (3.1), $\mathcal{M}_0$ attracts all trajectories at the exponential rate $e^{-\sigma t}$, for $t \geq 0$. Furthermore, let us assume that

$$(3.7) \qquad |D\mathbf{f}(\boldsymbol{\theta})| \leq \epsilon \quad \forall \boldsymbol{\theta} \in T^p, \quad \text{where } 0 < \epsilon \ll 1,$$

i.e., if $\mathbf{g} \equiv \mathbf{0}$ in (3.1), then the flow on $\mathcal{M}_0$ is almost parallel. From (3.7) it follows that $|DS^{-t}(\boldsymbol{\theta}_0)| \leq e^{\epsilon t}$ for all $\boldsymbol{\theta}_0 \in T^p$, $t \geq 0$, and therefore we have $|DS^{-t}(\boldsymbol{\theta}_0)| \cdot |M(t, S^{-t}(\boldsymbol{\theta}_0))|^s \leq e^{(\epsilon - \sigma s)t}$. In (3.5b) we obtain $\mu(\boldsymbol{\theta}_0) \leq \frac{\epsilon}{\sigma}$, for all $\boldsymbol{\theta}_0 \in T^p$. Thus, Theorem 3.2 guarantees a C^r solution $\mathbf{R}$ of (3.4) as long as $\mathbf{f}, C, \mathbf{g} \in C^r$ and $r\epsilon < \sigma$. The invariant manifold (3.3) still attracts trajectories at the exponential rate $e^{-\sigma t}$ for $t \to \infty$. This follows easily from (3.6) using linearity of (3.1) in $\mathbf{r}$. To summarize the discussion, the larger $\sigma > 0$ in (3.6) (that is, the stronger the attractivity), and the smaller $\epsilon > 0$ in (3.7) (that is, the closer the flow on $\mathcal{M}_0$ is to being parallel), the more derivatives of the solution $\mathbf{R}$ can be guaranteed, and the faster the solution trajectories approach $\mathcal{M}$.

Next, we propose a discretization scheme for (3.4), which we want to investigate. Assumption (3.6) will enable us to satisfy the condition (2.5) for the discretization matrix.

3.2. Numerical discretization. To discretize (3.4), we use equispaced grid points in each of the angular coordinates. We let $h_\nu = 2\pi/N_\nu$, $\nu = 1, \cdots, p$, and $\mathbf{h} = (h_1, \cdots, h_p)$, and replace the torus T^p by its discrete analog

$$(3.8) \qquad T_h^p = \{\boldsymbol{\theta}_h = (j_1 h_1, \cdots, j_p h_p),\ j_\nu \in \mathbb{Z} \bmod N_\nu,\ \nu = 1, \cdots, p\}.$$

Then T_h^p denotes a periodic grid with $N := N_1 \cdots N_p$ mesh points. The unknown grid function will be denoted by $\mathbf{R}_h, \mathbf{R}_h : T_h^p \to \mathbb{R}^q$.

In the usual way, we define the shift operators E_ν, $\nu = 1, \cdots, p$, as

$$(E_\nu \mathbf{R}_h)(\boldsymbol{\theta}_h) := \mathbf{R}_h(\cdots, (j_\nu + 1)h_\nu, \cdots)$$

(and the integer $j_\nu + 1$ is computed modulo N_ν). We also define the forward, backward, and centered divided difference operators as usual:

$$D_{+\nu} = \frac{1}{h_\nu}(E_\nu - I), \qquad D_{-\nu} = \frac{1}{h_\nu}(I - E_\nu^{-1}), \qquad D_{0\nu} = \frac{1}{2}(D_{+\nu} + D_{-\nu}).$$

We replace (3.4) by the following periodic difference equations of *upwinding type*

$$(3.9\text{a}) \qquad \sum_{\nu=1}^{p} \left[f_\nu(\boldsymbol{\theta}_h) D_{0\nu} \mathbf{R}_h - \frac{1}{2} h_\nu \phi(f_\nu(\boldsymbol{\theta}_h)) D_{+\nu} D_{-\nu} \mathbf{R}_h \right] + C(\boldsymbol{\theta}_h)\mathbf{R}_h = \mathbf{g}(\boldsymbol{\theta}_h), \qquad \boldsymbol{\theta}_h \in T_h^p,$$

where

$$(3.9\text{b}) \qquad \phi(\alpha) = (1 + \alpha^2)^{1/2}, \qquad D_{+\nu} D_{-\nu} = \frac{1}{h_\nu^2}(E_\nu - 2I + E_\nu^{-1}).$$

The "classical" upwind scheme consists in taking $\phi(\alpha) = |\alpha|$ in the above; the choice of a nonsmooth ϕ, however, does not allow the error expansion of §3.3. This motivates us to choose a smooth ϕ in (3.9b); the particular choice $\phi(\alpha) = (1 + \alpha^2)^{1/2}$ is considered in [St] for a convection-diffusion equation with dominating convection. Other choices are possible.

Remark. Our computational experience indicates that the "classical" ($\phi(\alpha) = |\alpha|$) and the "smooth" ($\phi(\alpha) = (1+\alpha^2)^{1/2}$) upwinding perform very similarly in accuracy terms. However, the classical choice leads to greater computational efficiency because the resulting matrix has a more exploitable structure. As we will see in the following, Theorems 3.3 and 3.4 also hold for the classical upwinding. For this reason, unless the smooth choice of $\phi(\alpha)$ is needed, as for the extrapolation procedure, we suggest the use of the classical upwinding scheme.

To obtain a matrix equation, we order the N grid points in a reverse lexicographic way, for example, and we keep the q components of $\mathbf{R}_h$ at each grid point together. So doing, we obtain a system matrix A_h, consisting of $(N \times N)$ blocks, each of size $(q \times q)$. The diagonal blocks have the form

$$C(\boldsymbol{\theta}_h) + \sum_{\nu=1}^{p} \frac{1}{h_\nu}\phi(f_\nu(\boldsymbol{\theta}_h)) \cdot I_q. \tag{3.10}$$

The outer diagonal blocks are either 0, or have the form

$$-\frac{1}{2h_\nu}(f_\nu(\boldsymbol{\theta}_h) + \phi(f_\nu(\boldsymbol{\theta}_h))) \cdot I_q \quad \text{and} \quad \frac{1}{2h_\nu}(f_\nu(\boldsymbol{\theta}_h) - \phi(f_\nu(\boldsymbol{\theta}_h))) \cdot I_q \tag{3.11}$$

(for the classical upwinding scheme, one of these two blocks in (3.11) is 0). Since $\phi(\alpha) \geq |\alpha|$, we satisfy condition (2.3) and because of assumption (3.6) we also satisfy (2.4) with all $e_j = 1$. Therefore, we can use Theorem 2.4 and Corollary 2.5, with all $e_j = 1$ and $\eta = \sigma$, to obtain Theorem 3.3.

THEOREM 3.3. *Assume that* (3.6) *holds and that the matrix A_h corresponding to* (3.9) *has been set up as described above. Then the difference equations* (3.9) *have a unique solution $\mathbf{R}_h$. Furthermore, the discretization is unconditionally stable in the sense that the following bound on A_h^{-1} holds uniformly in* $\mathbf{h}$

$$||A_h^{-1}|| \leq \frac{1}{\sigma}. \tag{3.12}$$

It is now standard to obtain error estimates and convergence for the scheme (3.9), if existence of a sufficiently smooth solution $\mathbf{R}$ of (3.4) is assumed. In fact, we can prove the following theorem.

THEOREM 3.4. *Assume that* (3.6) *holds and that* (3.4) *has a solution* $\mathbf{R} \in C^2(T^p, \mathbb{R}^q)$. *Let $\mathbf{R}|_h$ denote the restriction of $\mathbf{R}$ to T_h^p and let $\mathbf{R}_h$ denote the solution of the difference equation* (3.9). *Then we have*

$$||\mathbf{R}_h - \mathbf{R}|_h|| \leq \frac{1}{\sigma}|\mathbf{h}|_\infty \left(\frac{1}{2} + ||f||_\infty\right) ||D^2\mathbf{R}||, \tag{3.13}$$

where we have used the notations

$$|\mathbf{h}|_\infty = \max_{1\leq\nu\leq p} h_\nu,$$

$$||\mathbf{f}||_\infty = \max_{1\leq\nu\leq p} \max_{\boldsymbol{\theta}\in T^p} |f_\nu(\boldsymbol{\theta})|,$$

$$||D^2\mathbf{R}|| = \sum_{\nu=1}^{p} \max_{\boldsymbol{\theta}\in T^p} \left|\frac{\partial^2\mathbf{R}}{\partial\theta_\nu^2}(\boldsymbol{\theta})\right| = \sum_{\nu=1}^{p} \left|\left|\frac{\partial^2\mathbf{R}}{\partial\theta_\nu^2}\right|\right|$$

with $|\cdot|$ *the Euclidean norm in* $\mathbb{R}^q$.

Proof. Taylor's formula with remainder in integral form (or integration by parts) yields

$$\frac{\partial \mathbf{R}}{\partial \theta_\nu}(\theta) = D_{0\nu}\mathbf{R}(\theta) + \frac{h_\nu}{2}\mathbf{T}_\nu, \quad |\mathbf{T}_\nu| \le \left\|\frac{\partial^2 \mathbf{R}}{\partial \theta_\nu^2}\right\|, \quad |D_{+\nu}D_{-\nu}\mathbf{R}(\theta)| \le \left\|\frac{\partial^2 \mathbf{R}}{\partial \theta_\nu^2}\right\|.$$

We substitute $\mathbf{R}|_h$ into (3.9a), use (3.4), and subtract (3.9a) to obtain

$$\sum_{\nu=1}^{p} f_\nu D_{0\nu}(\mathbf{R}|_h - \mathbf{R}_h) - \frac{1}{2}\sum_{\nu=1}^{p} h_\nu \phi_\nu D_{+\nu}D_{-\nu}(\mathbf{R}|_h - \mathbf{R}_h) + C(\mathbf{R}|_h - \mathbf{R}_h) = \mathbf{E}_h$$

with

$$\phi_\nu(\boldsymbol{\theta}) = \phi(f_\nu(\boldsymbol{\theta}))$$

and

$$\mathbf{E}_h = -\frac{1}{2}\sum_{\nu=1}^{p} h_\nu f_\nu \mathbf{T}_\nu - \frac{1}{2}\sum_{\nu=1}^{p} h_\nu \phi_\nu D_{+\nu}D_{-\nu}\mathbf{R}.$$

Therefore,

$$|\mathbf{E}_h(\boldsymbol{\theta})| \le \tfrac{1}{2}|\mathbf{h}|_\infty \max_{1\le\nu\le p}(|f_\nu|_\infty + |\phi_\nu|_\infty)\, \|D^2\mathbf{R}\|,$$

and since we have $|\phi_\nu|_\infty \le 1 + |f_\nu|_\infty$ for our choice of ϕ, an application of the stability result Theorem 3.3 finishes the proof. □

Remarks. (1) Let J denote the union of the ranges of the functions $f_\nu, \nu = 1, \cdots, p$. Then Theorem 3.3 remains valid if we choose any function $\phi(\alpha)$ in (3.9a) with $\phi(\alpha) \ge |\alpha|$ for all $\alpha \in J$. Similarly, a result like Theorem 3.4 is valid for any ϕ with $|\alpha| \le \phi(\alpha) \le \text{const}\,(1+|\alpha|)$ for all $\alpha \in J$. In particular, these results are valid for classical upwinding corresponding to $\phi(\alpha) = |\alpha|$ and for schemes based on exponential fitting.

(2) The scheme (3.9) is only first order. In [DLR] we considered the leap-frog scheme, for which the local truncation error for a C^3-solution is second-order. A stability analysis based on block M-matrices seems to be restricted to first-order schemes, however, and different tools—like discrete L_2-estimates—will probably be necessary to analyze higher-order difference schemes. However, we can also resort to extrapolation (or deferred correction) techniques for the above first-order scheme to increase the order; see §3.3.

(3) To discuss the influence of the parameter σ in (3.6), let us assume that we keep the coefficients $f_\nu(\boldsymbol{\theta})$ and $\mathbf{g}(\boldsymbol{\theta})$ in (3.4) fixed whereas we choose $C(\boldsymbol{\theta}) = C(\boldsymbol{\theta}, \sigma) \ge_q \sigma I$ for different $\sigma > 0$. If σ is increased, we can, in general, expect increased smoothness of the solution $\mathbf{R}(\boldsymbol{\theta}, \sigma)$ of (3.4); see Theorem 3.2. Another consequence of increasing σ is a stronger attractivity of $\mathcal{M}$; see the discussion following Theorem 3.2. On the discrete level, we obtain from (3.12) an improved stability constant with increasing σ. Thus, for small σ, we must expect difficulties in the numerical calculations because of a possible lack of smoothness of $\mathbf{R}$ and because of a large stability constant of the discrete system. On the other hand, for large σ, the solution $\mathbf{R}$ will become smoother and the stability will become better. These occurrences are borne out in practice (see §4).

(4) Note that our results do not require any restriction on the mesh ratios h_ν/h_μ $(\nu \ne \mu)$. Thus, nothing like a CFL condition is required for stability, though one of the variables θ_ν in (3.1) might correspond to time.

(5) It is interesting to note that the discretization (3.9) can also be viewed as a discretization of the PDE

$$\sum_{\nu=1}^{p}\left[f_\nu(\boldsymbol{\theta})\frac{\partial \mathbf{R}}{\partial \theta_\nu}(\boldsymbol{\theta}) - \epsilon_\nu \frac{\partial^2 \mathbf{R}}{\partial \theta_\nu^2}(\boldsymbol{\theta})\right] + C(\boldsymbol{\theta})\mathbf{R}(\boldsymbol{\theta}) = \mathbf{g}(\boldsymbol{\theta}),$$

with $\epsilon_\nu > 0$ corresponding to $\frac{1}{2}h_\nu\phi(f_\nu)$. Thus the setting is closely related to "elliptic regularization," as also used, for example, by Sacker [Sa]. However, in Sacker's analysis the dissipation term is introduced to ensure smoothness of the solution of the modified continuous problem, whereas we add the artificial dissipation term to ensure the block M-matrix structure, which leads to stability.

3.3. Global error expansion and extrapolation. We again assume (3.6). Here we want to show that the scheme (3.9) allows an expansion of the error $\mathbf{R}|_h - \mathbf{R}_h$ in terms of powers of the stepsize. To prove such a result, we need to assume sufficient smoothness of the solution $\mathbf{R}$ of the continuous problem (3.4). In addition, to obtain the expansion, the PDE (3.4) must be solved with smooth right-hand sides different from $\mathbf{g}$, and we need existence and smoothness of the corresponding solutions. Sufficient conditions for these assumptions can be obtained by Theorem 3.2. For simplicity, we take all stepsizes h_ν as equal, $h_\nu = h$, $\nu = 1, \cdots, p$. Then we can show an expansion

$$\mathbf{R}|_h = \mathbf{R}_h + h\mathbf{z}_1|_h + h^2\mathbf{z}_2|_h + \cdots + h^j\mathbf{z}_j|_h + O(h^{j+1}), \tag{3.14}$$

where $\mathbf{z}_i : T^p \longrightarrow \mathbb{R}^q$ are smooth functions with restrictions $\mathbf{z}_i|_h$ on T_h^p. We give a precise formulation and a proof only for $j = 1$; a generalization to higher-order corrections follows along the same lines.

THEOREM 3.5. *Consider the discretization* (3.9) *for* (3.4), *and assume* $\mathbf{R} \in C^4(T^p, \mathbb{R}^q)$ *solves* (3.4). *Also, let* $\mathbf{f} \in C^2$, *and assume that the* PDE (3.4) *has a* C^2-*solution for any* C^2-*right-hand side. Then, there exists a function* $\mathbf{z}_1 \in C^2(T^p, \mathbb{R}^q)$ *such that*

$$\mathbf{R}|_h = \mathbf{R}_h + h\mathbf{z}_1|_h + O(h^2). \tag{3.15}$$

Proof. By Taylor's formula (for $\mathbf{R} \in C^3$),

$$\frac{\partial \mathbf{R}}{\partial \theta_\nu}(\theta) = D_{0\nu}\mathbf{R}(\theta) + \frac{h_\nu^2}{6}\mathbf{T}_\nu, \qquad |\mathbf{T}_\nu| \le \left\|\frac{\partial^3 \mathbf{R}}{\partial \theta_\nu^3}\right\|,$$
$$D_{+\nu}D_{-\nu}\mathbf{R}(\theta) = \frac{\partial^2 \mathbf{R}}{\partial \theta_\nu^2}(\theta) + \frac{h}{3}\mathbf{S}_\nu, \qquad |\mathbf{S}_\nu| \le \left\|\frac{\partial^3 \mathbf{R}}{\partial \theta_\nu^3}\right\|.$$

We substitute $\mathbf{R}|_h$ into (3.9a), use (3.4), and subtract (3.9a) to obtain

$$\sum_{\nu=1}^{p} f_\nu D_{0\nu}(\mathbf{R}|_h - \mathbf{R}_h) - \frac{1}{2}\sum_{\nu=1}^{p} h\phi_\nu D_{+\nu}D_{-\nu}(\mathbf{R}|_h - \mathbf{R}_h) + C(\mathbf{R}|_h - \mathbf{R}_h) = \mathbf{E}_h \tag{3.16}$$

with

$$\phi_\nu(\boldsymbol{\theta}) = \phi(f_\nu(\boldsymbol{\theta}))$$

and

$$\mathbf{E}_h = -\frac{h^2}{6}\sum_{\nu=1}^{p} f_\nu \mathbf{T}_\nu - \frac{h}{2}\sum_{\nu=1}^{p} \phi_\nu \frac{\partial^2 \mathbf{R}}{\partial \theta_\nu^2} - \frac{h^2}{6}\sum_{\nu=1}^{p} \phi_\nu \mathbf{S}_\nu.$$

Thus, the right-hand side of (3.16) has the form

$$\mathbf{E}_h(\boldsymbol{\theta}) = h\mathbf{r}_1(\boldsymbol{\theta}) + O(h^2)$$

where

$$\mathbf{r}_1(\boldsymbol{\theta}) = -\frac{1}{2}\sum_{\nu=1}^{p} \phi_\nu(\boldsymbol{\theta})\frac{\partial^2 \mathbf{R}}{\partial \theta_\nu^2}(\boldsymbol{\theta})$$

is a C^2-function. We define $\mathbf{z}_1 \in C^2$ to be the solution of

$$\sum_{\nu=1}^{p} f_\nu \frac{\partial \mathbf{z}_1}{\partial \theta_\nu} + C\mathbf{z}_1 = \mathbf{r}_1,$$

and we define $\mathbf{z}_{1,h}$ to be the solution of the discrete analogue,

$$A_h \mathbf{z}_{1,h} = \mathbf{r}_1|_h.$$

(Here we identify, as usual, vectors with grid functions, and difference equations with their matrix representations.) Then we have

$$\begin{aligned} A_h(\mathbf{R}|_h - \mathbf{R}_h) &= h\mathbf{r}_1|_h + O(h^2) \\ &= hA_h\mathbf{z}_{1,h} + O(h^2), \end{aligned}$$

and therefore (by Theorem 3.3)

$$\begin{aligned} \mathbf{R}|_h - \mathbf{R}_h &= h\mathbf{z}_{1,h} + O(h^2) \\ &= h\mathbf{z}_1|_h + O(h^2). \end{aligned}$$

To obtain the last equation, we have used the fact that

$$\mathbf{z}_1|_h = \mathbf{z}_{1,h} + O(h),$$

which follows from Theorem 3.4. This completes the proof of the theorem. □

4. Algorithm of solution and numerical examples. Here we present the results obtained for two sample problems, which highlight the considerations of the previous sections. We restrict our attention to two angular coordinates, the two-torus $T^2 = \{\boldsymbol{\theta} = (x, y) : x, y \in \mathrm{IR} \bmod 2\pi\}$, and two "radial" coordinates $\mathbf{r} = \binom{u}{v} \in \mathrm{IR}^2$. The PDE system (3.4) then assumes the form

$$(4.1) \qquad f_1(x,y)\begin{pmatrix} u \\ v \end{pmatrix}_x + f_2(x,y)\begin{pmatrix} u \\ v \end{pmatrix}_y + C(x,y)\begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} g_1(x,y) \\ g_2(x,y) \end{pmatrix},$$

with $C(x, y) \in \mathrm{IR}^{2\times 2}$.

The discretized periodic square is $T_h^2 = \{(x_i, y_j) = (ih_1, jh_2), h_1 = 2\pi/N, h_2 = 2\pi/M, i \in \mathbb{Z} \bmod N, j \in \mathbb{Z} \bmod M\}$, and we order the grid points as $(x_1, y_1), \cdots,$

$(x_N, y_1), (x_1, y_2), \cdots, (x_N, y_M)$. Then, the discretization matrix assumes the *macro*-structure:

$$(4.2) \qquad A_h = \begin{bmatrix} B_{11} & B_{12} & & & B_{1M} \\ B_{21} & B_{22} & B_{23} & & \bigcirc \\ & \ddots & \ddots & \ddots & \\ \bigcirc & & B_{M-1,M-2} & B_{M-1,M-1} & B_{M-1,M} \\ B_{M1} & & & B_{M,M-1} & B_{MM} \end{bmatrix},$$

where each $B_{ij} \in \mathrm{IR}^{2N \times 2N}$. Each outer diagonal B_{ij} has the form

$$\begin{pmatrix} \square & & \bigcirc \\ & \square & \\ & & \ddots & \\ \bigcirc & & & \square \end{pmatrix}$$

with (2×2) diagonal matrices $\square$ along the diagonal of B_{ij}. Each B_{ii} has the form

$$\begin{pmatrix} \square & \square & & & \square \\ \square & \square & \square & & \\ & \ddots & \ddots & \ddots & \\ & & \square & \square & \square \\ \square & & & \square & \square \end{pmatrix}$$

where all blocks $\square$ are again of size (2×2); the (2×2) blocks along the diagonal of B_{ii} are full, in general, whereas the outer diagonal blocks of B_{ii} are (2×2) diagonal matrices. This structure is typical for many discretizations of (4.1) (e.g., see [DLR]).

For the scheme (3.9), the (2×2) diagonal blocks are given by (3.10) and the (2×2) outer diagonal blocks are given by (3.11). We would like to stress that the matrix A_h, seen as a block matrix with blocks B_{ij}, is *not* a block M-matrix according to Definition 2.3, in general. We must look at the *micro*structure of (2×2) blocks in order to use block M-matrix theory.

There are various possibilities for solving systems of the type $A_h \mathbf{x} = \mathbf{b}$ with A_h as in (4.2). In [DLR], we described an efficient compactification procedure. This compactification takes advantage of the sparsity of the blocks B_{ij}, and it can be opportunely generalized to block M-matrices as well. However, in this paper we favor a direct factorization of the matrix A_h. This approach does not impose restrictions on the discretization, and it has its main limitation on storage requirements.

We gained experience with two (related, but not equivalent) factorization strategies for A_h. The first factorization relies on the *bordered* LU algorithm, which orginates from attempting the following block decomposition, $A_h = LU$, with L block unit lower triangular (see also [Ma]):

$$(4.3a) \qquad L = \begin{pmatrix} I & & & & \\ L_2 & I & & & \bigcirc \\ & \ddots & \ddots & & \\ \bigcirc & & L_{M-1} & & \\ E_1 & \cdots & E_{M-2} & E_{M-1} & I \end{pmatrix},$$

$$U = \begin{pmatrix} U_1 & B_{12} & & & G_1 \\ & U_2 & \ddots & \bigcirc & \\ & & \ddots & B_{M-1,M-1} & \vdots \\ \bigcirc & & & U_{M-1} & G_{M-1} \\ & & & & U_M \end{pmatrix}. \tag{4.3b}$$

We have successfully used this factorization as implemented in the solver LU2-SOL2,[1] where pivoting is performed only on the tridiagonal part of A_h; this reduces fill-in while retaining numerical stability in practice.

The second factorization, to be described next, and already mentioned in [DLR], uses a reordering of blocks. For our examples, we found this strategy to be more efficient, and the numerical results that we present below rely on this second strategy.

LEMMA 4.1. *Consider the permutation vector*

$$\mathbf{P} = \begin{cases} (1, M, 2, M-1, \cdots, \frac{M}{2}, \frac{M}{2}+1)^T, & M \text{ even} \\ (1, M, 2, M-1, \cdots, \lfloor \frac{M}{2} \rfloor, \lceil \frac{M}{2} \rceil + 1, \lceil \frac{M}{2} \rceil)^T, & M \text{ odd,} \end{cases} \tag{4.4}$$

and consider the block permutation matrix $\mathbb{P}$, *associated with* $\mathbf{P}$. *That is,* $\mathbb{P}$ *is zero except for identity blocks of dimension* $2N$, *which are placed in locations* (j, P_j), $j = 1, \cdots, M$. *Then,* $\mathbb{P}$ *transforms* A_h *into block-pentadiagonal structure:*

$$\bar{A}_h := \mathbb{P} A_h \mathbb{P}^T = \begin{pmatrix} B_{11} & B_{1M} & B_{12} & 0 & & \\ B_{M1} & B_{MM} & 0 & B_{M,M-1} & & \\ B_{21} & 0 & B_{22} & 0 & B_{23} & \\ & B_{M-1,M} & 0 & B_{M-1,M-1} & 0 & B_{M-1,M-2} \\ & \ddots & \ddots & \ddots & \ddots & \ddots \end{pmatrix}. \tag{4.5}$$

Proof. The proof is by direct verification. □

If M is even, we might consider $\bar{A}_h$ as a block tridiagonal matrix with blocks of dimension $4N \times 4N$. However, the results in [V] cannot be used, in general, because block diagonal dominance is not ensured. In any case, the block tridiagonal factorization of [V] would require as much work and storage as the factorization based on (4.3).

In our strategy, we disregard any block structure of $\bar{A}_h$ and consider $\bar{A}_h$ as a band matrix with upper and lower bandwidth $4N$; this takes into account that B_{ij} is diagonal for $i \neq j$. To compute the factorization, we use the LINPACK implementation. The factorization requires as much work and storage as the above-mentioned block factorization algorithms if no pivoting is performed (see [V]), and slightly more work and additional $4MN^2$ memory locations if partial pivoting is performed. Partial pivoting is necessary to retain numerical stability.

We also tried general-purpose sparse direct factorization software (using Harwell's routines MA28), but the performance was not competitive with the other approaches on our computational environment.

All computations below have been performed on a SPARC workstation in single precision arithmetic (unit roundoff is approximately 10^{-7}).

[1] This code was kindly provided to us by B. Fornberg.

Example 1. This problem, with a known analytical solution, has been chosen to confirm our theoretical results on the order of convergence and extrapolation, and to illustrate the dependence of the numerical error on the attractivity of the tori. If σ in (3.6) is small, we experience numerical difficulties because A_h has a large inverse. (In general, a small σ might also lead to a nonsmooth solution, but in the present example the solution is C^∞.) We have the system

$$u_x + u_y + \alpha u - v = \alpha(\sin x + \cos y),$$
$$v_x + v_y + u + \beta v = \beta(\cos x - \sin y),$$

as usual, subject to periodicity conditions, which has the exact solution $u(x,y) = \sin x + \cos y$, $v(x,y) = \cos x - \sin y$. It is easy to see that the matrix

$$C = \begin{pmatrix} \alpha & -1 \\ 1 & \beta \end{pmatrix}$$

is positive definite for any positive value of α and β, and that (3.6) is satisfied with $\sigma = \min(\alpha, \beta)$, and that (3.7) is satisfied with $\epsilon = 0$. The discretized problem leads to a block M-matrix, but not an M-matrix in the usual sense. The original dynamical system is simply

$$\dot{x} = 1,$$
$$\dot{y} = 1,$$
$$\dot{u} = -\alpha u + v + \alpha(\sin x + \cos y),$$
$$\dot{v} = -u - \beta v + \beta(\cos x - \sin y),$$

and it is clear that u and v approach the invariant torus (become functions of x and y only) approximately as fast as $e^{-\alpha t}$ and $e^{-\beta t}$, respectively. By changing α and β we change this speed. In Tables 1 and 2 we report on some results for various grids and values of α and β. The entries E_u and E_v refer to the max-error on the grid for u and v, respectively, and cond measures (as from LINPACK) the condition number of A_h. Obviously, the scheme is only first order.

For this particular problem, by using (2.1) to obtain $\|A_h^{-1}\| \leq 1/\sigma$, we might expect

$$\operatorname{cond}(A_h) \leq \left[\max(\alpha, \beta) + 1 + \frac{4}{h}\right] \cdot \frac{1}{\min(\alpha, \beta)},$$

and from Table 1 we observe that such a bound is essentially achieved for $\alpha = 10^{\pm 3}$ and $\beta = 1/\alpha$. For $\alpha = 10^{\pm 4}$, $\beta = 1/\alpha$, A_h is singular to working precision (that is, $\operatorname{cond}(A_h) > 5 * 10^{+7}$). From Tables 1 and 2, we clearly see that for $\alpha = \beta$ the stronger (weaker) the attractivity, the smaller (larger) the error, as we expected from the error estimates (3.13). For strongly attractive tori (say, $\alpha = \beta = 10^3$), very few grid points ($N = M = 10$) suffice for four digits accuracy, but for weakly attractive tori (say, $\alpha = \beta = 10^{-1}$ or 10^{-3}) even with $N = M = 80$, we have no significant digits at all. A higher-order scheme is of some help in this situation. In Table 3 we report on some typical results obtained with Richardson's extrapolation. The entry "Order" refers to the theoretical order of the procedure. Now we get one digit accuracy when $\alpha = \beta = .1$. The procedure is clearly second order, as can be appreciated when $\alpha = \beta = 1$.

Finally, an interesting occurrence can be inferred from Table 1: strong attractivity in only one of the u or v coordinates results in a very good approximation for that component and it also helps the approximation of the other one. The error estimates do not account for this behavior. This fact suggests that different (and more detailed) error estimates could be achieved.

in this context. The problem is adapted from an example in [Mo]. We have the scalar PDE

$$-u_x \cos x - u_y \sin y + bu = \sin^b y,$$

with b chosen so that $\sin^b y$ makes sense and with the usual periodicity conditions. The exact solution is a function of y only,

$$u(x,y) = u(y) = -2^b \tan^b(y/2) \int_{\pi/2}^{y/2} \frac{(\cos t)^{2b-1}}{\sin t} dt.$$

To satisfy (3.6) we take b positive (yielding, in this case, a standard M-matrix after discretization). Here we consider the case of $b = 1$ and $b = \frac{1}{3}$. We observe that (3.7) is satisfied with $\epsilon = 1$, and thus the discussion following (3.7) only guarantees a solution in C^0. In fact, with a bit of calculus and patience, we can find explicitly $u(y)$ when $b = 1$ and $b = \frac{1}{3}$, e.g., when $b = 1$,

$$u(y) = -2 \tan \frac{y}{2} \ln \left| \sin \frac{y}{2} \right|,$$

and when $b = \frac{1}{3}$,

$$u(y) = -\left(2 \tan \frac{y}{2}\right)^{1/3} \cdot \frac{1}{2} \left\{ \ln \left(1 - \cos^{2/3} \frac{y}{2}\right) \left(\cos^{4/3} \frac{y}{2} + \cos^{2/3} \frac{y}{2} + 1\right)^{-1/2} \right.$$
$$\left. - \sqrt{3} \arctan \left(\frac{2 \cos^{2/3} \frac{y}{2} + 1}{\sqrt{3}} \right) + \frac{\sqrt{3}\pi}{6} \right\}.$$

It is possible to check that, in both cases, u is a continuous function as $y \in [0, 2\pi)$ (in particular, $u(0) = u(\pi) = 0$), but the first derivative blows up at $y = 0$. When $b = \frac{1}{3}$, the first derivative of u is not even in L^2. The assumptions of Theorems 3.4 and 3.5 do not hold. Nonetheless, the upwinding scheme (3.9) works quite satisfactorily and the error behaves like $O(h)$ when $b = 1$. In Figs. 1 and 2 we show a plot of the solution $u(y)$ computed with 80 grid points for $b = 1$ and $b = \frac{1}{3}$, respectively. Of particular interest is that the computed approximation, even for $b = \frac{1}{3}$, does not crinkle (oscillate) and is qualitatively correct; that is, it reproduces the correct solution profile. However, for $b = \frac{1}{3}$ the solution has only one digit of accuracy near $y = 0$, when $N = M = 80$. In Tables 4 and 5, we have summarized the results of a few typical runs and of the extrapolation procedure for $b = 1$. The ∞-norm of the error has been computed at 10 equispaced points. For completeness, we point out that the classical upwinding scheme (see the discussion after (3.9)) performs better than the smooth upwinding for this problem, reducing the error by a factor of 2 in all runs. As already remarked, it is also computationally less expensive (much less). In any case, the good performance of the upwinding scheme is probably due to the very localized character of the singularity of the solution and to the smoothing ability of the upwinding scheme; there are similarities to the behavior of upwinding for shock calculations of hyperbolic PDEs. We plan to study these aspects, in our context, in the near future.

5. Conclusions. In this paper we have proposed a generalization of nonsingular M-matrices to block M-matrices. Such matrices arise when discretizing a linear first-order system of PDEs where each equation has the same principal part. PDEs with this structure arise in the study of invariant tori, and the setting we have studied in this paper allows us to numerically approximate a class of attracting invariant tori. The proposed discretization scheme leads to a block M-matrix under reasonable assumptions. We have proven unconditional stability and first-order convergence. Under smoothness assumptions, we have also shown an error expansion in powers of h (the mesh size), and have used this fact to achieve higher-order accuracy by Richardson's extrapolation. Finally, we have discussed some of the numerical linear algebra aspects of this and similar discretizations, and we have given numerical examples to highlight the theory and the interplay between attractivity and smoothness of the invariant tori, and accuracy of the numerical approximation. The extension to the nonlinear case will be the subject of future work.

ANALYSIS OF INITIAL TRANSIENT DELETION FOR PARALLEL STEADY-STATE SIMULATIONS*

PETER W. GLYNN† AND PHILIP HEIDELBERGER‡

Abstract. This paper investigates theoretical properties of a simple method for using parallel processors in discrete event simulations: running independent replications, in parallel, on multiple processors and averaging the results at the end of the runs. Specifically, the problem of estimating steady-state parameters from such an experiment is considered. Sampling plans are considered in which the replication lengths are given by limits on either simulated or computer time, and in which the beginning portion of each run may be deleted for the purpose of controlling initialization bias. The critical relative growth rates for the number of processors, the length of each replication, and the length of the deletion period that are required in order to produce valid confidence intervals for steady-state parameters are determined. When the replication length is determined by computer time, the straightforward estimator with deletion may not work for a large number of processors. In this case, the deletion is essentially useless due to an additional bias term that arises because the simulated time at the end of a replication is random. In this case, a new estimator can be used to remove this source of bias.

1. Introduction.

A simple way to exploit the power of parallel processing in computationally intensive discrete event simulations is to run multiple independent replications, in parallel, on the processors and to appropriately average the results at the end of the runs. At first glance, this method produces a p-fold speedup, i.e., reduction in completion time, over a sequential (one processor) simulation having the same variance where p is the number of processors. We call this the parallel replications approach.

An alternative approach is distributed simulation, in which all p processors cooperate on a single realization of the simulation. While significant speedups have been achieved using distributed simulation in specific problem domains (see, e.g., Fujimoto (1989, 1990); Goli, Heidelberger, Towsley, and Yu (1990); Lubachevsky (1989); Nicol (1988); Unger and Fujimoto (1989); Unger and Jefferson (1988); and Yu, Towsley, and Heidelberger (1989)), in our opinion, distributed simulation has not yet been demonstrated to be a robust and effective general purpose technique for dealing with the types of complex models arising in manufacturing, computer, and communications systems.

In contrast, parallel replications are conceptually and practically simple to apply and are almost universally applicable. The widespread applicability stems from the fact that a major reason why many models must run for a long time is the slow rate at which a simulation estimate's variance decreases. Essentially, parallel replications are inappropriate only when either

1. The model is such that a single replication cannot be completed on a single processor within a reasonable amount of time. This may be due to either an exceptionally large model, which, e.g., may not fit into the memory of a single processor, or, in steady-state simulations, to a model with a very slowly dissipating initial transient.

2. The variance from each replication is very small, in which case the output is nearly deterministic and having a large number of replications is merely a waste of computing resources.

A simple analytic model for comparing the statistical efficiencies of distributed simulation and parallel replications that justifies the above conclusion was developed in Heidelberger (1986).

However, there are some potentially serious statistical problems associated with the parallel replications approach, especially for a large number of processors. In the case of estimating expected values of so-called transient quantities, these problems have been studied in Heidelberger (1988) and Glynn and Heidelberger (1991a). The source of the problem can be illustrated as follows. Suppose that replications are run on each of p processors and that one sets a completion time constraint of t units of (computer) time per processor. The number of replications completed on each processor by time t is a random variable. While there are a number of different ways the output can be averaged, there is some sampling bias due to the fixed completion time t and the associated random number of replications. If t remains fixed, then as $p \to \infty$, the estimates can converge to the wrong quantity. A variety of estimators that alleviate this situation can be devised, but they have the property that some or all of the replications in progress at time t must be completed before the estimator can be formed. Thus one must pay a completion time penalty in order to obtain the correct convergence behavior. Even in the case of a single processor, some care needs to be taken in order to best handle the bias associated with stopping the simulation at time t; see Meketon and Heidelberger (1982), Glynn (1989b), and Glynn and Heidelberger (1990). In our discussion, the above results are described primarily in terms of estimating transient quantities, but they also apply to steady-state estimation in regenerative simulations (see Smith (1955) or Crane and Iglehart (1975)) since, in this case, steady-state performance measures can be expressed as a ratio of expected values of "transient" quantities. Bhavsar and Isaac (1987) discuss other properties associated with parallel replication schemes for transient quantities.

In this paper, we consider the parallel replications approach to the steady-state estimation problem in more generality. Specifically, we consider sampling schemes that delete some initial part of each run in order to reduce "initialization bias," i.e., bias due to the fact that the model cannot typically be started in its steady-state distribution (otherwise, there would be no need to simulate). We determine the critical relative growth rates for

1. the number of processors (replications),
2. the length of each replication, and
3. the length of the deletion period

that are required in order for the method of parallel replications with initial transient deletion to obey a usable central limit theorem. By a usable central limit theorem, we mean one that is centered about the unknown steady-state parameter and upon which confidence intervals for the steady-state parameter can be based.

Determining the length of each replication is a basic issue in such an experiment. We consider two approaches: the first, based on simulated time, and the second, based on computer time. The approach chosen makes a difference, in terms of both completion time and estimator bias. Deletion helps to reduce bias in the first approach;

however, the completion time is a random variable. On the other hand, when the replication length is based on computer time, the completion time is deterministic. However, an additional source of estimator bias is introduced in this case. Furthermore, this additional source of bias is not eliminated by deletion, and thus initial transient deletion is essentially useless in this case. This bias, which is of order one over the replication length, is due to the fact that the estimate from each processor takes the form of a ratio of two random variables. The denominator in this ratio is the (random) length of the replication in simulated time (minus the initialization period). When the run is based on simulated time, the denominator is deterministic and this additional bias is not introduced. A new estimator (also based on computer time) that gets around this problem is proposed and analyzed. This estimator has a deterministic stopping time and benefits from the initial transient deletion.

Some comments about the analysis techniques used in this paper are appropriate. First, we state limit theorems in a triangular array setting, i.e., we simultaneously let $p \to \infty$ and $t(p) \to \infty$ where p is the number of processors and $t(p)$ is the length of each replication. Since in practice only a fixed, finite number of processors are available, these results should be interpreted as determining (qualitatively) appropriate values for $t(p)$ in order to obtain proper convergence behavior for large values of p. Second, many of the results are established under regenerative assumptions that would appear to limit the applicability of the results. However, this is done mainly as a mathematical convenience and does not impose significant restrictions since

1. Many systems have (hidden) regenerative structure. For example, Glynn (1989a) shows that many finite state space generalized semi-Markov processes (GSMPs) are regenerative. Essentially all discrete event simulation models can be described as GSMPs.

2. The estimators involved do not make any specific use of the regenerative structure, i.e., one need not identify regeneration points and group the data by regenerative cycles. To further amplify this point, Glynn (1989b) derives bias expansions for certain integrals of regenerative processes and then proposes a bias-reducing technique based on the form of these expansions. However, to employ that method in practice requires identifying the regeneration times and estimating expectations of random variables defined over the regenerative cycles. No such requirement is made here.

Section 4 contains further discussion of these points.

In order to present a complete and self-contained description of the relevant results, certain theorems are restated from other papers, specifically, Glynn (1987, 1989b) and Glynn and Heidelberger (1991b). The rest of the paper is organized as follows. In §2 we describe the formal mathematical framework, and in §3 we consider estimators based on a fixed amount of simulated time, both with and without deletion. Section 4 treats estimators based on computer time but without deletion, while §5 treats estimators based on computer time with deletion. The proofs are contained in §6. Finally, the results are summarized in §7.

The focus of this paper is theoretical. However, in Glynn and Heidelberger (1992) we describe experiments with these estimators on simple queueing network models of computer systems. The experimental results reported in that paper confirm the theoretical results developed in this paper.

2. The framework. Suppose that our goal is to estimate the steady-state mean of $X = (X(t) : t \geq 0)$, where X is a real-valued stochastic process. We let $C = (C(t) : t \geq 0)$ be the associated *cumulative computer time* process, so that $C(t)$ represents the

random amount of computer time required to generate X over the interval $[0,t]$. Let $\Rightarrow$ denote weak convergence, or convergence in distribution (see Billingsley (1968)). We assume that (X, C) satisfies the following set of hypotheses:
(2.1)

(i) C is a nondecreasing process.

(ii) There exist (deterministic) constants α, λ^{-1} $(0 < \lambda^{-1} < \infty)$, and a 2×2 matrix G such that

$$Z_\varepsilon(\cdot) \Rightarrow GB(\cdot)$$

as $\varepsilon \downarrow 0$ in $D[0,\infty)$ (the Skorohod space of functions $x : [0,\infty) \to I\!R^2$ that are right continuous and have left limits), where B is a two-dimensional standard Brownian motion and

$$Z_\varepsilon(t) = \varepsilon^{-1}\left(\varepsilon^2 \int_0^{t/\varepsilon^2} X(s)ds - \alpha t,\ \varepsilon^2 C(t/\varepsilon^2) - \lambda^{-1}t\right).$$

Assumption (2.1) (i) is reasonable in view of the interpretation of $C(t)$. As for (2.1) (ii), we note that one consequence of the assumption is that X and C satisfy a joint central limit theorem (CLT):

$$T^{1/2}\left(\frac{1}{T}\int_0^T X(s)ds - \alpha,\ \frac{C(T)}{T} - \lambda^{-1}\right) \Rightarrow N(0,H) \tag{2.2}$$

as $T \to \infty$, where $H = GG^t$. (In this case note that $GN(0,I)$ has the same distribution as $N(0,H)$ where I is the identity matrix. In one dimension, $\sigma N(0,1)$ has the same distribution as $N(0,\sigma^2)$.) Thus, assumption (2.1) (ii) is best viewed as a strengthened version of the ordinary CLT. Because of the fact that (2.1) (ii) deals with weak convergence of stochastic processes (as opposed to ordinary random variables), it is typically termed a functional central limit theorem (FCLT) hypothesis. See Billingsley (1968) for further discussion of FCLTs.

It turns out that a great variety of stochastic processes exhibit FCLT behavior. For example, suppose that $C(\cdot)$ has a positive derivative so that it can be represented as

$$C(t) = \int_0^t \chi(s)ds, \quad \text{where} \quad \chi(t) > 0 \quad \text{a.s. for} \quad t \geq 0. \tag{2.3}$$

Under (2.3), $\chi(s)$ is the rate at which computer time is consumed at simulated time s. If the process $((X(t), \chi(t)) : t \geq 0)$ is regenerative and satisfies certain moment conditions, then (2.1) (ii) is known to be valid (see Glynn and Whitt (1987)). Regenerative structure is present in many of the stochastic models that are commonly simulated; see, for example, Glynn (1982). In addition, (2.1) (ii) holds if $((X(t), \chi(t)) : t \geq 0)$ is a martingale process or mixing process satisfying certain regularity hypotheses (see Ethier and Kurtz (1986)) or if it is an associated sequence (see Newman and Wright (1981)). Also, (2.1) (ii) is known to be valid for a large class of Markov processes (see Maigret (1978) and Nummelin (1984)). Because of the broad validity of (2.1) (ii), we view this condition as a mild regularity hypothesis that is satisfied by virtually all "real world" simulations.

One consequence of the joint CLT (2.2) is that

$$\frac{1}{T}\int_0^T X(s)ds \Rightarrow \alpha, \tag{2.4}$$

$$\frac{1}{T}C(T) \Rightarrow \lambda^{-1}, \tag{2.5}$$

as $T \to \infty$. The law of large numbers (2.4) states that the process X "settles down," on average, to the constant α; the parameter α is known as the *steady-state mean* of X. The goal of the steady-state simulation algorithms to be described in this paper is the efficient estimation of α. Also, (2.5) states that λ^{-1} may be interpreted as the long-run rate at which computer time is expended per unit of simulated time. Equivalently, λ is the long-run rate at which simulated time is generated per unit of computer time.

Two different (reasonable) strategies for estimating α can be employed by the simulation analyst. The first possibility is to generate a fixed amount of simulated time on each of the p processors, and to obtain an estimator for α by averaging the resulting observations over each of the p processors. This class of estimators, together with related initial transient deletion strategies, is discussed in §3. The second approach is to fix the amount of computer time available on each of the p processors, and to obtain an estimator for α by averaging over the random amount of simulated time generated on each of the p processors within the computational budget constraint. For $c \geq 0$, let $T_i(c) = \sup\{t \geq 0 : C_i(t) \leq c\}$ be the inverse process to $C_i(\cdot)$. The random variable (r.v.) $T_i(c)$ can be interpreted as the amount of simulated time that is generated on processor i in the first c units of computer time; we refer to $T_i(c)$ as the *cumulative simulated time* process associated with processor i. Hence, the second estimator involves averaging the process X_i over the random interval $[0, T_i(c)]$ and all p processors. Section 4 is devoted to studying this class of estimators when no initial transient deletion is applied, whereas §5 considers these estimators when initial transient deletion is applied.

3. Steady-state estimation using simulated time. Suppose that the process X is simulated up to (deterministic) time t on each of the p available processors. If the first $\beta(t)$ simulated time units are deleted from the initial segment of each copy X_i, we obtain the estimator

$$\alpha_s(p,t) = \frac{1}{p}\sum_{i=1}^{p} \frac{1}{t-\beta(t)} \int_{\beta(t)}^{t} X_i(s)ds$$

(the subscript s stands for simulated time).

In our limit theorems, we shall be interested in determining how large the time horizon t needs to be for the parallel estimation algorithm to work efficiently. We shall therefore view t as a deterministic function $t = t(p)$ of the number of processors. Then $\beta(t) = \beta(t(p))$ is also a deterministic function of p. The limit theorems will include growth conditions on $t(p)$ and $\beta(t(p))$. To simplify the notation, we shall write $\alpha_s(p)$ and $\beta_s(p)$ as shorthand for $\alpha_s(p, t(p))$ and $\beta(t(p))$, respectively.

A consequence of (2.2) (and hence (2.1)) is that

$$\begin{aligned} T\left(\frac{1}{T}\int_0^T X(s)ds - \alpha\right)^2 &\Rightarrow \sigma_1^2 N(0,1)^2, \\ T\left(\frac{C(T)}{T} - \lambda^{-1}\right)^2 &\Rightarrow \sigma_2^2 N(0,1)^2, \end{aligned} \tag{3.1}$$

as $T \to \infty$, where $\sigma_i^2 = H_{ii}$ $(i = 1, 2)$. In order to carry out certain arguments, we will need to assume that the expectation operator can be passed through (3.1):

$$TE\left(\frac{1}{T}\int_0^T X(s)ds - \alpha\right)^2 \to \sigma_1^2, \tag{3.2}$$
$$TE\left(\frac{C(T)}{T} - \lambda^{-1}\right)^2 \to \sigma_2^2,$$

as $T \to \infty$. A variety of stochastic processes obey (3.2), including regenerative processes (Smith (1955)), mixing and martingale process sequences (Ethier and Kurtz (1986)), and associated sequences (Newman and Wright (1981)) under appropriate moment conditions. Condition (3.2) is equivalent to asserting that $\{T(T^{-1}\int_0^T X(s)ds - \alpha)^2 : T > t_0\}$ and $\{T(C(T)/T - \lambda^{-1})^2 : T > t_0\}$ are uniformly integrable for some (finite) t_0 (see Chung (1974, p. 97)).

We will also need an assumption that controls the extent to which the initial transient biases the observations of the simulation. To be precise, let $b(t) = EX(t) - \alpha$. We assume that

$$\int_0^\infty |b(s)|ds < \infty. \tag{3.3}$$

Assumption (3.2) holds whenever $EX(t) \to \alpha$ exponentially fast (i.e., there exist constants $A, \lambda > 0$ such that $|b(t)| \leq Ae^{-\lambda t}$). This exponential rate of convergence is typical of most "real world" simulations. For example, finite-state irreducible aperiodic discrete-time Markov chains and finite-state irreducible continuous-time Markov chains both exhibit exponential convergence to their steady-state values (see Karlin and Taylor (1975)). Also, Nummelin and Tuominen (1982) prove exponential convergence rate results in a general state space Markov chain setting.

Our first theorem considers the case in which no initial bias deletion is performed, so that $\beta(t) \equiv 0$. Let $b = \int_0^\infty b(s)ds$.

THEOREM 1. *Assume* (2.1), (3.2), *and* (3.3) *are in force and that* $\beta(t) \equiv 0$. *Then,*

(i) *if* $p/t(p) \to \infty$, $t(p) \to \infty$, *and* $b \neq 0$, *then* $\sqrt{pt(p)}\ |\alpha_s(p) - \alpha| \Rightarrow \infty$ *as* $p \to \infty$,

(ii) *if* $p/t(p) \to m$ $(0 < m < \infty)$, *then* $\sqrt{pt(p)}\ (\alpha_s(p) - \alpha) \Rightarrow \sigma_1 N(0,1) + b\sqrt{m}$ *as* $p \to \infty$,

(iii) *if* $p/t(p) \to 0$, *then* $\sqrt{pt(p)}\ (\alpha_s(p) - \alpha) \Rightarrow \sigma_1 N(0,1)$ *as* $p \to \infty$.

The proof of this result appears in Glynn (1987). Note that if no truncation is used, $\alpha_s(1,t) = t^{-1}\int_0^t X_1(s)ds$. Then, (2.2) asserts that

$$\alpha_s(1,t) \overset{\mathcal{D}}{\approx} \frac{\sigma_1}{\sqrt{t}} N(0,1) \tag{3.4}$$

for large t ($\overset{\mathcal{D}}{\approx}$ denotes "approximately equal in distribution"). On the other hand, Theorem 1 (iii) states that

$$\alpha_s(p, t(p)) \overset{\mathcal{D}}{\approx} \frac{\sigma_1}{\sqrt{pt(p)}} N(0,1) \tag{3.5}$$

under the conditions stated there. Comparing (3.5) to (3.4), we see that (3.5) implies a p-fold speedup in the algorithm over that achieved with a single processor, i.e.,

$$\alpha_s(1, pt(p)) \overset{\mathcal{D}}{\approx} \alpha_s(p, t(p)).$$

Of course, a p-fold speedup is the best possible rate increase that we can expect in a parallel processing environment. Hence, Theorem 1 can be interpreted as stating that the time horizon $t = t(p)$ to be simulated on each of the p processors should satisfy $t >> p$, in order that the parallel algorithm achieve optimal efficiency.

Our next theorem considers the situation in which initial transient deletion is implemented. We note that $\beta_s(p)/t(p)$ is the fraction of the total simulated time that is deleted. The strategies that are considered here delete an asymptotically negligible fraction of the total observation set that is simulated.

THEOREM 2. *Assume* (2.1) *and* (3.2) *are in force and that* $b(t) \to 0$ *exponentially fast. Suppose* $\beta_s(p)/t(p) \to 0$ *as* $p \to \infty$. *If*

(i) $p/t(p) \to \infty$ *and* $\beta_s(p)/\log p \to \infty$, *or*

(ii) $p/t(p) \to m$ $(0 < m < \infty)$ *and* $\beta_s(p) \to \infty$, *or*

(iii) $p/t(p) \to 0$

as $p \to \infty$, *then*

$$\sqrt{pt(p)}(\alpha_s(p) - \alpha) \Rightarrow \sigma_1 N(0,1)$$

as $p \to \infty$.

For a proof, see Glynn and Heidelberger (1991b). Theorem 2 shows that with a modest amount of initial transient deletion, one can reduce the length of the time horizon significantly without affecting the p-fold speedup factor. In particular, if $t(p) = p^r$ $(r > 0)$, the p-fold speedup is retained so long as $\beta_s(p) = p^{\varepsilon}$ $(0 < \varepsilon < r)$. Thus, when initial transient deletion is suitably implemented, p-fold increases in efficiency ensue from time horizons that grow essentially arbitrarily slowly in p. A result similar to Theorem 2 can also be derived when the bias function $b(\cdot)$ decays polynomially fast (i.e., there exists $A, r > 0$, such that $|b(t)| \le At^{-r}$ for $t \ge 0$); see Glynn and Heidelberger (1991b) for further details.

In our next theorem, we consider the case in which the fraction of the total simulation time that is deleted is fixed, so that the fraction deleted is no longer negligible. As might be expected, this rule, although reasonable from an implementation viewpoint, has a cost in terms of (greater) asymptotic variability.

THEOREM 3. *Assume* (2.1) *and* (3.2) *are in force and that* $b(t) \to 0$ *exponentially fast. If* $\beta_s(p) = \beta t(p)$ $(0 < \beta < 1)$ *and* $t(p) = p^r$ $(r > 0)$, *then*

$$\sqrt{pt(p)}(\alpha_s(p) - \alpha) \Rightarrow (1 - \beta)^{-(1/2)}\sigma_1 N(0,1)$$

as $p \to \infty$.

For a proof, see Glynn and Heidelberger (1991b). Theorem 3, like Theorem 2, asserts that the time horizon over which we achieve a p-fold increase in efficiency is broadened considerably by using initial bias deletion. However, because of the fact that one deletes a fixed fraction of the total observation set, one pays a cost in the sense that the asymptotic variance is inflated by a factor of $(1 - \beta)^{-1}$. On the other hand, for $\beta = 0.1$, the increase in the variance is only about 11 percent. Thus, the statistical cost incurred in using such a procedure is quite modest.

We conclude this section with a discussion of the computational cost associated with using estimators based on simulated time. In particular, assuming that the machine is (temporarily) dedicated to the estimation of α, the question of the algorithm's completion time is of significant importance. Recalling that $C_i(t)$ is the time at which the ith processor completes the simulation of X over $[0,t]$, the completion time for a simulated time horizon of t is given by

$$C(p,t) = \max_{1\leq i\leq p} C_i(t).$$

An additional relevant performance characteristic is the total idle time cumulated over all p processors, assuming that each processor must remain idle until all p processors have completed their assigned tasks. The idle time quantity is defined as

$$I(p,t) = \sum_{i=1}^{p} [C(p,t) - C_i(t)].$$

Set $C_s(p) = C(p,t(p))$ and $I_s(p) = I(p,t(p))$. Our final theorem of this section examines the behavior of $C_s(p)$ and $I_s(p)$ when the number of processors p is large. We will need one further assumption. Note that one consequence of (2.2) is that if $\sigma_2^2 > 0$, then

$$F_t(x) \rightarrow \Phi(x) \tag{3.6}$$

as $t \rightarrow \infty$, where $F_t(x) = P\{t^{-(1/2)}(C(t)-\lambda^{-1}t)/\sigma_2 \leq x\}$ and $\Phi(x) = P\{N(0,1) \leq x\}$. We wish to strengthen (3.6) to

$$\sup_{-\infty<x<\infty} |F_t(x) - \Phi(x)| = 0(t^{-(1/2)}) \tag{3.7}$$

as $t \rightarrow \infty$. This condition is known, in the probability literature, as a Berry–Esséen condition. The convergence result (3.7) is usually valid for stochastic processes satisfying (2.1). For example, regenerative processes (Bolthausen (1980)) and general state space Markov chains (Bolthausen (1982)) are known to satisfy (3.7) under suitable regularity hypotheses.

THEOREM 4. *Assume that* (2.1) *is in force with* $\sigma_2^2 > 0$ *and that* (3.2) *and* (3.7) *hold. If* $t(p)/p^2 \rightarrow \infty$, *then*

(i)
$$\frac{C_s(p) - \lambda^{-1}t(p)}{\sigma_2\sqrt{2t(p)\log p}} \Rightarrow 1,$$

(ii)
$$\frac{I_s(p)}{\sigma_2 p\sqrt{2t(p)\log p}} \Rightarrow 1$$

as $p \rightarrow \infty$.

According to Theorem 4, if $t(p) >> p$, then we may approximate $C_s(p)$ and $I_s(p)$ as

$$\begin{aligned} C_s(p) &\overset{\mathcal{D}}{\approx} \lambda^{-1}t(p) + \sigma_2\sqrt{2t(p)\log p}, \\ I_s(p) &\overset{\mathcal{D}}{\approx} \sigma_2 p\sqrt{2t(p)\log p}. \end{aligned} \tag{3.8}$$

Since λ^{-1} and σ_2^2 are typically unknown, the magnitude of the completion time $C_s(p)$ is, to some extent, a priori unpredictable. This is clearly undesirable. Furthermore, (3.8) shows that the total idle time can potentially be quite large. As a consequence, the machine may be significantly underutilized with estimators of the type considered in this section (assuming that processors are not freed until time $C_s(p)$). For these reasons, the remainder of this paper explores estimators in which the completion time is fixed.

4. Steady-state estimation using computer time: No initial transient deletion. In this section, we suppose that each processor simulates X for a fixed (deterministic) amount of computer time c. At the completion time c, processor i will have generated X_i up to time $T_i(c)$. Given that no initial transient deletion is employed, two different estimators immediately suggest themselves:

$$\alpha_1(p,c) = \frac{1}{p}\sum_{i=1}^{p} \frac{1}{T_i(c)} \int_0^{T_i(c)} X_i(s)ds,$$

$$\alpha_2(p,c) = \frac{\sum_{i=1}^{p} \int_0^{T_i(c)} X_i(s)ds}{\sum_{i=1}^{p} T_i(c)}.$$

Note that $\alpha_2(p,c)$ bears a strong resemblance to the usual ratio estimator for steady-state parameters in regenerative simulations (identify $T_i(c)$ as the length of the ith regenerative cycle).

As in §3, we shall be interested in limit theorems that describe how large the (computer) time horizon c should be, relative to the number of processors, in order that a p-fold speedup ensues. We shall therefore take c as a deterministic function $c = c(p)$ of the number of processors p. The limit theorems will then provide appropriate growth conditions on $c(p)$. As a shorthand notation, we will write $\alpha_i(p) = \alpha_i(p, c(p))(i = 1, 2)$.

Our first task is to understand the behavior of the sample means obtained from the individual processors.

THEOREM 5. *Assume that* (2.1) *and* (2.3) *hold. Then,*

(i) $\tilde{Z}_\varepsilon(\cdot) \Rightarrow \tilde{G}B(\cdot)$ *as* $\varepsilon \downarrow 0$ *in* $D[0,\infty)$, *where*

$$\tilde{Z}_\varepsilon(c) = \varepsilon^{-1}\left(\varepsilon^2 \int_0^{T(c/\varepsilon^2)} X(s)ds - \alpha\varepsilon^2 T(c/\varepsilon^2),\ \varepsilon^2 T(c/\varepsilon^2) - \lambda c\right),$$

$$\tilde{G}\tilde{G}^t = \tilde{H} \quad \textit{and} \quad \tilde{H}_{11} = \lambda H_{11}, \quad \tilde{H}_{12} = \tilde{H}_{21} = -\lambda^2 H_{12}, \quad \tilde{H}_{22} = \lambda^3 H_{22}.$$

(ii)

$$c^{1/2}\left(\frac{\int_0^{T(c)} X(s)ds}{T(c)} - \alpha,\ \frac{T(c)}{c} - \lambda\right) \Rightarrow N(0, \underset{\sim}{H})$$

as $c \to \infty$, *where* $\underset{\sim}{H}_{11} = \lambda^{-1}H_{11}$, $\underset{\sim}{H}_{21} = -\lambda H_{12}$, *and* $\underset{\sim}{H}_{22} = \lambda^3 H_{22}$.

As in §3, we shall require that the cumulative processes defined on the time scale of computer time be appropriately uniformly integrable. Specifically, we shall need to assume that

$$cE\left(\frac{1}{T(c)}\int_0^{T(c)} X(s)ds - \alpha\right)^2 \to \lambda^{-1}\sigma_1^2,$$

$$c^{-1}E\left(\int_0^{T(c)} [X(s) - \alpha]ds\right)^2 \to \lambda\sigma_1^2, \tag{4.1}$$

$$cE\left(\frac{T(c)}{c} - \lambda\right)^2 \to \lambda^3\sigma_2^2,$$

as $c \to \infty$ (recall that $H_{ii} = \sigma_i^2$).

Theorem 5 asserts that the central limit behavior of X is preserved, in a qualitative sense, when the time scale is changed from that of simulated time to computer time. Since initial transient bias plays a critical role in the study of the estimators considered in this paper, it is incumbent upon us to also consider the extent to which the bias characteristics of X are altered by a change in the time scale.

We start by noting that if $E\int_0^{T(c)} |X(s)|ds < \infty$ and if (2.3) holds where $\chi(t) > 0$ almost surely for $t \geq 0$, a change-of-variables formula can be applied to obtain

$$\int_0^{T(c)} X(s)ds = \int_0^c Y(s)ds \quad \text{a.s.},$$

where $Y(s) = X(T(s))/\chi(T(s))$. The process $Y = (Y(t) : t \geq 0)$ is, in some sense, the original process X with its time scale transformed from simulated time to computer time. It turns out that the transformation that sends X into Y preserves any regenerative structure that may be present on the time scale of simulated time.

PROPOSITION 1. *Assume that* (2.3) *holds. If* $((X(t), \chi(t)) : t \geq 0)$ *is regenerative with respect to the random times* $(\tau_n : n \geq 1)$, *then* $(Y(t) : t \geq 0)$ *is regenerative with respect to the sequence* $(\eta_n : n \geq 1)$, *where* $\eta_n = C(\tau_n)$.

As indicated earlier in this paper, regenerative structure is to be found in many of the stochastic processes X that are simulated in practice. Given that X is regenerative, it is reasonable to further assume that the pair (X, χ) is also regenerative. Thus, we view regenerative hypotheses on the pair (X, χ) as a fairly mild restriction on the class of processes to be analyzed here. It is worth noting that while the proof techniques that appear in the remainder of this paper demand, to some extent, regenerative structure, our estimation strategies will be completely independent of the nature of the regenerations. As a consequence, our estimators will not require explicit identification of the regeneration points during the course of the simulation. The regenerative hypotheses will appear solely as mathematical regularity conditions and not as a vital component of the methodology itself.

The following hypotheses help to simplify certain proofs; they are not necessary to the development, however, and can be relaxed significantly, at the cost of greater mathematical complexity. Because we do not require that the simulation be started in the regeneration state, we need to make a distinction between the first (atypical) regeneration time τ_1 and the subsequent regeneration times. Let $\tilde{\eta} = \eta_2 - \eta_1$ and $\tilde{\tau} = \tau_2 - \tau_1$.

(4.2) There exists a constant $0 < x_1 < \infty$ such that $\chi(s) \geq x_1$ a.s.,

$$\begin{gathered} E[\eta_2] < \infty, \quad E[\tau_2] < \infty, \quad E[\eta_2\tau_2] < \infty, \\ E\left[\int_0^{\tau_2} |\chi(s)|ds\right] < \infty \quad \text{and} \quad E\left[\eta_2 \int_0^{\tau_2} |X(s)|ds\right] < \infty, \end{gathered} \tag{4.3}$$

Both η_1 and $\tilde{\eta}$ have probability density functions.

Assumption (4.2) merely states that there is a minimum rate at which computer time is consumed.

We are now ready to describe the behavior of the bias of the estimators $\alpha_1(p)$ and $\alpha_2(p)$.

THEOREM 6. *Assume that* (2.1), (2.3), (4.1), (4.2), *and* (4.3) *hold. If, in addition,* $c(p) \to \infty$ *as* $p \to \infty$, *then*

$$E\alpha_i(p) = \alpha + \frac{b_i}{c(p)} + o\left(\frac{1}{c(p)}\right)$$

as $p \to \infty$ $(i = 1, 2)$, *where* $b_1 = a + H_{12}$, $b_2 = a$, *and*

$$a = E\left[\int_0^{\tau_1} (X(s) - \alpha)ds\right] / \lambda - E\left[\int_0^{\tilde{\tau}} \int_0^s \chi(\tau_1 + u)du(X(\tau_1 + s) - \alpha)ds\right] / E\tilde{\tau}.$$

Roughly speaking, the bias in $\alpha_1(p)$ is due to two factors. First, the estimator $\alpha_1(p)$ is a ratio estimator, i.e., it is expressible as the ratio of two r.v.'s. The nonlinearity inherent in ratio estimators gives rise to the term $H_{12}/c(p)$. In addition, the expectation of the centered numerator r.v. $\int_0^{T(c)} [X(s) - \alpha]ds$ is nonzero, and this gives rise to the additional bias term $a/c(p)$. As for the bias of $\alpha_2(p)$, the ratio estimator bias is reduced by a factor of p because of the p-fold increase in the sample size of the numerator and denominator r.v.'s that appear in $\alpha_2(p)$.

Suppose that $\chi(s) = \lambda^{-1}$ almost surely. In this case, computer time is proportional to simulated time, i.e., $C(T) = T/\lambda$. Thus, $C(T)/T$ is deterministic, in which case $\sigma_2^2 = 0$ and $H_{12} = 0$. Therefore, $b_1 = b_2$ and the additional bias due to the randomness in $C(T)$ disappears.

The following theorem provides the analogue of Theorem 1 in the current setting, in which estimation occurs on the time scale of computer time rather than simulated time.

THEOREM 7. *Under the same hypotheses as in Theorem* 6, *the following results hold:*

(i) *If* $p/c(p) \to \infty$, $c(p) \to \infty$, *and* $b_i \neq 0$, *then* $\sqrt{pc(p)}|\alpha_i(p) - \alpha| \Rightarrow \infty$ *as* $p \to \infty$ $(i = 1, 2)$.

(ii) *If* $p/c(p) \to m$ $(0 < m < \infty)$, *then* $\sqrt{pc(p)}(\alpha_i(p) - \alpha) \Rightarrow \lambda^{-(1/2)}\sigma N(0, 1) + b_i m^{(1/2)}$ *as* $p \to \infty$ $(i = 1, 2)$.

(iii) *If* $p/c(p) \to 0$ *as* $p \to \infty$, *then* $\sqrt{pc(p)}(\alpha_i(p) - \alpha) \Rightarrow \lambda^{-(1/2)}\sigma N(0, 1)$ *as* $p \to \infty$ $(i = 1, 2)$.

According to Theorem 7, we typically need to choose $c(p) >> p$ when no initial bias deletion is used in order to achieve the desired p-fold increase in efficiency.

5. Steady-state estimation using computer time: Initial transient deletion. This section is devoted to analyzing modified versions of the estimators introduced in §4. Specifically, we shall modify the two estimators so that an initial segment is deleted from the observations generated by each processor. To precisely define the modified estimators, we let $\kappa(c) \leq c$ be a deterministic deletion point specified on the time scale of computer time. In other words, all observations generated in the first $\kappa(c)$ units of computer time are discarded. Of course, this just amounts to throwing away the initial segment $(X_i(t) : 0 \leq t \leq \gamma_i(c))$, where $\gamma_i(c) = T_i(\kappa(c))$. The modified versions of the two estimators studied in §4 are then defined as

$$\alpha_3(p, c) = \frac{1}{p} \sum_{i=1}^{p} \frac{1}{T_i(c) - \gamma_i(c)} \int_{\gamma_i(c)}^{T_i(c)} X_i(s)ds,$$

$$\alpha_4(p, c) = \frac{\sum_{i=1}^{p} \int_{\gamma_i(c)}^{T_i(c)} X_i(s)ds}{\sum_{i=1}^{p} [T_i(c) - \gamma_i(c)]}.$$

Once again, to simplify notation, we set $\alpha_i(p) = \alpha_i(p, c(p))$ $(i = 3, 4)$ and $\kappa_c(p) = \kappa(c(p))$. We note that the assumption $\kappa_c(p)/c(p) \rightarrow 0$ as $p \rightarrow \infty$ is just a statement that the fraction of computer time devoted to observations that will eventually be deleted tends to zero in the limit.

Just as Theorem 2 required exponentially decreasing bias (on the simulated time scale), we will need some additional hypotheses to generate exponentially decreasing bias on the computer time scale.

$$E \exp t\eta_2 < \infty \quad \text{for some } t > 0, \tag{5.1}$$

$$X \text{ is a bounded process, i.e., } \sup\{|X(t,w)| : t \geq 0,\ w \epsilon \Omega\} \overset{\Delta}{=} \|X\| < \infty. \tag{5.2}$$

Note that (5.1) is true if $E \exp t_2\tau_2 < \infty$ for some $t_2 > 0$ and $\chi(s) \leq M < \infty$ almost surely for all $s \geq 0$ (since $\eta_2 \leq M\tau_2$ in this case). Thus if X is a bounded process, exponential tail behavior of η_2 is inherited from that of τ_2.

THEOREM 8. *Suppose that* $\kappa_c(p)/c(p) \rightarrow 0$ *as* $p \rightarrow \infty$. *If, in addition to the hypotheses of Theorem* 6, (5.1) *and* (5.2) *hold, then*

(i) *if* $p/c(p) \rightarrow \infty$, $c(p) \rightarrow \infty$, *and* $H_{12} \neq 0$, *then* $\sqrt{pc(p)}|\alpha_3(p) - \alpha| \Rightarrow \infty$ *as* $p \rightarrow \infty$;

(ii) *if* $p/c(p) \rightarrow m$ $(0 < m < \infty)$, *then* $\sqrt{pc(p)}(\alpha_3(p) - \alpha) \Rightarrow \lambda^{-(1/2)}\sigma N(0,1) + H_{12}m^{(1/2)}$ *as* $p \rightarrow \infty$;

(iii) *if* $p/c(p) \rightarrow 0$, *then* $\sqrt{pc(p)}(\alpha_3(p) - \alpha) \Rightarrow \lambda^{-(1/2)}\sigma N(0,1)$ *as* $p \rightarrow \infty$.

Theorem 8 shows that even in the presence of initial bias deletion, the estimator $\alpha_3(p)$ does not effectively achieve a p-fold increase in efficiency unless the computer time $c(p)$ assigned to each processor is large (i.e., $c(p) >> p$). Thus, the estimator $\alpha_3(p)$ has essentially the same behavior as $\alpha_1(p)$ (see Theorem 7). In other words, $\alpha_3(p)$ does not benefit from the initial bias deletion present in the estimator. The basic problem is that deleting the initial segment from each processor's observations does not deal with the bias introduced by the nonlinearity of the ratio estimator obtained from each processor. This is reflected in Theorem 8 through the fact that the bias term that appears in part (ii) depends only on H_{12} and not also on the constant a that appears in Theorem 6.

Our next theorem describes the behavior of $\alpha_4(p)$.

THEOREM 9. *Suppose that* $\kappa_c(p)/c(p) \rightarrow 0$ *as* $p \rightarrow \infty$ *and that the same hypotheses as in Theorem* 8 *hold. If*

(i) $p/c(p) \rightarrow \infty$ *and* $\kappa_c(p)/\log p \rightarrow \infty$, *or*

(ii) $p/c(p) \rightarrow m$ $(0 < m < \infty)$ *and* $\kappa_c(p) \rightarrow \infty$, *or*

(iii) $p/c(p) \rightarrow 0$,

as $p \rightarrow \infty$, *then*

$$\sqrt{pc(p)}(\alpha_4(p) - \alpha) \Rightarrow \lambda^{-(1/2)}\sigma N(0,1)$$

as $p \rightarrow \infty$.

According to Theorem 9, initial bias deletion has a significant positive impact on the estimator $\alpha_4(p)$. With a modest amount of initial bias deletion from the observations associated with each processor, a p-fold speedup in efficiency can be obtained with computer time horizons that are significantly shorter than those associated with no initial transient deletion. Since the estimator $\alpha_4(p)$ incurs none of the completion time and idle time costs associated with the "simulated time" estimators of §3, this result suggests that the estimator $\alpha_4(p)$ is preferable to all the other estimators considered in this paper.

Our final theorem describes the behavior of $\alpha_4(p)$ when $\kappa(c) = \kappa c$ for $0 < \kappa < 1$, $c \geq 0$, i.e., when a proportion κ of all the observations are deleted before forming the estimator $\alpha_4(p)$.

THEOREM 10. *Assume the same hypotheses as in Theorem* 6. *If* $\kappa_c(p) = \kappa c(p)$ $(0 < \kappa < 1)$ *and* $c(p) = p^r$ $(r < 0)$, *then*

$$\sqrt{pc(p)}(\alpha_4(p) - \alpha) \Rightarrow (1-\kappa)^{-1/2}\lambda^{-1/2}\sigma N(0,1)$$

as $p \to \infty$.

The proof of Theorem 10 is similar to that of Theorem 9 and is therefore omitted. As in Theorem 3, deleting a positive fraction of all the observations leads to an asymptotic increase in the variability of the estimator of $(1-\kappa)^{-1}$. Of course, as pointed out in §3, this increase is quite modest if we choose κ small (say $\kappa = 0.1$).

6. Proofs.

Proof of Theorem 4. Let

$$\bar{\Phi}(x) = 1 - \Phi(x) \quad \text{and} \quad W_i(p) = (C_i(t(p)) - \lambda^{-1}t(p))/t(p)^{(1/2)}\sigma_2.$$

Note that the independence of the $W_i(p)$'s yields

$$\begin{aligned} P&\left\{C_s(p) \leq x\sigma_2\sqrt{2t(p)\log p} + \lambda^{-1}t(p)\right\} \\ &= P\left\{W_i(p) \leq x\sqrt{2\log p},\ 1 \leq i \leq p\right\} \\ &= F_{t(p)}(x\sqrt{2\log p})^p \\ &= \left(1 - \bar{\Phi}(x\sqrt{2\log p}) + O(1/\sqrt{t(p)})\right)^p. \end{aligned}$$

The quantity $\bar{\Phi}(x\sqrt{2\log p})$ may be estimated by using Lemma 2 of Feller (1968, p. 179). Noting that $O(1/\sqrt{t(p)}) = o(1/p)$, it is then straightforward to show that

$$P\{C_s(p) \leq x\sigma_2\sqrt{2t(p)\log p} + \lambda^{-1}t(p)\} \to \begin{cases} 0, & x < 1, \\ 1, & x > 1, \end{cases}$$

proving part (i). For part (ii), note that it is sufficient to prove that

$$\sum_{i=1}^{p} W_i(p)/p\sqrt{\log p} \Rightarrow 0$$

as $p \to \infty$. Fix $\varepsilon > 0$ and use Markov's inequality to obtain

$$P\left\{\left|\frac{1}{p}\sum_{i=1}^{p} W_i(p)\right| > \varepsilon\sqrt{\log p}\right\} \leq \frac{E|W_1(p)|}{\varepsilon\sqrt{\log p}}.$$

Assumption (3.2) states that $\{W(p)^2 : p > p_0\}$ is uniformly integrable for some (finite) p_0, from which one may conclude that $E|W_1(p)|$ is bounded in p. Hence, the right-hand side converges to zero as $p \to \infty$, proving (ii).

Proof of Theorem 5. We first note that (2.1) implies that

$$C_\varepsilon \Rightarrow \lambda^{-1}e$$

as $\varepsilon \downarrow 0$, where $C_\varepsilon(t) = \varepsilon^2 C(t/\varepsilon^2)$ and $e(t) = t$. Since χ is positive, it is evident that $C_\varepsilon^{-1}(\cdot)$ is continuous and satisfies $C_\varepsilon^{-1} \circ C_\varepsilon = e$. We may then apply Theorem 3.3 of Whitt (1980) to conclude that $C_\varepsilon^{-1} \Rightarrow \lambda e$ as $\varepsilon \downarrow 0$. But $C_\varepsilon^{-1} = T_\varepsilon$, where $T_\varepsilon(c) = \varepsilon^2 T(c/\varepsilon^2)$. Since composition is continuous as a mapping on the space of continuous functions (see Billingsley (1968, §17)), we obtain $Z_\varepsilon \circ T_\varepsilon \Rightarrow GB(\lambda e)$ as $\varepsilon \downarrow 0$. As a consequence, the continuous mapping principle implies that $h(Z_\varepsilon \circ T_\varepsilon) \Rightarrow h(GB(\lambda e))$, where $h(x, y) = (x, \lambda y)$; this proves part (i).

For part (ii), we let $\hat{X}(s) = X(s) - \alpha$. We note that part (i) implies that

$$c^{-(1/2)}\left(\int_0^{T(c)} \hat{X}(s)ds,\ T(c) - \lambda c\right) \Rightarrow N(0, \tilde{H})$$

as $c \to \infty$. Therefore, the continuous mapping principle shows that

$$\begin{aligned}\lambda^{-1}c^{-(1/2)} &\int_0^{T(c)} \hat{X}(s)ds - c^{(1/2)} \int_0^{T(c)} \hat{X}(s)ds/T(c) \\ &= \left(\lambda - \frac{c}{T(c)}\right) c^{-(1/2)} \int_0^{T(c)} \hat{X}(s)ds \Rightarrow 0\end{aligned}$$

as $c \to \infty$. The proof of part (ii) is complete, if we note that

$$c^{-(1/2)}\left(\lambda^{-1}\int_0^{T(c)} \hat{X}(s)ds,\ T(c) - \lambda c\right) \Rightarrow N(0, \underset{\sim}{H})$$

as $c \to \infty$, and apply a converging-together argument.

Proof of Proposition 1. We first note that $\sigma(Y(t) : t \leq \eta_n) \subseteq \sigma((X(t), \chi(t)) : t \leq \tau_n)$, so it suffices to show that

$$P\{Y(\eta_n + \cdot)\varepsilon A | X(t),\ \chi(t) : t \leq \tau_n\} = P\{Y(\eta_1 + \cdot)\varepsilon A\} \tag{6.1}$$

for arbitrary (measurable) sets A. Now, $Y(\eta_n + t) = V(T(\eta_n + t))$, where $V(t) = X(t)/\chi(t)$, and $T(\eta_n + t) = T(\eta_n) + \Delta T_n(t) = \tau_n + \Delta T_n(t)$, where $\Delta T_n(t) = T(\eta_n + t) - T(\eta_n)$. We now observe that $\Delta T_n(\cdot)$ is the inverse to the process $\Delta C_n(t) = C(\tau_n + t) - C(\tau_n)$, in the sense that $\Delta C_n \circ \Delta T_n = e$. As a consequence, ΔT_n can be represented as a function $g(\tilde{V}_n)$, where $\tilde{V}_n(t) = (V(\tau_n + t),\ \chi(\tau_n + t))$. Hence, $Y(\eta_n + t) = k(\tilde{V}_n(t))$, where $k(\tilde{x}) = x_1((g \circ \tilde{x})(t))$ and $\tilde{x} = (x_1, x_2)$. Thus, $Y(\eta_n + \cdot)$ is a functional of the "shifted path" $\tilde{V}_n$ and (7.1) is trivially satisfied.

Proof of Theorem 6. The proof for $\alpha_1(p)$ can be found in Glynn (1989b) (the assumptions 4.3 are heavily used there). For part (ii), we let $S_i(c) = \int_0^{T_i(c)}[X_i(s) - \alpha]ds$. Then,

$$\alpha_2(p) - \alpha = \frac{\sum_{i=1}^p S_i(c(p))}{\sum_{i=1}^p T_i(c(p))}.$$

We note that for $\varepsilon > 0$,

$$P\left\{\left|\sum_{i=1}^p \frac{T_i(c(p))}{pc(p)} - \lambda\right| > \varepsilon\right\} \leq \frac{1}{pc(p)\varepsilon^2} \text{ var}\left[\frac{T_i(c(p)) - \lambda c(p)}{\sqrt{c(p)}}\right] = O\left(\frac{1}{pc(p)}\right) \to 0 \tag{6.2}$$

as $p \to \infty$, where the uniform integrability condition (4.1) was used to guarantee that the variance term was bounded in p. Hence, $\sum_{i=1}^{p} T_i(c(p))/pc(p) \Rightarrow \lambda$ as $p \to \infty$ (this result will be used in Theorem 7). Expand $pc(p)/\sum_{i=1}^{p} T_i(c(p))$ in a first-order Taylor expansion about λ^{-1}, to obtain

$$\frac{pc(p)}{\sum_{i=1}^{p} T_i(c(p))} = \lambda^{-1} - \frac{1}{\xi(p)^2}\left(\sum_{i=1}^{p} \frac{T_i(c(p))}{pc(p)} - \lambda\right), \tag{6.3}$$

where $\xi(p)$ lies between λ and $\sum_{i=1}^{p} T_i(c(p))/pc(p)$.

Since $\chi(s)$ is bounded from below, there exists a finite constant M such that $|1/\xi(p)^2| \le M$. By using the Taylor expansion and taking expectations we have

$$\begin{aligned} E[(\alpha_2(p) - \alpha)] &= E\left[\sum_{i=1}^{p} \frac{S_i(c(p))}{\lambda pc(p)}\right] \\ &\quad - E\left[\sum_{i=1}^{p} \frac{S_i(c(p))}{pc(p)} \sum_{i=1}^{p} \frac{(T_i(c(p)) - \lambda c(p))}{\xi(p)^2 pc(p)}\right]. \end{aligned} \tag{6.4}$$

To handle the first term on the right-hand side of (6.4), we use Glynn (1989b) to show that

$$\frac{1}{\lambda pc(p)} E\left[\sum_{i=1}^{p} S_i(c(p))\right] = \frac{a}{c(p)} + o\left(\frac{1}{c(p)}\right) \tag{6.5}$$

as $p \to \infty$.

To deal with the second term on the right-hand side of (6.4), we bound it by

$$2E\left[\sum_{i=1}^{p} \frac{S_i(c(p))}{pc(p)}\right]^2 + 2E\left[\sum_{i=1}^{p} \frac{(T_i(c(p)) - \lambda c(p))}{\xi(p)^2 pc(p)}\right]^2. \tag{6.6}$$

The second term in (6.6) is dominated by

$$\begin{aligned} &2M^2 E\left[\sum_{i=1}^{p} \frac{(T_i(c(p)) - \lambda c(p))}{pc(p)}\right]^2 \\ &= \frac{2M^2}{c(p)^2}(E[T_1(c(p) - \lambda c(p))])^2 + \frac{2M^2}{pc(p)^2}\operatorname{var}(T_1(c(p)) - \lambda c(p)) \\ &= o(1/c(p)) + O(1/pc(p)), \end{aligned} \tag{6.7}$$

using (4.1)'s uniform integrability. The first term in (6.5) can be handled similarly, yielding an estimate of $O(1/c(p))$. Combining (6.4) through (6.6) yields the result for $\alpha_2(p)$.

Proof of Theorem 7. We first consider $\alpha_1(p)$. We note that Theorem 6 implies that

$$\begin{aligned} &\sqrt{pc(p)}(\alpha_1(p) - \alpha) \\ &= p^{-(1/2)} \sum_{i=1}^{p} V_i(p) + \sqrt{pc(p)}(E\alpha_1(p) - \alpha) \\ &= p^{-(1/2)} \sum_{i=1}^{p} V_i(p) + b_1\sqrt{\frac{p}{c(p)}} + \sqrt{p}o\left(\frac{1}{c(p)}\right), \end{aligned}$$

where

$$V_i(p) = \sqrt{c(p)}\frac{\int_0^{T_i(c(p))} X_i(s)ds}{T_i(c(p)) - E\alpha_1(p)}.$$

By condition (4.1), $\{V_i(p)^2 : p > p_0\}$ is uniformly integrable for some (finite) p_0. We can therefore apply the Lindeberg–Feller theorem (see Chung (1974, p. 205)) to conclude that

$$p^{-(1/2)}\sum_{i=1}^{p} V_i(p) \Rightarrow \lambda^{-(1/2)}\sigma N(0,1)$$

as $p \to \infty$; this proves all three implications for the estimator $\alpha_1(p)$.

The second estimator is handled similarly. We note that

$$\sqrt{pc(p)}(\alpha_2(p) - \alpha) = \frac{pc(p)}{\sum_{i=1}^{p} T_i(c(p))} \cdot \left[p^{-(1/2)}\sum_{i=1}^{p} \tilde{S}_i(p) - \sqrt{\frac{p}{c(p)}}E\tilde{S}_1(p)\right]$$

where $\tilde{S}_i(p) = c(p)^{-(1/2)}[S_i(c(p)) - ES_i(c(p))]$. From (7.2), it is evident that

$$pc(p)/\sum_{i=1}^{p} T_i(c(p)) \Rightarrow \lambda^{-1} \quad \text{as } p \to \infty.$$

A uniform integrability argument similar to that for $\alpha_1(p)$ then shows that

$$p^{-(1/2)}\sum_{i=1}^{p} \tilde{S}_i(p) \Rightarrow \lambda^{(1/2)}\sigma N(0,1).$$

To complete the proof, we refer to Glynn (1989b), where it is shown that $ES_i(c(p)) = \lambda b_2/c(p) + o(1/c(p))$.

Proof of Theorem 8. The argument largely mimics the proof of Theorem 7. The first step is to obtain an expression for the bias of $\alpha_3(p)$. We claim that the bias takes the form

$$E\alpha_c(p) = \alpha + \frac{H_{12}}{c(p)} + o\left(\frac{1}{c(p)}\right) \tag{6.8}$$

as $p \to \infty$. A careful study of Glynn (1989b) shows that the proof there needs to be modified in two respects. First, one needs to argue that

$$\left\{c^{-1}\left(\int_{\gamma(c)}^{T(c)}[X(s) - \alpha]ds\right)^2 : c > c_0\right\}$$

is uniformly integrable for some $c_0 < \infty$. This follows from the observation that

$$\int_{\gamma(c)}^{T(c)}[X(s) - \alpha]^2 ds \leq 2\left(\int_0^{T(\chi(c))}[X(s) - \alpha]ds\right)^2 + 2\left(\int_0^{T(c)}[X(s) - \alpha]ds\right)^2;$$

each of the processes on the right-hand side is uniformly integrable as a result of (4.1) and hence the left-hand side is uniformly integrable (Chung (1974, p. 100)). Second, we note that

$$E\int_{\gamma(c)}^{T(c)}[X(s) - \alpha]ds = \int_{\chi(c)}^{c} E\hat{Y}(s)ds,$$

where $\hat{Y}(c) = [X(T(c)) - \alpha]/\chi(T(c))$. Since $\|X\| < \infty$ and χ is bounded away from zero, it follows that $\hat{Y}$ is a bounded process. Hence, the results of Nummelin and Tuominen (1982) apply, showing that $E\hat{Y}(t) \to 0$ exponentially fast. It is then evident that

$$\int_{\chi(c)}^{c} E\hat{Y}(s)ds = o(1)$$

as $c \to \infty$. As a consequence, the term that contributes the quantity $a/c(p)$ to the asymptotic bias of $\alpha_1(p)$ is $o(1/c(p))$ in the current setting. This yields (6.7).

The proof of Theorem 8 is completed in much the same way as Theorem 7. The uniform integrability established above allows us to apply the Lindeberg–Feller theorem once again, finishing the proof.

Proof of Theorem 9. The analogue of (6.8) for the estimator $\alpha_4(p)$ is

$$E\alpha_4(p) = \alpha + o\left(1/c(p)\right),$$

and is established in basically the same way. The result of the proof goes through as in Theorem 8.

7. Summary. This paper has investigated theoretical properties of an attractive method for using parallel processors in discrete event simulations: running independent replications, in parallel, on multiple processors and averaging the results at the end of the runs. In previous papers, we considered the problem of estimating transient quantities, while in this paper we consider the steady-state estimation procedure. While the method of replications with initial transient deletion is conceptually simple to apply, some care needs to be taken in order to obtain estimators with the proper convergence behavior. Specifically, the growth rates for the number of processors (replications), the length of the replications, and the length of the deletion period need to be controlled in order to produce valid confidence intervals for steady-state parameters. In the parallel processing setting, a sampling plan in which the replication lengths are given by limits on computer time is particularly attractive since the completion time of the experiment is deterministic (assuming the machine is dedicated to running the simulation experiment). However, in this case, the leading term in the bias expansion of the straightforward estimator without deletion, $\alpha_1(p)$, is $(a + H_{12})/c(p)$ where $c(p)$ is the computer time per replication, a is due to initialization bias, and H_{12} is due to the fact that the denominator in the ratio estimate is random. Deleting an appropriate portion of each replication removes the initialization bias $a/c(p)$, but does not remove the ratio bias $H_{12}/c(p)$. Thus, when this estimator is used and the replication length is determined by computer time, deletion is essentially useless. On the other hand, the bias expansion of a new estimator, $\alpha_2(p)$, has leading term $a/c(p)$, which is removed entirely by appropriate deletion. Therefore, in practice, we recommend use of the new estimator with deletion, $\alpha_4(p)$.

Experimental results concerning the performance of these estimators in simulations of simple queueing network models are reported in Glynn and Heidelberger (1992). Those experimental results confirm the theoretical results presented here and reinforce our recommendation to use $\alpha_4(p)$ rather than $\alpha_3(p)$. Our experiments showed that $\alpha_4(p)$ outperforms $\alpha_3(p)$, in terms of exhibiting less bias and truer confidence interval coverage, when the number of processors is large and the amount of time per processor is relatively small.

While we have described the results in terms of a computer time constraint on the replication lengths, they remain valid for essentially any other measure of replication length. Examples include computing charges (which may involve costs for CPU, memory, and I/O use), real time (i.e., wall-clock time, which may differ in multiprogrammed environments), the total number of events processed, and the total number of events of a certain type processed (such as departures from a network). In addition, the results are applicable to simulation experiments on a single processor if the replication lengths are determined in the above fashion.

AN IMPLEMENTATION OF THE FAST MULTIPOLE METHOD WITHOUT MULTIPOLES*

CHRISTOPHER R. ANDERSON†

Abstract. An implementation is presented of the fast multipole method, which uses approximations based on Poisson's formula. Details for the implementation in both two and three dimensions are given. Also discussed is how the multigrid aspect of the fast multipole method can be exploited to yield efficient programming procedures. The issue of the selection of an appropriate refinement level for the method is addressed. Computational results are given that show the importance of good level selection. An efficient technique that can be used to determine an optimal level to choose for the method is presented.

Key words. Poisson equation, fast summation, point sources

AMS(MOS) subject classifications. 65C99, 35J05, 34B27

1. Introduction.

The purpose of this paper is three-fold. First we will present a method for computing N-body interactions that is similar to the fast multipole method (FMM) as developed by Greengard and Rokhlin [5], [6] and Van Dommelen and Rundensteiner [15], but one that does not use complex power series in two dimensions or spherical harmonic expansions in three dimensions. Our procedure will be based on the use of Poisson's formula for representing solutions of Laplace's equation. While the accuracy and operation count of the resulting method is almost identical to the fast multipole method, the method does offer some advantages. One advantage is that the component operations of the multipole method, such as shifting and combining multipoles, are very easy to formulate for approximations based on Poisson's formula. Another advantage is that the difference between the two- and three-dimensional methods is very slight, and so programming a three-dimensional method is relatively straightforward once a two-dimensional method has been programmed. The second aspect this paper discusses is how multigrid programming strategy can be used to facilitate the programming of our method and others like it (such as the original fast multipole method). Third, we wish to discuss the issue of parameter selection when using these "fast" methods. Essentially, the computational efficiency of these methods depends critically upon the choice of a level of refinement of physical space. A wrong choice can lead to a very inefficient algorithm. We shall present a procedure for obtaining an optimal choice of the refinement level.

The problem of calculating N-body interactions occurs in a wide variety of computational problems—discrete vortex calculations, galaxy simulations, plasma simulations, etc. For each of these computational problems the calculation takes on a slightly different form, but each shares the common feature that the interaction is determined via solutions of Laplace's equation. So, rather than address each different application, we will discuss the following N-body model problem: Given N charged particles at locations x_i with strengths κ_i the goal is to calculate the potential $\phi(x_i)$,

where ϕ is a solution of

$$\Delta\phi = \sum_{i=1}^{N} \delta(x - x_i)\kappa_i. \tag{1}$$

Here $\delta(x)$ is Dirac's delta function and Δ is the Laplacian. Since the key ideas behind the method presented here do not change much when one goes from two to three dimensions, we will primarily discuss the two-dimensional case. Those aspects that do change with dimension will be specifically addressed.

Often in simulations, one uses smoothed delta functions (or "blobs"), and the model problem in this case is identical to (1) but we solve

$$\Delta\phi = \sum_{i=1}^{N} \Psi_\epsilon(x, x_i)\kappa_i \tag{2}$$

where $\Psi_\epsilon(x, x_i)$ is a smoothed delta function whose support is contained within a disk of radius ϵ about x_i. The choice of Ψ and ϵ is important for accuracy, but not particularly important for the methods used to accelerate the computation of (2). We do make the assumption that the blobs have support contained within disks or spheres of radius ϵ, and so the blob functions cannot be completely general.

The solution ϕ of (1) is given by

$$\phi(x) = \sum_{i=1}^{N} \frac{\kappa_i}{2\pi} \log(|x - x_i|), \tag{3}$$

while for (2),

$$\phi(x) = \sum_{i=1}^{N} \frac{\kappa_i}{2\pi} \Phi_\epsilon(x - x_i) \tag{4}$$

where Φ_ϵ is the potential induced by a single blob. (This can often be calculated explicitly by solving $\Delta\Phi = \Psi_\epsilon(x)$ using the method of separation of variables.)

From (3) or (4) it is clear that if we evaluate the solution ϕ at each point $x_i, i = 1, \cdots N$, then this computation requires $O(N^2)$ operations. For particle simulations, the larger the value of N the better, and so there is great interest in reducing this operation count. The fast multipole method is a technique for reducing the operation count of this problem to $O(N)$ operations.

There are two basic ingredients to the fast multipole technique. One ingredient is the process of combining large numbers of particles into single computational elements. When a cluster of particles is "far away" from a particular point, then the potential of the cluster is approximated by the potential induced by a single computational element located inside the cluster. (How far "far away" is must be determined, of course.) In the fast multipole method the computational element is a multipole expansion located at the center of a disk containing the cluster of particles. If we identify the complex plane with R^2, then one can represent the potential induced by a collection of particles of strength α_i located at the points z_i by $\mathrm{Re}\left(\sum_{i=1}^{N_c} \alpha_i \log(z - z_i)\right)$. The approximation used is the following:

$$\phi(z) = \mathrm{Re}\left(\sum_{i=1}^{N_c} \alpha_i \log(z - z_i)\right) \approx \mathrm{Re}\left(a_0 \log(z - z_0) + \sum_{k=1}^{p} \frac{a_k}{(z - z_0)^k}\right). \tag{5}$$

Here z_0 is the center of a disk enclosing the particles z_i, p is the order of the multipole, and a_k are coefficients chosen so that the multipole is an accurate approximation of the potential. The efficiency of the method comes about because the evaluation of the potential of this single computational element, $O(p)$ operations, is typically much less work than that of computing the corresponding potential of the whole collection of particles, $O(N_c)$ operations. In the three-dimensional implementation of the method, the complex multipole is replaced by an expansion in spherical harmonics [6].

The second ingredient of the fast multipole method has to do with organizing the computations so that the application of the technique of combining particles is efficient and does not lead to inaccuracies. For example, when one combines particles into single elements, the more widely distributed in space the particles of a given cluster are, the greater the inaccuracy the approximation (5) becomes (for a fixed value of p and a fixed point of evaluation). However, if the particles are fixed and the evaluation position z is moved away from the center of the expansion z_0, then the accuracy of the potential approximation at z improves. The net effect is that if a fixed degree of accuracy is desired, one approximates the potential by using a hierarchy of approximations of the form (5). Close to an evaluation point one combines particles over small regions to form multipole approximations. Particles further away are combined over larger regions to form multipole approximations. (Essentially the size of the region over which particles are combined is inversely proportional to their distance to the evaluation point.) In the fast multipole method, this aspect is organized by decomposing the region containing all of the particles into boxes of different sizes. The particles in each of the boxes are combined and their potential is replaced by an approximation of the form (5). The potential at a particular point is then the sum of these approximations and the potential induced by the direct contribution of very close particles. In Fig. 1 we show a test particle and the surrounding regions in which the particles are combined into multipole expansions. The potential induced by particles in the region immediately surrounding the test particle is computed using the exact interaction formula (3) or (4).

In the approximation of the potential due to a cluster of particles by a single computational element, one is not forced to use multipoles. There is a possibility for other types of computational elements to be used and in this paper we shall discuss one alternative computational element. The basic strategy is to use Poisson's formula. In two dimensions we have that for points outside of a disk of radius a containing the particles, the potential can be represented by

$$\phi(r,\theta) = \kappa \log(r) + \frac{1}{2\pi}\int_0^{2\pi} \tilde{\phi}(a,s)\left[\frac{1-(\frac{a}{r})^2}{1-2(\frac{a}{r})\cos((\theta-s))+(\frac{a}{r})^2}\right] ds, \tag{6}$$

where the function $\tilde{\phi}(a,s)$ and the value of κ are determined from the values of ϕ on the circumference of the disk. (r,θ) is the position in polar coordinates of the evaluation point from the center of the disk. In the numerical method, the integral in Poisson's formula is converted into a sum of K quantities (where K is the number of points in an integration rule for (6)). Thus, the potential induced by a cluster of N_c particles can be reduced to the evaluation of a sum of K terms. The idea of using a numerical approximation of Poisson's formula to represent the potential is similar in spirit to an aspect of the method introduced by Rokhlin [12] for solving the equations of scattering theory. While the idea of using Poisson's formula is straightforward, getting Poisson's formula to work numerically proved quite troublesome. The problem is that

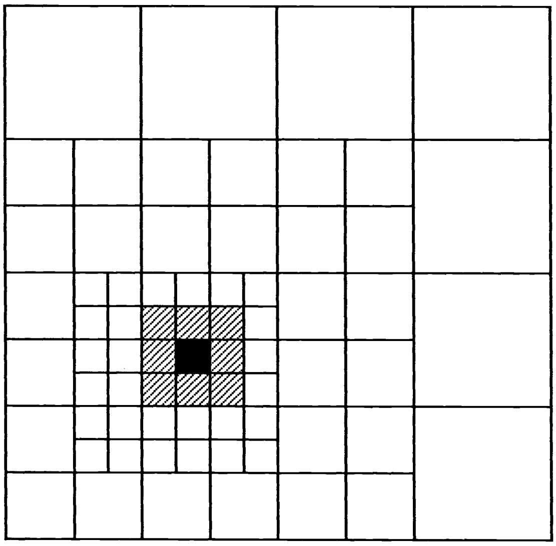

FIG. 1. *The hierarchical clustering of particles used to create a multipole approximation to the potential at a point. The evaluation point is within the darkened box. The potential induced by particles in unshaded boxes are combined into multipole approximations. The potential induced by particles in the lined boxes is computed using the direct interaction formula.*

the numerical evaluation of Poisson's kernel is difficult because of the singularity in the kernel. As the evaluation point approaches the ring where the integration is performed, the kernel becomes more and more singular, and the accuracy deteriorates rapidly. In the first section we discuss how this problem can be eliminated. In the first section we also present the necessary details (for both two and three dimensions) that facilitate the incorporation of this type of computational element into a fast multipole scheme. In order to distinguish this type of computational element based on Poisson's formula from a multipole element, we refer to them as "outer ring approximations" (two dimensions) or "outer sphere approximations" (three dimensions). (We shall also have use for these approximations inside rings or spheres and these will be "inner ring" and "inner sphere" approximations.) In Fig. 2, a schematic of the use of this element is presented. The computational particles (represented by the small circles) induce a potential at locations on the circumference of a ring that surrounds the particles. The potential outside the ring is evaluated by integrating these values against a Poisson kernel.

There are other possible choices for the computational elements, for example, Nowak [11] uses charge distributions over panels. While each different computational element will give rise to a different method, the structure of the algorithm is relatively independent of the type of element used. We shall therefore refer to the class of methods that uses the basic computational structure of the fast multipole method (but different elements) as "hierarchical element" methods.

As discussed earlier, in the multipole method one forms an approximation to the potential at a point by summing the potential induced by multipole approximations for different size clusters of particles. The same type of construction will be used with the computational elements based on Poisson's kernel. In both our method and the

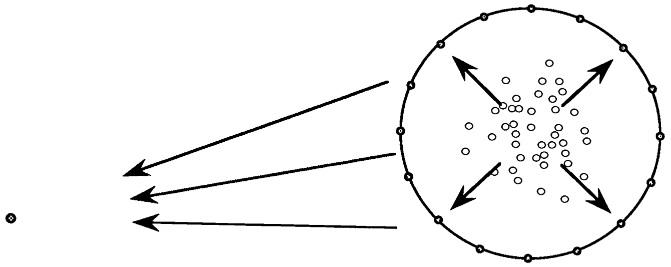

FIG. 2. *Schematic of an outer ring approximation. The computational particles (represented by the small circles) induce a potential at locations on the circumference of a ring that surrounds the particles. The potential outside the ring is evaluated by integrating these values against a (modified) Poisson kernel.*

original multipole method, when one chooses different evaluation points one sums a different collection of these approximations. The organization of the evaluation of the appropriate approximations presents a challenging computational problem. One important component of the fast multipole algorithm as presented by Greengard and Rokhlin [5] is an effective way to construct and evaluate this hierarchy of approximations. An observation that can be made about their method for carrying out this computation is that it is much like the multigrid method. The observation has some merit, and in the second section we show how this inherent multigrid structure can be exploited to yield an efficient programming strategy for the construction and evaluation of the hierarchical set of computational elements. (The identification of the multigrid, or tree structure, in the method is also useful in analyzing the performance of such methods on parallel processors; see [9], for example.) We shall present this discussion in the context of using Poisson kernel computational elements, but the results apply directly to the original multipole method as well.

The efficiency of hierarchical element methods comes about from the ability to represent a cluster of many particles by an approximation (multipole or otherwise) that can be evaluated with little numerical work. However, there is the possibility that the work to evaluate such an approximation may be more than that of evaluating the field induced by the particles in the cluster directly. This problem will certainly arise if the clusters contain only a very small number of particles. Thus, one is left with the problem of determining what is the minimal region size that should be used in forming the clusters of particles. This can be determined if the points are uniformly distributed, but if they are not, the problem is much more difficult. Fortunately, an a priori estimate of the computational time for any level of clustering is readily available and the level that requires the smallest time can be identified and chosen. In the third section we shall discuss this issue and present the details of a method for obtaining timing estimates for each level of clustering. We will also give computational results that illustrate the importance of appropriate level selection.

Finally, we present our conclusions and discuss some of the advantages and disadvantages of the techniques presented in this paper. The programs described in this paper are available from the author.

2. Derivation of computational elements. A basic component of the fast multipole method is the ability to represent the potential induced by a large number of particles by a single computational element that is relatively inexpensive to compute (i.e., the multipole expansion). The use of the multipole (or spherical harmonic) expansion is not a necessity, and in this section we present a computational element that is based on Poisson's formula for a circle in two dimensions and a sphere in three dimensions.

Let $\Psi(r,\theta)$ be the potential in two dimensions induced by a collection of N particles at locations $\vec{x}_i = (r_i, \theta_i)$ and strengths κ_i that are contained within a disk of radius a centered at the origin. This potential is a harmonic function outside of the disk, so one can use Poisson's formula (with a log term to satisfy the circulation requirements) to represent it. Set $\kappa = \sum_{i=1}^{N}(\kappa_i/2\pi)$ and $\tilde{\Psi}(r,\theta) = \Psi(r,\theta) - \kappa\log(r)$; then if (r,θ) is a point in the plane outside the disk, we have

$$\Psi(r,\theta) = \kappa\log(r) + \frac{1}{2\pi}\int_0^{2\pi} \tilde{\Psi}(a,s)\left[\frac{1-(\frac{a}{r})^2}{1-2(\frac{a}{r})\cos((\theta-s))+(\frac{a}{r})^2}\right] ds. \tag{7}$$

Our first attempt to get a representation suitable for numerical computation was to use the trapezoidal rule to approximate the integral in (7). Let M be an integer and set $K = 2M+1$. If we set $h = 2\pi/K$ and $s_i = (a\cos(ih), a\sin(ih)), i = 1,\cdots,K$, then an approximate representation is given by

$$\Psi(r,\theta) \approx \kappa\log(r) + \frac{1}{2\pi}\sum_{i=1}^{K} \tilde{\Psi}(a,s_i)\left[\frac{1-(\frac{a}{r})^2}{1-2(\frac{a}{r})\cos((\theta-s_i))+(\frac{a}{r})^2}\right] h. \tag{8}$$

However, the approximation in (8) is very ill conditioned. As the evaluation point moves towards the ring of radius a, the approximation is exceedingly inaccurate. In Fig. 3 the dashed lines are the errors in the potential that are obtained using the approximation (8). The ring is of radius $a = 2$ and the potential is that induced by a single particle of unit strength located at $r = \sqrt{2}/2$ and $\theta = \pi/3$. The upper, middle, and lower dashed lines correspond to $K = 9$, $K = 17$, and $K = 25$ points, respectively, in the integration formula.

The remedy for this problem becomes apparent when one considers the derivation of Poisson's formula. Let ϕ be a solution of Laplace's equation exterior to the disk of radius a, which has circulation κ. If $f(\theta)$ is the value of $\phi(r,\theta) - \kappa\log(r)$ at $r = a$ we have, using the method of separation of variables,

$$\phi = \kappa\log(r) + \sum_{k=-\infty}^{k=\infty} c_k \left(\frac{a}{r}\right)^{|k|} e^{ik\theta}, \tag{9}$$

where the coefficients c_k are the Fourier coefficients of the function $f(\theta)$,

$$c_k = \frac{1}{2\pi}\int_0^{2\pi} f(s)e^{-iks}\, ds. \tag{10}$$

If one combines (9) and (10) one obtains

$$\phi = \kappa\log(r) + \sum_{k=-\infty}^{\infty}\left[\frac{1}{2\pi}\int_0^{2\pi} f(s)e^{-iks}\, ds\right]\left(\frac{a}{r}\right)^{|k|} e^{ik\theta}. \tag{11}$$

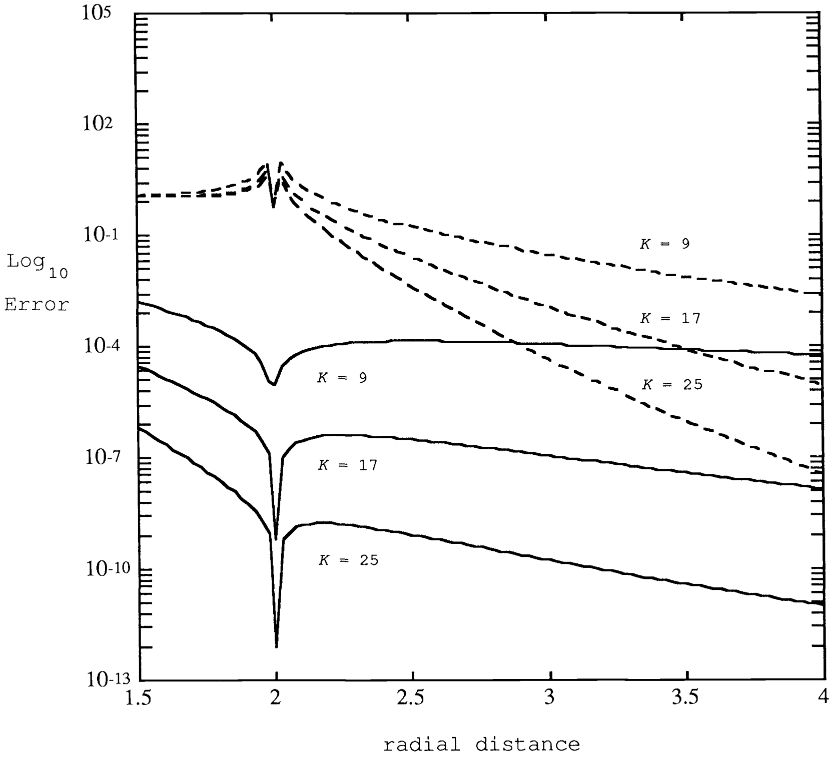

FIG. 3. *Error in the potential when outer ring approximations are used. The dashed lines correspond to an unmodified Poisson kernel, and the solid lines to a modified Poisson kernel. The ring radius was $a = 2$ and the value of K refers to the number of points in the integration formula.*

Poisson's formula results when one interchanges summation and integration in (11):

$$\begin{aligned}\phi &= \kappa\log(r) + \frac{1}{2\pi}\int_0^{2\pi} f(s)\left[\sum_{k=-\infty}^{\infty} \mathrm{e}^{-ik(\theta-s)}\left(\frac{a}{r}\right)^{|k|}\right] ds\\ &= \kappa\log(r) + \frac{1}{2\pi}\int_0^{2\pi} f(s)\left[\frac{1-(\frac{a}{r})^2}{1-2(\frac{a}{r})\cos((\theta-s))+(\frac{a}{r})^2}\right] ds.\end{aligned}$$

From this derivation one can see that using a trapezoidal rule approximation to the integral in (7) is equivalent to implicitly using the trapezoidal rule to approximate the Fourier coefficients (10). Clearly, if only $K = 2M + 1$ points are used in the quadrature rule, then one should not use any coefficients c_k with $|k| > M$, i.e., one should only use those Fourier modes in (9) that can be reliably estimated using K equispaced points. Thus we consider using (9) with only the first M modes,

$$\phi \approx \kappa\log(r) + \frac{1}{2\pi}\int_0^{2\pi}\left[\sum_{k=-M}^{M} \mathrm{e}^{-ik(\theta-s)}\left(\frac{a}{r}\right)^{|k|}\right] f(s)ds = \kappa\log(r) + \frac{1}{2\pi}\int_0^{2\pi} f(s)$$

$$\times\left[\frac{1-(\frac{a}{r})^2-2(\frac{a}{r})^{M+1}\cos((M+1)(\theta-s))+2(\frac{a}{r})^{M+2}\cos(M(\theta-s))}{1-2(\frac{a}{r})\cos((\theta-s))+(\frac{a}{r})^2}\right]ds.$$

Here, as in the original derivation of the Poisson kernel, the simplification arises from the formula for summing a geometric series. When this integral is approximated by the trapezoidal rule we obtain the numerical approximation

(12)

$$\phi(r,\theta)\approx\kappa\log(r)+\frac{1}{2\pi}\sum_{i=1}^{K}f(s_i)$$
$$\times\left[\frac{1-(a/r)^2-2(a/r)^{M+1}\cos((M+1)(\theta-s_i))+2(a/r)^{M+2}\cos(M(\theta-s_i))}{1-2(a/r)\cos((\theta-s_i))+(a/r)^2}\right]h$$

where the integration points s_i are equispaced on the ring with $h = 2\pi a/K$. By construction, this discrete approximation is precisely that which would be obtained if one formed an approximate solution of the exterior Laplace equation by combining solutions for the first M modes of the data $f(s)$. The Fourier coefficients used in the approximation are, however, those obtained from the discrete, rather than the continuous, Fourier decomposition of $f(s)$.

We will use (12) with $\kappa = \sum_{i=1}^{N}(\kappa_i/2\pi)$ and $f(s_i) = \Psi(a, s_i) - \kappa\log(a)$ to approximate the potential Ψ induced by N particles of strengths κ_i. The steps to create this approximation consist of summing the strengths of the particles in a region of space to obtain the strength of the log term in the approximation. This is then followed by the evaluation of the potential induced by the particles (minus the log term) at equispaced points on the ring of radius a that encompasses these points. To evaluate this approximation at some point outside the disk, one merely adds the contribution of the log term and the sum in (12). As before, if the number of particles N contained within the ring is large compared to K, a substantial savings in work is accomplished by using such an approximation. We shall refer to the approximation (12) as an outer ring approximation.

The improvement in accuracy when (12) is used is demonstrated by the solid lines in Fig. 3. In this figure, these lines indicate the error in the potential when (12) is used for the problem of a point charge located at $r = \sqrt{2}/2$ and $\theta = \pi/3$. The upper, middle, and lower solid lines correspond to $K = 9$, $K = 17$, and $K = 25$ integration points, respectively. As shown in the figure, the error remains sufficiently small as the evaluation point approaches the ring used in the approximation (a ring of radius 2). This behavior is in sharp contrast to the error in the approximation with the unmodified kernel (8), which gives $O(1)$ errors as the evaluation point approaches the ring.

Complete error estimates for the approximation have yet to be worked out, but the accuracy can be partially assessed using the results of Greengard and Rokhlin [5]. In particular, in the derivation of (12) one sees that the approximation is formed by combining the solutions of Laplace's equation corresponding to the first M Fourier modes associated with the data $f(s)$. If in this approximation we used the exact Fourier coefficients (10) instead of the discrete Fourier coefficients, then the approximation that would result would be identical to that of a multipole expansion with M terms. Hence, using the result of [5] we expect that if the particles are centered within a disk of radius α about the origin then the error in the potential at any test point with a radial distance r will be $O((\alpha/r)^M)$. It is important to note that this estimate of the error depends on the relative location of the evaluation point to the ring of radius α that surrounds the particles, and not on the relative location of the particle from the ring of radius a that is used in the approximation. For example, the solid lines in Fig. 3 indicate that the error in the approximation remains small even as the evaluation point moves inside the ring that is used for the approximation. This is expected, and in fact necessary, since in the complete algorithm we shall have reason to evaluate the approximation for points inside the ring. The ring radius that is used in the approximation (12) has an indirect effect on the accuracy. Essentially, the distance of the ring from the center of the disk that contains the particles affects the aliasing that occurs with the implicit use of discrete, rather than continuous, Fourier coefficients. If the ring is too close to the particles then large aliasing errors occur because of the higher harmonics that are present in the potential. Conversely, if one takes the ring radius too large, the coefficients that one is implicitly estimating are very small in magnitude and the effects of finite precision lead to accuracy problems. After some experimentation, we found that setting the ring radius $a = 2\alpha$ gives acceptable results.

In the complete method there is the need to represent the potential inside a given region. Following the same strategy for obtaining a numerically stable outer ring approximation we define an inner ring approximation by

$$\begin{aligned}(13)\qquad \phi(r,\theta) &\approx \frac{1}{2\pi}\sum_{i=1}^{K} f(s_i) \\ &\times \left[\frac{1-(\frac{r}{a})^2 - 2(\frac{r}{a})^{M+1}\cos((M+1)(\theta - s_i)) + 2(\frac{r}{a})^{M+2}\cos(M(\theta - s_i))}{1 - 2(\frac{r}{a})\cos((\theta - s_i)) + (\frac{r}{a})^2}\right] h,\end{aligned}$$

where (r,θ) is the evaluation point and $f(s_i)$ is the value of the potential induced by particles (or outer ring approximations) outside the ring of radius a. The evaluation point can be taken to be outside as well as inside the ring.

To make efficient use of approximations of the form (12), clustering is done on different levels, i.e., approximations are constructed for collections of particles in clusters of increasing size. In this construction it is necessary to combine several outer ring approximations into a single outer ring approximation. (In the multipole method, this is carried out by shifting the origin of the multipole expansions.) This operation of combining outer ring approximations is particularly simple to implement; one just evaluates the potential induced by the component outer ring approximations at the integration points of a single outer ring approximation under construction. (See Fig. 4.) The situation is similar for the other required combining operations in the method, i.e., forming inner ring approximations to represent the potential of outer ring approximations, etc., these are all carried out by just evaluating the component approximations at the set of points needed for the particular approximation. Due to the close relationship between these operations and those that are used in the original multipole method, the errors for ring approximations with $K = 2M + 1$ integration points can be expected to behave in a fashion similar to the errors in the multipole method when M terms in a multipole expansion are used. In particular, there is always concern that the hierarchical strategy of combining approximations may be unstable due to the accumulation of errors. While there is no proof of the stability for either the method based on ring approximations or on multipoles, all the computational results with which the author is familiar have indicated that the hierarchical

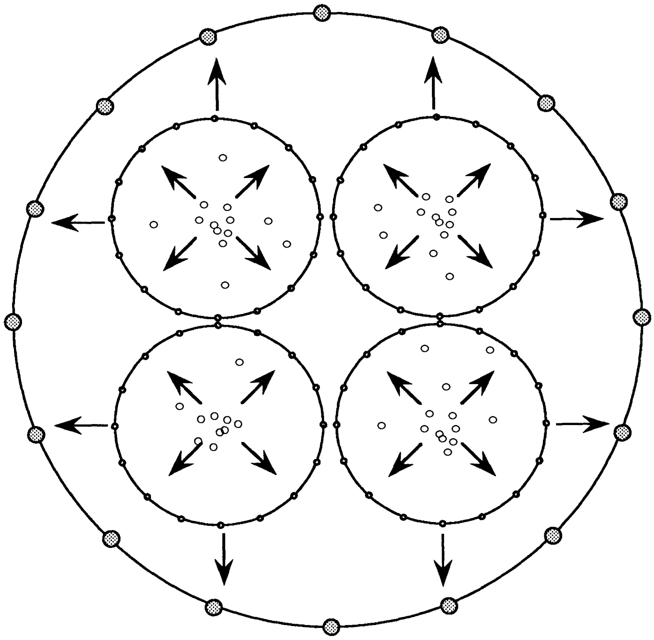

FIG. 4. *Schematic diagram of the operation of combining outer ring approximations. The coarse level outer ring approximation is obtained by evaluating the potential of the outer ring approximations contained within it.*

combination procedure is stable.

In three dimensions the construction is essentially the same. Let $g(x, y, z)$ denote values on a sphere of radius a and denote by Ψ the harmonic function external to the sphere with these boundary values. Given a point outside the sphere of radius a, $\vec{x}$ with spherical coordinates (r, θ, ϕ), let $\vec{x}_p = (\cos(\theta)\sin(\phi), \sin(\theta)\sin(\phi), \cos(\phi))$ be the point on the unit sphere that points in the direction of $\vec{x}$, then

$$\Psi(\vec{x}) = \frac{1}{4\pi}\int_{S^2}\left[\sum_{n=0}^{\infty}(2n+1)\left(\frac{a}{r}\right)^{n+1} \mathrm{P}_n(\vec{s}\cdot\vec{x}_p)\right] g(a\vec{s})\, ds, \tag{14}$$

where the integration is carried out over S^2, the surface of the unit sphere, and P_n is the nth Legendre function. (See [4, p. 513].)

As is the case with the ring approximations we shall refrain from using all of the terms in the kernel (14). Given a numerical formula for integrating functions on the surface of the sphere with K integration points $\vec{s}_i$ and weights w_i we use an approximation of the form

$$\Psi(\vec{x}) \approx \sum_{i=1}^{K}\left[\sum_{n=0}^{M}(2n+1)\left(\frac{a}{r}\right)^{n+1} P_n(\vec{s}_i\cdot\vec{x}_p)\right] g(a\vec{s}_i)\, w_i. \tag{15}$$

We call this approximation an outer sphere approximation.

A critical choice to be made is that of the appropriate number of terms M of the kernel in (15). If one uses an integration formula for the sphere of degree D (i.e., the formula integrates polynomials of up to and including degree D exactly) then an appropriate choice for M is $M \leq \frac{D}{2}$. The reasoning for this is as follows: Implicit in the use of Poisson's formula is the computation of an orthogonal expansion in spherical harmonics. If we keep $M+1$ terms in the kernel, then we are constructing an approximation by combining the potentials corresponding to the first $M+1$ terms of this expansion. In a numerical approximation of the type (15), we are implicitly using a discrete, and hence accuracy-limited, approximation to estimate the orthogonal expansion coefficients. We should therefore choose M on the basis of our ability to computationally estimate the coefficients of a spherical expansion with degree less than or equal to M. Given a function on the sphere comprised of spherical harmonics of degree m, then the spherical expansion coefficients of this function can be determined exactly by an integration formula with accuracy of degree $2m$. (Spherical harmonics of degree less than or equal to m can be expressed as the restriction of polynomials of at most degree m to a sphere, so a formula of degree $2*m$ can calculate inner products of two of these functions exactly.) Therefore, if we ignore the effects of aliasing, using $M \leq \frac{D}{2}$ allows us to determine the first $M+1$ coefficients in the orthogonal expansion accurately. The error in the resulting approximation can be expected to be on the order of the first neglected term in the expansion, i.e., if we keep $M+1$ terms, then the error in the potential induced by a collection of particles inside a sphere of radius α about the origin should behave like $O(\frac{\alpha}{r})^{M+2}$. (The highest power of r in the sum is $M+1$.)

Unlike two dimensions in which the trapezoidal rule furnishes us with the optimal integration formula for our integration, in three dimensions the choice of integration formula is more complicated. One obvious choice is the use of product integration formulas. The ones typically employed are those that use trapezoidal integration in the θ direction and then Gaussian quadrature in the ϕ direction. These are somewhat inefficient as the integration points are crowded near the poles, so we chose to use integration formulas from a nonproduct family, namely, those described in [13], which are taken from [10]. In Fig. 5 and Table 1 we present the results of computations obtained using (15). Each of the curves in Fig. 5 are the errors in the potential induced by a single unit strength particle located at $r = \sqrt{3}/2$, $\theta = \pi/3$, and $\phi = 0$. The test points are located along the x-axis ($\theta = 0, \phi = \pi/2$). This selection of points was chosen to be representative of the worst possible (most inaccurate) configuration that would occur when this element is incorporated into the complete method. The individual curves correspond to 5th, 7th, 9th, 11th, and 14th order integration formulas. These formulas required 12, 24, 32, 50, and 72 points, respectively. In Table 1 we present the rates of decay of the error as the radial distance to the evaluation point increases. As expected, the rate was approximately $M+2$. It is interesting to note that the 9th order formula has errors that are much better than expected—it appears that the integration formula is of higher order than advertised.

The approximation used to represent potentials inside a given region is

$$\Psi(\vec{x}) \approx \sum_{i=1}^{K} \left[\sum_{n=0}^{M} (2n+1) \left(\frac{r}{a}\right)^{n} \mathrm{P}_n(\vec{s}_i \cdot \vec{x}_p) \right] g(a\vec{s}_i)\, w_i, \tag{16}$$

where the notation is that used to define (15). (Note the change in the power of $\frac{r}{a}$ in this formula.) We shall refer to (16) as an inner sphere approximation.

The operations associated with forming and combining the outer and inner sphere approximations are essentially the same as those in two dimensions—one merely evaluates the component approximations at the integration points of the new approxi-

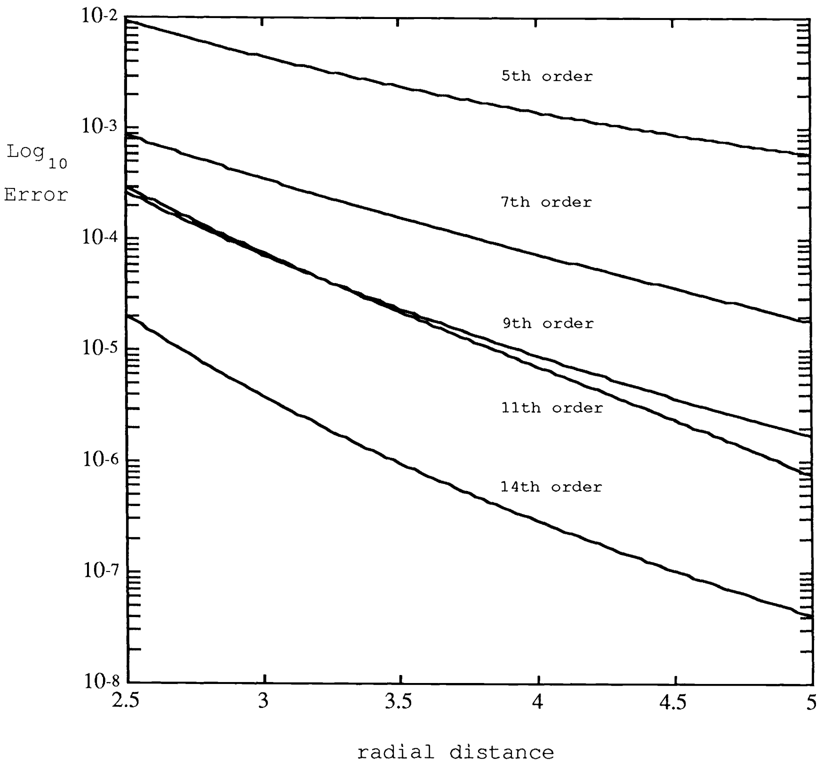

FIG. 5. *Error in the potential for an outer sphere approximation. Each curve represents the error for a given order of integration formula (and fixed number of terms in the Poisson kernel). The sphere was of radius* 3.

TABLE 1

Rate of the spatial decay of the error in the potential for an outer sphere approximation. The potential is assumed to decay like $O(\frac{1}{r})^\gamma$.

Order of Integration Method	Number of Terms in Kernel	Average Rate of Error Decay γ	Expected Rate of Error Decay γ
5	2	3.95	4
7	3	5.68	5
9	4	8.85	6
11	5	7.322	7
14	7	8.902	9

mation. If the integration points of the new approximation are sufficiently far away from the old approximation, then the accuracy degradation is minimal. One of the big advantages of using outer and inner sphere approximations is the simplicity of the process of combining them. This is in contrast to the complicated formulas that must be used if the approximations are based on spherical harmonics.

3. Hierarchical element implementation and multigrid. In this section we discuss an implementation strategy that uses the correspondence between the algorithmic structure of the fast multipole method [5] and the multigrid method. Although we shall discuss an implementation that uses computational elements based on the Poisson kernels (12) and (15), there is no explicit use of the particular features of this computational element, and so the results apply to programming with multipoles or any other type of element. Our goal here is to just outline the computational procedure that we have used (for more detailed information, one should see the programs in [1], [2]).

The basic algorithm structure used is that presented in [5]. The computation is broken down into two sweeps: the first sweep consists of constructing outer ring approximations for a hierarchical clustering of the computational particles. The second sweep consists of evaluating (in an efficient manner) the appropriate members of this hierarchy for each of the required evaluation points. There is no need for the evaluation points to be located at the same positions as the computational particles. In both sweeps the computational particles and evaluation points are assumed to lie in a bounded region Ω. A square box is then chosen which encloses Ω. The box is then recursively divided into smaller boxes. At the 0th level we have the original box, at the next level 4 boxes, the next 16, etc. Associated with each level n we have a uniform grid dividing up the original box into 4^n boxes. At the beginning of the calculation one chooses a highest (finest) level of discretization. We shall call this level n_f.

In the first sweep, outer ring approximations are constructed to represent the potential induced by the computational particles in each of the boxes at every level. This construction is performed recursively. Starting at the finest level, outer ring approximations are constructed for the computational particles in each of the boxes at that level. The center of the outer ring approximations are located at the centers of the respective boxes. The radius for the ring approximation is taken to be twice the size of the box. One then proceeds to the next lower (coarser) level and forms outer ring approximations for each of the particles contained within these coarser boxes. Instead of forming an outer ring approximation directly from the particles contained within a given box, one combines the four outer ring approximations associated with the finer boxes contained within the particular coarse box. The process of combining outer ring approximations is accomplished by evaluating the finer level outer ring approximations at the integration points of the coarse level outer ring approximation. Again, the centers of the outer ring approximations at this coarser level are located at the centers of their respective boxes and their radius is twice the coarse box size. This procedure is then repeated for all successively coarser levels. When the sweep is completed, outer ring approximations are available for the particles within each box at every level.

Two issues to be concerned with in implementing this sweep are avoiding unnecessary work and avoiding unnecessary storage requirements. A straightforward implementation would suggest that at each level one constructs an outer ring approximation for each box. If one uses K nodes in the approximation (12), then for n_f levels the storage required will be approximately $K \times (4^{(n_f+1)}/3)$ real numbers. Also, the work to construct all of these approximations for N uniformly distributed particles will be on the order of $K \times N + K^2\,(4^{(n_f+1)}/3)$. While this amount of work and storage is necessary if the particles are uniformly distributed, this amount is certainly not needed if they are not. If a given box (at any level) has no computational particles, then one need not compute an outer approximation for that box. Therefore, for nonuniform distributions (which are perhaps more prevalent in applications) one can save on storage and time by accounting for this fact.

The construction carried out in this first sweep is very similar to the computation that is performed in one sweep of a multigrid method. Both methods progress through a nested set of grids or boxes, and the operation of forming an outer approximation on a given level from the four outer approximations at the previous finer level is analogous to implementing the restriction operator (the forming of a coarse grid approximation from a fine grid approximation) in a multigrid method. However, in a hierarchical element method one is dealing with outer approximations associated with the grid boxes rather than solution values, so the programming strategy is to implement the equivalent of a multigrid restriction operator, but with this operator defined to act on approximations *pointed to* by address values in the boxes rather than acting on solution values. To carry out this computation a multigrid pointer structure F_n consisting of a nested set of integer arrays is first constructed. At a given level n, F_n is an integer array of size $2^n \times 2^n$. The (i,j)th element of F_n is the starting address in a storage array of the values used in the outer ring approximation associated with the (i,j)th box of the nth level partition of the computational domain. If there is no outer ring approximation associated with that box, then a negative integer is stored in the pointer array.

The computation is now performed as follows. The particles are sorted according to which box at the finest level (level n_f) they reside in. Particles in the same box are link-listed together, and the address of the first element of the link list for any given box is stored in a $2^{n_f} \times 2^{n_f}$ integer pointer array I_{n_f} associated with the boxes at the finest level. (By link-listing we mean that we associate with each particle an integer; the value of this integer gives the address of the next particle in the same box.) If there are no particles in a given box, then the value stored in I_{n_f} is a negative integer. Outer approximations are constructed for each of the boxes at the finest level. This is accomplished by looping over the array I_{n_f}. If there is a nonnegative element in I_{n_f}, then there are particles in the corresponding box and the potential induced by these particles are evaluated to obtain the values necessary for an outer ring approximation. These outer ring potential values are put into a storage array and the beginning address of these values is stored in the array F_{n_f}. Next, outer ring approximations are constructed for each coarser level. If we are at level k, then the pointer array corresponding to the finer level F_{k+1} is looped over. If there is an outer ring approximation associated with a given box at the finer level (indicated by a nonnegative entry in the pointer array), then the box at the coarser level which contains this finer level box (its parent box) will have an outer ring approximation associated with it. The potential induced by the finer level outer ring approximation is evaluated to construct the coarse box outer ring approximation. These new outer ring approximation values are put into a storage array and the beginning address of the values is stored in the F_k. A pictorial diagram of this process is depicted in Fig. 6. This process of constructing outer ring approximations is repeated until the second level is reached. (No outer ring approximations are needed for the first or zeroth levels.)

The second sweep, that in which the evaluation of the outer ring approximations is organized, utilizes the concept of being "well separated" [5]. Assume that the boxes on a given level are ordered by elements of $\mathbf{Z} \times \mathbf{Z}$; then, for a given level of refinement, one box is "well separated with distance L" from another box, if the maximum of the difference between their indices is greater than or equal to L (i.e., the boxes are at least L boxes apart). For a given level, the second sweep consists of constructing inner ring approximations for each box. The inner ring approximations are used to represent the potential from two sources. The first source is the inner ring approximation associated with the parent box at the previous coarser level. The second source is

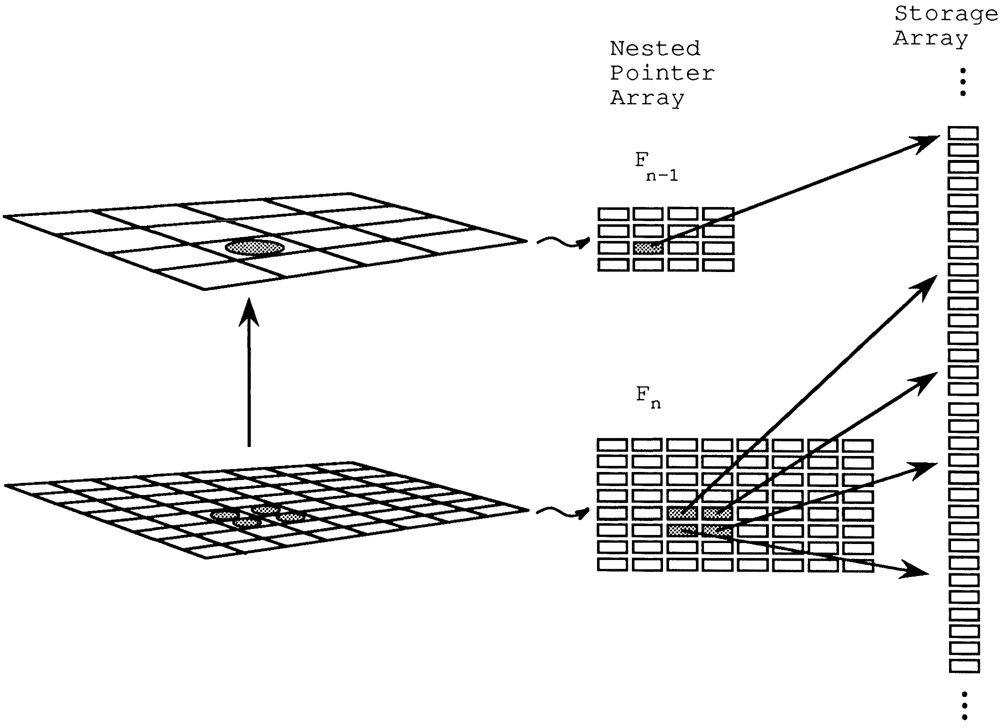

FIG. 6. *Schematic of outer ring construction. Formation of the coarse level outer ring approximation is performed by combing the four finer outer ring approximations beneath it. The storage array addresses for the outer ring approximation values are located in the nested arrays F_n.*

from all of the outer ring approximations from boxes that are well separated from the given box (with distance 1 in two dimensions and distance 2 in three dimensions) and are contained within boxes at the previous coarser level that are not well separated from the parent box. A graphical representation of this step is given in Fig. 7. This procedure is carried out for all levels except the finest. For this level, the inner ring approximations are only constructed from the inner ring approximations of the parents. At every level, the centers of the inner ring approximations are coincident with the centers of the boxes with which they are associated. The radius of the ring used in the approximation is one-half the box size. With the completion of this sweep, the potential at any given evaluation point is obtained by computing the potential of the inner ring approximation associated with the finest level box the point resides in. This potential is then added to the potential induced by particles in the nearby finest level boxes that are not well separated from the given evaluation points box. The reason for choosing a separation distance $L = 1$ in two dimensions and $L = 2$ in three dimensions is to ensure that the decay of the error in the approximations behaves like $O(\sqrt{2}/3)^\gamma$ where γ is determined by the number of modes kept in the kernel M. (See formula (12).)

As is the case with the first sweep, one must avoid using unnecessary storage and doing unnecessary work. Here, at any given level, if there is no evaluation point within a box, then one need not compute an inner ring approximation for that box. Work and storage space can be reduced by accounting for this fact.

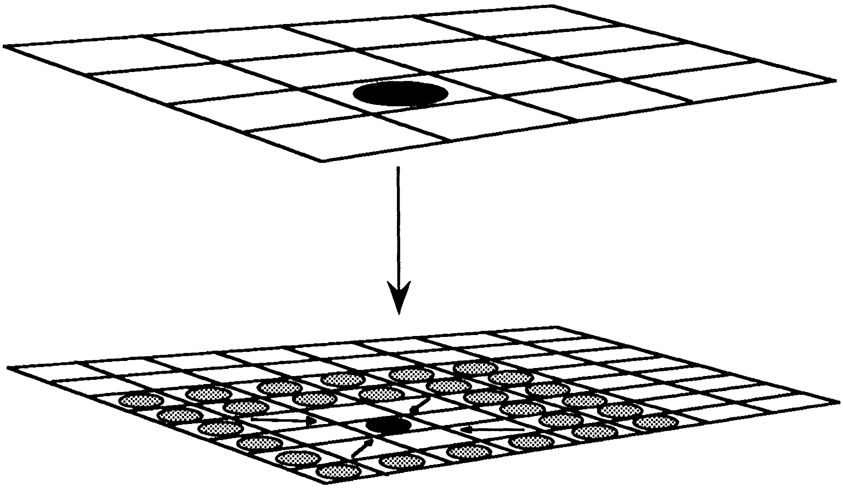

FIG. 7. *Formation of inner ring approximations from parent inner ring approximation and well-separated outer ring approximations.*

The construction carried out in this second sweep is also very similar to the computations that are performed in one sweep of a multigrid method. The process of creating an inner approximation from potential values induced by an inner ring approximation associated with a parent box is much like the prolongation operation of multigrid, i.e., the construction of a fine grid solution from a coarse grid solution. The process of combining the outer ring approximations from well-separated boxes is analogous to performing relaxation. Again, in this sweep we are working with approximations associated with the grid boxes rather than solution values, and so the programming strategy will be to implement multigrid-type operators, but with the operators defined to act on the approximations pointed to by address values in a given box rather than solution values. To implement this sweep, we again use a nested pointer array G_n similar to F_n. At a given level n the size of G_n is $2^n \times 2^n$ and the value at the (i,j)th element of this array is the starting address (in a storage array) of the inner ring approximation values associated with the (i,j)th box of the nth level partition. If there is no inner approximation associated with that box, then a negative integer is stored in the pointer array.

The first task in the actual computation is to identify which boxes will have inner ring approximations associated with them. The general rule is that if a box at any level has an evaluation point in it, then an inner ring approximation will be necessary for that box. The evaluation points are first sorted according to which box at the finest level (level n_f) they reside in. Particles in the same box are link-listed together, and the address of the first element of the link list for any given box is stored in an integer pointer array J_{n_f} associated with the finest level boxes. Next, the pointer structure G_n is swept through, starting at the finest level. At each level, a zero is stored in the pointer array if the corresponding box in the computational space with which it is associated contains at least one evaluation point. (This can be checked by considering the presence of zeros in the pointer array locations of the next finer level.) Once this initial sweep is performed, then any of the boxes whose pointer is zero indicates that an inner ring approximation will have to be formed for that box.

Now, starting at the coarsest level, each level of the nested pointer array G_n is swept through. If there is a zero in the pointer array location at a given level, then an inner ring approximation is constructed from a parent inner ring approximation and from the appropriate well-separated outer ring approximations. These approximations are combined by merely evaluating the potential they induce at the nodes of the inner ring approximation under construction. The addresses of the values needed to evaluate the parent inner ring approximation and the outer ring approximations are obtained from the pointer arrays G_n and F_n at the appropriate level. The values for this inner ring approximation being constructed are put in a storage array and the beginning address of these values is stored in the pointer array G_n. At the last (finest) level, inner ring approximations are formed from the parent inner ring approximations. The potential at the evaluation points is then obtained from these finest level inner ring approximations and direct evaluation of the potential from particles in nearby (not well separated) boxes. The particles in nearby boxes are accessed via the initially constructed link list whose starting addresses are pointed to by the entries in J_{n_f}.

The entire procedure consists of these two sweeps. The first sweep goes from a fine discretization of physical space to a coarse discretization and results in the construction of a hierarchy of outer ring approximations. The second sweep goes from a coarse discretization to a fine one and results in a hierarchy of inner ring expansions. If one considers the operations being performed on the pointer arrays, then the method is algorithmically similar to a multigrid V-cycle. In fact, the first version of the code was obtained by modifying an existing multigrid code. The modification consisted of changing the subroutines used in multigrid (like a relaxation routine) so that, instead of working with the values at the cell centers, the routine worked with the approximations that were pointed to by the values at cell centers. It proved to be very productive to use the programming techniques developed for multigrid, specifically those embodied in the sample code given in [14].

It is clear that if the computational particles and the evaluation points are distributed in a region that is not well represented by a square, then there will be a great number of elements in the pointer arrays that will be associated with no outer or inner approximations. In order to reduce storage space and shorten loops over the pointer structure, one can allow for regions that are nonsquare. This is most easily accomplished if the bounding region is constructed to be a rectangular box whose sides have an aspect ratio that is a power of two. To implement this, a rectangular box is constructed that contains the computational particles and the evaluation points. The sides of this box are then enlarged to create a rectangle that has an appropriate aspect ratio. The refinement of this rectangle proceeds by successively dividing the larger side by powers of two until the box side is equal to the length of the smaller side. From this point on, the refinement is accomplished by refining the boxes in both directions. (See Fig. 8, which depicts the refinement of a box with aspect ratio four to one.) The corresponding nested set of pointer arrays F_n, G_n, I_{n_f}, and J_{n_f} will be nonsquare and contain a number of elements corresponding to the number of boxes at each level of the decomposition of the original rectangle.

In three dimensions we found that using an outer sphere radius that was three times the box size was more accurate than using one that was only twice the box size. Other than this difference and the changes in the number of indices in the pointer arrays and the form of the kernel in Poisson's formula, the implementation of

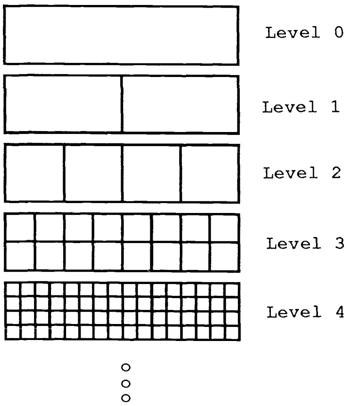

FIG. 8. *Refinement of a rectangle with an aspect ratio of* 4 *to* 1.

the three-dimensional method is identical to the two-dimensional method described above.

The particular implementation strategy just discussed works best when a large number of levels is not required in the computation. This will typically be the case when one requires a modest or high amount of accuracy. (The computations in the next section, performed with a tolerance of 1×10^{-4}, demonstrate this fact.) When one is interested in computations with a less severe accuracy criterion, then a larger number of levels is called for, and the multigrid pointer structure may be inefficient. In such cases other implementation strategies, such as those that use a tree-based data structure, should be considered. See, for example, the methods described in Barnes and Hut [3] or Hernquist [8].

4. Timing and level selection. As discussed in the introduction, the primary component of a hierarchical element method, which leads to a computational savings, is the representation of the potential induced by a large number of particles by a single computational element that requires less work to evaluate. On the other hand, it is clear that if one uses a computational element to represent the potential induced by only a small number of particles, then this may lead to more, rather than less, computational work. In the implementation of the method presented here, the computational domain is broken up into boxes, and as one increases the level of refinement, the size of these boxes decreases. Since the number of particles per box will ultimately decrease, and thus the number of particles per computational element will decrease, there is some level for which it is more expensive to use a hierarchical element method than to use the direct method. This is illustrated by the results in Figs. 9 and 10. (All of the computations where carried out on a SUN Sparcstation 1. There were 25 points in the ring approximations—a number of points that provides an accuracy of 10^{-4}.) The figures give the time it takes to compute the potential induced by all of the particles at the locations of all the other particles for different numbers of particles. (These times are estimated by the procedure described below.) For Fig. 9 the particles were uniformly distributed in a square and for Fig. 10 the particles were uniformly distributed in a rectangle with aspect ratio of ten to one. Each of the separate lines in the figures correspond to different finest levels of domain discretization. As is evident from the figures the level one should choose depends on

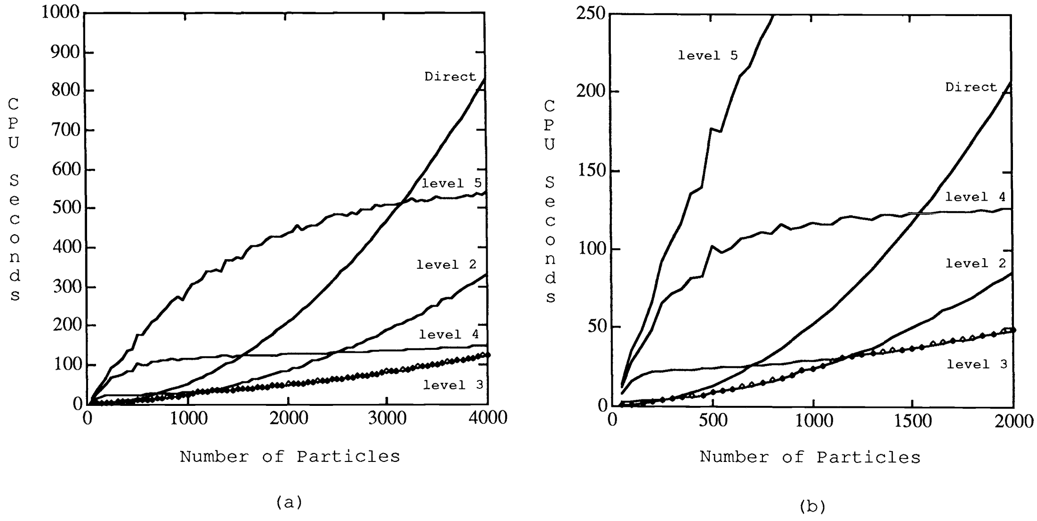

FIG. 9. CPU *time for a hierarchical element method based on ring approximations. The particles are distributed uniformly in a unit square. the number of particles. The more particles there are, the higher the level of refinement. The choice of level also depends on the distribution of particles. The fact that the timings vary greatly as the level is changed indicate that it is crucial to choose the appropriate level. If the particles are always uniformly distributed in some particular geometric arrangement, then one could work out estimates of the appropriate level of refinement one should choose. If the particles are not distributed in such a way, then the construction of a scheme for identifying the appropriate level seems difficult. However, a computationally efficient and optimal level selection scheme can be constructed.

The key observation is that the amount of computational work at each level in the hierarchical element method is completely determined (and hence one can estimate it) by the number of computational particles and evaluation points in any given box at any given level. In essence, the selection scheme is to "dry run" the hierarchical element method, and, instead of performing all the required operations, just increment counters. The counter increments are based on the population density of the particles in each box and models of the computational time necessary to carry out specific computational tasks. Timings are then estimated for the work required for different levels of refinement, and the level selected is the one with the least amount of estimated time. It is not necessary to perform a different timing computation for every level of refinement—the recursive nature of the method allows one to compute the amount of work for each level up to some ultimate level in one computation.

Before presenting the details of the implementation of this selection procedure, we present some results. In Table 2 we present the CPU time estimate (in seconds) from our selection code and the actual CPU time taken for a computation of the potential induced by 2000 points distributed in a unit square. As can be seen, one can get rather good estimates of the time it takes for any given level. The cost of performing

TABLE 2

Estimated and actual CPU *time for a hierarchical element method based on ring approximations. The timings are for* 2000 *particles distributed uniformly in a unit square.*

Level	Estimated CPU Time (Secs.)	Actual CPU Time (Secs.)
Direct	207.3	206.8
2	85.5	86.0
3	48.1	48.4
4	126.4	123.5
5	443.2	430.9

this estimation is very small. For 2000 points it takes .6 CPU seconds to estimate the running time for six levels of refinement. This time is about 1.25 percent of the time it takes to actually perform the calculation. Figures 9 and 10 also illustrate the accuracy of the timing estimates. The circles in these figures correspond to the actual CPU time taken to perform the computation when the level with the least amount of estimated time is selected. As desired, these circles coincide with a lower envelope for all of the timing curves in the figure.

In the implementation of the method for approximating the computational time we use a nested set of integer arrays set up like F_n and G_n of §3 (a nested set of arrays whose individual elements at any level are associated with individual squares in the decomposition of physical space at that same level of refinement). We have one nested set of arrays S_n associated with the computational particles and one nested set of arrays T_n associated with the evaluation points. At each level of these nested arrays we store in the (i,j)th element the number of particles (or evaluation points) contained within the (i,j)th box in computational space at that level. To construct these population values, a finest level of refinement is chosen and the number of particles in each box is stored in the corresponding array element of S_n associated with that level. Next, the other levels of the array S_n are swept through, and the number of particles in each box is determined by summing the number of particles in each of the boxes at the finer level which is contained within the given box. The same procedure is carried out for the evaluation points and the nested array T_n.

In order to use the population density information in the arrays S_n and T_n, we need models of the computational time necessary to carry out particular operations of the method. Assume there are n computational particles and m evaluation points. In two dimensions, if we are using an approximation of the type (12) with K points, then the models used are:

(0) *direct interaction* : $c_0 \times n \times m \ + b_0$,
(1) *formation of outer approximations* : $c_1 \times n \times K \ + b_1$,
(2) *combining; formation of outer approximations*
from outer approximations, etc. : $c_2 \times K \times K \ + b_2$,
(3) *evaluation of finest level inner approximations* : $c_3 \times m \times K \ + b_3$.

These models depend upon values of the constants $b_0, c_0, b_1, \cdots, b_3, c_3$. We call these formulas models because they are not exact—peculiarities in specific computational hardware or compilers may mean that the constants are not truly constants. However, on the machines the author has worked with, these formulas capture rather well the actual amount of computational time for a wide range of the parameters n, m, and K. In order to estimate the values for these constants, a small program was written which times the specific operations. Using the results of these timing estimates for several values of n, m, etc., the constants in the models were determined by a least squares procedure.

In three dimensions the models are slightly different because the finite sum in the integral kernel in Poisson's formula is not represented by a single closed formula. Assuming n computational particles, m evaluation points, K integration points, and M terms in the Poisson kernel, we use the following computational models:

(0) *direct interaction* : $c_0 \times n \times m \ + b_0$,
(1) *formation of outer approximations* : $c_1 \times n \times K \ + b_1$,
(2) *combining; formation of outer approximations*
from outer approximations, etc. : $c_2 \times K \times K \times M \ + b_2$,
(3) *evaluation of finest level inner approximations* : $c_3 \times m \times K \times M \ + b_3$.

Here, as before, values for these constants are obtained by using a least squares fit to the output of the program which times the particular operations.

With the computational model constants determined, complete timing estimates are obtained in two sweeps. In the first sweep the amount of computational time needed to construct the hierarchy of outer ring approximations is estimated. Let n_f denote a finest level of discretization chosen for the timing. (This level should always be greater than the finest level chosen for the actual computation.) Starting at this finest level, the time it takes to construct the outer ring approximation is estimated by using the model (1) and information in the array S_n at the finest level. If there is a nonzero value in any element of this array, then an outer ring approximation will be constructed for the particles associated with the corresponding box. The work to construct this outer approximation is estimated using (1), with the value of n being the value in that particular array element of S_n (i.e., the particle count for the box). Each of these estimates is added together to get a complete timing estimate for the construction of the outer approximations at the finest level. One then proceeds to the next coarser level. At this level two computational time estimates are computed. The first estimate is that of the time necessary to construct all of the outer approximations assuming that this particular level is the starting level—the same procedure as for the finest level. The second estimate is that of the time necessary for combining outer ring approximations from the finer level into the outer ring approximations at the current level. In this second estimate, the current level of S_n is swept through and if any element is nonzero, then an outer ring approximation must be constructed for the corresponding box. The time to compute this construction is obtained by using the model (2) and determining the number of finer level outer ring approximations that must be used in the construction. (This information can be obtained from the presence of a nonzero value in the next finer level elements of S_n.) One then proceeds to successively coarser levels, forming these same two estimates, until level one is reached. At this point one has information about the time necessary to form outer ring approximations starting from any level, as well as the time to create outer ring approximations from outer ring approximations at previous levels. By summing appropriate combinations of these timings, one can compute the time necessary to construct the complete hierarchy of outer ring approximations assuming one starts at any level. As a specific example, assume that 4000 points are uniformly distributed in a unit square. Then if the finest level chosen is $n_f = 5$, one obtains timing estimates such as those given in the second column of Table 3. Each entry in this column is the time it takes to compute the complete hierarchy of outer ring approximations starting from the given level.

In the second sweep, estimates of the required time are made for the construction of the hierarchy of inner ring approximations, as well as the time for direct local interaction. Starting at level one, the amount of work required for a direct calculation is estimated. This is obtained using model (0) and computing n and m by summing the values in the elements of the array S_1 and T_1 associated with level 1. One then proceeds to higher (finer) levels. At each finer level two estimates are computed. The first is an estimate of the time necessary to form an inner ring approximation from nearby outer ring approximations at the same level and the inner ring approximation at the previous coarser level. This time can be estimated by sweeping through the array T_n and determining whether or not an inner expansion will be constructed for any of the boxes in the computational domain. A construction for any box will be necessary if there is a nonzero value in the corresponding element in this array. One then employs the model (2) and determines the number of outer ring approximations and coarse inner ring approximations used in this construction from values in S_n at current level and values in T_n at the previous coarser level. Secondly, an estimate of the time necessary if one stops at the current level (i.e., the time to evaluate the inner expansions at this level as well as the local direct computation time) is formed. This time can be computed using the models (0) and (3) and population information for the evaluation points contained in the array T_n. Both of these timing estimates are performed for successively finer and finer levels. The computation is stopped at the finest level n_f. After this computation, we have, for every level, the time it takes to construct the inner ring approximations and the time it takes to use that level for the evaluation of the potential from the inner ring approximations and local direct calculations. By summing the appropriate values of these timings, it is possible to compute the time it takes to construct and evaluate the hierarchical set of inner approximations for each level from the first to the finest. In the example above

TABLE 3

Estimated CPU *time for a hierarchical element method based on ring approximations. The timings are for* 4000 *particles distributed uniformly in a unit square.*

Level	Outer Ring Const. Time (Secs.)	Inner Ring Const. and Eval. Time (Secs.)	Total Time (Secs.)
Direct	0.0	829.0	829.0
2	1.6	331.5	333.1
3	2.6	122.1	124.7
4	6.6	142.2	148.8
5	22.5	509.4	531.9

with 4000 points, the timings for this second step are presented in the third column of Table 3.

The complete estimate of the time it takes for the whole method consists of adding the amount of work to construct the outer ring approximations and the amount of work to construct and evaluate the inner ring approximations. The level one chooses for the actual computation is the level for which this total is the least. For example, an estimate of the total time is obtained by summing the elements (across the row) in the second and third column of Table 3. These times are presented in the fourth column of that table. One should choose level 3 for this computation.

5. Discussion and conclusions. The model problem discussed in this paper has been the computation of the potential induced by N charged particles. In many calculations one is interested in calculating the derivatives of this potential and not the potential itself. There are two ways to use a hierarchical element method to determine the derivatives of the potential. One way is to first create the complete hierarchy of inner ring and outer ring approximations and then, at the last step, to compute the derivatives at an evaluation point by summing the derivatives of the potential induced by nearby particles (particles that are not contained in well-separated boxes) and the derivative of the potential induced by the inner ring expansion associated with the finest level box the evaluation point resides in. The local interaction is computed by using the analytic derivative of (3) or (4). The derivative of the inner ring expansion is computed using the derivative (either numerical or analytical) of the approximation (13).

The other way to evaluate derivatives consists of computing each derivative by a separate hierarchical element computation. Each derivative of the potential induced by N charged particles is identical to a potential induced by N dipoles. Since the hierarchical element method requires only that the interaction be governed by solutions to Laplace's equation, we can use the method to compute the potential defined by a distribution of N dipoles. Each component of the derivative is therefore obtained by a separate computation and the formulas used for the initial ring construction and local direct evaluation are the analytic expressions for the derivatives of the potential.

In two dimensions, it seems best to use the first technique, i.e., compute the potential and then differentiate the result. While there is a loss of one order of accuracy in this procedure, this can be compensated for by increasing the accuracy with which the potential is calculated. (This is accomplished by increasing the number of integration points in the ring approximations, or by using more terms in a multipole approximation.) The extra cost to preserve accuracy is very small compared to performing completely separate computations for each derivative. The first approach is also likely to be better in three dimensions if one just wants the derivatives of a scalar potential. However, if one is interested in computing the velocity induced by a distribution of vorticity in three dimensions, then the second approach is more efficient. In this case, the velocity field is determined by the curl of a vector potential. To implement the first method, one must determine the three separate components of the vector potential by three different computations and then evaluate the velocity by taking the curl of the resulting function. In the second approach, each component of the velocity is determined directly via separate computations and there is no need to differentiate the result. Thus, one saves on both work and accuracy by using the second approach.

One is of course interested in a comparison between the multipole method and the method based on the use of Poisson's formula. Since the method that uses Poisson's formula is in some sense the discrete transform of the multipole method, one cannot expect there to be any great computational advantages in using one method over the other, i.e., they basically give the same results. The reason for considering using a method based on Poisson's formula is that it is perhaps more convenient to program and use. Since the operations for combining and constructing the hierarchical elements involve only function evaluation, they are easy to formulate and to program. Furthermore, these operations are essentially the same in two and three dimensions and this makes the implementation of the method in three dimensions very easy. A hierarchical element method based on Poisson's formula can also easily treat the problem of determining the potential induced by collections of sources which are more general than point charges. For example, one might be interested in computing the potential induced by collections of segments with some given charge distribution on them. The difficulty with using the multipole method for this computation occurs in the first step. In this step one needs to form a multipole approximation induced by collections of segments. While for point charges this initial multipole approximation can be analytically determined from the locations of the charges and their strengths, this may not be possible (or if possible, then it may be rather complicated) for segments. To get an initial ring approximation for such elements one need only evaluate the potential induced by these distributions at the integration points of the ring approximation. One disadvantage of using a Poisson formula representation is that techniques [7] for further reducing the computation time of the fast multipole method in three dimensions do not appear to be directly applicable.

For either the method presented here, or the original multipole method, one can and should take advantage of the inherent multigrid structure. This inherent structure allows one to take advantage of the variety of techniques that have been formulated for programming multigrid. We have used the techniques for programming on single processor machines, but there is undoubtedly some benefit to using multigrid techniques for multiprocessor computers. Also, as seen in §3, the timing of the hierarchical element method is very important. From the results of that section it is easy to see why some early experimenters with the method (ourselves included), who naively chose a high level of refinement, were not particularly pleased with the hierarchical element method performance. Fortunately, the recursive nature of the method allows for efficient and accurate timing estimates that can be used to select the appropriate level of refinement. The three contributions of the paper, the use of Poisson's formula, the use of multigrid programming strategy, and the use of timing estimates to obtain good level selection, certainly do not exhaust the set of tasks that could be done to improve on the hierarchical element method. Other improvements could come by making the method more adaptive, or improving the speed at which the component operations can be carried out. Such procedures will hopefully lead to even more efficient algorithms.

ON THE SPECTRUM OF A FAMILY OF PRECONDITIONED BLOCK TOEPLITZ MATRICES*

TAKANG KU† AND C.-C. JAY KUO†

Abstract. Research on preconditioning Toeplitz matrices with circulant matrices has been active recently. The preconditioning technique can be easily generalized to block Toeplitz matrices. That is, for a block Toeplitz matrix T consisting of $N \times N$ blocks with $M \times M$ elements per block, a block circulant matrix R is used with the same block structure as its preconditioner. In this research, the spectral clustering property of the preconditioned matrix $R^{-1}T$ with T generated by two-dimensional rational functions $T(z_x, z_y)$ of order (p_x, q_x, p_y, q_y) is examined. It is shown that the eigenvalues of $R^{-1}T$ are clustered around unity except at most $O(M\gamma_y + N\gamma_x)$ outliers, where $\gamma_x = \max(p_x, q_x)$ and $\gamma_y = \max(p_y, q_y)$. Furthermore, if T is separable, the outliers are clustered together such that $R^{-1}T$ has at most $(2\gamma_x + 1)(2\gamma_y + 1)$ asymptotic distinct eigenvalues. The superior convergence behavior of the preconditioned conjugate gradient (PCG) method over the conjugate gradient (CG) method is explained by a smaller condition number and a better clustering property of the spectrum of the preconditioned matrix $R^{-1}T$.

1. Introduction.

The systems of linear equations associated with block Toeplitz matrices arise in many two-dimensional digital signal processing applications, such as linear prediction and estimation [9], [12], [13], image restoration [7], and the discretization of constant-coefficient partial differential equations. To solve the block Toeplitz system $T\mathbf{u} = \mathbf{b}$, where T is an $N \times N$ matrix with $M \times M$ blocks, by direct methods, such as Levinson-type algorithms, requires $O(M^3N^2)$ operations [2], [14], [17]. Recently, there has been active research on the application of iterative methods such as the preconditioned conjugate gradient (PCG) method to the solution of Toeplitz systems. To accelerate the convergence rate, various preconditioners have been proposed for symmetric positive definite (SPD) Toeplitz matrices [6], [8], [10], [15]. The proposed preconditioning techniques can be easily generalized to block Toeplitz matrices. Simply speaking, we construct the preconditioner with a block circulant matrix R that has the same block structure as T. Since both $R^{-1}\mathbf{w}$ and $T\mathbf{w}$, where $\mathbf{w}$ denotes an arbitrary vector of length MN, can be performed with $O(MN \log MN)$ operations via two-dimensional fast Fourier transform, the computational complexity per PCG iteration is $O(MN \log MN)$ only. The PCG method can be much more attractive than direct methods for solving block Toeplitz systems if it converges fast.

The convergence rate of the PCG method depends on the eigenvalue distribution of the preconditioned matrix $R^{-1}T$ [1]. Generally speaking, the PCG method converges faster if $R^{-1}T$ has clustered eigenvalues and/or a small condition number. The spectral properties of preconditioned point Toeplitz matrices have been extensively studied. Chan and Strang [3], [5] have proved that, for a Toeplitz matrix with a positive generating function in the Wiener class, the spectrum of the preconditioned matrix has eigenvalues clustered around unity except for a finite number of outliers. If the Toeplitz matrix is generated by a positive *rational* function

$A(z)/B(z) + A(z^{-1})/B(z^{-1})$ in the Wiener class, an even stronger result has been derived by Trefethen [16] and Ku and Kuo [11]. That is, if $A(z)$ and $B(z)$ are polynominals in z of orders p and q without common roots, the number of outliers is equal to $2\max(p,q)$ and the PCG method converges in at most $\max(p,q)+1$ iterations asymptotically (see [11] and the discussion in §4 below). Therefore, an $N \times N$ preconditioned rational Toeplitz system can be solved with $\max(p,q) \times O(N \log N)$ operations.

The spectral properties of preconditioned block Toeplitz matrices have not yet been very well understood. In this research, we analyze the spectral *clustering* property for a class of preconditioned block Toeplitz matrices. The block Toeplitz matrix under consideration has a two-dimensional quadrantally-symmetric generating sequence generated by a rational function in the Wiener class (see the definition in §3). We divide our discussion into two cases depending on whether or not the generating sequence is separable. When the block Toeplitz matrix has a separable generating sequence, the spectrum of the preconditioned block Toeplitz can be easily derived by using the preconditioned point Toeplitz result as given in [11]. However, we derive the preconditioned point Toeplitz result from a new viewpoint in this paper so that the same approach can be used for both separable and nonseparable cases. With this viewpoint, we interpret the operation $T\mathbf{w}$, where T is an $MN \times MN$ block Toeplitz matrix, as a two-dimensional constant-coefficient mask operating on a certain two-dimensional sequence construction based on $\mathbf{w}$.

Our main results can be summarized as follows. Let T be an $MN \times MN$ doubly symmetric block Toeplitz matrix generated by a rational function of order (p_x, q_x, p_y, q_y), $\gamma_x = \max(p_x, q_x)$ and $\gamma_y = \max(p_y, q_y)$. For the separable generating sequence case, the eigenvalues of $R^{-1}T$ are clustered together such that it has asymptotically $(2\gamma_x + 1)(2\gamma_y + 1)$ distinct eigenvalues. The PCG method converges asymptotically in at most $\gamma_x\gamma_y + 1$ iterations, and the complexity of the PCG method is therefore $O(MN \log MN)$. For the nonseparable generating sequence case, the eigenvalues of $R^{-1}T$ are clustered around unity except for at most $O(M\gamma_y + N\gamma_x)$ outliers. Since the number of outliers is proportional to M and N, rather than being $O(1)$ as in the point Toeplitz case, the convergence rate of the PCG method cannot be completely characterized by the number of outliers. The condition number $\kappa(R^{-1}T)$ should also be taken into account. For this case, the superior performance of the PCG method over the CG method is explained by a better spectral clustering property as well as a smaller condition number of the preconditioned matrix $R^{-1}T$.

The outline of this paper is as follows. The construction of the block circulant preconditioner R for block Toeplitz matrices T is presented in §2. In §3, we study the spectral clustering property of preconditioned block Toeplitz matrices $R^{-1}T$. Toeplitz matrices with separable and nonseparable generating sequences are examined, respectively, in §§3.1 and 3.2. Numerical results are given in §4 to assess the performance of the PCG method.

2. Construction of block Toeplitz preconditioners. Let T be a block Toeplitz matrix consisting of $N \times N$ blocks with $M \times M$ elements per block, which can be expressed as

$$T = \begin{bmatrix} T_0 & T_{-1} & \cdot & T_{2-N} & T_{1-N} \\ T_1 & T_0 & T_{-1} & \cdot & T_{2-N} \\ \cdot & T_1 & T_0 & \cdot & \cdot \\ T_{N-2} & \cdot & \cdot & \cdot & T_{-1} \\ T_{N-1} & T_{N-2} & \cdot & T_1 & T_0 \end{bmatrix}, \tag{2.1}$$

where T_n with $|n| \leq N-1$ are $M \times M$ Toeplitz matrices with elements

$$[T_n]_{i,j} = t_{i-j,n} \quad \text{where} \quad 1 \leq i, \quad j \leq M.$$

Note that T is also known as the doubly Toeplitz matrix. The $MN \times MN$ block Toeplitz matrix T is completely characterized by the two-dimensional sequence

$$t_{m,n} \quad \text{where} \quad |m| \leq M-1, \ |n| \leq N-1, \tag{2.2}$$

known as the generating sequence of T. To construct the preconditioner for T, we generalize the idea in [5], [10], and [15], and consider an $MN \times MN$ block circulant matrix of the form

$$R = \begin{bmatrix} R_0 & R_{N-1} & \cdot & R_2 & R_1 \\ R_1 & R_0 & R_{N-1} & \cdot & R_2 \\ \cdot & R_1 & R_0 & \cdot & \cdot \\ R_{N-2} & \cdot & \cdot & \cdot & R_{N-1} \\ R_{N-1} & R_{N-2} & \cdot & R_1 & R_0 \end{bmatrix}, \tag{2.3}$$

where R_n with $0 \leq n \leq N-1$ are $M \times M$ circulant matrices with elements

$$[R_n]_{i,j} = r_{(i-j) \bmod M,n} \quad \text{where} \quad 1 \leq i,j \leq M.$$

Thus, the block circulant matrix R is completely characterized by the two-dimensional sequence

$$r_{m,n} \quad \text{where} \quad 0 \leq m \leq M-1, \ 0 \leq n \leq N-1. \tag{2.4}$$

The construction of R based on T is described below.

In (2.1) and (2.3), linear operators T and R are expressed in matrix form. Block Toeplitz (or circulant) systems are in fact just one way to describe linear (or circular) convolutions between two two-dimensional sequences. In the current context, it is more convenient to characterize T (or R) in terms of the relationship between input and output vectors. Consider two arbitrary MN-dimensional vectors $\mathbf{w}$ and $\mathbf{v}$ related via $\mathbf{v} = T\mathbf{w}$. By using the natural rowwise ordering, we can rearrange elements of these vectors into two-dimensional sequences

$$w_{m,n} \text{ and } v_{m,n} \quad \text{where} \quad 0 \leq m \leq M-1, \ 0 \leq n \leq N-1. \tag{2.5}$$

Then, the block Toeplitz system $\mathbf{v} = T\mathbf{w}$ can be interpreted as a linear operator characterized by the two-dimensional mask

(2.6)
$$\begin{bmatrix} t_{M-1,-N+1} & t_{M-2,-N+1} & \cdots & t_{0,-N+1} & \cdots & t_{-M+2,-N+1} & t_{-M+1,-N+1} \\ t_{M-1,-N+2} & t_{M-2,-N+2} & \cdots & t_{0,-N+2} & \cdots & t_{-M+2,-N+2} & t_{-M+1,-N+2} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ t_{M-1,0} & t_{M-2,0} & \cdots & t_{0,0} & \cdots & t_{-M+2,0} & t_{-M+1,0} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ t_{M-1,N-2} & t_{M-2,N-2} & \cdots & t_{0,N-2} & \cdots & t_{-M+2,N-2} & t_{-M+1,N-2} \\ t_{M-1,N-1} & t_{M-2,N-1} & \cdots & t_{0,N-1} & \cdots & t_{-M+2,N-1} & t_{-M+1,N-1} \end{bmatrix}$$

operating on an extended sequence

$$\bar{w}_{m,n} = \begin{cases} w_{m,n}, & 0 \le m \le M-1, \quad 0 \le n \le N-1, \\ 0, & \text{otherwise.} \end{cases} \tag{2.7}$$

To compute the output element v_{m_0,n_0}, $0 \le m_0 \le M-1$, $0 \le n_0 \le N-1$, we put the center of the mask (i.e., $t_{0,0}$) on $\bar{w}_{m_0,n_0}$, multiply $\bar{w}_{m,n}$ with the corresponding coefficients t_{m_0-m,n_0-n}, and sum the resulting products. Now let us use the mask (2.6) to operate on a periodic sequence

$$\tilde{w}_{m,n} = w_{m \bmod M, n \bmod N}, \qquad -\infty < m < \infty, \quad -\infty < n < \infty. \tag{2.8}$$

This defines a block circulant matrix-vector product $R\mathbf{w}$, which is close to the operation $T\mathbf{w}$. Since $R^{-1}\mathbf{v}$ can be computed efficiently with two-dimensional fast Fourier transform, it is natural to use R as a preconditioner for T.

The characterization of a block Toeplitz or circulant matrix by a two-dimensional operator mask is not new. It is basically the same as the stencil form used in the finite-difference discretization of the constant-coefficient partial differential operator. For example, the five-point stencil discretization of the Poisson equation can be interpreted as the mask

$$\begin{bmatrix} 0 & 1 & 0 \\ 1 & -4 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

operating on a two-dimensional sequence. By assuming the Dirichlet and periodic boundary conditions, we obtain block Toeplitz and circulant matrices, respectively.

The preconditioner constructed above can be described in matrix notation. First, for every point Toeplitz matrix T_n, $|n| \le N-1$, we construct a circulant preconditioner $\mathcal{R}_n$ with

$$t_{0,n}, \; t_{-1,n} + t_{M-1,n}, \; t_{-2,n} + t_{M-2,n}, \; \cdots, \; t_{1-M,n} + t_{1,n} \tag{2.9}$$

as the first row [10]. Then, we use $\mathcal{R}_n$ to construct R_n according to the linear combination

$$R_n = \begin{cases} \mathcal{R}_n, & n = 0, \\ \mathcal{R}_n + \mathcal{R}_{N-n}, & 1 \le n \le N-1, \end{cases} \tag{2.10}$$

which is used in (2.3) to define the block circulant preconditioner R.

It is worthwhile to point out that it is possible to design different preconditioners by considering different periodic extensions to form $\tilde{w}_{m,n}$. For readers interested in the design of preconditioners, we refer to [10].

3. The spectral clustering property of preconditioned block Toeplitz matrices. Let us consider a family of block Toeplitz matrices T whose generating sequences $t_{m,n}$ are quadrantally-symmetric,

$$t_{m,n} = t_{|m|,|n|}, \quad |m| \le M-1, \quad |n| \le N-1, \tag{3.1}$$

and absolutely summable (i.e., T is in the Wiener class),

$$\sum_{-\infty}^{\infty} \sum_{-\infty}^{\infty} |t_{m,n}| \le K < \infty, \tag{3.2}$$

and whose generating functions are of the form

$$T(z_x, z_y) \equiv \sum_{-\infty}^{\infty}\sum_{-\infty}^{\infty} t_{i,j} z_x^{-i} z_y^{-j}$$

$$= \frac{A(z_x, z_y)}{B(z_x, z_y)} + \frac{A(z_x^{-1}, z_y)}{B(z_x^{-1}, z_y)} + \frac{A(z_x, z_y^{-1})}{B(z_x, z_y^{-1})} + \frac{A(z_x^{-1}, z_y^{-1})}{B(z_x^{-1}, z_y^{-1})}, \tag{3.3a}$$

where

$$A(z_x, z_y) = \sum_{i=0}^{p_x}\sum_{j=0}^{p_y} a_{i,j} z_x^{-i} z_y^{-j}, \qquad B(z_x, z_y) = \sum_{i=0}^{q_x}\sum_{j=0}^{q_y} b_{i,j} z_x^{-i} z_y^{-j}. \tag{3.3b}$$

Note that the quadrantally-symmetric property of $t_{m,n}$ implies that T is doubly symmetric, i.e., $T_n = T_n^T$ and $T_n = T_{-n}$. We also assume that T has a nonsingular preconditioner R so that $R^{-1}T$ is also nonsingular. We call T satisfying (3.1)–(3.3) the $MN \times MN$ block Toeplitz matrix generated by a quadrantally-symmetric rational function of order (p_x, q_x, p_y, q_y). For convenience, we use the notation

$$\gamma_x = \max(p_x, q_x), \qquad \gamma_y = \max(p_y, q_y).$$

The following discussion focuses on the spectral clustering property of the preconditioned matrix $R^{-1}T$, namely, a bound on the number of eigenvalues clustered around unity. Note that the following spectral analysis does not depend on the positive-definiteness of T or R.

3.1. Separable generating sequences. One special case of block Toeplitz matrices described by (3.1)–(3.3) is that $T(z_x, z_y)$ is separable, i.e.,

$$T(z_x, z_y) = T_x(z_x) T_y(z_y), \tag{3.4a}$$

where

$$T_x(z_x) = \frac{A_x(z_x)}{B_x(z_x)} + \frac{A_x(z_x^{-1})}{B_x(z_x^{-1})}, \qquad T_y(z_y) = \frac{A_y(z_y)}{B_y(z_y)} + \frac{A_y(z_y^{-1})}{B_y(z_y^{-1})}, \tag{3.4b}$$

and where

(3.4c)

$$A_x(z_x) = \sum_{i=0}^{p_x} a_i z_x^{-i}, \quad B_x(z_x) = \sum_{i=0}^{q_x} b_i z_x^{-i}, \quad A_y(z_y) = \sum_{i=0}^{p_y} c_i z_y^{-i}, \quad B_y(z_y) = \sum_{i=0}^{q_y} d_i z_y^{-i}.$$

Note that the separability of $T(z_x, z_y)$ implies the separability of the generating sequence $t_{m,n}$, i.e.,

$$t_{m,n} = t_{x,m} t_{y,n}.$$

Based on $t_{x,m}$ (or $t_{y,n}$), we can construct Toeplitz matrix T_x (or T_y) and the corresponding preconditioner R_x (or R_y), where T_x and R_x (or T_y and R_y) are of dimension $M \times M$ (or $N \times N$). It is easy to see that the preconditioner R is also separable, and the eigenvalues of $R^{-1}T$ are the products of the eigenvalues of $R_x^{-1}T_x$ and $R_y^{-1}T_y$.

Thus, to understand the spectral properties of $R^{-1}T$, we only have to examine those of preconditioned (point) Toeplitz matrices $R_x^{-1}T_x$ and $R_y^{-1}T_y$.

According to the construction (2.9) and the symmetric property of $t_{x,m}$, we know that R_x is a circulant matrix with the first row

$$t_{x,0},\ t_{x,1}+t_{x,M-1},\ t_{x,2}+t_{x,M-2},\ \cdots,\ t_{x,M-1}+t_{x,1}.$$

When $B_x(z_x)=1$ (i.e., $q_x=0$), T_x is banded with bandwidth p_x, and R_x is almost the same as T_x except for the addition of elements in the northeast and southwest corners to make R_x circulant. Thus, the elements of $\triangle T_x = R_x - T_x$ are all zeros except the first and the last p_x rows. Consequently, $\triangle T_x$ has at least $M-2p_x$ $(=M-2\gamma_x)$ eigenvalues at zero and $R_x^{-1}T_x=(T_x+\triangle T_x)^{-1}T_x$ has at least $M-2p_x$ eigenvalues at one. This result can also be obtained by using the operator-mask interpretation. That is, the products $T_x\mathbf{w}$ and $R_x\mathbf{w}$, for arbitrary $\mathbf{w}=(w_0,\cdots,w_m,\cdots,w_{M-1})^T$, can be viewed as a linear operator characterized by the mask

$$[t_{x,p_x}\ \ t_{x,p_x-1}\ \ \cdots\ \ t_{x,1}\ \ t_{x,0}\ \ t_{x,1}\ \ \cdots\ \ t_{x,p_x-1}\ \ t_{x,p_x}]$$

operating, respectively, on two extended sequences

$$\bar{w}_m=\begin{cases} w_m, & 0\le m\le M-1,\\ 0, & \text{otherwise,}\end{cases} \quad \text{and} \quad \tilde{w}_m = w_{m \bmod M}.$$

It is clear that $T_x\mathbf{w}$ and $R_x\mathbf{w}$ give the same output elements if the center of the mask is located at $p_x\le m\le M-p_x-1$. There are $M-2p_x$ such elements and, as a consequence, the dimension of the null space of $\triangle T_x$ is at least $M-2p_x$. The operator-mask viewpoint will be generalized to the case of higher-dimensional generating sequences (see §3.2).

When $B_x(z_x)\ne 1$, we approximate the block matrix $\triangle T_x = R_x - T_x$ with an asymptotically equivalent block matrix $\triangle E_x$, and then use the recursive property of $t_{x,m}$ to show that $\triangle E_x$ has eigenvalues repeated at zero. The recursive property of $t_{x,m}$ is stated in the following lemma.

LEMMA 1. *The sequence $t_{x,m}$ generated by $T_x(z_x)$ in* (3.4b) *follows the recursion,*

(3.5)
$$t_{x,m+1}=-(b_1t_{x,m}+b_2t_{x,m-1}+\cdots+b_{q_x}t_{x,m-q_x+1})/b_0, \quad m\ge\gamma_x=\max(p_x,q_x).$$

Proof. The generating sequence associated with $A_x(z_x)/B_x(z_x)$ given by (3.4c) is

$$\tfrac{1}{2}t_{x,0},t_{x,1},t_{x,2},\cdots,t_{x,m},\cdots.$$

Thus, we have

$$\left(\frac{t_{x,0}}{2}+\sum_{m=1}^{\infty}t_{x,m}z^{-m}\right)(b_0+b_1z^{-1}+\cdots+b_{q_x}z^{-q_x})=a_0+a_1z^{-1}+\cdots+a_{p_x}z^{-p_x}.$$

The proof is completed by comparing the coefficients of the above equation. □

Consider the approximation of $\triangle T_x = R_x - T_x$ with $\triangle E_x = F_x + F_x^T$, where

$$F_x=\begin{bmatrix} t_M & t_{M-1} & \cdot & \cdot & t_2 & t_1\\ t_{M+1} & t_M & t_{M-1} & \cdot & \cdot & t_2\\ \cdot & t_{M+1} & t_M & \cdot & \cdot & \cdot\\ \cdot & \cdot & \cdot & \cdot & t_{M-1} & \cdot\\ t_{2M-2} & \cdot & \cdot & t_{M+1} & t_M & t_{M-1}\\ t_{2M-1} & t_{2M-2} & \cdot & \cdot & t_{M+1} & t_M \end{bmatrix},$$

and where the subscript x is omitted for simplicity and t_m with $m > \gamma_x$ is recursively constructed from (3.5). Since elements $t_{x,m}$ in F_x satisfy (3.5), the rank of F_x or F_x^T is at most γ_x. Consequently, $\triangle E_x$ has at least $M - 2\gamma_x$ eigenvalues at zero.

Then, we examine the difference between $\triangle T_x$ and $\triangle E_x$. Consider

$$\text{(3.6)} \qquad \mathbf{v} = (\triangle T_x - \triangle E_x)\mathbf{w},$$

for nonzero $\mathbf{w}$. The mth, $1 \le m \le M$, elements of $\triangle T_x\mathbf{w}$ and $\triangle E_x\mathbf{w}$ can be written, respectively, as

$$\text{(3.7)} \quad [\triangle T_x\mathbf{w}]_m = [R_x\mathbf{w}]_m - [T_x\mathbf{w}]_m = \sum_{i=m+1}^{M} t_{x,M+m-i}w_i + \sum_{i=1}^{m-1} t_{x,M-m+i}w_i,$$

and

$$\text{(3.8)} \quad [\triangle E_x\mathbf{w}]_m = [F_x\mathbf{w}]_m + [F_x^T\mathbf{w}]_m = \sum_{i=1}^{M} t_{x,M+m-i}w_i + \sum_{i=1}^{M} t_{x,M-m+i}w_i.$$

Therefore, $\mathbf{v}$ is bounded above by

$$\begin{aligned} ||\mathbf{v}||_\infty = ||\triangle E_x\mathbf{w} - \triangle T_x\mathbf{w}||_\infty &\le \max_{1\le m\le M} \left| \sum_{i=1}^{m} t_{x,M+m-i}w_i + \sum_{i=m}^{M} t_{x,M-m+i}w_i \right| \\ &\le 2 \sum_{m=M}^{2M-1} |t_{x,m}| ||\mathbf{w}||_\infty, \end{aligned}$$

where the ∞-norm of the vector $\mathbf{v}$ (or $\mathbf{w}$) is the maximum absolute value of elements v_m (or w_m), $1 \le m \le M$. We have

$$\text{(3.9)} \qquad ||\triangle T_x - \triangle E_x||_\infty \equiv \max_{\mathbf{w}} \frac{||\mathbf{v}||_\infty}{||\mathbf{w}||_\infty} \le 2 \sum_{m=M}^{2M-1} |t_{x,m}|,$$

which converges to zero as M goes to infinity, since $\sum_{m=0}^{\infty} |t_{x,m}|$ converges and $S_m = \sum_{m'=0}^{m} |t_{x,m'}|$ is a Cauchy sequence. The matrix $\triangle T_x - \triangle E_x$ is symmetric so that

$$||\triangle T_x - \triangle E_x||_1 = ||\triangle T_x - \triangle E_x||_\infty$$

and

$$||\triangle T_x - \triangle E_x||_2 \le (||\triangle T_x - \triangle E_x||_1 ||\triangle T_x - \triangle E_x||_\infty)^{1/2} = ||\triangle T_x - \triangle E_x||_\infty.$$

Thus, $\triangle T_x$ is asymptotically equivalent to $\triangle E_x$. It also follows that $\triangle T_x$ has at least $M - 2\gamma_x$ eigenvalues asymptotically converging to 0, or $R_x^{-1}T_x = (T_x + \triangle T_x)^{-1}T_x$ has at least $M - 2\gamma_x$ eigenvalues asymptotically converging to 1.

The $\triangle T_x$ and $\triangle E_x$ above are amenable to the operator-mask interpretation (see Fig. 1 with $M = 8$). One can easily verify that $\triangle T_x\mathbf{w}$ and $\triangle E_x\mathbf{w}$ correspond, respectively, to the use of the two masks

$$\begin{aligned} &\triangle T_x : [t_{x,M-1}\ t_{x,M-2}\ \cdots\ t_{x,1}\ t_{x,0}\ t_{x,1}\ \cdots\ t_{x,M-2}\ t_{x,M-1}], \\ &\triangle E_x : [\cdots\ t_{x,M}\ t_{x,M-1}\ \cdots\ t_{x,1}\ t_{x,0}\ t_{x,1}\ \cdots\ t_{x,M-1}\ t_{x,M}\ \cdots], \end{aligned}$$

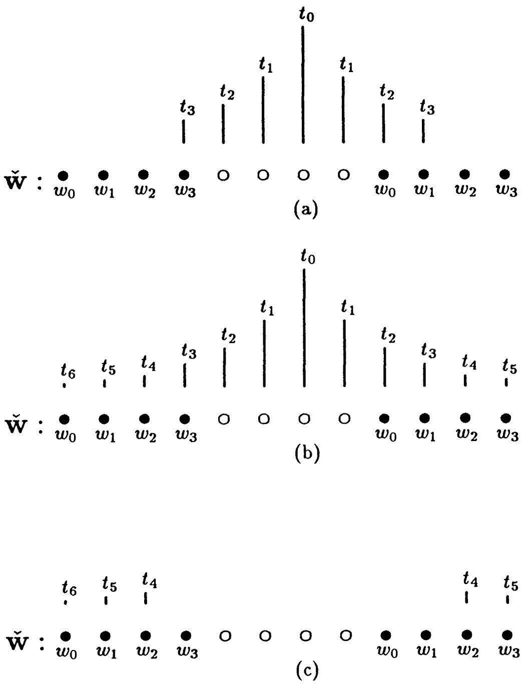

FIG. 1. *Operator-mask interpretations of* (a) $\triangle T_x \mathbf{w}$, (b) $\triangle E_x \mathbf{w}$, *and* (c) $(\triangle E_x - \triangle T_x)\mathbf{w}$.

operating on the same sequence

$$\check{w}_m = \begin{cases} w_{m \bmod M}, & -M \le m \le -1 \quad \text{or} \quad M \le m \le 2M-1, \\ 0, & \text{elsewhere.} \end{cases}$$

Note that the mask for $\triangle E_x$ is of infinite length. The corresponding mask for $\triangle E_x - \triangle T_x$ is

$$\triangle E_x - \triangle T_x : [\cdots \ t_{x,M+1} \ t_{x,M} \ 0 \ \cdots \ 0 \ 0 \ 0 \ \cdots \ 0 \ t_{x,M} \ t_{x,M+1} \ \cdots].$$

It is easy to derive (3.9) from the operator-mask viewpoint. Note that, for larger M, although there are more terms contributing to the ∞-norm of $\triangle E_x - \triangle T_x$, the weighting coefficient $t_{x,m}$, $m \ge M$, decays more rapidly. The resulting ∞-norm of $\triangle E_x - \triangle T_x$ asymptotically converges to zero. We conclude the above discussion as follows.

(a) When $B(z_x, z_y) = 1$, T_x (or T_y) is banded and $R_x^{-1}T_x$ (or $R_y^{-1}T_y$) has at most $2p_x + 1$ (or $2p_y + 1$) distinct eigenvalues, so that $R^{-1}T$ has at most $(2p_x+1)(2p_y+1)$ distinct eigenvalues.

(b) When $B(z_x, z_y) \ne 1$, $R_x^{-1}T_x$ (or $R_y^{-1}T_y$) has at most $2\gamma_x$ (or $2\gamma_y$) outliers not converging to unity and other eigenvalues are clustered between $(1-\epsilon_x, 1+\epsilon_x)$ (or $(1-\epsilon_y, 1+\epsilon_y)$). Thus, the eigenvalues of $R^{-1}T$ can be grouped into several clusters. The centers and clustering radii of these clusters and the numbers of eigenvalues contained are listed in Table 1, where $\lambda_{x,i}$ (or $\lambda_{y,j}$) denotes a typical outlier for

TABLE 1
Eigenvalues of $R^{-1}T$.

Center	$\lambda_{x,i}\lambda_{y,j}$	$\lambda_{x,i}$	$\lambda_{y,j}$	1
Radius	0	$O(\epsilon_y)$	$O(\epsilon_x)$	$O(\epsilon_x+\epsilon_y)$
Number	1	$N-2\gamma_y$	$M-2\gamma_x$	$(M-2\gamma_x)(N-2\gamma_y)$

$R_x^{-1}T_x$ (or $R_y^{-1}T_y$). Since ϵ_x and ϵ_y converge to zero as M and N become large, $R^{-1}T$ has asymptotically at most $(2\gamma_x+1)(2\gamma_y+1)$ distinct eigenvalues.

As a consequence, the PCG method converges in at most $(2\gamma_x+1)(2\gamma_y+1)$ iterations for positive definite T with sufficiently large M and N in both cases (a) and (b). This is confirmed numerically in §4.

3.2. Nonseparable generating sequences. For nonseparable generating functions $T(z_x,z_y)$ given by (3.3), we examine two typical cases, i.e., $B(z_x,z_y)=1$ and $B(z_x,z_y)\neq 1$ with $q_x>0$ and $q_y>0$.

When $B(z_x,z_y)=1$, we have a corresponding generating sequence of finite duration. As described in §2, the products $T\mathbf{w}$ and $R\mathbf{w}$ correspond to a linear operator characterized by the mask

$$\begin{bmatrix} t_{p_x,p_y} & t_{p_x-1,p_y} & \cdots & t_{0,p_y} & \cdots & t_{p_x-1,p_y} & t_{p_x,p_y} \\ t_{p_x,p_y-1} & t_{p_x-1,p_y-1} & \cdots & t_{0,p_y-1} & \cdots & t_{p_x-1,p_y-1} & t_{p_x,p_y-1} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ t_{p_x,0} & t_{p_x-1,0} & \cdots & t_{0,0} & \cdots & t_{p_x-1,0} & t_{p_x,0} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ t_{p_x,p_y-1} & t_{p_x-1,p_y-1} & \cdots & t_{0,p_y-1} & \cdots & t_{p_x-1,p_y-1} & t_{p_x,p_y-1} \\ t_{p_x,p_y} & t_{p_x-1,p_y} & \cdots & t_{0,p_y} & \cdots & t_{p_x-1,p_y} & t_{p_x,p_y} \end{bmatrix}$$

operating, respectively, on $\bar{w}_{m,n}$ and $\tilde{w}_{m,n}$ given by (2.7) and (2.8). The output elements of $T\mathbf{w}$ and $R\mathbf{w}$ are identical if the center of the mask is located at

$$p_x\le m\le M-p_x-1, \qquad p_y\le n\le N-p_y-1.$$

The dimension of the null space of $\Delta T=R-T$ is at least $(M-2p_x)(N-2p_y)$. Consequently, $R^{-1}T$ has at least $(M-2p_x)(N-2p_y)$ eigenvalues repeated at 1 or, equivalently, there are at most $2(Mp_y+Np_x)-4p_xp_y$ outliers. This result is summarized in the following theorem.

THEOREM 1. *Let T be an $MN\times MN$ block Toeplitz matrix characterized by (3.1)–(3.3) with $B(z_x,z_y)=1$. The preconditioned matrix $R^{-1}T$ has at least $MN-2(Mp_y+Np_x)+4p_xp_y$ eigenvalues repeated at one.*

When $B(z_x,z_y)\neq 1$ with $q_x>0$ and $q_y>0$, the products $T\mathbf{w}$ and $R\mathbf{w}$ correspond to a linear operator characterized by the mask

$$\begin{bmatrix} t_{M-1,N-1} & t_{M-2,N-1} & \cdots & t_{0,N-1} & \cdots & t_{M-2,N-1} & t_{M-1,N-1} \\ t_{M-1,N-2} & t_{M-2,N-2} & \cdots & t_{0,N-2} & \cdots & t_{M-2,N-2} & t_{M-1,N-2} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ t_{M-1,0} & t_{M-2,0} & \cdots & t_{0,0} & \cdots & t_{M-2,0} & t_{M-1,0} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ t_{M-1,N-2} & t_{M-2,N-2} & \cdots & t_{0,N-2} & \cdots & t_{M-2,N-2} & t_{M-1,N-2} \\ t_{M-1,N-1} & t_{M-2,N-1} & \cdots & t_{0,N-1} & \cdots & t_{M-2,N-1} & t_{M-1,N-1} \end{bmatrix} \tag{3.10}$$

operating on $\bar{w}_{m,n}$ and $\tilde{w}_{m,n}$, respectively. Let us exploit the quadrantally-symmetric property (3.1) and decompose $t_{m,n}$ into four sequences

$$t_{m,n} = \sum_{k=1}^{4} t_{k,m,n},$$

where $t_{k,m,n}$ is called the kth quadrant-support sequence and defined as

$$\text{(3.11a)} \qquad t_{1,m,n} = \begin{cases} t_{0,0}/4, & m = n = 0, \\ t_{m,0}/2, & 1 \le m \le M-1, \quad n = 0, \\ t_{0,n}/2, & m = 0, \quad 1 \le n \le N-1, \\ t_{m,n}, & 1 \le m \le M-1 \quad \text{and} \quad 1 \le n \le N-1, \\ 0, & m < 0 \quad \text{or} \quad n < 0, \end{cases}$$

and

$$\text{(3.11b)} \qquad t_{2,m,n} = t_{1,-m,n}, \qquad t_{3,m,n} = t_{1,-m,-n}, \qquad t_{4,m,n} = t_{1,m,-n}.$$

The following lemma is on the recursive property of $t_{1,m,n}$.

LEMMA 2. *Let $t_{m,n}$ be a quadrantally-symmetric sequence generated by the two-dimensional rational function $T(z_x, z_y)$ given in* (3.3), *and $t_{1,m,n}$ is the first quadrant-support sequence defined by* (3.11a). *Then,*

$$\text{(3.12)} \qquad \sum_{i=0}^{q_x} \sum_{j=0}^{q_y} b_{i,j} t_{1,m-i,n-j} = 0 \qquad \text{for } m > \gamma_x \quad \text{or} \quad n > \gamma_y.$$

Proof. It is clear that $A(z_x, z_y)/B(z_x, z_y)$ is the generating function for $t_{1,m,n}$. Therefore,

$$\frac{A(z_x, z_y)}{B(z_x, z_y)} = \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} t_{1,i,j} z_x^{-i} z_y^{-j}.$$

We multiply both sides of the above equation with $B(z_x, z_y)$, substitute (3.3b) for $A(z_x, z_y)$ and $B(z_x, z_y)$, and compare the corresponding coefficients. This gives the desired equation (3.12). □

Thus, we can use (3.12) to recursively define $t_{1,m,n}$ with $m > \gamma_x$ or $n > \gamma_y$ in the first quadrant, and the corresponding $t_{k,m,n}$ with $k = 2, 3, 4$ can be obtained from $t_{1,m,n}$ through the symmetry (3.11b).

As a generalization of the one-dimensional case, we define

$$\breve{w}_{m,n} = \begin{cases} w_{m \bmod M, n \bmod N}, & (m,n) \in [\cup_{-1 \le i,j \le 1} Q_{i,j}] - Q_{0,0}, \\ 0, & \text{elsewhere}, \end{cases}$$

where

$$Q_{i,j} = \{(m,n) : \quad iM \le m \le (i+1)M - 1, \quad jN \le n \le (j+1)N - 1\}.$$

Then, the operation $\triangle T\mathbf{w} = (R - T)\mathbf{w}$ corresponds to the mask (3.10) operating on $\breve{w}_{m,n}$. We choose the approximation $\triangle E\mathbf{w}$ to be an extended infinite mask, with recursively defined $t_{m,n}$ via (3.12), operating on $\breve{w}_{m,n}$. This is illustrated in Fig. 2, where we only show the first quadrant of the mask for $\triangle E$. For the rest of this

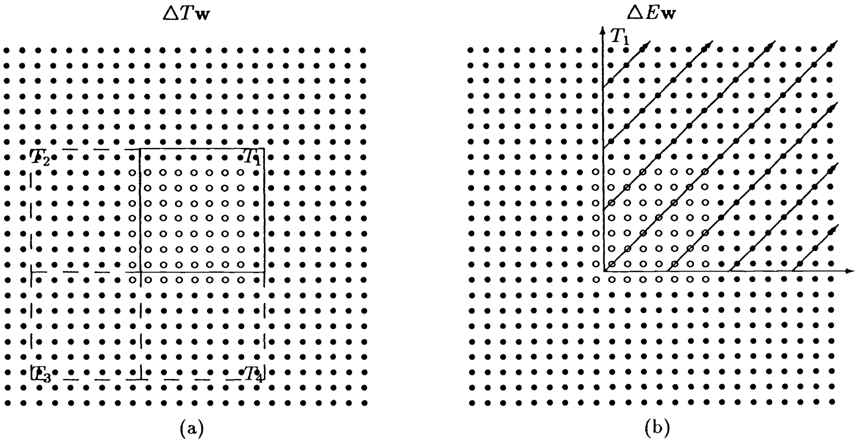

FIG. 2. *The matrix vector products* $\triangle T\mathbf{w}$ *and* $\triangle E\mathbf{w}$ *interpreted as* (a) *the operator-mask and* (b) *the extended operator-mask operating on* $\breve{w}$.

subsection, we are concerned with two issues: (i) the asymptotic equivalence of $\triangle T$ and $\triangle E$ and (ii) the number of eigenvalues of $\triangle E$ repeated at zero.

The operation $(\triangle E - \triangle T)\mathbf{w}$ corresponds to the difference between the extended mask and the original mask (3.10) operating on $\breve{w}_{m,n}$. The ∞-norm of the first quadrant of the difference mask $\triangle E - \triangle T$ operating on $\breve{w}_{m,n}$ in regions $Q_{1,0}$, $Q_{0,1}$, and $Q_{1,1}$ are bounded, respectively, by

$$K_{1,1,0} = \sum_{m=M}^{2M-1} \sum_{n=0}^{N-1} |t_{1,m,n}|, \quad K_{1,0,1} = \sum_{m=0}^{M-1} \sum_{n=N}^{2N-1} |t_{1,m,n}|, \quad K_{1,1,1} = \sum_{m=M}^{2M-1} \sum_{n=N}^{2N-1} |t_{1,m,n}|.$$

By exploiting the symmetry, we have the bound for $\triangle E - \triangle T$,

$$||\triangle E - \triangle T||_\infty \leq 4(K_{1,1,0} + K_{1,0,1} + K_{1,1,1}) = K.$$

With (3.2), we can order $t_{m,n}$ appropriately to be a Cauchy sequence and argue that K converges to zero for asymptotically large M and N. This establishes the asymptotic equivalence of $\triangle E$ and $\triangle T$.

The operator $\triangle E$ can be expressed as a superposition of 12 operators,

$$\begin{aligned} \triangle E &= F_{1,1,0} + F_{1,1,1} + F_{1,0,1} + F_{2,0,1} + F_{2,-1,1} + F_{2,-1,0}, \\ &\quad + F_{3,-1,0} + F_{3,-1,-1} + F_{3,0,-1} + F_{4,0,-1} + F_{4,1,-1} + F_{4,1,0}, \end{aligned} \tag{3.13}$$

where $F_{k,i,j}$ denotes the kth quadrant of the extended mask operating on sequences defined on $Q_{i,j}$. Consider operators $F_{1,1,0}$, $F_{1,0,1}$, and $F_{1,1,1}$. Their operations on $\mathbf{w}$ can be written as

$$F_{1,1,0} \ : \ v_{1,i,j} = \sum_{m=0}^{M-1} \sum_{n=j}^{N-1} t_{1,M+m-i,n-j} w_{m,n},$$

$$F_{1,0,1} \ : \ v_{2,i,j} = \sum_{m=i}^{M-1} \sum_{n=0}^{N-1} t_{1,m-i,N+n-j} w_{m,n},$$

$$F_{1,1,1}\ :\ v_{3,i,j}=\sum_{m=0}^{M-1}\sum_{n=0}^{N-1}t_{1,M+m-i,N+n-j}w_{m,n}.$$

With (3.12), we have

$$\sum_{i=i_0}^{i_0+q_x}\sum_{j=j_0}^{j_0+q_y}b_{i-i_0,j-j_0}v_{1,i,j}=\sum_{m=0}^{M-1}\sum_{n=j+j_0}^{N-1}\left[\sum_{i=0}^{q_x}\sum_{j=0}^{q_y}b_{i,j}t_{1,M+m-i_0-i,n-j_0-j}\right]w_{m,n}=0,$$

for $0\le i_0\le M-1-\gamma_x$;

$$\sum_{i=i_0}^{i_0+q_x}\sum_{j=j_0}^{j_0+q_y}b_{i-i_0,j-j_0}v_{2,i,j}=\sum_{m=i+i_0}^{M-1}\sum_{n=0}^{N-1}\left[\sum_{i=0}^{q_x}\sum_{j=0}^{q_y}b_{i,j}t_{1,m-i_0-i,N+n-j_0-j}\right]w_{m,n}=0,$$

for $0\le j_0\le N-1-\gamma_y$; and

$$\sum_{i=i_0}^{i_0+q_x}\sum_{j=j_0}^{j_0+q_y}b_{i-i_0,j-j_0}v_{3,i,j}=\sum_{m=0}^{M-1}\sum_{n=0}^{N-1}\left[\sum_{i=0}^{q_x}\sum_{j=0}^{q_y}b_{i,j}t_{1,M+m-i_0-i,N+n-j_0-j}\right]w_{m,n}=0,$$

for $0\le i_0\le M-1-\gamma_x$ or $0\le j_0\le N-1-\gamma_y$.

By combining the above three equations, we have

$$\sum_{i=i_0}^{i_0+q_x}\sum_{j=j_0}^{j_0+q_y}b_{i-i_0,j-j_0}(v_{1,i,j}+v_{2,i,j}+v_{3,i,j})=0,$$

for $0\le i_0\le M-1-\gamma_x$ and $0\le j_0\le N-1-\gamma_y$. Therefore, the rank of $F_1=F_{1,1,0}+F_{1,0,1}+F_{1,1,1}$ is at most $M\gamma_y+N\gamma_x-\gamma_x\gamma_y$. By using the symmetry, we can argue that the rank of $F_k=\sum_{i,j}F_{k,i,j}$, $k=2,3,4$, is also at most $M\gamma_y+N\gamma_x-\gamma_x\gamma_y$. Consequently, the rank of $\triangle E$ is at most $4(M\gamma_y+N\gamma_x-\gamma_x\gamma_y)$ or, equivalently, $\triangle E$ has at least $MN-4(M\gamma_y+N\gamma_x-\gamma_x\gamma_y)$ eigenvalues repeated at 0.

To conclude this section, we have the following theorem.

THEOREM 2. *Let T be an $MN\times MN$ block Toeplitz matrix satisfying* (3.1), (3.2), *and* (3.3) *with $q_x>0$ and $q_y>0$. Then, the preconditioned matrix $R^{-1}T$ has at least $MN-4(M\gamma_x+N\gamma_y-\gamma_x\gamma_y)$ eigenvalues asymptotically converging to one.*

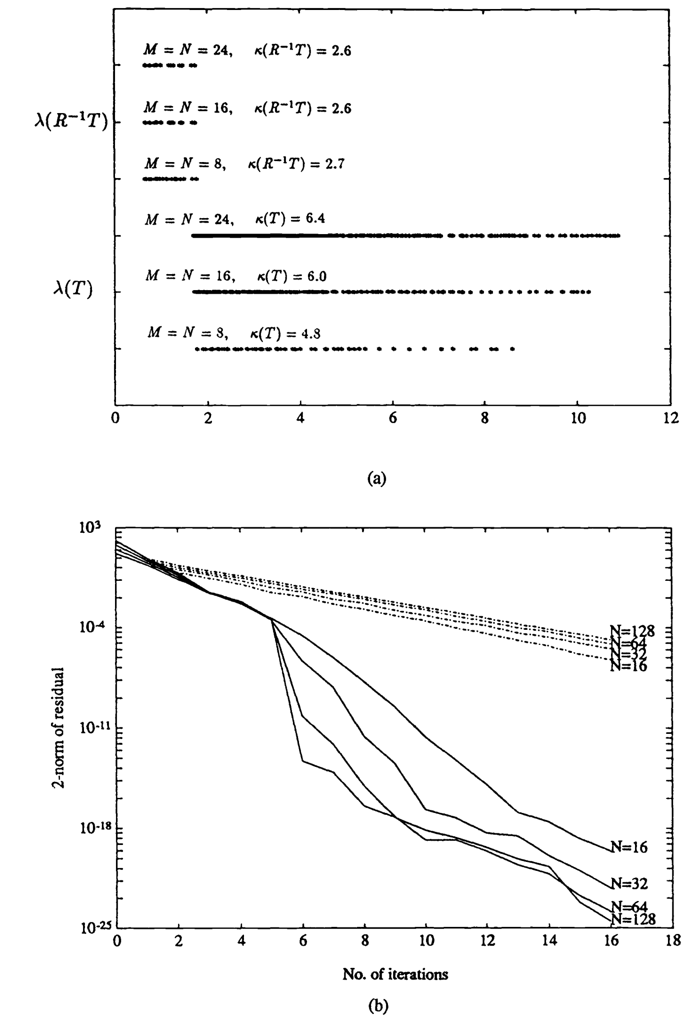
4. Numerical experiments.

4. Numerical experiments. Numerical experiments are performed to illustrate the spectra of T and $R^{-1}T$ and the convergence behavior of the CG and PCG methods. Note that the spectral clustering property derived in §3 does not require T to be positive definite. However, we focus on positive-definite T in our experiments so that the CG and PCG methods can be conveniently applied. For all test problems below, we choose $M=N$ and use $(0,\cdots,0)^T$ and $(1,\cdots,1)^T$ as the initial and right-hand-side vectors, respectively.

The first three test problems have positive rational generating functions in the Wiener class.

Example 1. Rational separable Toeplitz with $(p_x,q_x,p_y,q_y)=(0,2,0,2)$. The $T(z_x,z_y)$ is of the form (3.4) with $A_x(z_x)=A_y(z_y)=1$,

$$B_x(z_x)=(1+0.8z_x^{-1})(1-0.7z_x^{-1})\quad\text{and}\quad B_y(z_y)=(1+0.9z_y^{-1})(1-0.6z_y^{-1}).$$



(a)

(b)

FIG. 3. (a) *Eigenvalue distribution of* T *and* $R^{-1}T$ *and* (b) *convergence history for Example* 1.

Example 2. Rational Toeplitz with $(p_x, q_x, p_y, q_y) = (2, 0, 2, 0)$. The $T(z_x, z_y)$ is of the form (3.3) with $B(z_x, z_y) = 1$ and

$$A(z_x, z_y) = 0.25 - 0.02(z_x^{-1} + z_y^{-1}) + 0.015(z_x^{-2} + z_y^{-2}) + 0.03z_x^{-1}z_y^{-1}$$
$$-0.02z_x^{-1}z_y^{-1}(z_x^{-1} + z_y^{-1}) - 0.01z_x^{-2}z_y^{-2}.$$

Example 3. Rational Toeplitz with $(p_x, q_x, p_y, q_y) = (0, 2, 0, 1)$. The $T(z_x, z_y)$ is of the form (3.3) with $A(z_x, z_y) = 1$ and

$$B(z_x, z_y) = 1 + 0.5z_x^{-1} - 0.3z_y^{-1} - 0.2z_x^{-2} - 0.1z_x^{-1}z_y^{-1} + 0.2z_x^{-2}z_y^{-1}.$$

We plot the corresponding spectra of T and $R^{-1}T$, their condition numbers, and the convergence history of the CG (dashed lines) and PCG (solid lines) methods in Figs. 3(a),(b)–5(a),(b). Since the eigenvalues of T for Examples 1–3 all satisfy

$$0 < \delta_1 \leq \lambda(T) \leq \delta_2 < \infty,$$

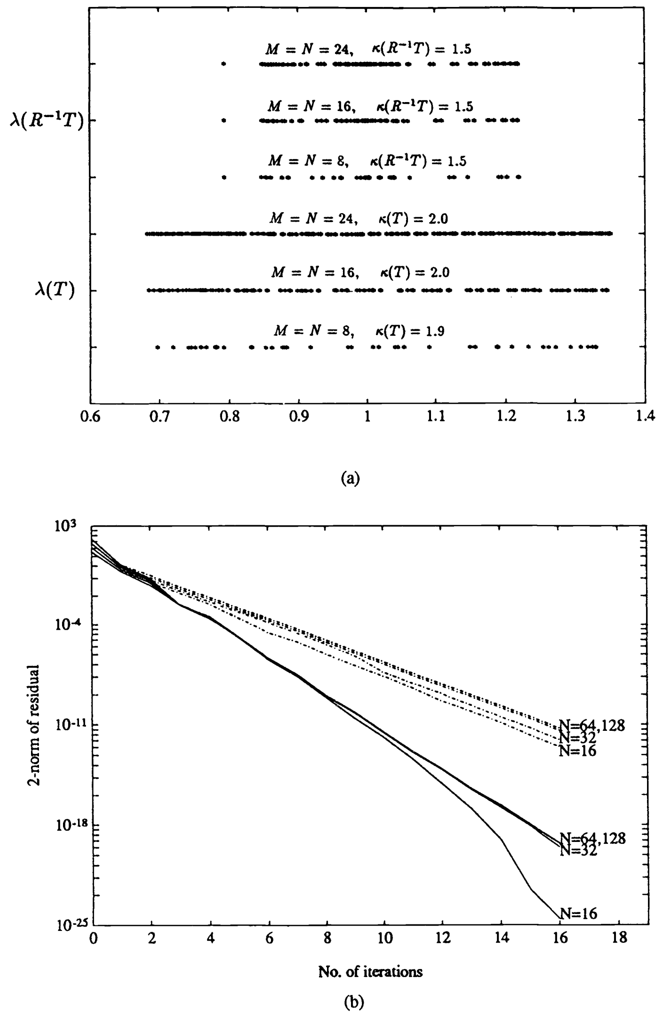


FIG. 4. (a) *Eigenvalue distribution of* T *and* $R^{-1}T$ *and* (b) *convergence history for Example* 2.

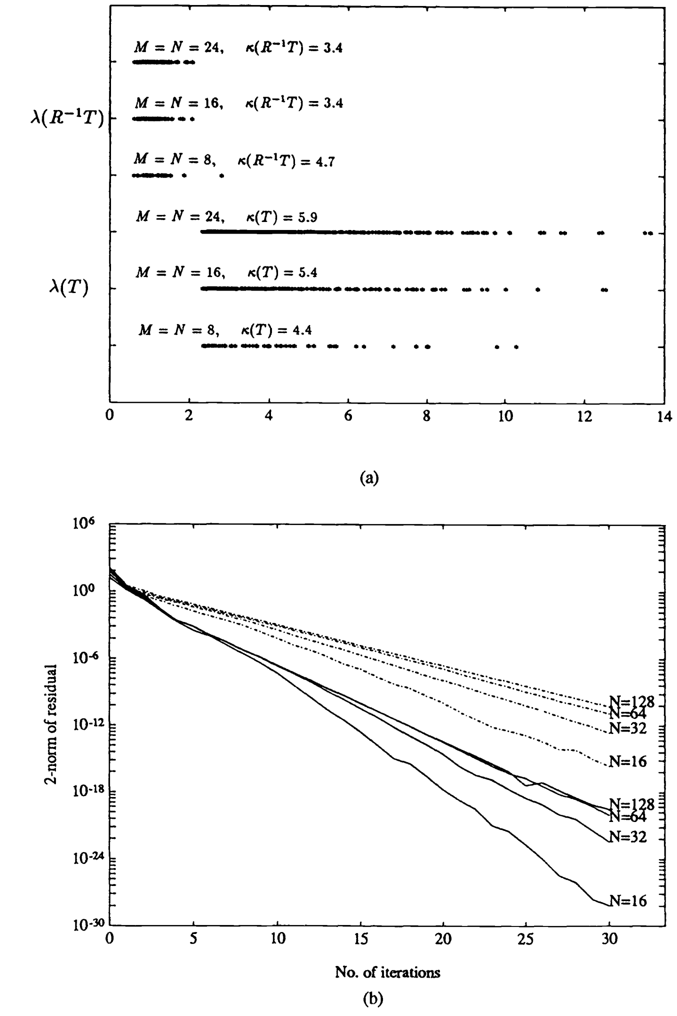
where δ_1 and δ_2 are constants independent of the dimensions M and N of the given block matrix, the condition number $\kappa(T)$ is bounded by $\delta_2/\delta_1 = O(1)$. Clearly, $R^{-1}T$ has a smaller condition number and a better clustering feature than T. Consequently, the PCG method performs better than the CG method.

One important difference between the separable and nonseparable cases is that, as N becomes larger, the PCG method converges faster for the separable case but more slowly for the nonseparable case. This can be easily explained by the analysis given in §3. When T is separable, the number of clusters is fixed and the clustering radius ϵ becomes smaller as N becomes larger. According to the analysis, $R^{-1}T$ has asymptotically 25 $(= (2\gamma_x + 1)(2\gamma_y + 1))$ distinct eigenvalues, including isolated outliers, clustered outliers, and clustered eigenvalues converging to 1. However, the 2-norm of the residual decreases rapidly in five iterations as given in Fig. 3(b). We observe an empirical formula for the separable case, namely, the PCG method converges



(a)

(b)

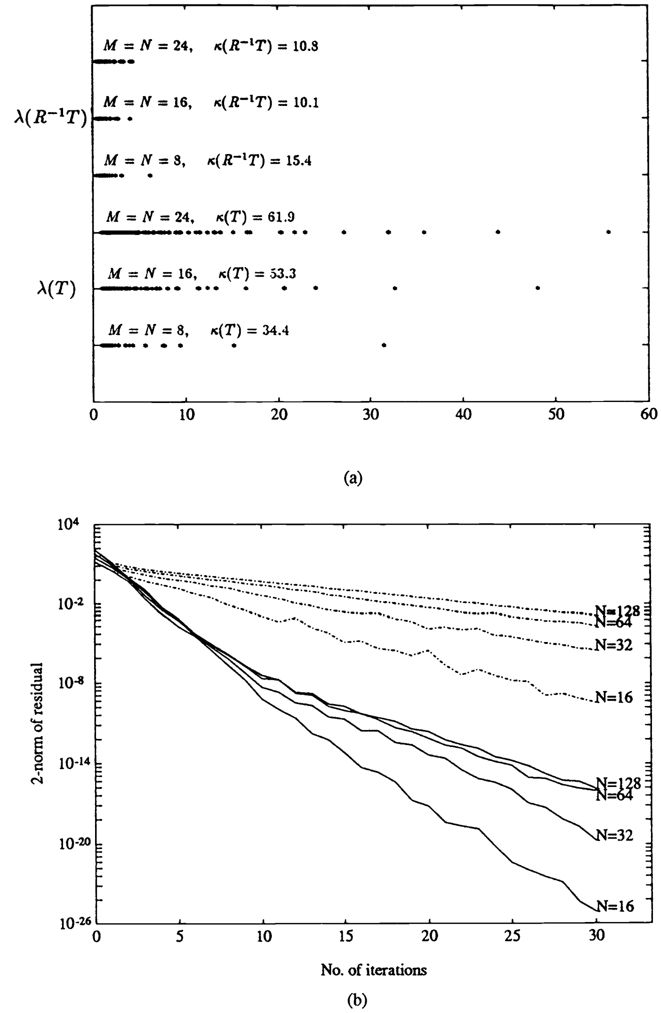
FIG. 5. (a) *Eigenvalue distribution of* T *and* $R^{-1}T$ *and* (b) *convergence history for Example* 3.

asymptotically in $\gamma_x\gamma_y + 1$ iterations. This phenomenon is closely related to the point Toeplitz result [10], where we found that although there are asymptotically $2\gamma_x + 1$ distinct eigenvalues, the PCG method converges asymptotically in $\gamma_x + 1$ iterations. When T is nonseparable, the number of outliers increases with N. Although the PCG method converges more slowly for larger N, the effect is not obvious until the 2-norm of the residual is very small. Besides, the convergence curves are getting closer for larger N. This indicates that the number of PCG (or CG) iterations required is $O(1)$, which is determined by the condition number rather than the number of outliers.

A block Toeplitz with a nonrational generating function is given in Example 4.

Example 4. Nonrational Toeplitz. The block Toeplitz matrix is generated by a spherically-symmetric sequence

$$t_{m,n} = 0.7^{\sqrt{m^2+n^2}} + 0.5^{\sqrt{m^2+n^2}} + 0.3^{\sqrt{m^2+n^2}}.$$



(a)

(b)

FIG. 6. (a) *Eigenvalue distribution of* T *and* $R^{-1}T$ *and* (b) *convergence history for Example* 4.

The spectra of T and $R^{-1}T$ and the convergence history of the CG and PCG methods are plotted in Fig. 6. Although our analysis in §3 is restricted to the rational generating function case, it appears that this case does not differ much from the rational case. The PCG method converges faster than the CG method due to a smaller condition number and a better spectral clustering property of $R^{-1}T$. The condition numbers of T and $R^{-1}T$ are again $O(1)$ so that the number of PCG (or CG) iterations required is $O(1)$, which is consistent with the observation that the convergence history curves are getting closer for larger N.

For the above four problems, T is well conditioned, i.e., $\kappa(T) = O(1)$, so that the condition number reduction through preconditioning is just a constant factor. To see a more dramatic condition number improvement, let us consider an ill-conditioned block Toeplitz below.

Example 5. Ill-conditioned Toeplitz with $(p_x, q_x, p_y, q_y) = (2, 0, 2, 0)$. The block

Toeplitz is characterized by the two-dimensional mask:

$$(-1)\times\begin{bmatrix} 0.01 & 0.02 & 0.04 & 0.02 & 0.01 \\ 0.02 & 0.04 & 0.12 & 0.04 & 0.02 \\ 0.04 & 0.12 & -1 & 0.12 & 0.04 \\ 0.02 & 0.04 & 0.12 & 0.04 & 0.02 \\ 0.01 & 0.02 & 0.04 & 0.02 & 0.01 \end{bmatrix}.$$

Note that the sum of the coefficients of the mask is zero. Masks of this nature arise in the discretization of constant-coefficient elliptic partial differential equations. However, the preconditioning block circulant matrix R is singular for this problem, since $R\mathbf{w} = 0$ for $\mathbf{w} = (1, 1, \cdots, 1, 1)^T$. In order to perform the preconditioning properly, we modify the preconditioner R slightly by replacing the zero eigenvalue with the smallest nonzero eigenvalue of R in our experiment.

The spectra of T and $R^{-1}T$, the convergence history of the CG and PCG methods, and the number of iterations required for the 2-norm of the relative residual less than 10^{-12} are plotted in Fig. 7 (a)–(c). As shown in Fig. 7(a), the condition numbers of T and $R^{-1}T$ increase at the rates of $O(N^2)$ and $O(N)$, respectively. Thus, the preconditioning provides an order of condition number improvement. A detailed analysis for the improvement of conditioned number from $O(N^2)$ to $O(N)$ is given in [4]. We see from Fig. 7(c) that PCG and CG methods converge in $O(\sqrt{N})$ and $O(N)$ iterations, respectively.

As far as the computational complexity is concerned, both the PCG and CG methods require $O(N^2 \log N)$ operations for Examples 1–4, where the condition numbers of T and $R^{-1}T$ are $O(1)$. For Example 5, the PCG and CG methods require, respectively, $O(N^{5/2} \log N)$ and $O(N^3 \log N)$ operations. For all above test problems, the PCG and CG methods require much lower computational complexity than the direct method, which requires $O(N^5)$ operations.

5. Conclusion. In this research, we extended the preconditioning technique from point Toeplitz matrices to block Toeplitz matrices. We interpreted the block Toeplitz matrix-vector $T\mathbf{w}$ in terms of a two-dimensional constant-coefficient mask operating on a certain two-dimensional sequence construction based on $\mathbf{w}$. This viewpoint provides a natural way to analyze the spectral clustering property of $R^{-1}T$. For block Toeplitz matrices T generated by two-dimensional rational functions $T(z_x, z_y)$ of order (p_x, q_x, p_y, q_y), we showed that the eigenvalues of $R^{-1}T$ are clustered around unity except at most $O(M\gamma_y + N\gamma_x)$ outliers, where $\gamma_x = \max(p_x, q_x)$ and $\gamma_y = \max(p_y, q_y)$. Furthermore, if T is separable, the outliers are clustered together such that $R^{-1}T$ has at most $(2\gamma_x + 1)(2\gamma_y + 1)$ asymptotic distinct eigenvalues. Thus, $R^{-1}T$ has a better spectral clustering property than T. Additionally, it was shown numerically that $R^{-1}T$ generally has a smaller condition number than T. These two spectral properties explain the superior convergence behavior of the PCG method over the CG method.

For point rational Toeplitz matrices, the number of outliers is often small ($= 2\max(p, q)$) and independent of the size of the problem so that it can be used to characterize the convergence rate of the PCG method. However, for block rational Toeplitz matrices, the number of outliers is proportional to the size of the problem, and is often too large to be useful for characterizing the convergence behavior of the PCG method. Hence, we have to examine both the condition number improvement and the spectral clustering effect. More research on the adaptation of the preconditioning technique to more general classes of block Toeplitz matrices, such as indefinite or

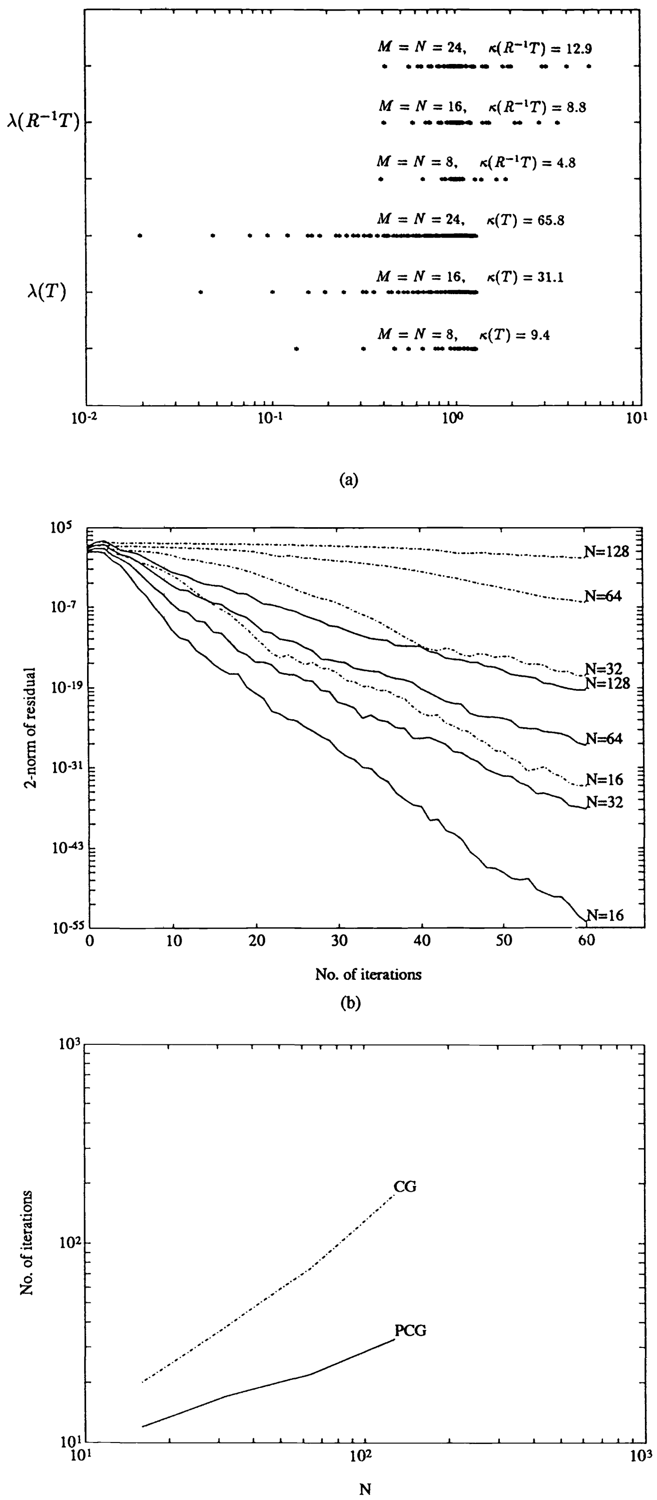


FIG. 7. (a) *Eigenvalue distribution of* T *and* $R^{-1}T$ *and* (b) *convergence history and* (c) *convergence rate of* CG *and* PCG *method for Example* 5.

nonsymmetric problems and the spectral analysis of the preconditioned matrices, is expected in the future.

DOMAIN DECOMPOSITION WITH LOCAL MESH REFINEMENT*

WILLIAM D. GROPP† AND DAVID E. KEYES‡

Abstract. A preconditioned Krylov iterative algorithm based on domain decomposition for linear systems arising from implicit finite-difference or finite-element discretizations of partial differential equation problems requiring local mesh refinement is described. To keep data structures as simple as possible for parallel computing applications, the fundamental computational unit in the algorithm is defined as a subregion of the domain spanned by a locally uniform tensor-product grid, called a tile. In the tile-based domain decomposition approach, two levels of discretization are considered at each point of the domain: a global coarse grid defined by tile vertices only, and a local fine grid where the degree of resolution can vary from tile to tile. One global level and one local level provide the flexibility required to adaptively discretize a diverse collection of problems on irregular regions and solve them at convergence rates that deteriorate only logarithmically in the finest mesh parameter, with the coarse tessellation held fixed. A logarithmic departure from optimality seems to be a reasonable compromise for the simplicity of the composite grid data structure and concomitant regular data exchange patterns in a multiprocessor environment. Some experiments with up to 1024 tiles are reported, and the evolution of the algorithm is commented on and contrasted with optimal nonrefining two-level algorithms and optimal refining multilevel algorithms. Computational comparisons with some other popular methods are presented.

1. Introduction.

The combination of domain decomposition with preconditioned iterative methods provides a framework that extends the usefulness of numerical techniques for certain special partial differential equation (PDE) problems to those of more general structure. Nonsmooth features, nonseparable geometries, or massive sizes of practical problems limit the application of many "standard" numerical techniques. Direct methods are rapidly defeated by problem size. "Fast" methods that take advantage of special coefficient and grid structure often do not apply globally. Iterative methods often depend, for efficient implementation, on regular grids that, if global in extent, are inconsistent with accurate and economical resolution of the physics of the problem. However, the domains of problems with these features can often be decomposed into smaller subdomains of simpler structure, increasing the utility of extant software libraries, particularly as components of preconditioners. Moreover, the domain decomposition can be made to produce a convenient mapping of many problems onto medium-scale parallel computers. Our primary focus in this paper is the incorporation of spatially varying mesh refinement requirements into a domain decomposition algorithm based on finite differences. We illustrate the convergence behavior of the algorithm on a variety of two-dimensional elliptic PDE problems,

$$\mathcal{L}u = f \text{ on } \Omega, \quad \text{with } au + bu_n = g \quad \text{on } \mathrm{d}\Omega, \tag{1}$$

including nonselfadjoint, nonseparable geometry cases. We also point out features of the method that are relevant to a parallel implementation. We defer most discussion that would be distinctly architecture- and performance-related to a companion paper [27].

Many PDE problems that are "large" in the discrete sense are so because the continuous problems from which they are generated require resolution of several different length scales for the production of a meaningful solution. The value of compromising between the extremes of globally uniform refinement (which leads to simple and usually vectorizable algorithms but wastes time and memory) and pointwise adaptive refinement (which minimizes the discrete problem size for a given accuracy requirement but leads to complicated data structures) has been recognized for some time and described in contexts too numerous to acknowledge fairly. Locally uniform mesh refinement (LUMR) characterizes one such class of discretizations, based on composites of highly structured subgrids. Many treatments of LUMR in the literature pertain to explicit methods for transient problems, a class with its own advantages (see [4] and references therein) and limitations [45], which is somewhat distinct from ours. Implicit treatments of locally regular refinement for elliptic problems include approaches arising out of classical multigrid ([8]; see [38] for a concise state-of-the-art treatment), a nonconforming spectral technique [35], and methods rooted in iterative substructuring for finite-element problems [6], [16].

Computationally practical locally uniform grids are usually expressible as the union of a coarse uniform tensor-product grid covering the entire domain with one or more refined tensor-product grids defined over subregions, including the possibility of multiple, nested levels. Generalizations of these grids within the LUMR framework include allowing the grids at any particular level of refinement to themselves be the union of tensor-product subgrids, and reinterpreting "uniform" as "quasi-uniform" to allow general curvilinear coordinates for custom body- or solution-fitting. Few *parallel* implementations of schemes of this generality have been reported thus far. Selected for consideration here is a structurally restricted form of LUMR in which refinement occurs exclusively within complete cells of a quasi-uniform coarse grid, as described in §3 below.

The goal of the present contribution is an LUMR methodology with starkly simple data structures for efficient portability to a variety of parallel machines. Current implementations on two distributed- and two shared-memory parallel machines share approximately 98 percent common code measured by line count, inclusive of comments, exclusive of standard libraries. The methodology borrows from the mesh refinement and domain decomposition literature and from the authors' own experience in these areas and in parallel computation [23], [24], [34]. The serial arithmetic complexity bows somewhat to modularity, portability, and overall parallel performance, in which we include both efficiency and total execution time. For example, by refining only in units of full coarse-grid cells, we often impose a tendency towards refinement in subregions where it would be unnecessary from the viewpoint of truncation error alone. As another example, the convergence rate of many domain decomposition algorithms is mildly dependent upon a coarse-grid resolution which may be chosen with criteria beyond convergence rate, such as the balance of work among multiple processors. Our algorithm therefore does not scale (with constant problem size) to indefinitely large numbers of processors, but it does sit comfortably on today's MIMD supercomputers. We comment in the final section about a hybridized two-level algorithm suitable for massive parallelism on an MIMD cluster of SIMD subclusters.

Prior to the discussion of LUMR, §2 describes a domain decomposition algorithm employing "nearly" parallel preconditioners in conjunction with generalized minimal residual (GMRES) iteration, a nonstationary method not dependent upon operator symmetry. In two dimensions, the preconditioner involves three phases: a global coarse-grid solve, independent solves along interfaces between subdomains, and independent solves in the subdomain interiors. The global coarse-grid solve is an essential feature, as it provides the only global exchange of information in the preconditioner itself. We introduce a simple "tangential" operator preconditioning for the subdomain interfaces that is preferable to the interface probe preconditioning advocated in our earlier work on convective-diffusive systems with stripwise decompositions [32]. We also prefer exact subdomain solves to incomplete factorizations. These "exact solves" can be performed by multigrid if the subdomains become too large for direct methods. For multicomponent problems in which source terms codominate with convection and diffusion, block incomplete factorization may also be an economical subdomain solver.

The main body of the paper (§4) is a collection of numerical experiments on two-dimensional elliptic boundary value problems (BVPs). The experiments include reentrant domains, nonselfadjoint operators, and mixed boundary conditions. Up to 1,024 coarse-grid elements, called *tiles*, are used. The last two subsections of §4 compare the boxwise decompositions used throughout the paper with stripwise decompositions exploiting physical anisotropies, as well as with some conventional undecomposed solvers.

Section 5 indicates some future directions for this methodology.

2. An iterative domain decomposition algorithm.

Preconditioned iterative methods and domain decomposition provide a framework that includes a wide class of algorithms. This framework comprises four elements:

1. a global operator arising from the discretization of the PDE (or system of PDEs);
2. an approximate inverse, or preconditioner, for the global operator;
3. an iterative method requiring only the application of the preconditioned operator; and
4. a geometry-based partition of the discrete unknowns so that size, locality, and uniformity can be exploited in forming the action of the preconditioned operator.

Since the numerical analysis literature contains many successful discretization schemes and iterative methods specialized for different operator properties, such as the presence or absence of definiteness and symmetry, the recent burgeoning effort in iterative domain decomposition algorithms has concentrated primarily (though not exclusively) on the interaction of the second and fourth of these elements. In the parallel context, this is a natural preoccupation because the bottleneck to parallelism usually (though not exclusively) lies in the requirement of the global transport of information in the preconditioner.

2.1. Iterative methods and operator structure.

Many of the numerical examples described in §4 rule out the use of iterative methods based on symmetry but permit the assumptions of definiteness and diagonal dominance. In particular, full or incomplete factorizations of preconditioner matrix blocks can be undertaken without pivoting. Because of its robustness, we adopt the parameter-free generalized minimal residual (GMRES) method [43] as the outer iteration. The main disadvantages of GMRES, its linear and quadratic (in iteration index) memory and execution time requirements, respectively, must be mitigated by scaling and preconditioning. For other acceleration schemes, such as Chebyshev, the memory and execution time requirements may be only constant and linear, respectively; however, GMRES dispenses with the difficulty of estimating parameters. The recently proposed, parameter-free, bounded recursion Bi-CGSTAB method [14] combines the above-mentioned advantages and deserves further study. In preliminary tests we have found it usually to be competitive in execution time with GMRES, but it can in some instances be substantially slower. Other methods for the iterative solution of nonsymmetric systems, such as QMR [21], also deserve broader investigation. In solving $Au = b$ each of these methods requires an initial iterate for x that it improves through repeated calls to a routine forming the product of A with a direction vector. For improved convergence we employ a change of variables, iteratively solving $(AB^{-1})y = b$ for y and then $Bx = y$ for x. Here, B is a right preconditioner matrix, whose inverse action should be convenient to compute and should cluster the eigenvalues of AB^{-1}. A arises from an FD, FE, or FV discretization, with a local stencil. The stencil is regarded as uniform in this section and generalized in §3.

The type of domain decomposition used here involves unit aspect ratio subdomains, as opposed to thin strips joining opposite sides of a domain; therefore, interior subdomain vertices are created. We denote all subdomain vertices "cross points" but distinguish between interior and boundary cross points. Ordering the interior points as well as the physical boundary points other than cross points first, the interfaces connecting the cross points plus the cross points on the boundary next, and the interior cross points last imposes the following outer tripartition on the global discrete operator A:

$$A \equiv \begin{pmatrix} A_I & A_{IB} & A_{IC} \\ A_{BI} & A_B & A_{BC} \\ A_{CI} & A_{CB} & A_C \end{pmatrix}. \tag{2}$$

Note that the partitions vary greatly in size. If H is a quasi-uniform subdomain diameter and h a quasi-uniform fine-mesh width, the discrete dimensions of A_I, A_B, and A_C are $\mathcal{O}(h^{-2})$, $\mathcal{O}(H^{-1}h^{-1})$, and $\mathcal{O}(H^{-2})$, respectively. The numerical experiments described below employ a five-point stencil (extended in [33] to second-order upwind differencing with a skew six- or seven-point stencil). No cross-derivative terms appear; therefore, there are no corner points in the stencil and blocks A_{IC} and A_{CI} may be set to zero.

The outer structure of our preconditioner B may be a conformally partitioned block upper triangular matrix:

$$B = \begin{pmatrix} \tilde{A}_I & \tilde{A}_{IB} & \tilde{A}_{IC} \\ 0 & B_B & \tilde{A}_{BC} \\ 0 & 0 & B_C \end{pmatrix}, \tag{3}$$

whose components are elucidated in the next subsection. The application of B^{-1} to a vector $v = (v_I, v_B, v_C)^T$ consists of solving $Bw = v$ for $w = (w_I, w_B, w_C)^T$. It begins with a cross-point solve with B_C for w_C. This updates through $\tilde{A}_{BC}$ the right-hand sides of a set of independent interface solves for subvectors of w_B. These, in turn, update the right-hand sides through $\tilde{A}_{IB}$ of a set of independent interior solves for subvectors of w_I. For a stencil with corner points, $\tilde{A}_{IC}$ would be nonzero, and the cross-point result would also update the interior block right-hand sides. Within the preconditioner, however, there is no dependence of the interface solution upon the result of the interior solution, or of the cross-point solution upon either. This fact distinguishes the method from [7] and [10] and means that the $\mathcal{O}(h^{-2})$-sized block of the preconditioner is visited only once per iteration.

A useful optimization is available when the tilde quantities in the top row are taken equal to their tilde-free counterparts. In this case, it is readily verified that the right-preconditioned form of the operator is

$$AB^{-1} = \begin{pmatrix} I & 0 & 0 \\ * & (A_B - A_{BI}A_I^{-1}A_{IB})B_B^{-1} & * \\ 0 & * & (A_C - A_{CB}B_B^{-1}\tilde{A}_{BC})B_C^{-1} \end{pmatrix}, \tag{4}$$

where the starred blocks are nonzero (and not necessarily small). The identity block row means that $\mathcal{O}(h^{-2})$ of the unknowns in the Krylov vectors can go untouched (except for scaling) throughout the entire solution process until the preconditioning is unwound in the final step, after the interface and cross-point values have converged. Since A_I^{-1} is needed to advance the solution on these separator sets, we cannot entirely escape solving subdomain problems, but substantial arithmetic work can be saved.

2.2. Components of the preconditioner. The derivation of the coefficients of the preconditioner blocks is as follows. The cross-point operator B_C is simply an H-scale coarse-grid discretization of the continuous PDE. To accommodate Neumann or Robin boundary conditions, we include physical boundary points lying at subdomain vertices in the cross-point system in this step. (Later the boundary cross-point values are overwritten with the results of more accurate h-scale data from the interface solve. This distinction is, of course, moot for Dirichlet data but important for boundary conditions involving spatial gradients.) The cross-point system right-hand side at interior points can be taken as the injected vertex values of the fine-grid right-hand side, though we remark on a better choice below. The current implementation supports a direct solve on the coarse-grid system. If strip decompositions are used, there is no cross-point system, and the lower right block of the preconditioner consists only of the interface system described next.

Unlike the coarse-grid and subdomain interior problems, which possess the full physical dimension of the domain of the underlying PDE and thus inherit a literature full of preconditionings, the lower-dimensional interfacial equations are properly derived from a pseudodifferential trace operator. (See [5, §3] for an informal theory.) The tangential interface preconditioner we employ below is the one-dimensional discretization of the terms of the underlying operator that remain when the derivatives normal to the interface are set to zero. It is equivalent to solving a two-point BVP with boundary conditions inherited from the interior cross-point values or from the physical boundary.

The subdomain interior equations consist of approximate fine-grid discretizations of the PDE over local regions, with physically appropriate boundary conditions along any true boundary segments and Dirichlet boundary conditions derived from the already available w_B at artificial interfaces. Only first-order interior differences are accommodated in the physical boundary conditions of the preconditioner, though first- *or* second-order boundary conditions may be elected in the operator A. The current implementation supports full LU Gaussian elimination with both banded and sparse data structures, fast cyclic reduction, incomplete LU decomposition, and modified incomplete LU decomposition. To maintain a reasonable scope, we concentrate on full elimination results here. Full elimination on the interiors yields the best iteration counts, although not always the best execution times (for large H/h). Like the interface solves, each subdomain interior solve may be performed independently.

2.2.1. A better variant of the cross-point system. In keeping with an exposition that is as independent as possible of particular discretization techniques, the right-hand side of the cross-point system was assumed above to be the injected vertex values of the fine grid weighted by the subdomain areas instead of the grid-cell areas. It is necessary, however, to rely on a finite-element discretization with a hierarchical basis to properly motivate the construction of a better cross-point system. In particular, we have obtained faster convergence by using the function space decomposition approach of [7], which yields essentially the same coefficient block B_C but replaces the simple injection of fine-grid values with ramp-weighted averages of interface values along all interfaces feeding a given cross point. Specifically, the element of the right-hand side v_C corresponding to an interior subdomain vertex is a discrete approximation to one-quarter of the sum of four line integrals of the form

$$\frac{2}{H}\int_0^H v(s)\left(1-\frac{s}{H}\right)\, ds\ , \tag{5}$$

where s parameterizes the interfaces leading from the vertex in question. This leads to the following sequence of steps to produce a preconditioned matrix-vector product u from input v, where $v = (v_I, v_B, v_C)^T$:

First, v_C is reweighted according to (5). The reweighting has the matrix representation $v' = Cv$, where

$$C = \begin{pmatrix} I & 0 & 0 \\ 0 & I & 0 \\ 0 & K & J \end{pmatrix},$$

J is diagonal with all positive elements, all elements of K are nonnegative, and the row sums of K and J together give unity. Then, as above, we solve for $w = B^{-1}v'$ and multiply by A to get $u = Aw$. Thus, the preconditioned matrix-vector product is $u = AB^{-1}Cv$. Treating everything apart from A itself as the effective preconditioner Q, we find that $Q^{-1} = B^{-1}C$, or equivalently, $Q = C^{-1}B$, which is straightforwardly seen to be

$$Q = \begin{pmatrix} \tilde{A}_I & \tilde{A}_{IB} & \tilde{A}_{IC} \\ 0 & B_B & \tilde{A}_{BC} \\ 0 & -J^{-1}KB_B & J^{-1}(B_C - K\tilde{A}_{BC}) \end{pmatrix}.$$

When tilde-free quantities are used in the first block row, AQ^{-1} has a first block row equal to the identity. Thus, the remark following (4) about not touching the upper portion of the Krylov vectors, except for scaling, remains valid. Although the preconditioner with ramp weighting of the right-hand side of the cross-point system is no longer strictly block triangular, it still requires only one solve with A_I per iteration.

2.3. Parallelism in the preconditioner. We note that the permutation into block matrix form described in this section is a purely formal one for notational convenience. The data structure used in a computer implementation is a local natural ordering of gridpoints within a natural ordering of tiles, as detailed in §3 below. The parallelism within $\tilde{A}_I$ and B_B is not visible at the level of blocking in (3), but the parallel bottleneck represented by communication-intensive B_C and the sequential use of that result in multiplications with $\tilde{A}_{BC}$ (and, generally, $\tilde{A}_{IC}$) blocks *is* evident. We mention variants of the algorithm that alleviate this bottleneck at the price of some extra local work and extra storage.

The solve with B_C itself can be performed in any of three ways: redundantly on each processor after broadcasting the required coefficient data, with single-threaded code between collecting the coefficients on a single processor and redistributing the results, or in a fully (or partially) distributed fashion. Determination of the most efficient technique is generally decomposition- and network-dependent, since problem size and computation-to-communication ratios enter the complexity estimate in nonisolable ways. Some global data exchange is necessary in this phase, so it may be desirable to prevent idling on a given multiprocessor to allow the remaining local exchange phases to proceed before the cross-point results are available.

The sequentiality of the cross-point solve can be broken by the following technique, which exploits the relatively small size of the cross-point system. Lumping the balance of the unknowns together, let (3) be condensed to

$$B = \begin{pmatrix} B_h & B_{hH} \\ 0 & B_H \end{pmatrix},$$

where B_h contains the upper 2×2 blocks of (3), and B_H is just another name for B_C. Consider the application of the preconditioner

$$B \begin{pmatrix} w_h \\ w_H \end{pmatrix} = \begin{pmatrix} v_h \\ v_H \end{pmatrix},$$

with the sequential solution

$$\begin{aligned} w_H &= B_H^{-1} v_H, \\ w_h &= B_h^{-1}(v_h - B_{hH} w_H). \end{aligned}$$

A preprocessing step can compute and store the vectors $g_k = (B_h^{-1})(B_{hH})e_k$, $k = 1, \cdots, K$, where there are K interior cross points and e_k is the kth unit vector in this K-dimensional space. Once $w_H = B_H^{-1} v_H$ and $w_h^{(1)} \equiv B_h^{-1} v_h$ are independently solved for, we can (through local computations) form $w_h = w_h^{(1)} - \sum_k (w_H)_k g_k$. By construction, the support of each g_k is limited to the four tiles sharing vertex k, and the cross points possess a four-coloring that allows the g_k to be computed in just four sets of independent subdomain solves (for a scalar PDE). This process was inspired by, and has an interpretation in terms of, function space decompositions. Indeed, the function space framework is critical in generalizations to multilevel preconditioners, but for a two-level preconditioner the algebraic description above is sufficient.

3. Mesh refinement by tiles. This section describes a simple mesh refinement philosophy based on a regular tessellation of two-dimensional domains into subdomain "tiles." A tile is a tensor-product of half-open intervals in each coordinate direction, except that a tile abutting a physical boundary along what would ordinarily be one of its open edges is closed along that edge. Each tile possesses its own interior, at least two of its four sides, and at least one of its four corners and is locally discretized on a tensor-product grid. Although the specific convention is arbitrary, we assume for definiteness that in its own local right-handed coordinate system, each tile contains its origin and its x and y axes (see Fig. 1).

We require that the cross points be embeddable in a tensor-product global quasi-uniform coarse grid, from which only points lying exterior to the (possibly multiply connected) boundary are missing. Irregular tiling patterns such as in Fig. 2(b) are ruled out for convenience in setting up the coarse-grid system and keeping the code

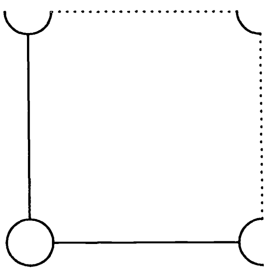

FIG. 1. *The anatomy of a tile. Unless closed by a physical boundary, a tile is open along its high-x and high-y perimeter.*

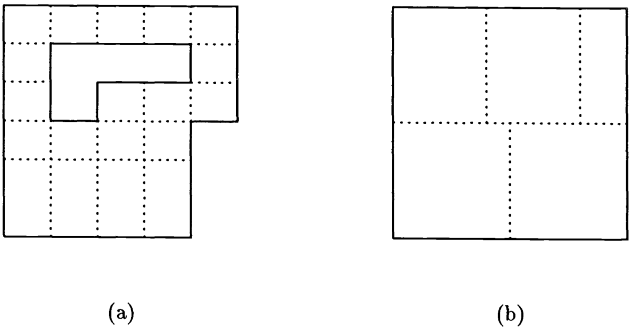

FIG. 2. *Sample tessellations:* (a) *is permissible,* (b) *is not.*

that manages the interfacial data exchanges short. However, there is no requirement that the domain itself be of tensor-product type; the decomposition in Fig. 2(a) is permissible. Without coordinate stretching and other body-fitted coordinate transformations, the embedding requirement would generally enslave the granularity of the decomposition to the geometric complexity of the domain, a situation that we wish to avoid since granularity has important implications on load balance and convergence rate. Although we have yet to fully implement them, domain-wide coordinate transformations represent a simple extension in principle. From an algebraic point of view, an orthogonal body-fitted coordinate transformation is indistinguishable from a perturbation to the operator coefficients. Preserving orthogonality should create less of a strain on a mesh generator acting over local regions than it does in much current practice using global mappings.

Associated with each tile is the data defined over a quasi-uniform grid covering its portion of the domain and a set of operators for executing its block-row portions of the preconditioner solve, as described in §2. In our object-oriented approach, these operators can vary widely from tile to tile. In our present examples, however, we assume that the grids covering individual tiles share a common parent uniform tile (of arbitrary discrete size) and are refined only in powers of two. We can therefore later indicate refinement levels using the graphical shorthand of Fig. 9, where the

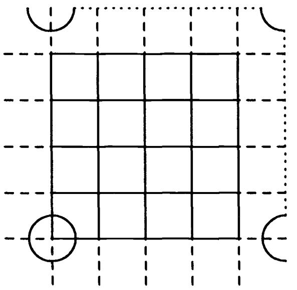

FIG. 3. *Sample tile, showing the computational buffer region (dashed extensions) required for the completion of standard five-point stencils centered at the points of the local grid.*

integer indicates the logarithm of the refinement ratio.

3.1. Tile-tile interfaces. To minimize restrictions on the structure of adjacent tiles (and to eliminate redundant communication between tiles in a multiprocessor implementation in which different tiles will generally be assigned to different processors), each tile stores and maintains, in addition to its own data, the data associated with a buffer region of phantom points equal in width to one-half of that of its associated discrete stencil. Figure 3 illustrates the buffer unknowns for a five-point stencil, superimposed on Fig. 1. With the exception of these redundant phantom points, each point of the domain is uniquely associated with a single tile.

Data at the phantom points is supplied in a manner dependent upon the internal structure and refinement ratios of the associated adjacent tiles. A finer tile obtains biquadratically interpolated data from its coarser neighbor. Since the problems studied here involve second-order operators, this allows the use of conventional finite-difference techniques in generating the difference equations at the subdomain interfaces. (Bilinear interpolation alone would limit the potential accuracy of a second-order differencing scheme, as observed in some preliminary experiments.) A coarser tile obtains its data by simple (unweighted) injection. That is, the value at the point in the finer neighboring tile that lies on the extended coarser tile stencil is scaled appropriately and used in the coarser grid.

We note that such a simple scheme neither guarantees discrete flux conservation nor delivers a symmetric A for a selfadjoint $\mathcal{L}$. However, the algebraic method does not depend on either property. The focus of this paper is on the solution of a consistent set of discrete equations. More careful attention has been given to the conservation properties of the discretization in the context of locally regular refinement in [19] and [38], for instance.

Each iteration of GMRES requires multiplying with A, which involves at most nearest-neighbor data exchanges between tiles to complete the local stencils, and solving with B, which likewise requires only nearest-neighbor data exchanges to form right-hand sides, *apart from* the globally cooperative task of solving with B_C.

The selection of refinement criteria is a much studied, yet still open, problem; see [30] and the collections [2] and [20] for representative work in this area. The refinement criteria, however, are orthogonal to the equation-solving aspect considered here, except to the extent that a part of the computational work required by one of these tasks may be a by-product of the other. In the examples, "good" refinement strategies can be done manually.

In general, tile interfaces can also be the site of changes in the discretization in addition to the refinement level. For instance, the discrete stencil can change order at interfaces. Even the form of the operators or the number of dependent variables can change at interfaces while still preserving the subdomain uniformity required for efficient subdomain solution algorithms. As a motivational example, a reacting flow problem frequently consists of large regions in which there is only transport of mass, momentum, and thermal energy but no reaction among stable constituents to all adequate orders of approximation. In other regions it is essential to retain a full set of composition variables, including trace radicals, and reaction terms must also be retained in the equations. To accommodate such generality, the routines that pack the buffer regions are responsible for providing the necessary mappings.

3.2. Physical boundaries. For generality, the equations for the physical boundaries are incorporated into the overall system matrix, including Dirichlet conditions. Our implementation allows inhomogeneous Robin boundary conditions at all boundary points, namely,

$$a(x,y)u + b(x,y)\frac{\partial u}{\partial n} = c(x,y).$$

Either first- or second-order one-sided difference approximations to the normal derivative term may be employed in the actual operator, but only first-order approximation is used in the preconditioners (to preserve uniformity of bandwidth). Although tempting in their simplicity, Dirichlet boundary conditions alone in the preconditioner were found to perform poorly in practice in mixed boundary condition (BC) problems, as expected. The hierarchical structure of the preconditioner renders the BC mismatch between the operator and preconditioner difficult to study theoretically. The theory in [36] and [40] reveals that spectral equivalence is generally lost in such BC mismatches, but only a small number of eigenvalues of the preconditioned operator may be responsible.

3.3. Comparison with other approaches. Before appealing to numerical experimention to illustrate the techniques presented above, we briefly compare them with other known techniques arising from similar motivations.

The field of locally uniform mesh refinement is spanned by a continuum of resolution strategies governed by clustering rules that control the size and shape of the refined subregions. Global refinement lies at one extreme and pointwise adaptive refinement at the other. As soon as the global tensor-product mesh is abandoned, a host of difficult practical decisions must be made about data structures and clustering algorithms. The logic required to handle the numerous types of subgrid-subgrid interactions that can arise and to ensure the consistency of the possibly distributed data structure can be a significant impediment to efficient parallelism. It is impractical to use domain-based "horizontal" decompositions to obtain distributed parallelism if refined subgrids are allowed to span the coarse grid in a general nested fashion. Instead, parallel decompositions of general, multilevel, locally uniform, composite grids should proceed by level, as argued and implemented in [37]. However, "horizontal" neighbor-neighbor interactions on a tensor-product grid of individually refined tiles are simple.

The tile algorithm requires only one grid that possesses connectivity with arbitrarily distant regions of the domain, namely, the grid of cross points. In the framework

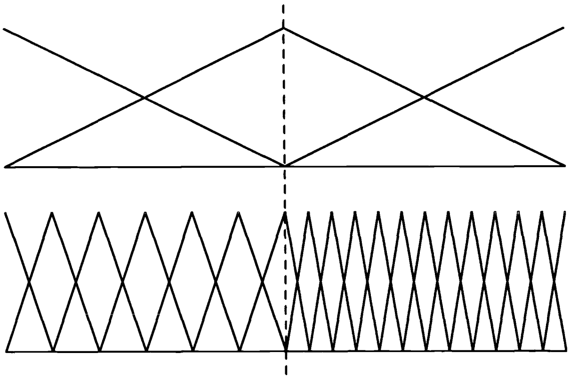

FIG. 4. *One-dimensional schematic of the tile basis functions.*

of the hierarchical basis function technique [3], [47], we have simply a two-level hierarchy, but the higher level may be different in different subregions. Figure 4 is a one-dimensional illustration. This represents a severe condensation of the range of intermediate scales present in multilevel local uniform refinement, on which the asymptotic convergence theory is based. Tiles are much closer to being the software equivalent of the "geometry-defining processors" (GDPs) of [1]. The tile algorithm shares the philosophy of commercial structural analysis packages offering libraries of elements that an engineer can assemble in composing a domain, although comparably transparent user interfaces have yet to be written. *Unlike* most structural analysis packages, no global linear system involving all of the degrees of freedom is formed, nor is an exact Schur complement derived through the expensive process of static condensation. Rather, an iterative path to parallelism is elected.

In the latter respect, the tile algorithm is similar to the original additive Schwarz method [15] and the techniques of [7]. All three rely upon a single, coarse-domain–spanning grid. The main differences between the techniques of [7] and [15] and the tile algorithm are in the treatment of the interfacial degrees of freedom. In the additive Schwarz technique, interior problems are solved on extended overlapped subdomains, so that the interfacial degrees of freedom of one subdomain are interior points of another and thus demand no special consideration. In [7], good preconditioners for the interfacial degrees of freedom of abutting subdomains are derived theoretically for selfadjoint operators. Near optimal algebraic convergence for the refined case has been proved for both classes of algorithms in [16] and [6], respectively, for selfadjoint systems. For nonselfadjoint systems, convergence proofs for the uniformly refined case have been given in [9] and [11] for overlapping and in [10] for abutting decompositions, respectively.

A disadvantage shared by all two-scale approaches is that the coarse grid—on which the optimal approaches perform an exact solve, and on which we also prefer one—cannot necessarily remain as coarse as one might like. In contrast, multilevel methods are not held hostage to a fine "coarse" grid. Even so, multilevel convergence estimates for nonselfadjoint operators are aided by sufficiently fine coarse grids, and complex domain geometry or "ragged" coefficients can also make a fine coarse grid

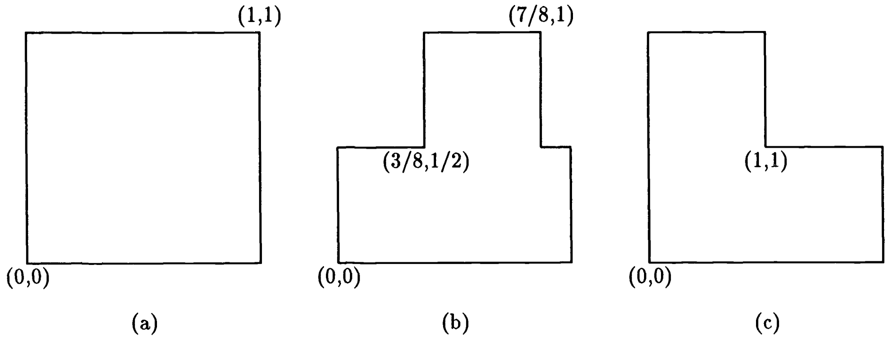

FIG. 5. *The three domains considered in this paper.*

desirable in practice.

General multilevel methods with a number of levels substantially larger than two maintain their optimal convergence rates at the price of increasingly complex data-dependency patterns with attendant degradation on multiprocessor architectures and intricacy of coding in practical problems. The additive or asynchronous methods [38] relieve most of the interlevel data traffic but do not obviate the need to collect data vertically across the levels at each iteration. The ability of a two-level approach to obtain convergence rates only a log factor worse than optimal is demonstrated in §4. Compelling overall superiority of approaches with a greater richness of scales has not been established in production-parallel software. In the course of establishing it, experience on parallel computers with a two-level algorithm will be beneficial and will aid in evaluating the complex tradeoffs.

We have too little experience with the full spectrum of methods discussed above to conjecture about the sizes of the relevant constants in asymptotic complexity analyses or to provide experimental comparisons (but see [10] for a comparison of the tile algorithm with additive Schwarz on a model scalar convection-diffusion problem). It is clear, however, that the limitations of the tile algorithm are shared to some degree by the optimal methods, while the simplicity of implementation and straightforwardness of generalization are not universally shared.

4. Numerical experiments.

To illustrate the effectiveness of the tile algorithm in terms of the convergence of the iterations, and the effectiveness of the locally uniform mesh refinement in terms of the convergence of the discretization, we consider a suite of experiments.

4.1. Model problems.

We present ten model problems, each containing a single dependent variable and two independent variables. Some of the problems below are selfadjoint and could be discretized in a symmetric manner and perhaps solved more cheaply with conjugate gradients than with GMRES. Our main interest, however, is in the more extensible formulation. In all the examples an exact solution of the continuous problem $\mathcal{L}u = f$ is specified. From this $u(x, y)$, all of the source terms f and boundary condition inhomogeneities g may be calculated. In cases where the expressions for f and g are sufficiently simple, they are written out along with the solution. The ten problems are defined over three different domains, pictured in Fig. 5.

The first two examples, with constant coefficients and an exact solution quadratic in each independent variable, are extremely simple and possess second-order finite difference representations free from truncation errors. They are identical except for the type of boundary conditions along one side of their square domain. These problems are not candidates for mesh refinement; rather, they were chosen to illustrate the deterioration in convergence rate caused when Dirichlet boundary conditions are replaced with Neumann, and to allow controlled experimentation on the effect of mismatched boundary conditions in the preconditioner. The poor convergence of Problem 2 using the preconditioner of Problem 1 originally forced the decision to expand the cross-point system to include physical boundary points in the general case.

PROBLEM 1. Pure isotropic diffusion with all Dirichlet boundaries.

$$\begin{gathered} \nabla^2 u = 4, \\ u(x,y) = x^2 + y^2, \\ \text{Dirichlet data on } \partial\Omega, \\ \Omega = \text{Unit square.} \end{gathered}$$

PROBLEM 2. Pure isotropic diffusion with a partial Neumann boundary.

$$\begin{gathered} \nabla^2 u = 4, \\ u(x,y) = x^2 + y^2, \\ \text{Dirichlet data on the three lower sides of } \partial\Omega, \\ \frac{\partial u}{\partial n}(x,1) = 2, \\ \Omega = \text{Unit square.} \end{gathered}$$

The next example is included to study orientation sensitivity of the substructuring resulting from anisotropic diffusion, for comparison with Problem 1, to which it is identical when $a = 1$. It is of further interest in that the order-of-magnitude ratio between the diffusion coefficients in the x and y directions is mathematically indistinguishable at the discrete level from an order-of-magnitude physical domain aspect ratio in an isotropic diffusion problem. Thus, the discretized version of Problem 3 covers two physical problem parameter extremes in one.

PROBLEM 3. Anisotropic diffusion.

$$\begin{gathered} \frac{\partial}{\partial x}\left(a\frac{\partial u}{\partial x}\right) + \frac{\partial^2 u}{\partial y^2} = 2(a+1), \\ u(x,y) = x^2 + y^2, \\ a = 10, \\ \text{Dirichlet data on } \partial\Omega, \\ \Omega = \text{Unit square.} \end{gathered}$$

The fourth example is a prototype convection-diffusion problem: a passive scalar in a plug flow that is well developed at the outflow. It is a companion problem to Problem 2 in the sense of possessing a smooth solution with one Neumann boundary, but it is asymmetric as a result of the convection term. In that its anisotropy comes from a first- rather than second-order operator, it also complements Problem 3.

PROBLEM 4. Plug-flow convection-diffusion with fully developed outflow boundary.

$$-\nabla^2 u + c\frac{\partial u}{\partial y} = f,$$

$$u(x,y) = \sin(\pi x)\sin\left(\frac{\pi y}{2}\right),$$
$$c = 10,$$
$$u = 0 \text{ on the three lower sides of } \partial\Omega,$$
$$\frac{\partial u}{\partial n}(x,1) = 0,$$
$$\Omega = \text{Unit square.}$$

The next two canonical examples (from the "population" of elliptic problems in [41] and [42]) bring in nonconstant coefficients, the latter in a nonselfadjoint way with Robin boundary conditions.[1]

PROBLEM 5. Selfadjoint, nonconstant coefficient, Dirichlet boundaries.

$$\frac{\partial}{\partial x}\left(e^{xy}\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(e^{-xy}\frac{\partial u}{\partial y}\right) - \frac{u}{1+x+y} = f,$$
$$u(x,y) = e^{xy}\sin(\pi x)\sin(\pi y),$$
$$u = 0 \text{ on } \partial\Omega,$$
$$\Omega = \text{Unit square.}$$

PROBLEM 6. Nonselfadjoint, nonconstant coefficient, Robin boundaries.

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial}{\partial y}\left((1+y^2)\frac{\partial u}{\partial y}\right) - \frac{\partial u}{\partial x} - (1+2y+y^2)\frac{\partial u}{\partial y} = f,$$
$$u(x,y) = 0.135(e^{x+y} + (x^2-x)^2\log(1+y^2)),$$
$$u - \frac{\partial u}{\partial n} = g \text{ on } \partial\Omega,$$
$$\Omega = \text{Unit square.}$$

The derivative is the outward normal.

The seventh example, from [5] and [31], is on an irregularly shaped domain with reentrant corners, but possesses a smooth solution. It emphasizes how an irregular domain may force a minimum granularity upon a tessellation comprising congruent tiles. For the problem at hand, however, the minimum granularity is near the ideal one.

PROBLEM 7. T-shaped domain.

$$\nabla^2 u = 4 - 2\cos(y)e^x,$$
$$u(x,y) = x^2 + y^2 - xe^x\cos(y),$$
$$\text{Dirichlet data on } \partial\Omega,$$
$$\Omega = \text{T-shaped region.}$$

The last three examples are obtained by taking three different values of the convection—respectively, $c = 0$, $c = -1$, and $c = 10$—in the convection-diffusion problem below.

PROBLEMS 8–10. Cylindrically separable reentrant corner convection-diffusion problem.

$$-\nabla^2 u + \frac{c}{r}\frac{\partial u}{\partial r} = 0,$$

[1] The more widely available reference [29] contains an identical listing of Problem 5 and a similar but not identical version of Problem 6. A typographical error in the latter renders it ill posed.

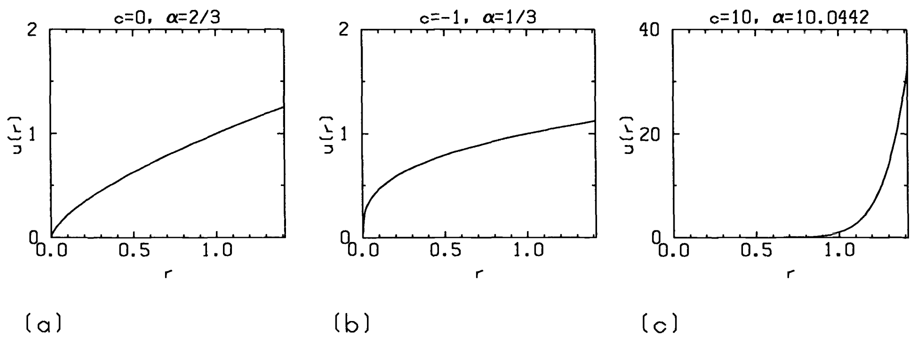

FIG. 6. *Cross section of $u(r)$ along the symmetry axis:* (a) *Problem* 8, *pure diffusion, nondifferentiable at $r = 0$;* (b) *Problem* 9, *convective inflow, strengthening the singularity;* (c) *Problem* 10, *convective outflow, eliminating the singularity.*

$$u(x,y) = r^{\alpha} \sin\left(\frac{2}{3}\left(\theta - \frac{1}{2}\pi\right)\right),$$
$$\text{where } r = \sqrt{(x-1)^2 + (y-1)^2},$$
$$\text{and } \theta = \arg((x-1) + i(y-1)),\ 0 \le \theta < 2\pi,$$
$$\text{Dirichlet data on } \partial\Omega,$$
$$\Omega = \text{L-shaped region.}$$

The first of these corresponds to pure diffusion, and the second and third to convection in towards the reentrant corner and away from it, respectively, at a rate inversely proportional to the radius. The respective values of the radial eigenfunction exponent α are $\frac{2}{3}$, $\frac{1}{3}$, and approximately 10.04, from the Euler equation formula $\alpha = \left[c + \sqrt{c^2 + (16/9)}\right]/2$. Figure 6 displays $u(r)$ along the ray $\theta = \frac{5\pi}{4}$, which is the symmetry axis of the three L-shaped problems. The first two solutions of this trio lack derivatives at the reentrant corner. The last is everywhere twice differentiable, but the solution is characterized by steep variation in the three *non*reentrant corner regions, where $r > 1$. Local mesh refinement is critical to improving the accuracy of a finite-difference solution. In [27] we show the complementary benefit of rediscretization of the tiles surrounding the reentrant corner in Problems 8 and 9 to fit the discrete solution to the known power-law radial dependence of the singular exact solution.

4.2. Parameters studied. Four categories of experiments are reported. First, a two-dimensional parameter space consisting of coarse-grid resolution and overall (uniform) resolution is explored by numerical experiment for each problem. The goal of these experiments is the evaluation of the convergence of the algorithm, in terms of iteration count and execution time, over a range of resolutions for comparison with a leading-term complexity analysis in §4.3 and related theory in §4.4. No adaptive refinement is performed.

Another set of experiments is performed on Problems 8–10 only with the goal of evaluating the economy of the locally uniform refinement technique. As previously shown in [27], LUMR is capable of significant CPU and memory savings with no sacrifice of accuracy relative to uniform refinement.

In a third set of experiments, the effect of orientation for nonunit-aspect ratio tiles is investigated. The limiting case of stripwise decompositions shows how physical anisotropies can be exploited in the decomposition for improved convergence.

Finally, we compare the domain-decomposed preconditioner of this paper with some popular global preconditioners and with the topologically related direct solve using a nested dissection ordering [22].

Additional studies, including modular replacement of $\tilde{A}_I$ or B_B with some of the alternatives listed in §2, are available in [25], upon which the present article is based. Use of two different orders of discretization in A and B is explored in [33]. (This approach loses the identity block in (4) but delivers higher-order upwinding while preserving monotonicity in the preconditioner.) In this study, we simply use $\tilde{A}_I = A_I$, $\tilde{A}_{IB} = A_{IB}$, and $\tilde{A}_{BC} = A_{BC}$ and derive B_B from the tangential terms of the differential operator.

The timings given below are from a SPARCserver 390 with 64-bit reals. The code was written in C except for low-level Fortran kernels, such as factoring or solving linear systems entirely resident on one processor. *Relative* comparisons of CPU times for alternative formulations of the same problem executed in the same hardware and software environment are an important part of our results. It should be borne in mind while studying the results that different organizations of the code and different compiler capabilities can account for large variations in execution times across architectures and software releases; therefore, *absolute* execution times are not very meaningful. We have run the same experiments (or representative subsets, to the extent supported by memory) in scalar mode on seven other Unix machines and find that even the *proportions* of time spent in factorization and solution phases may vary widely between machines. In spite of this, there are surprisingly few shifts in the overall performance rankings of alternative decompositions. In other words, while the timings in the tables are far from machine independent, the conclusions based thereon *are*, until parallelism enters the picture.

4.3. Convergence as a function of coarse-grid granularity . To test coarse-grid granularity over an interesting range, we fix the finest mesh spacing at $h^{-1} = 128$ (relative to the total length of the domain, whether that be 1 in the problems posed on the unit square or 2 in the problems on the L-shaped domain) and investigate the tradeoff between numbers of tiles and points per tile, as shown in Tables 1 and 2 and plotted in Fig. 7. The mesh is identical and uniform for all runs in these tables (with the obvious exception that pieces of the circumscribing square are missing from it in Problems 7–10, whose columns therefore lack entries at the coarsest tile subdivisions). The convergence criterion is a relative reduction in residual of five orders of magnitude. Throughout these studies we use an initial iterate of zero. Table 1 shows that the iteration count peaks in the middle of the granularity range, at four or eight tiles per side, and decreases to 1 in either degenerate limit of one tile per domain or one tile per point (not shown), where a global direct solve results.

Table 2 shows the deceptiveness of iteration count alone as a measure of overall performance. In execution time, the extreme runs, representing few-domain cases, suffer as a result of the high cost per iteration, even though the number of iterations required is very small. This table is a profound illustration of an earlier version of [12], entitled *Domain Decomposition Beneficial Even Sequentially.* The most favorable total *sequential* execution times are found for multidomain cases at 16 or 32 tiles per side.

The factorization of the banded matrix in the single subdomain case is the dom-

TABLE 1

Iteration count as a function of number of tiles per side of the circumscribing square, H^{-1}, and number of mesh points along a tile side, H/h, at constant refinement parameter, $h^{-1} = 128$, for a reduction in the initial residual of 10^{-5}.

16	8	5.5	8.0	18.3	14.4	22.1	9.6	5.7	6.0	6.7	7.2
32	4	6.8	7.9	17.9	16.3	27.2	7.9	6.5	6.4	7.1	6.4

inant contribution to the overall time. In Problems 1–6, over six minutes are spent doing the factorization alone. A similar penalty would accrue in an attempt to do direct solves on a very fine "coarse" grid, in which each tile contains just one point. However, this second peak is not visible since the table is truncated below tile sizes of $H/h = 4$. Even in modest-sized two-dimensional problems, direct solves on the undecomposed domain are inefficient relative to decomposition-preconditioned GMRES. Of course, there are many alternatives to direct solves for solving a smooth elliptic equation discretized on a tensor-product grid problem on a uniprocessor, some of which are considered in §4.7, but most are not coded or parallelized as cleanly as domain-decomposed Krylov iteration.

The behavior in Table 2 can be understood with reference to leading-term complexity estimates for the solution and factorization operators of the preconditioner. We observe that there are $\mathcal{O}(H^{-2})$ cross points, interfaces, and interiors. Naturally ordered banded direct factorizations and solves require $\mathcal{O}(Nb^2)$ and $\mathcal{O}(Nb)$ operators, respectively, where N is the number of unknowns and b the bandwidth. For the cross-point system, $N \approx H^{-2}$ and $b \approx H^{-1}$; for the interfaces, $N = H/h$ and $b = 1$; and for the subdomain interiors, $N = (H/h)^2$ and $b = H/h$. Thus, the interface operation counts are always asymptotically subdominant and can be omitted in the following. From choosing the larger of the cross-point and interior complexities,we see that factorization costs $\max\{\mathcal{O}(H^{-4}), \mathcal{O}(H^2h^{-4})\}$ and solves cost $\max\{\mathcal{O}(H^{-3}), \mathcal{O}(Hh^{-3})\}$. The first term grows with H^{-1} and the second decays with it. To the resolution of the table the minima for both factorization and solve costs occur at or between $H^{-1} = 16$ and 32 when $h^{-1} = 128$. The tendency of buffer overhead, neglected in these estimates, is to favor a slightly smaller number of tiles per side than thus estimated. It is important to note that the memory requirements follow the solve complexities above. Thus, for a fixed memory size, an intermediate cross-point grid granularity accommodates the largest problem in core. Of course, these per iteration complexity

estimates shift when the preconditioner blocks are other than banded direct solves.

4.4. Convergence as a function of refinement. In contrast to the preceding section, we here investigate iteration count as a function of overall resolution, for a fixed number of subintervals per tile. The results are shown in Table 3. The global mesh grows in refinement from 16 to 128 while the number of points per tile remains constant at 8. Thus, the fine grid in the last row of Table 3 corresponds to the $H^{-1} = 16$ row of the earlier tables. In spite of the fact that the truncation error improves with h^{-2} in some of these problems, we impose a constant convergence tolerance of 10^{-5} on the tests in Table 3, in order to focus on the algebraic convergence alone.

With the minor exception of Problem 5, which has not quite reached its iteration maximum at 16 tiles per side, the experiments suggest that the iteration count is bounded as resolution increases at constant H/h. In over half of the cases, the finest mesh results are even relatively *better* than the immediately preceding coarser ones. This fact is not surprising since there is a price for this favorable iteration count when H/h is held constant and h^{-1} is increased, namely, a larger cross-point system. The theory for conjugate gradient iteration for selfadjoint problems [7] and for GMRES iteration for nonselfadjoint problems [10] contains similar results for abutting domains, namely, constant upper bounds on the iteration count for constant H/h.

As representative convergence histories, we present Fig. 8, which follows the residual reduction over five orders of magnitude, and the time versus iteration count history for Problems 1 and 2. In the latter plots, the quadratic term in the GMRES work estimate (which comes from the need to orthogonalize each iterate over a subspace

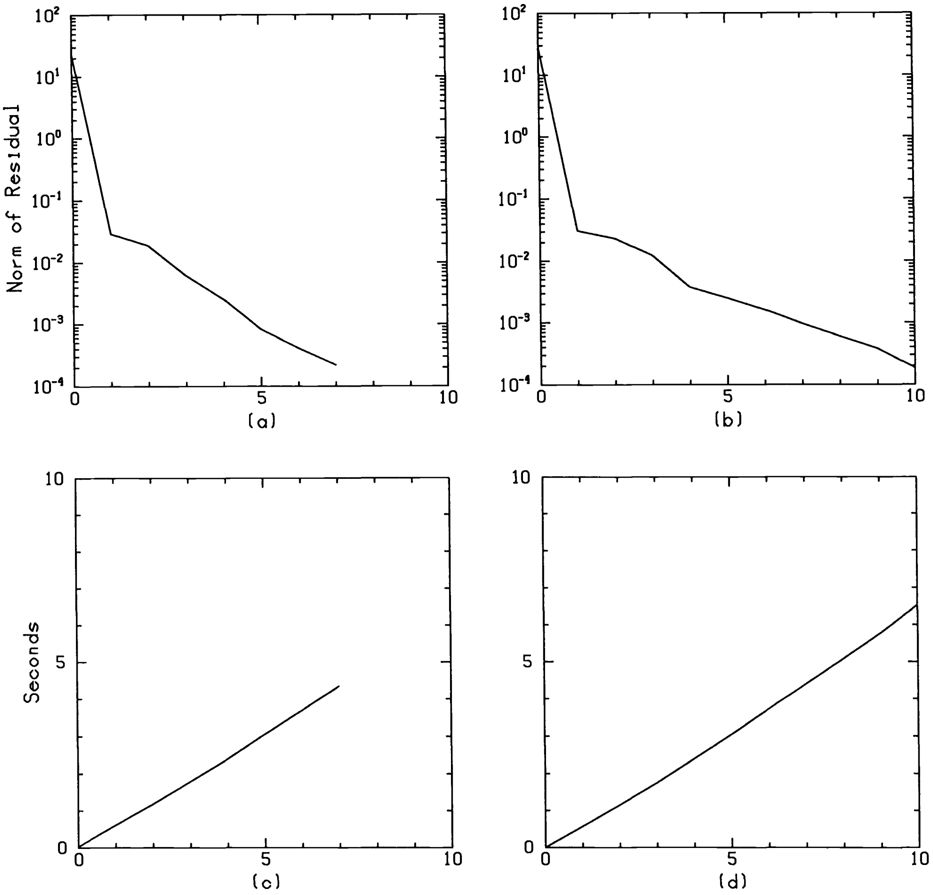

FIG. 8. *Convergence histories for Problems* 1 *and* 2, *for* $H^{-1} = 16$, $H/h = 8$, $h^{-1} = 128$. (a) *and* (b) *show the normalized Euclidean norm of the residual versus iteration count, and* (c) *and* (d) *show time versus iteration count.*

whose size grows linearly in iteration count) is almost invisible. This is due to the exploitation of the identity row in (4). This pair of figures also illustrates the poorer conditioning of Neumann problems, since the initial iterates and the solutions converged to are identical, and so are the operators, except for one Neumann boundary segment.

4.5. Economies of local mesh refinement. Problems 8–10 were used in [27] to illustrate the well-known benefits of locally uniform mesh refinement in elliptic problems: comparable accuracy in considerably fewer operations, compared with globally uniform refinement. These problems were solved at effective refinement levels of $h^{-1} = 32$, 64, and 128, based on the global grid using both global and local refinements for comparison. The tolerance for the relative reduction in the algebraic residual was set to 10^{-8} in these tests, well below the finite-difference discretization error, so that a clear demonstration could be made of the capability of the locally refined grid to provide the full discretization benefit of the globally refined grid. The choice of where

to refine was made manually. The local refinement is as illustrated in Fig. 9.

Table 4 shows the number of discrete unknowns for the globally and locally refined problems and the iteration counts and execution time ratios for each refinement level. All entries share a constant value of $H^{-1} = 8$ in order to fix in space regions of enhanced refinement that do not shrink as h does. Therefore, the "global" iteration columns of Table 4 incidentally provide a constant-H traverse through convergence rate parameter space, complementary to Table 1 (a constant-h traverse) and Table 3 (a constant-H/h traverse).

The linear increases of iteration count with each doubling of global refinement in the selfadjoint problem (Problem 8) and the nearly selfadjoint problem (Problem 9) are consistent with a logarithmic growth in conditioning with h^{-1}, though we reiterate that we have no proof of such a bound for the algorithm generating the tables. The locally refined examples likewise worsen mildly in conditioning with h^{-1} when H is held constant, but the CPU time advantage, (T_G/T_L), of local refinement increases with h^{-1} overall. Comparing iteration counts of globally and locally refined problems at the same effective refinement shows that the often drastically smaller number of unknowns in the latter does not much affect convergence. This observation leads to the hypothesis that in the case of variously refined tiles, $(\mathrm{H}/h_{\mathrm{finest}})$ is the convergence-controlling parameter, with the details of the tile-size distribution important only in estimating the work per iteration.

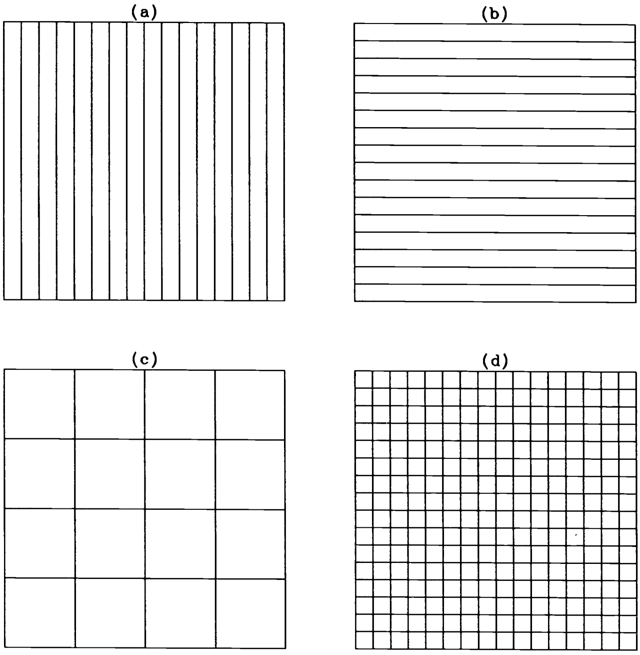

FIG. 10. *The four decompositions tested in Table* 5: (a) *vertical strips,* (b) *horizontal strips,* (c) *"large" boxes with the same granularity as the strips,* (d) *"small" boxes with the same bandwidth as the strips.*

4.6. Anisotropic decompositions. Throughout the foregoing, we have considered decompositions of the problem domain into uniform square tiles exclusively. More general decompositions are possible and should often be considered. Varying the aspect ratio and the orientation of tiles can lead to significant variations in convergence rate in anisotropic problems. Problems 1–4 of the test suite contain a sufficient variety of operators and boundary conditions to illustrate this point. Table 5, based on these four problems, provides a link between the boxwise decompositions studied in this report and the stripwise decompositions employed in many of our earlier studies, such as [34]. Four different decompositions are considered in this table: vertical strips, horizontal strips, a boxwise decomposition with the same number of tiles as the strip cases, and a boxwise decomposition whose tiles have the same bandwidth as that of the most compact natural ordering of the strip cases. These decompositions are shown in Fig. 10. In every case, the mesh spacing is held constant at $h^{-1} = 128$; thus these problems contain 16,641 discrete unknowns.

Among the two boxwise decompositions, the finer is always closer to the optimum found earlier in Table 1 for iteration count and in Table 2 for execution time.

Contrasting the boxwise and stripwise decompositions, we note that for isotropic Problems 1 and 2 the isotropic (boxwise) decompositions lead to significantly better iteration counts than the nonisotropic (stripwise) decompositions. The coarser boxwise decomposition nevertheless leads to poorer execution times than either stripwise decomposition because of the large bandwidth of its tiles, resulting in large factoriza-

TABLE 5

Iteration count I and total execution time T (sec) as a function of the tessellation parameters H_x^{-1} and H_y^{-1}, at constant mesh parameter $h^{-1} = 128$, for a reduction in the initial residual of 10^{-5}.

			#1		#2		#3		#4	
Case	H_x^{-1}	H_y^{-1}	I	T	I	T	I	T	I	T
a	16	1	20	13.7	29	20.5	52	40.5	4	3.5
b	1	16	20	13.7	23	15.9	12	8.4	16	10.9
c	4	4	11	34.7	15	39.7	24	51.9	25	53.3
d	16	16	7	5.5	10	8.0	22	18.3	18	14.4

tion costs in setting up the interior solves of the preconditioner. The finer boxwise decomposition yields the best execution times.

For the nonisotropic Problems 3 and 4, one or both of the nonisotropic decompositions is superior in both iteration count and execution time to both of the isotropic decompositions. In Problem 3, we note the major advantage of handling the strong x-directional diffusive coupling as implicitly as possible in the preconditioner when few (here 16) subdomains are employed. In Problem 4, where the diffusive part of the operator is isotropic, the decomposition that is aligned with the strong convection is superior. This is related to the relatively poorer performance of the tangential interface preconditioner in problems where the convection is normal to the interface rather than tangential to it [13]. In spite of the poor representation of the convection in the interface blocks for Problem 4, case (b), the "wrong" stripwise decomposition is still slightly superior to the best boxwise decomposition. Although the boxwise decomposition convergence rates are asymptotically superior to the stripwise decomposition convergence rates (see the theoretical arguments summarized in [31]), the crossover point is evidently strongly influenced by the physics of the problem.

4.7. Comparison with undecomposed preconditioners. Tables 1 and 2 produced the observation that among preconditioners employing direct banded factorizations for both the cross-point system and the subdomain interiors, a tessellation of intermediate granularity is much superior to one at either coarse or fine extremes. In other words, domain decomposition-preconditioned GMRES methods are superior to bandsolvers even on sequential computers and even in two dimensions. It is of interest to attempt to strengthen such a statement by comparing domain decomposition-preconditioned GMRES iteration with other candidate solvers in the sequential, two-dimensional context. For this purpose, a direct sparse matrix solver and three popular incomplete factorizations have been implemented as alternative subdomain interior preconditioners and compared with the domain-decomposed preconditioner on the first six problems of the test suite.

Table 6 lists the iteration counts and Table 7 the execution times for nine different solution algorithms callable from the same code used to generate all previous tables. (The global domain solvers contain just one tile.)

Six of these solvers are iterative methods based on GMRES and global preconditioners of the incomplete factorization type, tested in two sets of three each. In each set, we test ILU(0), ILU(1), and MILU(0) [17], [39], where the integer in parentheses denotes the number of diagonals of extra fill-in retained adjacent to the original five-diagonal structure of the discrete operator [46]. In the first set, the maximum size of the Krylov subspace used in GMRES is 90; in the second set, the maximum Krylov subspace has dimension 5. In a majority of cases, the globally preconditioned GM-

RES iteration converges in fewer than 90 iterations; thus, the first set consists mainly of full GMRES convergence results. In practical applications, restarted GMRES is often used to conserve memory or defeat the quadratic term in the GMRES work estimate that arises from orthogonalization over an ever-expanding Krylov subspace. GMRES(k) denotes a restart after k steps.

One of the solvers is a direct method, the Yale Sparse Matrix Package [18] using a global nested-dissection ordering (rather than the minimum degree ordering provided with YSMP), which naturally converges in one step.

Finally, we test two domain-decomposed GMRES algorithms based on a 16×16 array of 8×8 tiles. Both are slight variants of the algorithm used in preceding sections in which the bandsolver is replaced with the nested-dissection sparse solver. Full GMRES and GMRES(5) are considered.

Comparing first the convergence rates of the various global preconditioners, we observe that in the diffusively dominated problems with Dirichlet boundary conditions (Problems 1, 3, 5) the fill-capturing modified incomplete factorization MILU(0) is much superior to ILU(0) and ILU(1). The existence of a non-Dirichlet boundary segment weakens MILU (boundary conditions are the only difference between Problems 2 and 1), and the presence of convection weakens it substantially (Problems 4 and 6). As expected, ILU(1) uniformly requires fewer iterations than ILU(0) in these tests, and this convergence rate advantage translates into an execution time advantage even after the marginally higher cost of the ILU(1) preconditioner is taken into account. Experience with ILU(l) shows a law of diminishing returns as l increases beyond a fairly small problem-dependent value. The tests with GMRES(5) show how the higher iteration counts of a restarted method often translate into lower execution times for well-conditioned problems, but how poorly conditioned problems may fail to converge with too small a Krylov subspace.

Having noted the strong degree of problem dependence in the selection of the best global preconditioner, we note that this problem dependence extends to the relative ranking of globally preconditioned GMRES and the direct sparse nested dissection factorization. In terms of execution time, the nested dissection method loses out to the best global iterative method, GMRES(5)/MILU(0), in the odd-numbered problems, is close to the best global iterative method, GMRES(90)/ILU(1) in Problem 4, and beats all globally preconditioned methods in Problems 2 and 6.

Comparison of the nested dissection rows of Table 7 with the rows of Table 2 at corresponding granularity reveals, as expected, that the sparse direct subdomain solvers run faster than the banded direct subdomain solvers on large problems (approximately 70 sec versus approximately 370 sec on 128 × 128 tiles) and slower than bandsolvers on small ones (by approximately 20–30 percent on 8 × 8 tiles). The latter observation justifies our use of bandsolvers to perform the A_I^{-1} solves in the preconditioner throughout the majority of this report, where the focus is on relatively fine granularity.

Finally and most significantly, we observe that domain decomposition-preconditioned GMRES always beats the direct method, and it beats the best globally preconditioned method in all problems except for Problem 3, for which good preconditioners of both global and domain-decomposed varieties can be found. Overall, it is the fastest executing method and performs reliably and evenly over the range of problems considered. It is a compelling serial algorithm even apart from the virtues of modularity and adaptability.

5. Conclusions and future directions. Experiments on a variety of model problems demonstrate that a two-level domain decomposition algorithm with a single global coarse grid provides effective convergence and convenient refinement and permits a data structure amenable to parallel and vector implementations, as summarized in closing below. Although often motivated by parallelization, domain decomposition also yields runtime and memory use benefits as a sequential algorithm. Relative to traditional global preconditioners, domain-decomposed preconditioners can dramatically improve convergence rates. Furthermore, the simple structure of individual blocks of the domain-decomposed preconditioner means that new applications are found for the "standard solvers" in conventional software libraries. The traditional economies of local uniform mesh refinement can be incorporated into the domain decomposition framework at the small price of interface handlers with conditionals for refinement differences between adjacent subdomains. Because of the highly modular nature of a tile-oriented domain decomposition code, custom discretizations for certain classes of singularities may be archived into applications libraries for reuse. In short, software engineering is a major motivation for the restricted class of algorithms explored here.

The applicable problem class is greater than the present examples indicate; for instance, the tile algorithm has been extended to multiple-dependent variable cases. A two-independent-variable streamfunction-vorticity formulation of the incompressible Navier–Stokes equations is considered in [26] and [28]. The nonlinearity in this problem is handled by a Newton method wrapped around the domain-decomposed linear solver. The entire nonlinear code has been parallelized on shared- and distributed-memory machines, and the linear and nonlinear portions are comparable in their parallel efficiencies (which vary in the usual way from arbitrarily good to arbitrarily bad, depending upon problem size relative to number of processors).

Extension of the tile algorithm to a brick algorithm in three-dimensional problems is conceptually straightforward. The software engineering motivation for restriction to a tensor-product grid of substructure vertices is even more compelling in three dimensions than it is in two. One new feature is the presence of two-dimensional interfaces, upon which preconditioner blocks could be constructed by dropping normal derivative terms, by analogy with one-dimensional interfaces in the plane. The effectiveness of this straightforward extension is not demonstrated at present. For the theoretically endowed selfadjoint case it is known that the condition number of the hierarchically preconditioned system grows like the first power of (H/h), not merely like its logarithm. A discussion and some alternatives are presented in [44].

The tile algorithm is amenable to vectorization in either of two ways. The regular operation sequences on the tensor-product subgrid arrays are precisely the type for which vectorizing compilers were conceived. The vector lengths depend on the precise form of solvers used in the preconditioner but would tend to be rather small for the rows of individual 8×8 or 16×16 tiles found best in the two-dimensional applications above. An alternative form of vectorization can be realized by grouping together all tiles of a given (discrete) size and shape and operating in lock step on corresponding elements in each tile, assuming an identical solver is applied to each. A vector in this approach consists of the ith element from each of the subdomains. Thus, 8×8 arrays of tiles deliver optimal processing rates for machines with a vector length of 64.

Parallelization requires attention to the load balancer/mapper [27] and also to the coarse-grid solve in the preconditioner [24]. The main disadvantage of the two-level algorithm in the parallel context is that the choice of coarse-grid granularity is more of an "overdetermined" problem than in serial. Communication cost per iteration and convergence properties potentially inveigh against the lower bounds on the number of tiles imposed by domain geometry, solution and coefficient roughness, and parallel load balance. The key determination for future applications of the tile methodology will be whether this overdetermination is "consistent" in practice. Inasmuch as the early examples are representative of one or two dependent variable problems, and parallel communication costs generally comprise a *relatively* smaller proportion of the total work in coupled multicomponent problems, there are substantial grounds for optimism that this will be the case.

Acknowledgments. We express our deep appreciation to Dr. Xiao-Chuan Cai for his influence on the refinement of the tile algorithm through his mathematical insight and through his experience in using the code and in adapting it to additive Schwarz-type preconditioning. We are also indebted to two anonymous referees for constructively critical comments on an early version of this manuscript.

AN $O(n^2 \log n)$ TIME ALGORITHM FOR THE MINMAX ANGLE TRIANGULATION*

HERBERT EDELSBRUNNER†, TIOW SENG TAN†‡, AND ROMAN WAUPOTITSCH†

Abstract. It is shown that a triangulation of a set of n points in the plane that minimizes the maximum angle can be computed in time $O(n^2 \log n)$ and space $O(n)$. The algorithm is fairly easy to implement and is based on the edge-insertion scheme that iteratively improves an arbitrary initial triangulation. It can be extended to the case where edges are prescribed, and, within the same time- and space-bounds, it can lexicographically minimize the sorted angle vector if the point set is in general position. Experimental results on the efficiency of the algorithm and the quality of the triangulations obtained are included.

Key words. computational geometry, two dimensions, triangulations, minmax angle criterion, iterative improvement, edge insertion

1. Introduction. Let S be a finite set of points in the Euclidean plane. A *triangulation* of S is a maximally connected straight-line plane graph whose vertices are the points of S. By maximality, each face is a triangle except for the exterior face, which is the complement of the convex hull of S. Occasionally, we will call a triangulation of a finite point set a *general triangulation* in order to distinguish it from a *constrained triangulation*, which is a triangulation of a finite point set where some edges are prescribed. A special case of a constrained triangulation is the so-called *polygon triangulation*, where S is the set of vertices of a simple polygon and the edges of the polygon are prescribed. In this paper only the triangles *inside* the polygon will be of interest.

For a given set of n points there are, in general, exponentially many triangulations. Among them one can choose those that satisfy certain requirements or optimize certain objective functions. Different properties are desirable for different applications in areas such as finite element analysis [1], [3], [23], computational geometry [21], and surface approximation [12], [18]. The following are some important types of triangulations that optimize certain objective functions.

(i) The *Delaunay triangulation* has the property that the circumcircle of any triangle does not enclose any vertex [5].

(ii) The *constrained Delaunay triangulation* has the same property except that visibility constraints depending on the enforced edges are introduced [13].

(iii) The *minimum weight triangulation* minimizes the total edge length over all possible triangulations of the same set of points and prescribed edges [10], [17].

It is known that the Delaunay triangulation maximizes the minimum angle over all triangulations of the same point set [22]. This result can be extended to a similar statement about the sorted angle vector of the Delaunay triangulation [6] and to the constrained case [13]. The Delaunay triangulation of n points in the plane can be constructed in time $O(n \log n)$ [6], [19], and even if some edges are prescribed, its constrained version can be constructed in the same amount of time [20]. There is no polynomial time algorithm known for the minimum weight triangulation if the input

‡ This author is on study leave from the National University of Singapore, Republic of Singapore.

is a finite point set, but dynamic programming leads to a cubic algorithm [10] if the input is a simple polygon.

In this paper, we study the problem of constructing a triangulation that minimizes the maximum angle, over all triangulations of a finite point set, with or without prescribed edges. We call such a triangulation a *minmax angle triangulation.* Although avoiding small angles is related to avoiding large angles, the Delaunay triangulation does not minimize the maximum angle—four points are sufficient to give an example to this effect. Triangulations that minimize the maximum angle have potential applications in the area of finite element and surface approximation [1], [2], [8]. Our main result is summarized in the following statement.

MAIN THEOREM. *A minmax angle triangulation of a set of* n *points in the plane, with or without prescribed edges, can be computed in time* $O(n^2 \log n)$ *and space* $O(n)$.

Curiously, our algorithm has the same complexity for point sets and for simple polygons. Prior to this paper no polynomial time algorithm for constructing a minmax angle triangulation for a finite point set was known. On the other hand, if the input is a simple n-gon, then a cubic time and quadratic space solution can be derived simply by substituting the angle criterion for the edge-length criterion in the dynamic programming algorithm of [10]. Thus, it seemed that the problem for simple polygons is much simpler than for point sets. Indeed, our attempts to apply popular techniques such as local edge-flipping [11], [9], divide-and-conquer [21] and plane-sweep [7] to construct a minmax angle triangulation for a point set were not successful; see also [15].

Instead, we solve the problem by an iterative improvement method based on what we call the *edge-insertion scheme*. An *edge-insertion* step adds some new edge qs to the current triangulation, deletes edges that cross qs, and retriangulates the resulting polygonal regions to the left and the right of qs. The difference from the simpler edge-flip operation is that qs can cross up to a fraction of the current edges, whereas an edge added in an edge-flip crosses only one edge. This difference turns out to be crucial in the case of minimizing the maximum angle: the edge-flip scheme can get stuck in a nonglobal optimum [15], whereas the edge-insertion scheme is powerful enough to always reach the optimum. A proof of the latter property is sufficient to design a polynomial time implementation of the edge-insertion scheme. Clever strategies to find an edge qs that leads to an improvement of the current triangulation and to retriangulate the created polygonal regions are needed to obtain the claimed $O(n^2 \log n)$ time bound.

Section 2 presents the algorithm to construct a minmax angle triangulation, and §3 proves the crucial piece needed to show that the algorithm is correct. Section 4 gives the algorithmic details that lead to an efficient implementation of the algorithm. Section 5 discusses the extensions to the constrained case and to the problem of lexicographically minimizing the sorted angle vector. Finally, §6 presents experimental results, and §7 mentions some related open problems.

2. The global algorithm.

In general, there is more than one minmax angle triangulation for a given set of points. Below we outline an algorithm that constructs one such triangulation for a set S of n points in the plane. The maximum angle of a given triangulation $\mathcal{A}$ is denoted by $\mu(\mathcal{A})$.

```
Construct an arbitrary triangulation $\mathcal{A}$ of $S$.
repeat
(M1) Find a largest angle $\angle pqr$ of $\mathcal{A}$.
```

```
(M2) Apply the ear-cutting procedure (§4) to modify $\mathcal{A}$ by
        adding a "suitable" edge $qs$ to $\mathcal{A}$, where $s \in S - \{p, q, r\}$ and $pr \cap qs \neq \emptyset$,
        removing edges that intersect $qs$ (this step creates polygons $P$ and $R$
            which have $qs$ as a common edge), and
        constructing triangulations $\mathcal{P}$ of $P$ and $\mathcal{R}$ of $R$ so that $\mu(\mathcal{P}), \mu(\mathcal{R}) < \angle pqr$.
until the ear-cutting procedure fails to find such a $qs$.
```

To show that this algorithm is correct, we need the following two lemmas and some forward references to the cake-cutting lemma of §3 and the ear-cutting procedure of §4. We define $\angle xsy = 0$ if any two of the three points are identical.

LEMMA 2.1. *If xy is an edge in a triangulation $\mathcal{A}$ of a point set S, then $\mu(\mathcal{A}) \geq \max_{s \in S} \angle xsy$.*

Proof. Let t be a point so that $\angle xty = \max_{s \in S} xsy$. Thus no points of S lie inside the triangle xty. Clearly, if xty is a triangle in $\mathcal{A}$ then there is nothing to be proved. Otherwise, there exists a triangle utv in $\mathcal{A}$ so that either $u = x$, $v \in S - \{y, t\}$, and uv intersects ty or $u, v \in S - \{x, y, t\}$, and uv intersects both xt and ty. In both cases, $\mu(\mathcal{A}) \geq \angle utv > \angle xty$. □

The proof of the next lemma makes use of the cake-cutting lemma to be presented in §3. We suggest that the reader read the statement of that lemma (Lemma 3.1) and then return to the current discussion leading to Lemma 2.2. We call a triangulation $\mathcal{B}$ of S an *improvement* of $\mathcal{A}$ if

(i) $\mu(\mathcal{B}) < \mu(\mathcal{A})$, or

(ii) $\mu(\mathcal{B}) = \mu(\mathcal{A})$, every triangle abc in $\mathcal{B}$ with $\angle abc = \mu(\mathcal{B})$ is also a triangle in $\mathcal{A}$, and $\mathcal{B}$ has at least one fewer maximum angle than $\mathcal{A}$.

The next lemma asserts that the algorithm makes progress as long as the current triangulation is not yet a minmax angle triangulation. It does this by proving that there is at least one suitable edge qs. In its current version, the algorithm can be thought of as trying all possible edges going out of q, so if there exist edges qs that lead to an improvement of $\mathcal{A}$, then the algorithm finds one such edge.

LEMMA 2.2. *Assume that $\mathcal{A}$ is not yet a minmax angle triangulation. Then an iteration of the repeat-loop constructs an improvement of $\mathcal{A}$.*

Proof. Step (M1) of the repeat-loop finds a triangle pqr in $\mathcal{A}$ so that $\angle pqr = \mu(\mathcal{A})$. The main observation is that there is some edge qs that intersects pr and belongs to a minmax angle triangulation $\mathcal{T}$ of S. This is because $\mu(\mathcal{T}) < \mu(\mathcal{A})$ implies that $\angle pqr$ cannot exist in $\mathcal{T}$, and consequently, $pr \notin \mathcal{T}$ (by the previous lemma). Therefore, there exists a point $s \in S - \{p, q, r\}$ such that $qs \cap pr \neq \emptyset$ and qs is an edge of $\mathcal{T}$. With this edge qs, the cake-cutting lemma (§3) ensures that there are polygon triangulations of P and R such that the largest angle of any triangle within P and R is still smaller than $\angle pqr$. Section 4 shows that the ear-cutting procedure of step (M2) indeed finds such a point s and produces triangulations $\mathcal{P}$ and $\mathcal{R}$ of P and R such that $\mu(\mathcal{P}), \mu(\mathcal{R}) < \angle pqr$. □

The above two lemmas can now be used to analyze the running time of the algorithm. First, we address the number of iterations of the repeat-loop, which is one plus the number of successful iterations of step (M2).

LEMMA 2.3. *The above algorithm reaches a minmax triangulation after at most $O(n^2)$ iterations of the repeat-loop.*

Proof. Each iteration produces a triangulation with a smaller maximum angle than before, or with fewer maximum angles of the same size. Since the number of different triangulations is finite, an optimum must be reached. To get an upper bound on the number of iterations, notice that the edge pr removed from $\mathcal{A}$ during some iteration will not reappear in the future. The claim follows because S allows only $\binom{n}{2}$ different edges. □

We are now ready to argue that the above algorithm runs in time $O(n^2 \log n)$ and space $O(n)$. There are two data structures needed for the algorithm. First, the quad-edge structure of Guibas and Stolfi [9] is used to represent $\mathcal{A}$; it permits common operations, such as removing an edge, adding an edge, and walking from one edge to the next, in constant time each. Second, the angles of $\mathcal{A}$ are stored in a priority queue that admits insertions, deletions, and finding the maximum. Standard implementations support each such operation in time $O(\log n)$; see, e.g., [4]. The space needed for both data structures is $O(n)$.

With these preliminaries we can give the analysis of the algorithm. By Lemma 2.3, the number of times the priority queue is consulted to get a largest angle is $O(n^2)$, which implies that step (M1) takes total time $O(n^2 \log n)$. Section 4 will show that the ear-cutting procedure performs only a total of $O(n^2)$ operations on the quad-edge structure, each in constant time, and only $O(n^2)$ insertions into and deletions from the priority queue, each in time $O(\log n)$. We conclude that the running time of the algorithm is $O(n^2 \log n)$, as claimed.

3. The cake-cutting lemma.

The result of this section is a technical lemma, which is nevertheless the heart of this paper. It ensures that for some edge qs the generated regions, P and R, can be triangulated without angles that are too large. We first discuss the shape of these regions and then state and prove the lemma.

The regions P and R are generated in step (M2) of the algorithm by adding an edge qs and removing all edges that intersect qs. It follows that P (and by symmetry R) is very similar to a simple polygon; that is, it is simply connected and bounded by straight-line edges. The only difference is that there can be edges surrounded by P on both sides; these are the edges contained in the interior of the closure of P (see Fig. 1). To simplify the forthcoming discussion (and also in the implementation of the algorithm) we treat each such edge as if it consisted of two edges, one for each side. Effectively, this means that we can talk about P and R as if they were simple polygons.

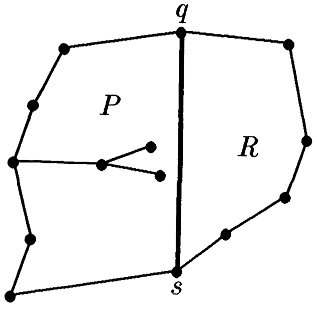

FIG. 1. *Regions P and R.*

With this note we now state and prove the cake-cutting lemma. The intuition behind the proof is that we look at a piece of an optimal triangulation $\mathcal{T}$ and argue about its edges. Keep in mind, however, that during the algorithm we have no way of knowing what $\mathcal{T}$ really is; we only know that it exists.

LEMMA 3.1. *Let $\mathcal{T}$ be a minmax angle triangulation of S, $\mathcal{A}$ a triangulation of S with $\mu(\mathcal{A}) > \mu(\mathcal{T})$, pqr a triangle in $\mathcal{A}$ so that $\angle pqr = \mu(\mathcal{A})$, and qs an edge in $\mathcal{T}$ that intersects pr. Let P and R be the polygons generated by adding qs to $\mathcal{A}$ and removing all edges that intersect qs. Then there are triangulations $\mathcal{P}$ and $\mathcal{R}$ of P and R so that $\mu(\mathcal{P}), \mu(\mathcal{R}) < \mu(\mathcal{A})$.*

Proof. We prove the claim for P; it follows for R by symmetry. Imagine we have $\mathcal{A}$ and $\mathcal{T}$ on separate pieces of transparent paper that we lay on top of each other so that the points match. Following step (M2) of the algorithm, we add qs to $\mathcal{A}$ and remove intersecting edges from $\mathcal{A}$, thus creating P and R. Next, we clip everything outside P. In $\mathcal{A}$ only P without intersecting edges is left, and in $\mathcal{T}$ there will generally be edges that cut through P. By assumption, qs is also in $\mathcal{T}$, which implies that none of these edges meets qs. We define a *clipped edge* as a connected component of such an edge of $\mathcal{T}$ intersected with P. Since P is not necessarily convex, some clipped edges can belong to the same edge of $\mathcal{T}$. Given a point x on the boundary of P, let the *path* from x to q (or x to s) be the part of the boundary between x and q (or x and s) that does not contain qs. We have four classes of clipped edges xy; see Fig. 2.

I. Both endpoints, x and y, are not vertices of P and thus lie on edges of P.
II. Both endpoints are vertices of P.
III. Endpoint x is a vertex of P, y is not, and y lies on the path from x to s.
IV. The same as class III except that y lies on the path from x to q.

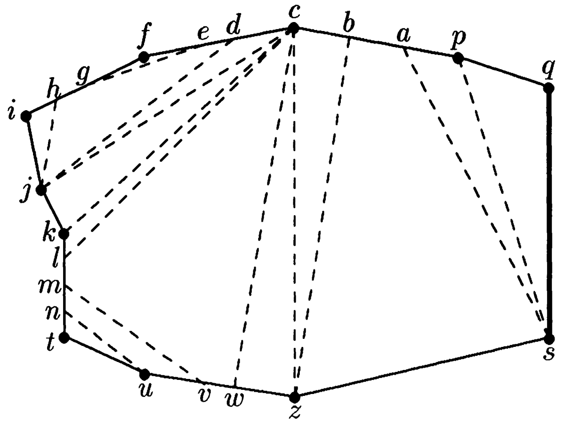

FIG. 2. *The class* I *edges in this example are eg and mv; the class* II *edges are cj, ck, cz, and sp; the class* III *edges are cl and cw; and the class* IV *edges are jh, jd, un, zb, and sa.*

At any vertex x of P, the clipped edges with one endpoint at x define angles at x that are all smaller than $\mu(\mathcal{A})$, because the clipped edges come from $\mathcal{T}$ and $\mu(\mathcal{T}) < \mu(\mathcal{A})$ holds by assumption. The only disadvantage of the partition of P defined by the clipped edges is that some of their endpoints lie on edges of P rather than at the vertices. We will now construct a triangulation of P based on the clipped edges. It proceeds step by step, where each step either removes or rotates a clipped edge or introduces a new edge.

1. All class I edges are removed. This does not harm any angle.
2. All class II edges remain where they are.
3. Let xy be a class III edge with y on the edge $\alpha\beta$ of P, where α precedes β

on the path from x to s. We replace xy by $x\beta$.

Note first that $x\beta$ is indeed a diagonal of P. Otherwise, it intersects the boundary of P, which implies that either x or β is not visible from qs. This is a contradiction to the way P is constructed. Note second that the angle at x that precedes xy in the counterclockwise order increases in step 3. Still, the angle formed by $x\beta$ is strictly contained in an angle at x in $\mathcal{A}$ because all edges of $\mathcal{A}$ that intersect P also intersect qs. It follows that the angle formed by $x\beta$ is smaller than $\mu(\mathcal{A})$. Another issue that comes up is that there can be class IV edges $x'y'$ with y' on the same edge $\alpha\beta$ of P—these edges now intersect $x\beta$. To remedy this situation we replace $x'y'$ by $x'x$. By the same argument as above, $x'x$ is a diagonal of P, and the angle at x' that precedes $x'y'$ in the clockwise order and that increases as we replace $x'y'$ by $x'x$ remains smaller than $\mu(\mathcal{A})$.

4. If xy is a class IV edge with y on the edge $\alpha\beta$ of P, where α precedes β on the path from x to q, then we replace xy by $x\beta$.

5. After steps 1–4 we have a partial triangulation of P, which we complete by adding edges arbitrarily. This finishes the construction of $\mathcal{P}$.

We have $\mu(\mathcal{P}) < \mu(\mathcal{A})$ since we started out with all angles smaller than $\mu(\mathcal{A})$; each time an angle increases it remains smaller than $\mu(\mathcal{A})$ as argued above, and step 5 decomposes angles, thus creating only smaller angles. □

Remark. Note that the only property of $\mathcal{T}$ used in the proof of the cake-cutting lemma is that $\mu(\mathcal{T}) < \mu(\mathcal{A})$. The lemma thus also holds if we replace $\mathcal{T}$ by an arbitrary triangulation $\mathcal{B}$ of S that satisfies $\mu(\mathcal{B}) < \mu(\mathcal{A})$. In fact, it suffices if $\mathcal{B}$ is an improvement of $\mathcal{A}$ and pqr is not a triangle in $\mathcal{B}$.

4. The ear-cutting procedure. The cake-cutting lemma in §3 shows that if $\mathcal{A}$ is not yet a minmax angle triangulation and qs is an edge in $\mathcal{T}$, chosen by the algorithm to improve $\mathcal{A}$, then there are triangulations of the generated polygons P and R with all angles smaller than $\angle pqr$. The two questions that remain are how to find such an edge qs and how to quickly triangulate P and R. One obvious way to find qs (not necessarily in $\mathcal{T}$ but in an improvement of $\mathcal{A}$) is to try all possible points s with $qs \cap pr \neq \emptyset$. For each such s we add qs to $\mathcal{A}$ and remove all edges that intersect qs. The thus-created polygons P and R are triangulated with minimum largest new angle using dynamic programming. If the largest new angle is smaller than $\angle pqr$ we have an improvement of $\mathcal{A}$ and thus a desired qs.

Apparently, the implementation of an iterative step sketched in the above paragraph is rather inefficient. We improve the performance with a more clever way to search for an appropriate point s and with a fast procedure for triangulating P and R. The two tasks are woven together to the extent that it is not advisable to look at them as separate steps. For a chosen point s we attempt to triangulate P and R with all angles smaller than $\angle pqr$. If this fails we get some guidance on where to look for a better point s. Following this guidance, a next point s is chosen so that we can reuse part of the work done during the unsuccessful triangulation attempt. The fundamental notion in all of this is that of an ear of a polygon triangulation.

4.1. Ears. An *ear* in a polygon triangulation is a triangle bounded by two polygon edges and one diagonal. It is easy to show that any triangulation of a simple polygon with more than three vertices has at least two ears [14].

In order to efficiently triangulate P and R, with all angles smaller than $\mu = \mu(\mathcal{A}) = \angle pqr$, we need two properties. The first guarantees that no expensive testing is necessary to recognize when an edge is a diagonal.

LEMMA 4.1. *Let P' be a polygon obtained from P by repeatedly removing ears not incident to qs. If a, b, c are three consecutive vertices of P' with $\{q, s\} \not\subseteq \{a, b, c\}$ and $\angle abc < \pi$, then ac is a diagonal of P'.*

Proof. By construction of P each of its vertices can be connected by a straight-line segment within P to a point on qs. This property is maintained whenever we remove an ear not incident to qs, so it also holds for P'. In particular, it holds for the vertices a, b, and c of P'. The edge ac can avoid being a diagonal only if it intersects the boundary of P' (it cannot lie outside P' because $\angle abc < \pi$). But this contradicts the above property for either a or c or for both. □

By symmetry, Lemma 4.1 also holds for R. It is now easy to identify ears because only one angle has to be checked. This is because the angles at a and c inside abc are always smaller than μ as they are properly contained in angles of $\mathcal{A}$. Thus, all three angles of abc are smaller than μ if and only if $\angle abc < \mu$.

The second property we need is that it does not matter which ears we remove, and in what sequence we remove them, as long as their angles are small enough. This property is implied by the following lemma whose proof is omitted because it is identical to that of the cake-cutting lemma.

LEMMA 4.2. *Let P' be a polygon obtained from P by repeatedly removing ears not incident to qs. If qs is an edge of $\mathcal{T}$ then there exists a triangulation of P' without angles larger than or equal to μ.*

The two lemmas suggest that we triangulate P and R simply by repeatedly finding consecutive vertices a, b, c, with $\angle abc < \mu$, and removing the ear abc. We remark that this strategy can also be used to get an inductive proof of the cake-cutting lemma. The next two subsections show how ear cutting and the search for an appropriate point s can be combined to yield an efficient implementation of an iterative step.

4.2. How to cut. The way we search for a point s (§4.3) guarantees a certain property of the polygons P and R that simplifies their triangulation by ear cutting. To be accurate we should mention that at the time we start the triangulation process for P and R, some ears will already have been removed as a result of earlier attempts to triangulate polygons generated for other points s. Consistent with our earlier notation, we therefore denote the two polygons that we attempt to triangulate by P' and R'. We state the mentioned property as an invariant of the algorithm after introducing some notation.

As justified above we pretend that P' and R' are simple polygons; by construction they share the edge qs. Let $k + 2$ be the number of vertices of P' and $m + 2$ the number of vertices of R', and label them consecutively as $q = p_0, p_1, \cdots, p_k, p_{k+1} = s$ and $q = r_0, r_1, \cdots, r_m, r_{m+1} = s$ (see Fig. 3). Define $\phi_i = \angle p_{i-1}p_ip_{i+1}$ for $1 \leq i \leq k$ and $\rho_j = \angle r_{j-1}r_jr_{j+1}$ for $1 \leq j \leq m$.

We can now state the property of P' and R'.

Invariant. $\phi_i \geq \mu$ for all $1 \leq i < k$ and $\rho_j \geq \mu$ for all $1 \leq j < m$.

This implies that p_{k-1}, p_k, s are the only three vertices that possibly define an ear of P' that is not incident to qs (provided $k > 1$) and has all three angles smaller than μ. Symmetrically, r_{m-1}, r_m, s are the only such three vertices of R'. If $\phi_k < \mu$ then $p_{k-1}p_ks$ is indeed such an ear and we can remove it from P'. This operation decreases ϕ_{k-1}, the angle at p_{k-1}, and leaves all other ϕ_i unchanged. Thus, P' still satisfies the invariant after setting $k := k - 1$. Similarly, the invariant is maintained if we remove $r_{m-1}r_ms$ from R' and set $m := m - 1$.

We now describe this process more formally as a procedure that alternates between removing an ear from P' and removing an ear from R'. It either completes its

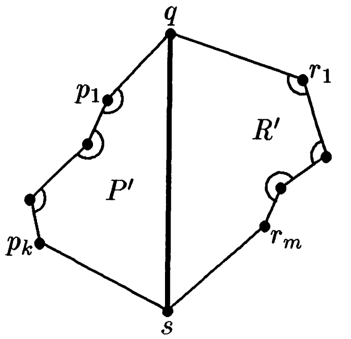

FIG. 3. *The circular arcs indicate angles that are known to be at least as large as μ.*

task of triangulating P' and R' or it stops because it encounters a situation where $\phi_k \geq \mu$ or $\rho_m \geq \mu$. To avoid repetition we separate out the code that tests an angle and removes an ear if the angle is small enough.

```
procedure CUTEARP'.
  if $\phi_k < \mu$ then
      if $k > 1$ then add the edge $p_{k-1}s$ to the triangulation endif;
      remove the triangle $p_{k-1}p_ks$ from $P'$ and set $k := k - 1$
    else set stop := true
  endif.
```

Similarly, we define a procedure CUTEARR$'$, which either removes $r_{m-1}r_ms$ from R' or raises the flag by setting *stop* := **true**. The attempt to triangulate P' and R' first alternates between the two polygons and, if one polygon is successfully triangulated, attempts to complete the polygon that remains.

```
stop := false;
while $k > 0$ and $m > 0$ and not stop do
  CUTEARP'; if not stop then CUTEARR' endif
endwhile;
while $k > 0$ and not stop do CUTEARP' endwhile;
while $m > 0$ and not stop do CUTEARR' endwhile.
```

If the procedure finishes without raising the flag (*stop* = **false**) then we must have $k = m = 0$ and the triangulation is complete. Otherwise, the flag is raised either while testing P' or while testing R' (so we should really have used two flags to be able to distinguish the two cases—and we pretend we did).

Assume the flag was raised because of $\phi_k \geq \mu$. Let $\vec{qs}$ be the half-line that starts at q and goes through s, and let p' be the point among $p_1, \cdots, p_k$ so that $\angle p'qs$ is a minimum. Note that p' is not necessarily equal to p_k, but $p' = p_k$ if P' is convex. We have the following lemma, which will be useful in searching for a new point s.

LEMMA 4.3. *Assuming $\phi_k \geq \mu$, there is no point $t \in S$ so that qt is an edge in a minmax angle triangulation $\mathcal{T}$ of S, $qt \cap p_ks \neq \emptyset$, and $qt \cap p's \neq \emptyset$.*

Proof. Suppose there is a point t that contradicts the assertion. Because $qt \cap p_ks \neq \emptyset$, this edge qt generates a polygon P'' so that $q = p_0, p_1, \cdots, p_k$ is a contiguous subsequence of its vertices (after removing appropriate ears). Let $p_{k+1}, \cdots, p_{k''}, p_{k''+1} = t$

be the other vertices of P''. By assumption we have $\angle p_{i-1}p_ip_{i+1} \geq \mu$ for $1 \leq i \leq k-1$. Furthermore, $\angle p_{k-1}p_kp_j \geq \mu$ for all $k+1 \leq j \leq k''+1$ because all these angles are larger than ϕ_k, the angle at p_k in P'. Hence, any attempt to triangulate P'' by removing ears (not incident to qs with angles all smaller than μ) must fail to cut off ears at p_i for all $1 \leq i \leq k$. □

Remark. As in the remark after the cake-cutting lemma, we can argue that Lemma 4.3 is also true if we replace $\mathcal{T}$ by an arbitrary triangulation that is an improvement of $\mathcal{A}$.

Lemma 4.3 suggests that the search for a new s continue between $\vec{qr'}$ and $\vec{qs}$ if the flag is raised while testing P', where r' is the counterpart of p' in R' and s is the old s. Thus, all ears removed from P' are safe and do not have to be considered again. However, all ears removed from R' have to be added back because they will intersect any future edge qs. Simultaneously, the value of m has to be adjusted. The amount of time needed to add these ears back in is proportional to the number of ears removed from P', because the ear cutting alternates between P' and R'. Symmetric actions are in order when the flag is raised while testing R'.

4.3. How to search. Let us go back to the triangulation $\mathcal{A}$ of S that is not yet a minmax angle triangulation, and as usual let p, q, r be the points so that pqr is a triangle in $\mathcal{A}$ and $\angle pqr = \mu = \mu(\mathcal{A})$. The first vertex s that we test is the third vertex of the other triangle of pr (if no such triangle exists, then pr is an edge of the convex hull of S and no appropriate point s exists). Thus we add qs and remove pr. If the new angles at p and r are both smaller than μ, then we are done. If $\angle qps < \mu$ and $\angle qrs \geq \mu$, then, by Lemma 4.3, the edges we should test must intersect ps. Symmetrically, if $\angle qps \geq \mu$ and $\angle qrs < \mu$, then we must search for edges that intersect sr. If both angles are at least μ, then no appropriate edge exists.

We now generalize and formalize this idea. For given polygons P' and R' we define vertices p' and r' as above, and we denote the open wedge between $\vec{qp'}$ and $\vec{qr'}$ by W. This wedge will get progressively smaller as we proceed with the search, and only points s within the wedge will be considered as endpoints of new edges qs. Initially, $p' = p$ and $r' = r$. We are now ready to describe the algorithm that searches for an appropriate point s.

Input. A triangulation $\mathcal{A}$ of S with maximum angle $\angle pqr = \mu = \mu(\mathcal{A})$.
Output. An improved triangulation or a message that the maximum angle cannot be decreased. In the latter case, the input triangulation is a minmax angle triangulation of S.
Define. THIRD(a, b) is the vertex c of the triangle abc so that q and c lie on opposite sides of the line through a and b. If such a vertex does not exist, which is the case if ab is an edge of the convex hull of S, then THIRD(a, b) is undefined. As before, W denotes the open wedge defined by p', q, and r'.

```
Initialize $k := 1$, $p_1 := p' := p$, $m := 1$, and $r_1 := r' := r$.
loop
 if THIRD$(p_k, r_m)$ is not defined then
   return the message that the maximum angle cannot be decreased and stop.
  else
   set $s :=$ THIRD$(p_k, r_m)$ and remove $p_kr_m$ from $\mathcal{A}$.
   if $s \in W$ then
     add $qs$ to $\mathcal{A}$ and attempt the triangulation of $P'$ and $R'$ as described in §4.2.
     case 1. The attempt succeeds. Return the new triangulation and stop.
```

```
      case 2. The flag was raised while testing $P'$. Set $k := k + 1$ & $p_k := p' := s$.
      case 3. The flag was raised while testing $R'$. Set $m := m + 1$ & $r_m := r' := s$.
    else (i.e., $s \notin W$)
      if $sr_m$ intersects $W$ then
        set stop := false; while not stop do CUTEARP' endwhile;
        set $k := k + 1$ and $p_k := s$.
      else (i.e., $sp_k$ intersects $W$)
        set stop := false; while not stop do CUTEARR' endwhile;
        set $m := m + 1$ and $r_m := s$.
      endif
    endif
  endif
forever.
```

We would like to point out a subtlety of the algorithm needed to prove its correctness. That is, the polygons P' and R' defined by any edge qs are obtained from $\mathcal{A}$ by removing *only* edges that intersect qs. Of course, some edges not in $\mathcal{A}$ have been added already to remove some ears. In other words, P' is the polygon P (as defined in §2) with some ears removed, and the same is true for R' and R.

4.4. The final analysis. The running time of an iterative step (the above algorithm) is proportional to the number of removed ears. Because of the alternation between removing an ear from P' and one from R', at most only one more than half of the removed ears are added back to the polygon. This is also true if one polygon is completely triangulated while ears are still removed from the other polygon, because in this case only the ears of the former polygons need to be added back in, and their number is smaller than the number of ears cut off from the other polygon. It follows that the total number of removed ears is $O(n)$. A single iteration therefore takes only $O(n)$ time. Together with Lemma 2.3, which states that there are only $O(n^2)$ iterations, this implies a cubic upper bound on the time complexity of our algorithm (if implemented without priority queue).

Below we argue that its running time is actually $O(n^2 \log n)$. To achieve this bound it is necessary to store the angles of the current triangulation in a priority queue, for otherwise finding all maximum angles costs time $\Omega(n^3)$. The crucial observation is that the time spent in an iterative step is proportional to the number of edges in the input triangulation that intersect the new edge qs. Each such edge has been removed and we argue that it will never be added again because every future triangulation will have an edge qt that intersects $p_k r_m$, the last edge before s. First note that every future triangulation is an improvement of $\mathcal{A}$. By Lemma 4.3 and the remark following it, every improvement of $\mathcal{A}$ has an edge qt in the final wedge W as maintained by the algorithm. Both p_k and r_m lie outside W (possibly on its boundary) and the edge $p_k r_m$ intersects W. The claim follows because all points of $W \cap S$ lie beyond $p_k r_m$ as seen from q. This implies the $O(n^2 \log n)$ bound because we have only $\binom{n}{2} = O(n^2)$ edges to work with. It should be noted that the maintenance of the priority queue storing the angles is the sole reason for the $\log n$ term in the $O(n^2 \log n)$ bound; all other operations take total time $O(n^2)$.

5. Extensions. We address two types of extensions of our algorithm for constructing minmax angle triangulations. The first extension is to the constrained case where the input consists of a set of n points plus some pairwise disjoint edges defined by the points that are required to be in the triangulation. The second extension discusses the optimization of the entire angle vector rather than just the maximum angle.

Only minor changes are necessary to adapt the algorithm presented in §§2 and 4 to the constrained case. The most important change is that no prescribed edge will be removed to give way to searching for a new point s. This modification takes no extra time, which implies the part of the Main Theorem that deals with prescribed edges.

Before we introduce angle vectors, note that for a given point set S all triangulations (whether constrained or not) have the same number of triangles and therefore the same number of angles. By Euler's formula for planar graphs the number of triangles is $t = 2n - h - 2$, where $n = |S|$ and h is the number of points of S that lie on the boundary of its convex hull. For any triangulation $\mathcal{A}$ of S we define its *angle vector* $V_{\mathcal{A}} = (\alpha_1, \alpha_2, \cdots, \alpha_{3t})$, with $\alpha_1 \geq \alpha_2 \geq \cdots \geq \alpha_{3t}$ the $3t$ angles of the t triangles. If $\mathcal{B}$ is another triangulation of S with angle vector $V_{\mathcal{B}} = (\beta_1, \beta_2, \cdots, \beta_{3t})$ we define $V_{\mathcal{B}} < V_{\mathcal{A}}$ if there is an index $1 \leq j \leq 3t$ so that $\beta_i = \alpha_i$ for $1 \leq i < j$ and $\beta_j < \alpha_j$. For example, $V_{\mathcal{B}} < V_{\mathcal{A}}$ if $\mathcal{B}$ is an improvement of $\mathcal{A}$, but the reverse is not necessarily true.

The problem of finding a triangulation with minimum angle vector is at least as difficult as finding a minmax angle triangulation. If any two angles defined by three points of S each are different we can construct the minimum angle vector triangulation—which is unique in this case—as follows.

> First, construct a minmax angle triangulation $\mathcal{T}_1$ and declare the three edges of the triangle that contains the maximum angle as prescribed. Second, construct a minmax angle triangulation $\mathcal{T}_2$ for the thus constrained input and introduce new constraints to enforce the second largest angle in future triangulations. Continue this way and construct triangulations $\mathcal{T}_3$, $\mathcal{T}_4$, and so on until the prescribed edges add up to a triangulation themselves. This triangulation minimizes the angle vector.

An $O(n^3 \log n)$ time-bound for this algorithm is obvious because it just iterates the minmax angle triangulation algorithm a linear number of times. Even better, we have an $O(n^2 \log n)$ time-bound if we use $\mathcal{T}_i$ as the input triangulation for the construction of $\mathcal{T}_{i+1}$. The improved bound follows because an edge once removed cannot appear in any future triangulation. We thus get the following result by the same argument as in §4.4.

THEOREM 5.1. *Given a set of n points in the plane so that no angles defined by three points each are equally large, the triangulation that lexicographically minimizes the angle vector can be constructed in time $O(n^2 \log n)$ and space $O(n)$.*

Remark. In the presence of multiple angles it is not clear how to adapt the approach of this paper without requiring an exponential amount of time in the worst case. We pose the existence of a polynomial algorithm for minimizing the angle vector in the presence of multiple angles as an open problem. A case where multiple angles can be handled relatively easily is that of a simple polygon. The straightforward cubic time algorithm for minimizing the maximum angle, derived from the dynamic programming algorithm of Klincsek [10], can be extended to an $O(n^4)$ time algorithm for minimizing the angle vector as follows. Instead of characterizing a (partial) triangulation by its maximum angle we store its sorted angle vector. The best triangulation of a sequence of vertices is then selected on the basis of these vectors. The cubic time increases to $O(n^4)$ because comparing two angle vectors takes $O(n)$ time in the worst case, in contrast to constant time for comparing maximum angles.

6. Experimental results. To demonstrate that the results of the preceding sections, which we believe are of theoretical interest, are significant also from a practical viewpoint, we implement the algorithm along with a few other triangulation algorithms from the literature. Using these implementations, we perform a small-scale comparative study of the triangulations they produce. A more extensive study and complete description of the findings will soon be available as the master's thesis of Waupotitsch. The difference between two triangulations is expressed in terms of their angles and edges (as in [16]).

The experimental study is based on implementations of four different triangulation algorithms. Three work by iterative improvement, and to construct an initial triangulation we use a plane-sweep strategy (see, e.g., [6, §8.3.1]). Triangulations constructed by plane-sweep are denoted by PS. The implementation of the edge-insertion algorithm of this paper minimizes the angle vector as discussed in §5. Its triangulations are referred to as MV. To avoid the difficulty that arises when two angles are equally large (see the remark at the end of §5), we use a heuristic that breaks ties in a consistent manner. Delaunay triangulations, *DEL*, are constructed by flipping the diagonals of convex quadrilaterals as long as the smallest angle involved increases (see, e.g., [11]). The third incremental improvement algorithm flips the diagonal of a convex quadrilateral if the largest of the six involved angles decreases. As shown in [15], this heuristic typically gets stuck in a local optimum depending on the initial triangulation as well as on the way the flips are scheduled. We use this algorithm to construct triangulations *FPD, FPN, FDD,* and *FDN,* where the middle letter distinguishes between PS and *DEL* as the initial triangulation and the final letter distinguishes between deterministic (largest angle first) and "nondeterministic" (first in first serve) scheduling.

The point sets chosen for our experimental study are drawn uniformly either inside a square or near a circle (see Fig. 4). To allow for exact arithmetic all points are chosen on the integer grid. For each of various point set sizes, 30 experiments are carried out and average statistics are compiled.

Table 1 compares triangulations and their quality. More specifically, it compares each triangulation $X \in \{PL, DEL, FPD, FPN, FDD, FDN\}$ with MV, the optimum triangulation. The parameter Δe gives the number of edges in X that are not in MV. The angle vectors of X and MV are compared using parameters $\angle_{eq}$, $\angle_{sm}$, and $(\angle/\angle_{MV})$. This means that the $\angle_{eq}$ largest angles of X and MV are the same and that the next $\angle_{sm}$ largest angles are smaller for *MV.* $(\angle/\angle_{MV})$ is the ratio between the $\angle_{eq}+1$ largest angle of each triangulation. The statistics show that for points uniformly distributed in a square the edge-flip heuristic produces triangulations that come close to the optimum. Consistent with the findings reported in [16], *DEL* differs from MV by slightly less than 10 percent of its edges. This is in sharp contrast to the relative performance of the algorithms for points chosen on or close to a circle. In this case, *DEL* and MV share very few nonconvex hull edges. The edge-flip heuristic produces triangulations that are superior in terms of angles to *DEL*, but they hardly share any more edges with MV.

It is interesting to note that the amount of work needed to construct MV is far less for points in a square than for points near a circle. Table 2 shows the number of edges removed during the construction of MV. While the difference between the two point distributions is striking, the choice of the initial triangulation seems to have far less

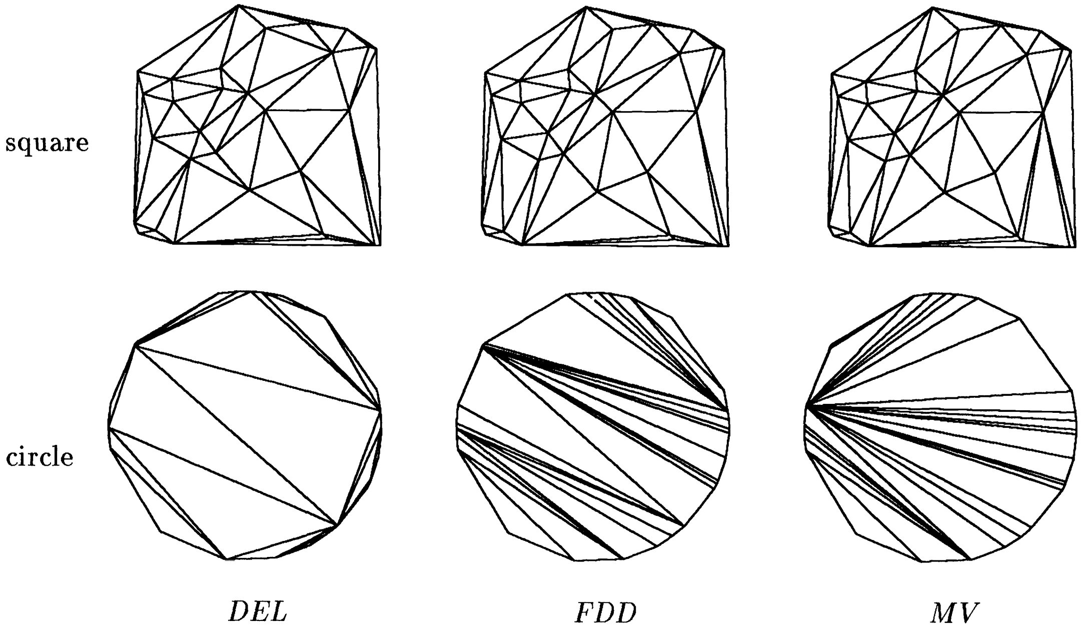

FIG. 4. *The Delaunay triangulation, DEL, a locally optimal triangulation, FDD, and the globally optimal triangulation, MV, for two small point sets.*

influence on the running time of the edge-insertion algorithm. In general, we observe that the edge-insertion algorithm is much faster on the average than expressed by the worst-case analysis in §4. We would also like to remark that there are no polynomial time-bounds known for the edge-flip heuristic used in our experimental study.

7. Conclusions. The main result of this paper is an $O(n^2 \log n)$ time algorithm for constructing a minmax angle triangulation of a set of n points in the plane, with or without prescribed edges. This seems fairly efficient considering that it is the first polynomial time algorithm for the problem and that it somehow avoids looking at all the $\binom{n}{3}$ angles defined by the n points. On the other hand, our algorithm is a factor n slower than the best algorithms for constructing Delaunay triangulations, at least in the worst case. We thus pose the question of whether a minmax angle triangulation can be constructed in $o(n^2 \log n)$ time.

In the nondegenerate case where no two angles defined by three points each are equal, the algorithm can be extended to compute the triangulation that lexicographically minimizes the sorted vector of angles. The running time is still $O(n^2 \log n)$ in the worst case, and our experiments indicate that the average run time is significantly less.

A problem related to minimizing the maximum angle is to construct a triangulation that minimizes the number of obtuse angles. It seems that the edge-insertion scheme does not work for this criterion. The problem thus remains open for point sets, although dynamic programming yields a cubic time algorithm if the input is a simple polygon. Still, the authors of this paper believe that the edge-insertion scheme is more generally applicable and plan to further investigate this paradigm.

WHICH CUBIC SPLINE SHOULD ONE USE?*

R. K. BEATSON† AND E. CHACKO†

Abstract. The aim of this paper is to provide a quantitative comparison of eight different C^1 and C^2 cubic spline interpolation schemes. The C^1 schemes discussed are local while the C^2 ones are global.

In practice cubic splines are often used when the smoothness of the function being interpolated/approximated is unknown. Also, it is often necessary, or advantageous, to use a nonuniform mesh. Therefore performance over a variety of smoothness classes, using uniform and also several thousand random meshes, is compared. The performance criteria used are the *quantitative* ones of exact operator and derived operator norms and best possible pointwise error estimates.

Key words. cubic splines, end conditions, operator norms, error estimates

AMS(MOS) subject classifications. 65D07, 65D10, 41A15

1. Introduction.

Our aim is to find an interpolant that will give good results when used to interpolate functions of unknown smoothness on a possibly nonuniform mesh. We consider eight different C^1 or C^2 cubic spline interpolation schemes and compare their operator and derived operator norms as well as the pointwise error

$$\sup_{f\in\mathcal{F}} |(f-s)(x)|$$

for uniform knot distributions, several thousand random knot distributions, and several smoothness classes $\mathcal{F}$. It is worth emphasizing that we do not seek the best interpolation method for a fixed smoothness class $\mathcal{F}$—the problem of optimal interpolation.

All the schemes considered fit cubic splines with knots at the nodes of interpolation t_i

$$s(t_i) = f(t_i), \qquad i = 0, 1, \cdots, n.$$

1.1. C^2 methods—not strictly local.

In the first six methods the spline is chosen to be C^2, so that each scheme corresponds to a different choice of two *end conditions.* Such schemes are not suitable for certain applications as they are not *strictly local.* Thus data far away from x can influence the value of $s(x)$. However, they are *semilocal,* meaning that the influence of data at point t_i on $s(x)$ falls off geometrically with the number of knots between x and t_i (see the discussion in §2.1 below).

Method A:

$$s^{(3)}(t_1-) = s^{(3)}(t_1+) \quad\text{and}\quad s^{(3)}(t_{n-1}-) = s^{(3)}(t_{n-1}+), \tag{1}$$

the well-known *not-a-knot* end condition. (See Kershaw [7] and de Boor [2].) This end condition forces the restrictions of the spline to the first two and the last two intervals to be single cubics. The maximum convergence rate, meaning the rate for a general C^∞ function, is $\mathcal{O}(\delta^4)$, where δ is the mesh size. Of course the limiting rate is actually achieved for C^3 functions with Lipschitz third derivative.

† Mathematics Department, University of Canterbury, Private Bag, Christchurch 1, New Zealand (rkb@math.canterbury.ac.n z and pec@math.canterbury.ac.nz).

Method B:

$$s'(t_0) = c_l'(t_0) \quad \text{and} \quad s'(t_n) = c_r'(t_n), \tag{2}$$

where c_l and c_r are cubic polynomials with

$$c_l(t_i) = f(t_i) \quad \text{and} \quad c_r(t_{n-i}) = f(t_{n-i}), \qquad 0 \le i \le 3.$$

Thus this spline is chosen to have the same first derivative as the local cubic interpolant through the first (last) four knots, at the first (last) knot. The maximum convergence rate is $\mathcal{O}(\delta^4)$.

Method C:

$$s''(t_0) = c_l''(t_0) \quad \text{and} \quad s''(t_n) = c_r''(t_n) \tag{3}$$

with c_l and c_r as above. Thus this spline is chosen to have the same second derivative as the local cubic interpolant through the first (last) four knots, at the first (last) knot. The maximum convergence rate is $\mathcal{O}(\delta^4)$.

Method D:

$$d_1 = d_2 \quad \text{and} \quad d_{n-2} = d_{n-1}, \tag{4}$$

where

$$d_i = s^{(3)}(t_i+) - s^{(3)}(t_i-).$$

Here the jump discontinuities in the third derivative at the second and third knots are forced to be the same, and similarly for the second and third to last knots. This method is known to minimize $\|f - s\|_\infty$ when the knots are equispaced and f is a quartic polynomial. The maximum convergence rate is $\mathcal{O}(\delta^4)$, and the method is not recommended for use with nonuniform meshes.

Method E:

$$s''(t_0) = 0 \quad \text{and} \quad s''(t_n) = 0, \tag{5}$$

the so-called *natural cubic spline* end condition. This *should not generally be used* for approximation purposes, as it throws away any second derivative information in the data and, as a consequence, the order of approximation near the endpoints is restricted to $\mathcal{O}(\delta^2)$.

Method F:

$$s'(t_0) = q_l'(t_0) \quad \text{and} \quad s'(t_n) = q_r'(t_n), \tag{6}$$

where q_l and q_r are quadratic polynomials with

$$q_l(t_i) = f(t_i) \quad \text{and} \quad q_r(t_{n-i}) = f(t_{n-i}), \quad 0 \le i \le 2.$$

Thus, this spline is chosen to have the same first derivative as the local quadratic interpolant through the first (last) three knots, at the first (last) knot. The maximum convergence rate is $\mathcal{O}(\delta^3)$.

1.2. C^1 methods—strictly local. The last two schemes are simple *strictly local* methods. This property allows easy modification of previously obtained fits, and is essential for some applications, such as CAD. However, there is a cost, namely, that the error estimates for smooth functions away from the ends of the interval are generally somewhat worse. The local methods we consider are C^1 rather than C^2.

Method G: s' agrees with the derivative of a local quadratic at every knot. Thus defining q_i as the quadratic that interpolates to f at t_i, t_{i+1}, and t_{i+2},

$$s'(t_j) = \begin{cases} q_0'(t_0), & j = 0, \\ q_{j-1}'(t_j), & 0 < j < n, \\ q_{n-2}'(t_n), & j = n. \end{cases} \tag{7}$$

The maximum convergence rate is $\mathcal{O}(\delta^3)$.

Method H: s' agrees with the derivative of a local cubic at every knot. Thus defining c_i as the cubic that interpolates to f at t_i, t_{i+1}, t_{i+2}, and t_{i+3},

$$s'(t_j) = \begin{cases} c_0'(t_0), & j = 0, \\ c_{j-1}'(t_j), & 0 < j \le n/2, \\ c_{j-2}'(t_j), & n/2 < j < n, \\ c_{n-3}'(t_n), & j = n. \end{cases} \tag{8}$$

The maximum convergence rate is $\mathcal{O}(\delta^4)$.

1.3. Outline of criteria used. The present work is an extension of that in [1], where it was shown that, for methods A, B, and C,

$$\|f - s\|_\infty \le K\delta^j \omega(f^{(j)}, \delta), \qquad 1 \le j \le 3, \tag{9}$$

where $\omega(f^{(j)}, \delta)$ is the modulus of continuity for $f^{(j)}$. For $j = 2, 3$, K is an absolute constant independent of the mesh $\mathbf{t}$. For $j = 1$ it depends on the spacing of the first few and last few knots. Estimate (9) implies, in particular, $\mathcal{O}(\delta^4)$ approximation to C^4 functions. However, [1] does not give any grounds for choosing a particular interpolant from amongst those methods with $\mathcal{O}(\delta^4)$ error estimates, and no information about strictly local methods, or those methods with maximum convergence rates less than $\mathcal{O}(\delta^4)$.

Our present aim was therefore to make a quantitative comparison of various commonly used cubic spline interpolants. Comparisons are made using uniform meshes and also several thousand nonuniform meshes. For each of these cases we computed the operator norms of the spline projector itself, and also of the first derived projectors $L' : f' \to s'$. For the C^2 methods we also computed the norm of the second derived projector $L'' : f'' \to s''$. These norms give a quantitative measure of the tendency of the particular spline operator to introduce *extraneous bumps and wiggles.* We also compute the *pointwise error multiplier*

$$K(j,x) = \sup_{f \in W_{j,\infty} \,:\, \|f^{(j)}\|_\infty \le 1} |f(x) - s(x)|,$$

$1 \le j \le 4$. The utility of these functions lies in the associated "tight" bounds

$$|f(x) - s(x)| \le K(j,x)\|f^{(j)}\|_\infty$$

and

$$\|f - s\|_\infty \le C_j \|f^{(j)}\|_\infty,$$

where $C_j = \sup_x K(j,x)$.

1.4. Summary of results. The results are presented in detail in §2, and the mathematics underlying the calculations, in §3. While we do reach a conclusion and recommend one method, namely, Method B, for general purpose use, the reader can use the results to analyze the pros and cons of other choices. For example, the results show the cost of using the *strictly local* Method H, rather than a more conventional cubic spline interpolant, when approximating C^4 functions in the middle of the interval. For uniform meshes this is a worsening of the error bound by a factor of approximately 1.8, which may be quite acceptable. They also show that giving up fourth-order convergence to smooth enough functions can result in better convergence to functions with fewer derivatives.

When a simple *strictly local* method is required we would recommend instead Method H. Clearly the norm of the latter interpolation operator can be bounded in terms of the local mesh ratio, $m_n = \max\{h_i/h_j : |i-j| = 1\}$, and independently of the number of knots. Marsden [8] has shown that this property fails to hold for several of the C^2 cubic spline interpolants we consider. We remind the reader that in an adaptive curve fitting setting the local mesh ratio may get very large, and the norm of all of the interpolation operators discussed here, including the strictly local ones, gets large with it. However, the norm of the interpolation operator can be kept bounded if one chooses the nodes of interpolation after the knots of the spline, or replaces interpolation by quasi interpolation. (See de Boor [2, pp. 191–196; 208–213].)

Method B fits a C^2 function and has fourth-order convergence when the data comes from a sufficiently smooth function. Define

$$\begin{aligned} W_{j,\infty}[a,b] &= \left\{ f \in C^{j-1}[a,b] : f^{(j-1)} \text{ absolutely continuous and} f^{(j)} \in L_\infty[a,b] \right\} \\ &= \left\{ f \in C^{j-1}[a,b] \text{ with } f^{(j-1)} \text{ Lipshitz} \right\}. \end{aligned}$$

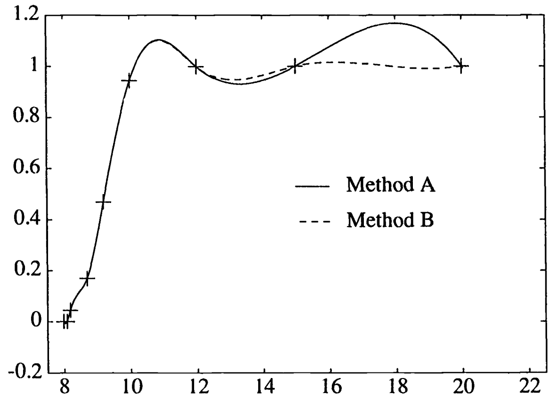

FIG. 1. *Different cubic spline fits to* RPN-14 *data.*

Method B's performance for $W_{4,\infty}$ functions is on average very slightly worse than the best of the other methods. However, it performs significantly better than the other C^2 fourth-order methods on functions of lower smoothness. Of course, the various C^2 cubic interpolatory splines will differ greatly only in the first and last few intervals. Figure 1 illustrates this. However, our contention is that the differences in these few intervals are important. This is particularly so since adapting a standard cubic spline code to end conditions of Method B is trivial, and the extra computational expense is at worst five or six *flops*.

2. Detailed results. In this section we present the results of our computations of exact error estimates and operator norms.

2.1. Differences between the C^2 and C^1 methods in the middle intervals. We wish to emphasize the point made at the end of the previous section, that the differences between the various C^2 interpolants are generally only significant in the first and last few intervals. For example, Kershaw [6] gives matrix estimates that, for a reasonably general set of end conditions, can be used to show the geometric decay of the influence of the end conditions, on the value of $s(x)$, as the number of knots between x and the endpoints grows.

To give a particular instance, if one considers the middle two intervals of a 30 subinterval uniform mesh, then the calculated least constant C_4 for which

$$\sup_{14h \le x \le 16h} |f(x) - s(x)| \le C_4 h^4 \|f^{(4)}\|_{[0,30h]},$$

for each of the C^2 methods, agrees to eight significant digits with the value 5/384 appropriate for cardinal interpolation on an infinite mesh. (For the infinite problem, see, for example, Powell [9].) Interestingly, 5/384 is also the optimal constant in the bound $\|f - s\| \le Ch^4 \|f^{(4)}\|$ for the error in complete cubic spline interpolation where one has extra first derivative information at the end points (see Hall [4] and Hall and Meyer [5]). In contrast, the strictly local methods can vary in their behavior in the middle intervals. Results are shown in Table 1 below. The values under the optimal column are values that can be achieved by a, possibly noncubic, spline interpolation method. That these values are lower bounds can be seen from the behavior of the Euler splines $\mathcal{E}_k$ (see Schoenberg [10]).

TABLE 1
Error constant in middle of a 30 *interval uniform mesh.*

Derivative	Optimal	C^2 methods	Method G	Method H
1	$1/2 = .5$	.7745	.6250	.6875
2	$1/8 = .125$	.1623	.1406	.1517
3	$1/24 \approx .0416$	.0431	.0468	.0468
4	$5/384 \approx .0130$	.0130	undefined	.0234

It is apparent that the C^2 methods do somewhat better than the strictly local methods when f is smooth.

2.2. Results for pseudorandom meshes. Fix for the moment the mesh $\mathbf{t}$ and the smoothness class $C^j[t_0, t_n]$, $1 \le j \le 4$. Then for each $x \in [t_0, t_n]$, and each method α that reproduces π_{j-1}, we can compute the *pointwise error multiplier* $K(\alpha; j, x)$, which is the smallest number for which the bound

$$|f(x) - s(x)| \le K(\alpha; j, x) \|f^{(j)}\|_\infty$$

holds for all $f \in C^j[t_0, t_n]$. For the interpolants considered here the same bound holds for $W_{j,\infty}[t_0, t_n]$. Then the *error constant* $C_{\alpha,j}$ is defined to be the smallest number for which the relationship

$$\|f - s\|_\infty \le C_{\alpha,j} \|f^{(j)}\|_\infty, \quad \forall f \in C^j[t_0, t_n]$$

holds. Clearly $C_{\alpha,j} = \sup_{x\in[t_0,t_n]} K(\alpha; j, x)$. We can compare interpolation methods by comparing the error constants $C_{\alpha,j}$. Using Method A as a standard, we compute for each fixed mesh, and method α, the *relative error constant*

$$e_{\alpha,j} = C_{A,j}/C_{\alpha,j}.$$

The performance of the interpolants on nonuniform meshes was compared by conducting 5000 pseudorandom trials. In each trial nine numbers were generated uniformly at random in $[0, 1]$, then sorted and scaled to obtain a mesh $\mathbf{t} : 0 = t_0 < t_1 < \cdots < t_8 = 1$. Then *relative error constants* were computed numerically. The resulting 5000 relative error constants were then sorted and the 1 percentile, mean, and 99 percentile points displayed in a bar graph. A logarithmic scale was used so that *relative error constants* of κ and $1/\kappa$ have the same visual impact.

2.2.1. Comparison of the overall error bounds. In the first two graphs of Fig. 2, we observe that the $\mathcal{O}(\delta^4)$ methods do not do as well as the lower-order methods for these not very smooth functions. This is perhaps a consequence of the reproduction of cubics. Method A does particularly badly. Intuitively, lacking knots at t_1 and t_{n-1}, it cannot be as flexible, or local, as the other methods.

In the last two graphs of Fig. 2, we note that the global methods do better than the strictly local methods for these smoother functions. Method A, the not-a-knot spline, does the best of any of the methods on $W_{4,\infty}$ functions.

2.2.2. Comparison of the first interval error bounds. In this section we compare the error bounds for the first interval only. Thus the first interval error constant $C'_{\alpha,j}$ is defined as the smallest number for which the bound

$$\sup_{[t_0,t_1]} |f(x) - s(x)| \le C'_{\alpha,j} \|f^{(j)}\|_\infty, \quad \forall f \in C^j[t_0, t_n],$$

holds. Clearly

$$C'_{\alpha,j} = \sup_{[t_0,t_1]} K(\alpha; j, x).$$

We first compute these first interval error constants, and then the corresponding relative error constant $e'_{\alpha,j} = C'_{A,j}/C'_{\alpha,j}$. The results from numerical experiments were graphed as in the last section. For the first and second derivative bounds the first interval results were very much like the overall results. These graphs were therefore omitted. The first interval results for third and fourth derivative bounds are more extreme than the overall results and appear in Fig. 3.

2.3. Comparison of operator norms. We also calculated the norm of L, and of the derived projector L', for each of the methods and eight random interval meshes. Bar graphs showing the 1 percentile, mean, and 99 percentile points over 20,000 trials are shown in Fig. 4. We remind the reader that the norm of L cannot be bounded independently of the mesh ratio (see de Boor [2, pp. 209–214] and the references therein); that the norm of L' (at least for Methods A, B, and C) can be bounded in terms of the mesh ratio in the first and last two intervals (see [1]); and that the norm of L'' can be bounded independently of the mesh. Table 2 shows the extreme values of $\|L''\|$ seen over 20,000 random trials with 28 interval meshes.

These norms represent a quantitative measure of the tendency of the various methods to introduce *spurious bumps and wiggles* in the fitted curve. We emphasize

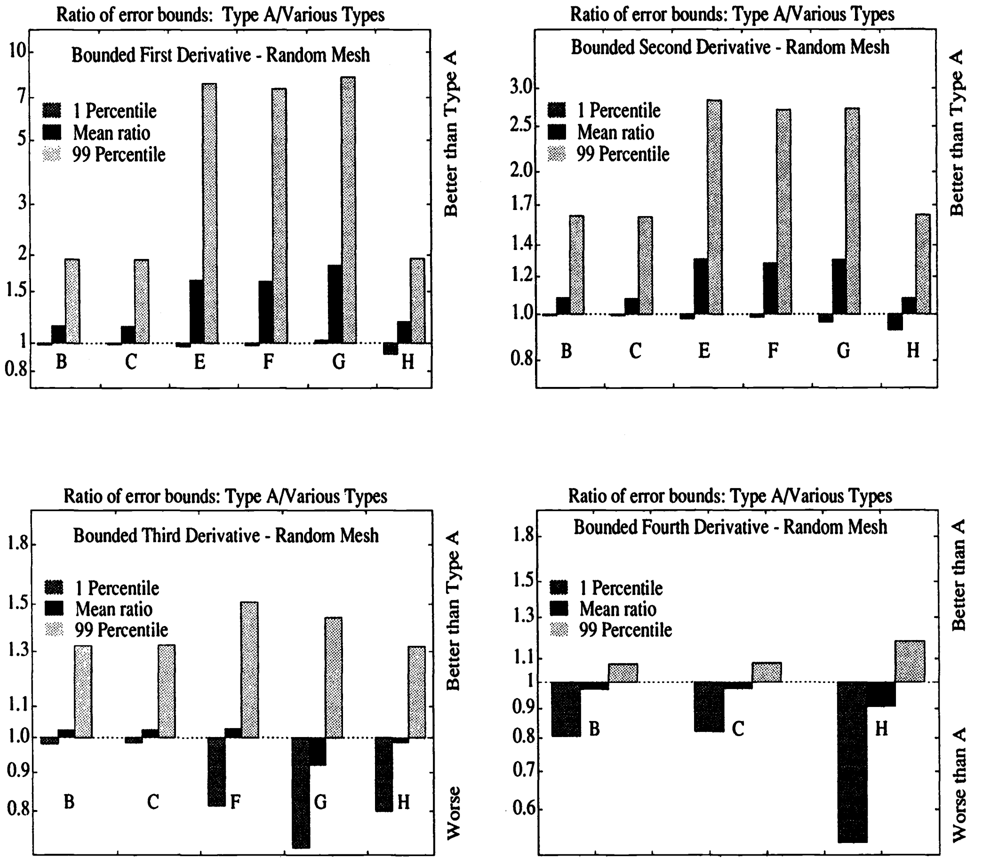

FIG. 2. *Error bounds: Type* A/*Various types; Overall.*

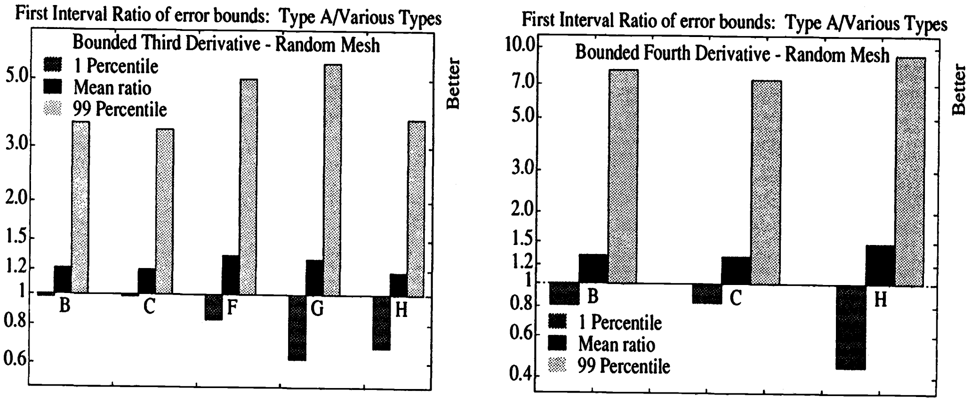

FIG. 3. *Error bounds: Type* A/*Various types; First interval.*

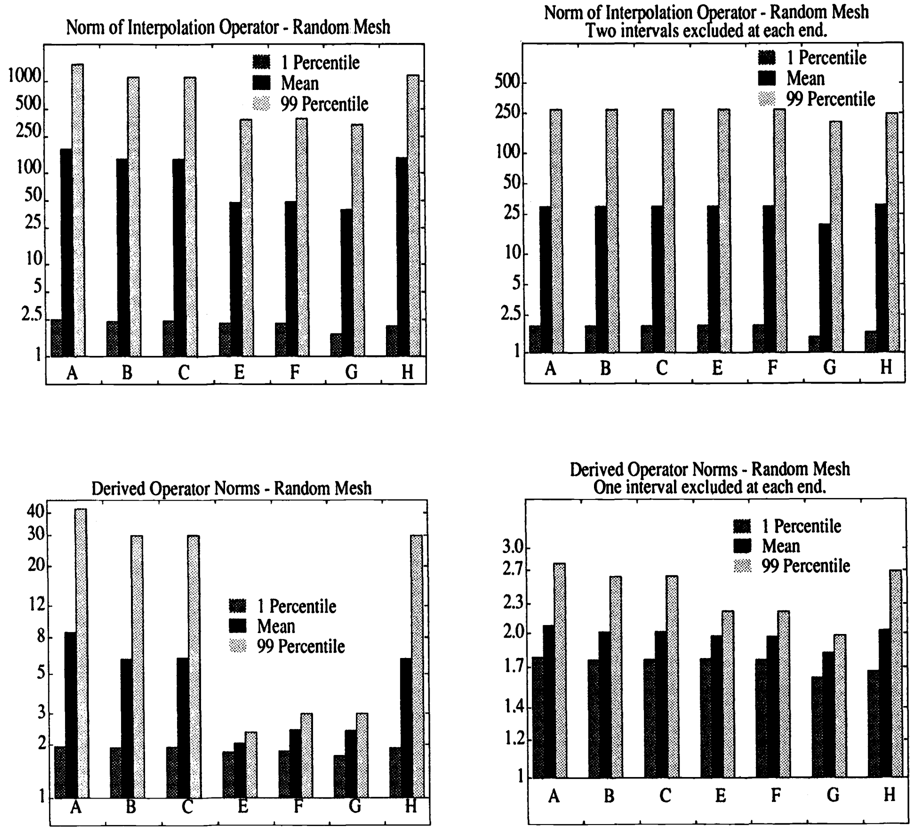

FIG. 4. *Operator norms; Random meshes.*

that, for the C^2 methods, the fitted curves will differ very little in the middle intervals, so that any large difference in operator norms corresponds to differing behavior in the first few or last few intervals.

2.4. Results for a uniform mesh. The graphs in Figs. 5 and 6 show the pointwise error multipliers $K(j, x)$ in the first three intervals of a uniform mesh of 30 intervals for each of the methods and the four smoothness classes. We do not show the plot for the interior subintervals where all the C^2 methods are practically indistinguishable. This is to be expected because of the semilocal nature of cubic splines.

We also calculated the norms of s and the derived projectors s' and s'' for uniform meshes of various sizes, with end intervals included and excluded. The results are shown in Tables 3–8.

The entries in the first of each pair of tables are the usual operator norms,

$$\|L\| = \sup_{f \neq 0} \|Lf\|_{[t_0,t_n]}/\|f\|_{[t_0,t_n]},$$

while for those in the second, the end intervals are excluded in the numerator. Thus,

$$\|L\|' = \sup_{f \neq 0} \|Lf\|_{[t_1,t_{n-1}]}/\|f\|_{[t_0,t_n]}.$$

Our interpretation of these results is as follows. For these uniform meshes the various C^2 methods differ very little when the end intervals are excluded.[1] Thus once again we see that the end conditions make a difference only near the end points. Also, as expected, the operator norms for a particular method hardly change as the number of intervals in the uniform mesh is increased beyond eight. The error curves for $W_{4,\infty}$ functions show the C^2 methods doing better than the strictly local Method H in the interior subintervals.

3. Mathematics underlying the computations.

3.1. Calculation of the optimal error bounds. Fix for the moment the mesh $\mathbf{t}$, the cubic spline interpolant L, and $\xi \in [t_0, t_n] = [a, b]$. Let

$$E(f,\xi) = f(\xi) - L(f,\xi).$$

[1] In fact the end intervals deleted operator norm rapidly approaches the value $(1 + 3\sqrt{3})/4 \approx 1.549038\cdots$ valid for C^2 cubic spline interpolation on an infinite uniform mesh (see Powell [9]).

Suppose that this error functional annihilates π_j for some $0 \le j \le 3$. The application of the Peano kernel theorem (Davis [3], Powell [9]) shows that if $f \in C^{j+1}[a,b]$, then

$$E(f,\xi) = \int_a^b f^{(j+1)}(t)K(t)dt \tag{10}$$

where

$$K(t) = \frac{1}{j!}E_x((x-t)_+^j,\xi) \tag{11}$$

and the notation $E_x((x-t)_+^j,\xi)$ means that the functional $E(\cdot,\xi)$ is applied to $(x-t)_+^j$ considered as a function of x. Because in the case we are considering, K will have only a finite number of sign changes, it follows easily from (10), (11), and smoothing arguments that

$$\sup_{\{f\in C^{j+1}[a,b]:\|f^{(j+1)}\|_\infty\le 1\}} |E(f,\xi)| = \|K\|_1,$$

or the equivalent: that the least value of C for which the relationship

$$|E(f,\xi)| \le C\|f^{(j+1)}\|_\infty$$

holds for all $f \in C^{j+1}[a,b]$ is $C = \|K\|_1$. These conclusions also hold when $C^{j+1}[a,b]$ is replaced by $W_{j+1,\infty}$.

It only remains to discuss how one can calculate K and $\|K\|_1$ numerically. First we let $\{\ell_i\}_{i=0}^n$ be the cardinal splines corresponding to the interpolant L. That is, ℓ_i is the cubic spline interpolant, $L(f)$, when $f(t_k) = \delta_{ik}$. Then for any f, ξ,

$$L(f,\xi) = \sum_{i=0}^{N} f(t_i)\ell_i(\xi)$$

and

$$E(f,\xi) = f(\xi) - \sum_{i=0}^{n} f(t_i)\ell_i(\xi).$$

Substituting from (11) it follows that

$$j!K(t) = (\xi - t)_+^j - \sum_{i=0}^{n}(t_i - t)_+^j\ell_i(\xi). \tag{12}$$

Hence for each $0 \le j \le 3$, $K(t)$ is a spline of degree j with possible knots at ξ and the t_i's, whose coefficients we can easily calculate. $\|K\|_1$ can then be calculated numerically by using a cubic root finder to find the zeroes of K and Simpson's rule to integrate $|K(t)|$ exactly over each subinterval within which it reduces to a cubic polynomial.

3.2. Computation of $\|L\|_\infty$ and $\|L'\|_\infty$. The methods of computing $\|L\|_\infty$ and $\|L'\|_\infty$ are essentially the same, so we will only give the details of the computation of $\|L'\|_\infty$.

Let Lf denote one of the cubic spline interpolants under consideration applied to the function f at the nodes $\mathbf{t} : t_0 < t_1 < \cdots < t_n$. Then assuming the map L is exact for polynomials of degree $j-1$, the derived projector $L^{(j)}$ given by

$$L^{(j)}(D^j f) = D^j(Lf)$$

is well defined. We define, as is usual, the operator norm

$$\|L^{(j)}\|_\infty = \sup_{g \in C[t_0,t_n] : \|g\|_\infty \leq 1} \|L^{(j)}(g)\|.$$

For convenience, denote $(Lf)(x)$ by $s(x)$. Assume L is exact for constants. Then considering the matrix system expressing the first derivatives of s at the knots in terms of the data, we see that the linear map from g to $L'(g)$ may be expressed as the composition of three linear maps

$$L' = E \circ P \circ S, \tag{13}$$

where $S : C[t_0, t_n] \rightarrow \mathbb{R}$ is the map taking $g = f'$ to the n-vector with ith component

$$f[t_i, t_{i+1}] = \frac{1}{t_{i+1} - t_i} \int_{t_i}^{t_{i+1}} g(t)dt.$$

$P : \mathbb{R}^n \rightarrow \mathbb{R}^{2n+1}$ is the map taking the vector $\boldsymbol{\alpha}$ to the $2n+1$ vector $\boldsymbol{\beta}$ with ith component

$$\beta_i = \begin{cases} \alpha_i, & i < n, \\ s'(t_{i-n}), & i \geq n, \end{cases}$$

and finally,

$$E : \mathbb{R}^{2n+1} \rightarrow C[t_0, t_n]$$

is the map taking $\boldsymbol{\beta}$ to the piecewise quadratic s', with specified end point and average values on each subinterval.

Because L' receives only the information about g given to it by the map S, we can rewrite (13) in a form more useful for computation. More precisely, as g ranges over

$$\{g \in C[t_0, t_n] : \|g\|_\infty \leq 1\},$$

$S(g)$ ranges over a set in $\mathbb{R}^n$ whose closure is the closed ℓ^∞ unit ball in $\mathbb{R}^n$. Hence (13) implies

$$\|L'\|_\infty = \sup_{\Omega = \{\alpha : \|\alpha\|_\infty \leq 1\}} \|(E \circ P)(\boldsymbol{\alpha})\|_\infty. \tag{14}$$

Finally, since $E \circ P(\cdot)$ is a linear function and $\|\cdot\|_\infty$ a convex function, the function whose supremum is taken on the right-hand side of (14) is convex. Hence it achieves its supremum at an extreme point of the closed, bounded, convex set Ω. This shows that for each fixed mesh $\mathbf{t}$, $\|L'\|_\infty$ can be found by a process of exhaustive search over the 2^n extreme points of Ω, computing for each extreme point the corresponding value of $\|s'\|_\infty$. Indeed, since the sign of the first slope can be fixed, without loss of generality, the search can be restricted to 2^{n-1} extreme points. We note that it is known [1] that if L reproduces cubics, then $\|L'\|_\infty$ cannot be bounded independently of $\mathbf{t}$.

The computation of $\|L\|_\infty$ is analogous to that of $\|L'\|_\infty$. In this case Ω is the ℓ^∞ unit ball in $\mathbb{R}^{n+1}$, extreme points of which correspond to function values $[f(t_0),\cdots,f(t_n)]^T$ to be interpolated. $\|L\|_\infty$ is computed by computing $\|s\|_\infty$ for 2^n of these 2^{n+1} extreme points.

3.3. Computation of $\|L''\|_\infty$. When L is exact for linear polynomials the map L'', from f'' to $L''(f'')$, is a well-defined linear map. It can be written as the composition of three linear maps

$$L'' = E \circ P \circ S.$$

Here S maps f'' to the $n-1$ vector of second divided differences $\mathbf{b}$ with

$$b_i = f[t_i, t_{i+1}, t_{i+2}] = \frac{1}{t_{i+2}-t_i}\int_{t_i}^{t_{i+2}} N_{i,2}(x) f''(x)dx.$$

P maps $\mathbf{b}$ to the vector of second derivatives $\boldsymbol{\sigma} = (s''(t_i))_{i=0}^n$ and therefore has the form $\boldsymbol{\sigma} = D\mathbf{b}$ for some $(n+1)\times(n-1)$ matrix D. Finally, E maps the vector of second derivative values $\boldsymbol{\sigma}$ to the piecewise linear interpolant s''.[2]

Since s'' is piecewise linear, $\|s''\|_\infty$ corresponds to a value of s'' at one of the knots. Hence

$$\|L''\|_\infty = \max_{0\le i\le n} \sup_{\{f: f\in L_\infty^2 \text{ and } \|f''\|_\infty \le 1\}} \left| \sum_j d_{ij} f[t_j, t_{j+1}, t_{j+2}] \right|.$$

Since values of f'' in one interval can affect two of the second differences b_i, we cannot simply choose the differences in a bang-bang way as we did in computing $\|L\|$ and $\|L'\|$. However, fixing i and writing e_j for $d_{i,j}$,

$$\begin{aligned}
s''(f;t_i) &= \sum_{j=0}^{n-2} e_j f[t_j, t_{j+1}, t_{j+2}] \\
&= \sum_{j=0}^{n-2} \frac{e_j}{t_{j+2}-t_j}\int_{t_j}^{t_{j+2}} N_{j,2}(x) f''(x)dx \\
&= \sum_{j=0}^{n-2} e_j \left[\left(\frac{t_{j+1}-t_j}{t_{j+2}-t_j}\right)\int_0^1 x f''(t_j + (t_{j+1}-t_j)x)dx \right. \\
&\qquad \left. + \left(\frac{t_{j+2}-t_{j+1}}{t_{j+2}-t_j}\right)\int_0^1 (1-x) f''(t_{j+1} + (t_{j+2}-t_{j+1})x)dx \right] \\
&= \omega_{0,2}\lambda_{0,2} + \sum_{j=1}^{n-2}(\omega_{j,1}\lambda_{j,1} + \omega_{j,2}\lambda_{j,2}) + \omega_{n-1,1}\lambda_{n-1,1},
\end{aligned}$$

[2] For the C^2 methods considered here the system for σ takes the form $A\sigma = Bb$, with A^{-1} and B bounded in the infinity norm (see, for example, [1, pp. 905–906] for explicit formulations). Hence $D = A^{-1}B$ is bounded and the relationship between second divided differences and second derivatives implies immediately that $\|L''\|_\infty \le \frac{1}{2}\|D\|_\infty < \infty$. This simple analysis provides, for example, the (not tight) upper bounds $\|L''_C\|_\infty \le 8$ and $\|L''_E\|_\infty \le 3$.

where

$$\omega_{j,2} = e_j \frac{(t_{j+1} - t_j)}{(t_{j+2} - t_j)}, \qquad \omega_{j,1} = e_{j-1} \frac{(t_{j+1} - t_j)}{(t_{j+1} - t_{j-1})},$$

and

$$\boldsymbol{\lambda}_j = \begin{bmatrix} \int_0^1 (1-x) f''(t_j + (t_{j+1} - t_j)x)dx \\ \int_0^1 x f''(t_j + (t_{j+1} - t_j)x)dx \end{bmatrix} = \begin{bmatrix} \int_0^1 (1-x) g_j(x)dx \\ \int_0^1 x g_j(x)dx \end{bmatrix}.$$

Hence defining Λ as the closed, convex set in $\mathbb{R}^2$,

$$\Lambda = \left\{ \begin{bmatrix} \lambda_1 \\ \lambda_2 \end{bmatrix} = \begin{bmatrix} \int_0^1 (1-x) g(x)dx \\ \int_0^1 x g(x)dx \end{bmatrix} : \|g\|_\infty \le 1 \right\},$$

the maximum of $s''(t_i)$ over functions f with $\|f''\| \le 1$ equals

$$\max_{\lambda_j \in \Lambda} \omega_{0,2}\lambda_{0,2} + \left(\sum_{j=1}^{n-2} (\omega_{j,1}\lambda_{j,1} + \omega_{j,2}\lambda_{j,2}) \right) + \omega_{n-1,1}\lambda_{n-1,1}. \tag{15}$$

Here the numbers $\omega_{j,k}$ depend only on the mesh $\mathbf{t}$ and the matrix D. Hence the problem (15) separates into the sum of n two-dimensional subproblems

$$\max_{\lambda \in \Lambda} \omega_{0,2}\lambda_2 + \left(\sum_{j=1}^{n-2} \max_{\lambda \in \Lambda} (\omega_{j,1}\lambda_1 + \omega_{j,2}\lambda_2) \right) + \max_{\lambda \in \Lambda} \omega_{n-1,1}\lambda_1 \ .$$

Since Λ is a closed, bounded, convex set the maxima in the subproblems occur at extreme points of Λ. Indeed the following lemma shows that the two-dimensional subproblems are trivial to solve.

LEMMA 3.1. *The set Λ defined above is the closed, bounded, convex set with boundary curves*

$$\gamma_1 = \left\{ \lambda = \begin{bmatrix} \alpha^2 - \frac{1}{2} \\ 2\alpha - \frac{1}{2} - \alpha^2 \end{bmatrix} : 0 < \alpha < 1 \right\}$$

and

$$\gamma_2 = \left\{ \lambda = \begin{bmatrix} 2\alpha - \frac{1}{2} - \alpha^2 \\ \alpha^2 - \frac{1}{2} \end{bmatrix} : 1 > \alpha > 0 \right\}$$

together with the points $A = \left(-\frac{1}{2}, -\frac{1}{2}\right)$ and $B = \left(\frac{1}{2}, \frac{1}{2}\right)$.

Proof. The proof is omitted.

Having defined Λ, we see that for each nonzero ω, $\omega^T\lambda$ is maximized at a unique point on the boundary of Λ. One can easily calculate that point. For example, when $\omega_1 > 0$, $\omega_2 < 0$, the maximum corresponds to the unique point in the interior of the lower boundary where ω is perpendicular to the tangent. Hence this maximum occurs at the point with parameter $\alpha = \omega_1/(\omega_1 - \omega_2)$. Other sign patterns for ω are dealt with similarly. This leads to a procedure for solving the two-dimensional subproblems and hence, with extra code, for computing $\|L''\|$.

INTEGRATING PRODUCTS OF B-SPLINES*

A. H. VERMEULEN†, R. H. BARTELS†, AND G. R. HEPPLER†

Abstract. This paper outlines several ways to evaluate the integral of the product of two B-spline functions, followed by a detailed description of an algorithm that is based on integration by parts. The algorithm reduces the integral to a sum of evaluations of a higher-order spline. This reduction involves differentiating one spline by differencing its coefficients, and integrating the other by summing its coefficients.

Key words. B-splines, integration, inner product, finite element method

AMS(MOS) subject classifications. 65D07, 65D30, 65N30

1. Introduction.

In this paper we consider the evaluation of integrals of the forms:

$$\int_a^b \left(\sum_i E_i B_{i,k,x}(t)\right)\left(\sum_j F_j B_{j,l,y}(t)\right) dt, \tag{1}$$

$$\int_a^b f(t)\left(\sum_i E_i B_{i,k,x}(t)\right) dt, \tag{2}$$

where $B_{i,k,x}$ is the ith B-spline of order k defined over the knots $x_i, x_{i+1}, \cdots, x_{i+k}$. We will consider B-splines normalized so that their integral is one. The splines may be of different orders and defined on different knot sequences x and y. Often the limits of integration will be the entire real line, $-\infty$ to $+\infty$. Note that (1) is a special case of (2) where $f(t)$ is a spline.

Integrals of these forms arise in applications such as the finite element method [1] and least squares function fitting [2], [3], [4] when B-splines are used as basis functions. In some problems, the function $f(t)$ in (2) may be nonpolynomial; for example, it may be a sinusoid [5]. It will be seen that the method we propose can be used to integrate such functions, provided that a sufficient number of antiderivatives of $f(t)$ are known.

There are five different methods for calculating (1) that will be considered:

1. Use Gauss quadrature on each interval.
2. Convert the integral to a linear combination of integrals of products of B-splines and provide a recurrence for integrating the product of a pair of B-splines.
3. Convert the sums of B-splines to piecewise Bézier format and integrate segment by segment using the properties of the Bernstein polynomials.
4. Express the product of a pair of B-splines as a linear combination of B-splines. Use this to reformulate the integrand as a linear combination of B-splines, and integrate term by term.
5. Integrate by parts.

Of these five, only methods 1 and 5 are suitable for calculating (2). The first four methods will be touched on and the last will be discussed at length.

2. Gauss quadrature. The integral (1) can be broken into a sum of integrals, where each integrand is a polynomial:

$$\int_a^b \left(\sum_i E_i B_{i,k,x}(t)\right)\left(\sum_j F_j B_{j,l,y}(t)\right) dt$$
$$= \sum_r \int_{t_r}^{t_{r+1}} \left(\sum_i E_i B_{i,k,x}(t)\right)\left(\sum_j F_j B_{j,l,y}(t)\right) dt,$$

where $t_1, \cdots, t_n$ is the union of the breakpoints of the two splines. Each integrand is polynomial, therefore the integrals can be computed exactly using Gauss quadrature:

$$\int_{t_r}^{t_{r+1}} e(t)f(t)dt = \sum_s H_s e(\xi_s)f(\xi_s). \tag{3}$$

The numbers ξ_s and H_s are the Gauss points and weights. Gauss quadrature can be used to approximate integrals of form (2), for general $f(t)$.

A different application of Gauss quadrature is to evaluate integrals of the form (2) by moving the summation out of the integral and integrating each term using Gauss quadrature, treating the B-spline as a weight function. If $f(t)$ is a polynomial,

$$\int_{-\infty}^{\infty} B_{i,k,x}(t)f(t)dt = \sum_s H_s f(\xi_s). \tag{4}$$

The numbers ξ_s and H_s are Gauss points and weights for the particular weighting function $B_{i,k,x}(t)$. Values for uniformly spaced B-splines are given in [6]. The Gauss points and weights must be recalculated for each different B-spline; if the basis is uniform this is not difficult, but if the basis is arbitrary then it may present a problem. This method is only capable of calculating integrals of form (1) approximately.

3. Integrating products of B-splines. The summations in (1) can be moved outside the integral to yield a linear combination of terms of the form:

$$\int_a^b B_{i,k,x}(t)B_{j,l,y}(t)dt. \tag{5}$$

In the case where integration is over the entire real line this quantity can be calculated using a recurrence [7]. If the limits are not $-\infty$ and $+\infty$ the procedure can still be used as follows. Insert enough knots [8], [9], [10] at a and b into the splines in the integrand so that no B-spline's support crosses the integration limits. Now consider only the B-splines in the integration region and integrate these over the entire real line.

The recurrence described in [7] to evaluate (5) proceeds as follows. Define the number $T_{i,j}^{k,l}$ as

$$T_{i,j}^{k,l} := (-1)^k[x_i, x_{i+1}, \cdots, x_{i+k} : t][y_j, y_{j+1}, \cdots, y_{j+l} : s](s-t)_+^{k+l+1}, \tag{6}$$

where $[x_i, x_{i+1}, \cdots, x_{i+k} : t]$ is the divided difference operator with respect to the sequence $x_i, \cdots, x_{i+k}$ acting on the variable t, and similarly for $[y_j, y_{j+1}, \cdots, y_{j+l} : s]$. It can be shown that

$$\int_{-\infty}^{\infty} B_{i,k,x}(t)B_{j,l,y}(t)dt = \frac{k!l!}{(k+l-1)!}T_{i,j}^{k,l}. \tag{7}$$

The quantities $T_{i,j}^{k,l}$ can be calculated using the definition of the divided difference and equation (6); however, this can lead to loss of significance if the knot spacing is uneven. A stable method of doing the calculation is to use the following recurrence. The recurrence begins by noting, from (6) and the divided difference definition of a B-spline, that for terms where one of $y_j = y_{j+l}$ or $x_i = x_{i+k}$ holds, $T_{i,j}^{k,l}$ is a scalar multiple of the value of a B-spline:

$$T_{i,j}^{k,l} = \begin{cases} \dfrac{(k+l-1)!}{k!l!} B_{i,k,x}(y_j), & y_j = y_{j+l}, \quad l \geq 0, \\ \dfrac{(k+l-1)!}{k!l!} B_{j,l,y}(x_i), & x_i = x_{i+k}, \quad k \geq 0. \end{cases} \tag{8}$$

Terms with higher numbers in the top indices can be calculated from terms of lower degree. The recurrence is

(9)

$$T_{i,j}^{k,l} = \begin{cases} \dfrac{(x_{i+k} - y_j)T_{i,j}^{k,l-1} + (y_{j+l} - x_{i+k})T_{i,j+1}^{k,l-1}}{y_{j+l} - y_j} + T_{i,j}^{k-1,l}, & x_{i+k} \leq y_{j+l}, \; y_j \leq y_{j+l} \\ \dfrac{(x_i - y_j)T_{i,j}^{k,l-1} + (y_{j+l} - x_i)T_{i,j+1}^{k,l-1}}{y_{j+l} - y_j} + T_{i+1,j}^{k-1,l}, & y_j \leq x_i, \qquad y_j \leq y_{j+l} \\ \dfrac{(y_j - x_i)T_{i,j}^{k-1,l} + (x_{i+k} - y_j)T_{i+1,j}^{k-1,l}}{x_{i+k} - x_i} + T_{i,j+1}^{k,l-1}, & x_i \leq y_j, \qquad x_i \leq x_{i+k} \\ \dfrac{(y_{j+l} - x_i)T_{i,j}^{k-1,l} + (x_{i+k} - y_{j+l})T_{i+1,j}^{k-1,l}}{x_{i+k} - x_i} + T_{i,j}^{k,l-1}, & y_{j+l} \leq x_{i+k}, \; x_i \leq x_{i+k}. \end{cases}$$

Thus the steps in the evaluation of (1) by this method are:

1. If necessary, insert enough knots into the two splines at the integration limits a and b, so that the support of no basis function extends past a or b.
2. Evaluate each of the splines $B_{i,k,x}$ at the points y_j and evaluate each of the splines $B_{j,l,y}$ at the points x_i.
3. Calculate the values $T_{i,j}^{k,l}$ recursively. The values obtained in step 2 provide an end to the recursion.
4. Evaluate the integral (1) by moving the summations and coefficients outside of the integral, replacing the integrals with scaled versions of $T_{i,j}^{k,l}$ according to (7), and summing over all pairs of B-splines.

4. Converting to Bézier form and integrating. The B-splines in the integrand of (1) can be converted to piecewise Bézier format and the result can be integrated segment by segment. On each segment, the B-spline combinations can be represented in Bézier form:

$$\sum_i E_i B_{i,k,x} = \sum_i G_i P_{i,k}, \tag{10}$$

$$\sum_j F_j B_{j,l,y} = \sum_j H_j P_{j,l} \,. \tag{11}$$

$P_{i,k}$ is the ith Bernstein polynomial of degree $k-1$ on the segment. The Bézier coefficients G_i and H_j can be calculated via knot insertion [8], [9], blossoming [11], or the tetrahedral algorithm of Sablonnière [12]. On each segment, the integral (1) can be expressed as a linear combination of inner products of Bernstein polynomials:

$$\int_a^b \left(\sum_i E_i B_{i,k,x}(t)\right)\left(\sum_j F_j B_{j,l,y}(t)\right) dt = \sum_i \sum_j G_i H_j \int_a^b P_{i,k}(t) P_{j,l}(t) dt. \tag{12}$$

The integrals can be evaluated using the formulae for products and integrals of Bernstein polynomials given by Farin [13]. For a segment of length L that lies in the interval (a, b), the integral evaluates to

$$\int_a^b P_{i+k}(t) P_{j,l}(t) dt = \left[\frac{(k+l-2)!i!j!(k-i-1)!(l-j-1)!}{(i+j)!(k+l-i-j-2)!(k-1)!(l-1)!(k+l)}\right] L. \tag{13}$$

5. Explicit multiplication of the integrand. The product of B-splines can be expressed as a linear combination of B-splines [14]:

$$\left(\sum_i E_i B_{i,k,x}(t)\right)\left(\sum_j F_j B_{j,l,y}(t)\right) = \sum_h G_h B_{h,p,z}(t). \tag{14}$$

The order of the product spline is $p = k + l - 1$; the knot vector z must contain sufficient knots to represent the product spline. Since the order of the product is higher than the order of the factors, yet the continuity is the same, the multiplicity of knots in the product spline is generally much higher than in the original splines. This means that there will, in general, be many more splines in the product than in either of the factors.

The procedure for constructing the knot vector z with the minimum possible number of knots will now be described. Begin by setting a single knot z_i at each point for which $z_i = x_\alpha$, a knot in x, or $z_i = y_\beta$, a knot in y. Assign multiplicity m_i to z_i as follows:

$$m_i = \begin{cases} \max(k + m_\beta - 1, l + m_\alpha - 1), & m_\alpha > 0 \quad \text{and} \quad m_\beta > 0, \\ k + m_\beta - 1, & m_\alpha = 0 \quad \text{and} \quad m_\beta > 0, \\ l + m_\alpha - 1, & m_\alpha > 0 \quad \text{and} \quad m_\beta = 0, \end{cases} \tag{15}$$

where m_α is the multiplicity of x_α and m_β is the multiplicity of y_β. Note that, if there is no knot in x at z_i or no knot in y at z_i, then either m_α or m_β will be zero.

The coefficients of the product spline are related to the coefficients of the factors via the following linear relationship [14]:

$$G_h = \sum_{i,j} \Gamma_{i,j,k,l}(h) E_i F_j. \tag{16}$$

The coefficients Γ can be calculated using the following recurrence:

$$\begin{aligned} \Gamma_{i,j,k,l}(h) = \frac{z_{h+p} - z_h}{p(z_{h+p-1} - z_h)} \Bigg(& \frac{k}{x_{i+k} - x_i} [(z_{h+p-1} - x_i)\Gamma_{i,j,k-1,l}(h) \\ & + (x_{i+k} - z_{h+p-1})\Gamma_{i+1,j,k-1,l}] \\ & + \frac{l}{y_{j+l} - y_j} [(z_{h+p-1} - y_j)\Gamma_{i,j,k,l-1}(h) \\ & + (y_{j+l} - z_{h+p-1})\Gamma_{i,j+1,k,l-1}] \Bigg). \end{aligned}$$

The recursion is initiated by specifying the values of Γ for $k = l = 1$:

(17)
$$\Gamma_{i,j,1,1}(h) = \begin{cases} \dfrac{(x_{i+1} - x_i)(y_{j+1} - y_j)}{z_{h+1} - z_h}, & x_i \leq z_h < x_{i+1} \quad \text{and} \quad y_j \leq z_h < y_{j+1}, \\ 0, & \text{otherwise.} \end{cases}$$

We can rewrite the integral (1) as:

$$\sum_{i,j,h} \Gamma_{i,j,k,l}(h) E_i F_j \int_a^b B_{h,p,z}(t)dt. \tag{18}$$

The integral of a B-spline over its entire support is one; we use this for cases where the entire B-spline support is within the limits of integration. This can be arranged by inserting knots at a and b as described previously. If the entire B-spline is not within the region of integration, the recurrence given to calculate definite integrals of B-splines described in [7] can be used, or the integrand can be converted to Bézier form and integrated as described previously.

6. Integration by parts. The final method of evaluating (1) is integration by parts.

$$\int_a^b e(t)f(t)dt = f^{(-1)}(b)e(b) - f^{(-1)}(a)e(a) - \int_a^b e^{(1)}(t)f^{(-1)}(t)dt, \tag{19}$$

where $f^{(-1)}(t)$ is the antiderivative of $f(t)$ and $e^{(1)}(t)$ is the derivative of $e(t)$. Integration by parts can be applied repeatedly to the integrand. After n applications:

$$\int_a^b e(t)f(t)dt = (-1)^n \int_a^b e^{(n)} f^{(-n)}(t)dt + \text{constant terms.} \tag{20}$$

If $e(t)$ and $f(t)$ are splines, then the degree of $e(t)$ will be lowered while the degree of $f(t)$ is raised. If we apply this enough times, $e(t)$ will be reduced to a simple enough form that its product with $f(t)$ can be integrated directly.

To apply this principle we need to recall some results relating the integration and differentiation of B-splines to Dirac delta functions.

6.1. Differentiating B-splines. The following two-term derivative formula for B-splines is well known:

$$\frac{d}{dt} B_{i,k}(t) = \frac{k}{u_{i+k} - u_i} \left[B_{i,k-1}(t) - B_{i+1,k-1}(t) \right]. \tag{21}$$

We will only concern ourselves with the case where $u_{i+k} > u_i$; thus the right side always has a nonzero denominator. When $u_{i+k-1} > u_i$ and $u_{i+k} > u_{i+1}$ the B-splines on the right side are defined in the normal way. Under the assumption that $u_{i+k} > u_i$, the only special cases that can arise are: (a) $u_{i+k-1} = u_i$ but $u_{i+k} > u_{i+1}$, for which $B_{i,k-1}(t)$ has zero support, and (b) $u_{i+k-1} > u_i$ but $u_{i+k} = u_{i+1}$, for which $B_{i+1,k-1}(t)$ has zero support.

Consider the case where

$$u_i = u_{i+1} = \cdots = u_{i+k-1} < u_{i+k}. \tag{22}$$

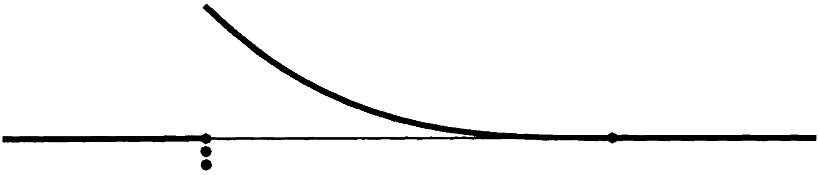

FIG. 1. *A cubic* B*-spline with a discontinuity.*

This situation is depicted for a cubic B-spline in Fig. 1. The spline $B_{i,k}$ is discontinuous at the point u_i. Specifically, with the convention that segment intervals are closed on the left,

$$B_{i,k}(u)\big|_{u<u_i} = 0, \qquad B_{i,k}(u)\big|_{u=u_i} = \frac{k}{u_{i+k} - u_i}. \tag{23}$$

Since the function is discontinuous at u_i, the derivative does not exist in the normal sense. One option is to consider only right-sided derivatives [15], [16]. With this approach splines with zero support are taken as zero. As pointed out in [16, p. 88], the problem with this option is that the Fundamental Theorem of Calculus does not hold. To see this, note that if the first Fundamental Theorem held, we would expect that

$$B_{i,k}(u) = \int_{-\infty}^{u} \frac{d}{dt} B_{i,k}(t)dt. \tag{24}$$

Substituting from (21) into the above integral, and using the definition that zero-support B-splines are to be interpreted as zero, yields

$$B_{i,k}(u) = \int_{-\infty}^{u} \frac{k}{u_{i+k} - u_i}\,[0 - B_{i+1,k-1}(t)]\,dt. \tag{25}$$

Yet at the point $u = u_{i+k}$ the left side of the equation evaluates to

$$\text{LS} = B_{i,k}(u_{i+k}) = 0, \tag{26}$$

while the right side yields (since the integral of a B-spline over its support is one)

$$\text{RS} = \int_{-\infty}^{u_{i+k}} \frac{k}{u_{i+k} - u_i}\,[0 - B_{i+1,k-1}(t)]\,dt = -\frac{k}{u_{i+k} - u_i} \neq 0. \tag{27}$$

This means that, if B-splines with zero support are taken as zero, we cannot use integration by parts to solve (1), because integration by parts is based on the Fundamental Theorem. Therefore, we will look at one of the alternative ways that B-splines with zero support have been defined.

We begin by recalling a result attributed to Curry and Schoenberg [7] that a kth order B-spline on the knots $u_i, \cdots, u_{i+k}$ can be defined as the function $B_{i,k}$, which satisfies

$$\int_{-\infty}^{\infty} B_{i,k}(t) g^{(k)}(t) dt = k! \left[u_i, u_{i+1}, \cdots, u_{i+k} : t \right] g(t) \tag{28}$$

for any function $g(t)$ with k continuous derivatives. Consider $B_{i,k}$ where $u_i = \cdots = u_{i+k} = \hat{u}$. In this case the right side of (28) becomes the kth derivative of $g(t)$ at $\hat{u}$. To be consistent, the left side must yield

$$\int_{-\infty}^{\infty} B_{i,k}(t) g^{(k)}(t) dt = g^{(k)}(\hat{u}). \tag{29}$$

Distribution theory [17], [18] provides an entity that behaves precisely as $B_{i,k}(t)$ must in this circumstance: the Dirac delta function $\delta(t-\hat{u})$. This function has the property that

$$\int_a^b \delta(t-\hat{u}) f(t) dt = \begin{cases} f(\hat{u}), & a < \hat{u} < b, \\ 0, & \hat{u} < a \text{ or } \hat{u} > b, \\ \text{undefined}, & \hat{u} = a \text{ or } \hat{u} = b \end{cases} \tag{30}$$

for any function $f(t)$ integrable on (a, b). Accordingly,

$$B_{i,k}(t) = \delta(t - \hat{u}), \quad u_i = u_{i+1} = \cdots = u_{i+k} = \hat{u}, \tag{31}$$

which is consistent with the Fundamental Theorem. Consider again the spline $B_{i,k}$ with knots as in (22). Using this definition, the two-term differentiation formula now yields

$$\frac{d}{dt} B_{i,k}(t) = \frac{k}{u_{i+k} - u_i} \left[\delta(t - \hat{u}) - B_{i+1,k-1}(t) \right]. \tag{32}$$

The revised version of (25) is

$$B_{i,k}(u) = \int_{-\infty}^{u} \frac{k}{u_{i+k} - u_i} \left[\delta(t - u_i) - B_{i+1,k-1}(t) \right]. \tag{33}$$

For $u < u_i$ or $u > u_{i+k}$ both left and right sides are zero. For $u_i < u < u_{i+k}$ we first note that the left side of (33) has polynomial form

$$\text{LS} = B_{i,k}(u) = \frac{k}{(u_{i+k} - u_i)} (u_{i+k} - u)^{k-1}. \tag{34}$$

The right side yields:

$$\text{RS} = \frac{k}{u_{i+k} - u_i} \left[\int_{\infty}^{u} \delta(t - u_i) dt - \int_{u_i}^{u} \frac{k-1}{(u_{i+k} - u_i)^{k-1}} (u_{i+k} - t)^{k-2} dt \right]. \tag{35}$$

Since $u > u_i$ the first integral has the value one. Expanding the second integral and simplifying yields

$$\text{RS} = \frac{k}{u_{i+k} - u_i} (u_{i+k} - u)^{k-1}. \tag{36}$$

Hence, the left side of (33) is equal to the right side.

The definition (31) is reasonable from another point of view as well. B-splines have been normalized to integrate to one:

$$\int_{-\infty}^{\infty} B_{i,k}(t)dt = 1. \tag{37}$$

This, too, is consistent with (30) for $f(t) = 1$.

6.1.1. Derivatives of B-spline combinations. The derivative of a linear combination of B-splines is a linear combination of B-splines of next lower order:

$$\frac{d}{dt}\sum_{i=0}^{m} V_i B_{i,k,u}(t) = \sum_{i=0}^{m+1} V_i^{(1)} B_{i,k-1,u}(t), \tag{38}$$

where the coefficients can be obtained by substituting the two-term differentiation formula into the left-hand side and shifting the summation:

$$V_i^{(1)} = \frac{k}{u_{i+k}-u_i}V_i - \frac{k}{u_{i+k-1}-u_{i-1}}V_{i-1}. \tag{39}$$

V_{-1} and V_{m+1} are defined to be zero.

6.2. Integrating B-splines. To obtain a formula for the indefinite integral of a B-spline combination, we integrate (38). This leads to this description of the indefinite integral of a B-spline combination

$$\int \sum_{i=0}^{m} V_i B_{i,k}(t) = \sum_{i=0}^{m} V_i^{(-1)} B_{i,k+1}(t), \qquad -\infty \le t < u_{m+1}, \tag{40}$$

where the coefficients are obtained by inverting (39):

$$V_i^{(-1)} = \frac{u_{i+k+1}-u_i}{k+1}\left[\frac{k+1}{u_{i+k}-u_{i-1}}V_{i-1}^{(-1)} + V_i\right]. \tag{41}$$

$V_{-1}^{(-1)}$ is defined to be zero.

The integral spline requires the existence of a new knot, u_{m+k+1}. The value of this new knot is arbitrary subject to $u_{m+k+1} \ge u_{m+k}$. Adopting the convention that knots with indices past the end of the given knot vector are equal to the last given knot can simplify implementation.

Also note that the integral spline in (40) is only valid on the interval $[-\infty, u_{m+1})$. This condition is necessary because the integral of a B-spline combination will, in general, have unbounded support. Such a function is not representable as a linear combination of a finite number of B-splines, but the portion to the left of u_{m+1} is representable in this way; hence the condition. An alternative method is to define B-spline–like basis functions that have unbounded support on one side. Suitable basis functions for this alternative are described in Barry and Goldman [19] and in de Boor, Lyche, and Schumaker [7].

6.3. The integration by parts algorithm. In this section the integration by parts algorithm will be described.

Begin by defining two splines

$$e(t) = \sum_{i=0}^{m} E_i B_{i,k,x}(t), \tag{42}$$

$$f(t) = \sum_{j=0}^{n} F_j B_{j,l,y}(t). \tag{43}$$

The integral we wish to compute is

$$\int_a^b e(t) f(t) dt. \tag{44}$$

Informally, the approach will be to use integration by parts to reduce the order of $e(t)$ while increasing the order of $f(t)$. This will reduce the support length of e's B-splines. When the support length of one of e's B-splines reaches zero, the B-spline becomes a Dirac delta function and thus the part of the integral on this basis function reduces to an evaluation of f. Eventually, all of e's B-splines will have zero support and the integral will be reduced to a sum of evaluations.

A detailed description of the algorithm is presented below. Step 0 serves to bring the integrand into a canonical form; steps 1–4 constitute the substance of the algorithm.

0. If the lower limit of integration, a, lies exactly on a knot, shift it an infinitesimal amount to the right. Similarly, if b lies exactly on a knot, shift it an infinitesimal amount to the left. This will not affect the value of the integral since the integral of a product of splines of order 1 or more varies continuously as the limits of integration are changed. The shifting of the limits is necessary to avoid the undefined condition in definition (30). In practical terms, however, such infinitesimal shifts correspond to consistently using one index ordering in making comparisons.

   Due to the formula chosen for spline integration, it is necessary that $b \leq y_{n+1}$. If this is not the case, let β be the index such that

$$y_\beta < b \leq y_{\beta+1}. \tag{45}$$

   Now add $\beta - n + 1$ knots into y, such that each of the new knots is larger than or equal to y_{n+l}. Correspondingly, increase the value of n by $\beta - n + 1$. This increases the number of basis splines used to represent $f(t)$. Since the new knots are outside the nonzero part of the spline, set the coefficients for each of the new basis splines to zero. Note that the function $f(t)$ is unchanged, but the new representation satisfies the condition that $b \leq y_{n+1}$.

   If $b = \infty$, then first replace b by $\min(y_{n+l}, x_{m+k})$. Since either $e(t)$ or $f(t)$ is zero past this point, this will not affect the value of the integral. Now adjust the representation of $f(t)$ as described above, if necessary.

   It is also required that y contain sufficient knots so that $B_{m,k+l,y}$ is defined. As previously mentioned, an easy way to implement this is to adopt the convention that added knots past the end of the given knot vector are equal to the last given knot.

1. Calculate the coefficients of $f^{(-1)}(t)$ using (41). We can now discard the coefficients of f itself and can calculate the two constant terms in the integration

by parts formula

$$\int_a^b e(t)f(t)dt = e(b)f^{(-1)}(b) - e(a)f^{(-1)}(a) - \int_a^b e^{(1)}(t)f^{(-1)}(t)dt, \tag{46}$$

leaving the integral term to be dealt with.

2. Calculate the coefficients of $e^{(1)}(t)$ using (39), and discard the coefficients of e.
3. Separate the basis splines of $e^{(1)}(t)$ into two categories: those with finite length support and those with zero length support. Let A and B be sets of integers such that:

$$i \in A \quad \text{if } 0 \le i \le m \quad \text{and} \quad x_i = x_{i+k-1}, \tag{47}$$

$$i \in B \quad \text{if } 0 \le i \le m \quad \text{and} \quad x_i < x_{i+k-1}. \tag{48}$$

The B-splines whose indices are in A are those whose support length is zero; they correspond to Dirac delta functions. We can write the spline $e^{(1)}(t)$ as

$$e^{(1)}(t) = \sum_{i\in A} E_i^{(1)}\delta(t - x_i) + \sum_{i\in B} E_i^{(1)} B_{i,k-1,x}(t). \tag{49}$$

4. Substitute (49) into the integral term in (46), noting that the integrals with delta terms reduce to function evaluations

$$\int_a^b e^{(1)}f^{(-1)}(t)dt = \sum_{i\in A} E_i^{(1)} f^{(-1)}(x_i) + \int_a^b \sum_{i\in B} E_i^{(1)} B_{i,k-1,x}(t)f^{(-1)}(t)dt. \tag{50}$$

The first set of terms require evaluations of the spline $f^{(-1)}(t)$. These terms can be calculated and added to the sum of terms calculated so far. If the set B is empty we are finished. If B is not empty then the integral term in (50) is the integral of a product of two splines. The first spline is the function $e^{(1)}(t)$ with the basis splines of zero support removed. The second is the spline $f^{(-1)}(t)$. Apply steps 1–4 recursively to this term, until all the splines in $e(t)$ are accounted for and B is reduced to the empty set.

Note that the same approach can be used to evaluate integrals of the form (2), provided that the first k antiderivatives of the function $f(t)$ can be calculated.

6.4. Computational cost. We will consider for simplicity problems of the form (1) where both splines are of order k. There are three computational components in the integration by parts algorithm:

1. Repeated differentiation of the spline $e(t)$. This step must be done k times. Each invocation takes one subtraction and one division per interval so the time spent on differentiation is on the order of k operations per segment.

2. Repeated integration of the spline $f(t)$. This step must be done k times. Each invocation takes one addition and one multiplication per interval so the time spent on antidifferentiation is also on the order of k operations per segment.

3. Evaluation of antiderivatives of the spline $f(t)$. One evaluation of an antiderivative of $f(t)$ must be done per segment; each evaluation takes on the order of k^2 operations.

The cost of the spline evaluations dominates the total computational cost. Thus the total cost is $O(k^2)$ operations per segment.

6.5. Stability. Of the three steps in the algorithm, only the third, evaluation, is unconditionally stable for all knot sequences. The other two steps, differentiation and antidifferentiation, may lead to numerical problems. It is also possible that forming the weighted sum of the evaluations may lead to loss of significance. To address these issues, a numerical comparison was made between integration by parts, Gauss quadrature, and direct evaluation of the divided difference formula (6). A similar comparison between Gauss quadrature and direct evaluation of (6) was made in [7].

The sample problem chosen was to evaluate the integral of the square of the order-k B-spline defined on the knot sequence $[5, 6, 6 + 10^{-r}, 8, \cdots, 5 + k]$. In Tables 1–3, values of $T_{0,0}^{k,k}$ are shown for r ranging from 0 to 15 for several different orders. The exact values were obtained symbolically using Maple [20]; the algorithmic results were calculated using double precision arithmetic on a DEC 5400 running Ultrix. In each result, the first significant digit in error is indicated using an underline. Note that the integration by parts algorithm is accurate to machine precision in the test case for all orders when the ratio of largest to smallest segment length is less than 10000:1; in

practical circumstances (e.g., finite elements) it is rare to see ratios this extreme. As r increases, the knots become less uniformly spaced and loss of significance becomes more pronounced in the integration by parts and divided difference algorithms. The accuracy of the divided difference scheme decreases as the order increases; it is interesting that the accuracy of the integration by parts algorithm *increases* as the order increases.

7. Comparison of the algorithms. In this section we present a brief comparison of the five methods considered for evaluation of the integral (1). We will consider for simplicity problems of the form (1) where both splines are of order k. Only rough estimates of the number of operations needed for each method are given.

The first method considered is the use of Gauss quadrature. To do the integration exactly requires evaluating each spline k times per interval. The cost of a B-spline evaluation is $O(k^2)$ operations, thus the total cost will be $O(k^3)$ operations per segment. The method exhibits no loss of significance for any order or knot sequence. Gauss quadrature extends to problems of the type given in (2).

The second method formulated the integrand as a linear combination of products of B-splines and used the recurrence given by de Boor, Lyche, and Schumaker [7] to calculate the integral of each B-spline pair. Each invocation of this recurrence requires $O(k^3)$ operations [7], and the recurrence must be carried out k times per segment, so the total cost is on the order of $O(k^4)$ operations per segment. The chief advantage of this approach is that it is very stable numerically. The disadvantages are that the recurrence is complicated, the approach does not extend to problems of the type given in (2), and this is the most expensive approach considered. It is worth noting that if a large number of integrations needs to be done using splines with the same bases but different coefficients, the inner products of the B-splines could be precalculated, thus reducing the computational expense.

The third method converted the splines to piecewise Bézier format and integrated segment by segment. To convert to Bézier format, we must compute the k Bézier coefficients on each segment. The calculation of these coefficients carries approximately the same price as the evaluation of a B-spline value, which is $k(k-1)/2$ linear combination operations. Thus the cost of converting both splines is about $k(k-1)$ linear combinations per segment. After the coefficients are obtained, we must calculate a weighted sum of all possible inner products of Bernstein polynomials on each interval. There are k^2 such inner products for two splines of order k. Thus the total cost of this method is of order $O(k^2)$. This algorithm cannot be extended to problems of the form (2).

The fourth method represented the integrand as a linear combination of B-splines. This involved the computation of numbers relating the coefficients of the factor splines to the coefficients of the product spline. It can be shown that these coefficients, Γ, are a generalization of the discrete B-splines. In fact, the computation of the Γ implicitly computes the discrete B-splines necessary to convert the splines to Bézier form. Thus we conclude that this method is at least as expensive as method 2. This algorithm also cannot be extended to problems of the form (2).

The final method is the integration by parts algorithm. Although it is not as stable as the other methods, good accuracy is obtained for reasonable knot vectors. The integration by parts method, in our implementation, is less expensive than the other methods; approximately three times as fast as Gauss quadrature for cubics, and about eight times as fast for degree 10 splines. In terms of order of operations, the method requires $O(k^2)$ operations, the same as the conversion to Bézier method and less than the other methods. In addition, this algorithm is extensible to problems of the form (2), provided that a sufficient number of antiderivatives of the function $f(t)$ can be calculated.

In conclusion, the integration by parts method is less expensive than the other methods considered, provides accurate results for reasonably uniform knot vectors, and generalizes to problems of the form (2).

ONE-STAGE PARALLEL METHODS FOR THE NUMERICAL SOLUTION OF ORDINARY DIFFERENTIAL EQUATIONS*

H. W. TAM†

Abstract. This paper studies one-stage block methods for solving the numerical solution of ordinary differential equations (ODEs) in parallel, and a new family of one-stage methods is introduced. Each member in this family has a stability region equal to the interior of that of the Euler method, together with the origin. Thus the stability regions remain unchanged as the order is increased. These methods lead to the discovery of a specific approach in deriving parallel ODE methods with good stability regions; zero-stable block methods with perfect power stability polynomials are considered. It is also found that the coupling between the equations of individual time points for block methods must be taken into account. The coupling between time points restricts the use of the new one-stage parallel methods. By a modification of the method parameters, this coupling effect is eliminated. The resulting one-stage parallel methods outperform the Adams-Bashforth methods in both stability and accuracy.

1. Introduction. We study parallel methods for the numerical solution of the ordinary differential equation (ODE)

$$y(t_0)=\eta,$$
$$y'(t)=f(y(t)), \qquad t_0\leqq t\leqq t_{\text{out}},$$

where y and $f\in\mathcal{R}^n$. A nonautonomous ODE of the form $z'(t)=f(t, z(t))$ can always be written in the above autonomous form. Hence the above form involves no loss of generality.

Depending on the nature of the applications, existing ODE methods can be classified into stiff and nonstiff categories. A method suitable for stiff ODEs is usually implicit, which means that systems of linear equations of the form $[I-h\beta_0 J_n]x=y$ must be solved. Since the time spent on these linear systems usually dominates the overall computing time, a good speedup for stiff ODE problems can be achieved by performing the linear algebra in parallel. For nonstiff ODEs, we can exploit parallelism by evaluating function values simultaneously. The research for parallel methods in this category is still in its infancy. In this paper we focus on parallel nonstiff methods.

Stability and accuracy are the main considerations in deriving good ODE methods. It is fairly easy to derive sequential methods of good accuracy, e.g., in multistep methods we merely interpolate enough previous information to obtain the desired order. The same approach can be applied to parallel ODE methods. It is, however, the relatively small stability regions of many methods that constrain their usefulness. The main concern of this paper is to obtain parallel methods with good stability.

A detailed study on the effect of stability on the potential for parallelism for ODEs has been done in [17]. We give a brief review here on some of the key ideas in that paper, starting with the following definitions.

DEFINITION 1.1. A *stage* of a method is a set of function evaluations performed in parallel (assuming there is an unlimited number of processors).

DEFINITION 1.2. The *stage number m* of a (parallel or serial) method is defined to be the number of stages (parallel or serial function evaluations) per step in the method.

DEFINITION 1.3. The *scaled stability region* of a method is defined to be

$$\frac{1}{m}S=\left\{\frac{1}{m}\mu\colon \mu\in S\right\},$$

where S is the stability region of the method and m is the stage number.

Since different methods have different numbers of stages, it is the scaled stability region that is appropriate for the comparison of stability properties of different methods.

DEFINITION 1.4. An *optimal* scaled stability region is one that cannot be properly contained in that of another method.

Optimality [12] is a desired condition for a method because there always exists a problem for which the method performs best due to its superior stability.

Roughly speaking, optimality theory [17] for parallel methods shows that if the scaled stability region of a serial method is optimal, it is still optimal among parallel and serial methods combined. Thus in the sense of optimal scaled stability regions, parallelism does not give any improvement. Due to the existence of optimal scaled stability regions among many ODE methods, numerous authors have proposed [12], [14], [5], [6] using instead the largest disk passing through the origin that can be inscribed into the scaled stability region of a method. Jeltsch and Nevanlinna [12] have demonstrated that such a measure is reasonable because the disks appear in an important way in the theory of error propagation for nonlinear problems. Again using optimality theory, we can prove that the largest disk that can be inscribed into a scaled stability region is the unit circle, for both parallel and serial methods. In this sense, the Euler method (the simplest serial method) has the best stability region. Unless otherwise noted, we will use the radius of the largest disk as a measure of how good the scaled stability region of a method is.

Although the above summary states that the largest scaled stability region a parallel ODE method can possibly have is the unit circle, there is no restriction on the order of such a method. The hope for success in finding good parallel methods is to find parallel methods with scaled stability regions that approach those of good (optimal) serial methods, such as the Euler method, but with higher order (or with significantly smaller error constants than serial methods of the same order). Alternatively, for a parallel and a serial ODE method of the same order, we would like to have a larger scaled stability region for the parallel method.

Existing work on finding parallel ODE methods with good stability properties has been unsatisfactory. In fact, many proposed parallel methods have smaller scaled stability regions than the Adams PECE method of the same order [17]. In this paper we study one-stage parallel ODE methods with good stability properties. In § 2 we introduce a two-processor, one-stage block method whose stability region is essentially that of the Euler method: the theoretical limit discussed above for a one-stage method, but now with an order equal to 2. This two-processor method can be generalized to higher orders. This new family of one-stage methods illustrates an important approach in deriving parallel methods with outstanding stability regions; we consider *zero-stable block methods with perfect power stability polynomials.* Methods with this property have an unchanged stability region as the order increases. This is an unconventional characteristic because the stability regions of existing methods all shrink as one raises the order. Although this family of one-stage methods is of restricted usage due to a phenomenon in block methods not seen before, the above specific approach nevertheless leads to the development of a successful family of two-stage methods that outperforms the Adams PECE methods by a sizeable margin. This two-stage family is described in an associated paper [18].

We show that conventional local error analysis is inadequate to predict the performance of the new one-stage parallel methods. For block methods we also need to take into account the coupling between time points, the effect of which appears in global errors. Although the local errors of these new parallel methods look reasonable in the sense of traditional multistep methods, global error analysis indicates that there is an accelerated error growth for eigenvalues along the imaginary axis of the $h\lambda$-plane. The details of the global error analysis will be studied in § 3. Despite the accelerated error growth, the new methods are the starting point from which useful one-stage parallel methods can be derived. In § 4 we will show that a slight variation of the above-mentioned methods yields one-stage parallel methods that outperform one-stage serial methods like the Adams–Bashforth methods. In § 5 we consider the effect of varying the spacing between time points within a block. It turns out that a nonuniform spacing has no benefit. Finally, numerical results are presented in § 6.

2. Derivation of a new one-stage method.

The discussion in § 1 states that the largest disk passing through the origin that can be inscribed into the scaled stability region of a (parallel or sequential) method is the unit circle centered at $(-1, 0)$. Any m-stage one-step method having the stability polynomial

$$\xi-\left(1+\frac{\mu}{m}\right)^m$$

possesses this scaled stability region. Such a stability polynomial may come from any variety of Runge–Kutta methods, e.g., a sequence of m identical Euler steps, each of length $\frac{h}{m}$ [10], or from a one-step method using higher derivatives [10]. The polynomial can also be realized by a method consisting of a predictor and $m-1$ correctors [12]. However, all these methods are of order one. Jeltsch and Nevanlinna [12] have shown that there exist explicit linear multistep methods of any order whose scaled stability regions can be made arbitrarily close to the unit circle, but the error coefficients also grow arbitrarily large, rendering these methods useless. Since the scaled stability regions of parallel methods are also limited by the unit circle, a natural question arises: "Can one obtain a parallel method of order-2 or higher with scaled stability region equal to (or close to) the unit circle?" Our goal is to find an order-2 or higher parallel method whose scaled stability region is close to that of Euler's method. In this paper we consider candidate methods with multiple saved values. Perhaps the simplest method of this nature is a one-stage block method that computes two new solution values from two previous solution values and their derivatives.

Let h be the stepsize (by which we mean the length of a block) for a block of two saved values y_n and $y_{n+1/2}$. In each computation step new values y_{n+1} and $y_{n+3/2}$ are calculated from y_n, $y_{n+1/2}$, $f_m=f(t_m, y_m)$, and $m=n$, $n+\frac{1}{2}$, as shown in Fig. 1. The stepsize h is the actual distance in t advanced per parallel function evaluation. (When we compare the performance of a block method to that of a serial method, the maximum allowable stepsize of the block method and the maximum allowable stepsize of the serial method per work unit for a fixed tolerance are the correct comparison quantities.) There are numerous ways to compute y_{n+1} and $y_{n+3/2}$ from y_n, $y_{n+1/2}$, f_n, and $f_{n+1/2}$ while maintaining second-order accuracy.

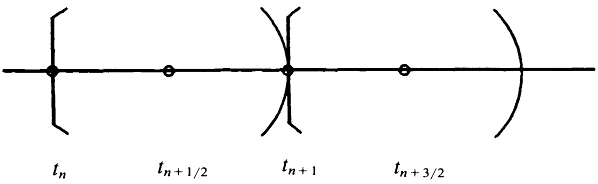

FIG. 1. *A simple block method.*

An example of an integration-based formula is given by

$$y_{n+1}=y_n+\int_{t_n}^{t_{n+1}} f_{n+1/2}+(t-t_{n+1/2})f_{n+1/2,n}\,dt=y_n+hf_{n+1/2}, \tag{2.1}$$

where $f_{n+1/2,n}$ is the backward divided difference involving $f_{n+1/2}$ and f_n. Alternatively, we can compute y_{n+1} from $y_{n+1/2}$, f_n, and $f_{n+1/2}$, and similarly in two ways for $y_{n+3/2}$. Taking a linear combination of the two equations for y_{n+1} and another linear combination of the two equations for $y_{n+3/2}$, we obtain a block method with two free parameters:

$$\begin{bmatrix} y_{n+3/2} \\ y_{n+1} \end{bmatrix}=\begin{bmatrix} 1-b & b \\ 1-a & a \end{bmatrix}\begin{bmatrix} y_{n+1/2} \\ y_n \end{bmatrix}+h\begin{bmatrix} 2+b/4 & -1+b/4 \\ \frac{3}{4}+a/4 & -\frac{1}{4}+a/4 \end{bmatrix}\begin{bmatrix} f_{n+1/2} \\ f_n \end{bmatrix}. \tag{2.2}$$

Equation (2.2) is the general second-order block method one obtained from the given previous values. Equation (2.2) can, of course, be derived from, e.g., the method of undetermined coefficients. However, an integration-based derivation paves the way for a variable stepsize extension.

We can manipulate free parameters a and b in (2.2) to obtain a good stability region. Of particular interest is the case $a=1$, $b=0$, giving

$$\begin{bmatrix} y_{n+3/2} \\ y_{n+1} \end{bmatrix}=\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} y_{n+1/2} \\ y_n \end{bmatrix}+h\begin{bmatrix} 2 & -1 \\ 1 & 0 \end{bmatrix}\begin{bmatrix} f_{n+1/2} \\ f_n \end{bmatrix}. \tag{2.3}$$

After applying (2.3) to the test problem $y'=\lambda y$, standard techniques give the stability polynomial

$$[\xi-(1+\mu)]^2,$$

where $\mu=h\lambda$. Conversely, the stability polynomial of (2.2) is such a perfect square only when $a=1$ and $b=0$. Conventionally, we do not consider methods having a perfect power stability polynomial because of the possible lack of zero stability. The lack of zero stability means that roundoff errors are amplified for the degenerate integration problem $y'(t)=f(t)$. However, (2.3) shows that when applied to the problem $y'=0$, the solution values remain unchanged.

In order to study the stability region of (2.4), we apply (2.3) to the test problem $y'=\lambda y$, $y(0)=1$ with exact initial values $y_0=1$, $y_{1/2}=e^{h\lambda/2}$, getting

$$\begin{aligned} \begin{bmatrix} y_{n+1/2} \\ y_n \end{bmatrix} &= \begin{bmatrix} 1+2\mu & -\mu \\ \mu & 1 \end{bmatrix}^n \begin{bmatrix} y_{1/2} \\ y_0 \end{bmatrix} \\ &= \begin{bmatrix} 1 & 1+\mu \\ 1 & \mu \end{bmatrix}\begin{bmatrix} 1+\mu & \mu \\ 0 & 1+\mu \end{bmatrix}^n \begin{bmatrix} 1 & 1+\mu \\ 1 & \mu \end{bmatrix}^{-1}\begin{bmatrix} y_{1/2} \\ y_0 \end{bmatrix} \\ &= \begin{bmatrix} (1+\mu)^n+n\mu(1+\mu)^{n-1} & -n\mu(1+\mu)^{n-1} \\ n\mu(1+\mu)^{n-1} & (1+\mu)^n-n\mu(1+\mu)^{n-1} \end{bmatrix}\begin{bmatrix} y_{1/2} \\ y_0 \end{bmatrix}. \end{aligned} \tag{2.4}$$

Equation (2.4) shows that any point on the boundary of the unit disk other than the origin is unstable. Therefore the stability region of (2.3) contains the interior of the unit disk $\{\mu : |1+\mu| \leqq 1\}$ together with the origin.

With $t = nh$, (2.4) gives

$$\begin{aligned} y_n &= (1+\mu)^n \left[y_0 + \frac{n\mu}{(1+\mu)} (y_{1/2} - y_0) \right] \\ &= e^{n \log(1+\mu)} \left[1 + \frac{\lambda t}{(1+\mu)} (e^{h\lambda/2} - 1) \right] \\ &= e^{\lambda t} \cdot e^{(-h\lambda^2 t/2 + \mathcal{O}(h^2\lambda^3 t))} \left[1 + \frac{h\lambda^2 t}{2} + \mathcal{O}(h^2 \lambda^3 t) \right] \\ &= e^{\lambda t} \left[1 - \frac{h\lambda^2 t}{2} + \cdots \right] \left[1 + \frac{h\lambda^2 t}{2} + \cdots \right]. \end{aligned}$$

A similar expansion can be obtained for $y_{n+1/2}$. This demonstrates how the method (2.3) achieves second order. In essence, the term $n\mu(1+\mu)^{n-1}$ is being used to remove the dominant error term in $(1+\mu)^n$ as an approximation to $(e^{\mu})^n$.

The algebraic order p_a of an ODE method is defined by the largest real number p_a such that

$$p_1(\mu) - e^{\mu} = c\mu^{p_a+1} + \mathcal{O}(\mu^{p_a+2}), \qquad c \neq 0,$$

for some principal branch $p_1(\mu)$ of the algebraic function satisfying the stability polynomial of the method. Classical methods such as linear multistep, multiderivative methods, and Runge-Kutta methods have the property that $p \leqq p_a$, where p is the consistency order of the method. The algebraic order of (2.3) (here $p_1(\mu) = 1+\mu$) is only 1, but local error analysis indicates that (2.3) is of consistency order-2. This unusual phenomenon is possible because the stability matrix of (2.4) is defective. We believe that $p > p_a$ is possible only when the stability matrix of the underlying method is defective.

The parallel method (2.3) falls just short of our goal of finding a second-order method whose stability region is the unit disk $\{\mu : |1+\mu| \leqq 1\}$, although only the arc $\xi = -1 + e^{i\theta}$, $0 < \theta < 2\pi$ is unstable. We do not know whether one can improve the stability region of a second-order parallel method beyond that of (2.3).

We can generalize (2.3) to higher-order methods while retaining the same stability properties. By using polynomials interpolating f_n, $f_{n+1/3}$, $f_{n+2/3}$, and the appropriate y_n, $y_{n+1/3}$, $y_{n+2/3}$, we obtain the third-order method

$$\begin{aligned} \begin{bmatrix} y_{n+5/3} \\ y_{n+4/3} \\ y_{n+1} \end{bmatrix} &= \begin{bmatrix} 1-c_1-c_2 & c_2 & c_1 \\ 1-b_1-b_2 & b_2 & b_1 \\ 1-a_1-a_2 & a_2 & a_1 \end{bmatrix} \begin{bmatrix} y_{n+2/3} \\ y_{n+1/3} \\ y_n \end{bmatrix} \\ &+ h \begin{bmatrix} \frac{19}{4} + c_1/9 + 5c_2/36 & -6 + 4c_1/9 + 2c_2/9 & \frac{9}{4} + c_1/9 - c_2/36 \\ \frac{19}{9} + b_1/9 + 5b_2/36 & -\frac{20}{9} + 4b_1/9 + 2b_2/9 & \frac{7}{9} + b_1/9 - b_2/36 \\ \frac{23}{36} + a_1/9 + 5a_2/36 & -\frac{4}{9} + 4a_1/9 + 2a_2/9 & \frac{5}{36} + a_1/9 - a_2/36 \end{bmatrix} \begin{bmatrix} f_{n+2/3} \\ f_{n+1/3} \\ f_n \end{bmatrix}. \end{aligned} \tag{2.5}$$

For $a_1 = 1$, $a_2 = 0$, $b_1 = 0$, $b_2 = 1$, $c_1 = 0$, and $c_2 = 0$, (2.5) becomes

$$\begin{bmatrix} y_{n+5/3} \\ y_{n+4/3} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} y_{n+2/3} \\ y_{n+1/3} \\ y_n \end{bmatrix} + h \begin{bmatrix} \frac{19}{4} & -6 & \frac{9}{4} \\ \frac{9}{4} & -2 & \frac{3}{4} \\ \frac{3}{4} & 0 & \frac{1}{4} \end{bmatrix} \begin{bmatrix} f_{n+2/3} \\ f_{n+1/3} \\ f_n \end{bmatrix}, \tag{2.6}$$

whose stability polynomial is

$$[\xi-(1+\mu)]^3.$$

The stability region of (2.6) is again the interior of the unit disk together with the origin. It is now obvious that the same procedure can lead to a qth-order method whose stability polynomial is $[\xi-(1+\mu)]^q$. Note that the qth-order method requires q processors in parallel. Henceforth we call the extension of (2.5) to q processors a q-processor block method and denote it by

$$Y_{n+1}=A_q Y_n + hB_q F_n. \tag{2.7}$$

Although (2.3) and (2.6) have the same stability region, the method (2.3) is nonetheless more stable in the following sense. Equation (2.4) shows that, when applied to the problem $y'=\lambda y$, the solution values y_n and $y_{n+1/2}$ of (2.3) consist of terms $(1+\mu)^n$ and $n\mu(1+\mu)^{n-1}$ multiplied by the initial values y_0 and $y_{1/2}$. The term $(1+\mu)^n$ behaves nicely for $|(1+\mu)|\leqq 1$. For $\mu=-2+\varepsilon$, $\varepsilon>0$, the term $n\mu(1+\mu)^{n-1}$ increases slowly before the effect of $n\mu$ is being annihilated by $(1+\mu)^{n-1}$ as n increases. The corresponding propagation matrix of (2.6) involves a term $n^2\mu^2(1+\mu)^{n-2}$ with even larger magnifying power than $n\mu(1+\mu)^{n-1}$ near the boundary of the unit circle. It is in this sense that the two-processor method is more stable than the three-processor method.

The above family of one-stage methods illustrates a simple but important approach in deriving parallel ODE methods with good stability properties; we consider zero-stable block methods with perfect power stability polynomials. Many proposed block methods contain arbitrary parameters with which we can manipulate the stability polynomials [15], [1], [4]. However, it is not usually possible to manipulate the method parameters so that the resulting stability polynomials are in the form of perfect powers of simple polynomials. As an example, let us consider a two-processor, two-block method (see Fig. 2), where the values $y_{n+3/2}$ and y_{n+1} of a new block are computed from the y and f values in two previous blocks. Using a derivation similar to that of (2.2), we can obtain the following fourth-order method with two free parameters.

Example 2.1. It holds that

$$\begin{aligned}\begin{bmatrix} y_{n+3/2} \\ y_{n+1}\end{bmatrix} &= \begin{bmatrix} 1-b & b \\ 1-a & a\end{bmatrix}\begin{bmatrix} y_{n+1/2} \\ y_n\end{bmatrix} + h\begin{bmatrix} \frac{9}{2}+3b/16 & -\frac{22}{3}+19b/48 \\ \frac{55}{48}+3a/16 & -\frac{59}{48}+19a/48\end{bmatrix}\begin{bmatrix} f_{n+1/2} \\ f_n\end{bmatrix} \\ &\quad + h\begin{bmatrix} \frac{31}{6}-5b/48 & -\frac{4}{3}+b/48 \\ \frac{37}{48}-5a/48 & -\frac{3}{16}+a/48\end{bmatrix}\begin{bmatrix} f_{n-1/2} \\ f_{n-1}\end{bmatrix}.\end{aligned} \tag{2.8}$$

There is no way to make the stability polynomial of (2.8) a perfect square for any choice of a and b. For the set $a=1$, $b=0$, the stability region is rather small (Fig. 3), with a stability interval equal to -0.18. Equation (2.8) is a simple method in the class of the multiblock methods of Chu and Hamilton [4]. Equation (2.8) is an example of a badly designed parallel method with a very small stability region (compared to the Adams–Bashforth method of the same order). Many existing parallel methods suffer from the weakness of having small stability regions [15], [7], [4], [1], so that their use

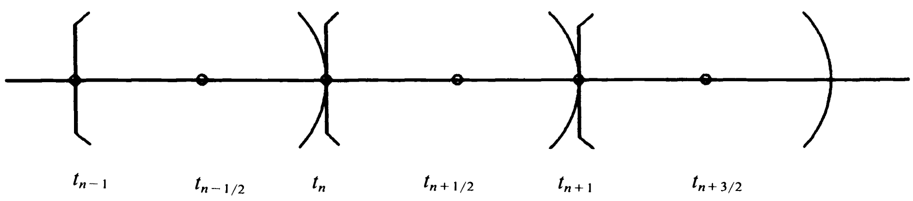

FIG. 2. *A two-block two-processor method.*

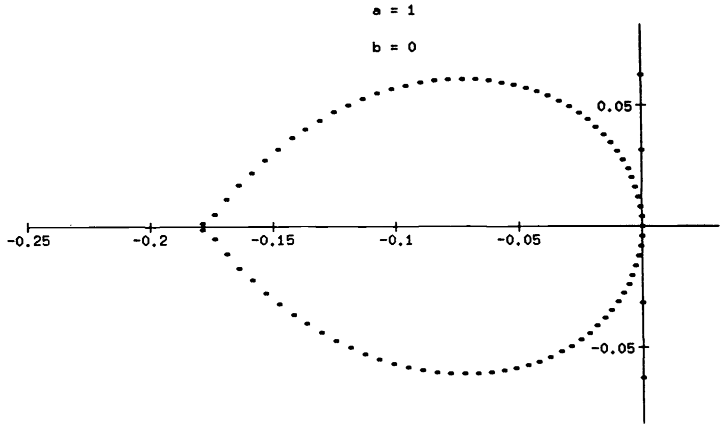

FIG. 3. *Stability region of Example* 2.1.

is limited to accuracy-bound applications. We believe, however, that the right combination of order, number of stored values, and method parameters will yield a parallel method with a good stability region. By choosing an appropriate order and number of stored values for the formula, we can derive useful zero-stable multiblock methods with stability polynomials equal to perfect powers of simple ones (see [17, Chap. 5]).

The one-stage block methods suggested in this section unfortunately have a drawback: due to coupling between time points, they are not accurate enough for eigenvalues along the imaginary axis of the $h\lambda$-plane. This drawback is significant for problems with natural frequencies on the imaginary axis that demand fairly high accuracy. An alternate approach is to have a different choice of the method parameters $a, b, \cdots$. The abnormal error behavior will be discussed in § 3 and the alternate approach in § 4.

3. Global error analysis of the block method. The local truncation error of the q-processor block method (2.7) is defined to be

$$\mathbf{d}_{n+1} = A_q Y(t_n) + hB_q f(Y(t_n)) - Y(t_{n+1}),$$

where $Y(t_n)$ is the exact solution $[y(t_{n+(q-1/q)}), \cdots, y(t_n)]^T$ of the given ODE. For the two-processor case,

$$\mathbf{d}_{n+1} = \begin{bmatrix} \dfrac{b-28}{96} h^3 y'''(\xi_1) \\ \dfrac{a-5}{96} h^3 y'''(\xi_2) \end{bmatrix}. \tag{3.1}$$

For comparison, the Euler method and the second-order Adams-Bashforth method have local errors $-\frac{1}{2}h^2 y''(\xi)$ and $-\frac{5}{12}h^3 y'''(\xi)$, respectively. Even though the individual components of (3.1) for $a=1$ and $b=0$ are smaller than that of the second-order Adams-Bashforth method, we should not be deceived by the behavior of (3.1). There is a classical theory in linear multistep methods (at least in the case of nonstiff ODEs) that relates the local error and global error. For the test problem $y' = \lambda y$, $y(0) = 1$, the second-order Adams-Bashforth method has a global error

$$y_n - y(t_n) = -\tfrac{5}{12}h^2 \int_0^{t_n} e^{(t_n - t)\lambda} y'''(t)\, dt + \mathcal{O}(h^3), \tag{3.2}$$

where $y(t)$ is the exact solution of the ODE. Note that the coefficient $-\frac{5}{12}$ of the local error is also that of the global error. For a block method, the individual equations for different time points may interact in a strange way so that the resulting global error has an unexpected growth. In this section we study the global error behavior of the method (2.3).

In linear multistep methods it is well known that an order-q method has a global error behaving like $\mathcal{O}(h^q)$. This relationship between the local error and global error extends to block methods. (See [9, Thm. 9.1].) Since the stability polynomial of (2.3) has no extraneous root at $\mu = 0$, if the given ODE has enough derivatives, (2.3) satisfies

$$\begin{bmatrix} y_{n+3/2} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} y(t_{n+3/2}) \\ y(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^2\, e_1(t_{n+3/2}) \\ h^2\, e_2(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^3 g_1(t_{n+3/2}) \\ h^3 g_2(t_{n+1}) \end{bmatrix} + \mathcal{O}(h^4), \tag{3.3}$$

where $e_1(t)$, $e_2(t)$, $g_1(t)$, and $g_2(t)$ are differentiable.

It is possible to explicitly determine the principal error functions $e_1(t)$ and $e_2(t)$. We first substitute (3.3) into the difference equation (2.3) and subtract both sides from the Taylor series

$$\begin{bmatrix} y(t_{n+3/2}) \\ y(t_{n+1}) \end{bmatrix} = \begin{bmatrix} y(t_{n+1/2}) \\ y(t_n) \end{bmatrix} + \begin{bmatrix} hy'(t_{n+1/2}) \\ hy'(t_n) \end{bmatrix} + \begin{bmatrix} \dfrac{h^2}{2} y''(t_{n+1/2}) \\ \dfrac{h^2}{2} y''(t_n) \end{bmatrix} + \begin{bmatrix} \dfrac{h^3}{6} y'''(t_{n+1/2}) \\ \dfrac{h^3}{6} y'''(t_n) \end{bmatrix} + \mathcal{O}(h^4).$$

Now expand every term in powers of h at the point t_n. The $\mathcal{O}(1)$, $\mathcal{O}(h)$, and $\mathcal{O}(h^2)$ terms on both sides of the resulting equation cancel each other. Dividing by h^3 yields

$$e_1'(t_n) = -\tfrac{7}{24} y'''(t_n) + f_y(y(t_n))[2e_1(t_n) - e_2(t_n)] + \mathcal{O}(h) \tag{3.4}$$

and

$$e_2'(t_n) = -\tfrac{1}{24} y'''(t_n) + f_y(y(t_n))\, e_1(t_n) + \mathcal{O}(h). \tag{3.5}$$

By assumption, (3.4) and (3.5) are true for any fixed value of t_n as $h \to 0$. Therefore one can drop the subscript n so that each of these equations holds for all values of t. Thus we have arrived at a set of ODEs from which $e_1(t)$ and $e_2(t)$ can be determined as follows:

$$\begin{bmatrix} e_1'(t) \\ e_2'(t) \end{bmatrix} = f_y(y(t)) \begin{bmatrix} 2 & -1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix} - \begin{bmatrix} \frac{7}{24} \\ \frac{1}{24} \end{bmatrix} y'''(t). \tag{3.6}$$

(Note that the coefficient matrix of the method (2.3), together with its local error (3.1), reappears in (3.6).)

If we use exact initial values for $y_{1/2}$ and y_0, set $n+1=0$ in (3.3), express every term in Taylor series at $t = t_0$, and equate coefficients of $\mathcal{O}(h^2)$, we obtain $e_1(t_0) = e_2(t_0) = 0$.

By making the transformation

$$\begin{bmatrix} \tilde{e}_1(t) \\ \tilde{e}_2(t) \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix},$$

equation (3.6) becomes

$$\begin{bmatrix} \tilde{e}_1'(t) \\ \tilde{e}_2'(t) \end{bmatrix} = f_y(y(t)) \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \tilde{e}_1(t) \\ \tilde{e}_2(t) \end{bmatrix} + \begin{bmatrix} -\frac{1}{24} \\ -\frac{1}{4} \end{bmatrix} y'''(t),$$

which, together with the initial condition $\tilde{e}_1(t_0) = \tilde{e}_2(t_0) = 0$, determines the solution

$$\tilde{e}_2(t) = -\tfrac{1}{4}\int_{t_0}^{t} G(t,s)y'''(s)\,ds,$$

$$\tilde{e}_1(t) = -\tfrac{1}{24}\int_{t_0}^{t} G(t,s)y'''(s)\,ds + \int_{t_0}^{t} G(t,s)f_y(y(s))\tilde{e}_2(s)\,ds,$$

where $G(t,s)$ satisfies

$$\frac{\partial G(t,s)}{\partial t} = f_y(y(t))G(t,s), \qquad G(t,t) = I.$$

When applied to the test problem $y' = \lambda y$, $y(0) = 1$, $\lambda = \text{constant}$, we have $G(t,s) = e^{(t-s)\lambda}$, so that

$$\tilde{e}_2(t) = -\tfrac{1}{4}\int_{0}^{t} e^{(t-s)\lambda}\,y'''(s)\,ds,$$

which is similar to the global error function (3.2) of the second-order Adams-Bashforth method. However,

$$\tilde{e}_1(t) = \int_0^t e^{(t-s)\lambda}\left[-\frac{1}{24} - \frac{(t-s)\lambda}{4}\right]\lambda^3\,e^{\lambda s}\,ds = e^{t\lambda}\left[-\frac{t}{24} - \frac{t^2\lambda}{8}\right]\lambda^3.$$

If $\lambda = -1$, then $\tilde{e}_1(t) = -e^{-t}[-(t/24) + t^2/8]$ and the growth of t^2 is damped by e^{-t}. When $\lambda = i$,

$$\tilde{e}_1(t) = e^{it}\left[-\frac{t}{24} - \frac{t^2 i}{8}\right]i^3$$

and the growth of t^2 is undamped. The above global error analysis demonstrates that (2.3) has good accuracy for eigenvalues on the negative real axis. For eigenvalues along the imaginary axis, the effective error constant is of order $\mathcal{O}(t^2)$, as compared to a customary $\mathcal{O}(t)$ for a normal serial method. The corresponding global error expression for the q-processor block method with stability polynomial $[\xi - (1+\mu)]^q$ contains a leading term of order $\mathcal{O}(t^q)\cdot e^{\lambda t}$.

We can demonstrate that the global error of the method (2.3), when applied to the model problem $y' = \lambda y$, $y(0) = 1$, can be expressed in the form

$$y_n - y(t_n) = e^{\lambda t_n}\{h^2[-\tfrac{1}{8}\lambda^4 t_n^2 - \tfrac{1}{24}\lambda^3 t_n] + h^3[\tfrac{1}{24}\lambda^6 t_n^3 + \tfrac{3}{16}\lambda^5 t_n^2 + \tfrac{7}{48}\lambda^4 t_n] + \cdots\}.$$

For comparison, the Euler method has a global error of the form

$$y_n - y(t_n) = e^{\lambda t_n}\{-\tfrac{1}{2}h\lambda^2 t_n + h^2[\tfrac{1}{8}\lambda^4 t_n^2 + \tfrac{1}{3}\lambda^3 t_n] + h^3[-\tfrac{1}{48}\lambda^6 t_n^3 - \tfrac{1}{6}\lambda^5 t_n^2 - \tfrac{1}{4}\lambda^4 t_n] + \cdots\},$$

while that of the second-order Adams-Bashforth method is given by

$$y_n - y(t_n) = e^{\lambda t_n}\{-\tfrac{5}{12}h^2\lambda^3 t_n + \tfrac{1}{4}h^3\lambda^4 t_n + \cdots\}.$$

Thus (2.3) is indeed more accurate than the Euler method by considering the $\mathcal{O}(h)$ and $\mathcal{O}(h^2)$ terms in the global errors. The $\mathcal{O}(h^2)$ term in the global error of (2.3) is worse than that of the second-order Adams-Bashforth methods. However, when $|\lambda t_n| < 1$, the method (2.3) has a global error comparable to that of the second-order Adams-Bashforth method, but with much better stability properties. Therefore the consequence of the accelerated error growth of (2.3) is a restriction on the length of the integration interval.

The previous paragraph suggests that a remedy to the accelerated error growth is to restart the method (2.3) every n_s steps for some n_s. As $n_s \to \infty$, the scaled stability region of this restarted method approaches the unit circle, but the accuracy gets worse. We believe there is an appropriate value of n_s for a reasonable balance between stability and accuracy. The value of n_s may be problem dependent. An algorithm to find the appropriate n_s is left for further research.

Although (2.3) and its higher-order analogs are of restricted usage, they still enlighten us to consider zero-stable parallel methods with perfect power stability polynomials. Using this approach one can derive two-stage block methods that outperform the Adams PECE methods by a sizeable margin. These two-stage methods are described in a separate paper [18]. In the remainder of this paper we study useful one-stage parallel methods based on (2.3) and its higher-order analogs.

4. Methods without accelerated error growth. The growth of the error of the one-stage, two-processor block method is due to the coefficient matrix

$$\begin{bmatrix} 2+b/4 & -1+b/4 \\ \frac{3}{4}+a/4 & -\frac{1}{4}+a/4 \end{bmatrix}, \quad a=1, \quad b=0,$$

being defective. By a different choice of the parameters a and b we can make the above matrix diagonalizable. This choice of parameters at the same time reduces the stability region of the method (2.2). This reduction in stability is tolerable, so long as the resulting stability region is still comparable to those of existing widely used methods that are less accurate. (Recall that we compare two scaled stability regions by using the largest disks passing through the origin that can be inscribed into each of them.) Our goal is to manipulate a and b such that the stability region of the resulting method is comparable to that of the second-order Adams-Bashforth method (the reference method), while at the same time the accuracy of this new method exceeds that of the reference method. Note that the stability polynomial is not a perfect square any more after this order enhancement.

It is possible to choose a and b so that the method (2.2) is of order 3. This order enhancement can be achieved by an analysis of the global error of (2.2). However, for arbitrary a and b the stability polynomial of (2.2) has an extraneous root equal to $a-b$ at $\mu=0$. The consequence of this extraneous root is that the global error expression (3.3) is not valid anymore. We need to make use of a result in Skeel [16].

LEMMA 4.1. *Let*

$$\begin{aligned} &\mathbf{u}_0 = \sigma(\eta; h), \\ &\mathbf{u}_n = S\mathbf{u}_{n-1} + h\Psi(t_{n-1}, \mathbf{u}_{n-1}; h), \quad 1 \leqq n \leqq N, \end{aligned} \tag{4.1}$$

denote an ODE *method with starting procedure $\sigma(\eta; h)$, where the vector $\mathbf{u}_{n-1}$ contains the stored values that the method requires. Assume that S has a simple eigenvalue equal to* 1 *and that all other eigenvalues are less than* 1 *in modulus. Let*

$$\begin{aligned} &\hat{\mathbf{u}}_0 = \sigma(\eta; h) + \mathbf{r}_0, \\ &\hat{\mathbf{u}}_n = S\hat{\mathbf{u}}_{n-1} + h\Psi(t_{n-1}, \hat{\mathbf{u}}_{n-1}; h) + \mathbf{r}_n, \end{aligned} \tag{4.2}$$

be a perturbed solution based on (4.1) *with perturbations $\mathbf{r}_0, \mathbf{r}_1, \cdots, \mathbf{r}_N$. If $\mathbf{v}^T$ is a left eigenvector of S corresponding to the eigenvalue* 1, *then*

$$\max_{0 \leqq n \leqq N} \|\hat{\mathbf{u}}_n - \mathbf{u}_n\| \leqq C_1 \sum_{n=1}^{N} \|\mathbf{v}^T \mathbf{r}_n\| + C_2 \max_{0 \leqq n \leqq N} \|\mathbf{r}_n\| \tag{4.3}$$

for some constants C_1, C_2. In particular, if $\max_{1 \leqq n \leqq N} \|\mathbf{v}^T\mathbf{r}_n\| = \mathcal{O}(h^{q+1})$ *and* $\max_{0 \leqq n \leqq N} \|\mathbf{r}_n\| = \mathcal{O}(h^q)$, *then* $\max_{0 \leqq n \leqq N} \|\hat{\mathbf{u}}_n - \mathbf{u}_n\| = \mathcal{O}(h^q)$.

Proof. Lemma 4.1 is a direct consequence of Theorem 3.6 in Skeel [16]. □

We can treat the true solution $Y(t_n)$ of the ODE as a perturbed approximation to the numerical solution (2.2) with perturbations $\mathbf{d}_{n+1}$. Therefore, by Lemma 4.1, if

$$\mathbf{v}^T\mathbf{d}_{n+1}=\mathcal{O}(h^4) \tag{4.4}$$

and $\|y_{1/2}-y(t_{1/2})\|$ and $\|y_0-y(t_0)\|$ are of order $\mathcal{O}(h^3)$ where $\mathbf{v}^T=(1-a,b)$ is a left eigenvector of A_2 corresponding to the eigenvalue 1, then $y_n-y(t_n)$ and $y_{n+1/2}-y(t_{n+1/2})=\mathcal{O}(h^3)$. Condition (4.4) holds if

$$0=(1-a)\frac{b-28}{96}+b\frac{a-5}{96} \quad\Leftrightarrow\quad b=7(a-1). \tag{4.5}$$

Thus if we use $\mathcal{O}(h^3)$ accurate starting values, the method (2.2) is of third order when $b=7(a-1)$, $a\neq 1$.

We are still left with one free parameter to ensure a good stability region. With the relationship (4.5), the stability polynomial of the method (2.2) becomes

$$\xi^2+(-8+6a-2a\mu)\xi+[(2-a)\mu^2+(6-4a)\mu+(7-6a)]. \tag{4.6}$$

To ensure that the extraneous root of (4.6) at $\mu=0$ is bounded by 1, we also need to require that

$$|7-6a|\leqq 1 \quad\Leftrightarrow\quad 1\leqq a\leqq\tfrac{4}{3}. \tag{4.7}$$

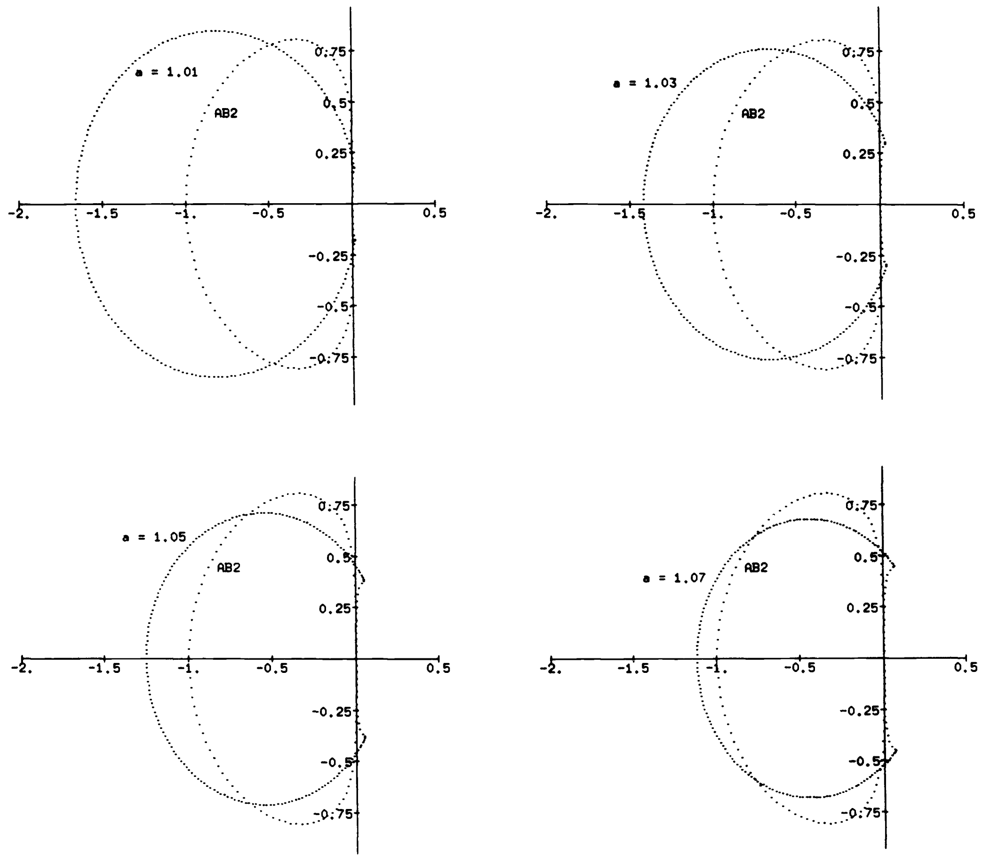

FIG. 4. *Stability region of* (2.2) *for different values of a.*

The stability regions of the method (2.2) for different choices of a's within the range (4.7) are shown in Fig. 4. The stability region of the reference method (second-order Adams-Bashforth method) is also sketched for comparison. The case $a=1$ gives the stability region with the largest inscribed circle. As a deviates from 1, the size of the inscribed circle shrinks. For $a \neq 1$, the stability region of the method (2.2) includes the boundary curves, like that of a conventional ODE method.

We must still ensure that the global error of (2.2) with $b=7(a-1)$, $a\neq 1$, behaves well. The following lemma shows that this is indeed the case.

LEMMA 4.2. *If* $b=7(a-1)$, $|a-b|\leqq 1$, $a\neq 1$ *in method* (2.2), *and* $Y_0 = Y(t_0)+\mathcal{O}(h^3)$, *then*

$$\begin{bmatrix} y_{n+1/2} \\ y_n \end{bmatrix} = \begin{bmatrix} y(t_{n+1/2}) \\ y(t_n) \end{bmatrix} + h^3 \begin{bmatrix} g_1(t_{n+1/2}) \\ g_2(t_n) \end{bmatrix} + h^3(7-6a)^n y'''(t_0) \begin{bmatrix} \delta_1 \\ \delta_2 \end{bmatrix} + \mathcal{O}(h^4), \tag{4.8}$$

where $\delta_1 = 7(a-5)/576(1-a)$, $\delta_2=(a-5)/576(1-a)$, *and*

$$\begin{aligned} g_1(t) &= -\delta_1 G(t,t_0)y'''(t_0) \\ &\quad + \int_{t_0}^{t} G(t,s)\left[\frac{9a-37}{576(a-1)} y^{IV}(s) + \frac{5-a}{576(a-1)} f_y(y(s))y'''(s)\right] ds, \\ g_2(t) &= g_1(t) - \frac{a-5}{96(a-1)} y'''(t). \end{aligned} \tag{4.9}$$

Proof. We can consider

$$\mathbf{z}_n = Y(t_n) + h^3 \begin{bmatrix} g_1(t_{n+1/2}) \\ g_2(t_n) \end{bmatrix} + h^3(7-6a)^n y'''(t_0) \begin{bmatrix} \delta_1 \\ \delta_2 \end{bmatrix}$$

as a perturbed approximation to the solution of the method (2.2). It can be shown that

$$\mathbf{z}_0 - Y_0 = h^3 \begin{bmatrix} g_1(t_{1/2}) \\ g_2(t_0) \end{bmatrix} + h^3 y'''(t_0) \begin{bmatrix} \delta_1 \\ \delta_2 \end{bmatrix} = \begin{bmatrix} \mathcal{O}(h^4) \\ 0 \end{bmatrix}.$$

If we define

$$\hat{\mathbf{d}}_{n+1} = \begin{bmatrix} \hat{d}_{n+3/2} \\ \tilde{d}_{n+1} \end{bmatrix} = A_2 \mathbf{z}_n + hB_2 f(\mathbf{z}_n) - \mathbf{z}_{n+1},$$

then

$$\begin{aligned} \hat{d}_{n+3/2} = {} & \frac{7(a-5)}{96} h^3 y'''(t_{n+1/2}) + \frac{-7a-1}{384} h^4 y^{IV}(t_{n+1/2}) + h^3 \delta_1 y'''(t_0)(7-6a)^n \\ & + 7(a-1)\left[h^3\left(g_2(t_{n+1/2}) - \frac{h}{2} g_2'(t_{n+1/2}) - g_1(t_{n+1/2}) \right) \right. \\ & \qquad \left. + h^3(\delta_2-\delta_1) y'''(t_0)(7-6a)^n \right] \\ & + \frac{7a+1}{4} hf_y(y(t_{n+1/2}))[h^3 g_1(t_{n+1/2}) + h^3\delta_1 y'''(t_0)(7-6a)^n] \\ & + \frac{7a-11}{4} hf_y(y(t_{n+1/2}))[h^3 g_2(t_{n+1/2}) + h^3\delta_2 y'''(t_0)(7-6a)^n] \\ & - h^4 g_1'(t_{n+1/2}) - h^3\delta_1 y'''(t_0)(7-6a)^{n+1} + \mathcal{O}(h^5), \end{aligned} \tag{4.10}$$

and

$$
\begin{aligned}
\hat{d}_{n+1} = {} & \frac{a-5}{96} h^3 y'''(t_n) + \frac{a-9}{384} h^4 y^{IV}(t_n) + (a-1)h^3\left[g_2(t_n) - g_1(t_n) - \frac{h}{2} g_1'(t_n)\right] \\
& + ah^3(\delta_2 - \delta_1) y'''(t_0)(7-6a)^n + h^3[\delta_1 - \delta_2(7-6a)] y'''(t_0)(7-6a)^n \\
& + \frac{3+a}{4} hf_y(y(t_n))[h^3 g_1(t_n) + h^3 \delta_1 y'''(t_0)(7-6a)^n] \\
& + \frac{-1+a}{4} hf_y(y(t_n))[h^3 g_2(t_n) + h^3 \delta_2 y'''(t_0)(7-6a)^n] - h^4 g_2'(t_n).
\end{aligned} \tag{4.11}
$$

As n becomes large, terms involving $(7-6a)^n$ become negligible. This argument and the second part of (4.9) imply that the $\mathcal{O}(h^3)$ terms in (4.10) and (4.11) cancel out. Hence $\hat{\mathbf{d}}_{n+1} = \mathcal{O}(h^4)$. We can also use the fact that $\sum_{n=1}^{N} (7-6a)^n = \mathcal{O}(1)$ and that

$$
\begin{aligned}
(1-a)g_1'(t) + 7(a-1)g_2'(t) = {} & \frac{7a^2 - 38a + 31}{192} y^{IV}(t) + \frac{7}{2}(1-a)^2(g_2'(t) - g_1'(t)) \\
& - 5(1-a) f_y(y(t)) g_1(t) - (1-a) f_y(y(t)) g_2(t)
\end{aligned}
$$

to show that $\sum_{n=1}^{N} \|\mathbf{v}^T \hat{\mathbf{d}}_n\| = \mathcal{O}(h^4)$. Hence by Lemma 4.1,

$$
Y_n - \mathbf{z}_n = Y_n - Y(t_n) - h^3 \begin{bmatrix} g_1(t_{n+1/2}) \\ g_2(t_n) \end{bmatrix} - h^3 (7-6a)^n y'''(t_0) \begin{bmatrix} \delta_1 \\ \delta_2 \end{bmatrix} = \mathcal{O}(h^4),
$$

and the lemma follows. □

Lemma 4.2 shows that with $b = 7(a-1)$, $a \neq 1$, the leading term for the global error is given by $h^3\, e^{\lambda t}[C_1 \lambda^4 t + C_2 \lambda^3]$ for some constants C_1 and C_2, when applied to the model problem $y' = \lambda y$. This is comparable to the global error behavior of a regular ODE method.

With the order enhanced, we can vary a to get a stability region with an inscribed disk that is comparable to that of the reference method. The choice $a = 1.07$, $b = 0.49$ appears to give an appropriate method. We have run some numerical tests comparing this choice with the reference method. Test results for $a = 1$, $b = 0$ are also presented simultaneously to demonstrate the accelerated error growth mentioned at the end of § 3. The results show that the choice $a = 1$, $b = 0$ has good speedup over the reference method on the negative real axis (a speedup of almost 2 for the problem $y' = -y$ for an accuracy of two digits), while it performs poorly on the imaginary axis (consider the orbit problem). The new choice $a = 1.07$, $b = 0.49$ regains a speedup over the reference method on the imaginary axis.

We can enhance the order of the three-processor method (2.6) in a way analogous to the two-processor case. Let

$$
\bar{\mathbf{d}}_{n+1} = h^4 \begin{bmatrix} (c_2/1944 - \frac{25}{216}) y^{IV}(\xi_1) \\ (b_2/1944 - \frac{8}{243}) y^{IV}(\xi_2) \\ (a_2/1944 - \frac{1}{216}) y^{IV}(\xi_3) \end{bmatrix}
$$

denote the local truncation error of the three-processor method (2.5). By Lemma 4.1, if we use $\mathcal{O}(h^4)$ initial values and choose parameters to make

$$
\bar{\mathbf{v}}^T \bar{\mathbf{d}}_{n+1} = \mathcal{O}(h^5), \tag{4.12}
$$

where

$$
\bar{\mathbf{v}} = \begin{bmatrix} \alpha \\ \beta \\ \gamma \end{bmatrix} = \begin{bmatrix} 1 - a_1 - a_2 b_1 - b_2 + a_1 b_2 \\ a_2 c_1 + c_2 - a_1 c_2 \\ c_1 - b_2 c_1 + b_1 c_2 \end{bmatrix}
$$

is a left eigenvector of A_3 corresponding to the eigenvalue 1, then (2.5) becomes order 4. The condition (4.12) is satisfied when

$$25\alpha + 7\beta + \gamma = 0. \tag{4.13}$$

However, we have not been able to get a fourth-order method with a good stability region for (2.5). We do obtain a third-order method using parameters

$$a_1 = 0.9, \quad a_2 = 0.1, \quad b_1 = 0, \quad b_2 = 1, \quad c_1 = 0, \quad c_2 = 0.1, \tag{4.14}$$

with stability region shown in Fig. 5. This stability region is much larger than those of the second- or third-order Adams–Bashforth methods. Numerical experiments for this third-order variation are given in § 6. The numerical results show that this third-order variation is an improvement over the third-order Adams–Bashforth method in both accuracy and stability.

5. Nonuniformly distributed time points. Thus far, the time points within each individual block of the q-processor block method have been equally spaced. The decision to use equally spaced time points has been based on simplicity and convenience. We have given no analysis on what kind of spacing yields the best stability or accuracy. In light of the order enhancement of one-step collocation methods, we might suspect a similar phenomenon in block methods. In this section we investigate whether a nonuniform spacing between the time points of the two-processor block method has any benefit.

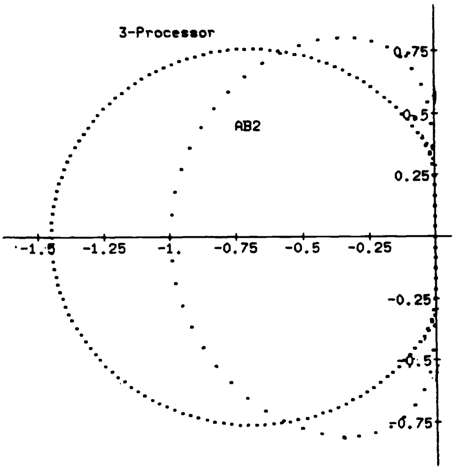

FIG. 5. *Stability region of* (2.5) *with parameters* (4.14).

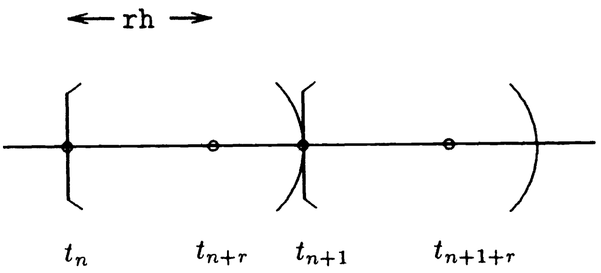

FIG. 6. *Variable spacing two-processor block method.*

Let the points of the variable spacing two-processor block method be represented by the diagram shown in Fig. 6. The two points t_n and t_{n+r} within a block are separated by the distance rh. The quantity r is assumed to be positive without loss of generality. We want to examine what the effect of the extra parameter r is on the stability or accuracy of the method. The quantity r can be either greater than or less than one. A value of $r=1$ makes the block method essentially a frontal method [13], [8]. The case $r>1$ represents a premature prediction of a block further ahead.

Equation (2.2) is a special case $r=\frac{1}{2}$ of the nonuniform time point two-processor block method

$$\begin{aligned}\begin{bmatrix} y_{n+1+r} \\ y_{n+1} \end{bmatrix} &= \begin{bmatrix} 1-b & b \\ 1-a & a \end{bmatrix}\begin{bmatrix} y_{n+r} \\ y_n \end{bmatrix} \\ &\quad + h\begin{bmatrix} 1+1/2r+br/2 & -1/2r+br/2 \\ 1/2r-r/2+ar/2 & 1-1/2r-r/2+ar/2 \end{bmatrix}\begin{bmatrix} f_{n+r} \\ f_n \end{bmatrix}.\end{aligned} \tag{5.1}$$

Equation (5.1) shows that the method coefficients grow large as the two time points approach one another. This indicates that allowing the time points to get too close together may have a negative effect on roundoff error.

The method (5.1) has a stability polynomial

$$\begin{aligned}&\xi^2+\xi\left[-1-a+b-2\mu+r\mu\left(\frac{1-a-b}{2}\right)\right]+\mu^2\left[\left(\frac{1+a-b}{2}\right)-r\left(\frac{1-a-b}{2}\right)\right] \\ &\quad +\mu\left[1+a-b-r\left(\frac{1-a-b}{2}\right)\right]+a-b,\end{aligned} \tag{5.2}$$

which, for $a=1$ and $b=0$, is equal to $[\xi-(1+\mu)]^2$. Thus the choice of r does not affect whether (5.2) can be made a perfect square. Conversely, the stability polynomial (5.2) is equal to $[\xi-(1+\mu)]^2$ only when $a=1$ and $b=0$.

The local truncation error of (5.1) is given by

$$\begin{bmatrix} (-\frac{1}{6}-r/4+br^3/12)h^3y'''(\xi_1) \\ (-\frac{1}{6}+r/4-r^3/12+ar^3/12)h^3y'''(\xi_2) \end{bmatrix}.$$

Again, since (5.1) has a second-order local truncation error, the global error for the case $a=1$, $b=0$ satisfies (by [9, Thm. 9.1]),

$$\begin{bmatrix} y_{n+1+r} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} y(t_{n+1+r}) \\ y(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^2e_1(t_{n+1+r}) \\ h^2e_2(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^3g_1(t_{n+1+r}) \\ h^3g_2(t_{n+1}) \end{bmatrix} + \mathcal{O}(h^4). \tag{5.3}$$

As in § 3, we can verify that $e_1(t)$ and $e_2(t)$ can be determined from

$$\begin{bmatrix} e_1'(t) \\ e_2'(t) \end{bmatrix} = f_y(y(t))\begin{bmatrix} 1+1/2r & -1/2r \\ 1/2r & 1-1/2r \end{bmatrix}\begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix} + \begin{bmatrix} -\frac{1}{6}-r/4 \\ -\frac{1}{6}+r/4 \end{bmatrix} y'''(t). \tag{5.4}$$

If we make the transformation

$$\begin{bmatrix} \tilde{e}_1(t) \\ \tilde{e}_2(t) \end{bmatrix} = \begin{bmatrix} 1-1/2r & 1/2r \\ 1/2r & -1/2r \end{bmatrix}\begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix},$$

then (5.4) becomes

$$\begin{bmatrix} \tilde{e}_1'(t) \\ \tilde{e}_2'(t) \end{bmatrix} = f_y(y(t)) \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \tilde{e}_1(t) \\ \tilde{e}_2(t) \end{bmatrix} + \begin{bmatrix} \frac{1}{12} - r/4 \\ -\frac{1}{4} \end{bmatrix} y'''(t).$$

Recall that in § 3, it is the defective error propagation matrix $[\begin{smallmatrix} 2 & -1 \\ 1 & 0 \end{smallmatrix}]$ in (3.6) that leads to an accelerated error growth on the imaginary axis. The error propagation matrix

$$\begin{bmatrix} 1+1/2r & -1/2r \\ 1/2r & 1-1/2r \end{bmatrix}$$

in (5.4) is always defective for any choice of $r \neq 0$. The defective error propagation matrix makes $\tilde{e}_1(t)$ explicitly dependent on $\tilde{e}_2(t)$. It is this explicit dependence of $\tilde{e}_1(t)$ on $\tilde{e}_2(t)$ that generates an $\mathcal{O}(t^2)$ term in $\tilde{e}_1(t)$ (when (5.1) is applied to the model problem $y' = \lambda y$). Because $\tilde{e}_2(t) \neq 0$ for any value of r, we cannot eliminate the $\mathcal{O}(t^2)$ term in the solution of $\tilde{e}_1(t)$. Hence it is impossible to avoid the accelerated error growth for eigenvalues along the imaginary axis for the case $a = 1$, $b = 0$ by varying the spacing between time points.

As in § 4, we can avoid the accelerated error growth on the imaginary axis by a different choice of the parameters a and b. When

$$0 = \left(\frac{-1+a-b}{6}\right) + r\left(\frac{-1+a+b}{r}\right)$$

and $a = 1$, $b = 0$ does not hold simultaneously, the method (5.1) becomes third order. By a proof analogous to that of Lemma 4.2, it can be shown that the global error of the third-order method has leading terms

$$g_1(t) - \frac{(2+3r)(-2+3r-r^3+ar^3)}{72r(a-1)} \left(\frac{-2-3r+6ra}{-2+3r}\right)^n y'''(t_0)$$

and

$$g_2(t) - \frac{(2-3r)(-2+3r-r^3+ar^3)}{72r(a-1)} \left(\frac{-2-3r+6ra}{-2+3r}\right)^n y'''(t_0),$$

where

$$\begin{aligned} g_1(t) = {} & \frac{(2+3r)(-2+3r-r^3+ar^3)}{72r(a-1)} G(t, t_0) y'''(t_0) \\ & + \int_{t_0}^{t} G(t, s) \left[\frac{-4+(a-1)r+9r^2+(1-a)r^3+(3a-3)r^4}{72r(a-1)} y^{IV}(s) \right. \\ & \qquad \left. + \frac{(1-3r)(-2+3r-r^3+ar^3)}{72r(a-1)} f_y(y(s)) y'''(s) \right] ds \end{aligned}$$

and

$$g_2(t) = g_1(t) - \frac{-\frac{1}{6} + r/4 - r^3/12 + ar^3/12}{(a-1)} y'''(t).$$

Thus the best we can do with varying r is to eliminate one of the component functions within the leading terms of the global error. Hence varying r does not improve the order of the variable time point two-processor block method. Based on this result, we believe that it is sufficient to consider uniformly spaced time points within a block.

6. Numerical results. We have tested the two-processor and three-processor block methods on selected problems of the standard test set DETEST [11]. These test problems are representative in demonstrating the stability and accuracy characteristics of the proposed methods on both the real and imaginary axes. The test problems, together with their analytic solutions, are listed below:

1.

$$y' = -y, \quad y(0) = 1, \quad t_{\text{out}} = 20, \quad y(t) = e^{-t},$$

2.

$$y' = -\frac{y^3}{2}, \quad y(0) = 1, \quad t_{\text{out}} = 20, \quad y(t) = \frac{1}{\sqrt{1+t}},$$

3.

$$y' = y \cos t, \quad y(0) = 1, \quad t_{\text{out}} = 20, \quad y(t) = e^{\sin t},$$

4.

$$y' = \frac{y}{4}\left(1 - \frac{y}{4}\right), \quad y(0) = 1, \quad t_{\text{out}} = 20, \quad y(t) = \frac{20}{1+19e^{-t/4}},$$

5.

$$\begin{bmatrix} y_1' \\ y_2' \\ y_3' \end{bmatrix} = \begin{bmatrix} -y_2 - y_2 y_3/r \\ y_1 - y_2 y_3/r \\ y_1/r \end{bmatrix}, \quad y(0) = \begin{bmatrix} 3 \\ 0 \\ 0 \end{bmatrix}, \quad y(t) = \begin{bmatrix} (2+\cos t) \cos t \\ (2+\cos t) \sin t \\ \sin t \end{bmatrix},$$

$$t_{\text{out}} = 20, \quad r = \sqrt{y_1^2 + y_2^2},$$

6.

$$\begin{bmatrix} y_1' \\ y_2' \\ y_3' \\ y_4' \end{bmatrix} = \begin{bmatrix} y_2 \\ -y_1/r^3 \\ y_4 \\ -y_3/r^3 \end{bmatrix}, \quad y(0) = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \quad y(t) = \begin{bmatrix} \cos t \\ -\sin t \\ \sin t \\ \cos t \end{bmatrix},$$

$$t_{\text{out}} = 25, \quad r = \sqrt{y_1^2 + y_3^2},$$

7.

$$\begin{bmatrix} y_1' \\ y_2' \end{bmatrix} = \begin{bmatrix} y_1/2(1+t) - 2ty_2 \\ y_2/2(1+t) + 2ty_1 \end{bmatrix}, \quad y(0) = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad y(t) = \begin{bmatrix} \sqrt{1+t}\cos t^2 \\ \sqrt{1+t}\sin t^2 \end{bmatrix},$$

$$t_{\text{out}} = 6.$$

The test problems include both linear and nonlinear examples. Problems 1-4 have eigenvalues on the real axis, while problems 5-7 contain eigenvalues with imaginary parts. The integration interval in each test problem is long enough to indicate any deficiency in the long-term behavior of each method.

The two-processor and three-processor methods are compared to the second- and third-order Adams–Bashforth methods. For the two-processor case, we use parameters $a=1$ and $b=0$ (with unit circle stability region) and the alternate choice $a=1.07$, $b=0.49$. For the three-processor case, we use parameters $a_1=1$, $a_2=0$, $b_1=0$, $b_2=1$, and $c_1=c_2=0$ (with unit circle stability region) and the alternate choice $a_1=0.9$, $a_2=0.1$, $b_1=0$, $b_2=1$, $c_1=0$, and $c_2=0.1$. A constant stepsize test is enough to compare the accuracy and stability properties of these methods. We believe that if a parallel method is inferior to existing serial methods for constant stepsizes, this method has no hope in a variable stepsize implementation. Also, we do not want to obscure the performance of the new methods by a crude error estimator. Therefore all numerical tests are done using constant stepsizes.

Because the proposed and the reference methods all require more than one starting point, we need to specify a starting criterion for each method. We believe that a fair start for all methods is the provision of sufficient information for each of them to compute the solution value at t_1. Thus for a stepsize h and initial time t_0, the second-order and third-order Adams–Bashforth methods are given exact values at t_{-1} and t_{-1}, t_{-2}, respectively. For the two-processor block method, we give exact starting values at t_0 and $t_{1/2}$. For the three-processor case, exact values at t_0, $t_{1/3}$, and $t_{2/3}$ are provided.

As the block methods generate more intermediate points than the Adams method, a fair comparison is to sample only the errors at gridpoints $t_1, t_2, \cdots$ of the block methods. (Incidentally, we know from global error analysis that within a block, the error is smallest at the first point, e.g., the error at t_n is smaller than that at $t_{n+1/3}$ or $t_{n+2/3}$ for the three-processor case.) We measure the error of each method by $\text{err} = \max_n \|y_n - y(t_n)\|_2$.

Since the test examples are of small scale, when run on a parallel computer, the communication time between different processors in the parallel methods will be a significant portion of the run time. Moreover, the usual consensus in measuring the performance of nonstiff ODE methods on a particular problem is to count the number of function evaluations required by each of them. In practice, when the problem size is large, the interprocessor communication time becomes relatively insignificant. Therefore, in the subsequent performance plots, we show the number of function evaluations per processor for each method. Because the new methods are conventional in nature (they belong to Butcher's [2], [3] class of general linear methods) and do not exploit special properties of the ODE system, it is reasonable to expect that their performance on small systems is indicative of their performance on large systems.

We run each method on a particular test problem using different constant values of h to complete the given integration interval. Dividing the integration interval by the stepsize gives the number of function evaluations per processor. The decimal places of accuracy in each plot are computed by $-\log_{10} \text{err}$. The tests are run on an Alliant FX/8 using double precision arithmetic, although it is obvious that the tests do not require the actual use of a parallel computer. The plots of accuracy versus number of function evaluations per processor for the test problems are shown in Figs. 7–13.

The results of problem 1 clearly indicates the improved stability of the two- and three-processor block methods with unit circle stability regions over the second- and third-order Adams–Bashforth methods. The stability properties of the two-processor case with a different parameter choice still match those of the second-order Adams–Bashforth method, while the stability characteristics of the three-processor block method with modified parameters are even better. In all test examples except problem 5, the modified parameter three-processor method has better accuracy than the

third-order Adams–Bashforth method, with a speedup of up to 3 in some cases (e.g., in problem 2 for an accuracy of two digits). Problem 6 shows the effect of imaginary eigenvalues on the two- and three-processor methods with unit circle stability regions. Both methods perform poorly on the imaginary axis. However, with a different choice of the parameters, both methods regain good accuracy.

7. Summary. In this paper we have derived a new family of one-stage q-processor parallel methods. The q-processor element has order q. This family of methods contains free parameters, which are at our disposal. For any number of processors q, there exists a unique set of parameters so that the stability region of the resulting method is essentially that of the Euler method. We discover that besides stability and local error analysis, we must also consider the coupling between time points for a block method. The effect of this coupling on the above methods with unit circle stability regions leads to an accelerated error growth on the imaginary axis of the $h\lambda$-plane. This accelerated error growth restricts the length of the integration interval for a given problem. Although the methods with unit circle stability regions are of restricted practical usage, the unique set of parameters is the starting point from which we obtain good one-stage parallel methods. By making modifications of the parameters around the unique set, we are able to obtain methods with relatively large stability regions, compared to the Adams–Bashforth methods, but now of better accuracy. The modified parameter methods of the two- and three-processor cases outperform the second- and third-order Adams–Bashforth methods, respectively, in both accuracy and stability. However, we have not been able to generalize this parameter modification to higher-order cases.

This paper also illustrates an important approach to obtaining parallel methods with good stability properties; we study zero-stable parallel methods with perfect power stability polynomials. Although the methods with unit circle stability regions studied in this paper are of restricted usage, they allow us to consider two-stage block methods with very little accelerated error growth. These two-stage methods also have unchanged stability regions as the order increases. They outperform the Adams PECE methods in both stability and accuracy by a sizeable margin. These methods are presented in [18].

TWO-STAGE PARALLEL METHODS FOR THE NUMERICAL SOLUTION OF ORDINARY DIFFERENTIAL EQUATIONS*

H. W. TAM†

Abstract. This is a continuation of a previous work on finding parallel ODE methods with good stability regions. Based on the approach of zero-stable methods with perfect power stability polynomials, a family of two-stage block methods with stability regions essentially equal to that of the second-order Taylor series method is derived. The stability regions of these methods remain unchanged as the order increases. These methods also have very low interprocessor communication cost compared to existing PECE block methods.

Key words. two-stage, block methods, parallel processing, ordinary differential equations

AMS(MOS) subject classification. 65L05

1. Introduction. This is a continuation of the work on parallel ordinary differential equation (ODE) methods in [10]. We would like to study parallel methods for the numerical solution of the ODE

$$y(t_0)=\eta,$$
$$y'(t)=f(y(t)), \qquad t_0 \leqq t \leqq t_{\text{out}},$$

where y and $f \in \mathscr{R}^n$. A nonautonomous ODE of the form $z'(t)=f(t, z(t))$ can always be written in the above autonomous form. Hence the above form involves no loss of generality.

A family of one-stage block methods, the two-processor element of which is given by

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix} + h \begin{bmatrix} 2 & -1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} f_{n+(1/2)} \\ f_n \end{bmatrix}, \tag{1.1}$$

has been studied in [10]. Equation (1.1) has the special property that its stability polynomial is equal to $[\xi-(1+\mu)]^2$ while the method remains zero-stable. (Usually a method whose stability polynomial is the power of another lacks zero-stability.) The stability region of (1.1) is equal to the interior of the unit circle centered at $(-1, 0)$ of the $h\lambda$-plane, together with the origin. This family of one-stage block methods has the peculiarity that the stability regions do not change with order. It has been shown in [9] that the best scaled stability region[1] one can achieve for explicit ODE methods is the unit circle. Therefore this upper bound is almost achieved by the above family of methods.

However, the coupling between each component of (1.1) renders the use of the method rather restrictive. If the global error of (1.1) satisfies

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} y(t_{n+(3/2)}) \\ y(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^2 e_1(t_{n+(3/2)}) \\ h^2 e_2(t_{n+1}) \end{bmatrix} + \mathscr{O}(h^3), \tag{1.2}$$

[1] The scaled stability region of a method is defined to be its stability region divided by m, where m is the number of stages per step of the method. Scaled stability regions are the fair entities for the comparison of stability properties of different methods.

where $e_1(t)$, $e_2(t)$ are differentiable, it is possible to show that, after a linear transformation

$$\begin{bmatrix} e_1 \\ e_2 \end{bmatrix} = T \begin{bmatrix} \tilde{e}_1 \\ \tilde{e}_2 \end{bmatrix},$$

$$\begin{bmatrix} \tilde{e}_1'(t) \\ \tilde{e}_2'(t) \end{bmatrix} = f_y(y(t)) \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \tilde{e}_1(t) \\ \tilde{e}_2(t) \end{bmatrix} + \begin{bmatrix} -\frac{1}{24} \\ -\frac{1}{4} \end{bmatrix} y'''(t).$$

The solutions of $e_1(t)$ and $e_2(t)$, when applied to $y' = \lambda y$, $y(0) = 1$, contain the component

$$e^{t\lambda}\left[-\frac{t}{24} - \frac{t^2\lambda}{8}\right]\lambda^3.$$

(For comparison, the leading term in the global error of a conventional ODE method is of the form $\mathcal{O}(t)\, e^{\lambda t}$). If $\lambda = -1$, the growth of t^2 is damped by e^{-t}. When $\lambda = i$, $|e^{it}| = 1$ and the growth of t^2 is undamped. We call this phenomenon an accelerated error growth. The above global error analysis demonstrates that (1.1) has good accuracy for eigenvalues on the negative real axis of the $h\lambda$-plane, but not for eigenvalues along the imaginary axis.

Method (1.1), nevertheless, is an example of a member of a broad class of formulas having stability polynomials that are perfect powers of simple ones and possessing good stability properties. Since two-stage methods have been proved to be useful in the sequential case (as in the Adams PECE methods), we would like to consider two-stage parallel methods. In this paper we show that there exists a family of zero-stable two-stage block methods that satisfies the aforementioned perfect power stability polynomial property. In § 2 we show that by using a one-stage method of the type discussed in [10] as the predictor, and by choosing an appropriate corrector, we are able to derive a family of zero-stable methods with stability polynomials equal to perfect powers of

$$\left[\xi - \left(\frac{\mu^2}{2} + \mu + 1\right)\right].$$

These methods have stability regions essentially identical to that of the second-order Taylor series method. However, the stability regions remain unchanged for all orders. (Stability regions of conventional ODE methods usually shrink as the order increases.) These methods also have the advantage of requiring much less interprocessor communication than existing predictor-corrector block methods. In § 3 we use global error analysis to show that the error functions of this new family of methods do not have as much accelerated growth as the family of (1.1). The global error analysis also suggests a unique way to calculate the predictor parameters leading to the above stability polynomials. In § 4 we discuss variants of the new family of two-stage methods. In § 5 we demonstrate how to enhance the accuracy of the methods by doing post-processing at the end of the integration. Numerical simulations in § 6 show that the new parallel methods outperform the Adams PECE family in both accuracy and stability by a sizable margin.

2. The corrector formula. In this section we would like to derive a family of two-stage formulas whose stability polynomials are perfect powers of simple ones. We believe that the derivation of the lowest-order formula serves as a pattern for the generalization to higher orders. Let us use the two-processor, one-stage block method of [10] as the predictor of our (as yet to be described) two-stage method:

$$\begin{bmatrix} y^p_{n+(3/2)} \\ y^p_{n+1} \end{bmatrix} = \begin{bmatrix} 1-b & b \\ 1-a & a \end{bmatrix} \begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix} + h \begin{bmatrix} 2+\frac{b}{4} & -1+\frac{b}{4} \\ \frac{3}{4}+\frac{a}{4} & -\frac{1}{4}+\frac{a}{4} \end{bmatrix} \begin{bmatrix} f_{n+(1/2)} \\ f_n \end{bmatrix}. \tag{2.1}$$

As in the Adams–Moulton methods, we can use the now available values $f^p_{n+(3/2)} = f(t_{n+(3/2)}, y^p_{n+(3/2)})$ and $f^p_{n+1} = f(t_{n+1}, y^p_{n+1})$, as well as the stored quantities y_n, $y_{n+(1/2)}$, f_n, $f_{n+(1/2)}$ to compute the corrected values y_{n+1} and $y_{n+(3/2)}$. We find that making the corrector one order higher than the predictor is a good decision. Since the predictor (2.1) is second order, we would like to make the corrector formula third order. We will use f^p_{n+1} in the computation of y_{n+1}, and $f^p_{n+(3/2)}$ in the computation of $y_{n+(3/2)}$. The third-order formula to calculate y_{n+1} from $y_n, f^p_{n+1}, f_{n+(1/2)}, f_n$ is given by

$$\begin{aligned} y_{n+1} = y_n + \int_{t_n}^{t_{n+1}} & f^p_{n+1} + (t-t_{n+1}) f^p_{n+1,n+(1/2)} \\ & + (t-t_{n+1})(t-t_{n+(1/2)}) f^p_{n+1,n+(1/2),n}\, dt \\ = y_n + h[\tfrac{1}{6} & f^p_{n+1} + \tfrac{2}{3} f_{n+(1/2)} + \tfrac{1}{6} f_n], \end{aligned} \tag{2.2}$$

where the divided differences $f^p_{n+1,n+(1/2),\dots}$ are evaluated from f^p_{n+1}, $f_{n+(1/2)}, \cdots$. Similarly, we obtain third-order formulas

$$y_{n+1} = y_{n+(1/2)} + h[\tfrac{5}{24} f^p_{n+1} + \tfrac{1}{3} f_{n+(1/2)} - \tfrac{1}{24} f_n], \tag{2.3}$$

$$y_{n+(3/2)} = y_n + h[\tfrac{3}{8} f^p_{n+(3/2)} + \tfrac{9}{8} f_{n+(1/2)}], \tag{2.4}$$

$$y_{n+(3/2)} = y_{n+(1/2)} + h[\tfrac{7}{18} f^p_{n+(3/2)} + \tfrac{5}{6} f_{n+(1/2)} - \tfrac{2}{9} f_n]. \tag{2.5}$$

Linear combinations of (2.2) and (2.3), and of (2.4) and (2.5) yield the corrector formula

$$\begin{aligned} \begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1-b^* & b^* \\ 1-a^* & a^* \end{bmatrix} \begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix} & + h \begin{bmatrix} \frac{7}{18}-\frac{b^*}{72} & 0 \\ 0 & \frac{5}{24}-\frac{a^*}{24} \end{bmatrix} \begin{bmatrix} f^p_{n+(3/2)} \\ f^p_{n+1} \end{bmatrix} \\ & + h \begin{bmatrix} \frac{5}{6}+\frac{7}{24}b^* & -\frac{2}{9}+\frac{2}{9}b^* \\ \frac{1}{3}+\frac{1}{3}a^* & -\frac{1}{24}+\frac{5}{24}a^* \end{bmatrix} \begin{bmatrix} f_{n+(1/2)} \\ f_n \end{bmatrix}, \end{aligned} \tag{2.6}$$

with a^*, b^* as free parameters. The coefficient matrix for the f^{p}'s is specifically chosen to be diagonal to reduce the communication costs associated with a parallel implementation of this formula.

We need to choose the parameters a, b, a^*, b^* so that the stability polynomial of (2.6) is a perfect power. Since the largest power of ξ in the stability polynomial of (2.6) is ξ^2, we would like to make this stability polynomial of the form $[\xi - (\frac{1}{2}\mu^2 + \mu + 1)]^2$. The choice $[\xi - (\frac{1}{2}\mu^2 + \mu + 1)]^2$ gives a method of high formal order [8]. It turns out that for

$$a^* = 1, \quad b^* = 0, \quad a = 5, \quad b = \tfrac{4}{7}$$

or

$$a^* = 17, \quad b^* = 16, \quad a = 5, \quad b = 28,$$

the stability polynomial of (2.6) is indeed $[\xi - (\frac{1}{2}\mu^2 + \mu + 1)]^2$. There are also some other uninteresting parameter choices such that the stability polynomial of (2.6) is also a perfect square. These cases are not discussed in this paper.

If we apply our two-processor, two-stage block method to the simple test problem $y'(t)=0$, we get

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1-b^* & b^* \\ 1-a^* & a^* \end{bmatrix} \begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix}.$$

If $a^*=17$ and $b^*=16$,

$$\begin{aligned} \begin{bmatrix} 1-b^* & b^* \\ 1-a^* & a^* \end{bmatrix} &= \begin{bmatrix} 1-b^* & b^* \\ -b^* & 1+b^* \end{bmatrix} \\ &= \begin{bmatrix} 1 & 1 \\ 1 & \frac{1+b^*}{b^*} \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 1 & \frac{1+b^*}{b^*} \end{bmatrix}^{-1}, \end{aligned} \tag{2.7}$$

so that

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix}$$

becomes unbounded as n increases. Therefore the only possibly useful set of parameters is $a=5$, $b=\frac{4}{7}$, $a^*=1$, $b^*=0$.

The corresponding three-processor, two-stage block method, where the second stage is derived in such a way that $y_{n+(i/3)}$ depends on $f^p_{n+(i/3)}$, $i=3, 4, 5$, is given by

$$\begin{aligned} \begin{bmatrix} y^p_{n+(5/3)} \\ y^p_{n+(4/3)} \\ y^p_{n+1} \end{bmatrix} &= \begin{bmatrix} 1-c_1-c_2 & c_2 & c_1 \\ 1-b_1-b_2 & b_2 & b_1 \\ 1-a_1-a_2 & a_2 & a_1 \end{bmatrix} \begin{bmatrix} y_{n+(2/3)} \\ y_{n+(1/3)} \\ y_n \end{bmatrix} \\ &\quad + h \begin{bmatrix} \frac{19}{4}+\frac{c_1}{9}+\frac{5c_2}{36} & -6+\frac{4c_1}{9}+\frac{2c_2}{9} & \frac{9}{4}+\frac{c_1}{9}-\frac{c_2}{36} \\ \frac{19}{9}+\frac{b_1}{9}+\frac{5b_2}{36} & -\frac{20}{9}+\frac{4b_1}{9}+\frac{2b_2}{9} & \frac{7}{9}+\frac{b_1}{9}-\frac{b_2}{36} \\ \frac{23}{36}+\frac{a_1}{9}+\frac{5a_2}{36} & -\frac{4}{9}+\frac{4a_1}{9}+\frac{2a_2}{9} & \frac{5}{36}+\frac{a_1}{9}-\frac{a_2}{36} \end{bmatrix} \begin{bmatrix} f_{n+(2/3)} \\ f_{n+(1/3)} \\ f_n \end{bmatrix}, \end{aligned} \tag{2.8}$$

$$\begin{aligned} \begin{bmatrix} y_{n+(5/3)} \\ y_{n+(4/3)} \\ y_{n+1} \end{bmatrix} &= \begin{bmatrix} 1-c_1^*-c_2^* & c_2^* & c_1^* \\ 1-b_1^*-b_2^* & b_2^* & b_1^* \\ 1-a_1^*-a_2^* & a_2^* & a_1^* \end{bmatrix} \begin{bmatrix} y_{n+(2/3)} \\ y_{n+(1/3)} \\ y_n \end{bmatrix} \\ &\quad + h \begin{bmatrix} \frac{5}{16}-\frac{c_2^*}{720} & 0 & 0 \\ 0 & \frac{2}{9}-\frac{b_2^*}{288} & 0 \\ 0 & 0 & \frac{1}{8}-\frac{a_2^*}{72} \end{bmatrix} \begin{bmatrix} f^p_{n+(5/3)} \\ f^p_{n+(4/3)} \\ f^p_{n+1} \end{bmatrix} \\ &\quad + h \begin{bmatrix} \frac{13}{8}+\frac{c_1^*}{9}+\frac{11c_2^*}{72} & -\frac{21}{16}+\frac{4c_1^*}{9}+\frac{29c_2^*}{144} & \frac{3}{8}+\frac{c_1^*}{9}-\frac{7c_2^*}{360} \\ \frac{7}{9}+\frac{b_1^*}{9}+\frac{23b_2^*}{144} & -\frac{4}{9}+\frac{4b_1^*}{9}+\frac{7b_2^*}{36} & \frac{1}{9}+\frac{b_1^*}{9}-\frac{5b_2^*}{288} \\ \frac{19}{72}+\frac{a_1^*}{9}+\frac{13a_2^*}{72} & -\frac{5}{72}+\frac{4a_1^*}{9}+\frac{13a_2^*}{72} & \frac{1}{72}+\frac{a_1^*}{9}-\frac{a_2^*}{72} \end{bmatrix} \begin{bmatrix} f_{n+(2/3)} \\ f_{n+(1/3)} \\ f_n \end{bmatrix}. \end{aligned} \tag{2.9}$$

As in the two-processor case, we now want to choose the parameters to make the stability polynomial of the form $[\xi-(\frac{1}{2}\mu^2+\mu+1)]^3$. Due to the large number of parameters and the complexity of the stability polynomial, we believe that the choice of the parameters requires some intuition. The two-processor, two-stage method suggests that an appropriate partial choice is $a_1^*=1$, $a_2^*=0$, $b_1^*=0$, $b_2^*=1$, $c_1^*=c_2^*=0$, which it is. However, this time more than a unique set of predictor parameters satisfy our requirement. For example, both

$$a_1=19, \quad a_2=-27, \quad b_1=\frac{45}{7}, \quad b_2=-8, \quad c_1=\frac{18}{5}, \quad c_2=-\frac{27}{5}$$

and

$$a_1=7, \quad a_2=-3, \quad b_1=-\frac{3}{7}, \quad b_2=\frac{40}{7}, \quad c_1=-\frac{6}{5}, \quad c_2=\frac{21}{5}$$

make the stability polynomial equal to

$$\left[\xi-\left(\frac{\mu^2}{2}+\mu+1\right)\right]^3.$$

We do not know yet how many more possible choices of the a's, b's, and c's there are.

It turns out that the stability regions of the proposed family of two-stage block methods are equal to the interior of that of the second-order Taylor series method (also the lowest-order Adams PECE method), together with the origin. What is interesting is that the stability regions do not shrink as we increase the order. Thus the new two-stage block methods have stability properties essentially identical to those of the lowest-order Adams PECE method. This is a significant improvement over the family of Adams PECE methods because the stability regions of the Adams PECE methods shrink by a large amount as one increases the order [6].

We will study the error growth of this two-stage family of methods in the next section. This will assist us in finding the right predictor parameters, the number of which is enormous as one increases the number of processors.

3. Global error analysis of the two-stage block method. In § 1 we have demonstrated that the one-stage block methods with stability polynomials equal to $[\xi-(1+\mu)]^q$ are not practical because of accelerated error growth. In this section we use global error analysis to show that accelerated error growth no longer plays a significant role in the two-stage case. This analysis also gives us a clue to compute the method parameters.

As in the previous section, we want to investigate the behavior of the two-processor case (with the hope that the conclusions generalize). The derivation of (2.6) indicates that the corrector formula for the two-processor, two-stage method is of the third order. Based on global error theory for ODE methods [3], it is reasonable to assume that, since the stability polynomial has no extraneous root at $\mu=0$,

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} y(t_{n+(3/2)}) \\ y(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^3 e_1(t_{n+(3/2)}) \\ h^3 e_2(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^4 g_1(t_{n+(3/2)}) \\ h^4 g_2(t_{n+1}) \end{bmatrix} + \mathcal{O}(h^5), \tag{3.1}$$

where the error functions $e_1(t)$, $e_2(t)$ as well as $g_1(t)$, $g_2(t)$ are differentiable, and $e_1(t)$, $e_2(t)$ are different from those of the one-stage methods in § 1. With the parameters $a=5$, $b=\frac{4}{7}$, $a^*=1$, $b^*=0$, if we substitute (3.1) into the corrector (2.6), subtract the Taylor series

$$\begin{bmatrix} y(t_{n+(3/2)}) \\ y(t_{n+1}) \end{bmatrix} = \begin{bmatrix} y(t_{n+(1/2)}) \\ y(t_n) \end{bmatrix} + \begin{bmatrix} hy'(t_{n+(1/2)}) \\ hy'(t_n) \end{bmatrix} + \begin{bmatrix} \frac{h^2}{2} y''(t_{n+(1/2)}) \\ \frac{h^2}{2} y''(t_n) \end{bmatrix}$$
$$+ \begin{bmatrix} \frac{h^3}{6} y'''(t_{n+(1/2)}) \\ \frac{h^3}{6} y'''(t_n) \end{bmatrix} + \begin{bmatrix} \frac{h^4}{24} y^{IV}(t_{n+(1/2)}) \\ \frac{h^4}{24} y^{IV}(t_n) \end{bmatrix} + \mathcal{O}(h^5)$$

from both sides of the resulting equation, and express all solution and function values at the point t_n, then the error functions $e_1(t)$ and $e_2(t)$ satisfy

$$\begin{aligned} h^4 e_1'(t_n) &= \tfrac{1}{36} h^4 y^{IV}(t_n) + h^4 \tfrac{7}{18}(-\tfrac{2}{7}) f_y(y(t_n)) y'''(t_n) \\ &\quad + h^4 \tfrac{7}{18} f_y(y(t_n))[\tfrac{3}{7} e_1(t_n) + \tfrac{4}{7} e_2(t_n)] \\ &\quad + h^4 \tfrac{5}{6} f_y(y(t_n)) e_1(t_n) - h^4 \tfrac{2}{9} f_y(y(t_n)) e_2(t_n) + \mathcal{O}(h^5), \end{aligned} \tag{3.2}$$

and

$$h^4 e_2'(t_n) = h^4 \tfrac{1}{6} f_y(y(t_n))[5e_2(t_n) - 4e_1(t_n)] + h^4 \tfrac{2}{3} f_y(y(t_n)) e_1(t_n) \\ + h^4 \tfrac{1}{6} f_y(y(t_n)) e_2(t_n) + \mathcal{O}(h^5). \tag{3.3}$$

Not surprisingly, the local errors of (2.1) and (2.6),

$$\begin{bmatrix} -\frac{2}{7} h^3 y'''(\tau_1) \\ 0 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} \frac{1}{36} h^4 y^{IV}(\tau_2) \\ 0 \end{bmatrix},$$

are embedded in (3.2) and (3.3).

If we fix t_n in (3.2) and (3.3) and let $h \to 0$, we can drop the subscript n and obtain

$$\begin{bmatrix} e_1'(t) \\ e_2'(t) \end{bmatrix} = f_y(y(t)) \left(\begin{bmatrix} \frac{7}{18} & 0 \\ 0 & \frac{1}{6} \end{bmatrix} \begin{bmatrix} \frac{3}{4} & \frac{4}{7} \\ -4 & 5 \end{bmatrix} + \begin{bmatrix} \frac{5}{6} & -\frac{2}{9} \\ \frac{2}{3} & \frac{1}{6} \end{bmatrix} \right) \begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix} \\ + f_y(y(t)) \begin{bmatrix} \frac{7}{18} & 0 \\ 0 & \frac{1}{6} \end{bmatrix} \begin{bmatrix} -\frac{2}{7} \\ 0 \end{bmatrix} y'''(t) + \begin{bmatrix} \frac{1}{36} \\ 0 \end{bmatrix} y^{IV}(t). \tag{3.4}$$

For comparison, the corresponding corrector formula (2.6) is given by

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix} + h \begin{bmatrix} \frac{7}{18} & 0 \\ 0 & \frac{1}{6} \end{bmatrix} \begin{bmatrix} f^p_{n+(3/2)} \\ f^p_{n+1} \end{bmatrix} \\ + h \begin{bmatrix} \frac{5}{6} & -\frac{2}{9} \\ \frac{2}{3} & \frac{1}{6} \end{bmatrix} \begin{bmatrix} f_{n+(1/2)} \\ f_n \end{bmatrix}. \tag{3.5}$$

The analogous error function equation for the second-order Adams–Bashforth–third-order Adams–Moulton PECE method has the form

$$e'(t) = f_y(y(t)) e(t) - [\gamma_3^* y^{IV}(t) + \beta_{3,0}^* \gamma_2 f_y(y(t)) y'''(t)], \tag{3.6}$$

where $\gamma_3^* = -\frac{1}{24}$, $\beta_{3,0}^* = \frac{5}{12}$, $\gamma_2 = \frac{5}{12}$. Notice the similarity between the arrangements of the coefficients of (3.4) and (3.6). It is obvious that (3.4) can be easily generalized to error functions of the higher-order two-stage block methods.

We are concerned that the propagation matrix

$$\begin{bmatrix} \frac{7}{18} & 0 \\ 0 & \frac{1}{6} \end{bmatrix} \begin{bmatrix} \frac{3}{7} & \frac{4}{7} \\ -4 & 5 \end{bmatrix} + \begin{bmatrix} \frac{5}{6} & -\frac{2}{9} \\ \frac{2}{3} & \frac{1}{6} \end{bmatrix} \tag{3.7}$$

of the error functions $e_1(t)$, $e_2(t)$ in (3.4) may be defective and lead to an accelerated error growth on the imaginary axis similar to that of the one-stage method (1.1). Surprisingly, (3.7) is actually the identity matrix. Recall that the defective error propagation matrix of the one-stage method (1.1) leads to the failure of that method. Such a defectiveness is absent in the current two-stage methods.

At this point there appears to be a natural choice of parameters for our q-processor, two-stage block method. This natural set of parameters simultaneously makes the stability polynomial equal to

$$\left[\xi - \left(\frac{\mu^2}{2} + \mu + 1 \right) \right]^q,$$

and the propagation matrix of the error function equation equal to an identity matrix. Although the number of these parameters increases tremendously as q increases, we will see shortly that the task of computing them is not very difficult.

For the natural set of parameters, the error function equation (3.4) becomes

$$\begin{bmatrix} e_1'(t) \\ e_2'(t) \end{bmatrix} = f_y(y(t)) \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix} + \begin{bmatrix} -\frac{1}{9} f_y(y(t)) y'''(t) + \frac{1}{36} y^{IV}(t) \\ 0 \end{bmatrix}. \tag{3.8}$$

The initial conditions are given by $e_1(t_0)=0$ and $e_2(t_0)=0$. Hence the component $e_2(t)$ is identically zero. Thus there is superconvergence for our two-processor, two-stage method at the gridpoints $t_1, t_2, \cdots, t_n, \cdots$. At the gridpoints, the two-processor method becomes fourth-order.

The error function equation provides us with a clue to calculate the natural choice of parameters for the family of two-stage block methods. Let us denote the predictor and corrector of the q-processor, two-stage block method by, respectively,

$$Y^p_{n+1}=A\cdot Y_n+B\cdot hF_n \tag{3.9}$$

and

$$Y_{n+1}=A^*\cdot Y_n+B^*\cdot hF_n+C^*\cdot hF^{\mathrm{p}}_{n+1}, \tag{3.10}$$

where A, B, A^*, B^*, and C^* are $q\times q$ matrices. Previous experience suggests that we should choose $A^*=I_{q\times q}$, the $q\times q$ identity matrix, and C^* a diagonal matrix. By making the corrector order $q+1$ we automatically fix B^*. The error analysis suggests that we compute the parameters $a_1, a_2, \cdots, b_1, b_2, \cdots, c_1, c_2, \cdots$ by setting the propagation matrix

$$C^*\cdot A+B^*=I_{q\times q}. \tag{3.11}$$

Thus we can solve for the a's, b's, $\cdots$ whenever C^* is nonsingular. (See Theorem 4.1.)

As an example, let us look at the three-processor, two-stage block method (2.8)-(2.9). Making $A^*=I_{3\times 3}$ transforms the second stage, (2.9), into

$$\begin{bmatrix} y_{n+(5/3)} \\ y_{n+(4/3)} \\ y_{n+1} \end{bmatrix}=\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}\begin{bmatrix} y_{n+(2/3)} \\ y_{n+(1/3)} \\ y_n \end{bmatrix}+h\begin{bmatrix} \frac{5}{16} & 0 & 0 \\ 0 & \frac{7}{32} & 0 \\ 0 & 0 & \frac{1}{8} \end{bmatrix}\begin{bmatrix} f^p_{n+(5/3)} \\ f^p_{n+(4/3)} \\ f^p_{n+1} \end{bmatrix}$$
$$+h\begin{bmatrix} \frac{13}{8} & -\frac{21}{16} & \frac{3}{8} \\ \frac{15}{16} & -\frac{1}{4} & \frac{3}{32} \\ \frac{3}{8} & \frac{3}{8} & \frac{1}{8} \end{bmatrix}\begin{bmatrix} f_{n+(2/3)} \\ f_{n+(1/3)} \\ f_n \end{bmatrix}.$$

Equating

$$\begin{bmatrix} \frac{5}{16} & 0 & 0 \\ 0 & \frac{7}{32} & 0 \\ 0 & 0 & \frac{1}{8} \end{bmatrix}\begin{bmatrix} 1-c_1-c_2 & c_2 & c_1 \\ 1-b_1-b_2 & b_2 & b_1 \\ 1-a_1-a_2 & a_2 & a_1 \end{bmatrix}+\begin{bmatrix} \frac{13}{8} & -\frac{21}{16} & \frac{3}{8} \\ \frac{15}{16} & -\frac{1}{4} & \frac{3}{32} \\ \frac{3}{8} & \frac{3}{8} & \frac{1}{8} \end{bmatrix}=\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

gives $a_1=7$, $a_2=-3$, $b_1=-\frac{3}{7}$, $b_2=\frac{40}{7}$, $c_1=-\frac{6}{5}$, $c_2=\frac{21}{5}$. The corresponding stability polynomial is indeed

$$\left[\xi-\left(\frac{\mu^2}{2}+\mu+1\right)\right]^3.$$

We also mentioned in § 2 that $a_1=19$, $a_2=27$, $b_1=\frac{45}{7}$, $b_2=-8$, $c_1=\frac{18}{5}$, $c_2=-\frac{27}{5}$ is an alternative set of parameters leading to the same stability polynomial. This alternative set makes the error propagation matrix

$$C^*\cdot A+B^*=\begin{bmatrix} \frac{5}{2} & -3 & \frac{3}{2} \\ \frac{3}{2} & -2 & \frac{3}{2} \\ \frac{3}{2} & -3 & \frac{5}{2} \end{bmatrix},$$

with eigenvalues also equal to $\{1, 1, 1\}$. However, this alternative error propagation matrix is defective, with a consequence of the error functions having an accelerated growth. In a straightforward way, one can now easily compute the predictor parameters for the four-processor, two-stage block method to be

$$a_1=\tfrac{83}{7},\quad a_2=-\tfrac{32}{7},\quad a_3=-\tfrac{12}{7},\quad b_1=\tfrac{32}{67},\quad b_2=\tfrac{255}{67},\quad b_3=\tfrac{160}{67},\quad c_1=\tfrac{380}{277},$$
$$c_2=-\tfrac{1728}{277},\quad c_3=\tfrac{4185}{277},\quad d_1=\tfrac{2560}{817},\quad d_2=-\tfrac{11060}{817},\quad d_3=\tfrac{17472}{817}.$$

With the natural choice of parameters for the two-stage block methods determined, one can show that the global error functions (for q-processors) satisfy

$$\begin{bmatrix} e_1'(t) \\ \vdots \\ e_q'(t) \end{bmatrix} = f_y(y(t)) \begin{bmatrix} e_1(t) \\ \vdots \\ e_q(t) \end{bmatrix} + C^*\mathbf{v} f_y(y(t)) y^{(q+1)}(t) + \mathbf{v}^* y^{(q+2)}(t), \tag{3.12}$$

where $\mathbf{v}$ and $\mathbf{v}^*$ are the coefficient vectors of the local errors of the predictor and corrector, respectively. For $q=3$ and 4, the driving terms in (3.12) are given by

$$\begin{bmatrix} -\frac{23}{648} \\ -\frac{17}{2592} \\ -\frac{1}{1296} \end{bmatrix} f_y(y(t)) y^{IV}(t) + \begin{bmatrix} \frac{23}{3240} \\ \frac{17}{12960} \\ \frac{1}{6480} \end{bmatrix} y^V(t)$$

and

$$\begin{bmatrix} -\frac{29}{3200} \\ -\frac{23}{9600} \\ -\frac{1}{2400} \\ 0 \end{bmatrix} f_y(y(t)) y^V(t) + \begin{bmatrix} \frac{29}{19200} \\ \frac{23}{57600} \\ \frac{1}{14400} \\ 0 \end{bmatrix} y^{VI}(t),$$

respectively. In general, it is possible to show that the order of the q-processor, two-stage block method at gridpoints $t_n, t_{n+1}, \cdots$ is given by

$$\begin{cases} q+1, & q \text{ odd}, \\ q+2, & q \text{ even}. \end{cases}$$

When q is even, the last component $e_q(t)$ in (3.12) turns out to be zero. We will investigate the form of the dominating term in the global error in this situation. As usual, the two-processor case may give us an idea of the general behavior. Therefore, we will compare the global error of the two-processor method, when expanded in a power series of h, to that of the Adams PECE method of comparable order. In this way we can be certain that there is no hidden error growth.

One can extend (3.1) to (for $a=5$ and $b=\frac{4}{7}$)

$$\begin{aligned} \begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} &= \begin{bmatrix} y(t_{n+(3/2)}) \\ y(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^3 e_1(t_{n+(3/2)}) \\ 0 \end{bmatrix} + \begin{bmatrix} h^4 g_1(t_{n+(3/2)}) \\ h^4 g_2(t_{n+1}) \end{bmatrix} \\ &\quad + \begin{bmatrix} h^5 w_1(t_{n+(3/2)}) \\ h^5 w_2(t_{n+1}) \end{bmatrix} + \mathcal{O}(h^6), \end{aligned} \tag{3.13}$$

with $w_1(t)$ and $w_2(t)$ being differentiable. By a tedious generalization of the derivations of (3.2) and (3.3), and making use of the now available function $e_1(t)$, one can prove that $g_1(t)$ and $g_2(t)$ in (3.13) satisfy

$$\begin{aligned} \begin{bmatrix} g_1'(t) \\ g_2'(t) \end{bmatrix} &= f_y(y(t)) \begin{bmatrix} g_1(t) \\ g_2(t) \end{bmatrix} + \begin{bmatrix} \frac{7}{960} \\ \frac{1}{2880} \end{bmatrix} y^V(t) + \begin{bmatrix} -\frac{5}{576} \\ -\frac{1}{576} \end{bmatrix} f_y(y(t)) y^{IV}(t) \\ &\quad + \begin{bmatrix} \frac{5}{6} \\ \frac{1}{3} \end{bmatrix} f_y(y(t)) f_y(y(t)) e_1(t) \\ &\quad + \begin{bmatrix} f_{yy}(y(t)) y'(t)(-\frac{1}{9} y'''(t) + \frac{1}{6} e_1(t)) - \frac{1}{2} e_1''(t) \\ -\frac{1}{3} f_{yy}(y(t)) y'(t) e_1(t) \end{bmatrix}. \end{aligned}$$

We would like to compare the global error expansion of the two-processor, two-stage method in power series form to those of the Adams PECE methods when applied to a linear test problem $y'(t)=\lambda y$. From the knowledge of the $e_i(t)$'s and $g_i(t)$'s, the two-processor, two-stage method has an error expansion of the form

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} y(t_{n+(3/2)}) \\ y(t_{n+1}) \end{bmatrix} + \begin{bmatrix} h^3\, e^{\lambda t_{n+(3/2)}} C_1 \lambda^4 t_{n+(3/2)} \\ 0 \end{bmatrix} \tag{3.14}$$
$$+ \begin{bmatrix} h^4\, e^{\lambda t_{n+(3/2)}} [C_2\lambda^6 t_{n+(3/2)}^2 + C_3\lambda^5 t_{n+(3/2)} + C_4\lambda^4] \\ h^4\, e^{\lambda t_{n+1}} [\hat{C}_2\lambda^6 t_{n+1}^2 + \hat{C}_3\lambda^5 t_{n+1}] \end{bmatrix} + \cdots .$$

The fourth-order Adams PECE method has a global error expansion of the form

$$y_{n+1} = y(t_{n+1}) + h^4\, e^{\lambda t_{n+1}} \tilde{C}_1 \lambda^5 t_{n+1} + \cdots .$$

The second component of (3.14) shows that even though the new two-processor, two-stage method is of order 4 at gridpoints, its global error is worse than that of the Adams PECE method with a fourth-order corrector, at least when $|\lambda t| > 1$. (One could think of the order of the two-processor, two-stage method as being 4^-.) This new method, however, outperforms the third-order Adams PECE method in accuracy because the $h^3\, e^{\lambda t}\mathcal{O}(\lambda^4 t)$ term in the global error of the block method is eliminated. Thus in general, the q-processor, two-stage method is more accurate than the $(q+1)$th-order Adams PECE method. (For the case when q is odd, the block method has a smaller error constant for the leading term of the global error.) Moreover, as q increases, the stability regions of the new methods do not shrink, while the stability regions of the Adams PECE methods shrink by a large amount. The stability regions for the first few elements of the Adams PECE family are plotted against that of the new two-stage block methods in Fig. 1. Based on the above discussion, we believe that the proposed family of two-stage parallel methods outperforms the Adams PECE

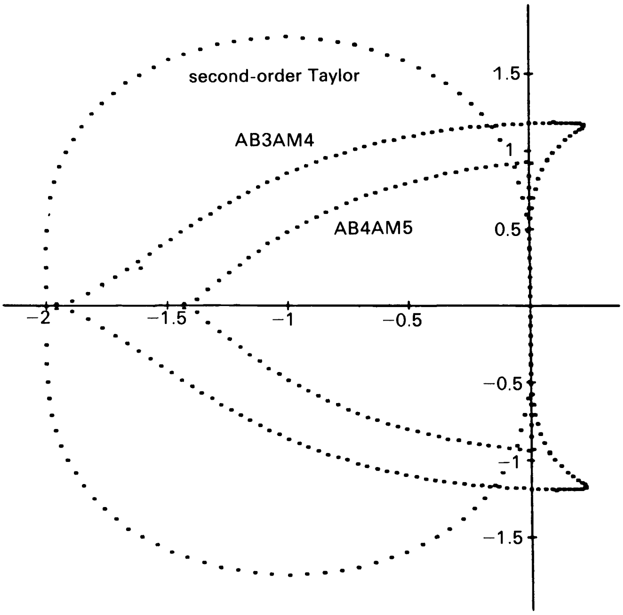

FIG. 1. *Stability regions of Adams* PECE *methods.*

family (a widely used class of serial methods) with a good speedup when executed on a parallel computer. Numerical simulations in § 6 appear to agree with this claim.

We would also like to discuss the implementation issues of the new family of two-stage block methods for a parallel computer. Existing two-stage parallel ODE methods, such as the predictor-corrector block methods in Shampine and Watts [7] or the predictor-corrector multiblock methods in Chu and Hamilton [2], all require two broadcasts per step. In these methods one has to share the function values of the predicted values computed in each processor. In the two-stage block methods in this paper, each processor uses only the function value of the predicted value computed by itself. Thus the number of broadcasts is cut by one-half. One should be aware that the amount of data to be communicated after the prediction, should it be necessary, and the amount of data communicated after the correction are not the same. In other existing parallel methods where one needs to communicate after the prediction, one broadcasts the function values of the intermediate solution values only. After the correction, however, one broadcasts both the solution values and their derivatives. Thus the amount of data broadcasted after the correction is twice that after the prediction. However, it takes startup overhead to initiate a broadcast in a parallel computer. Therefore the interprocessor communication time of the two-stage block methods in this paper is less than two-thirds of that of existing PECE parallel methods with the same number of saved values.

The way the new two-stage block methods are derived makes it easily transformable to a variable-step fashion. In a variable-step implementation of an ODE method, one needs to compute new method coefficients as the stepsize is changed. Shampine and Gordon [6] have derived an efficient way to evaluate the coefficients of the Adams PECE methods. One can derive a similar algorithm for the new two-stage block methods. To share this computational overhead, each processor can evaluate its own set of coefficients. Thus for the same number of previous time points, the amount of work each processor incurs is approximately equal to that of the Adams PECE methods. Since this load can be evenly distributed, the computational overhead of the new block methods is not much more than that of the Adams PECE methods. If we compare the two methods by order, the new block methods even have a smaller computational overhead per processor than the Adams PECE methods of the same order. Moreover, there are fewer step ratios in the block methods.

4. Variants of the two-stage block methods. We have abbreviated the q-processor, two-stage block method studied in § 3 by

$$Y_{n+1}^{p} = A \cdot Y_n + B \cdot hF_n, \tag{4.1}$$

$$Y_{n+1} = A^* \cdot Y_n + B^* \cdot hF_n + C^* \cdot hF_{n+1}^{p}. \tag{4.2}$$

Equations (4.1) and (4.2) represent, in fact, a whole class of methods of which the two-stage family of methods in the previous section are only some. It is interesting to study whether there exists any other element in the class of (4.1) and (4.2) that possesses a similar stability property, namely, that its stability polynomial is the perfect power of that of a simple method.

As in § 2, the complexity of the stability polynomial of (4.1) and (4.2) indicates that some insight is necessary. Previous experience in both the one-stage and two-stage methods suggests that $A^* = I_{q \times q}$ may be required. The condition (3.11) also turns out to be crucial. With these criteria it is possible to prove the following.

THEOREM 4.1. *Given an order $q+1$, $q \geq 0$ corrector for the two-stage block method* (4.1)-(4.2) *such that $A^* = I_{q\times q}$ and C^* is nonsingular, if A solves $C^* \cdot A + B^* = I_{q\times q}$, then*

(1) *the predictor* (4.1) *satisfies the zeroth order-condition, i.e., $Aw_1 = w_1$, where $w_1 = [1, \cdots, 1]^T$;*

(2) *if* (4.1) *is of order q, then B is uniquely determined, and the resulting stability polynomial is of the form*

$$\left[\xi - \left(\frac{\mu^2}{2} + \mu + 1\right)\right]^q.$$

Proof. The first order-condition for the corrector requires that $(B^* + C^*)w_1 = w_1$, which can be rewritten as $C^{*-1}(I - B^*)w_1 = Aw_1 = w_1$.

Since A satisfies the zeroth order-condition, if the predictor is of order q, B is uniquely determined by classical results on linear multistep methods.

The two-stage method, when applied to $y' = \lambda y$, is equivalent to

$$Y_{n+1} = [I + \mu B^* + \mu C^* \cdot (A + \mu B)]Y_n.$$

A necessary and sufficient condition for the stability polynomial of the two-stage method to equal

$$\left[\xi - \left(\frac{\mu^2}{2} + \mu + 1\right)\right]^q$$

is that A and B make

$$\left[\left(1 + \mu + \frac{\mu^2}{2}\right)I - (I + \mu(B^* + C^* \cdot A) + \mu^2 C^* \cdot B)\right]^q \tag{4.3}$$

equal to the zero matrix. The necessary condition is readily seen by the Cayley-Hamilton theorem. Conversely, if A and B make (4.3) equal to zero, then

$$\frac{\mu^2}{2} + \mu + 1$$

is the only eigenvalue of $I + \mu B^* + \mu C^* \cdot (A + \mu B)$. Hence the stability polynomial of the two-stage method must be

$$\left[\xi - \left(\frac{\mu^2}{2} + \mu + 1\right)\right]^q$$

by counting the number of eigenvalues.

Let

$$W(\mu) = \begin{bmatrix} e^{((q-1)/q)\mu} \\ \vdots \\ e^{(1/q)\mu} \\ 1 \end{bmatrix} = \begin{bmatrix} 1 + (\frac{q-1}{q})\mu + \cdots + (\frac{q-1}{q})^{q-1}\frac{\mu^{q-1}}{(q-1)!} \\ \vdots \\ 1 + (\frac{1}{q})\mu + \cdots + (\frac{1}{q})^{q-1}\frac{\mu^{q-1}}{(q-1)!} \\ 1 \end{bmatrix} + \mathcal{O}(\mu^q).$$

Since $C^* \cdot A + B^* = I_{q\times q}$, (4.3) becomes

$$[(\tfrac{1}{2}I - C^* \cdot B)\mu^2]^q.$$

If the predictor is of order q, the $(q+1)$th order-condition of the two-stage pair implies that

$$e^{\mu}W(\mu)=[(1+\mu)I+\mu^2C^*\cdot B]W(\mu)+\mathcal{O}(\mu^{q+2})$$

$$\Rightarrow(\tfrac{1}{2}I-C^*\cdot B)W(\mu)=\mathcal{O}(\mu)W(\mu)+\mathcal{O}(\mu^q)$$

$$\Rightarrow(\tfrac{1}{2}I-C^*\cdot B)^qW(\mu)=\mathcal{O}(\mu^q),$$

which, after equating coefficients of powers of μ, gives

$$(\tfrac{1}{2}I-C^*\cdot B)^q w_i(\mu)=0,$$

where

$$w_1=\begin{bmatrix}1\\ \vdots\\ 1\\ 1\end{bmatrix},\quad w_i=\begin{bmatrix}(\frac{q-1}{q})^{i-1}\\ \vdots\\ (\frac{1}{q})^{i-1}\\ 0\end{bmatrix},\quad i=2,\cdots,q.$$

Since the w_i's are linearly independent, $(\frac{1}{2}I-C^*\cdot B)^q=0$. Thus the stability polynomial of the two-stage method is equal to

$$\left[\xi-\left(\frac{\mu^2}{2}+\mu+1\right)\right]^q. \qquad \square$$

Example 4.1. With predictor parameters

$$a_1=7,\quad a_2=-3,\quad b_1=-21,\quad b_2=16,\quad c_1=42,\quad c_2=-39 \tag{4.4}$$

for (2.8), the coefficient matrices of the following corrector formula

$$\begin{bmatrix}y_{n+(5/3)}\\ y_{n+(4/3)}\\ y_{n+1}\end{bmatrix}=\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\end{bmatrix}\begin{bmatrix}y_{n+(2/3)}\\ y_{n+(1/3)}\\ y_n\end{bmatrix}+h\begin{bmatrix}\frac{1}{8}&\frac{3}{8}&\frac{3}{8}\\0&\frac{1}{8}&\frac{3}{8}\\0&0&\frac{1}{8}\end{bmatrix}\begin{bmatrix}f^{\mathrm{P}}_{n+(5/3)}\\ f^{\mathrm{P}}_{n+(4/3)}\\ f^{\mathrm{P}}_{n+1}\end{bmatrix}$$
$$+h\begin{bmatrix}\frac{1}{8}&0&0\\ \frac{3}{8}&\frac{1}{8}&0\\ \frac{3}{8}&\frac{3}{8}&\frac{1}{8}\end{bmatrix}\begin{bmatrix}f_{n+(2/3)}\\ f_{n+(1/3)}\\ f_n\end{bmatrix} \tag{4.5}$$

satisfy

$$\begin{bmatrix}\frac{1}{8}&\frac{3}{8}&\frac{3}{8}\\0&\frac{1}{8}&\frac{3}{8}\\0&0&\frac{1}{8}\end{bmatrix}\begin{bmatrix}1-c_1-c_2&c_2&c_1\\1-b_1-b_2&b_2&b_1\\1-a_1-a_2&a_2&a_1\end{bmatrix}+\begin{bmatrix}\frac{1}{8}&0&0\\ \frac{3}{8}&\frac{1}{8}&0\\ \frac{3}{8}&\frac{3}{8}&\frac{1}{8}\end{bmatrix}=\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\end{bmatrix}.$$

Equation (4.5) is simply the three-eighths rule in a repeated mode. The stability polynomial of this two-stage method is indeed

$$\left[\xi-\left(\frac{\mu^2}{2}+\mu+1\right)\right]^3.$$

By a global error analysis similar to the one given in § 3, one can verify that the propagation matrix of the error function of this two-stage method is the identity matrix $I_{3\times3}$.

Theorem 4.1 gives a constructive way to determine the predictor of a two-stage method with stability polynomial

$$\left[\xi-\left(\frac{\mu^2}{2}+\mu+1\right)\right]^q$$

once the corrector is fixed. The criterion that C^* be nonsingular seems to be essential in obtaining a perfect power stability polynomial. A fourth-order corrector example is given in [9] where no third-order predictor can be found to make the stability polynomial a perfect power. In that example C^* is singular.

Since there are numerous extensions to the two-stage block methods in § 3, we are led to question of which is the best and in what sense. It can be verified that when applied to the test problem $y'=\lambda y$, the error functions of both Example 4.1 and the pair (2.8), (2.9) with natural choice of parameters are equal. This is, incidentally, not surprising because both of them have the same stability polynomial. The following shows three two-processor, two-stage methods and their corresponding error function equations.

Example 4.2. The corrector (3.5) with the natural choice of parameters $a=5$, $b=\frac{4}{7}$ in the predictor (2.1), has an error function satisfying (3.8).

Example 4.3. The corrector

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix}=\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix}+h\begin{bmatrix} \frac{1}{6} & \frac{2}{3} \\ -\frac{2}{9} & \frac{5}{6} \end{bmatrix}\begin{bmatrix} f^p_{n+(3/2)} \\ f^p_{n+1} \end{bmatrix}$$
$$+h\begin{bmatrix} \frac{1}{6} & 0 \\ 0 & \frac{7}{18} \end{bmatrix}\begin{bmatrix} f_{n+(1/2)} \\ f_n \end{bmatrix},$$

with $a=\frac{11}{31}$, $b=-\frac{44}{31}$ in (2.1), has an error function equation

$$\begin{bmatrix} e_1'(t) \\ e_2'(t) \end{bmatrix}=f_y(y(t))\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix}+\begin{bmatrix} -\frac{1}{12}f_y(y(t))y'''(t) \\ \frac{1}{36}f_y(y(t))y'''(t)-\frac{1}{36}y^{IV}(t) \end{bmatrix}.$$

Example 4.4. The corrector

$$\begin{bmatrix} y_{n+(3/2)} \\ y_{n+1} \end{bmatrix}=\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} y_{n+(1/2)} \\ y_n \end{bmatrix}+h\begin{bmatrix} \frac{1}{6} & \frac{2}{3} \\ 0 & \frac{1}{6} \end{bmatrix}\begin{bmatrix} f^p_{n+(3/2)} \\ f^p_{n+1} \end{bmatrix}$$
$$+h\begin{bmatrix} \frac{1}{6} & 0 \\ \frac{2}{3} & \frac{1}{6} \end{bmatrix}\begin{bmatrix} f_{n+(1/2)} \\ f_n \end{bmatrix},$$

with $a=5$, $b=-20$ in (2.1), has an error function equation

$$\begin{bmatrix} e_1'(t) \\ e_2'(t) \end{bmatrix}=f_y(y(t))\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} e_1(t) \\ e_2(t) \end{bmatrix}+\begin{bmatrix} -\frac{1}{12}f_y(y(t))y'''(t) \\ 0 \end{bmatrix}.$$

For the test problem $y'(t)=\lambda y$, the driving term in each of the above three error functions is equal to $-\frac{1}{12}f_y(y(t))y'''(t)$. Hence, at least for the test problem, all these methods perform equally accurately.

Formula (2.9) and its higher-order extensions do give the lowest communication cost as compared to the other cases. Therefore we believe that (2.9) and its higher-order analogs are the most interesting ones.

There is only one minor drawback in the two-stage block methods. The magnitude of the coefficients increases as the order gets higher. The four-processor analog of

(2.8), (2.9) is given by

$$\begin{bmatrix} y^p_{n+(7/4)} \\ y^p_{n+(6/4)} \\ y^p_{n+(5/4)} \\ y^p_{n+1} \end{bmatrix} = \begin{bmatrix} \frac{8155}{817} & \frac{17482}{817} & -\frac{11060}{817} & \frac{2560}{817} \\ -\frac{2560}{277} & \frac{4185}{817} & -\frac{1728}{277} & \frac{380}{277} \\ -\frac{380}{67} & \frac{160}{67} & \frac{255}{67} & \frac{32}{67} \\ -\frac{32}{7} & -\frac{12}{7} & -\frac{32}{7} & \frac{83}{7} \end{bmatrix} \begin{bmatrix} y_{n+(3/4)} \\ y_{n+(2/4)} \\ y_{n+(1/4)} \\ y_n \end{bmatrix}$$

$$+h \begin{bmatrix} \frac{595}{43} & -\frac{21840}{817} & \frac{16590}{817} & -\frac{4480}{817} \\ \frac{1920}{277} & -\frac{2835}{277} & \frac{2160}{277} & -\frac{570}{277} \\ \frac{190}{67} & -\frac{120}{67} & \frac{195}{67} & -\frac{40}{67} \\ \frac{8}{7} & \frac{6}{7} & \frac{24}{7} & 1 \end{bmatrix} \begin{bmatrix} f_{n+(3/4)} \\ f_{n+(2/4)} \\ f_{n+(1/4)} \\ f_n \end{bmatrix},$$

$$\begin{bmatrix} y_{n+(7/4)} \\ y_{n+(6/4)} \\ y_{n+(5/4)} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} y_{n+(3/4)} \\ y_{n+(2/4)} \\ y_{n+(1/4)} \\ y_n \end{bmatrix}$$

$$+h \begin{bmatrix} \frac{817}{3150} & 0 & 0 & 0 \\ 0 & \frac{277}{1350} & 0 & 0 \\ 0 & 0 & \frac{67}{450} & 0 \\ 0 & 0 & 0 & \frac{7}{90} \end{bmatrix} \begin{bmatrix} f^p_{n+(7/4)} \\ f^p_{n+(6/4)} \\ f^p_{n+(5/4)} \\ f^p_{n+1} \end{bmatrix}$$

$$+h \begin{bmatrix} \frac{323}{90} & -\frac{416}{75} & \frac{158}{45} & -\frac{256}{315} \\ \frac{256}{135} & -\frac{21}{10} & \frac{32}{25} & -\frac{38}{135} \\ \frac{38}{45} & -\frac{16}{45} & \frac{13}{30} & -\frac{16}{225} \\ \frac{16}{45} & \frac{2}{15} & \frac{16}{45} & \frac{7}{90} \end{bmatrix} \begin{bmatrix} f_{n+(3/4)} \\ f_{n+(2/4)} \\ f_{n+(1/4)} \\ f_n \end{bmatrix}$$

with largest corrector coefficient $\frac{416}{75} \approx 5.5$ and largest predictor coefficient $\frac{21840}{817} \approx 26.7$. For the five-processor analog, the largest corrector coefficient has magnitude 21.5. The four-processor, two-stage method is still acceptable on a single precision machine, but the five-processor method may amplify noise in the derivative values. The corrector formula (4.5) and its higher-order analogs do have small enough coefficients, but the corresponding predictor coefficients are even larger than those of (2.9). For example, the corresponding predictor for (4.5) is given by

$$\begin{bmatrix} y^p_{n+(5/3)} \\ y^p_{n+(4/3)} \\ y^p_{n+1} \end{bmatrix} = \begin{bmatrix} -2 & -39 & 42 \\ 6 & 16 & -21 \\ -3 & -3 & 7 \end{bmatrix} \begin{bmatrix} y_{n+(2/3)} \\ y_{n+(1/3)} \\ y_n \end{bmatrix} + h \begin{bmatrix} 4 & 4 & 8 \\ 2 & -8 & -2 \\ 1 & 2 & 1 \end{bmatrix} \begin{bmatrix} f_{n+(2/3)} \\ f_{n+(1/3)} \\ f_n \end{bmatrix},$$

the largest coefficient of which is 42. Thus there is always a tradeoff between the magnitudes of the predictor and corrector coefficients. At this point it is not known how high one can push the order of case (4.5) without introducing intolerable noise amplification.

The problem of large formula coefficients is the nature of one-block parallel methods. It is the relatively large distance from t_{n+1} to $t_{n+1+((q-1)/q)}$, compared to h/q, that causes this drawback. To clarify this statement, let us look at the higher-order analogs of (2.9). The first component, with equation

$$y_{n+1+((q-1)/q)} = y_{n+((q-1)/q)} + \int_{t_{n+((q-1)/q)}}^{t_{n+1+((q-1)/q)}} \text{polynomial interpolating}$$

$$\{f^{\mathrm{p}}_{n+1+((q-1)/q)}, f_n, f_{n+(1/q)}, \cdots, f_{n+((q-1)/q)}\}\, dt,$$

is essentially a variable-stepsize Adams–Moulton formula having the stepsize changed abruptly from h/q to h. Hence it is not surprising that this equation will cause trouble (i.e., large coefficients) as q gets larger. A similar argument is valid for the predictor coefficients. One can, of course, manipulate the method parameters to keep the coefficients small (as is done in Shampine and Watts [7]), but the stability region will simultaneously diminish [1]. A better cure is simply to generalize the current one-block, q-processor, two-stage methods to multiblock methods.

5. Order enhancement by postprocessing. As the numerical integration of the ODE reaches the given output point t_{out}, where $t_N \leqq t_{\text{out}} \leqq t_{N+1}$, we need to generate an output value y_{out} at t_{out}. Usually t_{out} does not coincide with the gridpoints $t_N, \cdots, t_{N+((q-1)/q)}$. There are q values $y_N, y_{N+(1/q)}, \cdots, y_{N+((q-1)/q)}$ at our disposal. These values have global errors of the form

$$(5.1)\quad \begin{bmatrix} y_{N+((q-1)/q)} \\ \vdots \\ y_N \end{bmatrix} = \begin{bmatrix} y(t_{N+((q-1)/q)}) \\ \vdots \\ y(t_N) \end{bmatrix} + h^{q+1} \begin{bmatrix} e_1(t_{N+((q-1)/q)}) \\ \vdots \\ e_q(t_N) \end{bmatrix} + h^{q+2} \begin{bmatrix} g_1(t_{N+((q-1)/q)}) \\ \vdots \\ g_q(t_N) \end{bmatrix} + \cdots.$$

We would like to obtain y_{out} as accurately as possible by interpolating these q values of y. Recall that y_N is of order $q+2$ when q is even and order $q+1$ when q is odd, and the other y's are only of order $q+1$. It turns out that if we are willing to use the $f(y_n), \cdots, f(y_{N+((q-1)/q)})$ needed for the next step, we can make y_{out} of order $q+2$ at any point t_{out} for any q. The interpolation procedure can be illustrated by the case $q=3$. Let $t_{\text{out}} = t_{N+r} = t_N + rh$. When $q=3$, we have from (5.1) that

$$(5.2)\quad \begin{bmatrix} y_{N+(2/3)} \\ y_{N+(1/3)} \\ y_N \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} y(t_{N+r}) + h \begin{bmatrix} \frac{2}{3}-r \\ \frac{1}{3}-r \\ -r \end{bmatrix} y'(t_{N+r}) + \cdots + \frac{h^4}{4!} \begin{bmatrix} (\frac{2}{3}-r)^4 \\ (\frac{1}{3}-r)^4 \\ (-r)^4 \end{bmatrix} y^{IV}(t_{N+r}) + h^4 \begin{bmatrix} e_1(t_{N+r}) \\ e_2(t_{N+r}) \\ e_3(t_{N+r}) \end{bmatrix} + \mathcal{O}(h^5)$$

and

$$(5.3)\quad \begin{aligned} h \begin{bmatrix} f(y_{N+(2/3)}) \\ f(y_{N+(1/3)}) \\ f(y_N) \end{bmatrix} &= h \begin{bmatrix} f(y(t_{N+(2/3)}) + h^4 e_1(t_{N+(2/3)}) + \mathcal{O}(h^5)) \\ f(y(t_{N+(1/3)}) + h^4 e_1(t_{N+(1/3)}) + \mathcal{O}(h^5)) \\ f(y(t_N) + h^4 e_1(t_N) + \mathcal{O}(h^5)) \end{bmatrix} \\ &= h \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} y'(t_{N+r}) + h^2 \begin{bmatrix} \frac{2}{3}-r \\ \frac{1}{3}-r \\ -r \end{bmatrix} y''(t_{N+r}) + \cdots \\ &\quad + \frac{h^4}{3!} \begin{bmatrix} (\frac{2}{3}-r)^3 \\ (\frac{1}{3}-r)^3 \\ (-r)^3 \end{bmatrix} y^{IV}(t_{N+r}) + \mathcal{O}(h^5). \end{aligned}$$

Let

$$M_1=\begin{bmatrix} 1 & \frac{2}{3}-r & \frac{1}{2!}(\frac{2}{3}-r)^2 \\ 1 & \frac{1}{3}-r & \frac{1}{2!}(\frac{1}{3}-r)^2 \\ 1 & -r & \frac{1}{2!}(-r)^2 \end{bmatrix};$$

then (5.3) implies that

$$\begin{bmatrix} hy'(t_{N+r}) \\ h^2y''(t_{N+r}) \\ h^3y'''(t_{N+r}) \end{bmatrix} = M_1^{-1}\left\{ h\begin{bmatrix} f(y_{N+(2/3)}) \\ f(y_{N+(1/3)}) \\ f(y_N) \end{bmatrix} - \frac{h^4}{3!}\begin{bmatrix} (\frac{2}{3}-r)^3 \\ (\frac{1}{3}-r)^3 \\ (-r)^3 \end{bmatrix} y^{IV}(t_{N+r})\right\} + \mathcal{O}(h^5),$$

so that from (5.2),

$$\begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} y(t_{N+r}) = \begin{bmatrix} y_{N+(2/3)} \\ y_{N+(1/3)} \\ y_N \end{bmatrix} - M_2M_1^{-1}h\begin{bmatrix} f(y_{N+(2/3)}) \\ f(y_{N+(1/3)}) \\ f(y_N) \end{bmatrix} - h^4\begin{bmatrix} e(t_{N+r}) \\ e_2(t_{N+r}) \\ e_3(t_{N+r}) \end{bmatrix}$$

$$+\left\{ M_2M_1^{-1}\begin{bmatrix} \frac{1}{3!}(\frac{2}{3}-r)^3 \\ \frac{1}{3!}(\frac{1}{3}-r)^3 \\ \frac{1}{3!}(-r)^3 \end{bmatrix} - \begin{bmatrix} \frac{1}{4!}(\frac{2}{3}-r)^4 \\ \frac{1}{4!}(\frac{1}{3}-r)^4 \\ \frac{1}{4!}(-r)^4 \end{bmatrix}\right\} h^4y^{IV}(t_{N+r}) - \mathcal{O}(h^5),$$

where

$$M_2=\begin{bmatrix} \frac{2}{3}-r & \frac{1}{2!}(\frac{2}{3}-r)^2 & \frac{1}{3!}(\frac{2}{3}-r)^3 \\ \frac{1}{3}-r & \frac{1}{2!}(\frac{1}{3}-r)^2 & \frac{1}{3!}(\frac{1}{3}-r)^3 \\ -r & \frac{1}{2!}(-r)^2 & \frac{1}{3!}(-r)^3 \end{bmatrix}.$$

Using (3.12), if $\mathbf{u}^T$ satisfies

$$\mathbf{u}^T\left\{ M_2M_1^{-1}\begin{bmatrix} \frac{1}{3!}(\frac{2}{3}-r)^3 \\ \frac{1}{3!}(\frac{1}{3}-r)^3 \\ \frac{1}{3!}(-r)^3 \end{bmatrix} - \begin{bmatrix} \frac{1}{4!}(\frac{2}{3}-r)^4 \\ \frac{1}{4!}(\frac{1}{3}-r)^4 \\ \frac{1}{4!}(-r)^4 \end{bmatrix}, \begin{bmatrix} \frac{23}{648} \\ \frac{17}{2592} \\ \frac{1}{1296} \end{bmatrix}\right\} = 0,$$

then

$$\mathbf{u}^T\begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} y(t_{N+r}) = \mathbf{u}^T\begin{bmatrix} y_{N+(2/3)} \\ y_{N+(1/3)} \\ y_N \end{bmatrix} - \mathbf{u}^TM_2M_1^{-1}h\begin{bmatrix} f(y_{N+(2/3)}) \\ f(y_{N+(1/3)}) \\ f(y_N) \end{bmatrix} + \mathcal{O}(h^5).$$

The choice for $\mathbf{u}^T$ is not uniquely determined.

It is, however, impossible to further increase the order because it turns out that the g_i's in (5.1) cannot be annihilated.

The above procedure can be applied to any number of processors. The requirement to solve for M_1^{-1}, a $q \times q$ matrix, is insignificant since q is relatively small.

As a result of postprocessing, our two-stage block methods have order $q+2$ for q-processors.

6. Numerical results. The two-processor and four-processor two-stage methods are compared to the Adams PECE methods with third- and fifth-order correctors. We have done a number of experiments using selected test problems from [5] and [4]. The test problems and their analytic solutions are listed below:

1.

$$y'=-y, \quad y(0)=1, \quad t_{\text{out}}=20, \quad y(t)=e^{-t},$$

2.

$$y' = -\frac{y^3}{2}, \quad y(0) = 1, \quad t_{\text{out}} = 20, \quad y(t) = \frac{1}{\sqrt{1+t}},$$

3.

$$\begin{bmatrix} y_1' \\ y_2' \\ y_3' \end{bmatrix} = \begin{bmatrix} -y_2 - y_2 y_3/r \\ y_1 - y_2 y_3/r \\ y_1/r \end{bmatrix}, \quad y(0) = \begin{bmatrix} 3 \\ 0 \\ 0 \end{bmatrix}, \quad y(t) = \begin{bmatrix} (2+\cos t)\cos t \\ (2+\cos t)\sin t \\ \sin t \end{bmatrix},$$
$$t_{\text{out}} = 20, \quad r = \sqrt{y_1^2 + y_2^2},$$

4.

$$\begin{bmatrix} y_1' \\ y_2' \\ y_3' \\ y_r' \end{bmatrix} = \begin{bmatrix} y_2 \\ -y_1/r^3 \\ y_4 \\ -y_3/r^3 \end{bmatrix}, \quad y(0) = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \quad y(t) = \begin{bmatrix} \cos t \\ -\sin t \\ \sin t \\ \cos t \end{bmatrix},$$
$$t_{\text{out}} = 25, \quad r = \sqrt{y_1^2 + y_3^2},$$

5.

$$\begin{bmatrix} y_1' \\ y_2' \\ \vdots \\ y_{10}' \end{bmatrix} = \begin{bmatrix} -1 & & & \\ 1 & \ddots & & \\ & \ddots & -1 & \\ & & 1 & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_{10} \end{bmatrix}, \quad y(0) = \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}, \quad t_{\text{out}} = 20,$$
$$y(t) = \begin{bmatrix} e^{-t} \\ te^{-t} \\ \vdots \\ \frac{t^8}{8!} e^{-t} \\ 1 - (1 + t + \cdots + \frac{t^8}{8!}) e^{-t} \end{bmatrix},$$

6.

$$\begin{bmatrix} y_1' \\ y_2' \\ \vdots \\ y_{10}' \end{bmatrix} = \begin{bmatrix} -2 & 1 & & \\ 1 & \ddots & \ddots & \\ & \ddots & \ddots & 1 \\ & & 1 & -2 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_{10} \end{bmatrix} = T\Lambda T^{-1} \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_{10} \end{bmatrix},$$
$$t_{\text{init}} = 0, \quad t_{\text{out}} = 20, \quad y(t) = Te^{\Lambda t},$$

7.

$$y' = y, \quad y(0) = 1, \quad t_{\text{out}} = 10, \quad y(t) = e^t,$$

8.

$$\begin{bmatrix} y_1' \\ y_2' \end{bmatrix} = \begin{bmatrix} -\lambda & -\omega \\ \omega & -\lambda \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}, \quad y(0) = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad y(t) = \begin{bmatrix} e^{-\lambda t} \cos \omega t \\ e^{-\lambda t} \sin \omega t \end{bmatrix},$$
$$t_{\text{out}} = 20, \quad \lambda = 1, \quad \omega = \sqrt{3},$$

9.

$$y' = t(1-y) + (1-t)e^{-t}, \quad y(0) = 1, \quad t_{\text{out}} = 10,$$
$$y(t) = e^{-(t^2/2)} - e^{-t} + 1.$$

Problem 7 is an accuracy-bound example, while the rest are stability bound. These problems include tests on both the real and imaginary axes of the $h\lambda$-plane. Problems 5 and 6 show the behavior of the new methods on moderately large systems. The integration interval in each test problem is long enough to indicate any deficiency in the long-term behavior of each method. The problems are run using constant stepsizes on an Alliant FX/8. Exact starting information for each method is provided to compute the solution value at t_1. The number of decimal places of accuracy is computed by

$$-\log_{10}[\max_n \|y_n - y(t_n)\|_2].$$

Due to the small scale of the examples, we do not calculate the total run time, since the interprocessor communication time would have been a dominating portion of the overall timing.

The number of decimal places versus the number of functional evaluations per processor for various values of h are plotted in Figs. 2-10. These figures are sufficient to demonstrate the improvement of the block methods over the Adams PECE methods. In almost all cases, the four-processor block method outperforms the Adams PECE method with fifth-order corrector in both stability and accuracy. The average speedup is about 2.5 at an accuracy of four decimal places. This speedup does not include the effect of improved stability of the block method. A more conclusive speedup can be obtained by comparing the block methods against Adams PECE methods of all orders. As mentioned in the previous paragraph, we have not taken into account the delay in interprocessor communication. One has also to consider the overhead of the intrinsically sequential stepsize and order control in an ODE solver. These factors will degrade the performance of the block methods in practice. The current examples only indicate the

potential of the new methods. A more detailed comparison would take considerable effort and is not performed here.

7. Summary. In this paper we have discussed a useful family of parallel methods based on the approach of zero-stable methods with perfect power stability polynomials. These parallel methods have stability polynomials equal to

$$\left[\xi-\left(\frac{\mu^2}{2}+\mu+1\right)\right]^q$$

and stability regions essentially that of the second-order Taylor series method. Unlike conventional ODE methods, the stability regions of this new family remain unchanged as the order increases. While the one-stage methods in [10] with stability polynomials $[\xi-(1+\mu)]^q$ suffer from accelerated error growth due to coupling between time points, this family of two-stage methods has tolerable error growth. Numerical experiments show that the q-processor, two-stage block method outperforms the $(q+1)$th-order Adams PECE method in both stability and accuracy. The new family of methods also has a significantly lower interprocessor communication cost than other proposed parallel PECE methods. Extensions of this family of two-stage block methods to multiblock methods will be studied in a forthcoming paper.

SIMULATION AND APPROXIMATION OF STOCHASTIC PROCESSES BY SPLINE FUNCTIONS*

MICHAEL WEBA†

Abstract. Error bounds for simultaneous approximation of stochastic processes by means of spline functions are derived. As opposed to conventional methods, conditions such as regularity of covariances, stationarity, continuity of sample paths, etc. can be dropped, and the error bounds are valid with respect to arbitrary norms. Several applications are indicated: simulating solutions of some stochastic differential equations, computing distributions of continuous functionals by simulation as well as interpolation, numerical differentiation, and numerical integration of stochastic processes by splines.

Key words. stochastic processes, spline functions

AMS(MOS) subject classifications. 60G, 60H, 62E, 62M, 65C, 65D, 65U

1. Introduction. Let X be a stochastic process in continuous time that has been simulated or observed at distinct timepoints $t_1, \cdots, t_n \in [a, b]$. Many problems require "good" approximations of X on the whole interval $[a, b]$. The following may serve as examples:

—Simulate the output process

$$Y(s) = F(s, X(\cdot)), \qquad s \in \mathbb{R}$$

of a possibly nonlinear filter F depending on s and a complete trajectory of X on [a, b]. (In particular, solutions of certain stochastic differential or integral equations admit the above representation.) To this end the input process X has to be simulated at design points $t_i \in [a, b]$. The simulated values must be used to define an approximate version $\hat{X}$ of X; finally,

$$\hat{Y}(s) = F(s, \hat{X}(\cdot)), \qquad s \in \mathbb{R}$$

will be regarded as the simulated output process.

—Simulate the distribution of a continuous functional $\varphi \circ X$ by using $\varphi \circ \hat{X}$ where the approximation $\hat{X}$ of X is based on a finite number of simulated observations from X. For Gaussian processes this method has been studied by Eplett [9] and it can be applied to obtain the asymptotic distribution of rank test statistics.

—Produce a "smooth" representation of a time series X that has been recorded at distinct timepoints. If necessary, reconstruct missing data.

—Compute Stieltjes integrals and derivatives of stochastic processes and specify error bounds for the numerical calculations.

Spline functions are known to yield high-order approximations for differentiable nonrandom functions, and it is the purpose of this paper to examine the rate of convergence if random functions are considered instead. In certain cases splines can be interpreted as minimum variance unbiased linear (MVUL) predictors [14].

Hitherto, splines have frequently been used in nonparametric regression analysis where a nonrandom function $f(t)$ must be estimated if observations

$$Y(t_i) = f(t_i) + \varepsilon_i$$

* Received by the editors March 1, 1989; accepted for publication (in revised form) November 12, 1991.

† Institut für Mathematische Stochastik, Universität Hamburg, Bundesstraße 55, 2000 Hamburg 13, Germany.

are available. The quantities ε_i are random errors and spline estimators $h(t)$ of $f(t)$ are minimizing functionals such as

$$\lambda \cdot \int (h''(t))^2\,dt + \frac{1}{n} \cdot \sum_{i=1}^{n} (Y(t_i) - h(t_i))^2$$

with smoothing parameter $\lambda > 0$. (See Rice and Rosenblatt [19] and Wahba [28], [29].) The topics of this paper are completely different from this curve-fitting problem: the process itself is to be approximated rather than deterministic residuals, and the approximation is based on correct simulations or observations. For various applications of spline functions in stochastics, see also Karlin, Micchelli, and Rinott [12]; Miller and Wegman [17]; Wegman [31]; and Wegman and Wright [32]. Convergence of order-preserving splines is treated in Weba [30].

2. Basic definitions. $X = X(t)$, $t \in [a, b]$, always denotes a stochastic process on the probability space $(\Omega, \mathscr{A}, P)$ with real state space and the closed interval $[a, b] \subset \mathbb{R}$, $a < b$, as index set. Consider the linear space L_o of Borel measurable mappings from Ω into $\mathbb{R}$. It will be assumed that each random variable $X(t)$ lies in the normed vector space $(L, \|\cdot\|)$ where L is a linear subspace of L_o containing the constant mapping $Z_o(\omega) = 1$, $\omega \in \Omega$, and $\|\cdot\|$ stands for an arbitrary norm. (As usual, equivalent elements of L with respect to P will be identified. For simplicity, Z_o is required to satisfy $\|Z_o\| = 1$.) For example, L may be the space $L = L^p(\Omega, \mathscr{A}, P)$, $1 \leqq p \leqq \infty$, of random variables with finite pth moments being equipped with the L^p-norm, or L may be some Orlicz space.

Spline approximations are known to be efficient for differentiable functions $f: [a, b] \to \mathbb{R}$; therefore, some smoothness conditions must be imposed on X. Theorems on stochastic splines will be based on the space $C^m_\Omega[a, b]$ of processes having continuous derivatives[1] up to order $m \geqq 0$. Formally, $C^m_\Omega[a, b]$ is defined as

$$C^m_\Omega[a, b] = \{X: X^{(\mu)} \in C^0([a, b], L) \text{ for } 0 \leqq \mu \leqq m\},$$

where $[a, b]$ is endowed with the natural metric and $C^0([a, b], L)$ denotes the space of continuous mappings from $[a, b]$ into L. Under pointwise addition and scalar multiplication, $C^m_\Omega[a, b]$ becomes a normed linear space by setting

$$\|X\|_\infty = \max_{0 \leqq \mu \leqq m} \sup_{t \in [a, b]} \|X^{(\mu)}(t)\|.$$

By an obvious embedding, the space $C^m[a, b]$ of ordinary nonrandom functions with continuous derivatives up to order m can be viewed as a linear subspace of $C^m_\Omega[a, b]$.

In what follows, Δ always stands for a partition $a = t_0 < t_1 < \cdots < t_n = b$, $n \geqq 1$, of $[a, b]$ with fineness

$$|\Delta| = \max_{0 \leqq j \leqq n-1} h_{j+1}$$

where

$$h_{j+1} = t_{j+1} - t_j, \qquad 0 \leqq j \leqq n - 1.$$

Spline approximations $S_\Delta f$, which depend on Δ and $f \in C^m[a, b]$, are usually expressible as finite linear combinations

$$(S_\Delta f)(t) = d_0(t) + \sum_\mu \sum_i d_{\mu i}(t) \cdot f^{(\mu)}(t_{\mu i}), \qquad t \in [a, b]$$

[1] Derivatives are taken with respect to the norm on L.

with prescribed real-valued functions d_0 and $d_{\mu i}$ and fixed knots $t_{\mu i} \in \Delta$. Then the corresponding spline approximation $S_\Delta X$ of a process $X \in C^m_\Omega[a, b]$ is defined by

$$(S_\Delta X)(t) = d_0(t) + \sum_\mu \sum_i d_{\mu i}(t) \cdot X^{(\mu)}(t_{\mu i}), \qquad t \in [a, b].$$

Finally, the stochastic modulus of continuity $\eta(X; \varepsilon)$ of a process $X \in C^0_\Omega[a, b]$ is the function

$$\eta(X; \varepsilon) = \sup_{\substack{t_1, t_2 \in [a,b] \\ |t_1 - t_2| \leqq \varepsilon}} \|X(t_1) - X(t_2)\|, \qquad \varepsilon \geqq 0.$$

Note that, for $f \in C^0[a, b]$, $\eta(f; \varepsilon)$ coincides with the ordinary modulus of continuity because of $\|Z_o\| = 1$.

3. Convergence of stochastic splines. Error bounds for spline approximations of nonrandom functions $f \in C^m[a, b]$ can be established without additional conditions such as "regularity" or "stationarity"; therefore, it seems quite natural to pin one's hopes on the well-known procedures being applied to the paths of a stochastic process $X \in C^m_\Omega[a, b]$. Actually, an extension argument shows that the convergence properties can be carried over.

THEOREM. *Let $t_{\mu i} \in [a, b]$ be given knots and consider prescribed natural numbers $I(\mu)$, real numbers a_0* and *$a_{\mu i}$ and nonnegative real numbers b_μ, c_μ,and d_μ. Suppose the inequality*

$$\left| a_o + \sum_{\mu=0}^{m} \left(\sum_{i=1}^{I(\mu)} a_{\mu i} \cdot f^{(\mu)}(t_{\mu i}) \right) \right| \leqq \sum_{\mu=0}^{m} \left(b_\mu \cdot \sup_{t \in [a,b]} |f^{(\mu)}(t)| + c_\mu \cdot \eta(f^{(\mu)}; d_\mu) \right)$$

is valid for each $f \in C^m[a, b]$. Then each process $X \in C^m_\Omega[a, b]$ satisfies

$$\left\| a_0 \cdot Z_o + \sum_{\mu=0}^{m} \left(\sum_{i=1}^{I(\mu)} a_{\mu i} \cdot X^{(\mu)}(t_{\mu i}) \right) \right\| \leqq \sum_{\mu=0}^{m} \left(b_\mu \cdot \sup_{t \in [a,b]} \|X^{(\mu)}(t)\| + c_\mu \cdot \eta(X^{(\mu)}; d_\mu) \right).$$

Proof. Let $X \in C^m_\Omega[a, b]$ be a fixed process and consider

$$\xi = a_0 \cdot Z_o + \sum_{\mu=0}^{m} \left(\sum_{i=1}^{I(\mu)} a_{\mu i} \cdot X^{(\mu)}(t_{\mu i}) \right).$$

ξ lies in L; without loss of generality, one can assume $\xi \neq 0$. By the Hahn-Banach therorem there exists a bounded linear functional $\varphi : L \to \mathbb{R}$ having the properties $\|\varphi\| = 1$ and $\|\xi\| = \varphi(\xi)$. (See Corollary (14.13) in Hewitt and Stromberg [11].) Suppose $a_o \geqq 0$. Since the function $\varphi \circ X$ lies in $C^m[a, b]$ with

$$(\varphi \circ X)^{(\mu)} = \varphi \circ (X^{(\mu)}), \qquad 0 \leqq \mu \leqq m,$$

we obtain

$$\begin{aligned} \|\xi\| &= a_o \cdot \varphi(Z_o) + \sum_{\mu=0}^{m} \left(\sum_{i=1}^{I(\mu)} a_{\mu i} \cdot (\varphi \circ X)^{(\mu)}(t_{\mu i}) \right) \\ &\leqq \sum_{\mu=0}^{m} \left(b_\mu \cdot \sup_{t \in [a,b]} |(\varphi \circ X)^{(\mu)}(t)| + c_\mu \cdot \eta((\varphi \circ X)^{(\mu)}; d_\mu) \right) \\ &\leqq \sum_{\mu=0}^{m} \left(b_\mu \cdot \sup_{t \in [a,b]} \|X^{(\mu)}(t)\| + c_\mu \cdot \eta(X^{(\mu)}; d_\mu) \right). \end{aligned}$$

The case $a_0 < 0$ is treated analogously if we make use of the relations $\|(-\varphi)\| = 1$ and $\|\xi\| = (-\varphi)(-\xi)$. □

The above theorem will now be used to establish error bounds for simultaneous approximation of stochastic processes by piecewise cubic splines.

Let $f:[a, b]\to\mathbb{R}$ be a given function. A cubic interpolating spline function $S_\Delta f$ with respect to a partition Δ of $[a, b]$ is a real function with the properties: $S_\Delta f$ is twice continuously differentiable on $[a, b]$, $S_\Delta f$ coincides on every subinterval $[t_j, t_{j+1}]$ with a polynomial of maximal degree three, and $(S_\Delta f)(t_j)=f(t_j)$ holds for each j. In order to ensure uniqueness, the additional requirement

$$(S_\Delta f)'(a)=f'(a), \qquad (S_\Delta f)'(b)=f'(b)$$

is considered. (It is, of course, assumed that $f'(a)$ and $f'(b)$ exist.)

In the following corollary the symbols $(S_\Delta f)^{(3)}(t_j)$ and $(S_\Delta X)^{(3)}(t_j)$ stand for left-hand or right-hand limits. For any partition Δ of $[a, b]$ the quantity $\beta(\Delta)$ is defined by

$$\beta(\Delta)=\max_{0\leqq j\leqq n-1}\frac{|\Delta|}{h_{j+1}}.$$

In part (ii) of the corollary the space $L^p(\Omega, \mathcal{A}, P)$, $1\leqq p<\infty$, of random variables with finite pth moments is endowed with the usual L^p-norm

$$\|Z\|_p=(E|Z|^p)^{1/p}=\left(\int_\Omega |Z(\omega)|^p P(d\omega)\right)^{1/p}.$$

COROLLARY. *Suppose $X\in C^4_\Omega[a, b]$.*

(i) *For each partition Δ of $[a, b]$ and each $k\in\{0, 1, 2, 3\}$ the spline approximation $S_\Delta X$ fulfills*

$$\sup_{t\in[a, b]}\|X^{(k)}(t)-(S_\Delta X)^{(k)}(t)\|\leqq\beta_k\cdot\beta(\Delta)\cdot|\Delta|^{4-k}\cdot\sup_{t\in[a,b]}\|X^{(4)}(t)\|$$

with

$$\beta_0=\tfrac{7}{8}, \quad \beta_1=\beta_2=\tfrac{7}{4}, \quad \beta_3=2.$$

(ii) *Let L be the space $L=L^p(\Omega, \mathcal{A}, P)$, $1\leqq p<\infty$. If Δ_j, $j\geqq 1$, is a sequence of partitions satisfying the condition*

$$\sum_{j=1}^{\infty}(\beta(\Delta_j)\cdot|\Delta_j|^{4-k})^p<\infty$$

for some fixed $k\in\{0, 1, 2, 3\}$, then the relation

$$\lim_{j\to\infty}(S_{\Delta_j}X)^{(k)}(t)=X^{(k)}(t) \qquad (P\ \textit{almost surely})$$

holds for all $t\in[a, b]$.

Proof. Hold $t^*\in[a, b]$ and $k\in\{0, 1, 2, 3\}$ fixed. For each $f\in C^4[a, b]$, the approximation error $f^{(k)}(t^*)-(S_\Delta f)^{(k)}(t^*)$ is expressible as linear combination of $f(t_0)$, $f(t_1), \cdots, f(t_n)$, and $f'(t_0), f'(t_n), f^{(k)}(t^*)$, where coefficients depend on t^* but not on f. Moreover, we have

$$|f^{(k)}(t^*)-(S_\Delta f)^{(k)}(t^*)|\leqq\beta_k\cdot\beta(\Delta)\cdot|\Delta|^{4-k}\cdot\sup_{t\in[a,b]}|f^{(4)}(t)|$$

(see, e.g., [26, pp. 97-106]).

Therefore, part (i) of the corollary is an immediate consequence of the theorem. Part (ii) follows from (i) and the inequality

$$\sum_{j=1}^{\infty} E|X^{(k)}(t)-(S_{\Delta_j}X)^{(k)}(t)|^p<\infty. \qquad \square$$

Remarks. Let us note the following.

(1) By definition, the paths of the process $S_\Delta X$ are obtained by formal application of the spline operator S_Δ on the paths of X. For numerical calculations, we may therefore use standard algorithms for spline approximations. Note that the above error bounds hold with respect to the norm $\|\cdot\|$ of L; no explicit assumptions are made about the sample paths of X and nothing is said about the sample path behavior of $S_\Delta X$. However, if L is the space $L=L^p(\Omega, \mathcal{A}, P)$, then the pathwise approximation will be good "on the average," and under the mild summability condition of part (ii) convergence also occurs with probability 1.

(2) The corollary treats piecewise cubic splines with the boundary condition $(S_\Delta X)'(a)=X'(a)$, $(S_\Delta X)'(b)=X'(b)$. Analogously, error bounds can be carried over if the boundary conditions are changed or if splines are considered being defined by means of noncubic functions. Error bounds in the nonrandom case may be found in [4], [5], [24], or [27].

4. Applications. In the following, $S_\Delta X$ always denotes a fixed spline approximation of the process X, and $r_\Delta^{(k)}(X)$, $k\geqq 0$, stands for the error

$$r_\Delta^{(k)}(X)=\sup_{t\in[a,b]}\|X^{(k)}(t)-(S_\Delta X)^{(k)}(t)\|.$$

For piecewise cubic splines, upper bounds for $r_\Delta^{(k)}(X)$ have been derived in the preceding section.

4.1. Interpolation of stochastic processes. A classic approach to the problem of interpolating random functions, particularly in the field of time series analysis, is the following: given observations $X(t_0), \cdots, X(t_n)$, specification of a good approximation $\hat{X}(t)$ of $X(t)$, $t\in[t_0, t_n]$, is viewed as a special prediction problem. Typically, $\hat{X}(t)$ is chosen to be the linear combination of the observations, which minimizes the mean square error $E|X(t)-\hat{X}(t)|^2$.

Then $\hat{X}(t)$ may be calculated by using filtering techniques or by solving Yule–Walker equations (see [18] and [20]). To this end, however, assumptions about stationarity or the behavior of the spectrum have to be made. Also, the quantities involved such as autocovariances, spectral densities, etc. are usually unknown and must be estimated from the data. Unlike these methods, spline interpolation works for stationary and nonstationary processes. No information on spectral properties is needed and it is unnecessary to cope with estimation problems. Moreover, the derivatives of the process are approximated as well.

4.2. Numerical integration of stochastic processes. Similar to procedures in "ordinary" numerical analysis, splines can be utilized to compute integrals such as

$$\int_a^b g(t)\cdot X(t)\,dt.$$

Here $g:[a,b]\rightarrow\mathbb{R}$ is a given weight function, and the integral is an abstract Riemann integral; since this notion requires completeness, L is now assumed to be a Banach space.

If $S_\Delta(g\cdot X)$ is integrated instead of $g\cdot X$ one at least obtains the error bound

$$\left\| \int_a^b (S_\Delta(g\cdot X))(t)\,dt - \int_a^b g(t)\cdot X(t)\,dt \right\| \leqq (b-a)\cdot r_\Delta^{(0)}(g\cdot X),$$

provided $g\cdot X$ is sufficiently smooth.

In the literature, the problem of estimating the above integral is usually treated as a problem of statistical design or as a special regression problem. Conventional methods offer the following advantages: the sampling designs may be random designs, and within small classes of processes specific sampling designs such as median sampling (quantile sampling, respectively) are shown to yield asymptotically optimal estimates, and exact error rates including constants, rather than bounds are obtained. However, there are serious drawbacks. In addition to differentiability, regularity conditions have to be imposed on the covariance structure of the underlying process. It is also postulated that the process has exactly K derivatives; if the process has derivatives of arbitrary order, the theory gives no information. In particular, stationary processes with band-limited spectra cannot be treated. Furthermore, the whole theory deals exclusively with L^2-processes. For details, see [2], [3], [6], [8], [10], [21], [22], and [23].

Trapezoidal Monte Carlo integration of random processes is discussed in [16]. No regularity conditions are assumed, and for processes that are once mean-square continuously differentiable, it is shown that the rate of convergence of the mean-square approximation error is precisely n^{-4} (n is the sample size). The rate n^{-5} can be achieved for processes being twice mean-square continuously differentiable, provided stratified Monte Carlo integration is performed [7].

We now consider numerical integration by means of splines. No regularity conditions are required and the error bounds are valid with respect to an arbitrary Banach space $L\subset L_o$. The above rates of convergence may be substantially improved for smooth processes. For example, if piecewise cubic splines are used with equidistant knots $t_j = a+j\cdot h$, $0\leqq j\leqq n$, $h=(b-a)/n$, then $g\cdot X\in C_\Omega^4[a,b]$ already guarantees

$$E\left| \int_a^b (S_\Delta(g\cdot X))(t)\,dt - \int_a^b g(t)\cdot X(t)\,dt \right|^2 = O(n^{-8})$$

for $L=L^2(\Omega, \mathscr{A}, P)$.

4.3. Simulating solutions of ordinary stochastic differential equations. Assume $L=L^2(\Omega, \mathscr{A}, P)$. Consider the stochastic differential equation

$$X'(t) = -\alpha\cdot X(t) + Y'(t), \qquad t\in[0,T]$$

with initial condition

$$X(0)=Z,$$

where $\alpha>0$ is a given constant, Z a random variable with finite variance, and $Y\in C_\Omega^1[0,T]$ a stochastic process. If the random fluctuations of X are to be studied by simulation we have to simulate Z and the forcing function Y at timepoints t_i of a prescribed partition Δ of $[a,b]=[0,T]$. However, calculation of the unique solution

$$X(t) = Y(t) + e^{-\alpha t}\cdot(Z-Y(0)) - \alpha\cdot\int_0^t e^{-\alpha(t-s)}\cdot Y(s)\,ds, \qquad t\in[0,T]$$

requires knowledge of Y on the whole interval. Using $S_\Delta Y$, which is based on the simulated values $Y(0),\cdots, Y(T)$, and computing the approximate solution

$$\hat{X}_\Delta(t) = (S_\Delta Y)(t) + e^{-\alpha t}\cdot(Z-Y(0)) - \alpha\cdot\int_0^t e^{-\alpha(t-s)}\cdot(S_\Delta Y)(s)\,ds,$$

the discretization error satisfies

$$\|X(t)-\hat{X}_\Delta(t)\|_2 \leqq (2-e^{-\alpha t}) \cdot r_\Delta^{(0)}(Y)$$

for each $t \in [0, T]$. (Recall that $\|\cdot\|_2$ stands for the L^2-norm.) For simplicity, the discussion has been restricted to the above equation. Analogously, any functional equation in terms of the forcing function yields an approximation $\hat{X}_\Delta$. Representations for more complicated equations can be found, e.g., in [1] and [13].

4.4. Simulating distributions of continuous functionals. Let L be the space $L = L^2(\Omega, \mathscr{A}, P)$. Some topics in statistics require the distribution of $\varphi \circ X$ where φ is a continuous functional on a set of stochastic processes. Since it is often difficult to derive an explicit formula, this distribution must be computed by simulations. If X is a Gaussian process this problem has been studied by Eplett [9]. For certain functionals related to L^p-norms, a result is given by Weba [30] that holds for non-Gaussian processes as well. The idea is to simulate $\varphi \circ X$ by computing $\varphi \circ \hat{X}$; $\hat{X}$ is based on a finite number of simulated observations from X. For a smooth process X, spline approximations may be used, and there is the additional advantage that φ is also allowed to depend on derivatives of X. For example, assume $X \in C^1_\Omega[a, b]$ and consider

$$\varphi \circ X = \int_a^b X(t) \cdot X'(t)\, dt.$$

(Since both X and X' are L^2-continuous, the integrand is L^1-continuous. Hence $\varphi \circ X$ is a well-defined random variable with finite expectation being the L^1-limit of Riemann sums.) Set

$$\varphi \circ S_\Delta X = \int_a^b (S_\Delta X)(t) \cdot (S_\Delta X)'(t)\, dt$$

on condition that $(S_\Delta X)'$ is piecewise L^2-continuous. Then

$$\begin{aligned} &E|\varphi \circ X - \varphi \circ S_\Delta X| \\ &\quad \leqq (b-a) \cdot \sup_{t\in[a,b]} E|X(t) \cdot X'(t) - (S_\Delta X)(t) \cdot (S_\Delta X)'(t)| \\ &\quad \leqq (b-a) \cdot \sup_{t\in[a,b]} E|X(t) \cdot (X'(t) - (S_\Delta X)'(t))| \\ &\qquad + (b-a) \cdot \sup_{t\in[a,b]} E|(S_\Delta X)'(t) \cdot (X(t) - (S_\Delta X)(t))|, \end{aligned}$$

and the inequality of Cauchy-Schwarz gives

$$\begin{aligned} &E|\varphi \circ X - \varphi \circ S_\Delta X| \leqq (b-a) \\ &\qquad \cdot \left(r_\Delta^{(1)}(X) \cdot \sup_{t\in[a,b]} \|X(t)\|_2 + r_\Delta^{(0)}(X) \cdot \sup_{t\in[a,b]} \|(S_\Delta X)'(t)\|_2 \right). \end{aligned}$$

Furthermore, arbitrary $\alpha \in \mathbb{R}$ and $\varepsilon > 0$ satisfy

$$\begin{aligned} &P(\varphi \circ S_\Delta X \leqq \alpha - \varepsilon) - P(|\varphi \circ X - \varphi \circ S_\Delta X| \geqq \varepsilon) \\ &\quad \leqq P(\varphi \circ X \leqq \alpha) \leqq P(\varphi \circ S_\Delta X \leqq \alpha + \varepsilon) + P(|\varphi \circ X - \varphi \circ S_\Delta X| \geqq \varepsilon). \end{aligned}$$

By Markov's inequality,

$$P(|\varphi \circ X - \varphi \circ S_\Delta X| \geqq \varepsilon) \leqq \varepsilon^{-1} \cdot E|\varphi \circ X - \varphi \circ S_\Delta X|.$$

The distance between two distribution functions F and G is often expressed in terms of the Lévy distance

$$D(F, G)=\inf\{\delta>0\colon F(x-\delta)-\delta \leqq G(x) \leqq F(x+\delta)+\delta \text{ for each } x \in \mathbb{R}\}.$$

Consequently, the Lévy distance $D(\varphi \circ X, \varphi \circ S_\Delta X)$ between the distribution functions of $\varphi \circ X$ and $\varphi \circ S_\Delta X$ fulfills

$$D^2(\varphi \circ X, \varphi \circ S_\Delta X) \leqq (b-a) \cdot \Big(r_\Delta^{(1)}(X) \cdot \sup_{t \in [a,b]} \|X(t)\|_2 + r_\Delta^{(0)}(X) \cdot \sup_{t \in [a,b]} \|X'(t)\|_2 + r_\Delta^{(0)}(X) \cdot r_\Delta^{(1)}(X) \Big).$$

Under the assumptions of the above corollary one obtains

$$D(\varphi \circ X, \varphi \circ S_\Delta X) = O(|\Delta|^{3/2})$$

for piecewise cubic splines, provided that $\beta_\Delta = O(1)$ holds.

5. A numerical example. Stochastic differential equations of the type

$$X'(t) = F(t, X(t), Y(t))$$

are frequently used to describe phenomena in electrodynamics, population genetics, economics, etc., where random perturbations are involved. The stochastic properties of the forcing function Y may lead to substantial stochastic fluctuations of the solution X.

The probabilistic behavior of $X(t)$ can be studied by means of simulations. Consider, e.g., the assumptions of § 4.3, where the equation

$$X'(t) = -\alpha \cdot X(t) + Y'(t), \qquad t \in [0, T],$$

with $\alpha > 0$ and initial condition $X(0) = Z$, has been treated. This equation can be regarded as a model for a population that is dying out where the constant rate of "growth" is given by $-\alpha$.

As indicated above, we may simulate Y at timepoints t_i and compute the approximate solution $\hat{X}_\Delta$ by means of some spline function $S_\Delta Y$; the discretization error depends on Y and satisfies

$$\|X(t) - \hat{X}_\Delta(t)\|_2 \leqq (2 - e^{-\alpha t}) \cdot r_\Delta^{(0)}(Y)$$

for each $t \in [0, T]$.

The numerical calculations are based on the following assumptions:

—$T = 5$, $\alpha = (\ln 2)/5$, $\mathrm{X}(0) = \text{const.} = 100$.

—$\Delta = \{t_0, t_1, \cdots, t_n\}$, $t_i = ih$, $h = 0.2$, $n = 25$.

—The random variables $Y(t_0), \cdots, Y(t_n)$ are given by

$$Y(t_0) = 0, \quad Y(t_i) = Y(t_{i-1}) + \delta_i, \quad 1 \leqq i \leqq n,$$

where $\delta_1, \cdots, \delta_n$ are independent and normally distributed with mean value zero and standard deviation $\sigma > 0$.

—$S_\Delta Y$ is the piecewise linear spline function with

$$(S_\Delta Y)(t_i) = Y(t_i), \qquad 0 \leqq i \leqq n.$$

(In other words, $S_\Delta Y$ is a linear polynomial on each subinterval $[t_i, t_{i+1}]$ and interpolates Y. The theorem of the third section may be applied to derive upper bounds for $r_\Delta^{(0)}(Y)$; for instance, $Y \in C_\Omega^2[a, b]$ implies $r_\Delta^{(0)}(Y) = O(|\Delta|^2)$.)

TABLE 1
Values of $\hat{X}_\Delta$ $(\sigma = 1)$.

First, three different (independent) samples from $\delta_1, \delta_2, \cdots, \delta_n$ have been generated; in each case $(S_\Delta Y)(t)$ has been used to compute $\hat{X}_\Delta(t)$ at times $t_0, t_1, \cdots, t_n$. The results for $\sigma=1$ can be found in Table 1. In order to show that the influence of the perturbation process Y is substantial the procedure has been repeated with $\sigma=2$, $\sigma=3$, and $\sigma=5$; see Tables 2-4. In addition, the values of the function

$$f_0(t)=100\cdot\exp\left(-\frac{\ln 2}{5}\cdot t\right)$$

are also given where f_0 is the solution of the differential equation in the absence of random perturbation.

Acknowledgment. The author wishes to express his gratitude to an unknown referee for numerous suggestions and improvements.

A COMPARISON OF THREE MIXED METHODS FOR THE TIME-DEPENDENT MAXWELL'S EQUATIONS*

PETER MONK†

Abstract. Three mixed finite-element methods for approximating Maxwell's equations are compared. A dispersion analysis provides a Courant–Friedrichs–Lewy (CFL) bound that is necessary for convergence when a uniform mesh is used. The dispersion analysis also allows a comparison of the stability properties of the methods. Superconvergence at the interpolation points is proved for uniform grids, and demonstrated by three numerical examples. All three methods are shown to be able to handle discontinuous media without modification of the finite-element spaces. Since all three methods have three-dimensional counterparts, this study suggests that all three methods could be the basis of a successful three-dimensional code.

Key words. Maxwell's equations, finite elements, mixed methods

AMS(MOS) subject classifications. 65N30, 78-08

1. Introduction.

In a recent paper, Lee and Madsen [9] present numerical results for a novel mixed finite-element method for approximating the time-dependent Maxwell's equations. Applying the method to two-dimensional problems, they show, by numerical examples, that their method has good dispersion properties and can handle discontinuous dielectric constants without special modification of the finite-element spaces. The purpose of this paper is to investigate the dispersion properties of the Lee–Madsen method analytically, and to compare the algorithm to two other mixed finite-element methods due (in three dimensions) to Nédélec [13] and Monk [12]. The Nédélec scheme is of particular interest since it uses a special space of piecewise linear polynomials to approximate the electric field, yet does not need modification where the dielectric constant is discontinuous. This is in contrast to methods based on standard continuous piecewise linear elements (cf. [9]). Our analysis will also show the connection between the mixed finite-element methods analyzed in this paper and the standard Yee finite-difference method for Maxwell's equations [18].

Our study is limited to Maxwell's equations in two space dimensions. Of course this is not the setting of real physical interest; however, the two-dimensional case makes a convenient test problem for rapid comparison of methods. Unfortunately, some features of Maxwell's equations, such as the divergence-free nature of the magnetic flux density, are lost in the two-dimensional case.

Besides the paper of Lee and Madsen [9], Adam, Serveniere, Nédélec, and Raviart [1] have also examined the use of mixed methods to discretize Maxwell's equations. The method of Adam et al. [1] is closely related to the two-dimensional analogue of the method of Monk [12], but does not allow for discontinuous dielectric constant or conductivity. Adam et al. [1] present a dispersion and error analysis for their method in the case when the mass matrix is lumped. In this paper we deal with the full mass matrix and allow discontinuous coefficients.

The method of Lee and Madsen is also related to a prior method suggested by Cangellaris, Lin, and Mei [3]. They proposed and discussed a point-matching (or collocation) method based on the use of continuous bilinear finite-element spaces for

both the electric and magnetic fields, but on staggered grids. For other references concerning the use of finite-element methods in discretizing Maxwell's equations, see [9], and for a discussion of developments in finite-difference methods, see [16].

The plan of the paper is as follows. In §2 we discuss two general classes of variational principles for the time-dependent Maxwell system. Then in §3 we give details of the three finite-element methods examined in this paper. We discuss error estimates and derive the discrete equations in the special case of a uniform grid. These equations show the connections between the methods in this paper and standard finite-difference methods (cf. [18]). In §4, we use the discrete equations on a uniform grid to compare the three methods via a dispersion analysis. Section 5 is devoted to numerical experiments with the three methods. For ease of comparison, we have used examples from [9] as test problems.

2. Variational principles for Maxwell's equations. We begin by deriving two general classes of methods for Maxwell's equations [9], [13], [12], [11]. Since our numerical examples are all in two space dimensions, we consider Maxwell's equations for a linear isotropic material in which the magnetic field $\boldsymbol{H}$ is z-polarized. Thus if $\boldsymbol{E} = (E^{(1)}(\boldsymbol{x},t), E^{(2)}(\boldsymbol{x},t))$ and $\boldsymbol{H} = H(\boldsymbol{x},t)$ where $\boldsymbol{x} = (x,y)$, we have that

$$\epsilon \frac{\partial \boldsymbol{E}}{\partial t} + \sigma \boldsymbol{E} = \vec{\nabla} \times H - \boldsymbol{J}, \tag{1}$$

$$\mu \frac{\partial H}{\partial t} = -\nabla \times \boldsymbol{E}, \tag{2}$$

where ϵ, σ, and μ are known functions of $\boldsymbol{x}$ giving the dielectric constant (ϵ), permeability (μ), and conductivity (σ), respectively. $\boldsymbol{J} = (J^{(1)}, J^{(2)})$ is a function of space and time giving the current density. The vector curl ($\vec{\nabla}\times$) is defined by

$$\vec{\nabla} \times f = \left(\frac{\partial f}{\partial y}, -\frac{\partial f}{\partial x}\right), \tag{3}$$

and the scalar curl ($\nabla\times$) by

$$\nabla \times \boldsymbol{v} = \frac{\partial}{\partial x} v^{(2)} - \frac{\partial}{\partial y} v^{(1)} \tag{4}$$

(we use $v^{(j)}$ to refer to the jth component of a vector $\boldsymbol{v}$). Equations (1) and (2) are solved in a plane polygonal region Ω with boundary Γ and we assume the boundary condition

$$\boldsymbol{n} \times \boldsymbol{E} = \gamma, \tag{5}$$

where $\boldsymbol{n}$ is the unit outward normal to Ω, $\boldsymbol{n} \times \boldsymbol{E} = E^{(1)}n^{(2)} - E^{(2)}n^{(1)}$ and γ is a specified function. If $\gamma \equiv 0$, this boundary condition models a perfect conducting boundary. In addition, initial data must be specified so that we assume that

$$\boldsymbol{E}(0) = \boldsymbol{E}_0 \quad \text{and} \quad H(0) = H_0, \tag{6}$$

where $\boldsymbol{E}_0$ and H_0 are given functions. Equations (1), (2), (5), and (6) are a well-posed system of equations (cf. [5], [1], [10]) provided $\epsilon, \mu, \gamma, \sigma$, and $\boldsymbol{J}$ are sufficiently smooth and satisfy standard positivity and boundedness assumptions.

To derive a weak or variational formulation of (1)–(6), we proceed formally (for details of the function space setting, see [5], [12]). Multiplying (1) by a test function

$\boldsymbol{\phi}(\boldsymbol{x})$ and (2) by $\psi(\boldsymbol{x})$ and integrating over Ω, we obtain the following equations where $(\boldsymbol{u},\boldsymbol{v}) = \int_\Omega u^{(1)}v^{(1)} + u^{(2)}v^{(2)}\,dA$ and $(u,v) = \int_\Omega uv\,dA$,

$$(\epsilon \boldsymbol{E}_t + \sigma \boldsymbol{E}, \boldsymbol{\phi}) = (\vec{\nabla} \times H, \boldsymbol{\phi}) - (\boldsymbol{J}, \boldsymbol{\phi}), \tag{7}$$

$$(\mu, H_t, \psi) = -(\nabla \times \boldsymbol{E}, \psi). \tag{8}$$

This pair of equations is not suitable for discretization since, in general, it would not result in an energy-conserving discrete problem. Instead we choose to integrate one of the curl terms in (7) or (8) by parts. One choice will lead to the method of Lee and Madsen, the other to the method of Nédélec.

Let

$$H(\text{curl};\Omega) = \{\boldsymbol{u} \in (L^2(\Omega))^2 \mid \nabla \times \boldsymbol{u} \in L^2(\Omega)\},$$
$$H_0(\text{curl};\Omega) = \{\boldsymbol{u} \in H(\text{curl};\Omega) \mid \boldsymbol{n} \times \boldsymbol{u} = 0 \text{ on } \Gamma\},$$

and let $\boldsymbol{E}(t) = \boldsymbol{E}(\cdot,t)$ and $H(t) = H(\cdot,t)$ (see [6] for a complete discussion of the curl spaces). If we integrate (7) by parts, then provided $\boldsymbol{\phi} \in H_0(\text{curl};\Omega)$ we are led to the conclusion that $\boldsymbol{E}(t) \in H(\text{curl};\Omega), H(t) \in L^2(\Omega)$ satisfies

$$(\epsilon \boldsymbol{E}_t + \sigma \boldsymbol{E}, \boldsymbol{\phi}) = (H, \nabla \times \boldsymbol{\phi}) - (\boldsymbol{J}, \boldsymbol{\phi}) \quad \forall \boldsymbol{\phi} \in H_0(\text{curl};\Omega), \tag{9}$$

$$(\mu H_t, \psi) = -(\nabla \times \boldsymbol{E}, \psi) \quad \forall \psi \in L^2(\Omega), \tag{10}$$

and

$$\boldsymbol{n} \times \boldsymbol{E} = \gamma \quad \text{on}\, \Gamma, \tag{11}$$

together with the initial condition (6). Note that in this case the test function $\boldsymbol{\phi}$ must have a well-defined scalar curl and must satisfy the boundary condition $\boldsymbol{n} \times \boldsymbol{\phi} = 0$. In this formulation the boundary conditions are essential. Nédélec's method is based on (9)–(11).

Alternatively, we may integrate (8) by parts to obtain that $\boldsymbol{E}(t) \in (L^2(\Omega))^2$ and $H(t) \in H(\vec{\text{curl}};\Omega) \equiv \{v \in L^2(\Omega) | \vec{\nabla} \times v \in (L^2(\Omega))^2\}$ satisfy

$$(\epsilon \boldsymbol{E}_t + \sigma \boldsymbol{E}, \boldsymbol{\phi}) = (\vec{\nabla} \times H, \boldsymbol{\phi}) - (\boldsymbol{J}, \boldsymbol{\phi}) \quad \forall \boldsymbol{\phi} \in (L^2(\Omega))^2, \tag{12}$$

$$(\mu H_t, \psi) = -(\boldsymbol{E}, \vec{\nabla} \times \psi) + \langle \gamma, \psi \rangle \quad \forall \psi \in H(\vec{\text{curl}};\Omega), \tag{13}$$

together with the initial condition (6). Note that in this case neither trial nor test functions need to satisfy any boundary conditions, and the boundary condition $\boldsymbol{n} \times \boldsymbol{E} = \gamma$ is imposed naturally. The system (12)–(13) is the basis for the method of Lee–Madsen [9] and the method of Monk [12].

Next we discretize in space to produce an approximate method of lines for Maxwell's equations. Later we shall detail discretization in time. To discretize (9)–(11) we let $U_h^N \subset H(\text{curl};\Omega), U_{ho}^N = U_h^N \cap H_0(\text{curl};\Omega)$, and $V_h^N \subset L^2(\Omega)$ be finite-dimensional spaces indexed by h. In this paper each space will be a finite-element space, but at this stage we could allow other possibilities, such as spectral method spaces. The semidiscrete problem corresponding to (9)–(11) is to find $(\boldsymbol{E}^h(t), H^h(t)) \in U_h^N \times V_h^N$ such that

$$(\epsilon \boldsymbol{E}_t^h + \sigma \boldsymbol{E}^h, \boldsymbol{\phi}^h) = (H^h, \nabla \times \boldsymbol{\phi}^h) - (\boldsymbol{J}, \boldsymbol{\phi}^h) \quad \forall \boldsymbol{\phi}^h \in U_{ho}^N, \tag{14}$$

$$(\mu H_t^h, \psi^h) = -(\nabla \times \boldsymbol{E}^h, \psi^h) \quad \forall \psi^h \in V_h^N, \tag{15}$$

$$\boldsymbol{n} \times \boldsymbol{E}^h = \gamma^h \quad \text{on } \Gamma, \tag{16}$$

and

$$E^h(0) = E_0^h \quad \text{and} \quad H^h(0) = H_0^h, \tag{17}$$

where $\gamma^h \in \boldsymbol{n} \times U_h^N$ approximates $\gamma, \boldsymbol{E}_0^h \subset U_h^N$ approximates $\boldsymbol{E}_0$, and $H_0^h \subset V_h^N$ approximates H_0. Note that U_h^N need only be a subspace of $H(\text{curl};\Omega)$ and need not be in $(H^1(\Omega))^2$. Standard continuous linear finite elements are in $(H^1(\Omega))^2$ and thus are too smooth. This manifests itself in the complex way that standard elements must be adapted to handle interfaces where ϵ is discontinuous (cf. [9] and §5.3 of this paper). Nédélec's construction gives elements in $H(\text{curl};\Omega)$ but not in $(H^1(\Omega))^2$.

To discretize (12)–(13) we take finite-dimensional spaces $U_h^L \subset (L^2(\Omega))^2$ and $V_h^L \subset H(\vec{\text{curl}};\Omega)$. Then seek $(\boldsymbol{E}^h(t), H^h(t)) \in U_h^L \times V_h^L$ such that

$$(\epsilon \boldsymbol{E}_t^h + \sigma \boldsymbol{E}^h, \boldsymbol{\phi}^h) = (\vec{\nabla} \times H^h, \boldsymbol{\phi}^h) - (J, \boldsymbol{\phi}^h) \quad \forall \boldsymbol{\phi} \in U_h^L, \tag{18}$$

$$(\mu H_t^h, \psi^h) = -(\boldsymbol{E}^h, \vec{\nabla} \times \psi^h) + \langle \gamma, \psi^h \rangle \quad \forall \psi^h \in V_h^L, \tag{19}$$

and

$$\boldsymbol{E}^h(0) = E_0^h \quad \text{and} \quad H^h(0) = H_0^h, \tag{20}$$

where $\boldsymbol{E}_0^h \subset U_h^L$ and $H_0^h \subset V_h^L$, respectively, approximate $\boldsymbol{E}_0$ and H_0.

In this case, the boundary condition need not be imposed on the finite-element functions. Note that $V_h^L \subset H(\vec{\text{curl}};\Omega)$ and so, in this two-dimensional problem, we need $V_h^L \subset H^1(\Omega)$. Thus in this case, standard finite elements can be used to construct V_h^L. In fact, Lee and Madsen [9] use standard isoparametric piecewise bilinear functions on quadrilateral elements. The space $U_h^L \subset (L^2(\Omega))^2$, and thus a candidate space, is the space of piecewise constant vectors, which is the choice used by Lee and Madsen [9]. Monk [12] uses a slightly augmented space.

One final remark is that the general methods (14)–(17) and (18)–(20) both conserve energy (before time discretization). To see this, consider the case when $\sigma \equiv 0$, $\boldsymbol{J} \equiv 0$, $\gamma \equiv 0$. Then taking $\psi^h = H^h$ and $\boldsymbol{\phi}^h = \boldsymbol{E}^h$ in (14)–(17) or (18)–(19) and adding (14)–(15) or (18)–(19) we obtain

$$(\epsilon \boldsymbol{E}_t^h, \boldsymbol{E}^h) + (\mu H_t^h, H^h) = 0. \tag{21}$$

Thus

$$\frac{1}{2}\frac{d}{dt}\{(\epsilon \boldsymbol{E}^h, \boldsymbol{E}^h) + (\mu H^h, H^h)\} = 0,$$

and so,

$$(\epsilon \boldsymbol{E}^h(t), \boldsymbol{E}^h(t)) + (\mu H^h(t), H^h(t)) = (\epsilon \boldsymbol{E}^h(0), \boldsymbol{E}^h(0)) + (\mu H^h(0), H^h(0)), \tag{22}$$

which states that the energy in the discrete system is independent of time. This energy conservation is the reason for integrating by parts in (7) and (8) to ensure that the curl terms cancel. The above energy equality can be used to derive error estimates for the finite-element methods (see [11] and §3 of this paper).

3. Discretization in space and time. In this section we give details of each of the methods to be analyzed. We start by subdividing Ω using a collection of quadrilateral elements $\tau_h = \{K_i\}_{i=1}^{N_h}$ with maximum diameter h, which obey the usual finite-element mesh restrictions [4]. The basis functions for each finite-element space are obtained using the isoparametric method by mapping basis functions on a reference element to the target element. Let the domain of the reference element be

$$\hat{K} = \{(x, y) \mid 0 \le \hat{x} \le 1,\ 0 \le \hat{y} \le 1\}, \tag{23}$$

then let $\boldsymbol{F}_{K_i}$ be the bilinear map from $\hat{K}$ to K_i. If K_i has vertices with coordinates $\{\boldsymbol{a}_j^{(i)}\}_{j=1}^4$ and $\hat{\boldsymbol{x}} = (\hat{x}, \hat{y})$, then

$$\boldsymbol{F}_{K_i}(\hat{\boldsymbol{x}}) = \boldsymbol{a}_1^{(i)}(1-\hat{x})(1-\hat{y}) + \boldsymbol{a}_2^{(i)}\hat{x}(1-\hat{y}) + \boldsymbol{a}_3^{(i)}\hat{x}\hat{y} + \boldsymbol{a}_4^{(i)}(1-\hat{x})\hat{y}. \tag{24}$$

We denote the Jacobian of $\boldsymbol{F}_{K_i}$ by $\boldsymbol{J}_{K_i}(\hat{x})$.

In general,

$$\boldsymbol{E}^h(t) = \sum_{j=1}^{N_E} E_j(t)\boldsymbol{\phi}_j(\boldsymbol{x}) \quad \text{and} \quad H^h(t) = \sum_{j=1}^{N_H} H_j \psi_j(\boldsymbol{x}), \tag{25}$$

where N_E and N_H are the number of degrees of freedom for $\boldsymbol{E}^h$ and H^h, respectively, and $\{\boldsymbol{\phi}_j(\boldsymbol{x})\}_{j=1}^{N_E}$ and $\{\psi_j(x)\}_{j=1}^{N_H}$ are suitable basis functions.

In the remainder of the paper we use the notation that Q_{ij} is the set of all polynomials of degree at most i in x and at most j in y. Thus Q_{00} is the space of constant functions and $Q_{10} = \{p \mid p = a + bx \quad a, b \in \mathbb{R}\}$.

3.1. Lee and Madsen's method. This method has the simplest spaces. The electric field space is just the space of piecewise constant vectors. Thus

$$U_h^L = \{\boldsymbol{u}^h \mid \boldsymbol{u}^h|_K \in Q_{00} \times Q_{00} \quad \forall K \in \tau_h\}. \tag{26}$$

A suitable basis for this space is the set of piecewise constant vector functions in which one component is nonzero on exactly one element in the grid. The space V_h^L is the standard continuous piecewise bilinear isoparametric space. Thus to construct V_h^L, we define the reference element $(\hat{K}, P_{\hat{K}}, \Sigma_{\hat{K}})$ [4] by taking $\hat{K}$ to be the reference domain in (23) with vertices $\{\hat{\boldsymbol{a}}_i\}_{i=1}^4$, the local space $P_{\hat{K}}$ to be the standard space of bilinear polynomials so that $P_{\hat{K}} = Q_{11}$, and the local degrees of freedom to be

$$\Sigma_{\hat{K}} = \{p(\hat{\boldsymbol{a}}_i) \mid 1 \le i \le 4\}. \tag{27}$$

Then on each element $K \in \tau_h$ we have that the jth basis function is given by $\psi_j|_K(\boldsymbol{x}) = \hat{\psi}(F_K^{-1}(\boldsymbol{x}))$ for some $\hat{\psi} \in P_{\hat{K}}$. Thus

$$V_h^L = \{v_h \in C(\overline{\Omega}) \mid v_h|_K = \hat{v}_K \circ F_K^{-1} \quad \text{for some} \quad \hat{v}_K \in Q_{11} \quad \forall K \in \tau_h\}. \tag{28}$$

Following the isoparametric philosophy, all integrations are performed on $\hat{K}$ by mapping from a given element K to $\hat{K}$ using the mapping F_K^{-1}. We use four-point Gaussian quadrature on $\hat{K}$ to compute integrals. This is exact if F_K is affine and of precision three in general.

In summary, the degrees of freedom for the discontinuous electric field space U_h^L are the values of the electric field at the centroid of each element. The degrees of freedom for the magnetic field space V_h^L are the values of the field at the vertices of the mesh. In keeping with Lee and Madson [9], we refer to this method as ECHL (E constant, H linear).

We now apply the ECHL algorithm on a uniform mesh and consider the equations satisfied by the degrees of freedom. Figure 1 shows a portion of the mesh for the

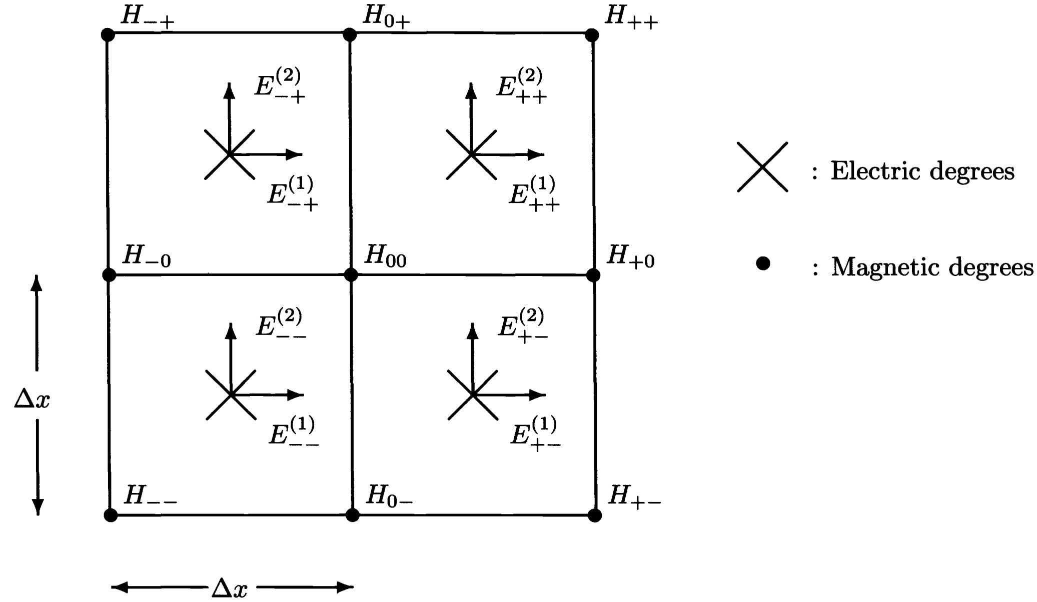

FIG. 1. *A portion of a uniform quadrilateral grid showing the positions of the degrees of freedom for Lee's method. The equations for the indicated degrees of freedom are given in* (29)–(31).

method with the degrees of freedom labeled. If we consider the very special case of (18)–(19) with $\boldsymbol{J} \equiv 0, \sigma \equiv 0, \epsilon = \mu = 1$, and (U_h^L, V_h^L) given by (26) and (28), we obtain the following equations for the degrees of freedom:

$$\frac{d}{dt}E^{(1)}_{++} - \left(\frac{(H_{0+}+H_{++})-(H_{00}+H_{+0})}{2\Delta x}\right) = 0, \tag{29}$$

$$\frac{d}{dt}E^{(2)}_{++} + \left(\frac{(H_{+0}+H_{++})-(H_{0+}+H_{00})}{2\Delta x}\right) = 0, \tag{30}$$

$$\begin{aligned}&\frac{d}{dt}\left[\frac{1}{36}[H_{+-}+H_{++}+H_{--}+H_{-+}]\right.\\ &\qquad\left.+\frac{1}{9}[H_{0-}+H_{-0}+H_{+0}+H_{0+}]+\frac{4}{9}H_{00}\right]\\ &+\frac{1}{2\Delta x}\left\{[(E^{(2)}_{++}+E^{(2)}_{+-})-(E^{(2)}_{-+}+E^{(2)}_{--})]\right.\\ &\qquad\left.-[(E^{(1)}_{++}+E^{(1)}_{-+})-(E^{(1)}_{+-}+E^{(1)}_{--})]\right\} = 0.\end{aligned} \tag{31}$$

Clearly (29)–(31) are a centered difference approximation to (1)–(2) and thus have local truncation error $O((\Delta x)^2)$ provided $\boldsymbol{E}$ and H are smooth enough. Given the stability result (21), this implies that on a uniform mesh, ECHL converges with error $O((\Delta x)^2)$ at the points indicated in Fig. 1 (convergence is in the discrete L^2 norm at each timestep [11]). More precisely, let us define the norms

$$\|u\|_{0,\epsilon} = \sqrt{(\epsilon u, u)} \quad \text{and} \quad \|u\|_{0,\mu} = \sqrt{(\mu u, u)}, \tag{32}$$

and let $r_h\boldsymbol{E} \in U_h^L$ interpolate $\boldsymbol{E}$ at the interpolation points shown in Fig. 1. Let $r_h H \in V_h^L$ be the interpolant for the magnetic field space. Then the stability estimate

(22) and the second-order local truncation error of the method imply that

$$\|(r_h\boldsymbol{E} - \boldsymbol{E}^h)(t)\|_{\epsilon,0} + \|(r_hH - H^h)(t)\|_{\mu,0} = O((\Delta x)^2), \tag{33}$$

provided the initial data is chosen to satisfy (33) at $t = 0$.

In trying to prove convergence on more general domains, we see that ECHL suffers from a big theoretical drawback in that the spaces (U_h^L, V_h^L) do not satisfy an appropriate inf-sup condition and hence ECHL is not included in the general theory of Brezzi [2]. In this context, the inf-sup condition would state that for every nonconstant $H^h \in V_h^L$ (i.e., a function such that $\int_\Omega |\nabla H^h|^2\, d\boldsymbol{x} \neq 0$) there should exist a function $\phi^h \in U_h^L$ such that $(\vec{\nabla} \times H^h, \phi^h) \neq 0$. However, at least for some meshes, it is easy to construct a function $H^{*h} \in V_h^L$ such that

$$(\vec{\nabla} \times H^{*h}, \phi^h) = 0 \quad \forall \phi^h \in U_h^L, \tag{34}$$

so that the inf-sup condition does not hold. To see this, consider first the reference element $\hat{K} = [0,1] \times [0,1]$. Let $\hat{H}^* \in Q_{11}$ be the bilinear function such that $\hat{H}^*(0,0) = \hat{H}^*(1,1) = 1$ and $\hat{H}^*(1,0) = \hat{H}^*(0,1) = -1$. Direct computation shows that $\vec{\nabla} \times \hat{H}^* = (2-4\hat{x}, -2+4\hat{y})^T$ and hence $\int_{\hat{K}} \vec{\nabla} \times \hat{H}^* \cdot \phi = 0$ for any constant vector ϕ. For a general mesh, copies of this function can often be used to construct a function $H^{*h} \in V_h^L$ that satisfies (34). For example, on a square domain, meshed with a uniform grid of squares, H^{*h} is the piecewise bilinear function that interpolates ± 1 at the vertices with the values of $+1$ and -1 arranged in a checkerboard configuration. We can use H^{*h} to show nonphysical behavior in ECHL. Suppose we solve (21)–(25) with $\boldsymbol{J} \equiv 0$ and $\gamma \equiv 0$ and with initial data

$$\boldsymbol{E}_0^h = 0, \qquad H_0^h = H^{*h}.$$

Then we see that the solution at later times is given by

$$\boldsymbol{E}^h(t) = 0, \qquad H^h(t) = H^{*h}.$$

Given the perfect conducting boundary condition, this solution is nonphysical. Of course, H^{*h} oscillates on a wavelength of order h and thus it is not surprising that the numerical method propagates this high frequency solution poorly. In §4, we use a dispersion analysis to investigate the accuracy of wave propagation as a function of frequency and wavelength for each of the methods discussed in this paper. The lack of an inf-sup condition makes general error estimation difficult and it is not proven, to our knowledge, that ECHL is convergent on general grids. Nevertheless, for smooth data it is possible for the method to converge and work well in practice, as we shall see.

The next method is based on the same variational formulation as ECHL, but the space for the electric field has been modified so that the inf-sup condition holds.

3.2. The MECHL method. This method is based on (18)–(20) and is obtained by restricting the three-dimensional method of [12] to two dimensions by assuming H is z-polarized and independent of z. Let us denote the spaces for the method by U_h^M and V_h^M. The method has the same space for the magnetic field as is used by Lee and Madsen, thus $V_h^M = V_h^L$. The electric field space U_h^M is the space U_h^L of ECHL augmented by some linear terms. Therefore, we refer to this method as the MECHL (modified ECHL).

To define the electric field space, denoted U_h^M, we first give the reference element $(\hat{K}, P_{\hat{K}}, \Sigma_{\hat{K}})$. Again $\hat{K}$ is given by (23), and

$$P_{\hat{K}} = \{\boldsymbol{p} \mid \boldsymbol{p} \in Q_{10} \times Q_{01}\},$$
$$\Sigma_{\hat{K}} = \left\{\boldsymbol{p} \cdot \hat{\boldsymbol{n}}(\boldsymbol{b}_i)\, 1 \leq i \leq 4 \mid, \text{ where } \boldsymbol{b}_i = \frac{\boldsymbol{a}_i + \boldsymbol{a}_{i+1}}{2}(\boldsymbol{a}_5 = \boldsymbol{a}_1)\right\}.$$

In these definitions $\hat{\boldsymbol{n}}$ is the unit outward normal to $\hat{K}$. This choice of $P_{\hat{K}}$ is made since $\vec{\nabla} \times Q_{11} \subset Q_{10} \times Q_{01}$, and we want to construct U_h^M such that $\nabla \times V_h^M \subset U_h^M$. Since V_h^M is an isoparametric space, this implies some care with the way that U_h^M is obtained from the reference element. By computing $\vec{\nabla} \times \psi$ for $\psi \in V_h^M$, we find that the correct choice is

$$U_h^M = \{\boldsymbol{u}^h \mid \boldsymbol{u}^h|_K = ((\det \boldsymbol{J}_K)^{-1}\boldsymbol{J}_K\hat{\boldsymbol{u}}_K) \circ F_K^{-1} \text{ for some } \hat{\boldsymbol{u}}_K \in Q_{10} \times Q_{01} \quad \forall K \in \tau_h\}. \tag{35}$$

This space has as degrees of freedom $\boldsymbol{u}^h \cdot \boldsymbol{n}$ at the midpoint of each edge of each element. However, since we wish to allow ϵ, the permittivity, to be discontinuous, we do not require continuity of $\boldsymbol{u}^h \cdot \boldsymbol{n}$ across element boundaries. So the actual degrees of freedom on element K are

$$\lim_{\substack{\boldsymbol{x} \to \boldsymbol{b} \\ \boldsymbol{x} \in K}} \boldsymbol{u}^h(\boldsymbol{x}) \cdot \boldsymbol{n}_K(\boldsymbol{b}),$$

where $\boldsymbol{n}_K$ is the outward normal to K and $\boldsymbol{b}$ is the midpoint of an edge. If we know that ϵ is continuous, we can decrease the dimension of U_h^M by enforcing continuity of normal components across element boundaries. In that case, U_h^M becomes the lowest-order Raviart–Thomas divergence-conforming space [14] and MECHL becomes essentially the method of Adam et al. [1] (but without mass lumping and with different boundary conditions).

The transformation used in (35) to obtain $\boldsymbol{u}^h|_K$ from $\hat{\boldsymbol{u}}$ implies that

$$\nabla \times V_h^M \subset U_h^M \tag{36}$$

so that the analysis of Monk [12] holds and we can be sure that, on a general mesh, the method converges with error

$$\|(\boldsymbol{E} - \boldsymbol{E}^h)(t)\|_{0,\epsilon} + \|(H - H^h)(t)\|_{0,\mu} = O(h), \tag{37}$$

provided the standard assumptions on isoparametric meshes hold [4], the exact solution is sufficiently smooth, and the initial data for the discrete problem satisfies (37). This is an optimal global estimate since U_h^M does not contain all vector linear polynomials on the reference element.

Note also that in the special case when $\epsilon = \mu = 1$ (or constant) and $\sigma \equiv 0, \boldsymbol{J} \equiv 0$, the fact that $\nabla \times V_h^M \subset U_h^M$ implies that (1) is satisfied pointwise exactly. In particular, we have that

$$\boldsymbol{E}_t^h = \vec{\nabla} \times H^h,$$

and hence $\nabla \cdot \boldsymbol{E}_t^h = 0$. Thus if the initial data $\boldsymbol{E}_0^h$ is chosen so that $\nabla \cdot \boldsymbol{E}_0^h$ is defined and $\nabla \cdot \boldsymbol{E}_0^h = 0$ in Ω, then we can be sure that

$$\nabla \cdot \boldsymbol{E}^h = 0$$

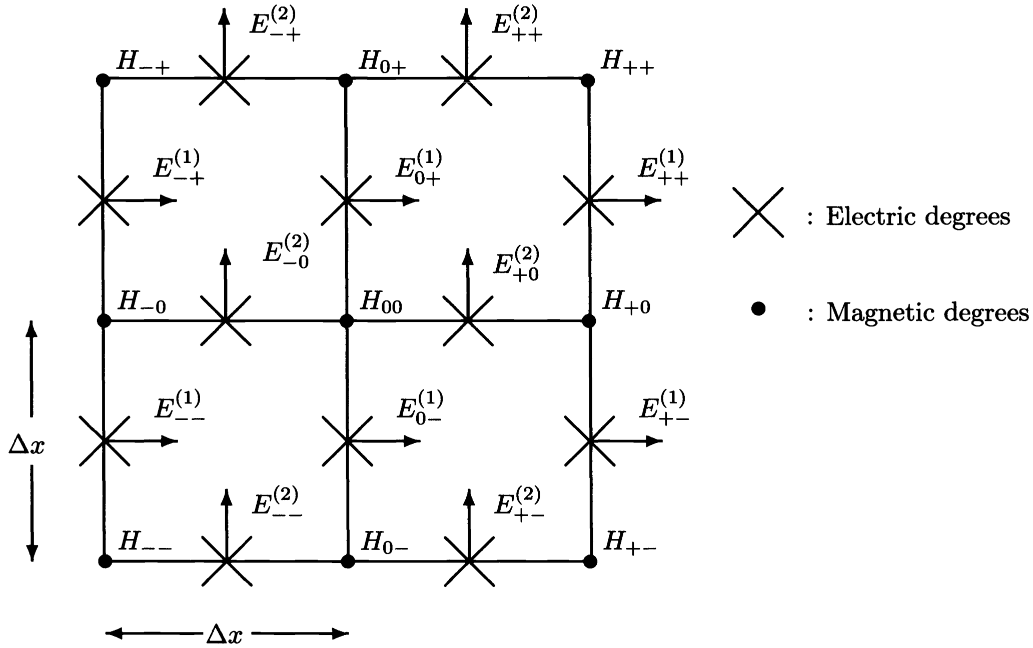

FIG. 2. *The degrees of freedom for* MECHL *on a uniform square grid. In this case we assume that the electric field has continuous normal component across the edge of each element. Thus the electric field degrees of freedom are the normal component of the field at the midpoint of each edge marked* ×. *The magnetic degrees of freedom (marked* •) *are the same as for* ECHL (*see Fig.* 1).

for all time. Thus in some cases, MECHL allows the exact satisfaction of the equations for the electric field. We remark that $\nabla \cdot \boldsymbol{E}_0^h$ is defined if $\boldsymbol{E}_0^h$ is chosen so that the normal components of $\boldsymbol{E}_0^h$ are continuous across each edge of the mesh [13].

We can also analyze MECHL on a uniform grid. We assume, as before, that $\epsilon = \mu = 1, \sigma \equiv 0, \boldsymbol{J} \equiv 0$, and since ϵ is continuous we assume that $\boldsymbol{E}^h$ has continuous normal component across each edge of the mesh. The arrangement of degrees of freedom is shown in Fig. 2. On the uniform mesh, we can derive the following equations for the degrees of freedom.

$$\frac{d}{dt}E^{(1)}_{0+} - \frac{H_{0+} - H_{00}}{\Delta x} = 0, \tag{38}$$

$$\frac{d}{dt}E^{(2)}_{+0} + \frac{H_{+0} - H_{00}}{\Delta x} = 0, \tag{39}$$

$$\begin{aligned} &\frac{d}{dt}\left[\frac{1}{36}[H_{++} + H_{--} + H_{+-} + H_{-+}]\right. \\ &\qquad \left. + \frac{1}{9}[H_{-0} + H_{0-} + H_{+0} + H_{0+}] + \frac{4}{9}H_{00}\right] \\ &\quad + \frac{1}{6\Delta x}\left[[(E^{(2)}_{++} + 4E^{(2)}_{+0} + E^{(2)}_{+-}) - (E^{(2)}_{-+} + 4E^{(2)}_{-0} + E^{(2)}_{--})]\right. \\ &\qquad \left. -[(E^{(1)}_{-+} + 4E^{(1)}_{0+} + E^{(1)}_{++}) - (E^{(1)}_{--} + 4E^{(1)}_{0-} + E^{(1)}_{+-})]\right] = 0. \end{aligned} \tag{40}$$

We see that this is another centered finite-difference analogue of (1)–(2) and hence has local truncation error $O((\Delta x)^2)$. Again the stability of the method implies that in the weighted discrete L^2 norm (cf. (32) and (33)), the order of convergence for the method is $O((\Delta x)^2)$ at the points shown in Fig. 2. The precise form of the estimate is exactly as given in (33), provided $\boldsymbol{r}_h$ and r_h are taken to be the interpolation operators for U_h^M and V_h^M, respectively. This is a superconvergence result since the order at selected points is one greater than the global error expected using U_h^M.

By comparison, a Yee-type [18] finite-difference scheme for this problem, with the grid and degrees of freedom shown in Fig. 2, would be

$$\frac{d}{dt}E_{0+}^{(1)} - \frac{H_{0+} - H_{00}}{\Delta x} = 0, \tag{41}$$

$$\frac{d}{dt}E_{+0}^{(2)} + \frac{H_{+0} - H_{00}}{\Delta x} = 0, \tag{42}$$

$$\frac{d}{dt}H_{00} + \frac{1}{\Delta x}\left[E_{+0}^{(2)} - E_{-0}^{(2)} - [E_{0+}^{(1)} - E_{0-}^{(1)}]\right] = 0. \tag{43}$$

Thus we see that the MECHL finite-element method on a uniform grid is just an averaged version of the Yee method.

3.3. Nédélec's method. This method is based on (14)–(17) and was first proposed in [13] (in three dimensions). The version presented here is modified to allow a discontinuity in μ. The magnetic field space is simple, but the electric field space is a subspace of $H(\text{curl};\Omega)$. Nédélec [13] shows that for a finite-element space U_h^N to be a subspace of $H(\text{curl};\Omega)$ it suffices that functions in U_h^N have continuous tangential component across edges in the mesh (i.e., $\boldsymbol{n} \times \boldsymbol{u}^h$ continuous across each internal edge in the mesh for each $\boldsymbol{u}^h \in U_h^N$). Following Nédélec [13] we define the reference element as follows:

$$\begin{aligned}
&\hat{K} \equiv \text{unit square} \quad \text{(see (23))},\\
&P_{\hat{K}} \equiv Q_{01} \times Q_{10},\\
&\Sigma_{\hat{K}} \equiv \left\{ (\hat{\boldsymbol{u}} \cdot \hat{\boldsymbol{t}})(\hat{\boldsymbol{b}}_i) \mid \boldsymbol{b}_i = \frac{\hat{\boldsymbol{a}}_i + \hat{\boldsymbol{a}}_{i+1}}{2},\ 1 \le i \le 4, \right.\\
&\qquad\qquad \left. \text{where } \boldsymbol{a}_5 = \boldsymbol{a}_1 \text{ and } \hat{\boldsymbol{t}} \text{ is the unit tangent to } \partial\hat{K} \right\}.
\end{aligned}$$

Nédélec [13] shows that a finite-element space constructed from this reference element is $H(\text{curl};\Omega)$-conforming (strictly speaking, Nédélec's results are for $\mathbb{R}^3$ but can be easily reinterpreted for $\mathbb{R}^2$). Care must be taken in the isoparametric method to ensure continuity of tangential components. Thus Nédélec shows that

$$\begin{aligned}
U_h^N = \{\boldsymbol{u}^h \in H(\text{curl};\Omega) | \boldsymbol{u}^h|_K = (\boldsymbol{J}_K^{-T}\hat{\boldsymbol{u}}_K) \circ F_K^{-1},\\
\hat{\boldsymbol{u}}_K \in Q_{01} \times Q_{10} \quad \forall K \in \tau_h\}.
\end{aligned} \tag{44}$$

Using the above space we define

$$U_{h0}^N = \{\boldsymbol{u}^h \in U_h^N \mid \boldsymbol{n} \times \boldsymbol{u}^h = 0 \text{ on } \Gamma\},$$

which can be constructed by enforcing a zero tangential component (zero degree of freedom) on each edge on Γ. The function γ^h required in (16) is the piecewise constant function interpolating γ at the midpoint of each boundary edge. Having defined U_h^N, we can essentially take V_h^N to be the space of piecewise constants. However, we would like $\nabla \times U_h^N \subset V_h^N$ and thus use an isoparametric mapping of the constant space:

$$V_h^N = \{v^h \mid v^h|_K = ((\det \boldsymbol{J}_K)^{-1}\hat{v}_K) \circ F_K^{-1}, \quad \hat{v}_K \in Q_{00} \quad \forall K \in \tau_h\}. \tag{45}$$

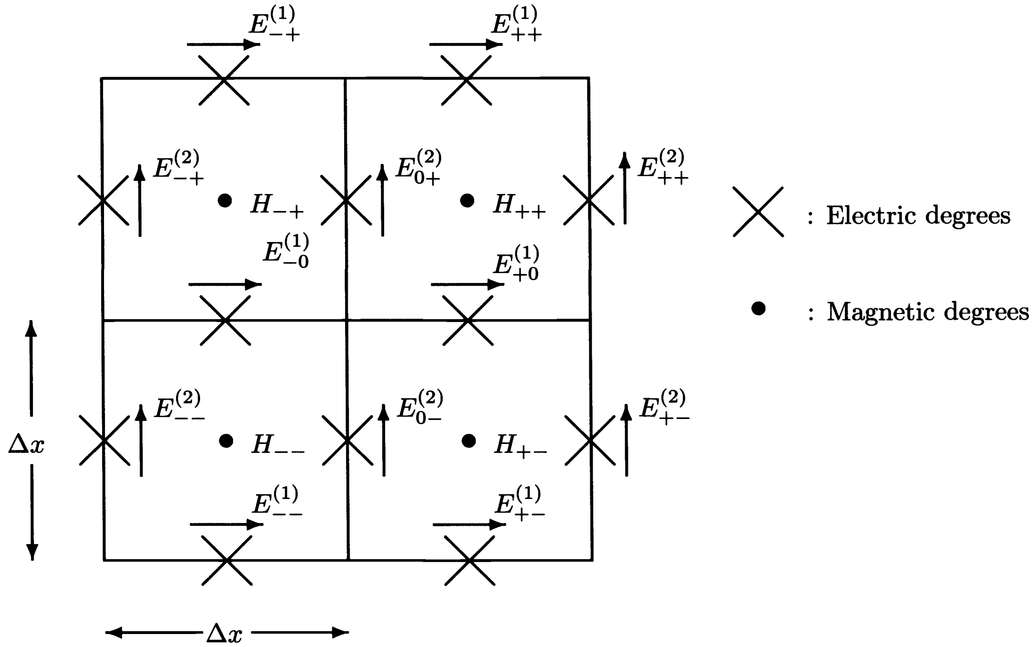

FIG. 3. *The degrees of freedom for* EL$_N$HC. *Electric field degrees of freedom are the tangential components of the electric field at the midpoint of each edge of the mesh, marked* × (*the nearby arrows show the direction of the degree of freedom at the interpolation point*). *The magnetic field has degrees of freedom marked* •.

Since $\nabla \times U_h^N \subset V_h^N$, we know that, provided μ is constant (as it is in all the examples here),

$$\mu H_t^h + \nabla \times \boldsymbol{E}^h = 0$$

pointwise in Ω, and the magnetic field equation is satisfied exactly. Since the electric field is approximated by Nédélec's linear elements, we refer to this method as EL$_N$HC. We emphasize that this is a different method than the method ELHC in [9], which is based on standard continuous linear elements.

This method is analyzed in [11] for the full Maxwell system in three space dimensions. In general, the method has global L^2 error at least $O(h)$ (see (37) for a more precise statement). Also in [11], we prove higher-order convergence rates at special points when the mesh is uniform. This is done as follows. If we use the notation in Fig. 3, we can derive the equations satisfied by the degrees of freedom as follows:

$$\frac{d}{dt}\frac{1}{6}\left\{E^{(1)}_{++} + 4E^{(1)}_{+0} + E^{(1)}_{+-}\right\} - \frac{H_{++} - H_{+-}}{\Delta x} = 0, \tag{46}$$

$$\frac{d}{dt}\frac{1}{6}\left\{E^{(2)}_{++} + 4E^{(2)}_{0+} + E^{(2)}_{-+}\right\} + \frac{H_{++} - H_{-+}}{\Delta x} = 0, \tag{47}$$

$$\frac{d}{dt}H_{++} + \frac{1}{\Delta x}\left\{(E^{(2)}_{++} - E^{(2)}_{0+}) - (E^{(1)}_{++} - E^{(1)}_{+0})\right\} = 0. \tag{48}$$

Again, we see that the method has local truncation error $O((\Delta x)^2)$ and the stability result (22) implies convergence in a suitable weighted discrete L^2 norm at the mesh points in the same sense as for the two previous methods discussed in this section [11].

For this grid the Yee finite-difference scheme [18] is

$$\begin{aligned}
&\frac{d}{dt}\, E^{(1)}_{+0} - \frac{H_{++} - H_{+-}}{\Delta x} = 0,\\
&\frac{d}{dt}\, E^{(2)}_{0+} + \frac{H_{++} - H_{-+}}{\Delta x} = 0,\\
&\frac{d}{dt}\, H_{++} + \frac{1}{\Delta x}\left\{(E^{(2)}_{++} - E^{(2)}_{0+}) - (E^{(1)}_{++} - E^{(1)}_{+0})\right\} = 0,
\end{aligned}$$

which we see is just (41)–(43) with a renaming of nodes. Thus, on a uniform grid, both MECHL and EL$_N$HC are essentially averaged Yee schemes.

3.4. Timestepping. In contrast to the rather unusual finite-element spaces used in the spatial discretization, we use the standard leapfrog method to discretize in time [18]. Each of the methods outlined above gives rise to a matrix problem of the following type. Let $(\vec{E}(t), \vec{H}(t))$ be the vectors of free degrees of freedom for the electric and magnetic field, respectively. Then using either (14)–(17) or (18)–(20), $(\vec{E}(t), \vec{H}(t))$ satisfies a matrix problem of the form

$$M^{\epsilon}_{uu}\frac{d\vec{E}}{dt} + M^{\sigma}_{uu}\vec{E} - C_{uv}\vec{H} = \vec{G}, \tag{49}$$

$$M^{\mu}_{vv}\frac{d\vec{H}}{dt} + [C_{uv}]^T\vec{E} = \vec{F}, \tag{50}$$

where $\vec{G}$ and $\vec{F}$ are vectors taking into account boundary data and the applied currents. For example, in the ECHL (respectively, MECHL) methods (see (25))

$$\begin{aligned}
[M^{\epsilon}_{uu}]_{ij} &= \textstyle\int_\Omega \epsilon\phi_i\phi_j dA, && 1 \le i,j \le N_E,\\
[M^{\sigma}_{uu}]_{ij} &= \textstyle\int_\Omega \sigma\phi_i\phi_j dA, && 1 \le i,j \le N_E,\\
[C_{uv}]_{ij} &= \textstyle\int_\Omega (\vec{\nabla} \times \psi_j)\phi_i dA, && 1 \le j \le N_H, \quad 1 \le i \le N_E,\\
[\vec{G}]_i &= \textstyle\int_\Omega \boldsymbol{J}\phi_i dA, && 1 \le i \le N_E,\\
[M^{\mu}_{vv}]_{ij} &= \textstyle\int_\Omega \mu\psi_i\psi_j dA, && 1 \le i,j \le N_H,\\
[\vec{F}]_j &= \textstyle\int_\Gamma \gamma\psi_j dA, && 1 \le j \le N_H,
\end{aligned}$$

where $\{\phi_i\}_{i=1}^{N_E}$ is a basis for U_h^L (respectively, U_h^M) and $\{\psi_i\}_{i=1}^{N_E}$ is a basis for V_h^L (respectively, V_h^M). Similar definitions hold for the Nédélec method after allowing for the fact that boundary degrees of freedom for U_h^N are specified via the boundary data (16). The fully discrete scheme is to compute a sequence $\{\vec{E}^n, \vec{H}^{n+1/2}\}_{n=0}^{\infty}$ that approximates $\{\vec{E}(t_n), \vec{H}(t_{n+1/2})\}_{n=1}^{\infty}$, where $t_n = n\Delta t$ and $t_{n+1/2} = (n + 1/2)\Delta t$. Given $(\vec{E}^n, \vec{H}^{n+1/2})$, we compute $(\vec{E}^{n+1}, \vec{H}^{n+3/2})$ by solving the system

$$M^{\epsilon}_{uu}\left(\frac{\vec{E}^{n+1} - \vec{E}^n}{\Delta t}\right) + M^{\sigma}_{uu}\left(\frac{\vec{E}^{n+1} + \vec{E}^n}{2}\right) - C_{uv}\vec{H}^{n+1/2} = \vec{G}^{n+1/2} \tag{51}$$

where $\vec{G}^{n+1/2} = \vec{G}(t_{n+1/2})$, then solving

$$M^{\mu}_{vv}\left(\frac{\vec{H}^{n+3/2} - \vec{H}^{n+1/2}}{\Delta t}\right) + [C_{uv}]^T\vec{E}^{n+1} = \vec{F}^{n+1}. \tag{52}$$

For ECHL, M^{ϵ}_{uu} and M^{σ}_{uu} are diagonal, while for MECHL they are block diagonal (with 4 × 4 diagonal blocks) and thus (51) may be solved rapidly. M^{μ}_{vv} is sparse (and identical for ECHL and MECHL) and we solve (52) using the preconditioned conjugate gradient method [7], using the mass-lumped matrix as a preconditioner. Precisely, we define the diagonal matrix $\overline{M}^{\mu}_{vv}$ with diagonal entry $[\overline{M}^{\mu}_{vv}]_i$ by

$$[\overline{M}^{\mu}_{vv}]_i = \sum_{j=1}^{N_H} [M^{\mu}_{vv}]_{ij},$$

and then solve

$$C\vec{Y} = (\overline{M}^{\mu}_{vv})^{-1/2} \left(\vec{F}^{n+1} - [C_{uv}]^T \vec{E}^{n+1} \right)$$

where $C = (\overline{M}^{\mu}_{vv})^{-1/2}(M^{\mu}_{vv})(\overline{M}^{\mu}_{vv})^{-1/2}$, and hence compute

$$\vec{H}^{n+3/2} = \vec{H}^{n+1/2} + \Delta t (\overline{M}^{\mu}_{vv})^{-1/2} \vec{Y}.$$

This method converges rapidly and we always iterate to completion (i.e., so that successive conjugate gradient iterates differ by less than 10^{-6} in the L^2 norm). In practice, a coarser error tolerance would produce good results.

In the case of the EL$_N$HC or Nédélec method, M^{μ}_{vv} is diagonal and hence easily inverted. Then (51) must be solved by conjugate gradients, and we also precondition with the mass-lumped matrix, although on a regular grid this is not necessary. The number of conjugate gradient iterations per step for the preconditioned EL$_N$HC matrix is usually less than for the preconditioned ECHL or MECHL methods. However, for EL$_N$HC, the dimension of M^{ϵ}_{uu} is approximately the number of edges in the mesh, while for ECHL/MECHL the dimension of M^{μ}_{vv} is the number of nodes in the mesh. Thus we must solve a larger system when timestepping EL$_N$HC than ECHL/MECHL.

To obtain $\vec{H}^{1/2}$, we use a Runge–Kutta-type method. First, we predict a value for $\vec{E}^{1/4}$ by solving

$$M^{\epsilon}_{uu} \left(\frac{\vec{E}^{1/4} - \vec{E}^0}{(\Delta t)/4} \right) + M^{\sigma}_{uu} \vec{E}^0 - C_{uv} \vec{H}^0 = \vec{J}^0,$$

where $\vec{E}^0$ and $\vec{H}^0$ are obtained by interpolating the initial data. Then we compute $\vec{H}^{1/2}$ by solving

$$M^{\mu}_{vv} \left(\frac{\vec{H}^{1/2} - \vec{H}^0}{(\Delta t)/2} \right) + [C_{uv}]^T \vec{E}^{1/4} = \vec{F}^{1/4}.$$

This procedure produces an $O((\Delta t)^2)$ approximation to $\vec{H}(t_{1/2})$. The timestepping scheme (51)–(52) is an $O((\Delta t)^2)$ scheme locally, and we expect that if $\Delta t/h$ is sufficiently small (a standard CFL condition [15]) the overall method will be stable and second order. On uniform grids, this condition is discussed further in §4. For more general grids and problems, convergence has been confirmed numerically, but has not yet been proven for the methods used in this paper.

4. Dispersion analysis. In this section, we assume that ϵ and μ are constants (which for simplicity we take to be unity), $\sigma \equiv 0$, $\boldsymbol{J} \equiv 0$. In this case, if Ω is an infinite domain (or if Ω is finite and γ chosen appropriately), (1) and (2) have solutions of the form

$$E(x,t) = E_0 \exp\left(i(wt - k \cdot x)\right), \tag{53}$$

$$H(x,t) = H_0 \exp\left(i(wt - k \cdot x)\right), \tag{54}$$

where k is a constant vector. Substituting these solutions into (1) and (2) (recalling $\epsilon = \mu = 1$) shows that w and k are related by the dispersion relation

$$w = |k|, \tag{55}$$

where $|k|$ is the Euclidean norm of k (other solutions are $w = 0$ or $w = -|k|$). The group velocity C is given [17] by

$$C = \nabla_{k} w = \frac{k}{|k|}, \tag{56}$$

and hence regardless of the wave number $|k|$ all plane waves move with the same group speed $|C|$. We can also analyze the dispersion relation for each of the numerical methods under consideration. Such an analysis describes how waves propagate in the numerical method far from boundaries, and gives information on the expected accuracy of the methods [17].

For a dispersion analysis, we assume a uniform grid of square elements of dimension $\Delta x \times \Delta x$ (see Figs. 1–3). We assume an infinite grid, and seek solutions of the discrete equations of the form (53)–(54). First we consider the case of exact integration in time, and start with the ECHL method. Substituting (53) and (54) into (29)–(31) we find that, if $E_0 = (E_0^{(1)}, E_0^{(2)}), \zeta_1 = k^{(1)}\Delta x, \zeta_2 = k^{(2)}\Delta x$, $\eta = w\Delta x$, and

$$\gamma(\zeta_1,\zeta_2) = \frac{4}{9} + \frac{2}{9}(\cos(\zeta_1) + \cos(\zeta_2)) + \frac{1}{18}(\cos(\zeta_1 - \zeta_2) + \cos(\zeta_1 + \zeta_2)), \tag{57}$$

then

$$\begin{pmatrix} \sin\left(\frac{\zeta_2-\zeta_1}{2}\right) + \sin\left(\frac{\zeta_1+\zeta_2}{2}\right) & \sin\left(\frac{\zeta_2-\zeta_1}{2}\right) - \sin\left(\frac{\zeta_2+\zeta_1}{2}\right) & \eta\,\gamma(\zeta_1,\zeta_2) \\ \eta & 0 & \sin\left(\frac{\zeta_2-\zeta_1}{2}\right) + \sin\left(\frac{\zeta_2+\zeta_1}{2}\right) \\ 0 & \eta & -\sin\left(\frac{\zeta_1-\zeta_2}{2}\right) - \sin\left(\frac{\zeta_1+\zeta_2}{2}\right) \end{pmatrix}$$

$$\cdot \begin{pmatrix} E_0^{(1)} \\ E_0^{(2)} \\ H_0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}. \tag{58}$$

For (58) to have a nontrivial solution, the determinant of the matrix must be zero. This defines η as a function of (ζ_1, ζ_2). If η°_{ECHL} denotes the positive solution, we find that

$$\eta^{\circ}_{ECHL}(\zeta_1,\zeta_2) = \left\{ \frac{6\sqrt{\sin^2\left(\frac{\zeta_1-\zeta_2}{2}\right) + \sin^2\left(\frac{\zeta_1+\zeta_2}{2}\right)}}{\sqrt{8 + 4\cos(\zeta_2) + \cos(\zeta_1 - \zeta_2) + 4\cos(\zeta_1) + \cos(\zeta_1 + \zeta_2)}} \right\} \tag{59}$$

(other solutions are $\eta = 0$ or η is the negative of the above expression). Hence, depending on the magnitude and direction of k, the numerically computed wave possesses an erroneous phase. This implies that a plane wave of the form (53) and (54) generally moves in the wrong direction at the wrong speed. Of course if $|\boldsymbol{\zeta}|$ is small, the frequency w_{ECHL} for ECHL with exact time integration is

$$w^{\circ}_{ECHL}(\zeta_1,\zeta_2,\Delta x) \equiv \frac{\eta^{\circ}_{ECHL}(\zeta_1,\zeta_2)}{\Delta x} \sim \sqrt{\frac{\zeta_1^2+\zeta_2^2}{(\Delta x)^2}} = |\boldsymbol{k}|,$$

so that waves with a sufficiently long wavelength compared to the grid move with essentially the correct phase. To derive the frequency w for the fully discrete scheme, we see that discretization in time corresponds to replacing η in (58) by $2\frac{\Delta x}{\Delta t}\sin\left(\frac{w\Delta t}{2}\right)$, and thus if we denote the frequency for the fully discrete scheme by $w^{\Delta t}_{ECHL}(\zeta_1,\zeta_2,\lambda,\Delta t)$ and let $\lambda = \Delta t/\Delta x$, we find that

$$w^{\Delta t}_{ECHL}(\zeta_1,\zeta_2,\lambda,\Delta t) = \frac{2}{\Delta t}\sin^{-1}\left(\frac{\lambda\eta^{\circ}_{ECHL}(\zeta_1,\zeta_2)}{2}\right) \tag{60}$$

and the group velocity

$$\boldsymbol{C}^{\Delta t}_{ECHL}(\zeta_1,\zeta_2,\lambda) = \frac{2}{\lambda}\nabla_{\zeta}\left[\sin^{-1}\left(\frac{\lambda\eta^{\circ}_{ECHL}(\zeta_1,\zeta_2)}{2}\right)\right]. \tag{61}$$

In Fig. 4 we show a plot of $|\boldsymbol{C}^{\Delta t}_{ECHL}-\boldsymbol{C}|$ as a function of $\boldsymbol{\zeta} \in [0,\pi]\times[0,\pi]$ (higher values of $\boldsymbol{\zeta}$ are aliased onto the grid [17]). $\boldsymbol{C}^{\Delta t}_{ECHL}$ depends only on $\lambda = \Delta t/\Delta x$, not Δt or Δx individually, and we choose $\lambda = 0.25$ in accordance with later numerical results (graphs for smaller λ are similar). The shaded area is where $|\boldsymbol{C}^{\Delta t}_{ECHL} - \boldsymbol{C}| < 0.1$, so that for a given $\boldsymbol{k}$, if we choose Δx such that $\boldsymbol{k}\Delta x$ lies in the shaded region, we can be sure that the wave will move with a wave speed and direction in error by less than 10 percent. A diagram like Fig. 4 can be invaluable for choosing step sizes.

Note also that λ must be chosen sufficiently small that

$$\lambda\left(\max_{(\zeta_1,\zeta_2)\in[0,\pi]\times[0,\pi]}|\eta^{\circ}_{ECHL}(\zeta_1,\zeta_2)|\right) \le 2, \tag{62}$$

so that $w^{\Delta t}_{ECHL}$ is real. This implies the condition that

$$\lambda \le \frac{2}{\sqrt{12}} \simeq 0.577\cdots. \tag{63}$$

With mass lumping, an examination of the stencil for ECHL suggests a CFL condition $\lambda \le 1$, but this CFL condition is not correct when the full finite-element mass matrix is used. Thus for the split-step, mixed, finite-element methods considered here some extra care is needed to ensure stability (the condition $\lambda \le 0.577\cdots$ has been checked numerically, and gives an accurate picture of stability for ECHL applied to boundary value problems on a uniform grid (see §5.1)).

We can perform the same dispersion analysis on EL$_N$HC and MECHL. Not surprisingly, these methods have identical dispersion relations (when $\epsilon = \mu = 1$) since both methods are restrictions of three-dimensional methods based on the same spaces (cf. [13] and [11]). Hence we need only analyze EL$_N$HC. In this case the matrix corresponding to (58) is

$$\begin{pmatrix} 2\sin\left(\frac{\zeta_2}{2}\right) & -2\sin\left(\frac{\zeta_1}{2}\right) & \eta \\ \eta\left(\frac{4+2\cos(\zeta_2)}{6}\right) & 0 & 2\sin\left(\frac{\zeta_2}{2}\right) \\ 0 & \eta\left(\frac{4+2\cos(\zeta_1)}{6}\right) & -2\sin\left(\frac{\zeta_1}{2}\right) \end{pmatrix},$$

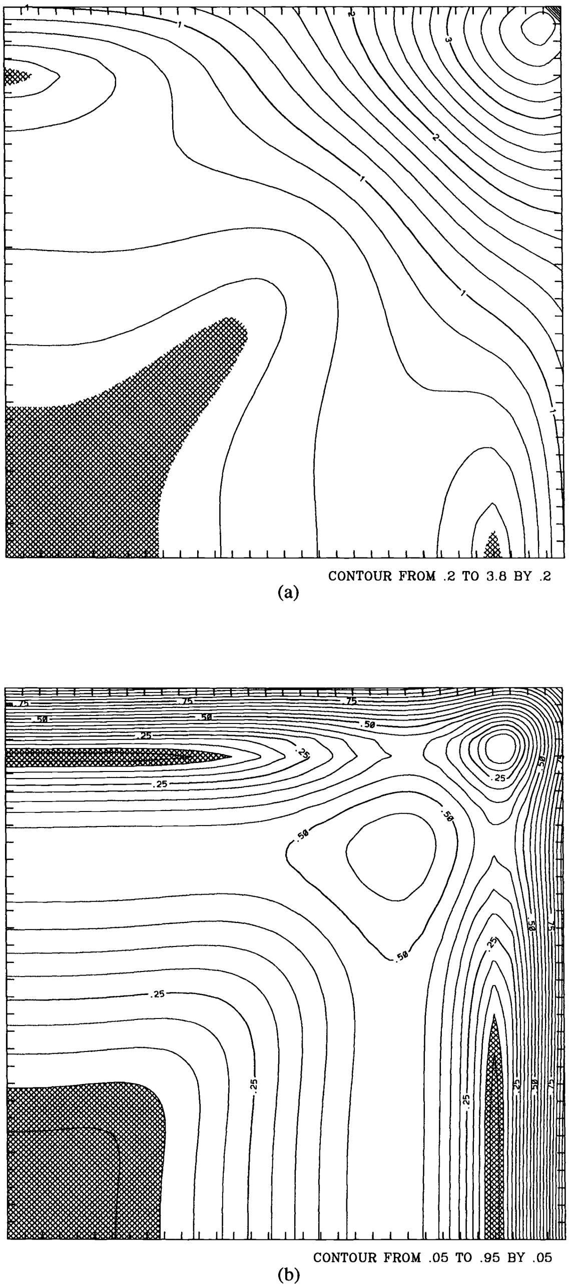

FIG. 4. *Graphs of the error in the group velocity for* $k\Delta x \in [0,\pi] \times [0,\pi]$. *We show contours of* $|C^{\Delta t} - C|$ *where* $C^{\Delta t}$ *is the numerical group velocity and* C *is the exact group velocity. and thus

$$\overset{\circ}{\eta}_{EL_NHC}(\zeta_1,\zeta_2)$$
$$= 2\sqrt{3}\sqrt{\frac{2\sin^2\left(\frac{\zeta_1}{2}\right)+\cos(\zeta_2)\sin^2\left(\frac{\zeta_1}{2}\right)+2\sin^2\left(\frac{\zeta_2}{2}\right)+\cos(\zeta_1)\sin^2\left(\frac{\zeta_2}{2}\right)}{4+2\cos(\zeta_1)+2\cos(\zeta_2)+\cos(\zeta_1)\cos(\zeta_2)}}.$$

The condition corresponding to (63) is

$$\lambda \leq 2/\sqrt{24}.$$

For the fully discrete method, $w^{\Delta t}_{EL_NHC}$ and $\boldsymbol{C}^{\Delta t}_{EL_NHC}$ are given by the analogues of (60) and (61). In Fig. 4(b) we show $|\boldsymbol{C}^{\Delta t}_{EL_NHC} - \boldsymbol{C}|$ against (ζ_1, ζ_2) and again shade the region with less than 10 percent error. Notice that the EL$_N$HC, ECHL, and MECHL methods have the same dispersion behavior for waves with $\boldsymbol{k} = (k_1, 0)$ or $\boldsymbol{k} = (0, k_2)$ (i.e., parallel to grid lines). This is because MECHL and ECHL are identical schemes in these cases (see (29)–(31), (38)–(40)), and MECHL and EL$_N$HC are based on the same spaces (but used in different ways) in three dimensions.

Clearly, from Fig. 4, the area in the (ζ_1, ζ_2) plane for which the numerical group velocity is in error by less than 10 percent is larger for ECHL than MECHL or EL$_N$HC. On the other hand, the error contours for MECHL/EL$_N$HC are more nearly circular than for ECHL, implying less grid anisotropy. Furthermore, the maximum error for MECHL and EL$_N$HC is approximately 100 percent, whereas that for ECHL is 400 percent. Thus ECHL will cause much worse dispersion for very high frequency waves than either MECHL or EL$_N$HC. In general, we must choose a grid on the basis of the worst-case behavior of the method. This occurs in all three methods for waves along the coordinate axis, and is identical for the three methods.

Since the worst case for plane wave propagation is for waves along a grid line, we can gain useful information on error by considering a one-dimensional plot of group velocity error, as shown in Fig. 5. Here we consider waves with wave number $\boldsymbol{k} = (k_1, 0)$ moving along the x-axis. We plot group velocity error against number of grid cells per half wave length defined by $N_p = \pi/(k_1 \Delta x)$. This graph implies that for an error of 10 percent in the group velocity, we need about eight grid cells per wavelength. For more complex waves (i.e., wave consisting of a superposition of plane waves), we can still use Fig. 5 by considering the plane wave components separately.

On the basis of dispersion, it is difficult to choose between the three methods. In addition, in real problems the mesh is not uniform, the coefficients not constant, and boundary conditions are important. We investigate these problems in §5 using essentially the same numerical examples as [9].

All algebra in the preceding section was manipulated using Mathematica.

5. Numerical results.

In this section, we further compare the three finite-element methods described in §3 by applying them to selected numerical examples. The examples are all taken from [9].

5.1. Plane wave propagation.

We shall compare the numerical solution of a simple wave propagation problem with the exact solution. We choose the functions in Maxwell's equations as follows: $\epsilon = \mu = 1$, $\sigma = 0$, and $\boldsymbol{J} = 0$. Then an exact solution of Maxwell's equations (on the entire plane) is

$$\boldsymbol{E}_e(\boldsymbol{x}, t) = \begin{pmatrix} -k_2 \\ k_1 \end{pmatrix} g(t - \boldsymbol{k}\cdot\boldsymbol{x}),$$
$$H_e(\boldsymbol{x}, t) = g(t - \boldsymbol{k}\cdot\boldsymbol{x}),$$

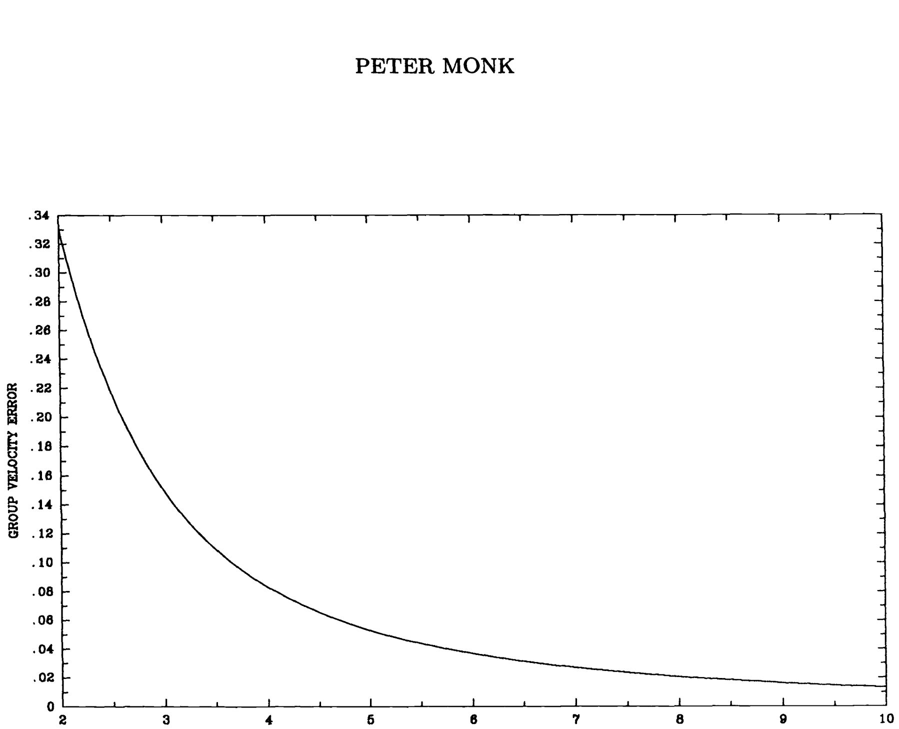

FIG. 5. *A graph of the error in the group velocity for a wave traveling along the x-axis with wave number $k = (k_1, 0)$. The error is plotted against number of grid blocks per half wave length defined as $N_p = \pi/(k_1 \Delta x)$. The* CFL *number $\lambda = 0.25$. A wave parallel to a grid direction is the worst case for all three methods. This graph can be used to select the grid size.*

where we take $\boldsymbol{k} = (\cos(1), \sin(1))$ and

$$g(s) = \begin{cases} \frac{\exp(-10(s-1)^2) - \exp(-10)}{1 - \exp(-10)}, & 0 \le s \le 2, \\ 0, & s > 2 \text{ or } s < 0. \end{cases} \tag{64}$$

We choose a finite domain $\Omega = [0,2] \times [0,2]$ and take $\boldsymbol{E}_0 = 0$, $H_0 = 0$, and $\boldsymbol{J}_0 = 0$. The boundary data is chosen consistent with the above exact solution so that $\gamma = \boldsymbol{n} \times \boldsymbol{E}_e$. We discretize the problem using a uniform grid on $\Omega = [0,2] \times [0,2]$ with N subintervals on each edge (thus N^2 quadrilaterals). In this case $\Delta x = 2/N$, $h = \sqrt{2}\Delta x$, and we choose the CFL parameter $\lambda = \Delta t / \Delta x = 0.25$. For each method, and a variety of N, we integrate until $t = 2$, and then compute the relative discrete L^2 norm error in the magnetic field H (for simplicity). Thus we compute

$$\|(H_e - H^h)(t)\|_{L^2,h} = \sqrt{\sum_{i=1}^{N_H} |H_e(\boldsymbol{x}_i, t) - H^h(\boldsymbol{x}_i, t)|^2}$$

at $t = 2$ where $\boldsymbol{x}_i$ is the ith node if using ECHL or MECHL, or the centroid of the ith quadrilateral if using EL$_N$HC. Then we define

$$\|H_e - H^h\|_{\text{rel}} = \frac{\|H_e - H^h\|_{L^2,h}}{\|H_e\|_{L^2,h}}. \tag{65}$$

A plot of error against N and error against CPU time (on a SUN SparcStation 1) is shown in Fig. 6. The plot of error against N confirms that on a uniform grid all three

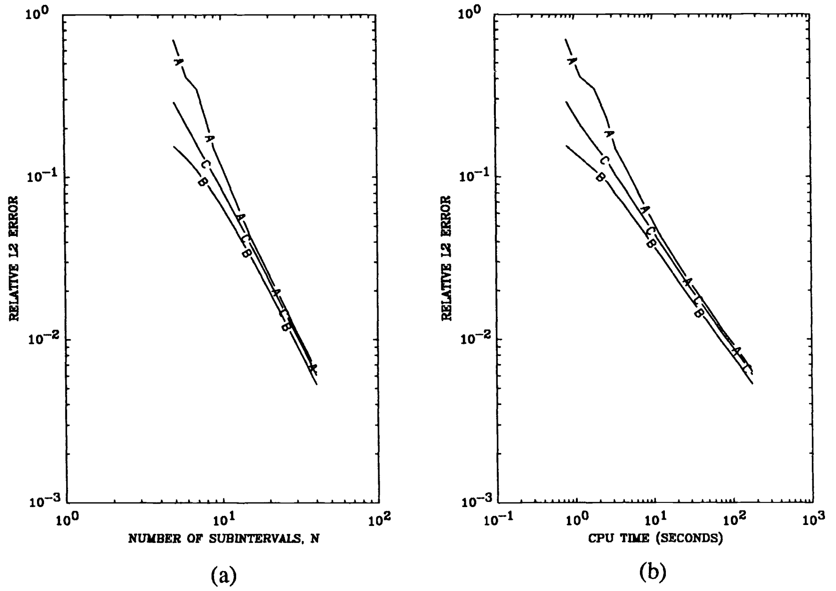

FIG. 6. *Plots of error against grid parameter N and* CPU *time for the example in* §5.1. *A plane wave moves across a uniform grid at an angle to the grid lines. The error reported is the relative discrete L^2 error given by* (65). *In each case* —A— *denotes* ECHL, —B— *denotes* EL$_N$HC, *and* —C— *denotes* MECHL. (a) *A plot of error against N. Here $h = 2\sqrt{2}/N$. This graph suggests second-order convergence in the norm of* (65) *for all three methods.* EL$_N$HC *is notably more accurate for coarse meshes.* (b) *A graph of error against* CPU *time* (*on a* SUN *SparcStation* 1). *Except possibly for very fine grids,* EL$_N$HC *produces a given error in least time* (*but see* §5.3). *For this example the conjugate gradient method in* EL$_N$HC *was not preconditioned, since satisfactory convergence was seen without preconditioning.*

methods are ultimately second-order convergent at the degrees of freedom (the slope of the graphs is 2). For a given N, EL$_N$HC is always the most accurate and ECHL the least accurate. The disparity is particularly obvious for small N. In view of the dispersion analysis, the difference between MECHL and EL$_N$HC must be due to the way that the boundary data is imposed. A slightly different picture emerges when we view error against CPU time. For a given error, EL$_N$HC is the most rapid method, but for a very low error (a fine mesh), it appears that ECHL may become the fastest method. Most time is spent in the conjugate gradient solver. ECHL and MECHL solve the same matrix problem, which has about half as many unknowns as EL$_N$HC. However, despite preconditioning, the ECHL/MECHL takes approximately twice as many iterations to solve the matrix problem to comparable accuracy.

Using this example, we have also checked the validity of the stability estimates (62) and (63) in the case of a boundary value problem. For the EL$_N$HC, scheme (63) implies that $\lambda \leq 2/\sqrt{24}$ is necessary for stability (for the pure initial value problem). When $N = 30$ this implies that $\Delta t \leq 0.0272\cdots$. We find divergence when $\Delta t = 0.029$, but find satisfactory results with $\Delta t = 0.027$ (at least up to time $t = 4$). For ECHL, $\lambda \leq 2/\sqrt{12}$, and hence if $N = 30, \Delta t \leq 0.0385\cdots$. When $\Delta t = 0.04$ the method is unstable, but converges satisfactorily until $t = 4$ when $\Delta t = 0.038$. These results indicate that (62) and (63) are pertinent to the stability of the boundary value problem.

5.2. Simple scattering. In the previous example we used a uniform grid and a plane wave. Our next example uses a nonuniform grid (which is uniform in polar coordinates) and more complex wave motion. Again following [9], we consider an infinite domain problem of scattering of a plane wave off a circular perfect conductor. We consider a plane wave

$$\boldsymbol{E}_i(\boldsymbol{x},t) = \begin{pmatrix} 0 \\ \sqrt{\mu_0/\epsilon_0}\, g((t-(x-0.1)\sqrt{\epsilon_0\mu_0})10^9) \end{pmatrix}, \tag{66}$$

$$H_i(\boldsymbol{x},t) = g((t-(x-0.1)\sqrt{\epsilon_0\mu_0})10^9) \tag{67}$$

(where g is given by (64)) incident on a perfectly conducting circular cylinder of radius 0.1m centered at the origin. We choose

$$\epsilon = \epsilon_0 = 8.85 \times 10^{-12} F/m^2, \qquad \mu = \mu_0 = 1.2566 \times 10^{-6} N/A^2.$$

Using special function theory, an exact solution is available for this problem [8].

For the numerical problem we take an annular domain with inner radius 0.1m and an outer radius of 1.1m. Since the problem is symmetric about the x-axis we use the half-domain

$$\Omega = \left\{(x,y) \mid 0.1 < \sqrt{x^2+y^2} < 1.1, y > 0\right\}.$$

On $y = 0$ we impose the symmetry condition $\boldsymbol{n} \times \boldsymbol{E} = 0$, and on $r = 1.1$ we impose the perfect reflecting boundary condition $\boldsymbol{n} \times \boldsymbol{E} = \gamma \equiv 0$. On $r = 0.1$ we impose $\boldsymbol{n} \times \boldsymbol{E} = \gamma \equiv \boldsymbol{n} \times \boldsymbol{E}_i$, which describes how the incident field scatters off a perfect conductor. The boundary condition $\boldsymbol{n} \times \boldsymbol{E} = 0$ on $r = 1.1$ generates spurious reflections for times greater than about time $t = 4$ nanoseconds (ns), so the exact solution is not useful beyond that time. The grid used has mesh points distributed uniformly in the (r, θ) plane, i.e., the mesh points are (r_i, θ_j), $0 \le i \le N_r$, $0 \le j \le N_\theta$, where

$$r_i = 0.1 + \frac{i}{N_r} \quad \text{and} \quad \theta_j = \pi\frac{j}{N_\theta}.$$

In Fig. 7, we show the computed and exact solutions at two interpolation points when $N_r = 30$, $N_\theta = 15$, and $\Delta t = 1 \times 10^{-3}$. With the small timestep used here, most of the error is due to spatial discretization. These results can be compared to [9, Fig. 3]. Clearly, all three methods compute reasonable solutions.

Table 1 shows the relative L_2 error in space at various times (error defined by (65)). The error ratios are consistent with second-order convergence (the ratios are shown in parentheses in the table). The small timestep $\Delta t = 1 \times 10^{-3}$ is chosen since we wish to focus on spatial error, and numerical experiments show that, with this timestep, the timestepping error is negligible compared to the spatial error. Thus the second-order convergence shown in Table 1 is evidence of second-order convergence in the spatial error. As yet, we have no theory to predict this rate of convergence. However, the fact of second-order convergence at the mesh points is encouraging since the mesh is slightly nonuniform.

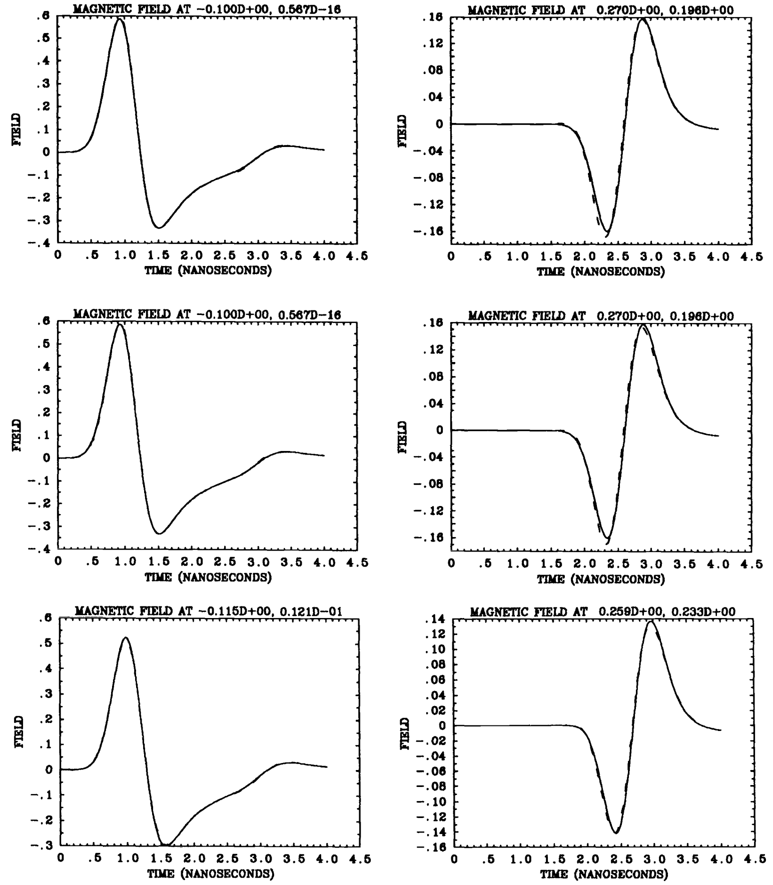

FIG. 7. *A comparison of exact and numerical solution for the simple scattering problem in* §5.2 *at selected spatial points. The exact solution is the solid line and the dashed line shows the computed solution. Here* $N_r = 30$, $N_\theta = 15$, *and* $\Delta t = 1 \times 10^{-3}$. *The coordinates of the spatial points are shown on each plot, and are chosen to be the interpolation point closest to the points A and B in* [9, *Fig.* 2]. *Top row: Results for* ECHL. *Middle row: Results for* MECHL. *Bottom row: Results for* EL$_N$HC.

5.3. Scattering by a dielectric cylinder. Our final example investigates a very nonuniform mesh and a case in which ϵ is discontinuous. Again the example is taken from [9]. At a line of discontinuity L separating two regions Ω_1 and Ω_2 with $\epsilon = \epsilon_1$ in Ω_1 and $\epsilon = \epsilon_2$ in Ω_2, we have the continuity condition

$$\epsilon_1(\boldsymbol{n} \cdot \boldsymbol{E})_1 = \epsilon_2(\boldsymbol{n} \cdot \boldsymbol{E})_2, \tag{68}$$

so there is a jump in the normal component of the electric field across L (cf. [9]). If standard continuous finite elements are used to discretize $\boldsymbol{E}$, a complex modification must be made along L to ensure (68) [9]. This modification is not required with any of the methods in this paper, although L must coincide with mesh lines.

To construct an exact solution, we consider the infinite domain-scattering problem

TABLE 1

Relative L_2 error in the magnetic field (as defined by (65)) at various times for two different discretizations of the example in §5.2 (see text for details of the domain and mesh). The numbers in parentheses give the ratio of errors in the table with a ratio of 4 being exactly second-order convergence. A ratio of 3.7 indicates $O(h^{1.9})$ convergence. In this case $\Delta t = 1 \times 10^{-3}$, thus the second-order convergence suggested by this table is the result of second-order convergence of spatial error and not due to the time discretization. By $t = 4$, the solution is polluted by reflections from the artificial boundary.

in which a plane wave is incident on an inhomogeneous cylinder of radius 0.25m centered at the origin. In this cylinder we assume that the dielectric constant $\epsilon = \epsilon_0/16$ and $\mu = \mu_0$ (see also Fig. 8). This problem can be solved by using special function theory on the infinite domain [8].

To approximate the infinite domain problem, we use the domain shown in Fig. 8. We use the half-domain $y \geq 0$ since the problem is symmetric about the x-axis, and use a symmetry boundary condition on the line $y = 0$. Following [9], we take $\boldsymbol{E}_0 = 0$, $H_0 = 0$, $\sigma \equiv 0$, $J \equiv 0$, and $\gamma = 0$ on $\Gamma\backslash\Sigma$. On Σ we take

$$\gamma = \begin{cases} 1/2\sqrt{\mu_0/\epsilon_0}(1 - \cos 2\pi t), & 0 \leq t \leq 1, \\ 0, & t > 1. \end{cases}$$

A wave with the cross-section of γ above has more slowly decaying harmonics than the incident wave in §5.2. Thus dispersion is more severe for this example than for the example in §5.2.

Using the finite domain shown in Fig. 8(a), we can compute an accurate approximate solution to the infinite domain-scattering problem until reflections from the artificial boundary are significant. We have not attempted to use absorbing boundary conditions on this boundary and instead, to minimize spurious reflections in the output shown in Fig. 9, we compute only up to $t = 6ns$.

We use a mesh similar to the one in [9]. An example is shown in Fig. 8(b) when $N = 16$. In this case N refers to the number of subintervals along the line $x = -1$. Table 2 shows the relative L^2 error on the subdomain $\{(x, y) \mid |x| \leq 0.5,\ 0 \leq y \leq 0.5\}$ at various times for $N = 16$ and $N = 32$ ($N = 32$ corresponds to subdividing every quadrilateral in the $N = 16$ mesh into four subquadrilaterals). We compute the error on a subdomain for two reasons: first, we want to investigate error behavior on the nonuniform portion of the mesh; and second, we want to avoid errors due to spurious reflections from the boundary. The timestep used gives an approximate CFL number of 0.25 in the inner circle where $\epsilon = \epsilon_0/16$. The results in Table 2 are consistent with an order convergence of at least $O(h^{1.6})$ for all three methods. It thus appears that three-halfs-order or possibly even second-order superconvergence is seen even on nonuniform meshes and in the presence of material discontinuities. This is unexpected and needs to be justified by further numerical and theoretical investigations. It is possible that for finer meshes the order of convergence would approach first order.

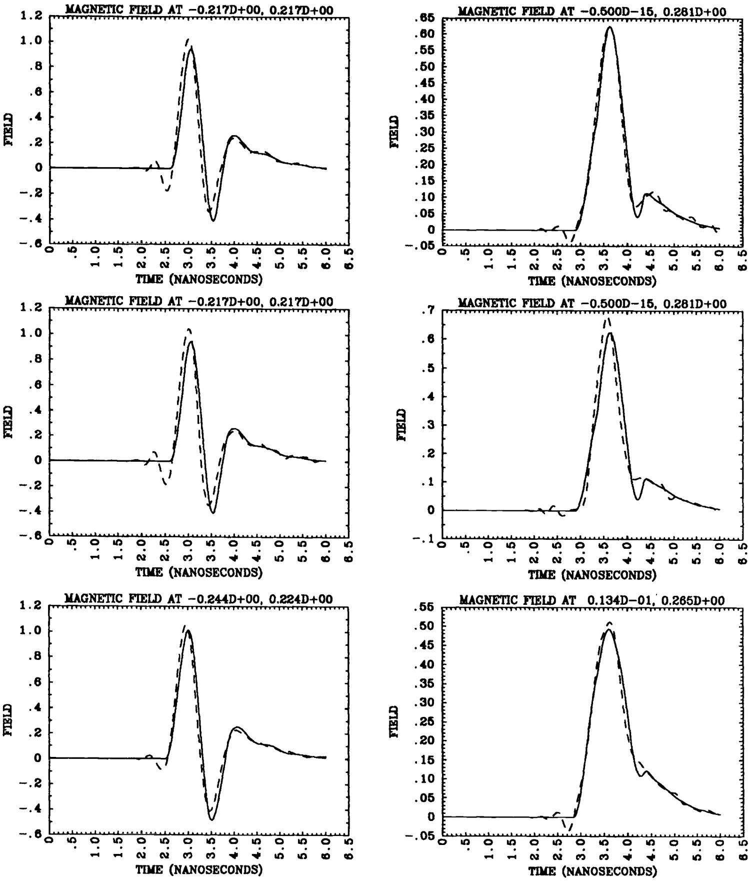

FIG. 9. *A comparison of exact and numerical solution for the simple scattering problem in* §5.3 *at selected spatial points. The exact solution is the solid line and the dashed line shows the computed solution. Here $N = 16$ and the* CFL *number for the inhomogeneous cylinder is approximately* 0.25. *The coordinates of the spatial points are shown on each plot, and are chosen to be the interpolation point closest to the points A and B in* [9, Fig. 4]. *Dispersion is visible in all plots, particularly along the leading edge of the wave. Top row: Results for* ECHL. *Middle row: Results for* MECHL. *Bottom row: Results for* $\mathrm{EL}_N\mathrm{HC}$.

Figure 9 shows the results of all three methods when $N = 16$ at two points in the domain. These are the interpolation points closest to the points A and B in [9, Fig. 4]. All three methods give qualitatively similar results. Significant dispersion occurs in the coarsely meshed region above the cylinder shown in Fig. 8(b), but this tends not to effect the solution at the points given in Fig. 9. Clearly, although dispersion is evident, all three methods produce qualitatively similar and reasonable results. In particular, all three methods can handle discontinuous media with no problem.

We have used a significantly smaller timestep in this example compared to that used in [9], and we find that all three methods are unstable with the mesh and time step parameters used in [9]. Note that our implementation of ECHL differs from that in [9] in that we solve (49) and (50) by conjugate gradients with a stringent stopping tolerance. If the iterative method is only allowed to perform a small number of iterations per timestep, it is possible that this incomplete iteration will smooth the solution and allow longer timesteps.

As a final remark on this example, we note that even with preconditioning, the conjugate gradient scheme for $\mathrm{EL}_N\mathrm{HC}$ was very slowly convergent for this example (particularly when $N = 32$). In this example, $\mathrm{EL}_N\mathrm{HC}$ was much slower than ECHL or MECHL.

6. Conclusions. The methods under consideration in this paper have quite similar features. All are based on mixed finite-element spaces approximating the full Maxwell system. Moreover, in the examples computed, none of the methods has a decisive edge over the rest. The ECHL method has a larger stability boundary or CFL condition, but is sometimes less accurate than the other methods and suffers from greater grid anisotropy. Generally, the $\mathrm{EL}_N\mathrm{HC}$ method is most accurate, and MECHL is either more accurate or approximately the same accuracy as ECHL. The state of theory for ECHL is not as well developed as for MECHL or $\mathrm{EL}_N\mathrm{HC}$, and in all three cases an improved understanding of superconvergence is desirable.

Clearly, a second important area of research is to examine other timestepping methods. The stability condition for these schemes should be better understood, and less restrictive timestepping methods should be investigated (cf. [1]).

All three schemes have three-dimensional counterparts, and the results in this paper and in [9] suggest they will be successful schemes. Given the ease of implementation of methods with natural boundary conditions, ECHL or MECHL may be preferable to $\mathrm{EL}_N\mathrm{HC}$ when the perfectly conducting boundary condition is appropriate. For more complex conditions, $\mathrm{EL}_N\mathrm{HC}$ may be preferable.

Acknowledgments. I would like to thank Professor F. Santosa for several useful discussions regarding dispersion relations.

ADAPTIVE APPROXIMATION BY PIECEWISE LINEAR POLYNOMIALS ON TRIANGULATIONS OF SUBSETS OF SCATTERED DATA*

SHMUEL RIPPA†

Abstract. Given a set V of data points in R^2 with corresponding data values, the problem of adaptive piecewise polynomial approximation is to choose a subset of points of V, to create a triangulation of this subset, and to define a piecewise linear surface over the triangulation such that the deviation of this surface from the data set is no more than a prescribed error tolerance. A typical numerical scheme starts with some initial triangulation and adds more points (and triangles) as necessary until the resulting piecewise linear surface satisfies the error bound. In this paper two ingredients of such schemes are discussed. The first problem is that of constructing a suitable triangulation of a subset of points. The use of data-dependent triangulations that depend on the given function values at the data points is discussed, and some data-dependent criteria for optimizing a triangulation are presented and compared to the Delaunay criterion leading to the well-known Delaunay triangulation traditionally used for this purpose. The second problem addressed in this paper is how to select a piecewise linear surface approximating the given data. A common approach is to use an interpolating surface, i.e., to require that the surface interpolates the data at the nodes of the triangulation. In this paper the least-square approximation to the data from the space of piecewise linear polynomials defined over a triangulation of a subset of V is used. It is proved that the matrix of the normal equations is always nonsingular and a bound for its condition number is derived. This bound is relatively low, hence the least-square surface can be computed by solving the normal equations, e.g., by the conjugate gradient scheme with no preconditioning. Various numerical experiments demonstrate the improvement in the quality of the approximation when certain data-dependent triangulations are used. Improvement is also reported when least-square surfaces are compared to interpolating surfaces.

Key words. triangulation, data-dependent triangulation, piecewise linear interpolation, least-squares fitting

1. Introduction.

Scattered data interpolation in R^2 consists of constructing a function $F_I = F_I(x,y)$ such that

$$F_I(x_i, y_i) = f_i, \qquad i = 1, \cdots, N,$$

where $V = \{v_i = (x_i, y_i) \in R^2, i = 1, \cdots, N\}$ is a set of distinct and noncollinear data points, and $f = (f_1, \cdots, f_N)$ is a (real) data vector.

The data vector f is regarded, in most cases, as being sampled from a (usually unknown) surface $F = F(x,y)$, which we wish to approximate by the interpolating surface F_I. In many applications interpolation is not desired, e.g., when the data is subject to errors or when there is much more data than is required to get a good approximation to the surface. In many cases, we would like to replace the interpolating surface F_I by an approximating function F_A, which depends on far fewer parameters than the number of data points. Interpolation and approximation methods are reviewed by Barnhill [1], Franke [8], Powell [16], and Schumaker [19].

In this paper we discuss some methods of approximation using spaces of piecewise polynomials defined on triangulations of subsets of V. Let Ω be a polygonal domain

such that $V \subset \Omega$, and its boundary $\partial\Omega$ is a polygon with vertices in V. We denote by $V^{(M_0)}$ the set of all vertices of $\partial\Omega$, M_0 being the number of vertices.

DEFINITION 1.1. We call the set $V^{(M)} \subset V$ a proper subset of V if $V^{(M_0)} \subset V^{(M)}$.

When considering a proper subset $V^{(M)}$ of V that contains M points, we assume for simplicity that the data points are numbered such that

$$V^{(M)} = \{v_i = (x_i, y_i)\}_{i=1}^{M}.$$

DEFINITION 1.2. Let $V^{(M)}$ be a proper subset of V. A set $T = \{T_i\}_1^t$ of nondegenerate, open triangles is a $V^{(M)}$-triangulation of Ω if:

- $V^{(M)}$ is the set of all vertices of triangles in T;
- Every edge of a triangle in T contains only two points from $V^{(M)}$, namely, its endpoints;
- $\overline{\Omega} = \bigcup_{i=1}^{t} \overline{T_i}$;
- $T_i \bigcap T_j = \emptyset\,,\ i \neq j$.

When there is no risk of ambiguity, we use the term "triangulation" instead of "$V^{(M)}$-triangulation."

DEFINITION 1.3. The space $S_d^r(T)$ is the space of piecewise polynomials of degree d and smoothness r defined over T, i.e.,

$$S_d^r(T) = \{g \in C^r(\Omega) \mid \ g|_{T_i} \in \Pi_d\},$$

where Π_d is the space of all bivariate polynomials of total degree d. (See [20], [22], and references therein for a comprehensive discussion of these spaces.)

In the present paper, we restrict ourselves to the approximation from the space $S_1^0(T)$ of piecewise linear functions defined on a $V^{(M)}$-triangulation T of Ω. Many of the ideas are, however, applicable to more general spaces. As a basis to $S_1^0(T)$, we use the pyramidal functions

$$(\phi_1(x,y,T), \phi_2(x,y,T), \cdots, \phi_M(x,y,T)),$$

satisfying

$$\phi_i(x_j, y_j, T) = \delta_{ij}, \qquad 1 \leq j \leq M.$$

The support of ϕ_i is the cell Ω_i, which is the union of all (closed) triangles in T having v_i as a vertex.

The problem of adaptive approximation with piecewise linear polynomials is that of selecting a proper subset $V^{(M)}$ of V and a $V^{(M)}$-triangulation of Ω such that the deviation of the piecewise linear approximating surface, defined on that triangulation, from the data set will be within a prescribed error tolerance ϵ. A basic scheme for adaptive approximation was proposed by various authors (see, e.g., Floriani, Falcidieno, and Pienovi [5] and Lee and Schachter [11]). The algorithm begins by constructing an initial proper subset $V^{(M_0)}$ consisting of the M_0 points in $\partial\Omega$. In the ith iteration a subset $V^{(M)}$ of M vertices, chosen during the previous iteration, is given. The Delaunay $V^{(M)}$-triangulation is constructed and the deviation of the piecewise linear interpolator $F_{T,f}$ from the data points is computed. If the maximal deviation is greater than ϵ, then the point attaining the maximal deviation is added to the subset $V^{(M)}$ resulting in a new proper subset $V^{(M+1)}$ of V. The iterations continue until the maximal deviation is less than ϵ. The output of the scheme is a

$V^{(M)}$-triangulation T and an interpolating surface $F_{T,f}$, which deviates from the data set by no more than ϵ.

In this paper we discuss and test two modifications of the basic scheme; namely, the use of data-dependent triangulations instead of Delaunay triangulations, and the use of least-square surfaces instead of interpolating surfaces.

One important question is how to select a proper $V^{(M)}$-triangulation T of Ω. The standard approach is to use the constrained Delaunay triangulation [2], [5]. A different approach, recently suggested in [3], is that of *data-dependent triangulation.* The basic idea is to use triangulations that depend on the data vector f rather than triangulations that are constructed by geometrical criteria that consider only the locations of the data points. The numerical experiments presented in [3] demonstrate that interpolating surfaces defined over data-dependent triangulations provide a considerably better approximation to the underlying surface F than interpolating surfaces defined over the Delaunay triangulation. Further studies on this matter are presented in [14] and [18]. In §2, two data-dependent criteria and the Delaunay criterion for optimizing a $V^{(M)}$-triangulation are presented together with an algorithm for the construction of a locally optimal triangulation. We note that the LS criterion that is described in §2 was independently suggested and tested by Quak and Schumaker [15].

The interpolating surface $F_{T,f}$ is defined by

$$F_{T,f}(x,y) = \sum_{i=1}^{M} f_i \phi_i(x,y,T),$$

and it interpolates the data vector f at the nodes of $V^{(M)}$, i.e.,

$$F_{T,f}(x_j,y_j) = F(x_j,y_j) = f_j, \qquad j = 1,\cdots,M.$$

The interpolating surface is easily constructed but it is obviously not the best approximation to the data set, since the values of F on the set $V \backslash V^{(M)}$, are not used in the definition of $F_{T,f}$. A better alternative is to consider the least-square surface $U_{T,f}(x,y)$, which minimizes the quantity

$$E(g) = \sum_{i=1}^{N} (f_i - g(x_i,y_i))^2$$

among all functions $g \in S_1^0(T)$. In §3, we show that the above least-square problem has a unique solution and that the matrix of the normal equations has a relatively low condition number and a sparse structure, which can be exploited to develop efficient schemes for the solution of the normal equations.

In §4, the basic adaptive scheme is reformulated and several variants are presented and compared numerically to the basic scheme. The numerical comparisons, involving various test functions, demonstrate that significant improvement in the performance of the scheme is achieved when using data-dependent triangulations and/or least-square approximation. This means that for a prescribed error tolerance ϵ fewer points are needed to represent the surface or, alternatively, for the same number of degrees of freedom, many more accurate approximations of the underlying surface are obtained.

2. Data-dependent triangulation of a subset. Given a proper subset $V^{(M)}$ of V, we construct a $V^{(M)}$-triangulation of Ω. There are many ways to triangulate a set of data points, and we look for a triangulation that is optimal in some sense. The

Delaunay triangulation has the property that it maximizes, over all possible triangulations, the minimal angle in a triangulation [2], [5], [10], [11], [21], [24]. In [3] the concept of data-dependent triangulation was introduced and it was shown, by various numerical examples, that data-dependent triangulations are superior to the Delaunay triangulation for piecewise linear interpolation schemes defined on triangulations.

In this section we discuss data-dependent ($V^{(M)}$-)triangulation of Ω. Data-dependent triangulations are chosen to be optimal with respect to a given data-dependent criterion. A given criterion selects a preferred triangulation from among several alternatives, thus defining an ordering on the set of all triangulations, and we use the notation $T' < T$ to denote that the criterion prefers T' to T.

In the current investigation, we have considered two data-dependent criteria for optimizing a $V^{(M)}$-triangulation. The first criterion tries to minimize the sum of square errors between the approximating function and the data vector f. The second criterion is taken from [3] and is one of the more successful criteria discussed there.

To introduce these criteria we need some notations: Let $T^{(0)}$ be an initial $V^{(M)}$-triangulation, and let $W_{T^{(0)},f} \in S_1^0(T^{(0)})$ be an approximating function, e.g., $W_{T^{(0)},f}$ might be the interpolating surface $F_{T^{(0)},f}$ or the least-square surface $U_{T^{(0)},f}$ (see the Introduction). We define the coefficient vector as

$$w = (w_1, \cdots, w_M),$$

where

$$w_i = W_{T^{(0)},f}(x_i, y_i), \qquad i = 1, \cdots, M,$$

and on any other $V^{(M)}$-triangulation T, we consider the function $F_{T,w}$ interpolating the vector w, i.e.,

$$F_{T,w}(x_i, y_i) = w_i \ , \qquad i = 1, \cdots, M.$$

Of course, $F_{T^{(0)},w} = W_{T^{(0)},f}$.

The least-square (LS) criterion. By this criterion, triangulation T' is preferred to T if $E(F_{T',w}) < E(F_{T,w})$, where

$$E(F_{T,w}) = \sum_{i=1}^{N} (f_i - F_{T,w}(x_i, y_i))^2.$$

This criterion was also suggested by Quak and Schumaker [15].

The angle between normals (ABN) criterion. This is one of the more successful criteria described in [3]. To each interior edge e of T, the ABN cost function $s = s(F_{T,w}, e)$ is assigned, measuring the angle between the two normal vectors to the planes defined in the two adjacent triangles having e as a common edge. The cost of an entire triangulation T is then defined by

$$R(F_{T,w}) = \sum_{\text{all interior edges } e} |s(F_{T,w}, e)|,$$

and the ABN criterion prefers triangulation T' to T if $R(F_{T',w}) < R(F_{T,w})$.

The third criterion considered here is a purely geometrical criterion, which yields the Delaunay triangulation.

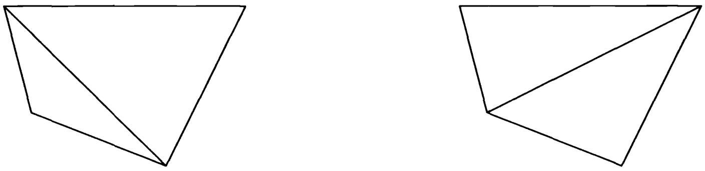

FIG. 1. *Two triangulations of a convex quadrilateral.*

The Delaunay criterion. For each triangle $T_i \in T$ a value σ_i, which is the minimum of the three interior angles of T_i, is assigned. The vector N_T is a vector of length t (the number of triangles in a triangulation T) containing the values σ_i. Furthermore, suppose that N_T is ordered in a nondecreasing manner. The Delaunay criterion (or MaxMin angle criterion) imposes the following ordering on triangulations: $T' < T$ means that $N_{T'}$ is lexicographically larger than N_T.

The Delaunay triangulation, which is globally optimal according to the Delaunay criterion, is a well-understood triangulation of a set of points and many efficient algorithms for its construction exist (see, e.g., [10], [11], and [20] and references therein). We do not know of any efficient schemes for the construction of triangulations that are globally optimal according to the LS or ABN and, in this case, we are content with locally optimal triangulations, a notion we now define. Let T be a triangulation of Ω, e an internal edge of T, and Q_e a quadrilateral formed from the two triangles having e as a common edge. If Q_e is strictly convex, then there are two possible ways of triangulating it (see Fig. 1).

DEFINITION 2.1. An edge e is called locally optimal if one of the following conditions holds:

1. The quadrilateral Q_e is not strictly convex;
2. The quadrilateral Q_e is strictly convex and $T \leq T'$ where T' is obtained from T by replacing e by the other diagonal of Q_e.

DEFINITION 2.2. A locally optimal triangulation of Ω is a triangulation T' in which all edges are locally optimal.

The term "data-dependent triangulation" frequently replaces the term "locally optimal triangulation of Ω" in cases where the triangulation criterion is data dependent.

Locally optimal triangulations are constructed by the local optimization procedure (LOP) of Lawson [10].

```
ALGORITHM 2.1 (LOP).
  1. Construct an initial $V^{(M)}$-triangulation $T$ of $\Omega$.
  2. As long as $T$ is not locally optimal:
         choose an interior edge $e$ that is not locally optimal and swap the
         edge: Replace it by the other diagonal of $Q_e$.
```

Each time an edge swap occurs, the resulting triangulation is strictly better with respect to the triangulation criterion. Since the number of triangulations of Ω is finite, the LOP converges, after a finite number of edge swaps, to a locally optimal triangulation. The locally optimal triangulation obtained by the LOP may depend on the specific order in which edges are swapped. Different ordering strategies are presented and compared in [4]. We note that in the case of the Delaunay criterion, the LOP always converges to a globally optimal triangulation independently of the order of edge swaps (see, e.g., [10]).

3. The least-square problem. In this section we discuss the least-square problem in the space $S_1^0(T)$ of piecewise linear functions defined over a $V^{(M)}$-triangulation T of Ω. The problem is to find a function

$$U_{T,f}(x,y) = \sum_{i=1}^{M} u_i \phi_i(x,y,T) \in S_1^0(T)$$

such that the sum of squares of the deviation from all data values

$$\sum_{j=1}^{N} (f_j - U_{T,f}(x_j,y_j))^2$$

is minimized.

In matrix notations we look for a vector $u = (u_1, u_2, \cdots, u_M)$ such that

$$||f - Au||_2 = \min_{v \in R^M} ||f - Av||_2,$$

where A is the $N \times M$ rectangular matrix

$$A = \{a_{ij}\} = \{\phi_j(x_i,y_i)\}, \qquad i = 1, \cdots, N, \quad j = 1, \cdots, M.$$

An equivalent formulation is to find a solution vector u to the normal equations

$$Bu = b, \tag{1}$$

where $B = A^T A$ and $b = A^T f$. System (1) is known to have at least one solution. We show that, in fact, the matrix B is of full rank.

THEOREM 3.1. *The system of equations* (1) *is nonsingular for any configuration of data points V and any selection of a proper subset $V^{(M)}$ of V.*

Proof. We prove the theorem by using a lower bound for the minimal singular value $\sigma_{\min}(A)$ of A (i.e., the minimal eigenvalue of $(A^T A)^{1/2}$). A convenient lower bound is given by Johnson [9]:

$$\sigma_{\min}(A) \geq \min_{1 \leq j \leq M} \left\{ |a_{jj}| - \frac{1}{2} \left(\sum_{\substack{i=1 \\ i \neq j}}^{M} (|a_{ij}| + |a_{ji}|) \right) \right\}. \tag{2}$$

Since the points of V were numbered such that

$$V^{(M)} = \{v_i \, , \, i = 1, \cdots, M\},$$

we have, by the choice of the basis functions $\phi_1, \cdots, \phi_M$, that

$$a_{ij} = \delta_{ij}, \qquad 1 \leq i,j \leq M,$$

and thus from (2) we conclude that

$$\sigma_{\min}(A) \geq 1, \tag{3}$$

and the theorem is proved. □

The solution of the normal equations is usually considered a bad alternative to solving the least-square problem, as these equations very often tend to become ill conditioned. It is interesting, therefore, to derive an upper bound for the condition number of the matrix B of the normal equations.

The spectral condition number of B is given by

$$\mathrm{cond}(B) = ||B||_2 \cdot ||B^{-1}||_2, \quad \text{where } ||B||_2 = \sigma_{\max}(B)$$

and $\sigma_{\max}(B)$ is the largest singular value of B.

THEOREM 3.2. *Let Ω_i be the union of all (closed) triangles having a vertex at the point v_i , $i = 1, \cdots, M$, and let N_i be the number of data points from V in the interior of Ω_i; then*

$$\mathrm{cond}(B) \leq N_{\max} = \max_{1 \leq i \leq M} N_i.$$

Proof. From the definition of B and (3) we conclude that

$$||B^{-1}||_2 = \frac{1}{\sigma_{\min}(B)} = \left(\frac{1}{\sigma_{\min}(A)}\right)^{1/2} \leq 1,$$

and thus

$$\mathrm{cond}(B) \leq ||B||_2.$$

The estimation of $||B||_2$ is done by using the well-known bound

$$||B||_2 \leq (||B||_1 \cdot ||B||_\infty)^{1/2},$$

where

$$||B||_\infty = \max_{1 \leq i \leq M} \sum_{j=1}^{M} |B_{ij}|$$

and

$$||B||_1 = \max_{1 \leq j \leq M} \sum_{i=1}^{M} |B_{ij}|.$$

Since B is symmetric, $||B||_1 = ||B||_\infty$ and $||B||_2 \leq ||B||_\infty$.

In the following, we prove that $||B||_\infty \leq N_{\max}$. We consider the ith row of B, i.e.,

$$B_{iq} = \sum_{s=1}^{N} \phi_i(x_s, y_s, T)\phi_q(x_s, y_s, T), \qquad q = 1, \cdots, M.$$

Since a data point $v_s \in V$ contributes to the ith row only if it is inside the cell Ω_i, we have that

$$B_{iq} = \sum_{(x_s, y_s) \in \Omega_i} \phi_i(x_s, y_s, T)\phi_q(x_s, y_s, T), \qquad q = 1, \cdots, M.$$

Let $v_s \in \Omega_i$, $s \neq i$ be some point from V. We denote by $v_i, v_{j(s)}$ and $v_{k(s)}$ the vertices of the triangle from T containing v_s (if v_s lies on an edge of two triangles in Ω_i, we assign it arbitrarily to one of the triangles). The point v_s contributes only to the elements B_{ii}, $B_{ij(s)}$, and $B_{ik(s)}$ of B. We note also that $\phi_i(x_s, y_s, T)$, $\phi_{j(s)}(x_s, y_s, T)$, and $\phi_{k(s)}(x_s, y_s, T)$ are just the barycentric coordinates of v_s with respect to the triangle $\triangle v_i v_{j(s)} v_{k(s)}$; hence

$$\phi_i(x_s, y_s, T) + \phi_{j(s)}(x_s, y_s, T) + \phi_{k(s)}(x_s, y_s, T) = 1,$$

and the contribution of v_s to the sum

$$\sum_{q=1}^{M} |B_{iq}| = \sum_{q=1}^{M} B_{iq}$$

is

$$\begin{aligned}\phi_i^2(x_s, y_s, T) &+ \phi_i(x_s, y_s, T)\phi_{j(s)}(x_s, y_s, T) \\ &+ \phi_i(x_s, y_s, T)\phi_{k(s)}(x_s, y_s, T) = \phi_i(x_s, y_s, T).\end{aligned}$$

Summing over all contributions of points inside the cell Ω_i, we get that

$$\sum_{q=1}^{M} B_{iq} = \sum_{(x_s, y_s) \in \Omega_i} \phi_i(x_s, y_s, T) \leq N_i,$$

and from the definition of $||B||_\infty$ we obtain the required upper bound:

$$||B||_\infty \leq N\text{max} = \max_{1 \leq i \leq M} N_i.$$

Using the above upper bound, we conclude that

$$\text{cond}(B) \leq ||B||_2 \leq ||B||_\infty \leq N\text{max},$$

and the proof of the theorem is completed. □

The fact that, in the worst possible case, the condition number of B depends linearly on the number of data points N, and is in fact much smaller in most cases, suggests that the solution of the normal equation is a practical way of solving the least-square problem. Of special interest are methods that take account of the sparsity and the special structure of B.

The storage requirements for the matrix B are very modest, as it is a sparse matrix that has a nice structure: any elements of $B_{ij} \neq 0$, $i \neq j$ correspond to an edge of the triangulation connecting the vertices v_i and v_j. Thus the nonzero B_{ij}'s can be stored in an array of M_e places where M_e denotes the number of edges in the $V^{(M)}$-triangulation T. The diagonal elements B_{ii} can be stored in an additional array of M places. Since $M_e \leq 3M$, the total memory requirement for the storage of the matrix B is $4M$ places at most. The structure of B can be used to derive efficient numerical schemes for the solution of the normal equations. In our tests we solved those equations with the conjugate gradient (CG) scheme [23, p. 572]. For its computation, the CG algorithm uses only operations of multiplications of vectors in R^M by the matrix B and scalar products of vectors in R^M. The sparsity of B is exploited by writing an efficient code for multiplication of a vector in R^M by B.

4. Numerical experiments with the COMPRESS scheme.

4.1. The COMPRESS scheme. The modified adaptive approximation scheme COMPRESS, which is a slight generalization of the basic scheme presented in [5] and [11], is formulated in the following algorithm.

ALGORITHM 4.1 (COMPRESS).

```
1. Let $\Omega$ be a region with a polygonal boundary $\partial\Omega$ consisting of $M_0$ vertices from $V$.
   Set $M \leftarrow M_0$ and let $V^{(M)} \subset V$ be the set of the $M_0$ vertices of $\partial\Omega$.
   Construct an initial $V^{(M)}$-triangulation $T$ of $\Omega$.
2. Construct a locally optimal $V^{(M)}$-triangulation $T'$ by the LOP scheme (Algorithm 2.1) with respect to a chosen criterion starting from the given triangulation $T$.
   Set $T \leftarrow T'$.
3. Construct $W_{T,f}$, an approximating surface to the data vector $f$ from $S_1^0(T)$.
   Compute the errors $E_i(W_{T,f}) = |f_i - W_{T,f}(x_i, y_i)|$, $i = 1, \cdots, N$ and let
       $E = \max_{1 \le i \le N} E_i(W_{T,f}).$
4. If $E \le \epsilon$ end the procedure; else go to step 5.
5. Select a point $v_k = (x_k, y_k) \in V \backslash V^{(M)}$ for which $E_k(W_{T,f})$ is maximal and add it to $V^{(M)}$:
       $V^{(M+1)} \leftarrow V^{(M)} \bigcup \{v_k\}.$
6. Update the triangulation $T$ to include the point $v_k$ in it, and attain a $V^{(M+1)}$-triangulation.
   Set $M \leftarrow M + 1$ and go to step 2.
```

The above algorithm in fact defines a family of schemes depending on the selection of the approximating function $W_{T,f}$ and on the triangulation criterion used for optimizing a triangulation during the LOP step. In the basic scheme [5], [11], the approximating surface was taken to be the interpolating surface $F_{T,f}$, and the LOP step was performed with the Delaunay criterion. In the following we describe the testing procedure and review some variants of the scheme that we have tested.

4.2. The testing procedure. In the numerical experiments a set V of data points, uniformly placed over the unit square, was constructed, i.e.,

$$V = \left\{ \left(\frac{i}{N}, \frac{j}{N} \right), 0 \le i, j \le N, N = 30 \right\}.$$

The data vectors $f = (f_1, \cdots, f_N)$ were obtained by evaluating five test functions $FI = FI(x, y)$ at the data points. Our experiments were performed with several data sets, including scattered data sets. These scattered test sets were generated from regular uniform grids by randomly moving the points of the regular grid by a distance not exceeding $h/4$, where h is the length of the grid cell. The results of those experiments, obtained using the data set V, were similar to the results presented in this section.

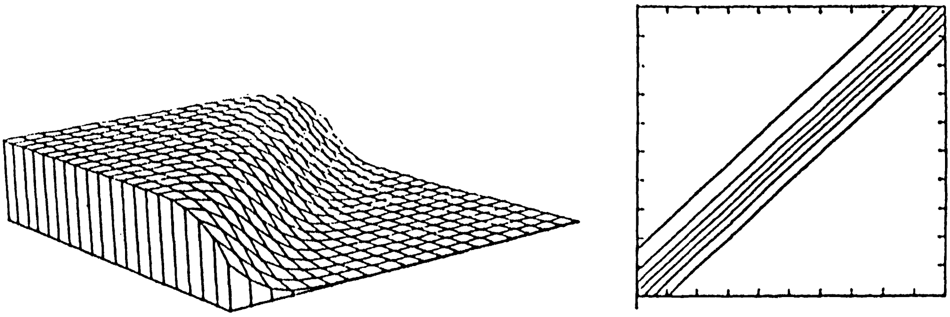

FIG. 2. *Perspective view and level curves of $F2$.*

All of the test functions are defined on the unit square. The first two test functions were taken from Franke [7]:

$$\begin{aligned} F1 = {} & .75\exp\left(-\frac{(9x-2)^2+(9y-2)^2}{4}\right) \\ & +.75\exp\left(-\frac{(9x+1)^2}{49}-\frac{9y+1}{10}\right) \\ & +.5\exp\left(-\frac{(9x-7)^2+(9y-3)^2}{4}\right) \\ & -.2\exp\left(-(9x-4)^2-(9y-7)^2\right), \\ F2 = {} & \frac{\tanh(9y-9x)+1}{9}. \end{aligned}$$

The function $F1$ is composed of two Gaussian peaks and a sharp Gaussian dip. The function $F2$ simulates a sharp rise running diagonally across the unit square (Fig. 2).

The third test function is taken from Ritchie [17]:

$$F3 = \begin{cases} 1 & \text{if } y-\xi \geq \frac{1}{2}, \\ 2(y-\xi) & \text{if } 0 \leq y-\xi \leq \frac{1}{2}, \\ (\cos(4\pi r(\xi,y))+1)/2 & \text{if } r(\xi,y) \leq \frac{1}{4}, \\ 0 & \text{otherwise,} \end{cases}$$

where

$$\begin{aligned} r(\xi,y) &= \sqrt{(\xi-\tfrac{3}{2})^2+(y-\tfrac{1}{2})^2}, \\ \xi &= 2.1x-0.1. \end{aligned}$$

This function represents a "hill" on a plane and a ramp leading to another plane (Fig. 3). It is a function with discontinuous first derivatives.

The last two test functions were taken from Lyche and Morken [12]:

$$F4 = \tanh(-3g(x,y))+1, \quad g(x,y) = 0.595576(y+3.79762)^2 - x - 10,$$

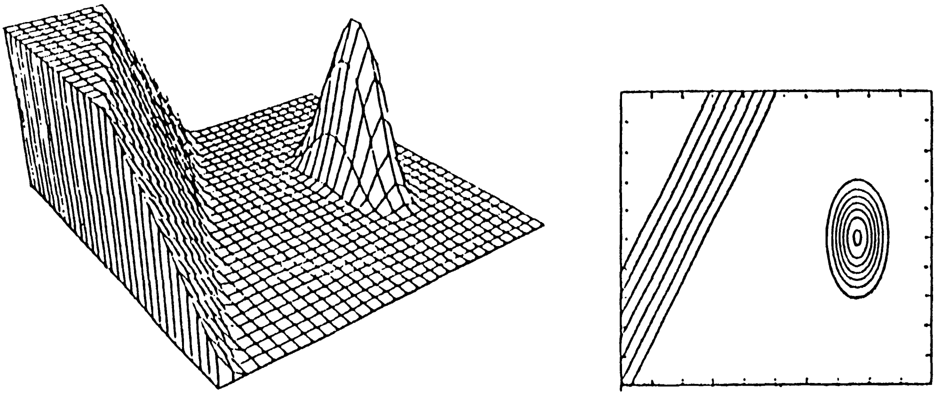

FIG. 3. *Perspective view and level curves of* $F3$.

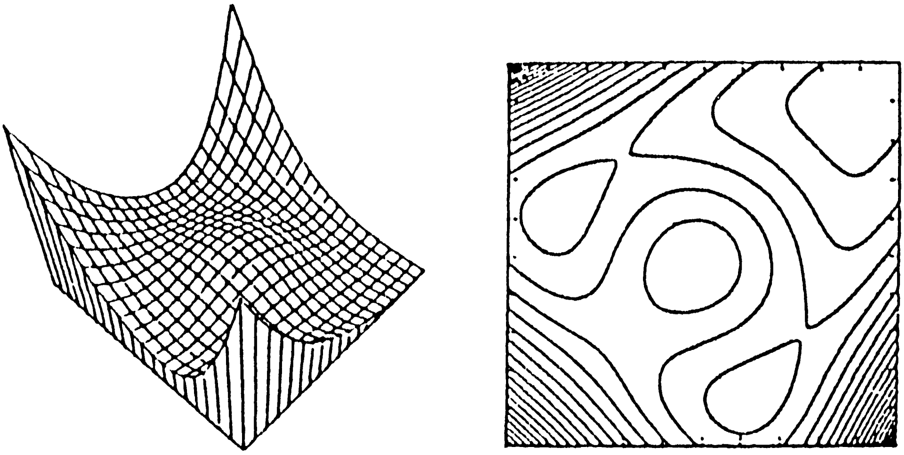

FIG. 4. *Perspective view and level curves of* $F5$.

$$F5 = \left(1-\frac{x}{2}\right)^6\left(1-\frac{y}{2}\right)^6 + 1000(1-x)^3x^3(1-y)^3y^3$$
$$+y^6\left(1-\frac{x}{2}\right)^6 + x^6\left(1-\frac{y}{2}\right)^6.$$

Function $F4$ resembles $F2$. Its contour lines are the parabolas $3g(x,y) = \text{const}$, while those of $F2$ are the straight lines $y - x = \text{const}$. Function $F5$ is a polynomial surface of degree 12 (Fig. 4).

It is convenient, during the numerical experiments, to use the number of points in the subset as a stopping criterion for the COMPRESS scheme, i.e., the iterations stop when the subset contains a predetermined number of points (and not when the deviation of the approximating surface at the data points is less than ϵ). For each of the five data sets we applied each variant of the COMPRESS algorithm twice for generating the final subsets $V^{(M)}$, with $M = 25$ and $M = 50$.

On each of the resulting subsets, with its corresponding triangulation T, the

piecewise linear approximating surface $W_{T,f}$ is constructed, and its deviation from the test function FI (generating f) is computed on a grid of 33 × 33 nodes placed uniformly over the unit square. The mean and the maximum values of these errors are tabulated and serve as a primary criterion for evaluating the various variants of the scheme. We note that this grid size was taken from the experiments in [7], and we found it satisfactory compared to a finer set of points.

4.3. Review of the numerical results. There are basically two alternatives for the use of least-square surfaces within the COMPRESS scheme. First, it is possible to perform all steps of the scheme using the interpolating surface $F_{T,f}$ and to compute the least-square surface $U_{T,f}$ only once upon leaving the routine. This strategy has the advantage of being economical in computer time and was found in our testing to be the most reasonable strategy. Only variants of the COMPRESS scheme using this strategy are presented in Tables 1–4. It is very clear from the tables that the final least-square surfaces usually provide better approximation to the selected test functions than the interpolating surfaces. The reduction of the errors is sometimes very significant, e.g., function $F4$ in Tables 1 and 3. The solution to the normal equations in our tests is computed by using conjugate gradient (CG) iterations with

TABLE 4

Hybrid	Least squares	0.04997	0.00267	0.08887	0.02435	0.02566

the values of the data vector $f|_{V(M)}$ taken as an initial guess. Since the condition number of the normal equations is relatively low, no preconditioning is required for the CG scheme, and since the matrix of the normal equations is sparse and structured, the CG code is very efficient. The condition number of the normal equations, for the model problems displayed in the tables, was between 3 and 65, and the CG scheme for the solution of these equations took between 3 and 13 iterations to converge.

A second alternative is to use the least-square surface as the approximating surface $W_{T,f}$ in various stages of the COMPRESS algorithm. The use of the least-square surface during the triangulation optimization (LOP) step resulted in slightly better locally optimal triangulations when the triangulation criterion was data dependent. The least-square surfaces may also be used to compute the deviation from the data set. Since the least-square error $E(U_{T,f})$ is usually smaller than the interpolation error $E(F_{T,f})$, a faster termination of the COMPRESS scheme results when using the former error. These advantages are not, however, enough to justify the extra computation needed for the generation of the least-square surfaces during intermediate stages of the COMPRESS scheme. We note that our numerical experiments indicate that it is *not advisable* to select the new point to be inserted (step 5 of the COMPRESS algorithm) using the errors $E_i(U_{T,f})$. Therefore, the selection step should always be carried out using the interpolation errors $E_i(F_{T,f})$, even if other steps of the COMPRESS scheme make use of the least-square surface. To conclude, we do not recommend the use of the least-square surface in intermediate steps of the COMPRESS algorithm when the data is exact.

If the data is subject to errors, it is recommended that all steps of the COMPRESS algorithm using the least-square surface instead of the interpolating surface be carried out. We note that the normal equations change only slightly when an edge swap occurs during triangulation optimization (LOP). The updating of the matrix of the normal equations is therefore efficient, and the least-square solution for the new triangulation after an edge swap can be computed by using the CG scheme taking the previous solution as an initial guess. We do not present experiments with noisy data in this paper.

We have tested the COMPRESS scheme with the Delaunay, LS, and ABN criteria (presented in §2) for optimizing a triangulation. The Delaunay criterion, used as the only criterion for the basic scheme in [5] and [11], usually results in locally optimal triangulations that are worse, i.e., the corresponding mean/max errors are larger, than triangulations corresponding to the LS or ABN criteria. However, at least one case was found, namely, test function $F1$, where the Delaunay criterion led to a better triangulation than the LS and ABN criteria.

The LS criterion often leads to a very good locally optimal triangulation, i.e., the interpolating/least-square surface defined over the corresponding locally optimal triangulation provides a good approximation to the test functions. However, this criterion has obvious limitations: Suppose that T and T' are two triangulations that differ only in the way a convex quadrilateral Q is triangulated. If no data point from V lies inside Q, then no triangulation is preferred by the criterion. Thus it is likely that the criterion performs well only when there are enough data points inside each triangle of the triangulation. In the numerical experiments, the LS criterion sometimes seems to produce locally optimal triangulations containing several "badly" shaped triangles, i.e., they are long and thin and have their long side in the direction of high curvature of the underlying test function. The number of these triangles is small, but they effect the quality of approximation, especially when the errors are measured in the max norm; see, e.g., functions $F1$ and $F5$ in Table 4. In Fig. 14, the triangulation of a subset of 50 points generated by the COMPRESS scheme with the LS criterion for data sampled from test function $F5$ is displayed. Figure 14 also displays the level curves of the piecewise linear interpolating surface defined on this triangulation. The effect of the long thin triangles on the quality of the approximation is clearly understood: The resulting locally optimal triangulation contains some long thin triangles resulting in a very poor approximation to the test function in the neighborhood of these triangles. The badly shaped triangles, once created, could not be optimized in subsequent iterations since they did not contain any data point. This behavior of the LS criterion is the reason we do not recommend, in general, the use of the LS criterion for optimizing a triangulation in the LOP step of the COMPRESS algorithm.

The ABN criterion performs nicely in most cases. Exceptions are some cases when the number of points in the subset is too small to properly reflect the characteristics of the data set; see, e.g., some cases in Tables 1 and 2. This phenomenon usually happens in the first COMPRESS iterations, and is corrected as more points are added to the subset.

An idea to improve the performance of the scheme is to use a hybrid scheme that switches, in various stages of the COMPRESS iterations, between the Delaunay triangulation TD and the ABN triangulations TA, selecting the one for which the corresponding interpolating (or least-square) surface has the least deviation from the data set (e.g., the ABN triangulation is selected if $E(F_{TA,f})$ is smaller than $E(F_{TD,f})$). The hybrid criterion was found to perform rather well overall and is thus recommended for use in practical applications.

The results of the numerical experiments with the COMPRESS algorithm using the Delaunay, LS, ABN, and hybrid triangulation criteria are displayed in Tables 1–4. The tables show, for each of these variants, the deviation of the interpolating surface $F_{T,f}$ and the least-square surface $U_{T,f}$ (for the same final $V^{(M)}$-triangulation T) from the test function. The variants of the COMPRESS algorithm displayed in the tables use the interpolating surface $F_{T,f}$ as the approximating surface $W_{T,f}$ in all intermediate steps of the algorithm.

Figures 5–13 display the triangulations of subsets containing 50 points that were generated by the COMPRESS scheme. The COMPRESS scheme was applied with two triangulation criteria: (a) the Delaunay criterion, resulting in a Delaunay triangulation TD of the subset; and (b) the hybrid criterion, resulting in the hybrid triangulation TH. The figures clearly demonstrate the success of the COMPRESS scheme in adapting to the behavior of the underlying test function, i.e., more points are spread by the scheme in areas of high curvature of the test function. It is clear that the hybrid triangulation results in a better approximation to the test functions than the Delaunay triangulation. We note that the hybrid triangulations produce sometimes long and thin triangles, which are traditionally considered bad for approximation. Such triangles, which also appear in the experiments in [3], are very desirable if their long side is positioned in the direction of low curvature of the underlying function [13], [18]. The resulting triangulations provide better approximation to the test functions than the nearly equiangular triangulations provided by the Delaunay triangulation.

5. Conclusions. In this paper, we have considered a scheme for generating a piecewise linear surface defined on a triangulation of a chosen subset of the set V of data points. It is demonstrated by a variety of numerical examples that the basic scheme, suggested in [5] and [11], can be improved significantly when the triangulation is optimized using a data-dependent criterion, and when least-square surfaces are used for approximation of the data values on the final triangulation. In practical terms, the improved scheme uses less data points from the set V to construct an approximating surface satisfying a prescribed error tolerance at all the data points. It is also proved that the condition number of the normal equations for the solution of the least-square problem is relatively low, so the solution of the normal equations can be considered a practical way to obtain the least-square surface. The ideas presented in this paper were formulated for piecewise linear surfaces but most of them can be extended to piecewise polynomials of higher degree. The use of piecewise polynomial spaces for the approximating surfaces in this scheme is currently under investigation.

Acknowledgments. I thank my advisors, Nira Dyn and David Levin of the School of Mathematical Sciences, Tel Aviv University, for their useful discussions and suggestions.

THE MODIFIED TRUNCATED SVD METHOD FOR REGULARIZATION IN GENERAL FORM*

PER CHRISTIAN HANSEN[†], TAKASHI SEKII[‡], AND HIROMOTO SHIBAHASHI[§]

Abstract. The truncated singular value decomposition (SVD) method is useful for solving the standard-form regularization problem: $\min \|\mathbf{x}\|_2$ subject to $\min \|A\mathbf{x} - \mathbf{b}\|_2$. This paper presents a modification of the truncated SVD method, which solves the more general problem: $\min \|L\mathbf{x}\|_2$ subject to $\min \|A\mathbf{x}-\mathbf{b}\|_2$, where L is a general matrix with full row rank. The extra work, associated with the introduction of the matrix L, is dominated by a QR-factorization of a matrix with dimensions smaller than those of L. In order to determine the optimal solution, it is often necessary to compute a sequence of regularized solutions, and it is shown how this can be accomplished with little extra computational effort. Finally, the new method is illustrated with an example from helioseismology.

Key words. truncated SVD, discrete ill-posed problems, regularization

AMS(MOS) subject classifications. 65F30, 65F20, 65R20

1. Introduction.

A variety of problems in astronomy, geodesy, image and signal processing, and statistics lead to so-called discrete ill-posed problems when they are solved numerically. By a *discrete ill-posed problem* we mean either a square or an overdetermined system of linear algebraic equations, i.e., $A\mathbf{x} = \mathbf{b}$ or $\min \|A\mathbf{x} - \mathbf{b}\|_2$, whose coefficient matrix A is very ill conditioned in such a way that its singular values decay rapidly to zero. Such discrete ill-posed problems often arise when one wants to solve an underlying, continuous, ill-posed problem, typically a Fredholm integral equation of the first kind. See [1, §26] and [9] for surveys of numerical aspects of discrete ill-posed problems.

Discrete ill-posed problems cannot be solved by standard methods in numerical linear algebra such as LU- or QR-factorizations due to the large condition number of the matrix A (note that the condition number is the ratio between the largest and the smallest singular value). However, the large condition number does not imply that the problem cannot be solved, it merely implies that the standard methods are not suited for solving the problem. Instead, a regularization method must be used to "filter out" the parts of the solution corresponding to all the small singular values.

A widely used regularization method is the *truncated singular value decomposition* (TSVD). This method amounts to truncating the singular value expansion of the coefficient matrix A in such a way that the smallest singular values of A are discarded, and then solving this modified least squares problem. The major advantage of using the TSVD method is that the singular value decomposition (SVD) itself provides important information about, and insight into, the discrete ill-posed problem. TSVD is equivalent to Tikhonov regularization in standard form, $\min \{\|A\mathbf{x}-\mathbf{b}\|_2^2+\lambda^2\|\mathbf{x}\|_2^2\}$, in the sense that for any truncation parameter in TSVD there exists a λ such that the solutions obtained by the two methods are close. Hence TSVD implicitly seeks to minimize the norm of the solution. See [7] for more details.

Although TSVD works well in some applications, there are other applications that explicitly require the minimization of a seminorm of the solution $\|L\,\mathbf{x}\|_2$ instead of minimization of $\|\mathbf{x}\|_2$. The matrix $L \in \Re^{p\times n}$ (with $p \leq n$ and with full rank) is usually a discrete approximation to some derivative operator. Since the SVD of the matrix A reveals so much information about the underlying ill-posed problem, we are interested in an SVD-based method for treating regularization problems with a general matrix L.

In this paper, we describe a new *modified* TSVD (MTSVD) *method.* This method is an extension of the TSVD method and, in addition to the computation of the SVD of the coefficient matrix A, it only requires a standard QR-factorization of a matrix that appears during the algorithm. The basic idea was originally outlined in [12]. Here we derive an efficient and numerically stable algorithm for implementing the MTSVD method that relies solely on standard linear algebra computations.

Our paper is organized as follows. In §2 we briefly summarize the TSVD method and define the new MTSVD method. Sections 3 and 4 give important computational aspects of computing the MTSVD solution and determining of the optimal truncation parameter. Finally, in §5 we give a practical example from helioseismology in astrophysics, which illustrates the use of the method.

2. The MTSVD method. Let us first briefly summarize the properties of the SVD of an $m \times n$ matrix A (we assume for simplicity that $m \geq n$). The SVD consists of the following decomposition:

$$A = \sum_{i=1}^{n} \mathbf{u}_i\,\sigma_i\,\mathbf{v}_i^T\,,$$

where the singular vectors are orthonormal, $\mathbf{u}_i^T\mathbf{u}_j = \mathbf{v}_i^T\mathbf{v}_j = \delta_{ij}$ for $i,j = 1,\cdots,n$, and the singular values σ_i are nonnegative and appear in nonincreasing order: $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq 0$. The TSVD of A is then defined as the rank-k matrix

$$(1) \qquad A_k \equiv \sum_{i=1}^{k} \mathbf{u}_i\,\sigma_i\,\mathbf{v}_i^T\,, \qquad k < n$$

obtained from A by neglecting its $n-k$ smallest singular values. The TSVD solution $\mathbf{x}_k$ is defined in terms of A_k as the solution with minimum two-norm to the least squares problem $\min \|A_k\mathbf{x} - \mathbf{b}\|_2$. In other words, $\mathbf{x}_k$ solves the problem

$$(2) \qquad \min_{\mathbf{x}\in\mathcal{S}} \|\mathbf{x}\|_2, \qquad \mathcal{S} = \{\,\mathbf{x}\,|\,\|A_k\,\mathbf{x} - \mathbf{b}\|_2 = \min\,\}.$$

It is straightforward to show that the TSVD solution defined by (2) can be written in terms of the SVD as

$$(3) \qquad \mathbf{x}_k = A_k^+\mathbf{b}, \qquad A_k^+ \equiv \sum_{i=1}^{k} \mathbf{v}_i\,\sigma_i^{-1}\,\mathbf{u}_i^T\,.$$

Here A_k^+ denotes the pseudo-inverse of the matrix A_k [1, §4]. The TSVD solution $\mathbf{x}_k$ is a regularized solution [7]. The integer k is usually called the *truncation parameter*, and the larger k is the larger $\|\mathbf{x}_k\|_2$ will be.

Let us now introduce the MTSVD solution $\mathbf{x}_{L,k}$ as the solution to (2) with $\|\mathbf{x}\|_2$ replaced by $\|L\,\mathbf{x}\|_2$, i.e., $\mathbf{x}_{L,k}$ solves the problem

$$(4) \qquad \min_{\mathbf{x}\in\mathcal{S}} \|L\,\mathbf{x}\|_2, \qquad \mathcal{S} = \{\,\mathbf{x}\,|\,\|A_k\,\mathbf{x} - \mathbf{b}\|_2 = \min\,\}.$$

Equation (4) is a natural generalization of (2), and the MTSVD solution $\mathbf{x}_{L,k}$ is obviously also a regularized solution.

In order to derive a formal as well as a computational expression for the MTSVD solution, we first need to define the following two matrices:

$$V_k \equiv [\mathbf{v}_{k+1}, \cdots, \mathbf{v}_n], \qquad U_k \equiv [\mathbf{u}_{k+1}, \cdots, \mathbf{u}_n]. \tag{5}$$

It is also convenient to define the $(n-k)\times(n-k)$ diagonal matrix

$$\Sigma_k \equiv \mathrm{diag}\,(\sigma_{k+1}, \cdots, \sigma_n) \tag{6}$$

consisting of the $n-k$ smallest singular values of A. Then the MTSVD solution $\mathbf{x}_{L,k}$ can be expressed as follows.

THEOREM 2.1. *Let A_k denote the* TSVD *of A, given by* (1)*, and let V_k be given by* (5)*. Then the* MTSVD *solution to* (4) *can be written as*

$$\mathbf{x}_{L,k} = (I_n - V_k\,(L\,V_k)^+ L)\,A_k^+\mathbf{b} = \mathbf{x}_k - V_k\,(L\,V_k)^+ L\,\mathbf{x}_k, \tag{7}$$

where $\mathbf{x}_k$ is the ordinary TSVD *solution* (3).

Proof. Following Eldén [4, Thm. 2.1], the MTSVD solution can be written formally as

$$\mathbf{x}_{L,k} = (I_n - (L\,(I_n - A_k^+ A_k))^+ L)\,A_k^+\mathbf{b}.$$

If we insert (1), (5), and (6) into this equation, use the relation $I_n - A_k^+ A_k = V_k V_k^T$, and also use the fact that $(L\,V_k V_k^T)^+ = V_k\,(L\,V_k)^+$, then we arrive at (7). The latter equation is proved by verifying the four Penrose conditions [1, Remark 4.1] and using the fact that $V_k^T V_k = I_{n-k}$. □

Remark. In (7), the matrix $(I - V_k\,(L\,V_k)^+ L)\,A_k^+$ is the so-called *L-weighted pseudo-inverse* of A_k (cf. [4]).

3. Computational aspects. We emphasize that (7) should not be used for computational purposes. However, it gives insight into the MTSVD solution. We see that $\mathbf{x}_{L,k}$ consists of two components: the ordinary TSVD solution $\mathbf{x}_k$ (3) minus a "correction" vector in the null space of A_k given by $V_k\,\mathbf{z}_k = V_k\,(L\,V_k)^+ L\,\mathbf{x}_k$. We also see that the vector $\mathbf{z}_k = (L\,V_k)^+ L\,\mathbf{x}_k$ is the solution to the following least squares problem:

$$\min \|(L\,V_k)\,\mathbf{z} - L\,\mathbf{x}_k\|_2. \tag{8}$$

This problem is most conveniently solved by means of a QR-factorization of the matrix $L\,V_k$, which ensures that $\mathbf{z}_k$ is computed in a numerically stable manner.

As we shall see in the next section, it is sometimes necessary to compute the MTSVD solution $\mathbf{x}_{L,k}$ for several values of k, in order to determine the optimal k. It is therefore important to solve the least squares problem (8) efficiently when stepping through several values of k. Note that decreasing k simply adds more columns to the left of $L\,V_k$, while a QR-factorization is easier to update when columns are appended to the right. Hence we want to operate with the matrix $L\,V_k\,E_k$, where $E_k \equiv \mathrm{antidiag}\,(1, \cdots, 1)$ is the $(n-k)\times(n-k)$ exchange matrix that reverts the columns of $L\,V_k$. Now let $k_{\min}$ denote the smallest desired truncation parameter and partition the QR-factorization of $L\,V_{k_{\min}}\,E_{k_{\min}}$ such that for any $k > k_{\min}$ we have that

$$\begin{pmatrix} L\,V_k E_k & L\,[\mathbf{v}_k, \cdots, \mathbf{v}_{k_{\min}+1}] \end{pmatrix} = \begin{pmatrix} Q_1^{(k)} & Q_2 \end{pmatrix} \begin{pmatrix} R_{11}^{(k)} & R_{12} \\ 0 & R_{22} \end{pmatrix}, \tag{9}$$

where $Q_1^{(k)} \in \Re^{p\times(n-k)}$ and $R_{11}^{(k)} \in \Re^{(n-k)\times(n-k)}$. Then it is easy to see that the QR-factorization of $L\,V_k\,E_k$ for $k > k_{\min}$ is given by

$$L\,V_k\,E_k = Q_1^{(k)} R_{11}^{(k)},$$

such that $\mathbf{z}_k$ is given by $\mathbf{z}_k = E_k\,(R_{11}^{(k)})^{-1}(Q_1^{(k)})^T\mathbf{x}_k$. Using this "trick," it is straightforward to step through a sequence of different truncation parameters k without having to compute a new QR-factorization for each k.

The complete algorithm for computing the MTSVD solution, including determination of the optimal truncation parameter k via inspection of the residual norm and the solution seminorm, thus takes the following form:

Algorithm MTSVD

```
1     Compute the SVD of $A$ and store $U^T\mathbf{b}$, $\Sigma$, and $V$.
2     Form $L\,V_{k_{\min}}E_{k_{\min}}$ and compute its QR-factorization.
3     For all the required values of $k$:
3.1       Compute $\mathbf{x}_k$ and $L\,\mathbf{x}_k$.
3.2       Compute $\mathbf{z}_k = E_k\,(R_{11}^{(k)})^{-1}(Q_1^{(k)})^T L\,\mathbf{x}_k$.
3.3       Compute $\|L\,\mathbf{x}_{L,k}\|_2$ and $\|A\,\mathbf{x}_{L,k} - \mathbf{b}\|_2$ (see §4).
3.4       Use this information to choose the optimal $k$.
4     Compute $\mathbf{x}_{L,k} = \mathbf{x}_k - V_k\,\mathbf{z}_k$.
```

The computational overhead associated with computation of the MTSVD solution, compared to that of computing the TSVD solution, is dominated by the QR-factorization, which requires approximately $2\,p\,(2\,n^2 - 3\,n\,k_{\min} + k_{\min}^2)$ flops, including formation of the matrix $L\,V_{k_{\min}}$. This overhead should be compared to the computational effort of computing the SVD of A, which amounts to approximately $(2\,m + 11\,n)\,n^2$ flops [6, §5.4.5]. Hence even for moderate values of m, the overhead associated with computing the MTSVD solution is only a fraction of that of computing the SVD of A.

Whenever there is a distinct gap in the singular value spectrum of A, it is natural to set the truncation parameter k in (1) equal to the numerical rank of A, i.e., such that the gap appears between singular values σ_k and σ_{k+1}. In such situations a search through several singular values of k is not required, and it is not even necessary to compute the SVD of A. Instead, one can take advantage of the computationally much less expensive *rank-revealing QR-factorization* of A, which is guaranteed to capture the numerical rank k of A. By means of a rank-revealing QR-factorization, we can easily compute a minimum-norm least squares solution as well as null-vectors of A (analogous to the vectors in V_k). We will not pursue this aspect further here, but instead refer to [2] and [3, §3] for theoretical and computational details.

4. Methods for choosing the regularization parameter. We now turn to the determination of the appropriate truncation parameter k. Often the optimal value of k is evident from a simple plot of the singular values σ_i and the corresponding "Fourier coefficients" $\mathbf{u}_i^T\mathbf{b}$ for $i = 1, \cdots, n$. See [8] for more details on this approach and why it works. If such a plot does not reveal the optimal truncation parameter, we suggest two alternative methods. One is the generalized cross-validation method discussed below, which requires computation of the norm of the residual vector corresponding to $\mathbf{x}_{L,k}$, i.e., $\|A\,\mathbf{x}_{L,k} - \mathbf{b}\|_2$. In the other method, one plots the seminorm of the solution $\|L\,\mathbf{x}_{L,k}\|_2$ versus the residual norm, and then chooses the k that corresponds to a characteristic L-shaped "corner" of the $(\|A\,\mathbf{x}_{L,k} - \mathbf{b}\|_2\,,\ \|L\,\mathbf{x}_{L,k}\|_2)$-curve.

For more details about this method for choosing k, as well as some alternative methods, we refer to [9, §6].

Both the solution seminorm $\|L\,\mathbf{x}_{L,k}\|_2$ and the residual norm $\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2$ can be computed efficiently by means of the following expressions.

THEOREM 4.1. *With the notation from* (5), (6), *and* (9), *the solution seminorm and the residual norm are given by:*

$$\|L\,\mathbf{x}_{L,k}\|_2 = \|(I_p - L\,V_k\,(L\,V_k)^+)L\,\mathbf{x}_k\|_2 = \|Q_2^T L\,\mathbf{x}_k\|_2, \tag{10}$$

$$\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2 = (\|U_k^T\mathbf{b}+\Sigma_k\,\mathbf{z}_k\|_2^2+\delta_o^2)^{1/2}, \tag{11}$$

where we have defined $\delta_o \equiv \left(\sum_{i=n+1}^m(\mathbf{u}_i^T\mathbf{b})^2\right)^{1/2}$.

Proof. It follows from (7) that $\|L\,\mathbf{x}_{L,k}\|_2$ is equal to the norm of the residual vector in (8). Using the factorization (9) we then obtain (10). The residual norm is given by $\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2 = \|A\,\mathbf{x}_k-\mathbf{b}-A\,V_k\,\mathbf{z}_k\|_2$. Since $\mathbf{x}_k=\sum_{i=1}^k\mathbf{v}_i\sigma_i^{-1}\mathbf{u}_i^T\mathbf{b}\Rightarrow A\,\mathbf{x}_k=\sum_{i=1}^k\mathbf{u}_i\mathbf{u}_i^T\mathbf{b}$, we can write $A\,\mathbf{x}_k-\mathbf{b}=-U_kU_k^T\mathbf{b}-\sum_{i=n+1}^m\mathbf{u}_i\mathbf{u}_i^T\mathbf{b}$. Moreover, $A\,V_k\,\mathbf{z}_k=U_k\Sigma_k\,\mathbf{z}_k$. The vector $\sum_{i=n+1}^m\mathbf{u}_i\mathbf{u}_i^T\mathbf{b}$ is obviously orthogonal to the vectors $U_kU_k^T\mathbf{b}$ and $U_k\Sigma_k\,\mathbf{z}_k$, and the residual norm is therefore given by $\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2^2 = \|U_k^T\mathbf{b}+\Sigma_k\,\mathbf{z}_k\|_2^2+\delta_o^2$. □

Since the seminorm of the MTSVD solution $\|L\,\mathbf{x}_{L,k}\|_2$ is simply the norm of the residual vector in (8), it can be computed with little overhead. The quantities $\mathbf{u}_i^T\mathbf{b}$ are available from most SVD programs such that $\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2$ can be computed in only $O(m)$ flops. Both norms can therefore be computed very efficiently, so that it is easy to monitor the $(\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2\,,\,\|L\,\mathbf{x}_{L,k}\|_2)$-curve during Algorithm MTSVD.

Next we consider the *generalized cross-validation* (GCV) method [5], [15]. To summarize this method in general terms, let $\mathbf{x}_\lambda = A_\lambda^I\,\mathbf{b}$ denote the solution computed by means of some regularization method with regularization parameter λ. Then the GCV method amounts to finding the regularization parameter λ that minimizes the GCV-function $G(\lambda)$, defined by

$$G(\lambda)\equiv\frac{\|A\,\mathbf{x}_\lambda-\mathbf{b}\|_2^2}{(\mathrm{trace}\,(I_m-A\,A_\lambda^I))^2}.$$

Here the matrix $A\,A_\lambda^I$ is called the influence matrix. For MTSVD we obtain the following simple expression.

THEOREM 4.2. *The* GCV-*function for* MTSVD *is given by*

$$G(k)=\frac{\|A\,\mathbf{x}_{L,k}-\mathbf{b}\|_2^2}{(m-k)^2}. \tag{12}$$

Proof. In the MTSVD solution the regularization parameter is $\lambda=k$, and from (7) we see that A_λ^I is the L-weighted pseudo-inverse of A, i.e., $A_\lambda^I=(I_n-V_k\,(L\,V_k)^+L)\,A_k^+$. Hence if we define $\bar\Sigma_k\equiv\mathrm{diag}\,(\sigma_1,\cdots,\sigma_k)$, $\bar V_k\equiv[\mathbf{v}_1,\cdots,\mathbf{v}_k]$, and $\bar U_k\equiv[\mathbf{u}_1,\cdots,\mathbf{u}_k]$, then the influence matrix for MTSVD is given by

$$\begin{aligned}A\,A_\lambda^I &= A\,(I_n-V_k\,(L\,V_k)^+L)\,A_k^+ = A\,A_k^+ - A\,V_k\,(L\,V_k)^+L\,A_k^+\\ &= \bar U_k\bar U_k^T - U_k\Sigma_k(L\,V_k)^+L\,\bar V_k\bar\Sigma_k^{-1}\bar U_k^T = \bar U_n\begin{pmatrix} I_k & 0\\ \Sigma_k(L\,V_k)^+L\,\bar V_k\bar\Sigma_k^{-1} & 0\end{pmatrix}\bar U_n^T.\end{aligned}$$

From this relation, it immediately follows that $\operatorname{trace}(I_m - A A_\lambda^I) = m - k$, and we therefore obtain (12). □

We suggest that this easily computed function be used in the above Algorithm MTSVD, in addition to monitoring the $(\|A\mathbf{x}_{L,k} - \mathbf{b}\|_2, \|L\mathbf{x}_{L,k}\|_2)$-curve as a criterion for choosing the optimal k.

5. An application from helioseismology. In this final section, we illustrate the use of the MTSVD method by applying it to an inverse problem from helioseismology in astrophysics. The sun is oscillating in millions of global eigenmodes, and by using information from these eigenmodes we are able to explore the internal structure of the sun. See [13] for an introductory review of helioseismology and [14] for more details. The fundamental equation in helioseismology is the following Fredholm integral equation of the first kind:

$$\int_0^R \int_0^\pi K_{nlm}(r,\theta)\, \Omega(r,\theta)\, d\theta\, dr = \delta\omega_{nlm}. \tag{13}$$

Here the unknown function $\Omega(r,\theta)$ is the solar internal rotational frequency at the spherical coordinate (r,θ). Moreover, the kernel $K_{nlm}(r,\theta)$ is a function that depends on the solar internal structure and the modes n, l, and m, which are quantum numbers that describe the eigenoscillations of the sun. Finally, the right-hand side quantities $\delta\omega_{nlm}$ are the so-called frequency splittings, which are essentially observed quantities. The number of observable modes is as many as a few thousand.

Since our purpose here is to illustrate the MTSVD method, rather than to discuss the physical meaning of the computed results, we assume that the function $\Omega(r,\theta)$ is a function of only r, in order to make the following discussion simple. The full two-dimensional inversion is discussed in other papers [10], [11]. In this numerical experiment, we prepare first an artificial (but plausible) function $\Omega(r)$ and calculate the resultant frequency splittings $\delta\omega_{nlm}$. We then treat them as observed values and solve the integral equation (13) to see how well we can reproduce $\Omega(r)$ as the solution of the integral equation.

We discretize the radial coordinate into nonequidistant mesh points r_j, which become denser towards the surface of the sun. We then compute approximations Ω_j to $\Omega(r_j)$ by substituting the integral in (13) with a simple summation. The integral equation is thus transformed into a discrete ill-posed problem, where the right-hand side is $\mathbf{b} \equiv \{\delta\omega_i\}$, the coefficient matrix A is given by $A \equiv \{K_i(r_j)\,(r_j - r_{j-1})\}$, and the solution is $\mathbf{x} \equiv \{\Omega_j\}$. The suffix i denotes the mode number, that is, the set of the quantum numbers $\{nlm\}$, and the suffix j denotes the mesh number. In the following examples, we use 250 mesh points and 1836 different modes. We impose "smoothness" on the computed solution by choosing the regularization matrix L as an approximation to the second derivative operator.

Figure 1 shows all the singular values σ_i of the matrix A. We see that they are clustered in two distinct groups with a narrow transition region between large and small σ_i. It is natural to choose the truncation parameter k somewhere in this transition region and thus avoid a search through many values of k. We have chosen $k = 82$, which gives an effective condition number σ_1/σ_k of A_k of the order 10^5. We then solve the system for two different cases of the function $\Omega(r)$.

Example 1. First we deal with slightly differential rotation. The TSVD and MTSVD solutions are shown in Fig. 2, and we see that the TSVD solution is unrealistically oscillatory. We also see that the MTSVD solution reproduces the original

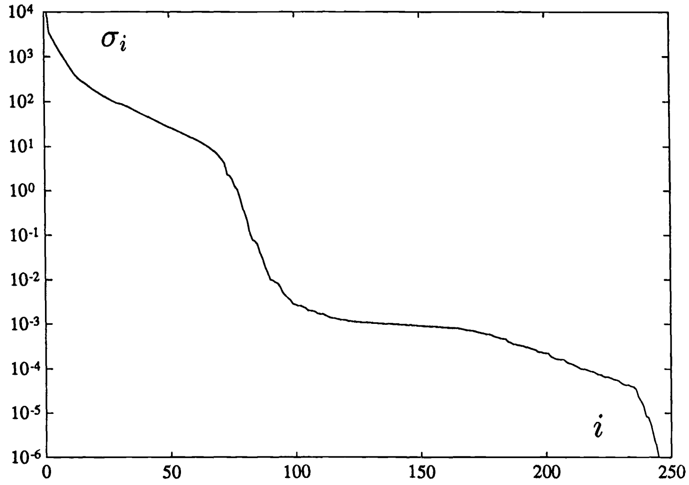

FIG. 1. *The singular values of the* 1836 × 250 *matrix A obtained from discretization of the integral equation* (13).

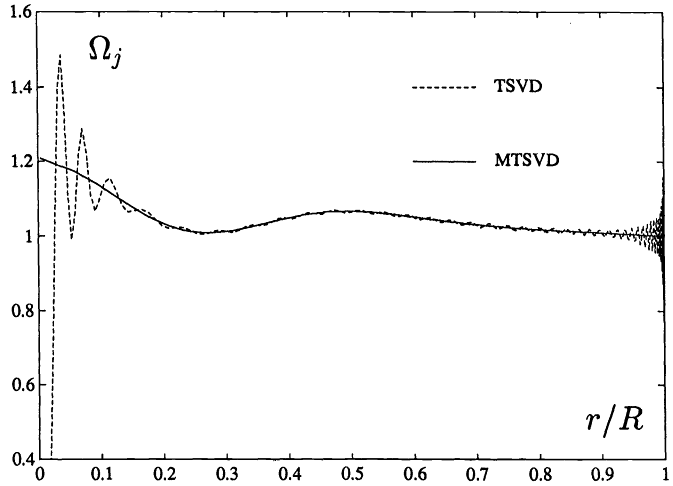

FIG. 2. *The computed solutions to Example* 1, *where $\Omega(r)$ varies slowly.*

function $\Omega(r)$ much better than the TSVD solution does, in fact, the MTSVD is indistinguishable from the exact $\Omega(r)$ in this plot.

Example 2. The second example features differential rotation with some steep gradients and a discontinuity. Figure 3 shows the TSVD and the MTSVD solutions. Again, the TSVD solution is unsatisfactory because it includes unrealistic oscillations. The MTSVD solution is much better, although (as expected) it cannot completely reproduce the step in $\Omega(r)$ at $r/R = 0.8$.

6. Conclusion. We have presented an efficient algorithm for regularization of discrete ill-posed problems in general form, i.e., for solving the problem min $\|L\mathbf{x}\|_2$

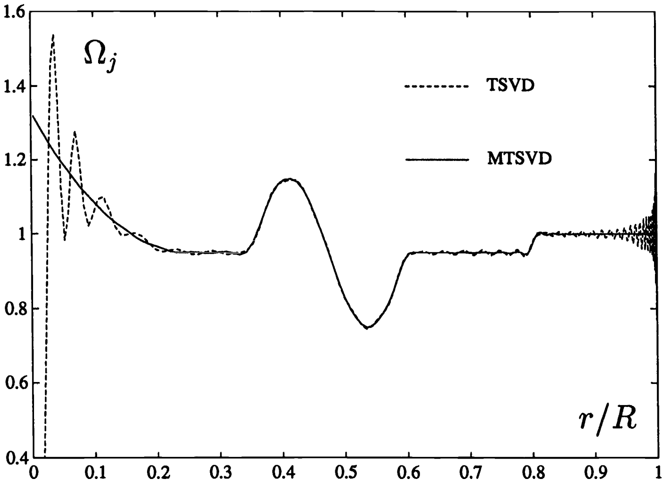

FIG. 3. *The computed solutions to Example* 2, *where* $\Omega(r)$ *has steep gradients and a discontinuity.*

subject to $\min \|A\mathbf{x} - \mathbf{b}\|_2$. The algorithm extends the well-known TSVD method (which corresponds to $L = I$) to the case with a general matrix L. The computational overhead associated with an $L \neq I$ is dominated by a QR-factorization, and this overhead is usually much smaller than the effort involved in computing the SVD of the matrix A.

We have also shown how the norms $\|L\mathbf{x}\|_2$ and $\|A\mathbf{x} - \mathbf{b}\|_2$ can be computed efficiently. This is important in connection with methods such as generalized cross-validation, which automatically seek to compute the optimal truncation parameter.

Finally, we have illustrated the use of our algorithm in connection with the numerical treatment of the inverse helioseismic problem in astrophysics. Our examples show the superiority of our new method with $L \neq I$, as compared to the case $L = I$, for this particular problem.

HIGHLY PARALLEL SPARSE CHOLESKY FACTORIZATION*

JOHN R. GILBERT[†] AND ROBERT SCHREIBER[‡]

Abstract. This paper develops and compares several fine-grained parallel algorithms to compute the Cholesky factorization of a sparse matrix. The experimental implementations are on the Connection Machine, a distributed-memory SIMD machine whose programming model conceptually supplies one processor per data element. In contrast to special-purpose algorithms in which the matrix structure conforms to the connection structure of the machine, this paper focuses on matrices with arbitrary sparsity structure.

The most promising alternative is a supernodal, multifrontal algorithm whose inner loop performs several dense factorizations simultaneously on a two-dimensional grid of processors. The key subroutine is a fine-grained parallel, dense-factorization algorithm. The sparse code attains execution rates comparable to those of the dense subroutine. Although at present architectural limitations prevent the dense factorization from realizing its potential efficiency, it is concluded that a regular data parallel architecture can be used efficiently to solve arbitrarily structured sparse problems.

A performance model is also presented and used to analyze these algorithms. Asymptotic analysis combined with experimental measurement of parameters is accurate enough to be useful in choosing among alternative algorithms for a complicated problem.

Key words. sparse matrix algorithms, Cholesky factorization, supernodal factorization, multifrontal factorization, systems of linear equations, parallel computing, data parallel algorithms, chordal graphs, clique trees, Connection Machine, performance analysis

1. Introduction.

1.1. Data parallelism.

Highly parallel, local-memory computer architectures promise to achieve high performance inexpensively by assembling a large amount of simple hardware in a way that scales without bottlenecks. A data parallel programming model simplifies the programming of local memory parallel architectures by associating a processor with every data element in a computation (at least conceptually), thus hiding from the programmer the details of distribution of data and work to the processors.

Some major challenges accompany these promises. Communication is expensive relative to computation, so an algorithm must minimize communication. Locality is important in communication, so it pays to substitute communication with nearby processors for more general patterns where possible. The sequential programmer tunes the inner loop of an algorithm for high performance, but simple data parallel algorithms tend to have "everything in the inner loop" because a sequential loop over the data is typically replaced by a parallel operation. (From this point of view, the advantage of the more complicated of our two algorithms, Grid Cholesky, is that it removes the general-pattern communication from the inner loop.)

Algorithms for data parallel architectures must make different trade-offs than sequential algorithms: They must exploit regularity in the data. For efficiency on single instruction, multiple data (SIMD) machines, they must also be highly regular in the time dimension. In some cases entirely new approaches may be appropriate; examples of experiments with such approaches include particle-in-box flow simulation, knowledge-base maintenance [5], and the entire field of neural computation [20]. On the other hand, the same kind of regularity in a problem or an algorithm can often be exploited in a wide range of architectures; therefore, many ideas from sequential computation turn out to be surprisingly applicable in the highly parallel domain. For example, block-oriented matrix operations are useful in sequential machines with hierarchical storage and conventional vector supercomputers [3]; we shall see that they are also crucial to efficient data parallel matrix algorithms.

1.2. Goals of this study. Data parallel algorithms are natural for computations on matrices that are dense or have regular nonzero structures arising from, for example, regular finite-difference discretizations. The main goal of this research is to determine whether data parallelism is useful in dealing with irregular, arbitrarily structured problems. Specifically, we consider computing the Cholesky factorization of an arbitrary sparse, symmetric, positive definite matrix. We make no assumptions about the nonzero structure of the matrix besides symmetry. We present evidence that arbitrary sparse problems can be solved nearly as efficiently as dense problems by carefully exploiting regularities in the nonzero structure of the triangular factor that come from the clique structure of its chordal graph.

A second goal is to perform a case study in analysis of parallel algorithms. The analysis of sequential algorithms and data structures is a mature and useful science that has contributed to sparse matrix computation for many years. By contrast, the study of complexity of parallel algorithms is in its infancy, and it remains to be seen how useful parallel complexity theory will be in designing efficient algorithms for real parallel machines. We argue by example that, at least within a particular class of parallel architectures, asymptotic analysis combined with experimental measurement of parameters is accurate enough to be useful in choosing among alternative algorithms for a single fairly complicated problem.

1.3. Outline. The structure of the remainder of the paper is as follows. In §2 we review the definitions we need from numerical linear algebra and graph theory, sketch the architecture of the Connection Machine, and present a timing model for a generalized data parallel computer that abstracts that architecture.

In §3 we present the first of two parallel algorithms for sparse Cholesky factorization. The algorithm, which we call Router Cholesky, is based on a theoretically efficient algorithm in the parallel random access machine (PRAM) model of parallel computation. We analyze the algorithm and point out two reasons that it fails to be practical, one having to do with communication and the other with processor utilization.

In §4 we present a second algorithm, which we call Grid Cholesky. Grid Cholesky is a data parallel implementation of a supernodal, multifrontal method that draws on the ideas of Duff and Reid [7] and Ashcraft et al. [1]. It improves on Router Cholesky by using a two-dimensional grid of processors to operate on dense submatrices, thus replacing most of the slow generally routed communication of Router Cholesky with faster grid communication. It also solves the processor utilization problem by assigning different data elements to the working processors at different stages of the computation. We present an analysis and experimental results for a pilot implementation of Grid Cholesky on the Connection Machine.

The pilot implementation of Grid Cholesky is approximately as efficient as a dense Cholesky factorization algorithm, but is still slow compared to the theoretical peak performance of the machine. Several steps necessary to improve the absolute efficiency of the algorithm, most of which concern efficient Cholesky factorization of dense matrices, are described. Finally, we draw some conclusions and discuss avenues for further research.

2. Definitions.

The first two subsections below summarize the linear algebra and graph theory needed to study sparse Cholesky factorization. Most of this material is covered in more detail by George and Liu [13], [23], [24]. The remainder of the section outlines the data parallel programming model and its implementation on the Connection Machine, and describes our parametric model of a data parallel computer.

2.1. Linear algebra.

Let $A = (a_{ij})$ be an $n \times n$ real, symmetric, positive definite sparse matrix. There is a unique $n \times n$ lower triangular matrix $L = (l_{ij})$ with positive diagonal such that $A = LL^T$. This is the Cholesky factorization of A. We seek to compute L; with it we solve the linear system $Ax = b$ by solving $Ly = b$ and $L^T x = y$. We discuss algorithms for computing L below. In general, L is less sparse than A. The nonzero positions of L that were zero in A are called *fill* or *fill-in*. For any matrix X, we write $\eta(X)$ to denote the number of nonzero elements of X.

The rows and columns of A may be symmetrically reordered so that the system solved is $PAP^T(Px) = Pb$, where P is a permutation matrix. We assume that such a reordering, chosen to reduce $\eta(L)$ and the number of operations required to compute L, has been done. We further assume that the structure of L has been determined by a symbolic factoring process. We ignore these preliminary computations in this study because the cost of actually computing L typically dominates. (In many cases, several identically structured matrices may be factored using the same ordering and symbolic factorization.) A study of the implementation of appropriate reordering and symbolic factorization procedures on data parallel architectures is in preparation [18].

If the matrix A is such that its Cholesky factor L has no more nonzeros than the lower triangle of A, i.e., there is no fill, then A is a *perfect elimination matrix.* If PAP^T is a perfect elimination matrix for some permutation matrix P, we call the ordering corresponding to P a *perfect elimination ordering* of A.

Let R and S be subsets of $\{1, \cdots, n\}$. Then $A(R, S)$ is the $|R| \times |S|$ matrix whose elements are $a_{r,s}$ for $r \in R$ and $s \in S$. (For any set S, we write $|S|$ to denote its cardinality.)

2.2. Graph theory.

2.2.1. Vertex elimination.

We associate two ordered, undirected graphs with the sparse, symmetric matrix A. First, $G(A)$, the graph of A, is the graph with vertices $\{1, 2, \cdots, n\}$ and edges $E(A) = \{(i, j) \mid a_{ij} \neq 0\}$. (Note that $E(A)$ is a set of unordered pairs.) Next, we define the *filled graph* $G^*(A)$ with vertices $\{1, 2, \cdots, n\}$ and edges $E^*(A) = \{(i, j) \mid l_{ij} \neq 0\}$, so that $G^*(A)$ is $G(L + L^T)$. The edges in $G^*(A)$ that are not edges of $G(A)$ are called *fill edges.* The output of a symbolic factorization of A is a representation of $G^*(A)$.

For every fill edge (i, j) in $E^*(A)$ there is a path in $G(A)$ from vertex i to vertex j whose vertices all have numbers lower than both i and j; moreover, for every such path in $G(A)$ there is an edge in $G^*(A)$ [28]. Consider renumbering the vertices of $G^*(A)$. With another numbering, this last property may or may not hold. If it does, then the new ordering is a perfect elimination ordering of $G^*(A)$; Liu [24] calls it an *equivalent reordering* of $G^*(A)$.

2.2.2. Chordal graphs. Every cycle of more than three vertices in $G^*(A)$ has an edge between two nonconsecutive vertices (a *chord*). Such a graph is said to be *chordal.* Not only is $G^*(A)$ chordal for every A, but every chordal graph is the filled graph of some matrix [27].

Let $G = G(V, E)$ be any undirected graph. A *clique* is a subset X of V such that for all $u, v \in X$, $(u, v) \in E$. A clique is *maximal* if it is not a proper subset of any other clique. For any $v \in V$, the *neighborhood* of v, written $\operatorname{adj}(v)$, is the set $\{u \in V \mid (u, v) \in E\}$. The *monotone neighborhood* of v, written $\operatorname{madj}(v)$, is the smaller set $\{u \in V \mid u > v, (u, v) \in E\}$. We extend adj and madj to sets of vertices in the usual way.

A vertex v is *simplicial* if $\operatorname{adj}(v)$ is a clique. Two vertices, u and v, are *indistinguishable* if $\{u\} \cup \operatorname{adj}(u) = \{v\} \cup \operatorname{adj}(v)$. Two vertices are *independent* if there is no edge between them. A set of vertices is independent if every pair of vertices in it is independent; two sets A and B are independent if no vertex of A is adjacent to a vertex of B.

It is immediate that any two simplicial vertices are either independent or indistinguishable. A set of indistinguishable simplicial vertices thus forms a clique, though not generally a maximal clique. The equivalence relation of indistinguishability partitions the simplicial vertices into pairwise independent cliques. We call these the *simplicial cliques* of the graph.

2.2.3. Elimination trees. A fundamental tool in studying sparse Gaussian elimination is the *elimination tree.* This structure was defined by Schreiber [30]; Liu [24] gives a survey of its many uses. Let A have the Cholesky factor L. The elimination tree $T(A)$ is a rooted spanning forest of $G^*(A)$ defined as follows. If vertex u has a higher-numbered neighbor v, then the parent $p(u)$ of u in $T(A)$ is the smallest such neighbor; otherwise u is a root. In other words, the first off-diagonal nonzero element in the uth column of L is in row $p(u)$. It is easy to show that $T(A)$ is a forest consisting of one tree for each connected component of $G(A)$. For simplicity we assume in what follows that A is irreducible, so that vertex n is the only root, though our algorithms do not assume this.

There is a monotone increasing path in $T(A)$ from every vertex to the root. If (u, v) is an edge of $G^*(A)$ with $u < v$ (that is, if $l_{vu} \neq 0$) then v is on this unique path from u to the root. This means that when $T(A)$ is considered a spanning tree of $G^*(A)$, there are no "cross edges" joining vertices in different subtrees. It implies that, if we think of the vertices of $T(A)$ as columns of A or L, any given column of L depends only on columns that are its descendants in the tree.

2.2.4. Clique trees. The elimination tree describes a Cholesky factorization in terms of operations on single columns. A description in terms of operations on full blocks can yield algorithms with better locality of reference, which is an advantage either on a machine with a memory hierarchy (registers, cache, main memory, disk) or on a distributed-memory parallel machine. The Connection Machine falls into both of these categories.

Describing symmetric factorization in terms of operations on full submatrices is the key idea in both Duff and Reid's "multifrontal" algorithm [7] and the "supernodal" algorithm of Ashcraft et al. [1], which can be traced back to the so-called element model of factorization [15], [33]. A full submatrix of L is a clique in the chordal graph $G^*(A)$. The clique structure of chordal graphs has been explored extensively in the combinatorial literature; representations of chordal graphs as trees of cliques date back at least to 1972 [10] and continue to be used [16], [25], [26].

A *clique tree* for matrix A is a tree whose nodes are sets that partition the vertices of $G^*(A)$ into cliques in such a way that all the vertices of a node N are indistinguishable simplicial vertices in the graph that results by deleting from $G^*(A)$ all vertices in nodes that are proper descendants of N. An equivalent definition is to think of starting with an elimination tree and collapsing vertices that are indistinguishable from their parents. (This definition differs slightly from that of Peyton [26], whose tree nodes are overlapping maximal cliques of $G^*(A)$.)

A clique that is a node in a clique tree is also called a *supernode.* If all vertices of $G^*(A)$ in proper descendants of some supernode are deleted, the supernode becomes a simplicial clique in the resulting graph. The clique tree is sometimes called a *supernode tree* or *supernodal elimination tree* [2]. A matrix may have many different clique trees—indeed, the elimination tree itself is one. Our numerical factorization algorithm Grid Cholesky can actually use any clique tree; the symbolic factorization we describe in §4.1 uses a block Jess–Kees algorithm to compute a shortest possible clique tree.

2.3. The Connection Machine.

2.3.1. Architecture. The Connection Machine (model CM-2) is a local-memory, SIMD parallel computer. The description we present here corresponds to the machine architecture presented by the assembly language instruction set Paris [34]. We programmed the CM in *lisp, which is compiled into Paris.

A full-sized CM has $2^{16} = 65{,}536$ processors, each of which can directly access 65,536 bits of memory. (Since this work was completed, larger memories have become available.) The processors are connected by a communication network called the *router*, which is configured by a combination of microcode and hardware to be a 16-dimensional hypercube.

The essential feature of the CM programming model is the *parallel variable* or pvar. A pvar is an array of data in which every processor stores and manipulates one element. The size of a pvar may be a multiple of the number of physical machine processors, p. If there are V times as many elements in the pvar X as there are processors, then (through microcode) each physical processor simulates V virtual processors; thus the programmer's view remains "one processor per datum." The ratio V is called the *virtual processor* (VP) *ratio.* The CM requires that V must be a power of two. Thus we find useful the notation $\lceil x \rceil$, meaning the smallest power of two not smaller than the real number x.

The *geometry* of each set of virtual processors (and its associated pvars) is also determined by the programmer, who may choose to view it as any multidimensional array with dimensions that are powers of two. The VP sets and their pvars are embedded in the machine (using Gray codes) so that neighboring virtual processors are simulated by the same or neighboring physical processors.

The Paris instruction set corresponds fairly well to the abstract model of data parallel programming that the CM attempts to present to the programmer, but it does not correspond closely to the actual hardware of the CM. Largely for this reason, it is hard to get high performance when programming in Paris or in a language that is compiled into Paris [31]. We shall discuss this point in detail later. Other ways to view and to program the hardware of the CM-2 to provide better performance are now becoming available to users.

2.3.2. Connection Machine programming. Parallel computation on the CM is expressed through elementwise binary operations on pairs of pvars that reside in the same VP set—that is, that have the same VP ratio and layout on the machine. (Optionally, we may specify a boolean mask that selects only certain virtual processors to be active.) These operations take time proportional to V, since the actual processors must loop over their simulated virtual processors. This remains true even when the set of selected processors is very sparse.

Interprocessor communication is expressed and accomplished in three ways, which we discuss in order of increasing generality but decreasing speed.

Communication with virtual processors at nearest-neighbor grid cells is most efficient. A pvar may be shifted along any of its axes using this type of communication. The shift may be circular or end-off at the programmer's discretion.

A second communication primitive, *scan*, allows broadcast of data. For example, if x is a one-dimensional pvar with the value [1, 2, 3, 4, 5, 6, 7, 8] then a scan of x yields [1, 1, 1, 1, 1, 1, 1, 1]. Scans are implemented using the hypercube connections. The time for a scan of length n is linear in $\log n$. Scans can also be used to broadcast along either rows or columns of a two-dimensional array. Scans that perform parallel prefix arithmetic operations are also available, but we do not use them.

Scans of subarrays are possible. In a *segmented scan*, the programmer specifies a boolean pvar, the *segment pvar*, congruent to x. The segments of x between adjacent T values in the segment pvar are scanned independently. Thus, for example, if we use the segment pvar [T F F F T F F T] and x is as above, then a segmented scan returns [1, 1, 1, 1, 5, 5, 5, 8].

The third and most general form of communication allows a virtual processor to access data in the memory of any other virtual processor. These operations go by several different names even within the CM environment; we refer to them in terms already familiar in sparse matrix computation: *gather* and *scatter*.

A gather allows processors to read data in the memory of other processors. The CM term for a gather is `pref!!` (for the *lisp programmer) or `get` (for the Paris programmer). In a gather, three pvars are involved: the source, the destination, and the address. The address of the processor whose memory is to be read is taken from the integer address pvar. Suppose that the source is the one-dimensional pvar $[15, 14, 13, \cdots, 2, 1, 0]$ and the address pvar is $[0, 1, 2, 0, 1, 2, \cdots, 0, 1, 2, 0]$. Then the data stored in the destination is $[15, 14, 13, 15, 14, 13, \cdots, 15, 14, 13, 15]$. The Fortran-90 or Matlab statement that accomplishes this is `dest = source(address)`; it performs the assignment $dest(i) \leftarrow source(address(i))$ for $1 \leq i \leq \text{length}(dest)$.

A scatter allows processors to write data to the memory of other processors. The CM term for a scatter is `*pset` (for the *lisp programmer) or `send` (for the Paris programmer). Again, the three pvars are a source, a destination, and an integer address. The Fortran-90 or Matlab version is `dest(address) = source`, and the effect is $dest(address(i)) \leftarrow source(i)$ for $1 \leq i \leq \text{length}(source)$.

In a scatter, when the address pvar has duplicate values, data from several source processors are sent to the same destination processor. (When this happens we say that a *collision* has occurred.) The programmer can select one of several different ways to combine colliding values by specifying a *combining operator*. For example, if the source and address are as above and the destination initially has the value $[1, 1, \cdots, 1]$, then after a scatter-with-add, the destination has the value $[45, 40, 35, 1, 1, 1, \cdots, 1]$. The sum of elements $source(j)$, such that $address(j) = k$, is stored in $dest(k)$ if there are any such elements; otherwise, $dest(k)$ is unchanged. Other combining operators

TABLE 1
Parameters of CM *model.*

Connection Machine parametric model		
Parameter	Description	Measured CM-2 value
V	Virtual processor ratio	
μ	Memory reference time	$4.8 \cdot V$ μsec
ϕ	Multiply or add time $\div\, \mu$	7
σ	Scan time $\div\, \phi$	$6.2 + 1.2 \log_2$ scan-distance
ν	News time $\div\, \phi$	3
ρ	Route time $\div\, \phi$	scatter (no collisions): 64 scatter-add (4 collisions): 110 scatter-add (100 collisions): 200 gather (many collisions): 430

include product, maximum, minimum, and "error." We have found combining scatter to be a powerful aid to data parallel programming.

2.3.3. Measured CM performance. We now develop a model of performance on data parallel architectures and use it to analyze performance of several algorithms for sparse Cholesky factorization. The essential machine characteristics in the model are described by five parameters:

μ: The memory reference time for a 32-bit word.
ϕ: The 32-bit floating-point multiply time, in units of μ.
ν: The 32-bit grid communication time, in units of ϕ.
σ: The 32-bit scan time, in units of ϕ.
ρ: The 32-bit router time, in units of ϕ.

(Floating-point addition takes the same time as multiplication: $\phi\mu$.) In our model, execution time scales linearly with VP ratio, which is essentially correct for the Connection Machine. Therefore, μ is proportional to VP ratio, and the other parameters are independent of VP ratio. In Table 1, we give measured values for these parameters obtained by experiment on the CM-2. We observe that router times range over a factor of four depending on the number of collisions; it is possible to design pathological routing patterns that perform even worse than this. For any given pattern, gather usually takes just twice as long as scatter, presumably because it is implemented by sending a request and then sending a reply. Therefore in our approximate analyses we generally choose a value of ρ for scatter corresponding to the number of collisions observed, and model gather as taking 2ρ floating-point times.

3. Router Cholesky.

Our first parallel Cholesky factorization algorithm is a parallel implementation of a standard column-oriented sparse Cholesky; it is based closely on Gilbert and Hafsteinsson's theoretically efficient algorithm [17] for the PRAM model of computation. Its communication requirements are too unstructured for it to be very efficient on a fine-grained multiprocessor like the CM, but we implemented and analyzed it to use as a basis for comparison and to help tune our performance model of the CM.

3.1. The Router Cholesky algorithm. Router Cholesky uses the elimination tree $T(A)$ to organize its computation. For the present, assume that both the tree and the symbolic factorization $G^*(A)$ are available. (In our experiments we computed the symbolic factorization sequentially; Gilbert and Hafsteinsson [17] describe a parallel algorithm.) Each vertex of the tree corresponds to a column of the matrix.

Following George et al. [12], we express a sequential column-oriented Cholesky factorization in terms of two primitive operations, *cdiv* and *cmod*.

```
procedure Sequential Cholesky (matrix $A$);
    for $j \leftarrow 1$ to $n$ do
        for each edge $(i, j)$ of $G^*(A)$ with $i < j$ do
            cmod $(j, i)$ od;
        cdiv $(j)$ od
end Sequential Cholesky;
```

Routine *cdiv* (j) divides the subdiagonal elements of column j by the square root of the diagonal element in that column, and routine *cmod* (j, i) modifies column j by subtracting a multiple of column i. This is called a *left-looking* algorithm because column j accumulates all necessary updates *cmod* (j, i) from columns to its left just before the *cdiv* (j) that completes its computation. By contrast, a *right-looking* algorithm would perform all the updates *cmod* (j, i) using column i immediately after the *cdiv* (i).

Now consider the elimination tree $T(A)$. A given column (vertex) is modified only by columns (vertices) that are its descendants in the tree [30]. Therefore a parallel left-looking algorithm can compute all the leaf vertex columns at once.

```
procedure Router Cholesky (matrix $A$);
    for $h \leftarrow 0$ to $height(n)$ do
        for each edge $(i, j)$ with $height(i) < height(j) = h$ pardo
            cmod $(j, i)$ od;
        for each vertex $j$ with $height(j) = h$ pardo
            cdiv $(j)$ od
        od
end Router Cholesky;
```

Here $height(j)$ is the length of the longest path in $T(A)$ from vertex j to a leaf. Thus the leaves have height 0, vertices whose children are all leaves have height 1, and so forth. The outer loop of this algorithm works sequentially from the leaves of the elimination tree up to the root. At each step, an entire level's worth of *cmod*'s and *cdiv*'s are done.

A processor is assigned to every nonzero of the triangular factor (or, equivalently, to every edge and vertex of the filled graph G^*). Suppose processor P_{ij} is assigned to the nonzero that is initially a_{ij} and will eventually become l_{ij}. (If l_{ij} is a fill, then a_{ij} is initially zero; recall that we assume that the symbolic factorization is already done, so we know which l_{ij} will be nonzero.) In the parallel *cdiv* (j), processor P_{jj} computes l_{jj} as the square root of its element, and sends l_{jj} to processors P_{ij} for $i > j$, which then divide their own nonzeros by l_{jj}. In the parallel *cmod* (j, i), processor P_{ji} sends the multiplier l_{ji} to the processors P_{ki} with $k > j$. Each such P_{ki} then computes the update $l_{ki}l_{ji}$ locally and sends it to P_{kj} to be subtracted from l_{kj}.

We call this a *left-initiated* algorithm because the multiplications in *cmod* (j, i) are performed by the processors in column i who then, on their own initiative, send these updates to a processor in column j. Each column i is involved in at most one *cmod* at a time because every column modifying j is a descendant of j in $T(A)$, and the subtrees rooted at vertices of any given height are disjoint. Therefore each processor participates in at most one *cmod* or *cdiv* at each parallel step. If we ignore the time taken by communication (including the time to combine updates to a single P_{kj} that may come from different P_{ki_1}, P_{ki_2}, $\cdots$), then each parallel step takes a constant amount of time and the parallel algorithm runs in time proportional to the height of the elimination tree $T(A)$.

3.2. CM implementation of Router Cholesky. To implement Router Cholesky on the CM, we must specify how to assign data to processors, and then describe how to do the communication in *cdiv* and *cmod.*

We use one (virtual) processor for each nonzero in the triangular factor L. We lay out the nonzeros in a one-dimensional array in column major order, as in many standard sequential sparse matrix algorithms [13]. This makes operations within a single column efficient because they can use the CM scan instructions. Each column is represented by a processor for its diagonal element followed by a processor for each subdiagonal nonzero. The symmetric upper triangle is not stored. We can also think of this processor assignment as a processor for each vertex j of the filled graph, followed by a processor for each edge (i, j) with $i > j$.

Router Cholesky, like many data parallel algorithms, is profligate of parallel variable storage. Each processor contains some working storage and the following pvars:

`l`: Element of factor matrix L, initially A.
`i`: Row number of this element.
`j`: Column number of this element.
`j_ht`: *height*(j) in $T(A)$.
`i_ht`: *height*(i) in $T(A)$.
`diagonal_p`: Boolean: Is this a diagonal element?
`e_parent`: In processor P_{ij}, a pointer to $P_{i,p(j)}$.
`next_update`: Pointer to next element this one may update.

(Recall that $p(j) > j$ is the elimination tree parent of vertex $j < n$.)

At each stage of the sequential outer loop, each processor uses `i_ht` and `j_ht` to decide whether it participates in a *cdiv* or *cmod.* By comparing the local processor's `i_ht` or `j_ht` to the current value of the outer loop index, a processor can determine if its element is in a column that is involved in a *cdiv* or a *cmod.*

The *cdiv* uses a scan operation to copy the diagonal element to the rest of the active column.

The *cmod* uses a similar scan to copy the multiplier l_{ji} down to the rest of column i. The actual update is done by a scatter-with-add, which uses the router to send the update to its destination.

To determine where to send the update, each element maintains a pointer called `next_update` to a later element in its row. The nonzero positions in each row are a connected subgraph of the elimination tree, and are linked together in this tree structure by the `e_parent` pointers. Each nonzero updates only elements in columns that are its ancestors in the elimination tree. At each stage, `next_update` is moved one step up the tree using the `e_parent` pointers.

3.3. Router Cholesky performance: Theory. Each stage of Router Cholesky does a constant number of router operations, scans, and arithmetic operations. The number of stages is $h+1$, where h is the height of the elimination tree. In terms of the parameters of the machine model in §2.3.2, its running time is

$$(c_1\rho + c_2\sigma + c_3)\phi\mu h.$$

Recall that the memory reference time μ is proportional to the virtual processor ratio, which in this case is $\lceil \eta(L)/p \rceil$. The c_i are constants.

The most time-consuming step is incrementing the `next-update` pointer; the router is used twice in this operation. The dominant term is the router term $c_1 \rho \phi \mu h$. Notice that we do not explicitly count time for combining updates to the same element from different sources, since this is handled within the router and is thus included in ρ.

To get a feeling for this analysis consider the model problem, a five-point finite-difference mesh in two dimensions ordered by nested dissection [11]. If the mesh has k points on a side, then the graph is a k by k square grid, and we have $n = k^2$, $h = O(k)$, and $\eta(L) = O(k^2 \log k)$. The number of arithmetic operations in the Cholesky factorization is $O(k^3)$, in either the sequential or parallel algorithms. Router Cholesky's running time is $O(\rho k^3 \log k/p)$. If we define performance as the ratio of the number of operations in the sequential algorithm to parallel time, we find that the performance is $O(p/\log k)$ (taking ρ to be a constant independent of p or k; this is approximately correct for the Connection Machine, although theoretically ρ should grow at least with $\log p$). This analysis points out two weak points of Router Cholesky. First, the performance on the model problem drops with increasing problem size. (This depends on the problem, of course; for a three-dimensional model problem a similar analysis shows that performance is $O(p)$ regardless of problem size.) Second, and more seriously, the constant in the leading term of the complexity is proportional to the router time ρ, because every step uses general communication.

This analysis can be extended to any two-dimensional finite-element mesh with bounded-node degree, ordered by nested dissection [17]. The asymptotic analysis is the same but the values of the constants will be different.

3.4. Router Cholesky performance: Experiments. In order to validate the timing model and analysis, we experimented with Router Cholesky on a variety of sparse matrices. We present one example here in detail. The original matrix is 2,500 × 2,500 with 7,400 nonzeros (counting symmetric entries only once), representing a 50 × 50 five-point square mesh. It is preordered by Sparspak's automatic nested dissection heuristic [13], which gives orderings very similar to the ideal nested dissection ordering used in the analysis of the model problem above. The Cholesky factor has $\eta(L) =$ 48,608 nonzeros, an elimination tree of height $h = 144$, and takes 1,734,724 arithmetic operations to compute.

We ran this problem on CM-2 computers at the Xerox Palo Alto Research Center and the NASA Ames Research Center. The results quoted here are from $p =$ 8,192 processors, with floating-point coprocessors, of the machine at NASA. The VP ratio was therefore $V = \lceil \eta(L)/p \rceil = 8$. (Rounding up to a power of two has considerable cost here, since we use only 48,608 of the 65,536 virtual processors.) We observed a running time of 53 seconds, of which about 41 seconds was due to gathers and scatters. Substituting into the analysis above (using $\rho = 200$ since there were generally many collisions), we would predict router time $c_1 \rho \phi \mu h = 39$ seconds and other time $(c_2 \sigma + c_3) \phi \mu h = 1.5$ seconds. This is not a bad fit for router time; it is not clear why the remaining time is such a poor fit, but the expensive square root and the data movement involved in the pointer updates contribute to it, and it seems that I/O may have affected the measured 53 seconds.

The observation, in any case, is that router time completely dominates.

3.5. Remarks on Router Cholesky. Router Cholesky is too slow as it stands to be a cost-effective way to factor sparse matrices. Each stage does two gathers and a scatter with exactly the same communication pattern. More careful use of the router could probably speed it up by a factor of two to five. However, this would not be enough to make it practical; something more like a hundredfold improvement in router speed would be needed.

The one advantage of Router Cholesky is the extreme simplicity of its code. It is no more complicated than the numeric factorization routine of a conventional sequential sparse Cholesky package [13]. It is interesting to note that column-oriented sparse Cholesky codes on multiple instruction, multiple data (MIMD) message-passing multiprocessors [12], [14], [35] are more complex. They exploit MIMD capability to implement dynamic scheduling of the *cmod* and *cdiv* tasks. They allow arbitrary assignment of columns to processors and therefore are required to use indirect addressing of columns. Finally, they are written with low-level communication primitives, the explicit "send" and "receive."

Router Cholesky's simplicity comes dearly. Flexibility in scheduling allows MIMD implementations to gain a modest performance advantage over any possible SIMD implementation. More important, we employ $\eta(L)$ virtual processors, regardless of the number of physical processors. It is essential that these virtual processors not all sit idle, consuming physical processor time slices, when there is nothing for them to do. As implemented by the Paris instruction set, they do sit idle.

We described Router Cholesky as a left-initiated, left-looking algorithm. In a right-initiated algorithm, processor P_{ij} would perform the updates to l_{ij}. In a right-looking algorithm, updates would be applied as soon as the updating column of L was computed instead of immediately before the updated column of L was to be computed. Router Cholesky is thus one of four cousins. It is the only one of the four that maps operations to processors evenly; the other three alternatives require an inner sequential loop of some kind. All four versions require at least h router operations.

4. Grid Cholesky.

In this section we present a parallel supernodal, multifrontal Cholesky algorithm and its implementation on the CM. Multifrontal methods, introduced by Duff and Reid [7], compute a sparse Cholesky factorization by performing symmetric updates on a set of dense submatrices. We follow Liu [23] in referring to an algorithm that uses rank-1 updates as "multifrontal" and the block version that uses rank-k updates as "supernodal multifrontal." The idea of using block methods to operate on supernodes has been used in many different sparse factorization algorithms [1], [7]. Parallel supernodal or multifrontal algorithms have been used on MIMD message-passing and shared-memory machines [2], [6], [32].

The algorithm uses a two-dimensional VP set (which we call the "playing field") to partially factor, in parallel, a number of dense principal submatrices of the partially factored matrix. By working on the playing field, we may use the fast grid and scan mechanisms for all the necessary communication during the factorization of the dense submatrices. Only when we need to move these dense submatrices back and forth to the playing field do we need to use the router. In this way we drastically reduce the use of the router: for the model problem on a $k \times k$ grid, we reduce the number of uses from $h = 3k - 1$ to $2 \log_2 k - 1$. The playing field can also operate at a lower VP ratio, in general, because it does not need to store the entire factored matrix at once.

This method, like all multifrontal methods, is in essence an "out of core" method in that the Cholesky factor is kept in a data structure that is not referred to while doing arithmetic, all of which is done on dense submatrices. The novelty here is the factorization of many of these dense problems in parallel; the simultaneous exploitation of the parallelism available *within* each of the dense factorizations; the use of a two-dimensional grid of processors for these parallel dense factorizations; the use of the machine's router for parallel transfers from the matrix storage data structure; and the use of the combining scatter operations for parallel update of the matrix storage data structure.

4.1. The Grid Cholesky algorithm.

4.1.1. Block Jess and Kees reordering. First, we describe an equivalent reordering of the chordal graph $G^* = G^*(A)$ that we call the *block Jess/Kees ordering.* Block Jess/Kees is a perfect elimination ordering that has two properties that make it the best equivalent reordering for our purposes: It eliminates vertices with identical monotone neighborhoods consecutively, and it produces a clique tree of minimum height.

Our reordering eliminates all the simplicial vertices of G^* simultaneously as one major step. In the process, it partitions all the vertices of G^* into supernodes. Each of these supernodes is a clique in G^*, and is a simplicial clique when its component vertices are about to be eliminated. Each vertex is labeled with the *stage*, or major step number, at which it is eliminated. In more detail, the reordering algorithm is as follows.

```
procedure Reorder (graph $G^*$)
    $active\_stage \leftarrow -1$;
    while $G^*$ is not empty do
        $active\_stage \leftarrow active\_stage + 1$;
        Number all the simplicial vertices in $G^*$, assigning
            consecutive numbers within each supernode;
        $stage(v) \leftarrow active\_stage$ for all simplicial vertices $v$;
        Remove all the simplicial vertices from $G^*$ od;
    $\hbar \leftarrow active\_stage$
end Reorder;
```

The cliques are the nodes of a clique tree whose height is $\hbar$, one less than the number of major elimination steps. The parent of a given clique is the lowest-stage clique adjacent to the given clique.

The name "block Jess/Kees" indicates a relationship with an algorithm due to Jess and Kees [21] that finds an equivalent reordering for a chordal graph so as to minimize the height of its elimination tree. The original (or "point") Jess/Kees ordering eliminates just one vertex from each simplicial clique at each major step. (This is a maximum-size independent set of simplicial vertices.) Each step of point Jess/Kees produces one level of an elimination tree, from the leaves up. The resulting elimination tree has minimum height over all perfect elimination orders on G^*. Our block Jess/Kees eliminates all the simplicial vertices at each major step, producing a clique tree one level at a time from the leaves up. This ordering may not minimize the height of the elimination tree. However, as Blair and Peyton [4] have shown, it does produce a clique tree of minimum height over all perfect elimination orders on G^*.

Every vertex is included in exactly one supernode. We number the supernodes as $\{S_1, \cdots, S_m\}$ in such a way that if $i < j$ then the vertices in S_i have lower numbers than the vertices in S_j. The *stage* at which a supernode S is eliminated is the iteration of the *while* loop at which its vertices are numbered and eliminated; thus for all $v \in S$, $stage(v) = stage(S)$ is the height of node S in the clique tree.

4.1.2. Parallel supernodal multifrontal elimination. Let C be a supernode. It is immediate that $K = \mathrm{adj}(C) \cup C$ is a clique, and that it is maximal. Our factorization algorithm works by forming the principal submatrices of A corresponding to vertices in the maximal cliques generated by supernodes. Let $\gamma = |C|$ and $\delta = |\,\mathrm{adj}(C)|$. Write $A(K, K)$ for the principal submatrix of order $|K| = \gamma + \delta$ consisting of elements $a_{i,j}$ with $i, j \in K$. It is natural to partition the principal submatrix $A(K, K)$ of A as

$$A(K,K) = \begin{pmatrix} X & E \\ E^T & Y \end{pmatrix},$$

where $X = A(C, C)$ is $\gamma \times \gamma$, $Y = A(\mathrm{adj}(C), \mathrm{adj}(C))$ is $\delta \times \delta$, and E is $\gamma \times \delta$.

In the terminology of the previous section, Grid Cholesky is a "block right-looking" algorithm. The details are as follows.

```
procedure Grid Cholesky(matrix $A$)
    for active_stage $\leftarrow 0$ to $\hbar$ do
        for each supernode $C$ with stage(C) = active_stage pardo
            Move $A(K, K)$ to the playing field,
                where $K = C \cup \mathrm{adj}(C)$;
            Set $Y$ to zero on the playing field;
            Perform $\gamma = |C|$ steps of parallel Gaussian elimination
                to compute the Cholesky factor $L$ of $X$,
                the updated submatrix $E' = L^{-1}E$,
                and the Schur complement $Y' = -E^T X^{-1} E$,
                where $X$, $E$, and $Y$ partition $A(K, K)$ as above;
            $A(C, C) \leftarrow L$;
            $A(\mathrm{adj}(C), C) \leftarrow E'^T$;
            $A(\mathrm{adj}(C), \mathrm{adj}(C)) \leftarrow A(\mathrm{adj}(C), \mathrm{adj}(C)) + Y'$ od
    od
end Grid Cholesky;
```

4.2. Multiple dense partial factorization. In order to make this approach useful, we need a fast dense matrix factorization on two-dimensional VP sets. To that end, we discuss an implementation of *LU* decomposition without pivoting. (We use *LU* instead of Cholesky here because we can see no efficient way to exploit symmetry with a two-dimensional machine; moreover, *LU* avoids the square root at each step and so is a bit faster.) We analyzed and implemented two methods: a systolic algorithm that uses only nearest-neighbor communication on the grid, and a rank-1 update algorithm that uses row-and-column broadcast. With either of these methods, all the submatrices $A(K, K)$ corresponding to supernodes at a given stage are distributed about the two-dimensional playing field simultaneously (each as a separate "baseball diamond"), and the partial factorization is applied to all the submatrices at once.

We describe the rank-1 algorithm in terms of its effect on a single submatrix $A(K, K)$, with a supernode of size γ and a Schur complement of size δ. A single rank-1 update consists of a division to compute the reciprocal of the diagonal element, a scan down the columns to copy the pivot row to the remaining rows, a parallel multiplication to compute the multiplier for each row, another scan to copy the multiplier across each row, and finally a parallel multiply and subtract to apply the update. The number of rank-1 updates is γ, the size of the supernode.

An entire stage of partial factorizations is performed at once, using segmented scans to keep each factorization within its own "diamond." The number of steps on the playing field at stage s is γ_s, the maximum value of γ over all supernodes at stage s. Then a stage of rank-1 partial factorization takes time $(c_3\sigma + c_4)\phi\mu$. Here c_3 is $2\gamma_s$, and c_4 is proportional to γ_s as well.

The relative cost of the various parts of the rank-1 update code are summarized below for a complete factorization (that is, one in which $\delta = 0$). The bookkeeping includes nearest-neighbor communication to move three one-bit tokens that control which processors perform reciprocals, multiplications, and so on at each step.

Scans (row and column broadcast): 79.7%.

News (moving the tokens): 5.5%.

Multiply (computing multipliers): 2.7%.

Divide (reciprocal of pivot element): 7.1%.

Multiply-subtract (Gaussian elimination): 4.8%.

Unlike the rank-1 implementation, the systolic implementation never uses a scan; all communication is between grid neighbors. Thus its communication terms are proportional to ν rather than σ. This advantage is more than offset by the fact that $3\gamma_s + 2\delta_s$ sequential iterations are necessary, while the rank-1 method only needs γ_s.

4.2.1. Remarks on dense partial factorization. Theoretically, systolic factorization should be asymptotically more efficient as machine size and problem size grow without bound, because scans must become more expensive as the machine grows. Realistically, however, the CM happens to have $\sigma \approx 6\nu$; for a full factorization ($\delta = 0$) a sixfold decrease in communication time per step more than balances the threefold increase in number of steps, and so the systolic method *is* somewhat faster. But for a partial factorization, the rank-1 algorithm is the clear winner. For example, for the two-dimensional model problem the average Schur complement size δ_s is about $4\gamma_s$, so the rank-1 code has an 11-to-1 advantage in number of steps. This more than makes up for the fact that scan is much slower than grid communication.

It is interesting to note that the only arithmetic that matters in a sequential algorithm, the multiply-subtract, accounts for only 1/21 of the total time in the rank-1 parallel algorithm. Moreover, only 1/3 of the multiply-subtract operations actually do useful work, since the active part of the matrix occupies a smaller and smaller subset of the playing field as the computation progresses. This gives the code an overall efficiency of one part in 63 for *LU* and one part in 126 for Cholesky. We have found this to be typical in *lisp codes for matrix operations, especially with high VP ratios. The reasons are these: scan is slow relative to arithmetic; the divide and multiply operations occur on very sparse VP sets; and the VP ratio remains constant as the active part of the matrix gets smaller.

Significant performance improvements could come from several possible sources. A more efficient implementation of virtual processors could improve performance substantially: the loop over V virtual processors should be restricted to those virtual processors that are active. Sometimes a determination that this is going to happen can readily be made at compile time. As an alternative, we could have rewritten the code: the VP set could shrink as the matrix shrinks, and the divides and the multiplies could be performed in a sparser VP set.

The scans could be sped up considerably within the hypercube connection structure of the CM. Ho and Johnsson [19] have developed an ingenious algorithm that takes $O(b/d + d)$ time to broadcast b bits in a d-dimensional hypercube, in contrast to the scan, which takes $O(b+d)$. The copy scans could also be implemented so that each physical processor gets only one copy of the data rather than V copies.

More efficient use of the low-level floating-point architecture of the CM-2 is possible. The Paris instruction set hides the fact that every 32 physical processors share one vector floating-point arithmetic chip. Performing 32 floating-point operations implies moving 32 numbers in bit-serial fashion into a transposer chip, then moving them in parallel into the vector chip, then reversing the process to store the result. While this mode of operation conforms to the one-processor-per-data-element programming model, it wastes time and memory bandwidth when only a few processors are actually active (such as computing multipliers or diagonal reciprocals in LU), since 32 memory cycles are required just to access one floating-point number.

This mode also requires intermediate results to be stored back to main memory, precluding the use of block algorithms [3] that could store intermediate results in the registers in the transposer. Thus the computation rate is limited by the bandwidth between the transposer and memory (about 3.5 gigaflops for a 64K processor CM) instead of by the operation rate of the vector chip (about 27 gigaflops total).

A more efficient dense matrix factorization can be achieved by treating each 32-processor-plus-transposer-and-vector-chip unit as a single processor, and representing 32-bit floating-point numbers "slicewise," with one bit per physical processor, so that they do not need to be moved bit-serially into the arithmetic unit. (Viewed this way, we were working with just 256 real processors!) Also, if virtualization is handled efficiently, we need only keep 256 processors busy. At the time this work was done (late in 1988) the tools for programming on this level were not easily usable. While CM Fortran allows this model, it does not allow scans and scatter with combining, so we still (early 1991) cannot use it.

4.3. CM implementation of Grid Cholesky. Grid Cholesky uses two VP sets with different geometries: the *matrix storage* stores the nonzero elements of A and L (doing almost no computation), and the *playing field* is where the dense partial factorizations are done. The top-level factorization procedure is just a loop that moves the active submatrices to the playing field, factors them, and moves updates back to the main matrix.

4.3.1. Matrix storage. The matrix storage VP set is a one-dimensional array of virtual processors that stores all of A and L in essentially the same form as Router Cholesky. Each of the following pvars has one element for each nonzero in L:

`l_value`: Elements of L, initially those of A.
`grid_i`: The playing field row in which this element sits.
`grid_j`: The playing field column in which this element sits.
`active_stage`: The stage at which j occurs in a supernode.
`updates`: Working storage for sum of incoming updates.

We use a scatter to move the active columns from matrix storage to the playing field. The supernodes C are disjoint, but their neighboring sets adj(C) may overlap; that is, more than one Y_C may be computing updates to the same element of L at the same stage. Therefore, we use scatter-with-add to move the partially factored matrix from the playing field back to matrix storage.

4.3.2. The playing field. The second VP set, called the playing field, is the two-dimensional grid on which the supernodes are factored. In our implementation it is large enough to hold all the principal submatrices for all maximal cliques at any stage, although it could actually use different VP ratios at different stages for more efficiency. Its size is determined as part of the symbolic factorization and reordering. The pvars used in this VP set are

- `dense_a`: The playing field for matrix elements.
- `update_dest`: The matrix storage location (processor) that holds this matrix element; an integer pvar array indexed by stage.

Some boolean flags are also used to coordinate the simultaneous partial factorization of all the maximal cliques.

The processors of the playing field compute LU factorizations by simultaneously doing rank-1 updates (see §4.2) of all the dense submatrices stored there, using segmented scans to distribute the pivot rows and columns within all submatrices at the same time. The number of rank-1 update steps is the size of the largest supernode at the current stage. The submatrices may be different sizes; each matrix does only as many rank-1 updates as the size of its supernode.

In order to use this procedure, we need to find a placement of all the submatrices $A(K, K)$ for all the maximal cliques K at every stage. This is a two-dimensional bin packing problem. In order to minimize CM computation time, we want to pack these square arrays onto the smallest possible rectangular playing field (whose borders must be powers of two). Optimal two-dimensional bin packing is, in general, an NP-hard problem, though various efficient heuristics exist [9]. Our experiments use a simple "first fit by levels" heuristic. This layout is done during the sequential symbolic factorization, before the numeric factorization is begun.

4.4. Grid Cholesky performance: Theory. We separate the running time for Grid Cholesky into time in the matrix storage VP set and time on the playing field. The former includes all the router traffic, and essentially nothing else. (There is one addition per stage to add the accumulated updates to the matrix.) There is a fixed number of router uses per stage, so the matrix storage time is $T_{MS} = c_5 \rho \phi \mu_{MS} \hbar$ for some constant c_5. The subscript MS indicates that the value of μ is taken in the matrix storage VP set, whose VP ratio set is $V_{MS} = \lceil \eta(L)/p \rceil$. In the current implementation $c_5 = 4$, since two scatters are used to move the dense matrices to the playing field at the beginning of a stage, and then two scatters are used to move the completely computed columns and the Schur complements back to matrix storage.

We express the playing field time as a sum over levels. At each level s the number of rank-1 updates is the size of the largest supernode at that level, which is γ_s. According to the analysis in §4.2,

$$T_{PF} = (c_6 \sigma + c_7) \sum_{s=0}^{\hbar} \gamma_s \phi \mu_s,$$

where c_6 and c_7 are constants (in fact, $c_6 = 2$), and the subscript s indicates that the value of μ is taken in the playing field VP set at stage s. The VP ratio in this VP set could be approximately the ratio of the total size of the dense submatrices at stage s to the number of processors, changing at each stage as the number and size of the maximal cliques vary. However, in our implementation, it is simply fixed at the maximum of this value over all stages.

Again, to get a feeling for this analysis, let us consider the model problem, a five-point finite-difference mesh on a $k \times k$ grid ordered by nested dissection. For this problem $n = k^2$, $\hbar = O(\log k)$, and $\eta(L) = O(k^2 \log k)$. The factorization requires $O(k^3)$ arithmetic operations. Table 2 summarizes the number and sizes of the cliques that occur at each stage. The columns in the table are as follows:

TABLE 2

Subproblem counts and playing field size for the model problem.

Stage s	$R(s)$	γ_s	$\gamma_s + \delta_s$	$\sum(\gamma_C + \delta_C)^2$
$\hbar$	1	k	k	k^2
$\hbar - 1$	2	$k/2$	$3k/2$	$4.5k^2$
$\hbar - 2$	4	$k/2$	$3k/2$	$9k^2$
$\hbar - 3$	8	$k/4$	$3k/2$	$18k^2$
$\hbar - 4$	16	$k/4$	$5k/4$	$25k^2$
$\hbar - 5$	32	$k/8$	$7k/8$	$24.5k^2$
$\hbar - 6$	64	$k/8$	$5k/8$	$25k^2$
$\hbar - 7$	128	$k/16$	$7k/16$	$24.5k^2$
$\hbar - 2r$	2^{2r}	$k/2^r$	$5k/2^r$	$25k^2$
$\hbar - 2r - 1$	2^{2r+1}	$k/2^{r+1}$	$7k/2^{r+1}$	$24.5k^2$

$R(s)$: Number of supernodes at stage s.
γ_s: Size of largest supernode at stage s.
$\gamma_s + \delta_s$: Size of largest maximal clique $C \cup \operatorname{adj}(C)$ at stage s.
$\sum(\gamma_C + \delta_C)^2$: Total area of all dense submatrices $A(K, K)$ at stage s.

The VP ratio in matrix storage for the model problem is $O(\eta(L))/p = O(k^2 \log k/p)$, so the matrix storage time is $O(k^2 \log^2 k/p)$. Our pilot implementation uses the same size playing field at every stage. According to Table 2, a playing field of size $\lceil 25k^2 \rceil$ suffices if the problems can be packed in without too much loss. The VP ratio is $O(k^2/p)$. The sum over all stages of γ_s is $O(k)$ (in fact, it is $3k + O(1)$), so the playing field time is $O(k^3/p)$. In summary, the total running time of Grid Cholesky for the model problem is

$$O\left(\frac{k^2 \log^2 k}{p}\rho + \frac{k^3}{p}\sigma\right).$$

Two things are notable about this. First, the performance, or ratio of sequential arithmetic operations to time, is $O(p)$; the $\log k$ inefficiency of Router Cholesky has vanished. This is because the playing field, where the bulk of the computation is done, has a lower VP ratio than the matrix storage structure. Second, and much more important in practice, the router speed ρ appears only in the second-order term. This is because the playing field computations are done on dense matrices with more efficient grid communication. This means that the router time becomes less important as the problem size grows, whether or not the number of processors grows with the problem size.

One way of looking at this analysis is to think of increasing both problem size and machine size so that the VP ratio remains constant. Then the model problem requires $O(k)$ total parallel operations, but only $O(\log k)$ router operations. The analysis of the model problem carries through (with different constant factors) for any two-dimensional finite-element problem ordered by nested dissection; a similar analysis carries through for any three-dimensional finite-element problem. Thus Grid Cholesky is a "scalable" parallel algorithm.

4.5. Grid Cholesky performance: Experiments. Here we present experimental results from a fairly small model problem, the matrix arising from the five-point discretization of the Laplacian on a square 63 × 63 mesh, ordered by nested dissection. This matrix has n = 3,969 columns and 11,781 nonzeros (counting symmetric entries only once). The Cholesky factor has $\eta(L)$ = 86,408 nonzeros, a clique tree with $\hbar = 11$ stages of supernodes, and takes 3,589,202 arithmetic operations to compute.

The matrix storage VP set requires 128K VPs. The fixed-size playing field requires 256×512 VPs. The results quoted here are from 8,192 processors, with floating-point coprocessors, of the machine at NASA. Both VP sets therefore had a VP ratio of 16. (A larger problem would need a higher VP ratio in the matrix storage than in the playing field.)

We observed a running time of 6.13 seconds. Of this, 4.09 seconds was playing field time (3.12 for the scans, 0.15 for nearest-neighbor moves of one-bit tokens, and 0.82 for local computation). The other 2.04 seconds was matrix storage time, consisting mostly of the four scatters at each stage. Our analytic model predicts playing field time to be about $3k \cdot (2\sigma + 4)\phi\mu_{PF}$. This comes to 4.0 seconds, which is in agreement with the experiment. The model predicts matrix storage time of about $\hbar \cdot 4\rho\phi\mu_{MS}$. This comes to between 1.5 and 4.7 seconds, depending on which value we choose for ρ. In fact three-fourths of the router operations are scatters with no collisions, and the other one-fourth are scatter-with-add, typically with two to four collisions. The fit to the model is therefore quite close.

4.6. Remarks on Grid Cholesky. On this small example, Grid Cholesky is about 20 times as fast as Router Cholesky. It is, however, only running at 0.586 megaflops on 8K processors, which would scale to 4.68 megaflops on a full 64K machine. A larger problem would run somewhat faster, but it is clear that making Grid Cholesky attractive will require major improvements. Some of these were sketched in §4.2.1.

A first question is whether Grid Cholesky is a router-bound code, as Router Cholesky is. For the small sample problem, the relative times for router and nonrouter computations are as follows:

Moving data to the playing field: 12%.
Factoring on the playing field: 67%.
Moving Schur complements back to matrix storage: 21%.

Evidently, the Grid Cholesky code is not router bound for this problem. For larger (or structurally denser) problems this situation gets better still: for a machine of fixed size, the time spent using the router grows like $O(\log^2 k)$, while the time on the playing field grows like $O(k^3)$ for a $k \times k$ grid, as we showed above. If we solved the same problem on a full-sized 64K processor machine, the relative times would presumably be the same as above; but if we solved a problem 8 times as large, the operation count would increase by a factor of about 22 while the number of stages, and router operations, would increase only by a factor of about 1.3.

Next, we ask whether our use of the playing field is efficient or not. The number of parallel elimination steps on the playing field is given by

$$\sum_{s=1}^{\hbar} \gamma_s,$$

which is 177 for the example. On the playing field of 131,072 processors, this allows us to do 22.8×10^6 multiply-adds or 45.6×10^6 flops. The number of flops actually done is 3.69×10^6, so the processor utilization is 7.9 percent. There are several reasons for this loss of efficiency.

- The algorithm does both halves of the symmetric dense subproblems (factor of 2).

TABLE 3
Factors affecting efficiency of Grid Cholesky.

Impediment removed	Time	Mflops	Speedup
None	6.13	4.8	
Virtualization	0.60	49.	10.
Slow router	0.33	89.	1.8
Slow scans	0.065	450.	5.0
SIMD	0.021	1,400.	3.1
Paris	0.0042	7,000.	5.0

- The implementation uses the same playing field size at every level (factor of about 4/3).
- The architecture forces the dimensions of the playing field to be powers of two (factor of about 4/3).
- The playing field is not fully covered by active processors initially, and as the dense factorization progresses, processors in the supernodes fall idle (factor of about 7/2).

These effects account for a factor of roughly 12.4, which is consistent with our measured result; $1/.079 = 12.6$. In other words, every step must use all 131,072 virtual processors, but on average, we only have work for about 10,500 of them. Thus the Paris virtualization method costs us a factor of roughly $(131{,}072/10{,}500) = 12.5$.

A similar analysis shows that virtualization slows the use of the router by a factor of 7.6.

We summarize the reasons that our achieved performance is so far below the CM's peak as follows:

- Virtualization. We used 2^{17} virtual processors. On average, we make use of 10,500 on the playing field and 5,600 in matrix storage. In actuality, there are 256 physical (floating-point) processors in the machine we used.
- The slow router.
- Communication costs for scans on the playing field, using the built-in suboptimal algorithm.
- The SIMD restriction. This causes us to have to wait for the divides and multiplies. (Since there are very few active virtual processors during these tasks, most of this effect could also be removed by efficient virtualization.)
- The Paris instruction set, which makes reuse of data in registers impossible, thus exposing the low memory bandwidth of the CM.

Table 3 gives an upper bound on the improvement that removal of each of these impediments to performance would provide. In each case, we hypothesize an "ideal" machine in which the corresponding cost is completely removed. Thus for example, the statistics for the third row of the table are for a marvelous machine in which a router operation takes no time whatever.

Clearly, good efficiency is possible, even on an SIMD machine with a router. The chief problems are the Paris virtualization method; the lack of a fast broadcast in the grid; and the memory-to-memory instruction set. All of these are peculiarities of Paris on the CM-2; none is fundamental to SIMD, data parallel computing.

5. Conclusions. We have compared two highly parallel general-purpose sparse Cholesky factorization algorithms, implemented for a data parallel computer. The first, Router Cholesky, is concise and elegant and takes advantage of the parallelism present in the elimination tree, but because it pays little attention to the cost of communication it is not practical.

We therefore developed a parallel algorithm, Grid Cholesky, that does most of its work with grid communication on dense submatrices. Analysis shows that the requirement for expensive general-purpose communication grows only logarithmically with problem size; even for modest problems the code is not limited by the CM router. Experiment shows that Grid Cholesky is about 20 times as fast as Router Cholesky for a moderately small sample problem.

Our pilot implementation of Grid Cholesky is not fast enough to make the Connection Machine cost effective for solving generally structured sparse-matrix problems. We believe, however, that our experiments and analysis lead to the conclusion that a parallel supernodal, multifrontal algorithm can be made to perform efficiently on a highly parallel SIMD machine. We showed in detail that Grid Cholesky could run two to three orders of magnitude faster with improvements in the instruction set of the Connection Machine. These suggestions for improvement make the chasm separating the five-megaflop performance of our pilot implementation from the 27-gigaflop theoretical peak performance of a 64K processor CM yawn somewhat less dauntingly.

Most of these improvements are below the level of the Paris virtual processor abstraction, which is to say, below the level of the assembly-language architecture of the machine. Although TMC has recently released a low-level language called CMIS in which a user can program below the virtual-processor level, we believe that ultimately most of these optimizations should be applied by high-level language compilers. Future compilers for highly parallel machines, while they will support the data parallel virtual processor abstraction at the user's level, will generate code at a level below that abstraction.

Although Grid Cholesky is more complicated than Router Cholesky, we are still able to use the data parallel programming paradigm to express it in a straightforward way. The high-level scan and scatter-with-add communication primitives substantially simplified the programming. The simplicity of our codes speaks well for this data parallel programming model.

In summary, even though our pilot implementation is not fast, we are nonetheless encouraged about the Grid Cholesky algorithm, and about the potential of data parallel programming and highly parallel architectures for solving unstructured problems. We believe that future generations of highly parallel machines may allow efficient parallel programs for complex tasks to be written nearly as easily as sequential programs. To get to that point, there will have to be improvements in compilers, instruction sets, and router technology. Virtualization will have to be implemented without sacrificing efficiency.

We mention four avenues for further research. The first is scheduling the dense partial factorizations efficiently. The tree of supernodes identifies a precedence relationship among the various partial factorizations. Our simple approach of scheduling these one level at a time onto a fixed-size playing field is not the only possible one. There is, in general, no need to perform all the partial factorizations at a single level simultaneously. It should be possible to use more sophisticated heuristics to schedule these factorizations onto a playing field of varying VP ratio, or even (for the Connection Machine) onto a playing field considered as a mesh of individual vector floating-point chips. Some theoretical work has been done on scheduling "rectangular" tasks onto a square grid of processors efficiently [8]. Kratzer [22] has experimented with sparse QR factorization on the Connection Machine using a dataflow model to schedule individual row operations.

The second avenue is improving the time spent in the matrix storage VP set. Of course, as problems get larger, this time becomes a smaller fraction of the total. At present, matrix storage time is not very significant even for a small problem, but it will become more so as the playing field time is improved.

Third, we mention the possibility of an out-of-main-memory version of Grid Cholesky for very large problems. Here the clique tree would be used to schedule transfers of data between the high-speed parallel disk array connected to the CM and the processors themselves.

Fourth and finally, we mention the possibility of performing the combinatorial preliminaries to the numerical factorization in parallel. Our pilot implementation uses a sequentially generated ordering, symbolic factorization, and clique tree. We are currently designing data parallel algorithms to do these three steps [18].

We conclude by extracting one last moral from Grid Cholesky. We find it interesting and encouraging that the key idea of the algorithm, namely partitioning the matrix into dense submatrices in a systematic way, has also been used to make sparse Cholesky factorization more efficient on vector supercomputers [32], and even on workstations [29]. In the former case, the dense submatrices vectorize efficiently; in the latter, the dense submatrices are carefully blocked to minimize traffic between cache memory and main memory. We expect that more experience will show that many techniques for attaining efficiency on sequential machines with hierarchical storage will turn out to be useful for highly parallel machines.

PARALLEL BLOCK-PARTITIONING OF TRUNCATED NEWTON FOR NONLINEAR NETWORK OPTIMIZATION*

STAVROS A. ZENIOS† AND MUSTAFA Ç. PINAR‡

Abstract. Using the primal truncated Newton algorithm for the solution of nonlinear network optimization problems gives rise to very large and sparse systems of linear equations. These systems are solved iteratively with conjugate gradient methods. Using the structural characteristics of the network basis the system of equations is partitioned into independent blocks. Each can be solved in a fraction of the time required for the original equations and can also be solved in parallel.

Partitioning schemes are developed for both pure and generalized network problems. Empirical results using problems with up to 15,000 nodes and 37,588 arcs demonstrate the efficiency of the block-partitioning techniques, both for serial and parallel computing. Details of the parallel implementation on a shared-memory multiprocessor, the Alliant FX/4, are given together with computational results on a CRAY X–MP vector supercomputer.

Key words. nonlinear programming, network optimization, truncated Newton, parallel computing

1. Introduction. In this paper we consider linearly constrained nonlinear network (NLNW) programs of the form

$$\min_{x\in\Re^n} F(x) \tag{1}$$

$$\text{s.t. } Ax = b \tag{2}$$

$$l \le x \le u \tag{3}$$

where $F : \Re^n \longmapsto \Re$ is convex and twice continuously differentiable; A is an $m \times n$ node–arc incidence matrix; b, l and $u \in \Re^n$ are given vectors; and $x \in \Re^n$ is the vector of decision variables. The node–arc incidence matrix A specifies conservation of flow constraints (2) on some network $G = (N, E)$ with $|N| = m$ and $|E| = n$. It can be used to represent pure networks, in which case each column has two nonzero entries: a "+1" and a "−1." Generalized networks are also represented by matrices with two nonzero entries in each column: a "+1" and a real number that represents the arc multiplier. The structure of the constraint matrices of network problems is described in [13] and [17].

Nonlinear network problems appear in several applications in operations research, transportation, economics, finance, engineering design, and so on. These problems are usually characterized by their very large size. Several theoretical and numerical studies have developed algorithms and software for NLNW problems. As a result of their form, NLNW problems are some of the largest nonlinear optimization problems solved in practice today. A recent survey of models and methods for network optimization is given in [8].

One of the most efficient algorithms for solving large instances of NLNW programs is the primal truncated Newton algorithm (PTN) of Dembo and Steihaug [9], implemented within the active set framework of Murtagh and Saunders [15]. In this paper we develop techniques for partitioning Newton's equations, which comprise the primary computational step of PTN, into blocks of equations of reduced size. These blocks of equations can be solved in a fraction of the time required by the original system. (For example, solving k systems of size n/k requires $O(1/k^2)$ fewer operations than solving the original system of size n.) Furthermore, the blocks can be solved in parallel both on message-passing and shared-memory architectures. The block-partitioning techniques exploit the special structure of the basis of network problems. Hence they can be executed efficiently even for very large problems. The partitioning schemes for pure networks formalize and generalize the procedures designed by Rosenthal [18] and Escudero [10], [11] for the partitioning of replicated pure network problems. The technique used for partitioning generalized networks extends the scheme proposed in Clark and Meyer [4] for the solution of linear generalized networks to nonlinear problems. Some related work on the partitioning of Newton's algorithm for unconstrained optimization is given in [16].

This paper makes three contributions. First, it develops the block-partitioning methods based on the structure of the network basis. Second, it evaluates the efficacy of the block-partitioned algorithm for solving large-scale problems on both serial and parallel computers. Third, it compares the efficiency of these methods with more standard partitioning techniques that do not exploit the basis structure. As a by-product, this study compares two alternative methods for parallel computing within PTN: the block-partitioning developed here and the implementation of Zenios and Mulvey [20], which emphasizes parallel execution of the linear algebra operations within PTN.

Our notation is as follows: B^T denotes the transpose of matrix B; $B_{.t}$ and $B_{t.}$ denote the tth column and row, respectively, of B. With the tth variable x_t we associate the tuple (i,j) where i is the row with "+1" in the tth column of A, and j is the row with the arbitrary real value in the tth column of A. In network terminology, i and j are called the incident nodes of arc (i,j). We use $t \sim (i,j)$ to indicate this association.

The remainder of this paper is organized as follows: §2 reviews concepts from PTN and active set methods that are relevant to our work. Section 3 reveals the relation between the structure of Newton's equations and the basis of network models and develops the block-partitioning schemes. Section 4 discusses implementation issues and reports results from numerical experimentation on serial computers, a shared-memory multiprocessor, the Alliant FX/4, and a vector supercomputer, the CRAY X-MP/48. Concluding remarks are given in §5.

2. The truncated Newton algorithm and active sets.

The primal truncated Newton algorithm is a feasible direction method within an active set framework. We describe the algorithm in two steps: First, we give a model Newton's algorithm for unconstrained optimization problems. Second, we discuss the active set method, which reduces a constrained optimization problem into a sequence of (locally) unconstrained problems in lower dimension. There exists an extensive literature on both techniques. Our desktop reference is [12]. The development of active set methods for large-scale constrained optimization is given in [15]. The truncated Newton algorithm for unconstrained optimization is given in [9]. The combination of both techniques for pure network problems is given in [6], and for generalized networks in [1].

2.1. Model truncated Newton algorithm for unconstrained optimization.

Consider the unconstrained problem

$$\min_{x\in\Re^n} F(x), \tag{4}$$

where $F(x)$ has the same properties as in (1). The PTN algorithm starts from an arbitrary feasible point $x^0 \in \Re^n$ and generates a sequence $\{x^k\}$, $k = 1, 2, 3, \cdots$, such that

$$\lim_{k\to\infty} x_k = x^*,$$

where x^* belongs to the set of optimal solutions to (4) (i.e., $x^* \in X^* = \{x | F(x) \leq F(y), \forall\, y \in \Re^n\}$). The iterative step of the algorithm is the following:

$$x^{k+1} = x^k + \alpha^k p^k. \tag{5}$$

$\{p^k\}$ is a sequence of descent directions computed by solving the system of (Newton's) equations:

$$\nabla^2 F(x^k) p^k = -\nabla F(x^k) + \eta^k. \tag{6}$$

$\nabla^2 F(x^k)$ and $\nabla F(x^k)$ denote the Hessian matrix and gradient vector of $F(x)$ evaluated at point x^k. The sequence η^k is a measure of accuracy in solving (6). A scale-independent measure of the residual error is

$$r^k = \frac{\|\nabla^2 F(x^k) p^k + \nabla F(x^k)\|_2}{\|\nabla F(x^k)\|_2}. \tag{7}$$

The step direction is computed from (6) such that the condition $r^k \leq \eta^k$ is satisfied and the sequence $\{\eta^k\} \to 0$ as $k \to \infty$. $\{\alpha^k\}$ is a sequence of step sizes computed by solving

$$\alpha^k = \arg\min_{\alpha\in\Re_+} \{F(x^k + \alpha p^k)\} \tag{8}$$

(i.e., at iteration k the scalar α^k is the step size that minimizes the function $F(x)$ along the direction p^k starting from point x^k). Computing α^k from (8) corresponds to an exact minimization calculation that may be expensive for large-scale problems. It is possible to use an inexact line search. The global convergence of the algorithm is preserved if the step length computed by inexact solution of (8) produces a sufficient descent of $F(x)$, satisfying Goldstein–Armijo-type conditions.

2.2. Model active set algorithm for constrained optimization.

Consider now the transformation of (1)–(3) into a locally unconstrained problem. Following [15], we partition the matrix A into the form

$$A = [\,B \;\; S \;\; N\,]. \tag{9}$$

B is a nonsingular matrix of dimension $m \times m$ whose columns form a basis. S is a matrix of dimension $m \times r$ and N is a matrix of dimension $m \times (n - m - r)$. We also use $\mathcal{B}$, $\mathcal{S}$, and $\mathcal{N}$ to denote the sets of basic, superbasic, and nonbasic variables, respectively. Similarly, we partition x^k into

$$x^k = [\, x_B^k \;\; x_S^k \;\; x_N^k \,]. \tag{10}$$

$x_B^k \in \Re^m$ are the basic variables, $x_S^k \in \Re^r$ are the superbasic variables, and $x_N^k \in \Re^{n-m-r}$ denote nonbasic variables. Nonbasic variables, for a given partitioning (9)–(10), are kept fixed to one of their bounds. If we now partition the step direction p as

$$p^k = [\, p_B^k \;\; p_S^k \;\; p_N^k \,], \tag{11}$$

then we require $p_N^k \equiv 0$ (i.e., nonbasic variables remain fixed) and furthermore, p^k should belong to the nullspace of A (i.e., $Ap^k = 0$), so that p^k is a feasible direction. Hence p^k must satisfy

$$Bp_B^k + Sp_S^k = 0 \quad \text{or} \quad p_B^k = -(B^{-1}S)p_S^k. \tag{12}$$

If the superbasic variables are strictly between their bounds and the basis B is maximal as defined in [7] (i.e., a nonzero step in the basic variables x_B is possible for any choice of direction $(p_B^k \;\; p_S^k \;\; 0)$), then the problem is locally unconstrained with respect to the superbasic variables. Hence a descent direction for p_S^k can be obtained by solving the (projected) Newton's equations:

$$\left(Z^T\nabla^2 F(x^k)Z\right) p_S^k = -Z^T\nabla F(x^k) + \eta^k, \tag{13}$$

where Z is a basis for the nullspace of A defined as

$$Z = \begin{bmatrix} -B^{-1}S \\ I \\ 0 \end{bmatrix}. \tag{14}$$

The primary computational requirement of the algorithm is in solving the system of equations (13) of dimension $r \times r$. This system is solved using conjugate gradient with a preconditioner matrix equal to the inverse of the diagonal of the reduced Hessian matrix $Z^T\nabla^2 F(x^k)Z$. Calculation of p_B^k from (12) involves only a matrix–vector product and is an easy computation. The partitioning of the variables and the matrix A into basic, superbasic, and nonbasic elements is also, in general, very fast. For some of the bigger test problems the solution of system (13) takes as much as 99 percent of the overall solution time. For example, solving problem MULTH2 of Table 1 gives rise to a system of equations of dimension $22,588 \times 22,588$. In spite of its very large size, system (13) is usually very sparse. In §3 we look at its sparsity pattern, and determine ways to partition it into smaller systems that can be solved independently and also in parallel.

3. Block-partitioning of Newton's equations.

We return now to (13), and try to identify a partitioning of the matrix $\left(Z^T\nabla^2 F(x^k)Z\right)$. Recall that

$$Z = \begin{bmatrix} -B^{-1}S \\ I \\ 0 \end{bmatrix}, \tag{15}$$

and assume that the function $F(x) = \sum_{t=1}^n F_t(x_t)$ is separable so that the Hessian matrix is diagonal. (This assumption is relaxed in §3.4.) If we momentarily ignore the dense submatrix $(B^{-1}S)$ and assume that

$$Z \doteq \hat{Z} = \begin{bmatrix} I \\ 0 \end{bmatrix} \tag{16}$$

(the identity I and null matrix 0 chosen such that Z is conformable to $\nabla^2 F(x^k)$), then the product $\hat{Z}^T \nabla^2 F(x^k) \hat{Z}$ is a matrix of the form H_I where H_I is a diagonal matrix with the tth diagonal element given by

$$\frac{\partial^2 F_t(x_t^k)}{\partial x_t^2}.$$

Hence the complication in partitioning (13) is the presence of the submatrix $(B^{-1}S)$. The structure of this submatrix is examined next.

3.1. The structure of $(B^{-1}S)$. The matrix B is a basis for the network flows of problem (1)–(3). It is well known (see, e.g., [5] or [13]) that the basis of a pure network problem is a lower triangular matrix. The graph associated with this basis matrix is a rooted tree. The basis of a generalized network is characterized by the following theorem (see, e.g., [5, p. 421]).

THEOREM 3.1. *Any basis B of a generalized network problem can be put in the form*

$$B = \begin{bmatrix} B^1 & & & & & \\ & B^2 & & & & \\ & & \cdot & & & \\ & & & B^\ell & & \\ & & & & \cdot & \\ & & & & & B^L \end{bmatrix},$$

where each square submatrix B^ℓ is lower triangular with at most one element above the diagonal.

The graph associated with each submatrix B^ℓ is a tree with one additional arc, making it either a rooted tree or a tree with exactly one cycle, and is called a quasi tree (abbreviated: q-tree). The graph associated with a generalized network basis is a forest of q-trees.

To describe the structure of $(B^{-1}S)$ we first define the *basic equivalent path* (BEP) for a superbasic variable x_t with incident nodes (i, j). For pure network problems, it is the set of arcs on the basis tree that lead from node j to node i. The BEP together with arc $t \sim (i, j)$ creates a loop.

In the case of a generalized network, it is the set of arcs that lead from nodes i and j to a cycle; the BEP includes all arcs on the cycle. The tth column of $(B^{-1}S)$ has nonzero entries corresponding to the BEP of the tth superbasic variable. The numerical values of $(B^{-1}S)$ are ±1 for pure network problems and arbitrary real numbers for generalized networks; the numerical values are of no consequence to our development. To illustrate the preceding discussion, Fig. 1 shows the basis of a pure network problem together with the BEP for a superbasic arc and the corresponding column of $(B^{-1}S)$. Figure 2 illustrates the same definitions for generalized network problems.

The matrix $(B^{-1}S)$ can be partitioned into submatrices with nonoverlapping rows if the columns of each submatrix have a BEP with no basic arcs in common with the columns of any other submatrix.

3.2. Partitioning of $(B^{-1}S)$ for pure networks. Let β_t denote an ordered set of binary indices such that $(\beta_t)_l = 1$ if the lth arc $(i,j) \in \mathcal{B}$ is in the BEP of the tth arc $(i',j') \in \mathcal{S}$, and $(\beta_t)_l = 0$ otherwise. We seek a partitioning of the set $\mathcal{S}$ into K disjoint independent subsets, say $\mathcal{S}^k$, $k \in \mathcal{K} = \{1,2,\cdots,K\}$ such that

$$\mathcal{S} = \bigcup_{k=1}^{K} \mathcal{S}^k \tag{17}$$

and

$$t,u \in \mathcal{S}^k \quad \text{if} \quad \beta_t \vee \beta_u \neq 0 \quad \forall\, k \in \mathcal{K} \tag{18}$$

(i.e., superbasic arcs t and u belong to the same subset, say $\mathcal{S}^k$, if the sets β_t and β_u have at least one overlapping nonzero element, and hence there is at least one common basic arc in the BEPs of the tth and uth superbasic arcs, respectively. Otherwise, t and u belong to two distinct subsets).

Escudero [11] was the first to propose the partitioning of $\mathcal{S}$ into independent superbasic subsets $\mathcal{S}^k$ according to (17)–(18), for replicated pure networks. These replicated networks consist of subnetworks with identical structure and are connected by linking arcs. (These linking arcs represent inventory flow for his problems that are multiperiod networks.) In the same reference Escudero gives a procedure for identifying the independent superbasic sets $\mathcal{S}^k$.

In this section we formulate the problem of identifying independent superbasic sets as problems from graph theory. Define the graph $G_{\mathcal{S}} = \{\mathcal{V}, \mathcal{E}_{\mathcal{S}}\}$ where the node and edge sets are defined as $\mathcal{V} = \{1,2,3,\cdots,|\mathcal{S}|\}$ and $\mathcal{E}_{\mathcal{S}} = \{(t,u) | t,u \in \mathcal{V}, \beta_t \vee \beta_u \neq 0\}$. A node is associated with each superbasic variable $t \in \mathcal{S}$, and an edge is incident to two nodes if and only if the BEP of the corresponding superbasic variables overlap. We call $G_{\mathcal{S}}$ the *connectivity graph* of the superbasic set $\mathcal{S}$. It can be constructed as the adjacency graph of the matrix $Z^T Z$.

The first partitioning scheme simply formalizes Escudero's procedures.

Partitioning Scheme I. Find the connected components of $G_{\mathcal{S}}$, say $\mathcal{V}^k \subseteq \mathcal{V}$, $k = 1,2,\cdots,K$. Then $\mathcal{S}^k = \{t | t \in \mathcal{V}^k\}$ will satisfy conditions (17)–(18), by definition of connected components, and hence $\mathcal{S}^k$, $k = 1,2,\cdots,K$ are independent superbasic sets. Finding connected components of $G_{\mathcal{S}}$ can be achieved with the algorithm of Tarjan [19]. Unfortunately it is not always possible to find more than one connected component of $G_{\mathcal{S}}$. For the case of replicated networks such a partitioning usually exists since the interaction among superbasics in different subnetworks is weak. This explains the success of Escudero's method for the multiperiod networks. The second partitioning scheme we propose here allows us to partition the superbasic set $\mathcal{S}$ for a broader class of problems.

Partitioning Scheme II. Find the articulation points of $G_{\mathcal{S}}$. Let $\mathcal{C} \subset \mathcal{V}$ be the set of articulation points and $\mathcal{S}_{\mathcal{C}}$ the set of superbasic variables corresponding to the set $\mathcal{C}$. Update the set of superbasic variables by $\mathcal{S}' = \mathcal{S} \setminus \mathcal{C}$ and let $\mathcal{N} = \mathcal{N} \cup \mathcal{C}$. The new superbasic set $\mathcal{S}'$ now consists of at least $|\mathcal{C}|$ independent subsets. The fact that identifying articulation points leads to partitioning of the superbasic sets can easily be seen by the definition of articulation points (see, e.g., [2]). An algorithm with linear time and space complexity for finding articulation points of a graph is given in [19], and was used in our implementation of this partitioning scheme. The variables in the set $\mathcal{S}_{\mathcal{C}}$ that have been eliminated from the superbasic set are kept fixed at their current value. The new superbasic set $\mathcal{S}'$, which leads to a block-diagonal form for the projected Hessian matrix, can be used to compute a preconditioner for the reduced Hessian matrix of the original superbasic set $\mathcal{S}$. An alternative approach, which has been followed in our implementation, is to optimize the objective function over the superbasic set $\mathcal{S}'$ while the variables in $\mathcal{S}_C$ remain nonbasic. Of course, the elements of $\mathcal{S}_C$ may change for different major iterations. However, this scheme is not guaranteed to produce an optimal solution since some eligible superbasic variables (i.e., those in $\mathcal{S}_C$) are kept fixed. Once the block-partitioned algorithm terminates, we start a new major iteration without using the block-partitioning scheme. Hence the algorithm reverts to the original PTN. We observed that, for our test problems, one major iteration without block-partitioning would suffice. Furthermore, the objective value was only improved by less than 0.5 percent when the last, non-block-partitioned major iteration was completed. (See also the discussion in §4.3.) In essence, the block-partitioned truncated Newton algorithm is used to compute an approximate solution. Higher accuracy can then be achieved by applying the original truncated Newton algorithm directly.

3.3. Partitioning of $(B^{-1}S)$ for generalized networks. The graph-partitioning schemes discussed in §3.2 for pure network problems can also be applied in the case of generalized networks. We refer to these procedures as scheme GN-I (for generalized networks-I). Here we develop alternative techniques to partition the superbasic set of generalized network problems that take advantage of the block structure of the generalized network basis.

In §3.1 we observed that the graph associated with the basis of a generalized network problem is a collection of quasi trees. Suppose the basis matrix B consists of submatrices B^ℓ, $\ell = 1, \cdots, L$. We denote the graph (q-tree) associated with B^ℓ by $G_\ell = (N_\ell, E_\ell)$. The superbasic set $\mathcal{S}$ can be partitioned into subsets $\mathcal{S}^\ell$ defined by

$$\mathcal{S}^\ell = \{(i,j) \in \mathcal{S} | i,j \in N_\ell\} \quad \forall\, \ell = 1, 2, \cdots, L, \tag{19}$$

with $\cup_{\ell=1}^{L} \mathcal{S}^\ell \subseteq \mathcal{S}$. This partitioning scheme will ignore any superbasic variables that connect basis submatrices. A partitioning scheme that includes additional superbasic variables is the following: Given indices k, $p(k) \leq L$ and $q(k) \leq L$, $p(k) \neq q(k)$, choose $B^{p(k)}$ and $B^{q(k)}$ and define

$$\mathcal{S}^{p(k)q(k)} = \{(i,j) \in \mathcal{S} | i \in N_{p(k)}, j \in N_{q(k)}\}, \tag{20}$$

$$\mathcal{S}^{p(k)} = \{(i,j) \in \mathcal{S} | i,j \in N_{p(k)}\}, \tag{21}$$

$$\mathcal{S}^{q(k)} = \{(i,j) \in \mathcal{S} | i,j \in N_{q(k)}\}, \tag{22}$$

and finally, $\mathcal{S}^k = \mathcal{S}^{p(k)q(k)} \cup \mathcal{S}^{p(k)} \cup \mathcal{S}^{q(k)}$. To ensure that two sets $\mathcal{S}^{k_1}, \mathcal{S}^{k_2}$ are independent we require that

$$B^{p(k_1)} \neq B^{p(k_2)} \neq B^{q(k_2)}, \qquad B^{q(k_1)} \neq B^{p(k_2)} \neq B^{q(k_2)}.$$

We now describe a procedure to identify these independent subsets $\mathcal{S}^k$ of superbasic arcs. The procedure works as follows: at each iteration, a pair of basis subgraphs connected with the largest number of superbasic arcs is identified; these superbasic arcs, together with the superbasic arcs that connect nodes in each subgraph, form a subset $\mathcal{S}^k$. To ensure the independence of the subsets thus formed, the basis subgraphs used in constructing the subsets are marked and not considered in subsequent iterations. A complete description of the procedure is given below.

```
$\mathcal{U} = \{1, 2, \cdots, L\}$; $k = 0$; $scount = 0$; $\rho \in [0.5, 1)$.
Repeat until $scount \geq \rho|\mathcal{S}|$ or $|\mathcal{U}| \leq 1$.
    1. $k = k + 1$.
    2. Find $r(k)$ and $s(k)$ such that $r(k) \neq s(k)$ and $|\mathcal{S}^{r(k)s(k)}| = \max_{p,q \in \mathcal{U}} |\mathcal{S}^{pq}|$.
    3. $scount = scount + |\mathcal{S}^{r(k)s(k)}| + |\mathcal{S}^{r(k)}| + |\mathcal{S}^{s(k)}|$.
    4. $\mathcal{S}^k = \mathcal{S}^{r(k)s(k)} \cup \mathcal{S}^{r(k)} \cup \mathcal{S}^{s(k)}$.
    5. $\mathcal{U} = \mathcal{U} \setminus \{r(k), s(k)\}$.
```

We refer to the procedure described above as partitioning scheme GN-II. We note that scheme GN-II may place some candidate superbasic arcs into the nonbasic set when creating the independent subsets $\mathcal{S}^k$. It is also advisable to choose ρ as close to 1 as possible. Some preliminary experimentation is needed to find a suitable value of ρ. We also remark that alternative procedures that take into account the interaction of more than two basis subgraphs can be designed. However, this scheme achieved a satisfactory partitioning of the superbasic set with the generalized networks problems used in this study.

To illustrate the partitioning procedure on the basis illustrated in Fig. 2, let us assume that the superbasic set is as follows:

$$\begin{aligned}\mathcal{S} = \{&(6,11), (3,8), (9,14), (14,17), (13,19), (7,19),\\ &(1,18), (16,20), (18,20), (14,16), (17,20)\}.\end{aligned}$$

Scheme GN-II will identify

$$\mathcal{S}^1 = \{(1,18), (7,19), (13,19), (6,11), (3,8)\}$$

and

$$\mathcal{S}^2 = \{(14,17), (14,16), (16,20), (17,20)\}.$$

In this example, superbasic arcs $(9,14), (16,20)$ are placed into the nonbasic set to ensure independence of $\mathcal{S}^1$ and $\mathcal{S}^2$.

3.4. Extensions to nonseparable problems. We can develop a partitioning of the system $\left(Z^T \nabla^2 F(x) Z\right)$ for the case when the function $F(x)$ is nonseparable. In this case the Hessian matrix is not diagonal. The partitioning condition (18) from §3.2 has to be modified as follows. Let $t, u \in \mathcal{S}$. Then

$$t \in \mathcal{S}^{k_1} \quad \text{and} \quad u \in \mathcal{S}^{k_2} \quad \text{iff} \quad \beta_t \vee \beta_u = 0 \quad \text{and} \quad \frac{\partial^2 F(x)}{\partial x_t x_u} = 0. \tag{23}$$

The connectivity graph associated with the superbasic set $\mathcal{S}$ is now defined as the graph $G_{\mathcal{S}} = \{\mathcal{V}, \mathcal{E}_{\mathcal{S}}\}$ where $\mathcal{V} = \{1, 2, 3, \cdots, |\mathcal{S}|\}$, as in §3.2, and

$$\mathcal{E}_{\mathcal{S}} = \left\{(t,u) |\, t, u \in \mathcal{V},\ \beta_t \vee \beta_u \neq 0 \text{ and } \frac{\partial^2 F(x)}{\partial x_t x_u} \neq 0\right\}$$

(i.e., an edge is incident to two nodes if and only if the BEP of the corresponding superbasics overlap and changes in the value of one variable, x_t, change the objective value for the second, x_u). The connectivity graph can be obtained from the adjacency graph of $(Z^T\nabla^2F(x)Z)$. With this definition of connectivity graph, we can now apply either partitioning scheme from §3.2. Similarly, we can extend the partitioning technique of §3.3 to handle nonseparable generalized network problems as well.

4. Computational experiments.

The partitioning techniques discussed earlier were implemented in the network optimizer GENOS of Mulvey and Zenios [14].[1] The modified code, which we call GENOS/PCG, was used to solve a collection of nonlinear problems, both pure and generalized. (PCG stands for partitioned conjugate gradient, since GENOS is using conjugate gradient to solve the partitioned systems of Newton's equations.) The objective of the numerical experiments is to establish the performance of PTN when Newton's equations are solved in block-partitioned form. Furthermore, we solved the test problems on a shared-memory vector multiprocessor to study the performance of the block-partitioned PTN with parallel computing. Finally, we compare the performance of the parallel implementation of GENOS/PCG to an alternative parallel implementation proposed by Zenios and Mulvey [20].

GENOS and the modifications in GENOS/PCG are written in Fortran 77. Experiments on serial computer were carried out on a VAX 8700 at the Wharton School, running VMS. The programs were compiled with the default compiler optimization option. Parallel computing experiments were carried out on an Alliant FX/4 of the HERMES Laboratory for Financial Modeling and Simulation at the Wharton School, running Ultrix. The level of optimization used was at least $-Og$ (i.e., global scalar optimizations). The flag $-O$ was used for experiments using the vector and parallel features of the Alliant. All times are reported in CPU seconds, exclusive of input and output. The termination tolerance η^k is adjusted dynamically using a forcing sequence; its final value is 10^{-2}.

4.1. Test problems.

The characteristics of the test problems are summarized in Table 1. In addition to the size of the problems, we give the number of superbasic arcs at optimality; this is the dimension of the system of equations we had to solve at the last iteration of the algorithm. The MULTxn problems were generated by the network problem generator of Chang and Engquist [3]. They are multiperiod networks: a basic generalized network structure is replicated for several time periods and inventory-type links connect the replicated components. All problems have a quadratic objective function of the form $\sum_t a_t x_t^2$ with $a_t \in [1, 100]$. The number at the end of each problem name indicates the number of replications. For example, MULTC2 is a two-period model; each single period network has 1000 nodes. MULTC8 is an eight-period model with a total of 8000 nodes. The STICKn and PTNn problems were obtained from [1].

4.2. Solving pure network problems.

We implemented both Partitioning Schemes I and II, discussed in §3.2. First, we must construct the connectivity graph G_S. This is the adjacency graph of the matrix Z^TZ. Due to the large size of the matrix Z, it is more efficient to construct the connectivity graph G_S based on the structural nonzeros of Z than to form the product Z^TZ. For example, finding the adjacency

[1] GENOS is a library of algorithms for solving network problems. It includes network simplex, primal truncated Newton, and simplicial decomposition. The partitioning techniques were implemented within the primal truncated Newton solver. Details on the implementation of this solver within GENOS using sparse graph data structures are given in [1].

TABLE 1

graph of $Z^T Z$ takes 21.6 seconds for PTN660 and 18.5 seconds for STICK1. Working on the matrix Z instead, the same graphs are constructed in 4.1 and 0.8 seconds, respectively. The most efficient implementation was adopted in all experiments.

Partitioning Scheme I was implemented using an algorithm for connected components due to Tarjan [19]. For the test problems we have available, the connectivity graphs G_S are very dense and in all cases there is only one connected component.

Partitioning Scheme II was implemented using an articulation point algorithm due to Tarjan [19]. This algorithm was then applied to the connectivity graph of the superbasic set for the pure network problems STICK1–4 and PTN150–660 at each major iteration of GENOS/PCG. The results are summarized in Table 2. Under the column "Size of components" we do not list the (usually large) number of components corresponding to a single superbasic variable. The difference between the size of the subspace and the total of the sizes of the disconnected components is the number of single-variable sets. We give the total CPU seconds spent in the graph-partitioning procedure during the execution of the primal truncated Newton algorithm under the heading "Partition. time."

We observe from the table that these test problems do not produce independent superbasic sets of (approximately) equal sizes. The largest independent set dominates the computations, and solution time for the block–partitioned Newton's equations is only marginally better than the solution time required in solving the equations over the original subspace. In addition some overhead is incurred in creating the connectivity graph and the subsequent partitioning. The connectivity graph of the superbasic sets tend to be dense, and hence very large. For example, the connectivity graph for the superbasic set of PTN660 has 236 nodes and 5768 arcs. The articulation point algorithm identified four articulation points in 0.1 seconds. However, creating the connectivity graph from the matrix $(B^{-1}S)$ takes 0.48 seconds.

We conclude that for pure network problems the block-partitioning techniques

TABLE 2

do not offer any computational savings. However, for problems that have additional structures, such as Escudero's multiperiod networks, the partitioning could be very effective. Nevertheless, since an attempt to partition the network can be executed very efficiently, it is included as an optional preprocessing phase in GENOS/PCG.

4.3. Solving generalized network problems. We implemented both partitioning schemes GN-I and GN-II. We observed that the scheme GN-II based on the structure of the basis graph is more efficient and produces better partitioning of the superbasic set $\mathcal{S}$. For example, problem MULTA4 is solved by GENOS in 40 seconds without partitioning. Using partitioning scheme GN-I takes 54 seconds, whereas with partitioning scheme GN-II the problem is solved in 15 seconds. We adopted the scheme GN-II in solving all the test problems, as shown in Table 3 together with the results from GENOS[2]. The speedup factor indicates the ratio of total solution times of GENOS by that of GENOS/PCG. For smaller problems where the network basis does not partition evenly, the savings are reduced due to overhead in creating the subspaces. Improvements in performance increase with the problem size. We observe an improvement in performance by a factor of 1.20 to 5.25.

One final observation on these experiments: We noted earlier that with the partitioning procedure described in §3.3 some superbasic arcs may be placed in the nonbasic set in order to achieve independence of the blocks. This usually affects the accuracy of the solution. However, as the optimality tolerance is sufficiently decreased, one iteration without partitioning the superbasic set is sufficient to achieve high accuracy. But this step is computationally expensive, particularly for larger problems. Ignoring

[2] **PTN** indicates the overhead in forming the network basis and other initializations, **SB** stands for subspace selection, i.e., the selection of the superbasic variables. This is the step where partitioning scheme GN-II is incorporated into the program. **CG** and **LS** stand for the conjugate gradient and linesearch procedures, respectively.

TABLE 3
Solution times with GENOS *and* GENOS/PCG *on the* VAX 8700.

this step results in significant savings in performance. The objective value at termination in this case is within 0.5 percent of the objective value given by GENOS. This observation is illustrated in Fig. 3. In all experiments the last step is performed and hence the problem is solved to optimality.

4.3.1. Parallel implementation.

Solving Newton's equations. First we tested the parallel implementation of GENOS/PCG in solving the set of blocks in a particular instance of Newton's equation. Using problem MULTB12, we isolated one block of dimension 750 × 750, replicated it 20 times, and solved it in parallel (i.e., we assumed that the system of equations in the case of MULTB12 would partition into 20 blocks of equal size. This would be the ideal situation.). Figure 4 shows the solution time when solving this set of 20 blocks using 1–4 processors. Significant speedup factors are observed when using parallel processors ranging from 1.6 on two computational elements (CE) to 3.4 on four. The speedup is not perfect due to the overhead incurred in concurrent subroutine calls. In Fig. 4 we also show the solution times when solving the actual set of 20 blocks, with dimensions ranging from 10 × 10 to 900 × 900. While we still observe significant speedup between the serial and parallel implementation, the speedup factors are lower than those observed in the previous experiment. The difference is attributed to the uneven load balancing among processors that is due to the varying sizes of the blocks.

The linesearch procedure. Parallel CEs were also used in the line search procedure of GENOS/PCG. The line search routine of GENOS (see [1]) is a quadratic interpolation with safeguards. At every iteration of the linesearch algorithm the function value, gradient vector, and Hessian matrix are evaluated for all the arcs. In GENOS/PCG we need only to evaluate this information for those basic and superbasic variables that appear in the current block. Furthermore, multiple processors can compute in parallel the required information for multiple arcs in the block. Figure 5 illustrates the speedup factor of both the routine that provides function, gradient, and Hessian values, as well as the speedup of the overall line search procedure.

4.3.2. Comparing GENOS with Parallel GENOS/PCG. As a concluding test on the Alliant, we run GENOS on one CE of the Alliant with the fully parallelized GENOS/PCG running on four CEs. The observed speedup factor for some of the bigger problems is shown in Table 4. The speedup factor in most cases exceeds four, which is the number of parallel CEs used. This is due to the combined effect of solving a sequence of smaller problems and the effect of multiprocessing. These two effects were analyzed separately in the results of Table 3 and in §4.3.1, respectively.

4.4. Comparison with alternative parallel implementations. In [20] we proposed an alternative parallel implementation of PTN based on the row-wise dis-

TABLE 5
Comparison of alternative parallel implementation methods.

Problem structure		Tightly coupled multiprocessor	Loosely coupled multiprocessor
Networks	Partitioning		
Pure	Poor	MPTN	MPTN
	Good	MPTN	BPTN
Generalized		MPTN	BPTN

tribution of the nullspace matrix among processors. This implementation produced significant speedups when implemented on the CRAY X–MP. We tested the same implementation on the Alliant FX/4. Hence we now have two alternative parallel implementations on two different architectures and can draw some conclusions on the relative merits of the two methods. Table 5 indicates which method should be preferred for different problem structures and computer systems (MPTN indicates the microtasked implementation of Zenios and Mulvey, BPTN indicates the block-partitioned methods developed here).

The advantage of MPTN is that its implementation does not require any additional computing, and it results in even load balancing among processors. The disadvantage is that the granularity of the parallel tasks is very small; the overhead in spawning tasks on some computers could be significant compared to the amount of computation performed by the task.

The advantage of BPTN is that it produces tasks of large granularity. The disadvantage is that it may produce uneven load balancing among processors. Furthermore, BPTN needs to execute the partitioning algorithms and this overhead can add significantly to the total solution time.

Hence for tightly coupled systems where the overhead of spawning a task is only a few machine cycles, as in the case of CRAY X–MP, MPTN should be preferred. From Fig. 6 we observed that MPTN achieves a speedup of 2.6 on three CPUs for both pure and generalized networks. BPTN does not achieve any speedups for the pure network test problems and a speedup of 1.41 is achieved for generalized networks.

For more loosely coupled systems, which may also include distributed-memory architectures, the BPTN is preferred unless the problems do not partition well. For example, MPTN achieves a speedup of 1.75 on a four-processor Alliant FX/4. BPTN achieves a speedup of 2.21 on the same system for generalized network problems that partition well.

4.5. Solving the test problems on a CRAY X–MP/48. Although we were able to achieve significant improvements both on sequential and parallel implementations, we observed that solving the multiperiod problems was still taking a considerable amount of time. As a final test, we conducted some experiments on the CRAY X–MP/48 to test the effectiveness of the partitioning schemes on a different parallel architecture. The results are summarized in Table 6. The tests were conducted with the default vector option of the CRAY FORTRAN compiler. The results are stated in CPU seconds. The last column gives the ratio of GENOS/PCG solution times on the CRAY to GENOS solution time on the VAX. As can be observed from the table, significant gains in computing resources were possible with a vector supercomputer like the CRAY X–MP/48.

5. Concluding observations. We developed here techniques for partitioning Newton's equations in the context of solving nonlinear network problems. The techniques appear to be quite effective and efficient for generalized network problems and are also well suited for parallel computations. In Fig. 7 we use our generalized network problems to illustrate the combined effect of both the partitioning schemes and the computer architecture. As observed in the figure, the reduction in the solution time increases as the problem size gets larger. The partitioning techniques can also be applied efficiently for pure network problems. However, our current collection of pure network test problems does not partition well. Our study also provides guidelines on

choosing between two alternative parallel implementations depending on characteristics of the problem and the parallel computing platform.

NEW BRANCH-AND-BOUND RULES FOR LINEAR BILEVEL PROGRAMMING*

PIERRE HANSEN†, BRIGITTE JAUMARD‡, AND GILLES SAVARD§

Abstract. A new branch-and-bound algorithm for linear bilevel programming is proposed. Necessary optimality conditions expressed in terms of tightness of the follower's constraints are used to fathom or simplify subproblems, branch and obtain penalties similar to those used in mixed-integer programming. Computational results are reported and compare favorably to those of previous methods. Problems with up to 150 constraints, 250 variables controlled by the leader, and 150 variables controlled by the follower have been solved.

Key words. bilevel programming, Stackelberg game, variable elimination, branch and bound

AMS(MOS) subject classifications. 90C27, 90D05

1. Introduction. In many situations, multiple decision makers with divergent objectives intervene in the decisions to be made (Wendell [38]). The simplest such case, in which there are only two decision makers, has long been studied in game theory. If there is some asymmetry between the decision makers in that one of them, called the *leader*, makes his decisions first, anticipating the reaction of the other one, called the *follower*, and cooperation is ruled out a priori, one has a Stackelberg game. Adding joint constraints on the strategies of the leader and the follower makes the model more realistic. This leads to *bilevel programming*, a topic which has attracted much attention recently, mostly in the linear case (see Fortuny-Amat and McCarl [19]; Candler and Townsley [16]; Papavassilopoulos [34]; Bard [5]; Bialas and Karwan [10], [11]; Ünlü [37]; Dempe [17]; Bard and Moore [9]; Judice and Faustino [27], [28]; Ben-Ayed and Blair [12]; Haurie, Savard, and White [24]; Anandalingam and White [4]). The nonlinear case and extensions to three or more levels are treated in a few papers (e.g., Aiyoshi and Shimizu [1], [2]; Bard [6], [7]; Bard and Falk [8]; Bard and Moore [9]; Al-Khayyal, Horst, and Pardalos [3]). Related bilevel and multilevel decision models and algorithms have also been extensively studied in control theory.

Applications of bilevel programming have been made in many domains; these include economic development policy (Candler and Norton [15]), agricultural economics (Candler, Fortuny-Amat, and McCarl [14]), road network design (Marcotte [30], Leblanc and Boyce [29]), and cogeneration of electrical energy (Savard [35], Haurie, Loulou, and Savard [23]). Mathematical programs with optimization problems in the constraints (e.g., Bracken and McGill [13]), arising in weapons allocation problems, can also be viewed as (nonlinear) bilevel programs.

The paper is organized as follows. In §2, the linear bilevel programming problem is stated mathematically. It is shown to be strongly NP-hard in §3. Our algorithm is

stated in §4 and illustrated in an example in §5. Computational experience is reported in §6.

2. Formulation. The linear bilevel program (LBP) may be written in the following general form:

$$\text{(1)} \qquad \underset{x}{\text{maximize}} \quad z_1(x, y(x)) = c^1x + d^1y(x)$$

subject to:

$$\text{(2)} \qquad A^1x + B^1y(x) \leq b^1,$$

$$\text{(3)} \qquad x \geq 0;$$

$$\text{(4)} \qquad \underset{y}{\text{maximize}} \quad z_2(x, y) = c^2x + d^2y,$$

subject to:

$$\text{(5)} \qquad A^2x + B^2y \leq b^2,$$

$$\text{(6)} \qquad y \geq 0,$$

where

$$\begin{array}{ccc} c^{1T}, c^{2T}, x \in \mathbb{R}^{n_1}; & d^{1T}, d^{2T}, y \in \mathbb{R}^{n_2}; & A^1 \in \mathbb{R}^{m_1} \times \mathbb{R}^{n_1}; \\ A^2 \in \mathbb{R}^{m_2} \times \mathbb{R}^{n_1}; & B^1 \in \mathbb{R}^{m_1} \times \mathbb{R}^{n_2}; & B^2 \in \mathbb{R}^{m_2} \times \mathbb{R}^{n_2}; \\ b^1 \in \mathbb{R}^{m_1}; & b^2 \in \mathbb{R}^{m_2}. & \end{array}$$

For simplicity, we assume the polyhedra defined by (3), (5), and (6) and by (2), (3), (5), and (6) to be nonempty and bounded. The constraints on $y(x)$ implicitly defined by (4)–(6) can be represented as

$$\text{(7)} \qquad y(x) \in \arg\max\{z_2(x, y) \, ; \, y \in \Omega^2(x)\},$$

where

$$\text{(8)} \qquad \Omega^2(x) = \{y \, : \, B^2y \leq b^2 - A^2x, y \geq 0\}.$$

A solution $(x, y(x))$ such that $y(x)$ satisfies (7) and (8) is called *rational.* The set of rational solutions of LBP is, in general, not convex and, in the presence of first-level constraints (2), may be empty (in which case LBP has no solution). If the set of rational solutions is nonempty, at least one optimal solution of LBP is obtained at an extreme point of the polytope defined by (2), (3), (5), and (6). This important property was proven by Candler and Townsley [16], Bialas and Karwan [10], and Bard [5]. (Their proofs are for the case in which there are no first-level constraints (2), but readily extend to the case where such constraints are present.)

The leader controls the variables of x, and the follower, those of y, which are chosen after those of x; i.e., by solving the follower's subproblem (4)–(6). The model (1)–(6), due to Aiyoshi and Shimizu [1], contains first-level constraints that are binding only for the leader but depend also on the decisions of the follower. Such constraints arise, for instance, when the leader, a central agency, decides upon public investments and has to bear the cost of their maintenance, which depends on the level of use, decided upon by the follower, i.e., the users. Another instance is the problem of cogeneration of electricity by the leader, a central agency, and by the follower, i.e., independent firms (Savard [35], Haurie, Loulou, and Savard [23]). Electricity produced by the latter is bought at marginal cost. If the constraint on demand satisfaction is introduced at the second level, the optimal decision of the central agency is to produce no electricity at all, which is clearly unrealistic. Introducing the demand constraint at the first level requires the leader to produce a sufficient amount of electricity for the remaining demand to be satisfied through voluntary decisions of the follower.

Some recent algorithms for LBP, e.g., those of Bard and Moore [9], which do not allow for y variables in the first-level constraints, can easily be modified to handle them (see §6).

Algorithms for linear bilevel programming may be grouped as follows:

(i) Branch-and-bound algorithms, in which branching is done on complementarity conditions (Fortuny-Amat and McCarl [19], Bard and Falk [8], Bard and Moore [9]).

(ii) Extreme point-ranking methods (Papavassilopoulos [34], Bialas and Karwan [11]).

(iii) Algorithms based on finding efficient solutions for the leader's and follower's objective functions (Bard [5], Ünlü [37]). These algorithms should be viewed as heuristics, as the set of efficient solutions may contain no optimal solution (see, e.g., Haurie, Savard, and White [24]).

(iv) Algorithms using complementary pivoting (Candler and Townsley [16]; Bialas and Karwan [11]; Judice and Faustino [27], [28]). The algorithm of Bialas and Karwan [11] does not always provide an optimal solution, as shown in Judice and Faustino [27]; the latter authors' parametric method provides an ε-optimal solution for any given ε.

(v) Penalty function methods (Dempe [17], Anandalingam and White [4]).

(vi) Reverse convex programming (Al-Khayyal, Horst, and Pardalos [3]).

The best computational results to date appear to be those of Bard and Moore [9] and of Judice and Faustino [27], [28].

In this paper we propose a new algorithm of class (i). It exploits necessary conditions for subsets of the follower's constraints to contain at least one constraint that is tight at the optimum. These conditions are new in linear bilevel programming, although similar ones have been used in global optimization in design. They allow fathoming of subproblems for which they cannot be satisfied and lead to better bounds, as well as penalties, similar to those used in mixed-integer programming. We also investigate many branching rules, some of them based on logical relations expressing the conditions on the tightness of constraints that have been detected.

For fixed $\overline{x}$ the follower's subproblem (4)–(6) has a single optimal solution $\overline{y}$ in the absence of dual degeneracy. Otherwise there is an infinity of optimal $\overline{y}$'s, not all of which need to be feasible or of equal value in the leader's problem. Then some further assumptions have to be made on the willingness of the follower to cooperate with the leader in order for the problem to be well defined. From the point of view of the leader, the best case is when the follower accepts the leader's preferences regarding the y_j's for which he (the follower) is indifferent (the tie cooperative case) and the worst case is when the follower adopts the opposite of the leader's preferences regarding these y_j's (the tie noncooperative case). In this paper, we present an algorithm for the tie cooperative case, and indicate briefly how it can be modified to solve the tie noncooperative case.

As cooperation between the leader and the follower is ruled out, except in the case of ties for the follower's objective function, the optimal solution of LBP need not be an efficient one. In other words, there might be another feasible solution with higher value for both objective functions.

The LBP includes as particular cases the *linear max-min* (LMM) problem and the bilinear programming problem and is equivalent to some cases of concave programming and of nonconvex quadratic programming (see Pardalos and Rosen [33] for definitions and references).

3. Complexity.

3. Complexity. Jeroslow [26] has shown that LBP is NP-hard, and a shorter proof has recently been given by Ben-Ayed and Blair [12]. We next show that this result can be strengthened; we consider the LMM problem, a more restricted model than LBP. LMM is obtained from LBP by omitting constraints (2) and setting $c^2 = -c^1$, $d^2 = -d^1$, as pointed out by Bard and Falk [8]. For definitions, see Garey and Johnson [20].

THEOREM 3.1. LMM *is strongly* NP*-hard.*

Proof. We use reduction to KERNEL, which has been proved to be NP-hard by Chvâtal (see Garey and Johnson [20, p. 204]). Recall that a kernel K of a graph $G = (V, E)$ is a vertex set that is stable (no two vertices of K are adjacent) and absorbing (any vertex not in K is adjacent to a vertex of K). Then consider the LMM

$$\max_x \min_y z = -\sum_{j=1}^{n} y_j, \tag{9}$$

$$\text{s.t.} \quad x_j + x_k \leq 1 \qquad \forall\, j,k|\{v_j,\, v_k\} \in E, \tag{10}$$

$$y_j \leq 1 - x_j \quad \forall\, j, \tag{11}$$

$$y_j \leq 1 - x_k \quad \forall\, j,k|\{v_j,\, v_k\} \in E, \tag{12}$$

$$x_j, y_j \geq 0 \qquad \forall\, j, \tag{13}$$

where variables x_j and y_j are both associated with the vertex v_j of G, for $j = 1, 2, \cdots, n$. We claim that G has a kernel if and only if the optimal solution to (9)–(13) has a value $z^* = 0$. Assume first that G has a kernel K. Then set $x_j = 1$ for all $j \,|\, v_j \in K$, $x_j = 0$ otherwise. This solution satisfies (10) as K is stable. It imposes $y_j = 0$ for all j through (11) and (12) as K is absorbing; so $z^* = 0$.

Assume next that G has no kernel. Then any optimal solution in which all x_j^*'s are integers defines a stable set $S = \{v_j \,|\, x_j^* = 1\}$. As this stable set cannot be absorbing, at least one y_j^* must be equal to 1 and $z^* \leq -1$. Moreover, any nonintegral optimal solution must contain at least one x_j^* taking a positive fractional value, and because of (10) no x_k^* such that $(v_j,\, v_k) \in E$ can be equal to 1. So y_j^* takes a positive value and $z^* < 0$. As KERNEL is not a number problem, this completes the proof. □

COROLLARY 3.2. LBP *is strongly* NP*-hard.*

Recall that a *fully polynomial approximation scheme* provides an ε-optimal solution to a given problem in time polynomial in the problem size and in ε. It follows from the above corollary that no fully polynomial approximation scheme can be found for LBP unless $P = NP$.

4. Algorithm.

4.1. Necessary conditions for optimality and penalties.

We next derive necessary optimality conditions, expressed in terms of tightness of constraints in the follower's subproblem, i.e., constraints (5) and (6). To this effect we associate with each such constraint a boolean variable α_i equal to 1 if the constraint is tight, and equal to 0 otherwise. These conditions will play a basic role in the branch-and-bound algorithm described in §4.2

THEOREM 4.1. *In any rational solution to* LBP *the tightness of the constraints in the follower's subproblem is such that*

$$\sum_{i|B_{ij}^2>0} \alpha_i \geq 1 \quad \textit{if } d_j^2 > 0, \tag{14}$$

$$\sum_{i|B_{ij}^2<0} \alpha_i + \alpha_{m_2+j} \geq 1 \quad \textit{if } d_j^2 < 0 \tag{15}$$

for $j = 1, 2, \cdots, n_2$.

Proof. Assume that by contradiction there is a rational solution $(\hat{x}, \hat{y})$ to LBP such that (14) does not hold for some $j \in \{1, 2, \cdots, n_2\}$ such that $d_j > 0$ or (15) does not hold for some $j \in \{1, 2, \cdots, n_2\}$ such that $d_j < 0$. In the former case, increasing the value of $\hat{y}_j$ by

$$\Delta\hat{y}_j = \min_{i|B_{ij}^2>0} \left\{ \frac{1}{B_{ij}^2} \cdot \left(b_i^2 - \sum_{k=1}^{n_1} A_{ik}^2 \hat{x}_k - \sum_{\substack{k=1 \\ k \neq j}}^{n_2} B_{ik}^2 \hat{y}_k \right) \right\} \tag{16}$$

yields a solution satisfying constraints (5) for $x = \hat{x}$ and (6) with a value larger by $d_j \Delta\hat{y}_j$ than that of $(\hat{x}, \hat{y})$. This contradicts $(\hat{x}, \hat{y})$ being rational. In the latter case, decreasing the value of $\hat{y}_j$ by

$$\Delta\hat{y}_j = \min \left[\hat{y}_j, \min_{i|B_{ij}^2<0} \left\{ \frac{1}{B_{ij}^2} \left(\sum_{k=1}^{n_1} A_{ik}^2 \hat{x}_k + \sum_{\substack{k=1 \\ k \neq j}}^{n_2} B_{ik}^2 \hat{y}_k - b_i^2 \right) \right\} \right] \tag{17}$$

yields a solution satisfying constraints (5) for $x = \hat{x}$ and (6) with a value larger by $-d_j \Delta\hat{y}_j$ than that of $(\hat{x}, \hat{y})$. This again contradicts $(\hat{x}, \hat{y})$ being rational. □

COROLLARY 4.2. *In any optimal solution to* LBP *the tightness of the constraints in the follower's subproblem is such that conditions* (14) *and* (15) *are satisfied for all* $j \in \{1, 2, \cdots, n_2\}$ *such that* $d_j > 0$ *and* $d_j < 0$, *respectively.*

Proof. This follows immediately from the fact that optimal solutions to LBP are rational. □

A weaker condition involving tightness of constraints was obtained by Falk [18] for the LMM problem. Falk indeed noted that at least one constraint in the follower's subproblem must be tight at the optimum, i.e., that

$$\sum_{i=1}^{m_2} \alpha_i + \sum_{j=1}^{n_2} \alpha_{m_2+j} \geq 1. \tag{18}$$

Falk [18] showed that using this relation at the first node while solving by a branch-and-bound algorithm does reduce computational effort, but he did not apply it for subproblems obtained by branching. We next discuss branching for the LBP. This leads us to show how further relations of type (14) or (15) can be obtained for all subproblems.

In all rules studied, branching is done by fixing some binary variable(s) α_i at 0 or at 1. Either a single variable α_i will be chosen for that purpose (dichotomous branching), or a logical relation (14) or (15), e.g., $\alpha_{i_1} + \alpha_{i_2} + \alpha_{i_3} + \cdots \geq 1$ will be chosen and branching will be done according to the rule $\alpha_{i_1} = 1$ or ($\alpha_{i_1} = 0$ and $\alpha_{i_2} = 1$) or ($\alpha_{i_1} = \alpha_{i_2} = 0$ and $\alpha_{i_3} = 1$) and so on (multiple branching).

If $\alpha_i = 1$, the ith constraint (in (5) or (6)) in the follower's subproblem becomes an equality. It can then be used to eliminate one of the follower's variables y_j (which is y_{i-m_2} in case of a constraint of type (6)). New logical relations of type (14) and (15) can then be derived.

Of course, variable elimination does not reduce the number of structural constraints in that the nonnegativity constraint $y_j \geq 0$ for the eliminated variable is replaced by an inequality involving several variables. If there are several possible choices for y_j, the variable with the smallest fill-in, i.e., which least augments the number of nonzero coefficients, is chosen.

If a subproblem is obtained in which no more y variables remain, its optimal solution is found by solving the problem obtained by deleting the objective function (4) of the follower (called leader relaxation below and denoted LR), as the leader controls all remaining variables. However, it will be necessary to check whether this solution is rational or not. This will be the case if the value of the follower's objective function, when the x variables are fixed at their values in the optimal solution of LR, is the same for the y_j values obtained from the tight constraints used to eliminate them, and for the optimal y_j values for the follower's subproblem.

If $\alpha_i = 0$, the ith constraint (15) in the follower's subproblem becomes a strict inequality, and from the complementary slackness theorem of linear programming, the ith variable in the dual of the follower's subproblem must be equal to 0. As it is not easy to handle constraints stating that a variable is strictly positive in linear programming, the dual of the follower's subproblem will be solved instead of the primal in one test of the algorithm described below. When many variables α_i are fixed at 0, this dual problem may be infeasible, in which case, from the duality theorem, the primal follower's subproblem together with the strict positivity constraints is also infeasible, as by assumption it is bounded.

In practice, variable elimination can be performed by pivoting in a simplex tableau and fixing the eliminated variable, which leaves the basis at 0. This is easily implemented in a linear programming package such as Marsten's XMP [31].

In the branch-and-bound algorithm described in the next subsection, depth-first search is used and the subset of logical relations (denoted by R) is updated after either branching or backtracking.

When a branch corresponding to $\alpha_i = 0$ is explored, all logical relations involving α_i are simplified by deleting α_i. When a branch corresponding to $\alpha_i = 1$ is explored, all logical relations involving α_i are deleted as they are trivially satisfied. Then new relations (14) or (15) are obtained after a variable y_j has been eliminated. Finally, redundant relations are eliminated from R. (Recall that a logical relation $r_k \equiv \sum_{i\in I_k} \alpha_i \geq 1$, where I_k denotes the set of indices of the logical variables in r_k, of R is redundant if R contains another logical relation $r_\ell \equiv \sum_{i\in I_\ell} \alpha_i \geq 1$ such that $I_\ell \subseteq I_k$, i.e., satisfaction of $r_\ell \geq 1$ implies that $r_k \geq 1$ is satisfied as all variables α_i appearing in r_ℓ appear also in r_k.) When backtracking occurs, we revert to the set R corresponding to the last explored node for which one branch is unexplored and then explore this branch, updating R accordingly.

When branching is done on the values of the α_i, at most $2^{m_2+n_2+1}-1$ subproblems will be generated. If multiple branching is used the number of subproblems will be less, as subproblems with $\alpha_i = 0$ for all $i \in I_k$ for relations $r_k \in R$ used for branching are excluded.

As in many other algorithms for LBP, linear programming will be used to obtain bounds on the optimal value. To this effect, the objective functions (4) of the follower will be deleted (in the original problem or in the current subproblem in which some variables y_j have been eliminated). Solving the so-obtained linear program LR gives such an upper bound (denoted z_L^*). Then the effect of fixing a variable α_i at 1, i.e., satisfying a constraint as an equality, can be anticipated to some extent by computing a penalty as in mixed-integer programming (see, e.g., Taha [36]). Consider the equations corresponding to an optimal tableau of the LR of the current subproblem

$$z = z_L^* - \sum_{j \in N} (z_j^* - c_j)x_j,$$

$$x_i = b_i^* - \sum_{j \in N} A_{ij}^* x_j, \qquad i \in B,$$

where B denotes the index set of basic and N the index set of nonbasic variables. Then if x_i is the slack variable of the ith constraint the down penalty for setting x_i at 0 is

$$p_i = b_i^* \min_{j \in N | A_{ij}^* > 0} \left\{ \frac{z_j^* - c_j}{A_{ij}^*} \right\}.$$

It corresponds to the decrease in the value of z_L during the first dual-simplex iteration after adding the constraint $x_i \leq 0$. Moreover, if $r_k \equiv \sum_{i \in I_k} \alpha_i \geq 1$ is a logical relation of type (14) or (15) that must be satisfied by any rational solution, then at least one of the slack variables x_i $(i \in I_k)$ must be set at 0. It follows that

$$z_L^{*'} = z_L^* - \min_{i \in I_k} p_i$$

is an upper bound on the optimal value of the current subproblem. Finally, taking into account all logical relations of type (14) or (15) leads to a stronger upper bound:

$$z_L^{*''} = z_L^{*'} - \max_{k | r_k \in R} \min_{i \in I_k} p_i.$$

4.2. Tests. Before giving the rules of the new algorithm, we recall and illustrate a classification of tests for branch-and-bound methods (Hansen, Jaumard, and Lu [21], [22]). Viewed abstractly, any test of a branch-and-bound algorithm consists in examining whether a sufficient condition for some proposition about the current subproblem to be true is satisfied or not, and making use of this proposition when it is the case to fathom or simplify the subproblem.

A *direct test* is such that the information provided by the proposition when the condition holds is all that is required for the solution of the current subproblem. This is the case when it can be shown: (i) that a known solution x^* is the globally optimal solution of the subproblem (*direct resolution test*); or (ii) that the subproblem has no solution better than the best one known, called *incumbent* (*direct optimality test*); or (iii) that the subproblem has no feasible solution (*direct feasibility test*).

One resolution test for LBP, which applies to subproblems in which all variables y_j have been eliminated, consists in solving LR for x_L^* and then checking whether the solution (x_L^*, y_L^*), where y_L^* is obtained by using the equations of elimination backwards, is rational or not. If it is rational, (x_L^*, y_L^*) is the optimal solution of the current subproblem. A stronger version of this test, in which some y_j may remain in LR, is given below. One direct optimality test for LBP consists of solving LR and checking if its optimal value z_L^* exceeds the value z_{opt} of the best solution found so far. One direct feasibility test for LBP, discussed above, consists in checking whether the dual of the follower's relaxation (FR) is feasible or not.

A *conditional test* is such that the information provided by the proposition when the condition holds is all that is required for the solution of the current subproblem when a variable is fixed at a given value (here a boolean variable α_i fixed at the value 1).

One conditional optimality test for LBP consists in solving LR, computing the penalties p_i for loose constraints (i.e., those with strictly positive slack variables in the basis) and checking if $z_L^* - p_i \leq z_{\text{opt}}$. If this last inequality holds, no better solution than the incumbent one can be found for the current subproblem with the ith constraint being tight (i.e., $\alpha_i = 1$), so α_i may be fixed at 0.

A *relational test* is such that the information provided by the proposition when the condition holds is all that is required for the solution of the current subproblem if some algebraic or (here) logical relation is not satisfied.

Applying Theorem 4.1 yields logical relations (14) and (15) for all y_j remaining in the current subproblem; if all α_i in one of these relations are equal to 0, the current subproblem contains no rational solution and is fathomed.

We next describe a depth-first branch-and-bound algorithm. The current subproblem is characterized by: (i) objective functions and constraints of type (1)–(6) in x and in the remaining y_j variables; (ii) the vector α specifying which of the initial constraints are tight, loose, or of unknown tightness; (iii) the logical relations obtained from monotonicity; and (iv) the list of eliminated variables and the equalities defining their values. This subproblem may be written as follows:

$$\max_x \quad \tilde{z}_1(x,\tilde{y}) = \tilde{c}^1 x + \tilde{d}^1 \tilde{y}, \tag{19}$$

subject to:

$$\tilde{A}^1 x + \tilde{B}^1 \tilde{y} \leq \tilde{b}^1, \tag{20}$$

$$x \geq 0; \tag{21}$$

$$\max_{\tilde{y}} \quad \tilde{z}_2(x,\tilde{y}) = \tilde{c}^2 x + \tilde{d}^2 \tilde{y}, \tag{22}$$

subject to:

$$\tilde{A}^2 x + \tilde{B}^2 \tilde{y} \leq \tilde{b}^2, \tag{23}$$

$$\tilde{y} \geq 0, \tag{24}$$

where $\tilde{y}$ denotes the vector of remaining y_j variables and the tilde indicates that the coefficients in (19)–(24) are those obtained by eliminating the variables of $y \setminus \tilde{y}$. In addition, the current subproblem is defined by $\alpha = (\alpha_1, \cdots, \alpha_{m_2+n_2})$, where the α_i can be fixed at 0 or at 1 or be free, and $R = \{r_k, k \in K\}$, where $r_k \equiv \sum_{i \in I_k} \alpha_i \geq 1$ with $I_k \subseteq \{1, 2, \cdots, m_2 + n_2\}$, as well as the linear equations used to eliminate the variables of $y \setminus \tilde{y}$.

As discussed above, elimination of variables can be done by pivoting and fixation of nonbasic variables at 0. For simplicity of exposition we will not distinguish between eliminated and noneliminated variables when stating the rules of the algorithm given below.

We use two relaxations of the subproblem: the *leader's relaxation* (LR) obtained, as explained above, by omitting (22), and the *follower's relaxation* (FR), which consists of (22)–(24) for x fixed to $\overline{x}$. We will also consider the *follower's subproblem* (FS), which consists of (4)–(6), for $x = \overline{x}$.

ALGORITHM HJS

a. Initialization.
Obtain an initial solution (x_h, y_h) with a heuristic (the choice of which is discussed below). Initialize the incumbent solution $(x_{\text{opt}}, y_{\text{opt}})$ to (x_h, y_h) and the incumbent value z_{opt} to $c^1 x_{\text{opt}} + d^1 x_{\text{opt}}$. If no heuristic solution can be found, initialize $(x_{\text{opt}}, y_{\text{opt}})$ to an arbitrary value and set $z_{\text{opt}} = -\infty$.
Consider all variables α_i $(i = 1, 2, \cdots, m_2 + n_2)$ to be free. Set $R = \emptyset$.

b. First direct optimality test.
Solve LR; let (x_L^*, y_L^*) denote an optimal solution.
If $z_L^* = c^1 x_L^* + d^1 y_L^* \leq z_{\text{opt}}$, go to step m (backtracking).

c. First direct feasibility test.
Solve the dual of FR(x). If it has no feasible solution, go to step m.

d. Direct resolution test, first part.
Consider again the optimal solution (x_L^*, y_L^*) of LR.
Check if (x_L^*, y_L^*) is rational for the current subproblem: solve FR(x_L^*), and let y_F^* be an optimal solution. If $d^2 y_L^* = d^2 y_F^*$ then (x_L^*, y_L^*) is rational; otherwise go to step f.

e. Direct resolution test, second part.
Consider again the optimal solution (x_L^*, y_L^*) of LR.
Check if (x_L^*, y_L^*) is rational for the initial problem: solve FS(x_L^*), and let y_{FS}^* be an optimal solution.
If $d^2 y_L^* = d^2 y_{FS}^*$ then (x_L^*, y_L^*) is rational; otherwise go to step f.
Update z_{opt} and $(x_{\text{opt}}, z_{\text{opt}})$ if $z_{\text{opt}} < c^1 x_L^* + d^1 y_L^*$ and go to step m.

f. Second direct optimality test.
Compute all penalties p_i associated with strictly positive slack variables in the optimal tableau of LR. Set the other p_i equal to 0. Then for all k such that $r_k \in R$, compute

$$\pi_k = \min_{i \in I_k} p_i,$$

and set

$$\Pi = \max_k \pi_k.$$

If $z_{\text{opt}} \geq z_L^* - \Pi$, go to step m.

g. Second direct feasibility test.
If LR is infeasible, go to step m.

h. First conditional optimality test.
Consider again LR with the penalties p_i. For all i such that $z_{\text{opt}} \geq z_L^* - p_i$, fix α_i at 0 and update R.

i. Third direct optimality test.
If R contains a relation r_k such that $\alpha_j = 0$ for all $j \in I_k$, go to step m.

j. Relational optimality test.
For all remaining y_j appearing in $z_2(x, y)$, add to R the logical relations (14) or (15) on the α_i, if they are nonredundant. Eliminate from R those relations that have become redundant.

k. Second conditional optimality test.
If R contains a relation r_k such that $\alpha_j = 0$ for all $j \in I_k$ except for one index i, set the corresponding α_i to 1. Eliminate from the subproblem a variable y_j remaining in the ith constraint such that fill-in is minimum and return to step b.

l. Branching.
Apply the selected branching rule (the choice of which is discussed in §5) to choose either a free variable α_i or a relation $r_k \in R$ for which all variables α_i with $i \in I_k$ are free. In the former case, branch by fixing α_i at 1. In the latter case, branch by fixing the first variable α_i in r_k equal to 1. Eliminate a variable y_j remaining in the ith constraint such that fill-in is minimum. Return to step b.

m. Backtracking.
If branching took place on a variable, find the last α_i branched upon and equal to 1, set this $\alpha_i = 0$ and free the α_j fixed at 0 after α_i was fixed at 1. Otherwise consider the last logical relation r_k for which less than $|I_k|$ branches have been explored; consider the next branch. If there is no such variable or relation, stop. Otherwise update the current subproblem and return to step b.

Various heuristics may be used to obtain a first rational solution in the absence of first-level constraints. One of them, used in our implementation, consists of solving LR with the objective function $\lambda c^1 x + (1-\lambda) d^2 y$, i.e., a weighted sum of the leader's objective function for the x variables and of the follower's objective function for the y variables. The weight λ was chosen to be equal to

$$\frac{n_1 + n_2}{n_1 + 2n_2}.$$

Better heuristic solutions could be obtained at higher computational cost, e.g., by varying λ between 0 and 1 in the following objective function $(1-\lambda)(c^1x + d^1y) + \lambda d^2 y$ and keeping the first rational solution obtained as in Bard's algorithm [5], or by using Judice and Faustino's algorithm as they suggest in [28].

THEOREM 4.3. *Algorithm* HJS *solves* LBP *in a finite time.*

Proof. As mentioned in §2, LBP has an optimal solution at an extreme point of Ω, or has no solution. Branching on the tightness of the follower's constraints implies an implicit enumeration of all bases of FS, which are finite in number, as is the number of values for the vector α. Moreover, all steps take a finite time and the algorithm cannot cycle, as they are done in sequence unless simplification or branching takes place, which can happen only a finite number of times. □

As mentioned above, Algorithm HJS is for the tie cooperative case. Therein, ties in the values of the follower's objective function are automatically resolved as the leader wishes. This is ensured by LR: the objective function is that of the leader, so that if in tests d and e the solution (x_L^*, y_L^*) is found to be rational, it is the best from the leader's point of view among all rational solutions with $\overline{x} = x_L^*$. Algorithm HJS is easily adapted to solve the tie noncooperative case. Indeed, it suffices to add a secondary objective function in the follower's subproblem equal to $-d^1 y$ and activated only in case of ties for the objective function $d^2 y$, in a similar way as in preemptive goal programming (see, e.g., Ignizio [25]).

This modification, which affects tests d and e, has two consequences: first, rational solutions in case of ties for $d^2 y$ will usually differ from (x_L^*, y_L^*), so more branches will have to be explored; second, again in case of ties for $d^2 y$, the optimal solution may be modified.

5. An example. Consider the following two-level linear program (from Candler and Townsley [16], with an additional first-level constraint). The α_i are written in parentheses next to the corresponding constraints:

$$\max_x z_1 = 8x_1 + 4x_2 - 4y_1 + 40y_2 + 4y_3, \tag{25}$$

$$\text{subject to: } x_1 + 2x_2 - y_3 \le 1.3, \tag{26}$$

$$x_1 \ge 0, \quad x_2 \ge 0, \tag{27}$$

$$\max_y z_2 = -2y_1 - y_2 - 2y_3, \tag{28}$$

$$\text{subject to:}$$

$$(\alpha_1) \qquad -y_1 + y_2 + y_3 \le 1, \tag{29}$$

$$(\alpha_2) \qquad 4x_1 - 2y_1 + 4y_2 - y_3 \le 2, \tag{30}$$

$$(\alpha_3) \qquad 4x_2 + 4y_1 - 2y_2 - y_3 \le 2, \tag{31}$$

$$(\alpha_4) \qquad y_1 \ge 0, \tag{32}$$

$$(\alpha_5) \qquad y_2 \ge 0, \tag{33}$$

$$(\alpha_6) \qquad y_3 \ge 0. \tag{34}$$

Solve the problem:

$$\max_{x,\,y} z_R = \lambda c^1 x + (1-\lambda) d^2 y \quad \text{with } \lambda = \frac{n_1 + n_2}{n_1 + 2n_2} = \frac{5}{7},$$

i.e., $z_R = 5x_1 + 2.5x_2 - 1.5y_1 - 15y_2 + 1.5y_3$ subject to constraints (26)–(27) and (29)–(34) (step a). Its optimal solution $(x_R^*, y_R^*) = (1.5, 0, 1, 0, 2)$, with value $z_R^* = 9$, is feasible for problem (25)–(34). Therefore, $(x_{\text{opt}}, y_{\text{opt}})$ is initialized to (x_R^*, y_R^*) and z_{opt} to 16.

Solving the LR leads to $(x_L^*, y_L^*) = (0, 0, 1.5, 1.5, 1)$ and $z_L^* = 58 > z_{\text{opt}}$ (step b). As no constraint has yet been imposed on the dual variables of the follower's problem, it is feasible (step c). Setting $\overline{x}$ to x_L^*, we obtain $y_F^* = (0, 0, 0)$ and $z_2(y_F^*) = 0 \neq z_2(y_L^*) = -6.5$; hence (x_L^*, y_L^*) is not rational (step d).

The penalties p_i associated with constraints (29)–(34) are equal to:

$$p_1 = 0\,,\ p_2 = 0\,,\ p_3 = 0\,,\ p_4 = 28.8\,,\ p_5 = 42, \text{and } p_6 = 22 \qquad \text{(steps f and h)}.$$

The set R of logical conditions

$$\begin{aligned} \alpha_1 + \alpha_2 + \alpha_4 &\ge 1 \quad (\text{w.r.t. } y_1),\\ \alpha_3 + \alpha_5 &\ge 1 \quad (\text{w.r.t. } y_2),\\ \alpha_2 + \alpha_3 + \alpha_6 &\ge 1 \quad (\text{w.r.t. } y_3) \end{aligned}$$

are obtained (step j). We branch on the second relation and first consider $\alpha_5 = 1$ as $p_5 > p_3$. This leads to $y_2 = 0$ and the problem reduces to

$$\max_x z_1 = 8x_1 + 4x_2 - 4y_1 + 4y_3,$$

$$\text{subject to: } x_1 + 2x_2 - y_3 \le 1.3,$$

$$x_1 \ge 0, \qquad x_2 \ge 0;$$

$$\max_{y_1,\,y_3} z_2 = -2y_1 - 2y_3,$$

$$\text{subject to:}$$

$$\begin{aligned} -y_1 + y_3 &\le 1,\\ 4x_1 - 2y_1 - y_3 &\le 2,\\ 4x_2 + 4y_1 - y_3 &\le 2,\\ y_1 \ge 0, \qquad y_3 &\ge 0. \end{aligned}$$

The optimal solution $(x_L^*,\, y_L^*)$ of LR is (1.5, 0, 1, 2) with a value $z_L^* = 16 \le z_{\text{opt}}$ (step b).

The incumbent solution remains: $z_{\text{opt}} = 16$, $(x_{\text{opt}},\, y_{\text{opt}}) = (1.5,\ 0,\ 1,\ 0,\ 2)$.

Backtracking (step m) leads to the branch $\alpha_5 = 0$, $\alpha_3 = 1$. Variable y_1 is eliminated, leading to the subproblem

$$\begin{aligned} &\max_x z_1 = 8x_1 + 8x_2 + 38y_2 + 3y_3 - 2,\\ &\text{subject to: } x_1 + 2x_2 - y_3 \ge 1.3,\\ &\qquad x_1 \ge 0, \qquad x_2 \ge 0,\\ &\qquad \max_{y_2,\, y_3} z_2 = 2x_2 - 2y_2 - 2.5y_3 - 1,\\ &\qquad\quad \text{subject to:}\\ &\qquad\quad (\alpha_1) \qquad\qquad x_2 + 0.5y_2 + 0.75y_3 \le 1.5,\\ &\qquad\quad (\alpha_2) \qquad\qquad 2x_1 + x_2 + 1.5y_2 - 0.75y_3 \le 1.5,\\ &\qquad\quad (\alpha_4) \qquad\qquad x_2 - 0.5y_2 - 0.25y_3 \le 0.5,\\ &\qquad\quad (\alpha_5) \qquad y_2 > 0,\\ &\qquad\quad (\alpha_6) \qquad y_3 \ge 0. \end{aligned}$$

The current set of logical relations R (step j) is equal to $\{\alpha_4 \ge 1\}$ (with respect to y_2 in the above subproblem). Indeed the constraint $\alpha_2 + \alpha_4 + \alpha_6 \ge 1$, corresponding to y_3 in the current subproblem, is redundant and the three previous constraints of R are eliminated, two of them because they contain $\alpha_3 = 1$ and the third one because $\alpha_4 = 1$ makes it redundant. Tightness of the fourth constraint (step k), i.e., $\alpha_4 = 1$, allows us to eliminate y_2, leading to the subproblem

$$\begin{aligned} &\max_x z_1 = 8x_1 + 84x_2 - 16y_3 - 40,\\ &\text{subject to: } x_1 + 2x_2 - y_3 \le 1.3,\\ &\qquad x_1 \ge 0, \qquad x_2 \ge 0,\\ &\qquad \max_{y_3} z_2 = -2x_2 - 1.5y_3 + 1,\\ &\qquad\quad \text{subject to:}\\ &\qquad\quad (\alpha_1) \qquad 2x_2 + 0.5y_3 \le 2,\\ &\qquad\quad (\alpha_2) \qquad 2x_1 + 4x_2 - 1.5y_3 \le 3,\\ &\qquad\quad (\alpha_5) \qquad -2x_2 + 0.5y_3 \le -1,\\ &\qquad\quad (\alpha_6) \qquad y_3 \ge 0. \end{aligned}$$

A new logical relation is found : $\alpha_2 + \alpha_6 \ge 1$. Computing the optimal solution $(x_L^*,\, y_L^*)$ of LR, its value z_L^* and the penalties p_i yield $(x^*,\, y_L^*) = (0,\ .833,\ .466)$, $z_L^* = 26.73 > z_{\text{opt}}$, and $p_1 = 0$, $p_2 = 8.333$, $p_6 = 12.333$. Setting $\overline{x}$ to x_L^* in FR yields the solution $y_{FR}^* = (.3555)$ and $z_2(y_F^*) = -1.3 \ne z_2(y_L) = -1.466$; hence $(x_L^*,\, y_L^*)$ is not rational.

Penalty $p_6 = 12.33$ is such that $z_{\text{opt}} > z_L^* - p_6$; hence $\alpha_6 = 0$ (step h). The set R reduces to $\{\alpha_2 \ge 1\}$. Tightness of the second constraint allows us to eliminate y_3, the last of the follower's variables. This gives the following subproblem

$$\begin{aligned} \max_x z_1 &= -13.33x_1 + 41.33x_2 - 8 \\ \text{subject to: } & -x_1 - 2x_2 \le -2.1 \\ & x_1 \ge 0, \qquad x_2 \ge 0; \\ & \max_y \ z_2 = -2x_1 - 6x_2 + 4 \\ & \quad \text{subject to:} \\ & \qquad (\alpha_1) \quad 2x_1 + 10x_2 \le 9, \\ & \qquad (\alpha_5) \quad x_1 - x_2 \le 0, \\ & \qquad (\alpha_6) \quad -2x_1 - 4x_2 \le -3. \end{aligned}$$

Solving LR yields $x_L^* = (0.5, 0.8)$ and $z_L^* = 18.4$, which is trivially rational for the current subproblem. Moreover, setting $\overline{x}$ to x_L^* in FS yields the solution $y_{FS}^* = (0, .2, .8)$ with $z_2(y_{FS}^*) = z_2(y_L^*) = -1.8$. Thus the solution (0.5, 0.8, 0, 2, 0.8) is rational for the initial problem, and the incumbent vector and value are updated. Backtracking brings the algorithm to stop. The problem is thus solved after examining three nodes only (see Fig. 1).

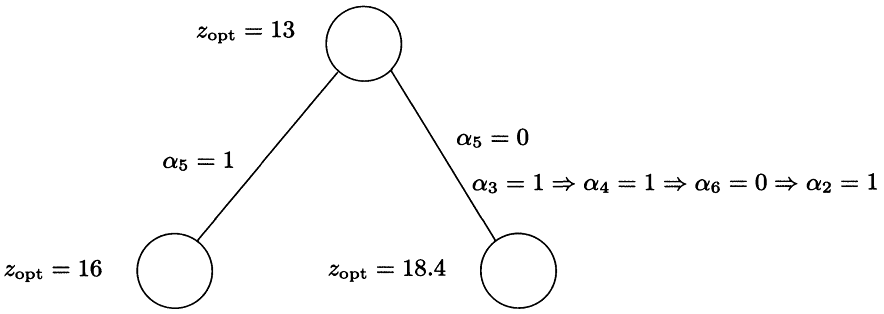

FIG. 1. *Branch-and-bound tree for the example.*

6. Computational experience. The algorithm of §4 has been coded in FORTRAN 77 and extensively tested on a SUN 3/50 and, for one series of tests, on a SUN SPARC computer. We also solved some test problems with the program of Bard and Moore [9] (referred to as BM below) on the same computer. Algorithm BM is similar to that of Fortuny-Amat and McCarl [19] in that both use branching on the complementary slackness conditions associated with the follower's subproblem. Fortuny-Amat and McCarl convert the complementary conditions into mixed-integer linear constraints before branching. The relaxation of the problem so obtained is less tight than in the BM algorithm. Bard and Moore consider the relaxation of LBP obtained by deleting the follower's objective function (i.e., program LR), then add the constraints of the dual of the follower's subproblem, solve in both the primal and dual variables, and branch on the complementary slackness conditions until they are satisfied. The program BM uses Marsten's code XMP [31] as a subroutine to solve the linear programs. We used the same code for that purpose.

Problems were generated randomly with the same characteristics as in Bard and Moore [9] for 40 percent and 17 percent density and as in Savard [35] for sparser (8 percent and 6 percent density) ones. To avoid empty columns, coefficients were generated column after column with these densities. To avoid unbounded optimal solutions in the follower's subproblem if all coefficients in a column corresponding to a variable y_j with $d_j^2 > 0$ are negative, the first one is multiplied by -1; then boundedness is checked and unbounded problems deleted.

The main parameters considered are the numbers n_1 and n_2 of leader and follower variables, m_1 and m_2 of first-level and second-level constraints and density d of the coefficient matrix. For each set of these values in each series of tests, 10 problems are solved. Mean (μ) and median (m) values as well as standard deviations (σ) for the number of nodes in the branch-and-bound tree and for the cpu times are given.

A first class of experiments was aimed at streamlining the algorithm and assessing which of its features are the most useful. Numerous branching rules were tested. In Table 1 we present results for the seven best rules, which are described next. We denote by s_i the slack variable associated with constraint i of type (5) or (6) and by u_i the corresponding dual variable for $i = 1, 2, \cdots, m_2 + n_2$.

BR1. *Multiple branching.* (i) Select the logical relation $r_k \in R$ with smallest cardinality. (ii) Break ties by choosing a relation with the largest number of slack variables s_i in basis. (iii) Order the variables α_i in r_k by decreasing values of the penalties p_i.

BR2. Same as BR1, except for (iii). Order the variables α_i by decreasing values of the products $s_i u_i$.

BR3. *Binary branching.* Select the boolean variable α_i associated with the largest penalty p_i.

BR4. Select the α_i associated with the largest product $s_i u_i$ (same rule as in Algorithm BM).

BR5. *Multiple or binary branching.* (i) Select the relation $r_k \in R$ with two variables α_i and both the corresponding slack variables s_i in basis, such that $\sum_{i \in I_k} u_i s_i$ is maximum. (ii) If there is no such relation, use BR4.

BR6. Same as BR5 except that in (ii), branch on the variable α_i with largest penalty p_i among those for which $s_i u_i > 0$.

BR7. Same as BR5 except that in (ii), branch on the variable with smallest product $s_i u_i > 0$.

It appears that:

(i) numbers of nodes generated and computation times are extremely sensitive to the chosen branching rule;

(ii) multiple branching on logical relations involving few α_i is less efficient than dichotomous branching on the α_i;

(iii) best results are obtained by a hybrid rule in which multiple branching is first used and one switches to dichotomous branching when no more logical relations with few α_i are available;

(iv) with all branching rules, difficulty of resolution varies greatly from problem to problem: often $\sigma > m$ and $m << \mu$. Many problems are easy to solve, with one or a few nodes in the branch-and-bound tree, while a few take several thousand nodes.

As branching rules BR5 and BR6 gave the best results, they were adopted in the remaining experiments.

In a second series of tests the effect of heuristics was assessed by obtaining an upper bound on the reduction in computing effort they can provide in the following

way: a series of test problems solved previously was solved again, first using no heuristic and then assuming the optimal value to be known a priori. Results are given in Tables 2a, 2b, and 2c (lines corresponding to BM will be discussed later) and are to be compared with those of Table 1. It appears that:

(i) a priori knowledge of the best solution significantly decreases computational effort (average cpu times are reduced by 21.3–42.2 percent);

(ii) some problems remain difficult to solve;

(iii) the heuristic described in §5 only entails small reductions in numbers of nodes and cpu time.

So, there is room for improved heuristics (e.g., as discussed above, those of Bard [5] and Judice and Faustino [27], [28]) but heuristics alone will not always render the solution of LBP easy.

In the next series of tests the effect of penalties was assessed by solving the same series of problems without and with them. Results, given in Table 3, show that:

(i) using penalties significantly reduces the number of nodes in the branch-and-bound tree (the average reduction in number of nodes is between 25.0 and 68.3 percent);

(ii) cpu times are not much affected (sometimes slightly increased and sometimes slightly decreased) except for the largest test problems, in which case using penalties reduces mean cpu time by 45.8 percent.

Table 3 also gives statistics on the number of times a variable α_i is fixed using a logical relation (rlog) and using a test involving penalties (pen). Note that the number of fixations due to logical relations increases when penalties are used, as these penalties can show that some α_i must be equal to 0 and hence sharpen the logical relations in which these α_i appear.

A second class of experiments aims at studying which parameters influence the difficulty of resolution of LBP. Results of a sensitivity analysis on the right-hand side vector are given in Table 4. Each component of this vector is chosen to be equal to s times the fraction of the right-hand side minus the sum of the negative coefficients over the sum of the absolute values of the coefficients in the corresponding constraint; s is varied from 0.4 to 0.8. No clear-cut tendency appears to be detectable. Contrasting with this result, very large differences in problem difficulty are observed when the amount by which the leader's and follower's objective functions are antagonistic varies (this amount depends on the ranges and the signs of the coefficients in both objective functions). Table 5 shows results obtained when coefficients d_j^1 in the leader's objective function and coefficients d_j^2 in the follower's objective function are randomly chosen in a uniform distribution on $[\ell, 20]$ where ℓ varies from -20 to $+12$. It appears that:

(i) computational effort regularly decreases when the lower bound ℓ increases, i.e., when the leader's and follower's objective functions become closer to being parallel.

(ii) computational difficulty of the hardest and easiest problems is very different (averages 33.3–56.3 times more nodes and 12.3–19.6 times more cpu time in the former than in the latter case).

This suggests that in reporting future experiments on algorithms for LBP, a parameter such as ℓ specifying the amount of antagonism between the two objective functions should be systematically specified.

In another series of experiments the number of first-level variables was varied while the numbers of second-level variables and of constraints were kept constant. Results of Table 6 show that computational effort significantly *decreases* when the number of first-level variables *increases.* It thus appears that the number of follower's variables is not in itself a sufficient measure of computational difficulty for LBP.

A third class of experiments was aimed at comparing our algorithm with the best previous ones, those of Bard and Moore [9] and of Judice and Faustino [27], [28]. A direct comparison with the algorithm of Bard and Moore was possible, as they kindly made their code available to us. Results are reported in Table 2 and Tables 7a and

TABLE 4
Sensitivity analysis on the right-hand side vector.

7b. It appears that:

(i) Algorithm HJS with branching rule BR5 always outperforms Algorithm BM and does the same with branching rule BR6 with two exceptions;

(ii) The ratios of computation times for Algorithms BM and HJS with branching rule BR5 are between 1.4 and 9.6 when $d = 40$ percent, 3.5 and 49.0 when $d = 17$ percent, 23 and 47.1 when $d = 8$ percent, but vary widely in each of these cases;

(iii) This ratio increases with problem size;

(iv) Similar conclusions hold even if no heuristic is used or if the optimum value of LBP is assumed to be known *a priori* (see Table 2).

Reasons for which Algorithm HJS is faster than Algorithm BM appear to be the following (probably in decreasing order of importance):

(i) use of logical relations (14) and (15); for sparse problems some of these logical relations may have only one α_i and thus lead to problem simplification and possibly to complete solution without branching;

(ii) solution of LR, and the dual of FR separately instead of jointly, thus reducing the size of the LPs solved in various tests (Algorithm BM includes the dual variables in the master program and hence contains m_2 more variables than does Algorithm HJS);

(iii) use of hybrid branching rules;

(iv) use of penalties.

In Table 8 we consider problems similar to those considered in the previous series of experiments but transfer some of the second-level constraints to the first level. These problems are solved by Algorithm HJS and a version of Algorithm BM, slightly modified to allow for first-level constraints with y variables. It appears that:

(i) computational difficulty sometimes increases and sometimes decreases when constraints are transferred from second to first level;

(ii) increase in computing time when there are first-level constraints does not exceed a factor of 3 with Algorithm HJS;

(iii) Algorithm HJS always outperforms Algorithm BM, and the ratios of computing times are higher when there are first-level constraints (from 2.83 to 53.3) than when there are none.

Comparison of Algorithm HJS with Algorithm JF of Judice and Faustino [27], [28] is more difficult, as a code for the latter is not generally available at this time.

Judice and Faustino [28] present computational results for several large sparse

problems with up to 150 constraints, 250 variables controlled by the leader, and 150 variables controlled by the follower, on a CYBER 180-830 computer. These problems belong to two classes: "nonconflicting" ones in which all coefficients in the leader's and follower's objective functions are positive, and "conflicting" ones in which a few coefficients in these objective functions differ in sign. We have generated similar problems with all coefficients of the objective functions taken randomly in $[0, 20]$ in the first case: 80 percent of them are taken in that way and 20 percent are taken in $[-20, 0]$ in the second case. Results obtained on a SUN SPARC computer are presented in Table 9 (which also contains results for a few slightly denser problems). It appears that computation times are roughly similar to those of JF, but the latter have been obtained on a much more powerful computer (CYBER) and with a tolerance of 1 or 2 percent of the optimal value, which is obtained by Algorithm HJS.

Acknowledgment. The authors are grateful to Jonathan F. Bard for making available to them the code for linear bilevel programming he recently wrote with J. T. Moore. They also thank Alain Haurie for several fruitful discussions of preliminary drafts, and one anonymous referee for his comments.

A FAMILY OF BLOCK PRECONDITIONERS FOR BLOCK SYSTEMS*

RAYMOND H. CHAN† AND XIAO-QING JIN†

Abstract. The solution of block system $A_{mn}x = b$ by the preconditioned conjugate gradient method where A_{mn} is an m-by-m block matrix with n-by-n Toeplitz blocks is studied. The preconditioner $c_F^{(1)}(A_{mn})$ is a matrix that preserves the block structure of A_{mn}. Specifically, it is defined as the minimizer of $\|A_{mn} - C_{mn}\|_F$ over all m-by-m block matrices C_{mn} with n-by-n circulant blocks. We prove that if A_{mn} is positive definite, then $c_F^{(1)}(A_{mn})$ is positive definite too. We also show that $c_F^{(1)}(A_{mn})$ is a good preconditioner for solving separable block systems with Toeplitz blocks and quadrantally symmetric block Toeplitz systems. We then discuss some of the spectral properties of the operator $c_F^{(1)}$. In particular, we show that the operator norms $\|c_F^{(1)}\|_2 = \|c_F^{(1)}\|_F = 1$.

Key words. Toeplitz matrix, circulant matrix, circulant operator, preconditioned conjugate gradient method

AMS(MOS) subject classifications. 65F10, 65F15

1. Introduction.

Preconditioned conjugate gradient methods have been used efficiently in solving large matrix problems. The idea of using the method with circulant preconditioners for solving symmetric positive definite Toeplitz systems $T_n x = b$ was proposed by Strang [16] and Olkin [15] independently. The number of operations per iteration is $O(n \log n)$ as circulant systems can be solved efficiently by the fast Fourier transform (FFT) and the matrix-vector multiplication $T_n v$ can also be computed by the FFT by first embedding T_n into a $2n$-by-$2n$ circulant matrix. The convergence rate of the preconditioned conjugate gradient method depends on the whole spectrum of the preconditioned matrix. In general, the more clustered the eigenvalues are, the faster the convergence rate will be.

There are many circulant preconditioners that can produce clustered spectra; see Chan and Yeung [5]. One good example is Chan's [9] circulant preconditioner, which is defined to be the minimizer of $\|T_n - C_n\|_F$ in Frobenius norm over all circulant matrices C_n. One can consider this circulant preconditioner from the operator point of view. Given any arbitrary n-by-n matrix A_n, we define an operator c_F which maps A_n to the matrix $c_F(A_n)$ that minimizes $\|A_n - C_n\|_F$ over all circulant matrices C_n. This circulant operator c_F has been studied in Chan, Jin, and Yeung [3].

In this paper, we generalize the idea to the case of block matrices. Our interest is in solving systems $T_{mn}x = b$ where T_{mn} is an m-by-m block matrix with n-by-n Toeplitz blocks. This kind of system occurs in a variety of applications, such as two-dimensional digital signal processing and the discretization of two-dimensional partial differential equations. Given such T_{mn}, we can use the mn-by-mn point-circulant matrix $c_F(T_{mn})$ as a circulant approximation to T_{mn}; see Chan and Olkin [10] and Chan and Chan [8]. In this paper, however, we consider another approximation to T_{mn} that preserves the block structure. The approximation extends the one proposed by Chan and Olkin [10]. We define the matrix $c_F^{(1)}(T_{mn})$ to be the minimizer of

*Received by the editors April 23, 1991; accepted for publication (in revised form) November 12, 1991.

$\|T_{mn} - C_{mn}\|_F$ over all m-by-m block matrices C_{mn} with n-by-n circulant blocks. We will show that the operator $c_F^{(1)}$ is well defined for all mn-by-mn complex matrices A_{mn}. Some properties of $c_F^{(1)}$ are then discussed. In particular, we prove that if A_{mn} is positive definite, then $c_F^{(1)}(A_{mn})$ is also positive definite. We also show that the operator $c_F^{(1)}$ has operator norms $\|c_F^{(1)}\|_2 = \|c_F^{(1)}\|_F = 1$.

We then consider the cost of using the preconditioned conjugate gradient method with the preconditioner $c_F^{(1)}(A_{mn})$ for solving block systems $A_{mn}x = b$. The convergence rate of the method is then analyzed for two specific types of block systems. The first is the quadrantally symmetric block Toeplitz systems. We show that in this case, if the generating sequence of the matrices is absolutely summable, then the method converges in at most $O(\min\{m, n\})$ steps. Next we consider block matrices that are of the form $A_m \otimes T_n$ where A_m is nonsingular and T_n is a Toeplitz matrix with a positive 2π-periodic continuous generating function. We show that the resulting preconditioned system has spectrum clustered around 1 and hence the method converges superlinearly. Our numerical experiments have shown that $c_F^{(1)}(A_{mn})$ is indeed a good preconditioner for solving these block systems—the number of iterations is roughly a constant in both cases.

The outline of the paper is as follows. In §2, we first recall some properties of the point-circulant operator c_F. Then we introduce three different possible block preconditioners that preserve the block structure of the given matrix. In §3, we consider the cost of using $c_F^{(1)}(A_{mn})$ as a preconditioner for solving block systems $A_{mn}x = b$. The convergence rate of the method is analyzed in §4 and numerical results are then given in §5.

2. Operators for block matrices. Let us begin by introducing the operator for point matrices. Given an n-by-n unitary matrix U, let

$$\mathcal{M}_U = \{U^*\Lambda_n U \mid \Lambda_n \text{ is an } n\text{-by-}n \text{ complex diagonal matrix}\},$$

where "$*$" denotes the conjugate transposition. We note that when U is equal to the Fourier matrix F, $\mathcal{M}_F$ is the set of all circulant matrices (see Davis [11]). Let $\delta(A_n)$ denote the diagonal matrix whose diagonal is equal to the diagonal of the matrix A_n. The following lemma was first proved by Chan, Jin, and Yeung [3] for the case $U = F$ and was extended to the general unitary case by Huckle [13].

LEMMA 1. *Let A_n be an arbitrary n-by-n matrix and $c_U(A_n)$ be the minimizer of $\|W_n - A_n\|_F$ over all $W_n \in \mathcal{M}_U$. Then*

(i) *$c_U(A_n)$ is uniquely determined by A_n and is given by*

$$c_U(A_n) = U^*\delta(UA_nU^*)U \ . \tag{1}$$

(ii) *If A_n is Hermitian, then so is $c_U(A_n)$. Furthermore, if $\lambda_{\min}(\cdot)$ and $\lambda_{\max}(\cdot)$ denote the largest and the smallest eigenvalues, respectively, then we have*

$$\lambda_{\min}(A_n) \le \lambda_{\min}\big(c_U(A_n)\big) \le \lambda_{\max}\big(c_U(A_n)\big) \le \lambda_{\max}(A_n) \ .$$

In particular, if A_n is positive definite, then $c_U(A_n)$ is also positive definite.

(iii) *The operator c_U is a linear projection operator from the set of all n-by-n complex matrices into $\mathcal{M}_U$ and has the operator norms*

$$\|c_U\|_2 = \sup_{\|A_n\|_2=1} \|c_U(A_n)\|_2 = 1$$

and

$$||c_U||_F = \sup_{||A_n||_F=1} ||c_U(A_n)||_F = 1.$$

(iv) *When U is the n-by-n Fourier matrix F,*

$$c_F(A_n) = \sum_{j=0}^{n-1} \left(\frac{1}{n} \sum_{p-q\equiv j \pmod n} a_{pq} \right) Q^j \ , \tag{2}$$

where Q is the n-by-n circulant matrix

$$Q \equiv \begin{bmatrix} 0 & & & & 1 \\ 1 & 0 & & & \\ 0 & 1 & \ddots & & \\ \vdots & & \ddots & \ddots & \\ 0 & & & 1 & 0 \end{bmatrix} . \tag{3}$$

The circulant matrix $c_F(A_n)$, first proposed by Chan [9], is a good preconditioner for solving some Toeplitz systems by the preconditioned conjugate gradient method (see Chan [6]). In the following, we call c_U the point operator in order to distinguish it from the block operators that we now introduce.

2.1. Block operator $c_U^{(1)}$. Let us now consider a general system $A_{mn}x = b$ where A_{mn} is an mn-by-mn matrix partitioned as

$$A_{mn} = \begin{bmatrix} A_{1,1} & A_{1,2} & \cdots & A_{1,m} \\ A_{2,1} & A_{2,2} & \cdots & A_{2,m} \\ \vdots & \ddots & \ddots & \vdots \\ A_{m,1} & A_{m,2} & \cdots & A_{m,m} \end{bmatrix} . \tag{4}$$

Here the blocks $A_{i,j}$ are square matrices of order n. We emphasize that we are interested in solving block systems where the blocks $A_{i,j}$ are Toeplitz matrices. In view of the point case, a natural choice of preconditioner for A_{mn} is

$$E_{mn} = \begin{bmatrix} c_F(A_{1,1}) & c_F(A_{1,2}) & \cdots & c_F(A_{1,m}) \\ c_F(A_{2,1}) & c_F(A_{2,2}) & \cdots & c_F(A_{2,m}) \\ \vdots & \ddots & \ddots & \vdots \\ c_F(A_{m,1}) & c_F(A_{m,2}) & \cdots & c_F(A_{m,m}) \end{bmatrix} ,$$

where the blocks $c_F(A_{i,j})$ are just the point-circulant approximations to $A_{i,j}$ (see (2)). We will show in §§4 and 5 that E_{mn} is a good preconditioner for solving some block systems. First, however, we study some of the spectral properties of the matrix E_{mn}.

Let $\delta^{(1)}(A_{mn})$ be defined by

$$\delta^{(1)}(A_{mn}) \equiv \begin{bmatrix} \delta(A_{1,1}) & \delta(A_{1,2}) & \cdots & \delta(A_{1,m}) \\ \delta(A_{2,1}) & \delta(A_{2,2}) & \cdots & \delta(A_{2,m}) \\ \vdots & \ddots & \ddots & \vdots \\ \delta(A_{m,1}) & \delta(A_{m,2}) & \cdots & \delta(A_{m,m}) \end{bmatrix} , \tag{5}$$

where each block $\delta(A_{i,j})$ is the diagonal matrix of order n whose diagonal is equal to the diagonal of the matrix $A_{i,j}$. The following lemma gives the relation between $\sigma_{\max}(A_{mn})$ and $\sigma_{\max}(\delta^{(1)}(A_{mn}))$, where $\sigma_{\max}(\cdot)$ denotes the largest singular value.

LEMMA 2. *Given any mn-by-mn complex matrix A_{mn} partitioned as in* (4), *we have*

$$\sigma_{\max}\left(\delta^{(1)}(A_{mn})\right) \le \sigma_{\max}(A_{mn}). \tag{6}$$

Furthermore, when A_{mn} is Hermitian, we have

$$\lambda_{\min}(A_{mn}) \le \lambda_{\min}\left(\delta^{(1)}(A_{mn})\right) \le \lambda_{\max}\left(\delta^{(1)}(A_{mn})\right) \le \lambda_{\max}(A_{mn}) \ . \tag{7}$$

In particular, if A_{mn} is positive definite, then $\delta^{(1)}(A_{mn})$ is also positive definite.

Proof. Let $(A_{mn})_{i,j;k,l} = (A_{k,l})_{ij}$ be the (i,j)th entry of the (k,l)th block of A_{mn}. Let P be the permutation matrix that satisfies

$$(P^*A_{mn}P)_{k,l;i,j} = (A_{mn})_{i,j;k,l}, \quad 1 \le i,j \le n, \quad 1 \le k,l \le m. \tag{8}$$

Then it is easy to see that $B_{mn} \equiv P^*\delta^{(1)}(A_{mn})P$ is of the form

$$B_{mn} = \begin{bmatrix} B_{1,1} & 0 & \cdots & 0 \\ 0 & B_{2,2} & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & B_{n,n} \end{bmatrix} .$$

Clearly, the matrices B_{mn} and $\delta^{(1)}(A_{mn})$ have the same singular values and eigenvalues. For each k, since $B_{k,k}$ is a principal submatrix of the matrix A_{mn}, it follows that

$$\sigma_{\max}(B_{k,k}) \le \sigma_{\max}(A_{mn});$$

see, for instance, Thompson [17]. Hence we have

$$\sigma_{\max}\left(\delta^{(1)}(A_{mn})\right) = \sigma_{\max}(B_{mn}) = \max_k \left(\sigma_{\max}(B_{k,k})\right) \le \sigma_{\max}(A_{mn}) \ .$$

When A_{mn} is Hermitian, by Cauchy's Interlace Theorem (see Golub and Van Loan [12]) we then have

$$\begin{aligned}\lambda_{\min}(A_{mn}) \le & \min_k \left(\lambda_{\min}(B_{k,k})\right) = \lambda_{\min}\left(\delta^{(1)}(A_{mn})\right) \\ \le & \lambda_{\max}\left(\delta^{(1)}(A_{mn})\right) = \max_k \left(\lambda_{\max}(B_{k,k})\right) \le \lambda_{\max}(A_{mn}) \ . \qquad \square\end{aligned}$$

In the following, we use $\mathcal{D}^{(1)}_{m,n}$ to denote the set of all m-by-m block matrices where each block is a complex diagonal matrix of order n, i.e., $\mathcal{D}^{(1)}_{m,n}$ is the set of all matrices of the form given in (5). Let

$$\mathcal{M}^{(1)}_U = \{(I \otimes U)^*\Lambda^{(1)}_{mn}(I \otimes U) \mid \Lambda^{(1)}_{mn} \in \mathcal{D}^{(1)}_{m,n}\} \ ,$$

where I is the m-by-m identity matrix and U is any given n-by-n unitary matrix. We then define the operator $c^{(1)}_U$ to be the mapping that maps every mn-by-mn matrix A_{mn} to the minimizer of $\|W_{mn} - A_{mn}\|_F$ over all $W_{mn} \in \mathcal{M}^{(1)}_U$. Some of the properties of this operator are given in the following theorem.

THEOREM 1. *For any arbitrary mn-by-mn complex matrix A_{mn} partitioned as in (4), let $c_U^{(1)}(A_{mn})$ be the minimizer of $\|W_{mn} - A_{mn}\|_F$ over all $W_{mn} \in \mathcal{M}_U^{(1)}$. Then*

(i) *$c_U^{(1)}(A_{mn})$ is uniquely determined by A_{mn} and is given by*

$$c_U^{(1)}(A_{mn}) = (I \otimes U)^* \delta^{(1)}\left[(I \otimes U) A_{mn} (I \otimes U)^*\right](I \otimes U). \tag{9}$$

(ii) *$c_U^{(1)}(A_{mn})$ is also given by*

$$c_U^{(1)}(A_{mn}) = \begin{bmatrix} c_U(A_{1,1}) & c_U(A_{1,2}) & \cdots & c_U(A_{1,m}) \\ c_U(A_{2,1}) & c_U(A_{2,2}) & \cdots & c_U(A_{2,m}) \\ \vdots & \ddots & \ddots & \vdots \\ c_U(A_{m,1}) & c_U(A_{m,2}) & \cdots & c_U(A_{m,m}) \end{bmatrix}, \tag{10}$$

where c_U is the point operator defined by (1).

(iii) *We have*

$$\sigma_{\max}\big(c_U^{(1)}(A_{mn})\big) \le \sigma_{\max}(A_{mn}). \tag{11}$$

(iv) *If A_{mn} is Hermitian, then $c_U^{(1)}(A_{mn})$ is also Hermitian and*

$$\lambda_{\min}(A_{mn}) \le \lambda_{\min}\big(c_U^{(1)}(A_{mn})\big) \le \lambda_{\max}\big(c_U^{(1)}(A_{mn})\big) \le \lambda_{\max}(A_{mn})\ .$$

In particular, if A_{mn} is positive definite, then $c_U^{(1)}(A_{mn})$ is also positive definite.

(v) *The operator $c_U^{(1)}$ is a linear projection operator from the set of all mn-by-mn complex matrices into $\mathcal{M}_U^{(1)}$ and has the operator norms*

$$\|c_U^{(1)}\|_2 \equiv \sup_{\|A_{mn}\|_2=1} \|c_U^{(1)}(A_{mn})\|_2 = 1$$

and

$$\|c_U^{(1)}\|_F \equiv \sup_{\|A_{mn}\|_F=1} \|c_U^{(1)}(A_{mn})\|_F = 1.$$

Proof. The following proves Theorem 1.

(i) Let $W_{mn} \in \mathcal{M}_U^{(1)}$ be given by

$$W_{mn} = (I \otimes U)^* \Lambda_{mn}^{(1)} (I \otimes U)\ ,$$

where $\Lambda_{mn}^{(1)} \in \mathcal{D}_{m,n}^{(1)}$. Since the Frobenius norm is unitary invariant, we have

$$\begin{aligned}\|W_{mn} - A_{mn}\|_F =& \|(I \otimes U)^* \Lambda_{mn}^{(1)} (I \otimes U) - A_{mn}\|_F \\ =& \|\Lambda_{mn}^{(1)} - (I \otimes U) A_{mn} (I \otimes U)^*\|_F\ .\end{aligned}$$

Thus the problem of minimizing $\|W_{mn} - A_{mn}\|_F$ over $\mathcal{M}_U^{(1)}$ is equivalent to the problem of minimizing $\|\Lambda_{mn}^{(1)} - (I \otimes U) A_{mn} (I \otimes U)^*\|_F$ over $\mathcal{D}_{m,n}^{(1)}$. Since $\Lambda_{mn}^{(1)}$ can only affect the diagonal of each block of $(I \otimes U) A_{mn} (I \otimes U)^*$, we see that the solution for the latter problem is $\Lambda_{mn}^{(1)} = \delta^{(1)}\left[(I \otimes U) A_{mn} (I \otimes U)^*\right]$. Hence

$$c_U^{(1)}(A_{mn}) = (I \otimes U)^* \delta^{(1)}\left[(I \otimes U) A_{mn} (I \otimes U)^*\right](I \otimes U)$$

is the minimizer of $\|W_{mn} - A_{mn}\|_F$. It is clear that $\Lambda_{mn}^{(1)}$ and hence $c_U^{(1)}(A_{mn})$ are uniquely determined by A_{mn}.

(ii) Since

$$\delta^{(1)}\left[(I \otimes U)A_{mn}(I \otimes U)^*\right] = \begin{bmatrix} \delta(UA_{1,1}U^*) & \delta(UA_{1,2}U^*) & \cdots & \delta(UA_{1,m}U^*) \\ \delta(UA_{2,1}U^*) & \delta(UA_{2,2}U^*) & \cdots & \delta(UA_{2,m}U^*) \\ \vdots & \ddots & \ddots & \vdots \\ \delta(UA_{m,1}U^*) & \delta(UA_{m,2}U^*) & \cdots & \delta(UA_{m,m}U^*) \end{bmatrix},$$

by (1) and (9) we see that $c_U^{(1)}(A_{mn})$ is also given by (10).

(iii) For general mn-by-mn matrix A_{mn}, we have by (9) and (6),

$$\begin{aligned}\sigma_{\max}\left(c_U^{(1)}(A_{mn})\right) =& \sigma_{\max}\left[\delta^{(1)}\left((I \otimes U)A_{mn}(I \otimes U)^*\right)\right] \\ \le& \sigma_{\max}\left[(I \otimes U)A_{mn}(I \otimes U)^*\right] = \sigma_{\max}(A_{mn}) \ .\end{aligned}$$

(iv) If A_{mn} is Hermitian, then it is clear from (10) and Lemma 1 (ii) that $c_U^{(1)}(A_{mn})$ is also Hermitian. Moreover, by (7) and (9), we have

$$\begin{aligned}\lambda_{\min}(A_{mn}) =& \lambda_{\min}\left[(I \otimes U)A_{mn}(I \otimes U)^*\right] \\ \le& \lambda_{\min}\left[\delta^{(1)}\left((I \otimes U)A_{mn}(I \otimes U)^*\right)\right] \\ =& \lambda_{\min}\left(c_U^{(1)}(A_{mn})\right) \le \lambda_{\max}\left(c_U^{(1)}(A_{mn})\right) \\ =& \lambda_{\max}\left[\delta^{(1)}\left((I \otimes U)A_{mn}(I \otimes U)^*\right)\right] \\ \le& \lambda_{\max}\left[(I \otimes U)A_{mn}(I \otimes U)^*\right] = \lambda_{\max}(A_{mn}) \ .\end{aligned}$$

(v) By (11), we have

$$\|c_U^{(1)}(A_{mn})\|_2 = \sigma_{\max}[c_U^{(1)}(A_{mn})] \le \sigma_{\max}(A_{mn}) = \|A_{mn}\|_2.$$

However, for the mn-by-mn identity matrix I_{mn}, we have $\|c_U^{(1)}(I_{mn})\|_2 = \|I_{mn}\|_2 = 1$. Hence $\|c_U^{(1)}\|_2 = 1$. For the Frobenius norm, we also have

$$\begin{aligned}\|c_U^{(1)}(A_{mn})\|_F =& \|\delta^{(1)}\left[(I \otimes U)A_{mn}(I \otimes U)^*\right]\|_F \\ \le& \|(I \otimes U)A_{mn}(I \otimes U)^*\|_F = \|A_{mn}\|_F \ .\end{aligned}$$

Since

$$\left\|c_U^{(1)}\left(\frac{1}{\sqrt{mn}}I_{mn}\right)\right\|_F = \frac{1}{\sqrt{mn}}\|I_{mn}\|_F = 1,$$

it follows that $\|c_U^{(1)}\|_F = 1$. □

2.2. Block operator $\tilde{c}_V^{(1)}$. For matrices A_{mn} partitioned as in (4), we can define another block approximation to them. Let $\tilde{\delta}^{(1)}(A_{mn})$ be defined by

$$\tilde{\delta}^{(1)}(A_{mn}) \equiv \begin{bmatrix} A_{1,1} & 0 & \cdots & 0 \\ 0 & A_{2,2} & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & A_{m,m} \end{bmatrix}. \tag{12}$$

In the following, we use $\tilde{\mathcal{D}}_{m,n}^{(1)}$ to denote the set of all m-by-m block diagonal matrices where each block is a complex matrix of order n, i.e., $\tilde{\mathcal{D}}_{m,n}^{(1)}$ is the set of all matrices of the form given by (12). Let

$$\tilde{\mathcal{M}}_V^{(1)} = \{(V \otimes I)^* \tilde{\Lambda}_{mn}^{(1)} (V \otimes I) \mid \tilde{\Lambda}_{mn}^{(1)} \in \tilde{\mathcal{D}}_{m,n}^{(1)}\} ,$$

where V is any given m-by-m unitary matrix and I is the n-by-n identity matrix.

We define the operator $\tilde{c}_V^{(1)}$ to be the mapping that maps every mn-by-mn matrix A_{mn} to the minimizer of $\|W_{mn} - A_{mn}\|_F$ over all $W_{mn} \in \tilde{\mathcal{M}}_V^{(1)}$. We have the following theorem, which is similar to Theorem 1.

THEOREM 2. *For any arbitrary mn-by-mn complex matrix A_{mn} partitioned as in* (4), *let $\tilde{c}_V^{(1)}(A_{mn})$ be the minimizer of $\|W_{mn} - A_{mn}\|_F$ over all $W_{mn} \in \tilde{\mathcal{M}}_V^{(1)}$. Then*

(i) *$\tilde{c}_V^{(1)}(A_{mn})$ is uniquely determined by A_{mn} and is given by*

$$\tilde{c}_V^{(1)}(A_{mn}) = (V \otimes I)^* \tilde{\delta}^{(1)} \left[(V \otimes I) A_{mn} (V \otimes I)^*\right] (V \otimes I). \tag{13}$$

(ii) *We have*

$$\sigma_{\max}\left(\tilde{c}_V^{(1)}(A_{mn})\right) \le \sigma_{\max}(A_{mn}).$$

(iii) *If A_{mn} is Hermitian, then $\tilde{c}_V^{(1)}(A_{mn})$ is also Hermitian and*

$$\lambda_{\min}(A_{mn}) \le \lambda_{\min}\left(\tilde{c}_V^{(1)}(A_{mn})\right) \le \lambda_{\max}\left(\tilde{c}_V^{(1)}(A_{mn})\right) \le \lambda_{\max}(A_{mn}) \ .$$

In particular, if A_{mn} is positive definite, then $\tilde{c}_V^{(1)}(A_{mn})$ is also positive definite.

(iv) *The operator $\tilde{c}_V^{(1)}$ is a linear projection operator from the set of all mn-by-mn complex matrices into $\tilde{\mathcal{M}}_V^{(1)}$ and has the operator norms*

$$\|\tilde{c}_V^{(1)}\|_2 = \|\tilde{c}_V^{(1)}\|_F = 1.$$

The proof of Theorem 2 is quite similar to that of Theorem 1, so we omit it here. We note, however, that Theorem 2 (ii)–(iv) can be proved easily by using the following relationship between $c_U^{(1)}$ and $\tilde{c}_V^{(1)}$.

LEMMA 3. *Let U be any given unitary matrix and P be the permutation matrix defined in* (8). *Then for any arbitrary mn-by-mn complex matrix A_{mn} partitioned as in* (4), *we have*

$$\delta^{(1)}(A_{mn}) = P \tilde{\delta}^{(1)}(P^* A_{mn} P) P^*$$

and

$$c_U^{(1)}(A_{mn}) = P \tilde{c}_U^{(1)}(P^* A_{mn} P) P^*.$$

Proof. To prove the first equality, we note that by the definition of $\tilde{\delta}^{(1)}$ and (8), we have

$$\begin{aligned}
[\tilde{\delta}^{(1)}(P^* A_{mn} P)]_{k,l;i,j} &= \begin{cases} (P^* A_{mn} P)_{k,l;i,j}, & i = j \ , \\ 0, & i \neq j \ , \end{cases} \\
&= \begin{cases} (A_{mn})_{i,j;k,l}, & i = j \ , \\ 0, & i \neq j \ . \end{cases}
\end{aligned}$$

Hence

$$[P\tilde{\delta}^{(1)}(P^*A_{mn}P)P^*]_{i,j;k,l} = [\tilde{\delta}^{(1)}(P^*A_{mn}P)]_{k,l;i,j} = \begin{cases} (A_{mn})_{i,j;k,l}, & i = j\ , \\ 0, & i \neq j\ , \end{cases}$$

which by definition is equal to $[\delta^{(1)}(A_{mn})]_{i,j;k,l}$.

To prove the second equality, we first note that

$$(I \otimes U)P = P(U \otimes I)$$

for any matrix U. Hence by (13) and (9), we have

$$\begin{aligned} P\tilde{c}_U^{(1)}(P^*A_{mn}P)P^* &= P(U \otimes I)^*\tilde{\delta}^{(1)}[(U \otimes I)P^*A_{mn}P(U \otimes I)^*](U \otimes I)P^* \\ &= (I \otimes U)^*P\tilde{\delta}^{(1)}[P^*(I \otimes U)A_{mn}(I \otimes U)^*P]P^*(I \otimes U) \\ &= (I \otimes U)^*\delta^{(1)}[(I \otimes U)A_{mn}(I \otimes U)^*](I \otimes U) = c_U^{(1)}(A_{mn}). \end{aligned}$$ □

2.3. Operator $c_{V,U}^{(2)}$. Intuitively, $c_U^{(1)}(A_{mn})$ and $\tilde{c}_V^{(1)}(A_{mn})$ resemble the diagonalization of A_{mn} along one specific direction. It is then natural to consider the matrix that results from diagonalization along both directions. Thus let $c_{V,U}^{(2)}$ denote the composite of the two operators, i.e., $c_{V,U}^{(2)} \equiv \tilde{c}_V^{(1)} \circ c_U^{(1)}$. The following lemma will be used to derive the properties of the operator $c_{V,U}^{(2)}$.

LEMMA 4. *For any given A_{mn} partitioned as in* (4), *we have*

$$(14) \qquad (I \otimes U)^*\tilde{\delta}^{(1)}(A_{mn})(I \otimes U) = \tilde{\delta}^{(1)}[(I \otimes U)^*A_{mn}(I \otimes U)]$$

and

$$(15) \qquad (V \otimes I)\delta^{(1)}(A_{mn})(V \otimes I)^* = \delta^{(1)}[(V \otimes I)A_{mn}(V \otimes I)^*]\ .$$

Furthermore,

$$(16) \qquad \tilde{\delta}^{(1)} \circ \delta^{(1)}(A_{mn}) = \delta(A_{mn}) = \delta^{(1)} \circ \tilde{\delta}^{(1)}(A_{mn})\ .$$

The proof of Lemma 4 is straightforward, so we omit it here. By using Lemma 4, we can prove the following theorem, which states that the operator $c_{V,U}^{(2)}$ is just a particular case of the point operator.

THEOREM 3. *For any given A_{mn} partitioned as in* (4), *we have*

$$c_{V,U}^{(2)}(A_{mn}) = c_{V\otimes U}(A_{mn})\ ,$$

where $c_{V\otimes U}$ is the point operator defined in Lemma 1.

Proof. For any given A_{mn}, by definitions of $c_U^{(1)}$ and $\tilde{c}_V^{(1)}$, we have

$$\begin{aligned} c_{V,U}^{(2)}(A_{mn}) =& \tilde{c}_V^{(1)}[c_U^{(1)}(A_{mn})] \\ =& (V \otimes I)^*\tilde{\delta}^{(1)}\big\{(V \otimes I)\big[(I \otimes U)^*\delta^{(1)}[(I \otimes U)A_{mn}(I \otimes U)^*](I \otimes U)\big] \\ & \times (V \otimes I)^*\big\}(V \otimes I) \\ =& (V \otimes I)^*\tilde{\delta}^{(1)}\big\{(I \otimes U)^*(V \otimes I)\delta^{(1)}[(I \otimes U)A_{mn}(I \otimes U)^*] \\ & \times (V \otimes I)^*(I \otimes U)\big\}(V \otimes I). \end{aligned}$$

Hence by (14), (15), and (16), we have

$$\begin{aligned} c^{(2)}_{V,U}(A_{mn}) &= (V \otimes U)^* \tilde{\delta}^{(1)}\{\delta^{(1)}[(V \otimes U)A_{mn}(V \otimes U)^*]\}(V \otimes U) \\ &= (V \otimes U)^* \delta[(V \otimes U)A_{mn}(V \otimes U)^*](V \otimes U) = c_{V\otimes U}(A_{mn}) \,. \qquad \Box \end{aligned}$$

Since $c^{(2)}_{V,U}$ is just another point operator, we will concentrate our discussion on $c^{(1)}_U$ and $\tilde{c}^{(1)}_V$ in the remainder of the paper. We remark that $c^{(2)}_{V,U}(A_{mn})$ is an approximation of A_{mn} in two directions, whereas $c^{(1)}_U(A_{mn})$ and $\tilde{c}^{(1)}_V(A_{mn})$ are approximations in one direction only (with the other direction being approximated exactly). Thus we expect that the $c^{(1)}_U(A_{mn})$ and $\tilde{c}^{(1)}_V(A_{mn})$ are better preconditioners than $c^{(2)}_{V,U}(A_{mn})$. This is confirmed by the numerical results in §5.

We now give two simple formulae for finding $c^{(1)}_U(A_{mn})$ and $\tilde{c}^{(1)}_V(A_{mn})$ in the case where U and V are just the Fourier matrix F. When $U = F$, we have by (10),

$$(17) \qquad c^{(1)}_F(A_{mn}) = \begin{bmatrix} c_F(A_{1,1}) & c_F(A_{1,2}) & \cdots & c_F(A_{1,m}) \\ c_F(A_{2,1}) & c_F(A_{2,2}) & \cdots & c_F(A_{2,m}) \\ \vdots & \ddots & \ddots & \vdots \\ c_F(A_{m,1}) & c_F(A_{m,2}) & \cdots & c_F(A_{m,m}) \end{bmatrix},$$

where each block $c_F(A_{i,j})$ is Chan's circulant preconditioner for $A_{i,j}$.

Next we find $\tilde{c}^{(1)}_F(A_{mn})$ by using Lemma 3. We first let $A_{mn} = P^* B_{mn} P$ and partition B_{mn} into n^2 blocks with each block $B_{i,j}$ an m-by-m matrix. Then by Lemma 3 and (17), we have

$$[\tilde{c}^{(1)}_F(A_{mn})]_{i,j;k,l} = [P^* c^{(1)}_F(B_{mn})P]_{i,j;k,l} = [c^{(1)}_F(B_{mn})]_{k,l;i,j} = (c_F(B_{i,j}))_{kl},$$

where $B_{i,j}$ is the (i,j)th block of the matrix B_{mn}. By (2), we see that the (k,l)th entry of the circulant matrix $c_F(B_{i,j})$ is given by

$$(c_F(B_{i,j}))_{kl} = \frac{1}{m} \sum_{p-q \equiv k-l \pmod m} (B_{i,j})_{pq}.$$

Since $(B_{i,j})_{pq} = (A_{p,q})_{ij}$, we have

$$[\tilde{c}^{(1)}_F(A_{mn})]_{i,j;k,l} = \frac{1}{m} \sum_{p-q \equiv k-l \pmod m} (A_{p,q})_{ij}, \quad 1 \le i,j \le n, \quad 1 \le k,l \le m.$$

Thus the (k,l)th block of $\tilde{c}^{(1)}_F(A_{mn})$ is given by $\frac{1}{m}\sum_{p-q\equiv k-l \pmod m}(A_{pq})$. Since it depends only on $k-l \pmod m$, we see that $\tilde{c}^{(1)}_F(A_{mn})$ is a block-circulant matrix. Using the definition of the matrix Q in (3), we have

$$\tilde{c}^{(1)}_F(A_{mn}) = \frac{1}{m} \sum_{j=0}^{m-1} \left(Q^j \otimes \sum_{p-q \equiv j \pmod m} A_{p,q} \right).$$

3. Block preconditioners for block systems. In this section, we consider the cost of solving block systems $A_{mn}x = b$ by the preconditioned conjugate gradient method with preconditioner $c^{(1)}_F(A_{mn})$. The analysis for $\tilde{c}^{(1)}_F(A_{mn})$ is similar. We first recall that in each iteration of the preconditioned conjugate gradient method, we have to compute the matrix-vector multiplication $A_{mn}v$ for some vector v and solve the system

$$(18) \qquad c^{(1)}_F(A_{mn})y = d$$

for some vector d (see Golub and Van Loan [12]).

3.1. General matrices. Let A_{mn} be a general mn-by-mn matrix. We note that by (9), the solution to (18) is given by

$$y = (I \otimes F)^* \left[\delta^{(1)}\left((I \otimes F)A_{mn}(I \otimes F)^*\right)\right]^{-1}(I \otimes F)d \, . \tag{19}$$

Hence before we start the iteration, we should form the matrix

$$\Delta \equiv \delta^{(1)}\left((I \otimes F)A_{mn}(I \otimes F)^*\right)$$

and compute its inverse. We note that by (17), the (i,j)th block of Δ is just $Fc_F(A_{i,j})F^*$. By (1), $Fc_F(A_{i,j})F^* = \delta(FA_{i,j}F^*)$ and hence it can be computed in n^2 operations and one FFT (see Chan, Jin, and Yeung [3]). Thus the cost of obtaining Δ is $O(m^2n^2)$ operations. Next we compute its inverse.

We first permute the matrix Δ by P to obtain

$$B_{mn} = P^*\Delta P = \begin{bmatrix} B_{1,1} & 0 & \cdots & 0 \\ 0 & B_{2,2} & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & B_{n,n} \end{bmatrix} .$$

We then compute the LU decompositions for all diagonal blocks $B_{k,k}$. That will take $O(nm^3)$ operations. It requires a total of $O(n^2m^2 + nm^3)$ operations in the initialization step.

After obtaining the LU factors of Δ, we start the iteration. For a general dense matrix A_{mn}, $A_{mn}v$ can be computed in $O(n^2m^2)$. To get the vector y in (19), we note that by using the FFT, vectors of the form $(I \otimes F)d$ can be computed in $O(mn \log n)$ operations. Using the LU factors of Δ, $O(nm^2)$ operations are need to compute $\Delta^{-1}d$ for any vector d. The total cost per iteration is $O(mn \log n) + O(nm^2)$ operations.

Thus the algorithm for solving system $A_{mn}x = b$ for the general matrix A_{mn} requires $O(n^2m^2 + nm^3)$ operations in the initialization step and $O(n^2m^2)$ operations per iteration. Clearly, if A_{mn} is sparse, the cost can be reduced. In the next two subsections, we will consider two types of block systems where the cost can be drastically reduced.

Finally, we note that some of the block operations mentioned above can be done in parallel. For instance, the diagonal $\delta(FA_{i,j}F^*)$ of the blocks $c_F(A_{i,j})$ can be obtained in $O(n^2)$ parallel steps with $O(m^2)$ processors and the LU decompositions of the blocks B_{kk} in B_{mn} can also be computed in parallel. This can further reduce the cost per iteration.

3.2. Quadrantally symmetric block Toeplitz matrices. Let us consider the family of block Toeplitz systems $T_{mn}x = b$ where T_{mn} is of the form

$$T_{mn} = \begin{bmatrix} T_{1,1} & T_{1,2} & \cdots & T_{1,m} \\ T_{2,1} & T_{2,2} & \cdots & T_{2,m} \\ \vdots & \ddots & \ddots & \vdots \\ T_{m,1} & T_{m,2} & \cdots & T_{m,m} \end{bmatrix} = \begin{bmatrix} T_{(0)} & T_{(1)} & \cdots & T_{(m-1)} \\ T_{(1)} & T_{(0)} & \cdots & T_{(m-2)} \\ \vdots & \ddots & \ddots & \vdots \\ T_{(m-1)} & T_{(m-2)} & \cdots & T_{(0)} \end{bmatrix} . \tag{20}$$

Here the blocks $T_{i,j} = T_{(|i-j|)}$ are themselves symmetric Toeplitz matrices of order n. Such T_{mn} are called quadrantally symmetric block Toeplitz matrices.

By (17), the blocks of $c_F^{(1)}(T_{mn})$ are just $c_F(T_{(k)})$. Hence by (2) and the fact that $T_{(k)}$ is Toeplitz, the diagonal $\delta(FT_{(k)}F^*)$ can be computed in $O(n \log n)$ operations. Therefore, we need $O(mn \log n)$ operations to form $\Delta = \delta^{(1)}\big((I \otimes F)T_{mn}(I \otimes F)^*\big)$. We emphasize that in this case, there is no need to compute the LU factors of Δ. In fact,

$$P^* \Delta P = \begin{bmatrix} \tilde{T}_{1,1} & 0 & \cdots & 0 \\ 0 & \tilde{T}_{2,2} & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & \tilde{T}_{n,n} \end{bmatrix},$$

where

$$(\tilde{T}_{k,k})_{ij} = \big(\delta(FT_{i,j}F^*)\big)_{kk} = \big(\delta(FT_{(|i-j|)}F^*)\big)_{kk}, \quad 1 \le i,j \le m, \quad 1 \le k \le n.$$

Hence we see that the diagonal blocks $\tilde{T}_{k,k}$ are still symmetric Toeplitz matrices of order m. Therefore, it requires only $O(m \log^2 m)$ operations to compute $\tilde{T}_{k,k}^{-1}v$ for any vector v (see Ammar and Gragg [1]). Thus the system $c_F^{(1)}(T_{mn})y = d$ can be solved in $O(nm \log^2 m)$ operations.

Next we consider the cost of the matrix-vector multiplication $T_{mn}v$. We recall that for any Toeplitz matrix $T_{(k)}$, the matrix-vector multiplication $T_{(k)}w$ can be computed by the FFT by first embedding $T_{(k)}w$ into a $2n$-by-$2n$ circulant matrix and extending w to a $2n$-vector by zeros. For the matrix-vector product $T_{mn}v$, we can use the same trick. We first embed T_{mn} into a (blockwise) $2m$-by-$2m$ block-circulant matrix where each block itself is a $2n$-by-$2n$ circulant matrix. Then we extend v to a $4mn$-vector by putting zeros in the appropriate places. Using FFT, or more precisely using $(F_{2m} \otimes F_{2n})$ to diagonalize the $2m$-by-$2m$ block-circulant matrix, we see that $T_{mn}v$ can be obtained in $O(mn(\log m + \log n))$ operations.

Thus we conclude that the initialization cost in this case is $O(mn \log n)$ and the cost per iteration is $O(nm \log^2 m + mn \log n)$. We emphasize that if $m > n$, then one should consider using $\tilde{c}_F^{(1)}(A_{mn})$ as preconditioner instead.

3.3. Separable matrices. Consider the following system $(A_m \otimes B_n)x = b$ where A_m is an m-by-m nonsingular matrix and B_n is an n-by-n Hermitian positive definite matrix. This system arises in solving the inverse heat problem in two dimensions (see Chan [7]). Since $\delta^{(1)}(A_m \otimes B_n) = A_m \otimes \delta(B_n)$, it follows that

$$c_F^{(1)}(A_m \otimes B_n) = A_m \otimes c_F(B_n).$$

Thus the preconditioned system becomes

$$(A_m \otimes c_F(B_n))^{-1}(A_m \otimes B_n)x = (A_m \otimes c_F(B_n))^{-1}b$$

or

$$(I \otimes c_F(B_n)^{-1}B_n)x = (A_m^{-1} \otimes c_F^{-1}(B_n))b.$$

For general B_n, $c_F(B_n)$ can be obtained in $O(n^2)$ operations and $c_F(B_n)^{-1}y$ can be obtained in $O(n \log n)$ operations for any vector y. By decomposing A_m into its LU factors first, we can then generate the new right-hand side vector

$$(A_m^{-1} \otimes c_F^{-1}(B_n))b = (A_m^{-1} \otimes I)(I \otimes c_F^{-1}(B_n))b$$

in $O(m^3+m^2n+mn\log n+n^2)$ operations. In each subsequent iteration, the matrix-vector multiplication $(I\otimes c_F(B_n)^{-1}B_n)v$ can be done in $O(mn\log n+mn^2)$ operations.

When B_n is a Hermitian positive definite Toeplitz matrix, $c_F(B_n)$ can be obtained in $O(n)$ operations. Hence the initialization cost is reduced to $O(m^3+m^2n+mn\log n)$. Moreover, since the cost of multiplying B_ny becomes $O(n\log n)$, we see that the cost per iteration decreases to $O(mn\log n)$.

4. Convergence rate.

In this section, we analyze the convergence rate of the preconditioned conjugate gradient method when applied to solving some special block systems.

4.1. Quadrantally symmetric block Toeplitz matrices.

Let us consider the system $T_{mn}x=b$ where T_{mn} is a quadrantally symmetric block Toeplitz matrix given by (20). Let the entries of the block $T_{(j)}$ be denoted by $t_{pq}^{(j)}=t_{|p-q|}^{(j)}$ for $1\le p,q\le n, 0\le j<m$. We assume that the generating sequence $t_k^{(j)}$ of T_{mn} is absolutely summable, i.e.,

$$\sum_{j=0}^{\infty}\sum_{k=0}^{\infty}|t_k^{(j)}|\le K<\infty\ .$$

In order to analyze the distribution of the eigenvalues of $T_{mn}-c_F^{(1)}(T_{mn})$, we need to introduce Strang's circulant preconditioner. For each $T_{(j)}$, Strang's preconditioner $s_F(T_{(j)})$ is defined to be the circulant matrix obtained by copying the central diagonals of $T_{(j)}$ and bringing them around to complete the circulant. More precisely, the entries $s_{pq}^{(j)}=s_{|p-q|}^{(j)}$ of $s_F(T_{(j)})$ are given by

$$s_k^{(j)}=\begin{cases} t_k^{(j)}, & 0\le k\le r,\\ t_{n-r}^{(j)}, & r\le k<n.\end{cases} \tag{21}$$

Here, for simplicity, we have assumed that $n=2r$. Define

$$s_F^{(1)}(T_{mn})=\begin{bmatrix} s_F(T_{(0)}) & s_F(T_{(1)}) & \cdots & s_F(T_{(m-1)})\\ s_F(T_{(1)}) & s_F(T_{(0)}) & \cdots & s_F(T_{(m-2)})\\ \vdots & \ddots & \ddots & \vdots\\ s_F(T_{(m-1)}) & s_F(T_{(m-2)}) & \cdots & s_F(T_{(0)})\end{bmatrix}. \tag{22}$$

We prove below that the matrices $c_F^{(1)}(T_{mn})$ and $s_F^{(1)}(T_{mn})$ are asymptotically the same.

LEMMA 5. *Let T_{mn} be given by* (20) *with an absolutely summable generating sequence. Then for all $m>0$,*

$$\lim_{n\to\infty}\|s_F^{(1)}(T_{mn})-c_F^{(1)}(T_{mn})\|_1=0.$$

Proof. Let $B_{mn}\equiv s_F^{(1)}(T_{mn})-c_F^{(1)}(T_{mn})$. By (17) and (22), we see that the block $B_{(j)}$ of B_{mn} are given by $s_F(T_{(j)})-c_F(T_{(j)})$. Hence by (2) and (21) they are circulant, with entries $b_{pq}^{(j)}=b_{|p-q|}^{(j)}$ given by

$$b_k^{(j)}=\begin{cases} \dfrac{k}{n}(t_k^{(j)}-t_{n-k}^{(j)}), & 0\le k\le r,\\ \dfrac{n-k}{n}(t_{n-k}^{(j)}-t_k^{(j)}), & r\le k<n.\end{cases}$$

Thus

$$\|B_{mn}\|_1 \le 2\sum_{j=0}^{m-1}\|B_{(j)}\|_1 \le 2\sum_{j=0}^{m-1}\sum_{k=0}^{n-1}|b_k^{(j)}| \le 4\sum_{j=0}^{m-1}\sum_{k=1}^{r}\frac{k}{n}|t_k^{(j)}| + 4\sum_{j=0}^{m-1}\sum_{k=r+1}^{n-1}|t_k^{(j)}|.$$

For all $\varepsilon > 0$, since the generating sequence is absolutely summable, we can always find an $N_1 > 0$ and an $N_2 > 2N_1$ such that

$$\sum_{j=0}^{\infty}\sum_{k=N_1}^{\infty}|t_k^{(j)}| < \varepsilon \quad\text{and}\quad \frac{1}{N_2}\sum_{j=0}^{\infty}\sum_{k=1}^{N_1}k|t_k^{(j)}| < \varepsilon.$$

Thus for all $n > N_2$,

$$\|B_{mn}\|_1 \le \frac{4}{N_2}\sum_{j=0}^{\infty}\sum_{k=1}^{N_1}k|t_k^{(j)}| + 4\sum_{j=0}^{\infty}\sum_{k=N_1+1}^{r}|t_k^{(j)}| + 4\sum_{j=0}^{\infty}\sum_{k=r+1}^{\infty}|t_k^{(j)}| < 12\varepsilon\,. \qquad \square$$

In view of Lemma 5 and the following equality,

$$T_{mn} - c_F^{(1)}(T_{mn}) = \left(s_F^{(1)}(T_{mn}) - c_F^{(1)}(T_{mn})\right) + \left(T_{mn} - s_F^{(1)}(T_{mn})\right)\,,$$

we see that the spectra of $T_{mn} - c_F^{(1)}(T_{mn})$ and $T_{mn} - s_F^{(1)}(T_{mn})$ are asymptotically the same. However, it is easier to obtain spectral information about the second matrix, as the following lemma shows.

LEMMA 6. *Let T_{mn} be given by* (20) *with an absolutely summable generating sequence. Then for all $\varepsilon > 0$, there exists an $N_3 > 0$ such that for all $n > N_3$ and $m > 0$,*

$$s_F^{(1)}(T_{mn}) - T_{mn} = W_{mn}^{(N_3)} + U_{mn}^{(N_3)},$$

where $\|W_{mn}^{(N_3)}\|_1 \le \varepsilon$ and $\operatorname{rank}(U_{mn}^{(N_3)}) \le 2N_3m$.

Proof. Define $W_{mn} \equiv s_F^{(1)}(T_{mn}) - T_{mn}$. It is clear from (21) that its blocks $W_{(j)} \equiv s_F(T_{(j)}) - T_{(j)}$ are symmetric Toeplitz matrices with entries $w_{pq}^{(j)} = w_{|p-q|}^{(j)}$ given by

$$w_k^{(j)} = \begin{cases} 0, & 0 \le k \le r\,, \\ t_{n-k}^{(j)} - t_k^{(j)}, & r < k < n\,. \end{cases}$$

For all $\varepsilon > 0$, since the generating sequence is absolutely summable, there exists an $N_3 > 0$ such that $\sum_{j=0}^{\infty}\sum_{k=N_3}^{\infty}|t_k^{(j)}| < \varepsilon$. Corresponding to this N_3, we define for each block $W_{(j)}$, the n-by-n matrix

$$W_{(j)}^{(N_3)} = \begin{bmatrix} \tilde{W}_{(j)} & 0 \\ 0 & 0 \end{bmatrix}\,,$$

where $\tilde{W}_{(j)}$ is the $(n - N_3)$-by-$(n - N_3)$ principal submatrix of $W_{(j)}$. Clearly, each $\tilde{W}_{(j)}$ is a Toeplitz matrix. Let $U_{(j)}^{(N_3)} \equiv W_{(j)} - W_{(j)}^{(N_3)}$ for all j. We note that $U_{(j)}^{(N_3)}$ is nonzero only in the last N_3 rows and N_3 columns; therefore, $\operatorname{rank}(U_{(j)}^{(N_3)}) \le 2N_3$.

Let

$$W_{mn}^{(N_3)} = \begin{bmatrix} W_{(0)}^{(N_3)} & W_{(1)}^{(N_3)} & \cdots & W_{(m-1)}^{(N_3)} \\ W_{(1)}^{(N_3)} & W_{(0)}^{(N_3)} & \cdots & W_{(m-2)}^{(N_3)} \\ \vdots & \ddots & \ddots & \vdots \\ W_{(m-1)}^{(N_3)} & W_{(m-2)}^{(N_3)} & \cdots & W_{(0)}^{(N_3)} \end{bmatrix} \tag{23}$$

and

$$U_{mn}^{(N_3)} = \begin{bmatrix} U_{(0)}^{(N_3)} & U_{(1)}^{(N_3)} & \cdots & U_{(m-1)}^{(N_3)} \\ U_{(1)}^{(N_3)} & U_{(0)}^{(N_3)} & \cdots & U_{(m-2)}^{(N_3)} \\ \vdots & \ddots & \ddots & \vdots \\ U_{(m-1)}^{(N_3)} & U_{(m-2)}^{(N_3)} & \cdots & U_{(0)}^{(N_3)} \end{bmatrix} .$$

Then $s_F^{(1)}(T_{mn}) - T_{mn} = W_{mn}^{(N_3)} + U_{mn}^{(N_3)}$. Since each block $U_{(j)}^{(N_3)}$ in $U_{mn}^{(N_3)}$ is an n-by-n matrix where the leading $(n - N_3)$-by-$(n - N_3)$ principal submatrix is a zero matrix, it is easy to see that $\text{rank}(U_{mn}^{(N_3)}) \le 2N_3 m = O(m)$. For $W_{mn}^{(N_3)}$, we have by (23) that

$$\begin{aligned} \|W_{mn}^{(N_3)}\|_1 &\le 2\sum_{j=0}^{m-1} \|W_{(j)}^{(N_3)}\|_1 = 2\sum_{j=0}^{m-1} \|\tilde{W}_{(j)}\|_1 \\ &= 2\sum_{j=0}^{m-1}\sum_{k=r+1}^{n-N_3-1} |w_k^{(j)}| = 2\sum_{j=0}^{m-1}\sum_{k=r+1}^{n-N_3-1} |t_{n-k}^{(j)} - t_k^{(j)}| \\ &\le 2\sum_{j=0}^{m-1}\sum_{k=N_3+1}^{n-N_3-1} |t_k^{(j)}| \le 2\sum_{j=0}^{\infty}\sum_{k=N_3}^{\infty} |t_k^{(j)}| < 2\varepsilon . \end{aligned}$$

□

Let $N = \max\{N_2, N_3\}$, where N_2 and N_3 are given in the proofs of Lemmas 5 and 6. Then for all $n > N$ and $m > 0$, we have

$$T_{mn} - c_F^{(1)}(T_{mn}) = M_{mn} + L_{O(m)} ,$$

where $M_{mn} = s_F^{(1)}(T_{mn}) - c_F^{(1)}(T_{mn}) + W_{mn}^{(N)}$ with $\|M_{mn}\|_1 < \varepsilon$ and $L_{O(m)} = U_{mn}^{(N)}$ with rank $(L_{O(m)}) = O(m)$. Since M_{mn} is symmetric, we have

$$\|M_{mn}\|_2 \le (\|M_{mn}\|_1 \|M_{mn}\|_\infty)^{1/2} = \|M_{mn}\|_1 < \varepsilon .$$

By using Cauchy's Interlace Theorem, we then have the following theorem.

THEOREM 4. *Let T_{mn} be given by* (20) *with an absolutely summable generating sequence. Then for all $\varepsilon > 0$, there exists an $N > 0$ such that for all $n > N$ and $m > 0$, at most $O(m)$ eigenvalues of $c_F^{(1)}(T_{mn}) - T_{mn}$ have absolute values exceeding ε.*

If T_{mn} is positive definite with the smallest eigenvalue $\lambda_{\min}(T_{mn}) \ge \delta > 0$, where δ is independent of m and n, then by Theorem 1 (iv), $\lambda_{\min}\big(c_F^{(1)}(T_{mn})\big) \ge \delta > 0$. Hence $\|\big(c_F^{(1)}(T_{mn})\big)^{-1}\|_2$ is uniformly bounded. By noting that

$$\big(c_F^{(1)}(T_{mn})\big)^{-1} T_{mn} = I - \big(c_F^{(1)}(T_{mn})\big)^{-1}\big(c_F^{(1)}(T_{mn}) - T_{mn}\big),$$

we then have the following immediate corollary.

COROLLARY 1. *Let T_{mn} be given by* (20) *with an absolutely summable generating sequence. If T_{mn} are positive definite for all m and n and $\lambda_{\min}(T_{mn}) \geq \delta > 0$, then for all $\varepsilon > 0$, there exists an $N > 0$ such that for all $n > N$ and $m > 0$, at most $O(m)$ eigenvalues of $\left(c_F^{(1)}(T_{mn})\right)^{-1} T_{mn} - I$ have absolute value larger than ε.*

As a consequence, the spectrum of $\left(c_F^{(1)}(T_{mn})\right)^{-1} T_{mn}$ is clustered around 1 except for at most $O(m)$ outlying eigenvalues. When the preconditioned conjugate gradient method is applied to solving the system $T_{mn}x = b$, Corollary 1 shows that the number of iterations will grow to a maximum similar to $O(m)$. We recall that in §3.2, the algorithm requires $O(mn \log n)$ operations in the initialization step and $O(mn \log^2 m + mn \log n)$ operations in each iteration. Thus the total complexity of the algorithm is bounded above by $O(m^2 n \log^2 m + m^2 n \log n)$.

We emphasize that for the quadrantally symmetric block Toeplitz systems we tested in §5, the number of iterations is independent of m and n and the complexity of the method is therefore $O(nm \log^2 m + nm \log n)$.

We remark again that when $m > n$, one should consider using the preconditioner $\tilde{c}_F^{(1)}(T_{mn})$ instead. Then, by repeating the whole argument we used, we can show that the preconditioned conjugate gradient method will converge in at most $O(n)$ steps for m sufficiently large. Hence the total complexity of the algorithm in this case is bounded above by $O(n^2 m \log^2 n + n^2 m \log m)$.

Before we close this subsection, we would like to point out that for the quadrantally symmetric block Toeplitz matrix T_{mn}, we can define the matrix $\tilde{s}_F^{(1)}(T_{mn})$ analogously to $\tilde{c}_V^{(1)}(T_{mn})$:

$$\tilde{s}_F^{(1)}(T_{mn}) = P^* s_F^{(1)}(P T_{mn} P^*) P,$$

where P is defined by (8). Then, as in §2.3, we can further define the doubly circulant block preconditioner $\tilde{s}_F^{(1)} \circ s_F^{(1)}(T_{mn})$. As remarked after the proof of Theorem 3, $\tilde{s}_F^{(1)} \circ s_F^{(1)}(T_{mn})$ is the approximation of T_{mn} in two directions. Therefore, it will not be a good preconditioner compared to either $s_F^{(1)}(T_{mn})$ or, in view of Lemma 5, $c_F^{(1)}(T_{mn})$. We finally remark that if Chan's preconditioner [6] is used in (22) instead of Strang's circulant preconditioner, then the corresponding doubly-circulant block preconditioner is the block preconditioner considered in Ku and Kuo [14].

4.2. Separable matrices. Next we consider the system $(A_m \otimes T_n)x = b$ where T_n is a Toeplitz matrix with generating function f, i.e., the diagonals of T_n are given by the Fourier coefficients $a_j(f)$ of f. More precisely, we have

$$(T_n)_{jk} = a_{j-k}(f), \qquad j, k = 1, 2, \cdots .$$

We assume that f is positive, 2π-periodic, and continuous, and denote T_n by $T_n(f)$. For such $T_n(f)$, we have the following result (see Chan and Yeung [4]).

LEMMA 7. *Let f be a positive, 2π-periodic, and continuous function. Then for all $\epsilon > 0$, there exist N and $M > 0$, such that for all $n > N$, at most M eigenvalues of the matrices $c_F^{-1}(T_n(f))T_n(f) - I_n$ have absolute values larger than ϵ.*

Since the preconditioned matrix is given by

$$\left[A_m \otimes c_F(T_n(f))\right]^{-1} \left(A_m \otimes T_n(f)\right) = I_m \otimes \left[c_F^{-1}(T_n(f)) T_n(f)\right],$$

it is clear that the number of distinct eigenvalues of the preconditioned matrix is the same as the number of distinct eigenvalues of $c_F^{-1}(T_n(f))T_n(f)$. In view of Lemma 7, we then see that for all $\epsilon > 0$, there exist N, $M > 0$, such that for all $n > N$ and $m > 0$, at most M distinct eigenvalues of the matrices $\{I_m \otimes [c_F^{-1}(T_n(f))T_n(f)]\} - I$ have absolute values large than ϵ. Thus the eigenvalues of the preconditioned matrix are clustered around 1 and hence the number of iterations required for convergence is a constant independent of n and m. Recalling the operation count in §3.3, the total complexity of the algorithm in this case is equal to $O(m^3 + nm^2 + mn \log n)$.

5. Numerical results.

In this section, we apply the preconditioned conjugate gradient method to the block systems we considered in §4. The stopping criteria for the method is set at

$$\frac{\|r_k\|_2}{\|r_0\|_2} < 10^{-7},$$

where r_k is the residual vector at the kth iteration. The right-hand side vector b is chosen to be the vector of all ones and the zero vector is the initial guess.

5.1. Quadrantally symmetric block Toeplitz matrices.

We consider T_{mn} of the form given in (20) with the diagonals of the blocks $T_{(j)}$ being given by $t_i^{(j)}$. Four different generating sequences were tested. They are

$$\text{(i)}\quad t_i^{(j)} = \frac{1}{(j+1)(|i|+1)^{1+0.1\times(j+1)}}, \qquad j \geq 0, \quad i = 0, \pm1, \pm2, \cdots,$$

$$\text{(ii)}\quad t_i^{(j)} = \frac{1}{(j+1)^{1.1}(|i|+1)^{1+0.1\times(j+1)}}, \qquad j \geq 0, \quad i = 0, \pm1, \pm2, \cdots,$$

$$\text{(iii)}\quad t_i^{(j)} = \frac{1}{(j+1)^{1.1} + (|i|+1)^{1.1}}, \qquad j \geq 0, \quad i = 0, \pm1, \pm2, \cdots,$$

$$\text{(iv)}\quad t_i^{(j)} = \frac{1}{(j+1)^{2.1} + (|i|+1)^{2.1}}, \qquad j \geq 0, \quad i = 0, \pm1, \pm2, \cdots.$$

The generating sequences (ii) and (iv) are absolutely summable while (i) and (iii) are not. Tables 1 and 2 show the number of iterations required for convergence. In all cases, we see that as $m = n$ increases, the number of iterations remains roughly a constant or increases very slowly for the preconditioned system with preconditioner $c_F^{(1)}(T_{mn})$ while it increases with other choices of preconditioners.

5.2. Separable matrices. We consider the separable block Toeplitz system $(\tilde{T}_m \otimes T_n)x = b$ where the diagonals of $\tilde{T}_m$ and T_n are given by $\tilde{t}_i = (|i|+1)^{-1}$ and $t_j = (|j|+1)^{-1.1}$, respectively, for $i, j = 0, \pm1, \pm2, \cdots$. We note that $\tilde{T}_m \otimes T_n$ is also a quadrantally symmetric block Toeplitz matrix with the generating sequence given by

$$t_j^{(i)} = \frac{1}{(i+1)(|j|+1)^{1.1}}, \quad i \geq 0, \quad j = 0, \pm1, \pm2, \cdots .$$

The preconditioner $c_F^{(1)}(\tilde{T}_m \otimes T_n)$ is given by $\tilde{T}_m \otimes c_F(T_n)$. Table 3 shows the number of iterations required for convergence. We notice that as $n = m$ increases, the number of iterations stays almost the same for the preconditioned system with preconditioner $c_F^{(1)}(\tilde{T}_m \otimes T_n)$ while it increases with other choices of preconditioners. We remark that since $\tilde{T}_m$ is a Toeplitz matrix, its inverse can be obtained in $O(m \log^2 m)$. Hence the total complexity of the algorithm is reduced to $O(mn \log^2 m + mn \log n)$.

EFFICIENT SOLUTION OF PARABOLIC EQUATIONS BY KRYLOV APPROXIMATION METHODS*

E. GALLOPOULOS† AND Y. SAAD‡

Abstract. This paper takes a new look at numerical techniques for solving parabolic equations by the method of lines. The main motivation for the proposed approach is the possibility of exploiting a high degree of parallelism in a simple manner. The basic idea of the method is to approximate the action of the evolution operator on a given state vector by means of a projection process onto a Krylov subspace. Thus the resulting approximation consists of applying an evolution operator of very small dimension to a known vector, which is, in turn, computed accurately by exploiting high-order rational Chebyshev and Padé approximations to the exponential. Because the rational approximation is only applied to a small matrix, the only operations required with the original large matrix are matrix-by-vector multiplications and, as a result, the algorithm can easily be parallelized and vectorized. Further parallelism is introduced by expanding the rational approximations into partial fractions. Some relevant approximation and stability issues are discussed. Some numerical experiments are presented with the method and its performance is compared with a few explicit and implicit algorithms.

1. Introduction.

In recent years there has been a resurgence of interest in explicit methods for solving parabolic partial differential equations (PDEs), motivated mainly by the desire to exploit the parallel and vector processing capabilities of new supercomputer architectures. The main attraction of explicit methods is their simplicity, since the basic operations involved in them are matrix-by-vector multiplications, which, in general, are rather easy to parallelize and vectorize. On the other hand, the stringent constraint on the size of the timesteps required to ensure stability reduces efficiency to such an extent that the use of implicit methods becomes almost mandatory when integrating on long time intervals. Implicit methods do not suffer from stability related restrictions but have another disadvantage: they require the solution of linear systems that are often large and sparse. For this reason implicit methods tend to be far more difficult to implement on parallel machines than their explicit counterparts, which only require matrix-by-vector multiplications. Thus the trade-off between the two approaches seems to be a large number of matrix-by-vector multiplications on the one hand, versus linear systems to solve on the other. For two-dimensional and, more important, for three-dimensional problems, methods of an explicit type might be attractive if implemented with care.

We next observe that in spite of the above conventional wisdom, the distinction between the explicit and implicit approaches is not always clear. Consider the simple system of ordinary differential equations $y' = Ay+f$. We first point out that if our only desire is to use matrix-by-vector products exclusively as operations with the matrix A, for example, for the purpose of exploiting modern architectures, then certainly standard explicit methods do not constitute the only possibility. For example, one may use an implicit scheme and solve the linear systems approximately by some iterative method, such as the conjugate gradient (CG) method, with no preconditioning or with diagonal preconditioning. When the accuracy required for each linear system is very low, then the method will be akin to an explicit scheme, although one of rather unusual type since its coefficients will vary at every step. As the accuracy required for the approximations increases, the method will start moving towards the family of purely implicit methods. Therefore, if we were to call any scheme that requires only matrix–vector products "explicit," then the borderline between the two approaches is not so well defined.

We would like to take advantage of this observation to develop schemes that are intermediate between explicit and implicit. In this paper we will use the term *polynomial approximation method* for any scheme for which the only operations required with the matrix A are matrix-by-vector multiplications. The number of such operations may vary from one step to another and may be large.

To derive such intermediate methods, we systematically explore the ways in which an approximation to the local behavior of the ordinary differential equations (ODEs) can be obtained by using polynomials in the operator A. Going back to the comparison sketched above, we note that the process involved in one single step of an implicit method is often simply an attempt to generate some approximation to the operation $\exp(\delta t\ A)v$ via a rational approximation to the evolution operator [52]. If a CG-like method is used to solve the linear systems arising in the implicit procedure, the result will be a polynomial scheme. Thus there are two phases of approximation: the first is obtaining a rational or polynomial approximation to the exponential, and the second is solving the linear systems by some iterative method. We would like to reduce these two phases to only one by attempting to directly approximate $\exp(\delta t\ A)v$. The basic idea is to project the exponential of the large matrix A into a small Krylov subspace.

To make the discussion more specific and introduce some notation, we consider the following linear parabolic PDE:

$$\begin{aligned} \frac{\partial u(x,t)}{\partial t} &= -Lu(x,t) + r(x), \qquad x \in \Omega, \\ u(x,0) &= u_0, \qquad x \in \Omega, \\ u(x,t) &= \sigma(x), \quad x \in \partial\Omega, \quad t > 0, \end{aligned} \tag{1.1}$$

where $-L$ is a second-order partial differential operator of the elliptic type, acting on functions defined on the open, bounded, and connected set Ω. Using a method of lines (MOL) approach, (1.1) is first discretized with respect to space variables, resulting in the system of, say, n ODEs

$$\frac{dw(t)}{dt} = -Aw(t) + r, \qquad w(0) = w_0. \tag{1.2}$$

Here w, r are vectors and A is a matrix of order n. For the remainder of our discussion, we will assume A to be time independent. In this situation the solution is explicitly given by

$$w(t) = A^{-1}r + e^{-tA}(w_0 - A^{-1}r). \tag{1.3}$$

If we let $\hat{w}(t) \equiv w(t) - A^{-1}r$, and accordingly, $\hat{w}_0 \equiv w_0 - A^{-1}r$, then (1.3) is equivalent to the following expression:

$$\hat{w}(t) = e^{-tA}\hat{w}_0.$$

Note that when $r = 0$, $w(t)$ is the same as $\hat{w}(t)$. An ideal one-step method would consist of a scheme of the form

$$\hat{w}(t + \delta) = e^{-\delta A}\hat{w}(t), \tag{1.4}$$

in which δ constitutes the timestep.

The basic operation in the above formula is the computation of the exponential of a given matrix times a vector. If we were able to perform this basic operation with high accuracy, we would have what is sometimes called a nonlinear one-step method [26], because it involves a nonlinear operation with the matrix A. We should stress that there is no need to actually evaluate the matrix exponential $\exp(-\delta A)$, but only its product with a given vector. This brings to mind an analogous situation for linear systems in which it is preferable to solve $Ax = b$ than to compute A^{-1} and then multiply the solution by b.

We point out that we follow an approach common in the literature [3], [42], putting the emphasis on the semidiscrete problem (1.2). As a result, our discussion of stability is purely from an ordinary differential equation point of view and is not concerned with the effect of space discretization errors and convergence. We establish conditions under which our methods, applied to the stiff system of ODEs (1.2), satisfy certain criteria of stability, which, in turn, is an important step toward any investigations of convergence. (See also [5] and [40].)

The Krylov subspace method presented here was introduced in [13] for general nonsymmetric matrices. However, similar ideas have been used previously in various ways in different applications for symmetric or skew-symmetric matrices. For example, recall the use of this basic idea in Park and Light [34] following the work by Nauts and Wyatt [30]. The idea of exploiting the Lanczos algorithm in order to evaluate terms of the exponential of Hamiltonian operators seems to have been first used in chemical physics by Nauts and Wyatt in the context of the recursive-residue-generation method [29]. More recently, Friesner, Tuckerman, Dornblaser, and Russo [9] have demonstrated that these techniques can be extended to solving nonlinear stiff differential equations. The approach developed in this paper is related to that of Gear and Saad [14] and Brown and Hindmarsh [1] on matrix-free methods in the Newton iteration of implicit multistep schemes. Our scheme uses a similar reduction of the underlying matrix but goes further in combining it with high-order approximation schemes for the reduced (exponential) operator. It is also related to the work of Nour-Omid [32], in which systems of ODEs are solved by first projecting into Krylov subspaces with an unsymmetric two-sided Lanczos process and then solving tridiagonal systems of ODEs, the approach of Tal-Ezer and Kosloff [46], and the work of Tal-Ezer [45] and Schaefer [41] on polynomial methods based on Chebyshev expansions. The idea of evaluating arbitrary functions of a Hermitian matrix with the use of the Lanczos algorithm has also been mentioned by van der Vorst [51]. The use of preconditioning for extending the stability interval of explicit methods, thus bringing them closer to fully implicit methods, has been discussed in [37] and [50]. Although our method works from a subspace, it does not suffer from some of the aspects of partitioning methods (see, for example, [55]). Partitioning methods rely on explicitly separating and treating differently the stiff and nonstiff parts. However, it is usually impractical to confine stiffness to a subsystem [4]. The Krylov method, on the other hand, relies on the nice convergence property of Krylov approximations to essentially reach a similar goal in an implicit manner [38]. The outermost eigenvalues, including the largest ones, will be well approximated by the Krylov subspace, so that the Krylov approximation to the matrix exponential will be accurate in those eigenvalues, thus accommodating stiffness. Note that there have been several recent efforts to design algorithms for the solution of time-dependent problems, some of which may be particularly suited to parallel processing; see [19], [21], [22], [43], [48], and [49] for a review. It should also be mentioned that the approach we are using to approximate and evaluate the exponential of the reduced operator has its roots in the work of Varga [52] and in previous work by the present authors and others; see §3 for details.

The structure of our paper is as follows. In §2 we formulate the Krylov subspace approximation algorithm and prove some a priori error bounds. In §3 we present a method for the accurate approximation of the exponential of the Hessenberg matrix produced in the course of the Arnoldi or Lanczos algorithm. In §4 we consider problems with time-dependent forcing and introduce two approaches to handle the integration of the nonhomogeneous term. We then proceed in §5 with a stability analysis of each approach in the context of the quadrature techniques used, leading to Theorem 5.3. In §6 we present numerical experiments for problems of varying difficulty and, finally, in §7, we offer concluding remarks.

2. Polynomial approximation and the use of Krylov subspaces.

In this section we consider using polynomial approximation to (1.4), that is, we seek an approximation of the form

$$e^{-A}v \approx p_{m-1}(A)v, \tag{2.1}$$

where p_{m-1} is a polynomial of degree $m-1$ and A and v are an order-n matrix and vector, respectively. There are several ways in which polynomial approximations can be found. The simplest technique is to attempt to minimize some norm of the error $e^{-z} - p_{m-1}(z)$ on a continuum in the complex plane that encloses the spectrum of A. For example, Chebyshev approximation can be used, but one disadvantage is that it requires some approximation to the spectrum of A. In this paper we consider only approaches that do not require any information on the spectrum of A. This will be considered in §2.1. A theoretical analysis then follows in §2.2.

2.1. The Krylov subspace approximation.

The approximation (2.1) to $e^{-A}v$ is to be taken from the Krylov subspace

$$K_m \equiv \text{span}\{v, Av, \cdots, A^{m-1}v\}.$$

In order to manipulate vectors in K_m, it is convenient to generate an orthonormal basis $V_m = [v_1, v_2, v_3, \cdots, v_m]$. We take as initial vector $v_1 = v/\|v\|_2$ and generate the basis V_m with the well-known Arnoldi algorithm, described below.

ALGORITHM: ARNOLDI.

```
1. Initialize:
   Compute $v_1 := v/\|v\|_2$.
```

```
2. Iterate: Do $j = 1, 2, \cdots, m$.
    1. Compute $w := Av_j$.
    2. Do $i = 1, 2, \cdots, j$.
        (a) Compute $h_{i,j} := (w, v_i)$.
        (b) Compute $w := w - h_{i,j}v_i$.
    3. Compute $h_{j+1,j} = \|w\|_2$ and $v_{j+1} = w/h_{j+1,j}$.
```

By construction, the above algorithm produces an orthonormal basis V_m of the Krylov subspace K_m, where $V_m = [v_1, v_2, \cdots, v_m]$. If we denote the $m \times m$ upper Hessenberg matrix consisting of the coefficients h_{ij} computed from the algorithm by H_m, we have the relation

$$AV_m = V_m H_m + h_{m+1,m} v_{m+1} e_m^{\mathrm{T}}. \tag{2.2}$$

For the remainder of this discussion, for any given k, e_k will denote the kth unit vector belonging to R^m. From the orthogonality of the columns of V_m we get that $H_m = V_m^{\mathrm{T}} A V_m$. Therefore H_m represents the projection of the linear transformation A to the subspace K_m, with respect to the basis V_m.

Since V_m is orthonormal, the vector $x_{\mathrm{opt}} = V_m V_m^{\mathrm{T}} e^{-A} v$ is the projection of $e^{-A}v$ on K_m, that is, it is the closest approximation to $\exp(-A)v$ from K_m. Since for $\beta \equiv \|v\|_2$, we can write $v = \beta v_1$ and $v_1 = V_m e_1$, it follows that

$$\begin{aligned} V_m V_m^{\mathrm{T}} e^{-A} v &= \beta V_m V_m^{\mathrm{T}} e^{-A} v_1 \\ &= \beta V_m V_m^{\mathrm{T}} e^{-A} V_m e_1. \end{aligned}$$

We can therefore write the optimal solution as $x_{\mathrm{opt}} \equiv V_m y_{\mathrm{opt}}$, where $y_{\mathrm{opt}} \equiv \beta V_m^{\mathrm{T}} e^{-A} V_m e_1$. Unfortunately, y_{opt} is not practically computable since it still involves e^{-A}. We can approximate $V_m^{\mathrm{T}} e^{-A} V_m$ by e^{-H_m}, leading to the approximation $y_{\mathrm{opt}} \approx \beta e^{-H_m} e_1$ and

$$e^{-A} v \approx \beta V_m e^{-H_m} e_1. \tag{2.3}$$

From the practical point of view there remains the issue of efficiently computing the vector $e^{-H_m} e_1$, which we address in §3.

The approximation (2.3) is central to our method, and its effectiveness is discussed throughout the remainder of the paper. The next section is devoted to providing the theoretical justification.

We also note that when A is symmetric, Arnoldi's algorithm simplifies into the Lanczos process, which entails a three-term recurrence. This is a result of the fact that the matrix $H_m = V_m^{\mathrm{T}} A V_m$ must be symmetric and therefore tridiagonal symmetric, and so all $h_{i,j} = 0$ for $i = 1, 2, \cdots, j-2$. However, the resulting vectors, which are in theory orthogonal to each other, tend to lose their orthogonality rapidly.

2.2. A priori error bounds and general theory. The next question that arises concerns the quality of the Krylov subspace approximation defined in §2.1. A first observation is that the above approximation is exact for $m = n$, because in this situation $v_{m+1} = 0$ and (2.2) becomes $AV_m = V_m H_m$, where V_m is an $n \times n$ orthogonal matrix. In fact, as with the conjugate gradient method and the Arnoldi process, the approximation is exact for m whenever m is larger than or equal to the degree of the minimal polynomial of v_1 with respect to A. As for these algorithms, we need to investigate what happens when m is much smaller than this degree.

In the sequel we need to use the concept of the *logarithmic norm* of a matrix. Let B be a given matrix. The logarithmic norm $\mu(.)$ is defined by

$$\mu(B) \equiv \lim_{h \to 0+} \frac{\|I + hB\| - 1}{h}.$$

Note that μ is associated with a particular norm. Unless it is otherwise specified, we assume that the reference norm is the usual two-norm. Then the logarithmic norm $\mu(B)$ is equal to the maximum eigenvalue of the symmetric part of B, that is,

$$\mu(B) = \lambda_{\max}\left(\frac{B + B^{\mathrm{T}}}{2}\right).$$

The function μ satisfies many norm-like properties, but it can also take negative values. We refer to [5] and [6] for a description of its properties. It can be shown in particular that

$$\|e^{Bt}\| \le e^{\mu(B)t}. \tag{2.4}$$

We assume throughout that A is a real matrix. We now state the main theorem of this section.

THEOREM 2.1. *Let A be any matrix and let $\rho \equiv \|A\|_2$, $\beta = \|v\|_2$, and $\eta \equiv \mu(-A)$. Then the error of the approximation* (2.3) *is such that*

$$\|e^{-A}v - \beta V_m e^{-H_m} e_1\|_2 \;\le\; 2\beta\rho^m \phi(\eta) \;\le\; 2\beta\frac{\rho^m}{m!}\max(1, e^{\eta}), \tag{2.5}$$

where

$$\phi(\eta) \equiv \frac{1}{\eta^m}\left(e^{\eta} - \sum_{k=0}^{m-1}\frac{\eta^k}{k!}\right).$$

The proof of the theorem is established in Appendix A.

To see what we can gain in using the logarithmic norm instead of a standard spectral norm, compare Theorem 2.1 with the bound proposed earlier in [13]:

$$\|e^{-A}v - \beta V_m e^{-H_m} e_1\|_2 \le 2\beta\frac{\rho^m e^{\rho}}{m!}. \tag{2.6}$$

For the sake of illustration, let

$$B = \begin{pmatrix} 0.5000 & -0.0938 & 0.0000 \\ -0.4063 & 0.5000 & -0.0938 \\ 0.0000 & -0.4063 & 0.5000 \end{pmatrix}$$

and let $A = I \otimes B + B \otimes I$, where $\otimes$ is the symbol for the Kronecker product, and I the identity matrix. Such an A arises after discretizing $-(u_{xx} + u_{yy}) + \xi(u_x + u_y)$ on the unit square with a grid distance of $\frac{1}{4}$ when $\xi = 5$ and after multiplying all coefficients of the discretization by the scale factor $\frac{1}{64}$ (e.g., representing a timestep). In that case $\mu(-A) = -0.2929$, whereas $\|A\|_2 = 1.7235$. When $m = 7$, the error in the approximation from (2.6) is bounded by 0.1004β, whereas Theorem 2.1 provides the sharper estimate 0.018β.

In general, the advantage of using the logarithmic norm follows from the inequality $\|A\| \geq \mu(-A)$, which is among the properties of $\mu(.)$ (cf. [6]). One can construct examples, however, for which the bounds from using $\mu(-A)$ are as loose as those obtained from using $\|A\|$ (cf. [5]). Also, asymptotically the rates of convergence as estimated by the bounds (2.6) and (2.5) are both of the form $\rho/(m!)^{1/m}$. The following corollary follows trivially from Theorem 2.1.

COROLLARY 2.2. *If the eigenvalues of the symmetric part of the matrix A are nonnegative, then*

$$\|e^{-A}v - \beta V_m e^{-H_m} e_1\|_2 \leq 2\beta \frac{\rho^m}{m!}.$$

Hence the bound of Corollary 2.2 holds for many important classes of matrices, including positive definite matrices and normal matrices with eigenvalues in the positive half-plane.

We note that when A is normal, the bound of Corollary 2.2 can be derived without invoking logarithmic norms because we can write $A = Q\Lambda Q^{\mathrm{H}}$ where Λ is the diagonal matrix of eigenvalues of A and Q is unitary. Let us denote the remainder after m terms of the Taylor series expansion of e^{-z} by $r_m(z)$. Then

$$\|r_m(A)\|_2 = \left\|\sum_{k=m}^{\infty} \frac{1}{k!}(-A)^k\right\|_2 = \left\|\sum_{k=m}^{\infty} \frac{1}{k!}(-\Lambda)^k\right\|_2 .$$

From the assumption on A, $\Re[\Lambda] \geq 0$. Applying componentwise a result of Landau [24] (cf. [36, p. 35, problem 151]), the remainder can be bounded by its first term:

$$\|r_m(A)\|_2 \leq \frac{\|-\Lambda^m\|_2}{m!} = \frac{\|A^m\|_2}{m!}.$$

The bound of Corollary 2.2 follows after using a similar treatment for H_m and combining the results as shown in Lemma A.1 of Appendix A.

When we know that A is symmetric positive definite, an even better bound can be obtained by applying the previous theory to $A-\zeta I$, where $\zeta \geq \lambda_{\min}(A)$ (the minimum eigenvalue of A). We refer to [12] for the proof.

THEOREM 2.3. *Let A be a symmetric positive definite matrix and let $\rho = \|A\|_2$ and $\beta = \|v\|_2$. Then the error of the approximation* (2.3) *is such that*

$$\|e^{-A}v - \beta V_m e^{-H_m} e_1\|_2 \leq \beta \frac{\rho^m}{2^{m-1} m!}. \tag{2.7}$$

These theorems show that in the nonstiff situation, which occurs at the beginning of the integration, the proposed method cannot be much worse than a more conventional explicit method. Experimental results in §6 show that in the stiff situation the actual errors are much smaller than suggested by the theorems. In the nonstiff region the theorems can serve as a guide to choosing the stepsize in a timestepping procedure. Indeed, if we were to replace A by the scaled matrix τA, then the Krylov subspace would remain the same, that is, V_m would not change and H_m would be scaled to τH_m. As a result, for arbitrary τ one can use the approximation

$$e^{-\tau A}v \approx \beta V_m e^{-\tau H_m} e_1, \tag{2.8}$$

and the bound (2.5) becomes

$$\|e^{-\tau A}v - \beta V_m e^{-\tau H_m} e_1\|_2 \leq 2\beta(\tau\rho)^m \phi(\mu(-\tau A)). \tag{2.9}$$

The consequence of (2.9) is that by reducing the stepsize one can always make the scheme accurate enough without changing the dimension m. We note that these bounds are most useful when m is much larger than what is usually used by standard explicit methods. Indeed, in our experiments, we have used large values of m to our advantage. We refer the reader to [39] for additional results on error bounds for this method.

3. Practical computation of $\exp(-H_m)e_1$.

We now address the problem of evaluating $y = e^{-H}e_1$, where H is the Hessenberg or tridiagonal matrix produced by Arnoldi's method or the Lanczos method. We drop the subscript m for convenience. Although H is a small matrix, the cost of computing y can easily become nonnegligible. See [28] for a review of methods for computing the matrix exponential. For example, when H is tridiagonal symmetric, the simplest technique for computing y is based on the QR algorithm. However, this is rather expensive. Therefore, we would like to use approximations that have high accuracy, possess desirable stability properties, and allow fast evaluation. The method we recommend is to use rational approximation to the exponential, evaluated by partial fraction expansion. This technique has been discussed in the context of implicit methods in [10] and [13], and we would like to take advantage of it in the present context. The (serial) complexity of the QR factorization algorithm is $O(m^3)$ for Hessenberg matrices and $O(m^2)$ for tridiagonal matrices, compared with a cost of $O(m^2)$ for Hessenberg and $O(m)$ for tridiagonal matrices when using the rational approximation method. In addition, parallelism can be exploited in this approach.

The rational approximation to the exponential has the form

$$e^{-z} \approx R_{\nu_1,\nu_2}(z) \equiv \frac{p_{\nu_1}(z)}{q_{\nu_2}(z)}, \tag{3.1}$$

where p_{ν_1} and q_{ν_2} are polynomials of degrees ν_1 and ν_2, respectively.

An approximation of this type, referred to as a Padé approximation, is determined by matching the Taylor series expansion of the left-hand side and right-hand side of (3.1) at the origin. Since Padé approximations are local, they are very accurate near the origin but may be inaccurate far away from it. Other schemes have been developed [3], [18], [52] to overcome this difficulty. For typical parabolic problems that involve a second-order partial differential operator $-L$ that is self-adjoint elliptic, the eigenvalues of L are located in the interval $[0, +\infty)$. It is therefore natural to follow the idea introduced by Varga in [52] (see also [2] and [3]) and seek the Chebyshev (uniform) rational approximation to the function e^{-z}, which minimizes the maximum error on the interval $[0, +\infty)$. To unify the Padé and uniform approximation approaches, we restrict ourselves to "diagonal" approximations of the form (ν, ν), that is, in which the numerator has the same degree ν as the denominator. We note, however, that alternative strategies (e.g., $(\nu-1, \nu)$) frequently work better for Padé approximations without altering the principle of the method. Note that the stability properties of the aforementioned rational approximations are discussed extensively in the literature [7], [20], [54].

A comparison between the Padé approximation and the Chebyshev rational approximation reveals the vast superiority of the latter in the context of the Krylov-based methods presented in this paper, at least for symmetric positive definite matrices H and relatively large values of m. To see why this is so, we note that the idea of the method presented in this paper is to allow the use of large timesteps by utilizing Krylov subspaces of relatively high order. However, for our method to be successful, the ability to use a large timestep δ must also carry over to the computation of $\exp(-H\delta)e_1$. We mentioned earlier that the Padé approximations provide good approximation only near the origin. Using the Chebyshev rational approximation to the function e^{-z} over the interval $[0, +\infty)$ [2], [52], it becomes possible to utilize timesteps as large as our Krylov-based method allows.

For example, in the diagonal Chebyshev rational approximation, the infinity norm of the error over the interval $[0, +\infty)$ is of the order of 10^{-10} as soon as ν reaches 10. For each additional degree the improvement is of the order of $9.289025\cdots$ [2]. This means that for all practical purposes e^{-z} can be replaced by a rational function of relatively small degree. When H is nonsymmetric and its eigenvalues are complex, then the rational function is no longer guaranteed to be an accurate approximation to the exponential. Although a rigorous analysis is lacking, we experimentally verified that for the examples we treated, the approximation still remained remarkably accurate when the eigenvalues were near the positive real axis. Although little is known concerning rational uniform approximation in general regions of the complex plane, a promising alternative is to use asymptotically optimal methods based on Faber transformations in the complex plane [8]. We also point out that there exist other techniques for approximating matrix exponentials by rational functions of A; see, for example, [18] and [31]. The restricted Padé approximations of [31] avoid complex arithmetic at the price of a reduced order of approximation and reduced levels of parallelism caused by the occurrence of multiple poles.

For compactness of notation in the diagonal approximations we simply write R_ν from now on for the (ν, ν) rational approximation to e^{-z}. Then, in order to evaluate the corresponding approximation to $e^{-H}e_1$, we need to evaluate the vector $\tilde{y}$, where

$$\tilde{y} = p_\nu(H)q_\nu(H)^{-1}e_1 = q_\nu(H)^{-1}p_\nu(H)e_1. \tag{3.2}$$

It has been proposed in several contexts that an efficient method for computing some rational matrix functions is to resort to their partial fraction expansions [10], [11], [13], [23], [25], [33], [44], [56]. The approach is possible since it can be proved analytically that the diagonal Padé approximation to e^{-z} has distinct poles [57]. Explicit calculations indicate that this seems to be true for the uniform approximation as well. In particular, we write

$$R_\nu(z) = \alpha_0 + \sum_{i=1}^{\nu} \frac{\alpha_i}{z - \lambda_i},$$

where

$$\alpha_0 \equiv \frac{\pi_\nu}{\kappa_\nu} \quad \text{and} \quad \alpha_i \equiv \frac{p_\nu(\lambda_i)}{q'_\nu(\lambda_i)}, \qquad i = 1, 2, \cdots, \nu,$$

in which π_ν, κ_ν are the leading coefficients of the polynomials p_ν and q_ν, respectively.

With this expansion the algorithm for computing (3.2) becomes

```
ALGORITHM
1. For $i = 1, 2, \cdots, \nu$ solve $(H - \lambda_i I)y_i = e_1$.
```

2. Compute $\tilde{y} = \alpha_0 e_1 + \sum_{i=1}^{\nu} \alpha_i y_i$.

The motivation in [10] for using the above scheme was parallelism. The first step in the above algorithm is entirely parallel since the linear systems $(H - \lambda_i I)y_i = e_1$ can be solved independently from one another. The partial solutions are then combined in the second step. The matrices arising in [10] are large and sparse, unlike those here. However, parallel implementation of the above algorithm can be beneficial for small Hessenberg matrices as well. For example, in a parallel implementation of the Krylov scheme, the "Amdahl effect" may cause severe reduction in efficiency unless all stages of the computation are sufficiently parallelized.

We should also point out that even on a scalar machine, the above algorithm represents the best way of computing $\tilde{y}$. It requires fewer operations than a straightforward use of the expression (3.2). It is also far simpler to implement. The poles λ_i and partial fraction coefficients α_i of $R_\nu(z)$ are computed once and for all and coded in a subroutine or tabulated. These are shown in Appendix B for $\nu = 10$ and $\nu = 14$ for the case of Chebyshev rational approximation.

4. The case of a time-dependent forcing term. In the previous sections we made the restrictive assumption that the function r in the right-hand side is constant with respect to time. In this section we address the more general case where r is time dependent. In other words, we now consider the system of ODEs of the form

$$\frac{dw(t)}{dt} = -Aw(t) + r(t). \tag{4.1}$$

As is well known, the solution of this system is

$$w(t) = e^{-tA}w_0 + \int_0^t e^{(s-t)A} r(s)ds.$$

Proceeding as in §1, we now express $w(t+\delta)$ as

$$\begin{aligned} w(t+\delta) &= e^{-\delta A}\left(w(t) + \int_t^{t+\delta} e^{-(t-s)A} r(s)ds\right) \\ &= e^{-\delta A}w(t) + \int_t^{t+\delta} e^{-(\delta+t-s)A} r(s)ds \\ &= e^{-\delta A}w(t) + \int_0^{\delta} e^{-(\delta-\tau)A} r(t+\tau)d\tau. \end{aligned} \tag{4.2}$$

In one way or another, the use of the above expression as the basis for a timestepping procedure requires numerical integration. Note, however, that under the assumption that we can evaluate functions of the form $e^{-As}v$ accurately, we have transformed the initial problem into that of evaluating integrals. Simple though this statement may seem, it means that the concerns about stability disappear as soon as we consider that we are using accurate approximations to the exponential. This is because the variable w does not appear in the integrand. (The issue of stability will be examined in detail in §5.)

We will now address how to evaluate the integral in (4.2); for this we consider two distinct approaches.

4.1. The first approach. Consider a general quadrature formula of the form

$$\int_0^\delta e^{-(\delta-\tau)A} r(t+\tau)d\tau \approx \delta \sum_{j=1}^{p} \mu_j e^{-(\delta-\tau_j)A} r(t+\tau_j), \tag{4.3}$$

where the τ_j's are the quadrature nodes in the interval $[0,\delta]$. One of the simplest rules is the trapezoidal rule on the whole interval $[0,\delta]$, which leads to

$$\begin{aligned} w(t+\delta) &= e^{-\delta A} w(t) + \frac{\delta}{2} e^{-\delta A} r(t) + \frac{\delta}{2} r(t+\delta) \\ &= e^{-\delta A}\left[w(t) + \frac{\delta}{2} r(t)\right] + \frac{\delta}{2} r(t+\delta). \end{aligned}$$

The above formula is attractive because it requires only one evaluation of an exponential times a vector. On the other hand, it may be too inaccurate to be of any practical value since it means that we may have to reduce the stepsize δ drastically in order to get a good approximation to the integrals. The next alternative is to use a higher-order formula, that is, a larger p in (4.3). For example, we tried a Simpson formula instead of trapezoidal rule. The improvements are noticeable, but we have to pay the price of an additional exponential evaluation at the midpoint $t+\delta/2$.

The recommended alternative is again based on a judicious exploitation of Krylov subspaces. In the formula (4.3) we note that each term $e^{-(\delta-\tau_j)A} r(t+\tau_j)$ need not be evaluated exactly. Observe that in the ideal situation where $r(s)$ is constant (equal to r) in the interval $[t, t+\delta]$, then formula (2.8) shows that we can evaluate $e^{-(\delta-\tau)A} r$ for all τ from the Krylov subspace generated for $\tau = 0$ (for example) via

$$e^{-(\delta-\tau)A} r \approx \beta V_m e^{-(\delta-\tau)H_m} e_1,$$

where V_m and H_m correspond to the Krylov subspace $K_m(A, r)$. In the more general case where r varies in the interval $[t, t+\delta]$, we can use a projection formula of the form

$$e^{-(\delta-\tau)A} r(t+\tau) \approx V_m e^{-(\delta-\tau)H_m} V_m^{\mathrm{T}} r(t+\tau). \tag{4.4}$$

The combination of the quadrature formula (4.3) and formula (4.4) has been tested and was found to be remarkably accurate. These tests were conducted in the context of a slightly modified approach, discussed next.

4.2. The second approach. In the above approach we need to compute two Krylov subspaces: one associated with the current iterate $w(t)$ and the other associated with $r(t)$. We show that we can reduce the computation to only one Krylov subspace. The resulting algorithm has different numerical properties from the one presented in §4.1.

The main idea is to use the identity

$$e^{-\delta A} = I - A\int_0^\delta e^{-sA} ds = I - A \int_0^\delta e^{-(\delta-\tau)A} d\tau,$$

which is obtained readily by integration. This is then substituted in the first term of the right-hand side of equation (4.2) to obtain

$$w(t+\delta) = w(t) + \int_0^\delta e^{-(\delta-\tau)A}[r(t+\tau) - Aw(t)]d\tau. \tag{4.5}$$

Note the important fact that the term $e^{-\delta A}w(t)$, which was in the previously used formula (4.2), has been removed at the slight expense of modifying the function $r(t+\tau)$ in the interval $\tau \in (0, \delta)$. The modification consists of subtracting a vector that is *constant* in the interval of integration. In terms of computations, this modification requires one matrix-by-vector multiplication, certainly an inexpensive overhead compared with that of applying the propagation operator to a vector.

With this transformation at hand, we can now proceed in the same manner as for the first approach, combining Krylov projection and numerical quadrature. More precisely, we evaluate the term $v = r(t+\tau) - Aw(t)$ at some point τ in the interval, for example in the middle, i.e., for $\tau = \delta/2$. Then a Krylov subspace is computed with the initial vector $v_1 = v/\|v\|_2$ and a formula similar to (4.4) based on this Krylov subspace is used to approximate the terms inside the integrand of (4.5). The integration is then carried out in a similar way with the appropriate quadrature formulas. The numerical experiments in §6 will illustrate an implementation based on this strategy.

Our experiment in §6.4 shows an example of a rapidly varying forcing term $r(t)$, where the method can perform adequately with only one additional exponential evaluation (at the midpoint). We note, however, that for some highly oscillatory forcing terms, a (preferably adaptive) scheme involving additional exponential evaluations or a reduction of the timestep δ may be needed.

There is one fundamental difference between the scheme (4.2) used in the first approach and the scheme (4.5) of the second approach: the function w now figures in the integrand. This may mean completely different numerical properties and, as is shown in §5, the loss of the unconditional stability.

5. Stability. In this section we investigate the linear stability of the Krylov timestepping methods when used for the solution of the semidiscrete system (1.2). As noted in the introduction, this discussion will not take into account the interaction between space and time discretizations.

We first consider the stability properties of the approximate evolution operator $V_m e^{-H_m} V_m^T$ implicitly involved in (2.3). If A is positive real,[1] i.e., if its symmetric part $S = \frac{1}{2}(A + A^{\mathrm{T}})$ is positive definite, then so is the matrix H_m [35]. Moreover, the eigenvalues of A and H_m have positive real parts and the smallest eigenvalue $\lambda_{\min}(S)$ of the symmetric part of A is a lower bound for the eigenvalues of $S_m = \frac{1}{2}(H_m + H_m^{\mathrm{T}})$, because $S_m = V_m^{\mathrm{T}} S V_m$. In terms of logarithmic norms, $\mu(-H_m) \leq \mu(-A) \leq 0$; see also Lemma A.3 in Appendix A. Since V_m has orthonormal columns, the approximate evolution operator satisfies

$$\|V_m e^{-H_m \delta} V_m^T\|_2 \leq \|e^{-H_m \delta}\|_2.$$

As a result, we can state that in the case where $\exp(-H_m\delta)$ is evaluated exactly, then

$$\begin{aligned} \|V_m e^{-H_m \delta} V_m^T\|_2 &\leq \|e^{-H_m \delta}\|_2 \\ &\leq e^{\mu(-H_m\delta)} \leq e^{\mu(-A\delta)} \\ &\leq 1. \end{aligned}$$

If, on the other hand, $\exp(-H_m\delta)$ is not computed exactly, then stability will depend upon the method of evaluation used. In particular, let $\exp(-H_m\delta)$ be evaluated using a diagonal (ν, ν) Padé approximation R_ν. Diagonal Padé approximations are

[1] A matrix B is positive real if $x^{\mathrm{T}} B x > 0$ for any real vector $x \neq 0$ [53].

A-acceptable, that is, $|R_\nu(z)| < 1$ for all z in the positive half-plane [42]. From above, $\Re x^{\rm H} H_m x \geq 0$ for any x and $\mu(-H_m) \leq 0$. We then obtain

$$\|V_m R_\nu(H_m\delta)V_m^T\|_2 \leq \|R_\nu(H_m\delta)\|_2 \leq 1$$

from a result of von Neumann, which states that, when the field of values of a matrix B is contained in $\mathcal{H}$ (the nonnegative half of the complex plane) and if a rational function f maps $\mathcal{H}$ into the unit disk, then $\|f(B)\|_2 \leq 1$; see also [47] and [15, Thm. 4]. A similar conclusion holds for the subdiagonal $(\nu-1, \nu)$ approximation. When a diagonal Chebyshev approximation is used this no longer holds, as these approximations may amplify small eigenvalues of H_m near zero. We can state only that for symmetric positive definite matrices and large enough values of ν, and $\delta\lambda_{\min}(H_m)$ bounded away from zero, $\|V_m R_\nu(H_m\delta)V_m^T\|_2 \leq 1$.

For the remainder of this section we assume that the exponential terms $\exp(-H_m\delta)$ are computed exactly.

5.1. Stability behavior of the first approach.

Consider a general solution scheme for (4.1) of the form

$$w_{N+1} = e^{-A\delta} w_N + s_N, \tag{5.1}$$

where s_N is some approximation to the integral (4.3). The above scheme is a one-step technique where δ is the timestep. If we assume that the exponential term is evaluated exactly, then the above methods are referred to as the nonlinear multistep methods of Lee [26]. It was remarked in [27] that these methods are stable. More generally, let us assume that the error incurred in the evaluation of the term $e^{-A\delta} w_N$ in (5.1) is $e_{1,N}$, while the error in the evaluation of the integral term s_N is $e_{2,N}$. Then the recurrence (5.1) is replaced by

$$w_{N+1} = e^{-A\delta} w_N + e_{1,N} + s_N^* + e_{2,N}, \tag{5.2}$$

in which s_N^* is the exact integral (4.3). In this situation, the total error at each step is of the form

$$e_{N+1} \equiv w(t_{N+1}) - w_{N+1} = e^{-A\delta} e_N + e_{1,N} + e_{2,N}. \tag{5.3}$$

This shows that if A has no eigenvalues in the negative half-plane of the complex domain, then the above procedure is stable. Note that this is independent of the procedure used to compute the approximation to the matrix exponential by vector product. If one uses the Krylov approximation to the exponential, then we essentially have an explicit procedure that is stable. Although this may seem like a contradiction, note that we have made very special assumptions. The important point is that we are essentially considering accurate one-step methods. In the extreme case where r is constant, the solution can be evaluated *in just one step* at any point in time provided the exponential is accurately approximated.

5.2. Stability behavior of the second approach.

As mentioned earlier, the alternative approach described in §4.2 is attractive from the point of view of efficiency but may have poor numerical properties. We outline in this section a stability analysis of this class of methods in an effort to determine how to select the quadrature formulas that are most likely to lead to robust procedures.

We consider the simple timestepping scheme derived by applying a quadrature formula to (4.5)

$$w_{N+1} = w_N + \delta \sum_{i=1}^{k} \mu_i e^{-(\delta-\tau_i)A}[r(t+\tau_i) - Aw_N], \tag{5.4}$$

where $\tau_i, i = 1, \cdots, k$ are the quadrature nodes in the interval $[0, \delta]$ and μ_i are their corresponding weights. Once more, we assume that the exponential terms in (5.4) are exactly calculated. The above equation can be recast in the form

$$w_{N+1} = \left(I - \delta \sum_{i=1}^{k} \mu_i e^{-(\delta-\tau_i)A} A \right) w_N + g_N,$$

in which g_N is a term that does not contain the variable w_N. We next assume that the matrix is normal. Then the stability of the above recurrence is easily studied by replacing the matrix A by a generic eigenvalue λ. This leads to the scalar recurrence

$$w_{N+1} = \left(1 - \delta \sum_{i=1}^{k} \mu_i e^{-(\delta-\tau_i)\lambda} \lambda \right) w_N + g_N.$$

We need to determine under which conditions the modulus of the evolution operator

$$a(\lambda) = 1 - \delta \sum_{i=1}^{k} \mu_i e^{-(\delta-\tau_i)\lambda} \lambda$$

does not exceed one.

Before proceeding with the more complicated general analysis, we first consider in detail two basic quadrature formulas: the trapezoidal rule and the midpoint rule. For the trapezoidal rule we have

$$a(\lambda) = 1 - \frac{\delta}{2}[\lambda e^{-\lambda\delta} + \lambda].$$

We restrict ourselves to the case where λ is real and positive. We need to have

$$-1 \le a(\lambda) = 1 - \frac{\delta\lambda}{2}[e^{-\lambda\delta} + 1] \le 1$$

or, since the second inequality is trivially satisfied,

$$\delta\lambda[e^{-\lambda\delta} + 1] \le 4. \tag{5.5}$$

Since $e^{-\lambda\delta} \le 1$, a sufficient condition for the above inequality to hold is that $\delta\lambda \le 2$, which is just as restrictive as an ordinary explicit method. Note that a *necessary condition* for (5.5) to be true is that $\delta\lambda \le 4$.

For the midpoint rule we have

$$a(\lambda) = 1 - \delta\lambda e^{-\lambda\delta/2}.$$

Considering again real and positive λ, we seek conditions under which we have

$$-1 \le a(\lambda) = 1 - \delta\lambda e^{-\lambda\delta/2} \le 1. \tag{5.6}$$

The second inequality is always satisfied and from the first we get the condition

$$\lambda\delta e^{-\lambda\delta/2} \le 2.$$

As is easily seen through differentiation, the maximum with respect to $\lambda\delta$ of the left-hand side is reached for $\lambda\delta = 2$, and its value is $2e^{-1}$, which is less than 2. Therefore, inequality (5.6) is *unconditionally satisfied.* This fundamental difference between the trapezoidal rule and the midpoint rule underscores the change of behavior in the second approach depending on the quadrature rule used. We will extend this analysis shortly.

The above development for the midpoint rule was restricted to λ being on the positive real line. Let us consider this case in more detail for λ complex. Setting $u = \lambda\delta = \alpha - i\beta$, we have

$$\begin{aligned} a(\lambda) &= 1 - ue^{-u/2} \\ &= 1 - (\alpha - i\beta)e^{-(\alpha - i\beta)/2} \\ &= 1 - \alpha e^{-\alpha/2}(\cos(\beta/2) + i\sin(\beta/2)) + i\beta e^{-\alpha/2}(\cos(\beta/2) + i\sin(\beta/2)) \\ &= 1 - e^{-\alpha/2}\left((\alpha c + \beta s) + i(\alpha s - \beta c)\right), \end{aligned}$$

where we have set $c = \cos(\beta/2)$ and $s = \sin(\beta/2)$. The modulus of $a(\lambda)$ is easily found to satisfy

$$\begin{aligned} |a(\lambda)|^2 &= 1 + e^{-\alpha}(\alpha^2 + \beta^2) - 2e^{-\alpha/2}(\alpha c + \beta s) \\ &= 1 + e^{-\alpha}\left(|u|^2 - 2e^{\alpha/2}(\alpha c + \beta s)\right). \end{aligned}$$

This leads to the region of stability, symmetric about the positive real axis, defined by

$$(\alpha^2 + \beta^2) \le 2e^{\alpha/2}\left(\alpha\cos(\beta/2) + \beta\sin(\beta/2)\right). \tag{5.7}$$

The shaded regions of Fig. 5.1 show the part of the complex domain $[0, 50] \times [-25, 25]$ that corresponds to values of u satisfying (5.7).

If we concentrate on the shaded region enveloping the positive real axis, we note that for large α, the limits of the curve bounding that section of the stability region are $\beta = \pm\pi$. This is because for $\pi < |\beta| \le 2\pi$, the coefficient $\cos(\beta/2)$ becomes negative, making (5.7) impossible to satisfy *for large* α (β being fixed). On the other hand, for fixed β such that $|\beta| \le \pi$, we have $\cos(\beta/2) \ge 0$ and there is always an α large enough to satisfy (5.7). In addition, all the lines $\beta = \pm 4k\pi, k = 0, 1, 2, \cdots$ belong partly to the region: specifically all those points in these lines with α larger than the (only) positive root of $x(2e^{x/2} - x) = \beta^2$ are acceptable points. As shown in Fig. 5.1, around each of these lines there is a whole subregion of stability, whereas in between, there are regions around the lines $\beta = \pm 2(2k+1)\pi$ that are unstable.

We return now to studying the general scheme and extending the above analysis to the general case. Again we restrict ourselves to the case where λ is real positive. This condition will be replaced by a weaker condition later. However, we do not necessarily assume that the weights are positive. Then we examine the conditions under which

$$-1 \le a(\lambda) = 1 - \delta\sum_{i=1}^{k}\mu_i e^{-(\delta - \tau_i)\lambda}\lambda \le 1$$

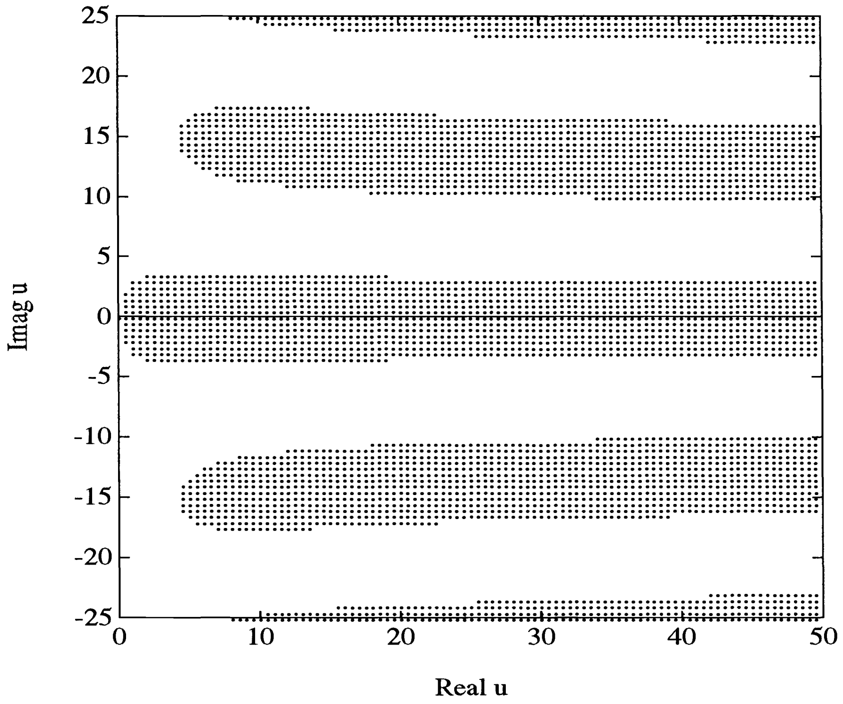

FIG. 5.1. *Stability region for the midpoint rule* (*cf.* (5.7)).

or

$$0 \le \delta\lambda e^{-\delta\lambda}\sum_{i=1}^{k}\mu_i e^{\tau_i\lambda} \le 2. \tag{5.8}$$

Consider now any quadrature rule that satisfies the following two conditions:

1. *Positivity condition.*

$$\sum_{i=1}^{k}\mu_i e^{\lambda\tau_i} \ge 0 \quad \text{for} \quad \lambda \ge 0. \tag{5.9}$$

2. *Undervaluation condition.*

$$E_k = \int_0^\delta e^{\lambda s}ds - \delta\sum_{i=1}^{k}\mu_i e^{\tau_i\lambda} \ge 0 \quad \text{for} \quad \lambda \ge 0. \tag{5.10}$$

The purpose of the positivity condition is to restrict the quadrature rule so that it yields nonnegative approximations to the integral of the function $e^{\lambda s}$ on any positive interval. It is verified whenever the quadrature weights are nonnegative. In particular, we have the following lemma.

LEMMA 5.1. *The positivity condition is satisfied for any Gaussian quadrature formula.*

Proof. The fact that the weights are positive for Gaussian quadrature is well known; see, e.g., [17, p. 328]. □

For the undervaluation condition, we can prove the following lemma.

LEMMA 5.2. (1) *Any composite or simple open Newton–Cotes formula satisfies the undervaluation condition* (5.10).

(2) *Any k-point Gaussian quadrature rule satisfies the undervaluation condition* (5.10).

Proof. This is a consequence of the well-known error formulas for open Newton–Cotes rules [17, pp. 313–314], and for Gaussian quadrature rules [17, p. 330], and the fact that all the derivatives of the function $e^{\lambda s}$ are positive in the interval $[0, \delta]$. □

Going back to condition (5.8), we first observe under the positivity condition (5.9) that the left-hand inequality is trivially satisfied. Moreover, under the undervaluation condition, we have that

$$\delta \sum_{i=1}^{k} \mu_i e^{\tau_i \lambda} \le \int_0^\delta e^{\lambda s} ds = \frac{e^{\lambda\delta} - 1}{\lambda},$$

and as a result,

$$0 \le \delta\lambda e^{-\delta\lambda} \sum_{i=1}^{k} \mu_i e^{\tau_i \lambda} \le \lambda e^{-\delta\lambda} \left(\frac{e^{\lambda\delta} - 1}{\lambda} \right) = 1 - e^{-\lambda\delta} \le 2. \tag{5.11}$$

We have therefore proved the following result.

THEOREM 5.3. *Consider the timestepping procedure* (5.4) *based on the second approach* (§4.2) *using a quadrature formula satisfying the positivity condition* (5.9) *and the undervaluation condition* (5.10). *Then the region of stability of this scheme contains the positive real line.*

Note that schemes with such properties are said to be A_0-stable in the literature [42]. In many of our numerical experiments, we have observed this difference in stability behavior between schemes that satisfy the conditions of the theorem and those that do not. In many instances the composite closed-type Newton–Cotes formulas tended to diverge for a small number of subintervals. On the other hand, we never noticed any stability difficulties with the open Newton–Cotes formulas or with the Gauss–Chebyshev quadrature.

As a general recommendation, it is advisable to use open Newton–Cotes formulas instead of closed formulas. Although these formulas satisfy the undervaluation condition according to the previous lemma, we do not know whether they satisfy the positivity condition (5.9). We know, however, that some of the low-order, closed Newton–Cotes rules (three-point, four-point, and six-point) do satisfy this condition since their weights are positive.

Gaussian rules are extremely attractive not only because of their stability properties but because of their potential to drastically reduce the number of function evaluations needed to produce a certain level of accuracy. There is still much work to be done to determine which of the quadrature formulas will yield the best results.

As is suggested by the analysis of the midpoint rule for complex λ, we expect the full analysis of the stability of the second approach to be very complicated for such cases.

6. Numerical experiments.

6.1. A symmetric model problem.

Our first test problem is issued from the semidiscretization of the heat equation

$$\begin{aligned}\frac{\partial u(x,y,z,t)}{\partial t} &= \Delta u(x,y,z,t)\ x,y,z \in (0,1),\\ u(x,y,z,t) &= 0 \quad (x,y,z) \quad \text{on the boundary,}\end{aligned}$$

where Δ stands for the three-dimensional Laplacian operator using 17 grid points in each direction, yielding a matrix of size $n = 15^3 = 3375$. The initial conditions are chosen after space discretization in such a way that the solution is known for all t. More precisely,

$$u(0, x_i, y_j, z_k) = \sum_{i',j',k'=1}^{n'} \frac{1}{i'+j'+k'} \sin\frac{ii'\pi}{n'+1} \sin\frac{jj'\pi}{n'+1} \sin\frac{kk'\pi}{n'+1},$$

where $n' = 15$. The above expression is simply an explicit linear combination of the eigenvectors of the discretized operator. In order to separate the influence of spatial discretization errors and emphasize the time evolution approximation, for the experiments in this section we consider the solution of the semidiscrete problem $u_t = -Au$ to be the exact solution. The exact solution is readily computed from the explicit knowledge of eigenvalues and eigenvectors of A.

The purpose of the first test is to illustrate one of the main motivations for this paper, namely, the effectiveness of using large-dimensional Krylov subspaces whenever possible. As shown in [10] and [13], similar conclusions also hold for methods based on rational approximations to the exponential.

Assume that we want to integrate the above equation between $t = 0$ and $t = 0.1$, and achieve an error-norm at $t = 0.1$, which is less than $\epsilon = 10^{-10}$. Here by error-norm we mean the two-norm of the absolute error.

We can vary both the degree m and the timestep δ. Normally we would prefer to first choose a degree m and then try to determine the maximum δ allowed to achieve the desirable error level. However, for convenience, we proceed in the opposite way: we first select a stepsize δ and then determine the minimum m that is needed to achieve the desirable error level. This experiment was performed on a Cray Y-MP. What is shown in Table 6.1 are the various timesteps chosen (column 1) and the minimum values of m (column 2) needed to achieve an error norm less than $\epsilon = 10^{-10}$ at $t = 0.1$. We show in the third column the total number of matrix-by-vector multiplications required to complete the integration. The times required to complete the integration on a Cray Y-MP are shown in column 4. We also timed the evaluations of $e^{-\delta H_m} e_1$ separately and found these times to be negligible with respect to the rest of the computation. The last column of the table shows the type of rational approximation used when evaluating $e^{-\delta H_m} e_1$, with $\mathrm{C}(\nu,\nu)$ representing the diagonal (ν,ν) Chebyshev approximation and $\mathrm{P}(\nu,\nu)$ representing the diagonal (ν,ν) Padé approximation.

Another point is that the matrix is symmetric, so we have used a Lanczos algorithm to generate the $v_i^{\prime}s$ instead of the full Arnoldi algorithm. No reorthogonalization of any sort was performed. The matrix consists of 7 diagonals, so the matrix-by-vector products are performed by diagonals resulting in a very effective use of the vector capabilities of the Cray architecture. Based on the time for the last entry of the table,

TABLE 6.1
Performance of the polynomial scheme with varying accuracy on the Cray Y-MP.

0.1000E+00	71	71	0.4186E−01	0.9993E−10	C(14,14)

we have estimated that the average Mflops rate reached, excluding the calculation of $e^{-\delta H_m}e_1$, was around 220. This is achieved with little code optimization.

Observe that the total number of matrix-by-vector products decreases rapidly as m increases. The ratio between the lowest degree, $m = 6$, and the highest degree, $m = 71$, is 169. The corresponding ratio between the two times is roughly 200. The case $m = 71$ can achieve the desired accuracy in just one step, that is, with $\delta = 0.1$. On the other hand, for $m = 6$, a timestep of $\delta = 5 \times 10^{-5}$ must be taken, resulting in a total of 2000 steps. We should point out that we are restricting ourselves to a constant timestep, but more efficient variable timestepping procedures are likely to reduce the total number of steps needed. These observations are qualitatively consistent wth Theorems 2.1 and 2.3. In effect, increasing the dimension of the Krylov subspace will increase the accuracy in such a way that a much larger ρ (i.e., a larger δ) can quickly be afforded.

6.2. A nonsymmetric problem with time-varying forcing term. In this section we consider the more difficult problem

$$\frac{\partial u(x,y,z,t)}{\partial t} = \Delta u(x,y,z,t) + \gamma\frac{\partial u(x,y,z,t)}{\partial x} + r(x,y,z,t), \tag{6.1}$$

defined as before on the unit cube, with homogeneous boundary conditions and the following initial conditions:

$$u(x,y,z,0) = x(x-1)y(y-1)z(z-1).$$

The function r is defined in such a way that the exact solution of the above PDE is given by

$$u(x,y,z,t) = \frac{x(x-1)y(y-1)z(z-1)}{1+t}. \tag{6.2}$$

As in the previous example, we took the same number of grid points in each direction, i.e., $n_x = n_y = n_z = 17$, yielding again a matrix of dimension $n = 15^3 = 3375$. This experiment was conducted on a Cray-2. Table 6.2 is the analogue of Table 6.1, except that we only report some representative runs with various values of m and δ. The parameter γ is set equal to 10.0. The integration is carried out from $t = 0.0$ to $t = 1.0$. We note that for the remaining experiments, unless otherwise mentioned, the rational approximation used for $e^{-\delta H_m}$ is the Chebyshev C(10,10).

TABLE 6.2

0.2500E−01	15	10	640	0.2109E+01	0.9887E−05
0.1000E−01	10	10	1100	0.3561E+01	0.1743E−05
0.1000E−01	7	10	800	0.2693E+01	0.9483E−05

An important characteristic of this example is that the exact solution of the discrete problem is also an exact solution of the continuous problem. This is because the exact solution is a polynomial of degree not exceeding 2 in each of the space variables. For these functions the centered difference approximation to the partial derivatives in the operator (6.1) entails no errors. This fact has also been verified experimentally. Therefore, all the errors in the computed solution are due to the time integration process and this allows a fair comparison of the various techniques from the standpoint of accuracy achieved in the time integration.

The second approach was used, in which the integrals were calculated with 11-point composite (closed) Newton–Cotes formulas. In most cases we had to take more than 11 points, in which case we simply used a composite rule with a total number of points equal to $1 + k \times 10$. The third column reports the total number of subintervals *npts* used to advance by one timestep of δ. Thus *npts* is a multiple of 10. The time shown in the fifth column is the time in seconds needed to advance the solution from $t = 0.0$ to $t = 1.0$, on a Cray-2. The sixth column shows the two-norm norm of the error with respect to the exact solution of the *continuous* system, that is, with respect to (6.2).

We observe that for larger timesteps a larger number of quadrature points must be used to keep a good level of accuracy. We show the results associated with the smallest number of points for which there are no significant qualitative improvements in the error when we increase *npts*, while keeping m and δ constant. Our tests indicate that the higher the order of the quadrature used, the better. This means that large gains in speed are still likely if we use more optimal Gaussian quadrature formulas. A noticeable difference from the previous simple example is that the increase in δ and the corresponding increase in m in achieving certain error tolerances cause a less significant reduction in the total number of matrix-by-vector multiplications and the total time required for the computation.

6.3. A comparison with other methods. Although an exhaustive comparison with other schemes is beyond the scope of this paper, we would like to give an idea of how the efficiency of the Krylov subspace propagation compares with some immediate contenders. The first of these contenders is simply the forward Euler scheme. This is an explicit scheme and, for not-too-small space mesh sizes, should not be excluded, given that the corresponding process is highly vectorizable. However, it may be far more challenging to use an implicit scheme such as the Crank–Nicolson method

$$\left(I+\frac{\delta}{2}A\right)w_{N+1}=\left(I-\frac{\delta}{2}A\right)w_N+\delta r(t_N+\delta/2), \tag{6.3}$$

combined with an iterative method, for example, the conjugate gradient method, for solving the linear systems. The main attraction here is that we can solve the linear systems inaccurately, making the solution process very inexpensive. From this viewpoint, this "inexact Crank–Nicolson" method shares many of the benefits of the Krylov method, as was already mentioned in the introduction. Finally, a well-known stiff ODE package such as LSODE [16] is also considered.

For this comparison we took the same problem as before, but we needed to take $\gamma = 0.0$ in order to make the matrix A symmetric. This was necessary in order to be able to utilize the usual conjugate gradient algorithm for the linear systems in the Crank–Nicolson scheme. The r function is defined as before, and the number of grid points in each direction is again $n_x = n_y = n_z = 17$, yielding $n = 15^3 = 3375$.

We point out that for the Crank–Nicolson method, we do not use preconditioning, and this is by no means a drawback. Because of timestepping, the matrix is usually very well conditioned and, as a result, the algorithm converges in a rather small number of steps. Moreover, because there is no need to solve the systems with high accuracy, the overhead in setting up the preconditioner would be difficult to amortize. Finally, the good preconditioners, such as the incomplete factorizations, do not generally yield a high performance on vector machines. In our tests, the CG algorithm is stopped as soon as the residual norm is reduced by a factor that does not exceed a tolerance ϵ. We always take the tolerance ϵ that yields the smallest (or close to the smallest) time for the Crank–Nicolson scheme to complete. In addition, note that the timesteps in the Crank–Nicolson scheme are chosen at the outset and, as with the Krylov method, they are not adaptively controlled. We show the performance for two timesteps only, namely, those that deliver close to the desired accuracy at the final point. In this test we used the Chebyshev rational approximation of order (6,6) throughout for the computation of $e^{-\delta H_m}e_1$. A final detail is that both the Crank–Nicolson method, which is able to use the usual CG method, and the Krylov method, in which the Lanczos version of the Arnoldi algorithm is used, take advantage of symmetry.

For LSODE we used the method flag MF = 24, which means that a stiff method is used, and the Jacobian is user-supplied in banded format. The Cray-optimized LINPACK banded solver is called to solve the linear systems. For LSODE we used a relative tolerance of `rtol` $= 10^{-7}$ and an absolute tolerance of `atol` $= 10^{-7}$ at each point is used. These have been chosen so that the level of error produced by LSODE at $t = 1$ is comparable to that of the other methods.

Table 6.3 shows the results. This comparison reveals that the Krylov scheme is superior when one considers the number of matrix-by-vector products to be the primary criterion. There are situations in which these may dominate the cost, in which case the execution time could be proportional to the number of matrix–vector products. When execution time is the primary criterion for comparison, then the Krylov scheme is still faster than Crank–Nicolson but not by as large a margin. The forward Euler scheme was unstable for the timesteps $\delta = 0.001$ and $\delta = 0.00075$. We also performed a set of tests with a larger version of this problem corresponding

TABLE 6.3
Performance comparison of a few methods on problem of §6.3.

Method used	Method parameters	Matrix–vec. products	Total Cray-2 time (sec.)	Final error
Krylov $\delta = 0.2$	$m = 30, npts = 40$	155	0.9374E+00	0.6670E−05

LSODE	MF = 24	400	0.1435E+02	0.2828E−05

to the grid sizes $n_x = n_y = n_z = 22$, leading to a problem of size $n = 8000$. The conclusion is essentially the same in that Crank–Nicolson and the Krylov method are comparable, but the time for the explicit Euler scheme becomes much higher. We should add that we have regarded the problem purely from the perspective of systems of ODEs, although we are aware that in practice a balanced accuracy between space and discretization is generally sought. However, this would lead to comparisons that are too complex.

6.4. A case with highly oscillating forcing term. We consider here an example of the same form as in §6.3; that is, the general equation is of the form (6.1), and the initial and boundary conditions are identical. However, we now consider a forcing term for which the exact solution is given by

$$u(x, y, z, t) = x(x-1)y(y-1)z(z-1)\cos(\alpha\pi t). \tag{6.4}$$

If the coefficient α is chosen to be large, then the problem can be difficult to solve. We take here $\gamma = 0.0$ and $\alpha = 20$. The discretization mesh and interval of time integration are the same as in the previous example. Note that as in the preceding example, the errors in the computed solutions are also entirely related to the time integration.

We compared the same four methods as those of the previous section, the forward Euler scheme, the Crank–Nicolson/CG scheme, LSODE, and the Krylov method using the second approach. In this example LSODE failed to complete in a reasonable amount of time.

One difference with the previous tests is that here we varied the quadrature formulas used. Thus $npts = 4 \times 8$ indicates that we used a composite rule in which the interval of integration is first divided by 4 and then a nine-point formula is used on each subinterval. Apart from this, all of the details concerning implementation are identical to those of §6.3, except that this time we used the Chebyshev rational approximation of order (8,8) instead of (6,6) to compute the vectors $e^{-\delta H_m} e_1$.

The results in Table 6.4 indicate that for this harder problem, the Krylov scheme performs far better than its competitors. The Crank–Nicolson scheme now requires smaller timesteps to achieve acceptable accuracies. The forward Euler scheme would

require a much smaller timestep that those of the other methods to achieve comparable performance.

7. Summary and conclusion. The goal of this paper was to show how to systematically develop explicit-type schemes or, to use our terminology, polynomial schemes for solving parabolic PDEs by the method of lines. We have proposed one such procedure that has the advantage of being very simple. The method proposed requires no information about the spectrum of the space discretization operator. We have recommended using high-dimension Krylov subspaces whenever possible. By using a Krylov subspace of high dimension to approximate the evolution operator, we are able to use larger timesteps. At each step there is an additional cost due to the increased dimension of the Krylov subspace, which translates into an increase in the number of matrix-by-vector multiplications. On the other hand, because of the larger timestep, the total number of steps required is reduced to such an extent that there is an appreciable net gain in performance. We have also proposed two approaches for handling nonconstant forcing terms, with the view of extending these methods for general ODEs and nonlinear PDEs. The stability analysis of these approaches shows that the first is unconditionally stable and the second is A_0-stable for a large class of integration schemes used. This has been widely confirmed by numerical experiments which indicate that the schemes proposed are competitive with standard methods such as Crank–Nicolson.

Improvements to the approach described in §4.2 are possible by developing quadrature formulas that are more elaborate and specialized than the simple Newton–Cotes formulas used in our numerical experiments. We believe that the method proposed here can be extended to the solution of general time-dependent nonlinear PDEs: the only subtlety is to isolate the action of the evolution operator, which is then well approximated by the schemes proposed here.

Appendix A. Proof of Theorem 2.1. The following lemma provides the basis for establishing error bounds for the error of the approximation (2.3).

LEMMA A.1. *Let A be any matrix, and p be any polynomial of degree smaller than m, approximating e^{-z} with the remainder $r_m(z) = e^{-z} - p(z)$. Then,*

$$\|e^{-A}v - \beta V_m e^{-H_m} e_1\|_2 \leq \beta(\|r_m(A)\|_2 + \|r_m(H_m)\|_2), \tag{A.1}$$

where $\beta = \|v\|_2$.

Proof. As a result of the relation $e^{-z} = p(z) + r_m(z)$, we have

$$e^{-A}v = \beta[p(A)v_1 + r_m(A)v_1]. \tag{A.2}$$

Using induction and the relation (2.2) we can show that $A^j v_1 = V_m H_m^j e_1$ for $j \leq m-1$, and as a consequence we have

$$p(A)v_1 = V_m p(H_m)e_1. \tag{A.3}$$

As a result of the definition of p and r_m, we write

$$p(H_m)e_1 = e^{-H_m}e_1 - r_m(H_m)e_1. \tag{A.4}$$

To complete the proof, we substitute (A.4) in (A.3) and the resulting equation in (A.2) to get

$$e^{-A}v = \beta V_m e^{-H_m} e_1 + \beta[r_m(A)v_1 - V_m r_m(H_m)e_1].$$

The result follows immediately. □

Thus the error can be estimated by bounding each of the two remainder terms. We now use the concept of the *logarithmic norm* of a matrix as defined in §2.2. We will specifically use the inequality $\|e^{Bt}\| \leq e^{\mu(B)t}$.

We next prove the following lemmas.

LEMMA A.2. *Let*

$$s_{m-1}(z) = \sum_{k=0}^{m-1} \frac{(-z)^k}{k!}$$

be the $(m-1)$th partial Taylor sum of e^{-z} and let $r_m(z)$ be the associated remainder $r_m(z) = e^{-z} - s_{m-1}(z)$. Define

$$\phi(\eta) \equiv \frac{1}{\eta^m}\left(e^{\eta} - \sum_{k=0}^{m-1} \frac{\eta^k}{k!}\right).$$

Then

$$\|r_m(A)\| \;\leq\; \|A^m\|\phi(\eta) \;\leq\; \|A^m\|\frac{\max(1, e^{\eta})}{m!}, \tag{A.5}$$

where $\eta \equiv \mu(-A)$.

Proof. The remainder after m terms of the Taylor series expansion in integral form applied to $\exp(-A)$ is given by

$$r_m(A) = \frac{(-A)^m}{(m-1)!} \int_0^1 e^{-A(1-\tau)}\tau^{m-1} d\tau \tag{A.6}$$

and therefore,

$$\|r_m(A)\| \le \frac{\|A^m\|}{(m-1)!}\int_0^1 \|e^{-A(1-\tau)}\|\tau^{m-1}d\tau.$$

Denoting $\eta = \mu(-A)$ for convenience, since $0 < \tau < 1$, we have from (2.4)

$$\|e^{-A(1-\tau)}\| \le e^{\mu(-A)(1-\tau)} \equiv e^{\eta(1-\tau)},$$

from which we get

$$\|r_m(A)\| \le \frac{\|A^m\|}{(m-1)!}\int_0^1 e^{\eta(1-\tau)}\tau^{m-1}d\tau. \tag{A.7}$$

The value of the integral in the above expression is determined by noting that the remainder of the $(m-1)$st Taylor expansion of e^η satisfies

$$e^\eta - \sum_{k=0}^{m-1}\frac{\eta^k}{k!} = \frac{\eta^m}{(m-1)!}\int_0^1 e^{\eta(1-\tau)}\tau^{m-1}d\tau,$$

which gives

$$\phi(\eta) = \frac{1}{(m-1)!}\int_0^1 e^{\eta(1-\tau)}\tau^{m-1}d\tau.$$

Incidentally, this expression shows that $\phi(\eta)$ is nonnegative. Substituting this in (A.7) proves the first inequality in (A.5).

To prove the second part of the inequality, we observe that

$$\phi(\eta) = \frac{1}{(m-1)!}\int_0^1 e^{\eta(1-\tau)}\tau^{m-1}d\tau \tag{A.8}$$

$$\le \frac{1}{(m-1)!}\int_0^1 \max(1, e^\eta)\tau^{m-1}d\tau = \frac{\max(1, e^\eta)}{m!}. \tag{A.9}$$ □

We remark that the upper bound for $\phi(\eta)$ used in the above lemma can be somewhat refined. More specifically, it can be shown that.

$$\phi(\eta) \le \begin{cases} \frac{1}{m!} & \text{if } \eta < 0, \\ \frac{e^\eta}{m!} & \text{if } 0 < \eta \le \sqrt[m-1]{(m-2)!m}, \\ \frac{e^\eta}{(m-1)\eta^{m-1}} & \text{if } \sqrt[m-1]{(m-2)!m} \le \eta. \end{cases}$$

Finally, we need the following lemma.

LEMMA A.3. *If A is any real matrix and H_m is the associated $m \times m$ upper Hessenberg matrix generated by m steps of the Arnoldi algorithm, then*

$$\mu(-H_m) \le \mu(-A).$$

Proof. By construction, V_m consists of m orthonormal vectors and H_m satisfies $H_m = V_m^{\mathrm{T}} A V_m$. Since the maximum eigenvalues of the symmetric parts of A and H_m can be characterized as the maximum values taken by their Rayleigh quotients, it easily follows that

$$\mu(-H_m) = \max_i \lambda_i\left(-\frac{V_m^{\mathrm{T}}AV_m + V_m^{\mathrm{T}}A^{\mathrm{T}}V_m}{2}\right) \le \max_i \lambda_i\left(-\frac{A + A^{\mathrm{T}}}{2}\right) = \mu(-A).$$ □

Proof of Theorem 2.1. First note that as in Lemma A.2 we can show that

$$\|r_m(H_m)\|_2 \leq \rho_m^m \phi(\mu(-H_m)),$$

where $\rho_m = \|H_m\|_2 = \|V_m^T A V_m\|_2$. The right-hand side of the above inequality is an increasing function of ρ_m and $\rho_m \leq \rho$. From Lemma A.3, $\mu(-H_m) \leq \mu(-A) = \eta$, and therefore,

$$\|r_m(H_m)\|_2 \leq \rho^m \phi(\eta). \tag{A.10}$$

Using Lemma A.1 the proof follows. □

Appendix B. Partial fraction coefficients. In Table B.1 we list some of the coefficients of the partial fraction expansion for the Chebyshev rational approximation to the exponential. These are the (ν, ν) approximations for $\nu = 10$ and $\nu = 14$. Note that because the roots go in complex conjugate pairs, we only need to show those with nonnegative imaginary parts. In fact there are exactly $\lceil \frac{\nu}{2} \rceil$ such roots for the (ν, ν) approximation. Moreover, in the case of a complex pair the corresponding coefficient α_i in the partial fraction expansion is doubled. The roots are also distinct and we can therefore write, for a real x,

$$e^{-x} \approx \alpha_0 + 2\Re \left[\sum_{i=1}^{\nu/2} \frac{\alpha_i}{x - \lambda_i} \right]. \tag{B.1}$$

Acknowledgments. We thank Professor Richard Varga for reading the paper and for providing many enlightening suggestions, Dr. Roland Freund for many helpful discussions, and Dr. Randall Bramley for his comments on an early version of the paper. We also thank the referees for their recommendations and for bringing to our attention reference [8].

MOVING MESH TECHNIQUES BASED UPON EQUIDISTRIBUTION, AND THEIR STABILITY*

YUHE REN† AND ROBERT D. RUSSELL†

Abstract. Various aspects of the moving mesh problem are investigated for the solution of partial differential equations (PDEs) in one space dimension. In particular, methods based (explicitly or implicitly) upon an equidistribution principle are studied. It is shown that equidistribution implicitly corresponds to finding a solution to a PDE involving a new set of computational coordinates. Implementation of a discrete version of equidistribution to compute a moving mesh corresponds to solving a weak form of the PDE. The stability of equidistribution is discussed, and it is argued that stability can be significantly affected by the way in which this solution process is carried out. Simple moving mesh methods are constructed using this framework, and numerical examples are given to illustrate their robustness.

Key words. moving mesh, monitor function, equidistribution, conservative methods for PDEs

AMS(MOS) subject classifications. 65M50, 65L50, 65N50

1. Introduction. One of the most important computational considerations when solving partial differential equations (PDEs) having nontrivial solutions is the decision of how to automatically and stably choose a nonuniform mesh that suitably adapts to the solution behaviour. For initial value PDEs, constructing a moving mesh in time can be essential if the problem is to be solved efficiently, and often if it is to be solved at all. The resolution of this issue has proven surprisingly difficult, and theoretical results have been particularly slow in forthcoming. Considerable controversy surrounds the questions of which overall strategy to use and how best to choose a moving mesh for a given strategy [14], even though few basic mesh selection principles are available. Here, we investigate one of the key mesh selection strategies: that in which equidistribution is explicitly done with respect to some nonnegative measure of the error. We also discuss the implications of these results with regard to some other strategies, and focus on PDEs in one space dimension.

First, consider the case of solving an ordinary differential equation (ODE), e.g.,

$$u_{xx}=f(x, u, u_x) \tag{1}$$

with boundary conditions $u(a)=\beta_1$, $u(b)=\beta_2$. The equidistribution idea, introduced by de Boor [7] and Dodson [10], is based upon the simple idea that if some measure of the error $M(x)$ is available, then a good choice for a mesh π: $a=x_0<x_1<\cdots<x_N=b$ would be one in which the contributions to the error over the subintervals are equalized (or "distributed equally"). In practice, most strategies find π by only approximately equidistributing with respect to the so-called monitor function $M(x)$, although White [41] provides a framework for doing this distribution exactly. He defines a change of variables

$$s=\frac{1}{\theta}\int_a^x M(\xi)\,d\xi, \qquad \theta=\int_a^b M(\xi)\,d\xi,$$

and then forms a new system of ODEs consisting of the original ODE (say, (1)) rewritten in terms of this computational variable s, and the ODE

$$\frac{dx}{ds}=\frac{\theta}{M(x)}. \tag{2}$$

Equidistribution then corresponds to choosing π with $s(x_{i+1})-s(x_i)=1/N, i=0,1,\cdots,N-1$.

This continuous form has been a useful theoretical tool for interpreting schemes, but it is generally unreliable computationally because the new ODE system can be extremely sensitive to solve. While all of the reasons for numerical difficulties are not well understood, a major one is that the *transformed* ODE (in s) can be extremely nonlinear and its solution badly behaved due to the introduction of interior layers [34], [36]. Still, equidistribution strategies are widely used in conjunction with the original ODE (such as (1)), and in this way they have enjoyed general success.

Now consider an initial boundary value PDE

$$u_t=f(u, u_x, u_{xx}), \tag{3}$$

with $u(x,0), a\leqq x\leqq b$, and $u(a,t), u(b,t), t>0$ given. Our concern is to investigate properties of an equidistribution procedure, and in many respects this does not depend upon the form of the PDE itself. For example, the PDE could be a system of equations in $\mathbf{u}=(u_1,\cdots,u_n)^T$ such as

$$\mathbf{F}(\mathbf{u}_t, \mathbf{u}_x, \mathbf{u}_{xx})=0. \tag{4}$$

Many variations of equidistribution strategies have been investigated in practice. The first ones generally did a *static regridding* [19], where equidistribution to determine a new mesh is done after the solution to the PDE is computed at the new time level (see, e.g., [2]). Later, the PDE and mesh solution processes were combined to do *dynamic regridding* [19]. Several moving mesh methods based upon equidistribution were investigated by Coyle, Flaherty, and Ludwig [8]. Hyman [19] studied a moving mesh strategy for PDEs of the form (3), and later Petzold [32] did so for the implicit PDE (4).

Mathematically, the goal of finding mesh *functions* $\{x_i(t)\}_{i=1}^{N-1}$, or moving meshes

$$\pi\colon \{a=x_0<x_1(t)<\cdots<x_{N-1}(t)<x_N=b\}, \tag{5}$$

which are equidistributing for all values of t means that we want

$$\int_{x_{i-1}(t)}^{x_i(t)} M(x,t)\,dx=\frac{1}{N}\int_a^b M(x,t)\,dx=:\frac{1}{N}\theta(t), \qquad i=1,\cdots,N. \tag{6}$$

This equidistribution equation can be written equivalently as

$$\int_a^{x_i(t)} M(x,t)\,dx=\frac{i}{N}\int_a^b M(x,t)\,dx=\frac{i}{N}\theta(t), \qquad i=0,1,\cdots,N. \tag{7}$$

With static regridding, (6) or (7) is approximately satisfied at every new time level, where the monitor function $M(x,t)$ depends upon the just computed solution of the PDE at this time level. (For notational convenience, the explicit dependence of M upon u is not specified.) With dynamic regridding, the PDE is solved together with (6) or (7), and the rate at which the mesh moves is a function of how θ changes with time.[1]

[1] In actual fact, the regridding strategies only solve (7) approximately, producing so-called *asymptotically equidistributing* meshes, but this distinction will not be a focus of our presentation.

White [42] also studies the PDE case. As for the ODE, he replaces the physical variables x, t with a new set of computational coordinates s, T defined via the exact equidistribution process, viz.,

$$s = \frac{1}{\theta} \int_a^x M(\xi, t)\, d\xi, \qquad T = t. \tag{8}$$

He obtains a new PDE system consisting of the original PDE for u rewritten in terms of s and T, and

$$\frac{\partial x}{\partial s} = \frac{\theta}{M(x, T)}. \tag{9}$$

Several attempts to solve this transformed PDE for u (as a function of these new computational variables) have been made (see, e.g., [42] and [12]). This involves forming a discretization of the transformed PDE and solving a coupled system for the numerical solution and the equidistributing mesh which (approximately) satisfies (6). The resulting system is, however, generally sensitive to solve numerically [37]. The transformed PDE is nonlinear even if the original one is linear, and sometimes physically meaningless solutions are obtained. Still, as we shall see, it provides a useful model with which to interpret particular numerical schemes.

In [8], the stability of the equidistribution process is studied. In particular, differentiating (7) with respect to t, they study the equations

$$M(x_i, t)\dot{x}_i + \int_a^{x_i} M_t(x, t)\, dx = \frac{i}{N}\frac{d\theta}{dt}, \qquad i = 1, \cdots, N-1. \tag{10}$$

Using linear perturbation techniques for the mesh points, they perturb x_i by δx_i and take

$$M(x_i + \delta x_i, t)(\dot{x}_i + \delta\dot{x}_i) + \int_a^{x_i+\delta x_i} M_t(x, t)\, dx = \frac{i}{N}\frac{d\theta}{dt}, \tag{11}$$

and linearize (11) to get the first-order terms

$$M(x_i(t), t)\delta\dot{x}_i(t) + \frac{\partial M}{\partial x}(x_i(t), t)\dot{x}_i(t)\delta x_i(t) + \frac{\partial M}{\partial t}(x_i(t), t)\delta x_i(t) = 0,$$

that is

$$\frac{d}{dt}[M(x_i(t), t)\delta x_i(t)] = 0. \tag{12}$$

Integrating from $t = 0$ to t,

$$\delta x_i(t) = \frac{M(x_i(0), 0)}{M(x_i(t), t)}\delta x_i(0). \tag{13}$$

Doing this analysis and an accompanying numerical study, they conclude that mesh equidistribution, while unquestionably a desirable property for the mesh points, requires extreme care for its implementation because of potential instabilities for dissipative PDEs, where the perturbation terms in (13) can grow rapidly.

A number of attempts have been made to eliminate this potential numerical instability and to prevent mesh points from crossing by solving various forms of differential equations for the moving meshes. Generally, these attempts have involved some form of regularization [21], [32]. In the next section, we discuss the equidistribution problem within another framework, showing why the stability analysis needs to be used cautiously.

It is interesting to conjecture about the stability properties of equidistribution as they relate to what is known about moving finite element (MFE) methods [30]. MFE methods have proven very effective for parabolic PDEs [15], especially convection-dominated problems [3]. The methods have been shown to be related to a weak form of equidistribution [13], [17], [38]. Also, the MFE matrix can only become singular if an equidistribution relationship is violated [17], and for hyperbolics, they run into difficulty at the very point where the equidistribution property is lost [14]. In order to avoid difficulties, Miller [28] introduces regularization terms, and the result is that the penalty function in this regularization plays the key role of preserving equidistribution [17]. Nevertheless, the practical implications of these often tenuous theoretical connections are difficult to interpret, leaving many stability issues open to question.

2. Equidistribution PDE. In order to analyze further the stability of moving meshes satisfying an equidistribution principle, we derive a PDE that provides a new interpretation of exact equidistribution. From (8), $s\theta(t)=\int_a^x M(\xi,t)\,d\xi$, so assuming that M is a smooth function, along lines where $s(t)$ is *constant* with respect to time t,

$$s_t\theta+s\dot{\theta}=s\dot{\theta}=\int_a^x \frac{\partial M}{\partial t}(\xi,t)\,d\xi+M\dot{x}, \tag{14}$$

implying

$$s_x\dot{\theta}+s\dot{\theta}_x=s_x\dot{\theta}=\frac{\partial M}{\partial t}(x,t)+\frac{\partial}{\partial x}(M\dot{x}). \tag{15}$$

Thus we have the differential form

$$\frac{\partial}{\partial t}M(x,t)+\frac{\partial}{\partial x}(M(x,t)\dot{x})=\frac{\dot{\theta}}{\theta}M(x,t), \tag{16}$$

or

$$\frac{\partial}{\partial t}M+\operatorname{div}(M\dot{x})=\frac{\dot{\theta}}{\theta}M. \tag{17}$$

Consequently, doing equidistribution implicitly corresponds to finding a solution to (16). Although this is technically an integro-differential equation, we refer to it as a hyperbolic conservation-type PDE. (In the next section, the integral term is eliminated through a change of variables.) Differentiating (6) with respect to t, it is not difficult to show that the discrete equidistribution process for the mesh (5) corresponds to finding a solution to

$$\int_{x_{i-1}}^{x_i}\left[\frac{\partial M}{\partial t}(x,t)+\frac{\partial}{\partial x}(M(x,t)\dot{x})\right]dx=\frac{1}{N}\dot{\theta}=\int_{x_{i-1}}^{x_i}\frac{\dot{\theta}}{\theta}M(x,t)\,dx. \tag{18}$$

This viewpoint is valuable in several respects. Practically, the effects of discretizing (6) and (16) are similar. However, considerable experience has been gained from solving PDEs in conservation-type form like (16), so it is natural to try to develop new methods and interpret previous ones using this formulation. It also provides a physical interpretation of these moving-mesh methods in terminology common in fluid dynamics. The mesh points serve a similar function as particles of flow. In particular, the equidistribution coordinates are chosen using a quasi-Lagrangian approach: The moving mesh is along lines of constant

$$s(t)=\int_a^{x(t)}\frac{M(\xi,t)}{\theta(t)}\,d\xi.$$

Here, (6) satisfies a finite version of the integral form (8), or a *weak form.* The weak form (6) of the PDE shows that the "flux" of the error density function M is equivalent across the subintervals, or across each cell $[x_{i-1}, x_i]$, for each fixed time level. If the total measure of error in the interval $[a, b]$ is constant, then $\dot{\theta}=0$, and the moving mesh equation (16) becomes the Euler equation for the "fluid" with density function $M(x, t)$. Finally, the case where meshes are calculated using static regridding can be viewed as corresponding to the steady flow case in fluid dynamics, where the error density function $M(x, t)$ is independent of time. It is interesting to observe how the choice $M(x, t)=u_x$ and $\dot{\theta}\equiv 0$ corresponds to a Lagrangian coordinate system. In particular, for this case the integration of (16) leads to the well-known conservation law [24]

$$u_t + u_x \dot{x} = 0, \tag{19}$$

and $x(t)$ is simply a characteristic. For the arclength monitor function

$$M(x, t)=\sqrt{1+u_x^2},$$

if $u_x \gg 0$ then $M(x, t)\approx u_x$, and we see how the moving mesh equation reflects the shock behaviour where characteristics cross. For hyperbolic PDEs, the MFE method with no regularization has also been shown to produce moving meshes along characteristics [4], [16].

While (16) has not, to our knowledge, been used previously to interpret mesh selection schemes in a general setting, similar approaches have been investigated in special contexts. Larrouturou [23] develops an inexpensive moving mesh method for which the mesh points move with a time-dependent velocity $\dot{x}(t)$, the monitor function is chosen as a physical quantity (temperature), and the total energy $\theta(t)$ is constant. This gives a PDE for solving $\dot{x}(t)$ which is similar to (16), but with $\dot{\theta}(t)=0$. In Larrouturou's actual implementation, the new mesh is computed using static regridding.

Theoretically, White's approach [42], being based upon equidistribution, involves satisfying (16) exactly. He writes the original PDE in terms of the computational quasi-Lagrangian coordinates (s, T), and, since the solution has no steep gradients in these coordinates, a uniform mesh with $s(x_{i+1})-s(x_i)=1/N$ is used for the transformed PDE. He works with arclength as the monitor function, i.e.,

$$M(x, t)=\sqrt{1+u_x^2}.$$

From the relation between the moving mesh problem with equidistribution and (16), it is easy to see how problems can arise computationally. Approximation to the left-hand side should generally be done with a conservative scheme, or one could expect difficulties to arise. While many excellent methods of such type are available, when $\dot{\theta}\neq 0$ this term can cause considerable numerical difficulty, and finding suitable numerical methods just to solve a PDE of this type is not well understood [25]. The situation here is, of course, further complicated because the moving mesh PDE is coupled to the *original* PDE.

To see how difficulties can generally arise for the moving mesh equation, suppose we assume that $\dot{\theta}=0$. Then (16) becomes

$$\frac{\partial M}{\partial t}+\frac{\partial}{\partial x}(M\dot{x})=0. \tag{20}$$

If we use the nonconservative form

$$\frac{\partial M}{\partial t}+M\frac{\partial}{\partial x}(\dot{x})+\frac{\partial M}{\partial x}\dot{x}(t)=0, \tag{21}$$

and discretize using a standard method of lines procedure, we obtain

$$\frac{\partial M}{\partial t}(x_i(t), t)+M(x_i(t), t)\frac{\dot{x}_{i+1}(t)-\dot{x}_i(t)}{x_{i+1}(t)-x_i(t)}+\frac{\partial M(x_i(t), t)}{\partial x}\dot{x}_i(t)=0,$$

or

$$\frac{\partial M}{\partial t}(x_i, t)(x_{i+1}-x_i)+M(x_i, t)(\dot{x}_{i+1}-\dot{x}_i)+\frac{\partial M}{\partial x}(x_i, t)\dot{x}_i(x_{i+1}-x_i)=0. \tag{22}$$

Thus

$$\frac{d}{dt}[M(x_i(t), t)(x_{i+1}(t)-x_i(t))]=0, \tag{23}$$

and upon integrating, we get

$$x_{i+1}(t)-x_i(t)=\frac{M(x_i(0), 0)}{M(x_i(t), t)}(x_{i+1}(0)-x_i(0)). \tag{24}$$

Unless

$$\frac{M(x_i(0), 0)}{M(x_i(t), t)}$$

remains small, which it generally would *not* do for dissipative PDEs, the moving mesh points can easily leave the domain $[a, b]$.

These observations apply as well to the differential equation (13) developed in [8] using linear perturbation techniques. It is useful to investigate this linear perturbation analysis further. Expanding (12) and dividing by δx_i, we have

$$M(x_i(t), t)\frac{\delta\dot{x}_i(t)}{\delta x_i(t)}+\frac{\partial M}{\partial x}\dot{x}_i(t)+\frac{\partial M}{\partial t}(x_i(t), t)=0. \tag{25}$$

Letting $\delta x_i \to 0$, we obtain

$$M(x_i(t), t)\frac{\partial}{\partial x}(\dot{x}_i(t))+\frac{\partial M}{\partial x}\dot{x}_i+\frac{\partial M}{\partial t}(x_i(t), t)=0, \tag{26}$$

or

$$\left[\frac{\partial M}{\partial t}+\frac{\partial}{\partial x}(M\dot{x})\right]_{x=x_i}=0. \tag{27}$$

The steps from (25) to (27) can be retraced.

Thus the perturbation equation (13), used in [8] to study stability of the equidistribution process, can be obtained from setting the right-hand side in (16) to zero and writing the resulting equation at $x=x_i$ in nonconservative form. In retrospect, we see that (13) resembles a conservation of mass equation, where θ corresponds to total mass, which is unchanging with time. It is obtained from perturbing only the left-hand side of (7) or (10), since there is no perturbation expansion for the term i/N. We conclude that, while (13) is extremely useful for interpreting the stability of many *implementations* of equidistribution procedures, the stability properties of the equidistribution principle itself are more complicated.

Through a simple change of variables, (16) can be converted from a differential-integral equation in $M(x, t)$ to a differential equation for which the stability analysis of [8] is more generally applicable. Introducing the transformation

$$W(x, t) := \frac{M(x, t)}{\theta(t)} = \frac{M(x, t)}{\int_a^b M(x, t)\, dx}, \tag{28}$$

it is easy to see that (16) takes the equivalent form

$$\frac{\partial W(x, t)}{\partial t} + \frac{\partial (W(x, t)\dot{x})}{\partial x} = 0. \tag{29}$$

Thus, the "average energy" function $W(x, t)$, for which

$$\int_a^b W(x, t)\, dx \equiv 1,$$

satisfies the conservation equation (29). The transformation (28) is similar to the Cole-Hopf transformation [40], although the context and purpose are quite different. From (6), the weak form of the PDE (29) is

$$\int_{x_i}^{x_{i+1}} W(x, t)\, dx = \frac{1}{N}, \qquad i = 1, \cdots, N,$$

i.e., the total "average energy" between any two mesh lines remains constant. In principle, there is no reason why the moving mesh approaches constructed in terms of $M(x, t)$ cannot use $W(x, t)$ instead. The derivation from (20) through (24) can be repeated with W replacing M and, under the appropriate corresponding conditions (except with no right-hand side that needs to be ignored), we see that the potential for mesh crossings now occurs if

$$\frac{W(x_i(0), 0)}{W(x_i(t), t)} = \frac{M(x_i(0), 0)}{M(x_i(t), t)} \frac{\theta(t)}{\theta(0)},$$

a measure of the *average* change in $M(x_i(t), t)$, grows. In comparison with (24), we hope that the moving mesh equations derived using this new variable would be more robust, if not necessarily more efficient. Finally, the analysis [8] *is* more directly applicable to (29), so stability for the discretization of a nonconservative form of an equidistribution process is given by (13), with W replacing M.

3. Implementations of equidistribution. In this section, we consider ways in which the equidistribution process can be implemented. First, we consider how to choose the monitor or density function that controls the movement of the mesh points. This is more difficult than for ODEs due to the additional variable t. There are three basic choices of $M(x, t)$, which have been widely used in practice: (i) an arclength monitor function [42], [11]; (ii) a combination of gradient and curvature [27], [12], [20], [11], [31]; and (iii) truncation error or solution residual—used directly for ODEs [34], and either explicitly [2], [5] or implicitly [30], [17] for moving finite element methods for PDEs.

Stability properties of the moving mesh equations, while dependent upon the choice of monitor function, are to some extent arbitrary, since they usually behave asymptotically much like some fractional power of a solution derivative (see, e.g., [35]). Here, we use the arclength monitor function

$$M(x, t) = \sqrt{1 + u_x^2(x, t)}. \tag{30}$$

Our first implementation of a moving mesh method involves using an approximation for (16) of the form

$$\frac{\partial}{\partial t}M(x_i(t),t)+\frac{M_{i+1}\dot{x}_{i+1}(t)-M_i\dot{x}_i(t)}{x_{i+1}(t)-x_i(t)}=\frac{\dot{\theta}}{\theta}M(x_i(t),t), \qquad 1\leqq i\leqq N-1. \tag{31}$$

For the numerical examples presented in the next section, $\dot{x}>0$, so this simple upwind approximation to $(M\dot{x})_x$ is sufficient. On the interval $[x_i, x_{i+1}]$, we use the monitor function discretization

$$M_i := M(x_i,t)=\sqrt{1+\left(\frac{u_{i+1}-u_i}{x_{i+1}-x_i}\right)^2}. \tag{32a}$$

To maintain discrete conservative laws,

$$\theta(t)=\int_a^b M(x,t)\,dx=\sum_{i=0}^{N-1}\int_{x_i}^{x_{i+1}} M(x,t)\,dx$$

and

$$\dot{\theta}(t)=\int_a^b M_t(x,t)\,dx=\sum_{i=0}^{N-1}\int_{x_i}^{x_{i+1}} M_t(x,t)\,dx$$

are approximated using left rectangle rules

$$\int_{x_i}^{x_{i+1}} M(x,t)\,dx\approx(x_{i+1}-x_i)M(x_i(t),t), \tag{32b}$$

$$\int_{x_i}^{x_{i+1}} M_t(x,t)\,dx\approx(x_{i+1}-x_i)M_t(x_i(t),t). \tag{32c}$$

We test this moving mesh strategy, hereafter called Method I, both with and without the right-hand side in (31). For both, only the fixed boundary case $\dot{x}_0(t)=\dot{x}_N(t)=0$ is considered.

We also consider a moving mesh method developed using (29). Approximating this PDE over $[x_i, x_{i+1}]$ at $t=t_{n+1}=(n+1)\Delta t$ by

$$\frac{W_i^{n+1}-W_i^n}{\Delta t}+\frac{W_i^{n+1}\dot{x}_{i+1}-W_{i-1}^{n+1}\dot{x}_i}{x_{i+1}-x_i}=0, \tag{33}$$

upon rearrangement, we obtain

$$W_i^{n+1}(x_{i+1}-x_i)+\Delta t(W_i^{n+1}\dot{x}_{i+1}-W_{i-1}^{n+1}\dot{x}_i)=(x_{i+1}-x_i)W_i^n. \tag{34a}$$

As it stands, (34a) would be awkward to implement because it depends upon $\theta(t_n)$ and $\theta(t_{n+1})$, and therefore on *all* of the solution approximations at time levels t_n and t_{n+1}. Fortunately, it is possible to simplify by working with two adjacent interval discretizations. A similar approximation to (34a) on $[x_{i-1}, x_i]$ gives

$$W_{i-1}^{n+1}(x_i-x_{i-1})+\Delta t(W_{i-1}^{n+1}\dot{x}_i-W_{i-2}^{n+1}\dot{x}_{i-1})=(x_i-x_{i-1})W_{i-1}^n. \tag{34b}$$

Equidistribution implies

$$\int_{x_i}^{x_{i+1}} W(x,t)\,dx=\int_{x_{i-1}}^{x_i} W(x,t)\,dx. \tag{35}$$

Equating the right-hand sides of (34a) and (34b), which are approximations to (35) at $t = t_n$, we obtain

$$W_i^{n+1}(x_{i+1} - x_i) + \Delta t(W_i^{n+1}\dot{x}_{i+1} - W_{i-1}^{n+1}\dot{x}_i) = W_{i-1}^{n+1}(x_i - x_{i-1}) + \Delta t(W_{i-1}^{n+1}\dot{x}_i - W_{i-2}^{n+1}\dot{x}_{i-1}).$$

Since each term involves

$$W(x, t_{n+1}) = \frac{M(x, t_{n+1})}{\theta(t_{n+1})},$$

$\theta(t)$ can be eliminated, leaving the discrete approximation

$$\tau(M_i\dot{x}_{i+1} - 2M_{i-1}\dot{x}_i + M_{i-2}\dot{x}_{i-1}) = M_{i-1}(x_i - x_{i-1}) - M_i(x_{i+1} - x_i) \tag{36}$$

at $t = t_{n+1}$. Here, to avoid confusion with the time integration steps later on (when the moving mesh equations are integrated with a method of lines approach), we write $\tau := \Delta t$. This moving mesh strategy, which we refer to as Method II (also using (32a) and with $\dot{x}_0(t) = \dot{x}_N(t) = 0$), is considered in the next section.

A great variety of moving mesh equations have been obtained by others, using the various choices of monitor functions and approximation schemes. In the remainder of this section, we show how some of these equations are related to the equidistribution relationships derived in § 2, either in the differential form (16) or the weak form (6).

For the moving finite element methods of Miller and Miller [30] and Herbst, Schoombie, and Mitchell [17], the moving mesh equations are derived from the weak form of the PDEs written in Lagrangian form. In particular, a given PDE $u_t = L(u)$ is converted to its Lagrangian form $\dot{u} - u_x\dot{x} = L(u)$. Suitable weight functions $\phi_i(x)$ and $\psi_i(x)$ are chosen, and the residual

$$R(u) = \dot{u} - u_x\dot{x} - L(u)$$

is required to satisfy the orthogonality relations

$$\int_a^b \phi_i(x)R(u)\,dx = 0, \tag{37}$$

$$\int_a^b \psi_i(x)R(u)\,dx = 0. \tag{38}$$

The choice

$$\phi_i(x) = \alpha_i(x) \tag{39}$$

and

$$\psi_i(x) = \beta_i(x) = -u_x\alpha_i(x), \tag{40}$$

where $\alpha_i(x)$ is the hat function and $\beta_i(x)$ is a discontinuous piecewise linear function on $[x_{i-1}, x_{i+1}]$, is made in [30], and the choice of the piecewise cubic Hermite polynomials

$$\phi_i(x) = [\alpha_i(x)]^2[3 - 2\alpha_i(x)], \tag{41}$$

$$\psi_i(x) = [\alpha_i(x)]^2[\alpha_i(x) - 1]\left[\frac{d\alpha_i(x)}{dx}\right]^{-1}, \tag{42}$$

is used in [17]. Both of these can be shown to be implicitly based upon a weak form of (16). In particular, requiring that

$$\int_{x_{i-1}}^{x_i} M(x, t)\,dx = \int_{x_i}^{x_{i+1}} M(x, t)\,dx \tag{43}$$

is satisfied, for the monitor function

$$M_i(x, u) = (x_i - x_{i-1})R(u_i),$$

we obtain the moving mesh equation corresponding to (41) and (42), and for

$$M(x, t) = \begin{cases} -u_x R(u), & x \in [x_{i-1}, x_i], \\ u_x R(u), & x \in [x_i, x_{i+1}], \end{cases}$$

we obtain the moving mesh equation corresponding to (39) and (40) [13].

Aside from stability, one of the most troublesome problems for a moving mesh method is the tendency for mesh points to cross. For equidistribution (6), this happens easily if M changes sign, so to avoid this, the early papers on equidistribution define a monitor function to be nonnegative. For MFE methods, the associated equidistribution property above holds for a monitor function that changes sign, and consistent with this is the fact that regularization terms generally must be added to prevent mesh crossings. In contrast, we find that for discretizations formed directly from (16), for positive monitor functions the problem of mesh crossing itself can be minimal (see §§ 4 and 5).

If instead of (16) we take

$$\frac{\partial}{\partial x}(M\dot{x}) = 0,$$

and write it in the nonconservative form

$$\frac{\partial M}{\partial x}\dot{x} + M\frac{\partial \dot{x}}{\partial x} = 0,$$

then the discretization

$$\frac{M_i - M_{i-1}}{x_i - x_{i-1}}\dot{x}_i + M_i\frac{\dot{x}_i - \dot{x}_{i-1}}{x_i - x_{i-1}} = 0$$

gives

$$\dot{x}_i - \dot{x}_{i-1} = -\frac{\dot{x}_i}{M_i}(M_i - M_{i-1}).$$

This is similar to the moving mesh equation of [1], except that they attempt to optimize a parameter value that is used in place of $\dot{x}_i/M_i$.

If the monitor function is simply the solution to the PDE, i.e., $M(x, t) = u$, then (16) becomes

$$\frac{\partial u}{\partial t} + \frac{\partial(u\dot{x})}{\partial x} = u\frac{\dot{\theta}}{\theta},$$

or, in nonconservative form,

$$\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x}\dot{x} + u\frac{\partial \dot{x}}{\partial x} = u\frac{\dot{\theta}}{\theta}. \tag{44}$$

In developing a moving mesh strategy, Petzold [32] attempts to minimize, for a suitable parameter α, the objective function

$$\phi(\dot{x}, \dot{u}) = \left(\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x}\dot{x}\right)^2 + \alpha\dot{x}^2,$$

which is a measure of the change in the solution u and mesh x with respect to time t.

Since meshpoints can easily cross with this choice, she introduces a penalty function

$$\lambda\left[\left(\frac{\dot{x}_i - \dot{x}_{i-1}}{x_i - x_{i-1}}\right)^2 + \left(\frac{\dot{x}_{i+1} - \dot{x}_i}{x_{i+1} - x_i}\right)^2\right].$$

This can be viewed as "compensation" for the extra term $u(\partial\dot{x}/\partial x)$ in (44), which gives a scheme that in some sense minimizes the source error energy $u(\dot{\theta}/\theta)$ for the PDE when moving mesh points in time. The usefulness of this interpretation of Petzold's scheme to develop other practical moving mesh strategies remains to be investigated.

One of the most reliable moving mesh discretizations is due to Dorfi and Drury [11] and analyzed in [39]. It is similar to (36), where the general relationship between them involves using an artificial dissipation term in conjunction with (36) [33].

4. Numerical results. Here we give some numerical examples to examine the moving mesh strategy from Method I, with and without the right-hand side of (31), and the strategy from Method II. We choose three examples, consisting of one hyperbolic and two parabolic problems.

To discretize the PDE

$$\frac{\partial u}{\partial t} = f(u, u_x, u_{xx}), \tag{45}$$

we first write it in the Lagrangian form

$$\dot{u} - u_x\dot{x} = f(u, u_x, u_{xx}). \tag{46}$$

Using a central difference scheme for the spatial derivatives, we obtain

$$\dot{u}_i - \frac{u_{i+1} - u_{i-1}}{x_{i+1} - x_{i-1}}\dot{x}_i = f_i, \qquad i = 2, \cdots, N. \tag{47}$$

Thus we solve the coupled system of equations (47) and (31), with and without $\dot{\theta} = 0$, and the coupled system (47) and (36). This ODE system is solved using the code LSODI of Hindmarsh [18]. An approximate Jacobian is computed by LSODI internally using difference quotients. For simplicity, an initial uniform mesh is used in each case. In the tables of numerical results reported, *nst* and *nje* are, respectively, the number of steps and number of Jacobian evaluations taken by LSODI up to the time given; and *nqn* and *tstep* are, respectively, the order of the last successful method and the last successful stepsize. All runs were made on Sparcstations in a distributed computing environment, and computer times are not given. Method I is more expensive using the right-hand side in (31) than not using it, but the difference is not very significant (always less than 20 percent for these problems).

Problem I. This problem, a scalar reaction diffusion problem from combustion theory, has been used by several authors to test their moving mesh strategies [2], [32], [14]. It is a model of a single-step reaction with diffusion,

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + D(1 + a - u)\, e^{-\delta/u}, \qquad t > 0, 0 < x < 1,$$

$$u_x(0, t) = 0, u(1, t) = 1, \qquad t > 0,$$

$$u(x, 0) = 1, \qquad 0 \leqq x \leqq 1,$$

where the constant heat release is a, reaction rate is R, activation energy is δ, and Damkohler number is $D = Re^{\delta}/(a\delta)$. The solution represents the temperature of a reactant in a combustion. For a short time, the temperature gradually increases from unity with a "hot spot" forming at $x=0$. At a finite time ignition occurs and the temperature at $x=0$ jumps rapidly from unity to $1+a$. A flame front then forms and propagates towards $x=1$ with speed proportional to $e^{a\delta}/2(1+a)$. Here, a is about unity and δ is large, so that the flame front moves exponentially fast after ignition. The solution reaches a steady state once the flame propagates to $x=1$. This problem serves as a good test of moving mesh methods because of the sensitivity of tracking the flame front [1], [2].

The derivative boundary condition $(\partial u/\partial x)(0, t) = 0$ is approximated by

$$\frac{u_1 - u_2}{x_1 - x_2} = 0 \quad \text{or} \quad u_1 - u_2 = 0.$$

The problem is solved for $a=1$, $\delta = 20$, and $R=5$, using a moving mesh with $N=20$ and with $N=40$. The results are compared with a reference solution (solid lines in the figures) obtained by LSODI, using the method of lines with standard central differences on (45) and $N=500$ equally spaced mesh points, with absolute tolerance $\text{atol} = 10^{-8}$ and relative tolerance $\text{rtol} = 10^{-6}$. The problem is quite sensitive to the tolerances for LSODI. For example, for $\text{atol} = \text{rtol} = 10^{-3}$, the numerical solution (not given here) moves too quickly and is very inaccurate.

Figure 1 shows the numerical solution computed using Method I with $\dot{\theta} \neq 0$, for $N=20$, $\text{atol} = 10^{-5}$, and $\text{rtol} = 10^{-4}$. The solution is fairly accurate except for an error caused by the solution moving too quickly, so that it gives a slight shift for $t=0.27$ and 0.28. This error is caused largely by the time integration, as the results change qualitatively when smaller tolerances are used in LSODI (see below). The corresponding results for $\dot{\theta} = 0$ are shown in Fig. 2. Note that the solution is inaccurate at the left boundary when $t=0.26$, and the solution is not very well equidistributed with respect to arclength, especially near the left boundary. The sensitivity of the problem with respect to integrator tolerances is severe, as performing the same runs with larger tolerances can easily give poorer results, but even using $\text{atol} = 10^{-6}$ and $\text{rtol} = 10^{-5}$ gives lower accuracy (cf. Figs. 3 and 4).

For Method II with $\text{atol} = 10^{-5}$, $\text{rtol} = 10^{-5}$, $\tau = 10^{-5}$, and $N=20$, the numerical solution moves slightly slower than the reference solution before reaching steady state (see Fig. 5). Reducing the spatial mesh to $N=40$, the solution has fairly high accuracy throughout, as shown in Fig. 6. Reducing τ or the integrator tolerances does not qualitatively affect the numerical solution, although from our experience τ should be kept smaller than the time integration stepsize used in LSODI. Note that the arclength is considerably better distributed between mesh points than for the other moving mesh equation.

The timestepping information for the runs summarized in the figures is given in Table 1. In particular, the number of steps and Jacobian evaluations, order of the integration method, and final stepsize used by LSODI are listed.

Problem II. Our next example is Burgers' equation

$$\frac{\partial u}{\partial t} = -\frac{\partial f(u)}{\partial x} + \varepsilon \frac{\partial^2 u}{\partial x^2}, \qquad t>0, 0<x<1,$$

$$u(0,t)=0, u(1,t)=0, \qquad t>0,$$

$$u(x,0)=u^0(x),$$

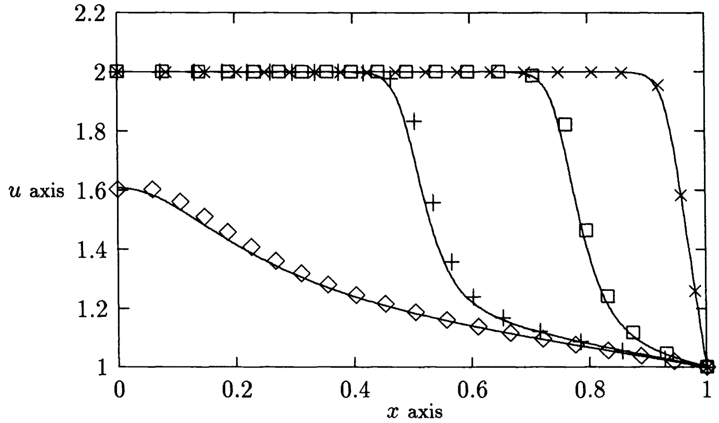

FIG. 1. *First example, using Method* I *with* $\dot{\theta} \neq 0$, $t = 0.26, 0.27, 0.28, 0.29$; atol $= 10^{-5}$, rtol $= 10^{-4}$, *mesh points* $N = 20$.

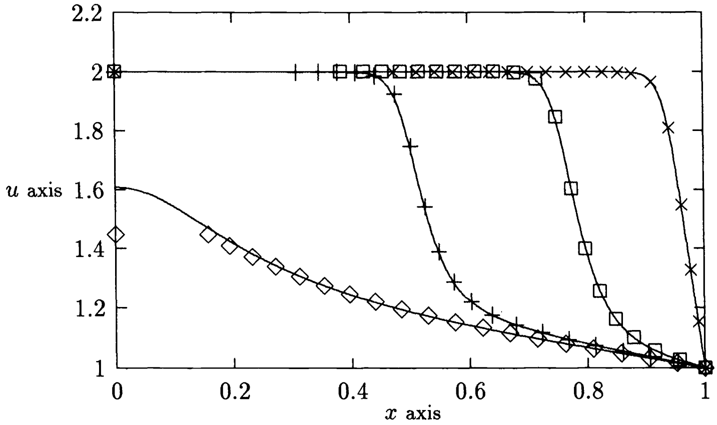

FIG. 2. *First example, using Method* I *with* $\dot{\theta} = 0$, $t = 0.26, 0.27, 0.28, 0.29$; atol $= 10^{-5}$, rtol $= 10^{-4}$, *mesh points* $N = 20$.

where $f(u)=u^2/2$. This problem is also often used as a test (occasionally the only test) of mesh selection strategies.

We use $\varepsilon=10^{-2}$ and $\varepsilon=10^{-4}$ and the smooth initial solution $u^0(x)=\sin(2\pi x)+\frac{1}{2}\sin(\pi x)$. For small times and ε, the exact solution is a pulse that moves in the positive x direction while steepening. The reference solution (solid lines) is computed as in Problem I except with $N=1000$, rtol $=10^{-6}$, and atol $=10^{-8}$. The solution is shown for time $=0.2, 0.4, 0.8, 1.0, 1.4$, and 2.0. For Method II, $\tau=10^{-5}$.

Using Method I with $\dot{\theta}=0$, the method easily breaks down due to mesh crossing for $\varepsilon=10^{-2}$. For example, for $N=20$, atol $=10^{-3}$, and rtol $=10^{-3}$, breakdown occurs because the second mesh point crosses the left boundary and becomes negative at $t=0.35$. For $\varepsilon=10^{-4}$, atol $=10^{-4}$, and rtol $=10^{-5}$ several mesh points cross each other on the interval $[0.519, 0.597]$ at $t=0.2$. This is consistent with the theoretical and numerical findings of [8] regarding potential instability of (20).

For $\varepsilon=10^{-2}$, the presence of the right-hand side term $\dot{\theta}\neq 0$ now stabilizes the results. Figures 7 and 8 show the solutions and mesh points for $N=20$ with atol $=10^{-3}$, rtol $=10^{-3}$ and atol $=10^{-4}$, rtol $=10^{-5}$, respectively. The corresponding timestepping information is given in Table 2. The solutions are quite accurate except at the points of zero gradient ($u_x=0$), where the graph is somewhat higher than that for the reference solution. This same problem occurs using Method II: results for the same parameter values are given in Fig. 9 and Table 2. Note, too, that the degree of equidistribution is rather poor in this region. Using $N=40$, these inaccuracies are remedied, and the problem resolution is generally quite satisfactory (see Fig. 9(a)).

For $\varepsilon=10^{-4}$, the problem causes considerable difficulty. At about $t=0.2$, a shock layer forms near $x=0.6$. Setting $N=20$, using Method I with $\dot{\theta}\neq 0$, LSODI stops at the very steep layer at $t=0.218224$ due to a small stepsize (tstep $=10^{-6}$ and nst $=955$ for atol $=10^{-4}$, rtol $=10^{-5}$). With (36) and corresponding parameter values, LSODI also stops, now at $t=0.341905$ with tstep $=0$ and nst $=949$. Using $N=40$, LSODI is able to progress further, but still soon fails. The same difficulty of breakdown when the shock develops can occur for this problem with a high-order MFE method using Hermite cubic test functions [16], although other methods are successful [14], [28].

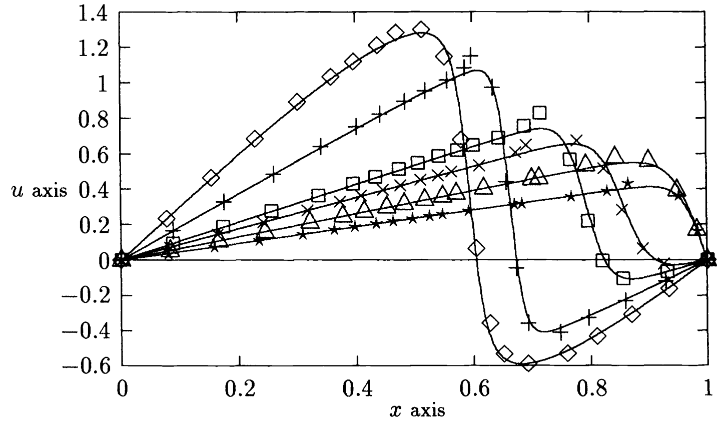

FIG. 7. *Burgers' problem, using Method* I *with* $\dot{\theta} \neq 0$, $\varepsilon = 10^{-2}$, $t = 0.2, 0.4, 0.8, 1.0, 1.4, 2.0$; atol $= 10^{-3}$, rtol $= 10^{-3}$, *mesh points* $N = 20$.

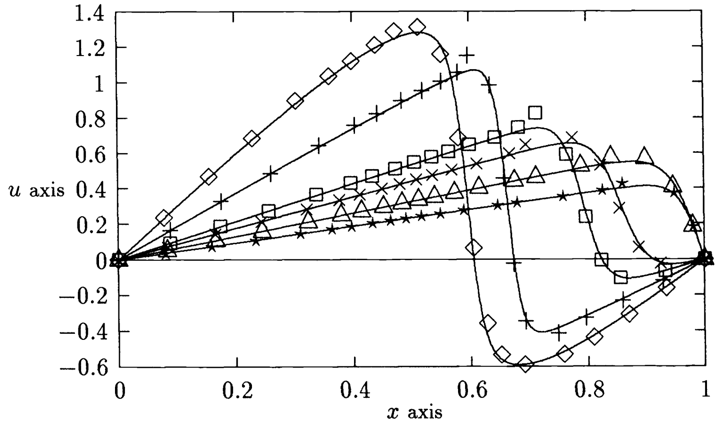

FIG. 8. *Burgers' problem, using Method* I *with* $\dot{\theta} \neq 0$, $\varepsilon = 10^{-2}$, $t = 0.2, 0.4, 0.8, 1.0, 1.4, 2.0$; atol $= 10^{-4}$, rtol $= 10^{-5}$, *mesh points* $N = 20$.

FIG. 9. (a) *Burgers' problem, using Method* II, $\varepsilon = 10^{-2}$, $t = 0.2, 0.4, 0.8, 1.0, 1.4, 2.0$; atol $= 10^{-4}$, rtol $= 10^{-5}$, *mesh points* $N = 40$. (b) *Burgers' problem, using Method* II, $\varepsilon = 10^{-2}$, $t = 0.2, 0.4, 0.8, 1.0, 1.4, 2.0$; atol $= 10^{-4}$, rtol $= 10^{-5}$, *mesh points* $N = 20$.

Problem III. The last example is the hyperbolic conservative Buckley-Leverett equation

$$u_t + f(u)_x = 0$$

with the nonconvex flux function

$$f(u) = \frac{u^2}{u^2 + \frac{1}{2}(1-u)^2},$$

as in, e.g., [9]. The moving mesh methods of [1] and [15] test the problem with an artificial viscosity term εu_{xx} added. (See also [22].)

We consider the continuous initial data condition

$$u(x,0) = \frac{0.1}{0.1+x}, \qquad 0 \leqq x \leqq 1,$$

and boundary conditions

$$u(0,t)=1, \qquad u(1,t)=\frac{1}{11},$$

where we express the right boundary condition for LSODI in the form $\dot{u}_N(t)=0$. The reference solution is determined as in the other two problems, with $N=500$, atol $=10^{-8}$, and rtol $=10^{-6}$, and the solution profile shown for $t=0.1, 0.2, 0.3, 0.4$. With $N=20$, results with and without the right-hand side term in Method I are given in Figs. 10 and 11, respectively. These numerical solutions are virtually identical and move faster than the reference solution. For Method II with atol $=10^{-4}$, rtol $=10^{-5}$, and $\tau=10^{-5}$, LSODI stops due to the steep layer for $t=0.303228$ with tstep $=0$ and nst $=575$. (Again, mesh crossing is not a problem.) Adding the artificial viscosity term mentioned above, here with $\varepsilon=10^{-4}$, the problem is solved more satisfactorily than before, using atol $=10^{-4}$ and rtol $=10^{-5}$. The results, given in Fig. 12, are qualitatively unchanged for smaller tolerances, for example, atol $=10^{-5}$ and rtol $=10^{-6}$ (see Table 3). The scheme developed in [1] has no difficulty for this problem when solved as a parabolic PDE

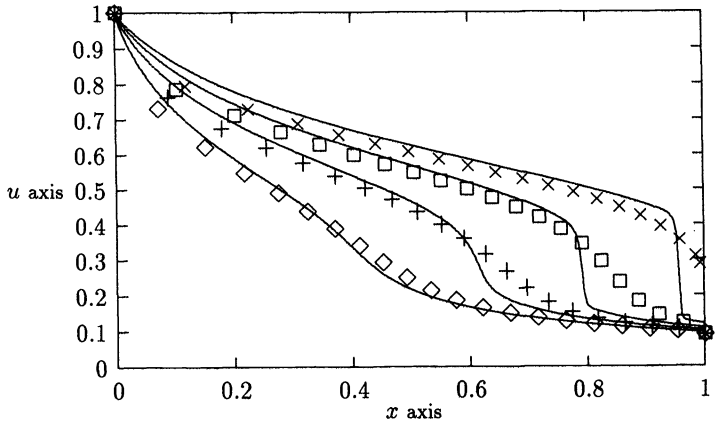

FIG. 10. *Buckley-Leverett problem, using Method* I *with* $\dot{\theta}\neq 0$, $t=0.1, 0.2, 0.3, 0.4$; atol $=10^{-5}$, rtol $=10^{-6}$, *mesh points* $N=20$.

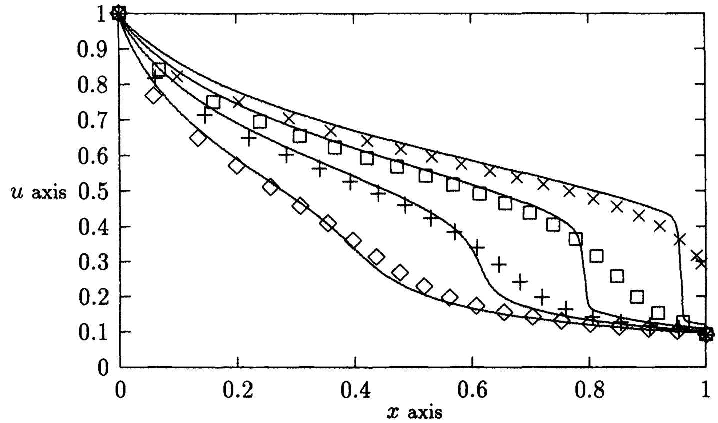

FIG. 11. *Buckley-Leverett problem, using Method* I *with* $\dot{\theta}=0$, $t=0.1, 0.2, 0.3, 0.4$; atol $=10^{-5}$, rtol $=10^{-6}$, *mesh points* $N=20$.

using real artificial viscosity, $\varepsilon = 10^{-3}$. However, it is interesting to wonder when a difficulty arises solving hyperbolic PDEs because the scheme is nonconservative when viewed as a scheme for solving the moving mesh PDE.

5. Conclusions. We have presented a new formulation of the equidistribution strategy in terms of a PDE. Previously, authors who have explicitly used equidistribution have generally developed moving mesh procedures that use (6), the integrated or weak form of the conservative integral. We intend to further develop robust moving mesh strategies based directly upon the differential form (16) or (29). Here, our intention has been to present some simple strategies. The purpose has not been to give extensive numerical results or a detailed comparison with other methods; this is done elsewhere [33]. Nevertheless, the results indicate that the schemes given here, with simple improvements such as smoothing of the mesh (for Problem II) when necessary, should prove competitive with those that have been recommended by others [14]. Use of conservative-type schemes to approximate the PDEs is natural and probably essential in many contexts. The importance of the right-hand side term of (16) is unclear, and we have included numerical results for $\dot{\theta} = 0$ partly to determine the effect and partly because this corresponds to what many previous implementations have used.

The numerical methods used here are quite simple and are presented mainly for illustrative purposes. Constructing more robust moving mesh methods could well require the incorporation of regularization terms as in [11], [14], [26], [29], [39], and possibly a more complicated monitor function, an obvious choice being some combination of arclength and curvature. However, while using the arclength monitor function can limit the number of mesh points that are placed in the transition region, strong nonlinearities that arise using a curvature monitor function can also cause computational difficulties [6]. Efficient ways to produce the moving mesh equations using this approach, particularly for higher-order systems (4), and for the higher-dimensional form of (17) or (29), remain to be investigated. Still, it is important to realize that the scheme is not plagued with mesh crossings the way most other simple moving mesh schemes are. When the PDE (16) (including the right-hand side) is approximated, we find very little difficulty of this type. In one case (Burgers' equation with different initial conditions than given here) (31) gave mesh crossing with a large tolerance, but this was fixed when the tolerance was reduced. While there is no need to add penalty functions for this reason, it may still be necessary to perform a mesh smoothing to prevent problem stiffness when steep solution layers occur (as was the difficulty in Problem II in the previous section). Obviously, a desirable ultimate goal is the development of a robust scheme with minimal requirements for a user to select contentious problem-dependent parameters.

This moving mesh PDE interpretation can be used to understand stability properties for moving mesh strategies, and extends the understanding of the stability properties as given in [8]. While the stability issue for methods based upon equidistribution is a very complicated one, and there is no doubt that a complicated interaction takes place between the PDE (3) and the mesh PDE (16) or (29), we expect that this viewpoint will be used to develop a deeper understanding of stability properties for currently used methods which have proven reliable. It is important to realize how many moving mesh methods are based upon equidistribution, making it possibly the single most important concept in the development of moving mesh methods. Many of these methods use equidistribution explicitly (e.g., [2], [20], [32], and those in [8]), and many of these often have stability difficulties [8]. There are also those, like the moving finite element methods [30], [17] and the elliptic grid generation methods [27], that have been developed from another viewpoint, but for which equidistribution has played a role—just how fundamental is unclear at this stage. The considerable success of some of these methods may be due in part to the fact that the moving mesh PDE (16) is solved implicitly, so that inadequate approximations from using nonconservative schemes, or from ignoring the important right-hand side term, have been circumvented. Of course, another underlying issue of critical importance is that of deciding what monitor function to use, and it is unrealistic to expect that a single choice for M would serve as a panacea for most problems.

Acknowledgments. The authors are very grateful to the referees, who suggested a number of significant improvements to the paper.

FINITE DIFFERENCE SCHEMES ON TRIANGULAR CELL-CENTERED GRIDS WITH LOCAL REFINEMENT*

P. S. VASSILEVSKI†, S. I. PETROVA‡, AND R. D. LAZAROV‡

Abstract. Based on approximation of the balance equation, finite difference schemes on triangular cell-centered grids are derived. A priori estimates and error analyses are provided. For certain regular triangulations, $\mathbb{O}(h^2)$ convergence in the discrete $\mathbb{H}^1$-norm is established. Also, finite difference schemes on triangular cell-centered grids with local refinement are derived with accuracy $\mathbb{O}(h^{1/2+\alpha})$, where $\alpha=0$ for a simple symmetric scheme, $\alpha=1$ for a nonsymmetric and a more accurate symmetric scheme, and $\alpha=\frac{3}{2}$ for a more accurate nonsymmetric scheme.

Certain algebraic properties of the corresponding matrices of the derived finite difference schemes are verified, thus allowing the recently proposed algebraic theory for the Bramble-Ewing-Pasciak-Schatz (BEPS) and Fact Adaptive Composite (FAC) two-grid preconditioners to apply.

Numerical experiments that demonstrate the accuracy of the difference schemes and the fast convergence of the two-grid BEPS and FAC preconditioners in conjugate gradient-type iterative methods are presented.

Key words. triangular grids, cell-centered grids, local refinement, two-grid preconditioner, conjugate gradients, finite volume method, elliptic problems

1. Introduction. The finite volume method (also called the control volume method or the balance method) has been used in many applications as a systematic approach to effective discretization of fluid flow equations (cf., e.g., Patankar and Spalding [18]). Pioneering work in this area for one-dimensional elliptic and parabolic equations with piecewise smooth coefficients has been done by Tikhonov and Samarskii [23] and Samarskii [20], [21]. Recently this approach was augmented by new techniques and results by Kreiss, Manteuffel, and White [11]; Manteuffel and White [13]; and Weiser and Wheeler [25]. An important feature of this approach is that the corresponding discretizations are based on approximation of the balance equation and therefore they satisfy exactly the discrete conservation law (of mass, heat, momentum, etc.). A key aspect here is the choice of finite volumes (control volumes). In this context, we distinguish two principal ways of choosing these volumes: by vertex-centered and cell-centered grids.

In the context of vertex-centered grids (which are closely related to the finite element discretization), finite difference schemes are studied by Hackbusch [9]; Bank and Rose [3]; Samarskii, Lazarov, and Makarov [22]; and Heinrich [10], where the basic theory of the stability and convergence analysis is developed. Such schemes on vertex-centered grids with local refinement were proposed by McCormick [14] and Cai and McCormick [5], [6] for the diffusion equation; see also the recent paper by Cai, Mandel, and McCormick [6].

Convergence analysis of the difference schemes for elliptic equations on rectangular cell-centered grids has been presented by Weiser and Wheeler in [25], where the relation of the constructed schemes with mixed finite element discretization is used.

The finite volume method based on cell-centered grids has been used by Pedrosa [19] for efficient computation of fluid flow in porous media, and by Ewing, Lazarov, and Vassilevski [7], [8] for elliptic equations on grids with local refinement.

The approximations on cell-centered and vertex-centered grids actually coincide on uniform rectangular partitionings. Essential differences in these two approximations appear when using partitioning of the domain into triangles. Then the finite volumes of the cell-centered grid are, by definition, the triangles of the partitioning, while those of the vertex-centered grid are the Voronoi volumes [26].

In this paper, we investigate approximations of second-order elliptic equations on model cell-centered grids with local refinement introduced by uniform triangulation of the domain. The uniformity of the triangulation allows us to derive error estimates of superconvergence type (see below). The results can be considered as an extension of the results of [7] and [8], where similar problems were considered on rectangular grids with local refinement.

Combining both discretizations, on triangular and rectangular finite volumes, we can cover a wide range of applications, including elliptic problems on general polygonal domains. The results presented here can also be extended with minor modifications to curvilinear triangles near the boundary of the domain.

The difference schemes we develop are constructed by appealing to the balance equation, which is valid for a general class of finite volumes. The first step in this construction is to partition the region into a number of triangles. We assume that they have angles less than $\pi/2$. (Such grids can be used in combination with rectangular grids, for example, when the original region can be partitioned into a number of rectangles and triangles.)

The grid points of the cell-centered grid are the centers of the circumscribed circle of every triangle. Note that they are internal nodes with respect to the triangles and any pair of two neighboring nodes is on the line perpendicular to the common edge of the corresponding triangles. Thus the derivative of a function in a direction normal to such an edge can be approximated using the difference of the values of the function at these nodes. Such approximations are required when we use the balance equations. The approximations on grids with local refinement are derived similarly. In this case, however, we must use certain interpolations of values of the grid functions near the interface boundary between refined and nonrefined triangles. Depending on this approximation, we derive simple symmetric and nonsymmetric schemes, as well as more accurate ones. These give rise to symmetric or nonsymmetric linear algebraic problems, correspondingly.

Requiring certain regularity of the triangulation, a priori estimates are established and corresponding error analysis is provided. In particular, we show $\mathbb{O}(h^2)$ convergence of the schemes in the discrete $\mathbb{H}^1$-norm for schemes without local refinement. For grids with local refinement, we prove a convergence rate in the discrete $\mathbb{H}^1$-norm of $\mathbb{O}(h^{1/2})$, $\mathbb{O}(h^{3/2})$, *or* $\mathbb{O}(h^2)$, depending upon the interpolation used (piecewise constant, linear, or quadratic).

The second question studied in the paper is related to the construction of optimal preconditioners for solving the resulting linear algebraic systems of equations (which can be symmetric or nonsymmetric) on the composite grid, that is, on the grid with local refinement. We verify the necessary algebraic properties of the composite grid matrix and apply the algebraic theory for the BEPS and FAC preconditioners proposed in Ewing, Lazarov, and Vassilevski [7].

Originally, the FAC method was proposed by McCormick [14], [15] and McCormick and Thomas [16], and the BEPS technique by Bramble, Ewing, Pasciak, and Schatz [4]. In Mandel and McCormick [12], these two methods were compared in the case of finite element discretization with local refinement, noting that the BEPS method can be viewed as a symmetrization of the FAC preconditioner. The theory in [7] is based on the strengthened Cauchy inequality, which, in our case of finite difference schemes, need not necessarily exist. None of these theories applies to the case of nonsymmetric matrices.

The main result from Ewing, Lazarov, and Vassilevski [7] is valid here also, namely, that the two-grid BEPS and FAC preconditioners B are spectrally equivalent to the composite grid matrix A. In the nonsymmetric case, this is understood as follows: the spectrum of $B^{-1}A$ is contained in a fixed subset of a disc in the right-half complex plane independent of the grid parameter h. This implies that the generalized conjugant gradient (GCG)-type methods, such as generalized minimum residual (GMRES) from Saad and Schultz [27] or the GCG least squares (LS) method from Axelsson [1], [2], have a rate of convergence independent of the grid parameter h. We point out that throughout this paper the so-called aspect ratio, h_c/h_f, i.e., the coarse-grid parameter h_c over the fine-grid parameter h_f, is assumed to be bounded.

The remainder of the paper is organized as follows. In § 2, we formulate the problem and derive approximations of the balance equation on regular grids and on grids with local refinement. In § 3, we state the discrete problem and verify certain algebraic properties of the finite difference matrices on the composite grid. In § 4, we provide the error analysis for the derived finite difference schemes on uniform grids and on grids with local refinement. Finally, in § 5, we formulate the BEPS and the FAC preconditioners and develop their spectral properties, while in § 6, a number of test examples are presented.

2. Approximations on regular cell-centered grids and on cell-centered grids with local refinement.

We consider the following differential equation in a polygonal region Ω. Find u such that

$$-\operatorname{div}(a\nabla u)=f(x), \qquad x\in\Omega, \tag{2.1}$$

with the following mixed boundary conditions

$$u(x)=g(x) \quad \text{on } \Gamma_D, \tag{2.2}$$

$$W_\nu \equiv -\nu\cdot a\nabla u=0, \qquad x\in\Gamma_N=\partial\Omega\backslash\Gamma_D, \tag{2.3}$$

where ν is the unit outward normal vector on $\partial\Omega$. The coefficient function $a(x)$ should be piecewise smooth (or piecewise continuous) and bounded away from the origin and from above; that is, for some constants a_1, a_2, we have that

$$0<a_1\leqq a(x)\leqq a_2, \qquad x\in\Omega. \tag{2.4}$$

We cover the region Ω by a set of triangles $\tilde{\tau}=\{T\}$ such that if two triangles are interesecting, they have either only a common edge or only a common vertex. For every finite volume $T\subset\tilde{\tau}$, the following balance equation is valid:

$$\int_{\partial T} W_\nu\, ds=\int_T f(\xi)\, d\xi. \tag{2.5}$$

Let T be the triangle shown in Fig. 2.1 with edges s_1, s_2, and s_3. Then (2.5) reads

$$\int_{s_1} W_{\nu_1}\, ds_1+\int_{s_2} W_{\nu_2}\, ds_2+\int_{s_3} W_{\nu_3}\, ds_3=\int_T f(\xi)\, d\xi, \tag{2.6}$$

where ν_l are outward unit normal vectors on s_l, $l=1, 2, 3$.

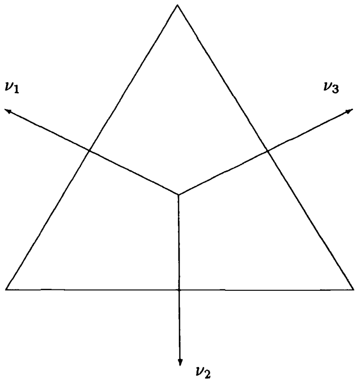

FIG. 2.1. *Triangle* $T \in \tau$.

Consider now the following model situation. We assume that all triangles in τ have no angles greater than or equal to $\pi/2$. Let the grid $\tilde{\omega}$ consist of the centers of the circumscribed circles of all the triangles $T \in \tilde{\tau}$. Here we consider only uniform partitionings of Ω, by which we mean that every two neighboring triangles form a parallelogram. We asume further that the triangles $T \in \tilde{\tau}$ have sides parallel to three fixed directions, or equivalently, the normal vectors to their edges are three fixed vectors ν_1, ν_2, and ν_3. Then we can introduce a coordinate system using ν_1 and ν_3 as coordinate axes. See Fig. 2.2 as an example of a region Ω covered by geometrically equal triangles.

The finite difference schemes are obtained by approximations of the fluxes W_{ν_l} across the edges s_l, $l = 1$, 2, 3, for every triangle $T \in \tilde{\tau}$. For every center x of the circumscribed circle of a triangle $T = T(x) \in \tau$, we denote by $w_l(x)$ some approximation to

$$\int_{s_l} W_{\nu_l}\, ds_l, \quad \text{i.e.,} \quad w_l(x) \approx \int_{s_l} W_{\nu_l}\, ds_l, \qquad l = 1, 2, 3.$$

These approximations can be derived in the following way. For definiteness we consider the four neighboring nodes $x_{i,j}$, $x_{i+1,j}$, $x_{i-1,j-1}$, and $x_{i,j+1}$ as shown in Fig. 2.2. Since $a(x) > 0$, then

$$\frac{\partial u}{\partial \nu_l} = -\frac{W_{\nu_l}(x)}{a(x)}, \qquad l = 1, 2, 3.$$

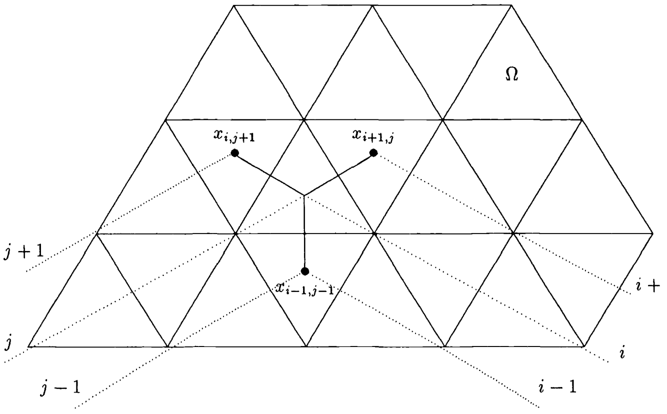

FIG. 2.2. *Region* Ω.

Then integrating for $l=1$ over the segment $(x_{i,j}, x_{i,j+1})$ along the vector ν_1 we get

$$u(x_{i,j+1})-u(x_{i,j})=-\int_{x_{i,j}}^{x_{i,j+1}} \frac{W_{\nu_1}(s)}{a(s)}\,ds \approx -W_{\nu_1}(x_{i,j+1/2})\int_{x_{i,j}}^{x_{i,j+1}} \frac{ds}{a(s)},$$

where $x_{i,j+1/2}$ is the point of intersection of s_1 and the segment $(x_{i,j}x_{i,j+1})$. For uniform partitioning this is the midpoint of the segment $(x_{i,j}x_{i,j+1})$. Thus we get the following approximation

$$W_{\nu_1}(x_{i,j+1/2}) \approx -(u(x_{i,j+1})-u(x_{i,j}))\bigg/\int_{x_{i,j}}^{x_{i,j+1}} \frac{ds}{a(s)}. \tag{2.7}$$

Then the integral $\int_{s_1} W_{\nu_1}\,ds$ can be approximated as follows:

$$\begin{aligned}\int_{s_1} W_{\nu_1}(s)\,ds &\approx W_{\nu_1}(x_{i,j+1/2}) \text{ meas } (s_1)\\ &\approx -\frac{\text{meas } (s_1)}{h_1}(u(x_{i,j+1})-u(x_{i,j}))\bigg/\frac{1}{h_1}\int_{x_{i,j}}^{x_{i,+1}} \frac{ds}{a(s)}\end{aligned} \tag{2.8}$$

where

$$\text{meas } (\Delta)=\int_{\Delta} ds.$$

We can approximate the other integrals similarly.

Let $y(x)=y_{i,j}$ be a grid function that approximates $u=u(x)$ for $x\in\tilde{\omega}$. According to (2.8), we define

$$\begin{aligned} w_1(x)&=\frac{\text{meas } (s_1)}{h_1}(y_{i,j}-y_{i,j+1})\bigg/\frac{1}{h_1}\int_{x_{i,j}}^{x_{i,j+1}}\frac{ds}{a(s)}\equiv k_1(x)\Delta_1 y(x),\\ w_2(x)&=\frac{\text{meas } (s_2)}{h_2}(y_{i,j}-y_{i-1,j-1})\bigg/\frac{1}{h_2}\int_{x_{i,j}}^{x_{i-1,j-1}}\frac{ds}{a(s)}\equiv k_2(x)\Delta_2 y(x),\\ w_3(x)&=\frac{\text{meas } (s_3)}{h_3}(y_{i,j}-y_{i+1,j})\bigg/\frac{1}{h_3}\int_{x_{i,j}}^{x_{i+1,j}}\frac{ds}{a(s)}\equiv k_3(x)\Delta_3 y(x), \end{aligned} \tag{2.9}$$

where

$$\begin{aligned} k_1(x)&=\frac{\text{meas } (s_1)}{h_1}\left(\frac{1}{h_1}\int_{x_{i,j}}^{x_{i,j+1}}\frac{ds}{a(s)}\right)^{-1},\\ k_2(x)&=\frac{\text{meas } (s_2)}{h_2}\left[\frac{1}{h_2}\int_{x_{i,j}}^{x_{i-1,j-1}}\frac{ds}{a(s)}\right]^{-1},\\ k_3(x)&=\frac{\text{meas } (s_3)}{h_3}\left[\frac{1}{h_3}\int_{x_{i,j}}^{x_{i+1,j}}\frac{ds}{a(s)}\right]^{-1}. \end{aligned} \tag{2.10}$$

For $l=1, 2, 3$, we define

$$\Delta_l y(x)=y(x)-y(x+\varepsilon h_l\nu_l)=-\Delta_l y(x+\varepsilon h_l\nu_l), \tag{2.11}$$

where h_l is the mesh size in the ν_l direction so that $x+\varepsilon h_l\nu_l$, $\varepsilon=\pm 1$ are the neighboring grid points in the same direction ($l=1, 2, 3$).

In this way, we get the following cell-centered finite difference scheme

$$w_1(x)+w_2(x)+w_3(x)=\phi(x)\equiv\int_{T(x)} f(\xi)\,d\xi \tag{2.12}$$

for all $T = T(x) \in \tau$ and the boundary conditions (2.3) for $w_2(x)$, $w_3(x)$ on $\partial\Omega\backslash\Gamma_D$ (see Fig. 2.3) and $y(x) = g(x)$, $x \in \Gamma_D$.

Consider approximation (2.12) at the grid points near the boundary Γ_D. Note that the triangles along Γ_D are aligned so that the centers of their circumscribed circles lie on Γ_D. For triangles about interior points that intersect Γ_D, we can apply the balance equation by supposing that the solution $u(x)$ is extended continuously in the whole triangle T (see Fig. 2.3).

Now consider the case with local refinement, where some of the triangles of $\tilde{\tau}$ are refined into a number of congruent triangles. This new triangulation we denote by τ. The circumcenters of all triangles form the new grid ω, called the composite grid.

The approximation of the balance equation written for every triangle $T \in \tau$ is derived as above if T has four neighbors. For an interface triangle T, as shown in Fig. 2.4, we introduce the slave nodes (denoted by the superscript*), which are centers of the circumscribed circles of the corresponding triangles obtained if T were to be refined into congruent triangles. Now the difference scheme is derived as in the regular case. However, the slave nodes are not grid points, so the values of the grid function at these nodes must be obtained by interpolation. In order to simplify the exposition, we suppose that the refinement process is organized so that any nonrefined cell has at most one refined adjacent cell.

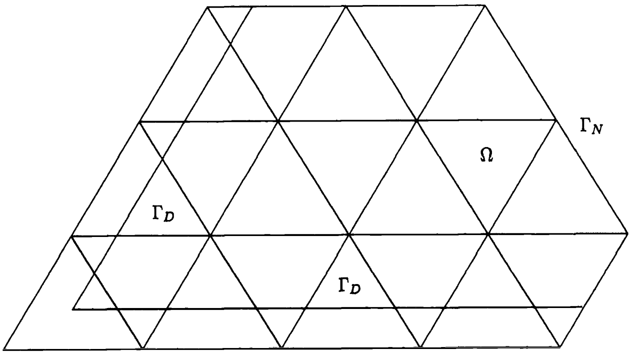

FIG. 2.3

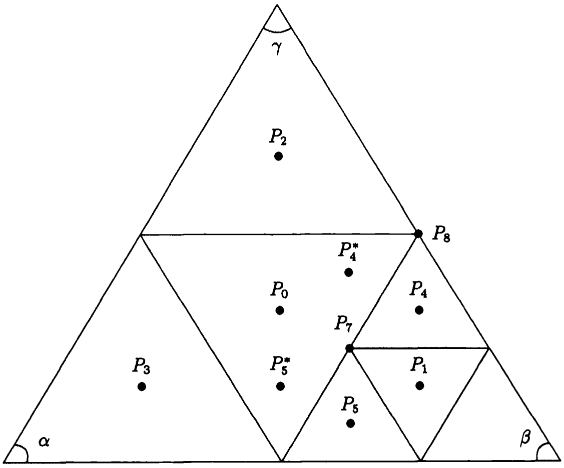

FIG. 2.4. *Interface triangle $T = T(x)$ with angles α, β, and γ.*

For definiteness, consider the case shown in Fig. 2.4. Let $y = y(x)$ be a grid function defined at the composite grid nodes $P_0, P_1, \cdots, P_5$. In order to derive the finite difference scheme on the composite grid, we need values of the grid function y at the points P_4^* and P_5^*. Let $p = p(x)$ be a polynomial that interpolates $y = y(x)$ at some of the nodes $P_0, P_1, \cdots, P_5$. For $x = P_4^*$ and P_5^* we set $y(x) = p(x)$. Then the relation

$$\int_s W_{\nu_1}\,ds = \int_{s_1} W_{\nu_1}\,ds + \int_{s_2} W_{\nu_1}\,ds \tag{2.13}$$

is approximated by

$$\begin{aligned} w_1(P_0) &= -k_1(P_4)(y(P_4) - y(P_4^*)) - k_1(P_5)(y(P_5) - y(P_5^*)) \\ &= -\frac{\text{meas}\,(s_1)}{\bar{h}}(y(P_4) - y(P_4^*)) \bigg/ \frac{1}{\bar{h}} \int_{P_4}^{P_4^*} \frac{ds}{a(s)} \\ &\quad -\frac{\text{meas}\,(s_2)}{\bar{h}}(y(P_5) - y(P_5^*)) \bigg/ \frac{1}{\bar{h}} \int_{P_5}^{P_5^*} \frac{ds}{a(s)}, \end{aligned} \tag{2.14}$$

where $\bar{h} = \text{dist}\,(P_4, P_4^*) = \text{dist}\,(P_5, P_5^*)$, i.e., $\bar{h}$ is the distance between the corresponding points.

We distinguish the following four cases for defining the polynomial $p = p(x)$.

2.1. Simple symmetric approximation. This corresponds to the choice of piecewise constant interpolation, i.e., $p = p(x) = y(P_0)$. Then

$$y(P_4^*) = y(P_5^*) = y(P_0),$$

and we get (for the particular case of Fig. 2.4)

$$w_1(P_4) = k_1(P_4)[y(P_4) - y(P_0)] = k_1(P_4)\Delta_1 y(P_4). \tag{2.15}$$

From this definition of the flux $w_1(P_4)$, we can see that the matrix corresponding to the finite difference scheme (2.12) is symmetric (the coefficient in front of $y(P_0)$ in the equation corresponding to the point P_4 equals the coefficient in front of $y(P_4)$ in the equation for P_0).

2.2. Simple nonsymmetric approximation. This scheme corresponds to piecewise linear interpolation, i.e., $p = p(x) = c_0 + c_1x_1 + c_2x_2$, $p(P_0) = y(P_0)$, $p(P_2) = y(P_2)$, and $p(P_3) = y(P_3)$. Then

$$y(P_4^*) = p(P_4^*), \qquad y(P_5^*) = p(P_5^*),$$

and

$$\begin{aligned} w_1(P_4) &= k_1(P_4)[y(P_4) - \tfrac{1}{4}(1 - \tan\gamma \text{ cotan } \beta)y(P_2) + \tfrac{1}{4}(1 + \tan\alpha \text{ cotan } \beta)y(P_3) \\ &\qquad - \tfrac{1}{4}((\tan\alpha + \tan\gamma) \text{ cotan } \beta + 4)y(P_0)] \\ &= k_1(P_4)[\Delta_1 y(P_4) + \tfrac{1}{4}(1 - \tan\gamma \text{ cotan } \beta)\Delta_2 y(P_0) \\ &\qquad - \tfrac{1}{4}(1 + \tan\alpha \text{ cotan } \beta)\Delta_3 y(P_0)]. \end{aligned} \tag{2.16}$$

For the case of equilateral triangles we have

$$\begin{aligned} w_1(P_4) &= k_1(P_4)[y(P_4) + \tfrac{1}{2}y(P_3) - \tfrac{3}{2}y(P_0)] \\ &= k_1(P_4)[\Delta_1 y(P_4) - \tfrac{1}{2}\Delta_3 y(P_0)]. \end{aligned} \tag{2.17}$$

Obviously, in the finite difference equation for the point P_4, the unknown $y(P_2)$, for example, enters with nonzero coefficient, while $y(P_4)$ is not included in the equation corresponding to the point P_2. This means that the finite difference matrix is not symmetric.

2.3. More accurate symmetric approximation. In this case, we again use the linear polynomial $p=p(x)=c_0+c_1x_1+c_2x_2$, but p now interpolates y using the nodes P_0, P_4, and P_5, that is, $p(P_0)=y(P_0)$, $p(P_4)=y(P_4)$, and $p(P_5)=y(P_5)$. Then

$$y(P_4^*)=p(P_4^*), \qquad y(P_5^*)=p(P_5^*),$$

and

$$\begin{aligned} w_1(P_4) &= \tfrac{1}{3}k_1(P_4)[-2y(P_0)+y(P_4)+y(P_5)] \\ &= \tfrac{1}{3}k_1(P_4)[\Delta_1 y(P_4)+\Delta_1 y(P_5)]. \end{aligned} \tag{2.18}$$

Here symmetry of the matrix can be established by inspection.

2.4. More accurate nonsymmetric approximation. Here we use the quadratic polynomial

$$p=p(x)=c_0+c_1x_1+c_2x_2+c_3x_1^2+c_4x_1x_2+c_5x_2^2$$

and interpolate $y=y(x)$ using the nodes P_0, P_1, P_2, P_3, P_4, and P_5. Then

$$y(P_4^*)=p(P_4^*), \qquad y(P_5^*)=p(P_5^*),$$

and when $\alpha=\beta=\gamma$, we get

$$\begin{aligned} w_1(P_4) &= \tfrac{1}{30}k_1(P_4)[-15y(P_0)+15y(P_1)-3y(P_2)+3y(P_3)+6y(P_4)-6y(P_5)] \\ &= \tfrac{1}{60}k_1(P_4)[6\Delta_2 y(P_0)-6\Delta_3 y(P_0)-15\Delta_2 y(P_4)-15\Delta_3 y(P_5) \\ &\qquad +27\Delta_1 y(P_4)+3\Delta_1 y(P_5)]. \end{aligned} \tag{2.19}$$

3. Formulation of the discrete problems and properties of the corresponding cell-centered composite grid matrices. All finite difference schemes derived in § 2 can be written in the general form

$$w_1(x)+w_2(x)+w_3(x)=\phi(x)\equiv\int_T f(\xi)\,d\xi, \quad T=T(x), \quad x\in\omega, \tag{3.1}$$

and

$$y=g(x) \quad \text{for } x\in\gamma_D, \quad w_\nu \text{ given for } x \text{ near } \partial\Omega\backslash\Gamma_D,$$

where $y=y(x)$ is the approximate solution at the grid nodes $x\in\omega$ and $w_l(x)$, $l=1, 2, 3$, are approximate fluxes defined accordingly by (2.9).

Since for every two regular neighboring triangles (see, e.g., Fig. 3.1.), we have $k_1(x)=k_1(x_+)$, then

$$w_1(x)=-w_1(x_+). \tag{3.2}$$

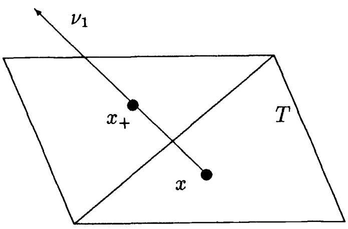

FIG. 3.1

For a regular grid without local refinement, we have the following identity, which is valid for every grid function $z(x)$ such that $z=0$ on γ_D.

$$\begin{aligned}&\sum_{x\in\omega}\{w_1(x)+w_2(x)+w_3(x)\}z(x)\\ &\quad=\sum_{x\in\omega}\{\alpha_1(x)w_1(x)\Delta_1 z(x)+\alpha_2(x)w_2(x)\Delta_2 z(x)+\alpha_3(x)w_3(x)\Delta_3 z(x)\},\end{aligned}\tag{3.3}$$

where, for example,

$$\Delta_1 z(x)=z(x)-z(x_+),$$

$$\alpha_1(x)=\begin{cases}\frac{1}{2} & \text{for } x\text{-internal node,}\\ 1 & \text{for } x \text{ near } \gamma_D,\end{cases}\qquad l=1,2,3.$$

The equation (3.3) is in accordance with (3.2) since, for example, in the ν_1-direction for the first two terms of the sum in the left-hand side of (3.3), we have

$$\begin{aligned}&w_1(x)z(x)+w_1(x_+)z(x_+)\\ &\quad=\tfrac{1}{2}w_1(x)z(x)-\tfrac{1}{2}w_1(x_+)z(x)+\tfrac{1}{2}w_1(x_+)z(x_+)-\tfrac{1}{2}w_1(x)z(x_+)\\ &\quad=\tfrac{1}{2}w_1(x)z(x)-\tfrac{1}{2}w_1(x_+)z(x)-\tfrac{1}{2}w_1(x)z(x_+)+\tfrac{1}{2}w_1(x_+)z(x_+)\\ &\quad=\tfrac{1}{2}w_1(x)\Delta_1 z(x)+\tfrac{1}{2}w_1(x_+)\Delta_1 z(x_+).\end{aligned}$$

In the case of a regular grid, since $w_1(x)=k_1(x)\Delta_1 y(x)$, $l=1$, 2, 3, we have

$$\begin{aligned}&\sum_{x\in\omega}\{w_1(x)+w_2(x)+w_3(x)\}z(x)\\ &\quad=\sum_{x\in\omega}\{\tilde{k}_1(x)\Delta_1 y(x)\Delta_1 z(x)+\tilde{k}_2(x)\Delta_2 y(x)\Delta_2 z(x)\\ &\qquad+\tilde{k}_3(x)\Delta_3 y(x)\Delta_3 z(x)\},\end{aligned}\tag{3.4}$$

where $\tilde{k}_l(x)=\alpha_l(x)k_l(x)$ and $k_l(x)$ are defined by (2.10).

Writing the difference scheme (3.1) as a system of linear algebraic equations

$$Ay=\phi,\tag{3.5}$$

then

$$z^tAy=\sum_{x\in\omega}\sum_{l=1}^{3}\tilde{k}_l(x)\Delta_l y(x)\Delta_l z(x).\tag{3.6}$$

Obviously, (3.6) represents a symmetric and positive definite form, hence the matrix A is invertible. In fact, A is an M-matrix (see, e.g., Varga [24]): it is weakly diagonally dominant with nonpositive off-diagonal entries.

Consider the case of the composite grid, where we prove that a similar formula is valid. Denote

$$z^tAy=\sum_{l=1}^{3}\sum_{x\in\omega}w_l(x)z(x)=\sum_{l=1}^{3}I_l.\tag{3.7}$$

Using (3.4) for every subregion of Ω with regular grid points (see Fig. 3.2, where Ω_2 is a subregion of Ω covered by a refined grid ω_2), we present the term I_1 in the following

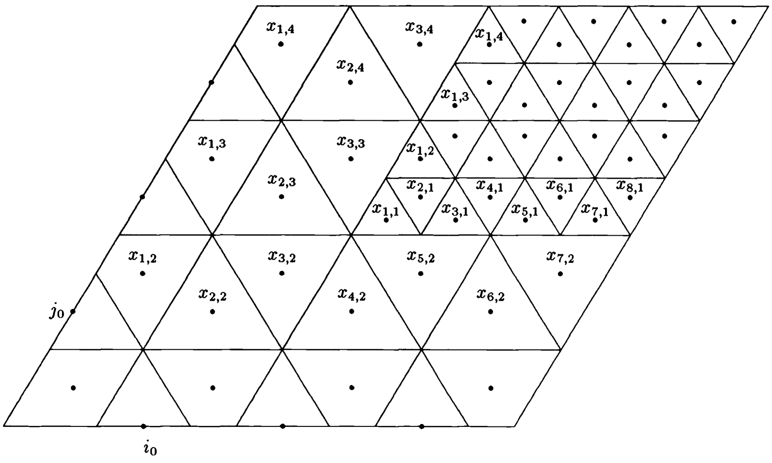

FIG. 3.2. *Composite grid* $(i_0=2, j_0=2)$.

form:

$$I_1=\sum_{\substack{x\in\tilde\omega\\ j\leq j_0}}\alpha_1(x_{i,j})w_1(x_{i,j})\Delta_1 z(x_{i,j})+\sum_{\substack{x\in\tilde\omega\\ j>j_0,i<2i_0-1}}\alpha_1(x_{i,j})w_1(x_{i,j})\Delta_1 z(x_{i,j})$$
$$+\sum_{\substack{x\in\tilde\omega\\ j>j_0}}w_1(x_{2i_0-1,j})z(x_{2i_0-1,j})$$
$$+\sum_{\substack{x\in\omega_2\\ i>1}}\alpha_1(x_{i,j})w_1(x_{i,j})\Delta_1 z(x_{i,j})+\sum_{\substack{x\in\omega_2\\ j\geq 1}}w_1(x_{1,j})z(x_{1,j}),$$

where, in accordance with (3.2) and the requirement for mass conservation, we have

$$w_1(x_{2i_0-1,j_0+k})=-(w_1(x_{1,2k-1})+w_1(x_{1,2k}))\quad\text{for } k=1,2,\cdots.$$

Define

$$\Delta_1 z(x_{1,2k-1})=z(x_{1,2k-1})-z(x_{2i_0-1,j_0+k}),$$
$$\Delta_1 z(x_{1,2k})=z(x_{1,2k})-z(x_{2i_0-1,j_0+k}).$$

Using these in the expression for I_1 above, we get

$$I_1=\sum_{x\in\omega\backslash S_1}\alpha_1(x)w_1(x)\Delta_1 z(x),$$

where $\alpha_1(x)=1$ for the irregular grid points in Ω_2 and $S_1=\{x=x_{i,j}, j>j_0,\ i=2i_0-1\}$ is the set of irregular coarse grid points for which $\Delta_1 z(x)$ is not defined.

Similarly, in the ν_2-direction we have

$$I_2=\sum_{\substack{x\in\tilde\omega\\ 1\leq i\leq 2i_0-1\\ j\geq j_0}}\alpha_2(x_{i,j})w_2(x_{i,j})\Delta_2 z(x_{i,j})+\sum_{\substack{x\in\tilde\omega\\ j<j_0}}\alpha_2(x_{i,j})w_2(x_{i,j})\Delta_2 z(x_{i,j})$$
$$+\sum_{\substack{x\in\tilde\omega\\ k\geq 1}}w_2(x_{2(i_0+k)-1,j_0})z(x_{2(i_0+k)-1,j_0})+\sum_{\substack{x\in\omega_2\\ j\geq 1}}\alpha_2(x_{i,j})w_2(x_{i,j})\Delta_2 z(x_{i,j})$$
$$+\sum_{\substack{x\in\omega_2\\ k\geq 1}}\alpha_2(x_{2k,1})w_2(x_{2k,1})\Delta_2 z(x_{2k,1})+\sum_{\substack{x\in\omega_2\\ k\geq 1\\ i=2k-1}}w_2(x_{i,1})z(x_{i,1}),$$

where

$$w_2(x_{2(i_0+k)-1,j_0}) = -(w_2(x_{4k-3,1}) + w_2(x_{4k-1,1})) \quad \text{for } k = 1, 2, \cdots .$$

Define

$$\Delta_2 z(x_{4k-3,1}) = z(x_{4k-3,1}) - z(x_{2(i_0+k)-1,j_0}),$$
$$\Delta_2 z(x_{4k-1,1}) = z(x_{4k-1,1}) - z(x_{2(i_0+k)-1,j_0}).$$

Then

$$I_2 = \sum_{x \in \omega \backslash S_2} \alpha_2(x) w_2(x) \Delta_2 z(x),$$

where $\alpha_2(x) = 1$ for the irregular grid points in Ω_2 and $S_2 = \{x = x_{i,j},\ i = 2(i_0 + k) - 1,\ j = j_0,\ k = 1, 2, \cdots\}$ is the set of irregular coarse-grid points for which $\Delta_2 z(x)$ is not defined.

Since in the direction of the normal vector ν_3 there are no irregular grid points (see Fig. 3.2), we get $I_3 = \sum_{x \in \omega} \alpha_3(x) w_3(x) \Delta_3 z(x)$ directly from (3.4). In general, inserting these expressions for I_1, I_2, and I_3 in (3.7), we get the basic representation

$$z^t A y = \sum (\alpha_1(x) w_1(x) \Delta_1 z(x) + \alpha_2(x) w_2(x) \Delta_2 z(x) + \alpha_3(x) w_3(x) \Delta_3 z(x)). \tag{3.8}$$

In (3.8) and in all expressions for $z^t Ay$ below, the summation $\sum$ is taken to mean over those grid points $x \in \omega$, for which $\Delta_l z(x)$ is defined $(l = 1, 2, 3)$.

In order to simplify the considerations below we suppose that $a(x) \equiv 1$. First, we consider the *simple symmetric scheme* for which the fluxes are defined in (2.15). In this case we have

$$z^t A_0 y = \sum_{x \in \omega} \sum_{l=1}^{3} \alpha_l(x) w_l(x) \Delta_l z(x) = \sum_{x \in \omega} \sum_{l=1}^{3} \tilde{k}_l(x) \Delta_l y(x) \Delta_l z(x). \tag{3.9}$$

Obviously, $z^t A_0 y$ is a symmetric bilinear form and

$$y^t A_0 y = \sum_{x \in \omega} \sum_{l=1}^{3} \tilde{k}_l(x) (\Delta_l y(x))^2.$$

Here A_0 is a positive definite matrix, since $y^t A_0 y = 0$ if and only if $y(x) \equiv 0$ (we have $y(x) = 0$, $x \in \gamma_D$).

Next we consider the *simple nonsymmetric approximation* of the fluxes at the irregular grid points defined by (2.16). In the particular case of equilateral triangles, by (2.17) we have

$$\begin{aligned} z^t A y = {} & \sum_{\omega} (\tilde{k}_1 \Delta_1 y \Delta_1 z + \tilde{k}_2 \Delta_2 y \Delta_2 z + \tilde{k}_3 \Delta_3 y \Delta_3 z) \\ & - \frac{1}{2} \sum_{k \geqq 1} \Big\{ \tilde{k}_1(x_{1,2k-1}) \Delta_2 y(x_{2i_0-1,j_0+k}) \Delta_1 z(x_{1,2k-1}) \\ & \qquad + \tilde{k}_1(x_{1,2k}) \Delta_3 y(x_{2i_0-1,j_0+k}) \Delta_1 z(x_{1,2k}) \Big\} \\ & - \frac{1}{2} \sum_{k \geqq 1} \Big\{ \tilde{k}_2(x_{4k-3,1}) \Delta_1 y(x_{2(i_0+k)-1,j_0}) \Delta_2 z(x_{4k-3,1}) \\ & \qquad + \tilde{k}_2(x_{4k-1,1}) \Delta_3 y(x_{2(i_0+k)-1,j_0}) \Delta_2 z(x_{4k-1,1}) \Big\}. \end{aligned} \tag{3.10}$$

It is a nonsymmetric bilinear form and, applying the Cauchy inequality to the right-hand side of (3.10), we get

$$|z^tAy| \leqq \tfrac{3}{2}(z^tA_0z)^{1/2}(y^tA_0y)^{1/2}.$$

For $z=y$ the estimate from below is obtained in the following way: the terms of the nonsymmetric part of the corresponding bilinear form are estimated from below using the inequality $-|ab| \geqq -(a^2+b^2)/2$ and compensated with the terms from the symmetric part. Thus

$$\tfrac{3}{4}y^tA_0y \leqq y^tAy \leqq \tfrac{3}{2}y^tA_0y.$$

In the case of the *more accurate symmetric scheme*, using (2.18), the following expression for the inner product is valid

$$\begin{aligned} z^tAy &= \sum_{\omega} (\tilde{k}_1\Delta_1 y\Delta_1 z + \tilde{k}_2\Delta_2 y\Delta_2 z + \tilde{k}_3\Delta_3 y\Delta_3 z) \\ &\quad + \frac{1}{3}\sum_{k\geqq 1}\Big\{\tilde{k}_1(x_{1,2k-1})[-2\Delta_1 y(x_{1,2k-1}) + \Delta_1 y(x_{1,2k})]\Delta_1 z(x_{1,2k-1}) \\ &\qquad + \tilde{k}_1(x_{1,2k})[-2\Delta_1 y(x_{1,2k}) + \Delta_1 y(x_{1,2k-1})]\Delta_1 z(x_{1,2k})\Big\} \\ &\quad + \frac{1}{3}\sum_{k\geqq 1}\Big\{\tilde{k}_2(x_{4k-3,1})[-2\Delta_2 y(x_{4k-3,1}) + \Delta_2 y(x_{4k-1,1})]\Delta_2 z(x_{4k-3,1}) \\ &\qquad + \tilde{k}_2(x_{4k-1,1})[-2\Delta_2 y(x_{4k-1,1}) + \Delta_2 y(x_{4k-3,1})]\Delta_2 z(x_{4k-1,1})\Big\}. \end{aligned} \tag{3.11}$$

Obviously, z^tAy is a symmetric bilinear form and, by the Cauchy inequality, we easily get the upper bound

$$|z^tAy| \leqq \tfrac{5}{3}(z^tA_0z)^{1/2}(y^tA_0y)^{1/2}.$$

When $z=y$, we obtain the lower bound

$$\tfrac{1}{3}y^TA_0y \leqq y^tAy \leqq \tfrac{5}{3}y^tA_0y.$$

Hence, in both cases of linear interpolation, we get that A is invertible and that the corresponding finite difference scheme has a unique solution.

Finally, we consider the case of the *more accurate nonsymmetric approximation* of the fluxes defined by (2.18) at the irregular grid points when $\alpha=\beta=\gamma$. Then

$$\begin{aligned} z^tAy &= \sum_{\omega} (\tilde{k}_1\Delta_1 y\Delta_1 z + \tilde{k}_2\Delta_2 y\Delta_2 z + \tilde{k}_3\Delta_3 y\Delta_3 z) \\ &\quad + \frac{1}{60}\sum_{k\geqq 1}\{\tilde{k}_1(x_{1,2k-1})[-33\Delta_1 y(x_{1,2k-1}) - 15\Delta_2 y(x_{1,2k-1}) - 15\Delta_3 y(x_{1,2k-1}) \\ &\qquad + 6\Delta_3 y(x_{2i_0-1,j_0+k}) - 6\Delta_2 y(x_{2i_0-1,j_0+k}) + 3\Delta_1 y(x_{1,2k})]\Delta_1 z(x_{1,2k-1})\} \\ &\quad + \frac{1}{60}\sum_{k\geqq 1}\{\tilde{k}_1(x_{1,2k})[-33\Delta_1 y(x_{1,2k}) - 15\Delta_3 y(x_{1,2k-1}) - 15\Delta_2 y(x_{1,2k}) \\ &\qquad - 6\Delta_3 y(x_{2i_0-1,j_0+k}) + 6\Delta_2 y(x_{2i_0-1,j_0+k}) + 3\Delta_1 y(x_{1,2k-1})]\Delta_1 z(x_{1,2k})\} \\ &\quad + \frac{1}{60}\sum_{k\geqq 1}\{\tilde{k}_2(x_{4k-3,1})[-33\Delta_2 y(x_{4k-3,1}) - 15\Delta_1 y(x_{4k-1,1}) - 15\Delta_3 y(x_{4k-3,1}) \\ &\qquad + 6\Delta_3 y(x_{2(i_0+k)-1,j_0}) - 6\Delta_1 y(x_{2(i_0+k)-1,j_0}) + 3\Delta_2 y(x_{4k-1,1})]\Delta_2 z(x_{4k-3,1})\} \\ &\quad + \frac{1}{60}\sum_{k\geqq 1}\{\tilde{k}_2(x_{4k-1,1})[-33\Delta_2 y(x_{4k-1,1}) - 15\Delta_3 y(x_{4k-3,1}) - 15\Delta_1 y(x_{4k-1,1}) \\ &\qquad - 6\Delta_3 y(x_{2(i_0+k)-1,j_0}) + 6\Delta_1 y(x_{2(i_0+k)-1,j_0}) + 3\Delta_2 y(x_{4k-3,1})]\Delta_2 z(x_{4k-1,1})\}. \end{aligned} \tag{3.12}$$

Applying the Cauchy inequality to the right-hand side of (3.12), we get

$$|z^tAy| \leqq \tfrac{31}{20}(z^tA_0z)^{1/2}(y^tA_0y)^{1/2}.$$

In order to obtain a lower bound for $z=y$, we combine this inequality with a similar one and get

$$\tfrac{1}{20}y^tA_0y \leqq y^tAy \leqq \tfrac{31}{20}y^tA_0y.$$

The following theorem summarizes the results for all four approximations.

THEOREM 3.1. *The following basic inequalities are valid*:

$$|z^tAy| \leqq \gamma_2(z^tA_0z)^{1/2}(y^tA_0y)^{1/2}, \tag{3.13}$$

$$\gamma_1 y^tA_0y \leqq y^tAy \leqq \gamma_2 y^tA_0y, \tag{3.14}$$

where A_0 is the matrix of the simple symmetric approximation and A is the matrix of any of the four approximations. For the case of the simple nonsymmetric or more accurate nonsymmetric scheme, γ_1 is a positive constant only under additional assumptions for the angles α, β, and *γ (see Remark* 3.1). *If $a(x)\equiv 1$ and the partition is with equilateral triangles $T\in\tau$, the constants γ_1 and γ_2 are*: $\gamma_1=\frac{3}{4}$, $\gamma_2=\frac{3}{2}$ *for the simple nonsymmetric scheme*; $\gamma_1=\frac{1}{3}$, $\gamma_2=\frac{5}{3}$ *for the more accurate symmetric scheme*; *and* $\gamma_1=\frac{1}{20}$, $\gamma_2=\frac{31}{20}$ *for the more accurate nonsymmetric scheme.*

Remark 3.1. In the general case (see Fig. 2.4) we have

(i) for the case of the simple nonsymmetric scheme,

$$\{1-\max(|c_1|,|c_2|)\}y^tA_0y \leqq y^tAy \leqq \{1+2\max(|c_1|,|c_2|)\}y^tA_0y,$$

where

$$c_1=\frac{1}{8}\left(1\pm\frac{\tan\gamma}{\tan\beta}\right) \quad\text{and}\quad c_2=\frac{1}{8}\left(1\pm\frac{\tan\alpha}{\tan\beta}\right).$$

Obviously, $\gamma_1=1-\max(|c_1|,|c_2|)$ and $\gamma_2=1+2\max(|c_1|,|c_2|)$ depend only on the angles α, β, and γ, but γ_1 is not always positive. Therefore, the matrix A in this case is invertible only for triangles for which $\tan\gamma \operatorname{cotan}\beta<7$ or $\tan\alpha\operatorname{cotan}\beta<7$.

(ii) For the case of the more accurate symmetric scheme,

$$\tfrac{1}{3}y^tA_0y \leqq y^tAy \leqq \tfrac{5}{3}y^tA_0y.$$

We get the same constants $\gamma_1=\frac{1}{3}$ and $\gamma_2=\frac{5}{3}$ as in our particular case. Hence the matrix A is always invertible, so that the more accurate symmetric scheme, in general, has a unique solution.

4. Error estimates.

4.1. An a priori estimate for the error. If $\varepsilon(x)=y(x)-u(x)$, where $x\in\omega$ is the error of the finite difference method, then $y(x)=\varepsilon(x)+u(x)$, $x\in\omega$, or, in vector form, $y=\varepsilon+u$. Substituting y into (3.5), we get

$$A\varepsilon=\phi-Au\equiv\psi, \tag{4.1}$$

where $Au(x)=w_1(x)+w_2(x)+w_3(x)$ and the approximate fluxes are defined by the values of $u(x)$ at the grid points, i.e., $w_l(x)=k_l(x)\Delta_lu(x)$, $x\in\omega$, $l=1,2,3$. The vector ϕ is defined by the right-hand side of (3.1). We represent the right-hand side of (4.1) in the form

$$\psi(x)=\sum_{l=1}^{3}\left\{\int_{s_l} W_{\nu_l}\,ds-w_l(x)\right\}\equiv\sum_{l=1}^{3}\eta_l(x), \tag{4.2}$$

where the approximate fluxes w_l, $l=1, 2, 3$, are defined by the values of $u(x)$ at the grid points. Here we have implicitly defined

$$\eta_l(x)=\int_{s_l} W_{\nu_l}\,ds - w_l(x), \qquad x\in\omega. \tag{4.3}$$

Obviously, according to (3.2) at the regular grid points (see Fig. 3.1), $\eta_1(x)=-\eta_1(x_+)$ holds.

On Γ_D we have Dirichlet boundary conditions, so that $y(x)=u(x)$ and $\varepsilon(x)=0$ for $x\in\gamma_D$. In order to prove convergence of the finite difference schemes in the energy norm, we are interested in a priori estimates for the error $\varepsilon(x)$. From (4.1) we get

$$\varepsilon^t A\varepsilon=\varepsilon^t\psi. \tag{4.4}$$

According to (3.8),

$$\begin{aligned}\varepsilon^t A\varepsilon&=\sum_{x\in\omega}\{w_1(x)+w_2(x)+w_3(x)\}\varepsilon(x)\\&=\sum_{x\in\omega}\sum_{l=1}^{3}\alpha_l(x)w_l(x)\Delta_l\varepsilon(x),\end{aligned} \tag{4.5}$$

where $w_l(x)=k_l(x)\Delta_l\varepsilon(x)$, $l=1, 2, 3$. On the other hand, from (4.2) and (3.8) we have

$$\varepsilon^t\psi=\sum_{x\in\omega}\psi(x)\varepsilon(x)=\sum_{x\in\omega}\sum_{l=1}^{3}\eta_l(x)\varepsilon(x)=\sum_{x\in\omega}\sum_{l=1}^{3}\alpha_l(x)\eta_l(x)\Delta_l\varepsilon(x). \tag{4.6}$$

Hence, by (4.4), we have

$$\varepsilon^t A\varepsilon\equiv\left|\sum_{\omega}\sum_{l=1}^{3}\alpha_l\omega_l\Delta_l\varepsilon\right|=\left|\sum_{\omega}\sum_{l=1}^{3}\alpha_l\eta_l\Delta_l\varepsilon\right|. \tag{4.7}$$

From (3.14) and the Cauchy inequality applied to the right-hand side of (4.7), we get

$$\gamma_1\varepsilon^t A_0\varepsilon\leqq(\varepsilon^t A_0\varepsilon)^{1/2}\left(\sum_{\omega}\sum_{l=1}^{3}\eta_l^2(x)\right)^{1/2}. \tag{4.8}$$

Since A_0 is symmetric and positive definite and $\varepsilon(x)=0$, $x\in\gamma_D$, we can define the energy norm

$$\|\varepsilon\|_{1,\omega}\equiv\|\varepsilon\|_{A_0}=(\varepsilon^t A_0\varepsilon)^{1/2}. \tag{4.9}$$

THEOREM 4.1. *The error* $\varepsilon(x)=y(x)-u(x)$, $x\in\omega$, *of the finite difference scheme* (3.1) *satisfies the a priori estimate*

$$\|\varepsilon\|_{1,\omega}\leqq C(\|\eta_1\|_{0,\omega}+\|\eta_2\|_{0,\omega}+\|\eta_3\|_{0,\omega}), \tag{4.10}$$

where the discrete $\mathbb{L}^2$*-norm is defined by*

$$\|y\|_{0,\omega}=\left(\sum_{x\in\omega}y^2(x)\right)^{1/2},$$

where η_l, $l=1, 2, 3$, *are the components of the local truncation error defined by* (4.3) *and* w_l, $l=1, 2, 3$, *are the approximate fluxes for our four difference schemes* (2.15)-(2.19).

4.2. Error estimates. If the diffusion coefficient satisfies $a(x)\equiv1$, from (4.3) we have that the local truncation error is

$$\eta_l(x)=-\int_{s_l}\frac{\partial u}{\partial\nu_l}\,ds-w_l(x), \qquad x\in\omega, \tag{4.11}$$

where the fluxes $w_l(x)$ are defined by the values $u(x)$ at the grid points $x \in \omega$ $(l=1, 2, 3)$. Now we estimate the terms $\eta_l(x)$, $l=1, 2, 3$.

In the case of regular grid points for $l=1$ (see Fig. 4.1(a)), using (2.15) we have

$$\eta_1(P_0) = -\int_{P_2}^{P_3} \frac{\partial u}{\partial \nu_1}(s)\, ds - k_1(P_0)[u(P_0)-u(P_1)],$$

where

$$k_1(P_0) = \frac{\text{dist}\,(P_2, P_3)}{\text{dist}\,(P_0, P_1)} = \tan \beta.$$

The expression on the right-hand side is a linear functional of $u(x)$, bounded in $\mathbb{H}^m(\bar{T})$, $m \geqq \frac{3}{2}$, $\bar{T} = \bar{T}(x) = \bar{T}(P_0) = T(P_0) \cup T(P_1)$. This functional vanishes for all polynomials of second degree. Therefore, by the Bramble–Hilbert lemma, we get

$$(4.12) \qquad |\eta_1(x)| \leqq Ch^m |u|_{m+1, \bar{T}(x)}, \qquad \tfrac{1}{2} < m \leqq 2,$$

where $h = \text{diam } T(P_0)$.

In the case of collection of uniform triangulation on the interface between these two uniform triangulations, we have the situation shown in Fig. 4.1(b). Since $P_0M \neq P_1M$, the linear functional $\eta_1(P_0)$ vanishes for polynomials of first degree and therefore

$$|\eta_1(x)| \leqq Ch|u|_{2, \bar{T}(x)} \quad \text{for } u \in \mathbb{H}^m(\bar{T}), \quad m \geqq 2.$$

Now consider the different cases of the flux approximation at the irregular grid points of ω.

First, in the case of the simple symmetric approximation, for the point P_4 from Fig. 2.4, the following expression is valid:

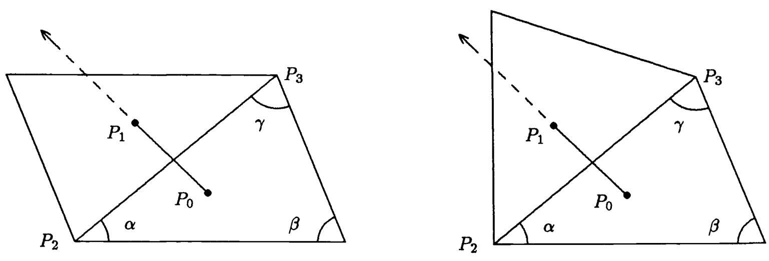
$$\eta_1(P_4) = -\int_{P_7}^{P_8} \frac{\partial u}{\partial \nu_1}(s)\, ds - k_1(P_4)[u(P_4)-u(P_0)],$$

where

$$k_1(P_4) = \frac{\text{dist}\,(P_7, P_8)}{\text{dist}\,(P_4, P_4^*)} = \tan \beta.$$

This functional vanishes only for $u \equiv \text{const}$. Then

$$(4.13) \qquad |\eta_1(x)| \leqq C(|u|_{1, \bar{T}(x)} + h^m |u|_{m+1, \bar{T}(x)})$$



(a) uniform

(b) piecewise uniform

FIG. 4.1. *Triangulation of* Ω.

and, with the help of (4.12) and (4.13), we get

$$\begin{aligned}\sum_{x\in\omega}\eta_1^2(x)&\leqq C\Bigg(\sum_{\substack{x\in\omega\\ x\text{-irregular}}}|u|^2_{1,\bar T(x)}+\sum_{x\in\omega}h^{2m}|u|^2_{m+1,\bar T(x)}\Bigg)\\ &\leqq C(|u|^2_{1,\Omega_h}+h^{2m}|u|^2_{m+1,\Omega}),\qquad m\geqq\frac{1}{2},\end{aligned}\tag{4.14}$$

where Ω_h is a strip of width $2h$ around the interface between the coarse- and fine-grid regions and h is the coarse-grid size.

The first term on the right-hand side of (4.14) can be estimated using the so-called Il'in's inequality (see [17])

$$\|\phi\|_{0,\Omega\delta}\leqq c\delta^{1/2}\|\phi\|_{m,\Omega},\qquad m>\tfrac{1}{2},\tag{4.15}$$

where Ω_δ is a strip in Ω with width δ. Therefore we have

$$\|\eta_1\|_{0,\omega}=\Bigg(\sum_{x\in\omega}\eta_1^2(x)\Bigg)^{1/2}\leqq Ch^{1/2}\|u\|_{m+1,\Omega},\qquad m>\tfrac{1}{2}.\tag{4.16}$$

In the same way, we can estimate $\|\eta_2\|_{0,\omega}$ and $\|\eta_3\|_{0,\omega}$, yielding in the case of the simple symmetric difference scheme an $\mathbb{O}(h^{1/2})$ rate of convergence in the energy norm:

$$\|y-u\|_{1,\omega}\leqq Ch^{1/2}\|u\|_{m+1,\Omega}\qquad m>\tfrac{1}{2}.\tag{4.17}$$

Second, for the case of the simple nonsymmetric difference scheme, using (2.16) we have (see Fig. 2.4)

$$\begin{aligned}\eta_1(P_4)=-\int_{P_7}^{P_8}\frac{\partial u}{\partial\nu_1}(s)\,ds-k_1(P_4)\Bigg[&u(P_4)-\frac{1}{4}(1-\tan\gamma\,\text{cotan}\,\beta)u(P_2)\\ &+\frac{1}{4}(1+\tan\alpha\,\text{cotan}\,\beta)u(P_3)\\ &-\frac{1}{4}((\tan\alpha+\tan\gamma)\,\text{cotan}\,\beta+4)u(P_0)\Bigg].\end{aligned}\tag{4.18}$$

For the case of the more accurate symmetric scheme, by (2.17) we have

$$\eta_1(P_4)=-\int_{P_7}^{P_8}\frac{\partial u}{\partial\nu_1}(s)\,ds-\frac{1}{3}k_1(P_4)[-2u(P_0)+u(P_4)+u(P_5)].\tag{4.19}$$

The functionals from (4.18) and (4.19) vanish for all linear polynomials, so the Bramble-Hilbert lemma yields

$$|\eta_1(x)|\leqq Ch^m|u|_{m+1,\bar T(x)},\qquad \tfrac{1}{2}<m\leqq 1.$$

In the same way as in the cases of linear interpolation, we get

$$\|\eta_1\|_{0,\omega}=\Bigg(\sum_{x\in\omega}\eta_1^2(x)\Bigg)^{1/2}\leqq Ch^{m+1/2}\|u\|_{m+3/2,\Omega},\qquad \tfrac{1}{2}<m\leqq 1.\tag{4.20}$$

For the case of the simple nonsymmetric or more accurate symmetric scheme, the rate of convergence in energy norm is $\mathbb{O}(h^{3/2})$:

$$\|y-u\|_{1,\omega}\leqq Ch^{m+1/2}\|u\|_{m+3/2,\Omega},\qquad \tfrac{1}{2}<m\leqq 1.\tag{4.21}$$

Third, in the case of the more accurate nonsymmetric scheme, when we consider equilateral triangles, using (2.18) for the approximate fluxes, the functional has the form

$$\eta_1(P_4) = -\int_{P_7}^{P_8} \frac{\partial u}{\partial \nu_1}(s)\,ds - \frac{1}{30}k_1(P_4)[-15u(P_0)+15u(P_1)-3u(P_2) \\ +3u(P_3)+6u(P_4)-6u(P_5)], \tag{4.22}$$

where $k_1(P_4)=\tan\beta=\sqrt{3}$. This functional vanishes for polynomials of second degree. Hence, for the irregular grid points, we have

$$|\eta_1(x)| \leqq Ch^m|u|_{m+1,\bar{T}(x)}, \qquad \tfrac{1}{2}<m\leqq 2.$$

Then, in a similar way as in (4.14) and (4.15), the following inequalities are valid:

$$\begin{aligned} \sum_{x\in\omega}\eta_1^2(x) &\leqq C\Bigg(\sum_{\substack{x\in\omega\\ x\text{-irregular}}} h^{2m}|u|^2_{m+1,\bar{T}(x)} + \sum_{x\in\omega} h^{2m}|u|^2_{m+1,\bar{T}(x)}\Bigg) \\ &\leqq C(h^{2m}|u|^2_{m+1,\Omega_h}+h^{2m}|u|^2_{m+1,\Omega}) \\ &\leqq Ch^{2m}\|u\|^2_{m+1,\Omega}, \qquad \tfrac{1}{2}<m\leqq 2. \end{aligned} \tag{4.23}$$

Thus the case of the more accurate nonsymmetric scheme yields the best convergence rate of $\mathbb{O}(h^2)$:

$$\|y-u\|_{1,\omega} \leqq Ch^m\|u\|_{m+1,\Omega}, \qquad \tfrac{1}{2}<m\leqq 2.$$

The following theorem summarizes the results.

THEOREM 4.2. *If the solution $u(x)$ of the problem* (2.1)-(2.3) *with constant coefficient $a(x)$ is $\mathbb{H}^m$-regular, $m\geqq\frac{3}{2}$, then the rate of convergence in the energy norm* (4.9) *is $\mathbb{O}(h^{1/2})$ for the simple symmetric scheme, $\mathbb{O}(h^{3/2})$ for the simple nonsymmetric and more accurate symmetric schemes, and $\mathbb{O}(h^2)$, $m\geqq 2$, for the more accurate nonsymmetric scheme.*

Remark 4.1. Let h_c be the coarse-grid cell size and h_f be the fine-grid cell size. Our analysis is done for $m=h_c/h_f=2$. It is easy to see that we can construct and study the corresponding schemes for any integer ratio m. For instance, in § 6 we have performed a series of computational experiments for $m=2$, 4.

From a more careful look at the proofs of the estimates (4.16), (4.20), and (4.23), we can see that the constant C in (4.16) does not depend on m, and estimates in (4.20) and (4.23) depend on m linearly.

Remark 4.2. In the case of collection of uniform triangulations, applying the estimate of $\eta_1(x)$ on the interface cells and Il'in's inequality (4.15), we can show that the rate of convergence in the energy norm is $\mathbb{O}(h^{1/2})$ for the simple symmetric scheme and $\mathbb{O}(h^{3/2})$ for all remaining approximations.

5. Efficient iterative methods.

5.1. Algebraic formulation of the BEPS preconditioner. We partition the nodes in the composite grid ω into two groups: ω_2, the nodes in the refined subregion Ω_2, and ω_1, the nodes in Ω_1. Then the matrix A admits the two-by-two block form

$$A=\begin{array}{cc}\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22}\end{bmatrix} & \begin{array}{l}\}\omega_2\\ \}\omega_1\end{array}\end{array}.$$

The coarse-grid matrix $\tilde{A}$ is partitioned in the same manner as the composite grid matrix A into a two-by-two block structure, where the first block represents the coarse-grid points in Ω_2

$$\tilde{A}=\begin{array}{cc}\begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} \\ \tilde{A}_{21} & \tilde{A}_{22}\end{bmatrix} & \begin{array}{l}\}\tilde{\omega}_2\\ \}\omega_1\end{array}\end{array}.$$

The preconditioner B of Bramble, Ewing, Pasciak and Schatz [4] can be constructed as follows.

For a given vector

$$b=\begin{bmatrix} b_1 \\ b_2 \end{bmatrix},$$

the solution of $B\,v=b$ is computed in the following steps: (i) solve in Ω_2:

$$A_{11}v_1^F=b_1;$$

(ii) compute the defect

$$d=b-A\begin{bmatrix} v_1^F \\ 0 \end{bmatrix}=\begin{bmatrix} 0 \\ b_2-A_{21}v_1^F \end{bmatrix}\}\omega_2;$$

(iii) form the coarse-grid correction (solve the coarse-grid problem)

$$\tilde{A}\tilde{v}=\begin{bmatrix} 0 \\ b_2-A_{21}v_1^F \end{bmatrix}\}\tilde{\omega}_2;$$

(iv) find v_1^H in ω_2 such that

$$A_{11}v_1^H+A_{12}\tilde{v}_2=0$$

(i.e., compute the harmonic component). Then set

$$v=B^{-1}b=\begin{bmatrix} v_1^F+v_1^H \\ \tilde{v}_2 \end{bmatrix}.$$

In matrix notation, we have the following factored form of the BEPS preconditioner [8]:

$$B=\begin{bmatrix} A_{11} & 0 \\ A_{21} & \tilde{S} \end{bmatrix}\begin{bmatrix} I & A_{11}^{-1}A_{12} \\ 0 & I \end{bmatrix}, \tag{5.1}$$

where $\tilde{S}=\tilde{A}_{22}-\tilde{A}_{21}\tilde{A}_{11}^{-1}\tilde{A}_{12}$ is the Schur complement for the coarse-grid matrix. The corresponding block Choleski factorization of A reads

$$A=\begin{bmatrix} A_{11} & 0 \\ A_{21} & S_2 \end{bmatrix}\begin{bmatrix} I & A_{11}^{-1}A_{12} \\ 0 & I \end{bmatrix}, \tag{5.2}$$

where $S_2=A_{22}-A_{21}A_{11}^{-1}A_{12}$ is the Schur complement for the composite-grid matrix. Note that factorizations of A and B agree except for these Schur complements.

5.2. Algebraic formulation of the two-grid FAC preconditioner of McCormick [14], [16]. Consider the composite-grid matrix A (symmetric or nonsymmetric) and the coarse-grid matrix $\tilde{A}$ partitioned into the two-by-two block structures according to the partitioning of Ω into regions Ω_1 and Ω_2. Then we formulate the FAC preconditioner B for solving the system

$$Av=b, \qquad v=\begin{bmatrix} v_1 \\ v_2 \end{bmatrix}\begin{matrix}\}\omega_2 \\ \}\omega_1\end{matrix}$$

as follows:

(i) solve the fine-grid problem in Ω_2:

$$A_{11}v_1^F=b_1;$$

(ii) restrict the defect to the coarse grid

$$\begin{aligned}\tilde{d} &= P^t\left[b - A\begin{bmatrix} v_1^F \\ 0 \end{bmatrix}\right] \\ &= P^t\left[b - \begin{bmatrix} b_1 \\ A_{21}v_1^F \end{bmatrix}\right] \\ &= P^t\begin{bmatrix} 0 \\ b_2 - A_{21}A_{11}^{-1}b_1 \end{bmatrix};\end{aligned}$$

(iii) solve for coarse-grid correction

$$\tilde{A}\tilde{c} = \tilde{d};$$

(iv) interpolate the correction

$$c = P\tilde{A}^{-1}P^t\begin{bmatrix} 0 \\ b_2 - A_{21}A_{11}^{-1}b_1 \end{bmatrix};$$

(v) then set

$$B^{-1}b = \begin{bmatrix} v_1^F \\ 0 \end{bmatrix} + c.$$

In matrix notation, we have [7]

$$B_{\mathrm{FAC}}^{-1} = \begin{bmatrix} A_{11}^{-1} & 0 \\ 0 & 0 \end{bmatrix} + (P\tilde{A}^{-1}P^t)\begin{bmatrix} 0 & 0 \\ -A_{21}A_{11}^{-1} & I \end{bmatrix}. \tag{5.3}$$

5.3. Optimal order two-grid preconditioners. As shown in [8], the following representation,

$$B^{-1}A = \begin{bmatrix} I & * \\ 0 & \tilde{S}^{-1}S_2 \end{bmatrix},$$

is valid for both two-grid preconditioners considered here. Using the local analysis technique from [8], we can show the following main result concerning the spectrum of $\tilde{S}^{-1}S_2$ and, hence, that of $B^{-1}A$.

THEOREM 5.1. *The Schur complements S_2 and $\tilde{S}$ are spectrally equivalent with constants independent of h. These constants are also independent of jumps in the coefficient $a = a(x)$ if it is continuous within each coarse-grid cell. In the nonsymmetric case the spectral equivalence reads as follows. The spectrum of $\tilde{S}^{-1}S_2$ is contained in a segment of the disc in the right-half complex plane*

$$\{z \in \mathbb{C}, \operatorname{Re} z \geqq \gamma_1, |z| \leqq \gamma_2\}$$

with γ_1 and γ_2 constants independent of h and of jumps in the coefficient $a = a(x)$.

Proof. From Theorem 3.1, we have a spectral equivalence between the composite-grid matrix A for any of our four approximations and the matrix of the simple symmetric approximation A_0. Hence it suffices to prove that A_0 and the coarse-grid matrix $\tilde{A}$ are spectrally equivalent, i.e., that there exist two positive constants γ_1 and γ_2, such that

$$\gamma_1\tilde{y}^t\tilde{A}\tilde{y} \leqq \inf_{\bar{y}} y^tA_0y \leqq \gamma_2\tilde{y}^t\tilde{A}\tilde{y} \tag{5.4}$$

and

$$y = \begin{bmatrix} \bar{y} \\ \tilde{y} \end{bmatrix}\begin{matrix} \}\omega\backslash\tilde{\omega} \\ \}\tilde{\omega} \end{matrix}.$$

Then by taking inf over all the nodes from ω_2, we obtain

$$\gamma_1 y_2^t \tilde{S} y_2 \leqq y_2^t S_2 y \leqq \gamma_2 y_2^t \tilde{S} y_2 .$$

The constants γ_1 and γ_2 in the above inequalities, which imply the desired result, are bounded uniformly with respect to h_c, as well as with respect to jumps of the coefficient $a(x)$, as long as it is continuous within each coarse-grid cell.

The estimate (5.4) from above holds immediately from (3.9) and the flow definition (2.15). We get

$$y^t A_0 y \leqq \tilde{y}^t \tilde{A} \tilde{y},$$

where $y(x)$ is a piecewise constant interpolant of $\tilde{y}$ over each coarse-grid cell. Hence $\gamma_2 = 1$ when $a(x)$ is constant over each coarse-grid cell.

The estimate below is based on local analysis. For simplicity, we consider the case when $a(x) \equiv 1$ in Ω.

We cover the region Ω with cells $E(x)$ obtained by connecting the centers of every six neighboring cells (see Fig. 5.1). Then the following representation of the quadratic form $y^t A_0 y$ is valid:

$$y^t A_0 y = \sum_{\substack{E(x) \\ x \in \tilde{\omega}}} \sum_{\xi \in E(x) \cap \omega} \sum_{l=1}^{3} \{\alpha_l(\xi) k_l(\xi) (\Delta_l y(\xi))^2\} = \sum_{x \in \tilde{\omega}} J(x; y),$$

where the cells $E(x)$ are counted only once.

Here

$$\alpha_l(\xi) = \begin{cases} \frac{1}{2} & \text{for the internal nodes,} \\ 1 & \text{for } \xi \text{ near } \gamma_D. \end{cases}$$

In a similar way, we have

$$\tilde{y}^t \tilde{A} \tilde{y} = \sum_{\substack{E(x) \\ x \in \tilde{\omega}}} \sum_{\xi \in E(x) \cap \tilde{\omega}} \sum_{l=1}^{3} \{\alpha_l(\xi) k_l(\xi) (\Delta_l \tilde{y}(\xi))^2\} = \sum_{x \in \tilde{\omega}} \tilde{J}(x; \tilde{y}).$$

Note that $J(x; y)$ and $\tilde{J}(x; \tilde{y})$ are nonnegative quadratic forms for each $x \in \tilde{\omega}$. They are positive definite if $E(x)$ has at least one point on $\gamma_D(u_{|_{\gamma_D}} = 0)$ or when $v|_{E(x)} \neq$ const and $\tilde{v}|_{E(x)} \neq$ const.

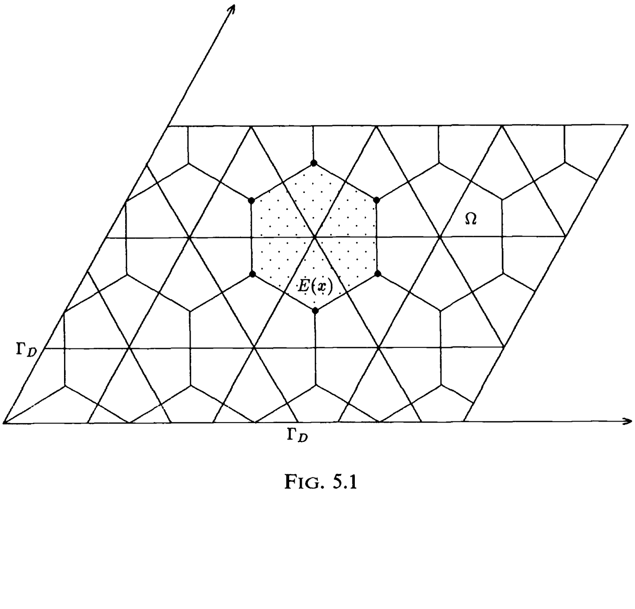


FIG. 5.1

We introduce

$$J(x; \bar{y}, \tilde{y}) = J(x; y), \qquad y = \begin{bmatrix} \bar{y} \\ \tilde{y} \end{bmatrix} \begin{matrix} \}\omega\backslash\tilde{\omega} \\ \}\tilde{\omega} \end{matrix}.$$

The local quadratic forms $\tilde{J}(x; \tilde{y})$ and $\inf_{\bar{y}} J(x; \bar{y}, \tilde{y})$ are defined in the finite-dimensional space associated with the coarse-grid unknowns in $E(x)$. Therefore, there exists a positive constant $\gamma_{1,E(x)}$, such that

$$\min_{\bar{y}} J(x; \bar{y}, \tilde{y}) \geqq \gamma_{1,E(x)} \tilde{J}(x; \tilde{y}).$$

The constant $\gamma_{1 \cdot E(x)}$, $x \in \tilde{\omega}$, do not depend on h_c but they are not, in general, bounded with respect to h_c/h_f. Hence

$$\begin{aligned} \min_{\bar{y}} y^t A_0 y &\geqq \sum_{x \in \tilde{\omega}} \min_{\bar{y}|_{E(x)}} J(x; \bar{y}, \tilde{y}) \geqq \sum_{x \in \tilde{\omega}} \gamma_{1,E(x)} \tilde{J}(x; \tilde{y}) \\ &\geqq \min_{x \in \tilde{\omega}} \gamma_{1,E(x)} \sum_{x \in \tilde{\omega}} \tilde{J}(x; \tilde{y}) = \gamma_1 \tilde{y}^t \tilde{A} \tilde{y}, \end{aligned}$$

where

$$\gamma_1 = \min_{x \in \tilde{\omega}} \gamma_{1,E(x)}.$$

We note that, since the coarse-grid cells are geometrically similar to a fixed number of triangles, the constant γ_1 is independent of the number of the coarse-grid cells, but our analysis allows some dependence on the aspect ratio h_c/h_f, which we have assumed to be bounded.

Actually, as demonstrated in Ewing, Lazarov, and Vassilevski [8], we can show that in the case of $a(x) \neq 1$, there exist constants γ_1 and γ_2 which are bounded independently of possible jumps of $a(x)$ as long as it is continuous within each coarse-grid cell. This has also been confirmed by our numerical experiments. □

Theorem 5.1 implies the following corollary.

COROLLARY 5.1. *The* GCG-LS *method from Axelsson* [1], [2] *for solving the composite grid system with any of the preconditioners B will have a rate of convergence independent of h and it will be insensitive to jumps in the coefficient* $a = a(x)$.

6. Numerical experiments. In this section, we present numerical results for solving model problems of type (2.1)-(2.3). We investigate experimentally the accuracy of the finite difference schemes and how rapidly the proposed preconditioned methods converge.

Our test problem is the diffusion equation on the region Ω, the unit parallelogram with acute angles equal to $\pi/3$:

$$\Omega = \{(x, y): 0 \leqq y \leqq \sqrt{\tfrac{3}{2}},\ y/\sqrt{3} \leqq x \leqq y\sqrt{3} + 1\}.$$

We assume the Dirichlet boundary

$$\Gamma_D = \{(x, 0): 0 \leqq x \leqq 1\} \cup \{(x, \sqrt{3}\,x): 0 \leqq x \leqq \tfrac{1}{2}\}.$$

The discretizations are done on a cell-centered grid, as shown in Fig. 6.1, with $h = 1/(n - \frac{1}{3})$ for some given integer n and ratio between coarse- and fine-grid cell sizes equal to m, $m \geqq 1$, integer.

We partition Ω into $\Omega_1 \cup \Omega_2$, where

$$\Omega_2 = \{(x, y): y_0 < y < \sqrt{\tfrac{3}{2}},\ x_0 + (y - y_0)/\sqrt{3} < x < y/\sqrt{3} + 1\}$$

and

$$x_0 = (i_0 + (j_0 - 1)/2)h, \qquad y_0 = (j_0 - \tfrac{1}{3})h\sqrt{\tfrac{3}{2}},$$

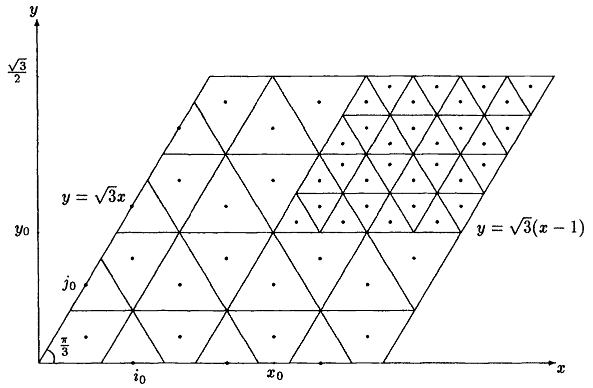

FIG. 6.1. *The composite grid* $(m = 2)$.

for some integers $0 < i_0 < n$, $0 < j_0 < n$, and $\bar{\Omega}_1 = \bar{\Omega} \backslash \Omega_2$. All numerical experiments were performed for $i_0 = j_0 = n/2$, i.e., the refined region is one-quarter of the whole domain.

We investigate the following cell-centered finite difference schemes: Scheme 0 (simple symmetric) and Scheme 1 (simple nonsymmetric). Our test problems are as follows.

PROBLEM 1 (a smooth solution).

$$u = y\left(y - \frac{\sqrt{3}}{2}\right)(y - \sqrt{3}x)(y - \sqrt{3}(x-1))$$

with a diffusion coefficient

$$a(x, y) = 1/(1 + 10(x^2 + y^2)).$$

PROBLEM 2 (a smooth solution with a discontinuous diffusion coefficient $a(x, y)$).

$$u = (\sqrt{3}(x - \hat{x}) - (y - \hat{y}))(y - \hat{y})\phi(x, y)/a(x, y),$$

where

$$\phi(x, y) = \sin\left(\frac{\pi}{2}(y - \sqrt{3}(x-1))\right) \sin\left(\frac{\pi}{2}\left(y - \frac{\sqrt{3}}{2}\right)\right) \sin\left(\frac{\pi}{2}y\right) \sin\left(\frac{\pi}{2}(y - \sqrt{3}x)\right),$$

$$a(x, y) = \begin{cases} 100 & \text{when } R < 0 \text{ or } y < \hat{y}, \\ 1 & \text{otherwise,} \end{cases}$$

$$R = \sqrt{3}(x - \hat{x}) - (y - \hat{y}),$$

and $\hat{x} = (\hat{i} + (\hat{j} - 1)/2)h$, $\hat{y} = (\hat{j} - \frac{1}{3})h\frac{\sqrt{3}}{2}$. For our experiments we choose $\hat{i} = i_0 + 2$ and $\hat{j} = j_0 + 2$.

PROBLEM 3 (a smooth solution with a support in Ω_2).

$$u = p(x, y)\phi(x, y),$$

where

$$p(x, y) = \begin{cases} (y - \sqrt{3}(x - \tilde{x}))(y - \tilde{y}), & \frac{y}{\sqrt{3}} + \tilde{x} < x < \frac{y}{\sqrt{3}} + 1, \quad \tilde{y} < y < \frac{\sqrt{3}}{2}, \\ 0, & \text{otherwise;} \end{cases}$$

$$\phi(x, y) = \begin{cases} \sin\left(\frac{\pi}{2}(y - \sqrt{3}(x - \tilde{x}))\right) \sin\left(\frac{\pi}{2}(y - \tilde{y})\right), & \frac{y}{\sqrt{3}} + \tilde{x} < x < \frac{y}{\sqrt{3}} + 1, \quad \tilde{y} < y < \frac{\sqrt{3}}{2}, \\ 0, & \text{otherwise;} \end{cases}$$

and $\tilde{x} = \tilde{y} = 0.75$.

We consider the following error estimators:

(i) the discrete $\mathbb{L}^2$-error, defined by

$$\varepsilon_0=\left(\sum_{x\in\omega} h^2(y(x)-u(x))^2\right)^{1/2};$$

(ii) the discrete $\mathbb{H}^1$-error, defined by

$$\varepsilon_1=|(y-u)^tA(y-u)|^{1/2}.$$

We also consider the following preconditioners: Preconditioner 1 (BEPS preconditioner) and Preconditioner 2 (FAC preconditioner).

We report on the number of iterations required of our preconditioned iterative methods: PCG in the symmetric case and GCG-LS in the nonsymmetric case. The stopping criterion is

$$r^tr<\varepsilon, \qquad \varepsilon=10^{-18},$$

where $r=b-Ay$ is the residual vector and y is the current iterate. As an initial guess, we always choose $P\tilde{A}^{-1}\tilde{b}$, i.e., a piecewise constant interpolant of the coarse-grid approximation. Also, we report on the average reduction factor

$$q=(\Delta/\Delta_0)^{1/\text{iter}},$$

where Δ_0 is the corresponding norm of the initial residual, Δ is the norm of the last residual, and iter is the number of iterations required to achieve the desired accuracy ε. The numerical results are collected on Tables 6.1-6.7. N is the number of unknowns and $\tilde{\varepsilon}_0$ and $\tilde{\varepsilon}_1$ are the corresponding discrete $\mathbb{L}^2$- and $\mathbb{H}^1$-errors of the coarse-grid approximations, which we interpolate piecewise constantly in order to get initial guesses in our iterative methods.

TABLE 6.2
Accuracy results for problems with local refinement ($m = 2$).

Problem 1

n	iter	Scheme	ε_0	ε_1	N
12	5	0	0.98-3	0.82-2	481
	6	1	0.54-3	0.53-2	
24	5	0	0.47-3	0.55-2	1969
	6	1	0.13-3	0.26-2	
48	5	0	0.23-3	0.38-2	7969
	6	1	0.34-4	0.12-2	

Problem 2

n	iter	Scheme	ε_0	ε_1	N
12	5	0	0.51-5	0.74-3	481
	7	1	0.54-5	0.43-3	
24	6	0	0.24-5	0.38-3	1969
	6	1	0.20-5	0.16-3	
48	6	0	0.10-5	0.26-3	7969
	6	1	0.61-6	0.54-4	

Problem 3

n	iter	Scheme	ε_0	ε_1	N
12	4	0	0.94-6	0.32-4	481
	4	1	0.94-6	0.32-4	
24	4	0	0.15-6	0.56-5	1969
	4	1	0.15-6	0.56-5	
48	3	0	0.32-7	0.18-5	7969
	3	1	0.32-7	0.18-5	

From Tables 6.2 and 6.3, which use two different refinement factors 2^m, we observe a monotonic improvement of the accuracy in both norms. Since the solution of Problem 3 has support entirely in the refined region, predictably both schemes give consistently the same results, since the truncation error is actually localized in the refined region. For Problem 2, where the solution is piecewise smooth and almost local, we obtain good convergence results. Both schemes behave in almost the same way, with the simple nonsymmetric scheme giving slightly better results.

Although symmetric and nonsymmetric schemes show almost the same accuracy and number of iterations, we recommend the use of the symmetric scheme since the PCG method is more effective in both storage and operational count (hence, more stable). Both preconditioners show fast convergence of the iterations which do not depend on the discretization parameters h and m (see Tables 6.4–6.7).

In the nonsymmetric case, we recommend the use of the FAC preconditioner because it is less expensive in operation counts (one fine-grid solution is replaced by interpolation, which is much faster).

Acknowledgments. The authors would like to express their gratitude to Professor Richard Ewing and Professor Steve McCormick for their useful comments and remarks which improved substantially the presentation. Careful comments by the referee are also gratefully acknowledged.

SEMICOARSENING MULTIGRID ON A HYPERCUBE*

RICHARD A. SMITH† AND ALAN WEISER‡

Abstract. A semicoarsening multigrid algorithm suitable for the kinds of problems arising in reservoir simulation has been implemented on the Intel iPSC/2 hypercube. The method is an extension to nonsymmetric problems of a method in [Dendy et al., *Paper SPE* 18409, presented at Society of Petroleum Engineers Symposium on Reservoir Simulation, Houston, TX, 1989]. It performs well for strongly anisotropic problems and problems with strongly discontinuous coefficients. For a test set of reservoir simulation problems, residual reduction factors for a full-multigrid V-cycle range from 0.0022 to 0.19. The current codes achieve about 50 percent parallel efficiency in two dimensions and about 30 percent parallel efficiency in three dimensions with about $\sqrt{N}/8$ processors for a grid with N unknowns.

Key words. multigrid, hypercubes, reservoir simulation

AMS(MOS) subject classifications. 15, 65, 68

1. Introduction.

Multigrid was first applied to reservoir simulation in the early 1980s [3]. For three-dimensional (3d) problems, multigrid was not found to be competitive with other solution methods because of the large expense per cycle of performing preconditioned conjugate gradient smoothing in the *xy*, *xz*, and *yz* planes. Subsequently, Dendy [6] reduced the cost of the method by using more efficient two-dimensional (2d) multigrid solvers for the smoothing subproblems. More recently, Dendy et al. [8] presented a semicoarsening version of multigrid for symmetric problems which performs well for reservoir simulation problems, with about the same (sequential) CPU cost per cycle but much simpler coding requirements than the previous multigrid methods.

We present an extension of this semicoarsening method to nonsymmetric problems. Among the features of the method are promising intergrid transfer operators due to Schaffer [7]. We investigate ways to implement the method efficiently on hypercube-type parallel processors, both to take advantage of current cost/benefit efficiencies of such machines and to predict how method performance scales with future massively parallel distributed-memory computers.

In the following five sections, respectively, we describe our method, describe several ways of implementing it on hypercube machines, present convergence results, present parallel timing results, and indicate future plans for this project.

2. The sequential method.

Consider a one-dimensional (1d) problem resulting from the one-dimensional pressure equation in reservoir simulation or any similar scalar second-order elliptic partial differential equation. The nonzero structure of the resulting tridiagonal matrix is depicted in Fig. 1. Let P be the permutation matrix ordering the unknowns red-black. The resulting red-black matrix P^TAP is depicted in Fig. 2.

In block form, the red-black linear system is

$$Ax = b \tag{1}$$

$$\begin{pmatrix} a & & & & b & & \\ & a & & & f & b & \\ & & a & & & f & b \\ & & & a & & & f \\ c & e & & & d & & \\ & c & e & & & d & \\ & & c & e & & & d \end{pmatrix}$$

FIG. 2. *One-dimensional red-black matrix nonzero structure.*

or

$$\begin{pmatrix} A_{rr} & A_{rb} \\ A_{br} & A_{bb} \end{pmatrix} \begin{pmatrix} x_r \\ x_b \end{pmatrix} = \begin{pmatrix} b_r \\ b_b \end{pmatrix}. \tag{2}$$

The nonzeros in Figs. 1 and 2 are labeled so that each nonzero diagonal of A_{rr}, A_{rb}, A_{br}, or A_{bb} is labeled with a different letter. One way to solve (2) is to form and solve the smaller Schur complement linear system

$$A_s x_b = b_s, \tag{3}$$

where

$$A_s = A_{bb} - A_{br} A_{rr}^{-1} A_{rb} \tag{4}$$

and

$$b_s = b_b - A_{br} A_{rr}^{-1} b_r, \tag{5}$$

and then backsolve

$$x_r = A_{rr}^{-1}(b_r - A_{rb} x_b). \tag{6}$$

Note that in this 1d case A_s is tridiagonal like A.

Now consider a two-level multigrid method for the original system, where the black unknowns are the coarse-grid unknowns. The main steps in such a method are:

(i) smooth on the fine grid,

(ii) transfer the fine-grid residual to the coarse grid and solve for the coarse-grid correction,

(iii) transfer the correction back to the fine grid and add it in to the current solution,

(iv) smooth again on the fine grid.

In the black-box multigrid framework [5] it is customary to construct the coarse-grid system $A_c x_c = b_c$ as follows:

$$(T_{br} \quad I_{bb})\begin{pmatrix} A_{rr} & A_{rb} \\ A_{br} & A_{bb} \end{pmatrix}\begin{pmatrix} T_{rb} \\ I_{bb} \end{pmatrix}(x_c) = (T_{br} \quad I_{bb})\begin{pmatrix} b_r \\ b_b \end{pmatrix}. \tag{7}$$

Here b_r and b_b denote the current residuals, and are only equal to the original right-hand side if the current iterate is zero. I_{bb} denotes the coarse-grid identity matrix: Pure injection is used for interpolating coarse-grid unknowns to black unknowns on the fine grid.

A key observation is that if

$$T_{br} = -A_{br}A_{rr}^{-1} \tag{8}$$

and

$$T_{rb} = -A_{rr}^{-1}A_{rb}, \tag{9}$$

then

$$A_c = T_{br}A_{rr}T_{rb} + T_{br}A_{rb} + A_{br}T_{rb} + A_{bb} \tag{10}$$

$$= A_{br}A_{rr}^{-1}A_{rb} - A_{br}A_{rr}^{-1}A_{rb} - A_{br}A_{rr}^{-1}A_{rb} + A_{bb} \tag{11}$$

$$= -A_{br}A_{rr}^{-1}A_{rb} + A_{bb} \tag{12}$$

$$= A_s \tag{13}$$

and

$$b_c = -A_{br}A_{rr}^{-1}b_r + b_b = b_s, \tag{14}$$

so that the coarse-grid multigrid system is identical to the Schur complement system. If the smoother on the fine grid solves exactly for the red unknowns in terms of the black unknowns, e.g., the smoother is red-black Gauss-Seidel, then the two-level multigrid solver is an exact solver. Furthermore, if the coarse-grid system itself is solved by a two-level multigrid solver, and so on recursively until the coarsest-grid system with one unknown is solved directly, the resulting multigrid V-cycle is a direct solver.

Now consider a two-dimensional problem with a nine-point operator. The resulting nine-diagonal matrix is depicted in Fig. 3. Let P be the permutation matrix ordering lines of unknowns red-black. The resulting red-black matrix P^TAP is depicted in Fig. 4.

As in the 1d case, if $T_{br} = -A_{br}A_{rr}^{-1}$ and $T_{rb} = -A_{rr}^{-1}A_{rb}$, then the coarse-grid system for two-level multigrid is exactly the Schur complement system $A_s x_s = b_s$. However, the Schur complement matrix is dense. Fill occurs for two reasons. First, A_{rr}^{-1} has dense diagonal blocks, so T_{br} and T_{rb} have dense diagonal blocks. Second, extra fill occurs in direction 1. For instance, the black unknowns corresponding to $(i1, i2) = (2, 1)$ and $(4, 3)$ are both connected to the red unknown corresponding to $(i1, i2) = (3, 2)$ via T_{rb} and T_{br} terms. Elimination of red terms results in direct connections between $(2, 1)$ and $(4, 3)$ in A_s even though their indices differ by more than 1 in direction 1. The only way to avoid this extra fill is to allow connections in T_{br} and T_{rb} in direction 2 only. The locations in Fig. 4 corresponding to connections in direction 2 only are the locations for diagonals c, g, k, and p.

Some new notation must be introduced to deal with connections in direction 2 only. Let an "l" (respectively, "r") superscript appended to A_{rb} or A_{br} denote the result of zeroing out all entries except those corresponding to connection of a black unknown to a red unknown with a smaller (respectively, larger) index in direction 2.

$$\begin{pmatrix}
a & b & & c & d & & & & & & & & & & \\

FIG. 4. *Two-dimensional red-black matrix nonzero structure.*

Then $A_{rb}=A^l_{rb}+A^r_{rb}$ and $A_{br}=A^l_{br}+A^r_{br}$. For example, in Fig. 4, A^l_{rb} may contain nonzeros on diagonals c, d, and f; A^r_{rb} may contain nonzeros on diagonals p, q, and r; A^l_{br} may contain nonzeros on diagonals g, h, and m; and A^r_{br} may contain nonzeros on diagonals k, l, and o. Similarly, let $\text{diag}^l_{rb}(v)$ (respectively, $\text{diag}^r_{rb}(v)$, $\text{diag}^l_{br}(v)$, $\text{diag}^r_{br}(v)$) denote the matrix with the same nonzero structure as A_{rb} (respectively, A_{rb}, A_{br}, A_{br}) with the only nonzero entries obtained from vector v and put on the diagonal corresponding to connections of black unknowns to red unknowns with lower (respectively, higher, lower, higher) index in direction 2 and with the same index in direction 1. For example, in Fig. 4, $\text{diag}^l_{rb}(v)$ (respectively, $\text{diag}^r_{rb}(v)$, $\text{diag}^l_{br}(v)$, $\text{diag}^r_{br}(v)$) puts nonzeros in the locations of diagonal c (respectively, p, g, k).

With this notation, we define the following transfer operators due to Steve Schaffer at the New Mexico Institute of Mining and Technology [7]:

$$T_{rb} = -(\text{diag}^{l}_{rb}\,(A_{rr}^{-1}A^{l}_{rb}e) + \text{diag}^{r}_{rb}\,(A_{rr}^{-1}A^{r}_{rb}e)), \tag{15}$$

$$T_{br} = -(\text{diag}^{l}_{br}\,(e^{T}A^{l}_{br}A_{rr}^{-1}) + \text{diag}^{r}_{br}\,(e^{T}A^{r}_{br}A_{rr}^{-1})), \tag{16}$$

where e is the vector of all ones.

We use (15) and (16) for transfer operators. We take the initial guess for the solution to (1) on a given grid to be the best constant solution

$$x_0 = \frac{b^T e}{e^T A e}\, e, \tag{17}$$

rather than zero. Here $(e^T A e)^{-1}$ is precomputed and calculation of $b^T e$ is very cheap, involving only adds. For our smoother we use red-black line Gauss-Seidel with lines oriented in direction 1. This completes the specification of our basic two-level 2d semicoarsening multigrid method. The adjective semicoarsening is used because the coarse grid is only coarsened in direction 2, while the usual "full coarsening" multigrid involves coarsening in both directions 1 and 2 simultaneously.

The method works particularly well for strongly anisotropic problems. Suppose connections are much stronger in direction 1 than direction 2. Then line Gauss-Seidel is a good iterative method in direction 1. Also, entries in A_{rb} and A_{br} are small, so entries in T_{rb} and T_{br} are small, and by (7), A_c is a good approximation to A_s (and A_{bb}). Conversely, suppose connections are much stronger in direction 2 than direction 1. Then A_{rr} is approximately diagonal, and A^{l}_{rb}, A^{r}_{rb}, A^{l}_{br}, and A^{r}_{br} are well approximated by $\text{diag}^{l}_{rb}\,(A^{l}_{rb})$, $\text{diag}^{r}_{rb}(A^{r}_{rb})$, $\text{diag}^{l}_{br}\,(A^{l}_{br})$, and $\text{diag}^{r}_{br}\,(A^{r}_{br})$, respectively. Thus T_{rb} and T_{br} are very good approximations to $-A_{rr}^{-1}A_{rb}$ and $-A_{br}A_{rr}^{-1}$ and hence the coarse-grid system is very close to the Schur complement.

This good convergence for strongly anisotropic problems is borne out in Tables 2, 3 and 4. (Here *ratio* is the anisotropy ratio in (18).)

Now consider a 3d model problem with a 15-point operator (a three-point operator in direction 3 tensored with a five-point operator in directions 1 and 2). The resulting 15-diagonal matrix is depicted in Fig. 5. Let P be the permutation matrix ordering planes of unknowns red-black. The resulting red-black matrix P^TAP is depicted in Fig. 6.

Again, the same two considerations cause fill in the Schur complement matrix. Our notation to deal with connections in direction 3 is similar to the 2d case. For Fig. 6, A^{l}_{rb} has nonzeros only in diagonals a and b, A^{r}_{rb} has nonzeros only in diagonals c and d, A^{l}_{br} has nonzeros only in diagonals a and b, A^{r}_{rb} has nonzeros only in diagonals g and h. Also, $\text{diag}^{l}_{rb}\,(v)$ (respectively, $\text{diag}^{r}_{rb}\,(v)$, $\text{diag}^{l}_{br}\,(v)$, $\text{diag}^{r}_{br}\,(v)$) has nonzeros only in diagonal a (respectively, c, e, g).

We would again like to use transfer operators (15) and (16). However, now A_{rr} is a five-point operator which is expensive to invert. Hence, following Schaffer [7], we use one cycle of our 2d semicoarsening multigrid method to approximately solve the A_{rr} systems needed in constructing T_{rb} and T_{br}.

We use (17) for initial guesses and approximate red-black Gauss-Seidel plane relaxation for our fine-grid smoothing step, where the 2d semicoarsening multigrid method approximately solves the plane Gauss-Seidel equations. This completes the specification of our basic two-level 3d semicoarsening multigrid method.

Note that a fine-grid 3d seven-point operator forms 15-point operators on the coarser 3d grids, and a fine-grid 2d five-point operator forms nine-point operators on the coarser 2d grids.

FIG. 6. *Three-dimensional red-black matrix nonzero structure.*

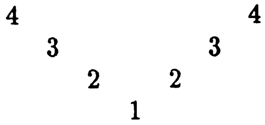

FIG. 7. V-*cycle.*

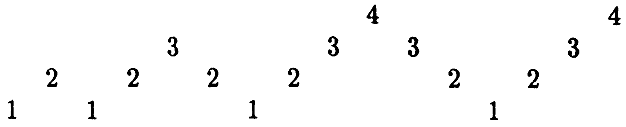

FIG. 8. FMV-*cycle.*

Again this method works particularly well for strongly anisotropic problems. This good convergence for strongly anisotropic problems is borne out in Table 5.

We have used several standard multigrid cycling approaches. The "V-cycle" (Fig. 7) starts on the finest grid with a two-level method and solves the resulting coarser-grid system recursively with another two-level method, and so on until the coarsest-grid system with one unknown is solved directly. The full multigrid V-cycle, or FMV-cycle (Fig. 8), generates an initial guess for the fine-grid system by preceding the fine-grid V-cycle recursively with another V-cycle on the next-finest grid, and so on so that the very first calculation is a direct solve on the coarsest grid. The initial FMV-cycle, or IFMV-cycle, takes the first cycle to be an FMV-cycle and the remaining cycles to be V-cycles.

Our 2d sequential code requires about $30N$ words of storage, where N is the number of unknowns on the fine grid. Our 3d sequential code requires about $148N$ words of storage. This is a large storage requirement for an iterative solver. It can be reduced if the matrix is known to be symmetric, if single precision is acceptable, or if the fine grids are known to be seven-point in three dimensions and five-point in two dimensions, rather than 15-point in three dimensions and nine-point in two dimensions.

3. The parallel method. We have implemented our method on distributed-memory parallel computers of hypercube type by partitioning the problem domain into subdomains and assigning a rectangular subdomain to each node (processor). We have left the number of subdomains in each direction variable, so that we can experiment with all possible rectangular mappings of our line and plane algorithms to our hypercube architecture. Our results in Tables 7–12 indicate experimentation with various node configurations. For each node, we pad local arrays by one at the lower and higher bounds of each array in each direction. The padding areas are used as buffers to exchange boundary information with neighbor nodes. Because the method mainly consists of subtasks of the form

```
for all unknowns in direction $i$
perform task $T$ in directions $j$ and $k$
```

or

```
for all unknowns in direction $i$
for all unknowns in direction $j$
perform task $T$ in direction $k$
```

where (i, j, k) = some permutation of $(1, 2, 3)$, the parallelization tasks required in directions 1, 2, and 3 are essentially independent. Boundary data are exchanged as needed before loops. In the following example, the call to *pad* exchanges boundary data for array *b* in direction 2, as needed by loop 10.

```
call pad(2,b)
do 10 i3 = i3l,i3h
do 10 i2 = i2l,i2h
do 10 i1 = i1l,i1h
   a(i1,i2,i3) = b(i1,i2-1,i3) + b(i1,i2+1,i3)
10 continue
```

A major aspect of parallel implementation is treatment of coarse grids with no unknowns for some nodes (such grids are designated "below C-level" in Briggs, Hart, McCormick, and Quinlan [4]). FMV-cycles tend to be relatively more expensive than V-cycles in parallel, because a greater portion of their computations are carried on below C-level. Both Hempel and Schuller [10] and Briggs et al. [4] use the "sleeping nodes" approach to C-level, in which nodes which are allocated no unknowns are set idle and then re-awakened when they rise above C-level again. We have taken two different approaches to C-level in our current 2d and 3d codes.

2d. Our current 2d code uses a 1d global approach. When the grid goes below C-level in direction *i*, global copies of the current problem are distributed to all nodes in direction *i*. The distribution is performed using a 1d version of a global concatenation operation (GCOL in [11]). Each node then proceeds to handle the global problem below C-level. No more internode communication is needed in this direction until computations resume above C-level. The penalty, of course, is that sub-C computations are duplicated many times, and extra communication is required for the global broadcasts.

This 1d global approach does not scale well. As the number of nodes grows large, so does the size of the sub-C level, and hence the parallel CPU time. However, for a moderate number of nodes good parallel efficiency is achieved, balancing the size of the sub-C level with the communication performed above the sub-C level. This approach can efficiently accommodate up to the order of $\sqrt{N}$ nodes, where $N = n1 \cdot n2$ is the number of fine-grid points.

Solution of the tridiagonal 1d linear systems in our 2d code is consistent with this approach. We solve the tridiagonal systems with line Gauss–Seidel using a version of two-level cyclic reduction (Johnsson [12]). The steps in two-level cyclic reduction are:

1. Forward solve local interior unknowns in each subgrid;
2. Broadcast and solve a small global system for boundary unknowns in each subgrid (1d global concatenate in direction 1);
3. Backsolve local interior unknowns in each subgrid (Fig. 9).

The small global system is distributed exactly at C-level. We combine the two-level cyclic reduction approach with the burn-at-both-ends (BABE) idea, assigning an upper and a lower node to each subgrid and eliminating unknowns for the two nodes for each subgrid in parallel (Fig. 10).

3d. Our current 3d code handles C-level using a 1d local duplication approach. As a node goes below C-level, it copies the local problem from a neighboring node. In this way all nodes stay busy working on systems of small size. This approach is closely related to the superconvergent parallel multigrid approach [9]. However, identical rather than different small systems are solved, so that the numerical answer is independent of the number of nodes.

$$\begin{pmatrix}
n & o & & & f & & & & & & & \\
o & n & o & & f & & & & & & & \\
& o & n & o & f & & & & & & & \\

& & & & d & n & b & \\
& & & & & d & n & b \\
& & & & & & d & n
\end{pmatrix}$$

n : nonzero

a : created zero in initial stage for upper node

b : created zero in initial stage for lower node

N : part of small shared system for center unknowns

c : created zero in final stage for upper node

d : created zero in final stage for lower node

FIG. 10. *Burn-at-both-ends elimination.*

As the grid gets coarser, the increment between neighboring nodes grows. Thus on the next-to-coarsest grid there are $n$node/2 copies of small system 1, $n$node/2 copies of small system 2, and a nodal increment to neighbors of $n$node/2. This situation is illustrated in Fig. 11, where there are 8 nodes and 16 fine-grid unknowns, and ninc = nodal increment to neighbors.

Solution of the tridiagonal 1d linear systems in our 3d code is consistent with our local duplication approach: We use the 1d semicoarsening multigrid direct solve outlined in § 2, which is equivalent to fully recursive cyclic reduction.

The local duplication approach scales fairly well. As a number of nodes grows large, the amount of work done by each node is proportional to log (N), the number of levels. However, in practice there is a penalty for using this approach, as well as the "sleeping nodes" approach: internode communication must continue at all sub-C levels.

	node 1	node 2	node 3	node 4	node 5	node 6	node 7	node 8
ninc = 1	*ab*	*cd*	*ef*	*gh*	*ij*	*kl*	*mn*	*op*

FIG. 11. *Duplication of neighboring systems.*

Our 2d hypercube code requires about $56N$ words of storage, where N is the number of unknowns on the fine-grid local subdomain. Our 3d sequential code requires about $136N$ words of storage. So far, storage has been the bottleneck in determining the size of problems we can run on hypercubes.

4. Convergence results (2d). Our 2d test problems are Neumann model problems

$$-(u_1)_1-(\text{ratio}\cdot u_2)_2=1 \tag{18}$$

in the unit square,

$$\frac{\partial u}{\partial n}=0 \tag{19}$$

on the boundary, with the matrix made nonsingular by doubling the first main diagonal entry.

The next few tables depict residual reduction factors for various runs. The initial guess x_0 for x is taken to be 0. The residual reduction factor is averaged over five iterations as

$$(\|b-Ax_5\|/\|b\|_2)^{1/5}.$$

Factors less than .005 or so are affected by roundoff and may actually represent even faster convergence.

The effect of (17) is seen for ratio = 1, FMV-cycles in Table 1. Based on these results, (17) is used in all other runs reported.

V-cycle, IFMV-cycle (one FMV-cycle followed by four V-cycles), and FMV-cycle residual reduction factors for different values of ratio are presented in Tables 2, 3, and 4, respectively. Residual reduction factors are generally largest for ratio near one and smaller for ratio either very large or very small. Since an FMV-cycle costs roughly twice as much as a V-cycle, the IFMV-cycle generally seems most efficient, with little more cost than a V-cycle and with residual reduction factors intermediate between those of V and FMV.

3d. We use the test set of reservoir simulation problems from Dendy et al. [8]. The problems are symmetric except for Problem 7, which was symmetrized before solution in [8]. Several of the problems have large coefficient discontinuities. Average residual reduction factors are given in Table 5 for the results from [8] and for our code running with V-cycles, IFMV-cycles, and FMV-cycles. In these runs our code used two-dimensional FMV-cycles to do the red-black smoothing by planes.

Our results for Problems 6 and 7 depend strongly on ordering of axes. Other solvers that do particularly well on anisotropic problems share this property, e.g., nested factorization [2]. Table 6 presents average residual reduction factors for an

FMV-cycle with our code for the various axis orderings. The results in Table 5 are given for ordering 312 for Problem 6.

5. Parallel timing results (2d). Table 7 (respectively, 8) presents timing results for a five-iteration V-cycle (respectively, FMV-cycle) of the 2d code on the iPSC/2 hypercube at Oak Ridge with 64 Intel scalar 386 nodes. CPU is seconds of dedicated wall clock hypercube CPU time, and efficiency is

$$\frac{\text{CPU}_1}{n\text{nodes} \cdot \text{CPU}_{n\text{nodes}}}.$$

The OLM optimizing compiler was used. An S indicates that the run ran out of storage and the CPU time was estimated based on other runs. The $n$node1 and $n$node2 columns show the numbers of nodes in directions 1 and 2, respectively. The shown values resulted in the smallest CPU time for that value of $n$nodes = $n$node1 · $n$node2. The fact that this usually occurred with an approximately square configuration of nodes indicates that the additional arithmetic incurred by using cyclic reduction in direction 1 is not a significant factor, and that communication costs comprise the bulk of the parallel inefficiency. The * values achieve about 50 percent efficiency. This is obtained with up to about $n1/8$ nodes, scaling as expected. The ·'s represent runs that were not made because of configuration or storage constraints.

3d. Table 9 (respectively, 11) presents timing results for a five-iteration V-cycle (respectively, FMV-cycle) of the 3d code on the iPSC/2 64-node hypercube at Oak Ridge. Table 10 (respectively, 12) presents the resulting efficiencies. For V-cycles, scaling behavior is more uniform than in the 2d case, in that CPU time for a given grid consistently decreases as more nodes are used. Unfortunately, efficiencies are not as high as in the 2d case. About 30 percent efficiency for V-cycles is achieved with

$\sqrt{n1 \cdot n2 \cdot n3}/8$ nodes, with relatively higher efficiencies for finer grids. The lower efficiency in three dimensions than in two dimensions may be partly due to the treatment of coarse grids, and partly due to the larger surface-to-volume ratio for 3d grids than 2d grids, with finer grids needed to get the same ratio of interior work to boundary work.

6. Plans. Plans include trying different coarse-grid approaches in three dimensions, timing our codes on the new generation of Intel RX hypercubes with faster communication networks, and writing a version of the codes for the Connection Machine.

We are grateful to Joel Dendy at Los Alamos for access to his sequential semi-coarsening multigrid codes and for many helpful conversations; and to Mary Wheeler, Lawrence Cowsar, and Ashok Chilakapati at Rice University for helpful conversations.

EFFICIENT PARALLEL ALGORITHMS FOR SOLVING INITIAL-BOUNDARY VALUE AND TIME-PERIODIC PARABOLIC PARTIAL DIFFERENTIAL EQUATIONS*

STEFAN VANDEWALLE† AND ROBERT PIESSENS†

Abstract. The numerical solution of a parabolic partial differential equation is usually calculated by a timestepping method. This precludes the efficient use of vectorization and parallelism if the problem to be solved on each time level is not very large. In this paper an algorithm that overcomes the limitations of the standard marching schemes by solving the problem at all the time levels simultaneously is discussed. The method is applicable to linear and nonlinear problems on arbitrary domains. It can be used to solve initial-boundary value problems as well as time-periodic equations. We have implemented the method on an Intel iPSC/2-VX hypercube. The numerical properties of the method are illustrated by two numerical examples and its performance is compared to that of the best standard solvers.

Key words. parallel processing, waveform relaxation, multigrid, parabolic partial differential equation

1. Introduction. The class of parabolic partial differential equations plays a very important role in many branches of science and engineering. As a result, considerable effort has been expended in formulating numerical solution methods that are both accurate and efficient. Due to the advent of parallel computers these well-known algorithms must be reconsidered, judged, and eventually restructured, to take advantage of the facilities offered by the new hardware.

In a previous study, we analyzed and compared the parallel characteristics of several classical techniques (see [16]). We illustrated that standard parabolic marching schemes can only be parallelized efficiently for problems that are *large* enough, i.e., the number of unknowns (and, consequently, the arithmetic complexity) per processor at each time level is large enough to outweigh communication. In that case, the best sequential algorithm will run efficiently and new parallel algorithms are not really needed. For relatively *small* problems, i.e., problems with few unknowns per time level or problems solved on large-scale parallel machines, only explicit methods retain some parallel efficiency. They suffer, however, from a severe stability constraint, which necessitates the use of very small timesteps and makes them numerically unattractive for solving problems on fine meshes. The best standard methods, e.g., implicit discretization with multigrid solution of the system of unknowns at each time level, perform totally unsatisfactorily.

New algorithms are therefore needed for solving parabolic problems on large-scale parallel machines. These algorithms should either improve the numerical quality of the explicit methods, or increase the parallel efficiency of the implicit methods. The former is explored in a series of papers by Evans (see, e.g., [3] and [4]) and in a paper by Rodrigue [12]. Both approaches essentially lead to new explicit methods with extended stability regions. An improvement in the implicit methods may be achieved by operating on several, or on all, time levels at once. With the *windowed relaxation* methods proposed by Saltz and Naik, the standard Jacobi and successive overrelaxation

(SOR) methods are extended to operate on a window of time levels [13]. In the *parallel timestepping* method of Womble, one or more processors are assigned to each time level [21]. While the solution is being calculated on one time level, other processors update the approximation on the subsequent time levels. In 1984, the multigrid technique was extended by Hackbusch to solve a parabolic equation on several time levels simultaneously (see [6]). A parallel implementation of this *parabolic multigrid* method was presented by Bastian, Burmeister, and Horton in [2].

In this paper, we discuss a technique that belongs to the latter class of methods. It is different from the previous approaches in that it can be defined without explicit reference to any time discretization technique or to any time levels. The method is based on *waveform relaxation*, which is briefly discussed in § 2. We discuss the application of waveform relaxation for solving initial-boundary value problems in § 3. In § 4, the solution of time-periodic parabolic equations is considered. We have implemented the method on an Intel hypercube. Some implementation aspects are discussed in § 5. The communication and arithmetic complexities are calculated in § 6. In § 7, we illustrate the method by two examples, and we compare its performance to that of a parallel implementation of the best standard methods. The results are summarized in the final section.

2. The waveform relaxation method. Waveform relaxation, also called dynamic iteration or Picard–Lindelöf iteration, is an iterative solution technique for systems of ordinary differential equations [10], [11], [20]. It differs from any other method in that the iteration in the algorithm is defined on functions. The successive iterates are defined as the solutions of a sequence of systems of differential equations. These systems may be derived similarly to the way in which the systems of equations are derived for the classical relaxation methods.

Consider the following linear, constant-coefficient system of d first-order differential equations:

$$\frac{d}{dt}U+LU=F, \quad \text{with } U(t_0)=U_0 \quad (L\in\mathbb{R}^{dxd};\ U(t), F(t)\in\mathbb{R}^d). \tag{2.1}$$

The application of a waveform relaxation step to $U^{(n)}$, an approximation of the solution U, corresponds to calculating the solution $U^{(n+1)}$ of the following equation:

$$\frac{d}{dt}U^{(n+1)}+NU^{(n+1)}=MU^{(n)}+F, \quad \text{with } U^{(n+1)}(t_0)=U_0 \quad (N, M\in\mathbb{R}^{dxd}). \tag{2.2}$$

The matrices N and M are the so-called splitting matrices and satisfy $L=N-M$. In the case of Jacobi, Gauss-Seidel, or SOR waveform relaxation, these matrices are identical to the splitting matrices used for solving the stationary problem $LU=F$ by the corresponding standard relaxation methods. With the above splittings, each of the d differential equations can be solved separately, one after the other. As such, the method is very similar to the iterative techniques for solving algebraic systems, except that each variable is a function of time rather than a scalar unknown. The idea immediately extends to variable-coefficient and nonlinear differential equations. It is straightforward to determine waveform equivalents to the familiar nonlinear relaxation methods. Furthermore, it may be advantageous to solve for the variables in groups of unknowns, which leads to a waveform extension of the block-relaxation procedures.

The waveform idea has proven very effective in solving the systems of differential equations that describe the behavior of large, complex, very large scale integration (VLSI) devices (see [20]). Its success is to a large extent due to the fact that it is a multirate integration method. Each equation or each block of equations may be solved independently with a timestep that reflects the behavior of the corresponding variables. A second reason for its success in the above application has to do with the loosely coupled nature of the governing equations. The speed of the Gauss-Seidel relaxation depends on the order in which the functions are updated. Because of the loose coupling, efficient orderings may be derived from the system dependency graph (see [8]). Finally, we should also mention the advantages of conceptual simplicity and ease of parallelization.

A theoretical analysis of the linear iteration (2.2) is presented in the papers of Miekkala and Nevanlinna [10], [11]. In [20], one of the basic papers on waveform relaxation in the electrical engineering literature, uniform convergence is proven for nonlinear systems. Further convergence results are given in [8], in which the relation is established between the number of iterations and the accuracy order, i.e., the number of correct terms in the Taylor expansion of a partially converged solution.

3. Waveform relaxation applied to initial-boundary value problems.

We consider the following linear parabolic initial-boundary value problem

$$\frac{\partial u}{\partial t}+Lu=f_1, \qquad (x,t)\in\Omega\times[t_0,t_f], \tag{3.1a}$$

$$Bu=f_2, \qquad (x,t)\in\partial\Omega\times[t_0,t_f], \tag{3.1b}$$

$$u(x,t_0)=u_0, \qquad x\in\Omega, \tag{3.1c}$$

where $\Omega\subset\mathbb{R}^n$, L is a uniformly elliptic linear operator, and B is the boundary operator. After spatial discretization and incorporation of the boundary conditions, the parabolic problem is transformed into a system of ordinary differential equations (ODEs) with one equation defined at each grid point.

3.1. Standard waveform relaxation.

The waveform relaxation algorithm may be applied to solving the semidiscretized parabolic equation. For instance, in the case of a five-point finite-difference discretization of the heat equation on a regular mesh with mesh spacing h, one iteration of the Jacobi algorithm would read as follows:

for all grid points (x_i, y_j):

$$\text{solve } \frac{d}{dt}u_{ij}^{(n+1)}=\frac{1}{h^2}\left(u_{i+1,j}^{(n)}+u_{i-1,j}^{(n)}-4u_{ij}^{(n+1)}+u_{i,j+1}^{(n)}+u_{i,j-1}^{(n)}\right) \quad \text{with } u_{ij}^{(n+1)}(t_0)=u_{ij,0}.$$

At each grid point a simple first-order differential equation is solved. This can be done by using any standard, stiff ODE integrator, possibly combined with variable-timestep variable-order techniques.

Attempts to use waveform relaxation in the way described above to solve parabolic problems have not led to a satisfactory algorithm. This is due to the slow convergence of the method, which, in turn, is due to the strong coupling between the grid-point variables. For the semidiscretized heat equation, it was shown in [10] that the convergence rates of the Jacobi, Gauss-Seidel, and SOR schemes are of order $1-O(h^2)$. (Strictly speaking, this result is only true in the case of infinite time intervals, as the *asymptotic* convergence rate equals zero on any finite time interval. However, for sufficiently long time intervals, the actual convergence behavior is adequately described by the above formula.) The convergence is thus rapidly deteriorating with an increasing number of grid lines and, unfortunately, successive overrelaxation does not significantly improve convergence characteristics.

3.2. Multigrid waveform relaxation. The convergence can be accelerated if the waveform algorithm is combined with the multigrid idea. The resulting algorithm was published by Lubich and Ostermann in [9] and rediscovered by the current authors [14], [15]. The multigrid method is extended to time-dependent problems in essentially the same way as the classical relaxation methods were extended. Each of the standard multigrid operations is replaced by a similar operation defined to operate on functions.

- *Smoothing* is performed by applying one or more damped Jacobi or Gauss-Seidel waveform relaxations of the form (2.2). In the latter case a red-black or any multicolor ordering can be used. Smoothing rates for these relaxations are defined in [9].
- The *defect* of an approximation $U^{(n+1)}$ is defined and calculated as follows:

$$D := \frac{d}{dt} U^{(n+1)} + LU^{(n+1)} - F = M(U^{(n)} - U^{(n+1)}), \tag{3.2}$$

where $U^{(n)}$ and $U^{(n+1)}$ are two successive iterates obtained with the smoothing procedure.

- *Restriction, prolongation, and correction* are calculated with identical formulae as in the elliptic case. However, these formulae now operate on functions. By way of illustration, we formulate the one-dimensional waveform full-weighting restriction operator

$$u_I(t) = (u_{i+1}(t) + 2u_i(t) + u_{i-1}(t))/4, \tag{3.3}$$

where $u_I(t)$ and $u_i(t)$ are corresponding grid-point functions on the coarse and the fine grid.

With the above changes to the elliptic multigrid algorithm, we may immediately state the waveform equivalent of the *multigrid correction scheme*, which is the usual variant for solving linear problems. Let G_i, $i = 0, 1, \cdots, k$, be the hierarchy of grids required in the multigrid procedure, with G_k the finest grid and G_0 the coarsest grid. Equation (2.1) or, equivalently, $dU_k/dt + L_k U_k = F_k$, with $U_k(t_0) = U_{k,0}$, is solved by iteratively calling the following procedure with the parameters k, F_k and an approximation of U_k.

```
PROCEDURE mgm ($k$, $F_k$, $U_k$)
    if $k = 0$ solve the coarse-grid problem $(dU_0/dt) + L_0 U_0 = F_0$ exactly
    else
        —perform $\nu_1$ smoothing operations (e.g., by red-black waveform
          relaxation)
        —compute the defect: $D_k := (dU_k/dt) + L_k U_k - F_k$
        —project the defect on $G_{k-1}$: $F_{k-1} := I_k^{k-1} D_k$
        —solve on $G_{k-1}$: $(dU_{k-1}/dt) + L_{k-1} U_{k-1} = F_{k-1}$ with $U_{k-1}(t_0) = 0$
            repeat $\gamma_k$ times mgm ($k-1$, $F_{k-1}$, $U_{k-1}$), starting with $U_{k-1} := 0$.
        —interpolate the correction to $G_k$ and correct $U_k$: $U_k := U_k - I_{k-1}^k U_{k-1}$
        —perform $\nu_2$ smoothing operations (e.g., by red-black waveform
          relaxation)
    endif
```

The algorithm is completely defined by specifying the grid sequence G_i, $i = 0, \cdots, k$, the discretized operators L_i, the intergrid transfer operators I_{i-1}^i (prolongation) and I_i^{i-1} (restriction), and the nature of the smoothing relaxations, and by assigning a value to ν_1, ν_2, and γ_i. Additionally, the algorithm can be combined with the idea of nested iteration, which leads to the waveform equivalent of the *full multigrid* *method.* The starting approximation on G_i is then derived from the solution obtained on G_{i-1} in the following way:

$$U_i(t)=\bar{I}^i_{i-1}U_{i-1}(t)+(U_{i,0}-\bar{I}^i_{i-1}U_{i-1}(t_0)). \tag{3.4}$$

The interpolation operator $\bar{I}^i_{i-1}$ may be different from the corresponding operator I^i_{i-1} in the multigrid procedure. The former is often biquadratic or bicubic while bilinear interpolation mostly satisfies for the latter. The second term in (3.4) is needed to satisfy the initial condition.

The linear multigrid waveform algorithm is theoretically analyzed in [9]. For a model problem, the authors explicitly calculate convergence rates. They show that convergence characteristics are not quite as good as those for the corresponding elliptic multigrid method, yet are sufficient to obtain typical multigrid convergence speeds. With some obvious modifications, the algorithm may be used for solving systems of parabolic partial differential equations. Furthermore, the multigrid waveform relaxation algorithm can be extended to nonlinear parabolic problems (see [14] and [17]). The nonlinear algorithm is easily derived from the well-known multigrid full approximation scheme.

4. Waveform relaxation applied to time-periodic parabolic problems.

We consider the nonautonomous parabolic problem (3.1a)-(3.1c) where the initial condition (3.1c) is replaced by the periodicity condition

$$u(x,t_0)=u(x,t_f). \tag{4.1}$$

This problem is of considerable importance in various areas of practical interest. A possible solution strategy is based on a dynamic simulation of the studied system, starting from an arbitrary initial condition and lasting until a stable periodic orbit is reached. A second approach uses difference methods where a large system of equations is obtained after discretization. A third approach is based on the shooting method. Finally, a very fast algorithm was presented by Hackbusch, in which the periodic problem is reformulated as an integral equation and solved by the multigrid method of the second kind (see [5]). We briefly review this algorithm here, as it will be compared with a new waveform relaxation-based algorithm.

4.1. Multigrid method of the second kind.

The solution of the linear initial-boundary value problem (3.1a)-(3.1c), restricted to t_f, can be written as the outcome of an affine mapping applied to the initial condition u_0, that is, $u_f=Ku_0+f$. The operator K is a linear integral operator, such that Ku_0 equals $u(x,t_f)$, the solution to (3.1a)-(3.1c) with homogeneous right-hand sides ($f_1=0$ and $f_2=0$), while $f(x)$ equals $u(x,t_f)$, the solution to (3.1a)-(3.1c) with zero initial condition ($u_0=0$). With this notation, the periodicity condition (4.1) becomes a Fredholm integral equation

$$y=Ky+f. \tag{4.2}$$

The unknown function $y(x)$, defined on Ω, is such that the solution of the initial-boundary value problem (3.1a)-(3.1c) with $u_0=y$, is the solution of the time-periodic problem. Equation (4.2) can be solved by the *multigrid method of the second kind.* We refer to [7] for an analysis of this technique and for a discussion of various applications. In a similar way as in the multigrid method for elliptic equations, (4.2) is discretized on a set of grids, G_i, $i=0,\cdots,k$, which results in a set of discrete equations

$$Y_i=K_iY_i+F_i, \quad \text{on } G_i. \tag{4.3}$$

The problem on the fine grid is solved by repeated application of the following procedure to an approximation of Y_k.

```
PROCEDURE mgm_2nd ($k$, $F_k$, $Y_k$)
    if $k=0$ solve $Y_0 = K_0 Y_0 + F_0$ exactly
    else
        —smoothing: $Y_k := K_k Y_k + F_k$
        —compute the defect: $D_k := Y_k - K_k Y_k - F_k$
        —project the defect on $G_{k-1}$: $F_{k-1} := I_k^{k-1} D_k$
        —solve on $G_{k-1}$: $Y_{k-1} = K_{k-1} Y_{k-1} + F_{k-1}$
            repeat 2 times mgm_2nd ($k-1, F_{k-1}, Y_{k-1}$), starting with $Y_{k-1} := 0$.
        —interpolate the correction to $G_k$ and correct $Y_k$: $Y_k := Y_k - I_{k-1}^{k} Y_{k-1}$
    endif
```

No explicit representation of the discretized integral operator K_i is required. Indeed, application of K_i to a function Y_i is equivalent to calculating the solution of one discrete initial-boundary value problem defined on G_i. $K_i Y_i$ may thus be computed by using standard parabolic solvers, such as a timestepping method, or by using the waveform relaxation algorithm of § 3. In [5], the convergence factor of the algorithm with proper choice of the time-integrator is shown to be of the order $O(h^2)$, where h is the fine-grid mesh size. As such, one iteration step is usually sufficient to solve (4.2) to discretization accuracy.

4.2. A waveform relaxation algorithm. Spatial discretization of the partial differential equation (3.1a)-(3.1b) with the periodicity condition (4.1) leads to the following system of ordinary differential equations:

$$\frac{d}{dt} U + LU = F \quad \text{with } U(t_0) = U(t_f). \tag{4.4}$$

This two-point boundary value problem can be solved with a waveform relaxation algorithm that is only slightly different from the algorithm discussed in § 2. The basic iteration step closely resembles (2.2) and is given by

$$\frac{d}{dt} U^{(n+1)} + NU^{(n+1)} = MU^{(n)} + F, \quad \text{with } U^{(n+1)}(t_0) = U^{(n+1)}(t_f). \tag{4.5}$$

Instead of repeatedly solving an ODE of initial value type at each grid point, one repeatedly solves a *periodic differential equation* at each grid point. This boundary value problem may be solved by a discretization method, which results in a sparse linear system. Application of an implicit one-step discretization method, such as the trapezoidal rule or the backward Euler method, leads to an easily solvable, almost bidiagonal system.

The modified waveform relaxation method can be used as such, or it can be integrated as a smoother into the multigrid waveform scheme of § 3. The only algorithmic change is then in the core of the ODE solver. The other multigrid operations remain totally unchanged. Numerical results show that the new method, *periodic multigrid waveform relaxation*, leads to a rapidly converging iteration, with typical multigrid convergence rates. The algorithm was theoretically analyzed in [18], where we proved that the convergence characteristics of the time-periodic iteration are closely related to those of initial-value iteration. There it is shown that convergence of the initial-value algorithm is a sufficient condition to guarantee the convergence of the time-periodic iteration.

5. Implementation aspects.

5.1. Time discretization. Up to this point, the waveform relaxation method has been defined without explicit reference to time discretization. We have not considered data structures or memory requirements either. We briefly address these issues now.

Any stiff integrator can be used to solve the differential equations that arise in the smoothing step of the algorithm. A sophisticated variable-timestep variable-order integrator from the ODEPACK library was used in our early experiments [14]. However, the overheads of stepsize and order selection, reoccurring at each grid point, badly deteriorated the execution times. Consequently, our experience now advocates the use of a simple but fast ODE integrator. Only then can the waveform method remain competitive with the standard techniques. For the examples in the next section, we used the second-order accurate trapezoidal rule (or Crank–Nicolson method) and the backward differentiation method, both with fixed timestep Δt. The same timestep was used for the integrations on the fine grid and on the coarse grids. This choice of time integration precludes taking advantage of waveform relaxation as a multirate integration method. However, it simplifies implementation and, as is explained in § 5.3, it allows for vectorization.

In the waveform method, several functions are associated with each grid point. For these functions, an effective and compact computer representation should be chosen. It should allow for efficient evaluation of the functions and, more importantly, for efficient algebraic manipulation (mainly the summation of functions and multiplication with a scalar). For the latter reason, we have represented each function as a *vector* of function values evaluated at equidistant time levels. We denote the vector length by n_t (number of time levels). The time increment is chosen equal to the time increment used by the integration formula. With the above implementation choices, a correspondence arises between the waveform method and standard timestepping techniques. A careful analysis shows that the set of equations that determines the unknowns in the waveform method is exactly the same as the set of equations that determines the solution when a timestepping method is used with the same discretization formula and the same time increment. Thus the solution of both techniques is identical.

In Fig. 5.1 we depict the set of unknowns for a problem on a one-dimensional domain. In the case of a timestepping procedure the unknowns must be stored in the computer memory on a few time levels only. In the case of waveform relaxation the values at every time level must be available. Storage requirements are therefore very high. However, if storage is a problem, the time interval of interest can be partitioned into several smaller *windows*, which can be solved in sequence (in the case of an initial-boundary value problem).

If we are willing to pay the memory price involved in waveform relaxation, we could wonder whether it is possible to apply multigrid on the whole of the *space-time* grid, i.e., with coarsening, restriction, and interpolation also in the time direction.

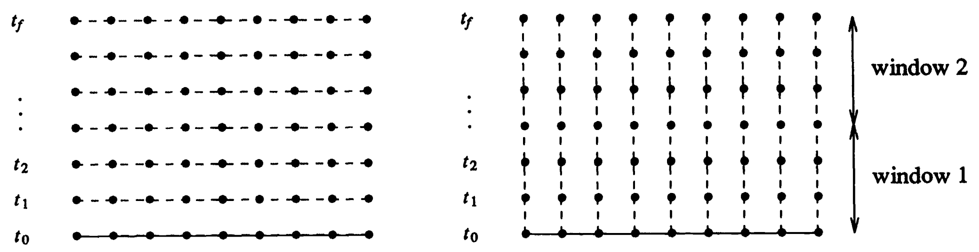

FIG. 5.1. *Distribution of grid points: timestepping method (left) and waveform relaxation (right).*

Although we certainly do not want to claim that such an approach is not possible, we may argue that it is not natural. Consider the following elliptic partial differential equation with an aligned anisotropy in the y-direction:

$$-\frac{\partial^2 u}{\partial x^2}-\varepsilon\frac{\partial^2 u}{\partial y^2}+\frac{\partial u}{\partial y}=f \qquad (\varepsilon \ll 1). \tag{5.1}$$

In the limiting case $\varepsilon=0$, this becomes the one-dimensional heat equation. Problems like (5.1) are often solved with the following multigrid parameter choices. For handling the ε-term, the use of either x-line smoothing or semicoarsening, i.e., coarsening only in the x-direction, is advocated [7, Chap. 10]. The first-order derivative term is handled by backward differencing, and either y-line smoothing or pointwise smoothing from low to high y-values. Thus two "natural" parameter choices arise: standard coarsening combined with x-line smoothing from low to high y-values, and semicoarsening combined with y-line smoothing or pointwise smoothing in the direction of increasing y. In the limiting case, when the elliptic problem becomes a parabolic problem, the first approach is equivalent to standard timestepping (the smoother is an exact solver). The second approach leads to a discrete multigrid waveform relaxation algorithm as defined above, i.e., without coarsening in the time direction.

5.2. Parallelization. We have implemented the algorithms on an Intel iPSC/2-VX hypercube. For a description of this multiprocessor, its hardware characteristics, and various performance benchmarks, see [1]. The implementation of the waveform algorithm and the parallelization of the standard timestepping methods are discussed in detail in our studies [15], [16]. In this section, we only review some of the main issues.

A classical data decomposition is used to evenly distribute the computational workload. The processors are arranged in a rectangular array and are mapped onto the domain of the partial differential equation, which, in our implementation, is restricted to be a rectangle. Each processor is responsible for doing all computations on the grid points in its part of the physical domain. This straightforward partitioning scheme ensures a fairly good load balance, especially when the number of grid points is large. However, some load imbalance cannot be avoided whenever the number of processors in a coordinate direction does not divide the number of grid lines in that direction. During the computation, communication with neighboring processors is needed mainly to update local boundary values. Some other communication strategies are further used to improve the parallel performance. We mention, in particular, the use of an *agglomeration* strategy to reduce the communication complexity of the coarse-grid operations [16]. Agglomeration is especially important for use with multigrid cycles that frequently visit the coarse grids, such as the W-cycle. Although this cycle has superior convergence properties, in a parallel environment without the use of agglomeration, this cycle is easily outdone by the less robust but more efficiently parallelizable V- and F-cycles.

We may now qualitatively analyze the parallel characteristics of the waveform methods. A more quantitative approach is presented in § 6. The arithmetic complexity of the waveform operators increases linearly with the value of n_t. In the same way, the total length of the messages exchanged during the computation is proportional to n_t. The number of messages, however, and the sequential overhead due to program control are independent of n_t. From the high message startup time on most parallel machines (and in particular on the iPSC/2), it is clear that the communication time-to-calculation time ratio will decrease with increasing function length. The larger the number of time levels calculated simultaneously, the better the parallel efficiency will be.

5.3. Vectorization. The use of vector processors for executing the multigrid waveform algorithm may result in a substantial reduction of computing time. Indeed, most of the operators can be expressed as simple arithmetic operations on functions, i.e., on *vectors* (see, e.g., the restriction operator (3.3)). In contrast to the standard approach *vectorization is in the time direction* and not in the spatial direction. The vector speedup of the arithmetic part of the computation mainly depends on the value of n_t. It is virtually independent of the size of the spatial grid, the number of multigrid levels, the multigrid cycle used, and the number of processors. This contrasts sharply with standard multigrid vectorization results. Standard vectorization does not lead to a performance improvement unless the number of grid points per processor is very large. Its application is therefore of very limited use on large-scale parallel processors.

The only operation that is not perfectly vectorizable is the core of the ODE integrator, which is used in the smoothing step. It consists of one or two first-order recurrence formulae of length n_t (one in the case of an initial value problem, and two in the case of a time-periodic problem solved by discretization with a one-step formula). This reduces the possible gain through vectorization. It can be shown, however, that the cost of the recurrence relation is only a small fraction of the total computation cost, typically 5 to 10 percent [19]. This leads to a possible vector speedup of 10 or more. As an additional advantage of vectorization in the time direction, we mention the ease of implementation. As the vector operations at each grid point involve the vectors at neighboring grid points only, no complex grid restructuring is needed.

6. A comparison of arithmetic and communication complexities. It is instructive to compare the complexities of the multigrid waveform algorithms with the complexities of the corresponding standard sequential methods. In this section, we assume that the discretization and integration formula used in the waveform algorithms is chosen as explained in § 5.1.

6.1. Initial-boundary value problems. We first introduce some notation. The grids are again denoted by $G_0, G_1, \cdots, G_k$, where G_k identifies the fine grid. Let N_i be the number of messages sent by each processor in one multigrid cycle, when an elliptic problem is solved on G_i. If N_i differs from processor to processor, we take the maximum value. Let L_i be the corresponding total message length. α_E denotes the number of multigrid cycles needed to solve the elliptic problem. α_{WR} is the number of multigrid waveform cycles needed for convergence of the waveform relaxation algorithm. The values of α_E and α_{WR} depend on the particular equation solved and the multigrid cycle used. Finally, $n_{t,i}$ is the number of time levels used for the time discretization of an initial-boundary value problem on G_i. If we further assume that the multigrid cycle type used in the timestepping algorithm corresponds to the one in the waveform method, and that α_E is the same on each time level, then we can immediately derive the communication complexity values presented in Table 6.1. TM_k and TL_k denote the total number of messages and the total message length to solve the initial-boundary value problem (IBVP) on G_k. In the case of the full multigrid approach, a value of 1 for α_E and α_{WR} frequently suffices to obtain a solution that is accurate to discretization

TABLE 6.1
Communication complexity of the initial-boundary value solvers.

	Timestepping algorithm	Multigrid waveform relaxation
TM_k(IBVP)	$n_{t,k}N_k\alpha_E$	$N_k\alpha_{WR}$
TL_k(IBVP)	$n_{t,k}L_k\alpha_E$	$n_{t,k}L_k\alpha_{WR}$

accuracy. The total message length in both solvers is then identical, whereas the number of messages differs by a factor of n_t.

In addition, a count of the number of floating point operations reveals that the arithmetic complexity of both methods is very similar (at least if the same cycle types and a same number of cycles are used). When using the Crank-Nicolson discretization, differences are typically in the range of 10 to 20 percent, with timestepping being more expensive. This higher cost is due to the cost of setting up the system of equations in each timestep, more precisely the cost of constructing the right-hand side (see [19]).

6.2. Time-periodic problems. To derive the complexities of the time-periodic solvers, some further assumptions are helpful. We assume, in particular, that the length of the messages in each of the multigrid operators is inversely proportional to the mesh size, and that the number of message exchanges is a constant independent of the discretization. For instance, in a Jacobi smoothing step, precisely four messages are needed on any grid, namely, one to each neighboring processor. The length of each message, however, is proportional to the number of grid lines. For simplicity, we only consider the use of multigrid V-cycles and standard coarsening, i.e., the mesh size is halved in going from a coarse to a fine grid. This immediately leads to the following formulae:

$$N_i = \frac{i}{k} N_k \quad \text{and} \quad L_i = \frac{2^i - 1}{2^k - 1} L_k \qquad (\approx 2^{i-k} L_k \text{ if } i, k \text{ sufficiently large}). \tag{6.1}$$

In the multigrid method of the second kind, several IBVPs are to be solved on every grid level. In each iteration, two such problems are to be solved on the fine grid. Each coarser grid, G_i, is visited 2^{k-i} times. In half of the visits, two IBVPs are to be solved (one in smoothing and one in defect calculation). In the other half, the problem in the smoothing step can be skipped. Indeed, when the initial condition is zero, the smoothing step simplifies to $Y_k := F_k$. Consequently, the number of IBVPs on G_i, with $i < k$, denoted by n_i, satisfies the formula

$$n_i = \frac{3}{2} 2^{k-i}. \tag{6.2}$$

If a time discretization method is used with sufficient smoothing behavior, e.g., a backward differentiation formula, the number of timesteps may be divided by 2 in going from one grid level to a coarser one. We assume that $n_{t,k}$ is large enough so that this process of halving the number of timesteps can be continued down to the coarsest grid. In that case, the number of timesteps used to solve an IBVP on G_i, denoted by $n_{t,i}$, equals

$$n_{t,i} = 2^{i-k} n_{t,k}. \tag{6.3}$$

The total number of messages and the total message length for solving a time-periodic problem (TPP) with α_M iterations of the multigrid method of the second kind can now be calculated as follows:

$$TM_k(\text{TPP}) = \left(2TM_k(\text{IBVP}) + \sum_{i=0}^{k-1} n_i TM_i(\text{IBVP})\right)\alpha_M = \frac{(5+3k)}{4} n_{t,k} N_k \alpha_E \alpha_M, \tag{6.4}$$

$$\begin{aligned} TL_k(\text{TPP}) &= \left(2TL_k(\text{IBVP}) + \sum_{i=0}^{k-1} n_i TL_i(\text{IBVP})\right)\alpha_M \\ &= \left(2 + \frac{3}{2}\left(1 - \frac{k}{2^k - 1}\right)\right) n_{t,k} L_k \alpha_E \alpha_M \end{aligned} \tag{6.5}$$

$$\approx \frac{7}{2} n_{t,k} L_k \alpha_E \alpha_M. \tag{6.6}$$

The communication complexity of one time-periodic multigrid waveform cycle is identical to that of one initial-value multigrid waveform cycle. However, the number of cycles needed to obtain convergence, α_{WRP}, may be different from α_{WR}.

A fair comparison of the time-periodic problem solvers should take the convergence characteristics into account. From several experiments, it is shown that an algorithm based on one iteration of the multigrid method of the second kind ($\alpha_M = 1$), or on one periodic full multigrid waveform step, is sufficient to obtain a solution accurate to discretization accuracy. Consequently, we should compare these two approaches. We have added a column to Table 6.2 for the full multigrid waveform step with one V-cycle on each grid level. Its communication complexity is derived from the formulae

$$TM_k(\text{TPP}) = \sum_{i=0}^{k} N_i = \frac{k+1}{2} N_k, \tag{6.7}$$

$$TL_k(\text{TPP}) = n_{t,k} \sum_{i=0}^{k} L_i = \left(2 - \frac{k}{2^k - 1}\right) n_{t,k} L_k \approx 2 n_{t,k} L_k. \tag{6.8}$$

The arithmetic complexity remains to be analyzed. By $W_k(\text{IBVP})$, we denote the complexity of solving one IBVP on G_k. The cost of solving a similar problem on G_i is then equal to

$$W_i(\text{IBVP}) = 8^{i-k} W_k(\text{IBVP}), \tag{6.9}$$

when we assume that an algorithm is used the complexity of which is proportional to the number of grid points. The cost of the multigrid method of the second kind equals

$$W_k(\text{TPP}) = \left(2 W_k(\text{IBVP}) + \sum_{i=0}^{k-1} n_i W_i(\text{IBVP})\right) \alpha_M \approx 2.5\, W_k(\text{IBVP}) \alpha_M. \tag{6.10}$$

The arithmetic complexity of a time-periodic multigrid waveform cycle with one-step time discretization hardly differs from that of the corresponding initial-value cycle [19]. Furthermore, since the convergence rates are very similar, we may safely state that the cost of solving a time-periodic problem by a waveform relaxation method is similar to the cost of solving the corresponding initial-boundary value problem with the waveform method.

The communication complexity of the periodic waveform relaxation algorithm is substantially smaller than that of the multigrid method of the second kind (see Table 6.2). Consider, e.g., the following typical set of parameters, taken from the example in § 7.2: $k = 4$, $n_{t,4} = 32$, $\alpha_E = 2$, $\alpha_M = 1$. With these parameters the total number of messages differs by a factor of more than 100, while the total length differs by a factor of 3.5. In addition, the arithmetic complexity of the time-periodic multigrid waveform

TABLE 6.2
Communication complexity of the time-periodic problem solvers.

	Multigrid second kind	Periodic MWR (cycling)	Periodic MWR (full mgrid)
$TM_k(\text{TPP})$	$(5+3k)/4 n_{t,k} N_k \alpha_E \alpha_M$	$N_k \alpha_{WRP}$	$(k+1)/2 N_k$
$TL_k(\text{TPP})$	$7/2 n_{t,k} L_k \alpha_E \alpha_M$	$n_{t,k} L_k \alpha_{WRP}$	$2 n_{t,k} L_k$

relaxation is smaller with a factor of 2.5. The latter holds, whenever the sequential complexity of the time integrator in the multigrid method of the second kind is similar to that of the initial-value multigrid waveform relaxation (MWR) method. (Numerical experiments have shown that this is very often the case.)

7. Numerical examples.

7.1. An initial-boundary value problem. We consider the following IBVP:

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}+xy\frac{\partial^2 u}{\partial x\,\partial y}+\frac{\partial^2 u}{\partial y^2}+f \quad \text{on } \Omega=[0,1]\times[0,1] \quad \text{for } t\in[0,0.5], \tag{7.1}$$

with Dirichlet conditions on the northern, eastern, and southern boundary, and a Neumann condition on the boundary to the west. The right-hand side function f is chosen in such a way that the solution is given by $u(t,x,y)=\sin(5x+y+10t)\,e^{-4t}$. For this problem, we compare the performance of MWR with a parallel implementation of the Crank-Nicolson method. In both cases, multigrid is used with a four-color nine-point Gauss-Seidel smoother, standard coarsening to a 3×3 coarse grid, full weighting restriction, bilinear interpolation, and a coarse-grid solver that performs two Gauss-Seidel iterations. The timestep Δt was set to 0.01, which leads to a vector length of 50. In the waveform method, we apply the trapezoidal rule to guarantee solutions identical to those obtained with Crank-Nicolson timestepping. The initial waveform solution is a function constant in time and equal to the value of the initial condition. The problem is solved on a 16-processor Intel iPSC/2 hypercube. Load distribution is performed by means of a two-dimensional partitioning with four processors in each coordinate direction.

The timing results are depicted in Fig. 7.1. The graphs show the accuracy of the solution (largest error at the grid points) versus execution time. The figures show *smooth curves* for the waveform method. The error of the initial waveform approximation decreases as more and more multigrid cycles are applied. (The results for the successive iterates are indicated by "∘" symbols.) The Crank-Nicolson results show up as *discrete points.* The Crank-Nicolson solution process is advanced timestep per timestep in a total of t seconds. The accuracy of the result is represented by a "+" sign at position (t, error) in the figure. Depending on the multigrid cycle type used, different execution times are needed. As such several results are presented for each technique. They are annotated in Fig. 7.1 in the following way: with "WR $V(1,1)$ with FMG" we mean "waveform relaxation using V-cycles with one pre- and one post-smoothing step and use of the full multigrid technique with one cycle at each grid level to determine the initial approximation on the fine grid." In the Crank-Nicolson method the initial approximation at a time level is either calculated by a linear extrapolation of the solutions at two previous time levels, or is determined by using full multigrid. It is then corrected by means of a fixed number of V- or F-cycles. This is denoted as "C-N, 1 $V(1,1)$ with FMG," which indicates the use of full multigrid with one $V(1,1)$ cycle on each grid level. Two sets of curves are given for the waveform method. The dashed lines represent the results obtained with vectorization, while the solid lines represent the results obtained in scalar execution mode.

On 16 processors, MWR is faster than the Crank-Nicolson method with a factor of 7 (for the 65×65 problem) up to a factor of 10 (for the 17×17 problem). This is due to the *smaller arithmetic complexity* of the waveform method, its *superior parallel characteristics,* and the use of *vectorization.* In Table 7.1, we have tabulated the execution time of the full multigrid solver with one $V(1,1)$ cycle on each grid level, on 1 and on 16 processors. We have also added the parallel speedup Sp. In this particular

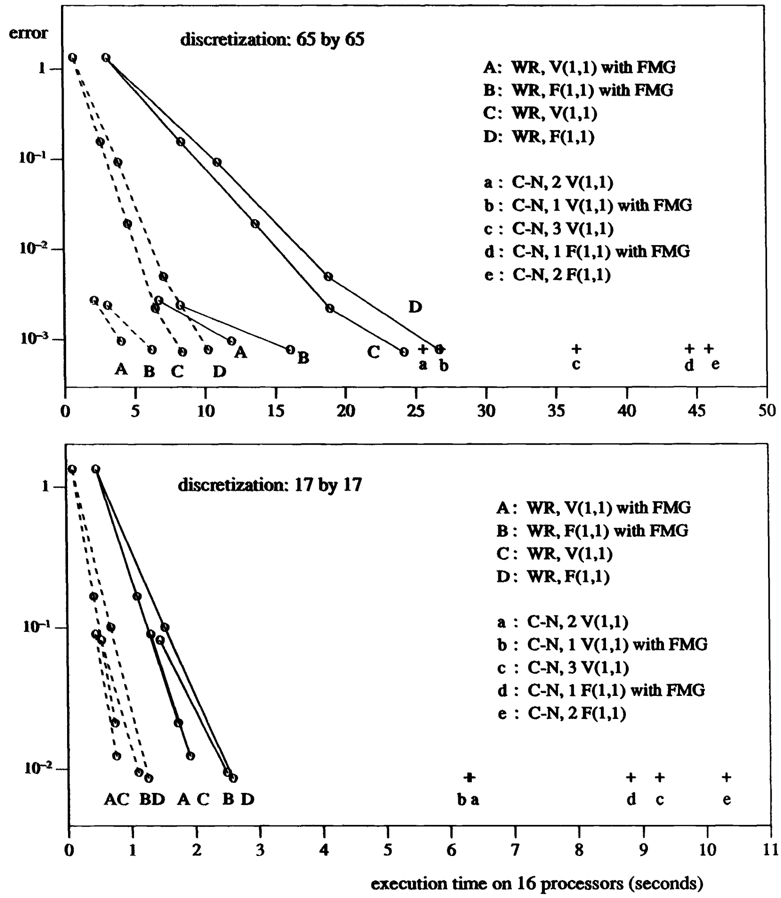

FIG. 7.1. *Comparison of Crank-Nicolson and multigrid waveform relaxation.*

TABLE 7.1
Execution time, in seconds, of the full multigrid solver on 1 *and* 16 *processors.*

	$h = 1/16, n_t = 50$			$h = 1/32, n_t = 50$		
Method	1 proc.	16 proc.	Sp	1 proc.	16 proc.	Sp
Waveform relaxation	9.35	1.91	5.0	36.00	4.30	8.4
Crank-Nicolson	12.90	6.32	2.0	48.29	12.52	3.9

example, waveform relaxation outperforms the standard method by a factor of approximately 1.3 on a single processor. This is due to a somewhat smaller arithmetic complexity, a reduced initialization cost (some intermediate results may be retained when setting up system (2.1), especially when evaluating the right-hand side), and the much lower computational overheads associated with program control (loop overhead, indexing overhead, procedure call overhead, etc.). An additional factor of 2 to 2.5 results from the better parallel characteristics of the MWR method. This immediately shows from the speedup figures.

The remaining performance difference is due to vectorization. In Table 7.2, we give the execution times of the full multigrid solver, together with the values of the

TABLE 7.2
Execution time, in seconds, of the WR FMG $V(1,1)$ *solver* (*on* 16 *processors*).

	$h=1/16$			$h=1/32$			$h=1/64$		
n_t	Scalar	Vector	Sp	Scalar	Vector	Sp	Scalar	Vector	Sp
100	3.54	1.12	3.16	8.20	2.42	3.39	(na)	(na)	(na)
50	1.91	0.76	2.51	4.30	1.59	2.70	11.88	4.02	2.96
25	1.10	0.59	1.86	2.43	1.20	2.03	6.53	2.91	2.24
10	0.62	0.49	1.27	1.29	0.97	1.33	3.21	2.25	1.43

speedup obtained by vectorization. (The largest problem, 65×65 grid lines and 100 timesteps, could not run on the machine due to lack of memory on the vector board.) The low values of the vector speedup are due to the high startup time of the vector operations on the iPSC/2. The speedup values should be substantially higher on a processor with more specialized vector hardware. The dependence of the speedup on the vector length is obvious. It should be noted that for problems of this size on a 16-processor machine, vectorization in the Crank-Nicolson method would not lead to any speedup.

7.2. A time-periodic problem. We consider the time-periodic parabolic partial differential equation,

$$\frac{\partial u}{\partial t}=\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}+f, \quad \text{with } u(0,x,y)=u(1,x,y), \tag{7.2}$$

defined on the unit square with four Dirichlet boundary conditions. The function f is chosen in such a way that the solution of the equation becomes $u(t,x,y)=1+100(x-x^2)^2(y-y^2)^2\sin(2\pi t)$. In Fig. 7.2, we represent the timing results which were again obtained on a 16-processor Intel iPSC/2 hypercube. However, no vectorization was used.

Three methods are compared. The first method is a parallel implementation of the multigrid method of the second kind. The second-order backward differentiation method (BDF(2)) is used for time integration. It has excellent smoothing properties and is of high accuracy. The spatial mesh size of each grid G_l is determined by standard coarsening from a fine grid, G_k, with 65 or 17 grid lines in the x- and y-direction. The time increment Δt_l is chosen equal to the mesh size. The linear systems obtained by the BDF(2) scheme on each time level are solved by using the standard multigrid method, with two $V(1,1)$ cycles or by full multigrid with one $V(1,1)$ cycle on each level. Due to its $O(h^2)$ convergence rate, one iteration of the method is sufficient to solve the problem to discretization accuracy. Various programming techniques are applied to optimize the parallel performance of the implementation. In particular, the use of an agglomeration technique is crucial to reducing the parallel overhead of the coarse-grid operations.

A related method is obtained if the multigrid waveform algorithm is used as the IBVP solver inside the multigrid method of the second kind. The resulting algorithm is about 1.5 to 2 times as fast as the method with timestepping, as shown in Fig. 7.2. This was to be expected, from the speedup values given in Table 7.1. The periodic multigrid waveform method is faster than the best standard algorithm, by a factor of 7 to 10. This is in part due to its *lower arithmetic complexity*, as explained in § 6. To verify the complexity estimates of both methods we report the one-processor execution times in Table 7.3.

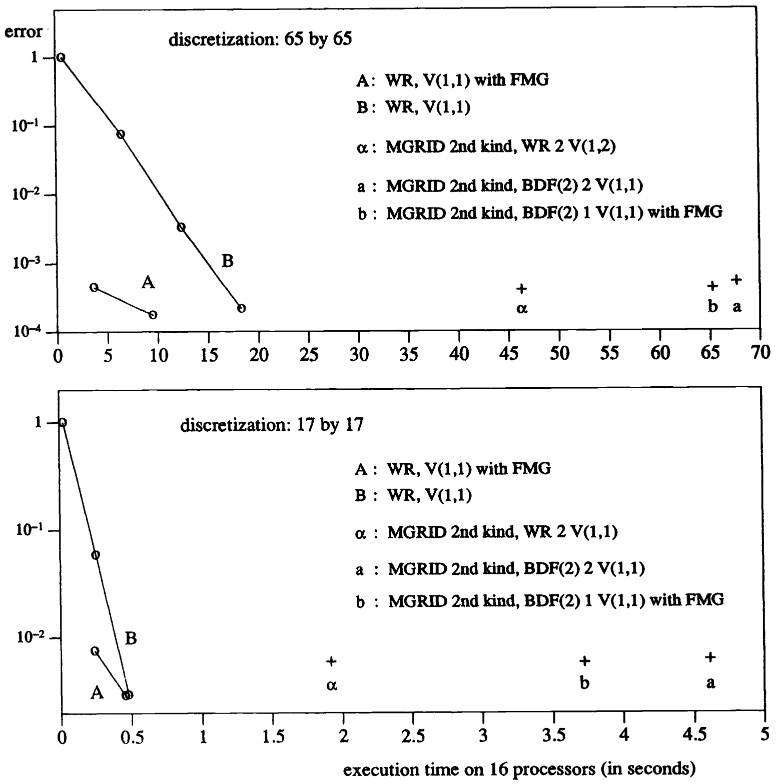

FIG. 7.2. *Comparison of multigrid waveform relaxation and multigrid of the second kind.*

TABLE 7.3

Execution time, in seconds, of two time-periodic problem solvers: time-periodic full multigrid waveform relaxation and one cycle of multigrid of the second kind.

	$h=1/16, n_t=16$			$h=1/32, n_t=32$		
Method	1 proc.	16 proc.	Sp	1 proc.	16 proc.	Sp
Waveform relaxation	1.77	0.46	3.9	14.33	1.78	8.1
Multigrid sec. kind	4.83	3.74	1.3	35.11	15.74	2.2

The remaining performance difference results from the *better parallel characteristics* of waveform relaxation. This is illustrated in Table 7.3, which shows that hardly any speedup is obtained with the multigrid method of the second kind. As noted above, it is difficult to parallelize coarse-grid operations efficiently. The multigrid method of the second kind visits the coarse grids very frequently because of its "double multigrid" nature. It is basically a multigrid *W*-cycle where, in each smoothing step, a timestepping method is used which applies standard multigrid for solving the elliptic problems on each time level. Consequently, the algorithm is not well suited for parallel implementation.

We should also note that vectorization leads to an additional speedup only in the case of the waveform algorithm. The performance difference on the 16-processor machine is then in the range of 20 to 40, depending on the problem size.

8. Summary and concluding remarks. The transformation of the parabolic problem into the sequential process of solving small problems on successive time levels seriously degrades the parallel efficiency of the standard marching schemes. While these methods can be used efficiently for problems with a very large number of grid points per processor, they perform totally unsatisfactorily for small problems and/or large numbers of processors.

To tackle these problems, we have presented a family of methods based on waveform relaxation. They show multigrid convergence speeds and are competitive with, or even surpass, the standard solvers on sequential processors. They can be implemented efficiently on parallel machines, as they have a very low communication complexity. As an added advantage they can be vectorized straightforwardly, with no substantial changes in the program code. This vectorization leads to an important reduction in execution time, even if the number of grid points per processor is too small to justify vectorization of the timestepping approach. In addition, the algorithms are not restricted to linear problems or rectangular domains; nonlinear problems and systems of equations on arbitrary domains can be treated in a similar way with qualitatively the same parallelization and vectorization characteristics. The main price to be paid is memory cost, as the iterates generated by the algorithm are to be stored along the entire time interval of interest.

EVALUATING BEST-CASE AND WORST-CASE VARIANCES WHEN BOUNDS ARE AVAILABLE*

GEORGE S. FISHMAN†, BORIS L. GRANOVSKY‡, AND DAVID S. RUBIN†§

Abstract. This paper describes procedures for computing the tightest possible best-case and worst-case bounds on the variance of a discrete, bounded, random variable when lower and upper bounds are available for its unknown probability mass function. An example from the application of the Monte Carlo method to the estimation of network reliability illustrates the procedures and, in particular, reveals considerable tightening in the worst-case bound when compared to the trivial worst-case bound based exclusively on range.

Key words. best-case variance, computational complexity, Monte Carlo, parametric linear programming, sample size, worst-case variance

AMS(MOS) subject classification. 62

Introduction. Let X denote a discrete random variable with unknown probability mass function (pmf) $\{\mu_i = \text{pr}(X=i);\ \mu_i > 0,\ 1 \leqq i \leqq r < \infty;\ \mu_1 + \cdots + \mu_r = 1\}$ and suppose one wishes to estimate

$$g(\boldsymbol{\mu}, \mathbf{w}) = \mu_1 w_1 + \cdots + \mu_r w_r, \tag{1}$$

where

$$\boldsymbol{\mu} = (\mu_1, \cdots, \mu_r),$$

and where $\mathbf{w} = (w_1, \cdots, w_r)$ is known, with $w_i \neq w_j$ for $i \neq j$. Let

$$\phi_i(j) = \begin{cases} 1 & \text{if } j = 1, \\ 0 & \text{otherwise} \quad 1 \leqq i, j \leqq r. \end{cases} \tag{2}$$

Then the random variable $Z = \phi_1(X) w_1 + \cdots + \phi_r(X) w_r$ has expectation (1) and variance

$$\text{var}\, Z = h(\boldsymbol{\mu}, \mathbf{w}) = \sum_{i=1}^{r} \mu_i w_i^2 - \left(\sum_{i=1}^{r} \mu_i w_i \right)^2. \tag{3}$$

This paper describes algorithms for evaluating the tightest possible worst-case lower bound and best-case upper bound on $h(\boldsymbol{\mu}, \mathbf{w})$ when nontrivial lower and upper bounds are available for $\boldsymbol{\mu}$. Formally, we solve the worst-case nonlinear program

$$h^*(w) = \max_{\boldsymbol{\mu}} h(\boldsymbol{\mu}, \mathbf{w}),$$

subject to

$$\text{(NLPW)} \qquad \begin{aligned} &\mu_i \geqq e_i \geqq 0, \\ &\mu_i \leqq f_i \leqq 1, \\ &e_i \leqq f_i, \qquad 1 \leqq i \leqq r \\ &\mu_1 + \cdots + \mu_r = 1, \end{aligned}$$

and we also solve the best-case nonlinear program (NLPB), the analogous problem of finding $h_*(\mathbf{w}) = \min_{\boldsymbol{\mu}} h(\boldsymbol{\mu}, \mathbf{w})$, subject to the same constraints. Knowing $h_*(\mathbf{w})$ and $h^*(\mathbf{w})$ is of considerable value when designing a sampling experiment to achieve a variance no greater than, say, a specified quantity $v(\mathbf{w})$. In particular, a sample size of no less than $n_*(\mathbf{w}) = \lceil h_*(\mathbf{w})/v(\mathbf{w}) \rceil$, but no larger than $n^*(\mathbf{w}) = \lceil h^*(\mathbf{w})/v(\mathbf{w}) \rceil$ is required to achieve this accuracy. Moreover, if we wish to estimate the function $\{g(\boldsymbol{\mu}, \mathbf{w}), \mathbf{w} \in \mathscr{W}\}$, where $\mathscr{W}$ denotes a set of alternative weight vectors, to achieve variance accuracies $\{v(\mathbf{w}), \mathbf{w} \in \mathscr{W}\}$, then

$$n = \left\lceil \max_{\mathbf{w} \in \mathscr{W}} [h^*(\mathbf{w})/v(\mathbf{w})] \right\rceil$$

gives the worst-case sample size.

For the trivial $\{0, 1\}$ bounds on each μ_i, the best-case bound for $h(\boldsymbol{\mu}, \mathbf{w})$ is zero, and we immediately derive the worst-case bound

$$h^{**}(\mathbf{w}) = \left(\max_{1 \leqq i \leqq r} w_i - \min_{1 \leqq i \leqq r} w_i \right)^2 /4. \tag{4}$$

As the example in § 2 makes clear, even relatively modest improvements in these bounds can lead to substantially tighter $h_*(\mathbf{w})$ and $h^*(\mathbf{w})$, thus significantly reducing their difference as well as the corresponding worst-case sample size. This improved bound is the reward for going to the effort of solving the nonlinear programs in (NLPW) and (NLPB).

Problems of this type arise in many areas where the setting of the problem makes a set of bounds $\mathbf{e} = (e_1, \cdots, e_r)$ and $\mathbf{f} = (f_1, \cdots, f_r)$ available to the analyst at low or no cost before data gathering begins. This is especially true when applying the Monte Carlo method where the mathematical structure of the problem often allows one to deduce the bounds. Section 1 describes the algorithms for solving (NLPW) and (NLPB) and § 2 illustrates their use in a Monte Carlo example designed to estimate system reliability in a stochastic network.

1. Method of solution.

1.1. Determining $h^*(\mathbf{w})$. We begin by characterizing the solution to (NLPW). Since (NLPW) has a continuous objective function, and since the set of points that satisfy its constraints is compact, the problem has an optimal solution.

THEOREM 1. *Let $w_i \neq w_j$ for $i \neq j$, and let $\boldsymbol{\mu}^0 = (\mu_1^0, \cdots, \mu_r^0)$ denote the solution to* (NLPW). *There exists a partition $\mathscr{S}_e$, $\mathscr{S}$, $\mathscr{S}_f$ of the integers $\{1, \cdots, r\}$ such that*

$$\mu_i^0 = \begin{cases} e_i & \text{for } i \in \mathscr{S}_e, \\ \theta_i, \quad e_i < \theta_i < f_i, & \text{for } i \in \mathscr{S}, \\ f_i & \text{for } i \in \mathscr{S}_f, \end{cases}$$

and $|\mathscr{S}| \leqq 2$.

Proof. The only result requiring proof is $|\mathscr{S}| \leqq 2$. Let $q = q(\boldsymbol{\mu}, \mathbf{w}) = h(\boldsymbol{\mu}, \mathbf{w}) + L(1 - \mu_1 - \cdots - \mu_r)$, with L a Lagrange multiplier, be the usual Lagrangian function for (NLPW). Let

$$\lambda^0 = \sum_{i=1}^{r} \mu_i^0 w_i,$$

and let L^0 be an optimal value for L. If $e_i < \mu_i^0 < f_i$, then at $\boldsymbol{\mu} = \boldsymbol{\mu}^0$ and $L = L^0$, $\partial q/\partial \mu_i = w_i^2 - 2\lambda^0 w_i - L^0 = 0$. Since λ^0 and L^0 are fixed, this can happen for at most two $i \in \{1, \cdots, r\}$, because $\partial q/\partial \mu_i$ is a quadratic polynomial in w_i, and the w_i are distinct.

Therefore, $|\mathcal{S}| \leqq 2$, implying that the remaining μ_j^0 must be either at their lower or upper bounds. □

The proposed method of computing $h^*(\mathbf{w})$ is based on consideration of a parametric family of linear programs related to (NLPW). Let

$$\Phi(\lambda) = \max \sum_{j=1}^{r} \mu_j w_j^2,$$

subject to

$$\text{(LPW}(\lambda)) \qquad \begin{aligned} &\sum_{j=1}^{r} \mu_j = 1, \\ &\sum_{j=1}^{r} \mu_j w_j = \lambda, \\ &e_j \leqq \mu_j \leqq f_j, \qquad 1 \leqq j \leqq r, \end{aligned}$$

where λ and $\mathbf{w}$ are fixed and the indices are assigned so that $w_1 > w_2 > \cdots > w_r$. Let $\Psi(\lambda) = \Phi(\lambda) - \lambda^2$,

$$\underline{\lambda} = \min \left(\sum_{i=1}^{r} \mu_i w_i : \sum_{i=1}^{r} \mu_i = 1;\ e_i \leqq \mu_i \leqq f_i,\ 1 \leqq i \leqq r \right),$$

and

$$\bar{\lambda} = \max \left(\sum_{i=1}^{r} \mu_i w_i : \sum_{i=1}^{r} \mu_i = 1;\ e_i \leqq \mu_i \leqq f_i,\ 1 \leqq i \leqq r \right).$$

Then (NLPW) has the equivalent representation

$$\text{(PW)} \qquad h^*(\mathbf{w}) = \max_{\underline{\lambda} \leqq \lambda \leqq \bar{\lambda}} \Psi(\lambda).$$

The proposed method solves a sequence of linear programs (LPW(λ)) for changing λ until the optimal solution to (PW) is found. Since (LPW(λ)) has two structural equations, there are exactly two variables that are basic in any basic feasible solution to (LPW(λ)), an observation consistent with the result in Theorem 1.

We assume that the w_i are distinct: if, in reality, $w_i = w_j$ for some $i \neq j$, we can replace μ_i and μ_j by $\hat{\mu}_i = \mu_i + \mu_j$, with bounds $\hat{e}_i = e_i + e_j$ and $\hat{f}_i = f_i + f_j$, and reduce the dimension of the problem by one.

For feasibility we must have $\sum_{i=1}^{r} e_i \leqq 1$ and $\sum_{i=1}^{r} f_i \geqq 1$, and these inequalities must be strict or else the problem is uninteresting, since $\sum_{i=1}^{r} e_i = 1$ implies that $\mu_i = e_i$, $1 \leqq i \leqq r$, is the only feasible solution, and $\sum_{i=1}^{r} f_i = 1$ implies that $\mu_i = f_i$, $1 \leqq i \leqq r$, is the only feasible solution.

We assume that $e_i < f_i$ for all $1 \leqq i \leqq r$: if for some $r' < r$, $e_i = f_i$ for $r' < i \leqq r$, then we prefer to work with the random variable

$$Z' = \sum_{i=r'+1}^{r} e_i w_i + \sum_{i=1}^{r'} \phi_i(X) w_i$$

and then maximize

$$\sum_{i=1}^{r'} \mu_i w_i^2 - \left(\sum_{i=1}^{r'} \mu_i w_i \right)^2$$

subject to $\mu_1 + \cdots + \mu_{r'} = 1 - e_{r'+1} - \cdots - e_r$, and $e_i \leqq \mu_i \leqq f_i$, $1 \leqq i \leqq r'$. A suitable reassignment of indices allows this reformulation to apply when $e_i = f_i$ for any i.

LEMMA 2. *$\Psi(\lambda)$ is continuous, piecewise differentiable, and strictly concave for λ in the interval $(\underline{\lambda}, \bar{\lambda})$.*

Proof. That $\Phi(\lambda)$ is a piecewise-linear, continuous, concave function of λ is a standard result in the theory of linear programming [4, p. 288]. The lemma now follows because $-\lambda^2$ is continuous, differentiable, and strictly concave. □

The next result is an immediate corollary of Lemma 2.

COROLLARY 2.1. *The quantity $\hat{\lambda} \in (\underline{\lambda}, \bar{\lambda})$ is optimal for* (PW) *if and only if*

$$\lim_{\lambda \uparrow \hat{\lambda}} \Psi'(\lambda) \geqq 0 \quad \text{and} \quad \lim_{\lambda \downarrow \hat{\lambda}} \Psi'(\lambda) \leqq 0;$$

$\underline{\lambda}$ is optimal for (PW) *if and only if* $\lim_{\lambda \downarrow \underline{\lambda}} \Psi'(\lambda) \leqq 0$; *$\bar{\lambda}$ is optimal for* (PW) *if and only if* $\lim_{\lambda \uparrow \bar{\lambda}} \Psi'(\lambda) \geqq 0$; *furthermore,* (PW) *has a unique optimal solution.*

Assume that λ initially takes the value λ^0 and suppose we have found (by the simplex algorithm or any other method) $\boldsymbol{\mu}^0 = (\mu_1^0, \cdots, \mu_r^0)$, an optimal basic solution to (LPW(λ^0)). Appendix A discusses the choice of a starting value for λ. Suppose the basic variables are μ_i and μ_j with $i < j$. Then the basis matrix is

$$\mathbf{B} = \begin{pmatrix} 1 & 1 \\ w_i & w_j \end{pmatrix}, \quad \text{with inverse } \mathbf{B}^{-1} = \frac{1}{w_i - w_j} \begin{pmatrix} -w_j & 1 \\ w_i & -1 \end{pmatrix}.$$

The usual linear programming optimality conditions now reduce to

$$-(w_k - w_i)(w_k - w_j) \begin{cases} >0 & \text{i.e., } i < k < j \Rightarrow \mu_k^0 = e_k, \\ <0 & \text{i.e., } k < i \quad \text{or} \quad k > j \Rightarrow \mu_k^0 = f_k. \end{cases}$$

In addition, we have

$$\begin{pmatrix} e_i \\ e_j \end{pmatrix} \leqq \begin{pmatrix} \mu_i^0 \\ \mu_j^0 \end{pmatrix} \leqq \begin{pmatrix} f_i \\ f_j \end{pmatrix}.$$

Let $\theta = w_i - w_j > 0$. Then

$$\frac{d\mu_i}{d\lambda} = \frac{1}{\theta}, \quad \frac{d\mu_j}{d\lambda} = -\frac{1}{\theta}, \quad \frac{d\Phi(\lambda)}{d\lambda} = w_i + w_j, \quad \text{and} \quad \frac{d\Psi(\lambda)}{d\lambda} = w_i + w_j - 2\lambda,$$

for all $\lambda \in [\lambda_L, \lambda_U]$, where

$$(5) \qquad \lambda_L = \lambda^0 - \theta \min(f_j - \mu_j^0, \mu_i^0 - e_i) \quad \text{and} \quad \lambda_U = \lambda^0 + \theta \min(f_i - \mu_i^0, \mu_j^0 - e_j).$$

The derivatives given above are to be interpreted as two-sided for $\lambda \in (\lambda_L, \lambda_U)$, but as one-sided derivatives to the right at $\lambda = \lambda_L$ and to the left at $\lambda = \lambda_U$.

The following algorithm solves (PW):

ALGORITHM 1.

1. If $((w_i + w_j)/2 \in [\lambda_L, \lambda_U]$, then the optimal solution to (LPW($(w_i + w_j)/2$)) is optimal in (PW). If $((w_i + w_j)/2) - \lambda_L < 0$, go to Step 2. If $((w_i + w_j)/2) - \lambda_U > 0$, go to Step 3.
2. If $\lambda_L = \underline{\lambda}$, then the optimal solution to (LPW($\underline{\lambda}$)) is optimal in (PW). If $\lambda_L > \underline{\lambda}$, then let $\lambda^0 = \lambda_L - \varepsilon$ (where ε is a positive infinitesimal). Use standard linear programming sensitivity analysis techniques to solve the new (LPW(λ^0)), to determine the new indices i and j, and to determine the new $[\lambda_L, \lambda_U]$. (Note that the new λ_U equals the old λ_L.) If $((w_i + w_j)/2) - \lambda_U \geqq 0$, then the optimal solution to (LPW(λ_U)) is optimal in (PW). Otherwise, go to Step 1.
3. If $\lambda_U = \bar{\lambda}$, then the optimal solution to (LPW($\bar{\lambda}$)) is optimal in (PW). If $\lambda_U < \bar{\lambda}$, then let $\lambda^0 = \lambda_U + \varepsilon$ (where ε is a positive infinitesimal). Use standard linear

programming sensitivity analysis techniques to solve the new (LPW(λ^0)), to determine the new indices i and j, and to determine the new $[\lambda_L, \lambda_U]$. (Note that the new λ_L equals the old λ_U.) If $((w_i+w_j)/2)-\lambda_L \leqq 0$, then the optimal solution to (LPW(λ_L)) is optimal in (PW). Otherwise, go to Step 1.

Finiteness of the algorithm follows from the fact that the sequence of the λ^0 values is monotone increasing if the initial λ^0 is too small and monotone decreasing if the initial λ^0 is too large. Hence, no pair (i, j) ever repeats. Optimality of the claimed solution to (PW) follows from Corollary 2.1 to Lemma 2. Given the structure of (LPW(λ)), the linear programming sensitivity analysis techniques can be specialized so that this algorithm can be implemented with $O(r)$ time complexity. Algorithmic details and the proof of this complexity result are given in Appendix A.

1.2. Determining $h_*(\mathbf{w})$. Let (LPB(λ)) be the linear program to determine

$$\phi(\lambda) = \min \sum_{j=1}^{r} \mu_j w_j^2$$

subject to the same constraints as (LPW(λ)), and let $\varphi(\lambda) = \phi(\lambda) - \lambda^2$. Then (NLPB) has the equivalent representation

$$\text{(PB)} \qquad h_*(\mathbf{w}) = \min_{\underline{\lambda} \leqq \lambda \leqq \bar{\lambda}} \varphi(\lambda).$$

Analogous to the results of § 1.1, if $\boldsymbol{\mu}^0$ is an optimal basic solution to (LPB(λ^0)), with basic variables μ_i and μ_j with $i<j$, it follows that

$$i<k<j \Rightarrow \mu_k^0 = f_k, \quad k<i \quad \text{or} \quad k>j \Rightarrow \mu_k^0 = e_k,$$

and

$$\begin{pmatrix} e_i \\ e_j \end{pmatrix} \leqq \begin{pmatrix} \mu_i^0 \\ \mu_j^0 \end{pmatrix} \leqq \begin{pmatrix} f_i \\ f_j \end{pmatrix}.$$

Again, let $\theta = w_i - w_j$ and determine λ_L and λ_U by (5). As before, $d\phi(\lambda)/d\lambda = w_i + w_j$ for $\lambda \in (\lambda_L, \lambda_U)$.

LEMMA 3. *Let* **B** *be an optimal basis matrix for* (LPB(λ^0)). *Then* $\varphi(\lambda)$ *is continuous and strictly concave for* λ *in the interval* $[\lambda_L, \lambda_U]$.

Proof. $\phi(\lambda)$ is linear on $[\lambda_L, \lambda_U]$ (see [4, p. 288]) and $-\lambda^2$ is continuous and strictly concave. □

COROLLARY 3.1. *If* $\hat{\lambda}$ *is optimal in* (PB), *then either* $\hat{\lambda} = \bar{\lambda}$, *or else* $\hat{\lambda} = \lambda_L$ *for some basis matrix* **B** *which is optimal in* (LPB($\hat{\lambda}$)).

Proof. This is immediate from Lemma 3 because of the concavity of $\varphi(\lambda)$. □

COROLLARY 3.2. (NLPB) *has an optimal solution in which at most one of the components of* $\boldsymbol{\mu}$ *lies strictly between its lower and upper bounds.*

Proof. This follows immediately from Corollary 3.1 and the theory of linear programming, since one of the basic variables is zero at the endpoint λ_L. □

The following algorithm solves (PB).

ALGORITHM 2.

1. Set $\lambda^0 = \bar{\lambda}$. Let $\boldsymbol{\mu}_B$ solve (LPB($\bar{\lambda}$)). Set $\lambda_B = \bar{\lambda}$ and $\varphi_B = \phi(\bar{\lambda}) - \bar{\lambda}^2$.
2. If $\phi(\lambda_U) - (w_i + w_j)(\lambda_U - \lambda_L) - \lambda_L^2 \geqq \varphi_B$, go to Step 3.
   Otherwise, set $\lambda_B = \lambda_L$, $\varphi_B = \phi(\lambda_U) - (w_i + w_j)(\lambda_U - \lambda_L) - \lambda_L^2$, let $\boldsymbol{\mu}_B$ solve (LPB(λ_L)), and go to Step 3.
3. If $\lambda_L = \underline{\lambda}$, stop: $\boldsymbol{\mu}_B$ is the optimal solution to (PB).
   Otherwise, let $\lambda^0 = \lambda_L - \varepsilon$ (where ε is a positive infinitesimal). Use standard linear programming sensitivity analysis techniques to solve the new (LPB(λ^0)),

to determine the new indices i and j, and to determine the new $[\lambda_L, \lambda_U]$. Go to Step 2.

Finiteness of the algorithm follows from the fact that the sequence of λ^0 values is monotone decreasing. Hence no pair (i, j) ever repeats. Optimality of the claimed solution to (PB) follows from Corollary 3.1 to Lemma 3. Given the structure of (LPB(λ)), the linear programming sensitivity analysis techniques can again be specialized so that this algorithm, too, can be implemented with $O(r)$ time complexity. Algorithmic details and the proof of their complexity result are given in Appendix B.

2. Example. We illustrate this method of determining lower and upper bounds on $h(\boldsymbol{\mu}, \mathbf{w})$ for the estimation of the all-points-connectedness reliability in network analysis. Let $G = (\mathscr{V}, \mathscr{E})$ denote an undirected network with node set $\mathscr{V}$ and arc set $\mathscr{E}$. Suppose that nodes operate perfectly but arcs fail randomly and independently, each with probability $1-p$. Let $m(p)$ denote the probability that all nodes in G are connected. The exact evaluation of $m(p)$ is known to belong to the $\#P$-complete class of problems, implying that no algorithm is known for solving this problem in time polynomial in $|\mathscr{V}|$ and $|\mathscr{E}|$. This limitation has encouraged analysts to apply the Monte Carlo method to the estimation of $m(p)$. In particular, Nel and Colbourn [5] recommend a Monte Carlo approach based on a partition of the set of all spanning trees of G due to Ball and Nemhauser [1], who show that one can represent the probability that all nodes are connected in the form

$$m(p) = p^{k-1} \sum_{i=0}^{l-k+1} H_i (1-p)^i, \tag{6}$$

where

$$H_i = |\mathscr{H}_i|, \qquad 0 \leqq i \leqq l-k+1,$$

$k = |\mathscr{V}|$, $l = |\mathscr{E}|$, and $\{\mathscr{H}_0, \mathscr{H}_1, \cdots, \mathscr{H}_{l-k+1}\}$ denotes a particular partition of the set of all spanning trees of G. A spanning tree is a set of $k-1$ arcs that connects all nodes. Using this formulation on each of n independent replications, Nel and Colbourn [5] randomly generate a spanning tree and determine the partition to which it belongs. They then demonstrate how to employ one version of the Ball and Provan [2] bounds together with these sample data to derive point estimates and confidence intervals for $\{H_i\}$ and for $m(p)$ for a range of values of the component reliability p. They illustrate their technique for the Advanced Research Projects Agency Network (ARPANET) in Fig. 1 with $k = 20$ nodes and $l = 32$ arcs. Our example consists of finding best-case and worst-case bounds for the variance of the point estimate for this network.

To place this problem in the context of this paper, let

$$x_i = \begin{cases} 1 & \text{if arc } i \text{ operates,} \\ 0 & \text{otherwise,} \quad 1 \leqq i \leqq l, \end{cases}$$

$$\mathbf{x} = (x_1, \cdots, x_l),$$

$$\mathscr{X} = \{0, 1\}^l = \text{set to which all } \mathbf{x} \text{ belong.}$$

Then

$$\mathscr{X}^* = \{\mathbf{x} \in \mathscr{X} \colon x_1 + \cdots + x_l = k-1 \text{ and all nodes are connected}\}$$

denotes the set of all spanning trees of G with size $\tau = |\mathscr{X}^*|$, and $\mathscr{H}_0, \mathscr{H}_1, \cdots, \mathscr{H}_{l-k+1}$

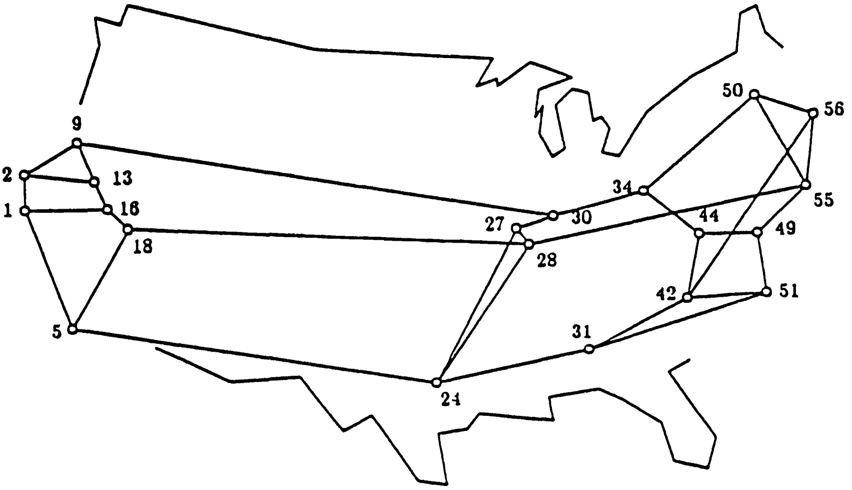

FIG. 1. *Skeleton of the* 1979 ARPANET.

is the partition of $\mathscr{X}^*$ of interest with

$$\phi_i(\mathbf{x}) = \begin{cases} 1, & \text{if } \mathbf{x} \in \mathscr{H}_i \\ 0, & \text{otherwise,} \end{cases}$$

$$w_i = p^{k-1}(1-p)^i,$$

and

$$\mu_i = H_i/\tau, \qquad i = 0, 1, \cdots, r = l - k + 1.$$

Suppose that we randomly draw $\mathbf{X}$ from $\mathscr{X}^*$. Then

$$Z = \tau[\phi_0(\mathbf{X})w_0 + \phi_1(\mathbf{X})w_1 + \cdots + \phi_r(\mathbf{X})w_r]$$

is an unbiased estimator of $m(p)$ in (6) with variance $\tau^2 h(\boldsymbol{\mu}, \mathbf{w})$ in (3). This is the essence of the Nel and Colbourn [5] approach.

Table 1 gives lower and upper bounds for $\{H_i\}$ based on the Ball-Provan method [2]. Note that these differ from the bounds given in [5] which are used to derive lower and upper bounds on $m(p)$, but not on each H_i. Since the lower and upper bounds are identical for H_i, $0 \leqq i \leqq 3$, there is no need to estimate these quantities. Accordingly, the worst-case variance is $\tau^2 h^*(\mathbf{w})$, where

$$h^*(\mathbf{w}) = \max_{\boldsymbol{\mu}} \left[\sum_{i=4}^{13} \mu_i w_i^2 - \left(\sum_{i=4}^{13} \mu_i w_i \right)^2 \right], \tag{7}$$

subject to

$$\mu_4 + \cdots + \mu_{13} = 1 - (H_0 + H_1 + H_2 + H_3)/\tau = \rho,$$

$$e_i \leqq \mu_i \leqq f_i, \qquad 4 \leqq i \leqq 13.$$

The suggested algorithm of § 1 and Appendix A continues to apply with α, defined in (A2), replaced everywhere in Appendix A by $\alpha^* = \alpha - 1 + \rho$. Table 1 also lists the lower and upper bounds for $\{\mu_i\}$.

Table 2 lists the resulting best-case and worst-case variance bounds apart from the factor τ^2. Observe that $3.90 \leqq h^*(\mathbf{w})/h_*(\mathbf{w}) \leqq 5.78$ for all values of p of interest. Also, the ratios $h^{**}(\mathbf{w})/h^*(\mathbf{w})$ make clear the benefit of solving (NLPW), suggesting that any worst-case sample size based on $\tau^2 h^{**}(\mathbf{w})$ would be at least 82.5 times greater than one based on $\tau^2 h^*(\mathbf{w})$.

Notes:

1. $h^{**}(\mathbf{w}) = (\max_{4\leq i\leq 13} w_i - \min_{4\leq i\leq 13} w_i)^2/4$.

2. Variables with indices between i and j are set to their lower bounds; those with indices below i or above j are set to their upper bounds.

3. In all cases, the value of $\mu_j(=\mu_{12})$ is strictly between e_{12} and f_{12}. At $p = .66$, $\mu_i(=\mu_8)$ is strictly between e_8 and f_8; for all other cases, μ_i is at its upper bound f_i.

Note that the trivial worst-case bound $h^{**}(\mathbf{w})$ is evaluated after deleting the μ_i's for which $e_i = f_i$ in Table 1. Had this not been done, the resulting $h^{**}(\mathbf{w})$ would have been considerably greater in magnitude. The entry at $p = .66$ demonstrates a case at which two interior point assignments are made. For the true $\boldsymbol{\mu}$, $1.03 \leqq h^{*}(\mathbf{w})/\mathrm{h}(\boldsymbol{\mu}, \mathbf{w}) \leqq 1.28$ for all $p \in \{.5 + .01(i-1), 1 \leqq i \leqq 50\}$, revealing that, in this particular example, the bound is remarkably tight in spite of the fact that the individual bounds in Table 1 are not particularly tight. This observation strengthens the argument for computing the bound before sampling begins.

The results in Table 2 also show a limitation of this approach for estimating $m(p)$. Observe that the worst-case variance $\tau^2 h^*(\mathbf{w})$ exceeds unity for $p = .66$, .70, .80, .90, .92, and .94. In retrospect, this is not surprising when we rewrite (6) in the form

$$m(p) = \tau p^{k-1} \sum_{i=0}^{l-k+1} (H_i/\tau)(1-p)^i,$$

and recognize that observations on each trial of the experiment range over $[\tau p^{k-1}(1-p)^{l-k+1}, \tau p^{k-1}]$, which widens with increasing p. This suggests that an alternative approach based on generating random subgraphs and checking for connectedness may be a more efficient approach since the variance of each observation there never exceeds one-fourth. An adaptation of the Monte Carlo proposal in [3] to the all-points-connectedness problem would do just that.

Appendix A. Algorithmic details and complexity for worst-case variances.

A.1. Preliminaries. Let $\lambda \in [\underline{\lambda}, \bar{\lambda}]$ be given and let μ_i and μ_j with $i < j$ be optimal basic variables in (LPW(λ)). Let

$$\theta = w_i - w_j > 0, \tag{A1}$$

$$\alpha = 1 - \sum_{k=1}^{i-1} f_k - \sum_{k=i+1}^{j-1} e_k - \sum_{k=j+1}^{r} f_k, \tag{A2}$$

$$\beta = \sum_{k=1}^{i-1} w_k f_k + \sum_{k=i+1}^{j-1} w_k e_k + \sum_{k=j+1}^{r} w_k f_k. \tag{A3}$$

Then the optimal simplex tableau for (LPW(λ)) is given schematically in Table 3.

For the nonbasic columns, this schematic tableau only indicates the signs of the entries; their exact values are given by the formulas in the "Typical entry" column.

This tableau is optimal as long as λ satisfies

$$\begin{pmatrix} e_i \\ e_j \end{pmatrix} \leqq \frac{1}{\theta} \begin{pmatrix} -\alpha w_j - \beta + \lambda \\ \alpha w_i + \beta - \lambda \end{pmatrix} \leqq \begin{pmatrix} f_i \\ f_j \end{pmatrix},$$

that is, as long as $\lambda \in [\lambda_L, \lambda_U]$, where

$$\lambda_L = \max\{\lambda_{Li} = \theta e_i + \alpha w_j + \beta,\ \lambda_{Lj} = -\theta f_j + \alpha w_i + \beta\},$$

$$\lambda_U = \min\{\lambda_{Ui} = \theta f_i + \alpha w_j + \beta,\ \lambda_{Uj} = -\theta e_j + \alpha w_i + \beta\}.$$

TABLE 3

	Nonbasic at f	Basic	Nonbasic at e	Basic	Nonbasic at f	
	$\mu_1 \cdots \mu_{i-1}$	μ_i	$\mu_{i+1} \cdots \mu_{j-1}$	μ_j	$\mu_{j+1} \cdots \mu_r$	Typical entry
$z = \Phi(\lambda)$	$- \cdots -$	0	$+ \cdots +$	0	$- \cdots -$	$-(w_k - w_i)(w_k - w_j)$
$\mu_i = (1/\theta)(-\alpha w_j - \beta + \lambda)$	$+ \cdots +$	1	$+ \cdots +$	0	$- \cdots -$	$(w_k - w_j)/(w_i - w_j)$
$\mu_j = (1/\theta)(\alpha w_i + \beta - \lambda)$	$- \cdots -$	0	$+ \cdots +$	1	$+ \cdots +$	$(w_i - w_k)/(w_i - w_j)$

The quantities λ_L and λ_U result from substituting into (5) the values of μ_i^0 and μ_j^0 (with $\lambda = \lambda^0$) given in the tableau above. It is straightforward to verify the following result.

LEMMA A.1. *$\lambda_L = \lambda_{Li} \Leftrightarrow f_j + e_i \geqq \alpha$; $\lambda_L = \lambda_{Lj} \Leftrightarrow f_j + e_i \leqq \alpha$ and $\lambda_U = \lambda_{Ui} \Leftrightarrow f_i + e_j \leqq \alpha$; $\lambda_U = \lambda_{Uj} \Leftrightarrow f_i + e_j \geqq \alpha$.*

A.2. Moving from one basis to another. Suppose that Algorithm 1 has us decreasing λ.

1. If $\lambda_L = \lambda_{Li} \geqq \lambda_{Lj}$, then decreasing λ to λ_L introduces a primal degeneracy in row 1 (because μ_i is driven down to e_i).

(a) If $i \geqq 2$, then pivoting in row 1 and column $i-1$ yields an alternate optimal tableau for $\lambda = \lambda_L$ with μ_{i-1} basic at its upper bound f_{i-1}. Further small decreases in λ decrease μ_{i-1}, but row 1 remains primal feasible (i.e., $\mu_{i-1} > e_{i-1}$) for sufficiently small decreases.

(b) If $i = 1$, then decreasing λ below λ_L introduces a primal infeasibility in row 1 which cannot be removed by any pivot that maintains dual feasibility, i.e., $\lambda_L = \underline{\lambda}$.

2. If $\lambda_L = \lambda_{Lj} > \lambda_{Li}$, then decreasing λ to λ_L introduces a primal degeneracy in row 2 (because μ_j is driven up to f_j).

(a) If $j \geqq i+2$, then pivoting in row 2 and column $j-1$ yields an alternate optimal tableau for $\lambda = \lambda_L$ with μ_{j-1} basic at its lower bound e_{j-1}. Further small decreases in λ increase μ_{j-1}, but row 2 remains primal feasible (i.e., $\mu_{j-1} < f_{j-1}$) for sufficiently small decreases.

(b) If $j = i+1$ and $i \geqq 2$, pivoting in row 2 and column $i-1$ (and switching rows 1 and 2) yields an alternate optimal tableau in which μ_{i-1} is basic at its upper bound f_{i-1}, and the discussion in 1(a) applies to further decreases in λ.

(c) If $j = 2$ and $i = 1$, the discussion in 1(b) applies.

If we are increasing λ, analogous results hold. The result of this discussion leads to the following implementation of steps 2 and 3 of Algorithm 1, for which we need not explicitly compute any simplex tableaus:

2. Since $((w_i + w_j)/2) - \lambda_L < 0$, attempt to decrease λ below λ_L.

A. If $f_j + e_i \geqq \alpha$, and

(a) If $i \geqq 2$, then set

$$i' = i-1, \quad j' = j,$$
$$\alpha' = \alpha - e_i + f_{i-1},$$
$$\beta' = \beta + w_i e_i - w_{i-1} f_{i-1}.$$

(b) If $i = 1$, then $\lambda = \lambda_L = \underline{\lambda}$ is optimal for (PW).

B. If $f_j + e_i < \alpha$, and

(a) If $j \geqq i+2$, then set

$$i' = i, \quad j' = j-1,$$
$$\alpha' = \alpha - f_j + e_{j-1},$$
$$\beta' = \beta + w_j f_j - w_{j-1} e_{j-1}.$$

(b) If $j = i+1 \geqq 3$, then set

$$i' = i-1, \quad j' = j-1,$$
$$\alpha' = \alpha - f_{i+1} + f_{i-1},$$
$$\beta' = \beta + w_{i+1} f_{i+1} - w_{i-1} f_{i-1}.$$

(c) If $i = 1$ and $j = 2$, then $\lambda = \lambda_L = \underline{\lambda}$ is optimal for (PW).

3. Since $((w_i+w_j)/2)-\lambda_U>0$, attempt to increase λ above λ_U.

A. If $f_i+e_j \geqq \alpha$, and

(a) If $j \leqq r-1$, then set

$$i'=i, \quad j'=j+1,$$
$$\alpha'=\alpha-e_j+f_i,$$
$$B'=\beta+w_je_j-w_if_i.$$

(b) If $j=r$, then $\lambda=\lambda_U=\bar{\lambda}$ is optimal for (PW).

B. If $f_i+e_j<\alpha$, and

(a) If $j \geqq i+2$, then set

$$i'=i+1, \quad j'=j,$$
$$\alpha'=\alpha-f_i+e_{i+1},$$
$$\beta'=\beta+w_if_i-w_{i+1}e_{i+1}.$$

(b) If $j=i+1 \leqq r-1$, then set

$$i'=i+1, \quad j'=j+1,$$
$$\alpha'=\alpha-f_i+f_{i+2},$$
$$\beta'=\beta+w_if_i-w_{i+2}f_{i+2}.$$

(c) If $i=r-1$ and $j=r$, then $\lambda=\lambda_U=\bar{\lambda}$ is optimal for (PW).

A.3. Finding an initial basis. Apply the following algorithm.

```
ALGORITHM 3
0. Let $\delta_0=\sum_{k=1}^r e_k<1$. Set $i=0$.
1. (a) If $\delta_i<1$, let $\delta_{i+1}=\delta_i-e_{i+1}+f_{i+1}$. Set $i=i+1$ and return to step 1.
   (b) If $i=r$, then $\mu_{r-1}$ and $\mu_r$ are the initial basic variables.
   (c) If $\delta_i>1$ (and $i<r$), then $\mu_i$ and $\mu_r$ are the initial basic variables.
```

It should be pointed out that this algorithm for getting started is actually calculating the optimal basis for $\lambda=\bar{\lambda}$. Changing step 1(a) to $\delta_{i+1}=\delta_i-e_{r-i}+f_{r-i}$ and making corresponding changes in steps 1(b) and 1(c) calculates the optimal basis for $\lambda=\underline{\lambda}$. Equally simple modifications yield bases for values of λ well into the interior of $(\underline{\lambda}, \bar{\lambda})$.

A.4. Complexity of Algorithm 1. In the analysis, both additions and subtractions are grouped together as additions.

A.4.1. Initial basis (via Algorithm 3), $i, j, \alpha, \beta, \theta, \lambda_L$, and λ_U.

1. δ_0 requires $r-1$ additions.
2. Each repetition of step 1(a) requires one comparison and two additions.
3. Step 1(a) is repeated at most r times; i.e., for $i=0, 1, \cdots, r-1$.
4. Given the basic variables i and r, (A2) reduces to

$$\alpha=\begin{cases} 1-\sum\limits_{k=1}^{r-2} f_k=1-\delta_r+f_{r-1}+f_r & \text{if } i=r-1, \\ 1-\sum\limits_{k=1}^{i-1} f_k-\sum\limits_{k=i+1}^{r-1} e_k=1-\delta_i+f_i+e_r & \text{if } i<r-1. \end{cases}$$

Hence, the computation of α requires three additions. The computation of β, using (A3), requires $r-2$ multiplications and $r-3$ additions, and θ in (A1) requires one addition.

5. Given α, one addition and one comparison are needed to determine if $\lambda_L = \lambda_{Li}$ or $\lambda_L = \lambda_{Lj}$. Once this is known, the computation of λ_L requires two multiplications and two additions. The computation of λ_U is analogous.

6. Hence, finding the initial basis, $i, j, \alpha, \beta, \theta, \lambda_L$, and λ_U, requires at most $4r+6$ additions, $r+2$ multiplications, and $r+2$ comparisons.

A.4.2. Typical iteration.

1. Checking the current basis for optimality:
(a) For each basis, determining if $((w_i + w_j)/2) \in (\lambda_L, \lambda_U)$ requires one addition, one multiplication and two comparisons.
(b) For each basis after the first, determining if λ_L or λ_U is optimal requires an additional comparison.

2. Computing $i', j', \alpha', \beta', \theta', \lambda'_L$, and λ'_U if the current basis is not optimal:
(a) Each of i' and j' requires at most one addition.
(b) α' requires two additions.
(c) β' requires two multiplications and two additions.
(d) θ' requires one addition.
(e) Either $\lambda'_L = \lambda_U$ or $\lambda'_U = \lambda_L$. To compute the other member of $\{\lambda'_L, \lambda'_U\}$ requires three additions, two multiplications, and one comparison.

3. Hence, each iteration requires at most eleven additions, five multiplications, and four comparisons.

A.4.3. Number of iterations. Since the successive values of λ considered by the algorithm are either monotonically increasing or else monotonically decreasing, the successive values of i and j are similarly either monotonically nondecreasing or else monotonically nonincreasing (although at each iteration at least one of i or j will change). Hence the number of iterations is at most $2r-4$ (which occurs if initially $i=1$ and $j=2$, but the optimal basis has $i=r-1$ and $j=r$, or vice versa).

A.4.4. Finding the optimal solution, given $i, j, \alpha, \beta, \theta$, and λ. From Table 3, we see that the computation of μ_i and μ_j requires four multiplications and four additions.

A.4.5. Overall complexity.

	Additions	Multiplications	Comparisons
Initial basis	$4r+6$	$r+2$	$r+2$
Successive iterations	$11(2r-4)$	$5(2r-4)$	$4(2r-4)$
Optimal solution	4	4	0
Total	$26r-34$	$11r-14$	$9r-14$

Appendix B. Algorithmic details and complexity for best-case variances.

B.1. Preliminaries. The results from § A1 hold verbatim, with the exceptions that now the optimal solution has $\mu_1, \cdots, \mu_{i-1}$ nonbasic at their lower bounds, $\mu_{i+1}, \cdots, \mu_{j-1}$ nonbasic at their upper bounds, and $\mu_{j+1}, \cdots, \mu_r$ nonbasic at their lower bounds. In addition, we redefine

$$\alpha = 1 - \sum_{k=1}^{i-1} e_k - \sum_{k=i+1}^{j-1} f_k - \sum_{k=j+1}^{r} e_k, \tag{B1}$$

$$\beta = \sum_{k=1}^{i-1} w_k e_k + \sum_{k=i+1}^{j-1} w_k f_k + \sum_{k=j+1}^{r} w_k e_k. \tag{B2}$$

B.2. Moving from one basis to another. Recall that Algorithm 2 has us decreasing λ from $\bar{\lambda}$ to $\underline{\lambda}$.

1. If $\lambda_L = \lambda_{Lj} \geqq \lambda_{Li}$, then decreasing λ to λ_L introduces a primal degeneracy in row 2 (because μ_j is driven up to f_j).

   (a) If $j \leqq r-1$, then pivoting in row 2 and column $j+1$ yields an alternate optimal tableau for $\lambda = \lambda_L$ with μ_{j+1} basic at its lower bound e_{j+1}. Further small decreases in λ increase μ_{j+1}, but row 2 remains primal feasible (i.e., $\mu_{j+1} < f_{j+1}$) for sufficiently small decreases.

   (b) If $j = r$, then decreasing λ below λ_L introduces a primal infeasibility in row 2, which cannot be removed by any pivot that maintains dual feasibility, i.e., $\lambda_L = \underline{\lambda}$.

2. If $\lambda_L = \lambda_{Li} > \lambda_{Lj}$, then decreasing λ to λ_L introduces a primal degeneracy in row 1 (because μ_i is driven down to e_i).

   (a) If $i \leqq j-2$, then pivoting in row 1 and column $i+1$ yields an alternate optimal tableau for $\lambda = \lambda_L$ with μ_{i+1} basic at its upper bound f_{i+1}. Further small decreases in λ decrease μ_{i+1}, but row 1 remains primal feasible (i.e., $\mu_{i+1} > e_{i+1}$) for sufficiently small decreases.

   (b) If $i = j-1$ and $j \leqq r-1$, pivoting in row i and column $j+1$ (and switching rows 1 and 2) yields an alternate optimal tableau in which μ_{j+1} is basic at its lower bound e_{j+1}, and the discussion in 1(a) applies to further decreases in λ.

   (c) If $i = r-1$ and $j = r$, the discussion in 1(b) applies.

The preceding discussion leads to the following implementation of step 3 of Algorithm 2. Again, no simplex tableau is ever explicitly computed.

3A. If $f_j + e_i \leqq \alpha$ and

(a) If $j \leqq r-1$, then set

$$i' = i, \qquad j' = j+1,$$
$$\alpha' = \alpha - f_j + e_{j+1},$$
$$\beta' = \beta + w_j f_j - w_{j+1} e_{j+1}.$$

(b) If $j = r$, then $\lambda_L = \underline{\lambda}$, and $\boldsymbol{\mu}_B$ is optimal in (PB).

B. If $f_j + e_i > \alpha$, and

(a) If $i \leqq j-2$, then set

$$i' = i+1, \qquad j' = j,$$
$$\alpha' = \alpha - e_i + f_{i+1},$$
$$\beta' = \beta + w_i e_i - w_{i+1} f_{i+1}.$$

(b) If $i = j-1 \leqq r-2$, then set

$$i' = i+1, \qquad j' = j+1,$$
$$\alpha' = \alpha - e_{j-1} + e_{j+1},$$
$$\beta' = \beta + w_{j-1} e_{j-1} - w_{j+1} e_{j+1}.$$

(c) If $i = r-1$ and $j = r$, then $\lambda_L = \underline{\lambda}$ and $\boldsymbol{\mu}_B$ is optimal in (PB).

B.3. Finding an initial basis. Step 1 of Algorithm 3 is modified as follows:
1. (b) If $i=r$, then μ_1 and μ_r are the initial basic variables.
(c) If $\delta_i > 1$ (and $i < r$), then μ_1 and μ_i are the initial basic variables.

B.4. Complexity of Algorithm 2. This algorithm is essentially identical to Algorithm 1 except that

(i) We do not check the current basis for optimality, thereby saving one addition, one multiplication, and three comparisons.

(ii) At each basis, we compute

$$\varphi(\lambda_L) = \phi(\lambda_U) - (w_i + w_j)(\lambda_U - \lambda_L) - \lambda_L^2$$

and compare it to φ_B, thereby doing four additions, two multiplications, and one comparison.

(iii) For each basis with $\varphi(\lambda_L) < \varphi_B$, it takes four multiplications and four additions to compute $\boldsymbol{\mu}_B$ from the tableau with $\lambda = \lambda_L$.

Since these differences change the number of operations at each basis by a constant, and since there are at most $2r-4$ bases to consider, the overall time complexity of this algorithm is also $O(r)$, as claimed.

Acknowledgments. We are grateful to Professor Scott Provan for his advice on computing the Ball-Provan bounds and to Stephen Yarberry and Ben Hao Wang for their programming assistance.

STABILITY AND INSTABILITY IN THE COMPUTATION OF FLOWS WITH MOVING IMMERSED BOUNDARIES: A COMPARISON OF THREE METHODS*

CHENG TU†‡ AND CHARLES S. PESKIN†

Abstract. This paper describes thee different numerical methods for the computation of flows with moving immersed elastic boundaries. A two-dimensional incompressible fluid and a boundary in the form of a simple closed curve are considered. The inertia is assumed to be negligible and the Stokes equations are solved. The three methods are explicit, approximate-implicit, and implicit. The first two have been used before, but the implicit method is new in the context of flows with moving immersed boundaries. They differ only with respect to the computation of the boundary force. The results of the above methods at various values of the time-step size are compared in order to explore the numerical stability of the computation.

Key words. stability, computational fluid dynamics, immersed boundaries, Stokes flow

AMS(MOS) subject classifications. 65C20, 65N99, 76Z99

1. Introduction. The purpose of this paper is to present a new method for the study of flows with immersed elastic boundaries and to compare its stability with two other existing methods [10], [11]. The essential features of these methods are: (1) that the fluid computation is done on a fixed, regular computational lattice, (2) that the (Lagrangian) representation of the immersed boundary is independent of this lattice and involves a collection of moving material points, (3) that the immersed boundary acts on the fluid by means of a system of forces computed from the elastic stresses in the immersed boundary and applied to the nearby lattice points of the fluid with the help of a computational model of the Dirac δ-function, and (4) that the representative material points of the immersed boundary move at the local fluid velocity, which is obtained by interpolation from the nearby lattice points of the fluid. The same δ-function weights are used in the interpolation step as in the application of the boundary forces to the fluid. Methods of this general type have now been applied to blood flow in the heart [5], [6], [7], [9]; aquatic animal locomotion [1]; platelet aggregation during blood clotting [2]; and flows with suspended particles [3]. Much of the recent work in this area has been concerned with the supercomputer implementation of such methods in the three-dimensional case [4], [8], [12].

In all of the applications cited above, there has been a serious issue of numerical stability. Explicit computation of the boundary forces (i.e., the computation of these forces from the boundary configuration at the beginning of each time step) has typically led to explosively unstable results when computations with reasonable time steps have been tried.

The practical cure for this problem, first introduced in [10], has been to compute the boundary forces from an *estimate* of the boundary configuration at the end of the

time step. For this to work, it is essential that the above-mentioned estimate take into account the influence of the (unknown) boundary forces themselves on the (unknown) boundary configuration at the end of the time step. Until now, the estimate that has been used for the boundary configuration at the end of the time step is based on the assumption that the force applied to the fluid by each boundary point acts exclusively on that point and not on any of the others. (This assumption is only made in the computation of the boundary forces. Once those forces are computed, they are applied to the fluid, and each element of force acts instantaneously everywhere, since the fluid is incompressible.)

In this paper, we compare three methods which differ only with regard to the computation of the boundary force. The three methods are:

(1) Explicit: boundary force computed from the boundary configuration at the *beginning* of the time step.

(2) Approximate-implicit: boundary force computed from an *estimate* of the configuration at the *end* of the time step.

(3) Implicit: boundary force computed from the configuration at the *end* of the time step.

Note that method (1) is essentially the forward-Euler method, while method (3), the principal subject of this paper, is essentially the backward-Euler method. Method (2), the one that has been used in practice, represents a compromise in which one hopes to achieve the good stability properties of the backward-Euler method at a smaller computational cost. In method (1), the boundary forces are obtained by evaluation of a definite formula; there are no equations to solve. In method (2), one must solve a nonlinear fixed-point problem for a self-consistent set of boundary forces and (estimated) final boundary configuration. Because only an estimate of the final boundary configuration is used, however, this nonlinear system may be formulated on the boundary itself, without reference to the fluid. Thus, method (2) leads to sparse systems of equations, since each boundary point is coupled only to its neighbors. In method (3), by contrast, the nonlinear fixed-point problem for the boundary forces involves the fluid-mediated interaction of each boundary point with every other boundary point. This leads to dense systems of equations which are much more expensive to solve.

The model problem that is used as a vehicle for the comparison of the three methods is as follows. We consider a two-dimensional incompressible fluid containing an immersed elastic boundary in the form of a simple closed curve. We assume that inertia is everywhere negligible, and so we use the Stokes equations, in which time enters in only as a parameter. Initially, the boundary is in the form of an ellipse, and it relaxes to a circular configuration. Area should be preserved during this transformation, since the fluid is incompressible. We compare the three methods for this problem at various values of the time-step parameter.

2. Assumptions and equations. We consider a two-dimensional viscous incompressible fluid containing an immersed elastic boundary. We assume that effects of inertia are negligible both for the fluid and for the immersed boundary. The boundary is in the form of a simple closed curve. Note that both the fluid inside and the fluid outside the immersed boundary curve are physically significant in the problem and influence the motion of the boundary. Although one might like the external region to extend to infinity, we put the entire problem in a periodic box. This keeps the domain finite while retaining the feature of translation invariance that the unbounded problem would have.

On the basis of the above assumptions, we can write the equations of motion that are valid for both the fluid and the immersed boundary as the Stokes equations

$$0 = -\nabla p + \eta \Delta \mathbf{u} + \mathbf{F}(\mathbf{x}, t), \tag{2.1}$$

$$0 = \nabla \cdot \mathbf{u}, \tag{2.2}$$

where $\mathbf{u}$ is the fluid velocity, p is the fluid pressure, η is the constant fluid viscosity, and $\mathbf{F}$ is the force density, which differs from zero only on the immersed boundary and which is infinite there; see below.

In order to calculate the force density $\mathbf{F}$ which arises from the elastic stress in the immersed boundary, we need to specify the material points of the boundary. Thus, we need a Lagrangian description of the boundary. Let $\mathbf{x} = \mathbf{X}(s, t)$ be the position of the material point whose label is s at time t. The parameter s indicates the unstressed length along the immersed boundary from some reference point denoted by $s = 0$. Let T be the tension in the immersed boundary. We assume that T obeys a possibly nonlinear generalization of Hooke's law

$$T = \sigma\left(\left|\frac{\partial \mathbf{X}}{\partial s}\right|\right); \tag{2.3}$$

then it can be verified [12] that the local density (with respect to the measure ds) of force applied by the boundary to the fluid is

$$\mathbf{f} = \frac{\partial}{\partial s}(T\boldsymbol{\tau}), \tag{2.4}$$

where $\boldsymbol{\tau}$ is the unit tangent to the boundary

$$\boldsymbol{\tau} = \frac{\partial \mathbf{X}}{\partial s}\bigg/\left|\frac{\partial \mathbf{X}}{\partial s}\right|. \tag{2.5}$$

To connect the boundary with the fluid we need to relate $\mathbf{F}$ and $\mathbf{f}$. Following [11], we can establish this correspondence using a Dirac δ-function:

$$\mathbf{F}(\mathbf{x}, t) = \int_0^{L_b} \mathbf{f}(s, t)\delta(\mathbf{x} - \mathbf{X}(s, t))\, ds, \tag{2.6}$$

where the integral is over the entire boundary and δ is a two-dimensional δ-function $\delta(\mathbf{x}) = \delta(x_1)\delta(x_2)$ where $\mathbf{x} = (x_1, x_2)$. The final assumption is that the fluid adheres to the boundary. Thus, we impose the no-slip condition

$$\frac{\partial \mathbf{X}}{\partial t}(s, t) = \mathbf{u}(\mathbf{X}(s, t), t). \tag{2.7}$$

Note that this plays the role of an equation of motion for the boundary and not the more standard role of a constraint on the fluid motion, since the boundary motion is unknown. We remark that $\mathbf{u}$ in (2.7) can be expressed in a form similar to (2.6) by using the definition of the δ-function

$$\mathbf{u}(\mathbf{X}(s, t), t) = \int_\Omega \mathbf{u}(\mathbf{x}, t)\delta(\mathbf{x} - \mathbf{X}(s, t))\, d\mathbf{x}. \tag{2.8}$$

We can summarize the equations of motion as follows: (2.1) and (2.2) are the Stokes equations of a viscous incompressible fluid with viscosity η. Equations (2.3)–(2.5) are elastic boundary equations enabling us to compute the boundary force density. Equations (2.6)–(2.8) are the connecting equations, which give the interaction between the boundary and the fluid.

3. Dimensionless form of the equations. It is useful to write these equations in terms of dimensionless variables. In this way once the solution for a particular flow with a particular immersed elastic boundary is known, we can obtain the solutions that are dynamically similar.

First, let us consider the equations describing the motion of the fluid. We arbitrarily choose a constant time t_0 (which will be specified at the end of this section) and a constant length L, which is the length of the regular square box on which the Stokes equations are solved. We then make the following change of variables:

$$t' = \frac{t}{t_0}, \quad \mathbf{x}' = \frac{\mathbf{x}}{L}, \quad \mathbf{u}' = \frac{\mathbf{u}t_0}{L}, \quad p' = \frac{pt_0}{\eta}, \qquad \mathbf{F}' = \frac{\mathbf{F}Lt_0}{\eta}.$$

Note that the variables denoted with the superscript $'$ are dimensionless for a two-dimensional fluid. Using these new variables we also have

$$\nabla = \frac{1}{L}\nabla', \qquad \Delta = \frac{1}{L^2}\Delta'.$$

Substituting the above into the fluid equations in the previous section gives

$$0 = -\nabla' p' + \Delta' \mathbf{u}' + \mathbf{F}', \tag{3.1}$$

$$0 = \nabla' \cdot \mathbf{u}'. \tag{3.2}$$

Next, we consider the equations for the elastic boundary. The particular choice of the function σ in this paper is

$$\sigma\left(\left|\frac{\partial \mathbf{X}}{\partial s}\right|\right) = \begin{cases} S_b\left(\left|\frac{\partial \mathbf{X}}{\partial s}\right| - 1\right), & \left|\frac{\partial \mathbf{X}}{\partial s}\right| \geqq 1, \\ 0, & \text{otherwise,} \end{cases}$$

where S_b is the stiffness of the elastic boundary. We make the following changes of variables:

$$\mathbf{X}' = \frac{\mathbf{X}}{L}, \quad s' = \frac{s}{L}, \quad T' = \frac{T}{S_b},$$

$$\sigma' = \frac{\sigma}{S_b}, \quad \boldsymbol{\tau}' = \boldsymbol{\tau}, \quad \mathbf{f}' = \frac{\mathbf{f}L}{S_b}.$$

Then (2.3)-(2.5) become

$$T' = \left(\left|\frac{\partial \mathbf{X}'}{\partial s'}\right| - 1\right), \tag{3.3}$$

$$\mathbf{f}' = \frac{\partial}{\partial s'}(T'\boldsymbol{\tau}'), \tag{3.4}$$

$$\boldsymbol{\tau}' = \frac{\partial \mathbf{X}'}{\partial s'} \bigg/ \left|\frac{\partial \mathbf{X}'}{\partial s'}\right|. \tag{3.5}$$

Finally, we consider the equations that describe the interaction of the boundary and the fluid. From the properties of the δ-function, we know that $\delta(Lx') = (1/L)\delta(x')$. Thus $\delta(\mathbf{x}) = (1/L^2)\delta(\mathbf{x}')$ for the two-dimensional δ-function.

Now we substitute the primed variables into (2.6)-(2.8) to obtain

$$\mathbf{F}'(\mathbf{x}', t') = \frac{S_b t_0}{\eta L} \int_0^{L_b/L} \mathbf{f}'(s', t')\delta(\mathbf{x}' - \mathbf{X}'(s', t'))\, ds', \tag{3.6}$$

$$\frac{\partial \mathbf{X}'}{\partial t'}(s', t') = \mathbf{u}'(\mathbf{X}'(s', t'), t'), \tag{3.7}$$

$$\mathbf{u}'(\mathbf{X}'(s', t'), t') = \int_\Omega \mathbf{u}'(\mathbf{x}', t')\delta(\mathbf{x}' - \mathbf{X}'(s', t'))\, d\mathbf{x}', \tag{3.8}$$

where L_b is the unstressed length of the boundary. If we pick t_0 such that $S_b t_0/\eta L = 1$, then the only parameter in this problem is L_b/L, which is dimensionless.

4. Discretization of the dimensionless equations. We now drop the primes in the dimensionless equations and discretize them for the numerical computation. The numerical scheme described below generalizes readily to the three-dimensional case, although the description of the immersed elastic boundary is then more complicated.

First, we introduce the notation that will be used to describe the numerical method. The Stokes equations are solved on a regular square box of length 1 with periodic boundary conditions. Let N be the number of lattice points in each direction; then $h = 1/N$ is the lattice width. We divide time into time steps of size Δt and use notation $\mathbf{u}_{ij}^n$ and $\mathbf{F}_{ij}^n$ for flow and force density evaluated at $t = n\Delta t$, $\mathbf{x} = (ih, jh)$. Note that all functions of $\mathbf{x}$ are periodic with period 1 in each direction, that is, all arithmetic involving lattice coordinates is modulo N.

We introduce the forward, backward, and centered difference operators as follows:

$$(D^+ g)_i = (g_{i+1} - g_i)/h,$$

$$(D^- g)_i = (g_i - g_{i-1})/h,$$

$$(D^0 g)_i = (g_{i+1} - g_{i-1})/2h.$$

We also use the subscript s to indicate the variable with respect to which the differencing is accomplished ($s = 1, 2$ denotes the two spatial dimensions), for example,

$$(D_1^+ \phi)_{ij} = (\phi_{i+1,j} - \phi_{ij})/h.$$

Moreover, let

$$\mathscr{D} \cdot \mathbf{u} = D_1^0 u_1 + D_2^0 u_2 \sim \nabla \cdot \mathbf{u}, \tag{4.1}$$

$$\mathscr{G} p = (D_1^0 p, D_2^0 p) \sim \nabla p, \tag{4.2}$$

$$\mathscr{L}\mathbf{u} = D_1^+ D_1^- \mathbf{u} + D_2^+ D_2^- \mathbf{u} \sim \Delta \mathbf{u}. \tag{4.3}$$

We discretize the Stokes equations with the above notation:

$$0 = -\mathscr{G} p + \mathscr{L}\mathbf{u} + \mathbf{F}, \tag{4.4}$$

$$0 = \mathscr{D} \cdot \mathbf{u}. \tag{4.5}$$

We now proceed to describe the notation used for discretization of the boundary equations. Recall that L_b here denotes $L_b' = L_b/L$, the dimensionless unstressed length of the boundary. Let N_b be the number of Lagrangian points used to represent the boundary. We define $\Delta s = L_b/N_b$ and use the notation $\mathbf{X}_k^n$ to denote the position of the kth point on the boundary at $t = n\Delta t$ where the subscript $k = 0 \cdots (N_b - 1)$. Since the boundary is a closed curve, the arithmetic on k is modulo N_b. According to the definition of the boundary tension T and the tangent vector $\boldsymbol{\tau}$, we discretize them as

$$T_{k+1/2} = \sigma(|\mathbf{X}_{k+1} - \mathbf{X}_k|/\Delta s) \tag{4.6}$$
$$= \begin{cases} \dfrac{|\mathbf{X}_{k+1} - \mathbf{X}_k|}{\Delta s} - 1, & \dfrac{|\mathbf{X}_{k+1} - \mathbf{X}_k|}{\Delta s} \geqq 1, \\ 0, & \text{otherwise}, \end{cases}$$

$$\boldsymbol{\tau}_{k+1/2} = \frac{\mathbf{X}_{k+1} - \mathbf{X}_k}{|\mathbf{X}_{k+1} - \mathbf{X}_k|}. \tag{4.7}$$

Finally, the discrete force density $\mathbf{f}_k$ is given by

$$\mathbf{f}_k = \frac{T_{k+1/2}\boldsymbol{\tau}_{k+1/2} - T_{k-1/2}\boldsymbol{\tau}_{k-1/2}}{\Delta s}. \tag{4.8}$$

Note that these equations define functions $\mathbf{f}_k = \mathbf{f}_k(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1})$ but that each $\mathbf{f}_k$ depends only on $\mathbf{X}_{k-1}$, $\mathbf{X}_k$, and $\mathbf{X}_{k+1}$.

We find that $\mathbf{f}_k$ can also be computed from an elastic energy function defined as

$$E(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1}) = \sum_{k=0}^{N_b-1} \mathscr{E}\left(\frac{|\mathbf{X}_{k+1} - \mathbf{X}_k|}{\Delta s}\right)\Delta s. \tag{4.9}$$

If $\mathscr{E}' = \sigma$, then grad $E = -\mathbf{f}$.

We now consider the equations connecting the fluid lattice and the boundary points. Since the positions of the boundary points generally do not coincide with those of the lattice points, we have to interpolate the velocity field from the fluid lattice to the boundary points and spread the boundary force from the boundary points to the nearby lattice points of the fluid. This problem is solved by introducing a sufficiently smooth approximation to the Dirac δ-function:

$$\delta_h(\mathbf{x}) = \delta_h(x_1)\delta_h(x_2), \tag{4.10}$$

where

$$\delta_h(x) = \begin{cases} \dfrac{1}{4h}\left(1 + \cos\dfrac{\pi x}{2h}\right), & |x| \leqq 2h, \\ 0, & |x| > 2h. \end{cases} \tag{4.11}$$

The reasons for the particular choice of δ-function are given in [11].

We define

$$\mathbf{U}_k = \sum_{i,j=0}^{N-1} \mathbf{u}_{ij}\delta_h(\mathbf{x}_{ij} - \mathbf{X}_k)h^2 \tag{4.12}$$

for the approximation to the identity (3.8).

Similarly, a discrete form of the force density (3.6) is given by

$$\mathbf{F}_{ij} = \sum_{k=0}^{N_b-1} \mathbf{f}_k(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1})\delta_h(\mathbf{x}_{ij} - \mathbf{X}_k)\Delta s. \tag{4.13}$$

Finally, the no-slip condition is discretized as

$$\frac{\mathbf{X}_k^{n+1} - \mathbf{X}_k^n}{\Delta t} = \mathbf{U}_k. \tag{4.14}$$

In (4.12)-(4.14) we have omitted the time index on certain quantities. Different choices of this index (e.g., n or $n+1$) will result in the different schemes that we consider below.

5. An FFT Stokes solver. In this section we will describe a method to solve the Stokes equations using the fast Fourier transform (FFT). Suppose we are given the force density **F**. We need a device to find the velocity **u** and the pressure p that satisfy the Stokes equations.

We consider a grid function ϕ and define the discrete Fourier transformation of ϕ as

$$(5.1)\qquad \hat{\phi}_{k_1k_2}=\sum_{j_1,j_2=0}^{N-1} e^{-i(2\pi/N)(j_1k_1+j_2k_2)}\phi_{j_1j_2},\qquad 0\leqq k_1,\,k_2\leqq N-1.$$

According to this definition, the discrete Fourier transform of the Stokes equations is as follows:

$$(5.2)\quad 0=\frac{-i}{h}\sin\left(\frac{2\pi k_s}{N}\right)\hat{p}_{k_1k_2}-\frac{4}{h^2}\sum_{s'=1}^{2}\sin^2\left(\frac{\pi k_{s'}}{N}\right)(\hat{u}_s)_{k_1k_2}+(\hat{F}_s)_{k_1k_2},\qquad s=1,2,$$

$$(5.3)\qquad 0=\sum_{s=1}^{2}\frac{i}{h}\sin\left(\frac{2\pi k_s}{N}\right)(\hat{u}_s)_{k_1k_2}.$$

Multiplying by

$$\frac{i}{h}\sin\left(\frac{2\pi k_s}{N}\right)$$

on both sides of (5.2) and summing over s from 1 to 2, then making use of (5.3), we get an algebraic equation for the Fourier transform of the pressure. The solution of this equation is:

$$(5.4)\qquad \hat{p}_{k_1k_2}=\frac{-\sum_{s=1}^{2}(i/h)\sin(2\pi k_s/N)(\hat{F}_s)_{k_1k_2}}{\sum_{s=1}^{2}(1/h^2)\sin^2(2\pi k_s/N)}.$$

Once $\hat{p}$ is known, (5.2) can be solved for $\hat{\mathbf{u}}$ as follows:

$$(5.5)\qquad (\hat{u}_s)_{k_1k_2}=\frac{-(i/h)\sin(2\pi k_s/N)\hat{p}_{k_1k_2}+(\hat{F}_s)_{k_1k_2}}{(4/h^2)\sum_{s'=1}^{2}\sin^2(\pi k_{s'}/N)}.$$

We remark that certain values of k_s will cause difficulty in (5.4) and (5.5). When $(k_1,k_2)=(0,0)$, $(0,N/2)$, $(N/2,0)$, or $(N/2,N/2)$, $\hat{p}_{k_1k_2}$ is undefined; see (5.4). In those cases, however, the value of $\hat{p}$ has no effect on $\hat{\mathbf{u}}$; see (5.5). Therefore, we may set $\hat{p}=0$ for these values of (k_1,k_2). In the case $(k_1,k_2)=(0,0)$, however, there is an additional problem that is not present in the other three cases, since the denominator in (5.5) is zero. To obtain a solution, the numerator must be zero also, and this means that $\hat{\mathbf{F}}_{00}=0$. Note that this is equivalent to

$$\sum_{i,j=0}^{N-1}\mathbf{F}_{ij}=0.$$

The latter condition follows directly from the discrete Stokes equations in a periodic domain by summing over all grid points. In our case, we know that this condition must be satisfied since we construct **F** from forces generated in links, since each link generates a pair of equal and opposite forces, and since total force is preserved by our δ-function method of spreading the forces onto the fluid grid. In this indeterminate case, we may set $\hat{\mathbf{u}}=0$, for there is an arbitrary constant in the general solution of the discrete Stokes equations.

In summary, the procedure to compute velocity $\mathbf{u}$ and pressure p from a given force density $\mathbf{F}$ is as follows: first, compute the Fourier transform of $\mathbf{F}$. This is accomplished by a fast Fourier transformation. We then use (5.4) to compute $\hat{p}$, and once $\hat{p}$ is found, we use (5.5) to compute $\hat{\mathbf{u}}$. Finally, the velocity $\mathbf{u}$ and the pressure p can be calculated by an inverse Fourier transformation on $\hat{\mathbf{u}}$ and $\hat{p}$, respectively, using an FFT.

6. The explicit method. We now describe the first of the three numerical methods for computing the boundary force in the presence of an elastic immersed boundary. This is the simplest among them and takes the smallest amount of computer time (per time step) and storage space. However, this method is not always stable. When the size of the time step is big, the boundary will explode.

The first step in the algorithm to compute $\mathbf{X}^{n+1}$ given $\mathbf{X}^n$ is to evaluate the force density. This is done using the energy function described in § 4:

$$\mathbf{f}_k^n = -\frac{\partial E}{\partial \mathbf{X}_k}(\mathbf{X}_0^n, \mathbf{X}_1^n, \cdots, \mathbf{X}_{N_b-1}^n). \tag{6.1}$$

Once the forces $\mathbf{f}_k^n$ have been computed, we use the δ-function to spread the force out on the computational lattice

$$\mathbf{F}_{ij}^n = \sum_{k=0}^{N_b-1} \mathbf{f}_k^n \delta_h(\mathbf{x}_{ij} - \mathbf{X}_k^n)\Delta s. \tag{6.2}$$

We next find the velocity at the lattice points by means of the FFT Stokes solver and use the δ-function again to interpolate the velocity to the boundary points

$$\mathbf{U}_k^n = \sum_{i,j=0}^{N-1} \mathbf{u}_{ij}^n \delta_h(\mathbf{x}_{ij} - \mathbf{X}_k^n) h^2. \tag{6.3}$$

Finally, we update the positions of the boundary points using

$$\mathbf{X}_k^{n+1} = \mathbf{X}_k^n + \Delta t \mathbf{U}_k^n. \tag{6.4}$$

Results will be given after the other methods have been described.

7. The approximate-implicit method. This method is similar to the foregoing except that here the force density is computed implicitly to avoid numerical instability. We define points $\mathbf{X}_0^{n+1,*}, \mathbf{X}_1^{n+1,*}, \cdots, \mathbf{X}_{N_b-1}^{n+1,*}$ by a system of equations of the form

$$\mathbf{X}_k^{n+1,*} = \mathbf{X}_k^n + \Delta t \lambda \mathbf{f}_k(\mathbf{X}_0^{n+1,*}, \mathbf{X}_1^{n+1,*}, \cdots, \mathbf{X}_{N_b-1}^{n+1,*}), \tag{7.1}$$

where λ is the magnitude of the velocity induced at a point by a unit force applied to that point. It can be estimated either by applying a unit force at a point and then measuring the displacement of that point after one time step or from the fundamental solution of the discrete Stokes equations. (This fundamental solution plays a critical role in the method that is described in the following section.) The quantity $\mathbf{X}^{n+1,*}$ is intended to approximate the positions of the boundary points at the end of the time step. The formula for $\mathbf{X}^{n+1,*}$, (7.1), takes into account the influence of the boundary force $\mathbf{f}$ but only in an approximate way. The approximation is that each element $\mathbf{f}_k$ is allowed to act only on the point $\mathbf{X}_k$. This approximation is removed in the implicit method that is the subject of the next section.

We now describe the method to solve the nonlinear fixed-point problem given by (7.1). We introduce the notation $\mathbf{X} = (\mathbf{X}_0^{n+1,*}, \mathbf{X}_1^{n+1,*}, \cdots, \mathbf{X}_{N_b-1}^{n+1,*})$; $\mathbf{X}^0 = (\mathbf{X}_0^n, \mathbf{X}_1^n, \cdots, \mathbf{X}_{N_b-1}^n)$; and $\mathbf{f} = (\mathbf{f}_0, \mathbf{f}_1, \cdots, \mathbf{f}_{N_b-1})$. Now the system in (7.1) can be rewritten as

$$\mathbf{X} = \mathbf{X}^0 + \Delta t \lambda \mathbf{f}(\mathbf{X}). \tag{7.2}$$

We can form a problem equilvalent to (7.2), which solves for the force density **f** instead of **X**. The motivation for this is to permit the consistent comparison to the implicit method discussed in the next section. Since $\mathbf{f} = -\text{grad } E$, we have

$$\begin{aligned}\mathbf{f}(\mathbf{X}) &= -\nabla E(\mathbf{X})\\ &= -\nabla E(\mathbf{X}^0 + \Delta t\lambda \mathbf{f}(\mathbf{X})).\end{aligned}$$

Treating **f** as a new independent variable, we then get

$$\mathbf{f} + \nabla E(\mathbf{X}^0 + \Delta t \lambda \mathbf{f}) = 0. \tag{7.3}$$

Next we consider the function

$$\phi(\mathbf{f}) = \frac{1}{2}(\mathbf{f}, \mathbf{f}) + \frac{1}{\Delta t\lambda} E(\mathbf{X}^0 + \Delta t \lambda \mathbf{f}). \tag{7.4}$$

If E is continuous and bounded from below, then ϕ has an absolute minimum at some point $\mathbf{f}^*$. That is, $\phi(\mathbf{f}^*) \leqq \phi(\mathbf{f})$ for all **f**. If E is also differentiable, then $\mathbf{f}^*$ is a solution of our fixed-point problem (7.3).

The numerical solution of (7.3) is found by Newton's method. Let $\mathbf{f}^m$ be the mth guess. (Here we use superscripts for the iteration number within Newton's method. This should not be confused with the time step, which is fixed during this discussion.) Then $\mathbf{f}^{m+1}$ is obtained by solving the following system of equations:

$$(\mathbf{I} + \Delta t \lambda H_E(\mathbf{X}^0 + \Delta t \lambda \mathbf{f}^m))(\mathbf{f}^{m+1} - \mathbf{f}^m) = -(\mathbf{f}^m + \nabla E(\mathbf{X}^0 + \Delta t \lambda \mathbf{f}^m)). \tag{7.5}$$

Here H_E is the Hessian matrix of E.

It can easily be verified that this is a periodic block-tridiagonal system (with 2×2 blocks, since each $\mathbf{f}_k$ is a 2-vector). A sufficient condition for this system to be positive definite is that σ and the derivative of σ be positive (see [12]). The solution of such a periodic, block-tridiagonal system is also described in [12]. The repeated solution of (7.5) results in a sequence $\mathbf{f}^m$ which converges quadratically to a force density $\mathbf{f}^*$ that solves (7.3).

We have just described how to compute the boundary force density implicitly. Once this new force is found, we use it to define the force density **F** that acts on the fluid, and we continue with the rest of the algorithm as in the explicit method.

We remark that the argument of δ_h used in this method is the same as in the explicit method. That is, it involves $\mathbf{X}^n$, not $\mathbf{X}^{n+1}$ or $\mathbf{X}^{n+1,*}$. This is because $\mathbf{X}^{n+1}$ is not yet known and $\mathbf{X}^{n+1,*}$ involves displacements from $\mathbf{X}^n$ that were not generated by an incompressible flow.

8. The implicit method. This new method is different from the above two methods because here the boundary force is computed from the unknown configuration at the end of the time step. It makes use of the fundamental solution of the Stokes equations to compute the fluid-mediated influence of one boundary point on another.

Ordinarily, the fundamental solution would be associated with a unit singular point force located at the origin:

$$\mathscr{F}^s = \mathbf{e}_s \delta(\mathbf{x}), \qquad s = 1, 2, \tag{8.1}$$

where $\mathbf{e}_s$ are the unit vectors in each of the two coordinate directions and $\delta(\mathbf{x})$ is a two-dimensional Dirac δ-function. We mentioned earlier, however, that the existence of the solution in a periodic domain requires that

$$\int_\Omega \mathbf{F}\, d\mathbf{x} = 0, \tag{8.2}$$

or in discrete form,

$$\sum_{i,j=0}^{N-1} \mathbf{F}_{ij} = 0. \tag{8.3}$$

Thus we need to subtract a uniform background force from $\mathcal{F}^s$ so that (8.2) will be satisfied. We define $\mathcal{F}^s$ as follows:

$$\mathcal{F}^s = (\delta(\mathbf{x}) - 1)\mathbf{e}_s, \tag{8.4}$$

or in the discrete case,

$$\mathcal{F}^s_{ij} = \left(\frac{1}{h^2}\delta_{i0}\delta_{j0} - 1\right)\mathbf{e}_s. \tag{8.5}$$

We note that any $\mathbf{F}$ that satisfies (8.3) can be written as

$$\mathbf{F}_{ij} = h^2 \sum_{i',j'=0}^{N-1} \sum_{s=1}^{2} \mathcal{F}^s_{i-i',j-j'}(F_s)_{i'j'}. \tag{8.6}$$

This can be shown by substituting (8.5) into (8.6) and using the definition of the Kronecker delta and (8.3).

If we let the solution corresponding to the singular force $\mathcal{F}^s$ be $(\mathbf{u}^s, p^s)$, then the velocity field $\mathbf{u}$ corresponding to $\mathbf{F}$ can be expressed in terms of $\mathbf{u}^s$ in the same way as (8.6) by linearity

$$\mathbf{u}_{ij} = h^2 \sum_{i',j'=0}^{N-1} \sum_{s=1}^{2} \mathbf{u}^s_{i-i',j-j'}(F_s)_{i'j'}. \tag{8.7}$$

Note that $\mathbf{u}^s$ does not depend on time. We can compute it by the FFT Stokes solver once and for all and store it in an $N \times N$ array $\mathbf{G}$ of 2×2 matrices. $\mathbf{G}$ is the discrete Green's function of the Stokes equations on a periodic domain. Each entry of $\mathbf{G}$ is a 2×2 matrix, since $\mathbf{u}^s_{ij}$ is a 2-vector for each s: $s=1$ corresponds to the fundamental solution for the singular point force applied in the x direction, while $s=2$ corresponds to that in which the singular point force is applied in the y direction. With the notation $\mathbf{G}$, we are able to write (8.7) as

$$\mathbf{u}_{ij} = h^2 \sum_{i',j'=0}^{N-1} \mathbf{G}(i-i', j-j')\mathbf{F}_{i'j'}. \tag{8.8}$$

We now seek an implicit method to compute the force density. It follows from (4.12) and (4.14) that

$$\mathbf{X}^{n+1}_k = \mathbf{X}^n_k + \Delta t h^2 \sum_{i,j=0}^{N-1} \mathbf{u}^{n+1}_{ij}\delta_h(\mathbf{x}_{ij} - \mathbf{X}^n_k). \tag{8.9}$$

Note that the argument of δ_h here is also $\mathbf{X}^n$, as in the previous two methods. In this sense, this method is not completely implicit. We call it the "implicit method" because the boundary force is computed from $\mathbf{X}^{n+1}$.

Now if we substitute (8.8) into (8.9), we get

$$\mathbf{X}^{n+1}_k = \mathbf{X}^n_k + \Delta t h^4 \sum_{i,j=0}^{N-1} \sum_{i',j'=0}^{N-1} \mathbf{G}(i-i', j-j')\mathbf{F}^{n+1}_{i'j'}\delta_h(\mathbf{x}_{ij} - \mathbf{X}^n_k). \tag{8.10}$$

From (4.13) we deduce

$$\begin{aligned}\mathbf{X}^{n+1}_k = \mathbf{X}^n_k + \Delta t \Delta s h^4 \sum_{k'=0}^{N_b-1} \sum_{i,j=0}^{N-1} \sum_{i',j'=0}^{N-1} \mathbf{G}(i-i', j-j')\delta_h(\mathbf{x}_{ij} - \mathbf{X}^n_k)\\ \cdot\, \delta_h(\mathbf{x}_{i'j'} - \mathbf{X}^n_{k'})\mathbf{f}_{k'}(\mathbf{X}^{n+1}_0, \mathbf{X}^{n+1}_1, \cdots, \mathbf{X}^{n+1}_{N_b-1}).\end{aligned} \tag{8.11}$$

Let

$$\tilde{\mathbf{G}}_{kl}=h^4\sum_{i,j=0}^{N-1}\sum_{i',j'=0}^{N-1}\mathbf{G}(i-i',j-j')\delta_h(\mathbf{x}_{ij}-\mathbf{X}_k^n)\delta_h(\mathbf{x}_{i'j'}-\mathbf{X}_l^n).$$

We can then rewrite (8.11) as

$$\mathbf{X}_k^{n+1}=\mathbf{X}_k^n+\Delta t\,\Delta s\sum_{l=0}^{N_b-1}\tilde{\mathbf{G}}_{kl}\mathbf{f}_l(\mathbf{X}_0^{n+1},\mathbf{X}_1^{n+1},\cdots,\mathbf{X}_{N_b-1}^{n+1}).\tag{8.12}$$

Let $\mathbf{X}=(\mathbf{X}_0^{n+1},\mathbf{X}_1^{n+1},\cdots,\mathbf{X}_{N_b-1}^{n+1})$; $\mathbf{X}^0=(\mathbf{X}_0^n,\mathbf{X}_1^n,\cdots,\mathbf{X}_{N_b-1}^n)$; and $\mathbf{f}=(\mathbf{f}_0^{n+1},\mathbf{f}_1^{n+1},\cdots,\mathbf{f}_{N_b-1}^{n+1})$. Let $\tilde{\mathbf{G}}$ be the matrix whose k, l entry is $\tilde{\mathbf{G}}_{kl}$. Equation (8.12) becomes

$$\mathbf{X}-\mathbf{X}^0-\Delta t\,\Delta s\,\tilde{\mathbf{G}}\mathbf{f}(\mathbf{X})=0.\tag{8.13}$$

This is again a nonlinear fixed-point problem. It is useful to put this problem in the form grad $\phi=0$ because then the linear problems that arise at each iteration of Newton's method will be symmetric. This can be done by using $\mathbf{f}$ as the independent variable instead of $\mathbf{X}$ and then by multiplying by $\tilde{\mathbf{G}}$ on the left. The result is

$$\tilde{\mathbf{G}}\mathbf{f}+\tilde{\mathbf{G}}\nabla E(\mathbf{X}^0+\Delta t\,\Delta s\,\tilde{\mathbf{G}}\mathbf{f})=0,\tag{8.14}$$

in which the left-hand side is the gradient of the function ϕ defined as follows:

$$\phi(\mathbf{f})=\frac{1}{2}(\mathbf{f},\tilde{\mathbf{G}}\mathbf{f})+\frac{1}{\Delta t\,\Delta s}E(\mathbf{X}^0+\Delta t\,\Delta s\,\tilde{\mathbf{G}}\mathbf{f}).\tag{8.15}$$

Now two comments relating to $\tilde{\mathbf{G}}$ are in order. First, we see that if we replace $\tilde{\mathbf{G}}$ by $\lambda I/\Delta s$, we obtain (7.3), the same problem that is solved when we use the approximate-implicit method. This implies that another (equivalent) method of estimating λ is to multiply the average value of the diagonal element of $\tilde{\mathbf{G}}$ by Δs.

Second, we note that $\tilde{\mathbf{G}}$ is positive semidefinite. This can be shown by applying $\mathbf{u}\,\cdot$ to the discrete form of the Stokes equations and summing over all the lattice points

$$0=h^2\sum_{i,j=0}^{N-1}\mathbf{u}_{ij}\cdot(-\mathscr{G}p_{ij})+h^2\sum_{i,j=0}^{N-1}\mathbf{u}_{ij}\cdot\mathscr{L}\mathbf{u}_{ij}+h^2\sum_{i,j=0}^{N-1}\mathbf{u}_{ij}\cdot\mathbf{F}_{ij}.\tag{8.16}$$

The first term after summation by part gives

$$h^2\sum_{i,j=0}^{N-1}(\mathscr{D}\cdot\mathbf{u})_{ij}p_{ij},$$

which is zero.

Operating in the same way on the second term yields

$$-h^2\sum_{i,j=0}^{N-1}(D_1^+\mathbf{u}_{ij}\cdot D_1^+\mathbf{u}_{ij}+D_2^+\mathbf{u}_{ij}\cdot D_2^+\mathbf{u}_{ij}).$$

This is always less than or equal to zero. It is equal to zero only if $\mathbf{u}$ is constant. But since

$$\sum_{i,j=0}^{N-1}\mathbf{u}_{ij}=0,$$

it is equal to zero only if $\mathbf{u}=0$.

Now we consider the third term:

$$\begin{aligned} h^2 \sum_{i,j=0}^{N-1} \mathbf{u}_{ij} \cdot \mathbf{F}_{ij} &= h^2 \sum_{i,j=0}^{N-1} \mathbf{u}_{ij} \cdot \sum_{k=0}^{N_b-1} \mathbf{f}_k(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1})\delta_h(\mathbf{x}_{ij} - \mathbf{X}_k)\Delta s \\ &= \Delta s \sum_{k=0}^{N_b-1} \mathbf{f}_k(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1}) \cdot h^2 \sum_{i,j=0}^{N-1} \mathbf{u}_{ij}\delta_h(\mathbf{x}_{ij} - \mathbf{X}_k) \\ &= \Delta s \sum_{k=0}^{N_b-1} \mathbf{f}_k(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1}) \cdot \mathbf{U}_k \\ &= \Delta s \sum_{k=0}^{N_b-1} \mathbf{f}_k(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1}) \cdot \sum_{l=0}^{N_b-1} \tilde{\mathbf{G}}_{kl}\mathbf{f}_l(\mathbf{X}_0, \mathbf{X}_1, \cdots, \mathbf{X}_{N_b-1}) \\ &= \Delta s\, \mathbf{f} \cdot \tilde{\mathbf{G}}\mathbf{f}. \end{aligned}$$

Note that it is important that we use the same δ-function for interpolating the velocity field from the fluid lattice to the boundary points and for spreading the boundary force from the boundary points to the nearby lattice points of the fluid. If different δ-functions were used, we would not have obtained the above proof. Combining the above results, we see that $\tilde{\mathbf{G}}$ is positive semidefinite, as was to be shown.

The foregoing argument shows only that $\tilde{\mathbf{G}}$ is positive *semi*definite. Does $\tilde{\mathbf{G}}$ have a nontrivial null space? By examining the proof that $\tilde{\mathbf{G}}$ is positive semidefinite we can see that $\tilde{\mathbf{G}}f = 0$ if and only if the velocity field $\mathbf{u}$ that results from the application of $\mathbf{f}$ is constant and hence 0. In fact, this can happen for nontrivial $\mathbf{f}$ when the boundary points are too close together in relation to the fluid mesh. Roughly speaking, this difficulty arises when there are four or more immersed boundary points per mesh width. Although we have no proof, our experience is that $\tilde{\mathbf{G}}$ is positive *definite* when such high densities of boundary points are avoided. The following method for finding the numerical solution of (8.14) applies to the situation in which $\tilde{\mathbf{G}}$ is positive definite.

As before, this numerical solution is found by Newton's method. Let $\mathbf{f}^m$ be the mth guess. Then $\mathbf{f}^{m+1}$ is obtained by solving the following system of equations:

$$(8.17) \quad [\tilde{\mathbf{G}} + \Delta t\, \Delta s\, \tilde{\mathbf{G}}H_E(\mathbf{X}^0 + \Delta t\, \Delta s\, \tilde{\mathbf{G}}\mathbf{f}^m)\tilde{\mathbf{G}}](f^{m+1} - \mathbf{f}^m) = -(\tilde{\mathbf{G}}\mathbf{f}^m + \tilde{\mathbf{G}}\nabla E(\mathbf{X}^0 + \Delta t\, \Delta s\, \tilde{\mathbf{G}}\mathbf{f}^m)).$$

As promised, this is a symmetric system of equations. Since it is positive definite (if high density of boundary points are avoided), we can use Cholesky factorization to find the solution. Once $\mathbf{f}^{n+1}$ is found, we update the position of the boundary points by

$$(8.18) \qquad \mathbf{X}^{n+1} = \mathbf{X}^0 + \Delta t\, \Delta s\, \tilde{\mathbf{G}}\mathbf{f}^{n+1}.$$

Note that this method makes no direct use of the Stokes solver during the computation for each time step, but it needs the Stokes solver to precompute the matrix $\mathbf{G}$.

Note also that this method is very expensive. First, computing $\tilde{\mathbf{G}}$ requires $O(N_b^2)$ operations even when $\mathbf{G}$ has been precomputed. (Only $O(1)$ operations per element of $\tilde{\mathbf{G}}$ are required because of the local character of δ_h.) Second, computing the matrix for solving the system of equations in (8.17) requires two matrix multiplications, each of which is $O(N_b^3)$ for a dense matrix. Third, solving the system of equations also requires $O(N_b^3)$. In the presence of many boundary points, this will imply heavy demands on both computer time and storage.

9. Results. The results of three sets of numerical experiments are given in Figs. 1, 2, and 3. In the experiments shown in Fig. 1, we compare the results of the three

14	0.1078	0.1236	0.1242
16	—	0.1236	0.1242

methods with different sizes of the time step parameter. Only the last step of each run is shown in Fig. 1. In Figs. 2 and 3, the time evolution is shown for all three methods at one fixed value of Δt. The area inside the boundary in each case is shown in Tables 1, 2, and 3.

The domain of the experiment is the 1×1 square box. We use a uniform square lattice with 64 points along each direction. The initial boundary configuration is an ellipse with 128 boundary points. Each experiment was allowed to run until the results diverged or until 20 time steps had been computed.

The pictures in the top row of Fig. 1 show the results of the three methods with a relatively small step size ($\Delta t = 15.65$) at time step 20. We find that in this circumstance all three methods are stable. The boundaries all converge to a circle. We see that the area inside the boundary is somewhat different in the three cases. The implicit method preserves the area better than the approximate-implicit method while the latter preserves the area better than the explicit method (the area within the initial boundary is 0.1256). In the middle row of Fig. 1 we depict the results of the three methods with a medium step size ($\Delta t = 23.48$). The implicit and approximate-implicit methods are shown at step 20 and the explicit method is shown at step 16, where it has already diverged. At this bigger step size, the explicit method is unstable. The boundary becomes very complex, diverging from the simple closed curve. However, the results for the other two methods are both stable and their boundaries converge to a circle, as in the case of a small step size. The results of the three methods with a relatively big step size ($\Delta t = 31.30$) are given in the bottom row of Fig. 1. The results are at step 20 except for the explicit method, which is at step 10. The explicit method is again unstable, with an explosive boundary diverging from the circle. At this high level of step size the approximate-implicit method shows signs of instability. While after 20 steps its boundary is still a simple closed curve, its star shape is a very poor approximation to a circle. Only the implicit method remains stable at this value of Δt.

We can obtain a more detailed comparison of the methods by observing the time evolution of the boundary configuration in each case. This is done in Fig. 2 for the intermediate step size ($\Delta t = 23.48$). The figure shows that both the implicit and approximate-implicit methods are stable and that their patterns of convergence over time are similar: the ellipse gradually becomes a circle. By contrast, the explicit method quickly diverges. By step 12, the boundary shows an oscillating pattern and eventually becomes a complicated curve.

The time evolution of the boundary configuration for the largest step size ($\Delta t = 31.30$) is shown in Fig. 3. At time step 0, the shapes are the same as in Fig. 2. The explicit method starts to show signs of instability at step 8 and quickly diverges at step 10. Beyond this step the results have exploded outside the boundary of the fluid domain. In the approximate-implicit method, the boundary becomes a star shape at step 16 and remains star-shaped at step 20. Only the implicit method is still stable in this case.

10. Summary and conclusions. We have presented a new method for computing the boundary force in problems with an elastic immersed boundary and have compared its stability with two other existing methods. The results clearly rank these methods from the standpoint of stability. The implicit method has the best stability properties and the explicit method has the worst. The approximate-implicit method will be stable for a larger range of the time-step parameter than the explicit method but for a smaller range of that parameter than the implicit method. When viewed from the perspective of required computational time (per time step) and storage space, the methods have the reverse ordering. The explicit method is the most economical, the approximate-implicit comes next, and the implicit method is the most expensive. Thus there appears to be a trade-off between stability and cost of the computations.

Indeed, in its present form, the fully implicit method is probably too expensive for practical application. One purpose of the present investigation, however, was to determine whether substantial improvement in stability could be achieved through the use of the fully implicit approach, which had not previously been tried on this type of problem. The answer appears to be "yes," and this should serve as a motivation to develop more efficient implementations of the fully implicit scheme. Other challenges for the future include extending this work to the Navier–Stokes equations and to the three-dimensional case.

NUMERICAL SOLUTION OF THE TIME-DEPENDENT AXISYMMETRIC BOUSSINESQ EQUATIONS ON PROCESSOR ARRAYS*

MICHAEL SCHÄFER†

Abstract. The paper deals with the numerical solution of time-dependent nonisothermal flow problems, governed by the axisymmetric incompressible Boussinesq equations, on array processors. Using finite difference methods for discretization and a pressure correction method in combination with a successive iteration process for linearization and decoupling of variables, the problem is approximated by a sequence of sparse linear systems. The parallel solution of these systems by preconditioned conjugate gradient (PCG) methods and multigrid (MG) methods is discussed. Numerical experiments on an array processor for a number of test problems, derived from a practical application in the field of crystal growth, are reported. Included are comparisons of the implicit Euler scheme and the Crank-Nicolson scheme for time discretization for different flows, as well as comparisons of PCG methods and MG methods.

Key words. viscous time-dependent flow, incompressible Boussinesq equations, finite differences, pressure correction methods, preconditioned conjugate gradient methods, multigrid methods, array processors

AMS(MOS) subject classifications. 65M05, 76D05

1. Introduction.

The numerical solution of time-dependent nonisothermal flow problems in cylindrical geometries is of practical interest in a variety of applications, especially in the field of material processing. Important examples are the common manufacturing techniques for semiconductor crystals, such as the widely used Czochralski method (see e.g., Derby and Brown [5]).

In this paper we consider the numerical solution of the time-dependent incompressible Boussinesq equations, which constitute an appropriate, widely accepted mathematical model for the flow problems considered here. We restrict ourselves to the axisymmetric case, but mention that a generalization of the examined methods to the fully three-dimensional case is straightforward.

It is well known that a numerical treatment of flow problems, especially in the time-dependent case, requires a large amount of computational work and storage capacity. Parallel computers, which are increasingly becoming available commercially, can help to treat such problems with the required accuracy in reasonable amounts of time.

Among the different concepts for parallel architectures, we concentrate here on the case of a two-dimensional mesh-connected array of processors working in single instruction multiple data (SIMD) mode (see, e.g., Hockney and Jesshope [10]), which seem to be a very natural architecture for the type of problems considered here. For the time being, the major advantages of SIMD architectures as against local memory multiple instruction multiple data (MIMD) machines (e.g., SUPRENUM, transputer arrays, etc.) are the larger numbers of processors and the much faster local data communication among the processors. The algorithms given in this paper take into account the considered architecture.

For space discretization, second-order finite differences on a staggered grid [7] are used. For time discretization, we consider the θ-method [4] including, in particular, the first-order implicit Euler (IE) scheme and the second-order Crank-Nicolson (CN)

scheme. The solution of the resulting nonlinear algebraic systems, one for each timestep, is reduced to the solution of a sequence of linear systems by means of a pressure correction approach [11] and a successive iteration process. For the solution of these sparse linear systems, we consider basic iterative-method preconditioned conjugate gradient (PCG) methods and multigrid (MG) methods [6]. Special attention is paid to the basic iterative methods involved herein, which are the crucial components with regard to an efficient parallelization. We consider a parallel Gauss–Seidel method, based on a domain decomposition and a multicolor ordering of the unknowns, which is easy to implement and which results in efficient algorithms for the considered type of parallel architectures.

By various numerical experiments on a DAP 510, a SIMD machine with a 32×32 array of single-bit processors, we study the numerical behaviour and the computational efficiency of the considered algorithms. The test problems are derived from a model of Czochralski crystal growth, a practical application proposed in [18] as a benchmark problem. The tests include an investigation of the IE scheme and the CN scheme for different kinds of flows, as well as a comparison of the considered PCG methods and MG methods. The results show, as proved in [11] for two-dimensional isothermal flows for the CN scheme, that the pressure correction approach does not spoil the accuracy of the underlying time discretization scheme. Rather, if the driving forces of the flows are not too large, due to the higher order, the CN scheme is superior to the IE scheme. For large driving forces (e.g., high Rayleigh number flows), especially when Hopf bifurcation effects become apparent due to the better stability properties, the implicit Euler scheme clearly shows its advantages.

Concerning the sparse linear system solves, we already find that for relatively small problem sizes the multigrid methods are superior to the PCG methods. Clearly, due to the optimal order of MG methods, this superiority grows with the problem size. For smoothing in the MG methods, as well as for preconditioning in the CG methods, the proposed multicolor Gauss–Seidel (MCGS) method is more efficient than the Jacobi method, which is known as an optimally parallel algorithm.

2. Statement of the problem. We consider nonisothermal flows of an incompressible viscous fluid in a vertical circular cylinder of height H and radius R. The mathematical description of such flows can be derived from the basic conservation laws of continuum mechanics for mass, momentum, and energy. We assume the validity of the Boussinesq approximation [14] and an axisymmetric flow. Using a cylinder coordinate system (r, z) as shown in Fig. 1, the nondimensional balance equations for

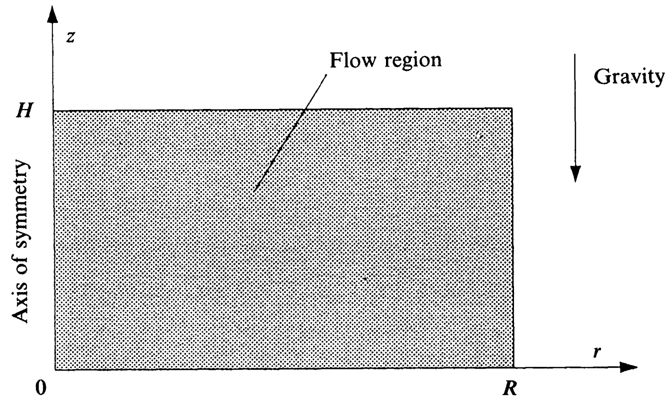

FIG. 1. *Problem configuration.*

the flow region can be written in the following compact form:

$$\begin{aligned} x_t+\mathbf{K}(x)x+\mathbf{G}p&=0,\\ Lx&=0, \end{aligned} \tag{1}$$

with

$$\mathbf{K}(x)=\begin{pmatrix} \mathbf{A}_u(u,w) & 0 & -\mathbf{B}(v) & 0\\ 0 & \mathbf{A}_w(u,w) & 0 & \mathbf{F}\\ \mathbf{B}(v) & 0 & \mathbf{A}_v(u,w) & 0\\ 0 & 0 & 0 & \mathbf{A}_T(u,w) \end{pmatrix},$$

$$\mathbf{G}=\begin{pmatrix}\mathbf{G}_r\\ \mathbf{G}_z\\ 0\\ 0\end{pmatrix},\quad \mathbf{L}=(\mathbf{L}_r,\mathbf{L}_z,0,0),$$

where $x=(u, w, v, T)^T$ and the differential operators are defined by

$$\begin{aligned} &\mathbf{A}_u(u,w)\phi=u\phi_r+w\phi_z-Pr(\Delta\phi-\phi/r^2),\\ &\mathbf{A}_w(u,w)\phi=u\phi_r+w\phi_z-Pr\Delta\phi,\\ &\mathbf{A}_v(u,w)\phi=\mathbf{A}_u(u,w)\phi,\\ &\mathbf{A}_T(u,w)\phi=u\phi_r+w\phi_z-\Delta\phi,\\ &\mathbf{G}_r\phi=\phi_r,\qquad \mathbf{G}_z\phi=\phi_z,\\ &\mathbf{L}_r\phi=(r\phi)_r/r,\qquad \mathbf{L}_z\phi=\phi_z,\\ &\mathbf{B}(v)\phi=v\phi/r,\qquad \mathbf{F}\phi=-RaPr\phi, \end{aligned}$$

for a scalar function ϕ. *Pr* and *Ra* are the Prandtl number and the Rayleigh number, respectively, and t denotes the time variable. A subscript denotes differentiation with respect to the subscript variable and Δ is the axisymmetric Laplace operator in cylindrical coordinates.

The (nondimensional) unknowns in (1) are the radial, axial, and azimuthal velocities u, w, and v; the temperature T; and the hydrostatic pressure p. In order to get a well-posed problem, the nonlinear system of partial differential equations (1) must be completed with boundary and initial conditions for the velocities and the temperature. On the symmetry axis $r=0$, we have the symmetry conditions

$$u=v=w_r=T_r=p_r=0. \tag{2}$$

We consider the numerical solution of (1), together with (2) and some boundary and initial conditions, on a parallel computer consisting of a mesh-connected array of $P_x \times P_y$ processors with local memories (Fig. 2). We assume that the processors work

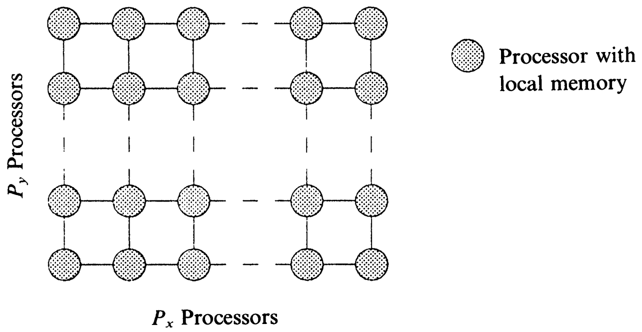

FIG. 2. *Processor array.*

in SIMD mode, which means that all processors perform the same operation at the same time, but on different data. As will be seen, for the type of problems considered here, the SIMD principle means no restriction with respect to the parallelization of the arithmetic operations, and it allows for a very fast local communication. Examples of currently available SIMD array computers are the distributed array processor (DAP), the connection machine, or the MasPar data-parallel computer.

3. Discretization and mapping. For the space discretization of (1), we use finite differences on a staggered grid, as introduced by Harlow and Welch [7]. The staggered arrangement of the unknowns and the grouping into cells is illustrated in Fig. 3 for an 8 × 4 grid. As discussed, for instance, in [15], a staggered grid has several advantages over an ordinary grid. Replacing the spatial derivatives by central differences and using standard second-order interpolation when needed (in consequence of the staggered grid), we obtain a system of ordinary differential equations for the unknown grid functions x_b and p_h:

$$\begin{aligned} x_{ht} + \mathbf{K}_h(x_h)x_h + \mathbf{G}_h p_h &= 0, \\ \mathbf{L}_h x_h &= 0. \end{aligned} \tag{3}$$

By Taylor expansion it can easily be shown that (3) is an $O(h^2)$ consistent approximation of (1), where $h > 0$ is a measure of the resolution of the grid (e.g., the maximum grid spacing). We remark that the boundary conditions for x are already included in (3). Because of the staggered grid, no artificial pressure boundary conditions are required. The initial conditions x_{0h} for (3) can be obtained as restrictions of the initial values for (1) to the grid points.

In order to allow an efficient mapping into our processor array, it is advantageous to take into account the size of the processor when choosing the grid. We assume here that the number of cells is given by

$$N_r \times N_z = k_r P_x \times k_z P_y$$

with some positive integers k_r and k_z. We subdivide the cell grid into $k_r \times k_z$ parts and map each part to one processor. As an example, Fig. 4 shows the mapping of an 8 × 4

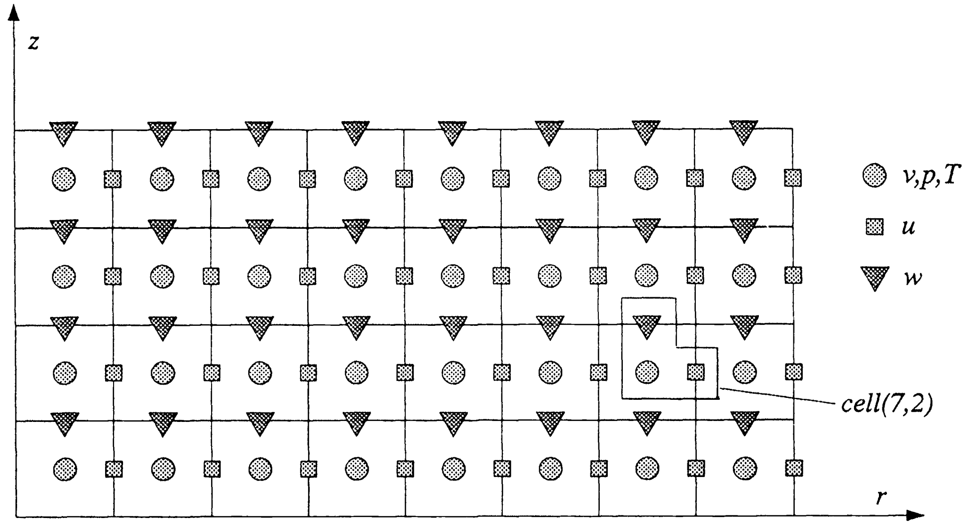

FIG. 3. *Staggered grid.*

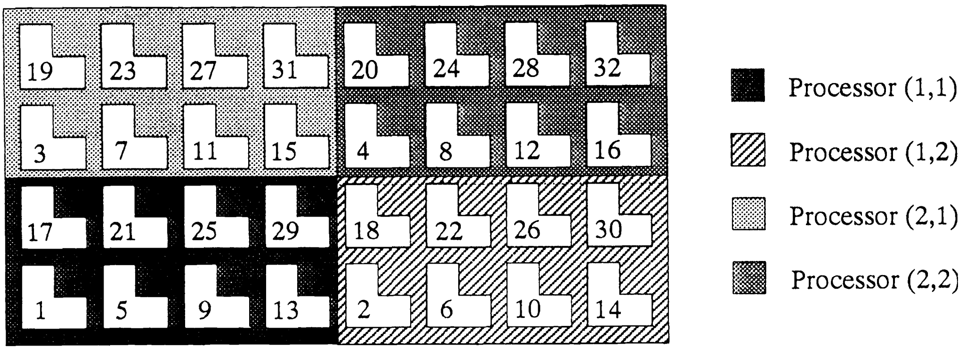

FIG. 4. *Distribution of the data to the processor array and multicolored numbering.*

cell grid onto a 2×2 processor array (the indicated numbering will be discussed later). For the time discretization, i.e., for the solution of the system (3), we consider the IE scheme and the CN scheme. In order to handle both schemes simultaneously, we formulate them in the setting of the θ-method [4]. The θ-method applied to (3) yields, starting from the initial values

$$x_h^0 = x_{0h}, \qquad p_h^0 = -(\mathbf{L}_h\mathbf{G}_h)^{-1}\mathbf{K}_h(x_h^0)x_h^0,$$

approximations x_h^n and p_h^n to x_h and p_h at the time levels $t_n = n\Delta t$, $n = 1, 2, \cdots$ from the solution of a nonlinear algebraic system of the form

$$\text{(4a)} \qquad x_h^n + \theta\Delta t[\mathbf{K}_h(x_h^n)x_h^n + \mathbf{G}_h p_h^n] = x_h^{n-1} + (\theta-1)\Delta t[\mathbf{K}_h(x_h^{n-1})x_h^{n-1} + \mathbf{G}_h p_h^{n-1}],$$

$$\text{(4b)} \qquad \mathbf{L}_h x_h^n = 0.$$

$\Delta t > 0$ is the timestep and, in general, the parameter θ can be in the interval [0, 1]. In the following, we only consider the cases $\theta = 1$, yielding the IE scheme, and $\theta = 0.5$, yielding the CN scheme. It can be shown by Taylor expansion that the CN scheme approximates (3) with a consistency error of $O(\Delta t^2)$, while the IE scheme is only $O(\Delta t)$ accurate. Both methods are unconditionally stable, but it is well known that for spatially nonsmooth solutions, the CN scheme may cause numerical oscillations [4]. The IE scheme does not show such behaviour. In § 7, we compare the two methods numerically for different kinds of problems.

4. Linearization and decoupling of variables. Each timestep with the θ-method requires the solution of the nonlinear algebraic system (4). Treating (4) directly, for instance with a Newton method, would be very inefficient, since the resulting linear systems would be very large and very poorly conditioned. We apply here a technique that reduces the solution of (4) to the solution of a sequence of smaller and better-conditioned linear systems. In a first step, we decouple the computation of x_h^n and p_h^n by means of a pressure correction approach that is based on a fractional step method due to Chorin [3]. We first compute an approximation $\tilde{x}_h^n$ to x_h^n from the system

$$\text{(5)} \qquad \tilde{x}_h^n + \theta\Delta t\mathbf{K}_h(\tilde{x}_h^n)\tilde{x}_h^n = x_h^{n-1} + (\theta-1)\Delta t\mathbf{K}_h(x_h^{n-1})x_h^{n-1} - \Delta t\mathbf{G}_h p_h^{n-1},$$

which results from (4a) by replacing the pressure term $\theta\Delta t\mathbf{G}_h p_h^n$ on the left side by $\theta\Delta t\mathbf{G}_h p_h^{n-1}$. Subtracting (5) from (4a) and neglecting the terms involving the operator $\mathbf{K}_h$ we obtain

$$\text{(6)} \qquad x_h^n = \tilde{x}_h^n - \theta\Delta t\mathbf{G}_h(p_h^n - p_h^{n-1}).$$

Applying the operator $\mathbf{L}_h$ to both sides of (6) together with (4b) yields the linear system

$$\theta\mathbf{L}_h\mathbf{G}_h p_h^n = \theta\mathbf{L}_h\mathbf{G}_h p_h^{n-1} + \frac{1}{\Delta t}\mathbf{L}_h\tilde{x}_h^n, \tag{7}$$

from which the new pressure p_h^n can be computed. Finally, x_h^n can be computed from (6).

Applying the same technique as in [11], where the above approach is used in combination with the Crank-Nicolson scheme for two-dimensional isothermal flows, it can be shown that the pressure correction (PC) method does not spoil the accuracy of the θ-method.

Summing up, solving (4) with the PC scheme requires the following steps:

PC1: Compute $\tilde{x}_h^n$ from (5).

PC2: Compute p_h^n from (7).

PC3: Compute x_h^n from (6).

The correction step PC3 consists of a direct computation and needs no further comment. Step PC2 requires the solution of a sparse system of linear equations. The coefficient matrix of the system is symmetric positive definite and it remains unchanged during the timestepping process. It can easily be verified [15] that the problem is equivalent to a discretization of a Poisson equation with Neumann boundary conditions.

Step PC1 requires the solution of a nonlinear algebraic system. We treat this problem by a successive iteration (SI) process involving a Gauss-Seidel technique, which results in a decoupling of the computation of the components $\tilde{u}_h^n$, $\tilde{w}_h^n$, $\tilde{v}_h^n$, and $\tilde{T}_h^n$ of $\tilde{x}_h^n$. The SI method is defined as follows:

SI1: $\tilde{x}_h^{n,0} = x_h^{n-1}$.

SI2: For $k = 1, \cdots, m$ compute $\tilde{x}_h^{n,k}$ from

$$\tilde{x}_h^{n,k} + \theta\Delta t\mathbf{S}_h(\tilde{x}_h^{n,k}, \tilde{x}_h^{n,k-1})\tilde{x}_h^{n,k} = x_h^{n-1} + (\theta - 1)\Delta t\mathbf{K}_h(x_h^{n-1})x_h^{n-1} - \Delta t\mathbf{G}_h p_h^{n-1}. \tag{8}$$

SI3: $\tilde{x}_h^n = \tilde{x}_h^{n,m}$.

In (8), the operator $\mathbf{S}_h(\tilde{x}_h^{n,k}, \tilde{x}_h^{n,k-1})$, an approximation to $\mathbf{K}_h(\tilde{x}_h^n)$, is defined by

$$\begin{pmatrix} \mathbf{A}_{uh}(\tilde{u}_h^{n,k-1}, \tilde{w}_h^{n,k}) & 0 & -\mathbf{B}_h(\tilde{v}_h^{n,k}) & 0 \\ 0 & \mathbf{A}_{wh}(\tilde{u}_h^{n,k-1}, \tilde{w}_h^{n,k-1}) & 0 & \mathbf{F}_h \\ \mathbf{B}_h(\tilde{v}_h^{n,k-1}) & 0 & \mathbf{A}_{vh}(\tilde{u}_h^{n,k-1}, \tilde{w}_h^{n,k-1}) & 0 \\ 0 & 0 & 0 & \mathbf{A}_{Th}(\tilde{u}_h^{n,k-1}, \tilde{w}_h^{n,k-1}) \end{pmatrix}.$$

Looking at this matrix we realize that the computation of $\tilde{x}_h^{n,k}$ in step SI2 can be performed by a back substitution process, which involves the successive solution of four linear systems for $\tilde{T}_h^{n,k}$, $\tilde{v}_h^{n,k}$, $\tilde{w}_h^{n,k}$, and $\tilde{u}_h^{n,k}$. We remark that the linearization of (5) by a Newton process, which would converge more rapidly, would not allow for such a decoupling. All components of $\tilde{x}_h^{n,k}$ would have to be computed simultaneously, resulting in a higher computational effort per iteration and higher memory requirements.

The number of iteration steps m in step SI2 either can be fixed (e.g., $m = 1$ may be sufficient), or it can be held variable by iterating until a stopping criterion such as

$$\frac{\|\tilde{x}^{n,k-1} - \tilde{x}^{n,k}\|}{\|\tilde{x}^{n,k}\|} < \varepsilon, \tag{9}$$

with a suitable norm $\|\cdot\|$ and some $\varepsilon > 0$ is reached. We investigate this question numerically in § 7.

In summation, we have reduced the solution of the nonlinear algebraic system (4) to the solution of $4m + 1$ sparse linear systems. So we are left with the problem of solving these systems in an efficient way on our processor array. This is the topic of § 5.

5. Parallel linear system solvers. For the solution of the sparse linear systems that arise in the algorithms of § 4, we consider MG methods and PCG methods, which rank among the most efficient methods for dealing with such problems. Let us denote by

$$\mathbf{M}y = b \tag{10}$$

the system that we wish to solve.

PCG methods [2] start with a transformation of (10) into an equivalent system

$$\mathbf{P}^{-1}\mathbf{M}y = \mathbf{P}^{-1}b, \tag{11}$$

with a nonsingular preconditioning matrix **P**. Applying a conjugate gradient algorithm to (11), we obtain a PCG method. For symmetric positive definite systems the classical conjugate gradient (CG) method of Hestenes and Stiefel [8] can be used. A generalization of this method to nonsymmetric systems is the conjugate gradient squared (CGS) method of Sonneveld [13].

The rate of convergence of PCG methods is determined by the ratio of the largest and smallest eigenvalues, the condition number, of the matrix $\mathbf{P}^{-1}\mathbf{M}$ [2]. The smaller the condition number the more rapid is the convergence. Therefore in order to obtain a rapidly convergent algorithm, **P** should be an approximation to **M** in some sense. On the other hand, since required one or more times in each step of a PCG method, the inverse of **P** should be as simple as possible. A compromise between the two extreme cases $\mathbf{P} = \mathbf{M}$ and $\mathbf{P} = \mathbf{Id}$ (identity matrix) must be found.

We concentrate here on basic iterative method preconditionings, as discussed, for instance, in [1]. In this approach, **P** is defined by

$$\mathbf{P}^{-1} = \sum_{i=0}^{s-1} (\mathbf{Id} - \mathbf{Q}^{-1}\mathbf{M})^i \mathbf{Q}^{-1},$$

with a positive integer s and a nonsingular matrix **Q** corresponding to a basic iterative method defined by a splitting $\mathbf{M} = \mathbf{Q} - \mathbf{R}$ of **M** and an iteration process of the form

$$y \leftarrow y - \mathbf{Q}^{-1}(\mathbf{M}y - b). \tag{12}$$

The resulting algorithm is known as s-step basic iterative PCG method. We shall return to the problem of choosing a suitable **Q** for the use on our processor array below.

The main components of MG methods, which are thoroughly treated in [6], are a sequence of coarsened grids, an interpolation procedure and a restriction procedure for the intergrid transfers, and an iterative method like (12) for smoothing on the different grids. As an example, we describe here the multigrid approach that is used for the solution of the pressure systems (7).

We coarsen the grid as indicated in Fig. 5 and choose the coarsest grid such that each subregion contains at least one grid point. Together with the induced mapping of the coarse-grid points (corresponding to that for the finest grid), this approach results in a uniform data distribution over the processor array for all grid levels and, therefore, ensures a full utilization of the processor array during the algorithm. It should be noted that for very large processor arrays, where, with the above strategy, the problem on the coarsest grid remains very large, it may be advantageous to put up with the full utilization and coarsen the grid below the numbers of processors.

The interpolation operator is illustrated on the right in Fig. 6. It results from piecewise linear interpolation and is of second order with respect to h. For restriction, we take the weighted restriction operator corresponding to the adjoint of the interpolation operator, shown on the left in Fig. 6. We remark that the seemingly natural and much easier to implement restriction operator, resulting from assigning each coarse-grid

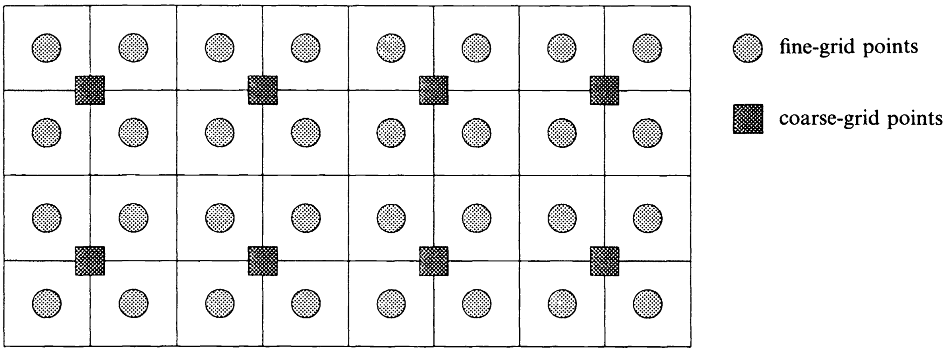

FIG. 5. *Grid coarsening.*

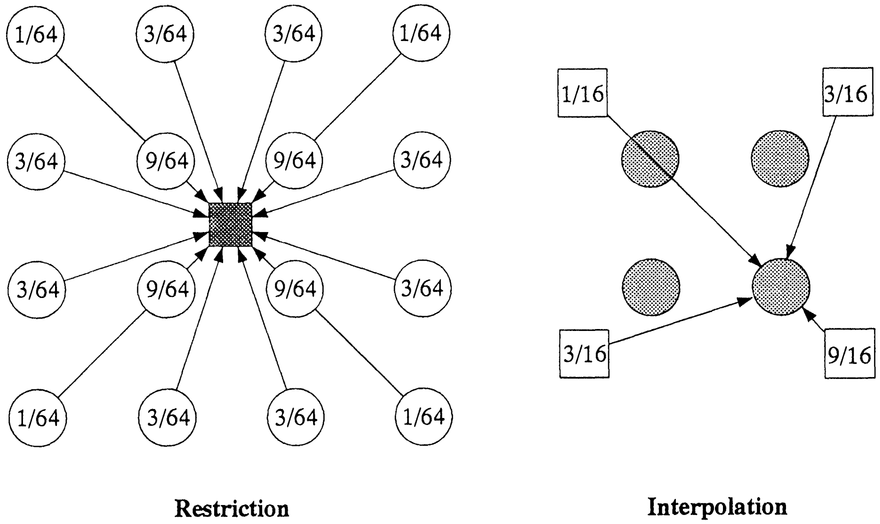

FIG. 6. *Second-order interpolation and corresponding weighted restriction.*

point the mean value of its four fine-grid neighbours, in connection with the corresponding piecewise constant first-order interpolation, would not be accurate enough to solve our second-order problems [17].

For the movement through the different grid levels, we use the standard V-cycle approach with a fixed number of presmoothing and postsmoothing steps [6]. The coarse-grid matrices are chosen according to the discretization on the respective grids. The solution on the coarsest grid is approximated by means of some steps of a PCG method. We found that the reduction in the required number of V-cycles when solving more exactly on the coarsest grid is too small to compensate for the additional work.

In order to obtain an efficient algorithm for a parallel computer, the crucial point for both PCG methods and MG methods is the choice of the iterative method (12). The parallelization of the other components of the methods, with the considered data mapping, is straightforward. Unfortunately, basic iterative methods that are very attractive with respect to their preconditioning or smoothing properties (for example, the powerful incomplete factorization methods [12], [16]) are inherently recursive and, therefore, not amenable to an efficient parallelization. It seems that a compromise between parallelism and convergence properties, which takes into account the type of problem and the available hardware, must be found.

The simple choice

$$\mathbf{Q}=\omega\mathbf{M}_D, \qquad 0<\omega\leqq 1,$$

where $\mathbf{M}_D$ denotes the diagonal matrix corresponding to the main diagonal of $\mathbf{M}$, results in the damped Jacobi (DJAC) method [6]. When used as a preconditioner, $\omega=1$ should be taken, and when used as a smoothing iteration, $\omega=0.5$ is a suitable choice. DJAC can be viewed as an ideally parallelizable algorithm. The degree of parallelism is equal to the number of grid points independent of the numbering of the unknowns.

As an improvement of DJAC, we consider here a parallel version of the Gauss-Seidel method, which can be described in the setting of multicolored basic iterative methods as discussed in Adams [1]. We choose a coloring that is induced by the number of processors and the problem size, as opposed to, for instance, the well-known red/black coloring [19], which is induced by the finite-difference discretization. The coloring strategy is as follows: all cells in the same subregion obtain a different color and all subregions are colored identically. Therefore, $k_r \times k_z$ colors are required, and the number of unknowns corresponding to the same color is equal to the number of processors. Numbering the unknowns color by color in the usual lexicographical way gives $\mathbf{M}$ a block structure such that each of the $k_r \times k_z$ diagonal blocks is a diagonal matrix, whose size equals the number of processors. As an example, Fig. 4 illustrates the multicolor numbering for an 8×4 grid and a 2×2 processor array.

With the usual splitting $\mathbf{M}=\mathbf{M}_L+\mathbf{M}_D+\mathbf{M}_U$ of $\mathbf{M}$ into the lower diagonal part $\mathbf{M}_L$, the diagonal part $\mathbf{M}_D$, and the upper diagonal part $\mathbf{M}_U$, the MCGS method is defined by

$$\mathbf{Q}=\mathbf{M}_D+\mathbf{M}_L.$$

The method is easy to implement and it is optimal concerning the utilization of the processor array. Since all points of the same color can be updated simultaneously, the degree of parallelism is equal to the number of processors. Concerning the convergence properties, the method lies somewhere between the Jacobi method and the lexicographical Gauss-Seidel method, depending on the number of subdomains (see [19, Ch. 4, Thm. 5.8]). If the processor array has the same size as the cell grid ($k_r=k_z=$ 1 color), the method is equivalent to the Jacobi method, and if we only have one processor ($k_r \times k_z = N_r \times N_z$ colors), it is equivalent to the lexicographical Gauss-Seidel method.

For use as a preconditioner, we also consider the symmetric variant (SMCGS) of the method, which is defined by

$$\mathbf{Q}=(\mathbf{M}_D+\mathbf{M}_U)\mathbf{M}_D^{-1}(\mathbf{M}_D+\mathbf{M}_L).$$

Using SMCGS, some symmetry properties of $\mathbf{M}$ carry over to $\mathbf{P}$, e.g., a symmetric positive definite $\mathbf{M}$ yields a symmetric positive definite $\mathbf{P}$, as is required when preconditioning the CG algorithm.

Concerning the data communication among the processors, we remark that only the summations in the innerproducts of the CG methods and the computations of some norm for checking the convergence require global communication. For all other components of the algorithms discussed above, only local communication is required. In § 8 we give a numerical comparison of the considered methods.

6. Test problems and implementation considerations. Our test problems are derived from a model of Czochralski crystal growth proposed in [18] as a benchmark problem. The (nondimensional) configuration consists of a rotating vertical cylindrical crucible of radius $r=1$ filled with a melt to a height $z=1$. The melt is bounded above by a rotating coaxial crystal of radius $r=0.4$. Concerning the boundary conditions the following assumptions are made:

- The surface of the melt between the crystal and the crucible is flat and free of shear stress with a linear temperature distribution from the crystal to the crucible wall;
- The crystal is isothermal with temperature $T=0$ and rotates with an angular velocity $v=g(t)$;
- The crucible rotates with an angular velocity $v=-g(t)/4$, the crucible wall is heated with a temperature $T=f(t)$ and the crucible base is a perfect insulator.

This leads us to the following set of boundary conditions:

$$\begin{aligned}
&u=w=0, \quad v=-g(t)/4, \quad T=f(t) \quad \text{for } r=1, \quad 0\leqq z\leqq 1,\\
&u=w=0, \quad v=-rg(t)/4, \quad T_z=0 \quad \text{for } 0\leqq r\leqq 1, \quad z=0,\\
&u_z=v_z=w=0, \quad T=(5r-2)f(t)/3 \quad \text{for } 0.4\leqq r\leqq 1, \quad z=1,\\
&u=w=T=0, \quad v=rg(t) \quad \text{for } 0\leqq r\leqq 0.4, \quad z=1.
\end{aligned}$$

The initial conditions are taken to be $u_0=w_0=v_0=T_0=0$.

Varying the Rayleigh number Ra and the functions f and g, this model allows us to investigate the numerical behaviour of the considered algorithms for the most relevant aspects of our flow problem: time-dependent thermal convection, time-dependent forced convection, and Hopf bifurcated oscillatory convection. We fix the Prandtl number to $Pr=0.05$, which is in the range of the values for semiconductor and metal melts (e.g., silicon, mercury, etc.).

The array processor that we use for our computations is an AMT DAP 510, which consists of a mesh-connected array of $P_x\times P_y=32\times 32$ single-bit processors working in SIMD mode (see, e.g., [10] for a detailed description of the hardware). The total memory size of the machine is 4 MBytes and the clock rate is 10 MHz. For the computations, we use 48-Bit arithmetic. In order to allow a classification of the performance, we remark that we can solve our test problems on the DAP 510 about 35 times faster than on a SUN 3/50 and about 1.2 times faster than on a CYBER 955.

For the space discretization, we use a uniform mesh with a grid spacing

$$h=\frac{1}{32k}, \qquad k=1,2,\cdots,$$

which results in a number of $N_r\times N_z=kP_x\times kP_y$ cells. Following the mapping strategy discussed in § 3 (see Fig. 4), we divide the cell grid in 32×32 subregions, and each processor obtains the data for the $k\times k$ cells contained in each subregion. We remark that the memory size of the DAP 510 only allows for calculations up to $k=4$. The mesh size of the coarsest grid in the multigrid methods is $h=1/32$. For all computations the stopping criterion for the linear system solvers is chosen to be

$$\frac{\|y^{k-1}-y^k\|_\infty}{\|y^k\|_\infty}<10^{-5},$$

where y^{k-1} and y^k are two consecutive iterates and $\|\cdot\|_\infty$ denotes the maximum norm. For the presentation of the results we introduce the stream function ψ, defined by

$$u=\psi_z/r, \qquad w=-\psi_r/r,$$

and $\psi=0$ on the boundary.

7. Comparison of discretization schemes. In the first instance, we study the convergence behaviour of the considered algorithms with respect to time. For this we consider our test problem in the time interval [0, 1] with the data sets

$$f(t)=\sin(\pi t/2),\quad g(t)=0,\quad Ra=500,$$

which results in a pure thermal convection flow driven by the temperature gradient between the crystal and the crucible wall, and

$$f(t)=0,\quad g(t)=10\sin(\pi t/2),\quad Ra=500,$$

which yields a pure forced convection flow driven by the rotation of the crucible and the crystal.

We want to compare the IE scheme and the CN scheme. For the number of iteration steps in the SI algorithm we consider the cases $m=1$, denoted by IE1 and CN1, and m according to (9) with the maximum norm and $\varepsilon=10^{-5}$, denoted by IE* and CN*. We fix the grid spacing to $h=1/64$.

In order to obtain reference values we first run CN* with the very small timestep $\Delta t=1/1000$. Next we compute the solution with IE1, IE*, CN1, and CN* for $\Delta t=1/10$, $1/20, 1/40, \cdots$. Figure 7 shows the results for the thermal convection problem. On the left-hand side plots of the relative errors of the maximum norms of the stream function ψ at $t=1$ as against the number of timesteps are shown, and on the right-hand side the relative errors are plotted against the required computing times. The corresponding results for the forced convection problem are shown in Fig. 8.

From the results we can conclude:

- As can be expected, due to the higher order, with the CN schemes the same accuracy can be reached faster, as with the corresponding IE schemes.

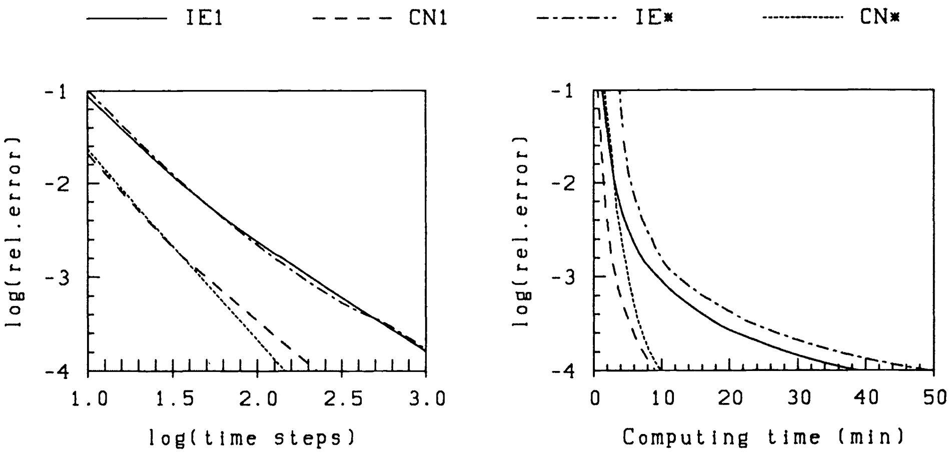

FIG. 7. *Convergence behaviour with respect to time for* IE1, IE*, CN1, *and* CN* *for the thermal convection problem.*

- For both problems the convergence behaviour of IE1 and IE* does not differ very much. Looking at the errors obtained with more than 100 timesteps, the linear convergence rate predicted by the theory can be observed for both schemes. Since one timestep with IE* takes longer than with IE1, it is not useful to choose $m>1$.

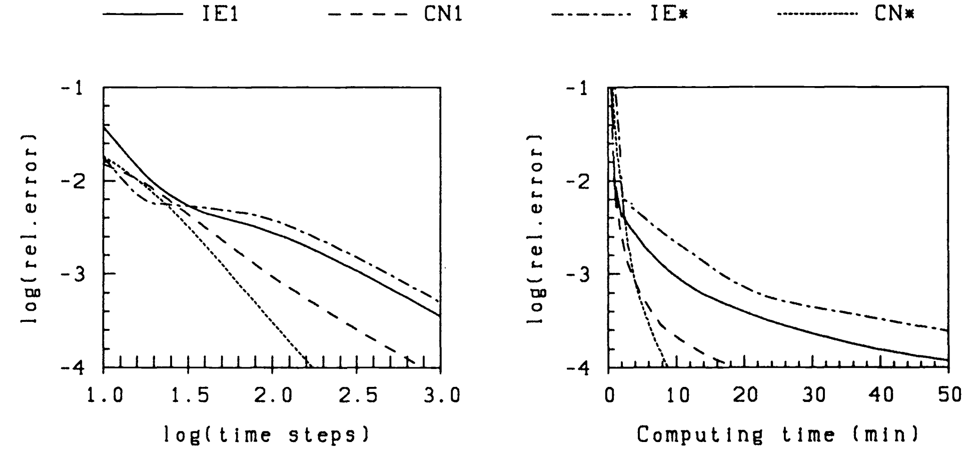

FIG. 8. *Convergence behaviour with respect to time for* IE1, IE*, CN1, *and* CN* *for the forced convection problem.*

- For both problems, CN* shows the quadratic convergence behaviour predicted by the theory for the Crank-Nicolson scheme. For the CN1 scheme the convergence order deteriorates with decreasing Δt. Due to the subdiagonal element $\mathbf{B}_h(\tilde{v}_h^n)$ in the matrix $\mathbf{K}_h(\tilde{x}_h^n)$ this effect is stronger for the forced convection problem. In this case, in order to improve the accuracy, it is preferable to choose $m > 1$ rather than a smaller Δt.

Now we investigate the behaviour of the IE and CN schemes when used for a high Rayleigh number problem having a Hopf bifurcated time-periodic solution. We consider our test problem in the time interval $[0, 0.4]$ with the data

$$f(t) = 1, \quad g(t) = 0, \quad Ra = 750{,}000.$$

We only present results for IE1 and CN1, because the schemes with variable m show the same behaviour. Figure 9 shows the variation of the maximal radial velocity with time obtained with the IE1 scheme using different values of Δt and h.

Let us first discuss the nature of the flow. Looking at the diagram for $\Delta t = 0.00005$ and $h = 1/128$, yielding the most accurate solution, we can see that after a startup phase with irregular oscillations, which is due to the incompatibility of the boundary conditions and the initial conditions (the initial temperature does not satisfy the boundary conditions on the crucible wall), the flow becomes periodic.

Now we turn to the numerical behaviour of the IE1 scheme. If Δt is chosen too large we do not find the periodic time dependency in the solution. Looking at the diagrams for $h = 1/128$, we see that with increasing Δt, the amplitude of the oscillations becomes smaller and smaller and finally disappears, such that we get a stationary solution corresponding to some mean value of the amplitude. For $h = 1/64$ this effect, which is due to the strong damping properties of the IE scheme, can also be observed.

If h is chosen too small we also get a stationary solution. Looking at the diagrams for $\Delta t = 0.00005$ we can see that by increasing h the amplitude of the oscillations decrease and disappear for $h = 1/32$. In this case, the stationary values for the maximal radial velocity are far away from the values for smaller h (observe the different scale in the diagrams for $h = 1/32$). This is because of spatial oscillations (also called wiggles) due to drastic changes of the solution in boundary layers at the rigid boundaries [4]. The oscillations can be suppressed by choosing a smaller h (the oscillations are no

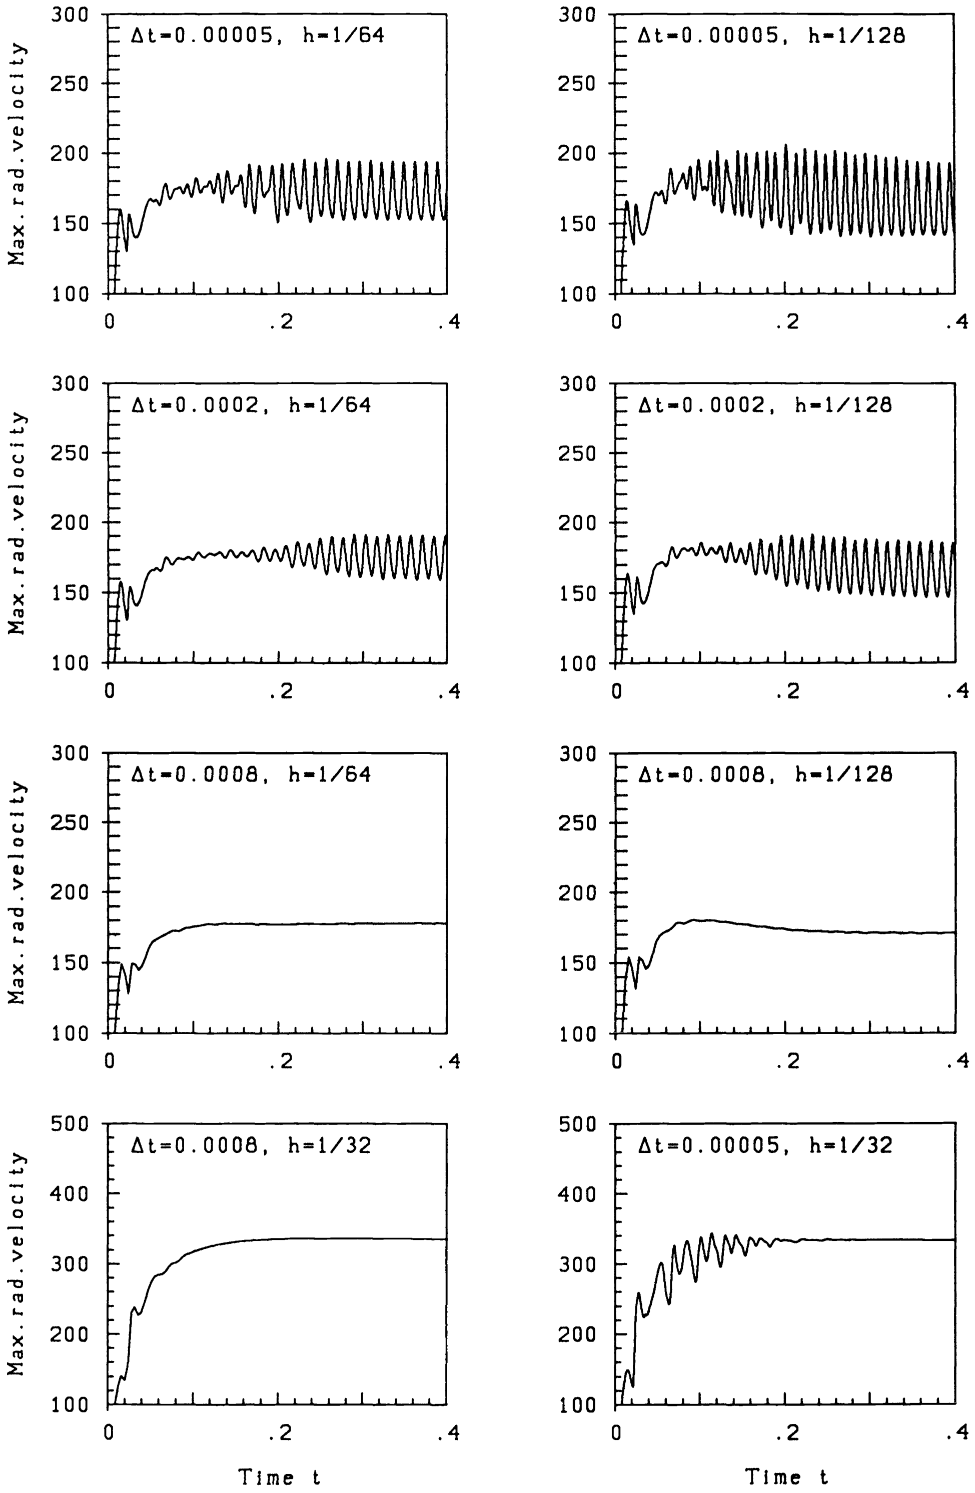

FIG. 9. *Maximal radial velocity versus time for the* IE1 *scheme with various* Δt *and* h.

longer apparent for $h=1/64$), a local refinement near the boundaries would be sufficient, or by choosing upwind differences for the first-order derivatives in the convective terms.

We were not able to compute a reasonable solution with the CN1 scheme. We tried stepsizes down to $\Delta t=0.000025$ and $h=1/128$ (due to the limited memory size, a smaller h is not possible on our DAP 510). As an example, Fig. 10 shows the maximal radial velocity as against time computed with $\Delta t=0.0001$ and $h=1/128$. For other values of Δt and h, we obtain similar results or, as in some cases, the program even terminates with an arithmetic overflow. While in the startup phase, the results are comparable to those for the IE1 scheme; they become chaotic when the flow enters the periodic phase. This effect seems to be due to the fact that the damping property of the CN scheme deteriorates for high-frequency components of permanently acting rough disturbances [4]. As suggested in [9], a damping by means of replacing some CN steps by IE steps or by shifting the CN scheme slightly to the implicit side may save the situation, but we have not yet investigated these techniques.

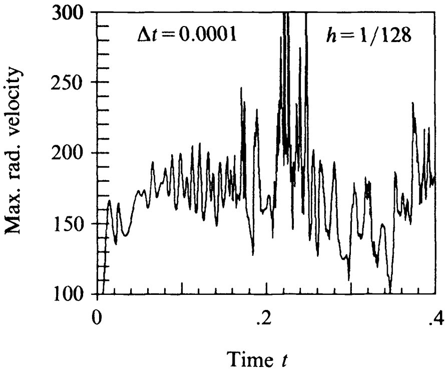

FIG. 10. *Maximal radial velocity versus time for the* CN1 *scheme with* $\Delta t=0.0001$ *and* $h=1/128$.

8. Comparison of linear system solvers. For a comparison of the sparse linear system solvers discussed in § 5, we consider the mixed convection problem in the time interval [0, 1] resulting with the data

$$f(t)=\sin(\pi t/2),\quad g(t)=10\sin(\pi t/2),\quad Ra=500.$$

We discretize with the CN1 algorithm and fix $\Delta t=1/80$.

MG-MCGS1	387	352	1.3	2.4
MG-MCGS2	370	330	1.4	2.9

First we study the convergence behaviour of the PCG and MG methods with varying h. The methods are applied to the symmetric positive definite systems (7) arising in the timestepping process. Table 1 shows the results for the PCG methods. Indicated are the numbers of iterations and the computing times required to solve all 80 systems for $h = 1/32, 1/64, 1/128$ with the different preconditionings. The corresponding results for the MG method for $1/64, 1/128$ ($h = 1/32$ corresponds to the coarsest grid), and the different smoothing methods are given in Table 2. Concerning the notation, CG-BIs denotes the CG method preconditioned with s steps of the basic iterative (BI) method. MG-BIs denotes the MG method with s BI presmoothing steps. We note that for $h = 1/32$, the basic iterative methods DJACs and MCGSs, as well as the methods DJAC2s and SMCGSs, are equivalent. Several conclusions can be drawn from the results:

- All PCG methods are considerably faster than the unpreconditioned CG method. The saving of computational work due to the fewer iterations is much larger than the additional work due to the preconditionings.
- Only a small number of basic iterative method steps for preconditioning is efficient. The optimal value is $s = 2$ for the DJAC preconditioning and $s = 1$ for the SMCGS preconditioning. The reduction in the number of iterations when using larger values of s is too small to compensate for the additional work due to the larger number of basic iterative method steps.
- In agreement with theoretical results in [1], the DJAC preconditioning for odd $s > 1$ is not as efficient as for even s (CG-DJAC3 needs more iterations than CG-DJAC2).
- The SMCGS preconditioning is more efficient than the JAC preconditioning. For all h, CG-SMCGS1 is the fastest PCG method.
- The MG methods are more efficient than the PCG methods. The smaller h is, the more superior the MG method becomes.
- Using only one presmoothing step and one postsmoothing step is sufficient. The reduction in the number of iterations when using more steps is not large enough to compensate for the additional work.
- The MCGS smoothing is more efficient than the DJAC smoothing. The superiority grows with decreasing h. For all h, MG-MCGS1 is the fastest method.

Finally, we investigate the performance of the preconditioned CGS methods. We use the methods for the solution of the nonsymmetric systems arising during the timestepping process for our test problem. The numbers of iterations and the computing times for solving the 320 systems are given in Table 3 for the different preconditionings.

The results are very similar to those for the PCG method in the symmetric positive definite case. The reduction of the computing time by the preconditionings is larger in the nonsymmetric case. For instance, for $h = 1/128$ the ratio of the computing time

TABLE 3
Numbers of iterations and timings for PCGS *methods with* $h = 1/32, 1/64, 1/128$.

	Iterations			Computing time (min)		
Method	h = 1/32	h = 1/64	h = 1/128	h = 1/32	h = 1/64	h = 1/128
CGS	9869	18291	33295	1.7	10.8	75.9
CGS-DJAC1	2831	4848	8581	0.6	3.2	21.7
CGS-DJAC2	1606	2615	4494	0.4	2.9	19.3
CGS-DJAC3	1744	3355	6020	0.7	5.2	36.6
CGS-DJAC4	1274	2005	3396	0.7	4.0	26.6
CGS-SMCGS1	1606	2383	3698	0.4	2.6	16.7
CGS-SMCGS2	1274	1811	2797	0.7	3.4	21.2

for CGS to those for CGS-SMCGS1 amounts to 4.5, while the ratio is only 2.3 for CG and CG-SMCGS1.

9. Conclusion. We have presented a highly parallel algorithm for the numerical solution of time-dependent nonisothermal flow problems. If the driving forces of the flow are not too large, the proposed method with the Crank-Nicolson discretization is well suited to solving the type of problems considered here on SIMD array processors. If the driving forces become larger, the arising stability problems can be resolved by the use of the implicit Euler discretization. For the solution of the sparse linear systems occurring during the algorithm it was shown that already for relatively small problem sizes, MG methods are superior to PCG methods. For the involved basic iterative methods the multicolor block Gauss-Seidel method is preferable to the simple Jacobi method.

STOCHASTIC BREAKTHROUGH TIME ANALYSIS OF AN ENHANCED OIL RECOVERY PROCESS*

HANS PETTER LANGTANGEN†

Abstract. Input data to mathematical models for petroleum reservoir flow are commonly subjected to a significant degree of uncertainty. In this paper, input data, such as porosity, absolute and relative permeabilities, and adsorption functions, are treated as stochastic quantities in a one-dimensional polymer flooding model. Tools from structural reliability theory are used to solve the governing stochastic partial differential equations. The statistics of the time T to water breakthrough in the production well are studied. In particular, the sensitivity of T to the input quantities are reported. Correlations between the input variables seem to have a considerable effect on their relative importance.

Key words. stochastic differential equations, polymer flooding, reliability methods, sensitivity analysis

1. Introduction. The input data to many mathematical models are subjected to significant uncertainty and may thereby cause unreliable simulation results. This is especially the case for the standard continuum models of multiphase/multicomponent porous media flow which are of particular importance in the petroleum recovery industry. Important decisions are made on the basis of results from mathematical models, and it is often desired to have measures of uncertainties available. The simplest approach to gaining insight into how input data uncertainties affect the solution is to carry out a deterministic sensitivity analysis [13]. Each input parameter is given a prescribed perturbation, expressing an "uncertainty," and the resulting perturbation of the output data is found by solving the equations entering the mathematical model. This approach has some deficiencies. The perturbation in input, reflecting some kind of uncertainty, is difficult to estimate. Often the perturbation corresponds to a statistical quantity such as one standard deviation. When using a deterministic model, the resulting perturbation in output can seldom be given any statistical significance. Another deficiency of deterministic sensitivity analysis is related to the fact that correlations between the input data cannot be taken into account. Changing one input parameter without changing others, according to some underlying physical structure among the input variables, may be unphysical. In practice, the relationship among input variables is seldom completely known, and covariances, which can be measured from physical experiments alone, may be an attractive way to represent such relationships. In order to incorporate information on correlations and to consistently compute statistics of the output data of a model, given input data statistics, one should use a *stochastic* mathematical model of the physical process.

In this paper, we are concerned with a stochastic flow model for a rather complicated oil recovery process where accurate measurements of the input data are almost impossible to obtain. Input data are modeled in terms of stochastic variables, or fields, and the governing stochastic partial differential equations are solved to produce statistics of an interesting output parameter in the model. Although there are very important applications for stochastic reservoir flow models, the major part of industrial reservoir simulations is based on deterministic analysis. In recent years,

statistical methods for describing reservoir geometry and reservoir parameters have emerged (see, e.g., [9]). Activity in the solution of flow models with stochastic input is also evolving [6], [17], [14], [18].

Also, in a stochastic simulator there are input data to the code that are subjected to uncertainties. These input data are usually associated with parameters entering statistical distributions, such as mean and standard deviation values. This paper is especially concerned with the sensitivity of the output parameters to perturbations in input parameters that enter the distributions.

The particular physical problem to be treated here is one-dimensional displacement of oil by an injected mixture of water and polymer. This is a widely used enhanced oil recovery (EOR) process. We study the output data in terms of the time to water breakthrough in the production well. The breakthrough time is an important parameter to petroleum engineers and decision makers. Moreover, it is also closely related to the total oil production until breakthrough. The mathematical model consists of a system of three, coupled, nonlinear, time-dependent partial differential equations. Uncertain input quantities, such as porosity, absolute and relative permeablity, and adsorption effects, are modeled as stochastic variables. The resulting stochastic partial differential equations must then be solved to find the statistics of the desired output quantities. Variants of Monte-Carlo simulation techniques are presently dominating for solving stochastic partial differential equations and applications to reservoir simulation can be found in [6] and [14]. In this paper, we employ an alternative approach by adapting methods from probabilistic structural analysis. The particular method to be used is the *first-order reliability method* (FORM). FORM analysis of finite-element discretized continua is emerging [12], and a feasibility study of possible applications to reservoir simulation has been performed [17]. The main reason for using FORM to solve stochastic differential equations is that it is efficient for the present type of problem, and that it gives sensitivity measures on how parameters in the distributions, like expectations and standard deviations, influence the statistical results. A general discussion of Monte-Carlo simulation and analytically based reliability methods, such as FORM, is given by Bjerager [5]. Contrary to most work on stochastic reservoir flow models, we do not focus on absolute permeability heterogeneities, but instead on the interplay between stochastic representations of many of the physical input parameters.

In §2, we present the governing partial differential equations. Section 3 discusses the FORM application to the present problem. Applications to porous media flow appear in §4. A short summary with conclusions is given in §5.

2. The governing equations. Polymer flooding is an EOR technique where a mixture of water and polymer is injected into the reservoir to displace oil. The appearance of the polymer causes the viscosity ratio between the injected and displaced fluid phases to decrease and hence enhance the recovery process [7]. The mathematical model for polymer flooding is based on the continuum mechanical equations for multiphase/multicomponent porous media flow. In the present case, we consider the flow of an oil phase and an aqueous phase in a porous medium. The phases are considered to be immiscible and incompressible. The aqueous phase consists of water and a polymer component which is totally miscible in water. Let $S(x,t)$ be the saturation of the aqueous phase, where x is the spatial coordinate and t denotes time. Only unidirectional flow is considered. Moreover, let $C(x,t)$ be the concentration of the polymer component in the aqueous phase. We may derive a system of partial differential equations governing S and C by applying Darcy's law and the principle of mass conservation. Neglecting capillary pressure effects results in the following equations

$$\phi\frac{\partial S}{\partial t}+v\frac{\partial F}{\partial x}=0, \tag{1}$$

$$\frac{\partial}{\partial t}\left[\phi SC+(1-\phi)A\right]+v\frac{\partial}{\partial x}\left[CF\right]=0, \tag{2}$$

where $0 < x < L$ and $t > 0$. We expect water to be injected in $x = 0$ (injection well) and oil to be produced in $x = L$ (production well). Moreover, we have v as the total Darcy filtration velocity (independent of x) and ϕ as the porosity. Furthermore, F is the fractional flow function [16] which depends on S and C. Adsorption of the polymer on the rock is modeled by the function A that depends on C. The two equations above determine S and C when v is known. This is the case if the velocity is controlled in the injection well. To model the influence of the absolute permeability adequately, we prescribe a pressure difference between the injection and production well. Then v will depend on the time-dependent pressure field P, which is governed by

$$\frac{\partial}{\partial x}\left(H\frac{\partial P}{\partial x}\right)=0. \tag{3}$$

We have $v = -H\partial P/\partial x$, where H is a function of S and C.

The fractional flow function has the form

$$F=\frac{k_{rw}}{k_{rw}+\mu k_{ro}}, \tag{4}$$

where k_{rw} and k_{ro} are the relative permeability of the aqueous and oil phases, respectively. Here $\mu = \mu_a/\mu_o$, where μ_a and μ_o are the viscosities of the aqueous and oil phases, respectively. Gravity effects are excluded in this paper. The viscosity of the aqueous phase depends on the polymer concentrations. In this work, we have used a linear relation between μ_a/μ_o and the concentration C (cf. Johansen, Tveito, and Winther [10], and the references therein):

$$\mu=\nu+\zeta\cdot 100C,$$

with $\nu = \mu_w/\mu_o$, where μ_w is the water viscosity.

The relative permeability curves have been written on the form

$$k_{rw}(S) = K_{wm}\left[\frac{S-S_{wr}}{1-S_{or}-S_{wr}}\right]^a, \tag{5}$$

$$k_{ro}(S) = K_{om}\left[\frac{1-S-S_{or}}{1-S_{wr}-S_{or}}\right]^b. \tag{6}$$

In these formulas K_{wm} and K_{om} are maximum values of k_{rw} and k_{ro}, respectively, S_{wr} is the irreducible saturation of the aqueous phase, and S_{or} is the irreducible oil saturation. The function H, which enters the pressure equation (3), has the form

$$H=\hat{K}\left(\frac{k_{rw}}{\mu_a}+\frac{k_{ro}}{\mu_o}\right).$$

Here $\hat{K}$ is the absolute permeability. However, it is convenient to define a characteristic absolute permeability κ, and to introduce $K = \hat{K}/\kappa$. Hereafter this K is referred to as the absolute permeability. The adsorption function is assumed to have the Langmuir form [2]

$$A = \frac{\xi \cdot 100C}{1 + \eta \cdot 100C},$$

where ξ and η are empirically determined constants.

As initial and boundary conditions for the equations (1), (2), and (3) we have used

$$\begin{aligned} S(x,0) &= S_{wr}, \\ S(0,t) &= 1 - S^0_{or}, \\ C(x,0) &= 0, \\ C(0,t) &= \begin{cases} \Lambda, & t < t_s, \\ 0, & t \geq t_s, \end{cases} \\ P(0,t) &= \Delta P, \\ P(L,t) &= 0, \end{aligned}$$

where S^0_{or} denotes S_{or} at $x = 0$. Only pressure differences, and not the pressure level, influence incompressible flow. The injection concentration Λ is usually small, typically $\Lambda = 0.01$.

If $S_{wr} = 0$, we can characterize the solution as follows. Without adsorption there is one shock in C, say, at $x = x_s$. C equals the constant Λ behind the shock, provided $t_s > t$. For $t_s < t$, the C profile becomes plug formed. With adsorption there are two shocks in S, one at $x = x_s$ and one for $x > x_s$. More details and examples can be found in [10]. Observe that the well-known Buckley–Leverett problem [16] is a special case of the polymer model where either C is constant or $\zeta = 0$.

In the stochastic analysis we need to solve the above inital-boundary value problem for a deterministic set of physical input parameters. This can generally only be accomplished by numerical methods. The elliptic pressure equation (3) is solved by a central finite-difference method. A first-order Godunov scheme is used for the two hyperbolic conservation laws (1) and (2). All equations are solved on a uniformly partitioned grid with N grid points. Let Δt be the timestep length and let Δx be the length of the intervals in the spatial grid. The stability condition for the Godunov scheme reads [10]

$$\Delta t \leq \Delta x \min_{0 \leq x \leq L} \left(\frac{\phi}{v \left| \frac{\partial F}{\partial S} \right|}, \frac{\phi}{v\xi} \right).$$

In each simulation we have chosen Δt as large as possible according to this stability criterion. The choice of Δx is discussed in §4.5.

The present numerical scheme leads to rather diffusive solutions for C, and the C shock usually extends over eight to ten intervals. If there is only a single shock in S, our scheme resolves this shock quite satisfactorily, that is, over about two grid intervals. When there are two shocks in S, the shock that has the same position as the shock in C is dispersed over eight to ten intervals. The shock in the front of the saturation profile is ordinarily resolved over a couple of grid intervals.

The output parameter to be studied in this paper is the time T to water breakthrough in the production well. For the present system of hyperbolic equations and boundary conditions, T can be defined mathematically as

$$T = \inf\{t : S(L,t) > S(L,0)\}.$$

This criterion is, of course, sensitive to the truncation error of the numerical method. However, the front shock in S is usually resolved over about two grid intervals and with a sufficiently small Δx, the errors can be made insignificant for the cases treated in this paper (see §4.5). If the numerical solution is guaranteed to be monotone, a more robust criterion is to let T equal the arrival time of the "rightmost" local minimum of $\partial S/\partial x$ at $x = L$. Numerical experiments showed that the differences between the two criteria are less than 1 percent for the numerical method and the parameter values of interest in this paper.

3. Stochastic analysis. Recently developed methods from structural reliability [15] will be employed for solving the the equations (1), (2), and (3) for S, C, and P, $0 < x < L$ and $0 < t \leq T$ when some of the input variables like ϕ, K, k_{rw}, and k_{ro} are modeled as stochastic quantities. Structural reliability methods have the advantage over sampling techniques (of the Monte-Carlo type) in that sensitivity of probabilities to variations in parameters in both the flow model and the input distributions are cheaply computed. In the problems studied herein reliability methods are also considerably more efficient than Monte-Carlo simulation. Reliability methods generally give accurate results when the computed probabilities are small. As we show below, it is likely that reliability methods may be accurate over the whole range of probabilities in the present reservoir flow problems.

Viewing the input data as a collection of real numbers, we choose r of these numbers to be modeled as stochastic variables. The stochastic variables are denoted by $\mathbf{X} \in \mathbf{R}^r$, $\mathbf{X} = (X_1, \cdots, X_r)^T$, and called *basic variables*. Given statistical information about $\mathbf{X}$ we want to establish statistics of the output parameter T. For this purpose FORM is used.

The next section reviews some of the basic theory. We also introduce notation and definitions and describe how the present problem can be formulated for FORM analysis.

Let $\mathbf{X} = (X_1, \cdots, X_r)^T$ be a vector of basic variables. We are interested in computing the probability of the event $\Pr\{g(\mathbf{X}) \leq 0\}$, where $g(\mathbf{X})$ is a *limit state function*. Let $\Omega \in \mathbf{R}^r$ be the set of points where $g \leq 0$ (the *failure domain*). Clearly, the probability can be computed as

$$\Pr\{g(\mathbf{X}) \leq 0\} = \int_\Omega f_{\mathbf{X}}(\mathbf{x}) d\mathbf{x}, \tag{7}$$

where $f_{\mathbf{X}}(\mathbf{x})$ is the joint probability density of the vector $\mathbf{X}$. We define the limit state function as $g = T - T_\omega$, giving $\Pr\{g \leq 0\} = \Pr\{T \leq T_\omega\}$, where $T_\omega = \omega\tilde{T}$. $\tilde{T}$ is the deterministic value of T when E[$\mathbf{X}$] is used as input to the governing equations (1), (2), and (3). Note that T must be computed by solving the differential equations from §2. There are two problems with using (7). First, it may be difficult to establish the joint density, and second, the evaluation of the integral, for example by quadrature rules, becomes very expensive even for moderate values of r. The first problem may be solved to some extent by using methods such as those in [11], discussed below. The second problem can be treated by FORM analysis.

In general, it is extremely difficult to assign a joint density to input variables in reservoir simulation. At most, we can hope to establish marginal distributions for each basic variable and perhaps some correlation coefficients. Let $\Theta_{X_i}(x_i)$ be the marginal distribution function of X_i. The associated density $d\Theta_{X_i}/dx_i$ is denoted by $\theta_{X_i}(x_i)$. If $\mathrm{Cov}[\cdot,\cdot]$ is the covariance operator and $\mathrm{D}[\cdot]$ is the standard deviation operator, the correlation coefficient is

$$\varrho(X_i, X_j) = \frac{\mathrm{Cov}[X_i, X_j]}{\mathrm{D}[X_i]\mathrm{D}[X_j]}.$$

The correlation matrix $\mathbf{R}$ is then $\{\mathbf{R}\}_{ij} = \varrho(X_i, X_j)$. The method used herein restricts the statistical information about the basic variables to only include Θ_{X_i}, $i = 1, \cdots, r$, and $\mathbf{R}$. We refer to [11] for extensions to cases where some or all joint distributions are prescribed.

3.1. FORM approximations to probabilities. Let $\langle \mathbf{x}^1, \mathbf{x}^2 \rangle$ be the Euclidian inner product of $\mathbf{x}^1, \mathbf{x}^2 \in \mathbf{R}^r$, and let $||\mathbf{x}^1|| = \sqrt{\langle \mathbf{x}^1, \mathbf{x}^1 \rangle}$ be the corresponding norm. In the case where the *failure surface*, defined by $g(\mathbf{X}) = 0$, is a hyperplane, and $f_{\mathbf{X}}(\mathbf{x})$ is a standardized, multivariate normal density,

$$f_{\mathbf{X}}(\mathbf{x}) = \frac{1}{(2\pi)^{r/2}} \exp\left(-\frac{1}{2}||\mathbf{x}||^2\right),$$

the integral in (7) can be calculated analytically:

$$\int_{\Omega} f_{\mathbf{X}}(\mathbf{x}) d\mathbf{x} = \Phi(-\beta). \tag{8}$$

Here Φ is the cumulative, univariate, standardized, normal distribution function, and β is the distance between $\mathbf{X} = \mathbf{0}$ and the (linear) failure surface $g = 0$. Let $\mathbf{x}^*$ be the point on $g = 0$ which is closest to the origin ($\mathbf{x}^*$ is called the *design point*). Then $\beta = ||\mathbf{x}^*||$.

To formulate a first-order reliability method, we consider a mapping $\mathbf{X} \rightarrow \mathbf{Z} \rightarrow \mathbf{Y}$, such that $\mathbf{Y} = (Y_1, \cdots, Y_r)^T$ is a vector of statistically independent, normally distributed variables with mean zero and unit variance. If the failure surface is linear in the $\mathbf{Y}$-space, the result (8) gives

$$\Pr\{g \leq 0\} = \Phi(-\beta), \qquad \beta = ||\mathbf{y}^*||, \tag{9}$$

with $\mathbf{y}^*$ as the design point in the $\mathbf{Y}$-space. In the general case where the failure surface is nonlinear, (9) holds approximately, i.e., $\Pr\{g \leq 0\} \approx \Phi(-\beta)$, provided the curvature of the surface at $\mathbf{y} = \mathbf{y}^*$ is small. FORM refers to this approximate method of calculating $\Pr\{g \leq 0\}$.

3.2. Transformation of the basic variables. In $\mathbf{Z}$-space the variables are assumed to be jointly normally distributed with correlation matrix $\mathbf{R}_0$, zero mean, and unit standard deviation. The mapping $\mathbf{Z} \rightarrow \mathbf{Y}$ will therefore be a linear transformation $\mathbf{Y} = \mathbf{L}_0^{-1}\mathbf{Z}$. $\mathbf{L}_0$ is here the lower triangular Cholesky decomposition of $\mathbf{R}_0$: $\mathbf{R}_0 = \mathbf{L}_0\mathbf{L}_0^T$. The mapping $\mathbf{X} \rightarrow \mathbf{Z}$ is given by

$$\Phi(z_i) = \Theta_{X_i}(x_i), \qquad i = 1, \cdots, r. \tag{10}$$

In addition, the $\mathbf{R}$ matrix must be transformed into $\mathbf{R}_0$. This may be done approximately by empirically based formulas (see [11]) for a wide range of distributions

Θ_{X_i}. However, we are exclusively concerned with normally or lognormally distributed variables in **X**-space. In this case, the transformation (10) and the formulas for transforming **R** to $\mathbf{R}_0$ can be simplified and made exact. Let $\{\mathbf{R}_0\}_{ij} = \varrho(Z_i, Z_j)$. If X_i is normally distributed with mean $\mathrm{E}[X_i]$ and standard deviation $\mathrm{D}[X_i]$, we have

$$Z_i = \frac{X_i - \mathrm{E}[X_i]}{\mathrm{D}[X_i]}.$$

If both X_i and X_j are normal variables, $\varrho(Z_i, Z_j) = \varrho(X_i, X_j)$. For a lognormally distributed variable X_i, the transformation (10) simplifies to

$$Z_i = \frac{\ln X_i - \mathrm{E}[\ln X_i]}{\mathrm{D}[\ln X_i]},$$

with

$$\mathrm{E}[\ln X_i] = \ln \mathrm{E}[X_i] - \frac{1}{2}\ln\left[\left(\frac{\mathrm{D}[X_i]}{\mathrm{E}[X_i]}\right)^2 + 1\right],$$

$$\mathrm{D}[X_i] = \sqrt{\ln\left[\left(\frac{\mathrm{D}[X_i]}{\mathrm{E}[X_i]}\right)^2 + 1\right]}.$$

Moreover, $\varrho(Z_i, Z_j) = \lambda\varrho(X_i, X_j)$, where

$$\lambda = \frac{\ln(1 + \varrho(X_i, X_j)\delta_i\delta_j)}{\varrho(X_i, X_j)\sqrt{\ln(1 + \delta_i^2)\ln(1 + \delta_j^2)}}, \tag{11}$$

when both X_i and X_j are lognormally distributed. The coefficient of variation, δ_i, is defined as

$$\delta_i = \frac{\mathrm{D}[X_i]}{\mathrm{E}[X_i]}.$$

If X_i is normally distributed and X_j is lognormally distributed, we have

$$\lambda = \frac{\delta_j}{\sqrt{\ln(1 + \delta_j^2)}}. \tag{12}$$

The formulas (11) and (12) are exact. We note that the joint normal distribution of **Z** is, of course, an assumption and implies a certain joint density of **X**. This joint density is generally different from the exact joint density which is unknown, but the two densities have the same correlation matrix **R**. The basic assumption is that the distribution is characterized to a large extent by second-order statistics. Note that uncorrelated basic variables imply stochastically independent variables when we use the transformation **X** → **Z** described above.

3.3. Determination of the design point. Let $g_y(\mathbf{y})$ be the limit state function in **Y**-space. The design point $\mathbf{y}^*$ is the solution of the constrained minimization problem

$$\mathbf{y}^* = \min_{g_y=0} ||\mathbf{y}||.$$

There are generally several local minima of the distance to the failure surface. The computation of a local minimum is carried out by a standard procedure [11]. In this work, we iterate in $\mathbf{X}$-space and linearize the transformation $\mathbf{X} \to \mathbf{Y}$ in each iteration. Define the vector $\widehat{\mathbf{M}} = (\hat{\mu}_1, \cdots, \hat{\mu}_r)^T$ and the matrix $\widehat{\mathbf{D}} = \operatorname{diag}(\hat{\sigma}_i, \cdots, \hat{\sigma}_r)$. Given an initial guess $\mathbf{x}^0 = (x_1^0, \cdots, x_r^0)^T$ for the design point in $\mathbf{X}$-space, we iterate for $\ell = 0, 1, \cdots$ as follows:

$$\hat{\sigma}_i^\ell = \frac{\varphi\left\{\Phi^{-1}\left[\Theta_{X_i}(x_i^\ell)\right]\right\}}{\theta_{X_i}(x_i^\ell)}, \qquad i = 1, \cdots, r, \tag{13}$$

$$\hat{\mu}_i^\ell = x_i^\ell - \hat{\sigma}_i^\ell \Phi^{-1}\left[\Theta_{X_i}(x_i^\ell)\right], \qquad i = 1, \cdots, r, \tag{14}$$

$$\mathbf{Q}^\ell = \widehat{\mathbf{D}}^\ell \mathbf{R}_0 \widehat{\mathbf{D}}^\ell, \tag{15}$$

$$\mathbf{x}^{\ell+1} = \widehat{\mathbf{M}}^\ell + \frac{\left\langle \mathbf{x}^\ell - \widehat{\mathbf{M}}^\ell, \nabla_x g(\mathbf{x}^\ell)\right\rangle - g(\mathbf{x}^\ell)}{\langle \nabla_x g(\mathbf{x}^\ell), \mathbf{Q}^\ell \nabla_x g(\mathbf{x}^\ell)\rangle} \mathbf{Q}^\ell \nabla_x g(\mathbf{x}^\ell), \tag{16}$$

$$\mathbf{y}^{\ell+1} = \mathbf{L}_0^{-1}\left[\widehat{\mathbf{D}}^\ell\right]^{-1}\left(\mathbf{x}^{\ell+1} - \widehat{\mathbf{M}}^\ell\right), \tag{17}$$

$$\beta^{\ell+1} = \sqrt{\langle \mathbf{y}^{\ell+1}, \mathbf{y}^{\ell+1}\rangle}. \tag{18}$$

In these equations, ∇_x is the gradient operator in $\mathbf{X}$-space, that is,

$$\nabla_x = \left(\frac{\partial}{\partial x_1}, \cdots, \frac{\partial}{\partial x_r}\right)^T.$$

φ denotes the univariate normal density function with zero mean and unit variance. Equation (17) shows that $\widehat{\mathbf{M}}$ and $\widehat{\mathbf{D}}$ can be interpreted as the instantaneous, or equivalent, means and standard deviations of $\mathbf{X}$. In fact, when $\mathbf{X}$ are jointly normally distributed, $\widehat{\mathbf{M}}$ and $\widehat{\mathbf{D}}$ contain the means and standard deviations, respectively. Since the value of g is a result of a numerical solution of partial differential equations, the gradient $\nabla_x g$ of g with respect to the basic variables must be computed numerically. In each iteration the algorithm above therefore requires $r+1$ evaluations of $g = T - T_\omega$. The iteration is stopped when $|\beta^{\ell+1} - \beta^\ell| \leq \epsilon_\beta$, where, for our purposes, $\epsilon_\beta = 0.01$ suffices. Having found β, we utilize the approximation

$$\Pr\{g(\mathbf{X}) \leq 0\} \approx \begin{cases} \Phi(-\beta), & g(\mathbf{x}^*) > 0, \\ \Phi(\beta), & g(\mathbf{x}^*) \leq 0. \end{cases}$$

We note that if $\mathbf{X}$ is jointly normally distributed, β coincides with the Hasofer–Lind reliability index [15].

3.4. Sensitivity measures. One of the attractive features of FORM is that we can compute sensitivity coefficients very efficiently. Let the transformation $\mathbf{X} \to \mathbf{Y}$ be denoted by $\mathbf{Y} = \mathbf{T}(\mathbf{X}; \mathrm{E}[\mathbf{X}], \mathrm{D}[\mathbf{X}])$. Then we have

$$\frac{\partial \beta}{\partial \mathrm{E}[\mathbf{X}]} = \frac{1}{\beta}\left\langle \mathbf{y}^*, \frac{\partial}{\partial \mathrm{E}[\mathbf{X}]}\mathbf{T}(\mathbf{x}^*; \mathrm{E}[\mathbf{X}], \mathrm{D}[\mathbf{X}])\right\rangle \tag{19}$$

and

$$\frac{\partial \beta}{\partial \mathrm{D}[\mathbf{X}]} = \frac{1}{\beta}\left\langle \mathbf{y}^*, \frac{\partial}{\partial \mathrm{D}[\mathbf{X}]}\mathbf{T}(\mathbf{x}^*; \mathrm{E}[\mathbf{X}], \mathrm{D}[\mathbf{X}])\right\rangle. \tag{20}$$

The limit state function may contain a set of parameters $\mathbf{r}$ besides the basic variables $\mathbf{X}$: $g = g(\mathbf{X}; \mathbf{r})$. In our case, $\mathbf{r}$ may be input variables that are not treated stochastically. It can be shown that

$$\frac{\partial \beta}{\partial \mathbf{r}} = \frac{\frac{\partial}{\partial \mathbf{r}} g(\mathbf{x}^*; \mathbf{r})}{\sqrt{\langle \nabla_x g(\mathbf{x}^*), \mathbf{Q}^* \nabla_x g(\mathbf{x}^*)\rangle}}, \tag{21}$$

where $\mathbf{Q}^*$ is the value of $\mathbf{Q}$ in the last iteration. Strictly speaking, the sensitivity coefficients above are approximately correct and approach the exact coefficients as $\beta \to \infty$. It is important to remark that the gradients of g with respect to limit state function parameters or distribution parameters must be determined numerically in our application. In practice, we are often interested in the sensitivity of $\Pr\{T \leq T_\omega\}$ to distribution or limit state function parameters. Such quantities are obtained straightforwardly:

$$\Upsilon_E \equiv \frac{\partial}{\partial \mathrm{E}[\mathbf{X}]}\Pr\{T \leq T_\omega\} = \varphi(\beta)\frac{\partial \beta}{\partial \mathrm{E}[\mathbf{X}]},$$

$$\Upsilon_D \equiv \frac{\partial}{\partial \mathrm{D}[\mathbf{X}]}\Pr\{T \leq T_\omega\} = \varphi(\beta)\frac{\partial \beta}{\partial \mathrm{D}[\mathbf{X}]},$$

$$\Upsilon_R \equiv \frac{\partial}{\partial \mathbf{r}}\Pr\{T \leq T_\omega\} = \varphi(\beta)\frac{\partial \beta}{\partial \mathbf{r}}.$$

Define the unit vector $\boldsymbol{\alpha} = (\alpha_1, \cdots, \alpha_r)^T$ as $\boldsymbol{\alpha} = \mathbf{y}^*/\beta$. The quantities $\alpha_1^2, \cdots, \alpha_r^2$ are termed *importance factors*, and since $\sum_{i=1}^r \alpha_i^2 = 1$, α_i^2 reflects the relative importance of $\mathbf{X}_i$ in determining β or $\Pr\{g \leq 0\}$.

Omission sensitivity factors reflect the error in β when one of the basic variables X_i is treated as a constant with value equal to, say, the median $\bar{m}_i$ of X_i. Generally, we have

$$\gamma_i \equiv \frac{1}{\sqrt{1-\alpha_i^2}} \to \frac{\beta(X_i = \bar{m}_i)}{\beta}, \qquad \alpha_i^2 \to 0. \tag{22}$$

Thus, when γ_i is close to unity, the variable X_i contributes little to β (or $\Pr\{g \leq 0\}$) and may be omitted from the stochastic analysis and instead replaced by its median value.

4. Results. In this section, we first present the exact analytical solution of a simplified oil recovery model. Then, some general considerations on the numerical search algorithm from §3 are reported. We discuss which of the input parameters in the problem should be modeled as stochastic variables and present a justification of the chosen values of statistical and physical parameters. A quantification of the numerical discretization errors is also given. Furthermore, we discuss the quality of the FORM approximations in the present application. Finally, the numerical method is applied to the hydrocarbon recovery model and the results are reported and discussed.

4.1. Analytical solution of a simplified model. With normally distributed variables and a linear limit state function g, $\Phi^{-1}(\beta)$ is the exact probability $\Pr\{T \leq T_\omega\}$. In this case, the numerical search algorithm converges to the exact solution in a single step. Let $\widehat{\mathbf{M}} = \mathrm{E}[\mathbf{X}]$, let $\widehat{\mathbf{D}} = \mathrm{diag}(\mathrm{D}[X_1], \cdots, \mathrm{D}[X_r])$, and let $\mathbf{R}_0$ be the correlation coefficient matrix. The exact FORM solution is then obtained by

$$\mathbf{Q} = \widehat{\mathbf{D}}\mathbf{R}_0\widehat{\mathbf{D}}, \tag{23}$$

$$\mathbf{x}^* = \widehat{\mathbf{M}} + \frac{\left\langle \mathbf{x}^0 - \widehat{\mathbf{M}}, \nabla_x g \right\rangle - g(\mathbf{x}^0)}{\langle \nabla_x g, \mathbf{Q}\nabla_x g\rangle} \mathbf{Q}\nabla_x g, \tag{24}$$

$$\mathbf{y}^* = \mathbf{L}_0^{-1} \left[\widehat{\mathbf{D}}\right]^{-1} \left(\mathbf{x}^* - \widehat{\mathbf{M}}\right), \tag{25}$$

$$\beta^* = \sqrt{\langle \mathbf{y}^*, \mathbf{y}^* \rangle}. \tag{26}$$

It is trivial to show that

$$\left\langle \mathbf{x}^0 - \widehat{\mathbf{M}}, \nabla_x g \right\rangle = g(\mathbf{x}^0) - \mathrm{E}[g].$$

Let us introduce the constant χ by

$$\chi = -\frac{\mathrm{E}[g]}{\langle \nabla_x g, \mathbf{Q}\nabla_x g\rangle}.$$

We then have

$$\mathbf{y}^* = \chi \mathbf{L}_0^T \widehat{\mathbf{D}} \nabla_x g.$$

The present polymer flooding model generally gives rise to nonlinear limit state functions. However, with a particular choice of the input parameters, it is possible to obtain a g that is linear in the basic variables. Let $\nu = 1$, $\zeta = 0$, $S_{wr} = S_{or} = 0$, $K_{wm} = K_{om} = 1$, and $a = b = 1$. Then the pressure field is constant throughout the spatial domain and the saturation fulfills the initial-boundary value problem

$$\phi S_t + cKS_x = 0, \quad S(x,0) = 0, \quad 0 < x < L, \quad S(0,t) = 1, \tag{27}$$

where c is a constant that depends on the pressure gradient κ and the viscosities. The general solution of this linear equation is

$$S(x,t) = 1 - \tilde{H}\left(x - \frac{cK}{\phi}t\right),$$

where $\tilde{H}(\cdot)$ is the Heaviside function. The corresponding breakthrough time becomes

$$T = \frac{\phi L}{cK}.$$

Assume that the porosity and the permeability are the only stochastic variables ($X_1 = \phi$, $X_2 = K$) and that both variables are normally distributed. Then the deterministic breakthrough time reads

$$\tilde{T} = \frac{\mathrm{E}[\phi]L}{\mathrm{E}[K]c}.$$

The limit state function has previously been defined as $g = T - T_\omega$, $T_\omega = \omega\tilde{T}$. Since only the failure surface $g = 0$ has any statistical significance, we may write $g = KT - K\omega\tilde{T}$ or

$$g(\phi, K) = \mathrm{E}[\phi]\frac{L}{c}\left(\frac{\phi}{\mathrm{E}[\phi]} - \omega\frac{K}{\mathrm{E}[K]}\right).$$

By introduction of the coefficients of variation $\delta_\phi = \mathrm{D}[\phi]/\mathrm{E}[\phi]$ and $\delta_K = \mathrm{D}[K]/\mathrm{E}[K]$, we achieve

$$\hat{\mathbf{D}}\nabla_x g = \mathrm{E}[\phi]\frac{L}{c}(\delta_\phi, -\omega\delta_K)^T.$$

The correlation coefficient matrix is written as

$$\mathbf{R} = \mathbf{R}_0 = \begin{pmatrix} 1 & \varrho \\ \varrho & 1 \end{pmatrix},$$

with lower triangular Cholesky factor

$$\mathbf{L}_0 = \begin{pmatrix} 1 & 0 \\ \varrho & \sqrt{1-\varrho^2} \end{pmatrix}.$$

This gives

$$\mathbf{y}^* = \tilde{\chi}\begin{pmatrix} \delta_\phi - \varrho\omega\delta_K \\ -\sqrt{1-\varrho^2}\omega\delta_K \end{pmatrix}, \tag{28}$$

where $\tilde{\chi} = \chi L\mathrm{E}[\phi]/c$.

Let us study the ratio of the importance factors

$$\frac{\alpha_1^2}{\alpha_2^2} = \left(\frac{1-\varrho\omega\hat{\delta}}{\sqrt{1-\varrho^2}\omega\hat{\delta}}\right)^2, \tag{29}$$

where $\hat{\delta} = \delta_K/\delta_\phi$. Without correlation and with $\delta_\phi = \delta_K$, the relative importance of ϕ vs. K depends on ω^{-2}. For small probabilities, ϕ is most important, while for probabilities close to 1, K is the dominating stochastic variable. It is obvious from the formula that the introduction of a correlation coefficient has significant influence on the relative importance of ϕ and K.

Although the physical and statistical simplifications that were required in this analytical model are highly questionable, the simple formula (29) gives valuable insight into the dynamics of a stochastic porous media flow model.

4.2. Performance of the search algorithm. When the partial differential equations are discretized, T can only be determined as $m\Delta t$, m being an integer. Numerical computations of limit state function derivatives, e.g.,

$$\frac{\partial g}{\partial x_1} \approx \frac{1}{\epsilon}[g(x_1+\epsilon, x_2, \cdots, x_r) - g(x_1, \cdots, x_r)],$$

may then result in a zero derivative if ϵ is so small that $g(x_1+\epsilon, x_2, \cdots, x_r) - g(x_1, \cdots, x_r) \leq \Delta t$. Even if ϵ is large enough to prevent vanishing derivatives, convergence problems of the search algorithm may occur. Of course, the value of ϵ when computing $\partial g/\partial x_i$ depends on the magnitude of x_i. We have scaled all basic variables such that their magnitudes are of order unity. In this work, we have obtained good results with $\epsilon = 0.1$ for all basic variables.

It is required that the entries in $\mathbf{R}$ must be chosen such that $\mathbf{R}_0$ becomes positive definite; for example, correlation coefficients $\varrho(X_i, X_j)$ close to ± 1 must be avoided, as these may result in $|\varrho(Z_i, Z_j)| > 1$. If a high correlation (e.g., $\varrho(X_i, X_j) \geq 0.7$) is assigned for many of the basic variables, convergence problems of the algorithm (13)–(18) may occur.

In general, the convergence rate of the search algorithm depends on ω. Usually, the algorithm requires about three iterations to converge. For ω values corresponding to very small probabilities or to probabilities close to 1, the convergence may be slower. When using FORM, convergence problems can sometimes be avoided by applying $\log g$ as limit state function instead of g. Such an approach was tested but not found necessary in the present study.

4.3. The choice of stochastic variables. Of the parameters entering the fractional flow function, it is physically reasonable to assume that ν and ζ can be treated as known constants with negligible uncertainty. On the contrary, ϕ, K_{wm}, K_{om}, S_{wr}, S_{or}, a, b, K, ξ, and η represent rock, or fluid–rock mixture, properties with a possibly significant inherent uncertainty. A deterministic sensitivity analysis of the present problem [13] indicated little sensitivity of T to perturbations in ξ and η. These two parameters are hence treated deterministically while the other parameters are represented by stochastic variables. If the reservoir is considered homogeneous, only one stochastic variable is needed to represent a stochastic physical parameter. However, in the general heterogeneous case, the physical parameters should be modeled as stochastic fields and then discretized to vectors of stochastic variables. The numerical examples in this section are limited to homogeneous reservoirs. We thus exclude the important effects of fine-scale permeability heterogeneity. The present model is therefore relevant when either the fine-scale permeability heterogeneities are negligible, or when some averaging procedures have been applied to approximate heterogeneity effects by an uncertain constant permeability value.

4.4. Statistical and physical parameters. The values of the rock parameters throughout the homogeneous reservoir are modeled by stochastic variables. The basic variables in the problem are defined as

$$X_1 = \phi, \quad X_2 = a, \quad X_3 = b, \quad X_4 = S_{wr},$$

$$X_5 = S_{or}, \quad X_6 = K_{wm}, \quad X_7 = K_{om}, \quad X_8 = K.$$

Adsorption parameters are taken as $\xi = 0.25$ and $\eta = 1.0$. Moreover, $\zeta = 2$ unless otherwise stated. In all calculations, we have used $L = 1000$ m, $\kappa = 10^{-11}$ m^2,

$\Lambda = 0.01$, $\nu = (\mu_w/\mu_o) = \frac{1}{4}$, and $\Delta P = 50$ GPa. Polymer is injected during the whole simulation ($t_s > T$).

In accordance with common practice, the porosity is assumed to be normally distributed, whereas the absolute permeability is assigned a lognormal distribution. The other basic variables can attain positive values only; some of them are also restricted to certain intervals, for example, $0 < K_{wm}, K_{om} \leq 1$ and $0 \leq S_{wr}+S_{or} \leq 1$. Due to lack of better knowledge, we let all variables except the porosity be lognormally distributed.

In order to achieve reliable conclusions regarding the present recovery process, the values of expectations, standard deviations, and correlations must be physically relevant. As an aid for evaluating the physical relevance of expectation and coefficient of variation values, we introduce an interval I_p^i for X_i such that $\Pr\{X_i \in I_p^i\} = p$. In Table 1 the intervals I_p^i, corresponding to a choice of $p = 0.997$, are listed for various values of δ_i. All values of $\mathrm{E}[X_i]$ and δ_i in Table 1 are considered physically relevant to the present displacement process; cf., for example, [1], [2], [3], [4], and [8].

TABLE 1
Relations between distribution parameters and intervals $I_{0.997}^i$, *where* $\Pr\{X_i \in I_{0.997}^i\} = 0.997$.

Quantity	Distribution	$\mathrm{E}[X_i]$	δ_i	$I_{0.997}^i$
ϕ	normal	0.2	1/10	[0.14, 0.26]
K	lognormal	1.0	1	[0.06, 8.60]
K	lognormal	1.0	1/2	[0.22, 3.69]
K	lognormal	1.0	1/10	[0.74, 1.34]
a, b	lognormal	2.0	1/10	[1.48, 2.68]
S_{wr}, S_{or}	lognormal	0.2	1/10	[0.15, 0.27]
K_{wm}, K_{om}	lognormal	0.6	1/10	[0.44, 0.81]
K_{wm}	lognormal	0.4	1/20	[0.34, 0.46]
K_{om}	lognormal	0.8	1/20	[0.69, 0.93]

Correlations among the basic variables do exist in the present problem, but numerical values of the correlation coefficients are difficult to assign. Lithologically similar samples show a linear relationship between porosity and the logarithm of the permeability [3], [1]. It is therefore widely accepted experimental evidence for setting $\varrho(\phi, \ln K)$ close to 1; here we use $\varrho(\phi, \ln K) = 0.8$. From both a numerical and a physical point of view, it may be interesting to investigate the impact of a stronger correlation between several of the basic variables, although the experimental data for such correlation coefficients are sparse. Based on a rough comparsion of different relative permeability curves in the literature, we make the assumption that increasing the curvature of k_{rw} is usually reflected in an increased curvature of k_{ro}. Moreover, a decrease in S_{wr} is assumed to be related to a decrease in S_{or}. This means that $\varrho(a, b) > 0$ and $\varrho(S_{or}, S_{wr}) > 0$. The latter two correlation coefficients are introduced in only one numerical example, since their physical relevance is not well documented. However, the results from such an example may reveal interesting features of the stochastic dynamics of the present flow model.

4.5. Numerical errors. It is important to identify which features of the results are due to numerical approximations and which are due to the mathematical model, that is, the physics in the problem. By running relevant examples on a sequence of grids with decreasing Δx, the sensitivity of the results to the discretization parameters can be demonstrated. We have chosen three test cases. In all cases, $\mathrm{E}[\phi] = \mathrm{E}[S_{wr}] = \mathrm{E}[S_{or}] = 0.2$, $\mathrm{E}[K_{wm}] = \mathrm{E}[K_{om}] = 0.6$, $\mathrm{E}[K] = 1$, and $\delta_i = 1/10$. Moreover, test cases

1 and 2 have E$[a]$ = E$[b] = 2$, while test case 3 has E$[a]$ = E$[b] = 1$. All basic variables are uncorrelated in test cases 1 and 3, while test case 2 has significant correlations: $\varrho(\phi, \ln K) = \varrho(S_{wr}, S_{or}) = \varrho(a, b) = 0.8$. The test cases are constructed to cover various expected numerical difficulties, such as strong correlations and linear relative permeability curves.

Table 2 presents the deterministic reference breakthrough time $\tilde{T}$ and the probability $\Pr\left\{T \leq 0.8\tilde{T}\right\}$ for $L/\Delta x = 40, 80, 160, 320$. It is seen that the errors in T are less than 3 percent for $L/\Delta x = 80$, while the errors in the probability are less than 1 percent. The variations of α_i^2 are not shown, but these were always less than 0.01. The fairly slow convergence of T as $\Delta x \to 0$ has little effect on the statistical results, since the latter is solely based on the failure surface $T = \omega\tilde{T}$. If the error δT in T is of the form $\delta T = pT$, the relative error p cancels in the expression for the failure surface.

Based on the results in Table 2 and our additional experience, the choice $L/\Delta x = 80$ seems to give sufficient accuracy. Variations of numerical parameters in the constrained optimization algorithm have less influence on the accuracy than Δx as long as these parameters are chosen as described in §§3 and 4.2.

TABLE 2

Variation of probabilities and deterministic breakthrough times with mesh partition, $p \equiv \Pr\{T \leq T_{0.8}\}$.

Test	$L/\Delta x = 40$		$L/\Delta x = 80$		$L/\Delta x = 160$		$L/\Delta x = 320$

4.6. Examples of failure surfaces in reservoir flow.

Recall that the accuracy of FORM depends on the curvature of the failure surface $g = 0$ at the design point in **Y**-space. If the failure surface is approximately linear, $\Phi(-\beta)$ will be a very good approximation to $\Pr\{g \leq 0\}$. There may frequently be many local minima of the distance to the failure surface, and the computation of the probabilities is then more complicated and expensive [15].

To gain insight into the quality of the FORM approximations in the present problem, we have plotted contour lines of the limit state function when there are only *two* basic variables. Deterministic input parameters or expected values of stochastic variables have the following values: $\phi = 0.2$, $K = 1.0$, $a = b = 2.0$, $K_{wm} = K_{om} = 0.6$, $S_{wr} = S_{or} = 0.2$, $\xi = 0.25$, $\eta = 1.0$, and $\zeta = 2$. In addition, we have used $\delta_i = 1/3$. A deterministic calculation gave $\tilde{T} = 1410$ days.

Figure 1 shows g as a function of a and b in **X**-space and as a function of transformed variables in **Y**-space. A lognormal distribution is assigned to a and b. The variables are uncorrelated. At this point it would be natural to introduce additional symbols to distinguish deterministic and stochastic quantities. However, with the widely used notation employed here for the input parameters, no simple rule (e.g., upper case stochastic variables, lower case deterministic variables) seems applicable. In Fig. 2 we have plotted g as a function of S_{wr} and S_{or}. These basic variables are lognormally distributed with correlation coefficient $\varrho(S_{wr}, S_{or}) = 0.5$. Fig. 3 visualizes g as a function of K_{wm} and K_{om}. These two basic variables are uncorrelated and lognormally distributed. Finally, in Fig. 4, g is plotted as a function of ϕ and

K, where $\varrho(\phi, \ln K) = 0.8$, and ϕ is normally distributed while K has a lognormal distribution function.

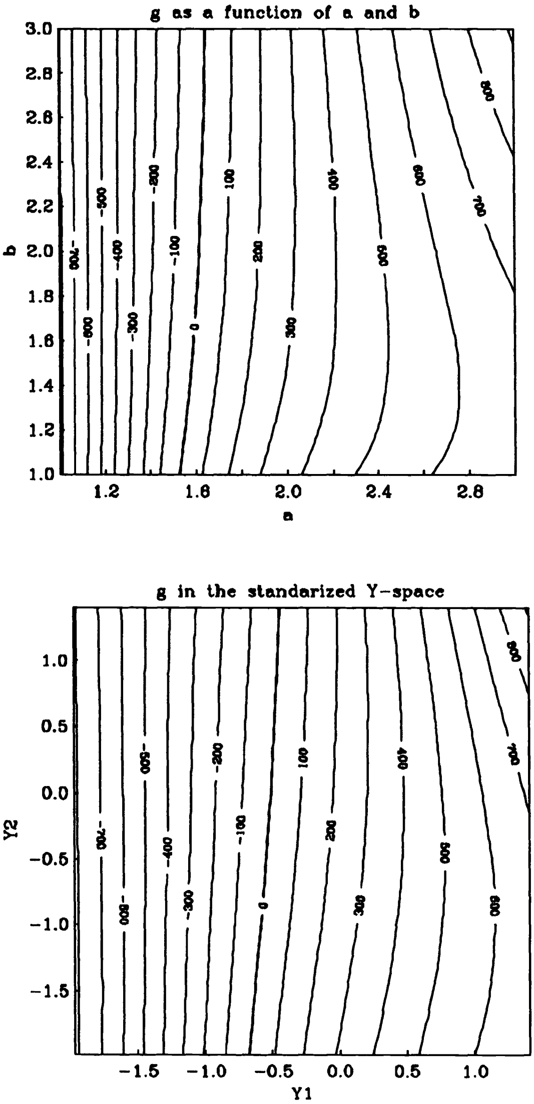

FIG. 1. *The limit state function $g = T - T_\omega$ as a function of $X_1 = a$ and $X_2 = b$ (top) and the corresponding transformed variables Y_1 and Y_2 (bottom). $\varrho(a, b) = 0$.*

The plots of $g(\mathbf{X})$ indicate how T varies with a, b, S_{wr}, S_{or}, K_{wm}, K_{om}, ϕ, and K, and can be of interest with respect to interpretation of the results from a deterministic simulator.

From the plot of g in $\mathbf{Y}$-space we see that the failure surfaces,which correspond to the contour lines of g, are approximately linear. This indicates satisfactory accuracy of FORM probabilities. We also see that there is not more than one local minimum

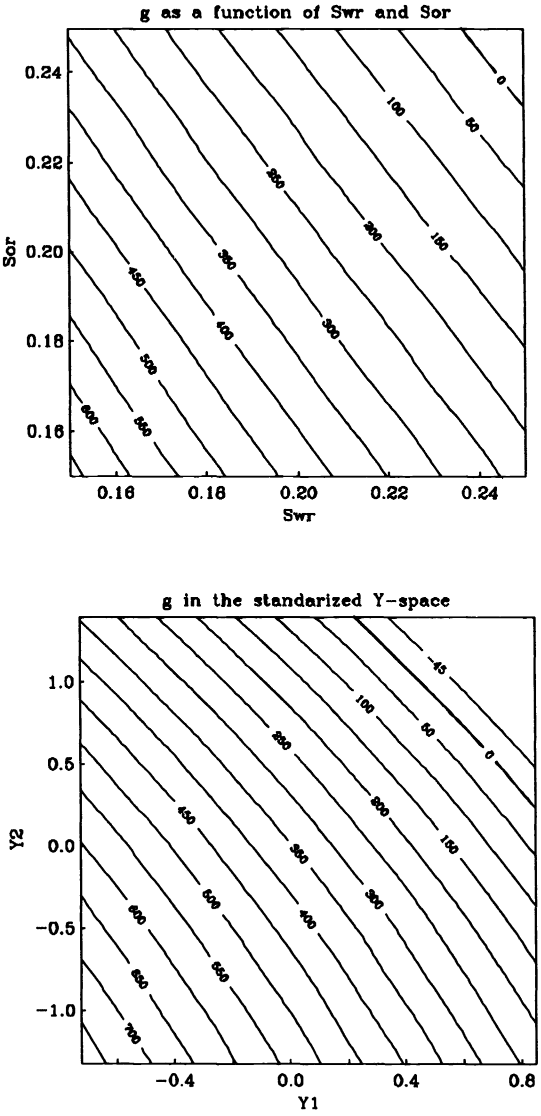

FIG. 2. *The limit state function $g = T - T_\omega$ as a function of $X_1 = S_{wr}$ and $X_2 = S_{or}$ (top) and the corresponding transformed variables Y_1 and Y_2 (bottom). $\varrho(S_{wr}, S_{or}) = 0$.*

of the distance to the failure surface, and that the formulas presented previously are, in this case, sufficient for calculating probabilities.

4.7. Stochastic polymer flooding. Some examples of FORM analysis applied to reservoir simulation are now given to indicate the potential of the proposed method. Most of the numerical examples are concerned with the computation of $\Pr\left\{T < 0.8\tilde{T}\right\}$, that is, the probability that the breakthrough time is underestimated by more than 20 percent when using a deterministic simulator. This probability is important for management decisions. We also give examples of complete probability

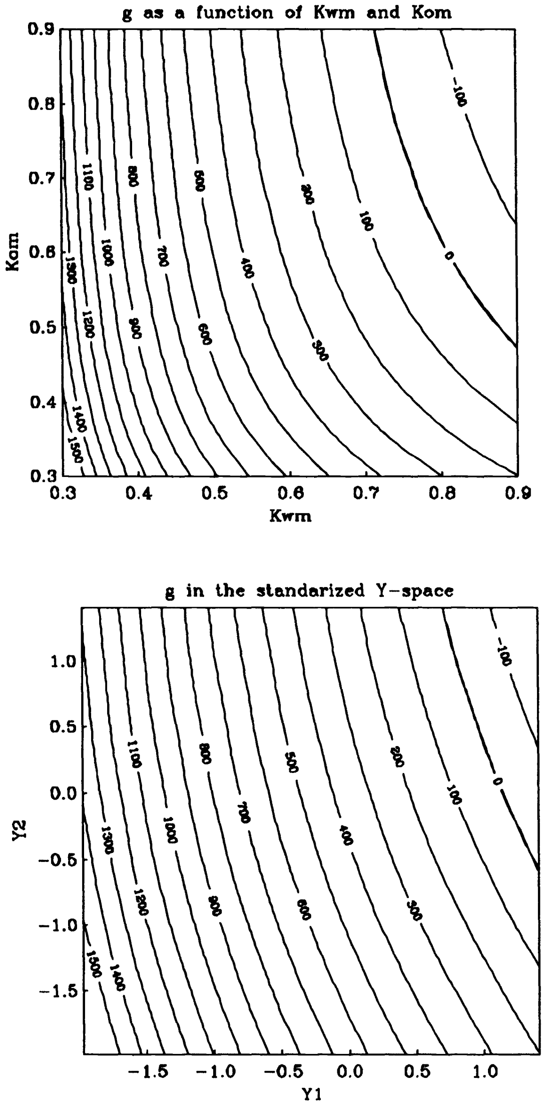

FIG. 3. *The limit state function $g = T - T_\omega$ as a function of $X_1 = K_{wm}$ and $X_2 = K_{om}$ (top) and the corresponding transformed variables Y_1 and Y_2 (bottom). $\varrho(K_{wm}, K_{om}) = 0$.*

distributions. All tables are written directly in the text processing format by the computer in order to minimize typing errors.

Selected results from the proposed stochastic model appear in Tables 3–9. Table 3 shows the statistical results for pure water flooding with uncorrelated basic variables. The corresponding polymer flooding problem gave the results presented in Table 4. There are minor differences in the statistical results. However, the deterministic breakthrough time is, as expected, significantly increased when polymer is injected. Imposing the physically relevant correlation coefficient $\varrho(\phi, \ln K) = 0.8$ on the problem

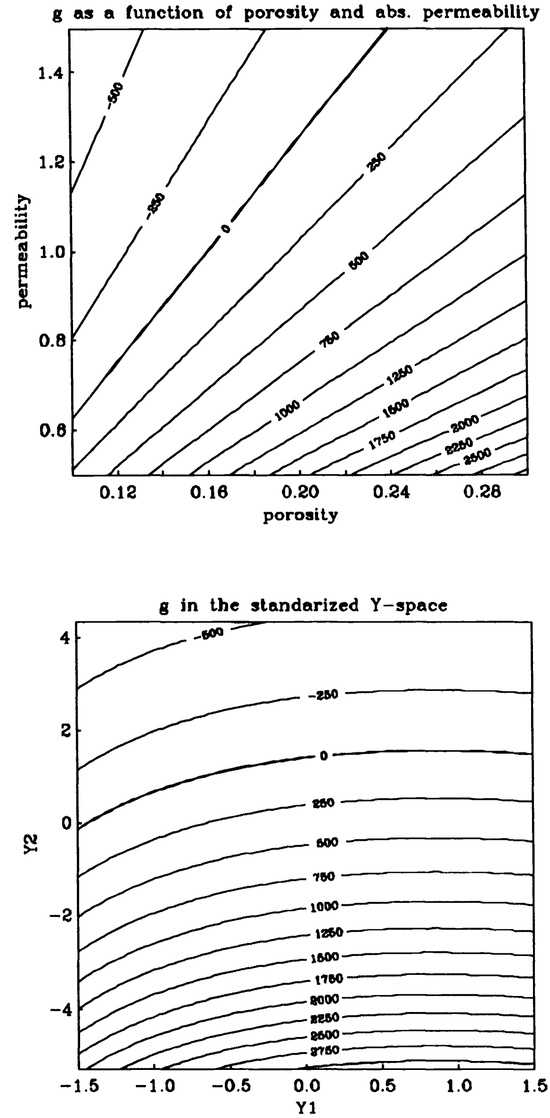

FIG. 4. *The limit state function $g = T - T_\omega$ as a function of $X_1 = \phi$ and $X_2 = K$ (top) and the corresponding transformed variables Y_1 and Y_2 (bottom). $\varrho(\phi, \ln K) = 0.8$.*

in Table 4 led to the results displayed in Table 5. Without correlations, ϕ has the largest importance factor. That is, ϕ is the input parameter that is most important to model as a stochastic variable. When ϕ and $\ln K$ are correlated, their importance factors decrease and become approximately equal, while the importance factor of S_{wr} increases significantly. It may be of interest to investigate the impact of additional correlations $\varrho(S_{wr}, S_{or}) = \varrho(a, b) = 0.8$. The corresponding results are presented in Table 6. In this case, S_{wr} is definitely the most important variable.

The coefficient of variations were fixed at 0.1 for ϕ, a, b, S_{wr}, S_{or}, and K in Tables 3–6. Although the associated standard deviations are physically reasonable for a ***homogeneous*** reservoir, it is interesting to investigate the effect of increasing the uncertainty in the absolute permeability. Table 7 corresponds to Table 4, with the exception that the coefficient of variation of the absolute permeability is five times larger in Table 7 than in Table 4. As expected, this leads to a larger importance factor of K. Less expected results arise, however, when the correlation $\varrho(\phi, \ln K) = 0.8$ is imposed (see Table 8). In this latter case ϕ is almost as important as K.

The stochastic analysis provides two different measures of input parameter importance: (1) the importance factor α_i^2, which reflects the importance of modeling a parameter as a random variable, and, (2) the Υ_E and Υ_D values, which give information about the parameters that are most important to measure accurately in laboratory experiments. It is seen from these tables that the sensitivity of $\Pr\{T \leq T_\omega\}$ to expectation values of the basic variables is significantly larger than the sensitivity to the standard deviations. We must also note that the degree of importance of a variable depends highly on the chosen importance measure: α_i^2, Υ_E, or Υ_D. For example, in the problem associated with the results in Table 7, K is the most important quantity to model as a stochastic variable, while ϕ has the most important expectation value. The sensitivity to expectation values is generally considerably less for K than for ϕ and S_{wr}.

A widely accepted assumption on the distribution functions is that ϕ follows a normal distribution while K is lognormally distributed. For the other basic variables, we have prescribed lognormal distributions, and it is therefore necessary to investigate the sensitivity of the results in the previous tables to variations in the type of distributions. If all the basic variables are assigned normal distribution functions in the physical problem associated with Table 5, we obtain the results shown in Table 9. It is evident that the particular choice of either normal or lognormal distributions has little influence on the results in this example. This observation increases the relevance of the analytical results obtained in §4.1, which required the permeability to be normally distributed.

The results in Tables 3–9 were restricted to the computations of $\Pr\{T \leq T_{0.8}\}$, i.e., $\omega = 0.8$. The sensitivity of the importance factors to variations in ω has also been investigated, and Table 10 displays an example of the extreme values of α_i^2 for ϕ and K when $\omega \in [0.5, 1.5]$. The physical problem corresponded to that in Tables 7 and 8. In contrast to the simplified analytical model in §3, ω has little impact on the relative ranking of the basic variables in the present example. Similar sensitivity studies of

Υ_E and Υ_D showed that the variation with ω was not significant. As $\omega \to 1$ (from both sides) Υ_E increased in absolute value for all basic variables. The variation of Υ_D with ω did not exhibit a regular pattern common to all X_i's.

The continuous variation of $\Pr\left\{T \le \omega\tilde{T}\right\}$ with ω is demonstrated by the cumulative distribution function of T in Fig. 5 with the corresponding density plotted in Fig. 6. The physical problem had expectation values as in Tables 3–9, while the coefficient of variation of *all* variables equaled 0.1. The effect of correlations on the computed probabilities is most pronounced in the tails of the distributions.

The importance measures in the tables indicate that only a few basic variables contribute significantly to the calculation of the probabilities. For example, b and K_{om} could be replaced by their median values with negligible effect on the statistical results. A natural way to reduce the number of basic variables, and hence increase the efficiency of the computations, is to omit basic variables for which γ_i are less than, say, 1.03 after the first iteration. We have tested this approach, but found that the iterative procedure converged more slowly, so that no overall increase in efficiency was achieved. However, after an initial study of a problem we can simply omit some basic variables completely (if $\gamma_i \approx 1$) from the description. This approach enhances the efficiency considerably.

It must be mentioned that increasing the coefficient of variation of the basic variables may give rise to results that deviate from those presented here. Particularly, if $\mathrm{D}[a]$ is increased, for example, to $\frac{2}{3}$, the importance of a increases considerably. This

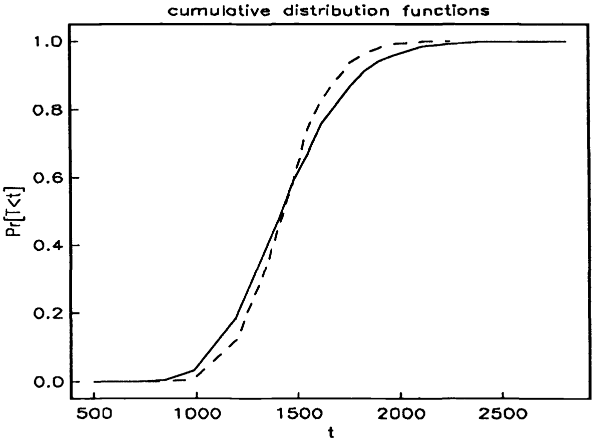

FIG. 5. *Probability distributions* $\Theta_T(t) = \Pr\{T \leq t\}$ *for the time* T *to water breakthrough. The solid line represents uncorrelated variables, while the dashed line represents correlated variables* $(\varrho(\phi, \ln K) = 0.8)$.

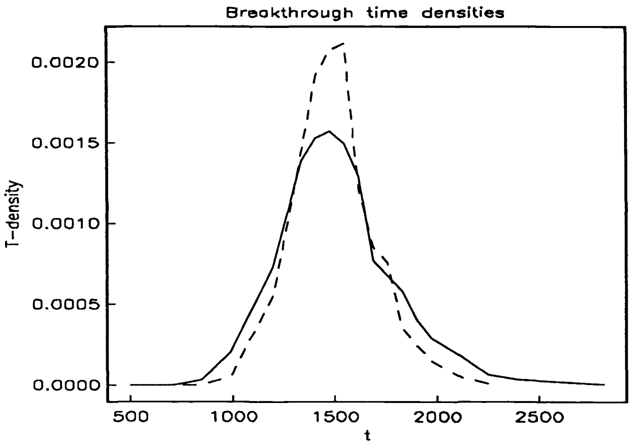

FIG. 6. *Probability densities corresponding to the distributions in Fig.* 5.

is probably because the breakthrough time is highly sensitive to variations in a when $a \sim 1$ [13] and, with $\mathrm{D}[a] = \frac{2}{3}$, a values in this regime have significant probabilities (e.g., $I^2_{0.997} = [0.72, 5.02]$).

5. Conclusion. The purpose of this paper has been to formulate and apply a one-dimensional mathematical model for polymer flooding where some of the geological input parameters were treated as stochastic variables. The time to water breakthrough in the production well constituted the investigated output parameter from the model. Using recently developed methods from structural reliability theory, the system of stochastic partial differential equations was solved as a sequence of the standard deterministic polymer flooding equations. Typically, about 30 deterministic problems must be solved to compute a point on the cumulative distribution curve for the breakthrough time in the present study. With only a few stochastic variables, the method is very efficient compared to Monte-Carlo simulation. An advantage of the method is the straightforward and efficient computation of the relative importance of stochastic variables and various input data, such as expectations and covariances. In one space dimension, the suggested numerical method seems appropriate. However, in higher space dimensions the discretization of heterogeneous stochastic fields implies that a large number of stochastic variables is introduced. In such cases, Monte-Carlo simulation is probably competitive.

One of the most serious deficiencies of a deterministic study is the problem with incorporation of the experimentally reported degree of functional relationship between the input parameters. The stochastic analysis in this paper showed that correlations between the stochastic variables had a significant effect on their relative importance in a stochastic analysis. The expectations of the residual saturation variables and the porosity were the most important input data to this stochastic simulator. On the other hand, the most important parameters to be modeled as stochastic variables were the porosity, the permeability, and the residual water saturation. The computed statistical quantities showed little sensitivity to the choice of either lognormal or normal distribution functions for the basic variables. It is emphasized that the numerical results that have been obtained here may be highly dependent on the probability level, the coefficients of variations, and the correlation coefficients, as was indicated by the simplified analytical solution to the problem.

If simulation methods of Monte-Carlo type are applied for further work concerning two- and three-dimensional problems, effort should be made to develop efficient procedures for calculating important measures of the kind used here. Such measures give valuable physical insight into the stochastic problem and provide information for increasing the efficiency by replacing unimportant stochastic quantities by deterministic values.

A FAST ALGORITHM TO SOLVE NONHOMOGENEOUS CAUCHY–RIEMANN EQUATIONS IN THE COMPLEX PLANE*

PRABIR DARIPA†

Abstract. An algorithm is provided for the fast and accurate computation of the solution of nonhomogeneous Cauchy–Riemann equations in the complex plane in the interior of a unit disk. The algorithm is based on the representation of the solution in terms of a double integral, some recursive relations in Fourier space, and fast Fourier transforms. The numerical evaluation of the solution at N^2 points on a polar coordinate grid by straightforward summation for the double integral would require $O(N^2)$ floating point operations per point. Evaluation of these integrals has been optimized in this paper giving an asymptotic operation count of $O(\ln N)$ per point on the average. In actual implementation, the algorithm has even better computational complexity, approximately of the order of $O(1)$ per point. The algorithm has the added advantage of working in place, meaning that no additional memory storage is required beyond that of the initial data. The performance of the algorithm has been demonstrated on several prototype problems. The algorithm has applications in many areas, particularly fluid mechanics, solid mechanics, and quasi-conformal mappings.

Key words. complex variable, nonhomogeneous Cauchy–Riemann equation, Beltrami equation

AMS(MOS) subject classifications. 65E05, 30C99, 65D30

1. Introduction.

Cauchy–Riemann (CR) equations arise in many areas including fluid mechanics, solid mechanics, and electrostatics. These equations are given by

$$\phi_x = \psi_y, \qquad \phi_y = -\psi_x, \tag{1.1}$$

where real variables ϕ and ψ are functions of x and y. The CR equations suggest that the complex function $u = \phi + i\psi$ is an analytic function of the complex variable $\sigma = x + iy$:

$$u = g(\sigma). \tag{1.2}$$

This equation can be equivalently written as $u_{\bar{\sigma}} = 0$. Henceforth we refer to this equation as the CR equation in the complex plane. The CR equation plays an important role for two main reasons: the first is the fact that these equations model many problems in many areas of applications; the second is that the power of complex variable theory may be used in solving these problems. It should be noted that the CR equation is linear and homogeneous. Thus it is not surprising that CR equations arise due to some linear approximations or some nonlinear transformations of the original equations that actually arise in applied fields.

An obvious extension of the CR equation would be to add a nonhomogeneous term to it:

$$u_{\bar{\sigma}} = h(u, \sigma, \bar{\sigma}), \tag{1.3}$$

where the complex function h may be a nonlinear function of u and depends explicitly on σ and $\bar{\sigma}$. This equation naturally reduces to a CR equation when h is identically zero. Note that this equation is nonlinear as well as nonhomogeneous. A well-known special case of (1.3) is the following Beltrami equation (see [1] and [2]):

$$u_{\bar{\sigma}} = \mu(u) u_{\sigma}, \tag{1.4}$$

* Received by the editors November 21, 1990; accepted for publication (in revised form) September 8, 1991. This research was partially supported by National Science Foundation grant DMS-8803669.

† Department of Mathematics, Texas A & M University, College Station, Texas 77843.

where μ may depend on u, σ, and $\bar{\sigma}$. This equation arises in many instances, most notably in the transformation of a quasi-linear partial differential equation to canonical form [2], in quasi-conformal mapping [7], and in compressible fluid flow [6]. In fact, recent work has been done by solving these equations in the real as well as complex plane (see [5] and [6]) in the context of compressible fluid flow and quasi-conformal mapping [7]. It may also arise in other applied areas.

In this paper we are interested in constructing a fast algorithm to solve an appropriate boundary value problem associated with the following linearized version of (1.3):

$$u_{\bar{\sigma}} = f(\sigma, \bar{\sigma}), \tag{1.5}$$

in the unit disk $|\sigma| \leq 1$. The nonanalytic function f is assumed to satisfy a Hölder condition with exponent α in a unit disk Ω: $|\sigma| \leq 1$. Henceforth we refer to this equation as the nonhomogeneous Cauchy–Riemann (NCR) equation. Below, we denote $f(\sigma, \bar{\sigma})$ by $f(\sigma)$.

In [6], Daripa introduced a numerical method to solve this problem. The method is based on splitting the solution of (1.5) as (see also [2])

$$u(\sigma) = u^p(\sigma) + u^a(\sigma), \tag{1.6}$$

where $u^a(\sigma)$ is the analytic part of the solution and $u^p(\sigma)$ is the nonanalytic part of the solution. The nonanalytic part $u^p(\sigma)$ is then given by

$$u^p(\sigma) = -\frac{1}{\pi} \int\int_{\Omega} \frac{f(\zeta)}{\zeta - \sigma} d\xi d\eta, \tag{1.7}$$

where $\zeta = \xi + i\eta$.

The analytic part admits a Taylor series representation which can be efficiently computed using the fast Fourier transform (FFT) (see [3], [4], [6], and [8]). However, there are two main difficulties in the computation of the nonanalytic part $u^p(\sigma)$. The first has to do with the singularity of the integrand in (1.7) at $\zeta = \sigma$. In [6, Appendix C], Daripa proposed a method of desingularizing the integral. This desingularized version of the integral can then be directly integrated, but with poor accuracy, as is explained in §5. The second has to do with the algorithmic complexity of straightforward integration. The straightforward computation of the double integral in (1.7) requires performing an integral with an operation count of the order of $O(N^2)$ for each node in the discretization. There are N^2 such nodes in the discretization of the domain and hence N^2 such integrals to be evaluated. Thus this method of evaluation is computationally very intensive. These are the main drawbacks of the method. However, our goal in this paper is to develop an efficient and accurate algorithm for evaluating this integral and to thus make this a desirable alternative to the above approach.

The process of evaluating these integrals is optimized in this paper, giving a net operation count of the order of $O(N^2 \ln N)$ for N^2 points. This algorithm has the added advantage of working in place, meaning that no additional memory storage is required beyond that of the initial data.

Our method is basically a recursive routine in Fourier space that divides the entire domain (the interior of the unit disk) into a collection of annular regions and expands the integral in Fourier series in angular direction with radius-dependent Fourier coefficients. A set of exact recursive relations are derived which are then used to produce the Fourier coefficients of the integral. These recursive relations involve appropriate scaling of one-dimensional integrals in annular regions. The desired integrals at all N^2 grid points are then easily obtained from the Fourier coefficients by the FFT.

The algorithm developed in this paper also provides a constructive analytical method for evaluating certain integrals that are otherwise difficult to evaluate. An example is provided in Appendix B.

The rest of the paper is structured as follows. Section 2 develops the mathematical foundation of the efficient algorithm to evaluate the particular solution $u^p(\sigma)$ within the unit disk. The fast algorithm and the algorithmic complexity are discussed in §3. In §4, an area integral is evaluated corroborating the algorithmic steps. Section 5 discusses the computational results in evaluating the particular solution using our algorithm of §4. In §6, Dirichlet problems associated with the NCR equation (1.5) and computations of their solution are discussed. We conclude in §7.

In a sequel, we shall apply our algorithm to equations of compressible fluid flow.

2. Mathematical foundation of the algorithm. In this section, we develop the theory needed to construct an efficient algorithm for evaluating the double integral that appears in (1.7).

In the following, we use the notations Ω_r: $|\sigma| \leq r < 1$, $\Omega_{\bar{r}}$: $\Omega \backslash \Omega_r$, and Ω_{ij}: $r_i \leq |\sigma| \leq r_j$. The following theorem is crucial for the later development of the algorithm.

THEOREM 2.1. *The particular solution of $u_{\bar{\sigma}} = f(\sigma)$ with $\sigma = re^{i\alpha}$ can be written as*

$$u^p(\sigma) = \sum_{n=-\infty}^{\infty} c_n(r) e^{in\alpha}, \tag{2.1}$$

where

$$c_n(r) = \begin{cases} \dfrac{1}{\pi} \displaystyle\iint_{\Omega_r} f(\zeta) \left(\frac{r}{\zeta}\right)^n \left(\frac{1}{\zeta}\right) d\xi d\eta, & n < 0, \\[2ex] -\dfrac{1}{\pi} \displaystyle\iint_{\Omega_{\bar{r}}} f(\zeta) \left(\frac{r}{\zeta}\right)^n \left(\frac{1}{\zeta}\right) d\xi d\eta, & n \geq 0. \end{cases} \tag{2.2}$$

Proof. If we introduce the notation

$$P_n(r, \zeta) = \int_0^{2\pi} \frac{e^{-in\alpha}}{\zeta - re^{i\alpha}} d\alpha, \tag{2.3}$$

then it follows from (1.7) and (2.1) that

$$-\pi c_n(r) = \frac{1}{2\pi} \iint_{\Omega} f(\zeta) P_n(r, \zeta) d\xi d\eta. \tag{2.4}$$

The integral in (2.3) can be evaluated using complex variables. It is an elementary exercise in complex variable theory to show that

$$P_n(r, \zeta) = -2\pi r^n S_n(\zeta), \tag{2.5}$$

where

$$S_n(\zeta) = -\delta(n)\zeta^{-(n+1)} + \begin{cases} \zeta^{-(n+1)}, & |\zeta| < |\sigma|, \\ 0.5\zeta^{-(n+1)}, & |\zeta| = |\sigma|, \\ 0, & |\zeta| > |\sigma|. \end{cases} \tag{2.6}$$

In (2.6), $\delta(n) = 0$ for $n < 0$ and $\delta(n) = 1$ for $n \geq 0$. Substitution of (2.5) into (2.4) yields the desired result, i.e., (2.2).

Remark 2.1. The above theorem can also be derived by first expanding $\frac{1}{\zeta-\sigma}$ in power of $\frac{\zeta}{\sigma}$ and $\frac{\sigma}{\zeta}$, followed by integration in the complex plane.

COROLLARY 2.1. *Suppose that $\zeta = \rho e^{i\theta}$ and $f(\zeta)$ has Fourier coefficients $f_n(\rho)$; then it easily follows that the coefficients $c_n(r)$ in* (2.2) *can be written as*

$$c_n(r) = \begin{cases} 2\displaystyle\int_0^r f_{n+1}(\rho)\left(\frac{r}{\rho}\right)^n d\rho, & n<0, \\ -2\displaystyle\int_r^1 f_{n+1}(\rho)\left(\frac{r}{\rho}\right)^n d\rho, & n\geq 0. \end{cases} \tag{2.7}$$

COROLLARY 2.2. *It follows directly from* (2.7) *that $c_n(1) = 0$ for $n \geq 0, c_n(0) = 0$ for all $n \neq 0$. It also follows from the Fourier expansion of $f(\zeta)$ that $f_n(0) = 0$ for $n \neq 0$, and $f_0(0) = f(0)$.*

COROLLARY 2.3. *Let $r_j > r_i$. Define*

$$c_n^{ij} = 2\int_{r_i}^{r_j} f_{n+1}(\rho)\left(\frac{R}{\rho}\right)^n d\rho, \tag{2.8}$$

where

$$R = \begin{cases} r_i, & n \geq 0, \\ r_j, & n < 0. \end{cases} \tag{2.9}$$

After some algebraic manipulation it follows from (2.7) *that*

$$c_n(r_j) = \left(\frac{r_j}{r_i}\right)^n c_n(r_i) + c_n^{ji}, \qquad n < 0, \tag{2.10}$$

and

$$c_n(r_i) = \left(\frac{r_i}{r_j}\right)^n c_n(r_j) - c_n^{ij}, \qquad n \geq 0. \tag{2.11}$$

COROLLARY 2.4. *Let $0 = r_1 < r_2 < r_3 \cdots < r_M = 1$. It follows from recursive applications of* (2.10) *and* (2.11) *and from using Corollary* 2.2 *that*

$$c_n(r_l) = \begin{cases} \displaystyle\sum_{i=2}^{l}\left(\frac{r_l}{r_i}\right)^n c_n^{i-1,i}, & \text{for } n<0 \text{ and } l = 2,\cdots,M, \\ -\displaystyle\sum_{i=l}^{M-1}\left(\frac{r_l}{r_i}\right)^n c_n^{i,i+1}, & \text{for } n\geq 0 \text{ and } l = 1,\cdots,M-1. \end{cases} \tag{2.12}$$

3. The fast algorithm. We construct the fast algorithm based on the theory of §2. The unit disk is discretized using $M \times N$ lattice points with M equidistant points in the radial direction and N equidistant points in the circular direction.

Initialization. Choose M and N. Define $K = \frac{N}{2}$.
Step 1. For $l \in [1, M]$ and $n \in [-K+1, K]$, compute the Fourier coefficients $f_n(r_l)$ of $f(\zeta)$ from the known values of $f(\zeta = r_j e^{2\pi i k/N}), j = 1, \cdots, M; k = 1, \cdots, N$.

Step 2. Compute $c_n^{i,i+1}, i \in [1, M-1]$ for $n \in [-K, K-1]$ using (2.8).

Step 3. Compute the Fourier coefficients $c_n(r_l), n \in [-K, K-1], l \in [1, M]$ using the relations (2.10) and (2.11).

```
set $c_n(r_M) = 0 \ \forall \ n \in [0, K-1]$
do $n = 0, \cdots, K-1$
    do $l = M-1, \cdots, 1$
    Use (2.11) of Corollary 2.4 to compute $c_n(r_l)$.
    $c_n(r_l) = \left(\frac{r_l}{r_{l+1}}\right)^n c_n(r_{l+1}) - c_n^{l,l+1}$
    enddo
enddo

set $c_n(r_1) = 0 \ \forall \ n \in [-K, -1]$
do $n = -K, \cdots, -1$
    do $l = 2, \cdots, M$
    Use (2.10) of Corollary 2.4 to compute $c_n(r_l)$
    $c_n(r_l) = \left(\frac{r_l}{r_{l-1}}\right)^n c_n(r_{l-1}) + c_n^{l-1,l}$
    enddo
enddo
```

Step 4. Finally compute $u^p(\sigma = r_j e^{2\pi i k/N}), j \in [1, M], k \in [1, N]$ using a truncated version of (2.1).

3.1. The algorithmic complexity. Here we consider the computational complexity of the above algorithm. We discuss the asymptotic operation count, the asymptotic time complexity, and asymptotic storage requirement, in that order. In Steps 1 and 4 above, there are 2M FFTs of length N and all other computations in Steps 2 and 3 are of lower order. With each FFT of length N contributing $N \ln N$ operations, the asymptotic operation count and hence the asymptotic time complexity is $O(MN \ln N)$.

The algorithm requires storing the MN Fourier coefficients $f_n(r_l)$ in Step 1, the MN Fourier coefficients $c_n(r_l)$ in Step 3, and the MN values of the desired u^p at MN grid points in Step 4. Therefore the asymptotic storage requirement is $O(MN)$.

Remark 3.1. The computation c_n^{ij} in Step 2 can be embedded within the inner do-loops of Step 3, thus avoiding the storage requirement for these. Note that we present the algorithm in the form shown above for the sake of clarity and without any sacrifice in the asymptotic time complexity.

4. Integral evaluation using the algorithmic steps. We illustrate the algorithmic steps mentioned above through an explicit example. There are three main reasons for doing this. The first is to give an explicit exposition of the operations in each of the algorithmic steps in detail, the second is to show the power of the algorithm to evaluate the integral analytically when function f is known explicitly in terms of the complex coordinates, and the third is to generate an explicit example to test the accuracy and the algorithmic complexity at each step of the algorithm by explicit numerical calculations. This is also useful for debugging various stages of the computation.

We first summarize our result in the following note, proof of which follows.

Note. If

$$f(\sigma) = \sigma^p \bar{\sigma}^q \tag{4.1}$$

where p and q are constants, so that $k = p - q$ is an integer, then the integral $u^p(\sigma)$ in (1.7) is given by the following.

For $k = p - q \geq 1$,

$$u^p(\sigma) = \begin{cases} \dfrac{\sigma^{(k-1)}}{q+1}(|\sigma|^{2(q+1)} - 1) & \text{if } q \neq -1, \\ 2\sigma^{k-1} \ln|\sigma| & \text{if } q = -1, \end{cases} \tag{4.2}$$

and, **For** $k = p - q < 1$,

$$u^p(\sigma) = \begin{cases} \dfrac{\sigma^{k-1}}{q+1}|\sigma|^{2(q+1)} & \text{if } q > -1, \\ \infty & \text{if } q \leq -1. \end{cases} \tag{4.3}$$

Proof. We prove this through the use of the algorithm described in §3.

Step 1. Since $\zeta = \rho e^{i\theta}$, we have from (4.1),

$$f_n = \begin{cases} \rho^{p+q} & \text{if } n = k, \\ 0 & \text{if } n \neq k. \end{cases} \tag{4.4}$$

Step 2. From (2.8) and (4.4)

$$c_n^{ij} = 0 \quad \text{for} \quad n \neq k - 1. \tag{4.5}$$

The nonzero coefficient c_{k-1}^{ij} is evaluated as follows according to the algorithm.

$$c_{k-1}^{i,i+1} = 2R^{k-1} \int_{r_i}^{r_{i+1}} \rho^{p+q+k-1} d\rho. \tag{4.6}$$

Since $k = p - q$, upon integration, (4.6) becomes

$$c_{k-1}^{i,i+1} = 2R^{k-1} \begin{cases} \dfrac{1}{2(q+1)} \left(r_{i+1}^{2(q+1)} - r_i^{2(q+1)}\right) & \text{if } q \neq -1, \\ \ln(r_{i+1}/r_i) & \text{if } q = -1. \end{cases} \tag{4.7}$$

Step 3. It follows from (2.10), (2.11), (4.5), and Corollary 2.2 that

$$c_n(r_j) = 0 \quad \text{for } n \neq k - 1, \quad \text{and} \quad j = 1, 2, \cdots, M. \tag{4.8}$$

The calculation of the coefficient $c_{k-1}(r_j), j = 1, 2, \cdots, M$, according to our algorithm, follows. There are two separate cases to be considered depending on whether $q = -1$ or $q \neq -1$.

Case 1. $q = -1$.

(i) **For** $k < 1$, upon using (4.7) in (2.12) we obtain, after some manipulation,

$$c_{k-1}(r_l) = 2r_\ell^{k-1} \sum_{i=2}^{\ell} \ln\left(\frac{r_i}{r_{i-1}}\right) = \infty, \tag{4.9}$$

where $0 \leq r_\ell \leq 1$. To arrive at the last equality in (4.9) we have used

$$\sum_{i=2}^{\ell} \ln\left(\frac{r_i}{r_{i-1}}\right) = \sum_{i=2}^{\ell} (\ln r_i - \ln r_{i-1}) = \ln r_\ell - \ln 0 = \infty. \tag{4.10}$$

(ii) **For** $k \geq 1$, upon using (4.7) in (2.12) we obtain, after some manipulation,

$$\begin{aligned} c_{k-1}(r_\ell) &= -2r_\ell^{k-1} \sum_{i=\ell}^{m-1} \ln\left(\frac{r_{i+1}}{r_i}\right) \\ &= 2r_\ell^{k-1} \ln(r_\ell), \end{aligned} \tag{4.11}$$

where $0 \leq r_\ell \leq 1$. To arrive at the last equality in (4.11) we have used

$$\begin{aligned} \sum_{i=\ell}^{m-1} \ln\left(\frac{r_{i+1}}{r_i}\right) &= (\ln(r_m) - \ln(r_{m-1})) + (\ln(r_{m-1}) - \ln(r_{m-2})) \\ &\quad + \cdots + (\ln r_{\ell+1} - \ln r_\ell) \\ &= \ln 1 - \ln r_\ell = -\ln r_\ell. \end{aligned} \tag{4.12}$$

Case 2. $q \neq -1$.

(i) **For** $k < 1$, upon using (4.7) in (2.12) we obtain, after some manipulation,

$$\begin{aligned} c_{k-1}(r_\ell) &= \frac{r_\ell^{k-1}}{q+1} \sum_{i=2}^{\ell} (r_i^{2(q+1)} - r_{i-1}^{2(q+1)}) \\ &= \frac{r_\ell^{k-1}}{q+1} (r_\ell^{2(q+1)} - r_1^{2(q+1)}) \\ &= \begin{cases} \frac{r_\ell^{k-1}}{q+1} r_\ell^{2(q+1)} & \text{if } q > -1, \\ \infty & \text{if } q < -1, \end{cases} \end{aligned} \tag{4.13}$$

where we have used

$$\sum_{i=2}^{\ell} (r_i^{2(q+1)} - r_{i-1}^{2(q+1)}) = r_\ell^{2(q+1)} - r_1^{2(q+1)}. \tag{4.14}$$

(ii) **For** $k \geq 1$, upon using (4.7) in (2.12) we obtain after some manipulation

$$\begin{aligned} c_{k-1}(r_\ell) &= -\frac{r_\ell^{k-1}}{q+1} \sum_{i=m-1}^{\ell} (r_{i+1}^{2(q+1)} - r_i^{2(q+1)}) \\ &= \frac{r_\ell^{k-1}}{q+1} (r_\ell^{2(q+1)} - 1), \end{aligned} \tag{4.15}$$

where $0 \leq r_\ell \leq 1$. To obtain the last equality in (4.15) we have used

$$\sum_{i=\ell}^{m-1} (r_{i+1}^{2(q+1)} - r_i^{2(q+1)}) = r_m^{2(q+1)} - r_\ell^{2(q+1)} = 1 - r_\ell^{2(q+1)}. \tag{4.16}$$

We can summarize the calculations of Step 3 by rewriting (4.9) and (4.13) into

(i) **For** $k < 1$,

$$c_{k-1}(r_\ell) = \begin{cases} \dfrac{r_l^{k-1}}{q+1} r_l^{2(q+1)} & \text{if } q > -1, \\ \infty & \text{if } q \leq -1, \end{cases} \tag{4.17}$$

and by rewriting (4.11) and (4.15) into

(ii) **For** $k \geq 1$

$$c_{k-1}(r_\ell) = \begin{cases} \dfrac{r_\ell^{k-1}}{q+1} (r_\ell^{2(q+1)} - 1), & q \neq -1, \\ 2r_\ell^{k-1} \ln(r_\ell), & q = -1. \end{cases} \tag{4.18}$$

Step 4. Using the Fourier coefficients given by (4.8), (4.9), (4.11), (4.13), and (4.15) in the Fourier series (2.1), we obtain our results (4.2) and (4.3).

Remark 4.1. The above method of integral evaluation is meant only to show the algorithmic steps explicitly. There are easier *analytical* methods to evaluate the above integral. For example, it is much easier to evaluate the coefficient c_{k-1} directly from (2.7).

Remark 4.2. We note that $u^p(\sigma)$ in the above example can be determined directly to within an arbitrary additive analytic function by simply integrating (4.1) with respect to the conjugate of the complex coordinate.

Remark 4.3. The above calculation is exact. In actual implementation, the errors will arise from finite truncation of Fourier series and approximate evaluation of the one-dimensional integrals. However, in this particular example there is only one mode, namely, $(p-q)$th mode, in $f(\sigma)$ (see (4.1)). Therefore, the error due to discrete Fourier approximation in this example is zero, provided this mode is included in the truncated Fourier series, i.e., $N > p$. In actual implementation, the errors due to numerical evaluation of the integrals depend on the method of integration and the values of p and q. In our implementation, we use trapezoidal rule and thus the error in Step 3 of the algorithm can be made zero if q is chosen to be zero in (4.1) (regardless of how many points are chosen in the radial integration).

The following two remarks have to do with the divergence of the double integral (1.7) for some specific choices for $f(\sigma)$. For the specific functional form (4.1) for $f(\sigma)$, the divergence of the double integral depends on the values of p and q.

Remark 4.4. From (4.3), it follows that $u^p(\sigma)$ blows up at all values of σ within the unit disk if $p - q - 1 < 0$ and $q \leq -1$, or equivalently, if $p < q + 1 \leq 0$.

Remark 4.5. From (4.2), it follows that $u^p(r = 0)$ blows up if $p - q - 1 \geq 0$ and $q = -1$, or equivalently, if $p \geq q + 1 = 0$.

5. Numerical results I. A computer program has been written which can compute the integral using the fast algorithm of this paper or using the naive method of directly integrating the double integral in [6, Appendix C, eq. (C.4)]. The program has been tested with various functions $f(\sigma)$ in (1.7). However, we present the performance of our fast algorithm using the example of §4. Since the exact value of the integral is available in this case, the relative maximum error in the numerical computation can easily be calculated.

Computations were carried out for different radial and angular grid spacings on a Cray Y-MP at Texas A&M University in single precision. The computations were performed in two ways: (i) using the fast algorithm, and (ii) using the direct method. We compare these two methods by monitoring CPU time and relative maximum error for various values of M and N. We summarize our numerical results below.

Computations were performed for various values of p and q such that $(p-q)$ is an integer. The results obtained with $q=0$ and with $N>p$ using the fast algorithm were accurate up to seven decimal places in single precision regardless of the number of radial grid points. In this calculation, the effect of the number of radial grid points is zero, as it should be according to Remark 4.3. The effect of the number of angular grid points is also zero since this number N has been chosen to be greater than p. Thus, the only error in this case is due to truncation error. However, there were no signs of truncation errors within seven decimal places in this case.

The results of the computations using $p=3$ and $q=1$ in the choice $f(\delta)$ is summarized in Table 1. The number of angular grid points N is kept constant at 17. The first column contains the number of radial grid points. The second and the third columns contain the CPU times T_{fast}, required by the fast algorithm of the present paper, and T_{dir}, required by the direct method, respectively. The fourth and fifth columns contain the maximum relative errors δ_{fast} and δ_{dir} in these two methods, respectively.

TABLE 1

CPU *times in seconds and maximum relative errors on Cray* Y-MP. *The terms within parentheses are approximate estimates.*

M	T_{fast}	T_{dir}	δ_{fast}	δ_{dir}
51	0.00913	1.61807	2.878941E-04	7.7745298E-02
101	0.01662	6.40785	7.1945221E-05	8.438147E-02
151	0.02408	14.3590	3.197717E-05	8.666666E-02
201	0.03157	25.41848	1.7987853E-05	8.78808483E-02
251	0.03987	39.65647	1.1513032E-05	8.88519315E-02
501	0.07786	158.16779	2.8797382E-06	8.9932327E-02
1001	0.15409	(632.67116)	7.2160367E-07	–

Remark 5.1. The fast algorithm of the present paper takes only 0.154 seconds of CPU time when $M=1001$. The CPU time when using the direct method with $M=1001$ is estimated by extrapolation (shown within parentheses in Table 1). It was not considered practical to use approximately 632 seconds of Cray CPU time to produce an exact value of this CPU time.

The following observations can be made about Table 1.

(i) The CPU time required by the fast algorithm increases linearly with M. In contrast, the CPU time required by the direct method increases quadratically with M.

(ii) The relative maximum error δ_{fast} decreases with increasing M. This is because the error in the numerical integration by the trapezoidal method in Step 2 decreases with increasing M.

(iii) The relative maximum error δ_{dir} decreases very slowly with increasing M. In this case, the function $f(\zeta)$ is very poorly resolved by only 17 points in the angular direction. Most of the error is probably due to this poor resolution.

(iv) The accuracy of the fast algorithm is remarkable. In contrast, the direct method has very poor accuracy.

The results of similar computations using $M = 101$ are shown in Table 2 for varying values of N. The first column contains the number of angular grid points N.

TABLE 2
CPU *times in seconds and maximum relative errors on Cray* Y-MP. *The terms within parentheses are approximate estimates.*

N	T_{fast}	T_{dir}	δ_{fast}	δ_{dir}
17	0.01662	6.40785	7.1945221E-05	8.438147E-02
33	0.03216	24.32479	7.1974139E-05	2.592902E-02
65	0.06680	93.81604	7.1972282E-05	6.968137E-03
129	0.13908	376.73983	7.1977357E-05	1.576032E-03
257	0.30031	(1500.00)	7.1972305E-05	6.520931E-04
513	0.64261	(6000.00)	7.1977943E-05	4.129121E-04
1025	1.36825	(24000.00)	7.1972308E-05	2.152631E-04

Remark 5.2. The Cray Y-MP CPU seconds shown within parentheses are approximate and were estimated from computations on the local MIPS computer. The corresponding errors were obtained on the local MIPS computer. The errors on Cray Y-MP and on the local MIPS computer for the same problem agree up to five decimal places.

The following observations can be made about Table 2.

(i) The CPU time required by the fast algorithm increases superlinearly with N and is less than the theoretical asymptotic estimate of $N \ln N$. In contrast, the CPU time required by the direct method increases quadratically with N.

(ii) The relative maximum error δ_{fast} does not change with changing N. This is expected since the values of N used are greater than $(p - q) = 2$ (see Remark 4.3).

(iii) The relative maximum error δ_{dir} decreases with increasing N. However, the accuracy of the fast algorithm is much better.

6. Dirichlet problems for nonhomogeneous Cauchy–Riemann equations. This section shows the application of our fast algorithm of §3 on a Dirichlet linear boundary value problem. Computations of nonlinear and other types of boundary value problems associated with (1.5) using our fast algorithm are under way and will be addressed elsewhere in detail. This section has been kept as brief as possible. We consider solving the following Dirichlet problem in the interior of a unit disk.

$$\text{(P)} \qquad \begin{cases} u_{\bar{\sigma}} = f(\sigma, \bar{\sigma}), & |\sigma| \leq 1, \\ \text{Real } [u(\sigma = e^{i\alpha})] = u_0(\alpha), & 0 \leq \alpha \leq 2\pi, \\ \text{Imag } [u(\sigma = 0)] = v_0. \end{cases}$$

We are interested in finding the solution of (P) in the entire domain.

It follows from the solution (1.6) of (1.5) that the above problem is equivalent to solving the following problem:

$$\text{(RP)}\qquad \begin{cases} u^a_{\bar\sigma} = 0, & |\sigma| \le 1, \\ \text{Real } [u^a(\sigma = e^{i\alpha})] = u_0(\alpha) - u^p(\alpha), & 0 \le \alpha \le 2\pi, \\ \text{Imag } [u^a(\sigma = 0)] = v_0 - u^p(\sigma = 0). \end{cases}$$

Once this problem has been solved, the solution of the problem (P) is constructed from (1.6). Therefore our method of solving (P) involves the following three steps:

(1) First, find the particular solution $u^p(\sigma)$ in the entire domain using the algorithm of the previous section. As shown previously, the algorithmic complexity of this stage of the computation is at worst $MN \ln N$ with MN grid points in the discretization of the unit disk.

(2) Second, construct the analytic function $u^a(\sigma)$ by solving the reduced problem (RP).

(3) Third, construct the solution of the original problem (P) by adding the above two solutions according to (1.6).

Note that the algorithmic complexity in solving the reduced problem (RP) must not exceed $MN \ln N$ so that the computational complexity of the entire calculation remains the same. There are many efficient algorithms that can be used to solve this problem. We use the following simple procedure in constructing the solution of the reduced problem (RP) at MN lattice points.

(i) The solution is expressed in terms of Taylor series

$$u^a(\sigma) = \sum_{n=0}^{\infty} c_n \sigma^n. \tag{6.1}$$

(ii) The FFT is used to construct the complex conjugate of the specified boundary values and the Fourier coefficients of the Taylor series. This step takes $N \ln N$ operations with N points on the boundary of the unit disk.

(iii) Next, the Fourier coefficients are used in constructing the solution $u^a(\sigma)$ at all interior points by using the FFT. This step takes $MN \ln N$ operations with M divisions in the radial direction.

Note that this approach has an asymptotic operation count of the order $MN \ln N$. Thus overall complexity is retained at the desired level.

Remark 6.1. More efficient algorithms can be constructed to solve the reduced problem (RP). We will implement better algorithms for this part of the calculation in the future.

6.1. Numerical results II. The following problems were numerically solved using the above steps.

Example 1.

$$\text{(E1)}\qquad \begin{cases} u_{\bar\sigma} = 1, & |\sigma| \le 1, \\ \text{Real } [u(\sigma = e^{i\alpha})] = 2\cos\alpha, & 0 \le \alpha \le 2\pi, \\ \text{Imag } [u(\sigma = 0)] = 0. \end{cases}$$

The exact solution to this problem is

$$u(\sigma) = \sigma + \bar\sigma, \qquad |\sigma| \le 1. \tag{6.2}$$

Example 2.

$$\text{(E2)} \qquad \begin{cases} u_{\bar{\sigma}} = -1, & |\sigma| \le 1, \\ \text{Real } [u(\sigma = e^{i\alpha})] = 0, & 0 \le \alpha \le 2\pi, \\ \text{Imag } [u(\sigma = 0)] = 0. & \end{cases}$$

The exact solution to this problem is

$$u(\sigma) = \sigma - \bar{\sigma}, \qquad |\sigma| \le 1. \tag{6.3}$$

Example 3.

$$\text{(E3)} \qquad \begin{cases} u_{\bar{\sigma}} = \sigma^k, & |\sigma| \le 1, \\ \text{Real } [u(\sigma = e^{i\alpha})] = \cos\alpha, & 0 \le \alpha \le 2\pi, \\ \text{Imag } [u(\sigma = 0)] = 0, & \end{cases}$$

where k is either 1 or 2. The exact solution to this problem is

$$u(\sigma) = \sigma + \bar{\sigma}\sigma^k - \sigma^{k-1}, \qquad |\sigma| \le 1. \tag{6.4}$$

The above three problems were numerically solved using our fast algorithm to obtain the solution at all $M \times N$ nodes with N=17 and M=101. The computed solutions were compared with the exact solutions for accuracy and the CPU times were recorded. These are shown in Table 3. The data for (E3) corresponds to $k = 2$ (see (E3) above). The first column contains the reference to one of the problems mentioned above. The second column contains the total CPU seconds (T_{tot}) required to solve these problems. The third and the fourth columns contain the breakup of T_{tot} into T_{h} (CPU seconds required to find $u^a(\sigma)$ at all interior points from the Taylor series (6.1)) and T_{nh} (CPU seconds required to find $u^p(\sigma)$ by evaluating the double integral using our algorithm of §3). The fifth column contains the maximum relative error δ.

TABLE 3
Computational results on boundary value problems (E1), (E2), *and* (E3) *using the fast algorithm.*

Examples	T_{tot}	T_{h}	T_{nh}	δ
E1	0.00932	0.00251	0.00681	5.6915101E-06
E2	0.00969	0.00269	0.00700	8.1740268E-06
E3	0.00932	0.00251	0.00681	7.3560102E-06

In Table 3, we note that our fast algorithm solves the boundary value problems within the entire unit disk with very good accuracy and within a fraction of a CPU second. The CPU seconds for computing the analytic part (T_{h}) is less than half of the CPU seconds T_{nh} needed to evaluate the particular solution $u^p(\sigma)$ at all interior points. Similar computations have been done on other types of boundary value problems with similar conclusions.

Remark 6.2. The computation of the analytic part can be accelarated by borrowing some of the ideas from [9], [12], and [13], which will be undertaken in the future.

7. Conclusions. The present work develops a fast algorithm to solve nonhomogeneous Cauchy–Riemann equations in the interior of a unit disk in the complex plane. It is based on computation of the particular solution from its Fourier coefficients. The recursive relations satisfied by these Fourier coefficients are derived, which is at the heart of the algorithm. The speedup provided by the algorithm is dramatic even for a moderate number of nodes in the domain. Our numerical experiments show that the actual CPU time requirements for the algorithm are even less than the asymptotic CPU estimate, which is very encouraging.

The algorithm has the limitation that the problem has to be solved within the interior of a unit disk. Therefore to construct a solution in a domain which is not circular, a conformal mapping of the domain to the interior of a unit disk must be done prior to the use of our algorithm. This should not be difficult, as there are many numerical methods these days to perform such conformal mapping (see [10] and [12]).

Prototype linear boundary problems have been solved here using the fast algorithm to provide some future directions. Nonlinear boundary value problems can be solved using this algorithm iteratively. Computations of nonlinear and other types of boundary value problems associated with the NCR equation using our fast algorithm are currently under way. The application of the algorithm is not limited to any particular field, thus its application to compressible fluid problems should be straightforward, since the compressible fluid flow equations already admit a formulation similar to (1.5) (see [6]). In fact, many compressible flow problems, including those solved in Woods [14] with the tangent gas approximation, can now be solved exactly, accurately, and very efficiently using the algorithm of this paper.

The algorithm presented here is suitable for implementation on a serial computer. However, the recursive set of equations of §2 has a structure suitable for implementation on a parallel computer, which will yield considerable savings in computational time depending on the number of processors. Construction of algorithms suitable for implementation on a parallel computer needs further work. Some of the ideas presented by Katzenelson [11] in connection with computational structure involving recursive relations may be useful here.

Appendix A. Application of the results of §2 in double integral evaluation. The results obtained in §2 provide an analytical technique to evaluate the double integral (1.8) with complicated $f(\zeta)$, which are otherwise difficult to evaluate analytically. We provide a prototype example.

Consider the following choice for the function $f(\zeta)$:

$$f(\zeta) = \zeta^p \sin\left(\frac{\zeta}{|\zeta|}\right) \quad \text{for} \quad p \geq 0. \tag{A.1}$$

Then the Fourier coefficients $f_n(r)$ are given by

$$f_n(r) = \frac{r^p}{2\pi}\int_0^{2\pi} e^{i(p-n)\theta}\sin(e^{i\theta})d\theta. \tag{A.2}$$

Using $\sigma = e^{i\theta}$, (A.2) reduces to

$$f_n(r) = \frac{r^p}{2\pi i}\oint \sigma^{p-n-1}\sin\sigma d\sigma. \tag{A.3}$$

Using the residues, we have from (A.3),

$$f_n(r) = r^p E(n-p), \tag{A.4}$$

where

$$E(n-p)=\begin{cases}0 & \text{if } (n-p)\le 0 \text{ or } (n-p)=\text{even integer},\\ \dfrac{1}{(n-p)!} & \text{if } (n-p)=1,5,9,\cdots,\\ \dfrac{-1}{(n-p)!} & \text{if } (n-p)=3,7,11,\cdots.\end{cases} \tag{A.5}$$

Using (A.4) in (2.8) we obtain

$$c_{n-1}^{i,i+1}=\begin{cases}0 & \text{for } n\le p,\\ \dfrac{2E(n-p)}{(n+p)}R^{n+1}(r_{i+1}^{n+p}-r_i^{n+p}) & \text{for } n>p.\end{cases} \tag{A.6}$$

It then follows from (2.12) that

$$c_{n-1}(r_j)=0 \quad \text{for} \quad n\le p, \text{ and } \quad j=1,2,\cdots,M. \tag{A.7}$$

For $n>p$, upon using (A.6) in (2.12) we obtain after some manipulation,

$$c_{n-1}(r_l)=\frac{2E(n-p)}{n+p}r_\ell^{n-1}(r_\ell^{n+p}-1). \tag{A.8}$$

Using (A.7), (A.8), and (A.5), we obtain

$$u^p(\sigma)=\sum_{n=p}^{\infty}\frac{2E(n+1-p)}{(n+p+1)!}r_\ell(r_\ell^{n+p+1}-1)e^{in\theta}. \tag{A.9}$$

Using $n-p=m$ and (A.5), we can rewrite (A.9) as

$$\begin{aligned}u^p(\sigma)&=\sum_{m=0}^{\infty}\frac{2}{(4m+1)!(4m+2p+1)}\sigma^{4m+p}(|\sigma|^{4m+2p+1}-1)\\&-\sum_{m=0}^{\infty}\frac{2}{(4m+3)!(4m+2p+3)}\sigma^{4m+p+2}(|\sigma|^{4m+2p+3}-1).\end{aligned} \tag{A.10}$$

Appendix B. Desingularization of $\tau^p=-\frac{1}{\pi}\int\int_\Omega f(\zeta)/(\zeta-\sigma)d\xi d\eta$. The desingularized version of this integral appears in Appendix C [6]. However, the equations (C.8) and (C.9) of that paper were in error and should be corrected, respectively, as (B.2) and (B.3) of this appendix. We prescribe here a much easier procedure than the one in [6] to desingularize this integral.

The above integral can be desingularized in the following manner:

$$\begin{aligned}u^p&=-\frac{1}{\pi}\int\int_\Omega\frac{f(\zeta)}{\zeta-\sigma}d\xi d\eta\\&=-\frac{1}{\pi}\int\int_\Omega\frac{f(\zeta)-f(\sigma)}{\zeta-\sigma}d\xi d\eta-\frac{f(\sigma)}{\pi}\int\int_\Omega\frac{d\xi d\eta}{\zeta-\sigma}.\end{aligned} \tag{B.1}$$

The second integral in (B.1) can be evaluated by using the integral evaluated in §4. With $p=0$ and $q=0$ in (4.1), we obtain the following from (4.3):

$$\int\int_\Omega\frac{d\xi d\eta}{\zeta-\sigma}=-\frac{\pi}{\sigma}|\sigma|^2. \tag{B.2}$$

From (B.1) and (B.2) we have

$$u^p = \bar{\sigma} f(\sigma) - \frac{1}{\pi} \int \int_\Omega \frac{f(\zeta) - f(\sigma)}{\zeta - \sigma} d\xi d\eta. \tag{B.3}$$

This desingularized version of the integral is suitable for numerical computation in the direct method (see also [6]).

PARALLEL IMPLEMENTATION OF THE *hp*-VERSION OF THE FINITE ELEMENT METHOD ON A SHARED-MEMORY ARCHITECTURE[*]

I. BABUŠKA[†], H. C. ELMAN[‡], AND K. MARKLEY[§]

Abstract. The costs incurred by an implementation of the *hp*-version of the finite element for solving two-dimensional elliptic partial differential equations on a shared-memory parallel computer are studied. For a collection of benchmark problems, the costs in CPU time of various individual subtasks performed by the finite element solver are systematically examined, including construction of local stiffness matrices, elimination of unknowns associated with element interiors, and global solution on element interfaces by a preconditioned conjugate gradient method. General observations are that the costs of the "naturally" parallel computations associated with local elements are significantly higher than any global computations, so that the latter do not represent a significant bottleneck to parallel efficiency. However, memory conflicts place some limitations on the sizes or number of local problems that can be handled efficiently in parallel.

Key words. finite element, *hp*-version, parallel, shared memory, domain decomposition

AMS(MOS) subject classifications. primary: 65F10, 65N20, 65W05

1. Introduction.

The finite element method is a standard computational tool for solving partial differential equations arising from engineering analysis. Variants include the standard *h*-version, which uses low-order basis functions and achieves accuracy by refining meshes [13]; the *p*-version, which uses a fixed mesh and achieves accuracy by increasing the order of the basis functions; and the *hp*-version, which combines these two approaches. See [7] for a survey and comprehensive list of references on the *p*- and *hp*-versions. For the first and last of these techniques, which divide domains into local elements and compute associated local stiffness operators, a large component of the required computations can be implemented very naturally on parallel architectures. In particular, for the *h*-version, *domain decomposition methods* (see, e.g., [8]–[12], [21], [22], [26], [27], [31]) group collections of elements into subdomains, or *super-elements*. The local stiffness operators associated with super-elements are independent of one another, so that they can be constructed in parallel on separate processors. Similarly, elimination of degrees of freedom internal to super-elements can be performed in parallel. For the *p*- and *hp*-version, we think of the space of high-order basis functions in each element as analogous to the grouping of *h*-elements into super-elements. Then, just as for domain decomposition methods, construction of local operators and partial elimination can be done in a natural way on independent processors. A combination of these points of view, with multiple high-order elements collected into super-elements, is also possible.

[§] Department of Mathematics, Rice University, Houston, Texas 77001.

After the fully local computations have been performed, the result is a subproblem with unknowns on super-element interfaces. If an iterative method such as the conjugate gradient method (CG) is used to solve this subproblem, then much of the required computation is also local, so that there is a large amount of natural parallelism. However, these computations entail some interaction across super-element interfaces, and, in addition, CG requires some global computations. Moreover, convergence of such methods is often significantly accelerated by some type of global preconditioner [3], [9]–[12], [21], [22], [31], which may be less natural to implement in parallel. The effects of both super-element interactions and global operations on overall performance on parallel architectures is not well understood.

In this paper, we describe the results of an experimental study of an implementation of the *hp*-version of the finite element method for solving two-dimensional linear elliptic problems on a shared-memory parallel computer. We examined the computational costs of the various subtasks required by the *hp*-method, including:

- construction of local stiffness matrices;
- partial elimination of unknowns associated with purely local elements;
- CG iteration; and
- preconditioning derived from low-order elements.

Our goals were to determine how efficiently such computations can be done on parallel architectures, and what bottlenecks may exist that limit efficiency. Some particular issues considered were:

- the relative costs of the various individual subtasks;
- the effects of global operations, especially preconditioning, on overall performance and parallel efficiency;
- the overhead of using unassembled local matrices to perform the matrix-vector products required by CG; and
- whether there are any limitations associated with the "natural" subdivision of problems based on independent elements.

Our tests were performed on an Alliant FX/8, an eight-processor shared-memory computer with a fast cache memory and vector processors. In addition to examining the general issues of parallel implementation, we also considered the effects of the latter two architectural features. In general, we found that the dominant costs come from the local computations, especially the construction of local stiffness matrices, and that global computations required for fast convergence do not represent a significant bottleneck. However, there are some drawbacks to having local computations that operate on large sets of data, which appear to be architecture-related, derived from inefficient data movement for parallel processing.

An outline of the paper is as follows. In §2, we present the continuous model problem used for experiments, and we describe the *hp*-version of the finite element method used for the discretization. In §3, we give a high level description of the solution algorithm and a detailed description of our implementation. Section 4 contains the main results of the paper, a series of experimental results for a set of benchmark problems. These include overviews of iteration counts and CPU times, as well as several refinements of timing statistics showing where computational efforts are spent, and analyses of the effects of synchronization and vectorization. Finally, in §5, we summarize our observations and discuss their implications for computations on other classes of problems and parallel computers.

2. The model problem and its finite element solution. Consider the model problem

$$-\left(\frac{\partial}{\partial x}a\frac{\partial u}{\partial x}+\frac{\partial}{\partial y}b\frac{\partial u}{\partial y}\right)=f \quad \text{on } \Omega, \tag{1}$$

$$u=g_d \quad \text{on } \Gamma_D, \quad \frac{\partial u}{\partial n_c}=g_n \quad \text{on} \quad \Gamma_N. \tag{2}$$

Here, $\Omega \subset \mathbf{R}^2$ is a bounded domain with piecewise smooth (e.g., polygonal) boundary; $\Gamma = \Gamma_D \cup \Gamma_N$ is the boundary of Ω; a, b, f, g_d and g_n are functions that satisfy the usual conditions guaranteeing existence and uniqueness of the solution; and n_c is the conormal. We are interested in the weak solution of (1)–(2), i.e., $u \in H^1_D(\Omega) \equiv \{u \in H^1(\Omega) \,|\, u = 0 \text{ on } \Gamma_D\}$ such that

$$B(u,v) \equiv \int_\Omega a\frac{\partial u}{\partial x}\frac{\partial v}{\partial x}+b\frac{\partial u}{\partial y}\frac{\partial v}{\partial y}\,dx\,dy=\int_\Omega fv\,dx\,dy+\int_{\Gamma_N} g_n v\,ds \equiv F(v)$$

holds for any $v \in H^1_D(\Omega)$. $H^1(\Omega)$ denotes the usual Sobolev space.

We now give a general description of the *hp*-version of the finite element discretization of (1)–(2). Let $\mathcal{P} = \{\Omega^i\}$ denote a partitioning of Ω into open subdomains such that $\bar{\Omega} = \cup\bar{\Omega}^i$ (where $\bar{\Omega}$ denotes the closure of Ω). Assume that Ω^i is a curvilinear polygon, typically a triangle or quadrilateral. Let

$$\Gamma^i = \cup_{j=1}^{m_i}\Gamma^i_j$$

denote the set of (curved) open sides of Ω^i, and let

$$\Delta^i = \cup_{j=1}^{m_i}\Delta^i_j$$

denote its vertices. Assume that

1. $\bar{\Omega}^i \cap \bar{\Omega}^j = \bar{\Gamma}^i_k = \bar{\Gamma}^j_l$, i.e., $\bar{\Omega}^i$ and $\bar{\Omega}^j$ have common entire sides; or
2. $\bar{\Omega}^i \cap \bar{\Omega}^j = \Delta^i_k = \Delta^j_l$, i.e., $\bar{\Omega}^i$ and $\bar{\Omega}^j$ have one vertex in common; or
3. $\bar{\Omega}^i \cap \bar{\Omega}^j = \emptyset$.

The set $(\cup_{i,j}\Gamma^i_j) \cup (\cup_{i,j}\Delta^i_j)$ will be denoted the *frame* of the partitioning $\mathcal{P}$.

On every $\Omega^i \in \mathcal{P}$, we use a set of linearly independent functions $\Phi^i_j \in H^1(\Omega^i)$, $j = 1, \cdots, \rho_i$, called *shape functions*, which are divided into three categories:

Internal shape functions: $\mathcal{I} \subset \{\Phi^{(\mathcal{I})} \in H^1(\Omega^i) \,|\, \Phi^{(\mathcal{I})} = 0 \text{ on } \Gamma^i\}$.

Side shape functions: $\mathcal{S} \subset \{\Phi^{(\mathcal{S},j)} \in H^1(\Omega^i) \,|\, \Phi^{(\mathcal{S},j)} = 0 \text{ on } \Gamma^i - \Gamma^i_j\}$.

Nodal shape functions: $\mathcal{N} \subset \{\Phi^{(\mathcal{N},j)} \in H^1(\Omega^i) \,|\, \Phi^{(\mathcal{N},j)} = 0 \text{ on } \Delta^i_k, k \neq j\}$.

The following typical examples will be used in the sequel. Let $\mathcal{E} = (-1,1) \times (-1,1)$ be called the *standard element*. The nodes and sides of $\mathcal{E}$ are given by

$$\Delta_1 = (1,-1), \quad \Delta_2 = (1,1), \quad \Delta_3 = (-1,1), \quad \Delta_4 = (-1,-1),$$

$$\Gamma_1 = \{(\xi,\eta) \,|\, \xi = 1, |\eta| < 1\}, \qquad \Gamma_2 = \{(\xi,\eta) \,|\, |\xi| < 1, \eta = 1\},$$

$$\Gamma_3 = \{(\xi,\eta) \,|\, \xi = -1, |\eta| < 1\}, \qquad \Gamma_4 = \{(\xi,\eta) \,|\, |\xi| < 1, \eta = -1\}.$$

(See Fig. 1.) Let

$$\phi_j(\xi) = \sqrt{\frac{2j-1}{2}} \int_{-1}^{\xi} P_{j-1}(t)dt, \qquad j \geq 2, \tag{3}$$

where $P_j(t)$ is the Legendre polynomial of degree j [14]. Thus $\phi_j(\xi)$ is a polynomial of degree j and $\phi_j(\pm 1) = 0$. Two spaces, $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$, are defined as the span of the following shape functions on $\mathcal{E}$:

Internal shape functions. For $\mathcal{Q}(p)$,

$$\Phi_{jk}^{(\mathcal{I})}(\xi,\eta) = \phi_j(\xi)\phi_k(\eta), \qquad 2 \leq j,k \leq p;$$

and for $\mathcal{Q}'(p)$,

$$\Phi_{jk}^{(\mathcal{I})}(\xi,\eta) = \phi_j(\xi)\phi_k(\eta), \quad j,k \geq 2, \quad j+k \leq p.$$

Hence for $\mathcal{Q}(p)$, there are $(p-1)^2$ internal shape functions, and for $\mathcal{Q}'(p)$ there are $(p-2)(p-3)/2$ internal shape functions when $p \geq 4$, and none when $p < 4$.

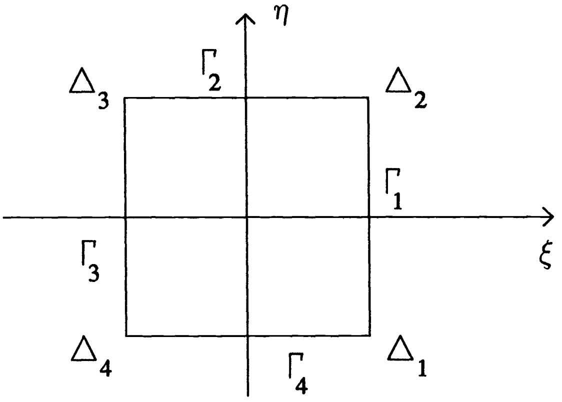

FIG. 1. *The standard element* $\mathcal{E}$.

Side shape functions. For both $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$, the side shape functions are given by

$$\begin{aligned} \Phi_j^{(\mathcal{S},1)}(\xi,\eta) &= \left(\frac{\xi+1}{2}\right)\phi_j(\eta), & \Phi_j^{(\mathcal{S},2)}(\xi,\eta) &= \phi_j(\xi)\left(\frac{\eta+1}{2}\right), \\ \Phi_j^{(\mathcal{S},3)}(\xi,\eta) &= \left(\frac{-\xi+1}{2}\right)\phi_j(\eta), & \Phi_j^{(\mathcal{S},4)}(\xi,\eta) &= \phi_j(\xi)\left(\frac{-\eta+1}{2}\right), \end{aligned} \qquad j = 2,\cdots,p.$$

Thus, there is a total of $4(p-1)$ side shape functions.

Nodal shape functions. For both $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$, the four nodal shape functions are given by

$$\begin{aligned} \Phi^{(\mathcal{N},1)}(\xi,\eta) &= \left(\frac{\xi+1}{2}\right)\left(\frac{-\eta+1}{2}\right), & \Phi^{(\mathcal{N},2)}(\xi,\eta) &= \left(\frac{\xi+1}{2}\right)\left(\frac{\eta+1}{2}\right), \\ \Phi^{(\mathcal{N},3)}(\xi,\eta) &= \left(\frac{-\xi+1}{2}\right)\left(\frac{\eta+1}{2}\right), & \Phi^{(\mathcal{N},4)}(\xi,\eta) &= \left(\frac{-\xi+1}{2}\right)\left(\frac{-\eta+1}{2}\right). \end{aligned}$$

Here, $\mathcal{Q}(p)$ contains all polynomials of degree p in each variable, and $\mathcal{Q}'(p)$ contains all polynomials of total degree p. For some choices of p, internal or side shape functions are not present, and the method can reduce to the standard h-version. Also, the spaces $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$ could be defined as the span of some other shape functions. For example, $\mathcal{Q}(p)$ is the span of all functions of the form $f_j(\xi)f_k(\eta)$ where $\{f_j(\xi)\}$ are Lagrange polynomials with interpolation points chosen to be the $(p+1)$ Gauss–Lobatto quadrature points [28]. Similar sets of standard shape functions can be defined on a triangular element.

Assume that $T_i(\xi,\eta)$ is a mapping of the standard element $\mathcal{E}$ onto Ω^i. Let $\mathcal{Q}^*$ denote either $\mathcal{Q}(p)$ or $\mathcal{Q}'(p)$, and let

$$\mathcal{V} = \{u \in H^1_D(\Omega) \,|\, u|_{\Omega^i}(x,y) = v(T_i^{-1}(x,y)),\ v \in \mathcal{Q}^*\}.$$

We impose on T_i the usual conditions of the finite element method, e.g., if Ω^i is a parallelogram, then T_i is a linear mapping. Thus the basis functions of $\mathcal{V}$ can easily be constructed using the three categories of standard shape functions. The finite element solution $u_{FE} \in \mathcal{V}$ is defined by

$$B(u_{FE},v) = F(v) \quad \text{for all } v \in \mathcal{V}. \tag{4}$$

Condition (4) uniquely defines u_{FE} except when $\Gamma_D = \emptyset$, in which case u_{FE} is determined up to a constant.

Accuracy of u_{FE} is achieved either by increasing the degree p of the shape functions, or by refining the partitioning $\mathcal{P}$. Consider the case where $\mathcal{P}$ partitions a rectangular domain Ω into an $m \times n$ rectangular grid composed of squares with side h. The following results contain typical error bounds for the finite element solution in the energy norm

$$\|u - u_{FE}\|_E \equiv B(u-u_{FE}, u-u_{FE})^{1/2} = \inf_{v\in\mathcal{V}} B(u-v,u-v)^{1/2}.$$

See [7] and references therein for further details.

THEOREM. (1) *Suppose h is such that $c_1h^{-1} \le m,\ n \le c_2h^{-1}$, and $u \in H^k(\Omega)$. Then*

$$\|u-u_{FE}\|_E \le C\frac{h^\alpha}{p^{k-1}}\|u\|_{H^k},$$

where $\alpha = \min\{k-1,p\}$ and C depends on k, c_1, c_2, and the discretization ($\mathcal{Q}(p)$ or $\mathcal{Q}'(p)$), but is independent of u, h, and p.

(2) *If u is analytic in $\bar{\Omega}$, then for any fixed $h > 0$,*

$$\|u-u_{FE}\|_E \le De^{-\beta p},$$

where D depends on u and h and $\beta > 0$ depends on the region in which u is analytic.

Thus for very smooth problems, the p and hp finite element solutions display exponential convergence.

For our investigation, we will restrict our attention to the case where $\Omega = (-1,1)\times(-1,1)$, $\mathcal{P}$ partitions Ω into a uniform $n\times n$ grid, T_i is a bilinear mapping, and $f=0$, $\Gamma_D = \emptyset$. We will consider the constant coefficient case $a = b = 1$. To ensure a unique solution, we will constrain the solution at the corners of $\partial\Omega$.

3. The solution algorithm and its implementation.

Formal specification of the finite element solution u_{FE} as a linear combination of the basis functions of $\mathcal{V}$ leads to a system of linear equations $S\alpha = s$, where S is the global stiffness matrix and α is the vector of coefficients of the basis functions. In this section, we present the algorithm used to solve this problem and describe the details of our implementation.

3.1. The solution algorithm.

Conceptually, the algorithm can be divided into four steps.

1. *Construction of the local stiffness matrices.* The global matrix has the form

$$S = \sum_i S_i,$$

where S_i is the local stiffness matrix associated with Ω^i. Formally, S_i is a large, sparse matrix with nonzero entries determined from shape functions in Ω^i. In the following, S_i will also be identified with the local matrix of order ρ_i given by the Gramm matrix $[B_{\Omega^i}(u,v)]$, where

$$B_{\Omega^i}(u,v) = \int_{\Omega^i} a\frac{\partial u}{\partial x}\frac{\partial v}{\partial x} + b\frac{\partial u}{\partial y}\frac{\partial v}{\partial y}\, dx\, dy, \tag{5}$$

and u and v range over all shape functions in Ω^i. The local contribution s_i to s is determined similarly from $\{F(v)\}$. For our study, we do not form S or s explicitly, but work directly with the local versions of S_i and s_i.

2. *Condensation of the local stiffness matrices.* The local stiffness matrices and right-hand sides have the form

$$S_i = \begin{bmatrix} A_i & B_i \\ B_i^T & C_i \end{bmatrix}, \qquad s_i = \begin{pmatrix} b_i \\ c_i \end{pmatrix}. \tag{6}$$

A_i corresponds to interactions among internal shape functions, C_i corresponds to interactions among side and nodal shape functions, and B_i corresponds to interactions between internal shape functions and side and nodal shape functions. Before solving for the unknowns associated with the frame of the partitioning $\mathcal{P}$, the unknowns associated with the interior Ω^i can be decoupled from the system. This process of *condensation*, or elimination of internal unknowns, entails computing the Schur complement

$$\tilde{C}_i = C_i - B_i^T A_i^{-1} B_i, \tag{7}$$

and modifying the right-hand side in a similar manner:

$$\tilde{c}_i = c_i - B_i^T A_i^{-1} b_i. \tag{8}$$

We will also normalize these quantities so that all local diagonal matrix entries are one, i.e.,

$$\hat{C}_i = D_i^{-1/2}\tilde{C}_i D_i^{-1/2}, \qquad \hat{c}_i = D_i^{-1/2}\tilde{c}_i, \tag{9}$$

where $D_i = \operatorname{diag}(\tilde{C}_i)$. This is equivalent to scaling the shape functions.

3. *Computation of the frame unknowns.* After the internal unknowns are eliminated, the result is a system of linear equations

$$\hat{S}\hat{\alpha} = \hat{s} \tag{10}$$

for the unknowns associated with the frame of $\mathcal{P}$. Here

$$\hat{S} = \sum_i \hat{C}_i, \qquad \hat{s} = \sum_i \hat{c}_i,$$

and $\hat{C}_i$ and $\hat{c}_i$ are determined from (9). We solve (10) using the preconditioned conjugate gradient method (PCG) [25]. For the preconditioner, we use the submatrix of $\hat{S}$ associated with *nodal* unknowns. That is, if the entries of $\hat{S}$ are arranged in the form

$$\begin{bmatrix} R & U \\ U^T & Q \end{bmatrix},$$

where Q corresponds to connections among nodal unknowns and R corresponds to connections among side unknowns, then the preconditioner for (10) is given by

$$\begin{bmatrix} I & 0 \\ 0 & Q \end{bmatrix}.$$

It is shown in [3] that the condition number of the resulting preconditioned matrix is

$$O(1 + (\log p)^2). \tag{11}$$

Hence the number of PCG iterations required for convergence is independent of h, and it grows very slowly as a function of p.

4. *Computation of the internal unknowns.* After the unknowns $\hat{\alpha}_i$ associated with the boundary Γ_i have been computed at step 3, the internal unknowns α_i associated with Ω^i can be computed by solving the system $A_i\alpha_i = b_i - B_i\hat{\alpha}_i$, using the Cholesky factorization of A_i computed in step 2.

3.2. Local stiffness matrix computations. Assume that the finite element discretization is made on an $n \times n$ element grid, and we have a parallel architecture with k processors where k divides n^2. The first two steps of the solution algorithm, construction of the local stiffness matrices and condensation, are naturally parallelizable. There are n^2 elements, so that there are n^2 local stiffness matrices to be constructed, each of which contains a subblock corresponding to a set of internal unknowns to be eliminated. All of these computations are obviously independent, so that they can be executed in parallel. Each processor has n^2/k elements assigned to it, for which it constructs the associated local stiffness matrices and then performs the corresponding condensation.

Consider the construction of the local stiffness matrices. The entries of S_i (6) are determined using (5). For general operators and domains, these entries must be computed by some quadrature rule that depends on the coefficients a and b, the shape of Ω^i, and the mapping T_i from $\mathcal{E}$ to Ω^i. In general, the resulting local stiffness matrix S_i is dense, although its nonzero structure may also be affected by these criteria. For rectangular elements, the shape functions specified in §2 have the form $\theta_j(x)\theta_k(y)$ where θ_j is a polynomial of degree j. Therefore, (5) simplifies to an expression of the form

$$B_{\Omega^i}(u,v) = \int\int a\theta_j'(x)\theta_l'(x)\theta_k(y)\theta_m(y) + b\theta_j(x)\theta_l(x)\theta_k'(y)\theta_m'(y)\,dxdy. \tag{12}$$

In this study, we are restricting our attention to the case where a and b are constant. For these problems, (12) further simplifies to

$$B_{\Omega^i}(u,v) = a\,I_x(j,k,l,m) + b\,I_y(j,k,l,m), \tag{13}$$

where

$$I_x(j,k,l,m) = I_1(j,l)I_0(k,m), \qquad I_y(j,k,l,m) = I_0(j,l)I_1(k,m), \tag{14}$$

and

$$I_0(s,t) = \int \theta_s\theta_t, \qquad I_1(s,t) = \int \theta'_s\theta'_t. \tag{15}$$

This reduces the costs of constructing S_i, since (15) can be computed in closed form, and many entries are zero. In particular, for both the $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$ discretizations, S_i has order $\rho_i = O(p^4)$, but only $O(p^2)$ entries are nonzero. (See Appendix.) For example, for the $\mathcal{Q}(p)$ discretization, if the rows and columns of S_i are ordered using the lexicographic ordering of shape functions

$$\Phi_{22}^{(\mathcal{I})}, \Phi_{32}^{(\mathcal{I})}, \cdots, \Phi_{p2}^{(\mathcal{I})}, \Phi_{23}^{(\mathcal{I})}, \cdots, \Phi_{pp}^{(\mathcal{I})},$$

$$\Phi_2^{(\mathcal{S},1)}, \cdots, \Phi_p^{(\mathcal{S},1)}, \Phi_2^{(\mathcal{S},2)}, \cdots, \Phi_p^{(\mathcal{S},2)}, \Phi_2^{(\mathcal{S},3)}, \cdots, \Phi_p^{(\mathcal{S},3)}, \Phi_2^{(\mathcal{S},4)}, \cdots, \Phi_p^{(\mathcal{S},4)},$$

$$\Phi^{(\mathcal{N},1)}, \Phi^{(\mathcal{N},2)}, \Phi^{(\mathcal{N},3)}, \Phi^{(\mathcal{N},4)},$$

then the nonzero structure for the $\mathcal{Q}(p)$ discretization is shown in Fig. 2.

In our code for constructing the local matrices, each entry of S_i is computed using (13)–(15), where the indices j, k, l, and m range over all values corresponding to the lower triangle of S_i. I_x, I_y, I_0, and I_1 can be thought of as representing FORTRAN functions, and (15) is computed in closed form using (23), (27), (28), and analogues for handling side and nodal shape functions. The routines corresponding to I_0 and I_1 are called only if the result is nonzero, as specified by (22). Thus the construction of S_i entails $O(1)$ scalar computations per entry, giving a total cost of $O(p^4)$. Computation of a zero entry entails several queries about the indices j, k, l, and m and at most three floating point operations; computation of a nonzero entry entails subroutine calls to I_x, I_y, I_0, and I_1, the latter two of which require on the order of 10 scalar floating point operations.

Now consider the other purely local operation, the condensation of the local stiffness matrix, to produce the Schur complement $\tilde{C}_i$ of (7). To perform this step, we compute the Cholesky factorization $A_i = L_iL_i^T$, and then compute $\tilde{B}_i = L_i^{-1}B_i$ and $C_i - \tilde{B}_i^T\tilde{B}_i$. These operations were implemented using (a slightly modified version of) off-the-shelf software from the BLAS2 subroutine library, which is designed to take advantage of vector architectures [17]. A general description of the algorithm is as follows. Assume that in (6), S_i has order ρ and A_i has order $\lambda \le \rho$. For any matrix M with the same dimensions as S_i, let

$$m_{\mu:\gamma,\nu} = (m_{\mu\nu}, m_{\mu+1,\nu}, \cdots, m_{\gamma,\nu})^T$$

denote the column vector consisting of entries μ through γ of the νth column of M, and let

$$M_\mu = \begin{cases} [m_{\sigma\tau}], \ \mu \le \sigma \le \rho, \ \nu \le \tau \le \mu - 1 & \text{if } \mu \le \lambda, \\ [m_{\sigma\tau}], \ \mu \le \sigma \le \rho, \ \nu \le \tau \le \lambda & \text{if } \mu > \lambda. \end{cases}$$

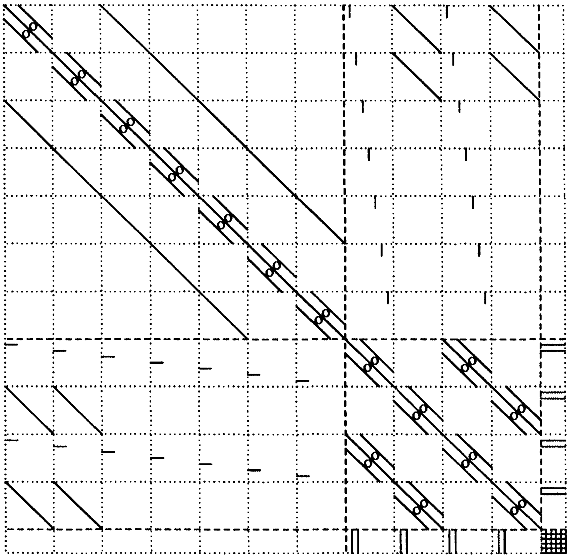

FIG. 2. *The nonzero structure of the local stiffness matrix for the $\mathcal{Q}(p)$ discretization. Solid lines indicate nonzeros; dashed lines delineate the sets $\mathcal{I}, S$, and $\mathcal{N}$; dotted lines delineate blocks of size $p-1$, and "o" identifies a zero band.*

M_μ is a submatrix of M in the lower left-hand corner of M. (See Fig. 3.) In the following code fragment, M initially contains the local matrix S_i of (6); as the computation proceeds, the contents of M are dynamically modified. In steps 1 through λ, the lower triangle of A_i is overwritten by the Cholesky factor L_i, and B_i^T is overwritten by $\tilde{B}_i^T$. In steps $\lambda+1$ through ρ, the lower triangle of C_i is overwritten with that of $\tilde{C}_i$.

(16)

```
for $\mu = 1$ to $\rho$ do
    $\nu_{max} \leftarrow \min\{\mu-1, \lambda\}$
    $m_{\mu:\rho,\mu} \leftarrow m_{\mu:\rho,\mu} - M_\mu m_{1:\nu_{max},\mu}$
    if $(\mu \le \lambda)$ then
        $m_{\mu\mu} \leftarrow \sqrt{m_{\mu\mu}}$
        $m_{\mu+1:\rho,\mu} \leftarrow m_{\mu+1:\rho,\mu}/m_{\mu\mu}$
    endif
enddo
```

Except for $m_{1:\nu_{\max},\mu}$, only the lower triangle of M is referenced. In the program used to implement this computation, only the lower triangle of M is stored, by column in *packed form.* That is, the contents of the array containing M are

$$m_{1,1}, m_{2,1}, \cdots, m_{\rho,1}, m_{2,2}, m_{3,2}, \cdots, m_{\rho,2}, m_{3,3}, \cdots m_{\rho,\rho}.$$

(Since the vector $m_{1:\nu_{\max},\mu}$ is, therefore, not available in contiguous storage, $m^T_{\mu,1:\nu_{\max}}$ is accumulated in a temporary vector at each step of the outer (μ) loop.) The sub-

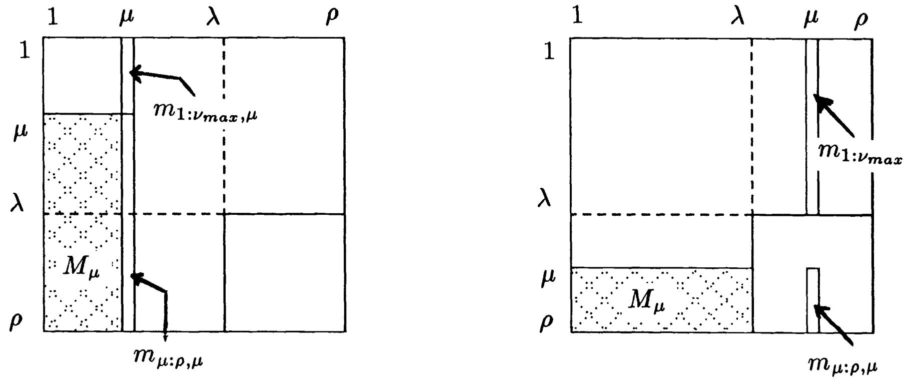

FIG. 3. *Submatrices and subvectors used for internal elimination. Quantities used for a Cholesky factorization step are shown on the left. Quantities used to compute the Schur complement are shown on the right.*

matrices and subvectors of M used in one step of internal elimination are depicted graphically in Fig. 3.

The algorithm (16) is essentially the "GAXPY" form of Gaussian elimination [19], [24], [25], in which the main large-scale operation at each step is a matrix-vector product

$$m_{\mu:\rho,\mu} \leftarrow M_\mu m_{1:\nu_{\max},\mu}. \tag{17}$$

The computations are arranged to take advantage of architectures with vector registers, by computing (17) as a linear combination of the columns of M_i. Our implementation is essentially that of the BLAS2 library [17].[1] In principle, the vector $m_{\mu:\rho,\mu}$ can be accumulated in one or more vector registers without being stored to memory until the computation (17) is complete.

For the $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$ discretizations, this implementation of the condensation step requires $O(p^4)$ floating point operations. This is determined by the cost of the matrix-vector product (17), and it is also strongly influenced by our choice of implementation. Consider the $\mathcal{Q}(p)$ discretization, where $\lambda = (p-1)^2$ and $\rho = (p+1)^2$. A feature of the BLAS2 software used for (17) is that only the nonzero entries of the vector $m_{1:\nu_{\max},\mu}$ are used for the linear combination of columns of M_μ. There are at most three such nonzeros for steps 1 through λ, and an average of $2.5(p-1)$ nonzeros for steps $\lambda+1$ through ρ. At step μ, the block M_μ contains $(p+1)^2 - (\mu-1)$ rows. Hence the number of floating point multiplications performed is approximately

$$\sum_{\mu=1}^{(p-1)^2} 3[(p+1)^2 - (\mu-1)] + \sum_{\mu=(p-1)^2+1}^{(p+1)^2} 2.5(p-1)[(p+1)^2 - (\mu-1)] \approx 1.5p^4 + 26p^3.$$

These computations are vectorized, but they do not take full advantage of sparsity, since M_μ is treated as a dense matrix. An implementation that operated only on the nonzeros of M_μ would require $O(p^2)$ operations.

[1] We used a slight modification of the subroutine DTPMV from the BLAS2 library. DTPMV computes a matrix-vector product $w \leftarrow Lv$ where L is a lower triangular matrix stored in packed form; our modification allows variations on outer loop counters to handle rectangular subblocks of L.

It is evident from this discussion that many factors contribute to the cost of construction and condensation of the local stiffness matrices. As we have noted, our program takes some advantage of the special structure of the test problem, but it does not make full use of sparsity in either construction or condensation. By way of comparison, consider the situation for more general problems, where the $O(p^4)$ entries of S_i are computed by applying a quadrature rule to (5) or, for rectangular domains, (12). Typically, $O(p)$ quadrature points are used in both the x and y coordinates, so that (ignoring the costs of function evaluations) (5) will require $O(p^6)$ floating point computations. For (12), this cost can be reduced to $O(p^5)$ by taking advantage of the tensor product structure [30]. The condensation is, asymptotically, an $O(p^6)$ computation. Of course, asymptotics also do not tell the whole story, since in general we work with relatively small values of p (on the order of 10); we expect asymptotic characterizations to be pessimistic for these values [4]. Both construction and condensation allow for significant amounts of vectorization, e.g., in the quadratures for construction and as in §3 for condensation. Our implementation is intended to take advantage of special problem structure in a "natural" way: in the matrix construction, by performing some computation for each entry, but not performing unnecessary quadratures; and in the condensation, by handling sparsity only in the manner inherited from standardized software. We believe that this implementation gives a plausible picture of the relative costs of construction and condensation; for more complex problems, absolute costs will be higher.

Step 4 of the solution algorithm, recovery of the internal unknowns, also entails purely local computations. However, because the solutions to our benchmark problems are identically zero, we did not experiment with this stage of the algorithm.

3.3. Computation of the frame unknowns. Next, consider the solution of the global linear system (10) by the preconditioned conjugate gradient method. We use the standard implementation of PCG, as described, for example, in [25, Algorithm 10.3.1]. Each step of the iteration requires a matrix-vector product by the coefficient matrix $\hat{S}$, a preconditioning solve of the form $w \leftarrow Q^{-1}v$, and a set of *vector operations* consisting of three inner products $\alpha \leftarrow v^T w$ and three daxpy's $w \leftarrow \alpha v_1 + v_2$. (This is one more inner product than specified in [25]. The extra one is used for a stopping test; see §4.1.)

The preconditioning operator and vectors required by PCG are represented with global indices; implementation issues associated with these quantities are discussed in §3.4. In this section, we focus on the matrix-vector product, which shares some of the purely local character of the local stiffness matrix computations. The global matrix $\hat{S}$ is not constructed explicitly; instead the matrix-vector product is computed as

$$w = \sum_i w_i = \sum_i \hat{C}_i v_i = \hat{S} v, \tag{18}$$

where the sum is taken over all elements, and $\hat{C}_i$ is the Schur complement associated with an individual element. The vector v_i is gathered from a globally indexed vector v, the local matrix-vector product $w_i = \hat{C}_i v_i$ is performed, and then w_i is used to update the global vector w. Hence the steps required for the local matrix-vector product are

a. *Index and copy*: determine the indices in v corresponding to v_i and copy v_i from v.

b. *Arithmetic*: $w_i = C_i v_i$.

c. *Update*: accumulate w_i into w.

For the parallel implementation, each processor performs this computation on all elements assigned to it. Ignoring any memory conflicts, all processors can read from the global vector v and compute the local matrix-vector product independently, so that steps a and b can be implemented with a high degree of parallelism. However, for the program to be correct, no more than one processor can write into a given location of w at any time. We enforce this by synchronizing all writes into w, so that execution of step c by different processors is performed serially. (See §3.4 for the method used to achieve this.) For the arithmetic step b, recall that only the lower triangle of $\hat{C}_i$ is stored, by column. The actual computation has the form shown in the following code fragment, in which $\gamma = \rho - \lambda$ is the order of $\hat{C}_i$, and for the sake of simplicity, the subscript i is omitted:

(19)

```
for $\mu = 1$ to $\gamma$ do
    $w \leftarrow w + v_\mu \hat{c}_{\mu:\gamma,\mu}$
    $w_\mu \leftarrow w_\mu + (\hat{c}_{\mu+1:\gamma,\mu})^T \hat{c}_{\mu+1:\gamma,\mu}$
enddo
```

That is, multiplication by the lower triangle is done using a linear combination of the columns, and the additional inner product and accumulation for the upper triangular multiplication are performed in the same loop. No extraneous vector writes (of w_i) or reads (of columns of $\hat{C}_i$) need be performed. (Thus this is also essentially a BLAS2-type computation [17].) For our test problems, approximately 50 percent of the entries of $\hat{C}_i$ are nonzero; however, as in the condensation, $\hat{C}_i$ is treated as a dense matrix.

3.4. Other coding conventions. We conclude this section with an outline of our coding conventions. All code was written in Alliant FX/8 FORTRAN and compiled using the global "-O" optimization switch. All vectorizable loops were preceded with the Alliant compiler directives `VECTOR` and (for global inner products) `ASSOC`. Thus all computations are fully vectorized. Although parallelism on the Alliant FX/8 can be achieved using compiler constructs, the compiler does not permit easy control of individual processors, and it also does not permit data-driven synchronization of the type required for the matrix-vector product. To circumvent these difficulties, we implemented all the local computations described above using the scheduling program SCHEDULE [20]. For a local computation such as construction of the local stiffness matrix, SCHEDULE runs on k processors by initiating k processes consisting of n^2/k matrix constructions. This is a relatively simple use of this software, which has the property that any overhead associated with it is amortized over n^2/k large-scale computations. Compiler-generated parallelism is explicitly prevented using Alliant FORTRAN compiler directives (i.e., `NOCONCUR`). Synchronization of the updates required by the matrix-vector products in PCG is enforced using SCHEDULE's *lockon* and *lockoff* primitives, which force processes to spin-wait when access to w is restricted. Finally, to handle SCHEDULE's requirement that multiple copies of subroutines be used simultaneously, all compilation was done with the "-recursive" switch.

Computations not discussed in detail above are the construction and factorization of the preconditioner, and the preconditioning and vector operations (inner products and scalar-vector products) performed during the PCG iteration. All these computations are *global* operations, in the sense that they are concerned with global quantities associated with the nodal and side unknowns. Constructing the preconditioner consists of assembling the (global) nodal operator Q from entries of the local stiffness matrices, and then computing the Cholesky factorization $Q = LL^T$. The factorization was performed using band elimination [25]. The preconditioning operation consists of forward-solves $w \leftarrow L^{-1}v$ and backsolves $w \leftarrow L^{-T}v$. The preconditioning and vector operations all contain a large amount of natural parallelism, but not at the element level. As a result, parallelism for these tasks was handled using Alliant compiler directives (CONCUR).

4. Experimental results. In this section, we present the results of a series of numerical tests of the algorithm of §3. For several problems, we give a general overview of costs, and then we show how these costs are broken down by individual computational tasks. Our objectives are both to show how the methods perform, and to understand what aspects of algorithms and computer architecture affect performance. In particular, we examine the influences of local and global computations required by algorithms, and of architectural considerations such as number of processors, vectorization, and cache memory. We remark that we are not examining the issue of accuracy of the computed solution here. Correlations between accuracy requirements and cost will be discussed in a subsequent report [5].

4.1. Machine independent results. For most results presented in this section, we used benchmark problems with the $\mathcal{Q}(p)$ discretization on $n \times n$ grids, with $p = 4$, 8, and 16, and $n = 4$, 8, 16, and 32. In addition, we have observed [5] that often the $\mathcal{Q}(p)$ and $\mathcal{Q}'(p)$ discretizations provide solutions of comparable accuracy when $p_{\mathcal{Q}} \approx \sqrt{2}p_{\mathcal{Q}'}$, so that we examined the $\mathcal{Q}'(p)$ discretization with $p = 6$, 11, and 23, on the same grids. The choices for degree represent moderate, large, and very large values. The values $p = 16$ for $\mathcal{Q}(p)$ and $p = 23$ for $\mathcal{Q}'(p)$ are larger than values typically used in practice and are studied primarily to see trends in the data; these values were not considered on the 32×32 grid. Tables 1 and 2 show the number of global and local unknowns of various types associated with these problems.[2]

In all experiments, the problems were posed with $s \equiv 0$, so that the solution to (10) is $\hat{\alpha} \equiv 0$. The stopping criterion for the PCG iteration was based on the relative error in the energy norm,

$$(\hat{\alpha}^{(j)}, \hat{S}\hat{\alpha}^{(j)})^{1/2}/(\hat{\alpha}^{(0)}, \hat{S}\hat{\alpha}^{(0)})^{1/2} \leq .5 \times 10^{-3},$$

where $\{\hat{\alpha}^{(j)}\}$ are the PCG iterates and the initial guess $\{\hat{\alpha}^{(0)}\}$ is a vector of random numbers between 0 and 1. Table 3 shows the number of iterations required to reach this stopping criterion. Note that these iteration counts are consistent with condition numbers of the form (11).

4.2. Overview of timing results. We first give a general overview of CPU times needed to solve these benchmark problems. For all experiments, reported times are in seconds, and they represent averages over three runs. The timings were determined from the "user time" returned by the Unix function *etime*; the measurements exclude timing overhead [1]. Speedup is defined to be the ratio of CPU time using one processor to CPU time on multiple processors; the same program was used in all experiments, so that the timings on one processor include a small amount of overhead associated with the scheduler.

[2] For simplicity of programming, we constrained the four vertices of $\partial\Omega$ by adding a constant to the diagonal entries of $\hat{C}_i$ associated with these vertices. This corresponds to constraining the vertices by spring supports. It does not influence any results discussed below.

Tables 4 and 5 show timing statistics and speedups for the $Q(p)$ and $Q'(p)$ discretizations, respectively, for the entire solution procedure. Table 6 shows the efficiencies of these computations, defined to be the ratio of speedup to number of processors. (Table 6 was computed with raw data, so there are some differences between these numbers and those obtainable from the rounded quantities shown in Tables 4 and 5.) These results show that, in general, speedups are higher for both larger values of p and for larger grid sizes. For the $Q(p)$ shape functions, efficiency on eight processors ranges from 40 percent for the smallest grid (4×4) and polynomial degree ($p = 4$), where scheduling overhead is high; to a maximum of 85 percent, corresponding to maximum speedup of slightly under 7. There are some examples of slight declines in efficiency when p increases from 8 to 16. The $Q'(p)$ shape functions incur larger costs and they have slightly higher efficiencies, but otherwise they produce qualitatively similar results to those for the $Q(p)$ shape functions.

Because the $Q(p)$ basis functions have lower costs, we restrict our attention to them in the sequel. Table 7 shows a breakdown of costs and speedups of several of the individual tasks performed by the solution algorithm, for $n = 16$ and three values of p. This data corresponds to the third row of each block row in Table 4. The computations are broken into three large-scale steps, consisting of the construction

and condensation of the local stiffness matrices, the construction and factorization of the nodal preconditioning matrix, and the preconditioned conjugate gradient iteration for computing the nodal and side unknowns. The first of these steps entails purely local computations, the second is associated with the global (nodal) mesh, and the third requires both local and global computations. We see the following trends in this data:

— The costs are dominated by local stiffness matrix computations (construction and elimination). Since these are purely local, they are very highly parallelizable, and we see speedups on eight processors of 7.47, 7.25, and 6.86, respectively, for $p = 4$, 8, and 16 (efficiencies of 93 percent, 91 percent, and 86 percent). Thus efficiencies are generally high, although there is a decline as p increases.

— The construction and factorization of the (nodal) preconditioning matrix represents a small percentage of the overall cost.

— The PCG iteration also represents a small percentage of the computation, although it is more costly than the construction of the preconditioner. The speedups achieved for this part of the computation are smaller than those of the local matrix computations, but they are strictly increasing as p increases.

Remark 1. The preconditioning operations and the CG vector operations were implemented in parallel using compiler directives, and we did not limit the number of processors on which these computations were performed. As a result, the timings for four and six processors are underestimates. However, as we show below, the contributions of both these operations to overall cost are small, so that these timings do give a reasonable picture of performance.

Figures 4 and 5 show the asymptotic behavior of the timings from Table 4, as functions of n and p, respectively, in loglog scale. Both figures reflect the fact that costs are dominated by the local matrix computations. Thus for any fixed p, there are n^2 independent local constructions and condensations, and the costs grow like n^2. For fixed n and large p, growth is slightly slower than $O(p^4)$, the asymptotic cost; for example, the line segment between $p = 8$ and $p = 16$, for one processor and $n = 16$,

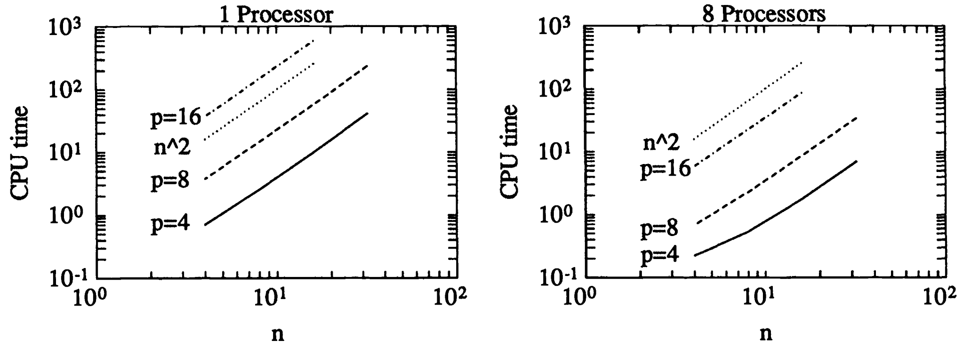

FIG. 4. *CPU times as functions of n, on* loglog *scale.*

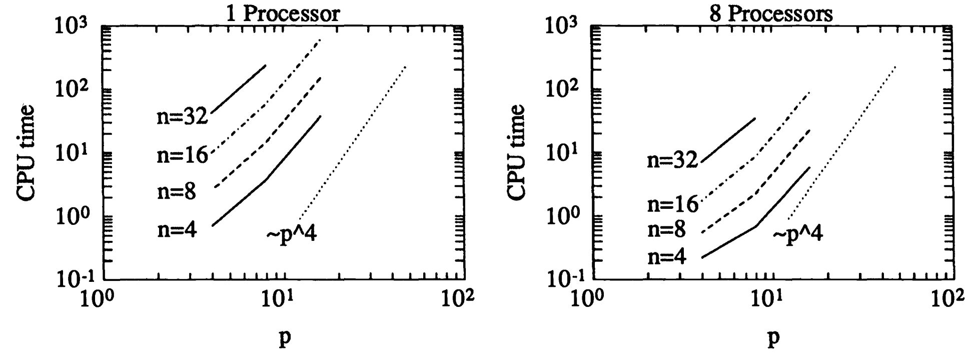

FIG. 5. *CPU times as functions of p, on* loglog *scale.*

has slope 3.34. For small p, growth is closer to $O(p^{2.5})$ because of the larger cost of computing the $O(p^2)$ nonzero entries.

4.3. Refined breakdown of costs. We now refine and elaborate on the timing results of Tables 4–7, showing how subsidiary steps of the tasks represented in Table 7 compare in cost. For these refined statistics, we compute costs on a single processor and supplement these results with discussion of how synchronization and memory conflicts affect performance on multiple processors.

First, consider the local stiffness matrix computations, i.e., construction and condensation of the local matrices. Table 8 shows the CPU times for each of these two steps on one processor, for $n = 16$ and $p = 4$, 8, and 16.[3] The results indicate that construction of the local matrices is more expensive than condensation. Since the matrix construction often involves a less regular set of computations than the condensation, we expect this phenomenon to be more pronounced for more general problems.

[3] To prevent calls to the timer from affecting measurements, the data in Tables 8 and 9 was generated separately from that in Tables 5 and 7, and Table 10 was produced separately from all of these. This is why these tables do not contain identical subtotals for identical computations.

TABLE 8

Breakdown of timing costs of local stiffness matrix computations on one processor, for a 16×16 *grid.*

Construct	3.98	33.24	366.28
Condense	2.58	15.06	184.99
Total	6.56	48.30	551.27

As noted above (see Table 7), although the local stiffness matrix computations corresponding to different elements are independent of one another, parallel efficiency declines as p increases. From Table 7, it is evident that efficiency also goes down as the number of processors grows. Figure 6 shows a more detailed picture of these phenomena. The curves represent speedups of the local matrix computations on four and eight processors, for $n = 8$, 12, and 16, and $p = 4$ through 18 in increments of 2. (As above, each curve represents average CPU times over three runs.) Here, the two sets of curves in each part of the figure correspond to two versions of the condensation step. The first version is the one used for all experiments described thus far; as shown in §3, it takes some advantage of sparsity of the local matrices. The second version takes no advantage of sparsity during the condensation, so that the computation (7) is performed as though all participating matrices are dense.[4] Thus this version is considerably more expensive. The same procedure for constructing the local matrices, as described in §3, was used with both versions of the condensation. The results of these figures show that there is indeed a decline in speedup as p increases, especially for the more costly version of condensation; in addition, efficiency is greater on four processors than on eight processors.

To understand these issues, it is necessary to examine the computer architecture in more detail. A feature of the Alliant FX/8 is that data moves between main memory and computational elements (i.e., processors) through a cache memory. Main memory and cache memory are connected by two buses, and cache memory and computational elements are connected by a crossbar switch with four paths to the cache [1], [18], [29]. Thus there are two sources of delay associated with movement of data between memory and processors: (i) it will take longer for data to move between processors and main memory than between processors and cache memory; (ii) when multiple processors are used, there will be contention for the buses (between main and cache memories), and possibly some delay in moving data through the crossbar switch (between cache memory and processors). We expect the crossbar switch to be less of a bottleneck than the buses [29]. However, if more than two processors attempt to move data to or from main memory, some processors will have to wait for access to the buses. Consequently, contention for the buses will tend to increase any delays caused by the need to move data between main and cache memories.

Although it is difficult to prove rigorously that these observations provide a complete explanation of parallel performance, the results of Fig. 6 are consistent with them. The machine used for these experiments has a cache memory with 512K bytes, or 64K double precision words. For the local stiffness matrix computations, each processor works with one block of storage of size equal to the number of entries in the upper triangle of the local stiffness matrix (approximately $(p+1)^4/2$). Consequently, k such blocks of storage fit into the cache provided $k \times (p+1)^4/2 \leq 65536$, which gives

[4] This entails removing checks for zero entries in the vector $m_{1:\nu_{\max},\mu}$ for the matrix-vector product (17).

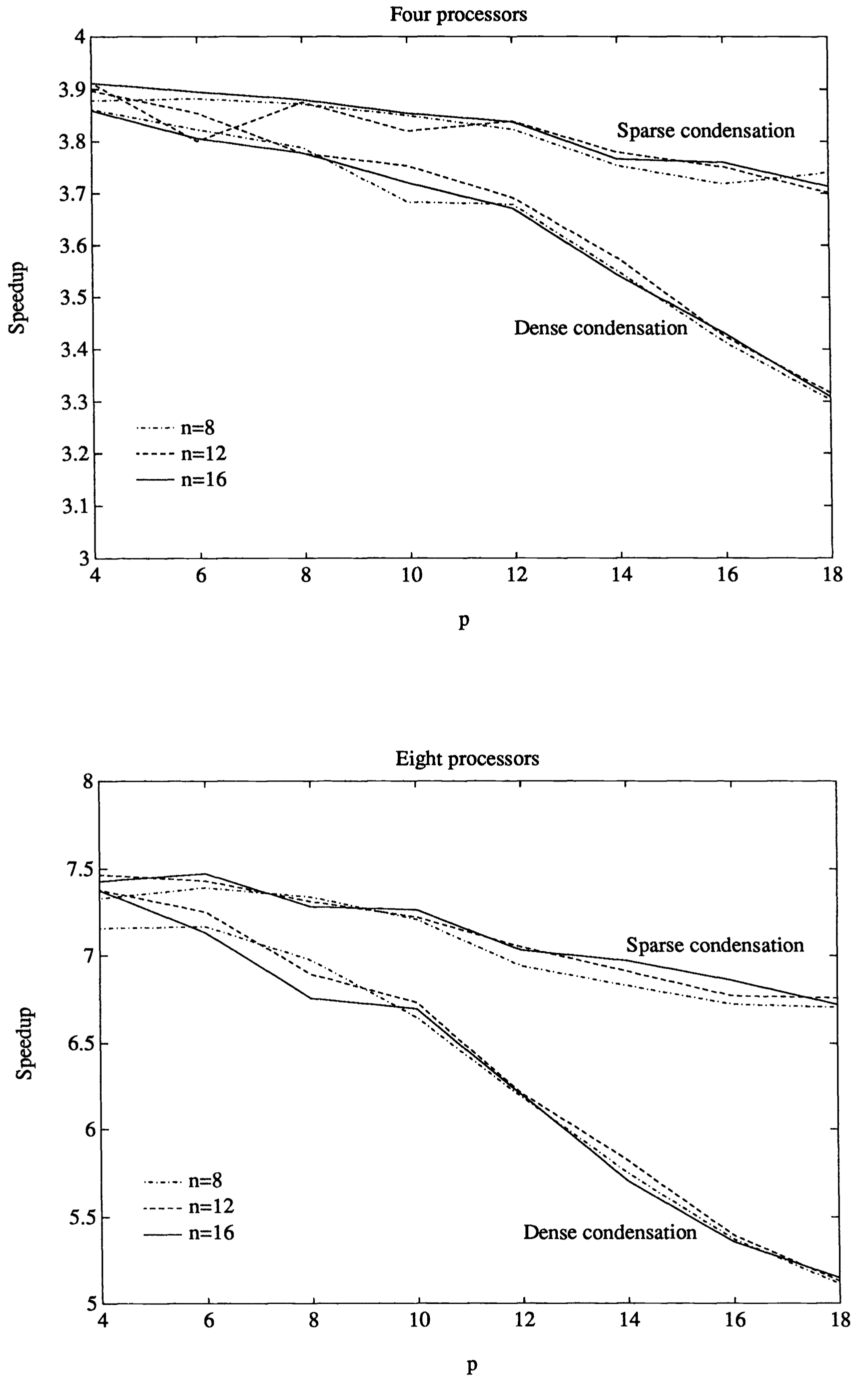

FIG. 6. *Speedups of local stiffness matrix computations for three meshes, on four and eight processors.*

$p \leq 12$ for $k = 4$ and $p \leq 10$ for $k = 8$. Examination of Fig. 6 shows steeper declines in speedups at precisely these values of p. The delays are greater for dense condensation, which we attribute to the additional memory references required for this version. We suspect that the (less pronounced) drops in speedup for smaller problems are partly explained by the lesser delays associated with the crossbar switch. In addition, in general we have no control over how data is distributed between cache memory and main memory, and it may be that the cache is not used with maximum efficiency even when all local matrices could fit into it. Thus there may be some additional congestion between the two levels of memory even for smaller problems. Finally, note that Fig. 6 suggests that speedup is essentially unaffected by the number of elements. This is substantiated by the following simple analysis. Let c_s denote the cost of processing a single local stiffness matrix in a serial computation, and assume that the parallel cost is increased to $c_p = (1 + \delta)c_s$, where δ (which may increase with k) reflects the delay due to memory contention. Then the speedup on k processors is

$$\frac{n^2 c_s}{n^2/(kc_p)} = k/(1 + \delta),$$

i.e., it is independent of the number of elements.

Remark 2. The last observation contrasts with our previous statement that speedups are somewhat lower for very coarse grids, i.e., $n = 4$, especially when p is also small. (See Tables 4 and 5.) For such small problems, smaller speedups are the result of scheduling overhead, which is amortized over a relatively small amount of computation.

Remark 3. The effects of memory conflicts of the type discussed above can also be diminished by implementing the condensation with BLAS3-type constructs [16], which are designed to use cache memory efficiently.

The PCG iteration does not contribute as much to overall cost as the local computations. Nevertheless, consideration of its individual steps still reveals some interesting properties of the particular form of the matrix-vector product (18), as well as some differences between global and local operations. We group the iterations into four subsidiary operations: matrix-vector products $w \leftarrow \hat{S}v$; preconditioning solves $w \leftarrow Q^{-1}v$; and two types of vector operations, inner products $\alpha \leftarrow v^T w$, and daxpy's $w \leftarrow \alpha v_1 + v_2$, of which there are three each. Table 9 shows a breakdown of the costs of these individual operations on a 16×16 grid, using one processor, and Table 10 further refines the details of the matrix-vector product. Here, "arithmetic" refers to the computation (19) used to perform the matrix-vector product; "index/copy" refers to the identification of global locations of local vectors and the copying of entries of global vectors (v in (18)) to local vectors (v_i); and "synchronize/copy" refers to the copy from w_i to w, plus the execution of the synchronization functions that prevent simultaneous writes to shared locations of w. "I/O" refers to the cost of copying the local stiffness matrix from one memory location to another.[5]

These results indicate that the matrix-vector product dominates the PCG iteration. This is largely a consequence of floating point operation counts (multiplications

[5] This cost is an artifact of the program design, which allows either in-core or out-of-core storage for local stiffness matrices, but in both cases requires that the local matrix be explicitly read from some source. This data movement could have been avoided, so that the cost of the matrix-vector is artificially high. It does not, however, alter our general conclusions. The cost of I/O would be much higher with out-of-core techniques.

and additions), which are summarized as follows:

$$\begin{aligned}&\text{matrix-vector product} : 32n^2p^2,\\ &\text{CG-vector operations} : 24n^2p,\\ &\text{preconditioning solves} : 4n^3.\end{aligned}$$

The first line of Table 11 shows the ratios of operation counts for the matrix-vector products to operation counts for the other two steps, for $n = 16$ and several values of p; the data reveals the dominance of the matrix-vector product. The second line of the table shows the analogous ratios of CPU times, where the timing data for the CG-vector and preconditioning operations comes from Table 9, and the data for the matrix-vector product is from the "Arithmetic" entry of Table 10. We see that the results for operation counts agree qualitatively with those for CPU times, but they do not tell the whole story. For example, in the comparison of matrix-vector product and CG-vector operations, the ratios for operation counts are smaller than those for CPU times, indicating that the CG-vector operations are implemented more efficiently. Other factors that affect performance are vector startups and vector lengths. Each of the n^2 local matrix-vector products requires $4p$ vector startups, giving a total of $4n^2p$ startup overhead for the matrix-vector product; this contrasts with just six vector startups for the CG-vector operations. In addition, we are using only the lower triangle of the matrix $\hat{C}_i$, so that some of the vectors used in (19) are smaller than the Alliant's basic vector length of 32. Hence, although all these computations are vectorizable, performance for the matrix-vector is somewhat lower than for the CG-vector operations. The effect of startup overhead will be diminished on multiple processors, since some startups will be performed in parallel. In the comparison of matrix-vector and preconditioning steps, we see that for $p \geq 8$, the cost of the preconditioning (band)-solve is higher than the operation counts predict (i.e., the ratios of CPU times are smaller than the ratios of operation counts); this is because its typical vector length is the bandwidth n, or 16 for these data, i.e., less than 32.

A second general issue, which limits the speedups achieved by the PCG computations (Table 7), is the need to synchronize the results of local matrix-vector products

TABLE 11
Ratios of costs of PCG *operations on a* 16 × 16 *grid.*

	Matrix-vector product vs. CG-vector operations			Matrix-vector product vs. preconditioning		
	p =4	p =8	p =16	p =4	p =8	p =16
Ratio of operation counts	5.7	10.7	21.3	4.0	32.0	128.0
Ratio of CPU times	16.2	16.7	27.7	8.0	18.0	48.0

in forming the global product (18). Consider the following analysis. Let c_p denote the fully parallel part of the local matrix-vector product, consisting of the "index/copy" and "arithmetic" and "I/O" steps; here, we are ignoring any memory conflicts that may exist in these steps. Let c_s denote the serial part, consisting of the "synchronize/copy" steps. The cost of the global matrix-vector product on one processor is $n^2(c_p + c_s)$. In a parallel computation, processes often have to wait for access to w, and the wait can be as long as $(k-1)c_s$. Suppose every local matrix-vector product waits this long. The cost of the parallel computation is then approximately

$$\frac{n^2}{k}(c_p + (k-1)c_s),$$

so that the speedup is approximately

$$\frac{n^2(c_p + c_s)}{\frac{n^2}{k}(c_p + (k-1)c_s)} = k\left(\frac{c_p + c_s}{c_p + (k-1)c_s}\right). \tag{20}$$

Since the matrix-vector product dominates the PCG iteration, we also take (20) as a measure of the speedup achievable by PCG. Table 12 compares the values of (20) (where c_p and c_s are taken from Table 10) with the actual speedups from Table 7. The results suggest that (20) is a good indicator of the qualitative behavior of the PCG iteration. We attribute the fact that the accuracy of the model decreases with additional processors to added memory conflicts.

TABLE 12
Comparison of speedup model with actual speedups of the PCG *iteration, for a* 16 × 16 *grid.*

	$p = 4$		$p = 8$		$p = 16$	
Processors	Model	Actual	Model	Actual	Model	Actual
4	3.35	2.84	3.45	3.26	3.66	3.51
6	4.32	3.53	4.56	4.26	5.07	4.54
8	5.06	3.95	5.43	5.01	6.27	5.34

Remark 4. Although this model is pessimistic in the sense that $(k-1)c_s$ may be a long waiting time, we have observed empirically that processors do not reach the synchronization step in a fixed order, so that there are large delays for many local computations. It is also possible to decrease synchronization overhead using better bookkeeping techniques to identify specific locations of w that are available.

4.4. Comments on performance. Finally, we discuss the performance, in terms of floating point operations, of parts of the code that are both vectorized and implemented in parallel. Consider the condensation of the local stiffness matrices, which entail Cholesky factorization and computation of the Schur complement. To simplify operation counts, in the experiments considered here we used the dense version of condensation, as described in the discussion of Fig. 6. For the $Q(p)$ discretization, the floating point operation (multiplications and additions) counts are:

$$\text{Factor } A_i = L_i L_i^T : \tfrac{1}{3}(p-1)^6 + (p-1)^4 - \tfrac{4}{3}(p-1)^2$$

$$\text{Compute } \hat{B}_i = L_i^{-1} B_i : 4(p-1)^2((p-1)^2+1)p$$

$$\text{Compute } \hat{C}_i = C_i - \hat{B}_i^T \hat{B}_i : 4p(4p+1)(p-1)^2.$$

CPU times on one processor, for $n = 16$ and $p = 8$ and 16, are 28.4 and 874.5 seconds, respectively, giving performances in millions of floating point operations per second (Mflops) of 1.55 for $p = 8$ and 2.35 for $p = 16$. Based on the speedups for the local computations from Fig. 6 (6.75 for $p = 8$ and 5.36 for $p = 16$), this gives performance estimates on eight processors of 10.5 and 12.6 Mflops, respectively. Similar results were also obtained for the matrix-vector product (18)–(19), with a maximum rate of three Mflops on one processor (for local matrices of order approximately 500).

By way of contrast, the LINPACK benchmark (for dense elimination with dense matrices of order 100) on a single processor of an Alliant FX/4 is 2.1 Mflops [15], and on eight processors, the BLAS2 kernels with arguments in main memory achieve 18–20 Mflops [24, p. 81]. Hence our performance on vectorized code is at best comparable to that of the BLAS2 kernels. Note that this is lower than performance achieved for a variety of matrix operations reported, e.g., in [24], where BLAS3-type blocking strategies lead to performance of upwards of 30 Mflops. There are several reasons for this. First, despite the fact that (17) and (19) are designed to avoid unnecessary stores of the accumulating products $m_{\mu:\rho,\nu}$ and w, examination of the generated assembler code reveals that the actual computations are not performed efficiently. For example, in principle, the outer loop of (17) requires a daxpy with one argument (columns of M_μ) taken from memory, but no loads or stores to memory; the actual code performs one store, one load, and a daxpy with one argument in memory. Thus there are three times as many memory references as are necessary, leading to a degradation of performance on the order of 50 percent. Second, we have little control over management of the cache memory; we suspect that because there are many local matrices being processed, they are likely to be located in main memory rather than cache memory. The good performances exhibited in [24] were achieved using hand-coded assembler [23]. We believe that better performance of the techniques under consideration here can be obtained using more sophisticated coding techniques. However, since these tasks do not have the dominant cost of the overall computation, further tuning will not affect our conclusions, and we have not pursued this issue. For more complex problems, e.g., where local stiffness matrices are constructed by (vectorized) quadrature, it would be imperative to implement the quadratures efficiently.

5. Conclusions. In this paper, we have examined the computational costs of an implementation of the *hp*-version of the finite element method on the Alliant FX/8, a shared-memory parallel computer. Our main conclusions are as follows:

1. Costs are dominated by the local computations, i.e., construction of local stiffness matrices and condensation of these matrices for elimination of internal unknowns.

2. Global operations, particularly the preconditioning associated with nodal unknowns, contribute a relatively small amount to overall cost.

3. Communication and synchronization costs associated with the use of unassembled local stiffness matrices for CG iteration do not greatly degrade performance, and their effects are understood.

4. The likelihood of memory conflicts places limitations on the sizes and number of local problems that can be handled efficiently. We expect this problem to be ameliorated through the use of more sophisticated coding techniques such as those available in the BLAS3 [16] or LAPACK [2] libraries, but we do not expect it to disappear entirely.

Thus the "natural parallelism" associated with the decomposition of problems by elements can be exploited in a straightforward manner to get good speedups, provided the size or number of local problems are not too large. These conclusions apply to a particular type of architecture, a shared-memory machine with a relatively small number of processors. We expect similar results to apply to other machines in this class, e.g., the CRAY-2.

We now discuss how we expect our observations to carry over to other classes of problems and computers.

1. *Different problem coefficients or domain topologies.* As long as the element grid is topologically rectangular, the general methodology described here should be applicable. As shown in §3, if the coefficients of (1) are more complex, or if the domain is less regular, then the fully local computations are more expensive, and we expect these costs to be more dominant. For highly anisotropic problems (e.g., large a/b) or discretizations with very flat rectangular elements, there may be an increase in PCG iteration counts, but we suspect this will not offset the dominance of the local computations.

2. *Use of the h-version.* If the h-version is used for discretization, then the analogue of the solution method presented here is domain decomposition, with local super-elements consisting, e.g., of p^2 elements. In this case, for PCG iterations to display convergence rates independent of problem size, it is necessary to perform some type of modification of the super-element side and internal shape functions [3], [6], [11]. We expect conclusions similar to those above to hold for such methodologies. An alternative for achieving fast convergence is to use standard shape functions, but to apply a relatively fine nodal preconditioner [27]. For such a strategy, a larger percentage of computational effort is devoted to the sparse matrix factorization and solves associated with preconditioning than we have observed.

3. *Adaptive methods.* In contrast to the methodology considered here, where all operators were computed "from scratch," the hp-method is often implemented in a hierarchical manner, where higher-order elements are used to supplement previously computed low-order operators. In this case, the local computations will be somewhat less dominant. Many issues along these lines, such as load balancing if different order basis functions are used in different elements, as well as mesh refinement strategies, remain open.

4. *Shared-memory computers with more processors.* Increasing the number of processors decreases the costs of the local stiffness matrix computations more than those of the other computations. For example, for all of the problems of Table 7, we estimate that increasing the number of processors by as much as a factor of four (to 32) will decrease the local costs significantly, but the effect on the costs of PCG will be small. In such a scenario, for $p \geq 8$ local costs will still dominate. In light of the fact that our local costs are artificially low, we expect our conclusions to apply for shared-memory machines with on the order of 50 processors. However, for this to be borne out, it will be necessary for the local matrix computations to be implemented so that memory conflicts do not limit efficiency.

5. *Local-memory computers.* We do not attempt to make a precise statement about this class of architectures, but to outline some of the issues. The memory conflicts associated with local matrix computations on shared-memory computers should not be a factor on local-memory machines, so that we expect the local computations to be more efficient on the latter class of architectures. The matrix-vector products entail exchanges of data corresponding to super-element boundaries, but we expect the effect of this overhead to be similar to that of the synchronization required by the shared-memory implementation. It is necessary to implement the global preconditioner and other CG operations efficiently.

Appendix. We outline the properties of the shape functions that give rise to sparse local stiffness matrices for constant coefficient problems. Consider the representation

$$S_i = \begin{bmatrix} (\mathcal{I},\mathcal{I}) & (\mathcal{I},\mathcal{S}) & (\mathcal{I},\mathcal{N}) \\ (\mathcal{S},\mathcal{I}) & (\mathcal{S},\mathcal{S}) & (\mathcal{S},\mathcal{N}) \\ (\mathcal{N},\mathcal{I}) & (\mathcal{N},\mathcal{S}) & (\mathcal{N},\mathcal{N}) \end{bmatrix}, \tag{21}$$

where each entry represents a block matrix containing all terms (5) in which the shape functions come from the indicated set. Thus, for example, the block $(\mathcal{S},\mathcal{I})$ contains all terms in which $u \in \mathcal{S}$ and $v \in \mathcal{I}$. (In (6), A_i corresponds to $(\mathcal{I},\mathcal{I})$.) From properties of the Legendre polynomials, it can be shown that the following relations hold:

(22)

$$\begin{array}{llll}
\text{In } (\mathcal{I},\mathcal{I}): & B_{\Omega^i}(\Phi^{(\mathcal{I})}_{jk},\Phi^{(\mathcal{I})}_{lm}) \neq 0 & \text{iff} & (j = l \text{ or } j = l \pm 2) \text{ and } k = m; \text{ or} \\
 & & & (k = m \text{ or } k = m \pm 2) \text{ and } j = l. \\
\text{In } (\mathcal{S},\mathcal{I}): & \left.\begin{array}{r} B_{\Omega^i}(\Phi^{(\mathcal{S},1)}_{j},\Phi^{(\mathcal{I})}_{lm}) \neq 0 \\ B_{\Omega^i}(\Phi^{(\mathcal{S},3)}_{j},\Phi^{(\mathcal{I})}_{lm}) \neq 0 \end{array}\right\} & \text{iff} & j = m \text{ and } (l = 2 \text{ or } l = 3). \\
 & \left.\begin{array}{r} B_{\Omega^i}(\Phi^{(\mathcal{S},2)}_{j},\Phi^{(\mathcal{I})}_{lm}) \neq 0 \\ B_{\Omega^i}(\Phi^{(\mathcal{S},4)}_{j},\Phi^{(\mathcal{I})}_{lm}) \neq 0 \end{array}\right\} & \text{iff} & j = l \text{ and } (m = 2 \text{ or } m = 3). \\
\text{In } (\mathcal{N},\mathcal{I}): & B_{\Omega^i}(\Phi^{(\mathcal{N},j)},\Phi^{(\mathcal{I})}_{lm}) \equiv 0. & & \\
\text{In } (\mathcal{S},\mathcal{S}): & B_{\Omega^i}(\Phi^{(\mathcal{S},l)}_{j},\Phi^{(\mathcal{S},m)}_{k}) \neq 0 & \text{iff} & l - m \text{ is even and } (j = k \\
 & & & \text{or } j = k \pm 2). \\
\text{In } (\mathcal{N},\mathcal{S}): & B_{\Omega^i}(\Phi^{(\mathcal{N},k)},\Phi^{(\mathcal{S},l)}_{j}) \neq 0 & \text{iff} & j = 2 \text{ or } j = 3. \\
\text{In } (\mathcal{N},\mathcal{N}): & B_{\Omega^i}(\Phi^{(\mathcal{N},j)},\Phi^{(\mathcal{N},k)}) \neq 0. & &
\end{array}$$

Relations in $(\mathcal{I},\mathcal{S})$, $(\mathcal{I},\mathcal{N})$, and $(\mathcal{S},\mathcal{N})$ are determined from symmetry.

As an example of how (22) is established, consider the entries of $(\mathcal{I},\mathcal{I})$. Let $(f,g) \equiv \int_{-1}^{1} f(\xi)g(\xi)d\xi$. The Legendre polynomials satisfy [14]

$$(P_j, P_k) = \begin{cases} 1/(2j+1) & \text{if } j = k, \\ 0 & \text{if } j \neq k; \end{cases} \tag{23}$$

$$P_j(\xi) = \frac{1}{2j+1}\left(P'_{j+1}(\xi) - P'_{j-1}(\xi)\right); \tag{24}$$

$$P_j(-1) = (-1)^j. \tag{25}$$

From (3) and (13)–(15), we have

$$B_{\mathcal{E}}(\Phi^{(\mathcal{I})}_{jk}, \Phi^{(\mathcal{I})}_{lm}) = a\,(\phi_j, \phi_l)(\phi'_k, \phi'_m) + b\,(\phi'_j, \phi'_l)(\phi_k, \phi_m). \tag{26}$$

Consequently, (3), (24), and (25) imply that

$$\phi_j(\xi) = \frac{1}{\sqrt{2(2j-1)}}\,(P_j(\xi) - P_{j-2}(\xi)),$$

so that

$$(\phi_j, \phi_l) = \begin{cases} [(P_j, P_j) + (P_{j-2}, P_{j-2})] \,/\, [2(2j-1)] & \text{if } j = l, \\ -(P_j, P_j) \,/\, [2\sqrt{(2j-1)(2j+3)}] & \text{if } j = l-2, \\ -(P_{j-2}, P_{j-2}) \,/\, [2\sqrt{(2j-1)(2j-5)}] & \text{if } j = l+2, \\ 0 & \text{otherwise.} \end{cases} \tag{27}$$

Moreover,

$$\phi'_k(\xi) = \sqrt{\frac{2k-1}{2}}\,P_{k-1}(\xi),$$

so that

$$(\phi'_k, \phi'_m) = \begin{cases} [(2k-1)/2]\,(P_{k-1}, P_{k-1}) & \text{if } k = m, \\ 0 & \text{otherwise.} \end{cases} \tag{28}$$

Thus the first term of (26) is nonzero if and only if $j = l$ or $j = l \pm 2$ and $k = m$; the second term is handled in an identical way.

Acknowledgment. We thank Kyle Gallivan for several helpful discussions.

A SEMICOARSENING MULTIGRID ALGORITHM FOR SIMD MACHINES [*]

J. E. DENDY, JR.[†], M. P. IDA[‡], AND J. M. RUTLEDGE[§]

Abstract. A semicoarsening multigrid algorithm suitable for use on single instruction multiple data (SIMD) architectures has been implemented on the CM-2. The method performs well for strongly anisotropic problems and for problems with coefficients jumping by orders of magnitude across internal interfaces. The parallel efficiency of this method is analyzed, and its actual performance is compared with its performance on some other machines, both parallel and nonparallel.

Key words. multigrid, parallel computing

AMS(MOS) subject classifications. 65N20, 65W05

1. Introduction. Some previous papers have examined multigrid methods for their suitability for calculation on machines with SIMD architectures. Frederickson and McBryan [FM] developed and analyzed a method that was designed to keep all the processors busy. Decker analyzed [D1] the performance on SIMD machines of more traditional multigrid methods. Both of these papers were restricted to Poisson's equation with periodic boundary conditions; neither paper attempted to address the sort of problem we are interested in, namely,

$$-\nabla \cdot (D(x,y)\nabla U(x,y)) + \sigma(x,y)U(x,y) = F(x,y) \tag{1.1}$$

in a bounded region Ω of R^2, where $D = (D^1, D^2)$, D^i is positive, $i = 1, 2$, and D^i, σ, and F are allowed to be discontinuous across internal boundaries Γ of Ω; moreover, $D_1 \gg D_2$ and $D_1 \ll D_2$ in different subregions of Ω is possible.

Another method was advocated by Hackbusch [H] and was shown to be robust for constant coefficient, periodic, anisotropic problems. It can be argued that this method, or at least its precursor, may be found in [T]. We refer to this method as the Brandt–Hackbusch–Ta'assan method, if only to arrive at the acronym BHT. The BHT method, like the Frederickson–McBryan algorithm, preserves the busyness of the processors, and has the added advantage of only needing point relaxation for anisotropic problems. However, as shown in §4, the BHT method, as described by Hackbusch, does not handle problems like (1.1), and it is unclear how to give the method this capability.

Both the Frederickson–McBryan and BHT methods have the presumed advantage of keeping all the processors busy. However, idleness of processors is unimportant; what is important is the convergence factor per machine cycle. If keeping all the processors busy led to a significantly smaller convergence factor, then the busyness of processors would indeed be important. Also, busyness of processors may be an important issue only on grids with less than one point per processor (virtual processor ratio (VP ratio) less than 1). When the VP ratio is greater than 1, the CM-2 makes use of virtual processors. In effect, serial do loops (VP loops) are created on each

[*] Received by the editors March 25, 1991; accepted for publication (in revised form) October 25, 1991. processor. Thus, when the VP ratio is greater than 1, "busy processor" methods actually incur a substantial computational penalty. Since moderate-size problems easily exceed VP ratios of 1 on today's machines, "busy processor" methods would seem to be, at best, methods for the future.

What about the more traditional methods of dealing with (1.1)? The first multigrid method to handle such problems successfully was given in [ABDP] and expanded in [D2]; it used standard coarsening (discussed below), interpolation induced by the operator, Galerkin coarsening, and alternating red-black line relaxation. An alternative was first discussed in [DMRRS] for three-dimensional problems. (However, we must point out that the robustness of line relaxation coupled with semicoarsening for constant coefficient anisotropic problems was first reported in [W].) The method discussed in this paper is the two-dimensional analogue of the method in [DMRRS]; it uses semicoarsening in y, interpolation induced by the operator, Galerkin coarsening, and red-black line relaxation by lines in x. Additionally, the method in this paper uses a technique due to Schaffer [S]; without this technique, the semicoarsening method would not be competitive. The method discussed in this paper is largely the same as the method given in [SW]. This fact should not be too surprising, since both papers had their genesis in a code written by Dendy.

One potential liability of the method considered in this paper is the necessity to perform line relaxation. The BHT method, were it robust, would avoid this difficulty. The suggestion was made in [B] that anisotropies could be avoided by the use of local grid refinement, under the assumption that physical problems are isotropic and that anisotropies arise from nonuniform gridding. One way to avoid nonuniform gridding is to use local grid refinement. In [D3], it was shown how to generalize [D2] to the case of local grid refinement. However, many person-years have been invested in codes that do not use local grid refinement, and all these codes would have to be rewritten to use this approach. Moreover, it is not clear how local grid refinement algorithms will perform on SIMD machines. Finally, there are important physical problems which are strongly anisotropic; an example is petroleum reservoir engineering [L]. For these problems, local grid refinement, although it may be desirable for other reasons, does not lead to isotropic problems on the local grids. Thus it appears that the issue of anisotropic problems must be directly attacked, not avoided.

Yet another method, due to Mulder [M], seems to have possibilities. The idea is that each grid has two offspring, one obtained by semicoarsening in x, the other by semicoarsening in y. When two offspring are of the same size in x and y, they are declared to be the same offspring. This method is discussed further in §2.

2. Standard versus semicoarsening. In [ABDP] and [D2] standard coarsening was used; that is, given a Cartesian grid, the coarser grid is obtained by deleting the even x- and y-lines. In this paper semicoarsening is used; that is, the coarser grid is obtained by deleting the even y-lines. To handle general anisotropic situations with standard coarsening seems to require alternating line relaxation, whereas with semicoarsening only, line relaxation by lines in x is required. (We note that there are some situations in both cases that cannot be handled by these choices of relaxation [ABDP], but for our purposes, these cases are pathological.) What is the sequential relaxation work for the two methods? Given an $nx \times ny$ grid, the relaxation work for semicoarsening is of the order of $2(nx)(ny)(1+1/4+\cdots) = (8/3)(nx)(ny)$. For semicoarsening, the relaxation work is of the order of $(nx)(ny)(1+1/2+\cdots) = 2(nx)(ny)$.

To do this same counting argument for a SIMD architecture requires a short discussion of the assumptions. We first consider the case where the VP ratio is less than or equal to 1. In the simplest model for the CM-2, it is important that the arrays be "compatible," that is, of the same size; otherwise, great inefficiencies in communication result. Thus, given a fine grid and a coarser grid, it is assumed that the data for each grid are stored in compatible arrays. Thus every other row of the coarse grid matrix contains no useful information. Moreover, on a relaxation sweep, a mask is employed which makes the processors for these rows idle. The assumption, therefore, is that for every grid, the amount of work required to solve the collection of tridiagonal systems on that grid depends only on the number of x- or y-points on the finest grid. Thus the relaxation work in the standard coarsening case is $2W(nx)\log_2 ny$, and the relaxation work in the semicoarsening case is $W(nx)\log_2 ny$, where $W(nx)$ is the work to solve an $nx \times ny$ tridiagonal system. (There are $\log_2 ny$ grids, and on each grid the relaxation work is $2W(nx)$ or $W(nx)$, respectively.) If sparse Gaussian elimination (a.k.a. the Thomas algorithm) is used, $W(nx) = O(nx)$. If straightforward cyclic reduction is used, $W(nx) = O(\log_2 nx)$.

The above argument is correct for the tridiagonal solver currently implemented in CMSSL (CM Scientific Subroutine Library). However, we can write a tridiagonal solver that yields the following relaxation work estimate for the standard coarsening case:

$$\begin{aligned} 2\left(\log_2 nx + \log_2 \frac{nx}{2} + \cdots\right) &= 2(\log_2 nx + (\log_2 nx - 1) + \cdots) \\ &= 2\left(\log_2 nx \log_2 ny - \frac{1}{2}(\log_2 ny - 1)(\log_2 ny)\right) \\ &\simeq \log_2 nx \log_2 ny. \end{aligned}$$

The point is that when we know that, for example, every other processor is idle, the cyclic reduction algorithm can be started further along, eliminating every fourth point instead of every second point. For a VP ratio less than 1, however, communication dominates computation, so it is unlikely that this improved algorithm will be twice as fast as using the CMSSL tridiagonal solver, particularly since the latter is written in carefully optimized assembly language.

When the VP ratio is greater than 1, a hybrid algorithm [J] becomes the algorithm of choice for solving the tridiagonal systems; this algorithm performs the traditional Thomas algorithm sequentially on the serial loop part of the i-index on each physical processor and uses cyclic reduction to solve between physical processors; it is in fact implemented in the tridiagonal solver in CMSSL. This algorithm is also used in [SW]. It is ironic that the same algorithm is the efficient one for these different architectures (SIMD and MIMD (multiple instruction, multiple data)); however, the algorithm used in [SW] is actually a SPMD (single program, multiple data) algorithm.

When the VP ratio is much greater than 1, the serial work on each processor dominates, and the work estimate for relaxation reverts to the serial case. In any case, the semicoarsening algorithm appears to be more efficient for all VP ratios than the standard coarsening algorithm. The semicoarsening algorithm is also conceptually simpler, particularly in three dimensions, when the alternative to coarsening in z and performing xy-plane relaxations (using multigrid) [DMRRS] is standard coarsening, performing alternating plane relaxation [D5]. Bandy and Brickner [BB], however, are investigating the standard coarsening approach on the CM-2; hence, we should eventually be able to compare directly the two approaches.

We briefly discuss how the interpolation operators are derived, even though the description in [SW] is excellent. Let us denote the interpolation operator from the coarse grid G^{k-1} to the fine grid G^k by I^k_{k-1}. (The coarse grid operator L^{k-1} is given by Galerkin coarsening from the fine grid operator L^k by forming $(I^k_{k-1})^* L^k (I^k_{k-1})$. We are interested in five-point or nine-point discretizations of (1.1); hence, we want the coarse grid operators also to be five- or nine-point operators.) In [ABDP], [D1], and [D3], I^k_{k-1} was described as follows: At coarse grid points coinciding with fine grid points, I^k_{k-1} is just the identity. At a fine grid point lying vertically between two coarse grid points, let the template of the operator be given by

$$\begin{pmatrix} NW & N & NE \\ W & C & E \\ SW & S & SE \end{pmatrix}. \tag{2.1}$$

Then I^k_{k-1} at $v_{i,j}$ is given by $av_{i,j-1} + bv_{i,j+1}$, where

$$a = -(SW + S + SE)/(W + C + E) \quad \text{and} \quad b = -(NW + N + NE)/(W + C + E).$$

That is, we think of summing away the x-dependence to obtain a three-point relation. A problem with this approach, when using standard coarsening, is that if $\rho = C - NW - N - NE - W - E - SW - S - SE$ is small, then instead of using $W + C + E$ in (2.1), we should use $SW + S + SE + NW + N + NE$ instead; this point is discussed in [D3]. With standard coarsening, results are relatively insensitive to switching between formulas based on the size of ρ; however, for semicoarsening this is not the case. With standard coarsening, interpolation is also being performed in the x-direction; hence, there is a possibility of coefficient variations being averaged out in that direction. In the semicoarsening case, some mechanism for averaging in the x-direction is apparently needed. Schaffer [S] also came to this conclusion and discovered the following scheme: Let

$$A^- v^- + A^0 v^0 + A^+ v^+ = 0$$

be the equation that would give the row $v^0 = (v_{i,j}, i = 1, \cdots, nx)$ in terms of the rows $v^- = (v_{i,j-1}, i = 1, \cdots, nx)$ and $v^+ = (v_{i,j+1}, i = 1, \cdots, nx)$. Then

$$v^0 = -(A^0)^{-1}(A^- v^- + A^+ v^+). \tag{2.2}$$

Unfortunately, use of (2.2) would lead to a nonsparse interpolation, leading to nonsparse coarse grid operators. Schaffer's idea is to assume that

$$-(A^0)^{-1}A^- \quad \text{and} \quad (-A^0)^{-1}A^+$$

can each be approximated by diagonal matrices in the sense that B^- and B^+ are diagonal matrices such that

$$-(A^0)^{-1}A^- e = B^- e \quad \text{and} \quad (-A^0)^{-1}A^+ e = B^+ e,$$

where e is the vector $(1, \cdots, 1)$. To find B^- and B^+ requires just two tridiagonal solves. The interpolation formula using B^- and B^+ is

$$v^0 = B^- v^- + B^+ v^+.$$

At first blush it would appear that the SIMD relaxation work of Mulder's algorithm [M] is comparable to the SIMD relaxation work of our method, since the number of grids in Mulder's method, if $nx = ny$, is approximately $(\log_2 ny)^2$. In [NR], however, Van Rosendale and Naik (to be identified with the author of [D1]) show that the subgrids in the Mulder method can be organized so that relaxation on all grids simultaneously (concurrent relaxation) can be done efficiently. This approach leads to a degradation in convergence factor as well as processor-to-processor communication between grids for interpolation and residual weighting. In two dimensions [NR], the grids can be packed in such a way that communication between grids is efficient, but then the efficiency of relaxation suffers. Nevertheless, implementation of the Mulder method on the CM-2 is planned, as is a comparison with the method of this paper.

3. Implementation. Implementation issues are complicated by the fact that we are aiming at a moving target. The first version of this paper was written when the compiler on the CM-2 was the bit-serial version. Subsequently, this version was replaced by the slicewise compiler. For some time there will continue to be improvements in the compiler, operating system, and CMSSL. Rather than delay publication of this paper indefinitely, we have chosen to report the current status, and to try to guess what the effects of future developments will be.

In the first version of this paper we discussed the inefficiencies present in the large VP ratio case when compatible arrays for intergrid communication are assumed. Let us denote the i-index as the tridiagonal solver direction and the j-index as the multigrid coarsening direction. If the j-index is declared parallel, then the code compiles so that the VP loop on a physical processor always remains the same size, regardless of the coarse grid size. Thus, if the j-index is declared such that the VP loop size is 64, it remains so, instead of decreasing to 32, 16, etc., thus reflecting the inactive j-direction grid elements on coarser grids. One way to avoid this difficulty is to code the VP loop by splitting the j-index into parallel and serial parts; this kind of splitting was done for the CM-2 implementation (by Gyan Bhanot of Thinking Machines) of Jameson's FLOW 67 code, a timestepping multigrid code. In the first version of this paper, this splitting was done for the relaxation routine only, since the coding for this splitting is extremely cumbersome. Moreover, this splitting does not solve the problem of wasted storage.

A better solution than splitting the j-index into parallel and serial parts is to have arrays that are not compatible on fine and coarser grids, and to use temporary arrays to achieve compatibility. For definiteness, assume that a fine grid array A is $nx \times ny$, and that a coarser grid array B is $nx \times \frac{ny}{2}$. If it is desired that A communicate with B, every other row of A needs to be placed in a temporary $nx \times \frac{ny}{2}$ array C. This is an intraprocessor move of data and can be accomplished efficiently with a routine written by Brickner. This solution has two difficulties associated with it. The first is that it creates a ragged array data structure not supported by FORTRAN 8X. (A and B in the example are really $D(k, \cdots)$ and $D(k-1, \cdots)$.) This difficulty has been cured by a routine written in C which does dynamic storage allocation. With each array $D(k, \cdots)$ is associated an array descriptor that contains the information on the dimensions of $D(k, \cdots)$. Thus the FORTRAN 8X compiler can be fooled into accepting a ragged array data structure. The second difficulty is that the current compiler aggressively monitors array layouts to assure that arrays are evenly distributed on processors. In many applications, this aggressiveness is a good strategy; however, in this application, because the semicoarsening leads to rectangular (as opposed to square) arrays, it can lead to reallocation to different processors of points which need to communicate and which should be on the same processor. We attempted to bypass this reallocation by writing routines which essentially informed the compiler to leave our arrays alone.

Unfortunately, the compiler still intervened when creating temporary arrays, yielding not only inefficiencies but also wrong answers. Our current remedy has been to code at a lower level than FORTRAN 8X; this remedy solves the problem of the compiler trying to take control of the layout, but does not generate as efficient code per processor as the compiler is capable of generating.

One important aspect of this work has been to identify this compiler shortcoming. (We must temper these whinings with the observation that the slicewise compiler was created in an incredibly short time.) Ours has not been the only application in which it is desirable for the programmer to take away control of the layouts from the compiler, and indeed, new versions of the compiler have been promised which will provide this capability. In the standard coarsening case, however, we may not need this new compiler capability; in this case, the compiler's choice of layout may be acceptable.

A final comment for the large VP ratio case is that line relaxation performs with nearly the same efficiency as point relaxation, since most of the work is serial work done on each processor. For large problems, the work performed on the grids with the VP ratio less than or equal to 1 is a small part of the overall calculation. Related to this issue is the question of when the coarse grids calculation should be done on the front-end machine. For a powerful front-end machine, the coarse grids may have to be fairly fine before it even pays to invoke the CM-2's power. This issue is addressed further in §4.

There are at least two versions of the Thomas algorithm. One computes the LU-decomposition on the tridiagonal matrix as it is needed. Other versions save the LU-decomposition (one such version was exploited in [ABDP] to avoid expensive divides on the CDC-7600). There is an analogous situation with respect to cyclic reduction. In the first version of this paper, we found that a version that saves the LU-decomposition ran two times faster on the CM-2 than a version that recomputes the LU-decomposition. However, for cyclic reduction, the LU-decomposition must be stored at each level of the parallel reduction. The result, for the i-index, is that the requirement for storage is proportional to $nx(\log_2 nx)$, where nx is the number of i-grid points. However, for the hybrid version [J], the storage requirement of the LU-decomposition is just proportional to nx, assuming that we do not save the two-cyclic LU-decomposition needed for the processor boundary grid points. (For high VP ratios, this assumption is reasonable since the cyclic reduction part of the tridiagonal solves is a small fraction of the overall computational time.)

4. Results. Many authors present gigaflop rates as a figure of merit while others report on speedup (of many processors compared to a single processor). While both these measures are useful in comparing the improved running speed of a specific algorithm, they can be misleading in determining the most efficient algorithm to solve a given problem. Point Jacobi, for example, applied to solve a discretization of (1.1), has an impressive gigaflop rate and speedup factor; however, it cannot compete with the multigrid algorithm of this paper since its convergence factor is abysmally near 1 for large problems while the multigrid convergence factor stays nicely bounded away from 1. Hence what we concentrate on in this paper is actual timing data. The convergence factors for various problems for the multigrid algorithm are reported in detail in [SW] and need not be repeated here. Finally, it is impossible to give speedup data for a CM-2 since it is impossible to access just one processor; we do, however, compare performance of one-quarter of a 2048-processor machine with one-quarter of a 1024-processor machine.

We present timing comparisons of several machines in Table 1. The timing results are given as seconds per V-cycle and were obtained by running five V-cycles (including setup time) and dividing by 5. Thus the timing results are independent of the difficulty of the problem run. All of the CM-2 timings reported in this section were done using one-quarter of a 2048-Weitek-processor machine or one-quarter of a 1024-Weitek-processor machine. (These timings may be used to address, at least partially, the issues of speedup and scalability.) The front end for the CM-2 was a Sun 4/90. The iPSC/2 machine had 64 nodes of 386-type processors; several configurations of these processors were considered for each problem size; here we have reported the timings only for the best [SW].

TABLE 1
Time per V-cycle on three machines.

Size of problem	iPSC/2	CRAY Y-MP	CM-2, one-quarter of 1024 processors	CM-2, one-quarter of 2048 processors
32 × 32	0.3	0.01	––	––
64 × 64	0.7	0.04	0.65	0.77
128 × 128	2.0	0.09	0.99	0.80
256 × 256	––	0.27	1.84	1.79
512 × 512	––	0.95	4.55	3.04
1024 × 1024	––	3.69	++	8.11
2048 × 2048	––	––	++	25.39

++ too large
–– no information

The timing results on the CRAY Y-MP were obtained in a time-sharing environment; with a dedicated Y-MP, we could have easily run problems larger than 2048 × 2048; however, if we had used all of a 2048-Weitek processor CM-2 we could have also run problems larger than 4096 × 4096. The results on the Y-MP show that great gains are easily made from vectorization for the smaller problems, but for the larger problems, the asymptote of time being linearly proportional to problem size has nearly been reached. The code used on the CRAY Y-MP uses only standard FORTRAN and is run only in single-processor mode. Presumably, speedups could be obtained using the multiprocessor capability of the Y-MP, but this is not considered here. The 512 × 512 and 1024 × 1024 cases were too large for the current loader and used a memory manager, to some obvious disadvantage in performance.

In the first version of this paper, we compared two versions of the hybrid tridiagonal solver: a version which recomputes the LU factorization on each call and a version which saves the LU factorization; the latter was about two times faster than the former. The figures in Table 1 use the CMSSL tridiagonal solve routine. This routine, which recomputes the LU factorization on each call, is as fast as the faster of our two versions since it is written in carefully optimized assembly language. If a factor-of-two speedup can be expected from the CMSSL tridiagonal solver which saves LU factorizations (not yet available), then we can expect to see nearly a factor-of-two decrease in the timings in Table 1 for the CM-2.

We report in Table 2 the effect of changing the size of the coarsest grid direct solve. The direct solve is done with a band solver on the front end with the LU-decomposition of that matrix being precomputed once. The problem in Table 2 has 256 × 256 grid points. (The timings in Table 2 use an earlier version of our code and should therefore only be considered in relation to each other and not to the timings in Table 1.) Note that there is a minimum for both the case of saving and not saving the cyclic reduction LU-decomposition. The reason for this is that on the coarser grids, so few Weitek processors are active that the front end (which is considerably faster than one Weitek processor) is more efficient, even when the time to transfer the data from the CM-2 to the front end is taken into account.

TABLE 2
Time per V*-cycle varying coarsest grid size.*

Size of coarsest grid	Number of grid levels	Recompute LU	Save LU
256 × 1	9	8.57	3.22
256 × 4	7	6.53	2.66
256 × 8	6	5.87	2.69
256 × 16	5	5.98	3.50
256 × 32	4	8.41	6.62

One other possibility for gaining efficiency from this algorithm is to make use of the multiwire (multiple NEWS communication) library written by R. Brickner and documented in [CM]. The routines in this library allow one to do simultaneous communication and computation in each index of an array. We have investigated the use of this library in a preliminary way, but have postponed further work until the other issues above have been satisfactorily resolved.

Let us now consider the BHT method; first, for the problem

$$\begin{cases} -\Delta U + U = 1 & \text{in } (0,1)\times(0,1), \\ U & \text{doubly periodic.} \end{cases}$$

On a 16 × 16 grid we compare the result of using the method of [D4] (standard coarsening, operator-induced interpolation, Galerkin coarsening, and red-black point relaxation) to the method of [H]. (We use the method in [D4] because we have not yet extended the method in this paper to handle periodic boundary conditions.) Both methods achieve an average convergence factor, over ten V-cycles, of 0.05 per V-cycle.

Now let us consider the problem

$$\begin{cases} -\nabla\cdot(D\nabla U) + U = F & \text{on } (0,16)\times(0,16), \\ U & \text{doubly periodic,} \end{cases} \tag{4.1}$$

where D and F are as shown in Fig. 1. Using a 16 × 16 grid, we again compare [D4] to [H]; the average convergence factor per V-cycle is 0.06 vs 0.54, respectively. If we modify the method in [H] to attempt to use the same operator-induced interpolation used in [D4], we obtain an average convergence factor of 0.09 instead. The problem is that within the context of the method in [H], it is no longer clear what operator-induced interpolation should be.

Finally, let us comment that we believe that some multigrid method is likely to be the fastest algorithm for solving problems like (1.1) on SIMD machines. We intend to substantiate this belief by timing the algorithm of this paper against some possible competitors, such as preconditioned conjugate gradient methods. In this comparison, the convergence factor per unit time must be considered for various problems, since clearly conjugate gradient with no conditioning will win against multigrid on SIMD machines for well-conditioned elliptic problems. In one sense the contest is over before it starts, since we already have an example in which a preconditioned conjugate gradient method stagnates badly, but for which the method of this paper is robust.

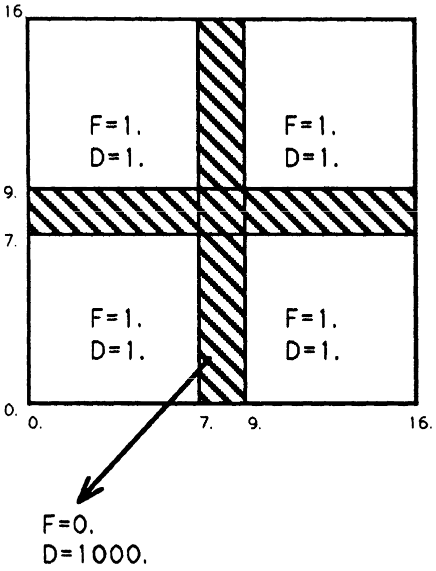

FIG. 1. *Diffusion coefficients and right-hand side for* (4.1).

Nevertheless, we hope to perform a comparison for a set of problems with a wide range of difficulty.

5. Conclusions. In this paper we have examined several multigrid methods in an attempt to find one that performs well on SIMD machines for problems with rough and anisotropic coefficients. We chose a semicoarsening multigrid algorithm for implementation on the CM-2 and have shown that it does perform well on that machine. We expect even better performance from this algorithm as compiler, operating systems, and library improvements become available.

Note added in proof. Recent advances in the version of BHT using operator-induced interpolation have led to an improved average convergence factor per V-cycle for (4.1): .09 per V-cycle instead of the .34 per V-cycle reported in this paper.

A MINIMUM-PHASE LU FACTORIZATION PRECONDITIONER FOR TOEPLITZ MATRICES*

TA-KANG KU† AND C.-C. JAY KUO†

Abstract. A new preconditioner is proposed for the solution of an $N \times N$ Toeplitz system $T_N\mathbf{x} = \mathbf{b}$, where T_N can be symmetric indefinite or nonsymmetric, by preconditioned iterative methods. The preconditioner F_N is obtained based on factorizing the generating function $T(z)$ into the product of two terms corresponding, respectively, to minimum-phase causal and anticausal systems and is therefore called the minimum-phase LU (MPLU) factorization preconditioner. Due to the minimum-phase property, $||F_N^{-1}||$ is bounded. For rational Toeplitz matrices T_N with generating function $T(z) = A(z^{-1}/Bz^{-1}) + C(z)/D(z)$, where $A(z)$, $B(z)$, $C(z)$, and $D(z)$ are polynomials of orders p_1, q_1, p_2, and q_2, it is shown that the eigenvalues of $F_N^{-1}T_N$ are repeated exactly at 1 except at most α_F outliers, where α_F depends on p_1, q_1, p_2, q_2, and the number w of the zeros of $\tilde{T}(z) = A(z^{-1})D(z) + B(z^{-1})C(z)$ outside the unit circle. A preconditioner K_N in circulant form generalized from the symmetric case is also presented for comparison.

1. Introduction.

Toeplitz matrices arise in many signal processing applications. To solve a general $N \times N$ Toeplitz system of equations $T_N\mathbf{x} = \mathbf{b}$, direct inverse algorithms based on Levinson recurrence [24] with $O(N^2)$ operations have been studied intensively in the past [13], [19], [32], [36]. Superfast algorithms with $(N \log^2 N)$ complexity have also been proposed [1], [3], [4], [12]. Although the computational complexity of these algorithms is lower than that of Gaussian elimination with pivoting, i.e., $O(N^3)$, their stability is still an issue when applied to indefinite or nonsymmetric T_N. It has been shown that these algorithms may become unstable if T_N is not symmetric positive definite (SPD) and well conditioned [5], [11]. A stable extension of the Levinson algorithm to general Toeplitz matrices has recently been studied by Chan and Hansen [9], [10].

In this research, we consider the use of preconditioned iterative methods for solving general Toeplitz systems $T_N\mathbf{x} = \mathbf{b}$ to reduce the computational complexity as well as to avoid the numerical instability. Various preconditioners in circulant form have been used in the the preconditioned conjugate gradient (PCG) algorithm [6], [8], [18], [20], [30] to solve SPD Toeplitz systems. All the preconditioners can be inverted via fast transform algorithms with $O(N \log N)$ operations. Besides, the spectra of the preconditioned Toeplitz matrices have such a nice clustering property that the PCG method converges superlinearly for T_N generated by a positive function in the Wiener class [7], [20]. Although it is possible to generalize this preconditioning technique to general Toeplitz matrices in a straightforward way (see §4), the focus of this paper is to develop a novel approach to construct a general Toeplitz preconditioner based on an approximate LU factorization. The resulting preconditioned systems are then solved by various iterative methods, such as the generalized minimal residual (GMRES) [28] and the conjugate gradient squared (CGS) [29].

The idea of constructing the LU factorization preconditioner can be simply stated as follows. Consider a banded Toeplitz matrix T_N with a finite-order generating function $T(z) = \sum_{n=-s}^{r} t_n z^{-n}$. Let us assume that $T(z)$ has no zeros on the unit circle. The $T(z)$ can be factorized into the product $T(z) = z^j L(z^{-1})U(z)$, where $L(z^{-1})$ and $U(z)$ have all zeros inside and outside the unit circle, respectively. We associate z^j, $L(z^{-1})$, and $U(z)$ with a shift matrix S_N, lower and upper triangular banded Toeplitz matrices L_N and U_N, correspondingly, and the product $F_N = S_N L_N U_N$ is the desired preconditioner for T_N. The above factorization procedure has been used frequently in the context of digital signal processing [26] to design the minimum-phase causal (or maximum-phase anticausal) linear filter. The F_N is therefore called the minimum-phase LU (MPLU) factorization preconditioner. To generalize the MPLU preconditioning technique to full Toeplitz matrices, we first obtain an approximating rational generating function for the original one with the Laurent Padé approximation. Since a rational Toeplitz matrix can be transformed to a banded matrix which is nearly Toeplitz, the appropriate MPLU preconditioner can also be constructed. A similar factorization procedure was used by Trench to derive a stable direct method for solving rational Toeplitz systems [35].

The condition number of the preconditioner F_N is bounded due to the minimum-phase factorization property. Thus, for well-conditioned Toeplitz matrices T_N, the condition number of the preconditioned matrix $A_N = F_N^{-1} T_N$ is also bounded so that the system $A_N \mathbf{x} = F_N^{-1}\mathbf{b}$ can be stably solved by iterative algorithms. One obvious choice is to form the SPD normal system $A_N^T A_N \mathbf{x} = A_N^T F_N^{-1}\mathbf{b}$, and to solve the resulting system by the CG method (known as the CGN method [17]). Thus, for well-conditioned nonsymmetric Toeplitz systems, numerical stability is easily obtained by using preconditioned iterative methods.

The spectral clustering properties of the MPLU-preconditioned Toeplitz matrix $F_N^{-1} T_N$ are studied for both banded and rational T_N. We prove that, for rational T_N with generating function $T(z) = A(z^{-1})/B(z^{-1}) + C(z)/D(z)$, where $A(z)$, $B(z)$, $C(z)$, and $D(z)$ are polynomials of orders p_1, q_1, p_2, and q_2, the eigenvalues of $F_N^{-1} T_N$ are repeated exactly at 1 except at α_F outliers, where α_F depends on p_1, q_1, p_2, q_2, and the number w of the zeros of $\tilde{T}(z) = A(z^{-1})D(z) + B(z^{-1})C(z)$ outside the unit circle. A direct consequence of these spectral properties is that the appropriate preconditioned iterative methods converge in at most $\alpha_F + 1$ iterations. This result should be compared to that of the circulant-preconditioned rational Toeplitz matrix $K_N^{-1} T_N$. In [23], we proved that the eigenvalues of $K_N^{-1} T_N$, except α_K outliers, are clustered in the disk centered at 1 with radius ϵ_K, where the clustering radius ϵ_K is proportional to the magnitude of the last elements used to construct the circulant preconditioner. It is clear that $\epsilon_K \geq \epsilon_F = 0$. Furthermore, if $w = \max(p_2, q_2)$, it can be shown that $\alpha_K = 2\alpha_F$ (see Theorems 3 and 4) so that the MPLU preconditioner provides better spectral clustering properties for a faster convergence rate. If $w \neq \max(p_2, q_2)$, we may have $\alpha_K < \alpha_F$ and $\epsilon_K \approx 0$ so that the circulant preconditioner K_N gives a faster convergence rate. In general, the MPLU preconditioner F_N has a better or a comparable convergence rate compared to the circulant preconditioner K_N.

Since the MPLU preconditioner F_N is a product of the shift matrix S_N and triangular banded Toeplitz matrices L_N and U_N, the preconditioning step $\mathbf{z} = F_N^{-1}\mathbf{r}$ can be achieved with a computational complexity proportional to $O(N)$ only. The total computational complexity for solving a rational Toeplitz system by MPLU-preconditioned iterative methods is $O(N)$, which is lower than the $O(N \log N)$ operations required by the circulant-preconditioned iterative methods and is in the same order as that required by several direct methods [14], [15], [33], [34], [35]. However, there is a drawback of the MPLU preconditioner in the context of parallel processing. That is, the MPLU preconditioning has to be performed sequentially, whereas the circulant preconditioning can be easily parallelized.

The outline of this paper is as follows. In §2, the procedure to construct the MPLU preconditioner for banded Toeplitz matrices is described, and the spectral properties of the preconditioned banded Toeplitz matrices are examined. In §3, the MPLU preconditioning technique is generalized to full Toeplitz matrices, including both rational and nonrational cases, and the spectral properties of the MPLU-preconditioned rational Toeplitz matrices are studied. In §4, we compare the MPLU preconditioner with the circulant preconditioner K_N. Finally, numerical results are given in §5 to assess the efficiency of the MPLU preconditioner.

2. MPLU preconditioner for banded Toeplitz matrices.

Consider a sequence of $m \times m$ banded Toeplitz matrices T_m, $m = 1, 2, \cdots$, generated by a polynomial

$$T(z) = \sum_{n=-s}^{r} t_n z^{-n}. \tag{2.1}$$

Let us assume that function $T(z)$ has no zeros on the unit circle, i.e.,

$$T(e^{i\theta}) \neq 0 \quad \forall \theta. \tag{2.2}$$

The system of linear equations

$$T_N \mathbf{x} = \mathbf{b} \tag{2.3}$$

can be solved by various iterative methods. To accelerate the convergence rate, a preconditioner P_N is introduced to solve the preconditioned system

$$P_N^{-1} T_N \mathbf{x} = P_N^{-1} \mathbf{b}, \tag{2.4}$$

where P_N is the preconditioner used to approximate T_N.

2.1. Construction of the preconditioner.

We can use a direct method to factorize T_N,

$$T_N = \mathcal{L}_N \mathcal{U}_N, \tag{2.5}$$

where $\mathcal{L}_N$ and $\mathcal{U}_N$ are lower and upper triangular matrices, respectively. The exact factorization (2.5) with the Schur-type algorithm requires $O(Nr + Ns)$ operations for banded T_N [14], [33]. If T_N is not SPD, the numerical stability of these algorithms cannot be guaranteed. Instead of performing the exact factorization, we propose to factorize T_N approximately as

$$T_N \approx S_N L_N U_N = F_N, \tag{2.6}$$

where S_N is a shift matrix and L_N and U_N are, respectively, lower and upper triangular banded Toeplitz matrices. Our objectives include that the approximate factorization (2.6) be achieved by a stable algorithm with operations independent of N, that F_N approximate T_N well, and that $||F_N^{-1}||$ be bounded. Then, the F_N can be used as a preconditioner in preconditioned iterative methods.

To derive the approximate factorization, it is convenient to consider the problem in the Z-transform domain and ignore the boundary effect arising in a Toeplitz system. When T_N is banded with lower bandwidth r and upper bandwidth s, its generating function can be expressed as

$$T(z) = \sum_{n=-s}^{r} t_n z^{-n} = t_{-s} z^s \prod_{i=1}^{d} (1 - z_i z^{-1}), \tag{2.7}$$

where $d = r + s$ and z_i is a root of $T(z)$. From (2.2), we know that $|z_i| \neq 1$. If $T(z)$ has w zeros outside the unit circle, we can factorize $T(z)$ as

$$T(z) = z^{s-w} L(z^{-1}) U(z), \tag{2.8}$$

where

$$L(z^{-1}) = \prod_{|z_i|<1} (1 - z_i z^{-1}), \qquad U(z) = t_{-s} \prod_{|z_i|>1} (z - z_i).$$

Note that the above factorization has a special feature, namely, all zeros of $L(z^{-1})$ (or $U(z)$) are inside (or outside) the unit circle. The following example is used to illustrate the factorization procedure.

Example 1. Let T_N be an $N \times N$ tridiagonal Toeplitz matrix with $t_1 = 1.5$, $t_0 = -6.5$, and $t_{-1} = 2$. Then, we have that

$$T(z) = 1.5z^{-1} - 6.5 + 2z = 2z(1 - 0.25z^{-1})(1 - 3z^{-1}) = L(z^{-1})U(z),$$

where

$$L(z^{-1}) = 1 - 0.25z^{-1}, \qquad U(z) = 2z - 6.$$

Since $r = s = w = 1$ in this example, the term z^{s-w} in (2.8) is equal to 1.

Let us associate the right-hand side of the factorization (2.8) with the following matrices:

$$L(z^{-1}) \longleftrightarrow L_N, \qquad U(z) \longleftrightarrow U_N, \qquad z^{s-w} \longleftrightarrow S_N \equiv E_N^{s-w}, \tag{2.9}$$

where L_N and U_N are $N \times N$ lower and upper triangular Toeplitz matrices with generating functions $L(z^{-1})$ and $U(z)$, respectively, E_N is the $N \times N$ unit row-shift matrix,

$$E_N = [e_N, e_1, e_2, \cdots, e_{N-1}],$$

and e_n is the $N \times 1$ unit vector with the nth element equal to 1 and zeros elsewhere. It is straightforward to verify that

$$E_N^{-1} = [e_2, e_3, \cdots, e_N, e_1]$$

and that E_N^k is the product of E_N (or E_N^{-1}) $|k|$ times for positive (or negative) integer k. The premultiplication of E_N (or E_N^{-1}) with an $N \times N$ matrix is equivalent to the circular upshift (or downshift) of its rows by one.

Then, the product of S_N, L_N, and U_N is used as the desired preconditioner

$$F_N = S_N L_N U_N = E_N^{s-w} L_N U_N. \tag{2.10}$$

Its inverse

$$F_N^{-1} = U_N^{-1} L_N^{-1} S_N^{-1} = U_N^{-1} L_N^{-1} E_N^{w-s}$$

can be performed effectively with $O(N)$ operations due to the special structures of S_N, L_N, and U_N. The factorization (2.8) has been frequently used in the context of digital signal processing [26] to design the minimum-phase causal (or maximum-phase anticausal) linear filter, which is by definition a system characterized by a lower (or upper) triangular matrix with a stable inverse. Thus we call F_N defined by (2.10) the MPLU factorization preconditioner.

2.2. Spectral properties. The minimum-phase factorization procedure guarantees that $||F_N^{-1}||$ is bounded, which is proved in the following theorem.

THEOREM 1. *Let T_N be a banded Toeplitz matrix with lower bandwidth r and upper bandwidth s satisfying condition* (2.2), *and L_N and U_N be obtained from the minimum-phase factorization* (2.8)–(2.10). *Then, the* 1-, 2-, *and* ∞-*norms of F_N^{-1} and F_N are bounded for all N.*

Proof. It is well known that there exists an isomorphism between the ring of the power series $G(z^{-1}) = \sum_{n=0}^{\infty} g_N z^{-n}$ and the ring of semi-infinite lower triangular Toeplitz matrices with $g_0, g_1, \cdots, g_N, \cdots$ as the first column, and that the power series multiplication is isomorphic to matrix multiplication [15]. With this isomorphism, we know that L_N^{-1} is a lower triangular Toeplitz matrix whose first column $\tau_0, \tau_1, \cdots, \tau_n, \cdots$ can be obtained from the coefficients of the power series, i.e.,

$$\frac{1}{L(z^{-1})} = \prod_{|z_i|<1} \frac{1}{(1 - z_i z^{-1})} = \sum_{n=0}^{\infty} \tau_n z^{-n}.$$

It is clear that $\sum_{n=0}^{\infty} |\tau_n|$ is bounded if and only if all poles of $1/L(z^{-1})$ are inside the unit circle, which is guaranteed by the minimum-phase factorization (2.8).

Since $T(z)$ has no zeros on the unit circle,

$$|z_i| \le 1 - \beta \quad \text{or} \quad 1 + \beta \le |z_i| < \infty,$$

where $\beta > 0$. Thus

$$||L_N^{-1}||_1 = ||L_N^{-1}||_\infty = \sum_{n=0}^{N-1} |\tau_n| \le \sum_{n=0}^{\infty} |\tau_n| \le \prod_{|z_i|<1} \frac{1}{1 - |z_i|} \le \beta^{-(d-w)}.$$

The 2-norm of L_N is bounded by

$$||L_N^{-1}||_2 \le (||L_N^{-1}||_1 ||L_N^{-1}||_\infty)^{1/2} = \sum_{n=0}^{N-1} |\tau_n| \le \beta^{-(d-w)}.$$

Similar arguments can be used to prove that $||U_N^{-1}||_2 \le \beta^{-w}$. Since $||E_N||_2 = ||E_N^{-1}||_2 = 1$, we have

$$||F_N^{-1}||_2 \le ||L_N^{-1}||_2 ||U_N^{-1}||_2 \le \beta^{-d},$$

which is independent of N. Besides, since $||L_N||_1 = ||L_N||_\infty$, we have

$$||L_N||_2 \leq (||L_N||_1||L_N||_\infty)^{1/2}.$$

Similarly, $||U_N||_2$ is bounded and $||F_N||_2 \leq ||L_N||_2||U_N||_2$ is also bounded. □

A direct consequence of the above theorem is that the condition number of preconditioner F_N is bounded for all N.

If $L(z^{-1})$ (or $U(z)$) is not chosen according to (2.8) so that there exist zeros of the polynomial $L(z^{-1})$ (or $U(z)$) with magnitude greater (or less) than one, i.e., nonminimum-phase factorization, we can easily check that $||L_N^{-1}||_2$ (or $||U_N^{-1}||_2$) is unbounded for asymptotically large N. For example, if we choose

$$\tilde{L}(z^{-1}) = 1 - 3z^{-1}, \qquad \tilde{U}(z) = 2z - 0.5,$$

for L_N and U_N in Example 1, the product $L_N U_N$ leads to an ill-conditioned matrix whose smallest eigenvalue converges to zero for asymptotically large N. Thus the minimum-phase factorization is crucial for the stability of the preconditioning step $\mathbf{z} = F_N^{-1}\mathbf{r}$.

Next, we study the spectral properties of $F_N^{-1}T_N$. For F_N to be a good preconditioner, it is desirable that $F_N^{-1}T_N$ has clustered eigenvalues. In Theorem 2 we will prove that it has only a finite number of eigenvalues different from 1. To derive this theorem, we need two lemmas.

LEMMA 1. *Let T_N be a banded Toeplitz matrix with lower bandwidth r and upper bandwidth s, where $r + s = d < N$, generated by $T(z)$ which has w zeros outside the unit circle. Then, for L_N and U_N obtained by the minimum-phase factorization* (2.8) *and* (2.9), *$L_N U_N$ is a banded Toeplitz matrix generated by $z^{w-s}T(z)$ with lower bandwidth $d - w$ and upper bandwidth w except its northwest $(d - w) \times w$ block.*

Proof. This lemma can be proved with definitions and direct matrix multiplication. □

Lemma 1 basically states that the product $L_N U_N$ is a nearly banded Toeplitz matrix. Despite the fact that T_N and $L_N U_N$ have the same total bandwidth d, they do not have the same lower bandwidth and upper bandwidth unless $w = s$. By shifting the rows of $L_N U_N$ circularly, we are able to construct another nearly banded Toeplitz matrix $F_N = E_N^{s-w} L_N U_N$, which has the same lower and upper bandwidth as T_N.

LEMMA 2. *Let T_N be a banded Toeplitz matrix with lower bandwidth r and upper bandwidth s, where $r + s = d < N$, generated by $T(z)$, which has w zeros outside the unit circle. Then, the matrix $F_N = E_N^{s-w} L_N U_N$ defined in* (2.10) *is a nearly banded Toeplitz matrix. Elements of matrices T_N and F_N are identical except for the following*:

(1) *the northwest $r \times s$ block when $s = w$;*

(2) *the northwest $r \times w$ block and the northeast $(w - s) \times r$ block when $s < w$;*

(3) *the northwest $r \times w$ block, the southwest $(s - w) \times s$ block, and the southeast $(s - w) \times (d - w)$ block when $s > w$.*

Proof. When $s = w$, it can be directly verified that $F_N = L_N U_N$ is a banded Toeplitz matrix generated by $T(z)$ with lower bandwidth r and upper bandwidth s except the northwest $r \times s$ block. When $s < w$, recall that the rows of $F_N = E_N^{s-w} L_N U_N$ are obtained from those of $L_N U_N$ with circularly downward-shift $w - s$ rows so that the last $w - s$ rows in $L_N U_N$ become the the first $w - s$ rows of F_N and the first $N - (w - s)$ rows in $L_N U_N$ become the last $N - (w - s)$ rows of F_N. By using Lemma 1, we can clearly see that F_N is a banded Toeplitz with lower bandwidth r

and upper bandwidth s generated by $T(z)$ except the northwest $r \times w$ block and the northeast $(w-s) \times r$ block. Similarly, we can prove the case $s > w$. □

Lemma 2 tells us that $\triangle E_N = F_N - T_N$ is a zero matrix except for at most three small blocks. Based on this lemma, we characterize the spectral properties of $F_N^{-1} T_N$ in Theorem 2.

THEOREM 2. *Let T_N be a banded Toeplitz matrix with lower bandwidth r and upper bandwidth s, where $r+s = d < N$, generated by $T(z)$ which has w zeros outside the unit circle. Then, there are at most α_F eigenvalues of $F_N^{-1}T_N$ not equal to 1, where*

$$\alpha_F = \begin{cases} \min(r,s), & s = w, \\ \min(r, 2w-s), & s < w, \\ \min(d-w, s), & s > w. \end{cases} \tag{2.11}$$

Proof. Since we have

$$F_N^{-1}T_N = F_N^{-1}(F_N - \triangle E_N) = I_N - F_N^{-1}\triangle E_N,$$

where I_N denotes the $N \times N$ identity matrix, the eigenvalue 1 of $F_N^{-1}T_N$ corresponds to the eigenvalue 0 of $F_N^{-1}\triangle E_N$, and the number of eigenvalues of $F_N^{-1}T_N$ not equal to 1 is determined by the rank of $\triangle E_N$. Notice that the rank of a matrix is bounded by the number of nonzero rows or columns, and the rank of the sum of two matrices is bounded by the sum of their individual ranks. All nonzero elements in $\triangle E_N$ are inside the blocks given by Lemma 2. When $s = w$, since all nonzero elements of $\triangle E_N$ are in the first r rows or the first s columns, the rank of $\triangle E_N$ is bounded by $\min(r, s)$. When $s < w$, we have $w - s \le d - s = r$. Since all nonzero elements of $\triangle E_N$ are either in the first r rows or in the union of the first w columns and the first $w - s$ rows, the rank of $\triangle E_N$ is bounded by $\min(r, 2w - s)$. When $s > w$, since all nonzero elements of $\triangle E_N$ are either in the union of the first r and the last $s - w$ rows or in the union of the first w columns and the last $s-w$ rows, the rank of $\triangle E_N$ is bounded by $\min(d - w, s)$. The proof is completed. □

Example 2 illustrates the above theorem.

Example 2. Consider the following $N \times N$ banded Toeplitz matrices with $N \ge 4$,

$$\begin{array}{lll} T_{N,1} & [(r,s) = (3,0)]: & t_3 = 2,\ t_2 = -5,\ t_1 = 6,\ t_0 = -2, \\ T_{N,2} & [(r,s) = (2,1)]: & t_2 = 2,\ t_1 = -5,\ t_0 = 6,\ t_{-1} = -2, \\ T_{N,3} & [(r,s) = (1,2)]: & t_1 = 2,\ t_0 = -5,\ t_{-1} = 6,\ t_{-2} = -2, \\ T_{N,4} & [(r,s) = (0,3)]: & t_0 = 2,\ t_{-1} = -5,\ t_{-2} = 6,\ t_{-3} = -2. \end{array}$$

$T(z)$ has zeros $0.5 + 0.5i$, $0.5 - 0.5i$, and 2, so that $w = 1$. For these matrices, the MPLU factorization results in the same L_N and U_N defined by the generating sequences

$$\begin{array}{llll} l_0 = 1, & l_1 = -1, & l_2 = 0.5, & l_n = 0 \quad n \ne 0,1,2, \\ u_0 = 4, & u_{-1} = -2, & & u_n = 0 \quad n \ne 0,-1. \end{array}$$

To illustrate Theorem 2, we list values of d, s, r, w, and α_F in Table 1.

Since $F_N^{-1}T_N$ has only at most $\alpha_F + 1$ distinct eigenvalues, appropriate preconditioned iterative methods, such as GMRES and CGS, converge in at most $\alpha_F + 1$ iterations with exact arithmetic (see Test Problems 1 and 4 in §5).

TABLE 1
An example to illustrate Theorem 2.

	d	r	s	w	α_F
$T_{N,1}$	3	3	0	1	2
$T_{N,2}$	3	2	1	1	1
$T_{N,3}$	3	1	2	1	2
$T_{N,4}$	3	0	3	1	2

3. Preconditioning full Toeplitz matrices.

In this section, we generalize the MPLU preconditioning technique to full Toeplitz matrices. It is known that a rational Toeplitz system $T_N\mathbf{x} = \mathbf{b}$ is equivalent to a banded system

$$\tilde{T}_N\tilde{\mathbf{x}} = \tilde{\mathbf{b}}, \tag{3.1}$$

where matrix $\tilde{T}_N$ is a banded Toeplitz matrix except for a northwest block. Thus we construct a MPLU preconditioner for $\tilde{T}_N$ as if it were an exact banded Toeplitz matrix and determine the solution of the rational Toeplitz system from (3.1) by preconditioned iterative methods. The equivalent MPLU preconditioner for rational Toeplitz matrix T_N is also a product of a shift matrix and triangular banded Toeplitz matrices, and can be inverted with $O(N)$ operations. The MPLU preconditioning scheme can also be generalized to nonrational Toeplitz matrices. The basic idea is to approximate the full Toeplitz matrix with a rational Toeplitz matrix, and then construct the MPLU preconditioner for the rational Toeplitz matrix.

3.1. Rational Toeplitz matrices.

Toeplitz matrices with a rational generating function can be transformed to banded ones [15]. We describe the transformation briefly as follows. Let the generating function of T_N be of the form

$$T(z) = \frac{A(z^{-1})}{B(z^{-1})} + \frac{C(z)}{D(z)}, \tag{3.2}$$

where $A(z)$, $B(z)$, $C(z)$, and $D(z)$ are polynomials in z with orders p_1, q_1, p_2, and q_2, respectively. Note that a special case of (3.2) is $A(z) = C(z)$ and $B(z) = D(z)$, which leads to a symmetric rational Toeplitz matrix of order (p, q) with $p_1 = p_2 = p$ and $q_1 = q_2 = q$. By applying the isomorphism between the ring of the power series and the ring of semi-infinite triangular Toeplitz matrices, we have the relationship

$$T_N = L_aL_b^{-1} + U_cU_d^{-1},$$

where L_a (or L_b) is an $N \times N$ lower triangular Toeplitz matrix with the first N coefficients in $A(z^{-1})$ (or $B(z^{-1})$) as its first column and U_c (or U_d) is an $N \times N$ upper triangular Toeplitz matrix with the first N coefficients in $C(z)$ (or $D(z)$) as its first row. Since power series multiplication is commutative, we have

$$\tilde{T}_N = L_bT_NU_d = L_aU_d + L_bU_c, \tag{3.3}$$

where $\tilde{T}_N$ is a banded and nearly Toeplitz matrix characterized by the following lemma.

LEMMA 3. *Let T_N be the $N \times N$ Toeplitz matrix generated by $T(z)$ in (3.2); the corresponding $\tilde{T}_N$ obtained from (3.3) is a banded Toeplitz matrix with lower bandwidth $r = \max(p_1, q_1)$ and upper bandwidth $s = \max(p_2, q_2)$ generated by*

$$\tilde{T}(z) = A(z^{-1})D(z) + B(z^{-1})C(z), \tag{3.4}$$

except for the northwest $r \times s$ block.

Proof. Consider $N \times N$ Toeplitz matrices L_a and U_d, where L_a is lower triangular with lower bandwidth p_1 generated by $A(z^{-1})$ and U_d is upper triangular with upper bandwidth q_2 generated by $D(z)$. We can verify that the product L_aU_d is a banded Toeplitz matrix generated by $A(z^{-1})D(z)$, except for its northwest $p_1 \times q_2$ block. This result can be easily generalized to the sum of two such products, i.e., $\tilde{T}_N = L_aU_d + L_bU_c$, and the proof is completed. □

Through (3.3), the system $T_N\mathbf{x} = \mathbf{b}$ is transformed to an equivalent system

$$\tilde{T}_N\tilde{\mathbf{x}} = \tilde{\mathbf{b}},$$

where $\mathbf{x} = U_d\tilde{\mathbf{x}}$ and $\tilde{\mathbf{b}} = L_b\mathbf{b}$. We then use the procedure described in §2.1 to construct the MPLU preconditioner $\tilde{F}_N$ for $\tilde{T}_N$ as if it were an exact banded Toeplitz matrix. The following theorem characterizes the spectral properties of $\tilde{F}_N^{-1}\tilde{T}_N$.

THEOREM 3. *Let T_N be the $N \times N$ rational Toeplitz matrix generated by $T(z)$ in* (3.2), *and $\tilde{F}_N$ the* MPLU *preconditioner constructed with respect to $\tilde{T}(z)$ in* (3.4). *In addition, $r = \max(p_1, q_1)$, $s = \max(p_2, q_2)$, and w denotes the number of zeros of $\tilde{T}(z)$ outside the unit circle. Then, when $r + s = d < N$, there are at most α_F eigenvalues of $\tilde{F}_N^{-1}\tilde{T}_N$ not equal to* 1, *where*

$$\alpha_F = \begin{cases} \min(r, s), & s = w, \\ \min(r, 2w - s), & s < w, \\ \min(d - w, 2s - w), & s > w. \end{cases}$$

Proof. By Lemma 3, $\tilde{T}_N$ is a banded Toeplitz matrix with generating function $\tilde{T}(z)$ except for the northwest $r \times s$ block. The $\tilde{F}_N$ is a banded Toeplitz matrix with generating function $\tilde{T}(z)$ except for the blocks described in Lemma 2. Define $\triangle\tilde{T}_N = \tilde{F}_N - \tilde{T}_N$. We can use arguments similar to those in proving Theorem 2 to determine the bound of the rank of $\triangle\tilde{T}_N$ and, hence, the number of eigenvalues of $\tilde{F}_N^{-1}\tilde{T}_N$ not equal to 1. □

Since $\tilde{F}_N^{-1}\tilde{T}_N$ has only at most $\alpha_F + 1$ distinct eigenvalues, appropriate preconditioned iterative methods converge in at most $\alpha_F + 1$ iterations with exact arithmetic (see Test Problems 2 and 5 in §5). Note that $\tilde{F}_N$ is a preconditioner for $\tilde{T}_N$ rather than T_N. However, since $\tilde{T}_N$ is related to T_N via (3.3), the equivalent preconditioner for matrix T_N is

$$F_N = L_b^{-1}\tilde{F}_NU_d^{-1} = L_b^{-1}E_N^{\tilde{s}-\tilde{w}}\tilde{L}_N\tilde{U}_NU_d^{-1},$$

where $\tilde{s}$, $\tilde{w}$, $\tilde{L}_N$, and $\tilde{U}_N$ are obtained with respect to $\tilde{T}(z)$ $(= A(z^{-1})D(z)+B(z^{-1})C(z))$. Thus the preconditioning step can be implemented as

$$F_N^{-1}\mathbf{r} = U_d\tilde{U}_N^{-1}\tilde{L}_N^{-1}E_N^{\tilde{w}-\tilde{s}}L_b\mathbf{r},$$

for arbitrary $\mathbf{r}$ with $O(N)$ operations.

3.2. Nonrational Toeplitz matrices. When T_N is generated by a nonrational function $T(z)$, we use the Laurent *Padé* approximation [4], [16] to approximate $T(z)$ with a certain rational function

$$T'(z) = \frac{A'(z^{-1})}{B'(z^{-1})} + \frac{C'(z)}{D'(z)},$$

where $A'(z)$, $B'(z)$, $C'(z)$, and $D'(z)$ are polynomials in z with orders p_1, q_1, p_2, and q_2, respectively. The coefficients of $A'(z)$, $B'(z)$, $C'(z)$, and $D'(z)$ are chosen such that

$$T_+(z^{-1})B(z^{-1}) - A(z^{-1}) = O(z^{-(p1+q1+1)}),$$
$$T_-(z)D(z) - C(z) = O(z^{p2+q2+1}),$$

where

$$T_+(z^{-1}) = ct_0 + \sum_{n=1}^{\infty} t_n z^{-n},$$
$$T_-(z) = (1-c)t_0 + \sum_{n=1}^{\infty} t_{-n} z^{n},$$

with given c. We then construct the preconditioner $\tilde{F}'_N$ with respect to $\tilde{T}'(z)$ $(= A'(z^{-1})D'(z) + B'(z^{-1})C'(z))$ or, equivalently, use F'_N $(= (L'_b)^{-1}\tilde{F}'_N(U'_d)^{-1})$ as preconditioner for T_N. Since $T(z) \neq T'(z)$, the eigenvalues of $(F'_N)^{-1}T_N$ are not repeated at, but are clustered around, 1. Also, we find from our experiment that small values of p_1, q_1, p_2, and q_2 such as 2, 3, or 4 are sufficient to give good performance (see Test Problems 3 and 6 in §5).

4. Comparison of factorization and circulant preconditioners. Various preconditioners in circulant form have been proposed for symmetric Toeplitz matrices [6], [8], [18], [20], [30]. All these preconditioners can be inverted effectively via fast transform algorithms with $O(N \log N)$ operations. This preconditioning technique can be easily generalized to nonsymmetric Toeplitz matrices. In the following, we discuss the generalization of the preconditioner $K_{1,N}$ [20] proposed by the authors to the nonsymmetric case.

Let T_N be an $N \times N$ Toeplitz matrix

$$T_N = \begin{bmatrix} t_0 & t_{-1} & \cdot & t_{-(N-2)} & t_{-(N-1)} \\ t_1 & t_0 & t_{-1} & \cdot & t_{-(N-2)} \\ \cdot & t_1 & t_0 & \cdot & \cdot \\ t_{N-2} & \cdot & \cdot & \cdot & t_{-1} \\ t_{N-1} & t_{N-2} & \cdot & t_1 & t_0 \end{bmatrix}.$$

We define a $2N \times 2N$ circulant matrix using elements of T_N as

$$R_{2N} = \begin{bmatrix} T_N & \triangle T_N \\ \triangle T_N & T_N \end{bmatrix}, \tag{4.1}$$

where

$$\triangle T_N = \begin{bmatrix} t_N & t_{N-1} & \cdot & t_2 & t_1 \\ t_{-(N-1)} & t_N & t_{N-1} & \cdot & t_2 \\ \cdot & t_{-(N-1)} & t_N & \cdot & \cdot \\ t_{-2} & \cdot & \cdot & \cdot & t_{N-1} \\ t_{-1} & t_{-2} & \cdot & t_{-(N-1)} & t_N \end{bmatrix}.$$

Since the augmented circulant system

$$\begin{bmatrix} T_N & \triangle T_N \\ \triangle T_N & T_N \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{x} \end{bmatrix} = \begin{bmatrix} \mathbf{b} \\ \mathbf{b} \end{bmatrix}$$

is equivalent to

$$(T_N + \triangle T_N)\mathbf{x} = \mathbf{b},$$

the $(T_N + \triangle T_N)^{-1}\mathbf{b}$ can be computed efficiently via fast Fourier transform (FFT) so that

$$K_N = T_N + \triangle T_N$$

can be used as a preconditioner for T_N. Note that K_N is also a circulant matrix.

When T_N is a symmetric Toeplitz matrix generated by a positive function in the Wiener class, it can be proved [7], [20] that the eigenvalues of the circulant-preconditioned Toeplitz matrix are clustered around 1 except at a finite number of outliers. When T_N is additionally rational of order (p, q), the eigenvalues of $K_N^{-1}T_N$ are clustered between $(1 - \epsilon_K, 1 + \epsilon_K)$ except at $\alpha_K = 2\max(p, q)$ outliers, where $\epsilon_K = O(|t_N|)$ [22], [31]. A special case of Theorem 3 is that when T_N is a symmetric rational matrix, we have $r = s = w$ and $\alpha_F = \max(p, q) = \frac{1}{2}\alpha_K$. A more general result applicable to the nonsymmetric case has been obtained under the following two conditions:

$$\sum_{-\infty}^{\infty} |t_n| \leq B_T < \infty, \tag{4.2}$$

$$|T(e^{i\theta})| = \left|\sum_{-\infty}^{\infty} t_n e^{-in\theta}\right| \geq \mu_T > 0 \quad \forall \theta. \tag{4.3}$$

THEOREM 4. *Let T_N be a rational Toeplitz matrix generated by $T(z)$ of order (p_1, q_1, p_2, q_2) as given by* (3.2), *and satisfying* (4.2) *and* (4.3). *For sufficiently large N, the preconditioned Toeplitz matrix $K_N^{-1}T_N$ has the following two properties:*

$P(1)$: The number of outliers is at most $\alpha_K = 2\min(r, s)$.

$P(2)$: There are at least $N - \eta$ eigenvalues confined in the disk centered at 1 *with radius $\epsilon_K = O(|t_N| + |t_{-N}|)$.*

Proof. See [23] for the proof. □

The spectral properties of $F_N^{-1}T_N$ and $K_N^{-1}T_N$ for rational T_N are compared as follows. One main difference is that the eigenvalues except at outliers are exactly repeated at 1 for $F_N^{-1}T_N$ but only clustered around 1 for $K_N^{-1}T_N$, i.e., $\epsilon_K \geq \epsilon_F = 0$. Another difference is the number of outliers that are, by definition, the eigenvalues not converging to 1 for asymptotically large N. Asymptotically, ϵ_K converges to 0 and the CGS method with preconditioners F_N and K_N converges in at most $\alpha_F + 1$ and $\alpha_K + 1$ iterations, respectively. For finite N, $\epsilon_K \neq 0$ and the performance of K_N are determined by both the number of the outliers α_K and the clustering radius ϵ_K. Although it may happen that $\alpha_K < \alpha_F$, the MPLU preconditioner, in general, provides a faster or a comparable convergence rate since $\epsilon_K \geq \epsilon_F = 0$.

The preconditioning step $F_N^{-1}\mathbf{r}$ can be accomplished with $O(N)$ operations by permutation, forward- and back-substitution, since F_N is a product of a shift matrix, lower- and upper-triangular banded Toeplitz matrices. In comparison, the preconditioning step $K_N^{-1}\mathbf{r}$ requires $O(N \log N)$ operations via FFT. Hence, in terms of computational complexity per iteration, preconditioner F_N is slightly better. However, note that $F_N^{-1}\mathbf{r}$ must be implemented sequentially, whereas $K_N^{-1}\mathbf{r}$ can be easily parallelized via the parallelism provided by FFT.

5. Numerical results. Our numerical experiments include both SPD and nonsymmetric Toeplitz matrices with banded, rational, and nonrational generating sequences. The SPD problems are solved by the PCG method. For nonsymmetric systems, there exist numerous iterative algorithms for their solution [2], [27]. As suggested by [25], we applied the preconditioned version of three iterative methods, i.e., CGN, GMRES, and CGS, for our numerical experiments. We observed that GMRES and CGS converge faster than CGN, and that CGS outperforms GMRES by a factor of 1 to 2 for all test problems. Since our focus is on the preconditioners rather than the iterative methods, only results solved by the CGS iteration are reported. All experiments are performed with $N = 32$, $\mathbf{b} = (1, \cdots, 1)^T$, and zero initial guess.

TEST PROBLEM 1 (symmetric banded Toeplitz system). The generating function is

$$T(z) = z^{-4} + 3z^{-3} + 4z^{-2} + 7z^{-1} + 11 + 7z + 4z^2 + 3z^3 + z^4.$$

The convergence history of the PCG method with preconditioners F_N and K_N is plotted in Fig. 1. We clearly see that the 2-norm of the residual is significantly reduced in four iterations for both F_N and K_N and that F_N performs slightly better than K_N. We point out that $F_N^{-1}T_N$ and $K_N^{-1}T_N$ have four and eight outliers, respectively. However, for this test problem, the outliers of $K_N^{-1}T_N$ are related in pairs and it takes only $\frac{1}{2}\alpha_K$ iterations to eliminate these α_K outliers. A similar kind of convergence behavior for $K_N^{-1}T_N$ was reported in [20]. In general, preconditioners F_N and K_N have a similar performance for symmetric banded Toeplitz matrices.

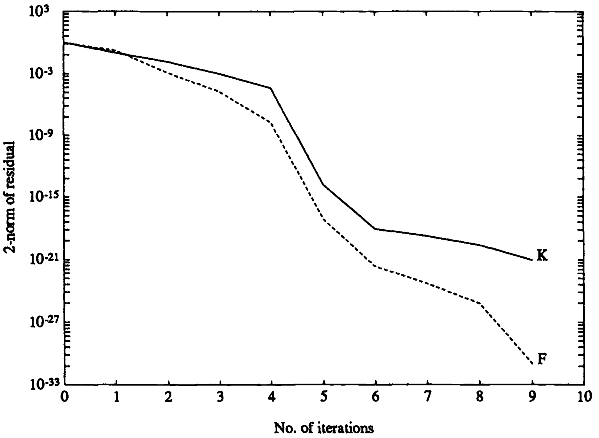

FIG. 1. *The convergence history of the* PCG *method with preconditioners* F_N *and* K_N *for Test Problem* 1.

TEST PROBLEM 2 (symmetric rational Toeplitz system). The generating function is

$$T(z) = \frac{(1-0.2z^{-1})(1+0.3z^{-1})(1-0.5z^{-1})}{(1-0.3z^{-1})(1+0.5z^{-1})(1-0.7z^{-1})} + \frac{(1-0.2z)(1+0.3z)(1-0.5z)}{(1-0.3z)(1+0.5z)(1-0.7z)}.$$

Since T_N is symmetric ($r = s = w = 3$), the eigenvalues of $F_N^{-1}T_N$ are repeated at 1 except at three outliers (see Theorem 3), and the eigenvalues of $K_N^{-1}T_N$ are clustered around 1 except at six outliers (see Theorem 4). The convergence history of the PCG method with preconditioners F_N and K_N is plotted in Fig. 2. Since $F_N^{-1}T_N$ has four distinct eigenvalues, the PCG method with preconditioner F_N converges in four iterations. However, although $K_N^{-1}T_N$ has six outliers, it only requires three iterations to eliminate the outliers. The convergence rate after the first three iterations depends on the clustering radius ϵ_K. It is clear that preconditioner F_N performs better than preconditioner K_N.

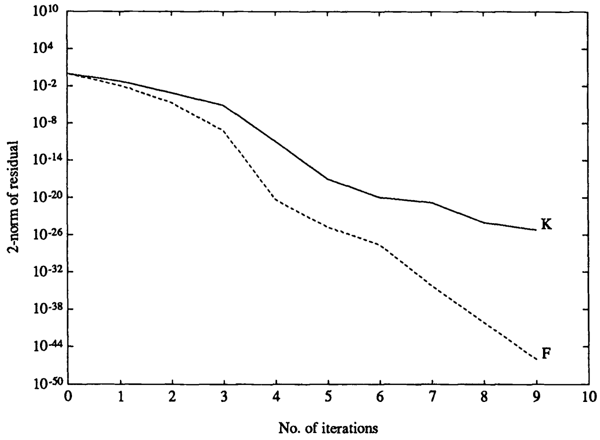

FIG. 2. *The convergence history of the* PCG *method with preconditioners F_N and K_N for Test Problem* 2.

TEST PROBLEM 3 (symmetric nonrational Toeplitz system). The generating sequence is

$$t_n = \begin{cases} 2, & n = 0, \\ 1/(1 + |n|), & n \neq 0, \end{cases}$$

and the corresponding generating function is

$$T(z) = T_+(z^{-1}) + T_+(z),$$

where

$$T_+(z^{-1}) = \sum_{n=0}^{\infty} \frac{z^{-n}}{1+n}.$$

Consider the *Padé* approximant of order (p, q), i.e., $A'_p(z^{-1})/B'_q(z^{-1})$, to $T_+(z^{-1})$. Preconditioners $F_{p,q,N}$ are then constructed with respect to

$$T'_{p,q}(z) = \frac{A'_p(z^{-1})}{B'_q(z^{-1})} + \frac{A'_p(z)}{B'_q(z)}.$$

In our experiment, (p, q) is chosen to be $(3, 3)$ and $(4, 4)$. The convergence history of the PCG method with preconditioners $F_{3,3,N}$, $F_{4,4,N}$, and K_N is plotted in Fig. 3. All these preconditioners converge at a similar rate.

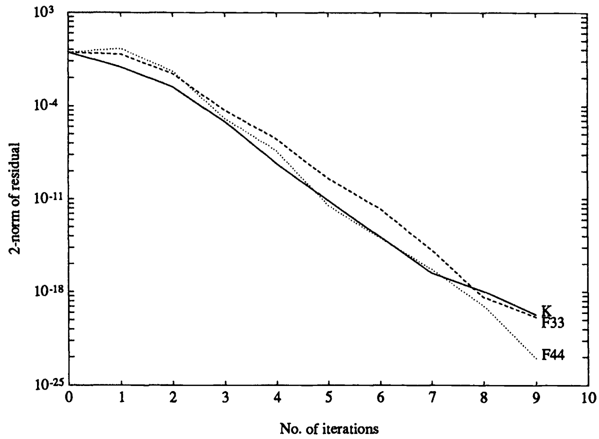

FIG. 3. *The convergence history of the* PCG *method with preconditioners* $F_{3,3,N}, F_{4,4,N}$*, and* K_N *for Test Problem* 3.

TEST PROBLEM 4 (nonsymmetric banded Toeplitz system). The generating function is

$$T(z) = -z^{-3} + 2z^{-2} + 9z^{-1} + 4 - 2z - 3z^2 + z^3,$$

so that T_N is a banded Toeplitz matrix with lower bandwidth $r = 3$ and upper bandwidth $s = 3$. Note also that $T(z)$ has $w = 4$ zeros outside the unit circle. The convergence history of the CGS method with preconditioners F_N and K_N is plotted in Fig. 4. According to Theorem 2, $F_N^{-1}T_N$ has three eigenvalues different from 1 and, consequently, the CGS method with preconditioner F_N converges in four iterations. According to Theorem 4, $K_N^{-1}T_N$ has six eigenvalues not equal to 1 so that the CGS method with preconditioner K_N converges in seven iterations. We see clearly that the CGS method with preconditioner F_N converges faster.

TEST PROBLEM 5 (nonsymmetric rational Toeplitz system). The generating function is

$$T(z) = \frac{(1-0.2z^{-1})(1+0.3z^{-1})(1-0.5z^{-1})}{(1-0.7z^{-1})(1+0.5z^{-1})} + \frac{1+2z}{(1.5-z)(2+z)(2-z)}.$$

We can transform T_N into a banded matrix with $r = s = w = 3$. From Theorems 3 and 4, we know that $F_N^{-1}T_N$ has only three eigenvalues not equal to 1 and the eigenvalues of $K_N^{-1}T_N$ are clustered around 1 except six outliers. The convergence history of the CGS method with preconditioners F_N and K_N is plotted in Fig. 5. The CGS method with preconditioner F_N performs better.

TEST PROBLEM 6 (nonsymmetric nonrational Toeplitz system). Let T_N be a nonsymmetric Toeplitz matrix with generating sequence

$$t_n = \begin{cases} 1/\log(2-n), & n \leq -1, \\ 1/\log(2-n) + 1/(1+n), & n = 0, \\ 1/(1+n), & n \geq 1. \end{cases}$$

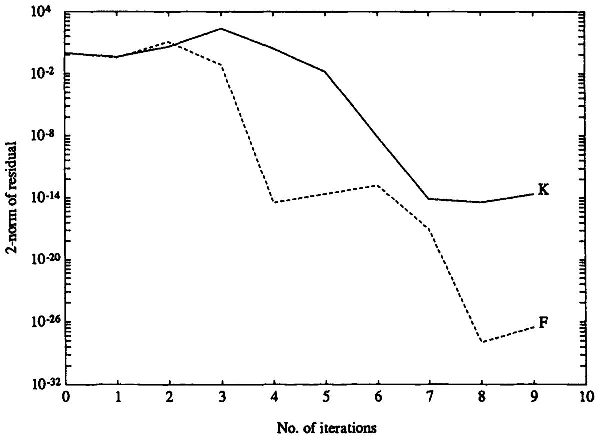

FIG. 4. *The convergence history of the* CGS *method with preconditioners* F_N *and* K_N *for Test Problem* 4.

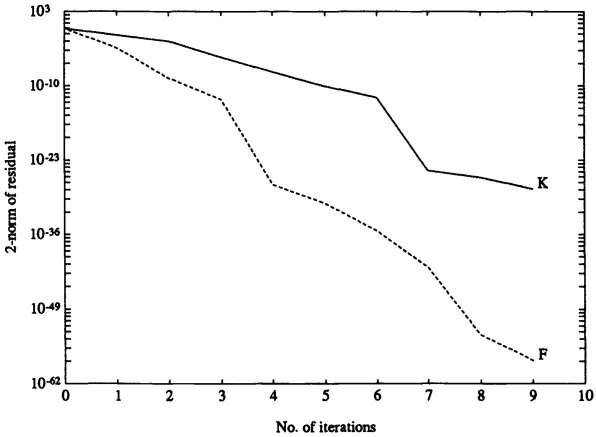

FIG. 5. *The convergence history of the* CGS *method with preconditioners* F_N *and* K_N *for Test Problem* 5.

The corresponding causal and anticausal generating functions can be written as

$$T_+(z^{-1}) = \sum_{n=0}^{\infty} \frac{z^{-n}}{1+n},$$

$$T_-(z) = \sum_{n=0}^{\infty} \frac{z^n}{\log(2+n)}.$$

Let the *Padé* approximants of order (p,q), to $T_+(z^{-1})$ and $T_-(z)$, be $A'_p(z^{-1})/B'_q(z^{-1})$ and $C'_p(z)/D'_q(z)$, respectively. We construct preconditioner $F'_{p,q,N}$ for

$$T'_{p,q}(z) = \frac{A'_p(z^{-1})}{B'_p(z^{-1})} + \frac{C'_q(z)}{D'_q(z)},$$

TABLE 2
Numbers of iterations required for the CGS *method.*

N	$F_{2,2,N}$	$F_{3,3,N}$	$F_{4,4,N}$	K_N
32	6	5	5	11
64	8	7	6	11
128	9	8	7	13

with $p = q = 2, 3, 4$. The convergence history of the CGS method with preconditioners $F_{p,q,N}$ and K_N is plotted in Fig. 6. To understand the asymptotical behavior of the preconditioned CGS method, we also performed experiments for this test problem with $N = 64, 128$. The numbers of iterations required with preconditioners $F_{p,q,N}$, $p = q = 2, 3, 4$, and K_N satisfying $||\mathbf{b} - T_N\mathbf{x}||_2 < 10^{-15}$ are summarized in Table 2 for different N. Note that the numbers of iterations required for all preconditioners increase slightly as N becomes larger. However, preconditioners $F_{p,q,N}$, $p = q = 2, 3, 4$ perform better than preconditioner K_N.

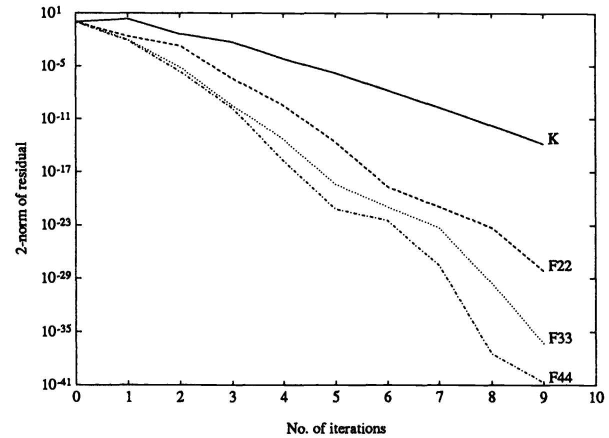

FIG. 6. *The convergence history of the* CGS *method with preconditioners* $P_{p,q,N}, p = q = 2, 3, 4$, *and* K_N *for Test Problem* 6.

6. Conclusion. In this paper, we applied the minimum-phase factorization technique to Toeplitz generating functions and obtained a new Toeplitz preconditioner called the MPLU preconditioner. This preconditioning technique is applicable to both banded and full Toeplitz matrices. We characterized the spectral properties of the MPLU preconditioned Toeplitz matrices, and showed that most of their eigenvalues are repeated exactly at unity for rational Toeplitz matrices. Thus an $N \times N$ rational Toeplitz system can be solved by preconditioned iterative methods with $O(N)$ complexity. We also demonstrate the superior performance of the MPLU preconditioner over another Toeplitz preconditioner in circulant form with several numerical examples, including both rational and nonrational cases.

Although our discussion on the MPLU factorization preconditioner has primarily focused on real nonsymmetric Toeplitz systems, its application to complex nonhermitian Toeplitz systems can be generalized in a straightforward way. However, the MPLU factorization preconditioning technique cannot be easily extended to higher-dimensional Toeplitz systems, such as block Toeplitz matrices. This is due to the absence of the fundamental theorem of algebra for multivariate polynomials. In contrast, higher-dimensional Toeplitz matrices can be preconditioned with higher-dimensional circulant matrices. See [21] for the two-dimensional case. Another limitation of the MPLU preconditioner is that it is not as easily parallelizable as the preconditioners in circulant form.

DERIVATION OF EFFICIENT, CONTINUOUS, EXPLICIT RUNGE–KUTTA METHODS*

BRYNJULF OWREN† AND MARINO ZENNARO‡

Abstract. Continuous, explicit Runge–Kutta methods with the minimal number of stages are considered. These methods are continuously differentiable if and only if one of the stages is the FSAL evaluation. A characterization of a subclass of these methods is developed for orders 3, 4, and 5. It is shown how the free parameters of these methods can be used either to minimize the continuous truncation error coefficients or to maximize the stability region. As a representative for these methods the fifth-order method with minimized error coefficients is chosen, supplied with an error estimation method, and analysed by using the DETEST software. The results are compared with a similar implementation of the Dormand–Prince 5(4) pair with interpolant, showing a significant advantage in the new method for the chosen problems.

Key words. Runge–Kutta, interpolant, continuous, optimal

AMS(MOS) subject classification. 65L05

1. Introduction.

We consider the first-order system of differential equations

$$y'(x) = f(x, y(x)), \quad y(x_0) = y_0, \quad x_0 \le x \le x_e, \tag{1}$$

where $f : \mathbf{R} \times \mathbf{R}^m \to \mathbf{R}^m$ defines m generally nonlinear equations, and y_0 is the m-vector of initial values. We are interested in a continuous approximation to the solution $y(x)$ for $x \in [x_0, x_e]$. A possible way to obtain such an approximation is to apply a continuous, explicit Runge–Kutta method (CERK method) as proposed by the authors in [16]. One may expect such a method to be appropriate in the case when (1) is nonstiff. CERK methods may also be used for solving certain types of functional differential equations, like delay differential equations, for which retarded arguments in the right-hand side of (1) might be estimated by continuous extensions over previous subintervals. The continuous approximation $u(x)$ is obtained on $[x_0, x_e]$ by using a mesh $\{x_0 < x_1 < \cdots < x_N = x_e\}$ and computing polynomials $u_{n+1}(x_n + \theta h_n)$, $n = 0, \ldots, N-1$, such that $u(x) = u_{n+1}(x_n + \theta h_n)$ for $x_n \le x = x_n + \theta h_n \le x_{n+1}$ where $h_n = x_{n+1} - x_n$. The continuity assumption on $u(x)$ requires that $u_n(x_n) = u_{n+1}(x_n) := y_n$, $n = 1, \ldots, N-1$. The general form of u_{n+1} is

$$K_i = f\left(x_n + c_i h_n, y_n + h_n \sum_{j=1}^{i-1} a_{ij} K_j\right), \qquad i = 1, \ldots, s,$$

$$u_{n+1}(x_n + \theta h_n) = y_n + h_n \sum_{i=1}^{s} b_i(\theta) K_i, \qquad \theta \in [0, 1],$$

where $b_i(\theta)$, $i = 1, \ldots, s$, are polynomials of degree $\le d$ for some positive integer d. We shall also require $c_i = \sum_{j=1}^{i-1} a_{ij}$, and $b_i(0) = 0$ for $i = 1, \ldots, s$; the last condition is necessary for continuity. Henceforth we shall denote by A the strictly lower triangular matrix defined by the coefficients a_{ij}. Observe that a conventional Runge–Kutta

method is obtained by putting $y_{n+1} = u_{n+1}(x_n + h_n)$. In fact, a CERK method is equivalent to a Runge–Kutta method supplied with an interpolant. On surveying the literature one finds such interpolants for most of the commonly used Runge–Kutta formulas, e.g., Shampine [17], [18]; Dormand and Prince [6], [7]; Calvo, Montijano, and Rández [4]; and Horn [13]. Enright, Jackson, Nørsett, and Thomsen [8] provides a general technique for constructing interpolants to a Runge–Kutta formula while Zennaro [20] discusses natural continuous extensions of Runge–Kutta methods which are especially suited for functional differential equations when certain restrictions are imposed on the mesh. In a recent paper Verner [19] elaborates on differentiable interpolants of higher order.

An important issue in many of these papers has been whether or not the continuous approximation should yield the same order of consistency in the interior of the step as at the end-points. Following [16] we shall define the uniform order, or simply the order of a CERK method, as the greatest integer p for which

$$\max_{0\leq\theta\leq 1} |y_{n+1}(x_n + \theta h_n) - u_{n+1}(x_n + \theta h_n)| = O(h_n^{p+1}) \tag{2}$$

where $y_{n+1}(x)$ is the local solution to the initial value problem $y'_{n+1}(x) = f(x, y_{n+1}(x))$, $y_{n+1}(x_n) = y_n$. Here $|\cdot|$ can be any norm on $\mathbf{R}^m$. Of course, the order q at the end-points satisfies $q \geq p$ and in this paper we shall not impose the possible additional requirement that $q > p$ for any of our methods. We shall always require (see [16]) that the degree d of the polynomials $b_i(\theta)$, $i = 1, \ldots, s$, satisfies $d \leq p$. Again, according to [16], for each order p one may define the order barrier as the smallest number of stages CEN(p) that a CERK method satisfying (2) can have. These order barriers were derived for $p \leq 5$. It was found that CEN(1) = 1, CEN(2) = 2, CEN(3) = 4, CEN(4) = 6, and CEN(5) = 8. The first examples of fifth-order CERK methods with only eight stages were developed. It should be made clear that these new continuous methods with the minimal number of stages may only be expected to be cheap when the continuous approximation is required along the entire interval of integration. In some applications the continuous approximation is needed only occasionally, e.g., when it is used to locate discontinuities; see, e.g., [9]. In such cases it is recommended that one use a discrete method that can be supplied with a continuous extension, possibly at more than the minimal cost.

In this paper, we consider CERK methods with CEN(p) stages for $p = 3, 4, 5$ with the additional property that they are $C^{(1)}$ continuous. We give a complete recipe for the construction of some if not all such methods, and we present pairs of formulas with optimized error constants and show how the regions of absolute stability may be optimized. Finally, we present some results based on tests made with the DETEST package [10]. These tests are made with a fifth-order representative of the CERK methods described in this paper, displaying the properties of the underlying discrete method.

2. Preliminary results. Henceforth we shall make extensive use of the theory of rooted trees and order conditions developed by Butcher [1], [2]. From [16] we find the continuous version of the order conditions

$$\sum_{j=1}^{s} b_j(\theta)\Phi_j(t) = \frac{\theta^{\rho(t)}}{\gamma(t)} \quad \text{for all trees } t \text{ such that } \rho(t) \leq p, \tag{3}$$

where $\Phi_j(t)$ is the jth elementary weight for the tree t, $\rho(t)$ is the order of t, and $\gamma(t)$ is a coefficient depending on the tree t. For each $r \geq 1$, let n_r be the number of trees such that $\rho(t) = r$. Thus a CERK method of order p must satisfy N_p conditions where $N_p = \sum_{r=1}^{p} n_r$. We number the N_p trees t increasingly in terms of $\rho(t)$, such that $\rho(t_i) > \rho(t_j)$ only if $i > j$. This ordering is not unique. By putting $z_j(\theta) := b_j'(\theta)$, $j = 1, \ldots, s$, (3) can be written as

$$(4) \qquad \sum_{j=1}^{s} \phi_{ij} z_j(\theta) = \frac{\rho(t_i)\theta^{\rho(t_i)-1}}{\gamma(t_i)}, \qquad i = 1, \ldots, N_p,$$

where $\phi_{ij} = \Phi_j(t_i)$. Moreover, by writing

$$z_j(\theta) = \sum_{k=0}^{p-1} z_{jk}\theta^k \quad \text{and} \quad \frac{\rho(t_i)\theta^{\rho(t_i)-1}}{\gamma(t_i)} = \sum_{l=0}^{p-1} q_{il}\theta^l,$$

and by defining the $N_p \times s$ matrix $\Phi := ((\phi_{ij}))$, the $s \times p$ matrix $Z := ((z_{jk}))$, and the $N_p \times p$ matrix $Q := ((q_{il}))$, (4) becomes

$$\Phi Z = Q.$$

The $N_p \times s$ matrix Φ depends on the $s \times s$ matrix A of the coefficients of the RK method, whereas the $N_p \times p$ matrix Q is independent of A. For convenience, we introduce the mappings

$$F_p : \bigcup_{s\geq 1} \mathcal{L}(\mathbf{R}^s, \mathbf{R}^s) \longrightarrow \bigcup_{s\geq 1} \mathcal{L}(\mathbf{R}^s, \mathbf{R}^{N_p}) \quad \text{such that } F_p(A) := \Phi,$$

and

$$G_p : \bigcup_{s\geq 1} \mathcal{L}(\mathbf{R}^s, \mathbf{R}^s) \longrightarrow \bigcup_{s\geq 1} \mathcal{L}(\mathbf{R}^{s+p}, \mathbf{R}^{N_p}) \quad \text{such that } G_p(A) := \Phi|Q,$$

where $\Phi|Q$ is the $N_p \times (s + p)$ matrix obtained by attaching the rows of Q to the rows of Φ. It was pointed out in [16] that a CERK method is of order p if and only if $\text{rank}(F_p(A)) = \text{rank}(G_p(A))$. These methods constitute a set

$$\begin{aligned}\mathcal{M}^p := \{A \in \textstyle\bigcup_{s\geq 1} \mathcal{L}(\mathbf{R}^s, \mathbf{R}^s) | \ & A \text{ is strictly lower triangular,} \\ & \text{rank}(F_p(A)) = \text{rank}(G_p(A))\}.\end{aligned}$$

Consider the subset of $\mathcal{M}^p$,

$$\mathcal{M}_*^p := \{A \in \mathcal{M}^p | \text{rank}(F_p(A)) = s\},$$

where s is the order of the matrix A. It was proved in [16] that a necessary condition for a CERK method of order p to have CEN(p) stages is that $A \in \mathcal{M}_*^p$. Thus, henceforth we shall only consider methods for which $A \in \mathcal{M}_*^p$.

3. Optimal $C^{(1)}$ approximations. A property possessed by all explicit Runge–Kutta methods is that the first stage of the step from x_{n+1} to x_{n+2} is given by $K_1 = f(x_{n+1}, y_{n+1})$. Many methods take advantage of this property by also using this stage in the previous step from x_n to x_{n+1}. In the literature, this reusable stage is sometimes referred to as the FSAL (first same as last) evaluation. Because the methods we consider are explicit, the FSAL evaluation cannot be involved in the end-point approximation, but it may be used to obtain an error estimate or for the continuous approximation. It turns out that there is a close connection between the reusable stage being included in the CERK method and the uniform approximation being continuously differentiable. We shall consider CERK methods where the last stage K_s is the FSAL evaluation, i.e., we impose the *stage reuse conditions*

$$(5) \qquad c_s = 1 \quad \text{and} \quad a_{sj} = b_j(1), \quad j = 1, \dots, s.$$

For the discussion that follows we need the following lemma.

LEMMA 1. *Let* $A \in \mathcal{M}^p$ *define a* CERK *method with stage reuse. Then* $\Phi := F_{p+1}(A) := ((\phi_{ij}))$ *is such that*

$$\phi_{is} = \frac{\rho(t_i)}{\gamma(t_i)}, \qquad i = 1, \dots, N_{p+1}.$$

Proof. The lemma is proved by induction on the row index. The result holds for $i = 1$ since the first row corresponds to the only tree, τ, of order 1 and since $\gamma(\tau) = \rho(\tau) = \phi_{1s}(\tau) = 1$. Then assume that the lemma is true for all i such that $i \leq n - 1$. The nth condition corresponds to a tree t_n which either has the form $[t_{n'}]$ for some tree $t_{n'}$ of order $\rho(t_n) - 1$ or the form $[t_{\nu_1}, \dots, t_{\nu_u}]$ for $u\,(\geq 2)$ trees t_{ν_i} where $1 \leq \rho(t_{\nu_i}) \leq \rho(t_n) - 2$ and $\rho(t_n) = 1 + \sum_{i=1}^{u} \rho(t_{\nu_i})$. In the latter case, with $t_{n_i} = [t_{\nu_i}]$, we immediately obtain from the definition of γ [3, p. 88] that

$$\gamma(t_n) = \rho(t_n) \prod_{i=1}^{u} \frac{\gamma(t_{n_i})}{\rho(t_{n_i})}$$

such that

$$\phi_{ns} = \prod_{i=1}^{u} \phi_{n_i s} = \prod_{i=1}^{u} \frac{\rho(t_{n_i})}{\gamma(t_{n_i})} = \frac{\rho(t_n)}{\gamma(t_n)}.$$

In the former case, we get

$$\phi_{ns} = \sum_{j=1}^{s-1} a_{sj} \phi_{n'j} = \sum_{j=1}^{s-1} b_j(1) \phi_{n'j} = 1/\gamma(t_{n'}) = \frac{\rho(t_n)}{\gamma(t_n)},$$

where we have applied the stage reuse conditions along with the order conditions at $\theta = 1$. Finally, observe that the induction works for all n such that $\rho(t_n) \leq p+1$ since we only used the order condition corresponding to $t_{n'}$ and $\rho(t_{n'}) = \rho(t_n) - 1$. □

With this result, the following theorem is now easy to prove.

THEOREM 2. *Let* $A \in \mathcal{M}_*^p$ *be a* CERK *method with stage reuse. Then the global continuous approximation is continuously differentiable.*

Proof. It is sufficient to prove that $u'(x_0) = K_1$ and that $u'(x_0 + h) = K_s$. By Lemma 1, the last column of $F_p(A)$ is equal to the right-hand side of (4) evaluated at $\theta = 1$. Moreover, the first column of $F_p(A)$ equals the right-hand side of (4) evaluated at $\theta = 0$. Since, by assumption, the columns of $F_p(A)$ are linearly independent, we obtain $z_i(1) = \delta_{is}$ and $z_i(0) = \delta_{i1}$ such that $u'(x_0) = K_1$ and $u'(x_0 + h) = K_s$. □

It is of interest to know whether there exist CERK methods with stage reuse having a total of CEN(p) stages. It is easy to prove that such methods cannot exist for $p \leq 2$ under the assumption that the degree d of the polynomial weights does not exceed p. We have not been able to answer this question for general $p > 2$, but we shall see that such methods exist for $p = 3, 4, 5$. During this discussion we shall sometimes impose some additional conditions, which we shall refer to as the simplifying assumptions; see, e.g., [3, p. 195],

$$\sum_{j=1}^{i-1} a_{ij}c_j = \frac{1}{2}c_i^2, \qquad i = 3, \ldots, s. \tag{6}$$

We begin by considering the case $p = 3$. By combining the four continuous order conditions with (5), we find that a third-order CERK method with four stages and stage reuse can be constructed in the following way:

- Choose c_2 and c_3 with $c_2 \neq 0$, $c_3 \neq 0$, $c_2 \neq c_3$, and $c_2 \neq \frac{2}{3}$ in order that $A \in \mathcal{M}_*^3$.
- Put $c_4 = 1$ and compute a_{32}, a_{42}, and a_{43} from the formulas

$$a_{32} = \frac{c_3(c_3 - c_2)}{c_2(2 - 3c_2)},$$
$$a_{42} = \frac{3c_3 - 2}{6c_2(c_3 - c_2)}, \qquad a_{43} = \frac{2 - 3c_2}{6c_3(c_3 - c_2)}.$$

- The continuous weights are then given by

$$\begin{aligned}
b_1(\theta) &= (1 - 2a_{41})\theta^3 + (3a_{41} - 2)\theta^2 + \theta, \\
b_2(\theta) &= -a_{42}(2\theta^3 - 3\theta^2), \\
b_3(\theta) &= -a_{43}(2\theta^3 - 3\theta^2), \\
b_4(\theta) &= \theta^3 - \theta^2.
\end{aligned}$$

Observe that this continuous extension of the three-stage discrete method above is nothing but the cubic Hermite interpolant based on the end-points x and $x + h$.

Considering order $p = 4$ we shall restrict ourselves to the methods derived in [16] having CEN(4) $= 6$ stages. These methods satisfy the simplifying assumptions (6) with $s = 6$ and, using the notation of [3], we let the row space of $G_4(A)$ be spanned by the rows corresponding to the order conditions arising from the trees

$$\tau,\ [\tau],\ [\tau^2],\ [_2\tau]_2,\ [\tau^3],\ [_3\tau]_3. \tag{7}$$

Combining these conditions with (5) we find that one may choose $c_2 \neq 0$ and c_3, c_4, c_5 nonzero and distinct. Then if $6c_3c_4 - 4(c_3 + c_4) + 3 \neq 0$, the remaining coefficients are uniquely determined. If $c_3 = \frac{1}{2}$ and $c_4 = 1$, there exists a one-parameter family of methods (with a_{54} arbitrary). Given c_2, c_3, c_4, c_5, one may use the following procedure to obtain a fourth-order CERK method with stage reuse having six stages.

- Put $c_6 = 1$, $a_{62} = 0$, and compute a_{63}, a_{64}, a_{65} from the linear system

$$\sum_{j=3}^{5} a_{6j}c_j^{k-1} = \frac{1}{k}, \qquad k = 2, 3, 4.$$

By assumption, there exists a unique solution.

- Consider the equation

$$12a_{65}a_{54}c_4(c_4 - c_3) = 1 - 2c_3,$$

arising from the condition corresponding to the tree $[_3\tau]_3$. If $a_{65} \neq 0$ this equation can be satisfied in any case and thereby a_{54} is uniquely determined. This requires that $6c_3c_4 - 4(c_3 + c_4) + 3 \neq 0$. If $a_{65} = 0$, then $c_3 = \frac{1}{2}$ leading to $c_4 = 1$, in which case a_{54} is arbitrary.

- We obtain the remaining coefficients from the formulas

$$\begin{aligned}
a_{32} &= \frac{c_3^2}{2c_2},\\
a_{42} &= \frac{(3c_3 - 2c_4)c_4^2}{2c_2c_3}, \qquad a_{43} = \frac{(c_4 - c_3)c_4^2}{c_3^2},\\
a_{52} &= \frac{(3c_3 - 2c_5)c_5^2 + 6a_{54}c_4(c_4 - c_3)}{2c_2c_3},\\
a_{53} &= \frac{(c_5 - c_3)c_5^2 - a_{54}c_4(3c_4 - 2c_3)}{c_3^2}.
\end{aligned}$$

The continuous weights are found by solving the linear 6×6 system of equations arising from the order conditions corresponding to the trees (7).

Also for the order-five case we shall impose the simplifying assumptions (6) with $s = \mathrm{CEN}(5) = 8$ and the row space of $G_5(A)$ is assumed to be spanned by the rows corresponding to the trees

$$\tau,\ [\tau],\ [\tau^2],\ [_2\tau]_2,\ [\tau^3],\ [_3\tau]_3,\ [\tau^4],\ [_4\tau]_4. \tag{8}$$

For a detailed discussion of such fifth-order CERK methods with eight stages, see [16]. Now, combining these conditions with the stage reuse conditions (5) and the assumption $A \in \mathcal{M}_*^5$, one finds after some long but straightforward algebra that $c_2 \neq 0$, $c_3 \neq 0$, $c_6 \neq 0$, $c_7 \neq 0$, and $a_{54} \neq 0$ can be chosen subject to the constraints $c_6 \neq c_3$, $c_6 \neq 2c_3$, $c_7 \neq c_3$, $c_7 \neq 2c_3$, $c_7 \neq c_6$, $c_8 \neq 2c_3$, i.e., $c_3 \neq \frac{1}{2}$ and $\frac{2}{3}c_3^2 - \frac{3}{4}c_3 + \frac{1}{5} \neq c_6(c_3 - \frac{1}{2})^2$. The following procedure provides the remaining coefficients:

- Put $c_5 = c_4 = 2c_3$.
- Put $c_8 = 1$ and $a_{82} = 0$. Compute a_{86} and a_{87} from the formulas

$$a_{86} = -\frac{\frac{2}{3}c_3^2 - \frac{3}{4}c_3 + \frac{1}{5} - c_7(c_3 - \frac{1}{2})^2}{c_6(c_6 - c_3)(c_6 - 2c_3)(c_7 - c_6)}, \qquad a_{87} = \frac{\frac{2}{3}c_3^2 - \frac{3}{4}c_3 + \frac{1}{5} - c_6(c_3 - \frac{1}{2})^2}{c_7(c_7 - c_3)(c_7 - 2c_3)(c_7 - c_6)}.$$

Observe that $a_{87} = 0$ would violate the assumption $\frac{2}{3}c_3^2 - \frac{3}{4}c_3 + \frac{1}{5} \neq c_6(c_3 - \frac{1}{2})^2$.

- We may now compute a_{76} from the formula

$$a_{76} = \frac{\frac{1}{3}c_3^2 - \frac{1}{4}c_3 + \frac{1}{20}}{a_{87}c_6(c_6 - c_3)(c_6 - 2c_3)}.$$

- Now we turn to the sixth stage, which is independent of the stage reuse conditions

$$\begin{aligned}
a_{62} &= \frac{c_6^2(2c_3 - c_6)}{2c_2c_3}, \qquad a_{63} = \frac{c_6^2(c_6 - c_3)}{3c_3^2},\\
a_{64} &= \frac{c_6^2(c_6 - c_3)(2c_3 + a_{54} - c_6)}{12a_{54}c_3^2}, \qquad a_{65} = \frac{c_6^2(c_6 - c_3)(c_6 - 2c_3)}{12a_{54}c_3^2}.
\end{aligned}$$

- The remaining coefficients of the seventh stage are given by

$$a_{75} = \frac{c_7^2(c_7-c_3)(c_7-2c_3) - a_{76}c_6(c_6-c_3)(3c_6-4c_3)}{12a_{54}c_3^2},$$

$$a_{74} = \frac{\frac{1}{12}c_7^2(c_7-c_3)(c_7-2c_3) + a_{76}c_6(c_3(\frac{1}{2}c_7-\frac{1}{3}c_3) - c_6(\frac{1}{2}c_7-\frac{1}{3}c_6))}{c_3^2(c_7-2c_3)} - a_{75},$$

$$a_{73} = \frac{\frac{2}{3}c_7^2(c_7-c_3)(c_7-2c_3) - a_{76}c_6(\frac{4}{3}(c_6-4c_3)(c_6-\frac{1}{2}c_3) + c_6c_7)}{c_3^2(c_7-2c_3)} - 4(a_{74}+a_{75}).$$

a_{72} is obtained from (6).

- We next give formulas for the remaining coefficients of the eighth stage:

$$a_{85} = \frac{(1-c_3)(1-2c_3) - a_{86}f_6 - a_{87}f_7}{12a_{54}c_3^2},$$

where $f_i = 4c_i^3 - 9c_i^2c_3 + 4c_ic_3^2 + 2c_2c_3a_{i2}, \subset= 6,7$;

$$a_{84} = \frac{\frac{1}{4}(1-c_3)(1-2c_3) - (1-2c_3+2a_{54})a_{85}c_3^2 - a_{86}g_6 - a_{87}g_7}{(1-2c_3)c_3^2},$$

where $g_i = \frac{1}{4}c_i(3c_i-2c_3)(1-2c_3) - \frac{1}{4}c_i^2 + \frac{1}{3}(c_i^3 + a_{i2}c_2c_3)$, $i = 6,7$;

$$a_{83} = \frac{1 - c_3 - a_{86}c_6(3c_6-2c_3) - a_{87}c_7(3c_7-2c_3)}{c_3^2} - 8(a_{84}+a_{85}).$$

- The remaining coefficients are independent of the stage reuse conditions

$$a_{32} = \frac{c_3^2}{2c_2}, \quad a_{42} = -\frac{2c_3^2}{c_2}, \quad a_{43} = 4c_3,$$

$$a_{52} = \frac{2c_3(3a_{54}-c_3)}{c_2}, \qquad a_{53} = 4c_3 - 8a_{54}.$$

The polynomials $b_1(\theta), \ldots, b_8(\theta)$ are found by solving the linear 8×8 system of equations arising from the order conditions corresponding to the trees (8).

Remark. An interesting question is whether there exist methods among this fifth-order class such that their first six stages define a discrete RK formula of order five. This would clearly require $a_{87} = b_7(1) = 0$, a case which is excluded in the formulas above because of the assumption $\frac{2}{3}c_3^2 - \frac{3}{4}c_3 + \frac{1}{5} \neq c_6(c_3 - \frac{1}{2})^2$. However, it can be shown that this condition is also necessary for the existence of eight-stage fifth-order CERK methods with stage reuse based on the simplifying assumptions and the choice of linearly independent rows of $G_5(A)$ made above.

4. Error estimation. Variable step Runge–Kutta methods are usually supplied with an error estimation device. We shall be concerned with the strategy based on embedded formulas (see [12] for details) and we shall see how this strategy can be adapted to pairs of CERK methods. Such a pair will be denoted by CERK(p,q), which means that the integration is proceeded by a continuous method of order p as described in the previous section, while a discrete formula of order q is used to obtain an error estimate at the end-point of each step. It is obvious that we must require $p \neq q$ and it is customary to assume that $|p-q| = 1$, but it is not clear whether one should have $q > p$ or $p > q$. Most implementations of the discrete pairs proposed by Fehlberg [11] are of the former type, while in the methods of Dormand and Prince [5] the intention is to impose $p = q + 1$ (local extrapolation). We will pay most of our attention to the latter type of pairs, mainly for two reasons. First, we have the following negative result for the typical Fehlberg-type implementations.

PROPOSITION 3. *There exist no* CERK$(p, p+1)$ *pairs with* $s =$CEN (p) *stages.*

Proof. Assume that $s = \mathrm{CEN}(p)$ for a method given by the $s \times s$ matrix A. Then, since $\mathrm{rank}(F_p(A)) = s$, it is impossible to find two distinct sets of weights that satisfy the first N_p discrete-order conditions. □

The second reason is based on a recent result by Jackiewicz and Zennaro [14]. They find that given a CERK method of order p with $s = \mathrm{CEN}(p)$ stages, it is possible to obtain a two-step Runge–Kutta method of order $p + 1$ at no additional cost. Hence, one may use this two-step approximation of order $p + 1$ to obtain an error estimate. The authors have no experience with practical use of such estimates.

Having constructed a CERK method of order p, several possibilities remain for the construction of a $(p - 1)$ st-order discrete formula. We suggest that the final reusable stage be omitted from the error estimation formula, as this will cause rejected steps to cost only $s - 2$ function evaluations if properly implemented. We shall take advantage of the fact that all our pth-order methods with CEN(p) stages, $p = 3, 4, 5$, described in the previous section turn out to have an imbedded CERK method of order $p - 1$ with CEN$(p - 1)$ stages. We shall use this method evaluated at $\theta = 1$ as the error estimation method.

5. Minimization of the error constant.

For a CERK method of order p, the local truncation error is given by

$$|y(x_0 + \theta h) - u(x_0 + \theta h)| = \frac{h^{p+1}}{(p+1)!}\left|\sum_{i=N_p+1}^{N_{p+1}} e_i(\theta)\alpha_i F_i(x_0, y_0)\right| + \mathcal{O}(h^{p+2}),$$

where $F_i := F(t_i)$ is the elementary differential corresponding to the tree t_i, $\alpha_i := \alpha(t_i)$ is a positive integer weight corresponding to the tree t_i and $e_i(\theta)$, $i = N_p + 1, \dots, N_{p+1}$ are the *error polynomials* given by

$$e_i(\theta) = \theta^{\rho(t_i)} - \gamma(t_i)\sum_{j=1}^{s}\phi_{ij}b_j(\theta), \qquad i = N_p + 1, \dots, N_{p+1}.$$

By considering the structure of the matrix $\Phi = ((\phi_{ij}))$, it is easy to see that all the error polynomials have vanishing zeroth- and first-degree coefficients such that both $e_i(0)$ and $e_i'(0)$ are zero. Moreover, for the CERK methods of the previous section, the derivatives of the error polynomials also vanish at $\theta = 1$. We have the following proposition.

PROPOSITION 4. *Let* $A \in \mathcal{M}_*^p$ *be a* CERK *method with stage reuse. Then all the error polynomials* $e_i(\theta)$, $i = N_p + 1, \dots, N_{p+1}$, *satisfy* $e_i'(1) = 0$.

Proof. The derivatives of the error polynomials are given by

$$e_i'(\theta) = \rho(t_i)\theta^{\rho(t_i)-1} - \gamma(t_i)\sum_{j=1}^{s}\phi_{ij}z_j(\theta), \qquad i = N_p + 1, \dots, N_{p+1}.$$

As in the proof of Theorem 2 we must have $z_s(1) = 1$ and $z_1(1) = \cdots = z_{s-1}(1) = 0$ and by Lemma 1 it follows that $e_i'(1) = 0$. □

Following, e.g., Calvo, Montijano, and Rández [4] we shall attempt to make the error polynomials small in some sense. The literature is not consistent with regard to what norm should be used on this n_{p+1}-vector of polynomials. Calvo, Montijano, and Rández [4] minimize the quantity

$$g^* = \int_0^1 g(\theta)d\theta$$

over the free parameters, where

$$g(\theta) = \sqrt{\frac{\sum_{i=N_p+1}^{N_{p+1}}[e_i(\theta)\alpha(t_i)]^2}{\sum_{i=N_p+1}^{N_{p+1}}[e_i(1)\alpha(t_i)]^2}}. \tag{9}$$

Enright, Jackson, Nørsett, and Thomsen [8] consider bounds for the principal error term on the intervals $0 \le \theta \le 1$ and $0 \le \theta \le 2$. They use the norm

$$\max_{N_p+1 \le i \le N_{p+1}} \{ \max_{\theta \in [0,\theta_e]} |e_i(\theta)| \}$$

where $\theta_e = 1$ or $\theta_e = 2$. This latter case is of interest when the continuous method is to be used beyond the current step, e.g., for the purpose of handling discontinuities. We present here method pairs of orders 3, 4, and 5 where the free parameters have been chosen to minimize the numerator of (9). The optimization was done numerically, and the values found for the free parameters were approximated by rational numbers. The weights $\hat{y}_{n+1}$ in Figs. 1–3 are those of the error estimation method and have nothing to do with the underlying discrete method of the CERK method. Several numerical investigations conducted with the methods derived in this paper show that the vector of error polynomials tends to have one dominating component, which is the polynomial that corresponds to the tree $[_p\tau]_p$. Moreover, this error polynomial turns out to be independent or only weakly dependent on some of the free parameters of our optimal CERK methods. We illustrate this point by considering the optimal third-order CERK methods of the previous section. The error polynomial $e_8(\theta)$ corresponding to the tree $[_3\tau]_3$ of order four is given by

$$e_8(\theta) = \theta^2(\theta-2)^2,$$

$$\begin{array}{c|cccc}

FIG. 2. *Optimal fourth-order* CERK *method with stage reuse.*

and hence is completely independent of the free parameters c_2 and c_3. For $0 \le \theta \le 1$ it attains the maximum value 1 at $\theta = 1$ and it can be shown that c_2 and c_3 can be chosen such that the three remaining error polynomials satisfy $|e_i(\theta)| < 0.05$, $\theta \in [0, 1]$. Consequently, one may suspect that the minima of the various error measures are flat and if the max-norm is used, the minimum is not likely to be unique.

Remark. Dormand and Prince attempt to minimize the denominator of (9) in their discrete pair RK5(4)7M [5]. If we use the same error measure for our discrete underlying formulas of the fifth-order methods, it turns out that we can only obtain an error at the end-point about three times the size of that of RK5(4)7M. The corresponding error for the optimized fifth-order method above is about four times that of RK5(4)7M.

6. Stability. When applied to ODEs, the methods of the previous sections will obviously have the stability characteristics of the underlying discrete method. The region of absolute stability of the methods of order four and five is influenced by the choice of the free parameters. We write the stability polynomials of pth-order CERK methods with CEN(p) stages and stage reuse in the form

$$p(z) = \sum_{k=0}^{\mathrm{CEN}(p)-1} \alpha_k \frac{z^k}{k!}$$

$$

\end{aligned}
$$

FIG. 3. *Optimal fifth-order* CERK *method with stage reuse.*

where $\alpha_0 = \cdots = \alpha_p = 1$. It can be shown that for our fourth-order methods we have $\alpha_5 = 5(1 - 2c_3)c_4$. Following [15] the largest disk of stability is obtained by choosing $\alpha_5 \approx 0.5806$; For example, the choice $c_3 = \frac{2}{5}$ and $c_4 = \frac{4}{7}$ leads to a nearly optimal stability region in the sense of [15]. The fifth-order methods yield

$$\alpha_6 = 6(-5c_3^2 + 2c_3) - 2c_6\beta, \qquad \alpha_7 = 14c_3c_6\beta$$

with $\beta = 20c_3^2 - 15c_3 + 3$.

Thus, for any $(\mu, \nu) \in \mathbf{R} \times \mathbf{R}$, there exist real c_3 and c_6 such that $\alpha_6 = \mu$ and $\alpha_7 = \nu$. So the stability polynomial is only restricted by the assumptions made in the construction of the CERK formulas. In particular, one may choose c_3 and c_6 such that $\alpha_6 \approx 0.7956$ and $\alpha_7 \approx 0.3305$ which, again according to [15], maximizes the region of absolute stability.

7. Numerical results with DETEST.

We have tested the fifth-order pair, henceforth denoted CM54, on some selected problems using the DETEST package [10]. We used absolute error control, attempting to control the local error at the end-point of each step. As reference we have performed the same tests with an identical implementation of the Dormand–Prince RK5(4)7M method [5], henceforth called DP54, with a continuous extension obtained at the additional cost of two stages per step; see, e.g., [4]. Hence, the effective cost per step is eight stages for the Dormand–Prince extension and seven stages for our fifth-order CERK method. In order to compare these two pairs, we have found it natural to use normalised efficiency, a feature of the DETEST software. Thus, instead of comparing the cost of the two pairs for a given tolerance, we make comparisons for a given *expected global accuracy* at the end-point of integration. This expected accuracy is obtained in terms of the tolerance by assuming a relation of the form

$$\text{global error} \approx C \cdot \text{TOL}^E,$$

where C and E are found by a least squares fit to the computed data. Piecewise linear interpolation then yields continuous extensions of the tabulated efficiency statistics. See [10] for a more detailed explanation.

We believe that the test problems chosen give a good idea of how the two methods perform with DETEST. On some of the omitted problems the discrepancy between equivalent tolerances (see tables) for the two methods were substantial or the least squares fit was too poor to be reliable.

Tables 1–4 show the efficiency of DP54 versus CM54. The first column contains the expected accuracy, while columns 2 and 3 predict the value of the tolerance that corresponds to this accuracy for the two methods. Note that CM54 is more pessimistic in estimating the error than DP54. Columns 4–7 show the expected number of steps and function evaluations for the two methods, respectively. Note that since the number of steps and the number of function calls are obtained by interpolation, they may disagree with the number of stages per step that each of the methods actually has.

DETEST itself does not support any feature for testing interpolants. But by carefully modifying the program code, we found that the maximum of the uniform global error of CM54 rarely exceeds the maximum global error of the underlying discrete method for any problem in the DETEST package. This can be explained by the fact that the underlying discrete method has the same local order as the continuous method. When comparing the error at the end-point of the first step (i.e., the local error) to the maximum of the uniform error over this step, we found a maximum ratio of about 6.14. The ratio was equal to 1.0 in 87 percent of the cases, and in the range 1.0–1.32 in 99 percent of the tests.

In this paper we have used the framework of [16] to characterize differentiable, continuous, explicit Runge–Kutta methods with the minimal number of stages for orders 3, 4, and 5. Of particular interest are the fifth-order methods with only seven effective stages, since no such methods have been presented before. It is by no means obvious that the number of stages per step is an appropriate efficiency measure for continuous Runge–Kutta methods of a given order. However, the numerical results presented in this section may indicate that the new fifth-order methods are at least comparable to those previously known.

Acknowledgement. We would like to express our thanks to the referees, who gave us many useful suggestions and pointed out several misprints in the manuscript.
