$$(-\mu)^k - \lambda_{G_2}^{(\underline{\ell})}\lambda_{H_2}^{(\underline{\ell})}(-\mu)^{k-2} - \cdots - \lambda_{G_k}^{(\underline{\ell})}\lambda_{H_k}^{(\underline{\ell})}(-\mu)^{k-2} = 0$$

or

$$(-\mu)^{k-2}\left[\mu^2 - \sum_{i=2}^{k} \lambda_{G_i}^{(\underline{\ell})}\lambda_{H_i}^{(\underline{\ell})}\right] = 0.$$

We conclude the proof of the theorem by observing that the eigenvalues of the $N \times N$ tridiagonal matrix $\mathcal{T}_{-2}$ are given by $-4\sin^2(\ell\pi/2(N+1)), \ell = 1, \ldots, N$. (See [14], [15], or [13].) □

The spectral radius $\rho(J)$ of the block Jacobi matrix of the iteration method (31) is obviously the largest modulus of $\mu^{(\underline{\ell})}$ given in (34) and in (35) for the second- and fourth-order collocation schemes, respectively. Explicit formulas have been found for $\rho(J)$, which are summarized in the following theorem.

THEOREM 3.2. *Let us denote by*

$$y_j(\lambda) := \left[\frac{\alpha_j}{h_j^2}\lambda + \gamma_j(6+\lambda)\right](6+\lambda)^{-1} \tag{38}$$

and by

$$z_j(\lambda) := \left[\frac{\alpha_j}{h_j^2}\lambda(12+\lambda) + 12\gamma_j(6+\lambda)\right](6+\lambda)^{-1}, \tag{39}$$

with $\lambda = \lambda_j^{(\ell_j)}$, $\gamma_1 = \frac{\gamma}{6}$, *and* $\gamma_j = 0, j = 2, \ldots, k$, *the expressions appearing in* (34) *and* (35), *respectively, and let* $s_j := -4\sin^2(\pi/(2N_j))$ *and* $c_j := -4\cos^2(\pi/(2N_j)), j = 1, \ldots, k$. *Then the spectral radii of the block Jacobi matrices corresponding to the second- and fourth-order collocation schemes are defined by the following expressions*:

$$\rho^2(J) \equiv \sum_{j=2}^{k} y_j(c_j)/y_1(s_1) \tag{40}$$

and

$$\rho^2(J) \equiv \sum_{j=2}^{k} z_j(c_j)/z_1(s_1). \tag{41}$$

Proof. First we note that in (34) and (35), $\alpha_j < 0$, $\lambda_j^{(\ell_j)} \in [c_j, s_j]$, and $\gamma_j \geq 0, j = 1, \ldots, k$. Hence the expressions $y_j := y_j(\lambda_j^{(\ell_j)}), j = 1, \ldots, k$, defined in (38) are positive and independent of each other. So are the z_j's ($:= z_j(\lambda_j^{(\ell_j)})$'s, $j = 1, \ldots, k$) defined in (39). Therefore, in order to determine the two spectral radii, it suffices to determine the maximum values of $y_j, z_j, j = 2, \ldots, k$, and the minimum values of y_1, z_1. For the extreme values of $y_j := y_j(\lambda), \lambda \in [c_j, s_j], j = 1, \ldots, k$, we differentiate y_j with respect to λ to obtain

$$\frac{\partial y_j}{\partial \lambda} = \frac{1}{(6+\lambda)^2} \frac{\alpha_j}{h_j^2} < 0.$$

Consequently,

$$\max y_j = y_j(c_j), \qquad \min y_j = y_j(s_j). \tag{42}$$

To determine the extreme values of $z_j := z_j(\lambda), j = 1, \ldots, k$, we work in a similar way. This time we have

$$\frac{\partial z_j}{\partial \lambda} = \frac{1}{(6+\lambda)^2} \frac{\alpha_j}{h_j^2} \left[(6+\lambda)^2 + 36\right] < 0.$$

This gives

$$\max z_j = z_j(c_j), \qquad \min z_j = z_j(s_j). \tag{43}$$

From the expressions (34), (35), (38), and (39), and the results in (42) and (43), the expressions (40) and (41) for the spectral radii readily follow. □

Remark. From the above theorem, it is easy to conclude that the *block Jacobi* iterative method defined by (31) does not always converge. Furthermore, the optimum *block extrapolated* SOR method is not an improvement compared to the optimum *block* SOR method (see [1], [11], and [5]).

Next we state two well-known theorems which in conjunction with (40) and (41) allow us to determine the convergence ranges and compute the optimal parameters in the case of EJ and SOR methods when the spectrum of the Jacobi matrix is purely imaginary. For their proofs, refer to [2]–[5], and [9], [12], [11], and [5], respectively.

THEOREM 3.3. *Let A be the coefficient matrix of a linear system in block partitioning form with square nonsingular diagonal blocks and J the corresponding Jacobi matrix. If all the eigenvalues of J^2 are nonpositive, then, for the convergence of the block EJ method, we have*

$$\rho(J_\omega) < 1 \quad \text{if } 0 < \omega < \frac{2}{\sqrt{1+\rho^2(J)}[\rho(J) + \sqrt{1+\rho^2(J)}]}, \tag{44}$$

$$\omega_{opt} = \frac{2}{1+\rho^2(J)} \quad \text{and} \quad \rho(J_{\omega_{opt}}) = \frac{\rho(J)}{\sqrt{1+\rho^2(J)}}. \tag{45}$$

THEOREM 3.4. *If, in addition to the assumptions of Theorem 3.3, A is block 2-cyclic consistently ordered, then, for the convergence and the optimal convergence of the block SOR method, we have the following conditions:*

$$\rho(\mathcal{L}_\omega) < 1 \quad \text{if } 0 < \omega < \frac{2}{1+\rho(J)}, \tag{46}$$

$$\omega_{opt} = \frac{2}{1+\sqrt{1+\rho^2(J)}} \quad \textit{and} \quad \rho(\mathcal{L}_{\omega_{opt}}) = 1 - \omega_{opt}. \tag{47}$$

A straightforward comparison of the optimal spectral radii in (45) and (47) leads to the following theorem.

THEOREM 3.5. *Under the assumptions of Theorems* 3.2, 3.3, *and* 3.4 *the optimal* SOR *method converges asymptotically faster than the optimal* EJ *method.*

For the efficiency of both the serial and parallel iterative solution of the collocation equations we reorder the system (23) following

(a) the *cyclic natural* ordering for the unknowns $U^i, i = 2, \dots, k$,

$$\mathcal{U}^i \equiv \left\{ \cdots \left\{ \left\{ \cdots \left\{ U^i_{j_1,\dots,j_{i-1},j_i,\dots,j_k} \right\}_{j_i=1}^{N_i-1} \cdots \right\}_{j_k=1}^{N_k-1} \right\}_{j_1=1}^{N_1-1} \cdots \right\}_{j_{i-1}=1}^{N_{i-1}-1} ; \tag{48}$$

(b) the ordering of (18) according to the ordering of $\mathcal{U}^1$; and

(c) the ordering of each block of auxiliary conditions (21) according to the ordering of the unknowns $\mathcal{U}^i$.

Assume that the matrices P_i are the permutation matrices that reorder the unknowns U^i from the *natural* ordering to the *cyclic natural* ordering (48), namely, $\mathcal{U}^i = P_i \mathbf{U}^i, i = 1, \dots, k$. In view of this transformation, the new form of (23) is

$$\begin{pmatrix} A_1 & A_2P_2^T & A_3P_3^T & \dots & A_kP_k^T \\ -P_2B_2 & P_2D_2P_2^T & & & \\ -P_3B_3 & & P_3D_3P_3^T & & \\ \vdots & & & \ddots & \\ -P_kB_k & & & & P_kD_kP_k^T \end{pmatrix} \begin{pmatrix} \mathbf{U}^1 \\ P_2\mathbf{U}^2 \\ P_3\mathbf{U}^3 \\ \vdots \\ P_k\mathbf{U}^k \end{pmatrix} = \begin{pmatrix} \mathbf{F}^1 \\ P_2\mathbf{F}^2 \\ P_3\mathbf{F}^3 \\ \vdots \\ P_k\mathbf{F}^k \end{pmatrix}. \tag{49}$$

The new structure of the collocation coefficient matrix for the second- and fourth-order scheme in two dimensions is given in Fig. 4.

THEOREM 3.6. *Let A and $\mathcal{A}$ be the coefficient matrices in* (23) *and* (49), *respectively, D and $\mathcal{D}$ their block diagonal parts, and J and $\mathcal{J}$ the associated block Jacobi matrices. We have that $\mathcal{A} = PAP^T$ and $\mathcal{J} = PJP^T$, where $P = (I, P_2, \dots, P_k)$, and therefore $\mathcal{A}$ and A as well as $\mathcal{J}$ and J are similar matrices.*

Proof. The relation $\mathcal{A} = PAP^T$ follows easily from the formulation of the method. For the relation $\mathcal{J} = PJP^T$, we have

$$\begin{aligned} \mathcal{J} &= I - \mathcal{D}^{-1}\mathcal{A}, \\ &= I - (\text{diag}(I, P_2D_2P_2^T, \dots, P_kD_kP_k^T))^{-1}(PAP^T), \\ &= I - (\text{diag}(I, P_2D_2^{-1}P_2^T, \dots, P_kD_k^{-1}P_k^T))(PAP^T), \\ &= I - P(\text{diag}(I, D_2^{-1}, \dots, D_k^{-1}))P^T(PAP^T), \\ &= I - PD^{-1}AP^T = P(I - D^{-1}A)P^T = PJP^T. \end{aligned}$$ □

In view of the previous theorem and because J is block 2-cyclic consistently ordered, the EJ and the SOR theory holds, and the optimal values of the various parameters of the block EJ and the block SOR methods associated with $\mathcal{A}$ are those obtained for the matrix A in Theorems 3.2–3.5.

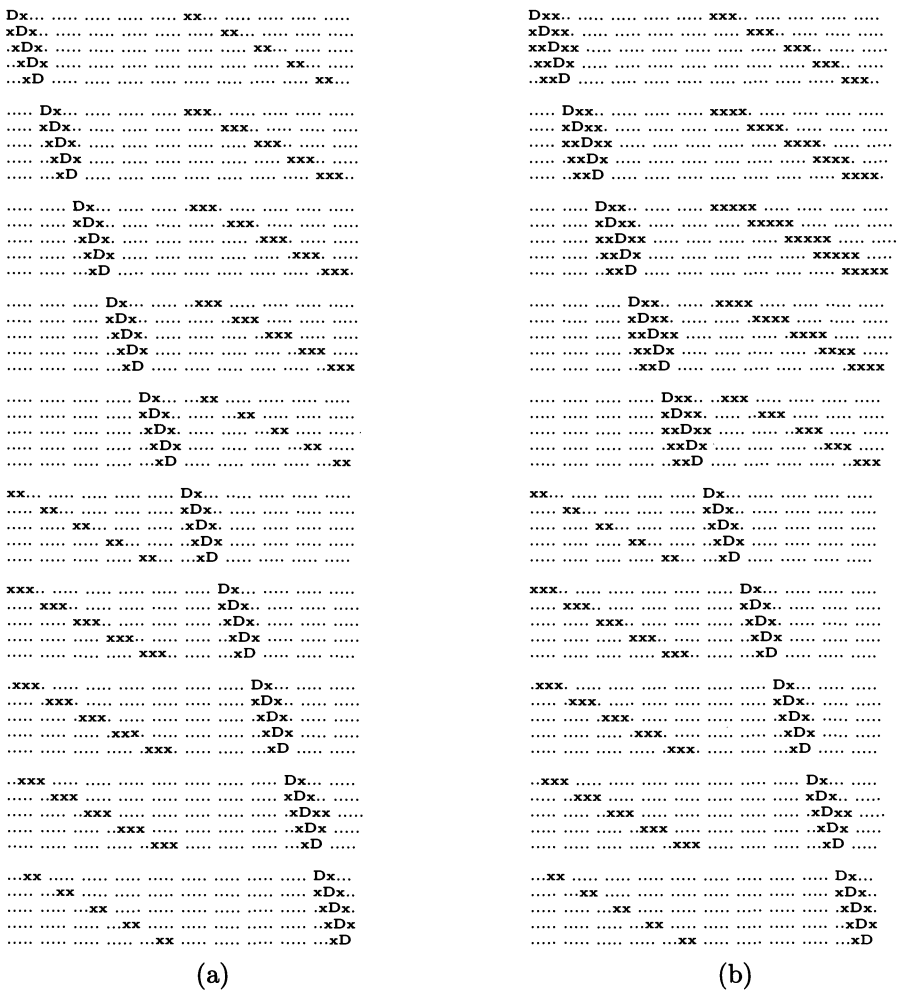

FIG. 4. *Structure of matrices from the* (a) *second-order and* (b) *fourth-order* LCSC *collocation methods for a two-dimensional problem. We have* $N_1 = N_2 = 6$ *with the notation* D = *diagonal nonzero element,* x = *off-diagonal nonzero element, and* . = *zero element.*

4. Numerical verification of convergence. In this section we present the results of some numerical experiments on the convergence properties of the LCSC method and the iterative solvers. These experiments verify the convergence properties of the LCSC discretization and the iterative solution methods of §3. They also indicate that these methods work equally well for more general problems than (1b), (2b) where our analysis does not apply. Specifically, we have applied the LCSC methods to approximate the known solution of the following PDE problems:

PDE A2: $D_x^2u + D_y^2u = f,$
PDE B2: $D_x^2u + 4D_y^2u - 10u = f,$
PDE C2: $D_x^2u + D_y^2u + 10e^{x+y}u = f,$
PDE A3: $D_x^2u + D_y^2u + D_z^2u = f,$
PDE B3: $D_x^2u + D_y^2u + 4D_z^2u - 10u = f,$
PDE C3: $D_x^2u + (x+z)D_y^2u + (4-x-z)D_z^2u + e^{x+y+z}u = f.$

All these problems are on the unit square or cube with homogeneous Dirichlet boundary conditions ($u = 0$), and f is such that the true solution is

$$u(x, y) = e^{x+y}(x^2 - x)(y^2 - y)$$

or

$$u(x, y, z) = e^{x+y+z}(x^2 - x)(y^2 - y)(z^2 - z).$$

The approximate solutions of the discretized problem are determined by the iterative methods presented and analyzed in §3. For the LCSC discretization, we estimate the maximum error ($||u - u_h||_\infty$) at the mesh points and compute an estimate of its order of convergence from the expression

$$(50) \qquad -\log\left(\frac{||(u - u_{h_1})||_\infty}{||(u - u_{h_2})||_\infty}\right) \Big/ \log\left(\frac{h_1}{h_2}\right),$$

where h_1, h_2 are the grid steps for the two different uniform partitions. All the computations were done on a SUN 4/110 in double-precision arithmetic. The linear systems from the LCSC discretization are solved by the iteration of §3, with termination criterion being that $||\mathbf{U}^{(s+1)} - \mathbf{U}^{(s)}||_\infty$ is within the interval $(0, 10^{-7})$. Tables 1 and 3 show the results for the six problems and the second-order LCSC method using an (NGRID by NGRID) or (NGRID by NGRID by NGRID) mesh for NGRID = 8, 16, 24, ... We see that the discretization error decreases regularly, and that the estimated order of convergence agrees well with the asymptotic result expected from Theorem 2.1. Similarly, Tables 2 and 4 show the results for the fourth-order LCSC discretization and, again, the estimated order of convergence agrees well with that expected from Theorem 2.1.

Tables 5 and 6 present the number of SOR iterations required to solve the discretized equations using a 10^{-7} stopping criterion for the second- and fourth-order LCSC methods. We see that the number of iterations increases a little faster than linearly in NGRID.

The number of iterations for the fourth-order case increases more rapidly as NGRID increases, apparently faster than linearly, but slower than quadratically. Of course, the fourth-order discretization is much more efficient as it achieves much higher accuracy. Restated, for PDE B2, we could use the fourth-order discretization with an 8×8 mesh and 132 iterations instead of the second-order discretization with a 24×24 mesh and 279 iterations. Both ways, we achieve an accuracy of about .006. It is important to note that the number of iterations does *not* increase going from two to three dimensions.

We also note in all these tables that the analytical results established for the Helmholtz problem are observed for the non-Helmholtz problems PDE C2 and PDE C3.

The nature of the convergence of the iterative methods is examined in more detail in Figures 5–7.

Figures 5–7 explore the accuracy of the theoretical predictions of the optimum relaxation factor ω_{opt} for three cases: second-order LCSC discretization in two dimensions (Fig. 5), fourth-order LCSC discretization in two dimensions (Fig. 6), and

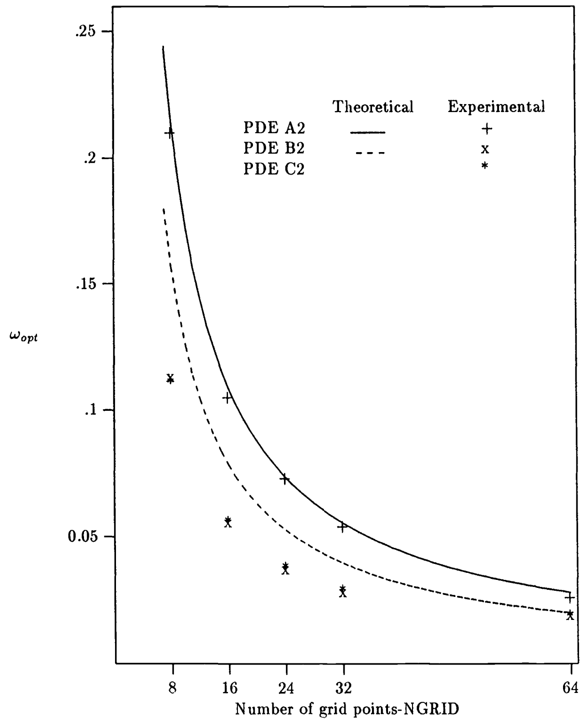

FIG. 5. *Graph of the ω_{opt} vs. the number of grid points for the second-order* LCSC *method applied to* PDE A2, PDE B2, *and* PDE C2.

second-order LCSC discretization in three dimensions (Fig. 7). The experimental values of ω_{opt} are determined by systematic search. In all cases we see that the theoretical optimum values are good estimates of the actual optimums. Furthermore, the theoretical ω_{opt} values for the Helmholtz problems are good estimates for the more general operator problems where our theory does not apply.

AN ALGORITHM FOR SYMMETRIC TRIDIAGONAL EIGENPROBLEMS: DIVIDE AND CONQUER WITH HOMOTOPY CONTINUATION[*]

KUIYUAN LI[†] AND TIEN-YIEN LI[‡]

Abstract. This paper presents a new algorithm for finding all the eigenvalues and corresponding eigenvectors of a symmetric tridiagonal matrix. The algorithm is based on the homotopy continuation approach coupled with the strategy of "divide and conquer." Evidenced by the numerical results, the algorithm given here provides a considerable advance over previous attempts to use the homotopy method for eigenvalue problems. Numerical comparisons of this algorithm with the methods in the widely used EISPACK library, as well as Cuppen's divide and conquer method, are presented. It appears that the algorithm is strongly competitive in terms of speed, accuracy, and orthogonality. The performance of the parallel version of this algorithm is also presented. The natural parallelism of the algorithm makes it an excellent candidate for a variety of advanced architectures.

Key words. eigenvalues, eigencurves, multiprocessors, homotopy method

AMS(MOS) subject classification. 65F15

1. Introduction.

In this paper, we propose a new algorithm, based on the continuation approach, for finding all the eigenvalues and eigenvectors of a symmetric tridiagonal matrix. Let A be an $n \times n$ real symmetric tridiagonal matrix of the form

$$A = \begin{pmatrix} \alpha_1 & \beta_2 & & & \\ \beta_2 & \alpha_2 & \beta_3 & & \\ & \ddots & \ddots & \ddots & \\ & & \beta_{n-1} & \alpha_{n-1} & \beta_n \\ & & & \beta_n & \alpha_n \end{pmatrix}. \tag{1.1}$$

In (1.1), if some $\beta_i = 0$, then $\mathbf{R^n}$ is clearly decomposed into two complementary subspaces invariant under A. Thus the eigenproblem is decomposed in an obvious way into two smaller subproblems. Therefore, we assume that each $\beta_i \neq 0$. That is, A is *unreduced.* Our algorithm uses the "divide and conquer" strategy. First, the matrix A is divided into two blocks by letting one of the β_i's equal to zero. Namely, we let

$$D = \begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix}, \tag{1.2}$$

* Received by the editors December 10, 1990; accepted for publication (in revised form) April 2, 1992.

where

$$D_1 = \begin{pmatrix} \alpha_1 & \beta_2 & & & \\ \beta_2 & \alpha_2 & \beta_3 & & \\ & \ddots & \ddots & \ddots & \\ & & \beta_{k-1} & \alpha_{k-1} & \beta_k \\ & & & \beta_k & \alpha_k \end{pmatrix}, \quad D_2 = \begin{pmatrix} \alpha_{k+1} & \beta_{k+2} & & & \\ \beta_{k+2} & \alpha_{k+2} & \beta_{k+3} & & \\ & \ddots & \ddots & \ddots & \\ & & \beta_{n-1} & \alpha_{n-1} & \beta_n \\ & & & \beta_n & \alpha_n \end{pmatrix}.$$

We then calculate the eigenvalues of unreduced matrices D_1 and D_2 by using the most efficient algorithm available. Unlike Cuppen's divide and conquer method [4], our algorithm conquers the matrix A by the homotopy $H : \mathbf{R^n} \times \mathbf{R} \times [\mathbf{0}, \mathbf{1}] \longrightarrow \mathbf{R^n} \times \mathbf{R}$, defined by

$$\begin{aligned} H(x, \lambda, t) &= (1-t)\begin{pmatrix} \lambda x - Dx \\ \dfrac{x^T x - 1}{2} \end{pmatrix} + t\begin{pmatrix} \lambda x - Ax \\ \dfrac{x^T x - 1}{2} \end{pmatrix} \\ &= \begin{pmatrix} \lambda x - [(1-t)D + tA]x \\ \dfrac{x^T x - 1}{2} \end{pmatrix} \\ &= \begin{pmatrix} \lambda x - A(t)x \\ \dfrac{x^T x - 1}{2} \end{pmatrix}, \end{aligned} \tag{1.3}$$

where $A(t) = (1-t)D + tA$. It can easily be seen that the solution set of $H(x, \lambda, t) = 0$ in (1.3) consists of disjoint smooth curves $(x(t),\ \lambda(t))$, each joining an eigenpair of D to one of A. We call each of these curves a *homotopy curve* or an *eigenpath* and its component $\lambda(t)$ an *eigenvalue path.* Thus, by following the eigenpaths emanating from the eigenpairs of D at $t = 0$, we can reach all the eigenpairs of A at $t = 1$.

Unlike curve-following strategies used in standard homotopy continuation methods, our algorithm mainly uses the homotopy continuation as a *backup* of Newton's method. Simple computation shows that Newton's method for the nonlinear problem of $n + 1$ equations

$$F(\lambda, x) = \begin{cases} \lambda x - Ax = 0, \\ \dfrac{x^T x - 1}{2} = 0 \end{cases} \tag{1.4}$$

in the $n + 1$ variables λ, $x_1, x_2, \ldots, x_n$ at $(\lambda^{(m)}, x^{(m)})$ is the inverse iteration of A on $x^{(m)}$ with shift $\lambda^{(m)}$, i.e.,

$$(A - \lambda^{(m)} I)y = x^{(m)}$$

and

$$\begin{cases} \lambda^{(m+1)} = \lambda^{(m)} + \dfrac{(x^{(m)})^T x^{(m)} + 1}{2(x^{(m)})^T y}, \\ x^{(m+1)} = (\lambda^{(m+1)} - \lambda^{(m)})y. \end{cases}$$

By making the initial matrix D close to A, the eigenpairs of D should be excellent starting points for applying Newton's method to the eigenproblem (1.4). Based on this observation, our algorithm solves the eigenvalues of the initial matrix D by using the most efficient method available first, and applying the inverse iteration with a random starting vector on (1.4), using each eigenvalue of D as a shift. This is essentially the first step of the usual curve-following scheme to follow the eigenpath $(x(t), \lambda(t))$ of the homotopy $H(x, \lambda, t) = 0$ in (1.3) with starting stepsize $h = 1$. After the first inverse iteration, we switch to Rayleigh quotient iteration (RQI), an inverse iteration with Rayleigh quotient as a shift, to speed up the convergence. We check the Sturm sequence at the convergent point and, if this procedure fails to provide the correct eigenpair, we cut the stepsize in half. That is, we repeat the process by applying the inverse iteration to (1.3) with $t = 0.5$ and then switch to RQI to return to the right eigenpath $(x(t), \lambda(t))$. Assuming that after i steps, the approximate value $(x(t_i), \lambda(t_i))$ is known, we always choose stepsize $h = 1 - t_i$ at $(x(t_i), \lambda(t_i))$. In this way, we follow the eigenpath from $t = 0$ to $t = 1$. A theoretical analysis of the eigenpath is given in §2, and the details of the algorithm are described in §3.

The search for fast, reliable methods for handling symmetric eigenproblems has produced a number of methods, most notably the QR algorithm, the bisection Sturm sequence method with inverse iteration [6], [7] and the divide and conquer method [4], [5], [15]. In §4.1 we present our numerical results, along with comparisons to results obtained with those methods. It appears that our algorithm is strongly competitive in terms of speed, accuracy, and orthogonality, and leads in speed in almost all cases.

Modern scientific computing is marked by the advent of vector and parallel computers and the search for algorithms that are, to a large extent, parallel in nature. A further advantage of our method is that, to a large degree, it is parallel in the sense that each eigenpath is followed independently of the others. It makes the parallel implementation of the homotopy method much simpler than the other methods. In §4.2, we show the performance of our parallel algorithm. The results suggest that our algorithm may be an excellent candidate for a variety of architectures.

The theoretical aspect of the continuation approach to the eigenvalue problems has been studied in [1]–[3] and [9]. A first attempt was made in [8] to make the method computationally efficient. Its parallel version appeared in [11]. Evidenced by the numerical results, our algorithms given here provide a considerable improvement over the algorithms in [8] and [11].

2. Preliminary analysis.

PROPOSITION 2.1. *Let $\lambda(t)$ be an eigenvalue path of the homotopy $H(x, \lambda, t) = 0$ in (1.3). Then, either $\lambda(t)$ is constant for all $t \in [0, 1]$ or strictly monotonic. (See Fig. 1.)*

Proof. For a symmetric tridiagonal matrix

$$M = \begin{pmatrix} a_1 & b_2 & & & \\ b_2 & a_2 & b_3 & & \\ & \ddots & \ddots & \ddots & \\ & & b_{n-1} & a_{n-1} & b_n \\ & & & b_n & a_n \end{pmatrix},$$

with $b_i \neq 0$, i =2, 3,..., n, let M_i be the $i \times i$ principle submatrix of M. Let

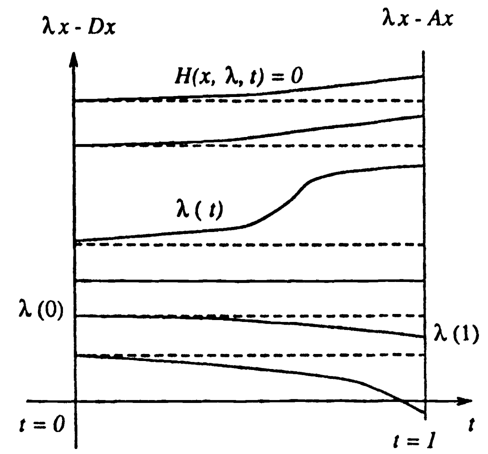

FIG. 1

$p_i(t) = \det(M_i - \lambda I)$. The well-known three-terms recurrence relation gives [13]

$$p_{i+1}(\lambda) = (a_{i+1} - \lambda)p_i(\lambda) - b_{i+1}^2 p_{i-1}(\lambda). \tag{2.1}$$

Applying (2.1) to

$$A(t) = (1-t)D + tA = \left(\begin{array}{cc|cc} D_1 & & & \\ & & t\beta_{k+1} & \\ \hline & t\beta_{k+1} & & \\ & & & D_2 \end{array}\right)$$

in our homotopy in (1.3), we can easily see that the variable t appears in $\det(A(t) - \lambda I)$ only in the second degree. Namely,

$$p(\lambda, t) \equiv \det(A(t) - \lambda I) = t^2 f_1(\lambda) + f_2(\lambda)$$

for certain polynomials $f_1(\lambda)$ and $f_2(\lambda)$. Thus, for any given λ_0, if $f_1(\lambda_0) \neq 0$, then $p(\lambda_0, t) = 0$ has two solutions

$$t = \pm\sqrt{-\frac{f_2(\lambda_0)}{f_1(\lambda_0)}}.$$

Thus, when $-f_2(\lambda(t_0))/f_2(\lambda(t_0)) > 0$, t is real and $p(\lambda_0, t) = 0$ can have at most one solution in [0,1]. It follows that the eigenvalue path $\lambda(t)$ of (1.3), a solution of $p(\lambda, t) = 0$ for each t in [0,1], is strictly monotonic. Otherwise, for certain values of λ_0, $p(\lambda_0, t) = 0$ will have more than one solution in [0,1]. (See Fig. 2.)

If an eigenvalue λ_0 of the initial matrix D satisfies $f_1(\lambda_0) = 0$, then $p(\lambda_0, 0) = \det(D - \lambda_0 I) = 0$ implies $f_2(\lambda_0) = 0$. Hence, $p(\lambda_0, t) = 0$ for all t in [0,1] and $\lambda(t) \equiv \lambda_0$ gives a constant eigenvalue path.

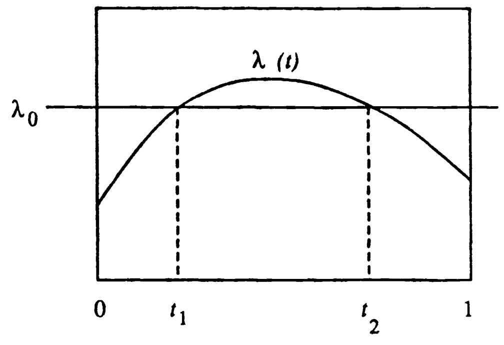

FIG. 2

Remark. It follows from the proof of the above proposition that if

$$\lambda_1(0) \leq \lambda_2(0) \leq \cdots \leq \lambda_n(0),$$

then

$$\lambda_{i-1}(0) \leq \lambda_i(t) \leq \lambda_{i+1}(t), \qquad 2 \leq i \leq n-1.$$

THEOREM 2.2 (HOFFMAN AND WIELANDT [16]). *Let M be an $n \times n$ symmetric matrix. Let $M' \equiv M + E$ where E is a symmetric perturbation of M. Denote the eigenvalues of M by $\{\xi_1 \leq \xi_2 \leq \cdots \leq \xi_n\}$, the eigenvalues of M' by $\{\xi_1' \leq \xi_2' \leq \cdots \leq \xi_n'\}$, and the eigenvalues of E by $\{\gamma_1 \leq \gamma_2 \leq \cdots \leq \gamma_n\}$, then*

$$\sum_{i=1}^{n} (\xi_i - \xi_i')^2 \leq \sum_{i=1}^{n} \gamma_i^2. \tag{2.2}$$

Applying this theorem to $M = A$ and $M' = A(t) = (1-t)D + tA = A + E$ with

$$E = \left(\begin{array}{c|c} O & (t-1)\beta_{k+1} \\ \hline (t-1)\beta_{k+1} & O \end{array} \right),$$

then (2.2) gives

$$\sum_{i=1}^{n} (\lambda_i - \lambda_i(t))^2 \leq 2(1-t)^2 \beta_{k+1}^2 \qquad \text{for all } t \text{ in } [0,1], \tag{2.3}$$

where λ_i and $\lambda_i(t)$ are the eigenvalues of A and $A(t)$, respectively.

From (2.3), together with the conclusion in Proposition 2.1 that each nonconstant $\lambda_i(t)$ is monotonic in t, we see that the smaller β_{k+1} is, the *flatter* the eigenvalue curves are, especially when n is very large. To make the eigencurves easy to follow, we intend to choose β_{k+1} as small as we can for k in a certain range, as described in §3.

3. Algorithms. The basic features of our algorithm to follow the eigenpath $(x(t), \lambda(t))$ are

(i) Initiating at $t = 0$,
(ii) Prediction,
(iii) Correction,
(iv) Checking,
(v) Detection of a cluster and space iteration,
(vi) Stepsize selection,
(vii) Terminating at $t = 1$.

In this section, we give a detailed description of these features.

(i) *Initiating at* $t = 0$. As mentioned in §2, we intend to choose k for which β_{k+1} is as small as possible. To make the sizes of the blocks D_1 and D_2 roughly the same, we limit the choice of k in the range $n/2 - \delta \le k \le n/2 + \delta$, where $\delta \approx n/20$ and find the smallest β_{k+1} by local sorting.

When the initial matrix D is decided, different from the homotopy algorithms in [8], [11] where all the eigenvalues and eigenvectors of D are calculated in order to start following the eigenpaths, our algorithm only calculates the eigenvalues of D_1 and D_2. These eigenvalues are obtained by using the most efficient method available. From our experience, for matrices of relatively small size, the QR algorithm is the fastest method for this purpose. Therefore, in the real implementation, we use the subroutine TQL1 in EISPACK [14] here. (Since the QL algorithm in TQL1 is highly serial, it is not very efficient with a modest number of processors on large problems. Thus, for parallel computing, if a modest number of processors are available, we use the multisection method. Otherwise, we still use TQL1.) At this stage, the precision of the eigenvalues of D_1 and D_2 is not crucial. Thus we only require that the accuracy stay within one-half or even one-third of the working precision. With this strategy, a considerable amount of computing time is reduced.

(ii) *Prediction.* Assume that after i steps the approximate value $(\tilde{x}(t_i), \tilde{\lambda}(t_i))$ on the eigenpath $(x(t), \lambda(t))$ at t_i is known and the next stepsize h is determined; that is, $t_{i+1} = t_i + h$. We want to find an approximate value $(\tilde{x}(t_{i+1}), \tilde{\lambda}(t_{i+1}))$ of $(x(t_{i+1}), \lambda(t_{i+1}))$ on the eigenpath at t_{i+1}. Note that $(\tilde{x}(t_{i+1}), \tilde{\lambda}(t_{i+1}))$ is an approximate eigenpair of $A(t_{i+1})$. Since $H(x(t), \lambda(t), t) = 0$, we have

$$A(t)x(t) = \lambda(t)x(t), \quad x^T(t)x(t) = 1.$$

Differentiating both equations with respect to t yields,

$$\begin{aligned} (A - D)x(t) + A(t)\dot{x}(t) &= \dot{\lambda}(t)x(t) + \lambda(t)\dot{x}(t), \\ x^T(t)\dot{x}(t) &= 0. \end{aligned} \tag{3.1}$$

For $t = t_i$, multiplying (3.1) on the left by $x^T(t_i)$ yields,

$$\dot{\lambda}(t_i) = x^T(t_i)(A - D)x(t_i) = 2\beta_{k+1}x_k(t_i)x_{k+1}(t_i), \tag{3.2}$$

where $x(t_i) = (x_1(t_i), \ldots, x_n(t_i))^T$. With $\dot{\lambda}(t_i)$ at hand, we use the Euler predictor to predict the eigenvalue at t_{i+1}, namely,

$$\lambda^0(t_{i+1}) = \lambda(t_i) + \dot{\lambda}(t_i)h.$$

It is easy to see that $\dot{\lambda}(0) = 0$ in (3.2), since $x(0)$ is either of form $(x_1(0), \ldots, x_k(0), 0, \ldots, 0)$ or $(0, \ldots, 0, x_{k+1}(0), \ldots, x_n(0))$. Consequently, $\lambda^0(t_1)$ always equals $\lambda(0)$. To predict the eigenvector, we use the inverse power method of $A(t_{i+1})$ on $x(t_i)$ with shift $\lambda^0(t_{i+1})$. That is, we first solve

$$(3.3) \qquad (A(t_{i+1}) - \lambda^0(t_{i+1})I)y^0(t_{i+1}) = x(t_i),$$

and let

$$x^0(t_{i+1}) = \frac{y^0(t_{i+1})}{||y^0(t_{i+1})||}.$$

At $t_i = 0$, since we skip the calculations of eigenvectors of D, $x(0)$ is not available. We chose a random vector to substitute for $x(0)$ in (3.3).

(iii) *Correction.* As a corrector, we use the standard RQI, starting with $x^0(t_{i+1})$. To be more precise, at $(x^{j-1}(t_{i+1}), \lambda^{j-1}(t_{i+1}))(j \geq 1)$ let

$$\lambda^j(t_{i+1}) = x^{j-1}(t_{i+1})^T A(t_{i+1}) x^{j-1}(t_{i+1}),$$

then solve

$$(A(t_{i+1}) - \lambda^j(t_{i+1})I)y^j(t_{i+1}) = x^{j-1}(t_{i+1}),$$

and let

$$x^j(t_{i+1}) = \frac{y^j(t_{i+1})}{||y^j(t_{i+1})||}.$$

We repeat the above process to within half of the working precision if single precision is used, and one-third of the working precision if double precision is used when $t_{i+1} < 1$, since precision in determining the curve is only of secondary interest. We polish $(x^j(t_{i+1}), \lambda^j(t_{i+1}))$ at the end of the path $(t_{i+1} = 1)$ by iterating the Rayleigh quotient to machine precision. The stop point $(x^j(t_{i+1}), \lambda^j(t_{i+1}))$ of RQI will be taken as an approximate eigenpair $(\tilde{x}(t_{i+1}), \tilde{\lambda}(t_{i+1}))$ of $A(t_{i+1})$. The cubic convergence rate of RQI makes the corrector highly efficient.

(iv) *Checking.* When $(\tilde{x}(t_{i+1}), \tilde{\lambda}(t_{i+1}))$ is taken as an approximate eigenpair of $A(t_{i+1})$, the Sturm sequences at $\tilde{\lambda}(t_{i+1}) \pm \epsilon\tilde{\lambda}(t_{i+1})$ are computed to check that, if we are trying to follow the curve of jth highest eigenvalues, we are still on that curve. Here, ϵ is chosen as half of the working precision if single precision is used, and one-third of the working precision if double precision is used. If the checking fails, we reduce the stepsize to $h/2$ and repeat the whole process once again, beginning with the eigenvalue prediction in (ii).

(v) *Detection of a cluster and subspace iteration.* At $t_i = 0$, when all the eigenvalues of D, $\lambda_1(0) \leq \lambda_2(0) \leq \cdots \leq \lambda_n(0)$, are available, we let $\delta = \max(10^{-5}, 10^{-2}(\lambda_n(0) - \lambda_1(0))/n)$ if double precision is used (or $\delta = \max(10^{-3}, 10^{-2}(\lambda_n(0) - \lambda_1(0))/n)$ if single precision is used). Set λ_i and λ_j in the same group if $|\lambda_i(0) - \lambda_j(0)| < \delta$. If the number of the eigenvalues in any group is bigger than 1, then a cluster is detected. At $t_i \neq 0$, or 1, when $(\tilde{x}(t_i), \tilde{\lambda}(t_i))$ is taken as an approximate eigenpair of $A(t_i)$, after the checking step in (iv) we compute the Sturm sequences at $\tilde{\lambda}(t_i) \pm \delta$ for the purpose of finding the number of eigenvalues of $A(t_i)$ in the interval $(\tilde{\lambda}(t_i) - \delta, \tilde{\lambda}(t_i) + \delta)$. When this number is bigger than 1, a cluster of eigenvalues of $A(t_i)$ is detected.

In those cases, the corresponding eigenvectors are ill conditioned and this ill-conditioning can cause the inefficiency of the algorithm. To remedy this problem, the inverse power method [13], [16] with $\tilde{\lambda}(t_i)$ as shifts is used to construct an approximation of the corresponding eigenspace S of dimension m (= the number of eigenvalues in the cluster) of $A(t_i)$. This approximate eigenspace S is used as an initial subspace of the subspace iterations at t_{i+1} when we approximate the eigenpairs of $A(t_{i+1})$.

(vi) *Stepsize selection.* In the first attempt, we always choose stepsize $h = 1-t_i$ at $t_i < 1$. If, after the prediction and correction steps, the checking step fails, we reduce the stepsize to $h/2$ as mentioned in (iv). This extremely liberal choice of stepsize can be justified because of the closeness of the matrix D to A as well as the effective checking algorithm. Indeed, since the initial matrix D is chosen to be so close to A, from our experience, the majority of the eigenpairs of A can be reached in one step, i.e., $h = 1$.

Very small stepsize can also cause inefficiency of the algorithm. Therefore, we impose a minimum γ on stepsize h. If $h < \gamma$, we simply give up following the eigenpath, and the corresponding eigenpair of A will be calculated at the end of the algorithm by the method of bisection with inverse iterations (see (vii)). We usually choose $\gamma \approx 0.25$.

(vii) *Terminating at* $t = 1$. At $t = 1$, when an approximate eigenvalue $\tilde{\lambda}(1)$ is reached, we compute the Sturm sequence at $\tilde{\lambda}(1) \pm \epsilon\tilde{\lambda}(1)$ with ϵ = machine precision to ensure the correct order. If the checking fails, we have jumped into a wrong eigenpath. More precisely, suppose that as we are following the ith eigenpair, the checking algorithm detects that we have reached the jth eigenpair instead. In this situation, we will save the jth eigenpair before the stepsize is cut. By saving the jth eigenpair, the computation of following the jth eigenpair is no longer needed.

As mentioned in (vi), we may give up following some eigenpaths to avoid adopting a stepsize that is too small. Without extra computation, we know exactly which eigenpairs are lost at $t = 1$. In order to find these eigenpairs, we first use the bisection to find the missing eigenvalues up to half the working precision and then use the inverse iteration and the RQI or subspace iteration (if there are some clusters) to find the eigenpairs.

4. Numerical results.

4.1. A serial comparison with the existing methods.

For symmetric tridiagonal matrices, the routine TQL2 in EISPACK implements explicit QL iteration to find all the eigenpairs. EISPACK also includes a Sturm sequence with inverse iteration method (BISECT+TINVIT), which is much faster than TQL2. However, it may fail to provide more accurate eigenvectors when the corresponding eigenvalues are very close. A new version by Jessup [7] (B/III) has considerably improved the reliability and the accuracy of the inverse iteration. The divide and conquer method for symmetric tridiagonal matrix was suggested by Cuppen [4] and was implemented, combined with a deflation and a robust root-finding technique, by Dongarra and Sorensen [5] (TREEQL) (see also [15]).

The homotopy continuation algorithm is in its preliminary stage, and much development and testing are necessary. But the numerical results on the examples we have looked at seem remarkable. The standard testing matrices are:

(1) The Toeplitz matrix [1,2,1].

(2) The random matrix with both diagonal and off-diagonal elements being uniformly distributed random numbers between 0 and 1.

(3) The Wilkinson matrix W_n^+, i.e., the matrix $[1, d_i, 1]$, where $d_i = \text{abs}((n + 1)/2 - i)$, $i = 1, 2, \ldots, n$ with n odd.

(4) The matrix $[1,\mu_i,1]$, where $\mu_i = i \times 10^{-6}$.

(5) The matrix T_2: same as matrix [2,8,2] except the first diagonal element $\alpha_1 = 4$.

(6) BW matrix: the matrix consists of two copies of Wilkinson matrices W_k^+ with even k along the diagonal and the off-diagonal elements at the position β_{k+1}, where the submatrices join equal to 10^{-6}.

We show the computational results comparing our homotopy continuation algorithm HOMO to those methods, TQL2, B/III, and TREEQL, mentioned above. The computations were done on a Sun SPARC station 1.

Tables 1, 2, and 3 show the comparisons in terms of speed, accuracy, and orthogonality, respectively. The homotopy method appears to be strongly competitive in every category and leads in speed by a considerable margin in comparison with all other methods in most of the cases.

Table 4 gives an analysis of our algorithm on those testing matrices. The fourth column on the table shows the total number of stepsize cuttings because of the curve jumping. The fifth column shows how many clusters occurred and the last column shows the largest dimension of the subspaces of the clusters.

As we mentioned in §§2 and 3, to form the initial matrix D, we usually choose the smallest off-diagonal entry β_{k+1}, for k in a certain range, of A, making it zero in D so that D is as close to A as possible. This strategy is crucial for the efficiency of our algorithm. To illustrate this, we perform our algorithm on Toeplitz matrices $[\beta, i, \beta]$. Table 5 shows that our algorithm is much faster when β is smaller.

We also execute our algorithm on 21 types of testing matrices in newly established LAPACK, a package that rewrites the widely used LINPACK and EISPACK libraries to make them efficient on vector and parallel computers. Tables 6 and 7 show the comparisons of HOMO with B/III (DSTEBZ+DSTEIN in LAPACK). Types 1–7 of those testing matrices are diagonal matrices, and Table 6 shows that both algorithms work very well. The matrices of types 9, 17, and 21 have a large cluster with dimensions around $4n/5$ where n is the order of the matrices. For these matrices, HOMO is not as fast as B/III. The matrices of types 10 and 18 have an even larger cluster with dimension around $n-2$. Although HOMO still works, time consumption does not compare with B/III. We have a similar result for matrices of type

$$\begin{pmatrix} 0 & \mu & & & \\ \mu & 0 & 1 & & \\ & 1 & \ddots & \ddots & \\ & & \ddots & 0 & 1 \\ & & & 1 & 0 \end{pmatrix},$$

where μ is so large that HOMO detects a cluster of size $n-2$. When $n = 250$, while B/III takes about 150 seconds to find all the eigenpairs, HOMO needs about 1000 seconds. Tables 6 and 7 show that HOMO leads in speed for the other types of testing matrices.

4.2. Numerical results in the parallel case. Scientific and engineering research has become increasingly dependent upon the development and implementation of efficient parallel algorithms on modern high-performance computers. The search for algorithms for advanced computers suitable for eigenvalue problems has produced several algorithms, such as divide and conquer (D&C)[5] and bisection/multisection (B/M)[12] for symmetric tridiagonal matrices.

The homotopy algorithm is, to a large degree, parallel since each eigenpath can be followed independently. This inherent nature of the homotopy method makes the parallel implementation much simpler than other methods.

In our parallel algorithm, after all the eigenvalues of D are computed and put in increasing order, we assign each processor to trace roughly n/p eigencurves, where n is the order of matrix A and p is the number of the processors being used. Let the first processor trace the first n/p smallest eigencurves from the smallest to the largest, and let the second processor trace the second n/p smallest eigencurves, and so on.

We present, in this section, the numerical results of the parallel implementation of our algorithm. All examples were executed on the BUTTERFLY GP 1000, a shared-memory multiprocessor machine.

The *speedup* is defined as

$$S_p = \frac{\text{execution time using one processor}}{\text{execution time using } p \text{ processors}}$$

and the *efficiency* is the ratio of the speedup over p.

TABLE 4
Analysis of the homotopy algorithm.

$[10^4,i,10^4]$	8.95	9.01	57	0		0	961

Table 8 shows the execution time and the speedup S_p, as well as the efficiency S_p/p of our algorithm HOMO on matrices [1,2,1] and T_2. The speedup of our method over TQL2, *TQL2/HOMO*, on [1,2,1] is also listed. Similar results on matrices $[1,\mu_i,1]$ and BW are shown in Table 9, and on random matrices, in Table 10. It appears that our homotopy algorithm is very efficient.

The eigenvalues of the initial matrices of our algorithm on the examples in Tables 8, 9, and 10 were computed by TQL1. Since TQL1 is highly serial, it is not very efficient with modest numbers of processors on large problems. Table 11 shows the results of HOMO on random matrices by computing the eigenvalues of the initial matrices with multisection method. From Tables 10 and 11, we can see that if only a small number of nodes are available, using TQL1 to compute the eigenvalues of the initial matrices is better than using the multisection method.

THE DUAL SCHUR COMPLEMENT METHOD WITH WELL-POSED LOCAL NEUMANN PROBLEMS: REGULARIZATION WITH A PERTURBED LAGRANGIAN FORMULATION*

CHARBEL FARHAT†, PO-SHU CHEN†, AND FRANCOIS-XAVIER ROUX‡

Abstract. The dual Schur complement (DSC) domain decomposition (DD) method introduced by Farhat and Roux is an efficient and practical algorithm for the parallel solution of self-adjoint elliptic partial differential equations. A given spatial domain is partitioned into *disconnected* subdomains where an incomplete solution for the primary field is first evaluated using a direct method. Next, intersubdomain field continuity is enforced via a combination of discrete, polynomial, and/or piece-wise polynomial Lagrange multipliers, applied at the subdomain interfaces. This leads to a smaller size symmetric *dual* problem where the unknowns are the "gluing" Lagrange multipliers, and which is best solved with a preconditioned conjugate gradient (PCG) algorithm. However, for time-independent elasticity problems, every floating subdomain is associated with a singular stiffness matrix, so that the dual interface operator is in general indefinite. Previously, we have dealt with this issue by filtering out at each iteration of the PCG algorithm the contributions of the local null spaces. We have shown that for a small number of subdomains, say less than 32, this approach is computationally feasible. Unfortunately, the filtering phase couples the subdomain computations, increases the numerical complexity of the overall solution algorithm, and limits its *parallel implementation scalability*, and therefore is inappropriate for a large number of subdomains. In this paper, we regularize the DSC method with a perturbed Lagrangian formulation which restores the positiveness of the dual interface operator, reduces the computational complexity of the overall methodology, and improves its parallel implementation scalability. This regularization procedure corresponds to a novel splitting method of the interface operator which entails well-posed local discrete Neumann problems, even in the presence of floating subdomains. Therefore, it can also be interesting for other DD algorithms such as those considered by Bjorstad and Widlund, Marini and Quarteroni, De Roeck and Le Tallec, and recently by Mandel.

1. Introduction.

Recently, Farhat and Roux have introduced a dual Schur complement (DSC) domain decomposition (DD) method for the efficient solution of static [1]–[4] and transient [5] finite element structural problems on parallel processors. The method was shown to outperform direct solvers on both serial and coarse-grained multiprocessors such as the CRAY Y-MP system, and to compare favorably with other domain decomposition algorithms on a 32-processor hypercube [2]. However, for a large number of subdomains and processors and for time-independent problems, the

DSC method may lose some of its efficiency because of its special treatment of floating subdomains. The objective of this paper is to present a regularization procedure that is based on a "balanced" perturbed Lagrangian formulation and that improves the overall computational efficiency of the DSC method. This regularization procedure corresponds to a novel splitting method of the interface operator which entails well-posed local discrete Neumann problems, even in the presence of floating subdomains. It provides a practical means to regularize several other DD algorithms using both Dirichlet and Neumann local solvers and which can suffer from the presence of floating subdomains [6]–[9].

The resulting regularized dual Schur complement (RDSC) method is a two-field alternative to the related three-field hybrid domain decomposition method introduced by Glowinski and Le Tallec [10]. Because of space limitations, we refer the reader to [2] and [3] for a background on the DSC method and for a discussion on the effect of floating subdomains on the algebraic properties and computational requirements of the resulting interface problem.

2. A regularized DSC method.

2.1. The two-subdomain problem. The variational form of the three-dimensional boundary-value problem to be solved is as follows. Given f and h, find the displacement function u that is a stationary point of the energy functional

$$J(v) = \tfrac{1}{2}a(v,v) - (v,f) - (v,h)_\Gamma \ , \tag{2.1}$$

where

$$a(v,w) = \int_\Omega v_{(i,j)} c_{ijkl} w_{(k,l)}\, d\Omega; \quad (v,f) = \int_\Omega v_i f_i \, d\Omega; \quad (v,h)_\Gamma = \int_{\Gamma_h} v_i h_i \, d\Gamma.$$

In the above, the indices i, j, k take the values 1–3, $v_{(i,j)} = (v_{i,j} + v_{j,i})/2$, $v_{i,j}$ denotes the partial derivative of the ith component of v with respect to the jth spatial variable, c_{ijkl} are the elastic coefficients, Ω denotes the volume of the elastostatic body, Γ its piecewise smooth boundary, and Γ_h is the piece of Γ where the tractions h_i are prescribed. If Ω is subdivided into two subdomains Ω_1 and Ω_2, solving the above elastostatic problem is equivalent to finding the displacement functions u_1 and u_2, which are stationary points of the perturbed Lagrangian functional

$$\begin{aligned} H(v_1, v_2, \lambda) &= J_1(v_1) + J_2(v_2) + \textstyle\int_{\Gamma_I} \lambda(v_1 - v_2)\, d\Gamma \\ &\quad -\tfrac{1}{2} \textstyle\int_{\overline{\Gamma}_I} \mathcal{L}(v_1|_{\overline{\Gamma}_I})^2 - \mathcal{L}(v_2|_{\overline{\Gamma}_I})^2 d\Gamma, \end{aligned} \tag{2.2}$$

where $\overline{\Gamma}_I \subset \Gamma_I$ is a subset of the interface boundary, and $\mathcal{L}$ is a linear operator that acts on the traces of v_1 and v_2 on $\overline{\Gamma}_I$. The proper selection of $\overline{\Gamma}_I$ and $\mathcal{L}$ is discussed later. In the remainder of this section, we assume that only Ω_2 is a floating subdomain, that is, a subdomain without sufficient Dirichlet boundary conditions to guarantee a nonsingular stiffness matrix. The finite element equations associated with (2.2) are given by

$$(\mathbf{K}_1 - \boldsymbol{\Delta})\mathbf{u}_1 = \mathbf{f}_1 - \mathbf{B}_1^T\boldsymbol{\lambda}; \quad (\mathbf{K}_2 + \boldsymbol{\Delta})\mathbf{u}_2 = \mathbf{f}_2 - \mathbf{B}_2^T\boldsymbol{\lambda}; \quad \mathbf{B}_1\mathbf{u}_1 + \mathbf{B}_2\mathbf{u}_2 = 0, \tag{2.3}$$

where $\mathbf{K}_1$ is positive definite, $\mathbf{K}_2$ is positive semidefinite, and $\boldsymbol{\Delta}$ is zero everywhere except on a subset of the interface boundary degrees of freedom. If discrete Lagrange multipliers are used, $\mathbf{B}_1$ and $\mathbf{B}_2$ are signed boolean matrices; otherwise, they are standard finite element matrices with full column rank. Clearly, $\mathbf{\Delta}$ serves the purpose of regularizing $\mathbf{K}_2$. However, $\mathbf{\Delta}$ is useful only if it is sparse and computationally inexpensive, and if it restores the positive definiteness nature of the stiffness in Ω_2, without destroying this algebraic property in Ω_1. In other words, the problem now is to find an economical matrix $\mathbf{\Delta}$—or its corresponding operator $\mathcal{L}$—which can stiffen Ω_2 enough so that $\mathbf{K}_2+\mathbf{\Delta}$ is symmetric positive definite, without softening Ω_1 enough so that $\mathbf{K}_1-\mathbf{\Delta}$ is singular or indefinite. We refer to this problem as a *balancing* problem, and we refer to the corresponding functional $H(v_1, v_2, \lambda)$ as a *balanced* perturbed Lagrangian.

Remark 2.1.1. Given that $\int_{\overline{\Gamma}_I} \mathcal{L}(v_1|_{\overline{\Gamma}_I})^2 - \mathcal{L}(v_2|_{\overline{\Gamma}_I})^2 \, d\Gamma$ depends only on the traces of v_1 and v_2 on the subset $\overline{\Gamma}_I$ of the interface boundary Γ_I where the Lagrange multipliers λ enforce the continuity equation $(v_1 - v_2)|_{\Gamma_I} = 0$, the solution $(\mathbf{u}_1, \mathbf{u}_2)$ of the system of equations (2.3) is independent of the operator $\mathcal{L}$ and its corresponding matrix $\mathbf{\Delta}$.

2.2. Balancing the subdomains. Here we consider the problem of constructing $\mathbf{\Delta}$ such that both $\mathbf{K}_1 - \mathbf{\Delta}$ and $\mathbf{K}_2 + \mathbf{\Delta}$ are symmetric positive definite. Homogeneous boundary conditions are assumed on part of Ω_1 (Fig. 1).

Let n_I and n_r denote, respectively, the total number of unknowns on Γ_I, and the exact number of rigid body modes associated with Ω_2, that is, the dimension of the null space of $\mathbf{K}_2$. These rigid body modes can be eliminated, for example, by fixing n_c degrees of freedom on Γ_I, where $n_r \leq n_c \leq n_I$. We define $\overline{\Gamma}_I$ as the spatial support of these n_c degrees of freedom (Fig. 1).

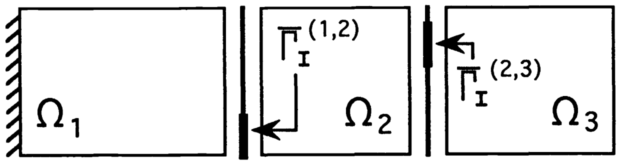

FIG. 1. $\overline{\Gamma}_I$ *for the two-subdomain problem with a local singularity.*

Next, we partition the subdomain stiffness matrices as

$$\mathbf{K}_1 = \begin{bmatrix} \mathbf{K}_1^{ff} & \mathbf{K}_1^{fc} \\ \mathbf{K}_1^{fc^T} & \mathbf{K}_1^{cc} \end{bmatrix} \quad \text{and} \quad \mathbf{K}_2 = \begin{bmatrix} \mathbf{K}_2^{ff} & \mathbf{K}_2^{fc} \\ \mathbf{K}_2^{fc^T} & \mathbf{K}_2^{cc} \end{bmatrix}, \tag{2.4}$$

where the superscript ^{c} denotes those degrees of freedom on $\overline{\Gamma}_I$, and the superscript ^{f} denotes all of the other degrees of freedom. The above partitioning is characterized by:

1. $\mathbf{K}_1^{ff}$ and $\mathbf{K}_2^{ff}$ are symmetric positive definite,
2. $\mathbf{K}_1^{fc}$ and $\mathbf{K}_2^{fc}$ have full column rank,
3. $\mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T} \mathbf{K}_1^{ff^{-1}} \mathbf{K}_1^{fc}$ is symmetric positive definite, and
4. $\mathbf{K}_2^{cc} - \mathbf{K}_2^{fc^T} \mathbf{K}_2^{ff^{-1}} \mathbf{K}_2^{fc}$ is symmetric positive semidefinite.

After all but the last n_c equations in each subdomain are reduced with a Gaussian elimination or a Cholesky decomposition, $\mathbf{K}_1$ and $\mathbf{K}_2$ are overwritten with

$$\mathbf{K}_1^R = \begin{bmatrix} \mathbf{K}_1^{ff^R} & \mathbf{K}_1^{fc^R} \\ \cdots & \mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T}\mathbf{K}_1^{ff^{-1}}\mathbf{K}_1^{fc} \end{bmatrix}, \qquad (2.5)$$
$$\mathbf{K}_2^R = \begin{bmatrix} \mathbf{K}_2^{ff^R} & \mathbf{K}_2^{fc^R} \\ \cdots & \mathbf{K}_2^{cc} - \mathbf{K}_2^{fc^T}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc} \end{bmatrix},$$

where the superscript ^{R} indicates a reduced matrix. Now, if $\mathbf{\Delta}$ is constructed as

$$\mathbf{\Delta} = \mathbf{\Delta}^* = \frac{1}{2}(\mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T}\mathbf{K}_1^{ff^{-1}}\mathbf{K}_1^{fc}), \qquad (2.6)$$

then it follows that

$$(\mathbf{K}_1 - \mathbf{\Delta}^*)^R = \begin{bmatrix} \mathbf{K}_1^{ff^R} & \mathbf{K}_1^{fc^R} \\ \cdots & \frac{1}{2}(\mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T}\mathbf{K}_1^{ff^{-1}}\mathbf{K}_1^{fc})^R \end{bmatrix}, \qquad (2.7)$$
$$(\mathbf{K}_2 + \mathbf{\Delta}^*)^R = \begin{bmatrix} \mathbf{K}_2^{ff^R} & \mathbf{K}_2^{fc^R} \\ \cdots & [\mathbf{K}_2^{cc} - \mathbf{K}_2^{fc^T}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc} + \frac{1}{2}(\mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T}\mathbf{K}_1^{ff^{-1}}\mathbf{K}_1^{fc})]^R \end{bmatrix},$$

which clearly demonstrates that both $\mathbf{K}_1 - \mathbf{\Delta}^*$ and $\mathbf{K}_2 + \mathbf{\Delta}^*$ are symmetric positive definite matrices.

The extreme values of n_c correspond to two extreme regularization strategies. For $n_c = n_I$, the local problems are better conditioned than for $n_c = n_r$, but a lot of fill-in may be introduced during the factorization of $\mathbf{K}_2 + \mathbf{\Delta}^*$. On the other hand, for $n_c = n_r$, the local problems are not as well conditioned as for $n_c = n_I$, but $\mathbf{K}_2 + \mathbf{\Delta}^*$ and $\mathbf{K}_2$ generally have the same sparsity pattern, and therefore the latter regularization strategy is cheaper to implement. The case $n_r \leq n_c \leq n_I$ corresponds to a compromise between the two extreme options. In the remainder of this paper, we consider only the case where $n_c = n_r$, and therefore we have

$$\mathbf{K}_2^{cc} - \mathbf{K}_2^{fc^T}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc} = 0. \qquad (2.8)$$

2.3. The multiple subdomain problem. For the sake of clarity, we first consider a strip-wise decomposed three-subdomain problem where Ω_1 is clamped at one end, and Ω_2 and Ω_3 are floating subdomains (Fig. 2). $\overline{\Gamma}_I^{(1,2)}$ is defined as the spatial support of $n_r^{(1,2)}$ degrees of freedom on the interface between Ω_1 and Ω_2 that must be constrained in order to remove the rigid body modes in Ω_2. Similarly, $\overline{\Gamma}_I^{(2,3)}$ is defined as the spatial support of $n_r^{(2,3)}$ degrees of freedom on the interface between Ω_2 and Ω_3 which must be constrained in order to eliminate the rigid body modes in Ω_3, *after* Ω_2 has been regularized. For subdomain Ω_2, we refer to the degrees of freedom on $\overline{\Gamma}_I^{(1,2)}$ as the *receiving* degrees of freedom, and to those on $\overline{\Gamma}_I^{(2,3)}$ as the *emitting* degrees of freedom.

We partition the subdomain stiffness matrices as

$$\mathbf{K}_1 = \begin{bmatrix} \mathbf{K}_1^{ff} & \mathbf{K}_1^{fc} \\ \mathbf{K}_1^{fc^T} & \mathbf{K}_1^{cc} \end{bmatrix}; \mathbf{K}_2 = \begin{bmatrix} \mathbf{K}_2^{ff} & \mathbf{K}_2^{fc^r} & \mathbf{K}_2^{fc^e} \\ \mathbf{K}_2^{fc^{rT}} & \mathbf{K}_2^{c^rc^r} & \mathbf{K}_2^{c^rc^e} \\ \mathbf{K}_2^{fc^{eT}} & \mathbf{K}_2^{c^rc^{eT}} & \mathbf{K}_2^{c^ec^e} \end{bmatrix}; \mathbf{K}_3 = \begin{bmatrix} \mathbf{K}_3^{ff} & \mathbf{K}_3^{fc} \\ \mathbf{K}_3^{fc^T} & \mathbf{K}_3^{cc} \end{bmatrix}, \qquad (2.9)$$

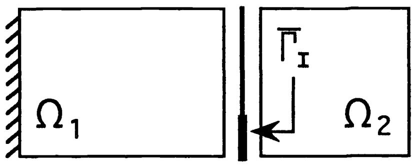

FIG. 2. *The strip-wise decomposed three-subdomain problem with local singularities.*

where the superscripts $^{c^r}$ and $^{c^e}$ indicate the receiving and emitting degrees of freedom in Ω_2, respectively. After all but the last $n_r^{(1,2)}$ equations in Ω_1 and Ω_2, and all but the last $n_r^{(2,3)}$ equations in Ω_3 are reduced, the subdomain stiffness matrices are overwritten with

(2.10)
$$\mathbf{K}_1^R = \begin{bmatrix} \mathbf{K}_1^{ff^R} & \mathbf{K}_1^{fc^R} \\ \cdots & \mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T}\mathbf{K}_1^{ff^{-1}}\mathbf{K}_1^{fc} \end{bmatrix}, \qquad \mathbf{K}_3 = \begin{bmatrix} \mathbf{K}_3^{ff^R} & \mathbf{K}_3^{fc^R} \\ \cdots & \mathbf{O} \end{bmatrix}$$

and

$$\mathbf{K}_2^R = \begin{bmatrix} \mathbf{K}_2^{ff^R} & \mathbf{K}_2^{fc^{r}R} & \mathbf{K}_2^{fc^{e}R} \\ \cdots & \mathbf{K}_2^{c^rc^r} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^r} & \mathbf{K}_2^{c^rc^e} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e} \\ \cdots & [\mathbf{K}_2^{c^rc^e} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e}]^T & \mathbf{K}_2^{c^ec^e} - \mathbf{K}_2^{fc^{eT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e} \end{bmatrix}.$$

First, Ω_2 is regularized with the $n_r^{(1,2)} \times n_r^{(1,2)}$ matrix

$$\mathbf{\Delta}^{(1,2)} = \frac{1}{2}(\mathbf{K}_1^{cc} - \mathbf{K}_1^{fc^T}\mathbf{K}_1^{ff^{-1}}\mathbf{K}_1^{fc}),$$

after which the factored stiffnesses in Ω_1 and Ω_2 become

$$(\mathbf{K}_1 - \mathbf{\Delta}^{(1,2)})^R = \begin{bmatrix} \mathbf{K}_1^{ff^R} & \mathbf{K}_1^{fc^R} \\ \cdots & \mathbf{\Delta}^{(1,2)^R} \end{bmatrix} \tag{2.11}$$

and

(2.12)
$$(\mathbf{K}_2 + \mathbf{\Delta}^{(1,2)})^R =$$
$$\begin{bmatrix} \mathbf{K}_2^{ff^R} & \mathbf{K}_2^{fc^{r}R} & \mathbf{K}_2^{fc^{e}R} \\ \cdots & [\mathbf{K}_2^{c^rc^r} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^r} + \mathbf{\Delta}^{(1,2)}]^R & [\mathbf{K}_2^{c^rc^e} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e}]^R \\ \cdots & \cdots & \mathbf{T}_2 \end{bmatrix},$$

where

$$\mathbf{T}_2 = \mathbf{K}_2^{c^ec^e} - \mathbf{K}_2^{fc^{eT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e} - [\mathbf{K}_2^{c^rc^e} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e}]^T$$
$$[\mathbf{K}_2^{c^rc^r} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^r} + \mathbf{\Delta}^{(1,2)}]^{-1}[\mathbf{K}_2^{c^rc^e} - \mathbf{K}_2^{fc^{rT}}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e}].$$

Next, Ω_3 is regularized with the $n_r^{(2,3)} \times n_r^{(2,3)}$ matrix $\mathbf{\Delta}^{(2,3)} = \frac{1}{2}\mathbf{T}_2$ and finally the factored stiffnesses in Ω_2 and Ω_3 become

$$\text{(2.13)} \quad (\mathbf{K}_2 - \mathbf{\Delta}^{(2,3)})^R =$$

$$\begin{bmatrix} \mathbf{K}_2^{ff^R} & \mathbf{K}_2^{fc^{r}R} & \mathbf{K}_2^{fc^{e}R} \\ \cdots & [\mathbf{K}_2^{c^r c^r} - \mathbf{K}_2^{fc^{r}T}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^r} + \mathbf{\Delta}^{(1,2)}]^R & [\mathbf{K}_2^{c^r c^e} - \mathbf{K}_2^{fc^{r}T}\mathbf{K}_2^{ff^{-1}}\mathbf{K}_2^{fc^e}]^R \\ \cdots & \cdots & \mathbf{\Delta}^{(2,3)^R} \end{bmatrix}$$

and

$$\text{(2.14)} \qquad (\mathbf{K}_3 + \mathbf{\Delta}^{(2,3)})^R = \begin{bmatrix} \mathbf{K}_3^{ff^R} & \mathbf{K}_3^{fc^R} \\ \cdots & \mathbf{\Delta}^{(2,3)^R} \end{bmatrix}.$$

For arbitrary mesh decompositions, the crucial point is to detect for a given subdomain Ω_s and a neighboring Ω_q, whether $\overline{\Gamma}_I^{(s,q)}$ is a "receiving" or "emitting" subset of Γ_I. If V_s denote the number of neighboring subdomains to Ω_s, the overall regularization algorithm can be implemented as follows:

Step 1. For every subdomain Ω_s, reduce all but the last $n_r^{(s)}$ equations of the corresponding stiffness matrix $\mathbf{K}_s$. (Note that $n_r^{(s)} \leq 3 \times V_s$ in two-dimensional problems, and $n_r^{(s)} \leq 6 \times V_s$ in three-dimensional ones.)

Step 2. Regularization proceeds from the nonfloating subdomains towards the floating ones. Floating subdomains which contain both "receiving" and "emitting" interface subsets are regularized first, and the "receiving" degrees of freedom are treated before the "emitting" ones.

Clearly Step 1 is a parallel step but Step 2 is a sequential one. However, for most large-scale problems, the CPU time corresponding to Step 2 is an extremely small fraction of the CPU time corresponding to Step 1, as the first step may involve millions of floating-point operations while the second one involves at most a few hundred. Interprocessor communication is required only in Step 2 and is limited to neighboring processors.

3. The regularized interface problem. If the floating subdomains are not regularized, the interface problem associated with (2.3) can be written in the case of N_s arbitrary subdomains as [1]

$$\text{(3.1)} \qquad \begin{bmatrix} \sum_{s=1}^{s=N_s} \mathbf{B}_s\mathbf{K}_s^*\mathbf{B}_s^T & -\mathbf{G}_I \\ -\mathbf{G}_I{}^T & \mathbf{O} \end{bmatrix} \begin{bmatrix} \boldsymbol{\lambda} \\ \boldsymbol{\alpha} \end{bmatrix} = \begin{bmatrix} \mathbf{d} \\ -\mathbf{e} \end{bmatrix}, \quad \text{where}$$
$$\mathbf{K}_s^* = \mathbf{K}_s^{-1} \text{ if } \Omega_s \text{ is not a floating subdomain,}$$
$$\mathbf{K}_s^* = \mathbf{K}_s^{+} \text{ if } \Omega_s \text{ is a floating subdomain,}$$

where $\mathbf{K}_s^+$ is a generalized inverse of $\mathbf{K}_s$, $\mathbf{G}_I$ is a full column rank matrix that stores the traces on the interface boundary of the null spaces corresponding to the floating subdomains, and $\boldsymbol{\alpha}$ stores the contributions of these null spaces to the local solutions. The above interface problem (3.1) is clearly indefinite and its solution requires special handling [1]–[3]. On the other hand, the regularized interface problem associated with (2.3) can be written for N_s arbitrary subdomains as

$$\left[\sum_{s=1}^{s=N_s} \mathbf{B}_s(\mathbf{K}_s + \delta_s\boldsymbol{\Delta}_s)^{-1}\mathbf{B}_s^T\right]\boldsymbol{\lambda} = \sum_{s=1}^{s=N_s} \mathbf{B}_s(\mathbf{K}_s + \delta_s\boldsymbol{\Delta}_s)^{-1}\mathbf{f}_s, \tag{3.2}$$

where δ_s is $+1$, -1, or 0 if Ω_s is a receiving, sending, or nonfloating subdomain, respectively. Clearly, the above regularized system (3.2) is symmetric positive definite. The PCG algorithm can be applied to the solution of (3.2) at little additional cost and using only subdomain-by-subdomain scalable and intrinsically parallel computations. As in the case of nonfloating subdomains, the above interface problem is preconditioned with $\mathbf{P}$ derived in [1] as

$$\mathbf{P}^{-1} = \sum_{s=1}^{s=N_s} \mathbf{B}_s\mathbf{K}_s\mathbf{B}_s^T. \tag{3.3}$$

4. Performance improvement. Here, we consider the static analysis of the cabin of a launch vehicle subjected to external aerodynamic loading and internal pressurization (Fig. 3). All computations are performed on an iPSC/860 Touchstone machine. The structure is discretized with triangular shell elements. Several meshes of different sizes are constructed, each corresponding to a different number of processors and therefore to a different total memory size. In order to highlight the improvement in performance induced by the regularization approach described in this paper, both the "filtered" DSC method [1] and the RDSC method are applied to the solution of the same problem. Also, the Jacobi preconditioned (diagonal scaling) conjugate gradient (JPCG) algorithm is used as a reference for CPU timings.

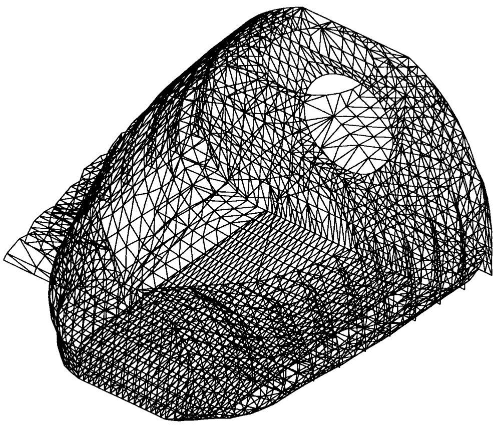

FIG. 3. *Finite element discretization of the cabin.*

All measured performance results are summarized in Table 1, where NP, NDOF, and T_p denote, respectively, the number of processors, the number of degrees of freedom, and the solution parallel time measured in seconds. The number of iterations is indicated in parentheses. For all solution algorithms, convergence is established by requiring that the normalized global residual be less than 10^{-3}:

$$\frac{||\mathbf{Ku} - \mathbf{f}||_2}{||\mathbf{f}||_2} \leq 10^{-3}. \tag{4.1}$$

TABLE 1
Performance results—iPSC/860.

NP	NDOF	T_p (JPCG)	T_p (DSC)	T_p (RDSC)
4	4,024	46 s. (700 it.)	23 s. (34 it.)	22 s. (38 it.)
16	16,456	110 s. (2308 it.)	54 s. (66 it.)	49 s. (62 it.)
32	31,928	168 s. (3980 it.)	79 s. (89 it.)	62 s. (92 it.)
64	59,064	295 s. (6127 it.)	189 s. (142 it.)	121 s. (144 it.)

The performance results reported above clearly indicate that

1. the regularization process does not seem to negatively affect the performance of the solution of the interface problem, since the DSC and RDSC method appear to converge after an almost identical number of iterations,
2. as expected, the performance improvement due to regularization is most important for an increasing number of processors, and
3. both DSC methods are shown to outperform the JPCG algorithm by a factor of three.

A SUPERNODAL CHOLESKY FACTORIZATION ALGORITHM FOR SHARED-MEMORY MULTIPROCESSORS*

ESMOND NG† AND BARRY W. PEYTON†

Abstract. This paper presents a parallel sparse Cholesky factorization algorithm for shared-memory MIMD multiprocessors. The algorithm is particularly well suited for vector supercomputers with multiple processors, such as the Cray Y-MP. The new algorithm is a straightforward parallelization of the left-looking supernodal sparse Cholesky factorization algorithm. Like its sequential predecessor, it improves performance by reducing indirect addressing and memory traffic. Experimental results on a Cray Y-MP demonstrate the effectiveness of the new algorithm. On eight processors of a Cray Y-MP, the new routine performs the factorization at rates exceeding one Gflop for several test problems from the Harwell–Boeing sparse matrix collection.

Key words. parallel algorithms, sparse linear systems, Cholesky factorization, supernodes

1. Introduction.

In this paper, we present a simple algorithm for computing a sparse Cholesky factorization on a shared-memory multiprocessor system. While our focus is on powerful multiprocessor vector supercomputers, our approach should perform well on any shared-memory multiprocessor with a modest number of processors and a bus that provides adequate bandwidth. The key features of our algorithm can be summarized as follows.

- It is both column oriented and left looking, like the algorithms used in several sparse matrix packages (e.g., see [11]).
- It uses supernodes to reduce both memory traffic and indirect addressing, as described in [4].
- The techniques used to implement the algorithm on a shared-memory multiprocessor are precisely those used in [10] to implement the left-looking algorithm in [11] on this class of machines.

Our primary contribution is to incorporate into one algorithm the supernodal techniques introduced in [4] and the parallel implementation techniques introduced in [10], and further to demonstrate the effectiveness of this simple approach on an important class of machines. Since the ideas upon which the algorithm is based are simple and well known, our discussion of previous work and the presentation of the new algorithm will be brief and, for the most part, informal. The reader can find most of the necessary details in [4], [10], and [11].

This note is organized as follows. Section 2 briefly discusses some background material. Section 3 provides a complete description of our algorithm. The timing results reported in §4 demonstrate the effectiveness of this approach on a Cray Y-MP with eight processors. Finally, §5 contains a few concluding remarks.

2. Background.

Let A be a symmetric positive definite matrix. The Cholesky factor of A, denoted by L, is a lower triangular matrix whose main diagonal is positive and for

†Mathematical Sciences Section, Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, Tennessee 37831-6367.

which $A = LL^T$. When A is sparse, fill occurs during the factorization; that is, some of the zero elements in A will become nonzero elements in L. In order to reduce time and storage requirements, only the nonzero positions of L are stored and operated on during *sparse* Cholesky factorization. Techniques for accomplishing this task and for reducing fill have been studied extensively (see [11] for details). In this paper we restrict our attention to the numerical factorization phase. We assume that the preprocessing steps, such as reordering to reduce fill and symbolic factorization to set up the compact data structure for L, have been performed. Details on the preprocessing can also be found in [11].

Column-oriented, left-looking, sparse Cholesky. The standard column-oriented, left-looking, sparse Cholesky algorithm is widely used in many sparse matrix packages, such as SPARSPAK [5]. When column $L_{*,j}$ is to be computed, the algorithm modifies column $A_{*,j}$ with multiples of previous columns of L, namely those columns $L_{*,k}$ for which $1 \leq k \leq j-1$ and $L_{j,k} \neq 0$. We shall let *cmod*(j, k) denote the operation of updating column $A_{*,j}$ with a multiple of the appropriate entries of $L_{*,k}$. The compute-intensive kernel used by the algorithm performs a single *cmod*(j, k) operation. A detailed description of this algorithm, along with a computer code that implements it, can be found in [11].

Supernodal sparse Cholesky. For many realistic problems, especially those from structural analysis applications, the fill generated during the factorization creates groups of contiguous columns that share the "same" sparsity structure. A group of such columns is referred to as a *supernode*. The reader should consult [12] and [16] for a detailed description of various *supernode partitions*. The first reference also presents an efficient algorithm for generating a supernode partition.

Recently, supernodes have been used to organize sparse numerical factorization algorithms around matrix-vector or matrix-matrix operations that reduce memory traffic, thereby making more efficient use of vector registers [3], [4] or cache [1], [17]. The role of supernodes in improving both left- and right-looking sparse Cholesky factorization algorithms is well documented [1], [3], [4], [8], [17], [19], with the references [4] and [17] providing the basis for the work in this note.

Let $\boldsymbol{K} = \{p, p+1, \ldots, p+q\}$ denote a supernode in L. Because of the sparsity pattern shared by all columns in $\boldsymbol{K}$, any column $A_{*,j}$ $(j > p+q)$ will be modified by either *all* columns of $\boldsymbol{K}$ or *no* column of $\boldsymbol{K}$. Consequently, a supernodal Cholesky algorithm is expressed in terms of the operation *cmod*$(j, \boldsymbol{K})$ $(j \notin \boldsymbol{K})$, which modifies column j with a multiple of each column in $\boldsymbol{K}$, and also the operation *cmod*$(j, \boldsymbol{J})$ $(j \in \boldsymbol{J})$, which modifies column j with a multiple of each column $k \in \boldsymbol{J}$ for which $k < j$. The *cmod*$(j, \boldsymbol{K})$ update, where $j \notin \boldsymbol{K}$, first uses a *dense matrix-vector multiplication* to accumulate the column modifications in a small work vector, after which the accumulated column update is applied to the target column $L_{*,j}$ using a single column operation that requires indirect addressing. In practice, this often greatly reduces the number of operations that require indirect addressing. Execution of the *cmod*$(j, \boldsymbol{J})$ update, where $j \in \boldsymbol{J}$, is even easier; the result of the matrix-vector multiplication is accumulated directly into factor storage for the target column $L_{*,j}$ and thus requires no work storage or indirect addressing. For both *cmod*$(j, \boldsymbol{K})$ and *cmod*$(j, \boldsymbol{J})$, unrolling the outer loop of the matrix-vector multiplication significantly reduces memory traffic, thereby improving the utilization of pipelined arithmetic units, especially on vector supercomputers. The interested reader should consult [4] and [17] for details.

Automatic parallelization of the supernodal algorithm. One approach to implementing sparse supernodal Cholesky factorization on a multiprocessor vector supercomputer has been described in [19]. The basic idea is to partition the work in *cmod*$(j, \boldsymbol{K})$ and *cmod*$(j, \boldsymbol{J})$ evenly among the available processors using the automatic parallelization capabilities of the target machine. This approach is similar to that employed in the LAPACK project [2], where, in the interest of software portability and reliability, use of multiple processors occurs *strictly within* each call to some compute-intensive variant of a matrix-matrix multiplication (BLAS3) or matrix-vector multiplication (BLAS2) kernel subroutine. Hence each call to the kernel involves a fork-and-join operation. For large dense matrices, where the vectors are quite long and each call to the kernel routine typically involves a substantial amount of work, this approach is quite effective [6]. For sparse matrices, however, short vectors and a limited amount of work within a typical call to the kernel routine make it quite difficult to implement this approach in an effective manner. As shall be shown in §4, the performance of the code in [19] apparently suffers from these defects.

Hand parallelization of the "nodal" algorithm. George, Heath, Liu, and Ng [10] introduced a parallel sparse Cholesky algorithm for shared-memory multiprocessors. Their algorithm is a straightforward parallel implementation of the sequential column-based, left-looking, sparse Cholesky factorization algorithm from [11]. The techniques we use to parallelize the supernodal factorization algorithm are taken directly from [10].

The task of computing column $L_{*,j}$ is referred to as a *column task* in the computation and is denoted by $Tcol(j)$. More precisely,

$$Tcol(j) := \{cmod(j,k) \mid k < j \text{ and } L_{j,k} \neq 0\} \cup \{cdiv(j)\},$$

where $cdiv(j)$ is the column scaling required to complete the computation of $L_{*,j}$. The parallel algorithm maintains a pool of column tasks, and the assignment of column tasks to processors is dynamic: when a processor completes one column task, it immediately seeks another column task from the pool. This approach is particularly appropriate for a shared-memory multiprocessor system with a fast bus, and, as might be expected, it typically achieves good load balance.

Clearly each task $Tcol(j)$ needs access to the set of column indices that constitute the sparsity pattern of row $L_{j,*}$. Because the computation and its data structures are both column oriented, special techniques are needed to generate these row-oriented sets in all the left-looking algorithms. The details of how to use a collection of linked lists to compute the "row structure" sets as the algorithm proceeds are well known and can be found in [11]. These linked lists are implemented with a single n-vector. To maintain the integrity of this dynamic data structure, it is modified in critical sections of the code, which are implemented by means of standard synchronizing primitives, which we shall call `lock` and `unlock`.

Finally, the column tasks $Tcol(j)$ are placed in the column-task queue in an order that exploits high-level parallelism in the computation. It is well known that the elimination tree associated with L fully describes the data dependencies in the computation [14]. We refer the reader to [15] for details on the many uses of elimination trees in sparse matrix computation, and to [14] for details on how the elimination tree reveals various levels of parallelism available in the factorization. Two columns are independent of one another if and only if the corresponding nodes in the elimination tree are not an ancestor-descendent pair in the tree. Consequently, an ordering obtained by a breadth-first, bottom-up traversal of the postordered elimination tree is ideal for preserving as much independence as possible among the columns currently being computed at any point in the algorithm.

3. Detailed algorithm.

In this section we give the details of an algorithm based on the ideas discussed in §2. The following notation and conventions are used in the algorithm, which is shown in Fig. 1.

```
Global initialization:
    $\mathcal{Q} \leftarrow \{Tcol(1), Tcol(2), \ldots, Tcol(n)\}$
    for $j = 1$ to $n$ do
        $\mathcal{S}_j \leftarrow \emptyset$
    end for

Work performed by each processor:
    while $\mathcal{Q} \neq \emptyset$ do
        pop $Tcol(j)$ from $\mathcal{Q}$ (critical section)
        let $\boldsymbol{J}$ be the supernode containing column $j$
        while column $j$ requires further cmod's from some $\boldsymbol{K} < \boldsymbol{J}$ do
            if $\mathcal{S}_j = \emptyset$ then
                wait until $\mathcal{S}_j \neq \emptyset$
            end if
            lock
            remove $\boldsymbol{K}$ from $\mathcal{S}_j$
            $q \leftarrow next(j, \boldsymbol{K})$
            if $q \leq n$ then
                $\mathcal{S}_q \leftarrow \mathcal{S}_q \cup \{\boldsymbol{K}\}$
            end if
            unlock
            $cmod(j, \boldsymbol{K})$
        end while
        $cmod(j, \boldsymbol{J})$
        $cdiv(j)$
        if $j$ is the last column of supernode $\boldsymbol{J}$ then
            $q \leftarrow next(\boldsymbol{J}, \boldsymbol{J})$
            if $q \leq n$ then
                lock
                $\mathcal{S}_q \leftarrow \mathcal{S}_q \cup \{\boldsymbol{J}\}$
                unlock
            end if
        end if
    end while
```

FIG. 1. *A parallel supernodal Cholesky factorization algorithm for shared-memory multiprocessor machines.*

The work queue is denoted by $\mathcal{Q}$ and the row structure set for updating column j is constructed in the set $\mathcal{S}_j$ as the algorithm progresses. It is worth noting that the set $\mathcal{S}_j$ contains *supernodes* that update column $L_{*,j}$, not *individual columns* that update the column. We let $next(j, \boldsymbol{K})$ be the next column after j to be updated by supernode $\boldsymbol{K}$. (Here we assume that $next(j, \boldsymbol{K})$ is $n+1$ if j is the last column updated by $\boldsymbol{K}$.) Similarly, $next(\boldsymbol{J}, \boldsymbol{J})$ is the first column to be updated by supernode $\boldsymbol{J}$.

A few comments on the algorithm in Fig. 1 are in order. First, note that a supernode $\boldsymbol{J}$ is inserted into $\mathcal{S}_q$, where $q = next(\boldsymbol{J}, \boldsymbol{J})$, only after the last column of $\boldsymbol{J}$ has been completed. We were concerned that delaying the availability of each individual column until after the supernode in which it resides is complete might hurt performance. We tried different strategies that avoided this problem, but found that the technique used in the algorithm, which is the simplest approach tried, was as effective as the others.

Second, a processor enters a "spin wait" condition whenever the set $S_j = \emptyset$ and the column modifications for $L_{*,j}$ are not complete.

Third, note that extra care is required to synchronize the *cmod*$(j, \boldsymbol{J})$ operation. Since some of the columns $j' < j$ belonging to $\boldsymbol{J}$ may not be completed, a flag has to be associated with each column to record each column's current status. The flag for a particular column is set immediately after the column has been completed. Thus one potential cause of delay in the computation is that a processor may spin while waiting for this flag to be set for a previous column in the same supernode.

Fourth, the number of `lock` and `unlock` synchronization operations required in the parallel supernodal Cholesky factorization algorithm is often much smaller than that required in the parallel column-based version. The number of synchronization operations (i.e., locking and unlocking operations) required by the latter is relatively high; it is proportional to the number of nonzeros in the Cholesky factor L. It is easy to see that the number of synchronizations required by the supernodal algorithm is proportional to the number of *compressed subscripts* [18], which is precisely the number of off-diagonal nonzero entries in the last columns of all supernodes. To illustrate the reduction in the amount of synchronization, consider a model $m \times m$ grid problem using either a five-point or a nine-point operator. Suppose the grid points are labelled using the nested dissection algorithm [9]. It is easy to show that the number of nonzeros in L is $O(m^2 \log m)$ [9] and the number of compressed subscripts is $O(m^2)$ [18]. Thus, the amount of synchronization in the parallel supernodal Cholesky factorization is reduced by a factor of $\log m$.

4. Numerical experiments.

Most of the test problems used in our numerical experiments were taken from the Harwell–Boeing sparse matrix collection [7]. In the experiments, each matrix was initially ordered using an implementation of the minimum-degree algorithm due to Liu [13], followed by a postordering of the elimination tree [15], which is helpful in computing the supernode partition [12]. Some statistics, such as the size of each matrix, nonzero counts for both A and L, number of subscripts required to represent the supernodal structure of L (denoted by $\mu(L)$), the number of supernodes in L, and the number of floating-point operations,[1] are provided in Table 1.

Throughout this section, we use `colfct` to refer to the column-based approach to Cholesky factorization, and we use `supfct` to refer to the supernode-based approach. For each approach there are two distinct but similar routines: a serial routine and a parallel routine. It is worth noting that the serial `colfct` routine is a version of SPARSPAK's `gsfct` routine that has been slightly modified for fair comparison with the other routines, which were written from scratch.

We compare parallel `colfct` and parallel `supfct` on a Cray Y-MP, a powerful vector supercomputer with 8 processors and 128 Mwords of memory. Loop unrolling to level eight was used in `supfct`, and Fortran compiler directives were used to exercise the machine's parallel capabilities and to perform the necessary synchronization operations. The code was compiled using the Fortran compiler `cf77` with optimization (the default) and preprocessing options on (i.e., `cf77 -Zu`).

The top half of Table 2 reports factorization times and speedup ratios (enclosed in parentheses) for both methods applied to some small problems in our test set. The bottom half of the table records performance data for `supfct` on the remaining problems in our test set.

[1]A single floating-point operation is either a floating-point addition, subtraction, multiplication, or division, and is denoted by "flop."

n: number of equations,
$|A|$: number of nonzeros in A,
$|L|$: number of nonzeros in L, including the diagonal,
$\mu(L)$: number of row subscripts required to represent the supernodal structure of L,
N: number of fundamental supernodes in L,
flops: number of floating-point operations required to compute L.

Not surprisingly, `supfct` performs much better than `colfct` on this machine. Loop unrolling is extremely important for good performance on the Cray Y-MP. Comparing the serial runs for the two methods, we find differences in performance ranging from a low of 53% to a high of 132%, due to loop unrolling and reduced indirect indexing in `supfct`. Similar results have been reported previously in [4]. We also find that `supfct` parallelizes much better than `colfct`. For example, on eight processors (p=8) the speedup ratios for `supfct` range from a low of 6.0 to a high of 6.9, which is quite good, especially on such small problems. The speedup ratios for `colfct`, however, are very poor, ranging from a low of 2.0 to a high of 3.7.

The performance of `supfct` on the large problems in the bottom half of the table is consistently good. Ignoring the three smallest problems in this portion of the table (NASA1824, NASA2910, and NASA4704), speedup ratios range from a low of 6.5 to a high of 7.4. On six out of seven of these problems the speedup ratio is 7.0 or greater, with the 6.5 speedup ratio reserved for the problem requiring the least work, namely BCSSTK25.

Table 3 compares the performance of `supfct` with the parallel supernodal factorization algorithm used in [19], which we will designate as `supfct-SVY`. The performance figures are expressed in Mflops,[2] as is commonly done for vector supercomputers such as the Cray Y-MP. We report the performance of both codes on those problems in our test set for which results for `supfct-SVY` were available to us. The performance data for `supfct-SVY` were obtained from an unpublished manuscript [20].

	`supfct-SVY`	250.6	531.6	625.2

[2]Mflops (megaflops) are millions of floating-point operations per second. Gflops (gigaflops) are billions of floating-point operations per second.

Consider the results obtained on eight processors (p=8). On six of the twelve problems, `supfct` performs the factorization at over a Gflop, with highs of 1.48 Gflops on NASASRB, 1.50 Gflops on BCSSTK31, and 1.53 Gflops on BCSSTK33. For two other problems, the computational rate is nearly a Gflop: .97 Gflop on BCSSTK16 and .95 Gflop on BCSSTK23. Thus, for 8 out of 12 of the problems, `supfct` computed the factorization at nearly a Gflop or more. Table 1 indicates that the remaining four problems (NASA1824, NASA2910, NASA4704, and BCSSTK24) are quite small. Moreover, in Table 2 we see that serial `supfct` requires less than half a second to factor any of these four matrices.

The performance of `supfct-SVY` is much poorer due to the problems with this approach mentioned earlier in §2. The code runs at less than a Gflop on every problem, despite having significantly higher serial efficiency due to assembly language programming of the compute-intensive kernel routines and other machine-specific optimizations. Our parallel implementation of `supfct` is a Fortran 77 code, with no machine-specific optimizations.

5. Concluding remarks. We have implemented a simple new parallel sparse Cholesky factorization algorithm for shared-memory multiprocessors. Our left-looking algorithm uses techniques from [4] and [10]: it uses supernodes to reduce indirect addressing and memory traffic [4], and it decomposes the computation into column tasks $Tcol(j)$ and schedules these tasks dynamically on the available processors [10]. Incorporation of supernodes into the algorithm in [10] reduces the synchronization overhead required to manage the row structure sets $\mathcal{S}_q$ from $O(|L|)$ to $O(\mu(L))$. In practice, $\mu(L)$ is often much smaller than $|L|$; consequently, contention for the critical sections is likely to be higher in `colfct` than in `supfct`, particularly on machines such as the Cray Y-MP, which have a limited number of lock variables.

Acknowledgment. The authors would like to thank Dr. Phuong Vu and Cray Research Inc. for providing us with dedicated time on a Cray Y-MP.

GENERATING LINEAR AND LINEAR-QUADRATIC BILEVEL PROGRAMMING PROBLEMS*

PAUL H. CALAMAI[†] AND LUIS N. VICENTE[‡]

Abstract. This paper describes a technique for generating both linear and linear-quadratic bilevel programming problems. The method is based on combining a number of single-parameter two-variable problems to obtain a separable multivariable problem with a number of desirable properties. The separability is then disguised using a simple transformation.

The proposed technique, which requires very little computational effort, allows the user control over, among other things, the number and type of minima and the data density.

Key words. bilevel programming, test problems, separable programs

AMS subject classifications. 90C30, 90D05

1. Introduction. An important field of mathematical programming is bilevel programming [5], [9], [11]. One reason for this interest is that problems involving hierarchical decision making can be modeled as bilevel problems [1], [2], [6]. Although several techniques have been designed for solving linear and linear-quadratic bilevel programming problems [3], [7], [8], [12], little has been done to compare the computational virtues of these techniques. One likely reason for this omission is the lack of an acceptably large and diverse set of test problems. In this paper we describe a computationally simple procedure for constructing problems that can be used to this end. Much of this work is based on a related technique for generating quadratic bilevel programming problems [4].

The method described here gives the user control over a number of important problem features that can be adjusted to test the performance of the various solution techniques. We demonstrate how the number and type of minima can be controlled and how the data density can be adjusted. Since several solution techniques start by solving the relaxed linear program that corresponds to the bilevel problem, we also show how the diversity between the solutions of these two problems can be controlled.

In §2 we describe how the linear bilevel programming problems are constructed. We start by introducing the single-parameter, two-variable, bilevel programming problem that is our fundamental building block. The solution properties of these problems are described using simple geometry. We then demonstrate how these simple problems can be combined to produce a separable linear bilevel problem with chosen properties. In §3 we describe how our basic linear bilevel problems can be modified and extended. We show how the number of inequality constraints can be reduced and how equality constraints can be added. The modifications required for constructing linear-quadratic bilevel programming problems are also included in this section. The transformation that is used to disguise the separability of the constructed problems is then described in §4. In §5 we illustrate our technique with an example. The paper concludes with §6, where

we report conclusions and demonstrate that the proposed method generates problems that meet the requirements of three different solution techniques.

2. The linear problem. Our intention is to construct purely linear bilevel programming (LBP) problems with a number of favorable properties. We accomplish this by starting with a simple single-parameter problem in one upper-level and one lower-level variable. We then combine several of these problems to obtain a separable multiparameter multivariable linear bilevel programming problem with several desirable properties. The separability of this problem is then disguised, without destroying these properties, using a simple, nonsingular transformation of variables.

2.1. A one-parameter, two-variable LBP. Consider the following linear bilevel programming problem in the variables x_k and y_k, denoted $LBP(\rho_k)$:

$$\begin{aligned}&\min_{x_k,y_k} L_k(x_k,y_k) = (3-x_k)+y_k,\\&\text{subject to } (x_k,y_k)\in\Omega_U^k\end{aligned}$$

(the upper-level problem), where $y_k = y(x_k)$ solves (the lower-level problem)

$$\begin{aligned}&\min_{y_k} l_k(x_k,y_k) = -y_k,\\&\text{subject to } (x_k,y_k)\in\Omega_L(\rho_k),\end{aligned}$$

with $3 \le \rho_k \le 9$, $\Omega_U^k = \{x_k : 1 \le x_k \le 3\}$, and $\Omega_L(\rho_k)$ consisting of those points (x_k, y_k) satisfying

$$\begin{aligned}x_k + y_k &\le \rho_k,\\-2x_k + y_k &\le 0.\end{aligned}$$

The relaxed feasible region for $LBP(\rho_k)$, $\Omega(\rho_k) = \Omega_U^k \bigcap \Omega_L(\rho_k)$, is thus the (unbounded) region bounded on the left by $x_k \ge 1$, on the right by $x_k \le 3$, and above by $-2x_k + y_k \le 0$ (to the left) and $x_k + y_k \le \rho_k$ (to the right).

The set of all feasible points of problem $LBP(\rho_k)$ is called the *induced region* (see [12, pp. 9–10] for a complete mathematical description).

PROPOSITION 2.1. *For problem $LBP(\rho_k)$ the induced region, denoted S, consists of the union of the following two sets:*

$$\begin{aligned}S_1 &= \{(x_k,y_k)\in\Omega(\rho_k) : -2x_k+y_k=0\},\\S_2 &= \{(x_k,y_k)\in\Omega(\rho_k) : x_k+y_k=\rho_k\},\end{aligned}$$

which describe two line segments in $\Omega(\rho_k)$.

Proof. The proof follows directly upon applying the Karush–Kuhn–Tucker conditions to the corresponding lower-level problem. □

The solution of problem $LBP(\rho_k)$ occurs at some point $(x_k, y(x_k)) \in S$ which depends on the value of the parameter ρ_k. There are five cases to consider:

1. Case 1 (Fig. 1), where $\rho_k = 3$.
2. Case 2 (Fig. 2), where $\rho_k = 7$.
3. Case 3 (Fig. 3), where $\rho_k = 9$.
4. Case 4, where $3 < \rho_k < 7$.
5. Case 5, where $7 < \rho_k < 9$.

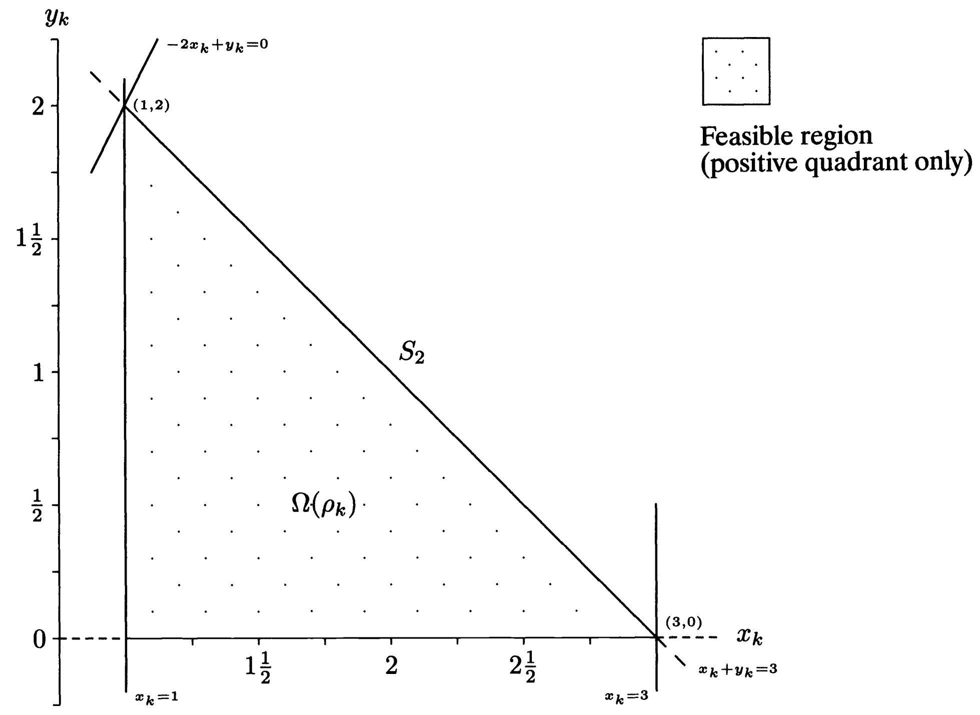

FIG. 1. *Case* 1, *where* $\rho_k = 3$.

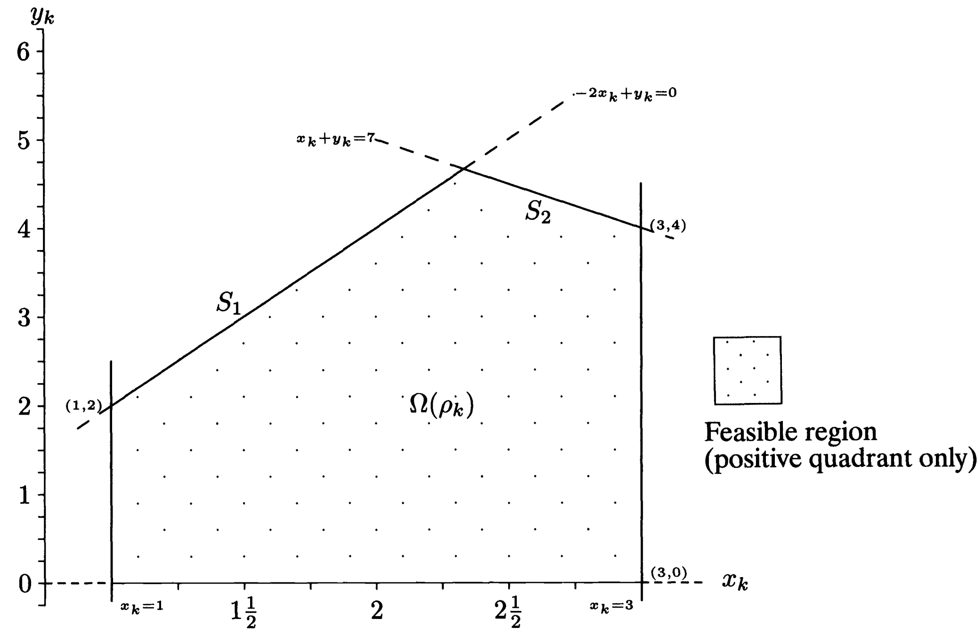

FIG. 2. *Case* 2, *where* $\rho_k = 7$.

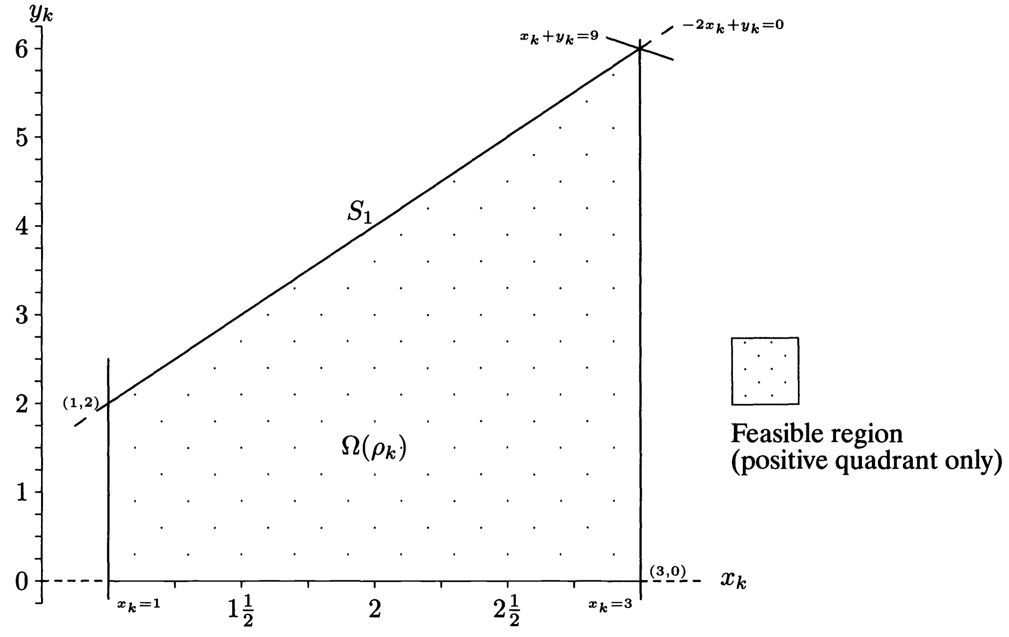

FIG. 3. *Case* 3, *where* $\rho_k = 9$.

What follows is an examination of problem $LBP(\rho_k)$ for each of these five cases. In each instance, the solutions are determined geometrically. This is a simple matter since, for $(x_k, y_k) \in S$, we have

$$\begin{aligned}\min_{x_k,y_k} L_k(x_k,y_k) &= (3-x_k)+y_k \\ &= |x_k-3|+|y_k| \\ &= \left\| \begin{pmatrix} x_k \\ y_k \end{pmatrix} - \begin{pmatrix} 3 \\ 0 \end{pmatrix} \right\|_1 \end{aligned}$$

This means that the global minima of problem $LBP(\rho_k)$, denoted (x_k^G, y_k^G), are simply those points in S closest to the point $(3,0)$ in the l_1 sense. Similarly, the local minima of problem $LBP(\rho_k)$, denoted (x_k^L, y_k^L), are points in S that are closer (in the l_1 sense) to the point $(3,0)$ than points in S in some nonempty neighborhood of (x_k^L, y_k^L).

Case 1. $\rho_k = 3$. In this case, depicted in Fig. 1, the set S equals S_2, and therefore includes the point $(3,0)$. Thus $(x_k^G, y_k^G) = (3,0)$ with $L_k(x_k^G, y_k^G) = 0$.

Case 2. $\rho_k = 7$. In this case, depicted in Fig. 2, the set S is the union of S_1 and S_2. By observing the l_1 contours centered at the point $(3,0)$, we find that $LBP(\rho_k)$ has two (strict) global minima, namely $(x_k^G, y_k^G) = (1,2)$ and $(x_k^G, y_k^G) = (3,4)$, with $L_k(x_k^G, y_k^G) = 4$.

Case 3. $\rho_k = 9$. Figure 3 depicts this case, where the set S equals S_1. In this case the closest point in S, in the l_1 sense, to $(3,0)$ is the point $(1,2)$. Thus $(x_k^G, y_k^G) = (1,2)$ with $L_k(x_k^G, y_k^G) = 4$.

Case 4. $3 < \rho_k < 7$. This case is similar to the situation depicted in Fig. 2 except that the line $x_k + y_k = 7$ is replaced with the line $x_k + y_k = \rho_k$ (i.e., the line $x_k + y_k = 7$ is shifted *down* $7 - \rho_k$ units), subsequently changing S_1 and S_2 (and therefore S). The closest point in S, in the l_1 sense, to $(3, 0)$ occurs at the intersection of S_2 with the line $x_k = 3$. Thus $(x_k^G, y_k^G) = (3, \rho_k - 3)$ with $L_k(x_k^G, y_k^G) = \rho_k - 3$.

In addition, the point $(1, 2)$, the left endpoint of S_1, is closer, in the l_1 sense, to the point $(3, 0)$ than any other point in S_1. Thus $(x_k^L, y_k^L) = (1, 2)$ with $L_k(x_k^L, y_k^L) = 4$.

Case 5. $7 < \rho_k < 9$. This case is also similar to the situation depicted in Fig. 2, except that this time the line $x_k + y_k = 7$ is shifted *up* $\rho_k - 7$ units (i.e., the line $x_k + y_k = 7$ is replaced with the line $x_k + y_k = \rho_k$), subsequently changing S_1 and S_2 (and therefore S). The closest point in S, in the l_1 sense, to $(3, 0)$ for this case occurs at the intersection of S_1 with the line $x_k = 1$ (as in Case 3). Thus $(x_k^G, y_k^G) = (1, 2)$ with $L_k(x_k^G, y_k^G) = 4$.

The point $(3, \rho_k - 3)$, the right endpoint of S_2, is closer, in the l_1-sense, to the point $(3, 0)$ than any other point in S_2. Thus $(x_k^L, y_k^L) = (3, \rho_k - 3)$ with $L_k(x_k^L, y_k^L) = \rho_k - 3$.

In the next section we demonstrate how a (separable) multiparameter multivariable linear bilevel programming problem, with specific properties, can be constructed by combining these simple one-parameter, two-variable problems.

2.2. A simple, separable parametric LBP. Let nx and ny be the desired number of upper-level and lower-level variables of the linear bilevel problem, respectively. In addition, let $m = \min\{nx, ny\}$.

Consider the following problem, which we denote $LBP(\rho)$:

$$\begin{aligned}\min_{x,y} L(x, y) &= \sum_{k=1}^{m} L_k(x_k, y_k) + \sum_{m<k\le nx} (3 - x_k) + \sum_{m<k\le ny} y_k \\ &= \sum_{k=1}^{nx} (3 - x_k) + \sum_{k=1}^{ny} y_k,\end{aligned}$$

subject to $(x, y) \in \Omega_U$

(the upper-level problem), where $y = y(x)$ solves (the lower-level problem)

$$\min_{y} l(x, y) = \sum_{k=1}^{m} l_k(x_k, y_k) = -\sum_{k=1}^{m} y_k,$$

subject to $(x, y) \in \Omega_L(\rho)$

with $3 \le \rho_k \le 9$, for $k = 1, \ldots, m$,

$$\Omega_U = \bigcap_{k=1}^{m} \Omega_U^k \quad \bigcap_{m<k\le nx} \{x_k : x_k \le 3\},$$

and

$$\Omega_L(\rho) = \bigcap_{k=1}^{m} \Omega_L(\rho_k) \quad \bigcap_{m<k\le ny} \{y_k : y_k \ge 0\}.$$

In addition, define the corresponding *relaxed* linear program $LP(\rho)$ as

$$\min_{x,y} \{L(x, y) : (x, y) \in \Omega_U \cap \Omega_L(\rho)\}.$$

From this construction we can easily see that the solution of the multiparameter problem $LBP(\rho)$ is simply composed of the solutions of the m single-parameter problems $LBP(\rho_k)$, $k = 1, \ldots, m$, plus the solution of the subproblem

$$\min \sum_{m<k\le nx} (3 - x_k) + \sum_{m<k\le ny} y_k,$$

subject to

$$x_k \leq 3, \qquad m < k \leq nx,$$
$$y_k \geq 0, \qquad m < k \leq ny.$$

If we define the five sets M_1 through M_5 (with corresponding cardinalities m_1 through m_5) as

$$\begin{aligned} M_1 &= \{k \in M : \rho_k = 3\}, \\ M_2 &= \{k \in M : \rho_k = 7\}, \\ M_3 &= \{k \in M : \rho_k = 9\}, \\ M_4 &= \{k \in M : 3 < \rho_k < 7\}, \\ M_5 &= \{k \in M : 7 < \rho_k < 9\}, \end{aligned}$$

where $M = \{1, \ldots, m\}$, then the following properties hold.

PROPERTY 1. Problem $LBP(\rho)$ has 2^{m_2} global minima with $x_k^G = 3$ $(m < k \leq nx)$, $y_k^G = 0$ $(m < k \leq ny)$, and

$$(x_k^G, y_k^G) = \begin{cases} (3,0), & k \in M_1, \\ (1,2) \text{ or } (3,4), & k \in M_2, \\ (1,2), & k \in M_3 \cup M_5, \\ (3, \rho_k - 3), & k \in M_4, \end{cases}$$

yielding $L(x^G, y^G) = 4(m_2 + m_3 + m_5) + \sum_{k \in M_4} (\rho_k - 3)$.

This property follows directly from the manner in which problem $LBP(\rho)$ is constructed and from the previous geometric analysis of problems $LBP(\rho_k)$, $k \in M$.

PROPERTY 2. Problem $LBP(\rho)$ has local minima (that are not global) only when $m_4 + m_5 > 0$. In this case there are $2^{m_2+m_4+m_5} - 2^{m_2}$ such minima. These local minima occur whenever one or more of the following hold

$$(x_k, y_k) = \begin{cases} (1,2), & k \in M_4, \\ (3, \rho_k - 3), & k \in M_5, \end{cases}$$

with all remaining components defined as in Property 1.

This property, like Property 1, follows directly from the manner in which problem $LBP(\rho)$ is constructed and from the geometric properties of problems $LBP(\rho_k)$, $k \in M$.

PROPERTY 3. The global minima of problem $LBP(\rho)$ do not coincide with any solution of the corresponding relaxed linear program $LP(\rho)$.

This result follows trivially since problem $LP(\rho)$ is unbounded. In fact, this result still holds (as long as $m_1 < m$) if one adds what might be considered the natural lower-bound constraints $y_k \geq 0$, $k = 1, \ldots, ny$, since the solution to the corresponding relaxed LP yields $x_k = 3$, $k = 1, \ldots, nx$, and $y_k = 0$, $k = 1, \ldots, ny$, which differs from the minima of $LBP(\rho)$ in $2(m - m_1)$ variables.

PROPERTY 4. The gradients, in the lower-level variables y, of the active constraints at the minima of problem $LBP(\rho)$ are linearly independent, and the complementarity conditions associated with the corresponding lower-level problem are *strictly* satisfied at these minima.

This property is a direct consequence of the separability of problem $LBP(\rho)$ and the strict complementarity of the minima of problems $LBP(\rho_k)$, $k = 1, \ldots, m$.

3. Extensions and modifications. Problem $LBP(\rho)$ can be extended and modified in a number of ways. In the subsections that follow we show how the number of inequality constraints in problem $LBP(\rho)$ can be reduced, how equality constraints can be added to problem $LBP(\rho)$, and how our technique can be modified to produce bilevel problems with quadratic lower-level objectives (i.e., linear-quadratic bilevel programs).

3.1. Reducing the number of inequality constraints. When $k \in M_1$, the constraints

$$x_k \geq 1 \quad \text{and} \quad -2x_k + y_k \leq 0$$

are redundant in problems $LBP(\rho_k)$. Similarly, when $k \in M_3$, the constraints

$$x_k \leq 3 \quad \text{and} \quad x_k + y_k \leq 9$$

are redundant in problems $LBP(\rho_k)$. Thus $2(m_1+m_3)$ constraints can be removed from problem $LBP(\rho)$ without consequence.

An additional $2(m-\bar{m})$ constraints can be removed by setting $\bar{m} < m = \min\{nx, ny\}$ and replacing the constraints

$$\begin{aligned} -x_k &\leq -1, & k &= \bar{m}+1, \dots, m, \\ x_k + y_k &\leq \rho_k, & k &= \bar{m}+1, \dots, m, \\ -2x_k + y_k &\leq 0, & k &= \bar{m}+1, \dots, m, \end{aligned}$$

with the constraints

$$y_k \geq 0, \qquad k = \bar{m}+1, \dots, m.$$

This requires redefining M_1 through M_5 (and their corresponding cardinalities m_1 through m_5) after setting $M = \{1, \dots, \bar{m}\}$.

With this modification, the minima of $LBP(\rho)$ satisfy $(x_k^G, y_k^G) = (3, 0)$ when $k \in \{\bar{m}+1, \dots, m\}$.

3.2. Adding equality constraints. Equality constraints can be added to problem $LBP(\rho)$ in a number of ways without changing its minima. Those analogous to the ones presented in §6.2 of [4] are:

1. $x_i - x_j = 0$, where $i \neq j$ and $i, j \in \{m+1, \dots, nx\}$ when $nx > ny = m$.
2. $y_i - y_j = 0$, where $i \neq j$ and $i, j \in \{m+1, \dots, ny\}$ when $ny > nx = m$.
3. $x_i - y_j = 3$, where $i, j \in M_1$ when $m_1 > 0$.
4. $x_i - y_j = 3$, where $i, j \in \{\bar{m}+1, \dots, m\}$, and $\bar{m}$ and M_1 through M_5 are defined as in the previous section.

In order to ensure the linear independence of the gradients (with respect to the lower-level variables y) of the constraints at optimality, the same conditions as those stated in §6.2 of [4] must hold.

3.3. Replacing the lower-level objective with a quadratic. After redefining $\bar{m}$ and M_1 through M_5 as in §3.1, and removing the constraints

$$-2x_k + y_k \leq 0, \qquad k = 1, \dots, \bar{m},$$

the linear, lower-level objective $l(x, y)$ can be replaced with the quadratic

$$\min_y q(x, y) = \frac{1}{2} \sum_{k=1}^{\bar{m}} y_k (y_k - 4x_k) - \sum_{k=\bar{m}+1}^{m} y_k$$

without affecting the foregoing analysis (since the induced region S is the same for (x_k, y_k) when $k \in M$).

With this modification we obtain a linear-quadratic bilevel programming problem, which we denote $LQBP(\rho)$.

4. The transformation. In order to describe our technique for disguising the separability of problem $LBP(\rho)$, we define problem $LBP(c, s, A_x, A_y, b)$ as

$$\min_{x,y} L(x,y) = c_x^T x + c_y^T y + \kappa$$

(the upper-level problem), where $y = y(x)$ solves (the lower-level problem)

$$\begin{aligned}&\min_{y} l(x,y) = s_x^T x + s_y^T y,\\ &\text{subject to } A_x x + A_y y \le b,\end{aligned}$$

with

$$\begin{gathered} c = \begin{bmatrix} c_x \\ c_y \end{bmatrix}, \qquad s = \begin{bmatrix} s_x \\ s_y \end{bmatrix}, \\ c_x, s_x, x \in \boldsymbol{R}^{nx}, \qquad c_y, s_y, y \in \boldsymbol{R}^{ny}, \\ A_x \in \boldsymbol{R}^{\beta \times nx}, \quad A_y \in \boldsymbol{R}^{\beta \times ny}, \quad b \in \boldsymbol{R}^{\beta} \quad \text{and} \quad \kappa \in \boldsymbol{R}. \end{gathered}$$

With the following substitutions,

$$c_x = -1_{nx}, \quad c_y = 1_{ny}, \quad s_x = 0_{nx}, \quad (s_y)_i = \begin{cases} -1, & 1, \ldots, m, \\ 0, & \text{otherwise,} \end{cases} \quad \kappa = 3nx,$$

$$A_x = \begin{bmatrix} P_x \\ -2P_x \\ \frac{1}{3}P_x \\ -P_x \\ Q_x \end{bmatrix}, \quad A_y = \begin{bmatrix} P_y \\ P_y \\ \mathbf{0} \\ \mathbf{0} \\ Q_y \end{bmatrix}, \quad \text{and} \quad b = \begin{bmatrix} \rho \\ 0_m \\ 1_m \\ -1_m \\ \epsilon \end{bmatrix},$$

where

$\mathbf{0}$ is the $m \times ny$ zero matrix and $\rho^T = [\rho_1 \cdots \rho_m]$,

1_γ is a ones-vector of length γ and 0_γ is a zeros-vector of length γ,

$$P_x \in \boldsymbol{R}^{m \times nx} \text{ and } P_y \in \boldsymbol{R}^{m \times ny} \text{ satisfy } P_{ij} = \begin{cases} 1, & 1 \le i = j \le m, \\ 0, & \text{otherwise,} \end{cases}$$

and, for $\alpha = \max\{nx, ny\} - m$,

$$Q_x \in \boldsymbol{R}^{\alpha \times nx} \text{ satisfies } (Q_x)_{ij} = \begin{cases} 0, & ny > nx \quad \text{or} \quad j \ne m + i, \\ \frac{1}{3}, & \text{otherwise,} \end{cases}$$

$$Q_y \in \boldsymbol{R}^{\alpha \times ny} \text{ satisfies } (Q_y)_{ij} = \begin{cases} 0, & nx > ny \quad \text{or} \quad j \neq m+i, \\ -1, & \text{otherwise,} \end{cases} \qquad \text{and}$$

$$\epsilon \in \boldsymbol{R}^{\alpha} \text{ satisfies } \epsilon_i = \begin{cases} 1, & nx > ny, \\ 0, & ny > nx, \end{cases}$$

problem $LBP(c, s, A_x, A_y, b)$ is equivalent to problem $LBP(\rho)$.

Now, for $n = nx + ny$, define the order-n matrix $\mathcal{M} = HDH$, where

$$H = \begin{bmatrix} H_x & 0 \\ 0 & H_y \end{bmatrix}$$

is a block-diagonal matrix with H_x and H_y constructed as random Householder matrices using

$$H_x = I_{nx} - 2v_x v_x^T, \quad \text{with } v_x^T v_x = 1 \quad \text{and} \quad v_x \in \boldsymbol{R}^{nx} \text{ sparse,}$$

$$H_y = I_{ny} - 2v_y v_y^T, \quad \text{with } v_y^T v_y = 1 \quad \text{and} \quad v_y \in \boldsymbol{R}^{ny} \text{ sparse,}$$

and D is a positive definite diagonal matrix with two-norm condition number $\kappa_2(D) = 10^6$, and let $\mathcal{W} = \mathcal{M}^{-1} = HD^{-1}H$ and $A = \begin{bmatrix} A_x & A_y \end{bmatrix}$.

PROPOSITION 4.1. *Problem $LBP(c, s, A_x, A_y, b)$ (and problem $LBP(\rho)$) in the variables x and y is equivalent to problem* LBP$(\mathcal{M}c, \mathcal{M}s, A\mathcal{M}, b)$ *in the variables $\bar{x}$ and $\bar{y}$ under the nonsingular transformation*

$$\begin{bmatrix} \bar{x} \\ \bar{y} \end{bmatrix} = \mathcal{W} \begin{bmatrix} x \\ y \end{bmatrix}.$$

Proof. For

$$\begin{bmatrix} x \\ y \end{bmatrix} = \mathcal{M} \begin{bmatrix} \bar{x} \\ \bar{y} \end{bmatrix},$$

problem $LBP(c, s, A_x, A_y, b)$ becomes

$$\min_{\bar{x},\bar{y}} L(\bar{x}, \bar{y}) = \begin{bmatrix} c_x \\ c_y \end{bmatrix}^T \mathcal{M} \begin{bmatrix} \bar{x} \\ \bar{y} \end{bmatrix} + \kappa$$

subject to $\bar{y} = \bar{y}(\bar{x})$ solving

$$\min_{\bar{y}} l(\bar{y}) = \begin{bmatrix} s_x \\ s_y \end{bmatrix}^T \mathcal{M} \begin{bmatrix} \bar{x} \\ \bar{y} \end{bmatrix},$$

$$\text{subject to } [A\mathcal{M}] \begin{bmatrix} \bar{x} \\ \bar{y} \end{bmatrix} \leq b,$$

which is problem $LBP(\mathcal{M}c, \mathcal{M}s, A\mathcal{M}, b)$ in the variables $\bar{x}$ and $\bar{y}$. □

Thus,

$$\begin{bmatrix} \bar{x}^G \\ \bar{y}^G \end{bmatrix} = \mathcal{W} \begin{bmatrix} x^G \\ y^G \end{bmatrix}$$

is a global solution to the transformed problem and this one-to-one correspondence holds for all minima of problem LBP.

Notes.

1. A similar technique can be applied to problem $LQBP(\rho)$ to disguise its separability.

2. The sparsity of v_x and v_y controls the sparsity of $\mathcal{M}$ (and consequently, the sparsity of the data).

3. The spectrum of D controls the spectrum of $\mathcal{M}$ (and consequently, affects the geometry of the problem).

4. The lower-level objective of problem $LQBP(\rho)$ is strictly convex in y.

5. The upper-level constraints of problem $LBP(\rho)$ have been moved into the lower level of problem $LBP(c, s, A_x, A_y, b)$ in order to simplify notation.

6. A paper of Marcotte and Savard [10] was brought to our attention after completing this work. In their report a transformation similar to that used here is used to establish the equivalence between bilevel problems and to prove that solutions to bilevel problems are not necessarily Pareto optimal.

5. Example. In order to illustrate some of the ideas that have been presented, consider the (untransformed) linear bilevel programming problem obtained when the following values are used for the control parameters:

$$nx = 4, \quad ny = 2 \quad \text{and} \quad m = 2,$$
$$m_1 = m_2 = m_3 = 0 \quad \text{and} \quad m_4 = m_5 = 1,$$

and

$$\rho_1 = 5 \quad \text{and} \quad \rho_2 = 8.$$

This corresponds to the following bilevel problem:

$$\min_{x,y} L(x,y) = \sum_{i=1}^{2} ((3 - x_i) + y_i) + \sum_{i=3}^{4} (3 - x_i),$$

subject to $y = y(x)$ solving

$$\min_{y} l(x,y) = -\sum_{i=1}^{2} y_i,$$

subject to

$$\begin{array}{rrrrrrr}
x_1 & & & & +\, y_1 & & \le\ 5, \\
 & x_2 & & & & +\, y_2 & \le\ 8, \\
-2x_1 & & & & +\, y_1 & & \le\ 0, \\
 & -\ 2x_2 & & & & +\, y_2 & \le\ 0, \\
x_1 & & & & & & \le\ 3, \\
 & x_2 & & & & & \le\ 3, \\
-x_1 & & & & & & \le -1, \\
 & -\ x_2 & & & & & \le -1, \\
 & & x_3 & & & & \le\ 3, \\
 & & & x_4 & & & \le\ 3,
\end{array}$$

where

$$x = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} \in \boldsymbol{R}^4 \quad \text{and} \quad y = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} \in \boldsymbol{R}^2.$$

Now suppose the following data was used in the transformation:

$$v_x^T = \begin{bmatrix} -0.7 & 0.7 & 0.1 & -0.1 \end{bmatrix}, \qquad v_y^T = \begin{bmatrix} 0.8 & -0.6 \end{bmatrix},$$

and

$$D = \text{diag}(20, 10, 20, 10, 10, 20).$$

This would yield the following (transformed) linear bilevel programming problem:

$$\min_{x,y} L(x,y) = \begin{bmatrix} -11.6 \\ -18.4 \\ -21.2 \\ -8.8 \end{bmatrix}^T \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} + \begin{bmatrix} 21.904 \\ 13.472 \end{bmatrix}^T \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} + 12$$

(the upper-level problem) subject to $y = y(x)$ solving (the lower-level problem)

$$\min_{y} l(x,y) = \begin{bmatrix} -21.904 \\ -13.472 \end{bmatrix}^T \begin{bmatrix} y_1 \\ y_2 \end{bmatrix},$$

subject to

$$\begin{array}{rrrrrrl}
10.2x_1 & & +\ 1.4x_3 & & +\ 19.216y_1 & +\ \ 2.688y_2 & \le\ \ 5,\\
 & 19.8x_2 & & -\ \ 1.4x_4 & +\ \ 2.688y_1 & +\ 10.784y_2 & \le\ \ 8,\\
-20.4x_1 & & -\ \ 2.8x_3 & & +\ 19.216y_1 & +\ \ 2.688y_2 & \le\ \ 0,\\
 & -39.6x_2 & & +\ \ 2.8x_4 & +\ \ 2.688y_1 & +\ 10.784y_2 & \le\ \ 0,\\
10.2x_1 & & +\ 1.4x_3 & & & & \le\ \ 3,\\
 & 19.8x_2 & & -\ \ 1.4x_4 & & & \le\ \ 3,\\
-10.2x_1 & & -\ \ 1.4x_3 & & & & \le -1,\\
 & -19.8x_2 & & +\ \ 1.4x_4 & & & \le -1,\\
1.4x_1 & & +\ 19.8x_3 & & & & \le\ \ 3,\\
 & -1.4x_2 & & +\ 10.2x_4 & & & \le\ \ 3,
\end{array}$$

where

$$x = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} \in \boldsymbol{R}^4 \quad \text{and} \quad y = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix} \in \boldsymbol{R}^2.$$

Since $m_2 = 0$ and $m_4 + m_5 = 2$ this problem has $2^{m_2+m_4+m_5} - 2^{m_2} = 3$ local solutions and a unique global minimum with value $L_G = 4(m_2+m_3+m_5)+(\rho_1-3) = 6$.

6. Remarks and conclusions. In designing these test problems careful attention has been placed on conforming to the requirements of several solution techniques. We elaborate on this point by considering three available solution techniques.

SLCP approaches [7], [8]. The requirements of these sequential linear complementarity approaches are met since the lower-level problems can be replaced with the corresponding Karush–Kuhn–Tucker conditions. In addition, for the linear-quadratic bilevel problems an initial basis for the first LCP is readily available.

Exact penalty approaches [3]. For the pure linear bilevel problems generated using the proposed techniques

• the feasible region Ω is nonempty,

• the lower-level variables satisfy a strict complementarity condition at all local minima, and

• the lower-level objective function is bounded below on the feasible region and the upper-level objective function is bounded below in the induced region.

Thus, the requirements of this exact penalty function approach are met.

The requirements of these techniques also hold for the linear-quadratic case, as demonstrated in [4].

Branch and bound techniques [12, pp. 19–22]. In respect to the pure linear bilevel problems, the requirements for these techniques are met since there is always an optimal solution for the generated problems and since the lower-level problem has a unique solution in y for every fixed x.

We have described a method for generating both linear and linear-quadratic bilevel test problems. The method requires very little computational effort (i.e., no subproblems need be solved) and gives the user control over the number and type of minima, the sparsity of the data, the diversity from the corresponding relaxed problem and, to a lesser extent, the geometry of the problems generated.

Note. A Fortran 77 code that implements the technique described in this paper can be obtained by sending an e-mail request to phcalamai@dial.waterloo.edu.

THE ACCURACY OF FLOATING POINT SUMMATION*

NICHOLAS J. HIGHAM†

Abstract. The usual recursive summation technique is just one of several ways of computing the sum of n floating point numbers. Five summation methods and their variations are analyzed here. The accuracy of the methods is compared using rounding error analysis and numerical experiments. Four of the methods are shown to be special cases of a general class of methods, and an error analysis is given for this class. No one method is uniformly more accurate than the others, but some guidelines are given on the choice of method in particular cases.

Key words. floating point summation, rounding error analysis, orderings

AMS subject classifications. primary 65G05, secondary 65B10

1. Introduction. Sums of floating point numbers are ubiquitous in scientific computing. They occur when evaluating inner products, means, variances, norms, and all kinds of nonlinear functions. Although, at first sight, summation might appear to offer little scope for algorithmic ingenuity, the usual "recursive summation" (with various orderings) is just one of several possible techniques. Most of the other techniques have been derived with the aim of achieving greater accuracy of the computed sum, but pairwise summation has the advantage of being particularly well suited to parallel computation.

In this paper we examine a variety of methods for floating point summation, with the aim of answering the question, "which methods achieve the best accuracy?" Several authors have used error analysis to compare summation methods; see, for example, [1], [2], [32], and [38]. Here we give a more comprehensive treatment that highlights the relationships between different methods; in particular, we give an error analysis for a general class of methods that includes most of the specific summation methods as special cases.

This work was motivated by two applications in which the choice of summation method has been found to have an important influence on the performance of a numerical method.

(1) In [24], Lasdon et al. derive an algorithm for solving an optimization problem that arises in the design of sonar arrays. The authors state [24, p. 145] that "the objective gradient ∇f in (4.1) is a sum of M terms. In problems with $M = 284$ and $n = 42$, the GRG2 optimizer encountered difficulties which stem from inaccuracies in ∇f.... We hypothesized that this was due to roundoff error resulting from cancellation of terms in ∇f of approximately equal magnitudes and opposite signs. These problems were eliminated by accumulating separately positive and negative terms (for each component of ∇f) in the sum (4.1), adding them together only after all M terms had been processed."

(2) Dixon and Mills [7] applied a quasi-Newton method to the extended Rosenbrock function

$$F(x_1, x_2, \dots, x_n) = \sum_{i=1}^{n/2} \bigl(100(x_{2i} - x_{2i-1}^2)^2 + (1 - x_{2i-1})^2\bigr). \tag{1.1}$$

This function and its derivatives possess certain symmetries; for example, $F(a, b, c, d) = F(c, d, a, b)$ when $n = 4$. It is observed in [7] that expected symmetries in the search

direction and Hessian approximation are lost in practice, resulting in more iterations for convergence of the quasi-Newton method than are predicted theoretically. Dixon and Mills attribute the loss of symmetry to rounding errors in the evaluation of certain inner products, which can cause identities such as the one quoted above to fail in floating point arithmetic. They restore symmetry (and thus reduce the number of iterations) by using a special summation algorithm when evaluating inner products: their algorithm evaluates $\sum_{i=1}^{n} x_i$ by sorting the x_i, dividing them into a list of negative numbers and a list of nonnegative numbers, and then repeatedly forming the sum of the largest nonnegative and most negative elements and placing the sum into the appropriate list, in order.

We return to these two applications in §7.

The five main summation methods that we consider are defined and analyzed in §§2 and 3. For the error analysis we will make use of the standard model of floating point arithmetic, in which u is the unit roundoff:

$$fl(x \text{ op } y) = (x \text{ op } y)(1+\delta), \qquad |\delta| \le u, \quad \text{op } = +,-,*,/. \tag{1.2}$$

This model is violated by machines that lack a guard digit, so we explain in §5 how our analysis has to be modified to accommodate such machines. We will assume that no floating point underflows occur; how to modify error analyses to allow for underflow is described by Demmel in [6]. An excellent tutorial on many aspects of floating point arithmetic is given by Goldberg [9].

In §4 we summarize some existing results on statistical estimates of accuracy of summation methods. Numerical experiments are presented in §6 and conclusions are given in §7.

2. Orderings of recursive summation.

Our task is to evaluate $S_n = \sum_{i=1}^{n} x_i$, where $x_1, \dots, x_n$ are real numbers. In this section we consider the standard recursive summation technique in which S_n is evaluated according to

```
$s = 0$
for $i = 1{:}\,n$
    $s = s + x_i$
end
```

In general, each different ordering of the x_i will yield a different computed sum $\widehat{S}_n$ in floating point arithmetic, and it is of interest to determine how the ordering affects the error

$$E_n = \widehat{S}_n - S_n.$$

To begin, we make no assumption on the ordering and obtain a standard bound for E_n. By a direct application of the model (1.2) we have, with $S_k = \sum_{i=1}^{k} x_i$,

$$\widehat{S}_k = fl(\widehat{S}_{k-1} + x_k) = (\widehat{S}_{k-1} + x_k)(1+\delta_k), \qquad |\delta_k| \le u, \quad k = 2{:}\,n. \tag{2.1}$$

By repeated use of this relation it follows that

$$\widehat{S}_n = (x_1 + x_2)\prod_{k=2}^{n}(1+\delta_k) + \sum_{i=3}^{n} x_i \prod_{k=i}^{n}(1+\delta_k). \tag{2.2}$$

To simplify the product terms we use the result that if $|\delta_i| \le u$ for $i = 1{:}\,n$ then

$$\prod_{i=1}^{n}(1+\delta_i) = 1 + \theta_n, \quad \text{where} \quad |\theta_n| \le \frac{nu}{1-nu} \equiv \gamma_n.$$

Thus we rewrite (2.2) as

$$\widehat{S}_n = (x_1 + x_2)(1 + \theta_{n-1}) + \sum_{i=3}^{n} x_i(1 + \theta_{n-i+1}), \tag{2.3}$$

which yields

$$|E_n| = |(x_1 + x_2)\theta_{n-1} + \sum_{i=3}^{n} x_i\theta_{n-i+1}| \tag{2.4}$$

$$\leq (|x_1| + |x_2|)\gamma_{n-1} + \sum_{i=3}^{n} |x_i|\gamma_{n-i+1}. \tag{2.5}$$

Note that x_1 and x_2 have the same factor γ_{n-1}, because they play identical roles in the summation. The bound (2.5) is essentially the same as the one derived by Wilkinson in [42, p. 323] and [43, p. 17]. As Wilkinson notes in [43, p. 17], the upper bound in (2.5) depends on the order of summation, and the bound is minimized if the x_i are arranged in order of increasing absolute value. We emphasize that this ordering minimizes an error *bound* and not necessarily the actual error (this is illustrated later in this section, and by numerical examples in §6). We can weaken (2.5) to obtain the bound

$$|E_n| \leq \gamma_{n-1} \sum_{i=1}^{n} |x_i| = (n-1)u \sum_{i=1}^{n} |x_i| + O(u^2), \tag{2.6}$$

which is independent of the ordering. It is natural to regard satisfaction of (2.6) as a minimal requirement of any summation method; in fact, all the methods we will examine do satisfy this bound.

We can rewrite (2.6) as the relative error bound

$$\frac{|\widehat{S}_n - S_n|}{|S_n|} \leq \gamma_{n-1} \frac{\sum_{i=1}^{n} |x_i|}{|S_n|} \equiv \gamma_{n-1} R_n.$$

In the special case where $x_i \geq 0$ for all u, $R_n \equiv 1$, and the relative error has a bound of order nu, but if $\sum_{i=1}^{n} |x_i| \gg |\sum_{i=1}^{n} x_i|$ we cannot guarantee that the relative error is small. The quantity R_n is easily seen to be the condition number of summation when perturbations $x_i \to x_i + \Delta x_i$ are measured by $\max_i |\Delta x_i|/|x_i|$.

Recursive summation by order of increasing absolute value can be improved upon in two possible ways. First, a method may satisfy a bound of the form (2.6) but with a constant smaller than γ_{n-1}. Second, a method may satisfy a bound that in the worst case is no better than (2.6), but the method might be expected to yield a more accurate computed sum for particular classes of $\{x_i\}$. In the rest of this section we consider two alternative orderings, which fall into the second category.

First, we derive a sharper error bound. From (2.1) we see that the error introduced on the kth step of the summation is $(\widehat{S}_{k-1} + x_k)\delta_k = \widehat{S}_k\delta_k/(1 + \delta_k)$. Summing these individual errors we find

$$E_n = \sum_{k=2}^{n} \widehat{S}_k \frac{\delta_k}{1 + \delta_k}, \tag{2.7}$$

which shows that, to first order, the overall error is the sum of the $n-1$ relative rounding errors weighted by the partial sums. We obtain the bound

$$|E_n| = |\widehat{S}_n - S_n| \leq \frac{u}{1-u} \sum_{k=2}^{n} |\widehat{S}_k|. \tag{2.8}$$

This bound involves the computed partial sums (excluding $\widehat{S}_1 = x_1$) but not the individual terms x_i. If we weaken (2.8) by bounding $|\widehat{S}_k|$ in terms of $|x_1|, |x_2|, \ldots, |x_k|$, then we recover (2.5), to within $O(u^2)$.

The bound (2.8) suggests the strategy of ordering the x_i so as to minimize $\sum_{k=2}^{n} |\widehat{S}_k|$. This is a combinatorial optimization problem that is too expensive to solve in the context of summation. A reasonable compromise is to determine the ordering sequentially by minimizing, in turn, $|x_1|, |\widehat{S}_2|, \ldots, |\widehat{S}_{n-1}|$. This ordering strategy, which we denote by Psum, can be implemented with $O(n \log n)$ comparisons. The principal difference between the Psum and increasing orderings is that the Psum ordering is influenced by the signs of the x_i, while the increasing ordering is independent of the signs. If all the x_i have the same sign then the two orderings are identical.

It is easy to show by example that the bounds (2.8), (2.5) and (2.6) are nearly attainable. Following Wilkinson [43, p. 19] we assume $u = 2^{-t}$, set $n = 2^r$ ($r \ll t$), and define

$$\begin{aligned} x(1) &= 1, \\ x(2) &= 1 - 2^{-t}, \\ x(3{:}4) &= 1 - 2^{1-t}, \\ x(5{:}8) &= 1 - 2^{2-t}, \\ &\vdots \\ x(2^{r-1}+1{:}2^r) &= 1 - 2^{r-1-t}. \end{aligned}$$

Then in the $(i-1)$st floating point addition the "2^{k-t}" portion of x_i does not propagate into the sum;[1] thus there is an error of 2^{k-t} and $\widehat{S}_i = i$. The total error is

$$2^{-t}(1 + 2^2 + 2^4 + \cdots + 2^{2(r-1)}) = 2^{-t}\frac{4^r - 1}{3},$$

while the upper bound of (2.6) is

$$\frac{(n-1)u}{1-(n-1)u} \sum_{i=1}^{n} |x_i| \le \frac{2^r 2^{-t}}{1 - 2^r 2^{-t}} 2^r \approx 2^{-t} 4^r,$$

which agrees with the actual error to within a factor 3; thus the smaller upper bounds of (2.5) and (2.8) are also correct to within this factor. The example just quoted is, of course, a very special one, and as Wilkinson [43, p. 20] explains, "in order to approach the upper bound as closely as this, not only must each error take its maximum value, but all the terms must be almost equal."

Next, we consider ordering the x_i by decreasing absolute value. For the summation of positive numbers this ordering has little to recommend it. The bound (2.8) is no smaller, and potentially much larger, than for the increasing ordering (the same is true for the weaker bound (2.5)). Furthermore, in a sum of positive terms that vary widely in magnitude, the decreasing ordering may not allow the smaller terms to contribute to the sum (which is why $\sum_{i=1}^{n} 1/i$ "converges" in floating point arithmetic as $n \to \infty$). However, consider the example with $n = 4$ and

$$x = [1, \quad M, \quad 2M, \quad -3M], \tag{2.9}$$

[1]We assume in this example that the floating point arithmetic uses round to nearest with ties broken by rounding to an even last bit or rounding away from zero.

where M is a power of the machine base and is so large that $fl(1+M) = M$ (thus $M \geq u^{-1}$). The three orderings considered so far produce the following results:

$$\begin{aligned}
\text{Increasing:} \quad & \widehat{S}_n = fl(1+M+2M-3M) = 0, \\
\text{Psum:} \quad & \widehat{S}_n = fl(1+M-3M+2M) = 0, \\
\text{Decreasing:} \quad & \widehat{S}_n = fl(-3M+2M+M+1) = 1.
\end{aligned}$$

Thus the decreasing ordering sustains no rounding errors and produces the exact answer, while both the increasing and Psum orderings yield computed sums with relative error 1. The reason why the decreasing ordering performs so well in this example is that it adds the "1" after the inevitable heavy cancellation has taken place, rather than before, and so retains the important information in this term.

If we evaluate the term $\mu = \sum_{k=2}^{n} |\widehat{S}_k|$ in the error bound (2.8) for the example (2.9) we find

$$\text{Increasing: } \mu = 4M, \qquad \text{Psum: } \mu = 3M, \qquad \text{Decreasing: } \mu = M+1,$$

so (2.8) "predicts" that the decreasing ordering will produce the most accurate answer, but the bound it provides is extremely pessimistic since there are no rounding errors in this instance. This example illustrates the main weakness of bounds from a rounding error analysis: they represent the worst case and so do not account for the possibility that rounding errors may cancel or be smaller than expected.

Extrapolating from this example, we conclude that the decreasing ordering is likely to yield greater accuracy than the increasing or Psum orderings whenever there is heavy cancellation in the sum, that is, whenever $|\sum_{i=1}^{n} x_i| \ll \sum_{i=1}^{n} |x_i|$. A numerical example that illustrates this assertion is given in §6 (see Table 6.1).

3. Other methods. In this section we consider in detail four more summation methods. The first three of these methods, together with recursive summation, have the following general form: with $T_k \equiv x_k$, $k = 1{:}\,n$, they perform $n-1$ additions

$$T_k = T_{k_1} + T_{k_2}, \quad k_1 < k_2 < k, \quad k = n+1{:}\,2n-1, \tag{3.1}$$

yielding $S_n = T_{2n-1}$. In recursive summation, $k_1 \leq n$ in each instance of (3.1), but for the other methods at least one addition involves two previously computed sums. A useful expression for the error in this general class of summation methods can be derived as follows. The computed quantities $\widehat{T}_k$ satisfy

$$\widehat{T}_k = (\widehat{T}_{k_1} + \widehat{T}_{k_2})(1+\delta_k), \quad |\delta_k| \leq u, \quad k = n+1{:}\,2n-1. \tag{3.2}$$

The local error introduced in forming $\widehat{T}_k$ is $(\widehat{T}_{k_1} + \widehat{T}_{k_2})\delta_k = \widehat{T}_k\delta_k/(1+\delta_k)$, so overall we have

$$\widehat{S}_n - S_n = \sum_{k=n+1}^{2n-1} \widehat{T}_k \frac{\delta_k}{1+\delta_k}. \tag{3.3}$$

The smallest possible error bound is therefore

$$|E_n| \leq \frac{u}{1-u} \sum_{k=n+1}^{2n-1} |\widehat{T}_k|. \tag{3.4}$$

It is easy to see that $|\widehat{T}_k| \le \sum_{i=1}^{n} |x_i| + O(u)$ for each k, and so we also have the weaker bound

$$|E_n| \le (n-1)u \sum_{i=1}^{n} |x_i| + O(u^2). \tag{3.5}$$

Note that in the case of recursive summation (3.3)–(3.5) are the same as (2.6)–(2.8). Finally, we note in passing that from (3.2) there follows a backward error result which shows that $\widehat{S}_n$ is the exact sum of terms $x_i(1+\theta_i)$, where $|\theta_i| = O(u)$.

The first method we consider is pairwise summation (also known as cascade summation), which was first discussed by McCracken and Dorn [29, pp. 61–63], Babuška [1], and Linz [27]. In this method the x_i are summed in pairs,

$$y_i = x_{2i-1} + x_{2i}, \quad i = 1 : \left[\tfrac{n}{2}\right] \quad (y_{[(n+1)/2]} = x_n \text{ if } n \text{ is odd}),$$

and this pairwise summation process is repeated recursively on the y_i, $i = 1 : [(n+1)/2]$. The sum is obtained in $\lceil \log_2 n \rceil$ stages. For $n = 6$, for example, pairwise summation forms

$$S_6 = \big((x_1 + x_2) + (x_3 + x_4)\big) + (x_5 + x_6).$$

Pairwise summation is attractive in parallel settings, because each of the $\lceil \log_2 n \rceil$ stages can be done in parallel [13, §5.2.2]. Caprani [4] shows how to implement the method on a serial machine using temporary storage of size $\lceil \log_2 n \rceil$ (without overwriting the x_i).

The error expression (3.3) holds for pairwise summation, but it is easy to derive a useful error bound independently. Assume for simplicity that $n = 2^r$. Unlike in recursive summation each addend takes part in the same number of additions, $\log_2 n$. Therefore, analogously to (2.2), we have a relation of the form

$$\widehat{S}_n = \sum_{i=1}^{n} x_i \prod_{k=1}^{\log_2 n} (1 + \delta_k^{(i)}), \qquad |\delta_k^{(i)}| \le u,$$

which leads to the bound

$$|E_n| \le \gamma_{\log_2 n} \sum_{i=1}^{n} |x_i|. \tag{3.6}$$

This is a smaller bound than (2.6) for recursive summation, since it is proportional to $\log_2 n$ rather than n. However, in special cases the bound (2.5) for recursive summation can be smaller than (3.6). For example, if $x_i = 1/i^3$, the bound (3.6) is

$$|E_n| \le 1.20 \log_2 n\, u + O(u^2) \tag{3.7}$$

(using $\sum_{i=1}^{n} 1/i^3 \approx \sum_{i=1}^{\infty} 1/i^3 \approx 1.20$), while for the increasing ordering (2.5) becomes

$$|E_n| \le u \sum_{i=1}^{n} \frac{1}{(n-i+1)^3}(n-i+1) + O(u^2) = u \sum_{i=1}^{n} \frac{1}{i^2} + O(u^2) \approx 1.64u + O(u^2)$$

(using $\sum_{i=1}^{n} 1/i^2 \approx \sum_{i=1}^{\infty} 1/i^2 = \pi^2/6 \approx 1.64$), and so pairwise summation has the larger error bound, by a factor $\approx \log_2 n$. (Expression (3.3) does not enable us to improve on the factor $\log_2 n$ in (3.7).)

In [35] an "insertion adder" is proposed for the summation of positive numbers. This method can be applied equally well to arbitrary sums. First, the x_i are sorted by order of increasing magnitude. Then $x_1 + x_2$ is formed, and the sum is inserted into the list $x_2, \dots, x_n$, maintaining the increasing order. The process is repeated recursively until the final sum is obtained. The motivation given in [35] for this strategy is that it tends to encourage the additions to be between numbers of similar magnitude. It can be argued that such additions are to be preferred, because they retain more of the information in the addends (by comparison, "large" plus "small" may lose many significant digits from "small"). A more convincing explanation of the insertion strategy is that it attempts to minimize, one at a time, the absolute values of the terms $\widehat{T}_{n+1}, \dots, \widehat{T}_{2n-1}$ in the error expression (3.3). Indeed, if the x_i are all positive the insertion method minimizes the bound (3.4) over all methods of the form (3.1).

In particular cases the insertion method reduces to earlier methods. For example, if $x_i = 2^i$, the insertion method is equivalent to recursive summation, since the insertion is always to the bottom of the list:

$$1\,2\,4\,8 \quad \to \quad \underline{3}\,4\,8 \quad \to \quad \underline{7}\,8 \quad \to \quad 15.$$

On the other hand, if $1 \le x_1 < x_2 < \cdots < x_n \le 2$, every insertion is to the end of the list, and the method is equivalent to pairwise summation if n is a power of 2; for example, if $0 < \epsilon < \frac{1}{2}$,

$$1,\ 1+\epsilon,\ 1+2\epsilon,\ 1+3\epsilon \quad \to \quad 1+2\epsilon,\ 1+3\epsilon,\ \underline{2+\epsilon} \quad \to \quad 2+\epsilon,\ \underline{2+5\epsilon} \quad \to \quad 4+6\epsilon.$$

The next method we consider is the one used in [24], as quoted in the Introduction. This method can be derived by the following specious reasoning: "A major source of inaccuracy in floating point summation is cancellation when numbers of nearly equal magnitude and opposite sign are added. To minimize the amount of cancellation we can accumulate the sum of the positive numbers, S_+, and the sum of the negative numbers, S_-, separately, and then form $S_n = S_+ + S_-$." There are two flaws in this argument. First, this "$+/-$" method does not reduce the amount of cancellation—it simply concentrates all the cancellation into one step. Second, cancellation is not a bad thing per se; the problem with cancellation is that it brings into prominence any loss of significant digits suffered earlier in the calculation (and it also brings into prominence any uncertainty in the data). Indeed, nearly equal floating point numbers are always subtracted *exactly* (assuming the presence of a guard digit)—it is any (relative) uncertainty in those numbers that is magnified. For an excellent and more detailed discussion of cancellation, we refer the reader to [34, pp. 25–29].

The $+/-$ method is of the form (3.1) (assuming that S_+ and S_- are computed using one of the methods discussed so far) and it is easy to see that it maximizes $\max_k |T_k|$ over all methods of this form. Moreover, when $\sum_{i=1}^n |x_i| \gg |\sum_{i=1}^n x_i|$ the value of $\max_k |T_k|$ tends to be much larger for the $+/-$ method than for the other methods we have considered. For example, if $n = 2m$ and the x_i are the values $\{-1, 1, -2, 2, \dots, -m, m\}$ then

$$|S_+| = |S_-| = |T_{2n-2}| = \sum_{i=1}^{m} k = m(m+1)/2,$$

whereas for recursive summation with the increasing ordering, $|T_k| \le m$ for all k. Despite this weakness, if S_+ and S_- are computed by recursive summation with the increasing ordering then the $+/-$ method satisfies a bound very similar to (2.5): if

$$x_p \le x_{p-1} \le \cdots \le x_1 < 0 \le x_{p+1} \le \cdots \le x_n,$$

then it is straightforward to derive the bound

$$|E_n| \le \sum_{i=1}^{p} \gamma_{p-i+1}|x_i| + \sum_{i=p+1}^{n} \gamma_{n-i+1}|x_i| + \frac{u}{1-u}|\widehat{S}_n|. \tag{3.8}$$

In summary, the $+/-$ method appears to have no advantages over the other methods considered here, and in cases where there is heavy cancellation in the sum it can be expected to be the least accurate method.

The final method that we examine has an interesting background. In 1951, Gill [8] noticed that the rounding error in the sum of two numbers could be estimated by subtracting one of the numbers from the sum, and he made use of this estimate in a Runge–Kutta code in a program library for the EDSAC computer. Gill's estimate is valid for fixed point arithmetic only. Kahan [16] and Møller [31] both extended the idea to floating point arithmetic. Møller shows how to estimate $a + b - fl(a + b)$ in chopped arithmetic, while Kahan uses a slightly simpler estimate to derive a "compensated summation" method for computing $\sum_{i=1}^{n} x_i$. The use of Kahan's method with a Runge–Kutta formula is described in [41] (see also the experiments in [26]).

The estimate used by Kahan is perhaps best explained with the aid of a diagram. Let a and b be floating point numbers with $|a| \ge |b|$, let $\widehat{s} = fl(a + b)$, and consider Fig. 3.1, which uses boxes to represent the mantissas of a and b. The figure suggests that if we evaluate

$$e = -\big[\big((a+b) - a\big) - b\big] = \big(a - \widehat{s}\big) + b$$

in floating point arithmetic, in the order indicated by the parentheses, then the computed $\widehat{e}$ will be a good estimate of the error $(a + b) - \widehat{s}$. In fact, for rounded floating point arithmetic in base 2, we have

$$a + b = \widehat{s} + \widehat{e}, \tag{3.9}$$

that is, the computed $\widehat{e}$ represents the error exactly. This result (which does not hold for all bases) is proved by Dekker [5, Thm. 4.7], Knuth [22, Thm. C, p. 221], and Linnainmaa [26, Thm. 3]. Note that there is no point in computing $fl(\widehat{s} + \widehat{e})$, since $\widehat{s}$ is already the best floating point representation of $a + b$!

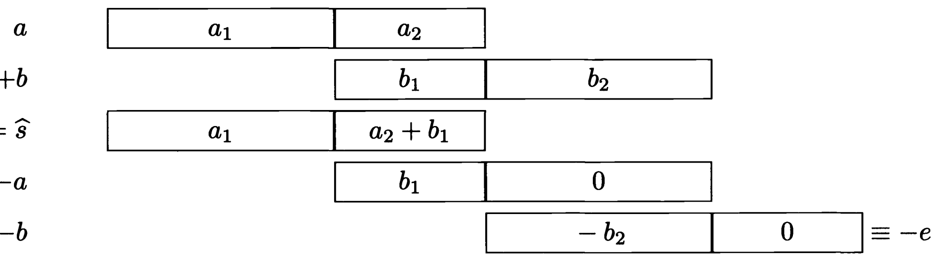

FIG. 3.1. *Recovering the rounding error.*

Kahan's compensated summation method employs the correction e on every step of a recursive summation. After each partial sum is formed, the correction is computed and immediately added to the next term x_i before that term is added to the partial sum.

Thus the idea is to capture the rounding errors and feed them back into the summation. The method may be written as follows.

```
$s = 0$; $e = 0$
for $i = 1{:}\,n$
    $temp = s$
    $y = x_i + e$
    $s = temp + y$
    $e = (temp - s) + y$
end
```

The compensated summation method has two weaknesses: $\widehat{e}$ is not necessarily the exact correction, since (3.9) is based on the assumption that $|a| \ge |b|$, and the addition $y = x_i + e$ is not performed exactly. Nevertheless, the use of the corrections brings a benefit in the form of an improved error bound. Knuth [22, Ex. 19, pp. 229, 572–573] shows that the computed sum $\widehat{S}_n$ satisfies

$$\widehat{S}_n = \sum_{i=1}^{n}(1+\mu_i)x_i, \qquad |\mu_i| \le 2u + O(nu^2), \tag{3.10}$$

which is an almost ideal backward error result (a more detailed version of Knuth's proof is given in [9]).

In [17] and [18], Kahan describes a variation of compensated summation in which the final sum is also corrected (thus "$s = s+e$" is appended to the algorithm above). Kahan states in [17] and proves in [18] that (3.10) holds with the stronger bound $|\mu_i| \le 2u+ O\big((n-i+1)u^2\big)$; note that with this bound for $|\mu_i|$, (3.10) is essentially (2.3) with the n dependency transferred from the u term to the u^2 term. The proofs of (3.10) given by Knuth and Kahan are similar, and involve a subtle induction using the model (1.2).

The forward error bound corresponding to (3.10) is

$$|E_n| \le \big(2u + O(nu^2)\big)\sum_{i=1}^{n}|x_i|. \tag{3.11}$$

As long as $nu \le 1$, the constant in this bound is independent of n, and so the bound is a significant improvement over the bounds (2.6) for recursive summation and (3.6) for pairwise summation. Note, however, that if $\sum_{i=1}^{n}|x_i| \gg |\sum_{i=1}^{n} x_i|$, compensated summation is not guaranteed to yield a small relative error.

Another version of compensated summation is described in [14], [15], [21], [32], and [33]. Here, instead of immediately feeding each correction back into the summation, the corrections are accumulated by recursive summation and then the global correction is added to the computed sum. For this version of compensated summation it is shown in [21] and [32] that

$$\widehat{S}_n = \sum_{i=1}^{n}(1+\mu_i)x_i, \qquad |\mu_i| \le 2u + n^2u^2, \tag{3.12}$$

provided $nu \le 0.1$; this is weaker than (3.10) in that the second-order term has an extra factor n. If $n^2u \le 0.1$ then in (3.12), $|\mu_i| \le 2.1u$. In [14], it is shown that by using a divide and conquer implementation of compensated summation the range of n for which $|\mu_i| \le cu$ holds in (3.12) can be extended, at the cost of a slight increase in the size of the constant c.

Finally, we mention briefly two further classes of algorithms. The first builds the sum in a series of accumulators, which are themselves added to give the sum. As originally described in [44], each accumulator holds a partial sum lying in a different interval. Each term x_i is added to the lowest level accumulator; if that accumulator overflows it is added to the next higher one and then reset to zero, and this cascade continues until no overflow occurs. Modifications of Wolfe's algorithm are presented in [28] and [36]. Malcolm [28] gives a detailed error analysis to show that his method achieves a relative error of order u. A drawback of the algorithm is that it is strongly machine dependent. An interesting and crucial feature of Malcolm's algorithm is that on the final step the accumulators are summed by recursive summation in order of *decreasing* absolute value, which in this particular situation precludes severe loss of significant digits and guarantees a small relative error.

Another class of algorithms, referred to as "distillation algorithms" by Kahan [19], iteratively constructs floating point numbers $x_1^{(k)}, \ldots, x_n^{(k)}$ such that $\sum_{i=1}^n x_i^{(k)} = \sum_{i=1}^n x_i$, terminating when $x_n^{(k)}$ approximates $\sum_{i=1}^n x_i$ with relative error at most u. Kahan states that these algorithms appear to have average run times of order at least $n \log n$. See [3], [19], [25] and [23] for further details and references.

4. Statistical estimates of accuracy. As we have noted, rounding error bounds can be very pessimistic, because they account for the worst-case propagation of errors. An alternative way to compare summation methods is through statistical estimates of the error, which may be more representative of the average case. A statistical analysis of three summation methods has been given by Robertazzi and Schwartz [35] for the case of nonnegative x_i. They assume that the relative errors in floating point addition are statistically independent and have zero mean and finite variance σ^2. Two distributions of nonnegative x_i are considered: the uniform distribution on $[0, 2\mu]$, and the exponential distribution with mean μ. Making various simplifying assumptions Robertazzi and Schwartz estimate the mean square error (that is, the variance of the absolute error) of the computed sums from recursive summation with random, increasing, and decreasing orderings, and from insertion summation and pairwise summation. Their results for the summation of n numbers are given in Table 4.1.

TABLE 4.1
Mean square errors.

Distribution	Increasing	Random	Decreasing	Insertion	Pairwise
Unif$(0, 2\mu)$	$0.20\mu^2n^3\sigma^2$	$0.33\mu^2n^3\sigma^2$	$0.53\mu^2n^3\sigma^2$	$2.6\mu^2n^2\sigma^2$	$2.7\mu^2n^2\sigma^2$
Exp(μ)	$0.13\mu^2n^3\sigma^2$	$0.33\mu^2n^3\sigma^2$	$0.63\mu^2n^3\sigma^2$	$2.6\mu^2n^2\sigma^2$	$4.0\mu^2n^2\sigma^2$

The results show that for recursive summation the ordering affects only the constant in the mean square error, with the increasing ordering having the smallest constant and the decreasing ordering the largest; since the x_i are nonnegative, this is precisely the ranking given by the rounding error bound (2.8). The insertion and pairwise summation methods have mean square errors proportional to n^2 rather than n^3 for recursive summation, and the insertion method has a smaller constant than pairwise summation. This is also consistent with the rounding error analysis, in which for nonnegative x_i the insertion method satisfies an error bound no larger than pairwise summation, and the latter method has an error bound with a smaller constant than for recursive summation ($\log_2 n$ versus n).

5. No guard digit model. The model (1.2) on which our error analysis is based is not valid on machines that lack a guard digit in addition, notable examples of which are Cray computers. On Cray computers, subtracting any power of 2 from the next smaller floating point number gives an answer that is either a factor of 2 too large or is zero, so the expression $fl(x+y) = (x+y)(1+\delta)$ holds with $|\delta| = 1$ but not with $|\delta| = O(u)$ [20]. For machines without a guard digit we have to use the weaker model [43, p. 12]

$$fl(x \pm y) = x(1+\alpha) \pm y(1+\beta), \qquad |\alpha|, |\beta| \le u. \tag{5.1}$$

We now summarize the effect on the rounding error analysis of using (5.1) in place of (1.2). The equality (2.4) remains valid provided we replace $(x_1+x_2)\theta_{n-1}$ by $x_1\theta_{n-1} + x_2\theta'_{n-1}$, so (2.5) and (2.6) are unchanged. The error expression (2.7) has to be replaced by

$$E_n = \sum_{k=2}^{n} (\widehat{S}_{k-1}\alpha_k + x_i\beta_k), \qquad |\alpha_k|, |\beta_k| \le u, \tag{5.2}$$

and so the analog of (2.8) is

$$|E_n| \le u \sum_{k=2}^{n} (|\widehat{S}_{k-1}| + |x_k|), \tag{5.3}$$

which is bounded above by $3u\sum_{k=1}^{n}|\widehat{S}_k| + O(u^2)$. Notice that (5.3) contains the term $\widehat{S}_1 = x_1$, which is not present in (2.8). The error expression (3.3) has to be replaced by an expression analogous to (5.2), and in (3.5) the factor $n-1$ has to be replaced by n. The bound (3.6) for pairwise summation remains valid under the no guard digit model, while in the bound (3.8) for the $+/-$ method we have to replace $u/(1-u)|\widehat{S}_n|$ by $u(|\widehat{S}_+| + |\widehat{S}_-|)$, which is bounded by $u\sum_{i=1}^{n}|x_i| + O(u^2)$.

Neither the correction formula (3.9) nor the result (3.10) for compensated summation holds under the no guard digit model. Indeed, Kahan [20] constructs an example where compensated summation fails to achieve (3.11) on Cray machines, but he states that such failure is extremely rare. In [17] and [18], Kahan gives a modification of the compensated summation algorithm in which the assignment "$e = (temp - s) + y$" is replaced by

```
$f = 0$
if sign($temp$) = sign($y$), $f = (0.46 * s - s) + s$, end
$e = ((temp - f) - (s - f)) + y$
```

Kahan shows in [18] that the modified algorithm achieves (3.10) "on all North American machines with floating hardware" and explains that, "the mysterious constant 0.46, which could perhaps be any number between 0.25 and 0.50, and the fact that the proof requires a consideration of known machines designs, indicate that this algorithm is not an advance in computer science."

6. Numerical experiments. In this section we describe some numerical experiments that give further insight into the accuracy of summation methods. All the experiments were done using MATLAB [30], which uses IEEE standard double precision arithmetic with unit roundoff $u \approx 1.1 \times 10^{-16}$.

First, we illustrate the behavior of the methods on four classes of data $\{x_i\}$ chosen a priori. In these tests we simulated single precision arithmetic of unit roundoff

$u_{SP} = 2^{-23} \approx 1.2 \times 10^{-7}$ by rounding the result of every arithmetic operation to 23 significant bits. We formed an approximation to the exact answer S_n by summing the single precision numbers x_i in double precision by recursive summation; in each case $nu \sum_{i=1}^{n} |x_i| < u_{SP}|S_n|$, so (2.6) guarantees that this approximation is correct to single precision. We give results for recursive summation with the original (Orig.), increasing (Inc.), decreasing (Dec.), and Psum orderings, and for the insertion (Ins.) method, the $+/-$ method (with S_+ and S_- computed by recursive summation with the increasing ordering), pairwise summation with the increasing ordering (Pair.), and compensated summation (Comp.).

The numbers reported are the relative error $|\widehat{S}_n - S_n|/|S_n|$, together with information that indicates the sharpness of the bounds. In square brackets is the value $T = \sum_{k=n+1}^{2n-1} |\widehat{T}_k|$ in (3.4), for all methods except compensated summation. In parentheses is the ratio $R = |\widehat{S}_n - S_n|/(u_{SP}\sum_{i=1}^{n} |x_i|)$, which, according to the error analyses, is certainly bounded (to first order) by n for recursive summation and the insertion and $+/-$ methods, $\log_2 n$ for pairwise summation, and 2 for compensated summation. The quantities T and R reveal how close the strongest and weakest of the error bounds are to being equalities.

(1) In the first example, x_i is the ith term in the Taylor series expansion of e^{-x} about the origin, with $x = 2\pi$ (this series provides the classic example of "catastrophic cancellation" [37]). Results for $n = 64$ are given in Table 6.1. In this example, recursive summation with the decreasing ordering yields by far the best accuracy. There is severe cancellation in the sum and the decreasing ordering allows the terms of smallest modulus to contribute fully to the computed sum; in the other methods the small terms are "swamped" by the large terms. The error bounds do not reflect the merit of the decreasing ordering, because the T terms (in square brackets in the table) are of similar magnitude for the first four methods. Note also that compensated summation produces no improvement over recursive summation with the original ordering, and the $+/-$ method yields one less correct significant figure than all the other methods (as predicted by the T values).

TABLE 6.1
x_i from $e^{-2\pi}$ expansion. $|\sum_{i=1}^{n} x_i| / \sum_{i=1}^{n} |x_i| = 3.48e-6$.

n	Orig.	Inc.	Dec.	Psum	Pair.	Ins.	$+/-$	Comp.
64	5.11e−4	2.27e−3	1.85e−7	2.27e−3	1.41e−4	2.27e−3	1.86e−2	5.11e−4
	[2.68e2	2.97e2	2.97e2	2.85e2	8.68e1	2.97e2	1.34e3]	
	(1.49e−2	6.64e−2	5.40e−6	6.64e−2	4.13e−3	6.64e−2	5.44e−1	1.49e−2)

(2) In this example the x_i are random numbers from the Normal(0,1) distribution and we report the results for $n = 2048$ and 4096 in Table 6.2. There is cancellation in both sums, although not as much as in the first example. Here the Psum ordering is clearly the best and the $+/-$ ordering the worst, and this is reflected in the T values.

The next two tests involve positive x_i, for which all the methods are guaranteed to produce a relative error no larger than $f(n)u$, where $f(n) \le n$ depends on the method. (Note that for positive x_i, "Psum $\equiv +/- \equiv$ Inc.")

(3) We take $x_i = 1/i^2$ and examine how the errors vary with n for recursive summation with the decreasing and increasing orderings. Results for $n = 500, 1000, \ldots, 5000$ are given in Table 6.3. As would be expected in view of the error bounds of §2, the decreasing ordering provides much lower accuracy than the increasing ordering when n is large.

TABLE 6.2
x_i from Normal (0,1) *distribution.* $|\sum_{i=1}^n x_i|/\sum_{i=1}^n |x_i| = 8.08e-3 (n = 2048), 3.48e-3 (n = 4096)$.

	(2.35e−1	3.04e−1	5.38e−2	7.76e−4	4.04e−3	2.00e−2	1.07e1	5.59e−3)

TABLE 6.3
$x_i = 1/i^2$.

n	500	1000	2000	3000	4000	5000
Inc.	1.04e−7	1.01e−7	1.74e−8	5.22e−8	1.36e−7	3.90e−8
Dec.	3.31e−7	6.24e−7	5.64e−6	2.30e−5	2.77e−5	5.81e−5

(4) In this example the numbers x_i are equally spaced on $[1, 2]$. We tried various $n \leq 4096$ and did not observe a great difference between the increasing and decreasing orderings; this is to be expected since the x_i vary little in magnitude. For the fairly large n in Table 6.4 pairwise summation out-performs recursive summation (the insertion method is equivalent to pairwise summation in this example). The errors for compensated summation are zero for all the n we tried!

TABLE 6.4
x_i equispaced on $[1, 2]$.

	[1.12e7	1.40e7	7.37e4]	
	(2.81e2	1.83e2	1.33e0	0.00)

In the next set of tests we used a MATLAB implementation [12] of the multidirectional search (MDS) method [39], [40] which attempts to locate a maximizer of $f : \mathbb{R}^n \to \mathbb{R}$ using function values only. We applied the maximizer to f defined as the relative error of the sum computed in single precision by recursive summation with the increasing ordering. With $n = 3$, starting with $x_0 = [\frac{1}{3}, \frac{2}{3}, 1]$, the maximizer located the following set of data after 280 function evaluations:

$$\begin{aligned} x &= [4.975987 \quad -2.495094 \quad -2.480894], \qquad f(x) = 1.0, \\ \widehat{S}_3 &= -9.5367 \times 10^{-7}, \qquad S_3 = -4.7684 \times 10^{-7}, \end{aligned}$$

where x and the S_3 values are quoted to seven and five significant figures, respectively. With f defined as the relative error for compensated summation, the MDS maximizer made little progress with the same starting value. But starting with $x_0 = [-\frac{1}{3}, 0, \frac{2}{3}]$, the maximizer found after 166 function evaluations the data

$$\begin{aligned} x &= [-0.8308306 \quad -0.7626623 \quad 1.593493], \qquad f(x) = 1.0, \\ \widehat{S}_3 &= 2.3842 \times 10^{-7}, \qquad S_3 = 1.1921 \times 10^{-7}. \end{aligned}$$

(If x is reordered with the increasing ordering then $f(x) = 1.0$, but $f(x) = 0$ for the decreasing ordering.)

These two examples are typical—using the maximizer it is straightforward to find data for which any of the summation methods yields no correct significant figures in the sum. The maximizer can also be used to compare two different methods, by defining f as the ratio of the errors from the two methods. With $n = 3$ we compared recursive summation (with the increasing ordering) with compensated summation. For both ratios of errors (E(Inc.)/E(Comp.) and its reciprocal) with certain starting values the maximizer was able to make the ratio arbitrarily large, by converging to data for which the error forming the denominator of f is zero. We observed similar behavior when comparing other methods.

Next, we describe an experiment with the forward substitution algorithm for solving a lower triangular system. We coded the inner product version of the algorithm and provided an option to choose between eight summation methods when evaluating the inner products. (The column-oriented form of forward substitution is not amenable to the use of different summation methods.) Lower triangular systems $Tx = b$ were solved in single precision and the forward error $\|\widehat{x} - x\|_\infty / \|x\|_\infty$ was evaluated for each of the eight summation options. We give results for $T = U^T$ where $PA = LU$ is the LU factorization with partial pivoting of the 10×10 Vandermonde matrix whose (i, j) element is $((j-1)/(n-1))^{i-1}$. In Table 6.5 we report results for the two systems with right-hand sides $b_i = Tx_i$, where x_i has elements equally spaced on the intervals $[1, 100]$ for $i = 1$ and $[0, 100]$ for $i = 2$. For this matrix $\kappa_\infty(T) = \|T\|_\infty \|T^{-1}\|_\infty \approx 3 \times 10^7$, and $\text{cond}(T, x_1) \approx \text{cond}(T, x_2) \approx 7 \times 10^5$, where $\text{cond}(T, x) = \| \, |T^{-1}||T||x| \, \|_\infty / \|x\|_\infty \le \kappa_\infty(T)$ is the condition number that appears in a forward error bound for the substitution algorithm [11]. The forward error varies over the different summation methods by a factor 98 for b_1 and a factor 39 for b_2; these are the largest variations we observed in tests with a variety of different matrices and right-hand sides. Throughout the tests there was no pattern to which summation method led to the smallest or largest forward error. This experiment shows that the choice of summation method for inner product evaluation can significantly affect the accuracy achieved by forward substitution, and this conclusion applies a fortiori to the solution of a full system via LU factorization. However, since there appears to be no straightforward way to predict which summation method will be the best for a given linear system, there is little reason to use anything other than recursive summation in the natural order when evaluating inner products within a general linear equation solver.

TABLE 6.5
Forward substitution with a 10×10 *matrix.*

	Orig.	Inc.	Dec.	Psum	Pair.	Ins.	+/−	Comp.
b_1	3.01e-4	1.18e-2	7.70e-3	1.18e-2	2.94e-2	1.18e-2	4.01e-3	7.70e-3
b_2	1.31e-2	2.64e-2	4.63e-3	2.64e-2	6.81e-4	1.06e-2	2.64e-2	2.04e-2

We have also experimented with compensated summation with the data arranged in order of decreasing magnitude. For all the problems we have tried, including those described above, the relative errors are $\le u_{SP}$. Our attempts to use the MDS maximizer to find a set of x_i for which the relative error exceeds u_{SP} have been unsuccessful. It is therefore natural to ask whether a relative error bound of the form $|E_n| \le cu|S_n|$ can be derived, where c is a constant independent of the x_i. The answer is no, because E_n can

can be nonzero when $S_n = 0$. Even when $n = 3$ and $S_n \neq 0$ it appears to be impossible to obtain such a bound. Nevertheless, our (limited) experience suggests that compensated summation with the decreasing ordering performs remarkably well in practice, and it would be interesting to determine why this is so.

Further test results can be found in the literature, although none are extensive. Linz [27] compares recursive summation with pairwise summation for uniform random numbers on $[0, 1]$ with $n = 2048$, averaging the errors over 20 trials, and Caprani [4] and Gregory [10] both conduct a similar experiment including compensated summation as well. Linnainmaa [26] applies recursive summation and compensated summation to series expansions, Simpson's rule for quadrature and Gill's Runge–Kutta method. Robertazzi and Schwartz [35] evaluate average mean square errors for recursive summation (with increasing, decreasing, and random orderings), pairwise summation and the insertion method, for the uniform $[0, 1]$ and exponential ($\mu = 0.5$) distributions with $n \leq 4096$.

7. Concluding remarks. No summation method from among those considered here can be regarded as superior to the rest from the point of view of accuracy, since for each method the error can vary greatly with the data, within the freedom afforded by the error bounds. However, some specific conclusions can be drawn.

1. For all but two of the methods the errors are, in the worst case, proportional to n. If n is very large, pairwise summation (error constant $\log_2 n$) and compensated summation (error constant of order 1) are attractive.

2. If the x_i all have the same sign, then all the methods yield a relative error of at most nu, and compensated summation guarantees perfect relative accuracy (as long as $nu \leq 1$). For recursive summation of one-signed data the increasing ordering is preferable to the decreasing ordering (and it is equivalent to the Psum ordering); however, the insertion method has the smallest bound (3.4) over all the methods considered here (excluding compensated summation).

3. For sums with heavy cancellation ($\sum_{i=1}^{n} |x_i| \gg |\sum_{i=1}^{n} x_i|$) recursive summation with the decreasing ordering is attractive (see Table 6.1), although it cannot be guaranteed to achieve the best accuracy (see Table 6.2).

Considerations of computational cost and the way in which the data are generated may rule out some of the methods. Recursive summation in the natural order, pairwise summation, and compensated summation can be implemented in $O(n)$ operations for general x_i, but the other methods are more expensive since they require searching or sorting. Furthermore, in an application such as the numerical solution of ordinary differential equations where the x_i are generated sequentially, and x_k may depend on $\sum_{i=1}^{k-1} x_i$, sorting and searching may be impossible. One way to achieve higher accuracy that we have not mentioned is simply to implement recursive summation in higher precision; if this is feasible, it may be less expensive (and more accurate) than using one of the alternative methods in working precision.

Finally, we return to the two practical applications mentioned in the introduction. In [24], the $+/-$ method was found to cure some problems with inaccurate gradients in an optimization method. This is a little surprising since we have found the $+/-$ method to be unattractive. It appears that there is some feature of this application, not apparent from [24], that encourages the $+/-$ method to perform better than recursive summation with the natural ordering. The loss of symmetry in a quasi-Newton method that was observed in [7] is easier to understand. For example, symmetries in F in (1.1) can be preserved by using any summation method whose computed answer does not depend on the given order of the data—such as recursive summation with the increasing ordering and with elements of equal magnitude ordered by sign.

Acknowledgments. I thank Jeremy Du Croz and Philip Gill for providing some of the references, and Des Higham, Nick Trefethen, and the referee for suggesting improvements to the manuscript.

ADAPTIVE LINEAR EQUATION SOLVERS IN CODES FOR LARGE STIFF SYSTEMS OF ODES*

K. R. JACKSON[†] AND W. L. SEWARD[‡]

Abstract. Iterative linear equation solvers have been shown to be effective in codes for large systems of stiff initial-value problems for ordinary differential equations (ODEs). While preconditioned iterative methods are required in general for efficiency and robustness, unpreconditioned methods may be cheaper over some ranges of the interval of integration. In this paper, a strategy is developed for switching between unpreconditioned and preconditioned iterative methods depending on the amount of work being done in the iterative solver and properties of the system being solved. This strategy is combined with a "type-insensitive" approach to the choice of formula used in the ODE code to develop a method that makes a smooth transition between nonstiff and stiff regimes in the interval of integration. As expected, it is found that for some large systems of ODEs, there may be a considerable saving in execution time when the type-insensitive approach is used. If there is a region of the integration that is "mildly" stiff, switching between unpreconditioned and preconditioned iterative methods also increases the efficiency of the code significantly.

Key words. type-insensitive ODE code, iterative linear solver, preconditioning

AMS subject classifications. 65L05, 65F10

1. Introduction.

In recent years, there have been several investigations of the use of iterative linear equation solvers in codes for the numerical solution of large systems of stiff initial-value problems (IVPs) for ordinary differential equations (ODEs). See, for example, [5], [6], [8], and [12]. Such work has established clearly the potential effectiveness of the combination of these methods, but there are many open questions concerning both the choice of iterative method and the way in which it interacts with strategies used in the ODE solver. Frequently, the iterative methods investigated have been of the "Krylov subspace" type, e.g., the conjugate gradient method, Orthomin [22], or GMRES [6]. In this paper, we also consider an iterative method of this type, but our results should apply to a broader class since we are primarily concerned with the interaction between the iterative method and the other strategies of the ODE solver.

We study the numerical solution of large systems of stiff IVPs for ODEs of the form

$$y' = f(t, y), \qquad y(t_0) \text{ given.} \tag{1}$$

Due to the stiffness, such problems are usually discretized using an implicit numerical method, most often the backward differentiation formulas (BDFs) [11]. We will concentrate on the BDFs, although many of our ideas apply to implicit numerical methods in general. Applied to (1), a k-step BDF has the form

$$y_n = \sum_{j=1}^{k} \alpha_n^j y_{n-j} + h_n \beta_n f(t_n, y_n). \tag{2}$$

To find y_n from (2), it is necessary to solve a system of equations of the form

$$F(y_n) = y_n - h_n \beta_n f(t_n, y_n) - \phi_n = 0, \tag{3}$$

*Received by the editors August 5, 1991; accepted for publication (in revised form) July 15, 1992. This work was supported in part by the Natural Sciences and Engineering Research Council of Canada and by the Information Technology Research Centre of Ontario.

where ϕ_n contains the terms in (2) that do not depend on y_n. In general, this system is nonlinear and is solved by Newton's method or some variant of it.

The usual form of Newton's method is

```
• select an initial guess $y_n^0$
• for $l = 0, 1, \ldots$
    —solve $F_y(y_n^l)\Delta_n^l + F(y_n^l) = 0$ for $\Delta_n^l$,
    —set $y_n^{l+1} = y_n^l + \Delta_n^l$,
```

where $F_y(y_n^l) = I - h_n\beta_n f_y(t_n, y_n^l)$. Most ODE codes use a chord method (often called a pseudo- or simplified-Newton method) in which $F_y(y_n^l)$ is replaced by some approximation W_n^l, generally the Newton iteration matrix F_y (or some approximation to it) from some earlier timestep. If the system of ODEs (1) is large, the linear algebra cost of the *solve* step is normally a major part of the cost of the integration. If W_n^l is sparse, as is usually the case for large systems, exploiting the sparsity can be an effective means of reducing this cost. Using a direct sparse matrix solver in Newton's method is reasonably straightforward and has been discussed in the context of ODE solvers by, for example, Berzins and Furzeland [3] and Sherman and Hindmarsh [19]. Chan and Jackson [8] compare direct and iterative methods in this context. In this paper, we concentrate on the use of iterative solvers.

When an iterative linear equation solver is used in the *solve* phase of Newton's method, an *inexact Newton method* [10] is obtained. In general, such a method has the form

```
• select an initial guess $y_n^0$
• for $l = 0, 1, \ldots$
    —find $\Delta_n^l$ satisfying $F_y(y_n^l)\Delta_n^l + F(y_n^l) = d_n^l$ for $d_n^l$ "sufficiently small,"
    —set $y_n^{l+1} = y_n^l + \Delta_n^l$.
```

This iteration converges at least linearly if

$$\|d_n^l\| \le \eta_l \|F(y_n^l)\|, \tag{4}$$

where $0 \le \eta_l \le \eta < 1$. In the case where an iterative linear equation solver is used to find y_n^l, the residual d_n^l is the final residual of the linear iteration.

Brown and Hindmarsh [5] consider iterative linear equation solvers based on Arnoldi's method for use in the ODE code LSODE [14]. In their approach, the matrix-vector product required in the iterative method is approximated by a finite difference based on f. This approach avoids explicitly forming the iteration matrix W_n^l needed in Newton's method and hence has been referred to as a "matrix-free" method. These methods are very efficient in storage and, as predicted by the theory of Krylov subspace methods [5], converge quickly if the eigenvalues of W_n^l are clustered. If this is not the case, preconditioning is usually required for efficiency and robustness in the ODE solver. In [6], preconditioning strategies for use with the "matrix-free" approach are discussed. These strategies require formation and storage of at least part of W_n^l in general, but are still very efficient in terms of storage. The authors find that, with preconditioning, a wider class of problems can be solved efficiently.

Chan and Jackson [8] also investigate both unpreconditioned and preconditioned Krylov-type iterative methods used with LSODE. The methods they use are not "matrix-free"—W_n^l is formed, stored and used explicitly to compute the matrix-vector products needed in the iterative method. The authors consider various ways of reducing the amount of time spent in forming and processing W_n^l. For example, if preconditioning is not being used, they show that it is not difficult to keep the factor $h_n\beta_n$ in W_n^l current, thus requiring fewer Jacobian evaluations for the integration.

Hence we observe that, for a variety of reasons, unpreconditioned iterative methods can be cheaper to use than preconditioned ones in stiff ODE solvers. However, preconditioning appears necessary in general for efficiency and robustness. This observation led us to study an adaptive approach to switching preconditioning on and off. In particular, if the eigenvalues of the Newton iteration matrix W_n^l are clustered, which always occurs when h_n is small, preconditioning may not be necessary. In other cases, it is likely that the number of iterations of the linear equation solver can be reduced significantly by preconditioning.

Instead of not preconditioning at all, our method uses *diagonal scaling*, a cheap preconditioner described in more detail below, when this seems to be effective, but switches to a more powerful preconditioner based on W_n^l when diagonal scaling appears to be ineffective. We expect that CPU time can be saved by avoiding unnecessary expensive preconditioning without sacrificing robustness since preconditioning is available when necessary.

The idea of switching preconditioning on and off combines naturally with the use of a "type-insensitive" ODE solver. A type-insensitive code switches between methods appropriate for nonstiff and stiff IVPs depending on the nature of the problem. This approach has been discussed by several authors for a variety of formulas. See, for example, [4], [15]–[18]. Petzold [16] developed a type-insensitive method based on the Adams formulas [11] and the BDFs that switches between the two classes of formulas based on Jacobian information and behaviour of the code. We have combined the ideas from [16] with our adaptive approach to preconditioning. Our code starts integrating with the Adams formulas and switches to the BDFs as described by Petzold. When this switch is made, the linear equation solver uses diagonal scaling only. Later the method may switch to a more expensive preconditioner described below. It can switch back to diagonal scaling and to the Adams formulas, if it predicts they will be more cost effective.

The basic iterative linear equation solver that we use is Orthomin [22]. Other reasonable choices include GMRES [5] and the stabilized version of the conjugate-gradient-squared (CGS) algorithm [21]. To focus on adaptive preconditioning, we chose to use one basic iterative solver only. We selected the well-known scheme Orthomin, in part because an effective implementation of it along with several preconditioners was readily available to us.

There is a variety of possible approaches for the "cheap" preconditioning. We could use no preconditioning at all, in which case a "matrix-free" method or an approach that updates $h_n\beta_n$ frequently might be very efficient. This approach would allow us to avoid forming W_n^l entirely or to form it infrequently during this phase. However, there may be hidden costs associated with such methods. For example, a "matrix-free" method requires one function evaluation per linear iteration. Forming the Newton iteration matrix W_n^l explicitly, on the other hand, is frequently a relatively inexpensive operation for a large sparse system of ODEs, costing a few function evaluations only.

In our numerical experiments, we chose to form W_n^l explicitly, according to the heuristics of the basic ODE solver, and to use diagonal scaling (that is, preconditioning by a diagonal matrix to make the diagonal elements of W_n^l all ones) as our cheap preconditioner. The improvement in performance when diagonal scaling is used can be significant even though the cost is low. Moreover, diagonal scaling often reduces the cost of the iterative solver since it is not necessary to multiply by the matrix diagonal in this case when computing matrix-vector products. So there is little point to omitting diagonal scaling if W_n^l is computed explicitly. Furthermore, diagonal scaling can be used with other approaches to forming W_n^l (see [5], for example, for a discussion of scaling with "matrix-free" methods), but we have not attempted any elaboration of our basic approach. For brevity, in the remainder of the paper, we occasionally refer to an iterative method with diagonal scaling only as an unpreconditioned method.

A more powerful preconditioner is switched on if diagonal scaling appears to be ineffective. The particular preconditioning strategies that we have studied are Level 0 and Level 1 incomplete LU (ILU) factorizations, as described in §2. We note that diagonal scaling is also used with the ILU preconditioners, as it is often found to improve their performance. These preconditioning strategies can be applied to any matrix in a "black box" fashion, and have been found to work well in solving time-dependent partial differential equations (PDEs). (See, for example, [1], [2], and [9].) While these preconditioners depend on the explicit presence of the Jacobian matrix, the idea of switching between preconditioners should be useful whenever a variety of strategies of differing costs are available.

We also develop criteria for switching these preconditioners off, and this is the only place in our adaptive strategy where we use Jacobian information directly. Our strategy looks at both the performance of the iterative solver and the spread of the eigenvalues of the Newton iteration matrix W_n^l. The eigenvalue information is useful since fast convergence of the iterative solver might be primarily due to the preconditioner. We have not investigated the case in which the Jacobian is not available explicitly. In most cases, the development of a good preconditioner requires at least some Jacobian information which could be used in our test, possibly in a more conservative form.

In the next section, we briefly describe the codes that were used in this investigation. Heuristics for identifying when to switch preconditioning on and off are discussed in §3. The use of adaptive preconditioning in type-insensitive codes is considered in §4. Test problems and numerical results are presented in both §3 and §4 to illustrate the performance of the techniques. We end with some conclusions in §5.

2. Codes used in the investigation. The ODE package used in this investigation was SPRINT [3]. This package is designed to offer the user a range of methods for the numerical solution of systems of IVPs in ODEs. It allows the user to select from four timestepping methods and three linear algebra packages to create the complete method appropriate for a particular problem. The three algebra routines are full, banded, and sparse direct solvers. Because of this modularity, the SPRINT package is well suited for testing the interaction of the iterative linear algebra solver with the ODE method, since it is possible to couple our iterative solver to a sophisticated, fully developed timestepping scheme.

SPRINT includes a space discretization module, but for one-dimensional PDE systems only. Consequently, the higher-dimensional PDE test problems used in this paper have been semidiscretized in space by our own routines. One motivation for our study of iterative linear solvers is the current work being done with SPRINT to develop modules for spatial discretization of PDE systems in higher dimensions.

The particular ODE method used in this investigation is based on the BDFs and is similar in implementation to the well-known code LSODE [14]. A variant of LSODE, called LSODA, was written by Hindmarsh and Petzold to incorporate the ideas for a type-insensitive method described in [16]. Our type-insensitive ODE solver was developed by altering the SPRINT BDFs module corresponding to the changes made to evolve LSODE into LSODA.

The iterative solver used in our study, WATSIT, was developed at the University of Waterloo based on methods described in [1], [2], and [9]. This code is designed to solve systems of linear equations of the form $Ax = b$ where the matrix A is large and sparse. The basic technique is an incomplete factorization scheme with acceleration. The user has several choices for both the acceleration method and the incomplete factorization. Possible acceleration methods include the conjugate gradient method, Orthomin [22], the CGS algorithm [20], and a stabilized version of CGS [21]. As noted in §1, since we wish to focus on our adaptive strategy in this paper, we use Orthomin acceleration only in our numerical tests and have not encountered any test problems where it breaks down.

The user has the choice of diagonal scaling only or preconditioning based on either Level 0 or Level 1 ILU factorization, denoted ILU(0) and ILU(1), respectively. These preconditioners are defined by discarding all or some of the fill elements that would arise during a complete LU decomposition of the matrix associated with the system to be solved. ILU(0), the simpler of the two preconditioners, discards all fill elements. Thus, this preconditioner has the same sparsity structure as the original matrix, which can be an advantage since the storage requirement is known a priori. The more powerful ILU(1) preconditioner retains the fill generated by eliminating the original nonzero elements. These and other more powerful preconditioners may reduce the number of iterations required to solve a linear system, although each iteration with a more powerful preconditioner is generally more expensive than one with diagonal scaling or no preconditioner at all. Whether a more powerful, but more expensive, preconditioner will be more cost effective than a weaker, but less expensive, one depends on the linear system to be solved. Further discussion of ILU preconditioners can be found in [9] and [13].

In Brown and Hindmarsh [5], convergence criteria for the iterative method are discussed in detail in the context of an ODE code. Both Brown and Hindmarsh [5] and Chan and Jackson [8] find that the residual reduction condition (4) is overly expensive: it forces linear iterations that do not seem to improve the accuracy of the ODE solution significantly. In [5], the authors propose and justify a strategy that accepts the result produced by the iterative linear solver if the residual is some small fraction of the tolerance level required on the solution of the nonlinear system. A similar strategy was developed in [8]. We adopt this approach and also use the same fraction that is suggested in [5], namely, $1/20$. The residual is measured in the weighted norm used by the ODE solver. Since the acceleration methods used in WATSIT return the residual directly, we do not need to scale the matrix to obtain the weighted norm, as is done in [5]. The linear iteration is started with a zero vector as its initial guess and always does at least one iteration. If the maximum iteration count is reached without the desired reduction of the residual on the first Newton iteration, the code accepts Δ_n^0 and updates $y_n^1 = y_n^0 + \Delta_n^0$ provided that the current residual, $F_y(y_n^0)\Delta_n^0 + F(y_n^0) = d_n^0$, is smaller than the initial one, $F(y_n^0)$. Otherwise, a failure is signalled to the ODE solver and either the Newton iteration or the timestep is retried, according to the criteria in the ODE code for a failure of Newton's method.

All numerical results reported in this paper were computed in double precision on an MIPS M/120 RisComputer.

3. Adaptive preconditioning.

In this section, the adaptive choice of preconditioning method is discussed independently of the type-insensitive approach for solving stiff ODEs. The two ideas are combined in §4. To develop strategies for switching between preconditioning methods, we need to assess the relative cost of the preconditioners as well as the expected saving when the switch is made.

For a particular iterative method and implementation, it is straightforward to estimate the relative cost of preconditioning by counting floating-point operations in the code. For simplicity, we estimate this operation count based on the number of elements per row of the matrix. If the original matrix has on average *nrow* nonzero elements per row and the preconditioned matrix has on average *pnrow* elements, then, for our implementation of Orthomin, the following table gives the costs for a matrix of dimension *neq*, where the cost of diagonal scaling is included in all cases.

Operation counts for the iterative methods.

Scheme	Initialization	k iterations
No pre	$(2\,nrow + 4)\;neq$	$(2\,nrow + 11)\;neq\;k + 3\;neq\;k\,(k-1)$
Pre	$(2\,pnrow + 4)\;neq$	$(4\,pnrow + 12)\;neq\;k + 3\;neq\;k\,(k-1)$

For example, for the heat equation $u_t = u_{xx} + u_{yy} + u_{zz}$ in three space dimensions and a centered finite difference spatial discretization, $nrow = 7$; for ILU(0), $pnrow = 7$; and, for ILU(1), $pnrow = 13$. Using these values, we can calculate the relative costs for different iteration counts shown in Table 1. We note that the iterations with ILU(0) preconditioning are only about 40% more expensive than those that use only diagonal scaling. Of course, the ILU-preconditioned iterations incur the extra cost of doing the ILU factorization, $O(pnrow^2 \cdot neq)$ floating-point operations. This cost is roughly that of doing a few linear iterations. Since we are using a chord method rather than full Newton iteration, and the factorization is only done when found necessary by the ODE solver, this cost is small compared to the total cost of linear iterations. We do not include here the cost of forming the matrix W_n^l, since this is done in all cases. If the cheap preconditioning strategy also avoided the formation of W_n^l, then forming W_n^l would be an additional cost of using a more powerful preconditioner.

TABLE 1
Relative cost of iterative methods applied to the heat equation.

Iterations	Scaling	ILU(0)	ILU(1)
1	43 *neq*	58 *neq*	94 *neq*
2	74 *neq*	104 *neq*	164 *neq*
3	111 *neq*	156 *neq*	240 *neq*
4	154 *neq*	204 *neq*	322 *neq*
5	203 *neq*	278 *neq*	410 *neq*

In one single solve of a linear system, a preconditioned method will be cheaper than an unpreconditioned one if the number of linear iterations is reduced sufficiently by preconditioning. The necessary reduction can be shown clearly, as in the tables above. Over the course of the integration of an ODE, the trade-off is more involved. The basic strategy for a general-purpose ODE solver must be to use a preconditioned iterative method for robustness. By substituting an unpreconditioned iteration in some cases, we hope to reduce the total cost of linear algebra, but we expect to see the total number of linear iterations increase, as a few expensive iterations are replaced by a larger number of cheaper ones.

We address the question of switching from diagonal scaling to a more powerful preconditioner first. Diagonal scaling is used at the start of the integration, since most ODE codes begin timestepping with a small stepsize, and it is usual to find an initial region of the integration where the stepsize remains small due to the accuracy requirement. The progress of the integration is then monitored with the aim of switching to a more powerful preconditioner when diagonal scaling appears to require too many iterations. An obvious strategy for assessing when the diagonally scaled method is using "too many" iterations is to wait until the iteration fails to meet the convergence criterion in the maximum number of iterations. Frequently, this maximum number is set fairly small. For example, Brown and Hindmarsh [5] found that five iterations worked well. In this case, switching preconditioning on when the diagonally scaled iteration "fails" is not unreasonable. In our tests, we have used a maximum value of 10 iterations to try to assess the switching strategy independently of convergence failures. We have found that the methods are more efficient if preconditioning is switched on when the diagonally scaled method is taking only a few (e.g., two to four) iterations per solve.

It turns out to be straightforward to assess the number of linear iterations that the method uses per solve. We have observed in practice that the number of linear iterations per Newton iteration tends to remain constant over several Newton iterations. That is, typically only one linear iteration per Newton iteration is required at the start of an integration. This number increases to two at some point as the stepsize increases, remains steady at two for a while, then increases to three, and so on. Consequently, it is possible to estimate the number of linear iterations per solve by taking the average over the last few Newton iterations.

We have not attempted to use any theoretical results to predict the reduction in the number of linear iterations when preconditioning is applied. Such results are available for some problems, preconditioners, and iterative methods, but they give upper bounds on, or asymptotic estimates of, the number of iterations required to reduce the residual to some fraction of its initial size. Since our convergence criterion, discussed in §2, only requires reducing the residual to a fixed value and since we expect to use only a few iterations per solve, the theoretical results are not particularly useful here.

When a differential equation yields linear systems with clustered eigenvalues, unpreconditioned and diagonally scaled iterative methods can be very effective. In [5], the authors use a reaction-diffusion system with two species in three space dimensions as a test problem. The differential equations have the form

$$\begin{gathered}
\frac{\partial c^i}{\partial t} = d_i \Delta c^i + f^i(c^1, c^2), \qquad i = 1, 2, \\
d_1 = 0.05, \qquad d_2 = 1.0, \\
f^1(c^1,c^2) = c^1(b_1 - a_{11}c^1 - a_{12}c^2), \qquad f^2(c^1,c^2) = c^2(b_2 - a_{21}c^1 - a_{22}c^2), \\
a_{11} = 10^6, \quad a_{12} = 1, \quad a_{21} = 10^6 - 1, \quad a_{22} = 10^6, \\
b_1 = b_2 = (1 + \alpha xyz)(10^6 - 1 + 10^{-6}).
\end{gathered} \tag{5}$$

The equations are defined on the unit cube with $t \in [0, 10]$, homogeneous Neumann boundary conditions and initial conditions

$$\begin{aligned}
c^1(x,y,z,0) &= 500 + 250\cos(\pi x)\cos(3\pi y)\cos(10\pi z), \\
c^2(x,y,z,0) &= 200 + 150\cos(10\pi x)\cos(\pi y)\cos(3\pi z).
\end{aligned}$$

The authors point out that, as $t \to \infty$, the solution approaches a steady state which is given roughly by the asymptotic solution of the problem without diffusion, namely,

$$c^1 = (1 - 10^{-6})(1 + \alpha xyz), \qquad c^2 = 10^{-6}(1 + \alpha xyz).$$

The spatial derivatives are discretized using a centered second-order finite difference approximation on an evenly spaced mesh with m subdivisions in each direction, yielding a system of $2(m+1)^3$ ODEs. Near the steady state, the interaction terms dominate the Jacobian and the dominant part of the spectrum is clustered in the interval -10^6 to $-10^6(1+\alpha)$. Brown and Hindmarsh [5] point out that, consequently, unpreconditioned iterative methods are expected to work well unless α is large. It does not necessarily follow that diagonal scaling will work well, but in this case it does, since all eigenvalues of the scaled matrix are of moderate size. In [5], the ODE problem is solved using a relative error tolerance of 10^{-6} and an absolute error tolerance of 10^{-8}. We use the same tolerances here, with the result that the code takes a very small stepsize (starting around 10^{-9}) through the transient region, which lasts to about $t = 0.5$. There is then an abrupt transition to the steady-state region, during which the stepsize increases by factors of two to five several times in rapid succession. The diagonally scaled method encounters difficulty once the transition to the steady-state region starts. Numerical results are shown in Tables 2 and 3 for the case $m = 9$ (2000 equations) and for $\alpha = 0$. The maximum number of linear iterations was set to 10.

TIME	278	280	284	295	280	281	288	293

Table 2 shows the number of function evaluations (NFCN), Jacobian evaluations (NJAC), Newton iterations (NNWT), linear iterations (NLIN), and the time in seconds (TIME) required to integrate the problem without adaptation of the preconditioning, using either diagonal, ILU(0), or ILU(1) preconditioning. Table 3 shows the effect of switching from diagonal scaling to ILU(0) or ILU(1) preconditioning during the integration. Each column corresponds to the number of linear iterations being used by the diagonally scaled method when the switch was made. This number was calculated by looking at the average number of iterations over the last four Newton iterations. The column labelled MAXIT indicates that the switch was made because the diagonally scaled method failed to converge in the maximum number of iterations. The criterion used in the program was to switch if the code took an average of eight linear iterations over the past four Newton iterations, but a convergence failure occurred in each case before this condition was met. The row of the table labelled TSWI shows the elapsed CPU time when the code switched on the preconditioning.

From these tables, we see that there is a definite advantage to using the combination of the diagonally scaled and preconditioned iterative methods, as most of the CPU time is spent with the diagonally scaled iteration. This reflects the fact that 75 to 90% of the work of the integration, measured in function evaluations, Jacobian evaluations, or nonlinear or linear iterations is done using that diagonally scaled method. There is little to choose between switching criteria in terms of total time, suggesting that there is a small range of the integration in which the diagonally scaled and preconditioned methods are equally expensive.

In the following tables, we show some numerical results obtained using the heat equation in three space dimensions as a test problem. It is well known that the eigenvalues of the associated Jacobian matrix are widely spread without clustering and that unpreconditioned and diagonally scaled iterative methods are generally inefficient. As described in [8], the PDE has the form

$$u_t = u_{xx} + u_{yy} + u_{zz} \tag{6}$$

on the unit square for $t \in [0, 10.24]$, with homogeneous Dirichlet boundary conditions and initial condition

$$u(0, x, y, z) = 64x(1-x)y(1-y)z(1-z).$$

The spatial derivatives were discretized using a centered second-order finite difference discretization on a mesh of m equal subdivisions, resulting in a system of $(m-1)^3$ ODEs. In this example, $m = 16$ (3375 equations). The maximum number of linear iterations was set to 10. The absolute error tolerance in the ODE solver was set to 10^{-4} and no relative error control was used. Table 4 shows the results without adaptation of the preconditioner, and Table 5 shows the effect of switching preconditioners. The number of linear iterations was calculated as the average over the last four Newton iterations.

The most efficient way to solve this particular problem is to use the ILU(1) preconditioner over all iterations. This seems to be due, at least in part, to accuracy considerations related to the use of the diagonally scaled iterative solver. Following Brown and

Hindmarsh [5], the solution of the linear system is accepted if

$$\|d_n^l\| \leq \epsilon,$$

where d_n^l is the residual at the last linear iteration. With two different iterative methods, it often happens that one method just meets this criterion while the other returns a solution with a much smaller residual. This difference in accuracy affects not only the acceptance of the Newton iteration but also the error control strategy and stepsize selection in the ODE solver. In the tables, we note that, as expected, the total number of linear iterations increases as we use the diagonally scaled method for a longer period. The other statistics are more variable because of this effect of the accuracy of the linear solver.

For the ILU(0) preconditioning, the approaches that switch when the diagonally scaled method is taking two or four iterations per solve are no worse than using preconditioning on all steps. Switching always leads to a deterioration in performance for the ILU(1) preconditioner.

For both the reaction-diffusion problem (5) and the heat equation (6), we have tested the effect of averaging the number of linear iterations over the last six and the last eight Newton iterations. Changing this parameter has little effect on the step at which preconditioning is switched on.

Based on the results from these two test problems and additional numerical experiments, it seems reasonable to use the following strategy to switch from a diagonally scaled method to a preconditioned one:

- Find the average number of linear iterations over the past four Newton iterations.
- Switch on preconditioning when the average is four or greater, and definitely when the diagonally scaled iteration fails to converge in the maximum number of iterations.

This approach sometimes yields a significant improvement in performance; for those problems where it is less efficient, it does not degrade performance very much. The particular value of *four* linear iterations obviously depends on the relative costs of the preconditioning strategies and hence is dependent on the problem class, but does seem appropriate for the PDE problems that we have tested.

For either the reaction-diffusion equation (5) or the heat equation (6), we observe that the number of linear iterations per solve is reduced when preconditioning is first switched on. As the integration continues with the preconditioned method, the number of iterations per solve increases again, along with the timestep, as the solution of the differential equation approaches a steady state. This is typical behaviour for many time-dependent systems, but problems exist for which phases similar to the initial transient recur. For such problems, it is reasonable to consider switching preconditioning off. We have developed a test to switch preconditioning off based on both the amount of work being done by the linear solver and the character of the iteration matrix. As the primary test, we require that the iterative solver takes one iteration only per solve over the last several Newton iterations. Around 15 to 20 Newton iterations seems appropriate since we wish to avoid cases where, say, the error estimate has forced an anomalously small stepsize over a few steps. This also avoids switching preconditioning off again immediately after switching it on.

A quantity relevant to convergence of a Krylov subspace-type iterative method is the *spectral ratio*—the ratio of the largest to the smallest eigenvalues of the matrix or, for clustered eigenvalues, the ratio of largest to smallest eigenvalues within each cluster. We use Gerschgorin circles to estimate the clustering of the eigenvalues of the Newton iteration matrix. We need to consider one cluster only since all the Gerschgorin circles of the diagonally scaled matrix will have center $(1,0)$. We also observe that the matrices $D^{-1}W_n^l$, $W_n^l D^{-1}$, and $D^{-1/2}W_n^l D^{-1/2}$ are similar; hence they have the same eigenvalues, but need not have the same Gerschgorin circles. ($D = \operatorname{diag}(W_n^l)$ is the diagonal scaling matrix.) When the Newton iteration matrix is formed by the ODE solver, the Gerschgorin circles for these three matrices are calculated by both rows and columns, giving six estimates of the eigenvalue range. If all the circles for a single case (particular scaling and row or column calculation) lie in the same half-plane, we call the ratio of the extreme real axis intercepts of the Gerschgorin circles a *Gerschgorin ratio* of the matrix. We take the minimum of our six calculated Gerschgorin ratios and use it to approximate the associated spectral ratio. When this value is small, it is reasonable to expect that an unpreconditioned iterative method will work well.

As the theory suggests, we have found for all our test problems that, at the start of the integration, the eigenvalues of the diagonally scaled iteration matrix are all contained in one small cluster centered at $(1,0)$. As the stepsize increases, the cluster usually expands. If any circle crosses the axis into the left half-plane, we consider the Gerschgorin ratio to be infinite. Here, we expect that the diagonally scaled iterative method will have difficulty and therefore we do not switch preconditioning off.

Van der Pol's equation (see, for example, [16]) is often used as an example of an ODE system in which transients recur throughout the integration. This second-order equation is frequently rewritten as a system of two first-order ODEs. We have extended it to a large system by using the two ODEs as the reaction terms in a reaction-diffusion PDE system, as follows.

$$(7) \qquad \frac{\partial c^i}{\partial t} = d_i \Delta c^i + f^i(c^1, c^2), \qquad i = 1, 2,$$

$$d_1 = 0.05, \qquad d_2 = 1.0,$$

$$f^1(c^1, c^2) = c^2, \qquad f^2(c^1, c^2) = \eta(1 - (c^1)^2)c^2 - c^1,$$

on the unit square with $\eta = 100$, homogeneous Neumann boundary conditions, and initial conditions

$$c^1(x, y, 0) = 1 - \cos(\pi x)\cos(2\pi y),$$

$$c^2(x, y, 0) = 1 + 2\cos(2\pi x)\cos(\pi y).$$

The spatial derivatives were discretized using a centered second-order finite difference approximation on an evenly spaced mesh with m subdivisions in each direction, yielding a system of $2(m+1)^2$ ODEs.

We solved this problem with $m = 10$ subdivisions, $t \in [0, 1000]$, relative and absolute error tolerances of 10^{-6} and 10^{-4}, respectively, and various switching strategies. As noted earlier, to be conservative about switching preconditioning off, it seems most appropriate to observe the number of linear iterations over a larger number of Newton iterations than is used in the test to switch it on. We require that the linear solver has taken only one iteration per solve over the last 16 Newton iterations before we consider switching preconditioning off. If we use this criterion only, and no information about the iteration matrices, the code switches preconditioning on 14 times and off 13 times in the interval $[0, 1000]$. We note that the original coupled pair of ODEs has period roughly 163, hence goes through six cycles in this time interval. Each cycle involves two intervals in which the solution is changing rapidly.

To use information about the matrix, a bound on the Gerschgorin ratio is chosen. If the smallest Gerschgorin ratio is less than the bound, then we switch preconditioning off if the requirement on number of iterations per solve is also met. We solved Van der Pol's equation again with the Gerschgorin bound set to two and observed the same number of switches as above. Comparing results from the two tests shows that the switches occur at about the same times in the integration; a reassuring result since the switches should be triggered by the stiffness of the continuous system rather than being artifacts of the code. However, we observe that, without matrix information, the code switches preconditioning off as much as one hundred timesteps earlier than when matrix information is used. The earlier switch seems more effective in the sense that the diagonally scaled method experiences no difficulties after the switch, converging in one or two iterations. This result suggests that using a larger Gerschgorin bound might be appropriate, a conclusion supported by tests using values of four and eight that also yield satisfactory behaviour of the switching strategy. With the value eight, we observe the same results as when no matrix information is used; that is, the condition on number of iterations controls the switch. There is no significant difference in total solution time in any case, including a comparison to doing the whole integration with preconditioning (ILU(1) preconditioning was used in all tests). This is due to the small size of the ODE system. We note that the Gerschgorin ratio in the right half-plane grew as large as 10^3 and that some circles extended into the left half-plane on several Jacobian evaluations.

With $m = 20$ subdivisions (882 equations), $t \in [0, 500]$, and the same error tolerances, the integration time using ILU(1) preconditioning on all iterations was 742 seconds, with 452 seconds spent in linear algebra. The time when switching was used with the Gerschgorin bound set to four was 722 seconds, including 435 seconds of linear algebra. The code switched preconditioning on seven times and off six times. Similar results were obtained when the Gerschgorin bound was set to two.

As the mesh is refined, the diffusion term in the PDE causes the ODE system to become stiffer. The results shown in Table 6 are for a grid with $m = 40$ subdivisions (3362 equations), $t \in [0, 500]$, and the same error tolerances. The code switched ILU(1) preconditioning on if the diagonally scaled method was taking four iterations per solve over the last four Newton iterations, and off if the ILU(1)-preconditioned method took only one iteration per solve over the last 16 Newton iterations. The Gerschgorin bound (G.B.) used in each test is given at the top of the column. Here, the most efficient solution technique is to use ILU(1) preconditioning on all steps. With the Gerschgorin bound set to two, preconditioning was switched on four times and off three times; with bound four, the code switched preconditioning on seven times and off six times. The grid size is sufficiently small that the diffusion terms keep the ODE stiff and preconditioning on all steps is the most efficient technique.

For the Van der Pol equation, we expect to encounter recurring transients during the integration, causing the ODE solver to use a small timestep to meet the accuracy requirement. Due to this small timestep, all the eigenvalues of the unscaled Newton iteration matrix will be of moderate size and will occur in one single cluster. Checking the Gerschgorin circles of the unscaled matrix confirms that, in the tests above, whenever the code switched preconditioning off, the circles of the unscaled matrix made up one small cluster. This is not the case for the following test problem, used in [5] and [7]. This PDE system, also of reaction-diffusion type, models ozone production in the stratosphere and has the following form.

$$\frac{\partial c^i}{\partial t} = K_h \frac{\partial^2 c^i}{\partial x^2} + \frac{\partial}{\partial z}\left(K_v(z)\frac{\partial c^i}{\partial z}\right) - V_h \frac{\partial c^i}{\partial x} + R^i(c^1, c^2, t), \qquad i = 1, 2, \tag{8}$$

$$K_h = 4 \cdot 10^{-6}, \quad K_v(z) = 10^{-8} e^{z/5}, \quad V_h = 0.01,$$

$$R^1(c^1, c^2, t) = -k_1 c^1 - k_2 c^1 c^2 + k_3(t) \cdot 7.4 \cdot 10^{16} + k_4(t) c^2,$$

$$R^2(c^1, c^2, t) = k_1 c^1 - k_2 c^1 c^2 - k_4(t) c^2,$$

$$k_1 = 6.031, \qquad k_2 = 4.66 \cdot 10^{-16},$$

$$k_3(t) = \begin{cases} \exp[-22.62/\sin(\pi t/43200)] & \text{for } t < 43200, \\ 0 & \text{otherwise,} \end{cases}$$

$$k_4(t) = \begin{cases} \exp[-7.601/\sin(\pi t/43200)] & \text{for } t < 43200, \\ 0 & \text{otherwise.} \end{cases}$$

The problem is posed for $x \in [0, 20]$, $z \in [30, 50]$ and $t \in [0, 86400]$ with homogeneous Neumann boundary conditions and initial conditions

$$c^1(x, z, 0) = 10^6 \alpha(x)\beta(z), \qquad c^2(x, z, 0) = 10^{12} \alpha(x)\beta(z),$$

$$\alpha(x) = 1 - (0.1x - 1)^2 + (0.1x - 1)^4/2,$$

$$\beta(z) = 1 - (0.1z - 4)^2 + (0.1z - 4)^4/2.$$

If the differential equations are discretized using central differences for both the diffusion and convection terms, as is done in [5] and [7], the eigenvalues of the Jacobian are found in two clusters, as discussed in [5].

The problem was solved with $m = 9$ subdivisions (200 equations) and relative and absolute error tolerances of 10^{-5} and 10^{-3}, respectively. With the Gerschgorin bound set to two, the code switches preconditioning on at $t = 13{,}340$, then off at $t = 42{,}064$, and completes the integration successfully using the diagonally scaled method. Checking the Gerschgorin circles of the unscaled matrix reveals that when preconditioning is switched off, the circles make up two small clusters although the ratio of the extreme limits of all the circles is over 100. In this case, the diagonal scaling has mapped these two clusters into a single small circle. With the bound set to four, the code switches preconditioning on, then off, twice between $t = 13{,}340$ and $t = 35{,}002$, finishing the integration with the diagonally scaled method. It is less efficient than when the bound is set to two.

The results in Table 7 are obtained with a discretization having $m = 19$ subdivisions (800 equations). The ODE solver has some difficulty with the integration, probably due to the central difference discretization, since it does not occur when upstream differencing is used for the convection term. With the Gerschgorin bound set to either two or four, the code switches preconditioning on five times and off five times between $t = 7734$ and t around 42,700; the switches occur at slightly different times depending on the bound. When preconditioning is switched off at $t = 42{,}700$, the Gerschgorin circles of the unscaled Newton iteration matrix form two small clusters. The earlier switches occur because the timestep is small enough, often after a failed step, to force all the circles of the unscaled matrix into one cluster. It is not clear if these switches should be made; the timestep tends to increase rapidly after a failed step and the possible higher accuracy of the more powerful preconditioner might be useful.

NLIN	3552	4985	4865
TIME	654	657	650

The results in Table 8 are obtained with $m = 39$ subdivisions (3200 equations). When the Gerschgorin bound is set to two, the code switches preconditioning on at $t = 7216$, then off at $t = 42{,}321$. With bound four, there are four on-off switches between $t = 7216$ and $t = 42{,}293$, and the integration again finishes using the diagonally scaled method. In this case, it is more efficient to switch preconditioning off when possible.

Overall, it seems that our strategy for switching preconditioning off does detect problem information correctly, i.e., nonstiffness of the Van der Pol oscillator. Also, the diagonal scaling is able to exploit the clustering of the eigenvalues in (8). Computing the six different Gerschgorin ratios can have an effect on when the switches occur. For the Van der Pol equation, all six values tend to be close on all Jacobian evaluations. For (8), where the components are of widely differing magnitudes, the six values can be very different particularly when they are large. When a Gerschgorin bound of two was used to switch preconditioning off, we found that the ratios were close when a switch occurred.

TABLE 8
Ozone production model; 3200 *equations.*

NLIN	5182	7490	7874
TIME	4559	4113	4168

In contrast, with a bound of four, some switches would not have occurred if all six values had not been computed. Any strategy for making a switch should certainly be conservative. A bound of two seems a better choice, although the value four yields better results in some cases.

4. Adaptive preconditioning in type-insensitive codes. In this section, we insert our strategies for adaptive preconditioning into the type-insensitive ODE solver described in §2. As noted, our code is based on the ideas of Petzold [16]. The method starts integrating with the Adams formulas and monitors the timestep, the eigenvalues of the Jacobian (indirectly), and the region of absolute stability. It switches to the BDFs when it estimates that it can increase the stepsize by a factor of five or more by doing so. When integrating with the BDFs, the code continues to monitor the same information (using the norm of the Jacobian matrix which is now available directly) and will switch back to the Adams formulas if it expects to maintain the same stepsize after the switch.

Our "combined" code incorporates our adaptive preconditioning strategy into the type-insensitive method. The code starts integrating with the Adams formulas and functional iteration and switches to using the BDFs and Newton's method as described above. When Newton's method is first selected, the code uses the iterative linear solver with diagonal scaling only. The performance of the linear solver is monitored and the code may select a more expensive preconditioner as described in §3. If the ODE is only mildly stiff, expensive preconditioning might never be needed.

The strategies for switching preconditioning off and switching from the BDFs to the Adams formulas are independent. The Adams formulas can be selected at any time when the BDFs are in use, regardless of the linear solver currently being used by the code. That is, if a transient component recurred abruptly in the course of the integration, the code could switch directly from the BDFs with the expensive preconditioner to the Adams formulas and functional iteration. In the numerical tests in §4.3, we will see that, for the van der Pol problem, the code actually switches preconditioning off before switching from BDFs to Adams formulas, indicating that it detects a region of "mild" stiffness in the transition from the stiff regime to the transient regime.

We report the results of numerical experiments with our combined code and several test problems. In these tests, the maximum number of linear iterations is always set to 10. Preconditioning is switched on if the diagonally scaled method took four iterations per solve over the last four Newton iterations and off if the Gerschgorin bound (2, unless otherwise specified) is met and only one iteration per solve was required over the last 16 Newton iterations.

In the tables, the preconditioning strategy (either ILU(0) or ILU(1)) and number of equations are shown in the caption. The column labels have the following meanings.

- No switch: BDF method; ILU preconditioning on all iterations.
- Switch: BDF method; switching from diagonal scaling to ILU preconditioning.
- Type-ins: Type-insensitive method; ILU preconditioning on all iterations.
- Combined: Combined method; type-insensitive and switching from diagonal scaling to ILU preconditioning.

4.1. Reaction-diffusion equation in three space dimensions. Equation (5) was solved on a number of different grids ($m = 9$, 2000 equations; $m = 14$, 5488 equations; $m = 20$, 16000 equations) with $\alpha = 100$ and $t \in [0, 100]$. All other problem and method parameters are the same as in §3. The results are shown in Tables 9–14. When $\alpha = 100$, the eigenvalues of the Jacobian are somewhat more widely spread than in the tests reported in §3. Extending the range of integration from $t = 10$ to $t = 100$ simply causes the code to take one large last step, of order 100 itself. This large step poses no problem for the iterative solver in this case.

We always find that the method that combines the type-insensitive approach with adaptive preconditioning is the most efficient, saving 18 to 24% of execution time with ILU(0) preconditioning, and 26 to 31% with ILU(1) preconditioning. Without adaptive preconditioning, the ILU(0) method is more efficient, but when preconditioning is applied only when necessary, it is just as efficient to use the more powerful ILU(1) approach.

4.2. Ozone production model. In §3, (8) was discretized using centered differences for both the diffusion and convection terms, following [5] and [7]. Since the convection coefficient $V_h = 0.01$ while the diffusion coefficients have magnitude 10^{-6} to 10^{-4}, this problem is convection-dominated and it is reasonable to use upstream differencing for the convection term. This discretization leads to a Jacobian matrix that is better conditioned than when centered differences are used and allows the code to take much larger timesteps. We do not expect that preconditioning will be switched off once it has been turned on. Upstream differencing was used in computing the results in Tables 15 and 16. The equations were discretized on a grid with 41 mesh points in each direction giving

$\Delta x = \Delta z = 0.5$ and a system of 3362 equations. As before, an absolute error tolerance of 10^{-3} and a relative tolerance of 10^{-5} were used.

Again, it is found that the method that combines the type-insensitive approach with adaptive preconditioning is the most efficient, although the saving is not as significant as for (5). The method with ILU(1) preconditioning on all steps does well, taking fewer function evaluations than any other approach. As mentioned previously, this seems to indicate that there is an advantage in accuracy to using ILU(1) preconditioning. Adaptive preconditioning alone degrades efficiency although it does well in combination with the type-insensitive method. With the combined method, the switch from the Adams formulas to the BDFs occurs at step 93, $t = 3.93$, then preconditioning is switched on at step 140, $t = 1142$. With adaptive preconditioning only, the switch occurs later at step 189, $t = 2167$.

In Table 17, we show results computed with the type-insensitive and combined methods and a central difference discretization of all terms, for comparison with results given in §3. (Those results are also included in this table.) In this case, the switching method and the combined method have comparable cost. In the switching method, preconditioning is turned on at $t = 7216$, then off at $t = 42,321$. In the combined method, the BDFs are selected as above at $t = 3.93$, step 93; preconditioning is turned on at $t = 5837$, and off at $t = 42{,}360$.

4.3. Van der Pol equation. We use the modified Van der Pol equation (7) to investigate the interaction between turning preconditioning on and off and switching from the BDFs back to the Adams formulas. As we noted in §3, on a grid with $m = 40$ subdivisions (3362 equations), the ODE system is quite stiff due to the effect of the diffusion terms regardless of the behaviour of the reaction terms. The results shown in Table 18 were computed using the same problem and method parameters as in §3 on the interval

In the "switching" code, preconditioning is first turned on at time $t = 0.025$, step 65. Since the total integration takes around 4000 steps, this is very early in the integration. With the Gerschgorin bound set to two, preconditioning is switched on four times and off three times; with bound four, the code switches preconditioning on seven times and off six times during the integration. The type-insensitive method is less effective than the code that uses ILU(1) preconditioning throughout, somewhat surprisingly, since the type-insensitive code switches from the Adams formulas to the BDFs at time $t = 0.0076$, step 85, and never switches back to the Adams formulas. The combined method with Gerschgorin bound 2 turns preconditioning on at $t = 0.026$, step 115, and never switches it off. With the bound set to 4, the combined method makes the same number of switches as the "switching" code, at essentially the same times in the integration.

This problem is best solved with ILU(1) preconditioning. The same set of tests was run using ILU(0) preconditioning and the same relative performances were observed. The total time to complete the integration was about 1000 seconds greater in all cases.

To investigate the effect of switching between the Adams formulas and the BDFs when the number of equations is large, the diffusion coefficients were reduced from 0.05 and 1 to 0.005 and 0.1, respectively. The numerical results using ILU(0) preconditioning are given in Table 19, those using ILU(1) preconditioning in Table 20. Other parameters of the problem and method are the same as in §3, with $t \in [0, 500]$.

With ILU(0) preconditioning, the "switching" method and the combined method turn preconditioning on seven times and off six times for both choices of Gerschgorin bound. The type-insensitive method selects the BDFs for the first time at $t = .709$, step

1285, where the total integration still takes around 4000 steps. Following the initial formula change, there are three subsequent switches to the Adams formulas then back to the BDFs. The combined method makes four subsequent switches between Adams formulas and BDFs. Three of these switches are at essentially the same values of t as the type-insensitive method, but there is one additional switch. There are two switches between preconditioning and diagonal scaling where the Adams formulas are not selected. A switch to the Adams formulas is always preceded by switching preconditioning off, typically by about 80 to 100 timesteps.

When ILU(1) preconditioning is used, the "switching" method and combined method still turn preconditioning on seven times and off six times for both choices of Gerschgorin bound. The type-insensitive method of course selects the BDFs for the first time at the same timestep as in the ILU(0) case, then there are four subsequent switches to the Adams formulas then back to the BDFs. The combined method makes the same switches, with either Gerschgorin bound. A switch to the Adams formulas is always preceded by switching preconditioning off; the switches occur at essentially the same times for ILU(0) preconditioning.

The strategy for formula selection appears to be robust with respect to effects of the linear algebra, as one would hope. Also, the switches between diagonal scaling and preconditioning always occur at about the same t values, indicating that the switching strategy is, in fact, detecting properties of the ODE system. It is, though, difficult to choose a value for the Gerschgorin bound based on these tests. As noted in §3, the value 2 appears preferable since it gives a saving whenever one is achieved by switching preconditioning and does better when a saving is not achieved.

4.4. A "dense" two-dimensional problem. The system of PDEs defined by (9) below is used as a test problem in [6]. Although this problem is similar in nature to (5)—both are reaction-diffusion systems modelling a predator-prey interaction—it poses a slightly different challenge to the iterative methods since it includes a large number of species, making the associated Jacobian matrix relatively dense.

$$\frac{\partial c^i}{\partial t} = d_i \Delta c^i + f^i(c), \qquad i = 1, 2, \ldots, s, \tag{9}$$

where $c = (c^1,\ c^2, \ldots, c^s)^T, p = s/2,$

$$\begin{aligned}
d_i &= 1, \qquad i = 1, 2, \ldots, p,\\
d_i &= 0.05, \qquad i = p+1, \ldots, s,\\
f^i(c) &= c^i \left(b_i + \sum_{j=1}^{s} a_{ij} c^j \right),\\
a_{ii} &= -1 \quad \forall i,\\
a_{ij} &= -0.5 \cdot 10^{-6}, \quad i \le p, \quad j > p,\\
a_{ij} &= 10^4, \quad i > p, \quad j \le p,\\
a_{ij} &= 0 \quad \text{for all other } i \text{ and } j;\\
b_i &= (1 + \alpha xyz), \quad i \le p,\\
b_i &= -(1 + \alpha xyz), \quad i > p.
\end{aligned}$$

The system (9) is defined on the unit square with $t \in [0, 10]$. The problem has homogeneous Neumann boundary conditions and initial conditions

$$c^i(x, y, 0) = 10 + i[16x(1-x)y(1-y)]^2, \qquad 1 \le i \le s.$$

Here, we take $s = 20$ ($p = 10$) and $\alpha = 50$. The steady state solution is spatially inhomogeneous and the Jacobian is highly nonsymmetric at equilibrium [6].

The spatial derivatives are discretized using a centered second-order finite difference approximation on an evenly spaced mesh with m subdivisions in each direction, yielding a system of $s(m+1)^2$ ODEs. Following [6], we take $m = 11$, which gives an ODE system of 2880 equations. This problem is solved using a relative error tolerance of 10^{-6} and an absolute error tolerance of 10^{-8}. Numerical results for ILU(0) and ILU(1) preconditioning are given in Tables 21 and 22, respectively.

The approaches that use ILU(0) preconditioning are always more efficient than those using ILU(1) preconditioning, due to the density of the Jacobian matrix, which has 42,240 nonzero entries, as does the ILU(0) preconditioner, while the ILU(1) preconditioner has 112,840 nonzeros. Hence, even though the code using ILU(1) preconditioning generally uses fewer function and Jacobian evaluations, nonlinear and linear iterations, the total CPU time is greater. In both cases, the combined method is the most efficient.

Brown and Hindmarsh [6] identify the nonstiff transient region for this problem as roughly $0 \le t \le 10^{-3}$. Our strategy for switching on preconditioning also picks out this region. While the switch from the Adams formulas to the BDFs takes place at $t = 2.88 \cdot 10^{-5}$, the switch from diagonal scaling to preconditioning takes place at

$t = 2.45 \cdot 10^{-3}$ when the "switching" code is used, and at $t = 2.76 \cdot 10^{-3}$ in the combined code.

The ratio of the number of linear iterations to the number of Newton iterations (AVDIM) is reported in [6]. This value provides a rough comparison of the work being done by the iterative method in the various approaches. For problem (9), it is also interesting to compare the work done in the nonstiff and stiff regimes, which we identify with the intervals $[0, 1]$ and $[1, 10]$, respectively, for convenience. Values are reported in Table 23. As expected, AVDIM increases when diagonal scaling is used and also when the type-insensitive method is used. The iterative solver works considerably harder in the stiff regime. The values for AVDIM found here are similar to those reported in [6].

5. Conclusions. We have developed a strategy for the adaptive choice of preconditioning when an iterative linear solver is used in an ODE code. This strategy successfully identifies characteristics of the problem and is able to switch preconditioning on or off according to those characteristics. This approach combines naturally with the use of a type-insensitive ODE solver. For the test problems considered, we found that, when the type-insensitive approach yields a saving in execution time, the combined method increases the saving. There are problems for which the adaptive approach is not effective; in these cases, it appears that the type-insensitive approach is not appropriate either. As a simple rule of thumb, the combined method is effective when both the Adams formulas and the diagonally scaled preconditioning are used over a significant percentage of steps.

There is a variety of ways of adapting the preconditioner that one might consider. Possible choices for the "cheap" preconditioner were discussed in the introduction. Another idea is to adapt through various more powerful preconditioners, say ILU(0) to ILU(1), possibly to a direct solution method if the ODE appears very difficult to solve. However, the difference in cost of the various preconditioning methods is not that great for a wide class of problems. As we noted earlier, for example, ILU(0) preconditioning is only about 40% more expensive than diagonal scaling on many problems derived from PDEs. This suggests that little additional saving would be achieved by this incremental approach. A "cheap" preconditioner that was effective over a longer range would be more useful. Switching to a direct method is possible if the problem size is not too great or if a sparse direct method does not suffer too much fill-in.

Our strategy exploits the availability of the Jacobian matrix during intervals of the integration in which the expensive preconditioner is in use, both in the choice of preconditioner and in the strategy for switching preconditioning off. Our choice of preconditioner was motivated by the fact that ILU factorization can be applied without knowledge of a particular matrix's properties, i.e., it can be supplied to a user as part of a "black-box" code. Also, implementations of these preconditioners were readily available to us. Our idea of switching between preconditioners that have different costs is independent of the choice of preconditioner, although parameters in the strategy would have to be adjusted to suit the relative costs. The problem of switching preconditioning off if Jacobian information is not available is somewhat more difficult. One possibility would be to use information about numbers of iterations only. The code might switch preconditioning off if a *reduction* in the number of iterations used by the preconditioned iterative method was noted and the number of linear iterations remained small over many Newton iterations. In addition, the code could have a flag that disabled switching off entirely. If the strategy was fooled, i.e., preconditioning had to be turned on again immediately after being turned off, the flag would be set. Another possibility is to use the Gerschgorin circles of the preconditioner in the switching strategy, since the preconditioner is an approximation to the Newton iteration matrix, although admittedly a rough one. In many cases, computing a finite-difference approximation to a sparse Jacobian matrix is, in fact, a relatively cheap operation and hence basing a preconditioning strategy on explicit Jacobian information is not unreasonable.

Both the ILU(0) and ILU(1) preconditioners worked well for these test problems. The choice between them depends on the amount of fill-in generated by the ILU(1) factorization and how difficult the ODE is to solve. As we saw for the last test problem, even though ILU(1) preconditioning can be significantly more efficient in terms of the number of linear iterations, the cost per iteration may make ILU(0) preferable. We note that the choice of the maximum number of iterations can have a significant effect on the overall performance of the code. In a method such as Orthomin or GMRES, the amount of storage restricts the choice of this maximum. (Although restarting can be used, it is not clear how effective it is.) If the ODE solver fails and reduces the stepsize because the iterative method did not converge, this can have a ripple effect throughout the rest of the

integration, significantly increasing the total number of steps and amount of work. The maximum should be chosen as large as possible, consistent with the storage available.

NUMERICAL METHODS FOR HYPERBOLIC CONSERVATION LAWS WITH STIFF RELAXATION II. HIGHER-ORDER GODUNOV METHODS*

RICHARD B. PEMBER†

Abstract. A higher-order Godunov method is presented for hyperbolic systems of conservation laws with stiff, relaxing source terms. The goal is to develop a Godunov method that produces higher-order accurate solutions using time and space increments governed solely by the nonstiff part of the system, i.e., without fully resolving the effect of the stiff source terms. It is assumed that the system satisfies a certain "subcharacteristic" condition. The method is a semi-implicit form of a method developed by Colella for hyperbolic conservation laws with nonstiff source terms. In addition to being semi-implicit, our method differs from the method for nonstiff systems in its treatment of the characteristic form of the equations. The method is applied to a model system of equations and to a system of equations for gas flow with heat transfer. Our analytical and numerical results show that the modifications to the nonstiff method are necessary for obtaining second-order accuracy as the relaxation time tends to zero. Our numerical results also suggest that certain modifications to the Riemann solver used by the Godunov method would help reduce numerical oscillations produced by the scheme near discontinuities. The development of a modified Riemann solver is a topic of future work.

Key words. hyperbolic conservation laws with relaxation, stiff source terms, finite difference methods, Godunov-type methods

AMS subject classifications. 35L65, 65M25, 76.65

1. Introduction. Hyperbolic conservation laws with relaxation appear in the study of a variety of physical phenomena, for example, in the modeling of thermally and chemically nonequilibrium fluid flows. The term "hyperbolic system of conservation laws with relaxation" is used here in the sense of Whitham [42], [43] and Liu [27] to denote a hyperbolic system of N partial differential equations in conservation form with source terms which has as a limit a hyperbolic system of M equations, $M < N$, called the equilibrium system as $N - M$ relaxation time parameters $\tau_i \rightarrow 0$. We call the system of N equations the nonequilibrium system. The characteristic speeds of the nonequilibrium system are called frozen characteristic speeds, while those of the equilibrium system are called equilibrium characteristic speeds. We say that a system of conservation laws with relaxation is stiff when at least one of its relaxation times is small compared to the time scale determined by the frozen characteristic speeds of the system and some appropriate length scale. In this paper we present a higher-order Godunov method for hyperbolic systems of conservation laws with stiff, relaxing source terms. Our goal is to develop a second-order Godunov method which produces higher-order accurate solutions using time and space increments governed solely by the nonstiff part of the system, i.e., without fully resolving the effect of the stiff source terms. We base our development on the higher-order Godunov method for hyperbolic conservation laws with nonstiff source terms presented by Colella [11].

We assume that the system of conservation laws with relaxation contains a single rate equation, i.e., $M = N - 1$. We also assume that the frozen and the equilibrium characteristic speeds of the system alternate in a particular way [27], [43]. Specifically, suppose that the dependent variables of the nonequilibrium system are $u_1, \ldots, u_N$, and

*Received by the editors February 12, 1992; accepted for publication (in revised form) July 27, 1992.

†Computing and Mathematics Research Division, Lawrence Livermore National Laboratory, L-316, P.O. Box 808, Livermore, California 94550 (pember@llnl.gov). This work was performed under the auspices of the U.S. Department of Energy, by the Lawrence Livermore National Laboratory, under contract W-7405-Eng-48. Partial support was provided by the Applied Mathematical Sciences Program of the Office of Energy Research.

that u_N is the dependent variable governed by a rate equation, i.e. the Nth equation of the system has a source term which acts to restore u_N to equilibrium. The equilibrium system is then found by substituting the equilibrium value of u_N, $u_*(u_1, \ldots, u_M)$, in the first M equations of the nonequilibrium system. We then say that the frozen characteristic speeds λ_i and the equilibrium characteristic speeds μ_i satisfy the *subcharacteristic condition* if they satisfy the inequality

$$\lambda_1 < \mu_1 < \lambda_2 < \mu_2 \cdots < \mu_M < \lambda_N, \tag{1.1}$$

where the λ_i are evaluated at the equilibrium state $(u_1, \ldots, u_M, u_*(u_1, \ldots, u_M))$. Hyperbolic systems of equations with relaxation whose frozen and equilibrium characteristic speeds satisfy (1.1) include the equations describing gas flow with vibrational nonequilibrium and with nonequilibrium due to chemical dissociation [39].

There are a number of theoretical results in the literature based on the subcharacteristic condition. Whitham [42], [43] shows that the condition is necessary for stability in the case of linearized systems with relaxation. Liu [27] shows for $N = 2$ that if the frozen and the equilibrium characteristic speeds always satisfy the subcharacteristic condition, then the corresponding equilibrium equation is stable under small perturbations and the time-asymptotic solutions of the system are completely determined by the equilibrium equation. Chen, Levermore, and Liu [8] show that if the subcharacteristic condition is always satisfied, then solutions of the system tend to solutions of the equilibrium equation as the relaxation time tends to zero.

In this paper we develop a higher-order Godunov method for solving hyperbolic systems of conservation laws with stiff relaxation under the assumption that the frozen and the equilibrium characteristic speeds of the system satisfy (1.1). Our results in an earlier paper [31] show that under this assumption one can always obtain first-order accurate solutions of these systems with a Godunov-type method which does not fully account for the effect of the stiff source terms. Four new issues must be addressed, however, in the development of a higher-order accurate Godunov method for hyperbolic conservation laws with stiff relaxation which incorporates the methodology in [11]. Two of the issues are relevant to other shock-capturing methods. (See the discussion by Yee and Shinn [46].) One issue is whether the method should be fully implicit or semi-implicit, i.e., implicit only with respect to the stiff source term. The second issue is if the method can use Strang splitting [33] to integrate the source term and the conservation laws in separate, fractional steps and still produce higher-order accurate results. A third issue is relevant to all Godunov-type methods. Godunov's original method [18] and subsequent Godunov-type methods (see [38], [44], and [45] for overviews) use either the exact or the approximate solution of Riemann problems to calculate numerical fluxes. The issue, then, is if the "Riemann solver" needs to account for the equilibrium equation and/or the presence of source terms. The fourth issue is specific to the higher-order Godunov method of Colella [11]. In this method the higher-order accuracy results from a step which uses the characteristic form of the equations. The step discards certain components of these equations depending on the signs of the characteristic speeds. The last issue, then, is if one needs to modify this step (and, if so, how) to account for the presence of stiff source terms and for the fact that waves propagate at the equilibrium characteristic speeds as the relaxation time approaches zero.

(*Remark.* The issue of whether to use a fractional step or an unsplit approach is not actually an issue per se in applying the methodology in [11]; the approach there is an unsplit one. We address this issue because there is a lack of consensus in the literature on this issue; see discussions in [16], [23], and [46].)

We resolve the first of these four issues by assuming that the stiffness in the equations is due entirely to the source term. Hence, a fully implicit method is unnecessary for stability [46], and we choose to use a semi-implicit approach for computational simplicity. In the remainder of this paper we address the other issues with analytical and numerical results. We present evidence in support of the following conclusions:

(1) The method must use an unsplit approach which couples the source term and the conservation laws in order to achieve higher-order accuracy for stiff systems.

(2) The Riemann solver does not have to account for the equilibrium equation nor for the presence of source terms for the purpose of accuracy. Nevertheless, the method should use a Riemann solver which satisfies the following:

(1.2)
(A) The Riemann solver reduces to a Riemann solver for the equilibrium equation in the limit as relaxation time tends to zero.
(B) The numerical flux determined by the Riemann solver implies that the method is an upwind scheme [21] for all positive values of the relaxation time.

A Riemann solver satisfying (1.2) ensures that the method reduces to an upwind-centered difference scheme [35] for the equilibrium equation in the limit as the relaxation time approaches zero. If the Riemann solver does not satisfy (1.2), the method is more likely to produce oscillations at discontinuities [35], [40], [41] when the system is stiff.

(3) The step of the higher-order Godunov method which uses the characteristic form of the equations does not have to account directly for the characteristic form of the equilibrium equations. However, the test for determining which components of the characteristic form of the nonequilibrium equations to discard must be modified in order to achieve higher-order accuracy for stiff systems. This change in turn requires a modification to the portion of the algorithm that helps preserve monotonicity [37].

In this paper we present a higher-order Godunov method that uses an unsplit approach and that implements a new test for determining which components of the characteristic form of the nonequilibrium equations to discard. Both of these features are needed to ensure that the method reduces to a second-order method for the equilibrium system as the relaxation time tends to zero.

Our method, however, does not actually use a Riemann solver which satisfies (1.2). We believe that the development of such a Riemann solver for a general hyperbolic conservation law with relaxation is an open problem. Bolstad et al. [4] discuss a semi-implicit, unsplit second-order Godunov method for a stiff system of equations modeling gas dynamics with heat sources and sinks. The Riemann solver in their method uses shock jump conditions which are correct for zero and infinite relaxation times, and which vary in a continuous way for intermediate values of the relaxation time. We are uncertain, however, whether their method is an upwind scheme for all intermediate values of the relaxation time.

The remainder of the paper is organized as follows:

In §2 we review the second-order Godunov method [1], [11] for hyperbolic conservation laws with nonstiff source terms in one space dimension. In §3 we discuss how to modify the method in [11] in order to obtain a second-order Godunov method for hyperbolic conservation laws with stiff, relaxing source terms. We refer to the methods in §§2 and 3 as the *nonstiff method* and the *frozen method*, respectively. In §4, we briefly present three variant methods. We present these methods not as potential alternatives to the frozen method but as aids in the analysis of the frozen method.

In §5 we develop a model system of equations and two specific test problems. In §6, we analyze the frozen method and the three variant methods presented in §4. We show that the frozen method is second-order accurate for smooth solutions in the limit as the relaxation time approaches zero. We also demonstrate that two of its features, the coupling of the source term and its modified treatment of the characteristic form of the equations, are necessary for obtaining higher-order accurate solutions when the model system is stiff. We also show that the method does not reduce to an upwind method for the equilibrium equation as the model system becomes increasingly stiff. In §7 we show numerical results which validate the analysis in §6.

In §8 we apply the frozen method and the three variant methods to the equations describing one-dimensional inviscid gas flow coupled to a constant temperature heat sink. We solve two test problems, an isothermal shock and an isothermal rarefaction. The results are consistent with the results discussed in §§6 and 7 for the model system. The results in §8 also show that the frozen method may produce numerical oscillations near shocks. We conclude that the numerical oscillations produced by the frozen method may be reduced if its Riemann solver were replaced by one which satisfies (1.2). In §9, we discuss some considerations in the development of a Riemann solver with the property in (1.2). We also discuss extending the method to the equations of gas flow with chemical and vibrational nonequilibrium.

Remark. The method introduced in §3 addresses the problem of obtaining higher-order accuracy for stiff hyperbolic conservation laws with relaxation for which the frozen and the equilibrium characteristic speeds satisfy some form of a subcharacteristic condition. The method does not solve the problem of spurious solutions of hyperbolic systems with relaxation for which the subcharacteristic condition is violated [31], or, more generally, of hyperbolic systems with stiff source terms for which the limits of vanishing viscosity and vanishing relaxation time do not commute. In particular, the method does not alleviate the problem of spurious solutions arising in the numerical approximation of the equations of reacting gas dynamics [13] or any of the model systems for reacting flow [26], [29]. In [31], we conjecture that there are inherent problems in using a purely shock capturing finite difference scheme to solve a system of hyperbolic conservation laws with stiff source terms for which the limits of vanishing viscosity and vanishing relaxation do not commute. The problem of spurious solutions for systems of this type can be solved, we believe, only by effectively resolving the time scales of the stiff source term via methodologies such as adaptive mesh refinement [2], front tracking [5], subcell resolution [20], [7], [19], and numerical induction [15].

2. Review: Method for nonstiff source terms.

In this section, we review the second-order Godunov method [1], [11] for hyperbolic systems of conservation laws with nonstiff source terms in one space dimension. We refer to this method as the *nonstiff method*. This method is based on earlier work by van Leer [36], [37] and by Colella and Woodward [14] for gas dynamics.

We consider a hyperbolic system of conservation laws with nonstiff source terms in one space dimension, i.e., a system of the form

$$\begin{gathered}\frac{\partial U}{\partial t}+\frac{\partial F(U)}{\partial x}=S(U,x), \quad t\geq 0, \quad -\infty<x<\infty, \\ U=U(x,t), \quad F(U), \quad S(U,x)\in \boldsymbol{R}^N,\end{gathered} \tag{2.1}$$

where for all U under consideration the Jacobian of F, $A(U)=\partial F/\partial U$, has N real eigenvalues $\lambda_1\leq\lambda_2\cdots\leq\lambda_N$, called the characteristic speeds of the system, corresponding to N linearly independent right eigenvectors $r^k, k = 1, \dots, N$. We assume that the ordering of the characteristic speeds is global, and that all N characteristic fields are either genuinely nonlinear or linearly degenerate. We also assume that the Riemann problem for (2.1) with $S(U,x) \equiv 0$,

$$\begin{aligned} U(x,0) &= U_L, \quad x < 0, \\ &= U_R, \quad x > 0, \end{aligned}$$

has a unique solution for all U_L, U_R under consideration. To aid in the description of the algorithm, we define the matrix of right eigenvectors of $A(U)$ by $R = (r_1 \cdots r_N)$ and the matrix of left eigenvectors by $L = R^{-1} = (l_1 \cdots l_N)^T$, where R and L have been normalized so that $LR = \boldsymbol{I}$.

We now describe the second-order Godunov method for (2.1). We pick a fixed spatial grid with cell width Δx indexed over j. To advance the solution at time t_n, we use a time step Δt which satisfies the Courant–Friedrichs–Lewy (CFL) stability condition,

$$\Delta t = \sigma \frac{\Delta x}{\max_{k,j} |\lambda^n_{k,j}|}, \tag{2.2}$$

where $\lambda^n_{k,j}$ is the kth eigenvalue of $A(U^n_j)$ and σ is a constant called the Courant number, $\sigma < 1$. We assume that the largest eigenvalue of the Jacobian matrix $\partial S(U,x)/\partial U$ is significantly smaller in magnitude than $(\max_{k,j} |\lambda^n_{k,j}|)/\Delta x$, i.e., the system is not stiff with respect to the source term.

The algorithm consists of four general steps:

(1) the calculation of limited central difference approximations of ΔU in each cell j, where $\Delta U/\Delta x$ is an approximation of $\partial U/\partial x$ at the cell center;

(2) the calculation of time-centered left and right states, $U^{n+1/2}_{j+1/2,l}$ and $U^{n+1/2}_{j+1/2,r}$, at each cell edge, i.e., at $t = (n + 1/2)\Delta t$, $x = (j + 1/2)\Delta x$. Since these values are calculated by integrating the linearized characteristic form of (2.1), we refer to this step as the *characteristic tracing* step;

(3) the solution of the Riemann problem at each cell edge with left and right states given by $U^{n+1/2}_{j+1/2,l}, U^{n+1/2}_{j+1/2,r}$ for (2.1) with $S(U,x) \equiv 0$ and the evaluation of that solution along the ray $x/t = 0$ to obtain $U^{n+1/2}_{j+1/2}$;

(4) the calculation of U^{n+1}_j by an application of the divergence theorem. The solution of the Riemann problem in (3) is used to approximate the flux terms $F^{n+1/2}_{j+1/2} = F(U^{n+1/2}_{j+1/2})$ and to approximate the average of $S(U,x)$ over $[(j-1/2)\Delta x, (j+1/2)\Delta x] \times [t_n, t_n + \Delta t]$:

$$\begin{aligned} U^{n+1}_j &= U^n_j + \frac{\Delta t}{\Delta x}\left(F^{n+\frac{1}{2}}_{j-\frac{1}{2}} - F^{n+\frac{1}{2}}_{j+\frac{1}{2}}\right) \\ &\quad + \frac{\Delta t}{2}\left(S\left(U^{n+\frac{1}{2}}_{j-\frac{1}{2}}, \left(j - \frac{1}{2}\right)\Delta x\right) + S\left(U^{n+\frac{1}{2}}_{j+\frac{1}{2}}, \left(j + \frac{1}{2}\right)\Delta x\right)\right). \end{aligned}$$

We refer to this step as the conservative differencing step. A dissipative flux term can be added to the numerical flux when strong shocks are present; see [11] and [14].

Step (4) is self-explanatory. We refer the reader to the literature for the details of step (3). Exact Riemann problem solvers exist for very few hyperbolic systems. Riemann solvers for gas dynamics [9], [12] and for gas dynamics with combustion [10], [34] have been developed. There are also a number of algorithms [1], [30], [32] for approximating the solution of the Riemann problem for general hyperbolic systems. We describe the details of the other two steps below. Throughout the description we often omit the superscript n to simplify the notation.

Remark. Steps (1)–(3) of the algorithm can be applied to any W that is related to U by an invertible map $U = U(W)$. For example, in the case of Eulerian gas dynamics in one space dimension where $U = (\rho, \rho u, \rho E)$, one can use $W = (\rho, u, p)$.

Remark. We want to stress here that there is no reason for the purpose of accuracy to include the effect of the source term in the solution of the Riemann problem. The left and right values calculated in the characteristic tracing step at a given edge are locally second-order accurate estimates of the solution at that edge at the half time level. The purpose of solving the Riemann problem is simply to resolve the instantaneous wave interactions of the left and right states in order to obtain an upwind state at the cell edge.

2.1. Limited central difference approximations. The first step of the algorithm calculates $(\Delta U)_j$, a monotonized central difference approximation to $(\partial U/\partial x)\,\Delta x$ at each cell center:

$$(\Delta U)_j = \sum_{k=1}^{N} (\alpha_{k,j})\,(r_{k,j})\,.$$

The $r_{k,j}$ are the right eigenvectors of $A(U_j^n)$. The $\alpha_{k,j}$ are calculated as follows. Define three vectors, α^C, α^L, and α^R, by

$$\begin{aligned}\alpha^C &= L_j(\tfrac{1}{2}(U_{j+1} - U_{j-1})),\\ \alpha^L &= L_j(U_j - U_{j-1}),\\ \alpha^R &= L_j(U_{j+1} - Uj),\end{aligned}$$

where L_j is the matrix of left eigenvectors of $A(U_j^n)$. $\alpha_{k,j}$ is then given by

$$\begin{aligned}\alpha_{k,j} &= \min(|\alpha_k^C|, 2|\alpha_k^L|, 2|\alpha_k^R|) \times \operatorname{sgn}(\alpha_k^C) && \text{if } \alpha_k^L\alpha_k^R > 0,\\ &= 0 && \text{otherwise.}\end{aligned} \tag{2.3}$$

We call the values $\alpha_{k,j}$ *expansion coefficients*. In a given cell j, the expansion coefficients are the slopes of the linear profiles of the solution in the space of the right eigenvectors of $A(U_j^n)$. We refer to (2.3) as the *slope limiting procedure* because it generally sets $\alpha_{k,j} = \alpha_k^C$ unless there are nearby local extrema or large gradients in U.

Remark. The slope limiting procedure is an attempt to preserve monotonicity in each characteristic field [37]. Additional dissipation can be added near strong shocks by a slope-flattening algorithm [11], [14].

2.2. Characteristic tracing. The second step of the algorithm computes the time-centered left and right states at the cell edges, $U_{j+1/2,l}^{n+1/2}$ and $U_{j+1/2,r}^{n+1/2}$. The left and right states at a given cell edge are computed by second-order accurate Taylor expansions about the cell centers of the cells to the left and the right of the edge. In computing the left state, however, we use a characteristic projection operator that discards those components in the $\partial U/\partial x$ term corresponding to characteristics which do not originate in the cell to the left of the cell edge, i.e., only characteristics with positive speeds are used in the calculation of the left state. A similar procedure is followed for the right state. This procedure has no effect for problems in which $F(U) = AU$ where A is a constant matrix, since the discarded components do not affect the solution of the Riemann problem in that case. However, using the characteristic projection operators results in a more robust algorithm for strongly nonlinear problems [11].

We first look at the calculation of the left state. ($\lambda_{k,j}$, $l_{k,j}$, and $r_{k,j}$ are the kth eigenvalue, left eigenvector, and right eigenvector, respectively, of $A(U_j^n)$.) From Taylor's theorem,we have

$$\begin{aligned} U_{j+\frac{1}{2},l}^{n+\frac{1}{2}} &= U_j^n + \frac{\Delta x}{2}\left(\frac{\partial U}{\partial x}\right)_j^n + \frac{\Delta t}{2}\left(\frac{\partial U}{\partial t}\right)_j^n \\ &= U_j^n + \frac{\Delta x}{2}\left(\frac{\partial U}{\partial x}\right)_j^n + \frac{\Delta t}{2}\left(S\left(U_j^n, x\right) - \left(\frac{\partial F(U)}{\partial x}\right)_j^n\right) \\ &= U_j^n + \frac{1}{2}\left(I - \frac{\Delta t}{\Delta x}A\left(U_j^n\right)\right)(\Delta U)_j + \frac{\Delta t}{2}S\left(U_j^n, j\Delta x\right), \end{aligned}$$

where $(\cdot)_j^n$ denotes evaluation at $(t^n, j\Delta x)$. We now replace

$$\left(I - \frac{\Delta t}{\Delta x}A\left(U_j^n\right)\right)(\Delta U)_j$$

in the above expression by

$$P_L\left(\left(I - \frac{\Delta t}{\Delta x}A\left(U_j^n\right)\right)(\Delta U)_j\right),$$

where P_L is defined by

$$P_L(w) = \sum_{k:\lambda_{k,j}>0} (l_{k,j}\cdot w)\, r_{k,j}. \tag{2.4}$$

The resulting algorithm for calculating $U_{j+1/2,l}^{n+1/2}$ is

$$U_{j+\frac{1}{2},l}^{n+\frac{1}{2}} = U_j^n + \frac{1}{2}\sum_{k:\lambda_{k,j}>0}\left(1 - \frac{\Delta t}{\Delta x}\lambda_{k,j}\right)\alpha_{k,j} r_{k,j} + \frac{\Delta t}{2}S\left(U_j^n, j\Delta x\right).$$

Similarly, $U_{j+1/2,r}^{n+1/2}$ is given by

$$U_{j+\frac{1}{2},r}^{n+\frac{1}{2}} = U_{j+1}^n - \frac{1}{2}P_R\left(\left(I + \frac{\Delta t}{\Delta x}A\left(U_{j+1}^n\right)\right)(\Delta U)_{j+1}\right) + \frac{\Delta t}{2}S\left(U_{j+1}^n, (j+1)\Delta x\right),$$

where P_R is defined by

$$P_R(w) = \sum_{k:\lambda_{k,j+1}<0} (l_{k,j+1}\cdot w)\, r_{k,j+1}. \tag{2.5}$$

The resulting algorithm for calculating $U^{n+1/2}_{j+1/2,r}$ is

$$U^{n+\frac{1}{2}}_{j+\frac{1}{2},r} = U^n_{j+1} - \frac{1}{2} \sum_{k:\lambda_{k,j+1}<0} \left(1 + \frac{\Delta t}{\Delta x}\lambda_{k,j+1}\right) \alpha_{k,j+1} r_{k,j+1} + \frac{\Delta t}{2} S\left(U^n_{j+1}, (j+1)\Delta x\right).$$

Remark. The slope limiting procedure and the characteristic projection operators together guarantee that the following is true in the calculation of each left and right state at each edge: The origin of the characteristic in each characteristic field used in computing the value of the state is in the cell in which the linear profile corresponding to that field cannot contain new local extrema.

3. Second-order Godunov method for stiff relaxation. We now modify the nonstiff method to obtain a second-order Godunov method which computes higher-order accurate solutions of a stiff hyperbolic system of conservation laws with relaxation without fully resolving the effects of the stiff source terms. We refer to this method as the *frozen method* because its Riemann solver does not account for the equilibrium equation.

We consider a hyperbolic system of conservation laws with relaxation for which there is a single rate equation, i.e., a system of the form

$$(3.1)\qquad \begin{gathered} \frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = S(U,x) + H(U), \quad t \geq 0, \quad -\infty < x < \infty, \\ U = U(x,t), \quad F(U), \quad S(U,x), \quad H(U) \in \boldsymbol{R}^N, \end{gathered}$$

where

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = S(U,x)$$

is a hyperbolic conservation law with nonstiff source terms. $H(U)$ has the form $(0,0,\ldots,0,h(U))^T$. Define $M = N-1$ and U_M to be a vector of the first M components of U. We assume that a function $u_N = f(U_M)$ is defined implicitly by $h(U) = c$ for all values of c. The equilibrium value of u_N equals $u_*(U_M)$, where $u_*(U_M)$ satisfies the equation $h(U_M, u_*(U_M)) = 0$. We refer to (3.1) as the *nonequilibrium* system. The *equilibrium* system corresponding to (3.1) is

$$(3.2)\qquad \frac{U_M}{\partial t} + \frac{\partial F_*(U_M)}{\partial x} = S(U_M, x),$$

where $F_*(U_M) = F(U_M, u_*(U_M))$. We assume that the characteristic speeds of (3.1) and (3.2) are all distinct and that they satisfy the subcharacteristic condition (1.1) for all U_M. We also assume that all M characteristic fields of the equilibrium equation are either genuinely nonlinear or linearly degenerate. We finally assume that

$$\frac{\partial h(U)}{\partial(u_N - u_*(U_M))} < 0$$

for all U. The reciprocal of the absolute value of the left-hand side of this inequality is the relaxation time $\tau(U)$.

In our second-order Godunov method for (3.1), we want to use the time step given by (2.2) to advance the solution at time t_n even though the system may be stiff, i.e., $\max_{k,j}(\Delta x/\tau(U^n_j))/|\lambda^n_{k,j}| \gg 1$. We therefore make the algorithm in §2 semi-implicit with respect to $H(U)$ by modifying the second and fourth steps of the nonstiff method. We also make modifications to the characteristic projection operator used in the characteristic tracing step and to the limiting procedure (2.3) of the central difference approximation step. The first of these two changes ensures that the method is second-order accurate for stiff problems with smooth solutions. The second change helps the characteristic tracing step maintain some of the same properties as the tracing step in the nonstiff method.

The third step of the nonstiff method, the Riemann solver, does not have to be modified for the purpose of accuracy. On the other hand, the Riemann solver should satisfy (1.2) so that the overall method is an upwind-centered difference scheme for all nonnegative values of the relaxation time. At the present time, we believe that the development of a Riemann solver that satisfies (1.2) for a general hyperbolic conservation law with stiff relaxation is an open problem. Bolstad et al. [4] have made some progress in this area for a particular system. (See the comments in §1 for further discussion.) In the method presented here, we solve the same Riemann problem as in the nonstiff method in §2, i.e., assuming $H(U) \equiv 0$. In all our applications of the method in this paper, we use an exact Riemann solver.

In our presentation of the frozen method, we discuss the characteristic tracing step before the central difference approximation step in order to motivate the changes we make to the limiting procedure.

3.1. Characteristic tracing. We now modify the characteristic tracing step of the method in §2. This step requires two modifications. The first one is simply that the stiff source term $H(U)$ be treated semi-implicitly in the Taylor expansions, i.e., in the case of a left edge, H must be evaluated at $U^{n+1/2}_{j+1/2,l}$, not at U^n_j:

$$U^{n+\frac{1}{2}}_{j+\frac{1}{2},l} = U^n_j + \frac{1}{2}\left(I - \frac{\Delta t}{\Delta x}A\left(U^n_j\right)\right)(\Delta U)_j$$
$$+ \frac{\Delta t}{2}\left(S\left(U^n_j, j\Delta x\right) + H\left(U^{n+\frac{1}{2}}_{j+\frac{1}{2},l}\right)\right).$$

Similarly,

$$U^{n+\frac{1}{2}}_{j+\frac{1}{2},r} = U^n_{j+1} - \frac{1}{2}\left(I + \frac{\Delta t}{\Delta x}A\left(U^n_{j+1}\right)\right)(\Delta U)_{j+1}$$
$$+\frac{\Delta t}{2}\left(S\left(U^n_{j+1}, j\Delta x\right) + H\left(U^{n+\frac{1}{2}}_{j+\frac{1}{2},r}\right)\right).$$

The second modification is in the definitions of the characteristic projection operators P_L and P_R defined in (2.4) and (2.5). This change is needed to maintain second-order accuracy when the source term is stiff. The numerical method should essentially reduce to a second-order method for the equilibrium equation as $\tau(U) \to 0$. The method, then, should not "discard" any components of $\partial U/\partial x$ used by such a method. If the kth field of the equilibrium equation is needed for a second-order accurate solution of the equilibrium equation, the method should use the components of $\partial U/\partial x$ corresponding to the kth or the $(k+1)$st characteristic fields of (3.1) as $\tau(U) \to 0$, since disturbances carried by the kth field of the equilibrium equation must be present in the disturbances carried by the two fields of (3.1) [27], [43]. If the projection operators as defined in [11] are used, however, the method may "discard" some components of $\partial U/\partial x$ which are needed for second-order accuracy.

For example, suppose that the kth equilibrium characteristic speed in the jth cell is positive. The method should then use the kth and the $(k+1)$st characteristic fields of (3.1) in computing $U^{n+1/2}_{j+1/2,l}$. Since the subcharacteristic condition is satisfied, the component of $\partial U/\partial x$ corresponding to the $(k+1)$st characteristic field is not discarded by the projection operator P_L in the nonstiff method. However, the kth characteristic speed can be positive or negative. If it is negative, the component of $\partial U/\partial x$ corresponding to the kth characteristic field is discarded, and accuracy is lost as $\tau(U) \to 0$.

We therefore modify the characteristic projection operators in order to avoid a loss of accuracy as the relaxation time tends to zero. We use the following criteria so that a direct calculation of the equilibrium characteristic speeds is unnecessary:

(1) Use the kth characteristic field in the computation of $U^{n+1/2}_{j+1/2,l}$ if $k = N$ and $\lambda_{k,j} > 0$ or $k < N$ and $\lambda_{k+1,j} > 0$.

(2) Use the kth characteristic field in the computation of $U^{n+1/2}_{j+1/2,r}$ if $k = 1$ and $\lambda_{k,j+1} < 0$ or $k > 1$ and $\lambda_{k-1,j+1} < 0$.

These criteria are conservative in the sense that more components of $\partial U/\partial x$ may be kept than are necessary for second-order accuracy.

One result of using these criteria is that additional limiting may be needed in some of the expansion coefficients $\alpha_{k,j}$, i.e., the magnitude of $\alpha_{k,j}$ may have to be smaller than the magnitude calculated in (2.3). In order to minimize the additional amount of limiting, we find two sets of expansion coefficients in the central difference approximation step. We compute coefficients $\alpha^l_{k,j}$, which are used in the calculation of $U^{n+1/2}_{j+1/2,l}$, and $\alpha^r_{k,j}$, which are used in the calculation of $U^{n+1/2}_{j+1/2,r}$.

The resulting algorithm for calculating $U^{n+1/2}_{j+1/2,l}$ is the following:

$$\begin{aligned} U^{n+\frac{1}{2}}_{j+\frac{1}{2},l} &= U^n_j + \frac{1}{2} \sum_{k:\lambda_{k,j}>0 \text{ or } \lambda_{k+1,j}>0} \left(1 - \frac{\Delta t}{\Delta x}\lambda_{k,j}\right) \alpha^l_{k,j} r_{k,j} \\ &\quad + \frac{\Delta t}{2}\left(S\left(U^n_j, j\Delta x\right) + H\left(U^{n+\frac{1}{2}}_{j+\frac{1}{2},l}\right)\right). \end{aligned} \tag{3.3}$$

Similarly, the algorithm for $U^{n+1/2}_{j+1/2,r}$ is as follows:

$$\begin{aligned} U^{n+\frac{1}{2}}_{j+\frac{1}{2},r} &= U^n_{j+1} - \frac{1}{2} \sum_{k:\lambda_{k,j+1}<0 \text{ or } \lambda_{k-1,j+1}<0} \left(1 + \frac{\Delta t}{\Delta x}\lambda_{k,j+1}\right) \alpha^r_{k,j+1} r_{k,j+1} \\ &\quad + \frac{\Delta t}{2}\left(S\left(U^n_{j+1}, (j+1)\Delta x\right) + H\left(U^{n+\frac{1}{2}}_{j+\frac{1}{2},r}\right)\right). \end{aligned} \tag{3.4}$$

Both expressions are explicit for U_M but implicit for u_N. The Nth components of $U^{n+1/2}_{j+1/2,l}$ and $U^{n+1/2}_{j+1/2,r}$ are found by solving the equations defined by these expressions for u_N.

3.2. Limited central difference approximations. Our method for stiff relaxation may generate unacceptable oscillations in the numerical solution of a nonstiff strong shock problem if it uses the same central difference approximation step as the nonstiff method. This possibility arises because of the characteristic tracing algorithm, (3.3) and (3.4). Suppose, for example, that a characteristic field corresponding to a characteristic with a negative speed is used in the calculation of a left state at a cell edge. The origin of that characteristic is in the cell to the right of the cell edge. In that cell, the linear profile corresponding to that field which originates in the cell to the left of the edge may contain new local extrema; the slope-limiting procedure (2.3) prohibits the introduction of new local extrema only within the cell where the profile originates [36].

To eliminate the introduction of new extrema, our method uses a more restrictive slope-limiting procedure to calculate two sets of expansion coefficients. One set is used in the calculation of left edge states (3.3); the other is used in the calculation of right edge states (3.4). Although we could use a single set of expansion coefficients for both cell edges, we use two sets to minimize the dissipative effect [37] of the additional slope limiting. We now show the details of calculating $\alpha^l_{k,j}$, the expansion coefficient for the kth characteristic field used in calculating $U^{n+1/2}_{j+1/2,l}$; the details of the calculation of the expansion coefficients used in calculating $U^{n+1/2}_{j+1/2,r}$ are similar.

α^C, α^L, and α^R are defined as in §2.1. If $\lambda_{k,j} > 0$, (2.3) is used to find $\alpha^l_{k,j}$. However, if $\lambda_{k,j} \le 0$, $\alpha^l_{k,j}$ is given by the following:

$$\begin{aligned} \alpha^l_{k,j} &= \min\left(\left|\alpha^C_k\right|, 2\left|\alpha^L_k\right|, \beta_{k,j}\left|\alpha^R_k\right|\right) \times \operatorname{sgn}\left(\alpha^C_k\right) && \text{if } \alpha^L_k\alpha^R_k > 0, \\ &= 0 && \text{otherwise,} \end{aligned} \tag{3.5}$$

where

$$\beta_{k,j} = 2 - \left|\lambda_{k,j}\right| \frac{\Delta t}{\Delta x}. \tag{3.6}$$

The CFL condition implies that $2 - \sigma \le \beta \le 2$. Since β is bounded away from 1, our method is still second-order accurate. (See van Leer [37] for further discussion.) Suppose $\lambda_{k,j} \le 0$ and the kth characteristic field is used in the calculation of $U^{n+1/2}_{j+1/2,l}$. The value of $\beta_{k,j}$ calculated in (3.6) is then the largest possible value that can be used in (3.5) which guarantees the following: if the kth characteristic field is used in the calculation of $U^{n+1/2}_{j+1/2,l}$, the linear profile corresponding to that field does not contain any value outside the range of values determined by cells j and $j+1$.

3.3. Conservative differencing. We now modify the fourth step of the method in §2. Suppose we wanted to obtain a globally second-order accurate numerical solution to the stiff *ordinary* differential equation

$$\frac{du_N}{dt} = h(U_M, u_N) \tag{3.7}$$

using a time step $\Delta t \gg \tau(U)$ where U_M is fixed. We want the numerical solution of u_N to decay rapidly to $u_*(U_M)$ as $\tau(U) \to 0$. Hence, we require a second-order method that is L-stable. An L-stable method is one for which numerical solutions of the test equation $y' = \lambda y$ decay rapidly to zero as $\lambda \to -\infty$. (See Lambert [24] for a detailed discussion of numerical methods for stiff ordinary differential equations.)

We see from this discussion that ideally we want to incorporate a second-order, single-step, L-stable method into the fourth step of the Godunov method to account for the contribution of $H(U)$. The condition that the method be single step requires us to use an L-stable, implicit R-stage Runge–Kutta method, $R \ge 2$. These methods, however, can be computationally expensive since each stage requires the solution of a nonlinear equation. Yee [45] discusses alternatives to using a second-order, single-step, L-stable method.

In this paper we defer the issue of a second-order L-stable method because our main concern is with maintaining second-order accuracy as the relaxation time approaches zero. Hence, for the purpose of this paper, it is sufficient to use any L-stable method, since any such method would set $u_{N,j}^{n+1}$ to $u_*(U_{M,j}^{n+1})$ in the limit of $\tau \to 0$. The method used to calculate the numerical results in this paper has a conservative differencing step which incorporates the backward Euler method, a first-order L-stable method:

$$(3.8)\quad \begin{aligned} U_j^{n+1} &= U_j^n + \frac{\Delta t}{\Delta x}\left(F_{j-\frac{1}{2}}^{n+\frac{1}{2}} - F_{j+\frac{1}{2}}^{n+\frac{1}{2}}\right) + \Delta t H\left(U_j^{n+1}\right) \\ &\quad + \frac{\Delta t}{2}\left(S\left(U_{j-\frac{1}{2}}^{n+\frac{1}{2}}, \left(j-\frac{1}{2}\right)\Delta x\right) + S\left(U_{j+\frac{1}{2}}^{n+\frac{1}{2}}, \left(j+\frac{1}{2}\right)\Delta x\right)\right). \end{aligned}$$

This expression is explicit for U_M but implicit for u_N. u_N is updated by solving the equation for $u_{N,j}^{n+1}$ defined by (3.8).

We note that the method used in calculating the results in this paper is second-order accurate only in the limit $\tau(U) \to 0$. For long relaxation times, the method is only first-order accurate because a second-order L-stable method is not incorporated into its conservative differencing step.

4. Three variant methods. We now briefly present three variants of the method in §3. These methods should not be considered potential alternatives to the method in the previous section. We introduce these variants solely to help us analyze and illustrate through numerical results certain features of the frozen method.

The first variant is a fractional step method which uses Strang splitting. In the first and third fractional steps, a second-order L-stable method is used to integrate

$$\frac{\partial U}{\partial t} = H(U)$$

for time steps of $\Delta t/2$. In the second step, the second-order Godunov method for nonstiff source terms is used to integrate

$$\frac{\partial U}{\partial t} + \frac{\partial F(U)}{\partial x} = S(U, x)$$

for a time step of Δt. The time step is governed by the CFL condition (2.2). We will refer to this variant as the *fractional step method.* We will use the method to demonstrate that an operator split treatment of the stiff source term is insufficient for obtaining higher-order accuracy.

The second variant is nearly identical to the method presented in the previous section. The only difference is that the characteristic projection operators P_L and P_R are identical to the ones used in the nonstiff method. We will refer to this variant as the *nonstiff projection method.* We will use the method to demonstrate that the characteristic projection operators in the frozen method must differ from the operators of the nonstiff method to obtain higher-order accuracy.

The third variant is also nearly identical to the method presented in the previous section. The only difference is that a Riemann solver for the equilibrium equation (3.2) is used in place of a Riemann solver for (3.1) to find the first M components of $U_{j+1/2}^{n+1/2}$; the nth component of $U_{j+1/2}^{n+1/2}$ is set to $u_*((U_M)_{j+1/2}^{n+1/2})$. We note that this variant is strictly applicable only in the limit $\tau(U) \to 0$. We will refer to this variant as the *equilibrium method*. We will use the method to demonstrate that the method in §3 may be improved if its Riemann solver satisfies (1.2).

5. Formulation of model system and test problems. In this section, we formulate a model hyperbolic system of conservation laws with relaxation. We then formulate two specific test problems. The model system is derived from the system in [31] by applying the following change of coordinates to that system:

$$x \leftarrow X + aT,$$
$$t \leftarrow T.$$

Our model is an example of the system examined by Liu [27]. It is also similar to the combustion model considered by Majda [29]; see the discussion in [31].

5.1. A model system for relaxation. We consider the following system of hyperbolic conservation laws with relaxation:

$$\frac{\partial}{\partial t}\begin{pmatrix} w \\ z \end{pmatrix} + \frac{\partial}{\partial x}\begin{pmatrix} \frac{1}{2}u^2 + aw \\ az \end{pmatrix} = \begin{pmatrix} 0 \\ -K(z - m(u - u_0)) \end{pmatrix}, \tag{5.1}$$

where $u = w - q_0 z$, and a, K, q_0, m, and u_0 are constants satisfying $K > 0$, $q_0 < 0$, $m < 0$, and $u_0 > 0$. a can be zero, positive, or negative. The relaxation time of the system is $1/K$. The system has characteristic speeds $\lambda_1(w, z) = a$ and $\lambda_2(w, z) = u + a$. We consider only those problems for which $u > 0$ for all x, t.

The equilibrium equation for (5.1) is

$$\frac{\partial w}{\partial t} + \frac{\partial}{\partial x}\left(\frac{1}{2}u_*(w)^2 + aw\right) = 0, \tag{5.2}$$

where $u_*(w)$ is defined by

$$\begin{aligned} u_*(w) &= w - q_0 z_*(w), \\ z_*(w) &= \frac{m}{1 + mq_0}(w - u_0). \end{aligned} \tag{5.3}$$

$z_*(w)$ is the equilibrium value of z for a given value of w. The equilibrium characteristic speed λ_* is

$$\lambda_*(w) = u_*(w)u_*'(w) + a = \frac{u_*(w)}{1 + mq_0} + a. \tag{5.4}$$

We observe that when $u > 0$, the frozen and the equilibrium characteristics satisfy the subcharacteristic condition.

5.2. Two test problems. We now formulate and solve two problems of the model system. Both problems consist of finding the limit as $K \to \infty$ of the solution of an initial value problem of (5.1). The problems are formulated so that the initial values are in equilibrium and $u_*(w) > 0$ for all x, t. We assume the results of Liu [28] and calculate these limits indirectly by finding solutions of the equilibrium equation. The solution of the first problem is a rarefaction wave of the equilibrium equation; the solution of the second is a shock wave.

The first test problem is to find $\lim_{K\to\infty} w(x,t)$ where

$$\begin{aligned}(w,z)(x,0) &= (w_l, z_*(w_l)), \qquad x < x_0,\\ &= (w_r, z_*(w_r)), \qquad x > x_0,\end{aligned}$$

and $0 < u_l = w_l - q_0 z_*(w_l) < u_r = w_r - q_0 z_*(w_r)$. The solution of this problem is

$$\begin{aligned}\lim_{K\to\infty} w(x,t) &= w_l, \qquad \frac{x-x_0}{t} \le \frac{u_l}{1+q_0 m} + a,\\ &= w_r, \qquad \frac{x-x_0}{t} \ge \frac{u_r}{1+q_0 m} + a,\\ &= \frac{x-x_0}{t}, \qquad \text{otherwise.}\end{aligned}$$

We will refer to this problem as the rarefaction test problem.

The second test problem is to find $\lim_{K\to\infty} w(x,t)$ where

$$\begin{aligned}(w,z)(x,0) &= (w_l, z_*(w_l)), \qquad x < x_0,\\ &= (w_r, z_*(w_r)), \qquad x > x_0,\end{aligned}$$

and $u_l = w_l - q_0 z_*(w_l) > u_r = w_r - q_0 z_*(w_r) > 0$. The solution of this problem is

$$\begin{aligned}\lim_{K\to\infty} w(x,t) &= w_l, \qquad x < x_0 + st,\\ &= w_r, \qquad x > x_0 + st,\end{aligned}$$

where $s = \frac{1}{2}(u_l^2 - u_r^2)/(w_l - w_r)$. We will refer to this problem as the shock test problem.

6. Analysis of numerical methods for stiff problems. In this section we analyze how well the methods in §3 and the variant methods in §4 approximate solutions of the model equations (5.1) as $K \to \infty$. There are two main goals of this analysis. The first is to show that two of the features of the method in §3, the coupling of the source term in the Godunov method and the modified characteristic tracing step are, in some sense, necessary features of a second-order Godunov method for stiff relaxation. The other goal is to show that the method in §3 may be more robust for stiff problems if the Riemann solver is modified so that the solver satisfies the property in (1.2). We accomplish the first goal by showing that the method in §3 is a second-order accurate method while the fractional step method and the nonstiff projection method in §4 are first-order accurate methods. The second goal is achieved by showing that the method in §3 does not reduce to an upwind method for the equilibrium equation as the relaxation time tends to zero. The equilibrium method, on the other hand, is an upwind method for the equilibrium equation by construction.

The analysis in this section is based on an observation and an assumption. The observation is that for the model equations in §5, the method in §3 and the three variants in §4 can be expressed in the following form as $K \to \infty$:

$$w_j^{n+1} = w_j^n + \frac{\Delta t}{\Delta x}\left(f_{w,j-\frac{1}{2}}^{n+\frac{1}{2}} - f_{w,j+\frac{1}{2}}^{n+\frac{1}{2}}\right),$$

$$z_j^{n+1} = z_*\left(w_j^{n+1}\right),$$

$$f_{w,j+\frac{1}{2}}^{n+\frac{1}{2}} = \frac{1}{2}\left(w_{j+\frac{1}{2}}^{n+\frac{1}{2}} - q_0 z_{j+\frac{1}{2}}^{n+\frac{1}{2}}\right)^2 + a w_{j+\frac{1}{2}}^{n+\frac{1}{2}}.$$

The only difference among the methods in this limit is in the calculations of $w_{j+1/2}^{n+1/2}$ and $z_{j+1/2}^{n+1/2}$. The assumption is that Liu's conjecture [28] is true for the model system, i.e., solutions of (5.1) tend to solutions of (5.2) as $K \to \infty$. The analysis then reduces to examining how well the four methods calculate solutions of the equilibrium equation in the limit $K \to \infty$.

In the analysis of accuracy we use the fact that all four methods are upwind-centered difference schemes. Any one of these methods, then, is a globally second-order accurate method (i.e., a locally third-order accurate method) in the limit $K \to \infty$ if and only if the local truncation errors in the calculation of $w_{j+1/2}^{n+1/2}$ and $z_{j+1/2}^{n+1/2}$ are $O(\Delta x^2)$, i.e.,

$$
\begin{aligned}
w_{j+\frac12}^{n+\frac12} &= w_j^n + \frac{\Delta x}{2}\left(\frac{\partial w}{\partial x}\right)_j^n + \frac{\Delta t}{2}\left(\frac{\partial w}{\partial t}\right)_j^n + O\left(\Delta x^2\right) \\
&= w_j^n + \left(\frac{\Delta x}{2} - \frac{\Delta t}{2}\left(u_*\left(w_j^n\right)u_*'\left(w_j^n\right) + a\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right)
\end{aligned} \tag{6.1}
$$

and

$$
\begin{aligned}
z_{j+\frac12}^{n+\frac12} &= z_*\left(w_j^n + \frac{\Delta x}{2}\left(\frac{\partial w}{\partial x}\right)_j^n + \frac{\Delta t}{2}\left(\frac{\partial w}{\partial t}\right)_j^n\right) + O\left(\Delta x^2\right) \\
&= z_*\left(w_j^n\right) \\
&\quad + z_*'\left(w_j^n\right)\frac{1}{2}\left(\Delta x - \Delta t\left(u_*\left(w_j^n\right)u_*'\left(w_j^n\right) + a\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right),
\end{aligned} \tag{6.2}
$$

where $(\cdot)_j^n$ denotes evaluation at t_n, $j\Delta x$.

Most of this analysis consists of examining the truncation error of the characteristic tracing step in each method. We assume that $\Delta w/\Delta x$ and $\Delta z/\Delta x$ are first-order approximations to $\partial w/\partial x$ and $\partial z/\partial x$, i.e., we do not attempt to include the effect of slope limiting, (2.3) or (3.5).

6.1. Characteristic tracing: Fractional step method. We first demonstrate that an unsplit methodology is necessary for obtaining second-order accurate solutions of the model system as $K \to \infty$. We verify this by showing that the Godunov step in the fractional step method in §4 is only first-order accurate in this limit.

It is sufficient to consider the case $a > 0$. When $a > 0$, the Riemann solver sets $z_{j+1/2}^{n+1/2} = z_{j+1/2,l}^{n+1/2}$. We expand in Taylor's series the terms of the expressions used in the characteristic tracing step to calculate $z_{j+1/2,l}^{n+1/2}$ as follows:

$$
\begin{aligned}
z_{j+\frac12,l}^{n+\frac12} &= z_j^n + \frac12\left(1 - \frac{\Delta t}{\Delta x}a\right)(\Delta z)_j^n \\
&= z_*\left(w_j^n\right) + \frac12\left(\Delta x - \Delta t a\right)\left(\frac{\partial z}{\partial x}\right)_j^n + O\left(\Delta x^2\right) \\
&= z_*\left(w_j^n\right) + \frac12\left(\Delta x - \Delta t a\right)z_*'\left(w_j^n\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right).
\end{aligned}
$$

Since the difference between (6.2) and the last expression on the right is $O(\Delta x)$, the fractional step method is only first-order accurate.

6.2. Characteristic tracing: Nonstiff projection method. We demonstrate that the characteristic projection operators in the tracing step of the frozen method must differ from those operators in the nonstiff method. The characteristic projection operators must be different in order for the frozen method to produce second-order accurate solutions of the model system as $K \to \infty$. We verify this by showing that the nonstiff projection method in §4 is only first-order accurate as $K \to \infty$ when the frozen and the equilibrium characteristic speeds of the model system do not have the same sign.

It is sufficient to consider the case $a < 0 < u + a$ for all u under consideration. When $a < 0 < u + a$ for all u, the Riemann solver calculates $w_{j+1/2}^{n+1/2}$ as follows:

$$w_{j+\frac{1}{2}}^{n+\frac{1}{2}} = w_{j+\frac{1}{2},l}^{n+\frac{1}{2}} - q_0 z_* \left(w_{j+\frac{1}{2},l}^{n+\frac{1}{2}}\right) + q_0 z_* \left(w_{j+\frac{1}{2},r}^{n+\frac{1}{2}}\right). \tag{6.3}$$

We expand in Taylor's series the terms of the expressions used in the characteristic tracing step to calculate $w_{j+1/2,l}^{n+1/2}$, $w_{j+1/2,r}^{n+1/2}$, $z_{j+1/2,l}^{n+1/2}$, and $z_{j+1/2,r}^{n+1/2}$ as follows:

$$\begin{aligned}
w_{j+\frac{1}{2},l}^{n+\frac{1}{2}} &= w_j^n + \frac{1}{2}\left(\Delta x - \left(u_*\left(w_j^n\right) + a\right)\Delta t\right)\left(\Delta w_j^n - q_0 \Delta z_j^n\right), \\
&= w_j^n + \frac{1}{2}\left(\Delta x - \Delta t\left(u_*\left(w_j^n\right) u_*'\left(w_j^n\right) + a\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right), \\
w_{j+\frac{1}{2},r}^{n+\frac{1}{2}} &= w_{j+1}^n - \frac{1}{2}\left(\Delta x + \left(u_*\left(w_j^n\right) + a\right)\Delta t\right)\left(\Delta w_{j+1}^n - q_0 \Delta z_{j+1}^n\right) \\
&= w_j^n + \left(\Delta x - \frac{1}{2}\left(\Delta x + \Delta t a\right)\left(1 - u_*'\left(w_j^n\right)\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right), \\
z_{j+\frac{1}{2},l}^{n+\frac{1}{2}} &= z_*\left(w_{j+\frac{1}{2},l}^{n+\frac{1}{2}}\right) \\
&= z_*\left(w_j^n\right) + z_*'\left(w_j^n\right)\left(\frac{1}{2}\left(\Delta x - \Delta t\left(u_*\left(w_j^n\right) u_*'\left(w_j^n\right) + a\right)\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n \\
&\quad + O\left(\Delta x^2\right), \\
z_{j+\frac{1}{2},r}^{n+\frac{1}{2}} &= z_*\left(w_{j+\frac{1}{2},r}^{n+\frac{1}{2}}\right) \\
&= z_*\left(w_j^n\right) + z_*'\left(w_j^n\right)\left(\Delta x - \frac{1}{2}\left(\Delta x + \Delta t a\right)\left(1 - u_*'\left(w_j^n\right)\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n \\
&\quad + O\left(\Delta x^2\right).
\end{aligned}$$

After substituting the above expressions into (6.3), we obtain after some manipulations the following equation:

$$\begin{aligned}
w_{j+\frac{1}{2}}^{n+\frac{1}{2}} = w_j^n + \Bigg(\frac{\Delta x}{2} - \frac{\Delta t}{2}\left(u_*\left(w_j^n\right) u_*'\left(w_j^n\right) + a\right) + q_0 z_*'\left(w_j^n\right) u_*'\left(w_j^n\right) \\
\left(\Delta x - u_*\left(w_j^n\right)\Delta t\right)\Bigg)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right).
\end{aligned}$$

Since the difference between the expression on the right and (6.1) is $O(\Delta x)$, the nonstiff projection method is only first-order accurate.

Remark. We emphasize that the first-order accuracy of the nonstiff projection method does not depend in any way on the order of the L-stable method incorporated into the conservative differencing step. In the analysis above, we examined the nonstiff projection method in the limit $K \to \infty$. In this limit, the method performs in the same manner regardless of the choice of L-stable scheme.

6.3. Characteristic tracing: Frozen method. We now show that the method in §3 is second order accurate as $K \to \infty$. The value of $z_{j+1/2}^{n+1/2}$ is either $z_*(w_{j+1/2,l}^{n+1/2})$ or $z_*(w_{j+1/2,r}^{n+1/2})$, depending on the sign of a. The value of $w_{j+1/2}^{n+1/2}$ calculated by the Riemann solver is some linear combination of the values of $w_{j+1/2,l}^{n+1/2}$, $w_{j+1/2,r}^{n+1/2}$, $z_*(w_{j+1/2}^{n+1/2}, l)$, and $z_*(w_{j+1/2,r}^{n+1/2})$. It is sufficient, then, to show that the truncation errors in the calculations of $w_{j+1/2,l}^{n+1/2}$ and $w_{j+1/2,r}^{n+1/2}$ are $O(\Delta x^2)$.

We expand in Taylor's series the terms of the expressions used in the characteristic tracing step to calculate $w_{j+1/2,l}^{n+1/2}$ and $w_{j+1/2,r}^{n+1/2}$ as follows:

$$\begin{aligned}
w_{j+\frac{1}{2},l}^{n+\frac{1}{2}} &= w_j^n + \frac{1}{2}\left(1 - \frac{\Delta t}{\Delta x}\left(u_*\left(w_j^n\right) + a\right)\right)\left(\Delta w - q_0 \Delta z\right) \\
&\quad + \frac{1}{2}\left(1 - a\frac{\Delta t}{\Delta x}\right) q_0 \Delta z \\
&= w_j^n + \frac{1}{2}\left(\Delta x - \Delta t\left(u_*\left(w_j^n\right) + a\right)\right) u_*'\left(w_j^n\right)\left(\frac{\partial w}{\partial x}\right)_j^n \\
&\quad + \left(\Delta x - a\Delta t\right) q_0 z_*'\left(w_j^n\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right) \\
&= w_j^n + \frac{1}{2}\left(\Delta x - \Delta t\left(u_*\left(w_j^n\right) u_*'\left(w_j^n\right) + a\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right), \\
w_{j+\frac{1}{2},r}^{n+\frac{1}{2}} &= w_{j+1}^n - \frac{1}{2}\left(1 + \frac{\Delta t}{\Delta x}\left(u_*\left(w_j^n\right) + a\right)\right)\left(\Delta w - q_0 \Delta z\right) \\
&\quad - \frac{1}{2}\left(1 + a\frac{\Delta t}{\Delta x}\right) q_0 \Delta z \\
&= w_{j+1}^n - \frac{1}{2}\left(\Delta x + \Delta t\left(u_*\left(w_{j+1}^n\right) + a\right)\right) u_*'\left(w_{j+1}^n\right)\left(\frac{\partial w}{\partial x}\right)_{j+1}^n + O\left(\Delta x^2\right) \\
&\quad + \left(\Delta x + a\Delta t\right) q_0 z_*'\left(w_{j+1}^n\right)\left(\frac{\partial w}{\partial x}\right)_{j+1}^n \\
&= w_{j+1}^n - \frac{1}{2}\left(\Delta x + \Delta t\left(u_*\left(w_{j+1}^n\right) u_*'\left(w_{j+1}^n\right) + a\right)\right)\left(\frac{\partial w}{\partial x}\right)_{j+1}^n + O\left(\Delta x^2\right) \\
&= w_j^n + \frac{1}{2}\left(\Delta x - \Delta t\left(u_*\left(w_j^n\right) u_*'\left(w_j^n\right) + a\right)\right)\left(\frac{\partial w}{\partial x}\right)_j^n + O\left(\Delta x^2\right).
\end{aligned}$$

Hence, the method is second-order accurate in the limit $K \to \infty$.

6.4. Riemann solvers: Frozen vs. equilibrium. We now compare the Riemann solvers in the frozen method in §3 and in the equilibrium method in §4 in order to show that the frozen method does not reduce to an upwind scheme for the equilibrium equation (5.2) as $K \to \infty$. The following are necessary conditions for either method to be an upwind scheme [21] for (5.2) in this limit:

(1) If $\lambda_*(w^{n+1/2}_{j+1/2,l}) < 0$ and $\lambda_*(w^{n+1/2}_{j+1/2,r}) < 0$, then

$$w^{n+\frac{1}{2}}_{j+\frac{1}{2}} = w^{n+\frac{1}{2}}_{j+\frac{1}{2},r} \quad \text{and} \quad z^{n+\frac{1}{2}}_{j+\frac{1}{2}} = z^{n+\frac{1}{2}}_{j+\frac{1}{2},r} = z_*(w^{n+\frac{1}{2}}_{j+\frac{1}{2},r}).$$

(2) If $\lambda_*(w^{n+1/2}_{j+1/2,l}) > 0$ and $\lambda_*(w^{n+1/2}_{j+1/2,r}) > 0$, then

$$w^{n+\frac{1}{2}}_{j+\frac{1}{2}} = w^{n+\frac{1}{2}}_{j+\frac{1}{2},l} \quad \text{and} \quad z^{n+\frac{1}{2}}_{j+\frac{1}{2}} = z^{n+\frac{1}{2}}_{j+\frac{1}{2},l} = z_*(w^{n+\frac{1}{2}}_{j+\frac{1}{2},l}).$$

The Riemann solver for the method in §3, which we will call the frozen Riemann solver, solves the Riemann problem for the system

$$\frac{\partial u}{\partial t} + \frac{\partial}{\partial x}\left(\frac{u^2}{2} + au\right) = 0,$$

$$\frac{\partial z}{\partial t} + \frac{\partial}{\partial x}(az) = 0.$$

(This system is derived from the system

$$\frac{\partial w}{\partial t} + \frac{\partial}{\partial x}\left(\frac{u^2}{2} + aw\right) = 0,$$

$$\frac{\partial z}{\partial t} + \frac{\partial}{\partial x}(az) = 0$$

by using $w = u + q_0 z$ and substituting the second equation into the first.) The equilibrium Riemann solver solves the Riemann problem for the equilibrium equation (5.2). Both Riemann solvers calculate the same values of $w^{n+1/2}_{j+1/2}$ and $z^{n+1/2}_{j+1/2}$ if the frozen and the equilibrium characteristic speeds of the left and right states at a cell edge all have the same sign. However, if the characteristic speeds are not all of the same sign, the two solvers may calculate different values of $w^{n+1/2}_{j+1/2}$ and $z^{n+1/2}_{j+1/2}$.

As an example, we consider the following situation. If

$$a < u^{n+\frac{1}{2}}_{j+\frac{1}{2},l}/(1 + mq_0) + a < 0 < u^{n+\frac{1}{2}}_{j+\frac{1}{2},l} + a,$$

$$a < u^{n+\frac{1}{2}}_{j+\frac{1}{2},r}/(1 + mq_0) + a < 0 < u^{n+\frac{1}{2}}_{j+\frac{1}{2},r} + a,$$

$$u^{n+\frac{1}{2}}_{j+\frac{1}{2},l} > u^{n+\frac{1}{2}}_{j+\frac{1}{2},r},$$

both Riemann solvers find that the solution of the Riemann problem contains a shock separating $u^{n+1/2}_{j+1/2,l}$ and $u^{n+1/2}_{j+1/2,r}$. However, the frozen Riemann solver calculates a positive shock speed and sets $u^{n+1/2}_{j+1/2} = u^{n+1/2}_{j+1/2,l}$, while the equilibrium Riemann solver calculates a negative shock speed and sets $u^{n+1/2}_{j+1/2} = u^{n+1/2}_{j+1/2,r}$. Consequently, the method in §3 does not reduce to an upwind method for the equilibrium equation. As a result, the method in §3 is more likely than the equilibrium method to generate numerical oscillations or overshoots at shocks [35] as $K \to \infty$ when solving problems in which the frozen and the equilibrium characteristic speeds do not all have the same sign. By the same reasoning, however, the equilibrium method is more likely to generate oscillations for nonstiff problems. The equilibrium method is thus not suitable for long relaxation times.

7. Numerical results: Model system. In this section we use the numerical method developed in §3 and the three variant methods presented in §4 to solve examples of the test problems formulated in §5 in order to verify the analysis of the methods in §6. We look at three sets of numerical solutions of rarefaction and shock test problems. The first set of solutions are generated by the fractional step method in §4 and by the frozen method in §3. The results show that the fractional step method produces less accurate solutions than the frozen method as $K \to \infty$. The second set is generated by the nonstiff projection method in §4 and by the frozen method. The results show that the nonstiff projection method also produces less accurate solutions for stiff problems. The last set of solutions is generated by the frozen method. The results are consistent with the method being second-order accurate for smooth solutions as $K \to \infty$. Furthermore, the results the frozen method for the shock problems in which the frozen and equilibrium characteristic speeds are not all of the same sign contain no oscillations or overshoots at the shocks. Hence, there is no degradation in the numerical solution due to the fact that the Riemann solver does not satisfy (1.2).

In every problem discussed in this section, we define the parameters (except a) of the model system in §5 as follows:

$$\begin{aligned} q_0 &= -1.0. \\ m &= -1.0, \\ u_0 &= 3.0, \\ K &= 10^8. \end{aligned}$$

The value of a is set in each problem; we use different values in different problems in order to illustrate certain numerical properties of the methods. We define the initial conditions of the rarefaction problems by

$$\begin{aligned} u_l &= 2.0, \\ z_l &= m(u_l - u_0) = 1.0, \\ w_l &= u_l + q_0 z_l = 1.0, \\ u_r &= 3.0, \\ z_r &= m(u_r - u_0) = 0.0, \\ w_r &= u_r + q_0 z_r = 2.0. \end{aligned}$$

We define the initial conditions of the shock problems by reversing the roles of the left and right states. In each rarefaction problem, we set the position of the initial discontinuity, x_0, according to the value of a so that the solutions of all the rarefaction problems are identical at $t = .3$:

$$\begin{aligned} u(x, t = .3) &= 2, && x \leq .7, \\ &= 2 + (x - .7)/(.85 - .7), && .7 < x < .85, \\ &= 3, && x \geq .85. \end{aligned} \tag{7.1}$$

In each shock problem, we set x_0 in a similar fashion so that

$$\begin{aligned} u(x, t = .3) &= 3, && x < .775, \\ &= 2, && x > .775. \end{aligned} \tag{7.2}$$

We use a grid spacing of $\Delta x = .0025$ and a Courant number of $\sigma = .9$ in each run. We also use the following measure of error so that we can compare the numerical results of the different methods:

$$\text{error} = \frac{1}{m} \sum_{j=1}^{m} \left| u\text{eq}(x_j, t_n) - u_j^n \right|. \tag{7.3}$$

$u_{\text{eq}}(x_j, t_n)$ is the exact solution of the equilibrium equation (5.2) given by (7.1) or (7.2), while u_j^n is the numerical approximation to the solution at (x_j, t_n). m is the number of computational cells.

7.1. Frozen method vs. fractional step method. In this set of problems, we set $a = 1.0$. We use the fractional step method in §4 and the method in §3 to solve a shock test problem and a rarefaction test problem. The values of the numerical solutions at $t = .3$ are displayed in the graphs in Fig. 1. We can see from the figure that the results generated by the fractional step method are less accurate than those generated by the frozen method. Specifically, in the numerical solutions produced by the fractional step method, the representations of the trailing and leading edges of the rarefaction and the representation of the shock are more smeared than those in the solutions produced by the frozen method. The errors at $t = .3$, as given by (7.3), in the shock and the rarefaction solutions calculated by the frozen method are 1.108×10^{-3} and 1.104×10^{-3}. The corresponding values for the fractional step method are 1.931×10^{-3} and 4.149×10^{-3}.

7.2. Frozen method vs. nonstiff projection method. In this set of problems, we set $a = -.9$ so that the frozen and the equilibrium characteristic speeds do not all have the same sign. We expect in this case that the numerical solutions generated by the nonstiff projection method will be less accurate. We use the nonstiff projection method in §4 and the frozen method in §3 to solve a shock test problem and a rarefaction test problem. The values of the numerical solutions at $t = .3$ are displayed in the graphs in Fig. 2. We can see from the figure that the results generated by the nonstiff projection method are less accurate than those generated by the frozen method. Specifically, we see that the representations of the trailing and leading edges of the rarefaction and the representation of the shock are more smeared in the solutions produced by the nonstiff projection method than in those produced by the frozen method. The errors at $t = .3$, as given by (7.3), in the shock and the rarefaction solutions calculated by the frozen method are 1.170×10^{-3} and 1.117×10^{-3}. The corresponding values for the nonstiff projection method are 6.684×10^{-3} and 1.291×10^{-2}.

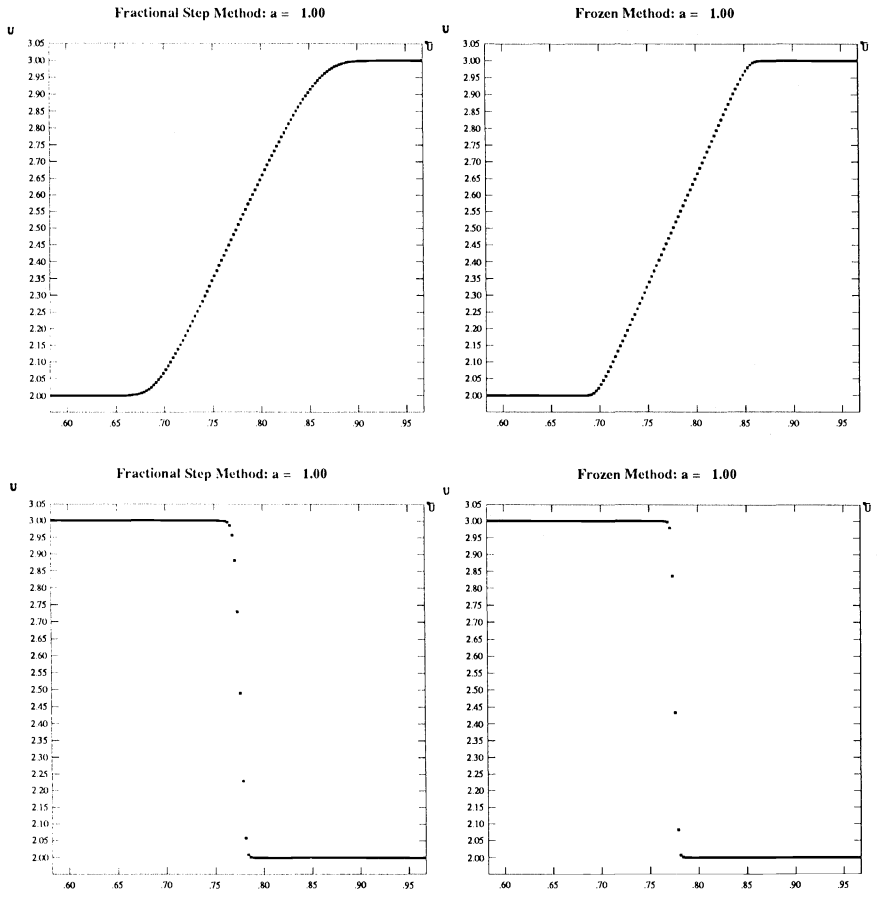

FIG. 1. *Numerical solutions of test shock and rarefaction problems by the fractional step and frozen methods for* $a = 1$.

7.3. Frozen method. In this set of problems, we set $a = -3.25, -2.5, -1.75, -1.25, -.9$, and 1.0. For each value of a we use the method in §3 to solve a shock test problem and a rarefaction test problem. The resulting twelve problems correspond to twelve different relations among the frozen and the equilibrium characteristic speeds of the left and right states. For example, when $a = -3.25$ the frozen and equilibrium characteristic speeds of the left and right states are all negative. The values of the numerical solutions for the first four values of a at $t = .3$ are displayed in the graphs in Figs. 3 and 4. The results for $a = -.9$ and for $a = 1.0$ are displayed in Fig. 2 and Fig. 1, respectively. The results are consistent with the method being second-order accurate, i.e., the frozen method produces sharply defined equilibrium shock and rarefaction solutions for all six values of a. The errors at $t = .3$, as given by (7.3), in the solutions to the six shock problems are, in order of increasing a, 1.069×10^{-3}, 1.046×10^{-3}, 1.182×10^{-3}, 1.213×10^{-3}, 1.170×10^{-3}, and 1.108×10^{-3}. The corresponding values for the six rarefaction problems are, in order of increasing a, 1.058×10^{-3}, 9.671×10^{-4}, 1.099×10^{-3}, 1.138×10^{-3}, 1.117×10^{-3}, and 1.104×10^{-3}.

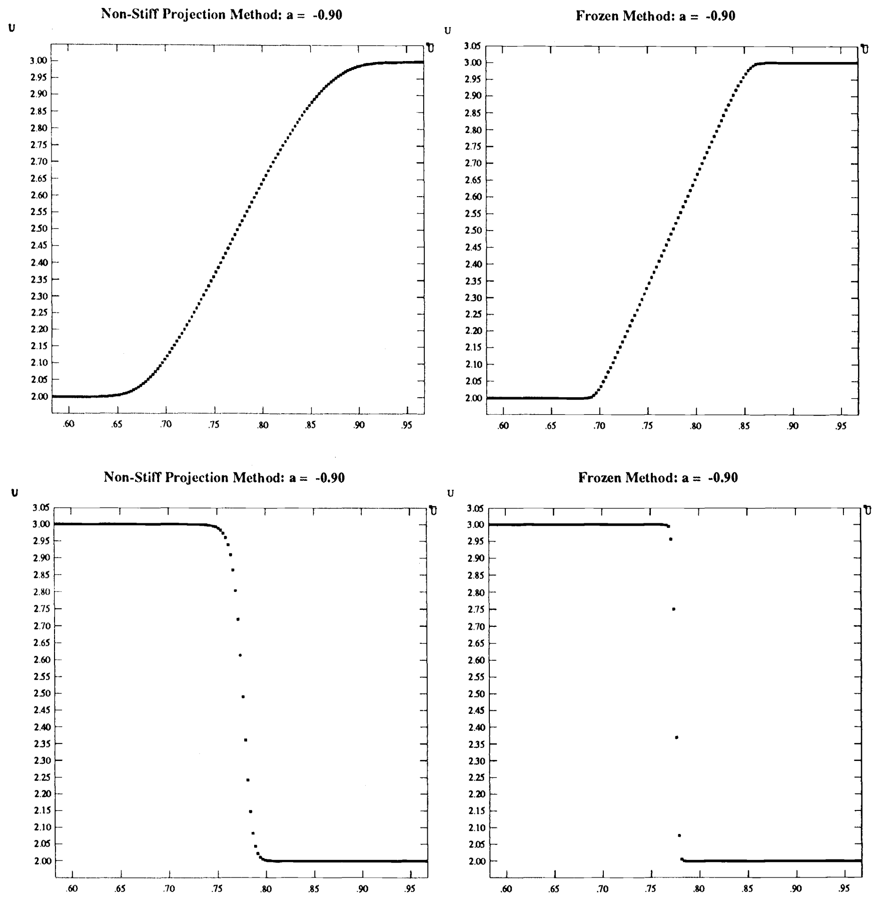

FIG. 2. *Numerical solutions of test shock and rarefaction problems by the frozen and the nonstiff projection methods for* $a = -.9$.

8. Numerical results: Eulerian gas dynamics with heat transfer. In this section we investigate using the method in §3 and the three variant methods in §4 to solve the Euler equations for gas dynamics, coupled with a simplified heat transfer rate equation, in one space dimension. The corresponding equilibrium equations are the Eulerian equations for isothermal flow. We formulate two initial value problems of the system whose time-asymptotic solutions are simple waves, an isothermal rarefaction, and an isothermal shock. We then look at three sets of numerical solutions of these two problems. The numerical results are consistent with the conclusions of the analysis in §6 for the model system.

8.1. Formulation of equations and test problems. We consider the Eulerian equations governing the one-dimensional flow of gas in contact with a constant temperature bath:

$$\frac{\partial}{\partial t}\begin{pmatrix}\rho\\ \rho u\\ \rho E\end{pmatrix}+\frac{\partial}{\partial x}\begin{pmatrix}\rho u\\ \rho u^2+p\\ \rho uE+up\end{pmatrix}=\begin{pmatrix}0\\ 0\\ -K\rho(T-T_0)\end{pmatrix}. \tag{8.1}$$

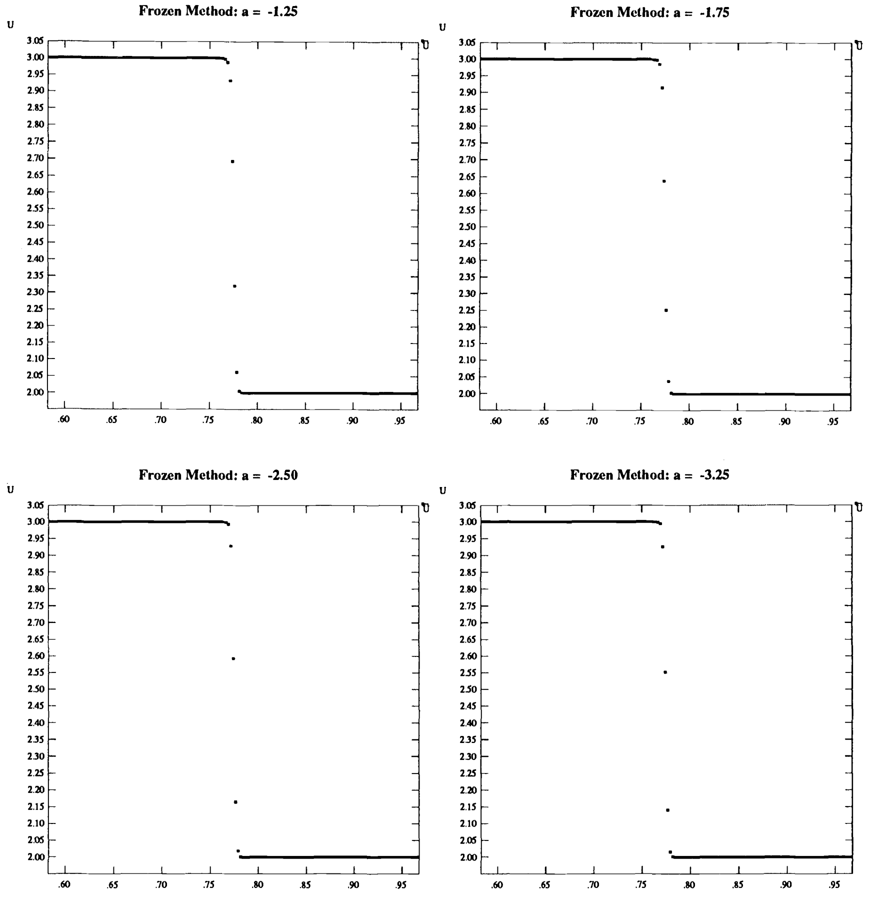

FIG. 3. *Numerical solutions of test shock problems by the frozen method for* $a = -1.25, -1.75, -2.5,$ *and* -3.25.

In this system, ρ is the density, u the velocity, $E = e + u^2/2$ the energy per unit mass, e the internal energy, T the temperature, and p the pressure. Away from equilibrium we assume that the gas is a γ-law gas, i.e., $p = (\gamma - 1)\rho e$. We choose units of temperature so that $T = e$. K and T_0 are positive constants. K is the heat transfer coefficient. T_0 is the temperature of the constant temperature bath. The frozen characteristic speeds of the system are $u - c$, u, and $u + c$, where $c = (\gamma p/\rho)^{1/2}$. At equilibrium, the flow is governed by the Eulerian equations for isothermal flow:

$$(8.2) \qquad \frac{\partial}{\partial t}\begin{pmatrix}\rho \\ \rho u\end{pmatrix} + \frac{\partial}{\partial x}\begin{pmatrix}\rho u \\ \rho u^2 + p_*\end{pmatrix} = \begin{pmatrix}0 \\ 0\end{pmatrix}.$$

The pressure p_* is governed by an isothermal gas law: $p_*(\rho) = (\gamma - 1)\rho e_0$, where e_0 is the internal energy of the gas at $T = T_0$. The equilibrium characteristic speeds are $u - c_*$ and $u + c_*$, where

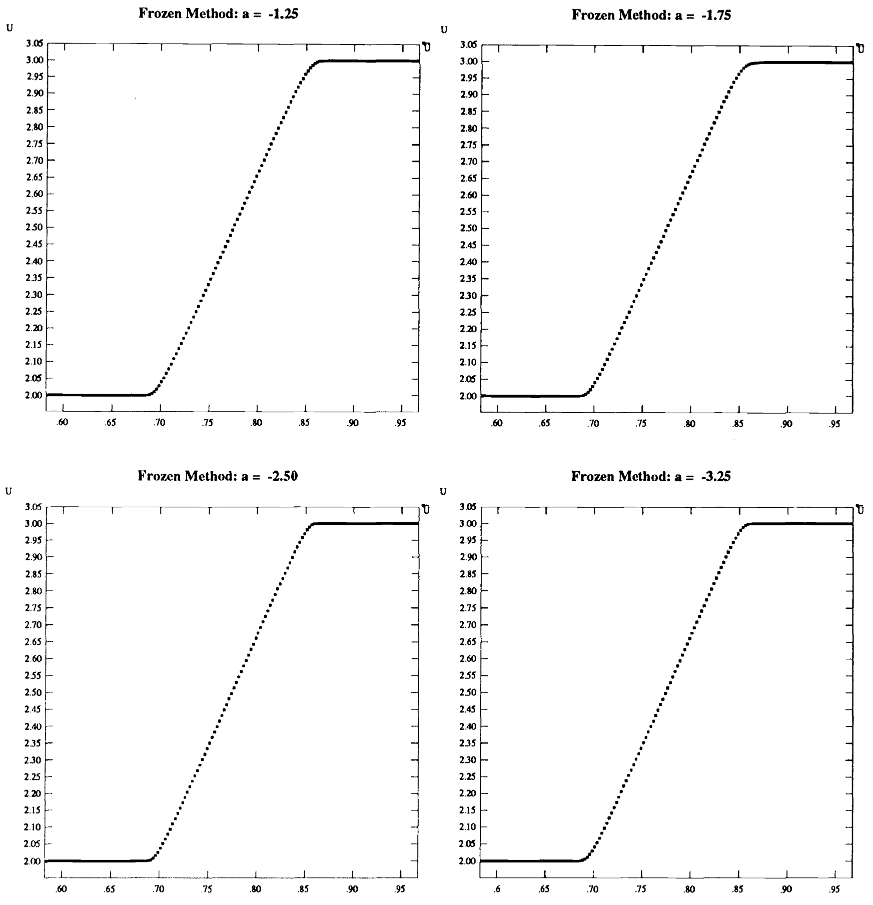

FIG. 4. *Numerical solutions of test rarefaction problems by the frozen method for* $a = -1.25, -1.75, -2.5,$ *and* -3.25.

$$c_* = \left(\frac{p}{\rho}\right)^{\frac{1}{2}} = \left((\gamma - 1)\, e_0\right)^{\frac{1}{2}}.$$

The frozen and the equilibrium characteristic speeds thus satisfy the subcharacteristic condition (1.1).

We now formulate two general initial value problems of (8.1). Under the assumption that Liu's conjecture [28] extends to (8.1), the solutions of these two problems tend to simple wave solutions of (8.2) as $K \to \infty$. We specify the solution at $t = 0$ in terms of the primitive variables ρ, u, and p as follows:

$$(8.3) \qquad \begin{aligned} (\rho,\ u,\ p)\,(x,0) &= (\rho_l,\ u_l,\ p_*(\rho_l))\,, \qquad x < x_0, \\ &= (\rho_r,\ u_r,\ p_*(\rho_l))\,, \qquad x > x_0. \end{aligned}$$

The left and right states of an initial value problem whose solution as $K \to \infty$ is an isothermal shock with speed s satisfy the following:

$$\begin{aligned} W &= ((\gamma-1)e_0\rho_l\rho_r)^{\frac{1}{2}}, \\ W(u_r-u_l) &= (\gamma-1)e_0(\rho_r-\rho_l), \\ p_l &= p_*(\rho_l), \\ p_r &= p_*(\rho_r), \\ s &= \frac{\rho_r u_r - \rho_l u_l}{\rho_r-\rho_l}. \end{aligned} \tag{8.4}$$

(W is the Lagrangian isothermal shock speed.) The left and the right states of an initial value problem whose solution as $K \to \infty$ is an isothermal rarefaction in the $u + c_*$ characteristic family satisfy these relations:

$$\begin{aligned} ((\gamma-1)e_0)^{\frac{1}{2}} \ln\tfrac{\rho_r}{\rho_l} &= u_r - u_l, \\ p_l &= p_*(\rho_l), \\ p_r &= p_*(\rho_r). \end{aligned} \tag{8.5}$$

We now use the results stated in the previous paragraph to formulate a set of test problems for the numerical methods. We define the constants in (8.1) as follows:

$$T_0 = e_0 = 1.0,$$

$$K = 10^8,$$

$$\gamma = 1.4.$$

At equilibrium, then, $c = .748$ and $c_* = .632$. Since $K >> 0$, i.e., the relaxation time is much smaller than the time scales associated with the fluid velocity and sound speed, we expect that a solution of (8.1) whose initial conditions satisfy (8.3) rapidly develops in time to a time-asymptotic solution of (8.1) which closely approximates a solution of the isothermal flow equations (8.2). The shock problems are defined as follows:

$$\begin{aligned} u_l &= u_r + .6, \\ \rho_l &= 2.5, \\ \rho_r &= 1.0, \\ p_l &= 1.0, \\ p_r &= .4. \end{aligned} \tag{8.6}$$

For a given value of u_r, we set the location x_0 of the initial discontinuity so that the location of the shock at $t = .4$ is $x = .81$. The rarefaction problems are defined as follows:

$$\begin{aligned} u_r &= u_l + .5795, \\ \rho_l &= 1.0, \\ \rho_r &= 2.5, \\ p_l &= .4, \\ p_r &= 1.0. \end{aligned} \tag{8.7}$$

For a given value of u_l, we set the location x_0 of the initial discontinuity so that the rarefaction wave extends from $x = .664$ to $x = .904$ at $t = .4$. We use a grid spacing of $\Delta x = .0025$ and a Courant number of $\sigma = .9$ in each run. We also use the following measure of error for the rarefaction problems so that we can compare the numerical results of the different methods:

$$\text{error} = \frac{1}{m} \sum_{j=1}^{m} \left| u_{\text{iso}}(x_j, t_n) - u_j^n \right| . \tag{8.8}$$

$u_{\text{iso}}(x_j, t_n)$ is the value of u, the fluid velocity, in the exact solution of the equations of isothermal flow (8.2) for the initial value problem given by (8.3) and (8.7), while u_j^n is the numerical approximation to the value of u in the solution at (x_j, t_n). m is the number of computational cells.

Remark. We need to make two statements about our claim that, given our particular choice of parameters, a solution of (8.1) whose initial conditions satisfy (8.3) rapidly tends to a time-asymptotic solution of (8.1) which closely approximates a solution of (8.2). First, there is an assumption that the spatial scale (and, by the CFL condition, the time scale as well) on which we want to resolve the solution is too small to fully resolve the relaxation process. We are assuming, then, not that K itself is large but that $K\Delta x$ is large compared to the magnitudes of the sound speeds and the fluid velocities, where Δx is the desired spatial resolution. Our second remark is that there are at this time no definitive theoretical results regarding the time-asymptotic behavior for $N \times N$ hyperbolic systems of conservation laws with relaxation where $N \geq 3$. There are definitive results only for 2×2 systems [8]. For our particular set of problems, however, the numerical results below do suggest that the time-asymptotic behavior of solutions of the frozen equations (8.1) is determined by the equilibrium system (8.2).

8.2. Frozen method. We use the frozen method of §3 to solve a series of isothermal rarefaction and shock problems of (8.1). The initial conditions of the rarefaction problems are given by (8.3), (8.7), and $u_l = -1.4, -.8, -.3, .3$, and $.8$. The initial conditions of the shock problems are given by (8.3), (8.7), and $u_r = -1.4, -.8, -.3, .3$, and $.8$. The resulting ten problems correspond to different relations among the frozen and the equilibrium characteristic speeds of the left and right states. For example, when $u_l = -1.4$, the frozen and the equilibrium characteristic speeds of the left and right states are all negative. The values of u in the numerical solutions of the rarefaction problems at $t = .4$ are displayed in the graphs in Fig. 5. The values of p in the numerical solutions of the shock problems at $t = .4$ are displayed in the graphs in Fig. 6. We can see from the figures that the results are consistent with the method being second-order accurate as $K \rightarrow \infty$, i.e., the frozen method produces sharply defined equilibrium shock and rarefaction solutions for all the test problems. Furthermore, the numerical results show approximately the same level of accuracy. The numerical solutions are oscillatory at discontinuities, however, in some of the shock problems for which the equilibrium and the

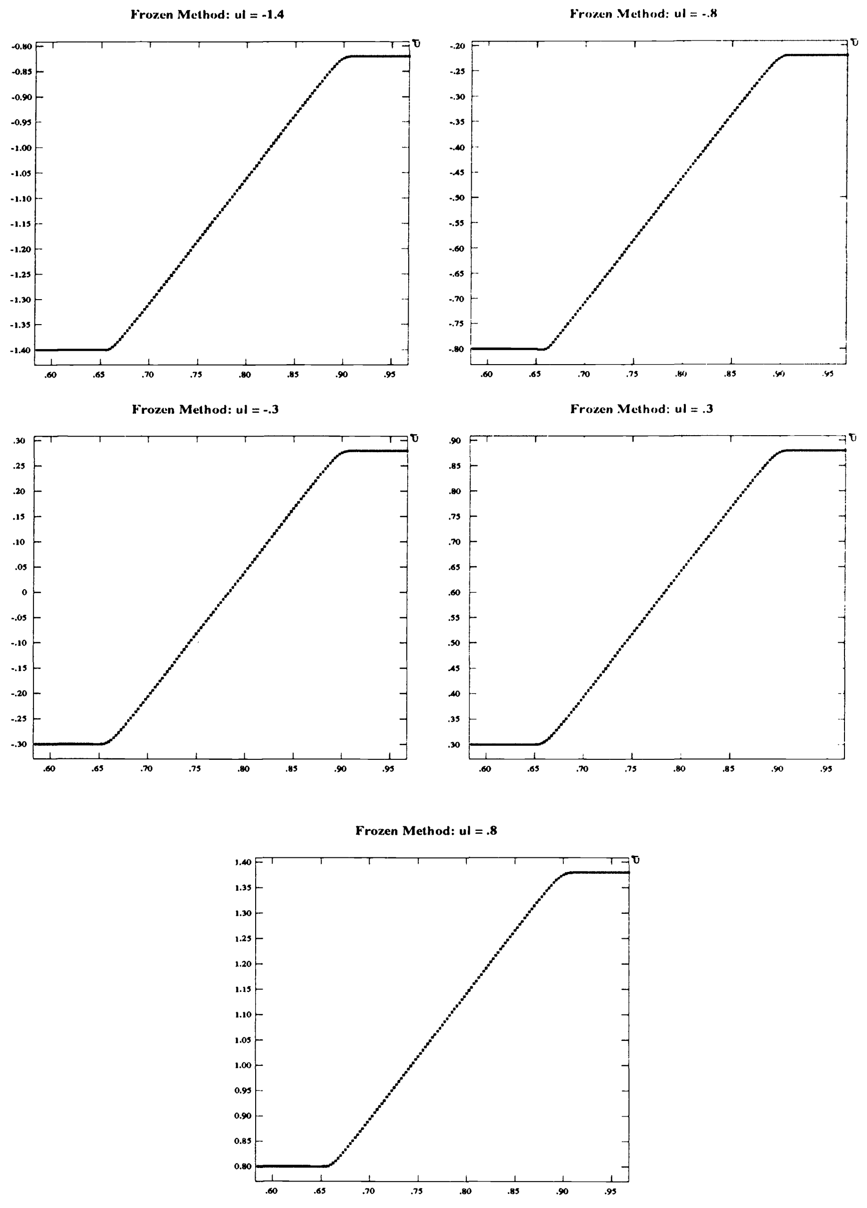

FIG. 5. *Numerical solutions of isothermal rarefaction problems by the frozen method for* $u_l = -1.4, -.8, -.3, .3,$ *and* $.8$.

frozen characteristic speeds do not all have the same sign, i.e., when $u_l = -.8$ and $-.3$. The errors at $t = .4$, as given by (8.8), in the solutions to the six rarefaction problems are, in order of increasing u_l, 2.185×10^{-3}, 2.261×10^{-3}, 2.534×10^{-3}, 2.506×10^{-3}, and 2.508×10^{-3}.

8.3. Fractional step and nonstiff projection methods. We use the fractional step and the nonstiff projection methods of §4 to solve two of the isothermal rarefaction problems discussed in §8.2. The initial conditions of the rarefaction problems are given by

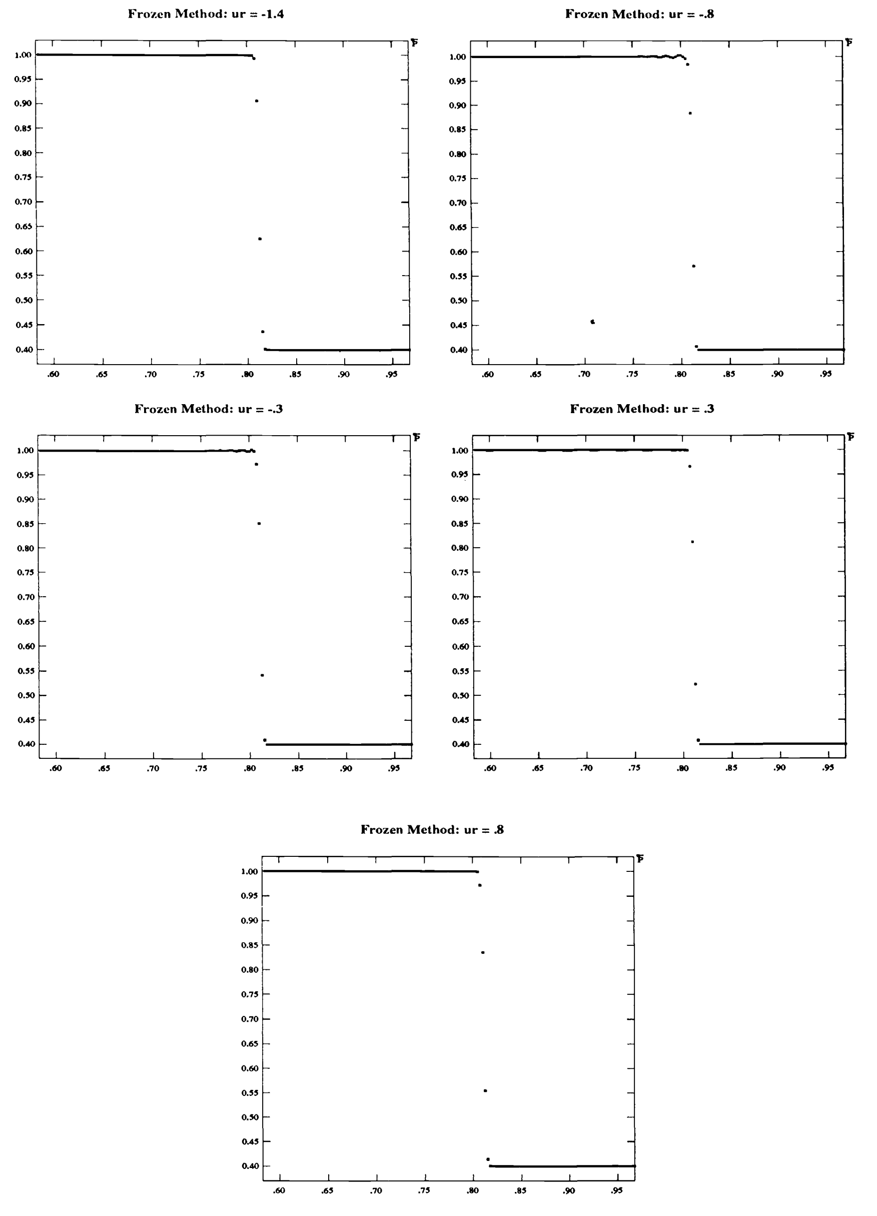

FIG. 6. *Numerical solutions of isothermal shock problems by the frozen method for* $u_r = -1.4, -.3, .3,$ *and* $.8$.

(8.3), (8.7), and $u_l = -.8$ and $-.3$. The values of u in the numerical solutions at $t = .4$ are displayed in the graphs in Fig. 7. We can see by comparing this figure with Fig. 5 that the results generated by the two methods are less accurate than those generated by the frozen method of §3. In particular, the positions of the trailing and leading edges of the rarefactions calculated by the fractional step method correspondingly trail and lead the same positions as calculated by the frozen method. The lower accuracy of the non-stiff projection method is even more apparent. We see that there are numerical "kinks" in the two solutions produced by this method. These appear where one of the frozen

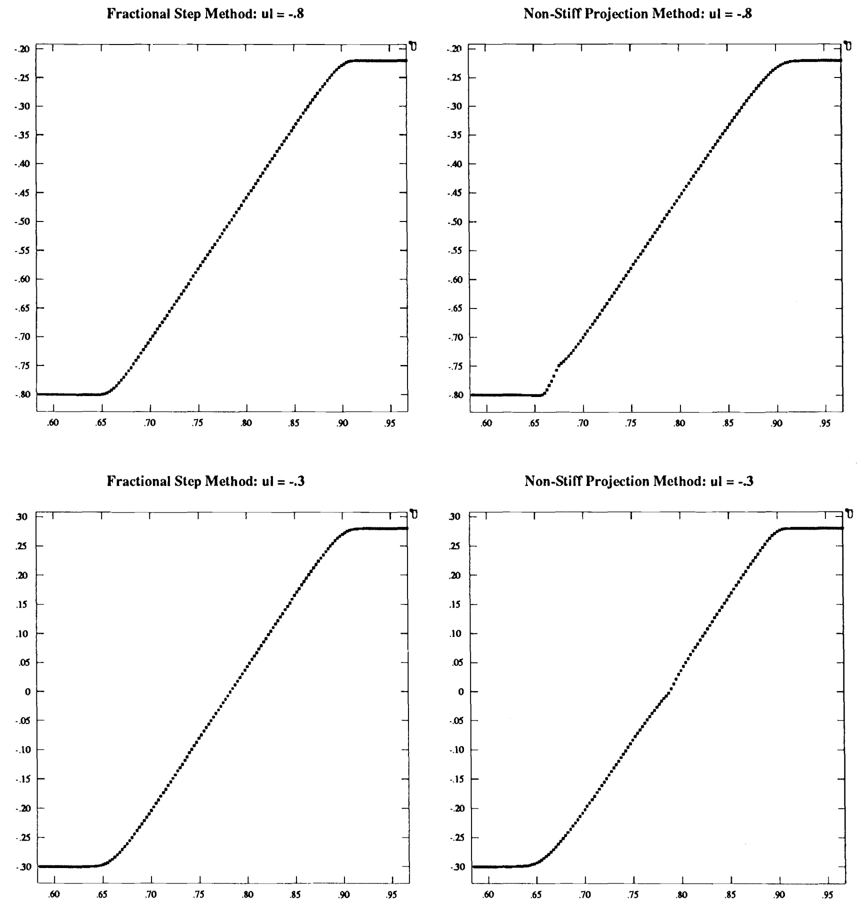

FIG. 7. *Numerical solutions of isothermal rarefaction problems by the fractional step and the nonstiff projection methods for* $u_l = -.8$ *and* $-.3$.

characteristic speeds u or $u + c$ equals 0. The errors at $t = .4$, as given by (8.8), in the two solutions produced by the fractional step method are 2.479×10^{-3} when $u_l = -.8$ and 2.867×10^{-3} when $u_l = -.3$. The corresponding values for the nonstiff projection method are 3.021×10^{-3} and 2.675×10^{-3}. The values for the frozen method, for comparison, are 2.261×10^{-3} and 2.534×10^{-3}.

8.4. Frozen method vs. equilibrium method. We use the equilibrium method of §4 to solve the two shock problems discussed in §8.2 for which the frozen method produced oscillations at the discontinuity. The initial conditions of the problems are given by (8.3), (8.6), and $u_r = -.8$ and $-.3$. The values of p in the numerical solutions at $t = .4$ are displayed in the graphs in Fig. 8; graphs of the solution produced by the frozen method are included for comparison. The solutions produced by the equilibrium method are less oscillatory than the solutions produced by the frozen method.

9. Additional considerations and extensions. In this section we discuss some considerations in developing a Riemann solver which satisfies (1.2). We also propose how to extend the methodology in §3 to the equations of gas flow with vibrational and

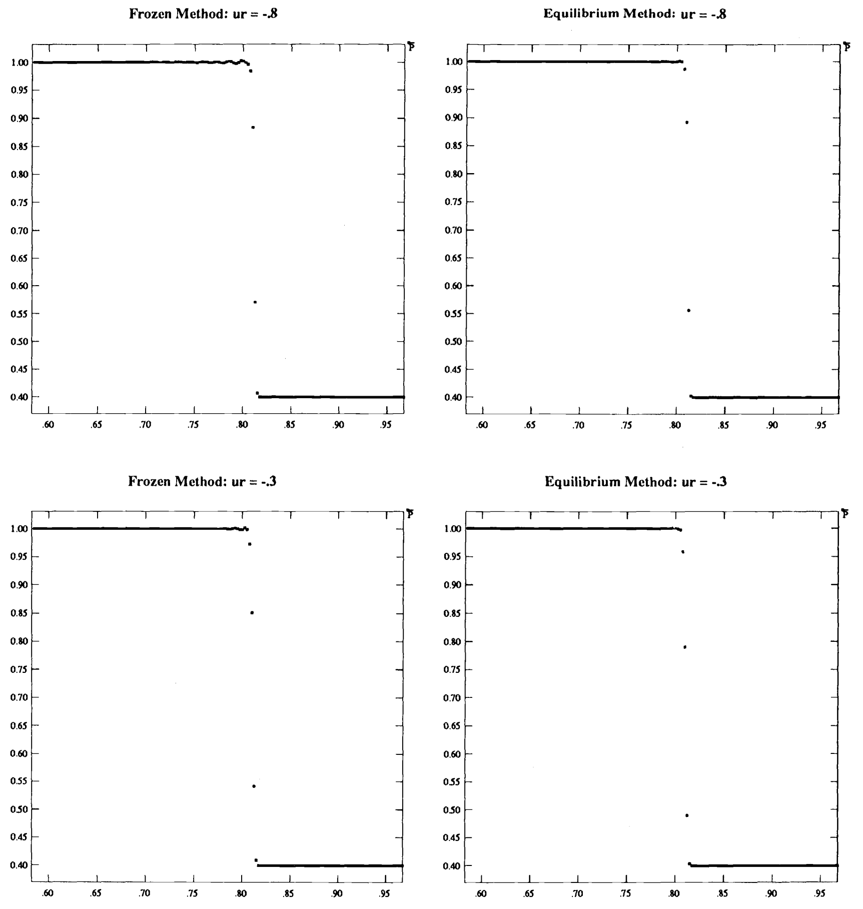

FIG. 8. *Numerical solutions of isothermal shock problems by the equilibrium and frozen methods for* $u_r = -.8$ *and* $-.3$.

chemical nonequilibrium, and, more generally, to systems in which one or more of the frozen characteristic speeds coincide.

9.1. Riemann solver. The numerical results in §8 demonstrate that a Riemann solver which satisfies (1.2) is a desirable component of a higher-order Godunov method for hyperbolic conservation laws with stiff relaxation. We now briefly evaluate five possible approaches to the development of such a Riemann solver.

One approach is simply to switch from a frozen Riemann solver to an equilibrium Riemann solver when $\tau/\Delta x$ drops below some threshold. We performed a numerical experiment to test this approach. We consider a traveling wave problem of (8.1) for which the states at $\pm\infty$ satisfy the isothermal shock relations (8.4). We numerically solve a series of traveling wave problems of this type in which K alone is varied. We use the frozen method of §3 and the equilibrium method of §4 to obtain solutions for $K = 50$, 400, and 10^8. The results are displayed in Fig. 9. For $K = 50$, the frozen method produces a reasonable numerical solution, while the equilibrium method does not. (Note that the exact solution at $K = 50$ is a traveling wave consisting of a shock followed by a smooth compression wave.) For $K = 10^8$, the equilibrium method produces a nonoscillatory

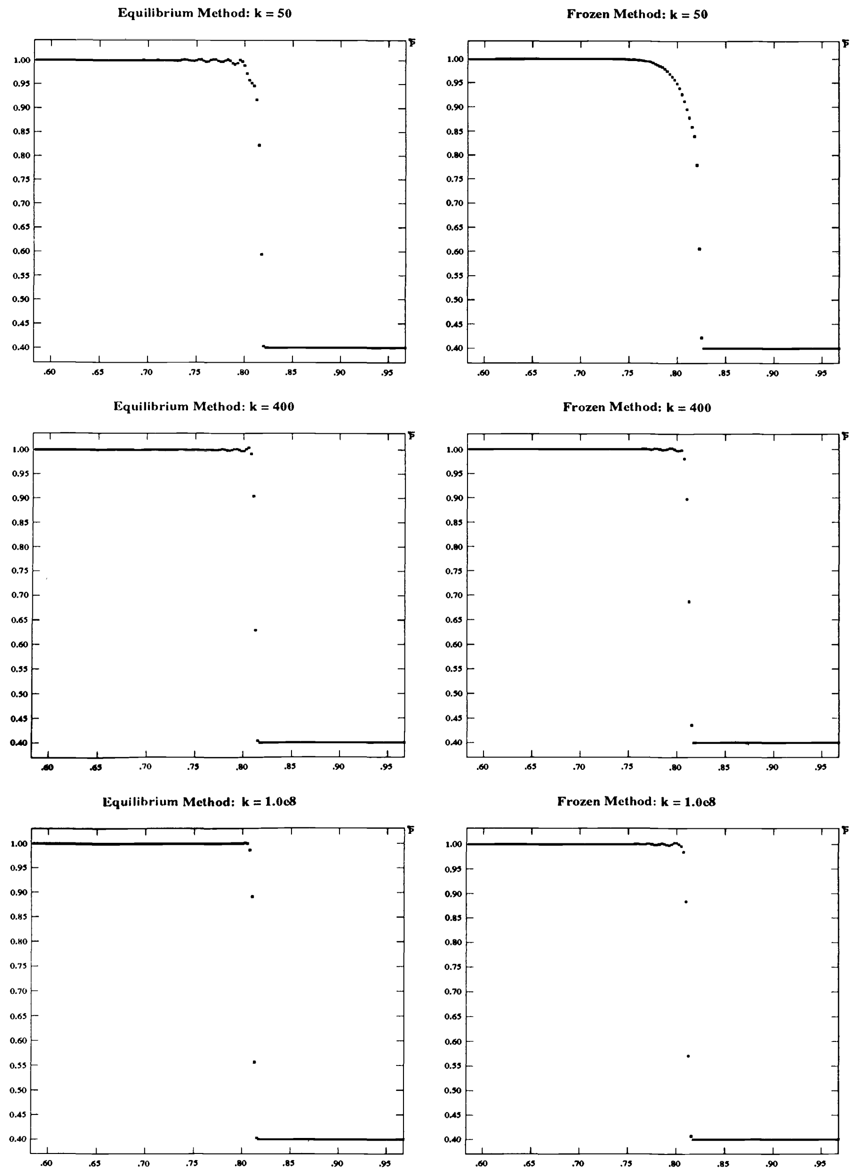

FIG. 9. *Numerical solutions of traveling wave problems by the equilibrium and the frozen methods for* $k = 50, 400, 10^8$.

representation of an isothermal shock, while the frozen method does not. However, for $K = 400$, both methods produce oscillatory results. Hence, it appears that a Riemann solver that simply switches between a frozen and an equilibrium Riemann solver depending on the size of the relaxation time would not significantly reduce the problem of numerical oscillations at shocks for nonzero, finite relaxation times. Furthermore, for a certain range of relaxation times, it appears that the Riemann solver must do something other than simply solve the frozen or the equilibrium Riemann problems.

The next three approaches also have shortcomings. One approach is to find the solution of the nonequilibrium system (3.1) for the initial value problem

$$U(x,0) = U^{n+\frac{1}{2}}_{j+\frac{1}{2},l}, \qquad x < 0, \tag{9.1}$$
$$= U^{n+\frac{1}{2}}_{j+\frac{1}{2},r}, \qquad x > 0$$

and evaluate the solution at $t = 0$. (Methods that use approaches similar to this are discussed in [3] and [17].) We do not actually gain anything by using this approach rather than the approach used in §3; however, because in effect its results are the same as a Riemann solver for the system with $S(U,x) \equiv H(U) \equiv 0$ except at equilibrium. Another approach is to find the time-asymptotic solution of the nonequilibrium system for the initial value problem (9.1) and evaluate that solution at $t = 0$. This approach has the opposite problem of always solving the Riemann problem for the equilibrium equation except when the relaxation time is infinite. A third approach is to somehow average the solutions of Riemann problems for the nonequilibrium equations and the equilibrium equations according to the value of the relaxation time. Although this approach works for zero and infinite relaxation times, it is unclear whether this technique is appropriate for intermediate values.

Another possible approach to this development could be based on redefining what is meant by an upwind method for a hyperbolic conservation law with relaxation. In particular, it may be the case that speeds other than the characteristic speeds should be used in determining upwind states. Linear [6], [22], [25], [39], [43] and nonlinear [8], [27] analyses suggest that this might be the case. In general, these analyses show that although wave fronts move with speeds determined by the frozen characteristic speeds, the overall signal carried by a wave moves at a speed intermediate to the frozen and equilibrium characteristic speeds. Perhaps one could apply these results in developing a numerical flux function which is appropriate for hyperbolic conservation laws with relaxation.

9.2. Flow with chemical and vibrational nonequilibrium. We assumed in developing the method in §3 that the frozen and equilibrium characteristic speeds were all distinct. This assumption is often not met by hyperbolic conservation laws with relaxation that are based on physical systems. In these systems, two or more of the frozen characteristic speeds often coincide. We now briefly examine one such system and show how to extend the method to that system.

We consider the equations describing gas flow with chemical and vibrational nonequilibrium. (See [39] for a more complete description.) For the sake of a simple exposition, we assume that the internal energy has two components, a translational component that is a function of temperature, e_{tr}, and a nonequilibrium component, q, i.e., $e = e_{\text{tr}} + q$. We assume q is governed by a rate equation which takes the following form in Lagrangian coordinates:

$$\frac{\partial q}{\partial t} = h(\rho, s, q) = \frac{q_*(\rho, s) - q}{\tau(\rho, s, q)}.$$

s, q_*, and τ are the entropy, the equilibrium value of q, and the relaxation time, respectively. The Eulerian equations of motion are then given by the following:

$$(9.2)\qquad \frac{\partial}{\partial t}\begin{pmatrix}\rho\\ \rho u\\ \rho E\\ \rho q\end{pmatrix}+\frac{\partial}{\partial x}\begin{pmatrix}\rho u\\ \rho u^2+p\\ \rho uE+up\\ \rho uq\end{pmatrix}=\begin{pmatrix}0\\ 0\\ 0\\ \rho h(\rho,s,q)\end{pmatrix}.$$

The frozen characteristic speeds are $u-c$, u, u, and $u+c$, while the equilibrium speeds are $u-c_*$, u, and $u+c_*$. c and c_* are the frozen and the equilibrium speeds of sound. $c=(\partial p(\rho,s,q)/\partial\rho)^{1/2}$ and $c_*=(\partial p(\rho,s,q_*(\rho,s))/\partial\rho)^{1/2}$, where s is the entropy of the gas. We assume that $c_*<c$.

We now modify the method in §3 for the system of equations (9.2). Specifically, we modify the characteristic projection operators in the characteristic tracing step. We use the following criteria to determine which characteristic fields to include in the computation of $U^{n+1/2}_{j+1/2,l}$; the criteria for the computation of $U^{n+1/2}_{j+1/2,r}$ are similar:

(1) Use the $u-c$ characteristic field if $u_j>0$.

(2) Use the two u characteristic fields if $u_j+c_j>0$.

(3) Use the $u+c$ characteristic field if $u_j+c_j>0$.

Remark. The above methodology is easily extended to cases in which there are any number of nonequilibrium components of the internal energy, as long as the frozen and the equilibrium speeds of sound c and c_* satisfy $c_*<c$ for all possible states. However, if this inequality is not always satisfied (and, in particular, if any of the relaxation processes involved are exothermic in nature, such as in the case of chemically reacting flow), then it is necessary to resolve the time scales of the relaxation processes which contribute to the violation of the subcharacteristic condition. Otherwise, the numerical solution may contain nonphysical waves. See the remark at the end of §1.

10. Discussion and conclusions.

We have completed the initial stage of development of a second-order Godunov method for stiff hyperbolic systems of conservation laws with relaxation. Our method produces higher-order accurate solutions using time and space increments governed solely by the nonstiff part of the system, i.e., without fully resolving the effect of the stiff source terms. The method (§3) is a semi-implicit version of a second-order Godunov method [1], [11] for hyperbolic conservation laws with nonstiff source terms. Our method, which we refer to as the *frozen* method, differs from the nonstiff method in three ways. These differences are needed to ensure that the method is stable and second-order accurate for stiff problems.

(1) In the monotonized central difference calculation, two sets of expansion coefficients are calculated. One set is used in the calculation of left edge states in the characteristic tracing step; the other is used in finding the right edge states. The slope-limiting procedure is modified to account for the characteristic projection operator.

(2) In the characteristic tracing step, the stiff source term is treated in a semi-implicit fashion. Furthermore, the characteristic projection operators allow certain characteristic fields corresponding to negative frozen characteristic speeds to contribute to the value of left edge states, and certain fields corresponding to positive speeds to contribute to the value of right edge states.

(3) In the conservative differencing step, the stiff source term is treated in a semi-implicit fashion.

We note that these key components—the slope-limiting procedure, the characteristic projection operator, and the implicit differencing in the tracing and the conservative differencing steps—can be readily incorporated into the two-dimensional method described in [11].

The reasons for the modifications to the nonstiff method are easily stated. The stiff source term is treated semi-implicitly for stability. The modifications to the characteristic projection operators are necessary for the method to reduce to a second-order method for the equilibrium equation as the relaxation time tends to zero. As this limit is approached, disturbances carried by a given characteristic field of the equilibrium equation must be present in the two corresponding characteristic fields of the nonequilibrium system [27], [43]. Hence, the projection operator must take into account the signs of the equilibrium characteristic speeds as well as the signs of the frozen speeds. Given the modified projection operators, the modified slope-limiting procedure helps minimize oscillations at discontinuities in strongly nonlinear problems.

We have analyzed the method as applied to a simple model system and used the method to produce numerical solutions of the model system and of the Euler equations for gas dynamics with heat transfer. Our analysis shows that the method is second-order accurate for smooth solutions. Furthermore, analytical and numerical results show that the unsplit nature of the method and the modified characteristic projection operators are necessary for second-order accuracy as the relaxation time approaches zero.

Our method lacks one key desirable feature, namely, that it reduce to an upwind method for the equilibrium equation as the relaxation time tends to zero. We have shown that as $\tau \to 0$, the numerical results obtained with a method using a Riemann solver for the equilibrium equation are better than the results obtained with the frozen method in that the former are less oscillatory at shocks. These results suggest that the method in §3 would be improved if its Riemann solver satisfied the following: that it reduce to a Riemann solver for the equilibrium equation as $\tau \to 0$, and that the numerical method using the solver be an upwind scheme for all nonzero relaxation times. The development of such a Riemann solver is a topic for future work.

Acknowledgments. This work was done as part of a Ph.D. thesis under the guidance of Alexandre Chorin. I would like to thank him for his helpful suggestions, inspiration, and support. I would also like to thank the other two members of my dissertation committee, Phillip Colella and Ole Hald, as well as John Bell, Louis Howell, Gerry Puckett, and John Trangenstein, for helpful discussions during the course of my research. Finally, I would like to thank my wife, Camilla, whose love and support enabled me to finish this work.

OPTIMIZING THE NUMERICAL INTEGRATION OF INITIAL VALUE PROBLEMS IN SHOOTING METHODS FOR LINEAR BOUNDARY VALUE PROBLEMS*

L. RÁNDEZ†

Abstract. In this paper two new embedded Runge–Kutta (RK) methods RK5(4) specially designed for linear ODEs [L. F. Shampine, *J. Comput. Appl. Math.*, 15 (1986), pp. 293–300] are derived with (a) "small" principal truncation terms in the fifth-order formula, and (b) minimum number of Jacobian matrix evaluations per step. Numerical tests comparing their efficiency to the classical RKF5(4)#2 [E. Fehlberg, *Tech. Rep.* R-315, NASA, 1969], with the SUPORT code [M. R. Scott and H. A. Watts, *SIAM J. Numer. Anal.*, 1 (1977), pp. 40–70], are presented.

Key words. boundary value problems, shooting methods, Runge–Kutta methods

AMS subject classifications. 65L07, CR517

1. Introduction.

Let us consider the numerical solution of the linear boundary value problem (BVP)

$$(1.1)_a \qquad y'(t) = J(t)y(t) + g(t), \qquad t \in (a,b),$$

$$(1.1)_b \qquad B_a y(a) = \alpha, \qquad B_b y(b) = \beta,$$

where $y, g \in I\!R^m$, $J \in I\!R^{m\times m}$, $B_a \in I\!R^{(m-k)\times m}$, $B_b \in I\!R^{k\times m}$, $\alpha \in I\!R^{m-k}$, and $\beta \in I\!R^k$, by shooting methods. Such a class of methods reduces the BVP (1.1) to solving a linear system of equations involving the numerical integration of initial value problems. Usually, the method of superposition [1], [2], [5], [6], [9], [10], [13] is used to represent the solution as a combination of the fundamental and particular solutions, and it is necessary to integrate them numerically, e.g., by a Runge–Kutta (RK) method. The most popular method is the RK pair RKF4(5)#2 of formulas of orders 4 and 5 due to Fehlberg [4] and implemented as a BVP solver in the codes SUPORT [13] and MUSL and MUSN [1], [10].

In the numerical solution of (1.1) we can use algorithms for nonlinear problems, ignoring the linearity of the problem, but we cannot expect to obtain a particularly efficient algorithm in this way [6]. So, the most recent codes for solving BVP are split in linear and nonlinear problems (MUSL, MUSN, respectively [1]).

For nonlinear problems, the author [12] has proposed a combination of a RK triple for the differential equation and a special RK for the variational problem, but if it is used in linear problems, we can expect a loss of efficiency.

Since the initial value problem (IVP) to be integrated has the differential equation given by $(1.1)_a$, it is worth noting that a large portion of the cost of evaluating the derivative function comes from evaluating functions of the independent variable, i.e., mainly the Jacobian matrix $J(t)$. So, to advance from t_n to $t_n + h$, the RKF4(5)#2 requires evaluations at $t_n + c_i h$ where the c_i are $(0, \frac{1}{4}, \frac{3}{8}, \frac{12}{13}, 1, \frac{1}{2})$. Because no pair of successive evaluations is at the same point, this RK needs six Jacobian evaluations per step and the same number of stages.

The main idea of this paper is to exploit the linearity of the problem, because an important part of the multiple shooting method is the integration of the associated IVPs.

*Received by the editors November 13, 1991; accepted for publication (in revised form) July 28, 1992. This work was partially supported by Research Grant PS900121 DGICYT.

†Departamento de Matemática Aplicada, Universidad de Zaragoza, 50009 Zaragoza, Spain.

While Shampine [15] proposed using extrapolation with England's method, we prefer to develop new special explicit embedded pairs of RK formulas of orders 4 and 5 with six effective stages, but with a reduction in the number of Jacobian matrix evaluations involved in the process by using more than one function value corresponding to a single independent variable value, i.e., with several c_i's equal and consecutive. We construct two new pairs that require three and four evaluations of Jacobian matrix per step, respectively. Furthermore, the ratio between the size of the truncation error coefficients of the new pairs when compared with the RKF4(5)#2 are about 3 and 10 times smaller, respectively, for the new pairs.

These pairs are developed for general IVP, mainly because no substantial reduction is achieved in the number of order conditions for linear variable coefficient problems (the elementary differentials up to fourth order are the same, and only one for fifth order and three for sixth order are not present) and are also able to integrate nonlinear problems, for example, quasi linearization. A feature of the new formulas is the provision of a continuous solution, e.g. to plot the graph of the solution or to be used in a quasi linearization of a nonlinear problem.

The paper is organized as follows. In §2 we construct a family of RK pairs of orders 4 and 5 depending on four parameters such that it only requires four Jacobian evaluations per step. A similar analysis is carried out in §3, but now the RK pair requires only three Jacobian evaluations per step. In §4 a fourth-order continuous RK method is proposed for each method with no extra cost. Finally, in §4, some numerical tests showing the efficiency of the new pairs relative to Fehlberg's pair are presented using the code SUPORT [13].

2. The family of embedded RK5(4) methods. We are concerned with the numerical integration of the IVP associated with the BVP (1.1). In particular, we consider an IVP like

$$\left\{ \begin{array}{l} z'(t) = J(t)\, z(t) + g(t), \\ z(t_n) = z_n, \end{array} \right. \tag{2.1}$$

to be solved by an explicit RK method with six stages. The intermediate function evaluations are

$$g_i = J(t_n + c_i h) \left(z_n + h \sum_{j=1}^{i-1} a_{ij} g_j \right) + g(t_n + c_i h), \qquad i = 1, \ldots, 6, \tag{2.2}$$

and the approximation z_{n+1} to $z(t_{n+1})$ is given by

$$z_{n+1} = z_n + h \sum_{i=1}^{6} b_i g_i, \tag{2.3}$$

where h is the stepsize, and a_{ij}, b_i, and c_i are parameters defining the RK method. Using matrix notation $A = (a_{ij}) \in I\!R^{6\times 6}$, $b = (b_i)$, $c = (c_i) \in I\!R^6$, the procedure can be specified by its Butcher table of coefficients

$$\begin{array}{c|c} c & A \\ \hline & b^T \end{array}. \tag{2.4}$$

It is important to observe from (2.2) that if the coefficients $c_i's$ are different, it is necessary to evaluate the Jacobian matrix $J(t)$ at least six times; but if $c_6 = 1$, the last evaluation of the current step can be re-used as the first one of the next step. So, the goal is the construction of RK methods with several coefficients $c_i's$ equal and consecutive in order to save Jacobian evaluations.

Throughout this paper, we will use the notation RK$p(q)l$ for an embedded pair of orders p and q $(p \geq q+1)$ requiring l Jacobian evaluations per step. Note that for the pair RKF5(4)#2, $p=5$, $q=4$, and $l=6$.

Let $z(t; t_n, z_n)$ be the local solution of (2.1) at the point (t_n, z_n). Then the local error of the method (2.2), (2.3) at the point t_{n+1} is defined by

$$e(t_{n+1}) = z(t_n + h; , t_n, z_n) - z_{n+1} = \sum_{\rho(\tau)\geq 1} C(\tau)F_n(\tau)\frac{h^{\rho(\tau)}}{\rho(\tau)!},$$

where τ denotes a rooted tree of order $\rho(\tau)$, the vector $F_n(\tau) \in \mathbb{R}^m$ is the elementary differential associated with τ at (t_n, z_n), and the scalar $C(\tau)$ is the corresponding weight. It must be remarked that $F_n(\tau)$ depends only on the differential equation (2.1) and the point (t_n, z_n), while $C(\tau)$ depends only on the parameters (A, b). The RK formula (2.2), (2.3) has order p if and only if $e(t_{n+1}) = O(h^{p+1})$.

To construct a family of RK methods of order 5 with six stages, assume that the parameters (A, b) satisfy

$$(2.5)_a \qquad b^TA = b^T - (b.c)^T,$$

$$(2.5)_b \qquad Ac = c^2/2 - (c_2^2/2)e_2,$$

$$(2.5)_c \qquad b_2 = 0,$$

where $c^j = (c_1^j, \dots, c_6^j)^T$, e_j is the vector with components $(e_j)_i = \delta_{ij}$, and $(u.v)$ denotes the componentwise product of vectors u and v, i.e., $(u.v)_i = u_iv_i$. Obviously, the last equation of $(2.5)_a$ implies $c_6 = 1$, so the last evaluation of the Jacobian matrix in the current step can be re-used in the following step. It can be verified that (2.2), (2.3) has order 5 if and only if $b_2 = 0$ and

$$(2.6) \qquad \begin{cases} b^Tc^j = 1/(j+1), & j = 0, \dots, 4, \\ b^T(Ac^2.c) = 1/15, \\ b^T(Ae_2.c) = 0. \end{cases}$$

Operating with the above set of equations, it is easy to show that there exists a family of methods with five free parameters $\overline{\gamma} = (c_2, c_3, c_4, c_5, a_{42})$.

In order to embed the fourth-order formula, the so-called FSAL (first same as last) condition is assumed. This means that for the fourth-order solution a new stage which is identical to the first evaluation of the next step is used. So, the table of coefficients for our pairs will have the form

$$\begin{array}{c|c} c & A \\ 1 & b^T \\ \hline & b^T \\ & \overline{b}^T \end{array} := \begin{array}{c|c} \overline{c} & \overline{A} \\ \hline & b^T \\ & \overline{b}^T \end{array},$$

with the solution of fourth order given by

$$(2.7) \qquad \overline{z}_{n+1} = z_n + h\sum_{i=1}^{7} \overline{b}_i g_i.$$

order 4	$\frac{344139203}{3839083152}$	0	$\frac{371432256250}{773135066691}$	$\frac{386648544825}{531046526192}$	$-\frac{1692035942272}{3798491284161}$	$\frac{21356179}{219494520}$	$\frac{1}{20}$

For the fourth-order solution (2.7) it is very easy to see that the order conditions reduce to $\bar{b}_2 = 0$ and

$$\left\{\begin{array}{ll} \bar{b}^T \bar{c}^j = 1/(j+1), & j = 0,\ldots,3, \\ \bar{b}^T \bar{A}\,\bar{c}^2 = 1/12, & \\ \bar{b}^T \bar{A}\, e_2 = 0. & \end{array}\right. \tag{2.8}$$

Clearly, the linear system (2.8) is satisfied by the fifth-order solution. So, we will use the value a_{42} to make (2.8) compatible. From the first five equations of (2.8), we have a linear system in $\bar{b}_1, \bar{b}_3, \ldots, \bar{b}_6$ whose matrix is singular if

$$c_4 = \frac{c_3}{2(5c_3^2 - 4c_3 + 1)}.$$

Solving the linear system and taking c_2, c_3, c_4, c_5, and $\bar{b}_7$ as parameters, we arrive at the value

$$a_{42} = \frac{c_4^2(3c_3 - 2c_4)}{2c_3c_2},$$

to compatibilize the coefficients of the fourth-order solution.

The choice of the parameters $\gamma = (c_2, c_3, c_4, c_5, \bar{b}_7)$ leads to the following cases studied in this paper.

(i) Taking the values $c_2 = c_3 = 31/100$, $c_4 = 38/45$, $c_5 = 251/272$, and $\bar{b}_7 = 1/20$ as tuning parameters of the embedded pair leads to the formula RK5(4)4 presented in Table 1. For this formula, the ℓ_2 norm of the principal truncation term in the fifth-order solution is $\|C_6(\tau,\gamma)\| = 3.20 \times 10^{-4}$.

(ii) Taking $c_2 = c_3 = (5-\sqrt{5})/10$, $c_4 = c_5 = (5+\sqrt{5})/10$, $b_5 = 1/5$, and $\bar{b}_5 = 11/50$ as tuning parameters of the embedded pair leads to the formula RK5(4)3 presented in Table 2. Here, we obtain $\|C_6(\tau,\gamma)\| = 9.92 \times 10^{-4}$.

TABLE 2

order 5	$\frac{1}{12}$	0	$\frac{5}{12}$	$\frac{13}{60}$	$\frac{1}{5}$	$\frac{1}{12}$	0
order 4	$\frac{1}{12}$	0	$\frac{5}{12}$	$\frac{59}{300}$	$\frac{11}{50}$	$\frac{11-3\sqrt{5}}{240}$	$\frac{3+\sqrt{5}}{80}$

Note that for the formula RK5(4)3, the main drawback is that for quadrature problems, the local error estimate is zero. In this case, we can use the pair RK5(4)4 to avoid this deficiency, but in the numerical tests it has not been observed, since in general $J(t) \neq 0$.

On the other hand, we give in Table 3 some characteristic values of the new pairs proposed by Prince and Dormand [11] where

$$A^{(6)}(\gamma) = \|C_6(\tau,\gamma)\|,$$
$$B^{(6)}(\gamma) = \|\hat{C}_6(\tau,\gamma)\| \;/\; \|\hat{C}_5(\tau,\gamma)\|,$$
$$C^{(6)}(\gamma) = \|\hat{C}_6(\tau,\gamma) - C_6(\tau,\gamma)\| \;/\; \|\hat{C}_5(\tau,\gamma)\|,$$

and $\|C_{p+1}\|$ (or $\|\hat{C}_{p+1}\|$, $\|\hat{C}_{p+2}\|$) is the ℓ_2 norm of the coefficients in the expansion of the local error of z_{n+1} ($\bar{z}_{n+1}$, respectively), i.e.,

$$\|C_{p+1}(\tau,\gamma)\| = \sqrt{\sum_{\rho(\tau)=p+1} C(\tau,\gamma)^2}. \tag{2.9}$$

D is the largest coefficient of the RK method, S_R^p is the interval of absolute stability for the pth-order formula, and s is the number of stages.

TABLE 3

3. A fourth-order interpolant for the RK5(4) pairs. If the pairs developed in the last section are used in a quasi-linearization process, the provision of a continuous solution may be important. So, the aim of this section is to develop a fourth-order family of interpolants for the RK pairs of the above section with no additional function evaluations.

To construct such a continuous solution we follow the interpolatory approach of Shampine [14]. We have at our disposal

$$z_n, \;\; z_n' = J(t_n)z_n + g(t_n), \;\; z_{n+1}, \;\; z_{n+1}' = J(t_{n+1})z_{n+1} + g(t_{n+1}),$$

where z_{n+1}' and z_{n+1}' are $O(h^6)$ approximations to the local solution and its derivative at t_{n+1}, respectively. Since we are interested in a local Hermite interpolation polynomial of fourth degree in the interval $[t_n, t_n+h]$, we need an additional datum. We ask whether there are $\sigma \in (0,1)$ and $\hat{b}_i$, $i = 1,\ldots,7$ such that

$$z_{n+\sigma} = z_n + h\sum_{i=1}^{7} \hat{b}_i g_i \tag{3.1}$$

is a fourth-order approximation, i.e.,

$$\|z(t_n+\sigma h; t_n, z_n) - z_{n+\sigma}\| = O(h^5). \tag{3.2}$$

We have found that an approximation satisfying (3.1) and (3.2) exists for all $\sigma \in (0,1)$ with the coefficients $\hat{b}_i$ given as the solution of the linear system

$$\begin{pmatrix} c_3 & c_4 & c_5 & 1 \\ c_3^2 & c_4^2 & c_5^2 & 1 \\ c_3^3 & c_4^3 & c_5^3 & 1 \\ c_3^2 & c_4^2 & c_5^2 & 1 \\ a_{32} & a_{42} & a_{52} & a_{62} \end{pmatrix} \begin{pmatrix} \hat{b}_3 \\ \hat{b}_4 \\ \hat{b}_5 \\ \hat{b}_6 \end{pmatrix} = \begin{pmatrix} \sigma/2 - \hat{b}_7 \\ \sigma^2/3 - \hat{b}_7 \\ \sigma^3/4 - \hat{b}_7 \\ 0 \end{pmatrix},$$

in the case $c_2 = c_3$, where $\hat{b}_7$ is an arbitrary parameter, and

$$\begin{pmatrix} c_3 & c_4 & 1 & 1 \\ c_3^2 & c_4^2 & 1 & 1 \\ c_3^3 & c_4^3 & 1 & 1 \\ c_3^2 & c_4^2 & 1 & 1 \\ a_{32} & a_{42} & a_{62} & 0 \end{pmatrix} \begin{pmatrix} x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} = \begin{pmatrix} \sigma/2 \\ \sigma^2/3 \\ \sigma^3/4 \\ \hat{b}_5(a_{42} - a_{52}) \end{pmatrix},$$

in the case $c_2 = c_3$, $c_4 = c_5$, where $\hat{b}_5$ is an arbitrary parameter and the values of the vector $\hat{b}$ are given by

$$\hat{b}_3 = x_3, \quad \hat{b}_4 = x_4 - \hat{b}_5, \quad \hat{b}_6 = x_5, \quad \hat{b}_7 = x_6, \quad \hat{b}_1 = \sigma - \sum_{i=3}^{7} \hat{b}_i,$$

with $\sigma = \frac{1}{2}$.

We select the value of the free parameter to minimize the quantity

$$r^*(u) = \int_0^1 r(\theta)\, d\theta \quad \text{with} \quad r(\theta) = \frac{\|C_\theta(\tau)\|}{\|\hat{C}(\tau)\|},$$

where u is the free parameter.

Here, $\|\hat{C}(\tau)\| = 2.44 \times 10^{-3}$ is the ℓ_2 norm of the coefficients $\hat{C}$ of the elementary differentials of the local error of the fourth-order solution of the RK5(4)4 pair. For the RK5(4)3 pair we obtain $\|\hat{C}(\tau)\| = 2.85 \times 10^{-3}$, and $\|C_\theta(\tau)\|$ is the corresponding value of the continuous solution (3.1). These quantities have been computed with the help of the program developed in [8], which provides a FORTRAN code to evaluate the expressions (2.9) for a given RK formula for any order.

By a numerical search it was found that $r^*(\theta)$ is minimized for

$$\hat{b}_7 = 27/1000 \quad \text{for the RK5(4)4 and} \quad \hat{b}_5 = 13/2000 \quad \text{for the RK5(4)3},$$

and the coefficients $\hat{b}_i$ for each pair in $\sigma = \frac{1}{2}$ are shown in Table 4.

Finally, to show the quality of our interpolants we have plotted in Fig. 1 the functions $r(\theta)$ for the optimal interpolants. From Fig. 1, it is clear that the interpolant shows a very satisfactory behavior at intermediate points.

TABLE 4

$\hat{b}_i$	RK5(4)4	RK5(4)3
1	80930065829/383908315200	17/96
2	0	0
3	3647975007125/4638810400146	$(40+15\sqrt{5})/96$
4	−281400845553/2124186104768	$(4922-1875\sqrt{5})/12000$
5	63405740574112/284886846312075	13/2000
6	−2508796489/21949452000	$(-189\sqrt{5}+533)/9600$
7	27/1000	$(63\sqrt{5}-211)/3200$

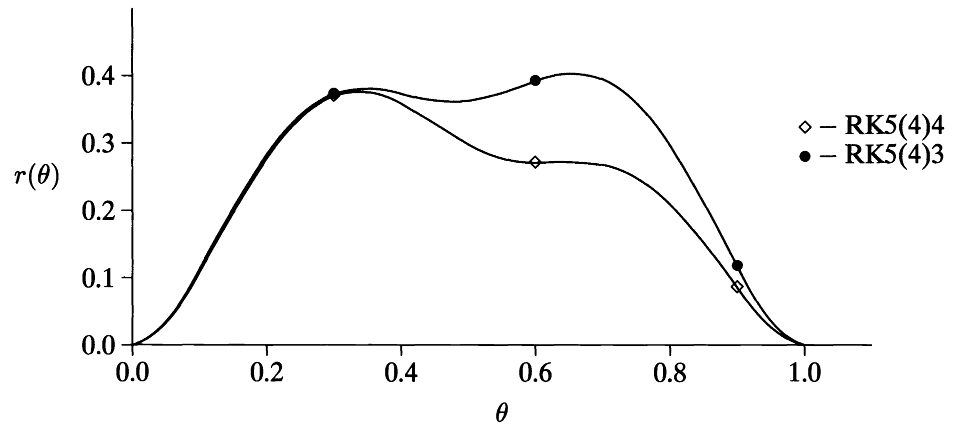

FIG. 1

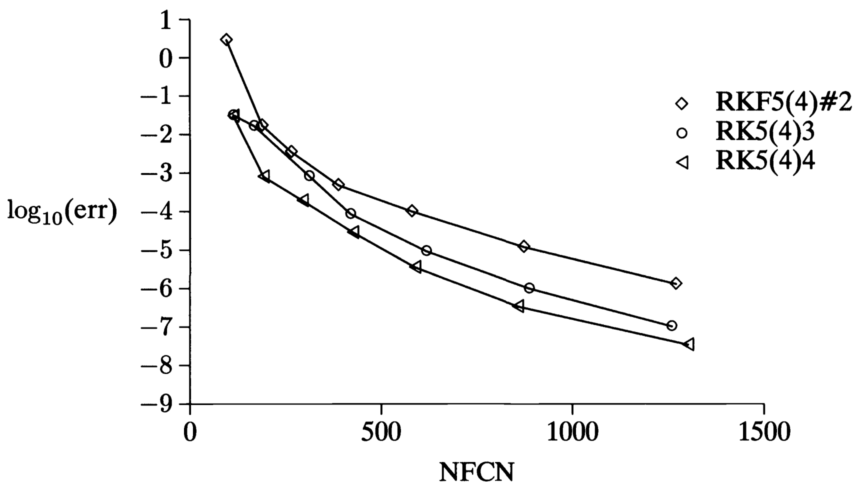
4. Numerical experiments. The new RK5(4) pairs obtained in the above section have been tested on several IVPs, but we give only results obtained with the linear problem A3 from DETEST [3], which is

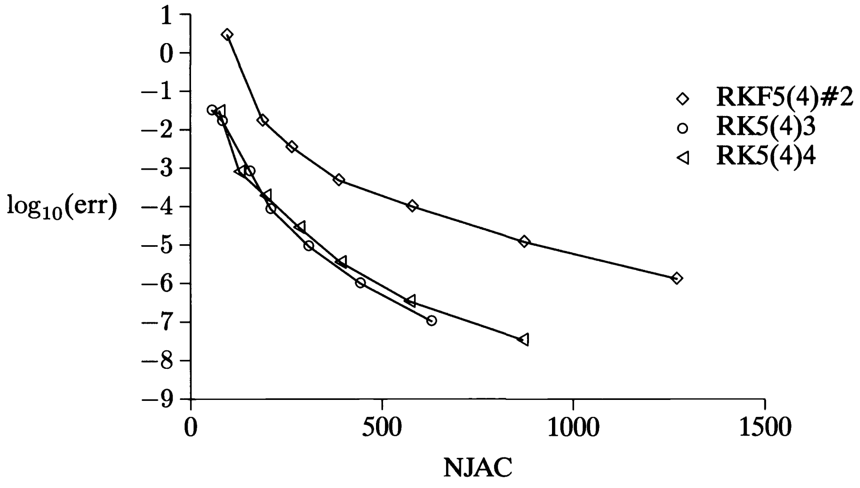
$$\begin{cases} y'(t) = \cos(t)y(t), & t \in (0,20), \\ y(0) = 1 \end{cases}$$

in unscaled form, for absolute tolerances in the range $10^{-2}, \dots, 10^{-8}$ and local extrapolation. Then, in Fig. 2(a) we plot, for each tolerance, the maximum global error $|y_n - y(t_n)|$ over the whole interval against NFCN, the number of function evaluations required. In Fig. 2(b) we plot the maximum global error against NJAC, the number of Jacobian evaluations.

Any code for solving linear BVPs, such as MUSL or SUPORT, is susceptible to a change of integrator, but as we have the SUPORT code of Scott and Watts [13], it was modified so that Fehlberg's pair and our new pairs might be used. With each pair, the numerical examples were integrated with a mixed absolute-relative control for tolerances $10^{-2}, \dots, 10^{-8}$. Briefly, we give results of two of the problems that appear in [13].



(a)



(b)

FIG. 2

Example 1. The first problem we wish to consider is

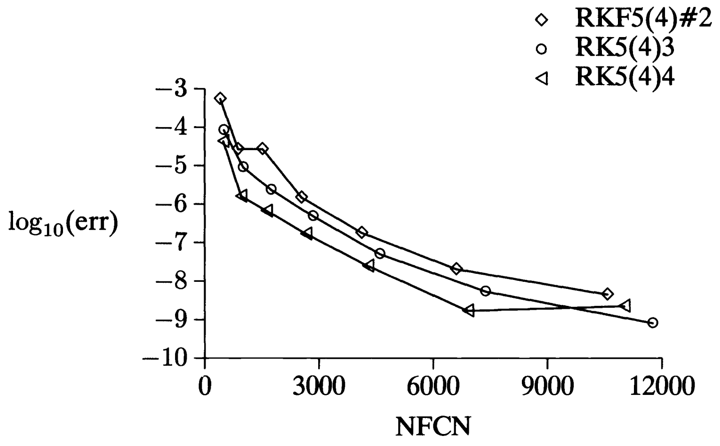
$$y''(t) + 3(\text{cotan}(x) + 2\tan(x))\, y'(t) + 0.7\, y(t) = 0,$$

subject to the boundary conditions

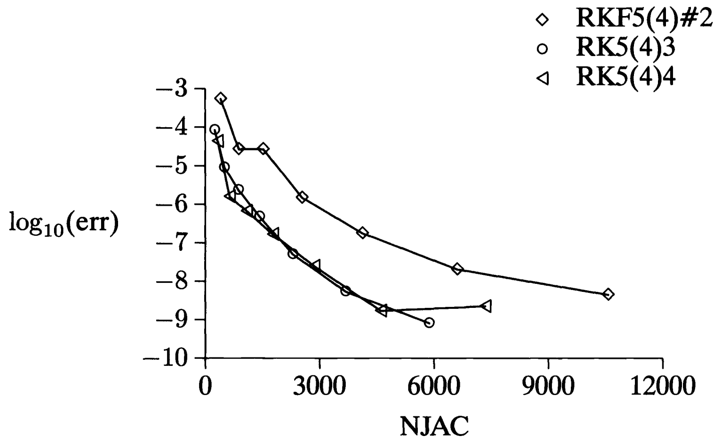
$$y(30^o) = 0, \qquad y(60^o) = 5.$$

It is worth noting that the independent variable t is taken in degrees, as in [13]. In this case, the problem is hard to solve due to a sharp spike in the solution. On the other hand, the two eigenvalues of the differential equation are negative. So, integrating the equations from 30° to 60°, the problem is easily solved. However, when the integration proceeds from 60° to 30° we have a difficult problem, due to the instability of the associated IVP. We give results only for the more difficult case.

In Fig. 3(a) we plot the maximum relative error in the solution at 15 points across the interval against NFCN, and in Fig. 3(b) we plot the maximum relative error against NJAC, the number of Jacobian evaluations. In all computations the number of orthonormalizations performed by the SUPORT code was 7.



(a)



(b)

FIG. 3

Example 2. Consider the boundary value problem [13]

$$y'' + \frac{3\epsilon}{(\epsilon + t^2)} y = 0,$$

$$y(-0.1) = -0.1(\epsilon + 0.01)^{-1/2},$$

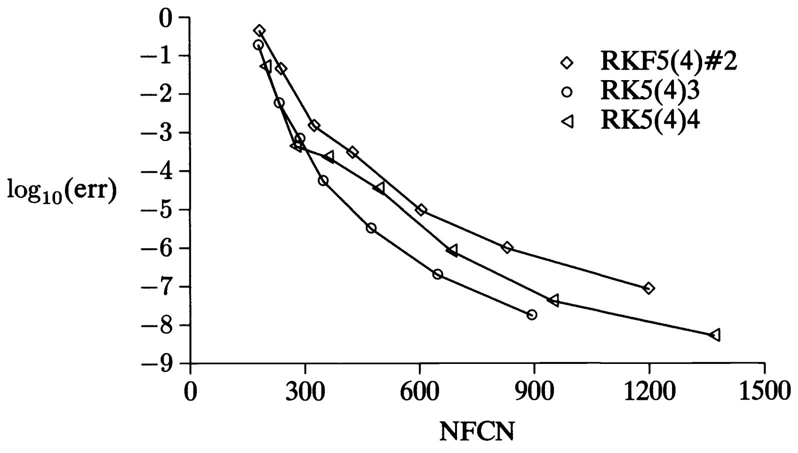
$$y(0.1) = -y(-0.1),$$

which has the exact solution

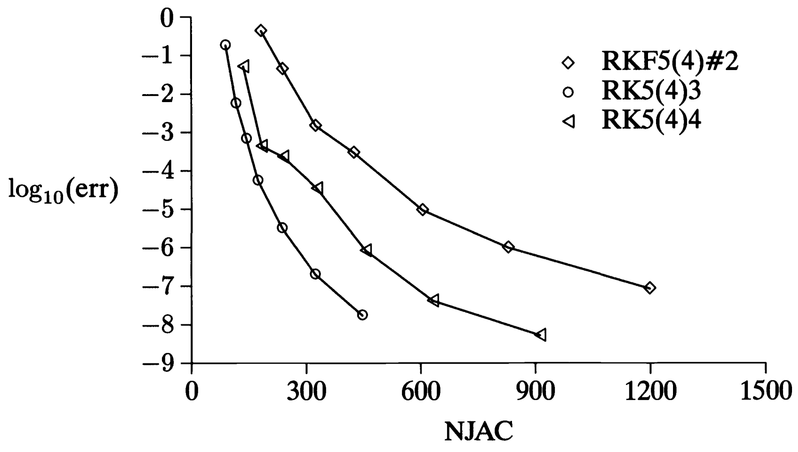
$$y(t) = t(\epsilon + t^2)^{-1/2}.$$

This problem was chosen by Scott and Watts [13] because it requires no orthonormalizations and it has a boundary layer of thickness $\sqrt{\epsilon}$ centered about $t = 0$. So, it is necessary for the code to have an efficient procedure for varying the stepsize of the integration.

The results of using the three integrators for $\epsilon = 10^{-6}$ are presented in Figs. 4(a) (global error against NFCN) and 4(b) (global error against NJAC). The maximum absolute error in the solution was sampled at 21 uniformly spaced points about the origin.



(a). $\epsilon = 10^{-6}$.



(b). $\epsilon = 10^{-6}$.

Fig. 4

The computations were carried out in double precision (16 significant digits) on a VAX STATION 3100 at the University of Zaragoza.

5. Conclusions. We feel that the solution of the initial value problem is a very important part of a shooting method code. So, with the new pairs developed in this paper, we get better numerical results with less computational cost. In the case of the RK5(4)3 pair, it uses 50% fewer Jacobian evaluations than the RKF5(4)#2 pair, while the size of the truncation error is about 3 times smaller; and the RK5(4)4 uses about 67% of the Jacobian evalutations used by RKF4(5)# 2, while the size of the truncation error is 10 times smaller.

In addition, the numerical experiments carried out in the preceding section show the importance of the study and construction of new special RK pairs for structured ODEs.

Finally, if intermediate values are required the two new pairs provide a fourth-order interpolant with no extra cost. In contrast, the RKF5(4)#2 requires one additional evaluation per step in order to obtain a fourth-order interpolant [7].

Acknowledgments. The author wishes to thank the referees and Prof. R. D. Skeel for their suggestions, which greatly improved the original paper.

ESTIMATING WAVEFORM RELAXATION CONVERGENCE*

B. LEIMKUHLER†

Abstract. Critical limitations of the waveform relaxation method concern the unsolved problems of estimating convergence and controlling the iteration. In this paper, waveform relaxation is applied to a linear, second-order model system and is studied in the Laplace domain. By placing the iteration in a weighted space, computable estimates for a window of rapid convergence are developed. Numerical experiments illustrate the utility of the approach.

Key words. waveform relaxation method, splittings, circuit simulation, parallel computing

AMS subject classification. 65L05

1. Introduction.

The waveform relaxation (WR) method can be applied to exploit parallel computers in the solution of large systems of ordinary differential equations (ODEs). The method was originally proposed for very large scale integration (VLSI) circuit simulation [8], but has since been adapted to problems in multibody dynamics [5] and to solving systems of spatially discretized partial differential equations [14].

WR relies on a splitting or decoupling of a given system of differential equations into a set of weakly coupled subsystems. At each *sweep*, the equations modelling each subsystem are solved independently in a fixed interval or *window*, treating the solutions or *waveforms* from other subsystems as input functions determined at the previous sweep or at an earlier stage of the current sweep. Although this paper is largely self-contained, the reader may find the book by Sangiovanni-Vincentelli and White [19] or papers by Miekkala and Nevanlinna [9], [10], useful background material.

The interest is in waveform relaxation as a parallel (or distributed processing) method for accelerating the time-domain simulation of a large ODE system. Although WR has not yet fulfilled its promise in terms of parallel speedups in general implementations, the method is highly competitive in many cases. The primary limiting factor in the development of waveform relaxation as a general method for VLSI circuit simulation has been the need for an efficient automatic partitioning algorithm that identifies a rapidly convergent splitting [16]. We do not present such an algorithm here, but we do examine conditions for the rapid and stable convergence of WR, which could be used as acceptance criteria in a partitioning algorithm.

We restrict ourselves primarily to splittings (decouplings) of the block Jacobi form which might be used in a parallel implementation. We avoid the issue of discretization here, relying on the work in [11] to insure that for sufficiently small stepsizes, the discrete version of the iteration will mimic the behavior of the continuous one.

In §2, a model linear second-order system is examined and several concepts (e.g., *stable convergence*) are discussed. Stable convergence of waveform relaxation is related to spectral properties of the iteration matrix in the Laplace transform of the waveform relaxation iteration. The matrices which define a linear system are decomposed using the *stamp representation* of electronic circuit simulation. Using the stamp representation, it is easy to obtain relations between the quadratic forms on the various matrices. A concept of the speed of the splitting is defined in terms of a proportionality constant between quadratic forms of the matrices defining the splitting.

*Received by the editors January 14, 1991; accepted for publication (in revised form) May 18, 1992.

The problem of determining the spectral radius of the Laplace domain iteration matrix $R(z)$ is then considered in §3. Sufficient conditions for $\rho(R(z)) \leq \omega$ are derived. These estimates generalize earlier estimates of [10] for convergence rate on an infinite interval.

Section 4 contains two numerical experiments. In particular, a curious relationship between block size and convergence rate for the equations describing a linear resistor-capacitor (RC) network (or, alternatively, the spatially discretized one-dimensional diffusion equation) is explained in terms of our theory, and a spring-mass particle system is used to illustrate the correctness of an estimate obtained for undamped problems.

2. Linear systems. In this section we describe the WR iteration, and outline the methods used for its analysis for a model class of linear ODE systems that includes multiparticle mechanical systems [3] and linear VLSI resistor-inductor-capacitor (RLC) circuits [8]. These results could also be extended to nonlinear problems via linearization or to include constraints (e.g., as indicated in [6] or [5]).

We consider here the following second-order problem:

$$M\ddot{p} = -Kp - D\dot{p} + f(t), \quad p(0) = p_0, \quad \dot{p}(0) = q_0. \tag{1}$$

For multiparticle systems, K and D are, respectively, spring and damper matrices which have $N \times N$ symmetric, positive semidefinite structure. For such a network, M, also $N \times N$, would typically be positive and diagonal, but we assume only positive definiteness for the moment. Note that the springs in (1) have zero rest states. In general, nonzero rest states lead to nonlinearities. It is also straightforward to interpret (1) in terms of RLC circuits, where the condition that M be positive definite can be interpreted to mean that there is a capacitor to ground from every node.

Given a splitting ($K = K^+ - K^-$, $D = D^+ - D^-$) of the system (1), we define the WR iteration process by the equation

$$\begin{aligned} &M\ddot{p}^{(k+1)} = -K^+p^{(k+1)} - D^+\dot{p}^{(k+1)} + K^-p^{(k)} + D^-\dot{p}^{(k)} + f(t), \\ &p^{(k+1)}(0) = p_0, \qquad \dot{p}^{(k+1)}(0) = q_0. \end{aligned} \tag{2}$$

Note that this framework does not allow the matrix M to be split.

Following the approach of [10] and [6], we analyze the iteration in the Laplace domain:

$$z^2M\hat{p}^{(k+1)} = -K^+\hat{p}^{(k+1)} - zD^+\hat{p}^{(k+1)} + K^-\hat{p}^{(k)} + zD^-\hat{p}^{(k)} + \phi,$$

where ϕ consists of terms involving $\hat{f}$ and the initial values, so that

$$\hat{p}^{(k+1)} = R(z)\hat{p}^{(k)} + \tilde{\phi}$$

with

$$R(z) = (z^2M + zD^+ + K^+)^{-1}(zD^- + K^-). \tag{3}$$

We will be concerned with spectral properties of $R(z)$.

2.1. Growth and the window of stable convergence. Although the iteration on finite intervals is always (eventually) superlinearly convergent, during the early sweeps of the iteration on long intervals, convergence may be quite slow or there may even be substantial growth; theoretically, all growth eventually settles down, but numerically speaking, the increase in the initial sweeps of the iteration can lead to serious instability. One problem is to estimate the length of a *window of stable convergence* wherein the growth during the early stages of the iteration is moderate in some sense. More generally, the problem is to estimate the length of a window wherein convergence is approximately geometric with a given rate of decay.

Although proper window length is a highly problem-dependent quantity, and it is apparent that any general-purpose program must incorporate an adaptive estimator for the proper window length, good theoretical estimates are needed to guide the development of such algorithmic devices.

Another motivation for pursuing this sort of spectral analysis of the WR iteration is for the purpose of making qualitative comparisons between splittings.

Separating nonphysical behavior in the computation of sweeps due to inaccuracies in the WR iteration from the true dynamics of the physical problem requires some estimation of the growth or decay mechanism of the iteration; here we use the exponentially weighted norm (following [13]) to try to find an interval where the convergence is rapid.

The starting point for our discussion is the formula of Proposition 2.1 (first shown in [10] in a slightly different setting) which affords us a means of computing the spectral radius of the iteration operator in a weighted space. Let $\mathcal{R}$ represent the iteration operator for (2).

PROPOSITION 2.1 (Miekkala–Nevanlinna). *Let $\rho_\xi(.)$ be the spectral radius in $L_{\xi,\infty}$, the ξ-weighted L_∞ space, $\xi > 0$, whose norm satisfies*

$$\|x\|_{\xi,\infty} = \sup_{t\in[0,\infty)} |e^{-\xi t}x(t)|,$$

with $|.|$ the Euclidean norm. Then

$$\rho_\xi(\mathcal{R}) = \sup_{\mathrm{Re}\{z\}>\xi} \rho(R(z)). \tag{4}$$

It can also be demonstrated that, in case the poles of $R(z)$ are located to the left of the vertical line $\mathrm{Re}(z) = \xi$, then the supremum in (4) is always achieved on that line.

We would like to choose a T for which $|\mathcal{R}^n f|_T$, the sup norm of the nth iterate on $[0, T]$, has moderate growth. It is convenient to treat f as a function whose domain is $[0, \infty)$ and whose support is in $[0, T]$. Then for $\xi \geq 0$,

$$\begin{aligned}|\mathcal{R}^n f|_T &= |e^{\xi t}e^{-\xi t}\mathcal{R}^n f|_T \\ &\leq e^{\xi T}\sup\nolimits_{0\leq t\leq T}|e^{-\xi t}\mathcal{R}^n f| \\ &\leq e^{\xi T}\sup\nolimits_{0\leq t\leq\infty}|e^{-\xi t}\mathcal{R}^n f| \\ &= e^{\xi T}\|\mathcal{R}^n f\|_{\xi,\infty} \\ &\leq e^{\xi T}\|\mathcal{R}^n\|_{\xi,\infty}\|f\|_{\xi,\infty} \\ &\leq e^{\xi T}\|\mathcal{R}^n\|_{\xi,\infty}|f|_T,\end{aligned}$$

by the assumption placed on f.

It is difficult to obtain simple, computable estimates for the norms of powers of $\mathcal{R}$, but, as we shall see in the next section, an estimate of the spectral radius is obtainable.

The sequence of norms of powers of $\mathcal{R}$ does not necessarily obey a uniform geometric decay. Although it is possible to obtain a bound on ξ which insures that $\|\mathcal{R}\|_{\xi,\infty} < \omega$ (see [17] and [7] for the techniques used in special cases), we expect spectral estimates to be somewhat finer, mimicing the situation for linear splittings of linear algebraic equations [20].

One can say that as $\operatorname{Re}\{z\} \to \infty$, the matrix $R(z)$ looks like an $O(1/z)$ perturbation to a normal matrix, which suggests that the spectral radius will, asymptotically as $T \to 0$, model the convergence rate of the iteration (even in the early sweeps).

DEFINITION 2.1. *The abscissa of ω-convergence is defined as*

$$\xi_\omega = \inf\{\xi : \rho_\xi(\mathcal{R}) < \omega\}.$$

Let $\xi = \xi_\omega$ and $T = T_\omega = \frac{1}{\xi_\omega}$. Then

$$|\mathcal{R}^n f|_{T_\omega} \tilde{<} e\omega^n |f|_{T_\omega},$$

where the symbol $\tilde{<}$ means "approximately bounded by." Up to the quality of this approximate bound, T_ω is an estimate for a window of convergence with rate ω.

If the concept of ω-convergence were formulated in the time domain, it would correspond to the notion of the "uniform convergence" defined by Sangiovanni–Vincentelli and White [19]. The translation of the results developed in the Laplace domain for the abscissa of ω-convergence to the time domain by simple inversion of the Laplace variable is a simplification, but as our numerical experiments show, enough of the important phenomena are captured by it for the technique to be of some usefulness for comparison of splittings and relative assessment of choices of window size.

2.2. Structure of linear systems: The stamp representation. We would like to restrict the class of splittings to a subset with practical benefit for parallel processing, namely, block Jacobi splittings. We first discuss the structure of the matrices involved in the description of (1) using *stamps*, and then describe the splitting matrices with the same tool.

We refer the reader to Collar and Simpson [3] for a discussion of formulating mechanical systems, and to Singal and Vlach [18] for a discussion of the stamp representation in the context of electronic circuits. The stamp representation is a powerful tool for decomposing the structure of a system of differential equations defined on a network.

We assume, first of all, that the network we are studying is connected. Furthermore, we assume that actions take place in some *relative coordinate frame*: one node of the network is distinguished and fixed. (The choice of this node is arbitrary, and there may be more than one fixed node.) Let N be the number of nonfixed nodes.

The flow of information in many network problems is determined by three types of elements: those (K) which relate solution values x, those (D) which relate the derivatives of the solution $\dot{x}$, and those (M) which relate second derivatives $\ddot{x}$. The equations describing the flow of information are obtained by summing the three types of contributions and setting the sum equal to any driving term f. The structures of the $N \times N$ matrices K and D and of M are precisely analogous, so we analyze only the first.

Let n_K elements of type K have positive coefficients $k_1, k_2, \ldots, k_{n_K}$. Suppose element i connects node l_i with node r_i. The matrix K may be written as a sum of simple rank-1 stamp matrices K_i, where, if neither terminal of element number i is fixed, the (l_i, l_i) and (r_i, r_i) elements of K_i are k_i, the (l_i, r_i) and (r_i, l_i) elements are $-k_i$, and the matrix is otherwise zero. (If either of the terminals of the element is a fixed node, this formula must be slightly modified: the associated stamp has just one nonzero element in the diagonal position corresponding to the index of the nonfixed terminal; its value is k_i.)

The block Jacobi splitting relaxes the interconnections between subsystems, so that D^+ and K^+ in (2) have a block diagonal structure (or may be permuted to a block diagonal matrix). We will assume that with a certain partitioning of the nodes of the network, the type M elements connect only nodes of a given block. We assume that all the interface elements (elements linking nodes of separated subsystems) connect a pair of nonfixed nodes.

We can very easily define the described splitting technique using stamps. If element i is a splitting element, let $\hat{K}_i$ represent the diagonal part of K_i. Let $Spl(K)$ denote the corresponding set of indices of the splitting elements. With i in $\{1, \dots, n_K\}$,

$$K = \sum_i K_i,$$

$$K^+ = \sum_{i \notin Spl(K)} K_i + \sum_{i \in Spl(K)} \hat{K}_i,$$

$$K^- = \sum_{i \in Spl(K)} (\hat{K}_i - K_i).$$

A similar decomposition may be used for D.

For future reference, we denote by $\mathcal{G}$ the graph that underlies the network, and by $\mathcal{G}_K$ ($\mathcal{G}_D$) the subgraph with nodes corresponding to all nodes of the network and edges corresponding to elements of type K (D). We always assume that the type-D and -K elements together describe a connected graph.

2.3. Bounds on quadratic forms. The equation satisfied by an eigenvector/eigenvalue pair (u, λ) of $R(z)$ is

$$(zD^- + K^-)u = \lambda(z^2M + zD^+ + K^+)u.$$

Multiplying by u^* and solving for λ, we have

$$\lambda = \frac{z\delta_- + \kappa_-}{z^2\mu + z\delta_+ + \kappa_+}, \tag{5}$$

where $\delta_\pm = u^*D^\pm u/(u^*u)$, $\kappa_\pm = u^*K^\pm u/(u^*u)$, and $\mu = u^*Mu/(u^*u)$. All these quantities are real, since they are quadratic forms on real, symmetric matrices. Note, too, that they are z-dependent, as the eigenvector u is dependent on z.

In the following propositions we give some facts about $\kappa_\pm$ and $\delta_\pm$.

PROPOSITION 2.2. *$\kappa_+ \geq |\kappa_-|$ and $\delta_+ \geq |\delta_-|$.*

Proof. The proofs of the two inequalities are precisely parallel; we consider the type-K case here.

Assume first for simplicity that none of the elements are connected to fixed nodes; we will see that this is of no consequence. Using the stamp representation of §2.2, we have

$$\begin{aligned}\kappa_+ &= \frac{1}{u^*u}\left[\sum_{i\notin Spl(K)} u^*K_iu + \sum_{i\in Spl(K)} u^*\hat{K}_iu\right]\\ &= \frac{1}{u^*u}\left[\sum_{i\notin Spl(K)} k_i(|u_{l_i}|^2 - 2\mathrm{Re}\{\bar{u}_{l_i}u_{r_i}\} + |u_{r_i}|^2) + \sum_{i\in Spl(K)} k_i(|u_{l_i}|^2 + |u_{r_i}|^2)\right]\\ &= \frac{1}{u^*u}(\eta + \sum_{i\in Spl(K)} k_i\sigma_i),\end{aligned}$$

where $\eta \geq 0$ and $\sigma_i \geq 0$. Similarly, we have

$$\begin{aligned}\kappa_- &= \frac{1}{u^*u}\sum_{i\in Spl(K)} u^*(\hat{K}_i - K_i)u\\ &= \frac{1}{u^*u}\sum_{i\in Spl(K)} 2k_i\mathrm{Re}\{\bar{u}_{l_i}u_{r_i}\}\\ &= \frac{1}{u^*u}\sum_{i\in Spl(K)} k_i\zeta_i.\end{aligned}$$

Now,

$$|\kappa_-| \leq \frac{1}{u^*u}\sum_{i\in Spl(K)} k_i|\zeta_i|.$$

By the Cauchy–Schwarz inequality, we may easily observe that $\eta \geq 0$ and that $|\zeta_i| \leq \sigma_i$, and this establishes the desired result.

Now if some of the (nonsplitting) elements were connections to fixed nodes, η in the above would be formulated slightly differently, but η would remain nonnegative, so the argument would go through unaltered. □

PROPOSITION 2.3. *κ_+ and δ_+ are never simultaneously zero.*

Proof. Assume the contrary, that $\kappa_+ = \delta_+ = 0$. By Proposition 2.2, $\kappa_- = \delta_- = 0$ and it follows that also

$$\frac{u^*Ku}{u^*u} = \kappa_+ - \kappa_- = 0, \qquad \frac{u^*Du}{u^*u} = \delta_+ - \delta_- = 0,$$

so that u is a singular vector of $K + D$.

The matrix $K + D$ is weakly diagonally dominant since it is the sum of stamp matrices. The associated graph of the matrix $K + D$ is precisely $\mathcal{G}$, the graph underlying the network; by assumption, this graph is connected. Furthermore, there is some fixed node. Let the ith node of the network be connected directly to this fixed node. From the stamp representation, it is evident that in the ith row of $K + D$, the diagonal element is strictly greater than the sums of the absolute values of the off-diagonal elements. Evidently the matrix $K + D$ is irreducibly diagonally dominant, and this contradicts the existence of a singular vector. □

Using these facts about the Rayleigh quotients, it is possible to locate the poles of $R(z)$.

PROPOSITION 2.4. *The poles of $R(z)$ all lie in the closed half-plane $\mathbf{C}_- = \{z : \text{Re}\{z\} \le 0\}$.*

Proof. If z is a pole of $R(z)$, then there is a $u \in \mathbf{C}^n$ such that $(Mz^2+D^+z+K^+)u = 0$. Taking Rayleigh quotients, letting $z = x + iy$ with $x, y \in \mathbf{R}$, and examining the real and imaginary parts, we obtain

$$\mu(x^2 - y^2) + x\delta_+ + \kappa_+ = 0, \qquad 2xy + y\delta_+ = 0.$$

Using the nonnegativity of the coefficients, we see that if $y \neq 0$, then the second equation implies that $x \le 0$, while if $y = 0$, then the first equation implies that $x \le 0$. $\square$

Note that in case there are only type-K elements present ($D = D^+ = D^- = 0$), poles occur at each of the points iy, where y is the square root of an eigenvalue of $M^{-1}K^+$. Observe that for (λ, u) an eigenpair of $M^{-1}K^+$, $M^{-1}K^+u = \lambda u$, so $M^{-1/2}K^+u = \lambda M^{1/2}u$, where $M^{-1/2}$ is real and symmetric positive definite (s.p.d.). Thus $M^{-1/2}K^+M^{-1/2}w = \lambda w$ where $w = M^{1/2}u$, implying that $\lambda \in \mathbf{R}_+$. The poles of $R(z)$ are continuous functions of the coefficients; as type-D elements are added to the system, it can be seen that the poles move continuously into the left half-plane.

2.4. Speed of a splitting. It is clear that ξ_ω will depend critically on the extent to which the system was naturally decoupled at the splitting; in other words, on the relative influence of the coupling elements. Our estimates for ξ_ω are determined based on the following concept of the *speed of the splitting.*

DEFINITION 2.2. *The speed of the splitting of the matrix K is the quantity*

$$\omega_K = \inf\left\{\omega \ge 0 : \inf_{u\in\mathbf{C}^n} u^*K^+u - \frac{1}{\omega}\left|u^*K^-u\right| \ge 0\right\}.$$

The speed of the splitting of the matrix D is defined analogously.

When $\omega_K = 0$, for example, then the subsystems are coupled only through type-D elements. From earlier propositions, it is apparent that ω_K and ω_D both lie in the intervals $[0, 1]$.

If K^+ is nonsingular, then we have simply

$$\omega_K = \rho((K^+)^{-1}K^-) = \rho((K^+)^{-1/2}K^-(K^+)^{-1/2}).$$

However, ω_K (or ω_D) may also be easily computed in singular cases if we use the graph structure to partition the matrices K^+ and K^-. Suppose K^+ and K^- are obtained as the splitting network in such a way that all elements of the splitting are connected between nodes of an index set I (the "interface" nodes). Let J be another set of indices constructed as follows: for each index $i \in I$, J contains i and the indices of all of the nodes that lie in the component of $\mathcal{G}_K$ to which node i belongs. We may assume without loss of generality that the indices in the set J are sequential beginning with 1. Then K^+ and K^- can be partitioned as follows:

$$K^+ = \begin{bmatrix} K_J^+ & 0 \\ 0 & K_2^+ \end{bmatrix}$$

and

$$K^- = \begin{bmatrix} K_J^- & 0 \\ 0 & 0 \end{bmatrix},$$

where $K_J^{\pm}$ corresponds to the indices in J. The matrix K_J^+ is weakly diagonally dominant; furthermore, in any connected component of the associated graph there is at least one node (a node of the interface) for which the corresponding diagonal element of K_J^+ is strictly greater than the sum of moduli of off-diagonal elements. This is sufficient to conclude that K_J^+ is positive definite (in particular, it is nonsingular). The speed of convergence is the least ω such that the matrix

$$\begin{bmatrix} K_J^+ - \frac{1}{\omega}K_J^- & 0 \\ 0 & K_2^+ \end{bmatrix}$$

is positive semidefinite. K_2^+ is always positive semidefinite. Evidently we must have $K_J^+ - \frac{1}{\omega}K_J^-$ positive semidefinite. The infimum over all such ω occurs when $\omega = \omega_K = \rho((K_J^+)^{-1}K_J^-)$.

3. Estimates for ξ_ω.

Let

$$r(z) = \frac{z\delta_- + \kappa_-}{\mu z^2 + z\delta_+ + \kappa_+},$$

where $z = x + iy$, with $x, y \in R$. In this section we treat the case $M = I$, so that $\mu = 1$. If $M \neq I$, we make the substitution $p = M^{-1/2}\bar{p}$ in (1), and premultiply by the equation by the same factor. This results in a simple row and column scaling of K and D. In this case, the estimate for ξ_ω given in Theorem 3.1, below, instead of depending on properties of $K^{\pm}$ and $D^{\pm}$, would depend on analogous properties of $M^{-1/2}K^{\pm}M^{-1/2}$ and $M^{-1/2}D^{\pm}M^{-1/2}$.

3.1. Upper bounds for ξ_ω.

For fixed ω, we derive computable conditions on $x \geq 0$ that insure that $\sup_{y\in\mathbf{R}} |r(x+iy)| \leq \omega$. Note that in light of Proposition 2.4, this condition insures that $\sup_{\mathrm{Re}\{z\}>x} \rho(R(z)) < \omega$ and hence that $x \geq \xi_\omega$.

Define $s(x,y) = |r(x+iy)|^2 = \frac{p(x,y)}{q(x,y)}$, where

$$p(x,y) = (x\delta_- + \kappa_-)^2 + (y\delta_-)^2$$

and

$$q(x,y) = (x^2 - y^2 + x\delta_+ + \kappa_+)^2 + (2x + \delta_+)^2 y^2.$$

If all of the coefficients were fixed, we could maximize $s(x,y)$ for y by solving the equation

$$\frac{\partial}{\partial y} s(x,y) = 0.$$

On the other hand, the coefficients are definitely *not* fixed with respect to x and y. Since we do not know the eigenvectors of $R(z)$, the best we can do is to seek a value of x which causes $s(x,y) \leq \omega^2$ when $y \in R$ and the coefficients of p and q are determined by *any* $u \in C^n$. The challenge, however, is that this estimate must be computable.

$s(x,y) \leq \omega^2$ when

$$q(x,y) - \frac{1}{\omega^2}p(x,y) \geq 0.$$

This leads to the relation

$$\begin{aligned}(6)\qquad &(x^2+y^2)^2 + \delta_+^2(x^2+y^2) + 2x\delta_+(x^2+y^2) + 2\kappa_+(x^2-y^2) + 2\delta_+\kappa_+x + \kappa_+^2 \\ &- \frac{1}{\omega^2}\left[\delta_-^2(x^2+y^2) + 2\delta_-\kappa_-x + \kappa_-^2\right] \geq 0.\end{aligned}$$

By appropriate regrouping of the terms in this expression, it is possible to develop sufficient conditions for $s(x,y) < \omega^2$. Assuming the following condition allows us to distinguish a case where the bound so derived appears to be particularly computable.

CONDITION 3.1. *When the quadratic forms are consistently defined (i.e., determined by the same vector $u \in \mathbf{C}^n$),*

$$\delta_+\kappa_+ - \frac{1}{\omega^2}\delta_-\kappa_- \geq 0.$$

Note that always

$$\delta_+\kappa_+ - \frac{1}{\omega_D\omega_K}\delta_-\kappa_- \geq 0,$$

so that if $\omega > \sqrt{\omega_D\omega_K}$, then Condition 3.1 holds, but this is a somewhat stronger assumption.

THEOREM 3.1. *Suppose that Condition* 3.1 *holds, then*

$$\xi_\omega \leq \max\{\theta_D\rho(D^-), \theta_K\sqrt{\rho(K^+)}, 0\},$$

where

$$\theta_D = \frac{1}{\omega} - \frac{1}{\omega_D}$$

and

$$\theta_K = \begin{cases} \left[2\left(3 - \sqrt{3^2 - \frac{\omega_K^2}{\omega^2}}\right)\right]^{\frac{1}{2}}, & 0 \leq \frac{\omega_K^2}{\omega^2} < 5, \\ \left[\frac{1}{2}\left(\frac{\omega_K^2}{\omega^2} - 1\right)\right]^{\frac{1}{2}}, & \frac{\omega_K^2}{\omega^2} \geq 5. \end{cases}$$

Proof. Regrouping the terms in (6), we obtain the relation

$$\begin{aligned}(x^2+y^2)\left((x+\delta_+)^2 - \frac{1}{\omega^2}\delta_-^2\right) + 2x\left(\delta_+\kappa_+ - \frac{1}{\omega^2}\delta_-\kappa_-\right)\\ + (x^2+y^2)y^2 + 2\kappa_+(x^2-y^2) + \kappa_+^2 - \frac{1}{\omega}^2\kappa_-^2 \geq 0.\end{aligned} \tag{7}$$

If $x \geq \theta_D\rho(D^-)$, then the first term is nonnegative. The second term is nonnegative when Condition 3.1 holds.

The third term is nonnegative when

$$\gamma(y^2;x) = y^4 + (x^2 - 2\kappa_+)y^2 + 2\kappa_+x^2 + \left(1 - \frac{\omega_K^2}{\omega^2}\right)\kappa_+^2 \geq 0.$$

Suppose first that $\omega_K^2/\omega^2 \leq 9$ and that

$$x^2 \geq 2\left(3 - \sqrt{3^2 - \frac{\omega_K^2}{\omega^2}}\right)\kappa_+;$$

then

$$\gamma(y^2;x) \geq y^4 + 2\left(2 - \sqrt{3^2 - \frac{\omega_K^2}{\omega^2}}\right)\kappa_+ y^2 + \left(13 - 4\sqrt{3^2 - \frac{\omega_K^2}{\omega^2}} - \frac{\omega_K^2}{\omega^2}\right)\kappa_+^2$$
$$= \left[y^2 + 2\left(2 - \sqrt{3^2 - \frac{\omega_K^2}{\omega^2}}\right)\kappa_+\right]^2 \geq 0.$$

On the other hand, if $\omega_K^2/\omega^2 \geq 1$, and if

$$x^2 \geq \frac{1}{2}\left(\frac{\omega_K^2}{\omega^2} - 1\right)\kappa_+,$$

then

$$\gamma(y^2;x) \geq y^4 + \left[\frac{1}{2}\left(\frac{\omega_K^2}{\omega^2} - 1\right) - 2\right]\kappa_+ y^2 + \left(\frac{\omega_K^2}{\omega^2} - 1\right)\kappa_+^2 + \left(1 - \frac{\omega_K^2}{\omega^2}\right)\kappa_+^2$$
$$= y^4 + \left[\frac{1}{2}\left(\frac{\omega_K^2}{\omega^2} - 1\right) - 2\right]\kappa_+ y^2.$$

This last expression is nonnegative regardless of y if $\omega_K^2/\omega^2 \leq 5$.

It is easy to see that

$$2\left(3 - \sqrt{3^2 - \frac{\omega_K^2}{\omega^2}}\right) \geq \frac{1}{2}\left(\frac{\omega_K^2}{\omega^2} - 1\right) \quad \text{if } \frac{\omega_K^2}{\omega^2} \in [5,9],$$

so the second choice is the better bound on ξ_ω whenever it is valid. □

Note that the final result only depends on the speeds of the splittings of K and D and on the spectral radii of K^+ and D^-. The result when $K = 0$ is of some special interest since it corresponds to the case of RC circuits or semidiscretized diffusion equations. More generally, we have the following useful special cases which follow directly from eliminating unnecessary steps in the proof of Theorem 3.1 for the cases $D^- = 0$ or $K^- = 0$.

THEOREM 3.2. *If* $K^- = 0$, *then*

$$\xi_\omega \leq \max\left\{(1/\omega - 1/\omega_D)\rho(D^-), 0\right\}.$$

If $D^- = 0$, *then*

$$\xi_\omega \leq \frac{1}{2}\frac{\sqrt{\omega_K}}{\omega}\sqrt{\rho(K^-)}.$$

Proof. In the first case $K^- = 0$, Condition 3.1 automatically holds and the third term on the left-hand side of (7) can be reorganized as

$$(y^4 - 2\kappa_+ y^2 + \kappa_+^2) + x^2(y^2 + 2\kappa_+).$$

Both of these terms are clearly nonnegative, regardless of x and y; all that is left is the first term in (7), which is nonnegative under the stated condition.

On the other hand, if $D^- = 0$, a sufficient condition for (7) to be satisfied can be written as

$$(x^2 + y^2)^2 + 2\kappa_+(x^2 - y^2) + \kappa_+^2 - \frac{1}{\omega^2}\kappa_-^2 \geq 0.$$

Reorder the terms in powers of y^2 to get

$$y^4 + 2(x^2 - \kappa_+)y^2 + (x^2 + \kappa_+)^2 - \frac{1}{\omega^2}\kappa_-^2 \geq 0.$$

Clearly, this is satisfied if

$$(x^2 + \kappa_+)^2 - \frac{1}{\omega^2}\kappa_-^2 \geq (x^2 - \kappa_+)^2.$$

Expanding the powers and cancelling, this reduces to

$$4\kappa_+ x^2 - \frac{1}{\omega^2}\kappa_-^2 \geq 0.$$

Noting that $\kappa_+ \geq \frac{1}{\omega_K}|\kappa_-|$, it is enough to demand

$$\frac{4}{\omega_K}|\kappa_-|x^2 - \frac{1}{\omega^2}\kappa_-^2 \geq 0,$$

which holds under the condition of the theorem. □

3.2. Estimates asymptotically correct as $\omega \to 0$. Although Theorems 3.1 and 3.2 provide insight into the WR process, our experience in computations suggests that a different line of reasoning can sometimes yield rather better estimates, particularly as $\omega \to 0$. To begin, let us examine the graph of $R(z)$ more closely. As a simple example, we consider the splitting of the spring network of Fig. 1 into "left" and "right" subsystems, each containing two of the mass points. With this splitting, $\rho(R(x+iy))$ is plotted in Fig. 2 against x and y. A second graphic in Fig. 3 shows the view along the x-axis looking towards the origin, demonstrating that the maximum over lines parallel to the imaginary axis ultimately occurs at $y = 0$ (for large enough x). This illustration is representative of the general case, and in fact we can say that if x is sufficiently large, the maximum value of $\rho(R(x+iy))$ over $y \in R$ occurs on the x-axis.

This means that if ω is sufficiently small, we may take $y = 0$, and this simplifies the calculation of ξ_ω.

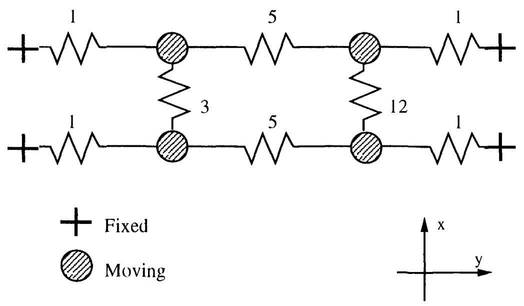

FIG. 1. *A simple spring-mass network.*

In what follows we assume $K^- \neq 0$. If $K^- = 0$, then one cannot easily improve on the estimate of Theorem 3.1.

The key idea is to rewrite the left-hand side of (6) as a polynomial in y^2:

$$\phi(y^2) = y^4 + by^2 + c,$$

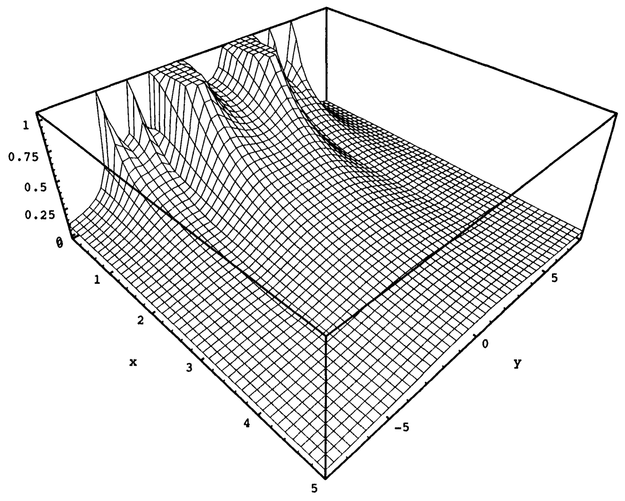

FIG. 2. *Plot of* $\rho(R(z))$.

where

$$b = b(x, u; \omega) = 2x^2 + \delta_+^2 + 2x\delta_+ - 2\kappa_+ - \frac{1}{\omega^2}\delta_-^2$$

and

$$c = c(x, u; \omega) = x^4 + \delta_+^2 x^2 + 2x^3\delta_+ + 2\kappa_+ x^2 + 2\delta_+\kappa_+ x + \kappa_+^2$$
$$-\frac{1}{\omega^2}\left(\delta_-^2 x^2 + 2\delta_-\kappa_- x + \kappa_-^2\right)$$

for $u \in C^n$, the vector on which the quadratic forms are consistently defined. $\phi(y) = 0$ for some y means that $\rho(R(x + iy)) \geq \omega$.

The following lemmas summarize the character of b and c.

LEMMA 3.3. *If* $\omega < \omega_K$ *there exists* x_ω *such that* (i) $c(x_\omega, u; \omega) \geq 0$ *for all* u, *and* (ii) $c(x_\omega, u; \omega) = 0$ *for some* u.

Proof. For x sufficiently large, the quartic term dominates and it is easy to see that $c(x, u; \omega) > 0$ for all u. On the other hand, $c(0, u; \omega) = \kappa_+^2 - \frac{1}{\omega^2}\kappa_- < 0$ for some choice of u, since $\omega < \omega_K$. $\min_u c(x, u; \omega)$ is defined and is a continuous function of x, and this guarantees the existence of an intermediate value x_ω with the required properties. □

LEMMA 3.4. *Let* $K^- \neq 0$. *If* $D^- \neq 0$, *then there exist positive constants* $\tilde{d}_0$ *and* $\bar{d}_0 \neq 0$ *such that* $\bar{d}_0 \geq \omega x_\omega \geq \tilde{d}_0$ *for* ω *sufficiently small.*

Proof. The proof of this fact is slightly technical, but the idea is simple. First, write $c(x_\omega, u; \omega) = c_+(x, u) + \frac{1}{\omega^2}c_-(x_\omega, u)$, where $c_-(x_\omega, u) = (\delta_- x + \kappa_-)^2$. If x_ω stays bounded as $\omega \to 0$, the only possibility is $\max_u c_-(x_\omega, u) \to 0$. Returning to the stamp representation for D^- and K^-, we know that these are both nonpositive matrices. Then taking u_0 to be a vector of all 1's, we see that $\max_u c_-(x_\omega, u) \geq (x_\omega d_0 + k_0)^2$ with nonnegative constants d_0 and k_0. Evidently, the only situation that would allow $\max_u c_-(x_\omega, u) \to 0$ is if $K^- = 0$, we have disallowed by an assumption. The only possibility is $x_\omega \to \infty$, as $\omega \to 0$.

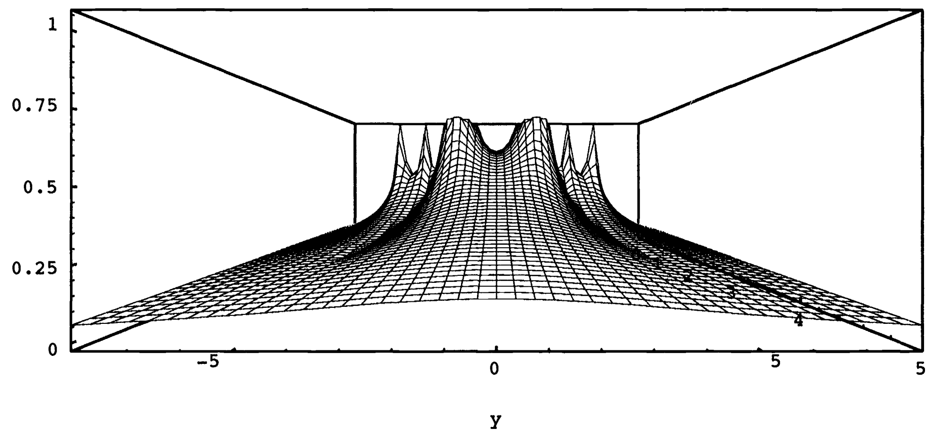

FIG. 3. *View toward O along the real axis.*

Now divide $c(x_\omega, u; \omega)$ by x_ω^4 to get

$$c(x_\omega, u; \omega) = 1 - \frac{\delta_-^2}{\omega^2 x_\omega^2} + O\left(\frac{1}{x_\omega}\right) + O\left(\frac{1}{\omega^2 x_\omega^3}\right).$$

If this is to be (i) nonnegative for all u and (ii) zero for some u, then the only possibility is that $\bar{d}_0 \geq \omega x_\omega \geq \tilde{d}_0$ for some nonnegative constants $\bar{d}_0$ and $\tilde{d}_0$. □

LEMMA 3.5. *For ω sufficiently small, $b(x_\omega, u; \omega) > 0$ for all u.*

The proof follows by grouping the terms in the expression for b as, e.g.,

$$b(x_\omega, u; \omega) = \left[\frac{1}{2}x_\omega^2 - 2\kappa_+\right] + \left[\frac{1}{2}x_\omega^2 + (x_\omega + \delta_+)^2 - \frac{1}{\omega^2}\delta_-^2\right].$$

The first term is ultimately positive since $x_\omega \to \infty$. The second term can be seen to be ultimately positive by use of the proof of the previous lemma.

LEMMA 3.6. *If ω is sufficiently small, then the maximum value of $\rho(R(x_\omega + iy))$ for all y is uniquely achieved at $y = 0$.*

Proof. For ω sufficiently small, $b(x_\omega, u; \omega) > 0$ independent of u. Since $c(x_\omega, u; \omega) \geq 0$, clearly $\phi(y) > 0$ for all $y \neq 0$. On the other hand, $\phi(0)$ reduces to the term $c(x_\omega, u; \omega)$, which we know is zero for some choice of u. In other words, $\rho(R(x_\omega)) \geq \omega$, and $\rho(R(x_\omega + iy)) < \omega$ for $y \neq 0$. Clearly, then, for ω sufficiently small, the maximum value of $\rho(R(x_\omega + iy))$ over y is achieved at $y = 0$. □

THEOREM 3.7. *Suppose $K^- \neq 0$. If $D^- \neq 0$, then, asymptotically as $\omega \to 0$,*

$$\xi_\omega \leq \max\{(1/\omega - 1/\omega_D)\rho(D^-), 0\}$$

(*independendent of K*).

If $D^- = 0$, then the asymptotic estimate becomes

$$\xi_\omega \leq \max\left\{\sqrt{(1/\omega - 1/\omega_K)\rho(K^-)}, 0\right\},$$

Proof. For ω sufficiently small, by Lemma 3.6, we may take $y = 0$ in (6), yielding

$$(8) \quad x^2\left((x + \delta_+)^2 - \frac{1}{\omega^2}\delta_-^2\right) + 2x\left(\delta_+\kappa_+ - \frac{1}{\omega^2}\delta_-\kappa_-\right) + 2\kappa_+ x^2 + \kappa_+^2 - \frac{1}{\omega^2}\kappa_-^2 \geq 0$$

as the condition for $x \geq \xi_\omega$.

If $D^- = 0$, then one requires only that

$$x^4 + 2\kappa_+ x^2 + \kappa_+^2 - \frac{1}{\omega^2}\kappa_-^2 \geq 0,$$

which reduces to the stated condition.

If, on the other hand, $D^- \neq 0$, divide the inequality (8) by x^2 to get

$$(9) \qquad (x+\delta_+)^2 - \frac{1}{\omega^2}\delta_-^2 + \frac{2}{x}\left(\delta_+\kappa_+ - \frac{1}{\omega^2}\delta_-\kappa_-\right) + 2\kappa_+ + \frac{\kappa_+^2 - \frac{1}{\omega^2}\kappa_-^2}{x^2} \geq 0.$$

Now fix $\epsilon > 0$. Define $\hat{x}_\omega = (1/\omega - 1/\omega_D)\rho(D^-)$ and let $x = (1+\epsilon)\hat{x}_\omega$, then the left-hand side of (9) becomes

$$(10) \qquad (\hat{x}_\omega + \delta_+)^2 - \frac{1}{\omega^2}\delta_-^2$$

$$+2\epsilon\hat{x}_\omega(\hat{x}_\omega + \delta_+) + \epsilon^2\hat{x}_\omega^2$$

$$+\frac{2}{x}\left(\delta_+\kappa_+ - \frac{1}{\omega^2}\delta_-\kappa_-\right)$$

$$(11) \qquad +2\kappa_+ + \frac{\kappa_+^2 - \frac{1}{\omega^2}\kappa_-^2}{x^2}.$$

Clearly the first term here is nonnegative. Furthermore, as $\omega \to 0$, making use of Lemma 3.4, the second term is positive and $O(\frac{1}{\omega^2})$, while the third and fourth terms are, respectively, $O(\frac{1}{\omega})$ and $O(1)$. Evidently, $x = (1+\epsilon)\hat{x}_\omega$ implies that $x \geq \xi_\omega$. Since ϵ was arbitrary, the best choice for the estimate is, asymptotically speaking, $\hat{x}_\omega$. $\square$

This confirms our observations in many computational experiments that the D-type elements dominate the convergence behavior of the iteration in the late sweeps or on a short window. On long windows, or in the early sweeps, it is our experience that the K-type elements are more important since they introduce oscillatory modes that are often difficult to resolve.

4. Numerical experiments.

4. Numerical experiments. We first detail some experiments with the simple RC interconnect (or RC line) of Fig. 4, and then turn to a multiparticle mechanical system.

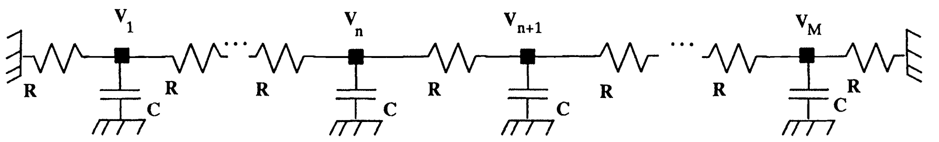

FIG. 4. RC *line.*

A problem similar to the RC line was considered in [10] and it has recently been examined in more detail by Leimkuhler and Ruehli [7] from another point of view. Here we compare the observed convergence rate of the iteration for several block sizes and several window sizes and attempt to relate our observations to the estimates obtained in the last section. In doing so, we must be careful to understand those estimates in

TABLE 1
Observed convergence rate for block G-J *iteration.*

Block size s	Time interval		
	[0,1]	[0,.5]	[0,.25]
1	.49/.38	.25/.20	.16/.12
2	.27/.22	.15/.12	.084/.064
4	.28/.21	.16/.12	.087/.065
30	.29/.21	.16/.12	.087/.065
60	.28/.21	.16/.12	.086/.065

the proper context: they are essentially heuristic in that they are based on a simplified transition from Laplace to time variable and on assumptions that are only strictly valid asymptotically as $\mathrm{Re}\{z\} \to \infty$ or as $\omega \to 0$. Despite the limitations, the examples of this section show that the estimates do have practical value.

The equations describing the nodal voltages in Fig. 4 are the familiar $\dot{x} = Ax$, where A is the tridiagonal matrix with 1, -2, and 1 on, respectively, the sub-, main, and super-diagonal. A pseudorandom initial vector was supplied to insure that all parts of the circuit were approximately equally active over the time interval. We used the backward Euler method and a sufficiently small fixed stepsize $h = 0.025$ so that the convergence results were not substantially different for smaller values of h (and hence mimic the behavior of the time-continuous iteration). In Table 1, we give our observations for the convergence rate of the iteration obtained by splitting the equations of the RC line of length 120 into various size blocks. The entries in the table are of the form r_3/r_6, where r_i represents the rate of convergence observed over the first i sweeps (computed as $(e_i/e_1)^{i-1}$, where e_i is the difference between the ith and $i-1$st iterates in maximum over both time and components). The pair of entries is just meant to give some indication of how much variation there is in the first few sweeps (bear in mind that the convergence rate will ultimately tend to 0 as $i \to \infty$, due to the superlinear convergence). We can also directly compute the spectral radius of the iteration matrix when $z = 0$, or ω_D for the purposes of our estimation technique, and establish that for the given problem, the spectral radius $\rho((D^+)^{-1}D^-)$ varies between about .983 and .997 in this case.

We were surprised to see that the rate of convergence fell so dramatically when the block size s changed from 1 to 2, while the change was nearly insignificant going from, e.g., $s = 2$ to $s = 4$, although this behavior has been observed in other computations [15]. We are prepared to give a partial explanation based on our estimates for convergence.

First note that there is substantial agreement between the values of spectral radius of $(D^+)^{-1}D^-$ for all cases. Thus no explanation is found in the existing spectral framework (in $L_2([0,\infty))$). On the other hand, computing $\rho(D^-)$ for each splitting, we find that $\rho(D^-) \approx 2$ for $s = 1$ and $\rho(D^-) = 1$, $s > 1$! This agrees qualitatively with the observations, since taking $C/T = \hat{\xi}_\omega = (1/\omega - 1/\omega_K)\rho(K^-)$, we have

$$\omega = \frac{T\rho(D^-)\omega_D}{T\rho(D^-) + C},$$

which is essentially proportional to $T\rho(D^-)$ in case (as here) $\omega_D \approx 1$ regardless of splitting and $T\rho(D_-)$ is small.

We can get some indication of how good of a *quantitative* window estimate $C/\hat{\xi}_\omega$ is by substituting an observed convergence rate r into $\hat{T} = C/\hat{\xi}_r$ and comparing with the time interval on which r was observed. These calculations have been performed in

TABLE 2
$C/\hat{\xi}_r$ for observed convergence rate r, $C = 2.7$.

Block size s	Time interval		
	[0,1]	[0,.5]	[0,.25]
1	1.31	.45	.26
2	1.00	.51	.25
4	1.05	.51	.26
30	1.10	.51	.26
60	1.05	.51	.26

Table 2; the number r_3 corresponding to the third sweep convergence rate estimate was used in each case; the number in the table should be compared to the endpoint of the time interval given at the top of the column in which it appears. We found that taking $C \approx 2.7$ gives reasonable agreement with the computations in all but the $s = 1, T = 1$ case. The results are certainly in keeping with our expectations, bearing in mind the points mentioned in the first paragraph of this section.

4.1. Multiparticle system. We conducted a large number of experiments with spring/mass networks. These problems were solved using an experimental multiparticle system solver developed by the author to serve as a software laboratory during the formulation of the mathematical theory. Here we summarize the results for Fig. 5 which were representative of our findings.

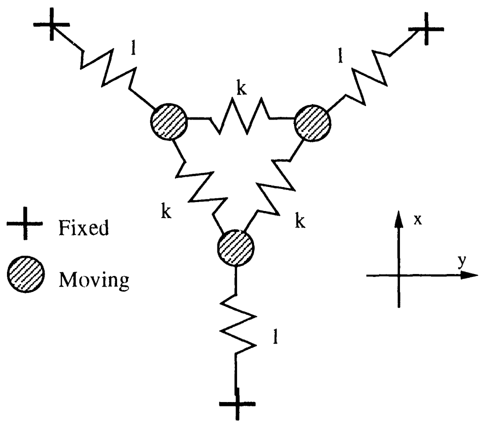

FIG. 5. *Spring-mass network.*

The network of Fig. 5 was split into three subsystems, each containing a single node. The splitting spring coefficient was varied from $k = 1$ to $k = 4$ and the integration was conducted on windows ranging from $[0, .3]$ to $[0, .9]$. The observed convergence rates (r_3) are summarized in Table 3.

We then inserted the estimates into the formula of Theorem 3.7 and scaled using the constant multiple $C = 3.9$. The results are given in Table 4. Again, there is reasonable agreement, given the substantial complexity of the phenomenon.

5. Conclusion. The techniques used here can also be applied to handle constrained systems through a projection technique [5].

Although a priori estimates cannot tell the whole story, particularly as we turn to nonlinear systems and attempt to apply the spectral procedure to a linearization of the equations, the a priori estimates do give substantial useful information for little computational expense, and should guide the development of adaptive algorithmic estimates.

PERFORMANCE ENHANCEMENTS AND PARALLEL ALGORITHMS FOR TWO MULTILEVEL PRECONDITIONERS*

H. C. ELMAN† AND XIAN-ZHONG GUO‡

Abstract. Several new variants of the hierarchical basis (HB) preconditioner and Bramble, Pasciak, and Xu's multilevel preconditioner (BPX) are presented and studied, and new parallel algorithms are introduced for both methodologies. It is shown that the performance of both preconditioners is improved by not solving the linear system associated with the initial (coarsest) grid, which need not be a trivial grid. For a class of problems consisting of anisotropic and "piecewise anisotropic" problems, a grid-generation strategy that relates the multilevel preconditioners to the underlying operator is developed, and it is demonstrated that this strategy is effective in terms of both iteration counts and elapsed time. In addition, a new parallel algorithm is presented for the BPX preconditioner that is as efficient as parallel algorithms for the HB preconditioner, requiring $O(j)$ parallel steps for problems with j levels; and a parallel algorithm is presented for the HB preconditioner that requires $O(\lceil \log_2 j \rceil)$ parallel steps. Numerical results on a Connection Machine are reported.

1. Introduction.

Consider the model elliptic partial differential equation

$$\text{(1)} \qquad \begin{cases} -\sum_{i=1}^{d} \frac{\partial}{\partial x_i}(a_i(x)\frac{\partial u}{\partial x_i}) = f \quad \text{on} \quad \Omega \subset R^d, \\ u\,|_{\partial\Omega} = 0, \end{cases}$$

where $\{a_i(x)\}$ satisfy $0 < m \leq a_i(x) \leq M$ for positive constants m and M, independent of $x \in \Omega$ and i. Discretization of (1) by finite difference methods or finite element methods leads to a linear system of equations

$$\text{(2)} \qquad A\underline{x} = \underline{b},$$

where A is the stiffness matrix, which is symmetric and positive definite. We are interested in solving the system (2) using the preconditioned conjugate gradient method (PCG), for which it is known that an upper bound on the number of iterations for convergence is proportional to the square root of the condition number of the preconditioned matrix; see, e.g., [6]. We study in this paper two multilevel preconditioners, the hierarchical basis (HB) preconditioner [10], [17] and the Bramble–Pasciak–Xu (BPX) multilevel preconditioner [3], [13]. HB is known to be nearly optimal for two-dimensional boundary value problems, producing condition numbers that grow like $O((\log h^{-1})^2)$ [17]. BPX is proved in [3] to be nearly optimal, with condition numbers growing like $O((\log h^{-1})^2)$ for both two-dimensional and higher problems. (Recently Oswald [11] proved that the condition number of the BPX-preconditioned system can actually be bounded independently of the level numbers.)

Both of these preconditioners are defined in terms of an initial grid, and both require the solution (at each step of PCG) of a linear system with coefficient matrix A_0, where A_0 is the stiffness matrix associated with the initial grid. Unless the initial grid is coarse, the cost of the direct solution may be expensive, especially in three dimensions. To avoid the expense of the direct solution, one may replace A_0 by an appropriate preconditioner, as suggested in [3], [13], and [15]. In this paper, we consider variants of HB and BPX preconditioners in which A_0 is simply replaced by the identity matrix. We refer to these variants as incomplete multilevel preconditioners, and we refer to the multilevel preconditioners that apply A_0^{-1} as complete multilevel preconditioners. We demonstrate empirically that the incomplete versions actually converge at about the same rate as or faster than the complete versions, as long as the initial grid is not very fine. Moreover, the incomplete versions appear to be superior in terms of total cost for a fairly large range of nontrivial initial triangulations.

The HB method is defined only in terms of meshes, and not in terms of the differential operators. Because of this, the performance of the preconditioner may vary dramatically depending on the underlying operator. (This phenomenon can be observed from numerical experiments in this paper.) One method developed to make the HB preconditioner more closely related to the differential operator is to combine diagonal scaling with the hierarchical basis method [7]. Diagonal scaling is economical but it is ineffective for highly anisotropic problems. Another approach is the hierarchical basis multigrid method (HBMG), developed by Bank, Dupont, and Yserentant [2], which combines the multigrid idea with the hierarchical basis. HBMG is sophisticated but appears to be expensive. Aimed at a class of problems comprised by anisotropic and "piecewise anisotropic" problems, we develop another technique to relate the multilevel preconditioners to the underlying operator. Our idea is to choose the initial grid according to properties of the underlying operator coefficients, i.e., the initial grid is chosen in such way that data movement associated with the multilevel preconditioners mimics the physical process modeled by the differential equation. This technique does not need any extra work and it is very effective in terms of both iteration counts and elapsed time, and it works well for both the HB and BPX methods.

Implementations of the two multilevel preconditioners on parallel computers have been studied in various references. The hierarchical basis preconditioner has been considered on a shared memory Flexible-32 [1], [9], a Cray X-MP/24 [10], an NYU Ultracomputer Prototype [7], and a Connection Machine [4], [12]. An implementation of the BPX preconditioner has been considered on an iPSC/2 in [16]. The implementations of the HB preconditioner use a parallel version of the algorithm given in [17]. Essentially, this algorithm parallelizes all operations on each level, and different levels are treated serially. Thus, the cost of this parallel algorithm is $O(j)$, where j is the number of levels. Based on this parallel algorithm for the HB preconditioner, we will present a parallel algorithm for the BPX preconditioner that also costs $O(j)$. In two dimensions, this parallel algorithm makes the cost of BPX preconditioner exactly the same as that of the HB preconditioning equation. In addition, we will present in this paper a new parallel algorithm for the HB preconditioner that is more efficient than the standard version.

The paper is organized as follows. Section 2 introduces the HB and BPX preconditioners and briefly discusses their relationship from a matrix point of view. Section 3 shows the performance of the incomplete versions of the two multilevel preconditioners. Section 4 describes the effect of diagonal scaling and introduces a new efficient technique that uses the initial triangulation to relate the multilevel preconditioners more closely to the underlying partial differential operator. Section 5 examines parallel algorithms for the multilevel preconditioners.

All the numerical experiments described in this paper were done on a Connection Machine-2 (CM2). Computations were done in bit serial double precision with a zero initial guess, and the stopping criterion for convergence was

$$\| r^{(k)} \|_2 < 10^{-6} \times \| r^{(0)} \|_2,$$

where $r^{(k)}$ is the residual at the kth iteration and $\| \bullet \|_2$ is the vector Euclidean norm. Unless otherwise specified, the CM times reported in this paper came from a CM2 with 8,192 physical processors, and the HB preconditioner was implemented using Algorithm I of §5.

The following test problems on a unit square (for two-dimensional problems) or on a unit cube (for three-dimensional problems) will be used for our numerical experiments throughout the paper:

Problem 2-1. $d = 2$, $a_1 = a_2 = 1$, $u = x_1(x_1 - 1)x_2(x_2 - 1)$.

Problem 2-2. $d = 2$, $a_1 = 100, a_2 = 1$, $u = x_1(x_1 - 1)x_2(x_2 - 1)$.

Problem 2-3. $d = 2$, $f = 1$,

$$a_1 = \begin{cases} 100 & \text{if } 0 \le x_1 < 0.5, \\ 1 & \text{if } 0.5 \le x_1 \le 1; \end{cases} \qquad a_2 = \begin{cases} 1 & \text{if } 0 \le x_1 < 0.5, \\ 100 & \text{if } 0.5 \le x_1 \le 1. \end{cases}$$

Problem 2-4. $d = 2$, $f = 1$,

$$a_1 = \begin{cases} 1 & \text{if } 0.25 \le x_1, x_2 < 0.75, \\ 100 & \text{otherwise}; \end{cases} \qquad a_2 = \begin{cases} 100 & \text{if } 0.25 \le x_1, x_2 < 0.75, \\ 1 & \text{otherwise}. \end{cases}$$

Problem 3-1. $d = 3$, $a_1 = a_2 = a_3 = 1$, $u = x_1(x_1 - 1)x_2(x_2 - 1)x_3(x_3 - 1)$.

Problem 3-2. $d = 3$, $a_1 = a_2 = a_3 = 0.01 + x_1^2 + x_2^2 + x_3^2$, $u = x_1(x_1 - 1)x_2(x_2 - 1)x_3(x_3 - 1)$.

Problem 3-3. $d = 3$, $f = 1$,

$$a_1 = \begin{cases} 100 & \text{for } x_1 < 0.5, \\ 50.5 & \text{for } x_1 = 0.5, \\ 1 & \text{for } x_1 > 0.5; \end{cases} \qquad a_2 = a_3 = \begin{cases} 1 & \text{for } x_1 < 0.5, \\ 50.5 & \text{for } x_1 = 0.5, \\ 100 & \text{for } x_1 > 0.5. \end{cases}$$

Problems 2-2, 2-3, 2-4, and 3-3 are used to examine the effects of anisotropy and discontinuous coefficients. Problem 3-2 is used to examine the effects of variable coefficients.

2. Two multilevel preconditioners.

In this section, we introduce the HB and BPX preconditioners and briefly discuss their relationship from a matrix point of view. Let $\mathcal{T}_0, \ldots, \mathcal{T}_j$ denote a nested family of triangulations of Ω, as defined in [17]. For simplicity, assume that the finite element method with linear elements is used. Let M_k denote the finite dimensional space of all continuous piecewise linear functions on $\mathcal{T}_k$. Let $\mathcal{N}_k$ denote the set of unknown nodes (vertices) of $\mathcal{T}_k$ (e.g., the set of all interior nodes for Dirichlet boundary conditions), let $\mathcal{U}_k$ denote the set of new unknown nodes introduced at level k, and let n_k denote the number of nodes in $\mathcal{N}_k$. Clearly,

$$\mathcal{N}_k \subset \mathcal{N}_{k+1}, \qquad n_k \le n_{k+1},$$
$$\mathcal{U}_k = \mathcal{N}_k \setminus \mathcal{N}_{k-1}\ (k > 0), \qquad \mathcal{U}_0 = \mathcal{N}_0.$$

Let $H_0^1(\Omega)$ denote the usual Sobolev space; see, e.g., [5], and let $\mathcal{I}_k$: $H_0^1(\Omega) \to M_k$ denote the interpolation operator such that

$$\mathcal{I}_k u(x) = u(x) \quad \forall x \in \mathcal{N}_k.$$

Define the nodal basis of M_k as $\{\phi_l^{(k)}\}_{l \in \mathcal{N}_k}$, where $\phi_l^{(k)}$ is a piecewise linear polynomial on $\mathcal{T}_k$ and has value 1 at node l and value 0 at all other nodes of $\mathcal{T}_k$. The hierarchical basis of M_k is defined as $\bigcup_{s=0}^{k} \{\phi_l^{(s)}\}_{l \in \mathcal{U}_s}$.

Let A denote the global stiffness matrix derived from the nodal basis, let S denote the transformation matrix from the hierarchical basis to the nodal basis, and let A_0 denote the nodal basis discretization matrix with respect to $\mathcal{T}_0$. Assume that $A_0 = L_0 L_0^T$ is the Cholesky factorization. It is known [10], [17] that

$$\kappa(M^{-1}A) \le \begin{cases} C(j^2) & \text{in two dimensions,} \\ C(2^j) & \text{in three dimensions,} \end{cases} \tag{3}$$

with the preconditioner defined by

$$M^{-1} = S \tilde{L}_0^{-T} D_d^{-1} \tilde{L}_0^{-1} S^T, \tag{4}$$

where $\kappa(\cdot)$ stands for the condition number,

$$\tilde{L}_0 = \begin{pmatrix} L_0 & 0 \\ 0 & I \end{pmatrix},$$

and

$$D_d = \begin{pmatrix} h_0^{d-2} I_0 & & & & \\ & h_1^{d-2} I_1 & & & \\ & & h_2^{d-2} I_2 & & \\ & & & \ddots & \\ & & & & h_j^{d-2} I_j \end{pmatrix}.$$

Here, we order all nodes in a hierarchical ordering, i.e., we order the nodes in $\mathcal{U}_0$ first, followed by those in $\mathcal{U}_1$, etc. I_k is the identity matrix of order $n_k - n_{k-1}$, with $n_{-1} \equiv 0$.

Evaluating $L_0^{-T} v^{(0)}$ and $L_0^{-1} v^{(0)}$, i.e., solving two triangular systems $L_0^T x^{(0)} = v^{(0)}$ and $L_0 x^{(0)} = v^{(0)}$, could be expensive except for a very coarse initial triangulation $\mathcal{T}_0$. To avoid solving these systems, we define a new preconditioner by omitting L_0 and L_0^T, giving

$$M_I^{-1} = S D_d^{-1} S^T. \tag{5}$$

We refer to the preconditioner defined by (4) as the complete hierarchical basis (CHB) preconditioner and that defined by (5) as the incomplete hierarchical basis (IHB) preconditioner.

We can derive an upper bound on the condition number of the IHB-preconditioned system as follows. For any vector $x \neq 0$,

$$\frac{(Ax, x)}{(M_I x, x)} = \frac{(Ax, x)}{(Mx, x)} \frac{(Mx, x)}{(M_I x, x)},$$

where for vectors x and y, (x, y) is the usual Euclidean inner product. Thus

$$\begin{aligned}\lambda_{\max}(M_I^{-1}A) &= \max_{x\neq 0}\frac{(Ax,x)}{(M_Ix,x)}\\ &\leq \max_{x\neq 0}\frac{(Ax,x)}{(Mx,x)}\times\max_{x\neq 0}\frac{(Mx,x)}{(M_Ix,x)},\\ \lambda_{\min}(M_I^{-1}A) &= \min_{x\neq 0}\frac{(Ax,x)}{(M_Ix,x)}\\ &\geq \min_{x\neq 0}\frac{(Ax,x)}{(Mx,x)}\times\min_{x\neq 0}\frac{(Mx,x)}{(M_Ix,x)},\end{aligned}$$

and therefore

$$\kappa(M_I^{-1}A) = \frac{\lambda_{\max}(M_I^{-1}A)}{\lambda_{\min}(M_I^{-1}A)} \leq \kappa(M^{-1}A)\times\kappa(M_I^{-1}M).$$

By (3) and the fact that

$$\kappa(M_I^{-1}M) = \kappa(A_0) \leq Ch_0^{-2},$$

where h_0 is the minimum mesh size of $\mathcal{T}_0$, we get the following theorem.

THEOREM 2.1. *If M_I is defined by* (5), *then*

$$\kappa(M_I^{-1}A) \leq \begin{cases} C(h_0^{-2}j^2) & \textit{in two dimensions},\\ C(h_0^{-2}2^j) & \textit{in three dimensions},\end{cases} \tag{6}$$

where h_0 is the minimum mesh size of $\mathcal{T}_0$.

We next consider the BPX preconditioner, using the algebraic framework developed in [13] and [15]. Let T_k denote the representation matrix of the nodal basis $\{\phi_l^{(k)}\}_{l\in\mathcal{N}_k}$ in terms of the nodal basis $\{\phi_l^{(j)}\}_{l\in\mathcal{N}_j}$:

$$\begin{bmatrix}\phi_1^{(k)}\\ \vdots\\ \phi_{n_k}^{(k)}\end{bmatrix} = T_k\begin{bmatrix}\phi_1^{(j)}\\ \vdots\\ \phi_{n_j}^{(j)}\end{bmatrix}.$$

In matrix form, the BPX preconditioner is defined by [13]

$$M^{-1} = h_j^{2-d}I + \sum_{k=1}^{j-1} h_k^{2-d}T_k^TT_k + h_0^{2-d}T_0^TA_0^{-1}T_0, \tag{7}$$

where h_k is the mesh size of $\mathcal{T}_k$ and d is the number of dimensions. (We assume here that a uniform mesh is used; for locally refined meshes, see [3] and [13].) It is shown in [3] and [13] that

$$\kappa(M^{-1}A) \leq \begin{cases} C(j^2) & \text{in general},\\ Cj & \text{for regular problems}.\end{cases} \tag{8}$$

More recently, it has been shown [11] that the condition number of the BPX-preconditioned matrix can actually be bounded independently of mesh size.

As above, one may avoid applying A_0^{-1} by using a modified preconditioner defined by

$$M_I^{-1} = h_j^{2-d} I + \sum_{k=0}^{j-1} h_k^{2-d} T_k^T T_k. \tag{9}$$

We refer to the preconditioner defined by (7) as the complete BPX (CBPX) preconditioner, and that defined by (9) as the incomplete BPX (IBPX) preconditioner. It is shown in [13] that

$$\kappa(M_I^{-1}A) \le \begin{cases} C(h_0^{-2} + j)j & \text{in general,} \\ C(h_0^{-2} j) & \text{for regular problems.} \end{cases} \tag{10}$$

As in the proof of Theorem 2.1, we can also show that the IBPX-preconditioned matrix has condition number bounded by Ch_0^{-2}, based on the results in [11].

The HB and BPX preconditioners are closely related to each other [13], [14], [15], [18]. Here, we briefly discuss the relation between them from a matrix point of view; see [15] for some related analysis. Let T_k^{k+1} be the matrix that represents the nodal basis $\{\phi_l^{(k)}\}_{l \in \mathcal{N}_k}$ in terms of the nodal basis $\{\phi_l^{(k+1)}\}_{l \in \mathcal{N}_{k+1}}$:

$$\begin{bmatrix} \phi_1^{(k)} \\ \vdots \\ \phi_{n_k}^{(k)} \end{bmatrix} = T_k^{k+1} \begin{bmatrix} \phi_1^{(k+1)} \\ \vdots \\ \phi_{n_{k+1}}^{(k+1)} \end{bmatrix}. \tag{11}$$

Clearly,

$$T_k = T_k^{k+1} \cdots T_{j-1}^{j}.$$

Define $\hat{S}_k = (T_{k-1}^k)^T$. Then (7) can be rewritten as [13]

$$\begin{aligned} M^{-1} &= h_j^{2-d} I + \sum_{k=2}^{j} h_{k-1}^{2-d} (\hat{S}_j \cdots \hat{S}_k)(\hat{S}_k^T \cdots \hat{S}_j^T) \\ &\quad + h_0^{2-d} \hat{S}_j \cdots \hat{S}_1 A_0^{-1} \hat{S}_1^T \cdots \hat{S}_j^T \end{aligned} \tag{12}$$

and (9) can be rewritten as

$$M_I^{-1} = h_j^{2-d} I + \sum_{k=1}^{j} h_{k-1}^{2-d} (\hat{S}_j \cdots \hat{S}_k)(\hat{S}_k^T \cdots \hat{S}_j^T). \tag{13}$$

Now consider the matrix S which transforms the hierarchical basis to the nodal basis. S can be factored as [17]

$$S = S_j \cdots S_1.$$

Given $u \in \mathcal{M}_j$, its nodal basis coefficients are $\{u_i = u(x_i) \mid x_i \in \mathcal{N}_j\}$ and its hierarchical basis coefficients are $\{(\mathcal{I}_k - \mathcal{I}_{k-1})u(x_i) \mid x_i \in \mathcal{U}_k, 0 \le k \le j\}$, where $\mathcal{I}_{-1} \equiv 0$. Let v

denote the vector of the hierarchical basis coefficients of u. Then Sv is the vector of the nodal basis coefficients of u. S_k describes the computation of $\{u_i \mid i \in \mathcal{U}_k\}$ from $\{(\mathcal{I}_k - \mathcal{I}_{k-1})u(x_i) \mid x_i \in \mathcal{U}_k\}$ and $\{u_i \mid i \in \mathcal{N}_{k-1}\}$. Thus, in order to evaluate the action of S_k, one first needs to evaluate the function $\mathcal{I}_{k-1}u$ at nodes from $\mathcal{U}_k$. This turns out to be a simple interpolation process [17]. Then one adds the values of $\mathcal{I}_k u - \mathcal{I}_{k-1}u$ at these nodes to the interpolated values, giving the values of u at nodes from $\mathcal{U}_k$. If we order the nodes in a hierarchical ordering, then for $1 \le k \le j$, S_k has the structure

$$S_k = \begin{pmatrix} I_0 & & & & & & \\ & \ddots & & & & & \\ & & I_{k-1} & & & & \\ R_0 & \cdots & R_{k-1} & I_k & & & \\ & & & & I_{k+1} & & \\ & & & & & \ddots & \\ & & & & & & I_j \end{pmatrix}. \tag{14}$$

In terms of entries of S_k, the interpolated values of $\mathcal{I}_{k-1}u$ at nodes from $\mathcal{U}_k$ are given by

$$\sum_{s=0}^{k-1} R_s \underline{u}_s, \tag{15}$$

where $\underline{u}_s$ is the vector of values of u at nodes from $\mathcal{U}_s$.

On the other hand, since $\mathcal{I}_{k-1}u \in \mathcal{M}_{k-1}$ and $\mathcal{I}_{k-1}u(x_i) = u(x_i) = u_i$ for $i \in \mathcal{N}_{k-1}$, we have

$$\mathcal{I}_{k-1}u = \sum_{i=1}^{n_{k-1}} u_i \phi_i^{(k-1)} = (\phi_1^{(k-1)}, \dots, \phi_{n_{k-1}}^{(k-1)}) \begin{bmatrix} u_1 \\ \vdots \\ u_{n_{k-1}} \end{bmatrix}.$$

From (11) and the equality $\hat{S}_k = (T_{k-1}^k)^T$, one obtains

$$(\phi_1^{(k-1)}, \dots, \phi_{n_{k-1}}^{(k-1)}) = (\phi_1^{(k)}, \dots, \phi_{n_k}^{(k)})\hat{S}_k.$$

Therefore

$$\mathcal{I}_{k-1}u = (\phi_1^{(k)}, \dots, \phi_{n_k}^{(k)})\hat{S}_k \begin{bmatrix} u_1 \\ \vdots \\ u_{n_{k-1}} \end{bmatrix},$$

and the values of $\mathcal{I}_{k-1}u$ at nodes from $\mathcal{N}_k$ are then given by

$$\hat{S}_k \begin{bmatrix} u_1 \\ \vdots \\ u_{n_{k-1}} \end{bmatrix}.$$

But $\mathcal{I}_{k-1}u(x_i) = u_i$ for $i \in \mathcal{N}_{k-1}$, so that $\hat{S}_k$ has the structure

$$\hat{S}_k = \begin{bmatrix} I_0 & & \\ & \ddots & \\ & & I_{k-1} \\ \hat{R}_0 & \cdots & \hat{R}_{k-1} \end{bmatrix}.$$

It is now easy to see that the interpolated values of $\mathcal{I}_{k-1}u$ at nodes from $\mathcal{U}_k$ are represented in terms of entries of $\hat{S}_k$ as

$$\sum_{s=0}^{k-1} \hat{R}_s \underline{u}_s. \tag{16}$$

Since (15) and (16) both represent the same interpolated values of $\mathcal{I}_{k-1}u$ at nodes from $\mathcal{U}_k$, it follows that

$$R_s = \hat{R}_s, \qquad s = 0, \ldots, k-1.$$

In other words, $\hat{S}_k$ is composed of the first k block columns and the first $k+1$ block rows of S_k:

$$\hat{S}_k = \begin{pmatrix} I_0 & & \\ & \ddots & \\ & & I_{k-1} \\ R_0 & \cdots & R_{k-1} \end{pmatrix}. \tag{17}$$

S_k is square and of size $n_j \times n_j$, whereas $\hat{S}_k$ is rectangular and of size $n_k \times n_{k-1}$.

3. Performance of the IHB and IBPX preconditioners. We now present the results of some numerical experiments that give us insight into the computational properties of the incomplete multilevel preconditioners. In our numerical experiments, the finite element method with linear elements is used for two-dimensional problems. The triangulation has the uniform mesh size $h = 1/n$, and the initial triangulation corresponds to a uniform grid with $h_0 = 1/n_0$, where $n_0 = n/2^j$ and j is the number of levels excluding the initial level. For simplicity of implementation, the standard seven-point centered difference scheme on a uniform mesh is used to discretize the three-dimensional problems, and our multilevel preconditioning matrices correspond to those derived from the finite element method with trilinear elements, except that A_0 is the matrix derived from the difference scheme. From the spectral equivalence of the standard seven-point centered difference operator and that derived from the finite element method with trilinear elements, we know that the HB and BPX preconditioners have the same convergence properties as those given in §2.

Table 1 shows the number of PCG iterations using the complete and incomplete versions of the HB and BPX preconditioners for Problem 2-1, where "-" stands for "data not available." Table 2 shows analogous results for Problem 3-1. We see that when the initial grid is not very fine, the incomplete versions of the preconditioners actually require about the same number of iterations (and fewer, in many cases) as the complete versions.

Taking into account the extra work for the complete versions to apply A_0^{-1}, particularly in three dimensions, we see that PCG with the IHB or IBPX preconditioner costs less than with its complete counterpart, at least when the initial grid is not very fine.

Note that the upper bounds of the IHB- or IBPX-preconditioned matrices in §2 increase as j decreases. However, from Tables 1 and 2, we see that as j decreases from its largest value (i.e., as we vary the initial grid from very coarse to slightly less coarse), the iteration counts for both the IHB and IBPX preconditioners essentially do not increase. Since the cost per PCG step decreases as j decreases, we conclude that better performance will be achieved when the initial grid is not as coarse as possible. This conclusion is further substantiated by Tables 3 and 4, which show the CPU times of PCG with the IHB and IBPX preconditioners for Problem 2-1 and Problem 3-1, respectively, with different numbers of levels. Here the CM times for the three-dimensional $64 \times 64 \times 64$ grid problem come from a CM2 with 16,384 (instead of 8,192) physical processors.

TABLE 3

Remark. We saw the same general behavior for problems with variable and discontinuous coefficients, and also with random initial guesses, although only the results of the Laplacian with a zero initial guess are reported here.

4. Relating multilevel preconditioners to the underlying operator.

The HB and BPX preconditioners under consideration are defined independently of the underlying differential operator, and their effectiveness may vary dramatically depending on this operator. In this section, we examine two techniques for relating multilevel preconditioners to the differential operator.

One strategy is to use a diagonal scaling, as suggested for the HB preconditioner by Greenbaum, Li, and Chao [7]. Combining a diagonal scaling with IHB leads to the preconditioner

$$M^{-1} = SD^{-1}S^T, \tag{18}$$

where D is a diagonal mattrix. One choice for D is $D = \operatorname{diag}(\hat{A})$, where $\hat{A}$ is the global discretization matrix derived from the hierarchical basis. A drawback of this choice is that the matrix $\hat{A}$ is a preconditioned matrix that is typically not explicitly formed. An alternative that avoids the cost of computing $\operatorname{diag}(\hat{A})$ is the choice $D = \operatorname{diag}(A)$, as suggested in [7]. Numerical experiments with these two choices for D produce almost identical iteration counts for discrete partial differential operators with continuous coefficients of the partial differential equations, as reported in [7] for two-dimensional problems with the complete hierarchical basis diagonal scaled preconditioner. Therefore, we will only use $D = \operatorname{diag}(A)$ for diagonal scaling. We refer to (18) with $D = \operatorname{diag}(A)$ as the incomplete hierarchical basis diagonal (IHBD) scaled preconditioner. One can also combine diagonal scaling with BPX [3], [13], [15], [19], and define the incomplete BPX diagonal (IBPXD) scaled preconditioner by

$$M^{-1} = h_j^{2-d} D_j^{-1} + \sum_{k=1}^{j} h_k^{2-d} (\hat{S}_k \cdots \hat{S}_1) D_k^{-1} (\hat{S}_1^T \cdots \hat{S}_k^T),$$

where D_k is the submatrix of diag(A) corresponding to the nodes from $\mathcal{N}_k$. This can be thought of as a Jacobi preconditioner at level k; cf. [15] for generalizations of this idea that more closely relate the preconditioner to the underlying operator.

Table 5 reports the iteration counts of PCG with IBPX and IBPXD preconditioners of all possible levels for Problem 3-2, and Table 6 reports some of the corresponding CPU times, together with the CPU time of red-black ICCG(0) [8] for comparison. In Table 6, CGD stands for PCG with the preconditioner $D =$ diag(A), and the parallel algorithm developed later in §5 is used for both the IBPX and IBPXD preconditioners. Tables 5 and 6 suggest that the diagonal scaled multilevel preconditioners work well for the problems with variable coefficients. We also see from Table 6 that with the diagonal scaled multilevel preconditioners, better performance is achieved when the initial grid is not as coarse as possible, as we observed with the IHB and IBPX preconditioners in §3.

TABLE 5

IBPXD(3)		31	36	41		3.78	19.72	99.92

Diagonal scaling has little or no effect on another class of problems, comprised by anisotropic problems, such as Problem 2-2, and "piecewise anisotropic" problems, such as Problems 2-3, 2-4, and 3-3. For instance, for any of these problems (with a uniform mesh), diag$(A) = cI$ for some scalar c and IHBD (or IBPXD) reduces to IHB (or IBPX). We now describe a technique, aimed at this class of problems, to relate the multilevel preconditioners more closely to the underlying operator. Note that the solution of the elliptic partial differential equation (1) can be interpreted as a distribution of heat, where the coefficients $\{a_i\}$ are the conducting coefficients. Thus, for example in two dimensions, if $a_1 > a_2$, then heat conducts more rapidly in the horizontal direction than in the vertical direction. We would like our computational algorithm to mimic the physical process, by patterning data movement after the physics. The initial triangulation used for the multilevel preconditioners provides a natural vehicle for achieving this.

For an example, assume that the discretization is made on a 4×4 grid, as in the top picture of Fig. 1. Three possible choices for the initial grid are shown in the second row of Fig. 1, and they give rise to the three partitionings of the nodes shown in the third row of Fig. 1. Assume that $x_{I1(i)}, x_{I2(i)} \in N_0$ are the two nodes that are directly connected

to the node $x_i \in \mathcal{U}_1$, and that the data at node x_i is stored in $X(i)$. When we apply the HB preconditioner with a uniform mesh, the following algorithm may be used [17]:

```
for $i \in \mathcal{U}_1$
    $X(I1(i) = X(I1(i)) + X(i)/2$
    $X(I2(i) = X(I2(i)) + X(i)/2$
next $i$
for $i \in \mathcal{U}_1$
    $X(i) = X(i) + (X(I1(i)) + X(I2(i)))/2$
next $i$
```

It is useful to take the point of view that each node x_i corresponds to a processor, processor i, on a parallel computer. Thus, to apply the HB preconditioner, processor i needs to communicate with processors $I1(i)$ and $I2(i)$, to send some data to processors $I1(i)$ and $I2(i)$ and then to get some data from them. For the partitioning on the left in the third row of Fig. 1 (derived from an initial 2×2 grid), node (1,1) will communicate with its NE and SW neighbors, node (0,1) with its N and S neighbors, and node (1,0) with its E and W neighbors; for the partitioning in the center (derived from an initial 4×2 grid), every node from level 1 will communicate only with its N and S neighbors; and finally for the partitioning on the right (derived from an initial 2×4 grid), every node from level 1 will communicate only with its E and W neighbors. Therefore, the initial 2×2 grid results in data movement at the same rate in the horizontal and vertical directions, the initial 4×2 grid results in more rapid data movement in the vertical direction, and the initial 2×4 grid results in more rapid data movement in the horizontal direction.

Note that the initial 4×2 and 2×4 grids result in nonnested sequences of finite element subspaces $\{\mathcal{M}_k\}_{k=0}^{1}$, i.e., $\mathcal{M}_0 \not\subset \mathcal{M}_1$, because some triangles at level 0 cannot be expressed as unions of triangles at level 1. However, each rectangle of the initial triangulation can be expressed as a union of some rectangles of the next level triangulation, see the last row of Fig. 1. The analysis of the HB and BPX preconditioners applies only for the nested case [3], [10], [13], [17]. Nevertheless, all analysis is based on elementwise arguments, i.e., all inequalities and equalities are proven on each element and the sum over all elements is taken to get the results on the domain. Replacing triangle by rectangle, one can generalize the analysis of HB and BPX [3], [10], [13], [17] in a straightforward manner to cover the nonnested case described above.

As an example of the use of such initial triangulations, consider Problem 2-2. Table 7 shows the iteration counts for various initial grids. The results indicate that the initial 2×2 grid does not give the best performance among all possible initial triangulations. In this case, an initial 2×16 grid gives the best or almost best performance for both IBPX and IHB. The data of Table 7 typifies our experiments. In general, assume both a_1 and a_2 are constant and without loss of generality assume $a_2 > a_1$. Numerical experiments indicate that an initial $2 \times m_0$ grid will be close to optimal when $(m_0/2)^2$ is as close to a_2/a_1 as possible.

TABLE 7
Iteration counts on grid 256×256 *for Problem* 2-2.

Initial grid	2×2	2×4	2×8	2×16	2×32	2×64	2×128	2×256
IHB	159	98	64	55	51	55	76	121
IBPX	144	75	47	33	39	51	66	95

This idea can also be generalized to piecewise anisotropic problems. Consider Problem 2-3 first; see Fig. 2. For this problem, the discussion above suggests that the initial grid on the left half subregion should be finer in the y-direction than in the x-direction, and the opposite should hold on the right half subregion. Suppose again that the discretization is on a 4×4 grid. One way to choose such an initial triangulation is so that $(h_x^{(0)}, h_y^{(0)}) = (1/2, 1/4)$ on the left half region and $(h_x^{(0)}, h_y^{(0)}) = (1/4, 1/2)$ on the right half region, where $h_x^{(0)}$ and $h_y^{(0)}$ are the step sizes of the corresponding initial grid in the x- and y-directions, respectively; see Fig. 2. (The initial triangulation is designed in such a way that conforming finite element methods can be applied; see, e.g., [5].)

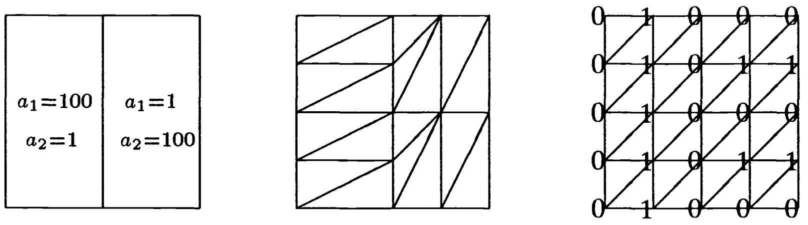

FIG. 2. *Left: Problem* 2-3. *Center: initial grid. Right: partitioning of the nodes.*

Table 8 reports the iteration counts of PCG with the IHB and IBPX preconditioners for Problem 2-3, where initial grid 2×2 means that $(h_x^{(0)}, h_y^{(0)}) = (1/2, 1/2)$ on both the left and right half regions, and initial grid $2 \times 16, 16 \times 2$ means that $(h_x^{(0)}, h_y^{(0)}) = (1/2, 1/16)$ on the left half subregion and $(h_x^{(0)}, h_y^{(0)}) = (1/16, 1/2)$ on the right half subregion.

TABLE 8
Iteration counts for Problem 2-3.

Initial grid	n=32	n=64	n=128	n=256	n=32	n=64	n=128	n=256
	IHB				IBPX			
2×2	112	136	152	169	114	143	160	175
$2 \times 16, 16 \times 2$	30	39	50	61	41	50	56	63

We can apply our technique to Problem 2-4 (Fig. 3) in a similar way. We will choose the initial triangulation such that the corresponding initial grid is finer in the x-direction on the inner subregion and it is finer in y-direction on the outer subregion. Figure 4 shows one such initial triangulation, together with the refined ones, for an 8×8 grid. Numerical results for various initial grids are reported in Table 9, where initial grid 2×2 means that $(h_x^{(0)}, h_y^{(0)}) = (1/2, 1/2)$ on both inner and outer subregions, and initial grid $2 \times 16, 16 \times 2$ means that $(h_x^{(0)}, h_y^{(0)}) = (1/2, 1/16)$ on the outer subregion and $(h_x^{(0)}, h_y^{(0)}) = (1/16, 1/2)$ on the inner subregion.

TABLE 9
Iteration counts for Problem 2-4.

Initial grid	n=32	n=64	n=128	n=256	n=32	n=64	n=128	n=256
	IHB				IBPX			
2×2	119	148	168	191	117	151	172	187
$2 \times 16, 16 \times 2$	45	51	61	75	44	59	70	76

The generalization of this technique to higher dimensional problems is straightforward. Table 10 shows the iteration counts for a three-dimensional problem, Problem 3-3, where initial grid $2 \times 2 \times 2$ means that $(h_x^{(0)}, h_y^{(0)}, h_z^{(0)}) = (1/2, 1/2, 1/2)$ on the whole region, and initial grid $2 \times 8 \times 8, 8 \times 8 \times 2$ means that $(h_x^{(0)}, h_y^{(0)}, h_z^{(0)}) = (1/2, 1/8, 1/8)$

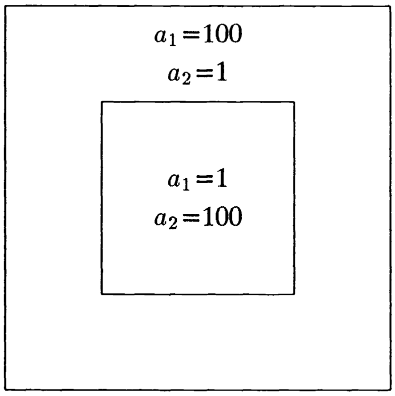

FIG. 3. *Problem* 2-4.

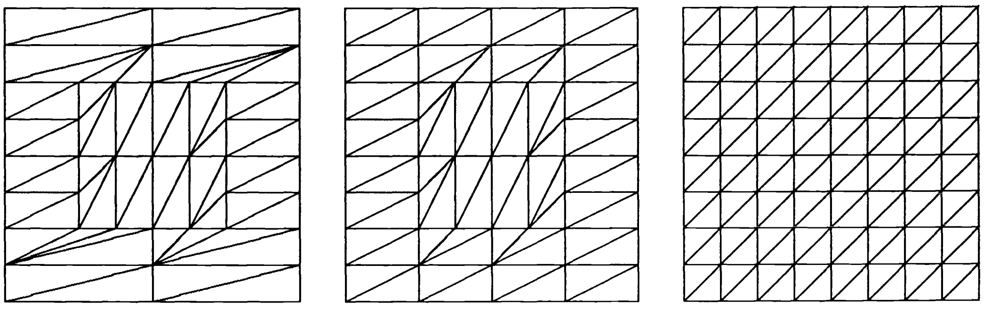

FIG. 4. *Sequence of triangulations for Problem* 2-4.

on the subregion $x_1 < 0.5$, and $(h_x^{(0)}, h_y^{(0)}, h_z^{(0)}) = (1/8, 1/8, 1/2)$ on the subregion $0.5 < x_1$.

TABLE 10
Iteration counts of IBPX-preconditioned CG for Problem 3-3.

Initial grid	n=8	n=16	n=32	n=64
$2\times2\times2$	39	82	146	201
$2\times8\times8, 8\times8\times2$	24	47	67	90

The new technique has the feature that it does not need any extra work and the implementation of the technique does not create any extra difficulty. For example, Table 11 reports iteration counts and CPU times for PCG with various preconditioners for Problem 2-4. We see from this table that our technique does work well for piecewise anisotropic problems. The technique can be generalized to problems with variable coefficients by first freezing the coefficients on each element of the initial triangulation, i.e., defining some constant value of the coefficients on each element, and then applying the technique to the corresponding stiffness matrix.

5. Parallel algorithms for multilevel preconditioners. In this section, we discuss parallel algorithms for the IHB and IBPX preconditioners. For simplicity, all algorithms

are described in detail only for one-dimensional problems; some issues for higher dimensional problems are outlined. Since each node corresponds to a unique index, we do not distinguish a node x_i from its index i.

With the IHB preconditioner, the core of solving the preconditioning equation is to compute $S^T v$ and Sv for an arbitrary vector v. Suppose the hierarchical basis coefficients are stored in a vector X. Given a node $x_i \in \mathcal{U}_k$, let $x_{I1(i)} \equiv \max\{x \mid x \in \mathcal{N}_{k-1},\ x < x_i\}$ and $x_{I2(i)} \equiv \min\{x \mid x \in \mathcal{N}_{k-1},\ x_i < x\}$. We refer to $x_{I1(i)}$ and $x_{I2(i)}$ as the parents of x_i and to x_i as a child of its parents. Assume that a uniform mesh is used. The standard parallel algorithms for computing Sv and $S^T v$ are the following straightforward variants of the serial algorithms of [17]. Here and in the sequel, we are assuming that there are as many processors as grid points.

Parallel Algorithm I Sv:

```
1  for $k = 1$ to $j$, do
2      for all $i \in \mathcal{U}_k$
3          $X(i) = X(i) + (X(I1(i)) + X(I2(i)))/2$
4      all $i$ in parallel
5  next $k$
```

Parallel Algorithm I $S^T v$:

```
1  for $k = j$ to 1, do
2      for all $i \in \mathcal{U}_k$, do
3          $X(I1(i)) = X(I1(i)) + X(i)/2$
4          $X(I2(i)) = X(I2(i)) + X(i)/2$
5      all $i$ in parallel
6  next $k$
```

Lines 2–4 of the algorithm for Sv compute the action of S_k, and lines 2–5 of the algorithm for $S^T v$ compute the action of S_k^T, where S_k $(k = 1, \ldots, j)$ are the factors of S defined in §2. Figures 5 and 6 show two symbolic representations of these algorithms. Figure 5 shows the flow of data between processors during the course of the computation for $j = 3$; arrows indicate the required interprocessor communication. In Fig. 6, the column associated with $\mathcal{U}_k$ contains a compact representation of the contents of all processors handling nodes in $\mathcal{U}_k$, where n/m means that all processors handling $x \in \mathcal{U}_k$ now contain $(\mathcal{I}_n u - \mathcal{I}_m u)(x)$. For example, after step 2, all processors handling $x \in \mathcal{U}_2$ contain $\mathcal{I}_2 u(x)$, whereas for $k \geq 3$, all processors handling $x \in \mathcal{U}_k$ contain $(\mathcal{I}_k u - \mathcal{I}_{k-1} u)(x)$. It is obvious that both Sv and $S^T v$ require j parallel steps and each step costs $O(1)$. Thus, this algorithm costs $O(j)$.

FIG. 6. *Symbolic representation of Parallel Algorithm* I Sv.

We now present a parallel algorithm for the BPX preconditioner that is based on Parallel Algorithm I for the HB preconditioner and also costs $O(j)$. From (13), we have

$$M^{-1} = h_j^{2-d}I + \hat{S}_j\{h_{j-1}^{2-d}I + \hat{S}_{j-1}[h_{j-2}^{2-d}I + \hat{S}_{j-2}(\cdots)\hat{S}_{j-2}^T]\hat{S}_{j-1}^T\}\hat{S}_j^T. \tag{19}$$

A high-level description of the BPX algorithm based on (19) is as follows.

Algorithm BPX
```
1  $v^j = v$
2  for $k = j$ down to 1, do
3      $v^{k-1} = \hat{S}_k^T v^k$
4  end
5  $w^0 = h_0^{2-d} v^0$
6  for $k = 1$ to $j$, do
7      $w^k = h_k^{2-d} v^k + \hat{S}_k w^{k-1}$
8  end
comment: $M^{-1}v = w^j$
```

This algorithm has been developed independently by Xu and Qin [15]. We now discuss how to implement it efficiently on a parallel computer.

As shown in §2, $\hat{S}_k$ is a block submatrix of S_k. Thus we may use Parallel Algorithm I for the HB preconditioner to compute $\hat{S}_k v$ and $\hat{S}_k^T v$ as follows.

Algorithm $\hat{S}_k v$
```
1  for all $i \in \mathcal{U}_k$
2      $X(i) = (X(I1(i)) + X(I2(i)))/2$
3  all $i$ in parallel
```

Algorithm $\hat{S}_k^T v$
```
1  for all $i \in \mathcal{U}_k$
2      $X(I1(i)) = X(I1(i)) + X(i)/2$
3      $X(I2(i)) = X(I2(i)) + X(i)/2$
4  all $i$ in parallel
```

where $I1$ and $I2$ are defined as in Parallel Algorithm I for the HB preconditioner. We summarize the above algorithms for BPX as follows.

Parallel Algorithm BPX

```
1  for all $i \in \mathcal{N}_j$, do
2       $v^j(i) = v(i)$
3  all $i$ in parallel
4  for $k = j$ down to 1, do
5       for all $i \in \mathcal{U}_k$, do
6            $v^{k-1}(I1(i)) = v^k(I1(i)) + v^k(i)/2$
7            $v^{k-1}(I2(i)) = v^k(I2(i)) + v^k(i)/2$
8       all $i$ in parallel
9  next $k$
10 for all $i \in \mathcal{N}_0$, do
11      $X(i) = h_0^{2-d} v^0(i)$
12 all $i$ in parallel
13 for $k = 1$ to $j$, do
14      for all $i \in \mathcal{U}_k$
15           $X(i) = (X(I1(i)) + X(I2(i)))/2$
16      all $i$ in parallel
17      for all $i \in \mathcal{N}_k$, do
18           $X(i) = h_k^{2-d} v^k + X(i)$
19      all $i$ in parallel
20 next $k$
```

For two-dimensional problems, the scaling factors $\{h_k^{2-d}\}_{k=0}^{j}$ equal 1 and this algorithm costs exactly the same as Parallel Algorithm I for HB. For three or higher dimensional problems, the BPX preconditioner needs $j+1$ parallel multiplications to evaluate the action of the scaling by the factors $\{h_k^{2-d}\}_{k=0}^{j}$. The HB preconditioner also needs to be scaled by a diagonal matrix D_d consisting of $\{h_k^{2-d}\}_{k=0}^{j}$. But the action of D_d can be evaluated with only one parallel multiplication. Therefore for three or higher dimensional problems, the parallel BPX algorithm requires j more multiplications than Parallel Algorithm I for HB.

Note that both Figs. 5 and 6 indicate that Parallel Algorithm I for the HB preconditioner leaves many processors idle, especially in the part of the computation corresponding to the coarse grids. We now describe an alternative parallel algorithm that makes use of some of these idle processors and requires fewer steps than parallel Algorithm I. The new algorithm is depicted symbolically in Figs. 7 and 8, which are analogous to Figs. 5 and 6. The computation of Sv can be defined precisely by the following three rules.

RULE I. Let $l = \sum_{s=0}^{\infty} c_s 2^s$ (c_s =0 or 1). $\mathcal{U}_l$ is updated at step $k+1$ if and only if $c_k = 1$.

This rule determines when a level is updated. For example, $7 = 2^0 + 2^1 + 2^2$ so that $\mathcal{U}_7$ is updated at steps 1, 2, and 3, whereas $5 = 2^0 + 2^2$, so that $\mathcal{U}_5$ is updated at steps 1 and 3, but not at step 2. (See Fig. 8.)

To specify the second rule, we will say that level l depends on level d if all processors handling $i \in \mathcal{U}_l$ contain $(\mathcal{I}_l u - \mathcal{I}_d u)(x)$ (where $\mathcal{I}_d \equiv 0$ for $d < 0$).

RULE II. Let $l = \sum_{k=0}^{\infty} c_k 2^k$ (c_k =0 or 1). Level l depends on level $d = l - 2^k + \sum_{s=0}^{k-1}(1 - c_s)2^s$ after step k.

To see how this rule applies, consider the case of $l = 5 = 2^0 + 2^2$. (See Fig. 8.) Initially, $d = 5 - 2^0$, so that level 5 depends on level 4. After step 1, $d = 5 - 2^1$ so that

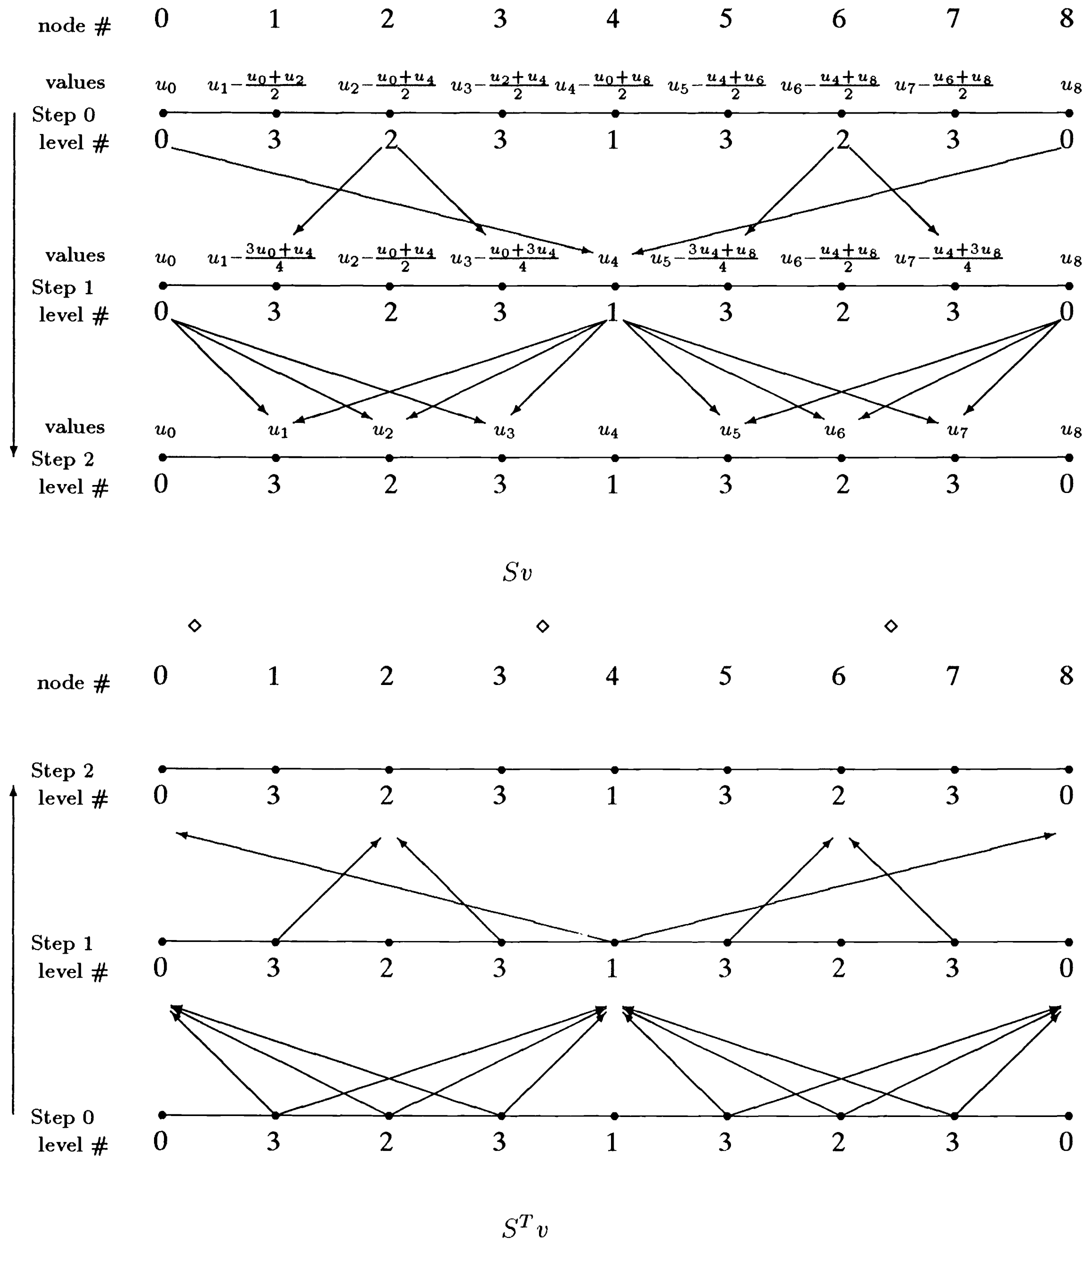

FIG. 7. *Parallel Algorithm* II *for the* IHB *preconditioner.*

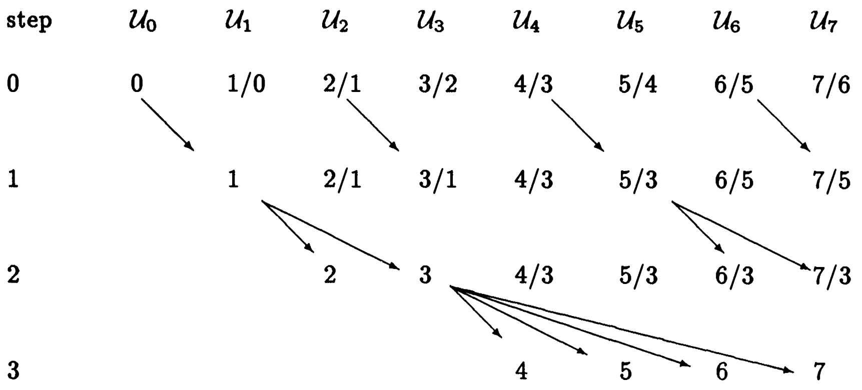
level 5 depends on level 3, and after step 2, $d = 5-2^2+\sum_{s=0}^{1}(1-c_s)2^s = 5-4+(0+2)$, so that level 5 still depends on level 3. Note that according to Rule I, the update of level 5 with level 3 is not performed until step 3.

To specify the third rule, we need some additional notation. Let $J = \lceil \log_2 j \rceil$. Given a node i, let $l(i)$ denote its level number, i.e., $l(i)$ is the integer such that $i \in \mathcal{U}_{l(i)}$.



step
$\mathcal{U}_0$ $\mathcal{U}_1$ $\mathcal{U}_2$ $\mathcal{U}_3$ $\mathcal{U}_4$ $\mathcal{U}_5$ $\mathcal{U}_6$ $\mathcal{U}_7$

2: 2 3 4/3 5/3 6/3 7/3
3: 4 5 6 7

FIG. 8. *Symbolic representation of Parallel Algorithm* II Sv.

Let $(c_0(i),\dots,c_{J-1}(i))$ be the vector such that $l(i)=\sum_{s=0}^{J-1}c_s(i)2^s$ ($c_s=0$ or 1), let $(d_0(i),\dots,d_J(i))$ be the vector such that level $l(i)$ depends on level $d_k(i)$ after step k in the sense of Rule II. Note that $\{l(i)\}$, $\{c_k(i)\}$ and $\{d_k(i)\}$ are just more precise delineations of the quantities l, c_k and d used in Rules I and II. Finally, let $I1_k(i)$ (or $I2_k(i)$) denote the nodes closest to node i among all nodes from $\mathcal{N}_{d_k(i)}$ on the right (or left) side of i. Thus, i lies between $I1_k(i)$ and $I2_k(i)$ and no node from $\mathcal{N}_{d_k(i)}$ lies between $I1_k(i)$ and $I2_k(i)$. We call $I1_k(i)$, $I2_k(i)$ the parents at level k of node i. For example, after step 1 of the computation of Sv, the parents of node 7 are $I1_1(7)=8$ and $I2_1(7)=4$. These are the sources of the arrows between steps 1 and 2 in the top part of Fig. 7. Let X be the vector initialized with the hierarchical basis coefficients and let $\mathcal{N}_k=\emptyset$ for $k<0$.

RULE III. When level l is to be updated according to Rule I, the data at a node $i\in\mathcal{U}_k$ will be updated in the following two steps:

```
1   if $I1_{k-1}(i)\in\mathcal{N}_{d_{k-1}(i)}\setminus\mathcal{N}_{d_k(i)}$, then
2       $X(i)=X(i)+\frac{I2_{k-1}(i)-i}{I2_{k-1}(i)-I1_{k-1}(i)}X(I1_{k-1}(i))$
3   end if
4   if $I2_{k-1}(i)\in\mathcal{N}_{d_{k-1}(i)}\setminus\mathcal{N}_{d_k(i)}$, then
5       $X(i)=X(i)+\frac{I1_{k-1}(i)-i}{I1_{k-1}(i)-I2_{k-1}(i)}X(I2_{k-1}(i))$
6   end if
```

Lines 1 and 4 of Rule III are necessary for Rule II to be satisfied, i.e., for all processors handling $x_i\in\mathcal{U}_l$ to contain $(\mathcal{I}_lu-\mathcal{I}_{d_k(i)}u)(x_i)$. Note that given the values $X(I1_{k-1}(i))$ and $X(I2_{k-1}(i))$ at the parents $I1_{k-1}(i)$ and $I2_{k-1}(i)$, the value of their linear interpolant at node i is

$$\left[\frac{I2_{k-1}(i)-i}{I2_{k-1}(i)-I1_{k-1}(i)}\right]X(I1_{k-1}(i))+\left[\frac{I1_{k-1}(i)-i}{I1_{k-1}(i)-I2_{k-1}(i)}\right]X(I2_{k-1}(i)),$$

where the terms in brackets are the corresponding linear interpolation coefficients.

To see how Rule III applies, consider node $i=1$ in the example shown by Fig. 7. (All nodes are numbered from left to right starting with 0.) Since $l(1)=3=2^0+2^1$, node 1 will be updated at steps 1 and 2 according to Rule I, and node 1 will depend on levels 2, 1 and -1 after step 0, 1 and 2, respectively, according to Rule II, i.e., $(d_0(i),d_1(i),d_2(i))$=(2,1,-1). Here $(I1_0(i),I1_1(i))=(2,4)$ and $(I2_0(i),I2_1(i))=(0,0)$. Thus, one adds only $\frac{1}{2}X(2)$ to $X(1)$ at step 1, since $I1_0(i)=2\in\mathcal{N}_2\setminus\mathcal{N}_1$ and $I2_0(i)=$

$0 \notin \mathcal{N}_2 \setminus \mathcal{N}_1$. At step 2, one adds both $\frac{1}{4}X(4)$ and $\frac{3}{4}X(0)$ to $X(1)$, since both $I1_1(i) = 4$ and $I2_1(i) = 0$ are in $\mathcal{N}_1 \setminus \mathcal{N}_{-1} = \mathcal{N}_1$.

Combining the three rules, we formulate the new parallel algorithm for computing Sv as follows.

Parallel Algorithm II Sv

```
1  for $k = 1$ to $J$, do
2    for all $i \in \mathcal{U}_{l(i)}$ such that $s_{k-1}(i) = 1$, do
3      If $I1_{k-1}(i) \in \mathcal{N}_{d_{k-1}(i)} \setminus \mathcal{N}_{d_k(i)}$, then
4        $X(i) = X(i) + \frac{I2_{k-1}(i)-i}{I2_{k-1}(i)-I1_{k-1}(i)} X(I1_{k-1}(i))$
5      end if
6      If $I2_{k-1}(i) \in \mathcal{N}_{d_{k-1}(i)} \setminus \mathcal{N}_{d_k(i)}$, then
7        $X(i) = X(i) + \frac{I1_{k-1}(i)-i}{I1_{k-1}(i)-I2_{k-1}(i)} X(I2_{k-1}(i))$
8      end if
9    all $i$ in parallel
10 next $k$
```

The analogous algorithm for computing $S^T v$ is as follows:

Parallel Algorithm II $S^T v$

```
1  for $k = J$ down to 1, do
2    for all $i \in \mathcal{U}_{l(i)}$ such that $s_{k-1}(i) = 1$, do
3      if $I1_{k-1}(i) \in \mathcal{N}_{d_{k-1}(i)} \setminus \mathcal{N}_{d_k(i)}$, then
4        $X(I1_{k-1}(i)) = X(I1_{k-1}(i)) + \frac{I2_{k-1}(i)-i}{I2_{k-1}(i)-I1_{k-1}(i)} X(i)$
5      end if
6      if $I2_{k-1}(i) \in \mathcal{N}_{d_{k-1}(i)} \setminus \mathcal{N}_{d_k(i)}$, then
7        $X(I2_{k-1}(i)) = X(I2_{k-1}(i)) + \frac{I1_{k-1}(i)-i}{I1_{k-1}(i)-I2_{k-1}(i)} X(i)$
8      end if
9    all $i$ in parallel
10 next $k$
```

For higher dimensional problems, Rule III has to be modified slightly. For example, the modification for the two-dimensional problem is as follows: (a) For each node $i \in \mathcal{U}_l$, there are three parents $I1_k(i), I2_k(i), I3_k(i)$ at level $k < l$, which are defined as the three vertices of the element at level k including node i inside or on the boundary. (For the case on the boundary, there are two elements at level k including i, and we choose one of them.) (b) The linear interpolation coefficients are the barycentric coordinates of nodes i with respect to $I1_k(i), I2_k(i), I3_k(i)$. The barycentric coordinates $\lambda_j = \lambda_j(x), 1 \le j \le d+1$ of any point $x \in \mathbf{R}^d$, with respect to the $(d+1)$ vertices a_j of a simplex, are the (unique) solutions of the linear system:

$$\begin{cases} \sum_{j=1}^{d+1} a_j \lambda_j = x \\ \sum_{j=1}^{d+1} \lambda_j = 1. \end{cases}$$

Now consider the costs of Parallel Algorithm II. Rule I implies that for all nodes at level l, no update is required after step $\lceil \log_2 l \rceil$. Consequently, this algorithm requires at most $\lceil \log_2 j \rceil$ parallel steps. A direct comparison of its costs with those of Algorithm I for the HB preconditioner is somewhat problematic. For the computation of Sv, each step of Algorithm II requires $O(1)$ arithmetic operations, so that the total cost of arithmetic is $O(\lceil \log_2 j \rceil)$. However, for step k of the computation of $S^T v$, as many as $O(4^{\lceil log_2 j \rceil - k})$ processors send data to one individual processor, say processor i, and the numerical sum of these data is then stored. (See Fig. 7.) If processor i performs the summation serially, then this leads to an arithmetic cost of $C \sum_{k=1}^{\lceil \log_2 j \rceil} 4^{\lceil \log_2 j \rceil - k} = O(j)$. This is of the same order of magnitude as the cost of Algorithm I. Moreover, it is evident that Algorithm II has more complex communication patterns than Algorithm I. To get some further insight into the comparative costs of these algorithms, consider their performance on the Connection Machine. This computer has the feature that if a set of numbers is sent to an individual processor and the numerical sum is to be stored there, then for items that meet at other processors en route to their final destination, partial sums are computed. This process of "enroute combining" reduces congestion and speeds up both communication and arithmetic, because as messages are combined their number is reduced. For one-dimensional problems, Fig. 9 shows the CPU times of the two algorithms. The results indicate that for both the Sv and $S^T v$ computations, the cost of Algorithm II is close to $O(\lceil \log_2 j \rceil)$. Moreover, the new algorithm is more efficient than Algorithm I for all but the smallest problems. In two or higher dimensions, a larger number of levels is required for Algorithm II to be superior to Algorithm I. Based on an extrapolation of experimental results for two-dimensional problems up to eight levels (the largest number of levels we could fit into memory), we estimate that Algorithm I becomes more efficient for roughly 20 or more levels.

PARALLEL COMPACT FFTs FOR REAL SEQUENCES*

RICHARD B. PELZ†

Abstract. Eight algorithms for the in-place, compact, fast Fourier transform (FFT) of real and conjugate-symmetric sequences are presented for single instruction multiple data (SIMD) and multiple instruction multiple data (MIMD) distributed-memory multiprocessors. The "conditional ordering" is introduced for conjugate-symmetric sequences as the natural ordering that leads to minimal communication costs. For a transform of a real, naturally ordered, input sequence of length N distributed evenly across P processors, $2+\log_2 P$ nearest neighbor communication exchanges of $\frac{1}{2}N/P$ contiguous elements (i-cycles) are necessary. For a transform of a conjugate-symmetric, conditionally ordered input sequence, $1+\log_2 P$ i-cycles are necessary. In all cases the computational complexity is $\frac{5}{2}N/P\log_2 N$, and there are no extra memory requirements. The algorithms require about half the communication of a parallel FFT of a real sequence that involves a complex FFT and pre- or postprocessing. Communication complexity is based on the hypercube topology; the algorithms, however, can be implemented on general connection topologies. Some of the schemes are implemented on an nCUBE/2 MIMD multiprocessor, and timings are given.

Key words. fast Fourier transform, parallel algorithms

AMS subject classifications. 65J20, 65Y05, 65Y20

1. Introduction.

Cooley, Lewis, and Welch (CLW) [4] showed that the discrete Fourier transform of a real sequence can be accomplished with a Fourier transform of an associated complex sequence of half the length and a pre- or postprocessing step. Coupled with the FFT of complex data, the CLW algorithm provides an efficient way to compute the real Fourier transform on scalar and vector computers. A similar algorithm for two real sequences uses one FFT of an associated complex vector and pre- or postprocessing.

In Table 1, we give information about the four common, in-place, FFT algorithms for a complex sequence. The first two, CT1 and CT2, were developed by Cooley and Tukey [5]. The latter two, GS1 and GS2, were developed by Gentleman and Sande [7]. Table 2 contains the eight possible FFTs for a real sequence.

TABLE 1
Characteristics of in-place FFTs. RU *refers to roots of unity.*

CT1	natural	bit-reversed	bit-reversed	GS2
CT2	bit-reversed	natural	natural	GS1
GS1	natural	bit-reversed	natural	CT2
GS2	bit-reversed	natural	bit-reversed	CT1

Salmon [11] was the first to implement the complex FFT on a parallel machine. A refined in-place parallel algorithm, which was given independently by Swarztrauber [13] and Walker [14], has the minimum amount of interprocessor communication on hypercube, distributed-memory multiprocessors: $\log_2 P+1$ nearest-neighbor communication exchanges of $N/(2P)$ complex numbers.

On the distributed-memory multiprocessor, the Swarztrauber–Walker FFT can be used as the first step of the CLW method for the transform of a real sequence; however, we shall see that the postprocessing step requires as much communication as the complex FFT on hypercubes. Furthermore, it can be shown that for input data with n symmetries (e.g., one symmetry is for real transforms, two are for cosine and sine, three are for quarter-even and quarter-odd), the CLW method requires n times the amount of communication of the associated complex FFT.

On many distributed-memory multiprocessors, communication time is already a significant part of the total time in the FFT. Increasing the communication time lowers the parallel efficiency and reduces the performance of numerical methods that have the real FFT as an integral part.

A class of FFTs for symmetric sequences, called compact algorithms, were developed by Swarztrauber [12], Bergland [1], and Briggs [2]. They showed that, by using the symmetries during each stage, FFTs of symmetric data could be generated with similar complexity to the CLW FFT, but without the pre- or postprocessing. Bergland attributes this idea to Edson.

Swarztrauber [12] described the compact FFT, which is equivalent to GS2R or CT2R depending on how the roots of unity are computed. The real input is in bit-reversed order and conjugate-symmetric output is in natural order. This transform is known as the Edson transform. The inverse transforms are CT1CS and GS1CS. Briggs [2] developed the compact FFT, which is an extension of GS1R or CT1R, again depending on the roots of unity. The real input is in natural order and the conjugate-symmetric output is in bit-reversed order. The inverse transforms are CT2CS and GS2CS.

This paper presents algorithms for the eight compact FFTs of real data given in Table 2, which can be implemented efficiently on distributed-memory multiprocessors [17]. Similar work is also reported in [15] and [16] in the context of global climate models. All the schemes were designed according to the following principles.

1. All communication is in the form of i-cycles, nearest-neighbor exchanges on a hypercube. The communication is kept to a minimum.
2. The instructions are similar on each processor. This will allow for concurrency on both MIMD and SIMD multiprocessors.
3. Real and imaginary parts of each element are contiguous in memory and not distributed across processors.
4. Computational complexity is similar to that of the sequential schemes (divided by the number of processors).
5. The algorithms require no extra memory.

For an input sequence that is conjugate symmetric, a new ordering which we shall call "conditional ordering" replaces the natural ordering. Using natural ordering of a conjugate-symmetric sequence resulted in an awkward and inefficient communication structure. Conditional ordering is similar to natural ordering, but results in lower communication complexity.

As in the Swarztrauber–Walker FFT for a complex sequence, the output is in "processor-transposed," bit-reversed order. To reorder the output requires at least as much communication time as the FFT. We shall not consider this reordering nor shall we consider the conversion of a conjugate-symmetric sequence from conditional to natural ordering. Because of this, these algorithms may not be useful for general software libraries. Many applications in computational physics, such as evaluation of convolutions and nonlinear terms (e.g., the Fourier pseudospectral method for fluid dynamics [3]), do not require a special ordering of the output sequence. The algorithms presented here are aimed at such applications.

The structure of the paper is as follows. Information on communication, conditional ordering, and reduced operations due to symmetries are described in § 2. In § 3 the serial and parallel versions of the CLW FFT algorithm are presented. In §§ 4 and 5, the Briggs and Edson transforms, respectively, are reviewed, the parallel algorithms are developed, and performance analyses are given. Numerical results and timings are presented in § 6.

2. Preliminaries. In this section we review the *i*-cycle permutation that will be used for communication, define the conditional ordering, and define the reduced operations that occur due to the symmetries of the input sequence.

The length of the real sequence is N, and the number of processors is P. We denote $m = \log_2 N$ and $d = \log_2 P$, the dimension of the hypercube. The input sequence is distributed evenly and contiguously between P processors. We also desire an even distribution of the output sequence. On a hypercube connection topology, the subsequences are sequentially mapped onto the processors. The index k of the input sequence is then written in binary form as

$$k_{m-1}\, k_{m-2} \dots k_{m-d} \,|\, k_{m-d-1} \dots k_0. \tag{2.1}$$

The binary index of the processor label is to the left of the vertical bar, and the binary index of the local memory is to the right.

We shall use an *i*-cycle [13], which is a binary index-digit permutation, to describe the communication exchanges in the compact FFTs. Swarztrauber [13] showed that by using *i*-cycles in his complex FFT, the communication is minimized. In an *i*-cycle, a digit in the processor label (called the target digit) and the left-most digit in the local memory (called the pivot) are switched. This corresponds to an exchange of the last half of the subsequence in the processor whose target digit is zero with the first half of the subsequence in the processor whose target digit is one. It is a nearest-neighbor exchange of $N/2P$ contiguous elements. No extra memory is required.

Definition. Conditional ordering of a conjugate-symmetric sequence is a way of packing a conjugate-symmetric sequence of length N into a complex array of length $N/2$. First, we select from the conjugate-symmetric sequence only those elements whose binary index has the following property: the binary place to the left of the first nonzero bit from the right is zero. For example, for $N = 16$, the sequence is

$$\{0, 1, 2, 4, 5, 8, 9, 10, 13\}. \tag{2.2}$$

This reduces the set of elements to $N/2 + 1$. Since mode 0 and $N/2$ are real, we pack them into a complex mode 0. The elements are then placed into position within the set equal to each element's index without the "zero" place. For example,

$$\begin{aligned}&\{(0,8)\,1,2,5,4,9,10,13\} \quad \text{for } N=16 \quad \text{and}\\&\{(0,16),1,2,5,4,9,10,13,8,17,18,21,20,25,26,29\} \quad \text{for } N=32.\end{aligned} \tag{2.3}$$

Due to the way in which we take advantage of the symmetries of the sequences, this ordering is necessary to streamline the communication. I-cycle communication and nonnearest-neighbor communication results if this ordering is used instead of the first $N/2+1$ elements of a naturally ordered conjugate-symmetric array.

DEFINITION. Second conditional ordering of a conjugate-symmetric sequence is another way of packing. We first take a sequence of integers $0, 1, \ldots, \mathrm{N}-1$; we then select $N/2+1$ elements of the sequence that have a zero bit to the right of the first nonzero bit from the left. We pack the first two elements together into a complex integer. The reduced sequence for $N=32$ is

$$\{(0,1)\;2\;4\;5\;8\;9\;10\;11\;16\;17\;18\;19\;20\;21\;22\;23\}. \tag{2.4}$$

The bit-reversed indexing of this sequence is

$$\{(0,16)\;8\;4\;20\;2\;18\;10\;26\;1\;17\;9\;25\;5\;21\;13\;29\}. \tag{2.5}$$

Two reduced operations that result from the symmetries of the input sequence are now presented.

DEFINITION. Operation A. Given two real numbers x and y, we define operation A as $x+y$ replaces x and $x-y$ replaces y.

DEFINITION. Operation B. If we let the output number z be complex, then operation B is defined as x is the real part of z and y is the imaginary part of z. z then replaces (x, y) in memory.

3. The parallel CLW algorithm.

In this section we present the parallel method for the CLW algorithm. We begin by reviewing the serial algorithm.

3.1. The serial CLW FFT.

Let the Fourier transform of a sequence of N real numbers, $Y(j), j=0,1,\ldots,N-1$, be $C(n)$, $n=0,1,\ldots,N-1$. C is conjugate symmetric, $C(n)=C(N-n)^*$, and the imaginary parts of $C(0)$ and $C(N/2)$ are zero.

The first step of the CLW algorithm is to create the complex array X from Y, as follows:

$$X(j)=Y(2j)+iY(2j+1), \qquad j=0,1,\ldots,N/2-1, \tag{3.1}$$

where $i=\sqrt{-1}$. Then an $N/2$-point complex FFT, $X\leftrightarrow A$, is performed. The final step is to perform the following operation:

$$\begin{aligned}C(n)&=\tfrac{1}{4}\{A(n)+A^*(N/2-n)-i\omega_{N^n}^*[A(n)-A^*(N/2-n)]\},\\C(N/2-n)&=\tfrac{1}{4}\{A(N/2-n)+A^*(n)+i\omega_{N^n}[A(N/2-n)-A^*(n)]\},\end{aligned} \tag{3.2}$$

where $n=0,1,\ldots,N/4$, ω_{N^n} is the nth root of N roots of unity and $(\cdot)^*$ denotes the complex conjugate.

3.2. The parallel CLW FFT.

For the parallel algorithm, we assume that Y is evenly distributed across P processors. If $P\le N/2$, then (3.1) is done within each processor and no communication is required. The ordering of the input sequence is such that X is bit-reversed. The complex FFT is performed using the inplace algorithm of Swarztrauber [13] and Walker [14]. The transformed sequence is in sequential order. In addition, the processor binary index is transposed such that $(n_0\, n_{d-1}\, n_{d-2}\ldots n_1)$.

Operation (3.2) requires a pair of elements reflected about the midpoint of the sequence and hence requires communication to complete. If A is sequentially ordered, and $P = N/2$, then the odd index pairs (n and $N/2 - n$) are on opposite vertices of a $d-1$ hypercube. In this case the Hamming distance is $d-1$. If $P < N/2$, then the distance increases to d, because the right-most binary place of the index is not in the processor label. The processor transposition has no effect on the Hamming distance.

Operation (3.2) requires only one major communication of data if the binary reflected grey code mapping is used. Unfortunately, this also increases the communication distance in the FFT to next-nearest-neighbors. Both mappings produce a similar product of distance times amount of communicated data.

We are led to the conclusion that operation (3.2), while requiring little computation, requires nearly as much communication (defined as message length times Hamming distance) as the complex FFT. For an example of the degradation of performance in the Fourier pseudospectral method for Navier–Stokes simulations, see [8]. For a discussion of this algorithm on distributed SIMD and MIMD multiprocessors, see [9] and [10] and [16], respectively.

4. The parallel, compact FFT for a real, naturally ordered input sequence.

In this section, we present an extension of the compact FFT presented by Briggs [2] for the transform of a real, naturally ordered input sequence (CT1R). His approach was to develop an FFT for a conjugate-symmetric sequence in bit-reversed order in a manner similar to Swarztrauber [12]. The output sequence is real and in natural order. The inverse of this transform is then what is desired.

4.1. A serial CT1R algorithm.

There are many ways to implement the CT1R transform. We shall describe one that is easily parallelizable. We denote the binary index of the real input sequence as

$$(k_{m-1}\, k_{m-2} \ldots k_0), \tag{4.1}$$

and the binary index of the complex output sequence as

$$(n_0\, n_1 \ldots n_{m-1}). \tag{4.2}$$

Because the output is complex, only $m-1$ bits have the range $[0, 1]$. We shall pack the zero- and $N/2$-mode coefficients that are real into a zero-mode complex number.

The fact that the input array is real can be used during each stage of the transform. The first stage, the summation over k_{m-1}, has real output, if the input is real. This is operation A as defined in § 2. The binary index k_{m-1} of the input vector is replaced by n_{m-1} in the output index.

The second stage proceeds in two parts. If $n_{m-1} = 0$, then the summation over k_{m-2} is similar to that of the first stage. If $n_{m-1} = 1$, then the output of this stage is a complex number in which the $k_{m-2} = 0$ element is the real part and the associated $k_{m-2} = 1$ element is the imaginary part. The element with $n_{m-2} = 1$ is the complex conjugate of the element with $n_{m-2} = 0$. Only the $n_{m-2} = 0$ element is calculated. This is operation B as defined in § 2. The real and imaginary parts are placed in contiguous memory. The binary index of the output of the second stage is then

$$\begin{aligned} &(n_{m-1} = 0\; n_{m-2}\, k_{m-3}\, k_{m-4} \ldots k_1\, k_0) \quad \text{and} \\ &(n_{m-1} = 1\; n_{m-2} = 0\; k_{m-3}\, k_{m-4} \ldots k_1\, k_0\, c), \end{aligned} \tag{4.3}$$

where c represents complex elements.

The third stage has three parts. For $n_{m-1} = n_{m-2} = 0$, the summation over k_{m-3} has real input and real output (operation A). For $n_{m-1} = 0$ and $n_{m-2} = 1$, the complex elements are formed as in the preceding stage (operation B). For $n_{m-1}=1$, CT1 operations for a complex input sequence are performed. The binary index of the output is

$$(4.4)\qquad \begin{aligned}&(n_{m-1}=0\ n_{m-2}=0\ n_{m-3}\ k_{m-4}\dots k_1\ k_0),\\ &(n_{m-1}=0\ n_{m-2}=1\ n_{m-3}=0\ k_{m-4}\dots k_1\ k_0\ c),\quad\text{and}\\ &(n_{m-1}=1\ n_{m-2}=0\ n_{m-3}\ k_{m-4}\dots k_1\ k_0\ c).\end{aligned}$$

The remaining stages are similar to the last. After the mth stage, there will be two real numbers with index $n_{m-1}=n_{m-2}=\cdots=n_1=0$; these correspond to the elements of the zero mode and the $N/2$ mode and will be contiguous in memory. The other $N/2-1$ elements are complex and are indexed such that at least one of the m binary digits is one.

The output sequence is in the second-conditional, bit-reversed order. Table 3 illustrates how this ordering occurs with an example.

TABLE 3
Example of the reduced sequence for a compact transform $n=16$. y = yes, the element is needed. n = no, the element is the conjugate of an existing element and is not needed.

Base 10	Base 2	Stage 1	Stage 2	Stage 3	Stage 4	Remaining	Bit-reversed base 10
0	0000	y	y	y	y	0000	0
1	0001	y	y	y	y	0001	8
2	0010	y	y	y	y	0010	4
3	0011	y	y	y	n		
4	0100	y	y	y	y	0100	2
5	0101	y	y	y	y	0101	10 = 6*
6	0110	y	y	n	n		
7	0111	y	y	n	n		
8	1000	y	y	y	y	1000	1
9	1001	y	y	y	y	1001	9 = 7*
10	1010	y	y	y	y	1010	5
11	1011	y	y	y	y	1011	13 = 3*
12	1100	y	n	n	n		
13	1101	y	n	n	n		
14	1110	y	n	n	n		
15	1111	y	n	n	n		

The inverse transform can be accomplished by reversing the stages and operations. The input data should be in the same order as the output of the forward transform. This corresponds to the GS2CS algorithm.

4.2. The parallel CT1R algorithm. Now we present the parallel extension of the CT1R algorithm just desribed. Table 4 shows the binary index of the vector during each step of the transform for $m=6$, $d=3$.

In order to perform the first stage, operation A, the i-cycle with the $(m-1)$st digit as the target is executed. The first stage is then performed on all processors as described above, and the input digit k_{m-1} changes to the output digit n_{m-1}. Anticipating the fact that complex numbers will be created during the second stage, and that real and imaginary parts are to be contiguous, a local rearrangement of the sequence is done. The transpose leaves the index of the array as shown in Table 4. Note that since k_{m-d-1} has moved into the processor label, it must be moved back using an i-cycle to complete the FFT; hence, the number of communications is at least $d+1$.

TABLE 4

Binary index table of the compact transform with a real, naturally ordered input sequence and conjugate-symmetric, bit-reversed order output sequence. The c_j represents a complex number composed of real elements of binary digit j. $m = 6$, $d = 3$.

					$k_5\, k_4\, k_3 \mid k_2\, k_1\, k_0$	Input
					$k_2\, k_4\, k_3 \mid k_5\, k_1\, k_0$	1st *i*-cycle

	$0_4\, 0_3\, 0_5 \mid n_1\, k_0\, 0_2$	$0_4\, 0_3\, 0_5 \mid c_1\, k_0\, 1_2$	$0_4\, 1_3\, 0_5 \mid n_1\, k_0\, c_2$	$1_4\, n_2\, 0_5 \mid n_1\, k_0\, c_3$	$n_3\, n_2\, 1_5 \mid n_1\, k_0\, c_4$	Stage 5
	$0_4\, 0_3\, 0_5 \mid 0_2\, k_0\, n_1$	$0_4\, 0_3\, 0_5 \mid 1_2\, k_0\, c_1$				Digit switch
$0_4\, 0_3\, 0_5 \mid 0_2\, n_0\, 0_1$	$0_4\, 0_3\, 0_5 \mid 0_2\, c_0\, 1_1$	$0_4\, 0_3\, 0_5 \mid 1_2\, n_0\, c_1$	$0_4\, 1_3\, 0_5 \mid n_1\, n_0\, c_2$	$1_4\, n_2\, 0_5 \mid n_1\, n_0\, c_3$	$n_3\, n_2\, 1_5 \mid n_1\, n_0\, c_4$	Stage 6
$0_4\, 0_3\, 0_5 \mid 0_2\, 0_1\, n_0$	$0_4\, 0_3\, 0_5 \mid 0_2\, 1_1\, c_0$					Digit switch
$0_4\, 0_3\, 0_5 \mid 0_2\, 0_1\, n_0$	$0_4\, 0_3\, 0_5 \mid 0_2\, 1_1\, c_0$	$0_4\, 0_3\, 0_5 \mid 1_2\, n_2\, c_1$	$0_4\, 1_3\, 0_5 \mid n_1\, n_0\, c_2$	$1_4\, n_2\, 0_5 \mid n_1\, n_0\, c_3$	$n_3\, n_2\, 1_5 \mid n_1\, n_0\, c_2$	Output

In the second i-cycle the $(m-2)$nd digit is the target. Because another k digit has moved to the processor label, the total number of i-cycles needed for the transform is at least $d+2$. State 2 is then performed on all processors as described above. This is a combination of operations A and B. The complex elements formed are then positioned contiguously in the last half of the distributed array using a local left-most/right-most digit switch. This positions n_{m-1} in the pivot place; hence the maximum number of i-cycles will remain at $d+2$ after the next i-cycle.

The third i-cycle brings k_{m-3} into the pivot. In the third stage, all processors with $n_{m-1} = 1$ perform a third CT1 stage on their subsequence. The other processors perform an operation that is similar to the second stage including the local digit switch.

To make this stage efficient on a SIMD multiprocessor, we must make the combined operations A and B look similar to a CT1 operation. As is evident, operation A is performed on all even elements of the subsequence. This is similar to a CT1 operation with roots (1., 0.). Operation B, which is executed on all odd elements, does not conform to a CT1 operation. One way of accomplishing this is to change the CT1 operation

$$\text{(4.5)} \qquad \text{from } x + \omega^n y \quad \text{to } Wx + \omega^n y,$$

where W is a real array. The roots-of-unity array and W can then be set so that each processor, given the same instruction, will perform either a CT1 operation or an A/B operation. The local digit switch, however, must be a masked operation.

The fourth to the dth stages proceed similarly to the previous stage. On the ith stage, only those processors with $n_{m-1} = n_{m-2} = \cdots = n_{i+2} = 0$ perform an operation equivalent to stage 2. These stages are not seen in Table 4 since $d = 3$.

The next two stages also require i-cycles before they can be executed. The i-cycles reposition k_{m-d-1} and k_{m-d-2} into the pivot. On the $(d+2)$nd stage, only processor 0 performs the stage 2 operation. For the remaining stages, $d+3$ to m, no communication is required. Processor 0 executes an $(m-d-2)$-stage CT1 transform, and the others complete their stages. Figure 1 shows a graph of the complete CT1R algorithm for

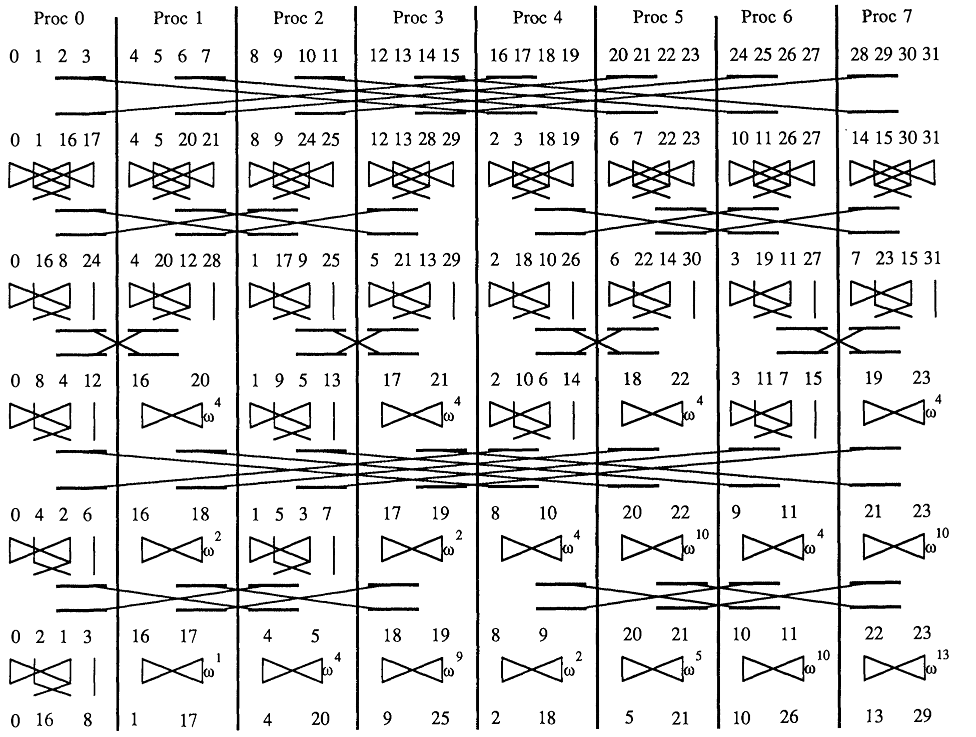

FIG. 1. *Graph of the* CT1R *algorithm with* $m = 5$, $d = 3$. *The input is a real, naturally ordered sequence and the output is a complex, bit-reversed, second-conditionally ordered, processor transposed sequence. Operation* A *is executed on the first stage on the first and third, and second and fourth elements. The transpose is shown just below that. The second stage involves operation* A *on even elements and* B *on odd. The digit switch is shown just below. On the third stage, the odd processors execute the complex* CT1 *operation, shown as a single butterfly with a root of unity.*

$m = 5$, $d = 3$. This completes the description of the transform; there is a total of $d+2$ i-cycles.

4.3. Ordering, roots, and inverse transform. In addition to the output sequence being in the second-conditional, bit-reversed order, the processor index is not in the proper bit-reversed order. The two left-most digits should be on the right. It requires $d+2$ i-cycles and local permutations to correct this.

For the CT1R algorithm we have chosen to precompute the roots of unity. For stages 3 to $d+2$ with $d \geq 2$, each processor requires one root per stage. For the pth processor, we first form p_0 by

$$p_0 = 4p/P + 4(p)_{\bmod P/4}, \tag{4.6}$$

which is the adjusted processor label. Let j be the first nonzero binary digit from the left in p_0. Then the adjusted processor label is modified so that the 1 in the jth place is moved one place to the left,

$$p_1 = 2^{j+1} + (p_0)_{\bmod 2^j}. \tag{4.7}$$

The argument for root of unity is then

$$\tfrac{1}{4} 2\pi/P \text{ bit-reverse } (p_1 \text{ with } d+1 \text{ places}). \tag{4.8}$$

The roots from stages $d+3$ to m build on the roots from stage $d+2$ in the standard way.

The inverse transform can be accomplished by reversing the stages, i-cycles, and local permutations. The input data should be in the same order as the output of the forward transform. As in the serial case, this corresponds to the GS2CS algorithm.

4.4. Performance analysis. In order to estimate the parallel performance of the algorithm presented above, we first must establish the operation count for each processor during each stage. We shall analyze the load imbalance that occurs at each stage and note the amount of local memory transfers. We shall denote the number of transforms by q. It is then a simple matter to calculate the amount of communication overhead. Together with the communication time, we shall predict such measures as overhead and parallel efficiency.

In the first and second stages the computations are completely balanced; the total number of floating-point operations is $\frac{3}{2}qN/P$ for each processor. There are $(m-d-1)qN/2P$ elements exchanged in the local transpose and $qN/2P$ elements exchanged in the local digit switch. For stages 3 to $d+2$, processors either perform the real summation with an operation count of $\frac{1}{2}qN/P$ or the CT1 operation with a count of $5qN/2P$. In stages $d+3$ to m the total operation count is $5q(m-d-2)N/2P-2qN/P$ for processor 0 and $5q(m-d-2)N/2P$ for the others.

Totaling only the maximum operation count for each stage and ignoring the local memory exchanges, the operation count for the transform is

$$T_P^{\text{calc}} = (5m-2)Nq/2P, \tag{4.9}$$

which is similar to the operation count for a complex FFT of length $N/2$.

$d+2$ i-cycles are required for the transform; hence there are $d+2$ nearest-neighbor communication exchanges of contiguous data of length $Nq/2P$. The equivalent number of floating-point operations required by the i-cycles is then

$$T_P^{\text{comm}} = 2(d+2)\left(\alpha+\beta\frac{Nq}{2P}\right), \tag{4.10}$$

where α is the number of floating-point operations per communication startup, and β is the number of floating-point operations per word transmitted.

Overhead is defined as

$$f=(PT_P-T_1)/T_1, \tag{4.11}$$

where T_1 is the number of operations required for the transform run on one processor. The operation count for the serial algorithm is $(5m-2)Nq/2$. The overhead for the real transform is then

$$f=\frac{5}{2}\frac{d+2}{m-2}\left(\beta+\alpha\frac{2P}{Nq}\right). \tag{4.12}$$

The first term in the parentheses comes from the message-passing communication. The last is message startup and is inversely proportional to the granularity $Nq/2P$. It will most likely be small when granularity is large. Multiplying the expression is approximately $\log P/\log N$. The overhead is proportional to the dimension and inversely proportional to m.

The efficiency is $[1+f]^{-1}$. Neglecting startup and taking the first term of the binomial series, it can be expressed as

$$e\sim 1-\frac{2}{5}\frac{d+2}{m-2}\beta. \tag{4.13}$$

An efficiency close to one is expected for problems with large granularity and multiprocessors with small β (ratio of message passing to computational rates).

4.5. A serial GS1R algorithm. An attraction of the GS1 forward transform is that it has a less complicated power distribution for the roots-of-unity multiplication than does the CT1 transform. The former has sequentially ordered roots while the latter has bit-reversed ordered roots. For completeness and simplicity, we present a discussion of a parallel GS1R algorithm for a real, naturally ordered sequence in this and the next two sections. We have chosen this particular way of implementing the GS1R for ease in parallelization.

As in the CT1R algorithm, the first step involves only the k_{m-1} summation, which is operation A. In the output, k_{m-1} is replaced by n_{m-1}.

The second step is split into two parts. For input data with $n_{m-1}=0$, the ω_N term is unity and the k_{m-2} summation (operation A) is done. The index of the output is $(n_{m-1}=0\ n_{m-2}\ k_{m-3}\dots k_0)$ and the data are real. For $n_{m-1}=1$, we combine the roots calculation with the k_{m-2} summation. Since the input sequence is real, the output with $n_{m-2}=1$ are the complex conjugates of the corresponding output data with $n_{m-2}=0$; hence, the former output data are not calculated. The $\omega_{N/2}$ term is unity for the output calculated. This is operation B with a roots-of-unity multiplication.

The third stage is split into three parts. For the real subsequences with $n_{m-1}=n_{m-2}=0$, the k_{m-3} summation is performed and the output is real. For $n_{m-1}=0$ and $n_{m-2}=1$, we have a situation similar to the second part of stage 2. The last part of stage 3 is for complex input sequences with $n_{m-1}=1$; the GS1 stage is executed.

Stages 4 to m proceed similarly to the proceeding stage. If all n digits to the left of the current place are zero, then the summation of real input to real output is performed. If all n digits to the left are zero except the adjacent one, then the real-to-complex operation is executed and is similar to stage 2. In all other cases, the GS1 operation stage is executed.

The output vector has the second-conditional, bit-reversed ordering; the inverse is the CT2CS algorithm.

4.6. The parallel GS1R. The previous section provided a description of the GS1R algorithm for a real, naturally ordered sequence. Now we develop the parallel version.

Table 4 contains the index representations at each stage and i-cycle for the parallel GS1R (as well as CT1R) for $m=6$ and $d=3$. All the communications and local digit permutations are the same as the CT1R algorithm; the only differences are the roots of unity and the operations at each state. Figure 2 shows a graph of the GS1R with $m=5$, $d=3$.

Stage 1 is operation A. Stage 2 is in two parts. If $n_{m-1}=0$, then just the operation A is executed. If $n_{m-1}=1$, then the complex number is created (operation B) and then multiplied by the suitable root of unity. The local digit switch is then done.

The third i-cycle brings the $(m-3)$rd place to local memory and moves n_{m-1} or q_{m-2} to the processor label. In all subsequent i-cycles, only n or q indices will move into the processor label. Thus, the number of i-cycles for the transform stands at $d+2$. The third stage is split into three parts. If $n_{m-1}=n_{m-2}=0$, then the simple real summation is performed. If $n_{m-1}=0$ and $n_{m-2}=1$, then the complex number/roots-of-unity operation is done followed by a reindexing with q replacing n. If $q_{m-2}=1$, then a standard GS operation is done. A local index switch is done on those processors with $n_{m-1}=0$.

The subsequent stages 4 through $d+2$ proceed similarly. Stages $d+3$ to m and index switches proceed as shown in the table. The resulting index order is shown in

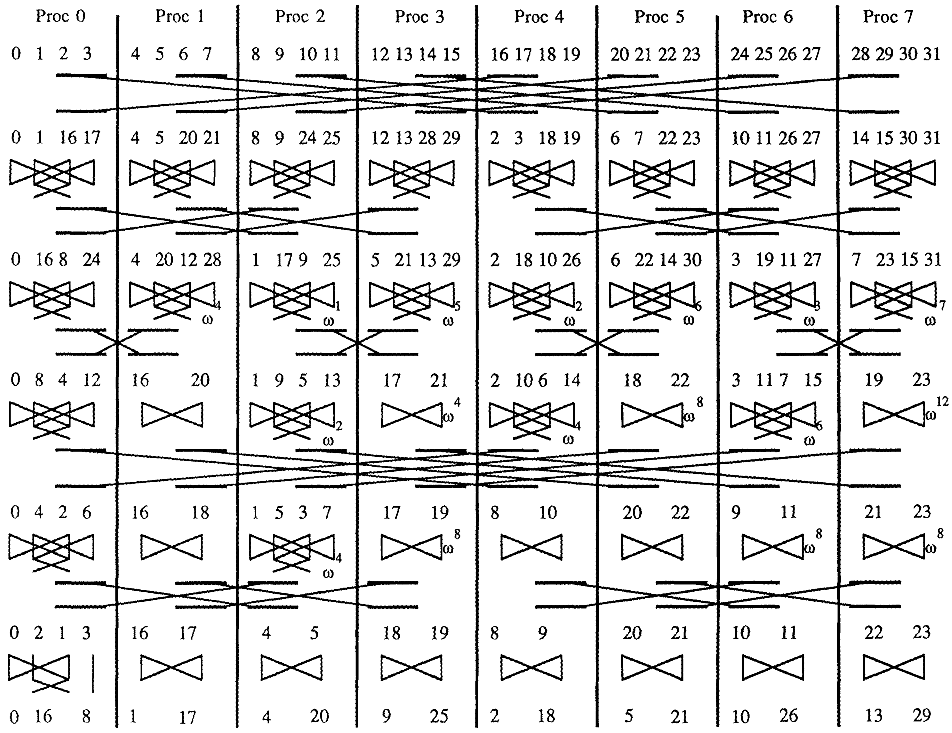

FIG. 2. *Graph of the* GS1R *algorithm with $m=5$, $d=3$. The input is a real, naturally ordered sequence and the output is a complex, bit-reversed, second-conditionally ordered, processor transposed sequence. The first stage is the same as in Fig.* 1. *On the second stage, even elements execute* A *and odd execute* B *plus a roots-of-unity multiplication. On subsequent stages the single butterfly with root represents a complex* GS1 *operation.*

the last entry of the table. This completes the development of the parallel GS1R algorithm.

4.7. Ordering, roots, and the inverse transform. The ordering of the output data is the same as in the parallel CT1R algorithm.

We have chosen to compute the roots of unity in the standard way by precomputing the first root, or the increment for each stage,

$$\delta\omega_j = \exp(i\pi/2^{m-j}), \quad \text{where } j \text{ is the stage index.} \tag{4.14}$$

During each stage, the actual roots are calculated. With this method, the starting root for each processor is not necessarily $(1,0)$ and so a starting root of unity; $\omega_j^0(k)$ must also be precomputed for each processor and each stage.

One way of computing the starting roots of unity for $d>1$ is

$$\begin{aligned}
\omega_1^0(k) &= \exp[i(k_{m-3}, k_{m-4}, \dots, k_{m-d-2})\pi/2P],\\
\omega_2^0(k) &= \exp[i(k_{m-3}, k_{m-4}, \dots, k_{m-d-2})\pi/P],\\
\omega_3^0(k) &= \exp[i(k_{m-4}, \dots, k_{m-d-2}, 0)\pi/P],\\
\omega_4^0(k) &= \exp[i(k_{m-3}, \dots, k_{m-d-2}, 0, 0)\pi/P],\\
&\ \ \vdots\\
\omega_{d+1(k)}^0(k) &= \exp[i(k_{m-d-2}, 0, \dots, 0)\pi/P],\\
\omega_j^0(k) &= (1,0) \text{ for } j=d+2 \text{ to } m.
\end{aligned} \tag{4.15}$$

If $d=1$, then

$$\omega_1^0(k)=\exp[1(m-2)\pi/2P], \qquad \omega_j^0(k)=(1,0) \quad \text{for } j=2 \text{ to } m. \tag{4.16}$$

The inverse transform can be accomplished by reversing the stages and operations. The input data should be in the same order as the output of the forward transform. This corresponds to the CT2CS algorithm.

4.8. Performance analysis. The first and second stages have completely balanced computations; the total number of floating-point operations is Nq/P and $N/2P(5q+3)$ for each processor, respectively. For stages 3 to $d+2$, processors also have a balanced computational load of $N/2P(5q+3)$. The total operation count for stages $d+3$ to m is $N/2P[(m-d-2)5q+6]$ for processor 0 and $N/2P[(m-d-2)5q+3]$ for all others. Since processor 0 has slightly more work and the local permutation, an imbalance may occur. Totaling the maximums for each stage, the operation count for the transform is

$$T_P^{\text{calc}}=N/2P[(m-3/5)5q+3d+9]. \tag{4.17}$$

The second term in parentheses comes from redundant roots-of-unity calculations during stages 2 to $d+2$.

There are $d+2$ nearest-neighbor communication exchanges of contiguous data of length $n/2P$. The communication time is

$$T_P^{\text{comm}}=2(d+2)\left(\alpha+\beta\frac{Nq}{2P}\right). \tag{4.18}$$

The operation count for the serial algorithm is $N/2[(m-3/5)5q+P]$. The overhead for the real transform is then

$$f=\frac{[3d/q+2(d+2)\alpha][2P/Nq+2(d+2)\beta]}{(m-3/5)+9/q}. \tag{4.19}$$

The first term in the numerator comes from the redundant roots-of-unity calculations and is small for large q. The second term is from message startup and is inversely proportional to the granularity $Nq/2P$. The third term is from the message-passing communication and is proportional to the dimension and message-passing rate. For large granularity, defined as $\alpha/\beta \ll Nq/2P$, and large, q, $q \gg d$, the overhead tends to 2β d/m.

The efficiency is $[1+f]^{-1}$. Taking the first term of the binomial expansion, the efficiency is

$$e \sim 1-2\beta\ \text{d/m} \tag{4.20}$$

for the assumptions made above.

5. The parallel, compact FFT for a conditionally ordered, conjugate-symmetric sequence.

In this section we present the parallel compact CT1CS and GS1CS algorithms. The conjugate-symmetric input sequence is conditionally ordered and the real output sequence is in bit-reversed order.

5.1. The parallel GS1CS algorithm. To describe the algorithm, we first describe the inverse transform CT2R, which has as its input, a real, bit-reversed sequence. Much of this algorithm is the same as CT1R; the reader is referred to §§ 4.1 and 4.2 for details of the operations at each stage.

Let the binary index of the real sequence be

$$(n_0\, n_1 \ldots n_{m-1}). \tag{5.1}$$

The index of the distributed, bit-reversed sequence is then

$$(n_{m-1}\, n_{m-2} \dots n_{m-d} \,|\, n_{m-d-1}\, n_{m-d-2} \dots n_0). \tag{5.2}$$

We also assume that the input sequence has the processor transposition [13]; the index of the input sequence is then

$$(n_{m-d}\, n_{m-1}\, n_{m-2} \dots n_{m-d+1} \,|\, n_{m-d-1}\, n_{m-d-2} \dots n_0). \tag{5.3}$$

Table 5 has an example of the index configurations in the transform for $m=6$, $d=3$. The first stage of the algorithm is the summation over n_0, which is operation A described in § 2. The second stage is a summation over n_1. If $k_0=0$, then operation A is executed; if $k_0=1$, then operation B is executed and a complex number is created from the two real elements. The complex number is denoted by a c_1 in the table. The indices k_1 and k_0 are switched.

TABLE 5

Binary index table of the inverse compact transform with a real, bit-reverse-ordered input sequence and conjugate symmetric, naturally ordered output sequence. The c_j represents a complex number composed of real elements of binary digit j. $m=6$, $d=3$.

					$n_3 n_5 n_4 \vert n_2 n_1 n_0$	Initial index
					$n_3 n_5 n_4 \vert n_2 n_1 k_0$	Stage 1
				$n_3 n_5 n_4 \vert n_2 k_1 0_0$	$n_3 n_5 n_4 \vert n_2 c_1 1_0$	Stage 2
				$n_3 n_5 n_4 \vert n_2 0_0 k_1$	$n_3 n_5 n_4 \vert n_2 1_0 c_1$	Digit switch
			$n_3 n_5 n_4 \vert k_2 0_0 0_1$	$n_3 n_5 n_4 \vert c_2 0_0 1_1$	$n_3 n_5 n_4 \vert k_2 1_0 c_1$	Stage 3
			$n_3 n_5 n_4 \vert 0_1 0_0 k_2$	$n_3 n_5 n_4 \vert 1_1 0_0 c_2$		Digit switch
			$0_1 n_5 n_4 \vert n_3 0_0 k_2$	$1_1 n_5 n_4 \vert n_3 0_0 c_2$	$k_2 n_5 n_4 \vert n_3 1_0 c_1$	1st i-cycle
		$0_1 n_5 n_4 \vert k_3 0_0 0_2$	$0_1 n_5 n_4 \vert c_3 0_0 1_2$	$1_1 n_5 n_4 \vert k_3 0_0 c_2$	$k_2 n_5 n_4 \vert k_3 1_0 c_1$	Stage 4
		$0_1 n_5 n_4 \vert 0_2 0_0 k_3$	$0_1 n_5 n_4 \vert 1_2 0_0 c_3$			Digit switch
		$0_1 n_5 0_2 \vert n_4 0_0 k_3$	$0_1 n_5 1_2 \vert n_4 0_0 c_3$	$1_1 n_5 k_3 \vert n_4 0_0 c_2$	$k_2 n_5 k_3 \vert n_4 1_0 c_1$	2nd i-cycle
	$0_1 n_5 0_2 \vert k_4 0_0 0_3$	$0_1 n_5 0_2 \vert c_4 0_0 1_3$	$0_1 n_5 1_2 \vert k_4 0_0 c_3$	$1_1 n_5 k_3 \vert k_4 0_0 c_2$	$k_2 n_5 k_3 \vert k_4 1_0 c_1$	Stage 5
	$0_1 n_5 0_2 \vert 0_3 0_0 k_4$	$0_1 n_5 0_2 \vert 1_3 0_0 c_4$				Digit switch
	$0_1 0_3 0_2 \vert n_5 0_0 k_4$	$0_1 1_3 0_2 \vert n_5 0_0 c_4$	$0_1 k_4 1_2 \vert n_5 0_0 c_3$	$1_1 k_4 k_3 \vert n_5 0_0 c_2$	$k_2 k_4 k_3 \vert n_5 1_0 c_1$	3rd i-cycle
$0_1 0_3 0_2 \vert k_5 0_0 0_4$	$0_1 0_3 0_2 \vert c_5 0_0 1_4$	$0_1 1_3 0_2 \vert k_5 0_0 c_4$	$0_1 k_4 1_2 \vert k_5 0_0 c_3$	$1_1 k_4 k_3 \vert k_5 0_0 c_2$	$k_2 k_4 k_3 \vert k_5 1_0 c_1$	Stage 6
$0_1 0_3 0_2 \vert 0_4 0_0 k_5$	$0_1 0_3 0_2 \vert 1_4 0_0 c_5$					Digit switch
$0_4 0_3 0_2 \vert 0_1 0_0 k_5$	$1_4 0_3 0_2 \vert 0_1 0_0 c_5$	$k_5 1_3 0_2 \vert 0_1 0_0 c_4$	$k_5 k_4 1_2 \vert 0_1 0_0 c_3$	$k_5 k_4 k_3 \vert 1_1 0_0 c_2$	$k_5 k_4 k_3 \vert k_2 1_0 c_1$	4th i-cycle

The third to $(m-d)$th stages proceed as follows. On the jth stage, operation A is executed if all k bits are zero. Operation B is executed if all k bits are zero except k_{j-2}. Complex CT2 operations are executed on the complement. In a local memory exchange, indices k_{j-2} and k_{j-1} are switched.

Before the $(m-d-1)$st stage, an i-cycle places the right-most target bit into the pivot position. On the $(m-d-1)$st stage, the lower half of the processors execute a combined A/B operation, and the upper half execute CT2 operations.

For the next $d-1$ stages, $m-d+2$ to m, we first perform i-cycles with the target starting from the right-most processor bit and moving progressively to the left with each stage. Those processors with zero k bits execute operation A/B and the local digit switch, while the complement execute the CT2 operations. Finally, after an i-cycle with the right-most bit as the target is done, the transform is complete and the complex output sequence is in conditional order.

Figure 3 shows the graph of the GS1CS transform for $m=5$ and $d=3$. The complex input, which is part of the conjugate-symmetric sequence, is in conditional order. The first i-cycle has the right-most processor bit as the target. Processor 0 must execute an operation $(\mathrm{A/B})^{-1}$ and the others a GS1 operation. The resulting index of

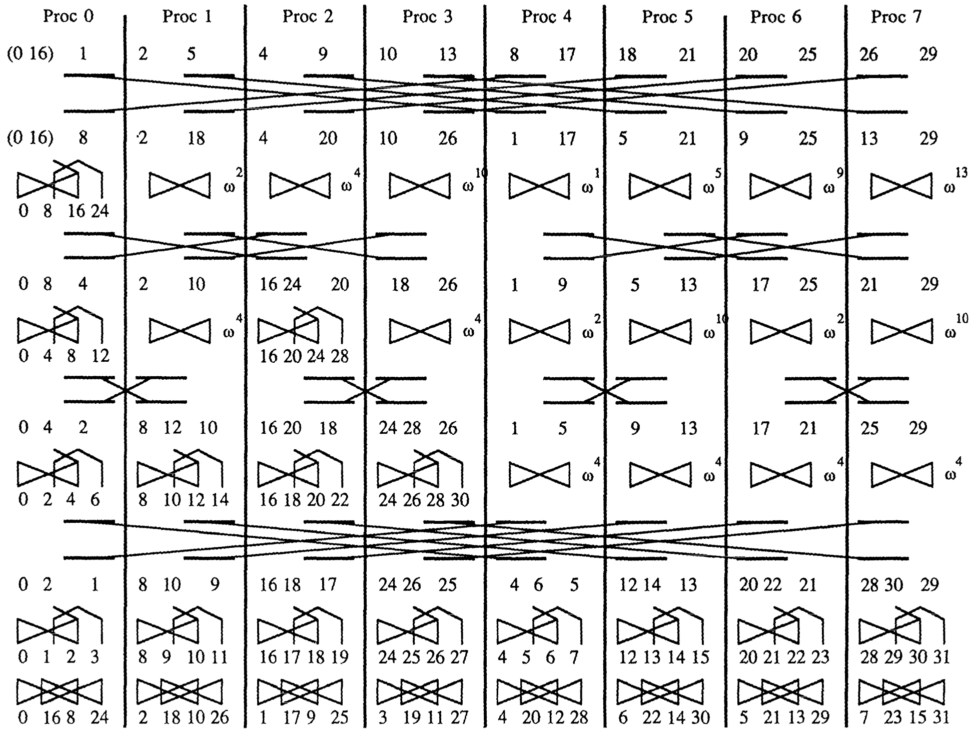

FIG. 3. *Graph of the* GS1CS *algorithm with $m=5$, $d=3$. The input is a complex, conditionally ordered sequence, and the input is a real, bit-reversed, processor-transposed sequence. The zero processor executes a digit switch and* A^{-1} *on the even elements and* B^{-1} *on the odd. The rest of the processors execute complex* GS1 *operations. On the final stage, operation* A^{-1} *is executed on first and third, second, and fourth elements.*

real elements is shown. Note that first a digit switch is done to make the $(A/B)^{-1}$ operation have a similar form to that of GS1. Operations $(A/B)^{-1}$ and GS1 can be combined as in (4.5) for SIMD multiprocessors. The argument for the starting roots of unity is

$$2(p_{\mathrm{mod}\,P/2})+\frac{p}{P/2}, \tag{5.4}$$

where p is the base-10 processor index.

The second i-cycle has the middle processor bit as the target. We define a reduced processor index on stage j as

$$p_j=p_{j-1}-2^{d-j}, \tag{5.5}$$

where $p_1=p$. All processors with positive reduced processor index execute GS1 operations; the complement execute operation $(A/B)^{-1}$. Hence, on the second stage, processors 0 and 2 execute $(A/B)^{-1}$. The argument for the roots on the jth stage is

$$2\pi 2^{j-1}(p_{\mathrm{mod}\,P/2})/2N. \tag{5.6}$$

The target in the third i-cycle is the right-most processor bit. The lower half of the processors execute $(A/B)^{-1}$ and the upper half execute GS1. The final i-cycle is the same as the first. All processors execute $(A/B)^{-1}$ on the fourth stage and A^{-1} on the fifth. The last line has the index of the bit-reversed real sequence.

This completes the description of the algorithm. Only $d+1$ i-cycles are necessary to transform a conjugate-symmetric sequence in conditional order into a real, m bit-reversed, processor-transposed sequence. The starting roots of unity for each processor for each stage are given in (5.4) and (5.6), and the increment is given in (4.14). The transform CT2R is obtained by formally inverting the GS1CS operations and i-cycles. The parallel performance is similar to the GS1R algorithm. See § 4.6 for more details.

5.2. The parallel CT1CS algorithm. We have presented three parallel algorithms (and their inverses) for the transform of real data. In the first two, a real naturally ordered sequence was input, and a complex sequence of bit-reversed, second-conditional ordering was the output. The third, based on the compact GS1 algorithm, has a complex input sequence in conditional ordering and a real bit-reversed output sequence. The final transform has the same ordering of sequences as the third, but is based on the CT1 algorithm.

The evolution of the binary indices is the same as in the previous transform and is best explained using the inverse transform. Table 5, which was used to illustrate GS1CS, is also valid for CT1CS.

Figure 4 shows a graph of the forward transform for $m=5$, $d=3$. The scheme follows the GS1R scheme in reverse except that the sequences are in a different ordering. The CT1CS has a conjugate-symmetric, conditionally ordered input sequence and a real, bit-reversed output sequence, whereas the GS1R scheme has a real, naturally ordered input sequence and a conjugate-symmetric, second-conditionally ordered, bit-reversed output sequence. Roots of unity can be obtained from (4.6) to (4.8). We chose to precompute the roots of unity; the operation count is the same as in the CT1R algorithm (4.9). The inverse of this transform is GS2R.

6. Results. To complete the presentation of parallel compact FFTs for real sequences, we give timings of four of the eight algorithms as implemented on the nCUBE/2, an MIMD multiprocessor with version 3.0beta of the operating system. All code is written in FORTRAN-77 with explicit calls to the communication routines and run using single precision (32 bit words).

A 64-processor machine was employed for the tests. We chose to report one sequence length, 4096, with the number of sequences being 1, 8, and 16. With these parameters all the tests could be run on one processor (4 Mbytes RAM per processor), so that parallel efficiencies could be computed. The scheme that was run on one processor is the same as was run on multiprocessors. The transpose and index switch, not necessary for the single-processor run, was nonetheless executed. Due to limitations on the communications buffer, a few low-dimension tests could not be run. All results reported are an average of times over all processors. The timings are taken from a forward/inverse pair after many pairs have been executed.

Tables 6(a), 6(b), and 6(c) show the times in milliseconds for the CT1R (forward) transform and the GS2CS (inverse) transform. The first column is the processor dimension, which is the log (base 2) of the number of processors used to calculate the transform. The other columns from left to right are the total time for one transform, the calculation time, the communication time including idle time, the time taken in the transpose and index switches, and the parallel efficiency. These columns are repeated for the inverse transform.

Immediately obvious is that the time for index switch, which consists of local memory references only, takes from 37% to 14% of the total time, depending superlinearly on the processor number. In order for these algorithms to be competitive with

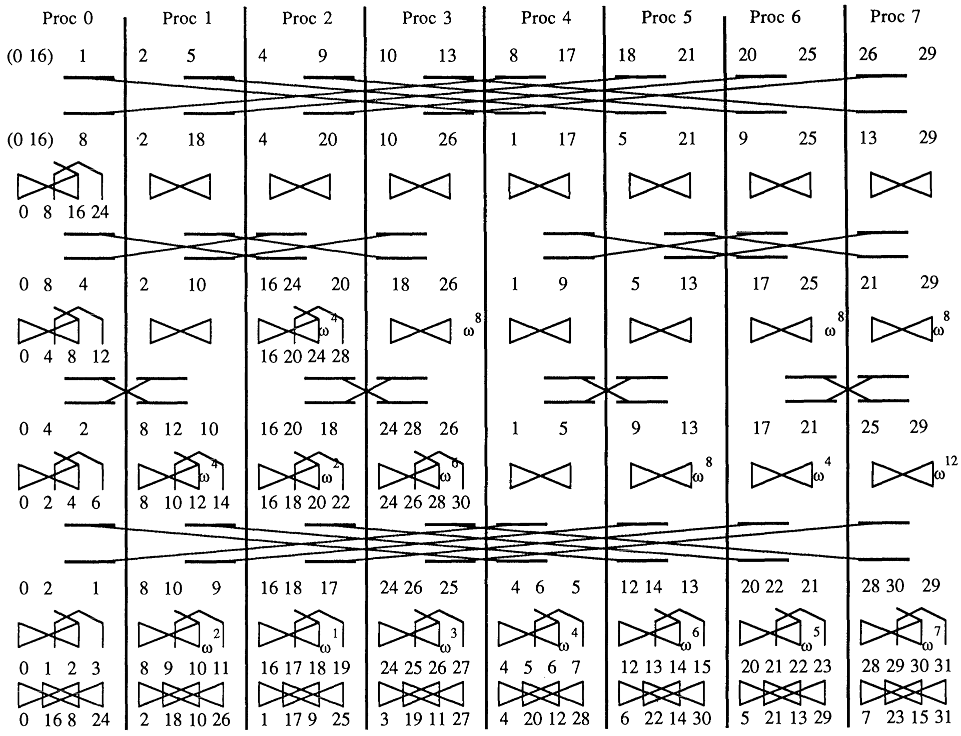

FIG. 4. *Graph of the* CT1CS *algorithm with $m = 5$, $d = 3$. The input is a complex, conditionally ordered sequence, and the input is a real, bit-reversed, processor-transposed sequence. The first and last stages are the same as in Fig.* 3. *On the second stage processor* 2 *executes a digit switch, roots-of-unity multiplication and* B^{-1}.

CLW, local memory referencing must be done more efficiently; transpose and index switch routine should be coded in assembler.

The calculation time diverges from linear scaling as the dimension increases. Loop overhead is thought to be responsible for this behavior. Since the roots of unity are precomputed and stored in this implementation, the nonlinear (in P) term in (4.17) is not present in the operation count. The less-than-linear scaling of the communication time reflects the fact that message startup time scales as the dimension and the message-passing time scales as the dimension/P (see (4.18)). An efficiency of 58% is obtained on 64 processors and a subsequence length of 64.

Comparing the inverse transform GS2CS to the forward transform in Table 6(a), the higher total time is due to the normalization performed on the inverse, which increases the calculation time. The communication time is higher also. The reason for this is that the forward transform, executed first, sets a certain processor synchronization, which causes an increased idle time on the inverse. The transpose and index switch times of the inverse are essentially the same as those of the forward. Efficiencies of the inverse are slightly lower than those of the forward.

Table 6(b) contains information similar to Table 6(a), except that eight sequences are transformed instead of one. An example of loop overhead can be seen in the comparison of the dimension 0 calculation times of Tables 6(a) and 6(b). There is a factor of 4.6 instead of 8 between them. The calculation and communication times scale more linearly with processor number for eight transforms. Transpose and index switch times still scale superlinearity. An efficiency of 77% is achieved on 64 processors.

The calculation and communication times are slightly higher for the inverse due to the same reasons as in Table 6(a).

Timings for the transform of 16 sequences are shown in Table 6(c). Comparing calculation times of Tables 6(b) and 6(c), it is seen that loop overhead is small and that scaling is nearly linear with the processors' number. Memory references still take a significant amount of the total time. Efficiency is 81% for 64 processors. The timings for the inverse have a trend similar to Table 6(b).

Tables 7(a), 7(b), and 7(c) show the times in milliseconds for the GS1R (forward) transform and the CT2CS (inverse) transform for 1, 8, and 16 sequences of length 4096. The columns are arranged similarly to those in Table 6(a), 6(b), and 6(c). The roots of unity are not precomputed, although the root increments are precomputed and stored.

As can be seen in the comparison of Table 6(a) to Table 7(a), the calculation times for the GS1R are higher than the CT1R. This is due to the roots-of-unity

calculation. We have chosen to normalize on the forward transform, which also adds to the calculation time. The communication time, transpose and index switch times, and efficiencies are effectively the same as for the CT1R transform.

When compared to the forward transform GS1R, the inverse transform CT2CS has a lower calculation time, which results from no normalization being performed. A higher idle time is reflected in a higher communication time and is caused by a particular processor synchronization, which minimizes the idle time of the forward transform. These two factors combine to create lower parallel efficiencies for the inverse. Similar comparisons are found for all three sequences.

Tables 8(a), 8(b), and 8(c) show timings for transforms of real sequences using the CLW algorithm. We shall briefly review the implementation; see [8] for more details. Walker, Worley, and Drake [16] have implemented the CLW algorithm on the Intel iPSC/860. The real input sequence is treated as a complex sequence following (3.1). The ordering of the complex array is assumed to be bit-reversed. A CT2 transform is then performed on the complex sequence. The roots of unity are not precomputed. The output from the transform is in sequential order to simplify the postprocessing step, (3.2).

Before executing (3.2), the sequence is written into a work array which is then redistributed in index-reversed order. As discussed in § 3.2, the reordering takes at least $d-1$ communications. Because we chose here to completely reorder the sequence, the message length is $(Nq/p-1)$. After the reordering of the work array, (3.2) is executed and the conjugate-symmetric output sequence is in sequential order. The inverse proceeds with a preprocessing step and a GS1 transform of a complex sequence. The suffixes f and p on the column headings of Tables 8(a), 8(b), and 8(c) relate the complex FFT and the pre- and postprocessing, respectively.

Because of the roots-of-unity computation it is best to compare the results of the GS1R/CT2CS transform (Tables 7(a), 7(b), and 7(c)) with the results of the CLW transform (Tables 8(a), 8(b), and 8(c)). Comparing dimension 0 timings in Tables 7(a) and 8(a), we see that the total time for CLW-CT2 is about half that of GS1R. The GS1R calculation time is about 30% higher. Similar trends, though progressively less severe, are seen in the dimension 1 to 5 results. The $d+2$ communications of the GS1R can be compared to the $d+1$ communications of the complex FFT of CLW (commf). Results of dimension 6 show that the total time of the GS1R is less than CLW-CT2. The calculation time of the CLW-CT2 is still less than that of GS1R, but the postprocessing communication has become dominant over the index switch time.

Comparing Table 7(b) to Table 8(b) for the transform of eight sequences, the dimension 0 case shows that the total time for the CLW-CT2 is still lower than the GS1R, but the calculation times are about the same. This latter result is reinforced by estimates of operation count. For dimension 2 and higher, the total and communication times for GS1R are less. The GS1R communication times are comparable to the commf times of the CLW-CT2. The commp times are greater than the commf times because the message lengths are higher. The differences increase with dimension. Tables 7(c) and 8(c) show similar trends illustrated in Tables 7(b) and 8(b). The timings of the inverse transform CLW-GS1 are similar to those of the forward transform.

To conclude the experimental comparison of the CLW and compact transforms for real sequences, the computational times of the two are about the same. The differences in the dimension 0 timings are not understood, however. The index switch time makes up a nontrivial percentage of the total time for low dimensions and decreases the viability of the compact transforms. The local movement of data could be speeded up considerably by efficient use of cache. The communication times for the compact

transforms are about half those of the CLW scheme. When the communication time becomes significant, i.e., at higher dimensions, the compact transforms offer a time savings over CLW.

7. Summary. We have presented eight in-place, compact FFTs of real sequences for distributed-memory multiprocessors. i-cycles are used for communication and result in minimal communication costs on hypercubes. While the algorithms are written for

MIMD processors, by suitable redefinition of operations, they can be implemented efficiently on SIMD processors also. If the real sequence is naturally ordered, then the transform requires $d+2$ i-cycles, where d is the dimension. If the conjugate-symmetric sequence is in conditional ordering, which is nearly natural ordering, then only $d+1$ i-cycles are required. The communication time is comparable to the complex FFT due to Swarztrauber [13] and Walker [14], whereas the computational complexity is comparable to the parallel CLW [4] algorithm.

The parallel overhead for all the schemes scales as $\beta\, d/m$ in the large granularity limit, where β is the message-passing rate, d is the processor dimension, and m is the base 2 log of the sequence length.

We believe that the conditional ordering is the key to efficient algorithms for cosine, sine, and quarter-wave transform.

A comparison of the compact and CLW algorithms as implemented on an nCUBE/2 multiprocessor shows that while computational times are similar, the communication times are about half in the compact algorithms. Local memory access time must be increased, however, for the compact schemes to compete at low dimensions with the CLW scheme.

Acknowledgments. I would like to thank Roland Sweet at the University of Colorado,Denver, Paul Swarztrauber at the National Centre for Atmospheric Research, and David Walker at the Oak Ridge National Laboratory for helpful suggestions. Timings were run at the CAIP Parallel Processing Laboratory. THE DEVELOPMENT OF VARIABLE-STEP SYMPLECTIC INTEGRATORS, WITH APPLICATION TO THE TWO-BODY PROBLEM*

M. P. CALVO† AND J. M. SANZ-SERNA†

Abstract. The authors develop and test variable step symplectic Runge-Kutta-Nyström algorithms for the integration of Hamiltonian systems of ordinary differential equations. Numerical experiments suggest that, for symplectic formulae, moving from constant to variable stepsizes results in a marked decrease in efficiency. On the other hand, symplectic formulae with constant stepsizes may outperform available standard (nonsymplectic) variable-step codes. For the model situation consisting in the long-time integration of the two-body problem, our experimental findings are backed by theoretical analysis.

Key words. symplectic integration, Kepler's problem, Runge-Kutta-Nyström methods

1. Introduction.

In mechanics, optics, chemistry, etc., situations where dissipation does not play a significant role may be modelled by means of Hamiltonian systems of ordinary differential equations (ODEs) or partial differential equations (PDEs) [2]. Hamiltonian systems of ODEs are of the form

$$\dot{p}^I = -\partial H/\partial q^I, \quad \dot{q}^I = \partial H/\partial p^I, \quad 1 \leqq I \leqq d, \tag{1.1}$$

where the integer d is the number of degrees of freedom, the Hamiltonian $H = H(\mathbf{p}, \mathbf{q}) = H(p^1, \dots, p^d, q^1, \dots, q^d)$ is a sufficiently smooth, real function of $2d$ real variables, and a dot represents differentiation with respect to t (time). There has been much recent interest in the numerical integration of (1.1) by means of so-called symplectic or canonical integrators, starting with the work of Ruth [12], Feng [7], and Channell and Scovel [4]. An extensive list of references can be found in the survey [14].

In order to explain in simple terms the meaning and relevance of symplecticness, it is advisable to consider first the question of how to tell, from the knowledge of the *solutions* of a system of ODEs, whether the *system* is of Hamiltonian form or otherwise. More precisely, let $\mathscr{S}$ be an autonomous system of ODEs for the dependent variables $(\mathbf{p}, \mathbf{q})$, and let us introduce the $\mathbb{R}^{2d}$-valued function $\varphi_t(\mathbf{p}_0, \mathbf{p}_0)$ such that, for fixed $\mathbf{p}_0$ and $\mathbf{q}_0$ and varying t, $(\mathbf{p}(t), \mathbf{q}(t)) = \varphi_t(\mathbf{p}_0, \mathbf{q}_0)$ is the solution of $\mathscr{S}$ with initial condition $\mathbf{p}(0) = \mathbf{p}_0$, $\mathbf{q}(0) = \mathbf{q}_0$. If we now see t as a parameter and $\mathbf{p}_0, \mathbf{q}_0$ as variables, $\varphi_t(\mathbf{p}_0, \mathbf{q}_0)$ defines a transformation in the space $\mathbb{R}^{2d}$ (the phase space). This transformation is the *flow* of the differential system $\mathscr{S}$. If we were given φ_t and at the same time $\mathscr{S}$ were concealed from us, could we tell whether $\mathscr{S}$ is a Hamiltonian system or otherwise? The answer to this question is affirmative. The system $\mathscr{S}$ is Hamiltonian *if and only if, for each* t, φ_t *is a symplectic transformation.* Now a transformation $\mathscr{T}$ in phase space is said to be symplectic [2] if for any bounded two-dimensional surface D in phase space, the sum of the two-dimensional (signed) areas of the d projections of D onto the planes (p^I, q^I) is the same as the sum of the two-dimensional (signed) areas of the d projections of $\mathscr{T}(D)$ onto the planes (p^I, q^I). Thus the symplectic character of

† Departamento de Matemática Aplicada y Computación, Facultad de Ciencias, Universidad de Valladolid, Valladolid, Spain (Maripaz@cpd.uva.es and sanzserna@cpd.uva.es).

the flow is the hallmark of Hamiltonian systems. Hamiltonian problems have many specific features not shared by other systems of differential equations. All such specific features (absence of attractors, recurrence, etc.) directly derive from the symplecticness of the corresponding flow [2].

A one-step numerical method used with steplength h defines a transformation in phase space $\psi_h(\mathbf{p}_0, \mathbf{q}_0)$ that advances the solution h units of time, starting from $(\mathbf{p}_0, \mathbf{q}_0)$. Of course, $\psi_h(\mathbf{p}_0, \mathbf{q}_0)$ is an approximation to $\varphi_h(\mathbf{p}_0, \mathbf{q}_0)$, and the numerical method approximates $\varphi_{nh} = \varphi_h^n$ by iterating n times ψ_h. For Hamiltonian problems integrated by classical methods, such as explicit Runge-Kutta methods, the transformation ψ_h turns out to be *nonsymplectic.* Then the numerical method misses the important specific features associated with symplectic transformations. However, there are *symplectic* methods for which ψ_h is guaranteed to be symplectic for Hamiltonian problems.

Numerical experiments have shown that for Hamiltonian problems, symplectic integrators may well be an improvement over their nonsymplectic counterparts. However, the development of symplectic methods has so far been confined to *constant stepsize* formulae and, accordingly, numerical tests have used as reference algorithms constant stepsize implementations of classical methods. Such implementations are, by modern numerical ODE standards, very naive, and the question arises of whether, for Hamiltonian problems, a symplectic method with constant stepsizes, may actually be more efficient than a modern variable-step code. Before we carried out the experiments reported in this paper, we felt that the answer to that question would be no. On the other hand, we suspected that for Hamiltonian problems, variable stepsize symplectic algorithms would improve on standard variable stepsize algorithms. Accordingly, we decided to develop variable stepsize symplectic algorithms.

In this paper we report on our experience with the construction and assessment of *variable-step, symplectic, explicit Runge-Kutta-Nyström algorithms.* We used Runge-Kutta-Nyström (RKN) methods rather than Runge-Kutta methods because all symplectic Runge-Kutta formulae are implicit [13]. It appears that both our guesses above were wrong: *constant stepsize symplectic methods may beat standard variable stepsize codes, but variable stepsize symplectic codes are not more advantageous than standard variable stepsize codes.*

Section 2 is devoted to the construction of the symplectic RKN code. The results of the numerical experiments are presented in § 3, where we use as a test problem the well-known two-body (Kepler) problem. In § 4 we analyze our experimental findings. In particular, we provide a complete theoretical study of the performance of general one-step numerical methods in the integration of the two-body problem. Finally, in § 5, we present our conclusions.

2. Construction of a symplectic RKN code.

2.1. RKN methods. We restrict our attention to systems of the special form

$$\dot{\mathbf{p}} = \mathbf{f}(\mathbf{q}), \qquad \dot{\mathbf{q}} = \mathbf{p} \tag{2.1}$$

(i.e., to second-order systems $\ddot{\mathbf{q}} = \mathbf{f}(\mathbf{q})$). If $\mathbf{f}$ is the gradient of a scalar function $-V(\mathbf{q})$, then (2.1) is a Hamiltonian system with

$$H = H(\mathbf{p}, \mathbf{q}) = T(\mathbf{p}) + V(\mathbf{q}), \qquad T(\mathbf{p}) = \tfrac{1}{2}\mathbf{p}^T\mathbf{p}.$$

In mechanics, the $\mathbf{q}$ variables represent Lagrangian coordinates, the $\mathbf{p}$ variables the corresponding momenta, $\mathbf{f}$ the forces, T is the kinetic energy, V the potential energy, and H the total energy [2].

An explicit RKN method for (2.1) takes the form [5], [8]

$$
\begin{aligned}
\mathbf{Q}_i &= \mathbf{q}_n + h\gamma_i \mathbf{p}_n + h^2 \sum_{j<i} \alpha_{ij}\mathbf{f}(\mathbf{Q}_j),\\
\mathbf{p}_{n+1} &= \mathbf{p}_n + h \sum_{i=1}^{s} b_i \mathbf{f}(\mathbf{Q}_i),\\
\mathbf{q}_{n+1} &= \mathbf{q}_n + h\mathbf{p}_n + h^2 \sum_{i=1}^{s} \beta_i \mathbf{f}(\mathbf{Q}_i),
\end{aligned}
\tag{2.2}
$$

where we assume, unless otherwise stated, that the following well-known condition [5], [8] holds:

$$\beta_i = b_i(1-\gamma_i), \qquad 1 \leqq i \leqq s. \tag{2.3}$$

As in [5], we consider first same as last (FSAL) methods, i.e., methods with

$$\gamma_1 = 0, \qquad \gamma_s = 1, \tag{2.4a}$$

$$\alpha_{sj} = \beta_j, \qquad 1 \leqq j \leqq s-1. \tag{2.4b}$$

Note that (2.4a) implies, via (2.3), that $\beta_s = 0$, and then the last stage $\mathbf{Q}_s$ of the current step coincides with $\mathbf{q}_{n+1}$, which, in turn, is the first stage of the next step. Therefore, a step of an FSAL s-stage method requires only $s-1$ evaluations of $\mathbf{f}$.

The method (2.2) is symplectic if [21], [11], [3], [14]

$$\alpha_{ij} = b_j(\gamma_i - \gamma_j), \qquad i > j. \tag{2.5}$$

For symplectic methods with s stages, we have s coefficients b_i and s coefficients γ_i as free parameters; the coefficients β_i and α_{ij} are determined by (2.3) and (2.5), respectively. On the other hand (2.3), (2.4a), and (2.5) imply (2.4b), so that a symplectic FSAL method has s coefficients b_i and $s-2$ coefficients $\gamma_i, 2 \leqq i \leqq s-1$, as free parameters.

2.2. Derivation of a fourth-order, symplectic, FSAL RKN method. To construct a variable-step symplectic code, we decided to begin with a fourth-order formula. While higher-order formulae are expected to be more efficient, they are also more difficult to construct. For a method (2.2)-(2.3) to have order four, the coefficients should satisfy *seven* order conditions [8]. However, for symplectic methods, not all order conditions are independent [1], [3], [14], [15] and, in fact, it turns out [3] that it is sufficient to impose only *six* of them. For FSAL symplectic methods, four stages furnish six free coefficients, and after imposing order four, no room is left for "tuning" the formula. We then settle for five-stage FSAL symplectic methods, for which a two-parameter family of order-four methods exists. Following a standard practice (see [5] and [6]) we choose among the members of this family the method with "smallest" truncation error.

For smooth problems the $\mathbf{p}$-truncation and $\mathbf{q}$-truncation errors of an RKN method, respectively, possess Taylor expansions of the form [5], [8]

$$\sum_{i=0}^{\infty} h^{i+1} \sum_j c_j'^{(i+1)} \mathbf{F}_j^{(i+1)} \tag{2.6a}$$

and

$$\sum_{i=1}^{\infty} h^{i+1} \sum_k c_k^{(i+1)} \mathbf{F}_k^{(i)}, \tag{2.6b}$$

where the $\mathbf{F}_j^{(i)}$ are the elementary differentials that only depend on the problem (2.1) being integrated, and the $c_j'^{(i+1)}$ and $c_k^{(i+1)}$ are polynomials in the method coefficients α_{ij}, γ_i, β_i, b_i. In (2.6a), the sum in j is extended to all special Nyström trees with $i+1$ nodes, while in (2.6b), the sum in k is extended to all special Nyström trees with i nodes. For fourth-order methods, $c_j'^{(i)}$ and $c_k^{(i)}$ vanish for $i \leqq 4$ and we try to minimize $c_j'^{(5)}$ and $c_k^{(5)}$. We proceed as follows. Let us denote by $\mathbf{c}'^{(i)}$ and $\mathbf{c}^{(i)}$, respectively, the vectors with components $c_j'^{(i)}$ and $c_k^{(i)}$, and set

$$A'^{(5)} = \|\mathbf{c}'^{(5)}\|, \qquad A^{(5)} = \|\mathbf{c}^{(5)}\|. \tag{2.7}$$

(The norm is the standard Euclidean norm.) We consider $\phi = (A'^{(5)})^2 + (A^{(5)})^2$ as a function of the eight free coefficients γ_i, $2 \leqq i \leqq 4$, and b_j, $1 \leqq j \leqq 5$, and use the NAG subroutine E04UCF to minimize ϕ subject to the six equality constraints that impose order four and subject to bounds $-1.5 \leqq \gamma_i, b_j \leqq 1.5$. Of course, the minimization subroutine requires an initial guess for the minimum and converges only to a local minimum that depends on the initial guess. A thousand random initial guesses (subject to $-1.5 \leqq \gamma_i, b_j \leqq 1.5$) were taken, and we kept the local minimum with the smallest value of ϕ. The method thus obtained does not satisfy to machine precision the conditions for order four, because the NAG routine fails in exactly enforcing the equality constraints. We then kept the values b_1 and b_2 provided by the minimization routine and determined γ_i, $2 \leqq i \leqq 4$, and b_j, $3 \leqq j \leqq 5$, by solving the six equations for order four by means of Newton's method in quadruple precision. This of course resulted in a solution that, while being close to that provided by the minimization procedure, satisfies the order conditions to a very high precision. The coefficients are given by

$$\begin{aligned} &\gamma_1 = 0, && b_1 = 0.061758858135626325,\\ &\gamma_2 = 0.205177661542286386, && b_2 = 0.338978026553643355,\\ &\gamma_3 = 0.608198943146500973, && b_3 = 0.614791307175577566,\\ &\gamma_4 = 0.487278066807586965, && b_4 = -0.140548014659373380,\\ &\gamma_5 = 1, && b_5 = 0.125019822794526133, \end{aligned} \tag{2.8}$$

along with (2.3) and (2.5).

For this method the quantities in (2.7) are $A'^{(5)} = 0.00067$ and $A^{(5)} = 0.00071$. As a reference method for the numerical tests, we employ the fourth-order, FSAL, nonsymplectic formula of Dormand, El-Mikkawy, and Prince [5, Table 3]. This has four stages (three evaluations) and $A'^{(5)} = 0.0018$, $A^{(5)} = 0.00046$. Thus, per step, the reference method achieves an accuracy comparable to that of the symplectic method (2.8), but is cheaper by a factor of 3/4. In general, symplectic integrators require, for the same accuracy, more work than their nonsymplectic counterparts since, to impose symplecticness, free parameters are sacrificed that could otherwise be directed at achieving accuracy.

2.3. Error estimation. The standard way [5], [8] of estimating the errors in a pth-order RKN method (2.2) is to supplement (2.2) with formulae

$$\begin{aligned} \hat{\mathbf{p}}_{n+1}\mathbf{p}_n + h \sum_{i=1}^{s} \hat{b}_i \mathbf{f}(\mathbf{Q}_i),\\ \hat{\mathbf{q}}_{n+1} = \mathbf{q}_n + h\mathbf{p}_n + h^2 \sum_{i=1}^{s} \hat{\beta}_i \mathbf{f}(\mathbf{Q}_i) \end{aligned} \tag{2.9}$$

in such a way that $(\mathbf{p}_n, \mathbf{q}_n) \mapsto (\hat{\mathbf{p}}_{n+1}, \hat{\mathbf{q}}_{n+1})$ is an RKN method of order $q<p$ (usually $q=p-1$ or $q=p-2$). Of course, the computation of $(\hat{\mathbf{p}}_{n+1}, \hat{\mathbf{q}}_{n+1})$ employs *the same* function evaluations $\mathbf{f}(\mathbf{Q}_i)$ that are used to compute $(\mathbf{p}_{n+1}, \mathbf{q}_{n+1})$. The difference between the low-order $(\hat{\mathbf{p}}_{n+1}, \hat{\mathbf{q}}_{n+1})$ and high-order $(\mathbf{p}_{n+1}, \mathbf{q}_{n+1})$ results is then taken to be an approximation to the local error at the step $n \mapsto n+1$. For (2.8), we take the order q of the embedded method to be 3.

The weights $\hat{b}_i$, $1 \leqq i \leqq 5$, must satisfy four equations for the local error in $\hat{\mathbf{p}}_{n+1}$ to be $O(h^4)$. These equations are linear in the $\hat{b}_i$'s and it is a simple matter to express $\hat{b}_i$, $1 \leqq i \leqq 4$, in terms of $\hat{b}_5$, which remains a free parameter. The value of $\hat{b}_5$ is chosen according to a procedure suggested by Dormand and Prince. The quantities

$$C'^{(5)} = \frac{\|\mathbf{c}'^{(5)} - \hat{\mathbf{c}}'^{(5)}\|}{\|\hat{\mathbf{c}}'^{(4)}\|}, \qquad B'^{(5)} = \frac{\|\hat{\mathbf{c}}'^{(5)}\|}{\|\hat{\mathbf{c}}'^{(4)}\|} \tag{2.10}$$

should be made as small as possible (letters with a hat refer, of course, to the lower-order method). The Taylor expansion of the $\mathbf{p}$-component of the error estimator $\mathbf{p}_{n+1} - \hat{\mathbf{p}}_{n+1}$ has coefficients $-\hat{c}_j'^{(4)}$ in the order $O(h^4)$ terms and coefficients $c_j'^{(5)} - \hat{c}_j'^{(5)}$ in the order $O(h^5)$ terms (cf. (2.6a)). Thus, a small $C'^{(5)}$ ensures that, in the ($\mathbf{p}$-component of) the error estimator, the leading $O(h^4)$ term dominates over the next, $O(h^5)$, term of the Taylor expansion. This is beneficial, since the mechanism for stepsize selection assumes an $O(h^4)$ behaviour in the estimator. On the other hand, a small $B'^{(5)}$ ensures that the third-order formula used for estimation is sufficiently different from the fourth-order formula used for timestepping. (Note that as the third-order formula comes closer to the fourth-order formula, the denominator in $B'^{(5)}$ tends to 0 and hence $B'^{(5)}$ tends to infinity.) We minimize the function $\phi(\hat{b}_5) = (B'^{(5)})^2 + (C'^{(5)})^2$ by the simple procedure of evaluating ϕ at uniformly spaced values of $\hat{b}_5$ (the spacing used was 0.01). This yields $\hat{b}_5 = 0.2$.

The coefficients $\hat{\beta}_i$, $1 \leqq i \leqq 5$, are seen as free parameters, i.e., they are not derived from $\hat{b}_i$ through (2.3). For the local error in $\hat{\mathbf{q}}_{n+1}$ to be $O(h^4)$, the $\hat{\beta}_i$, $1 \leqq i \leqq 5$, must satisfy two (linear) equations; this leaves three free parameters. We arbitrarily set $\hat{\beta}_5 = 0$ and expressed $\hat{\beta}_1$ and $\hat{\beta}_2$ in terms of $\hat{\beta}_3$ and $\hat{\beta}_4$. The free $\hat{\beta}_3, \hat{\beta}_4$ are now chosen to minimize $(B^{(5)})^2 + (C^{(5)})^2$, where

$$C^{(5)} = \frac{\|\mathbf{c}^{(5)} - \hat{\mathbf{c}}^{(5)}\|}{\|\hat{\mathbf{c}}^{(4)}\|}, \qquad B^{(5)} = \frac{\|\hat{\mathbf{c}}^{(5)}\|}{\|\hat{\mathbf{c}}^{(4)}\|}. \tag{2.11}$$

The minimization was again performed by sampling the objective function on a grid with 0.01×0.01 spacing. The weights of the third-order formula (2.9) embedded in (2.5) are as follows:

$$\begin{aligned}
&\hat{b}_1 = -0.127115143890665440, &&\hat{\beta}_1 = 0.110014238746029571,\\
&\hat{b}_2 = 0.698831995430764851, &&\hat{\beta}_2 = 0.189985761253970428,\\
&\hat{b}_3 = 0.375269477646788521, &&\hat{\beta}_3 = 0.25,\\
&\hat{b}_4 = -0.146986329186887931, &&\hat{\beta}_4 = -0.05,\\
&\hat{b}_5 = 0.2, &&\hat{\beta}_5 = 0.
\end{aligned} \tag{2.12}$$

With this choice the quantities in (2.10) and (2.11) are

$$C'^{(5)} = 1.06, \quad B'^{(5)} = 1.06, \quad C^{(5)} = 0.47, \quad B^{(5)} = 0.25.$$

For the fourth-order nonsymplectic scheme used as a reference method, Dormand, El-Mikkawy, and Prince [5] provide an embedded formula with

$$C'^{(5)} = 1.19, \quad B'^{(5)} = 1.20, \quad C^{(5)} = 1.02, \quad B^{(5)} = 1.03.$$

This shows that the minimizations we carried out above are as successful as those in [5].

2.4. Implementation. The embedded pair (2.8), (2.12) and the reference-embedded pair of Dormand, El-Mikkawy, and Prince were implemented in a standard way following very closely the code DOPRIN in [8].

3. Numerical results. Several test problems, including integrable and nonintegrable Hamiltonians, were used. The main conclusions as to the relative merit of the various algorithms do not greatly depend on the particular test problem, and hence we only report on the results corresponding to the Newton potential [2] $V(q^1, q^2) = -1/\|\mathbf{q}\|$ with initial condition

$$p^1 = 0, \quad p^2 = \sqrt{\frac{1+e}{1-e}}, \quad q^1 = 1-e, \quad q^2 = 0.$$

Here e is a parameter $0 \leqq e < 1$. The solution is 2π-periodic and its projection onto the (configuration) $\mathbf{q}$-space is an ellipse with eccentricity e and major semiaxis 1. Initially, the moving mass is at the pericentre of the ellipse (i.e., the closest it can be to the coordinate origin). After half a period (apocentre), its distance r to the origin is $1+e$. Thus $r_{\max}/r_{\min} = (1+e)/(1-e)$, which is large for large eccentricities. Moreover, the ith derivatives of the force $\mathbf{f}$ behave like $r^{-(i+2)}$, so that, for large eccentricities, the elementary differentials of high order may vary by several orders of magnitude along the orbit. In fact, this well-known test problem with large e (say, $e = 0.9$) is often taken as a "severe test for the stepsize control procedure" of ODE algorithms [6].

The test problem was integrated by combining each of the eccentricities 0.1, 0.3, 0.5, 0.7, and 0.9 with each of the final times $10 \times 2\pi$, $30 \times 2\pi$, $90 \times 2\pi$, $270 \times 2\pi$, $810 \times 2\pi$, $2430 \times 2\pi$, $7290 \times 2\pi$, and $21870 \times 2\pi$. We were particularly interested in long time intervals, as it is in this sort of simulation that the advantages of symplecticness should be felt (see [14]). For short time intervals, the local error of the formula is of paramount importance, and it is as the time interval gets larger that advantages derived from a better qualitative behaviour become more prominent. In celestial mechanics very long time integrations are often required with potentials that are small perturbations of the two-body potential considered here.

In the tests we used the symplectic variable-step code (SV), the nonsymplectic variable-step code (NSV), and also fixed-step implementations of the symplectic formulae (SF) and nonsymplectic formulae (NSF). The variable-step codes were tried with absolute error tolerances of $10^{-4}, 10^{-5}, \ldots, 10^{-11}$, and the fixed-step algorithms were run with stepsizes $2\pi/16, 2\pi/32, \ldots, 2\pi/2048$. Errors were measured in the Euclidean norm of $\mathbb{R}^4$.

Figure 1 gives, for $e = 0.5$ and a final time of 21870 periods, the final error against the computational effort measured by the number of $\mathbf{f}$-evaluations. The figure contains information for the runs that yielded errors in the 10^{-1} to 10^{-4} range, namely,

(i) SV with tolerances 10^{-10}, 10^{-11} (plus signs joined by a dashed line);

(ii) NSV with tolerances 10^{-9}, 10^{-10}, 10^{-11} (circles joined by a solid line);

(iii) SF with timestep $2\pi/256$, $2\pi/512$, $2\pi/1024$ (stars joined by a dashed-dotted line);

(iv) NSF with timestep $2\pi/2048$ ($a \times$ sign).

Let us first compare the results of SF and NSF. Recall that these RKN formulae have error constants of roughly the same size, but SF has four evaluations per step against three evaluations per step in NSF. Thus, on *local error considerations alone*,

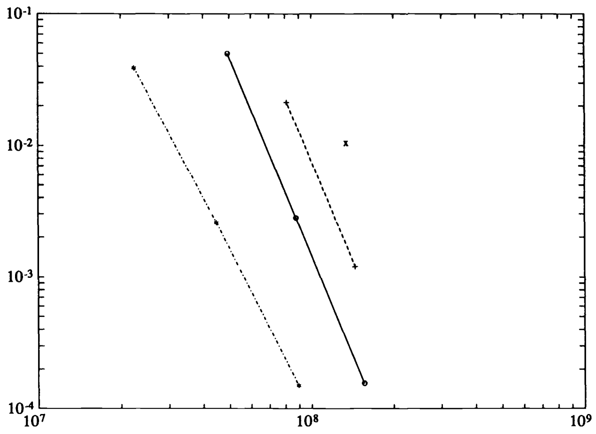

FIG 1. *Error against number of function evaluations, after* 21870 *periods,* $e = 0.5$.

we would expect that for the same global error, the numbers of evaluations of the NSF and SF would be in a ratio 3/4. On the contrary, the experimental results show that, for the same error, the symplectic formula is *four times* less expensive than the nonsymplectic process (ratio 4/1). This shows that there is something in the error propagation mechanism of the symplectic algorithm that gives it a clear advantage over its nonsymplectic counterpart. In the next section we prove rigorously that in the asymptotic expansion of the global error of the symplectic formula, the coefficient of the powers h^4, h^5, h^6, and h^7 grows linearly with the integration time t. Thus in the symplectic formula, for small errors, we need h to be small with respect to $t^{-1/4}$. On the other hand, for the nonsymplectic formula, the coefficient of the leading h^4 term of the global error also increases linearly with t, but the h^5, h^6, and h^7 terms possess coefficients that grow like t^2. If t is large, for small errors, h should be small with respect to $t^{-2/5}$. This is to be compared with $h \ll t^{-1/4}$ for the symplectic case. This shows that for large t symplecticness pays. In fact, when $e = 0.5$, SF improves on NSF if t_{final} is larger than, say, 30 periods.

Turning now to a comparison between NSF and NSV, we observe that for the formula of Dormand, El-Mikkawy, and Prince the use of variable-stepsizes results in a gain in efficiency by a factor of two. In the apocentre, the variable-stepsize code takes stepsizes about seven times as large as those it takes near the pericentre, with the result that, as expected, NSV saves on function evaluations for a given error. Note that the line which joins the NSV points has slope -5 in spite of the method having order four. This is again due to the fact that the coefficient in the leading h^4 term in the global error grows linearly with t, while the coefficients of the subsequent terms grow like t^2; for t large, $t^2h^5 \gg th^4$ and the method behaves as if its order were five (see § 3).

On the other hand, for the symplectic formula, going from fixed to variable-stepsizes results in a *decrease* in efficiency. We will return to this point later. For the present, let us note that, with variable stepsizes, the line joining the points of the symplectic algorithm are in agreement with fifth-order behaviour of the error. In fact, SV and NSV show very similar behaviour. The only difference between them lies in the fact that, for a given error, the costs of NSV and SV are in a ratio 3/4, i.e., in the ratio we would have anticipated from a study of the local errors without taking symplecticness into account.

Like Fig. 1, Fig. 2 corresponds to a final time $21870 \times 2\pi$, but now $e = 0.3$. Again we have displayed the results corresponding to runs for which the errors lie in the 10^{-1} to 10^{-4} range. These are the following:

(i) SV with tolerances 10^{-10}, 10^{-11} (plus signs joined by a dashed line);

(ii) NSV with tolerances 10^{-9}, 10^{-10} (circles joined by a solid line);

(iii) SF with timestep $2\pi/128$, $2\pi/256$, $2\pi/512$ (stars joined by a dashed-dotted line);

(iv) NSF with timestep $2\pi/1024$, $2\pi/2048$ ($\times$ sign, dotted line).

We see that the overall pattern is not changed by changing the eccentricity. The NSV and SV algorithms have efficiencies that are still in the predicted 3/4 ratio. On the other hand, with $e = 0.3$, the advantages of NSV over NSF are less marked, as we would have expected. In fact, for $e = 0.3$, both variable-step codes only vary the stepsize along the orbit by a factor of 3. The NSF points, which for $e = 0.5$ were to the right of the SV dashed line, are now exactly on this SV line.

Figure 3 corresponds to the same final time with $e = 0.7$. The following runs are represented (results for NSF are not reported for stepsizes used, as errors below 10^{-1} could not be obtained):

(i) SV with tolerances 10^{-10}, 10^{-4} (plus signs joined by a dashed line);

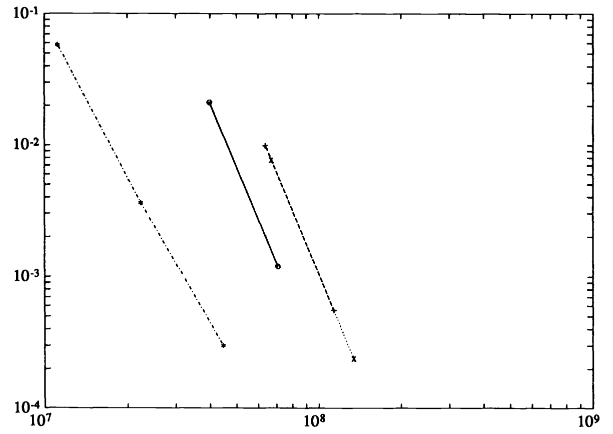

FIG. 2. *Error against number of function evaluations, after* 21870 *periods,* $e = 0.3$.

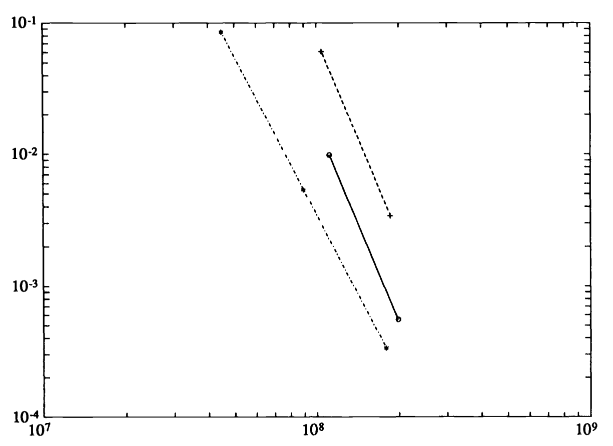

FIG. 3. *Error against number of function evaluations, after* 21870 *periods,* $e = 0.7$.

(ii) NSV with tolerances 10^{-10}, 10^{-11} (circles joined by a solid line);

(iii) SF with time step $2\pi/512, 2\pi/1024, 2\pi/2048$ (stars joined by a dashed-dotted line).

Now SV and NSV become more efficient and change h by a factor of 22. Nevertheless, SF is still the most efficient method: the advantages of symplecticness are not offset by the disadvantages of constant h.

For the smaller values of t_{final} that we tried, the picture is very much the same, except if t_{final} is not large and e is large, SF is the most efficient method, NSV is second, and SV is 4/3 times worse than NSV. For fixed t_{final}, as e approaches 1, the benefits of variable steps become more prominent and NSV improves on SF. For fixed e, as t_{final} increases, the benefits of symplecticness dominate and SF improves on NSV.

Figure 4 gives, for $e = 0.5$, error against time for SV (tolerance 10^{-10}), NSV (tolerance 10^{-9}), SF ($h = 2\pi/1024$), and NSF ($h = 2\pi/2048$). For SF the error shows a linear behaviour with respect to t, as stated earlier. For the other methods the error grows like t^2.

Figure 5 displays, for $e = 0.5$, the error in energy $|H(\mathbf{p}_n, \mathbf{q}_n) - H(\mathbf{p}(t_n), \mathbf{q}(t_n))|$ against time. Of course, the theoretical solution preserves energy $H(\mathbf{p}(t), \mathbf{q}(t)) = H(\mathbf{p}(0), \mathbf{q}(0))$ and consequently the error in energy equals the energy growth

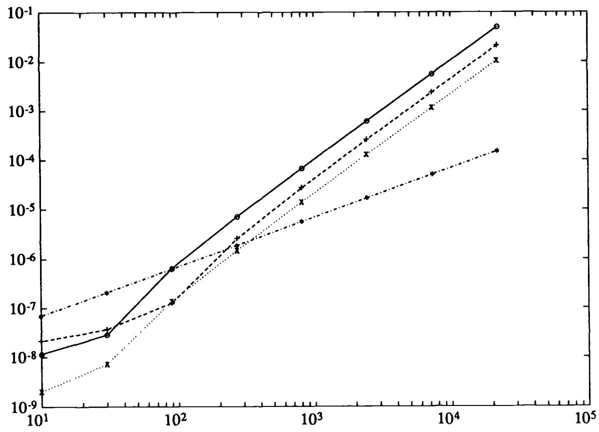

FIG. 4. *Error against time in periods*, $e = 0.5$.

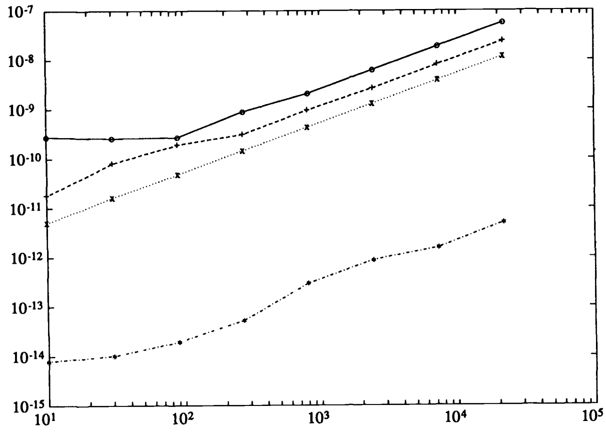

FIG. 5. *Error in energy against time in periods*, $e = 0.5$.

$|H(\mathbf{p}_n, \mathbf{q}_n) - H(\mathbf{p}(0), \mathbf{q}(0))|$. The runs displayed are similar to those shown in Fig. 4. In SV, NSV, and NF the error in energy grows linearly with t. This is somewhat surprising since for SV, NSV, and NF, the errors $|(\mathbf{p}_n, \mathbf{q}_n) - (\mathbf{p}(t_n), \mathbf{q}(t_n))|$ grow like t^2. Also note that SF fails in exactly conserving energy, but its energy errors are much smaller than those associated with the remaining algorithms.

4. Integration of Kepler's problem by one-step methods. We now investigate theoretically some of the experimental findings presented above. Our analysis is not restricted to the RKN case and covers general one-step methods.

4.1. Some remarks on Kepler's problem. Let us begin by rewriting Kepler's problem in the compact form

$$\dot{\mathbf{Y}} = \mathbf{F}(\mathbf{Y}), \tag{4.1}$$

where $\mathbf{Y} = [p^1, p^2, q^1, q^2]^T$ and $\mathbf{F} = [\mathbf{f}^T, \mathbf{p}^T]^T$, with $\mathbf{f} = \mathbf{f}(\mathbf{q})$ the force (cf. (2.1)). The notation $\mathbf{G} = \mathbf{G}(\mathbf{Y})$ will be used to refer to the gradient ∇H of the Hamiltonian H with respect to $\mathbf{Y}$. Note that $\mathbf{F}$ and $\mathbf{G}$ are orthogonal at each point $\mathbf{Y}$ because H is an invariant quantity for (4.1).

We consider (4.1) in the region Ω of $\mathbf{Y}$-space covered by elliptic motions, i.e., the region where the energy H is less than 0 (so that escape to ∞ is not possible), and the angular momentum does not vanish (thus avoiding the case where the trajectory in $\mathbf{q}$-space degenerates into a straight segment). All solutions in Ω are periodic with a period

$$T = T(H) = 2\pi/\sqrt{(2|H|)^3}, \tag{4.2}$$

which only depends on the energy H. A reference for Kepler's problem is, e.g., [2, § 8E].

Let us, once and for all, fix an initial condition $\mathbf{Y}_0 \in \Omega$ and set $\mathbf{F}_0 = \mathbf{F}(\mathbf{Y}_0)$, $\mathbf{G}_0 = \mathbf{G}(\mathbf{Y}_0)$. We denote by Φ the one-period map φ_{T_0}, $T_0 = T(H(\mathbf{Y}_0))$. The analysis to follow relies heavily on the properties of the differential Φ_0' of Φ at $\mathbf{Y}_0$ (this is sometimes referred to as the monodromy operator of the periodic solution that goes through $\mathbf{Y}_0$).

LEMMA 1. *The differential Φ_0' is a rank-one modification of the identity given by*

$$\Phi_0' = I + \mathbf{W}_0 \mathbf{G}_0^T, \tag{4.3}$$

with $\mathbf{W}_0 = T'(H(\mathbf{Y}_0))\mathbf{F}_0$ a nonzero vector in $\mathbb{R}^4$ tangent at $\mathbf{Y}_0$ to the solution of Kepler's problem being investigated. Equivalently, Φ_0' is the linear operator in $\mathbb{R}^4$ such that, for vectors $\mathbf{V}$ orthogonal to $\mathbf{G}_0$,

$$\Phi_0' \mathbf{V} = \mathbf{V} \tag{4.4}$$

and

$$\Phi_0' \mathbf{G}_0 = \mathbf{G}_0 + (\mathbf{G}_0^T \mathbf{G}_0) \mathbf{W}_0. \tag{4.5}$$

Proof. We present two different proofs. The first is analytic and is due to R. D. Skeel. Set

$$\Phi(\mathbf{Y}) = \varphi_\tau(\varphi_{T(H(\mathbf{Y}))}(\mathbf{Y})) = \varphi_\tau(\mathbf{Y}),$$

where $\tau = T_0 - T(H(\mathbf{Y}))$ is a function of $\mathbf{Y}$. Then

$$\begin{aligned}\Phi'(\mathbf{Y}) = &= \varphi_\tau'(\mathbf{Y}) + \left(\frac{d}{d\tau}\varphi_\tau(\mathbf{Y})\right)(\nabla\tau)^T \\ &= \varphi_\tau'(\mathbf{Y}) - \left(\frac{d}{d\tau}\varphi_\tau(\mathbf{Y})\right) T'(H(\mathbf{Y}))\mathbf{G}(\mathbf{Y})^T,\end{aligned}$$

and, since φ_t as a function of t satisfies (4.1),

$$\Phi'(\mathbf{Y}) = \varphi'_\tau(\mathbf{Y}) - \mathbf{F}(\varphi_\tau(\mathbf{Y}))T'(H(\mathbf{Y}))\mathbf{G}(\mathbf{Y})^T.$$

Now evaluation at $\mathbf{Y}=\mathbf{Y}_0$ leads to $\tau=0$ and hence to φ_τ equal to the identity map so that $\varphi'_\tau(\mathbf{Y}_0)=I$ and (4.3) follows.

The second proof is more geometric. Consider a vector $\mathbf{V}$ orthogonal to $\mathbf{G}_0$ and consider the new initial condition $\tilde{\mathbf{Y}}_0=\mathbf{Y}_0+\varepsilon\mathbf{V}$ with ε small. Since the increment $\varepsilon\mathbf{V}$ is orthogonal to the energy gradient $\mathbf{G}_0$, the new energy $H(\tilde{\mathbf{Y}}_0)$ equals the old energy $H(\mathbf{Y}_0)$ and the new period $T(H(\tilde{\mathbf{Y}}_0))$ equals the old period T_0 (see (2.1)). Here and later "equal" is understood to mean "equal except for $O(\varepsilon^2)$ terms." Hence $\Phi(\tilde{\mathbf{Y}}_0)=\varphi_{T_0}(\tilde{\mathbf{Y}}_0)$ equals $\tilde{\mathbf{Y}}_0$, which implies, by the definition of differential, that $\Phi'_0(\varepsilon\mathbf{V})=\varepsilon V$. This proves (4.4). Assume now that the new initial condition is chosen to be $\tilde{\mathbf{Y}}_0=\mathbf{Y}_0+\varepsilon\mathbf{G}_0$. Now the new energy is in excess of $H(\mathbf{Y}_0)$ by an amount $\varepsilon(\mathbf{G}_0^T\mathbf{G}_0)$ and, accordingly, the new period is in excess from T_0 by an amount $\delta=\varepsilon T'(H(\mathbf{Y}_0))(\mathbf{G}_0^T\mathbf{G}_0)$. Hence after T_0 units of time $\mathbf{Y}$ has not had time to return to its initial position and rather lags *behind* by a vector $\delta\mathbf{F}_0$, because $\mathbf{F}_0$ is the velocity of the flow at $\mathbf{Y}_0$. This proves (4.5).

After (4.3) it is a simple matter to compute the Nth power of Φ'_0. This is given by

$$\Phi_0'^N = I + N\mathbf{W}_0\mathbf{G}_0^T. \tag{4.6}$$

This formula essentially says (cf. the second proof of the lemma above) that if $\tilde{\mathbf{Y}}_0$ is an initial condition of the form $\mathbf{Y}_0+\varepsilon\mathbf{V}$, ε small, then after N time increments of length T^0, the solution $\varphi_{NT^0}(\tilde{\mathbf{Y}}_0)$ that starts at $\tilde{\mathbf{Y}}_0$ differs from the solution $\varphi_{NT^0}(\mathbf{Y}_0)=\mathbf{Y}_0$ by terms $\varepsilon\mathbf{V}+\varepsilon N(\mathbf{G}_0^T\mathbf{V})\mathbf{W}_0$. The difference grows linearly with N; this growth is in the direction of $\mathbf{W}_0$, tangent at $\mathbf{Y}_0$ to the solution curve, and furthermore only depends on the initial deviation $\varepsilon\mathbf{V}$ through its component $\varepsilon(\mathbf{G}_0^T\mathbf{V})$ in the direction of $\mathbf{G}_0$.

4.2. Basic error estimate. Let us consider a smooth one-step method ψ_h for the numerical integration of Kepler's problem. This method is assumed to be convergent of order p, i.e., $\psi_h^n(\mathbf{Y}_0)-\varphi_h^n(\mathbf{Y}_0)=O(h^p)$ as $h\to 0$ with nh in a bounded time interval. Furthermore, we assume that the differentials (Jacobian matrices) $(\psi_h^n)'(\mathbf{Y})$ also converge with order p to the differential of the flow, i.e., $(\psi_h^n)'(\mathbf{Y})-(\varphi_h^n)'(\mathbf{Y})=O(h^p)$, $h\to 0$, nh bounded. This is automatically satisfied by most standard methods, including Runge-Kutta and Runge-Kutta-Nyström methods.

For simplicity, we only consider the case where the steplength h is of the form T_0/ν, with ν a positive integer, and look at the difference $\mathbf{E}_N$ between the numerical $\psi_h^{\nu N}(\mathbf{Y}_0)$ and theoretical $\varphi_h^{\nu N}(\mathbf{Y}_0)=\varphi_{NT_0}(\mathbf{Y}_0)=\mathbf{Y}_0$ after N periods of the motion. The extension to general values of h and times which are not whole multiples of T_0 is possible but messy, and provides no further insight.

Set $\Psi_h=\psi_h^\nu$ so that Ψ_h is the mapping that advances the numerical solution T_0 units of time. We can then write

$$\begin{aligned}\mathbf{E}_N &= \Psi_h^N(\mathbf{Y}_0)-\mathbf{Y}_0=\Psi_h(\Psi_h^{N-1}(\mathbf{Y}_0))-\Psi_h(\mathbf{Y}_0)+\mathbf{E}_1\\ &=\Psi'_h\mathbf{E}_{N-1}+O(\|\mathbf{E}_{N-1}\|^2)+\mathbf{E}_1\\ &=\Psi'_h\mathbf{E}_{N-1}+\mathbf{E}_1+O(h^{2p})\\ &=\Phi'_0\mathbf{E}_{N-1}+\mathbf{E}_1+O(h^{2p}).\end{aligned}$$

Here and later, the constant implied in the O symbol depends on N. By induction,

$$\mathbf{E}_N=[I+\Phi'_0+\cdots+\Phi_0'^{N-1}]\mathbf{E}_1+O(h^{2p}).$$

We apply (4.6) to conclude the following theorem.

THEOREM 1. *Under the hypothesis above,*

$$\mathbf{E}_N = N\mathbf{E}_1 + \tfrac{1}{2}(N^2 - N)(\mathbf{G}_0^T\mathbf{E}_1)\mathbf{W}_0 + O(h^{2p}). \tag{4.7}$$

In other words, except for $O(h^{2p})$ terms, the error $\mathbf{E}_N$ after N periods of the solution have been computed grows quadratically with N. The leading N^2 growth is in the direction tangent to the solution at $\mathbf{Y}_0$, corresponding to a phase error along the trajectory. After taking the inner product of (4.7) and the energy gradient $\mathbf{G}_0$, we conclude, in view of the orthogonality of $\mathbf{G}_0$ and $\mathbf{F}_0$, that the energy error after N periods is, except for $O(h^{2p})$ terms, N times the energy error after the first period (cf. Fig. 5).

4.3. The symplectic case. In this subsection we look at the situation where ψ_h is symplectic. The key fact for the analysis [14] is that, given an arbitrarily large positive integer q, it is possible to construct a modified autonomous Hamiltonian function $\tilde{H}_h = H + O(h^p)$ such that ψ_h is consistent of order q with the Hamiltonian problem with Hamiltonian $\tilde{H}_h$, i.e., $\psi_h - \varphi_{h,\tilde{H}_h} = O(h^{q+1})$, where $\varphi_{h,\tilde{H}_h}$ is the h-flow of the problem with Hamiltonian $\tilde{H}_h$. In other words, the mapping ψ_h we are using to integrate Kepler's problem can be seen (except for $O(h^{q+1})$ terms) as the exact flow of a nearby Hamiltonian problem with Hamiltonian $\tilde{H}_h$. Here we choose $q = 2p$. The computed points $\mathbf{Y}_n$, which are $O(h^p)$ away from the solution $\mathbf{Y}(t_n)$ of Kepler's problem, are only $O(h^{2p})$ away from the solution through $\mathbf{Y}_0$ of the modified problem. In particuular,

$$\Psi_h(\mathbf{Y}_0) - \varphi_{T_0,\tilde{H}_h}(\mathbf{Y}_0) = O(h^{2p})$$

and, by implication,

$$\tilde{H}_h(\Psi_h(\mathbf{Y}_0)) - \tilde{H}_h(\varphi_{T_0,\tilde{H}_h}(\mathbf{Y}_0)) = O(h^{2p}). \tag{4.8}$$

On the other hand, $\tilde{H}_h$ is a conserved quantity for the flow $\varphi_{T_0,\tilde{H}_h}$ so that (4.8) can be rewritten

$$\tilde{H}_h(\Psi_h(\mathbf{Y}_0)) - \tilde{H}_h(\mathbf{Y}_0) = O(h^{2p}). \tag{4.9}$$

Taylor expansion of the left-hand side of (4.9) yields

$$\tilde{H}_h(\Psi_h(\mathbf{Y}_0)) - \tilde{H}_h(\mathbf{Y}_0) = \mathbf{G}_0^{h^T}\mathbf{E}_1 + O(\|\mathbf{E}_1\|^2) = \mathbf{G}_0^{h^T}\mathbf{E}_1 + O(h^{2p}), \tag{4.10}$$

where $\mathbf{G}_0^h$ is the gradient of $\tilde{H}_h$ at $\mathbf{Y}_0$. Comparison of (4.9) with (4.10) shows that $\mathbf{G}_0^{h^T}\mathbf{E}_1 = O(h^{2p})$; the error after one period $\mathbf{E}_1$ is "almost" orthogonal to the gradient $\mathbf{G}_0^h$ of the modified energy $\tilde{H}_h$. Finally,

$$|\mathbf{G}_0^T\mathbf{E}_1| = |(\mathbf{G}_0 - \mathbf{G}_0^h)^T\mathbf{E}_1 + \mathbf{G}_0^{h^T}\mathbf{E}_1| \leqq \|\mathbf{G}_0 - \mathbf{G}_0^h\|\,\|\mathbf{E}_1\| + |\mathbf{G}_0^{h^T}\mathbf{E}_1| = O(h^{2p}).$$

Here we have used the fact that the derivatives of $\tilde{H}_h$ approximate the derivatives of H to the same order, $O(h^p)$, to which $\tilde{H}_h$ approximates H; see [14]. The last bound implies that for a symplectic method the component $\mathbf{G}_0^T\mathbf{E}_1$ of the error $\mathbf{E}_1$ is $O(h^{2p})$, so that in view of (4.7), we may state (cf. the dashed-dotted lines in Figs. 4 and 5) the following theorem.

THEOREM 2. *For a constant-stepsize symplectic method,*

$$\mathbf{E}_N = N\mathbf{E}_1 + O(h^{2p}).$$

Furthermore, the energy error satisfies

$$H(\Psi_h^N(\mathbf{Y}_0)) - H(\mathbf{Y}_0) = O(h^{2p}).$$

4.4. The nonsymplectic case. In this section we explain the experimental fact that the fourth-order method NSF employed in § 3 behaves as if its order were five. We consider a general one-step method as in § 4.3, but now assume that the order p is *even* ($p \geqq 2$) and, furthermore, that ψ_h possesses some symmetries. First, we assume that

$$(\mathbf{p}, \mathbf{q}) = \psi_h(\mathbf{p}_0, \mathbf{q}_0) \Rightarrow (-\mathbf{p}, \mathbf{q}) = \psi_{-h}(-\mathbf{p}_0, \mathbf{q}_0). \tag{4.11}$$

This symmetry holds for the flow of any problem of the form (2.1). Note that according to (2.2), RKN methods obey (4.11). Second, we assume that $(\mathbf{p}, \mathbf{q}) = \psi_h(\mathbf{p}_0, \mathbf{q}_0)$ inherits from φ_t the rotational symmetry of Kepler's problem. Again, this is true for standard methods.

Let us denote by $\mathbf{M}(t)$ the coefficient of the leading $O(h^p)$ term in the asymptotic expansion of the global error of the method ψ_h. It is well known that $\mathbf{M}$ satisfies the variational equation

$$\frac{d\mathbf{M}(t)}{dt} = J(t)\mathbf{M}(t) + \mathbf{L}(t), \tag{4.12}$$

where $J(t)$ is the Jacobian of the vector field evaluated at the theoretical solution $\varphi_t(\mathbf{Y}_0)$, and $\mathbf{L}(t)$ is the coefficient of the leading $O(h^{p+1})$ term in the expansion of the local error. We need the following lemma.

LEMMA 2. *Let $dy/dt = f(y)$ be any smooth differential system with a conserved quantity H. Let*

$$\frac{dm(t)}{dt} = J(t)m(t) + l(t) \tag{4.13}$$

be the corresponding variational equation at a solution of the system. Then,

$$\frac{d}{dt}((\nabla H)^T m) = (\nabla H)^T l.$$

Proof. From (4.13),

$$\frac{d}{dt}(\nabla H)^T m = (\nabla H)^T J(t) m + (\nabla H)^T l + \left(\frac{d}{dt}\nabla H\right)^T m.$$

Differentiation with respect to y of the identity $(\nabla H)^T f \equiv 0$ and evaluation of the result at the solution of $dy/dt = f(y)$ leads to $(\nabla H)^T J + (d\nabla H/dt)^T = 0$, and the proof is complete.

The application of Lemma 2 to (4.12) reveals that

$$\frac{d}{dt}\mathbf{G}^T\mathbf{M} = \mathbf{G}^T\mathbf{L}.$$

We integrate over one period to get

$$\mathbf{G}_0^T\mathbf{M}(T_0) = \int_0^{T_0} \mathbf{G}^T\mathbf{L}\, dt. \tag{4.14}$$

Now let us express $\mathbf{G}^T\mathbf{L}$ in terms of polar coordinates r, $\dot{r}$, θ, $\dot{\theta}$. The rotational symmetry assumed above implies that $\mathbf{G}^T\mathbf{L}$ does not depend on θ. By conservation of angular momentum along the solution, $\dot{\theta}$ can be expressed in terms of r. Thus, in (4.14) the integrand is a function of r and $\dot{r}$. Furthermore, $\mathbf{G}^T\mathbf{L}$ must be *odd* in $\dot{r}$. This is because $h^{p+1}\mathbf{G}^T\mathbf{L}$ is the leading term in energy error after one step, and by (4.11) such an error remains invariant when h is changed into $-h$ and $\dot{r}$ into $-\dot{r}$, while keeping r constant. Now, as t increases from 0 to T_0, the solution takes each value of r twice with opposite values of $\dot{r}$. (This occurs when the moving point passes through points in Kepler's ellipse that are symmetric with respect to the major axis.) Hence, the integral in (4.14) vanishes and $\mathbf{G}_0^T\mathbf{M}(T_0)=0$, i.e., $\mathbf{G}_0^T\mathbf{E}_1=O(h^{p+1})$. When this information is taken into (4.7) we see that $\mathbf{E}_N$ contains $O(Nh^p)$ and $O(N^2h^{p+1})$ terms. Assume that N is very large. The terms Nh^p, N^2h^{p+1} are of the same size when $h=1/N$, which is unrealistically small since for $h=1/N$, $Nh^p=N^2h^{p+1}=N^{-p+1}\ll 1$. Hence, for realistic choices of h, N^2h^{p+1} is much larger than Nh^p, and the method behaves as an order $p+1$ method with a large N^2 error constant.

4.5. Variable steps. Let us now study the situation for the variable-step integrators. In the experiments we only used *one* initial condition $\mathbf{Y}_0$. The choice of initial condition and tolerance determines the sequence of stepsizes $h_1, h_2, \ldots$ used in the integration. In a "thought experiment," let us imagine that even if other neighbouring initial conditions had been used, we would have still employed the same sequence $h_1, h_2, \ldots$ used for $\mathbf{Y}_0$, rather than letting the step-changing mechanism dictate the choices of stepsizes. This is actually a recommended procedure that ensures that the output of an automatic code is a smooth function of the initial data [8, § II.5]. In our context it also ensures that, if a symplectic formula ψ_h is used, then the transformation $\psi_{h_m}\cdots\psi_{h_1}$, which advances the solution from time $t=0$ to time $t_m=h_1+\cdots+h_m$, is indeed a symplectic transformation. In extending the analysis above to the variable-step experiments, we encounter some difficulties. Previously, we used the fact that we advanced the solution from time $t=0$ to time $t=NT_0$ by iterating N times an operator Ψ_h that advances the solution T_0 units of time. This is not quite true now; it is possible for T_0 not to be a steppoint t_m. But even if it is a steppoint, the sequence of stepsizes employed to go around the orbit in the second, third, ... period is likely to be slightly different from the sequence used in the first period. These difficulties will be ignored for the analysis: we assume that T_0 is a steppoint t_m, and that the sequence of stepsizes used to cover the nth period $(n-1)T_0\leqq t\leqq nT_0$ is just a duplicate of the sequence used to cover the first period $0\leqq t\leqq T_0$. These assumptions are "almost" satisfied for small tolerances; see [20], where it is rigorously shown that, essentially, variable-step algorithms employ a steplength that only depends on the current point in phase space so that, for periodic problems, stepsizes repeat themselves periodically. With our assumptions, the solution after N orbits is given by $\Psi_h^N(\mathbf{Y}_0)$, where $\Psi_h=\psi_{h_m}\cdots\psi_{h_1}$. Then the analysis in § 4.2 leading to Theorem 1 holds with h, the maximum stepsize. Furthermore, the cancellation described in § 4.4 also holds. The functions $\mathbf{M}$ and $\mathbf{L}$ still make sense [16] provided that the stepsizes satisfy

$$h_n=\gamma(t_n)h+O(h^2),$$

with γ a stepsize function; (4.12) must be replaced by [16]

$$\frac{d\mathbf{M}(t)}{dt}=J(t)\mathbf{M}(t)+\gamma(t)\mathbf{L}(t),$$

and (4.14) becomes

$$\mathbf{G}_0^T\mathbf{M}(T_0)=\int_0^{T_0}\gamma^p\mathbf{G}^T\mathbf{L}\,dt.$$

From here we conclude that $\mathbf{G}_0^T\mathbf{E}_1=O(h^{p+1})$ under the extra hypothesis that γ takes the same value as the moving body passes through points in configuration space that are mutually symmetric with respect to the major axis. This hypothesis is certainly reasonable.

On the other hand, the material in § 4.3 does not appear to be extensible to the variable-step situation. Indeed, the experiments indicate that it *cannot* be extended. When trying to extend the analysis in § 4.3 to variable steps, we encounter the difficulty that the modified Hamiltonian $\tilde{H}_h$ depends on the steplength. The computed $(\mathbf{p}_1, \mathbf{q}_1)$ is close to the solution S_1 of the system with Hamiltonian $\tilde{H}_{h_1}$ which at $t=0$ passes through $(\mathbf{p}_0, \mathbf{q}_0)$. The computed $(\mathbf{p}_2, \mathbf{q}_2)$ is close to the solution S_2 of the system associated with $\tilde{H}_{h_2}$ that at $t=h_1$ passes through $(\mathbf{p}_1, \mathbf{q}_1)$, etc. Clearly, $S_1 \neq S_2$ (unless $\tilde{H}_{h_1} = \tilde{H}_{h_2}$) and we do not have a single trajectory near which the computed points stay. There is not a single pseudoenergy $\tilde{H}_h$ "almost" conserved by the numerical points, and nothing can be said of the projection $\mathbf{G}_0^T\mathbf{E}_1$, whose smallness is the key to the success of the symplectic constant-stepsize integrators.

4.6. Remarks and extensions. The fact that for Kepler's problem standard integrators lead to quadratic error growth while symplectic constant-stepsize integrators lead to linear error growth has been noted before in the literature; see Kinoshita, Yoshida, and Nakay [10]. In [22], Yoshida studies the energy error in the symplectic integration of Kepler's problem. His analysis is only formal and, like ours, resorts to a modified Hamiltonian $\tilde{H}_h$. Yoshida assumes that the modified Hamiltonian can be chosen to satisfy

$$\psi_h - \phi_{h,\tilde{H}_h} = 0, \tag{4.15}$$

i.e., that a modified Hamiltonian problem exists so that the computed points exactly solve the modified problem. However, it is known that for nonlinear problems, while it is possible to construct a divergent formal power series for $\tilde{H}_h$ fulfilling (4.15), no actual function $\tilde{H}_h$ can satisfy (4.15). Therefore, the analysis in [22] is only of heuristic value. (Note that rather than (4.15), we assumed only that $\psi_h - \phi_{h,\tilde{H}_h} = O(h^{2p})$.)

On the other hand, the ideas used in the analysis in this section are not restricted to Kepler's problem. For instance, in §§ 4.2–4.4, it is enough to assume that all solutions of the problem being integrated are periodic with a period that only depends on the value of the energy H (and actually changes with H). These assumptions are satisfied by all nonlinear one-degree-of-freedom oscillators, such as the well-known pendulum equation. Therefore, the conclusions in §§ 4.2–4.4 hold for such oscillators. This proves Conjecture 3 in § IV.6 D of Stoffer's thesis [18], which states that for nonlinear oscillators, standard methods have quadratic error growth, and that symplectic methods produce errors that only grow linearly. (Nonlinearity is essential to guarantee a nontrivial dependence of the period on the energy, leading to $\mathbf{W}_0 \neq \mathbf{0}$ in (4.6).)

5. Conclusions. Let us summarize our findings.

(i) The experiments with Kepler's problem reported above and experiments with other Hamiltonian problems (not reported in this paper) reveal that constant-stepsize symplectic integrators can be more efficient than variable-step codes. This provides motivation for the further study of symplectic integration. Comparisons between symplectic and nonsymplectic formulae presented so far in the literature (see [14] for references) have concentrated on constant stepsizes. Our experiments indicate that it is reasonable to expect that, in the future, symplectic software can be developed which outperforms, on Hamiltonian problems, standard variable-step codes. The paper by Herbst and Ablowitz [9], written after the present work was completed, provides a dramatic example of a simple symplectic algorithm outperforming NAG library software.

(ii) The advantages of using symplectic formulae are lost when these formulae are used in a variable-stepsize environment. This came as a surprise to us. However, after completing this work, we discovered that in 1988, Stoffer [19] had argued that symplectic integrators should not be used with variable stepsizes. His argument is as follows. Integrating a system of ODEs $d\mathbf{y}/dt = \mathbf{f}(\mathbf{y})$ with a variable-step algorithm is "equivalent" [20] to integrating, with constant stepsizes, a transformed problem $d\mathbf{y}/d\tau = r(\mathbf{y})\mathbf{f}(\mathbf{y})$, where the new time τ is related to the old time by $dt/d\tau = r(\mathbf{y})$. The transformed system is not Hamiltonian, even if the original system is, so that the advantages of symplecticness are lost in the transformation. An alternative argument to justify the failure of variable-step symplectic algorithms has been put forward in [14]. A key property of symplectic formulae ψ_h for a Hamiltonian problem with Hamiltonian H is the existence of a modified Hamiltonian $\tilde{H}_h$ in such a way that ψ_h "almost" coincides with the h-flow $\phi_{h,\tilde{H}_h}$ of $\tilde{H}_h$. "Almost" means that, given any large integer q, $\tilde{H}_h$ can be found in such a way that $\psi_h - \phi_{h,\tilde{H}_h} = O(h^{q+1})$. With constant stepsizes, it is possible to interpret the error in a "backward" way: a numerically calculated solution corresponding to H is "almost" an exact solution of a neighbouring Hamiltonian $\tilde{H}_h$. In § 4.5 we saw how such a backward-error analysis interpretation fails in a variable-stepsize situation. An additional reference useful in connection with variable steps for symplectic integrators is [17].

(iii) For the particular cases of Kepler's problem and nonlinear one-degree-of-freedom oscillators, a complete analysis has been presented of the performance of symplectic and nonsymplectic integrators. It has been shown that the advantages of symplectic integrators include not only better qualitative behaviour, but also better quantitative properties in the error growth mechanism.

ITERATIVE DEFECT CORRECTION AND MULTIGRID ACCELERATED EXPLICIT TIME STEPPING SCHEMES FOR THE STEADY EULER EQUATIONS*

MARIE-HÉLÈNE LALLEMAND† AND BARRY KOREN‡

Abstract. Analytical and experimental convergence results are presented for a novel pseudo-unsteady solution method for higher-order accurate upwind discretizations of the steady Euler equations. Comparisons are made with an existing pseudo-unsteady solution method. Both methods make use of nonlinear multigrid for acceleration and nested iteration for the fine-grid initialization. The new method uses iterative defect correction. Analysis shows that it not only has better stability but it also has better smoothing properties. The analytical results are confirmed by numerical experiments, which show better convergence and efficiency.

Key words. defect correction, multigrid, explicit time stepping, Euler equations

AMS subject classifications. 65B05, 65N10, 65N20, 65N30, 65N40, 76G15

1. Introduction.

1.1. Equations. The equations considered are the steady, two-dimensional, compressible Euler equations

$$\frac{\partial F(W)}{\partial x}+\frac{\partial G(W)}{\partial y}=0, \tag{1.1}$$

where

$$W=\begin{pmatrix}\rho\\ \rho u\\ \rho v\\ \rho e\end{pmatrix},\quad F(W)=\begin{pmatrix}\rho u\\ \rho u^2+p\\ \rho uv\\ \rho u(e+p/\rho)\end{pmatrix},\quad G(W)=\begin{pmatrix}\rho v\\ \rho vu\\ \rho v^2+p\\ \rho v(e+p/\rho)\end{pmatrix}. \tag{1.2}$$

Assuming a perfect gas, the total energy e satisfies $e=p/(\rho(\gamma-1))+\frac{1}{2}(u^2+v^2)$. The ratio of specific heats γ is assumed to be constant.

1.2. Spatial discretization. The computational grid is obtained by a hybrid finite element—finite volume partition. A (possibly unstructured) finite element triangularization is used as the basic partition. A cell-centered finite volume partition is derived from the finite element partition by connecting the centers of the triangle sides in the manner illustrated in Fig. 1. The finite volume grid gives us the easy possibility of grouping together the nodes associated with contiguous finite volumes. If we take unions of control volumes this results in a new coarser mesh. Repetition of this operation gives coarser and coarser meshes. For details about this hybrid way of constructing finite volume grids, see [1]. For applications in single-grid Euler and Navier-Stokes flow computations, we refer to [5] and [23], respectively. For details about the coarsening process (multilevel gridding), we refer to [16].

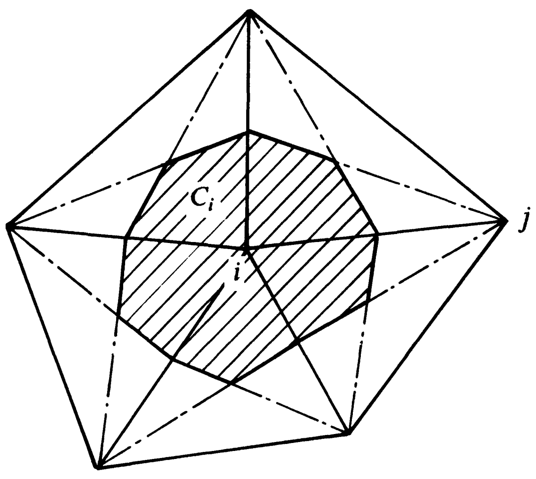

FIG. 1. *Finite volume C_i.*

On the finest grid, for all finite volumes C_i, $i=1,2,\dots,N$, we consider the integral form

$$(1.3)\qquad \oint_{\partial C_i} (F(W)n_x + G(W)n_y)\,ds = 0, \qquad i=1,2,\dots,N,$$

with n_x and n_y the x- and y-component of the outward unit normal on the volume boundary ∂C_i. For the Euler equations, because of their rotational invariance, (1.3) may be rewritten as

$$(1.4)\qquad \oint_{\partial C_i} T^{-1}(n_x, n_y)F(T(n_x, n_y)W)\,ds = 0, \qquad i=1,2,\dots,N,$$

where $T(n_x, n_y)$ is the rotation matrix

$$(1.5)\qquad T(n_x, n_y) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & n_x & n_y & 0 \\ 0 & -n_y & n_x & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

For simplicity, we assume the flux to be constant across each bisegment ∂C_{ij} of the boundary ∂C_i, where $\partial C_{ij} = \partial C_i \cap \partial C_j$ is the common boundary between the neighboring volumes C_i and C_j (Fig. 2(a)). Hence, $\partial C_i = \bigcup \partial C_{ij}, j=1,2,\dots,n_i$, with n_i the number of neighboring volumes C_j. (In the example of Fig. 1; $n_i=5$.) Since we have assumed that the flux is constant along ∂C_{ij}, it is equal to the flux across the straight segment

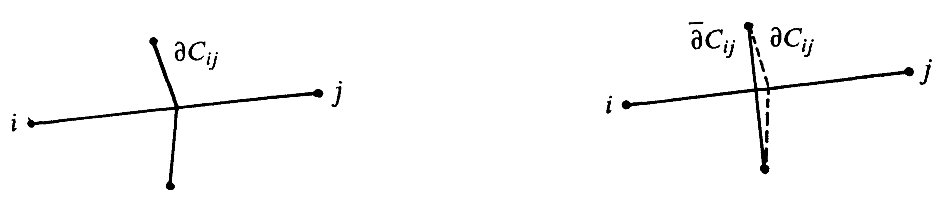

FIG. 2. *Segments in between finite volumes C_i and C_j.* (a) *Bisegment ∂C_{ij}.* (b) *Straight segment $\bar{\partial} C_{ij}$.*

$\bar{\partial} C_{ij}$ connecting the two extreme points of ∂C_{ij} (Fig. 2(b)). If we introduce the outward unit normal $\bar{n}_{ij} = ((\bar{n}_x)_{ij}, (\bar{n}_y)_{ij})^T$ along each $\bar{\partial} C_{ij}, j = 1, 2, \ldots, n_i$, with the assumption of a constant flux, the contour integral (1.4) can be rewritten as the sum

$$\sum_{j=1}^{n_i} \bar{T}_{ij}^{-1} F(\bar{T}_{ij} W_{ij}) l_{ij} = 0, \qquad i = 1, 2, \ldots, N, \tag{1.6}$$

where $\bar{T}_{ij} = T((\bar{n}_x)_{ij}, (\bar{n}_y)_{ij})$, where W_{ij} is some value of W depending on for instance W_i and W_j, and where l_{ij} is the length of the segment $\bar{\partial} C_{ij}$.

Crucial in (1.6) is the way in which the cell face flux $F(\bar{T}_{ij} W_{ij})$ is evaluated. For this we use an upwind scheme that follows the Godunov principle [8], which assumes that the constant flux vector along each segment $\bar{\partial} C_{ij}$ is determined only by a uniformly constant left and right cell face state (W_{ij}^l and W_{ij}^r). The one-dimensional Riemann problem, which then arises at each cell face, is solved in an approximate way. With this, (1.6) can be further written as

$$\sum_{j=1}^{n_i} \bar{T}_{ij}^{-1} \Phi(\bar{T}_{ij} W_{ij}^l, \bar{T}_{ij} W_{ij}^r) l_{ij} = 0, \qquad i = 1, 2, \ldots, N, \tag{1.7}$$

where Φ denotes the approximate Riemann solver. Several approximate Riemann solvers exist (see, for example, [20] and [22]). In this paper, without any particular motivation, we restrict ourselves to the application of Osher's approximate Riemann solver [20].

The flux evaluation, and so the space discretization, may be either first- or higher-order accurate. First-order accuracy is obtained in the standard way; at each finite volume wall, the left and right cell face state, which must be inserted in the numerical flux function, are taken equal to those in the corresponding adjacent volumes

$$W_{ij}^l = W_i, \tag{1.8a}$$

$$W_{ij}^r = W_j. \tag{1.8b}$$

Whereas the first-order accurate discretization is applied at all levels, the higher-order discretization is applied at the finest grid only, using the finite element partition existing there. Higher-order accuracy is obtained with a MUSCL approach [18]. Here, W_{ij}^l and W_{ij}^r are derived from linear interpolations. On each volume C_i around the triangle-vertex i an approximate gradient, denoted by $(\bar{\nabla} W)_i$, is derived by integrating the gradient of the linear interpolant of W over all the triangles that have i as a vertex:

$$(\bar{\nabla} W)_i = \left[\left(\frac{\bar{\partial} W}{\partial x} \right)_i, \left(\frac{\bar{\partial} W}{\partial y} \right)_i \right]^T, \tag{1.9a}$$

with

$$\left(\frac{\bar{\partial} W}{\partial x} \right)_i = \frac{\int_{\text{supp}\,(i)} (\partial W / \partial x)\, dx\, dy}{\int_{\text{supp}\,(i)} dx\, dy}, \tag{1.9b}$$

$$\left(\frac{\bar{\partial} W}{\partial y} \right)_i = \frac{\int_{\text{supp}\,(i)} (\partial W / \partial y)\, dx\, dy}{\int_{\text{supp}\,(i)} dx\, dy}. \tag{1.9c}$$

Here, supp (i) denotes the union of triangles which have i as a vertex. Then for each pair of neighboring vertices (i, j) we compute the extrapolated values

$$W_{ij}^l = W_i + \tfrac{1}{2} (\bar{\nabla} W)_i \cdot \overline{ij}, \tag{1.10a}$$

$$W_{ij}^r = W_j - \tfrac{1}{2} (\bar{\nabla} W)_j \cdot \overline{ij}. \tag{1.10b}$$

On equidistant grids, this higher-order accurate discretization can be formally proved to be second-order accurate. The proof is still valid for nearly equidistant grids. In this paper we do not analyze orders of accuracy; the discretization is already known. It has been described in more detail in other papers; see, for example, [7].

In order to ensure monotonicity, while preserving the higher-order accuracy in smooth flow regions, the higher-order values W^l_{ij} and W^r_{ij} according to (1.10) can be replaced by limited values that do not affect the order of accuracy.

1.3. Existing solution method. To solve the steady discretized system (1.7), we consider the unsteady, semidiscrete system of ordinary differential equations

$$\frac{dW_i}{dt} = R_i, \qquad i = 1, 2, \ldots, N. \tag{1.11}$$

The natural choice for R_i is

$$R_i = \frac{-1}{A_i} \sum_{j=1}^{n_i} \bar{T}_{ij}^{-1} \Phi(\bar{T}_{ij} W^l_{ij}, \bar{T}_{ij} W^r_{ij}) l_{ij}, \tag{1.12}$$

where A_i is the area of finite volume C_i.

As an upwind analogue to Jameson's central method [13], in [16] and [17] an explicit four-stage Runge–Kutta (RK4) scheme is applied for the temporal integration of (1.11)-(1.12). The benefits of the upwind analogue are evident: better shock capturing, greater robustness, and no tuning of explicitly added artificial viscosity. Similarly, just as in [13], in [16], multigrid is applied for accelerating the solution process. Furthermore, just as in [13], time accuracy is not pursued, and optimal Runge–Kutta coefficients are applied to get good stability as well as good smoothing properties. It seems that the solution method presented in [16] is already competitive with Jameson's method, without the introduction of a further acceleration technique such as, for example, residual averaging.

It is interesting that the upwind analogue allows a further efficiency improvement by exploitation of the direct availability of the corresponding first-order upwind discretization, with its better stability and smoothing properties. Since a first-order central discretization is not readily available, a standard central method does not easily allow this improvement.

2. Novel solution method.

2.1. Explicit time stepping. Compared with the existing solution method, the new solution method only uses a more extensive right-hand side in the explicit time stepping scheme. The extension consists of two first-order upwind defects; one which is evaluated at each stage of the multistage scheme, and another which is kept frozen during a fixed number of ν_t RK4 time steps ($\nu_t \geqq 1$), and which compensates for the other first-order defect by its opposite sign. Furthermore, significantly, the higher-order defect is kept frozen as well during ν_t RK4 steps. The four-stage time stepping scheme is written as

```
(2.1a)    $W_i^{0,4} := W_i^{0,0}, \quad i = 1, 2, \ldots, N$
          for $\nu$ from 1 to $\nu_t$ do
(2.1b)      $W_i^{\nu,0} := W_i^{\nu-1,4}, \quad i = 1, 2, \ldots, N$
            for $k$ from 1 to 4 do
(2.1c)        $W_i^{\nu,k} := W_i^{\nu,0} + \Delta t_i \alpha_k R_i^{\nu,k-1}, \quad i = 1, 2, \ldots, N$
            enddo
          enddo
```

Here, ν is the time step number, k the stage number, Δt_i the local time step, and α_k the kth Runge-Kutta coefficient. In the existing higher-order method the right-hand side $R_i^{\nu,k-1}$ is

$$(2.2)\qquad R_i^{\nu,k-1} = \frac{-1}{A_i}\sum_{j=1}^{n_i} \bar{T}_{ij}^{-1}\Phi(\bar{T}_{ij}(W_{ij}^l)^{\nu,k-1}, \bar{T}_{ij}(W_{ij}^r)^{\nu,k-1})l_{ij},$$

with $(W_{ij}^l)^{\nu,k-1}$ and $(W_{ij}^r)^{\nu,k-1}$ higher-order accurate. So, nothing is kept frozen in the existing method's right-hand side. For the novel method, we take

$$(2.3)\qquad \begin{aligned} R_i^{\nu,k-1} = \frac{-1}{A_i}\sum_{j=1}^{n_i} \bar{T}_{ij}^{-1}(&\Phi(\bar{T}_{ij}W_i^{\nu,k-1}, \bar{T}_{ij}W_j^{\nu,k-1}) - \Phi(\bar{T}_{ij}W_i^{0,0}, \bar{T}_{ij}W_j^{0,0}) \\ &+ \Phi(\bar{T}_{ij}(W_{ij}^l)^{0,0}, \bar{T}_{ij}(W_{ij}^r)^{0,0}))l_{ij}, \end{aligned}$$

where only $(W_{ij}^l)^{0,0}$ and $(W_{ij}^r)^{0,0}$ are higher-order accurate. The frozen first-order cell face states ($W_i^{0,0}$ and $W_j^{0,0}$) and the frozen higher-order cell face states ($(W_{ij}^l)^{0,0}$ and $(W_{ij}^r)^{0,0}$) are updated in an additional outer iteration, which will be explained in the next section. In the following, for convenience, $W^{\nu,4}$ will also be denoted as $W_{\mathrm{RK4}}(\nu, R^{0,0}, W^{0,0})$.

2.2. Complete solution method. The novel solution method is of defect correction type [2]. Though defect correction iteration is not as necessary for a pseudo-unsteady solution method as it is for a solution method that directly tackles steady discretized equations [12], [14], [15], it may lead to an improved efficiency. In § 3, we will show that the defect correction method proposed here can take advantage of a *greater stability* domain (larger local time steps) guaranteed by the first-order defects in the right-hand side. Furthermore, we will show that with multigrid as an acceleration technique, advantage can also be taken of *better smoothing* properties.

The new solution method can be divided into two successive stages. The first stage is *nested iteration* [10, p. 98], also called *full multigrid* (FMG) method [4], which is applied to obtain a good initial solution on the finest grid. The second stage is an *iterative defect correction* (IDeC) method [2], [10, p. 282], which is used to iterate until the higher-order accurate solution is obtained. The initial solution for the defect correction process is the solution obtained by the nested iteration. The inner iteration of both stages is a *nonlinear multigrid* method [10, p. 181], viz. the *full approximation storage* (FAS) algorithm [3], [4]. In the following sections we discuss successively: the nested iteration (§ 2.2.1), the iterative defect correction method (§ 2.2.2), and the building block of these two iterations: the nonlinear multigrid iteration (§ 2.2.3).

2.2.1. Nested iteration. To apply multigrid we construct a nested set of grids. Let $\Omega_1, \Omega_2, \dots, \Omega_L$ be a sequence of nested grids with Ω_1 the coarsest and Ω_L the finest grid. (For a description of the coarsening rule applied here, we refer to [16].) The nested iteration (FMG) starts with a user-defined initial estimate of W_1: the solution on the coarsest grid Ω_1. To obtain an initial solution on Ω_2, the solution on Ω_1 is first improved by a few FAS cycles. (The number of FAS cycles that is applied in each FMG step can be either fixed, $\nu_{\mathrm{FAS}} = \text{constant}$, or dependent on the residual.) After this, the improved solution W_1 is prolongated to Ω_2. The process is repeated until Ω_L has been reached.

The prolongation of the solution can be the simple piecewise constant prolongation I_{l-1}^l, $2 \leqq l \leqq L$, or it can be a smoother one. If we denote the area of finite volume C_i^l at level l by A_i^l, and the number of neighboring volumes C_j^l of C_i^l by n_i^l, a smooth prolongation operator $\mathcal{I}^l_{l-1}$ is defined by

$$(2.4)\qquad (\mathcal{I}^l_{l-1}(W_{l-1}))_i \equiv \frac{A^l_i(I^l_{l-1}(W_{l-1}))_i + \sum_{j=1}^{n^l_i} A^l_j(I^l_{l-1}(W_{l-1}))_j}{A^l_i + \sum_{j=1}^{n^l_i} A^l_j}, \qquad 2 \leqq l \leqq L.$$

We note that since I^l_{l-1} strictly obeys the physical conservation laws by the prolongation of cell-integrated amounts of mass, momentum, and energy, $\mathcal{I}^l_{l-1}$ is strictly conservative as well.

2.2.2. Iterative defect correction. Let $\mathcal{F}^1_L(W_L) = 0$ and $\mathcal{F}^+_L(W_L) = 0$ denote the first-order and higher-order discretized Euler equations, respectively, on the finest grid. Then, IDeC can be written as

$$(2.5a)\qquad \mathcal{F}^1_L(W^0_L) = 0,$$

$$(2.5b)\qquad \mathcal{F}^1_L(W^n_L) = \mathcal{F}^1_L(W^{n-1}_L) - \mathcal{F}^+_L(W^{n-1}_L), \qquad n = 1, 2, \dots, n_{\mathrm{IDeC}},$$

where W^0_L is the solution yielded by FMG. From (2.5b), it is immediately clear that at convergence ($W^n_L = W^{n-1}_L = W_L$), we have solved the higher-order discretized Euler equations $\mathcal{F}^+_L(W_L) = 0$. Therefore, we emphasize that the present defect correction method is *not* mixed defect correction iteration [11]. (A mixed defect correction method would yield a solution whose accuracy is not well defined; its solution would be a vague mixture of the first-order and higher-order accurate solutions.) Though both theory [6] and practice [6] show that IDeC gives poor convergence of the residual, theory [9], [10, p. 282] and practice [12], [15] also show that for smooth problems, a single IDeC cycle ($n_{\mathrm{IDeC}} = 1$) is sufficient to obtain second-order solution accuracy. Furthermore, for solutions with discontinuities, a few IDeC cycles ($n_{\mathrm{IDec}} \approx 5$) may improve the accuracy to a sufficient extent [12], [14]. In summary, for both smooth and nonsmooth flow problems, numerical experiments with IDeC show this phenomenon of *slow convergence* but of *fast solution improvement* [6], [12], [14], [15]; a phenomenon that is understood by theory [6], [9], [10, p. 282].

In each IDeC cycle we must solve a first-order system with an appropriate right-hand side. From [14] it is known that it is inefficient to solve this system very accurately. With a steady approach, application of only a single FAS cycle per IDeC cycle appears to be the most efficient strategy in [14]. In this paper, with our unsteady approach, we will re-investigate what is the most efficient number of FAS cycles per IDeC cycle (see § 3).

2.2.3. Nonlinear multigrid iteration. Let us denote by $(W_l)_{V(\nu_{\mathrm{pre}},\nu_{\mathrm{post}})}(\nu_{\mathrm{FAS}}, R_l, W^0_l)$ the solution obtained on level l, after ν_{FAS} FAS $V(\nu_{\mathrm{pre}}, \nu_{\mathrm{post}})$-cycles have been applied to $\mathcal{F}^1_l(W_l) = R_l$, with initial solution W^0_l. A single FAS $V(\nu_{\mathrm{pre}}, \nu_{\mathrm{post}})$-cycle on level l, $1 \leqq l \leqq L$, is then recursively defined by the following successive steps:

(i) Improve on the grid Ω_l the initial solution W^0_l by applying ν_{pre} RK4 steps to

$$(2.6)\qquad \mathcal{F}^1_l(W_l) = R_l.$$

Let us denote the resulting solution $(W_l)_{\mathrm{RK4}}(\nu_{\mathrm{pre}}, R_l, W^0_l)$ by $\bar{W}_l$.

(ii) Coarse-grid correction step: Approximate on the underlying coarser grid Ω_{l-1} the solution of

$$(2.7a)\qquad \mathcal{F}^1_{l-1}(W_{l-1}) = R_{l-1},$$

$$(2.7b)\qquad R_{l-1} = \mathcal{F}^1_{l-1}(I^{l-1}_l(\bar{W}_l)) - \tilde{I}^{l-1}_l(\mathcal{F}^1_l(\bar{W}_l) - R_l),$$

by applying a single FAS $V(\nu_{\mathrm{pre}}, \nu_{\mathrm{post}})$-cycle on level $l-1$. Let us denote the resulting approximate solution $(W_{l-1})_{V(\nu_{\mathrm{pre}},\nu_{\mathrm{post}})}(1, R_{l-1}, I^{l-1}_l(\bar{W}_l))$ by $\bar{W}_{l-1}$.

(iii) Improve the solution on Ω_l by first correcting the approximate solution $\bar{W}_l$ obtained in step (i):

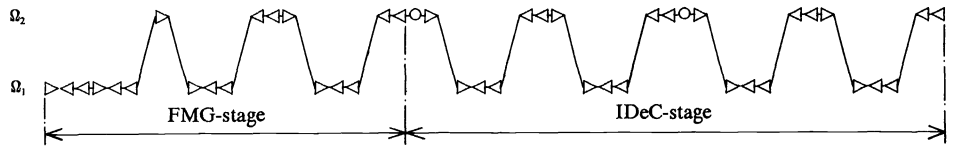
(2.8) $$\bar{W}_l := \bar{W}_l + I_{l-1}^{l}(\Delta W_{l-1}),$$

where $\Delta W_{l-1} = \bar{W}_{l-1} - I_l^{l-1}\bar{W}_l$ is the result of the coarse-grid correction step (ii). Furthermore, improve $\bar{W}_l$ by applying ν_{post} RK4 steps to (2.6): $W_l := (W_l)_{\text{RK4}}(\nu_{\text{post}}, R_l, \bar{W}_l)$.

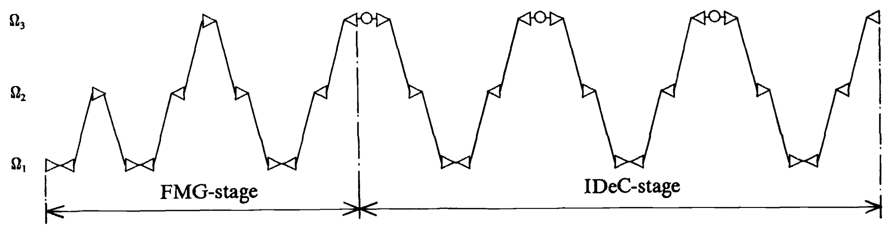
In the FMG-stage in step (i), we have on each starting (locally finest) grid Ω_l, $1 \leqq l \leqq L$: $R_l = 0$. Hence, the initial solution for IDeC as obtained by FMG is at most first-order accurate. In the IDeC stage the starting grid is always the globally finest grid Ω_L, and there we have: $R_L = \mathscr{F}_L^1(W_L) - \mathscr{F}_L^+(W_L)$. This higher-order right-hand side is kept frozen during ν_{FAS} FAS $V(\nu_{\text{pre}}, \nu_{\text{post}})$-cycles per IDeC cycle. Note that with the novel method, we evaluate the higher-order operator at most once per FAS $V(\nu_{\text{pre}}, \nu_{\text{post}})$-cycle, instead of $4 \times (\nu_{\text{pre}} + \nu_{\text{post}}) + 1$ times per FAS $V(\nu_{\text{pre}}, \nu_{\text{post}})$-cycle with the existing method.

In step (ii), note that in the RK4 scheme, the complete right-hand side R_{l-1} is kept frozen. Just as the prolongation operator I_{l-1}^{l}, the restriction operator I_l^{l-1} is such that it also exactly obeys the conservation of cell-integrated mass, momentum, and energy. The restriction operator $\tilde{I}_l^{l-1}$ restricts the defect in the standard way; by summation of mass, momentum, and energy defects over fine-grid cells whose union is a coarse cell. On the coarsest grid (Ω_1), step (ii) (the coarse-grid correction step) is skipped of course.

To illustrate the structure of the complete novel solution method, we give two examples of a complete higher-order solution schedule in Fig. 3. The schedule in Fig. 3(a) is fixed by $L = 2$, $\nu_{\text{pre}} = 1$, $\nu_{\text{post}} = 2$, $\nu_{\text{FAS}} = 2$, $n_{\text{IDeC}} = 2$. The schedule in Fig. 3(b) is fixed by $L = 3$, $\nu_{\text{pre}} = \nu_{\text{post}} = 1$, $\nu_{\text{FAS}} = 1$, $n_{\text{IDeC}} = 3$. In both figures, the marker $\rhd$ denotes a single RK4 step (over Ω_l) preceding a coarse-grid correction, whereas the marker $\lhd$ denotes a single RK4 step after the coarse-grid correction. The marker $\bigcirc$ denotes the computation of $R_L = \mathscr{F}_L^1(W_L) - \mathscr{F}_L^+(W_L)$. Note that the corresponding first-order variants of both schedules (i.e., the variants without any marker $\bigcirc$) are simply obtained by taking $n_{\text{IDeC}} = 0$.



(a)



(b)

FIG. 3. *Examples of complete solution schedule.* (a) $L = 2$, $\nu_{\text{pre}} = 1$, $\nu_{\text{post}} = 2$, $\nu_{\text{FAS}} = 2$, $n_{\text{IDeC}} = 2$. (b) $L = 3$, $\nu_{\text{pre}} = \nu_{\text{post}} = 1$, $\nu_{\text{FAS}} = 1$, $n_{\text{IDeC}} = 3$.

2.3. Analysis. To analyze the convergence properties of the IDeC method proposed, we consider the unsteady, linear, scalar, one-dimensional model equation

$$\frac{\partial w}{\partial t}+c\frac{\partial w}{\partial x}=0, \qquad c>0. \tag{2.9}$$

For the spatial discretization, we consider a grid with a uniformly constant mesh size h. Then we have, for fixed time t, for the first-order upwind discretization,

$$\frac{\partial w}{\partial x}=\frac{-w_{i-1}+w_i}{h}+O(h). \tag{2.10}$$

As a higher-order upwind discretization, we take the Fromm scheme (i.e., van Leer's κ-scheme [19] with $\kappa=0$), which leads to

$$\frac{\partial w}{\partial x}=\frac{w_{i-2}-5w_{i-1}+3w_i+w_{i+1}}{4h}+O(h^2). \tag{2.11}$$

For these two spatial discretizations and the existing explicit solution method, the following Runge-Kutta coefficients can be derived by maximizing the maximally allowable CFL number: $\alpha_1=0.11$, $\alpha_2=0.2767$, $\alpha_3=0.5$ (see [17]). Consistency requires $\alpha_4=1$. The optimization can be redone for our new solution method. However, in the next section we will show that if we simply omit the optimization, the new method already yields both better stability and better smoothing with the α_k's given above (i.e., the α_k's found for the existing higher-order method).

2.3.1. Stability analysis. First we will perform a stability analysis for IDeC with an explicit RK4 scheme as the inner solution method. Let us denote the steady-state analogue of (2.9) by

$$Aw=c\frac{dw}{dx}. \tag{2.12}$$

Assuming that we have periodic boundary conditions, we denote by A_1 and A_+ the first-order and higher-order accurate, linear operators, approximating A. Then, the IDeC process to solve the discrete linear system

$$A_+W=0 \tag{2.13}$$

can be written as

$$A_1W^0=0, \tag{2.14a}$$

$$A_1W^n=(A_1-A_+)W^{n-1}, \qquad n=1,2,\ldots,n_{\text{IDeC}}, \tag{2.14b}$$

where A_1 denotes the matrix resulting from the first-order discretization. Assuming A_1 to be invertible, the corresponding amplification matrix M reads

$$M=I-A_1^{-1}A_+. \tag{2.15}$$

From (2.15) it is clear that to have convergence of IDeC, the spectral radius of M should be smaller than one. It is also clear that the better the resemblance between A_1 and A_+, the faster the convergence of IDeC. (Also important for good efficiency of IDeC is, of course, that A_1 can be inverted in an efficient way.)

Instead of solving each W^n from (2.14b) exactly, we approximate it by means of the explicit RK4 scheme (2.1) with

$$W^{0,0}=W^{n-1}, \tag{2.16a}$$

$$R^{\nu,k-1}=-(A_1W^{\nu,k-1}-(A_1-A_+)W^{0,0}). \tag{2.16b}$$

With ν the number of RK4 steps which allows us to define an (approximate) solution W^n, we now investigate how the corresponding amplification matrix M_ν is related to the amplification matrix M, which corresponds with the exact solution of W^n from (2.14b). If we consider the approximate solution $W^{\nu,4}$, for $\nu = 1$ we have

(2.17) $$W^{1,4} = (P + Q(A_1 - A_+))\,W^{n-1},$$

with

(2.18a) $$P = P(-\Delta t A_1),$$

(2.18b) $$Q = I - A_1^{-1}P,$$

(2.18c) $$P(Z) = I + Z + \alpha_3 Z^2 + \alpha_3\alpha_2 Z^3 + \alpha_3\alpha_2\alpha_1 Z^4.$$

We can easily verify that $A_1 Q = QA_1$, and that $A_1^{-1}P = PA_1^{-1}$. Hence, for M_1 we can write

(2.19) $$M_1 = P + Q(A_1 - A_+).$$

For $\nu > 1$, we can easily find the recurrence relation

(2.20) $$M_\nu = PM_{\nu-1} + Q(A_1 - A_+),$$

which leads to

(2.21) $$M_\nu = (I + P + P^2 + \cdots + P^{\nu-1})Q(A_1 - A_+) + P^\nu.$$

THEOREM. *Let* $\|\cdot\|$ *be some matrix norm. If* $\|P\| < 1$ *and if* P *is invertible, then* $\lim_{\nu\to\infty} M_\nu = M$.

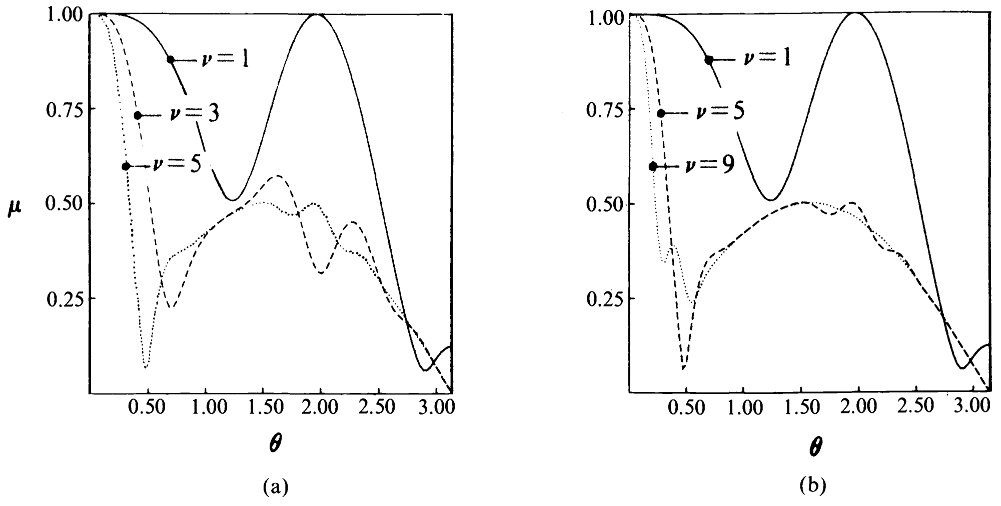
Proof. For all $\nu > 1$, $I + P + P^2 + \cdots + P^{\nu-1} = (I - P)^{-1}(I - P^\nu)$. If $\|P\| < 1$, then $\lim_{\nu\to\infty}(I-P)^{-1}(I - P^\nu) = (I - P)^{-1}$. Hence,

$$\lim_{\nu\to\infty} M_\nu = (I - P)^{-1}Q(A_1 - A_+) = (A_1 Q)^{-1}Q(A_1 - A_+)$$
$$= A_1^{-1}Q^{-1}Q(A_1 - A_+) = M. \qquad \square$$

Local mode analysis, applied to (2.14b) with A_1 and A_+ according to (2.10) and (2.11), respectively, yields for the maximally allowable value of $\sigma \equiv c\Delta t/\Delta x$, $\sigma_{\nu=1} = 2.21$ and $\sigma_{\lim\, \nu\to\infty} = 2.12$. Note that the difference between both values is very small. For an arbitrary ν it is safe and still efficient to take $\sigma = 2.12$. The value $\sigma = 2.12$ is lower than that for the existing method applied to the first-order upwind system ($\sigma = 2.5105$), but higher than that for the existing method applied to the higher-order system ($\sigma = 1.9186$).

For $\sigma = 2.12$ and for increasing ν, Fig. 4 shows the behavior of the convergence factor μ, versus the frequency θ in the range $[0, \pi]$, for the new higher-order method. Already for $\nu = 1$, it appears that the convergence behavior of the new higher-order method is better than that of the existing higher-order method (Fig. 5). Clearly visible for increasing ν is the rapid improvement of the smoothing (i.e., the convergence in the range $\theta \in [\pi/2, \pi]$) and the tendency towards coincidence of the curves. The curves converge to the one that corresponds with the exact solution of (2.14b): $\mu = \frac{1}{2}\sin\theta$, $\theta \in [0, \pi]$. In the next section we will further investigate the smoothing properties of IDeC.

2.3.2. Smoothing analysis. Local mode analysis yields that with the new method, optimal smoothing of the highest frequency, $\theta = \pi$, is obtained for $\sigma = 1.8921$ and $\sigma = 1.4869$. Just as for $\sigma = 2.12$ (Fig. 4), Figs. 6 and 7 give the convergence behavior for $\sigma = 1.8921$ and $\sigma = 1.4869$ with increasing ν. For both values of σ the smoothing is clearly better than for $\sigma = 2.12$. For $\sigma = 1.4869$ it is best.



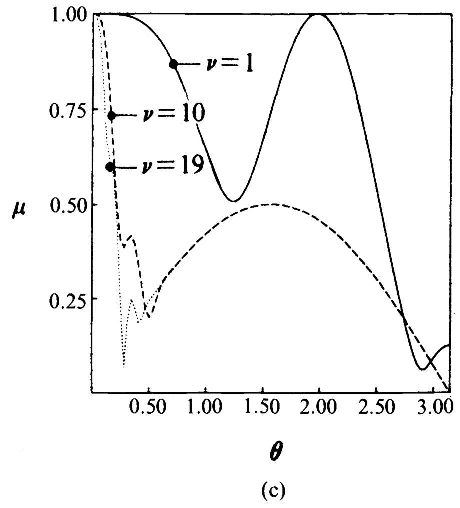


FIG. 4. *Convergence behavior novel higher-order method, for* $\sigma = 2.12$. (a) $\nu = 1, 3, 5$. (b) $\nu = 1, 5, 9$. (c) $\nu = 1, 10, 19$.

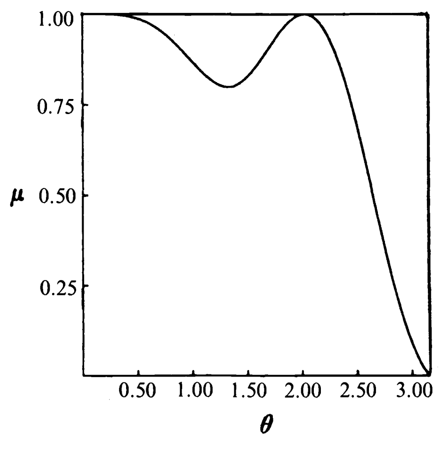

FIG. 5. *Convergence behavior existing higher-order method, for* $\sigma = 1.9186$.

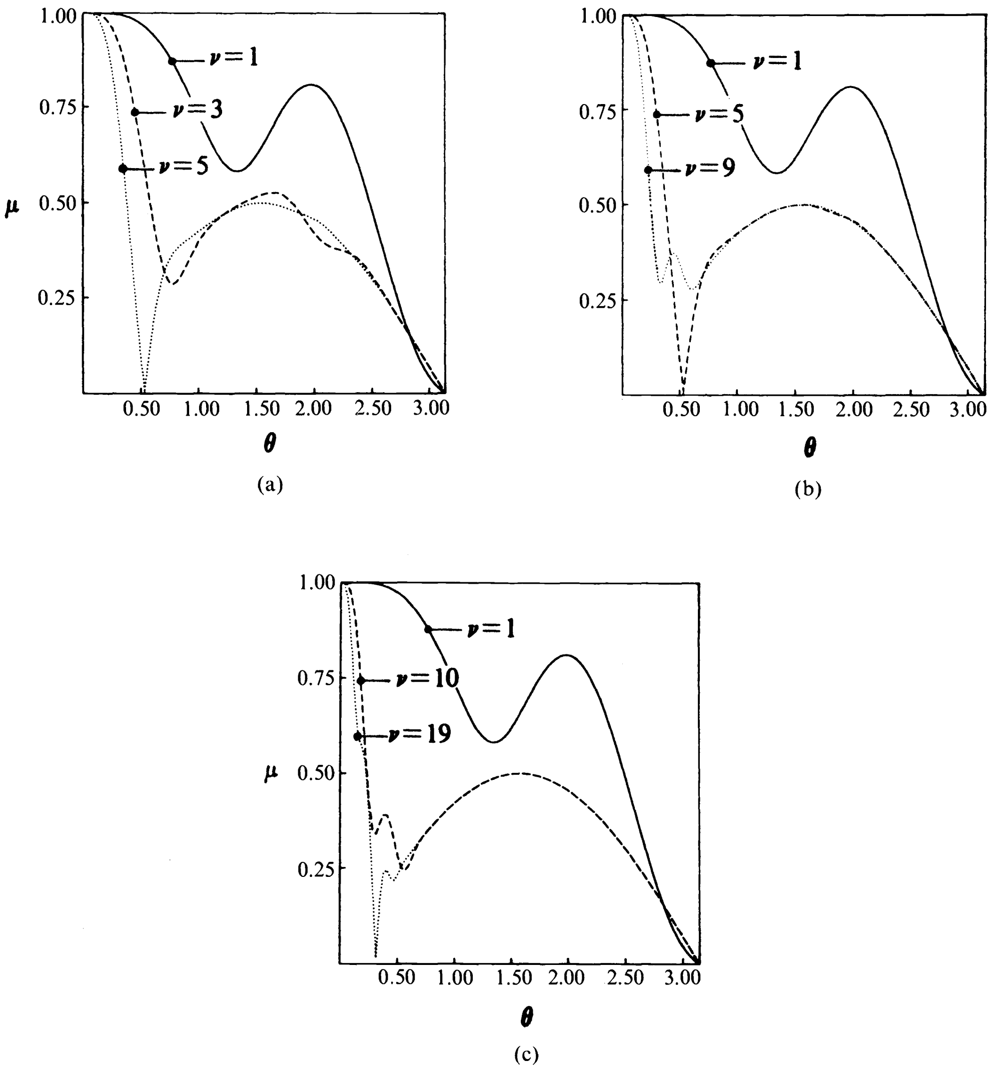

FIG. 6. *Convergence behavior novel higher-order method, for* $\sigma = 1.8921$. (a) $\nu = 1, 3, 5$. (b) $\nu = 1, 5, 9$. (c) $\nu = 1, 10, 19$.

In Figs. 8, 9, and 10 we show the smoothing behavior for varying σ, the θ-range considered being $[\pi/2, \pi]$, and the quantity μ along the vertical axis being the maximum smoothing factor found over this range. We consider successively: the first-order method (Fig. 8), the existing higher-order method (Fig. 9), and the new higher-order method (Fig. 10). When we compare the results of the existing higher-order method and the new higher-order method (Figs. 9 and 10), we find that the new method clearly has better smoothing properties. The new method appears to have even better smoothing properties than the first-order method (compare Figs. 8 and 10). Note in particular that the σ-range over which its smoothing is good is much wider.

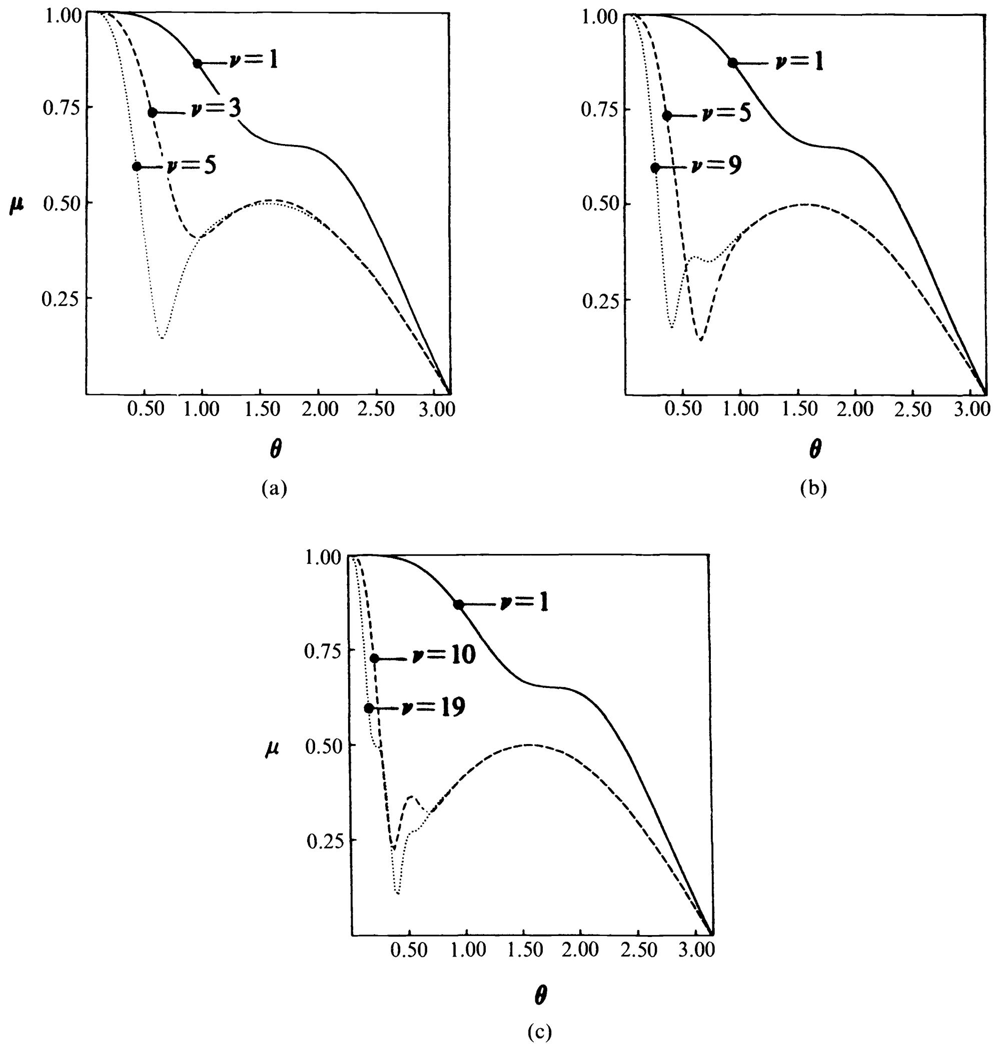

FIG. 7. *Convergence behavior novel higher-order method, for* $\sigma = 1.4869$. (a) $\nu = 1, 3, 5$. (b) $\nu = 1, 5, 9$. (c) $\nu = 1, 10, 19$.

3. Numerical results. In order to verify the previously predicted better stability and convergence properties of the novel higher-order method, we compute the standard transonic channel flow from [21] with the two-dimensional Euler equations. Three finest grids are considered: a 161-vertices grid (Fig. 11), a 585-vertices grid that is about twice as fine (see [16]), and a 2225-vertices grid that is about four times as fine. The corresponding solution schedules applied are a four-, five, and six-level schedule ($L = 4, 5, 6$), respectively, all with $\nu_{\text{pre}} = \nu_{\text{post}} = 1$, for all l.

In Figs. 12(a)–12(c) we present various convergence histories as obtained for $L = 4, 5, 6$, respectively. The convergence results presented are those of (i) the first-order discretized Euler equations solved by means of the nonlinear multigrid iteration (dotted lines), and those of higher-order discretized Euler equations solved by means of (ii) the existing higher-order method (dashed lines), and (iii) the novel higher-order method

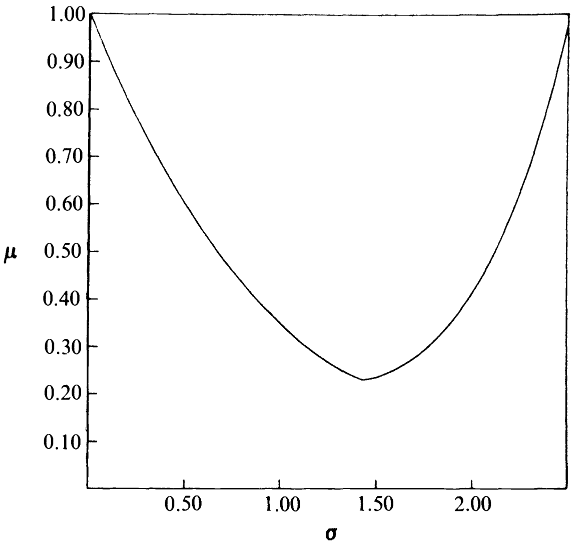

FIG 8. *Smoothing behavior for varying σ, first-order method.*

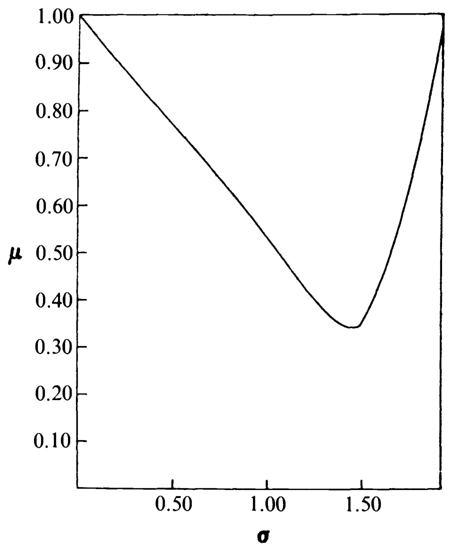

FIG 9. *Smoothing behavior for varying σ, existing higher-order method.*

(solid lines). In all three graphs, the residual considered is the L_2-norm of the error in the conservation of mass over all the finest-grid cells. Furthermore, in all three graphs the number of cycles indicated along the horizontal axis is (i) the number of FAS cycles in case of both the first-order method and the existing higher-order method, and (ii) the number of IDeC cycles in case of the new higher-order method. Note that with the new higher-order method, for $\nu_{\text{FAS}} = 2, 5, 10$ the number of inner FAS cycles is, respectively, 2, 5, and 10 times larger than the number of indicated IDeC cycles. (Only for $\nu_{\text{FAS}} = 1$ does the number of FAS cycles equal the number of IDeC cycles.)

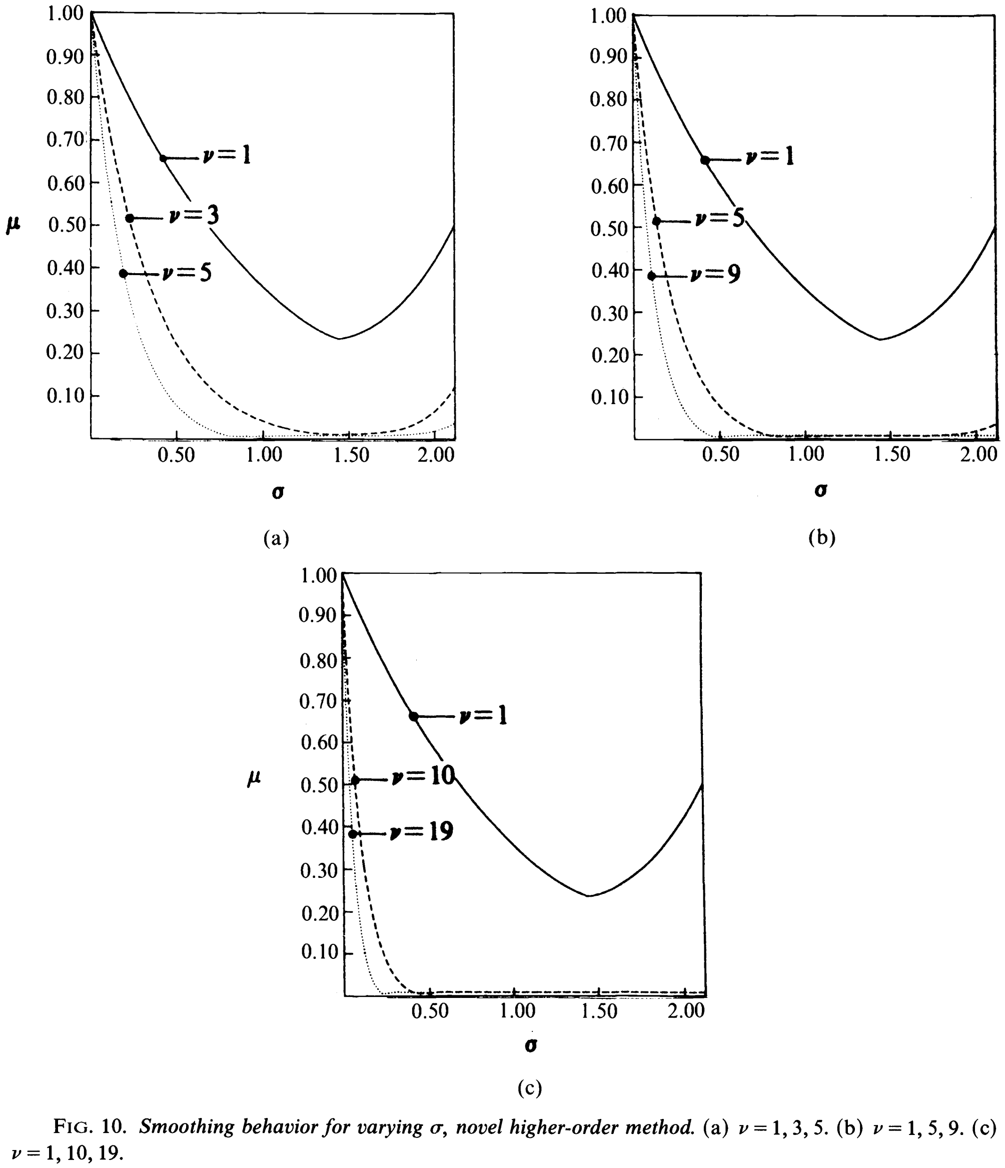

FIG. 10. *Smoothing behavior for varying σ, novel higher-order method.* (a) $\nu = 1, 3, 5$. (b) $\nu = 1, 5, 9$. (c) $\nu = 1, 10, 19$.

FIG. 12. *Convergence histories*: *first-order method*, $\cdots\cdot$; *existing higher-order method*, ----; *novel higher-order method*, ——. (a) 161-*vertices grid* ($L=4$). (b) 585-*vertices grid* ($L=5$). (c) 2225-*vertices grid* ($L=6$).

All convergence histories start at the end of the FMG stage (Fig. 3). In agreement with the theoretical results found in § 2.3, for all four values of ν_{FAS} (so also for $\nu_{\text{FAS}}=1$), the new method does indeed give a better convergence than the existing higher-order method. For decreasing mesh width, the convergence of the new higher-order method becomes even relatively better than that of the first-order method. (For all four values of ν_{FAS} under consideration, the corresponding convergence histories in Fig. 12 show a better grid-independency than those of the multigrid method applied to the first-order discretized equations.) This better performance is probably due to better smoothing in the new method. (In § 2.3, by model analysis, we have found that the new method has better smoothing properties than the first-order method.)

As for the actual order of accuracy, if we took the converged higher-order accurate solution obtained on the 2225-vertices grid as the reference solution, we measured local orders of accuracy in the range $[O(h^{1.4}), O(h^{2.3})]$ for the solutions on the coarser

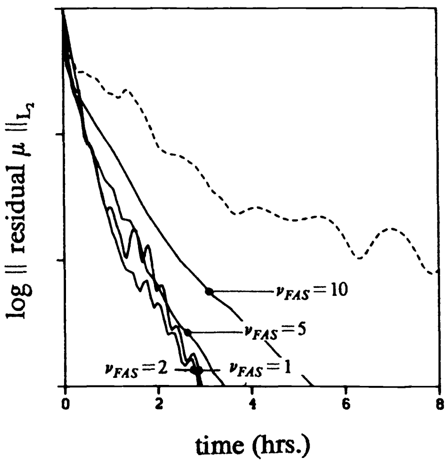
(b)



(c)

FIG. 13. *Efficiency histories: existing higher-order method, - - - -; novel higher-order method, ——.* (a) 161-*vertices grid* ($L=4$). (b) 585-*vertices grid* ($L=5$). (c) 2225-*vertices grid* ($L=6$).

grids (the 585-vertices grid and the 161-vertices grid). The global order of accuracy appears to be almost $O(h^2)$.

Finally, the important question of which of the various higher-order methods is the most efficient still remains. To answer this question, we give the higher-order efficiency histories in Figs. 13(a)–13(c). The indicated computing times have been obtained on a Sequent. (No efforts have been undertaken to make efficient use of the parallelization features of the machine. What interests us here is the relative efficiency of the higher-order methods only.) Since the sizes of the three grids considered are related to each other by approximately a factor 4, we have related the scales along the horizontal axes accordingly. Concerning the relative efficiency of the novel higher-order method, for the four values of ν_{FAS} considered, it appears that for all three grids the best efficiency is obtained with $\nu_{\text{FAS}}=1$ (so just as in [14], for the schedule with only a single FAS cycle per IDeC cycle). Furthermore, it is significant that the novel method with $\nu_{\mathrm{FAS}} = 1$ appears to be more efficient than the existing higher-order method. Due to the better grid-independency of the novel method, this relatively better efficiency becomes even increasingly better with decreasing meshwidth.

4. Conclusions. Fully implicit solution methods for higher-order discretized equations may strongly benefit from iterative defect correction when these systems of discretized equations are not easily invertible, which is often the case with higher-order accurate discretizations. Fully explicit solution methods may also profit from iterative defect correction. Here the profits are faster convergence and higher efficiency. The defect correction method appears to lead to greater stability (and hence to greater robustness) than the existing (standard) explicit method. Compared to the existing explicit method, it possesses remarkably good smoothing properties, in fact even better than the first-order method. Last but not least, its convergence rate appears to be grid-independent. For upwind discretizations, the "price" which has to be paid for using defect correction iteration, a slightly more complex algorithm, is negligible, because of the direct availability of an appropriate approximate operator; the first-order upwind operator.

Acknowledgments. The authors want to thank Joke Sterringa, P. Wesseling, and the referees for their suggestions in improving this paper.

THE ASYMPTOTIC SPECTRA OF BANDED TOEPLITZ AND QUASI-TOEPLITZ MATRICES*

RICHARD M. BEAM[†] AND ROBERT F. WARMING[†]

Abstract. Toeplitz matrices occur in many mathematical as well as scientific and engineering investigations. This paper considers the spectra of *banded* Toeplitz and *quasi*-Toeplitz matrices with emphasis on nonnormal matrices of arbitrarily large order and relatively small bandwidth. These are the type of matrices that appear in the investigation of stability and convergence of difference approximations to partial differential equations. Quasi-Toeplitz matrices are the result of non-Dirichlet boundary conditions for the difference approximations. The eigenvalue problem for a banded Toeplitz or quasi-Toeplitz matrix of large order is, in general, analytically intractable and (for nonnormal matrices) numerically unreliable. An asymptotic (matrix order tends to infinity) approach partitions the (asymptotic) spectrum of a quasi-Toeplitz matrix into two parts; namely, the analysis for the boundary condition *independent* spectrum and the analysis for the boundary condition *dependent* spectrum. The boundary condition independent spectrum is the same as the *pure* Toeplitz matrix spectrum. Algorithms for computing both parts of the asymptotic spectrum are presented. Examples are used to demonstrate the utility of the algorithms, to present some interesting spectra, and to point out some of the numerical difficulties encountered when conventional matrix eigenvalue routines are employed for nonnormal matrices of large order. The analysis for the Toeplitz spectrum also leads to a diagonal similarity transformation that improves conventional numerical eigenvalue computations. Finally, the algorithm for the asymptotic spectrum is extended to the Toeplitz generalized eigenvalue problem which occurs, for example, in the stability analysis of Padé type difference approximations to differential equations.

1. Introduction.

A Toeplitz matrix has the property that the entries are constant along diagonals parallel to the main diagonal. If we define the sequence

$$a_{-p}, a_{-p+1}, \cdots, a_0, \cdots, a_{q-1}, a_q; \quad \text{where} \quad a_{-p}, a_q \neq 0 \tag{1.1}$$

and p and q are specified positive integers, then the elements of a *banded* square Toeplitz matrix of order J and bandwidth $p+q+1$ are given by

$$a_{ij} = a_{j-i} \tag{1.2}$$

if a_{j-i} is a member of the sequence (1.1) and zero otherwise. Since the eigenvalue analysis for triangular matrices is trivial, we have restricted our attention to *nontriangular* matrices ($p, q > 0$). For example, if we choose $p = 1$ and $q = 2$ and denote

*Received by the editors October 25, 1991; accepted for publication (in revised form) August 28, 1992. The main results of this paper were presented at the 14th Biennial Conference on Numerical Analysis, Dundee, Scotland, June 25-28, 1991.

[†]Computational Fluid Dynamics Branch, NASA Ames Research Center, Moffett Field, California 94035

the banded Toeplitz matrix by $\mathbf{A}$ then

$$(1.3)\qquad \mathbf{A} = \begin{bmatrix} a_0 & a_1 & a_2 & & & & & & \\ a_{-1} & a_0 & a_1 & a_2 & & & & & \\ & a_{-1} & a_0 & a_1 & a_2 & & O & & \\ & & \cdot & \cdot & \cdot & \cdot & & & \\ & & & \cdot & \cdot & \cdot & \cdot & & \\ & & & & \cdot & \cdot & \cdot & \cdot & \\ & & O & & & a_{-1} & a_0 & a_1 & a_2 \\ & & & & & & a_{-1} & a_0 & a_1 \\ & & & & & & & a_{-1} & a_0 \end{bmatrix},$$

where the bandwidth is four and the matrix order J is arbitrary. Our interest is in the spectra, i.e., the eigenvalues, for banded Toeplitz matrices of arbitrarily large order, i.e, $J \to \infty$.

A banded *quasi*-Toeplitz matrix is defined to be a banded Toeplitz matrix where there are a limited number of row changes constrained as follows: There are at most p altered rows among the first p rows and at most q altered rows among the last q rows. Since p and q are fixed and J is assumed to be large, there are only a relatively few altered rows. Here we use *quasi* in the conventional sense meaning *almost* or *nearly.* For example, a quasi-Toeplitz cousin of the Toeplitz matrix (1.3) is

$$(1.4)\qquad \mathbf{A} = \begin{bmatrix} b_{11} & b_{12} & b_{13} & b_{14} & & & & & \\ a_{-1} & a_0 & a_1 & a_2 & & & & & \\ & a_{-1} & a_0 & a_1 & a_2 & & O & & \\ & & \cdot & \cdot & \cdot & \cdot & & & \\ & & & \cdot & \cdot & \cdot & \cdot & & \\ & & & & \cdot & \cdot & \cdot & \cdot & \\ & & O & & & a_{-1} & a_0 & a_1 & a_2 \\ & & & & & c_{24} & c_{23} & c_{22} & c_{21} \\ & & & & & c_{14} & c_{13} & c_{12} & c_{11} \end{bmatrix}.$$

(The advantage of the unusual indexing for the c entries of $\mathbf{A}$ will become apparent in §4.2). We assume that the modified elements are constants and therefore independent of J. The bandwidth of a quasi-Toeplitz matrix may be larger than the bandwidth of its pure Toeplitz cousin, e.g., the quasi-Toeplitz matrix defined by (1.4) has a larger bandwidth than its Toeplitz cousin defined by (1.3).

Another important relative of a banded Toeplitz matrix is its *circulant* cousin. Each row of a circulant matrix is constructed by cycling the previous row forward one element. For example, if the first row of a matrix of order J is

$$(1.5)\qquad [a_0, a_1, \cdots, a_q, 0, \cdots, 0, a_{-p}, \cdots, a_{-2}, a_{-1}],$$

this process defines the circulant cousin of the Toeplitz matrix defined by (1.2). In particular, the circulant cousin of the Toeplitz matrix (1.3) is

$$
\mathbf{A} = \begin{bmatrix}
a_0 & a_1 & a_2 & & & & & a_{-1} \\
a_{-1} & a_0 & a_1 & a_2 & & & & \\
& a_{-1} & a_0 & a_1 & a_2 & & O & \\
& & \cdot & \cdot & \cdot & \cdot & & \\
& & & \cdot & \cdot & \cdot & \cdot & \\
& & & & \cdot & \cdot & \cdot & \cdot \\
& & O & & a_{-1} & a_0 & a_1 & a_2 \\
a_2 & & & & & a_{-1} & a_0 & a_1 \\
a_1 & a_2 & & & & & a_{-1} & a_0
\end{bmatrix}. \tag{1.6}
$$

We will also refer to the matrix defined by (1.5) as the circulant cousin of a quasi-Toeplitz matrix, e.g., (1.6) is the circulant cousin of (1.4). A circulant matrix is also Toeplitz because the entries are constant along diagonals. The eigenvalues (and eigenvectors) of any circulant matrix can be determined analytically [1]. The spectrum for a circulant banded Toeplitz matrix is a subset of the spectrum for the doubly infinite (order) banded Toeplitz matrix [9].

Toeplitz matrices are important in mathematics as well as scientific and engineering applications [5], [4]. Our interest [15] arose from an investigation of stability and convergence of difference approximations to initial-boundary-value problems for partial differential equations. The analysis of these difference approximations leads to a study of the spectra for banded quasi-Toeplitz matrices of large order. The element changes from the pure Toeplitz matrix are the result of applying non-Dirichlet boundary conditions to the difference equations. The bandwidth of the matrix is determined by the width of the difference stencil and is small compared with the order of the matrix. For example, if the method of lines is applied to a scalar hyperbolic partial differential equation and if a four-point spatial difference approximation is used to approximate the spatial derivative, one obtains the quasi-Toeplitz matrix

$$
\begin{bmatrix}
-\frac{2\alpha+3}{2} & 3\alpha+2 & -\frac{6\alpha+1}{2} & \alpha & & & & \\
-\frac{1}{3} & -\frac{1}{2} & 1 & -\frac{1}{6} & & & & \\
& -\frac{1}{3} & -\frac{1}{2} & 1 & -\frac{1}{6} & & O & \\
& & \cdot & \cdot & \cdot & \cdot & & \\
& & & \cdot & \cdot & \cdot & \cdot & \\
& & & & \cdot & \cdot & \cdot & \cdot \\
& & O & & -\frac{1}{3} & -\frac{1}{2} & 1 & -\frac{1}{6} \\
& & & & & -\frac{1}{3} & -\frac{1}{2} & 1 \\
& & & & & -\beta & \frac{6\beta-1}{2} & -3\beta
\end{bmatrix}, \tag{1.7}
$$

where the parameters α and β are introduced by the numerical boundary conditions [15]. If we choose $\alpha = 6/5$ and $\beta = -4/5$ and calculate the spectrum of (1.7) for a family of increasing matrix orders, we obtain the spectra shown by the open circles in the complex plane in Fig. 1.1. Note the four "isolated" eigenvalues in Fig. 1.1(d). (The abscissa and the ordinate of each eigenvalue, respectively, represent the real part and the imaginary part of the eigenvalue.) In the Lax stability analysis of a difference method for an initial-boundary-value problem, the location of the spectrum in the complex plane determines a necessary (but not sufficient) condition for stability. The GKS (Gustafsson, Kreiss, and Sundström [6]) stability analysis involves checking the Cauchy stability (location of the circulant cousin spectrum) and also checking the

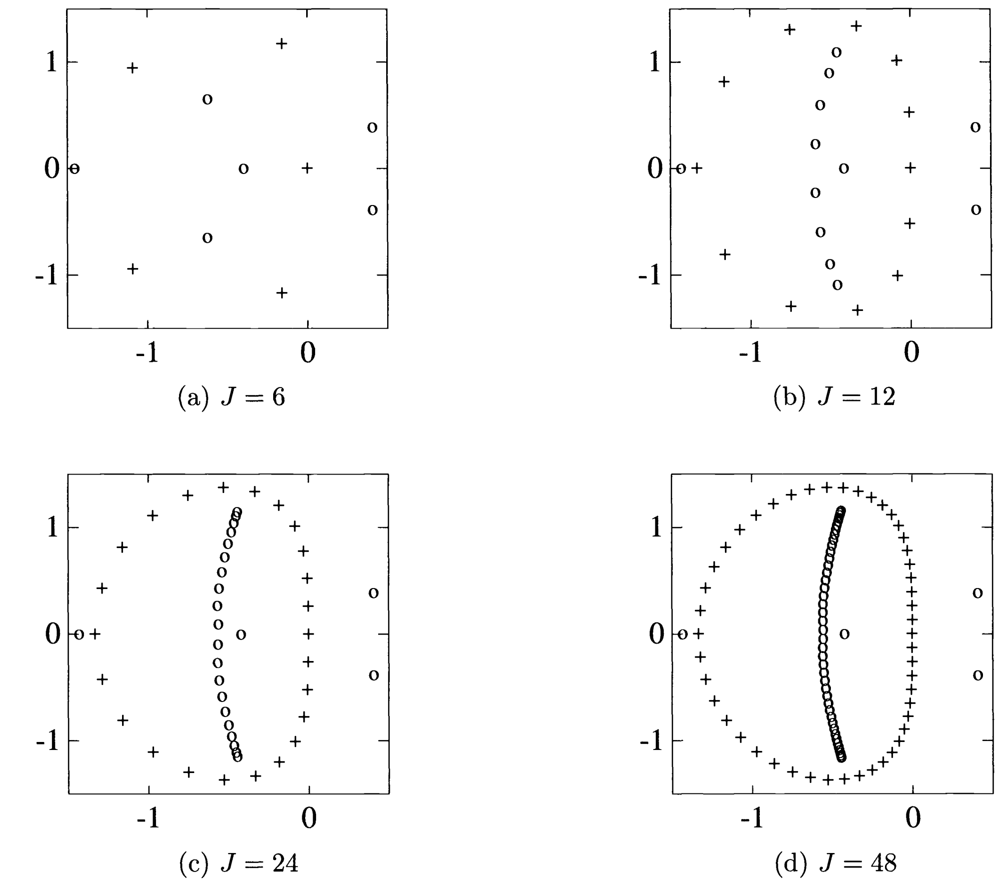

FIG. 1.1. *Spectra for the quasi-Toeplitz matrix* (1.7), *with* $\alpha = 6/5$ *and* $\beta = -4/5$, (o *symbol) and the spectra for the circulant Toeplitz cousin* (+ *symbol) for matrix order* J.

location and asymptotic behavior of "isolated" eigenvalues. The spectrum (spectral radius) also determines the asymptotic iterative convergence rate for fixed J. For the purposes of this paper we are interested in the spectrum for large matrix order, e.g., Fig. 1.1(d). For reference we have also plotted the spectrum (+ symbols) for the circulant cousin of (1.7) in Fig. 1.1.

In §2 the eigenvalue problem for a banded Toeplitz or quasi-Toeplitz matrix is formulated as a difference equation with appropriate boundary conditions. In general, the resulting boundary value problem is analytically intractable. In §3 we assume that the order of a quasi-Toeplitz matrix is large ($J \to \infty$) and use an asymptotic approach to partition the spectrum into two independent sets. The partition is between boundary condition *independent* spectrum and boundary condition *dependent* spectrum. Algorithms for the computation of both parts of the spectrum are described in §4. These algorithms involve the solution of algebraic equations with degree proportional to the bandwidth of the matrix. The algorithm for the boundary condition dependent spectrum closely parallels the eigenvalue analysis of Godunov and Ryabenkii [2], Kreiss

[7] and Gustafsson, Kreiss, and Sundström [6]. Plots of the asymptotic spectra of Toeplitz matrices often exhibit surprising geometrical shapes. Some illustrative examples are shown in §5. The algorithms for computing the spectra are applied to both Toeplitz and quasi-Toeplitz matrices in §6. If conventional numerical eigenvalue algorithms are used to compute the spectra for nonnormal matrices of large order, errors in the spectra may be encountered. In §7 we introduce a simple similarity transformation that improves the accuracy of conventional eigenvalue algorithms for a large class of banded Toeplitz and quasi-Toeplitz matrices. Finally, the algorithm for the asymptotic Toeplitz spectrum is extended to the generalized eigenvalue problem in §8.

2. The eigenvalue problem: a difference equation representation.

Let $\mathbf{A}$ represent a $J \times J$ banded Toeplitz matrix defined by (1.2). The eigenvalue problem for $\mathbf{A}$ is defined by

$$\mathbf{A}\boldsymbol{\phi} = \lambda\boldsymbol{\phi} \tag{2.1}$$

where λ is the eigenvalue and $\boldsymbol{\phi}$ is the eigenvector:

$$\boldsymbol{\phi}^T = [\phi_1, \phi_2, \cdots, \phi_{J-1}, \phi_J]. \tag{2.2}$$

The eigenvalue problem (2.1) is equivalent to the system of homogeneous equations

$$\sum_{m=-p}^{q} a_m \phi_{j+m} = \lambda \phi_j, \qquad j = 1, 2, \cdots, J \tag{2.3}$$

with p homogeneous Dirichlet boundary conditions at the left boundary and q homogeneous boundary conditions at the right boundary

$$\phi_{-m} = 0, \quad m = 0, 1, \cdots, p-1, \tag{2.4a}$$

$$\phi_{J+m} = 0, \quad m = 1, 2, \cdots, q. \tag{2.4b}$$

Note that fictitious points have been introduced in defining the boundary conditions (2.4). It is apparent that (2.3) is the generic or jth equation of the system (2.1). A difference equation representation of the eigenvalue problem, e.g., (2.3) and (2.4), has been used for the purposes of analysis, e.g., [13], and occurs naturally in the stability analysis of finite difference approximations.

Equation (2.3) is a $(p+q)$th order difference equation for ϕ_j, and we look for a solution of the form

$$\phi_j = \kappa^j, \tag{2.5}$$

where κ is a complex constant. Insertion of (2.5) into (2.3) yields

$$\lambda = \sum_{m=-p}^{q} a_m \kappa^m. \tag{2.6}$$

This is an algebraic equation of degree $p+q$ in the unknown κ. If there are $p+q$ distinct κ's, the general solution of (2.3) is

$$\phi_j = \sum_{m=1}^{p+q} \beta_m \kappa_m^j, \tag{2.7a}$$

where the κ_m's are the roots of (2.6) and the β_m's are arbitrary constants. If there are only d ($d < p+q$) distinct κ's with multiplicity $r_1, r_2, \cdots, r_d$, then the general solution of (2.3) is

$$\phi_j = \sum_{m=1}^{d} \sum_{n=0}^{r_m-1} \beta_{mn} j^n \kappa_m^j. \tag{2.7b}$$

The constants β are determined by inserting (2.7) into the boundary conditions (2.4). If the bandwidth is three, i.e., $p=q=1$, the eigenvalue problem for the pure Toeplitz problem can be solved analytically [10], [15]. However, if the bandwidth is greater than three, the problem is analytically intractable.

For a quasi-Toeplitz matrix the difference equation formulation of the eigenvalue problem differs from the pure Toeplitz problem only in the boundary conditions. The difference equation (2.3) is still valid if appropriate extrapolation boundary conditions are generated. These extrapolation boundary conditions depend on the matrix entries that change the matrix from Toeplitz to quasi-Toeplitz. Extrapolation boundary conditions have the general form

$$P_m(E)\phi_{-m} = 0, \quad m = 0, 1, \cdots, p-1, \tag{2.8a}$$

$$Q_m(E)\phi_{J+m} = 0, \quad m = 1, 2, \cdots, q, \tag{2.8b}$$

where $P_m(E)$ and $Q_m(E)$ are polynomial operators and E is the shift operator defined by $E\phi_j = \phi_{j+1}$. The subscripts on the operators indicate that, in general, the operators are different for each value of m. As an example, the extrapolation boundary conditions for the matrix (1.7) are

$$P_0(E)\phi_0 = 0, \tag{2.9a}$$

$$Q_1(E)\phi_{J+1} = 0, \tag{2.9b}$$

$$Q_2(E)\phi_{J+2} = 0, \tag{2.9c}$$

where, after some algebra, one finds

$$P_0(E) = (E-1)^3(3\alpha E - 1), \tag{2.10a}$$

$$Q_1(E) = 1, \tag{2.10b}$$

$$Q_2(E) = (1 - E^{-1})^3(1 + 6\beta E^{-1}). \tag{2.10c}$$

Although the extrapolation boundary conditions are easy to derive, we will find it more convenient to implement an eigenvalue algorithm that uses the boundary difference equations directly. For example, the first row and the last two rows of the matrix (1.4) have entry changes. For the eigenvalue problem (2.1) the difference equation (2.3) is still valid at $j = 2, 3, \cdots, J-2$ and modified difference equations apply at $j = 1, J-1, J$. The general form of difference equations for the *left* boundary is

$$\mathbf{B}\tilde{\boldsymbol{\phi}} = \lambda \mathbf{D}\tilde{\boldsymbol{\phi}}, \tag{2.11}$$

where $\mathbf{B}$ is a rectangular matrix with p rows and r columns and $\tilde{\boldsymbol{\phi}}^T = [\phi_1, \phi_2, \cdots, \phi_r]$. The matrix $\mathbf{D}$ is a $p \times r$ rectangular diagonal matrix with unit entries on the diagonal. Similar equations apply at the right boundary.

The eigenvalue problem for the circulant cousin of (1.2) is (2.3) with periodic boundary conditions

$$\phi_j = \phi_{j+J}. \tag{2.12}$$

It is well known that the eigenvalue problem for any circulant matrix can be solved analytically. By inserting (2.5) into (2.12), one obtains

$$\kappa^J = 1. \tag{2.13}$$

Hence the κ's are the J roots of unity

$$\kappa_\ell = e^{i\theta_\ell}, \quad \text{where} \quad \theta_\ell = 2\ell\pi/J, \quad \ell = 1, 2, \cdots, J. \tag{2.14}$$

The circulant spectrum is obtained by substituting (2.14) into (2.6):

$$\lambda_\ell = \sum_{m=-p}^{q} a_m e^{im\theta_\ell}. \tag{2.15}$$

As an example, the spectrum of the circulant matrix (1.6) with coefficients

$$[a_{-1}, \underline{a_0}, a_1, a_2] = [-1/3,\ \underline{-1/2},\ 1,\ -1/6] \tag{2.16}$$

reduces to the compact form

$$\lambda_\ell = -4w_\ell^2/3 - i[1 + 2w_\ell/3]\sin\theta_\ell, \tag{2.17}$$

where

$$w_\ell = \sin^2(\theta_\ell/2), \quad \theta_\ell = 2\ell\pi/J, \quad \ell = 1, 2, \cdots, J. \tag{2.18}$$

The eigenvalue locus is the oval shaped dashed curve plotted in Fig. 5.1. In equation (2.16) and the remainder of this paper we use the underline to indicate the main diagonal element.

3. Partition of the asymptotic spectrum. Let A_J be a $J \times J$ banded quasi-Toeplitz (or Toeplitz) matrix. Here A_J denotes the Jth member of a family of matrices of arbitrarily large order. In the limit $J \to \infty$ one can partition the asymptotic spectrum into two sets. The partition is between the set which is *independent* of the boundary conditions and the set (possibly empty) which is *dependent* on the boundary conditions.

First we introduce some definitions. The spectrum of A_J is denoted by

$$\sigma_J = \{\lambda | \det(A_J - \lambda I) = 0\}. \tag{3.1}$$

DEFINITION 3.1. The asymptotic spectrum of the family $\{A_J\}$ is the set $\mathcal{S}$ defined by

$$\mathcal{S} = \{\lambda \mid \lambda = \lim_{m\to\infty} \lambda_m, \lambda_m \in \sigma_{i_m}, \lim_{m\to\infty} i_m = \infty\}. \tag{3.2}$$

In the special case where A_J is a pure Toeplitz matrix, we denote the asymptotic spectrum by the set $\mathcal{B}$, i.e.,

$$\mathcal{B} = \mathcal{S} \tag{3.3}$$

to conform with the notation of Schmidt and Spitzer [9].
The set $\mathcal{S}$ (or $\mathcal{B}$) defines the subset of the complex plane which is "filled in" by the points of σ_J as $J \to \infty$.

There are two additional sets that play major roles in the computational algorithms of the next section and they are defined in terms of the κ's. We assume without loss of generality that the $p+q$ roots of the algebraic equation (2.6) are ordered as

$$|\kappa_1(\lambda)| \le |\kappa_2(\lambda)| \le \cdots \le |\kappa_p(\lambda)| \le |\kappa_{p+1}(\lambda)| \le \cdots \le |\kappa_{p+q}(\lambda)|. \tag{3.4}$$

The crucial inequality in (3.4) is between $|\kappa_p(\lambda)|$ and $|\kappa_{p+1}(\lambda)|$, i.e.,

$$|\kappa_p(\lambda)| = |\kappa_{p+1}(\lambda)|, \quad \text{or} \tag{3.5a}$$

$$|\kappa_p(\lambda)| < |\kappa_{p+1}(\lambda)|. \tag{3.5b}$$

DEFINITION 3.2. The (boundary condition independent) set $\mathcal{C}$ is defined to be

$$\mathcal{C} = \{\lambda \mid |\kappa_p(\lambda)| = |\kappa_{p+1}(\lambda)|\}. \tag{3.6}$$

Schmidt and Spitzer [9] proved that the asymptotic Toeplitz spectrum defined by the set $\mathcal{B}$ is equivalent to the set $\mathcal{C}$, i.e.,

$$\mathcal{B} = \mathcal{C}. \tag{3.7}$$

Let

$$\mathbf{K}_{rs}(\lambda) = \begin{bmatrix} \kappa_1 & \kappa_2 & \kappa_3 & \cdots & \kappa_s \\ \kappa_1^2 & \kappa_2^2 & \kappa_3^2 & \cdots & \kappa_s^2 \\ \kappa_1^3 & \kappa_2^3 & \kappa_3^3 & \cdots & \kappa_s^3 \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ \kappa_1^r & \kappa_2^r & \kappa_3^r & \cdots & \kappa_s^r \end{bmatrix}, \tag{3.8}$$

which is an $r \times s$ matrix.

DEFINITION 3.3. The (boundary condition dependent) set $\mathcal{D}$ is defined to be

$$\mathcal{D} = \{\lambda \mid |\kappa_p(\lambda)| < |\kappa_{p+1}(\lambda)|, \det[(\mathbf{B} - \lambda\mathbf{D})\mathbf{K}_{rp}] = 0 \vee \det[(\mathbf{C} - \lambda\mathbf{D})\mathbf{K}_{rq}] = 0\}, \tag{3.9}$$

where $\mathbf{B}$ and $\mathbf{C}$ are the left and right boundary matrices with p and q rows, respectively, and r columns. The matrix $\mathbf{D}$ is a $p \times r$ rectangular diagonal matrix with unit entries on the diagonal. (As examples of the left and right boundary matrices see (2.11) and (4.10).)

Kreiss [7] proved that the asymptotic spectrum for non-Dirichlet boundary conditions (the quasi-Toeplitz matrix) is equal to the asymptotic spectrum for Dirichlet boundary conditions (the Toeplitz matrix) plus a set (possibly empty) of isolated eigenvalues (set $\mathcal{D}$), i.e.,

$$\mathcal{S} = \mathcal{B} \cup \mathcal{D}. \tag{3.10}$$

With the Schmidt and Spitzer identity (3.7) we have

$$\mathcal{S} = \mathcal{C} \cup \mathcal{D}. \tag{3.11}$$

The investigation of the set $\mathcal{D}$ is an integral part of the work of Gustafsson, Kreiss, and Sundström [6]. In the next section we present algorithms for numerically determining the sets $\mathcal{C}$ and $\mathcal{D}$ and thus the asymptotic spectra for banded quasi-Toeplitz matrices.

For a pure Toeplitz matrix the asymptotic spectrum is the set $\mathcal{C}$. For the quasi-Toeplitz cousin matrix, which can have arbitrary boundary conditions, the set $\mathcal{C}$ is a subset of the asymptotic spectrum $\mathcal{S}$. We say therefore that the set $\mathcal{C}$ is the boundary condition independent part of the the asymptotic spectrum and the set $\mathcal{D}$ is the boundary condition dependent part of the asymptotic spectrum. Note that the asymptotic spectrum for a pure Toeplitz matrix is the boundary condition independent spectrum.

4. Algorithms for computing the asymptotic spectra. In this section we present algorithms for computing the asymptotic spectra of Toeplitz and quasi-Toeplitz matrices. We separate the algorithms for the two sets: (a) boundary condition independent (pure Toeplitz) set $\mathcal{C}$, and (b) boundary condition dependent set $\mathcal{D}$. The application of each algorithm involves the solution of algebraic equations whose degree is proportional to the bandwidth $p + q + 1$ of the matrix.

4.1. Boundary condition independent (Toeplitz) spectrum. The algorithm for the pure Toeplitz asymptotic spectrum (set $\mathcal{C}$) is based on the observation that separated the spectrum into two sets, i.e., we seek those eigensolutions whose κ's satisfy (3.4) with the equality (3.5a). First we seek the solutions of the algebraic equation (2.6) with two distinct but equal modulus κ's. We denote these κ's by

$$\kappa_a = \hat{\kappa} e^{i\psi_\ell}, \quad \kappa_b = \hat{\kappa} e^{-i\psi_\ell}, \quad 0 < \psi_\ell < \pi, \tag{4.1}$$

where $\hat{\kappa}$ is a complex variable. For computational convenience, the interval $[0, \pi]$ is divided into $M + 1$ subintervals of size $\Delta\psi$ where $(M + 1)\Delta\psi = \pi$ and $\psi_\ell = \ell\Delta\psi$, $\ell = 1, 2, \cdots, M$. (The choice of the integer M determines the number of computed points on the asymptotic spectrum, i.e., the resolution of the spectrum, but does not affect the accuracy of the computed points.) An equation for $\hat{\kappa}$ (independent of λ) is easily obtained. Since κ_a and κ_b must each give the same value of λ when inserted in (2.6), we can eliminate λ and obtain a polynomial in $\hat{\kappa}$ with coefficients that are functions of the Toeplitz matrix elements and ψ_ℓ. In particular,

$$\lambda(\kappa_a) = \sum_{m=-p}^{q} a_m \hat{\kappa}^m e^{im\psi_\ell}, \qquad \lambda(\kappa_b) = \sum_{m=-p}^{q} a_m \hat{\kappa}^m e^{-im\psi_\ell}, \tag{4.2}$$

and since

$$\lambda(\kappa_a) = \lambda(\kappa_b), \tag{4.3}$$

one obtains a polynomial equation of order $p+q$ for $\hat{\kappa}$:

$$\sum_{m=-p}^{q} a_m \sin(m\psi_\ell)\hat{\kappa}^m = 0. \tag{4.4}$$

The algorithm for the boundary condition independent spectrum, set $\mathcal{C}$, is the following.

ALGORITHM 4.1. For each of the M values of ψ_ℓ:

(i) Solve (4.4) for the $p+q$ roots $\hat{\kappa}$.

(ii) Check the corresponding κ's to determine if they satisfy (3.4) with (3.5a), i.e., that κ_a and κ_b from (4.1) are in fact κ_p and κ_{p+1}. This is done as follows.
For each $\hat{\kappa}$ obtained in (i)

(iia) Calculate κ_a and κ_b from (4.1) and insert κ_a (or κ_b) in (2.6) to find λ. Substitute this value for λ back into (2.6) and solve the algebraic equation to determine the remaining $(p+q-2)$ κ's.

(iib) If the $p+q$ κ's satisfy the inequality (3.4) with (3.5a), i.e., $|\kappa_a| = |\kappa_b| = |\kappa_p| = |\kappa_{p+1}|$, then λ is a point on the asymptotic Toeplitz spectrum. If the κ's do not satisfy the inequality test, discard the λ.
Return to (iia) until all $\hat{\kappa}$'s from (i) have been tested.
Replace ψ_ℓ by $\psi_{\ell+1}$ and return to step (i).

It should be emphasized that the algorithm (4.1) requires the solution of many algebraic equations but their degree is proportional to the bandwidth of the matrix and not the order of the matrix. Note that the boundary conditions do not enter the calculation. An implementation of the algorithm in MATLAB is given in the Appendix. The algorithm will become more transparent in the examples of §6.

4.2. Boundary condition dependent spectrum. The algorithm for the boundary condition dependent asymptotic spectrum (set $\mathcal{D}$) closely parallels the eigenvalue analysis of Kreiss [7] and Gustafsson, Kreiss, and Sundström [6]. There are however some differences since their analysis for hyperbolic initial-boundary-value problems makes two assumptions: (I) Cauchy stability (an assumption about the spectrum of the Toeplitz matrix's circulant cousin), and (II) the quarter-plane eigensolutions are *unstable* (i.e., the eigenvalues are in a particular part of the complex plane). Since we are interested in the entire spectrum for any quasi-Toeplitz matrix, we do not impose conditions (I) and (II). The relaxation of these two conditions leads to a slightly more complicated algorithm.

The algorithm for the boundary condition dependent part of the spectrum is straightforward. We seek p (or q) values of κ that satisfy (2.6) and satisfy the left p (or right q) boundary difference equations. The remaining q (or p) κ's must satisfy

(3.4) with inequality (3.5b). The algorithm for the eigenvalues associated with the *left* boundary is as follows.

ALGORITHM 4.2.

(i) Assume a solution of the form

$$\phi_j = \sum_{m=1}^{p} \beta_m \kappa_m^j. \tag{4.5}$$

Substitute ϕ_j from (4.5) into the p left boundary difference equations (2.11) to obtain

$$(\mathbf{B} - \lambda\mathbf{D})\mathbf{K}_{rp}\boldsymbol{\beta} = 0, \tag{4.6}$$

where $\mathbf{K}_{rp}$ is defined by (3.8) and

$$\boldsymbol{\beta}^T = [\beta_1, \beta_2, \cdots, \beta_p]. \tag{4.7}$$

Equation (4.6) is a system of p equations for the $2p+1$ unknowns: p κ_m's, p β_m's, and λ. This system of p equations is linear and homogeneous in the β's and therefore a nontrivial solution exists if and only if

$$\det[(\mathbf{B} - \lambda\mathbf{D})\mathbf{K}_{rp}] = 0. \tag{4.8}$$

The determinant condition leads to a single equation for the p κ's and λ. An additional p equations are required and they are derived from the algebraic equation (2.6) since each of the p κ's must give the same value of λ. This system of polynomial equations can be reduced to a single polynomial equation for a single variable and we choose κ_p.

(ii) The roots of the polynomial equation from (i) contain all *candidate* κ_p's for the (left) boundary condition dependent spectrum. For each κ_p the corresponding κ_m's must be checked. This is accomplished by calculating the corresponding λ ($\kappa = \kappa_p$) from (2.6) and then computing the $p+q$ roots of (2.6) for the given λ. Finally, we compare those roots with the p κ_m's which satisfy the boundary difference equations (2.11). If (3.4) and (3.5b) are both satisfied, the λ is an eigenvalue in the boundary condition dependent part of the spectrum.

The algorithm for the eigenvalues associated with the right boundary is similar. If the algorithm has been implemented for the left boundary problem, it can be used for the right boundary problem by pre- and post-multiplying $\mathbf{A}$ by the permutation matrix

$$\mathbf{P} = \begin{bmatrix} & & & & 1 \\ & O & & 1 & \\ & & \cdot & & \\ & & \cdot & & \\ & \cdot & & & \\ & 1 & & O & \\ 1 & & & & \end{bmatrix}, \tag{4.9}$$

i.e., $\mathbf{PAP}$. Note that $\mathbf{P}^{-1} = \mathbf{P}$. The matrix $\mathbf{PAP}$ is most easily obtained by interchanging the columns of $\mathbf{A}$ "left to right" and then interchanging the rows "up and down." The boundary difference equations associated with the left boundary for **PAP** are

$$\mathbf{C}\tilde{\phi} = \lambda \mathbf{D}\tilde{\phi}. \tag{4.10}$$

As an example, the matrices **C** and **D** associated with **PAP** where **A** is (1.4) are

$$\mathbf{C} = \begin{bmatrix} c_{11} & c_{12} & c_{13} & c_{14} \\ c_{21} & c_{22} & c_{23} & c_{24} \end{bmatrix}, \qquad \mathbf{D} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}. \tag{4.11}$$

This explains the somewhat unconventional indexing for the c elements of (1.4). (Note that a pure Toeplitz matrix **A** is persymmetric, i.e., it is symmetric about its northeast-southwest diagonal [3]. Consequently $\mathbf{A}^T = \mathbf{PAP}$. However if **A** is *quasi*-Toeplitz then **PAP** is *not* the transpose of **A**.)

The details of the algorithm are illustrated by the examples of §6. Note that there may be no eigenvalues in the boundary condition dependent part of the spectrum even if non-Dirichlet boundary conditions are specified, i.e., the set $\mathcal{D}$ may be empty.

The algorithm for the boundary condition dependent spectrum is straightforward, but finding a polynomial equation in a single variable can be algebraically involved and the degree of the polynomial can be large. The system of equations for the κ's in (i) are symmetric polynomials; therefore, the algebraic complexity can be somewhat reduced by the use of the elementary symmetric functions. We have implemented Algorithm 4.2 in MACSYMA, and it performs satisfactorily on an IRIS workstation for the matrix **B** with two rows and a quasi-Toeplitz matrix **A** with bandwidths up to five.

4.3. Alternative boundary condition dependent algorithm. The algebraic complexity of the boundary condition dependent algorithm of §4.2 led us to consider alternative methods. In the GKS (Gustafsson, Kreiss and Sundström [6]) theory a GKS (i.e., *unstable*) eigenvalue is a member of the boundary condition dependent eigenvalue set $\mathcal{D}$ of this paper. Kreiss [7] recognized that it is often very difficult to find GKS eigenvalues by analytical methods. He proposed finding GKS eigenvalues (if they exist) by a numerical eigenvalue computation of the finite-domain problem where the boundary condition (or conditions) to be checked are on the left boundary and Dirichlet boundary conditions are imposed on the right boundary. Kreiss showed that GKS eigenvalues converge exponentially fast with increasing J. However, we found difficulties in numerically delineating the GKS eigenvalues (or other boundary condition dependent eigenvalues) for *nonnormal* matrices. The numerical difficulties are often alleviated if the matrix is rescaled as described in §7.

We have found the following algorithm to be useful although not always completely reliable since it will sometimes "miss" an eigenvalue. The reliability is improved if the algorithm is repeated for several matrix orders.

ALGORITHM 4.3.
(i) Place the boundary conditions of interest on the left boundary and Dirichlet conditions on the right boundary.
(ii) Apply the similarity transformation described in §7 and use a conventional eigenvalue algorithm to find the spectrum for large J.
(iii) Test each eigenvalue found in (ii) using part (ii) of Algorithm 4.2.

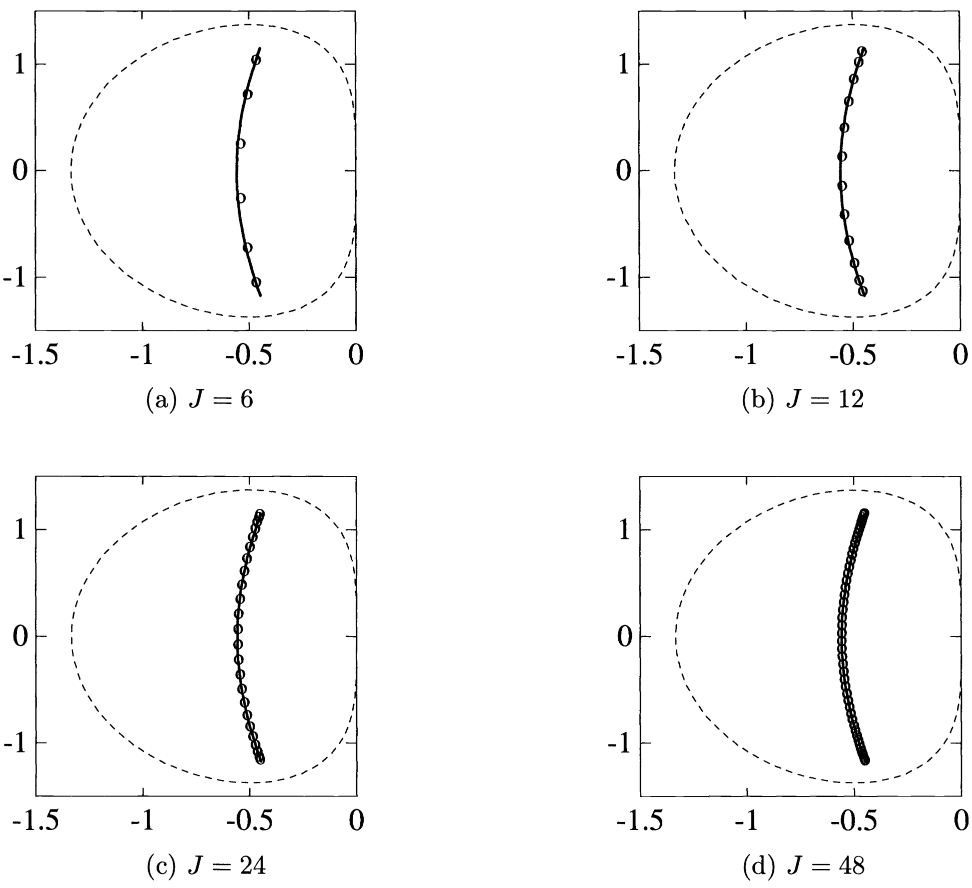

FIG. 5.1. *Toeplitz matrix* $[-1/3, \underline{-1/2}, 1, -1/6]$ *spectra "fill in" for increasing matrix order* J. *The symbol* o *denotes an eigenvalue. Asymptotic spectra* (*Algorithm 4.1*) *are denoted by solid curves and asymptotic circulant spectra* (2.17) *by dashed curves.*

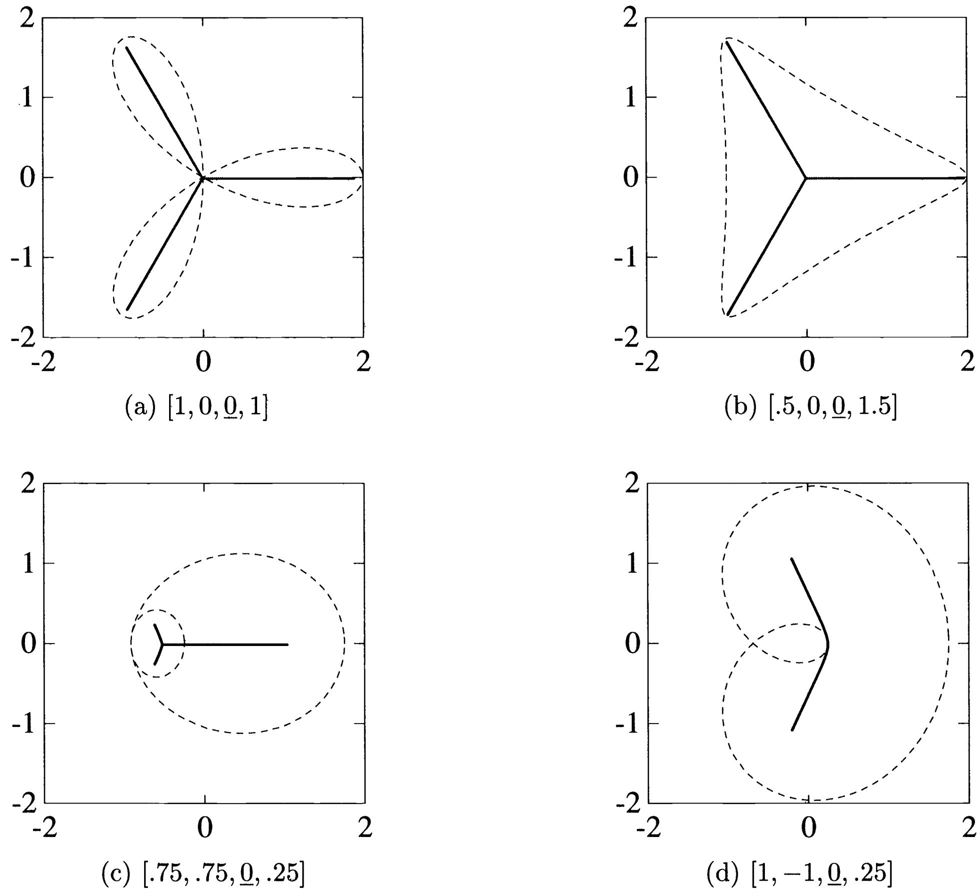
5. Numerical application of algorithms. Plots of the asymptotic spectra of Toeplitz matrices present some interesting and sometimes surprising geometrical shapes. In this section we present some spectra that were obtained with the algorithms described in §4. The matrix coefficients were selected more or less at random to give a flavor of the geometric patterns that may occur.

In each figure we show the spectra plotted in the complex plane. Open circles represent eigenvalues computed using MATLAB $eig(A_J)$ for the matrix order (J) specified in the figure legend. The "solid" curve (which is formed by closely spaced dots) is the asymptotic spectrum for the Toeplitz matrix and was computed using Algorithm 4.1. The star symbol ($*$) is used to represent the boundary condition dependent part of the asymptotic spectrum computed using Algorithm 4.2 or 4.3. The dashed curve represents the asymptotic spectrum for the circulant cousin of the pure Toeplitz matrix.

5.1. Toeplitz spectra. First we summarize the known properties of the asymp-



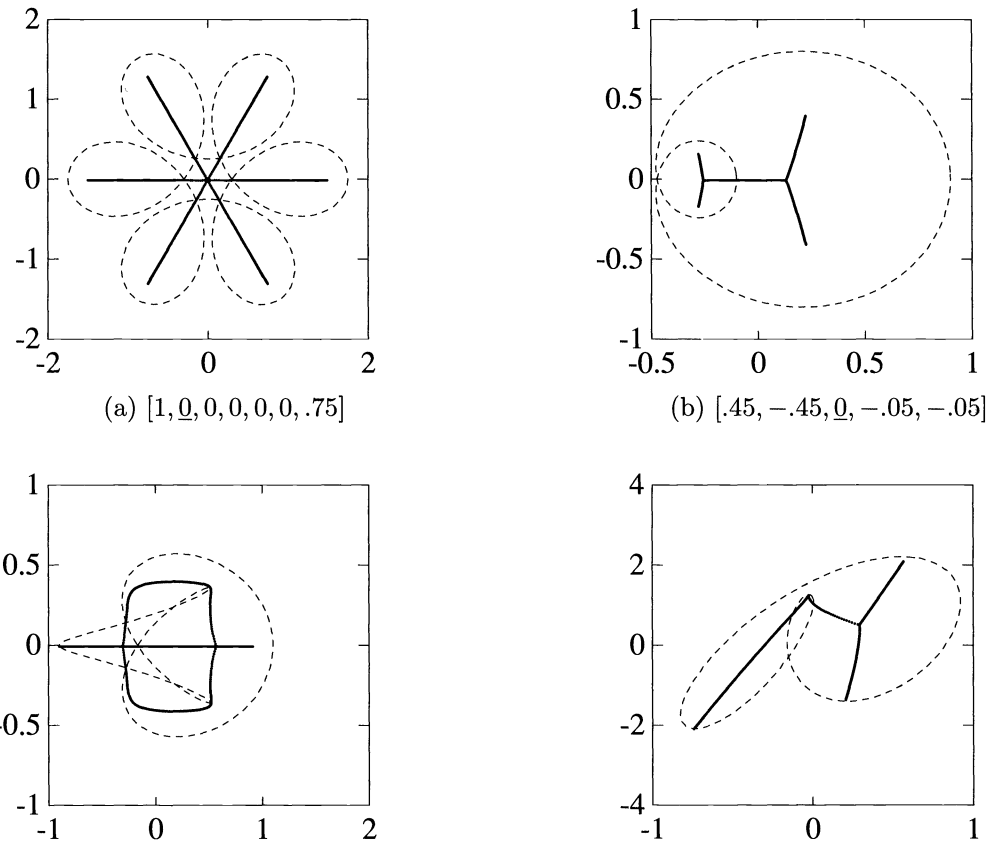
(a) $[1, 0, \underline{0}, 1]$ (b) $[.5, 0, \underline{0}, 1.5]$

(c) $[.75, .75, \underline{0}, .25]$ (d) $[1, -1, \underline{0}, .25]$

FIG. 5.2. *Asymptotic spectra for pure Toeplitz matrices (Algorithm 4.1) indicated by solid curves and the asymptotic spectra for the circulant cousin Toeplitz matrices indicated by dashed curves.*

totic spectra of pure Toeplitz matrices and show some examples that illustrate these properties. Definition 3.1 involves a family of matrices $\mathbf{A}_J$ where the dimension J tends to infinity. As J increases a subset of the complex plane is "filled in" by the spectrum σ_J and as $J \to \infty$ one obtains the asymptotic spectrum [9]. This is illustrated in Fig. 5.1 for a quadridiagonal pure Toeplitz matrix defined by the sequence (2.16). Note that the spectrum σ_J is close to the asymptotic spectrum even for small values of J.

The asymptotic spectrum of a banded pure Toeplitz matrix is compact and locally it consists of analytical arcs [9]. Furthermore, it possesses no isolated points [9]. This property will be of interest in considering the asymptotic spectra of quasi-Toeplitz matrices. Ullman [14] has shown that the asymptotic spectrum is connected. Asymptotic spectra illustrating these properties are plotted in Figs. 5.2 and 5.3. The defining sequence (1.1) is shown under each figure. Algorithm 4.1 is not restricted to Toeplitz matrices with *real* coefficients and this is demonstrated in Fig. 5.3(d). As the bandwidth of the matrix increases, the asymptotic spectrum becomes increasingly



(a) $[1, \underline{0}, 0, 0, 0, 0, .75]$

(b) $[.45, -.45, \underline{0}, -.05, -.05]$

(c) $[-.2, -.2, -.2, \underline{.1}, -.2, .2, -.4]$

(d) $[.7i, .3, \underline{0}, .5i, .3 + i]$

FIG. 5.3. *Asymptotic spectra for Toeplitz matrices (Algorithm 4.1) indicated by solid curves and their circulant cousin Toeplitz matrices indicated by dashed curves.*

complex.

According to Schmidt and Spitzer [9] it is not easy to give a simple geometric description of the asymptotic Toeplitz spectrum for nonnormal matrices. An exception is the special case where the defining sequence is $[a_{-p}, 0, \cdots, 0, a_q]$, i.e., all members of the sequence are zero except the two "outriders." In this case the spectrum is a star-shaped figure. Examples of star-shaped spectra for quadridiagonal matrices are shown in Figs. 5.2(a) and 5.2(b) and for a septadiagonal matrix in Fig. 5.3(a). The spectrum for the tridiagonal case is known analytically and consists of a straight line segment (connecting the foci of the ellipse which is the spectrum of its circulant cousin) [16].

It is a general result [9] that the asymptotic Toeplitz spectrum is "enclosed" by the spectrum of its circulant cousin. This is illustrated in Figs. 5.2 and 5.3. However, for finite J the spectrum σ_J is not necessarily enclosed by the asymptotic spectrum of the circulant cousin of $\mathbf{A}$. This is illustrated in Fig. 5.4.

5.2. Quasi-Toeplitz spectra. The properties of the asymptotic spectrum of a

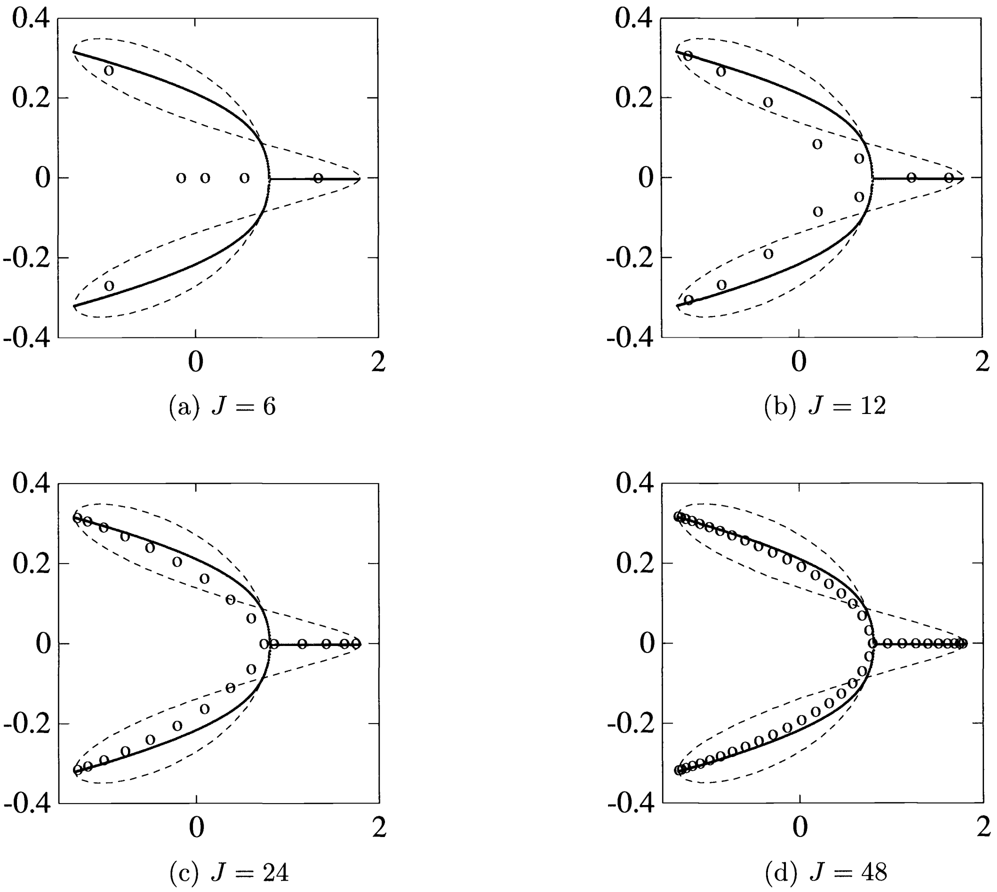


FIG. 5.4. *Spectra for finite matrix order J (o symbol) and the asymptotic circulant spectrum (dashed curves). Asymptotic Toeplitz spectra indicated by solid curves. The Toeplitz matrix is* $[.7, .1, \underline{0}, .4, .6]$.

quasi-Toeplitz matrix are illustrated in Fig. 5.5 for the matrix (1.7). The asymptotic spectrum consists of the asymptotic pure Toeplitz spectrum, set $\mathcal{C}$, plus (possible) isolated eigenvalues corresponding to boundary condition dependent eigenvalues, set $\mathcal{D}$. The isolated eigenvalues (see, e.g., Fig. 5.5(b)) must be boundary condition dependent eigenvalues associated with set $\mathcal{D}$ because the pure Toeplitz spectrum can have no isolated points [9]. Note also that, in contrast to the pure Toeplitz spectrum, the quasi-Toeplitz spectrum may have (isolated) eigenvalues outside the circulant spectrum, e.g., Figs. 5.5(b), 5.5(c), and 5.5(d). For $\alpha = \beta = 0$ the matrix (1.7) has no boundary condition dependent eigenvalues and the asymptotic quasi-Toeplitz spectrum is the pure Toeplitz spectrum shown in Fig. 5.5(a). In this example set $\mathcal{D}$ is empty. A fundamental property of the eigenvalues associated with set $\mathcal{D}$ is that the "left" and "right" boundary dependent eigenvalues are uncoupled. This is illustrated in Figs. 5.5(b), 5.5(c), and 5.5(d). For $\beta = -.8$ there are three isolated eigenvalues to the right of the pure Toeplitz spectrum. These eigenvalues are completely independent of the parameter α of the left boundary condition (see matrix (1.7)). This fact

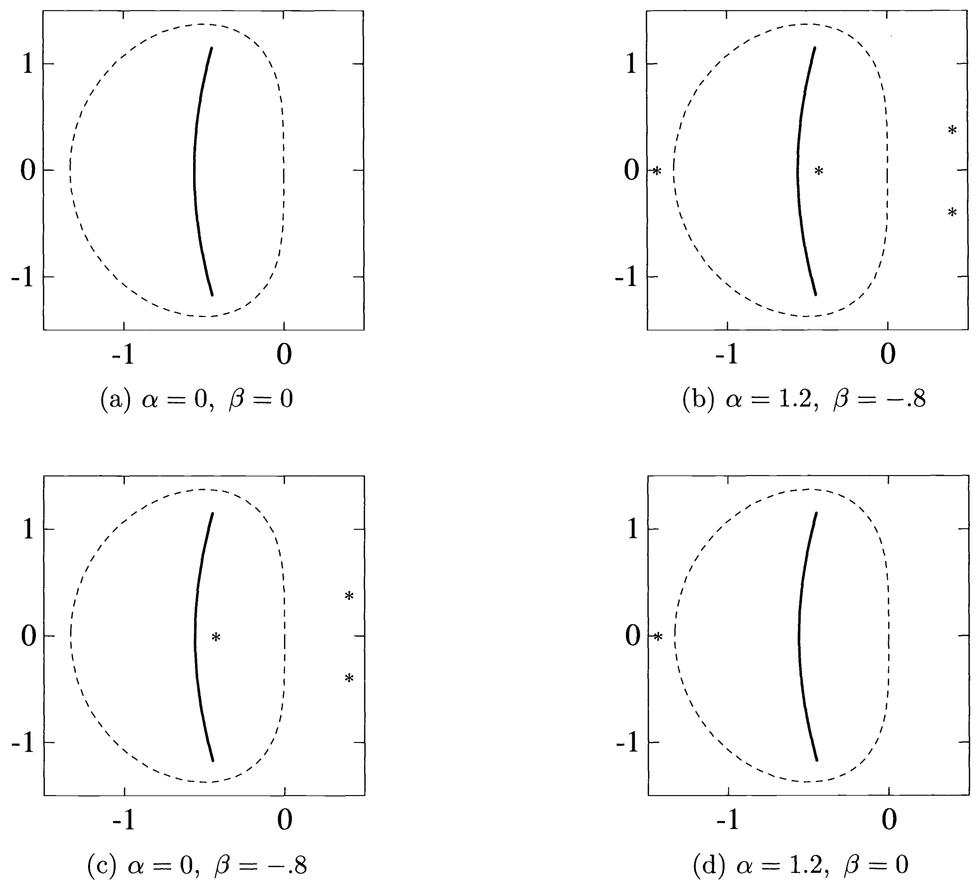

FIG. 5.5. *Asymptotic spectra for the quasi-Toeplitz matrix* (1.7). *Boundary condition independent spectra computed with Algorithm 4.1* (*solid curve*), *boundary condition dependent spectra* ($*$ *symbol*) *computed with Algorithm 4.2, and asymptotic circulant spectra* (*dashed curves*).

is illustrated by comparing Figs. 5.5(b) and 5.5(c) where β is fixed and α is changed. For $\alpha = 1.2$ there is one isolated eigenvalue to the left of the circulant spectrum. This eigenvalue is independent of the parameter β of the right boundary condition as is indicated by comparing Figs. 5.5(b) and 5.5(d).

6. Analytical application of algorithms. If the bandwidth of the matrix is sufficiently small (≈ 3) the algorithms of §4 can be used as analytical methods. In this section we elucidate the algorithms of the previous section by considering small bandwidth examples for both Toeplitz and quasi-Toeplitz matrices.

6.1. Toeplitz tridiagonal matrix. A tridiagonal Toeplitz matrix is defined by the sequence $[a_{-1}, a_0, a_1]$ where $p = q = 1$ (see (1.1)). For this case the spectrum for arbitrary order J can be determined analytically. The solution is "well known" although the eigenvalue formula does not appear in many references. A derivation is given by Smith [10, p. 113]. The algebraic equation (2.6) becomes

$$\lambda = a_{-1}\kappa^{-1} + a_0 + a_1\kappa. \tag{6.1}$$

By rewriting (6.1), one obtains

$$a_1\kappa^2 + (a_0 - \lambda)\kappa + a_{-1} = 0. \tag{6.2}$$

We denote the roots of this quadratic by κ_1, κ_2. The product of the roots is

$$\kappa_1\kappa_2 = \frac{a_{-1}}{a_1}. \tag{6.3}$$

We follow the algorithm for the boundary condition independent part of the spectrum from §4.1. Equation (4.4) for $\hat{\kappa}$ reduces to

$$a_1\hat{\kappa}^2 - a_{-1} = 0. \tag{6.4}$$

In step (i) we solve for the roots of (6.4), i.e.,

$$\hat{\kappa} = \pm\sqrt{a_{-1}/a_1}. \tag{6.5}$$

In step (iia) we find

$$\kappa_a = \sqrt{a_{-1}/a_1}\,e^{i\psi_\ell}, \tag{6.6a}$$

$$\kappa_b = \sqrt{a_{-1}/a_1}\,e^{-i\psi_\ell}, \tag{6.6b}$$

where we have chosen the positive square root. (The negative square root gives the same spectrum.) Since there are only two roots of (6.1), i.e., κ_1 and κ_2, they must be κ_a and κ_b. They obviously have equal modulus, therefore equality (3.5a) is satisfied and the corresponding λ is part of the Toeplitz spectrum. (In this simple example step (ii) of the Algorithm 4.1 is rather trivial.) Substitution of κ_a given by (6.6a) into (6.1) yields

$$\lambda_\ell = a_0 + 2\sqrt{a_1 a_{-1}}\cos\psi_\ell, \quad 0 < \psi_\ell < \pi, \tag{6.7}$$

which is the asymptotic spectrum for a tridiagonal Toeplitz matrix.

Although not part of the asymptotic analysis we note that for the tridiagonal case, the roots κ_1 and κ_2 have equal modulus regardless of the order J of the matrix. In fact, the exact roots are given by

$$\kappa_1 = \hat{\kappa}e^{i\psi_\ell}, \qquad \kappa_2 = \hat{\kappa}e^{-i\psi_\ell}, \quad \text{where} \quad \psi_\ell = \ell\pi/(J+1), \quad \ell = 1, 2, \cdots, J, \tag{6.8}$$

and $\hat{\kappa}$ is given by (6.5) (see, e.g. [16]). Consequently, the exact spectrum for a $J \times J$ matrix is (6.7) where ψ_ℓ is defined in (6.8). It should be emphasized that if the bandwidth of a Toeplitz matrix is larger than three, then Algorithm 4.1 is, in general, exact only in the asymptotic limit $J \to \infty$.

6.2. Quasi-Toeplitz tridiagonal matrix. The asymptotic spectrum for a quasi-Toeplitz tridiagonal matrix is given by (6.7) plus any boundary condition dependent eigenvalues, i.e., set $\mathcal{D}$. We first show that a pure Toeplitz tridiagonal matrix does not have any boundary condition dependent eigenvalues, i.e., the homogeneous (Dirichlet) boundary conditions (2.4) introduce no boundary condition dependent eigenvalues. For a tridiagonal matrix the homogeneous conditions (2.4) are simply

$$\phi_0 = 0, \tag{6.9a}$$

$$\phi_{J+1} = 0. \tag{6.9b}$$

By substituting (4.5), i.e.,

$$\phi_j = \beta_1 \kappa_1^j \tag{6.10}$$

into (6.9a), one concludes that either $\beta_1 = 0$ or $\kappa_1 = 0$. But the product of the roots (6.3) is nonzero and $\beta_1 = 0$. Hence there is no nontrivial eigenfunction and no eigenvalue is introduced by the (left) boundary condition (6.9a). By substituting (6.10) into (6.9b), one finds the similar result that no eigenvalue is introduced by the (right) boundary condition (6.9b).

For the general Toeplitz matrix there are p homogeneous Dirichlet boundary conditions at the left boundary and q homogeneous Dirichlet boundary conditions at the right boundary, i.e., (2.4a) and (2.4b). Substitution of (4.5) into the left boundary conditions leads to a homogeneous system $\mathbf{V}\boldsymbol{\beta} = 0$ where $\mathbf{V}$ is a $p \times p$ Vandermonde matrix and $\boldsymbol{\beta} = [\beta_1, \beta_2, \cdots, \beta_p]^T$. The determinant of $\mathbf{V}$ equals zero if and only if two κ's are equal which violates the assumption of distinct κ's. The assumption of nondistinct κ's also leads to the trivial case $\boldsymbol{\beta} = 0$. Therefore Dirichlet boundary conditions introduce no boundary condition dependent eigenvalues, i.e., the set $\mathcal{D}$ is empty.

Consider now boundary conditions that introduce nontrivial solutions. Suppose that when (6.10) is introduced into the left boundary condition we obtain

$$\kappa_1 = \kappa_\sigma, \tag{6.11}$$

where κ_σ is some nonzero complex constant. Does this introduce an eigenvalue? It does if inequality (3.5b) is satisfied, i.e., $|\kappa_1| < |\kappa_2|$. From (6.3) one obtains

$$|\kappa_2| = |a_{-1}/a_1|/|\kappa_\sigma|. \tag{6.12}$$

Inequality (3.5b) is satisfied if

$$|\kappa_1| = |\kappa_\sigma| < \sqrt{|a_{-1}/a_1|} \tag{6.13}$$

and the corresponding eigenvalue λ is obtained by substituting κ_σ into (6.1).

We give an example of a quasi-Toeplitz matrix where there is a boundary condition dependent eigenvalue. Consider the matrix

$$\mathbf{A} = \begin{bmatrix} 0 & -2 & 2 & & & \\ -1 & 0 & 1 & & O & \\ & \cdot & \cdot & \cdot & & \\ & & \cdot & \cdot & \cdot & \\ & & & \cdot & \cdot & \cdot \\ & O & & -1 & 0 & 1 \\ & & & & -1 & 0 \end{bmatrix}. \tag{6.14}$$

Here

(6.15) $$a_{-1} = -1, \quad a_0 = 0, \quad a_1 = 1, \quad b_{11} = 0, \quad b_{12} = -2, \quad b_{13} = 2.$$

The eigenvalue problem is (2.3) with $p = q = 1$, and the boundary difference equation (2.11) is

(6.16) $$-2\phi_2 + 2\phi_3 = \lambda\phi_1.$$

Substitution of (6.10) into (6.16) yields

(6.17) $$-2\kappa_1 + 2\kappa_1^2 = \lambda.$$

The second equation relating κ_1 and λ is (6.2) with $\kappa = \kappa_1$ and coefficients (6.15)

(6.18) $$\kappa_1^2 - \lambda\kappa_1 - 1 = 0.$$

Elimination of λ from (6.17) and (6.18) yields

(6.19) $$(\kappa_1 - 1)^2(2\kappa_1 + 1) = 0.$$

The roots of (6.19) are

(6.20) $$\kappa_1 = 1, 1, -1/2.$$

In the tridiagonal case, step (ii) of Algorithm 4.2 is simplified to checking inequality (6.13). The inequality (6.13), with (6.15),

$$|\kappa_1| = |\kappa_\sigma| < 1$$

is satisfied for $\kappa_1 = -1/2$. Substitution of $\kappa_1 = -1/2$ into (6.17) gives $\lambda = 3/2$.

The asymptotic spectrum of the quasi-Toeplitz matrix (6.14) consists of two parts. The boundary condition independent (pure Toeplitz) spectrum, set $\mathcal{C}$, is (6.7)

(6.21) $$\lambda = i2\cos\psi, \quad 0 < \psi < \pi,$$

and the boundary condition dependent part of the spectrum, set $\mathcal{D}$, is $\lambda = 3/2$. Consequently, the asymptotic spectrum is a line segment on the imaginary axis between $\pm 2i$ and the single eigenvalue $\lambda = 3/2$.

6.3. Toeplitz quadridiagonal matrix. A more interesting example is the quadridiagonal matrix (1.3) where $p = 1$ and $q = 2$. The algebraic equation (2.6) is

(6.22) $$\lambda = a_{-1}\kappa^{-1} + a_0 + a_1\kappa + a_2\kappa^2.$$

For the boundary condition independent spectrum (set $\mathcal{C}$) , the three roots of the cubic (6.22) must satisfy (3.4) and (3.5a)

(6.23) $$|\kappa_1| = |\kappa_2| \le |\kappa_3|.$$

The product of the roots of (6.22) is $-a_{-1}/a_2$ and therefore

(6.24) $$|\kappa_1||\kappa_2||\kappa_3| = |a_{-1}/a_2|.$$

The polynomial (4.4) for $\hat{\kappa}$ becomes

$$a_{-1}\sin(-\psi_\ell)\hat{\kappa}^{-1} + a_1\sin(\psi_\ell)\hat{\kappa} + a_2\sin(2\psi_\ell)\hat{\kappa}^2 = 0$$

or

$$2a_2(\cos\psi_\ell)\hat{\kappa}^3 + a_1\hat{\kappa}^2 - a_{-1} = 0. \tag{6.25}$$

In (i) of Algorithm 4.1 we solve (6.25) numerically for specified coefficients a_ℓ.

In (iia) of Algorithm 4.1 we proceed as follows. For each root $\hat{\kappa}$ we substitute $\kappa_a = \hat{\kappa}e^{i\psi_\ell}$ into (6.22) and calculate the corresponding λ. Then with λ given, we solve the cubic (6.22) for the roots $\kappa_1, \kappa_2, \kappa_3$. Of course, two of the roots are already known, i.e., $\kappa_a = \hat{\kappa}e^{i\psi_\ell}$ and $\kappa_b = \hat{\kappa}e^{-i\psi_\ell}$. In (iib) we check to see if the three roots satisfy inequality (6.23)

$$|\kappa_a| = |\kappa_b| = |\kappa_1| = |\kappa_2| \le |\kappa_3|. \tag{6.26}$$

If this inequality is satisfied, then the corresponding λ is a point of the boundary condition independent spectrum. If the κ's fail to satisfy inequality (6.26), we discard the λ. We repeat (i) and (ii) for all of the ψ_ℓ's where $\ell = 1, 2, \cdots, M$.

For the particular example under consideration, the test (6.26) can be simplified as follows. Recall that the roots of equal modulus κ_1 and κ_2 are denoted by (4.1) and rewrite (6.23) as

$$|\hat{\kappa}| = |\hat{\kappa}| \le |\kappa_3| \tag{6.27}$$

and (6.24) as

$$|\hat{\kappa}||\hat{\kappa}||\kappa_3| = |a_{-1}/a_2|. \tag{6.28}$$

Inequality (6.27) is satisfied if

$$|\hat{\kappa}| \le |a_{-1}/a_2|^{1/3}. \tag{6.29}$$

Hence if $|\hat{\kappa}|$ satisfies (6.29), then the corresponding λ computed by inserting $\kappa_a = \hat{\kappa}e^{i\psi_\ell}$ into (6.22) is a point of the boundary condition independent spectrum.

The asymptotic spectrum for the Toeplitz matrix (1.3) with coefficients (2.16) was computed with Algorithm 4.1 (see also the Appendix) and is the solid curve in each of the figures of Fig. 5.1. The asymptotic spectrum for the circulant cousin (1.6) is the dashed curve in each of the figures of Fig. 5.1.

6.4. Quasi-Toeplitz quadridiagonal matrix. An example of a quasi-Toeplitz quadridiagonal matrix is (1.4) where $p = 1$ and $q = 2$. The eigenvalue problem is equivalent to (2.3), i.e.,

$$\lambda\phi_j = a_{-1}\phi_{j-1} + a_0\phi_j + a_1\phi_{j+1} + a_2\phi_{j+2}, \qquad j = 2, 3, \cdots, J \tag{6.30}$$

with left boundary difference equation (2.11)

$$b_{11}\phi_1 + b_{12}\phi_2 + b_{13}\phi_3 + b_{14}\phi_4 = \lambda\phi_1. \tag{6.31}$$

The spectrum for the matrix (1.4) is the spectrum for the pure Toeplitz matrix (plotted in Fig. 5.5(b) for coefficients (2.16)) plus any boundary condition dependent eigenvalues. For the boundary condition dependent spectrum the roots of the cubic (6.22) must satisfy

$$|\kappa_1| < |\kappa_2| \leq |\kappa_3| \tag{6.32}$$

(see (3.4) and (3.5b)).

In the analysis of the boundary condition dependent part of the spectrum, the left and right boundary conditions are uncoupled and consequently we consider each boundary separately.

6.4.1. Left boundary dependent spectrum. The left boundary difference equation is given by (6.31). We follow the algorithm for the boundary condition dependent part of the spectrum given in §4.2. Recall that for this example $p = 1$ and in the first step (i), we look for a solution of the form (4.5)

$$\phi_j = \beta_1 \kappa_1^j. \tag{6.33}$$

Insertion of this equation into the boundary difference equation (6.31) yields

$$b_{11} + b_{12}\kappa_1 + b_{13}\kappa_1^2 + b_{14}\kappa_1^3 = \lambda. \tag{6.34}$$

As a particular example we consider the special case for the matrix (1.4) where the coefficients a_ℓ are given by (2.16) and the coefficients b_{1j} are given by

$$b_{11} = -\alpha - 3/2, \quad b_{12} = 3\alpha + 2, \quad b_{13} = -3\alpha - 1/2, \quad b_{14} = \alpha. \tag{6.35}$$

The algebraic equation (6.22) with $\kappa = \kappa_1$ becomes

$$6\lambda = -\frac{2}{\kappa_1} - 3 + 6\kappa_1 - \kappa_1^2 = -(\kappa_1 - 1)(\kappa_1^2 - 5\kappa_1 - 2)/\kappa_1, \tag{6.36}$$

and the boundary difference equation (6.34) with coefficients (6.35) becomes

$$-(\alpha + 3/2) + (3\alpha + 2)\kappa_1 - (3\alpha + 1/2)\kappa_1^2 + \alpha\kappa_1^3 = \lambda. \tag{6.37}$$

If we eliminate λ from (6.36) and (6.37), the polynomial for κ_1 is

$$(\kappa_1 - 1)^3(3\alpha\kappa_1 - 1) = 0. \tag{6.38}$$

Note that if we formulate the problem in terms of the extrapolation boundary conditions (2.9), then (6.38) follows by inserting (6.33) into (2.9a).

Example 6.1. As our first example we let $\alpha = 0$ and (6.38) becomes

$$(\kappa_1 - 1)^3 = 0. \tag{6.39}$$

The repeated roots of (6.39) are

$$\kappa_1 = 1, \tag{6.40}$$

and from (6.36) the corresponding eigenvalue is $\lambda = 0$. Recall that the roots of the cubic equation (6.36) are denoted by κ_1, κ_2, and κ_2. By inserting $\lambda = 0$ into (6.36), one finds that the roots are

$$\kappa_1 = 1, \tag{6.41a}$$

$$\kappa_2 = (5 - \sqrt{33})/2 \approx -0.372, \tag{6.41b}$$

$$\kappa_3 = (5 + \sqrt{33})/2 \approx 5.372. \tag{6.41c}$$

It is obvious that inequality (6.32) is not satisfied. Therefore, if $\alpha = 0$ the left boundary condition does not introduce any boundary condition dependent eigenvalues.

Example 6.2. Although the boundary condition (6.34) with (6.35) and $\alpha = 0$ does not introduce any boundary condition dependent eigenvalues, they are introduced for a range of nonzero values of the parameter α. The roots of (6.38) are

$$\kappa_1 = 1,\ 1,\ 1,\ 1/(3\alpha) \qquad (\alpha \neq 0). \tag{6.42}$$

Are there any values of α for which $\lambda = 0$ is a boundary condition dependent eigenvalue? For $\lambda = 0$, the roots of (6.36) are

$$\kappa = 1, \quad \kappa = (5 - \sqrt{33})/2 \approx -0.372, \quad \kappa = (5 + \sqrt{33})/2 \approx 5.372. \tag{6.43}$$

It is obvious that inequality (6.32) is not satisfied if $\kappa_1 = 1$ which excludes the repeated roots in (6.42). Inequality (6.32) is satisfied if

$$\kappa_1 = (5 - \sqrt{33})/2 \approx -0.372, \tag{6.44a}$$

$$\kappa_2 = 1, \tag{6.44b}$$

$$\kappa_3 = (5 + \sqrt{33})/2 \approx 5.372. \tag{6.44c}$$

In order to have a boundary condition dependent eigenvalue $\lambda = 0$ we must choose α in (6.42), i.e.,

$$\kappa_1 = 1/(3\alpha) \tag{6.45}$$

so that κ_1 is (6.44a). By equating (6.45) and (6.44a), one obtains

$$\alpha = -(5 + \sqrt{33})/12 \approx -0.895. \tag{6.46}$$

Consequently, for this value of α the boundary condition (6.34) with (6.35) will introduce the boundary condition dependent eigenvalue $\lambda = 0$.

If one carries out a GKS normal mode analysis for the semidiscrete approximation with (2.16) and the numerical boundary condition (6.34) with (6.35), one finds that the semidiscrete approximation is unstable for $\alpha < \hat{\alpha}$ where $\hat{\alpha}$ is defined by (6.46).

An explicit formula for λ in terms of the parameter α is found by substituting (6.45) into (6.37)

$$\lambda = (3\alpha - 1)(-18\alpha^2 - 15\alpha + 1)/(54\alpha^2). \tag{6.47}$$

If one chooses a particular value of α, the corresponding value of λ is a boundary condition dependent eigenvalue if and only if the corresponding κ's satisfy inequality (6.32).

Example 6.3. Is it possible to choose α so that there is an eigenvalue

$$\lambda = -4/3 \tag{6.48}$$

which falls on the oval shaped circulant spectrum where the *oval* crosses the real axis (see Fig. 5.5a)? This value of λ is an eigenvalue of the circulant matrix (1.6) with (2.16) as one can easily verify from the formula (2.17) for $\theta = \pi$. (The corresponding κ for the circulant case is $\kappa = -1$.) By substituting $\lambda = -4/3$ into the cubic equation (6.36) one obtains the roots

$$\kappa = -1, \tag{6.49a}$$

$$\kappa = (7 - \sqrt{41})/2 \approx .298, \tag{6.49b}$$

$$\kappa = (7 + \sqrt{41})/2 \approx 6.70. \tag{6.49c}$$

Inequality (6.32) is satisfied if and only if

$$\kappa_1 = (7 - \sqrt{41})/2 \approx .298, \tag{6.50a}$$

$$\kappa_2 = -1, \tag{6.50b}$$

$$\kappa_3 = (7 + \sqrt{41})/2 \approx 6.70. \tag{6.50c}$$

If α in (6.45) is chosen so that κ_1 is (6.50a), one obtains

$$\alpha = 1/(3\kappa_1) = (7 + \sqrt{41})/12 \approx 1.117. \tag{6.51}$$

Hence $\lambda = -4/3$ is a point of the boundary condition dependent spectrum for the value of α given by (6.51).

6.4.2. Right boundary dependent spectrum. In the analysis for the boundary condition dependent part of the spectrum, the left and right boundary conditions are uncoupled. It is convenient to have a single algorithm for both the left and right boundary condition problems. This can be accomplished by *switching* the matrix so that the right and left boundary conditions are interchanged. For example, if the matrix (1.4) is switched as described in §4.2 one obtains the the matrix

$$\widehat{\mathbf{A}} = \begin{bmatrix} c_{11} & c_{12} & c_{13} & c_{14} & & & & \\ c_{21} & c_{22} & c_{23} & c_{24} & & & O & \\ \hat{a}_{-2} & \hat{a}_{-1} & \hat{a}_0 & \hat{a}_1 & & & & \\ \cdot & \cdot & \cdot & \cdot & & & & \\ & \cdot & \cdot & \cdot & \cdot & & & \\ & & \cdot & \cdot & \cdot & \cdot & & \\ & O & & \hat{a}_{-2} & \hat{a}_{-1} & \hat{a}_0 & \hat{a}_1 & \\ & & & & \hat{a}_{-2} & \hat{a}_{-1} & \hat{a}_0 & \hat{a}_1 \\ & & & & b_{14} & b_{13} & b_{12} & b_{11} \end{bmatrix}, \tag{6.52}$$

where $\hat{a}_j = a_{-j}$. For this matrix $p = 2$ and $q = 1$ and the left boundary difference equations are given by

$$c_{11}\phi_1 + c_{12}\phi_2 + c_{13}\phi_3 + c_{14}\phi_4 = \lambda\phi_1, \tag{6.53a}$$

$$c_{21}\phi_1 + c_{22}\phi_2 + c_{23}\phi_3 + c_{24}\phi_4 = \lambda\phi_2. \tag{6.53b}$$

For the matrix (6.52), the algebraic equation (2.6) is

$$\lambda = \hat{a}_{-2}\kappa^{-2} + \hat{a}_{-1}\kappa^{-1} + \hat{a}_0 + \hat{a}_1\kappa. \tag{6.54}$$

There are two boundary conditions (6.53) and following the algorithm for the boundary condition dependent spectrum we seek a solution of the form (4.5), i.e.,

$$\phi_j = \beta_1\kappa_1^j + \beta_2\kappa_2^j. \tag{6.55}$$

From (6.53a) and (6.53b) one obtains

$$\begin{aligned} c_{11}(\beta_1\kappa_1 + \beta_2\kappa_2) + c_{12}(\beta_1\kappa_1^2 + \beta_2\kappa_2^2) + c_{13}(\beta_1\kappa_1^3 + \beta_2\kappa_2^3) \\ + c_{14}(\beta_1\kappa_1^4 + \beta_2\kappa_2^4) = \lambda(\beta_1\kappa_1 + \beta_2\kappa_2), \end{aligned} \tag{6.56a}$$

$$\begin{aligned} c_{21}(\beta_1\kappa_1 + \beta_2\kappa_2) + c_{22}(\beta_1\kappa_1^2 + \beta_2\kappa_2^2) + c_{23}(\beta_1\kappa_1^3 + \beta_2\kappa_2^3) \\ + c_{24}(\beta_1\kappa_1^4 + \beta_2\kappa_2^4) = \lambda(\beta_1\kappa_1^2 + \beta_2\kappa_2^2). \end{aligned} \tag{6.56b}$$

Since κ_1 and κ_2 must each give the same λ, we use (6.54) to obtain two additional equations

$$\lambda = \hat{a}_{-2}\kappa_1^{-2} + \hat{a}_{-1}\kappa_1^{-1} + \hat{a}_0 + \hat{a}_1\kappa_1, \tag{6.56c}$$

$$\lambda = \hat{a}_{-2}\kappa_2^{-2} + \hat{a}_{-1}\kappa_2^{-1} + \hat{a}_0 + \hat{a}_1\kappa_2. \tag{6.56d}$$

The system of (four) equations (6.56) has (five) unknowns $\beta_1, \beta_2, \kappa_1, \kappa_2, \lambda$. Since the equations (6.56a) and (6.56b) are linear and homogeneous in β_1 and β_2 and (6.56) are algebraic equations, they can be reduced to a single algebraic equation in a single variable (we choose κ_2), i.e.,

$$P(\kappa_2) = 0. \tag{6.57}$$

The roots of (6.57) are all possible values of κ_2 that may introduce boundary condition dependent eigenvalues. Each κ_2 is tested as follows: Substitute $\kappa = \kappa_2$ into (6.54). Solve the new equation for $\lambda(\kappa_2)$. Substitute $\lambda(\kappa_2)$ back into (6.54) and solve the resulting equation for $\kappa_1, \kappa_2, \kappa_3$. If the κ's satisfy (3.4) with (3.5b), i.e.,

$$|\kappa_1| \le |\kappa_2| < |\kappa_3|, \tag{6.58}$$

then $\lambda(\kappa_2)$ is a boundary condition dependent eigenvalue, otherwise it is not part of the asymptotic spectrum.

If the bandwidth of the matrix is large and the number of rows in the boundary condition matrix **B** becomes large, the algebraic reduction of the system, e.g., (6.57), becomes hopeless even for good symbolic systems such as MACSYMA. In these cases we recommend the less reliable but more efficient algorithm of §4.3.

An alternative solution procedure for (6.56) is the following. The system of equations, e.g., (6.56) is symmetric in the κ's so the algebra can be simplified by the introduction of the elementary symmetric functions. As an example, we consider the relatively simple right boundary problem for the matrix (1.7) and introduce the elementary symmetric functions [11]

$$y = \kappa_1 + \kappa_2 \tag{6.59}$$

and

$$x = \kappa_1 \kappa_2. \tag{6.60}$$

It can be shown that the system (6.56) reduces to

$$\begin{aligned} -c_{13}\left(\frac{\hat{a}_1}{\hat{a}_{-2}}\right)^2 x^5 + \frac{2c_{13}\hat{a}_{-1}\hat{a}_1}{\hat{a}_{-2}^2}x^4 + \left[-\frac{c_{13}\hat{a}_{-1}^2}{\hat{a}_{-2}^2} + \frac{(\hat{a}_1 - c_{12})\hat{a}_1}{\hat{a}_{-2}}\right]x^3 \\ + \left[c_{13} - \frac{(\hat{a}_1 - c_{12})\hat{a}_{-1}}{\hat{a}_{-2}}\right]x^2 + (\hat{a}_0 - c_{11})x - \hat{a}_{-2} = 0, \end{aligned} \tag{6.61}$$

where $c_{11} = -3\beta$, $c_{12} = 3\beta - 1/2$, and $c_{13} = -\beta$ and

$$y = (\hat{a}_1 x^2 - \hat{a}_{-1} x)/\hat{a}_{-2}. \tag{6.62}$$

It is not practical to proceed analytically, so for a particular set of matrix coefficients we solve (6.61) numerically for x and proceed as in the general Algorithm 4.2.

7. Eigenvector scaling. If conventional numerical eigenvalue packages, e.g., IMSL, EISPACK, etc., are used to compute the spectra for nonnormal Toeplitz matrices, large errors in the spectra may be encountered for matrices of relatively low order. For example if we choose the matrix

$$[-1/6, 1, \underline{-1/2}, -1/3] \tag{7.1}$$

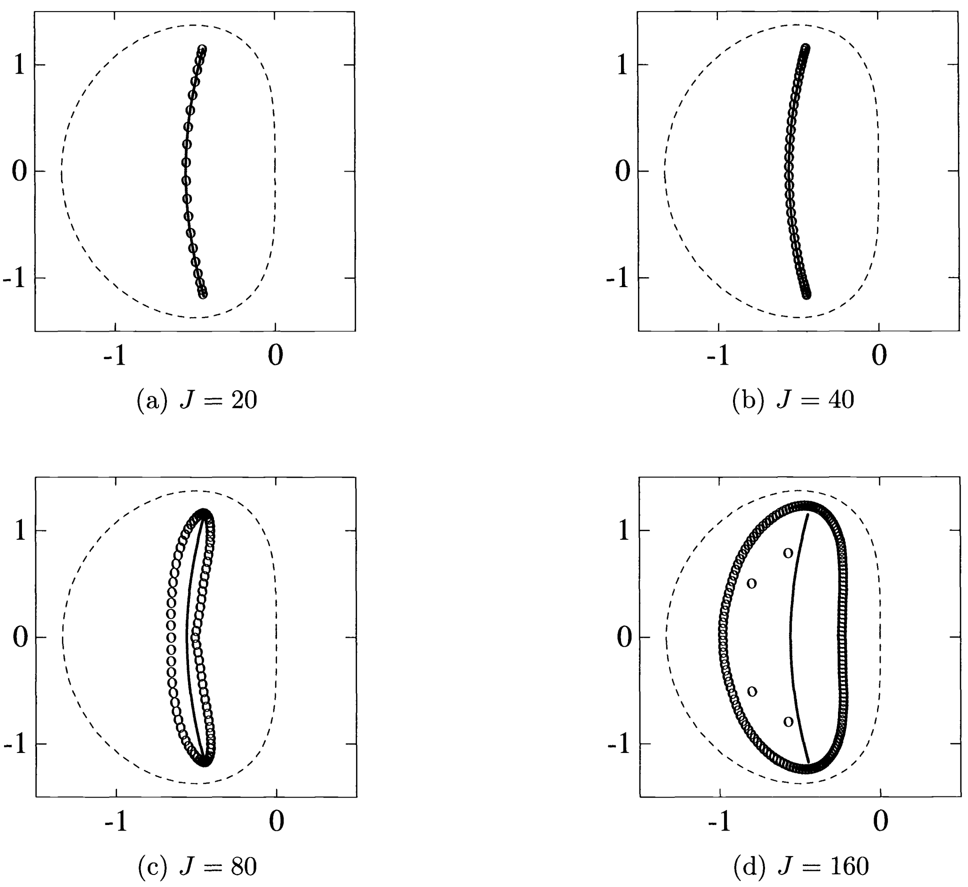

FIG. 7.1. *Numerically computed spectra with rounding errors* (o *symbol*) *for the unscaled Toeplitz matrix* $[-1/6, 1, \underline{-1/2}, -1/3]$. *Asymptotic Toeplitz spectra and asymptotic circulant spectra indicated by solid and dashed curves, respectively.*

and use the MATLAB routine *eig*($\mathbf{A}$) on an IRIS workstation to compute the spectrum, we obtain the sequence of spectra (for increasing matrix order) shown in Figs. 7.1(a) through 7.1(d). The Toeplitz matrix defined by (7.1) is the transpose of the Toeplitz matrix defined by (2.16).

The numerical spectra of the Toeplitz matrix (2.16), e.g., see Fig. 5.1, for $J = 80$ and 160, fall on the asymptotic spectra. In general, the numerical spectra of a nonnormal matrix $\mathbf{A}$ and its transpose $\mathbf{A}^T$ (for sufficiently large J) will differ in spite of the fact that the analytical spectra are identical. This phenomenon, which is a result of rounding errors, is discussed at the end of this section.

A nonnormal Toeplitz matrix (e.g., (7.1)) can have the property that the spectrum is very sensitive to perturbations of the matrix elements. For such matrices, Trefethen [12] and Reichel and Trefethen [8] suggest that an eigenvalue analysis may lead to incorrect conclusions, and it is more meaningful to analyze *pseudo*-eigenvalues. The *erroneous* eigenvalues (induced by rounding errors) plotted in Fig. 7.1 are a manifestation of the pseudospectra of the matrix (7.1) for increasing J. The numerical

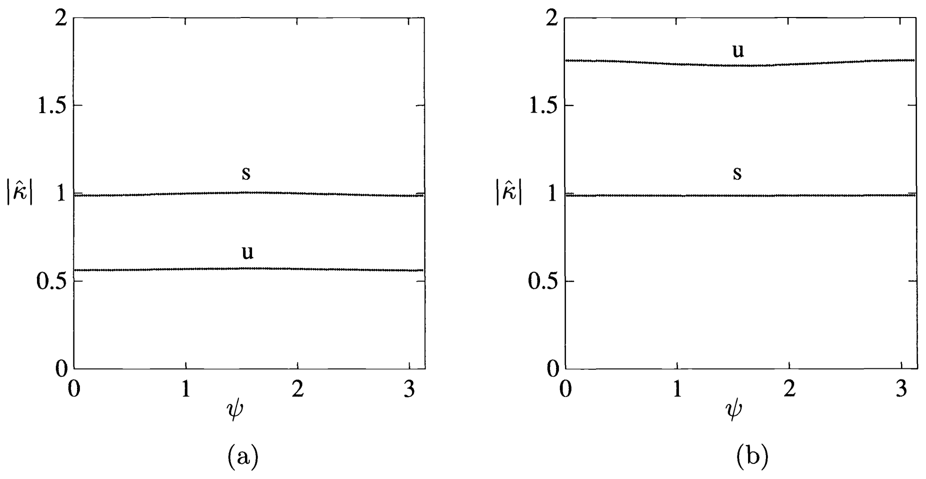

FIG. 7.2. *Modulus of* $\hat\kappa$ *vs* ψ_ℓ *for* (a) *matrix* (2.16) *unscaled,* u, *and scaled,* s, *and* (b) *the transpose matrix (7.1) unscaled,* u, *and scaled,* s.

error can be reduced by using higher numerical precision. However, for any numerical precision the qualitative behavior illustrated in Fig. 7.1 will always appear for sufficiently large J. Qualitatively, the numerical Toeplitz spectrum approaches the spectrum of its Toeplitz circulant cousin as $J \to \infty$.

The difficulty in numerically computing the eigenvalues of a nonnormal Toeplitz matrix is related to the exponential character of the eigenvectors. We illustrate this with an example by comparing the eigenvectors of the matrix (2.16) with the eigenvectors of its transpose (7.1). Since (2.16) is a Toeplitz matrix, the asymptotic spectrum is independent of the boundary conditions and the κ roots satisfy (6.23). In this example the moduli of the roots of equal modulus (4.1), $|\hat\kappa|$, are only weakly dependent on the angle ψ_ℓ as illustrated in Fig. 7.2. From (4.4) with coefficients given by (2.16) and $\psi = \pi/2$ one obtains $|\hat\kappa| = 1/\sqrt{3}$. Hence for the roots of equal modulus, one finds

$$|\kappa_1| = |\kappa_2| = |\hat\kappa| \approx 1/\sqrt{3}, \tag{7.2}$$

and consequently the moduli of the eigenvector elements behave as

$$|\phi_j| \approx (1/\sqrt{3})^j, \tag{7.3}$$

i.e., they decrease exponentially with increasing j.

For the transpose $\mathbf{A}^T$, defined by (7.1), one has

$$|\check\kappa_1| \le |\check\kappa_2| = |\check\kappa_3|, \tag{7.4}$$

where the check symbol indicates that the κ's in (6.23) and (7.4) are not the same. In fact, the κ's of (6.23) and (7.4) are reciprocals. Consequently, for $\mathbf{A}^T$ one has

$$|\check\kappa_2| = |\check\kappa_3| = |\hat\kappa| \approx \sqrt{3}, \tag{7.5}$$

and the moduli of the eigenvector elements

$$|\phi_j| \approx (\sqrt{3})^j \tag{7.6}$$

grow exponentially with increasing j.

A simple scaling attenuates the exponential behavior of the eigenvectors. Let $\mathbf{A}$ denote an arbitrary banded Toeplitz matrix. If the κ's of equal modulus (3.5a) are not on the unit circle, then either $\mathbf{A}$ or $\mathbf{A}^T$ will have exponentially growing eigenvectors. Assume that $\mathbf{A}$ has κ's of equal modulus (4.1) which are outside the unit circle. Define $\tilde{\kappa}$ to be

$$\tilde{\kappa} = \underset{0<\psi_\ell<\pi}{\text{mean}} (|\hat{\kappa}|). \tag{7.7}$$

For the matrix $\mathbf{A}$ we rescale the eigenvectors by

$$\tilde{\phi}_j = \frac{\phi_j}{\tilde{\kappa}^j}. \tag{7.8}$$

The scaling is effectively a normalization of the $\hat{\kappa}$'s so their moduli are approximately equal to unity.

The *scaling* similarity transformation is

$$\mathbf{S}^{-1} = \begin{bmatrix} 1/\tilde{\kappa} & & & & \\ & 1/\tilde{\kappa}^2 & & O & \\ & & \cdot & & \\ & & & \cdot & \\ & & & & \cdot \\ & O & & 1/\tilde{\kappa}^{J-1} & \\ & & & & 1/\tilde{\kappa}^J \end{bmatrix}. \tag{7.9}$$

Hence the rescaled eigenvalue problem is

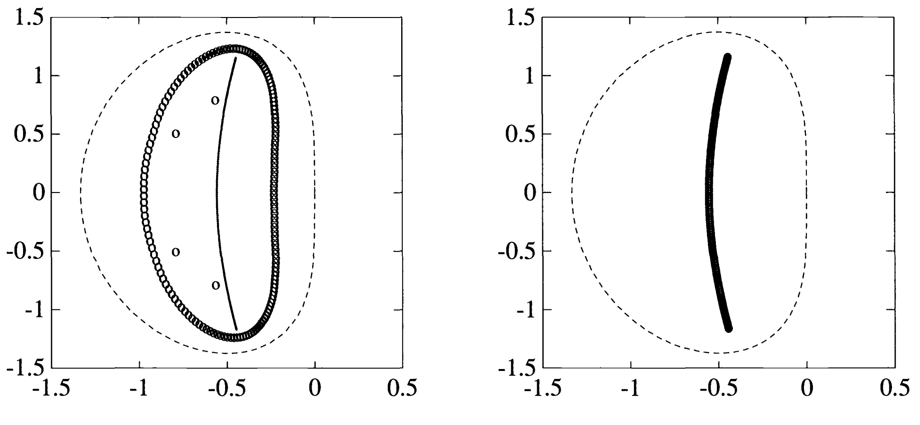
$$(\mathbf{S}^{-1}\mathbf{A}\mathbf{S})\mathbf{S}^{-1}\phi = \lambda \mathbf{S}^{-1}\phi. \tag{7.10}$$

If $a_{ij} = a_{j-i}$ are the nonzero elements of the Toeplitz matrix $\mathbf{A}$, the elements $\tilde{a}_{ij}$ of the rescaled matrix $\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$ are

$$\tilde{a}_{ij} = a_{j-i}\tilde{\kappa}^{j-i}. \tag{7.11}$$

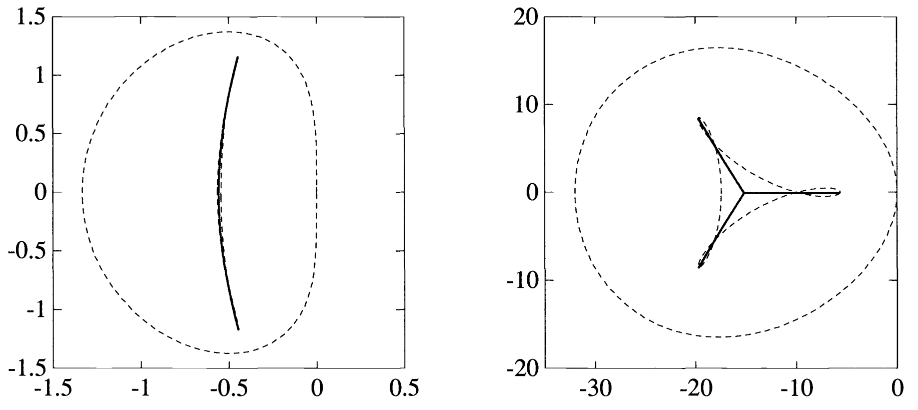
To numerically compute the spectrum of the rescaled eigenvalue problem, one simply replaces the matrix elements by (7.11). One should not make the *numerical* matrix multiplies indicated by $\mathbf{S}^{-1}\mathbf{A}\mathbf{S}$ because of potentially large rounding errors. The implementation of Algorithm 4.1 in the Appendix computes $\hat{\kappa}(\psi)$, which can be used to compute (7.7).

In Fig. 7.3 we compare the computed (MATLAB) spectrum of the scaled and unscaled Toeplitz matrix defined by (7.1). One can predict a bound on the numerical eigenvalue distribution of a Toeplitz matrix for large J. In Fig. 7.4(a) the outer dashed curve is the circulant cousin spectrum of the Toeplitz matrix defined by (7.1) and the inner dashed curve is the circulant cousin of the corresponding *scaled* Toeplitz matrix. The solid curve is the asymptotic Toeplitz spectrum. For the unscaled matrix the outer dashed curve of Fig. 7.4(a) is the bound on the numerically computed spectrum for large J. For the scaled matrix, the inner dashed curve is the asymptotic bound on the numerically computed spectrum. For the scaled matrix the circulant spectrum is tightly "wound" around the asymptotic Toeplitz spectrum and one can



(a) $J = 160$ (b) $J = 160$

FIG. 7.3. *Numerically computed spectra with rounding errors* (o *symbol*) *for* (a) *the unscaled Toeplitz matrix* $[-1/6, 1, \underline{-1/2}, -1/3]$, *and* (b) *the scaled matrix. Asymptotic Toeplitz spectra and asymptotic circulant spectra are indicated by solid and dashed curves, respectively.*



(a) $[-1/6, 1, \underline{-1/2}, -1/3]$ (b) $[-1.5, 16, \underline{-15}, 0, .5]$

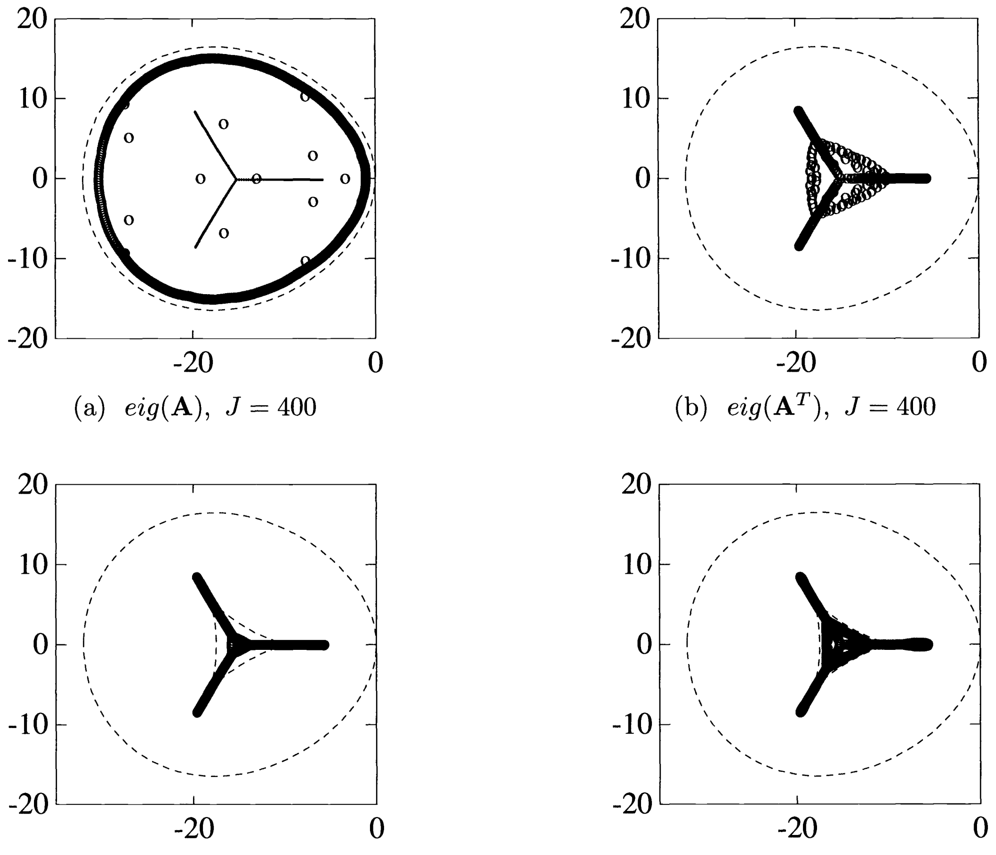
FIG. 7.4. *Asymptotic circulant spectra for unscaled* (*"outer" dashed curves*) *and scaled* (*"inner" dashed curves*) *matrices. Asymptotic Toeplitz spectra are indicated by solid curves.*

expect an accurately computed spectrum for large J. These bounds are illustrated by the numerical spectra shown in Fig. 7.3.

As a second example, we plot in Fig. 7.4(b) the spectra of the unscaled and scaled circulant cousins of the pentadiagonal Toeplitz matrix defined by

$$[-1.5, 16, \underline{-15}, 0, .5]. \tag{7.12}$$

The solid curve, i.e., the *propeller*, is the asymptotic Toeplitz spectrum. Numerically



(a) *eig*($\mathbf{A}$), $J = 400$ (b) *eig*($\mathbf{A}^T$), $J = 400$

(c) *eig*(*scaled*($\mathbf{A}$)), $J = 400$ (d) *eig*(*scaled*($\mathbf{A}^T$)), $J = 1000$

FIG. 7.5. *Numerically computed spectra with rounding errors* (o *symbols*) *for* (a) $\mathbf{A} = [-1.5, 16, \underline{-15}, 0, .5]$, (b) $\mathbf{A}^T$, (c) *scaled* $\mathbf{A}$, $J = 400$, *and* (d) *scaled* $\mathbf{A}^T$, $J = 1000$.

computed (MATLAB) spectra of the Toeplitz matrix and its transpose are plotted in Figs. 7.5(a) and 7.5(b) for $J = 400$. The spectra for both $\mathbf{A}$ and $\mathbf{A}^T$ are erroneous for large J. The inner dashed curve of Fig. 7.4(b) is the asymptotic bound on the numerical eigenvalue distribution of the scaled matrix for large J. Numerical eigenvalue computations for the scaled matrix are shown in Figs. 7.5(c) and 7.5(d).

One can also predict how well the scaling will work. If a graph of $|\hat{\kappa}|$ vs ψ_ℓ (see Algorithm 4.1) for the unscaled matrix is a single flat band as in Fig. 7.2, then the scaling will yield a tight bound for the circulant cousin around the asymptotic Toeplitz spectrum as illustrated in Fig. 7.4(a). On the other hand, if $|\hat{\kappa}|$ vs ψ_ℓ forms multiple and/or nonuniform bands as illustrated in Fig. 7.6, then one has multiple scales and a simple scaling will not yield a closely wound circulant cousin spectrum as illustrated in Fig. 7.4(b).

If one starts with a quasi-Toeplitz matrix, then the appropriate scaling is the same as for its pure Toeplitz cousin.

8. The generalized eigenvalue problem. If Padé type difference approxima-

tions are used to approximate differential equations the associated stability analysis leads to a generalized eigenvalue problem. In addition, the analysis of implicit time integration schemes leads to a generalized eigenvalue problem. Let $\mathbf{A}$ and $\mathbf{B}$ represent $J \times J$ banded Toeplitz matrices. The generalized eigenvalue problem is defined by

$$\mathbf{A}\boldsymbol{\phi} = \lambda \mathbf{B}\boldsymbol{\phi}, \tag{8.1}$$

where $\boldsymbol{\phi}$ is the eigenvector and λ is the eigenvalue. Here we assume that the matrix $\mathbf{A}$ is defined by the sequence $[a_i, -p_A \le i \le q_A]$ and $\mathbf{B}$ is defined by the sequence $[b_i, -p_B \le i \le q_B]$, where p_A, q_A, p_B, q_B are positive integers. The eigenvector $\boldsymbol{\phi}$ is given by

$$\boldsymbol{\phi}^T = [\phi_1, \phi_2, \cdots, \phi_{J-1}, \phi_J]. \tag{8.2}$$

The eigenvalue problem (8.1) is equivalent to the set of homogeneous equations

$$\sum_{m=-p_A}^{q_A} a_m \phi_{j+m} = \lambda \sum_{m=-p_B}^{q_B} b_m \phi_{j+m}, \quad j = 1, 2, \cdots, J \tag{8.3}$$

with $p = \max[p_A, p_B]$ homogeneous boundary conditions at the left boundary and $q = \max[q_A, q_B]$ homogeneous boundary conditions at the right boundary

$$\phi_{-m} = 0, \quad m = 0, 1, \cdots, p-1, \tag{8.4a}$$

$$\phi_{J+m} = 0, \quad m = 1, 2, \cdots, q. \tag{8.4b}$$

Equation (8.3) is a $(p+q)$th order difference equation for ϕ_j and we look for a solution of the form

$$\phi_j = \kappa^j, \tag{8.5}$$

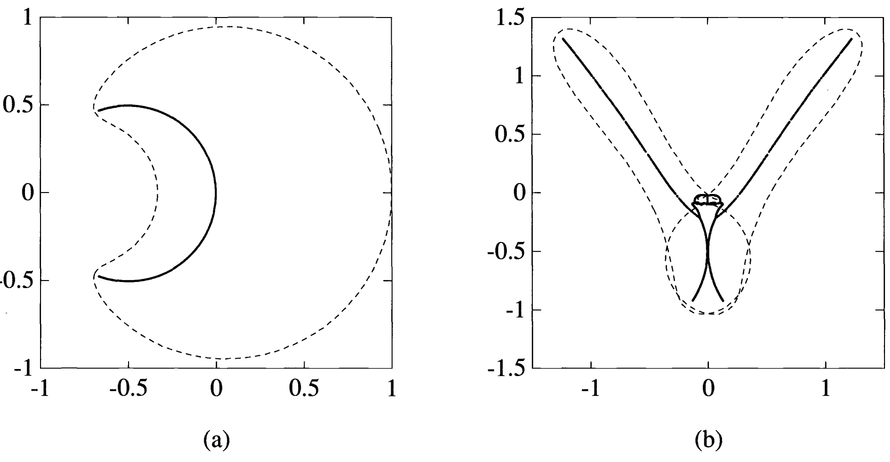

FIG. 8.1. *Spectra for the generalized Toeplitz eigenvalue problem* (8.1), (a) $\mathbf{A} = [2, \underline{0}, -1]$ *and* $\mathbf{B} = [-2, \underline{2}, 1]$ *and* (b) $\mathbf{A} = [.38, .13, -.43, .15, \underline{.25}, -.06, .27, -.02, -.26]$ *and* $\mathbf{B} = [.28i, .38i, .50i, .07i, \underline{.95i}, .99i, .49i, .27i, .09i]$.

where κ is a complex constant. Substitution of (8.5) into (8.3) yields

$$\lambda \sum_{m=-p_B}^{q_B} b_m \kappa^m = \sum_{m=-p_A}^{q_A} a_m \kappa^m. \tag{8.6}$$

This is an algebraic equation of degree $p+q$ in the unknown κ. The general solution of (8.3) is (2.7). The constants β are determined by inserting (2.7) into the boundary conditions (8.4). If the bandwidth is three, i.e., $p = q = 1$, the eigenvalue problem for the pure Toeplitz problem can be solved analytically [16]. However, if the bandwidth is greater than three, the problem is analytically intractable.

The eigenvalue problem for the circulant cousin of (8.1) is (8.3) with periodic boundary conditions (2.12). Insertion of (8.5) into (2.12) yields

$$\kappa^J = 1. \tag{8.7}$$

Hence the κ's are the J roots of unity given by (2.14) and the circulant spectrum is obtained by substituting (2.14) into (8.6)

$$\lambda_\ell \sum_{m=-p_B}^{q_B} b_m e^{im\theta_\ell} = \sum_{m=-p_B}^{q_B} a_m e^{im\theta_\ell}. \tag{8.8}$$

The partition of the asymptotic Toeplitz spectrum is the same (§3) as for the standard eigenvalue problem. The algorithm follows that of §4.1. To construct the polynomial for κ's of equal modulus we use (4.1). Since κ_a and κ_b (defined by 4.1) must each give the same value of λ when inserted in (8.6), we can eliminate λ and obtain a polynomial in $\hat{\kappa}$ with coefficients which are functions of the Toeplitz matrix coefficients and ψ_ℓ. In particular,

$$\lambda(\kappa_a) \sum_{m=-p_B}^{q_B} b_m \hat{\kappa}^m e^{im\psi_\ell} = \sum_{m=-p_A}^{q_A} a_m \hat{\kappa}^m e^{im\psi_\ell}, \tag{8.9a}$$

$$\lambda(\kappa_b) \sum_{m=-p_B}^{q_B} b_m \hat{\kappa}^m e^{-im\psi_\ell} = \sum_{m=-p_A}^{q_A} a_m \hat{\kappa}^m e^{-im\psi_\ell}, \tag{8.9b}$$

and since

$$\lambda(\kappa_a) = \lambda(\kappa_b), \tag{8.10}$$

one obtains, after some algebraic simplification,

$$\sum_{m=-p_A}^{q_A} \sum_{n=-p_B}^{q_B} a_m b_n \hat{\kappa}^{(m+n)} \sin[(m-n)\psi_\ell] = 0. \tag{8.11}$$

The algorithm follows that of (i) and (ii) in §4.1. The implementation of the generalized eigenvalue algorithm is a straightforward modification of the standard eigenvalue algorithm (Appendix).

As an example of the $\hat{\kappa}$ polynomial (8.11), if we choose $\mathbf{A}$ and $\mathbf{B}$ to be the quadridiagonal matrices represented by the sequences $[a_{-2}, a_{-1}, a_0, a_1]$ and $[b_{-2}, b_{-1}, b_0, b_1]$, the equation for the κ's of equal modulus is

$$\begin{aligned}(a_1 b_0 - a_0 b_1)\hat{\kappa}^4 &+ 2(a_1 b_{-1} - a_{-1} b_1)\cos(\psi_\ell)\hat{\kappa}^3 \\ &+ [(a_0 b_{-1} - a_{-1} b_0) + (a_1 b_{-2} - a_{-2} b_1)(4\cos^2(\psi_\ell) - 1)]\hat{\kappa}^2 \\ &+ 2(a_0 b_{-2} - a_{-2} b_0)\cos(\psi_\ell)\hat{\kappa} + (a_{-1} b_{-2} - a_{-2} b_{-1}) = 0.\end{aligned} \tag{8.12}$$

Note that (6.4) and the "transpose" of (6.25) are easily obtained as special cases of (8.12). As examples of the spectra of the generalized eigenvalue problem we choose two examples. The spectra for the Toeplitz and the associated circulant Toeplitz matrices are plotted in Fig. 8.1

9. Concluding remarks.

The algorithms presented in §4 provide a practical and accurate method for obtaining the asymptotic spectra of banded Toeplitz and quasi-Toeplitz matrices. They are especially useful for nonnormal matrices where conventional algorithms may give erroneous results. The extension of the algorithms for the generalized eigenvalue problem for Toeplitz matrices was presented in §8. The asymptotic analysis also provides a similarity transformation, §7, which can increase the spectrum accuracy if conventional eigenvalue algorithms (finite J) are employed.

A NEW PREPROCESSING ALGORITHM FOR THE COMPUTATION OF THE GENERALIZED SINGULAR VALUE DECOMPOSITION*

ZHAOJUN BAI† AND HONGYUAN ZHA‡

Abstract. In this note a new algorithm is proposed for the preprocessing phase of Paige's algorithm for computing the generalized singular value decomposition (GSVD). This new algorithm substantially reduces the complexity of Paige's algorithm and makes it much easier to implement. It is also proved that the preprocessing phase is backward stable and a numerical example is demonstrated.

Key words. generalized singular value decomposition, URV decomposition

CR classification. G1.3

1. Introduction. This note is concerned with the numerical computation of the generalized singular value decomposition (GSVD) of two matrices having the same number of columns. The GSVD was first proposed by Van Loan [9]. Like the singular value decomposition (SVD) of one matrix, the GSVD of matrix pairs is a very useful tool in many numerical linear algebra problems. The following formulation of the GSVD is due to Paige and Saunders [5], and is more suitable for numerical computation.

THEOREM 1.1. *Given a matrix pair (A, B) with $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{p\times n}$, there exist orthogonal matrices U, V, and Q such that*

$$U^TAQ = \Sigma_A(\,0 \;\; R\,), \qquad V^TBQ = \Sigma_B(\,0 \;\; R\,), \tag{1}$$

where R is $k \times k$ nonsingular upper triangular with $k = \operatorname{rank}(A^T, B^T)^T$, and Σ_A and Σ_B are $m \times k$ and $p \times k$ diagonal matrices such that

$$\Sigma_A^T\Sigma_A + \Sigma_B^T\Sigma_B = I.$$

Paige's algorithm for computing the above-mentioned decomposition consists of two phases: (1) reducing the given matrix pairs to upper triangular (or trapezoidal) forms by orthogonal transformations, which is designated as the preprocessing phase; (2) implicitly applying the Kogbetliantz algorithm to find the GSVD of two triangular matrices [6]. The existing preprocessing procedure may result in an *irregular* triangular pair, which gives rise to several different cases in the second phase and makes the numerical implementation quite complicated [2]. In this note the authors propose a new preprocessing algorithm that essentially leaves only one case in the next phase. More precisely, the authors reduce the problem to the computation of the GSVD of a matrix pair (A, B), where A and B are upper triangular and B nonsingular, which is called a *regular* matrix pair.[1] Our current interest in developing algorithms for computing the GSVD stems

[1]The generalized singular values of a regular matrix pair are all finite.

from Bai's involvement in the linear algebra software package LAPACK [1]. Paige's algorithm for computing the GSVD will be included in the future release of LAPACK. For an alternative GSVD algorithm via the CS decomposition, the reader is referred to [7] and [10].

2. A new preprocessing algorithm. The purpose of the preprocessing phase is to reduce the given matrix pair (A, B) to a condensed form, so that the implicit Kogbetliantz algorithm can be applied. Our approach is to extract a regular matrix pair from (A, B) by applying orthogonal transformations to the individual matrices A and B. A similar idea was also used in [11] for computing the *restricted singular value decomposition* of matrix triplets. The algorithm consists of three steps. The transformation from step k to step $k+1$ is denoted as

$$\begin{pmatrix} A^{(k+1)} \\ B^{(k+1)} \end{pmatrix} = \begin{pmatrix} (U^{(k)})^T A^{(k)} (Q^{(k)}) \\ (V^{(k)})^T B^{(k)} (Q^{(k)}) \end{pmatrix},$$

where $U^{(k)}, V^{(k)}$, and $Q^{(k)}$ are orthogonal; $A^{(k)}$ and $B^{(k)}$ are the transformed A and B at step k with initial values

$$A^{(0)} = A, \qquad B^{(0)} = B.$$

For brevity, in the following description of the algorithm, we only specify the transformed A and B at each step; the corresponding orthogonal transformation matrices can be easily constructed.

Before we proceed, we need to recall a matrix decomposition, which will be the building block of our preprocessing algorithm: for any $m \times n$ matrix A, there exist orthogonal matrices U and V such that A can be decomposed as

$$A = U \begin{pmatrix} 0 & R \\ 0 & 0 \end{pmatrix} V^T,$$

where R is a nonsingular upper triangular matrix. The decomposition is called the *complete orthogonal decomposition*, or simply the *URV decomposition* [3]. Now we are ready to present the preprocessing algorithm.

Step 1. Compute the URV decomposition of B such that

$$\begin{pmatrix} A^{(1)} \\ B^{(1)} \end{pmatrix} = \left(\begin{array}{cc} A_{11}^{(1)} & A_{12}^{(1)} \\ \hline 0 & B_{12}^{(1)} \\ 0 & 0 \end{array} \right),$$

where $B_{12}^{(1)}$ is upper triangular and nonsingular.

Step 2. Compute the URV decomposition of $A_{11}^{(1)}$ (if $A_{11}^{(1)}$ is not empty) and update $A_{12}^{(1)}$, so that we have

$$\begin{pmatrix} A^{(2)} \\ B^{(2)} \end{pmatrix} = \left(\begin{array}{ccc} 0 & A_{12}^{(2)} & A_{13}^{(2)} \\ 0 & 0 & A_{23}^{(2)} \\ \hline 0 & 0 & B_{13}^{(2)} \\ 0 & 0 & 0 \end{array} \right),$$

where $A_{12}^{(2)}$ is upper triangular and nonsingular, and $B_{13}^{(2)} = B_{12}^{(1)}$.

Step 3. Compute the QR decomposition of $A_{23}^{(2)}$, such that

$$\begin{pmatrix} A^{(3)} \\ B^{(3)} \end{pmatrix} = \left(\begin{array}{ccc} 0 & A_{12}^{(3)} & A_{13}^{(3)} \\ 0 & 0 & A_{23}^{(3)} \\ \hline 0 & 0 & B_{13}^{(3)} \\ 0 & 0 & 0 \end{array} \right),$$

where $A_{12}^{(3)} = A_{12}^{(2)}$, $A_{13}^{(3)} = A_{13}^{(2)}$, and $B_{13}^{(3)} = B_{13}^{(2)}$. For $A_{23}^{(3)}$, we need to distinguish two cases. Let $A_{23}^{(3)} \in R^{s\times r}$.

1. If $s \geq r$, then

$$A_{23}^{(3)} = \begin{pmatrix} \tilde{A}_{23}^{(3)} \\ 0 \end{pmatrix},$$

where $\tilde{A}_{23}^{(3)}$ is $r \times r$ upper triangular.

2. If $s < r$, then the first s columns of $A_{23}^{(3)}$ is an upper triangular matrix. We append $r - s$ rows of zeros to $A_{23}^{(3)}$ and denote the resulting matrix $\tilde{A}_{23}^{(3)}$, which is also an upper triangular matrix.

In either case, we end up with a matrix pair $(\tilde{A}_{23}^{(3)}, B_{13}^{(3)})$, where $\tilde{A}_{23}^{(3)}$ and $B_{13}^{(3)}$ are square upper triangular and of the same size; moreover, $B_{13}^{(3)}$ is nonsingular. Therefore, computing the GSVD of $(\tilde{A}_{23}^{(3)}, B_{13}^{(3)})$ is equivalent to computing the SVD of $\tilde{A}_{23}^{(3)}(B_{13}^{(3)})^{-1}$. Using the implicit Kogbetliantz algorithm [6], [2], we can find three orthogonal matrices U_1, V_1, and Q_1 such that

$$U_1^T \tilde{A}_{23}^{(3)} (B_{13}^{(3)})^{-1} V_1 = \text{diagonal},$$

and

$$U_1^T \tilde{A}_{23}^{(3)} Q_1 = \Sigma_1 R_1, \qquad V_1^T B_{13}^{(3)} Q_1 = \Sigma_2 R_1, \tag{2}$$

where Σ_1 and Σ_2 are diagonal, R_1 is upper triangular, and

$$\Sigma_1^T \Sigma_1 + \Sigma_2^T \Sigma_2 = I.$$

Combining Steps 1–3 and the results from the implicit Kogbetliantz algorithm (2), and accumulating the corresponding orthogonal transformations, we have

$$U^T A Q = \Sigma_A \begin{pmatrix} 0 & R \end{pmatrix} \quad \text{and} \quad V^T B Q = \Sigma_B \begin{pmatrix} 0 & R \end{pmatrix}, \tag{3}$$

where

$$\Sigma_A = \begin{pmatrix} I & 0 \\ 0 & \Sigma_1 \\ 0 & 0 \end{pmatrix} \quad \text{and} \quad \Sigma_B = \begin{pmatrix} 0 & \Sigma_2 \\ 0 & 0 \end{pmatrix},$$

and the upper triangular matrix R is given by

$$R = \begin{pmatrix} A_{12}^{(3)} & A_{13}^{(3)} Q_1 \\ 0 & R_1 \end{pmatrix}.$$

Equation (3) gives the desired GSVD of A and B in Theorem 1.1.

3. Backward stability and numerical example. In this section, we first discuss the numerical stability of the new preprocessing algorithm and then present one example as a demonstration. The crux of the numerical stability of the new preprocessing algorithm is how to stably compute the URV decomposition. In the current implementation, this is done by first applying the QR decomposition with column pivoting, and then squeezing the resulting trapezoidal form into upper triangular form by applying a sequence of Householder transformations. Let quantities with an overbar denote computed quantities. From the standard backward error analysis of the QR decomposition [3], we know that for the above preprocessing algorithm, the computed $\bar{A}^{(3)}$ and $\bar{B}^{(3)}$ satisfy

$$\bar{U}^T(A+E)\bar{Q} = \bar{A}^{(3)}, \qquad \bar{V}^T(B+F)\bar{Q} = \bar{B}^{(3)},$$

where

$$\|E\|_F \leq \tau\|A\|_2, \qquad \|F\|_F \leq \tau\|B\|_2,$$

and where τ is a user-specified tolerance value, which is used in the QR decomposition with column pivoting to determine the effective numerical rank of the matrix. We also mention that there exist more sophisticated algorithms for computing the URV decomposition, for example, the one proposed by Hanson and Lawson [4] and Stewart [8].

To conclude this note, we apply the new preprocessing algorithm and the implicit Kogbetliantz algorithm to a numerical example.[2] Our emphasis here is the backward stability of the preprocessing algorithm. The matrix pair (A, B) is given as follows:

$$A = \begin{pmatrix} 1 & 2 & 3 & 1 & 5 \\ 0 & 3 & 2 & 0 & 2 \\ 1 & 0 & 2 & 1 & 0 \\ 0 & 2 & 3 & 0 & -1 \\ 1 & 0 & 2 & 1 & 1 \\ 0 & 2 & 1 & 0 & 1 \end{pmatrix}, \qquad B = \begin{pmatrix} 1 & -2 & 2 & 1 & 1 \\ 0 & 3 & 0 & 0 & 0 \\ 1 & -2 & 2 & 1 & 1 \\ 0 & 2 & 0 & 0 & 0 \\ 2 & -4 & 4 & 2 & 2 \\ 1 & 3 & 2 & 1 & 1 \end{pmatrix}.$$

After the three steps of preprocessing algorithm with the tolerance value set as $\epsilon_M\|A\|_F$ and $\epsilon_M\|B\|_F$ for the matrices A and B, respectively, we have

$$\bar{A}^{(3)} = \left(\begin{array}{c|cc|cc} 0 & 3.6017\text{E}+00 & -1.7136\text{E}+00 & 3.3819\text{E}-01 & 1.8012\text{E}+00 \\ 0 & 0 & -2.6088\text{E}+00 & 4.4448\text{E}+00 & 4.9805\text{E}+00 \\ \hline 0 & 0 & 0 & -1.0628\text{E}+00 & 6.4454\text{E}-02 \\ 0 & 0 & 0 & 0 & 4.2699\text{E}+00 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{array}\right),$$

[2]For brevity, only five decimal digits are displayed for all the data, though all the results are obtained using our FORTRAN routines run in double precision on an HP Apollo workstation with machine precision $\epsilon_M \approx 2.2204 \times 10^{-16}$.

$$\bar{B}^{(3)} = \left(\begin{array}{c|cc|cc} 0 & 0 & 0 & -6.7823\text{E}+00 & 3.5109\text{E}+00 \\ 0 & 0 & 0 & 0 & 6.0559\text{E}+00 \\ \hline 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \end{array}\right),$$

where the partitioning of the matrix pair $(\bar{A}^{(3)}, \bar{B}^{(3)})$ corresponds to that in Step 3 of the preprocessing algorithm. At the second phase, we use the scheme proposed by Bai and Demmel [2] to compute the GSVD of the (2,3) block of $\bar{A}^{(3)}$ and the (1,3) block of $\bar{B}^{(3)}$; we obtain

$$\begin{pmatrix} -1.0628\text{E}+00 & 6.4454\text{E}-02 \\ 0 & 4.2699\text{E}+00 \end{pmatrix} = \begin{pmatrix} 1.5379\text{E}-01 & 0 \\ 0 & 5.7885\text{E}-01 \end{pmatrix} \bar{R}_1$$

and

$$\begin{pmatrix} -6.7823\text{E}+00 & 3.5109\text{E}+00 \\ 0 & 6.0559\text{E}+00 \end{pmatrix} = \begin{pmatrix} 9.8810\text{E}-01 & 0 \\ 0 & 8.1544\text{E}-01 \end{pmatrix} \bar{R}_1,$$

where

$$\bar{R}_1 = \begin{pmatrix} -6.9692\text{E}+00 & 3.5064\text{E}+00 \\ 0 & 7.3144\text{E}+00 \end{pmatrix}.$$

Combining the above two phases, we have

$$\bar{U}^T(A+E)\bar{Q} = \bar{\Sigma}_A(0 \;\; \bar{R}), \qquad \bar{V}^T(B+F)\bar{Q} = \bar{\Sigma}_B(0 \;\; \bar{R}), \tag{4}$$

where

$$\bar{\Sigma}_A = \begin{pmatrix} 1.0000\text{E}+00 & 0 & 0 & 0 \\ 0 & 1.0000\text{E}+00 & 0 & 0 \\ 0 & 0 & 1.5379\text{E}-01 & 0 \\ 0 & 0 & 0 & 5.7885\text{E}-01 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

$$\bar{\Sigma}_B = \begin{pmatrix} 0 & 0 & 9.8810\text{E}-01 & 0 \\ 0 & 0 & 0 & 8.1544\text{E}-01 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix},$$

and

$$\bar{R} = \begin{pmatrix} 3.6017\text{E}+00 & -1.7136\text{E}+00 & 2.8436\text{E}-01 & 1.8104\text{E}+00 \\ 0 & -2.6088\text{E}+00 & 4.2944\text{E}+00 & 5.1107\text{E}+00 \\ 0 & 0 & -6.9692\text{E}+00 & 3.5064\text{E}+00 \\ 0 & 0 & 0 & 7.3144\text{E}+00 \end{pmatrix},$$

with the backward errors of the computed decomposition

$$\|E\|_F = \|\bar{U}^{\mathrm{T}}A\bar{Q} - \bar{\Sigma}_A\bar{R}\|_F = 4.5118\text{E}-15 \approx \epsilon_{\mathrm{M}}\|\mathrm{A}\|_{\mathrm{F}},$$

$$\|F\|_F = \|\bar{V}^{\mathrm{T}}B\bar{Q} - \bar{\Sigma}_B\bar{R}\|_F = 5.6621\text{E}-15 \approx \epsilon_{\mathrm{M}}\|\mathrm{B}\|_{\mathrm{F}}.$$

The computed orthogonal matrices $\bar{U}$, $\bar{V}$, and $\bar{Q}$ are orthogonal within machine precision. The decomposition in (4) gives the desired GSVD of A and B in Theorem 1.1.

FAST ITERATIVE SOLVERS FOR TOEPLITZ-PLUS-BAND SYSTEMS*

RAYMOND H. CHAN† AND KWOK-PO NG†

Abstract. The authors consider the solutions of Hermitian Toeplitz-plus-band systems $(A_n + B_n)x = b$, where A_n are n-by-n Toeplitz matrices and B_n are n-by-n band matrices with bandwidth independent of n. These systems appear in solving integrodifferential equations and signal processing. However, unlike the case of Toeplitz systems, no fast direct solvers have been developed for solving them. In this paper, the preconditioned conjugate gradient method with band matrices as preconditioners is used. The authors prove that if A_n is generated by a nonnegative piecewise continuous function and B_n is positive semidefinite, then there exists a band matrix C_n, with bandwidth independent of n, such that the spectra of $C_n^{-1}(A_n + B_n)$ are uniformly bounded by a constant independent of n. In particular, we show that the solution of $(A_n+B_n)x = b$ can be obtained in $O(n \log n)$ operations.

1. Introduction.

In this paper, we consider the solution of systems of the form $(A_n + B_n)x = b$, where A_n is an n-by-n Hermitian Toeplitz matrix (i.e., the entries of A_n are the same along its diagonals) and B_n is an n-by-n Hermitian band matrix with bandwidth independent of n. These systems appear in solving Fredholm integro-differential equations of the form

$$L\{x(\theta)\} + \int_\alpha^\beta K(\phi - \theta)x(\phi)d\phi = b(\theta).$$

Here $x(\theta)$ is the unknown function to be found, $K(\theta)$ is a convolution kernel, L is a differential operator, and $b(\theta)$ is a given function. After discretization, K will lead to a Toeplitz matrix, L a band matrix, and $b(\theta)$ the right-hand side vector; see Delves and Mohamed [6, p. 343]. Toeplitz-plus-band matrices also appear in signal processing literature and have been referred to as peripheral innovation matrices; see Carayannis, Kalouptsidis, and Manolakis [2].

For Toeplitz systems $A_n x = b$, fast and superfast direct solvers of complexity $O(n^2)$ and $O(n \log^2 n)$, respectively, have been developed; see, for instance, Trench [10] and Ammar and Gragg [1]. However, there exists no fast direct solvers for solving Toeplitz-plus-band systems. This is mainly because the displacement rank of the matrix $A_n + B_n$ can take any value between 0 and n. Hence fast Toeplitz solvers that are based on small displacement rank of matrices cannot be applied.

We note that given any vector x, the product $(A_n + B_n)x$ can be computed in $O(n \log n)$ operations. In fact, $A_n x$ can be obtained by fast Fourier transform by first embedding A_n into a $2n$-by-$2n$ circulant matrix; see Strang [9]. Thus iterative methods such as the conjugate gradient method can be employed for solving these systems. The convergence rate of the conjugate gradient method depends on the spectrum of the matrix $A_n + B_n$; see Golub and Van Loan [8]. However, generally, the spectrum of A_n, and hence of $A_n + B_n$, is not clustered and the method will therefore converge slowly. Hence a suitable preconditioner should be chosen to speed up the convergence.

For Toeplitz systems $A_n x = b$, circulant preconditioners have been proved to be successful choices under the assumption that the diagonals of A_n are Fourier coefficients of a positive 2π-periodic continuous function. In that case, Chan and Yeung [3] proved that

*Received by the editors November 18, 1991; accepted for publication (in revised form) August 17, 1992.
†Department of Mathematics, University of Hong Kong, Hong Kong.

the convergence rate of the method is superlinear. However, circulant preconditioners do not work for Toeplitz-plus-band systems. In fact, Strang's circulant preconditioner [9] is not even defined for non-Toeplitz matrices. T. Chan's circulant preconditioner, while defined for $A_n + B_n$, will not work well when the eigenvalues of B_n are not clustered; see the numerical results in §4. Even if we approximate A_n by a circulant preconditioner M_n, the matrix $M_n + B_n$ cannot be used as a preconditioner since the system $(M_n + B_n)z = y$ cannot be solved easily.

In this paper, we use band matrices C_n as preconditioners. We will assume that B_n is an arbitrary Hermitian positive semidefinite band matrix with bandwidth independent of n, and the diagonals of A_n are Fourier coefficients of a nonnegative piecewise continuous function f. In that case, $A_n + B_n$ will be Hermitian positive definite. We prove that if the essential infimum of f is attained by finitely many points in $[-\pi, \pi]$ and if f is sufficiently smooth around these points, then there exists a Hermitian positive definite band matrix C_n, with bandwidth independent of n, such that the spectra of $C_n^{-1}(A_n + B_n)$ are uniformly bounded by a constant independent of n. Hence for a given tolerance, the number of iterations required for convergence is independent of n. Since the band matrix system $C_n x = b$ can be solved in $O(n)$ operations, the total complexity of the method is $O(n \log n)$.

The outline of the rest of the paper is as follows. In §2, we introduce our preconditioners C_n and study the spectral properties of $A_n + B_n$ and C_n. In §3, we show that the spectra of $C_n^{-1}(A_n + B_n)$ are uniformly bounded by constants independent of n. Finally, numerical examples and concluding remarks are given in §4.

2. Construction of the preconditioner C_n.

To begin with, let $\mathcal{C}^+$ be the set of all nonnegative piecewise continuous functions defined on $[-\pi, \pi]$. For all $f \in \mathcal{C}^+$, let

$$t_k[f] = \frac{1}{2\pi} \int_{-\pi}^{\pi} f(\theta) e^{-ik\theta} d\theta, \qquad k = 0, \pm 1, \pm 2, \ldots$$

be the Fourier coefficients of f. Since f is real-valued,

$$t_{-k}[f] = \bar{t}_k[f], \qquad k = 0, \pm 1, \pm 2, \ldots.$$

Let $A_n[f]$ be the n-by-n Hermitian Toeplitz matrix with the (j, l)th entry given by $t_{j-l}[f]$. The function f is called the generating function of the matrices $A_n[f]$. We recall that a point θ_0 is said to be a zero of f with order ν if $f(\theta_0) = 0$ and ν is the smallest positive integer such that $f^{(\nu)}(\theta_0) \neq 0$ and $f^{(\nu+1)}(\theta)$ is continuous in a neighborhood of θ_0.

In the following, we denote the essential infimum and the essential supremum of f by $f_{\min}$ and $f_{\max}$, respectively. We will assume that f attains $f_{\min}$ at finitely many points in $[-\pi, \pi]$ and that f is smooth around these points. More precisely, we assume that $f(\theta) - f_{\min}$ has finitely many zeros in $[-\pi, \pi]$ and that the orders of these zeros are finite and positive. Notice that the matrix $A_n[f]$ is unchanged when f is redefined at finitely many points. Thus we can always assume without loss of generality that f is continuous at those minimum points.

From the assumptions, we see that $f_{\max} \neq f_{\min}$. Then by using the fact that

$$u^* A_n[g] u = \frac{1}{2\pi} \int_{-\pi}^{\pi} |\sum_{j=1}^{n} u_j e^{i(j-1)\theta}|^2 g(\theta) d\theta \tag{1}$$

for any $g \in \mathcal{C}^+$ and any n-vector $u = (u_1, \ldots, u_n)^*$, Chan [4, Lemma 1] proved that

$$\lambda_{\min}(A_n[f]) > f_{\min}. \tag{2}$$

Here $\lambda_{\min}(A_n[f])$ is the smallest eigenvalue of $A_n[f]$. Since f is nonnegative, $A_n[f]$ is positive definite for all n. In the following, we will assume that the band matrices B_n are Hermitian positive semidefinite matrices with bandwidth $2\omega + 1$ and that ω is independent of n. Clearly the matrix $A_n[f] + B_n$ is positive definite for all n.

For all $n > 0$, our preconditioners C_n are defined as

$$C_n \equiv A_n[b_\mu] + B_n + f_{\min} \cdot I_n. \tag{3}$$

Here

$$b_\mu(\theta) = (2 - 2\cos\theta)^\mu = \left(2\sin\left(\frac{\theta}{2}\right)\right)^{2\mu},$$

and it has a unique zero of order 2μ at $\theta = 0$. We remark that $A_n[b_\mu]$ is a symmetric band Toeplitz matrix of bandwidth $(2\mu + 1)$ and its diagonals are given by the Pascal triangle; see Chan [4]. Clearly, C_n is a symmetric band matrix of bandwidth

$$2\ell + 1 = \max\{2\mu + 1, 2\omega + 1\}.$$

Moreover, since the minimum of b_μ is 0, it follows from (2) and (3) that

$$\lambda_{\min}(C_n) \geq \lambda_{\min}(A_n[b_\mu]) + \lambda_{\min}(B_n) + f_{\min} > f_{\min} \geq 0.$$

In particular, the preconditioner C_n is positive definite for all n. We note that in [4, Thm. 2], we have shown that $A_n[b_\mu(\theta)] + f_{\min} \cdot I_n$ is a good preconditioner for $A_n[f]$. Thus intuitively, we expect C_n so defined to be a good preconditioner for $A_n[f] + B_n$.

3. Condition number of the preconditioned matrix. In this section, we show that the spectra of $C_n^{-1}(A_n + B_n)$ are uniformly bounded by constants independent of n. We first consider generating functions f in C^+ where $f(\theta) - f_{\min}$ has only one zero at θ_0. Let the order of θ_0 be ν. We note that $f^{(\nu)}(\theta_0) > 0$ and ν must be even. We remark also that we can assume without loss of generality that $\theta_0 = 0$. In fact the function $f(\theta + \theta_0) - f_{\min}$ has a zero at $\theta = 0$ and

$$A_n[f(\theta + \theta_0)] = V_n^* A_n[f(\theta)] V_n,$$

where $V_n = \operatorname{diag}(1, e^{-i\theta_0}, e^{-2i\theta_0}, \ldots, e^{-i(n-1)\theta_0})$; see Chan [4, Lemma 2].

THEOREM 1. *Let $f \in C^+$. Suppose that $f(\theta) - f_{\min}$ has a unique zero at $\theta = 0$ with order equal to 2μ. Let $C_n = A_n[b_\mu] + B_n + f_{\min} \cdot I$. Then $\kappa(C_n^{-1}(A_n[f] + B_n))$ is uniformly bounded for all $n > 0$.*

Proof. By assumption, there exists a neighborhood N of 0 such that f is continuous in N. Define

$$F(\theta) = \frac{f(\theta)}{(2 - 2\cos\theta)^\mu + f_{\min}}.$$

Clearly F is continuous and positive for $\theta \in N \setminus \{0\}$. Since

$$\lim_{\theta \to 0} F(\theta) = \begin{cases} 1 & f_{\min} > 0, \\ \dfrac{f^{(2\mu)}(0)}{(2\mu)!} & f_{\min} = 0 \end{cases}$$

is positive, F is a continuous positive function in N. Since f is piecewise continuous and positive almost everywhere in $[-\pi, \pi] \setminus N$, we see that F is a piecewise continuous function with a positive essential infimum in $[-\pi, \pi]$. Hence there exist constants $b_1, b_2 > 0$, such that $b_1 \le F(\theta) \le b_2$ almost everywhere in $[-\pi, \pi]$. Without loss of generality, we assume that $b_2 \ge 1 \ge b_1$. By using (1), we then have

$$b_1 \le \frac{u^* A_n[f] u}{u^*(A_n[b_\mu] + f_{\min} \cdot I_n) u} \le b_2$$

for any n-vector u. Recall that B_n is positive semidefinite and $C_n = A_n[b_\mu] + B_n + f_{\min} \cdot I_n$. We then have

$$b_1 \le \frac{u^*(A_n[f] + B_n) u}{u^* C_n u} \le b_2$$

for any n-vector u. Hence $\kappa(C_n^{-1}(A_n[f] + B_n)) \le b_2/b_1$, which is independent of n. □

We remark that the results can be readily generalized to the case where $f_{\min}$ is attained at finitely many points; cf. Chan [4, Thm. 3]. The bandwidth of C_n will be given by

$$2\ell + 1 = \max\left\{ \sum_j \nu_j + 1, 2\omega + 1 \right\},$$

where ν_j are the orders of the zeros of $f(\theta) - f_{\min}$ and the summation is over all such zeros.

Next we consider the computational cost and storage requirement of our method. The number of operations per iteration in the preconditioned conjugate gradient method depends mainly on the work of computing the matrix–vector multiplication $C_n^{-1}(A_n[f] + B_n)y$; see, for instance, Golub and Van Loan [8]. In this case, the matrix–vector multiplication $B_n y$ requires only $(2\omega + 1)n$ operations and the product $A_n[f]y$ can be done in $O(n \log n)$ operations by the fast Fourier transform. The system $C_n y = z$ can be solved by using any band matrix solver. The cost of factorizing C_n is about $\frac{1}{2}\ell^2 n$ operations and then each subsequent solve requires an extra $(2\ell + 1)n$ operations. Hence the total operations per iteration is of order $O(n \log n)$ as ℓ and ω are independent of n. It is well known that the number of iterations required to attain a given tolerance ϵ is bounded by

$$\frac{1}{2}\sqrt{\kappa(C_n^{-1}(A_n + B_n))} \log\left(\frac{1}{\epsilon}\right) + 1.$$

Since the condition number is uniformly bounded in this case, the overall work required to attain the given tolerance is of $O(n \log n)$ operations.

As for the storage, we need five n-vectors in the conjugate gradient method. The diagonals of A_n and the bands of B_n require extra $(\omega + 2)$ n-vectors, and finally, we need an n-by-$(\ell + 1)$ matrix to hold the factors of the preconditoner C_n. Thus the overall storage requirement is about $(8 + \ell + \omega)n$, which is significantly less than the $O(n^2)$ storage required by Gaussian elimination method.

4. Numerical results and concluding remarks.

To test the convergence rate of the preconditioner, we considered two different band matrices. The first one is the diagonal matrix

$$D_n = f_{\max} \cdot \operatorname{diag}\left[0, \frac{1}{n}, \frac{2}{n}, \ldots, \frac{n-1}{n}\right]$$

TABLE 1
Number of iterations for $B_n = D_n$.

f	θ^4				$\cosh\theta$				$J(\theta)$			
n	No	C_n	E_n	T_n	No	C_n	E_n	T_n	No	C_n	E_n	T_n
16	16	9	8	16	15	8	8	15	14	12	9	14
32	26	11	9	23	21	9	9	18	18	14	12	16

128	50	14	16	40	29	10	11	23	30	15	18	24
256	68	15	21	53	32	10	12	25	39	15	23	30
512	91	15	32	70	34	10	14	27	50	15	28	38
1024	122	16	64	91	36	10	16	27	63	15	35	47

whose eigenvalues are distributed uniformly in the interval $[0, f_{\max}]$. The second one is a symmetric tridiagonal matrix given by

$$B_n^{(\alpha)} = (n+1)^\alpha \cdot \frac{2\pi}{n+1} \begin{bmatrix} 2 & -\frac{3}{2} & & & \\ -\frac{3}{2} & 4 & -\frac{5}{2} & & \\ & -\frac{5}{2} & 6 & \ddots & \\ & & \ddots & \ddots & -\frac{2n-1}{2} \\ & & & -\frac{2n-1}{2} & 2n \end{bmatrix}.$$

Notice that $B_n^{(2)}$ is the discretization matrix of the operator

$$\frac{d}{d\theta}\left\{(\theta+\pi)\frac{d}{d\theta}\right\}$$

in $[-\pi, \pi]$. Clearly, the matrices $B_n^{(\alpha)}$ are irreducibly diagonally dominant; hence they are positive definite.

In our tests, the vector of all ones is the right-hand side vector, the zero vector is the initial guess, and the stopping citerion is $||r_q||_2/||r_0||_2 \le 10^{-7}$, where r_q is the residual vector after q iterations. The computations are done with 8-byte arithmetic on a Vax 6420. Three different generating functions were tested. They are θ^4, $\cosh\theta$, and

$$J(\theta) \equiv \begin{cases} \theta^2 & |\theta| \le \pi/2, \\ 1 & |\theta| > \pi/2. \end{cases}$$

The corresponding bandwidths of C_n are 5, 3, and 3, respectively.

For comparison, we also solved the problems with two other preconditioners. The first one is the T. Chan circulant preconditioner T_n corresponding to the matrix $A_n[f] + B_n$. The second preconditioner E_n, which has the same bandwidth as C_n, is obtained by just copying the diagonals of $A_n[f]+B_n$. We note that some of the E_n may be indefinite. In contrast, C_n and T_n are always positive definite. Tables 1–4 show the number of iterations required for convergence (** means more than 1000 iterations). We see that as n increases, the number of iterations stays almost the same when C_n is used as the preconditioner while it increases if others are used.

We conclude that our algorithm solves the system $(A_n + B_n)x = b$ in $O(n \log n)$ operations for a certain class of Toeplitz matrices A_n. The cost is significantly less than the $O(n^3)$ cost required by Gaussian elimination method. We note that the spectra of $C_n^{-1}(A_n[f] + B_n)$ generally will not be clustered around 1 although they are uniformly

bounded. We finally remark that our results in this paper extend those obtained in Chan [4]. More precisely, in [4], we proved that $\kappa(C_n^{-1}A_n[f])$ is uniformly bounded whenever f is 2π-periodic continuous. However, using Theorem 1 with B_n equal to a zero matrix, we see that the same conclusion holds whenever f is 2π-periodic piecewise continuous.

Acknowledgment. We would like to thank Professor Israel Koltracht of the University of Connecticut for his valuable suggestions.

MARTIN H. GUTKNECHT†

Abstract. Recently Van der Vorst [*SIAM J. Sci. Statist. Comput.*, 13 (1992), pp. 631–644] proposed for solving nonsymmetric linear systems $Az = b$ a biconjugate gradient (BICG)-based Krylov space method called BICGSTAB that, like the biconjugate gradient squared (BICGS) method of Sonneveld, does not require matrix-vector multiplications with the transposed matrix A^T, and that has typically a much smoother convergence behavior than BICG and BICGS. Its nth residual polynomial is the product of the one of BICG (i.e., the nth Lanczos polynomial) with a polynomial of the same degree with real zeros. Therefore, nonreal eigenvalues of A are not approximated well by the second polynomial factor. Here, the author presents for real nonsymmetric matrices a method BICGSTAB2 in which the second factor may have complex conjugate zeros. Moreover, versions suitable for complex matrices are given for both methods.

Key words. Lanczos algorithm, biconjugate gradient algorithm, conjugate gradient squared algorithm, BICGSTAB, formal orthogonal polynomial, nonsymmetric linear system, Krylov space method

AMS subject classification. 65F10

1. From BICG to complex BICGSTAB.

The *biconjugate gradient method* (BICG) of Lanczos [7] and Fletcher [1] is a Krylov space method for solving (real or complex) non-Hermitian linear system $Az = b$, where A is, say, a nonsingular $N \times N$ matrix. (Typically, this matrix will be the result of applying a preconditioner to the original system matrix.) Starting from some initial guess z_0 for the solution, BICG generates a sequence z_n with the property that the nth residual $r_n := b - Az_n$ lies in the Krylov space generated by A from r_0, i.e.,

$$r_n \in \mathcal{K}_{n+1} := \text{span}\,(r_0, Ar_0, \ldots, A^n r_0), \tag{1}$$

and is orthogonal to another Krylov space generated from some other initial vector y_0 by the Hermitian transpose A^H

$$r_n \perp \mathcal{L}_n := \text{span}\,(y_0, A^H y_0, \ldots, (A^H)^{n-1} y_0). \tag{2}$$

The sequence of residual polynomials ρ_n, which are implicitly defined by

$$r_n = \rho_n(A) r_0, \tag{3}$$

is in view of (2) a sequence of formal orthogonal polynomials: if we define a linear functional Φ on the space of polynomials with complex coefficients by setting $\Phi(\zeta^k) := y_0^H A^k x_0$, the formal orthogonality relation $\Phi(\pi_k \rho_n) = 0$ holds for every polynomial π_k of degree $k < n$; see [5], [3] for further details and references. As a consequence of the consistency condition for polynomial acceleration methods, these residual polynomials are normalized by $\rho_n(0) = 1$. They are often called *Lanczos polynomials*. In general, neither these polynomials nor the residuals satisfy a minimality condition, in contrast to the case in which A is Hermitian positive definite and $y_0 = r_0$, where the method reduces to the classical conjugate gradient method. Theoretically, the BICG algorithm terminates in at most $\nu(A, r_0)$ steps if this number denotes the degree of the minimal polynomial of the restriction of A to the maximum Krylov space generated by A from

r_0. In practice this property is often irrelevant because $\nu(A, r_0)$ may be very large and the orthogonality (2) is partly lost due to roundoff. What counts in practice is the good convergence behavior and the small memory requirement of the method.

The algorithm can break down, namely, due to

$$r_n \perp \mathcal{L}_{n+1}; \tag{4}$$

but in most cases such a breakdown or a corresponding near-breakdown can be overcome by a look-ahead step, see [8], [3], [4], [2] and further references cited there.

In the standard version of the BiCG method, which we call BioMin, a second sequence $\{\sigma_n\}$ of formal orthogonal polynomials plays a role. The algorithm is based on the following mixed recurrence formulas (in which we suppress the independent variable ζ by writing ρ_n instead of $\rho_n(\zeta)$, and σ_n instead of $\sigma_n(\zeta)$):

$$\rho_{n+1} := \rho_n - \omega_n \zeta \sigma_n, \tag{5a}$$

$$\sigma_{n+1} := \rho_{n+1} - \psi_{n+1}\sigma_n, \tag{5b}$$

where the coefficients ω_n and ψ_{n+1} are computed as indicated below. These formulas are implicitly used to generate two pairs of finite vector sequences

$$x_n := \rho_n(A)x_0, \quad y_n := \overline{\rho_n}(A^H)y_0, \tag{6a}$$

$$u_n := \sigma_n(A)x_0, \quad v_n := \overline{\sigma_n}(A^H)y_0, \tag{6b}$$

satisfying the biorthogonality conditions

$$y_n^H x_m = \delta_n \delta_{m,n}, \tag{7a}$$

$$v_n^H A u_m = \delta'_n \delta_{m,n}. \tag{7b}$$

(In (6), $\overline{\rho_n}$ and $\overline{\sigma_n}$ have the complex conjugate coefficients of ρ_n and σ_n, and in (7), $\delta_n \neq 0$, $\delta'_n \neq 0$ are constants and $\delta_{m,n}$ is the Kronecker symbol. The scaling of the vectors y_n and v_n is, theoretically, irrelevant; but in practice, a scaling different from the one chosen here may be more appropriate, e.g., one may choose y_n and v_n to have unit length.)

Theoretically one proceeds until the algorithm terminates or breaks down; in practice, one stops when the residual is sufficiently small. Here, $x_n = r_n$ is actually the nth residual vector of BiCG, but as we will see, there are other algorithms that are also based on the recursions (5) yet have other residual vectors. In any case, the recurrences (5) are not used to generate the polynomials, but are translated into recurrences for the vectors specified by (6). For the iterates z_n, an additional recurrence related to the one for the residual vectors $x_n = r_n$ is easily derived. The coefficients ω_n and ψ_{n+1} in (5) are determined from the biorthogonality conditions (7) and the consistency condition $\rho_n(0) = 1$ (see [5]); in fact, only the case $m = n + 1$ of (7) is enforced:

$$\omega_n := \delta_n / (y_n^H A u_n) = \delta_n / (v_n^H A u_n), \tag{8a}$$

$$\delta_{n+1} := y_{n+1}^H x_{n+1}, \tag{8b}$$

$$\psi_{n+1} := (y_{n+1}^H A u_n)/(v_n^H A u_n) = -\delta_{n+1}/\delta_n. \tag{8c}$$

(In the equalities in (8a) and (8c), one makes use of the formal orthogonality of the polynomials and of the fact that, in view of (5), ρ_{n+1}, σ_{n+1}, and $-\omega_n \zeta \sigma_n$ have the same leading coefficient.)

It is the great advantage of the Lanczos approach based on (5) that observing the conditions (7) for $m = n+1$ implies theoretically that they hold for all $m \le n$. The short recurrences (5) mean very small memory requirements. Moreover, although in practice the biorthogonality with respect to the earlier constructed vectors (i.e., for large $|m-n|$) tends to get lost due to roundoff, it is this biorthogonality that accounts for the normally observed gradual decrease of the residual length. The biorthogonality is related to a Padé approximation problem. However, the convergence is still not well understood, and in practice is often far from monotonic. But for very large problems, Lanczos-type methods, due to their small memory requirements, are often the best choice.

One disadvantage of the unsymmetric Lanczos process and BICG is that the construction of y_n requires one application of A^H in each step in addition to the one application of A to compute z_n and r_n. (In BICG, u_n and v_n are then found without further matrix–vector products.) In 1984 Sonneveld [11] with his *(bi)conjugate gradient squared* (CGS or BICGS) *method* proposed a way to get around A^H. He uses a set of recurrences that allows him to compute other iterates z_n whose residuals $r_n := b - Az_n$ satisfy

$$r_n = \rho_n^2(A)r_0, \tag{9}$$

where the polynomials ρ_n are still the Lanczos polynomials. In fact, the iterates and their residuals, together with the vectors defined by

$$p_n := \rho_n(A)\sigma_n(A)r_0, \quad q_n := \rho_n(A)\sigma_{n-1}(A)r_0, \quad s_n := \sigma_n^2(A)r_0, \tag{10}$$

can be generated by the Krylov space analogs of the polynomial recurrences

$$\begin{aligned}
\rho_{n+1}\sigma_n &= \rho_n\sigma_n - \omega_n\zeta\sigma_n^2, && \text{(11a)}\\
\rho_{n+1}\sigma_{n+1} &= \rho_{n+1}^2 - \psi_{n+1}\rho_{n+1}\sigma_n, && \text{(11b)}\\
\rho_{n+1}^2 &= \rho_n^2 - \omega_n\zeta(\rho_n\sigma_n + \rho_{n+1}\sigma_n), && \text{(11c)}\\
\sigma_{n+1}^2 &= \rho_{n+1}\sigma_{n+1} - \psi_{n+1}\rho_{n+1}\sigma_n + \psi_{n+1}^2\sigma_n^2, && \text{(11d)}
\end{aligned}$$

which are readily derived from (5). Due to the squaring of the residual polynomial, the sometimes erratic convergence behavior of BICG is even more pronounced here.

Of course, the recurrences (11) need to be complemented by formulas for determining ω_n and ψ_{n+1}. Using (6) and (10), the expressions (8) are readily transformed into

$$\begin{aligned}
\omega_n &= \delta_n/(y_0^H A s_n), && \text{(12a)}\\
\delta_{n+1} &= y_0^H r_{n+1}, && \text{(12b)}\\
\psi_{n+1} &= -\delta_{n+1}/\delta_n. && \text{(12c)}
\end{aligned}$$

As mentioned before, these coefficients ω_n and ψ_{n+1} result basically from observing the biorthogonality conditions (7) for $m = n+1$, i.e.,

$$y_n^H x_{n+1} = 0, \qquad v_n^H A u_{n+1} = 0. \tag{13}$$

At this point it is worth noting that for $m \ne n$, (7) is equivalent to

$$\begin{aligned}
&y_n \perp \mathcal{K}_n, \;\; x_n \perp \mathcal{L}_n\,, && \text{(14a)}\\
&A^H v_n \perp \mathcal{K}_n, \;\; A u_n \perp \mathcal{L}_n\,. && \text{(14b)}
\end{aligned}$$

In view of (6) these conditions are not independent; those on the left-hand side are equivalent to those on the right-hand side. If $\mathcal{P}_n$ denotes the set of polynomials of degree at most n, the latter can be expressed as

$$y_0^H \pi_n(A) x_{n+1} = 0 \quad (\forall \pi_n \in \mathcal{P}_n), \tag{15a}$$
$$v_0^H \tilde{\pi}_n(A) A u_{n+1} = 0 \quad (\forall \tilde{\pi}_n \in \mathcal{P}_n). \tag{15b}$$

The conditions (13) are just the special case of (15) with $\pi_n = \rho_n$ and $\tilde{\pi}_n = \sigma_n$. But the same restrictions can be taken into account by choosing for π_n and $\tilde{\pi}_n$ any other polynomial of exact degree n. Van der Vorst [14] (following an earlier proposal by Sonneveld) discovered that a simple implementation and an often excellent convergence behavior can be attained by choosing for π_n and $\tilde{\pi}_n$ polynomials τ_n that are built up in factored form

$$\tau_n(\zeta) = (1 - \chi_0 \zeta)(1 - \chi_1 \zeta) \cdots (1 - \chi_{n-1} \zeta) \tag{16}$$

by adding a suitable new zero $1/\chi_n$ at each step. Clearly,

$$\tau_{n+1} = (1 - \chi_n \zeta) \tau_n, \tag{17}$$

so that

$$\rho_{n+1} \tau_{n+1} = (1 - \chi_n \zeta) \rho_{n+1} \tau_n. \tag{18}$$

Multiplication of (5a) and (5b) by τ_n and τ_{n+1} yields the further recurrences

$$\rho_{n+1} \tau_n = \rho_n \tau_n - \omega_n \zeta \sigma_n \tau_n, \tag{19}$$
$$\sigma_{n+1} \tau_{n+1} = \rho_{n+1} \tau_{n+1} - \psi_{n+1} (1 - \chi_n \zeta) \sigma_n \tau_n. \tag{20}$$

Equations (18)–(20) are a set of recurrence relations that after the translation from polynomials to Krylov space vectors can be used to build up the vector sequences

$$\tilde{r}_n := \rho_n(A) \tau_n(A) r_0, \quad \tilde{w}_n := \rho_n(A) \tau_{n-1}(A) r_0, \quad \tilde{s}_n := \sigma_n(A) \tau_n(A) r_0. \tag{21}$$

Van der Vorst [14], assuming real data (i.e., a real matrix A and $b, z_0, y_0 \in \mathbb{R}^N$), chooses in the nth step of BiCGStab the new zero $1/\chi_n$ so that the new residual norm $||\tilde{r}_{n+1}|| = ||\tilde{w}_{n+1} - A\tilde{w}_{n+1}\chi_n||$ is minimized over $\chi_n \in \mathbb{R}$. Here and in the following, the norm is the Euclidean one. Our first aim is to generalize this approach to complex data. In particular, we allow $\chi_n \in \mathbb{C}$ now. Starting from

$$||\tilde{r}_{n+1}||^2 = ||\tilde{w}_{n+1} - A\tilde{w}_{n+1}\chi_n||^2 = ||\tilde{w}_{n+1}||^2 - 2\,\mathrm{Re}\,\{\tilde{w}_{n+1}^H A \tilde{w}_{n+1} \chi_n\} + \chi_n^2\, ||A\tilde{w}_{n+1}||^2, \tag{22}$$

one can conclude by inserting $\chi_n = \xi_n + i\eta_n$, and computing the partial derivatives $\partial/\partial\xi_n$ and $\partial/\partial\eta_n$, that this minimization leads to

$$\chi_n := \frac{(A\tilde{w}_{n+1})^H \tilde{w}_{n+1}}{||A\tilde{w}_{n+1}||^2}. \tag{23}$$

This is no surprise, since one obtains the same formula easier by noting that the minimization problem can be solved by orthogonal projection of $\tilde{w}_{n+1}$ onto $A\tilde{w}_{n+1}$ in $\mathbb{C}^N$; the image of this projection must be equal to $A\tilde{w}_{n+1}\chi_n$. (If we had restricted χ_n to be real, we would have obtained $\chi_n := \mathrm{Re}\,\{(A\tilde{w}_{n+1})^H \tilde{w}_{n+1}\}/||A\tilde{w}_{n+1}||^2$ instead.)

Formulas for the coefficients ω_n and ψ_{n+1} are found by modifying (12) for taking the leading coefficient $(-1)^n\chi_0 \cdots \chi_{n-1}$ of τ_n into account. Noting that σ_n and ρ_n have leading coefficient $(-1)^n\omega_0 \cdots \omega_{n-1}$ and setting $\tilde{\delta}_n := \delta_n(\chi_0 \cdots \chi_{n-1})/(\omega_0 \cdots \omega_{n-1})$, we get

$$\text{(24a)} \qquad \omega_n = \frac{\delta_n}{y_0^H A s_n} = \frac{\delta_n}{y_0^H A \sigma_n^2(A) x_0} = \frac{\tilde{\delta}_n}{y_0^H A \sigma_n(A)\tau_n(A) x_0} = \frac{\tilde{\delta}_n}{y_0^H A \tilde{s}_n},$$

$$\text{(24b)} \qquad \tilde{\delta}_{n+1} = y_0^H \tilde{r}_{n+1},$$

$$\text{(24c)} \qquad \psi_{n+1} = -\frac{\delta_{n+1}}{\delta_n} = \frac{\tilde{\delta}_{n+1}\omega_n}{\tilde{\delta}_n \chi_n}.$$

Altogether, one obtains the following complex version of BiCGStab. If applied to real data, it is identical with Van der Vorst's algorithm. The letter o denotes the zero vector.

ALGORITHM 1 (BiCGStab). *For solving $Az = b$ choose an initial approximation $z_0 \in \mathbb{C}^N$ and set $\tilde{r}_0 := \tilde{s}_0 := b - Az_0$. Choose $y_0 \in \mathbb{C}^N$ such that $\tilde{\delta}_0 := y_0^H \tilde{r}_0 \neq 0$ and $\varphi_0 := y_0^H A \tilde{s}_0 / \tilde{\delta}_0 \neq 0$. Then compute for $n = 0, 1, \ldots$*

$$\text{(25a)} \qquad \omega_n := 1/\varphi_n,$$

$$\text{(25b)} \qquad \tilde{w}_{n+1} := \tilde{r}_n - A\tilde{s}_n\omega_n,$$

$$\text{(25c)} \qquad \chi_n := (A\tilde{w}_{n+1})^H \tilde{w}_{n+1} / \|A\tilde{w}_{n+1}\|^2,$$

$$\text{(25d)} \qquad \tilde{r}_{n+1} := \tilde{w}_{n+1} - A\tilde{w}_{n+1}\chi_n,$$

$$\text{(25e)} \qquad z_{n+1} := z_n + \tilde{s}_n\omega_n + \tilde{w}_{n+1}\chi_n,$$

$$\text{(25f)} \qquad \tilde{\delta}_{n+1} := y_0^H \tilde{r}_{n+1},$$

$$\text{(25g)} \qquad \psi_{n+1} := -\omega_n\tilde{\delta}_{n+1}/(\tilde{\delta}_n\chi_n),$$

$$\text{(25h)} \qquad \tilde{s}_{n+1} := \tilde{r}_{n+1} - (\tilde{s}_n - A\tilde{s}_n\chi_n)\psi_{n+1},$$

$$\text{(25i)} \qquad \varphi_{n+1} := y_0^H A \tilde{s}_{n+1} / \tilde{\delta}_{n+1}.$$

If $\tilde{r}_{n+1} = o$, the process terminates and z_{n+1} is the solution of $Az = b$; if $\tilde{r}_{n+1} \neq o$ but $\tilde{\delta}_{n+1} = 0$ or $\varphi_{n+1} = 0$, the algorithm breaks down.

We need to comment on the conditions under which this algorithm breaks down. Clearly, in exact arithmetic, a breakdown of BiCG, caused by $\varphi_n = 0$ or $\delta_n = 0$, see [5], is paralleled by a breakdown of BiCGStab, caused by $\varphi_n = 0$ or $\tilde{\delta}_n = 0$, since $\tilde{\delta}_n := \delta_n(\chi_0 \cdots \chi_{n-1})/(\omega_0 \cdots \omega_{n-1})$. However, in the above formulation, BiCGStab obviously also breaks down if $\chi_n = 0$. A closer look shows that ψ_{n+1} may still be finite in this case, cf. (24c), so that one might try to find an alternative formula for (25g). However, if $\chi_n = 0$, then $\tilde{r}_{n+1} = \tilde{w}_{n+1} = \rho_{n+1}(A)\tau_n(A)r_0$, and it follows from (15a) that $\tilde{\delta}_{n+1} := y_0^H \tilde{r}_{n+1} = y_0^H \rho_{n+1}(A)\tau_n(A)r_0 = y_0^H \tau_n(A) x_{n+1} = 0$. Consequently, $\chi_n = 0$ implies $\tilde{\delta}_{n+1} = 0$, so it suffices to check the two conditions $\tilde{\delta}_{n+1} = 0$ and $\varphi_{n+1} = 0$, although this conceals the fact that $\tilde{\delta}_{n+1} = 0$ can be caused by $\delta_{n+1} = 0$ or $\chi_n = 0$. The new pitfall here is that we do not advance in the Krylov space if $\chi_n = 0$. Then $\tilde{r}_{n+1} \in \mathcal{K}_{2n+2}$, but $\tilde{r}_{n+1} = \rho_{n+1}(A)\tau_{n+1}(A)r_0$ should be in $\mathcal{K}_{2n+3}\backslash\mathcal{K}_{2n+2}$.

2. Two-dimensional local minimization: BiCGStab2. As is well known and is indicated by (3), the convergence of a polynomial acceleration method like BiCG hinges on the damping properties of the residual polynomials ρ_n. Ideally, the lemniscates $|\rho_n(\zeta)| = \varepsilon$ should already for some small ε embrace the spectrum of A or, in the case of a nonnormal A, rather the pseudospectrum [12]. The residual polynomials $\rho_n\tau_n$ of BiCGStab combine the damping properties of the Lanczos polynomials ρ_n (which not only depend on A but also on $r_0 = x_0$ and y_0) with those of τ_n. If one had $\rho_n \equiv 1$ for all n (which is impossible since ρ_n has exact degree n), the polynomials τ_n would be the residual polynomials of GMRES(1) [10], i.e., of GMRES restarted at each step. The factor ρ_n causes a modification of the restart vector, but in any case, one cannot expect τ_n to have an excellent global damping effect. Although the success of BICGSTAB shows that τ_n is normally good enough to level out the irregular convergence of the Lanczos polynomials ρ_n, it has an obvious deficiency when the method (in its original version proposed by Van der Vorst) is applied to a real nonsymmetric system: while generally a nonsymmetric real matrix A has a complex spectrum, all the zeros of τ_n are real if x_0 and y_0 are real vectors.[1] It is therefore natural to try to modify the method so that in the real case τ_n may have pairs of complex conjugate zeros. This is the basic idea for the method BICGSTAB2 defined next. We formulate it also for complex data, but the reader must keep in mind that it also brings a major improvement in the real case.

Let us redefine the polynomials τ_n according to $\tau_0 :\equiv 1$ and the recurrences

$$\tau_{2m+1} := (1 - \chi_m\zeta)\tau_{2m}, \tag{26a}$$

$$\tau_{2m+2} := (1 - \xi_m)\tau_{2m} + (\xi_m + \eta_m\zeta)\tau_{2m+1}, \tag{26b}$$

with $\chi_m, \xi_m, \eta_m \in \mathbb{C}$. (In the case of real data, $\chi_m, \xi_m, \eta_m \in \mathbb{R}$.) Note that $\tau_n(0) = 1$ (for all n) by induction. Clearly, τ_{2m+1} has, as in the original BICGSTAB, the new zero $1/\chi_m$, but in the next step τ_{2m+2} is chosen as a linear combination of τ_{2m}, τ_{2m+1} and $\zeta\tau_{2m+1}$, restricted only by $\tau_{2m+2}(0) = 1$. Hence, the zero $1/\chi_m$ is dismissed and τ_{2m} is supplemented by two new zeros, i.e., there holds

$$\tau_{2m+2} = (1 - \zeta_{2m}\zeta)(1 - \zeta_{2m+1}\zeta)\tau_{2m}, \tag{27}$$

where in the case of real data ζ_{2m} and ζ_{2m+1} are either real or complex conjugate. These zeros can, but need not, be computed. The parameters χ_m, ξ_m, and η_m are again chosen to minimize the residual locally (i.e., within a one- or two-dimensional subspace, respectively). But first, we want to look at the recurrences, which are actually independent of these choices.

Clearly, (19) is again valid for all n, and an analogous relation follows by multiplying (5a) with τ_{n-1} instead of τ_n:

$$\rho_{n+1}\tau_n = \rho_n\tau_n - \omega_n\zeta\sigma_n\tau_n, \tag{28}$$

$$\rho_{n+1}\tau_{n-1} = \rho_n\tau_{n-1} - \omega_n\zeta\sigma_n\tau_{n-1} \quad \text{if } n \geq 1. \tag{29}$$

Equations (18) and (20) remain correct for even n after replacing χ_n by χ_m:

$$\rho_{n+1}\tau_{n+1} = (1 - \chi_m\zeta)\rho_{n+1}\tau_n \quad \text{if } n = 2m, \tag{30}$$

$$\sigma_{n+1}\tau_{n+1} = \rho_{n+1}\tau_{n+1} - \psi_{n+1}(1 - \chi_m\zeta)\sigma_n\tau_n \quad \text{if } n = 2m. \tag{31}$$

When n is odd, one obtains instead by using (26b):

$$\rho_{n+1}\tau_{n+1} = (1 - \xi_m)\rho_{n+1}\tau_{n-1} + \xi_m\rho_{n+1}\tau_n + \eta_m\zeta\rho_{n+1}\tau_n \quad \text{if } n = 2m+1. \tag{32}$$

$$\begin{aligned} \sigma_{n+1}\tau_{n+1} &= \rho_{n+1}\tau_{n+1} - \psi_{n+1}\sigma_n\tau_{n+1} \\ &= \rho_{n+1}\tau_{n+1} - \psi_{n+1}[(1 - \xi_m)\sigma_n\tau_{n-1} + (\xi_m + \eta_m\zeta)\sigma_n\tau_n] \quad \text{if } n = 2m+1. \end{aligned} \tag{33}$$

[1]This is analagous to the fact that Newton's method will never find a complex zero of a real polynomial when started on the real axis.

Finally, multiplying (5b) by τ_n, we get for all n

$$\sigma_{n+1}\tau_n = \rho_{n+1}\tau_n - \psi_{n+1}\sigma_n\tau_n. \tag{34}$$

The relations (28)–(34) are a set of recurrence formulas for the products $\rho_n\tau_n$, $\rho_n\tau_{n-1}$, $\rho_n\tau_{n-2}$, $\sigma_n\tau_n$, and $\sigma_n\tau_{n-1}$. Hence, we must build up the vector sequences

$$\text{(35a)}\quad \tilde{r}_n := \rho_n(A)\tau_n(A)r_0, \quad \tilde{w}_n := \rho_n(A)\tau_{n-1}(A)r_0, \quad \approx{w}_n := \rho_n(A)\tau_{n-2}(A)r_0,$$
$$\text{(35b)}\quad \tilde{s}_n := \sigma_n(A)\tau_n(A)r_0, \quad \tilde{t}_n := \sigma_n(A)\tau_{n-1}(A)r_0.$$

The coefficients ω_n and ψ_{n+1} are found by adapting (24). Since (19) and (28) are identical, i.e., since $\tilde{w}_{n+1}$ is given by the same formula (25b) as in BiCGStab, (24a) and (24b) still hold. Because the leading coefficient of τ_n is now $(-1)^m\chi_0\eta_0\cdots\chi_{m-1}\eta_{m-1}$ if $n=2m$ and $(-1)^m\chi_0\eta_0\cdots\chi_{m-1}\eta_{m-1}\chi_m$ if $n=2m+1$, (24c) transforms into

$$\psi_{n+1} = -\frac{\delta_{n+1}}{\delta_n} = \begin{cases} -(\tilde{\delta}_{n+1}\omega_n)/(\tilde{\delta}_n\chi_m) & \text{if } n=2m, \\ +(\tilde{\delta}_{n+1}\omega_n)/(\tilde{\delta}_n\eta_m) & \text{if } n=2m+1. \end{cases} \tag{36}$$

Finally, we need to give formulas for the parameters χ_m, ξ_m, and η_m, which are determined by a one- and a two-dimensional minimization problem, respectively, cf. (26), (30), (32), and (35):

$$\text{(37a)}\quad \|\tilde{r}_{n+1}\| = \|\tilde{w}_{n+1} - A\tilde{w}_{n+1}\chi_m\| = \min \quad \text{if } n=2m,$$
$$\text{(37b)}\quad \|\tilde{r}_{n+1}\| = \|\,\approx{w}_{n+1} + (\tilde{w}_{n+1} - \approx{w}_{n+1})\xi_m + A\tilde{w}_{n+1}\eta_m\| = \min \quad \text{if } n=2m+1.$$

Of course, these minimization problems are again solved by orthogonal projection: as before in (23),

$$\chi_m := \frac{(A\tilde{w}_{n+1})^H\tilde{w}_{n+1}}{\|A\tilde{w}_{n+1}\|^2} \quad \text{if } n=2m. \tag{38}$$

For the projection onto the two-dimensional subspace spanned by $\tilde{w}_{n+1} - \approx{w}_{n+1}$ and $A\tilde{w}_{n+1}$, we define the two-column matrix

$$B_{m+1} := \left[\tilde{w}_{n+1} - \approx{w}_{n+1} \,|\, A\tilde{w}_{n+1}\right] \quad \text{if } n=2m+1, \tag{39a}$$

in terms of which the projection of $\approx{w}_{n+1}$ is given by $B_{m+1}(B_{m+1}^H B_{m+1})^{-1}B_{m+1}^H\,\approx{w}_{n+1}$. Hence, the optimal coefficients ξ_m and η_m for (37b) are

$$\begin{bmatrix}\xi_m \\ \eta_m\end{bmatrix} := -(B_{m+1}^H B_{m+1})^{-1}B_{m+1}^H\,\approx{w}_{n+1} \quad \text{if } n=2m+1. \tag{39b}$$

The 2×2 matrix $B_{m+1}^H B_{m+1}$ can be singular, namely, when the vectors $\tilde{w}_{n+1} - \approx{w}_{n+1}$ and $A\tilde{w}_{n+1}$ are linearly dependent. The solution (ξ_m, η_m) of the minimization problem (37b) is then not unique, and one might want to compute a particular one in a regularized fashion. However, since $\tilde{w}_{n+1} - \approx{w}_{n+1} \in \mathcal{K}_{2n+2}$, this can only happen if $A\tilde{w}_{n+1}$ is in the same space, which again means that we do no longer advance in the Krylov space. Here, assuming no previous breakdown, we can even conclude that $\mathcal{K}_{2n+3} = \mathcal{K}_{2n+2}$ since the polynomial $\zeta\rho_{n+1}(\zeta)\tau_n(\zeta)$ that corresponds to $A\tilde{w}_{n+1}$ has exact degree $2n+2$. In view of $\tilde{r}_{n+1} \in \mathcal{K}_{2n+2}$, we conclude as in the discussion at the end of §1 that $\tilde{\delta}_{n+1} = 0$ due to (15a). The same is true if the minimization problem (37b) has a unique solution, but the second component η_m happens to be zero.

Summarizing we obtain the following two-step algorithm BiCGStab2 for real nonsymmetric or complex linear systems.

Algorithm 2. (BiCGStab2) *For solving $Az = b$ choose an initial approximation $z_0 \in \mathbb{C}^N$ and set $\tilde{r}_0 := \tilde{s}_0 := b - Az_0$. Choose $y_0 \in \mathbb{C}^N$ such that $\delta_0 := y_0^H \tilde{r}_0 \neq 0$ and $\varphi_0 := y_0^H A\tilde{s}_0/\delta_0 \neq 0$. Then compute for $n = 0, 1, \ldots$*

```
(40a)  $\omega_n := 1/\varphi_n$,
(40b)  $\tilde{\tilde{w}}_{n+1} := \tilde{w}_n - A\tilde{t}_n\omega_n$   (if $n \geq 1$),
(40c)  $\tilde{w}_{n+1} := \tilde{r}_n - A\tilde{s}_n\omega_n$;
       if n is even, set $m := n/2$, compute $\chi_m$ by (38) and let
(40d)      $\tilde{r}_{n+1} := \tilde{w}_{n+1} - A\tilde{w}_{n+1}\chi_m$,
(40e)      $z_{n+1} := z_n + \tilde{s}_n\omega_n + \tilde{w}_{n+1}\chi_m$,
(40f)      $\tilde{\delta}_{n+1} := y_0^H\tilde{r}_{n+1}$,
(40g)      $\psi_{n+1} := -\omega_n\tilde{\delta}_{n+1}/(\tilde{\delta}_n\chi_m)$,
(40h)      $\tilde{s}_{n+1} := \tilde{r}_{n+1} - (\tilde{s}_n - A\tilde{s}_n\chi_m)\psi_{n+1}$,
       else set $m := (n-1)/2$, compute $\xi_m$ and $\eta_m$ by (39) and let
(40i)      $\tilde{r}_{n+1} := \tilde{\tilde{w}}_{n+1}(1-\xi_m) + \tilde{w}_{n+1}\xi_m + A\tilde{w}_{n+1}\eta_m$,
(40j)      $z_{n+1} := [z_{n-1} + \tilde{s}_{n-1}\omega_{n-1} + \tilde{t}_n\omega_n](1-\xi_m) + [z_n + \tilde{s}_n\omega_n]\xi_m - \tilde{w}_{n+1}\eta_m$,
(40k)      $\tilde{\delta}_{n+1} := y_0^H\tilde{r}_{n+1}$,
(40l)      $\psi_{n+1} := \omega_n\tilde{\delta}_{n+1}/(\tilde{\delta}_n\eta_m)$,
(40m)      $\tilde{s}_{n+1} := \tilde{r}_{n+1} - [\tilde{t}_n(1-\xi_m) + \tilde{s}_n\xi_m + A\tilde{s}_n\eta_m]\psi_{n+1}$
       endif;
(40n)  $\tilde{t}_{n+1} := \tilde{w}_{n+1} - \tilde{s}_n\psi_{n+1}$,
(40o)  $A\tilde{t}_{n+1} := A\tilde{w}_{n+1} - A\tilde{s}_n\psi_{n+1}$,
(40p)  $\varphi_{n+1} := y_0^H A\tilde{s}_{n+1}/\tilde{\delta}_{n+1}$.
```

If $\tilde{r}_{n+1} = o$, the process terminates and z_{n+1} is the solution of $Az = b$; if $\tilde{r}_{n+1} \neq o$ but $\tilde{\delta}_{n+1} = 0$ or $\varphi_{n+1} = 0$, the algorithm breaks down.

Like BiCGS and BiCGStab this algorithm requires two applications of A per step, i.e., one per degree of the residual polynomial, namely for $A\tilde{s}_n$ in (40c) and for $A\tilde{w}_{n+1}$ in (40d) or (40i). $A\tilde{t}_{n+1}$ is then obtained in (40o). In case of real data all the computation remains real. But even in the complex case BiCGStab2 is an improvement over BiCGStab since one performs a two-dimensional residual minimization in each other step. Of course, one could try to accomplish even higher dimensional minimizations in this framework, but clearly this would further complicate the algorithm and increase the memory requirement.

The methods BiCGStab and BiCGStab2 are examples of a class of methods that one might call *product methods* and which are characterized by residual polynomials that are the product of residual polynomials emerging from two different methods. Here, one factor is a Lanczos polynomial, while the other one comes from a one- or two-step minimal residual approach. Such product methods are truly *hybrid* methods, and deserve this name much more than many of the other approaches to which this notion has been applied. Note that the recursions of BiCGStab hold whenever the polynomials τ_n can be updated according to (16), and those of BiCGStab2 are valid whenever these polynomials satisfy (26). Only the definitions of the parameters χ_m, ξ_m, and η_m must be replaced.

For example, one might try a hybrid method that first applies another Krylov space method, say, GMRes, until it becomes too expensive; after computing a real factorization of the obtained residual polynomial τ_M of, say, degree M, one could from then on use this polynomial and its powers to create residuals of the form $r_{kM} = \rho_{(k-1)M}(A)\tau_M^k(A)r_0$ and intermediate ones where not yet all factors of τ_M appear with multiplicity k. The factored form of the GMRes residual τ_M yields recurrences (27) that can be reformulated to conform with (26). First experiments on this approach gave promising results, but not as good as those of BiCGStab2.

Moreover, if in generalization of (26) the polynomials τ_n satisfy a general three-term recursion that takes the condition $\tau_n(0) = 1$ into account, i.e., if

$$\tau_{n+1} := (1 - \xi_n)\tau_{n-1} + (\xi_n + \eta_n\zeta)\tau_n, \tag{41}$$

then the system of recurrences (28), (29), (32)–(34) is still valid if we replace χ_m, η_m by χ_n, η_n in (32)–(34). In the Krylov space these recurrences turn into (40c), (40b), (40i), (40m), and (40n), respectively, and they also yield (40j) and (40o). Consequently, (40a)–(40c) and (40i)–(40p) also yield a realization of a product method in which the Lanczos polynomials are combined with a sequence of polynomials τ_n satisfying a three-term recursion (41). For example, one could use shifted and scaled Chebyshev polynomials here to obtain a *Lanczos–Chebyshev method.*

It is known, see, e.g., [5], that the zeros of ρ_n and σ_n can be determined from the coefficients $\psi_1, \ldots, \psi_{n-1}$ and $\omega_0, \ldots, \omega_{n-1}$. In fact, if

$$L_n := \begin{bmatrix} \omega_0^{-1} & & & \\ -\omega_0^{-1} & \omega_1^{-1} & & \\ & \ddots & \ddots & \\ & & -\omega_{n-2}^{-1} & \omega_{n-1}^{-1} \end{bmatrix}, \quad R_n := \begin{bmatrix} 1 & \psi_1 & & \\ & 1 & \ddots & \\ & & \ddots & \psi_{n-1} \\ & & & 1 \end{bmatrix},$$

then the eigenvalues of the tridiagonal matrix L_nR_n are the zeros of ρ_n, and those of the $n \times n$ leading principal submatrix of the tridiagonal matrix $R_{n+1}L_{n+1}$ are the zeros of σ_n. The zeros of either of the two polynomials are often considered as approximations of eigenvalues of A. (This is, basically, the approach of the unsymmetric Lanczos algorithm for finding eigenvalues of A.) Experiments indicate, however, that the coefficients ψ_n and ω_n produced by BiCGS and BiCGStab are less accurate than those found by BiCG or by the Lanczos biorthogonalization algorithm (the "unsymmetric" Lanczos algorithm).

In BiCGStab2, the zeros $1/\zeta_j$ of the polynomials τ_n are, if $n = 2m$, the zeros of the quadratic factors

$$1 + (\eta_k - \chi_k\xi_k)\zeta - \eta_k\xi_k\zeta^2, \quad k = 0, \ldots, m-1. \tag{42}$$

These zeros can at best in a very vague way be considered as approximations to individual eigenvalues of A. Note in particular that they have no influence on the polynomials ρ_n and σ_n, and, a fortiori, on their zeros.

3. Numerical examples. First, we present several examples with non-Hermitian banded Toeplitz matrices of order $N = 200$. For these matrices, the behavior of the spectrum in the limit $N \to \infty$ is known [6], [13], but this is nearly irrelevant here. What counts for the convergence of iterative methods is the ε-pseudospectrum Λ_ε, which, when N is large and ε is small, is according to Reichel and Trefethen [9] approximately equal to the following union of three sets:

$$\Lambda_\varepsilon \equiv (\Lambda + \Delta_\varepsilon) \cup \Omega_r \cup \Omega^R. \tag{43}$$

Here, $\Lambda + \Delta_\varepsilon$ denotes the exact spectrum with disks of radius ε around each eigenvalue. To describe Ω_r and Ω^R, we need to look at the images $\phi(S_r)$ and $\phi(S_R)$ of the circles of radius r and R, respectively, under the mapping by the symbol ϕ of the Toeplitz matrix. Ω_r and Ω^R contain the points $\zeta \in \mathbb{C}$ with respect to which $\phi(S_r)$ and $\phi(S_R)$ have positive and negative, respectively, winding number. The radii $r < 1$ and $R > 1$ depend on ε and N according to $r := (\varepsilon/c)^{1/N}$ and $R := (\varepsilon/C)^{-1/N}$, where c and C are some constants, which for the plots in [9] have been set to 1. See Reichel and Trefethen [9] for details and for plots corresponding to some of our examples.

Banded Toeplitz matrices are of relevance in applications, since the discretization of partial differential equations often leads to such a matrix or a low-rank modification of one.

Example 1. Let us first consider the tridiagonal matrix

$$A := \begin{bmatrix} 4 & -2 & & \\ 1 & 4 & -2 & \\ & 1 & 4 & \ddots \\ & & \ddots & \ddots \end{bmatrix} \tag{44}$$

with the symbol $\phi(\zeta) = -2\zeta + 4 + \zeta^{-1}$. Its (unimportant) exact spectrum lies on the complex interval $[4 - 2i\sqrt{2}, 4 + 2i\sqrt{2}]$. The image $f(S_1)$, which is the boundary of the (continuous) spectrum of the associated Toeplitz operator with $N = \infty$ is an ellipse with foci $4 \pm 2i\sqrt{2}$, major semiaxis 3 and minor semiaxis 1. The ε-pseudospectrum is the interior of a slightly smaller ellipse with the same foci. Hence, Chebyshev iteration or second-order Richardson iteration, adapted to the family of ellipses with these foci, would have asymptotically optimal linear convergence. It is therefore no surprise that the generalized minimal residual method GMRES converges also approximately linearly.[2] As right-hand side b of the system $Az = b$ and for the initial vectors z_0 and y_0 we choose random vectors. (Of course, the same vectors are used for all the methods tested.)

In Fig. 1 we display the residual norm convergence of BIOMIN(= BICG), BIOMINSQ (= BICGS = CGS), BICGSTAB, the new algorithm BICGSTAB2, and a brute force implementation of GMRES(∞) (= GCR). The numbers on the x-axis give the iteration count, except for GMRES, where only every other iteration is counted. In GMRES each iteration requires just one application of A, in contrast to the other methods where multiplications both by A and A^H are needed; hence, it is fair to divide the numbers of iteration of GMRES by two, although, on the other hand, the long recurrences of GMRES(∞) become very expensive with respect to memory and arithmetic operations when n becomes large.

[2]The author is indebted to L. N. Trefethen for this interpretation of his numerical result.

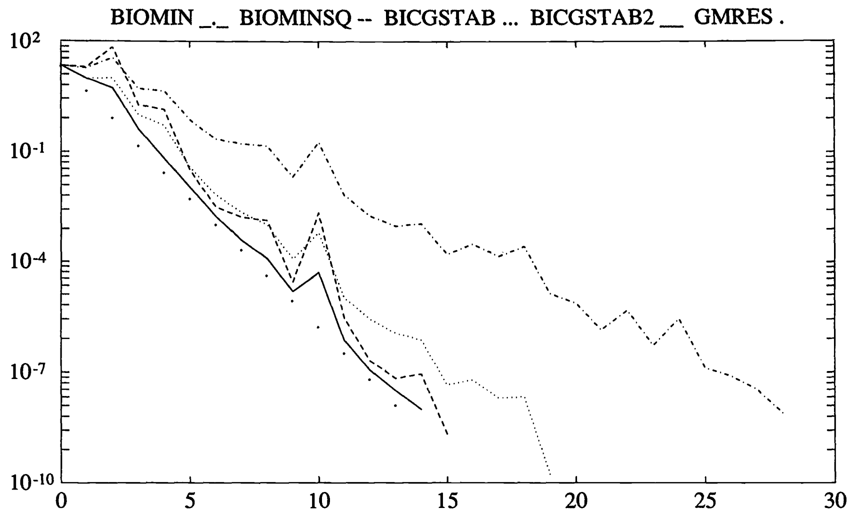

FIG. 1. *The residual norm history (i.e.,* $||r_n||/||r_0||$ *vs.* n*) for a linear system with the matrix* (44) *of order* 200, *solved by* BIOMIN = BICG *(dotted-dashed)*, BIOMINSQ = BICGS = CGS *(dashed)*, BICGSTAB *(dotted)*, BICGSTAB2 *(solid)*, *and* GMRES(∞) = GCR *(dotted). For* GMRES(∞) *only every other iteration is shown and counted, i.e.,* $||r_{2n}||/||r_0||$ *is plotted.*

In this example the convergence of all methods is rather fast, but it is interesting that the squared method BICGSTAB and BICGSTAB2 are considerably faster than BICG, and nearly as fast as GMRES(∞), which is optimal with respect to the measure of residual norm used in our figures. The same general behavior will be noted in our other examples. In this first example, where the matrix is real but the spectrum is complex, BICGSTAB2 is clearly better than the competing methods that require the same amount of work.

Example 2. As our second example we take

$$A := \begin{bmatrix} 2 & 1 & & & \\ 0 & 2 & 1 & & \\ 1 & 0 & 2 & 1 & \\ & 1 & 0 & 2 & \ddots \\ & & \ddots & \ddots & \ddots \end{bmatrix} \tag{45}$$

with the symbol $\phi(\zeta) = \zeta + 2 + \zeta^{-2}$. Its spectrum and pseudospectrum is three-fold rotationally symmetric with respect to its center at $\zeta = 2$; see Fig. 8 in [9] for a plot. This symmetry increases the chance of breakdown in the Lanczos process, and we noticed in fact many breakdowns in examples of this type. (Breakdowns also depend on the initial vectors z_0 and y_0, but since these are chosen real for this real matrix, they are not really in general position with respect to the eigenvectors.) In this particular example, BICGSTAB broke down in step 26.

Our results are shown in Fig. 2. The convergence is slower and rougher than in Example 1, but the relative performance of the various methods remains the same.

Example 3. While both previous examples are real matrices, we consider now the complex Toeplitz matrix

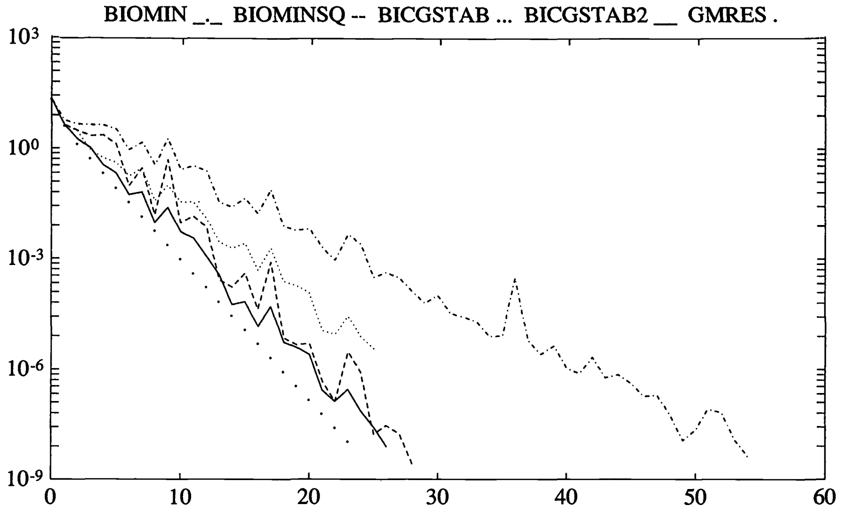

FIG. 2. *The residual norm history for a linear system with the real Toeplitz matrix* (45) *of order* 200. *The selection of methods and the labels of the axes are the same as in Fig.* 1.

$$A := \begin{bmatrix} 4 & 0 & 1 & .7 & & \\ 2i & 4 & 0 & 1 & .7 & \\ & 2i & 4 & 0 & 1 & \ddots \\ & & 2i & 4 & 0 & \ddots \\ & & & 2i & 4 & \ddots \\ & & & & \ddots & \ddots \end{bmatrix} \tag{46}$$

with the symbol $\phi(\zeta) = .7\zeta^3 + \zeta^2 + 4 + 2i\zeta^{-1}$. Its pseudospectrum plot is interpreted as "Picasso's head of a bull" by Reichel and Trefethen; see their Fig. 7 in [9]. Our results are shown in Fig. 3. Both our complex BiCGStab and the (also complex) BiCGStab2 do very well, but the difference in their behavior is now, not unexpectedly, much smaller. Again, one needs to point out that the dots for GMRes(∞) represent the optimal residual norm convergence, but that the computational and, in particular, the memory requirements for this method are considerably higher.

Example 4. We finally consider a "real world" example from the Harwell–Boeing collection of large sparse test matrices, namely OILGEN1, a matrix of order 2205 with 14'133 nonzeros, which comes from an oil reservoir simulation on a $21 \times 21 \times 5$ grid. Figure 4 shows the convergence history for BiCGStab and BiCGStab2, both applied *without* preconditioning. BiCG and BiCGS were also tried, but the former converges again only about half as fast (requiring more than 200 iterations to reduce the relative residual to 10^{-5}) and the latter has so many steep peaks in its residual convergence history that the curve would cover up most of what is now shown in Fig. 4. In this difficult example these methods are no longer able to produce a smooth convergence curve, but they do much better than BiCG and BiCGS.

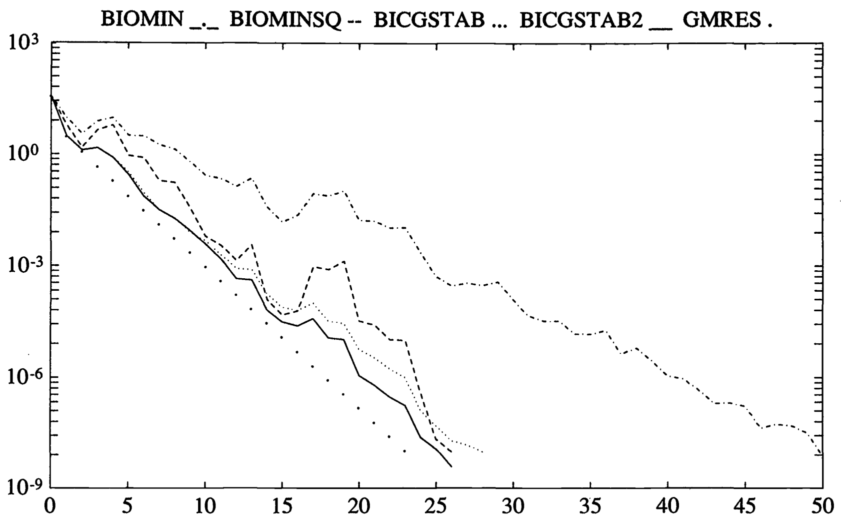

FIG. 3. *The residual norm history for a linear system with the complex Toeplitz matrix* (46) *of order* 200. *The selection of methods and the labels of the axes are the same as in Fig.* 1.

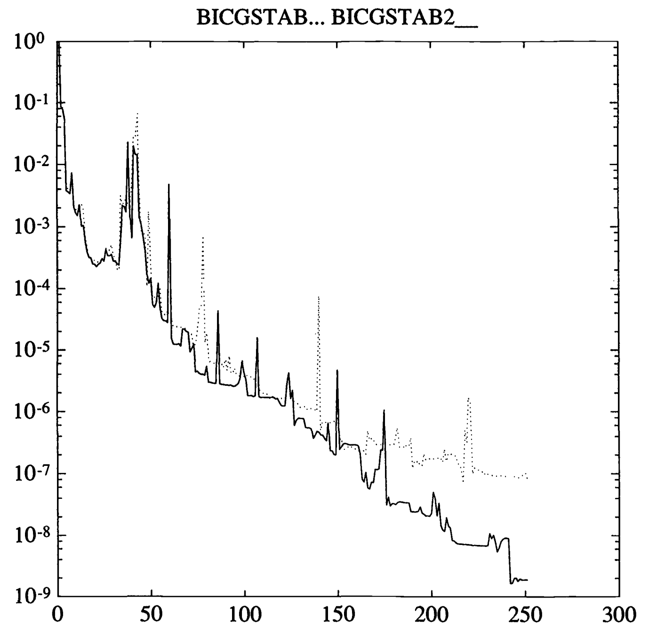

FIG. 4. *The residual norm history* (*i.e.*, $||r_n||/||r_0||$ *vs.* n) *for a linear system with the* OILGEN1 *matrix of the Harwell-Boeing collection, solved with* BiCGSTAB (*dotted*) *and* BiCGSTAB2 (*solid*).

Acknowledgment. The author would like to thank Noël Nachtigal for running Example 4 on a test installation of MATLAB 4.

Note added in proof. The algorithm BiCGSTAB2 introduced here should not be considered as a black box solver for sparse linear systems. As we have pointed out, there are situations where BiCGStab2 (as well as BiCG and BiCGStab) can break down or become unstable. A reliable program would have to be able to take appropriate measures in these situations. There are also cases where single steps of BiCGStab should be executed between some of the (double) steps of BiCGStab2; in the present version of the latter, the zeros of the intermediate steps are always dismissed, and this can be a disadvantage.

BLOCK SPARSE CHOLESKY ALGORITHMS ON ADVANCED UNIPROCESSOR COMPUTERS*

ESMOND G. NG† AND BARRY W. PEYTON†

Abstract. As with many other linear algebra algorithms, devising a portable implementation of sparse Cholesky factorization that performs well on the broad range of computer architectures currently available is a formidable challenge. Even after limiting the attention to machines with only one processor, as has been done in this paper, there are still several interesting issues to consider. For dense matrices, it is well known that block factorization algorithms are the best means of achieving this goal. This approach is taken for sparse factorization as well.

This paper has two primary goals. First, two sparse Cholesky factorization algorithms, the multifrontal method and a blocked left-looking sparse Cholesky method, are examined in a systematic and consistent fashion, both to illustrate the strengths of the blocking techniques in general and to obtain a fair evaluation of the two approaches. Second, the impact of various implementation techniques on time and storage efficiency is assessed, paying particularly close attention to the work-storage requirement of the two methods and their variants.

Key words. sparse linear systems, Cholesky factorization, supernodes, block algorithms, advanced computer architectures

AMS subject classifications. 65F, 65W

1. Introduction. Many scientific and engineering applications require the solution of large sparse symmetric positive definite systems of linear equations. *Direct* methods use Cholesky factorization followed by forward and backward triangular solutions to solve such systems. For any $n \times n$ symmetric positive definite matrix A, its Cholesky factor L is the lower triangular matrix with positive diagonal such that $A = LL^T$. When A is sparse, it will generally suffer some fill during the computation of L; that is, some of the zero elements in A will become nonzero elements in L. In order to reduce time and storage requirements, only the nonzero positions of L are stored and operated on during *sparse* Cholesky factorization. Techniques for accomplishing this task and for reducing fill have been studied extensively (see [12], [19] for details). In this paper we restrict our attention to the numerical factorization phase. We assume that the preprocessing steps, such as reordering to reduce fill and symbolic factorization to set up the compact data structure for L, have been performed. Details on the preprocessing can be found in [12], [19].

As with many other linear algebra algorithms, devising a portable implementation of sparse Cholesky factorization that performs well on the broad range of computer architectures currently available is a formidable challenge. Even after limiting our attention to machines with only one processor, as we have done herein, there are still several interesting issues to consider. In this paper we will investigate sparse Cholesky algorithms designed to run efficiently on vector supercomputers (e.g., the Cray Y-MP) and on powerful scientific workstations (e.g., the IBM RS/6000, the DEC 5000, and the Stardent P3000). To achieve high performance on such machines, the algorithms must be able to exploit vector processors and/or pipelined functional units. Moreover, with the dramatic increases in processor speed during the past few years, rapid memory access has become a very important factor in determining performance levels on several of these

machines. To be efficient, algorithms must reuse data in fast memory (e.g., cache) as much as possible. Consequently, a highly localized and regular memory-access pattern is ideal for many of today's fastest machines.

It is well known that block factorization algorithms are the best means of achieving this goal. Perhaps the best-known example of a software package based on this approach is LAPACK, a software package for performing dense linear algebra computations on advanced computer architectures including shared-memory multiprocessor systems [2]. Each block algorithm in LAPACK is built around some computationally intensive variant of a matrix-matrix (BLAS3) or matrix-vector (BLAS2) multiplication kernel subroutine, which can be optimized for each computing platform on which the package is run.

The sparse block Cholesky algorithms discussed in this paper take essentially the same approach; we do not, however, include multiprocessors nor do we tune the kernels for efficiency on specific machines. We investigate two algorithms:

1. The multifrontal method [15], [24], which is based on the right-looking formulation of the Cholesky factorization algorithm.
2. A left-looking block algorithm that has, until recently, received little attention in the literature [28].

Both methods will use the same kernel subroutines to do all the numerical work required during the factorization. The differences are limited to such issues as:

- indirect addressing and other integer operations related to the *structural* aspects of sparse factorization,
- the ability to reuse data in cache,
- the amount of data movement,
- the memory-access pattern, and
- the working storage requirement.

In general, variations in the efficiency of the block algorithms and their variants are not very large. However, our tests indicate significant differences in the amount of working storage and expensive data movement required.

This paper has two primary goals. First, we will look at the two block Cholesky factorization algorithms in a systematic and consistent fashion, both to illustrate the strengths of the blocking techniques in sparse matrix computations in general and to obtain a fair evaluation of the two basic approaches. Second, we will assess the value of various implementation techniques on time and storage efficiency, paying particularly close attention to the working storage requirement of the two methods and their variants.

Rothberg and Gupta [28] have studied these algorithms independently. They consider the caching issue in more detail and implement a more complicated and effective loop-unrolling scheme than we do. However, they do not compare the working storage requirements of the various algorithms as we do. We have introduced enhancements to the multifrontal algorithm that greatly reduce the amount of stack storage and data movement overhead required by that algorithm. Also, we consider the performance of these algorithms on a vector supercomputer and a high-performance workstation with vector hardware.

This paper is organized as follows. Section 2 contains notation and other background material needed to present the algorithms, including a discussion of previous work on block sparse Cholesky algorithms. Section 3 describes the left-looking block Cholesky algorithm and some of its key features. Presented in §4 are implementation details and enhancements for both the left-looking block algorithm and the multifrontal algorithm. Section 5 contains the results of our performance tests on several of the

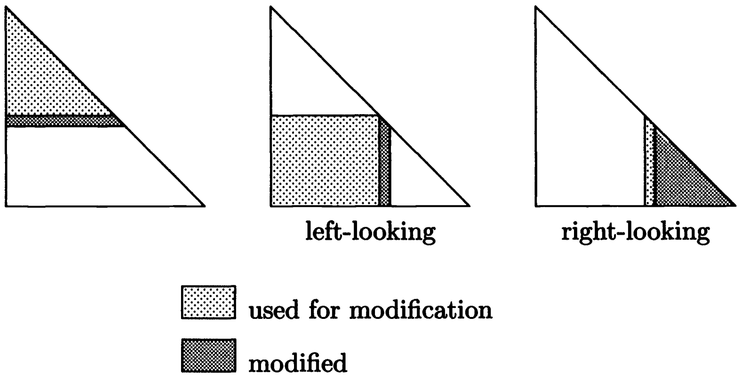

FIG. 1. *Three forms of Cholesky factorization.*

machines mentioned earlier in this section. Finally, concluding remarks and speculations on future work appear in §6.

2. Background material.

2.1. Column-based Cholesky factorization methods.

The bulk of the work in Cholesky factorization of a symmetric positive definite matrix A occurs in a triply nested loop around the single statement

$$A_{ij} = A_{ij} - (A_{ik}A_{kj})/A_{kk}.$$

By varying the order in which the loop indices i, j, and k are nested, we obtain three different formulations of Cholesky factorization, each with a different memory access pattern.

1. *Bordering Cholesky*. Taking i in the outer loop, successive rows of L are computed one by one, with the inner loops solving a triangular system for each new row in terms of the previously computed rows (see Fig. 1).
2. *Left-looking Cholesky*. Taking j in the outer loop, successive columns of L are computed one by one, with the inner loops computing a matrix-vector product that gives the effect of previously computed columns on the column currently being computed.
3. *Right-looking Cholesky*. Taking k in the outer loop, successive columns of L are computed one by one, with the inner loops applying the current column as a rank-1 update to the remaining partially reduced submatrix.

The various versions of Cholesky factorization can be used to take better advantage of particular architectural features of a given machine (cache, virtual memory, vectorization, etc.) [11]. For more details concerning these three versions of Cholesky factorization, consult George and Liu [19, pp. 18–21].

The bordering method requires a row-oriented data structure for storing the nonzeros of L. Liu [25] has devised a compact row-oriented data structure for this purpose, but currently the technique has not been successfully adapted to run efficiently on modern workstations and vector supercomputers. Consequently, our paper will focus on block versions of the left-looking and right-looking algorithms (also known as column-Cholesky and submatrix-Cholesky, respectively). Both the left-looking and right-looking algorithms naturally require a column-oriented data structure, which is easy to construct [31]. Thus, we restrict our attention to column-oriented implementations of the left-looking and right-looking algorithms.

We need the following definitions to write down the algorithms. Let M be an $n \times n$ matrix, and denote the jth column of M by $M_{*,j}$. The sparsity structure of column j in the *lower triangular* part of M is denoted by $Struct(M_{*,j})$. That is,

$$Struct(M_{*,j}) := \{s \geq j : M_{s,j} \neq 0\}.$$

Column-oriented Cholesky factorization algorithms can be expressed in terms of the following two subtasks:

1. $cmod(j, k)$: modification of column j by a multiple of column k, $k < j$,
2. $cdiv(j)$: division of column j by a scalar.

Of course, sparsity in columns j and k is exploited when A and L are sparse. Using these basic operations, Figs. 2 and 3 give high-level descriptions of the basic left-looking and right-looking sparse Cholesky factorization algorithms, respectively. (We will refer to these two algorithms as left-looking and right-looking `col-col`.)

```
for $j = 1$ to $n$ do
   for $k$ such that $L_{j,k} \neq 0$ do
      $cmod(j, k)$
   $cdiv(j)$
```

FIG. 2. *Left-looking sparse Cholesky factorization algorithm* (*left-looking* `col-col`).

```
for $k = 1$ to $n$ do
   $cdiv(k)$
   for $j$ such that $L_{j,k} \neq 0$ do
      $cmod(j, k)$
```

FIG. 3. *Right-looking sparse Cholesky factorization algorithm* (*right-looking* `col-col`).

Left-looking sparse Cholesky is the simpler of the two algorithms to implement, and it appears in several well-known commercially available sparse matrix packages [8], [16]. For implementation details, the reader should consult George and Liu [19]. Straightforward implementations of the right-looking approach are generally quite inefficient because matching the updating column k's sparsity pattern with that of each column j in the updated submatrix requires expensive searching through the row indices in $Struct(L_{*,k})$ and $Struct(L_{*,j})$, $j \in Struct(L_{*,k}) - \{k\}$. Consequently, we will not pursue such an implementation in this paper. However, Rothberg and Gupta [28] have recently reported that a block version of this approach is reasonably competitive, because for practical problems the blocking greatly reduces the amount of index matching needed. Note also that a straightforward implementation of the right-looking approach forms the basis for a distributed-memory parallel factorization algorithm known as the *fan-out method* [6], [18], [20]. In this paper we will study a left-looking block algorithm and also the *multifrontal* algorithm [15], [24], which can be viewed as an efficient implementation of right-looking sparse Cholesky factorization as we shall see in §2.3.

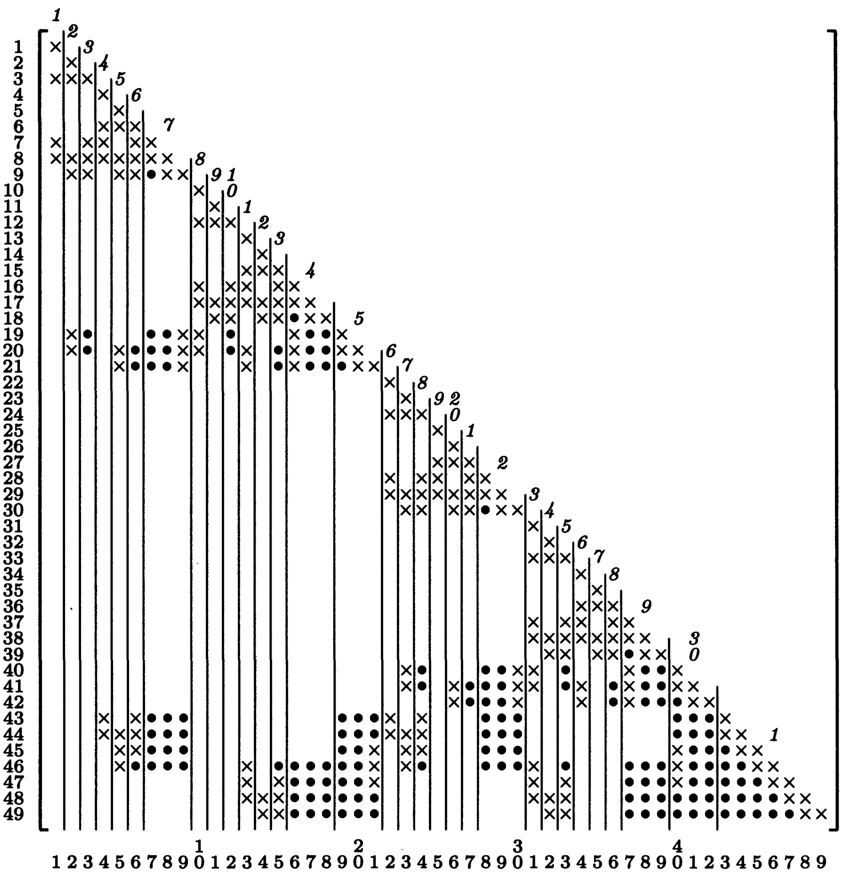

FIG. 4. *Supernodes for* 7 × 7 *nine-point grid problem ordered by nested dissection.* (× *and* • *refer to nonzeros in A and fill in L, respectively. Numbers over diagonal entries label supernodes.*)

2.2. Supernodes and elimination trees. Efficient implementations of both the multifrontal algorithm and left-looking block algorithms require that columns of the Cholesky factor L sharing the same sparsity structure be grouped together into *supernodes*. More formally, the set of contiguous columns[1] $j, j+1, \ldots, j+t$ constitutes a supernode if $Struct(L_{*,k}) = Struct(L_{*,k+1}) \cup \{k\}$ for $j \le k \le j+t-1$. Most commonly used in practice is the set of *fundamental supernodes* associated with the factor L. Each fundamental supernode satisfies the following additional requirement: It is a maximal supernode for which the first column is the only column of the supernode that can have more than one child in the elimination tree associated with L. (Elimination trees are defined in the next paragraph.) The fundamental supernodes for an example matrix is shown in Fig. 4.

Note that the columns of a supernode $\{j, j+1, \ldots, j+t\}$ have a dense diagonal block and have *identical* column structure below row $j+t$. Note also that columns in the same supernode can be treated as a unit for both computation and storage. (See, for example, [26] for further details.)

[1]It is convenient to denote a column $L_{*,j}$ belonging to a supernode by its column index j. It should be clear by context when j is being used in this manner.

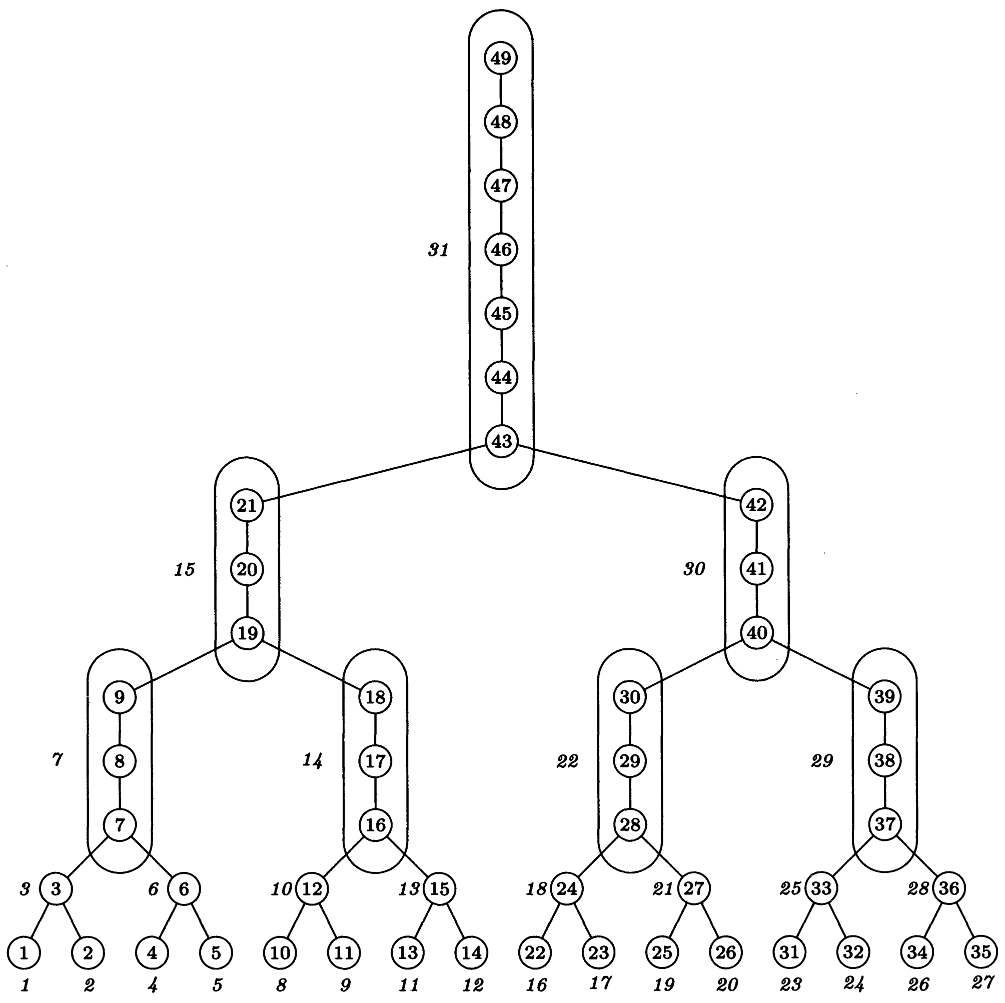

FIG. 5. *Elimination tree (and supernode elimination tree) for the matrix shown in Fig. 4. Ovals enclose supernodes that contain more than one node. Nodes not enclosed by an oval are singleton supernodes. Italicized numbers label supernodes.*

The multifrontal method makes explicit use of the elimination tree associated with L. For each column $L_{*,j}$ having off-diagonal nonzero elements, we define the *parent* of j to be the row index of the first off-diagonal nonzero in that column. For example, the parent of node 9 is node 19 for the matrix in Fig. 4. It is easy to see that the parents of the columns define a tree structure, which is called the *elimination tree* of L. Associated with any supernode partition is a *supernodal elimination tree*, which is obtained from the elimination tree essentially by collapsing the nodes (columns) in each supernode into a single node (block column). This can be done because the nodes in each supernode form a chain in the elimination tree. Fig. 5 (see above) displays the elimination tree for the matrix in Fig. 4. The supernodal elimination tree for the partition in Fig. 4 is also shown in Fig. 5, superimposed on the underlying elimination tree. Throughout this paper we use N to denote the number of supernodes in L.

2.3. Supernode-based Cholesky factorization algorithms: previous work. Figures 2 and 3 contain high-level descriptions of sparse Cholesky algorithms whose innermost loop updates a single column j with a multiple of a single column k. The next two subsections briefly describe two well-known sparse Cholesky algorithms that exploit the shared sparsity structure within supernodes to improve performance. The first is the left-looking `sup-col` algorithm, whose atomic operation is updating the target column j with every column in a supernode not containing j or with a subset of columns in the supernode containing j (in either case, a BLAS2 operation). The other is the more widely known multifrontal method.

2.3.1. Left-looking `sup-col` Cholesky factorization. The basic idea behind the left-looking `sup-col` Cholesky algorithm is very simple. Let $K = \{p, p+1, \ldots, p+q\}$ be a supernode[2] in L and consider the computation of $L_{*,j}$ for some $j > p+q$. It follows from the definition of supernodes that column $A_{*,j}$ will be modified by *no* columns of K or *every* column of K. Previous studies [7], [26], [27], [29] have demonstrated that this observation has important ramifications for the performance of left-looking sparse Cholesky factorization. Loosely speaking, when used to update the target column $L_{*,j}$, the columns in a supernode K can now be treated as a single unit (or *block column*) in the computation. Since the columns in a supernode share the same sparsity structure below the dense diagonal block, modification of a particular column $j > p+q$ by these columns can be accumulated in a work vector using *dense* vector operations, and then applied to the target column using a single *sparse* vector operation that employs indirect addressing. Moreover, the use of *loop unrolling* in the accumulation, as described in [10], reduces memory traffic.

In Fig. 6 we present the left-looking `sup-col` Cholesky factorization algorithm. The reader will find a more detailed implementation of the algorithm presented in [26]. In order to keep the notation simple, K is to be interpreted in one of two different senses,

```
for $J = \mathit{1}$ to $N$ do
    Scatter $J$'s relative indices into indmap.
    for $j \in J$ (in order) do
        for $K$ such that $L_{j,K} \neq 0$ do
            $t \leftarrow cmod(j, K)$
            Assemble $t$ into $L_{*,j}$ using indmap.
        $cmod(j, J)$
        $cdiv(j)$
```

FIG. 6. *Left-looking* `sup-col` *Cholesky factorization algorithm.*

depending on the context in which it appears. In one context (e.g., line 3 of Fig. 6), K is interpreted as the set of columns in the supernode, i.e., $K = \{p, p+1, \ldots, p+q\}$. In the first line of the algorithm, the supernodes are treated as an ordered set of loop indices $\mathit{1}, \mathit{2}, \ldots, K, \ldots, N$, where $K < J$ if and only if $p < p'$, where p and p' are the first columns of K and J, respectively. This dual-purpose notation is also illustrated in Fig. 4, where the supernode labels are written over the diagonal entries, yet we can still write $\mathit{30} = \{40, 41, 42\}$, for example. We denote both the last supernode and the number of supernodes by N.

[2]Throughout the remainder of the paper the numbers designating a supernode will be italicized, and the letters denoting a supernode will be capitalized.

Suppose $K = \{p, p+1, \ldots, p+q\}$. Whenever $j > p+q$ and $L_{j,p+q} \neq 0$, the task *cmod*(j, K) consists of the operations *cmod*(j, k), where $k = p, p+1, \ldots, p+q$. When $j \in K$, *cmod*(j, K) consists of the operations *cmod*(j, k), for $k = p, p+1, \ldots, j-1$. We let $L_{j,K}$ denote the 1 by $|K|$ submatrix in L induced by row j and the columns in K.

The indirect addressing scheme used by the algorithm is as follows. The indices in each list $Struct(L_{*,j})$ are sorted in ascending order during the preprocessing stage (i.e., symbolic factorization). For each row index $i \in Struct(L_{*,j})$, the corresponding *relative index* is the position ℓ of i relative to the bottom of the list. For example, $\ell = 0$ for the last index in the list, $\ell = 1$ for the next-to-the-last one, and so forth. For each supernode $J = \{p, p+1, \ldots, p+q\}$, define

$$Struct(L_{*,J}) = Struct(L_{*,p}).$$

The relative position ℓ of each row index $i \in Struct(L_{*,J})$ is stored in an n-vector *indmap* as follows: *indmap*$[i] \leftarrow \ell$. First the update *cmod*(j, K) is accumulated in a work vector t whose length is the number of nonzero entries in the update. That is, the update is computed and stored as a *dense* vector t. Then the algorithm assembles (scatter-adds) t into factor storage, using *indmap*$[i]$ to map each active row index $i \in Struct(L_{*,K})$ to the appropriate location in $L_{*,j}$ to which the corresponding component of t is added. The notion of relative indices apparently was first proposed by Schreiber [30].

2.3.2. Multifrontal Cholesky factorization. The multifrontal method, introduced by Duff and Reid in [15], is well documented in the literature. With much of its work performed within dense frontal matrices, this method has proven to be extremely effective on vector supercomputers [1], [3], [7], [9]. Moreover, the multifrontal method is naturally expressed and implemented as a block method, and several of the advantages it derives from block matrix operations have already been explored in the literature: e.g., its ability to reuse data in fast memory [1], [29] and its ability to perform well on machines with virtual memory and paging [23]. Implementation of the multifrontal method is more complicated and involves more subtleties than do any of the left-looking Cholesky variants. For the purposes of this paper, it is adequate to restrict our presentation to an informal outline of the method. For a detailed survey of the multifrontal method and the techniques required for an efficient implementation, the reader should consult Liu [24]. The following paragraphs discuss the informal statement of the algorithm, found in Fig. 7.

The outer loop of the supernodal multifrontal algorithm processes the supernodes $1, 2, \ldots, N$, where the supernodes have been renumbered by a postorder traversal of the supernodal elimination tree. After moving the required columns of $A_{*,J}$ into the leading columns of J's dense *frontal matrix* F_J, the algorithm pops from the *update matrix stack* an update matrix U_K for each child K of J in the supernodal elimination tree and assembles these accumulated update columns into F_J. (The postordering enables the use of a simple and efficient stack for the update matrices.) The update matrix U_K is a dense matrix containing *all* updates destined for ancestors of K from columns in the subtree of the supernodal elimination tree rooted at K. The assembly operation adds each entry of U_K to the corresponding entry of F_J. These are sparse operations requiring indirect indexing because an update matrix generally modifies a *proper subset* of the entries in the target frontal matrix. These are the only sparse operations required by the multifrontal method.

Now with all the necessary data accumulated in F_J, the next step in the main loop applies dense left-looking Cholesky factorization to the first $|J|$ columns in F_J (which we will call a *cdiv*(J) operation) to compute the block column $L_{*,J}$ and then accumulates

```
Initialize the update matrix stack.
for $J = 1$ to $N$ (in postorder) do
    Move $A_{*,J}$ into $F_J$.
    for each child $K$ of $J$ on top of the stack do
        Pop $U_K$ from stack.
        Assemble $U_K$ into $F_J$.
    Within $F_J$,
        compute the columns of $L_{*,J}$ ($cdiv(J)$),
        and compute all update columns from $L_{*,J}$
        (i.e., $cmod(k, J)$, where $k \in Struct(L_{*,J}) - J$).
    Move the new factor columns from $F_J$ to $L_{*,J}$.
    Move $U_J$ to the top of the stack.
```

FIG. 7. *Supernodal multifrontal Cholesky factorization algorithm.*

in the trailing columns of F_J all column updates $cmod(k, j)$, where $j \in J$ and $k \in Struct(L_{*,J}) - J$. At this point, the leading $|J|$ columns of F_J contain the columns of $L_{*,J}$, and the other columns have accumulated every update column for ancestors of J contributed by J and its descendants in the supernodal elimination tree. The algorithm then moves the newly computed columns to the appropriate location in the data structure for L, moves the update matrix U_J down onto the top of the stack, and proceeds with the next step of the major loop.

Three issues will occupy our attention when we take up the multifrontal algorithm again in §4. First, since all updates from the columns in $L_{*,J}$ are computed immediately after the new factor columns are computed, the multifrontal method provides the opportunity for optimal reuse of columns loaded in cache. Second, the costs of data movement overhead are potentially significant. We are referring here to the movement of matrix columns between each frontal matrix and L's data structure, and the movement of each update matrix from the location in working storage, where it was computed, to its storage-saving location at the top of the stack. This issue is of particular concern on machines with cache, where moving large amounts of data in this manner will cause expensive cache misses not incurred by the left-looking algorithms. Third, we will be concerned with the amount of storage required for the stack of update matrices, an issue that has received considerable attention in past studies [3], [22], [24].

3. Left-looking sup–sup Cholesky factorization. The idea behind the left-looking sup–sup Cholesky factorization algorithm is simple: The $cmod(j, K)$ operation is blocked one level higher, creating a supernode-to-supernode block-column updating operation $cmod(J, K)$ around which the new algorithm is constructed. The $cmod(J, K)$ operation performs $cmod(j, K)$ for every column $j \in J$ updated by the columns of K (a BLAS3 operation). The idea of constructing a sparse Cholesky algorithm around this operation is not new. Ashcraft and Peyton wrote a left-looking sup–sup sparse Cholesky factorization code, which was mentioned in [7], but was not presented there. The indexing scheme they used, however, was unnecessarily complex. Though efficient, it had the side effect of destroying the row indices of the nonzeros in L so that they had to be recomputed later for use during the triangular solution phase or any future factorizations of matrices with the same structure. For these reasons, they ultimately concluded that their implementation was unacceptable. Ashcraft recently sketched out a high-level version of the algorithm in a report on a different topic [4]. He has also created a single-parameter hybrid sparse Cholesky algorithm that performs a left-looking sup-sup factorization when the parameter takes on one extreme value and performs a supernodal multifrontal factorization when it takes on the opposite extreme value [5]. The left-looking sup-sup approach was proposed again by Ng and Peyton [26] as a promising candidate for parallelization on shared-memory multiprocessors. Parts of this work are steps toward completing the goals stated in the conclusion of that report. Recently and independently, Rothberg and Gupta examined the caching behavior of three block Cholesky factorization algorithms, including the multifrontal and left-looking sup-sup methods [28].

The following paragraphs discuss the left-looking sup-sup Cholesky factorization algorithm in Fig. 8 and its more basic implementation issues. One new item of notation is introduced; we let $L_{J,K}$ denote the $|J|$ by $|K|$ submatrix in L induced by the members of J and the members of K.

```
for $J = 1$ to $N$ do
    Scatter $J$'s relative indices into indmap.
    for $K$ such that $L_{J,K} \neq 0$ do
        Compute the number of columns of $J$ to be updated by the columns of $K$.
        $T \leftarrow cmod(J, K)$
        Gather $K$'s indices relative to $J$'s structure from indmap into relind.
        Using relind, assemble $T$ into $L_{*,J}$.
    $cdiv(J)$
```

FIG. 8. *Left-looking* sup-sup *Cholesky factorization algorithm.*

The bulk of the work is performed within the *cmod*(J, K) and *cdiv*(J) operations. The underlying matrix–matrix multiplication subroutine, which performs most of the work in the implementation, is used by the block multifrontal code as well, enabling a fair comparison of the two approaches. As in the left-looking sup-col approach, the update columns are accumulated in working storage. Naturally, far more working storage is required to accumulate the *cmod*(J, K) updates than is required to accumulate the *cmod*(j, K) updates, which consists of a single dense column no larger than the column of L with the most nonzero entries. This storage overhead will receive further attention in §§4 and 5.

Another distinction between the left-looking sup-col and sup-sup algorithms is that the sup-sup algorithm must compute the number of columns of J to be updated by the columns of K, which it does by searching for all row indices $i \in J \cap Struct(L_{*,K})$ in K's sorted index list.

The algorithm handles indirect addressing in much the same way that the sup-col algorithm in Fig. 6 does, with one key difference that generally improves its efficiency. (See §2.3.1 for other details about the indexing scheme.) The sup-sup algorithm gathers the indices of *K relative to J* from *indmap* into a temporary vector *relind*: Each active row index $i \in Struct(L_{*,K})$ is replaced by *indmap*$[i]$ in the integer vector *relind*. This single gather operation provides the indexing information for assembling the entire block update into factor storage (i.e., the storage that will contain $L_{*,J}$). The sup-col algorithm essentially has to repeat this gather operation each time it assembles a *cmod*(j, K) update ($j \in J$) into factor storage.

4. Implementation details and options. Section 5 reports performance statistics for implementations of the multifrontal and the left-looking `sup-sup` Cholesky factorization algorithms on several powerful uniprocessor computing systems. Our Fortran codes have not been tuned for performance on any *specific machine* except for our choice of the level of loop unrolling. To run efficiently on some of these machines, however, our implementations cannot afford to ignore other architectural considerations altogether. Unless they make effective use of data (i.e., columns of the matrix) once they have been loaded into cache, their performance will be severely penalized by an excessive number of cache misses. Thus, our implementations must be designed with this goal in mind. Our codes need to know the cache size on each machine to reuse cached data effectively (see §4.1). The cache size and the level of loop unrolling are the *only* machine-dependent parameters in our codes. Other implementation options and enhancements, which are entirely independent of the computer architecture, are also discussed in this section.

4.1. Reuse of data in cache. Consider the computation of a *cmod*(J, K) update during the left-looking `sup-sup` Cholesky factorization. Suppose the operation updates q columns of J with the columns of K. The number of columns updated may be as few as 1 or as many as $|J|$. We can compute *cmod*(J, K) as a sequence of `sup-col` updates *cmod*(j, K) for the q columns $j \in J$. If the columns of K, which happen to be stored contiguously in main memory, fit into cache memory, then the first *cmod*(j, K) loads the columns of K into cache, while the following $q - 1$ *cmods* will have extremely fast access to this data because it is already in cache.

Quite often, however, the columns of a supernode do not fit into the 32K or 64K caches used on current workstations. This can dramatically increase the number of cache misses associated with the final $q - 1$ *cmods*, as the columns of K overwrite one another as they are repeatedly read into cache. To avoid this problem, the algorithm partitions large supernodes into "panels" of contiguous columns that fit into the cache, as Rothberg and Gupta have done in their studies [27]–[29]. If K has been partitioned into two panels, then the *cmod*(J, K) update is performed by applying the *cmods* from the first panel to the q target columns of J, then applying the *cmods* from the second panel to the q target columns of J. We use essentially the same strategy to increase the reuse of data in cache by our multifrontal codes. This simple strategy has proven effective for the problems, machines, and factorization methods used in our tests. Extremely large problems, however, may require more complicated techniques that involve both horizontal and vertical partitioning and perhaps even sweeping changes in the data structure used to store L. The reader should consult Rothberg and Gupta [28] for a thorough discussion of these and many other issues associated with improving reuse of data in cache by both the multifrontal and the left-looking `sup-sup` sparse Cholesky algorithms.

4.2. Traversing row-structure sets. The left-looking `col-col` algorithm needs access to the row-structure sets $\mathcal{R}_j = \{k : L_{j,k} \neq 0\}$ (see Fig. 2). These row-structure sets must be computed from or traversed within the strictly column-oriented data structure used by the algorithm. By far the most commonly used method is to maintain the row-structure sets as linked lists within a single integer n-vector. Every column belongs to one and only one row-structure list at any given time during the course of the factorization. After a column update is completed, the column is placed in the list belonging to the next column it will modify. Details of this approach can be found in George and Liu [19, pp. 152–155] and in Ng and Peyton [26]. The same technique applies to the row-structure sets for the left-looking `sup-col` and `sup-sup` algorithms.

There is another way to determine the row-structure sets in the left-looking `col-col` algorithm, which relies on the fact that each row-structure set $\mathcal{R}_j$ is a pruned subtree of the elimination tree [21], [30]. Consequently, if the elimination tree is made available to the factorization algorithm, each member of $\mathcal{R}_j$ can be visited by performing a depth-first traversal of the appropriate pruned subtree. Implementation details can be found in Schreiber [30]. Again, the same technique applies to the row-structure sets for the left-looking `sup-col` and `sup-sup` algorithms. This approach is particularly attractive in a parallel implementation of the left-looking factorization algorithms for shared-memory multiprocessor systems since it eliminates the need for critical sections when manipulating the row-structure sets. We are currently pursuing this idea.

For the `sup-col` algorithm, our tests indicate that the total factorization time using the tree-traversal technique is slightly larger than that using the linked-list approach. However, for the `sup-sup` algorithm, the difference in total factorization time using the two approaches is negligible because the total time required to traverse the row-structure sets is extremely small in this algorithm for both techniques. Because overall factorization times differ by so little when the two approaches are compared, we have not included timing results for the more complicated of the two (the tree-traversal method) in §5. The important point to note is that either approach can be used in the `sup-sup` algorithm, and moreover, we believe that the tree-walking technique may ultimately be preferable in a parallel implementation for shared-memory multiprocessors [26].

4.3. Enhancements to the multifrontal method. The size of the stack of update matrices in the multifrontal method is a major issue associated with this method. A large stack obviously requires greater storage; perhaps not so obvious is that a large stack usually creates a great deal of overhead data movement that can erode efficiency. We have implemented two variants of the multifrontal algorithm. The first is a straightforward implementation of the algorithm in Fig. 7. One standard enhancement has been incorporated into both the basic and enhanced multifrontal code. Using a technique introduced by Liu [22], we have reordered the children of each parent in the supernodal elimination tree to minimize the storage requirement for the stack. This section describes the techniques incorporated solely into our enhanced version of the multifrontal method.

We are aware of multifrontal implementations [32] that compute the new factor columns $\boldsymbol{L}_{*,J}$ in factor storage rather than in $\boldsymbol{F}_J$ and then compute only the update matrix $\boldsymbol{U}_J$ within the frontal matrix $\boldsymbol{F}_J$. This simple change reduces the size of the frontal matrix and eliminates the need to move matrix columns back and forth between factor storage and the frontal matrix. We have implemented this technique and also further pursued the idea of reducing stack storage and limiting data movement by incorporating updates into factor storage as early as possible. More specifically, our enhanced version of the multifrontal method computes the update matrix $\boldsymbol{U}_J$ in working storage just as the basic version does. The enhanced version, however, incorporates some leading columns of $\boldsymbol{U}_J$ into factor storage, and thus stores on the stack only the trailing columns of $\boldsymbol{U}_J$ that were not incorporated into factor storage. It uses the following two techniques to implement this scheme in an efficient manner.

First, let P be the parent of J in the supernodal elimination tree. We say that J is *dense relative to P* if

$$Struct(\boldsymbol{L}_{*,P}) \subseteq Struct(\boldsymbol{L}_{*,J}).$$

If J is dense relative to P, then the update $cmod(P, J)$, which would normally fill the leading columns of $\boldsymbol{U}_J$, can be applied directly to $\boldsymbol{L}_{*,P}$, the columns of P in factor storage. This shrinks the size of the update matrix $\boldsymbol{U}_J$, and thus reduces data movement when $\boldsymbol{U}_J$ is ultimately moved to its final position at the top of the stack. Since this condition usually holds for the root supernode and one or more of its children, both of which usually have very large frontal matrices, this simple enhancement can save a lot of storage.

The second technique pushes this idea a bit further. Consider the update matrix $\boldsymbol{U}_J$ and again consider J's parent P. For the multifrontal method, the relative indices of each child with respect to its parent have been computed in advance. The relative indices used to assemble $\boldsymbol{U}_J$ into $\boldsymbol{F}_P$ can also be used to assemble the columns of $\boldsymbol{U}_J$ destined for $\boldsymbol{L}_{*,P}$ directly into factor storage. But there is no reason to limit this technique to the parent just because only the indices relative to P are available. If J happens to update its grandparent supernode P', then J's indices relative to P' can be obtained by gathering the appropriate indices of P (relative to P') into an integer work vector *relind*; they can then be used to assemble the appropriate columns of $\boldsymbol{U}_J$ into factor storage (i.e., $\boldsymbol{L}_{*,P'}$). If J happens to update its great-grandparent P'', then the process can be repeated with the old indices in *relind* (relative to P') used to gather some of the indices of P' (relative to P'') into *relind*, giving us the indices of J relative to P''.

The enhanced algorithm continues this process until it encounters either the last supernode requiring updates from the columns of J or an ancestor of J that is *not* updated by the columns of J. In consequence, factor storage for an ancestor supernode K of J is updated by the columns of J during this process if and only if factor storage for every ancestor on the path from J to K is similarly updated by the columns of J. When the first stopping criterion terminates the process, all columns of $\boldsymbol{U}_J$ have been incorporated into factor storage, and no columns of the update matrix $\boldsymbol{U}_J$ are placed on the stack. (One could think of it as stacking a null update matrix.) When the second stopping criterion terminates the process, the algorithm stacks a reduced update matrix, which includes only the trailing columns of $\boldsymbol{U}_J$ that have not been incorporated into factor storage. Thus, each assembly into factor storage reduces the amount of storage required for the reduced version of $\boldsymbol{U}_J$ and the amount of time required to move it to the top of the stack. The only overhead computation required, the sequence of integer gather operations, is negligible compared to the savings in data movement, and this technique is surprisingly effective at reducing the stack storage requirement, as we shall see in §5.

Last, one commonly used stack-reduction technique is the *in-place extension* of the update matrix for the child on top of the stack into the parent's new frontal matrix, which is initially set to zero. Liu [22] points out that this technique is used in the Harwell MA27 code, and Ashcraft [3] reports that overlapping the new frontal matrix with the topmost update matrix in this fashion saves a surprising 15%–27% in stack storage for his test problems. We have incorporated it into our enhanced multifrontal code.

4.4. Refinements for left-looking `sup-col` and `sup-sup` Cholesky factorization algorithms. Three refinements have been incorporated into our implementations of the left-looking `sup-col` and `sup-sup` Cholesky factorization algorithms, several of which concern the incorporation of update columns that are dense relative to the target column directly into factor storage. First, whenever K has only one column, the `sup-col` (`sup-sup`) code accumulates the column modification $cmod(j, K)$ ($cmod(J, K)$) directly into factor storage, avoiding use of the real work vector $\boldsymbol{t}$ ($\boldsymbol{T}$) altogether. This is extremely simple to implement, avoids some useless data movement, and is valuable for problems with many singleton supernodes. Second, all column modifications where the source and target columns come from the same supernode are performed as dense updates incorporated directly into factor storage using no indirect indexing. That is, they are performed as a dense update would be performed. Third, whenever the length of update columns from K matches the length of a target column(s) from J, it is also handled as a dense update. No indirect indexing is used, and the update is accumulated directly into factor storage.

Two minor refinements are incorporated into the left-looking `sup-sup` Cholesky algorithm only. Unlike the `sup-col` algorithm, the block algorithm explicitly computes and records relative indices as they are needed. By taking the difference between the first and the last of these indices and checking the difference against the length of the target, the algorithm is now capable of checking for *all remaining* dense updates, thereby avoiding some data movement and indirect addressing normally associated with these operations. Finally, note that the size of the block of working storage $\boldsymbol{T}$ needed by the algorithm is the size of the largest block update $cmod(J, K)$ generated by the algorithm that is *not dense* relative to its target factor columns. In practice, the children of the root supernode are usually dense relative to their parent and, moreover, the largest block update is often found among the block updates they generate for the root. Consequently, the practice of accumulating dense block updates directly into factor storage often reduces the amount of working storage needed for the algorithm.

5. Performance results. In this section we compare the performance of various sparse Cholesky factorization algorithms discussed in this paper, which include

- left-looking `col-col` Cholesky,
- left-looking `sup-col` Cholesky,
- left-looking `sup-sup` Cholesky,
- a basic multifrontal method, and
- an enhanced multifrontal method.

All algorithms were coded in Fortran, and all floating-point operations were performed in double precision, except on the Cray Y-MP. The code for left-looking `col-col` Cholesky was taken from SPARSPAK [8]. All codes were compiled with optimization turned on and were run on a vector supercomputer and a number of high-performance scientific workstations. It should be noted that identical code was run on each machine, except for the level of loop unrolling used in the block update routines.

The machines used in the experiments include

- an IBM RS/6000 model 530,
- a DEC 5000,
- a Stardent P3000, and
- one processor of a Cray Y-MP.

Each of the workstations has 64 kilobytes of cache memory. The cache on the IBM RS/6000 is four-way set-associative, while those on the DEC 5000 and Stardent P3000 are direct mapped. The cache line size on the IBM RS/6000 is 128 bytes, compared to 4 bytes on the DEC 5000 and Stardent P3000. The IBM RS/6000 and DEC 5000 have 16 megabytes of main memory, while the Stardent P3000 has 32 megabytes. Since we restricted our tests to problems that fit into the main memory, there was no paging and, hence, differences in memory size had no effect on performance. Both the DEC 5000 and Stardent P3000 use the same central processing unit (MIPS 3000), but they have different floating-point coprocessors. Moreover, the Stardent P3000 has special vector floating-point hardware that can be enabled or disabled during code compilation. The DEC 5000 and Stardent P3000 (with vectorization disabled) are similar in so many respects that we expect similar performance on these machines.

The vector supercomputer we used, the Cray Y-MP, has no memory hierarchy and has enough main memory for the largest of our test problems. It is also worth noting that this machine performs floating-point arithmetic far more efficiently than integer arithmetic, in contrast to the workstations where integer and floating-point performance is better balanced.

As we pointed out in previous sections, loop unrolling was employed in our implementation of the *cmod*(j, K) and *cmod*(J, K) block update operations. The optimal level of loop unrolling varies from machine to machine. In our experiments, we tried level-p loop unrolling, for $p = 1$, 2, 4, and 8. To limit the amount of data presented in our tables, we report data for only the level of loop unrolling that performed best on the specific machine under consideration. The best level was $p = 4$ for the DEC 5000 and Cray Y-MP, and $p = 8$ for the IBM RS/6000 and Stardent P3000.

Almost all the test problems were taken from the Harwell–Boeing Test Collection [13], which is widely used in testing and evaluating sparse matrix algorithms. The problems we selected and some of their characteristics are provided in Tables 1 and 2, respectively. To ensure that no paging occurs, only the small-to-medium-size problems were run on the workstations. All problems were run on the Cray Y-MP.

The tables presented in the following subsections contain the times required to run the factorization algorithms on several different machines. All execution times are in seconds. For machines that have cache memory, the notation `method(`s`)` is used, where `method` is either `sup-sup` or `mf` (multifrontal). When $s = 0$, supernodes are not subdivided into panels; when $s > 0$, large supernodes are subdivided into panels that fit into the s-kilobyte cache available on that machine. For example, on all the workstations $s = 64$ when the supernodes are subdivided. It is worth noting that all the test problems have many supernodes small enough to fit into cache, and both the multifrontal and left-looking `sup-sup` algorithms fully "reuse" the columns of such supernodes once they are loaded into cache, regardless of whether or not the larger supernodes have been subdivided to fit into cache.

5.1. IBM RS/6000. Table 3 contains the execution times (in seconds) required by the various factorization methods on an IBM RS/6000 model 530. We make the following observations from these results.

First, we see that `sup-col` consistently reduces factorization times by roughly a factor of 2 over `col-col`. Part of this large improvement is due to reductions in memory traffic and indirect addressing, which are, in turn, due respectively to the loop unrolling

and the dense matrix-vector multiplication used to implement the *cmod*(j, K) operation. However, the improvement of `sup-col` over `col-col` observed on this machine is considerably larger than that observed on the other workstations, which obtain the same reductions in memory traffic and indirect indexing. We believe that the large cache line size (128 bytes) on the IBM RS/6000 is responsible largely for this phenomenon. The memory-access pattern of the `col-col` algorithm is far more disordered and contains far fewer stride one vector reads and writes[3] than that of the `sup-col` algorithm. As a result, the `sup-col` algorithm is far more likely to use most or all of the floating-point numbers in a line as it is loaded into cache. Consequently, it often uses several (up to $16 = 128/8$) double precision numbers at the cost of a single cache miss.

[3]A stride one read or write accesses contiguous entries in a vector or array.

We see that `sup-sup(0)` usually improves performance over `sup-col` by 10%–15%. This improvement is partly due to further reductions in the cost of indirect indexing and the integer overhead associated with the row-structure lists. It is likely, however, that most of the improvement is due to reuse of data in the cache when the supernodes are small enough.

By partitioning supernodes whose columns overflow the cache into panels of contiguous columns that fit into cache and, moreover, by organizing the matrix–matrix multiplication operations to operate on these panels, data in cache is reused more effectively, and thus the amount of data moved to and from main memory is reduced. This leads to another 6%–10% improvement in factorization times for `sup-sup(64)` when it is used on the medium- and large-sized problems in the test set. Smaller increases are obtained for the small problems because most or all of their supernodes already fit into cache. This improvement is quite modest compared to that observed on the other workstations. We further explore this issue in the next subsection.

As expected, subdividing supernodes into panels that fit into cache improves the performance of both the basic and enhanced multifrontal methods in much the same manner that it improves the performance of the `sup-sup` algorithm. Enhanced `mf` performs significantly better than basic `mf`, probably because the former method typically requires much less data movement. Similarly, `sup-sup` performs slightly better than enhanced `mf`, probably because the former requires more data movement than the latter, despite the enhancements. Where applicable, these observations hold true on the other machines as well.

One of the most widely used implementations of the multifrontal method is the MA27 routine in the Harwell library [14]. To verify that our implementations of this method are adequate for fair comparisons, we have compared their performance with that of the MA27 routine in Table 4. Since loop unrolling and techniques for exploiting cache memory have not been incorporated into MA27, the fairest comparison is between the first two columns of the table. The second column contains the times required by basic `mf` with no loop unrolling and with no subdivision of the supernodes to improve cache usage. While this code outperforms MA27, the comparison is not really fair because of the additional cost of MA27's extremely flexible method for inputting the matrix entries. In any case, it is clear that our code is quite competitive. The last column demonstrates the value of the enhancements incorporated into our best implementation of the multifrontal method.

5.2. DEC 5000. Table 5 contains factorization times for the various factorization methods on a DEC 5000. In contrast to the IBM RS/6000, the reduction in factorization time of sup-col over col-col is only 30%–38%. (All percentages used in comparisons are relative to the smaller of the two times.) Due to the 4-byte cache line size on the DEC 5000, the contrasting memory access patterns of the col-col and sup-col algorithms do not incur, respectively, nearly as severe a penalty or nearly as great a performance boost as those noted earlier on the IBM workstation.

However, the improvement of the sup-sup algorithm over the sup-col algorithm is much more substantial on this machine. Mainly due to the 4-byte cache line and the larger penalty associated with each cache miss (two misses per floating-point number), the sup-sup algorithm generally obtains very significant performance improvements over the sup-col algorithm, whose capacity to reuse data in cache is quite limited for the larger test problems. The sup-sup(0) algorithm improves performance over the sup-col algorithm by 13%–30% for the larger problems and 31%–48% for the smaller problems. The sup-sup(64) algorithm improves performance over the sup-sup(0) algorithm by 40%–59% for the larger problems and 0%–22% for the smaller problems. The cumulative improvement is 70%–85% for the larger problems and 4%–48% for the smaller problems. A more detailed look at the the effect of cache size and organization on the performance of both the sup-sup and multifrontal algorithms can be found in Rothberg and Gupta [28].

5.3. Stardent P3000 (without vectorization). As mentioned earlier in this section, the Stardent P3000 and DEC 5000 have identical central processing units but different floating-point coprocessors. Thus, when vectorization is not used on the Stardent P3000, we expect performance to be quite similar on these two machines. The results in Tables 5 and 6 indicate that this is indeed the case, with one exception. For reasons we don't understand, loop unrolling is considerably less effective on this machine than it is on the DEC 5000. With the exception of the col-col to sup-col comparison, the various methods compare with each other very much as they did on the DEC 5000.

5.4. Stardent P3000 (with vectorization). The Stardent P3000 has floating-point vector hardware, which can be enabled or disabled when the code is compiled. Table 7 contains factorization times for the various factorization methods with *vectorization turned on*. An important observation is that subdividing the supernodes into panels that fit into the 64K cache has virtually no effect on performance. To avoid the

complication of resolving cache misses during a vector operation, the vector hardware bypasses the cache altogether, and instead reads data directly from main memory in a pipelined fashion. This explains why paneling the supernodes is entirely ineffective in the sup-sup and the two multifrontal algorithms. It is worth noting, however, that reduced integer overhead and reduced indirect indexing in the sup-sup and multifrontal algorithms enable them to run faster than the sup-col algorithm. For instance, the sup-sup algorithm runs 5%–10% faster than the sup-col algorithm (excluding the two smallest problems from consideration). Evidently, our implementation of the dense matrix update kernels performs well on the Stardent P3000's vector hardware. For example, sup-sup is about 3.8–4.5 times faster than col-col (again, excluding the two smallest problems from consideration).

5.5. Cray Y-MP. Unlike the workstations considered in previous subsections, the Cray Y-MP has no cache memory. Its floating-point hardware is extremely fast due to vector pipelining. We have run the codes on a Cray Y-MP, and the results are provided in Table 8. As observed in [7] and [26], sup-col generally outperforms col-col by roughly a factor of 2. The use of loop unrolling, dense matrix-vector multiplication kernels, and the consequent large reductions in indirect addressing are responsible for these gains in performance. For medium to large problems, sup-sup outperforms sup-col by 6%-21%. (The performance gains are larger for the smaller problems.) The improvement is due to reductions in the cost of the indirect indexing and other integer processing overhead. The differences in performance among sup-sup, basic mf, and enhanced mf are very small.

5.6. Working storage requirements. The preceding subsections compare the *time* efficiency of the sparse Cholesky factorization algorithms under study on various high-performance uniprocessor computers. This subsection compares the *storage* efficiency of the various Cholesky factorization algorithms. More specifically, we computed the amount of auxiliary *floating-point* storage locations required by each method for accumulating column updates. Note that this ignores the floating-point storage required for the nonzero entries of L, which is the same for each method. It also ignores the amount of *integer* working storage required, since it is the sum of a small number of quantities $\leq n$, where n is the order of A, and, hence, does not vary much from one method to the next.

The `col-col` and `sup-col` algorithms have the lowest auxiliary working storage requirement because the columns are computed one at a time. For `col-col`, a floating-point work array of length n is needed to accumulate the updates. For the `sup-col` algorithm, the size of the floating-point work array is the maximum, over all columns $L_{*,j}$, of the number of nonzero entries in $L_{*,j}$. (Recall that an extra integer n-vector *indmap* is required to implement the indirect indexing scheme.)

The `sup-sup` and `mf` algorithms require more floating-point working storage. The two versions of the multifrontal method need auxiliary floating-point storage for stacking the update matrices. The `sup-sup` algorithm needs auxiliary floating-point storage to accumulate individual block updates $cmod(J, K)$. Thus, we are particularly interested in the storage requirements for `sup-sup` and `mf`.

Table 9 reports the floating-point working storage requirements for each method, normalized as a *percentage* of the number of nonzeros in L. As expected, the `sup-col` and `col-col` methods do indeed require the smallest amount of floating-point working storage. Without the enhancements to reduce the stack usage, the basic multifrontal method requires by far the most working storage. For two problems, the size of the stack is roughly 60% of the "size" of L. The enhanced multifrontal algorithm required far less floating-point working storage than the basic multifrontal algorithm requires, but still considerably more than the `sup-sup` algorithm requires.

6. Concluding remarks. We have studied three different left-looking sparse Cholesky factorization algorithms: the `col-col`, `sup-col`, and `sup-sup` algorithms. The use

of supernode-to-column updates in the `sup-col` algorithm (instead of the column-to-column updates in the `col-col` algorithm) reduces the amount of memory traffic and indirect addressing overhead. Our tests have shown the effectiveness of this well known technique on a wide range of high-performance uniprocessor computers. The use of supernode-to-supernode updates in the `sup-sup` algorithm further reduces the amount of memory traffic on machines with high-speed local memory, such as a cache. For our test problems, the `sup-sup` algorithm obtains virtually the same performance improvements via reuse of cached data that the multifrontal method obtains. Similar test results have appeared in Rothberg and Gupta [28]. On machines without a cache, the `sup-sup` algorithm obtains modest improvements over the `sup-col` algorithm by further reducing the integer overhead and indirect indexing costs.

Although the performance of the various left-looking factorization algorithms is machine dependent, it is interesting to note that for three high-performance workstations (the IBM RS/6000, the DEC 5000, and the Stardent P3000 without vectorization), the `sup-sup` algorithm with subdivided supernodes is the most efficient algorithm and often runs 2.5 times faster than the `col-col` algorithm. On the Stardent P3000 with vectorization, the `sup-sup` algorithm is roughly 4–4.5 times faster than the `col-col` algorithm.

For the test problems and workstations considered in this paper, the enhanced multifrontal algorithm is slightly slower than the `sup-sup` algorithm (by roughly 5%–10%). The results also indicate that the enhancements we have made to the multifrontal method greatly reduce the amount of auxiliary storage required for the stack and the amount of data movement required to stack the update matrices. The working storage requirement in `sup-sup`, however, remains smaller than that in the enhanced multifrontal method.

One of the goals in this study is to identify the "best" sequential sparse Cholesky factorization algorithm. This algorithm will be used to evaluate the performance of various parallel sparse Cholesky factorization methods. Based on our results, we conclude that the left-looking `sup-sup` algorithm is the most efficient algorithm, both in terms of its execution time and working storage requirement. Parallel versions of left-looking `col-col` and `sup-col` algorithms have appeared in [17] and [26], respectively. Parallel implementation of the left-looking `sup-sup` algorithm is currently under investigation, and performance results will be reported elsewhere.

It should be noted that the basic multifrontal method has at least two advantages over the left-looking methods. First, the multifrontal algorithm has long been recognized as the better candidate for out-of-core implementation: Only the stack of update matrices and the current frontal matrix are needed in main memory. Second, its superior data locality is of great value when solving very large problems on machines with virtual memory and paging [23]. The impact of paging on performance is not considered in this paper because our main concern is the working storage requirement and the use of blocking to exploit the first level in the memory hierarchy (i.e., fast memory or cache). The paging issue, however, will be investigated elsewhere.

A MONOTONE PETROV–GALERKIN METHOD FOR QUASILINEAR PARABOLIC DIFFERENTIAL EQUATIONS*

ØISTEIN BØE[†]

Abstract. To stabilize convection-dominated flows, artificial diffusion is often introduced by upstream weighting. A fundamental question is therefore: What amount of artificial diffusion should be introduced to avoid numerical oscillations? Obviously, that amount needs to be minimized, since artificial diffusion causes smearing of sharp fronts and less spatial accuracy. This paper analyzes the Petrov–Galerkin method with linear basis functions and quadratic, asymmetric test functions. The author uses the ideas of monotonicity to control the artificial diffusion introduced so that the numerical schemes are a priori monotone, i.e., numerical oscillations will not form if the discrete equations are solved exactly.

Key words. Petrov–Galerkin method, monotonicity, monotonic matrices, M-matrices

AMS subject classifications. 65M60, 65M12, 76S06, 35K55

1. Introduction.

In this paper we study numerical solutions of the parabolic equation

$$\frac{\partial S}{\partial t} + \frac{\partial f}{\partial x} = 0, \qquad x \times t \in \Omega = (0,1) \times (0,\infty), \tag{1.1}$$

$$f(S) = A(S) + H(S) + D(S)\frac{\partial S}{\partial x}. \tag{1.2}$$

The convective flux consists of two parts, $A(S)$ and $H(S)$. $A(S)$ is a strictly increasing S-shaped function with $A(0) = 0$. $H(S)$ is a bell-shaped positive function of S with $H(0) = 0$ and $H(1) = 0$. The diffusive coefficient $D(S)$ is a negative function of S with possible zeros for $S = 0$ and $S = 1$.

We shall first state a monotonicity property for (1.1). Let $\Gamma = ([0,1] \times 0) \cup (0 \times [0,\infty)) \cup (1 \times [0,\infty))$ be the boundary of Ω. Then let S and S^* be two solutions of (1.1) in $\Omega \cup \Gamma$. Then the following continuous monotonicity property holds [22], [10]:

$$\text{If } S - S^* \geq 0 \text{ on } \Gamma \text{ then } S - S^* \geq 0 \text{ in } \Omega.$$

Equation (1.1), together with appropriate initial and boundary conditions, may model immiscible two-phase incompressible porous medium flow (such as oil and water) in a one-dimensional reservoir or core. S is then the water saturation. $A(S)$ represents the part of convection proportional to the total Darcy velocity u, while $H(S)$ represents the part proportional to the gravitational acceleration. $D(S)\partial S/\partial x$ represents diffusion caused by capillary pressure (difference in phase pressures) [20]. In industrial mathematics it is important to have structurally stable numerical methods at hand. The computer programs are used over and over for different sets of parameters. In this nonlinear application, numerical oscillations may force us to evaluate the flux function f for unphysical values of S. This may create unstable behavior, especially near the boundaries [4]. Consequently, monotonicity is an important property. In this paper, we will construct a Petrov–Galerkin method that has proved to give nonoscillatory numerical solutions. The method is capable of handling both Neumann and Dirichlet boundary conditions and variable mesh spacing.

*Received by the editors September 18, 1991; accepted for publication (in revised form) September 9, 1992.

[†]Norsk Hydro A/S, Research Centre, N-5020 Bergen, Norway.

Time t is discretized into time levels $t_n = t_{n-1} + s_n, n = 1, 2, \ldots$ with $t_0 = 0$. Without loss of generality for the analysis to come, we set $s_n = s$ for all n. The space interval $x \in [0, 1]$ is partitioned into N intervals defined by $N + 1$ points, $x_i = x_{i-1} + h_{i-1}, i = 1, 2, \ldots, N$ with $x_0 = 0$ and $x_N = 1$. Suppose some numerical scheme results in a discrete solution vector S_h^n at time level n. The components of S_h^n are $\{S_i^n\}, i = 0, 1, \ldots, N$, where each S_i^n represents the solution at the point given by the coordinate x_i. Moreover, let $S_h^n = F(S_h^{n-1})$ denote a two-level in-time explicit scheme, and let $G(S_h^n) = S_h^{n-1}$ denote a two-level in-time implicit scheme. F and G are vector functions having the same dimension as the vector S_h^n. It will be crucial for monotonicity properties of a numerical scheme that the discretization of the second-order term is based on the use of the following potential [1]:

$$\Psi(S) = \int_{S_r}^{S} D(S^*)dS^*, \tag{1.3}$$

where S_r is some reference value. $\Psi(S)$ will be referred to as the PSI potential.

We have $\partial\Psi/\partial x = D(S)\partial S/\partial x$ by the chain rule. $\Psi(S)$ is a decreasing function of S and might be tabulated by using the numerical integration of (1.3). Typical shapes of the nonlinear functions A, H, D, and Ψ are shown in Fig. 1.

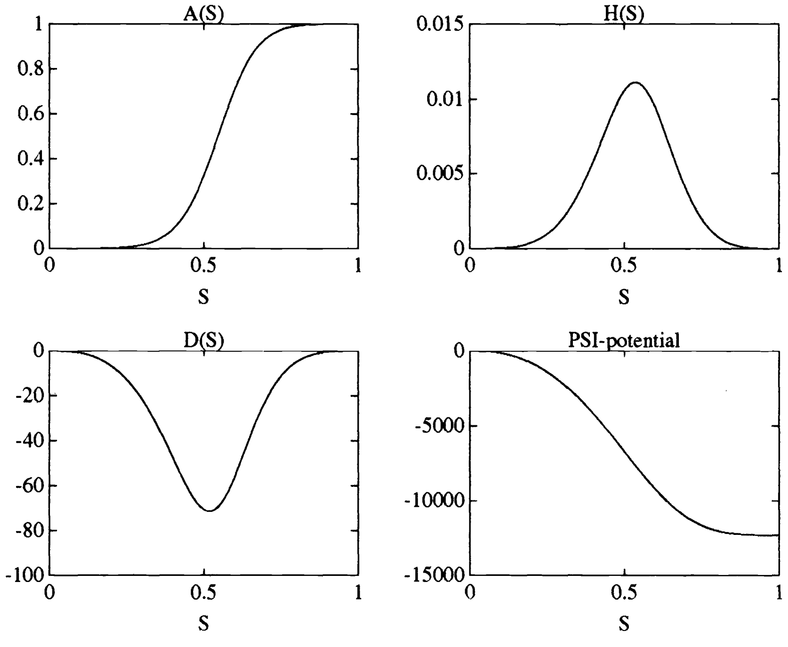

FIG. 1. *Nonlinear coefficients.*

Methods for avoiding or reducing numerical oscillations have been the theme of many papers. Much of this research has been concerned with hyperbolic conservation laws. Harten [12] introduced the concept of the TVD (total variation diminishing) property as a discrete version of the nonincreasing variation property of the solution of the continuous problem. The TVD property forces a condition on the coefficients of the numerical scheme. These "coefficients" are generally functions of both the discrete solution and its derivative. Many authors have used flux limiters as a tool for deriving TVD schemes. Such schemes represent a modification of a first-order scheme in the sense that they add a limited amount of antidiffusive flux in order to satisfy the TVD property. Sweby [25] compared various limiters both analytically and numerically. For hyperbolic conservation laws with variable mesh spacing, Sanders [24] showed convergence in L_1 for both implicit and explicit monotone difference schemes.

In this paper, we will formulate a discrete version of the continuous monotonicity property by using the concepts of M-matrices and monotone matrices. These concepts will be useful for analyzing the monotonicity properties of a numerical scheme. This analysis is based on examining the Jacobian matrix for the discrete system of difference equations. Consequently, a discrete equation centered at a certain node will be represented by a row in the Jacobian. The first and last rows will correspond to the discrete equation at the boundaries. Therefore the effect of boundary conditions is taken into account. The Petrov–Galerkin method will be constructed using these concepts.

The Petrov–Galerkin method is used for damping the numerical oscillations in the Galerkin method by adding numerical diffusion. Numerical oscillations may still form, although they appear to be more damped than for the Galerkin method. Petrov–Galerkin methods for diffusion-convection problems have been studied by several authors. It is well known that the use of linear basis functions and quadratic test functions will add numerical diffusion to the Galerkin method [19]. Barrett and Morton [2] introduced so-called optimal test functions in order to achieve an approximate symmetrization of the bilinear form arising from the variational formulation. Let H^1 be the Sobolev space where the functions and their first-order partial derivatives are square integrable. Let $B_m(\cdot,\cdot)$ be a symmetric coercive bilinear form on $H^1 \times H^1$. From the Riesz representation theorem there exists a representer $R_m : H^1 \times H^1$ such that $B(v,w) = B_m(v, R_m w)$ for all $v, w \in H^1$. The idea is to construct a test space T_h from the space of basis functions N_h such that $\text{span}(R_m T_i) = \text{span}(N_i)$ for each function i. This symmetrization (or approximate symmetrization in practice) will ensure that the optimal approximation property of the Galerkin method also holds (or "nearly" holds) for the Petrov–Galerkin method. Barrett and Morton applied their theory to constant and variable coefficient problems. The ideas of Barrett and Morton were adopted by Demkowicz and Oden [8] who presented a method for localizing the optimal test functions and obtained superconvergence results. Dahle, Espedal, and Ewing [7] used this formalism to obtain a Petrov–Galerkin method for (1.1)–(1.2) with Dirichlet boundary conditions.

The outline of this paper is as follows. In §2 we define monotonicity for implicit and explicit numerical schemes. Then we derive sufficient conditions for monotonicity by using the theory of M-matrices and monotone matrices. In §3 it is shown that monotonicity is not guaranteed for finite-element methods unless the mass matrix is lumped. Section 4 is concerned with the construction of the a priori monotone Petrov–Galerkin method. In §5 we present some numerical examples. Finally, we give some closing remarks in §6.

2. Monotonicity for implicit and explicit numerical schemes. We want to construct numerical schemes that possess a monotonicity property. The following definitions of monotonicity for numerical schemes approximating (1.1) seem natural in view of the "continuous" monotonicity property; see [1].

DEFINITION 1. An explicit numerical scheme $S_h^n = F(S_h^{n-1})$ is said to be monotone with respect to time if $S_h - S_h^* \geq 0$ implies $F(S_h) - F(S_h^*) \geq 0$.

DEFINITION 2. An implicit numerical scheme $G(S_h^n) = S_h^{n-1}$ is said to be monotone with respect to time if $G(S_h) - G(S_h^*) \geq 0$ implies $S_h - S_h^* \geq 0$.

In these two definitions the inequalities hold for all elements of the vectors. The essence of the two definitions above is as follows. Assume that we want to advance the solution from time level $n-1$ to n and assume $S_h^{n-1} - S_h^{n-2} \geq 0$. For the explicit schemes we have $S_h^n - S_h^{n-1} = F(S_h^{n-1}) - F(S_h^{n-2})$. Therefore, if $S_h^{n-1} - S_h^{n-2} \geq 0$, we would like to have $F(S_h^{n-1}) - F(S_h^{n-2}) \geq 0$ so that $S_h^n - S_h^{n-1} \geq 0$. For the implicit schemes we have $S_h^{n-1} - S_h^{n-2} = G(S_h^n) - G(S_h^{n-1})$. For the solution to be monotone in time, $G(S_h^n) - G(S_h^{n-1}) \geq 0$ must imply $S_h^n - S_h^{n-1} \geq 0$.

The above conditions for monotonicity in time could be analyzed by the concepts of monotonic matrices and M-matrices. For these concepts we refer to [3], [6], and [21]. Let A be a regular quadratic matrix with elements $\{a_{ij}\}$ of dimension $N+1$, and let y be a column vector of dimension $N+1$. If all the elements of A are nonnegative, we say that A is nonnegative and write $A \geq 0$, and if all components of the vector y are nonnegative, we write $y \geq 0$.

DEFINITION 3. The matrix A is monotone if $y \geq 0 \Rightarrow Ay \geq 0$. The implication is equivalent to $A \geq 0$.

DEFINITION 4. A matrix A is of monotone type if the implication $Ay \geq 0 \Rightarrow y \geq 0$ holds. The implication is equivalent to $A^{-1} \geq 0$.

DEFINITION 5. A matrix A is an L-matrix if the splitting $A = B - C$, where $B = \operatorname{diag}(b_i)$ is the diagonal matrix $b_i = a_{ii}$, has the property $B \geq 0$ and $C \geq 0$.

DEFINITION 6. A matrix A is an M-matrix if and only if the following conditions hold: (i) A is an L-matrix.

(ii) There exists a diagonal matrix $D = \operatorname{diag}(d_i) \geq 0$ such that DA is columnwise strictly diagonally dominant ($\sum_i a_{ij} d_i > 0$) or AD is rowwise strictly diagonally dominant ($\sum_j a_{ij} d_j > 0$).

Let A be an M-matrix with the splitting $A = B - C$ given in Definition 5. A^{-1} may be written

$$A^{-1} = B^{-1}(I - CB^{-1})^{-1}. \tag{2.1}$$

For the spectral radius $\rho(CB^{-1})$ we have

$$\begin{aligned} \rho(CB^{-1}) &= \rho(D(CB^{-1})D^{-1}) = \rho(DC(DB)^{-1}) \\ &\leq \|DC(DB)^{-1}\|_1 = \max_j \sum_i \frac{c_{ij} d_i}{b_j d_j} < 1. \end{aligned} \tag{2.2}$$

By use of the Neumann expansion [23] for the inverse of the matrix A, we get

$$A^{-1} = B^{-1}(I - CB^{-1})^{-1} = B^{-1} \sum_{k=0}^{\infty} (CB^{-1})^k \geq 0. \tag{2.3}$$

Consequently, an M-matrix is of monotone type.

Now assume that the vector functions F and G have a Gâteaux-derivative at each point of the interval $[S_h^*, S_h^{**}]$. Assume also that the derivatives of F and G are Riemann-integrable. Then the mean-value theorem holds in integral form [23, p. 70]. Let J denote the vector function F or G

$$\begin{aligned} J(S_h^{**}) - J(S_h^*) &= (S_h^{**} - S_h^*) \int_{S_h^*}^{S_h^{**}} [J'(S_h^* + t(S_h^{**} - S_h^*))]\, dt \\ &= E(S_h^{**} - S_h^*). \end{aligned} \tag{2.4}$$

Let the Jacobian J' be monotone (explicit case) or an M-matrix (implicit case). In both cases the integrated matrix E will have the same properties.

Now assume that $S_h^{**} - S_h^* \geq 0$ and $F'(S_h) \geq 0$ for all $S_h \in [S_h^*, S_h^{**}]$, then $F(S_h^{**}) - F(S_h^*) \geq 0$. Moreover, given $G(S_h^{**}) - G(S_h^*) \geq 0$ and the condition $G'(S_h)^{-1} \geq 0$ for all $S_h \in [S_h^*, S_h^{**}]$, then $S_h^{**} - S_h^* \geq 0$. Consequently, the explicit schemes are monotone in time if the Jacobian $F'(S_h)$ is monotone, and the implicit schemes are monotone if the Jacobian $G'(S_h)$ is an M-matrix (and hence of monotone type). We remark that these conditions are sufficient but not necessary for the solution to be monotone. It is an open question whether or not the conditions are too restrictive.

Using the above concepts it may be shown that one-point upstream weighting is monotone, while central differencing is not monotone. This will be clear from the analysis in §4.

Aavatsmark [1] discussed implicit finite-difference approximations and their monotonicity properties of (1.1). The implicit Lax–Friedrichs scheme [18] is monotone under the restrictive CFL (Courant–Friedrichs–Lewy) condition $s/h \leq 1/\|f\|_\infty$. The implicit variant of the first-order Godunov method [11] is unconditionally monotone, but the flux function $A(S)$ is not continuously differentiable. This may cause problems if Newton iteration is used. The Engquist–Osher method [9] is unconditionally monotone, and the flux function is differentiable. But the Engquist–Osher method introduces more artificial diffusion compared to the first-order Godunov method.

3. Generalization to finite-element schemes. For finite-element techniques, the mass matrix in front of the time derivatives generally contains nondiagonal contributions. Such schemes will be in the form

$$TS_h^n = F^*(S_h^{n-1}) + TS_h^{n-1}, \tag{3.1}$$

$$TS_h^{n-1} = G^*(S_h^n) + TS_h^n, \tag{3.2}$$

where T is the mass matrix.

To obtain such schemes in the standard form given in Definitions 1 and 2, multiply (3.1) and (3.2) by T^{-1} (assuming that T is nonsingular). The schemes then become

$$S_h = T^{-1}J^*(S_h^*) + S_h^* = J(S_h^*). \tag{3.3}$$

Here $J^* = F^*, S_h^* = S_h^{n-1}$, and $S_h = S_h^n$ for the explicit schemes and $J^* = G^*, S_h^* = S_h^n$, and $S_h = S_h^{n-1}$ for the implicit schemes. The Jacobian J' becomes

$$J' = I + T^{-1}J^{*\prime}. \tag{3.4}$$

The inversion of the matrix T complicates the monotonicity analysis. For the Petrov–Galerkin method presented in §4, the matrix T is tridiagonal and nonsymmetric. The inverse is generally a full matrix. We may avoid this problem by writing

$$J' = I + T^{-1}J^{*\prime} = T^{-1}(J^{*\prime} + T). \tag{3.5}$$

The inverse becomes

$$J'^{-1} = (T^{-1}(J^{*\prime} + T))^{-1} = (J^{*\prime} + T)^{-1}T. \tag{3.6}$$

According to (3.4), the explicit schemes are monotone in time if the matrix $T^{-1}J^{*\prime}$ is monotone. This condition may be met by requiring T to be an M-matrix and the Jacobian $J^{*\prime}$ to be nonnegative. For the implicit schemes we consider (3.6): It is clear that implicit schemes are monotone in time if the matrix T is monotone and if, in addition, the Jacobian $J^{*\prime} + T$ is of monotone type. This condition is satisfied if T is nonnegative and $J^{*\prime} + T$ is an M-matrix. A nondiagonal, nonnegative matrix T imposes a lower bound on the time step in order to ensure that $J^{*\prime} + T$ is an M-matrix. This is because T contains nonnegative elements of order $O(h/s)$ outside the main diagonal. In fact, this condition is also necessary in some cases; see §5 Example 1. This indicates that the mass matrix T should be lumped (diagonalized) in order to guarantee monotonicity.

4. An a priori monotone time-discretized Petrov–Galerkin method.

To simplify, we transform element i (the interval $x \in [x_i, x_{i+1}]$) to the unit element by

$$\xi_i = \frac{x - x_i}{x_{i+1} - x_i}, \quad i = 0, 1, \ldots, N-1. \tag{4.1}$$

Let $H^1(\langle 0,1\rangle)$ denote the Sobolev space on $\langle 0,1\rangle$ where the functions and their first-order derivatives are square integrable (i.e., members of L_2). Let (u, v) denote the inner product in L_2.

We now seek the discrete solution S_h in the finite dimensional subspace $M^1 \subset H^1$, consisting of piecewise linears.

On each element i the saturation is interpolated linearly by

$$\begin{aligned} S_{h_i} &= S_{i,1}v_{i,1}(\xi) + S_{i,2}v_{i,2}(\xi) \\ &= S_i v_{i,1}(\xi) + S_{i+1}v_{i,2}(\xi), \end{aligned} \tag{4.2}$$

with basis

$$v_{i,1}(\xi) = 1 - \xi, \tag{4.3}$$

$$v_{i,2}(\xi) = \xi, \tag{4.4}$$

where $S_{i,1} = S_i$ and $S_{i,2} = S_{i+1}$ are the unknowns at x_i and x_{i+1}, respectively.

For the test space we choose the asymmetric basis

$$T_{i,1}(\xi) = v_{i,1}(\xi) + 3\alpha_i\xi(1-\xi), \tag{4.5}$$

$$T_{i,2}(\xi) = v_{i,2}(\xi) - 3\alpha_i\xi(1-\xi), \tag{4.6}$$

where α_i is to be chosen to introduce artificial diffusion.

On each element, the interpolant S_{h_i} is substituted for S and the saturation equation is multiplied by the test functions (4.5)–(4.6) and integrated over the element

$$\begin{aligned} e_{i,j} = \left(h_i\left(\frac{\partial S_{h_i}}{\partial t}, T_{i,j}\right) - A(S_{h_i}) + \frac{1}{h_i}\frac{\partial \Psi(S_{h_i})}{\partial \xi}, \frac{\partial T_{i,j}}{\partial \xi}\right) \\ + fT_{i,j}\big|_0^1 = 0, \qquad j = 1, 2, \\ i = 0, 1, \ldots, N-1. \end{aligned} \tag{4.7}$$

The flux term is integrated by parts and the two-point trapezoidal rule is used. This will diagonalize the mass matrix in front of the time derivatives and, as we commented in §3, is necessary to guarantee monotonicity. By the discretization $\partial\Psi(S_{h_i})/\partial\xi = \Psi(S_{i,2}) - \Psi(S_{i,1})$, the quadratic terms of the test functions (4.5)–(4.6) will not affect the diffusion term in (1.1). We neglect gravity effects and define $H(S) \equiv 0$. The Petrov–Galerkin scheme is now constructed by forming the discrete system of equations. We set $E_0 = e_{0,1}$, $E_i = e_{i-1,2} + e_{i,1}$, $i = 1, 2, \ldots, N-1$, and $E_N = e_{N-1,2}$. In the summations for constructing E_i, the flux f will cancel over the interior element boundaries (conservation).

The following scheme results:

$$
\begin{aligned}
E_0 = {} & \frac{1}{2}h_0\frac{S_0^n - S_0^{n-1}}{s} \\
& + \frac{1}{2}\left((1-3\alpha_0)A(S_0^\nu) + (1+3\alpha_0)A(S_1^\nu)\right) \\
& + \frac{\Psi(S_1^\nu) - \Psi(S_0^\nu)}{h_0} + f|_{x=0} = 0,
\end{aligned}
\tag{4.8}
$$

$$
\begin{aligned}
E_i = {} & \frac{1}{2}(h_{i-1} + h_i)\frac{S_i^n - S_i^{n-1}}{s} \\
& + \frac{1}{2}\left(-(1-3\alpha_{i-1})A(S_{i-1}^\nu) - (3\alpha_{i-1} + 3\alpha_i)A(S_i^\nu) + (1+3\alpha_i)A(S_{i+1}^\nu)\right) \\
& - \frac{\Psi(S_i^\nu) - \Psi(S_{i-1}^\nu)}{h_{i-1}} + \frac{\Psi(S_{i+1}^\nu) - \Psi(S_i^\nu)}{h_i} = 0, \qquad i = 1, 2, \ldots, N-1,
\end{aligned}
\tag{4.9}
$$

$$
\begin{aligned}
E_N = {} & \frac{1}{2}h_N\frac{S_N^n - S_N^{n-1}}{s} \\
& - \frac{1}{2}\left((1-3\alpha_{N-1})A(S_{N-1}^\nu) + (1+3\alpha_{N-1})A(S_N^\nu)\right) \\
& - \frac{\Psi(S_N^\nu) - \Psi(S_{N-1}^\nu)}{h_{N-1}} - f|_{x=1} = 0.
\end{aligned}
\tag{4.10}
$$

The system given by (4.8)–(4.10) is written in the form $S_h^n = F(S_h^{n-1})$ (explicit case, $\nu = n-1$) and $S_h^{n-1} = G(S_h^n)$ (implicit case, $\nu = n$).

Let

$$
\chi_i = \begin{cases} h_0 & \text{if } i = 0, \\ h_{i-1} + h_i & \text{if } 1 \le i \le N-2, \\ h_{N-1} & \text{if } i = N-1. \end{cases}
\tag{4.11}
$$

The column structures of the tridiagonal Jacobians F' and G' become

$$
\frac{\partial F_0}{\partial S_0} = 1 - (1-3\alpha_0)\frac{sA'(S_0)}{\chi_0} + 2\frac{s\Psi'(S_0)}{h_0\chi_0},
\tag{4.12}
$$

$$\frac{\partial F_{i-1}}{\partial S_i} = -(1+3\alpha_{i-1})\frac{sA'(S_i)}{\chi_{i-1}} - 2\frac{s\Psi'(S_i)}{h_{i-1}\chi_{i-1}}, \qquad i=1,2,\ldots,N, \tag{4.13}$$

$$\frac{\partial F_i}{\partial S_i} = 1 + (3\alpha_{i-1}+3\alpha_i)\frac{sA'(S_i)}{\chi_i} + 2s\left(\frac{1}{h_{i-1}\chi_i} + \frac{1}{h_i\chi_i}\right)\Psi'(S_i), \qquad i=1,\ldots,N-1, \tag{4.14}$$

$$\frac{\partial F_{i+1}}{\partial S_i} = (1-3\alpha_i)\frac{sA'(S_i)}{\chi_{i+1}} - 2\frac{s\Psi'(S_i)}{h_i\chi_{i+1}}, \qquad i=0,1,\ldots,N-1, \tag{4.15}$$

$$\frac{\partial F_N}{\partial S_N} = 1 + (1+3\alpha_{N-1})\frac{sA'(S_N)}{\chi_{N-1}} + 2\frac{s\Psi'(S_N)}{h_{N-1}\chi_{N-1}}, \tag{4.16}$$

$$\frac{\partial G_0}{\partial S_0} = 1 + (1-3\alpha_0)\frac{sA'(S_0)}{\chi_0} - 2\frac{s\Psi'(S_0)}{h_0\chi_0}, \tag{4.17}$$

$$\frac{\partial G_{i-1}}{\partial S_i} = (1+3\alpha_{i-1})\frac{sA'(S_i)}{\chi_{i-1}} + 2\frac{s\Psi'(S_i)}{h_{i-1}\chi_{i-1}}, \qquad i=1,2,\ldots,N, \tag{4.18}$$

$$\frac{\partial G_i}{\partial S_i} = 1 - (3\alpha_{i-1}+3\alpha_i)\frac{sA'(S_i)}{\chi_i} - 2s\left(\frac{1}{h_{i-1}\chi_i} + \frac{1}{h_i\chi_i}\right)\Psi'(S_i), \qquad i=1,\ldots,N-1, \tag{4.19}$$

$$\frac{\partial G_{i+1}}{\partial S_i} = -(1-3\alpha_i)\frac{sA'(S_i)}{\chi_{i+1}} + 2\frac{s\Psi'(S_i)}{h_i\chi_{i+1}}, \qquad i=0,1,\ldots,N-1, \tag{4.20}$$

$$\frac{\partial G_N}{\partial S_N} = 1 - (1+3\alpha_{N-1})\frac{sA'(S_N)}{\chi_{N-1}} - 2\frac{s\Psi'(S_N)}{h_{N-1}\chi_{N-1}}. \tag{4.21}$$

Equations (4.13) and (4.18) impose the following inequality for each parameter α_i in order to ensure that the Jacobian is nonnegative (explicit case) or is an M-matrix (implicit case).

$$\alpha_i \le \min\left\{ -\frac{2\Psi'(S_{i+1})}{3h_iA'(S_{i+1})} - \frac{1}{3}, 0\right\}, \qquad i=0,\ldots,N-1. \tag{4.22}$$

The inequalities for the parameters α_i may be interpreted as follows: Ideally, a set of parameters with minimum absolute value should be selected. If all the parameters could be chosen equal to zero, the discrete convection term in (4.9) would be $(A(S_{i+1}) - A(S_{i-1}))/2$. Consequently, this choice corresponds to central differencing. For points where the diffusion vanishes, a value of $-\frac{1}{3}$ must be selected. In this case, the discrete term would be $A(S_i) - A(S_{i-1})$, and one-point upstream weighting is in effect. By choosing the α_i's as small as possible in absolute value according to (4.22), one would generally do better than simple one-point upstream weighting. Therefore, each parameter α_i should be chosen to satisfy

$$\alpha_i = \begin{cases} \left|\dfrac{2\Psi'(S_{i+1})}{3h_iA'(S_{i+1})}\right| - \dfrac{1}{3} & \text{if } \left|\dfrac{2\Psi'(S_{i+1})}{3h_iA'(S_{i+1})}\right| - \dfrac{1}{3} < 0, \\ 0, & \text{otherwise}, \end{cases} \qquad i = 0,\dots,N-1. \tag{4.23}$$

The Jacobian G' for the implicit scheme has positive diagonal elements and negative off-diagonal elements provided the α_i's are chosen as in (4.23). By scaling with the diagonal matrix $D = \operatorname{diag}(\chi_i)$, the matrix DG' becomes columnwise diagonally dominant. The Jacobian is therefore an M-matrix for arbitrary time step s and mesh sizes h_i and we have unconditional monotonicity. If the diffusion vanishes one must do upstream weighting in order to ensure that the Jacobian is an M-matrix. When the fraction between diffusion and convection increases in absolute value, the scheme tends towards central differences (Galerkin). Note that given $\Psi'(S_i)$ and $A'(S_i)$ locally, (4.23) can be used to determine the maximum mesh size h_i for central differencing to be monotone.

We now discuss the explicit case. For this case, we get a restriction on the time step s. The Jacobian F' is nonnegative if $\partial F_i/\partial S_i \geq 0, i = 0, 1, \dots, N$. From the expressions (4.12), (4.14), and (4.16) it follows that

$$\begin{aligned} s \leq \min\Bigg\{ & \frac{h_0^2}{|2\Psi'(S_0)| + h_0|(1-3\alpha_0)A'(S_0)|}, \\ & \frac{h_{i-1}h_i\chi_i}{|\chi_i\Psi'(S_i)| + |h_{i-1}h_i(3\alpha_{i-1}+3\alpha_i)A'(S_i)|}, \\ & \frac{h_{N-1}^2}{|2\Psi'(S_N)| - h_{N-1}|(1+3\alpha_{N-1})A'(S_N)|} \Bigg\}, \end{aligned} \tag{4.24}$$

provided $|2\Psi'(S_N)| - h_{N-1}|(1+3\alpha_{N-1})A'(S_N)| > 0$. If this last expression is less than or equal to zero, the third bound in (4.24) disappears.

For linear parabolic problems on a uniform mesh the stability limit is $h^2/2\Psi'$. The monotonicity limit given by (4.24) indicates the same limit. For linear hyperbolic problems the stability limit, or CFL condition, is h/A'. If all parameters $\alpha_i = 0$, the same bound is forced by (4.24).

The restrictions on s and the α_i's given by (4.24) and (4.23) must hold for all solutions between two consecutive time levels. This is easy to verify for linear problems since the elements of the Jacobian are independent of the solution. For nonlinear problems, the two conditions must hold for all $S_i \geq \bar{S}_i$, $i = 0, 1, \dots, N$, where $\bar{S}_i$, $i = 0, 1, \dots, N$, is the solution at the previous time level (according to (2.4)).

The scheme developed so far is for Neumann-type boundary conditions where the flux is given at the boundaries. Dirichlet boundary conditions of the type $d(S) = e(t)$ are handled by writing either one or both of (4.8) and (4.10) in the form

$$\operatorname{sgn}(d'(S_i))d(S_i) = \operatorname{sgn}(d'(S_i))e(t), \qquad i = 0 \text{ and/or } i = N, \tag{4.25}$$

where $\operatorname{sgn}(x)$ is the sign of x. This gives positive contributions to the main diagonal of the Jacobian matrix. Diagonal dominance is ensured by the scaling of (4.25).

We will refer to the lumped Petrov–Galerkin scheme (4.8)–(4.10) as the LPG scheme. If the "upstream weighting" parameters α_i are chosen in the "optimal sense" given by (4.23), we will refer to that scheme as the OLPG scheme.

To guarantee monotonicity when $H(S) \neq 0$, one should use the Engquist–Osher flux [1].

The discretization of the second derivative in the traditional form (1.1) may cause nonmonotone schemes. This is because $D(S)$ may have local minima. Consider, for instance, the following discretization of the diffusion inner product in (4.7). The following diffusion term would then have appeared in (4.9) for a uniform mesh.

$$\begin{aligned} &\frac{1}{h}\left[-\int_0^1 D(S_h^{i-1})\frac{\partial S_h^{i-1}}{\partial \xi_{i-1}}\frac{\partial T_2^{i-1}}{\partial \xi_{i-1}}d\xi_{i-1} - \int_0^1 D(S_h^i)\frac{\partial S_h^i}{\partial \xi_i}\frac{\partial T_1^i}{\partial \xi_i}d\xi_i\right] \\ &= -\frac{1}{h}\left[(S_i - S_{i-1})\int_0^1 D(S_h^{i-1})\frac{\partial T_2^{i-1}}{\partial \xi_{i-1}}d\xi_{i-1} + (S_{i+1} - S_i)\int_0^1 D(S_h^i)\frac{\partial T_1^i}{\partial \xi_i}d\xi_i\right] \\ &\approx \frac{1}{h}\left[D(S_{i+\frac{1}{2}})(S_{i+1} - S_i) - D(S_{i-\frac{1}{2}})(S_i - S_{i-1})\right], \end{aligned} \tag{4.26}$$

$$S_{i-\frac{1}{2}} = \frac{1}{2}(S_{i-1} + S_i), \tag{4.27}$$

$$S_{i+\frac{1}{2}} = \frac{1}{2}(S_i + S_{i+1}). \tag{4.28}$$

Use of this discretization will make the elements of the Jacobian matrix dependent upon the local sign of $D'(S)$. This may destroy the monotonicity structure of the Jacobian matrices. This may be seen by considering the analogs of (4.14) and (4.19).

Using the PSI potential, the diffusive term in (4.9) is

$$\frac{1}{h}\left[(\Psi(S_{i+1}) - 2\Psi(S_i) + \Psi(S_{i-1}))\right]. \tag{4.29}$$

This discretization leads to a monotone scheme. We remark that (4.26) turns into the form of (4.29) for linear problems, for which $D = \text{const}$. To conclude, the discretization using the PSI potential constitutes a method for constructing monotone schemes for nonlinear parabolic operators.

5. Examples.

Example 1. The need for lumping. Consider the linear hyperbolic problem

$$\frac{\partial S}{\partial t} + \frac{\partial f}{\partial x} = 0 \tag{5.1}$$

$$f = S, \tag{5.2}$$

$$S(t)|_{x=0} = 1.0, \tag{5.3}$$

$$S(x)|_{t=0} = 0.2, \tag{5.4}$$

on a uniform mesh with all $\alpha_i = -4/11$.

Integrating the first innerproduct in (4.7) analytically gives the following analog scheme of (4.8)–(4.10):

$$S_0 = 1.0, \tag{5.5}$$

TABLE 1

Numerical solutions, example 1				
	$s = 1.0 \cdot 10^{-3}$		$s = 1.0 \cdot 10^{-2}$	
	$t = 2.0 \cdot 10^{-3}$		$t = 2.0 \cdot 10^{-2}$	
NODE	LPG	PG	LPG	PG
0	1.00	1.00	1.00	1.00
1	.251	.193	.547	.570
2	.202	.198	.323	.332
3	.200	.200	.240	.242
4	.200	.200	.212	.213
5	.200	.200	.204	.204
6	.200	.200	.201	.201

(5.6)
$$\frac{h}{s}\left(\frac{5}{66}(S^n_{i-1} - S^{n-1}_{i-1}) + \frac{2}{3}(S^n_i - S^{n-1}_i) + \frac{17}{66}(S^n_{i+1} - S^{n-1}_{i+1})\right)$$
$$-\frac{23}{22}S^n_{i-1} + \frac{12}{11}S^n_i - \frac{1}{22}S^n_{i+1}, = 0, \quad i = 1, 2, \ldots, N-1,$$

(5.7)
$$S_N = 0.20.$$

To ensure that the matrix $(J^{*\prime} + T)$ is of monotone type, we must impose the condition

(5.8)
$$\frac{5}{66}\frac{h}{s} - \frac{23}{22} \leq 0 \quad \Rightarrow \quad s \geq \frac{5}{69}h.$$

With $h = 1/33$, (5.8) yields $s \geq 5/2277 \approx 2.2 \cdot 10^{-3}$. Table 1 shows simulation results using the implicit lumped version (LPG) (4.8)–(4.10) and the implicit Petrov–Galerkin (PG) scheme (5.5)–(5.7) using different time steps. The LPG scheme is monotone, while the PG scheme tends to create some numerical oscillations when the lower bound for s forced by (5.8) is violated. For this case, such oscillations are not present as the "front" moves away from the boundary $x = 0$. The oscillations seem to be a consequence of the discontinuous initial condition forced by (5.3)–(5.4).

Example 2. Burgers equation. As an example of a nonlinear equation we consider the well-known Burgers equation. Here $A(S) = S^2/2$ and $D(S) = \epsilon = \text{const}$. Consider the initial condition $S = 0$ for $t = 0$. For a vanishing ϵ, the solution of the hyperbolic equation is two constant states separated by a shock moving from $x = 0$ to the right with speed $\frac{1}{2}$.

(5.9)
$$S(x,t) = \begin{cases} 1 & \text{if } x < \frac{1}{2}t, \\ 0 & \text{otherwise.} \end{cases}$$

The mesh spacing is constant, $h = 0.02$, $\epsilon = 0.0015$, and the OLPG scheme is chosen to minimize the need for artificial diffusion in accordance with (4.23). In Fig. 2 this solution is compared to the solutions from central differencing and from one-point upstream weighting. The reference solution using central differences (Galerkin) with h=0.002 is shown as a solid line. (For this mesh size the solution is monotone by (5.10).) The implicit version of the schemes was used, and the time step was controlled automatically with an overall maximum allowed solution change in each time step of 0.25. Since $A'(S) = S$ is strictly increasing for this case, the Jacobian is an M-matrix for all saturations $S_i \in [S_i^{n-1}, S_i^n]$ if the α_i's are chosen as

$$(5.10)\quad \alpha_i = \begin{cases} \left|\dfrac{2\epsilon}{3h_i\hat{S}_{i+1}}\right| - \dfrac{1}{3} & \text{if } \left|\dfrac{2\epsilon}{3h_i\hat{S}_{i+1}}\right| - \dfrac{1}{3} < 0, \\ 0, & \text{otherwise,} \end{cases} \qquad i = 0, 1, \ldots, N-1,$$

where $\hat{S}_{i+1} = \min[S_{i+1}^{n-1} + 0.25, 1.0]$. We note that the central-difference (Galerkin) scheme is not monotone, and one-point upstream weighting gives more smearing than the OLPG scheme.

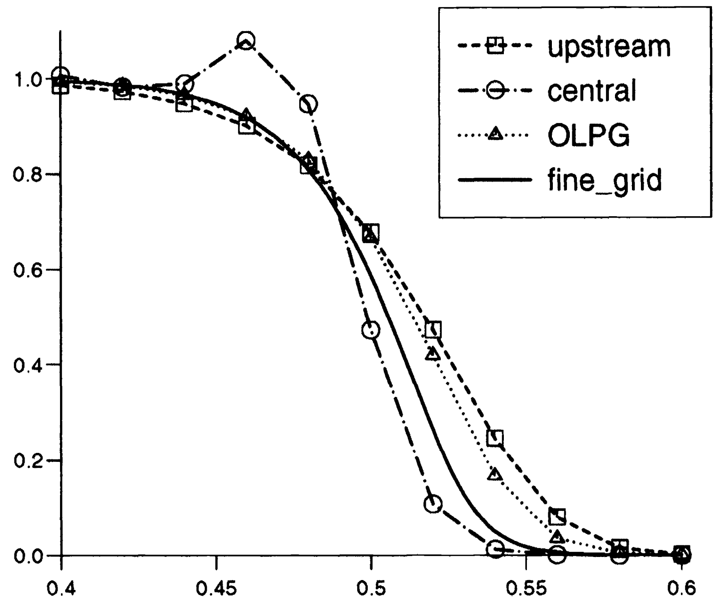

FIG. 2. *Burgers equation. Solution at* $t = 1.0$ *near* $x = 0.5$.

Example 3. The Buckley–Leverett equation with capillary diffusion. Here S represents the water saturation, and $0 \le S_{wc} \le S \le 1 - S_{or} \le 1$. For this problem $A(S)$ is an S-shaped function with $A(0) = 0$ and $A(1) = 1$. $D(S)$ is a bell-shaped function with $D(0) = 0$ and $D(1) = 1$. As initial and boundary conditions, we take

$$(5.11)\qquad S(x)_{t=0} = S_{wc}(x),$$

$$(5.12)\qquad f(S)_{x=0} = 1,$$

$$(5.13)\qquad f(S)_{x=1} = 0 \text{ as long as } S_{x=1} < 1 - S_{or},$$

or

$$S_{x=1} = 1 - S_{or}. \tag{5.14}$$

Such flux functions, together with the conditions (5.11)–(5.14), model immiscible incompressible displacement of oil by water in a porous core. Water is injected at a constant rate at the boundary $x = 0$. One or both of the fluids are produced at the boundary $x = 1$. More details about this phenomenon may be found in [20]. When the lumped Petrov–Galerkin method is used, a monotone solution is achieved both for Neumann and Dirichlet conditions. Figure 3 shows simulation results. As the advancing water front reaches the outlet $x = 1$, a boundary layer is formed by the capillary pressure effect; see [20].

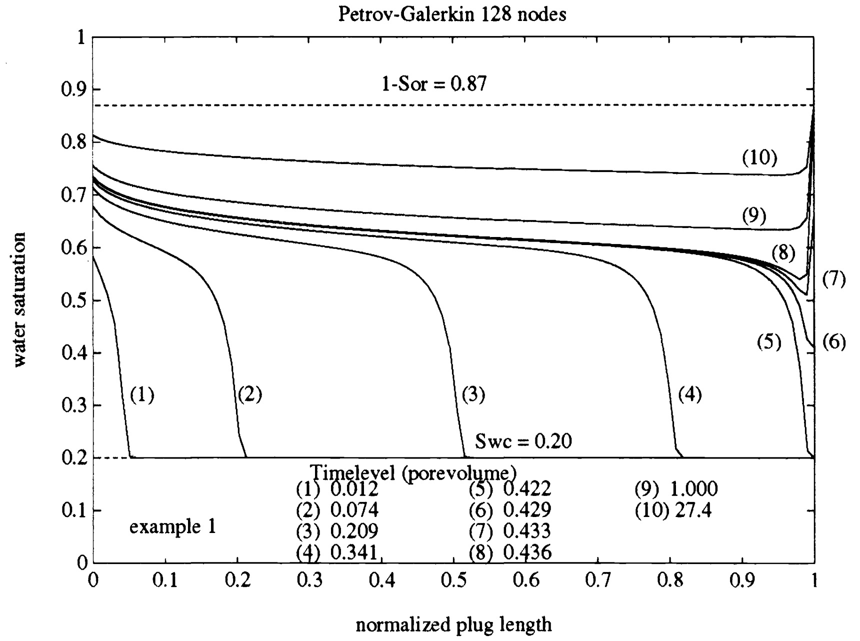

FIG. 3. *Simulation of a laboratory displacement experiment.*

6. Closing remarks. For the linear diffusion-convection problem $b\,\partial^2 S/\partial x^2 + a\,\partial S/\partial x = 0$ with Dirichlet boundary conditions, Hemker [13] used exponential fitting (to the true solution) of the differential operator in order to resolve the boundary layer for small b [13, p. 44]. Hemker used weighted finite differences and showed that the following choice of the parameters α_i gave exact solution at the nodes

$$\alpha_i = \left|\frac{2b}{3h_i a}\right| - \frac{1}{3}\coth\left(\frac{h_i a}{2b}\right). \tag{6.1}$$

This result was originally given by Il'in [17].

We remark that as the ratio between convection and diffusion increases, $\coth(h_i a/2b)$ approaches unity, and we are left with (4.23). Equation (4.23) may also be obtained by the approximate symmetrization process of Barrett and Morton [2]. Dahle, Espedal, and

Ewing [7] obtained the choice of parameters given by (6.1). In their work, the constants $a = A'$ and $b = \Psi'$ were representative values on each element (averages).

To conclude, we point out that the choice of parameters α_i given by (4.23) adds more artificial diffusion to the scheme than (6.1), but with (4.23) we ensure monotonicity for nonlinear problems with variable mesh spacing and for both Dirichlet and Neumann boundary conditions.

The test for monotonicity is not restricted to Petrov–Galerkin methods, but could be applied to any two-level in-time difference scheme. It could also be extended to higher dimensions. It is straightforward to show that the standard five-point scheme (two dimensions) and seven-point scheme (three dimensions) using upstream weighting result in monotone preserving schemes. The parabolic equation (1.1) is used in modelling of incompressible two-phase flow. In two and three dimensions, the equation is coupled to an elliptic pressure-velocity equation. For a fully implicit scheme the analysis may not be straightforward, since pressure appears as an additional variable. In higher dimensions, cross-derivative terms may also complicate the analysis.

Suitable choices of test functions for Petrov–Galerkin methods represent a problem. Most work has been done in two dimensions and for bilinear rectangular elements. Barrett and Morton discussed the exponential test functions of Hemker [13], the discontinuous test functions of Hughes and Brooks [15], and the quadratic test functions of Heinrich et al. [14]: The exponential test functions appear difficult to extend. The discontinuous test functions form the basis of a nonconforming method known as the streamline diffusion method. This method avoids crosswind diffusion. The test functions used by Heinrich et al. are products of the corresponding one-dimensional test functions and represent a simple extension. For triangular elements, Huyakorn [16] indicated suitable test functions. Recently, there has been great interest in the Eulerian Lagrangian localized adjoint method (ELLAM) [5]. The test functions are constructed (elementwise) from the local adjoint equation. Also, the weak form is considered in space and time so that the test functions become time-dependent. The method gives promising results, although some small numerical oscillations are reported. Its performance for variable coefficient and nonlinear problems remains to be seen.

To use the ideas presented in this paper, the test functions must be chosen in such a way that the Jacobian satisfies the required monotonicity properties. If this is feasible, one could minimize the amount of artificial diffusion. But the generalization of the ideas needs to be studied in more detail.

MULTILEVEL ITERATION FOR MIXED FINITE ELEMENT SYSTEMS WITH PENALTY*

ZHIQIANG CAI[†], CHARLES I. GOLDSTEIN[‡], AND JOSEPH E. PASCIAK[‡]

Abstract. In this paper, the authors consider the solution of the discrete systems that arises when a mixed finite element approach is used to approximate the solution of second-order elliptic boundary value problems. By the introduction of a penalty parameter, these equations can be approximated by the solution of a symmetric and positive definite penalty system on the velocity subspace. Iterative procedures are developed and analyzed for this penalty system based on the hierarchical basis approach as well as on the standard multigrid approach. Finally, numerical experiments are presented that illustrate the convergence behavior suggested by the theory.

Key words. mixed approximation of elliptic boundary value problems, multigrid techniques, multilevel, preconditioners, hierarchical preconditioners

AMS subject classifications. primary 65N30; secondary 65F10

1. Introduction.

In this paper, we shall be concerned with solving the discrete system of equations that result from mixed approximation of second-order elliptic boundary value problems. Specifically, we consider mixed approximation based on the "so-called" Raviart–Thomas [23] approximation spaces. Such approximations lead to the solution of linear systems involving block matrices of the form

$$M = \begin{pmatrix} A & B^t \\ B & 0 \end{pmatrix}. \tag{1.1}$$

Here A is symmetric and positive definite and B^t denotes the transpose of the matrix B. The matrix M is clearly symmetric and indefinite.

There have been a number of approaches discussed in the literature for solving these discrete systems (e.g., [6], [13], [15], [16], [21], and references in [24]). Instead of solving this system directly, we consider solving the penalty approximation to it proposed in [2]. This approximation involves the use of a small parameter ϵ and results in a matrix problem involving the block matrix

$$\begin{pmatrix} A & B^t \\ B & -\epsilon I \end{pmatrix}. \tag{1.2}$$

Obvious manipulations show that problems involving (1.2) can be reduced to the solution of a matrix system involving the first block of unknowns and the matrix

$$A + \epsilon^{-1} B^t B. \tag{1.3}$$

This system, although symmetric and positive definite, can have a rather large condition number depending on ϵ. In this paper, we shall consider multilevel iterative techniques for solving linear systems with matrix (1.3).

Multilevel approaches have had a long and successful history applied to standard finite element and finite difference approximation of second-order boundary value problems (cf., for example, [1], [3], [7], [9], [10], [12], [17], [18], [20], [25], and the references in [22]). Two basic approaches have emerged. The standard multigrid approach involves the combination of simple iterative methods on a sequence of successively coarser approximation subspaces of the given approximation space (cf. [7], [9], [18], [20], and the references in [22]). In contrast, the hierarchical approach involves the decomposition of the original approximation subspace into "hierarchical components" associated with the successively coarser approximation subspaces. In the hierarchical approach, subspace iteration only involves the degrees of freedom associated with the hierarchical component [3], [25]. We shall consider both the multigrid and hierarchical approaches for solving (1.3) in this paper. In particular, we shall be interested in understanding how the parameter ϵ influences the rate of convergence for the respective methods.

In §3, we develop and analyze a hybrid hierarchical preconditioner for (1.3). This development involves two distinct phases. In the first phase, the original matrix (1.3) is preconditioned by the corresponding block diagonal matrix associated with the hierarchical subspace decomposition. The second phase involves replacing the hierarchical blocks in the block diagonal matrix by easily solved preconditioners. In contrast to the standard finite element and finite difference hierarchical matrices, the hierarchical blocks associated with (1.3) are not well conditioned. To develop efficient preconditioners for the hierarchical block problems, we use a variation of static condensation (or local domain decomposition). We then show that this "hybrid" hierarchical approach leads to a preconditioned system for (1.3) with condition number that is independent of ϵ and the mesh size of the fine grid approximation. It does, however, depend on the number of coarser grid approximation levels.

In §4, we develop and analyze the multigrid method applied to (1.3). The multigrid method is simple to apply since (1.3), in the case of Raviart–Thomas elements, fits into the standard variational multigrid framework [4], [7], [20]. We provide what appears to be a very crude analysis for the resulting procedure leading to estimates which deteriorate rather badly when ϵ or the fine grid mesh size become small. However, these estimates are probably sharp since they are in agreement with the results of numerical experiments reported in §5. We conclude that the natural multigrid approach is not very effective when directly applied to (1.3). We emphasize, however, that alternative multigrid methods have been proposed for other formulations of problem (1.1) (see [5], [11], [19], and references cited therein).

2. Penalty finite element method. In this section, we first define the continuous and discrete mixed variational problems. Next, the penalty formulation of this mixed method is given. Finally, we discuss the lowest-order Raviart–Thomas finite element space on triangles and the resulting system of linear equations.

Let Ω be a bounded open subset of R^2 with boundary Γ. Consider the boundary value problem

$$\begin{aligned} -\nabla\cdot(k\nabla p) &= f \quad \text{in} \quad \Omega, \\ p &= 0 \quad \text{on} \quad \Gamma, \end{aligned} \tag{2.1}$$

where $f \in L^2(\Omega)$ and $k(x) = k(x_1, x_2)$ is bounded from above and below by some positive constants.

We shall use the following space to define the mixed variational problem. Let

$$H(\text{div};\Omega) \equiv \{\mathbf{v} \in [L^2(\Omega)]^2 | \nabla\cdot\mathbf{v} \in L^2(\Omega)\}.$$

$H(\mathrm{div};\Omega)$ is a Hilbert space with norm given by

$$\|\mathbf{v}\|^2_{H(\mathrm{div};\Omega)} \equiv \|\mathbf{v}\|^2_{L^2(\Omega)} + \|\nabla\cdot\mathbf{v}\|^2_{L^2(\Omega)}. \tag{2.2}$$

We set $\mathbf{u} \equiv k\nabla p$ where p is the solution of (2.1). Note that the pair $(\mathbf{u}, p)$ satisfies

$$\begin{aligned} (k^{-1}\mathbf{u}, \mathbf{v}) + (p, \nabla\cdot\mathbf{v}) = 0 \quad \forall \quad \mathbf{v} \in H(\mathrm{div};\Omega),\\ (\nabla\cdot\mathbf{u}, q) = -(f, q) \quad \forall \quad q \in L^2(\Omega), \end{aligned} \tag{2.3}$$

where $(\cdot,\cdot)$ denotes the inner product in $L^2(\Omega)$ or $[L^2(\Omega)]^2$.

To discretize the mixed formulation (2.3), we assume that we are given two finite element subspaces

$$M \subset H(\mathrm{div};\Omega) \quad \text{and} \quad W \subset L^2(\Omega),$$

defined on a quasi-uniform mesh with elements of size $O(h)$. The mixed approximation of $(\mathbf{u}, p)$ is defined to be the pair, $(\mathbf{u}^h, p^h) \in M \times W$, satisfying

$$\begin{aligned} (k^{-1}\mathbf{u}^h, \mathbf{v}) + (p^h, \nabla\cdot\mathbf{v}) = 0 \quad \forall \quad \mathbf{v} \in M,\\ (\nabla\cdot u^h, q) = -(f, q) \quad \forall \quad q \in W. \end{aligned} \tag{2.4}$$

We refer to [23] for the definition of a class of approximation subspaces M, W. In this manuscript, we shall only consider the lowest-order Raviart–Thomas spaces defined on a triangulation of Ω. These spaces will be described in detail later in this section.

Problem (2.4) can be restated in terms of operators. To this end, we define $A : M \to M$, $B : M \to W$ and $B^* : W \to M$ by

$$(A\mathbf{v}, \mathbf{v}') \equiv (k^{-1}\mathbf{v}, \mathbf{v}') \quad \forall \quad \mathbf{v}' \in M, \tag{2.5a}$$

$$(B\mathbf{v}, q) \equiv (\nabla\cdot\mathbf{v}, q) \quad \forall \quad q \in W, \tag{2.5b}$$

$$(B^* q, \mathbf{v}) \equiv (q, \nabla\cdot\mathbf{v}) \quad \forall \quad \mathbf{v} \in M. \tag{2.5c}$$

With this notation, (2.4) can be rewritten

$$\begin{pmatrix} A & B^* \\ B & 0 \end{pmatrix} \begin{pmatrix} \mathbf{u}^h \\ p^h \end{pmatrix} = \begin{pmatrix} 0 \\ -f^h \end{pmatrix}, \tag{2.6}$$

where f^h denotes the $L^2(\Omega)$ orthogonal projection of f into W. System (2.6) is indefinite and the number of degrees of freedom, N, is given by

$$N = N_M + N_W \equiv \dim(M) + \dim(W).$$

The solution $(\mathbf{u}^h, p^h)$ can be approximated by solving a perturbed reduced system using a penalty approximation. Let $\varepsilon > 0$ be a small parameter and perturb (2.6) to obtain

$$\begin{pmatrix} A & B^* \\ B & -\varepsilon I \end{pmatrix} \begin{pmatrix} \mathbf{u}^h_\varepsilon \\ p^h_\varepsilon \end{pmatrix} = \begin{pmatrix} 0 \\ -f^h \end{pmatrix}. \tag{2.7}$$

Eliminating p_ε^h above gives rise to the following equation for $\mathbf{u}_\varepsilon^h$:

$$A^\varepsilon \mathbf{u}_\varepsilon^h \equiv (A + \varepsilon^{-1} B^* B)\mathbf{u}_\varepsilon^h = -\varepsilon^{-1} B^* f^h. \tag{2.8}$$

The operator A^ε is obviously positive definite symmetric and involves N_M degrees of freedom. Once (2.8) has been solved for $\mathbf{u}_\varepsilon^h$, p_ε^h can be computed by

$$p_\varepsilon^h = \varepsilon^{-1}(B\mathbf{u}_\varepsilon^h + f^h). \tag{2.9}$$

The penalty method was analyzed in [2] for a class of mixed methods. In particular, it follows from these results that for the finite element spaces in [23],

$$\begin{aligned} \|\mathbf{u} - \mathbf{u}_\varepsilon^h\|_{H(\mathrm{div};\Omega)} + \|p - p_\varepsilon^h\|_{L^2(\Omega)} \le C \Bigg(& \inf_{\mathbf{v}\in M} \|\mathbf{u} - \mathbf{v}\|_{H(\mathrm{div};\Omega)} \\ & + \inf_{q\in W} \|p - q\|_{L^2(\Omega)} + \varepsilon \|p\|_{L^2(\Omega)} \Bigg), \end{aligned} \tag{2.10}$$

where the constant C *is independent of both h and ε.*

In the remainder of this section, we describe the lowest-order Raviart–Thomas spaces M and W and the resulting system of linear equations corresponding to (2.8), (2.9). To define M, first consider a reference triangle $\hat{T}$ in the $\hat{x} = (\hat{x}_1, \hat{x}_2)$-plane with vertices $(1,0)$, $(0,1)$, and $(0,0)$. Let $P_1(\hat{T})$ denote the set of polynomials on $\hat{T}$ of degree 1 or less. Define

$$V(\hat{T}) \equiv \{\hat{\mathbf{v}} \in P_1(\hat{T})^2 | \hat{\mathbf{v}} = (a + b\hat{x}_1, c + b\hat{x}_2)\},$$

where a, b, c are real numbers. $V(\hat{T})$ is a three-dimensional vector space whose elements are vector-valued functions with constant normal components on each edge of $\hat{T}$.

Now suppose that $\mathcal{T}$ is a partitioning of Ω into triangles T such that

$$\max_{T\in\mathcal{T}} \mathrm{diam}(T) \le h.$$

In the subsequent discussion, we shall always consider these triangles to be closed sets including their boundary. We assume that the intersection of any two distinct triangles either consists of a common side, a common vertex, or is empty. Any $T \in \mathcal{T}$ is the image of $\hat{T}$ under an affine transformation

$$x = F_T(\hat{x}) = B_T \hat{x} + b_T,$$

with B_T a two-by-two matrix. Define

$$V(T) \equiv \{\mathbf{v} = B_T(\hat{\mathbf{v}} \circ F_T^{-1}), \hat{\mathbf{v}} \in V(\hat{T})\}.$$

We now define

$$M \equiv \{\mathbf{v} \in H(\mathrm{div};\Omega) \; : \; \mathbf{v}|_T \in V(T) \quad \forall \quad T \in \mathcal{T}\}.$$

Note that the normal components of $\mathbf{v} \in M$ across the edges of triangles in $\mathcal{T}$ are continuous. The dimension N_M is equal to the number of edges in the triangulation of Ω. Choose a unit normal direction $\vec{n}_E$ on each edge E. In the following, the normal components across E of functions in M are taken with respect to $\vec{n}_E$. A convenient basis for M consists of the set of functions φ_E that are defined to have a normal component equal to one on E and a normal component of zero on the remaining edges.

Finally, the space W consists of piecewise constants with respect to the triangulation $\mathcal{T}$. Clearly,

$$\nabla \cdot \mathbf{v} \in W \quad \forall \quad \mathbf{v} \in M.$$

A simple basis for W consists of the set of functions $\{p_i\}$ such that $p_i = 1$ on the ith triangle and vanishes on all other triangles in $\mathcal{T}$. Since the support of p_i is contained in only one triangle, it follows that the mass matrix with respect to this basis is diagonal. Hence once (2.8) is solved for $\mathbf{u}_\varepsilon^h$, we may compute p_ε^h from (2.9) by inverting a diagonal matrix of degree N_W, where N_W is the number of triangles.

It is easy to see that the stiffness matrix corresponding to (2.8) is sparse, symmetric, and positive definite. Moreover, it can be shown that the condition number of this system is on the order of $\epsilon^{-1}h^{-2}$. In the remaining sections, we discuss various methods for solving this system.

3. Hierarchical preconditioner. In this section, we derive and analyze a hierarchical preconditioner for the penalty equation (2.8). This preconditioner is defined in terms of a hierarchical decomposition of the space $\mathcal{M}$. The first step is to analyze the block hierarchical form as a preconditioner for (2.8). The stiffness matrix associated with A^ε restricted to the hierarchical subspace, which forms the hierarchical block, is still nontrivial to invert. The final preconditioner involves replacing these hierarchical blocks by preconditioners. The main results provide estimates for the condition number of the resulting preconditioned operators for (1.3) (see Theorem 3.1 and Theorem 3.2).

We start with a coarse initial triangulation $\mathcal{T}_0$ of the domain Ω and construct a nested family,

$$\mathcal{T}_0, \mathcal{T}_1, \dots, \mathcal{T}_J \equiv \mathcal{T},$$

of triangulations of the domain Ω by subdividing any triangle of $\mathcal{T}_j$ into four congruent subtriangles to obtain $\mathcal{T}_{j+1}$. For each $j = 0, 1, \dots, J$, corresponding to the triangulation $\mathcal{T}_j$, we consider the lowest-order Raviart–Thomas velocity space $\mathcal{M}_j$ defined in §2. Let $\mathcal{E}_j$ denote the set of edges of all triangles in $\mathcal{T}_j$, and let $\mathcal{E} = \mathcal{E}_J$. It was noted in §2 that any vector function $\mathbf{v}$ in $\mathcal{M}_j$ is uniquely determined by its normal component, α_E, on each $E \in \mathcal{E}_j$. For any vector function $\mathbf{v} \in \mathcal{M}_j$,

$$\mathbf{v} = \sum_{E \in \mathcal{E}_j} \alpha_E \varphi_E, \tag{3.1}$$

where φ_E is the basis function in $\mathcal{M}_j$ associated with the edge $E \in \mathcal{E}_j$. It is easy to see that for any triangle $T \in \mathcal{T}_j$, there exist constants $c_1 > 0$ and $c_2 > 0$ independent of the mesh size such that

$$c_1 \int_T \mathbf{v} \cdot \mathbf{v}\, dx \le \sum_{\substack{E \in \mathcal{E}_j \\ E \subset T}} \alpha_E^2 \mid T \mid \le c_2 \int_T \mathbf{v} \cdot \mathbf{v}\, dx \quad \forall \quad \mathbf{v} \in \mathcal{M}_j. \tag{3.2}$$

Here and henceforth, we use c, with or without subscript, to denote generic positive constants independent of ε, J, and the mesh size. $|T|$ (respectively, $|E|$) denotes the area of T (respectively, the length of E). Because of the construction of the nested family of triangulations, it is easy to check that the family of spaces $\{\mathcal{M}_j\}$ is nested, i.e.,

$$\mathcal{M}_0 \subset \mathcal{M}_1 \subset \cdots \subset \mathcal{M}_J \equiv \mathcal{M}.$$

For any vector functions $\mathbf{u}, \mathbf{v} \in \mathcal{M}$, define the bilinear form

$$A^{\varepsilon}(\mathbf{u}, \mathbf{v}) = (a\mathbf{u}, \mathbf{v}) + \frac{1}{\varepsilon}(\nabla \cdot \mathbf{u}, \nabla \cdot \mathbf{v}), \tag{3.3}$$

where $a = k^{-1}$. We note that for the Raviart–Thomas elements,

$$(A^{\varepsilon}\mathbf{u}, \mathbf{v}) = A^{\varepsilon}(\mathbf{u}, \mathbf{v}) \quad \forall \quad \mathbf{u}, \mathbf{v} \in \mathcal{M}.$$

Our final aim is to derive a preconditioner for the penalty form A^{ε} on $\mathcal{M} \times \mathcal{M}$. First, we introduce the operators

$$I_j : \mathcal{M} \longrightarrow \mathcal{M}_j, \quad j = 0, 1, \dots, J$$

as follows: For any vector function $\mathbf{v} \in \mathcal{M}$, we write

$$\mathbf{v} = \sum_{e \in \mathcal{E}} \alpha_e \varphi_e, \tag{3.4}$$

where α_e and φ_e are the normal component of $\mathbf{v}$ and the basis function for $\mathcal{M}$ related to the edge $e \in \mathcal{E}$, respectively. Then $I_j\mathbf{v} \in \mathcal{M}_j$ is defined by

$$I_j\mathbf{v} = \sum_{E \in \mathcal{E}_j} \alpha_E \varphi_E, \tag{3.5}$$

where φ_E is the basis function for $\mathcal{M}_j$ associated with the edge $E \in \mathcal{E}_j$ and α_E is defined to be the mean value of the normal components of $\mathbf{v}$ on E, i.e.,

$$\alpha_E = \frac{1}{m_j} \sum_{\substack{e \in \mathcal{E} \\ e \subset E}} \alpha_e. \tag{3.6}$$

Here $m_j = 2^{J-j}$. Note that α_E is just the mean value of the coefficients $\{\alpha_e\}$ corresponding to edges $e \in \mathcal{E}$ with $e \subset E$. For convenience, let $I_{-1} = 0$. Clearly, $I_J = I$ where I is the identity operator on $\mathcal{M}$. With the above definitions, the hierarchical subspace $\tilde{\mathcal{M}}_j$ is defined to be the image of $I_j - I_{j-1}$, i.e.,

$$\tilde{\mathcal{M}}_j = \{\mathbf{w} \mid \mathbf{w} = (I_j - I_{j-1})\mathbf{v}, \mathbf{v} \in \mathcal{M}\}.$$

Remark 3.1. $\tilde{\mathcal{M}}_j$ is the set of functions in $\mathcal{M}_j$ whose normal components have zero mean value on the edges in $\mathcal{E}_{j-1}$.

For any vector function $\mathbf{v}$ in $\mathcal{M}$, we have the hierarchical decomposition,

$$\mathbf{v} = \sum_{j=0}^{J} \mathbf{v}_j, \quad \mathbf{v}_j = (I_j - I_{j-1})\mathbf{v}. \tag{3.7}$$

We will first consider preconditioning the original bilinear form $A^{\varepsilon}(\mathbf{u}, \mathbf{v})$ by the block hierarchical form

$$B^{\varepsilon}(\mathbf{u}, \mathbf{v}) = \sum_{j=0}^{J} A^{\varepsilon}(\mathbf{u}_j, \mathbf{v}_j). \tag{3.8}$$

The subsequent analysis shows that the condition number of the preconditioned system is bounded by $cJ2^J$, where c is a constant independent of ε, J, and the mesh size.

LEMMA 3.1. *For any vector function* $\mathbf{v} \in \mathcal{M}$, *we have*

$$\sum_{j=0}^{J} | \nabla \cdot I_j \mathbf{v} |^2_{L^2(\Omega)} \le (J+1) \, | \nabla \cdot \mathbf{v} |^2_{L^2(\Omega)} \,. \tag{3.9}$$

Proof. Fix $j \in [0,1,\dots,J]$ and let $\mathbf{v} \in \mathcal{M}$. Let $E \in \mathcal{E}_j$. It follows from the definition of I_j that

$$\int_E I_j \mathbf{v} \cdot \vec{n} \, ds = \sum_{\substack{e \in \mathcal{E} \\ e \subset E}} \int_e \mathbf{v} \cdot \vec{n} \, ds.$$

Since the divergence of $I_j\mathbf{v}$ on any triangle $T \in \mathcal{T}_j$ is constant, by using the Gauss divergence theorem and the above equality, we have for $x \in T$

$$\begin{aligned} \nabla \cdot I_j \mathbf{v}(x) &= \frac{1}{|T|} \int_{\partial T} I_j \mathbf{v} \cdot \vec{n} \, ds \\ &= \frac{1}{|T|} \sum_{\substack{E \in \mathcal{E}_j \\ E \subset T}} \sum_{\substack{e \in \mathcal{E} \\ e \subset E}} \int_e \mathbf{v} \cdot \vec{n} \, ds \\ &= \frac{1}{|T|} \int_T \nabla \cdot \mathbf{v} \, dx. \end{aligned}$$

Hence, we have

$$\int_T | \nabla \cdot I_j \mathbf{v} |^2 \, dx \le \frac{1}{|T|} \left(\int_T | \nabla \cdot \mathbf{v} | \, dx \right)^2 \le \int_T |\nabla \cdot \mathbf{v}|^2 \, dx.$$

The lemma immediately follows by summing the above inequality.

LEMMA 3.2. *For any vector function* $\mathbf{v} \in \mathcal{M}$, *we have*

$$\sum_{j=0}^{J} (a I_j \mathbf{v}, I_j \mathbf{v}) \le c 2^J (a\mathbf{v}, \mathbf{v}), \tag{3.10}$$

where c is a constant independent of J and the mesh size.

Proof. Fix $j \in \{0,1,\dots,J\}$, $\mathbf{v} \in \mathcal{M}$, and write $\mathbf{v}$ as in (3.4). $I_j\mathbf{v}$ is thus defined by (3.5). By (3.2), we have

$$\int_T a |I_j \mathbf{v}|^2 dx \le c \, | T | \sum_{\substack{E \in \mathcal{E}_j \\ E \subset T}} \alpha_E^2.$$

By the definition of α_E in (3.6) and the Cauchy-Schwarz inequality,

$$\begin{aligned} \int_T a |I_j \mathbf{v}|^2 \, dx &\le c \frac{|T|}{m_j} \sum_{\substack{E \in \mathcal{E}_j \\ E \subset T}} \sum_{\substack{e \in \mathcal{E} \\ e \subset E}} \alpha_e^2 \le c m_j \sum_{\substack{t \in \mathcal{T} \\ t \subset T}} \left(\sum_{\substack{e \in \mathcal{E} \\ e \subset t}} \alpha_e^2 \right) | t | \\ &\le c 2^{J-j} \int_T a |\mathbf{v}|^2 \, dx. \end{aligned}$$

Hence,

$$(aI_j\mathbf{v}, I_j\mathbf{v}) \le c2^{J-j}(a\mathbf{v}, \mathbf{v}).$$

The lemma follows by summing the above inequality from 0 to J.

From the definition of $B^\varepsilon(\cdot,\cdot)$, it immediately follows that

$$A^\varepsilon(\mathbf{v},\mathbf{v}) \le (J+1)B^\varepsilon(\mathbf{v},\mathbf{v}).$$

Moreover, Lemmas 3.1 and 3.2 imply that

$$B^\varepsilon(\mathbf{v},\mathbf{v}) \le c2^J A^\varepsilon(\mathbf{v},\mathbf{v}).$$

We have proved the following theorem.

THEOREM 3.1. *For any vector function* $\mathbf{v} \in \mathcal{M}$, *we have*

$$c2^{-J}B^\varepsilon(\mathbf{v},\mathbf{v}) \le A^\varepsilon(\mathbf{v},\mathbf{v}) \le (J+1)B^\varepsilon(\mathbf{v},\mathbf{v}), \tag{3.11}$$

where c is a constant independent of ε, J, *and the mesh size.*

The above theorem shows that the form B^ε can be used to effectively precondition the form A^ε on the subspace $\mathcal{M}$ as long as J is not too large. This, however, does not lead to an effective algorithm in practice since the block hierarchical problems are not easily solved. To define a computationally effective preconditioner, we replace these block hierarchical problems by preconditioners.

Preconditioning the hierarchical problems amounts to preconditioning the bilinear form $A^\varepsilon(\cdot,\cdot)$ on the hierarchical subspaces $\tilde{\mathcal{M}}_j$ $\quad (j = 1, 2, \dots, J)$. We solve the problem corresponding to $A^\varepsilon(\cdot,\cdot)$ or a preconditioner for it on $\tilde{\mathcal{M}}_0 = \mathcal{M}_0$.

For $j > 0$, the preconditioner for the bilinear form $A^\varepsilon(\cdot,\cdot)$ on $\tilde{\mathcal{M}}_j$ is developed by using a variation of domain decomposition (static condensation). We first define the subspace $\tilde{\mathcal{M}}_j^0$ of $\tilde{\mathcal{M}}_j$ to be the functions that have zero normal components on the edges in $\mathcal{E}_{j-1}$. That is,

$$\tilde{\mathcal{M}}_j^0 = \{\mathbf{v} \in \tilde{\mathcal{M}}_j \mid \mathbf{v}\cdot\vec{n} = 0 \quad \text{on} \quad E \quad \forall \quad E \in \mathcal{E}_{j-1}\}. \tag{3.12}$$

We next decompose vector functions in $\tilde{\mathcal{M}}_j$ as follows: For any $\mathbf{v} \in \tilde{\mathcal{M}}_j$, write

$$\mathbf{v} = \mathbf{v}_H + \mathbf{v}_P, \tag{3.13}$$

where $\mathbf{v}_P \in \tilde{\mathcal{M}}_j^0$ and satisfies

$$A^\varepsilon(\mathbf{v}_P, \mathbf{w}) = A^\varepsilon(\mathbf{v}, \mathbf{w}) \quad \forall \quad \mathbf{w} \in \tilde{\mathcal{M}}_j^0. \tag{3.14}$$

Thus, $\mathbf{v}_H$ satisfies the homogeneous equation

$$A^\varepsilon(\mathbf{v}_H, \mathbf{w}) = 0 \quad \forall \quad \mathbf{w} \in \tilde{\mathcal{M}}_j^0. \tag{3.15}$$

We clearly have that

$$A^\varepsilon(\mathbf{v}, \mathbf{w}) = A^\varepsilon(\mathbf{v}_H, \mathbf{w}_H) + A^\varepsilon(\mathbf{v}_P, \mathbf{w}_P) \tag{3.16}$$

holds for any vector functions $\mathbf{v}, \mathbf{w} \in \tilde{\mathcal{M}}_j$, where $\mathbf{w} = \mathbf{w}_H + \mathbf{w}_P$ is decomposed as in (3.13).

For $E \in \mathcal{E}_{j-1}$, define the basis function $\theta_E \in \tilde{\mathcal{M}}_j$ as follows:

θ_E has normal component plus and minus one on the respective two halves of E.

θ_E has zero normal component on the remaining edges in $\mathcal{E}_j$.

The subspace $\tilde{\mathcal{M}}'_j$ is defined as the space spanned by these functions $\{\theta_E\}$. Clearly, $\tilde{\mathcal{M}}'_j \oplus \tilde{\mathcal{M}}^0_j$ gives a direct sum decomposition of $\tilde{\mathcal{M}}_j$. Let $\mathbf{v}, \mathbf{w}$ in $\tilde{\mathcal{M}}_j$ be decomposed as in (3.13) and write

$$\mathbf{v}_H = \mathbf{v}'_H + \mathbf{v}^0_H, \qquad \mathbf{w}_H = \mathbf{w}'_H + \mathbf{w}^0_H, \tag{3.17}$$

where $\mathbf{v}'_H, \mathbf{w}'_H \in \tilde{\mathcal{M}}'_j$. Let $\{\alpha_E\}$ and $\{\beta_E\}$ denote the coefficients of $\mathbf{v}'_H$ and $\mathbf{w}'_H$ respectively, with respect to the basis $\{\theta_E\}$. The preconditioner for the hierarchical block is defined by replacing the $A^\varepsilon(\mathbf{v}_H, \mathbf{w}_H)$ term in (3.16) by

$$K(\mathbf{v}_H, \mathbf{w}_H) \equiv \sum_{E\in\mathcal{E}_{j-1}} \alpha_E \beta_E (a\theta_E, \theta_E). \tag{3.18}$$

Thus, we define the preconditioning form $\tilde{B}^\varepsilon_j(\cdot,\cdot)$ by

$$\tilde{B}^\varepsilon_j(\mathbf{v}, \mathbf{w}) = K(\mathbf{v}_H, \mathbf{w}_H) + A^\varepsilon(\mathbf{v}_P, \mathbf{w}_P). \tag{3.19}$$

We now prove the following lemma.

LEMMA 3.3. *For any vector function* $\mathbf{v} \in \tilde{\mathcal{M}}_j$, *there exist constants* $c_1 > 0$ *and* $c_2 > 0$ *independent of* ε, j, *and the mesh size such that*

$$c_1 \tilde{B}^\varepsilon_j(\mathbf{v}, \mathbf{v}) \le A^\varepsilon(\mathbf{v}, \mathbf{v}) \le c_2 \tilde{B}^\varepsilon_j(\mathbf{v}, \mathbf{v}). \tag{3.20}$$

Proof. By mapping the triangles of the jth grid onto a reference triangle, it is easily seen that

$$c'_3 K(\mathbf{v}_H, \mathbf{v}_H) \le h_j^2 \sum_{E\in\mathcal{E}_{j-1}} \alpha_E^2 \le c'_4 K(\mathbf{v}_H, \mathbf{v}_H). \tag{3.21}$$

Here α_E is the nodal coefficient in the decomposition of $\mathbf{v}'_H$ as discussed above and $h_j = 2^{-j}$. Consequently, the first inequality in (3.20) follows from (3.16), (3.18), (3.19), and (3.2).

To prove the second inequality, we note that for any $\chi \in \tilde{\mathcal{M}}^0_j$, we have

$$A^\varepsilon(\mathbf{v}_H, \mathbf{v}_H) \le A^\varepsilon(\mathbf{v}_H + \chi, \mathbf{v}_H + \chi).$$

Let T be any triangle in $\mathcal{T}_{j-1}$ and $t_i \subset T$, $i = 1,2,3,4$, be the triangles in $\mathcal{T}_j$ (see Fig. 3.1). By choosing χ_0 in $\tilde{\mathcal{M}}^0_j$ such that its normal component (pointing outward from t_i) on the edge $t_i \cap t_4 \in \mathcal{E}_j$, $i = 1,2,3$, is equal to

$$\alpha_i = -\frac{1}{|\, t_i \cap t_4 \,|} \int_{\partial t_i} \mathbf{v}_H \cdot \vec{n}_{t_i}\, ds,$$

we have

$$\int_{\partial t_i} \chi_0 \cdot \vec{n}_{t_i}\, ds = \int_{t_i\cap t_4} \chi_0 \cdot \vec{n}_{t_i}\, ds = -\int_{\partial t_i} \mathbf{v}_H \cdot \vec{n}_{t_i}\, ds. \tag{3.22}$$

Here and below, the notation $\vec{n}_t$ is used to denote the outward pointing normal with respect to the set t. Clearly, $\mathbf{v}_H + \chi_0$ is divergence free on t_i for $i = 1,2,3$. The divergence of $\mathbf{v}_H + \chi_0$ on t_4 is equal to

$$\begin{aligned}\nabla \cdot (\mathbf{v}_H + \chi_0)|_{t_4} &= |t_4|^{-1} \int_{\partial t_4} (\mathbf{v}_H + \chi_0) \cdot \vec{n}_{t_4}\, ds \\ &= |t_4|^{-1} \sum_{i=1}^{3} \int_{\partial t_i \setminus (t_i \cap t_4)} \mathbf{v}_H \cdot \vec{n}_{t_i}\, ds \\ &= |t_4|^{-1} \int_{\partial T} \mathbf{v}_H \cdot \vec{n}_T\, ds = 0.\end{aligned}$$

The last equality follows from Remark 3.1. Hence, we have

$$A^\epsilon(\mathbf{v}_H, \mathbf{v}_H) \le (a(\mathbf{v}_H + \chi_0), \mathbf{v}_H + \chi_0). \tag{3.23}$$

It is elementary to see, using (3.22), that the normal component of $\mathbf{v}_H + \chi_0$ on any edge in $\mathcal{E}_j$ can be written as a linear combination of the normal components of $\mathbf{v}_H$ on the neighboring edges in $\mathcal{E}_j$, which lie on the coarse grid edges in $\mathcal{E}_{j-1}$. The corresponding coefficients only depend on the angles in the coarsest grid triangulation. Thus, (3.2), (3.21), and (3.23) imply that

$$A^\epsilon(\mathbf{v}_H, \mathbf{v}_H) \le cK(\mathbf{v}_H, \mathbf{v}_H).$$

Now, the second inequality in (3.20) follows from (3.16) and (3.19). This completes the proof of the lemma.

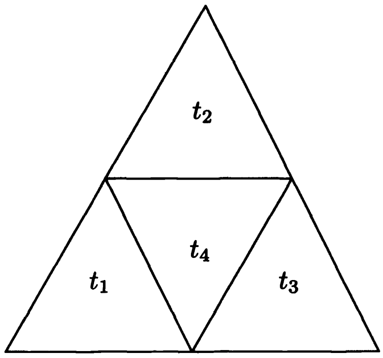

FIG. 3.1. *A typical triangle* $\mathcal{T}_{j-1}$.

To avoid solving coarse grid problems, we introduce a uniformly spectrally equivalent form $\tilde{B}_0(\cdot,\cdot)$ for $A^\epsilon(\cdot,\cdot)$. This means we assume that there are positive constants C_1 and C_2 satisfying

$$C_1 A^\epsilon(\mathbf{v},\mathbf{v}) \le \tilde{B}_0^\epsilon(\mathbf{v},\mathbf{v}) \le C_2 A^\epsilon(\mathbf{v},\mathbf{v}) \quad \forall \quad \mathbf{v} \in \mathcal{M}_0.$$

Let the quadratic form $\tilde{B}^\epsilon(\cdot,\cdot)$ be defined by

$$\tilde{B}^\epsilon(\mathbf{v},\mathbf{w}) = \sum_{j=0}^{J} \tilde{B}_j^\epsilon(\mathbf{v}_j, \mathbf{w}_j) \tag{3.24}$$

for any vector functions $\mathbf{v}, \mathbf{w} \in \mathcal{M}$ with $\mathbf{v}_j, \mathbf{w}_j$ as in (3.7). Using Theorem 3.1 and Lemma 3.3 we have the following theorem.

THEOREM 3.2. *For any vector function* $\mathbf{v} \in \mathcal{M}$, *there exist constants* $c_1 > 0$ *and* $c_2 > 0$ *independent of* ε, J, *and the mesh size such that*

$$c_1 2^{-J} \tilde{B}^{\varepsilon}(\mathbf{v},\mathbf{v}) \le A^{\varepsilon}(\mathbf{v},\mathbf{v}) \le c_2 J \tilde{B}^{\varepsilon}(\mathbf{v},\mathbf{v}). \tag{3.25}$$

Remark 3.2. The coarse grid bilinear form $\tilde{B}_0^{\varepsilon}(\ ,\ )$ may be defined, for example, by replacing the mass matrix corresponding to the first term on the right side of (3.3) by a suitable diagonal matrix D (cf. [13]). Since the mesh is quasi-uniform, we can choose D to be a weighted identity matrix. Other choices of D, such as the "lumped mass matrix" will possibly yield a better preconditioner.

Fix $j \in [1, \dots, J]$. We now demonstrate how to solve the problem: Given a linear functional F, find $\mathbf{v} \in \tilde{\mathcal{M}}_j$ such that

$$\tilde{B}_j^{\varepsilon}(\mathbf{v},\mathbf{w}) = F(\mathbf{w}) \quad \forall \quad \mathbf{w} \in \tilde{\mathcal{M}}_j. \tag{3.26}$$

If $\mathbf{w}$ is in $\tilde{\mathcal{M}}_j^0$, then $\mathbf{w}_H = 0$ and hence $\mathbf{v}_P$ can be obtained by solving

$$A^{\varepsilon}(\mathbf{v}_P,\mathbf{w}) = F(\mathbf{w}) \quad \forall \quad \mathbf{w} \in \tilde{\mathcal{M}}_j^0. \tag{3.27}$$

Note that the stiffness matrix corresponding to (3.27) consists of a block diagonal matrix where the blocks are 3×3 matrices connecting the three unknowns corresponding to normal components along the edges of the center triangle of $\mathcal{T}_j$ inside a triangle of $\mathcal{T}_{j-1}$.

With $\mathbf{v}_P$ now known, we are left to compute $\mathbf{v}_H$. Note that

$$\begin{aligned} K(\mathbf{v}_H,\mathbf{w}_H) &= F(\mathbf{w}) - A^{\varepsilon}(\mathbf{v}_P,\mathbf{w}_P) \\ &= F(\mathbf{w}) - A^{\varepsilon}(\mathbf{v}_P,\mathbf{w}) \end{aligned} \tag{3.28}$$

for any $\mathbf{w} \in \tilde{\mathcal{M}}'_j$. Since by (3.18), the left side of (3.28) gives a symmetric positive definite quadratic form on $\tilde{\mathcal{M}}'_j \times \tilde{\mathcal{M}}'_j$, (3.28) provides an equation for determining the normal components of $\mathbf{v}_H$ on the edges of the triangulation $\mathcal{T}_{j-1}$. The computation of these edge values involves the inversion of a diagonal matrix. Let $\mathbf{v}_B$ denote any extension of these edge values (e.g., the function that has vanishing normal components on the nodes of the jth grid that are in the interior of triangles $t_{j-1} \in \mathcal{T}_{j-1}$). Then, the difference $\mathbf{v}_I = \mathbf{v}_H - \mathbf{v}_B \in \tilde{\mathcal{M}}_j^0$ can be computed from

$$\begin{aligned} A^{\varepsilon}(\mathbf{v}_I,\mathbf{w}) &= A^{\varepsilon}(\mathbf{v}_H,\mathbf{w}) - A^{\varepsilon}(\mathbf{v}_B,\mathbf{w}) \\ &= -A^{\varepsilon}(\mathbf{v}_B,\mathbf{w}) \quad \forall \quad \mathbf{w} \in \tilde{\mathcal{M}}_j^0. \end{aligned} \tag{3.29}$$

We summarize the process for solving the problem (3.26) in the following algorithm.

ALGORITHM 3.1.

(1) Find $\mathbf{v}_P$ by solving (3.27).
(2) Compute the normal components of $\mathbf{v}_H$ on the coarse grid edges in $\mathcal{E}_{j-1}$ by (3.28).
(3) Find the normal components of $\mathbf{v}_H$ on the edges in $\mathcal{E}_j$, which do not lie on the edges in $\mathcal{E}_{j-1}$, by solving the problem (3.29).
(4) Compute $\mathbf{v} = \mathbf{v}_P + \mathbf{v}_H$.

Remark 3.3. The preceding results can be extended to grids that are not quasi-uniform, such as locally refined grids. Stability for the Raviart–Thomas spaces in such applications was considered in [14]. As an example, suppose we have a family of nested subdomains,

$$\Omega_J \subseteq \Omega_{J-1} \subseteq \ldots \subseteq \Omega_0 = \Omega.$$

To define the triangulation on each Ω_j, first assume we have a quasi-uniform coarse grid triangulation $\mathcal{T}_0$ of Ω. Next, given that $\mathcal{T}_{j-1}$ has been defined for $j\epsilon[1,\ldots,J]$, we define $\mathcal{T}_j$ by subdividing each triangle of $\mathcal{T}_{j-1}$ contained in Ω_j into four congruent subtriangles. We assume that $\partial\Omega_j$ aligns with the mesh corresponding to $\mathcal{T}_{j-1}$. The space $\mathcal{M}$ is now defined to be the Raviart–Thomas space defined as in §§2 and 3 corresponding to the triangles in $\mathcal{T}_J$. Suppose the triangle $T_{j-1} \subset \Omega_{j-1}$ intersects Ω_j on an edge E_{j-1} of T_{j-1}. Then there are two triangles, t_j^ℓ in Ω_j with edges e_j^ℓ on $\Omega_j \cap \Omega_{j-1}, \ell = 1, 2$, such that $e_j^1 \cup e_j^2 = E_{j-1}$. We define the nodal values for the "slave nodes" corresponding to e_j^1 and e_j^2 to be the nodal value corresponding to E_{j-1}. Hence $\mathbf{v}\cdot n$ is constant on $e_j^1 \cup e_j^2$ for each $\mathbf{v}\epsilon\mathcal{M}$. It is easily seen that this sequence of spaces is nested and Theorems 3.1 and 3.2 hold. The proofs are essentially the same as before.

4. A multigrid method. In this section, we first define a natural class of multigrid methods for solving the penalty equation (2.8) in the variational framework of §§2 and 3. We then prove some crude estimates that, when combined with results in [7] and [8], give rise to convergence bounds for the multigrid algorithms. These bounds only guarantee a very slow rate of convergence which deteriorates drastically as ϵ and h become small. The rates are in agreement with those observed in the numerical experiments of §5. Thus, the penalty system (2.8) provides an example where the natural multigrid formulation leads to an extremely ineffective algorithm.

This discussion is included to illustrate an example of a problem on which the most natural multigrid algorithm fails. Alternative multigrid algorithms not involving the penalty reformulation have been analyzed and have been shown to be more effective (see, e.g., [5], [11], and [19]).

Consider the nested family of spaces, $\{\mathcal{M}_j\}$, of vector functions defined in §3. Let A_j denote the positive definite symmetric operator on $\mathcal{M}_j$ defined by

$$(A_j\mathbf{v},\mathbf{w}) = A^\epsilon(\mathbf{v},\mathbf{w}) \quad \forall \quad \mathbf{v},\mathbf{w} \in \mathcal{M}_j, \tag{4.1}$$

where A^ϵ is defined by (3.3); $(\cdot,\cdot)$ again denotes the inner product on $L^2(\Omega)\times L^2(\Omega)$ with corresponding norm, $\|\cdot\|$. Let λ_j denote the largest eigenvalue of A_j. Define smoothing operators $\{R_j\}$ on $\mathcal{M}_j$ for $j = 1,\ldots,J$ by

$$R_j\mathbf{u} = \frac{1}{3}\sum_{E\in\mathcal{E}_j} d_E^{-1}(\mathbf{u},\varphi_E)\,\varphi_E \quad \forall \quad \mathbf{u} \in \mathcal{M}_j, \tag{4.2}$$

where $d_E = A^\epsilon(\varphi_E,\varphi_E)$ and φ_E is the basis element for M_j associated with the edge E defined in §3. R_j is clearly symmetric and positive definite on M_j equipped with the $[L^2(\Omega)]^2$ inner product. Furthermore, applying Theorem 3.1 [8] and Remark 3.2 of [8] shows that R_j satisfies the inequalities

$$(R_jA_j\mathbf{u},A_j\mathbf{u}) \le (A_j\mathbf{u},\mathbf{u}) \quad \forall \quad \mathbf{u} \in M_j, \tag{4.3}$$

and

$$\frac{\|\mathbf{u}\|^2}{\lambda_j} \le C_R(R_j\mathbf{u},\mathbf{u}) \quad \forall \quad \mathbf{u} \in \mathcal{M}_j. \tag{4.4}$$

Here λ_j denotes the largest eigenvalue of A_j and the constant C_R does not depend on ϵ, j or h. Estimates of the form (4.3) and (4.4) are standard hypotheses for smoothers used in analyses of multigrid procedures.

We define a symmetric multigrid operator $B_J : \mathcal{M} \longrightarrow \mathcal{M}$ by induction. Let P^0_{j-1} denote the L^2 projection operator from $\mathcal{M}_j$ onto $\mathcal{M}_{j-1}$.

ALGORITHM 4.1.

Suppose n_j is a given positive integer for each $j = 1, \ldots, J$. Set $B_0 = A_0^{-1}$. For $j > 0$, assume that B_{j-1} has been defined and define $B_j\mathbf{g}$ for $\mathbf{g} \in \mathcal{M}_j$ as follows:

(i) Set $\mathbf{u}^0 = 0$ and define $\mathbf{u}^l$ for $l = 1, \ldots, n_j$ by

$$\mathbf{u}_j^l = \mathbf{u}_j^{l-1} + R_j(\mathbf{g} - A_j\mathbf{u}_j^{l-1}). \tag{4.5}$$

(ii) Define $\mathbf{u}_j^{n_j+1} = \mathbf{u}_j^{n_j} + \mathbf{q}$, where $\mathbf{q} \in \mathcal{M}_{j-1} \subset \mathcal{M}_j$ is defined by

$$\mathbf{q} = B_{j-1}P^0_{j-1}(\mathbf{g} - A_j\mathbf{u}^{n_j}) \tag{4.6}$$

(iii) Set $B_j\mathbf{g} = \mathbf{u}_j^{2n_j+1}$, where $\mathbf{u}_j^l$ is defined for $l = n_j + 2, \ldots, 2n_j + 1$ by (4.5).

Remark 4.1. Because of the operator P^0_{j-1} appearing in (4.6), it appears that it is necessary to solve a mass matrix problem associated with the subspace $\mathcal{M}_{j-1}$ each time q is calculated. In fact, it is possible to implement the above algorithm in a way which avoids such mass matrix problems. A discussion of how this can be done is given in the appendix of [9].

Algorithm 4.1 defines a symmetric operator acting on $\mathcal{M}_j$. This is referred to as a symmetric V-cycle. If step (iii) is omitted and we set $B_j\mathbf{g} = \mathbf{u}_j^{n_j+1}$, we have a nonsymmetric V-cycle. For the standard V-cycle, n_j is the same for all j. If the coarse grid correction in step (ii) is performed twice, we have a W-cycle algorithm.

Remark 4.2. Often, multigrid algorithms are developed as iterative processes in contrast to the operator approach taken above. The convergence rate of the multigrid process is determined by the norm of the iterative reduction operator. In terms of the operators defined above, the iterative reduction operator is equal to $I - B_JA_J$. It can be shown in the case of (4.3) that $I - B_JA_J$ is a nonnegative operator in the $A^\epsilon(\cdot,\cdot)$ inner product for symmetric cycling algorithms. Thus, convergence estimates for the multigrid processes follow directly from estimates for the lowest eigenvalue of the operator B_JA_J.

There are a number of equivalent conditions used in the literature that form a basis for the analysis of multigrid methods. For our purposes, we use a so-called "regularity and approximation" estimate (cf. [4] and [7]). To describe this condition, let P_{j-1} denote the A^ϵ-projection from $\mathcal{M}_j$ into $\mathcal{M}_{j-1}$, i.e., $P_{j-1}\mathbf{v} = \mathbf{w}$, where $\mathbf{w}$ is the unique function in $\mathcal{M}_{j-1}$ satisfying

$$A^\epsilon(\mathbf{w}, \theta) = A^\epsilon(\mathbf{v}, \theta) \quad \forall \quad \theta \in \mathcal{M}_{j-1}.$$

The regularity and approximation assumption involves inequalities of the form

$$A^\epsilon((I - P_{j-1})\mathbf{u}, \mathbf{u}) \le c(\epsilon, h)\lambda_j^{-1} \|A_j\mathbf{u}\|^2_{L^2(\Omega)} \quad \forall \quad \mathbf{u} \in \mathcal{M}_j, \qquad j = 1, \ldots, J. \tag{4.7}$$

Under (4.3), (4.4) and (4.7), it is possible to show (e.g., [7]) that the norm of the multigrid reduction operator $I - B_JA_J$ is bounded by $(1 + C/c(\epsilon, h))^{-1}$ where the constant C does not depend on ϵ and h. This is equivalent to saying that the condition number of the system B_JA_J is bounded by $1 + c(\epsilon, h)/C$.

In the case of standard finite element and finite difference multigrid applications, it is often possible to prove that the inequalities corresponding to (4.7) hold with a constant $c(\epsilon, h)$ which can be bounded independently of h [1], [7]. Thus, in the standard applications, it is often possible to prove uniform rates of convergence for the multigrid process. Equivalently, it is possible to show that the condition number of the system $B_J A_J$ remains bounded independently of the mesh parameters. Moreover, in cases when (4.7) does not hold uniformly due to deficient elliptic regularity, it is still possible to show that the rate of convergence can deteriorate at worst like a power of the number of grid levels [7], [12].

Returning to the application at hand, we note that $I - P_{j-1}$ is bounded with norm one as an operator with respect to the norm $(A^\epsilon(\cdot,\cdot))^{1/2}$. Consequently,

$$A^\epsilon((I - P_{j-1})\mathbf{u}, \mathbf{u}) \le A^\epsilon(\mathbf{u}, \mathbf{u}) \le c_j^{-1} \|A_j \mathbf{u}\|^2_{L^2(\Omega)} \quad \forall \quad \mathbf{u} \in \mathcal{M}_j.$$

Here c_j denotes the smallest eigenvalue of A_j. Consequently, (4.7) holds with $c(\epsilon, h) = \lambda_j / c_j$. It is not difficult to see that c_j is of unit size, while λ_j grows proportional to $\epsilon^{-1} h_j^{-2}$ with $h_j = 2^{J-j} h$. The multigrid analysis then shows that the reduction rate for the multigrid process (see Remark 4.2) is bounded by

$$\frac{1}{1 + Ch^2\epsilon},$$

and that the condition number of $B_J A_J$ is bounded by

$$1 + (Ch^2\epsilon)^{-1}. \tag{4.8}$$

The numerical results presented in §5 suggest that this extremely pessimistic bound for multigrid is qualitatively sharp. Thus, estimates with lesser asymptotic order of growth are not likely to hold.

The above estimate is indeed pessimistic. Note that the condition number of the original system is λ_J / c_J. Thus, application of the multigrid method does not appear to change the asymptotic behavior of the number of iterations required for convergence. However, there may be a possible improvement associated with application of the multigrid preconditioner since some initial convergence acceleration was observed in unreported preconditioned conjugate gradient examples. It is quite likely that this improvement may be attributed to the preconditioner tending to cluster the eigenvalues without significantly improving the condition number.

5. Numerical results.

We present the results of numerical experiments illustrating the condition numbers of the preconditioned systems discussed earlier. The numerical results for the hierarchical method show that this approach is relatively effective. In contrast, the numbers reported suggest that the multigrid iteration gives rise to a system with an extremely large condition number. This is in agreement with the estimates provided in §4.

We consider the model problem (2.1) with coefficient $k(x) \equiv 1$ where Ω is the unit square $(0,1) \times (0,1)$. The problem is discretized by the mixed finite element method with penalty. Specifically, the domain Ω is first partitioned into $n \times n$ square subdomains of side length $1/n$. The $n \times n$ subsquares are then divided into pairs of triangles by connecting the bottom left and upper right corners. Subsequently, finer grids are developed as in §3, i.e., by dividing each triangle into four triangles formed by the edges of the original triangle and the lines connecting the centers of these edges. The approximation spaces $\{\mathcal{M}_j\}$ are defined to be the set of vector functions that are piecewise linear with respect to the triangulations with continuous normal components across the edges of the triangles as described in §3.

We will illustrate the rate of convergence of the hierarchical and multigrid preconditioned algorithms for solving the penalty equation (2.8), where $A^\epsilon(\cdot,\cdot)$ is defined in (3.3) with $a \equiv 1$. In the case of the hierarchical preconditioner, we numerically compute the largest and smallest generalized eigenvalues of the system

$$\lambda \tilde{B}^\epsilon(\mathbf{v},\cdot) = A^\epsilon(\mathbf{v},\cdot). \tag{5.1}$$

Theorem 3.2 provides the bounds $\lambda_{\max} \le c_2 J$ and $\lambda_{\min} \ge c_1 2^{-J}$ where c_1 and c_2 are the constants appearing in (3.25). The rate of convergence for preconditioned iterative schemes for solving (2.8) with preconditioner $\tilde{B}^\epsilon$ can be bounded in terms of the condition number $K(\tilde{B}^\epsilon A^\epsilon) = \lambda_{\max}/\lambda_{\min}$. In the case of preconditioned conjugate gradient iteration, the asymptotic reduction per step can be bounded by

$$\rho = \frac{\sqrt{\lambda_{\max}} - \sqrt{\lambda_{\min}}}{\sqrt{\lambda_{\max}} + \sqrt{\lambda_{\min}}}. \tag{5.2}$$

We note that both the hierarchical and multigrid methods require solving or preconditioning the coarse grid problem. In the reported runs, we always solved the coarse grid problems exactly.

Table 5.1 gives the largest and smallest eigenvalues of (5.1) as a function of J, $n = 1/h$ and ϵ. These results clearly demonstrate that the largest and smallest eigenvalues can be bounded independently of the parameter ϵ for a fixed number of levels. We also note that the largest generalized eigenvalue increases somewhat less than linearly with the number of levels. The smallest eigenvalues decrease with the number of levels but not as fast as suggested by the theory. This may be because we are not yet into the asymptotic range. Overall, the numerically computed eigenvalues are in agreement with the theory of §3.

The corresponding condition numbers can be computed by taking the ratio of the largest to smallest eigenvalue in Table 5.1. For all of the runs reported, the condition numbers are in the interval [8, 56].

In the case of multigrid iteration, the rate of convergence is determined by the smallest eigenvalue. If the multigrid process is directly applied, then the reduction is

$$\rho = 1 - \lambda_{\min}.$$

Alternatively, if the multigrid operator is used to accelerate the convergence of conjugate gradient, the average reduction per step is bounded by (5.2) where $\lambda_{\max} = 1$.

We ran into some numerical difficulty computing the lowest eigenvalue for the multigrid process. This is because iterative eigenvalue estimation procedures can converge rather slowly when applied to systems with large condition numbers and possible eigenvalue clustering. We ran the eigenvalue iteration for a thousand iterations on each problem. Although in some cases it was hard to be completely satisfied that the eigenvalue iteration converged, the procedure always provided a valid upper bound for the lowest eigenvalue. Thus, the actual eigenvalue is always smaller than that reported in Table 5.2 and the actual condition number is always worse than the reported estimate.

The numerical results given in Table 5.2 for the symmetric multigrid V-cycle show that the method does not perform well on this application. We see that a decrease in ϵ of a factor of ten leads to roughly a factor of ten increase in the condition number. Similarly, a decrease in mesh size by a factor of two leads to roughly a factor of four increase in the condition number. This is in qualitative agreement with the theoretical estimate (4.8).

TABLE 5.2
The smallest eigenvalue and condition number for the multigrid process.

	$\epsilon = 1$		$\epsilon = .1$		$\epsilon = .01$	
$1/h$	$\lambda_{\max}$	K	$\lambda_{\max}$	K	$\lambda_{\max}$	K
8	1.3×10^{-3}	7.7×10^{2}	1.7×10^{-4}	6.0×10^{3}	1.8×10^{-5}	5.7×10^{4}
16	4.0×10^{-4}	2.5×10^{3}	4.5×10^{-5}	2.2×10^{4}	4.6×10^{-6}	2.2×10^{5}
32	1.1×10^{-4}	9.1×10^{3}	1.2×10^{-5}	8.8×10^{4}	1.2×10^{-6}	8.8×10^{5}

Remark 5.1. We also numerically tested the number of iterations required for a prescribed error reduction using multigrid both as a solver by itself and as a preconditioner for conjugate gradient. Multigrid used by itself failed to converge in a realistic number of iterations. This is consistent with the condition number estimates in Table 5.2. However, when used as a preconditioner, the results were somewhat better. A reasonable rate of reduction (although not as fast as that corresponding to the hierarchical method) was observed in the earlier iterations. This is probably due to some clustering of the eigenvalues.

ON A MULTIVARIATE EIGENVALUE PROBLEM, PART I: ALGEBRAIC THEORY AND A POWER METHOD*

MOODY T. CHU† AND J. LOREN WATTERSON‡

Abstract. Multivariate eigenvalue problems for symmetric and positive definite matrices arise from multivariate statistics theory where coefficients are to be determined so that the resulting linear combinations of sets of random variables are maximally correlated. By using the method of Lagrange multipliers such an optimization problem can be reduced to the multivariate eigenvalue problem. For over 30 years an iterative method proposed by Horst [*Psychometrika*, 26 (1961), pp. 129–149] has been used for solving the multivariate eigenvalue problem. Yet the theory of convergence has never been complete. The number of solutions to the multivariate eigenvalue problem also remains unknown. This paper contains two new results. By using the degree theory, a closed form on the cardinality of solutions for the multivariate eigenvalue problem is first proved. A convergence property of Horst's method by forming it as a generalization of the so-called power method is then proved. The discussion leads to new formulations of numerical methods.

1. Introduction.

Given a symmetric and positive definite matrix $A \in R^{n\times n}$ and a set

$$P := \{n_1, \dots, n_m\} \tag{1}$$

of positive integers with $\sum_{i=1}^m n_i = n$, let A be partitioned into blocks

$$A = \begin{bmatrix} A_{11} & A_{12} & \cdots & A_{1m} \\ A_{21} & A_{22} & \cdots & A_{2m} \\ \vdots & \vdots & & \vdots \\ A_{m1} & A_{m2} & \cdots & A_{mm} \end{bmatrix} \tag{2}$$

with $A_{ii} \in R^{n_i \times n_i}$. A *multivariate eigenvalue problem* (MEP) is to find real scalars $\lambda_1, \dots, \lambda_m$ and a real column vector $x \in R^n$ such that equations

$$Ax = \Lambda x, \tag{3}$$

$$\|x_i\| = 1, \qquad i = 1, \dots, m \tag{4}$$

are satisfied, where Λ is the diagonal matrix

$$\Lambda = \operatorname{diag}\{\lambda_1 I^{[n_1]}, \dots, \lambda_m I^{[n_m]}\} \tag{5}$$

and where $I^{[n_i]}$ is the identity matrix of size n_i and $x \in R^n$ is partitioned into blocks

$$x = [x_1^T, \dots, x_m^T]^T, \tag{6}$$

with $x_i \in R^{n_i}$.

‡Department of Mathematics, North Carolina State University, Raleigh, North Carolina 27695-8205.

We first note that a multivariate eigenvalue problem is fundamentally different from the so-called multiparameter eigenvalue problem [19]. The latter problem is, given $A_i, B_{is} \in R^{n_i \times n_i}$, to solve the equations

$$\left(A_i - \sum_{s=1}^{m} \lambda_s B_{is}\right) x_i = 0, \qquad i = 1, \ldots, m, \tag{7}$$

for $\lambda = [\lambda_1, \ldots, \lambda_m]^T \in R^m$ and $x_i \in R^{n_i}$.

Equations (3) and (4) represent a nonlinear algebraic system in $n + m$ unknowns. Trivially, if $m = 1$, then (3) is simply a classical symmetric eigenvalue problem. In this case it is well understood that, counting multiplicity, there are exactly n eigenvalues and that, counting negative signs, there are exactly $2n$ eigenvectors if all eigenvalues are distinct. When $m > 1$, however, the concept of characteristic polynomial is no longer applicable. In fact, very little theory is known concerning the characteristic of a solution to the MEP.

The first contribution of this paper is that we are able to determine the cardinality of solutions to the MEP by using degree theory. We prove that a total of $\prod_{i=1}^{m} 2n_i$ solutions exist for the MEP in the generic case. Our method is similar in spirit to that developed in [3], with generalizations. The result apparently is new. As a by-product, homotopy may also be used as a numerical method to find *all* solutions, if so desired, of the MEP.

The MEP has its origins in the determination of canonical correlation coefficients for multivariate statistics [10], [12], [13]. Its history goes back to when Hotelling [10] first studied the so-called maximal correlation problem, which later was developed into what is known as canonical correlation analysis. The numerical method proposed then was somewhat awkward and inefficient. Later, Horst [12] proposed an iterative approach for solving the maximal correlation problem. In spite of a seemingly successful numerical experiment, however, no rigorous proof has ever been developed to show that the iterative procedure converges and that the limit point obtained gives maximal correlation.

The second contribution of this paper is that we reformulate Horst's iterative algorithm as a generalization of the so-called power method [8]. We provide a proof that shows the method does converge monotonically, but only to a *local* maximal correlation. We give an example that shows that Horst's iteration has a good chance of not converging to the *absolute* maximal correlation.

The paper is organized as follows. The statistical background of the MEP is reviewed in §2. Readers who are familiar with the background of the MEP or who are interested only in linear algebra may pass over this section entirely. In §3 we use homotopy theory to prove the cardinality of solutions to the MEP. To accomplish this we establish several auxiliary lemmas that are of interest in their own right. In §4 we reformulate Horst's algorithm and prove the convergence properties. The key of our success lies in the fact that there are only finitely many solutions to the MEP.

Many open questions remain to be studied. The power method can be thought of as a Jacobi-like iterative scheme. Thus other iterative techniques used for linear algebraic equations [9], such as the Gauss–Seidel method or the SOR method, can be modified for solving the MEP. Multivariate shifting is another possible way to find other solutions of the MEP. Some of these issues are briefly mentioned in §5. The details of these new formulations will be discussed in a forthcoming paper [6].

2. Statistical background.

In this section we provide a somewhat detailed statistical background of the MEP. The discussion should also make this paper more self-contained.

However, readers may choose to skip this section entirely without worries of discontinuity. For clarity, the following rule is used in establishing the notation. A calligraphic letter, e.g., $\mathcal{X}$, denotes a scalar random variable, an accented letter, e.g., $\tilde{X}$, denotes an array of random variables, and an uppercase letter, e.g., X or Ω, denotes a matrix.

Given an n-dimensional random variable $\tilde{X} := (\mathcal{X}_1, \ldots, \mathcal{X}_n)$ with a certain distribution function, let $[x_{\xi 1}, \ldots, x_{\xi n}]$, $\xi = 1, \ldots, k$, denote a random sample of size k of this variable. For convenience we use

$$X := [x_{\xi i}] \tag{8}$$

to denote the $k \times n$ sample matrix. Since the notion for a random variable can be carried over in a parallel manner to a random sample and vice versa, in what follows we shall not make a careful distinction between a random variable $\mathcal{X}_i$ and its corresponding random sample $[x_{1i}, \ldots, x_{ki}]^T$.

By shifting if necessary, we may assume without loss of generality that the sample mean $\mu_i := \sum_{\xi=1}^{k} \frac{x_{\xi i}}{k}$ for each of the random variable $\mathcal{X}_i$ is zero. It follows then that the $n \times n$ matrix

$$\Delta := X^T X \tag{9}$$

represents the covariance matrix of the random sample X. Clearly, Δ is symmetric. We further assume as a generic case that there is no degenerate component and no linear dependence among the components $\mathcal{X}_1, \ldots, \mathcal{X}_n$. It is well known that Δ is positive definite [22].

Corresponding to the same conformation as in (6), let the components of $\tilde{X}$ be divided into mutually disjoint groups

$$\tilde{X} = (\tilde{X}_1, \ldots, \tilde{X}_m). \tag{10}$$

Then each $\tilde{X}_i$ is an n_i-dimensional random variable. Let the matrix

$$\Delta = [\Delta_{ij}] \tag{11}$$

be partitioned in the same way as (2). Then Δ_{ii} represents the covariance matrix of the $k \times n_i$ sample block X_i, where the sample matrix X is partitioned as

$$X = [X_1, \ldots, X_m]. \tag{12}$$

In practice it is often desirable to simplify the analysis by combining all n_i components of $\tilde{X}_i$ linearly into a single new variable $\mathcal{Z}_i$. For $i = 1, \ldots, m$ let $b_i \in R^{n_i}$ denote the coefficients of linear combinations for variable $\tilde{X}_i$. Define the $n \times m$ matrix

$$B := \begin{bmatrix} b_1 & 0 & \cdots & 0 \\ 0 & b_2 & & 0 \\ \vdots & & \ddots & \vdots \\ 0 & & \cdots & b_m \end{bmatrix}. \tag{13}$$

Then the sample matrix X is transformed into the $n \times m$ matrix

$$Z := XB := [Z_1, \ldots, Z_m]. \tag{14}$$

The covariance matrix corresponding to the new random sample Z is given by

$$\Omega := Z^T Z = B^T \Delta B. \tag{15}$$

Consider the case $m = 2$ as an example. It is often desirable to use $\mathcal{Z}_1$ to predict $\mathcal{Z}_2$. Thus it is imperative to find b_1 and b_2 so that the correlation coefficient between the two new random samples Z_1 and Z_2 is as large as possible. The covariance matrix of Z is seen to be the 2×2 matrix

$$\Omega = \begin{bmatrix} b_1^T \Delta_{11} b_1 & b_1^T \Delta_{12} b_2 \\ b_2^T \Delta_{21} b_1 & b_2^T \Delta_{22} b_2 \end{bmatrix}. \tag{16}$$

The correlation coefficient ρ to be maximized is

$$\rho = \frac{b_1^T \Delta_{12} b_2}{\sqrt{b_1^T \Delta_{11} b_1}\sqrt{b_2^T \Delta_{22} b_2}}. \tag{17}$$

If the variances of Z_1 and Z_2 are normalized to unity, then to maximize ρ is equivalent to

$$\text{maximize} \quad b^T \Delta b \tag{18}$$

$$\text{subject to} \quad b_i^T \Delta_{ii} b_i = 1 \quad \text{for } i = 1, 2, \tag{19}$$

where

$$b := [b_1^T, b_2^T]^T. \tag{20}$$

Since each Δ_{ii} is symmetric and positive definite, the Cholesky decomposition

$$\Delta_{ii} = T_i^T T_i \tag{21}$$

exists. Introduce the block diagonal matrix

$$T := \operatorname{diag}\{T_1, T_2\}, \tag{22}$$

and define

$$x := Tb := [x_1^T, x_2^T]^T, \tag{23}$$

$$A := T^{-T} \Delta T^{-1}, \tag{24}$$

where $T^{-T} = {T^{-1}}^T$. Clearly, A is still symmetric and positive definite. The problem (18) and (19) is now transformed into

$$\text{maximize} \quad x^T A x \tag{25}$$

$$\text{subject to} \quad x_i^T x_i = 1 \quad \text{for } i = 1, 2. \tag{26}$$

Using the method of Lagrange multipliers [17], we now form the Lagrangian function

$$\phi(x, \lambda_1, \lambda_2) := x^T A x - \sum_{i=1}^{2} \lambda_i (x_i^T x_i - 1), \tag{27}$$

with λ_1 and λ_2 as the Lagrange multipliers. Upon differentiating (27) it is clear that the maximal correlation problem (18) and (19) for $m = 2$ is reduced to the 2-variate eigenvalue problem (3) and (4).

When $m > 2$ the requirement of maximizing the correlation coefficients among the m random samples $Z_1, \ldots, Z_m$ needs to be modified. Intuitively, the more *similar* the vectors $Z_1, \ldots, Z_m$ are to each other, the more closely the correlation coefficients will approach unity. Thus it makes sense to require that the sum of the off-diagonal elements of $m \times m$ matrix Ω in (15) be maximized subject to the condition that the diagonal elements of Ω be unity. Apparently, the maximal correlation problem for the $m > 2$ case can now be formulated in the same way as (18) and (19). We may repeat the same procedure as for the case $m = 2$ to argue that a solution to the maximal correlation problem

$$\text{(28)} \qquad \text{maximize} \quad x^T A x$$

$$\text{(29)} \qquad \text{subject to} \quad x_i^T x_i = 1 \quad \text{for } i = 1, \ldots, m$$

is necessarily a solution to the multivariate eigenvalue problem.

Suppose that a set of solutions $\{b_1^{(1)}, \ldots, b_m^{(1)}\}$ to the maximal correlation problem has been determined. We may wish to find yet another set of solutions $\{b_1^{(2)}, \ldots, b_m^{(2)}\}$ so that the resulting composites $Z_1^{(2)}, \ldots, Z_m^{(2)}$ are also maximally correlated. Since the second measurement is conducted independently of the first, it is natural to require that variables within the same class are uncorrelated, that is, each $Z_i^{(2)}$ is correlated zero with the corresponding $Z_i^{(1)}$. This procedure may be repeated until we have obtained $p := \min\{n_1, \ldots, n_m\}$ sets of solutions. The zero correlation is required between any two variables in the class $\{Z_i^{(1)}, \ldots, Z_i^{(p)}\}$. The reason that such a repeated measurement is needed can be found from many practical applications [10], [12], [13]. We note that variables from different classes are not subject to any correlation restrictions, although ideally we would like these variables to be zero correlated as well.

The new problem mentioned above was originally studied by Hotelling [10], who mainly focused on the case in which $m = 2$, but the numerical method proposed was very inefficient. Horst [12] then developed a direct approach (for $m = 2$), which we found to use techniques of what is now known as singular-value decomposition. It is worthwhile to rewrite the direct method in terms of the current notion as follows.

We first generalize the notation B in (13) to be the $n \times 2p$ matrix

$$\text{(30)} \qquad B := \begin{bmatrix} B_1 & 0 \\ 0 & B_2 \end{bmatrix} := \begin{bmatrix} b_1^{(1)} & \cdots & b_1^{(p)} & 0 & \cdots & 0 \\ 0 & \cdots & 0 & b_2^{(1)} & \cdots & b_2^{(p)} \end{bmatrix}.$$

The random sample Z then becomes an $n \times 2p$ matrix

$$\text{(31)} \qquad Z := XB := [Z_1^{(1)}, \ldots, Z_1^{(p)}, Z_2^{(1)}, \ldots, Z_2^{(p)}].$$

Consider the $2p \times 2p$ covariance matrix $\Omega = B^T \Delta B$ of Z. Recall that each Δ_{ii} has a Cholesky decomposition (21). Let

$$\text{(32)} \qquad T_1^{-T} \Delta_{12} T_2^{-1} = Q_1^T D Q_2$$

be the singular-value decomposition [8] of the $n_1 \times n_2$ matrix $T_1^{-T}\Delta_{12}T_2^{-1}$. It follows that

$$(33)\quad \Omega = \begin{bmatrix} B_1^T T_1^T Q_1^T & 0 \\ 0 & B_2^T T_2^T Q_2^T \end{bmatrix} \begin{bmatrix} I^{[n_1]} & D \\ D & I^{[n_2]} \end{bmatrix} \begin{bmatrix} Q_1 T_1 B_1 & 0 \\ 0 & Q_2 T_2 B_2 \end{bmatrix}.$$

If we choose the vectors in B_1 and B_2 to be

$$(34)\qquad B_1 = T_1^{-1} Q_1^T I_{n_1 \times p},$$

$$(35)\qquad B_2 = T_2^{-1} Q_2^T I_{n_2 \times p},$$

where $I_{s \times t}$ means the first $s \times t$ submatrix of the identity, then

$$(36)\qquad \Omega = \begin{bmatrix} I^{[p]} & \Sigma \\ \Sigma & I^{[p]} \end{bmatrix},$$

where Σ is the diagonal matrix of singular values $\sigma_1 \geq \cdots \geq \sigma_p \geq 0$. In other words, if (34) and (35) are satisfied, then σ_i is precisely the highest correlation coefficient between $Z_1^{(i)}$ and $Z_2^{(i)}$, and each of these two variables is uncorrelated to any other $Z_s^{(t)}$ for $s =$ 1 or 2 and $t \neq i$.

For $m > 2$ the coefficient matrix B is generalized to a block diagonal matrix

$$(37)\qquad B := \operatorname{diag}\{B_1, \ldots, B_m\},$$

where each B_i is an $n_i \times p$ matrix

$$(38)\qquad B_i := \left[b_i^{(1)}, \ldots, b_i^{(p)}\right]$$

and the random sample becomes

$$(39)\qquad Z := XB := [Z_1^{(1)}, \ldots, Z_1^{(p)}, \ldots, Z_m^{(1)}, \ldots, Z_m^{(p)}].$$

Unfortunately, Horst's direct method cannot be generalized to solve the general m case. The reason is simply that there is no way to transform all $m \times m$ blocks of size $p \times p$ in

$$(40)\qquad \Omega = [B_i^T \Delta_{ij} B_j]$$

into diagonal matrices simultaneously when $m > 2$. To remedy this, it was at this point that Horst introduced his iterative method [12], [13] without a proof.

3. Homotopy method and cardinality.

In this section we use degree theory to prove the cardinality of solutions to the MEP. The theory has been used as a major tool in analysis to prove the existence of solutions for a wide variety of problems. For a complete mathematical treatment of the theory, we refer the reader to [16]. Degree theory can often be implemented as a numerical means, known as the homotopy method, of computing a solution of a nonlinear system. Applications of homotopy methods can be found, for example, in [1]–[5], [7], [15], [18], [20], [21].

Rewrite the multivariate eigenvalue problem as a nonlinear system:

$$(41)\qquad F(x, \Lambda) = 0,$$

where $F : R^n \times R^m \longrightarrow R^n \times R^m$ is defined by

$$F(x, \Lambda) := \begin{bmatrix} \Lambda x - Ax \\ \frac{x_1^T x_1 - 1}{2} \\ \vdots \\ \frac{x_m^T x_m - 1}{2} \end{bmatrix}. \tag{42}$$

In general, it is not an easy task to find a solution for (41). It seems perhaps even harder to count the total number of solutions. On the other hand, consider a simple MEP:

$$\begin{aligned} Dx &= \Lambda x, \\ \|x_i\| &= 1, \qquad i = 1, \ldots, m, \end{aligned} \tag{43}$$

where D is a diagonal matrix with distinct elements $d_1^{(1)}, \ldots, d_{n_1}^{(1)}, \ldots, d_1^{(m)}, \ldots, d_{n_m}^{(m)}$. It is trivial to see the following lemma.

LEMMA 3.1. *The problem* (43) *has exactly* $\prod_{i=1}^m 2n_i$ *solutions. These are, for* $i = 1, \ldots, m$,

$$\begin{aligned} \lambda_i &= d_{j_i}^{(i)}, \\ x_i &= \pm e_{j_i}^{[n_i]}, \end{aligned} \tag{44}$$

where $j_i = 1, \ldots, n_i$ *and* $e_s^{[t]}$ *denotes the sth column of the identity matrix* $I^{[t]}$.

Our basic idea is to construct a homotopy between (43) and (3) so that no homotopy curve will escape to infinity or turn back. Toward this end we define a function $H : R^n \times R^m \times R \longrightarrow R^n \times R^m$ as follows:

$$H(x, \Lambda, t; D) := \begin{bmatrix} \Lambda x - [D + t(A - D)]x \\ \frac{x_1^T x_1 - 1}{2} \\ \vdots \\ \frac{x_m^T x_m - 1}{2} \end{bmatrix}, \tag{45}$$

where D is a diagonal matrix whose elements will be specified later. The main concern is to show that the Jacobian $D_{x,\Lambda,t}H$ of H is of full rank if D is appropriately chosen. In what follows we establish several auxiliary lemmas to help this investigation. The lemmas, which themselves are of interest, concern the spectrum property when a simple matrix M is perturbed by a diagonal matrix.

A matrix M is simple if and only if the algebraic multiplicities and geometric multiplicities of each of its eigenvalues coincide. Symmetric matrices are automatically simple. We begin with a fact that follows from a more general result in [11, Thm. 1.4.9].

LEMMA 3.2. *Suppose that* M *is a simple matrix in* $R^{n \times n}$ *and that* $r \geq 1$ *is a positive integer. Then* λ *is an eigenvalue of* M *of multiplicity* r *if and only if* λ *is an eigenvalue of all* $q \times q$ *principal submatrices of* M *whenever* $q \geq n - r + 1$.

For convenience we denote the diagonally perturbed matrix by

$$\mathcal{M} = \mathcal{M}(D) := M + D, \tag{46}$$

with $D = \operatorname{diag}\{d_1, \ldots, d_n\}$. We claim the following.

LEMMA 3.3. *Let $E := \{(d_1, \ldots, d_n) \in R^n | \mathcal{M}$ has multiple eigenvalues$\}$. Then the complement U of E is open, is dense, and has full Lebesgue measure in R^n.*

Proof. Let

$$E_r := \{(d_1, \ldots, d_n) \in R^n | \mathcal{M} \text{ has zero eigenvalue of multiplicity } r\}. \tag{47}$$

By Lemma 3.2 there exists an $(n - r) \times (n - r)$ principal submatrix $\hat{\mathcal{M}}$ of $\mathcal{M}$ such that $\hat{\mathcal{M}}$ is nonsingular. Without loss of generality we may assume $\hat{\mathcal{M}}$ is the leading principal submatrix of $\mathcal{M}$, i.e., $\hat{\mathcal{M}}$ is indexed by $\{1, \ldots, n - r\}$. All principal submatrices of $\mathcal{M}$ with size $\geq n - r + 1$ are singular. In particular, for $i = 1, \ldots, r$ the principal submatrix $\mathcal{M}_i$ indexed by $\{1, \ldots, n - r, n - r + i\}$ is singular.

Define

$$f_i(d_1, \ldots, d_n) := \det(\mathcal{M}_i). \tag{48}$$

Then the value of $(d_1, \ldots, d_n)$ that causes $\mathcal{M}$ to have rank $n - r$ must satisfy the system of equations

$$\mathcal{F}(d_1, \ldots, d_n) = 0, \tag{49}$$

where $\mathcal{F} : R^n \longrightarrow R^r$ is defined by $\mathcal{F} := (f_1, \ldots, f_r)$.

Observe that

$$\frac{\partial f_i}{\partial d_{n-r+i}} = \det(\hat{\mathcal{M}}) \neq 0, \tag{50}$$

and hence

$$\frac{\partial \mathcal{F}}{\partial(d_{n-r+1}, \ldots, d_n)} = \det(\hat{\mathcal{M}}) I^{[r]} \tag{51}$$

is nonsingular. By the implicit function theorem we thus know that $\{d_{n-r+1}, \ldots, d_n\}$ can be rewritten as functions of $\{d_1, \ldots, d_{n-r}\}$. Thus E_r is necessarily embedded in a manifold of dimension $n - r$.

Let $e := [1, \ldots, 1] \in R^n$. Obviously, $\langle e \rangle \oplus E_r$ contains all values of $(d_1, \ldots, d_n)$ such that $M + D$ has an eigenvalue of multiplicity r. From the fact that

$$E = \langle e \rangle \oplus \bigcup_{r=2}^{n} E_r \tag{52}$$

we see that U is open, is dense, and has full Lebesgue measure in R^n. $\square$

By using the resultant theorem a complex version of the above lemma has been proved in [5, Thm. 2.3]. The new contribution here is that Lemma 3.3 is for real simple matrices perturbed by real diagonal matrices.

We note that (49) is only a necessary condition for $\mathcal{M}$ being rank deficient by r. Conceivably, the set E_r could be much smaller than what the dimension $n - r$ suggests. This is especially so when M is a symmetric matrix since we have the following observation.

Rewrite $\mathcal{M}$ as

$$\mathcal{M} = \begin{bmatrix} \hat{\mathcal{M}} & \hat{\mathcal{P}} \\ \hat{\mathcal{P}}^T & \hat{\mathcal{R}} \end{bmatrix}. \tag{53}$$

Let

$$\hat{\mathcal{L}} = \begin{bmatrix} I^{[n-r]} & 0 \\ -(\hat{\mathcal{M}}^{-1}\hat{\mathcal{P}})^T & I^{[r]} \end{bmatrix}. \tag{54}$$

Then the rank condition of $\mathcal{M}$ is the same as that of

$$\mathcal{N} := \hat{\mathcal{L}}\mathcal{M}\hat{\mathcal{L}}^T = \begin{bmatrix} \hat{\mathcal{M}} & 0 \\ 0 & \hat{\mathcal{R}} - \hat{\mathcal{P}}^T\hat{\mathcal{M}}^{-1}\hat{\mathcal{P}} \end{bmatrix}. \tag{55}$$

In particular, if $\mathcal{M}$ is of rank $n-r$, then the lower-right $r \times r$ block of $\mathcal{N}$ must be identically zero, which gives rise to $r(r+1)/2$ equations in the $d_1, \ldots, d_n$.

The r diagonal elements of $\hat{\mathcal{R}} - \hat{\mathcal{P}}^T\hat{\mathcal{M}}^{-1}\hat{\mathcal{P}}$ are readily solvable for $d_{n-r+1}, \ldots, d_n$ in terms of $d_1, \ldots, d_{n-r}$, as is predicted by the implicit function theorem in the proof of Lemma 3.3. The off-diagonal elements impose $r(r-1)/2$ extra conditions that $d_1, \ldots, d_{n-r}$ must satisfy. For $r = 2$ it is easy to see that this extra condition is not a trivial equation for $d_1, \ldots, d_{n-2}$. Therefore, E_2 should be a manifold of dimension $n-3$ (rather than $n-2$). It should be rather obvious (although tedious to prove) that E_r is generally a manifold of codimension $r(r+1)/2$ since there are a total of $r(r+1)/2$ equations that $d_1, \ldots, d_n$ must satisfy. Obviously, E_r is empty if r is too large. Indeed, by the Wilson–Ledermann bound [14], E_r is empty if

$$r > \left\lceil \frac{2n+1-\sqrt{8n+1}}{2} \right\rceil. \tag{56}$$

We do not intend to provide here a proof for the exact dimension of each E_r. For the purpose of this paper it suffices to see from the above argument that the following lemma holds.

LEMMA 3.4. *For any generic and symmetric matrix M,* $\dim(E_r) \leq n-3$ *for $r \geq 2$ and hence* $\dim(E) \leq n-2$.

We demonstrate the case $n = 4$ and $r = 2$ as an example. Suppose M is denoted as $M := [m_{ij}]$. The extra equation to be satisfied by d_1 and d_2 is

$$m_{34} = \frac{m_{13}m_{22}m_{14}+m_{14}m_{13}d_2-m_{12}m_{14}m_{23}+d_1m_{24}m_{23}-m_{12}m_{13}m_{24}+m_{24}m_{23}m_{11}}{m_{11}m_{22}+m_{11}d_2+d_1m_{22}+d_1d_2-m_{12}^2},$$

and E_2 is made of points (d_1, d_2, d_3, d_4), where

$$d_2 = \frac{d_1m_{24}m_{23}-d_1m_{22}m_{34}-m_{22}m_{34}m_{11}+m_{13}m_{22}m_{14}+m_{34}m_{12}^2+m_{24}m_{23}m_{11}-m_{12}m_{14}m_{23}-m_{12}m_{13}m_{24}}{d_1m_{34}+m_{34}m_{11}-m_{14}m_{13}},$$

$$d_3 = \frac{d_1m_{23}m_{34}-d_1m_{33}m_{24}+m_{11}m_{23}m_{34}-m_{13}m_{14}m_{23}+m_{24}m_{13}^2-m_{12}m_{13}m_{34}+m_{12}m_{33}m_{14}-m_{11}m_{33}m_{24}}{d_1m_{24}+m_{24}m_{11}-m_{14}m_{12}},$$

$$d_4 = \frac{d_1m_{24}m_{34}-d_1m_{23}m_{44}+m_{11}m_{24}m_{34}-m_{14}m_{13}m_{24}-m_{12}m_{14}m_{34}-m_{11}m_{23}m_{44}+m_{23}m_{14}^2+m_{12}m_{13}m_{44}}{d_1m_{23}-m_{13}m_{12}+m_{23}m_{11}}.$$

Obviously, E_2 is a 1-dimensional manifold parameterized in d_1.

We are now ready to establish one of the major results.

LEMMA 3.5. *The set of D such that the matrix $\Lambda - (D + t(A-D))$ is of rank less than $n-m$ for some Λ and some $t \in (0,1)$ is of measure zero.*

Proof. For convenience we denote

$$\mathcal{A} = \mathcal{A}(\Lambda, t, D) := \Lambda - (D + t(A - D)). \tag{57}$$

Observe that each of the m diagonal blocks of $\mathcal{A}$ takes the form

$$\mathcal{A}_{ii} = \lambda_i I^{[n_i]} - (1-t)\text{diag}(d_1^{(i)}, \ldots, d_{n_i}^{(i)}) - tA_{ii}. \tag{58}$$

If the rank of $\mathcal{A}$ is less than $n - m$, then one of the diagonal blocks of $\mathcal{A}$ must be rank deficient by at least two. Equivalently, this implies that for some $\tau \in (0, \infty)$ the matrix τ diag $(d_1^{(i)}, \ldots, d_{n_i}^{(i)}) + A_{ii}$ has an eigenvalue with multiplicity at least two. By Lemma 3.4 the union over τ

$$\bigcup_{\tau \in (0,\infty)} \{(d_1^{(i)}, \ldots, d_{n_i}^{(i)}) | \tau \text{ diag } (d_1^{(i)}, \ldots, d_{n_i}^{(i)}) + A_{ii} \text{ has multiple eigenvalues}\}$$

is of dimension at most $n_i - 1$. Thus, overall, the set of D such that $\Lambda - (D + t(A - D))$ is of rank less than $n - m$ for some Λ and some $t \in (0, 1)$ is at most of geometric dimensional $n - 1$. $\square$

Henceforth we shall assume that D in (45) has been chosen so that $\mathcal{A}(\Lambda, t, D)$ has rank at least $n - m$ for all Λ and all t. We now prove the existence of the homotopy curves.

LEMMA 3.6. *The point* $0 \in R^n \times R^m$ *is a regular value for* H. *That is, for each* $(x, \Lambda, t) \in R^n \times R^m \times R$ *such that* $H(x, \Lambda, t) = 0$, *the Jacobian matrix* $D_{(x,\Lambda,t)}H$ *has rank* $n + m$.

Proof. For convenience we divide the Jacobian matrix $D_{(x,\Lambda,t)}H$ into blocks:

$$\begin{bmatrix} \mathcal{A} & \mathcal{B} & \mathcal{C} \\ \mathcal{B}^T & 0 & 0 \end{bmatrix}, \tag{59}$$

where $\mathcal{A}$ is as given in (57),

$$\mathcal{B} := \begin{bmatrix} x_1 & 0 & \ldots & 0 \\ 0 & x_2 & \cdots & 0 \\ \vdots & & \ddots & \vdots \\ 0 & & \cdots & x_m \end{bmatrix}, \tag{60}$$

and

$$\mathcal{C} := (D - A)x. \tag{61}$$

If $H(x, \Lambda, t) = 0$, then

$$\mathcal{A}x = 0, \tag{62}$$

which indicates that x is an eigenvector of $\mathcal{A}$ with corresponding eigenvalue zero.

Suppose that for a certain $1 \leq i \leq m$ there exists $y_i \in R^n$ such that

$$\mathcal{A}y_i = \begin{bmatrix} 0 \\ \vdots \\ x_i \\ 0 \\ \vdots \end{bmatrix}. \tag{63}$$

Then, by the symmetry of $\mathcal{A}$, we know

$$\langle \mathcal{A}y_i, x\rangle = \langle y_i, \mathcal{A}x\rangle = 0. \tag{64}$$

On the other hand, we should have

$$\langle \mathcal{A}y_i, x\rangle = \langle x_i, x\rangle = 1. \tag{65}$$

This contradiction implies that none of the m columns of $\mathcal{B}$ can be in the range of $\mathcal{A}$.

Since $\mathcal{A}$ is at least of rank $n-m$ by Lemma 3.5, it is now clear that the $n \times (n+m)$ matrix $[\mathcal{A}, \mathcal{B}]$ is of rank n. It is also clear the rows of $[\mathcal{B}^T, 0]$ are not in the row space of $[\mathcal{A}, \mathcal{B}]$. Thus the assertion is proved. □

By now the following theorem is a standard result from the differential topology.

THEOREM 3.7. *The set* $\Gamma := \{(x, \Lambda, t) | H(x, \Lambda, t) = 0\}$ *is a* 1*-dimensional smooth submanifold in* $R^n \times R^m \times R$.

Furthermore, since $D_{(x,\Lambda,t)}H$ is nonsingular, the implicit function theorem asserts that each component of Γ can be characterized as a function of t. Also, if $(x, \Lambda, t) \in \Gamma$, then

$$\sum_{i=1}^{m} \lambda_i^2 = ||\Lambda x|| = ||((1-t)D + tA)x|| \leq m(||(1-t)D|| + ||tA||), \tag{66}$$

which implies that no homotopy curve can diverge to infinity for $t \in (0,1)$.

Putting all the above arguments together, we have proved that for $i = 1, \dots, m$, the solution to the initial-value problem

$$\frac{d}{dt}\begin{bmatrix} x_1 \\ \vdots \\ x_m \\ \lambda_1 \\ \vdots \\ \lambda_m \end{bmatrix} = \begin{bmatrix} \mathcal{A} & \mathcal{B} \\ \mathcal{B}^T & 0 \end{bmatrix}^{-1} \begin{bmatrix} -\mathcal{C} \\ 0 \end{bmatrix}, \tag{67}$$

$$x_i(0) = \pm e_{j_i}^{[n_i]}, \tag{68}$$

$$\lambda_i(0) = d_{j_i}^{(i)} \tag{69}$$

is a curve in $R^n \times R^m$ that extends from $t = 0$ to $t = 1$. From Lemma 3.1 we thus conclude the following.

THEOREM 3.8. *For a generic and symmetric matrix A the MEP has exactly $\prod_{i=1}^{m} 2n_i$ solutions.*

We believe the result of Theorem 3.8 is new. Moreover, it should be pointed out that the positive definiteness of the matrix A is not needed in the proof of Theorem 3.8.

4. Power method and convergence.

Horst's algorithm may be reformulated as follows.

ALGORITHM 4.1 (Horst's algorithm).

Given $x^{(0)} = (x_1^{(0)^T}, \dots, x_m^{(0)^T})^T$ *with* $||x_i^{(0)}|| = 1$, *do*

```
for $k = 1, 2, \dots$
    for $i = 1, \dots, m$
```

$$y_i^{(k)} := \sum_{j=1}^{m} A_{ij} x_j^{(k)}, \tag{70}$$

$$\lambda_i^{(k)} := \|y_i^{(k)}\|, \tag{71}$$

$$x_i^{(k+1)} := \frac{y_i^{(k)}}{\lambda_i^{(k)}}. \tag{72}$$

```
    end
end
```

Theoretically, it is possible that $\|y_i^{(k)}\| = 0$ and hence that (72) is not well defined. Such a breakdown, although rarely occurring in practice, can easily be remedied by redefining $x_i^{(k+1)}$ to be an arbitrary unit vector in R^{n_i}, say, $x_i^{(k)}$ itself, and then continuing the iteration.

To our knowledge, Horst's iterative algorithm has never been rigorously proved to converge, although some intuitive support as well as some numerical evidence are mentioned in [12], [13]. In this section we prove a convergence property of Algorithm 4.1 for the MEP.

We find that it is more convenient to write the above algorithm in the compact form

$$Ax^{(k)} = \Lambda^{(k)} x^{(k+1)}, \tag{73}$$

where

$$x^{(k)} := [x_1^{(k)^T}, \dots, x_m^{(k)^T}]^T \tag{74}$$

and

$$\Lambda^{(k)} := \operatorname{diag}\{\lambda_1^{(k)} I^{[n_1]}, \dots, \lambda_m^{(k)} I^{[n_m]}\}. \tag{75}$$

The iterative scheme may be viewed as a generalization of the classical power method. The convergence property of this method, nonetheless, is not nearly obvious. As an example, without the positive definiteness the method may fail to converge. This can be seen from the 2×2 matrix $A = \begin{bmatrix} 1 & b \\ b & c \end{bmatrix}$ with $m = 2$. There are exactly four feasible solutions $(\pm 1, \pm 1)$. For any values of b and c satisfying $|b| < 1$, $c < 0$, and $|b| < -c$, the matrix A is not positive definite. In this case the iterations alternate between $(1, 1)$ and $(1, -1)$ or between $(-1, -1)$ and $(-1, 1)$. No convergence occurs. As another example that will be illustrated later, a limit point of the method may depend on the starting point. The maximal correlation problem may have multiple local solutions even if the matrix A is positive definite.

To study the convergence property of Horst's algorithm for the MEP, we denote the objective function in (28) by

$$r(x) := x^T A x \tag{76}$$

for $x \in R^n$. We claim the following theorem.

THEOREM 4.2. *Suppose A is symmetric and positive definite. Then $\{r(x^{(k)})\}$ with $x^{(k)}$ generated by (73) is a monotonically increasing sequence and converges.*

Proof. From (73) we know that

$$r(x^{(k)}) = x^{(k+1)^T}\Lambda^{(k)}x^{(k)}. \tag{77}$$

We also know that

$$r(x^{(k+1)}) = x^{(k+1)^T}Ax^{(k+1)} + x^{(k+1)^T}\Lambda^{(k)}x^{(k+1)} - x^{(k+1)^T}Ax^{(k)}. \tag{78}$$

Subtracting (77) from (78), we obtain

$$r(x^{(k+1)}) - r(x^{(k)}) = x^{(k+1)^T}\Lambda^{(k)}(x^{(k+1)} - x^{(k)}) + x^{(k+1)^T}A(x^{(k+1)} - x^{(k)}). \tag{79}$$

On the other hand, observe that

$$\begin{aligned} & x^{(k)^T}\Lambda^{(k)}(x^{(k+1)} - x^{(k)}) + x^{(k)^T}A(x^{(k+1)} - x^{(k)}) \\ &= x^{(k)^T}Ax^{(k)} - x^{(k)^T}\Lambda^{(k)}x^{(k)} + x^{(k+1)^T}\Lambda^{(k)}x^{(k+1)} - x^{(k)^T}Ax^{(k)} \\ &= 0 \end{aligned} \tag{80}$$

because $x^{(k)^T}\Lambda^{(k)}x^{(k)} = \sum_{i=1}^m \lambda_i^{(k)}$. Subtracting (80) from the right-hand side of (79), we find that

$$r(x^{(k+1)}) - r(x^{(k)}) = (x^{(k+1)} - x^{(k)})^T(A + \Lambda^{(k)})(x^{(k+1)} - x^{(k)}). \tag{81}$$

Since $\Lambda^{(k)}$ is a diagonal matrix with positive elements, the matrix $A + \Lambda^{(k)}$ remains to be symmetric and positive. It follows that

$$r(x^{(k+1)}) \geq r(x^{(k)}). \tag{82}$$

The convergence of the monotone sequence $\{r(x^{(k)})\}$ is obvious since for all x we have

$$\mu_n\|x\|^2 \leq r(x) \leq \mu_1\|x\|^2, \tag{83}$$

where

$$\mu_1 \geq \cdots \geq \mu_n \tag{84}$$

are the eigenvalues of A. □

It is instructive to motivate Theorem 4.2 from another viewpoint. Let $S_i := \{x_i | x_i \in R^{n_i},\ \|x_i\| = 1\}$. The feasible set (29) for the maximal correlation problem may be regarded as the manifold $\prod_{i=1}^m S_i$ embedded in $\prod_{i=1}^m R^{n_i}$ with product topology. The tangent space $\mathcal{T}_{(x_1,\ldots,x_m)}\prod_{i=1}^m S_i$, therefore, is given by $\prod_{i=1}^m \mathcal{T}_{x_i}S_i$. It is easy to show that the gradient $\nabla r(x)$ projected onto $\mathcal{T}_{x_i}S(i)$ is twice the vector

$$g_i(x) := \sum_{j=1}^m A_{ij}x_j - \left\langle x_i, \sum_{j=1}^m A_{ij}x_j \right\rangle x_i. \tag{85}$$

Observe then that

$$
\begin{aligned}
\langle x^{(k+1)} - x^{(k)}, g(x^{(k)})\rangle &= \sum_{i=1}^{m} \langle x_i^{(k+1)} - x_i^{(k)}, g_i(x^{(k)})\rangle \\
&= \sum_{i=1}^{m} \left(\|y_i^{(k)}\| - \frac{\langle x_i^{(k)}, y_i^{(k)}\rangle^2}{\|y_i^{(k)}\|} \right),
\end{aligned} \tag{86}
$$

while each term in (86) is nonnegative. That is, the vector $x^{(k+1)} - x^{(k)}$ forms an acute angle with the projected gradient $g(x^{(k)})$ of $r(x^{(k)})$ and thus probably (although not necessarily) points to an ascent direction for $r(x)$.

Define the residual

$$
\begin{aligned}
\delta(x^{(k)}) &:= Ax^{(k)} - \Lambda^{(k)} x^{(k)} \\
&= \Lambda^{(k)}(x^{(k+1)} - x^{(k)}),
\end{aligned} \tag{87}
$$

where the second equality follows from (73). If the equality in (82) holds for some k, then from (81) it must be $x^{(k+1)} = x^{(k)}$. We find from (87) that $x^{(k)}$ solves (3) exactly. In general, we have the following theorem.

THEOREM 4.3. *The residual* $\{\delta(x^{(k)})\}$ *in Horst's algorithm converges to zero as* $k \longrightarrow \infty$.

Proof. By the definition (71) all $\lambda_i^{(k)}$ remain bounded as $\|x^{(k)}\|^2 \le m$ for all k. It follows from (81) that there exists a constant $\kappa > 0$ such that

$$
r(x^{(k+1)}) - r(x^{(k)}) \ge \kappa \|x^{(k+1)} - x^{(k)}\|^2 \tag{88}
$$

for all k. The assertion follows from (87) and the fact that $\{r(x^{(k)})\}$ converges. □

At this point it is not obvious that the sequence $\{x^{(k)}\}$ itself converges, but it is clear that the sequence $\{x^{(k)}\}$ does have have cluster point(s) due to its boundedness. From Theorem 4.3, it follows that every cluster point x^* satisfies (3) with eigenvalues $\lambda_i^* := \|\sum_{j=1}^{m} A_{ij} x_j^*\|$.

Define

$$
\tilde{\lambda}^{(k)} := \min_{1 \le j \le m} \lambda_j^{(k)} \tag{89}
$$

and

$$
\tilde{\lambda} := \liminf \tilde{\lambda}^{(k)}. \tag{90}
$$

Consider the case in which $\tilde{\lambda} = 0$. Then there exists a subsequence $\{k_j\}$ of positive integers such that

$$
\tilde{\lambda}^{(k_j)} < \frac{1}{j}. \tag{91}
$$

Any convergent subsequence of the subsequence $\{x^{(k_j)}\}$ must be such that one of the eigenvalues λ_i^* is zero. We do not think this will happen often for a generic A.

The following lemma from real analysis is useful.

LEMMA 4.4. *Let $\{a_k\}$ be a bounded sequence of real numbers with the property $|a_{k+1} - a_k| \longrightarrow 0$ as $k \longrightarrow \infty$. If there are only finitely many limit points for the sequence, then $\{a_k\}$ converges to a unique limit point.*

Proof. Suppose $\{a_{\alpha_k}\}$ and $\{a_{\beta_k}\}$ are two subsequences of $\{a_k\}$ that converge, respectively, to two distinct limit points, x and y. Let z denote any fixed real number between x and y. For a positive number r let $B_x(r)$ denote the neighborhood $[x-r, x+r]$ of x.

For any $\epsilon > 0$ that is less than $\frac{1}{4}\min\{|x-z|, |y-z|\}$, there exists a large enough integer $K = K(\epsilon)$ such that

$$a_{\alpha_k} \in B_x(\epsilon), \quad a_{\beta_k} \in B_y(\epsilon), \quad |a_{k+1} - a_k| < \epsilon$$

for all $k \geq K$. Infinitely many elements of $\{a_k\}$ must leave $B_x(\epsilon)$ to enter $B_y(\epsilon)$ and vice versa. Thus there exists an index $\gamma \geq K$ such that $a_\gamma \in B_z(\epsilon)$. This shows that z is also a limit point.

Since z is arbitrary, we have shown that any number between x and y is a limit point. This contradicts the assumption that there are only finitely many limit points. $\square$

In the following we prove that Algorithm 4.1 generates a convergent sequence $\{\Lambda^{(k)}, x^{(k)}\}$. We believe this result is new.

First we prove the following theorems.

THEOREM 4.5. *The sequence $\{\Lambda^{(k)}\}$ converges as k goes to infinity.*

Proof. We have seen already that the sequence $\{\Lambda^{(k)}\}$ is bounded. Suppose $\{\Lambda^{(k_j)}\}$ is a convergent subsequence. Then the corresponding $\{x^{(k_j)}\}$ also has a convergent subsequence. Without causing any ambiguity, we may assume the subsequence $\{(\Lambda^{(k_j)}, x^{(k_j)})\}$ converges. By Theorem 4.3 it follows that the limit point of $\{(\Lambda^{(k_j)}, x^{(k_j)})\}$ is a solution of the MEP. By Theorem 3.8 there are only finitely many such limit points.

For convenience we rewrite the matrix A as a column of m blocks, that is, $A = [A_1, \ldots, A_m]^T$, where $A_i := [A_{i1}, \ldots, A_{im}]$. Then $\lambda_i^{(k)} = \|A_i x^{(k)}\|$. Observe that

$$|\lambda_i^{(k+1)} - \lambda_i^{(k)}| = \big|\, \|A_i x^{(k+1)}\| - \|A_i x^{(k)}\| \,\big| \leq \|A_i(x^{(k+1)} - x^{(k)})\|.$$

From (88) and Theorem 4.2 it follows that $|\lambda_i^{(k+1)} - \lambda_i^{(k)}| \longrightarrow 0$ as $k \longrightarrow \infty$. The assertion now follows by applying Lemma 4.4 to the sequence $\{\lambda_i^{(k)}\}$ for each $i = 1, \ldots, m$. $\square$

THEOREM 4.6. *The sequence $\{x^{(k)}\}$ converges as k goes to infinity.*

Proof. The proof basically is the same as that of Theorem 4.5 since we observe from (88) and Theorem 4.2 that componentwise the difference between $x^{(k+1)}$ and $x^{(k)}$ converges to zero as k goes to infinity. $\square$

We now illustrate the dependence of the method on the starting point. Consider the positive definite matrix

$$A = \begin{bmatrix} 4.3299 & 2.3230 & -1.3711 & -0.0084 & -0.7414 \\ 2.3230 & 3.1181 & 1.0959 & 0.1285 & 0.0727 \\ -1.3711 & 1.0959 & 6.4920 & -1.9883 & -0.1878 \\ -0.0084 & 0.1285 & -1.9883 & 2.4591 & 1.8463 \\ -0.7414 & 0.0727 & -0.1878 & 1.8463 & 5.8875 \end{bmatrix},$$

with $m = 2$, $n_1 = 2$, and $n_2 = 3$. It turns out that the sequence $\{x^{(k)}, \lambda_1^{(k)}, \lambda_2^{(k)}\}$ converges to

$$\begin{aligned} x^* &= [0.9357, 0.3528, -0.9341, 0.3508, 0.0667]^T, \\ \lambda_1^* &= 6.5186, \\ \lambda_2^* &= 8.2116 \end{aligned}$$

if $x^{(0)} = [0.9777, 0.2098, 0.5066, 0.5069, 0.6975]^T$ and to

$$\begin{aligned} x^{**} &= [0.7166, 0.6975, 0.5654, -0.4327, -0.7022]^T, \\ \lambda_1^{**} &= 6.2405, \\ \lambda_2^{**} &= 7.8607 \end{aligned}$$

if $x^{(0)} = [0.7914, 0.6114, 0.4753, 0.2517, -0.8431]^T$. On the other hand, if the method is repeatedly applied to randomly generated starting points, it is interesting that approximately 60% of the points give convergence to x^*, whereas all the remaining converge to x^{**}. This ratio stays about the same regardless of whether a normal distribution or a uniform distribution is used as the generator. This is a clear indication that out of the 24 solutions to this MEP, there are *two* local maxima to the maximal correlation problem. The example also illustrates that Horst's algorithm has a substantial possibility of not converging to the absolute maximal correlation.

5. Conclusion and future research. Although we have demonstrated the convergence of Horst's algorithm for the MEP, it is clear that there are still many other numerical issues worthy of investigation. For example, let

$$\Gamma := \operatorname{diag}\{\gamma_1 I^{[n_1]}, \ldots, \gamma_m I^{[n_m]}\}, \tag{92}$$

where each γ_i is a real number. Then $(A - \Gamma)x = \Lambda x$ if and only if $Ax = (\Gamma + \Lambda)x$. In other words, like the power method, multivariate shifting is a possible strategy for finding other solutions of the MEP. Determining which solution the algorithm converges to on the basis of the starting value for $x^{(0)}$ and the shift parameters is thus an interesting problem. A theoretical problem associated with the multivariate shifting is related to the so-called educational testing problem; that is, for what Γ will the matrix $A - \Gamma$ become positive semidefinite?

On the other hand, the scheme involved in (71) is very analogous to the so-called Jacobi method used in solving linear equations. It is thus rather natural to formulate the following Gauss–Seidel method for the MEP.

ALGORITHM 5.1 (Gauss–Seidel algorithm).

```
Given $x^{(0)} = (x_1^{(0)^T}, \ldots, x_m^{(0)^T})^T$ with $||x_i^{(0)}|| = 1$, do
    for $k = 1, 2, \ldots$
        for $i = 1, \ldots, m$
```

$$y_i^{(k)} := \sum_{j=1}^{i-1} A_{ij} x_j^{(k+1)} + \sum_{j=i}^{m} A_{ij} x_j^{(k)}, \tag{93}$$

$$\lambda_i^{(k)} := ||y_i^{(k)}||, \tag{94}$$

```
(95)        $x_i^{(k+1)} := \frac{y_i^{(k)}}{\lambda_i^{(k)}}.$

        end
    end
```

Let the matrix A be decomposed as

(96) $$A = D + U^T + U,$$

where D is the main diagonal part of A and U is the strictly upper triangular part of A. Then Algorithm 5.1 may be written as

(97) $$(D + U)x^{(k)} = (\Lambda^{(k)} - U^T)x^{(k+1)}.$$

Similarly, an SOR algorithm may be formulated as follows.

ALGORITHM 5.2 (SOR algorithm).

```
Given $x^{(0)} = (x_1^{(0)^T}, \ldots, x_m^{(0)^T})^T$ with $||x_i^{(0)}|| = 1$, do
    for $k = 1, 2, \ldots$
        for $i = 1, \ldots, m$
(98)        $\overline{y}_i^{(k)} := \sum_{j=1}^{i-1} A_{ij}x_j^{(k+1)} + \sum_{j=i}^{m} A_{ij}x_j^{(k)},$
(99)        $\xi_i^{(k)} := ||\overline{y}_i^{(k)}||,$
(100)       $\overline{z}_i^{(k+1)} := \frac{\overline{y}_i^{(k)}}{\xi_i^{(k)}}.$
(101)       $y_i^{(k)} := \omega_i \overline{z}_i^{(k+1)} + (1 - \omega_i)x_i^{(k)},$
(102)       $\lambda_i^{(k)} := ||y_i^{(k)}||,$
(103)       $x_i^{(k+1)} := \frac{y_i^{(k)}}{\lambda_i^{(k)}}.$
        end
    end
```

We note that the relaxation parameters ω_i in each block may be chosen differently. We also remark that the scaling in (100) may be done differently; this includes the possibility of defining $\xi_j^{(k)} := 1$ for all j and all k.

If we define

(104) $$\Xi^{(k)} := \text{diag}\,\{\xi_1^{(k)} I^{[n_1]}, \ldots, \xi_m^{(k)} I^{[n_m]}\}$$

and

(105) $$\Omega := \text{diag}\,\{\omega_1 I^{[n_1]}, \ldots, \omega_m I^{[n_m]}\},$$

then Algorithm 5.2 may be written in matrix form:

$$[(I-\Omega)\Xi^{(k)}+\Omega(D+U)]x^{(k)}=(\Xi^{(k)}\Lambda^{(k)}-\Omega U^T)x^{(k+1)}, \tag{106}$$

which includes (97) as a special case.

Apparently, a partial list of topics that deserves further research should include proof of convergence, rate of convergence, and acceleration of convergence for each of these methods. Work on some of these aspects to the MEP will be expounded on in a forthcoming paper.

HIGH-ORDER AND EFFICIENT METHODS FOR THE VORTICITY FORMULATION OF THE EULER EQUATIONS*

J. S. LOWENGRUB[†], M. J. SHELLEY[‡], AND B. MERRIMAN[§]

Abstract. In this work, the authors develop new methods for the accurate and efficient solution of the two-dimensional, incompressible Euler equations in the vorticity form. Here, the velocity is recovered directly from the Biot–Savart relation with vorticity, and the vorticity is evolved through its transport equation. Using a generalized Poisson summation formula, the full asymptotic error expansion is constructed for the second-order point vortex approximation to the Biot–Savart integral over a rectangular grid. The expansion is in powers of h^2, and its coefficients depend linearly upon only local derivatives of the vorticity. In particular, the second-order term depends only upon the vorticity gradient. Except at second-order, the coefficients also involve rapidly convergent, two-dimensional lattice sums. At second-order, the sum is conditionally convergent, but can be calculated easily and rapidly. Therefore, we can remove the second-order term explicitly from the point vortex approximation to obtain a fourth-order discretization. In the special case of a square grid, the second-order error term is orthogonal to the vorticity gradient. The convective derivative of vorticity is thus calculated to fourth order using the unmodified point vortex approximation and automatically yields a fourth-order evolution. These methods have been implemented. For the vorticity transport equation, the point vortex sums are evaluated very rapidly using the fast Fourier transform (FFT) algorithm, and vorticity gradients are approximated using high-order difference methods. With high resolution, the authors solve numerically the roll-up of a thin layer of vorticity through the Kelvin–Helmholtz instability, and the interaction of two oppositely signed vortices driven together under an external strain flow. In the latter case, a simple time dependence of the grid is introduced to maintain resolution of the flow.

1. Introduction.

In this work, we develop and test new methods for the accurate and efficient solution of the two-dimensional, incompressible Euler equations in the vorticity form. Here, the velocity is recovered directly from the Biot–Savart relation with the vorticity, and the vorticity itself is evolved through its transport equation. This is in itself not a new idea (see [22], for example). However, we perform a new analysis of the point vortex approximation to the Biot–Savart integral, and construct explicitly its asymptotic error expansion for rectangular grids. This analysis is used to develop new methods that are efficient and fourth-order accurate.

Traditional numerical methods for fluid mechanics have concentrated on either the primitive variable formulation of velocity-pressure or the vorticity-stream formulation (see [23], for example). A Poisson equation for either the pressure or the stream function is discretized and inverted at each time step with appropriate boundary conditions suitably accounted for. Advantages of these methods include their rapid evaluation and their overall accuracy. They are not so naturally adaptive as an adaptive grid would require inverting an elliptic equation with nonconstant coefficients.

Lagrangian vortex methods (see [10], as well as other references listed at the end of this paper, for example) also exploit the relationship between velocity and vorticity to

pose the Euler equations as a closed system of differential equations for the motion of the curvilinear coordinate system moving with the fluid velocity (flow map). Advantages of the Lagrangian methods include their natural adaptivity, ease of implementation, and the existence of fast inversion algorithms [17]. However, their accuracy is difficult to maintain due to grid distortion and the singular nature of the Biot–Savart kernel.

Ideally, one would like to retain the adaptivity of the Lagrangian methods while controlling the grid motion so as to reduce distortion effects and to retain high-order accuracy. An advantage of the vorticity formulation is that adaptive meshes can be incorporated very easily. An adaptive mesh is included by making a specific choice of an underlying coordinate system. This choice of coordinate system merely introduces metric functions in the evolution equation for the vorticity and a Jacobian term in the Biot–Savart integral. In this way, we avoid numerically inverting an elliptic equation with nonconstant coefficients, as we use a discretization of the exact inversion formula. An important side benefit is that there is no ambiguity about the far-field boundary conditions, for open or periodic problems, since they are built into the formula exactly. We view this work as a partial step in the development of such adaptive methods. However, the special case of rectangular grids is very useful and interesting in its own right.

Using an appropriately generalized Poisson summation formula, we construct the full asymptotic error expansion for the point vortex approximation to the Biot–Savart integral evaluated on a rectangular grid. The existence of the error expansion was proved by Goodman, Hou, and Lowengrub [16] more generally on smooth, curvilinear grids, but the method of proof was not constructive. Thus in the case of a rectangular grid, we have provided an explicit example of the expansion. Beginning at the second order, the expansion is in powers of h^2, the spatial discretization size. The error is local in that the expansion coefficients depend linearly upon derivatives of the vorticity evaluated only at the mesh point at which the velocity is calculated. In particular, the second-order error term depends only upon the gradient of the vorticity. The error also has a global part in that the coefficients involve two-dimensional lattice sums. However, these sums do not depend on the point of evaluation. These sums are also rapidly convergent except, apparently, at the second order where the sum is only conditionally convergent. We show how this lattice sum can be calculated both easily and rapidly. Thus we can remove the second-order term explicitly from the point vortex approximation to obtain a fourth-order discretization. In the special case of a square grid, even this is unnecessary as the second-order error term is orthogonal to the vorticity gradient. The convective derivative of vorticity is thus calculated to fourth order using the unmodified point vortex approximation, and yields automatically a fourth-order evolution. We also find that in the square grid case, the error expansion contains only powers of h^4 after the second-order term. A single Richardson extrapolation to remove the fourth-order term of the point vortex quadrature leaves the second-order and the eighth-order terms remaining. Thus, in the evolution equation, the second-order term falls out to yield eighth-order evolution.

We note that in the case of more general curvilinear grids, extrapolation can be used to generate high-order accurate methods. A difficulty with extrapolation is that although its order of accuracy is higher than the original method, in general, its error coefficients are also larger.

We have also implemented these methods to demonstrate their utility and present numerical results on two difficult test problems. As the point vortex sums over rectangular meshes are discrete convolutions, they are evaluated using the FFT algorithm and the discrete convolution theorem in $O(N^2 \ln N)$ operations where N^2 is the number of mesh points. Vorticity gradients are approximated by high-order difference methods. The first test problem is the nonlinear roll-up of a thin shear layer through the Kelvin–Helmholtz instability. This is a difficult problem as the vorticity develops spatial complexity and steep gradients. The second test problem is the interaction of two oppositely signed vorticies being driven together by an external straining flow. This problem also features strong vorticity gradient production and is relevant to the study of three-dimensional vortex interaction and reconnection [27]. However, the steepest gradients tend to align in a single direction. Consequently, we employ a simple time dependency of the grid to retain resolution of the flow. We compare it to the case where the grid is held fixed. It is a simple, but nontrivial, problem that nicely illustrates how the appropriate choice of time dependency in the grid can greatly improve the calculation.

Our future work includes further consideration of the vorticity transport equation. For example, our time integration method does not make use of the fact that the vorticity equation is a conservation law. The use of methods constructed for such transport equations as essentially nonoscillatory (ENO) methods [19] or other high-order Godunov-type schemes would likely improve the robustness of these methods [7]. It would also be useful to fund the second-order coefficient for the point vortex approximate on a generally smooth, curvilinear coordinate system so that more general fourth-order methods could be constructed without resorting to extrapolation. For the three-dimensional Euler equations, we note that there is a technical difficulty in applying the method developed here to the point vortex approximation. The difficulty involves the sufficiency conditions for applying the special Poisson summation formula for the Biot–Savart kernel (A.29). See Remark 3 at the end of Appendix A. However, we note that the general Poisson summation formula for singular functions (A.9) is still valid. This is currently under study. While the existence of asymptotic error expansions has been proved for the three-dimensional Biot–Savart integral [13], the method is not constructive. Another very important extension is the inclusion of boundaries with and without viscosity. Finally, we note that there is a proof of convergence for a lower-order accurate version of our current method. It will be presented elsewhere.

The outline of the paper is as follows. In §2, we present the method, its implementation, and the special form of its error expansion (the appendices contain the mathematical details of its derivation). In §3, we present some numerical results, and in §4, we give concluding remarks. In Appendix A, the singular Poisson summation formula is derived. In Appendix B, the singular Poisson summation formula is applied to the point vortex discretization of the Biot–Savart integral, and the expansion is proved. In Appendix C, the explicit second-order coefficient is obtained.

2. The vorticity formulation and smooth grid methods.

The Euler equations for two-dimensional, incompressible fluid flow, in the vorticity formulation, are given by

$$\omega_t + \mathbf{u} \cdot \nabla \omega = 0 \tag{2.1a}$$

and

$$\mathbf{u}(\mathbf{x}, t) = \int_{\mathbf{R}^2} \mathbf{K}(\mathbf{x} - \mathbf{x}')\omega(\mathbf{x}', t)dx_1'dx_2', \tag{2.1b}$$

where $\mathbf{u}(\mathbf{x}, t) = (u_1(\mathbf{x}, t), u_2(\mathbf{x}, t))$ is the fluid velocity, $\omega(\mathbf{x}, t)$ is the scalar vorticity, $\mathbf{x} = (x_1, x_2)$, and

$$\mathbf{K}(\mathbf{x}) = \frac{1}{2\pi|\mathbf{x}|^2}(-x_2, x_1) \tag{2.1c}$$

is the Biot–Savart kernel. Equation (2.1a) expresses that the vorticity in two dimensions is conserved along particle paths, while (2.1b) and (2.1c), the Biot–Savart integral, give the relation between the velocity and the vorticity due to the incompressibility constraint and definition of the vorticity. It is assumed that ω is smooth and rapidly decaying at infinity.

Although we will soon restrict ourselves to considering the case of rectangular grids, it is instructive to recast the Euler equations in terms of a more general curvilinear coordinate system. Consider the transformation $\mathbf{X}(\mathbf{b},t) = (x_1(b_1,b_2,t), x_2(b_1,b_2,t))$, which, for example, might arise as the solution to the evolution equation

$$\frac{d}{dt}\mathbf{X}(\mathbf{b},t) = \mathbf{F}(\mathbf{X}(\mathbf{b},t),t) \tag{2.2a}$$

for some $\mathbf{F}$. This yields the formulation

$$\frac{d}{dt}\omega(\mathbf{X}(\mathbf{b},t),t) = [(\mathbf{F}(\mathbf{X}(\mathbf{b},t),t) - \mathbf{u}(\mathbf{X}(\mathbf{b},t),t))] \cdot [[\nabla_{\mathbf{b}}\mathbf{X}]^{-1} \cdot \nabla_{\mathbf{b}}\omega] \tag{2.2b}$$

with

$$\mathbf{u}(\mathbf{X}(\mathbf{b},t),t) = \int_{\mathbf{R}^2} \mathbf{K}(\mathbf{X}(\mathbf{b},t) - \mathbf{X}(\mathbf{b}',t))\omega(\mathbf{X}(\mathbf{b}',t),t)J(\mathbf{b}')db_1'db_2', \tag{2.3}$$

where J is the Jacobian of the coordinate transformation given by

$$J = \det\nabla_{\mathbf{b}}\mathbf{X}.$$

A Lagrangian vortex method [10] uses the specific choice $\mathbf{F} = \mathbf{u}$. In this frame, $\mathbf{X}(\mathbf{b},t)$ is the trajectory of a fluid particle along which the vorticity is conserved. Furthermore, the transformation is area preserving due to incompressibility. An Eulerian vortex method, on the other hand, uses the choice $\mathbf{F} = \mathbf{0}$. Here, $\mathbf{X}(\mathbf{b},t) = \mathbf{b}$ and describes a fixed coordinate system. The vorticity is not conserved in this frame and must be advected. The transformation is trivially area preserving.

There are many possible choices of a quadrature method for this integral. For example, there is the point-vortex approximation [22], [26] or quadrature methods based upon mollification of the singular kernel (see [1], [2], [4], [5], [10], [15], [18], [24], for example). We have chosen a fourth-order quadrature method on a rectangular grid that is related to the point vortex method. It has the advantages of ease of implementation, can be summed by a fast method, and is easily generalized to higher orders.

Let the transformation $\mathbf{X}(\mathbf{b},t)$ be discretized uniformly in $\mathbf{b}$. Define $\mathbf{X}_{\mathbf{j}} = \mathbf{X}(\mathbf{b}_{\mathbf{j}},t)$, with $\mathbf{b}_{\mathbf{j}} = (j_1h, j_2h)$. Similar definitions hold for J and ω. Let $\mathbf{I}[\omega]_{\mathbf{j}}$ denote the value of the Biot–Savart integral evaluated at $\mathbf{X}_{\mathbf{j}}$. The point vortex approximation $\mathbf{I}[\omega]_{\mathbf{j}}^0(h)$ is simply the trapezoidal rule approximation to (2.3), where the singular self-induction term is omitted:

$$\mathbf{I}[\omega]_{\mathbf{j}}^0(h) = h^2 \sum_{k\neq j} \mathbf{K}(\mathbf{X}_{\mathbf{j}} - \mathbf{X}_{\mathbf{k}})J_{\mathbf{k}}\omega_{\mathbf{k}}. \tag{2.4}$$

The error is then

$$\mathbf{E}[\omega]_{\mathbf{j}}^0(h) = \mathbf{I}[\omega]_{\mathbf{j}}^0 - \mathbf{I}[\omega]_{\mathbf{j}}^0(h). \tag{2.5}$$

Even though the integrand of the Biot–Savart integral is singular, it was proved by Goodman, Hou, and Lowengrub [16] that there exists a regular asymptotic expansion in powers of h^2 for the error. That is, for sufficiently small h, there exists constants $\mathbf{C}[\omega]_{\mathbf{j},2p}$ independent of h, such that

$$\mathbf{E}[\omega]_{\mathbf{j}}^{0}(h) = \mathbf{C}[\omega]_{\mathbf{j},2}h^2 + \mathbf{C}[\omega]_{\mathbf{j},4}h^4 + \cdots. \tag{2.6}$$

In general, it appears difficult to find explicit formulae for the coefficients $\mathbf{C}[\omega]_{\mathbf{j},2p}$. For example, in the analysis of Goodman, Hou, and Lowengrub, the second-order coefficient $\mathbf{C}[\omega]_{\mathbf{j},2}$ arises only as an undetermined constant of integration. This particular coefficient is arguably the most useful to know explicitly, as it might then be removed explicitly to yield a higher-order method.

In the special (but very useful) case of a rectangular grid, we give an alternative derivation of the error expansion in which the coefficients $\mathbf{C}[\omega]_{\mathbf{j},2p}$ are given explicitly. We only outline the method here, and refer the interested reader to the appendices for the full details. The main tool is the Poisson summation formula generalized to singular functions. The Poisson summation formula (see, for example, [14]) expresses the trapezoidal sum (say, over the plane) as a sum of Fourier coefficients of the summand. The asymptotic behavior of these Fourier coefficients then allows an analysis of the error in the trapezoidal approximation. However, the integrand of (2.1b) lacks the smoothness necessary for direct application of the Poisson summation formula, which, if used naively, leads to sums of Fourier coefficients that are not absolutely, but only conditionally, convergent. The value of such a sum depends upon how the sum is evaluated. Instead, the integrand of (2.1b) is first smoothed by convolution with an approximate δ-function δ_ϵ of width ϵ. The Poisson summation formula is then applied to the trapezoidal approximation of the smoothed integral and the limit $\epsilon \to 0$ is taken. This leads to the Poisson summation formula generalized to singular functions. The particular choice of δ_ϵ leads to a particular interpretation of the conditionally convergent sum, and produces a compensating residue from the singular self-induction term omitted in (2.4). We have chosen δ_ϵ so as to actually yield rapidly and absolutely convergent sums, and an explicitly calculable residue term.

There is at least an apparent difficulty in applying these methods to the general curvilinear case to find *explicit* expressions for the error coefficients. We would require the Fourier transform of the kernel $\mathbf{K}(\mathbf{X}(\mathbf{b}))$ in the $\mathbf{b}$ variable. This is not generally known.

Let $\mathbf{X}_{\mathbf{j}} = (j_1h_1, j_2h_2) = (j_1\alpha_1h, j_2\alpha_2h)$ be the rectangular grid. Let $\omega_{x_2,\mathbf{j}}$ denote the value of ω_{x_2} evaluated at $\mathbf{X}_{\mathbf{j}}$, and similarly for $\omega_{x_1,\mathbf{j}}$. The point vortex approximation is now simply

$$\mathbf{I}[\omega]_{\mathbf{j}}^{0}(h) = h_1h_2 \sum_{\mathbf{k}\neq\mathbf{j}} \mathbf{K}((j_1-k_1)h_1, (j_2-k_2)h_2)\omega_{\mathbf{k}}. \tag{2.7}$$

We then have the following theorem.

Error Expansion Theorem. *Let $\omega(\mathbf{x})$ be smooth and rapidly decaying and $\alpha = \alpha_1/\alpha_2$.*

Part A. *The second-order error coefficient is given by*

$$\mathbf{C}[\omega]_{\mathbf{j},2}h^2 = \left(\frac{-\omega_{x_2,\mathbf{j}}}{4\pi}C_2(\alpha), \frac{\omega_{x_1,\mathbf{j}}}{4\pi}C_2(1/\alpha)\right) h_1h_2, \tag{2.8a}$$

where

$$C_2(\alpha) = \frac{4}{\pi}\arctan(1/\alpha) - \frac{4\alpha}{\pi}\sum_{m=1}^{\infty}\frac{1}{m}f(m;\alpha), \tag{2.8b}$$

and

$$f(m;\alpha) = \frac{1}{m}\sum_{l=0}^{m}{}' \left(\frac{(l/m)^2-\alpha^2}{((l/m)^2+\alpha^2)^2} + \frac{1-\alpha^2(l/m)^2}{(1+\alpha^2(l/m)^2)^2}\right). \tag{2.8c}$$

By $\sum'$ *is meant the trapezoidal sum; that is, the terms at* $l = 0$ *and* m *are weighted by a factor of* $\frac{1}{2}$.

Remark 1. In the special case of a square grid ($\alpha = 1$), $C_2(\alpha) = C_2(1/\alpha) = 1$, and it follows that

$$\mathbf{C}[\omega]_{\mathbf{j},2} = \frac{1}{4\pi}\nabla^{\perp}\omega|_{\mathbf{j}h}, \tag{2.9}$$

where $\nabla^{\perp}\omega = (-\partial_{x_2}, \partial_{x_1})\omega$ is the perpendicular gradient of ω. Thus, the second-order error term in (2.4) is orthogonal to $\nabla\omega$ (i.e., $h^2\nabla^{\perp}\omega\cdot\nabla\omega = 0$), and the method of lines discretization of (2.1a), is

$$\frac{d}{dt}\omega_{\mathbf{j}}^{h} = -\mathbf{I}[\omega^h]_{\mathbf{j}}^{0}(h)\cdot(\nabla_h\omega^h)_{\mathbf{j}}, \tag{2.10}$$

where ∇_h is an approximation to ∇ to at least fourth order. Equation (2.10) then has a fourth-order consistency error in space, even though the velocity approximation is only second order. That this error is realized in numerical simulations of fluid motions will be demonstrated in the next section.

Remark 2. For the case of the rectangular grid, the calculation of the coefficient $C_2(\alpha)$ appears formidable. And indeed, a straightforward implementation of the sum (2.8b), for $\alpha = 2$, produces summands of the size 10^{-14} only by $m = 12600$. Fortunately, the convergence of this sum can be considerably improved by using the Euler–MacLaurin summation formula (see, for example, [29]) to successively remove the dominant behavior of the summand. From the summation formula applied to (2.8c), we have for $m >> 1$,

$$\begin{aligned} f(m;\alpha) &= \frac{1}{6}\frac{\alpha^2-1}{(1+\alpha^2)^2}\frac{1}{m^2} - \frac{1}{30}\frac{(\alpha^2-1)(\alpha^4-10\alpha^2+1)}{(1+\alpha^2)^4}\frac{1}{m^4} + O\left(\frac{1}{m^6}\right) \\ &= f_2(\alpha)\frac{1}{m^2} + f_4(\alpha)\frac{1}{m^4} + O\left(\frac{1}{m^6}\right). \end{aligned}$$

Thus, we can rewrite the sum in (2.8b) as

$$\begin{aligned} \sum_{m=1}^{\infty}\frac{1}{m}f(m;\alpha) &= \sum_{m=1}^{\infty}\frac{1}{m}\left[f(m;\alpha) - f_2(\alpha)\frac{1}{m^2} - f_4(\alpha)\frac{1}{m^4}\right] \\ &\quad + f_2(\alpha)\zeta(3) + f_4(\alpha)\zeta(5), \end{aligned} \tag{2.11}$$

where

$$\zeta(s) = \sum_{m=1}^{\infty}\frac{1}{m^s}, s > 1,$$

is the Riemann zeta function. In particular, $\zeta(3) = 1.202056903159594$ and $\zeta(5) = 1.036927755143370$. The sum in (2.8b) now converges as $O((1/m)^7)$, and is trivial to compute; for $\alpha = 2$, the above formula produces summands of magnitude 10^{-14} by $m = 45$. Figure 1 shows $C_2(\alpha)$ calculated by the above formulae.

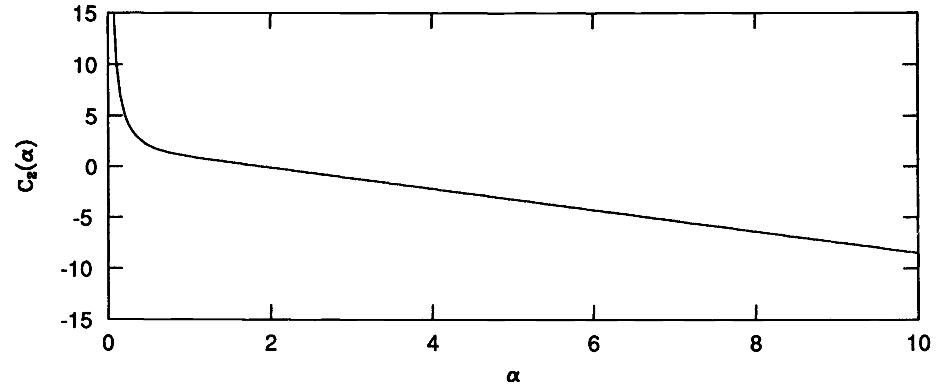

FIG. 1. *The second-order error coefficient* $C_2(\alpha)$.

Remark 3. We can use the calculation of $C_2(\alpha)$ to obtain a fourth-order quadrature rule for the Biot–Savart integral by subtracting the second-order term

$$\tilde{\mathbf{I}}_{\mathbf{j}}(h) = \mathbf{I}[\omega]^0_{\mathbf{j}}(h) - \left(\frac{-\omega^h_{x_2,\mathbf{j}}}{4\pi} C_2(\alpha), \frac{\omega^h_{x_1,\mathbf{j}}}{4\pi} C_2(1/\alpha) \right) h_1 h_2. \tag{2.12}$$

We have assumed that $\omega_{x_2,\mathbf{j}}$ and $\omega_{x_1,\mathbf{j}}$ are approximated to at least fourth order by $\omega^h_{x_2,\mathbf{j}}$ $\omega^h_{x_1,\mathbf{j}}$. Use of this formula requires little effort, since for the calculation of ω_t, these spatial derivatives must be approximated anyway.

Remark 4. That the error coefficients only depend on derivatives of ω at $\mathbf{X_j}$ is true also for the higher-order coefficients. This type of expression for $\mathbf{C}[\omega]_{\mathbf{j},2}$ is also very similar to that derived by Sidi and Israeli [29] for quadrature rules of one-dimensional integrals with Cauchy singularities, and which was subsequently used by Shelley [28] in a study of singularity formation in vortex sheet motion.

Remark 5. The second-order error coefficient (2.8a) can also be found without recourse to the Poisson summation formula. This is done by dividing the quadrature error (2.5) into local and nonlocal contributions. The nonlocal contributions can be estimated by using the Euler–MacLaurin summation formula, and the local contributions lead to sums similar to those in (2.8). It may be that the more general curvilinear case could be handled by such an approach. Furthermore, in the case of the square grid, the expression of $\mathbf{C}[\omega]_{\mathbf{j},2}$, (2.9), can be found by manipulating both integral and sum so as to have a smoother integrand and summand, to which standard quadrature estimates can then be applied.

Part B (*Error Expansion Theorem*). *The higher-order error coefficients* ($p > 1$) *are given by*

$$\mathbf{C}[\omega]_{\mathbf{j},2p} = \frac{1}{(2\pi)^{2p}} \sum_{\substack{r,q \\ r+q=2p-1}} (-D^{q,r}(\alpha)[\omega], D^{r,q}(1/\alpha)[\omega])|_{\mathbf{x_j}}, \tag{2.13}$$

where $D^{r,q}(\alpha)$ is a linear differential operator of order r in x_1 and order q in x_2, and whose coefficients depend upon α, r, and q.

Remark 6. The operator $D^{q,r}(\alpha)$ involves lattice sums analogous to those in (2.8). These sums are absolutely convergent, and their values are independent of the choice of smoothing function δ_ϵ. It is only the second-order coefficient for which there is a question of interpretation of the sum.

Remark 7. In the special case of a square grid ($\alpha = 1$), it can be shown that $\mathbf{C}[\omega]|_{\mathbf{j},2p} = \mathbf{0}$ for $p > 1$ and odd. That is, after the h^2 term, the expansion has only powers of h^4. Thus, an eighth-order method could be easily obtained by performing one Richardson extrapolation of the point vortex approximation to remove the fourth-order term. The second-order and eighth-order terms remain, but the second-order term disappears in the evolution equation as before.

The proof of the error expansion theorem is given in the appendices. In Appendix A the derivation of the Poisson summation formula for singular functions is given. In Appendix B, the extended Poisson summation formula is used to rigorously derive the coefficients $\mathbf{C}[\omega]_{\mathbf{j},2p}$ of the error expansion (2.6). In Appendix C, the second-order error term is expressed in terms of rapidly convergent series as given in (2.8).

It has now been shown how, for rectangular grids, fourth-order methods can be found by a trivial and explicit removal of the second-order error (and even this was not necessary in the square grid case). We also note that the point vortex approximation can be evaluated very efficiently in this case. Equation (2.7) can be written as

$$\mathbf{I}[w]_{\mathbf{j}}^{0}h = \sum_{\mathbf{k}} \tilde{\mathbf{K}}_{\mathbf{j}-\mathbf{k}}\omega_{\mathbf{k}}, \tag{2.14}$$

where

$$\tilde{\mathbf{K}}_{\mathbf{j}} = h_1 h_2 \mathbf{K}(j_1 h_1, j_2 h_2).$$

That is, (2.14) is a discrete convolution. In such cases, through the discrete Fourier transform and its associated discrete convolution theorem, the FFT algorithm can be used to evaluate such sums very rapidly. To employ these techniques, the kernel $\tilde{\mathbf{K}}_{\mathbf{j}}$ and vorticity $\omega_{\mathbf{j}}$ must be extended appropriately as periodic functions, and then represented as discrete Fourier transforms. The details of this are straightforward and will not be given here. For a rectangular mesh the computational complexity of forming the velocity on the mesh is thus $O(N^2 \ln N)$, where N is the number of grid points in each direction. There are now very well developed multidimensional FFT packages that are highly vectorized, and that realize the asymptotic complexity of the algorithm for relatively small values of N.

In the more general case of a curvilinear coordinate system, the existence of the error expansion also allows the derivation of higher-order methods through Richardson extrapolation. Here we give explicitly a fourth-order formula. Using

$$\mathbf{E}[\omega]_{\mathbf{j}}^{0}(2h) = \mathbf{I}[\omega]_{\mathbf{j}} - \mathbf{I}[\omega]_{\mathbf{j}}^{2h} = 4\mathbf{C}[\omega]_{\mathbf{j},2}h^2 + 16\mathbf{C}[\omega]_{\mathbf{j},4}h^4 + \cdots$$

together with (2.5), we find that defining the new quadrature rule $\mathbf{I}[\omega]_{\mathbf{j}}^{1}(h)$ by

$$\mathbf{I}[\omega]_{\mathbf{j}}^{1}(h) = \frac{1}{3}\left[4\mathbf{I}[\omega]_{\mathbf{j}}^{0}(h) - \mathbf{I}[\omega]_{\mathbf{j}}^{0}(2h)\right] = \frac{4}{3}h^2 \sum_{\substack{j_1+k_1 \text{ odd} \\ \text{or} \\ j_2+k_2 \text{ odd}}} \mathbf{K}(\mathbf{X}_{\mathbf{j}} - \mathbf{X}_{\mathbf{k}})J_{\mathbf{k}}\omega_{\mathbf{k}} \tag{2.15}$$

and gives the error

$$\mathbf{E}[\omega]_{\mathbf{j}}^{1}(h) = \mathbf{I}[\omega]_{\mathbf{j}} - \mathbf{I}[\omega]_{\mathbf{j}}^{1}(h) = -12\mathbf{C}[\omega]_{\mathbf{j},4}h^4 + \cdots. \tag{2.16}$$

A method of lines treatment of (2.2b) would then have the form

$$\frac{d}{dt}\omega_{\mathbf{j}}(t) = [(\mathbf{F}(\mathbf{X}_{\mathbf{j}}(t),t) - \mathbf{I}[\omega(t)]_{\mathbf{j}}^{1}(h))] \cdot [\nabla_{h,\mathbf{b}}\mathbf{X}]_{\mathbf{j}}^{-1} \cdot (\nabla_{h,\mathbf{b}}\omega)_{\mathbf{j}}. \tag{2.17}$$

Obviously, further extrapolations to gain higher order could be done computationally, or by calculation of the specific formula. However, we note that further extrapolations would involve computing further doublings of the mesh size, which generally leads to larger error coefficients in the error expansions.

The fourth-order quadrature method given by (2.15), $\mathbf{I}[\omega]_{\mathbf{j}}^{1}(h)$, can be efficiently implemented in a number of ways. If the grid is nonrectangular, then fast summation techniques such as those using hierarchical elements [1], or multipole expansions [17] can be employed. Equation (2.15) can be interpreted as dividing the grid into four interlaced subgrids, as shown in the schematic in Fig. 2. Each grid point is labeled as belonging to subgrid M_1, M_2, M_3, or M_4. Then the quadrature rule $\mathbf{I}[\omega]_{\mathbf{j}}^{1}(h)$ for $\mathbf{b}_{\mathbf{j}} \in M_i$ becomes

$$\mathbf{I}[\omega]_{\mathbf{j}}^{1}(h) = \frac{4}{3}h^2 \sum_{\mathbf{b}_{\mathbf{k}} \notin M_i} \mathbf{K}(\mathbf{X}_{\mathbf{j}} - \mathbf{X}_{\mathbf{k}})J_{\mathbf{k}}\omega_{\mathbf{k}}. \tag{2.18}$$

Thus, this fourth-order quadrature rule for the Biot–Savart integral is seen as an abstracted point vortex approximation, where instead of a singular self-interaction term being omitted, a subgrid of quadrature points is omitted. Also, the set of field points M_1 all use the same set of vortex points M_2, M_3, and M_4 to find the velocity on M_1, and the quadrature weights are independent of the field point position. These are the types of quadrature rules to which fast summation methods are applicable. In principle, fast summation methods based on multipole expansions or hierarchical elements have computational complexities of $O(N^2)$ or $O(N^2 \ln N)$. However, we have not found these methods to be competitive in evaluating the sum when summation using the FFT can be employed.

3. Some numerical results.

We have implemented these methods to numerically solve two incompressible open-flow problems of enduring interest. The first is the nonlinear roll-up of a thin shear layer through the Kelvin–Helmholtz instability. The second is the interaction of two oppositely signed vortices being driven together by an external straining flow.

For a flow periodic in one direction (say, 2π-periodic in x_1), the Biot–Savart integral can be summed exactly over each period to yield an integral, with modified kernel, over a single periodic strip. In particular, $\mathbf{K}$ in (2.1c) is replaced by

$$\mathbf{K}_{\text{per}}(x_1, x_2) = \frac{1}{4\pi}\frac{(-\sinh(x_2), \sin(x_1))}{\cosh(x_2) - \cos(x_1)},$$

and the domain of integration is $[0, 2\pi] \times (-\infty, +\infty)$. We assume that the vorticity is rapidly decaying as $|x_2| \to \infty$.

We consider the initial data

$$\omega(x_1, x_2) = -\exp(-\alpha(x_1)^2 x_2^2),$$

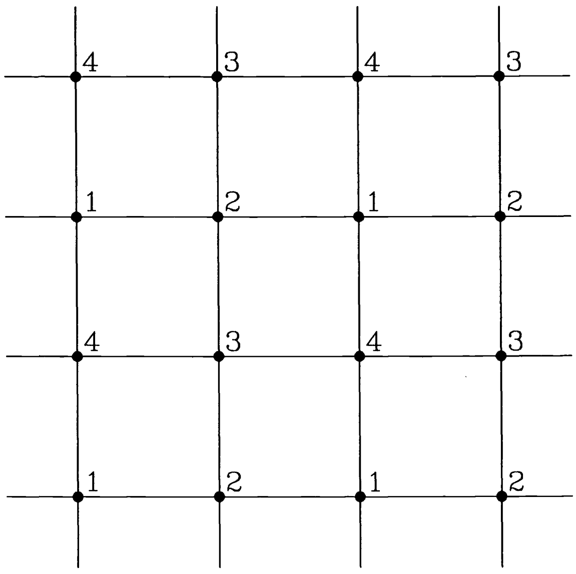

FIG. 2. *A schematic of the four-grid decomposition, M_1, M_2, M_3, and M_4.*

where $\alpha(x_1)^2 = \beta[1+\epsilon(\cos x_1 - 1)]$. That is, ω describes a flat shear layer of characteristic width $1/\sqrt{\beta}$, whose width is sinusoidally perturbed with nondimensional amplitude ϵ. If the vorticity amplitude were likewise scaled as $\sqrt{\beta}$ (fixing the circulation independently of β) and $\beta \to \infty$, this would yield vortex sheet initial data with an initially flat sheet and a sinusoidal perturbation to a constant vortex sheet strength.

We have chosen $\beta = 10$ and $\epsilon = .1$. This is a fairly thin shear layer with aspect ratio of about 20:1. As this flow develops very steep gradients in the vorticity, it is a severe test of any method. Figures 3(a)–3(d) show contours of the evolving vorticity at the times $t = 0$, 20, 25, and 30, respectively. The computational domain is $[0, 2\pi] \times [-5\pi/8, 5\pi/8]$ and vorticity is initially of the size $2 \cdot 10^{-17}$ on the upper and lower boundaries. Figures 3(a)–3(c) are with $N_1 = 512$ and $N_2 = 320$, and Fig. 3(d) is with $N_1 = 1024$ and $N_2 = 640$. The tick marks on the box boundaries correspond to the grid. These choices for N_1 and N_2 give a square mesh covering the computational domain. The contour lines are from -0.95 up to -0.05 at intervals of 0.05.

Here, the velocity on the grid is computed by the point vortex approximation (2.7) using the periodic kernel $\mathbf{K}_{\text{per}}$, and the sums are evaluated rapidly using the FFT. By scaling both N_1 and N_2 as N, the amount of work per time step is then $O(N^2 \ln N)$. On a Cray Y-MP, with $N_1 = 1024$ and $N_2 = 640$, evaluation of the velocity took about one second. The vorticity gradient is computed by cubic splines in each direction, assuming periodic boundary conditions in the x_1-direction, and zero data on the upper and lower boundaries. Cubic splines with such boundary conditions yield fourth-order derivative approximations on the mesh points. Then, since $h_1 = h_2$, and by Remark 1 of §2, the method of lines discretization (2.10) of the vorticity transport equation (2.1a) has a fourth-order spatial consistency error. The method of time integration used is a fourth-order, Adams–Moulton predictor-corrector method. The time step was $\Delta t = .00625$, which, for the $N_1 = 1024$ calculation, was halved at $t = 20$ to satisfy the CFL condition.

The time steps used are small enough to effectively remove time discretization errors from the calculation.

Figures 3(a)–3(d) trace the usual course of vortex layer roll-up (see, for example, [3] for such calculations with layers of constant vorticity). The Kelvin–Helmholtz instability initially causes vorticity to advect towards the center, leading to a relative concentration there (see Fig. 3(b)). The layer rolls up subsequently and forms a central rotating vortex with trailing arms. As the vorticity is strained into the center, the outer arms thin and large gradients in the vorticity are created there. As the contour lines are also material curves for the flow, their considerable stretching and folding likewise lead to large gradients.

The error in the calculations can be estimated through use of its asymptotic expansion. For example, by assuming that for the vorticity

$$E^h_{\omega,\mathbf{j}} = \omega_{\mathbf{j}} - \omega^h_{\mathbf{j}} = A_4h^4 + A_6h^6 + \cdots, \tag{3.1}$$

we then have the estimate

$$E^h_{\omega,\mathbf{j}} = \frac{\omega^{2h}_{\mathbf{j}} - \omega^h_{2\mathbf{j}}}{2^4 - 1} + O(h^6). \tag{3.2}$$

Then

$$L_{h,\infty}[\omega] = \max_{\mathbf{j}} \left| \frac{\omega^{2h}_{\mathbf{j}} - \omega^h_{2\mathbf{j}}}{2^4 - 1} \right| \tag{3.3}$$

is an approximation to maximum error in the vorticity.

The left-hand box in Fig. 4 shows $L_{h,\infty}[\omega]$ (solid) and $L_{h,\infty}[u]$ (dashed) for $h = 2\pi/N_1$ with $N_1 = 128, 256, 512$, and 1024 for $0 \le t \le 30$, while the right-hand box shows the order of the calculations approximated by the expression $\log_2(L_{2h,\infty}/L_{h,\infty})$. Here u is the velocity in the x_1-direction and is calculated on the grid using (2.12). All the evidence suggests a stable and convergent scheme. For a single calculation, the error shows a monotonic increase as the layer rolls up. This is hardly surprising (referring to Figs. 3(a)–3(d)); gradients of vorticity evolving under the Euler equations grow very rapidly, and in fact obey an evolution equation similar to that for the vorticity vector in three dimensions. As the resolution is improved, the accuracy is improved upon the entire range of integration. The approximation of the order shows a clear fourth-order error for a range of time that increases as the resolution is improved. The velocity error shows generally a slower decrease than does the vorticity error. This is true as well for the decrease away from fourth-order error. This is likely a consequence of the velocity being one degree smoother than the vorticity.

A difficulty of the $L_{h,\infty}$ measure of the error in ω^h is that it assumes that ω^{2h} is still well represented by (3.1). Other measures of the error, which do not depend as strongly on expansion (3.1), are the approximated circulation and maximum vorticity. For this flow the circulation C in a periodic strip is a conserved quantity. The graph at the left in Fig. 5 shows $-\log_{10}|C - C_h|$, as a function of time, for the four successive doublings of the mesh size beyond $N_1 = 64$. C_h is calculated using the trapezoidal rule over the computational box, which would be of infinite order in the absence of discretization errors in ω (this explains the very high accuracy at $t = 0$). The calculated order of the convergence is shown in the graph at right, and the fourth-order convergence is seen clearly over nearly the entire range of integration. We note however that the circulation is an integral measure of the error, and as such is a weak measure of accuracy.

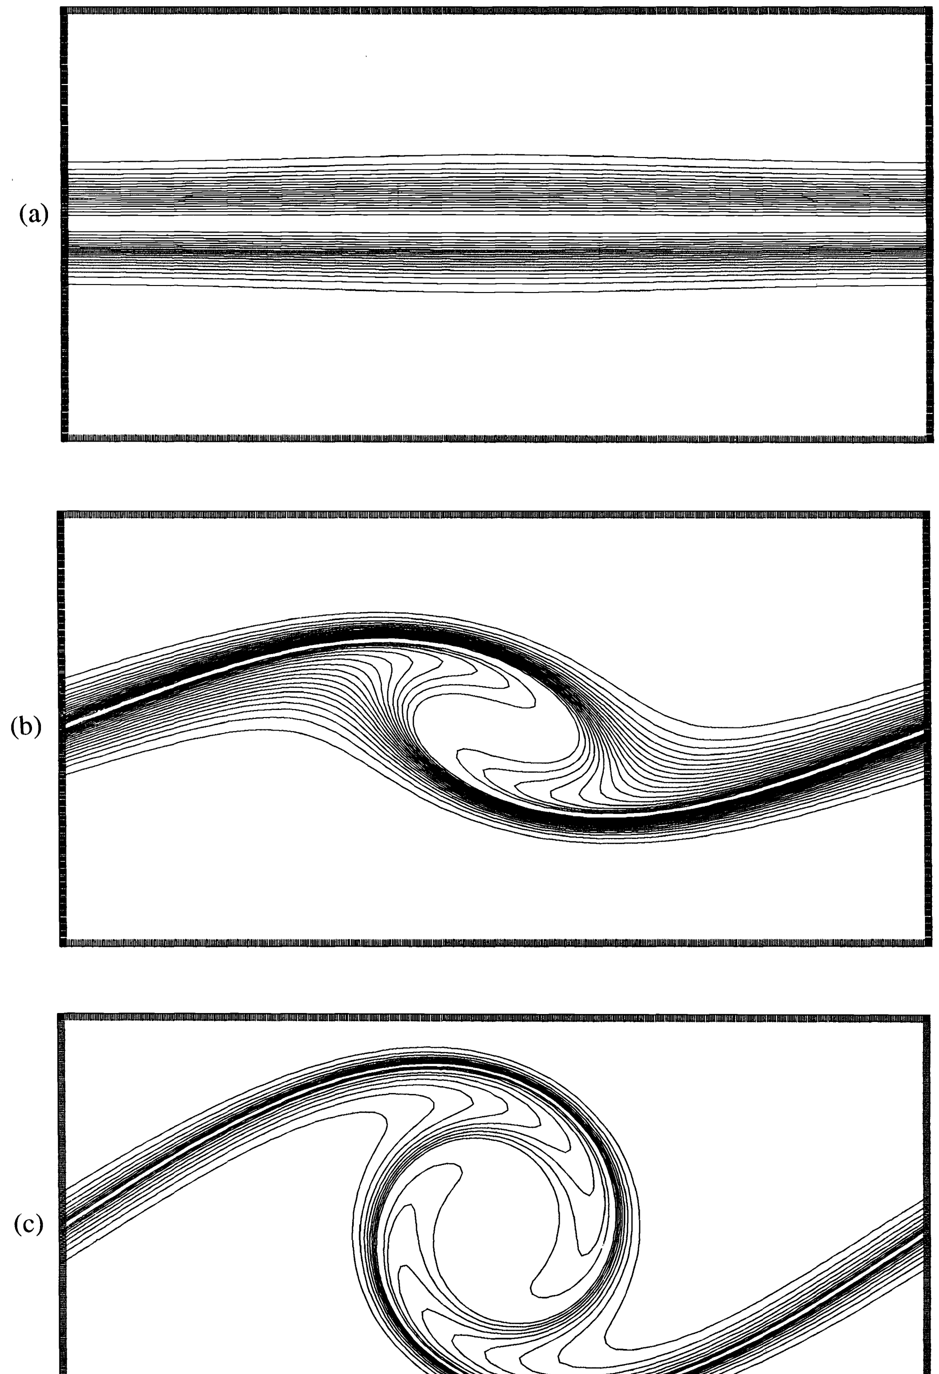

FIG. 3. *Contours of the vorticity for an evolving thin shear layer at times $t = 0, 20, 25,$ and 30. The contour levels run from -0.95 to $-.05$, at intervals of .05.*

(d)

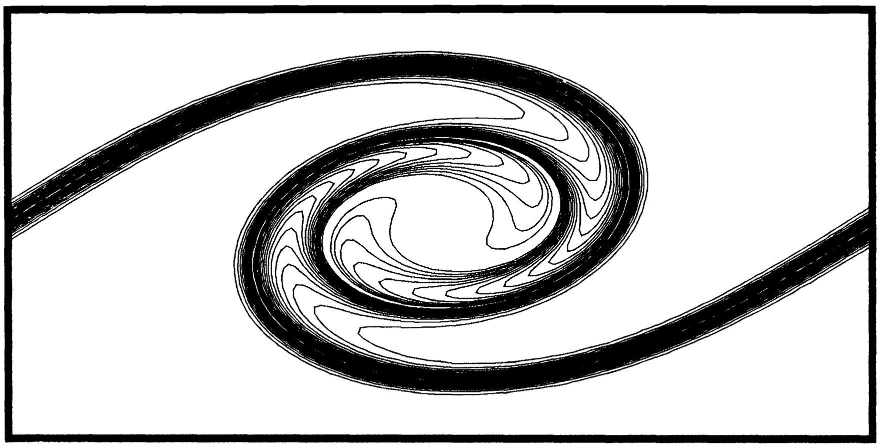

FIG. 3. *Continued.*

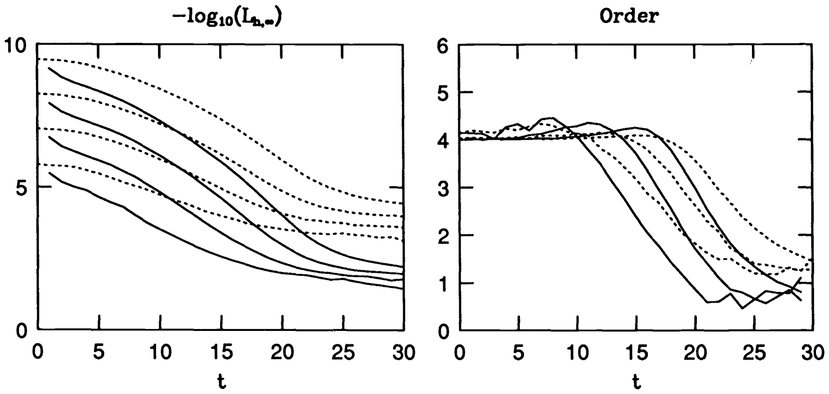

FIG. 4. *The approximated error in vorticity (solid) and velocity (dashed) for $h = 2\pi/N_x$ with $N_x = 128, 256, 512,$ and 1024 for $0 \le t \le 30$. The accuracy improves as N is increased. The right-hand box shows the order of the calculations.*

Another invariant of the two-dimensional Euler equations is $\|\omega\|_\infty$, the maximum modulus of the vorticity. This quantity must be estimated point-wise. As such, it is a stronger measure of error than the circulation. Figure 6 shows $\|\omega\|_{h,\infty}$, or the maximum vorticity on the mesh, for the five different resolutions. For the initial condition used, $\|\omega\|_\infty = 1$, and $|\omega(x_1, x_2, t = 0)| = 1$ along the entire curve $x_2 = 0$. While convergence is plainly seen, the spatial location of the maximum value jumps around the mesh as the flow evolves, and it is difficult to estimate an order of convergence from this quantity. We note specifically, that for the calculation with $N_1 = 1024$ and $N_2 = 640$, $\|\omega\|_{h,\infty} \simeq 1.001$ at $t = 30$.

We have also performed these calculations using the more general fourth-order point vortex approximation (2.15), obtained by extrapolation of the second-order quadrature. The extrapolated method also shows fourth-order convergence, and appears stable

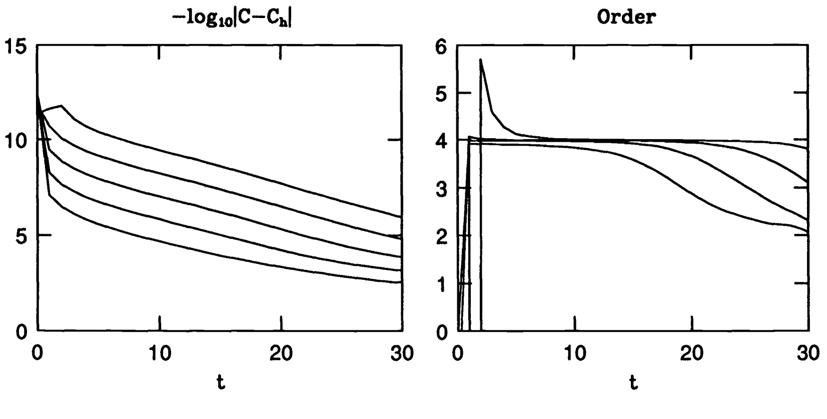

FIG. 5. *The error in circulation, with its approximation calculated by using the trapezoidal rule over the computational box for* $N_x = 64, 128, 256, 512$, *and* 1024. *The accuracy improves as N is increased. The right-hand box shows the orders of the computations.*

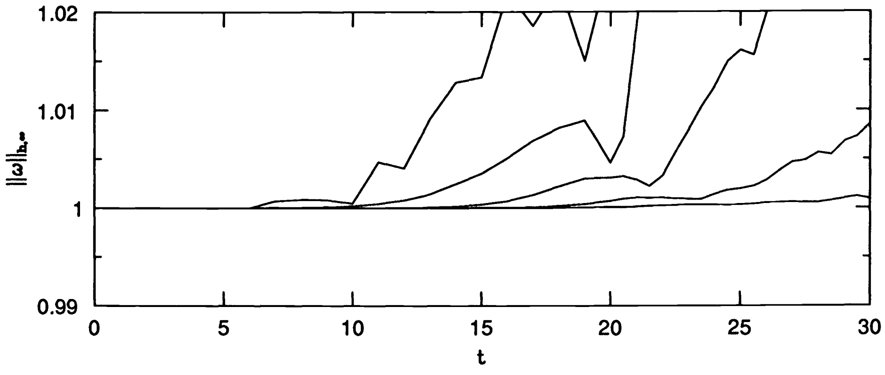

FIG. 6. *The maximum vorticity on the grid* $\|\omega\|_{h,\infty}$ *for* $N_2 = 64, 128, 256, 512$, *and* 1024. *The difference from* 1 *decreases as N is increased.*

and convergent. Its associated errors are typically larger by about a factor of twelve than those associated with using (2.10), which is consistent with the change in the fourth-order error coefficient introduced by the extrapolation.

We now consider a much different problem. We calculate the motion of two oppositely signed vortices that interact under the imposition of an external straining flow. This problem features a strong vorticity gradient production that quickly taxes any method. However, the steepest gradients tend to be aligned in a single direction, and the introduction of a simple time-dependency of the grid helps retain resolution of the flow. The behavior of such flows is relevant to the study of three-dimensional vortex interaction and reconnection (see, for example, [27]). It is a simple, but nontrivial, problem that nicely illustrates how appropriate choice of time dependency in the grid motion can greatly improve the accuracy of a calculation.

Consider special solutions to the three-dimensional Euler equations that are of the form

$$
\begin{aligned}
\mathbf{U} &= (u, v, w) \\
&= (\tilde{u}(x_1, x_2, t) - \gamma x_1, \tilde{v}(x_1, x_2, t) + \beta x_2, \tilde{\omega}(x_1, x_2, t) + (\gamma - \beta)x_3).
\end{aligned} \tag{3.4}
$$

Here, while there are components of velocity and vorticity in all three directions, the only true x_3-dependency is through the irrotational and incompressible straining field

$$(-\gamma x_1, \beta x_2, (\gamma - \beta)x_3).$$

For solutions of this form, the full Euler equations reduce to two-dimensional evolution equations for u and v, in which the only effect of the velocity component w is through the rate-of-strain in that direction, namely, $\gamma - \beta$. Here, w is simply advected as a scalar field in the two-dimensional velocity field $\mathbf{V} = (\tilde{u} - \gamma x_1, \tilde{v} + \beta x_2)$. In terms of the scalar vorticity $\omega = v_{x_1} - u_{x_2} = \tilde{v}_{x_1} - \tilde{u}_{x_2}$, the evolution equations can be given in a form very similar to equation set (2.1). Namely,

$$\omega_t + \mathbf{V} \cdot \nabla\omega = \omega(\gamma - \beta), \tag{3.5a}$$

and

$$(\tilde{u}, \tilde{v})(\mathbf{x}, t) = \int_{\mathbf{R}^2} \mathbf{K}(\mathbf{x} - \mathbf{x}')\omega(\mathbf{x}', t)dx_1'\, dx_2', \tag{3.5b}$$

where $\mathbf{K}$ is defined as before by (2.1c). As initial data we take

$$\omega(\mathbf{x}, 0) = a(\exp((x_1 - 1/2)^2 + x_2^2)/d^2 - \exp((x_1 + 1/2)^2 + x_2^2)/d^2). \tag{3.6}$$

The initial vorticity is then two Gaussian cores of opposite sign and with width d, centered at $\pm 1/2$. The rates-of-strain are set as $\gamma = 2$ and $\beta = 1$. That is, there is a compressive external flow in the x_1-direction that pushes the two vortices together and extensional flows in the x_2 and x_3-directions. The extensional rate-of-strain in the x_2-direction elongates the vortices in that direction, while that in x_3 leads to vortex stretching. Furthermore, we choose $a = 10$ and $d = 1/4$.

Such a flow could be considered as a model for the interaction of two adjacent vortices being driven together by strains induced by other vorticity distributions in the flow, or as a model of the effect of three-dimensional vortex tube curvature, where the two vortices are cross sections of two adjacent vortex tubes. Such a flow illustrates the effect of external strains producing core deformation and thus altering the interaction of the vortices with each other.

The primary difficulty in computing such a flow is that as the two vortices are driven together by the external straining flow, large gradients are rapidly produced in the vorticity. To maintain good resolution of the flow, we found it necessary to introduce a simple time dependence of the grid. Namely, we allowed the grid to collapse with the compressive strain in the x_1-direction, so as to maintain resolution of the sharp vertical gradients that have formed. In addition, as two vortices translate vertically through their mutually induced velocities, the x_2-position of the grid must be chosen accordingly so that the vorticities are kept within the computational domain. That is,

$$\frac{d}{dt}x_1(\mathbf{b}, t) = -\gamma x_1(\mathbf{b}, t) \quad \text{with } x_1(\mathbf{b}, t = 0) = b_1,$$

$$\frac{d}{dt}x_2(\mathbf{b}, t) = \bar{v}_2(t) \quad \text{with } x_2(\mathbf{b}, t = 0) = b_2,$$

where $\bar{v}_2(t)$ is chosen to keep the x_2-centroid of the vortices fixed at $x_2 = 0$. This requires the computation of the circulation, the x_2-centroid and its time derivative all on a half-plane of the domain (since the circulation over the whole domain is zero). We calculated these integrals on the right half-plane by Simpson's rule. This choice maintains a rectangular grid.

For this time-dependent coordinate system we can find $\nabla_b \mathbf{X}$ in closed form, and thus also the Jacobian J for (2.3). Thus, we can evolve the vorticity transport equation (2.2b) (with the forcing term from the strain included). More importantly, the grid is no longer square, and the point vortex approximation (2.7) does not yield a fourth-order evolution without modification. Accordingly, we now use the quadrature rule (2.12), where $C_2(\alpha(t)), \alpha = h_1/h_2$, must be calculated at each time step. As noted in Remark 2 of §2, this can be done easily and rapidly through the use of formula (2.11), and only requires $\nabla\omega$, whose computation is already necessary. Again, it is assumed that ω is zero on the boundaries. For variety we use fourth-order differences rather than splines to calculate $\nabla\omega$. This appears to have little effect on the computation.

Figures 7(a)–7(c) show the contours of the computed vorticity field at $t = 0, .5$ and 1.0 with $N_1 = N_2 = 256$ and $\Delta t = .00078125$. The perimeter in Figs. 7(a)–7(c) is the boundary of the time-dependent computational domain. The computational box is initially of length 4.2 on a side. The time step was chosen small enough to effectively remove time discretization errors from this calculation (as well as the calculation where the initial x_1-positions of the grid were held fixed).

Figure 8 shows the errors in ω (solid) and u (dashed), as well as their orders, as approximated by (3.3). The errors in ω are normalized by the maximum vorticity, $\|\omega\|_\infty(t) = a\exp(\gamma - \beta)t$. Here, $N_1 = N_2 = 128$ and 256. This is to be contrasted with Fig. 9, which shows the same quantities, but for the same calculations with the initial x_1-grid locations held fixed. The errors for the calculation with the moving grid is much smoother in time, and increase more slowly. Indeed, by $t = 0.4$, the moving grid calculation with $N_1 = 128$ is as accurate as that for the fixed grid with $N_1 = 256$, and becomes more accurate (by virtue of its slower increase) by the end of the calculation.

The total conserved circulation of the two vortices is zero. However, it is also true that circulation computed from vorticity of a single sign is conserved, and in particular the circulation in the left or right half-plane is conserved (note that $x_1 = 0$ is a free-slip surface for this flow). Figure 10 shows the error in the circulation for the right-hand vortex (calculated on the right half-plane using Simpson's rule), and its computed order, for the moving (solid) grid calculation at the three resolutions $N_1 = N_2 = 64, 128$, and 256 and the fixed (dashed) grid at the $N_1 = N_2 = 256$ resolution. This figure only serves to further illustrate the advantage in accuracy the moving grid affords over the fixed calculation. There is a slight degradation in accuracy near $t = 1$ for the $N_1 = N_2 = 256$ calculation. This is due to the vertical boundary (upon which the vorticity and its derivatives are assumed to be zero) coming too close to the support of the vorticity. The lower resolution runs are less sensitive to such a boundary effect. Figure 11 shows the normalized maximum vorticity on the mesh

$$\|\omega\|_{h,\infty}/\|\omega\|_\infty = ae^{-(\gamma-\beta)t}\|\omega\|_{h,\infty}$$

for the moving grid calculations (solid). The fixed grid quantity with $N_1 = N_2 = 256$ is included as the dashed curve. Again, convergence is observed as N is increased. The normalized maximum vorticity for the $N_1 = N_2 = 256$ calculation with moving grid is 0.9985 at $t = 1$.

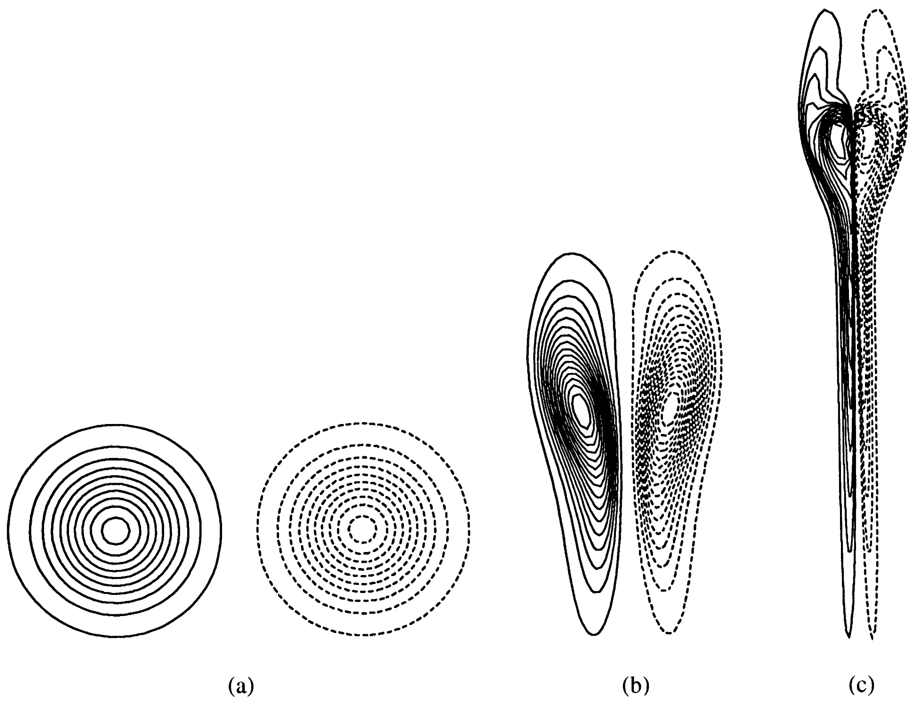

FIG. 7. *Contours of the vorticity for the two-vortex straining flow at* $t = 0, .5,$ *and* 1. *The contour levels in Fig.* 7(a) *from* -9.4 *to* 9.6, *in Fig.* 7(b) *from* -16.3 *to* 16.4, *and in Fig.* 7(c) *from* -28.4 *to* 28.5, *all with increments of* 1. *Here, the initial box size is* 4.2 *on a side,* $N_x = N_y = 256$, *and* $\Delta t = .00078125$.

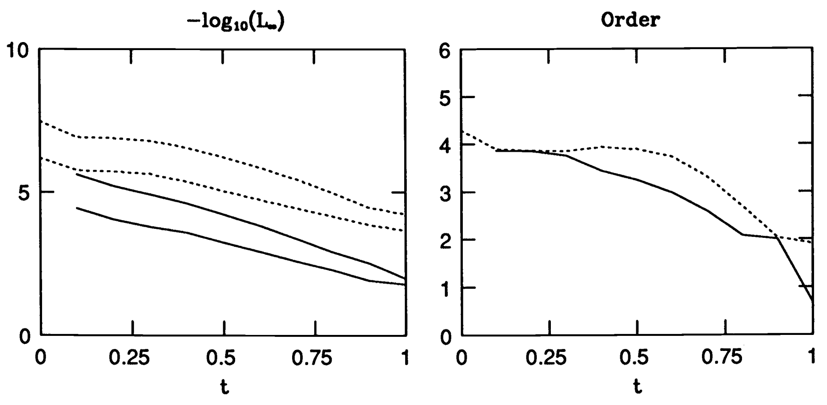

FIG. 8. *The approximated error in vorticity (solid) and velocity (dashed) with their orders in the right-hand box for* $N_x = N_y = 128, 256$. *The errors in vorticity are normalized by the maximum vorticity* $\|\omega\|_\infty(t) = a\exp(\gamma - \beta)t$. *The accuracy improves as N is increased. The right-hand box shows the orders of the computations.*

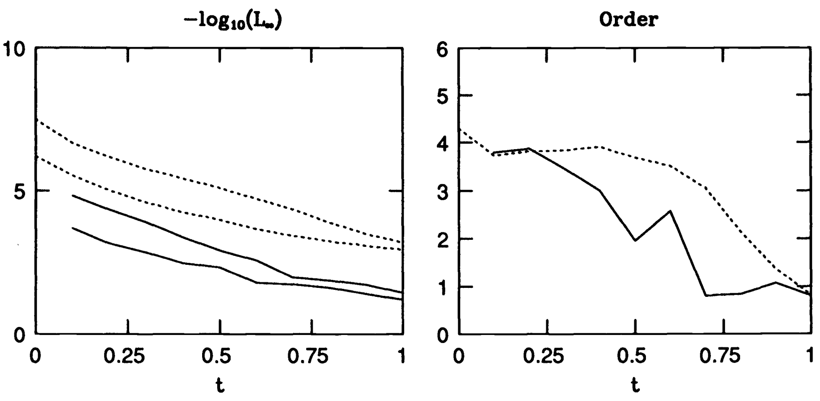

FIG. 9. *The same quantities as in Fig. 7, but with the initial grid held fixed.*

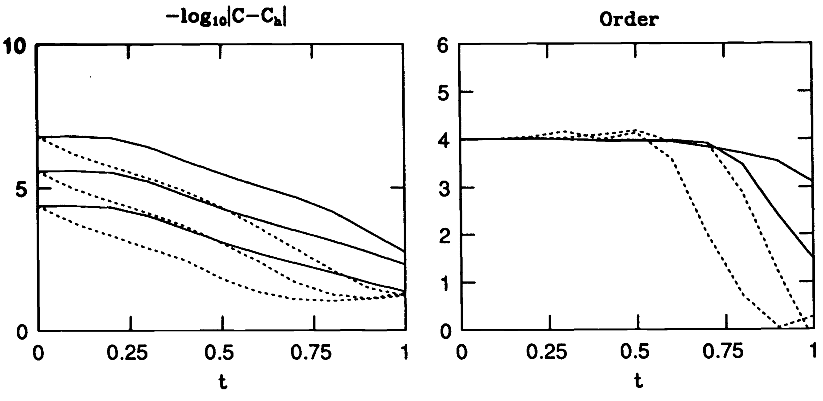

FIG. 10. *The circulation error in the right half-plane, with its approximation computed by using Simpson's rule in the right half-plane. The* solid *curves are for the* moving *grid and the* dashed *curves are for the* fixed *grid. The errors are for $N_x = N_y = 64, 128, 256$. The accuracy improves as N is increased. The order of these errors is presented in the right-hand box.*

Finally, we note that in recent work, Fishelov [15] also considered a fixed-grid method for the vorticity formulation of the two-dimensional, incompressible Euler equations. She used a vortex blob discretization evaluated by direct summation. This approach may be more useful for long times and for cases where the grid is allowed to move since the blob discretization provides improved stability for Lagrangian methods (see [5], for example). However, the blob approach is not likely to be useful for fixed grids and for short times, as we found that a vortex blob discretization with a Beale and Majda fourth-order kernel (using $\delta = h^{.95}$) gave velocity errors that were two orders of magnitude larger than those for our fourth-order modified point vortex discretization (2.12) at $t = 0$ and for the initial data (3.6) and $N_1 = N_2 = 256$.

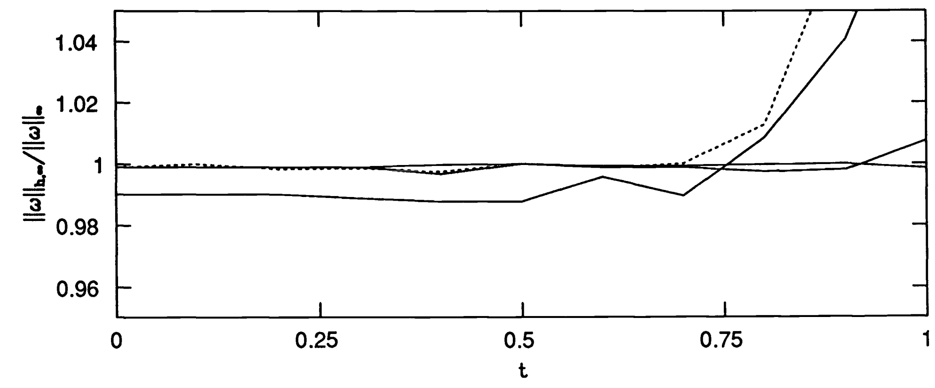

FIG. 11. *The normalized maximum vorticity on the grid,* $\|\omega\|_{h,\infty}/\|\omega\| = ae^{-(\gamma-\beta)t}\|\omega\|_{h,\infty}$. *The* solid *curves are for the* moving *grid with* $N_x = N_y = 64, 128, 256$, *and the* dashed *curve is for the* fixed *grid with* $N_x = N_y = 256$. *The difference from* 1 *decreases as N is increased.*

4. Conclusion. In this work we have developed new numerical methods, based on the vorticity formulation, for solving the two-dimensional, incompressible Euler equations. In the vorticity formulation of the Euler equations, the velocity is obtained directly from the vorticity through the Biot–Savart integral, and the vorticity is updated on the computational grid. An advantage of this formulation for open and periodic problems is that asymptotic boundary conditions on the velocity are explicitly incorporated into the Biot–Savart kernel, and the focus is then simply on finding accurate and efficient methods for evaluating the Biot–Savart integral over a regular mesh. Here we have considered the point vortex approximation on rectangular meshes.

Using the Poisson summation formula generalized to include singular integrands, we constructed the explicit error expansion for the point vortex approximation to the Biot–Savart integral. The existence of the error expansion was proved by Goodman et al. more generally on smooth, curvilinear grids, but the method of proof was not constructive. Thus in the case of a rectangular grid, we have proved an explicit example of the expansion. We found that the leading second-order error term depends on the vorticity only through the local value of its gradient. The coefficient is expressible as a two-dimensional lattice sum, and we demonstrate how its calculation can be done easily and rapidly. This leads to a simple modification of the point vortex approximation that yields fourth-order accuracy. In the special case of a square grid, the method of lines formulation of the vorticity transport equation, using the unmodified, second-order point vortex approximation and a fourth-order gradient approximation, automatically yields a fourth-order evolution of the vorticity. We note also that in the square grid case, the error expansion contains terms with only fourth powers of h after the leading second-order term.

Furthermore, we have demonstrated the utility of these methods through their employment to solve both the nonlinear roll-up of a thin, spatially periodic shear layer, and the interaction of two oppositely signed vortices being pushed together under an external, three-dimensional straining flow. As the summations were done on a rectangular grid, the FFT algorithm was used (through use of the discrete convolution theorem) to rapidly evaluate the velocity on the grid. Thus, the calculations are performed at high resolution. We were able to accurately follow the evolution of the shear layer well into the nonlinear regime, where the bulk of the vorticity has concentrated itself into a central vortex. This concentration is linked, in the thin layer limit, to the formulation of singularities observed in vortex sheets [3]. By employing a grid that collapsed naturally with the external compressive flow, we were able to compute the motion of two vortices driven together under the strain. Physically, the interest lies in their severe deformation and elongation, which yields enhanced dissipation in the presence of viscosity (see, for example, [9] for viscous calculations).

These methods have already found application in the study of buoyancy-driven flows, including both two-dimensional Boussinesq and fully stratified fluids [25]. In both these cases, the incompressibility constraint gives the Biot–Savart relation between velocity and vorticity, and the methods are directly applicable. There are several other directions that further work should take. Our time integration method does not make use of the fact that the vorticity transport equation is a conservation law. The use of methods constructed for such transport equations, such as ENO methods [19], or other high-order Godunov type schemes, would improve the robustness of these methods (see also [7]). It would also be useful to find the second-order error coefficient for the point vortex approximation on a generally smooth, curvilinear coordinate system. This would allow the construction of fourth-order methods together with more general adaptivity, without resorting to explicit extrapolation to gain additional accuracy. For the three-dimensional Euler equations, we have seen that there is an apparent difficulty in directly applying the methods developed here to the so-called grid-free point vortex approximation. We are currently studying this. We note that the existence of asymptotic error expansions has been proved not only for the three-dimensional Biot–Savart integral, but also for its gradient whose computation is necessary to compute the stretching term in the vorticity transport equation (see [13]). Another very important extension is to devise methods to treat the presence of walls, both with and without the presence of viscosity.

Appendix A. Poisson summation formula for singular functions. In this appendix, we present a version of the usual Poisson summation formula (see [14], for example) extended to the case of a function with an isolated and integrable singularity at the origin and in two space dimensions. It will be clear from this analysis how to obtain more general results. We begin by introducing some notation.

Define the Fourier transform in two dimensions by

$$\hat{f}(\mathbf{k}) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} e^{-i\mathbf{k}\cdot\mathbf{x}} f(\mathbf{x})\,dx_1 dx_2, \tag{A.1}$$

where $\mathbf{k} = (k_1, k_2)$ and $\mathbf{x} = (x_1, x_2)$. Its inverse transform is given by

$$f(\mathbf{x}) = \frac{1}{(2\pi)^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} e^{-i\mathbf{k}\cdot\mathbf{x}} \hat{f}(\mathbf{x})\,dk_1 dk_2. \tag{A.2}$$

Define the convolution of the functions f, g by

$$f * g(\mathbf{x}) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(\mathbf{x}-\mathbf{x}')g(\mathbf{x}')\,dx_1' dx_2'. \tag{A.3}$$

By the convolution theorem,

$$\widehat{f * g}(\mathbf{k}) = \hat{f}(\mathbf{k})\hat{g}(\mathbf{k}) \tag{A.4}$$

and

$$\widehat{fg}(\mathbf{k}) = \frac{1}{(2\pi)^2}\hat{f} * \hat{g}(\mathbf{k}). \tag{A.5}$$

Denote a smoothing function by $\delta_\epsilon(\mathbf{x})$, and let it satisfy the usual properties of an approximate identity [31]. Then for any f, a smoothed version of it is given by

$$f_\epsilon(\mathbf{x}) = f * \delta_\epsilon(\mathbf{x}). \tag{A.6}$$

Define the physical space grid by

(A.7)

$$\Lambda(\alpha_1,\alpha_2) = \{\mathbf{x_j} \,|\mathbf{x_j} = (j_1h_1, j_2h_2) \text{ with } h_1 = \alpha_1 h, h_2 = \alpha_2 h \quad\text{and}\quad \mathbf{j} = (j_1,j_2) \in \mathbf{Z}^2\},$$

and the dual phase space grid by

$$\Lambda^*(\alpha_1,\alpha_2) = \left\{\mathbf{k_j} \mid \mathbf{k_j} = \left(\frac{1}{\alpha_1}j_1, \frac{1}{\alpha_2}j_2\right) \quad\text{and}\quad \mathbf{j} = (j_1,j_2) \in \mathbf{Z}^2\right\}. \tag{A.8}$$

Then we obtain the following formula.

POISSON SUMMATION FORMULA FOR SINGULAR FUNCTIONS. *Let $f(\mathbf{x})$ be rapidly decaying in* $\mathbf{x}$, *and smooth except for an isolated and integrable singularity at* $\mathbf{x} = \mathbf{0}$. *Then,*

$$\begin{aligned}\sum_{\mathbf{x}\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} f(\mathbf{x_j})h_1h_2 - \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(\mathbf{x})dx_1dx_2 = \\ \lim_{\epsilon\to 0}\left[\sum_{\mathbf{k_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}_\epsilon\left(\frac{2\pi}{h}\mathbf{k_j}\right) - f_\epsilon(\mathbf{0})h_1h_2\right],\end{aligned} \tag{A.9}$$

where f_ϵ is the smoothed version of f.

Remark 1. As the function f has a singularity at the origin, its Fourier coefficients may decay too slowly to be absolutely summable. Consequently, the smoothing function $\delta_\epsilon(\mathbf{x})$ provides the mechanism to interpret their sum. In addition, the smoothing also gives rise to a residue, or self-induction term. However, since the left-hand side of (A.9) is independent of the choice of smoothing function, so is the right-hand side. Thus all smoothing effects in it must cancel.

Remark 2. Under certain circumstances, depending on the function f *and* the smoothing function δ_ϵ, the limit of the right-hand side of (A.9) exists for each term separately. We discuss this in detail after the proof.

Remark 3. Equation (A.9) can be generalized to functions with nonintegrable singularities provided they can be interpreted in the principle value sense. In this case, the choice of smoothing functions is restricted to the ones that give the correct principle value in the continuous case, i.e., in the integral on the left-hand side of (A.9) is replaced by

$$\text{P.V.}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(\mathbf{x})dx_1dx_2,$$

while the rest of the formula (A.9) remains unchanged.

Remark 4. The formula (A.9) can also be generalized to functions with several isolated singularities. For example, suppose that the singular points are $\mathbf{z}_1,\ldots,\mathbf{z}_n$. Let the smoothed version of f be f_ϵ as before. If the singular points lie on the grid $\Lambda(\alpha_1,\alpha_2)$, then (A.9) becomes

$$\sum_{\substack{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)\\ \mathbf{x_j}\neq z_1,\ldots,z_n}} f(\mathbf{x_j})h_1h_2 - \int\int f(\mathbf{x})dx_1dx_2 = \lim_{\epsilon\to 0}\left[\sum_{\mathbf{k_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}_\epsilon\left(\frac{2\pi}{h}\mathbf{k_j}\right) - \sum_{l=1}^{n} f_\epsilon(\mathbf{z}_l)h_1h_2\right]. \tag{A.10}$$

Proof of summation formula. The proof of (A.9) is almost trivial. We rely on the Poisson summation formula for smooth functions [12] as stated in the following.

POISSON SUMMATION FOR SMOOTH FUNCTIONS. *Let $g(\mathbf{x})$ be smooth and rapidly decaying. Then,*

$$\sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)} g(\mathbf{x_j})h_1h_2 - \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} g(\mathbf{x})dx_1dx_2 = \sum_{\mathbf{k_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{g}\left(\frac{2\pi}{h}\mathbf{k_j}\right). \tag{A.11}$$

Now we apply this formula to f_ϵ, which is the smoothed version of f. Thus, we have

$$\sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)} f_\epsilon(\mathbf{x_j})h_1h_2 - \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f_\epsilon(\mathbf{x})dx_1dx_2 = \sum_{\mathbf{k_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}_\epsilon\left(\frac{2\pi}{h}\mathbf{k_j}\right). \tag{A.12}$$

Now write

$$\sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)} f_\epsilon(\mathbf{x_j})h_1h_2 = \sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} f_\epsilon(\mathbf{x_j})h_1h_2 + f_\epsilon(\mathbf{0})h_1h_2. \tag{A.13}$$

Therefore, we get

$$\sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} f_\epsilon(\mathbf{x_j})h_1h_2 - \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f_\epsilon(\mathbf{x})dx_1dx_2 = \sum_{\mathbf{k_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}_\epsilon\left(\frac{2\pi}{h}\mathbf{k_j}\right) - f_\epsilon(\mathbf{0})h_1h_2. \tag{A.14}$$

The limit as $\epsilon\to 0$ of the left-hand side of (A.14) clearly exists. Consequently, the limit as $\epsilon\to 0$ of the right-hand side exists and yields the result (A.9).

It is natural here to address the question of whether the limit of the right-hand side of (A.9) can be taken for each term separately. It is sufficient to determine whether the limit as $\epsilon\to 0$ of $f_\epsilon(\mathbf{0})$ exists. If it does, the existence of the limit of the left-hand side of (A.9) implies that the limit of the sum of Fourier coefficients must then also exist and hence the limit can be separated.

Suppose that $f(\mathbf{x})$ can be written as

$$f(\mathbf{x}) = H(\mathbf{x})g(\mathbf{x}), \tag{A.15}$$

where $H(\mathbf{x})$ contains the local singularity and $g(\mathbf{x})$ is smooth and rapidly decaying. Then we have

$$f_\epsilon(\mathbf{0}) \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} H(\mathbf{x})g(\mathbf{x})\delta_\epsilon(\mathbf{x})dx_1dx_2. \tag{A.16}$$

Define a characteristic function χ_R by

$$\chi_R(\mathbf{x}) = \begin{cases} 1 \text{ if } |x_1| \leq R \text{ and } |x_2| \leq R, \\ 0 \text{ otherwise}. \end{cases} \tag{A.17}$$

Furthermore, define $\tilde{g}(\mathbf{x})$ by

$$\tilde{g}(\mathbf{x}) = g(\mathbf{x}) - [g(\mathbf{0}) + \nabla g(\mathbf{0}) \cdot \mathbf{x}]\chi_R(\mathbf{x}). \tag{A.18}$$

Then $f_\epsilon(\mathbf{0})$ becomes

$$\begin{aligned} f_\epsilon &= g(\mathbf{0}) \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} H(\mathbf{x})\delta_\epsilon(\mathbf{x})\chi_R(\mathbf{x}) dx_1 dx_2 \\ &\quad + \nabla g(\mathbf{0}) \cdot \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \mathbf{x} H(\mathbf{x})\delta_\epsilon(\mathbf{x})\chi_R(\mathbf{x}) dx_1 dx_2 \\ &\quad + \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} H(\mathbf{x})\tilde{g}(\mathbf{x})\delta_\epsilon(\mathbf{x}) dx_1 dx_2 \\ &\equiv I_{\epsilon,R} + II_{\epsilon,R} + III_{\epsilon,R}. \end{aligned} \tag{A.19}$$

Since $H(\mathbf{x}), \mathbf{x}H(\mathbf{x})$, and $H(\mathbf{x})\tilde{g}(\mathbf{x})$ have successively smoother behavior as $|\mathbf{x}| \to 0$, there is no hope for cancellation of divergent terms by summing the different integrals. Therefore, the limit as $\epsilon \to 0$ of $f_\epsilon(\mathbf{0})$ exists if and only if the limit as $\epsilon \to 0$ of $I_{\epsilon,R}$, $II_{\epsilon,R}$, and $III_{\epsilon,R}$ exists separately.

Consider $I_{\epsilon,R}$ first.

$$\lim_{\epsilon \to 0} I_{\epsilon,R} = \lim_{\epsilon \to 0} \int_{-R}^{+R} \int_{-R}^{+R} H(\mathbf{x})\delta_\epsilon(\mathbf{x}) dx_1 dx_2. \tag{A.20}$$

Since $H(\mathbf{x})$ has a local singularity at the origin, the only way such a limit can exist is by some cancellation. Therefore, suppose that

$$H(\mathbf{x}) = -H(-\mathbf{x}), \qquad \delta_\epsilon(\mathbf{x}) = \delta_\epsilon(-\mathbf{x}). \tag{A.21}$$

Then, $I_{\epsilon,R} = 0$ for any ϵ and R and hence the limit (A.20) exists and is equal to 0.

Consider $III_{\epsilon,R}$ next. By construction, $H(\mathbf{x})\tilde{g}(\mathbf{x}) = O(|\mathbf{x}|)$ as $|\mathbf{x}| \to 0$ and is integrable. Therefore,

$$\lim_{\epsilon \to 0} III_{\epsilon,R} = \lim_{\epsilon \to 0} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} H(\mathbf{x})\tilde{g}(\mathbf{x})\delta_\epsilon(\mathbf{x}) dx_1 dx_2 = 0 \tag{A.22}$$

by standard arguments such as the Riemann–Lebesgue lemma if δ_ϵ is the Dirichlet kernel (see below).

Finally, it remains to consider $II_{\epsilon,R}$. The existence of this limit is a classical question in harmonic analysis. In general, this limit will exist if and only if $\mathbf{x} = \mathbf{0}$ is a Lebesgue or a Dirichlet point (see [30]) of the function $\mathbf{x}H(\mathbf{x})$. We do not give the most generally known conditions for the existence of such points here, but it is easy to show that if $H(\mathbf{x}) = K_i(\mathbf{x})$ then these limits exist. K_1 with $i = 1, 2$ denotes the components of the Biot–Savart kernel.

For simplicity, we consider two standard types of smoothing functions: scaled and dilated L^1 functions

$$\delta_\epsilon(\mathbf{x}) = \frac{1}{\epsilon^2}\eta\left(\frac{x_1}{\epsilon}, \frac{x_2}{\epsilon}\right) \tag{A.23}$$

with η even, positive, and of mean 1, and the Dirichlet kernel

$$\delta_\epsilon(\mathbf{x}) = \delta_{\frac{1}{M}}(\mathbf{x}) = \frac{\sin\left(\frac{Mx_1}{\alpha_1}\right)}{\pi x_1}\frac{\sin\left(\frac{Mx_2}{\alpha_2}\right)}{\pi x_2}, \tag{A.24}$$

where α_1, α_2 serve to weight the coordinate directions (see Appendix C).

Now correspondingly, write $II_{\epsilon,R}$ as $II^s_{\epsilon,R}$ for the scaled smoothing function

$$II^s_{\epsilon,R} = \int_{-\frac{R}{\epsilon}}^{+\frac{R}{\epsilon}}\int_{-\frac{R}{\epsilon}}^{+\frac{R}{\epsilon}} \tilde{\mathbf{H}}(\epsilon\mathbf{x})\eta(\mathbf{x})dx_1dx_2, \tag{A.25}$$

where $\tilde{\mathbf{H}}(\mathbf{x}) = \mathbf{x}H(\mathbf{x})$, and as $II^D_{\epsilon,R}$ for the Dirichlet kernel

$$II^D_{\frac{1}{M},R} = \frac{1}{\pi^2}\int_{-\frac{RM}{\alpha_2}}^{+\frac{RM}{\alpha_2}}\int_{-\frac{RM}{\alpha_1}}^{+\frac{RM}{\alpha_1}} \tilde{\mathbf{H}}\left(\frac{\alpha_1 x_1}{M}, \frac{\alpha_2 x_2}{M}\right)\frac{\sin(x_1)}{x_1}\frac{\sin(x_2)}{x_2}dx_1dx_2. \tag{A.26}$$

The question reduces to whether the limit as $\epsilon \to 0$ exists for $II^s_{\epsilon,R}$ or $II^D_{\epsilon,R}$. Now take $H(\mathbf{x}) = \mathbf{K}_i(\mathbf{x})$. Then notice that with this choice, $\tilde{\mathbf{H}}(\mathbf{x})$ is homogeneous of degree 0 so that

$$II^s_{\epsilon,R} = \int_{-\frac{R}{\epsilon}}^{+\frac{R}{\epsilon}}\int_{-\frac{R}{\epsilon}}^{+\frac{R}{\epsilon}} \tilde{\mathbf{H}}(\mathbf{x})\eta(\mathbf{x})dx_1dx_2 \tag{A.27}$$

and

$$II^D_{\frac{1}{M},R} = \frac{1}{\pi^2}\int_{-\frac{RM}{\alpha_2}}^{+\frac{RM}{\alpha_2}}\int_{-\frac{RM}{\alpha_1}}^{+\frac{RM}{\alpha_1}} \tilde{\mathbf{H}}(\alpha_1 x_1, \alpha_2 x_2)\frac{\sin(x_1)}{x_1}\frac{\sin(x_2)}{x_2}dx_1dx_2. \tag{A.28}$$

It is clear that the limit as $\epsilon \to 0$ of $II^s_{\epsilon,R}$ exists since $\tilde{\mathbf{H}}(\mathbf{x})$ is bounded on the plane and $\eta \in L^1(\mathbf{R}^2)$. The limit as $M \to \infty$ of $II^D_{\frac{1}{M},R}$ is directly calculable by contour integration (see Appendix C). Consequently, the limit of the right-hand side of (A.9) can be separated as follows.

SPECIAL POISSON SUMMATION FORMULA FOR THE BIOT–SAVART KERNEL. *If $f(\mathbf{x}) = K_i(\mathbf{x})g(\mathbf{x})$, g is smooth and rapidly decaying, and δ_ϵ is either the scaled smoothing function or the Dirichlet kernel, then*

$$\begin{aligned}\sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} f(\mathbf{x_j})h_1h_2 - \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} f(\mathbf{x})dx_1dx_2 &= \\ \text{P.V.}\sum_{\mathbf{k_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}\left(\frac{2\pi}{h}\mathbf{k_j}\right) - \lim_{\epsilon\to 0} f_\epsilon(\mathbf{0})h_1h_2&,\end{aligned} \tag{A.29}$$

where the P.V. *denotes the principal value sum defined by*

$$\text{P.V.}\sum_{\mathbf{k}_j\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}\left(\frac{2\pi}{h}\mathbf{k_j}\right) = \lim_{\epsilon\to 0}\sum_{\mathbf{k}_j\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{f}\left(\frac{2\pi}{h}\mathbf{k_j}\right). \tag{A.30}$$

Remark 1. We use this formula (A.29) with $g(\mathbf{x}) = \omega(\mathbf{x})$ in Appendices B and C to construct the explicit error expansion.

Remark 2. Although the result (A.29) is independent of the smoothing function, the rate of convergence as $\epsilon \to 0$ is highly dependent on the choice. In Appendix C, we exploit this property by using the Dirichlet kernel as the smoothing function. This yields rapidly and absolutely convergent sums and thus enables us to obtain very accurate approximations of error expansion coefficients.

Remark 3. Of course, the formula (A.29) holds for more general functions $f = Hg$. Generally, if the limit as $\epsilon \to 0$ of $I_{\epsilon,R}$, II_ϵ, R, and $III_{\epsilon,R}$ exists, then (A.29) holds, although even this is not the most general case. Notice, though, that the three-dimensional version of $II_{\epsilon,R}$ does not have a limit since there the Biot–Savart kernel is $O(1/|x|^2)$ as $|x| \to 0$ so that the corresponding $\mathbf{x}H(\mathbf{x})$ is unbounded at the origin. This is currently under study.

Appendix B. Error Expansion. In this appendix we obtain an error expansion for the point vortex approximation to the Biot–Savart integral on a rectangular mesh. The expansion is obtained through an asymptotic analysis of the Fourier coefficients appearing in the special Poisson formula for the Biot–Savart kernel (A.29).

In previous work, Goodman, Hou, and Lowengrub [16] proved the existence of such an error expansion. However, it is difficult to determine the coefficients of the expansion from their method of proof. For example, their second-order coefficient contains an undetermined constant of integration. Our proof is similar to theirs in spirit, but our method provides a prescription for the explicit determination of the coefficients.

In this appendix, we do not derive explicit expressions for the coefficients, although we indicate how it is done. We save their explicit evaluation for Appendix C where we obtain an expression for the second-order coefficient. This term is the most delicate to obtain. The Biot–Savart kernel in two dimensions is

$$\text{(B.1)} \qquad \mathbf{K}(\mathbf{x}) = \frac{1}{2\pi}\frac{(-x_2, x_1)}{{x_1}^2 + {x_2}^2},$$

where $\mathbf{x} = (x_1, x_2)$. We want to describe the discretization error between the Biot–Savart integral and the point vortex approximation

$$\text{(B.2)} \qquad \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{K}(\mathbf{x_l} - \mathbf{x})\omega(\mathbf{x})dx_1dx_2 - \sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{x_l}} \mathbf{K}(\mathbf{x_l} - \mathbf{x_j})\omega(\mathbf{x_j})h_1h_2,$$

where $\Lambda(\alpha_1, \alpha_2)$ is the rectangular grid defined in (A.7), $h_1 = \alpha_1 h$ and $h_2 = \alpha_2 h$.

It would be routine to describe this error if the integrand were smooth. However, $\mathbf{K}(\mathbf{x})$ has an isolated integrable singularity at $\mathbf{x} = \mathbf{0}$. Thus, to handle this, we use the special Poisson summation formula (A.29).

Without loss of generality, and for the sake of clarity, we study the error $\mathbf{I}(\mathbf{0}) - \mathbf{I}_h(\mathbf{0})$, where

$$\text{(B.3)} \qquad \mathbf{I}(\mathbf{0}) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{K}(\mathbf{x})\omega(\mathbf{x})dx_1dx_2$$

and

$$\text{(B.4)} \qquad \mathbf{I}_h(\mathbf{0}) = \sum_{\mathbf{x_j}\in\Lambda(\alpha_1,\alpha_2)\backslash\mathbf{0}} \mathbf{K}(\mathbf{x_j})\omega(\mathbf{x_j})h_1h_2.$$

This corresponds to taking $\mathbf{x}_1 = \mathbf{0}$ in (B.2) and dropping the minus sign inside the kernel. Now, following the prescription of Appendix A, w define the smoothed version of the integrand in (B.3) by

$$(\mathrm{B.5}) \qquad (\mathbf{K}\omega)_\epsilon(\mathbf{x}) = (\mathbf{K}\omega) * \delta_\epsilon(\mathbf{x}) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{K}(\mathbf{x}')\omega(\mathbf{x}')\delta_\epsilon(\mathbf{x}-\mathbf{x}')dx_1'dx_2',$$

where $\delta_\epsilon(\mathbf{x})$ is given by (A.23) or (A.24).

The purpose of this section is now to prove the following result.

THEOREM 1 POINT VORTEX ERROR EXPANSION. *For $\omega(\mathbf{x})$ smooth and rapidly decaying, there exist coefficients $\tilde{\mathbf{C}}(\alpha)[\omega]_{0,2n}$ such that*

$$(\mathrm{B.6}) \qquad \mathbf{I}(\mathbf{0}) - \mathbf{I}_h(\mathbf{0}) = \lim_{\epsilon\to 0}(\mathbf{K}\omega)\,\epsilon(\mathbf{0})h_1h_2 + \sum_{n=1}^{N-1}\left(\frac{h}{2\pi}\right)^{2n}\tilde{C}(\alpha)[\omega]_{0,2N} + O(h^{2N})$$

for any N, α is the grid aspect ratio α_1/α_2. Furthermore, the coefficients $\tilde{C}$ are given by

$$(\mathrm{B.7}) \qquad \tilde{\mathbf{C}}(\alpha)[\omega]_{0,2n} = \sum_{\substack{r,q\\ r+q=2n-1}}\left(-D^{r,q}(\alpha)[\omega](\mathbf{0}), D^{q,r}\left(\frac{1}{\alpha}\right)[\omega](\mathbf{0})\right),$$

and $D^{r,q}(\alpha)$ is a linear differential operator of order r in x_1 and q in x_2 and whose coefficients depend on α, r, q.

Remark 1. For $n > 1$, these coefficients are the coefficients shown in (2.6) and (2.13) of §2. The second-order term $\mathbf{C}(\alpha)[\omega]_{0,2}$ in (2.8a) differs from $\tilde{\mathbf{C}}(\alpha)[\omega]_{0,2}$ exactly by the self-induction term in (B.6).

Remark 2. Our method of proof relies on the application of the special Poisson summation formula for the Biot–Savart kernel (A.29), asymptotics of the resulting Fourier lattice sums, and controlling the error from the asymptotics. The method is very general and can be applied in many other contexts where singular integrals arise.

Proof. We begin with the following lemma.

DISCRETIZATION LEMMA. *Suppose that $\omega(\mathbf{x})$ is smooth and rapidly decaying. Then the discretization error $\mathbf{I}(\mathbf{0}) - \mathbf{I}_h(\mathbf{0})$ is given by*

$$(\mathrm{B.8}) \qquad \mathbf{I}(\mathbf{0}) - \mathbf{I}_h(\mathbf{0}) = \lim_{\epsilon\to 0}(\mathbf{K}\omega)_\epsilon(\mathbf{0})h_1h_2 - \mathrm{P.V.}\sum_{\mathbf{l_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}}\widehat{\mathbf{K}\omega}\left(\frac{2\pi}{h}\mathbf{l_j}\right),$$

where

$$(\mathrm{B.9}) \quad \mathrm{P.V.}\sum_{\mathbf{l_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}}\widehat{\mathbf{K}\omega}\left(\frac{2\pi}{h}\mathbf{l_j}\right) = \lim_{\epsilon\to 0}\sum_{\mathbf{l_j}=\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}}\widehat{\mathbf{K}\omega}\left(\frac{2\pi}{h}\mathbf{l_j}\right)\hat{\delta}_\epsilon\left(\frac{2\pi}{h}\mathbf{l_j}\right).$$

The proof of this lemma is a straightforward application of (A.29) with $\mathbf{f}_\epsilon = (\mathbf{K}\omega)_\epsilon$.

Thus, to determine the error expansion, we must now examine the lattice sum that appears on the right-hand side of (B.8).

Define the function

$$(\mathrm{B.10}) \qquad \mathbf{F}(l_1, l_2, m_1, m_2, \tau) = (F_1, F_2) = \frac{(-l_2 + m_2\tau, l_1 - m_1\tau)}{(l_1 - m_1\tau)^2 + (l_2 - m_2\tau)^2}$$

with $\tau = \frac{h}{2\pi}$ as a small parameter. We now use $\mathbf{F}$ to evaluate $\widehat{\mathbf{K}\omega}(\frac{2\pi}{h}\mathbf{l})$ as follows.

LEMMA. *The Fourier transform of* $\mathbf{K}\omega$ *is*

$$\widehat{\mathbf{K}\omega}\left(\frac{2\pi}{h}\mathbf{l}\right) = \frac{-i}{(2\pi)^2}\tau \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{F}(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1, dm_2, \tag{B.11}$$

where $\tau = \frac{h}{2\pi}$.

Proof. Direct calculation gives

$$\hat{\mathbf{K}}(\mathbf{l}) = -i\frac{(-l_2, l_1)}{l_1^2 + l_2^2} \tag{B.12}$$

with $\mathbf{l} = (l_1, l_2)$. Now, by the convolution theorem, we get

$$\widehat{\mathbf{K}\omega}(\mathbf{l}) = \frac{1}{(2\pi)^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \hat{\mathbf{K}}(\mathbf{l} - \mathbf{m})\hat{\omega}(\mathbf{m})dm_1 dm_2. \tag{B.13}$$

Then, combining (B.12), (B.13), and (B.10) gives the result (B.11).

Now, using the result (B.11) in (A.9), we get

$$\begin{aligned}\text{P.V.} \sum_{\mathbf{l_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \widehat{\mathbf{K}\omega}\left(\frac{2\pi}{h}\mathbf{l_j}\right) &= -\tau \lim_{\epsilon\to 0} \sum_{\mathbf{l_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{\delta}_\epsilon\left(\frac{\mathbf{l_j}}{\tau}\right)\frac{i}{(2\pi)^2} \\ &\quad\cdot \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{F}(l_{j,1}, l_{j,2}, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1 dm_2,\end{aligned} \tag{B.14}$$

where $\mathbf{l_j} = (l_{j,1}, l_{j,2})$. Thus, we need to consider the integral

$$\frac{i}{(2\pi)^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{F}(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1, dm_2, \tag{B.15}$$

where $\mathbf{l} \in \Lambda^*(\alpha_1, \alpha_2)\backslash\mathbf{0}$. As τ is a small parameter, we want to expand (B.15) in τ (recall that $\tau = h/2\pi$). It is this expansion that, combined with the self-induction term, yields the error expansion. Of course, the function $\mathbf{F}$ has a singularity, and so we must be careful how we do this.

FOURIER LATTICE SUM EXPANSION LEMMA. *Suppose that* $\omega(\mathbf{x})$ *is smooth and rapidly decaying, and define* α *to be the aspect ratio of the grid* $\alpha = \alpha_1/\alpha_2$. *Then we obtain the following expansion for the Fourier lattice sum* (B.14):

$$\text{P.V.} \sum_{\mathbf{l_j}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \widehat{\mathbf{K}\omega}\left(\frac{2\pi}{h}\mathbf{l_j}\right) = \sum_{n=1}^{N-1}\left(\frac{h}{2\pi}\right)^{2n} \tilde{\mathbf{C}}(\alpha)[\omega]_{0,2n} + O(h^{2n}) \tag{B.16}$$

for any N, *where*

$$\tilde{\mathbf{C}}(\alpha)[\omega]_{0,2n} = \sum_{\substack{r,q \\ r+q=2n-1}} \left(-D^{r,q}(\alpha)[\omega](\mathbf{0}), D^{q,r}\left(\frac{1}{\alpha}\right)[\omega](\mathbf{0})\right), \tag{B.17}$$

and $D^{r,q}(\alpha)$ *is a linear differential operator of order* r *in* x_1 *and* q *in* x_2 *whose coefficients depend on* α, r, q.

Remark 1. As we will see, the differential operators $D^{r,q}$ arise because an expansion of $\mathbf{F}$ in (B.15) leads to the calculation of moments of $\hat{\omega}$. These moments are then identified with the derivatives of ω.

Remark 2. Although the coefficients $\tilde{C}(\alpha)[\omega]_{0,2n}$ depend on principle value lattice sums, only the value of the second-order term ($n = 1$) will change according to the smoothing function. This term involves a lattice sum that is not absolutely summable and thus its value will depend on how it is summed. For $n > 1$, there is no ambiguity in how the sum is taken as the relevant lattice sums are absolutely convergent.

Remark 3. As a result of the special sensitivity of the second-order term, we will discuss it in more detail in Appendix C. In particular, we will see how its value depends on the type of smoothing. Of course, as the resulting expansion is independent of the smoothing function, the self-induction term compensates for the dependence on the smoothing function here. This is analogous to the undetermined constant of integration in the analysis of Goodman, Hou, and Lowengrub [16].

Remark 4. The symmetry of the coefficients $\tilde{C}$ in α and r, q is a result of the relationship between F_1 and F_2, i.e., $F_2(l_1, l_2, m_1, m_2, \tau) = -F_1(l_2, l_1, m_2, m_1, \tau)$.

Remark 5. In the square grid case $\alpha = 1$, it can be shown that $\tilde{C}(\alpha)[\omega]_{0,2n} = \mathbf{0}$ for n odd. Thus, but for the second-order term, expansion is in powers of h^4. We do not present this here.

Proof. We begin by examining $\mathbf{F}$. Notice that $\mathbf{F}$ has a singular point at

$$(m_1, m_2) = \left(\frac{l_1}{\tau}, \frac{l_2}{\tau}\right). \tag{B.18}$$

Thus, since τ is a small parameter, we can expand $\mathbf{F}$ away from the singular point (B.18) in a series about $\tau = 0$:

$$\mathbf{F}(l_1, l_2, m_1, m_2, \tau) = \sum_{n=0}^{\infty} \partial_\tau^n \mathbf{F}(l_1, l_2, m_1, m_2, 0)\frac{\tau^n}{n!}. \tag{B.19}$$

We define a box in m-space about the singular point (B.18) by

$$\mathbf{B} = \left[\frac{l_1 - \tau}{\tau}, \frac{l_1 + \tau}{\tau}\right] \times \left[\frac{l_2 - \tau}{\tau}, \frac{l_2 + \tau}{\tau}\right]. \tag{B.20}$$

Then, consider the integral (B.15):

$$\begin{aligned}
&\frac{i}{(2\pi)^2}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \mathbf{F}(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1 dm_2 \\
&= \frac{i}{(2\pi)^2}\int\int_{\mathbf{R}^2\setminus B} \mathbf{F}(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1 dm_2 \\
&+\frac{i}{(2\pi)^2}\int\int_{B} \mathbf{F}(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1 dm_2 \\
&\equiv I + II.
\end{aligned} \tag{B.21}$$

Now, the expansion (B.19) of $\mathbf{F}$ can be used in I. We will show later that II is of arbitrarily high order in $\tau = (h/2\pi)$. Using the expansion, we write I as

$$I = \sum_{n=0}^{\infty} \frac{\tau^n}{n!}\frac{i}{(2\pi)^2}\int\int_{\mathbf{R}^2\setminus B} \partial_\tau^n \mathbf{F}(l_1, l_2, m_1, m_2, 0)\hat{\omega}(\mathbf{m})dm_1 dm_2. \tag{B.22}$$

Furthermore, we notice that $\partial_\tau^n \mathbf{F}(l_1, l_2, m_1, m_2, 0)$ is separable. That is, in each component of $\mathbf{F}$, we can separate the $\mathbf{l}$ and $\mathbf{m}$ dependence as follows:

$$\frac{i}{(2\pi)^2}\partial_\tau^n F_1(l_1, l_2, m_1, m_2, 0) = \frac{i}{(2\pi)^2}\sum_{\substack{r,q \\ r+q=n}} c_1^{r,q}(l_1, l_2) m_1^r m_2^q \tag{B.23}$$

and

$$\begin{aligned}\frac{i}{(2\pi)^2}\partial_\tau^n F_2(l_1,l_2,m_1,m_2,0) &= \frac{i}{(2\pi)^2}\sum_{\substack{r,q\\ r+q=n}} c_2^{r,q}(l_1,l_2)m_1^r m_2^q\\ &= -\frac{i}{(2\pi)^2}\sum_{\substack{r,q\\ r+q=n}} c_1^{r,q}(l_2,l_1)m_2^r m_1^q\\ &= -\frac{i}{(2\pi)^2}\sum_{\substack{r,q\\ r+q=n}} c_1^{r,q}(l_2,l_1)m_1^q m_2^r,\end{aligned}\tag{B.24}$$

since $F_2(l_1,l_2,m_1,m_2,\tau) = -F_1(l_1,l_2,m_1,m_2,\tau)$.

Equations (B.23) and (B.24) give the form of the differential operator in (B.17). For example, the first two terms are given by

$$c_1^{0,0}(\mathbf{l}) = -\frac{l_2}{l_1^2+l_2^2},\tag{B.25}$$

$$c_1^{0,1}(\mathbf{l}) = \frac{l_1^2-l_2^2}{(l_1^2-l_2^2)^2} \quad\text{and}\quad c_1^{1,0}(\mathbf{l}) = -\frac{2l_1l_2}{(l_1^2+l_2^2)^2}.\tag{B.26}$$

Now, we use the formulae (B.23), (B.24) in the expansion (B.22) for I to get

$$I_j = \sum_{n=0}^{\infty}\frac{\tau^n}{n!}\sum_{\substack{r,q\\ r+q=n}} c_j^{r,q}(\mathbf{l})\frac{i}{(2\pi)^2}\int\int_{\mathbf{R}^2\backslash B} m_1^r m_2^q\hat\omega(\mathbf{m})dm_1dm_2,\tag{B.27}$$

where $j = 1,2$ identifies the component. We want to identify the moments of $\hat\omega$ (in (B.27)) with derivatives of ω. To do this however, we need to extend the region of integration to all $\mathbf{R}^2$. We must also analyze the error in doing this. Write,

(B.28)

$$\begin{aligned}&\frac{i}{(2\pi)^2}\int\int_{\mathbf{R}^2\backslash B} m_1^r m_2^q\hat\omega(\mathbf{m})dm_1dm_2\\ &\quad= \frac{i}{(2\pi)^2}\int\int_{\mathbf{R}^2} m_1^r m_2^q\hat\omega(\mathbf{m})dm_1dm_2 - \frac{i}{(2\pi)^2}\int\int_{B} m_1^r m_2^q\hat\omega(\mathbf{m})dm_1dm_2\\ &\quad= i^{1-r-q}[\partial_x^r\partial_y^q\omega](\mathbf{0}) - \frac{i}{(2\pi)^2}\int\int_{B} m_1^r m_2^q\hat\omega(\mathbf{m})dm_1dm_2.\end{aligned}$$

The error term (the second term of (B.28)) can be seen to be of arbitrary order since $\mathbf{l}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}$. This is shown as follows: Since $|\hat\omega(\mathbf{m})| \le \frac{c}{|\mathbf{m}|^M}$ for any M with $|\mathbf{m}|$ sufficiently large (because ω is smooth), we get

(B.29)

$$\begin{aligned}E \equiv \left|\int\int_B m_1^r m_2^q\hat\omega(\mathbf{m})dm_1dm_2\right| &\le c\int\int_B |\mathbf{m}|^n\frac{1}{|\mathbf{m}|^M}dm_1dm_2\\ &\le c\int\int_B |\mathbf{m}|^{n-M}dm_1dm_2\\ &\le c\tau^{M-n}\int_-^+\int_-^+\frac{d\tilde m_1 d\tilde m_2}{[(\tau\tilde m_1+l_1)^2+(\tau\tilde m_2+l_2)^2]^{\frac{M-n}{2}}}\end{aligned}$$

by changing variables. Now, let us suppose that $\mathbf{l} = (l_1, l_2) \in \Lambda^*(\alpha_1, \alpha_2)\backslash\mathbf{0}$. Then, we can choose $\tau(= \frac{h}{2\pi})$ small enough

$$\text{(B.30)} \qquad \tau < \tfrac{1}{4}\min(1/\alpha_1, 1/\alpha_2),$$

so that there is no singularity in the integrand of (B.29), and obtain the bound

$$\text{(B.31)} \qquad E \leq c\frac{(2\tau)^{M-n}}{(l_1^2 + l_2^2)^{\frac{M-n}{2}}}.$$

As this is true for any M, this term is of arbitrary order. Therefore, combining (B.27), (B.28), (B.31), we get

$$\text{(B.32)} \qquad I_j = \sum_{n=0}^{N-1} \frac{\tau^n}{n!} \sum_{\substack{r,q \\ r+q=n}} c_j^{r,q}(\mathbf{l}) i^{1-r-q}[\partial_x^r \partial_y^q \omega](\mathbf{0}) + O\left(\frac{\tau^N}{|l|^N}\right)$$

for any N and $\mathbf{l} \in \Lambda^*(\alpha_1, \alpha_2)\backslash\mathbf{0}$. This takes care of the first term in (B.21).

It now remains to consider the second term.

$$\text{(B.33)} \qquad II = \frac{i}{(2\pi)^2}\int\int_B \mathbf{F}(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1 dm_2.$$

This term is also seen to be of arbitrary order.

Without loss of generality, we consider the case with F_1. We have

$$\text{(B.34)} \qquad II_1 = \frac{i}{(2\pi)^2}\int\int_B F_1(l_1, l_2, m_1, m_2, \tau)\hat{\omega}(\mathbf{m})dm_1 dm_2.$$

By changing variables and using again that $|\hat{\omega}(m)| \leq \frac{c}{|\mathbf{m}|^M}$, for any M, we obtain

$$\text{(B.35)} \qquad |II_1| \leq c\tau^{-2}\int_{-\tau}^{+\tau}\int_{-\tau}^{+\tau} \frac{|\tilde{m}_2|}{\tilde{m}_1^2 + \tilde{m}_2^2} \frac{d\tilde{m}_1 d\tilde{m}_2}{\left[\left(\frac{\tilde{m}_2 + l_2}{\tau}\right)^2 + \left(\frac{\tilde{m}_1 + l_1}{\tau}\right)^2\right]^{\frac{M}{2}}}.$$

Now, if $\mathbf{l} \in \Lambda^*(\alpha_1, \alpha_2)\backslash\mathbf{0}$ and τ satisfies (B.30), then the only singularity of the integrand is due to the term $1/(\tilde{m}_1^2 + \tilde{m}_2^2)$, which is integrable. Consequently, we have

$$\text{(B.36)} \qquad |II_1| \leq c\frac{(2\tau)^{M-1}}{(l_1^2 + l_2^2)^{M/2}},$$

and thus this term is also of arbitrary order.

Now, combining the results, (B.14), (B.21), (B.32), and (B.36), we get the result

(B.37)

$$\text{P.V.} \sum_{l_\mathbf{j} \in \Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} (\widehat{\mathbf{K}\omega})_m\left(\frac{1}{\tau}\mathbf{l_j}\right) = -\sum_{n=0}^{N-1}\frac{\tau^{n+1}}{n!}\lim_{\epsilon \to o}\sum_{l_\mathbf{j} \in \Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \hat{\delta}_\epsilon\left(\frac{1}{\tau}\mathbf{l_j}\right)$$
$$\cdot \sum_{\substack{r,q \\ r+q=n}} c_m^{r,q}(\mathbf{l_j}) i^{1-r-q}[\partial_x^r \partial_y^q \omega](\mathbf{0}) + O(\tau^{N+1})$$

for any N sufficiently large, and where $m = 1, 2$ denotes the component.

Finally, the $n = 0$ term, all the terms even in n, and parts of the odd terms vanish due to oddness of the summands in the lattice sum. (See (B.25), (B.26) for example.) Therefore, identifying $\tau = h/2\pi$ and the surviving terms with $\tilde{\mathrm{C}}(\alpha)[\omega]$ yields the result (B.16), and thus completes the proof of the Fourier lattice sum expansion lemma. This lemma, combined with the self-induction term, proves the result (A.6) and completes the proof of the point vortex error expansion.

Appendix C. Calculating the Second-Order Coefficient. In this appendix, we derive the expression in (2.8) for the second-order error coefficient $C[\omega]_{j,2}$. Although the value of the second-order term is independent of the choice of smoothing function used, the ease with which it can be actually computed depends very much on this choice. The higher-order coefficients present no such difficulty as their associated lattice sums converge absolutely and can thus be calculated (if necessary) in a straightforward manner.

We begin with some notation. Define the lattice sum by

$$S(\alpha) = 4\sum_{m=1}^{\infty} \frac{1}{m}[f(m;\alpha)], \tag{C.1}$$

where

$$f(m;\alpha) = \frac{1}{m}\sum_{l=0}^{m}{}' \left[\frac{(l/m)^2-\alpha^2}{[(l/m)^2+\alpha^2]^2} + \frac{1-\alpha^2(l/m)^2}{[1+\alpha^2(l/m)^2]^2}\right], \tag{C.2}$$

and $\sum'$ denotes the trapezoidal sum(i.e., the endpoints are weighted by $\frac{1}{2}$). The purpose of this appendix is to prove the following result given in §2.

THEOREM. SECOND-ORDER ERROR COEFFICENT. *For $\omega(\mathbf{x})$ smooth and rapidly decaying, the second-order error coefficient can be given as*

$$\mathrm{C}[\omega]_{\mathrm{j},2}h^2 = \frac{1}{4\pi}(-\omega_y(\mathbf{x_j})C_2(\alpha), \omega_x(\mathbf{x_j})C_2(1/\alpha))h_1h_2, \tag{C.3}$$

where $h_1 = \alpha_1 h$, $h_2 = \alpha_2 h$, α is the grid aspect ratio α_1/α_2, and

$$C_2(\alpha) = \frac{4}{\pi}\arctan(1/\alpha) - \frac{\alpha}{\pi}S(\alpha). \tag{C.4}$$

Remark 1. In the special case of a square grid $\alpha = 1$, we have $S(1) = 0$ and the second-order term then has the form

$$\mathrm{C}[\omega]_{\mathrm{j},2}h^2 = \frac{1}{4\pi}\nabla^{\perp}\omega(\mathbf{x_j})h_1h_2,$$

where $\nabla^{\perp}\omega = (-\omega_{x_2}, \omega_{x_1})$.

Remark 2. In the analysis of Goodman, Hou, and Lowengrub [16], it is essentially the smoothing function that gives rise to the undetermined constant of integration appearing in their second-order coefficient. We determine it explicitly.

Proof. Without loss of generality, we consider the case $\mathbf{x}_j = \mathbf{0}$. From (B.6), (B.9), (B.14), (B.26), and (B.27) $\mathrm{C}[\omega]_{0,2}$ can be given as

(C.5)

$$\mathrm{C}[\omega]_{0,2}h^2 =$$

$$\lim_{\epsilon\to 0}(\mathbf{K}w)_\epsilon(\mathbf{0})h_1h_2 - \nabla^{\perp}w(\mathbf{0})\left(\frac{h}{2\pi}\right)^2 \lim_{\epsilon\to 0}\sum_{\mathbf{l}\in\Lambda^*(\alpha_1,\alpha_2)\backslash\mathbf{0}} \frac{l_1^2-l_2^2}{|\mathbf{l}|^4}\hat{\delta}_\epsilon\left(\frac{2\pi}{h}\mathbf{l}\right),$$

where $\mathbf{l} = (l_1, l_2)$ and $h_1 = \alpha_1 h, h_2 = \alpha_2 h$.

The two terms to be considered are the self-induction term

$$\lim_{\epsilon\to 0} (\mathbf{K}\omega)_\epsilon(\mathbf{0}) \tag{C.6}$$

and the lattice sum

$$\lim_{\epsilon\to 0} \sum_{\mathbf{l}\in\Lambda^*(\alpha_1,\alpha_2)\setminus\mathbf{0}} \frac{l_1^2 - l_2^2}{(l_1^2 + l_2^2)^2} \hat{\delta}_\epsilon\left(\frac{2\pi}{h}\mathbf{l}\right). \tag{C.7}$$

Setting $\epsilon = 0$ in (C.7) gives a sum that is only conditionally convergent, and whose value depends upon how it is summed. The specific summation rule is dictated by $\hat{\delta}_\epsilon$. Here, we choose a sharp square cutoff. Let $\epsilon = \frac{1}{M}$ and

$$\hat{\delta}_{\frac{1}{M}}\left(\frac{2\pi}{h}\mathbf{l}\right) = \begin{cases} 1 \text{ if } |l_1| \le \dfrac{M}{\alpha_1} \text{ and } |l_2| \le \dfrac{M}{\alpha_2}, \\ 0 \text{ otherwise.} \end{cases} \tag{C.8a}$$

This in turn gives the Dirichlet kernel

$$\delta_{\frac{1}{M}}(x_1, x_2) = \frac{1}{\pi^2} \frac{\sin\left(\dfrac{Mx_1}{\alpha_1}\right)}{x_1} \frac{\sin\left(\dfrac{Mx_2}{\alpha_2}\right)}{x_2}. \tag{C.8b}$$

Now, using (C.8a) in (C.7) gives the lattice sum

$$\alpha\alpha_1\alpha_2 \lim_{M\to\infty} \sum_{l_1=-M}^{+M} \sum_{\substack{l_2=-M \\ l\neq 0}}^{+M} \frac{l_1^2 - \alpha^2 l_2^2}{(l_1^2 + \alpha^2 l_2^2)^2}, \tag{C.9}$$

and using (C.8b) in (C.6) yields

(C.10)

$$\lim_{M\to\infty} (\mathbf{K}\omega)_{\frac{1}{M}}(\mathbf{0}) = \frac{1}{\pi^2} \lim_{M\to\infty} \int\int_{\mathbf{R}^2} \mathbf{K}(\mathbf{x})\omega(\mathbf{x}) \frac{\sin(Mx_1/\alpha_1)}{x_1} \frac{\sin(Mx_2/\alpha_2)}{x_2} dx_1 dx_2.$$

Thus, we need to determine (C.9) and (C.10). We begin with the self-induction term (C.10).

SELF-INDUCTION LEMMA. *For $\omega(\mathbf{x})$ smooth and rapidly decaying, the self-induction term is given by*

$$\lim_{M\to\infty} (\mathbf{K}\omega)_{\frac{1}{M}}(\mathbf{0}) = \frac{1}{\pi^2}\left(-\omega_{x_2}(0) \arctan\left(\frac{1}{\alpha}\right), \omega_{x_1}(0) \arctan(\alpha)\right). \tag{C.11}$$

Proof. Apply (A.19) with $f = K_i\omega$, where $i = 1, 2$ denotes the component of $\mathbf{K}$. In light of (A.18), (A.20)–(A.22), and (A.28), it is clear that the proof reduces to evaluating

(C.12)

$$\lim_{M\to\infty} (K_i\omega)_{\frac{1}{M}}(\mathbf{0}) = \lim_{M\to\infty} \frac{1}{\pi^2} \nabla\omega(\mathbf{0})$$
$$\cdot \int_{\frac{-RM}{\alpha_1}}^{\frac{+RM}{\alpha_1}} \int_{\frac{-RM}{\alpha_2}}^{\frac{+RM}{\alpha_2}} \tilde{\mathbf{H}}_i(\alpha_1 x_1, \alpha_2 x_2) \frac{\sin(x_1)}{x_1} \frac{\sin(x_2)}{x_2} dx_2 dx_1,$$

where $\tilde{\mathbf{H}}_i(\mathbf{x}) = \mathbf{x}K_i(\mathbf{x})$. Without loss of generality, take $i = 2$. Then, (C.12) reduces to (C.13)

$$\lim_{M\to\infty}(K_2\omega)_{\frac{1}{M}}(\mathbf{0}) = \frac{\omega_{x_1}(\mathbf{0})}{\pi^2}\lim_{M\to\infty}\int_{\frac{-RM}{\alpha_1}}^{\frac{+RM}{\alpha_1}}\int_{\frac{-RM}{\alpha_2}}^{\frac{+RM}{\alpha_2}}\frac{x_1^2}{x_1^2+\left(\frac{x_2}{\alpha}\right)^2}\frac{\sin(x_2)}{x_2}\frac{\sin(x_1)}{x_1}dx_2dx_1,$$

where $\alpha = \alpha_1/\alpha_2$ is the grid aspect ratio. The term involving ω_{x_2} vanishes due to oddness of the integrand in each coordinate direction. With some care, the inner integral can be evaluated by contour integration. In particular, the regions of integration of both the inner and outer integrals must be divided appropriately so that the contour integration is justified. We do not present the details here. The K_1 integral is evaluated similarly. It now remains to consider the lattice sum (C.9). We obtain the following result.

LATTICE SUM LEMMA. *The sum in* (C.9), *omitting the $\alpha\alpha_1\alpha_2$ prefactor, is given by* (i)

$$\text{(C.14)}\qquad S(\alpha) = \lim_{M\to\infty}\sum_{l_1=-M}^{+M}\sum_{\substack{l_2=-M\\ l\neq o}}^{+M}\frac{l_1^2-\alpha^2l_2^2}{(l_1^2+\alpha^2l_2^2)^2} = 4\sum_{m=1}^{\infty}\frac{1}{m}f(m;\alpha),$$

where

$$\text{(C.15)}\qquad f(m;\alpha) = \frac{1}{m}\sum_{k=0}^{m}{}'\left[\frac{(k/m)^2-\alpha^2}{[(k/m)^2+\alpha^2]^2}+\frac{1-\alpha^2(k/m)^2}{[1+\alpha^2(k/m)^2]^2}\right],$$

where $\sum'$ denotes the trapezoidal sum (i.e., the endpoints are weighted by $\frac{1}{2}$). For $m \gg 1$, we have (ii)

$$\text{(C.16)}\qquad \begin{aligned} f(m;\alpha) &= \frac{1}{6}\frac{\alpha^2-1}{(1+\alpha^2)^2}\frac{1}{m^2} - \frac{1}{30}\frac{(\alpha^2-1)(\alpha^4-10\alpha^2+1)}{(1+\alpha^2)^4}\frac{1}{m^4} + O\left(\frac{1}{m^6}\right)\\ &\equiv f_2(\alpha)\frac{1}{m^2} + f_4(\alpha)\frac{1}{m^4} + O\left(\frac{1}{m^6}\right). \end{aligned}$$

Proof of Lemma. (i) Using the four-fold symmetry of the summand over quadrants, we rewrite the sum (C.9) as

$$\text{(C.17)}\quad S(\alpha) = \lim_{M\to\infty}\sum_{l_1=-M}^{+M}\sum_{\substack{l_2=-M\\ l\neq 0}}^{+M}\frac{l_1^2-\alpha^2l_2^2}{(l_1^2+\alpha^2l_2^2)^2} = \lim_{M\to\infty}4\sum_{l_1=0}^{M}{}''\sum_{\substack{l_2=0\\ l\neq 0}}^{M}{}''\frac{l_1^2-\alpha^2l_2^2}{(l_1^2+\alpha^2l_2^2)^2},$$

where $\sum''$ denotes that terms with $l_1 = 0$ or $l_2 = 0$ are weighted by $\frac{1}{2}$. Then, by summing first out along the diagonal of the lattice, we get

$$\text{(C.18)}\qquad S(\alpha) = \lim_{M\to\infty}4\sum_{m=1}^{M}\sum_{k=0}^{m}{}'\left[\frac{k^2-\alpha^2m^2}{(k^2+\alpha^2m^2)^2}+\frac{m^2-\alpha^2k^2}{(m^2+\alpha^2k^2)^2}\right],$$

$$\text{(C.19)}\qquad = \lim_{M\to\infty}4\sum_{m=1}^{M}\frac{1}{m}\left[\frac{1}{m}\sum_{k=0}^{m}{}'\frac{(k/m)^2-\alpha^2}{((k/m)^2+\alpha^2)^2}+\frac{(1-\alpha^2(k/m)^2)^2}{(1+\alpha^2(k/m)^2)^2}\right],$$

$$= 4\sum_{m=1}^{\infty} \frac{1}{m} f(m;\alpha), \tag{C.20}$$

which gives the result (i).

The self-induction lemma and result (i) of the lattice sum lemma together give the second-order error coefficient in (C.3) and (C.4), and completes the proof of the theorem. We now consider result (ii) of the lattice sum lemma, which gives the large m asymptotics of f and leads to our rapid summation corollary.

The function $f(m;\alpha)$, (C.15), is the trapezoidal rule approximation of the integrals

$$\int_0^1 \frac{x^2-\alpha^2}{(x^2+\alpha^2)^2}dx + \int_0^1 \frac{1-\alpha^2x^2}{(1+\alpha^2x^2)^2}dx. \tag{C.21}$$

Thus, $f(m;\alpha)$ can be written as

$$f(m;\alpha) = \int_0^1 \frac{x^2-\alpha^2}{(x^2+\alpha^2)^2}dx + \int_0^1 \frac{1-\alpha^2x^2}{(1+\alpha^2x^2)^2}dx + E_1(m;\alpha) + E_2(m;\alpha), \tag{C.22}$$

where the errors E_1 and E_2 are given by

$$E_1(m;\alpha) = \frac{1}{m}\sum_{k=0}^{m}{}' \frac{(k/m)^2-\alpha^2}{((k/m)^2+\alpha^2)^2} - \int_0^1 \frac{x^2-\alpha^2}{(x^2+\alpha^2)^2}dx \tag{C.23}$$

and

$$E_2(m;\alpha) = \frac{1}{m}\sum_{k=0}^{m}{}' \frac{1-\alpha^2(k/m)^2}{(1+\alpha^2(k/m)^2)^2} - \int_0^1 \frac{1-\alpha^2x^2}{(1+\alpha^2x^2)^2}dx. \tag{C.24}$$

Now, by direct calculation,

$$\int_0^1 \frac{x^2-\alpha^2}{(x^2+\alpha^2)^2}dx + \int_0^1 \frac{1-\alpha^2x^2}{(1+\alpha^2x^2)^2}dx = 0. \tag{C.25}$$

And, for $m \gg 1$, the error terms can be found through the Euler–MacLaurin expansion. This gives the result (ii).

We can now rapidly and accurately sum $S(\alpha)$ using the asymptotic form of f. In particular, we obtain the following corollary.

RAPID SUMMATION COROLLARY. *The sum $S(\alpha)$ can be rewritten so as to converge like $O(1/m^7)$ by using the expansion* (ii) *in the following way*:

$$S(\alpha) = \sum_{m=1}^{\infty} \frac{1}{m}\left[f(m;\alpha) - f_2(\alpha)\frac{1}{m^2} - f_4(\alpha)\frac{1}{m^4}\right] + f_2(\alpha)\zeta(3) + f_4(\alpha)\zeta(5), \tag{C.26}$$

where

$$\zeta(s) = \sum_{m=1}^{\infty} \frac{1}{m^s}, \qquad s > 1,$$

is the Riemann–Zeta function. In particular, $\zeta(3) = 1.202056903159594$ *and* $\zeta(5) = 1.036927755143370$.

Acknowledgments. We thank Chris Anderson, Jonathan Goodman, Tom Hou, Joe Keller, Omar Knio, and Vered Rom-Kedar for valuable discussions. We thank the referees for their careful examination of the paper and their useful comments. We especially thank one of the referees for noticing a problem with our original formulation of the Poisson summation formula for singular functions. MJS would also like to thank the Mathematics Department at UCLA, where some of the writing and work on this paper was done, for their hospitality. Likewise, JSL would like to thank the Courant Institute for their hospitality.

HYPERCUBE ALGORITHMS FOR DIRECT N-BODY SOLVERS FOR DIFFERENT GRANULARITIES*

JEAN-PHILIPPE BRUNET[†], JILL P. MESIROV[†], AND ALAN EDELMAN[‡]

Abstract. Algorithms for the N-body problem are compared and contrasted, particularly those where N is in the range for which direct methods outperform approximation methods. With fewer bodies than processors, the so-called "replicated orrery" on a three-dimensional grid has been used successfully on the Connection Machine CM-2 architecture. With more bodies, the "rotated and translated Gray codes" is an ideal direct algorithm for machines such as the CM-2 in that it takes optimal advantage of the communications bandwidth of the machine.

A classical Latin square can be used to abstractly denote any direct N-body calculation. Computational windows superimposed on this square illustrate the granularity of the computation. This point of view naturally illustrates a sequence of algorithms ranging along a granularity scale in the following order: "massively parallel," "replicated orrery," "orrery," "rotated/translated Gray codes," and "serial."

Key words. N-body, hypercube, CM-2, parallel computing, Latin square, Gray code

1. Introduction.

In a wide variety of applications areas, including astronomy [5], [18], [29]; molecular dynamics [17], [27], [32], [33]; and fluid dynamics [16], [25], [30], [31], a serious computational bottleneck occurs from the need to determine the mutual interaction of N bodies. Directly computing the N^2 pairwise interactions given by

$$\text{Force(body } i) = \sum_j \text{Force(body } i \text{ due to body } j)$$

on a conventional computer can take an unacceptably long amount of time for values of N which are exactly in the range of interest for the application.

Approximation methods are one approach towards reducing computational complexity. Examples of this are the particle/mesh [21], local correction [1], hierarchical [2], [7], and multipole [15] methods. The structure of such algorithms has been investigated by Katzenelson [24].

Another approach is to keep to the naive direct method, but to design algorithms that take advantage of advanced computer architectures like the Connection Machine CM-2. We have chosen to take this path and to explore only direct methods in this work. Although this approach has asymptotically higher complexity, these algorithms remain useful for two important reasons: 1) they are simpler to code and maintain thus minimizing the important commodity of programming effort, and 2) they give competitive performance for a relevant range of N. Though the approximation algorithms must ultimately be advantageous for large values of N, for a number of problems of physical interest, N is in the range where direct N-body algorithms are superior. See [30] for further discussion of the advantages of a direct algorithm over an approximation algorithm.

The algorithms for direct N-body solvers that we will discuss in this paper are designed for use on a parallel architecture with a hypercube network topology. In fact, we

feel that hypercube architectures are ideally suited to the direct method. For nondirect methods on the hypercube, see [4], [14], [19], and [34].

We focus on two different algorithms, but we take a point of view that we have not yet seen in the literature: We show that the two algorithms fit along a continuous spectrum. Perhaps we can make an analogy with the notion that X-rays and radio waves properly fit along one axis. However, instead of using frequency, the important parameter here is *granularity* measured by the ratio P/N.

For the case where the number of processors P satisfies $N \leq P \leq N^2$, we describe an optimal mapping of a family of *replicated orreries* onto a hypercube. For the case where $P < N$, we present a multiwire all-to-all broadcast algorithm which utilizes "rotated and translated Gray codes" to make optimal use of the communication bandwidth of the hypercube. Thus, in this approach, the communication time of the algorithm is negligible for large values of N.

Both of these algorithms have been implemented on the Connection Machine CM-2. There are two programming models for the CM-2 and each algorithm lends itself more naturally to one of them. The older model (which is becoming more and more obsolete) is known as the "fieldwise model," while the more recent model is the "slicewise model." From a conceptual point of view, the value of P is 32 times greater for the fieldwise model than it is for the slicewise model. Both approaches, and thus both programming models, were used for the N-body solver in the implementation of a random vortex method for numerical simulation of fluid flow [30]; we will analyze the computational complexity of each approach.

Section 2 discusses N-body problems in an abstract mathematical context. In §§3 and 4 we present two concrete algorithms with complexity analyses: the replicated orrery and a multiwire algorithm. The CM-2 implementation of both algorithms is briefly described in §5. A sample application is described in §6 and the performance of the CM-2 implementation of both approaches is discussed.

2. Latin squares and N-body problems.

Before we analyze in detail two particular approaches to solving direct N-body problems that have been successful, we would like to abstract out the important mathematical features of an N-body computation on a parallel machine. In particular, the two important questions are *where* (which processor?) and *when* (which timestep?) does each interaction occur. By timestep we mean those taken in calculating the forces for a given particle configuration rather than those taken to move the particle positions.

Implicit in the knowledge of the "where and when" of the computation is the communication that occurs. Since we know which data needs to be where at a particular moment, the only degree of freedom might be how soon the data arrives at a particular processor before a computation starts.

As a mathematical abstraction, we consider it enlightening to display the "where and when" of an N-body computation on a *Latin square*. The basic idea is quite simple, however, almost any N-body problem on any parallel machine can be defined as a Latin square.

A *Latin square* is an N by N table of entries $1, 2, \ldots, N$ with the property that each number i appears exactly once in each column and once in each row. Perhaps the earliest known reference is a puzzle requiring that the 16 lettered cards (A,K,Q,J) of an ordinary 52-card deck be arranged so that no letter appears twice in the same column or row nor along a diagonal [13]. Classically, Latin squares have had many uses including the design of experiments, displays of multiplication tables of finite groups, and other recreational puzzles (see [9] and [13]). Their first systematic study was performed by Euler [13].

As an example, Fig. 1 displays a Latin square of order 4. In the context of an N-body computation, the entry a in row i and column j can symbolize a force law interaction of body i with body j. Thus in Fig. 1, the first column depicts the interactions of body 1 with bodies 2, 3, 4, and 1, respectively. We remark that in practice, self-interactions are usually omitted. Also in practice, symmetric interactions may be avoided, giving a speedup of a factor at most equal to 2.

Body:	1	2	3	4
	2	3	4	1
	3	4	1	2
	4	1	2	3
	1	2	3	4

FIG. 1. *A Latin square of order 4. To indicate an* N-*body calculation, we let the entry in row i and column j denote an interaction between that body and body j. A serial algorithm could proceed from left to right and from top to bottom along this square, one box at a time.*

In the sections to follow, we study the five possibilities given in Fig. 2. Specifically, the replicated orrery is described in detail in §3, while the rotated and translated Gray codes are described in §4. Before we give the details of the algorithms, however, we can already describe some necessary features based on the granularity alone.

			Example		
			P	N	$O(T_{comm})$
Case I	$P = N^2$	Massively parallel	16	4	$\log N$
Case II	$N < P < N^2$	Replicated orrery	8	4	$N^2/P + \log(P/N)$
Case III	$P = N$	Orrery	4	4	N
Case IV	$1 < P < N$	Rot/trans Gray codes	2	4	$N/\log P$
Case V	$P = 1$	Serial	1	4	0

FIG. 2. *Possible granularities (Example for $N = 4$). The communications complexities are discussed in Sections 3 and 4.2. The actual communications complexity for Case IV is the order of $\lceil \frac{N}{P \log P} \rceil P$. The approximation listed in the table breaks down for P near N.*

For each of the five cases in Fig. 2, Fig. 3 exhibits the simultaneity of one parallel computation when $N = 4$. For clarity of exposition, we omit the entries of the square, but instead superimpose a computational "window" upon the square. The size of this window is exactly the number of processors. In each window, there is one interaction for each processor. The computation proceeds by sweeping the window across the square. Of course, if the number of bodies is held constant, then the size of the window grows with the number of processors, and the number of timesteps (equals the number of windows needed to cover the square) decreases.

The two extremes are given by Case I, massively parallel, and Case V, serial, in Fig. 3. In Case I, where $P = N^2$, there is only one window—all N-body computations occur in parallel. On the other hand, in Case V where $P = 1$, the algorithm is serial and only one interaction occurs in any given timestep. The processors are labeled p_i in the windows, and the computation proceeds by shifting the windows and the corresponding processors over the Latin square.

We now see that once the relationship between P and N is given, all that we need to specify a direct N-body computation is (i) a choice of Latin square and (ii) a mapping

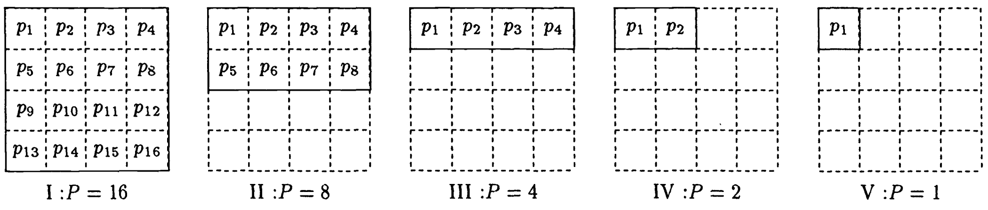

FIG. 3. *Computational windows superimposed on the Latin square ($N = 4$). The entries of the square are omitted, while the processor numbers for the first timestep of the computation are included. Later timesteps are obtained by sweeping the window across the square, so as to completely cover the square.*

from the processors to the window. We explore this in further detail in later sections, but we can give an illustrative example as we do in Fig. 4. This figure illustrates an example when $N = 8$ and $P = 4$. The square on the left is readily checked to be a Latin square. The construction of the square is quite simple. We assume that there are two bodies per node as illustrated on the two-dimensional hypercube in the figure. One copy of the bodies remains static, while one circulates; the first body circulates counterclockwise, while the second body circulates clockwise.

			body				
1	2	3	4	5	6	7	8
			interacts with				
1	2	3	4	5	6	7	8
5	6	7	8	1	2	3	4
2	3	4	1	8	5	6	7
8	5	6	7	2	3	4	1
3	4	1	2	7	8	5	6
7	8	5	6	3	4	1	2
4	1	2	3	6	7	8	5
6	7	8	5	4	1	2	3

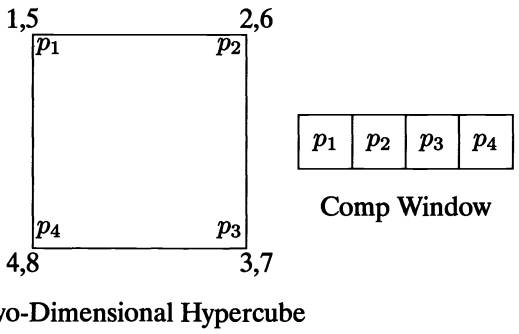

FIG. 4. *Latin square and computational windows for an 8-body problem with four processors. Each 1×4 rectangle denotes the four interactions of one timestep, one in each processor. The entries of the Latin square are obtained by circulating a dynamic copy of the first body counterclockwise, while circulating the second body clockwise on the square. A static copy of each body remains in the processor. Communication is indicated by the vertical space between pairs of lines. After the first circulation, body 1 can interact with bodies 2 and 8, while body 5 can also interact with bodies 2 and 8 without further communication. Thus a total of four windows can pass over the square before another communication need occur.*

3. $N \leq P \leq N^2$: Orreries and replicated orreries. One standard approach to N-body solvers uses N processors connected as a ring. Processor i accumulates the forces on body i. At each timestep, N of the pairwise interactions are computed, then the appropriate data are passed around the ring so that in N steps all N^2 interactions have been computed and accumulated into the correct processor; see Fig. 5. This particular parallel implementation of the N-body algorithm has been referred to as the "digital orrery" [3], as the "systolic loop" [33], and as "systolic loop double" [27].

As a Latin square, this is the addition table of the Abelian cyclic group of order N: the square is circulant, and the (i, j)th entry is essentially $i - j$ modulo n. This case is illustrated in Fig. 3 as Case III, which shows that one row of interactions is computed in each timestep.

FIG. 5. *Digital orrery: $P = N$. Cycle through N shifts.*

With more than N processors one can replicate the orrery, perform a different piece of the computation on each copy, and accumulate the summands for the forces at the end [6]. For example, with $2N$ processors the computation takes place on two rings of processors (see Fig. 6), each of which passes its data only $N/2$ times. More generally, with MN processors we use M rings of N processors each. At each computation step MN interactions are computed; N/M steps with cyclic message passing of the data are required to compute the N^2 interactions. Thus the arithmetic complexity of the algorithm is $O(N/M)$. By "arithmetic complexity," we mean the number of parallel numerical computations executed by the parallel algorithm. The time of execution of a parallel algorithm is a linear combination of its arithmetic complexity and communication complexity.

FIG. 6. *Replicated orrery: $P = 2N$. Cycle through $N/2$ shifts.*

An efficient processor topology comes from mapping the replicated orrery onto a three-dimensional cube of processors as observed in [26]. We assume the cube is embedded in a larger dimensional hypercube in such a way that we can distribute a value to, or sum the contents of, M processors along an axis of the cube with $O(\log M)$ communications [22].

To understand how that data mapping works, assume that the hypercube is configured as an N/M by M by M cube (see Fig. 7). The data is initially resident on the front face of the cube and is sent to the top of the cube. The data on the front face is spread back, in $\log M$ time, along the y-dimension of the cube, and the data on top is spread down along the z-dimension of the cube. The data is now distributed through the cube so that each plane parallel to the xz-axis contains a copy of the orrery. The computation proceeds by computing a pairwise interaction and doing one-dimensional cyclic message passing along the x-axis. This process is repeated N/M times until all N^2 pairwise interactions have been completed. Now the corresponding results for each individual body are accumulated, in $\log M$ time, along the y-axis back to the front face of the cube.

$v_{\frac{(M-1)N}{M}+1}$ • • • v_N
Spread
N = number of bodies
M = number of replications
P = NM = number of processors

FIG. 7. *Cube data mapping.*

In most cases we are restricted to M and N being powers of two. This ensures the correct wraparound for cyclic message passing, and efficient logarithmic time spreading and accumulating. Observe also that as the number of replications M increases from 1 to N, and thus the number of processors increases from N to N^2, the cube grows out from the x-axis and then projects onto the yz-plane. Thus, the dimensions of the cube can be changed to accommodate a family of parallel N-body solvers where the number of processors ranges from N to N^2. In particular, with MN processors, the solver runs in $O(N/M) + O(\log M)$ time. Note that this gives the correct complexity bounds for the extremes, i.e., $O(N)$ for the case $M = 1$, and $O(1) + O(\log N)$ when $M = N$.

Since the number of processors P is usually fixed given some particular piece of hardware, there is another useful way to view the complexity of the algorithm. Note that $P = MN$, thus, the complexity bound $O(N/M) + \log(M)$ becomes $O(N^2/P) + O(\log(P/N))$.

We remark that the algorithms described above are essentially grid algorithms. Once the data is set up, all communication is performed through cyclic message passing. Though this is the easiest conceptually, there are other approaches that make far better use of the hypercube bandwidth. In the next section, we describe a multiwire algorithm that makes optimal use of the bandwidth when $N > P$ or, to be more precise, when N is a multiple of dP, where d is the dimension of the hypercube. There are other communications primitives that make better use of the hypercube bandwidth in the orrery, such as the "multinode broadcast under the MLA assumption" described in [8] and an equivalent algorithm related to us by Ho [20]. We have chosen not to pursue this here.

Figure 8 depicts the Latin square for a replicated orrery case for $N = 8$ and $P = 16$. Note how the cube unfolds onto the computational window.

4. $P < N$: Multiwire algorithm.

4.1. The approach. In the case where $P < N$ the data mapping is much simpler. We divide the N bodies evenly over the $P = 2^d$ processors of a d-dimensional hypercube. For simplicity, assume the number of bodies in each node N/P is an integer multiple of d. To compute the N^2 interactions, the data for each body must be transmitted to all of the other processors. We want to do this using as much of the communications bandwidth of the hypercube as possible. If the processors have enough memory, then this transmission can be performed initially, and afterwards, all the arithmetic can be performed locally. This type of communication in a hypercube has been called *all-to-all broadcasting* [23] and *multinode broadcast* [8].

We do not follow this strategy exactly. We can interleave pieces of the computation with the communications and have no need to store the data for all the bodies at each node. Thus, we can use the idea of "rotated and translated Gray codes" described in [23]. Although this method has "limited potential for pipelining," it is just right for the N-body problem. A Gray code is rotated to construct as many conflict-free paths as possible leaving a node, visiting all others, and returning to its starting point. By translating the starting point of each of these paths to every node of the hypercube, the data in each node circulates to every other one in as short a time as possible.

More precisely, the rotated and translated Gray codes produce $d2^d$ timewise edge disjoint Hamiltonian paths through the hypercube, d of them starting at each node. A *Hamiltonian path* in a graph visits all the nodes in the graph only once. *Timewise edge disjoint* means that, although the paths may share edges of the hypercube, no two paths traverse the same edge in the same direction on the same communication step. Consequently, assuming bidirectionality, there is no contention for communication channels. The data is circulated on these paths, but not retained, avoiding the memory waste. Furthermore, from a programming point of view, this approach is very simple and one can take advantage of the symmetry of the hypercube. The combination of the simplicity and the optimal use of communication bandwidth makes this communication pattern one of the fastest that a hypercube architecture can perform.

4.2. Complexity analysis. The complexity analysis of the algorithm is straightforward. The computation time, T_{arith}, scales like $N^2/2^d$, where N is the total number of bodies and d is the dimension of the hypercube. The communication time, T_{comm}, scales like $\lceil \frac{N}{2^d d} \rceil (2^d - 1)$; where $\lceil x \rceil$ denotes the ceiling of x, i.e., the smallest integer greater than or equal to x. Since there are $N/2^d$ bodies per node and d wires leaving each node, the first factor in T_{comm} represents the number of communication operations needed to empty a node of data. The second factor is the length of the path through the hypercube that the data must traverse.

Given a value of N such that $N/2^d \gg d$, T_{comm} is at first a linearly decreasing function of d. Then, as the number of dimensions increases, the number of required communication operations will eventually decrease to one and the second factor in the expression of T_{comm} starts to dominate. Because at least one such communication operation must be performed, even if there are less than d data items at a node, we get, for a fixed value of N,

$$\lim_{d \to \infty} T_{comm}(d) \simeq 2^d.$$

The function T_{comm} therefore exhibits a minimum that roughly occurs when the number of bodies per node is equal to the size of the bandwidth d. As the number of bodies per node decreases, one is making less and less effective use of the communications bandwidth of the hypercube and T_{comm} becomes a more significant portion of the total execution time. In fact, when $N/2^d \leq 1$, i.e., the number of bodies is much smaller than the number of processors, then the replicated orrery approach becomes more cost effective. Note that in the boundary case $N = P$, the total computational complexity reduces to $O(N)$ which agrees with the orrery algorithm.

4.3. Rotated and translated Gray codes. A d-dimensional hypercube is a graph with 2^d nodes labeled by the d-bit binary representation of the integers 0 to $2^d - 1$. Each bit in the d-bit representation is associated with a different dimension of the cube. There is an edge between two nodes i and j in the hypercube if and only if their binary representations differ in only one bit. We can think of the edges as traversing different dimensions of the hypercube.

A *Gray code* is a circuit of all binary d-tuples, such that only one coordinate position changes at each step. Thus, a Gray code represents a Hamiltonian path on the hypercube. There are many ways to construct Gray codes, but the most famous is the binary reflected Gray code [28]. To simplify the terminology, we will refer to this code as *the* Gray code. We define the *transition sequence* [28] corresponding to a Gray code as the list of positions that change at each step of the code or the list of dimensions traversed on the hypercube at each step of the circuit. Given the Gray code beginning at 0, we can "translate" it to node i by taking the *exclusive or* of i with the d-tuples in the original code. The transition sequence of the translated Gray code is identical to the original. In Fig. 9, we show the binary reflected Gray code for $d = 3$, the corresponding transition sequence, the associated Hamiltonian path on the cube, and the translated code starting at node 5 = 101.

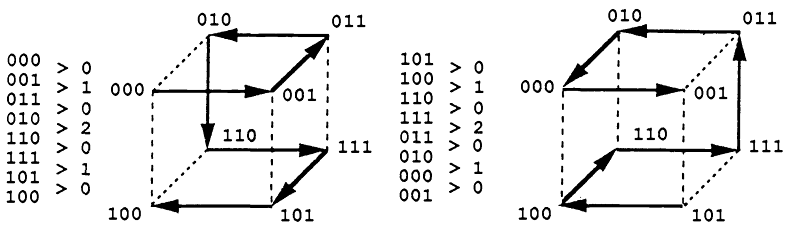

FIG. 9. *On the left is the binary reflected Gray code, the corresponding transition sequence, and the associated Hamiltonian path originating at node* 0 *on a three-dimensional cube. On the right, the same transition sequence is used to generate a translated code to node* 101 = 5 *and the associated Hamiltonian path.*

Given the Gray code beginning at 0, we can "rotate" it by performing circular shifts of the bits in the original code. In the tables below, we list the three rotated Gray codes and the corresponding transition sequences when $d = 3$. Note that generally, the transition sequence of the rotated code i is obtained by adding i modulo d to the transition sequence of the binary reflected Gray code.

Rotated Gray Codes								
Code 0	000	001	011	010	110	111	101	100
Code 1	000	010	110	100	101	111	011	001
Code 2	000	100	101	001	011	111	110	010

Transition Sequences							
Code 0	0	1	0	2	0	1	0
Code 1	1	2	1	0	1	2	1
Code 2	2	0	2	1	2	0	2

By taking all of the 2^d possible translations of the d rotated Gray codes beginning at 0, we can generate a set H of $d2^d$ Hamiltonian paths on the hypercube. This set H is more elegantly described as the paths generated by applying a group of $d2^d$ symmetries (rotations and translations) of the hypercube to the binary reflected Gray code[1] starting from node 0. These symmetries are the subgroup of all the hypercube symmetries that rotate the dimension numbers modulo d. It is straightforward to verify that two distinct symmetries of a hypercube transform a directed edge into two distinct directed edges. It follows that the collection of paths H have the nice property of being timewise edge disjoint: i.e., if $j \in 1, 2, \ldots, 2^d - 1$, then there is no overlap among the jth edges of the paths in H. This implies that if we have d packets of information in each node of the hypercube, we can circulate the data, one packet to a Hamiltonian path, in $2^d - 1$ communication steps. Furthermore, we can perform the arithmetic on the data in between each communication step eliminating the need for data storage.

[1]The use of the binary reflected Gray code is merely for convenience of implementation; any other Hamiltonian path will suffice.

5. CM-2 implementations.

5.1. The Connection Machine architecture. In this section we describe the basic design of the Connection Machine CM-2 so as to draw the distinction between the *slicewise* and *fieldwise* programming models. The Connection Machine CM-2 is composed of a microsequencer and a maximum of 65,536 single-bit processing elements. The processors run in SIMD (single instruction multiple data) mode, with the instruction stream broadcast by the sequencer. The sequencer is controlled by an external front-end machine, usually a SUN®.[2]

Each processor can have up to 1 Megabit of local RAM, with a single high-speed floating point unit for every 32 processors. There are 16 processors on a CM-2 chip and the chips are connected in a boolean d-cube topology, e.g., a 12-cube for a 64K processor machine.

The CM-2 supports three basic communication mechanisms. There is general pointer-based communication, known as the router, by which data can be exchanged between the memories of different processors. We refer to this type of communication as a *send*. The other two mechanisms involve direct control of the hypercube network by the user known as *cube swaps* and NEWS. These are used for more structured communication patterns. For example, the machine can be efficiently configured as a k-dimensional grid, which is automatically superimposed by the system software onto the boolean cube using a multidimensional Gray code mapping. Motion of the data from all processors to their nearest grid neighbors is known as a NEWS communication. These communications patterns are periodic in each dimension of the grid. Particularly useful primitives available on the Connection Machine computer are *scans*, parallel prefix operations [10] that combine computations and communications. In logarithmic time, these operators allow one to *spread* data through the CM-2, as well as accumulate summands (*plus-scan*) from each processor.

There are two programming models for the CM-2. In the *fieldwise* model, the storage of a 32-bit word would be allocated in 32 consecutive bits of a physical processor's memory. However, when performing floating-point computations, better performance is usually obtained by viewing the processors in a *slicewise* configuration. That is, we consider processing nodes on the machine to be the ensemble of a floating-point unit and the memory of the 32 associated physical processors of the CM-2. In this approach, a word is stored in 32-bit slices across the memories of the 32 processors in the node, i.e., 1-bit per processor. From this viewpoint, a 64K processor CM-2 becomes 2048 floating-point nodes, connected as an 11-dimensional hypercube with two bidirectional communication channels between connected nodes instead of one. In particular, this means that the communication complexity bound for the multiwire algorithm becomes

$$T_{comm} \approx \left\lceil \frac{N}{2^d 2d} \right\rceil (2^d - 1),$$

since $2d$ wires leave each node. Moreover, this model of the machine meshes efficiently with the way in which the floating-point units actually access data from their associated processors, i.e., in one cycle a 32-bit slice across processors is read into the floating-point unit. We should note that it is possible, by transposing data, to go back and forth between the slicewise and fieldwise models of the machine.

[2]SUN is a trademark of Sun Microsystems, Inc.

5.2. Implementation of the replicated orrery. Using the fieldwise programming model for the CM-2, we typically have $N \leq P \leq N^2$, thus the replicated orrery N-body algorithm is most appropriate. We describe the details of the implementation here.

In configuring the CM-2 as k-dimensional grids, we are required to restrict the lengths in each dimension to a power of 2. Thus, the data mapping of the replicated orrery onto a three-dimensional grid proceeds as follows. Pick n such that 2^n is the first power of 2 greater than or equal to N. Then we will actually use an orrery of size 2^n with only N valid entries. We are assuming that $N \leq P \leq N^2$, so we can write $P = 2^{n+m}$, where $m \leq n$. We will want to replicate the orrery $M = 2^m$ times. We configure a 2^{n+m} processor CM-2 as an 2^{n-m} by 2^m by 2^m cube (N/M by M by M). This configuration allows us to use versions of the parallel prefix scan operations to spread or accumulate data along any of the three coordinate directions in logarithmic time, and ensures the correct wraparound for grid communications. The cube mapping, complete with sends, spreads, and accumulates, is drawn in Fig. 7.

There will be two copies of the data for each body; one dynamic and one static. The static data is initially resident on the front face of the cube. It is sent to the top of the cube by a low density send. The data on the front face is spread back along the y-dimension of the cube, and the data on top is spread down along the z-dimension of the cube. The data is now distributed through the cube so that each plane parallel to the xz-axis contains a copy of the orrery. The computation now proceeds by computing a pairwise interaction according to the relevant force law and doing a one-dimensional wraparound NEWS communication along the x-axis. This process is repeated 2^{n-m} times until all N^2 pairwise interactions have been completed. Now the contributing forces for each individual body are accumulated by doing a plus-scan along the y-axis back to the front face of the cube.

Because of the power of 2 restrictions noted above, the time required to do the computation for any value of N between 2^n and $2^{n+1} - 1$ is the same. As N increases above the next power of 2, we can reconfigure the grid to the appropriate size.

5.3. Implementation of the multiwire algorithm. Using the slicewise model of the CM-2, we are generally in the case where $P < N$, and so we use the multiwire algorithm described above.

If we have d words at every node, and if we wish to circulate the data using the Hamiltonian paths described in the §3, one might expect that we would either need to attach some labeling information to be transmitted with the data or else use a look-up table that specifies the dimension over which data needs to be sent. Neither of these operations is without cost. In our implementation, as we shall now describe, we avoid both of these types of methods. In fact, the information in the transition sequence for the binary reflected Gray code is all that is needed.

Using the slicewise model, the CM-2 architecture allows for the loading of as many as $2d$ words to be sent over the d dimensions simultaneously, two words in each dimension. Typically, one loads one set of d words for the d dimensions followed by another set of d words. For simplicity, we will concentrate on one set with the understanding that the other set follows exactly the same pattern. Another important feature of the CM-2 architecture is that it is particularly efficient to load consecutive words, or more generally, words with a constant stride, to be sent over consecutive dimensions.

To illustrate how the CM-2 works, let us first assume that we only have one word in each processor and each of these words will follow the Hamiltonian path specified by the transition sequence of the Gray code: $g = \{0, 1, 0, 2, 0, 1, \ldots\}$. Furthermore, assume we have only one memory location (location 0) in each node where the word is stored.

Then Algorithm 1 is simply:

```
For $k = 1, 2, \ldots, 2^d - 1$
In each node, the data at location 0 is
1. Loaded to be sent over dimension $g_k$.
2. Transmitted.
3. Stored in location 0.
```

Now, if we have d words in each node at memory locations 0 through $d-1$, we can quite readily ensure that the word at location j in each node follows the jth transition sequence. The method is to store this word at location j as it passes through each node like a traveler who prefers the same hotel in each city. Then, at step k, we send the data in each node at location j over dimension $g_k + j \pmod{d}$. To take advantage of the Connection Machine's ability to load consecutive words, we in fact use Algorithm 2 below.

```
For $k = 1, 2, \ldots, 2^d - 1$
In each node
1. Data at locations 0 through $d - g_k - 1$ is loaded to
   be sent over dimensions $g_k$ through $d - 1$, respectively.
2. Data at location $d - g_k$ through $d - 1$ is loaded to
   be sent over dimensions 0 through $g_k - 1$, respectively.
3. Data is transmitted.
4. Data received over dimensions $g_k$ through $d - 1$ is
   stored at locations 0 through $d - g_k - 1$, respectively.
5. Data received over dimensions 0 through $g_k - 1$ is
   stored at locations $d - g_k$ through $d - 1$, respectively.
```

Note that steps 2 and 5 are vacuous if $g_k = 0$, which is half of the time. The actual code to perform this operation is not much longer than the pseudocode above.

In the real algorithm, we assume there is a multiple of $2d$ bodies in each node, and each body may contain more than one word of information. In the example described in the next section, there are two words of coordinate information and also a coefficient, giving three words for each body. Since we can transmit $2d$ words simultaneously, we loop over all the data until it is all transmitted. After the data is transmitted, we perform a computation such as the one described in the next section, and then we repeat for $k = 1, 2, \ldots, 2^d - 1$.

The ideas we presented in this section have now been coded up as a Connection Machine Scientific Software Library Primitive. See [12] for details.

6. A sample application.

6.1. Description. As an application example, we computed the velocities of a collection of interacting point vortices in two dimensions. This N-body problem is at the heart of the vortex method to solve the Navier–Stokes equation for incompressible viscous flows [30]. A Lagrangian perspective of the vorticity-stream function formulation of the Navier–Stokes equation leads to the introduction of discrete vortex elements that interact according to a Biot–Savart-type force law. To avoid potential numerical instability caused by very close encounters of particles, finite-size vortex elements should be used. However, in these timing runs, we have considered the interaction of point vortices.

In two dimensions, the (u, v) velocity components of a point vortex at position (x, y) are given by the following formulae:

$$u(i) = \frac{1}{2\pi}\sum_{j=1}^{N}\frac{c(j)\Delta y(i,j)}{\Delta r(i,j)^2}, \qquad i = 1,\ldots,N,$$

$$v(i) = \frac{-1}{2\pi}\sum_{j=1}^{N}\frac{c(j)\Delta x(i,j)}{\Delta r(i,j)^2}, \qquad i = 1,\ldots,N,$$

with

$$\Delta x(i,j) = x(j) - x(i), \qquad \Delta y(i,j) = y(j) - y(i),$$

$$\Delta r(i,j)^2 = \Delta x(i,j)^2 + \Delta y(i,j)^2, \quad \text{and} \quad c(j) = \text{ circulation of point vortex } j.$$

6.2. Timings and analysis. We performed several calculations for both the replicated orrery and the multiwire algorithm with a varying number of particles on various machine sizes. Timing results, in seconds, are shown in the Tables 1 and 2 below. Figure 10 is a graph of the performance given in those tables for the two algorithms on an 8K processor CM-2. Both time and N, the number of bodies, are graphed using a logarithmic scale. We have made the piecewise constant performance behavior of the replicated orrery algorithm clearly visible. Timings for the replicated orrery algorithm were run on 4K and 8K processor configurations. The multiwire timings were obtained on CM-2 configurations with 2^{d+5} processors for $d = 4, 5, 7, 8, 9$, i.e., with 2^d floating point nodes. Typically, 14,000 vortices interact in 2 seconds on a 512 floating-point node machine (16K processors) using the multiwire algorithm, and 17 seconds on an 8K processor machine using the replicated orrery. Counting the divide operation as one operation, the execution rate of the multiwire algorithm is about 5.2 Gflops on a fully configured CM-2 (2048 nodes and 64K processors).[3]

It is difficult to compare timings of these two algorithms because they use different models of the machine (slicewise vs. fieldwise). For a crude approximation, on a fixed CM-2 configuration, one can compare the timing for N bodies using the multiwire algorithm to the timing for the next largest power of 2 bodies using the replicated orrery. Doing this, for an equivalent number of bodies, the multiwire algorithm outperforms the replicated orrery by a factor of 3 to 5. Some loss in performance of the replicated orrery algorithm is due to the necessity of transposing fieldwise data back and forth for the floating-point units. There is an additional loss due to the fact that the CM-2 fieldwise model forces the sizes in the replicated orrery to be powers of 2. Thus, one does as much arithmetic as if N were rounded up to the next power of 2.

Keeping the number of bodies constant, the time to compute the velocity components appears inversely proportional to the number of floating-point nodes of the hypercube. This is the kind of behavior we expect given the complexity analysis of both algorithms. Note that, for a fixed number of processors, the proportion of time spent in the communications for the replicated orrery decreases very slowly as the number of

[3]On the 32-bit floating-point unit of the CM-2, a divide operation requires the explicit implementation of two Newton–Raphson iterations of the initial value which is provided by an internal look-up table. This amounts to a total of six atomic operations that we count as one.

TABLE 1

	14336	2.1	9%

bodies increases. In the multiwire algorithm the proportion of communication time is much smaller and the decrease is more rapid. We get a more accurate picture of what is going on in the multiwire algorithm from Fig. 11 which plots the actual speedup of the implementation against the optimal speedup of 2^d (the number of processors). We calculated the speedup by taking the ratio of T_{arith} times the number of processors and the total execution time of the calculation. Note that again the curves behave as predicted by the complexity analysis. For a fixed hypercube dimension, as the number of bodies increases the speedup approaches optimality. In particular, over the range of test cases we ran, T_{comm} varies from a few percent to fifty percent of the total execution time as the number of bodies approaches the number of processors.

Acknowledgments. We would like to thank Washington Taylor for his help in the first implementation of the replicated orrery and Adam Greenberg for running a set of timings of the replicated orrery for us.

ANALYSIS OF THE MULTIGRID FMV CYCLE ON LARGE-SCALE PARALLEL MACHINES*

RAY S. TUMINARO† AND DAVID E. WOMBLE†

Abstract. On serial computers it is well known that the multigrid FMV cycle is preferable to the V cycle both asymptotically and in practical use over a wide range of applications. However, on massively parallel machines, the parallel efficiency of the FMV (full multigrid V cycle) scheme is noticeably lower than that of the V cycle due to a large percentage of time spent on coarse grids. Thus the question arises: are the additional coarse grid computations within the FMV cycle warranted on massively parallel machines? To answer this, a number of issues are addressed regarding parallel FMV cycles: what efficiencies can be achieved; how do these compare with V cycle efficiencies; are FMV cycles still preferable to V cycles in a massively parallel environment?

A model is used to analyze the efficiency of both FMV and V cycles as a function of relaxation efficiency. Using this model, the standard FMV grid-switching criterion is modified to incorporate the efficiency of the coarse grid processing. Numerical results obtained from a multigrid implementation on a 1024-processor nCUBE 2 are used in conjunction with the model to quantify the performance and efficiency of the FMV cycle. Finally, comments are made regarding limitations of parallel processors based on FMV efficiencies.

Key words. parallel computing, multigrid, FMV cycle

1. Introduction. Multigrid algorithms are used within a variety of scientific disciplines and are among the fastest iterative methods for many problems of practical interest. Unlike conventional schemes, multigrid methods use a hierarchy of coarse meshes to accelerate convergence on the finest mesh. Depending on the order and frequency of these coarse grid computations, different multigrid variations are possible (e.g., V cycle, FMV cycle, W cycle, F cycle). While tradeoffs between these variations have been studied on serial computers, far less is known on parallel machines. For the most part, only the parallel V cycle has been studied extensively (see, [2], [4]–[6], and [8]–[13]). Given that the FMV cycle (full multigrid V cycle) is usually faster than the V cycle on serial computers, we feel it is appropriate to contrast the parallel performance of the FMV and V cycle iterations.

The key tradeoff between V and FMV cycles lies in the choice of initial guess. Specifically, the standard V cycle begins the computation on the finest grid using an arbitrary initial guess. The FMV cycle, on the other hand, starts with the coarsest grid, which is used to compute a good initial approximation on the finest grid. Thus, a greater percentage of time is spent on coarse grid computations (and hence less time on the fine grid) within the FMV iteration. Since coarse grid processing is inexpensive on serial computers, the FMV approach is usually very beneficial. However, on massively parallel computers the situation can be quite different. In particular, it is much more difficult to efficiently parallelize coarse grid computations due to the fact that there is less parallelizable work. Consequently, the cost differential between fine and coarse grid processing may be so small that the overall execution time of a simple FMV cycle is not necessarily better than that of the V cycle.

In this paper, we analyze the FMV cycle on massively parallel computers. The purpose of this analysis is to quantify the performance and efficiency of an FMV iteration as a function of the relaxation efficiency. That is, how much efficiency (from a parallel computing standpoint) is lost due to the heavy use of coarse grids in the FMV cycle? To answer this, we review the grid switching criterion within FMV cycles. This criterion determines when the coarse grid approximation is interpolated for use as an initial guess on the next finest grid. The switching criterion is a function of computation times for fine and coarse grid iterations. Since these times depend on parallel efficiency, we modify the switching criterion to incorporate parallel efficiency. A model of the FMV cycle as a function of relaxation operations is developed. We compare the V and FMV cycles using this model and numerical results obtained from a multigrid implementation on a 1024-processor nCUBE 2. Based on this analysis, conclusions are drawn about the merits of the parallel FMV cycle as well as the limitations of parallel processors.

2. The FMV cycle. We begin with a brief description of the V and FMV cycles. It is assumed that the reader is already familiar with the multigrid method (see [3] for introductory material).

Consider the discrete problems

$$A_i u_i = f_i,$$

where A_i is an $n \times n$ matrix corresponding to the discretization of a partial differential equation (PDE) problem on grid $\mathcal{G}_i$ with mesh spacing $h = 2^{-i}$, and f_i and u_i are n-vectors. One iteration of a multigrid V cycle can be written as follows:

```
ALGORITHM 1. $u_i \leftarrow \mathrm{MV}(u_i, f_i)$.
    1. Relax $\nu_1$ times on $A_i u_i = f_i$ with initial guess $u_i$.
    2. If $i > 0$,  $f_{i-1} \leftarrow I_i^{i-1}(f_i - A_i u_i)$    /* $I_i^{i-1}$: projection from $\mathcal{G}_i$ to $\mathcal{G}_{i-1}$ */
                $u_{i-1} \leftarrow 0$
                $u_{i-1} \leftarrow \mathrm{MV}(u_{i-1}, f_{i-1})$
                $u_i \leftarrow u_i + I_{i-1}^i u_{i-1}$    /* $I_{i-1}^i$: interpolation from $\mathcal{G}_{i-1}$ to $\mathcal{G}_i$ */
       Endif
    3. Relax $\nu_2$ times on $A_i u_i = f_i$ with initial guess $u_i$.
```

The V cycle procedure starts with an initial guess and uses relaxation iterations on a series of coarser and coarser grids to improve the guess. To enhance the V cycle, an initial approximation can be obtained by first "solving" the PDE problem on a coarser grid using the multigrid procedure. This leads to the FMV cycle written recursively as follows:

```
ALGORITHM 2. $u_i \leftarrow \mathrm{FMV}(f_i)$.
    1. If $i > 0$,  $f_{i-1} \leftarrow I_i^{i-1} f_i$
                $u_{i-1} \leftarrow \mathrm{FMV}(f_{i-1})$
                $u_i \leftarrow I_{i-1}^i u_{i-1}$
       Endif
    2. $u_i \leftarrow \mathrm{MV}(u_i, f_i)$   $\eta_i$ times,
```

where the parameter η_i determines how many V cycles are performed on level i.

On serial machines, the FMV cycle is faster than the V cycle both asymptotically and in practical use. In particular, it is possible to show that the FMV cycle requires $O(N)$ operations on a serial computer compared to $O(N \log N)$ operations for the V cycle where N is the number of grid points on the fine grid.[1] However, on parallel machines the relative performance of the two schemes is not as clear. In particular, multigrid methods are parallelized by performing computations within a grid in parallel but still processing each grid in the hierarchy in sequence. Therefore, the parallel efficiency on each individual grid needs to be considered. Unfortunately, when computing on coarse grids, many processors are inactive due to the lack of computational work. Consequently, the FMV iteration (which uses coarse grids heavily) makes significantly less efficient use of parallel processors than the V cycle. Thus, even though the FMV cycle is superior on serial machines, parallel V and FMV cycles require the same number of operations asymptotically, $O(\log^2 N)$, on a parallel machine with N processors. The remainder of this paper explores the relationship between the two cycling strategies on parallel machines.

3. Switching criteria. We begin our discussion of the parallel FMV process by considering the proper choice of the η_i's. Specifically, we wish to minimize the overall run time in the FMV process. To do this, we balance the time saved on a fine grid (due to a better initial guess) versus the time required to produce an approximation on the coarser grid. Thus, η_i depends on the run times required for V cycles at levels i and $i-1$. For a serial computer, the ratio of these times is fixed. However, for a parallel computer, it is necessary to consider the efficiency of the computer which, in turn, depends on machine parameters and grid size. The basic idea is given in [1] for serial computations. Here, we generalize the arguments to include parallel processors.

To obtain a grid switching criterion, it is useful to first develop an expression relating the errors on different meshes. In particular,

$$u(\mathcal{G}_i) = \tilde{u}_i + e_i + E_i, \tag{1}$$

where

$$\begin{aligned} u(\mathcal{G}_i) &= \text{exact PDE solution evaluated on } \mathcal{G}_i, \\ u_i &= \text{exact discrete solution on grid } \mathcal{G}_i, \\ \tilde{u}_i &= \text{current numerical approximation on } \mathcal{G}_i, \\ E_i &= u(\mathcal{G}_i) - u_i \qquad \text{(truncation error)}, \\ e_i &= u_i - \tilde{u}_i \qquad \text{(algebraic error)}. \end{aligned}$$

If we assume that the approximation on $\mathcal{G}_{i-1}$ is interpolated such that the interpolation errors are negligible (i.e., sufficiently high order), a simple expression relating algebraic and truncation errors can be derived. Specifically, we use (1) on two adjacent grids to obtain

$$e_i^0 - I_{i-1}^i e_{i-1}^* = I_{i-1}^i E_{i-1} - E_i, \tag{2}$$

where 0 denotes an initial approximation obtained by interpolating the current solution from the previous grid, $*$ denotes the final approximation which is to be interpolated to the next grid, and I_{i-1}^i denotes a suitably high-order interpolation operator from $\mathcal{G}_{i-1}$ to $\mathcal{G}_i$. In the remainder of this section we omit the interpolation operator. However, it is

[1]This operation count corresponds to obtaining a solution whose accuracy is approximately the same magnitude as the discretization error. It is assumed that the V cycle convergence rate is independent of the mesh spacing. This is true when multigrid methods are applied to many elliptic problems.

understood that interpolation takes place whenever two quantities defined on different grids are combined.

Since the goal is to minimize work, we switch from $\mathcal{G}_{i-1}$ to $\mathcal{G}_i$ when the greater error reduction associated with a V cycle on $\mathcal{G}_i$ outweighs the increased cost of operating on $\mathcal{G}_i$ (see the Appendix for details). This occurs when

$$\|e_i^0\| = \xi_{i,p}\ \|e_{i-1}^*\|, \tag{3}$$

where

$$\xi_{i,p} = \frac{\tau_{i,p}(V)}{\tau_{i-1,p}(V)}$$

and $\tau_{i,p}(V)$ is the V cycle execution time starting on $\mathcal{G}_i$ using p processors. Combining (2) and (3) and assuming that the local truncation errors satisfy

$$E_i \approx 2^{-q} E_{i-1} \tag{4}$$

for a qth-order discretization of a PDE, we obtain

$$\|e_{i-1}^*\| \le \left(\frac{1-2^{-q}}{\xi_{i,p}-1}\right) \|E_{i-1}\|. \tag{5}$$

This expression can be used for determining convergence. For now, we use (5) to obtain the required algebraic error reduction on $\mathcal{G}_{i-1}$ so that (3) is satisfied. In particular, (3), (4), and (5) on $\mathcal{G}_{i-2}$ yield

$$\|e_{i-1}^0\| \le \xi_{i-1,p} \left(\frac{1-2^{-q}}{\xi_{i-1,p}-1}\right) 2^q \|E_{i-1}\|. \tag{6}$$

If, in (5) and (6) we assume equality,[2] the necessary error reduction condition follows

$$\begin{aligned} \frac{\|e_{i-1}^*\|}{\|e_{i-1}^0\|} &\approx \left(\frac{\xi_{i-1,p}-1}{\xi_{i,p}-1}\right) \frac{2^{-q}}{\xi_{i-1,p}} \\ &\approx \frac{\tau_{i-1,p}(S)}{\tau_{i,p}(S)} 2^{-q} \\ &\approx \frac{\varepsilon_{i,p}(S)}{\varepsilon_{i-1,p}(S)} 2^{-q-d}, \end{aligned} \tag{7}$$

where

$$\tau_{i,p}(S) = \tau_{i,p}(V) - \tau_{i-1,p}(V)$$

is the time for operations associated with $\mathcal{G}_i$ and

$$\varepsilon_{i,p}(S) = \frac{\tau_{i,1}(S)}{p\tau_{i,p}(S)}$$

is the efficiency of the operations corresponding to $\tau_{i,p}(S)$. Since the ratio of the smoother times is representative of the ratio between operations on $\mathcal{G}_i$ and $\mathcal{G}_{i-1}$, we

[2]We must assume equality to account for the worst-case situation and guarantee that the final error is sufficiently small.

take $\tau_{i,p}(S)$ to be the time required for smoothing on $\mathcal{G}_i$. Thus, the formula states that the switching of grids is determined by the ratio of the relaxation time on $\mathcal{G}_i$ and $\mathcal{G}_{i-1}$. No other operations need be considered. Note that in the serial computing case (i.e., $p = 1$), the ratio between the smoother times at two levels is usually 2^d (where d is the dimension of the problem) giving an error reduction criterion of 2^{-q-d} which is consistent with [1]. Furthermore, in the case of one point per processor and negligible communication costs, we have $\tau_{i-1,p}(S) \approx \tau_{i,p}(S)$ yielding a reduced switching criterion of 2^{-q}. Thus, the net effect of the new switching criterion is to shift more of the computation away from the coarser grids where the parallel efficiency is low to the finer grids where the parallel efficiency is higher.

4. Experimental results. A parallel multigrid algorithm was implemented on a 1024 processor nCUBE 2 system. On each level the algorithm uses one red-black Gauss–Seidel iteration as a smoother. Bilinear interpolation and full weighted restriction are used for grid transfer operators within the V cycle. Bicubic interpolation is used between grids in the FMV process (i.e., interpolation errors can be ignored in the analysis). Parallelization is obtained by decomposing the problem spatially in that each processor maintains a region of the domain. On coarse grids, it is possible that some processors may contain no points within their subdomain. In this case, processors without grid points perform redundant work in parallel to the useful work proceeding on other processors.

The algorithm is applied to a two-dimensional central difference approximation of a model anisotropic problem

$$\frac{\partial^2 u}{\partial x^2} + \gamma \frac{\partial^2 u}{\partial y^2} = f(x, y) \tag{8}$$

defined on the unit square with Dirichlet boundary conditions, $\gamma = .18$, and suitable right-hand side. Three cases are considered here.

• V cycle. $\lceil -\log_2 N/\log_2 \beta \rceil$ V cycle iterations are performed where β is the V cycle convergence rate. This corresponds to the number of iterations required to reduce errors to level of truncation error assuming that the initial guess on the fine grid satisfies: $\|e_i^0\| \approx 1$ and $\|E_i\| \approx h^2$, where h is the mesh spacing. β is .77 for our experiments.[3]

• FMVS cycle. An FMV cycle is performed using the standard grid switching criterion. That is, the error is reduced by a factor of 16 on the coarse grids. This corresponds to $\lceil -4/\log_2 \beta \rceil$ V cycles on each of the coarse grids before interpolation to the next grid. On the finest grid, (6) is used (with $p = 1$) to determine the number of iterations required to reduce the algebraic error below the level of truncation error. This corresponds to $\lceil -2/\log_2 \beta \rceil$ iterations on the finest grid. Note that the number of iterations is always increased to an integer value.

• FMVP cycle. An FMV is performed using the parallel grid switching criterion. The ratio of the smoother times in (7) is estimated using a timing model (see (12)). On the finest level (6) is used to determine the final number of iterations. For a 64×64 grid on 1024 processors, the following number of V cycles were performed on each level starting from the second coarsest grid and ending with the finest grid: 5, 6, 6, 4, and 10. This corresponds to less work on the coarse grid and more work on the fine grid when compared to the FMVS cycle which performs the following V cycles: 11, 11, 11, 11, and 6.

[3]Experiments were performed with a somewhat poor V cycle convergence rate so that the effects of rounding the grid switching criterion (e.g., when the switching criterion determines that 1.8 V cycles is optimal, we perform 2 V cycles) would be minimal. However, γ was not chosen so small as to make the V cycle with point smoothing a bad choice of algorithm.

In Tables 1 and 2, we compare the total run times and efficiencies[4] for the V, FMVS, and FMVP schemes on both a 64×64 grid and a 1024×1024 grid. For the larger problem, the relative performance is similar to the serial computing case. That is, both FMV schemes outperform the V cycle method by a substantial margin despite the fact that the overall FMV efficiencies are not good (even for the large problem). That is, the heavy use of coarse grids results in fairly low FMV efficiencies. On the smaller grid the situation is much worse. In particular, the time differential between the the V cycle and FMV cycles is not large and the overall efficiencies are extremely low. In other words, when efficiencies are low, it is not clear if the FMVS iteration is superior to the V cycle. In the remainder of this paper, the relationship between V and FMV cycles is explored in more detail.

FMVP	35.3 (1.0)	11.1 (.80)	4.7 (.47)

5. Execution model. We can express the execution time of V and FMV cycles as a function of the time on each level. For the V cycle we have

$$\tau_{i,p}(V) = \sum_{j=0}^{i} \tau_{j,p}(S). \tag{9}$$

Similarly, the FMV cycle can be expressed as

$$\tau_{i,p}(F) = \sum_{j=0}^{i} \eta_j \tau_{j,p}(V). \tag{10}$$

Note that when $\eta_j = 1$, we have the same relation between FMV and V cycles as we have between the V cycle and the smoother. This will be discussed in more detail in the next section. Using the following definition of efficiency

$$\varepsilon = \frac{\text{serial time}}{p \ * \ \text{time using } p \text{ processors}},$$

we can obtain expressions relating the efficiency of the smoother, V cycle, and FMV cycle (similar to those in [13]). In particular, we have

[4]Efficiencies are calculated based on the execution time on the smallest number of processors used for the problem.

$$\varepsilon_{l,p}(V) = \frac{2^{d(l+1)} - 1}{(2^d - 1)\sum_{i=0}^{l} \frac{2^{di}}{\varepsilon_{i,p}(S)}},$$

$$\varepsilon_{l,p}(F) = \frac{\sum_{i=0}^{l} \eta_i \; 2^{di}}{\sum_{i=0}^{l} \frac{\eta_i \; 2^{di}}{\varepsilon_{i,p}(V)}},$$

and for $\eta_i = \eta_j$ and large l, we get

$$\varepsilon_{l,p}(F) \approx \frac{2^{d(l+1)} - 1}{(2^d - 1)^2 \;\sum_{i=0}^{l} \frac{(l-i+1)2^{d(i-1)}}{\varepsilon_{i,p}(S)}}.$$

Note that the overall efficiencies are just weighted harmonic averages of the efficiencies of the smoother. Since the larger weights are applied to the fine grid efficiencies, we can conclude that the efficiencies of the fine grid smoother dominate the overall efficiency. However, the fine grid weights for the FMV cycle are lower relative to the fine grid weights for the V cycle (due to the $l - i + 1$ term). Thus, we would expect that the FMV efficiencies are governed much more by coarser grids than the V cycle. In the next section, we use this model to explore the performance of V and FMV schemes in a variety of situations.

6. Performance of the V, FMVS, and FMVP cycles. A program was written using the model and grid switching criterion given in the previous sections to estimate run time and efficiencies under different circumstances. We use this model to explore the performance of the different multigrid cycles beginning with the special situation of one grid point per processor. In our model we assume that the time required on each grid level is constant (i.e., $\tau_{i,p}(V) = 1$). In this case, (9) and (10) can be used in conjunction with convergence and grid switching criteria to determine the required number of operations.[5] For example, one V cycle takes α operations where α is the number of grid levels and a total of $-2\alpha/\log_2(\beta)$ iterations to reduce the algebraic error below truncation error. A summary of the operations counts for the different cycles is given below.

V (2d & 3d):	$\gamma\alpha^2$,
FMVS (2d):	$\gamma\alpha^2$,
(3d):	$\gamma[\frac{5}{4}\alpha(\alpha-1) + \alpha\log_2(\sqrt{24/7})]$,
FMVP (2d & 3d):	$\gamma[\frac{1}{2}\alpha(\alpha-1) + \alpha\log_2(\sqrt{3\alpha})]$,

where

$$\alpha = log_2(N^{1/d}), \qquad \gamma = -2/\log_2(\beta), \tag{11}$$

β is the convergence rate of the V cycle, N is the total number of grid points, and d is the dimension of the problem. Note that asymptotically the FMVP cycle has the fastest execution time, which is less than a factor of two better than the FMVS execution time. Furthermore, the FMVS cycle is competitive with the V cycle even in the extreme case

[5]The number of iterations are based on the same assumptions given in §4. The only difference is that we use the V cycle run times to determine the η_i's in conjunction with (6). Additionally, we note that in this analysis the number of V cycles need not be an integer.

of one point per processor. In particular, the FMVS cycle requires the same number of operations as the V cycle on two-dimensional problems while only slightly more in the three-dimensional case. Thus, the FMV cycle (even without the new switching criterion) performs almost as well as the V cycle despite a large percentage of time spent on coarse grids.

Of course, in most situations we have more grid points than processors. To model this, we consider run times that are proportional to the number of grid points per processor. That is,

$$\tau_{i,p}(S) = C\left\lceil \frac{N}{2P} \right\rceil,$$

where N is the number of grid points on $\mathcal{G}_i$, P is the number of processors, and C is a constant independent of N and P. Note that the factor of two occurs because half the processors are idle during a red/black Gauss–Seidel iteration when each processor contains only one point. This model might correspond to the case where communication costs are negligible. Figures 1 and 2 show the run time of the three schemes on 4096 processors. As the figures illustrate, the performance of the different schemes is comparable to the one point per processor case. That is, the FMV iteration usually outperforms the V, and the FMVP scheme slightly outperforms the FMVS iteration. For the most part, the execution times do not vary significantly for the different cycling schemes when there is only one point per processor. However, when each processor contains many points, the FMV cycles significantly outperform the V cycle.

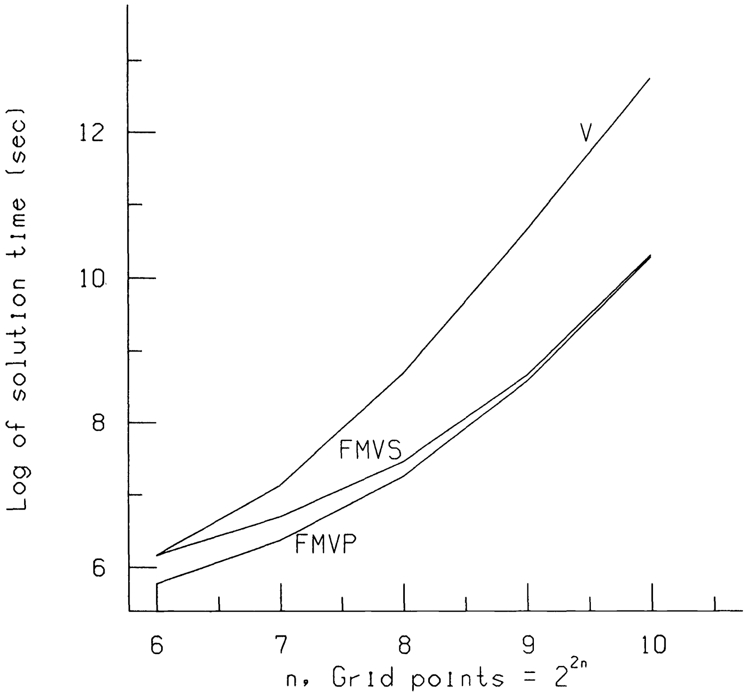

FIG. 1. *Logarithm of execution time for a two-dimensional problem using* V, FMVS, *and* FMVP *cycles on* 4096 *processors assuming zero communication costs on a* 4096 *processor machine.*

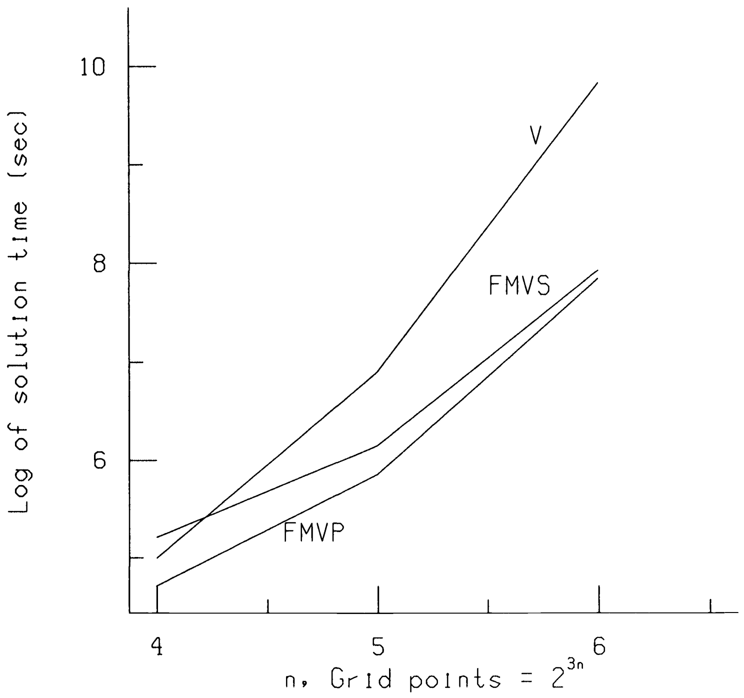

FIG. 2. *Logarithm of execution time for a three-dimensional problem using* V, FMVS, *and* FMVP *cycles assuming zero communication costs on a* 4096 *processor machine.*

Finally, we account for communication costs by considering the following model for the run time on each level:

$$\tau_{i,p}(S) = C_1 + C_2 \left\lceil \frac{N}{P} \right\rceil^{\frac{d-1}{d}} + C_3 \left\lceil \frac{N}{2P} \right\rceil, \tag{12}$$

where the C_i's are determined by doing a least-squares fit to nCUBE 2 timing data for the Gauss–Seidel routine. Specifically, we obtain the following for the nCUBE 2:

$$C_1 = 2.14 \times 10^{-3}, \quad C_2 = 2.02 \times 10^{-5}, \quad C_3 = 4.43 \times 10^{-5}.$$

In Table 3 we can see the close correspondence between the predicted run times using this smoother model and the actual run times obtained on the nCUBE 2 for the smoother.[6]

Using (9), (10), and (12) with the above constants, we obtain the run times and efficiencies for the two- and three-dimensional problems shown in Figs. 3–6. From these plots we can obtain a great deal of information about the performance of the FMV cycle. The first and most important observation is that the FMV cycles significantly outperform the V cycle when each processor contains many grid points, and that the time differential between V and FMV execution times grows quite rapidly as the number of grid points increases. For example, the V cycle calculation on a 1024 × 1024 grid requires almost twice

[6]*Note.* Modelling only the smoother is sufficient because the actual time on each grid level (including projection, interpolation, residual calculation, etc.) is proportional to the smoother time. For our experiments in §4, the actual time per level is about four times larger than the smoother times.

TABLE 3

as much time as the corresponding FMVP calculation. Conversely, it is possible that the FMVS scheme may require more time than the V cycle when each processor contains a modest number of points. In these cases, however, the time differential between the V and FMVS schemes is not large and, thus, need not be considered too seriously. Additionally, the FMVP method is the best performer regardless of the number of points per processor. While its performance is better than the FMVS iteration, the time savings between the two FMV methods is not enormous. In our figures, for example, the most significant differences between FMV schemes correspond to the FMVP iteration requiring two-thirds of the time of the FMVS method. Thus, we recommend using the FMVP iteration because it requires the least run time in all cases. However, if it is difficult or inconvenient to compute the optimal grid switching criterion, it is still better to use the standard FMV cycle over the V cycle because it requires substantially less time when there are many points per processor.

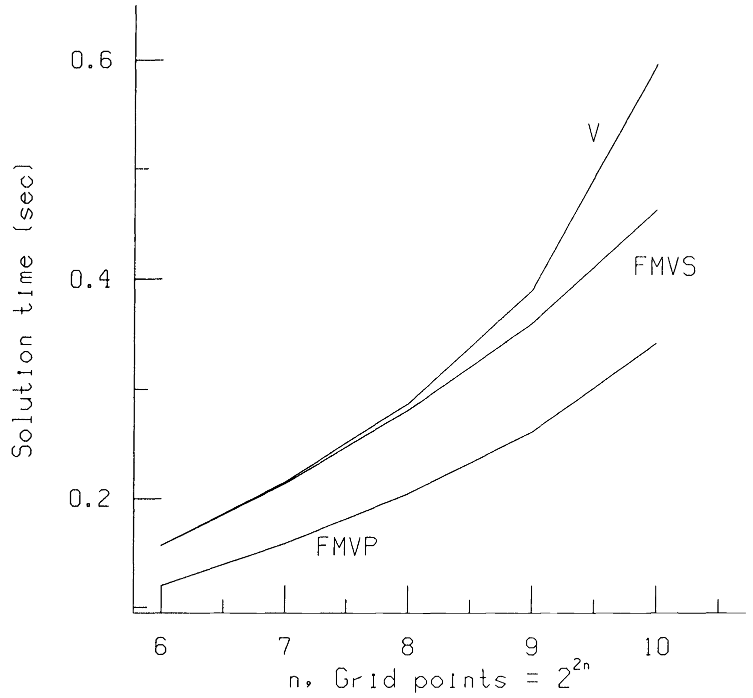

FIG. 3. *Predicted execution time for a two-dimensional problem using* V, FMVS, *and* FMVP *cycles on a* 4096 *processor* nCUBE 2.

Unfortunately, the FMV efficiencies can be extremely low even for large problems. For example, by inspecting Fig. 6 it can be verified that using 4K processors on a 256 ×

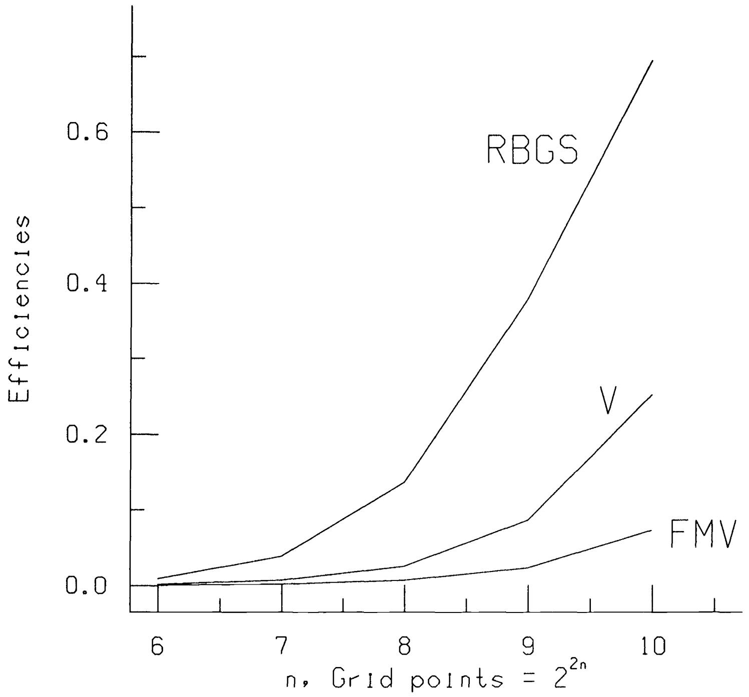

FIG. 4. *Predicted efficiencies for a red/black Gauss–Seidel smoother, a* V *cycle, and an* FMVP *cycle on a two-dimensional problem using a* 4096 *processor* nCUBE 2.

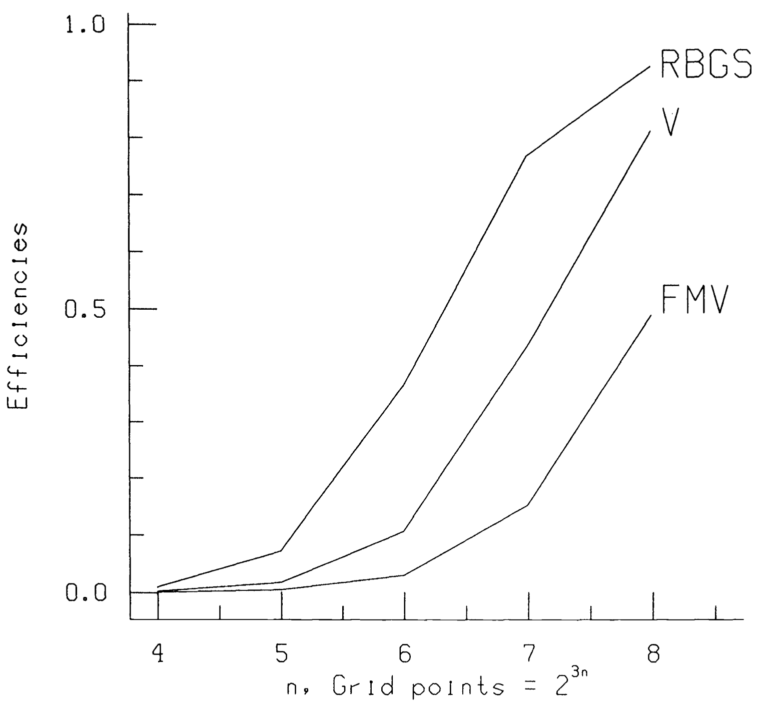

FIG. 6. *Predicted efficiencies for a red/black Gauss–Seidel smoother, a* V *cycle, and an* FMVP *cycle on a three-dimensional problem using a* 4096 *processor* nCUBE 2.

256 × 256 grid yields a smoother that is 92% efficient, a V cycle algorithm that is 82% efficient, and an FMV cycle algorithm that is only 50% efficient. While 50% efficiency is not terrible, a higher efficiency would normally be expected for an explicit algorithm on a grid containing over 16 million points. Note that the drop in efficiency between the smoother and the V cycle is related to the efficiency drop associated with using an FMV cycle as opposed to a V cycle. In fact, the efficiency curves in Figs. 4 and 6 are approximately the same distance apart. For example, in Fig. 6 the smoother runs at 40% efficiency when there are approximately $8^{6.1}$ grid points. Due to the coarse grid computations, the V cycle requires 5.3 times as many points as the smoother to achieve the same parallel efficiency, and the FMV cycle requires 5.3 times as many points as for the V cycle to achieve that same efficiency. The fact that approximately the same increase in points appears is not entirely a coincidence, but is related to the fact that (9) and (10) are identical when the η_i's are the same (which is nearly the case). Though it is somewhat cumbersome to exactly characterize the mathematical relationship between the efficiency curves, we simply state that over a very wide range of communication characteristics (i.e., different C_i's) the same basic relationship holds. That is, the efficiency curves of the smoother, V cycle, and FMV cycle are approximately equidistant. Overall, the FMV efficiencies gradually approach one as the grid becomes larger (similar to other explicit methods). However, it takes many more grid points to achieve these high efficiencies than simple explicit schemes. In our examples, a grid with $42N$ ($28N$) unknowns is necessary to achieve the same efficiency over a wide range of efficiencies as

the smoother applied to N unknowns on a two-dimensional (three-dimensional) grid. That is,

$$\varepsilon_s(N/42) \approx \varepsilon_v(N/7) \approx \varepsilon_{fmvp}(N) \quad \text{in two dimensions}$$

and

$$\varepsilon_s(N/28) \approx \varepsilon_v(N/5.3) \approx \varepsilon_{fmvp}(N) \quad \text{in three dimensions}$$

for the nCUBE hypercube. It is important to remember, however, that despite the poor efficiencies the overall FMV run times are among the fastest for these problems.

We conclude this section by remarking that the characteristics displayed by the various cycles above are seen for a wide range of values of C_1, C_2, and C_3. We also remark that the V cycle and FMVS cycle can be considered special cases of the FMVP cycle, which is optimized for overall solution time. Hence, in the case where communication time dominates computation time (C_1 and C_2 large), the FMVP cycle is the fastest of the three, even though the V cycle may be heavily favored over the FMVS cycle.

7. Implications for parallel processors. While we have focused on two particular multigrid variants, we feel that this study has much more general implications regarding the global mixing of data and the corresponding low efficiencies. In this section, we make a few remarks along these lines.

Within the iterative method community, it has become accepted that the fastest algorithms for elliptic problems require some global mixing of information. That is, the update at a given point should use some information from every other grid point within the domain. Since this global mixing of information requires additional communication and possible load imbalance, the question remains: how much global mixing is desirable on a parallel machine? While it is sometimes stated that a fast iterative method (one which converges independent of mesh size) with a minimal global operations is preferable (e.g., domain decomposition algorithms [7] typically require only one coarse grid problem to be solved), we wish to argue that this reasoning is far too simplistic. That is, there are many situations where the heavy use of global information may be beneficial despite low efficiencies. Clearly, in the multigrid context, the additional use of coarse grids within the FMV cycle is warranted even on massively parallel machines.

Finally, it is really not clear what kind of efficiencies should be expected when solving elliptic PDE systems with "optimal" algorithms. In fact, it can be shown (see [14]) that a lower bound for solving elliptic PDE systems is given by $O(N)$ on serial machines and $O(\log N)$ on parallel machines where N is the number of grid points. Thus, it must be expected that any numerical algorithm that achieves this optimal performance will have an efficiency that drops off sharply when a large number of processors are used. It can be argued that when the FMV cycle is applied to well-behaved systems, the performance is sufficiently close to the theoretical lower bound that the predicted drop in efficiency can be observed. Thus, from this point of view, the low FMV efficiencies should not be that surprising. That is, as one gets closer to an optimal algorithm for solving elliptic problems, lower parallel efficiencies should occur. It is important, however, to realize that in most practical problems the computations are so difficult (or perhaps the algorithms are not sophisticated enough) that the lower bound is not attained and, hence, the sharp drop in efficiency is not observed.

8. Conclusions. We have analyzed the parallel FMV cycle. In particular, a new grid switching criterion was developed to account for parallel processor efficiencies. Using this new criterion, FMV algorithms were implemented and analyzed in a massively parallel setting. Based on this analysis, it was determined that the modified FMV cycle always requires less run time than the corresponding V cycle. This occurs even though the FMV cycle makes far poorer use of parallel processors than the V cycle. Furthermore, the performance of the FMV cycle with the new grid switching criterion is better than that with the standard criterion. However, the overall performance differential is not so great that the user needs to be greatly concerned with implementing the "optimal" switching criterion. In fact, even with the standard switching criterion, the FMV cycle almost always outperforms the V cycle and is within a factor of two of the "optimal" FMV performance. Unfortunately, the overall efficiencies obtained on the nCUBE are somewhat low even on very large grids. While the efficiencies improve as the grid becomes larger, it requires many more grid points to achieve high efficiencies for FMV cycles. Nonetheless, the overall solution times are quite fast and are among the fastest possible with current methods and machines.

Appendix. "Optimal" error ratios between grids. We seek an expression for the ratio of algebraic errors between two consecutive grid levels in an optimal FMV cycle. Consider an FMV cycle on two levels, $l-1$ and l. The algebraic error corresponding to the approximate solution on $\mathcal{G}_{l-1}$ is given by e_{l-1}. On $\mathcal{G}_l$, an approximate solution is obtained from the solution on $\mathcal{G}_{l-1}$ by high-order interpolation. Thus, the algebraic error on level l is given by

$$e_l = e_{l-1} + \delta,$$

where

$$\delta = E_l - E_{l-1}$$

(the difference of the truncation errors). Assume that after k V cycle iterations on $\mathcal{G}_{l-1}$, the norms of the algebraic errors are bounded by $\|\beta^k e_{l-1}\|$ and $\|\beta^k e_{l-1}\| + \|\delta\|$. After k iterations starting from the coarse level, we proceed with j iterations on the fine level resulting in an algebraic error on the fine grid of

$$\beta^j(\beta^k\|e_{l-1}\| + \|\delta\|) \geq \|e_l^{\text{final}}\|. \tag{13}$$

Since we wish to bound the final error, we assume equality in (13) and proceed to determine the k that minimizes the total work necessary to attain a fixed algebraic error bound. Let the cost of a coarse grid V cycle be $\tau_{l-1,p}(V)$ and the cost of a fine grid V cycle be $\xi_{l,p}\tau_{l-1,p}(V)$. Then the total cost is

$$W = (k + j\xi_{l,p})\tau_{l-1,p}(V),$$

where

$$j = \frac{\log\|e_l^{\text{final}}\| - \log(\beta^k\|e_{l-1}\| + \|\delta\|)}{\log(\beta)}.$$

The best choice of k can be found by differentiating W with respect to k and setting the result equal to zero. Namely,

$$0 = 1 - \xi_{l,p}\frac{\beta^k\log(\beta)\|e_{l-1}\|}{\log(\beta)(\beta^k\|e_{l-1}\| + \|\delta\|)}.$$

Thus, we find that the optimal k occurs when

$$\frac{\beta^k \|e_{l-1}\| + \|\delta\|}{\beta^k \|e_{l-1}\|} = \xi_{l,p}.$$

That is, the optimum occurs when the ratio of the algebraic error bounds on the two grids is $\xi_{l,p}$.

FAST INVERSE QR FACTORIZATION FOR TOEPLITZ MATRICES*

JAMES G. NAGY†

Abstract. Fast orthogonalization schemes for $m \times n$ Toeplitz matrices T, introduced by Bojanczyk, Brent, and de Hoog (BBH) and Chun, Kailath, and Lev-Ari (CKL), are extended to compute directly an inverse QR factorization of T using only $O(mn)$ operations. An inverse factorization allows for an efficient parallel implementation, and the algorithm is computationally less expensive for computing a solution to the Toeplitz least squares problem than previously studied inverse QR methods. In addition, it is shown that regularization can be incorporated into the algorithm with virtually no extra work. Thus it is possible to compute regularized solutions to ill-conditioned Toeplitz least squares problems using only $O(mn)$ operations. An application to ill-conditioned problems occurring in signal restoration is provided, illustrating the effectiveness of this method.

Key words. least squares problem, QR factorization, Toeplitz matrix, regularization

1. Introduction.

An $m \times n$ matrix T is a Toeplitz matrix if its entries are constant down each diagonal. This can be expressed by denoting the (i, j) entry of T as t_{i-j}. In this paper we will consider solving least squares (LS) problems of the form

$$\text{minimize } \|b - Tx\|_2, \tag{1.1}$$

where T is an $m \times n$ Toeplitz matrix of full column rank, b is an $m \times 1$ vector and $\|\cdot\|_2$ denotes the usual Euclidean norm. Toeplitz least squares problems occur in many engineering applications such as signal restoration [12], data compression [12], seismic exploration [14], and speech echo cancellation [2].

Least squares problems of the form (1.1) can be solved effectively using the QR factorization of T, which can be computed using $O(mn^2)$ operations. By exploiting the Toeplitz structure of T, we can obtain a *fast* QR factorization which requires only $O(mn)$ operations. This is the case for the algorithms of Sweet [18], Bojanczyk, Brent, and de Hoog [5], Chun, Kailath, and Lev-Ari [8], and Cybenko [9]. It also has been proposed recently to use the preconditioned conjugate gradient (PCG) algorithm to solve Toeplitz least squares problems [7], [15], [16]. For certain Toeplitz matrices it is shown that the PCG method is effective in solving these LS problems.

The first $O(mn)$ method for computing the QR factorization of a Toeplitz matrix was developed by Sweet [18], which he has more recently extended to block Toeplitz matrices [19]. Bojanczyk, Brent, and de Hoog [5] modified the ideas of Sweet to develop a slightly faster QR factorization. (We will denote the fast QR factorization of Bojanczyk, Brent, and de Hoog by BBH.) Chun, Kailath, and Lev-Ari introduced a fast, and more general, QR factorization algorithm based on the displacement structure of T and T^TT. (We denote this method by CKL.) Although they use a different approach, their method is essentially equivalent to that of BBH. Moreover, in the CKL algorithm, certain parameters generated in obtaining R can also be used to compute R^{-1} in $O(n^2)$ operations. Finally, a different orthogonalization scheme for Toeplitz matrices was proposed by Cybenko [9]. This algorithm uses inner products to construct Q and R^{-1}, but requires the computation of Q to obtain R^{-1}.

In §2 of this paper we describe the method of BBH for computing R and show in §3 how it can be modified, using an inverse factorization scheme by Pan and Plemmons [17], to compute R^{-1} directly. Our algorithm does not require the computation of R to obtain R^{-1}, and hence is less expensive than the CKL method. In §4 we then combine this with the CKL approach for computing Q, to obtain a fast inverse QR factorization algorithm. Moreover, we show that Q^Tb can easily be computed without explicitly forming Q. This provides considerable savings in the computational work in obtaining the LS solution, which cannot be attained in Cybenko's algorithm. Finally, in §5 we consider ill-conditioned problems that occur often in signal processing applications. We use the method of regularization to alleviate the problems caused by the ill conditioning, and show that the fast orthogonalization schemes discussed here extend nicely for these problems. Some numerical examples are provided in §6.

2. Computation of R: Algorithm BBH-R.

Let T be an $m \times n$ Toeplitz matrix of full column rank, and let R be the Cholesky factor of T^TT. In this section we give a brief description of how the BBH algorithm constructs R one row at a time.

Since T has the Toeplitz structure, we can partition T as

$$T = \begin{bmatrix} t_0 & u^T \\ v & T_0 \end{bmatrix} = \begin{bmatrix} T_0 & \tilde{u} \\ \tilde{v}^T & t_{m-n} \end{bmatrix}, \tag{2.1}$$

where T_0 is a submatrix of T, u and $\tilde{v}$ are $n-1$ dimensional vectors, v and $\tilde{u}$ are $m-1$ dimensional vectors, and t_0 and t_{m-n} are scalars. In addition, consider partitioning R as

$$R = \begin{bmatrix} r_{11} & z^T \\ 0 & R_b \end{bmatrix} = \begin{bmatrix} R_t & \tilde{z} \\ 0^T & r_{nn} \end{bmatrix}, \tag{2.2}$$

where z and $\tilde{z}$ are $n-1$ dimensional vectors and r_{11} and r_{nn} are scalars.

Setting $R^TR = T^TT$ and using the partitionings (2.1) and (2.2), we have

$$\begin{bmatrix} r_{11}^2 & r_{11}z^T \\ r_{11}z & zz^T + R_b^TR_b \end{bmatrix} = \begin{bmatrix} t_0^2 + v^Tv & t_0u^T + v^TT_0 \\ t_0u + T_0^Tv & uu^T + T_0^TT_0 \end{bmatrix} \tag{2.3}$$

and

$$\begin{bmatrix} R_t^TR_t & R_t^T\tilde{z} \\ \tilde{z}^TR_t & \tilde{z}^T\tilde{z} + r_{nn}^2 \end{bmatrix} = \begin{bmatrix} T_0^TT_0 + \tilde{v}\tilde{v}^T & T_0^T\tilde{u} + t_{m-n}\tilde{v} \\ \tilde{u}^TT_0 + t_{m-n}\tilde{v}^T & \tilde{u}^T\tilde{u} + t_{m-n}^2 \end{bmatrix}. \tag{2.4}$$

From (2.3) and (2.4) we see that

$$zz^T + R_b^TR_b = uu^T + T_0^TT_0 \quad \text{and} \quad R_t^TR_t = T_0^TT_0 + \tilde{v}\tilde{v}^T.$$

Combining the above two relations, we obtain

$$R_b^TR_b = R_t^TR_t + uu^T - \tilde{v}\tilde{v}^T - zz^T. \tag{2.5}$$

Observe also from (2.3) that $r_{11}^2 = t_0^2 + v^Tv$ and $z^T = (t_0u^T + v^TT_0)/r_{11}$, and so the first row of R can easily be computed.

Equation (2.5) is used to compute R one row at a time as follows. First rewrite (2.5) as

$$R_1^T R_1 = R_t^T R_t + uu^T, \tag{2.6}$$

$$R_2^T R_2 = R_1^T R_1 - \tilde{v}\tilde{v}^T, \tag{2.7}$$

and

$$R_b^T R_b = R_2^T R_2 - zz^T, \tag{2.8}$$

where R_1 and R_2 are upper triangular matrices. Notice that (2.6) is an updating problem and (2.7) and (2.8) are downdating problems.

It is well known (see, for example, [11]) that, for the updating problem, we can find a product of Givens rotations $Q = G(n-1, n, \theta_{n-1}) \cdots G(1, n, \theta_1)$ so that

$$Q \begin{bmatrix} R_t \\ u^T \end{bmatrix} = \begin{bmatrix} R_1 \\ 0^T \end{bmatrix}, \tag{2.9}$$

where $G(i, j, \theta_i)$ is an elementary Givens rotation; that is, a matrix which is the identity everywhere except $g_{ii} = g_{jj} = c$ and $g_{ji} = -g_{ij} = s$, where $c = c(\theta) = \cos(\theta)$ and $s = s(\theta) = \sin(\theta)$ for some θ. We will use the notation

$$[c, s] = [c(\theta), s(\theta)] = \text{givens}(\alpha, \beta)$$

to be the 2×2 Givens rotation for which

$$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \bar{\alpha} \\ 0 \end{bmatrix}.$$

For the downdating problems, we attempt to find products of Hyperbolic rotations $Y^{(1)} = H(n-1, n, \phi_{n-1}) \cdots H(1, n, \phi_1)$ and $Y^{(2)} = H(n-1, n, \rho_{n-1}) \cdots H(1, n, \rho_1)$ such that

$$Y^{(1)} \begin{bmatrix} R_1 \\ \tilde{v}^T \end{bmatrix} = \begin{bmatrix} R_2 \\ 0^T \end{bmatrix} \tag{2.10}$$

and

$$Y^{(2)} \begin{bmatrix} R_2 \\ z^T \end{bmatrix} = \begin{bmatrix} R_b \\ 0^T \end{bmatrix}. \tag{2.11}$$

It can be shown that if the downdated matrices are nonsingular then such products exist [2]. The matrix $H(i, j, \phi)$, called an elementary Hyperbolic rotation, is a matrix which is the identity everywhere except $h_{ii} = h_{jj} = c$ and $h_{ij} = h_{ji} = -s$, where $c = c(\phi) = \cosh(\phi)$ and $s = s(\phi) = \sinh(\phi)$ for some ϕ. As with Givens rotations, we will use the notation

$$[c, s] = [c(\phi), s(\phi)] = \text{hyp}(\alpha, \beta)$$

to be the 2×2 Hyperbolic rotation for which

$$\begin{bmatrix} c & -s \\ -s & c \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \bar{\alpha} \\ 0 \end{bmatrix}.$$

Equations (2.9), (2.10), and (2.11) provide a method for computing R one row at a time. This can be done by observing that for each i, $G(i, n, \theta_i)$, $H(i, n, \phi_i)$ and $H(i, n, \rho_i)$ affect only rows i and n. Since the first row of R_t is (modulo a shift) the same as the first row of R, we know the first row of R_t. Thus $G(1, n, \theta_1)$ can be applied to the first row of R_t and u^T to obtain the first row of R_1. Since, now, the first row of R_1 is known, we can apply $H(1, n, \phi_1)$ to the first row of R_1 and $\tilde{v}^T$ to obtain the first row of R_2. Thus since the first row of R_2 is now known, we can apply $H(1, n, \rho_1)$ to the first row of R_2 and z^T to obtain the first row of R_b.

Observe from (2.2) that the first row of R_b is the second row of R, which is (modulo a shift) the second row of R_t. Thus we repeat the above process with $G(2, n, \theta_2)$, $H(2, n, \phi_2)$, and $H(2, n, \rho_2)$, etc.

The following algorithm summarizes the above results, where r_t, r_1, r_2, and r_b are vectors used in intermediate steps of the algorithm.

Algorithm BBH-R. *Let T be an $m \times n$ Toeplitz matrix, and let u, v, and $\tilde{v}$ be defined as in* (2.1). *Then this algorithm computes the Cholesky factor, R, of $T^T T$.*

```
$R(1,1) = r_{11} = \sqrt{t_0^2 + t_1^2 + \cdots + t_{m-1}^2}$
$z = (t_0 u + T_0^T v)/r_{11}$
$R(1, 2:n) = z^T$
for $k = 1, 2, \ldots, n-1$
    $r_t(k:n-1) = R(k, k:n-1)$
    $[c, s] =$ givens$(r_t(k), u(k))$
    $\begin{bmatrix} r_1^T \\ u^T \end{bmatrix} := \begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} r_t^T \\ u^T \end{bmatrix}$
    $[c, s] =$ hyp$(r_1(k), \tilde{v}(k))$
    $\begin{bmatrix} r_2^T \\ \tilde{v}^T \end{bmatrix} := \begin{bmatrix} c & -s \\ -s & c \end{bmatrix} \begin{bmatrix} r_1^T \\ \tilde{v}^T \end{bmatrix}$
    $[c, s] =$ hyp$(r_2(k), z(k))$
    $\begin{bmatrix} r_b^T \\ z^T \end{bmatrix} := \begin{bmatrix} c & -s \\ -s & c \end{bmatrix} \begin{bmatrix} r_2^T \\ z^T \end{bmatrix}$
    $R(k+1, k+1:n) = r_b(k:n-1)$.
```

Algorithm BBH-R requires $mn + 6n^2 + O(n)$ multiplications to compute R. We remark here that the CKL method for computing R also requires $mn + 6n^2 + O(n)$ multiplications but can also compute R^{-1} using only an additional $O(n^2)$ multiplications [8]. In the next section we will use the approach of BBH to develop a scheme to compute R^{-1} which does not require computing R, and hence is computationally less expensive than the CKL method.

3. Computation of R^{-1}: Algorithm BBH-L. In this section we show how Algorithm BBH-R can be modified to compute R^{-T}, rather than R. The modification is based on an inverse factorization scheme by Pan and Plemmons [17]. The results we need from

[17] can be stated as follows. Let R_0 be an $(n-1)\times(n-1)$ upper triangular matrix and let g be an $n-1$ dimensional vector. Suppose Q is a product of Givens rotations such that

$$Q\begin{bmatrix} R_0 & 0 \\ g^T & 1 \end{bmatrix} = \begin{bmatrix} \tilde{R}_0 & q \\ 0^T & \kappa \end{bmatrix}, \tag{3.1}$$

where $\tilde{R}_0$ is an upper triangular matrix. Assuming R_0 is nonsingular, then it follows that $\kappa \neq 0$. Inverting and transposing both sides of (3.1), we obtain

$$Q\begin{bmatrix} R_0^{-T} & -a \\ 0^T & 1 \end{bmatrix} = \begin{bmatrix} \tilde{R}_0^{-T} & 0 \\ h^T & \delta \end{bmatrix}, \tag{3.2}$$

where $a = R_0^{-T}g$, $h = -\tilde{R}_0^{-1}q/\kappa$, and $\delta = 1/\kappa$. By equating the last columns in (3.2), it follows that Q can be determined from a by finding the product of Givens rotations, $Q = G(n-1, n, \theta_{n-1})\cdots(1, n, \theta_1)$, such that

$$Q\begin{bmatrix} -a \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ \delta \end{bmatrix}.$$

Moreover, since Q is an orthogonal matrix, it is easy to see that $\delta = \sqrt{1 + \|a\|_2^2}$.

Similarly, if Y is a product of Hyperbolic rotations such that

$$Y\begin{bmatrix} R_0 & 0 \\ g^T & 1 \end{bmatrix} = \begin{bmatrix} \tilde{R}_0 & q \\ 0^T & \kappa \end{bmatrix},$$

then

$$Y\begin{bmatrix} R_0^{-T} & a \\ 0^T & 1 \end{bmatrix} = \begin{bmatrix} \tilde{R}_0^{-T} & 0 \\ -h^T & \gamma \end{bmatrix},$$

where $a = R_0^{-T}g$ and $\gamma = \sqrt{1 - \|a\|_2^2}$. In this case, Y can be determined by finding the product of Hyperbolic rotations $Y = H(n-1, n, \phi_{n-1})\cdots H(1, n, \phi_1)$ such that

$$Y\begin{bmatrix} a \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ \gamma \end{bmatrix}.$$

Recall that in the last section we obtained the relations

$$Q\begin{bmatrix} R_t \\ u^T \end{bmatrix} = \begin{bmatrix} R_1 \\ 0^T \end{bmatrix}, \quad Y^{(1)}\begin{bmatrix} R_1 \\ \tilde{v}^T \end{bmatrix} = \begin{bmatrix} R_2 \\ 0^T \end{bmatrix}, \quad Y^{(2)}\begin{bmatrix} R_2 \\ z^T \end{bmatrix} = \begin{bmatrix} R_b \\ 0^T \end{bmatrix}.$$

It follows from the above remarks that

$$Q\begin{bmatrix} R_t^{-T} \\ 0^T \end{bmatrix} = \begin{bmatrix} R_1^{-T} \\ h_1^T \end{bmatrix}, \quad Y^{(1)}\begin{bmatrix} R_1^{-T} \\ 0^T \end{bmatrix} = \begin{bmatrix} R_2^{-T} \\ h_2^T \end{bmatrix},$$

$$Y^{(2)}\begin{bmatrix} R_2^{-T} \\ 0^T \end{bmatrix} = \begin{bmatrix} R_b^{-T} \\ h_3^T \end{bmatrix},$$

for some vectors h_1, h_2, and h_3.

Thus to compute R^{-T} one row at a time, we will need to (i) relate the rows of R^{-T} to the rows of R_t^{-T} and R_b^{-T} and (ii) compute the first row of R^{-T}. To accomplish this, we rewrite (2.2) as

$$R^{-T} = \begin{bmatrix} 1/r_{11} & 0^T \\ -R_b^{-T} z/r_{11} & R_b^{-T} \end{bmatrix} = \begin{bmatrix} R_t^{-T} & 0 \\ -\tilde{z}^T R_t^{-T}/r_{nn} & 1/r_{nn} \end{bmatrix}. \tag{3.3}$$

From (3.3) it is easy to see that the first row of $R^{-T} = [\ 1/r_{11} \ \ 0 \ \cdots \ 0\ ]$ and that the rows of R_t^{-T} are (essentially) the same as those of R^{-T}. Furthermore, if the kth row of R_t^{-T}, say l_t^T, is known, then $G(k, n-1, \theta_k)$ can be found using the following steps.

- Set (the scalar) $\alpha = l_t^T u$,
- $[c, s]$ =givens$(\delta_{k-1}, -\alpha)$,
- $\delta_k = -s a + c\delta_{k-1}$,

where $\delta_1 = 1$. $H(k, n-1, \phi_k)$ and $H(k, n-1, \rho_k)$ are found in a similar manner.

Now, applying $G(k, n-1, \theta_k)$, $H(k, n-1, \phi_k)$, and $H(k, n-1, \rho_k)$ to the kth rows of R_t^{-T}, R_1^{-T}, and R_2^{-T}, respectively, we obtain the kth rows of R_1^{-T}, R_2^{-T}, and R_b^{-T}, respectively. Moreover, if we denote the kth row of R_b^{-T} by l_b^T, then, from the first partitioning in (3.3), we see that the $(k+1)$st row of $L = R^{-T}$ is

$$L(k+1, 1:k+1) = \begin{bmatrix} -l_b^T z/r_{11} & l_b^T \end{bmatrix}.$$

Putting the above results together, we obtain the following algorithm for computing R^{-T}.

Algorithm BBH-L. *Let T be an $m \times n$ Toeplitz matrix, and let u, v, and $\tilde{v}$ be defined as in* (2.1). *Then this algorithm computes $L = R^{-T}$, where R is the Cholesky factor of $T^T T$.*

```
$r_{11} = \sqrt{t_0^2 + t_1^2 + \cdots + t_{m-1}^2}$
$z = (t_0 u + T_0^T v)/r_{11}$, $L(1,1) = 1/r_{11}$
$\delta = \gamma_1 = \gamma_2 = 1$, $h_1^T = h_2^T = h_3^T = 0^T$
for $k = 1, 2, \ldots, n-1$
    $l_t(1:k) = L(k, 1:k)$
    $\alpha = l_t^T u(1:k)$
    $[c, s]$ =givens$(\delta, -\alpha)$
    $\delta = s\alpha + c\delta$
    $\begin{bmatrix} l_1^T \\ h_1^T \end{bmatrix} = \begin{bmatrix} c & s \\ -s & c \end{bmatrix} \begin{bmatrix} l_t^T \\ h_1^T \end{bmatrix}$
    $\beta = l_1^T \tilde{v}(1:k)$
    $[c, s]$ =hyp$(\gamma_1, \beta)$
    $\gamma_1 = -s\beta + c\gamma_1$
    $\begin{bmatrix} l_2^T \\ h_2^T \end{bmatrix} = \begin{bmatrix} c & -s \\ -s & c \end{bmatrix} \begin{bmatrix} l_1^T \\ h_2^T \end{bmatrix}$
    $\beta = l_2^T z(1:k)$
    $[c, s]$ =hyp$(\gamma_2, \beta)$
    $\gamma_2 = -s\beta + c\gamma_2$
    $\begin{bmatrix} l_b^T \\ h_3^T \end{bmatrix} = \begin{bmatrix} c & -s \\ -s & c \end{bmatrix} \begin{bmatrix} l_2^T \\ h_3^T \end{bmatrix}$
    $L(k+1, 1:k+1) = \begin{bmatrix} -l_b^T z/r_{11} & l_b^T \end{bmatrix}$.
```

Algorithm BBH-L requires $mn + 8n^2 + O(n)$ multiplications to compute R^{-1}, whereas the CKL method requires $mn + 12n^2 + O(n)$ multiplications.

4. Computation of Q and Q^Tb. In this section we describe the CKL method for computing the QR factorization of T and show that this method for computing R is equivalent to Algorithm BBH-R. It will then follow that the elementary Givens and Hyperbolic rotations, used in the previous section to compute R^{-T}, can be used to obtain Q and Q^Tb.

Let T and R have the partitionings given in (2.1) and (2.2), respectively, and define $U(w) \in \Re^{n\times k}$ to be the upper triangular Toeplitz matrix with first row $w^T \in \Re^k$.

LEMMA 4.1. *Let T be a Toeplitz matrix and let R be the Cholesky factor of T^TT. Let $w_1^T = [\, r_{11} \quad z^T \,]$, $w_2^T = [\, 0 \quad u^T \,]$, $w_3^T = [\, 0 \quad \tilde{v}^T \,]$, and $w_4^T = [\, 0 \quad z^T \,]$, where z, u, and $\tilde{v}$ are defined from the partitionings* (2.1) *and* (2.2). *Then*

$$T^TT = \sum_{i=1}^{2} U^T(w_i)U(w_i) - \sum_{i=3}^{4} U^T(w_i)U(w_i). \tag{4.1}$$

Proof. For the proof, see [8, Lemma 2]. □

The right-hand side of (4.1) is known as the displacement representation of T^TT [8].

It can be shown that the triangular factors $U(w_i)$ can be used to obtain R as follows. Define the matrix $\Gamma \in \Re^{4n\times n}$ as

$$\Gamma = \begin{bmatrix} U(w_1) \\ U(w_2) \\ U(w_3) \\ U(w_4) \end{bmatrix} \tag{4.2}$$

and let $S \in \Re^{4n\times 4n}$ be defined as $S = \mathrm{diag}(I_n, I_n, \tilde{I}_n, \tilde{I}_n)$, where $\tilde{I}_n = \left[\begin{smallmatrix} -I_{n-1} & 0 \\ 0^T & 1 \end{smallmatrix}\right]$. Then a matrix $B \in \Re^{4n\times 4n}$ is said to be S-orthogonal if $B^TSB = S$.

THEOREM 4.2. *Suppose Θ is an S-orthogonal matrix such that*

$$\tilde{\Gamma} = \Theta\Gamma = \begin{bmatrix} R \\ 0 \\ 0 \\ 0 \end{bmatrix},$$

where R is upper triangular. Then $R^TR = T^TT$.

Proof. For the proof, see [8, Thm. 2]. □

We will now show how a particular Θ can be constructed from the elementary Givens and Hyperbolic rotations used in §3 to compute R^{-T}. Recall that Q, $Y^{(1)}$, and $Y^{(2)}$ are defined as

- $Q = G(n-1, n, \theta_{n-1}) \cdots G(2, n, \theta_2)G(1, n, \theta_1)$,
- $Y^{(1)} = H(n-1, n, \phi_{n-1}) \cdots H(2, n, \phi_2)H(1, n, \phi_1)$,
- $Y^{(2)} = H(n-1, n, \rho_{n-1}) \cdots H(2, n, \rho_2)H(1, n, \rho_1)$,

where $G(i, j, \theta_i)$, $H(i, j, \phi_i)$, and $H(i, j, \rho_i)$ are elementary Givens, Hyperbolic, and Hyperbolic rotations, respectively.

Now notice that the matrices $U(w_i)$ are determined by the vectors u, $\tilde{v}$, and z. Furthermore, the first row of R_t is the same (modulo a shift) as the second row of $U(w_1)$. This observation is the motivation for the following theorem.

THEOREM 4.3. *Let* Γ *be defined as in* (4.2), *and let*

$$\Theta = \tilde{H}^{(2)}_{n-1}\tilde{H}^{(1)}_{n-1}\tilde{G}_{n-1}\cdots\tilde{H}^{(2)}_{2}\tilde{H}^{(1)}_{2}\tilde{G}_2\tilde{H}^{(2)}_{1}\tilde{H}^{(1)}_{1}\tilde{G}_1, \tag{4.3}$$

where

$$\begin{aligned}
\tilde{G}_k &= G(n, 2n-k, \theta_k)\cdots G(k+2, n+2, \theta_k)G(k+1, n+1, \theta_k),\\
\tilde{H}^{(1)}_k &= H(n, 3n-k, \phi_k)\cdots H(k+2, 2n+2, \phi_k)H(k+1, 2n+1, \phi_k),\\
\tilde{H}^{(2)}_k &= H(n, 4n-k, \rho_k)\cdots H(k+2, 3n+2, \rho_k)H(k+1, 3n+1, \rho_k).
\end{aligned}$$

Then

$$\Theta\Gamma = \begin{bmatrix} R \\ 0 \\ 0 \\ 0 \end{bmatrix},$$

where R *is upper triangular.*

Proof. Let R_t, R_1, R_2, and R_b be defined as in §2, and recall that the Givens rotations $G(k, n, \theta_k)$ were constructed so that

$$\begin{bmatrix} k\text{th row of } R_1 \\ u^T \end{bmatrix} := \begin{bmatrix} c(\theta_k) & -s(\theta_k) \\ s(\theta_k) & c(\theta_k) \end{bmatrix} \begin{bmatrix} k\text{th row of } R_t \\ u^T \end{bmatrix}, \tag{4.4}$$

where the emphasis on θ_k is used to indicate which rotation is used. The vector u^T on the right-hand side of (4.4) has the form

$$[\underbrace{0 \cdots 0}_{k-1} * \cdots *]$$

and on the left-hand side u^T has the form

$$[\underbrace{0 \cdots 0\, 0}_{k} * \cdots *],$$

where $*$ indicates an element which may not be 0. Similar relations hold for the Hyperbolic rotations $H(k, n, \phi_k)$ and $H(k, n, \rho_k)$.

Observe that

$$\begin{bmatrix} \text{2nd row of } U(w_1) \\ \text{1st row of } U(w_2) \end{bmatrix} = \begin{bmatrix} 0 & \text{1st row of } R_t \\ 0 & u^T \end{bmatrix}.$$

From the above remarks, we know that $G(1, n, \theta_1)$ is constructed so that

$$\begin{bmatrix} c(\theta_1) & -s(\theta_1) \\ s(\theta_1) & c(\theta_1) \end{bmatrix} \begin{bmatrix} 0 & \text{1st row of } R_t \\ 0 & u^T \end{bmatrix} =: \begin{bmatrix} 0 & \text{1st row of } R_1 \\ 0 & u^T \end{bmatrix},$$

where u^T has been overwritten and now has the form $[\,0\ * \cdots *\,]$.

The Toeplitz structure of $U(w_1)$ and $U(w_2)$ implies that $c(\theta_1)$ and $s(\theta_1)$ can be used to zero out the first super diagonal of $U(w_2)$. This is equivalent to applying the product of Givens rotations

$$\tilde{G}_1 = G(n, 2n-1, \theta_1) \cdots G(3, n+2, \theta_1) G(2, n+1, \theta_1)$$

to Γ.

Assume Γ is overwritten with $\tilde{G}_1\Gamma$. Then observe that

$$\begin{bmatrix} \text{2nd row of } U(w_1) \\ \text{1st row of } U(w_3) \end{bmatrix} = \begin{bmatrix} 0 & \text{1st row of } R_1 \\ 0 & \tilde{v}^T \end{bmatrix}.$$

We know that $H(1, n, \phi_1)$ is constructed so that

$$\begin{bmatrix} c(\phi_1) & -s(\phi_1) \\ -s(\phi_1) & c(\phi_1) \end{bmatrix} \begin{bmatrix} 0 & \text{1st row of } R_1 \\ 0 & \tilde{v}^T \end{bmatrix} =: \begin{bmatrix} 0 & \text{1st row of } R_2 \\ 0 & \tilde{v}^T \end{bmatrix},$$

where $\tilde{v}^T$ has been overwritten and now has the form $[\, 0 \ * \cdots * \,]$.

The Toeplitz structure of $U(w_1)$ and $U(w_3)$ implies that $c(\phi_1)$ and $s(\phi_1)$ can be used to zero out the first super diagonal of $U(w_3)$. This is equivalent to applying the product of Hyperbolic rotations

$$\tilde{H}_1^{(1)} = H(n, 3n-1, \phi_1) \cdots H(3, 2n+2, \phi_1) H(2, 2n+1, \phi_1)$$

to $\Gamma = \tilde{G}_1\Gamma$.

Assume Γ is overwritten with $\tilde{H}_1^{(1)}\tilde{G}_1\Gamma$. Then observe that

$$\begin{bmatrix} \text{2nd row of } U(w_1) \\ \text{1st row of } U(w_4) \end{bmatrix} = \begin{bmatrix} 0 & \text{1st row of } R_2 \\ 0 & z^T \end{bmatrix}.$$

We know that $H(1, n, \rho_1)$ is constructed so that

$$\begin{bmatrix} c(\rho_1) & -s(\rho_1) \\ -s(\rho_1) & c(\rho_1) \end{bmatrix} \begin{bmatrix} 0 & \text{1st row of } R_2 \\ 0 & z^T \end{bmatrix} =: \begin{bmatrix} 0 & \text{1st row of } R_b \\ 0 & z^T \end{bmatrix},$$

where z^T has been overwritten and now has the form $[\, 0 \ * \cdots * \,]$.

The Toeplitz structure of $U(w_1)$ and $U(w_4)$ implies that $c(\rho_1)$ and $s(\rho_1)$ can be used to zero out the first super diagonal of $U(w_4)$. This is equivalent to applying the product of Hyperbolic rotations

$$\tilde{H}_1^{(2)} = H(n, 4n-1, \rho_1) \cdots H(3, 3n+2, \rho_1) H(2, 3n+1, \rho_1)$$

to $\Gamma = \tilde{H}_1^{(1)}\tilde{G}_1\Gamma$.

Now, assuming Γ has been overwritten with $\tilde{H}_1^{(2)}\tilde{H}_1^{(1)}\tilde{G}_1\Gamma$, we have

$$\text{2nd row of } U(w_1) = [\, 0 \ \ \text{1st row of } R_b \,] = \text{2nd row of } R.$$

Thus the first two rows of $U(w_1)$ are the same as those in R. Furthermore, we have zeros in all the super diagonals of $U(w_2)$, $U(w_3)$, and $U(w_4)$.

Because of the Toeplitz structure of $U(w_1)$, we have

$$\begin{bmatrix} \text{3rd row of } U(w_1) \\ \text{2nd row of } U(w_2) \end{bmatrix} = \begin{bmatrix} 0 & \text{2nd row of } R_t \\ 0 & u^T \end{bmatrix}.$$

It is now easy to see that, by repeating the above arguments for $G(2,n,\theta_2)$, $H(2,n,\phi_2)$, and $H(2,n,\rho_2)$ we will zero out the second super diagonals of $U(w_2)$, $U(w_3)$, and $U(w_4)$ and obtain the first three rows of R in $U(w_1)$.

Thus by repeating the above arguments for $G(k,n,\theta_k)$, $H(k,n,\phi_k)$, and $H(k,n,\rho_k)$ the result follows. □

THEOREM 4.4. *Let Θ be defined as in* (4.3). *Then Θ is S-orthogonal.*

Proof. We show first that for each k, $\tilde{G}_k$, $\tilde{H}_k^{(1)}$, and $\tilde{H}_k^{(2)}$ are all S-orthogonal. Now $\tilde{G}_k$ is an orthogonal matrix which only affects rows 2 through $2n-1$. Thus we can write

$$\tilde{G}_k = \begin{bmatrix} \tilde{Q} & & \\ & I_n & \\ & & I_n \end{bmatrix},$$

where $\tilde{Q}^T\tilde{Q} = I_{2n}$. Using this observation it is easy to see that $\tilde{G}_k^T S \tilde{G}_k = S$, and hence $\tilde{G}_k$ is S-orthogonal.

To show that each $\tilde{H}_k^{(1)}$ is S-orthogonal requires a little more work. First, we define S_j to be the identity matrix except that the (j,j) entry is -1. Then notice that $H(i,l,\phi)S_j = S_j H(i,l,\phi)$, provided $j \neq i,l$. Also observe that

$$H^T(k+j,n+j,\phi_k)S_{n+j}H(k+j,n+j,\phi_k) = S_{n+j}.$$

From the commutative property stated above, it follows that each $\tilde{H}_k^{(1)}$ is $\hat{S}$-orthogonal where $\hat{S}$ =diag$(I_n, I_n, \bar{I}_n, I_n)$. But since $\tilde{H}_k^{(1)}$ does not affect rows $3n+1$ through $4n$, it follows that $\tilde{H}_k^{(1)}$ is S-orthogonal.

A similar argument holds for $\tilde{H}_k^{(2)}$, and since the product of S-orthogonal matrices is S-orthogonal, we have that Θ is S-orthogonal. □

Since we already have an algorithm that computes R^{-T}, the preceding results may seem redundant. But, as we will shortly see, a transformation Θ which satisfies Theorem 4.2 can be used to obtain Q and Q^Tb.

LEMMA 4.5. *Let T be an $m \times n$ Toeplitz matrix, and let $a \in \Re^m$ be the first column of T. If $y_1 = a/\|a\|_2 = -y_4$, $y_2 = e_1$, $y_3 = 0$, and w_i are defined as in Lemma* 4.1, *then*

$$T = \sum_{i=1}^{4} U^T(y_i)U(w_i).$$

Proof. For the proof, see [8, Lemma 6]. □

THEOREM 4.6. *If Θ is an S-orthogonal matrix that satisfies Theorem* 4.2, *then*

$$\Theta\Delta = \Theta \begin{bmatrix} U(y_1) \\ U(y_2) \\ -U(y_3) \\ -U(y_4) \end{bmatrix} = \begin{bmatrix} Q^T \\ * \\ * \\ * \end{bmatrix}.$$

Proof. For the proof, see [8, Thm. 2]. □

Theorem 4.6 provides us with a scheme for computing Q. Taking advantage of the Toeplitz structure of the matrices $U(y_i)$, we can write an algorithm for computing Q^T one row at a time that requires $12mn$ multiplications [8]. Thus combining this result with those in the previous section, Q and R^{-T} can be computed using a total of $13mn + 8n^2$ multiplications.

Recall that we only need Q^Tb, and not Q explicitly, to compute the LS solution to $Tx = b$. Using this observation, we now show how we can obtain considerable savings in computational work in computing the least squares solution. From Theorem 4.6, it follows that

$$\Theta\Delta b = \begin{bmatrix} Q^T \\ * \\ * \\ * \end{bmatrix} b = \begin{bmatrix} Q^Tb \\ * \\ * \\ * \end{bmatrix}.$$

Define the vectors $c_i \in \Re^n$ by $c_i = U(y_i)b$, and let $c \in \Re^{4n}$ be defined by $c^T = [c_1^T \; c_2^T \; c_3^T \; c_4^T]$. Then Q^Tb can be computed using the following steps.

```
For $k = 1, 2, \ldots, n-1$,
    $c := \Theta_k c$,
```

where $\Theta_k = \tilde{H}_k^{(2)}\tilde{H}_k^{(1)}\tilde{G}_k$ and b_1 is overwritten with Q^Tb.

The amount of work required to compute $c_1 = U(y_1)b$ is $mn - \frac{1}{2}n^2$ multiplications. Once c_1 is computed, c_4 can be obtained for free. Furthermore, c_2 and c_3 can be found without any computations. Each of the products $\Theta_k c$ require $12(n-k-1)$ multiplications. Thus Q^Tb can be computed with a total of $mn + \frac{11}{2}n^2$ multiplications. Combining the above method for computing Q^Tb with Algorithm BBH-L, the total work to compute the least squares solution to $Tx = b$ is $2mn + 14n^2 + O(n)$ multiplications.

In Table 4.1 we summarize the numerical complexities of the BBH, CKL, and Cybenko methods and the scheme presented in this paper. The table shows the number of multiplications required to compute the factorizations, as well as the LS solution, for each method. Cybenko's scheme is abbreviated CYB and our inverse factorization algorithm is denoted by IF. An $*$ (or $**$) in the table indicates that independent computation of that quantity is not possible by the given algorithm (or is not discussed by the particular authors).

TABLE 4.1
Numerical complexities for fast orthogonalization methods.

	BBH	CKL	CYB	Our IF
R	$mn + 6n^2$	$mn + 6n^2$	$**$	$**$
R^{-1}	$**$	$mn + 12n^2$	$*$	$mn + 8n^2$
Q	$12mn$	$12mn$	$**$	$**$
Q^Tb	$**$	$**$	$*$	$mn + \frac{11}{2}n^2$
x	$13mn + 7n^2$	$13mn + \frac{25}{2}n^2$	$9mn + 14n^2$	$2mn + 14n^2$

In practice, in addition to numerical complexities, it is important to consider space requirements. As with the above algorithms, our algorithm can be implemented using only linear storage. Specifically, the inverse QR factorization algorithm discussed in this paper can be implemented using only $O(m)$ storage as follows:

```
Initialize: $x = 0$,
For $k = 1, 2, \ldots, n-1$,
    compute $k$th row of $R^{-T} =: r^T$,
    compute $k$th entry of $Q^T b =: \sigma$,
    update solution: $x := x + \sigma * r$.
```

5. Ill-conditioned problems. In this section we consider solving ill-conditioned Toeplitz LS problems that arise in many signal and image processing applications. Specifically, we will be concerned with solving systems of the form

$$b = Tx + \eta, \tag{5.1}$$

where T is an ill-conditioned Toeplitz matrix and η is a random vector representing additive noise.

Such systems often arise from discretization of ill-posed problems in partial differential and integral equations. For example, in certain signal restoration problems, the integral equation

$$b(\tau) = \int_{-\infty}^{\infty} h(\tau - \tau_1)x(\tau_1)d\tau_1 + \eta(\tau)$$

is discretized to obtain a linear system of the form (5.1). In this case the vectors b, x, and η represent the observed signal, the original (or desired) signal, and the additive noise, respectively. The matrix T represents the degradation (or blur) in the signal.

Because of the ill-conditioned nature of T, naively solving $Tx = b$ will lead to extreme instability with respect to perturbations in b (e.g., additive noise). Stability can be attained through regularization [4], which amounts to solving the LS problem

$$\min \| \begin{bmatrix} b \\ 0 \end{bmatrix} - \begin{bmatrix} T \\ \alpha D \end{bmatrix} x(\alpha) \|_2. \tag{5.2}$$

D is a $p \times n$ matrix, called a regularization operator, and is usually chosen to be the identity matrix or some discretization of a differentiation operator [10]. Thus D is usually Toeplitz. The scalar α, called the regularization parameter, is used to control the degree of smoothness of the solution. In some applications a priori information about the signal and the degree of perturbation in b is known, and can be used to choose α [1]. But if no a priori information is known, then it may be necessary to solve (5.2) for several values of α [10].

One approach to solving regularized Toeplitz least squares problems is the PCG algorithm, which has been investigated recently by Nagy [15] and Chan, Nagy, and Plemmons [7]. It can be shown that, using an appropriate circulant preconditioner, the PCG algorithm can be an effective method for solving certain ill-conditioned Toeplitz LS problems. In this section we use a direct method, which is based on a modification of the fast orthogonalization scheme discussed in the previous sections of this paper.

Because of the remarks above on the matrix D, we will assume D is a Toeplitz matrix. Let A be the augmented matrix

$$A = \begin{bmatrix} T \\ \alpha D \end{bmatrix}.$$

Using the Toeplitz structures of T and D, partition A as

$$A = \begin{bmatrix} t_0 & u^T \\ v & T_0 \\ \alpha d_0 & \alpha f^T \\ \alpha g & \alpha D_0 \end{bmatrix} = \begin{bmatrix} T_0 & \tilde{u} \\ \tilde{v}^T & t_{m-n} \\ \alpha D_0 & \alpha \tilde{f} \\ \alpha \tilde{g}^T & \alpha d_{p-n} \end{bmatrix},$$

where u, $\tilde{v}$, f, and $\tilde{g}$ are $n-1$ vectors, v and $\tilde{u}$ are $m-1$ vectors, g and $\tilde{f}$ are $p-1$ vectors, and t_0, t_{m-n}, d_0, and d_{p-n} are scalars.

Let $A = QR$ be the QR factorization of A, where R is an $n \times n$ upper triangular matrix. Suppose R is partitioned as

$$R = \begin{bmatrix} r_{11} & z^T \\ 0 & R_b \end{bmatrix} = \begin{bmatrix} R_t & \tilde{z} \\ 0^T & r_{nn} \end{bmatrix},$$

where z and $\tilde{z}$ are $n-1$ vectors and r_{11} and r_{nn} are scalars. Then, using an approach similar to that in §2, setting $A^TA = R^TR$, we obtain the relations

$$\begin{aligned} R_b^T R_b &= R_t^T R_t + uu^T - \tilde{v}\tilde{v}^T - zz^T + \alpha^2 ff^T - \alpha^2 \tilde{g}\tilde{g}^T, \\ r_{11}^2 &= t_0^2 + v^T v + \alpha^2 d_0^2 + \alpha^2 g^T g, \end{aligned} \tag{5.3}$$

and

$$z^T = (t_0 u^T + v^T T_0 + \alpha^2 d_0 f^T + \alpha^2 g^T D_0)/r_{11}.$$

Rewriting (5.3) as

$$\begin{aligned} R_1^T R_1 &= R_t^T R_t + uu^T, \\ R_2^T R_2 &= R_1^T R_1 - \tilde{v}\tilde{v}^T, \\ R_3^T R_3 &= R_2^T R_2 - zz^T, \\ R_4^T R_4 &= R_3^T R_3 + \alpha^2 ff^T, \\ R_b^T R_b &= R_4^T R_4 - \alpha^2 \tilde{g}\tilde{g}^T, \end{aligned}$$

where R_1, R_2, R_3, and R_4 are upper triangular matrices, we can compute R one row at a time using Givens and Hyperbolic rotations. The method is analogous to that given in §2, except we are required to do an extra update and an extra downdate. Moreover, it is easy to see that R^{-1}, Q, and $Q^T b$ can easily be computed using methods similar to those given in §§3 and 4.

We remark that D is usually a banded Toeplitz matrix with small bandwidth. Thus the vector $\tilde{g}$ will have the form

$$[0 \cdots 0 \underbrace{* \cdots *}_{q}],$$

where q is small compared to n. In fact, if $D = I$, then the vectors g, f, $\tilde{g}$, and $\tilde{f}$ are all zero, and $d_0 = d_{p-n} = 1$. Thus in this case,

$$R_b^T R_b = R_t^T R_t + uu^T - \tilde{v}\tilde{v}^T - zz^T,$$

$$r_{11} = t_0^2 + v^T v + \alpha^2,$$

and

$$z^T = (t_0 u^T + v^T T_0)/r_{11}.$$

We see that for this choice of D the only change to the algorithms given in §§2, 3, and 4 is in the computation of r_{11}. Thus a regularized solution to (5.1) can be obtained in $O(mn)$ operations, and requires virtually no extra work than our nonregularized algorithm.

Also note that when D is the second difference equation,

$$D = \begin{bmatrix} 1 & & & & & & \\ -2 & 1 & & & & & \\ 1 & -2 & 1 & & & & \\ & 1 & -2 & 1 & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & 1 & -2 & 1 \\ & & & & 1 & -2 \\ & & & & & 1 \end{bmatrix},$$

then we also have $f = \tilde{g} = 0$. In this case the only changes to the algorithms are in the computation of r_{11} and z. Again the regularized solution can be computed in only $O(mn)$ operations.

6. Numerical examples. The algorithms in this paper exploit the Toeplitz structure of the data matrix to obtain fast methods for solving Toeplitz LS problems. It is well known that the $O(n^2)$ and $O(n \log n)$ methods which solve $n \times n$ Toeplitz systems may be unstable if T is not symmetric positive definite [6], [13]. Luk and Qiao [13] analyze the fast orthogonalization scheme due to Sweet [18]. They show that if certain submatrices of T are ill conditioned then Sweet's algorithm can produce poor results.

In this section we provide some computational results to test the performance of the inverse QR factorization presented in this paper. It will be seen that our algorithm seems to perform well except when T is ill conditioned. In addition we show through numerical examples that our fast regularization scheme produces results that are comparable to those obtained by regularizing a stable $O(mn^2)$ method. Because of the ill conditioning of T, we cannot expect even a stable method to perform well when the data is noisy, which is also illustrated.

Five test matrices are used in this section, four of which are taken from Luk and Qiao [13]. These four examples are constructed so that each has a different submatrix which is ill conditioned. Two of these submatrices are T_0 and T itself, with the other two being defined as follows. T_1 is the matrix obtained by deleting the first row and last column of T, and T_2 is the leading 2×2 principal submatrix of T.

The fifth test matrix is ill conditioned and arises in signal processing applications. All examples were performed using Pro-Matlab software on an Apollo workstation. The machine epsilon for Pro-Matlab on this system is approximately 2.2204×10^{-16}.

In the first four examples we construct the matrices from [13], each with one of T, T_0, T_1, or T_2 being ill conditioned. Several experiments were performed, varying the degree of ill conditioning for each. The right-hand side b is chosen so that the exact solution is the vector e of all ones. The quantities reported will be

$$r_M = \frac{\|x_M - e\|_2}{\|e\|_2} \quad \text{and} \quad r_I = \frac{\|x_I - e\|_2}{\|e\|_2},$$

where x_M is the solution computed by Matlab (i.e., $x_M = T\backslash b$) and x_I is the solution computed using the inverse factorization scheme presented in §§3 and 4.

Example 1. Let T be defined as

$$T = \frac{1}{24}\begin{bmatrix} 8 & 4 & 2 & 1-\varepsilon \\ 4 & 8 & 4 & 2 \\ 2 & 4 & 8 & 4 \\ 1-\varepsilon & 2 & 4 & 8 \end{bmatrix}.$$

In this case T_1 is ill conditioned, with ε controlling the degree of ill conditioning, while T_0, T_2, and T are well conditioned. Table 6.1 shows r_M, r_I, and $\kappa(T_1)$ for several values of ε.

TABLE 6.1
Relative errors for Example 1.

ε	$\kappa(T_1)$	r_M	r_I
1×10^{-2}	1.7×10^{3}	2.0×10^{-16}	2.0×10^{-15}
1×10^{-3}	1.7×10^{4}	3.4×10^{-16}	1.1×10^{-15}
1×10^{-4}	1.7×10^{5}	1.1×10^{-16}	9.6×10^{-16}
1×10^{-5}	1.7×10^{6}	3.4×10^{-16}	1.3×10^{-15}
1×10^{-6}	1.7×10^{7}	1.7×10^{-16}	1.3×10^{-15}
1×10^{-7}	1.7×10^{8}	1.1×10^{-16}	1.3×10^{-15}

Example 2. In this example T is defined as

$$T = \begin{bmatrix} 1 & 1-\varepsilon & 2 & 0 & 0 & 0 \\ 1-\varepsilon & 1 & 1-\varepsilon & 2 & 0 & 0 \\ 2 & 1-\varepsilon & 1 & 1-\varepsilon & 2 & 0 \\ 0 & 2 & 1-\varepsilon & 1 & 1-\varepsilon & 2 \\ 0 & 0 & 2 & 1-\varepsilon & 1 & 1-\varepsilon \\ 0 & 0 & 0 & 2 & 1-\varepsilon & 1 \end{bmatrix},$$

where in this case T_2 is ill conditioned and T_0, T_1, and T are well conditioned. Table 6.2 shows the results for this example.

TABLE 6.2
Relative errors for Example 2.

ε	$\kappa(T_2)$	r_M	r_I
1×10^{-2}	2.0×10^{2}	3.9×10^{-16}	4.6×10^{-14}
1×10^{-3}	2.0×10^{3}	4.6×10^{-16}	3.9×10^{-14}
1×10^{-4}	2.0×10^{4}	1.2×10^{-15}	1.0×10^{-13}
1×10^{-5}	2.0×10^{5}	4.3×10^{-16}	4.3×10^{-14}
1×10^{-6}	2.0×10^{6}	1.2×10^{-15}	1.7×10^{-13}
1×10^{-7}	2.0×10^{7}	6.0×10^{-16}	1.6×10^{-14}

Example 3. In this example we let

$$T = \frac{1}{7}\begin{bmatrix} 1 & 3 & 1-\varepsilon & -1 \\ 3 & 1 & 3 & 1-\varepsilon \\ 1-\varepsilon & 3 & 1 & 3 \\ -1 & 1-\varepsilon & 3 & 1 \end{bmatrix},$$

where, in this case, T_1, T_2, and T are well conditioned and T_0 is ill conditioned. The results for this example are shown in Table 6.3.

TABLE 6.3
Relative errors for Example 3.

ε	$\kappa(T_0)$	r_M	r_I
1×10^{-2}	5.8×10^{2}	1.9×10^{-16}	4.5×10^{-16}
1×10^{-3}	5.8×10^{3}	3.2×10^{-16}	1.1×10^{-15}
1×10^{-4}	5.8×10^{4}	2.3×10^{-16}	1.1×10^{-15}
1×10^{-5}	5.8×10^{5}	2.0×10^{-16}	3.2×10^{-15}
1×10^{-6}	5.8×10^{6}	2.3×10^{-16}	8.0×10^{-16}
1×10^{-7}	5.8×10^{7}	2.2×10^{-16}	7.6×10^{-16}

Example 4. In this example we consider the ill-conditioned matrix

$$T = \frac{1}{27}\begin{bmatrix} 27 & 9 & 3 & -23+\varepsilon \\ 9 & 27 & 9 & 3 \\ 3 & 9 & 27 & 9 \\ -23+\varepsilon & 3 & 9 & 27 \end{bmatrix}.$$

Table 6.4 shows the results for this example, where we see that the inverse QR algorithm performs poorly due to the ill conditioning of T. We note, though, that in most practical examples we can expect that the right-hand side, b, is not known exactly. Instead, what is known is $b+\eta$, where η represents additive noise. In this case, as discussed in §5, regularization is often used to compute a meaningful solution. In the next example, we illustrate that the inverse factorization algorithm can perform well for these ill-conditioned problems.

Example 5. In this example we consider solving an ill-conditioned problem of the form (5.1). Let T be the 100×100 Toeplitz matrix whose (i, j) entry is given by

$$t_{ij} = \begin{cases} 0 & \text{if } |i-j| > 8, \\ \frac{4}{51} g(0.15, x_i - x_j) & \text{otherwise}, \end{cases}$$

TABLE 6.4
Relative errors for Example 4.

ε	$\kappa(T)$	r_M	r_I
1×10^{-2}	5.7×10^{3}	1.0×10^{-13}	3.9×10^{-9}
1×10^{-3}	5.7×10^{4}	4.4×10^{-12}	2.3×10^{-7}
1×10^{-4}	5.7×10^{5}	3.9×10^{-12}	9.6×10^{-6}
1×10^{-5}	5.7×10^{6}	3.9×10^{-11}	3.0×10^{-4}
1×10^{-6}	5.7×10^{7}	4.4×10^{-10}	2.3×10^{-1}
1×10^{-7}	5.7×10^{8}	9.3×10^{-9}	2.3×10^{-1}

where

$$x_i = \frac{4i}{51}, \qquad i = 1, 2, \ldots, 100$$

and

$$g(\sigma, \gamma) = \frac{1}{2\sqrt{\pi}\sigma} \exp\left(-\frac{\gamma^2}{4\sigma^2}\right).$$

Matrices of this form occur in signal restoration applications, and are used to model certain degradations in the recorded signal [3], [10], [12]. The spectral condition number of T is approximately 2.43×10^6.

To simulate a signal restoration application, we first constructed the (original) signal x with 100 data points as shown in Fig. 6.1. We then constructed the degraded, noisy (i.e., observed) signal as shown in Fig. 6.2, by computing

$$b = Tx + \eta,$$

where η is a vector whose elements were chosen randomly from a uniform distribution in $(0, 10^{-3})$. For this example $\|\eta\|_2 \approx 5.9 \times 10^{-3}$.

Our goal, given T and b, is to recover an approximation to the original signal x. In Fig. 6.3, we show the computed solution using our inverse factorization algorithm. The solution computed using Matlab (i.e., $x = T\backslash b$) also produces poor results, the graph of which looks very similar to Fig. 6.3. In fact, if we denote the solutions computed by Matlab and the inverse factorization algorithm by x_M and x_I, respectively, then our computed solutions satisfied $\|x_M - x_I\|_2 / \|x_M\|_2 \approx 1.2 \times 10^{-5}$. We see that, due to the ill-conditioned nature of T and the presence of additive noise, neither method performs well.

To obtain a reasonable solution, we use the method of regularization as discussed in §5. Here we take $D = I$ and $\alpha = 2.1 \times 10^{-4} \approx \|\eta\|_2 / \|x\|_2$. In Fig. 6.4, we show the computed solution, $\hat{x}_I$, to (5.2) using the fast regularized inverse QR method discussed in §5. The result computed by Matlab, $\hat{x}_M = \hat{T}\backslash\hat{b}$ where

$$\hat{T} = \begin{bmatrix} T \\ \alpha I \end{bmatrix} \quad \text{and} \quad \hat{b} = \begin{bmatrix} b \\ 0 \end{bmatrix},$$

produced similar results. In this case $\|x_M - x_I\|_2 / \|x_M\|_2 \approx 7.3 \times 10^{-10}$. Thus, both methods produced solutions with similar accuracy.

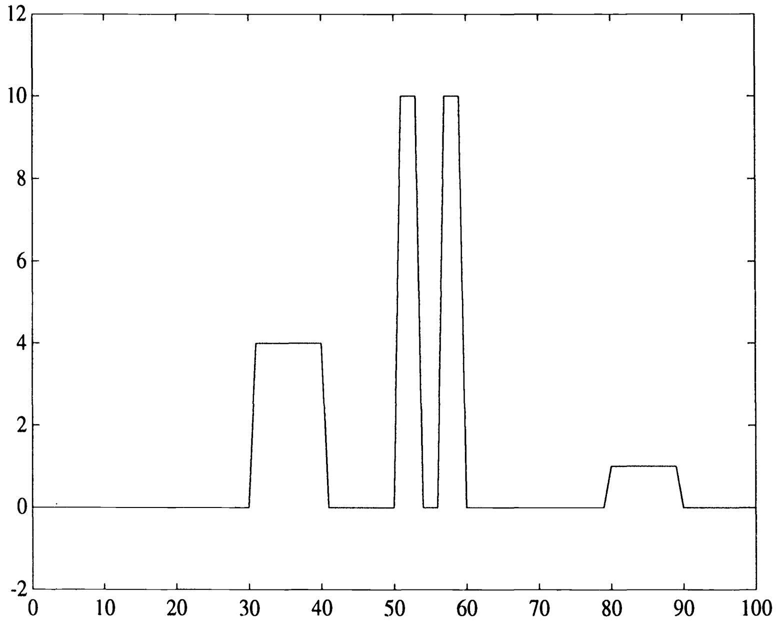

FIG. 6.1. *Original signal.*

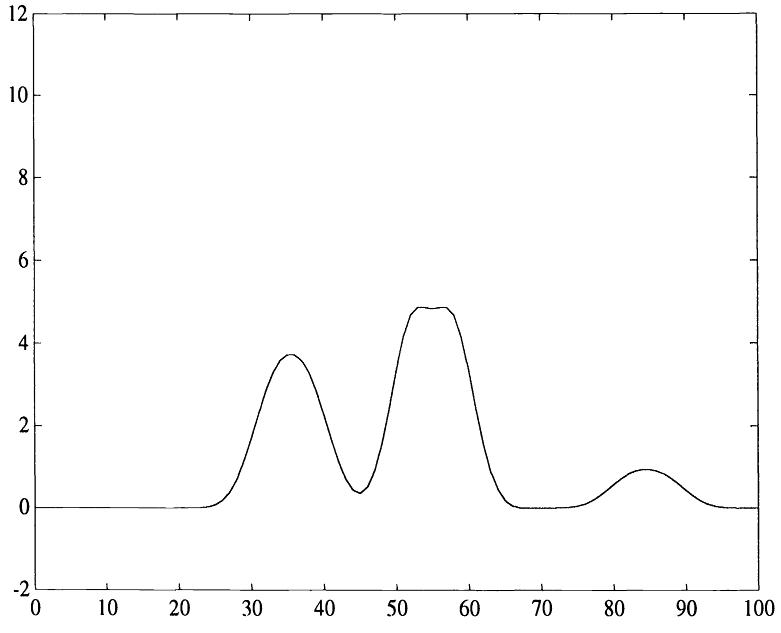

FIG. 6.2. *Blurred, noisy signal.*

7. Concluding remarks. In this paper we described the fast orthogonalization schemes of Bojanczyk, Brent, and de Hoog [5] and Chun, Kailath, and Lev-Ari [8]. We have extended these results to obtain an $O(mn)$ method for computing the inverse QR factorization of a Toeplitz matrix. Although our numerical results have shown that our

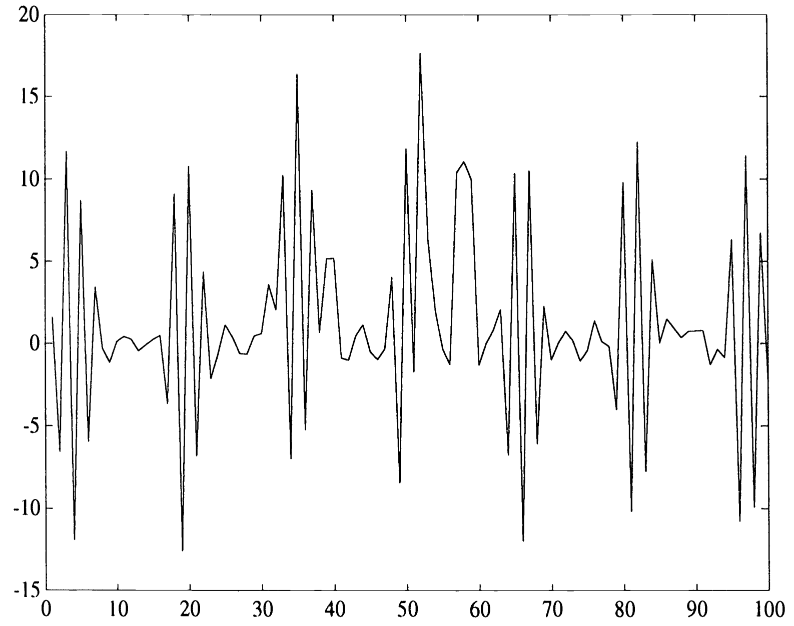

FIG. 6.3. *Computed solution using our inverse scheme with no regularization.*

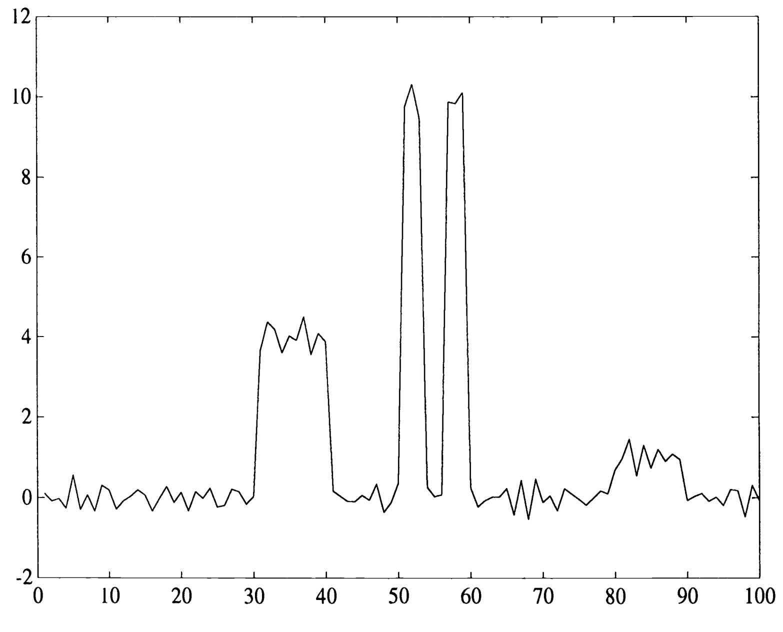

FIG. 6.4. *Computed solution using regularized inverse scheme.*

algorithm may not perform well when T is ill conditioned, we showed how our algorithm can be easily modified to incorporate regularization. A numerical example was presented showing that our regularized algorithm may be useful in solving certain ill-conditioned signal restoration problems.

Finally, we remark that further computational savings can be attained. Specifically, we can use fast Fourier transforms (FFTs) to compute the Toeplitz matrix-vector product $T_0^T v$, required in the initialization stage of Algorithm BBH-L. Using FFTs, this can be done in $O(m \log n)$ operations, rather than $O(mn)$. Furthermore, our numerical results indicate that, for at least some ill-conditioned problems, the error in the computed solution from the inverse QR scheme behaves like $\kappa^2(T)$. Thus, we may consider using the seminormal equations $R^T R x = T^T b$, since this would reduce the cost in computing x to $2mn + 9n^2$ multiplications (or less, if FFTs are used). In particular, the solution $x = R^{-1} R^{-T} T^T b$ can be computed using the BBH-L approach (or the regularized BBH-L approach from §5), which can also be implemented using only linear storage.

USING IMPLICIT ODE METHODS WITH ITERATIVE LINEAR EQUATION SOLVERS IN SPECTRAL METHODS*

IVAR LIE[†]

Abstract. The use of Chebyshev spectral methods in space on an evolution partial differential equation results, in many cases, in a stiff system of ordinary differential equations (ODEs). ODE solvers based on explicit methods will therefore be inefficient for such equations. The use of conventional implicit ODE solvers is difficult since the Jacobian matrix of the ODE system is full and large.

It is shown how to apply ODE solvers with iterative linear equation solvers to ODEs coming from spectral discretizations. These ODE solvers do not use the Jacobian explicitly, but good preconditioners for the Newton matrix are needed for their efficient operation. Preconditioners of the tensor product type are developed for certain classes of hyperbolic partial differential equations (PDEs), and numerical experiments show that these preconditioners give a good performance of the ODE solver and are a substantial improvement over the performance of explicit solvers.

Key words. partial differential equations, spectral approximations, preconditioning, ordinary differential equations

AMS subject classifications. 65N35, 65F10

1. Introduction.

Consider the numerical solution of the evolution equation

$$u_t = Lu + f \quad \text{on } \Omega \times [0,T], \quad \Omega \subset \mathbb{R}^d \tag{1.1}$$

with appropriate initial and boundary conditions. L denotes a differential operator in space, and f and u are assumed to be sufficiently regular.

When we discretize (1.1) in space by spectral methods using N_i points in each dimension, we get a set of ordinary differential equations (ODEs):

$$V_t = F(x,t,V), \quad V \in \mathbb{R}^N, \quad F : \mathbb{R}^d \times \mathbb{R} \times \mathbb{R}^N \to \mathbb{R}^N \tag{1.2}$$

where $N = \prod_{i=1}^d N_i$.

Using Chebyshev spectral methods in one space dimension, it is well known that the spectral radius of the differentiation matrix is $\Theta(N^2)$ and that there are eigenvalues $\Theta(1)$, see, e.g., [25]. (We say that $f(N) = \Theta(g(N))$ if there exist positive constants c and C such that $c\,g(N) \le f(N) \le C\,g(N)$.) Hence the resulting ODE system will be stiff for moderate and large values of N, even for linear partial differential equations (PDEs).

An implicit ODE solver should therefore be more efficient in solving (1.2) than an explicit solver, and that is illustrated in the following for a model problem. Stability considerations based on stability regions and eigenvalues for the Jacobian matrix of the ODE system are not straightforward for spectral methods. However, by using so-called pseudo eigenvalues instead of the real eigenvalues, the standard theory still applies; for a discussion of this, see, e.g., [21].

The differentiation matrices for spectral methods are full, and that implies that the Jacobian for (1.2) is full even for the simplest linear PDE. It is evident that for two-dimensional and three-dimensional problems and moderate values of N the Jacobians will be intractable both in terms of storage and computation. Hence we will have to use solvers that do not use the Jacobian explicitly. So-called reduced storage iterative methods will be described briefly in §2. These methods require good preconditioners to the Newton matrix, and the main part of this paper contains development of such

*Received by the editors November 8, 1989; accepted for publication (in revised form) October 8, 1992.
[†]NDRE Division for Electronics, P.O. Box 25, N-2007 Kjeller, Norway (ivar@ffi.ndre.no).

preconditioners. For multidimensional problems it turns out that the tensor product-type of preconditioners works well. The use of tensor product-type of formulas in the numerical solution of PDEs is well known, see, e.g., [18]. In the development of the preconditioners we use a preconditioning matrix derived by Funaro [8] for the Chebyshev spectral differentiation matrix. The reason for not using the differentiation matrix itself is that it is difficult to invert and that the preconditioning matrix is a product of two matrices that are easily computed.

A variable-stepsize implicit ODE solver will, in many cases, be more efficient than a fixed-stepsize implicit method (Crank–Nicholson or backward Euler, for example), since the optimal stepsize for a prescribed error tolerance will vary considerably during the integration interval.

Fixed-step implicit integration and semi-implicit integration are extensively used in spectral methods, see, e.g., [19] for the use of the Adams–Moulton family of methods, [17] for a discussion of the so-called Lerat schemes, and [7] for a discussion of the Morchiosne scheme, which can be constructed to have arbitrary high accuracy.

In the following, we will consider the use of implicit ODE solvers. Looking at the eigenvalues of the Chebyshev differentiation matrix D, see, e.g., [25], we see that there are eigenvalues close to the imaginary axis $\Theta(N)$ from the origin. Hence it is likely that an A-stable method is a good choice for integration.

The purpose of the two tables below is to show that an implicit solver really takes far fewer steps than an explicit solver for the one-dimensional model problem:

$$u_t + Au_x = 0 \quad \text{on } [-1,1] \tag{1.3}$$

where

$$u = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \qquad A = \begin{bmatrix} a & 0 \\ -1 & b \end{bmatrix}$$

with $a > 0, b > 0$ and the boundary condition: $u(-1,t) = 0$. No boundary condition is specified at $x = 1$. The initial function is $\exp(-10x^2)$. In the experiment we have set $a = 1$, the time integration interval is $[0.0, 2.0]$ and the error tolerance is 10^{-4}.

We use the implicit ODE solver SIMPLE [24], which is based on a singly diagonally implicit Runge–Kutta pair. By choosing $b \gg a$, for example, we can model two interacting waves, one fast and one slow. The analytical solution of (1.3) is used to compute the actual error in the computation.

The implicit solver is also more efficient even if each step costs more as shown in Tables 1.1 and 1.2 below. The CPU times are given in seconds. The explicit solver DOPRI5 is described in [13].

TABLE 1.1
Number of steps for model problem using SIMPLE.

N	17	17	17	33	33
b	10	20	100	10	20
no. of steps	37	32	33	36	36
CPU time	5.2	4.4	4.6	5.0	5.0

We see that SIMPLE (and hopefully other implicit solvers) has the nice property that the number of steps is almost independent of the values of N and b, whereas for DOPRI5 (and other explicit solvers) the number of steps is $\Theta(N^2 b)$. The two methods produced solutions with almost the same global error.

TABLE 1.2
Number of steps for model problem using DOPRI5.

N	17	17	17	33	33
b	10	20	100	10	20
no. of steps	186	351	889	669	1291
CPU time	9.8	19.2	48.0	36.2	64.8

2. Implicit ODE methods with iterative linear solvers. In this section we will describe briefly ODE solvers where we don't have to compute the Jacobian explicitly.

All implicit ODE solvers for the generic ODE $y'(t) = f(t, y)$ will have to solve one or several systems of nonlinear algebraic equations of the form

$$y = \gamma + h\beta f(t, y), \qquad \beta \in \mathbb{R}, \gamma \in \mathbb{R}^n \tag{2.1}$$

for each step.

Most ODE solvers use a variant of modified Newton iteration to solve these equations, and the essence of such an iteration is the solution of a linear system

$$B \cdot (y^{[i+1]} - y^{[i]}) = -(y^{[i]} - \gamma - h\beta f(t, y^{[i]})) \tag{2.2}$$

where $B = I - h\beta J$, $y^{[i]}$ denotes iterate i of y, and J is some approximation to $\partial f/\partial y|_{y=y^{[i]}}$. The usual method is to use an LU factorization of B adapted to the sparsity structure and corresponding forward and backward substitutions. B can, in many cases, be used over several steps which reduces the cost of the iteration.

The main problem in spectral methods is, as remarked above, that J is full and it will be prohibitively costly to store and operate with it for large ODE systems. An alternative way to proceed is to solve (2.2) iteratively. In many iterative methods B is not needed explicitly; what is needed is $B \cdot v$, where v is a vector of appropriate dimension. Hence, we avoid storing and factoring of B. Two of the most efficient classes of iterative methods in use today are the Krylov subspace based methods, e.g., the conjugate gradient method for symmetric positive definite systems and IOM and GMRES for nonsymmetric systems. See [3] and [2] for a description of these methods in the ODE context. Krylov subspace methods can also be combined with globally convergent methods for the solution of nonlinear equations; see [4]. Other iterative techniques for ODEs are discussed in [11], [6], and the recent survey [22].

In [2] a so-called matrix-free iterative method is described. It is based on approximating $B \cdot v$ by the difference quotient

$$v - h\beta \frac{f(y + \sigma v) - f(y)}{\sigma}, \qquad \sigma \in \mathbb{R}.$$

This method is not very efficient unless the spectrum of J is tightly clustered around a few eigenvalues (see [2]), and that is definitely not the case for most semidiscretizations of PDEs. In addition, we have to consider the error contribution from the difference approximation to $B \cdot v$ and the coupling between the local error and the error tolerance for the iterative solution of (2.2).

Some form of preconditioning of B is therefore needed to speed up the iterative methods. In [3] the so-called reduced-storage methods are discussed and analyzed. For these methods the linear system

$$Bx = b$$

is replaced by

$$\hat{S}^{-1} P_1^{-1} B x = \hat{S}^{-1} P_1^{-1} b \tag{2.3}$$

where $\hat{S}$ is a diagonal scaling matrix and P_1 is the preconditioning matrix. It is also possible to use right preconditioning and scaling, but we will not use these in this paper. The requirements for a good preconditioner are as usual: P_1 should be a good approximation to B, and linear systems $P_1 x = b$ should be easy to solve compared to solving $Bx = b$. When using iterative methods for solving (2.3) we need to compute $\hat{S}^{-1} P_1^{-1} B v$, and that can often be done without storing B and P_1.

The work reported in [3] resulted in the code LSODPK, based on the LSODE family of ODE solvers. The reduced-storage methods were tested on several relatively large test problems in [3], and the results are encouraging for IOM, GMRES, and appropriate preconditioners. The choice of preconditioners for certain classes of problems is also discussed in [3].

3. A hyperbolic system in one space dimension. Now consider the Chebyshev spectral discretization of the one-dimensional model equation (1.3) on N points. We get the following set of ODEs:

$$V_t + A \otimes D \cdot V = 0 \tag{3.1}$$

where $V \in \mathbb{R}^{2N}$, and we see that the Jacobian is $J = -A \otimes D$, and hence we have $\rho(J) = \Theta(N^2 b)$ by the properties of D (see, e.g., [25]), and the properties of the Kronecker product of matrices, see, e.g., [16].

Funaro [8] has constructed an efficient preconditioner, Q, for the differentiation matrix and has shown that $1 \le \lambda(Q^{-1}D) < \frac{\pi}{2}$. His result is as follows.

LEMMA 3.1. *The preconditioning matrix Q for the Chebyshev differentiation matrix is given by*: $Q = Z\tilde{D}$. *$\tilde{D}$ is the upwind difference operator for the grid points $\{x_j\}_{j=0}^{N-1}$, $x_j = \cos\frac{j}{N}\pi$, and Z is the matrix of the interpolation operator $\mathcal{Z} : \mathbb{R}^N \to \mathbb{R}^N$ from the points $\xi_j = \cos\frac{2j-1}{2N}\pi$ to the points $x_j = \cos\frac{j}{N}\pi$. For a polynomial of degree $N-1$:*

$$\{\phi'(\xi_1), \dots, \phi'(\xi_N)\} \overset{\mathcal{Z}}{\mapsto} \{\phi'(x_1), \dots, \phi'(x_N)\}.$$

The elements of Z and $\tilde{D}$ are the following:

$$\tilde{d}_{ij} = \begin{cases} -1/(x_{i-1} - x_i) & j = i \\ 1/(x_{i-1} - x_i) & j = i+1 \\ 0 & \textit{otherwise} \end{cases}$$

$$z_{ik} = \frac{(-1)^{i+k-1}\sqrt{1-\xi_k^2}}{(x_i - \xi_k)N}.$$

Proof. The proof is $\tilde{D}$: straightforward, since $\tilde{D}$ is the upwind difference operator for $\{x_j\}_{j=0}^{N-1}$. Consider the Lagrange interpolation polynomials $\{\ell_j\}$ on the points $\{\xi_i\}$. We then have:

$$\{\ell_j'(x_i)\} = Z \cdot \{\ell_j'(\xi_i)\}$$

or

$$Z = \{\ell_j'(x_i)\} \cdot \{\ell_j'(\xi_i)\}^{-1}.$$

Now apply the interpolation formula:

$$\ell_j'(x) = \sum_{k=1}^{N} \ell_j'(\xi_k)\,\ell_k(x) = \sum_{k=1}^{N} \ell_j'(\xi_k)\frac{T_N(x)}{T_N'(\xi_k)(x-\xi_k)}.$$

We have $T_N(x_i) = (-1)^i$ and $T_N'(\xi_k) = N\sin\frac{(2k-1)}{2}\pi/\sqrt{1-\xi_k^2}$ and

$$\ell_j'(x_i) = \sum_{k=1}^{N} \ell_j'(\xi_k)\frac{(-1)^{i+k+1}\sqrt{1-\xi_k^2}}{N(x_i-\xi_k)} = \sum_{k=1}^{N} \ell_j'(\xi_k) z_{ik}$$

and the result follows. □

Note that the $\tilde{D}$ matrix in [8] is different from ours. The operator in [8] is given for the grid $\{x_j\}_{j=1}^{N}$ and zero boundary conditions to the right, even if it is not explicitly stated in the paper. An explicit expression for the elements in the preconditioned differentiation matrix $Q^{-1} \cdot D$ can also be found in [8], and this expression will also be slightly different in our case.

Since

$$\lambda((A^{-1} \otimes Q^{-1})(A \otimes D)) = \lambda(I_2 \otimes Q^{-1}D) = \lambda(Q^{-1}D)$$

we see from the results of [8] that $-A \otimes Q$ will be a good preconditioner for the Jacobian J, and for the Newton matrix $I + h\beta A \otimes D$ we may use the preconditioner $I + h\beta A \otimes Q$. The advantages of using Q instead of D in the preconditioner for the Newton matrix are not so evident, since it is not known how to factor and solve linear systems using $I + \bar{h}\beta A \otimes Q$ significantly faster than using $I + \bar{h}\beta A \otimes D$. One advantage of using Q is that the D matrix is difficult to compute with high precision and D^{-1} may not be very accurate. The matrix Q is easier to compute.

The preconditioners to be presented in the following three sections will be derived using the D matrix. The matrix Q can be substituted for D in all these preconditioners.

In ODE solvers with iterative linear solvers, such as LSODPK [3] and KRYSI [14], linear systems with the preconditioner are solved for each inner iteration and for every stage, and the preconditioner is used (with an old value of h) as long as the iteration converges at a reasonable rate. When convergence problems occur, the preconditioner is updated with the current value of h and, if needed, a reevaluation of the Jacobian approximation is performed. If the linear system with the preconditioner is solved by direct methods, the new Newton matrix is factored to save time in the solution process.

Large variations in stepsize during an integration will imply more reevaluation and refactorizations than for slowly varying stepsize. In order to study the effect of these variations, let

$$\lambda_{ij} = \lambda((I + \bar{h}\beta A \otimes D)^{-1}(I + h\beta A \otimes D))$$

where $\bar{h}$ is the stepsize used in the last factorization. From standard theorems in matrix theory (see [16]), we have:

$$\lambda_{ij} = \frac{1 + h\beta\lambda_{A,i}\lambda_{D,j}}{1 + \bar{h}\beta\lambda_{A,i}\lambda_{D,j}}$$

where $\lambda_{A,i}$ and $\lambda_{D,j}$ are the eigenvalues of A and D, respectively. Let $h = \kappa\bar{h}$ and $\beta\lambda_{A,i}\lambda_{D,j} = \gamma_{ij}$. Then

$$\lambda_{ij} = \frac{1+\kappa\bar{h}\gamma_{ij}}{1+\bar{h}\gamma_{ij}} = 1 + \frac{\bar{h}\gamma_{ij}(\kappa - 1)}{1+\bar{h}\gamma_{ij}}.$$

Let $z = \bar{h}\gamma_{ij}$ and hence we have

$$|\lambda_{ij}| \leq \frac{1+\kappa|z|}{|1+z|},$$

and if $\kappa < 1$, then λ_{ij} is contained in a small region independent of the size of $|z|$. If κ is large, λ_{ij} is contained in a larger region and the convergence of the modified Newton method will be bad. As an example of how the above mapping works, consider the region $-\frac{1}{2} \leq \Re z \leq 0$, $|\Im z| \leq 10$, which is supposed to contain the spectrum of a scaled differentiation matrix. For $\kappa = \frac{1}{2}$ this region is mapped into the circle $|\lambda - 1| = \frac{1}{2}$, but with the circle $|\lambda - \frac{3}{4}| = \frac{1}{4}$ cut out of it. For even smaller κ the circles become smaller, but the center of the largest one is always $(1,0)$. For $\kappa = 4$ the region is mapped into the circle $|\lambda - 1| = 3$, but with the circle $|\lambda - 2.5| = 1.5$ cut out of it. This means that for $\kappa < 1$, i.e., the stepsize has decreased since the last factorization, the linear iteration should converge quickly. For increasing stepsize ($\kappa > 1$) the eigenvalues are more widely spread and the linear iteration may converge more slowly.

Using Q instead of D in the preconditioner should not alter these results significantly since the spectra of Q and D are close.

In order to show that an ODE solver with iterative linear solver works reasonably well for our test example, we have run the same experiment whose results are shown in Tables 1.1 and 1.2, on the ODE solver KRYSI [14] where the linear system for the preconditioner is solved by LU factorization. The matrix Q is used in the construction of the preconditioner. We see from Table 3.1 that the number of steps is practically independent of the stiffness of the problem. SIMPLE uses fewer steps than KRYSI, but that is fairly common, at least for small problems; see the numerical tests in [14] and [3].

TABLE 3.1
Number of steps for model problem using KRYSI.

N	17	17	17	33	33
b	10	20	100	10	100
no. of steps	51	49	41	51	40

For our one-dimensional model problem and other one-dimensional problems we cannot save much space for J by using iterative methods because the matrix D is needed, anyway, and the number of PDEs is assumed to be small compared to N. The savings will come on two-dimensional and three-dimensional problems where the Jacobian is so large that using implicit ODE solvers in the conventional way will be inefficient. In addition we will see that a tensor product type of preconditioner works well for two-dimensional problems.

4. A hyperbolic PDE in two space dimensions. Now consider the following model problem in two space dimensions:

$$v_t + c_1 v_x + c_2 v_y = 0, \qquad c_1, c_2 \in \mathbb{R} \tag{4.1}$$

by Chebyshev spectral methods with M points in the x-direction and N points in the y-direction.

The resulting ODE system can be written as follows:

$$V_t + c_1(I_N \otimes D_1)V + c_2(D_2 \otimes I_M)V = 0 \tag{4.2}$$

where $V \in \mathbb{R}^{NM}$ and D_1 and D_2 are the differentiation matrices in the x- and y-directions, respectively. Note that $N = M \Rightarrow D_1 = D_2$.

The Jacobian is:

$$J = -c_1(I_N \otimes D_1) - c_2(D_2 \otimes I_M) \in \mathbb{R}^{NM \times NM}$$

and from [16] we have the following:

$$\lambda_{ij}(J) = -c_1\lambda_i(D_1) - c_2\lambda_j(D_2)$$

$$\rho(J) = c_1\rho(D_1) + c_2\rho(D_2).$$

We see that $-J$ is the Kronecker sum of the matrices c_1D_1 and c_2D_2.

If $M = N$, then $\rho(J) = (c_1 + c_2)\rho(D_1)$, so the spectral radius for J in the two-dimensional case is not significantly larger than for an equivalent one-dimensional problem if c_1 and c_2 are of the same order of magnitude.

The Newton matrix is $B = I_{MN} + h\beta(c_1(I_N \otimes D_1) + c_2(D_2 \otimes I_M))$. We may construct a preconditioner P_2 for B with the same structure as B. The only difference between B and P_2 is that in the latter the stepsize used at the time of preconditioner evaluation is applied instead of the current stepsize. In the following the current stepsize is denoted by h and the stepsize in the preconditioner is denoted by $\hat{h}$. The solution of linear systems with P_2 is obviously as costly as using the matrix B itself.

If we use a linear solver of Krylov subspace type, we need to compute Bv, $v \in \mathbb{R}^{NM}$ (if this is not done by differences as discussed in §2). The terms of Bv can be computed as follows: If we partition the vector v into N blocks v_i of size M, the product $(I_N \otimes D_1)v$ is:

$$\begin{bmatrix} D_1 & & & \\ & D_1 & & \\ & & \ddots & \\ & & & D_1 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_N \end{bmatrix}.$$

This computation can be performed by doing N matrix-vector multiplications of size M. The cost is $\Theta(M^2N)$ and only D_1 and v need to be stored.

Alternatively, if we let $\{v_i\}$ form the columns of a matrix $\mathcal{V}$, i.e., $v = \operatorname{vec}(\mathcal{V})$ in the notation of [16, §12.1], we can use the relation

$$(I_N \otimes D_1)\ \operatorname{vec}(\mathcal{V}) = \operatorname{vec}(D_1\mathcal{V}) \tag{4.3}$$

and compute the required matrix-vector product by doing the matrix multiplication $D_1\mathcal{V}$ and transform back to a vector if needed. The cost of this operation is of course the same as for the former method.

For the term $(D_2 \otimes I_M)v$ we use the same partitioning of the vector v and we can write:

$$\begin{bmatrix} d_{11}I_M & d_{12}I_M & \cdots & d_{1N}I_M \\ d_{21}I_M & d_{22}I_M & \cdots & d_{2N}I_M \\ \vdots & \vdots & \ddots & \vdots \\ d_{N1}I_M & d_{N2}I_M & \cdots & d_{NN}I_M \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_N \end{bmatrix}$$

where $D_2 = \{d_{ij}\}$. We see that one block of the resulting vector is obtained by N scalar-vector multiplications, i.e., $\Theta(N^2)$ operations. The complete vector is then computed in $\Theta(MN^2)$ operations, and only storage for D_2 and v is needed. Note that we don't have to form the two large block matrices explicitly. An alternative computation here is based on the relation

$$(D_2 \otimes I_M)\text{vec}(\mathcal{V}) = \text{vec}(\mathcal{V}D_2^T), \tag{4.4}$$

and we see that we can form the matrix-vector product above by computing $\mathcal{V}D_2^T$.

The total cost is $\Theta(M^2N + N^2M)$. We could have performed the Chebyshev differencing by fast Fourier transforms (FFTs) using $\Theta(NM(\log_2 N + \log_2 M))$ operations. The fastest alternative in practice will depend on N and M as well as computer architecture and implementation aspects, see, e.g., [23]. As a rule of thumb, matrix multiplication is fastest for $M, N \leq 100$.

We can write the equation $Bx = b$ in the following way using the relations (4.3), (4.4), and the result in [16, §12.1, Cor. 2].

LEMMA 4.1. *If* $A_1 \in \mathbb{R}^{m\times m}$, $A_2 \in \mathbb{R}^{n\times n}$, *and* $X \in \mathbb{R}^{m\times n}$, *we have*:

$$\text{vec}(A_1X + XA_2) = (I_n \otimes A_1 + A_2^T \otimes I_m)\ \text{vec}(X).$$

Applying the lemma to $Bx = b$ gives immediately:

$$(I + \hat{h}\beta c_1 D_1)X + \hat{h}\beta c_2 X D_2^T = \mathcal{B}, \qquad b = \text{vec}(\mathcal{B}). \tag{4.5}$$

This equation has a unique solution if the matrices $I + \hat{h}\beta c_1 D_1$ and $-\hat{h}\beta c_2 D_2$ have no eigenvalues in common; see [16, Thm. 2, p. 414]. This holds, e.g., when $c_1 > 0$, $c_2 > 0$. We can find the solution of (4.5) by using a result in [1, Chap. 10, Misc. Ex. 21].

LEMMA 4.2. *Consider the matrix equation* $X = C + \epsilon(AX + XB)$, $\epsilon \in \mathbb{R}$ *and assume that* $|\epsilon|(\|A\| + \|B\|) < 1$. *The solution is given by*

$$X = C + \sum_{n=1}^{\infty} \epsilon^n \Phi_n(A, B) \tag{4.6}$$

where Φ_n *is given by the recurrence*:

$$\Phi_n = A\Phi_{n-1} + \Phi_{n-1}B, \qquad \Phi_0 = C$$

or by the explicit formula

$$\Phi_n = \sum_{i=0}^{n} A^{n-i}CB^i \binom{n}{i}.$$

In our case we can write the equation as follows:

$$X - \hat{h}\beta(c_1 D_1 X + c_2 X D_2^T) = \mathcal{B}$$

and application of the above lemma gives directly:

$$X = \mathcal{B} + \sum_{n=1}^{\infty} (\hat{h}\beta)^n \sum_{i=0}^{n} (c_1 D_1)^{n-i} \mathcal{B} (c_2 D_2^T)^i \binom{n}{i}. \tag{4.7}$$

From this expression we can construct polynomial preconditioners recursively. Note that the convergence requirement for the series in the lemma implies a restriction on the stepsize: $\hat{h} = O(1/(M^2 + N^2))$ so, formally, the preconditioner is hardly applicable to implicit time integrators. The preconditioners of first and second order are:

$$X = \mathcal{B} + \hat{h}\beta(c_1 D_1 \mathcal{B} + \mathcal{B} c_2 D_2^T) + O(\hat{h}^2 \cdot \max(M^4, N^4))$$

$$X = \mathcal{B} + \hat{h}\beta(c_1 D_1 \mathcal{B} + c_2 \mathcal{B} D_2^T) + (\hat{h}\beta)^2 (c_1^2 D_1^2 \mathcal{B} + 2c_1 c_2 D_1 \mathcal{B} D_2^T + \mathcal{B} c_2^2 D_2^{T2})$$

$$+ O(\hat{h}^3 \cdot \max(M^6, N^6)).$$

Numerical experiments have shown that this type of preconditioner can be used for implicit integrators, but the performance is not very good because of the stepsize restriction.

We are now going to investigate another class of preconditioners, namely, the tensor product type or dimensional splitting type. The advantage of using these preconditioners is fairly obvious; only "one-dimensional problems" have to be solved.

Consider the solution of $P_2 x = b$ and we will now use a part of $I - \hat{h}\beta J_1 - \hat{h}\beta J_2$ where $J_1 = -c_1 I_N \otimes D_1$ and $J_2 = -c_2 D_2 \otimes I_M$. We can write

$$I - \hat{h}\beta J_1 - \hat{h}\beta J_2 = I - \hat{h}\beta J_2 (I + J_2^{-1} J_1) = I - \hat{h}\beta J_2 \left(I + \frac{c_1}{c_2} D_2^{-1} \otimes D_1 \right).$$

If $\frac{|c_1|}{|c_2|} \|D_2^{-1} \otimes D_1\|$ is small, i.e., $|c_2| \gg |c_1|$, we can approximate the last factor with the identity matrix and instead solve the "one-dimensional" system

$$(I - \hat{h}\beta J_2) x = b,$$

which we will consider in more detail below.

If c_1 is of the same magnitude as c_2, we may also use a splitting approach. Let

$$(I - \hat{h}\beta J_1 - \hat{h}\beta J_2)^{-1} = (I - (I - \hat{h}\beta J_2)^{-1} \hat{h}\beta J_1)^{-1} (I - \hat{h}\beta J_2)^{-1}$$

by Woodbury's formula. The splitting is done as follows.

Find $\alpha \in \mathbb{R}$ such that:

$$I - \alpha \hat{h}\beta J_1 \approx I - (I - \hat{h}\beta J_2)^{-1} \hat{h}\beta J_1. \tag{4.8}$$

Assume that $M = N$. The eigenvalues of the matrix on the right-hand side are:

$$\lambda_{ij} = 1 + \frac{\hat{h}\beta c_1 \mu_i}{1 + \hat{h}\beta c_2 \bar{\mu}_j}$$

where μ_i and $\bar{\mu}_j$ are the eigenvalues of $I_N \otimes D_1$ and $D_2 \otimes I_M$, respectively. One way of choosing α is then:

$$\alpha = \frac{1}{1 + \hat{h}\beta c_2 \rho(D_2)}. \tag{4.9}$$

The eigenvalues of $(I - \alpha\hat{h}\beta J_1) \cdot (I - \hat{h}\beta J_2)$ are:

$$1 + \hat{h}\beta c_2 \bar{\mu}_j + \hat{h}\beta \mu_i c_1 \frac{1 + \hat{h}\beta c_2 \bar{\mu}_j}{1 + \hat{h}\beta c_2 \rho(D_2)}.$$

This approximation will be good for large eigenvalues (close to $\rho(D_2)$) and not so good for small eigenvalues. However, the large eigenvalues will normally be the most troublesome, so the preconditioner should work reasonably well. If $c_1 \gg c_2$, we can solve the linear system by using the matrix $I - \hat{h}\beta J_1$ only.

Another preconditioner that approximates B is the tensor product type:

$$\tilde{P}_2 = (I + \hat{h}\beta c_1 (I_N \otimes D_1)) \cdot (I + \hat{h}\beta c_2 (D_2 \otimes I_M)) = \tilde{P}_{21} \cdot \tilde{P}_{22}.$$

This type of operator splitting preconditioner is also suggested in [3] for reaction-transport equations.

Solving linear systems $\tilde{P}_2 x = b$ is a two-stage process; first solve $\tilde{P}_{21} y = b$, then solve $\tilde{P}_{22} x = y$. Iterative methods could be used for these linear systems, but we show in the following that direct methods can be applied, and the cost is not larger than for the matrix-vector product Bv shown previously.

First consider $\tilde{P}_{21} y = b$, and assume that we have factored the one-dimensional Newton matrix:

$$I_M + \hat{h}\beta c_1 D_1 = \bar{L} \cdot \bar{U},$$

which takes $\Theta(M^3)$ operations. Note that this also applies to (4.8). Then

$$\tilde{P}_{21} = I_N \otimes (I_M + \hat{h}\beta c_1 D_1) = I_N \otimes \bar{L} \cdot \bar{U} = (I_N \otimes \bar{L}) \cdot (I_N \otimes \bar{U}).$$

Since $(I_N \otimes \bar{L})$ and $(I_N \otimes \bar{U})$ are block diagonal matrices with lower, respectively, upper triangular blocks of size M, we can solve $\tilde{P}_{21} y = b$ by doing forward and backward substitution simultaneously on all blocks of y (the blocks are of size M). This amounts to $\Theta(M^2)$ operations per block and $\Theta(M^2 N)$ operations for the complete process. Note that this process is ideal for parallel computation. We see this clearly if we consider $(I_N \otimes \bar{L}) y = b$ with $y = \text{vec}(\mathcal{Y})$ and $b = \text{vec}(\mathcal{B})$ giving the equation $\bar{L}\mathcal{Y} = \mathcal{B}$. This is a matrix equation for $\mathcal{Y}$ and we can solve it by operating on all columns in parallel.

To solve $\tilde{P}_{22} x = y$ we assume that

$$(I_N + \hat{h}\beta c_2 D_2) = L \cdot U;$$

hence,

$$\tilde{P}_{22} = (I_N + \hat{h}\beta c_2 D_2) \otimes I_M = L \cdot U \otimes I_M = (L \otimes I_M) \cdot (U \otimes I_M).$$

The matrix $(L \otimes I_M)$ is $N \times N$ block lower triangular and block (i, j) is $l_{ij} I_M$. If we partition a vector $v \in \mathbb{R}^{MN}$ into blocks of size N, we can solve $(L \otimes I_M)v = b$ by performing the forward substitution process treating each block of v as a single unknown. The matrix version of this is $\mathcal{V} L^T = \mathcal{B}$, where $v = \text{vec}(\mathcal{V})$ and $b = \text{vec}(\mathcal{B})$. The backward substitution is done in the same way. Both processes take $\Theta(MN^2)$ operations.

Note that if $M = N$, we only need to store one differentiation matrix, but we would still have to store and factor two Newton matrices since $c_1 \neq c_2$ in general. We can save space by using $(I/\hat{h}\beta c_i) - J_i$ as the Newton matrices instead of $I - \hat{h}\beta c_i J_i$.

We use the same updating strategy for the Newton matrix as was applied in the one-dimensional case, reevaluate and refactor only when the convergence of the iterative linear solver demands it. The only difference here is that we have to reevaluate and refactor two Newton matrices.

We see that

$$\tilde{P}_2 - P_2 = c_1 c_2 (\hat{h}\beta)^2 (I_N \otimes D_1) \cdot (D_2 \otimes I_M)$$

so $\|\tilde{P}_2 - P_2\| = |c_1|\,|c_2|\,O(\hat{h}^2 M^2 N^2)$ which is not small except for $\hat{h}$ very small. Hence in stiff regions where $\hat{h} = O(1)$ the splitting is not an efficient preconditioner.

If $c_2 \gg c_1$ and $\hat{h} = O(1)$ we see that $\|\tilde{P}_{22}\| \gg \|\tilde{P}_{21}\|$ and we might as well solve only $\tilde{P}_{22}x = b$. This works better than doing both solution processes for an example with $c_1 = 1$ and $c_2 = 100$. Note that the procedure for solving only for $\tilde{P}_{22}x = b$ is in agreement with the condition for solving only for $(I - \hat{h}\beta J_2)x = b$ in the method of direct inversion described above. A possible computational scheme is to use the method of direct inversion when the stepsize $\hat{h}$ is expected to be relatively large, and to use the splitting method when $\hat{h}$ is expected to remain small throughout the integration interval.

5. A hyperbolic system in two space dimensions. We now go on to study preconditioning for the linear system of PDEs:

$$u_t + A_1 u_x + A_2 u_y = 0, \quad u \in \mathbb{R}^k, \quad A_1, A_2 \in \mathbb{R}^{k\times k},$$

which, after spectral discretization, becomes:

$$V_t + A_1 \otimes (I_N \otimes D_1)V + A_2 \otimes (D_2 \otimes I_M)V = 0, \qquad V \in \mathbb{R}^{kMN}$$

where A_1 and A_2 are constant coefficient matrices.

The Newton matrix is:

$$B = I_{kNM} + \hat{h}\beta(A_1 \otimes (I_N \otimes D_1) + A_2 \otimes (D_2 \otimes I_M)),$$

and we will again consider tensor product type of preconditioners. A preconditioner based on operator splitting is:

$$\tilde{P}_3 = [I_{kMN} + \hat{h}\beta A_1 \otimes (I_N \otimes D_1)] \cdot [I_{kMN} + \hat{h}\beta A_2 \otimes (D_2 \otimes I_M)].$$

Linear systems with $\tilde{P}_3$ can be solved iteratively; however, solution of $\tilde{P}_3 x = b$ can also be done by direct methods.

Let $\tilde{P}_3 = \tilde{P}_{31} \cdot \tilde{P}_{32}$. We factor $\tilde{P}_{32}$ as follows:

$$\begin{aligned}\tilde{P}_{32} &= I_{kMN} + \hat{h}\beta A_2 \otimes D_2 \otimes I_M \\ &= (I_{kN} + \hat{h}\beta A_2 \otimes D_2) \otimes I_M \\ &= L \cdot U \otimes I_M = (L \otimes I_M) \cdot (U \otimes I_M).\end{aligned}$$

Solution of linear systems with $\tilde{P}_{32}$ can be performed in the same way as described for $\tilde{P}_{22}$ above. A more efficient approach in the case where A_2 is diagonalizable, $A_2 = T\Lambda T^{-1}$, $\Lambda = \operatorname{diag}(\lambda_i)$ is to transform $\tilde{P}_{32}x = b$ into $(I_{kMN} + \hat{h}\beta\Lambda \otimes D_2 \otimes I_M)\tilde{x} = \tilde{b}$. This linear system can be solved by factoring the k matrices $I_N + \hat{h}\beta\lambda_i D_2$ and using these LU factors in the solution process. The cost of factoring A_2 is usually negligible because the number of PDEs is small compared to M and N. Each transform by $T^{-1} \otimes I_N \otimes I_M$ costs $\Theta(k^2MN)$, and this is also negligible compared to the total cost which is $\Theta(kN^3 +$

kMN^2). The major contributions are the factoring of the k matrices $I + \hat{h}\beta\lambda_i D_2$ of size N and the solves for the total linear system, each costing $\Theta(kMN^2)$ operations.

If A_1 is diagonalizable by T_1: $A_1 = T_1\Lambda_1 T_1^{-1}$, $\Lambda_1 =$ diag(λ_{1i}) we can write $\tilde{P}_{31}x = b$ as

$$(I_{kMN} + \hat{h}\beta\Lambda_1 \otimes I_N \otimes D_1)\tilde{x} = \tilde{b}$$

where $\tilde{x} = (T_1^{-1} \otimes I_{MN})x$, $\tilde{b} = (T_1^{-1} \otimes I_{MN})b$. The transformed linear system decouples into k blocks, each having the same form as $P_{21}x = b$ considered in the previous section, and can be solved by factoring the k matrices $I_M + \hat{h}\beta\lambda_{1i}D_1$ and using a blockwise substitution process as described for the solution of $P_{21}x = b$. The total cost of factoring and solving is $\Theta(kM^3 + kM^2N)$ operations. If k, the number of PDEs, is large, we can use a more efficient procedure. If

$$I_M + \hat{h}\beta\lambda_{11}D_1 = S\,H\,S^{-1},$$

then

$$I_M + \hat{h}\beta\lambda_{1i}D_1 = \frac{\lambda_{1i}}{\lambda_{11}} S\left(\left(\frac{\lambda_{11}}{\lambda_{1i}} - 1\right)I + H\right)S^{-1}.$$

If S is chosen such that H is diagonal, then no additional factoring is necessary for $I_M + \hat{h}\beta\lambda_{1i}D_1, i = 2, \ldots, k$. If H is upper Hessenberg, then factoring of $((\lambda_{11}/\lambda_{1i})-1)I+H$ is required, but this is cheaper ($\Theta(kM^2)$ operations compared to $\Theta(kM^3)$) than factoring the matrices $I_M + \hat{h}\beta\lambda_{1i}D_1$ for $i = 2, \ldots, k$.

We may also use the direct inversion scheme for linear two-dimensional systems. Let

$$P_3 = I - \hat{h}\beta J_1 - \hat{h}\beta J_2$$

where $J_1 = -A_1 \otimes I_N \otimes D_1$ and $J_2 = -A_2 \otimes D_2 \otimes I_M$.

As for the single two-dimensional equation, we solve only for $(I - \hat{h}\beta J_2)x = b$ if $\|J_2\| \gg \|J_1\|$, i.e., $\rho(A_2) \gg \rho(A_1)$ (if we assume $M = N$). Even if $\rho(A_2) \approx \rho(A_1)$, numerical experiments show that the one-dimensional preconditioner will work reasonably well at least in the cases where $M = N$. When $\rho(A_2) \approx \rho(A_1)$ we may use the approximation

$$P_3 = (I - \hat{h}\beta\alpha J_1)(I - \hat{h}\beta J_2)$$

with

$$\alpha = \frac{1}{1 + \hat{h}\beta\rho(A_2 \otimes D_2 \otimes I_M)} = \frac{1}{1 + \hat{h}\beta\rho(A_2)\rho(D_2)}.$$

The performance of the preconditioner will depend on the spectra of A_1 and A_2, and may therefore be less predictable than for the single two-dimensional equation.

6. Remarks on quasi-linear PDEs. For nonlinear systems of PDEs the Jacobian will no longer be constant, and an approximation to the Jacobian has to be computed several times during the integration to make the ODE solver work properly. The corresponding Newton matrix can be operated on without forming it explicitly, similar to the approach for linear systems shown previously.

Quasi-linear systems comprise an important special case, and for these equations we can do a local linearization and recompute the preconditioner when the dependent variables and/or the stepsize have changed significantly. The control mechanism for recomputing the Jacobian is still the convergence of the linear solver. With the local linearization we can solve the ODE system in the same way as described previously for linear systems of PDEs.

As an illustration, consider the spectral discretization of the PDE

$$u_t + u\,u_x = 0$$

which can be written:

$$V_t + V \odot D \cdot V = 0, \qquad V \in \mathbb{R}^N,$$

or

$$V_t + \operatorname{diag}(V) \cdot D \cdot V = 0 \tag{6.1}$$

where $\odot$ denotes the componentwise product of two vectors, and $\operatorname{diag}(V)$ is the diagonal matrix formed by the components of the vector V. The Jacobian is formed by taking the Fréchet derivative of $\operatorname{diag}(V) \cdot D \cdot V$. The result is:

$$J = -\operatorname{diag}(V) \cdot D - \operatorname{diag}(D \cdot V).$$

We see that J depends directly on the approximate solution vector V. The spectral discretization of a local linearization of the PDE gives:

$$V_t + \operatorname{diag}(\hat{V}) \cdot D \cdot V = 0$$

where $\hat{V}$ is the point of linearization. The Jacobian in this case is obviously $-\operatorname{diag}(\hat{V}) \cdot D$, which may not be a good approximation to the exact Jacobian. A better choice would be to insert $\hat{V}$ into the formula for the exact Jacobian.

Now consider the quasi-linear system

$$u_t + A(u)\,u_x = 0, \quad u \in \mathbb{R}^k, \quad A(u) = \{a_{ij}(u)\}. \tag{6.2}$$

If $A(u) = A$ is a constant matrix, this problem reduces to the one-dimensional model problem considered in §3. Spectral discretization with N points gives the following ODE system:

$$V_t + \{\operatorname{diag}(a_{ij}(V))\}_{i,j=1}^{k} \cdot (I_k \otimes D) \cdot V = 0, \qquad V \in \mathbb{R}^{kN} \tag{6.3}$$

where $a_{ij}(V)$ is interpreted as follows: In the continuous case a_{ij} is a function of all k components of u, and the value of a_{ij} is a real number. In the discrete case a_{ij} takes the k N-vectors of V as arguments and produces an N-vector. The expression $\{\operatorname{diag}(a_{ij}(V))\}_{i,j=1}^{k}$ is therefore a matrix consisting of diagonal matrices of the N-vectors a_{ij}. We see that this spectral discretization formula applied to the single PDE above gives (6.1). In order to compute the Jacobian for the ODE system we take the Fréchet derivative of

$$\{\operatorname{diag}(a_{ij}(V))\}_{i=1}^{k} \cdot (I_k \otimes D) \cdot V.$$

This gives after some algebraic manipulations:

$$J = -\{\operatorname{diag}(a_{ij}(V))\}_{i,j=1}^{k} \cdot (I_k \otimes D) - \left\{\operatorname{diag}\left(\sum_{m=1}^{k} DV_m \odot \frac{\partial a_{im}}{\partial V_j}\right)\right\}_{i,j=1}^{k} \tag{6.4}$$

where $V = [V_1, \ldots, V_k]^T$, $V_m \in \mathbb{R}^N$, and $\partial a_{ij}/\partial V_j$ have values in $\mathbb{R}^N$. The Jacobian is a $Nk \times Nk$ matrix. Preconditioners for J can be constructed as shown in the previous sections.

Example. Nonlinear wave propagation in the atmosphere can be modelled by the following quasi-linear PDE system:

$$u_t + A(u)\, u_x = b$$

where

$$A(u) = \begin{bmatrix} u_2 & u_1 & 0 \\ 0 & u_2 & 1/u_1 \\ 0 & \gamma u_3 & u_2 \end{bmatrix}, \qquad \gamma \in \mathbb{R}.$$

Spectral discretization gives:

$$V_t + \begin{bmatrix} \operatorname{diag}(V_2) & \operatorname{diag}(V_1) & 0 \\ 0 & \operatorname{diag}(V_2) & \operatorname{diag}(1/V_1) \\ 0 & \gamma \operatorname{diag}(V_3) & \operatorname{diag}(V_2) \end{bmatrix} \cdot (I_3 \otimes D) \cdot V = B. \tag{6.5}$$

Using the previous formula for the Jacobian, we get the following result:

$$\begin{aligned} J = &- \begin{bmatrix} \operatorname{diag}(V_2) & \operatorname{diag}(V_1) & 0 \\ 0 & \operatorname{diag}(V_2) & \operatorname{diag}(1/V_1) \\ 0 & \gamma \operatorname{diag}(V_3) & \operatorname{diag}(V_2) \end{bmatrix} \cdot (I_3 \otimes D) \\ &- \begin{bmatrix} \operatorname{diag}(DV_2) & \operatorname{diag}(DV_1) & 0 \\ -\operatorname{diag}(DV_3 \odot 1/V_1^2) & \operatorname{diag}(DV_2) & 0 \\ 0 & \operatorname{diag}(DV_3) & \gamma \operatorname{diag}(DV_2) \end{bmatrix}. \end{aligned} \tag{6.6}$$

For the two-dimensional quasi-linear system

$$u_t + A_1(u)\, u_x + A_2(u)\, u_y = b, \qquad u \in \mathbb{R}^k,$$

we get, after spectral discretization:

$$\begin{aligned} V_t &+ \left\{\operatorname{diag}(a_{ij}^{(1)}(V))\right\} \cdot (I_k \otimes I_N \otimes D_1) V \\ &+ \left\{\operatorname{diag}(a_{ij}^{(2)}(V))\right\} \cdot (I_k \otimes D_2 \otimes I_M) V = B, \qquad V \in \mathbb{R}^{MNk} \end{aligned}$$

because the differentiation matrices are $I_N \otimes D_1$ and $D_2 \otimes I_M$ in the x- and y-direction, respectively. Using the same procedure as in the one-dimensional case, we get the following Jacobian:

$$\begin{aligned} J = &- \left\{\operatorname{diag}(a_{ij}^{(1)}(V))\right\}_{i,j=1}^{k} \cdot (I_k \otimes I_N \otimes D_1) \\ &- \left\{\operatorname{diag}\left(\textstyle\sum_{m=1}^{k} (I_N \otimes D_1) V_m \odot \frac{\partial a_{im}^{(1)}}{\partial V_j}\right)\right\}_{i,j=1}^{k} \\ &- \left\{\operatorname{diag}(a_{ij}^{(2)}(V))\right\}_{i,j=1}^{k} \cdot (I_k \otimes D_2 \otimes I_M) \\ &- \left\{\operatorname{diag}\left(\textstyle\sum_{m=1}^{k} (D_2 \otimes I_M) V_m \odot \frac{\partial a_{im}^{(2)}}{\partial V_j}\right)\right\}_{i,j=1}^{k} \end{aligned}$$

where $V = [V_1, \ldots, V_k]^T$, $V \in \mathbb{R}^{MN}$ and $\partial a_{im}^{()}/\partial V_j$ have values in $\mathbb{R}^{MN}$. Preconditioners for J can be constructed in the same way as before. The Jacobian is relatively complex, and it may be possible to use a preconditioner that uses only the most significant terms from the Jacobian. However, this simplification will depend entirely on the actual system to be solved.

Refactoring of the Newton matrix $I - \hat{h}\beta J$ requires more monitoring for a nonlinear system since we have to decide if the Jacobian should be reevaluated or if we should just use the current stepsize with the old Jacobian. Practice among existing codes varies considerably. The LSODE family always reevaluates the Jacobian when convergence failure occurs, whereas SIMPLE reevaluates only when the iteration using the current stepsize in the Newton matrix diverges.

Stiffness is normally not a problem in nonlinear equations like the simple model equation above, but quasi-linear systems coming from, e.g., gas dynamics and wave propagation, show considerable stiffness. Explicit ODE solvers work very inefficiently for such systems, and implicit solvers could be more efficient as we have seen for the linear test problems.

7. Numerical examples. In this section we will give a few examples to show that the preconditioners developed in the previous sections work reasonably well. More extensive testing is, however, required in order to assess the true quality of the preconditioners. All the tests reported have been run on VAX stations using double precision arithmetic.

Consider the two-dimensional equation treated in §4:

$$u_t + c_1 u_x + c_2 u_y = 0, \qquad c_1 > 0, c_2 > 0$$

in $[-1, 1] \times [-1, 1]$ with the following boundary conditions: $u(-1, y, t) = 0, u(x, -1, t) = 0$, and open boundaries along $x = 1$ and $y = 1$. The initial function is the "Gaussian hill" $\exp(-10(x^2 + y^2))$ and the integration interval is $[0, 2]$. Both the absolute and the relative error tolerance were set to 10^{-4}.

In Table 7.1 we give some results for this equation using the ODE solver KRYSI, varying the number of spectral points and the "wave speeds" c_1 and c_2. The preconditioner used is the "one-dimensional" version: $I - \hat{h}\beta J_2$ based on the preconditioning matrix Q.

TABLE 7.1
ODE *statistics for* KRYSI *applied to a two-dimensional model equation.*

M=N	9	9	9	17	17	17
c_1	1	1	1	1	1	1
c_2	10	100	1000	10	100	1000
steps	132	130	137	102	100	105
fixp. steps	116	109	109	73	73	73
func. eval.	1285	1285	1383	975	961	1043

We see that the number of steps and the number of function evaluations is not increasing with N (it is even decreasing), and that the number of fixpoint steps is large compared to the total number of steps. This indicates that the ODE system is not very stiff, but what is happening is the following: As long as the wave is inside the region (corresponds to $t \leq 1$) the stepsize is relatively small due to the tracking of the relatively steep wave. Mainly fixpoint steps are used in this time interval. When the wave has left the region, the solver switches to Newton steps, and the stepsize increases sharply.

This is illustrated in Table 7.2 where we have used the case $M = N = 9, c_1 = 1, c_2 = 100$ and variable integration interval. The performance of KRYSI on this model problem is good, the internal statistics of the solver show that there are few, if any, convergence failures in the linear solver, and 2–3 nonlinear iterations are used for each step. The cost of preconditioning for the cases shown in Table 7.1 is low. There are 4–6 evaluations and factorizations of the preconditioner for each case.

TABLE 7.2
Number of steps as a function of integration interval.

t_{end}	2.0	10.0	100.0
steps	130	137	143
fixp. steps	109	109	109

As a comparison to KRYSI we have used the explicit solver DOPRI5 on some of the cases displayed in Table 7.1. We see clearly from Table 7.3 that the explicit solver uses many more steps and function evaluations than KRYSI. The right-most case in the table was aborted after $\approx$ 25000 steps.

TABLE 7.3
Statistics for DOPRI5 *on the two-dimensional model problem.*

$M = N$	9	9	17
c_1	1	1	1
c_2	10	100	1
steps	344	2094	$\approx \infty$
func. eval.	2408	14658	$\approx \infty$

When using the modified preconditioner

$$(I - \alpha\hat{h}\beta J_1)(I - \hat{h}\beta J_2)$$

with $c_1 = c_2$, we got results that were almost identical to those obtained with the "one-dimensional" preconditioner. This can be partly explained by looking at the eigenvalues λ_{ij} of the matrix $(I - \hat{h}\beta J_1)^{-1}(I - \hat{h}\beta J_1 - \hat{h}\beta J_2)$ in the $M = N$ case:

$$\lambda_{ij} = (1 + \hat{h}\beta c_2\mu_i)^{-1}(1 + \hat{h}\beta c_1\mu_i + \hat{h}\beta c_2\bar{\mu}_j).$$

If we take $c_1 = c_2$, we get $\lambda_{ij} = 1 + a_j/(1 + a_i)$ where $a_i = \hat{h}\beta c_1\mu_i$, and we see that the location of the spectrum depends on a_i. If $a_i = O(1)$, i.e., $\hat{h}\beta c_1 = O(N^{-2})$, then the spectrum will be fairly close to $(1, 0)$. A preliminary recommendation will therefore be to use the "one-dimensional" preconditioner $I - \hat{h}\beta J_2$ for $c_2 \geq c_1$ and to use $(I - \hat{h}\beta J_1)$ for $c_1 > c_2$.

We have also run the same model equation on the ODE solver LSODPK with the "one-dimensional" preconditioner and using the same settings for the ODE parameters. Some results are given in Table 7.4:

TABLE 7.4
Statistics for LSODPK *applied to the model problem.*

$M = N$	9	9	9	17	17
c_1	1	1	1	1	1
c_2	1	10	100	1	10
steps	67	187	1363	73	377
func. eval.	202	608	4329	201	1400

We see that the performance is not satisfactory, especially when c_2 is large. It is well known that the BDF family of methods, on which LSODPK is based, is not A-stable for order > 2; see [10] for plots of the stability regions. The spectrum of the differentiation matrix is discussed in [25], and there are eigenvalues close to the imaginary axis, which can cause stability problems, and hence the solver will use an unnecessary small stepsize. A further complication is the high sensitivity of the eigenvalues of the differentiation matrix to machine precision (see [25]), and it is reasonable to expect that the stability restrictions will be a function of the machine precision.

When inspecting the order used by the ODE solver in the integration of the examples in Table 7.4, it was discovered that order four was used in most of the steps, and even order five was used sometimes. So by looking at the stability regions for these methods it is fairly clear that stability did play a role in the performance of LSODPK shown in Table 7.4.

Fortunately, LSODPK contains an option to put an upper bound on the order to be used by the solver. We set this maximum value to three, so the resulting family of methods would be almost A-stable. This gave much better results as shown in Table 7.5.

TABLE 7.5
Statistics for LSODPK *with maximum order* = 3.

$M = N$	9	9	9	17	17	17
c_1	1	1	1	1	1	1
c_2	10	100	1000	10	100	1000
steps	133	122	120	98	94	71
func. eval.	429	382	363	306	299	219
ave. N.	1.14	1.15	1.13	1.16	1.12	1.14
ave. lin.	1.83	1.72	1.66	1.70	1.83	1.69
pre. eval.	16	17	17	14	14	14
CPU time	3.5	3.2	3.2	4.1	5.0	5.1

We see that, compared to KRYSI, the number of steps is approximately equal for the test cases, but the number of function evaluations is much smaller. In Table 7.5 we have included more statistics in order to show the performance of the preconditioner. The parameter "ave. N." is the average number of Newton iterations per step, and this is indeed small for these tests. The parameter "ave. lin." is the average number of linear iterations per Newton step and this is probably the best measure on the performance of the preconditioner. The numbers are very small indicating that the preconditioner works well. Another indication is that there were no convergence failures of the linear iteration in any of the tests. The parameter "pre. eval." is the number of preconditioner evaluations which, in this case, is also the number of Jacobian evaluations. Analytical Jacobians were used for both ODE solvers, so Jacobian evaluations do not show up in the function evaluation figure.

Restricting the order to 2 in LSODPK did not produce better results than shown for maximum order = 3, nor did runs with maximum order = 4.

The next test example is the one-dimensional atmosphere model whose spectral discretization is given in (6.5). The Jacobian matrix for the ODE system is given in (6.6). Since we know the exact Jacobian, we can, in principle, compute the exact Newton matrix for preconditioning. But computing the Newton matrix for each change in stepsize is normally too costly, and the LSODPK solver which is used in this example tries to minimize the number of Newton matrix computations. Convergence of the Newton iteration may be bad for "old" Jacobians and for increasing stepsizes as the analysis in §3 indicates.

The Newton matrix in this case is $I - \bar{h}\beta J$ where J is the Jacobian in (6.6), and we use the matrix Q in the construction of the preconditioner. We see that the Jacobian contains two terms, the first term is what is obtained if local linearization is done before differentiation, while the second term is a true property of quasi-linear systems of first order PDEs.

Two versions of the preconditioner have been investigated in the tests. The first version is using the full Jacobian, while the second version is using only the first term. It turns out that the latter version gives the best results, and is therefore used in this test example. The difference between the two versions of the preconditioner may be due to the fact that Jacobians are computed only when needed to assure convergence of the iterations. Meanwhile the variables may have changed so much that the second term, which depends strongly on the values of the variables, is making the convergence worse than if the term was not there.

Note that the structure of the Jacobian as well as the Newton matrix is as follows (cf. (6.6)):

$$\begin{bmatrix} A_{11} & A_{12} & 0 \\ A_{21} & A_{11} & 0 \\ 0 & A_{32} & A_{33} \end{bmatrix}.$$

In order to solve $(I - \hat{h}\beta J)x = b$, we have used the capacitance matrix technique in [15].

Boundary treatment in spectral methods for hyperbolic systems has been discussed in [5] for fixed stepsize and Dirichlet boundary conditions. In our case we have open boundary conditions and variable stepsize.

To address the issue of boundary conditions properly, we perform a diagonalization of the PDE system. We get the following eigenvalues (=characteristic speeds): $u_2 - a, u_2, u_2 + a$ where a is the local speed of sound: $a = \sqrt{\gamma u_3/u_1}$. The corresponding characteristic variables are $u_3 - u_1 a u_2, u_1 - u_3/a^2, u_3 - u_1 a u_2$. Assuming subsonic conditions, we get one left-going characteristic, one right-going, and one characteristic whose direction depends on $\text{sign}(u_2)$. Following the principles for boundary treatment in [5], we compute the first characteristic variable at the left boundary, the third characteristic variable at the right boundary, and the second characteristic variable at the boundary points determined by $\text{sign}(u_2)$. For inflow boundary points we supply appropriate inflow values. From both outflow and inflow characteristic variables we compute the boundary values for the physical variables.

The initial conditions are given by hydrostatic equilibrium and a state equation:

$$u_{3,x} = -u_1\, g, \qquad u_3\, u_1^{\gamma-1} = \text{constant},$$

plus a small perturbation in u_3 of the form $0.1 \cdot \exp(-50.0 * x^2)$.

The test results for an explicit ODE solver (DOPRI5) and the implicit solver LSODPK, both with error tolerances set to 10^{-4}, are shown in the Tables 7.6 and 7.7. We see that the number of steps is $\Theta(N^2)$ for DOPRI5, while for LSODPK the number of steps is only slowly varying with N. The performance of the preconditioner is still satisfactory, but not so good as for the single two-dimensional hyperbolic PDE shown in Table 7.5. The difference in CPU time between DOPRI5 and LSODPK is large for large N and, in particular, for longer integration intervals even if the stiffness is relatively moderate here. However, we might have used a cheaper explicit method since DOPRI5 has seven stages and the stepsize is determined by the stability requirement. For example, a low order Runge–Kutta method or an Adams method would probably do better in this test example. The number of function evaluations for LSODPK is reasonably low, and using this solver with a good preconditioner on the atmosphere model seems to be an efficient method. Hopefully, the method can be used to solve other important quasi-linear hyperbolic systems with the same efficiency.

8. Conclusion.

We have shown how to apply implicit ODE solvers with iterative linear equation solvers on ODEs coming from spectral discretization of some hyperbolic model problems. The tensor product-type developed preconditioners perform satisfactorily, and the use of implicit ODE solvers gives a significant reduction in the number of timesteps and computing time compared to explicit ODE solvers. In cases where the integration interval is long, the advantage of using implicit solvers seems to be substantial.

The application to quasi-linear PDEs is straightforward (by local linearization), but because of the nonlinearity the preconditioners may be less efficient if the solution is rapidly changing. A test example from atmospheric physics shows that application of implicit ODE solvers to quasi-linear PDE systems gives promising results. We will describe preconditioning techniques for quasi-linear systems of PDEs in more detail in a forthcoming paper.

For PDEs containing second order derivatives, different types of preconditioners have been suggested. Orszag [20] has derived a preconditioner based on centered finite differences of the Chebyshev points $\{x_j\}$, and that preconditioner has proven to be very effective, see, e.g., [12]. The numerical experiments indicates that the spectral radius of the preconditioned second derivative matrix is $\Theta(1)$ compared to $\Theta(N^4)$ for the unpreconditioned case. However, the use of these preconditioners in the ODE context will meet the same problems as for the preconditioners described in this paper.

Note that preconditioning of the second derivative matrix is in many ways simpler than for the first derivative matrix due to the fact that the latter matrix is nearly defective. The paper [26] discusses in detail the eigenvalues of the second derivative matrix.

METHODS FOR REDUCING APPROXIMATE-FACTORIZATION ERRORS IN TWO- AND THREE-FACTORED SCHEMES*

ERLENDUR STEINTHORSSON† AND TOM I-P. SHIH†

Abstract. Three methods are presented for reducing approximate-factorization (AF) errors that exist in two- and three-factored schemes, such as the popular ADI, LU, and LU-SSOR methods. For problems in which AF errors are larger than both time-discretization and time-linearization errors, these methods can be used to lower the AF errors so that larger time-step sizes can be used when transient solutions are of interest. When only steady-state solutions are of interest, these methods can be used to accelerate the convergence rate. The methods presented also can be used to stabilize schemes that are unstable because of AF errors (e.g., the three-factored ADI scheme applied to the linear advection equation with central-difference approximation of the spatial derivatives). The three methods presented can be added easily to existing codes using any two- or three-factored schemes.

1. Introduction.

All implicit finite-difference (FD) and finite-volume (FV) methods for partial differential equations (PDEs), such as the Euler and Navier–Stokes equations, require simultaneous algebraic equations to be solved. For computational efficiency it is desirable that such methods solve only those simultaneous equations that can be analyzed efficiently, namely, those that are linear, are of as low an order as possible, and have coefficient matrices that possess certain structures, such as tridiagonal or triangular (e.g., bidiagonal) matrices. Systems of nonlinear algebraic equations can always be converted to systems of linear equations by the Newton–Raphson iteration or by variations of it. To reduce the order of simultaneous equations and to change the structure of their coefficient matrices, a technique known as approximate factorization (AF) can be used.

AF has been used in three ways. The first approach, factorization according to spatial dimensions, is used in ADI methods [1], [2] and their variations [3], [4]; schemes based on ADI factoring are two-factored for two-dimensional (2-D) problems and are three-factored for three-dimensional (3-D) problems. The second approach, factorization according to the signs of certain eigenvalues, is used in the LU [5]–[7] and LU-SSOR [8] schemes; schemes based on eigenvalue splitting are always two-factored whether the problem being analyzed is 2-D or 3-D. The third approach, which involves a combination of the first two approaches, is used in the partially split method of Steger and of Ying [9]. Note that AF should always be used with delta formulation in order to produce consistently split FD and FV methods [10].

Although AF is a useful technique for developing efficient schemes, FD and FV methods constructed by using it can have problems. For example, with ADI schemes the three-factored versions are less stable numerically than are the two-factored versions. In fact, Fourier analysis has shown that for the linear advection equation with central-difference approximation of spatial derivatives, the three-factored scheme is unconditionally unstable. With LU schemes the problem is not stability but rather the physical meaning of the intermediate variables. This makes implicit implementation of

boundary conditions at the intermediate step difficult. Implicit boundary conditions can significantly affect the accuracy of transient solutions and the convergence rate to steady state. Also, even though all schemes constructed by using AF wit delta formulation yield steady-state solutions that are independent of errors arising from AF, transient solutions are affected by those errors. Thus if transient solutions are of interest, then time-step sizes may need to be kept excessively small in order to minimize those errors.

If errors introduced by AF can be eliminated in an economic manner, then schemes constructed by using AF will improve in performance and accuracy. Thus the objective of this study is to devise methods that can be used to reduce or eliminate errors that arise from AF. In this paper three such methods are devised. These methods can be applied to reduce or eliminate AF errors in any scheme constructed by AF for any PDE, including the Euler and the Navier–Stokes equations. Here these three AF-error-reduction methods are presented in the framework of a three-factored ADI scheme applied to the linear advection equation.

The rest of this paper is organized as follows. First, the model equation and the algorithm used to present the AF-error-reduction methods are given. Second, three AF-error-reduction methods are described, and then one of the three AF-error-reduction methods is analyzed for its convergence and stability properties. Finally, results that show the capabilities of the three AF-error-reduction methods are given.

2. Model equation and algorithm. In this study the linear advection equation is used as the model PDE and the three-factored ADI scheme is used as the model algorithm whose AF errors are to be reduced or eliminated.

The 3-D linear advection equation is given by

$$\frac{\partial u}{\partial t} + c_x \frac{\partial u}{\partial x} + c_y \frac{\partial u}{\partial y} + c_z \frac{\partial u}{\partial z} = 0, \tag{1}$$

where $u = u(t, x, y, z)$ and c_x, c_y, and c_z are real constants. Suppose that (1) is supplied with appropriate initial and boundary conditions and that the domain is discretized so that the time-step size (Δt) and grid spacings ($\Delta x, \Delta y$, and Δz) are all constants. If the time derivative is replaced by a generalized time-differencing formula [1] and if all spatial derivatives are replaced by difference operators, (1) becomes

$$\left[1 + \frac{\gamma \Delta t}{1+\theta}(c_x D_x + c_y D_y + c_z D_z)\right] \Delta u_{ijk}^{n+1} = \mathrm{RHS}_{ijk}, \tag{2}$$

where

$$\mathrm{RHS}_{ijk} = -\frac{\Delta t}{1+\theta}(c_x D_x + c_y D_y + c_z D_z) u_{ijk}^n + \frac{\theta}{1+\theta}\Delta u_{ijk}^n. \tag{3}$$

In the above equations $\Delta u^{n+1} = u^{n+1} - u^n$ and $u_{ijk}^n = u(n\Delta t, i\Delta x, j\Delta y, k\Delta z)$, where n, i, j, and k are nonnegative integers; D_x, D_y, and D_z are the difference operators (central or upwind) that approximate the first-order x, y, and z derivatives, respectively; and θ and γ are constants that determine the time-differencing formula (e.g., $\gamma = 1$ and $\theta = 0$ give the Euler implicit formula, and $\gamma = 1$ and $\theta = \frac{1}{2}$ give the three-point backward formula).

Equation (2) can be approximately factored in several different ways. Approximate factorization according to spatial dimensions gives the following three-factored ADI scheme:

$$\left(1 + \frac{\gamma \Delta t}{1+\theta} c_x D_x\right)\left(1 + \frac{\gamma \Delta t}{1+\theta} c_y D_y\right)\left(1 + \frac{\gamma \Delta t}{1+\theta} c_z D_z\right) \Delta u_{ijk}^{n+1} = \mathrm{RHS}_{ijk}, \tag{4}$$

which can be split as

(5a) $$\left(1 + \frac{\gamma \Delta t}{1+\theta} c_x D_x\right) \Delta u^*_{ijk} = \mathrm{RHS}_{ijk},$$

(5b) $$\left(1 + \frac{\gamma \Delta t}{1+\theta} c_y D_y\right) \Delta u^{**}_{ijk} = \Delta u^*_{ijk},$$

(5c) $$\left(1 + \frac{\gamma \Delta t}{1+\theta} c_z D_z\right) \Delta u^{n+1}_{ijk} = \Delta u^{**}_{ijk}.$$

When (2) was approximately factored to produce (4), an error was introduced into (4). If (2) had been factored without introducing this error, then the following equation would have been obtained:

(6a)
$$\left(1 + \frac{\gamma \Delta t}{1+\theta} c_x D_x\right)\left(1 + \frac{\gamma \Delta t}{1+\theta} c_y D_y\right)\left(1 + \frac{\gamma \Delta t}{1+\theta} c_z D_z\right) \Delta u^{n+1}_{ijk} = \mathrm{RHS}_{ijk} + \Phi_{\mathrm{AF}},$$

where

(6b) $$\begin{aligned}\Phi_{\mathrm{AF}} = &\left(\frac{\gamma \Delta t}{1+\theta}\right)^2 [(c_x D_x)(c_y D_y) + (c_x D_x)(c_z D_z) + (c_y D_y)(c_z D_z)]\Delta u^{n+1}_{ijk} \\ &+ \left(\frac{\gamma \Delta t}{1+\theta}\right)^3 (c_x D_x)(c_y D_y)(c_z D_z)\Delta u^{n+1}_{ijk}.\end{aligned}$$

The term Φ_{AF} on the right-hand side of (6a) is the AF error in the three-factored ADI scheme given by (4). If we want to reduce the AF error in (4), then we must add the term Φ_{AF}, or part thereof, back to the right-hand side of (4).

The Fourier method of stability analysis shows that when second-order-accurate central-differencing formulas are used for the spatial derivatives, the three-factored ADI scheme given by (4) is unconditionally unstable [11]. In contrast, the scheme given by (2) is unconditionally stable when used with the same second-order-accurate central-differencing formulas. This implies that the AF error destabilized the scheme. This also implies that if the AF errors in (4) can be reduced or eliminated (e.g., by adding Φ_{AF}), then the three-factored ADI scheme can be stabilized.

Here it is emphasized that it is unnecessary to add all of the terms in Φ_{AF} given by (6b) to (4) in order to stabilize the three-factored ADI scheme. To illustrate this point, we consider another way of factoring (2) that yields the following unconditionally stable scheme when second-order-accurate central-differencing formulas are used for the spatial derivatives:

(7) $$\left[1 + \frac{\gamma \Delta t}{1+\theta}(c_x D_x + c_y D_y)\right]\left(1 + \frac{\gamma \Delta t}{1+\theta} c_z D_z\right) \Delta u^{n+1}_{ijk} = \mathrm{RHS}_{ijk},$$

which can be split as

(8a) $$\left[1 + \frac{\gamma \Delta t}{1+\theta}(c_x D_x + c_y D_y)\right] \Delta u^{**}_{ijk} = \mathrm{RHS}_{ijk},$$

$$\text{(8b)}\qquad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_zD_z)\right]\Delta u_{ijk}^{n+1}=\Delta u_{ijk}^{**}.$$

Equation (8a) can be rewritten as

$$\text{(9a)}\qquad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)\right]\Delta u_{ijk}^{*}=\text{RHS}_{ijk}+\left(\frac{\gamma\Delta t}{1+\theta}\right)^2(c_xD_x)(c_yD_y)\Delta u_{ijk}^{**},$$

$$\text{(9b)}\qquad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_yD_y)\right]\Delta u_{ijk}^{**}=\Delta u_{ijk}^{*},$$

so that (9a), (9b), and (8b) appear as a three-factored scheme and can be compared with the three-factored ADI scheme given by (5). If these equations are compared, it can be seen that to stabilize (4) it is necessary to add only the last term in (9a) to the right-hand side of (4). Adding this term would effectively convert the three-factored scheme given by (4) to the two-factored scheme given by (7).

3. AF-error-reduction techniques. This section presents three AF-error-reduction methods for reducing or eliminating AF errors in the three-factored ADI scheme given by (4). The first technique is designed to stabilize the three-factored ADI scheme by eliminating some, but not all, AF errors. The remaining two techniques are designed to eliminate all AF errors.

3.1. Technique 1: Stabilize the three-factored ADI scheme. As mentioned in §2, one way to stabilize the three-factored ADI scheme given by (4) is to convert it to the two-factored scheme given by (7). This can be achieved by adding

$$\left(\frac{\gamma\Delta t}{1+\theta}\right)^2(c_xD_x)(c_yD_y)\Delta u_{ijk}^{**}$$

to the right-hand side of (4) or, equivalently, to the right-hand side of (5a). The resulting scheme, given by (9a), (9b), and (8b), is repeated below for convenience:

$$\text{(10a)}\qquad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)\right]\Delta u_{ijk}^{*}=\text{RHS}_{ijk}+\left(\frac{\gamma\Delta t}{1+\theta}\right)^2(c_xD_x)(c_yD_y)\Delta u_{ijk}^{**},$$

$$\text{(10b)}\qquad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_yD_y)\right]\Delta u_{ijk}^{**}=\Delta u_{ijk}^{*},$$

$$\text{(10c)}\qquad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_zD_z)\right]\Delta u_{ijk}^{n+1}=\Delta u_{ijk}^{**}.$$

Note that the term that was added to (5a) to obtain (10a) is a cross derivative that couples together all grid points in a constant-z plane, and since it involves Δu^{**} it also couples (10b) to (10a). Thus in order to obtain an economical AF-error-reduction method, the cross-derivative term must be eliminated and (10a) and (10b) must be decoupled.

The cross-derivative term in (10a) is eliminated by rewriting (10b) as

$$\text{(11)}\qquad \frac{\gamma\Delta t}{1+\theta}(c_yD_y)\Delta u_{ijk}^{**}=\Delta u_{ijk}^{*}-\Delta u_{ijk}^{**}$$

and by substituting it into (10a) to give

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^{*}_{ijk} = \mathrm{RHS}_{ijk}+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u^{*}_{ijk}-\Delta u^{**}_{ijk}). \tag{12}$$

Equation (12) shows the cross derivative eliminated, but it also shows that (12) (which now replaces (10a)) is still coupled to (10b) since Δu^* and Δu^{**} appear in both.

To decouple (12) from (10b) we suggest the following iterative scheme:

Predictor Step

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^{*\prime}_{ijk} = \mathrm{RHS}_{ijk}, \tag{13a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u^{**\prime}_{ijk} = \Delta u^{*\prime}_{ijk}. \tag{13b}$$

Corrector Step

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^{*\prime\prime}_{ijk} = \mathrm{RHS}_{ijk}+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u^{*\prime}_{ijk}-\Delta u^{**\prime}_{ijk}), \tag{14a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u^{**\prime\prime}_{ijk} = \Delta^{*\prime\prime}_{ijk}, \tag{14b}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u^{n+1}_{ijk} = \Delta u^{**\prime\prime}_{ijk}. \tag{14c}$$

Depending on the problem and the time-step size, the corrector step given by (14a) and (14b) may need to be iterated a few times before (14c) is solved. Iterating (14a) and (14b) permits $\Delta u^{*\prime}$ and $\Delta u^{**\prime}$ to be made as close as desired to $\Delta u^{*\prime\prime}$ and $\Delta u^{**\prime\prime}$, respectively. In the limit, when $\Delta u^{*\prime} = \Delta u^{*\prime\prime}$ and $\Delta u^{**\prime} = \Delta u^{**\prime\prime}$, (14a) becomes

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^{*\prime\prime}_{ijk} = \mathrm{RHS}_{ijk}+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u^{*\prime\prime}_{ijk}-\Delta u^{**\prime\prime}_{ijk}).$$

If (14b) is substituted for $\Delta u^{*\prime\prime}$, the above equation becomes

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u^{**\prime\prime}_{ijk} = \mathrm{RHS}_{ijk}+\left(\frac{\gamma\Delta t}{1+\theta}\right)^2(c_xD_x)(c_yD_y)\Delta u^{**\prime\prime}_{ijk},$$

which is identical to

$$\left[1+\frac{\gamma\Delta t}{1+\theta}(c_xD_x+c_yD_y)\right]\Delta u^{**\prime\prime}_{ijk} = \mathrm{RHS}_{ijk}.$$

Thus in the limit the AF-error-reduction scheme given by (13) and (14) can be used to convert the unconditionally unstable three-factored ADI scheme given by (4) to the unconditionally stable two-factored scheme given by (7).

In §4 it will be shown that when central-differencing formulas are used for all spatial derivatives, the iteration process given by (14a) and (14b) is convergent for all values of Δt. This iteration process can, therefore, be said to be *unconditionally convergent*. It is also shown in §4 that the overall algorithm given by (13) and (14) can be made conditionally stable and that its stability characteristics improve as the number of iterations of (14a) and (14b) is increased.

3.2. Technique 2: Reduce all AF errors in the three-factored ADI scheme. The AF-error-reduction method presented in the previous subsection eliminated only AF errors associated with one out of the two factorizations in the three-factored ADI scheme. This subsection presents a method of reducing or eliminating AF errors associated with all factorizations in the three-factored ADI scheme.

Consider the exactly factored scheme given by (6), which can be split as follows:

(15a)
$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^*_{ijk} = \mathrm{RHS}_{ijk} + \left(\frac{\gamma\Delta t}{1+\theta}\right)^2[(c_xD_x)(c_yD_y)+(c_xD_x)(c_zD_z)+(c_yD_y)(c_zD_z)]\Delta u^{n+1}_{ijk} + \left(\frac{\gamma\Delta t}{1+\theta}\right)^3[(c_xD_x)(c_yD_y)(c_zD_z)]\Delta u^{n+1}_{ijk},$$

(15b)
$$\left[1+\frac{\gamma\Delta t}{1+\theta}(c_yD_y)\right]\Delta u^{**}_{ijk} = \Delta u^*_{ijk},$$

(15c)
$$\left[1+\frac{\gamma\Delta t}{1+\theta}(c_zD_z)\right]\Delta u^{n+1}_{ijk} = \Delta u^{**}_{ijk}.$$

To eliminate the cross-derivative terms in (15a), (15b), and (15c) are rewritten as

(16a)
$$\frac{\gamma\Delta t}{1+\theta}(c_zD_z)\Delta u^{n+1}_{ijk} = \Delta u^{**}_{ijk} - \Delta u^{n+1}_{ijk},$$

(16b)
$$\frac{\gamma\Delta t}{1+\theta}(c_yD_y)\Delta u^{**}_{ijk} = \Delta u^{*}_{ijk} - \Delta u^{**}_{ijk}.$$

Inserting (16a) and (16b) into (15a) gives

(17)
$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^*_{ijk} = \mathrm{RHS}_{ijk} + \frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u^*_{ijk} - \Delta u^{n+1}_{ijk}) + \frac{\gamma\Delta t}{1+\theta}(c_yD_y)(\Delta u^{**}_{ijk} - \Delta u^{n+1}_{ijk}).$$

This suggests the following method for eliminating all AF errors.

Predictor Step

(18a)
$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u^{*\prime}_{ijk} = \mathrm{RHS}_{ijk},$$

(18b)
$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u^{**\prime}_{ijk} = \Delta u^{*\prime}_{ijk},$$

(18c)
$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u^{(n+1)\prime}_{ijk} = \Delta u^{**\prime}_{ijk}.$$

Corrector Step

$$\text{(19a)}\quad \left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u_{ijk}^{*\prime\prime} = \mathrm{RHS}_{ijk} + \frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u_{ijk}^{*\prime} - \Delta u_{ijk}^{(n+1)'}) + \frac{\gamma\Delta t}{1+\theta}(c_yD_y)(\Delta u_{ijk}^{**\prime} - \Delta u_{ijk}^{(n+1)'}),$$

$$\text{(19b)}\quad \left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u_{ijk}^{**\prime\prime} = \Delta u_{ijk}^{*\prime\prime},$$

$$\text{(19c)}\quad \left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u_{ijk}^{(n+1)''} = \Delta u_{ijk}^{**\prime\prime},$$

where the corrector step may have to be repeated more than once.

When second-order-accurate central-differencing formulas are used for the spatial derivatives, it can be shown that the iteration process given by (19) is conditionally convergent, i.e., it converges only if the time-step Δt is smaller than some critical value. For ensuring convergence the Δt used must satisfy the following condition:

$$\text{(20)}\quad 2a_xa_ya_z(a_x+a_y+a_z) - (a_x^2+a_y^2+a_z^2) \leqq 1,$$

where

$$\text{(21)}\quad \begin{gathered} a_x = \frac{\gamma}{1+\theta}v_x, \quad a_y = \frac{\gamma}{1+\theta}v_y, \quad a_z = \frac{\gamma}{1+\theta}v_z, \\ v_x = \frac{|c_x|\Delta t}{\Delta x}, \quad v_y = \frac{|c_y|\Delta t}{\Delta y}, \quad v_z = \frac{|c_z|\Delta t}{\Delta z}. \end{gathered}$$

If $a_x = a_y = a_z = a$, then the convergence condition becomes

$$\text{(22)}\quad a \leqq 0.85,$$

or

$$\text{(23)}\quad \Delta t \leqq 0.85\frac{1+\theta}{\gamma}\left(\frac{\Delta x}{c_x}\right).$$

The convergence criterion given above is quite restrictive. Thus the AF-error-reduction method given by (18) and (19) is uneconomical. Below, a more economical method for reducing all AF errors in the three-factored ADI scheme is presented.

3.3. Technique 3: Reduce all AF errors in the ADI three-factored scheme. The AF-error-reduction method presented in §3.2 was based on the exact factoring of (2) given by (6). This subsection presents an AF-error-reduction scheme that is based on a different exact factoring of (2).

A different exact factoring of (2) proceeds as follows. First, factor and split (2) as

$$\text{(24a)}\quad \left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u_{ijk}^{*} = \mathrm{RHS}_{ijk} + \left(\frac{\gamma\Delta t}{1+\theta}\right)^2 (c_xD_x)(c_yD_y+c_zD_z)\Delta u_{ijk}^{n+1},$$

$$\text{(24b)}\quad \left[1+\frac{\gamma\Delta t}{1+\theta}(c_yD_y+c_zD_z)\right]\Delta u_{ijk}^{n+1} = \Delta u_{ijk}^{*}.$$

Then, factor and split (24b) as

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u_{ijk}^{**}=\Delta u_{ijk}^{*}+\left(\frac{\gamma\Delta t}{1+\theta}\right)^2(c_yD_y)(c_zD_z)\Delta u_{ijk}^{n+1}, \tag{25a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u_{ijk}^{n+1}=\Delta u_{ijk}^{**}. \tag{25b}$$

By eliminating the cross-derivative terms in the same manner as before, we obtain

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u_{ijk}^{*}=\mathrm{RHS}_{ijk}+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u_{ijk}^{*}-\Delta u_{ijk}^{n+1}), \tag{26a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u_{ijk}^{**}=\Delta u_{ijk}^{*}+\frac{\gamma\Delta t}{1+\theta}(c_yD_y)(\Delta u_{ijk}^{**}-\Delta u_{ijk}^{n+1}), \tag{26b}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u_{ijk}^{n+1}=\Delta u_{ijk}^{**}. \tag{26c}$$

Equations (26a), (26b), and (26c) suggest the following AF-error-reduction method:

Predictor Step

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u_{ijk}^{*\prime}=\mathrm{RHS}_{ijk}, \tag{27a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u_{ijk}^{**\prime}=\Delta u_{ijk}^{*\prime}, \tag{27b}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u_{ijk}^{(n+1)\prime}=\Delta u_{ijk}^{**\prime}. \tag{27c}$$

Corrector Step

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\Delta u_{ijk}^{*\prime\prime}=\mathrm{RHS}_{ijk}+\frac{\gamma\Delta t}{1+\theta}(c_xD_x)(\Delta u_{ijk}^{*\prime}-\Delta u_{ijk}^{(n+1)\prime}), \tag{28a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\Delta u_{ijk}^{**\prime\prime}=\Delta_{ijk}^{*\prime\prime}+\frac{\gamma\Delta t}{1+\theta}(c_yD_y)(\Delta u_{ijk}^{**\prime}-\Delta u_{ijk}^{(n+1)\prime}), \tag{28b}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_zD_z\right)\Delta u_{ijk}^{(n+1)\prime\prime}=\Delta u_{ijk}^{**\prime\prime}. \tag{28c}$$

Note that in the AF-error-reduction method given by (18) and (19), the terms corresponding to the AF error were all put in the first factor (19a). In the current AF-error-reduction method the AF error terms are split between the first and the second factors ((28a) and (28b)).

As in the previous AF-error-reduction methods, the corrector step given by (28) may have to be repeated several times. Equations (28) can be iterated in two ways. The first way is to iterate (28a) to (28c) within a single iteration loop until a converged solution for Δu^{n+1} is obtained. The convergence criteria for this algorithm is complicated and difficult to analyze.

The second way to iterate (28) is to use two nested loops. Within the inner loop, (28b) and (28c) are iterated (for a fixed Δu^*) until a converged (interim) solution for Δu^{n+1} is achieved. Then, in the outer loop, (28a) is used to compute a new Δu^*, based on the interim solution for Δu^{n+1}, before the inner loop is executed again. This algorithm can be shown to be unconditionally convergent, provided that the inner loop of the iteration scheme is carried out until a fully converged (interim) solution is obtained. This result follows from the observation that the inner loop is simply an unconditionally convergent two-factored scheme similar to that given in §3.1. If, for each of the steps in the outer iteration loop, the inner loop is carried out to full convergence, then the outer iteration loop also corresponds to a two-factored scheme that can be shown to be unconditionally convergent. With the above arguments it can be deduced that the iteration scheme given by (28) is unconditionally convergent.

In this section, three AF-error-reduction methods were presented. Although all three methods were presented in the framework of the three-factored ADI scheme, these methods can easily be extended and applied to other schemes constructed by using AF.

4. Analysis. In this section, the AF-error-reduction method given by (13) and (14) is analyzed for its convergence and stability properties. The other two AF-error-reduction methods can be analyzed in a similar way.

For the AF-error-reduction method given by (13) and (14) to be useful, the iteration process given by (14) must be convergent and the overall algorithm given by (13) and (14) must be stable. Below, the convergence property is analyzed first, and then the stability property is analyzed.

To analyze the convergence property of the iteration process given by (14), we note that if the iteration process converges, then (14a) must approach (12) and (14b) must approach (10b) as the number of iterations increases. Subtracting (14a) from (12) and subtracting (14b) from (10b) gives

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\epsilon_{ijk}^m = \frac{\gamma\Delta t}{1+\theta}(c_xD_x)[\epsilon_{ijk}^{m-1}-\delta_{ijk}^{m-1}], \tag{29a}$$

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\delta_{ijk}^m = \epsilon_{ijk}^m, \tag{29b}$$

where ϵ_{ijk}^m is the error in Δu^* after the mth iteration and δ_{ijk}^m is the error in Δu^{**} after the mth iteration, i.e.,

$$\epsilon_{ijk}^m = \Delta u_{ijk}^* - \Delta u_{ijk}^{*\prime\prime}, \tag{30a}$$

$$\delta_{ijk}^m = \Delta u_{ijk}^{**} - \Delta u_{ijk}^{**\prime\prime}. \tag{30b}$$

Substituting (29b) into (29a) gives

$$\left(1+\frac{\gamma\Delta t}{1+\theta}c_xD_x\right)\left(1+\frac{\gamma\Delta t}{1+\theta}c_yD_y\right)\delta_{ijk}^m = \left(\frac{\gamma\Delta t}{1+\theta}\right)^2(c_xD_x)(c_yD_y)\delta_{ijk}^{m-1}. \tag{31}$$

Now, suppose that the error δ^m_{ijk} has the following form:

$$\delta^m_{ijk} = D^m \exp[I(k_x x_i + k_y y_j + k_z z_k)], \tag{32}$$

where $I = \sqrt{-1}$; k_x, k_y, and k_z are the wave numbers in the x, y, and z, directions, respectively; and x_i, y_j, and z_k are the coordinates of the grid point at (i, j, k). Since the spatial derivatives are approximated by central-difference operators, (32) implies

$$D_x\delta^m_{ijk} = I\delta^m_{ijk}\frac{\sin(k_x\Delta x)}{\Delta x}, \tag{33a}$$

$$D_y\delta^m_{ijk} = I\delta^m_{ijk}\frac{\sin(k_y\Delta y)}{\Delta y}. \tag{33b}$$

Substituting (32) and (33) into (31) and dividing through by

$$\exp[I(k_x x_i + k_y y_j + k_z z_k)]$$

gives

$$\begin{aligned} &D^m(1 + Ia_x\sin(k_x\Delta x))(1 + Ia_y\sin(k_y\Delta y)) \\ &= -D^{m-1}a_x a_y \sin(k_x\Delta x)\sin(k_y\Delta_y), \end{aligned} \tag{34}$$

where

$$a_x = \frac{\gamma}{1+\theta}v_x, \quad a_y = \frac{\gamma}{1+\theta}v_y, \quad v_x = \frac{c_x\Delta t}{\Delta x}, \quad v_y = \frac{c_y\Delta t}{\Delta y}. \tag{35}$$

Equation (34) can be rearranged to give the following amplification factor:

$$G = \frac{D^m}{D^{m-1}} = \frac{-a_x a_y\sin(k_x\Delta x)\sin(k_y\Delta y)}{(1 + Ia_x\sin(k_x\Delta x))(1 + Ia_y\sin(k_y\Delta y))} \tag{36}$$

or

$$|G|^2 = \frac{a_x^2 a_y^2\sin^2(k_x\Delta x)\sin^2(k_y\Delta y)}{1 + a_x^2\sin^2(k_x\Delta x) + a_y^2\sin^2(k_y\Delta y) + a_x^2 a_y^2\sin^2(k_x\Delta x)\sin^2(k_y\Delta y)}. \tag{37}$$

From (37) it is clear that $|G|^2$ is less than unity for all wave numbers. This indicates that the iteration process given by (14a) and (14b) is unconditionally convergent.

With the unconditional convergence of the iteration process shown, the stability of the overall algorithm given by (13) and (14) is now analyzed. For simplicity, the Euler implicit time-differencing formula is used, so that $\gamma = 1$ and $\theta = 0$. For this case, (13) and (14), along with (3) can be written as

$$\begin{aligned} &(1 + \Delta t c_x D_x)(1 + \Delta t c_y D_y)(1 + \Delta t c_z D_z)\Delta u^{n+1}_{ijk} \\ &= -\Delta t(c_x D_x + c_y D_y + c_z D_z)u^n_{ijk} \\ &\quad + \Delta t^2(c_x D_x)(c_y D_y)\Delta u^{**\prime}_{ijk}. \end{aligned} \tag{38}$$

Now we introduce a parameter α defined by

$$(c_x D_x)(c_y D_y)\Delta u^{**\prime} = \alpha(c_x D_x)(c_y D_y)\Delta u^{**}. \tag{39}$$

Note that as the number of iterations of (14a) and (14b) is increased, the value of α approaches unity and $\Delta u^{**\prime}$ approaches Δu^{**}. If we use (10c) and the parameter α defined by (39), equation (38) becomes

$$\begin{aligned}&\{1+\Delta t(c_xD_x+c_yD_y+c_zD_z)+\Delta t^2[(1-\alpha)(c_xD_x)(c_yD_y)\\&\quad+(c_xD_x)(c_zD_z)+(c_yD_y)(c_zD_z)]\\&\quad+(1-\alpha)\Delta t^3(c_xD_x)(c_yD_y)(c_zD_z)\}\Delta u_{ijk}^{n+1}\\&\quad=-\Delta t(c_xD_x+c_yD_y+c_zD_z)u_{ijk}^n.\end{aligned} \tag{40}$$

Application of the Fourier method of stability analysis to (40) readily yields an amplification factor with the following modulus:

$$|G|^2=\frac{(1-\xi)^2-\eta(\zeta-\eta)}{(1-\xi)^2+(\zeta-\eta)^2}, \tag{41}$$

where

$$\begin{aligned}\xi=&(1-\alpha)v_xv_y\sin(k_x\Delta x)\sin(k_y\Delta y)\\&+v_xv_z\sin(k_x\Delta x)\sin(k_z\Delta z)\\&+v_yv_z\sin(k_y\Delta y)\sin(k_z\Delta z),\end{aligned} \tag{42a}$$

$$\eta=(1-\alpha)v_xv_yv_z\sin(k_x\Delta x)\sin(k_y\Delta y)\sin(k_z\Delta z), \tag{42b}$$

$$\zeta=v_x\sin(k_x\Delta x)+v_y\sin(k_y\Delta y)+v_z\sin(k_z\Delta z), \tag{42c}$$

$$v_x=\frac{c_x\Delta t}{\Delta x},\quad v_y=\frac{c_y\Delta t}{\Delta y},\quad v_z=\frac{c_z\Delta t}{\Delta z}. \tag{43}$$

For numerical stability, the modulus given by (41) must be less than or equal to unity, i.e., $|G|\leqq 1$. From (42), it is clear that if $\alpha=1$, then $|G|\leqq 1$ for all wave numbers. This indicates that if the iteration of (14a) and (14b) is carried out until a converged solution is obtained, then the method given by (13) and (14) is unconditionally stable. If only a finite number of iterations of (14a) and (14b) are carried out, then α will be less than unity, and this results in a conditionally stable algorithm. Another way to state this is that, for a given Δt, there is a certain number of iterations that need to be carried out before the algorithm becomes stable. The number of iterations needed to stabilize the algorithm is problem dependent.

Note that for the original three-factored ADI scheme given by (4), $\alpha=0$. For that case Ying [9] has shown that the maximum $|G|$ is greater than unity, indicating unconditional instability.

5. Numerical experiments. In this section the usefulness of the AF-error-reduction methods developed in this study are demonstrated by applying them to a test problem. The test problem selected is to obtain a steady-state solution of (1) by using the three-factored ADI scheme. Since the three-factored ADI scheme applied to (1) is unconditionally unstable when central-differencing formulas are used to approximate the spatial derivatives, this problem is a stringent test of the AF-error-reduction methods presented.

5.1. Test problem and solution algorithm. In this subsection the test problem is formulated and the solution algorithms with the AF-error-reduction methods applied to the test problem are summarized.

All exact steady-state solutions to (1) must satisfy

$$\mathbf{c} \cdot \nabla u = 0,$$

where $\mathbf{c} = (c_x, c_y, c_z)^T$. This implies that steady-state solutions must be constant on lines parallel to the velocity vector $\mathbf{c}$. Thus steady-state solutions of (1) are functions of the vector $\mathbf{X} = (\xi, \eta, \zeta)^T$ given by

$$\mathbf{X} = \mathbf{r} - (\mathbf{r} \cdot \mathbf{s})\mathbf{s}, \tag{44}$$

where

$$\mathbf{r} = \begin{bmatrix} x \\ y \\ x \end{bmatrix}, \qquad \mathbf{s} = \frac{\mathbf{c}}{|\mathbf{c}|}.$$

The components of $\mathbf{X}$ can be written as

$$\xi = x - c_x \left(\frac{c_x x + c_y y + c_z z}{c_x^2 + c_y^2 + c_z^2} \right), \tag{45a}$$

$$\eta = y - c_y \left(\frac{c_x x + c_y y + c_z z}{c_x^2 + c_y^2 + c_z^2} \right), \tag{45b}$$

$$\zeta = z - c_z \left(\frac{c_x x + c_y y + c_z z}{c_x^2 + c_y^2 + c_z^2} \right), \tag{45c}$$

Note that $\mathbf{X}$ is constant on lines parallel to the vector $\mathbf{c}$ and that this constant is zero for the line passing through the origin.

With (44) and (45) a test problem that has a known steady-state solution to (1) can be constructed. The test problem selected is as follows: the spatial domain is taken to be a unit cube, i.e.,

$$0 \leqq x \leqq 1, \quad 0 \leqq y \leqq 1, \quad 0 \leqq z \leqq 1. \tag{46}$$

The velocity vector $\mathbf{c}$ is taken as

$$\mathbf{c} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}, \tag{47}$$

so that it has nonzero component in all three coordinate directions. With this choice of $\mathbf{c}$, boundaries at $x = 0$, $y = 0$, and $z = 0$ are inflow boundaries and the boundaries at $x = 1$, $y = 1$, and $z = 1$ are outflow boundaries. The boundary conditions imposed at the inflow boundaries are those that yield the following steady-state solution to (1):

$$u_s(\xi, \eta, \zeta) = \cos(2\pi\xi) + \cos(2\pi\eta) + \cos(2\pi\zeta). \tag{48}$$

Note that the steady-state solution given by (48) has nonzero first-order derivatives in all three coordinate directions. The initial condition used for (1) is given by

$$u(t=0,x,y,z) = u_s(\xi,\eta,\zeta) + 0.51\sin\left(\frac{\pi x}{10}\right)\sin\left(\frac{\pi y}{20}\right)\sin\left(\frac{\pi z}{30}\right), \tag{49}$$

which differs from the steady-state solution given by (48) by the sinusoidal disturbance.

To obtain solutions to (1) constrained by (46)–(49) by using an FD or FV method, such as those described in the previous sections, the domain must be discretized and additional boundary conditions (known as numerical boundary conditions) must be provided at the outflow boundaries at $x = 1$, $y = 1$, and $z = 1$.

Here the temporaral domain was replaced by equally incremented time steps. Time-step sizes of 0.001, 0.002, 0.008, 0.01, 0.015, 0.02, 0.03, 0.04, and 0.06 s were investigated. The spatial domain given by (46) was replaced by (IL $= 59$) $\times$ (JL $= 53$) $\times$ (KL $= 47$) equally spaced grid points, where IL, JL, and KL are the number of grid points in the x, y, and z directions, respectively. Note that with this choice of IL, JL, and KL, the grid spacings in the x, y, and z directions are different.

The numerical boundary conditions used at the outflow boundaries are

$$u_{\mathrm{IL},j,k} = 2u_{\mathrm{IL}-1,j,k} - u_{\mathrm{IL}-2,j,k}, \tag{50a}$$

$$u_{i,\mathrm{JL},k} = 2u_{i,\mathrm{JL}-1,k} - u_{i,\mathrm{JL}-2,k}, \tag{50b}$$

$$u_{i,j,\mathrm{KL}} = 2u_{i,j,\mathrm{KL}-1} - u_{i,j,\mathrm{KL}-2}. \tag{50c}$$

Since the three-factored ADI scheme and the AF-error-reduction methods are implicit, all boundary conditions, including those given above, were implemented implicitly as follows:

$$\Delta u^{n+1}_{1,j,k} = \Delta u^{n+1}_{i,1,k} = \Delta u^{n+1}_{i,j,1} = 0, \tag{51a}$$

$$\Delta u^{n+1}_{\mathrm{IL},j,k} = 2\Delta u^{n+1}_{\mathrm{IL}-1,j,k} - \Delta u^{n+1}_{\mathrm{IL}-2,j,k}, \tag{51b}$$

$$\Delta u^{n+1}_{i,\mathrm{JL},k} = 2\Delta u^{n+1}_{i,\mathrm{JL}-1,k} - \Delta u^{n+1}_{i,\mathrm{JL}-2,k}, \tag{51c}$$

$$\Delta u^{n+1}_{i,j,\mathrm{KL}} = 2\Delta u^{n+1}_{i,j,\mathrm{KL}-1} - \Delta u^{n+1}_{i,j,\mathrm{KL}-2}. \tag{51d}$$

Numerical solutions to (1), along with (46)–(50), were obtained by using the following three methods:

(i) The original three-factored ADI scheme given by (5).

(ii) The three-factored ADI scheme with AF-error-reduction Technique 1 given by (13) and (14) (henceforth referred to as AFRT-1), which stabilizes the three-factored scheme by converting it to a two-factored scheme.

(iii) The three-factored ADI scheme with AF-error-reduction Technique 3 given by (27) and (28) (henceforth referred to as AFRT-3), which stabilizes the three-factored scheme by reducing all AF errors.

Note that AF-error-reduction Technique 2, presented in §3.2, was not tested because of the stringent criteria that must be satisfied in order for the iteration process involved to converge.

To illustrate that the AF-error-reduction methods developed in this study can easily be incorporated into existing codes based on two- or three-factored schemes, the algorithms for implementing the three methods listed above are given below.

Three-Factored ADI *Scheme*

```
specify initial conditions
for $n = 1$ to $N_{\mathrm{MAX}}$ do:
    compute $\Delta u^*$ (equation (5a))
    compute $\Delta u^{**}$ (equation (5b))
    compute $\Delta u^{n+1}$ (equation (5c))
    compute $\Delta u^{n+1}$ on boundaries (equations (51))
    $u^{n+1} \leftarrow u^n + \Delta u^{n+1}$
end do
STOP
```

AF-Error-Reduction Technique 1 (AFRT-1)

```
specify initial conditions
for $n = 1$ to $N_{\mathrm{MAX}}$ do:
    Predictor Step:
    compute $\Delta u^{*\prime}$ (equation (13a))
    compute $\Delta u^{**\prime}$ (equation (13b))
    Iterative Corrector Step:
    for $m = 1$ to $M_{\mathrm{MAX}}$ do:
        compute $\Delta u^{**\prime}$ on boundaries (equations (51))
        compute $\Delta u^{*\prime\prime}$ (equation (14a))
        compute $\Delta u^{**\prime\prime}$ (equation (14b))
        $\Delta u^{**\prime} \leftarrow \Delta u^{**\prime\prime}$
        $\Delta u^{*\prime} \leftarrow \Delta u^{*\prime\prime}$
    end do
    compute $\Delta u^{n+1}$ (equation (14c))
    compute $\Delta u^{n+1}$ on boundaries (equations (51))
    $u^{n+1} \leftarrow u^n + \Delta \quad u^{n+1}$
end do
STOP
```

AF-Error-Reduction Technique 3 (AFRT-3)

```
specify initial conditions
for $n = 1$ to $N_{\mathrm{MAX}}$ do:
    Predictor Step:
    compute $\Delta u^{*\prime}$ (equation (27a))
    compute $\Delta u^{**\prime}$ (equation (27b))
    compute $\Delta u^{(n+1)\prime}$ (equation (27c))
    compute $\Delta u^{(n+1)\prime}$ on boundaries (equations (51))
    Iterative Corrector Step:
    for $m = 1$ to $M_{\mathrm{MAX}}$ do:
        compute $\Delta u^{*\prime\prime}$ (equation (28a))
        for $l = 1$ to $L_{\mathrm{MAX}}$ do:
            compute $\Delta u^{**\prime}$ on boundaries (equations (51))
            compute $\Delta u^{**\prime\prime}$ (equation (28b))
```

```
                compute $\Delta u^{(n+1)''}$ (equation (28c))
                compute $\Delta u^{(n+1)''}$ on boundaries (equations (51))
                $\Delta u^{**'} \leftarrow \Delta u^{**''}$
                $\Delta u^{(n+1)'} \leftarrow \Delta u^{(n+1)''}$
            end do
        end do
        $u^{n+1} \leftarrow u^n + \Delta u^{n+1}$
    end do
    STOP
```

For the algorithms given above, N_{MAX} is the total number of time steps taken; M_{MAX} is the total number of corrector steps (i.e., the number of times the corrector step is iterated), and L_{MAX} is the total number of iterations performed within each corrector step (used only with AFRT-3). In this study L_{MAX} was always taken to be three times M_{MAX}. Note that the boundary conditions given by (51) were used not only for computing Δu^{n+1} but also for computing the intermediate variables Δu^* and Δu^{**}. This was found to be necessary in order to ensure convergence of the iteration processes involved.

5.2. Results. The AF-error-reduction techniques developed in this study were tested by applying them to the test problem described in §5.1 and by using the algorithms described there. In this subsection the results of these tests are presented.

The results of all numerical tests conducted are shown in Figs. 1–10. These figures show the L_2 norm of Δu^{n+1} plotted against time (Fig. 1) and against the number of time steps (Figs. 2–10).

Figure 1 shows the results obtained by using the ADI three-factored scheme without any AF-error-reduction technique. The results plotted are the convergence histories of the solutions obtained by using time-step sizes ranging from 0.001 to 0.01 s. As can be seen in the figure, converged solutions were obtained for all time-step sizes tested with this range. These converged solutions were obtained despite the prediction by the Fourier method of stability analysis, which states that the three-factored ADI scheme is unconditionally unstable. This apparent contradiction can be explained by the fact that the Fourier method does not consider the effects of finite-size domains and boundary conditions on numerical stability. In this study the boundary conditions used ($\Delta u = 0$ at inflow boundaries and upwind extrapolation at outflow boundaries) helped stabilize the three-factored ADI scheme. Note that for time-step sizes larger than 0.01 s the ADI three-factored scheme was found to be unstable.

Figures 2–10 show results obtained by using the AF-error-reduction techniques AFRT-1 and AFRT-3. Each figure shows the results obtained by using time-step size.

Figure 2 shows the results obtained by using time-step $\Delta t = 0 \cdot 001$ s. As can be seen, the AF-error-reduction techniques have no effect on the convergence rate except near the beginning of the computations. This indicates that for small time-step sizes AF errors are not significant and do not affect the solution.

Figures 3 and 4 show the results obtained by using $\Delta t = 0.008$ s for AFRT-1 and AFRT-3, respectively. From these figures it can be seen that the AF-error-reduction techniques do improve the convergence rate slightly. Figure 3 shows that for AFRT-1 one corrector step has the same effect on the convergence rate as two, four, or eight corrector steps. This indicates that for $\Delta t = 0.008$ s the iteration process used in AFRT-1 converges fully in only one corrector step. Comparison of Figs. 3 and 4 shows that

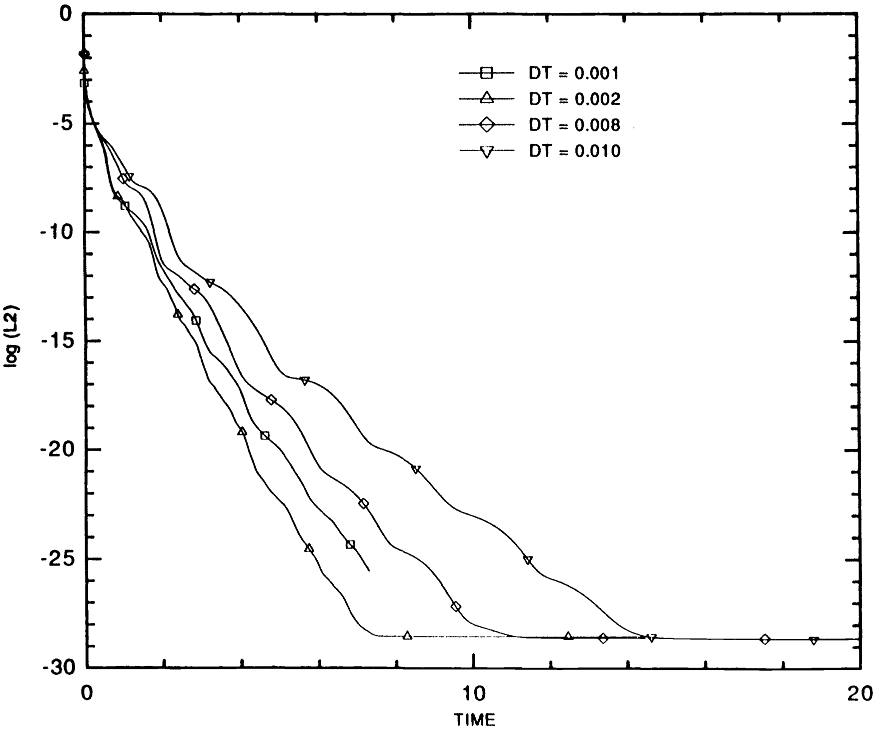

FIG. 1. L_2 *norm versus time for* ADI *three-factored scheme with* Δt *ranging from* 0.001 *to* 0.01 s.

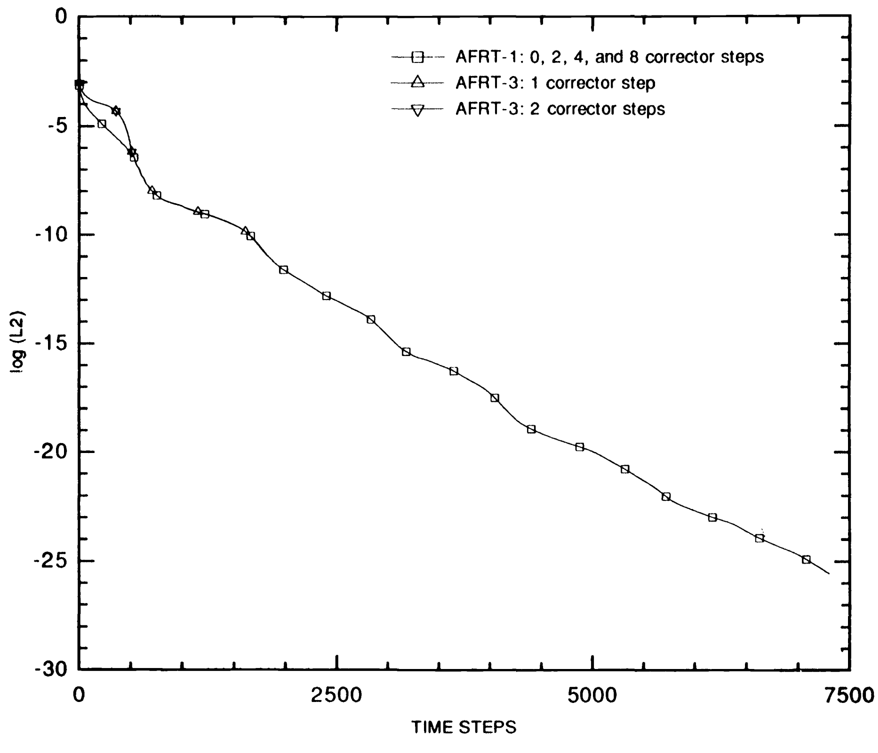

FIG. 2. L_2 *norm versus time steps for* AFRT-1 *and* AFRT-3 *with* $\Delta t = 0.001$ s.

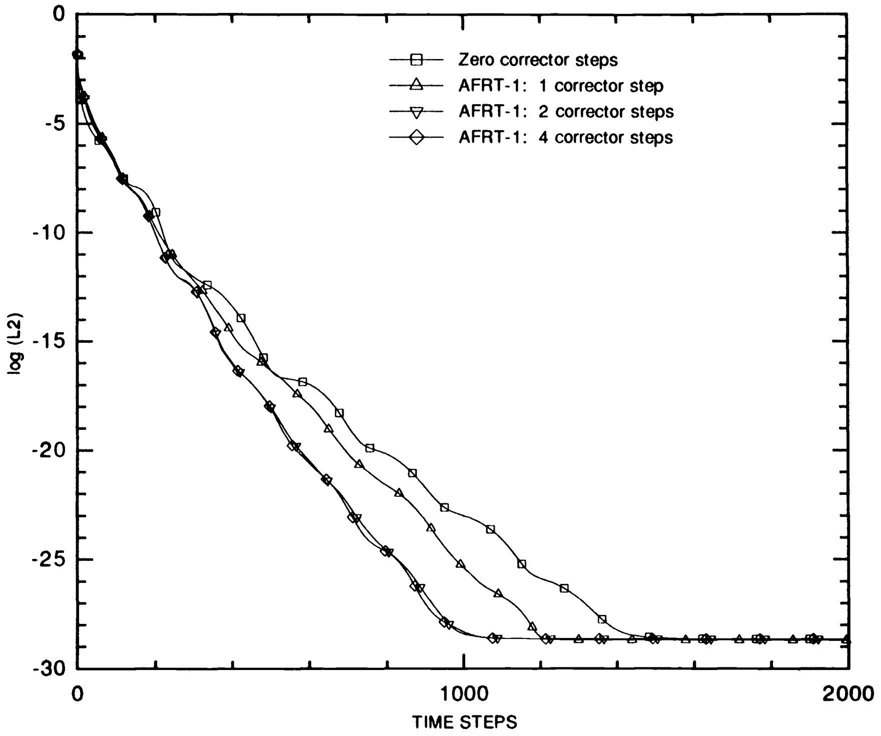

FIG. 5. L_2 *norm versus time steps for* AFRT-1 *with* $\Delta t = 0.01$ s.

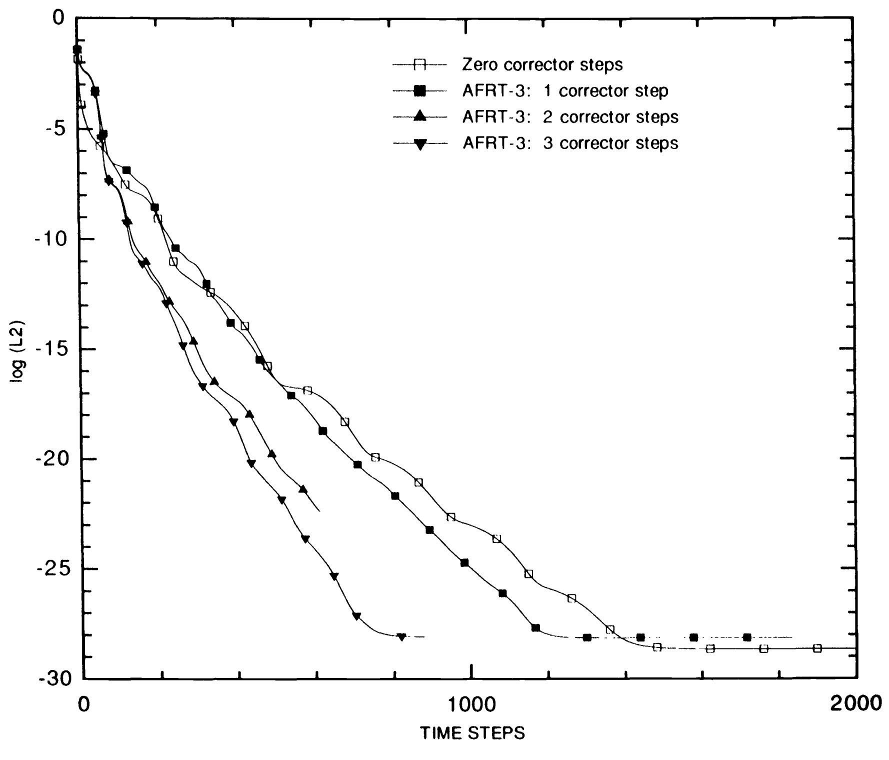

FIG. 6. L_2 *norm versus time steps for* AFRT-3 *with* $\Delta t = 0.01$ s.

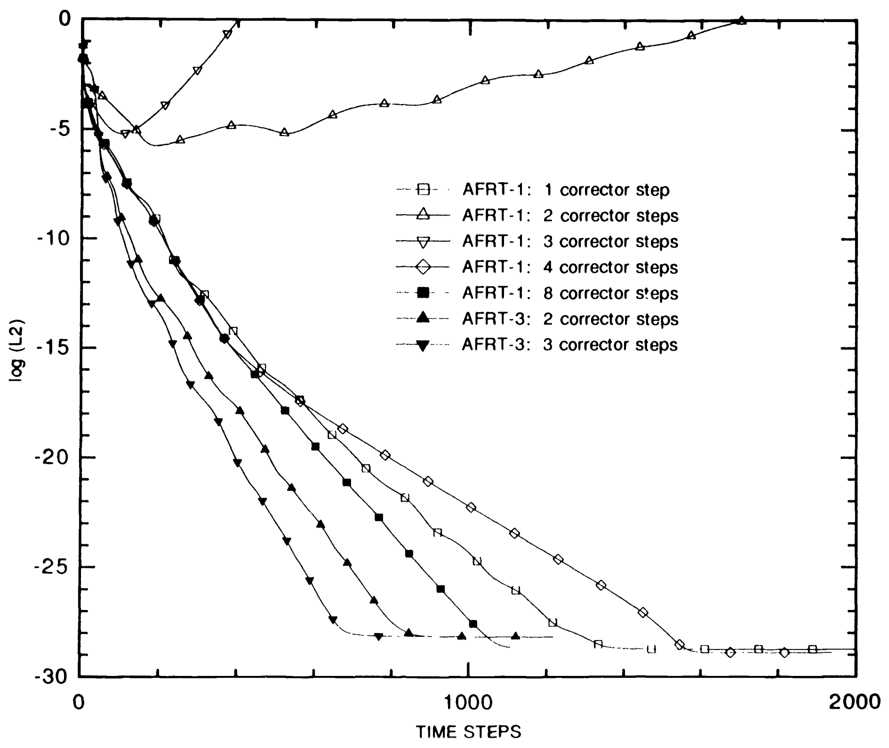

FIG. 7. L_2 *norm versus time steps for* AFRT-1 *and* AFRT-3 *with* $\Delta t = 0.015$ s.

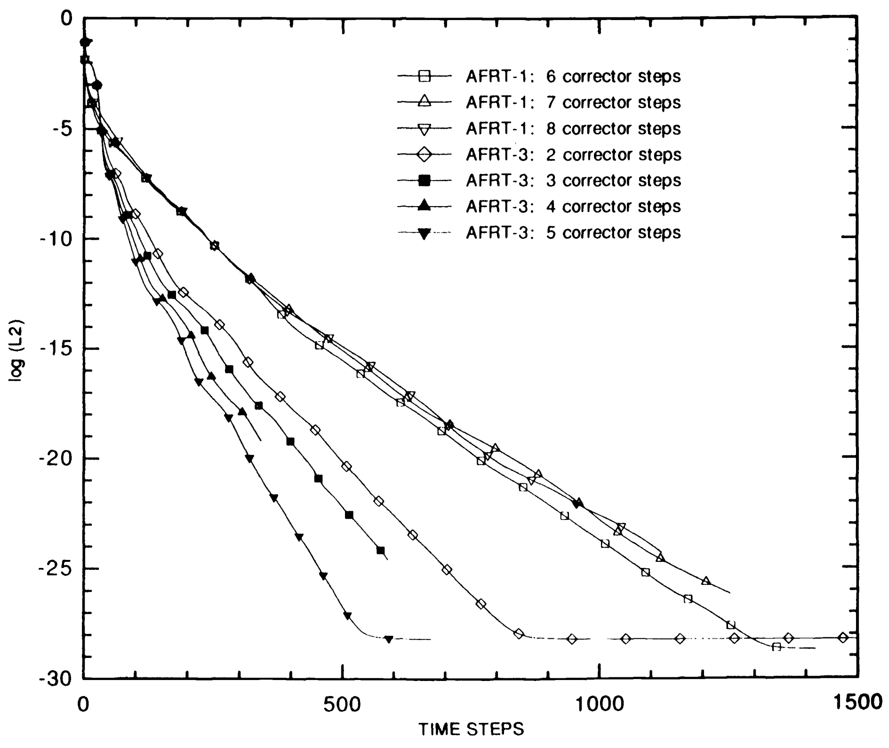

FIG. 8. L_2 *norm versus time steps for* AFRT-1 *and* AFRT-3 *with* $\Delta t = 0.02$ s.

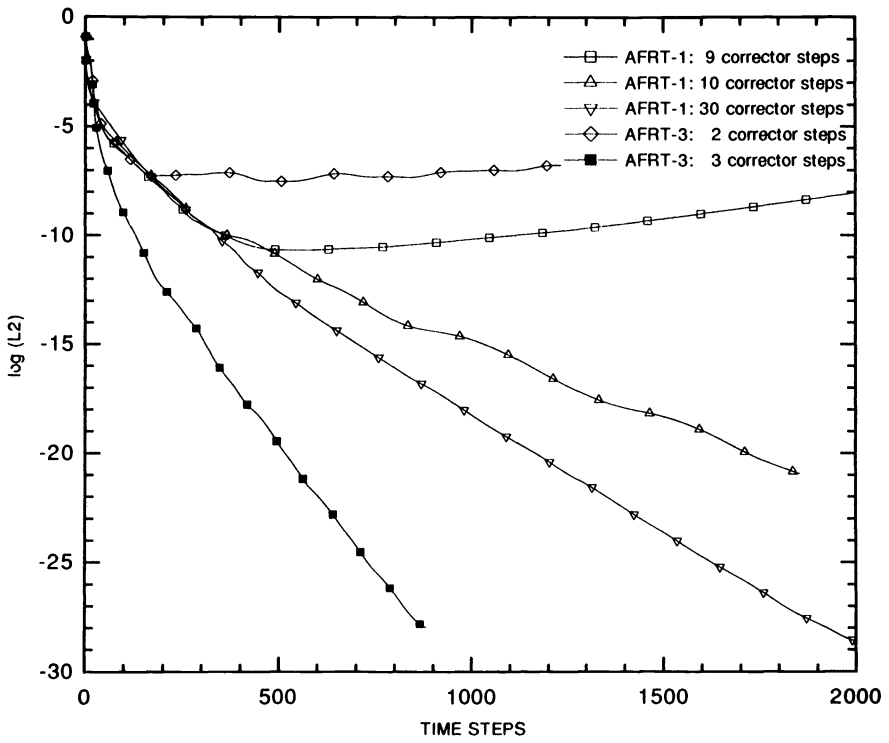

FIG. 9. *L_2 norm versus time steps for* AFRT-1 *and* AFRT-3 *with* $\Delta t = 0.03$ s.

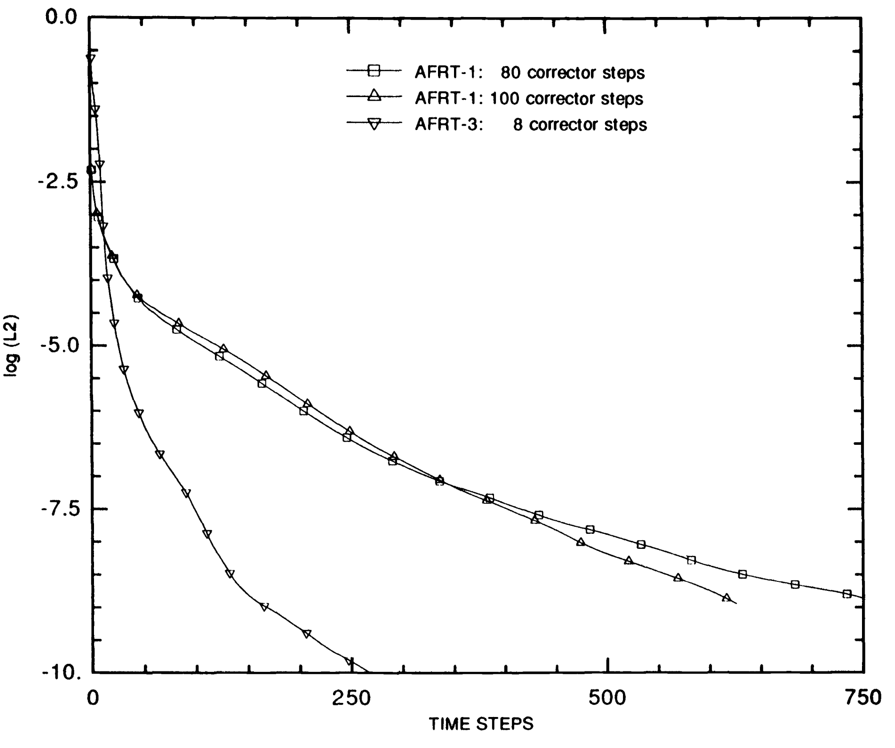

FIG. 10. *L_2 norm versus time steps for* AFRT-1 *and* AFRT-3 *with* $\Delta t = 0.06$ s.

solutions obtained by using AFRT-3 converged slightly faster than solutions obtained by using AFRT-1, provided that more than one corrector step is taken in AFRT-3.

Figures 5 and 6 show the results obtained by using $\Delta t = 0.01$ s for AFRT-1 and AFRT-3, respectively. The results shown in these figures are qualitatively similar to those shown in Figs. 3 and 4. As can be seen in Fig. 5, when AFRT-1 is used, one or two corrector steps improve the convergence rate, but more than two corrector steps bring no further improvements. This indicates that the iteration process used in AFRT-1 converges in two iterations when $\Delta t = 0.01$ s, compared to only one iteration when $\Delta t = 0.008$ s. Figure 6 shows that for AFRT-3 the use of only one corrector step has little effect on the convergence rate, but two and three corrector steps bring considerable improvements. If three corrector steps are used, the number of time steps needed to reach steady state is half of that needed by the original ADI three-factored scheme. This indicates that AF errors are quite significant for this larger time-step size. Note that the time-step size used here was the largest one for which the ADI three-factored scheme was able to yield converged solutions without the use of AF-error-reduction techniques. This time-step size can therefore be considered as the practical stability limit for the three-factored ADI scheme used in this study.

Figure 7 shows the results obtained by using $\Delta t = 0.015$ s. This figure shows the results for both AFRT-1 and AFRT-3. For this time-step size the three-factored ADI scheme was found to diverge. In Fig. 7 it can be seen that when AFRT-1 was used, a converged solution was obtained if one corrector step or four corrector steps were used. However, if two or three corrector steps were used, the solution diverged. For AFRT-3 it was found that two corrector steps were needed in order to obtain a converged solution and that the convergence rate improved as the number of corrector steps increased.

Figure 8 shows the results obtained by using $\Delta t = 0.02$ s. For this time-step size, when AFRT-1 was used, six corrector steps were needed to stabilize the ADI three-factored scheme. If AFRT-3 was used, then only two corrector steps were needed to stabilize the scheme. Again, when AFRT-3 was used, the convergence rate improved as the number of corrector steps was increased.

Figure 9 shows the results obtained by using $\Delta t = 0.03$ s. This time-step size is three times the practical stability limit for the ADI three-factored scheme. For this time-step size, when AFRT-1 was used, 10 corrector steps were needed to stabilize the scheme. Increasing the number of corrector steps to 30 improved the convergence rate significantly. When AFRT-3 was used, three corrector steps were needed to stabilize the scheme, and this resulted in a considerably better convergence rate than that obtained by using AFRT-1.

Figure 10 shows the results obtained by using $\Delta t = 0.06$ s, which is six times the practical stability limit for the ADI three-factored scheme. It was found that when AFRT-1 was used, at least 80 corrector steps were needed in order to stabilize the scheme. Increasing the number of corrector steps to 100 brought only a moderate improvement in convergence rate. When AFRT-3 was used, eight corrector steps were found to be adequate in stabilizing the scheme. Thus AFRT-3 has a considerably better convergence rate than does AFRT-1. However, it should be noted that the operation count needed to execute the corrector step in AFRT-3 increases quadratically with the number of corrector steps, whereas in AFRT-1 that increase is linear. This rapid increase in operation found in AFRT-3 is due to the iterations that must be performed within each corrector step.

The results of the numerical experiments described above indicate that the AF-error-reduction methods presented in this study are capable of reducing AF errors and increasing convergence rate. All results were obtained by applying the AF-error-reduction methods to a very stringent test problem, one in which the algorithm is unconditionally unstable. If the AF-error-reduction methods presented here were applied to algorithms that are inherently stable, better performance could be expected.

6. Concluding remarks. In this paper three methods were presented that can be used to reduce or eliminate AF errors that exist in two- and three-factored schemes such as the ADI, LU, and LU-SSOR schemes. These AF-error-reduction methods were illustrated and tested in the framework of the unconditionally unstable three-factored ADI scheme applied to the linear advection equation. Also, the convergence and stability properties of one AF-error-reduction method were analyzed.

The results of the tests and analyses indicate that the AF-error-reduction methods presented are capable of reducing AF errors and of increasing convergence rate. Thus the methods developed should be useful in stabilizing the commonly used unconditionally unstable three-factored ADI scheme, which is currently being stabilized by adding artificial dissipation. For factored schemes that are inherently stable, the AF-error-reduction methods should be useful for problems in which transient solutions are of interest and AF errors are larger than the time-discretization and time-linearization errors. When only steady-state solutions are of interest, the methods presented here can be used to accelerate convergence to steady state.

Finally, it is noted that the AF-error-reduction techniques presented can easily be incorporated into existing codes using two- and three-factored schemes. Also, there are several ways to improve the computational efficiency of these methods. For example, the number of iterations performed within each corrector step of AFRT-3 can be optimized. Also, convergence acceleration techniques, such as relaxation, can be incorporated into the iterative parts of AFRT-1 and AFRT-3.

Acknowledgments. The authors thank Richard J. Roelke, NASA Lewis Research Center, and they also thank an anonymous referee for careful reading of the manuscript and helpful suggestions.

HIGH-ORDER SYMPLECTIC RUNGE–KUTTA–NYSTRÖM METHODS*

M. P. CALVO† AND J. M. SANZ-SERNA†

Abstract. A numerical method for ordinary differential equations is called symplectic if, when applied to Hamiltonian problems, it preserves the symplectic structure in phase space, thus reproducing the main qualitative property of solutions of Hamiltonian systems. The authors construct and test symplectic, explicit Runge–Kutta–Nyström (RKN) methods of order 8. The outcome of the investigation is that existing high-order, symplectic RKN formulae require so many evaluations per step that they are much less efficient than conventional eighth-order nonsymplectic, variable-step-size integrators even for low accuracy. However, symplectic integration is of use in the study of qualitative features of the systems being integrated.

1. Introduction.

In this paper we are concerned with Runge–Kutta–Nyström (RKN) methods for the numerical integration of second-order systems of differential equations of the special form

$$d^2\mathbf{y}/dt = \mathbf{f}(\mathbf{y}), \qquad y = [y^1, y^2, \dots, y^N]^T, \tag{1.1}$$

or, equivalently, of first-order systems

$$\frac{d\mathbf{y}}{dt} = \dot{\mathbf{y}}, \qquad \frac{d\dot{\mathbf{y}}}{dt} = \mathbf{f}(\mathbf{y}).$$

For the RKN formula specified by the tableau

$$\begin{array}{c|ccc} \gamma_1 & \alpha_{11} & \cdots & \alpha_{1s} \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_s & \alpha_{s1} & \cdots & \alpha_{ss} \\ \hline & b_1 & \cdots & b_s \\ \hline & \beta_1 & \cdots & \beta_s \end{array}, \tag{1.2}$$

the equations that describe the step $t_n \to t_{n+1} = t_n + h$ take the form

$$\mathbf{Y}_i = \mathbf{y}_n + h\gamma_i\dot{\mathbf{y}}_n + h^2\sum_{j=1}^{s}\alpha_{ij}\mathbf{f}(\mathbf{Y}_j),$$

$$\dot{\mathbf{y}}_{n+1} = \dot{\mathbf{y}}_n + h\sum_{i=1}^{s} b_i\mathbf{f}(\mathbf{Y}_i),$$

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h\dot{\mathbf{y}}_n + h^2\sum_{i=1}^{s}\beta_i\mathbf{f}(\mathbf{Y}_i),$$

where $\mathbf{Y}_i$ denote the internal stages. Throughout the paper we suppose that in (1.2)

$$\beta_i = b_i(1-\gamma_i), \qquad 1 \le i \le s; \tag{1.3}$$

this is a standard assumption that significantly decreases the number of order conditions that must be imposed on the method coefficients to ensure a given order of consistency; see [10, Chap. 2, Lemma 13.13].

If the function $\mathbf{f}$ in (1.1) is the gradient of a scalar potential $-V = -V(\mathbf{y})$ and we set $\mathbf{p} = \dot{\mathbf{y}}$, $\mathbf{q} = \mathbf{y}$, then (1.1) may obviously be rewritten as

$$\frac{dp^I}{dt} = -\frac{\partial V}{\partial q^I}, \qquad \frac{dq^I}{dt} = p^I, \quad 1 \le I \le N. \tag{1.4}$$

This is the Hamiltonian system of ordinary differential equations

$$\frac{dp^I}{dt} = -\frac{\partial H}{\partial q^I}, \qquad \frac{dq^I}{dt} = \frac{\partial H}{\partial p^I}, \quad 1 \le I \le N$$

with Hamiltonian function

$$H = H(\mathbf{p},\mathbf{q}) = T(\mathbf{p}) + V(\mathbf{q}), \quad T(\mathbf{p}) = \frac{1}{2}\mathbf{p}^T\mathbf{p}.$$

In mechanics the q variables represent Lagrangian coordinates, the p variables represent the corresponding momenta, T represents the potential energy, V represents the potential energy and H represents the total energy.

The recent literature has devoted much attention to the integration of Hamiltonian systems by means of canonical or symplectic methods; see [17] for a survey. A one-step numerical method is said to be canonical or symplectic if it preserves the so-called symplectic structure of the space of variables $(\mathbf{p}, \mathbf{q})$, thus reproducing the main qualitative property of solutions of Hamiltonian systems [2]. Suris [19] showed that the RKN method (1.2) is symplectic when applied to systems (1.4) if the coefficients satisfy the relations

$$b_i(\beta_j - \alpha_{ij}) = b_j(\beta_i - \alpha_{ji}), \qquad 1 \le i,j \le s; \tag{1.5}$$

see also [13]. On the other hand, if (1.2) does not possess redundant stages, (1.5) is also necessary for symplecticness; a rigorous proof of this necessity can be seen in [3] (cf. [1, §5]). In the remainder of the paper we use the expression "symplectic RKN method" to refer to RKN methods (1.2) that satisfy (1.5).

Okunbor and Skeel [14] studied the families of explicit, symplectic RKN methods with one, two, or three stages. The present authors [4], [5], [7] have constructed and tested an explicit, five-stage, fourth-order symplectic RKN method with optimized error constants. This method uses four function evaluations per step: the evaluation for the fifth stage of the current step coincides with the first evaluation in the next step (FSAL (first same as last) technique). In [15] Okunbor and Skeel construct explicit symplectic RKN formulae with five stages and seven stages and orders 5 and 6, respectively. For separable Hamiltonian systems [1], Yoshida [20] derives explicit, symplectic methods with order 8. When applied to problems of the form (1.1), Yoshida's methods reduce to RKN schemes of order 8 with 16 stages and 15 evaluations per step.

The experiments in [7] show that in the accurate long-time integration of problems of the form (1.4) the constant-step-size implementation of the fourth-order symplectic formula constructed there is more efficient than a variable-step-size, fourth-order code based on an embedded RKN pair due to Dormand, El-Mikkawy, and Prince [8], [9]. The purpose of the present paper is to construct explicit, symplectic RKN methods of order 8 and to compare them with standard nonsymplectic RKN codes of the same order. The outcome of our investigation is that existing high-order, symplectic RKN formulae require so many evaluations per step that they are much less efficient than conventional eighth-order nonsymplectic, variable-step-size integrators, even for low accuracy. However, symplectic integration is of use in the study of qualitative features of the systems being integrated.

The structure of the paper is as follows. Section 2 reviews the theory of order conditions for symplectic RKN. Section 3 deals with the simplifying assumptions used later in the derivation of methods. In §4 we present a family of explicit, symplectic RKN methods. Specific order-7 methods within this family are constructed in §5. Section 6 is devoted to order-8 formulae, and §7 contains some numerical illustrations.

2. Order conditions for symplectic RKN methods. The conditions that must be imposed for an RKN method (1.2) for (1.1) to have order $\geq r$ are well known; the reader is referred to [10], whose terminology we follow. There is an order equation for each (rooted) SN-tree with r or fewer vertices (recall that (1.3) is assumed throughout). As an illustration, we have depicted in Fig. 1 the 10 SN-trees with six vertices. Furthermore, Table 1 displays the number m of SN-trees with r vertices, $1 \leq r \leq 10$. Clearly, for (1.2) to have order $\geq r$, the required number of order conditions is $\sum_{i=1}^{r} m_i$, a quantity that has also been tabulated in Table 1. Apparently, the generating function $M(z) = \sum_{i=1}^{\infty} m_i z^i$ for the sequence $\{m_r\}_{r=1}^{\infty}$ was first studied in [6].

In [6] we proved that the symplecticness conditions (1.5) act as simplifying assumptions, i.e., when (1.5) holds, not all order conditions are independent and some of them are implied by the remaining ones. For instance, for a symplectic method with order ≥ 5, the order condition associated with the tree $t_{6,2}$ is equivalent to the order condition associated with $t_{6,8}$. This comes about because $t_{6,2}$ and $t_{6,8}$ consist of the same vertices and edges and differ only in the location of the root. In other words, $t_{6,2}$ and $t_{6,8}$ are the same as unrooted SN-trees. For the same reason there is equivalence between $t_{6,3}$ and $t_{6,9}$, between $t_{6,4}$ and $t_{6,5}$, and among $t_{6,6}$, $t_{6,7}$ and $t_{6,10}$. Thus for a symplectic method with order ≥ 5 to have order 6 it is enough to impose five order conditions, one for each equivalence class $\{t_{6,1}\}$, $\{t_{6,2}, t_{6,8}\}$, $\{t_{6,3}, t_{6,9}\}$, $\{t_{6,4}, t_{6,5}\}$, $\{t_{6,6}, t_{6,7}, t_{6,10}\}$. The number m_r^* of corresponding equivalence classes for SN-trees with r vertices, $1 \leq r \leq 10$, is given in Table 1. The accumulated quantity $\sum_{i=1}^{r} m_i^*$ gives the total number of conditions for (1.2) subject to (1.5) to have order $\geq r$. A comparison of the third and fifth columns of Table 1 bears out the substantial reduction in order conditions implied by symplecticness.

3. Standard simplifying assumptions. Let us now leave aside the symplecticness conditions (1.5) and consider the well-known simplifying assumptions [10, Chap. 2, Lemma 13.14]

$$\sum_{j=1}^{s} \alpha_{ij} = \frac{\gamma_i^2}{2}, \qquad 1 \leq i \leq s, \tag{3.1}$$

that are often used in the construction of high-order RKN methods. When (1.2) satisfies (3.1), it is possible to disregard the order conditions associated with SN-trees with two or more vertices where at least one end vertex is fat. The order conditions for such trees are equivalent to order conditions for trees where all end vertices are meager. The basis

for this equivalence is illustrated in Fig. 2, where the order conditions for both trees are equivalent provided that the circle with the three branches at the bottom denotes in both cases the same arbitrary SN-tree. By iteration of the reduction in Fig. 2, the order condition for any tree with two or more vertices can be seen to be equivalent to order conditions for trees with only meager end vertices. For instance, in Fig. 1 the order condition for $t_{6,2}$ is the same as the order condition for $t_{6,1}$ and may be disregarded. For analogous reasons the order conditions for $t_{6,3}$, $t_{6,6}$, $t_{6,7}$, $t_{6,9}$ may be ignored, and this leaves five trees with six vertices to be considered. For general r we have the following result (caution: a prime does not mean differentiation!).

THEOREM 3.1. *Let m_r', $r \geq 2$ denote the number of* SN-*trees with r vertices without fat end vertices, and set $m_1' = 1$. Then*

$$m_r' = \sum_{\substack{k, j_1, j_3, \ldots, j_k \\ j_1 + 3j_3 + \cdots + kj_k = r-1}} \binom{m_2' + j_3 - 1}{j_3} \cdots \binom{m_{k-1}' + j_k - 1}{j_k}, \tag{3.2}$$

and the corresponding generating function $M'(z) = \sum_{r=1}^{\infty} m_r' z^r$ satisfies the equation

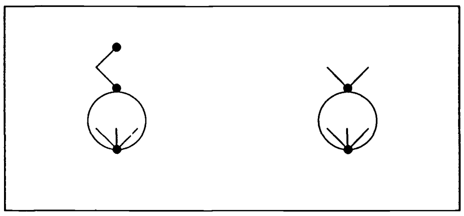

FIG. 2. *Equivalent* SN-*trees if* (3.1) *holds.*

$$M'(z) = \frac{z}{(1-z)(1-z^3)^{m'_2}\cdots(1-z^k)^{m'_{k-1}}\cdots}. \tag{3.3}$$

Proof. For $r \geq 2$ consider a special Nyström tree t with r vertices and remove its root. This gives rise to, say, j_1 graphs with one vertex, j_2 graphs with two vertices, etc. If t had no fat end vertex, then $j_2 = 0$ and for $k \geq 2$ each among the j_k graphs with k vertices consist of a meager vertex (that was a child of the root in the original t) followed by a special Nyström tree of order $k-1$ where all end vertices are meager. Hence for $k \geq 2$ the j_k graphs with k vertices can be chosen in

$$\binom{m'_{k-1} + j_k - 1}{jk}$$

different ways. This leads to (3.2). Equation (3.3) is a direct consequence of (3.2), along with the formula

$$\frac{1}{(1-z^r)^m} = \sum_{j=0}^{\infty} \binom{m+j-1}{j} z^{jr}. \qquad \square$$

The theorem makes it possible to recursively compute the m'_r. These have been tabulated in Table 1 for $1 \leq r \leq 10$. A comparison of the values of the quantities $\sum m_i^*$ and $\sum m'_i$ reveals that (1.5) and (3.1) leave roughly the same number of independent conditions to be considered. Therefore, in a sense (1.5) and (3.1) are as effective as simplifying assumptions. However, in (3.1) there are only s conditions to be imposed, whereas (1.5) comprises $s(s-1)/2$ relations (note that i and j play a symmetric role). Thus if one is not interested in Hamiltonian problems, (3.1) should clearly be preferred to (1.5). On the other hand, if to achieve symplecticness we impose (1.5), then we have reduced the number of order conditions by roughly the same amount we would have reduced that number by imposing the familiar simplifying assumptions (3.1).

The question arises of what happens when *both* (1.5) and (3.1) hold. For instance, for $r = 6, t_{6,1}, t_{6,2}, t_{6,3}$ are equivalent after (3.1) and $\{t_{6,2}, t_{6,8}\}$ and $\{t_{6,3}, t_{6,9}\}$ are equivalence classes for (1.5), so that $t_{6,1}, t_{6,2}, t_{6,3}, t_{6,8}, t_{6,9}$ all become equivalent. For the same reason, the order conditions for the remaining order-6 trees $t_{6,4}, t_{6,5}, t_{6,6}, t_{6,7}, t_{6,10}$ form a second equivalence class. Hence under (1.5) and (3.1) there are only two order conditions arising from order-6 trees. For general r let us say that two SN-trees t, t^* r vertices are S-equivalent if there exist a sequence of SN-trees $t_1, t_2, \ldots, t_k$ with $t_1 = t, t_k = t^*$, where t_i and t_{i+1}, $1 \leq i \leq k-1$, either are related as in Fig. 2 or differ only in the location of the root. Thus if (1.5) and (3.1) hold and (1.2) has order $\geq r-1$, then order conditions for t and t^* are equivalent whenever t and t^* are S-equivalent.

THEOREM 3.2. *Let $m_r'^*$ denote the number of equivalence classes of* SN-*trees of order r under the relation* S. *Then the generating function $M'^*(z) = \sum_{r=1}^{\infty} m_r'^* z^r$ is given by*

$$M'^*(z) = M'(z) - \tfrac{1}{2}z(M'(z)^2 - M'(z^2)). \tag{3.4}$$

Proof. For a given $r \geq 2$ let us consider the m_r^* free or unrooted SN-trees. There is one such tree for each equivalence class based on (1.5). Those free trees that have one or more fat end vertex can be deleted in view of (3.1). Our task is to count the free trees that remain after such a deletion. As in [6], we resort to the notion of centroid of a free tree; see, e.g., [12], [18].

The following cases are possible for the free trees that remain.

(i) There is one centroid that is a meager vertex. By chopping off the centroid we obtain two (rooted) SN-trees. These must have the same order j, in view of the definition of centroid. Hence in this case r must be odd and $j = (r-1)/2$. For r odd $r > 3$ in view of the definition of m_j', $j \geq 2$, there are

$$\binom{m_{r-1/2}' + 1}{2} = \frac{1}{2} m_{(r-1)/2}'(m_{(r-1)/2}' + 1) \tag{3.5}$$

free trees in this case. For $r = 3$ obviously there is no free tree in this case.

(ii) There are two centroids. In this situation r must be even and the centroids are adjacent; one of them is fat and the other is meager. Chop off the meager centroid to get a rooted SN-tree of order $r/2$ without fat end vertices and to get a rooted SN-tree of order $r/2-1$ without fat end vertices. Therefore, for r even, $r > 4$, there are

$$m_{r/2}' m_{r/2-1}' \tag{3.6}$$

free trees in this category. For $r = 4$ this category is empty.

(iii) There is one centroid, and this is fat. The number of equivalence classes in this case is

$$m_r' - (m_1' m_{r-2}' + \cdots + m_{r-\max(3,r/2)}' m_{\max(3,r/2)}') \tag{3.7}$$

if r is even and

$$m_r' - (m_1' m_{r-2}' + \cdots + m_{r-\max(3,(r+1)/2)}' m_{\max(3,(r+1)/2)-1}') \tag{3.8}$$

if r is odd. These formulae are proved by an argument similar to that used to obtain [12, §2.3.4.4, formula (8)].

Formula (3.4) is a consequence of (3.5)–(3.8). $\square$

The last column in Table 1 bears out the important reduction in the number of order conditions brought about by the combination of (1.5) and (3.1). In Fig. 3 we have depicted representatives of the 12 S-classes of equivalence to be considered for order ≥ 7, together with the corresponding order conditions.

	$\tau_{1,1}$	$\Phi_{1,1} \equiv \Sigma b_i - 1 = 0$
	$\tau_{2,1}$	$\Phi_{2,1} \equiv \Sigma b_i \gamma_i - 1/2 = 0$
	$\tau_{3,1}$	$\Phi_{3,1} \equiv \Sigma b_i \gamma_i^2 - 1/3 = 0$
	$\tau_{4,1}$	$\Phi_{4,1} \equiv \Sigma b_i \gamma_i^3 - 1/4 = 0$
	$\tau_{5,1}$	$\Phi_{5,1} \equiv \Sigma b_i \gamma_i^4 - 1/5 = 0$
	$\tau_{5,2}$	$\Phi_{5,2} \equiv \Sigma b_i \gamma_i \alpha_{ij} \gamma_j - 1/30 = 0$
	$\tau_{6,1}$	$\Phi_{6,1} \equiv \Sigma b_i \gamma_i^5 - 1/6 = 0$
	$\tau_{6,2}$	$\Phi_{6,2} \equiv \Sigma b_i \gamma_i^2 \alpha_{ij} \gamma_j - 1/36 = 0$
	$\tau_{7,1}$	$\Phi_{7,1} \equiv \Sigma b_i \gamma_i^6 - 1/7 = 0$
	$\tau_{7,2}$	$\Phi_{7,2} \equiv \Sigma b_i \gamma_i^3 \alpha_{ij} \gamma_j - 1/42 = 0$
	$\tau_{7,3}$	$\Phi_{7,3} \equiv \Sigma b_i \gamma_i^2 \alpha_{ij} \gamma_j^2 - 1/84 = 0$
	$\tau_{7,4}$	$\Phi_{7,4} \equiv \Sigma b_i \gamma_i \alpha_{ij} \alpha_{jk} \gamma_k - 1/840 = 0$

FIG. 3. *Order conditions for order* ≥ 7 *under* (1.5) *and* (3.1).

4. Family of explicit, symplectic RKN methods. Explicit symplectic RKN methods are of the form [14]

$$
\text{(4.1)} \qquad
\begin{array}{c|cccccc}
\gamma_1 & 0 & 0 & \cdots & 0 & 0 \\
\gamma_2 & b_1(\gamma_2-\gamma_1) & 0 & \cdots & 0 & 0 \\
\vdots & \vdots & \vdots & \iddots & \vdots & \vdots \\
\gamma_{s-1} & b_1(\gamma_{s-1}-\gamma_1) & b_2(\gamma_{s-1}-\gamma_2) & \cdots & 0 & 0 \\
\gamma_s & b_1(\gamma_s-\gamma_1) & b_2(\gamma_s-\gamma_2) & \cdots & b_{s-1}(\gamma_s-\gamma_{s-1}) & 0 \\
\hline
 & b_1 & b_2 & \cdots & b_{s-1} & b_s \\
\hline
 & \beta_1 & \beta_2 & \cdots & \beta_{s-1} & \beta_s
\end{array}
$$

subject to (1.3). Thus with s stages there are $2s$ free parameters. For $s \geq 2$ we consider the subclass of methods given by

$$\gamma_1 = 0, \qquad \gamma_s = 1 \tag{4.2}$$

and

$$b_1 = \gamma_2/2; \quad b_i = (\gamma_{i+1} - \gamma_{i-1})/2, \quad 2 \leq i \leq s-1; \quad b_s = (1 - \gamma_{s-1})/2. \tag{4.3}$$

Note that (4.2) and (4.3) leave only $s - 2$ free parameters $\gamma_2, \dots, \gamma_{s-1}$ in (4.1). For arbitrarily fixed values of $\gamma_2, \dots, \gamma_{s-1}$, the following properties are easily verified.

(i) Method (4.1)–(4.3) has the FSAL property: the sth stage of the current step coincides with the first stage of the next step. Thus (4.1)–(4.3) effectively require $s - 1$ evaluations per step.

(ii) Method (4.1)–(4.3) satisfies the standard simplifying assumptions (3.1).

(iii) Method (4.1)–(4.3) has order ≥ 2, i.e., the conditions $\sum b_i = 1$, $\sum b_i \gamma_i = \frac{1}{2}$ are implied by the structure of tableau (4.1) and relations (4.2) and (4.3).

It is also useful to observe that a step of length h with (4.1)–(4.3) is a concatenation of $s - 1$ steps of successive lengths $(\gamma_2 - \gamma_1)h, (\gamma_3 - \gamma_2)h, \dots, (\gamma_s - \gamma_{s-1})h$ with the simple method

$$\begin{array}{c|cc} 0 & 0 & 0 \\ 1 & \frac{1}{2} & 0 \\ \hline & \frac{1}{2} & \frac{1}{2} \\ \hline & \frac{1}{2} & 0 \end{array} \tag{4.4}$$

that results after setting $s = 2$ in (4.1)–(4.3). Let us be more precise. Let ψ_h represent the transformation in $(\dot{\mathbf{y}}, \mathbf{y})$-space that effects a step of length h with (4.1)–(4.3), i.e., $(\dot{\mathbf{y}}_{n+1}, \mathbf{y}_{n+1}) = \psi_h(\dot{\mathbf{y}}_n, \mathbf{y}_n)$ if $(\dot{\mathbf{y}}_{n+1}, \mathbf{y}_{n+1})$ is the result of a step of length h from the preceding approximation $(\dot{\mathbf{y}}_n, \mathbf{y}_n)$. Let $\psi_h^{[2]}$ represent the corresponding transformation for (4.4). Then

$$\psi_h = \psi^{[2]}_{(\gamma_s - \gamma_{s-1})h} \cdots \psi^{[2]}_{(\gamma_2 - \gamma_1)h}. \tag{4.5}$$

This formula makes it easy to find the adjoint method ψ_h^* of ψ_h. Recall that by definition [10] ψ_h^* is the method such that ψ^*_{-h} inverts ψ_h, i.e., a step of length h with (4.1)–(4.3) followed by a step of length $-h$ with the adjoint method of (4.1)–(4.3) leaves the numerical solution unchanged. From (4.5)

$$\psi_h^* = [\psi^{[2]}_{(\gamma_s - \gamma_{s-1})h} \cdots \psi^{[2]}_{(\gamma_2 - \gamma_1)h}]^* = \psi^{[2]*}_{(\gamma_2 - \gamma_1)h} \cdots \psi^{[2]*}_{(\gamma_s - \gamma_{s-1})h},$$

but (4.4) is easily seen to be selfadjoint and hence

$$\psi_h^* = \psi^{[2]}_{(\gamma_2 - \gamma_1)h} \cdots \psi^{[2]}_{(\gamma_s - \gamma_{s-1})h}.$$

Comparison with (4.5) reveals that ψ_h^* is the method of the family (4.1)–(4.3) based on the abscissae $\gamma_2^*, \dots, \gamma_{s-1}^*$ defined by $\gamma_i^* = 1 - \gamma_{s+1-i}$.

5. Constructing seventh-order methods. In this section we describe our experience in constructing order-7 methods of the form (4.1)–(4.3). Since both (1.5) and (3.1) hold, the last column in Table 1 shows that there are 12 order conditions to be imposed (see Fig. 3). However, the order conditions $\Phi_{1,1} = 0$, $\Phi_{2,1} = 0$ that guarantee order ≥ 2 are automatically satisfied, so that the choice of the $s - 2$ free parameters $\gamma_2, \dots, \gamma_{s-1}$ should be directed toward enforcing the 10 remaining conditions

$$\Phi_{3,1} = 0, \quad \Phi_{4,1} = 0, \dots, \quad \Phi_{7,4} = 0. \tag{5.1}$$

This suggests $s \geq 12$. The choice $s = 12$ leaves no freedom to tune the formula, and we set $s = 13$. We therefore undertook the task of numerically solving the nonlinear system (5.1) comprising 10 equations in the 11 unknowns $\gamma_2, \dots, \gamma_{12}$. The solutions form curves in $\mathcal{R}^{11}$ that can be followed by continuation once a particular solution has been found.

Finding initial solutions of (5.1) to start the continuation procedure was not an easy task. After many unsuccessful attempts the following strategy was adopted. We began by considering the function

$$\lambda = \Phi_{3,1}^2 + \Phi_{4,1}^2 + \Phi_{5,1}^2 + \Phi_{5,2}^2 + \Phi_{6,1}^2$$

(see Fig. 3) of the variables $\gamma_2, \dots, \gamma_{12}$. We minimized λ subject to bounds $-5 \leq \gamma_i \leq 5$, $2 \leq i \leq 12$, and to the equality constraints $\Phi_{6,2} = \Phi_{7,1} = \Phi_{7,2} = \Phi_{7,3} = \Phi_{7,4} = 0$. To this end the NAG routine E04UCF was used with the starting values for $\gamma_2, \dots, \gamma_{12}$ generated randomly with the NAG routine G05DAF. Clearly, a solution of (5.1) is found whenever the objective function γ is successfully brought to its global minimum $\lambda = 0$ by the minimization routine.

For the continuation procedure we used one of the unknowns $\gamma_2, \dots, \gamma_{12}$ as a continuation parameter. The particular unknown to be used at each step of the continuation procedure was determined as follows. Gaussian elimination with column pivoting was performed in the 10×11 Jacobian matrix of the system (5.1) evaluated at the current value of the solution. The parameter was chosen to be the unknown that was not used as a pivot, i.e., the unknown whose column would be in the 11th place if the columns were actually interchanged to carry out the pivoting. In a sense this identifies the unknown that is (locally in the solution curve) least constrained by (5.1) and that therefore is (locally) best suited for parametrizing the solutions of the system. Once the index $i_0, 2 \leq i_0 \leq 12$, of the unknown to be used as a parameter has been determined, we solved by Newton's method the 11×11 system given by (5.1), along with the equation $\gamma_{i_0} = \gamma_{i_0}^0 + \delta$, where $\gamma_{i_0}^0$ is the value of γ_{i_0} at the current solution and $\delta = 0.01$ denotes the increment in the parameter.

The coefficients of a specific method constructed by following this methodology are presented later in the paper.

6. Eighth-order methods. Once a method ψ_h of the class (4.1)–(4.3) with order $r = 7$ and $s = 13$ has been obtained, it is possible to use it so as to have eighth-order symplectic integration. In fact, it is enough to consider the method [16]

$$\bar{\psi}_h = \psi_{h/2}^* \psi_{h/2}. \tag{6.1}$$

A step of length h with the new method $\bar{\psi}_h$ consists of a step of length $h/2$ with the given order-7 formula followed by a step of length $h/2$ with the adjoint formula. The method $\bar{\psi}_h$ is symplectic as obtained by concatenating symplectic formulae and obviously has order ≥ 7. Furthermore, $\bar{\psi}_h$ is clearly selfadjoint, so that it has even order. Hence $\bar{\psi}_h$

is an eighth-order method. Note that $\bar{\psi}_h$ uses 24 evaluations per step as ψ_h and ψ_h^* are FSAL methods with 13 stages. The ratio number of stages per order is 26/8 versus the minimum 17/8 suggested by Table 1, but the situation is not bad at all. The approximation obtained after taking the first half-step $\psi_{h/2}$ is also globally accurate of the eighth order; the first half-step starts from an approximation with (global) error $O(h^8)$ and introduces a local error $O(h^8)$, so that the global error after the first half-step is $O(h^8)$. Hence output with global accuracy $O(h^8)$ is available after every 12 function evaluations. On the other hand, having 24 evaluations per step is certainly a drawback if variable step sizes are used: if a step is rejected, too many evaluations are wasted. Fortunately, symplectic integration should be used with constant step sizes [4], [5], [7] and so we feel that to find eighth-order formulae it is better to resort to the technique in (6.1) than to look directly at methods of the family (4.1)–(4.3).

The parameter in the continuation procedure used to find the seventh-order method ψ_h is chosen for the method $\bar{\psi}_h$ in (6.1) to have small error constants (see [8]). The $\dot{\mathbf{y}}$-truncation error and $\mathbf{y}$-truncation error of an eighth-order RKN method such as $\bar{\psi}_h$ have, respectively, the forms

$$h^9 \sum_j \Phi'_{9,j} \mathbf{F}_{9,j} + O(h^{10}) \tag{6.2}$$

and

$$h^9 \sum_k \Phi_{9,k} \mathbf{F}_{8,k} + O(h^{10}), \tag{6.3}$$

where $\mathbf{F}_{8,k}$ and $\mathbf{F}_{9,j}$ are elementary differentials that depend only on the system (1.1) being integrated and $\Phi'_{9,j}$, $\Phi_{9,k}$ are polynomials in the method coefficients α_{ij}, γ_i, β_i, b_i. In (6.2) the sum is extended to the 72 SN-trees of order 9, and in (6.3) the sum is extended to the 36 SN-trees of order 8 (see Table 1). (Note that in (6.2) and (6.3) the coefficients that are featured are those of the order-8 method, whereas in (5.1) we deal with the coefficients of the order-7 method. Also, in (6.2) and (6.3) all SN-trees are considered, whereas in (5.1) we took only one SN-tree per S-class of equivalence.) We try to minimize the Euclidean norm N of the vector with $72+36$ components $\Phi'_{9,j}$, $\Phi_{9,k}$. To this end, at each step of the continuation procedure described in §5 we evaluate N for the eighth-order method obtained $\bar{\psi}_h$, by means of (6.1), from the current seventh-order method ψ_h. The following coefficients identify the formula ψ_h that, among those we found, leads to the $\bar{\psi}_h$ with the lowest $N (N = 1.6 \times 10^{-5})$:

$$\gamma_2 = 0.60715821186110352503,$$

$$\gamma_3 = 0.96907291059136392378,$$

$$\gamma_4 = -0.10958316365513620399,$$

$$\gamma_5 = 0.05604981994113413605,$$

$$\gamma_6 = 1.30886529918631234010,$$

$$\gamma_7 = -0.11642101198009154794,$$

$$\gamma_8 = -0.29931245499473964831,$$

$$\gamma_9 = -0.16586962790248628655, \tag{6.4}$$

$$\gamma_{10} = 1.22007054181677755238,$$

$$\gamma_{11} = 0.20549254689579093228,$$

$$\gamma_{12} = 0.86890893813102759275.$$

7. Numerical results. Although the numerical experiments presented in this section provide information on the advantages and disadvantages of symplectic integrators, they are limited in scope. More extensive testing is required before definite conclusions can be put forward.

We consider three explicit, symplectic methods, used with constant step sizes:

(i) S8: order 8, 26 stages, 24 evaluations per step, symplectic RKN formula associated with (6.4) by means as of (6.1). This has error constant $N = 1.6 \times 10^{-5}$.

(ii) Y8: order 8, 15 evaluations per step, symplectic method given in [20, Table 2, column D]. This is the order-8 method with the lowest value of N among those constructed in [20] and has $N = 4.4 \times 10^{-3}$.

(iii) S4: order 4, five stages, four evaluations per step, symplectic RKN formula constructed in [7].

As a reference standard (i.e., nonsymplectic) method we consider the following:

(iv) D8: order 8, nine stages, eight evaluations per step, RKN formula by Dormand, El-Mikkawy, and Prince [9, Table 1]. This has $N = 8.3 \times 10^{-7}$. An embedded order-6 method presented in [9] was used to estimate the error in a variable-step implementation. There are some printing errors in the method coefficients in the original [9], and the reader should see the corresponding corrigendum.

The values of N given above cannot be directly compared because the work per step is different for different methods. More informative error coefficient values can be obtained by assuming that a method with q function evaluations per step uses a step size of qh. If the method is of order p, this multiplies the values of N by q^p. For S8, Y8, and D8 the normalized values of the error coefficient turn out to be 1.8×10^6, 1.1×10^7, and 14, respectively. On raising these values to the power $-1/p = -1/8$, we obtain a crude measure of the efficiency of the various methods. The result is 0.16 for S8, 0.13 for Y8, and 0.71 for D8. The formulae S8 and Y8 are very demanding in function evaluations and are hence inefficient when compared with the nonsymplectic formula D8. This inefficiency is due to the $O(s^2)$ number of degrees of freedom in the RKN tableau that are used to enforce the symplecticness conditions (1.5).

Our first test problem was used in [7]. It corresponds to the Newton potential $V(q^1, q^2) = -1/\|\mathbf{q}\|$ (Kepler's problem) with initial condition

$$p^1 = 0, \quad p^2 - \sqrt{\frac{1+e}{1-e}}, \quad q^1 = 1 - e, \quad q^2 = 0.$$

Here e is the eccentricity of the orbit, $0 \leq e < 1$, that in the experiments to be reported is chosen to be $e = 0.5$. (The value of e does not significantly influence the outcome of the experiments.) The solution is 2π-periodic. Errors are measured in the Euclidean norm of $\mathcal{R}^4$.

Figure 4 corresponds to a final integration time $T = 810 \times 2\pi$ and depicts error at $t = T$ against number of function evaluations. The following runs are presented:

(i) S8, with step sizes $h = 2\pi/32, 2\pi/64, 2\pi/128$ (asterisks joined by a solid line).

(ii) Y8, with step sizes $h = 2\pi/64, 2\pi/128, 2\pi/256$ (plus signs joined by a dotted line).

(iii) S4, with step sizes $h = 2\pi/128, 2\pi/256, 2\pi/512, 2\pi/1024, 2\pi/2048$ ($\times$ joined by a dashed line).

(iv) D8, with absolute error tolerances $10^{-7}, 10^{-8}, 10^{-9}, 10^{-10}, 10^{-11}, 10^{-12}$ (circles joined by dash-dot line).

Clearly, S8 is more efficient than Y8. Yoshida's method Y8 is more efficient than the lower-order method S4 when small errors are required. Otherwise, S4 is more efficient than Y8. However, the nonsymplectic method S8 is clearly more efficient than any of the symplectic formulae tested.

Figure 5 is similar to Fig. 4, but now the final time $T = 21870 \times 2\pi$ is longer. The runs depicted are as follows:

(i) S8, with step sizes $h = 2\pi/32, 2\pi/64, 2\pi/128$.

(ii) Y8, with step sizes $h = 2\pi/128, 2\pi/256$.

(iii) S4, with step sizes $h = 2\pi/256, 2\pi/512, 2\pi/1024, 2\pi/2048$.

(iv) D8, with absolute error tolerances $10^{-9}, 10^{-10}, 10^{-11}, 10^{-12}$.

The conclusions as to the relative efficiency of the methods are the same as above. However, the advantage of D8 is not so marked as before. This is due to the better error propagation properties of symplectic integrators [7]. In Fig. 6 we have depicted error against t (measured in periods) for S8 ($h = 2\pi/32$), Y8 ($h = 2\pi/128$), S4 ($h = 2\pi/256$), and D8 (TOL $= 10^{-9}$). Note that in this figure different methods are working differently; only the slopes in the different lines should be compared. In the symplectic methods the error grows linearly with t, whereas in the nonsymplectic method D8 the growth is as t^2, as is proved rigorously in [7]. Therefore, as the final integration time T increases, S8 and Y8 improve their efficiency relative to D8. However, the crossover point T for which S8 becomes more efficient than D8 is too large: perhaps T corresponds to millions of periods of the planet whose motion is being integrated.

From this experiment we conclude that if accurate solutions are needed, even for long integration times, a high-order standard code may easily be a better choice than a symplectic algorithm. For high-order RKN integrators too many ($O(s^2)$) degrees of freedom in the tableau are sacrificed to achieve symplecticness, and this sacrifice makes the formula very expensive relative to standard RKN methods. This should be compared with the conclusions in [7], where it is shown that for Kepler's problem fourth-order symplectic integrators are more efficient than fourth-order variable-step standard codes. In [7] the work per step of the fourth-order symplectic algorithm is $\frac{4}{3}$ of the work per step of the reference standard fourth-order algorithm and the advantages of symplecticness

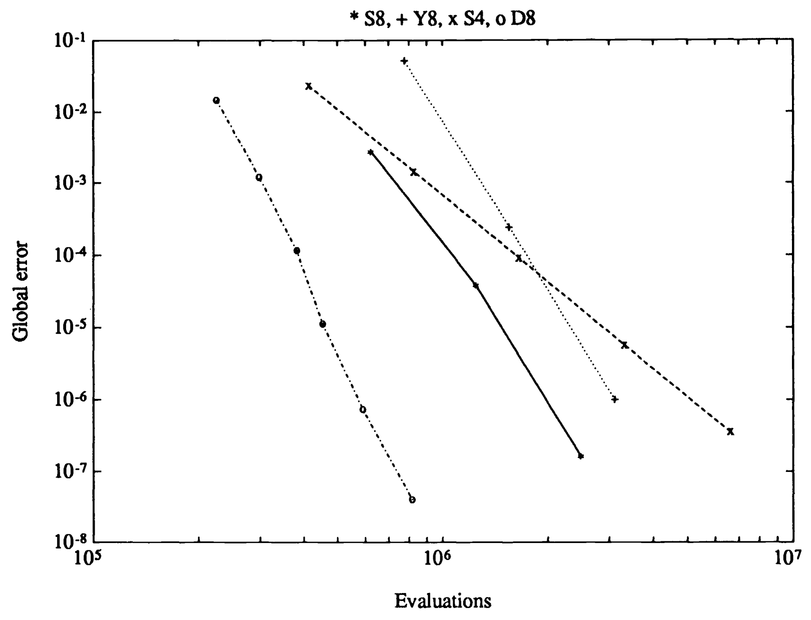

FIG. 4. *Efficiency plot at* $T = 810 \times 2\pi$.

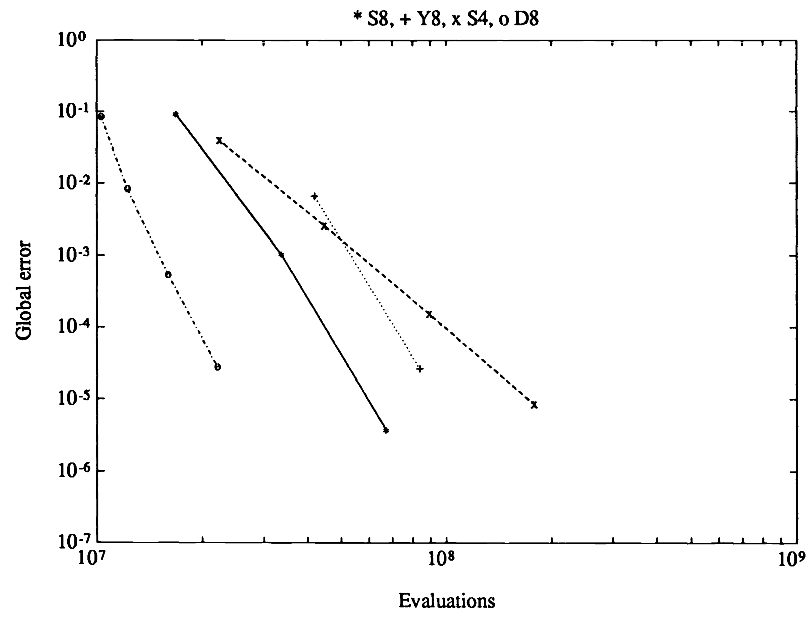

FIG. 5. *Efficiency plot at* $T = 21870 \times 2\pi$.

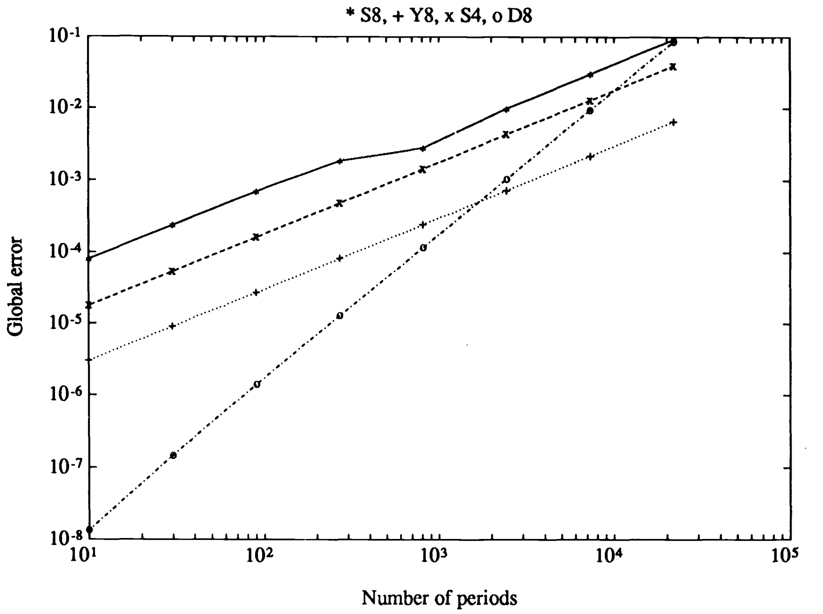

FIG. 6. *Error against t.*

make up for the increased cost per step. Here the work per step in S8 is three times the work per step in D8.

The second test problem is taken from Herbst and Ablowitz [11]. It originates from the sine-Gordon equation

$$u_{tt} - u_{xx} + \sin u = 0, \qquad 0 < x < L = 2\sqrt{2}\pi, \quad t > 0. \tag{7.1}$$

subject to periodic boundary conditions and to the initial conditions

$$u(x,0) = \pi + 0.1\cos(2\pi x/L), \qquad u_t(x,0) = 0. \tag{7.2}$$

Equation (7.1) may be thought of as describing the motion of a family of pendula. At each value of $x, 0 < x < L$, we have one pendulum. The term u_{xx} provides coupling between the motions of neighboring pendula. It represents a force that tries to keep a common value of the angle u for all the pendula. From the initial condition (7.2) we see that all pendula are initially left near the unstable equilibrium $u = \pi$. The pendula in $0 < x < L/4$ or $3L/4 < x < L$ start *above* the value $u = \pi$ and hence will increase u in order to approach the stable equilibrium at $u = 2\pi$. The pendula in $L/4 < x < 3L/4$ start *below* the value $u = \pi$ and will decrease u to approach the stable equilibrium at $u = 0$. This causes the term u_{xx} to become important. The effect of the restoring force is that the pendula are prevented from reaching the lowest $u = 2\pi$ or $u = 0$ positions and, rather, start going upward back to the initial positions, leading to a periodic motion. The solid curve in Fig. 7 represents u as a function of $t, 0 < t < 16L$, for the pendulum at $x = L/2$.

As in [11], (7.1) is discretized in space by the standard pseudospectral technique, with a mesh length $\Delta x = L/32$. This leads to a Hamiltonian system of the form (1.1),

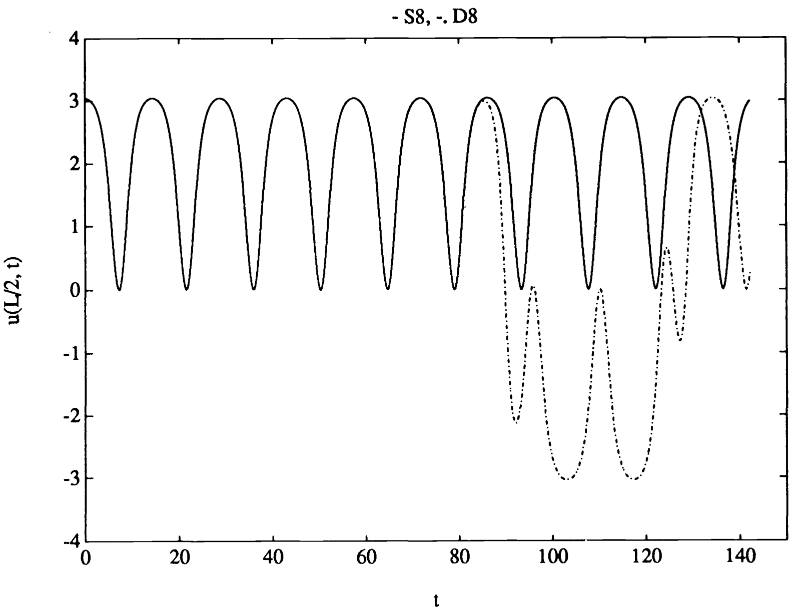

FIG. 7. *$u(L/2,t)$ against t.*

where the dependent variables $\mathbf{y}$ are the 32 discrete Fourier coefficients of the solution. This system of ordinary differential equations was integrated with the methods S8, Y8, S4, and D8 on $0 < t < 16L \approx 142.17$.

The standard method D8 was run with absolute error tolerances in the range 10^{-8} to 10^{-13}. Smaller tolerances were not tried because we felt that they would be too close to the size of the round-off error associated with the evaluation of the force $\mathbf{f}$ (this requires a couple of discrete Fourier transforms). None of the values of TOL we tried led to a successful integration, and D8 was not able to come up with the right qualitative behavior of the solution. The dash-dot line in Fig. 7 corresponds to TOL $= 10^{-13}$, $x = L/2$; the computed solution is completely wrong for $t > 80$. For this value of the tolerance the D8 code uses 32,810 function evaluations.

On the other hand, the symplectic algorithms S8, Y8, S4 were all able to identify the right qualitative behavior when run with suitable values of the step length h. With $h = \frac{1}{4}$ method S8 cannot faithfully describe the behavior of the solution up to the final time $t = 16L$. Halving the value of h to $h = \frac{1}{8}$ (27,312 evaluations) leads to a successful integration (see the curve in Fig. 7). For Y8, h has to be reduced down to $h = \frac{1}{16}$ (34,125 evaluations) and S4 requires $h = \frac{1}{32}$ (18,200 evaluations). Hence S4 was the most efficient, followed by S8 and Y8. Additional experiments show that if the final integration time is increased, further reduction of h is necessary to attain the correct qualitative behavior.

Following a referee's suggestion, we also integrated (7.1) and (7.2) in time by non-symplectic methods implemented with constant step sizes. The classical fourth-order Runge–Kutta method required $h = \frac{1}{64}$. This implies 36,400 function evaluations, which is more than any of the symplectic methods we tried. On the other hand, the order-8 formula of Dormand, El-Mikkawy, and Prince, when implemented with constant step sizes, was found to be able to identify the correct qualitative behavior. However, this needed $h = \frac{1}{64}$ and 72,800 function evaluations, i.e., more than twice as much computational effort, as the least efficient symplectic formula Y8.

Acknowledgments. The authors are grateful to J. de Frutos (Valladolid) for his help in programming the pseudospectral method and to R. Fletcher (Dundee) for his suggestions in connection with the continuation procedure. We also thank J. Dormand (Teeside), who kindly provided us with several of his RKN codes.

A MAPPING ALGORITHM FOR PARALLEL SPARSE CHOLESKY FACTORIZATION*

ALEX POTHEN[†] AND CHUNGUANG SUN[‡]

Abstract. A task-to-processor mapping algorithm is described for computing the parallel multifrontal Cholesky factorization of irregular sparse problems on distributed-memory multiprocessors. The performance of the mapping algorithm is compared with the only general mapping algorithm previously reported. Using this mapping, the distributed multifrontal algorithm is nearly as efficient on a collection of problems with irregular sparsity structure as it is for the regular grid problems.

Key words. sparse Cholesky factorization, clique tree, distributed-memory multiprocessor, mapping algorithms, multifrontal method, parallel computing

AMS subject classifications. 65F50, 65F05

1. Introduction. Several implementations of parallel algorithms for sparse Cholesky factorization on distributed-memory multiprocessors have been described in the literature [1]–[3], [6], [8], [12]. Extensive discussions and bibliographies of previous work may be found in Liu's recent survey [11] of the multifrontal method, and in the Heath, Ng, and Peyton survey [9] of parallel sparse matrix factorization algorithms. Geist and Ng [4] have discussed a bin-pack mapping strategy for the fan-out algorithm suitable for mapping irregular problems. However, performance results for distributed sparse Cholesky factorization algorithms have been limited to regular model problems—e.g., the $n \times n$ nine-point grid ordered by optimal nested dissection [5] and a slightly less regular L-shaped problem. Most practical problems are far more irregular in structure than these model problems, and several algorithmic issues need to be addressed to obtain good performance on such problems. One important issue here is the mapping of tasks to processors to achieve load balance and low communication costs.

In this paper we describe a new task-to-processor mapping algorithm suitable for irregular sparse problems and apply it to the computation of a distributed multifrontal factorization. We compare the performance of the mapping algorithm with an adaptation of the sole previously reported general mapping algorithm—the bin-pack mapping algorithm [4]. We have experimented with a collection of problems with irregular sparsity structure and have obtained efficiencies comparable to those for the regular grid problems.

A multifrontal factorization is computed as a sequence of partial factorizations of a set of dense submatrices. We have chosen these dense submatrices to correspond to the maximal cliques from a clique tree representation of the Cholesky factor. Discussions of clique trees in the context of sparse matrix algorithms may be found in [10] and elsewhere. We have found the clique tree to be a convenient data structure for organizing the distributed multifrontal factorization. It also affords clear and concise descriptions and implementations of the distributed assembly and factorization algorithms. A detailed description of these algorithms is provided in [14], [16]. We denote the number of maximal cliques in the clique tree by m, the size of the clique tree (the sum of the number of vertices in the maximal cliques) by q, and the number of processors by ρ.

2. Mapping schemes. The *subtree-to-subcube mapping* scheme was proposed by George, Liu, and Ng [7] for the model grid problem. This scheme is only effective for problems with balanced tree structure and almost balanced workload distribution such as the model problem ordered by optimal nested dissection. Gilbert and Schreiber [8] use a two-dimensional bin-pack mapping strategy to allocate processors for factoring the frontal matrices at a stage in their CM-2 multifrontal factorization, and Ashcraft (personal communication) has considered a generalization of the subtree-to-subcube mapping scheme within his domain-separator model of Cholesky factorization.

Geist and Ng [4] have employed a bin-pack mapping scheme to map tasks associated with the elimination tree within the fan-out algorithm. We have adapted their scheme to map tasks associated with the clique tree for multifrontal factorization. In this scheme, the clique tree is explored beginning at the root until at least ρ vertex-disjoint subtrees are obtained. The subtrees are then packed into ρ bins using the *first-fit-decreasing* bin-packing heuristic. (In the heuristic, subtrees are processed in decreasing order of workloads, and a subtree is packed into the currently lightest bin.) The weight imbalance among the bins, α, is the ratio of the lightest bin to the heaviest bin. If α is larger than or equal to a user-specified tolerance τ, then the bin-pack mapping process terminates. Otherwise, the heaviest subtree in a bin is explored from its root and split further into subtrees, the ρ bins are repacked, and the ratio α recalculated and compared with τ. This process is repeated until $\alpha \geq \tau$, or the largest subtree cannot be split any further; in the latter case, we accept the imbalance among the bins.

The subtrees in a bin are assigned to a single processor; the cliques that lie on the path from the roots of these subtrees to the root of the clique tree remain to be mapped. We call such cliques *dominating cliques*. If a dominating clique K dominates a set of subtrees $T_1, \ldots, T_p$, then K is mapped to the subset of processors which compute these subtrees. This differs from the Geist–Ng scheme which wrap-maps the dominating cliques among all the processors. The latter scheme causes high communication costs and idle-waits in the factorization. The mapping algorithm can be implemented in $\mathcal{O}(m^2 \log m + q)$ time.

The *proportional mapping algorithm* may be viewed as a generalization of the subtree-to-subcube mapping in which both the structure and the workload distribution of the tree are taken into consideration. A variant of this mapping has been considered in the context of distributed sparse orthogonal factorization and the fan-in and fan-out algorithms [15]. The algorithm is described in Fig. 1. The variable $tree(K)$ denotes the set of subtrees rooted at the child cliques of a clique K, $proc(T)$ the set of processors allocated to a subtree T, and $w(T)$ the workload associated with a subtree T.

Many details are important in obtaining a correct and effective proportional mapping algorithm since rounding to integral numbers of processors causes several problems. The algorithm processes the subtrees of a clique in decreasing order of their workloads to avoid unnecessary communication. Rounding may cause unallocated processors to remain after an initial mapping of processors to the subtrees of a clique; it also may

```
prop_map($\widehat{T}$: clique tree, $P$: set of processors)
$S := P, \rho := |P|$;
if ($\rho = 1$) then
    map the subtree $\widehat{T}$ to the only processor in $P$;
else
    let $K$ be the root of $\widehat{T}$;   wrap-map the columns of $K$ to processors in $P$;
    if $K$ is a leaf then return;
    {process the subtrees of $K$ one by one}
    $w := \sum_{T \in tree(K)} w(T)$;
    while not all subtrees in $tree(K)$ are processed do
        choose a heaviest subtree $T$ in $tree(K)$ not yet processed;
        $k = \lfloor (w(T)/w) * \rho + 0.5 \rfloor$;
        if $k = 0$ or $S = \emptyset$ then
            find a processor $p \in P$ with the least workload;   $proc(T) := \{p\}$;
        else
            if $k > |S|$ then $k := |S|$;
            $proc(T) :=$ a set of $k$ processors in $S$;   $S := S \setminus proc(T)$;
        end if
    end while
    {allocate processors which may be left unallocated}
    while $S \neq \emptyset$ do
        let $p$ be a processor in $S$;   $S := S \setminus \{p\}$;
        find a subtree $T$ in $tree(K)$ such that
        processors computing $T$ have the highest workload;
        $proc(T) := proc(T) \cup \{p\}$;
    end while
    {map the subtrees of $K$ recursively}
    for each subtree $T$ in $tree(K)$ do prop_map($T, proc(T)$);
end if
```

FIG. 1. *The proportional mapping algorithm.*

cause unmapped subtrees to remain after all processors have been allocated in an initial mapping. Our algorithm deals with all these issues; its time complexity is $O(m \log m + q)$.

3. Computational results. The performance of the distributed multifrontal algorithm was tested on the model problem and on a set of problems chosen from the Harwell–Boeing and the NASA Ames collections. Preprocessing steps were done sequentially. All programs were written in C, and run on an Intel iPSC/2 multiprocessor using double precision arithmetic. Version 3.2 of the the iPSC/2 UNIX operating system was employed, and the default compiler optimization was used.

The characteristics of the test problems are shown in Table 1. In this table, n is the order of a matrix, $|A|$ ($|L|$) is the number of nonzeros in the lower triangle of the matrix A (L), m is the number of maximal cliques in the clique tree, and "op_count" is the total number of flops.

For each problem, tolerances of 40%, 60%, and 80% have been used to test the bin-pack mapping algorithm. The model nine-point grid problem is ordered by optimal nested dissection (ND), and all other problems are ordered by the multiple minimum degree (MMD) ordering. Running times are shown in Table 2; times for the subtree-to-subcube mapping for irregular problems are not shown because it performs much worse than the other mappings.

	32	16.62	25.65	35.03	36.23	

The results clearly show that proportional mapping performs better than the bin-pack mapping as the number of processors increases. Furthermore, the performance of the bin-pack mapping is sensitive to the tolerance used, and one value of the tolerance is not uniformly better than another over varying the number of processors for a given problem. This is a serious drawback since it is difficult to determine an appropriate tolerance a priori.

For the NASA4704 problem when 32 processors are used the efficiency is 0.60; on the other hand, for BCSPWR10 the efficiency is only 0.15 when 32 processors are used. These results are a consequence of two facts. First, on the iPSC/2 the cost of communicating data is high relative to the cost of floating point work. Second, the number of elements communicated is asymptotically a lower-order term than the number of floating point operations performed. Hence efficiencies are high only when there is a sufficient amount of arithmetic work per processor for the arithmetic costs to dominate the communication and data structure overhead costs.

Another factor that influences efficiency is the balance of the clique tree. Well-balanced clique trees are mapped more efficiently since, for such trees, rounding to integral numbers of processors creates less load imbalance. Optimal nested dissection of the model problem creates well-balanced trees, while the MMD ordering of the less regular problems leads to less balanced trees. The effect of recent orderings with low fill and good balance such as spectral nested dissection [13] remains to be evaluated.

BLOCK-CYCLIC DENSE LINEAR ALGEBRA*

WOODY LICHTENSTEIN† AND S. LENNART JOHNSSON†‡

Abstract. Block-cyclic order elimination algorithms for LU and QR factorization and solve routines are described for distributed memory architectures with processing nodes configured as two-dimensional arrays of arbitrary shape. The cyclic-order elimination, together with a consecutive data allocation, yields good load balance for both the factorization and solution phases for the solution of dense systems of equations by LU and QR decomposition. Blocking may offer a substantial performance enhancement on architectures for which the level-2 or level-3 BLAS (basic linear algebra subroutines) are ideal for operations local to a node. High-rank updates local to a node may have a performance that is a factor of four or more higher than a rank-1 update.

This paper shows that in many parallel implementations, the $O(N^2)$ work in the factorization may be of the same significance as the $O(N^3)$ work, even for large matrices. The $O(N^2)$ work is poorly load balanced in two-dimensional nodal arrays, which are shown to be optimal with respect to communication for consecutive data allocation, block-cyclic order elimination, and a simple, but fairly general, communications model.

In this Connection Machine system CM-200 implementation, the peak performance for LU factorization is about 9.4 Gflops/s in 64-bit precision and 16 Gflops/s in 32-bit precision. Blocking offers an overall performance enhancement of an approximate factor of two. The broadcast-and-reduce operations fully utilize the bandwidth available in the Boolean cube network interconnecting the nodes along each axis of the two-dimensional nodal array embedded in the cube network.

1. Introduction.

The main contributions of this paper are: (i) empirical evidence that a block-cyclic order elimination can be used effectively on distributed memory architectures to achieve load balance as an alternative to block-cyclic data allocation; (ii) a discussion of the issues that arise when the block-cyclic orderings of rows and columns are different, which is the typical case when the number of processing nodes is not a square; and (iii) a proof that within a wide class of regular data layouts, two-dimensional nodal arrays with consecutive (block) data allocation and cyclic elimination order are optimal for elimination-based dense linear algebra routines. This last result applies to communication systems in which the communication time is a function only of the number of elements entering or leaving a node. The effectiveness of the block-cyclic order elimination demonstrates the utility of equivalencing block-distributed and block-cyclic distributed arrays in Fortran D [7] and Vienna Fortran [31].

The programs described in this article were written for an implementation of the Connection Machine Scientific Software Library (CMSSL) [27] on the Connection Machine system CM-200 [28]. This system is a distributed memory computer with up to 2048 nodes. Each node has hardware support for floating-point addition and multiplication in 32-bit and 64-bit precision. Each node has up to 4 Mbytes of local memory, a single 32-bit wide data path between the floating-point processor and the local memory, and separate communication circuitry. Data paths internal to the floating-point unit are 64 bits wide. The processing units are interconnected as an 11-dimensional Boolean cube, with a pair of channels between adjacent nodes. Data may be exchanged on all 22 (11 × 2) channels of every node concurrently. This property is exploited for data copying (spread) and data summation (reduction) in the algorithms described below.

We consider LU factorization, QR factorization (with and without partial pivoting), and solution routines for both LU factorization (triangular system solvers) and QR factorization. Our triangular solver encompasses both the routine _TRSV in the level-2 BLAS (basic linear algebra subroutines) [6] and the routine _TRSM in the level-3 BLAS [4], [5]. It is easy to show that a cyclic data allocation with consecutive order elimination, or a consecutive allocation and a cyclic order elimination, yields a factor of three higher processor utilization on two-dimensional nodal arrays than consecutive allocation and consecutive elimination order [17]. Coleman [22], [23] reports some results from an implementation of triangular system solvers using consecutive order elimination and cyclic data allocation on multiprocessors with up to 128 nodes. Van de Geijn [30] uses consecutive order elimination and cyclic data allocation for an implementation of LU factorization and triangular system solvers. Since the Connection Machine system compilers by default use consecutive data allocation, we use a cyclic-order elimination. We use a similar implementation strategy for routines for reduction of a symmetric or Hermitian matrix to real tridiagonal form (EISPACK_TRED and _HTRID [26], LAPACK_SYTRD and _HETRD [1]). Details concerning these routines will appear elsewhere.

We use blocking of row and column operations to increase the efficiency of operations in each node. The level-2 BLAS is used in each node to achieve maximum performance. The difference in peak performance between a rank-1 update and a higher-rank update is about a factor of four on a Connection Machine system CM-200 node. The difference in peak performance is mostly determined by the difference in need for memory bandwidth between a rank-1 and a high rank update. In our CMSSL implementation of the BLAS local to each Connection Machine system CM-200 node [20], LBLAS, each node achieves a peak performance of about 9.3 Mflops/s in 64-bit precision on matrix multiplication (high rank updates). Our implementation of LU factorization of matrices distributed over all nodes achieves a peak performance, including communication, of 4.6 Mflops/s per node in 64-bit precision. As a comparison, our CMSSL implementation of dense matrix multiplication with operands distributed across all nodes achieves a peak performance of 4.8 Gflops/s in 64-bit precision [24].

This article provides sufficient insight into the details of the algorithms to account for the difference in performance between local matrix multiplication and global factorization and solves routines for dense matrices. We also describe how the performance scales with problem and machine size. In §2 we review the merits of higher-level local BLAS for a class of common processor architectures. Section 3 discusses the performance of the level-1 and level-2 LBLAS used in CMSSL. Section 4 describes the layouts of data arrays created by the Connection Machine Run-Time System. Section 5 explains how we use block-cyclic ordering of the elimination steps to keep the work load balanced across all nodes. Section 6 discusses the performance characteristics of the different parts of the algorithms. Finally, we show in §7 that a two-dimensional consecutive data layout is optimal for elimination algorithms using a cyclic order elimination and communication systems where the times for data copying and reduction are determined by the number of data items leaving or entering a node.

2. Blocking for improved performance of local BLAS.

Memory bandwidth is the most critical resource in high-performance architectures. Therefore, proper attention must be given to the primitives used in constructing linear algebra libraries. Nearly all floating-point computation in linear algebra occurs as multiply-add pairs. This fact is evident in the BLAS used to perform many operations in the solution of linear systems of equations, eigenanalysis, optimization, and the solution of partial differential equations. The first BLAS were vector routines (like DSCAL and DDOT) [21]. But, these routines require large memory bandwidth for peak floating-point performance, and algorithm designers turned to higher-level BLAS, such as level-2 BLAS for matrix-vector operations, and level-3 BLAS for matrix-matrix operations. Next, we give a few examples to illustrate this fact.

Today, most high-performance floating-point processors have the ability to perform concurrently one multiplication and one addition. The data for these operations is nearly always read from registers, and the results are written to registers. The peak performance can only be achieved when multiplication and addition can be performed concurrently, and the data they require can flow in and out of registers fast enough. The memory bandwidth required to match the computational bandwidth depends on the computation being performed.

For example, the DSCAL operation, which multiplies a vector by a scalar with all operands in 64-bit precision, reads one scalar into a register, and then, for each component of the result, reads one element of the argument vector, multiplies it by the constant, and writes one result to memory. Thus, each multiplication requires 8 bytes to be loaded into a register and 8 bytes to be stored from a register, or 16 bytes of memory bandwidth per floating-point operation. As a contrast, the DDOT routine, which computes the inner product of two vectors in 64-bit precision, reads two 8-byte quantities for each multiply-add it performs, then stores one 8-byte result at the end. Thus 16 bytes of memory bandwidth is required per two floating-point operations, or 8 bytes per floating-point operation. Similarly, it is easy to show that the rank-1 update routine DGER requires a memory bandwidth of 8 bytes per floating-point operation.

Matrix-vector multiplication, performed by the routine DGEMV, can be organized such that the vector is read into registers, and the matrix-vector multiplication computed through the accumulation of scaled vectors as $y \leftarrow \alpha x + y$. With α and y allocated to registers, and x representing a column of the matrix read from memory, 8 bytes of memory bandwidth is required for every pair of floating-point operations in 64-bit precision.

A level-3 BLAS routine such as DGEMM allows for a further reduction in memory bandwidth requirement. It performs the operation $C \leftarrow A \times B$, which may be performed as a sequence of operations on $b \times b$ subblocks. If the blocks fit into the registers, then $2b^3$ floating-point operations may be computed using $3b^2$ input elements (b^2 elements per operand), producing b^2 results. If all contributions to a block of C are accumulated in registers, then it suffices to load $2b^2$ inputs for each set of $2b^3$ floating-point operations. All stores are delayed until all computations for a $b \times b$ block of C are completed. Therefore, $16b^2/2b^3$ bytes of memory bandwidth are required per floating-point operation in 64-bit precision, or $8/b$ bytes/flop. A high-rank update of a matrix is equivalent to matrix multiplication.

Table 1 summarizes the memory bandwidth requirements for a subset of the BLAS. The significance of the difference in memory bandwidth requirement of the different routines depends upon the available memory bandwidth. For example, a computer with three 8-bytes wide data paths between each processor and the memory, i.e., a 12-bytes/flop computer such as the Cray-YMP, can perform DAXPY operations at peak rates. A 2-bytes/flop computer, such as an Intel i860 [10] and a Connection Machine system CM-200 node, may not have enough registers to achieve peak rates even for level-3 BLAS local to each node, such as for the DGEMM routine. As a rule of thumb, the less memory bandwidth is available, the more blocking is desirable, but more blocking is only useful if there is a sufficient number of registers.

This simplified performance picture is in reality often complicated by pipeline delays and looping overheads. For short vectors and small register sets, minimizing these

TABLE 1
Memory bandwidth requirement for full utilization of a floating-point unit with one adder and one multiplier.

Operation	Memory bandwidth bytes/flop

quantities may be as important for performance as minimizing the demand for memory bandwidth.

3. Local BLAS on the Connection Machine system CM-200. In the following, we refer to the BLAS local to each node as LBLAS to distinguish it from BLAS for data arrays distributed over several nodes, DBLAS. Each node of the Connection Machine system CM-200 is a 2-bytes/flop computer, based on the memory bandwidth. There is a single 32-bit wide data path between each floating-point processor and its local memory. The data paths internal to a processor are 8 bytes wide (i.e., internally each floating-point processor is a 4-bytes/flop computer). Each floating-point processor has 32 floating-point registers and operates at 10 MHz. There is a one-cycle delay for loading data from memory and a three-cycle arithmetic pipeline delay. Each vector operation incurs an overhead of at least six cycles. Moreover, the memory is organized into pages, and a page fault incurs a delay of one cycle. Stores are relatively more expensive and require close to two cycles. The floating-point processor can achieve close to peak performance in 32-bit precision for level-2 LBLAS with the operands local to a node and at least half of the peak performance in 64-bit precision. The floating-point processor does not have enough registers to achieve its full peak rate on level-3 LBLAS. Table 2 gives the actual performance for the SAXPY, DAXPY, SDOT, and DDOT routines as a function of the vector length for *each* Connection Machine system CM-200 node. Tables 3 and 4 give the performance for SGEMV and DGEMV as a function of matrix size.

Figure 1 shows the performance for the DAXPY and DDOT routines on each Connection Machine system CM-200 node as a function of the vector length. The figure also shows the performance of the routine DGEMV as a function of the number of columns for 64 matrix rows. The peak measured performance for the _AXPY routine is about 60% of the peak performance of the _DOT routine. In 32-bit precision the performance is comparable up to a vector length of about 30, while for 64-bit precision the difference is measurable even for short vectors. Note that the _AXPY routine requires twice the memory bandwidth of the _DOT routine. The performance of the _GEMV routine is about twice that of the _DOT routine. This behavior is expected, since the memory bandwidth requirement of the _GEMV routine is about half of that of the _DOT routine.

Our implementation of the rank-1 update makes use of _AXPY operations, while the higher-rank updates are based on matrix-vector or vector-matrix multiplication, depending upon the shape of the operands [20].

Given the performance characteristics of the LBLAS on the Connection Machine system CM-200, it is desirable to base linear algebra algorithms on the level-2 LBLAS. The potential performance gain from blocking the operations on b rows and columns is illustrated in Table 5. This table shows the speedup of rank-b updates relative to a rank-1

update of a 32×32 matrix and a 512×512 matrix local to a Connection Machine system CM-200 node.

Blocking yields a larger relative performance gain for small matrices than for big matrices. For large submatrices per node a performance gain by a factor in excess of 3.5 is possible through the use of high rank updates. About 90% of this gain is achieved for a blocking factor of 16. For relatively small submatrices per node a performance gain in excess of a factor of 4.5 is possible through the use of high rank updates. About 85% of this gain is achieved by the use of a blocking factor of 16.

4. Standard data layouts. The routines described in this article are designed to operate in place on arrays passed to the routines from high-level language programs. The data motion requirements and the performance depend strongly upon the data allocation of the operands. The default allocation of data arrays to nodes determined by the Connection Machine Run-Time System is based entirely on the shape of the data arrays. Each array is by default distributed evenly over all nodes, i.e., the Connection Machine systems support a global address space. In the default array allocation mode, the nodes are configured for each array such that the number of axes in the data array and in the nodal array is the same. The ordering of the axes is also the same. When there are more matrix elements than nodes, consecutive elements along each data array axis (a block) are assigned to a node. The ratios of the lengths of the axes of the nodal array are approximately equal to the ratios between the lengths of the axes of the data array [29]. In such a configuration the lengths of the local segments of all axes are approximately the same, and the communication needs are minimized when references along the different axes are equally frequent. The default array layout is known as a *cannonical layout.* In §7 we show that the canonical layout is optimum for LU and QR factorization for a simple, but realistic, communications model. In [24] we show that the canonical layout is also optimal for matrix multiplication.

The canonical layout can be altered through compiler directives. An axis can be forced to be local to a node by the directive SERIAL, if there is sufficient local memory. The length of the local segment of an axis can also be changed by assigning *weights* to the axes. High weights are used for axes with frequent communication, and low weights for axes with infrequent communication. A relatively high weight for an axis increases the length of the local segment of that axis, at the expense of the lengths of the segments of the other axes. The total size of the subarray is independent of the assignment of weights. Only the shape of the subarray changes. The shape of the nodal array is important, since it affects the performance of global operations such as data copying, data summation, and pivot selection. The nodal array shape is also important for the performance of the LBLAS, since it affects the shape of the subarrays assigned to each node and, hence, vector lengths and the relative importance of loop overhead.

In many computations more than one array is involved, and the relative layouts of the arrays may be important. For instance, in solving a linear system of equations there are two arrays involved when the computed solutions overwrite the right-hand sides. The required communication in the triangular systems solver depends in a significant way on how the triangular factors and the right-hand sides are allocated to the nodes. With the original matrix factored in place, the triangular factors are stored in a two-dimensional data array, for which the default nodal array shape is a two-dimensional array. For a single right-hand side, the default nodal array shape is a one-dimensional array. Even if there are many right-hand sides, there is no guarantee that the shapes of the nodal arrays are the same for the data array to be factored and the data array of right-hand sides. The ALIGN compiler directive may be used to assure that different data arrays are assigned to nodes using the same nodal array shape for the allocation.

The consecutive allocation scheme [17] selects elements to be assigned to the same node. Compiler directives, such as axis weights, SERIAL and ALIGN, address the issue of choosing the nodal array shape. Another data layout issue is the assignment of data sets to nodes, where a set is made up of consecutive elements along each data array axis. The network topology and the data reference pattern are two important characteristics in this assignment. The nodes of the Connection Machine system CM-200 are interconnected as a Boolean cube with up to 11 dimensions. A Boolean cube network of n dimensions has 2^n nodes.

The nodes of a Boolean cube can be given addresses such that adjacent nodes differ in precisely one bit in their binary encoding. Assigning subarrays to nodes using the standard binary encoding of the subarray index along an axis does not preserve adjacency along an axis. For instance, three and four differ in all three bits in the encoding of the addresses of eight nodes and are at a distance of three apart. In general, $2^{n-1} - 1$ and 2^{n-1} differ in n bits in their binary encoding and are at a distance of n. The number of bits in which two indices differ translates directly into distance in a Boolean cube architecture.

Binary-reflected Gray codes [25] generate embeddings of arrays into Boolean cube networks that preserve adjacency [17]. Gray codes have the property that the encoding of successive integers differ in precisely one bit. In a Boolean cube network successive indices are assigned to adjacent nodes. The binary-reflected Gray code is efficient, both in preserving adjacency and in node utilization, when the length of the axes of the data array is a power of two [11]. For arbitrary data array axes' lengths, the Gray code may be combined with other techniques to generate efficient embeddings [3], [12].

The binary-reflected Gray code embedding is the default embedding on the Connection Machine system CM-200, and is enforced by the compiler directive NEWS for each axis. The standard binary encoding of each axis is obtained through the compiler directive SEND. The performance of global operations, such as pivot selection and broadcast required in the factorization and solve routines, is insensitive to the data distribution along each axis. Our factorization and solver routines also require permutations for rectangular nodal arrays. These permutations may exhibit some sensitivity to whether arrays are allocated in NEWS or SEND order.

5. Cyclic-order factorization and triangular system solution. We consider the solution of a system of equations $AX = Y$ through factorization and forward and backward substitution. We consider both single and multiple right-hand sides. We present algorithms for load-balanced factorization and triangular systems solution on data arrays allocated to nodes by a consecutive data allocation scheme. The matrix is factored in place, and the solutions overwrite the right-hand sides.

5.1. Factorization.

5.1.1. Balanced work load.

For an $N \times N$ matrix assigned to a $p \times q$ nodal array, each node is assigned a submatrix of shape $N/p \times N/q$. With the consecutive allocation scheme, the submatrix on node (i,j), $1 \leq i \leq p$, $1 \leq j \leq q$ consists of elements (a,b) with $(i-1) * N/p < a \leq i * N/p$ and $(j-1) * N/q < b \leq j * N/q$.

An LU factorization algorithm steps through the rows of a matrix, subtracting a multiple of a row, the pivot row, from all rows not yet selected as pivot rows. If the matrix is allocated to the nodes with a consecutive allocation scheme, and the pivot rows are selected in order, then after N/p rows have been chosen, the first row of nodes will no longer have any work to do. One method for avoiding this imbalance is to redistribute the rows and columns of the matrix periodically, as the work load becomes unbalanced. This approach leads to substantial communications overhead. The characteristics of QR decomposition are similar, though instead of subtracting the pivot row from rows not yet selected as pivots, a normalized linear combination of those rows is subtracted from each of them.

A more elegant technique is to use a cyclic data allocation scheme [8], [17], [22], [23], [30]. In a cyclic data allocation scheme the first row of the matrix is placed on the first row of nodes, the second row of the matrix on the second row of nodes, and so on until one matrix row has been assigned to each of the p rows of nodes. Then, the $(p+1)$st matrix row is assigned to the first row of nodes, etc. With this method, matrix rows are consumed evenly from the different rows of nodes during elimination, so that no row of nodes ever has more than one more active matrix row than any other row of nodes. Columns are treated similarly.

The space (rows and columns) and time (pivot selection) dimensions are interchangeable [13]–[16]. Hence instead of distributing rows and columns cyclically over the two-dimensional nodal array, pivot rows and columns can be selected cyclically to achieve the desired load balance. We have chosen this approach for our implementation. To allow for the use of level-2 LBLAS, blocking of rows and columns on each node is used. In LU factorization a blocking of the operations on b rows and columns means that b rows are eliminated at a time from all the other rows.

In summary, we factor a matrix in place using a *block-cyclic elimination order* for both rows and columns. For block size b we first eliminate rows $1, \ldots, b$, then rows $(p+1), \ldots, (p+b)$, etc. We are eliminating b matrix rows at a time from each row of nodes. A block-cyclic elimination order was recommended in [15] for load-balanced solution of banded systems.

Below we give an example of a block-cyclic ordered elimination for a square array of nodes and a block size of two. Pivot rows and columns are indicated by numbers, eliminated elements by periods, and all other elements are shown as an asterisk.

Example I: $N = 16, p = q = 4, b = 2$.

As can be seen from Example I, the result of the factorization is not two block triangular matrices, but *block-cyclic triangles.* A block-cyclic triangle can be permuted to a block triangular matrix, as discussed in §5.2. However, it is not necessary to carry out this permutation for the solution of the block-cyclic triangular system of equations. Indeed, it is desirable to use the block-cyclic triangle for the forward and back substitutions, since the substitution process is load balanced for the block-cyclic triangles. Using block triangular matrices stored in a square data array (A) allocated to nodes with a consecutive data allocation scheme would result in poor load balance. Before discussing block-cyclic triangular solvers, and the relationship between pivoting strategies and the block-cyclic elimination order, we consider rectangular nodal arrays.

5.1.2. Rectangular arrays of processing nodes. Rectangular nodal arrays result in different row and column orderings, since the length of the cycle for the cyclic elimination order is different for rows and columns. Let $\hat{P}_1$ give the relationship between consecutive order and block-cyclic order elimination for rows, and let $\hat{P}_2$ give the relationship between consecutive order and block-cyclic order elimination for columns. Then, $\hat{P}_1(i) = j$ means that the ith row to be eliminated is row j. Specifically, for a matrix allocated to the $p \times q$ nodal array with the consecutive (block) allocation scheme, as described in §5.1, the block-cyclic ordered elimination with a block size $b = 1$ yields

$$\hat{P}_1 = 1, \frac{N}{p} + 1, 2\frac{N}{p} + 1, \ldots, \qquad \hat{P}_2 = 1, \frac{N}{q} + 1, 2\frac{N}{q} + 1, \ldots.$$

Thus, $\hat{P}_1 \neq \hat{P}_2$ if $p \neq q$. Clearly, if the number of nodes in the entire machine is not a square (as is the case for a 2048-node Connection Machine system CM-200, and the Intel Delta [30]), and all nodes are used, then $p \neq q$ and $\hat{P}_1 \neq \hat{P}_2$. How to choose p and q for optimum performance under the constraint $pq = \text{const}$ is discussed in §7.

Note that even though $\hat{P}_1 \neq \hat{P}_2$ naturally occurs when $p \neq q$, choosing a different blocking factor for rows and columns yields the same result.

5.2. Solving block-cyclic triangular systems. In an algorithm eliminating rows and columns consecutively, transformations are applied to an original matrix A, until it has been reduced to an upper triangular matrix T. In block-cyclic-ordered elimination, A is reduced to a block-cyclic triangular matrix $V = P_1 T P_2^{-1}$, where T is upper triangular. Block-cyclic triangles are just as easy to invert as standard block triangles, but they are load balanced across the nodes of a distributed memory machine. The block-cyclic triangle V for the example above (Step 8, Example I), and the corresponding permutation matrix P_1, are shown below. Example II shows a block-cyclic triangle for a rectangular nodal array ($P_1 \neq P_2$).

Example I: $N = 16, p = q = 4, b = 2$.

$$V = P_1 T P_2^{-1} = \left[\begin{array}{cccc@{\quad}cccc@{\quad}cccc@{\quad}cccc}

\end{array}\right].$$

In our block-cyclic triangular solver, the solution matrix X overwrites the right-hand sides Y. The solver requires that the set of right-hand sides Y and the matrix A are *aligned*. The alignment of Y and A ensures that the shape of the nodal array is the same for A and Y. For a single right-hand side, the alignment implies that the components of Y are allocated to the first column of the nodal array using the consecutive allocation scheme. With several right-hand sides, the alignment implies that the consecutive allocation scheme is used to allocate right-hand sides and columns of the matrix A to the same number of node columns with each right-hand side being allocated to a single-node column. The alignment of A and Y can be accomplished without data motion by using the compiler directive ALIGN. Alignment at run-time generally will require data motion. It can be performed by the Connection Machine router. Our library routine validates that the arrays are aligned and, if the arrays are not prealigned, performs the alignment through a call to the router.

Our column-oriented algorithm for solving block-cyclic upper triangular systems of the form $P_1 T P_2^{-1} X = Y$ starts with the last block column of $P_1 T P_2^{-1}$ and progresses toward its first block column, in a way similar to a standard column-oriented upper triangular system solver. A multiple of each block column of $P_1 T P_2^{-1}$ is subtracted from Y in each backward elimination step. The multiple of block column k, which is subtracted from Y at the kth stage of this process, is the kth block component (row) of the solution vector X. If the kth block column consists of columns $\hat{P}_2(j)$, $\hat{P}_2(j+1), \ldots, \hat{P}_2(j+b-1)$, then the last b elements of each column in this block column are in rows $\hat{P}_1(j)$, $\hat{P}_1(j+1), \ldots, \hat{P}_1(j+b-1)$. If X overwrites Y, then it is natural to record the multiplier of the kth block column in components (rows) $\hat{P}_1(j), \hat{P}_1(j+1), \ldots, \hat{P}_1(j+b-1)$ of Y. But these components (rows) of the result belong in components (rows) $\hat{P}_2(j), \hat{P}_2(j+1), \ldots, \hat{P}_2(j+b-1)$ of Y. Hence, after completing the iterative process of block column subtractions, the permutation $P_2 P_1^{-1}$ (a generalized shuffle [19]) must be applied to Y to obtain X.

The ordering of Y after the in-place substitution process, and the correct ordering of the solution are illustrated in Fig. 2 for an 8×8 matrix mapped to a 2×4 nodal array. The numbers indicate the pivoting order for the factorization and the placement of the solution components after the in-place back substitution and after the postpermutation. In the example, the destination address in the postpermutation is obtained by a right cyclic shift of the row index in the solution matrix. For instance, with indices labeled from 0, the content in location 1 of Y is sent to location 4, the content of location 4 to location 2, and the content of location 2 to location 1.

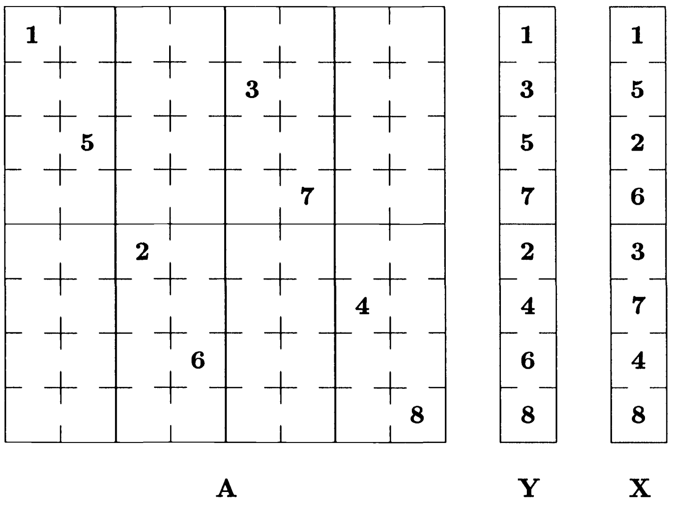

FIG. 2. *Block-cyclic triangular backsubstitution. In-place ordering* (Y) *and correct ordering* (X) *of solutions.*

Briefly put, the natural process for solving block-cyclic triangular systems evaluates $W = (P_1TP_1^{-1})^{-1}Y$. But $X = (P_1TP_2^{-1})^{-1}Y = (P_2P_1^{-1})(P_1TP_1^{-1})^{-1}Y = (P_2P_1^{-1})W$. Thus the solutions X, aligned with A and overwriting the aligned matrix Y, are obtained through a postpermutation $P_2P_1^{-1}$ applied to the result of the in-place block-cyclic triangular solver.

Note that in applying a block-cyclic elimination order to data allocated by a consecutive allocation scheme, the computations are load balanced both for factorization and triangular system solution without permuting the matrix A or the block-cyclic triangles. For instance, whenever $P_1 \neq P_2$ for rectangular nodal arrays, a shuffle permutation of the solution matrix is required. But, for few right-hand sides, the amount of data permuted is considerably less than if the input matrix and the right-hand side matrix had been permuted from consecutive to cyclic allocation and the solution matrix permuted from cyclic to consecutive allocation.

5.3. LU factorization and block-cyclic triangular system solution with partial pivoting. We now have presented all the elements of our algorithm for solving dense systems of equations with partial pivoting for a consecutive data allocation. The complete algorithm is as follows.

- Factor the matrix A in place using a block-cyclic elimination order. Exchange each selected pivot row with the appropriate row defined by the block-cyclic elimination order. Record the pivot selection.
- Align the right-hand side matrix Y with the matrix A (the array storing the block-cyclic triangles). Y and A can be aligned at compile time through the use of the compiler directive ALIGN.
- Perform a forward block-cyclic triangular system solve in place using the recorded pivoting information.
- Perform a backward block-cyclic triangular system solve in place.

• Whenever the row and column permutation matrices P_1 and P_2 are different, as in the case of rectangular nodal arrays, perform a postpermutation (generalized shuffle) of the solution matrix (or prepermutation (generalized shuffle) of the matrix A as explained in the next subsection).

• Align the solutions with Y, assuming that the solutions overwrite the right-hand sides.

No permutation of the matrix A or the block-cyclic triangular factors, is made for load balance. A permutation of the solution matrix is only required when $P_1 \neq P_2$, as in the case of rectangular nodal arrays. For a few right-hand sides, the size of the solution matrix is insignificant compared to the matrix A, and the time for permutation of the result is of little influence on the performance. For a large number of right-hand sides, a prepermutation of the matrix A, as explained in the next section, may yield better performance. In our implementation, the permutation of the result, when required, is performed by the Connection Machine system router. Optimal algorithms [19] are known for the generalized shuffle permutations required in pre or postpermutation when $N/\max(p,q)$ is a multiple of the block size. However, no implementation of such algorithms is currently available on the Connection Machine systems.

Note that if the data arrays A and Y are not aligned at compile time, then the last two steps could be combined into a single routing operation. Note further that if there are more right-hand sides than columns of A, then it may be preferable to align A with Y, if the optimal nodal array shapes for factorization and solution phases are different, or if alignment is made at run time, since fewer data elements must be moved if the layout of Y is the reference. Optimal array shapes are discussed further in §7.

In our implementation, the location of the pivot block row is defined by the block-cyclic elimination order. Selected pivot rows are exchanged with rows of the pivot block row in order to assure load balance.

The forward and backward solution in our implementation corresponds to the routine _TRSM in the level-3 BLAS, but it is not identical since a block-cyclic ordered elimination is used.

5.4. LU factorization and triangular system solution without pivoting: prepermutation vs. postpermutation. In §5.2 we showed that in case $P_1 \neq P_2$, backward elimination of a block-cyclic triangular system consists of two parts: a fairly standard backward elimination with reverse block-cyclic ordered block column subtractions from the right-hand side and a postpermutation of the result when $P_1 \neq P_2$. For such block-cyclic elimination orders, successive blocks are *not* selected from the diagonal of the matrix.

LU factorization without pivoting selects pivots from the diagonal of a matrix and works well for diagonally dominant systems precisely because the large diagonal elements are guaranteed to be the pivots in the factorization process. However, in block-cyclic ordered elimination with $\hat{P}_1 \neq \hat{P}_2$, the matrix entries used as pivots will be on the block-cyclic diagonal, i.e., in locations of the form $(\hat{P}_1(i), \hat{P}_2(i))$. Thus for diagonally dominant matrices factored on, for instance, a rectangular nodal array with a no-pivoting strategy, it is necessary to prepermute the original matrix in some way that maps the original diagonal to the block-cyclic diagonal.

One obvious prepermutation is to replace A with $B = P_1AP_2^{-1}$. Then, given a factorization $L_B^{-1}B = P_1T_BP_2^{-1}$ and routines to apply L_B^{-1} and $(P_1T_BP_1^{-1})^{-1}$, $AX = Y$ can be solved as $X = P_1^{-1}\ (P_1T_BP_1^{-1})^{-1}L_B^{-1}P_1Y$. But a more efficient approach is to replace A with $C = AP_1P_2^{-1}$. A block-cyclic elimination order applied to C yields $L_C^{-1}C = P_1T_CP_2^{-1}$. Furthermore, $L_C^{-1}A = P_1T_CP_1^{-1}$, and the solution of $AX = Y$ is obtained as $X = (P_1 T_C P_1^{-1})^{-1} L_C^{-1} Y$. In summary, a prepermutation of A required for numerical stability can be used to cancel the postpermutation of the result.

Thus in a block-cyclic elimination order on rectangular nodal arrays, LU factorization with pivoting on the diagonal is performed as follows:

Apply $P_1 P_2^{-1}$ from the right.	$A \leftarrow A P_1 P_2^{-1}$
Factor C in place.	$L_C, P_1 T_C P_2^{-1}$
Forward solve in place.	$Y \leftarrow L_C^{-1} Y$
Backward solve in place.	$X = (P_1 T_C P_1^{-1})^{-1} Y$

Note that if $P_1 = P_2$, then the first step has no effect on the data ordering and should be omitted. In this case, the factorization with no pivoting should be faster than with pivoting, since no time is required for finding pivots and for exchanging selected pivot rows with the rows of the block pivot row. However, when $P_1 \neq P_2$, then the no-pivot option requires a prepermutation of the matrix A, while the pivot option requires postpermutation of the solution matrix X in addition to the data rearrangement required for pivoting. In our implementation, we find that no pivoting is always faster than pivoting even when $P_1 \neq P_2$ and there is only one right-hand side (see Fig. 3).

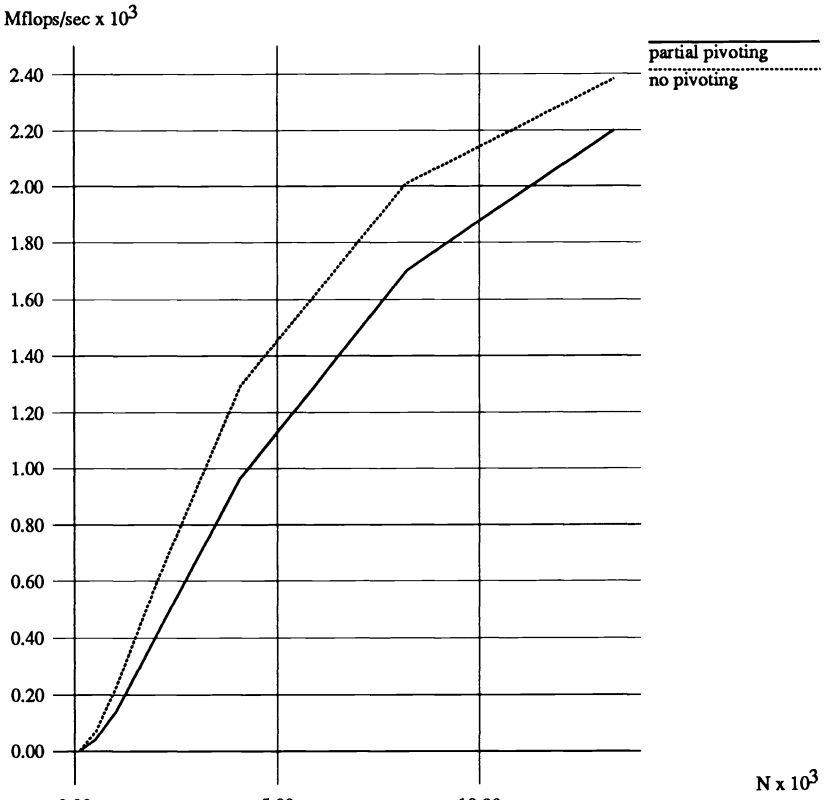

FIG. 3. *Execution rates for* LU *factorization with and without pivoting on a* 512*-node Connection Machine system* CM-200 *with blocking factor* 8, 64*-bit precision. Nodes in Gray code order.*

Note further that the prepermutation $A \leftarrow AP_1P_2^{-1}$ can be used also for the LU factorization with pivoting, thus removing the need for the postpermutation of the result. This technique gives improved performance when there are more columns in the right-hand side array Y than in the original matrix A. Thus prepermuting the matrix A when there are many right-hand sides should result in better performance for the no-pivoting option than for the pivoting option.

5.5. QR factorization and system solution. QR factorization and the solution of the factored matrix equations can be performed in a manner analogous to the LU factorization and the solution of triangular systems. In the factorization, pivoting is replaced by an inner product of the current column with all other columns, i.e., a vector-matrix multiplication. This vector-matrix multiplication doubles the number of floating-point operations and replaces two copy-spread operations with one physical spread-with-add operation. The result is an operator Q^T in factored form, satisfying $Q^TA = R$, where $R = P_1TP_2^{-1}$ is a block-cyclic upper triangular. If A has m rows and n columns with $m \geq n$, then the QR factorization may be used to find the vector X that minimizes the residual 2-norm $\|AX - Y\|_2$. The procedure is

$$\begin{array}{ll} \textit{Apply } Q^T. & Y \leftarrow Q^TY, \\ \textit{Backward solve.} & X = \Pi(P_2P_1^{-1})(P_1TP_1^{-1})^{-1}Y, \end{array}$$

where Π is projection onto the first n components. The backsolve $(P_1TP_1^{-1})^{-1}$ operates on the first n rows in block-cyclic order of Y. The final permutation $P_2P_1^{-1}$ moves the first n block-cyclic rows to the first n rows.

6. Performance. In this section we report first the performance achieved on a few matrix sizes. Then we analyze the performance and discuss factors that contribute to the discrepancy between the performance of the local matrix kernels and the performance of the global factor and solve routines. Communication and arithmetic are considered separately. All arrays are allocated with default compiler layouts. This implies that nodes are in Gray code order along each axis, and that Y is aligned with A only in the case that the number of right-hand sides is equal to the number of equations. A 2048-node and a 512-node Connection Machine system CM-200 were used for the performance measurements. Both systems result in rectangular nodal arrays. Alignment of Y with A (when necessary) and postpermutation of the solution(s) were performed using the Connection Machine router. Times for these data motion steps are included in the solve timings. In all cases we used random data for the matrix A. In this section, LU factorization always means LU factorization with partial pivoting. In this section, QR factorization always means QR factorization with no pivoting.

6.1. Measurements. In 64-bit precision the peak performance for LU factorization is 9.4 Gflops/s, or close to 4.6 Mflops/s per node, which is about 50% of the peak performance of the level-2 LBLAS. Table 6 shows the performance of LU and QR factorization for a few matrix sizes on a 2048-node Connection Machine system CM-200. The execution rate for LU factorization is computed based on $(2/3)N^3$ floating-point operations, and the QR factorization rate based on $\frac{4}{3}N^3$ operations, regardless of the blocking factor. For the solvers, the execution rates are based on $2RN^2$ operations for the LU solver and $3RN^2$ for the QR solver.

Tables 7 and 8 give some performance data for the factorization and the forward and backward solution of dense systems. R denotes the number of right-hand sides in the systems of equations being solved. The improved efficiency with an increasing matrix

size, increased number of right-hand sides, and increasing blocking factor is apparent. For LU factorization in 32-bit precision, the performance increases by a factor of over 700 for an increase in matrix dimension N by a factor of 132 and a blocking factor of 1. With a blocking factor of 16, the same increase in matrix size yields a performance increase by a factor of over 1300. The performance increase in 64-bit precision for an increase in N by a factor of 104 is 425 and 840, respectively. For small values of N, the performance increases much faster than N. For large values of N, the performance increase is still substantial and roughly proportional to N. This characteristic is true for both the factorization and the solution phases.

The execution rate for the forward and backward block-cyclic triangular system solvers increases significantly with the matrix size for a large number of right-hand sides. With the number of right-hand sides equal to the number of equations, the performance of the triangular solvers is about 50% higher than for LU factorization.

Comparing the execution rates of the LU and QR factorization routines, we observe that except for large matrices, the execution rates of the QR factorization routine are approximately twice that of the LU factorization routine. Hence, the execution times are approximately equal. However, for large matrices in 64-bit precision, the execution rate for QR factorization is only 15–20% higher than for LU decomposition, and the execution time for QR factorization is significantly longer than for LU factorization.

Comparing the LU and QR solve routines, we observe that the QR solve routine benefits more from an increased blocking factor than does the LU solve routine. The execution rate of the QR solve routine is about 20% higher than the LU solve routine for a large number of right-hand sides and a blocking factor of 1. But, for a blocking factor of 16, the QR solve routine has an execution rate that is about 40% higher than that of the LU solve routine.

The optimum blocking factors for LU factorization and triangular system solution are summarized in Fig. 4. The optimum blocking factor increases with an increased matrix size. For LU factorization the sensitivity of the execution rate with respect to the blocking factor is small (on the order of 20%) for small matrices, while for large matrices an increase in the blocking factor from 1 to 16 may increase the performance by a factor of more than two. The behavior is similar for the LU solve routine. The optimum blocking factor increases with the matrix size. In our implementation the optimum blocking factor for LU factorization is 4 for matrices of size up to 1024, 8 for matrices of size between 1024 and 8096, and 16 for sizes 8096 to 16896, the maximum size used in our test. Note that the optimum blocking factor for the LU solve routine is generally higher than for the factorization routine. Figures 5 and 6 show the execution rate as a

function of matrix size and blocking factor for LU factorization and solve, respectively. Figure 7 shows the execution rate of the LU solve routine as a function of matrix size and the number of right-hand sides.

The optimum blocking factor for the QR factorization routine increases somewhat slower with the matrix size than for the LU factorization routine. The optimum blocking factor for the QR solve routine is higher than for the QR factorization routine, just as in the case of LU factorization and solve. Figure 8 shows the execution rate as a function of matrix size and blocking factor for QR factorization.

In the next few subsections we analyze the performance behavior of the communication functions and the local arithmetic as a function of matrix and machine size and provide a model to predict the performance.

6.2. Communication. Two main types of communication are required: (i) *Spreads* copy data from a single row (or column) of nodes to all other rows (or columns); (ii) *Reductions* to select the pivot row in LU factorization with partial pivoting and for col-

umn summations in QR factorization. In addition, general *sends* are used to align the right-hand sides Y with the columns of A, to realign the solutions with the input array Y, and, when $P_1 \neq P_2$, to prepermute the matrix A, or to postpermute the solution(s). In a spread of a pivot column, N/p elements per node must be communicated to every other node in a row for the consecutive data allocation described in §5.1. With a blocking factor of b rows and columns, the number of elements to be spread for a block column is Nb/p. Similarly, a block row requires that Nb/q elements be spread to every other node in a column.

On the Connection Machine system CM-200, where the nodes are interconnected as a Boolean cube, there exist several paths from the node that must spread the data to any of the nodes receiving the data. Indeed, since p and q are always chosen such that the nodes form subcubes of the Boolean cube, there exist $\log_2 p$ and $\log_2 q$ edge-disjoint paths between a node and every other node in a column and row subcube. Hence, the data set that a node must spread can be divided up among the different paths to balance the communications load and maximize the effective use of the available communications bandwidth [18]. Spreads on the Connection Machine system CM-200 are implemented in this manner and use the communications bandwidth optimally [18]. Note that for a fixed data set per node, the time for a spread decreases with an increased number of nodes. Table 9 gives some timings for spreads of different size data sets on Connection Machine systems CM-200 of various sizes. For a large data set per node, increasing

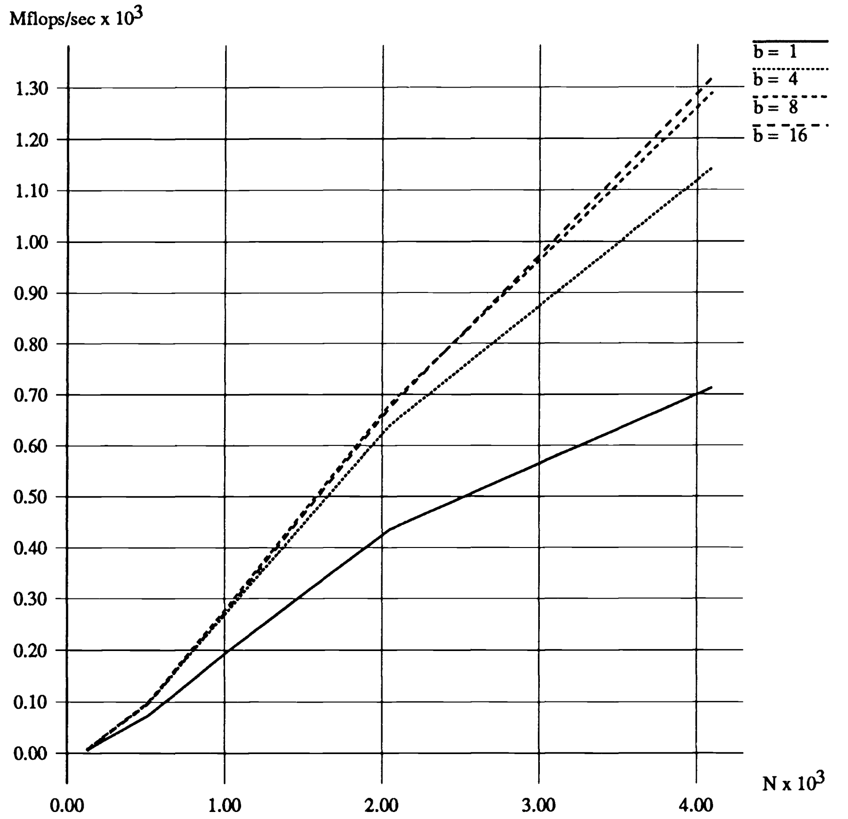

FIG. 6. *Execution rates for solution of block-cyclic triangular systems of equations with N right-hand sides for* LU *decomposition on a* 512*-node Connection Machine system* CM-200 *with a blocking factor b,* 64*-bit precision. Nodes in Gray code order.*

the number of cube dimensions by a factor of 10 (from 1 to 10) reduces the time for a spread by a factor of 3.41. Increasing the number of dimensions by a factor of 5 yields a reduction in the time for a spread of a large data set by a factor of 2.06. The overhead is quite substantial, making the speedup significantly less than the increase in the number of cube dimensions.

The prepermutation $P_1 P_2^{-1}$, or the postpermutation $P_2 P_1^{-1}$, when required, is performed by the Connection Machine system CM-200 router in our implementation. These permutations are *generalized shuffle* permutations. Optimal algorithms for Boolean cube networks are known for these permutations when $N/\max(p,q)$ is a multiple of the block size [19], but not implemented on the Connection Machine system CM-200. In cases with only one right-hand side, the cost of the alignment and postpermutation is only a small fraction of the total cost of the solve.

Note that, on the Connection Machine systems, the default layout of the matrix A and the right-hand sides Y is typically not the same, since the nodal array shape depends upon the data array shape. Aligning A and Y at compile time avoids data motion at run time. With a default layout of Y and A, the alignment constitutes a shuffle permutation, which would be performed by the router. Similarly, with the solutions overwriting the right-hand sides, the default data allocation requires a reallocation of the result from being aligned with A, to the default layout. This reallocation could be combined with

a postpermutation of the solution matrix X, when necessary, into a single permutation. Such a combined permutation would require the same time as either the postpermutation itself, or the reallocation of X, using optimal algorithms [19].

Note also, that if all arrays have a default layout, then for many right-hand sides it may be advantageous with respect to performance to align the matrix A with Y and, if a prepermutation of A is necessary, combine this permutation with the alignment operation.

6.3. Arithmetic efficiency. Not all the work is well load-balanced, even in the block-cyclic order elimination. Some work is applied only to a single row (or column) of the matrix at a time. For example, in LU factorization with partial pivoting, it is necessary to find the location of the largest element in the current column. Though this work is of order $O(N)$ for a single (block) row or column, compared to the $O(N^2)$ work for a rank-b update, it is magnified in importance because the grid-based layouts do not load balance individual rows and columns across the whole machine. Despite this drawback, grid-based layouts are optimal for communication systems in which the communication time is determined by the data volume leaving or entering a node, as shown in §7.

6.4. Detailed performance analysis. For simplicity, in this section and the next, we consider only the case $p = q$.

Assuming that αN^3 floating-point operations are carried out on p^2 nodes running at rate r, while the time per unit of work spent on N^2 work (some arithmetic and communication) on p nodes is C, the total time is $\alpha N^3/rp^2 + C(N^2/p)$. The achieved computational rate is

$$R = \frac{\alpha N^3}{\frac{\alpha N^3}{rp^2} + C\frac{N^2}{p}}$$

or

$$R = rp^2\left(\frac{\theta}{\theta+1}\right),$$

where

$$\theta = \left(\frac{N}{p}\right)\left(\frac{\alpha}{rC}\right).$$

For LU factorization on a 2048-node Connection Machine system CM-200, the compilers by default configure the nodes as a 32 x 64 array. The algorithm we use requires three spreads for each row and column that is eliminated; two to accomplish the pivoting row swap and one to spread the column of coefficients. From Table 9, we conclude that the time for a row spread is $570 + 3.1*$ (number of 32-bit words per column of nodes) msec, and the time for a column spread is $640 + 2.7*$ (number of 32-bit words per row of nodes) msec. For the largest matrices in Table 7, $N/p \approx 630$ (actually the submatrices assigned to each node are rectangular 448×896, and $\sqrt{(448 * 896)} \approx 630$). Some straightforward calculus shows that communication contributes about 15 msec to C. By counting cycles for the $O(N^2)$ arithmetic part of the code, we estimate that it contributes another 12 msec to C. For LU factorization $\alpha = 2/3$. We used a blocking factor of $b = 16$ for the timings reported in Table 7, i.e., all $O(N^3)$ work is performed by rank-16 updates. These run at a peak rate of about 7.6 Mflops/s per node. However, including the effect of DRAM page faults reduces this performance to a little over 7 Mflops/s. Hence, $\alpha/(rC) \approx 2/(3\cdot 7.0\cdot 27) \approx 1/(285)$, and $\theta \approx 2.2$, for which the performance loss factor is $\theta/(\theta+1) \approx 0.69$. Altogether, this analysis predicts a performance of about 4.85 Mflops/s per node, which is very close to the measured performance.

The important conclusion is that for $\theta \ll 1$, or N/p small relative to rC/α, the performance increases roughly linearly in N/p. Because rC is large, nearly all interesting cases fall into this range of submatrix sizes.

A minor point relevant for fine tuning is that smaller problems should use smaller block sizes. This need arises because one of the contributions to C is work occurring entirely within block rows or block columns, which grows quadratically with the block size b.

6.5. Scalability. As the matrix size N increases for a fixed machine size, the number of rows and columns assigned to a node increases proportionally. Hence, if N is doubled, so is the amount of data per row *and* column per node. Hence, the time required for the $O(N^2)$ term increases in proportion to N^2. But the amount of work that must be performed by each node for the factorization increases in proportion to the cube of the local matrix size. Hence, the importance of the $O(N^2)$ term decreases with increases N for a fixed number of nodes. However, the significance does not decrease in proportion to N, since the efficiency of the level-2 LBLAS increases with increased N. The variation in the computational rate r spans a range of more than one order of magnitude, while the performance loss factor may span two orders of magnitude. Hence, the dramatic variation in performance as a function of the local submatrix size.

Scaling the problem size with the number of nodes such that size of the submatrix assigned to each node remains fixed increases the efficiency of our current Connection Machine system CM-200 implementation. The performance of the level-2 LBLAS is unaffected by this form of scaling, but the communication is sped up because more channels are available for spreads and reductions. Thus, increasing the number of nodes decreases the value of C.

7. Optimal layouts. Communication is inevitable for the solution of full rank factorization problems on a distributed memory computer [9]. Another source of inefficiency in our implementation is the poorly load-balanced $O(N^2)$ work. We now consider the impact on the data communication (for spreads and reductions) of some alternative data layouts intended to improve the load balance for the $O(N^2)$ work.

Consider an arbitrary layout of an $N \times N$ matrix on p^2 nodes, which is regular in the following sense:

Each column intersects exactly c nodes in N/c elements.
Each row intersects exactly r nodes in N/r elements.
There are exactly N^2/p^2 elements on each node.
Each node intersects exactly cN/p^2 columns.
Each node intersects exactly rN/p^2 rows.

Figure 9 shows a two-dimensional data array assigned to nodes forming a one-dimensional array in a Boolean cube. A binary-reflected Gray code encoding [25] is used for the array embedding. Each square subarray of the data array is assigned to one of four nodes, as indicated by the number in the corresponding box. In effect, the data array is assigned to the nodes of the embedded one-dimensional array in a block-skewed way. This layout satisfies the regularity conditions with $c = 4$, $r = 4$, and $p = 2$.

1	0	2	3
3	2	0	1
2	3	1	0

FIG. 9. *Layout of a two-dimensional data array on a Boolean cube configured as a one-dimensional array.*

It is clear that by making $rc > p^2$, the load balance can be improved for row-and-column oriented operations. To evaluate the impact on the time for a spread, we assume that the time of the spread is proportional to max(*inject, eject*), where *inject* is the maximum number of data elements injected into the communications system by any node, and *eject* is the maximum number of elements ejected from the communications system by any node. Hence, we assume that communication operations are limited by the bandwidth at the nodes. Then, the time of a column spread is $\max(N/c, rN/p^2)$ and the time of a row spread is $\max(N/r, cN/p^2)$. Now, consider an algorithm consisting of local computation, row spreads, and column spreads. Suppose that local computation consists of a perfectly load-balanced part, a part which takes place on a single column at one time, and a part which takes place on a single row at one time. By making $rc > p^2$, we can reduce the cost of the single-column and single-row operations. In return, the cost of the row spreads and the column spreads will grow. In fact, it is likely that distributing rows and columns across more processors will also increase the cost of the perfectly load-balanced part of the computation, since more distributed layouts will reduce local vector lengths. If we ignore this effect of reduced vector lengths, then an optimal layout should minimize $cost = \alpha * \max(N/c, rN/p^2) + \beta * \max(N/r, cN/p^2) + \gamma * N/r + \delta * N/c$, where α, β, γ, and δ, are parameters describing the relative importance of column spread, row spread, single-row work, and single-column work, respectively.

To find the values of c and r that minimize this expression, we first assume that $rc = K$ with $K \geq p^2$. Then, $cN/p^2 \geq N/r$ and $rN/p^2 \geq N/c$, and the minimization problem reduces to finding the minimum of $(\alpha/p^2) * r + (\beta/p^2) * c + \gamma/r + \delta/c$, subject to the constraint $rc = K$. Using the constraint to eliminate c, and solving for the critical value of r, gives

$$r^2 = \frac{(\beta/p^2) * K + \gamma}{(\alpha/p^2) + \delta/K}.$$

Here, $\text{cost}(K) = 2 * \sqrt{((\alpha/p^2) + \delta/K) * ((\beta/p^2) * K + \gamma)}$. Minimizing this minimum cost with respect to K gives $K_{\min} = \sqrt{(\gamma * \delta)/(\alpha * \beta)} * p^2$. For $K > K_{\min}$, $\text{cost}(K)$ is increasing. So if $\gamma\delta < \alpha\beta$, the minimum cost for all $K \geq p^2$ occurs for $K = p^2$. If we take $K < p^2$, then the minimization problem reduces to finding the minimum of $(\alpha + \delta)/c + (\beta + \gamma)/r$ subject to the constraint $rc = K$. In this case, the minimum is a decreasing function of K, so the minimum cost for all $K < p^2$ occurs for $K = p^2$.

The above analysis assumes that the number of columns is equal to the number of rows, which is true for LU factorization on a matrix that fits in primary storage. For the triangular solve, the number of right-hand sides R is often not equal to the number of rows N. With R right-hand sides, the assumption that each column intersects c nodes in N/c elements is still valid. But each row now intersects r nodes in R/r elements. With NR/p^2 elements on each node, each node intersects cR/p^2 columns (instead of cN/p^2 columns) and rN/p^2 rows, as before. It is easily verified that even for the triangular solve, $K = p^2$ is optimal.

The overall conclusion is that, provided $\gamma\delta < \alpha\beta$, i.e., provided the geometric mean of the single-row and single-column work is less than the geometric mean of the row and column spread work, the best choice is $K = p^2$. The condition $rc = p^2$ implies that the optimal layout is indeed based on two-dimensional subgrids for both factorization and triangular system solution. This conclusion is true, because any column intersects a node in N/c elements and $N/c = rN/p^2$, which is the number of rows that meet any node. Thus, the rows meeting any node must be exactly those N/c rows that meet any one of the columns meeting that node. In our implementations of LU and QR factorization, the condition $\gamma\delta < \alpha\beta$ is satisfied (although not by a wide margin). The optimal value of r/c under the constraint $rc = p^2$ is $\frac{\beta+\gamma}{\alpha+\delta}\ \frac{R}{N}$. Thus, the ratio of the lengths of the axes of the two-dimensional nodal array is proportional to the ratio between the corresponding axes of the data array operated upon for both factorization and triangular system solution.

The above communications model applies to some, but not all architectures. For instance, for hypercubes with concurrent communication on all channels of every node, such as the Connection Machine system CM-200, the above communications model must be modified. In the example given by the diagram above, a column spread and a row spread are actually all-to-all broadcasts [2], [18]. The time for such an operation is proportional to the number of elements entering a node divided by the number of communication channels per node, i.e., the number of hypercube dimensions spanning their set of nodes involved in the all-to-all broadcast. For a two-dimensional hypercube, all-to-all broadcast is no more expensive than a standard column spread. Although twice as much data must be received by each node, there are twice as many channels available for the data to use. Therefore, on a four-node CM-200, the data layout shown in Fig. 9 would give better performance for dense linear algebra than any layout currently used, because with the Fig. 9 layout and cyclic elimination order, all vector operations would be perfectly load balanced.

8. Summary. We describe LU and QR factorization and solve algorithms for a block-cyclic ordered elimination for both square and rectangular nodal arrays. We show how prepermutation can be performed to guarantee pivoting on the diagonal for diagonally dominant matrices, without a need for postpermutation. The algorithms have been implemented on the Connection Machine systems CM-2 and CM-200 and are part of the CMSSL [27]. The peak execution rate of the LU factorization routine on a Connection Machine system CM-200 is about 9.4 Gflops/s in 64-bit precision.

The routines accept any data layout that can be created in the higher-level languages on the Connection Machine systems, either by the default layout rules, or through the use of compiler directives. The routines also perform operations on multiple instances concurrently, with instances distributed over different sets of nodes. The algorithms use standard communication functions, such as multiple instance (segmented) broadcast and reduction, and generalized shuffle permutations. Optimized routines are used for broadcast and reduction, while the router currently is used for the generalized shuffle permutations.

For small matrices the *execution times* for QR factorization without pivoting and LU factorization with partial pivoting are comparable, while for large matrices the *execution rates* become comparable, and hence the execution time for LU factorization with partial pivoting is considerably shorter. The execution rate for the block cyclic triangular solve for LU decomposition is 50–100% higher than for the factorization for a number of right-hand sides equal to the number of unknowns. The behavior is similar for QR factorization.

The value of blocking operations on rows and columns increases with matrix size. For small matrices, blocking may yield an enhanced execution rate by 20%, while for large matrices the blocking may offer an increased execution rate of about a factor of two. In our implementations, the optimum blocking factor for LU factorization with partial pivoting increases from 4 to 16 with the matrix size increasing from 128 to 16896. The optimum blocking factor for QR decomposition without pivoting was observed to increase slower with the matrix size than for LU factorization. The optimum blocking factors for the solve routines were always higher than for the factorization routines.

The execution rate for LU factorization without partial pivoting is higher than when partial pivoting is used. The difference in performance depends upon the problem size, but is typically in the 10–20% range.

The peak performance for the global factorization routines is about two-thirds of the peak performance of the local level-2 BLAS routines used for the $O(N^3)$ work in the factorization (but approximately equal to the performance of the global matrix multiplication routine in the CMSSL). The $O(N^3)$ work is well load balanced and performed at high efficiency through blocking of row and column operations. The $O(N^2)$ work introduces a significant performance penalty, even for very large matrices, and a few thousand nodes. For submatrices of a size of about 600×600, about one-third of the time is spent on $O(N^2)$ work on the Connection Machine system CM-200 with 2048 nodes. About two-thirds of this overhead time is spent in communication with the remainder spent in poorly load-balanced arithmetic.

We also show that for architectures with a very simple communication performance model and for data layouts from a very large regular family, it is not possible to eliminate the overhead from poorly load-balanced arithmetic. Specifically, we show that in a communication model in which the time for a spread or reduction is determined only by the amount of data that either leaves or enters a node regardless of the configuration of the nodes, assignment of subarrays to nodes based on a two-dimensional nodal array is optimal both for the factorization and the triangular system solution. We also show that the ratio between the lengths of the axes of the two-dimensional nodal array is proportional to the ratio between the corresponding axes of the data array operated upon, i.e., the matrix subject to factorization, or the set of right-hand sides for triangular system solution. This proof does not apply directly to the CM-200, because for hypercubes the available bandwidth for a spread depends upon the node configuration, and the simple communication model does not fully capture the communications capabilities.

Acknowledgments. Many people at Thinking Machines Corp. provided support for the dense linear algebra work reported here. These include Mark Bromley, Tim Harris, Steve Heller, Robert L. Krawitz, Doug MacDonald, Kapil K. Mathur, Jill P. Mesirov, Luis F. Ortiz, and Leo Unger. Special thanks go to Hank Dardy at the Naval Research Laboratories, Washington, D.C., who made the Laboratories' Connection Machine system CM-200 available for the benchmarks presented in Tables 7 and 8. Robert Whaley's assistance in this effort is greatly appreciated. Last, but not least, we would like to thank the referees for their careful reading of the manuscript and several helpful comments and suggestions.

COMPUTING THE EXACT LEAST MEDIAN OF SQUARES ESTIMATE AND STABILITY DIAGNOSTICS IN MULTIPLE LINEAR REGRESSION*

ARNOLD J. STROMBERG†

Abstract. The difficulty in computing the least median of squares (LMS) estimate in multiple linear regression is due to the nondifferentiability and many local minima of the objective function. Several approximate, but not exact, algorithms have been suggested. This paper presents a method for computing the exact value of the LMS estimate in multiple linear regression. The LMS estimate is a special case of the least quantile of squares (LQS) estimate, which minimizes the qth smallest squared residual for a given data set. For LMS, $q = [n/2] + [(p+1)/2]$ where [ ] is the greatest integer function, n is the sample size, and p is the number of columns in the X matrix. The algorithm can compute a range of exact LQS estimates in multiple linear regression by considering $\binom{n}{p+1}$ possible θ values. It is based on the fact that each LQS estimate is the Chebyshev (or minimax) fit to some q element subset of the data. This yields a surprisingly easy algorithm for computing the exact LQS estimates. These and other estimates are used to study the stability of the LMS estimate in several examples.

Key words. least median of squares estimator, multiple linear regression, Chebyshev, minimax

1. Introduction.

Linear regression treats the problem of estimating θ_o where:

$$y_i = x_i\theta_o + \epsilon_i \quad i = 1, 2, \ldots, n,$$

where $(x_i, y_i) \in (R^p, R)$ are data points and θ_o is an unknown p-dimensional parameter vector and the ϵ_i are unknown errors. We will denote estimators of θ_o by $\hat{\theta}$. The residuals, $y_i - x_i\theta$, $i = 1, 2, \ldots, n$, are denoted $r_i(\theta)$. The best known estimators of θ_o is the least squares estimator $\hat{\theta}_{\text{LS}}$ which is

$$\underset{\theta}{\text{Argmin}} \quad \sum_{i=1}^{n} r_i^2(\theta).$$

The least squares estimator has the drawback that it is heavily influenced by outliers. It also suffers from the problem of masking [1]; that is, it is possible that multiple outliers may be present in the data set, yet they are not detected by common least squares diagnostic procedures.

The breakdown point of an estimator [5] has been shown to be a useful measure of the robustness of an estimator. It can be thought of as the least amount of arbitrary contamination that can drive the estimate to infinity. It is clear that the breakdown point of the least squares estimate in linear regression is $1/n$. Recent research [12], [13] has shown the usefulness of estimators with breakdown point approximately equal to $\frac{1}{2}$. These estimators ignore outliers and seem to be able to detect masking when least squares diagnostic procedures do not. The most studied, and probably most used, high breakdown estimator is the least median of squares (LMS) estimator [11]. It is denoted $\hat{\theta}_{\text{LMS}}$ and defined as

$$\underset{\theta}{\text{Argmin}} \quad \underset{1 \le i \le n}{\text{Median}} \; r_i^2(\theta).$$

To obtain the highest possible breakdown point for $\hat{\theta}_{\rm LMS}$ when the data are in general position, meaning that any p points give a unique determination of θ, the median is defined as the kth order statistic where $k = [n/2] + [(p+1)/2]$ and $[\cdot]$ indicates the greatest integer function. The LMS estimate is a special case of a more general estimate called the least quantile of squares (LQS) estimate [12, p. 124], which minimizes the qth smallest squared residual. The LMS estimate is used as a starting value for a number of other high breakdown estimators, including MM estimators [20], τ estimators [21], and the Simpson, Ruppert, and Carroll (SRC) estimator [16].

The stability of computed LMS estimates under minor shifts in the data is currently questioned by many statisticians. Hettmansperger and Sheather [9] and Ruppert [14] discuss the engine knock data where the PROGRESS approximation to the LMS estimate is vastly di erent for the original data and the data with one point changed slightly. In these articles, it is unclear whether this instability is due to the use of an approximation algorithm or is inherent in the LMS estimator. Their example is discussed in §3 of this paper. As discussed in [14], the problem with the LMS estimate is that it may be unstable for some data sets. This is undoubtedly due to its low efficiency and large number of local minima. Ruppert argues for the use of S estimators which have a 50% breakdown point, 28.7% asymptotic efficiency under normal errors, and apparently many fewer local minima than the LMS estimate. He suggests that extensive comparisons be done among S estimators, the LMS estimator, and other high breakdown estimators. The likely conclusion of such comparisons would be that S estimators are much more stable than LMS estimators, but it is also likely that the S estimate will be unstable for some data sets. For high breakdown estimates to be useful in practice, we must have methods for investigating the stability of the fit. In this paper we are concerned with whether or not the exact LMS estimate can be unstable for minor shifts in the data for some data sets, and if so, we are concerned with detecting instability of the LMS fit. Similar techniques could be used to detect instability in other high breakdown estimators.

Cook and Hawkins [3, p. 643] suggest that the LMS estimate be computed over a range of values for q (LQS) "to gain some reassurance that there is one consistent story in the data." Rousseeuw and van Zomeren agree [13, p. 649]. This paper provides a method for computing a range of LQS estimates exactly, and thus the exact LMS estimate is computed. With approximate algorithms, the "story" for di erent values of q may be di erent because of the algorithm used. The exact algorithm presented here rules out that possibility. The algorithm also provides an additional check on the stability of the LMS estimate by computing the exact LMS estimate for all $n-1$ element subsets of the data at the same time it is computing the exact LQS estimates for a range of values of q. Again, the goal here is to investigate the consistency of the story told by the high breakdown estimate.

One of the drawbacks of the LMS estimate and LQS estimates is that they are quite difficult to compute. The objective function is continuous, but not di erentiable, and it has many local minima. The PROGRESS algorithm of Rousseeuw and Leroy [12] is the most widely used algorithm for estimating $\hat{\theta}_{\rm LMS}$ in linear regression. It could easily be modified to compute LQS estimates. For a given data set and regression function, the PROGRESS algorithm computes the exact fit, $\hat{\theta}_{ef}$, to many randomly chosen p point elemental subsets of the data set. Denote the $\hat{\theta}_{ef}$ with the smallest median squared residual $\hat{\theta}$. If the regression function has no intercept, $\hat{\theta}$ is the PROGRESS estimate of $\hat{\theta}_{\rm LMS}$. If an intercept is used in the model, the intercept of $\hat{\theta}$ is adjusted to yield the smallest possible median residual. This adjusted $\hat{\theta}$ is then the PROGRESS estimate of $\hat{\theta}_{\rm LMS}$. Rousseeuw and Leroy [12] note that at the expense of additional computation time, the intercept adjustment can be done for each elemental set. Unfortunately the latter algorithm, which Steele and Steiger [17] show will find the exact value of $\hat{\theta}_{\mathrm{LMS}}$ when $p = 2$, does not yield the exact LMS estimate in multiple linear regression when $p > 2$.

The MVELMS algorithm of Hawkins and Simonoff [8], which is also based on the selection of p point elemental sets, but which uses an intercept adjustment for all elemental sets, has been proposed as an alternative to the PROGRESS algorithm. In general, it produces estimates of θ_o with a smaller objective function than the PROGRESS algorithm.

Using a geometric argument, Tichavsky [18] argued that the exact LMS estimate in multiple linear regression can be found by considering all $p+1$ point elemental sets and for each elemental set finding the values of θ where the magnitudes, but not the signs, of all $p+1$ residuals are equal. The method leads to $(2^p - 1)\binom{n}{p+1}$ values of θ that must be considered in order to compute the exact value of $\hat{\theta}_{\mathrm{LMS}}$ in multiple linear regression. Given the complexity of the problem for moderately large n and p, Tichavsky suggests approximating $\hat{\theta}_{\mathrm{LMS}}$ by selecting p point elemental sets and checking the median squared residual for the values of θ generated by the selected elemental sets.

Because an LQS estimate minimizes the qth smallest residual for a given data set, it must minimize the maximum squared residual for some q element subset of the data. Thus, the qth LQS estimate is the Chebyshev (or minimax) fit (see, e.g., Cheney [2]) to that q element subset. Section 2 presents two theorems that can be used to find the Chebyshev fit for given data set. The first implies that each LQS estimate must be the Chebyshev fit to some $p+1$ element subset of the data, and the second provides a surprisingly easy method for computing the Chebyshev fit to $p+1$ points. The theorems are used to develop an algorithm that, by considering $\binom{n}{p+1}$ possible θ values, computes exact LQS estimates in multiple linear regression. At the same time, the algorithm computes the LQS estimate for a range of values of q and for $n-1$ element subsets of the data as a check on the stability of the LMS estimate. Section 3 presents several examples.

2. The Chebyshev fit. In this section we adapt theorems found in Cheney [2] to provide a method for computing the Chebyshev fit, and thus the LQS estimates, in linear regression. The first relevant theorem can be restated in the context of regression as follows.

THEOREM 1 [2, p. 36]. *In linear regression, the Chebyshev fit, $\hat{\theta}_c$, will be the Chebyshev fit to some $p+1$ element subset of the data.*

By Theorem 1, if we can find $\hat{\theta}_c$ for all $p+1$ element subsets of the data, then we can find $\hat{\theta}_c$ for the entire data set. Theorem 2 provides a method for finding $\hat{\theta}_c$ when the sample size is $p+1$. The Haar condition says that there is one and only one exact fit to any p points. More formally, a set of points in $\mathbb{R}^p$ satisfies the Haar condition if every subset of p points is linearly independent (see, e.g., [2, p. 45].) Let $Y = (y_1, y_2, \ldots, y_n)^T$ and x be the $n \times p$ matrix given by $(x_1, x_2, \ldots, x_n)^T$.

THEOREM 2 [2, p. 41]. *Consider the linear regression setting described in* §1 *with sample size $p+1$. Assume that the Haar condition is satisfied. Then*

$$\hat{\theta}_{\mathrm{LS}} = \mathrm{MY}, \quad \textit{where } \mathrm{M} = (X^T X)^{-1} X^T$$

is the least squares fit to the data. Let

$$\epsilon = \frac{\sum_{i=1}^{p+1} r_i^2(\hat{\theta}_{\mathrm{LS}})}{\sum_{i=1}^{p+1} \left| r_i(\hat{\theta}_{\mathrm{LS}}) \right|}$$

and S *be the* $p+1$ *dimensional vector where* $s_i = \mathrm{sgn}(r_i(\hat{\theta}_{\mathrm{LS}}))$, $i = 1, 2, \ldots, p+1$. *Then*

$$\hat{\theta}_c = \mathrm{M}(\mathrm{Y} - \epsilon \mathrm{S}).$$

Remarks. Since the LQS estimate, denoted $\hat{\theta}_{(q)}$, is the Chebyshev fit for some sample of $p+1$ points, the following algorithm (Fig. 2.1) can be used for computing the exact value of the LQS estimates in multiple linear regression: for each $p+1$ point elemental set, use Theorem 2 to compute the Chebyshev fit, denoted $\hat{\theta}_c$. The $\hat{\theta}_c$ with the least qth smallest squared residual will be the exact value of $\hat{\theta}_{(q)}$. As with the algorithms of §1, implementations should take advantage of the fact that for many $\hat{\theta}_c$, computing all the squared residuals and/or the sort to find the qth smallest squared residual can be avoided. Suppose $\hat{\theta}$ is the current best estimate of $\hat{\theta}_{(q)}$ and $\hat{\theta}_c$ is the Chebyshev fit to the $p+1$ point elemental set being considered. The squared residuals at $\hat{\theta}_c$ need only be computed until $n-q$ are more than $r^2_{(q)}(\hat{\theta})$ because then it must be that $r^2_{(q)}(\hat{\theta}_c) > r^2_{(q)}(\hat{\theta})$. Should this not be the case, $\hat{\theta}_c$ becomes the new estimate of $\hat{\theta}_{(q)}$ and the squared residuals are sorted to find the qth smallest squared residual at the new estimate of $\hat{\theta}_{(q)}$.

The fact that $\hat{\theta}_{(q)}$ is the Chebyshev fit to some $p+1$ point elemental set seems intuitive, but it is quite surprising that the computation of $\hat{\theta}_c$ provided by Theorem 2 is only moderately more computationally difficult than computing the exact fit, $\hat{\theta}_{ef}$ to p points as is done in the approximate algorithms of §1. This suggests that algorithms based on computing $\hat{\theta}_{ef}$ could be improved by computing $\hat{\theta}_c$ instead of $\hat{\theta}_{ef}$. For example, the PROGRESS algorithm could be significantly improved by having it compute $\hat{\theta}_c$ for $p+1$ point subsets instead of $\hat{\theta}_{ef}$ for p point subsets. Because of the complexity of computing $\hat{\theta}_c$ for all $p+1$ point subsets of the data, the exact LMS fit can only be computed for reasonably small n and p, say $n \leq 50$ and $p \leq 5$. Using the GAUSS programming language on an IBM 386-33, such a computation could be expected to take about 33 hours. It seems clear that there is still a need for appropriately modified approximate algorithms. One such algorithm is discussed in Hawkins [7].

The theorems generalize results of Steel and Steiger [17]. If the Chebyshev fits are distinct, then the LMS fit will have $p+1$ points with squared residuals equal to the median squared residual, $q-p-1$ points with squared residuals less than the median squared residual, and $n-q$ points with squared residuals more than the median squared residual.

The exact algorithm can easily be modified to compute LQS estimates for a range of values of q in one pass through the $\hat{\theta}_c$. Use one row of a matrix Q to hold the current best estimate of $\hat{\theta}_{(q)}$ for the range of q's being computed. At each $\hat{\theta}_c$, compute and sort the squared residuals. Then update $\hat{\theta}_{(q)}$ if $r^2_{(q)}(\hat{\theta}_c)$ is less than the previous smallest value for $r^2_{(q)}(\theta)$. After considering all $\hat{\theta}_c$, the matrix K will contain the exact values of $\hat{\theta}_{(q)}$ for the values of q selected. As discussed in §1, the $\hat{\theta}_{(q)}$ can be used to check the stability of the LMS estimate.

The algorithm can also be modified to compute $\hat{\theta}_{-i}$, the LMS estimate for the data set with the ith data point deleted. This can be done at the same time as the computation

of the LQS estimates for the full data set. In general, use the ith row of an $n \times p$ matrix to hold the current best estimate of $\hat{\theta}_{-i}$. For each $\hat{\theta}_c$, check for improvement in each of the $\hat{\theta}_{-i}$. Of course, those $\hat{\theta}_c$ based on elemental sets that contain point i must be excluded from the possible $\hat{\theta}_{-i}$ values. For any other $\hat{\theta}_c$, the median squared residual for the data set with the ith point deleted will be the $(q + j)$th smallest residual for the entire data set where

$$j = \begin{cases} 0 & \text{if } r_i^2(\hat{\theta}_c) > r_{(q)}^2(\hat{\theta}_c), \\ 1 & \text{if } r_i^2(\hat{\theta}_c) \leq r_{(q)}^2(\hat{\theta}_c). \end{cases}$$

Thus the squared residuals need only be computed once at each $\hat{\theta}_c$ to find $\hat{\theta}_{(q)}$ for a range of q values and $\hat{\theta}_{-i}, i = 1, 2, \ldots, n$. As discussed in §1, these estimates can be used as a diagnostic tool. If their residuals are quite di erent than the exact LMS residuals for the entire data set, then the LMS estimate can be considered unstable.

The stability of the LMS fit could also be checked by listing fits to the N elemental sets with smallest values of the objective function. Instability in these fits would indicate instability in the LMS estimate.

The algorithms discussed here have been programmed by the author in GAUSS, version 2.0. A FORTRAN version is currently being developed. Its implementation will be considered elsewhere.

3. Examples.

3.1. Regression through the origin. The most notable difference between the approximate algorithms and the exact algorithm is that the elemental sets consist of $p + 1$ points for the exact algorithm, but only p points for the approximate algorithms. As an example of how this can affect the $\hat{\theta}_{\text{LMS}}$ fit, consider the data in Table 3.1, fit by a simple linear regression through the origin model. Both the PROGRESS and MVELMS algorithms use one point elemental sets, while the exact algorithm uses two point elemental sets. The PROGRESS and MVELMS algorithms find the line that passes through point 8 which has slope .657225 and median squared residual .107. According to this fit, points 0 through 4 should be considered outliers. The exact LMS fit is the Chebyshev fit to points 4 and 5, which has slope .38485 and median squared residual .075. According to the exact fit, points 6 through 9 should be considered outliers. The regression lines are depicted in Fig. 3.1.

The $\hat{\theta}_{-1}$ are useful in understanding the LMS fit to this data. If any of the first five points are removed, the LMS fit shifts to fit the upper five points, while removing any one of the upper five points has little impact on the LMS fit. It seems that considering any of the points to be outliers when the LMS fit to the $\hat{\theta}_{-1}$ is so variable is questionable.

TABLE 3.1

y:	0.3302	0.6590	0.9888	1.3194	1.6495	0.6596	1.3192	1.9815	2.6289	3.3011

3.2. Cloud seeding data. This data, which can be found in Cook and Weisberg [4, p. 4], summarizes the results of a cloud seeding experiment done in Florida in 1975. On each of 24 days suitable for seeding, the following six explanatory variables were recorded:

A: "Action" was set to zero if no seeding took place and to one if seeding occurred.

B: "Time" was the number of days since the beginning of the experiment.

S: "Suitability" was a measure of the day's suitability for seeding.

C: "Echo coverage" was the percent of cloud coverage in the experimental area.

P: "Prewetness" was the total rainfall in the target area in the hour before seeding.

E: "Echo motion" was set to one for a moving radar echo and two for a stationary radar echo.

The data was fit using a multiple linear regression model with the preceding six explanatory variables and an intercept. The response variable was ln (rainfall) in a target area for a six-hour period. The PROGRESS approximation to $\hat{\theta}_{\text{LMS}}$ (1.43, .695, $-.016$, $-.455$, $-.039$, .941, 1.08) is based on the exact fit to points 0, 1, 9, 16, 17, 19, and 20. Its median squared residual was .0601. The MVELMS approximation to $\hat{\theta}_{\text{LMS}}$ (.740, 1.13,

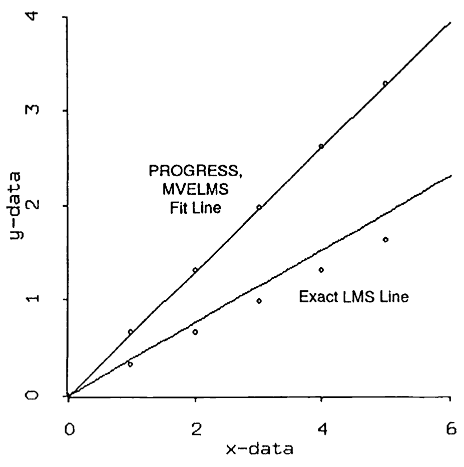

FIG. 3.1. PROGRESS, MVELMS, *and exact* LMS *fit of a simple linear regression through the origin model for the data in Table* 3.1.

$-.0047$, $-.567$, $-.056$, 3.60, .990) is based on the exact fit to points 2, 3, 5, 8, 11, 21, and 23. Its median squared residual was .0278. Neither of these approximations use a seven-point subset of the eight points (2, 3, 4, 8, 9, 11, 16, 23) that determine the exact LMS fit (.715, 1.13, $-.0052$, $-.551$, $-.056$, 3.61, .962) which has median squared residual .0241. The exact LMS computation took approximately 90 minutes on an IBM 386-33. The MVELMS basis does have five points in common with the exact basis, which explains why it is close to the exact LMS fit.

The plot of the LMS residuals versus fit values has been suggested [12] for assisting in detecting outliers in multiple linear regression. The PROGRESS, MVELMS, and exact LMS residual plots for the cloud seeding data are given in Fig. 3.2. Note that with the exception of point 6 and possibly 15, the PROGRESS algorithm identifies outliers di erent from the other two methods. The MVELMS plot is very close to the exact LMS plot, but there would be no way to know this without computing the exact LMS fit. For this data set, none of the residuals based on $\hat{\theta}_{-i}, i = 1, 2, \dots, n$ vary much from the residuals for the full data set (Fig. 3.2(a)); thus none of the data points are flagged as particularly influential.

The ability to compute the exact LMS estimate allows us to study the stability of $\hat{\theta}_{\text{LMS}}$ under shifts in the observed values. Let the modified cloud seeding data be the cloud seeding data with the response at point 4 shifted from 0.8961 to 1.1061. The residual plots for the three methods are almost identical to those given in Fig. 3.2. If we shift the response for point 4 from 1.1061 to 1.1161, the PROGRESS and MVELMS fits are virtually unchanged from those in Fig. 3.2, but the exact LMS residual plot is now similar to the PROGRESS plot of Fig. 3.2. It is interesting that, although the PROGRESS and exact LMS residual plots are similar in this case, the MVELMS fit has a smaller median squared residual than the PROGRESS fit. The instability of the LMS residual plot is shown in Fig. 3.3 where the shift of point 4 from 1.1061 to 1.1161 causes a di erent set of outliers to be identified. In the modified data set with point 4 at 1.1161, the influence of point 4 on the fit is evident from $\hat{\theta}_{-4}$, which yields a residual plot quite di erent from the residual plot for the entire data set (Fig. 3.3(b)). As expected, since only point 4 has been modified, the $\hat{\theta}_{-4}$ residual plot is similar to Fig. 3.3(a).

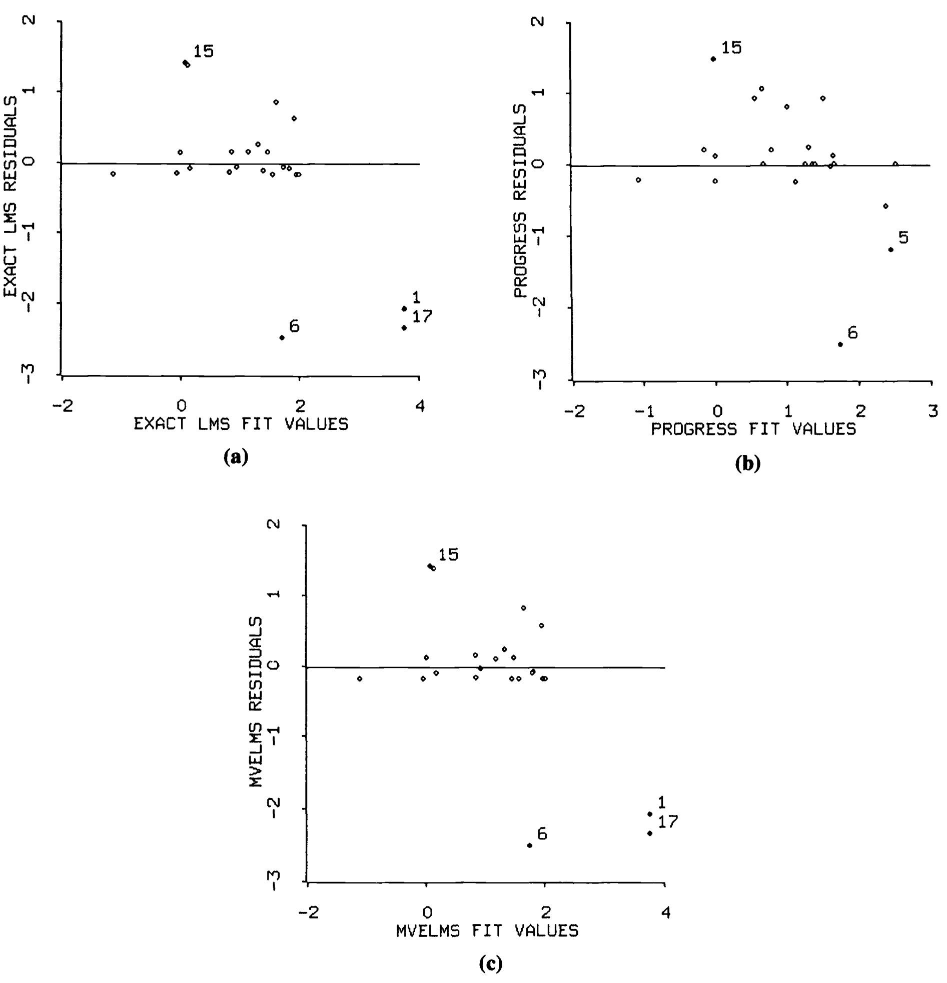

FIG. 3.2. LMS *residuals versus fit values for the cloud seeding data using*: (a) *Exact* LMS, (b) PROGRESS, *and* (c) MVELMS.

3.3. Engine knock data. This data set [10] has been discussed in several recent papers on high breakdown estimators. Hettmansperger and Sheather [9] and Ruppert [14] point out that a small recording error in the second point ("air" = 15.1 instead of 14.1) resulted in a vastly different LMS residual analysis than the correct data. Because they use the PROGRESS algorithm, it is possible that this instability was due to the use of an approximate algorithm. As discussed in Ruppert [14], the exact LMS algorithm is not sensitive to the recording error. To continue the discussion of the data set, we can compute the stability diagnostics suggested in this paper along with the exact LMS fit for the data with the recording error. Table 3.2 contains the residuals from the estimates that minimize the ninth through twelfth smallest residuals. Note that all the estimators yield similar residuals and thus similar analyses; therefore we can conclude that the LMS estimate is stable over the range of q's considered.

To further consider the stability of the LMS fit, we can consider the residuals from the exact LMS fit to 15 point subsets of the data. Table 3.3 presents residuals from these fits with various points deleted. The instability in these residuals can be considered a

lack of stability in the LMS fit for the entire data set; thus conclusions based on the LMS fit are questionable at best.

The same diagnostics were computed for the data without the recording error. Interestingly, no instability was detected. The LMS residuals for 15 point subsets of the data and the LQS estimate residuals were fairly stable.

3.4. Salinity data. This data was analyzed by Ruppert and Carroll [15]. It has $n = 28$ and $p = 4$, and computation time for the exact LMS fit is about 12 minutes. One of their conclusions was that the third and sixteenth points masked the influence of point 5, i.e., after those points were deleted the influence of point 5 was evident. Rousseeuw and Leroy [12] show that the PROGRESS approximation to the LMS estimate flags points 5, 8, 16, 23, and 24 as outliers and thus detects the influence of point 5. If the LMS estimate is unstable for this data set, then the detection of point 5 by Rousseeuw and Leroy was just chance. On the other hand, if the LMS estimate is fairly stable, their claim that the LMS estimate detected masking is reasonable in this case. Table 3.4 presents the

residuals from a range of LQS estimates. Although the $q = 18$ residuals are somewhat di erent from the others, the residuals are fairly stable over the range of q's considered. Note that, although reasonably stable, the residuals for points 8, 23, and 24 in Table 3.3 are not large for most of the q's; thus they should probably not be considered outliers. Points 5 and 16 appear to be stable LMS outliers. Consideration of the LMS fits to 27 point subsets of the data yields similar conclusions and detects no additional instability; thus this data set appears to be one in which the LMS estimate truly detects masking.

Remark. The first three examples were chosen to show that the suggested diagnostics can detect instability in the LMS estimate when it is presented. The last example is one in which the LMS estimate is stable and thus provides useful information. The exact LMS fit and the proposed diagnostics have been computed for many of the data sets found in [12]. In most cases, the LMS estimate was stable; thus it appears that the argument by Rousseeuw and Leroy that LMS is a useful statistical procedure is valid. It is the investigator's responsibility to check the stability of the LMS estimate for any given data set before making inferences based on the LMS fit.

Acknowledgments. The author thanks Douglas Hawkins, Jeff Simonoff, Simon Sheather, and David Ruppert for many helpful comments.

NUMERICAL AND ASYMPTOTIC SOLUTIONS FOR PERISTALTIC MOTION OF NONLINEAR VISCOUS FLOWS WITH ELASTIC FREE BOUNDARIES*

DALIN TANG† AND SAMUEL RANKIN†

Abstract. A mathematical model for peristaltic motion of nonlinear viscous flows with elastic free boundaries is introduced. An iterative numerical method is used to solve the free boundary problem. Long wave asymptotic expansion is developed and the zeroth order approximation is used as the numerical initial condition. The existence and uniqueness of the solution for the free boundary equation derived from the long wave expansion are proved. Computations were conducted to study the long wave approximation, the numerical solutions for the exact equations, and the influences of the parameters on the solutions.

Key words. peristaltic, Navier–Stokes, long wave, free boundary, elasticity

AMS subject classifications. 76, 39, 41, 34

1. Introduction. Peristaltic pumping, the physiological phenomenon of a circumferential progressive wave propagating along a flexible tube, plays an essential role in transporting fluid inside living organisms. Many modern mechanical devices have been designed on the principle of peristaltic pumping to transport fluids without internal moving parts, for example, the blood pump in the heart-lung machine and peristaltic transport of noxious fluid in the nuclear industry. Earlier mathematical work on the problem of peristaltic transport was based upon a viscous fluid model governed by the Navier–Stokes equations subject to a prescribed velocity on the boundary of the tube [11], [3]. A review of the research results can be found in the articles by Jaffrin and Shapiro [8] and Winet [21]. Numerical study of two-dimensional and axisymmetric peristaltic flows can be found in the articles by Takabatake, Ayukawa, and Mori [17], [18]. Recently, more refined models have been developed to deal with the peristaltic transport of a fluid-particle mixture or a heat-conducting fluid. The former was studied by Hung and Brown [7] and Kaimal [9], and the latter by Bestman [1] and Tang and Shen [19], [20].

In reality, the shape of the tube walls (e.g., blood vessels) is often unknown. They should be treated as free boundaries and solved as part of the solution. Experiments also suggest that the elastic properties of the tube walls should be taken into consideration [6], [10], [12]. In this paper, we introduce a three-dimensional (axisymmetric) model for viscous peristaltic motion with elastic free boundaries that combines three important factors: viscosity, elasticity, and free boundary. With the free boundary, this model should give a better representation of the actual physical situation than the fixed boundary models. Investigation of the free boundary model will provide useful information for designing equipment applying peristaltic motions and will lead to better understanding of some physiological processes involving peristalsis. However, the introduction of the free boundary makes this model difficult to solve. The fact that the domain is unknown makes it difficult to change the partial differential equation (PDE) system to a discretized difference system, which is the first step necessary to solve the PDE system using the finite difference method. To overcome this difficulty, we introduce a global iterative method for this model. The idea was originated from Fung [4]. To explain, we outline the method below.

Step 1. Obtain the long wave solution, which will be used as the numerical initial condition. The free boundary solution obtained from the long wave approximation will

*Received by the editors April 1, 1992; accepted for publication (in revised form) December 11, 1992. This research was supported in part by National Science Foundation grants DMS-9006043 and DMS-9209129.

†Mathematical Sciences Department, Worcester Polytechnic Institute, Worcester, Massachusetts 01609.

be used as the initial guess for the exact free boundary.

Step 2. With the boundary $\Gamma : r = H(x)$ obtained from Step 1 ($H(x)$ is the radius of the tube), use a local successive overrelaxation (SOR) method [20] to solve the system as a fixed boundary problem without the elasticity. The mapping

$$\xi = x, \tag{1.1}$$
$$\eta = r/H(x) \tag{1.2}$$

is used to map the (x, r) domain to a rectangular (ξ, η) domain. The number of iterations of the SOR method needed here should be determined by numerical experiment.

Step 3. Update the free boundary function $H(x)$ by using the elastic condition.

Step 4. With the newly updated $H(x)$, repeat Steps 2 and 3 until the desired accuracy is achieved. Adjust the number of local iterations if necessary to achieve the best convergence.

There are three key points in this method worth mentioning. (1) By using this procedure, the unknown domain becomes "known" at each global iteration and discretizing the PDE system becomes possible. (2) Using the long wave solution as the numerical initial condition is important to gain fast convergence. (3) The introduction of the mapping (1.1)–(1.2) makes the transformation of the (x, r) domain to a rectangular domain a fairly easy job.

In §2, we formulate the problem. The long wave asymptotic expansion is developed and solved in §3. The global iterative method is explained in §4. Results and discussions are given in §5.

2. Formulation.

We consider viscous flow in an elastic tube while the shape of the tube is to be determined. A tension function is prescribed on the boundary to reflect the elastic property of the tube wall. The tube and the motion are assumed to be axisymmetric and the wave traveling along the tube (x-direction) is periodic. By choosing a coordinate system moving with the wave, the boundary becomes stationary. The problem is formulated in Fig. 1.

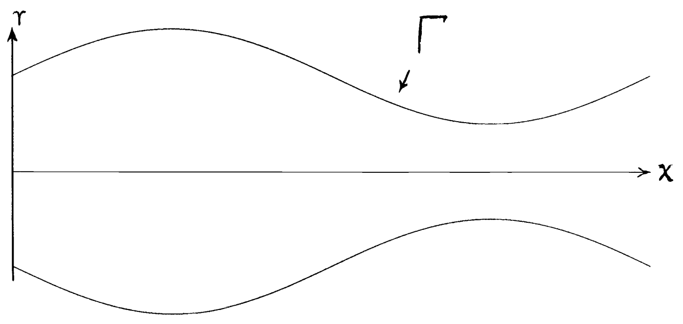

FIG. 1. *Peristaltic motion in an elastic tube.*

Equations of motion and continuity. Assuming the flow is Newtonian, viscous, and incompressible, we use the Navier–Stokes equations as the governing equations:

$$\rho \mathbf{u}_t + \rho(\mathbf{u} \cdot \nabla)\mathbf{u} = -\nabla p + \mu \nabla^2 \mathbf{u}, \quad \nabla \cdot \mathbf{u} = 0, \quad t \geq 0, x \in \Omega,$$

where ρ is the density, $\mathbf{u}$ the velocity with respect to the moving coordinate system, p the pressure, μ the dynamic viscosity, and Ω is the domain consisting of one period of the tube. In terms of cylindrical coordinates, the nondimensionalized equations of motion and continuity with axisymmetry are

$$\frac{\partial v_x}{\partial t}+v_x\frac{\partial v_x}{\partial x}+v_r\frac{\partial v_x}{\partial r}=-\frac{\partial p}{\partial x}+\frac{1}{R}\left(\frac{\partial^2 v_x}{\partial x^2}+\frac{1}{r}\frac{\partial v_x}{\partial r}+\frac{\partial^2 v_x}{\partial r^2}\right), \tag{2.1}$$

$$\frac{\partial v_r}{\partial t}+v_x\frac{\partial v_r}{\partial x}+v_r\frac{\partial v_r}{\partial r}=-\frac{\partial p}{\partial r}+\frac{1}{R}\left(\frac{\partial^2 v_r}{\partial x^2}+\frac{\partial^2 v_r}{\partial r^2}+\frac{1}{r}\frac{\partial v_r}{\partial r}-\frac{v_r}{r^2}\right), \tag{2.2}$$

$$\frac{\partial v_x}{\partial x}+\frac{v_r}{r}+\frac{\partial v_r}{\partial r}=0, \tag{2.3}$$

where v_x and v_r are longitudinal and radial components of the velocity relative to the moving frame and R is the Reynolds number.

Free boundary. The free boundary $\Gamma : r = H(x)$ is to be determined as part of the solutions where $H(x)$ is the radius of the tube. We assume that $H(x)$ is periodic. Our result shows that for each prescribed initial opening

$$H(0) = H_0, \tag{2.4}$$

there is a solution to the free boundary equation obtained from the long wave approximation if certain conditions are met (see §3). This leads to the existence of the exact free boundary when the numerical method converges. However, the theoretical proof of the existence and uniqueness of the exact free boundary is a much harder problem and remains to be solved in the future.

Boundary conditions for the velocity and pressure. Considering boundary conditions, we assume no slipping between the fluid and wall, no penetration through the wall, and no horizontal motion of the wall. These lead to the following boundary conditions:

$$\mathbf{u}|_\Gamma = (v_x, v_r)|_\Gamma = (-C, f),$$

where Γ is the free boundary, C is the wave velocity, and f is determined by the radial motion of the free boundary. Recalling that the free boundary is $H = H(x) = H(x^* - Ct)$, where $H(x)$ is the radius of the free boundry and x^* is the old x-coordinate, we obtain

$$v_r|_\Gamma = \frac{dH}{dt} = \frac{\partial H}{\partial x^*}\frac{dx^*}{dt} + \frac{\partial H}{\partial t} = -CH'(x),$$

where the no-horizontal-motion condition $dx^*/dt = 0$ has been used. Now we have

$$\mathbf{u}|_\Gamma = (v_x, v_r)|_\Gamma = (-C, -CH'(x)). \tag{2.5}$$

It is easy to check that

$$\mathbf{u}\cdot\mathbf{n}|_\Gamma = 0,$$

i.e., the normal component of the velocity at the boundary is zero. Wave velocity C is prescribed with the tension function that is discussed below.

At $r = 0$, because of the symmetry, we assume

$$\frac{\partial v_x}{\partial r} = 0, \qquad v_r = 0.$$

At the two ends of the tube, we impose periodic conditions on the velocity and the pressure

$$v_x|_{x=0} = v_x|_{x=\ell'}, \tag{2.6}$$

$$v_r|_{x=0} = v_r|_{x=\ell'}, \tag{2.7}$$

$$p|_{x=0} = p|_{x=\ell'}, \tag{2.8}$$

where ℓ is the wave length. These periodic conditions are actually implied by the periodicity of the tension function and the Laplace law to be described below. Some numerical boundary conditions for the pressure at $r = 0$ and $\Gamma : r = H(x)$ will also be imposed. The details will be discussed later.

Additional boundary condition from elasticity—the Laplace law. Because the boundary is free, an additional boundary condition is needed to make the model complete. That condition comes from the consideration of the elastic property of the tube. Because of the complexity of structure of the tube walls in real application, there are many ways to introduce elasticity into a model. For simplicity, we will adopt the Laplace law to represent the elastic property of the wall [13]:

$$p|_\Gamma = \frac{T(x,r)}{r}, \tag{2.9}$$

where $T(x, r)$ is the prescribed tension function. Several cases are discussed in this paper. In practice, various functions can be introduced to find the best agreement with experimental data. When necessary, we may introduce more complicated elasticity laws involving stresses and strains of the walls, which would make the model more practical. The change of the elastic condition will affect only the part of updating the free boundary. Therefore, the numerical method will still be applicable with minor adjustments.

Remark. The prescribed tension is fundamental to the whole mechanism. We assume that it takes the form of a traveling wave

$$T = T(x^*, t, r) = T(x^* - Ct, r) = T(x, r),$$

with given wave speed C, period, and wave length. We are then looking for solutions in which the fluid velocity, pressure, and the free boundary also adopt the form of traveling waves with the same wave speed, period, and wave length as the imposed wave of elasticity.

From the Laplace law, it is clear that prescribing T is equivalent to prescribing the pressure at the free boundary.

Flux condition. Using $\mathbf{u} \cdot \mathbf{n}|_\Gamma = 0, \nabla \cdot \mathbf{u} = 0$, and the divergence theorem, we can prove [19]

$$\int_{A(x)} \mathbf{u} \cdot \mathbf{n} dA = \text{const} = Q,$$

where $A(x)$ is the cross section at x and Q is the flux. This is the so-called flux condition.

In terms of cylindrical coordinates, the flux condition can be written as

$$\int_{A(x)} \mathbf{u} \cdot \mathbf{n} dA = \int_0^{2\pi} \int_0^{H(x)} v_x \, r \, dr \, d\theta = Q$$

or

$$\int_0^{H(x)} v_x r dr = \frac{Q}{2\pi} = \text{const.} \tag{2.10}$$

For the fixed boundary model, it has been proved that for each prescribed flux, there exists a unique solution to the system [19]. A similar conclusion is also true for the fixed boundary model if we replace the flux condition by the pressure drop condition, i.e.,

$$p|_{x=\ell} - p|_{x=0} = \text{const} = P_d,$$

where P_d is the prescribed pressure drop. The relation between the flux and the pressure drop is almost linear for the fixed boundary model [20].

For the free boundary model, the situation is different. Due to the periodicity of the free boundary and the Laplace law just introduced, the pressure drop over one period of the tube must be zero. That means the pressure drop cannot be prescribed for the free boundary model. It is found in this paper that prescribing the flux is equivalent to prescribing the intial tube opening $H(0) = H_0$ for the free boundary model. For theoretical convenience, we choose to prescribe H_0.

Although we cannot prescribe the flux condition once H_0 is given, we still have that identity which will be used to derive the free boundary equation from the long wave approximation. The constant Q will be determined as part of the solution.

Remark. To prescribe pressure drop, tapering of the tube must be taken into consideration. This will be treated in a separate paper.

Remark. Recall that we are using a moving coordinate system. The laboratory longitudinal velocity u^* can be expresssed in terms of v_x by

$$u^* = v_x + C. \tag{2.11}$$

So the laboratory flux

$$Q^*(x^*) = \int_{A(x^*)} u^* dA = \int_{A(x^*)} v_x dA + \int_{A(x^*)} C dA = \text{const} + C \int_{A(x^*)} dA \tag{2.12}$$

will be a function of x^*, not a constant.

From the above, we have the mathematical model for the viscous flow with an elastic free boundary (in nondimensionalized version):

$$\begin{aligned}
&\mathbf{u}_t + (\mathbf{u} \cdot \nabla)\mathbf{u} = -\nabla p + \frac{1}{R}\nabla^2 \mathbf{u}, && \text{(equation of motion)},\\
&\nabla \cdot \mathbf{u} = 0, && \text{(equation of continuity)},\\
&\mathbf{u}|_\Gamma = \left(-C, -C\frac{dH}{dx}\right), && \text{(boundary conditions for } \mathbf{u} \text{ at } \Gamma),\\
&\frac{\partial v_x}{\partial r}|_{r=0} = 0, \quad v_r|_{r=0} = 0, && \text{(boundary conditions for } \mathbf{u} \text{ at } r = 0),\\
&\mathbf{u}|_{x=0} = \mathbf{u}|_{x=\ell}, && \text{(periodic condition for } \mathbf{u}),\\
&p|_{x=0} = p|_{x=\ell}, && \text{(periodic condition for } p),
\end{aligned}$$

$$\Gamma : r = H(x), \qquad H(0) = H(\ell) = H_0, \text{ (conditions for the free boundary)},$$
$$p|\Gamma = \frac{T(x,r)}{r}, \qquad \text{(Laplace law)}.$$

Assuming axisymmetry, the stationary system can be expressed in terms of cylindrical coordinates as

$$v_x \frac{\partial v_x}{\partial x} + v_r \frac{\partial v_x}{\partial r} = -\frac{\partial p}{\partial x} + \frac{1}{R}\left(\frac{\partial^2 v_x}{\partial x^2} + \frac{1}{r}\frac{\partial v_x}{\partial r} + \frac{\partial^2 v_x}{\partial r^2}\right), \tag{2.13}$$

$$v_x \frac{\partial v_r}{\partial x} + v_r \frac{\partial v_r}{\partial r} = -\frac{\partial p}{\partial r} + \frac{1}{R}\left(\frac{\partial^2 v_r}{\partial x^2} + \frac{\partial^2 v_r}{\partial r^2} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{v_r}{r^2}\right), \tag{2.14}$$

$$\frac{\partial v_x}{\partial x} + \frac{v_r}{r} + \frac{\partial v_r}{\partial r} = 0, \tag{2.15}$$

$$(v_x, v_r)|_\Gamma = (-C, -CH'(x)), \tag{2.16}$$

$$\frac{\partial v_x}{\partial r}|_{r=0} = 0, \qquad v_r|_{r=0} = 0, \tag{2.17}$$

$$v_x|_{x=0} = v_x|_{x=\ell}, \qquad v_r|_{x=0} = v_r|_{x=\ell}, \tag{2.18}$$

$$p|_{x=0} = p|_{x=\ell}, \tag{2.19}$$

$$\Gamma : r = H(x), \quad H(0) = H(\ell) = H_0, \tag{2.20}$$

$$p|_\Gamma = \frac{T(x,r)}{r}, \qquad 0 \le x \le \ell, 0 < r \le H(x). \tag{2.21}$$

Compared with the fixed boundary model, this model treats the boundary as a free boundary. An additional boundary condition is introduced by using the Laplace law of elasticity. Instead of prescribing the flux condition, the initial opening of the tube $H_0 = H(0)$ is prescribed to ensure a unique solution of the system.

3. Long wave asymptotic approximation. Assume that $0 < d/\ell = \epsilon << 1$, where d is the average radius of the tube and ℓ is the wave length. Our previous experience indicates that $p = O(\epsilon^{-2})$. The Laplace law implies $T = O(p) = O(\epsilon^{-2})$. Then by assuming $R = O(\epsilon)$, the zeroth order long wave approximation will be essentially a one-dimensional linear system with free boundary; therefore, it is much easier to handle. Please note that although we made the assumption $R = O(\epsilon)$, it does not imply that our numerical method will be valid only for small Reynolds numbers since we are basically using this approximation as the numerical initial condition. The numerical method covered in §4 does apply to finite Reynolds number cases. For simplicity, when we simply replace, respectively, $x, \partial/\partial x, p, \ell, R, T$, by $x/\epsilon, \epsilon(\partial/\partial x), p\epsilon^{-2}, \ell/\epsilon, \epsilon R, T\epsilon^{-2}$ in (2.13)–(2.21), the system becomes

$$
\begin{aligned}
&\epsilon^2 v_x \frac{\partial v_x}{\partial x} + \epsilon v_r \frac{\partial v_r}{\partial r} = -\frac{\partial p}{\partial x} + \frac{1}{R}\left(\epsilon^2 \frac{\partial^2 v_x}{\partial x^2} + \frac{1}{r}\frac{\partial v_x}{\partial r} + \frac{\partial^2 v_x}{\partial r^2}\right),\\
&\epsilon^2 v_x \frac{\partial v_r}{\partial x} + \epsilon v_r \frac{\partial v_r}{\partial r} = -\epsilon^{-1}\frac{\partial p}{\partial r} + \frac{1}{R}\left(\epsilon^2 \frac{\partial^2 v_r}{\partial x^2} + \frac{\partial^2 v_r}{\partial z^2} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{v_r}{r^2}\right),\\
&\epsilon \frac{\partial v_x}{\partial x} + \frac{v_r}{r} + \frac{\partial v_r}{\partial r} = 0,\\
&(v_x, v_r)|_\Gamma = (-C, -C\epsilon H'(x)),\\
(3.1)\quad &\frac{\partial v_x}{\partial r}|_{r=0} = 0, \qquad v_r|_{r=0} = 0,\\
&v_x|_{x=0} = v_x|_{x=\ell}, \qquad v_r|_{x=0} = v_r|_{x=\ell},\\
&p|_{x=0} = p|_{x=\ell},\\
&\Gamma : r = H(x), \qquad H(0) = H(\ell) = H_0,\\
&p|_\Gamma = \frac{T(x,r)}{r}.
\end{aligned}
$$

Because of the asymptotic assumptions, the odd terms of the asymptotic expansions of $\mathbf{u}, p$, and H will turn out to be zero. Therefore, we assume

$$
\begin{aligned}
\mathbf{u} &= \mathbf{u}_0 + \epsilon^2 \mathbf{u}_2 + \epsilon^4 \mathbf{u}_4 + \cdots,\\
p &= p_0 + \epsilon^2 p_2 + \epsilon^4 p_4 + \cdots,\\
H &= H_0 + \epsilon^2 H_2 + \epsilon^4 H_4 + \cdots,
\end{aligned}
$$

where $\mathbf{u}_i = (v_x^i, v_r^i)$. Substituting these into (3.1) for the zeroth order approximation, we obtain (in the following, we use H for $H_0(x)$ and H_0 for the initial opening),

$$\frac{1}{R}\left(\frac{1}{r}\frac{\partial v_x^0}{\partial r} + \frac{\partial^2 \partial v_x^0}{\partial r^2}\right) = \frac{\partial p_0}{\partial x}, \tag{3.2}$$

$$\frac{\partial p_0}{\partial r} = 0, \tag{3.3}$$

$$\frac{\partial v_r^0}{r} + \frac{\partial v_r^0}{\partial r} = 0, \tag{3.4}$$

$$(v_x^0, v_r^0)|_\Gamma = (-C, 0), \tag{3.5}$$

$$\frac{\partial v_x^0}{\partial r}|_{r=0} = 0, \qquad v_r^0|_{r=0} = 0, \tag{3.6}$$

$$v_x^0|_{x=0} = v_x^0|_{x=\ell}, \qquad v_r^0|_{x=0} = v_r^0|_{x=\ell}, \tag{3.7}$$

$$p_0|_{x=0} = p_0|_{x=\ell}, \tag{3.8}$$

$$\Gamma : r = H(x), \quad H(0) = H(\ell) = H_0, \tag{3.9}$$

$$p_0|_\Gamma = \frac{T(x,r)}{r}, \tag{3.10}$$

while

$$\int_0^H v_x^0 r dr = \frac{Q}{2\pi} \tag{3.11}$$

is an identity we will need in deriving the free boundary equation.

From (3.3), we see that $p_0 = p_0(x)$. Using (3.2) and the corresponding boundary conditions, we obtained

$$v_x^0 = \frac{1}{4}R(r^2 - H^2)\frac{\partial p_0}{\partial x} - C. \tag{3.12}$$

Plug into (3.11) and integrate

$$-\frac{R}{8}\frac{\partial p_0}{\partial x}H^4 - CH^2 = \frac{Q}{\pi}. \tag{3.13}$$

From (3.10), p_0 can be expressed in terms of $H(x)$ as

$$p_0 = \frac{T(x, H(x))}{H(x)}.$$

Thus (3.13) contains one unknown function $H(x)$ only. If $H(x)$ can be solved from (3.13) and (3.9), then p_0 and v_x^0 are also determined. It is easy to see from (3.4)–(3.6) that

$$v_r^0 = 0.$$

We consider the three cases below that are chosen because they are the three easiest simplifications of the general function $T(x, r)$. Comparison between the numerical and experimental results must be done to see how realistic these conditions are.

Case 1. $T(x, r) = T(r)$. From (3.10), $p_0 = (T(H))/(H) = p_0(H)$. Using this information and also letting $\ell = 1$ for simplicity, (3.13) and (3.9) become

$$-\frac{R}{8}\frac{\partial p_0}{\partial H}\frac{dH}{dx}H^4 - CH^2 = \frac{Q}{\pi}, \qquad H(0) = H(1) = H_0. \tag{3.14}$$

Equation (3.14) has a constant solution

$$H = \left(-\frac{Q}{(\pi C)}\right)^{1/2}. \tag{3.15}$$

It follows from here that

$$p_0 = \text{const}, \tag{3.16}$$

$$v_x^0 = -C, \tag{3.17}$$

$$v_r^0 = 0. \tag{3.18}$$

We also solved (3.14) numerically and (3.15) was the only solution we found. It turns out that (3.15)–(3.18) is also the exact solution to (2.13)–(2.21). Therefore, we suspect that the constant solution is the only solution to the system. However, we cannot yet provide a theoretical proof.

Case 2. $T(x,r) = T_0 b(x)$, where $b(x)$ is continuously differentiable and periodic with period $1, 0 < r_1 \leq b(x) \leq r_2 < \infty$. Now we have

$$p_0 = \frac{T_0 b(x)}{H}, \qquad p_{0x} = \frac{T_0 b'(x) H - T_0 b(x) H'}{H^2}.$$

The free boundary equation is

$$(3.19) \quad H'(x) = \frac{b'}{b} H + \frac{8}{RT_0}\left(\frac{C}{b(x)} + \frac{Q}{\pi b(x) H^2(x)}\right), \qquad H(0) = H(1) = H_0.$$

For (3.19), we have the following theorem.

THEOREM. *Let $b(x) \in C^1[0,1]$ be periodic with period 1, $b(0) = b(1) = 1$, $0 < b_1 \leq b(x) \leq b_2 < \infty$, $C \cdot Q \leq 0$, $\epsilon = (8/RT_0)$. Then for each $H_0 > 0$, there is $\epsilon_0 > 0$, such that for $\epsilon < \epsilon_0$, there exists a Q such that the free boundry equation* (3.19) *has a unique solution.*

Proof. We need the following lemma.

LEMMA ([2, Thm. 15.1, p. 148]). *Let $\mathbf{X}$, $\mathbf{Y}$, $\mathbf{Z}$ be Banach spaces, and let $\mathbf{U} \subset \mathbf{X}$, and $\mathbf{V} \subset \mathbf{Y}$ be neighborhoods of x_0 and y_0, respectively. Let $\mathcal{F}(x,y) : \mathbf{U} \times \mathbf{V} \to \mathbf{Z}$ be continuous and continuously differentiable with respect to y. Suppose also that $\mathcal{F}(x_0, y_0) = 0$ and $\mathcal{F}_y^{-1}(x_0, y_0) \in \mathbf{L(Z,Y)}$. Then there exist balls $\overline{\mathbf{B}}_{\delta_x}(x_0) \subset \mathbf{U}$, $\overline{\mathbf{B}}_{\delta_y}(y_0) \subset \mathbf{V}$ and exactly one map $\mathcal{T} : \mathbf{B}_{\delta_x}(x_0) \to \bar{B}_{\delta_y}(y_0)$ such that $\mathcal{T} x_0 = y_0$ and $\mathcal{F}(x, \mathcal{T} x) = 0$ on $\mathbf{B}_{\delta_x}(x_0)$. This map $\mathcal{T}$ is continuous.* □

Proof of the theorem. Let $f(x) = 1/H(x)$, (3.16) is changed to

$$(bf)' = -\epsilon\left(Cf^2 + \frac{Q}{\pi} f^4\right).$$

Integrate from 0 to x,

$$b(x) f(x) = f(0) - \epsilon \int_0^x \left(Cf^2 + \frac{Q}{\pi} f^4\right) dx,$$

where $f(0) = 1/H(0)$. $f(0) = f(1)$ implies

$$(3.20) \qquad Q = -\pi C \frac{\int_0^1 f^2 dx}{\int_0^1 f^4 dx}.$$

The equation now becomes a nonlinear integral equation

$$(3.21) \qquad b(x) f(x) - f(0) + \epsilon C \int_0^x \left(f^2 - \frac{\int_0^1 f^2 dx}{\int_0^1 f^4 dx} f^4\right) dx = 0.$$

Introducing

$$(3.22) \qquad g(x) = f(x) - \frac{f(0)}{b(x)},$$

$$(3.23) \qquad \mathcal{L} g = b(x) f(x) - f(0) = b(x) g(x),$$

$$\begin{aligned}\mathcal{N}g &= C\int_0^x \left(f^2 - \frac{\int_0^1 f^2dx}{\int_0^1 f^4dx} f^4\right) dx \\ &= C\int_0^x \left(\left(g(x)+\frac{1}{bH_0}\right)^2 - \frac{\int_0^1 \left(g+\frac{1}{bH_0}\right)^2 dx}{\int_0^1 \left(g+\frac{1}{bH_0}\right)^4 dx}\left(g+\frac{1}{bH_0}\right)^4\right) dx, \qquad (3.24)\\ g\in \mathbf{Y} &= \{g|g(x)\in C[0,1], g(0)=g(1)=0\},\end{aligned}$$

then $\mathcal{L}:\mathbf{Y}\to\mathbf{Y}$ is one-to-one and onto, $\mathcal{L}^{-1}$ exists. Equation (3.20) becomes

$$\mathcal{L}g + \epsilon\mathcal{N}g = 0. \qquad (3.25)$$

Define

$$\mathcal{F}(\epsilon, g) = \mathcal{L}g + \epsilon\mathcal{N}g.$$

Then $\mathcal{F}$ is an operator from $\mathbf{R}\times\mathbf{Y}$ to $\mathbf{Y}$. It is easy to check that

$$\mathcal{F}(0,0)=0, \quad \mathcal{F}_g(0,0)=\mathcal{L}, \quad \mathcal{F}_g^{-1}(0,0)=\mathcal{L}^{-1}.$$

Then, by the lemma, there exist balls $\mathbf{B}_{\epsilon_0}(0)\subset R$, $\mathbf{B}_{\delta_y}(0)\subset\mathbf{Y}$, and a unique mapping $\mathcal{T}:\mathbf{B}_{\epsilon_0}(0)\to\mathbf{B}_{\delta_y}(0)$ such that

$$\mathcal{F}(\epsilon,\mathcal{T}\epsilon)=0 \quad \text{for } \epsilon<\epsilon_0.$$

Furthermore, the mapping $\mathcal{T}$ is continuous, i.e., for δ small, we can choose ϵ such that

$$|\mathcal{T}_\epsilon| = |g(x)| \le \delta.$$

We choose δ small so that

$$f(x) = g(x) + \frac{1}{b(x)H_0} \ge d_1 > 0.$$

Then

$$H(x) = \frac{1}{g(x)+\frac{1}{b(x)H_0}} = \frac{H_0 b(x)}{H_0 b(x) g(x)+1} \qquad (3.26)$$

is the solution to the free boundary equation (3.19) and Q is given by (3.20). The proof is complete.

Case 3. $T(x,r)=T(r)b(x)$, where $b(x)$ is the same as in Case 2. For simplicity, let $T(r)=T_0+T_1r$. Similar calculation leads to

$$\frac{dH}{dx} = \frac{b'}{b}H + \frac{1}{T_0}\left(\frac{b'}{b}T_1H^2 + \frac{8C}{Rb} + \frac{8Q}{\pi RbH^2}\right). \qquad (3.27)$$

Equation (3.27) is similar to (3.19). By using the same procedure, similar results can be proved. We omitted the details here.

Remark. Although we have the existence and uniqueness of the free boundary for a long wave free boundary such as (3.19), we do not yet have the corresponding result for the exact system.

4. Numerical method for the exact system. The method is outlined in §2. As a numerical example, let $T = T_0(1 + a\sin 2\pi\alpha x)$, $0 \le x \le 1/\alpha$, where $\alpha = 1/\ell$ is the long wave parameter and ℓ is the wave length. Here we have assumed that the average radius of the tube $d = O(1)$ (Note: d is unknown.). The system to be solved is

$$(4.1)\quad \begin{aligned}
&v_x\frac{\partial v_x}{\partial x} + v_r\frac{\partial v_x}{\partial r} = -\frac{\partial p}{\partial x} + \frac{1}{R}\left(\frac{\partial^2 v_x}{\partial x^2} + \frac{1}{r} - \frac{\partial v_x}{\partial r} + \frac{\partial^2 v_x}{\partial r^2}\right),\\
&v_x\frac{\partial v_r}{\partial x} + v_r\frac{\partial v_r}{\partial r} = -\frac{\partial p}{\partial r} + \frac{1}{R}\left(\frac{\partial^2 v_r}{\partial x^2} + \frac{\partial^2 v_r}{\partial r^2} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{v_r}{r^2}\right),\\
&\frac{\partial v_x}{\partial x} + \frac{v_r}{r} + \frac{\partial v_r}{\partial r} = 0.\\
&(v_x, v_r)|_\Gamma = (-C, -CH'(x)),\\
&\frac{\partial v_x}{\partial r}|_{r=0} = 0, \qquad v_r|_{r=0} = 0,\\
&\mathbf{u}|_{x=0} = \mathbf{u}|_{x=\ell},\\
&p|_{x=0} = p|_{x=\ell},\\
&\Gamma : r = H(x), \qquad H(0) = H(\ell) = H_0,\\
&p|_\Gamma = \frac{T_0(1 + a\sin 2\pi\alpha x)}{H}, \quad 0 < x < \ell, \quad 0 < r < H(x).
\end{aligned}$$

Step 1. Obtain the long wave approximation. In terms of the new parameters introduced during the long wave equation derivation, the free boundary equation is

$$(4.2)\qquad \frac{dH}{dx} = \left[(2\pi a\cos 2k\pi x)H + \frac{8Q}{\pi RT_0H^2} + \frac{8C}{RT_0}\right]/[1 + a\sin 2\pi x],$$

$$(4.3)\qquad H(0) = H(1) = H_0,$$

where H_0 is the prescribed initial radius, C the wave velocity, and Q is to be determined with the solution. Equations (4.2)–(4.3) are solved numerically to get H_x. Back to the original parameters and variables (indicated by *), the pressure and velocity obtained from the long wave approximation are given by

$$(4.4)\qquad p_0^* = \frac{T_0^*(1 + a\sin 2\pi\alpha x^*)}{H},$$

$$(4.5)\quad v_x^{0^*} = \frac{\alpha R^*}{4}(r^2 - H^2)\frac{T_0^* 2\pi a\cos 2\pi\alpha x^* H - T_0^*(1 + a\sin 2\pi\alpha x^*)dH/dx}{H^2} - C,$$

$$(4.6)\qquad v_r^{0^*} = 0,$$

where dH/dX is given by

$$(4.7)\quad \frac{dH}{dx} = \left[(2\pi a\cos 2\pi\alpha x^*)H + \frac{8\alpha Q}{\pi R^* T_0^* H^2} + \frac{8C\alpha}{R^* T_0^*}\right]/[1 + a\sin 2\pi\alpha x^*].$$

Step 2. With the $H(x)$ obtained from Step 1, solve the fixed boundary problem on the domain $0 \le x \le 1/\alpha, 0 \le r \le H(x)$. Using (1.1)–(1.2), $\xi = x, \eta = r/H(x)$, we can transform the domain $0 \le x \le 1/\alpha$, $0 \le r \le H(x)$ to $0 \le \xi \le 1/\alpha$, $0 \le \eta \le 1$. In computing derivatives, the following formulas are useful:

$$\begin{aligned} f_x &= f_\xi + f_\eta \eta_x, \\ f_r &= f_\eta \eta_r, \\ f_{xx} &= f_{\xi\xi} + 2f_{\xi\eta}\eta_x + f_{\eta\eta}\eta_x^2 + f_\eta \eta_{xx}, \\ f_{rr} &= f_{\eta\eta}\eta_r^2, \\ f_{xx} + f_{rr} &= f_{\xi\xi} + 2f_{\xi\eta}\eta_x + f_{\eta\eta}(\eta_x^2 + \eta_r^2) + f_\eta \eta_{xx}, \end{aligned} \tag{4.8}$$

where

$$\eta_x = -\frac{rH'(x)}{H^2}, \quad \eta_r = \frac{1}{H(x)}, \quad \eta_{xx} = -\frac{rHH'' - 2rH'^2}{H^3}.$$

Using the notation (u, v) for (v_x, v_r), the system in terms of (ξ, η) assumes the form

(4.9)

$$\begin{aligned} u(u_\xi + u_\eta \eta_x) + v u_\eta \eta_r &= -(p_\xi + p_\eta \eta_x) \\ &\quad + \frac{1}{R}\left(u_{\xi\xi} + 2u_{\xi\eta}\eta_x + u_{\eta\eta}(\eta_x^2 + \eta_r^2) + u_\eta \eta_{xx} + \frac{1}{r}u_\eta \eta_r\right), \end{aligned}$$

(4.10)

$$\begin{aligned} u(v_\xi + v_\eta \eta_x) + v v_\eta \eta_r &= -p_\eta \eta_r \\ &\quad + \frac{1}{R}\left(v_{\xi\xi} + 2v_{\xi\eta}\eta_x + v_{\eta\eta}(\eta_x^2 + \eta_r^2) + v_\eta \eta_{xx} + \frac{1}{r}v_\eta \eta_r - \frac{v}{r^2}\right), \end{aligned}$$

$$u_\xi + u_\eta \eta_x + \frac{v}{r} + v_\eta \eta_r = 0, \tag{4.11}$$

$$(u, v)|_\Gamma = \left(-C, -C\frac{dH}{d\xi}\right), \tag{4.12}$$

$$u_\eta|_{r=0} = 0, \qquad v|_{r=0} = 0, \tag{4.13}$$

$$u|_{x=0} = u|_{x=\ell}, \qquad v|_{x=0} = v|_{x=\ell}, \tag{4.14}$$

$$p|_{x=0} = p|_{x=\ell}, \tag{4.15}$$

$$\Gamma : \eta = 1, \qquad 0 \le \xi \le \frac{1}{\alpha}, \tag{4.16}$$

$$p|_\Gamma = \frac{T_0(1 + a \sin 2\pi\alpha\xi)}{H}, \tag{4.17}$$

where u, v, p, and the free boundary $H(x)$ are all periodic in ξ with period $1/\alpha$.

We use the regularized central difference scheme and the extended successive over-relaxation (ESOR) iterative method suggested by Strikwerda [14], [15] to solve this fixed boundary problem. The method has been used by the author successfully in [20] as it is relatively easy to program, is of second-order accuracy, and provides good convergence. The finite difference scheme used here is briefly explained below. Let d_1 and d_2 be the spans of finite differences for ξ, η, respectively. We use the following formulas for the derivatives to convert the differential equations into finite difference equations.

$$\begin{aligned}
f(i,j) &= f(\xi_i,\eta_j) = f(i\cdot d_1, j\cdot d_2).\\
f_{\xi\xi}(i,j) &= [f(i+1,j)+f(i-1,j)-2f(i,j)]/d_1^2,\\
f_{\eta\eta}(i,j) &= [f(i,j+1)+f(i,j-1)-2f(i,j)]/d_2^2,\\
f_{\xi\eta}(i,j) &= [f(i+1,j+1)-f(i-1,j+1)-f(i+1,j-1)+f(i-1,j-1)]/(4d_1d_2),\\
f_\xi(i,j) &= \delta_{\xi o}f-(1/6)d_1^2\delta_{\xi-}\delta_{\xi+}^2 f,\\
f_\eta(i,j) &= \delta_{\eta o}f-(1/6)d_2^2\delta_{\eta-}\delta_{\eta+}^2 f,
\end{aligned}$$

where

$$\begin{aligned}
(\delta_{\xi o}f)(i,j) &= [f(i+1,j)-f(i-1,j)]/(2d_1),\\
(\delta_{\xi+}f)(i,j) &= [f(i+1,j)-f(i,j)]/d_1,\\
(\delta_{\xi-}f)(i,j) &= [f(i,j)-f(i-1,j)]/d_1,
\end{aligned}$$

and the corresponding differences for η can be defined similarly. The third-order terms in the first difference formulas are necessary to have a regular scheme. The iterative scheme is given below:

(4.18)

$$\begin{aligned}
u^*(i,j) &= u(i,j)\\
&-\omega\left\{u(i,j) - \left[\frac{u(i+1,j)+u(i-1,j)}{d_1^2} + \frac{u(i,j+1)+u(i,j-1)}{d_2^2}(\eta^2+\eta_r^2)\right.\right.\\
&\qquad + 2u_{\xi\eta}\eta_x + u_\eta\eta_{xx} - R(u(u_\xi+u_\eta\eta_x)+vu_\eta\eta_r)\\
&\qquad \left.\left. - R(p_\xi+p_\eta\eta_x)+u_\eta\eta_r/r\right] \Big/ \left[\frac{2}{d_1^2}+\frac{2}{d_2^2}(\eta_x^2+\eta_r^2)\right]\right\},
\end{aligned}$$

(4.19)

$$\begin{aligned}
v^*(i,j) &= v(i,j)\\
&-\omega\left\{v(i,j) - \left[r^2\left(\frac{v(i+1,j)+v(i-1,j)}{d_1^2} + \frac{v(i,j+1)+v(i,j-1)}{d_2^2}(\eta_x^2+\eta_r^2)\right)\right.\right.\\
&\qquad \left. + r^2(2v_{\xi\eta}\eta_x+v_\eta\eta_{xx}) - Rr^2(u(v_\xi+v_\eta\eta_x)+vv_\eta\eta_r+p_\eta\eta_r)+rv_\eta\eta_r\right]\\
&\qquad \left. \Big/ \left[r^2\left(\frac{2}{d_1^2}+\frac{2}{d_2^2}(\eta_x^2+\eta_r^2)\right)+1\right]\right\},
\end{aligned}$$

$$p^*(i,j) = p(i,j) - \gamma\{r(u_\xi + u_\eta \eta_x) + v + rv_\eta \eta_r\}, \tag{4.20}$$

where u^*, v^*, and p^* are the updated values of the corresponding functions, and ω and γ are iteration constants. We used both finite differences and derivatives in (4.18)–(4.20) to shorten the formulas. When computing, those derivatives were calculated first and then (4.18)–(4.20) were performed.

We impose periodic boundary conditions on u, v, and p in ξ-direction. At $\eta = 0$, cubic interpolation was used for pressure, e.g.,

$$p(i,0) = 3(p(i,1) - p(i,2)) + p(i,3). \tag{4.21}$$

Cubic interpolation was also used for pressure at $\eta = 1$. Boundary condition (4.12) was used for (u, v) at $\eta = 1$. At $\eta = 0$, using second-order difference, (4.13) implies

$$u(i,0) = (4u(i,1) - u(i,2))/3, \tag{4.22}$$

$$v(i,0) = 0. \tag{4.23}$$

For computation, our experience indicates that $\omega = 0.001$—1.5 and $\gamma = 0.1\omega$ give good convergence. When the Reynolds number R is small, we chose $\omega = 1.5$, $\gamma = 0.1$. For larger $R (100 \leq R \leq 2000)$, we chose smaller ω and γ to make the algorithm converge.

Remark. The PDE needs two boundary conditions at $\eta = 0, 1$, and those conditions are given by (4.12)–(4.14). The cubic interpolations for the pressure at $\eta = 0, 1$ are numerical boundary conditions and do not make the system overdetermined. For reference on this regard, see [16, p. 298].

Step 3. We use the long wave approximation as the first guess. After a few local iterations for the fixed boundary problem, the boundary is updated according to (4.17):

$$H^*(\xi) = \frac{T_0(1 + a \sin 2\pi\alpha\xi)}{p(\xi, \eta)}\Big|_{\eta=1}.$$

Then the transformation (1.1)–(1.2) is modified using the new H^* and $\eta_x, \eta_r, \eta_{xx}$ are updated. This is one global iteration.

Step 4. Repeat Steps 2 and 3 as many times as needed. Our experience indicates that for most cases the number of local iterations is around 20. For some cases, we can achieve convergence by adjusting the number several times between 10 and 100 at the beginning stage of the computation.

Remark. "Convergence" is used here in the sense that the corrections to the numerical solutions made at each iteration, or, equivalently, the imbalances of the equations when the numerical solutions are plugged in will become and remain small after some iterations. (The imbalances are the L_2 norms of the parts inside $\{\cdots\}$ in (4.18)–(4.20). The relative imbalances are the above imbalances divided by the L_2 norms of u, v, and p, respectively.) The theoretical justification of the numerical method will be done in the future.

Computations were carried out for various situations and the results are given in §5.

5. Results of the computations and discussions.

Since there are five parameters (α, R, T_0, a, H_0) and the solution contains the free boundary $H(x)$, velocity $(u, v) = v_x, v_r)$, pressure p, and flux Q, computations were carried out by changing each of the parameters, and solutions were observed to study the properties of the flow. We have made the following observations.

1. *Accuracy of the long wave approximation and numerical method.* From Table 1 we can see that the numerical method is roughly of second-order accuracy. The long wave and numerical solutions agree with each other very well (Tables 2 and 3).

2. *Influence of T_0 on the flow.* (i) Phase shift of the max–min of the free boundary. From Fig. 2 we see the phase shift of the max–min of the free boundary when T_0 is not large. However, when T_0 becomes large, the phase shift becomes small, and eventually becomes zero.

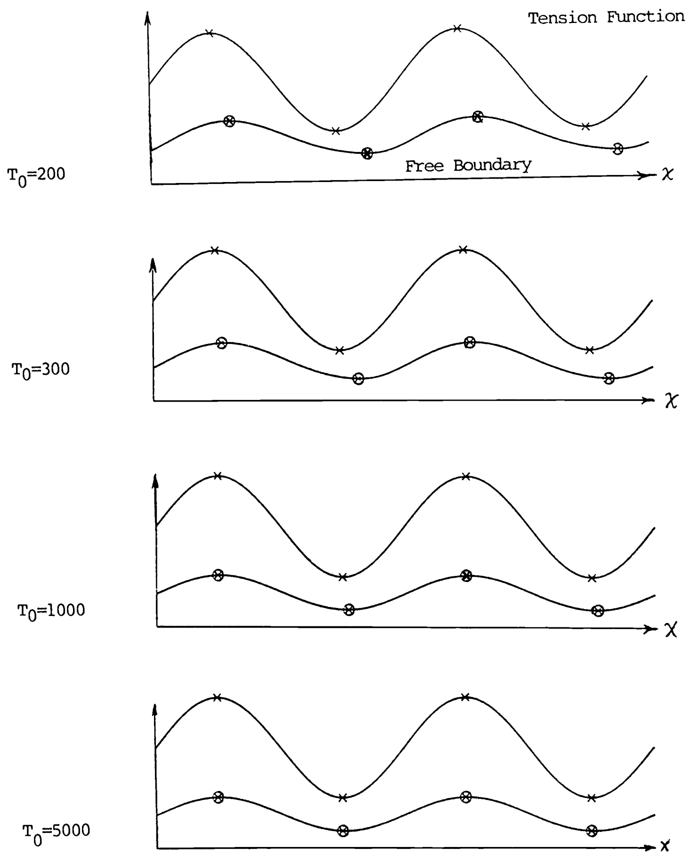

FIG. 2. *Free boundaries with T_0 changing.* $\alpha = 0.1$, $R = 0.1$, $H_0 = 0.5$, $a = 0.5$, $T_0 = 200$—5000.

(ii) Flow pattern. Our computation also indicates when T_0 becomes larger, the positive flow portion becomes larger and the tube becomes narrower.

(iii) $T_0 - Q$ curve. Figure 3 shows that the relation between T_0 and flux is not linear, and especially that the flux increases with T_0 very slowly when T_0 is greater than 2000.

(iv) Table 4 shows the max–min of the solutions with T_0 changing.

3. *Backflow and positive motion.* The v_x-minimum (negative) always appears at the narrower part of the tube, indicating that the fluid is leaking there. On the other hand, there are parts of "positive motion" at the wider part of the tube indicating the fluid is pushed forward by the wave. Usually the positive motion part is of a torus shape (note that the tube is axisymmetric).

4. *Pressure field.* Figure 4 gives the contour lines of the pressure fields. The picture shows the maximum of pressure appears at the right side of the "neck" and minimum

TABLE 1

Order of accuracy of the numerical method. $R = 0.2$, $T_0 = 250$, $a = 0.5$, $H_0 = 0.5$, $\ell = 5$, $d = 1$, $\alpha = 0.2$. *Numerical parameters:* $d_1 = \ell/m$, $d_2 = d/n$, $\omega = 1.5$, $\gamma = 0.1$, *local iteration* $= 20$, *main iteration* $= 200$.

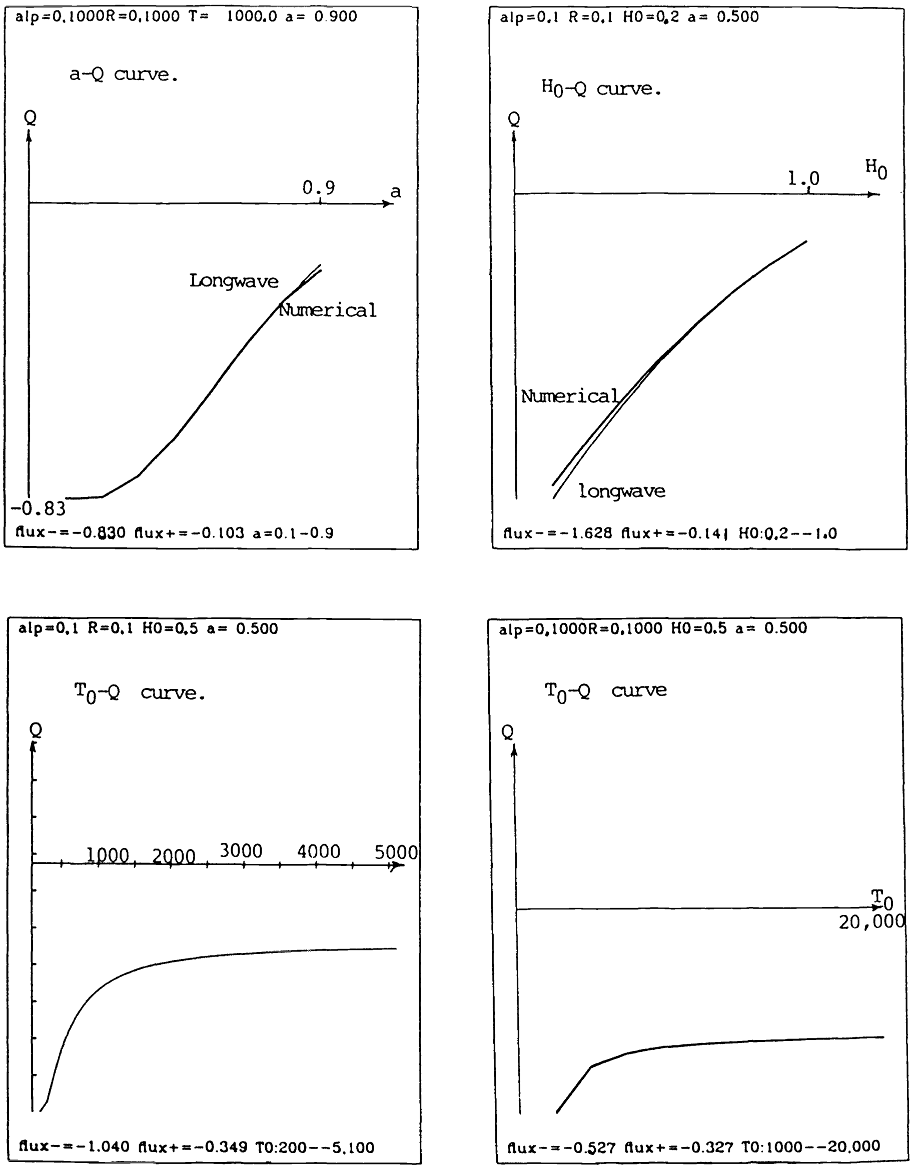

FIG. 3. *Relations between flux Q and other parameters.*

appears at the left side of the neck. So the pressure increases when passing the neck and decreases when going through the wider part of the tube. This agrees with the velocity pictures.

5. *Influence of Reynolds number on the flow.* Table 5 shows that the solution is not sensitive to the changes of Reynolds number when $0.001 \leq \text{Re} \leq 1000$ while $\text{Re} \cdot T_0 = 100$ is maintained. Numerically, smaller iterative parameters should be chosen to compute for large R values.

6. *Influence of a-change on the flow.* Figure 5 gives the velocity fields with respect

to the moving frame for $a = 0.2$ and 0.9. When a is small, there is no positive flow and no trapping. When a gradually increases, a small positive flow region appears near the center of the tube. When a becomes larger, the positive flow region becomes larger. a is the main parameter that has a major influence on flux, i.e., the efficiency of the fluid transport. The $a - Q$ curve is given in Fig. 3 for the a values between 0.1–0.9. The curves show that (i) when a is too small ($a \leq 0.2$), the flux is not sensitive to a change for the simple reason that the wave is not deep enough to push the fluid forward. (ii) When a is greater than 0.3, the flux increases almost linearly with a.

A PARALLEL ALGORITHM FOR REDUCING SYMMETRIC BANDED MATRICES TO TRIDIAGONAL FORM*

BRUNO LANG†

Abstract. An algorithm is presented for reducing symmetric banded matrices to tridiagonal form via Householder transformations. The algorithm is numerically stable and is well suited to parallel execution on distributed memory multiple instruction multiple data (MIMD) computers. Numerical experiments on the iPSC/860 hypercube show that the new method yields nearly full speedup if it is run on multiple processors. In addition, even on a single processor the new method usually will be several times faster than the corresponding EISPACK and LAPACK routines.

Key words. symmetric banded matrix, orthogonal reduction, eigenvalues, parallel, error analysis

1. Introduction.

Reduction to tridiagonal form is a major step in eigenvalue computations for symmetric matrices. If the matrix is full, then usually Householder's or Givens' algorithms are the methods of choice [9], [16]. However, for banded matrices, which is the case to be considered in the present paper, these algorithms are not optimal as they do not fully exploit the band structure. Then each reduction step produces fill-in until eventually the matrix will be full, resulting in $O(n^3)$ time and $O(n^2)$ memory requirements.

A "chasing" algorithm by Schwarz [15], [14] avoids this problem by removing *any* fill-in as soon as it occurs. This algorithm is implemented in the routine BANDR of the EISPACK library [8]. The algorithm relies on (fast) Givens rotations to selectively introduce zeroes into the band and to remove intermediate fill-in. The main part of the computations *could* be done with the _AXPY operation of the level-1 BLAS (basic linear algebra subprograms) [5], [6], [13]. However, as the EISPACK library dates back farther than the evolution of the BLAS, the routine BANDR contains no call to the latter.

Another version of the same underlying method is due to Kaufman [10]; by rearranging the computations she was able to increase the vector lengths, if the bandwidth d is very small compared to the matrix dimension n. This algorithm is incorporated into the routines _SBTRD of the recent LAPACK library [1]. Again, rotations are used to transform the matrix, but now in the form of ordinary Givens' rotations. This leads to an increased overall floating point operation (flop) count of $6n^2d$ versus $4n^2d$ flops of the BANDR version. Another drawback of this method lies in the fact that the bulk of computation is coded in explicit loops since there are no appropriate BLAS routines to cover them.

Both algorithms make full use of the symmetry in the given matrix and require only the lower (or upper) half of the band to be stored. Thus, $(d+1)n$ memory locations are needed.

In this paper we introduce a new reduction algorithm SBTH (symmetric banded matrix, reduction to tridiagonal form via Householder transformations) which is based—as the name indicates—on Householder transformations. The flop count for this algorithm is roughly the same as for the _SBTRD routines from LAPACK and therefore about 50% higher than that of the EISPACK routine.

*Received by the editors June 15, 1992; accepted for publication (in revised form) November 12, 1992. The numerical experiments were carried out on the 8 node and 128 node iPSC/860 hypercubes of the Advanced Computing Research Facility at Argonne National Laboratory and of Oak Ridge National Laboratory, respectively.

†Fachbereich 7—Mathematik, Bergische Universität GH Wuppertal, Gauss-Str. 20, W-5600 Wuppertal 1, Germany.

The new method has some distinct advantages over the above-mentioned implementations. First, almost all the computations can be done within the level-2 BLAS; thus, SBTH benefits from a considerably higher *data locality* than the other algorithms, a significant bonus on machines with low bandwidth from the main memory to the (vector) arithmetical unit(s). In fact, if all three algorithms are run on *one* processor of the iPSC/860 hypercube parallel computer, the new method may perform several times better than the other algorithms. In addition, the new algorithm is well suited to parallel execution. Theoretical considerations as well as numerical experiments show that execution of this algorithm on multiple processors will yield nearly full speedup, provided that the matrix is "reasonably large." The only major drawback of the new algorithm is its higher storage requirements ($2dn$ memory locations).

The remainder of the paper is organized as follows. Section 2 introduces a block decomposition of the band matrix and a serial version of our new reduction algorithm SBTH, which is based on this decomposition. In §3 we show how to efficiently parallelize this algorithm by mapping the blocks to different processors. An additional level of parallelism can be obtained by also performing the transformation of each block in parallel, as explained in §4. The reader may be warned that, in order to achieve optimal performance, the algorithms will become increasingly tricky. But the additional complexity is paying well, as will be demonstrated by performance data from experiments on the iPSC/860 hypercube (§5). Finally, §6 concludes with the summary of a detailed error analysis and with comments on another variant of the reduction scheme.

2. The reduction process.

2. The reduction process. Throughout the paper, $A = (a_{ij})$ always denotes a symmetric banded matrix of dimension n and (semi)bandwidth d, i.e., $a_{ij} = 0$ for $|i-j| > d$.

The reduction process consists of applying $n-2$ orthogonal transformations

$$A^{(\nu+1)} := Q^{(\nu)^T} \cdot A^{(\nu)} \cdot Q^{(\nu)}, \qquad \nu = 1, \ldots, n-2, \tag{1}$$

to the matrix $A^{(1)} := A$. The νth of these steps eliminates the νth column (and row) of the band, i.e., the elements $a_{\nu+2,\nu}, \ldots, a_{\nu+d,\nu}$ are made zero. Since all the $A^{(\nu)}$ are symmetric, only their lower triangle will be stored and used during the reduction.

Suppose that for the νth step we are able to partition $A^{(\nu)}$ as follows.

$$A^{(\nu)} = \left(\begin{array}{ccccc} T_\nu & & & & 0 \\ & A_{10}^{(\nu)T} & & & \\ A_{10}^{(\nu)} & A_{11}^{(\nu)} & A_{21}^{(\nu)T} & & \\ & A_{21}^{(\nu)} & A_{22}^{(\nu)} & \ddots & \\ 0 & & \ddots & \ddots & A_{b,b-1}^{(\nu)T} \\ & & & A_{b,b-1}^{(\nu)} & A_{bb}^{(\nu)} \end{array}\right)$$

The first $\nu - 1$ columns (and rows) of the band have already been removed; thus, the leading $\nu \times \nu$ submatrix T_ν of $A^{(\nu)}$ is tridiagonal. Let $n - \nu = (b-1) \cdot d + r$, $1 \le r \le d$. Then the blocks $A_{\beta\beta}^{(\nu)} \in \mathbb{R}^{d \times d}$ $(1 \le \beta < b)$ and $A_{bb}^{(\nu)} \in \mathbb{R}^{r \times r}$ along the diagonal are symmetric. At the beginning of the algorithm ($\nu = 1$), the subdiagonal blocks $A_{\beta+1,\beta}^{(\nu)} \in \mathbb{R}^{d \times d}$ $(1 \le \beta < b-1)$ are upper triangular, and $A_{b,b-1}^{(\nu)} \in \mathbb{R}^{r \times d}$ is upper trapezoidal. For $\nu > 1$, however, these subdiagonal blocks will be full. $A_{10}^{(\nu)}$ denotes the first of the remaining columns of the band (except for its first element, which is contained in T_ν).

The corresponding partition of $Q^{(\nu)}$ is

$$Q^{(\nu)} = \begin{pmatrix} \boxed{I_\nu} & & & & 0 \\ & \boxed{Q_1^{(\nu)}} & & & \\ & & \boxed{Q_2^{(\nu)}} & & \\ 0 & & & \ddots & \\ & & & & \boxed{Q_b^{(\nu)}} \end{pmatrix}$$

with a $\nu \times \nu$ identity matrix I_ν and "suitable" orthogonal blocks $Q_\beta^{(\nu)} \in \mathbb{R}^{d \times d}$ $(1 \le \beta < b)$ and $Q_b^{(\nu)} \in \mathbb{R}^{r \times r}$.

Then the transformed matrix $\tilde{A} := Q^{(\nu)^T} \cdot A^{(\nu)} \cdot Q^{(\nu)}$ has a block structure compatible with that of $A^{(\nu)}$. For its blocks we obtain the relations

$$\begin{aligned} \tilde{A}_{10} &= Q_1^{(\nu)^T} \cdot A_{10}^{(\nu)}, \\ \tilde{A}_{\beta\beta} &= Q_\beta^{(\nu)^T} \cdot A_{\beta\beta}^{(\nu)} \cdot Q_\beta^{(\nu)} \quad (1 \le \beta \le b), \\ \tilde{A}_{\beta+1,\beta} &= Q_{\beta+1}^{(\nu)^T} \cdot A_{\beta+1,\beta}^{(\nu)} \cdot Q_\beta^{(\nu)} \quad (1 \le \beta < b). \end{aligned}$$

Remember that, by (1), we also should have $\tilde{A} = A^{(\nu+1)}$. The block decomposition of the matrix $A^{(\nu+1)}$, however, is shifted one column to the right and one row to the bottom as compared to the decomposition of $A^{(\nu)}$ and $\tilde{A}$. This implies that some of the elements of $\tilde{A}$ will no longer be included in the blocks of $A^{(\nu+1)}$. To be more specific, the elements at positions $(2,1), \ldots, (d,1)$ in the first column of each subdiagonal block $\tilde{A}_{\beta+1,\beta}^{(\nu)}$ $(0 \le \beta < b)$ will be lost when the block decomposition is shifted. Therefore, we must make sure that they *are already zero*; this can be enforced by a suitable choice of the transformation matrices $Q_{\beta+1}^{(\nu)}$ (see below).

This leads to the following serial reduction algorithm (for ease of reading, the superscripts $^{(\nu)}$ have been dropped):

ALGORITHM 2.1. *Serial reduction algorithm, based on Householder transformations.*

```
for $\nu = 1$ to $n-2$
    (adopt the block decomposition for step $\nu$)
    determine $b$ and $r$ such that $n - \nu = (b-1) \cdot d + r$ with $1 \leq r \leq d$
    determine an orthogonal matrix $Q_1$ such that $\tilde{A}_{10} := Q_1^T \cdot A_{10}$ has the
        form $(*, 0, \ldots, 0)^T$; replace $A_{10}$ by $\tilde{A}_{10}$
    for $\beta = 1$ to $b$
        replace $A_{\beta\beta}$ by $\tilde{A}_{\beta\beta} := Q_\beta^T \cdot A_{\beta\beta} \cdot Q_\beta$
        if $\beta < b$
            determine an orthogonal matrix $Q_{\beta+1}$ such that the first column
                of $\tilde{A}_{\beta+1,\beta} := Q_{\beta+1}^T \cdot (A_{\beta+1,\beta} \cdot Q_\beta)$ has the form $(*, 0, \ldots, 0)^T$;
            replace $A_{\beta+1,\beta}$ by $\tilde{A}_{\beta+1,\beta}$
```

As indicated earlier, the blocks Q_β may be chosen as Householder matrices of size $d \times d$ or—in the case of Q_b—$r \times r$. Q_1 eliminates all but the first elements of A_{10}, which is the first of the remaining columns in the band. To determine $Q_{\beta+1}$ $(\beta > 0)$, one computes the first column of the matrix $A_{\beta+1,\beta} \cdot Q_\beta$ and then choses $Q_{\beta+1}$ to eliminate all but the first elements of this column d-vector.

3. Parallelism between different blocks. The serial algorithm bears a twofold potential for exploiting parallelism. First, *different* blocks may be transformed simultaneously. In this section we will use a modified pipelined approach to make use of this medium-grained *parallelism between different blocks*. An additional level of parallelism can be obtained by further distributing the work for the transformation of *single* blocks to multiple processors. This—slightly finer-grained—*parallelism within the blocks* will be treated in §4.

In the sequel, we will always treat the blocks by pairs; to make this explicit we introduce the notation of a *block pair*:

$$B_\beta := \begin{pmatrix} A_{\beta\beta} \\ A_{\beta+1,\beta} \end{pmatrix} \quad (\beta \geq 0).$$

To keep the parallel algorithms concise we need some more abbreviations.

$$\text{“}\textit{eliminate } B_0 \rightarrow Q_1\text{”}$$

stands for the fourth and fifth line of Algorithm 2.1 (“*determine* ... $\tilde{A}_{10}$”),

$$\text{“}Q_\beta \rightarrow \textit{transform } B_\beta \rightarrow Q_{\beta+1}\text{”}$$

comprises lines 7 through 10 of the algorithm. These abbreviations emphasize another important point: the new transformation matrix $Q_{\beta+1}$ is determined during the transformation of B_β (more precisely, of $A_{\beta+1,\beta}$).

There are three major steps in changing the serial algorithm into an efficient parallel program that makes best use of the parallelism between different blocks. First, we will make it a *distributed* algorithm. This means that the work is distributed among the processors, but that at any given time only one processor is active. Then, a “local view” of the block decomposition introduced in §2 will be the key for introducing parallelism. Last, we will optimize the data layout and the algorithmic flow to improve the performance.

We begin by distributing the block pairs to different *clusters* C_β of processors, $\beta = 0, 1, \ldots$, such that block pair B_β is assigned to cluster C_β (cf. the first picture of Fig. 1).

Here, a cluster consists of $p \geq 1$ processors. At the moment, it is sufficient to think of the clusters as of single processors (i.e., $p = 1$) as the value of p has no direct bearing on the algorithms in this section. (The use of multiple processors per cluster will be explained in §4, when we discuss the implementation of the block transformations in some detail.) We assume that the clusters are linearly connected to form a chain.

To match the data distribution, the work of Algorithm 2.1 must also be distributed among the clusters. In each pass through the ν loop, cluster C_0 begins by eliminating the first of the remaining columns of the band. Then C_0 sends the transformation matrix $Q_1^{(\nu)}$ to C_1 which transforms its block pair B_1 and thereby generates a new transformation matrix $Q_2^{(\nu)}$. Now C_1 passes this matrix to its successor C_2 which in turn transforms its block pair B_2 and determines $Q_3^{(\nu)}$. Continuing in this way, the activity moves along the chain of clusters until all the block pairs are processed. At this moment, the block decomposition must be shifted for the next pass through the ν loop. This implies that—except for C_0—each cluster C_β must send the first column of its transformed block pair to its predecessor $C_{\beta-1}$.

A simple modification of this scheme allows some of the clusters to operate simultaneously. The key observation is that the first column of the transformed B_1 is not affected by the ensuing operations in any block pair $B_\beta, \beta > 1$. Therefore, C_1 can send this column back to C_0 as soon as the transformation of B_1 is completed; there is no need to wait until *all* the computations corresponding to $Q^{(\nu)}$ are done. This enables C_0 to *locally* shift its block pair B_0 and to eliminate the $(\nu + 1)$st column of the band, while C_2 is still transforming its block pair according to $Q_2^{(\nu)}$. The same argument also applies to the other clusters C_β. As soon as they receive a column from their successor $C_{\beta+1}$ they locally shift their own block pair and apply the next transformation to it.

Figure 1 gives a sketch of the "start up" of the resulting parallel Algorithm 3.1. To let the complete tridiagonal matrix T assemble in C_0 the ν loop ends with $n - 1$ instead of $n - 2$, as it did in Algorithm 2.1. The additional last pass requires no computation. Of course, we do not send the Householder matrices as such, but only the associated Householder vectors.

ALGORITHM 3.1. *Parallel reduction algorithm, raw version (two different programs for cluster* 0 *and for the remaining clusters, respectively).*

```
$C_0$   :   for $\nu = 1$ to $n - 1$
              eliminate $B_0 \to Q_1$
              send $(Q_1)$ to $C_1$
              receive $(B_0)$ from $C_1$

$C_\beta$ $(\beta \geq 1)$ for $\nu = 1$ to $n - 1$
              if $B_\beta$ is not empty
                 receive $(Q_\beta)$ from $C_{\beta-1}$
                 $Q_\beta \to$ transform $B_\beta \to Q_{\beta+1}$
                 send (first column of $B_\beta$) to $C_{\beta-1}$
                 shift $B_\beta$ to the right/bottom by one column/row
                 if $B_{\beta+1}$ is not empty
                    send $(Q_{\beta+1})$ to $C_{\beta+1}$
                    receive (last column of $B_\beta$) from $C_{\beta+1}$
```

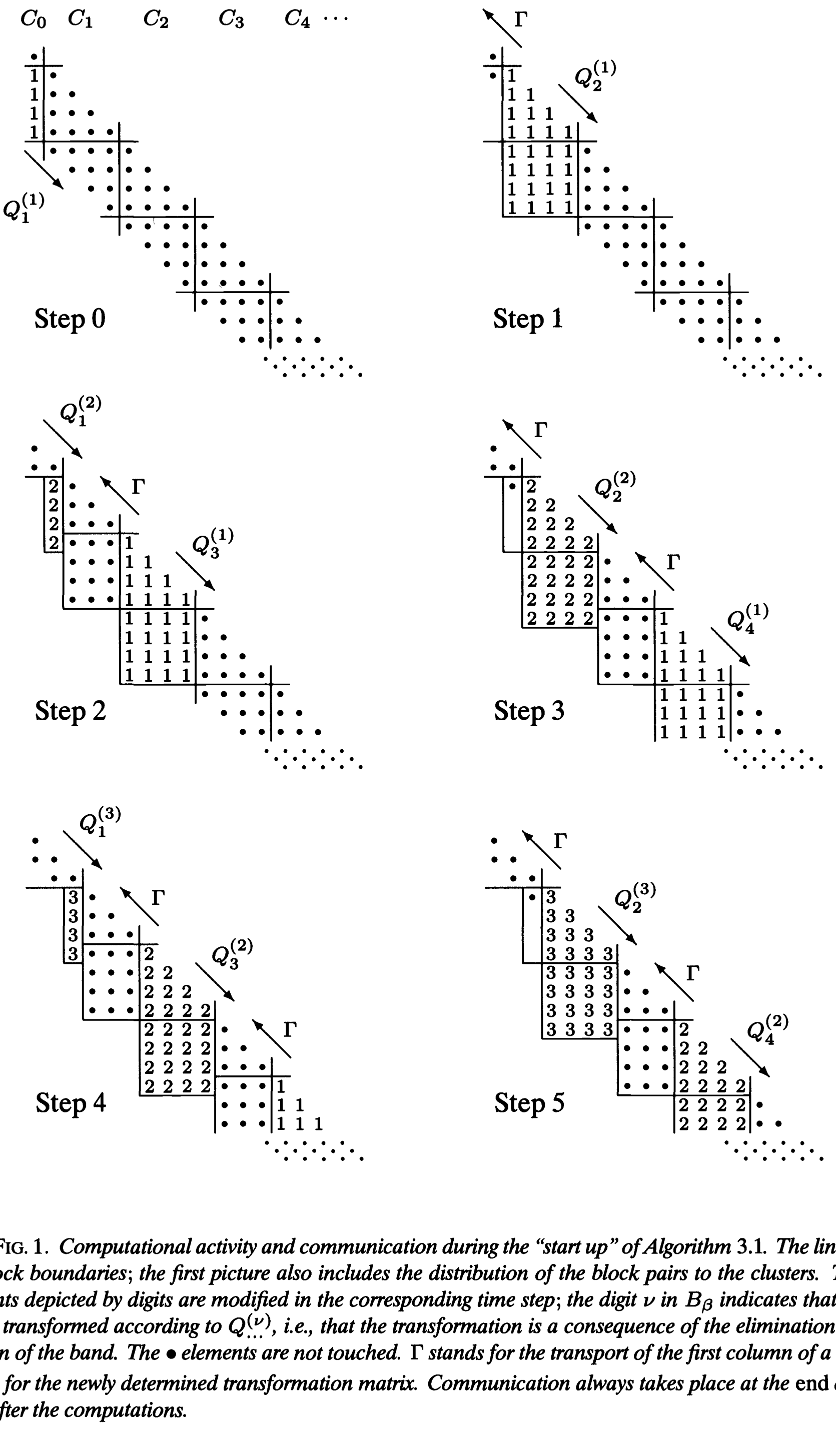

FIG. 1. *Computational activity and communication during the "start up" of Algorithm* 3.1. *The lines indicate the block boundaries; the first picture also includes the distribution of the block pairs to the clusters. The matrix elements depicted by digits are modified in the corresponding time step; the digit ν in B_β indicates that this block pair is transformed according to $Q_{\dots}^{(\nu)}$, i.e., that the transformation is a consequence of the elimination of the νth column of the band. The • elements are not touched. Γ stands for the transport of the first column of a block pair, $Q_{\beta+1}^{(\nu)}$ for the newly determined transformation matrix. Communication always takes place at the* end *of the time step, after the computations.*

As the transformations according to $Q^{(1)}$ progress along the band, more and more clusters become active (cf. Fig. 1), until the end of the band is reached. Later on, as the remaining band becomes shorter, an increasing number of clusters fall back to inactivity because their block pairs are "empty." It is not hard to see [12] that on the average, of the $c^* = \lceil (n-1)/d \rceil + 1$ clusters that shared the band at the start of the algorithm, only one half will hold a nonempty block pair. Therefore, one-half of the available computational power is lost by load imbalance.

In addition, only one-half of the clusters with nonempty block pairs can work at any given time, as may be observed from Fig. 1. The other clusters are idle because they are waiting for transformation matrices from their left neighbors and for columns from their right neighbors. Thus, the attainable speedup is reduced by another factor of 2.

Fortunately, there is a simple way to circumvent much of this loss in efficiency if we are willing to use less than the c^* clusters that were assumed for Algorithm 3.1. By halving the number of clusters we can completely eliminate the "idle waiting" time mentioned above, and further reduction of the number of clusters (to $n/(10d)$, say) almost eliminates the load imbalance resulting from empty block pairs. (In §4 we will show that this does not preclude utilizing a much larger number of processors.)

The "idle waiting" time is a result of the fact that adjacent block pairs cannot be transformed at the same time. Therefore, we now do not distribute the band to the clusters by block pairs but by *logical blocks* L_λ $(\lambda \geq 0)$, where a logical block consists of $l \geq 2$ consecutive block pairs. l is called the *blocking factor*. (L_0 is an exception; it contains only the first column of the band, that is, B_0.) In addition, we use a cyclic (wrapped) mapping: if c clusters $C_1, \ldots, C_c$ are available, then C_γ obtains the logical blocks L_λ with $\lambda \equiv \gamma \bmod c$. This requires the clusters to be connected as a ring. Note that now C_c holds the first column B_0 of the band and therefore takes on the work of cluster C_0 from Algorithm 3.1.

Now, in each pass through the ν loop of the algorithm, a cluster generally will have to process more than one logical block, and for each logical block there are l consecutive block pairs to transform. To this end we subdivide the body of the ν loop into l *phases* $\varphi = 1, \ldots, l$. Before the first phase starts, the cluster receives b transformation matrices from its left neighbor. (b varies with the progress of the algorithm. It starts with $b = 0$ as long as the activity has not yet reached the cluster, then slowly increases to the number of logical blocks that are stored in the cluster, and finally decreases with the number of nonempty logical blocks.) During the first phase the cluster transforms the first block pair of (the first b of) its logical blocks and determines the new transformation matrices. Between the first and the second phase, the first columns of the transformed block pairs are sent back to the left neighbor where they are stored as the last columns of the corresponding lth block pairs. In the phases $\varphi = 2, \ldots, l$ the cluster transforms the φth block pair in each logical block, using the most recently determined transformation matrices and producing new ones. Only after the lth phase, further communication is needed, as the transformation matrices must be passed to the right neighbor.

A more formal description of the above is given in Algorithm 3.2. To save space, the selection "**if** *me* $= C_c$ ..." is condensed to "[...]"; thus, statements in square brackets are executed only by cluster C_c. To keep the indices readable, we have used a "local" numbering of the block pairs: $B_{(\gamma:\beta:\varphi)}$ is the φth block pair in the βth logical block of cluster C_γ (that is, the block pair $(\beta-1)lc+(\gamma-1)l+\varphi$ of the band). The transformation matrices are indexed correspondingly.

Figure 2 sketches the "start up" of this algorithm.

ALGORITHM 3.2. *Parallel reduction algorithm, optimized version (one program for all clusters $C_\gamma, \gamma = 1, \dots, c$).*

```
$b := 0$                          (* number of "active" (transformable) block pairs *)
[ eliminate $B_0 \to Q_1$ ]
for $\nu = 2$ to $n$
  send $([Q_1,]\ Q_{(\gamma:\beta:l+1)}\ :\ 1 \le \beta \le b)$ to $C_{\gamma+1}$
  receive $(Q_{(\gamma:\beta:1)}\ :\ 1 \le \beta \le b)$ from $C_{\gamma-1}$
          (* phase 1 *)
  for $\beta = 1$ to $b$
    $Q_{(\gamma:\beta:1)} \to$ transform $B_{(\gamma:\beta:1)} \to Q_{(\gamma:\beta:2)}$
    shift $B_{(\gamma:\beta:1)}$ by one column/row
  send (first column of $B_{(\gamma:\beta:1)}\ :\ 1 \le \beta \le b$) to $C_{\gamma-1}$
  receive $([B_0,]$ last column of $B_{(\gamma:\beta:l)}\ :\ 1 \le \beta \le b')$ from $C_{\gamma+1}$
          (* remaining phases *)
  for $\varphi = 2$ to $l$
    if $b > 0$ and $B_{(\gamma:b:\varphi)}$ is empty
      $b := b - 1$              (* my last logical block is not full *)
    for $\beta = 1$ to $b$
      $Q_{(\gamma:\beta:\varphi)} \to$ transform $B_{(\gamma:\beta:\varphi)} \to Q_{(\gamma:\beta:\varphi+1)}$
      shift $B_{(\gamma:\beta:\varphi)}$ by one column/row
  [ eliminate $B_0 \to Q_1$ ]
          (* for the next pass through the $\nu$ loop: *)
  if $b > 0$ and $B_{(\gamma+1:b:1)}$ is empty
    $b := b - 1$            (* the last block pair of $C_\gamma$ has no successor in $C_{\gamma+1}$ *)
```

In Algorithm 3.2 the integers b and b' are set by the **receive** operation. Thus, the algorithm is "self-regulating" in the sense that the number of logical blocks to transform and the number of block pairs to complete by a new column are automatically determined from the number of items received.

The communication pattern created by this algorithm is very regular, as indicated in Fig. 2. For each pass through the ν loop there is a cyclic shift to the left after phase 1 (columns) and a cyclic shift to the right after phase l (transformation matrices).

As compared to Algorithm 3.1, the overall volume of communication is reduced by a factor of l because only one out of every l transformation matrices and columns must be passed between different clusters. This might suggest that large values of l are desirable.

On the other hand, the loss of speedup, which results from the band getting shorter, is also reduced from a factor of 2 to approximately $1 + 1/\omega$, where ω is the initial *wrap* (the number of logical blocks assigned to each cluster at the beginning of the algorithm) [12, Lemma 5.2]. Because of $\omega \approx n/(cld)$ this implies that while a large value of l decreases communication volume, it also reduces the wrap and so increases the load imbalance between the clusters. In all our experiments $l = 2$ turned out to be optimal.

As mentioned above, the loss of efficiency due to the shrinking band is reduced from a factor of 2 to about $1 + 1/\omega$. This is a benefit of multiply wrapping the logical blocks onto the cluster ring. In addition, the grouping of the block pairs into logical blocks completely removes the idle waiting time and therefore prevents losing the second factor of 2 in efficiency. Thus, if we run the algorithm on c clusters and neglect the communication costs, we may expect a speedup of nearly $c/(1+1/\omega)$ over the one-cluster version. Taking a few percent (5, say) off this estimate to account for the overhead of parallel execution gives a very good prediction for the speedup attainable in practice (see §5).

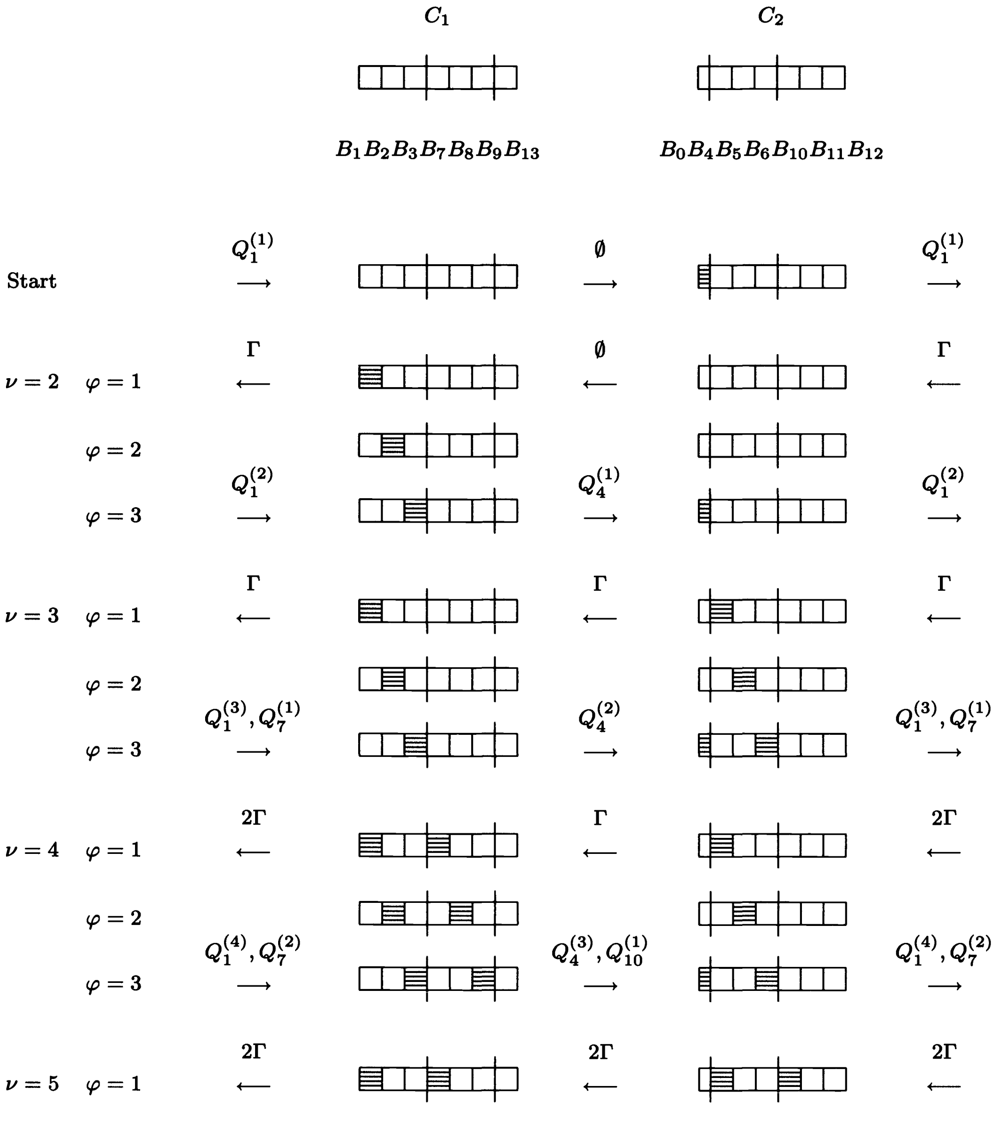

FIG. 2. *Distribution of the block pairs (for $c = 2$ clusters and blocking factor $l = 3$) and "start up" of Algorithm* 3.2. *The shaded block pairs are modified in the respective phase, the others remain unchanged. The Q's indicate communication of transformation matrices,* Γ *and* 2Γ *stand for the transport of one and two columns, respectively, and* $\emptyset$ *denotes empty communication. The communication is cyclic (indicated by the duplicated arrows and labels in front of the block pairs of cluster* C_1 *and behind those of* C_2*, respectively) and always takes place at the* end *of the phase, after the computations.*

4. Parallelism within each block. In this section we will focus on the implementation of the block operation "$Q_\beta \rightarrow$ *transform* $B_\beta \rightarrow Q_{\beta+1}$."

Let $Q_\beta = I - vv^T$ and $Q_{\beta+1} = I - \tilde{v}\tilde{v}^T$ with $||v|| = ||\tilde{v}|| = \sqrt{2}$. Then the computations for the transformation of the two blocks may be arranged as follows:

$$Q_\beta^T A_{\beta\beta} Q_\beta = A_{\beta\beta} - vw^T - wv^T$$

with

$$w := x - \frac{1}{2}(v^T x) \cdot v, \quad \text{where} \quad x := A_{\beta\beta} \cdot v,$$

cf. [7]. Analogously, we have

$$Q_{\beta+1}^T A_{\beta+1,\beta} Q_\beta = A_{\beta+1,\beta} - \tilde{x} v^T - \tilde{v} \tilde{w}^T$$

with

$$\tilde{x} := A_{\beta+1,\beta} \cdot v \quad \text{and} \quad \tilde{w} := \tilde{z} - (\tilde{v}^T \tilde{x}) \cdot v, \quad \text{where} \quad \tilde{z}^T := \tilde{v}^T \cdot A_{\beta+1,\beta}.$$

If the cluster consists of just one processor, then the following serial algorithm may be used to transform B_β. ($A_{\beta+1,\beta}(1 : d, 1)$ denotes the first column of that block.)

ALGORITHM 4.1. *"$I - vv^T = Q_\beta \rightarrow$ transform $B_\beta \rightarrow Q_{\beta+1} = I - \tilde{v}\tilde{v}^T$," serial algorithm.*

```
$x := A_{\beta\beta} \cdot v$
$\tilde{x} := A_{\beta+1,\beta} \cdot v$
        (* new Householder vector *)
$h := A_{\beta+1,\beta}(1 : d, 1) - v_1 \cdot \tilde{x}$        (* first column of $A_{\beta+1,\beta} Q_\beta$ *)
determine a Householder vector $\tilde{v}$, $||\tilde{v}|| = \sqrt{2}$, such that $(I - \tilde{v}\tilde{v}^T) \cdot h = (*, 0, \ldots, 0)^T$
        (* auxiliary vectors *)
$\tilde{z}^T := \tilde{v}^T \cdot A_{\beta+1,\beta}$
$w := x - \frac{1}{2}(v^T x) \cdot v, \quad \tilde{w} := \tilde{z} - (\tilde{v}^T \tilde{x}) \cdot v$
        (* rank-2 modifications *)
$A_{\beta\beta} := A_{\beta\beta} - vw^T - wv^T$
$A_{\beta+1,\beta} := A_{\beta+1,\beta} - \tilde{x}v^T - \tilde{v}\tilde{w}^T$
```

Note that the bulk of work can be done with level-2 BLAS. The computation of x, $\tilde{x}$, and $\tilde{z}^T$ requires a symmetric matrix vector product (remember that $A_{\beta\beta}$ is symmetric with only the lower triangle stored) and two general matrix vector products. The update of $A_{\beta\beta}$ is a symmetric rank-2 modification, whereas the update of $A_{\beta+1,\beta}$ may be realized by two subsequent general rank-1 modifications. These six calls to level-2 BLAS routines account for approximately $12d^2$ flops. The remaining $O(d)$ flops are covered by the level-1 BLAS.

If the number of available processors is not too high, then the "only parallelism between different blocks" version of our parallel algorithm performs best. The need for also exploiting parallelism within the transformation of single block pairs arises if the number of processors exceeds $c' = n/(ld)$. Since the band contains only c' logical blocks, adding more than c' clusters cannot further increase the speedup. Therefore, the only way to make use of a higher number of processors is to group multiple processors into a cluster and to distribute the work for one transformation among the processors of the cluster.

In the following discussion we assume that each cluster consists of $p \geq 1$ processors P_π, $\pi = 1, \ldots, p$, and that $2p \leq d$. Then we subdivide the block pair into $2p$ *block columns* of $\lfloor d/(2p) \rfloor$ or $\lceil d/(2p) \rceil$ consecutive columns each. Two block columns $\pm\pi$ are assigned to processor P_π, as indicated in Fig. 3. Thus, the first p of the block columns are distributed to the processors in reverse order, the other p block columns are distributed in their natural order. The boundary between $A_{\beta\beta}$ and $A_{\beta+1,\beta}$ further subdivides each block column σ into two *subblocks* $S_{1\sigma}$ and $S_{2\sigma}$; see Fig. 3.

A formal description of how the processors work together to transform the block pair is given in Algorithm 4.2. To simplify the notation, we partition the vectors $v, x, w, \tilde{w}$, and

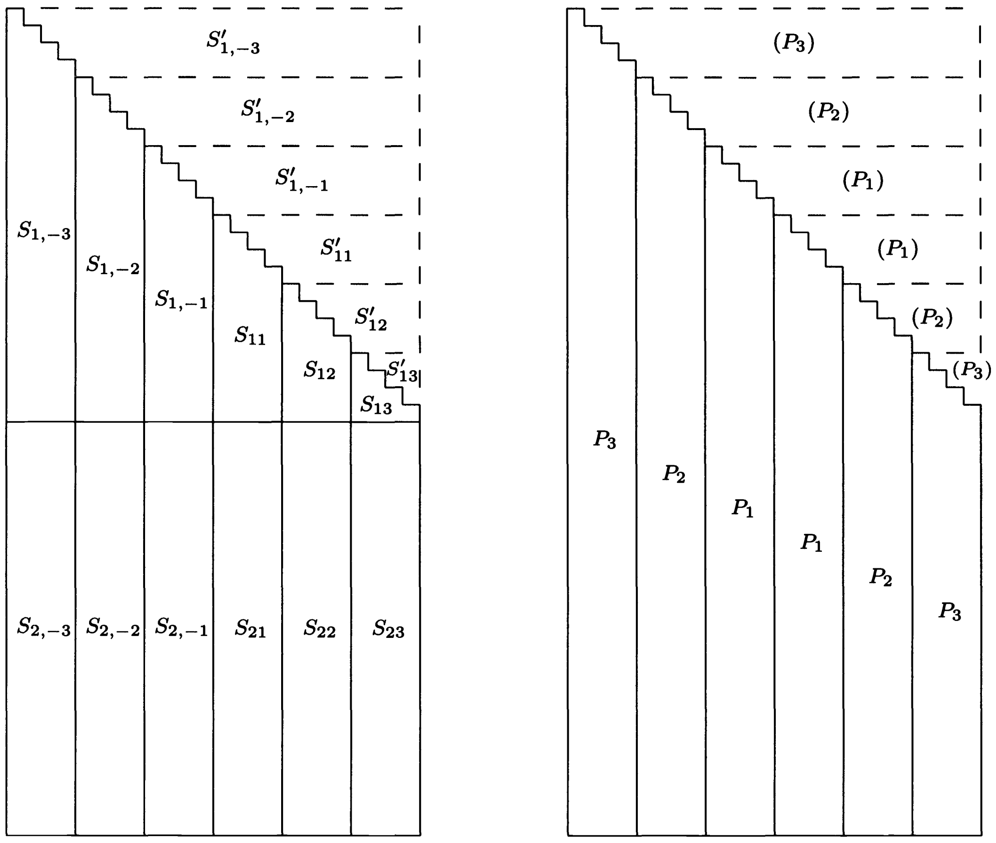

FIG. 3. *Distribution of the block pair to the processors of the cluster (second picture) and numbering of the subblocks for (semi)bandwidth $d = 24$ and $p = 3$ processors. The strict upper triangle of the block $A_{\beta\beta}$ is not explicitly stored; its entries are only indirectly accessible by transposing the lower triangle.*

$\tilde{z}$ to match the decomposition of B_β into block columns, e.g., $v^T = ({v^{(-p)}}^T, \ldots, {v^{(-1)}}^T, {v^{(1)}}^T, \ldots, {v^{(p)}}^T)$.

The computation of the matrix vector products $x = A_{\beta\beta} \cdot v$ and $\tilde{x} = A_{\beta+1,\beta} \cdot v$ is based on a decomposition of the sums involved. For example, we have

$$\tilde{x} = \sum_{\pi=\pm p,\ldots,\pm 1} S_{2\pi} \cdot v^{(\pi)}.$$

First, each processor P_π forms its "local contribution" $S_{2,-\pi} \cdot v^{(-\pi)} + S_{2\pi} \cdot v^{(\pi)}$ to the sum, and then these contributions are added across the processors to form the entire product $\tilde{x}$ in processor P_p. This final summation may be done with a **fan-in**-type operation. The computation of x is similar, with a slight complication. Here one must account for the upper triangle of $A_{\beta\beta}$; these elements are accessible by transposing the subblocks of the lower triangle [11]. When x and $\tilde{x}$ are collected in P_p, this processor—which also holds the first column of $A_{\beta+1,\beta}$—determines the new Householder vector $\tilde{v}$. As all the processors need the vectors x, $\tilde{x}$, and $\tilde{v}$ to proceed, these are broadcast from P_p.

It turns out that each processor needs to know only parts of the auxiliary vectors $\tilde{w}$ and $\tilde{z}$. In particular, the "local parts" ${\tilde{z}^{(\pm\pi)}}^T$ of the matrix product $\tilde{z}^T = \tilde{v}^T \cdot A_{\beta+1,\beta}$

can be computed without any communication. The same is true for the ensuing rank-2 updates of the subblocks held in each processor.

Finally, to prepare for the next transformation, the block pair—together with its decomposition into subblocks—is shifted by one row and one column. This requires the processors P_π, $\pi = 1, \ldots, p-1$, to send one column to their successors and the processors P_π, $\pi = 2, \ldots, p$, to send one column to their predecessors.

ALGORITHM 4.2. *"$I - vv^T = Q_\beta \rightarrow$ transform $B_\beta \rightarrow Q_{\beta+1} = I - \tilde{v}\tilde{v}^T$," parallel algorithm (one program for all processors P_π, $\pi = 1, \ldots, p$, of the cluster).*

```
                              (* compute $x$ and $\tilde{x}$ *)
$\begin{pmatrix} x \\ \tilde{x} \end{pmatrix} := \begin{pmatrix} S_{1,-\pi} \\ S_{2,-\pi} \end{pmatrix} v^{(-\pi)} + \begin{pmatrix} S_{1\pi} \\ S_{2\pi} \end{pmatrix} v^{(\pi)}$          (* stored elements *)
$x^{(\pm\pi)} := x^{(\pm\pi)} + S'_{1,\pm\pi}\, v$                                (* by transposition *)
fan-in ($\begin{pmatrix} x \\ \tilde{x} \end{pmatrix}$) at $P_p$
                              (* new Householder vector *)
if me = $P_p$
    $h := A_{\beta+1,\beta}(1:d,1) - v_1 \cdot \tilde{x}$                  (* first column of $A_{\beta+1,\beta}Q_\beta$ *)
    determine a Householder vector $\tilde{v}$, $||\tilde{v}|| = \sqrt{2}$, such that
    $(I - \tilde{v}\tilde{v}^T) \cdot h = (*, 0, \ldots, 0)^T$
broadcast $(x, \tilde{x}, \tilde{v})$ from $P_p$ to $P_\pi$ $(1 \le \pi \le p-1)$
                              (* locally needed parts of the auxiliary vectors *)
$\tilde{z}^{(\pm\pi)^T} := \tilde{v}^T S_{2,\pm\pi}$
$w := x - \frac{1}{2}(v^T x) \cdot v$
$\tilde{w}^{(\pm\pi)} := \tilde{z}^{(\pm\pi)} - (\tilde{v}^T \tilde{x}) \cdot v^{(\pm\pi)}$
                              (* rank-2 modifications *)
$S_{1,\pm\pi} := S_{1,\pm\pi} - vw^{(\pm\pi)^T} - wv^{(\pm\pi)^T}$
$S_{2,\pm\pi} := S_{2,\pm\pi} - \tilde{x}v^{(\pm\pi)^T} - \tilde{v}\tilde{w}^{(\pm\pi)^T}$
                              (* shift the subblock partitioning *)
shift the block columns $-\pi$ and $\pi$ by one column/row
if $\pi \ne p$
    send (first column of block column $-\pi$) to $P_{\pi+1}$
if $\pi \ne 1$
    receive (last column of block column $-\pi$) from $P_{\pi-1}$
if $\pi \ne 1$
    send (first column of block column $\pi$) to $P_{\pi-1}$
if $\pi \ne p$
    receive (last column of block column $\pi$) from $P_{\pi+1}$
```

An efficient implementation will not simply substitute this algorithm for the corresponding lines in Algorithm 3.2. To improve performance, it is better to break up the β loops of Algorithm 3.2 and to move them into Algorithm 4.2. More precisely, each processor first computes its contribution to the matrix vector products x and $\tilde{x}$ for *all* of its b "active" block pairs; then these vectors are summed up in a *single* **fan-in** operation. Analogously, the vectors x, $\tilde{x}$, and $\tilde{v}$ for all the active block pairs (and later the columns) are sent together. By packing the communication in this way, we significantly reduce the startup cost but not the amount of data to send.

The "reflected distribution" of the block columns to the processors balances the work load within the cluster fairly well. A detailed analysis [12, Lemma 5.6] reveals that, of the approximately $12d^2$ flops that are necessary to transform a block pair, each processor has a share of $12/p \cdot d^2 \cdot (1+O(d/p))$. Thus, we might hope for nearly full speedup for the transformation of the block pair on a cluster of size p, as compared to a single-processor cluster.

In practice, three factors reduce the attainable speedup. First, the relative cost of communication is higher than for the parallelism between different blocks: each processor communicates $O(d)$ elements for every $O(d^2/p)$ flops, whereas neglecting the parallelism within the block pairs allows $O(ld^2)$ flops for every $O(d)$ elements to communicate. Also, the communication pattern is slightly more complicated. Second, even though the constant in the above O-term is rather small (about 2), the number d/p of columns per processor must be quite large to make the load imbalance negligible. Third, and often most important, the level-2 BLAS may be *very* sensitive to the size and shape of the (sub)matrices with which they are called. If we exploit the parallelism within the block pair, then the bulk of computation can still be handled by calls to the BLAS 2. But now each processor needs to call them more often (16 times in our implementation), and these calls operate on (sub)matrices that are much smaller than the $d \times d$ blocks used in Algorithm 4.1. Thus, the BLAS performance may—but need not—be significantly lower.

Note that the data distribution used in Algorithm 4.1 differs significantly from the cyclic distributions that were proposed for the Householder reduction of *dense* symmetric matrices (e.g., [2]–[4]). In the dense case each transformation affects one row and one column less than the previous transformation. Therefore, optimizing the *overall* load balance requires consideration of not only the layout of the original matrix but also of all the intermediate transformed matrices. Cyclic distribution of rows or columns seems to be appropriate for small numbers of processors, while torus-wrapped distribution is better for large numbers of processors. If the use of level-3 BLAS is essential, then a cyclic distribution of blocks or block columns (block rows) should be used. In contrast to the dense case, our (sub)algorithm repeatedly transforms a block pair of constant size. Thus, we can optimize the *overall* load balance by considering only one single transformation. Apart from the different data layout our (sub)algorithm is similar to those cited above.

5. Numerical experiments on the iPSC/860 hypercube. The numerical experiments were performed on the 8 node and 128 node iPSC/860 hypercube parallel computers at Argonne National Laboratory and at Oak Ridge National Laboratory, respectively.

For all three algorithms the reduction time is nearly independent of the matrix entries. The timings reported in the sequel were made with banded Toeplitz matrices containing δ on the δth subdiagonal, $\delta = 1, \ldots, d$, and 0 on the principal diagonal, and with band matrices containing i in the ith column.

All programs are written in Fortran77, the calls to the BLAS were directed to the optimized assembly-coded BLAS of Kuck and Associates. All computations were done in double precision and do *not* include accumulation of the transformation matrix.

The EISPACK routine BANDR is available via Netlib. As the LAPACK library was not yet public at the time of the experiments, we had to use the final test version of the library; thus, the DSBTRD (double precision version of _SBTRD) results are only preliminary.

The flop counts are exact for the SBTH algorithm with Householder transformations. We use the *same* flop count for the algorithms BANDR and DSBTRD although they actually have different operation counts: BANDR needs about $4n^2d$ flops, DSBTRD and SBTH require roughly $6n^2d$ flops. Thus, the Mflops performance of the EISPACK routine is overestimated by about 50%.

By adopting this "biased" flop count we are able to compare the *execution time* of the library algorithms BANDR and DSBTRD with the new algorithm SBTH (run on one processor), as well as with each other. For example, if the indicated Mflops rate of BANDR is twice that of SBTH, then SBTH needs twice as long to complete. This information seems to be more relevant for practical use than mere Mflops throughput.

From the Mflops/processor figures for parallel execution of the algorithm SBTH, it is easy to obtain two other figures often reported in the literature: the overall performance (just multiply by the number of processors in use) and the speedup (divide the overall parallel performance by the performance on one processor).

Figures 4–8 summarize measurements for the parallel algorithm when only the parallelism between different blocks is exploited. As pointed out in §4, this allows for a simpler and more efficient calling sequence to the BLAS.

Figure 4 comprises the results for matrices of (semi)bandwidth $d = 5$ and varying matrix dimension n. The curves indicate that the EISPACK routine is about two times faster than the LAPACK counterpart and three times faster than our algorithm, run on a single processor. But, if the latter is run on multiple processors, and if each processor holds a "sufficient" number of columns (about 100), we obtain nearly full speedup. Thus, the parallel algorithm will be superior if it is run on four or more processors.

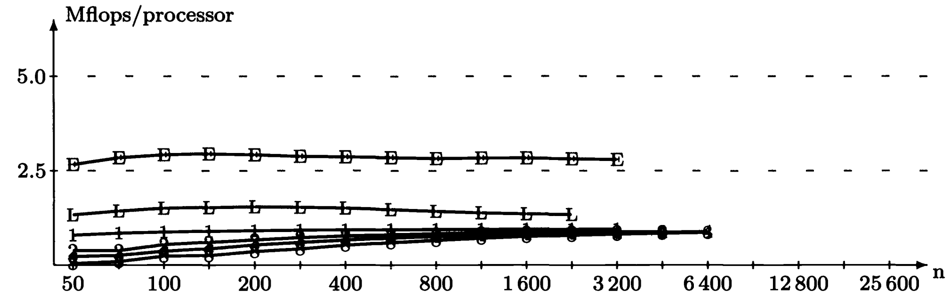

FIG. 4. *Performance of the reduction algorithms for (semi)bandwidth d = 5. The "E" and "L" curves correspond to the algorithms of the EISPACK and LAPACK library, respectively, which are run on one processor. The curves "1", "2", "4," and "8" (from top to bottom) correspond to the parallel algorithm run on the respective number of processors (parallelism between different block pairs only).*

For $d = 10$ the situation has slightly changed. Now, the parallel algorithm has caught up with the LAPACK routine even if it is run on a single processor. Both perform at about 2–2.5 Mflops while the EISPACK routine still leads with some 3 Mflops.

It is noteworthy that the *absolute time* for reducing a matrix with semibandwidth 10 with the new algorithm is *less* than for a matrix of the same order with semibandwidth 5, although nearly twice as many operations are needed.

This is due to the varying performance of the underlying BLAS. For very small blocks ($d = 5$), the overhead for calling a subroutine more than outweighs the gain from assembly coding within the BLAS, and, therefore, a Fortran program with all arithmetic coded in loops would be about twice as fast as the BLAS-based code we used for our timings. With increasing semibandwidth, however, there are *fewer* calls to the BLAS, and the blocks are bigger. Thus, for $d = 10$ our program is competitive with its loop-based counterpart.

For $d = 20$—and all values of n—the situation has turned completely in favor of the new algorithm (see Fig. 5). It now achieves about 5 Mflops on one processor while the EISPACK and LAPACK routines are well below.

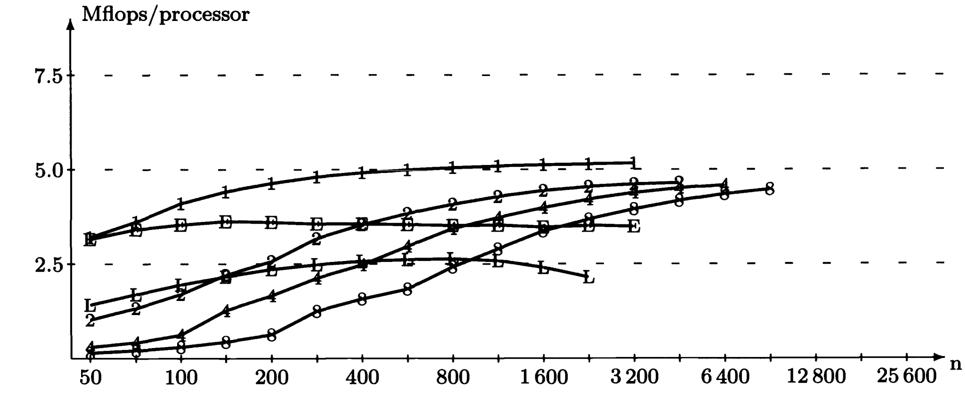

FIG. 5. *Performance of the reduction algorithms for (semi)bandwidth $d = 20$. For* SBTH, *only parallelism between different block pairs is exploited.*

Again, the absolute time for reducing a matrix of semibandwidth 20 with SBTH is less than for a matrix of the same order and $d = 10$. This still is an effect of increasing BLAS performance: doubling the blocksize from 5 to 10 more than doubles the Mflops performance of the BLAS, and it does again for $d = 10/d = 20$.

With increasing semibandwidth, the performance of the new algorithm further increases (Figs. 6 and 7) and reaches nearly 15 Mflops on one processor for $d = 113$, which is about four times the highest performance we were able to obtain from the EISPACK and LAPACK routines.

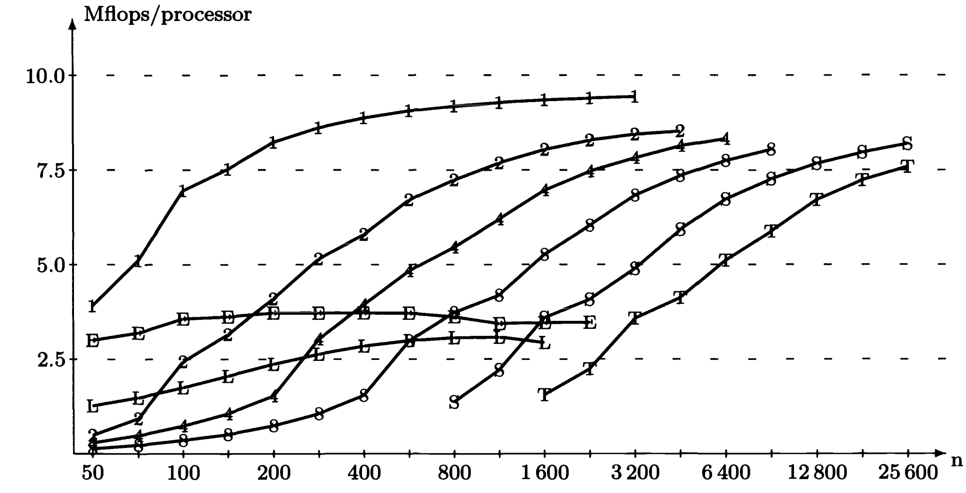

FIG. 6. *Performance of the reduction algorithms for (semi)bandwidth $d = 40$. The curves "S" and "T" correspond to the parallel algorithm run on 16 and 32 processors, respectively. For* SBTH, *only parallelism between different block pairs is exploited.*

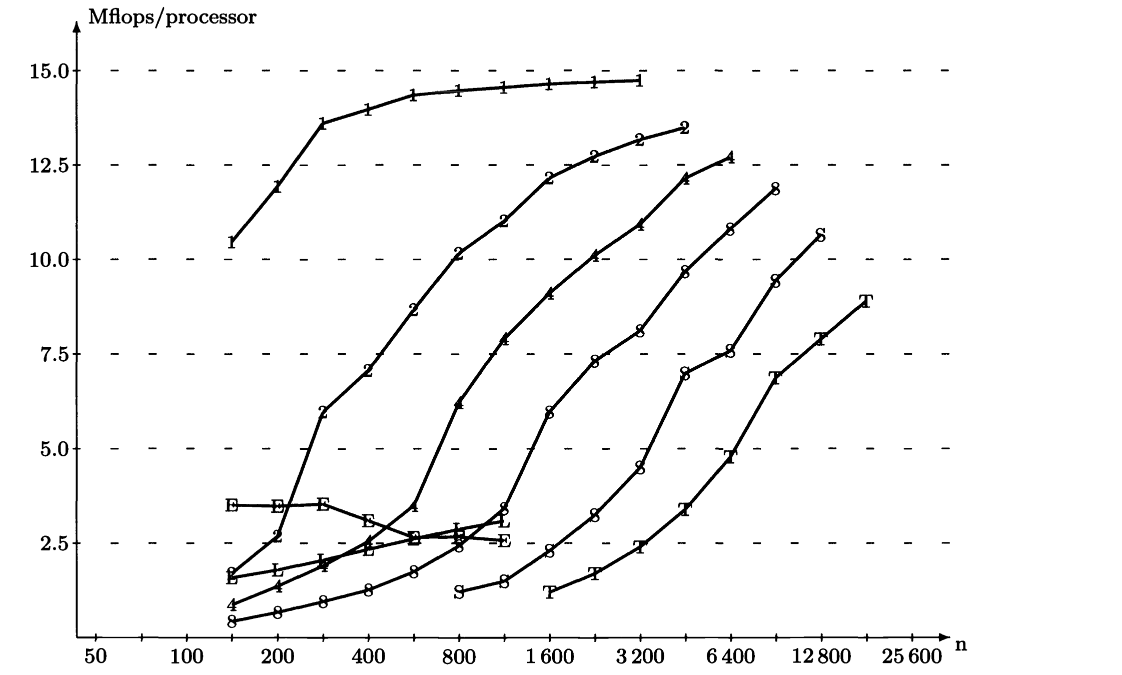

FIG. 7. *Performance of the reduction algorithms for (semi)bandwidth* $d = 113$. *For* SBTH, *only parallelism between different block pairs is exploited.*

In order to provide at least some representative "raw" Mflops and speedup figures we summarize some of the data of Fig. 6 in Table 1. For matrix sizes $n \geq 3\,200$ the serial time had to be estimated; this is indicated by a "$\sim$".

TABLE 1

Performance of the routines BANDR from EISPACK and DSBTRD from LAPACK and comparison with the parallel algorithm SBTD, *run on* 1, 8, *and* 32 *processors. For* SBTH, *only parallelism between different block pairs is exploited. The (semi)bandwidth is* $d = 40$.

To demonstrate that the parallel algorithm *scales* well if the problem size is increased with the number of processors, we draw the data for $d = 80$ in a slightly different way: now we plot the performance against the wrap ω (i.e., the number of logical blocks *per processor*) instead of the matrix dimension n. Figure 8 then indicates that the performance per processor is almost independent of the number of processors as long as we keep the wrap constant. In fact, the curves for 4, 8, 16, and 32 processors nearly coincide. The curves also confirm very well the speedup prediction which was given at the end of §3. If the band is not long enough to reach all the processors ($\omega < 1$), then the speedup is proportional to the wrap (which, in this case, is just the percentage of processors holding a portion of the band). As soon as all the processors are contributing to the reduction process ($\omega \geq 1$), the speedup is approximately $p/(1 + 1/\omega)$.

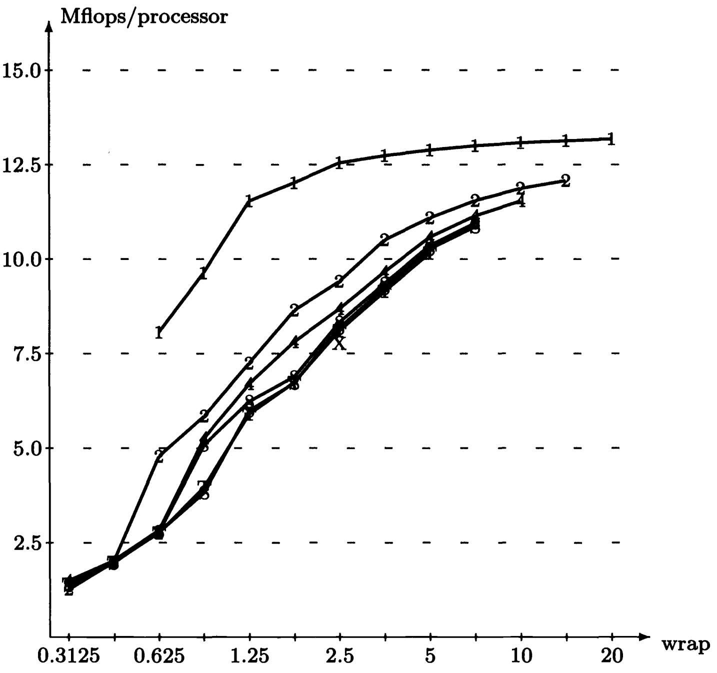

FIG. 8. *Performance of the algorithm* SBTH *for (semi)bandwidth $d = 80$ as a function of the wrap (number of logical blocks per processor). The "X" indicates a single run on* 64 *processors. Only parallelism between different block pairs is exploited.*

Finally, we investigate the performance of the algorithm if the parallelism within the blocks is also exploited. For the runs collected in Fig. 9 we keep the number of processors constant at eight and vary their grouping into clusters, from eight single-processor clusters to a single cluster consisting of eight processors. As expected, the "one processor per cluster" version performs best if the number of logical blocks in the band is large enough. As mentioned earlier, the level-2 BLAS on the iPSC/860 put a severe penalty on using small (sub)matrices in their calls. This explains the massive drop in performance for larger matrices if we increase the number of processors in each cluster from $p = 1$ to $p = 2$, the Mflops per processor are nearly halved! Remember that in Algorithm 4.1 the BLAS are called with (square) blocks of size d, whereas the width of the subblocks in Algorithm 4.2 is only $d/(2p)$ and their height ranges from $d/(2p)$ to d. Even so, if the number of logical blocks is smaller than the number of processors, then it may pay to reduce the number of clusters (and thereby to increase the wrap) by using clusters with more than one processor. In fact, for $n \approx 500, \ldots, 800$ the configuration into four clusters with two processors each is optimal. This superiority of the case $p > 1$ would be more pronounced if the BLAS performance were better balanced with respect to the matrix size.

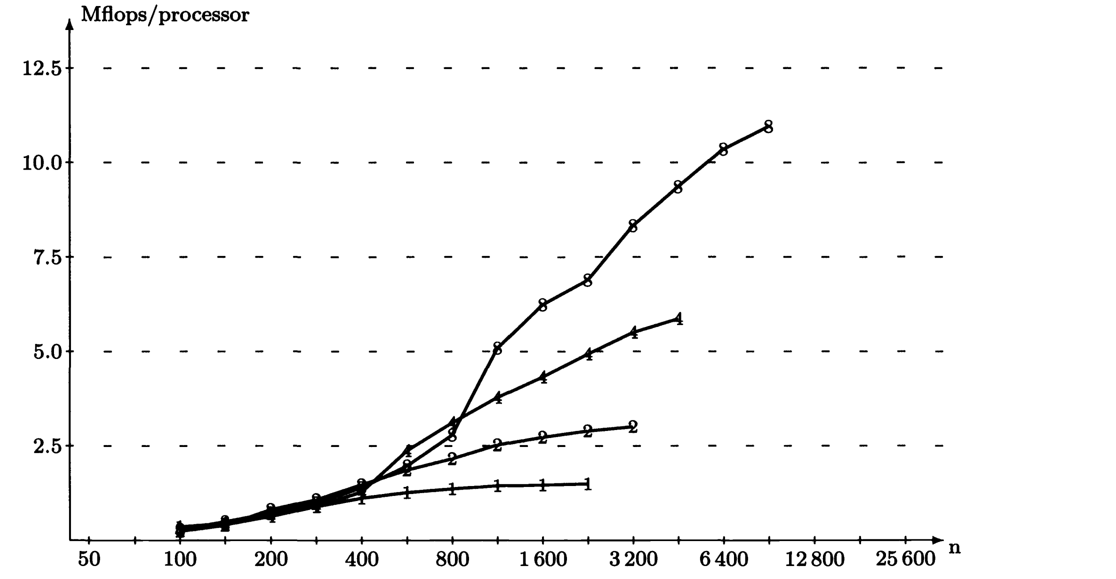

FIG. 9. *Performance of the algorithm* STBH *if also the parallelism within the blocks is exploited. The overall number of processors is* eight *for all the curves. The digits indicate the number of clusters in use. For example, the "4" curve corresponds to four clusters of two processors each.*

6. Concluding remarks. A detailed error analysis [12, Thm. 4.3] shows that if the computations are carried out in finite precision arithmetic with a relative error $\leq \vartheta$ in each operation, then the computed tridiagonal matrix $\bar{T}$ is *exactly* orthogonally similar to a symmetric (but generally not banded) matrix $\bar{A}$ with

$$||\bar{A} - A||_F = O(nd) \cdot \vartheta \cdot ||A||_F.$$

Here, $|| \cdot ||_F$ denotes the Frobenius norm of a matrix. By the Wielandt–Hoffman theorem [16, p. 104], this implies that the eigenvalues $\bar{\lambda}_i$ of the computed tridiagonal matrix cannot differ too much from the eigenvalues λ_i of the original band matrix A:

$$\left(\sum_{i=1}^{n}(\bar{\lambda}_i - \lambda_i)^2\right)^{1/2} \leq O(nd) \cdot \vartheta \cdot ||A||_F.$$

Therefore, the parallel reduction algorithm is numerically stable. The error bounds for the EISPACK and LAPACK algorithms are of the same form, although with smaller constants in the O-term [12, Thm. 4.2].

In this paper we do not deal with updating the transformation matrix, an option available in the EISPACK and LAPACK routines. It is, however, not very difficult to include these updates in our parallel algorithm.

In [12] we also developed a parallel algorithm based on (fast) Givens rotations, which is somewhat nearer to the EISPACK and LAPACK routines than the method discussed in this paper. This algorithm also relies on the block decompositions introduced in §2 and on the "parallel frame" given in Algorithm 3.2. It combines the advantages of the EISPACK routine (lower memory requirements and lower operation count) with a medium-grained parallelism, but the arithmetic must be done with the level-1 BLAS. In addition, although there is still some potential for parallelism within the blocks, it is much more difficult to utilize than with the Householder approach.

To conclude, the algorithm SBTH seems very promising on the iPSC/860 hypercube, as it should be on all machines with optimized BLAS-2 kernels and low bandwidth from the main memory to the arithmetical unit(s). The algorithm performs well if it is run on a single processor, and also it offers nearly full speedup if the band is long enough to be wrapped several times onto the processors.

Acknowledgments. This paper summarizes and extends major parts of my Ph.D. thesis. I am very grateful to my advisors G. Alefeld and A. Frommer for their support and advice. Many thanks to Argonne National Laboratory and to Oak Ridge National Laboratory for providing access to their hypercube parallel computers. Special thanks to Christian Bischof for initiating my visit at Argonne National Laboratory. I would also like to thank the unknown referees for their valuable comments.

COMPUTING PERIODIC GRAVITY WAVES ON WATER BY USING MOVING COMPOSITE OVERLAPPING GRIDS*

N. ANDERS PETERSSON†

Abstract. The composite overlapping grid method is applied to compute periodic gravity waves on water of finite constant depth. One component grid is made to follow the free surface while the remaining components are independent of the location of the surface. A pseudo-arclength continuation method is used to compute the solution as function of the phase velocity of the wave. The type of equation associated with some grid points and the number of equations in the discretized problem will change when the surface moves. The author expounds a stable way of switching the composite grid during the continuation procedure that works close to limit points. An adaptive technique is also developed to efficiently resolve the solution where sharp gradients develop.

Numerical examples are presented that show very good agreement with existing results.

Key words. adaptive grid, composite overlapping grid, pseudo-arclength continuation, water wave

AMS subject classifications. 65N50, 76B15

1. Introduction.

We consider two-dimensional irrotational gravity waves moving with constant phase velocity on water of finite constant depth. Both the infinitely deep case [2], [10] and the present case [4], [14] have been previously studied extensively. The aim of the research described here is to develop an accurate method that can be easily extended to compute the subcritical flow around an underwater obstacle, where we feel that the existing methods [9] still need improvement. We remark that an efficient method, based on a boundary integral formulation, has been devised for the special case when the flow behind the obstacle is supercritical, i.e., when waves are absent behind the obstacle [5]. This paper can be seen as the next step from [11] towards the solution of the subcritical problem. We prefer to first develop the method for the periodic case to be able to make comparisons with existing results.

We apply the composite overlapping grid method [3]. The basic idea is to make one component grid follow the free surface and let the remaining components be independent of the location of the surface. To resolve sharp gradients in the solution we also develop an adaptive technique. The adaptation is done locally on each component grid by changing the number of grid points and the stretching function. We would like to point out that the adaptive, moving grid approach developed here is general to problems where the shape of the domain is a function of the solution and/or the solution develops sharp gradients. One advantage of the composite overlapping grid method compared to the more commonly used boundary integral techniques is that the composite overlapping grid approach can also be used if effects of vorticity and viscosity are included. Those effects are not straightforward to include in a boundary integral formulation.

We use a pseudo-arclength continuation technique [8] to compute the solution as function of the phase velocity. When the surface moves, the type of equation associated with some grid points and the number of equations in the discretized problem change. The basic method therefore needs to be modified to allow for changes in the composite grid during the continuation procedure. A stable way of doing this that works close to limit points is devised.

The remainder of the paper is organized as follows. In §2 we scale the problem and present the governing equations. We discuss how to construct the composite overlapping grid in §3 and the problem is discretized in §4. Thereafter, in §5, we present the continuation method. A stable way of switching composite grid is presented in §6. Here, we also describe how the resolution of the grid is adapted to the solution. In §7 we discuss some implementational issues and we make numerical comparisons with existing results in §8. Very good agreement is found.

2. The governing equation. We describe the motion in Cartesian coordinates in a frame of reference fixed with respect to the wave, where the x-axis points opposite to the forward velocity and the z-axis is directed vertically upwards. We assume the motion to be steady in this coordinate system. Let the phase velocity be U and the wavelength be λ, which is defined as the shortest period of the wave. We scale the physical quantities by the length $\lambda/2\pi$ and the velocity $\sqrt{g\lambda/2\pi}$, where g is the acceleration of gravity. In the scaled variables, $z = -d$ corresponds to the bottom and $z = 0$ to the undisturbed free surface. We split the total velocity potential into a free stream potential plus a perturbation potential: $\Phi(x,z) = \mu x + \phi(x,z)$, where $\mu = U/\sqrt{g\lambda/2\pi}$ is the scaled phase velocity. The perturbation potential is governed by (cf. [15])

$$(1) \qquad \Delta\phi = 0, \quad -d \le z \le \eta(x), \quad -\infty < x < \infty,$$

where $\eta(x)$ is the elevation of the free surface. The perturbation potential is subject to the boundary condition

$$(2) \qquad \phi_z(x,-d) = 0, \qquad -\infty < x < \infty.$$

Furthermore, at the free surface we require both the Bernoulli equation and the kinematic condition to be satisfied,

$$(3) \qquad \mu\phi_x + \frac{1}{2}(\phi_x^2 + \phi_z^2) + \eta = 0, \quad -\infty < x < \infty, \quad z = \eta(x),$$

$$(4) \qquad (\mu + \phi_x)\eta_x - \phi_z = 0, \quad -\infty < x < \infty, \quad z = \eta(x).$$

The choice of constant in the right-hand side of (3) fixes the origin in z to the level of the free surface where the velocity, $\sqrt{(\mu+\phi_x)^2 + \phi_z^2}$, equals the phase velocity, μ.

The problem is to find the perturbation potential ϕ and the surface elevation η as functions of the phase velocity μ. We are interested in solutions that are l-periodic in the x-direction, with $l = 2\pi k$, $k = 1, 2, \dots$. The surface elevation will be studied in the interval $0 \le x \le l$ and the perturbation potential in the domain $(x,z) \in \Omega$, $\Omega: \ 0 \le x \le l, \ -d \le z \le \eta(x)$. A convenient measure of a solution is its wave height, which is defined as the vertical distance between the highest crest and the deepest trough of the wave.

A solution of (1)–(4) at a fixed μ is not isolated. This is due to the Galilean invariance in the x-direction and the fact that ϕ is only determined up to a constant. Denote a solution (ϕ,η) by ψ and let $\mathcal{L}[\psi,\mu]$ be the operator described by (1)–(4). Expanding $\mathcal{L}$ around a solution $\psi^{(0)}$ yields

$$(5) \qquad \mathcal{L}[\psi^{(0)} + \psi', \mu] = \mathcal{L}[\psi^{(0)}, \mu] + \mathcal{L}_\psi[\psi^{(0)}, \mu]\psi' + \mathcal{O}(|\psi'|^2).$$

The two degrees of freedom correspond to two zero eigenvalues of $\mathcal{L}_\psi$. It is easy to see that the eigenfunction connected to the undetermined constant is $\phi' = \text{const.}$, $\eta' = 0$. The eigenfunction corresponding to the Galilean invariance is the x-derivative of the present solution, i.e., $\phi' = \phi_x^{(0)}$, $\eta' = \eta_x^{(0)}$.

3. The composite overlapping grid. The composite overlapping grid method is a general tool for solving partial differential equations (PDEs) on complex domains (cf. [3]). The basic idea is to divide the complex domain into simple overlapping subdomains, the union of which completely covers the region of interest. Each subdomain is covered by a structured component grid and the set of component grids taken together is called the composite grid.

There are three different kinds of grid points in the composite grid: discretization, interpolation, and unused grid points. The discrete version of the differential equation or the boundary condition operator is applied at a discretization point. The interpolation points are situated at an interior boundary where the subdomains overlap. Here, the solution is interpolated from an overlapping component grid. The unused points are, as the name indicates, not used in the discretization of the differential equation. Henceforth, the discretization plus the interpolation points will be called the grid points used in the composite grid.

From previous investigations of the present problem, it is known that the spatial scales of the solution can be very small close to the surface. The scales are also known to grow rapidly with the distance from the surface. To resolve the solution without wasting grid points, we will use a coarse component grid close to the bottom, a fine component grid close to the surface, and component grids of intermediate grid sizes in between.

The component grid that includes the surface will be called the surface grid. To make the discretization of the boundary conditions (3), (4) straightforward and accurate, we locate the uppermost grid line of the surface grid at the position of the surface, $\eta(x)$. In order to keep the dependence on η close to the surface and simplify the discretization, we choose the remaining component grids to be Cartesian and independent of η.

Let there be Q component grids and denote by Ω_q the subdomain in the (x, z)-plane that corresponds to grid number q. The component grids are numbered beginning at the bottom and increasing towards the surface (see Fig. 1). The grid number equals the priority of that component in the composite grid. The composite grid will primarily use grid points from the component with the highest priority, secondarily from the grid with the second highest priority, and so on.

3.1. The mapping functions. For each subdomain, we will design a one-to-one mapping function that transforms the unit square in the (r, s)-plane onto Ω_q. These mapping functions are used to construct the component grids by transforming the grid points in a Cartesian grid in the (r, s)-plane onto the (x, z)-plane. In the following, the (r, s)-plane will also be called the parameter space.

For the Cartesian component grids, the mapping functions are simply

$$x^q(r) = lr, \tag{6}$$

$$z^q(r, s) = a_q(1 - s) + b_q s, \tag{7}$$

where a_q and b_q are constants; q is the grid number, $1 \leq q \leq Q - 1$.

To make the dependence of η in the transformed Laplace equation reasonably simple, we choose the mapping function for the surface grid to be

$$x^Q(r) = lt_Q(r), \tag{8}$$

$$z^Q(r, s) = \eta(lt_Q(r)) - b_Q(1 - u_Q(s)). \tag{9}$$

Here, b_Q is the constant vertical thickness of the grid. The function $t_Q(r)$ clusters grid points in a layer around the crest of the wave and the function $u_Q(s)$ is used to concentrate grid points in a layer close to the surface. For example, $t_Q(r) = R^{-1}(r)$, where $R(t) = (t + U_p(t) - U_p(0))/(1 + U_p(1) - U_p(0))$ and

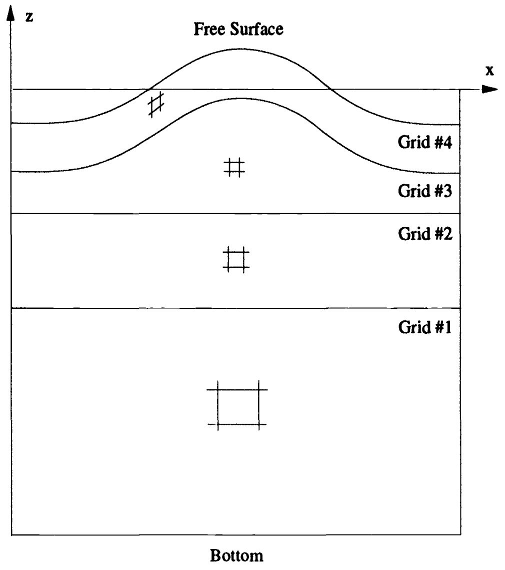

FIG. 1. *The numbering of the component grids. In this case, $Q = 4$.*

$$U_p(t) = \sum_{\nu=-\infty}^{\infty} U(t+\nu), \; U(t) = \frac{\alpha_r}{2} \tanh \beta_r (t - \gamma_r). \tag{10}$$

The stretching is concentrated around $t = \gamma_r$ and the parameter β_r determines the ratio between the smallest and the largest grid size. The constant α_r governs the width of the layer, i.e., the number of grid points that will be in the layer compared to the number outside it. The derivatives of the function $u_Q(s)$ are not required to be periodic. Therefore, the function U replaces U_p in the corresponding expression.

The grid points of grid q are given by $x_j^q = x^q(r_j^q)$ and $z_{j,k}^q = z^q(r_j^q, s_k^q)$, where

$$r_j^q = (j-1)h_r^q, j = 1, 2, \dots, N_q, \tag{11}$$
$$s_k^q = (k-1)h_s^q, k = 1, 2, \dots, M_q, \tag{12}$$

with $h_r^q = 1/(N_q - 1)$ and $h_s^q = 1/(M_q - 1)$; $N_q > 1$ and $M_q > 1$ are natural numbers.

4. Discretizing the equations. In this section, we will describe how the Laplace equation and the boundary conditions are discretized by a second-order accurate scheme on a composite grid. We adopt the mapping method which uses the previously constructed mapping functions to form the discrete set of equations on each component grid. The component grid problems are coupled to each other by interpolation relations at the interior boundaries where the subdomains overlap.

We begin with some definitions. We define a component grid function on grid q by $g_{j,k}^q = g(x_j^q, z_{j,k}^q)$ and a surface grid function on grid Q by $f_j = f(x_j^Q)$. The forward, backward, and central divided difference operators in the r-direction on grid q are defined as

$$D_{+j} g_{j,k}^q = \frac{g_{j+1,k}^q - g_{j,k}^q}{h_r^q},$$
$$D_{-j} g_{j,k}^q = D_{+j} g_{j-1,k}^q,$$

$$D_{0j}g^q_{j,k} = \frac{1}{2}\left(D_{+j} + D_{-j}\right)g^q_{j,k}.$$

A corresponding notation is used in the s-direction.

On the Cartesian grids, we discretize (1) by

$$\left(l^{-2}D_{+j}D_{-j} + (b_q - a_q)^{-2}D_{+k}D_{-k}\right)\phi^q_{j,k} = 0. \tag{13}$$

This stencil is applied to the discretization points with indices in the range $1 \leq j \leq N_q - 1$, $2 \leq k \leq M_q - 1$. The periodicity in the x-direction implies periodicity in the r-direction for all component grid functions. It is enforced by $\phi^q_{0,k} = \phi^q_{N_q-1,k}$ and $\phi^q_{N_q,k} = \phi^q_{1,k}$. We discretize the boundary condition at the bottom (2) by the second-order accurate one-sided formula

$$(b_1 - a_1)^{-1}\left(D_{+k} - \frac{h^1_s}{2}D_{+k}D_{+k}\right)\phi^1_{j,k} = 0, \tag{14}$$

for $k = 1$ and $1 \leq j \leq N_1 - 1$.

To discretize the Laplace equation on the surface grid, we transform it to the parameter space and replace the derivatives of ϕ in the resulting expression by second-order accurate divided differences. This yields

$$\left(\mathcal{A}_{j,k}D_{+j}D_{-j} + \mathcal{B}_{j,k}D_{0j}D_{0k} + \mathcal{C}_{j,k}D_{+k}D_{-k} + \mathcal{D}_{j,k}D_{0j} + \mathcal{E}_{j,k}D_{0k}\right)\phi^Q_{j,k} = 0, \tag{15}$$

for the discretization points in $1 \leq j \leq N_Q - 1$, $2 \leq k \leq M_Q - 1$. The coefficients are (cf. [13])

$$\mathcal{A} = (r^Q_x)^2 + (r^Q_z)^2, \quad \mathcal{B} = 2(r^Q_x s^Q_x + r^Q_z s^Q_z), \quad \mathcal{C} = (s^Q_x)^2 + (s^Q_z)^2, \tag{16}$$

and

$$\mathcal{D} = r^Q_{xx} + r^Q_{zz}, \; \mathcal{E} = s^Q_{xx} + s^Q_{zz}. \tag{17}$$

Here, r^Q and s^Q are the inverses of the mapping functions x^Q and z^Q, respectively, evaluated at the grid point in question. The subscripts on the metric quantities denote partial differentiation, i.e., $r^Q_x = \partial r^Q/\partial x$, etc.

The boundary conditions at the free surface are discretized by the same technique as the Laplace equation. This yields

$$\begin{aligned}\mu(r^Q_x D_{0j} + s^Q_x D_{1k})\phi^Q_{j,k} &+ \frac{1}{2}\left((r^Q_x D_{0j} + s^Q_x D_{1k})\phi^Q_{j,k}\right)^2 \\ &+ \frac{1}{2}\left((r^Q_z D_{0j} + s^Q_z D_{1k})\phi^Q_{j,k}\right)^2 + \eta_j = 0,\end{aligned} \tag{18}$$

$$\left(\mu + (r^Q_x D_{0j} + s^Q_x D_{1k})\phi^Q_{j,k}\right) r^Q_x D_{0j}\eta_j - \left(r^Q_z D_{0j} + s^Q_z D_{1k}\right)\phi^Q_{j,k} = 0. \tag{19}$$

In these formulae we used $D_{1k} = D_{-k} + h_s D_{-k}D_{-k}/2$, which is a second-order accurate approximation of the s-derivative. We apply (18), (19) to $k = M_Q$ and $1 \leq j \leq N_Q - 1$.

The component grid functions are coupled by interpolation relations. Our difference scheme is a second-order accurate approximation of a second-order equation and the component grids have an overlap which is proportional to the grid size. To get second-order accuracy for the total solution, it is necessary to use (at least) third-order accurate interpolation (cf. [3]). For example, let $\phi^a_{n,m}$ be an interpolation point with interpolation location (j, k, b). This means that $\phi^a_{n,m}$ will be interpolated from $\phi^b_{j+p,k+q}$,

$-1 \le p, q \le 1$. Let $(\tilde{r}, \tilde{s})$ satisfy $x^a_n = x^b(\tilde{r})$ and $z^a_{n,m} = z^b(\tilde{r}, \tilde{s})$. The biquadratic interpolation yields

$$\phi^a_{n,m} - \sum_{p=-1}^{1} \sum_{q=-1}^{1} \alpha_p(\tilde{r})\beta_q(\tilde{s})\phi^b_{j+p,k+q} = 0, \tag{20}$$

where α_p and β_q are quadratic polynomial base-functions.

5. Continuation in μ. We will use a pseudo-arclength continuation method to calculate (ϕ, η) as function of the phase velocity μ. The basic method described in [8] cannot be used directly due to the two degrees of freedom that make the linearized operator singular. The method also needs to be modified because the number of grid points used in the composite grid depends on the surface elevation. However, the discussion of that aspect will be postponed to §6.

To handle the two degrees of freedom, one can add two new degrees of freedom and two extra equations such that the Jacobian of the extended problem becomes nonsingular [7]. However, it is possible to avoid adding extra unknowns and equations by instead enforcing the increments in the Newton iteration to be orthogonal to the nullspace connected to the two zero eigenvalues. This is equivalent to solving (1)–(4) in the subspace orthogonal to the nullspace. The part of the solution in the nullspace is of no interest, since it only corresponds to adding a constant to the perturbation potential and shifting the solution in the x-direction.

To enforce the orthogonality of the increments in the Newton iteration, we also need the nullspace of the adjoint operator. Unfortunately, it is difficult to numerically compute accurate approximations of these nullspaces. To overcome this difficulty, we modify the boundary condition at the bottom to fix the constant part of the solution. Instead of (2), we use

$$\phi_z(x, -d) + \phi(0, -d) = 0, \qquad 0 \le x \le l. \tag{21}$$

The discrete boundary condition (14) is modified in a corresponding way. The idea is that a solution with $\phi(0, -d) = 0$ satisfies the original boundary condition without introducing an undetermined constant. The linearized modified operator will therefore only have one zero eigenvalue. This makes an accurate computation of the corresponding nullspace much easier. Due to nonconservation, we cannot expect $\phi(0, -d)$ to be zero in the discrete approximation. Instead, it will get a small value that indicates how well the continuous conservation property is satisfied. We regard this value as a measure of the accuracy of the discrete solution.

The discrete set of equations can be written in abstract form as $L[u, \mu] = 0$, where $L : \mathcal{X} \times \Re \to \mathcal{X}$. Here, $\mathcal{X}$ is an n-dimensional vectorspace and n is the number of grid points used in the composite grid plus the number of grid points along the surface. The vector u contains ϕ at every used grid point and η at the grid points along the surface. We define a scalar product and a norm for $x, y \in \mathcal{X}$ by

$$\langle x, y \rangle = \frac{1}{n} \sum_{i=1}^{n} x_i y_i, \qquad \|x\| = \sqrt{\langle x, x \rangle}. \tag{22}$$

The eigenvalue connected to the Galilean invariance will henceforth be called the shift-eigenvalue. Let e_r and e_l denote the right and left eigenvectors of the Jacobian matrix $\partial L / \partial u$ corresponding to the shift-eigenvalue. Let the eigenvectors be normalized to have $\|e_r\| = 1$ and $\langle e_l, e_r\rangle = 1$. The projection P maps $\mathcal{X}$ onto the eigenspace according to $Pf = \langle e_l, f\rangle e_r$, $f \in \mathcal{X}$.

We will consider solving

$$(I - P[u,\mu])L[u,\mu] = 0, \tag{23}$$

for part of the solution in $(I - P)\mathcal{X}$. The part in $P\mathcal{X}$ corresponds to the phase of the solution and it will be determined during the solution procedure. A point (u, μ) that satisfies $(I - P[u,\mu])L[u,\mu] = 0$ will be called a solution point and we will call a point nonsingular if all eigenvalues of $\partial L/\partial u$ except the shift-eigenvalue are bounded away from zero.

5.1. The nonsingular case. Following [8], the solution (u, μ) will be considered as a function of the pseudo-arclength σ, $u = u(\sigma)$ and $\mu = \mu(\sigma)$. Assume that a nonsingular solution point (u_0, μ_0) is known, and let it have pseudo-arclength σ_0. We define the pseudo-arclength relative to that point by

$$\sigma = \sigma_0 + \langle \dot u_0, u - u_0\rangle + \dot\mu_0(\mu - \mu_0). \tag{24}$$

The tangent $(\dot u_0, \dot\mu_0)$ is the solution of

$$L_u[u_0, \mu_0]\dot u_0 = -L^I_\mu[u_0, \mu_0]\dot\mu_0. \tag{25}$$

Here we used the notation $L^I_\mu[u_0,\mu_0] = (I - P[u_0,\mu_0])L_\mu[u_0,\mu_0]$. Equation (25) is solved under the side-condition $P\dot u_0 = 0$ and the normalization $\|\dot u_0\|^2 + |\dot\mu_0|^2 = 1$. We also require the scalar product between the previous and the present tangent to be positive.

To get the same number of equations as dependent variables, we augment $(I - P[u,\mu])L[u,\mu] = 0$ by the arclength equation $N[u,\mu;\sigma] = 0$, where

$$N[u,\mu;\sigma] = \langle \dot u_0, u - u_0\rangle + \dot\mu_0(\mu - \mu_0) - (\sigma - \sigma_0). \tag{26}$$

We use the predictor $(u^0, \mu^0) = (u_0 + \dot u_0\Delta\sigma, \mu_0 + \dot\mu_0\Delta\sigma)$ as initial guess for the solution at $\sigma = \sigma_0 + \Delta\sigma$. The predictor is corrected by Newton's method on the augmented system, where the improvements of the solution are found by solving

$$\begin{pmatrix} L_u[u^k,\mu^k] & L^I_\mu[u^k,\mu^k] \\ N_u[u^k,\mu^k] & N_\mu[u^k,\mu^k] \end{pmatrix} \begin{pmatrix} \Delta u^k \\ \Delta\mu^k \end{pmatrix} = -\begin{pmatrix} L^I[u^k,\mu^k] \\ N[u^k,\mu^k] \end{pmatrix} \tag{27}$$

by the bordering algorithm, under the side-condition $P[u^k,\mu^k]\Delta u^k = 0$. The solution is then updated according to

$$u^{k+1} = u^k + \Delta u^k, \tag{28}$$

$$\mu^{k+1} = \mu^k + \Delta\mu^k. \tag{29}$$

We iterate until $\|u^{k+1} - u^k\| + |\mu^{k+1} - \mu^k| < \epsilon$.

If the iteration converges, we may repeat the procedure after the composite grid has been updated. The number of iterations which was required to get convergence is used to determine next stepsize $\Delta\sigma$. However, if the iteration diverges, we halve the stepsize and try again.

The continuation method requires the knowledge of the Jacobian matrix $\partial L/\partial u$ and the derivative $\partial L/\partial \mu$. Only the boundary conditions at the surface (18), (19) depend explicitly on μ. Hence, $\partial L/\partial \mu$ will only be nonzero along the surface. The Jacobian matrix is most naturally split into the two parts $\partial L/\partial \phi$ and $\partial L/\partial \eta$. L depends nonlinearly on ϕ only in (18) and (19), so $\partial L/\partial \phi$ is very straightforward to form. We refer the reader to [12] for a detailed description of how to set up the part $\partial L/\partial \eta$.

5.2. The singular case. The smallest eigenvalue, except for the shift-eigenvalue, is monitored along the solution curve to detect singular points. The pseudo-arclength method easily passes through limit points, but special care is necessary to switch branches at a bifurcation point. One can proceed as in [8]. In that method, the tangent to the solution curve on the other branch is computed by using second derivative information of L. The continuation then proceeds in the direction of the new tangent starting at the singular point. In the present work, we have instead used a Lyapunov–Schmidt reduction technique that does not use the second derivatives of L.

We only consider the situation when $\partial L/\partial u$ has exactly two small eigenvalues, one of which is the shift-eigenvalue. We further assume the eigenvectors of the two small eigenvalues to be linearly independent. Our task is to find one point on every solution curve (u,μ) that satisfies $(I-P[u,\mu])L[u,\mu]=0$, close to the singular point.

Let e'_r and e'_l be the right and left eigenvectors of the second small eigenvalue, normalized to have $\|e'_r\|=1$ and $\langle e'_l, e'_r\rangle = 1$. Let P' be the projection that maps $\mathcal{X}$ onto the second eigenspace. It is defined by $P'f = \langle e'_l, f\rangle e'_r$, $f\in\mathcal{X}$.

Let (u_0,μ_0) be a solution point close to the singular point and set $u=u_0+x$ and $\mu=\mu_0+\tau$. We split x into three parts, $x=x^I+x^{II}+x^{III}$, where $x^I=(I-P-P')x$, $x^{II}=P'x$, and $x^{III}=Px$. The part of x in P' can also be expressed as $x^{II}=\alpha e'_r$, $\alpha=\langle e'_l,x\rangle$, and the part in P will be set to zero, $x^{III}=0$, since it only shifts the solution. We now split the problem according to

$$(I-P')(I-P)L[u,\mu]=0, \tag{30}$$

$$P'(I-P)L[u,\mu]=0. \tag{31}$$

Let $A=\partial L/\partial u[u_0,\mu_0]$ denote the Jacobian matrix. We can solve the linear system $Ax=b$ for $b\in(I-P-P')\mathcal{X}$ uniquely in $(I-P-P')\mathcal{X}$, where P and P' are evaluated at (u_0,μ_0). Therefore, (30) can be used to compute $x^I=x^I(\alpha,\tau)$ by iteration. First, we choose some values of α and τ that will be fixed throughout the iteration. We take the initial guess to be $x_0^I=0$ and compute the subsequent iterates by solving

$$L_u[u_0,\mu_0]\Delta x_k = -(I-P-P')L[u_0+x_k^I+\alpha e'_r, \mu_0+\tau], \tag{32}$$

$$x_{k+1}^I = x_k^I + (I-P-P')\Delta x_k. \tag{33}$$

We truncate the iteration when $\|x_{k+1}^I - x_k^I\| < \epsilon$. The iteration will converge for sufficiently small α and τ because, by assumption, $\partial L/\partial u$ has only two small eigenvalues and the corresponding parts of the solution are kept constant by the projections. The iteration only requires L_u to be factored once; it is therefore relatively inexpensive compared to the Newton iteration.

The second relation (31) is equivalent to the scalar equation $g(\alpha,\tau)=0$, where

$$g(\alpha,\tau)=\langle e'_l, L[u_0+x^I(\alpha,\tau)+\alpha e'_r, \mu_0+\tau]\rangle. \tag{34}$$

This equation can, for instance, be solved by the following two-step technique. We first approximately locate the zeros of g by evaluating it at a number of points on the small circle $\alpha^2+\tau^2=r^2, r \ll 1$. For each zero, we solve $g=0$ by bisection with the approximate location as initial guess.

We can proceed with the nonsingular continuation approach starting from a solution point sufficiently far away from the singularity in the (α,τ)-plane. We trace out all solution curves that connect at the singular point by doing this for one point on each branch.

6. Changing the composite grid. When the surface moves during the continuation procedure, the amount of overlap between the subdomains Ω_Q and Ω_{Q-1} will change. Component grid Q has the highest priority so all its grid points will always be used in the composite grid. The situation is different for grid $Q-1$. After the surface has moved, some grid points that were previously used might no longer be needed, while some formerly unused grid points might be required in the composite grid. Therefore, the type of equation associated with a grid point and the number of used grid points in grid $Q-1$ will depend on the location of the surface. Furthermore, even if the type of equation remains unchanged for all grid points, the interpolation locations might be different for some interpolation points. For these reasons, the continuation method must be modified to allow for changes in the composite grid.

The basic idea is to fix the interpolation locations and the type of equation associated with each grid point during the Newton iteration and only update the mapping function for the surface grid. This means that, for instance, the discretization points are prevented from changing to interpolation points or unused points. For stability reasons, the amount the surface is allowed to move between two solution points is restricted by the amount of overlap, i.e., we do not allow for extrapolation in the interpolation relations. With the notation of (20), extrapolation occurs if at least one of the following inequalities is satisfied: $\tilde{r} < r^b_{j-1}$, $\tilde{s} < s^b_{k-1}$, $r^b_{j+1} < \tilde{r}$ or $s^b_{k+1} < \tilde{s}$. If extrapolation should occur in any interpolation relation, we stop the Newton iteration, decrease the stepsize $\Delta\sigma$ and restart the continuation from the previous solution point.

Once the iteration has converged to a solution where there is no extrapolation in the interpolation relations, we verify that the composite grid is consistent with the position of the surface. This is done by ensuring that the interpolations are sufficiently centered. The criterion

$$(35)\qquad r^b_j - 0.6h^b_r \le \tilde{r} \le r^b_j + 0.6h^b_r, \qquad s^b_k - 0.6h^b_s \le \tilde{s} \le s^b_k + 0.6h^b_s,$$

has been found to work well in practice. We have a valid solution if all interpolation points satisfy (35); we may then proceed with the continuation. Otherwise, the composite grid and the solution must first be corrected.

6.1. The correction step. We begin by constructing a corrected composite grid. We mention in passing that this can be done at a much lower computational cost than would be involved in constructing a completely new grid. Thereafter, we repeat the last continuation step on the corrected grid. We get u_0 on the corrected grid by interpolation from the previous grid. With this approach, it is possible to correct the grid close to a limit point. The simpler idea to solve $(I-P[u,\mu])L[u,\mu]=0$ on the corrected composite grid, but fixing μ at the current value, might fail close to a limit point because its location depends slightly on the grid (see Fig. 2). The correction step has been found to be very stable with the present restriction on the movement of the surface.

The reason for allowing the interpolation points to be slightly noncentered is to ensure that the corrected solution will satisfy (35) on the corrected grid. The difficulty which otherwise might arise is illustrated in Fig. 3. Consider the situation when 0.6 is

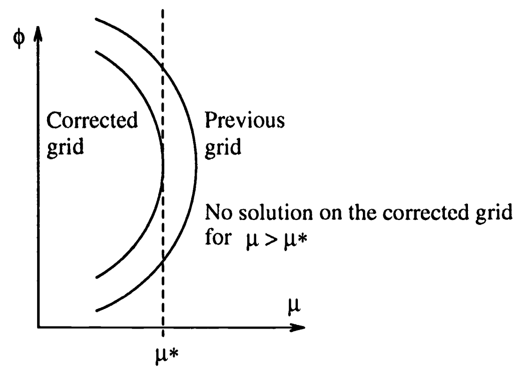

FIG. 2. *The location of a limit point might depend slightly on the grid.*

replaced by 0.5 in (35). Let some interpolation point have $\tilde{s} = s^b_k + 0.5h^b_s + \epsilon$, $0 < \epsilon \ll 1$ before the correction step. The corrected composite grid will use more grid points in grid b to make $\tilde{s} = s^b_{k+1} - 0.5h^b_s + \epsilon$. The problem is that the solution on the corrected grid might be slightly different than the solution on the previous grid. In particular, the corrected location of the surface can make $\tilde{s} = s^b_{k+1} - 0.5h^b_s - \tilde{\epsilon}$, $0 < \tilde{\epsilon} \ll 1$, which would call for correcting the composite grid back to the initial state. This problem does not occur if a less restrictive tolerance is used. Instead, both composite grids in Fig. 3 would be valid. The history of the previous locations of the surface determines which of the possible composite grids will be used. This is acceptable because we can expect the solutions on the different grids to be very similar if the solution is well resolved.

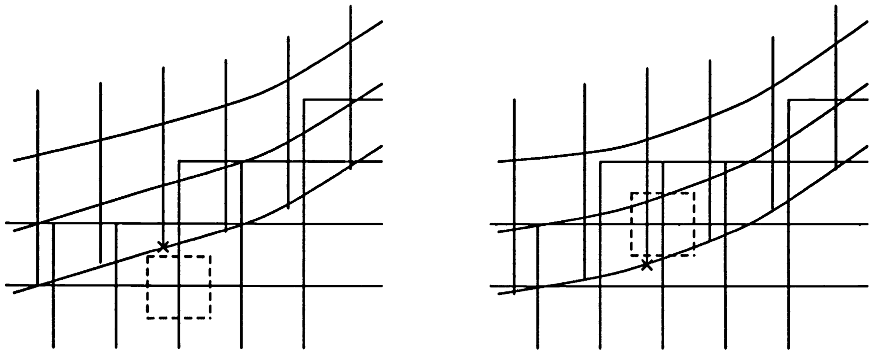

FIG. 3. *The oscillation between two very similar composite grids that can be avoided by allowing for slightly noncentered interpolation points.*

6.2. Adapting the grid to the solution. The solution becomes steeper as the wave height increases. In particular, the derivative of the surface elevation tends to a discontinuity at the crest of the wave. A very fine grid is therefore necessary to resolve the solution close to that point, but it is difficult to a priori estimate how fine the grid needs to be for a certain wave height. It is also very uneconomical to use the fine grid all the way from the trivial solution. For these reasons, we have developed an adaptive technique where we allow the resolution in each component grid and the stretching in the surface grid to change during the continuation procedure.

Ideally, one would like to monitor the truncation error of the discrete solution and increase the resolution when and where it is necessary. In the present work, we have used a simpler approach, namely, to monitor how well the solution is resolved on the grid. In particular, for the perturbation potential, we look at the largest difference in each direction, i.e.,

$$\text{(36)} \qquad \text{diff}_r\phi^q := \max|h_r^q D_{+j}\phi^q_{j,k}|, \qquad \text{diff}_s\phi^q := \max|h_s^q D_{+k}\phi^q_{j,k}|.$$

For the surface elevation, we are concerned with resolving the sharp gradient in η_x that develops when the wave height gets close to its limiting value (see Fig. 4). We therefore monitor $\text{diff}_r\eta_x$.

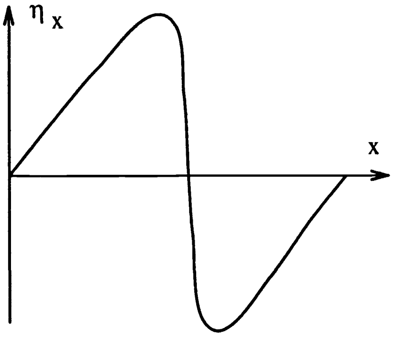

FIG. 4. *The x-derivative of the surface elevation close to the maximum wave height.*

At each valid solution point, we calculate $\text{diff}_r\phi^q$, $\text{diff}_s\phi^q$, and $\text{diff}_r\eta_x$. The idea is to keep these quantities in the predetermined ranges

$$\text{(37)} \qquad A_\phi < \text{diff}_r\phi^q < B_\phi, \quad A_\phi < \text{diff}_s\phi^q < B_\phi \quad \text{and} \quad A_\eta < \text{diff}_r\eta_x < B_\eta$$

by changing the number of grid points and the parameters in the stretching function. The constants A_ϕ, B_ϕ, A_η, and B_η will be called the resolution thresholds.

Initially, the solution is trivial, and we can use a coarse grid to start the continuation. During the continuation, some difference will eventually exceed its limit and we then need to construct a grid with better resolution. For example, let $\text{diff}_r\phi^q > B_\phi$. We increase the number of grid points in the r-direction of grid q by changing N_q such that the solution on the new grid approximately satisfies $\text{diff}_r\phi^q = A_\phi$.

We control the stretching function (10) by monitoring $\eta_x(x)$ (see Fig. 4). To avoid wasting grid points, we adjust the parameters β_r and γ_r to make $h_r^Q D_{+j}\eta_x(x_j^Q)$ as uniform over the grid as possible. It is clear that $|\eta_{xx}|$ has maxima at the crest ($x = x_{\text{crest}}$) and at the trough ($x = x_{\text{trough}}$) of the wave. To concentrate the layer in the stretching function around the crest, we choose $\gamma_r = x_{\text{crest}}/l$. The ratio between the largest and the smallest grid sizes equals approximately β_r. We therefore take $\beta_r = |\eta_{xx}(x_{\text{crest}})/\eta_{xx}(x_{\text{trough}})|$.

When the number of grid points and the stretching have been properly adjusted, we perform a correction step (§6.1) to update the grid and get a valid solution on the refined grid. To make the process stable and reliable, the solution must be reasonably well resolved on the grid before we try to change the resolution. If it is not, we decrease the stepsize $\Delta\sigma$ and compute an intermediate, more well-resolved, solution before we change the resolution. Without this precaution, the correction step might diverge. Another important rule is to avoid changing the resolution too drastically. Practically, we found that the correction step converges quickly if the number of grid points changes by less than 20% in each direction on each component grid, and the stretching strength β_r changes by less than an absolute amout of 5.0.

7. Implementation. In the present implementation we have used the software package CMPGRD (cf. [1]) to generate the composite grids. A composite grid is created by calling CMPGRD as a subroutine with an input consisting of the component grid transformations, the number of grid points in each direction on each grid, and the priority between the component grids. On output, each grid point is labeled according to how it will be used and the interpolation locations are also given for the interpolation points.

When CMPGRD is called to correct an existing grid, the previous composite grid and the corrected mapping function for the surface grid are given as input. For the case when the resolution has been changed, the new number of grid points is also supplied. The fast algorithm for correcting the composite grid only works if the new interpolation points can be found, at most, one grid point away from some previous interpolation point in the same component of the previous composite grid (cf. Fig. 5). This restriction is consistent with the aforementioned requirement to disallow for extrapolation in the interpolation relations. However, we have encountered situations when the fast algorithm fails after the stretching has been changed drastically. In those rare cases, a new composite grid must be constructed from scratch.

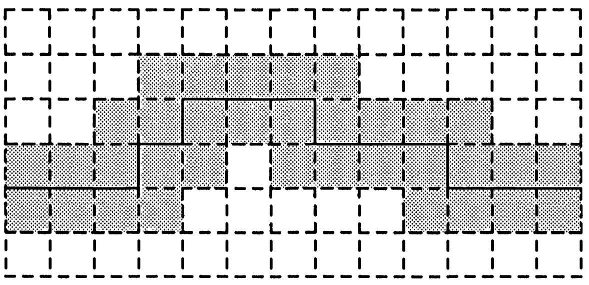

FIG. 5. *The band in the (r, s)-plane that is searched for the location of the interpolation points in the corrected grid. The solid line indicates the position of the interpolation points in the previous grid.*

The information supplied by CMPGRD is sufficient to form the discrete set of equations for a composite grid that is composed of an arbitrary number of component grids, each having an arbitrary number of grid points. The only restriction on the component grids is that they must overlap sufficiently. However, the implementation of a general solver in FORTRAN-77 requires a dynamic memory allocator. For this purpose, we have used the DSK-package, which is an autonomous part of CMPGRD.

The emerging linear systems of equations were solved by the YALE sparse matrix package (cf. [6]). We found experimentally that the accuracy of the solution was improved when the equations corresponding to the boundary conditions at the surface were inserted early in the system matrix. Actually, this trick was necessary to make the Newton iteration converge properly for solutions with wave heights close to the limiting value. The reason for this behavior might be that this package does not pivot for numerical stability when it LU-decomposes the matrix. Our main motivation for using this package despite this deficiency is that it is fast.

8. Numerical results. We begin by studying a single wave, i.e., $l = 2\pi$, on deep water. We compare our results with those reported by [2] and [10] for the infinitely deep case. To investigate the effect of the finite depth in our computation, we performed two sets of calculations with $d = 2\pi$ and $d = 4\pi$, respectively. To also investigate the dependence of the grid size, we varied the resolution thresholds. For simplicity, we used $A_\phi = A_\eta$ and $B_\phi = B_\eta = A_\phi + 5\times10^{-3}$. We used a composite grid with four components and the mapping functions for the component grids had the parameters $a_1 = -d$, $b_1 = -2.5$, $a_2 = -3.0$, $b_2 = -0.7$, $a_3 = -1.2$, $b_3 = 0.65$, and $b_4 = 0.4$. In the case $l = d$, we used the following number of grid points in the start grid: $N_1 = 14$, $M_1 = 8$, $N_2 = 23$, $M_2 = 11$, $N_3 = 39$, $M_3 = 13$, $N_4 = 63$, and $M_4 = 7$. For the deeper case, we used $M_1 = 20$.

For the continuous problem, the bifurcation from the trivial solution occurs at $\mu_0 = \sqrt{\tanh d}$. With the present start grid, it was displaced by $\mathcal{O}(10^{-4})$.

Let h denote the wave height. In Tables 1 and 2 we present h/l as function of the resolution thresholds. The three different μ-values correspond to solutions where the maximum slope of the surface is approximately 17.0, 22.4, and 27.8 degrees, respectively. For $A_\phi = 10^{-2}$, the absolute difference between our results and those reported by [10] are of the order $\mathcal{O}(10^{-3})$. We conjecture that the discrepancies are mainly caused by truncation errors and not by the finite depth. Both the accuracy and the efficiency of the present method would probably be improved by using a higher-order difference scheme.

3.0×10^{-2}	0.092083	0.117908	0.135623
2.0×10^{-2}	0.092557	0.118228	0.136455
1.0×10^{-2}	0.092257	0.117877	0.136353

The value of $\phi(0, -d)$, which occurs in (21), indicates how well the conservation property of the continuous problem is satisfied. By starting from the trivial solution, it is initially zero. For $A_\phi = 10^{-2}$ it was of the order $\mathcal{O}(10^{-6})$ along the solution curve.

To demonstrate the result of the adaptation technique, we present the start grid in Fig. 6 and the grid corresponding to $A_\phi = 3\times10^{-2}$, $\mu = 1.09184$ in Fig. 7.

In Figs. 8 and 9, we plot h/l as function of the phase velocity for the depth $d = l$ and the resolution $A_\phi = 10^{-2}$. During the computation of this solution curve, the stepsize in the pseudo-arclength was chosen to make the Newton iteration converge in approximately four steps. We calculated 43 solution points and the resolution was changed 24 times. The composite grid was corrected 43 times due to noncentered interpolations; six of those were done after the resolution had been changed. The fast algorithm for correcting the composite grid did not fail during any correction step. This implies that the

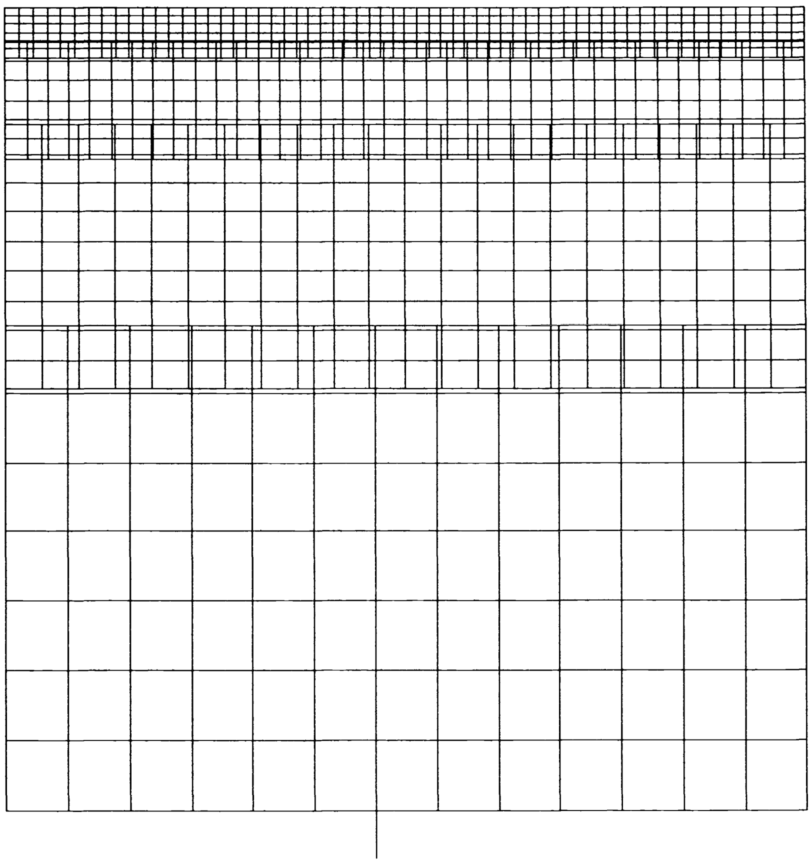

FIG. 6. *The start grid.*

overhead for changing the resolution corresponded to 30 out of a total of 110 continuation steps, i.e., approximately 27%. To give an example of the amount of work that was saved by using an adaptive grid, we report the number of equations as function of h/l in Fig. 10. The sparse matrix solver requires of the order $\mathcal{O}(n^2)$ operations to perform one Newton step. This means that one Newton iteration with 10^4 grid points requires the same effort as performing $\mathcal{O}(100)$ iterations with 10^3 grid points. These figures clearly show the benefit of using an adaptive grid.

Next, we investigate the subharmonic bifurcation reported by [2] for the infinitely deep case. In this computation, we started with two waves in the domain $l = 4\pi$. The depth was $d = 2\pi$ and the grid sizes for the start grid were the same as in the single-wave case. We used the resolution threshold $A_\phi = 10^{-2}$. The smallest eigenvalue except for the shift-eigenvalue was monitored along the solution curve to detect singular points. Initially, the solution has period $l/2$ and it is identical to two adjacent single wave solutions. A solution with this property will be called regular.

In close agreement with [2], we found a singular point in the vicinity of $\mu = 1.08414$, $h/l = 0.06447$. By applying the technique described in §5.2, we detected a bifurcating solution curve that connects to the regular solution curve at the singular point. The eigenfunction corresponding to the second small eigenvalue is given in Fig. 11. It has period l in the x-direction, which implies that the solution on the bifurcated curve also has

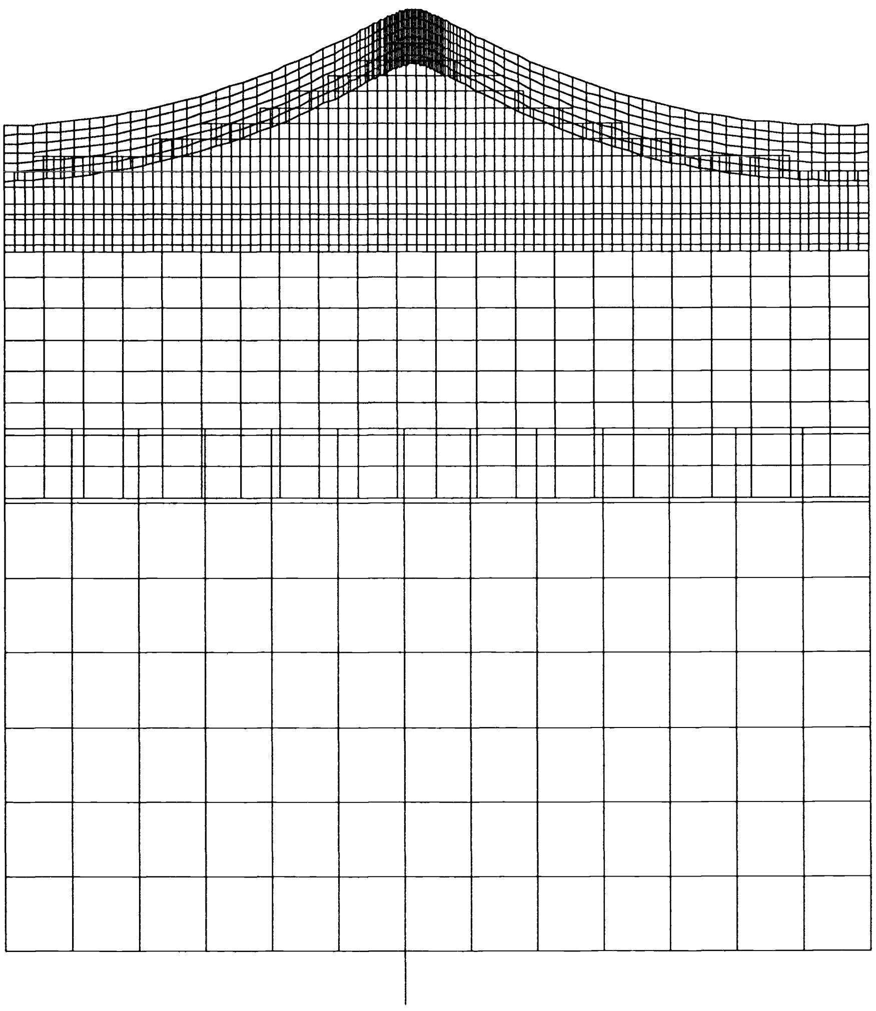

FIG. 7. *The grid at* $\mu = 1.09184$ *with the resolution* $A_\phi = 3 \times 10^{-2}$.

period l, i.e., twice the period of the regular solution. The bifurcated solution curve was traced out with the nonsingular continuation method starting on the bifurcated branch close to the singular point. On the bifurcated solution curve, one of the crests becomes sharp while the other stays rounded when the wave height increases (see Fig. 12). Obviously, the two possible locations of the sharp crest correspond to identical solutions shifted by $l/2$; they are found by proceeding in opposite directions along the solution curve. In Fig. 13, we give h/l as function of the phase velocity for the bifurcated solution. The continuation was truncated when the number of equations exceeded 25,000.

A direct comparison with previous results for the shallow water case [4], [14] was not possible because those results were obtained by keeping the flux μd constant during the continuation. In the present method, we instead kept the constant in the Bernoulli equation (3) fixed, which implies that the flux varies slightly along our solution curves. The average depth in the two approaches will therefore be different at the same velocity for nonzero wave heights. However, an approximate comparision was performed by interpolating between the results in [4] for different depths. We made the comparison

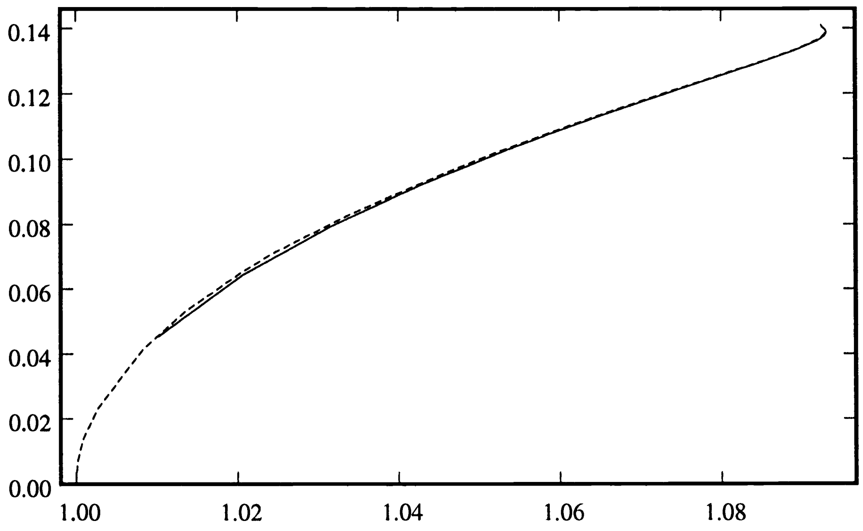

FIG. 8. *h/l as function of the phase velocity for the case $d = 2\pi$ and $A_\phi = 10^{-2}$. The solid line represents the result reported by* [10]; *the dashed line corresponds to the present work.*

for the solution curve with the initial depth $d = 1.2039728$, which corresponds to Table A3 in [4]. In our computation, we used the resolution threshold $A_\phi = 10^{-2}$ and traced out the solution until the number of gridpoints exceeded 15,000. The average depth

$$\bar{d} = \frac{1}{l}\int_0^l (\eta(\xi) + d)\, d\xi$$

was computed along the the present solution curve to make a comparison with Cokelet's results possible. The difference in depth did not exceed 5% between the solution curves, and the average depth in the present calculation was always smaller than those in Table

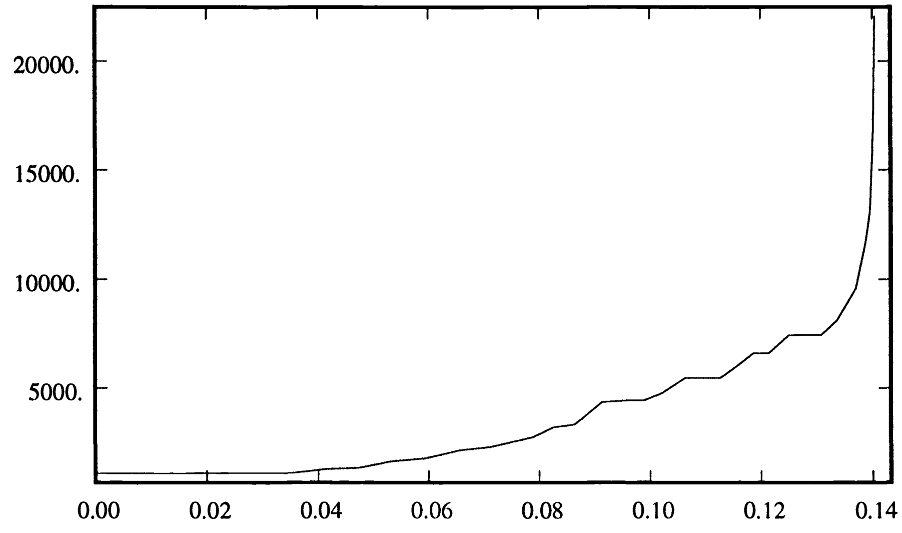

FIG. 10. *The number of equations as function of h/l for the case $d = 2\pi$ and $A_\phi = 10^{-2}$. The first grid had* 1,086 *points and the last grid had* 22,053 *points.*

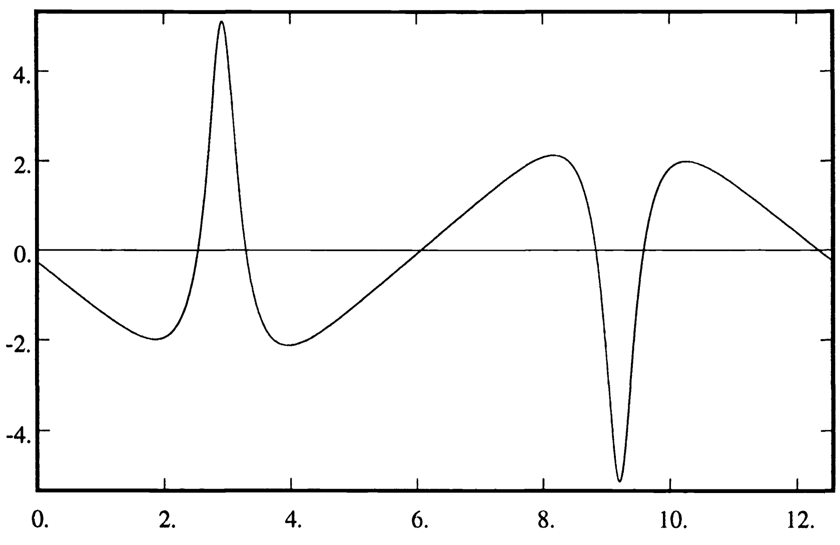

FIG. 11. *The surface component of the eigenfunction connected to the second small eigenvalue, close to the bifurcation point.*

A3. In order to interpolate, we also used the data for the initial depths $d = 1.6094379$ and $d = 0.91629073$, i.e., Tables A2 and A4 in [4], respectively. For each solution curve, a scaled phase velocity was defined by $c = (\mu - \min \mu)/(\max \mu - \min \mu)$. Let the data points in the present computation be denoted c_i, $\bar{d}_i$, and h_i, $i = 1, 2, \dots, n_p$, and let those corresponding to Table Ak be denoted $c_i^{(k)}$, $\bar{d}_i^{(k)}$, and $h_i^{(k)}$, $i = 1, 2, \dots, n_c$. The following interpolation procedure was applied: A cubic spline parametrized by the index was interpolated through the data points in each of Cokelet's tables: $c_{\text{int}}^{(k)}(\xi)$, $\bar{d}_{\text{int}}^{(k)}(\xi)$, and $h_{\text{int}}^{(k)}(\xi)$, $k = 2, 3, 4$. For each $i = 1, 2, \dots, n_p$, we solved $\xi_{ki} : c_{\text{int}}^{(k)}(\xi_{ki}) = c_i$ and evalu-

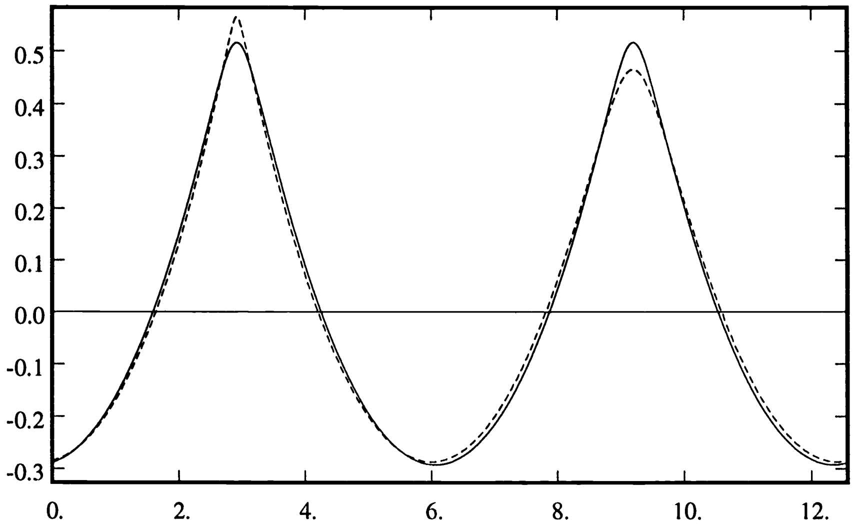

FIG. 12. *The surface elevation as function of x. The solid line represents the regular solution close to the bifurcation point* ($\mu = 1.08414$, $h/l = 0.06447$) *and the dashed line corresponds to the bifurcated solution at* $\mu = 1.08132$, $h/l = 0.06786$.

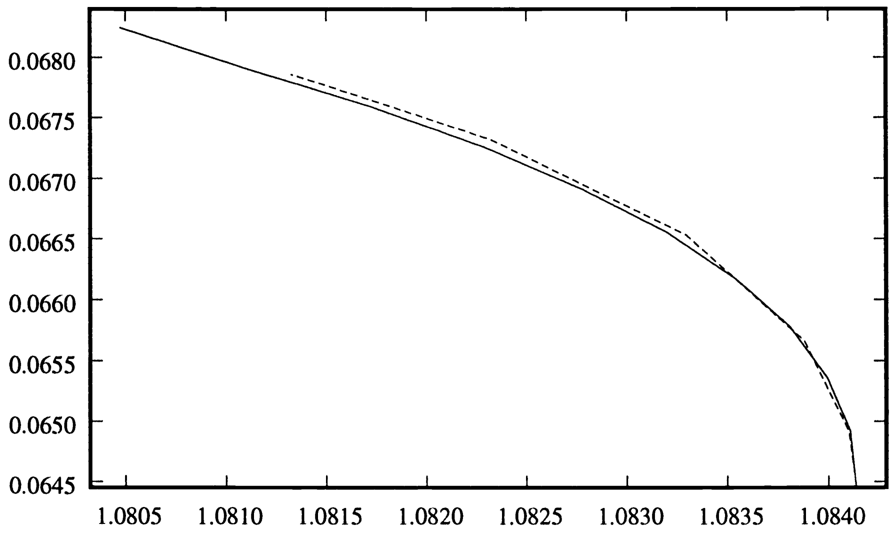

FIG. 13. *h/l as function of the phase velocity for the bifurcated solution. Here, $d = 2\pi$ and $A_\phi = 10^{-2}$. The solid line represents the infinitely deep case reported by* [2] *and the dashed line corresponds to the present work.*

ated $h_{\mathrm{int}}^{(k)}(\xi_{ki})$ and $\bar{d}^{(k)}(\xi_{ki})$. We then assumed the interpolated average depth to behave like

$$(38)\quad \bar{d}(\eta) = \frac{(\eta-1)(\eta-2)}{2}\bar{d}^{(2)}(\xi_{2i}) - \eta(\eta-2)\bar{d}^{(3)}(\xi_{3i}) + \frac{\eta(\eta-1)}{2}\bar{d}^{(4)}(\xi_{4i}).$$

Thereafter, (38) was solved for $\eta_i : \bar{d}(\eta_i) = \bar{d}_i$. The wave height was also assumed to vary parabolically for each fixed, i.e.,

$$(39) \quad h(\eta) = \frac{(\eta-1)(\eta-2)}{2} h^{(2)}(\xi_{2i}) - \eta(\eta-2)h^{(3)}(\xi_{3i}) + \frac{\eta(\eta-1)}{2} h^{(4)}(\xi_{4i}).$$

The interpolated wave height was found by evaluating (39) for η_i. The results are given in Fig. 14. The absolute difference in relative wave height was of the order $\mathcal{O}(10^{-2})$. The discrepancy between the results is one order of magnitude larger for the shallow water case compared to the deep water case. We conjecture that this is related to the interpolation error.

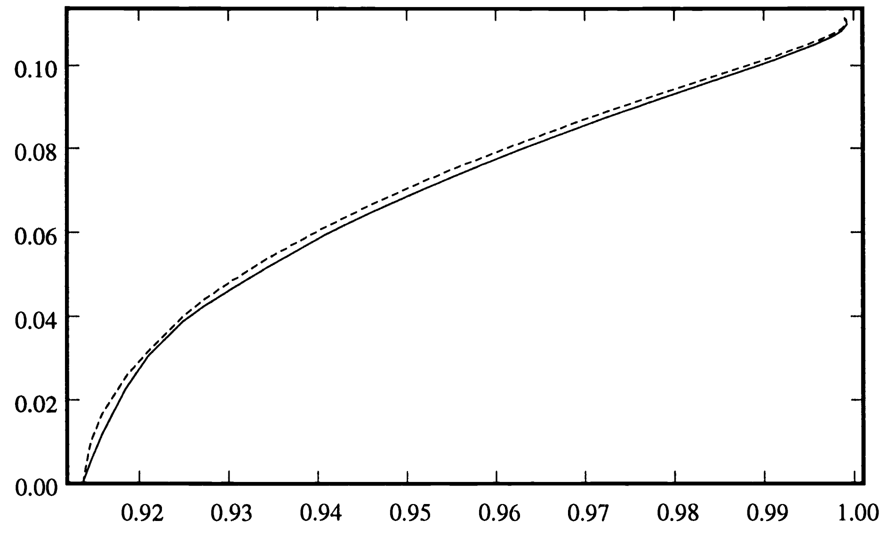

FIG. 14. *h/l as function of the phase velocity for the case $d = 1.2039728$ and $A_\phi = 10^{-2}$. The solid line represents results interpolated from data reported by* [4] *and the dashed line corresponds to the present work.*

9. Conclusions. In this paper, it has been shown that composite overlapping grids together with finite difference methods can be used to accurately calculate steep periodic water waves. It has been indicated that an adaptive grid is necessary to achieve well-resolved solutions close to the wave of maximum height. We have shown that the overhead connected with changing the grid is small compared to the cost involved in always using a fine grid.

An underwater obstacle could easily be introduced by adding a component grid close to the obstacle and replacing the periodicity in the x-direction with appropriate in- and out-flow boundary conditions. The solution is only asymptotically periodic behind the obstacle, and it would be interesting to see if the subharmonic bifurcation also appears here. This will be investigated in a future paper.

Acknowledgment. Professor H. -O. Kreiss is gratefully acknowledged for many inspiring discussions on the present problem. I am indebted to Dr. G. Chesshire who designed and implemented the algorithm for effectively constructing a corrected composite grid. He and Dr. D. L. Brown are also thanked for sharing their thorough knowledge on composite overlapping grids.

A MODIFIED BROYDEN UPDATE WITH INTERPOLATION*

MIGUEL F. ANJOS†

Abstract. A new class of Hessian updates is introduced for quasi-Newton methods obtained by modifying the Broyden class of updates so that it interpolates function values. In general, the members of this new class do not satisfy the quasi-Newton equation. Through the use of a weak inverse updating strategy, a specific choice of update within this class is then introduced. Numerical results are given to illustrate the behaviour of this new update and to compare it with other updating sequences.

Key words. unconstrained optimization, quasi-Newton methods, Broyden class, interpolation, inverse sizing, weak sizing, nonlinear optimization

AMS subject classifications. 65K, 90C, 49M

1. Introduction. This paper considers quasi-Newton methods for solving

$$\min_{x \in \Re^n} f(x), \tag{1.1}$$

where f is assumed to be twice continuously differentiable. However, only first derivative (gradient vector) evaluations are required by these methods.

These methods are iterative. The required initial data is a starting point $x_0 \in \Re^n$ and an initial approximation B_0 for the Hessian $\frac{\partial^2 f}{\partial x^2} \in \Re^{n \times n}$ of f, which is typically chosen as $B_0 = I_{n \times n}$, when no additional information about f is known a priori.

Given this initial information, at the kth iteration, a local quadratic model $\overline{f}$ is used to approximate f

$$\overline{f}(x_k + s) = f(x_k) + g_k^T s + \frac{1}{2} s^T B_k s, \tag{1.2}$$

where $g_k \equiv \nabla f(x_k)$, and B_k is the current approximation to the Hessian. Minimizing $\overline{f}$ gives the descent direction

$$p = -B_k^{-1} g_k,$$

which is used for f in a line search satisfying the Wolfe conditions (see [1] and [3] for more details). A new point x_{k+1} is computed and then taken as the next point for the iteration.

A key element of each iteration is the updating of the B_k matrix by taking advantage of the new information about f gathered during the current iteration. Usual requirements are that the update B_{k+1} must be symmetric positive definite and satisfy the secant or quasi-Newton equation

†School of Computer Science, McGill University, Montreal, Quebec, Canada, H3A 2A7. Present address: Scientific Computing and Computational Mathematics, Building 460, Stanford University, Stanford, California 94305-2140 (na.anjos@na-net.ornl.gov).

$$B_{k+1}\, s = y, \tag{1.3}$$

where $s \equiv x_{k+1} - x_k$ and $y \equiv g_{k+1} - g_k$. This equation effectively requires that B_{k+1} approximate the curvature of f along the step s. The main motivation for imposing that B_{k+1} satisfies (1.3) follows from the fact that if the real Hessian were constant (i.e., if f were a quadratic function), then after n quasi-Newton linearly independent steps, B_n would equal the real Hessian [4].

One class of updates satisfying these conditions is the Broyden family of updates:

$$B_{k+1} = B_k - \frac{B_k\, s\, s^T B_k}{s^T B_k\, s} + \frac{y\, y^T}{y^T\, s} + (1-\phi) s^T B_k\, s\, w\, w^T, \tag{1.4}$$

where $y^T\, s > 0$, B_k is symmetric positive definite, and

$$w \equiv \frac{y}{y^T\, s} - \frac{B_k\, s}{s^T B_k\, s}.$$

Since B_{k+1} positive definite is required, an additional condition is that $\phi < \frac{ac}{ac-b^2}$, where we have

$$a = y^T B_k^{-1} y, \quad b = y^T s \quad \text{and} \quad c = s^T B_k\, s.$$

For $\phi = 1$ this becomes the BFGS update; for $\phi = 0$ the DFP update is obtained.

Corresponding update formulas for B_k^{-1} can also be used. For more details, refer to [1]–[3].

2. Recent developments. In this section we introduce two updating techniques that have been developed recently. The first is a Broyden class update which incorporates sizing techniques. The second is a BFGS update modified to satisfy an interpolation condition used in the study of conic methods for unconstrained optimization.

2.1. The Dennis–Wolkowicz update. The research and extensive testing of Dennis and Wolkowicz in [2] yielded a Broyden class update that improves on the BFGS update. This update possesses a self-scaling property as we now describe. Scaling is presented by Oren and Luenberger in [6] as a way to improve the performance of quasi-Newton updates. Following [2], we shall term it *sizing*.

Sizing consists in replacing at each iteration the current B_k by a scalar multiple of it and subsequently applying an updating formula. Both B_k and B_k^{-1} can be sized and the results are generally different. Sizing the latter is termed inverse sizing and we only discuss this technique.

Inverse sizing is effective in the first iteration of a quasi-Newton algorithm, but in subsequent iterations it may ruin the spectral information previously gathered in B_k. Dennis and Wolkowicz [2] observe that inverse sizing

$$\tilde{B}_k \leftarrow \frac{y^T B_k^{-1} y}{y^T\, s} B_k \tag{2.1}$$

effectively yields a matrix for which the condition

$$y^T \tilde{B}_k^{-1} y = y^T s \tag{2.2}$$

holds. They thus suggest that while this condition is satisfied, the change in the spectrum of B_k should be minimized. They then show that the rank-one update of B_k^{-1}

$$\overline{B}_k^{-1} = B_k^{-1} + \frac{1}{(y^T B_k^{-1} y)^2} (y^T s - y^T B_k^{-1} y) B_k^{-1} y y^T B_k^{-1} \tag{2.3}$$

is the unique solution to

$$\min_{\tilde{B}} \| W^T (\tilde{B}^{-1} - B_k^{-1}) W \|_F, \tag{2.4}$$

$$\text{s.t.} \qquad y^T \tilde{B}^{-1} y = y^T s \tag{2.5}$$

for any W such that $B_k = W W^T$. In this sense, $\overline{B}_k^{-1}$ is the closest matrix to B_k^{-1} satisfying (2.2). We note also that $\overline{B}_k^{-1}$ is symmetric positive definite if and only if $y^T s > 0$. The use of the update (2.3) to obtain a matrix satisfying (2.2) is termed *weak inverse updating*. Refer to [2] for more details.

The Dennis–Wolkowicz update performs weak inverse updating with the rank-one update (2.3) followed by a BFGS update of $\overline{B}_k^{-1}$. Interestingly, this sequence of two inverse updates is equivalent to a single rank-two update of B_k. This update is performed as follows: let

$$a = y^T B_k^{-1} y, \quad b = y^T s \quad \text{and} \quad c = s^T B_k s.$$

1. *First iteration*: Inverse size the current Hessian approximation, i.e.,

$$B_0 \leftarrow \frac{a}{b} B_0$$

and perform a BFGS ($\phi = 1$ in (1.4)) update on the sized matrix. Inverse sizing is done explicitly to avoid possible ill conditioning.

2. *Subsequent iterations*: Use the Broyden class update with

$$\phi = \phi^* \equiv \frac{1}{\frac{b}{c} - \frac{b^2}{ac} + 1},$$

which is equivalent to weak inverse updating followed by BFGS [2, Thm. 4.5 (iv)].

This update is hereditarily positive definite and it satisfies the quasi-Newton equation (1.3).

2.2. The Yuan update. The modified BFGS update introduced by Yuan in [8]

$$B_{k+1} = B_k - \frac{B_k\, s\, s^T\, B_k}{s^T\, B_k\, s} + t_k\, \frac{y\, y^T}{y^T\, s} \tag{2.6}$$

is a modification of the BFGS update arising from considering the interpolation condition

$$s^T\, B_{k+1}\, s = \alpha \equiv 2\,[f(x_k) - f(x_{k+1}) + s^T\, g_{k+1}], \tag{2.7}$$

which is used in Davidon's study of conic models, as summarized in [7]. This condition is equivalent to requiring function values from the previous iteration to be matched by the conic model. It is motivated by considering that the use of function values as well as gradient values should increase the efficiency of the overall optimization algorithm [7].

While such conic models can satisfy both the quasi-Newton equation (1.3) and (2.7), this is not possible with the quadratic model $\overline{f}$. However, Yuan [8] shows that condition (2.7) will be satisfied by B_{k+1} in (2.6) if we let

$$t_k = \frac{\alpha}{y^T\, s},$$

which is then truncated if necessary to lie in the interval

$$0.01 \le t_k \le 100.$$

Yuan [8] argues that this truncation ensures global convergence for convex f with the inexact line searches typically used by these methods. Furthermore, B_{k+1} is symmetric positive definite if and only if $t_k > 0$ together with B_k symmetric positive definite and $b > 0$. This update is not a member of the Broyden class (1.4) and, in general, it does not satisfy the quasi-Newton equation (1.3).

3. The new MBI update. Motivated by wanting to exploit the information available in known function values, the interpolation (2.7) contains valuable new information about f at each iteration. We thus consider imposing it on the entire Broyden class. For B_{k+1} a member of the Broyden class (1.4), we have

$$\begin{aligned} s^T\, B_{k+1}\, s &= s^T\, B_k\, s - s^T\, B_k\, s + s^T\, y + (1-\phi)s^T\, B_k\, ss^T\, ww^T\, s \\ &= s^T\, y \end{aligned}$$

since it is easily verified that

$$w^T\, s = s^T\, w = 0,$$

which implies that the last term of the Broyden class of updates has no influence on whether or not the interpolation condition is satisfied. Making the same minor modification to its general member as the modification made in [8] will yield a class of updates satisfying the interpolation condition (2.7), namely,

$$B_{k+1} = B_k - \frac{B_k\, s\, s^T B_k}{s^T B_k\, s} + t_k \frac{y\, y^T}{y^T s} + (1-\phi) s^T B_k\, s\, w\, w^T, \tag{3.1}$$

where $t_k = \frac{\alpha}{y^T s}$ and truncated to $0.01 \le t_k \le 100$ for the same reasons as in [8].

This new class is the basis for defining a new Hessian update, which we shall denote by MBI (modified Broyden update satifying the interpolation condition), and into which we incorporate the weak inverse updating properties of the Dennis–Wolkowicz update via the ϕ parameter.

The MBI update is performed as follows: Again let $a = y^T B_k^{-1} y$, $b = y^T s$, and $c = s^T B_k s$;

1. *First iteration*: Inverse size the current Hessian approximation

$$B_0 \leftarrow \frac{a}{b} B_0$$

to avoid possible ill conditioning and perform the $\phi = 1$ update of the class (3.1).

2. *Subsequent iterations*: Use the update of the class (3.1) with

$$\phi = \phi^* \equiv \frac{1}{\frac{b}{c} - \frac{b^2}{ac} + 1}.$$

Positive definiteness of the MBI update follows from $t_k > 0$ and the hereditary positive definiteness of the Dennis–Wolkowicz update.

It is important to note that the MBI update will not generally satisfy the quasi-Newton equation (1.3). Furthermore, because of the choice $\phi = \phi^*$, it is not simple to extend one of the classical convergence arguments in quasi-Newton methods to the MBI update.

However, the quasi-Newton equation and the interpolation (2.7) will be simultaneously satisfied when

$$t_k = \frac{\alpha}{y^T s} = 1$$

and the MBI update is then a member of the Broyden class. Standard local Q-superlinear convergence results should then be extendable to the MBI update. Our numerical tests have shown that this seems to correspond to the asymptotic behaviour of the MBI update. To illustrate this fact, we include in the numerical results section an example of the behaviour of t_k for the MBI update when solving the Wood function problem. Thus, as in [8], we believe it is reasonable to expect local Q-superlinear convergence for a quasi-Newton algorithm using the MBI updating formula.

4. Numerical results. The update MBI was tested for comparison with the $\phi = 1$ Broyden update (BFGS), the Dennis–Wolkowicz update (DW) and the Yuan modified BFGS update (Yuan). We also included two other updating sequences, namely the BFGS and Yuan updates with inverse sizing at the first iteration only (BFGS+IS and Yuan+IS, respectively).

The tests were performed on a DECstation 3100 using the same MATLAB code as in [2] that implements the routines described in [1]. The algorithm followed the minimization procedure for quasi-Newton methods described in §1 of this paper. In particular, a failure to converge for a method was declared after 450 unsuccessful iterations. At each step of the algorithm, a line search (Algorithm LINESEARCHMOD in [1]) was used to find a step satisfying the Wolfe conditions. Finally, we note that the criteria used to declare that a minimum of f has been reached is developed and commented on thoroughly in [1]. We thus refer the reader to that reference for further details on the algorithm.

We include the results for the six updating sequences on six test problems from [5]. For each problem three different starting points were considered:

- the suggested starting point in [5];
- the suggested starting point scaled by 10;
- the suggested starting point scaled by 100.

We tested the updates on all the problems from [5] and report a sample of these results which suggests the types of problems for which the MBI update appears to offer an improvement over the other methods. They also reveal instances where the MBI behaves rather poorly.

In the listings, F denotes a failure to solve the problem after 450 iterations. The data is reported in the format *number of iterations/number of function evaluations*.

The first problem shows that as the scaling increases, the sized updates are performing much better than the other two updates. It is not simple to determine a dominating update here, though.

Problem 1. *Wood function* (*dimension* $= 4$). Starting point: $(-3, -1, -3, -1)$. Exact minimizer: $(1, 1, 1, 1)$.

Scaling	BFGS	DW	Yuan	BFGS+IS	Yuan+IS	MBI
1	40/44	37/41	36/38	35/39	38/40	36/38
10	100/107	62/65	101/108	67/69	64/67	64/66
100	324/333	105/110	324/326	104/110	107/116	106/115

The same difference between sized and nonsized updates is observed in the next problem. It is possible though to observe a difference in performance between the updates. We note that the BFGS+IS and Yuan+IS updates dominate while the MBI performs rather poorly.

Problem 2. *Extended Powell function* (*dimension* $= 16$). Starting point: $(3, -1, 0, 1, \ldots, 3, -1, 0, 1)$. Exact minimizer: $(0, \ldots, 0)$.

Scaling	BFGS	DW	Yuan	BFGS+IS	Yuan+IS	MBI
1	45/47	34/36	51/53	39/41	51/53	46/48
10	137/145	70/75	93/99	89/96	78/81	71/75
100	F	122/126	F	104/113	102/105	159/166

Problem 3 shows the MBI update dominating for the given starting point. As the scaling increases, however, the Yuan+IS update is slightly better overall. Note the excellent performance of DW for the scaling 10, which, together with the MBI performance, indicates the positive effects of weak inverse updating when solving this problem.

Problem 3. *Box* 3D *function* (*dimension* $= 3$). Starting point: $(0, 10, 20)$. Exact minimizer: several.

Scaling	BFGS	DW	Yuan	BFGS+IS	Yuan+IS	MBI
1	40/44	36/39	39/42	37/40	38/40	32/34
10	59/69	59/68	68/75	71/80	69/75	66/71
100	F	41/46	F	40/45	38/42	40/44

Like Problem 1, the next problem also illustrates the importance of a sizing strategy. Furthermore, it is an example where the sized *and* interpolating updates seem to outperform the others. In particular, for large scaling, the MBI update is second only to the Yuan+IS update.

Problem 4. *Penalty function* I (*dimension* $= 10$). Starting point: $(1, 2, \ldots, 10)$. Exact minimizer: not available.

Scaling	BFGS	DW	Yuan	BFGS+IS	Yuan+IS	MBI
1	65/74	61/74	58/66	62/74	61/70	60/69
10	F	71/73	F	70/72	71/74	68/71
100	F	242/246	F	276/278	170/172	206/208

Problem 5 illustrates the same advantages for the interpolating updates as Problem 4, but in this case the MBI update dominates for the large scaling of the initial guess, while being competitive for the other scalings.

Problem 5. *Trigonometric function* (*dimension* $= 10$). Starting point: $(1, \frac{1}{2}, \ldots, \frac{1}{10})$. Exact minimizer: not available.

Scaling	BFGS	DW	Yuan	BFGS+IS	Yuan+IS	MBI
1	23/25	26/28	23/25	27/29	26/28	25/28
10	47/51	40/43	90/93	40/43	41/44	42/45
100	145/149	103/107	143/145	104/108	56/59	52/54

Finally, Problem 6 is an example where the MBI update seems to be the overall best update.

Problem 6. *Brown and Dennis function* (*dimension* $= 4$). Starting point: $(25, 5, -5, -1)$. Exact minimizer: not available.

Scaling	BFGS	DW	Yuan	BFGS+IS	Yuan+IS	MBI
1	44/46	31/33	42/44	33/35	32/34	29/31
10	95/97	64/66	94/96	66/68	65/67	62/64
100	F	84/86	408/410	91/93	88/90	85/87

Overall, from these results, we observe that interpolation can improve the performance of a quasi-Newton algorithm using a Hessian update satisfying it.

Among the interpolating updates, we see that the MBI update consistently outperforms both the Yuan and Yuan+IS updates for the usual starting point of these problems, but is sometimes superseded by Yuan+IS for a large scaling of the initial guess.

Finally, we report the following data to exemplify the behaviour of t_k for the MBI update. This data comes from minimizing the Wood function (Problem 1) with the initial guess suggested in [5].

Iteration	t_k	Iteration	t_k
1	0.930058	19	1.00128
2	0.888828	20	0.993555
3	0.901655	21	0.999559
4	0.897605	22	1.00006
5	0.897991	23	1
6	0.894728	24	1
7	0.885345	25	1
8	0.84989	26	1
9	0.528055	27	1
10	1.90101	28	1.00002
11	0.717606	29	1.00012
12	1.18575	30	1.00038
13	1.0616	31	1.00044
14	0.996262	32	0.999271
15	0.995617	33	0.999504
16	1.03186	34	0.999988
17	1.00877	35	0.999965
18	1.0261	36	1

5. Conclusion. We have obtained a new family of Hessian updates satisfying the interpolation condition introduced by Yuan in [8] by generalizing his development to the well-known Broyden class. We then introduced the MBI update, a specific choice of update in this class that simultaneously incorporates the weak inverse updating techniques introduced by Dennis and Wolkowicz in [2]. Our numerical results showed the merits of these two approaches and illustrated the performance of the MBI update on typical test problems. We conclude that the MBI update seems to offer a slight improvement for certain problems over the other updates tested.

Acknowledgments. The author would like to thank his supervisor Henry Wolkowicz for introducing him to the subject of this paper and for his patience and support during our work together at the University of Waterloo. This paper was much improved thanks to the many comments and suggestions of both Chris Paige and Henry Wolkowicz and by the critiques and suggestions of the editor and two anonymous referees.

FAST FOURIER TRANSFORMS FOR NONEQUISPACED DATA*

A. DUTT[†] AND V. ROKHLIN[†]

Abstract. A group of algorithms is presented generalizing the fast Fourier transform to the case of noninteger frequencies and nonequispaced nodes on the interval $[-\pi, \pi]$. The schemes of this paper are based on a combination of certain analytical considerations with the classical fast Fourier transform and generalize both the forward and backward FFTs. Each of the algorithms requires $O(N \cdot \log N + N \cdot \log(1/\varepsilon))$ arithmetic operations, where ε is the precision of computations and N is the number of nodes. The efficiency of the approach is illustrated by several numerical examples.

Key words. fast Fourier transform, Fourier analysis, trigonometric series, interpolation, approximation theory

AMS subject classifications. 65R10, 65T10, 65T20, 65Y20

1. Introduction.

Fourier techniques have been a popular analytical tool in the study of physics and engineering for more than two centuries. A reason for the usefulness of such techniques is that the trigonometric functions $e^{i\omega x}$ are eigenfunctions of the differentiation operator and can be effectively used to model solutions of differential equations which arise in the fields mentioned above.

More recently, the arrival of digital computers and the development of the fast Fourier transform (FFT) algorithm in the 1960s (see [6]) have established Fourier analysis as a powerful and practical numerical tool. The FFT, which computes discrete Fourier transforms (DFTs), is now central to many areas, most notably spectral analysis and signal processing. In some applications, however, the input data is not uniformly spaced, a condition that is required for the FFT. In this paper we present a set of algorithms for computing more efficiently some generalizations of the DFT, namely, the forward and inverse transformations described by the equations

$$f_j = \sum_{k=0}^{N} \alpha_k \cdot e^{i\omega_k x_j} \tag{1}$$

for $j = 0, \ldots, N$, where $f_j \in \mathbf{C}$, $\alpha_k \in \mathbf{C}$, $\omega_k \in [-N/2, N/2]$, and $x_j \in [-\pi, \pi]$. Each algorithm requires a number of arithmetic operations proportional to

$$N \cdot \log N + N \cdot \log\left(\frac{1}{\varepsilon}\right), \tag{2}$$

where ε is the desired accuracy, compared with $O(N^2)$ operations required for the direct evaluation of (1) and $O(N^3)$ for the direct inversion.

Remark 1.1. The DFT can be described by either of the two closely related formulae

$$f_j = \sum_{k=0}^{N-1} \alpha_k \cdot e^{2\pi ikj/N} \tag{3}$$

*Received by the editors June 17, 1992; accepted for publication (in revised form) November 19, 1992.

for $j = 0, \dots, N-1$, and

$$f_j = \sum_{k=-N/2}^{N/2-1} \alpha_k \cdot e^{2\pi ikj/N} \tag{4}$$

for $j = -N/2, \dots, N/2-1$. While the form (3) is normally used when the FFT is discussed, the form (4) is usually preferred in applications of the DFT to analysis (see, for example, [2], [9]).

Remark 1.2. The FFT algorithm reduces the number of operations for the DFT from $O(N^2)$ to $O(N \cdot \log N)$ by a sequence of algebraic manipulations (for more details on FFTs, see [4], [6], [7], [12]–[14]). In the more general case of (1), the structure of the linear transformation is also exploitable, and the algorithms of this paper combine certain analytical results with the existing FFT.

The plan of the paper is as follows. We start in §2 with some results from the analysis and approximation theory which are used in the design of the algorithms. An exact statement of the problem in §3 is then followed by informal descriptions of the algorithms in §4. In §5 we introduce some notation that is used in a set of more detailed algorithm descriptions in §6. Six numerical examples are presented in §7 to illustrate the performance of the schemes. Finally, §8 lists some generalizations and conclusions.

2. Mathematical and numerical preliminaries.

2.1. Elementary analytical tools.

In this subsection we summarize some well-known results to be used in the remainder of the paper. Lemmas 2.1 and 2.2 are obvious, and Lemmas 2.3 and 2.4 can be found, for example, in [10].

LEMMA 2.1. *For any real c,*

$$\int_{-\pi}^{\pi} e^{icx} dx = \frac{2}{c} \sin(c\pi). \tag{5}$$

LEMMA 2.2. *For any integer k,*

$$\frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ikx} dx = \begin{cases} 1 & \text{if } k = 0, \\ 0 & \text{otherwise.} \end{cases} \tag{6}$$

LEMMA 2.3. *For any real $b > 0$ and complex z,*

$$\int_{-\infty}^{\infty} e^{-bx^2} \cdot e^{zx} dx = \sqrt{\frac{\pi}{b}} \cdot e^{z^2/4b}. \tag{7}$$

LEMMA 2.4. *For any real $b > 0$ and $a > 0$,*

$$\int_{a}^{\infty} e^{-bx^2} dx < \frac{e^{-ba^2}}{2ba}. \tag{8}$$

Proof.

$$\int_{a}^{\infty} e^{-bx^2} dx = \int_{0}^{\infty} e^{-b(x+a)^2} dx < e^{-ba^2} \int_{0}^{\infty} e^{-2bax} dx = \frac{e^{-ba^2}}{2ba}. \tag{9}$$ □

2.2. Relevant facts from approximation theory. The principal tool of this paper is a somewhat detailed analysis of Fourier series of functions $\phi : [-\pi, \pi] \to \mathbf{C}$ given by the formula

$$\phi(x) = e^{-bx^2} \cdot e^{icx}, \tag{10}$$

where $b > \frac{1}{2}$ and c are real numbers. We present this analysis in the lemmas and theorems of this subsection, numbered 2.5–2.10.

Lemmas 2.5 and 2.6 provide two inequalities that are used in Theorem 2.7, and Theorems 2.7–2.9 are intermediate results leading to Theorem 2.10. This final theorem explains how to approximate functions of the form e^{icx} using a small number of terms, and the algorithms of this paper are based upon this result. We derive error bounds for all approximations that allow us to perform numerical computations to any specified accuracy.

LEMMA 2.5. *For any real $b > \frac{1}{2}$, c and any integer k,*

$$\left|2\int_{\pi}^{\infty} e^{-bx^2} \cos((c-k)x)dx + e^{-b\pi^2} \cdot \int_{-\pi}^{\pi} e^{i(c-k)x}dx\right| < 2\pi e^{-b\pi^2} \cdot \left(1 + \frac{1}{\pi^2}\right). \tag{11}$$

Proof. Using the triangle inequality and Lemma 2.4, we have

$$\begin{aligned} &\left|2\int_{\pi}^{\infty} e^{-bx^2} \cdot \cos((c-k)x)dx + e^{-b\pi^2} \cdot \int_{-\pi}^{\pi} e^{i(c-k)x}dx\right| \\ &\le 2\int_{\pi}^{\infty} e^{-bx^2}dx + 2\pi e^{-b\pi^2} < 2\pi e^{-b\pi^2} \cdot \left(\frac{1}{2b\pi^2} + 1\right) \\ &< 2\pi e^{-b\pi^2} \cdot \left(\frac{1}{\pi^2} + 1\right). \quad \square \end{aligned} \tag{12}$$

LEMMA 2.6. *For any real $b > \frac{1}{2}$, c and any integer k,*

(13)

$$\left|2\int_{\pi}^{\infty} e^{-bx^2} \cos((c-k)x)dx + e^{-b\pi^2} \cdot \int_{-\pi}^{\pi} e^{i(c-k)x}dx\right| < \frac{8b\pi e^{-b\pi^2}}{(c-k)^2} \cdot \left(1 + \frac{1}{\pi^2}\right).$$

Proof. Integrating by parts, we have

$$\begin{aligned} &2\int_{\pi}^{\infty} e^{-bx^2} \cdot \cos((c-k)x)dx \\ &= \frac{2}{c-k}\left[e^{-bx^2} \sin((c-k)x)\right]_{\pi}^{\infty} + \frac{4b}{c-k}\int_{\pi}^{\infty} xe^{-bx^2} \sin((c-k)x)dx \\ &= -\frac{2}{c-k}e^{-b\pi^2} \sin((c-k)\pi) + \frac{4b}{c-k}\int_{\pi}^{\infty} xe^{-bx^2} \sin((c-k)x)dx. \end{aligned} \tag{14}$$

After rearranging the terms in (14) and integrating by parts again, we obtain

(15)

$$\left|2\int_{\pi}^{\infty} e^{-bx^2} \cos((c-k)x)dx + \frac{2e^{-b\pi^2}}{c-k} \sin((c-k)\pi)\right|$$

$$= \left| \frac{4b}{c-k} \int_\pi^\infty xe^{-bx^2} \sin((c-k)x)dx \right|$$

$$= \left| -\frac{4b}{(c-k)^2} \left(\left[xe^{-bx^2} \cos((c-k)x) \right]_\pi^\infty - \int_\pi^\infty (1-2bx^2)e^{-bx^2} \cos((c-k)x)dx \right) \right|$$

$$\leq \frac{4b}{(c-k)^2} \left(\pi e^{-b\pi^2} + \int_\pi^\infty e^{-bx^2} dx + \int_\pi^\infty x \cdot 2bxe^{-bx^2} dx \right)$$

$$< \frac{4b}{(c-k)^2} \left(\pi e^{-b\pi^2} + \int_\pi^\infty e^{-bx^2} dx + \left[-xe^{-bx^2} \right]_\pi^\infty + \int_\pi^\infty e^{-bx^2} dx \right).$$

Finally, due to (15) and Lemmas 2.1 and 2.4, we have
(16)

$$\left| 2 \int_\pi^\infty e^{-bx^2} \cos((c-k)x)dx + e^{-b\pi^2} \cdot \int_{-\pi}^{\pi} e^{i(c-k)x} dx \right| < \frac{4be^{-b\pi^2}}{(c-k)^2} \cdot \left(2\pi + \frac{2}{2b\pi} \right)$$
$$< \frac{8b\pi e^{-b\pi^2}}{(c-k)^2} \cdot \left(1 + \frac{1}{\pi^2} \right). \quad \square$$

The following theorem provides an explicit expression for the coefficients of a Fourier series that approximates functions of the form (10).

THEOREM 2.7. *Let $\phi(x) = e^{-bx^2} e^{icx}$ for any real $b > \frac{1}{2}$, c. Then, for any $x \in (-\pi, \pi)$,*

$$\left| \phi(x) - \sum_{k=-\infty}^{\infty} \rho_k e^{ikx} \right| < e^{-b\pi^2} \cdot \left(4b + \frac{70}{9} \right), \tag{17}$$

where

$$\rho_k = \frac{1}{2\sqrt{b\pi}} e^{-(c-k)^2/4b} \tag{18}$$

for $k = -\infty, \ldots, \infty$.

Proof. We denote by σ_k the kth Fourier coefficient for ϕ, so that for $x \in (-\pi, \pi)$,

$$\phi(x) = \sum_{k=-\infty}^{\infty} \sigma_k e^{ikx}, \tag{19}$$

and due to Lemma 2.3 and (18), we have
(20)

$$\sigma_k = \frac{1}{2\pi} \int_{-\pi}^{\pi} \phi(x) e^{-ikx} dx$$
$$= \frac{1}{2\pi} \left(\int_{-\infty}^{\infty} e^{-bx^2} e^{icx} e^{-ikx} dx - \int_{-\infty}^{-\pi} e^{-bx^2} e^{icx} e^{-ikx} dx - \int_\pi^\infty e^{-bx^2} e^{icx} e^{-ikx} dx \right)$$
$$= \frac{1}{2\pi} \left(\sqrt{\frac{\pi}{b}} \cdot e^{-(c-k)^2/4b} + \int_\infty^\pi e^{-bx^2-icx+ikx} dx - \int_\pi^\infty e^{-bx^2+icx-ikx} dx \right)$$
$$= \rho_k - \frac{1}{\pi} \int_\pi^\infty e^{-bx^2} \cos((c-k)x)dx.$$

Rearranging (20) and applying Lemmas 2.5 and 2.6, we obtain the inequalities

$$\left|\sigma_k - \rho_k - \frac{e^{-b\pi^2}}{2\pi}\int_{-\pi}^{\pi} e^{icx}e^{-ikx}dx\right| \quad < \quad e^{-b\pi^2}\cdot\left(1+\frac{1}{\pi^2}\right), \tag{21}$$

$$\left|\sigma_k - \rho_k - \frac{e^{-b\pi^2}}{2\pi}\int_{-\pi}^{\pi} e^{icx}e^{-ikx}dx\right| \quad < \quad \frac{4be^{-b\pi^2}}{(c-k)^2}\cdot\left(1+\frac{1}{\pi^2}\right), \tag{22}$$

and it now follows from the combination of (19), (21), and (22) that, for any $x \in (-\pi,\pi)$,

$$\begin{aligned} &\left|\phi(x) - \sum_{k=-\infty}^{\infty}\rho_k e^{ikx} - e^{-b\pi^2}\cdot e^{icx}\right| \\ &= \left|\sum_{k=-\infty}^{\infty} e^{ikx}\cdot\left(\sigma_k - \rho_k - \frac{e^{-b\pi^2}}{2\pi}\int_{-\pi}^{\pi} e^{icx}e^{-ikx}dx\right)\right| \\ &< \sum_{k,|c-k|\geq 3}\frac{4be^{-b\pi^2}}{(c-k)^2}\cdot\left(1+\frac{1}{\pi^2}\right) + \sum_{k,|c-k|<3} e^{-b\pi^2}\cdot\left(1+\frac{1}{\pi^2}\right) \\ &< 4be^{-b\pi^2}\cdot\frac{9}{8}\cdot 2\cdot\sum_{k=3}^{\infty}\frac{1}{k^2} + 6e^{-b\pi^2}\cdot\frac{10}{9}. \end{aligned} \tag{23}$$

Some elementary analysis yields

$$\sum_{k=3}^{\infty}\frac{1}{k^2} < \frac{1}{9} + \int_3^{\infty}\frac{dx}{x^2} = \frac{1}{9}+\frac{1}{3} = \frac{4}{9}, \tag{24}$$

and substituting (24) into (23), we have

$$\left|\phi(x) - \sum_{k=-\infty}^{\infty}\rho_k e^{ikx} - e^{-b\pi^2}\cdot e^{icx}\right| \quad < \quad e^{-b\pi^2}\cdot\left(4b+\frac{60}{9}\right). \tag{25}$$

To complete the proof we make use of the triangle inequality and (25) to obtain

$$\begin{aligned} \left|\phi(x) - \sum_{k=-\infty}^{\infty}\rho_k e^{ikx}\right| &\leq \left|\phi(x) - \sum_{k=-\infty}^{\infty}\rho_k e^{ikx} - e^{-b\pi^2}\cdot e^{icx}\right| + \left|e^{-b\pi^2}\cdot e^{icx}\right| \\ &< e^{-b\pi^2}\cdot\left(4b+\frac{70}{9}\right). \quad \square \end{aligned} \tag{26}$$

Remark 2.1. According to Theorem 2.7, functions of the form $e^{-bx^2}e^{icx}$ can be approximated by a Fourier series whose coefficients are given analytically, and the error of the approximation decreases exponentially as b increases.

Remark 2.2. The coefficients ρ_k as defined by (18) have a peak at $k = [c]$, the nearest integer to c, and decay exponentially as $k \to \pm\infty$. We keep only the $q+1$ largest coefficients, where the integer q is chosen such that

$$q \geq 4b\pi, \tag{27}$$

so as to satisfy the inequality

$$e^{-(q/2)^2/4b} \leq e^{-b\pi^2}. \tag{28}$$

The following theorem estimates the truncation error under the conditions of Remark 2.2 and thus provides a way of approximating functions of the form (10) by a $(q+1)$-term series.

THEOREM 2.8. *Let $\phi(x) = e^{-bx^2} e^{icx}$ for any real $b > \frac{1}{2}$, c, and let q be an even integer such that $q \geq 4b\pi$. Then, for any $x \in (-\pi, \pi)$,*

$$\left| \phi(x) - \sum_{k=[c]-q/2}^{[c]+q/2} \rho_k e^{ikx} \right| < e^{-b\pi^2} \cdot (4b+9), \tag{29}$$

where $\{\rho_k\}$ are defined by (18).

Proof. For any $x \in (-\pi, \pi)$,

$$\begin{aligned} &\left| \phi(x) - \sum_{k=[c]-q/2}^{[c]+q/2} \rho_k e^{ikx} \right| \\ &\leq \left| \phi(x) - \sum_{k=-\infty}^{\infty} \rho_k e^{ikx} \right| + \left| \sum_{k>[c]+q/2} \rho_k e^{ikx} \right| + \left| \sum_{k<[c]-q/2} \rho_k e^{ikx} \right| . \end{aligned} \tag{30}$$

Due to (18) and the triangle inequality, we have the inequalities

$$\left| \sum_{k>[c]+q/2} \rho_k e^{ikx} \right| \leq \sum_{k=[c]+q/2+1}^{\infty} \frac{e^{-(c-k)^2/4b}}{2\sqrt{b\pi}} < \sum_{k=q/2}^{\infty} \frac{e^{-k^2/4b}}{\sqrt{2\pi}}, \tag{31}$$

$$\left| \sum_{k<[c]-q/2} \rho_k e^{ikx} \right| \leq \sum_{k=-\infty}^{[c]-q/2-1} \frac{e^{-(c-k)^2/4b}}{2\sqrt{b\pi}} < \sum_{k=q/2}^{\infty} \frac{e^{-k^2/4b}}{\sqrt{2\pi}}. \tag{32}$$

Some elementary analysis and an application of Lemma 2.4 yields

$$\sum_{k=q/2}^{\infty} e^{-k^2/4b} < e^{-(q/2)^2/4b} + \int_{q/2}^{\infty} e^{-x^2/4b} dx < e^{-(q/2)^2/4b} \cdot \left(1 + \frac{4b}{2q/2}\right), \tag{33}$$

and it follows from the combination of (27), (28), and (33) that

$$\sum_{k=q/2}^{\infty} e^{-k^2/4b} < e^{-b\pi^2} \cdot \left(1 + \frac{1}{\pi}\right). \tag{34}$$

Substituting (34) into (31) and (32), we have

$$\left| \sum_{k>[c]+q/2} \rho_k e^{ikx} \right| + \left| \sum_{k<[c]-q/2} \rho_k e^{ikx} \right| < \frac{2e^{-b\pi^2}}{\sqrt{2\pi}} \cdot \left(1 + \frac{1}{\pi}\right) < e^{-b\pi^2} \cdot \frac{10}{9}, \tag{35}$$

and finally, substituting (26) and (35) into (30), we obtain

$$\left| \phi(x) - \sum_{k=[c]-q/2}^{[c]+q/2} \rho_k e^{ikx} \right| < e^{-b\pi^2} \cdot \left(4b + \frac{70}{9} + \frac{10}{9}\right) < e^{-b\pi^2} \cdot (4b+9). \tag{36}$$ □

The following corollary describes a formula for approximating e^{icx} using a series of $q+1$ terms.

COROLLARY 2.9. *Suppose that $m \geq 2$ is an integer and that the conditions of Theorem 2.8 are satisfied. Then, multiplying both sides of* (29) *by e^{bx^2}, we obtain*

$$\left| e^{icx} - e^{bx^2} \cdot \sum_{k=[c]-q/2}^{[c]+q/2} \rho_k e^{ikx} \right| < e^{bx^2} \cdot e^{-b\pi^2} \cdot (4b+9) \tag{37}$$
$$< e^{b\pi^2/m^2} \cdot e^{-b\pi^2} \cdot (4b+9)$$

for any $x \in [-\frac{\pi}{m}, \frac{\pi}{m}]$.

Finally, Theorem 2.10 makes use of a simple linear scaling to generalize the inequality (37) from $[-\frac{\pi}{m}, \frac{\pi}{m}]$ to any interval $[-d, d]$. This is the principal result of the section.

THEOREM 2.10. *Let $b > \frac{1}{2}, c, d > 0$ be real numbers, and let $m \geq 2, q \geq 4b\pi$ be integers. Then, for any $x \in [-d, d]$,*

$$\left| e^{icx} - e^{b(x\pi/md)^2} \cdot \sum_{k=[cmd/\pi]-q/2}^{[cmd/\pi]+q/2} \rho_k e^{ikx\pi/md} \right| < e^{-b\pi^2(1-1/m^2)} \cdot (4b+9) \tag{38}$$

where $\{\rho_k\}$ are defined by (18).

Remark 2.3. The error bounds obtained in the above theorems are rather pessimistic. Numerical estimates for the actual errors can be found in the Appendix to this paper.

3. Exact statement of the problem.

In the remainder of this paper we will operate under the following assumptions:

1. $\omega = \{\omega_0, \ldots, \omega_N\}$ and $x = \{x_0, \ldots, x_N\}$ are finite sequences of real numbers.
2. $\omega_k \in [-N/2, N/2]$ for $k = 0, \ldots, N$.
3. $x_j \in [-\pi, \pi]$ for $j = 0, \ldots, N$.
4. $\alpha = \{\alpha_0, \ldots, \alpha_N\}$, $f = \{f_{-N/2}, \ldots, f_{N/2}\}$, $\beta = \{\beta_{-N/2}, \ldots, \beta_{N/2}\}$, $g = \{g_0, \ldots, g_N\}$, $\gamma = \{\gamma_0, \ldots, \gamma_N\}$ and $h = \{h_0, \ldots, h_N\}$ are finite sequences of complex numbers.

We will consider the problems of applying and inverting the Fourier matrix and its transpose, i.e., we are interested in the transformations $F, G : \mathbf{C}^{N+1} \to \mathbf{C}^{N+1}$ and their inverses defined by the formulae

$$f_j = F(\alpha)_j = \sum_{k=0}^{N} \alpha_k \cdot e^{i\omega_k \cdot 2\pi j/N} \tag{39}$$

for $j = -N/2, \ldots, N/2$, and

$$g_j = G(\beta)_j = \sum_{k=-N/2}^{N/2} \beta_k \cdot e^{ikx_j} \tag{40}$$

for $j = 0, \ldots, N$.

Remark 3.1. If $x_k = -\omega_k \cdot 2\pi/N$ for $k = 0, \ldots, N$, then (39) can be rewritten as

$$f_j = \sum_{k=0}^{N} \alpha_k \cdot e^{-ijx_k}, \tag{41}$$

or alternatively as $F = G^*$.

We will also consider the more general transformation $H : \mathbf{C}^{N+1} \rightarrow \mathbf{C}^{N+1}$ defined by the formula

$$h_j = H(\gamma)_j = \sum_{k=0}^{N} \gamma_k \cdot e^{i\omega_k x_j}. \tag{42}$$

More formally, we consider the following problems:

- Problem 1. Given α, find $f = F(\alpha)$.
- Problem 2. Given β, find $g = G(\beta)$.
- Problem 3. Given γ, find $h = H(\gamma)$.
- Problem 4. Given f, find $\alpha = F^{-1}(f)$.
- Problem 5. Given g, find $\beta = G^{-1}(g)$.

Remark 3.2. We wish to perform all calculations with a fixed relative accuracy $\varepsilon > 0$. In the case of Problem 1, for instance, we are looking for a vector $\tilde{f} = \{\tilde{f}_{-N/2}, \ldots, \tilde{f}_{N/2}\}$ such that

$$\frac{||\tilde{f} - f||}{||f||} \leq \varepsilon. \tag{43}$$

In this sense, all algorithms described in this paper are approximate ones.

4. Informal descriptions of the algorithms. In this section we give informal outlines of algorithms for Problems 1–5 of §3. More formal descriptions of these algorithms are presented in §6.

4.1. Algorithms 1, 2, and 3 for Problems 1, 2, and 3. The algorithms for these problems are based on the following principal observation.

Observation 4.1. According to Theorem 2.10, any function of the form e^{icx} can be accurately represented on any finite interval on the real line using a small number of terms of the form $e^{bx^2} \cdot e^{ikx}$, and this number of terms, q, is independent of the value of c.

The FFT algorithm applies the Fourier matrix to arbitrary complex vectors in $O(N \log N)$ operations when $\{\omega_k\}$ are integers and $\{x_j\}$ are equally spaced in $[-\pi, \pi]$. For the efficient application of the transformations described by (39), (40), and (42), we relate these more general cases to the equispaced case of the FFT. Observation 4.1 is used in two ways to achieve this:

- to approximate each $e^{i\omega_k x}$ in terms of a q-term Fourier series;
- to approximate the value of a Fourier series at each x_j in terms of values at the nearest q equispaced nodes.

This interpolation between equispaced and nonequispaced sets of points can thus be performed in $O(Nq)$ operations.

Observation 4.2. The overall complexity of each such algorithm that couples the FFT with the interpolation scheme will be $O(N \log N + Nq)$ operations.

4.2. Algorithms 4 and 5 for Problems 4 and 5. Here we are interested in applying the complex matrices A^{-1} and $(A^*)^{-1}$ to arbitrary complex vectors where the elements of A are defined by

$$A_{jk} = e^{ikx_j} \tag{44}$$

for $j = 0, \ldots, N$ and $k = -N/2, \ldots, N/2$.

We make use of the following two simple observations.

Observation 4.3. The matrix AA^* is Toeplitz, and furthermore, its $2N+1$ distinct elements can be computed in $O(N \log N + Nq)$ operations due to Observation 4.2.

Proof. It is obvious from (44) that

$$(AA^*)_{jl} = \sum_{k=0}^{N} e^{ijx_k} \cdot e^{-ilx_k} = \sum_{k=0}^{N} e^{i(j-l)x_k}, \tag{45}$$

which is a function only of $(j-l)$, and is of the same form as (41), the description for Problem 1. □

Observation 4.4. From elementary matrix identities we see that

$$A^{-1} \equiv A^*(AA^*)^{-1}, \tag{46}$$

$$(A^*)^{-1} \equiv (AA^*)^{-1}A. \tag{47}$$

The Toeplitz matrix AA^* can be applied to arbitrary vectors in $O(N \log N)$ operations using an FFT-based discrete convolution. $(AA^*)^{-1}$ can therefore be applied to a vector in $O(\kappa(A) \cdot N \log N)$ operations using the conjugate gradient method where $\kappa(A)$ is the condition number of A.

Observation 4.5. A^{-1} and $(A^*)^{-1}$ can be applied to arbitrary vectors using $O(\kappa(A) \cdot N \log N + Nq)$ operations due to Observations 4.2 and 4.4.

Remark 4.6. It is well known that the condition number of A is 1 if the points $\{x_j\}$ are equally spaced. While the condition number deteriorates as the distribution of points becomes more nonuniform, in many cases of practical interest the points will be fairly uniformly spaced, so the condition number will not be very large.

4.3. Algorithm 6 for a variant of Problem 5. The following lemma describes a way of computing the coefficients of an $(N/2+1)$-term Fourier series that is tabulated at $N+1$ points.

LEMMA 4.1. *Suppose that the $N+1$ function values $g_0, \dots, g_N$ are given by the formula*

$$g_j = \sum_{k=-N/4}^{N/4} \beta_k \cdot e^{ikx_j}, \tag{48}$$

and the vector $\xi = \{\xi_0, \dots, \xi_N\}$ is the unique solution of the linear system described by the equations

$$\sum_{j=0}^{N} \xi_j \cdot e^{ikx_j} = \begin{cases} 1 & \text{if } k = 0, \\ 0 & \text{otherwise} \end{cases} \tag{49}$$

for $k = -N/2, \dots, N/2$. Then, for $k = -N/4, \dots, N/4$,

$$\beta_k = \sum_{j=0}^{N} \xi_j \cdot g_j \cdot e^{-ikx_j}. \tag{50}$$

Proof. Substituting for g_j from (48), we have for $k = -N/4, \dots, N/4$

$$\sum_{j=0}^{N} \xi_j \cdot g_j \cdot e^{-ikx_j} = \sum_{j=0}^{N} \xi_j \cdot e^{-ikx_j} \cdot \sum_{l=-N/4}^{N/4} \beta_l \cdot e^{ilx_j} \tag{51}$$

$$= \sum_{l=-N/4}^{N/4} \beta_l \cdot \sum_{j=0}^{N} \xi_j \cdot e^{i(l-k)x_j} \tag{52}$$

$$= \beta_k. \quad \square \tag{53}$$

Remark 4.7. According to (49) and Lemma 2.2,

$$\sum_{j=0}^{N} \xi_j \cdot e^{ikx_j} = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ikx} dx \tag{54}$$

for $k = -N/2, \ldots, N/2$. Thus, the set of numbers $\{\xi_j\}$ can be considered as quadrature weights that integrate exactly all Nth order trigonometric polynomials at the nodes $\{x_j\}$.

Observation 4.8. Rewriting (49) in matrix notation, we see that

$$A^T \xi = (0, \ldots, 0, 1, 0, \ldots, 0)^T = A^* \xi, \tag{55}$$

where $A_{jk} = e^{ikx_j}$, so the vector ξ is real and can be computed using $O(\kappa(A) \cdot N \log N + Nq)$ operations due to Observation 4.5.

Observation 4.9. Equation (50) is of the same form as (41). Thus, provided the vector ξ is known, the vector β can be computed in $O(N \log N + Nq)$ operations due to Observation 4.2.

Remark 4.10. According to Observation 4.9, if a function described by an $(N/2+1)$-term Fourier series is tabulated at $N+1$ arbitrary nodes, the $(N/2+1)$ coefficients can be obtained in $O(N \log N + Nq)$ operations. Also, due to Observation 4.8, the precomputation of the numbers $\{\xi_j\}$ needed for this algorithm requires $O(\kappa(A) \cdot N \log N + Nq)$ operations.

5. Notation. In this section we introduce the notation to be used in the next section for the detailed algorithm descriptions.

For an integer $m \geq 2$ and a real number $b > 0$, we will define a real number $\varepsilon > 0$ by

$$\varepsilon = e^{-b\pi^2(1-1/m^2)} \cdot (4b+9), \tag{56}$$

and we will denote by q the smallest even natural number such that

$$q \geq 4b\pi. \tag{57}$$

For an integer m and a set of real numbers $\{\omega_k\}$, we will denote by μ_k the nearest integer to $m\omega_k$ for $k = 0, \ldots, N$, and by $\{P_{jk}\}$ a set of real numbers defined by the formula

$$P_{jk} = \frac{1}{2\sqrt{b\pi}} \cdot e^{-(m\omega_k-(\mu_k+j))^2/4b} \tag{58}$$

for $k = 0, \ldots, N$ and $j = -q/2, \ldots, q/2$.

Observation 5.1. Setting $d = \pi$ in Theorem 2.10, we see that

$$\left| e^{i\omega_k x} - e^{b(x/m)^2} \cdot \sum_{j=-q/2}^{q/2} P_{jk} \cdot e^{i(\mu_k+j)x/m} \right| < \varepsilon \tag{59}$$

for any $k = 0, \dots, N$ and any $x \in [-\pi, \pi]$, where ε is defined by (56).

For a given set of complex numbers $\{\alpha_k\}$, we will denote by $\{\tau_j\}$ the unique set of complex coefficients such that

$$\sum_{k=1}^{N} \alpha_k \cdot \sum_{j=-q/2}^{q/2} P_{jk} \cdot e^{i(\mu_k+j)x/m} = \sum_{j=-mN/2}^{mN/2-1} \tau_j e^{ijx/m}, \tag{60}$$

so that

$$\tau_l = \sum_{j,k,\mu_k+j=l} \alpha_k \cdot P_{jk}. \tag{61}$$

We will denote by $\{T_j\}$ a set of complex numbers defined by the formula

$$T_j = \sum_{k=-mN/2}^{mN/2-1} \tau_k \cdot e^{2\pi ikj/mN} \tag{62}$$

for $j = -mN/2, \dots, mN/2 - 1$.

Furthermore, we will denote by $\{\tilde{f}_j\}$ another set of complex numbers defined by the formula

$$\tilde{f}_j = e^{b(2\pi j/mN)^2} \cdot T_j \tag{63}$$

for $j = -N/2, \dots, N/2$.

Observation 5.2. Combining (59)–(63) with the triangle inequality, we see that

$$|f_j - \tilde{f}_j| < \varepsilon \cdot \sum_{k=0}^{N} |\alpha_k| \tag{64}$$

for $j = -N/2, \dots, N/2$, where $\{f_j = F(\alpha)_j\}$ are defined by (39).

For an integer m and a set of real numbers $\{x_j\}$, we will denote by ν_j the nearest integer to $x_j mN/2\pi$ for $j = 0, \dots, N$, and by $\{Q_{jk}\}$ a set of real numbers defined by the formula

$$Q_{jk} = \frac{1}{2\sqrt{b\pi}} \cdot e^{-(x_j mN/2\pi - (\nu_j + k))^2/4b} \tag{65}$$

for $j = 0, \dots, N$ and $k = -q/2, \dots, q/2$.

Observation 5.3. Setting $d = N/2$ in Theorem 2.10, we see that

$$\left| e^{ikx_j} - e^{b(2\pi k/mN)^2} \cdot \sum_{l=-q/2}^{q/2} Q_{jk} \cdot e^{i(\nu_j+l)2\pi k/mN} \right| < \varepsilon \tag{66}$$

for any $j = 0, \dots, N$ and any $k \in [-N/2, N/2]$, where ε is defined by (56).

For a given set of complex numbers $\{\beta_k\}$, we will denote by $\{u_k\}$ a set of complex numbers defined by the formula

$$u_k = \beta_k \cdot e^{b(2\pi k/mN)^2} \tag{67}$$

for $k = -N/2, \dots, N/2$, and by $\{U_l\}$ a set of complex numbers defined by the formula

$$U_l = \sum_{k=-N/2}^{N/2} u_k \cdot e^{2\pi ikl/mN} \tag{68}$$

for $l = -mN/2, \dots, mN/2 - 1$.

Furthermore, we will denote by $\{\tilde{g}_j\}$ another set of complex numbers defined by the formula

$$\tilde{g}_j = \sum_{l=-q/2}^{q/2} Q_{jl} \cdot U_{\nu_j + l} \tag{69}$$

for $j = 0, \dots, N$.

Observation 5.4. Combining (66)–(69) with the triangle inequality, we see that

$$|g_j - \tilde{g}_j| < \varepsilon \cdot \sum_{k=0}^{N} |\beta_k| \tag{70}$$

for $j = 0, \dots, N$, where $\{g_j = G(\beta)_j\}$ are defined by (40).

For a set of real numbers $\{x_j\}$, we will denote by η_j the nearest integer to $x_j N/2\pi$ for $j = 0, \dots, N$, and by $\{R_{jk}\}$ a set of real numbers defined by the formula

$$R_{jk} = \frac{1}{2\sqrt{b\pi}} \cdot e^{-(x_j N/2\pi - (\eta_j + k))^2/4b} \tag{71}$$

for $j = 0, \dots, N$ and $k = -q/2, \dots, q/2$.

Observation 5.5. Setting $d = N/2$ in Theorem 2.10, we see that

$$\left| e^{ikx_j/m} - e^{b(2\pi k/mN)^2} \cdot \sum_{l=-q/2}^{q/2} R_{jk} \cdot e^{i(\eta_j + l)2\pi k/mN} \right| < \varepsilon \tag{72}$$

for any $j = 0, \dots, N$ and any $k \in [-N/2, N/2]$, where ε is defined by (56).

For a given set of complex numbers $\{\gamma_k\}$, we will denote by $\{v_j\}$ the unique set of complex coefficients such that

$$\sum_{k=0}^{N} \gamma_k \cdot \sum_{j=-q/2}^{q/2} P_{jk} \cdot e^{i(\mu_k + j)x/m} = \sum_{j=-mN/2}^{mN/2} v_j \cdot e^{ijx/m}, \tag{73}$$

so that

$$v_l = \sum_{j,k,\eta_k + j = l} \gamma_k \cdot P_{jk}. \tag{74}$$

We denote by $\{V_l\}$ a set of complex numbers defined by the formula

$$V_l = \sum_{k=-mN/2}^{mN/2} v_k \cdot e^{b(2\pi k/m^2 N)^2} \cdot e^{2\pi ikl/m^2 N} \tag{75}$$

for $l = -m^2 N/2, \dots, m^2 N/2 - 1$.

Furthermore, we will denote by $\{\tilde{h}_j\}$ another set of complex numbers defined by the formula

$$\tilde{h}_j = e^{b(x_j/m)^2} \cdot \sum_{l=-q/2}^{q/2} R_{jl} \cdot V_{\eta_j+l} \tag{76}$$

for $j = 0, \dots, N$.

Observation 5.6. Combining (59) and (72)–(76) with the triangle inequality, we see that

$$|h_j - \tilde{h}_j| < \delta \cdot \sum_{k=0}^{N} |\gamma_k| \tag{77}$$

for $j = 0, \dots, N$, where $\{h_j = H(\gamma)_j\}$ are defined by (42), and

$$\delta = 2e^{-b\pi^2(1-2/m^2)} \cdot (4b + 9). \tag{78}$$

For a set of real numbers $\{x_j\}$, A will denote a complex matrix whose elements are given by

$$A_{jk} = e^{ikx_j} \tag{79}$$

for $k = -N/2, \dots, N/2$ and $j = 0, \dots, N$, and $a = \{a_{-N}, \dots, a_N\}$ will denote a set of complex numbers defined by the formula

$$a_k = \sum_{j=0}^{N} e^{ikx_j}. \tag{80}$$

Finally, $\xi = \{\xi_0, \dots, \xi_N\}$ will denote a real vector defined by

$$\xi = (A^*)^{-1}(0, \dots, 0, 1, 0, \dots, 0)^T. \tag{81}$$

Remark 5.7. It is clear from Observation 4.3 that

$$(AA^*)_{jk} = a_{j-k}. \tag{82}$$

6. Detailed descriptions of the algorithms.

This section contains step-by-step descriptions and operation counts for the six algorithms of this paper. In the tables below we will make use of the facts that $q \sim \log(\frac{1}{\varepsilon})$ and $m^2 \ll N$.

ALGORITHM 1.

Step	Complexity	Description
Init	$O(Nq)$	**Comment** [Input parameter is the vector $\{\omega_0, \dots, \omega_N\}$.]

```
Comment [Input parameter is the vector $\{\omega_0, \dots, \omega_N\}$.]
Choose precision $\varepsilon$ to be achieved.
Set $b \approx \log(1/\varepsilon)$ and $q = \lceil 4b\pi \rceil$.
do $k = 0, N$
    Determine $\mu_k$, the nearest integer to $m\omega_k$
    do $j = -q/2, q/2$
        Compute $P_{jk}$ according to (58)
    end do
end do
do $j = -N/2, N/2$
    Compute $e^{b(2\pi j/mN)^2}$
end do
```

```
1      $O(Nq)$             Comment [Input parameter is the vector $\{\alpha_0, \dots, \alpha_N\}$.]
                           Comment [Compute Fourier coefficients $\tau_j$.]
                           do $k = 0, N$
                              do $j = -q/2, q/2$
                                 $\tau_{\mu_k+j} \leftarrow \tau_{\mu_k+j} + P_{jk} \cdot \alpha_k$
                              end do
                           end do

2      $O(mN \log N)$      Comment [Evaluate this Fourier Series at equispaced points in $[-m\pi, m\pi]$ us-
                           ing inverse FFT of size $mN$.]
                           Compute $T_j = \sum_{k=-mN/2}^{mN/2-1} \tau_k \cdot e^{2\pi ikj/mN}$ for
                              $j = -mN/2, \dots, mN/2 - 1$.

3      $O(N)$              Comment [Scale the values at those points which lie in $[-\pi, \pi]$.]
                           do $j = -N/2, N/2$
                              $\tilde{f}_j = T_j \cdot e^{b(2\pi j/mN)^2}$
                           end do

Total  $O(N \cdot \log(\frac{1}{\varepsilon}) + mN \cdot \log N)$
```

ALGORITHM 2.

```
Step   Complexity          Description

Init   $O(Nq)$             Comment [Input parameter is the vector $\{x_0, \dots, x_N\}$.]
                           Choose precision $\varepsilon$ to be achieved.
                           Set $b \approx \log(1/\varepsilon)$ and $q = \lceil 4b\pi \rceil$.

                             do $k = -mN/2, mN/2$
                                 $v_k \leftarrow v_k \cdot e^{b(2\pi k/m^2 N)^2}$
                             end do

3     $O(m^2 N \log N)$      Comment [Evaluate this Fourier Series at equispaced points in
                             $[-m\pi, m\pi]$ using inverse FFT of size $m^2 N$.]
                             Compute $V_j = \sum_{k=-mN/2}^{mN/2} v_k \cdot e^{2\pi i k j/m^2 N}$
                                 for $j = -m^2 N/2, \dots, m^2 N/2 - 1$.

4     $O(Nq)$                Comment [Compute approximate values at desired points in
                             terms of the values at equispaced points.]
                             do $j = 0, N$
                                 do $k = -q/2, q/2$
                                     $\tilde{h}_j \leftarrow \tilde{h}_j + R_{jk} \cdot V_{\eta_j+k}$
                                 end do
                             end do
```

5	$O(N)$	**Comment** [Scale the values.]

```
do $j = 0, N$
    $\tilde{h}_j \leftarrow \tilde{h}_j \cdot e^{b(x_j/m)^2}$
end do
```

Total $O(m^2N \cdot \log N + N \cdot \log(\frac{1}{\varepsilon}))$

ALGORITHM 4.

Step	Complexity	Description
Init	$O(N \log N + Nq)$	Initialization for Algorithm 1. Initialization for Algorithm 2. Compute elements $\{a_k\}$ of Toeplitz matrix $(AA^*)^{-1}$ as defined by (80) using Algorithm 1.
1	$O(N \log N + Nq)$	Compute Af using Algorithm 2.
2	$O(\kappa(A) \cdot N \log N)$	Compute $\tilde{\alpha} = (AA^*)^{-1}(Af)$ using Conjugate Gradient algorithm.
Total	$O(\kappa(A) \cdot N \cdot \log N + N \cdot \log(\frac{1}{\varepsilon}))$	

ALGORITHM 5.

Step	Complexity	Description
Init	$O(N \log N + Nq)$	Initialization for Algorithm 1. Compute elements $\{a_k\}$ of Toeplitz matrix $(AA^*)^{-1}$ as defined by (80) using Algorithm 1.
1	$O(\kappa(A) \cdot N \log N)$	Compute $(AA^*)^{-1}g$ using Conjugate Gradient algorithm.
2	$O(N \log N + Nq)$	Compute $\tilde{\beta} = A^*((AA^*)^{-1}g)$ using Algorithm 1.
Total	$O(\kappa(A) \cdot N \cdot \log N + N \cdot \log(\frac{1}{\varepsilon}))$	

ALGORITHM 6.

Step	Complexity	Description
Init	$O(\kappa(A) \cdot N \log N + Nq)$	Initialization for Algorithm 5. Compute ξ as defined by (81) using Algorithm 5.
1	$O(N)$	Compute $\hat{g}_j = \xi_j g_j$ for $j = 0, \ldots, N$.
2	$O(N \log N + Nq)$	Compute $\tilde{\beta} = A^* \hat{g}$ using Algorithm 1.
Total	$O(N \cdot \log N + N \cdot \log(\frac{1}{\varepsilon}))$	

The storage requirements of an algorithm are also an important characteristic. From the above descriptions for the initialization steps, the asymptotic storage requirements for each algorithm are of the form

$$\lambda \cdot N \cdot q, \tag{83}$$

where the coefficient λ is software- and hardware-dependent.

7. Implementation and numerical results. We have written FORTRAN implementations of the six algorithms of this paper in both single and double precision arithmetic and have applied these programs to a variety of situations. In this section we discuss several details of our implementations and demonstrate the performance of the algorithms with six numerical examples.

Several technical details of our implementations appear to be worth mentioning here.

1. Each implementation consists of two main subroutines: the first is an initialization stage in which the matrix operators of the algorithm are precomputed and stored, and the second is an evaluation stage in which these operators are applied. Successive application of the linear transformations to multiple vectors requires the initialization to be performed only once.

2. For the single precision versions of each algorithm our choice of parameters was $m = 2$, $b = 0.5993$, and $q = 10$. For double precision we chose $m = 2$, $b = 1.5629$, and $q = 28$.

3. The algorithms as described in this paper all require an FFT of size proportional to N, and thus will perform efficiently whenever the FFT does. This restriction on the FFT size can be removed by extending the input vector to length $2^{\lceil \log_2 N \rceil}$ (i.e., the smallest power of 2 which is greater than N) and padding it with zeroes. This ensures that the algorithms will perform efficiently for any choice of N. In our implementations, these changes were made.

4. Each of the algorithms of this paper requires the evaluation of sums of the form

$$f_j = \sum_{k=-N/2}^{N/2-1} \alpha_k \cdot e^{2\pi ikj/N} \tag{84}$$

for $j = -N/2, \dots, N/2-1$, whereas most FFT software computes sums of the form

$$f_j = \sum_{k=0}^{N-1} \alpha_k \cdot e^{2\pi ikj/N} \tag{85}$$

for $j = 0, \dots, N-1$. We used a standard FFT to evaluate sums of the form (84) by defining $\hat{\alpha}_k = \alpha_k$ for $k = 0, \dots, N/2-1$, $\hat{\alpha}_k = \alpha_{k-N}$ for $k = N/2, \dots, N-1$, $\hat{f}_j = f_j$ for $j = 0, \dots, N/2-1$, and $\hat{f}_j = f_{k-N}$ for $j = N/2, \dots, N-1$. This substitution converts the form (84) to the form (85).

Our implementations of the algorithms of this paper have been tested on the Sun SPARCstation 1 for a variety of input data. Six experiments are described below and their results are summarized in Tables 1–6. These tables contain accuracies and CPU timings for the algorithms with computations performed in both single and double precision arithmetic, and the input size N varying between 64 and 4096. In addition, each table contains the CPU times required to solve the same set of problems via a direct calculation, and Tables 1–3 include timings for an FFT of the same size. Tables 1–3 also contain the accuracies of the direct single precision calculations.

Two measures of accuracy were chosen for each example. In Examples 1, 2, and 3, these are defined by the formulae

$$E_\infty = \max_{0 \le j \le N} |\tilde{f}_j - f_j| \Bigg/ \sum_{j=0}^{N} |\alpha_j| , \tag{86}$$

and

$$E_2 = \sqrt{\sum_{j=0}^{N} |\tilde{f}_j - f_j|^2 \Bigg/ \sum_{j=0}^{N} |f_j|^2}, \tag{87}$$

where α is the input vector, f is the result of a direct computation in double precision arithmetic, and $\tilde{f}$ is the result of the computation being considered.

In Examples 4, 5, and 6, they are defined by

$$E_\infty = \max_{0\le j\le N} |\tilde{\alpha}_j - \alpha_j| \Big/ \max_{0\le j\le N} |\alpha_j| \tag{88}$$

and

$$E_2 = \sqrt{\sum_{j=0}^{N} |\tilde{\alpha}_j - \alpha_j|^2 \Big/ \sum_{j=0}^{N} |\alpha_j|^2}, \tag{89}$$

where α is the input for a direct double precision computation, and $\tilde{\alpha}$ is the result of applying the algorithm to the result of this computation.

Remark 7.1. The formulae (86)–(89) measure fairly accurately the errors of all single precision computations. However, they can only provide rough estimates of the errors produced by the double precision versions of the algorithms.

Remark 7.2. In the direct methods for Problems 1 and 2, we used the fact that $e^{ikx_j} = (e^{ix_j})^k$ to reduce the number of exponential computations from N^2 to N. N^2 exponentials are required in the direct method for Problem 3, and, for larger N, the available memory on the machine is insufficient for the precomputation and storage of these numbers. The direct implementation we used for this problem computes each exponential when it is needed.

Remark 7.3. Standard LINPACK Gaussian elimination subroutines were used as the direct methods for comparing timings in Examples 4, 5 and 6. Estimated timings are presented for larger N, where this computation became impractical.

Following are the descriptions of the experiments and the tables of numerical results.

Example 1. Here we consider the transformation $F : C^{N+1} \to C^{N+1}$ of Problem 1 as defined by the formula

$$F(\alpha)_j = \sum_{k=0}^{N} \alpha_k \cdot e^{i\omega_k \cdot 2\pi j/N} \tag{90}$$

for $j = -N/2, \ldots, N/2$. In this example, $\{\omega_0, \ldots, \omega_N\}$ were randomly distributed on the interval $[-N/2, N/2]$, and $\{\alpha_0, \ldots, \alpha_N\}$ were generated randomly on the unit square in the complex plane defined by the formulae

$$0 \le \mathrm{Re}(z) \le 1, \qquad 0 \le \mathrm{Im}(z) \le 1. \tag{91}$$

The results of applying Algorithm 1 to this problem are presented in Tables 1(a) and 1(b).

Example 2. Here we consider the transformation $G : \mathbf{C}^{N+1} \to \mathbf{C}^{N+1}$ of Problem 2 as defined by the formula

$$G(\beta)_j = \sum_{k=-N/2}^{N/2} \beta_k \cdot e^{ikx_j} \tag{92}$$

for $j = 0, \ldots, N$. In this example, $\{x_0, \ldots, x_N\}$ were randomly distributed on the interval $[-\pi, \pi]$, and $\{\beta_{-N/2}, \ldots, \beta_{N/2}\}$ were generated randomly on the unit square in the complex plane defined by the formulae

$$0 \le \mathrm{Re}(z) \le 1, \qquad 0 \le \mathrm{Im}(z) \le 1. \tag{93}$$

Example 4. Here we consider Problem 4 of §3. In this example, the numbers $\{\omega_k\}$ were defined by the formula

$$\omega_k = -\frac{N}{2} + (k + 0.5 + \delta_k) \cdot \frac{N}{N+1} \tag{96}$$

for $k = 0, \ldots, N$, where δ_k were randomly distributed on the interval $[-0.1, 0.1]$. In addition, the numbers $\{\alpha_0, \ldots, \alpha_N\}$ were generated randomly on the unit square in the complex plane defined by the formulae

$$0 \le \mathrm{Re}(z) \le 1, \qquad 0 \le \mathrm{Im}(z) \le 1, \tag{97}$$

and the numbers $\{f_{-N/2}, \ldots, f_{N/2}\}$ were computed directly in double precision arithmetic according to the formula

$$f_j = \sum_{k=0}^{N} \alpha_k \cdot e^{i\omega_k \cdot 2\pi j/N}. \tag{98}$$

The vector f was then used as input for Algorithm 4. Results of this experiment are presented in Tables 4(a) and 4(b).

Example 5. Here we consider Problem 5 of §3. In this example, the numbers $\{x_j\}$ were defined by the formula

$$x_j = -\pi + 2\pi \cdot \frac{j + 0.5 + \delta_j}{N+1} \tag{99}$$

for $j = 0, \ldots, N$, where δ_j were randomly distributed on the interval $[-0.1, 0.1]$. In addition, the numbers $\{\beta_{-N/2}, \ldots, \beta_{N/2}\}$ were generated randomly on the unit square in the complex plane defined by the formulae

$$0 \le \mathrm{Re}(z) \le 1, \qquad 0 \le \mathrm{Im}(z) \le 1, \tag{100}$$

and the numbers $\{g_0, \ldots, g_N\}$ were computed directly in double precision arithmetic according to the formula

$$g_j = \sum_{k=-N/2}^{N/2} \beta_k \cdot e^{ikx_j}. \tag{101}$$

The vector g was then used as input for Algorithm 5. Results of this experiment are presented in Tables 5(a) and 5(b).

Example 6. Here we consider the variant of Problem 5 which was described in §4.3. In this example, the numbers $\{x_j\}$ were defined by the formula

$$x_j = -\pi + 2\pi \cdot \frac{j + 0.5 + \delta_j}{N+1} \tag{102}$$

for $j = 0, \dots, N$, where δ_j were randomly distributed on the interval $[-0.1, 0.1]$. In addition, the numbers $\{\beta_{-N/4}, \dots, \beta_{N/4}\}$ were generated randomly on the unit square in the complex plane defined by the formulae

$$0 \le \mathrm{Re}(z) \le 1, \qquad 0 \le \mathrm{Im}(z) \le 1, \tag{103}$$

and the numbers $\{g_0, \dots, g_N\}$ were computed directly in double precision arithmetic according to the formula

$$g_j = \sum_{k=-N/4}^{N/4} \beta_k \cdot e^{ikx_j}. \tag{104}$$

The vector g was then used as input for Algorithm 6. Results of this experiment are presented in Tables 6(a) and 6(b).

The following observations can be made from Tables 1–6 above and are in agreement with results of our more extensive experiments.

1. The errors produced by Algorithms 1, 2, and 3 are comparable with those produced by the corresponding direct methods.

TABLE 6(a)

2. The timings for Algorithms 1 and 2 are similar, which is to be expected since Problem 2 is the adjoint of Problem 1. Algorithm 3 is about twice as costly, which is in agreement with the fact that it is a synthesis of Algorithms 1 and 2.

3. In single precision computations for this particular architecture, implementation and range of N, Algorithms 1 and 2 are less than four times as costly as an FFT of the same size. For double precision the ratio is roughly six. These ratios decrease as N increases.

4. The extrapolated break-even point of Algorithms 1 and 2 is at roughly $N = 32$ if the initialization time is ignored. If the initialization time is included, the break-even point is at $N = 256$. For Algorithm 3, the break-even points are at $N = 8$ without initialization and at $N = 32$ with initialization.

5. The timings for Algorithms 4 and 5 are similar as expected, since Problem 5 is the adjoint of Problem 4.

6. The break-even points of Algorithms 4 and 5 are at roughly $N = 32$. For Algorithm 6, the break-even points are at $N = 32$ if the initialization time is taken into account and at $N = 16$ if it is ignored.

7. Algorithms 1 and 2 tend to be slightly more accurate than their inverses, Algorithms 4 and 5.

8. The initialization for Algorithm 6 is computationally costly, but subsequent evaluations require much less CPU time than evaluations for Algorithm 5.

Remark 7.4. The CPU timings for Algorithms 1, 2, and 3 are independent of the particular distributions of ω and x, whereas the timings for Algorithms 4 and 5 are sensitive to the distributions of these vectors.

8. Generalizations and conclusions. The results of this paper can be generalized in the following ways.

1. Simple modifications to Algorithms 1, 2, and 3 will allow the efficient application of the linear transformations $F_1, G_1, H_1 : \mathbf{C}^{N+1} \to \mathbf{C}^{M+1}$ defined by

$$F_1(\alpha)_j = \sum_{k=0}^{N} \alpha_k \cdot e^{i\omega_k \cdot 2\pi j/M} \quad \text{for } j = -\frac{M}{2}, \dots, \frac{M}{2}, \tag{105}$$

$$G_1(\beta)_j = \sum_{k=-N/2}^{N/2} \beta_k \cdot e^{ikx_j} \quad \text{for } j = 0, \dots, M, \tag{106}$$

$$H_1(\gamma)_j = \sum_{k=0}^{N} \gamma_k \cdot e^{i\omega_k x_j} \quad \text{for } j = 0, \dots, M. \tag{107}$$

These changes have been implemented.

2. The algorithms of this paper also assume that $\omega_k \in [-N/2, N/2]$ and $x_j \in [-\pi, \pi]$. Other distributions can be handled by appropriately partitioning the vectors ω and x, treating each partition separately and finally combining the results. The following observation describes translation operators which can be used for each partition, in combination with one of Algorithms 1, 2, or 3.

Observation 8.1. Let $a, b > 0, c, d > 0$ be real numbers and suppose that $\omega_k \in [a-b, a+b]$ for $k = 0, \dots, N$ and $x_j \in [c-d, c+d]$ for $j = 0, \dots, M$. Then we can write

$$\sum_{k=0}^{N} \alpha_k \cdot e^{i\omega_k x_j} = e^{iax_j} \cdot \sum_{k=0}^{N} \alpha_k \cdot e^{i(\omega_k - a)c} \cdot e^{i(\omega_k - a)(x_j - c)} \tag{108}$$

$$= e^{iax_j} \cdot \sum_{k=0}^{N} \alpha'_k \cdot e^{i\omega'_k x'_j}, \tag{109}$$

where

$$\begin{aligned} \alpha'_k &= \alpha_k e^{i(\omega_k - a)c}, \\ \omega'_k &= (\omega_k - a)d/\pi, \\ x'_j &= (x_j - c)\pi/d \in [-\pi, \pi]. \end{aligned} \tag{110}$$

Remark 8.2. Such an algorithm will perform efficiently when the points within a partition are close together and there are very few partitions and not so efficiently if the points are widely separated and there are many partitions. Most cases likely to be encountered in practice fall in the former category.

3. The algorithms of this paper are based on a special case of a more general idea, namely, the adaptive use of interpolation techniques to speed up large scale computations. Other examples of this approach include the use of wavelets for the construction of fast numerical algorithms (see, for example, [1], [3]) and the use of multipole or Chebyshev expansions for the compression of certain classes of linear operators (see, for example, [5], [11]).

4. A paper describing a set of algorithms based on a different interpolation technique is currently in preparation.

5. One of the more far-reaching extensions of the results of this paper is a set of algorithms for higher dimensional discrete Fourier transforms. Investigations into this are currently in progress.

6. The Helmholtz equation in two dimensions is given by

$$\nabla^2\phi + \kappa^2\phi = 0, \tag{111}$$

and has particular solutions of the form

$$\phi(x,y) = e^{i\mu x} \cdot e^{i\nu y}, \tag{112}$$

where $\mu^2 + \nu^2 = \kappa^2$. Solutions of this equation consist of linear combinations of such functions that satisfy a set of boundary conditions, and the results of this paper admit a generalization that constitutes a fast Helmholtz solver.

In conclusion, a group of algorithms has been presented for the rapid application and inversion of matrices of the Fourier kernel. These problems can be viewed as generalizations of the discrete Fourier transform, and the algorithms, while making use of certain simple results from analysis, are very versatile and have wide-ranging potential applications in many branches of mathematics, science, and engineering.

Appendix. In this Appendix we present numerical estimates of error bounds for Theorem 2.10 of §2.2. For our experiments we chose $c = 0$ and $d = \pi$ and chose the two sets of values of m, b, and q, which are used in our single and double precision implementations of the algorithms of this paper. The expression

$$r(x) = 1 - e^{bx^2} \cdot \sum_{k=-q/2}^{q/2} \rho_k \cdot e^{ikx}, \tag{113}$$

where ρ_k is defined by (18), was evaluated at $n = 1000$ equally spaced nodes $\{x_k\}$ in the interval $[-\frac{\pi}{m}, \frac{\pi}{m}]$, and the following three quantities were computed:

- the maximum absolute error E_∞ defined by the formula

$$E_\infty = \max_{1\le k\le n} |r(x_k)|, \tag{114}$$

- the relative L_2 error E_2 defined by the formula

$$E_2 = \sqrt{\frac{\sum_{k=1}^{n} |r(x_k)|^2}{n}}, \tag{115}$$

- the error bound E_B of Theorem 2.10 defined by the formula

$$E_B = e^{-b\pi^2(1-1/m^2)} \cdot (4b+9). \tag{116}$$

The results of these two experiments are presented in Table 7.

TABLE 7

m	b	q	E_∞	E_2	E_B
2	0.5993	10	0.825 E−05	0.176 E−05	0.135 E−00
2	1.5629	28	0.400 E−13	0.580 E−14	0.163 E−03

We observe from Table 7 that the error bound E_B of Theorem 2.10 is very weak compared with the experimentally obtained bounds. Indeed, the requirement that E_B be appropriately small would impose much larger values of b and q than are actually needed for the algorithms.

NUMERICAL SOLUTION OF THE RIEMANN PROBLEM FOR TWO-DIMENSIONAL GAS DYNAMICS*

CARSTEN W. SCHULZ-RINNE[†], JAMES P. COLLINS[‡], AND HARLAND M. GLAZ[§]

Abstract. The Riemann problem for two-dimensional gas dynamics with isentropic or polytropic gas is considered. The initial data is constant in each quadrant and chosen so that only a rarefaction wave, shock wave, or slip line connects two neighboring constant initial states. With this restriction sixteen (respectively, fifteen) genuinely different wave combinations for isentropic (respectively, polytropic) gas exist. For each configuration the numerical solution is analyzed and illustrated by contour plots. Additionally, the required relations for the initial data and the symmetry properties of the solutions are given. The chosen calculations correspond closely to the cases studied by T. Zhang and Y. Zheng [*SIAM J. Math. Anal.*, 21 (1990), pp. 593–630], so that the analytical theory can be directly compared to our numerical study.

Key words. Riemann problem, gas dynamics, Godunov method, wave interaction

AMS subject classifications. 35A40, 35L65, 35L67, 65M06, 76N15

1. Introduction. The interaction of elementary waves for systems of hyperbolic conservation laws is the key mechanism in determining the qualitative properties of solutions to more general initial value problems. For the genuinely nonlinear case and one space dimension, these basic interactions along with the Riemann problem can be worked out analytically, at least for small enough jumps in wave strength [16], and are often solvable for large jumps as well [3], [18]. This knowledge is the basic building block in using techniques such as the random choice method (RCM) to obtain existence results [8] as well as information about the qualitative behavior of solutions [12], and this is especially the case for certain systems that are derived from physical principles, e.g., gas dynamics. Indeed, one can go further and conjecture that RCM, with enough mesh points and sufficient accuracy in the Riemann problem solution, will almost always produce a very close approximation to the exact solution for scalar conservation laws, gas dynamics, and certain other systems in the one-dimensional planar case.

It is natural to try to use elementary waves and Riemann problems as building blocks in constructing solutions in two and three dimensions since the idea is so successful in one dimension. For the scalar case, a great deal of work has been done [10], [11], [17], [19], and much is known about the analytic structure of solutions. However, even here it seems difficult to work in analogy to the methods of [8] and [12] and obtain deep results for general data; also, finite difference schemes based directly on two-dimensional Riemann problem solutions have not appeared.

For gas dynamics and two space dimensions, the situation can be expected to be quite complex and is certainly difficult; very few analytic results are available. Our approach here is to use a high-resolution finite difference scheme as an experimental tool and to try to catalogue the phenomenology of the two-dimensional gas dynamic Riemann problem for a restricted set of initial data; our choices have been strongly influenced by

the conjectures reported in [20]. A similar approach using the front tracking method is also possible [9], but our results here indicate that such an effort would be awkward to implement. However, the set of results obtained here, suitably augmented to account for a larger data set, might be useful in constructing numerical methods along these lines by supplying the appropriate jump conditions at solution singularities.

The most important feature of elementary waves and Riemann problems is that their solutions may be assumed to be self-similar; this reduces the number of dimensions by one and leads to the analytic theory for the one-dimensional case. The dimensional reduction in two-dimensions is from three to two dimensions and the resulting system is still a partial differential equation (PDE). A set of interesting self-similar data for gas dynamics, from a historical point of view, is the problem of oblique shock wave reflection, which can be experimentally simulated by situating a wedge in a shock tube downstream of the incident shock. Experimental, analytical, and numerical investigations of this problem go back to Mach and von Neumann; the extensive literature is discussed in [5]. The numerical scheme used to obtain the results in our work here has been implemented for this configuration as well [6], [7]. It has been conjectured [20], and will be shown here (by computational experiments), that at least some of these results also arise from two-dimensional Riemann problems.

The collection of self-similar data in two-dimensions is very diverse, as already illustrated by the possible wedge configurations and their solutions. Actually, any collection of rays centered at some point (always the origin here) and separated by constant states will lead to a self-similar solution. Our study here is restricted to the special case of four constant states, one in each quadrant. We impose a further restriction by insisting that the waves separating each pair of adjoining states be a single elementary wave; this corresponds to the set of conjectures proposed in [20], which partially inspired the work here.

We remark that even the case of a single planar shock wave situated in $\mathbb{R}^2$ is not necessarily trivial, at least numerically. Indeed, certain conditions must be satisfied by the data and the equation of state in order that the wave be stable [13], [14]. However, stability is guaranteed for the genuinely nonlinear case and our work so far has been for polytropic gases.

All computations are performed using the second-order Eulerian Godunov method as formulated in [1] along with the dissipative mechanisms discussed in [2]. The capabilities of this scheme applied to a wide variety of applications are summarized in [4]. The boundary conditions are trivial for this study, of course. The initial data is laid down on the grid with the jumps at (the Cartesian) grid interfaces. The calculations are started smoothly by taking the initial Courant–Friedrichs–Lewy (CFL) constraint to be very severe and gradually relaxing it. The (x, y)-plane is covered with a uniform mesh containing 400 cells in each direction for all problems reported here. The calculations were performed on Sun workstations at the ETH Zurich.

The equations of motion, the Riemann problem initial data, and the resulting self-similar equations are discussed in §2; this section also contains a summary of the classification based on [20] and derived in [15].

In §3 the numerical solutions and their structures are presented and analyzed. Through observation of the time-dependent solution, it is clear that our mesh is sufficient for the solutions to relax to their pseudosteady states; thus, our illustrations may be assumed to be situated in the (ξ, η)-plane. A few computations exhibit an unsteady Kelvin–Helmholtz instability across slip surfaces. For these cases, we cannot assume the existence of a true pseudosteady state although the overall structures are stable in time;

see [5] for further discussion. The results are illustrated by contour plots of the density and self-similar Mach number. In the (ξ, η)-plane the pseudostationary flow is transonic. The four elementary waves, extending from the boundary of the domain parallel to the coordinate axes, interact and/or reach the region of subsonic flow. In the cases with four shock waves, the interaction of the shock fronts results in simple, complex, or double Mach reflections depending on the initial strength of the waves. Four slip lines lead to large-scale vortex creation in one case. With some wave combinations the region of subsonic flow is partly bounded by newly created shocks. Our conclusions are presented in §4.

2. Problem formulation and classification. The Riemann problem for gas dynamics in two space dimensions, both for isentropic and polytropic gas, is formulated as follows. We start with the Euler equations of inviscid compressible isentropic flow consisting of the equations for conservation of mass and momentum. For polytropic gas we have an additional equation for the conservation of energy. The conservation form of these equations in Cartesian coordinates is

$$U_t + F(U)_x + G(U)_y = 0, \tag{1}$$

where

$$U = \begin{pmatrix} \rho \\ \rho u \\ \rho v \end{pmatrix}, \quad F(U) = \begin{pmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \end{pmatrix}, \quad G(U) = \begin{pmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \end{pmatrix}$$

for isentropic gas and

$$U = \begin{pmatrix} \rho \\ \rho u \\ \rho v \\ \rho E \end{pmatrix}, \quad F(U) = \begin{pmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ u(\rho E + p) \end{pmatrix}, \quad G(U) = \begin{pmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ v(\rho E + p) \end{pmatrix}$$

for polytropic gas. Here ρ is the density, u the x-velocity component, v the y-velocity component, p the pressure, and E the total specific energy. The system is closed by specifying an equation of state. For isentropic gas we take $p = A\rho^\gamma$, where $A > 0$ and $\gamma > 1$ are constants. For polytropic gas we have instead

$$E = \frac{1}{(\gamma - 1)} \frac{p}{\rho} + \frac{u^2 + v^2}{2},$$

where $\gamma > 1$ is constant. The number γ is called the polytropic exponent and, since it is assumed constant in the present study, may be interpreted physically as the ratio of specific heats for the polytropic case.

The eigenvalues of the Jacobian matrix $\nabla_U F$ (or $\nabla_U G$) are $\lambda_- = u - c$, $\lambda_0 = u$ and $\lambda_+ = u + c$ (or $\lambda_- = v - c$, $\lambda_0 = v$ and $\lambda_+ = v + c$). These are the characteristic speeds for one-dimensional gas dynamics and are needed here only for the implementation of the (operator split) numerical method. The sound speed c is defined by $c^2 = \gamma p/\rho$.

The Riemann problem in the (x, y)-plane is the initial value problem for (1) with initial data

$$(\rho, u, v)(x, y, 0) = (\rho_i, u_i, v_i), \qquad i = 1, \ldots, 4 \tag{2}$$

for isentropic gas and

$$(p, \rho, u, v)(x, y, 0) = (p_i, \rho_i, u_i, v_i), \qquad i = 1, \dots, 4 \tag{2'}$$

for polytropic gas where i denotes the ith quadrant.

The solution is a function of the similarity variables $\xi = x/t$ and $\eta = y/t$. In these new variables, (1) becomes

$$-\xi U_\xi - \eta U_\eta + F(U)_\xi + G(U)_\eta = 0\,. \tag{3}$$

Introducing the so-called pseudovelocities $\tilde{u} = u - \xi$ and $\tilde{v} = v - \eta$, the system (3) is equivalent to

$$F(\tilde{U})_\xi + G(\tilde{U})_\eta + S(\tilde{U}) = 0, \tag{4}$$

where

$$\tilde{U} = \begin{pmatrix} \rho \\ \rho\tilde{u} \\ \rho\tilde{v} \end{pmatrix}, \qquad S(\tilde{U}) = \begin{pmatrix} 2\rho \\ 3\rho\tilde{u} \\ 3\rho\tilde{v} \end{pmatrix}$$

for isentropic gas and

$$\tilde{U} = \begin{pmatrix} \rho \\ \rho\tilde{u} \\ \rho\tilde{v} \\ \rho\tilde{E} \end{pmatrix}, \qquad S(\tilde{U}) = \begin{pmatrix} 2\rho \\ 3\rho\tilde{u} \\ 3\rho\tilde{v} \\ 2(\rho\tilde{E} + p) + \rho(\tilde{u}^2 + \tilde{v}^2) \end{pmatrix}$$

with

$$\tilde{E} = \frac{1}{(\gamma - 1)}\frac{p}{\rho} + \frac{\tilde{u}^2 + \tilde{v}^2}{2}$$

for polytropic gas. The system (4) can be expressed in quasilinear form as

$$V_\xi + AV_\eta + B = 0,$$

where

$$A = \left[\frac{\partial F}{\partial V}\right]^{-1}\left[\frac{\partial G}{\partial V}\right], \qquad B = \left[\frac{\partial F}{\partial V}\right]^{-1} S,$$

and V represents an arbitrary change of coordinates satisfying $\det(A) \neq 0$. Then the eigenvalues of A are

$$\tilde{\lambda}_0 = \frac{\tilde{v}}{\tilde{u}} \quad \text{and} \quad \tilde{\lambda}_\pm = \frac{\tilde{u}\tilde{v} \pm c\sqrt{\tilde{u}^2 + \tilde{v}^2 - c^2}}{\tilde{u}^2 - c^2} = \frac{\tilde{v}^2 - c^2}{\tilde{u}\tilde{v} \mp c\sqrt{\tilde{u}^2 + \tilde{v}^2 - c^2}}.$$

The initial value problem becomes a boundary value problem at infinity:

$$\left.\begin{array}{c} (\rho, u, v)(\xi, \eta) \to (\rho_i, u_i, v_i) \\ \text{or} \\ (p, \rho, u, v)(\xi, \eta) \to (p_i, \rho_i, u_i, v_i) \end{array}\right\} \text{ for } \xi^2 + \eta^2 \to \infty \text{ and } \left\{\begin{array}{l} \xi > 0,\ \eta > 0,\ i = 1 \\ \xi < 0,\ \eta > 0,\ i = 2 \\ \xi < 0,\ \eta < 0,\ i = 3 \\ \xi > 0,\ \eta < 0,\ i = 4. \end{array}\right.$$

The self-similar solution in the (ξ, η)-plane is called pseudostationary flow. Far enough away from the origin the general solution consists of four planar waves, each parallel to one of the coordinate axes, separating the four constant initial states; also, the eigenvalues $\tilde{\lambda}_\pm$ are guaranteed to be real. In general, a planar wave is formed by up to three elementary waves corresponding to the eigenvalues λ_-, λ_0, and λ_+: a backward rarefaction wave $\overleftarrow{R}$ or shock wave $\overleftarrow{S}$, a slip line (respectively, a contact discontinuity) for isentropic (respectively, polytropic) gas[1] J, and a forward rarefaction wave $\overrightarrow{R}$ or shock wave $\overrightarrow{S}$. In our study of the interaction of the four planar waves we restrict ourselves to situations where each planar wave is a single elementary wave.

The Riemann problem is classified according to the combination of the four elementary planar waves used to define it. Thus we assume that the initial data (2) or (2′) are chosen so that only a rarefaction wave, shock wave, or slip line connects two neighboring constant states. Under this assumption it was proved in [15] that sixteen (respectively, fifteen) different configurations for the Riemann problem for isentropic (respectively, polytropic) gas in two space dimensions exist (symmetric or rotated configurations are systematically eliminated).

$4\,R$:	$\overrightarrow{R}_{21}\overrightarrow{R}_{32}\overrightarrow{R}_{34}\overrightarrow{R}_{41}$	$\overrightarrow{R}_{21}\overleftarrow{R}_{32}\overleftarrow{R}_{34}\overrightarrow{R}_{41}$	
$4\,S$:	$\overleftarrow{S}_{21}\overleftarrow{S}_{32}\overleftarrow{S}_{34}\overleftarrow{S}_{41}$	$\overleftarrow{S}_{21}\overrightarrow{S}_{32}\overrightarrow{S}_{34}\overleftarrow{S}_{41}$	
$2\,R+2\,S$:		$\overrightarrow{R}_{21}\overrightarrow{S}_{32}\overleftarrow{R}_{34}\overleftarrow{S}_{41}$	(only for isentropic gas)
$4\,J$:	$\overleftrightarrow{J_{21}\,J_{32}\,J_{34}\,J_{41}}$	$\overrightarrow{J_{21}\,J_{32}\,J_{34}\,J_{41}}$	
$2\,J+2\,R$:	$\overrightarrow{R}_{21}\,J_{32}\,J_{34}\overrightarrow{R}_{41}$	$\overleftarrow{R}_{21}J_{32}\,J_{34}\,\overleftarrow{R}_{41}$	$J_{21}\,\overrightarrow{R}_{32}J_{34}\,\overrightarrow{R}_{41}$
$2\,J+2\,S$:	$\overleftarrow{S}_{21}\,J_{32}\,J_{34}\,\overleftarrow{S}_{41}$	$\overrightarrow{S}_{21}\,J_{32}J_{34}\,\overrightarrow{S}_{41}$	$J_{21}\,\overleftarrow{S}_{32}\,J_{34}\,\overleftarrow{S}_{41}$
$2\,J+R+S$:	$\overrightarrow{R}_{21}\,J_{32}\,J_{34}\,\overleftarrow{S}_{41}$	$\overleftarrow{R}_{21}\,J_{32}\,J_{34}\,\overrightarrow{S}_{41}$	$J_{21}\,\overleftarrow{S}_{32}\,J_{34}\,\overrightarrow{R}_{41}$

In this table and in the following, E_{ij} with $E \in \{J, \overleftarrow{R}, \overrightarrow{R}, \overleftarrow{S}, \overrightarrow{S}\}$ and $i, j \in \{1, 2, 3, 4\}$ denotes an elementary wave E between the ith and jth quadrant. The notation in the $4\,J$ cases serves to distinguish the two possibilities which are explained in the next section.

3. Computational results. In this section we present the numerical solutions to the configurations one by one. For each of them, we give the relations that must be satisfied by the initial data and the symmetry properties of the solution. The formulas for one-dimensional elementary waves between two constant states, which follow from the simple wave and Rankine–Hugoniot relations [3], are stated in [15]. We use the formulas and the abbreviations introduced there; that is, for a given left and right state (denoted by the indices l and r), we define

$$\Phi_{lr} := \frac{2\sqrt{\gamma}}{\gamma - 1}\left(\sqrt{\frac{p_l}{\rho_l}} - \sqrt{\frac{p_r}{\rho_r}}\right), \qquad \Psi_{lr}^2 := \frac{(p_l - p_r)(\rho_l - \rho_r)}{\rho_l \rho_r} \quad (\Psi_{lr} > 0),$$

and

$$\Pi_{lr} := \left(\frac{p_l}{p_r} + \frac{(\gamma-1)}{(\gamma+1)}\right) \Big/ \left(1 + \frac{(\gamma-1)}{(\gamma+1)}\frac{p_l}{p_r}\right).$$

[1]In the following, the use of the term *slip line* always denotes a slip line for isentropic gas, but should be read to include the possibility of a contact discontinuity for polytropic gas.

Furthermore, we describe the main features of the solution in the (ξ, η)-plane. It always contains a subsonic area ($\tilde{M} < 1$) that is separated from the supersonic area ($\tilde{M} > 1$) by the sonic curve ($\tilde{M} = 1$). Here the self-similar Mach number $\tilde{M}$ is defined by $\tilde{M}^2 = (\tilde{u}^2 + \tilde{v}^2)/c^2$. In the supersonic domain the curves given by $d\eta/d\xi = \tilde{\lambda}_\pm$ are called the $\lambda_\pm$ characteristic lines. As in [20] we outline the behavior of these lines inside the rarefaction waves. The numerical solutions are illustrated by contour plots of the density and self-similar Mach number in the (ξ, η)-plane. In the Mach number plots the subsonic contour lines are dashed. For some configurations containing rarefaction waves the $\lambda_{+(-)}$ characteristic lines inside the fan are shown as solid (dashed) lines. The initial data listed in the figure captions, together with the relations given for the corresponding configuration, are always sufficient to uniquely define the solution.

3.1. Cases not involving slip line initial data. *Four rarefaction waves.* In this case the flow is isentropic.

Configuration 1. $\overrightarrow{R}_{21}\overrightarrow{R}_{32}\overrightarrow{R}_{34}\overrightarrow{R}_{41}$ (Figs. 1 and 3(a)). We have

$$p_1 > p_2, \; p_4 > p_3$$

and

$$\begin{array}{llll} u_2 - u_1 = \Phi_{21}, & u_3 - u_4 = \Phi_{34}, & u_3 = u_2, & u_4 = u_1, \\ v_4 - v_1 = \Phi_{41}, & v_3 - v_2 = \Phi_{32}, & v_2 = v_1, & v_3 = v_4. \end{array}$$

This gives the so-called compatibility condition $\Phi_{21} = \Phi_{34}$. For polytropic gas, we must include the following equations:

$$\rho_i/\rho_j = (p_i/p_j)^{1/\gamma} \quad \text{for} \quad (i,j) \in \{(2,1), (3,4), (3,2), (4,1)\}.$$

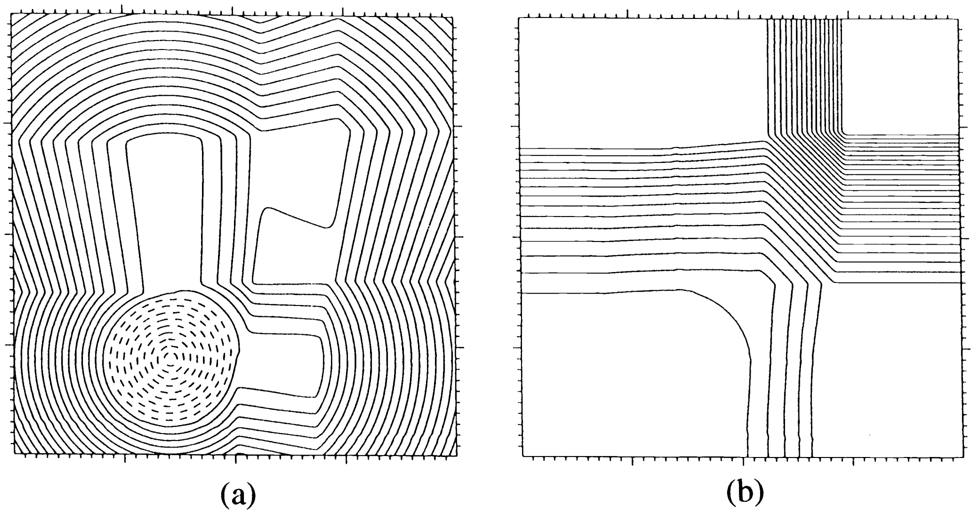

FIG. 1. *Configuration* 1. $p_1 = 1$, $p_2 = .4$, $p_4 = .15$, $\rho_1 = 1$, $u_1 = 0$, $v_1 = 0$. (a) *Self-similar Mach no.* (0.01 *to* 2.99); 29 *contour lines*: 0.10 *to* 2.90 *step* 0.10. (b) *Density* (0.102 *to* 1.000); 30 *contour lines*: 0.11 *to* 0.98 *step* 0.03.

For the case of a vanishing pressure jump in the η-direction, the sonic curve consists of a circle behind the rarefaction fan and a straight line called the sonic stem extending horizontally from the circle to the front of the wave. Inside the rarefaction fan the $\lambda_\pm$ characteristic lines are parallel to the contour lines between the boundary and the sonic stem. There the lines turn downwind to end at the sonic circle.

For the general case, the sonic circles of $\overrightarrow{R}_{32}$ and $\overrightarrow{R}_{34}$ jointly form the subsonic area behind the interaction of the waves. The rarefaction waves $\overrightarrow{R}_{21}$ and $\overrightarrow{R}_{41}$ meet at a point P in the first quadrant. The λ_- characteristic through P forms the lower boundary of the undisturbed $\overrightarrow{R}_{21}$ wave. It crosses $\overrightarrow{R}_{21}$, continues in the second quadrant, turns downward, crosses $\overrightarrow{R}_{32}$, enters the third quadrant, and ends at the sonic curve. Analogously, the λ_+ characteristic through P forms the left boundary of the undisturbed $\overrightarrow{R}_{41}$ wave. It crosses $\overrightarrow{R}_{41}$, continues in the fourth quadrant, turns left, crosses $\overrightarrow{R}_{34}$, and ends at the sonic curve in the third quadrant. The λ_- characteristic lines inside $\overrightarrow{R}_{34}$ are parallel to the contour lines inside the fan and turn downwind to end at the sonic curve. The equivalent is true for the λ_+ characteristic inside $\overrightarrow{R}_{32}$. The traces of the sonic stems in $\overrightarrow{R}_{32}$ and $\overrightarrow{R}_{34}$ are easily found in the Mach number plot (Fig. 1).

For an extensive range of initial data, we found that an intersection of the $\lambda_\pm$ characteristic lines at the lower left side of the subsonic area does not occur; compare [20, Figs. 4.2 and 4.3].

Configuration 2. $\overrightarrow{R}_{21}\overleftarrow{R}_{32}\overleftarrow{R}_{34}\overrightarrow{R}_{41}$ (Figs. 2 and 3(b)). We have

$$p_1 > p_2,\ p_4 < p_3$$

and

$$\begin{array}{llll} u_2 - u_1 = \Phi_{21}, & u_4 - u_3 = \Phi_{34}, & u_3 = u_2, & u_4 = u_1, \\ v_4 - v_1 = \Phi_{41}, & v_2 - v_3 = \Phi_{32}, & v_2 = v_1, & v_3 = v_4 \end{array}$$

so that the compatibility conditions are $\Phi_{21} = -\Phi_{34}$ and $\Phi_{41} = -\Phi_{32}$. For polytropic gas we include the same additional equations as in Configuration 1.

Thus we must have $p_1 = p_3$ and $p_2 = p_4$ implying $u_2 - u_1 = v_4 - v_1$ and $u_4 - u_3 = v_2 - v_3$. Consequently, the solutions are symmetric to $\eta - \xi = v_1 - u_1$ and $\xi + \eta = u_2 + v_2$. Therefore the description focuses on the region $\xi + \eta > u_2 + v_2$ of the domain.

The nonconvex subsonic area lies between the four rarefaction waves. On the segment of the sonic curve facing the first quadrant a shock wave appears. The rarefaction waves $\overrightarrow{R}_{21}$ and $\overrightarrow{R}_{41}$ meet at a point P in the first quadrant. The λ_- characteristic through P forms the lower boundary of the undisturbed $\overrightarrow{R}_{21}$ wave. It crosses $\overrightarrow{R}_{21}$ and turns slightly downward ending at the sonic curve. Analogously, the λ_+ characteristic through P forms the left boundary of the undisturbed $\overrightarrow{R}_{41}$ wave. It crosses $\overrightarrow{R}_{41}$ and turns slightly left ending at the sonic curve. The other $\lambda_\pm$ characteristic lines inside the fans are almost parallel to the corresponding characteristics mentioned above.

The overall structure of our solution corresponds reasonably well with the prediction of [20, Fig. 4.5], although the computed shock on the sonic curve is not present in the prediction. Also, for the calculation presented here, as well as for many others performed by us, the $\lambda_\pm$ characteristic structure never exhibited tangential incidence with the sonic curve and the behavior depicted in [20, Fig. 4.6] was not observed.

Four shock waves.

Configuration 3. $\overleftarrow{S}_{21}\overleftarrow{S}_{32}\overleftarrow{S}_{34}\overleftarrow{S}_{41}$ (Figs. 4 and 5). We have

$$p_1 > p_2,\ p_4 > p_3$$

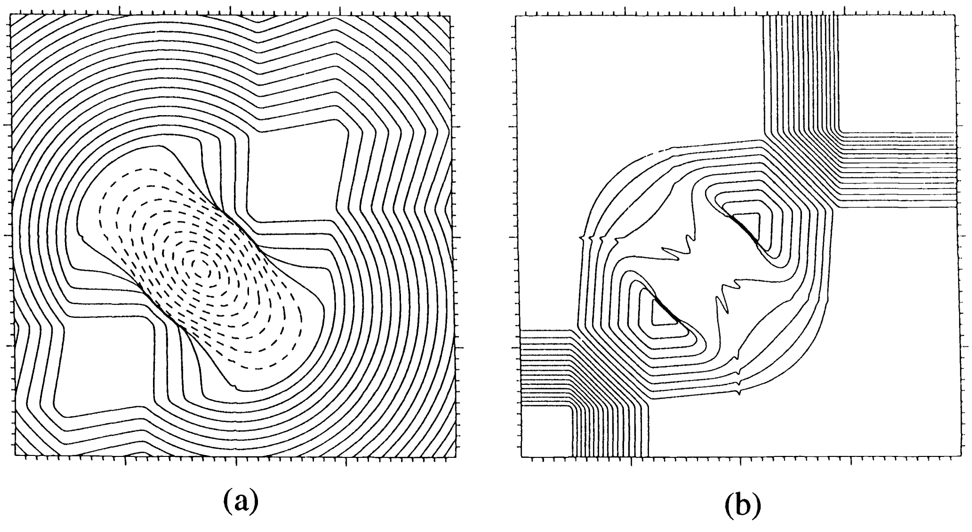

FIG. 2. *Configuration* 2. $p_1 = 1,\ p_2 = .4,\ \rho_1 = 1,\ u_1 = 0,\ v_1 = 0$. (a) *Self-similar Mach no.* (0.01 *to* 2.95); 29 *contour lines*: 0.10 *to* 2.90 *step* 0.10. (b) *Density* (0.258 *to* 1.000); 25 *contour lines*: 0.26 *to* 0.98 *step* 0.03.

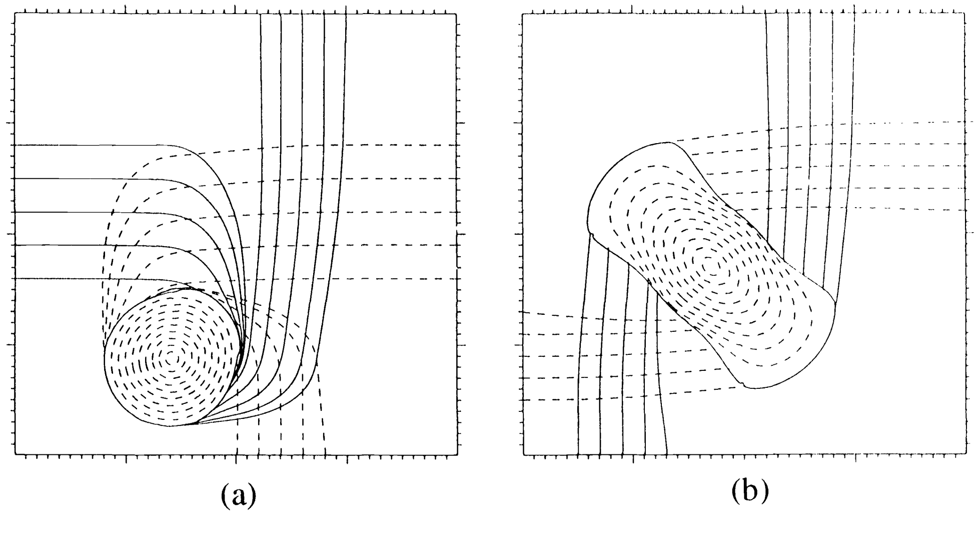

FIG. 3. (a) *Configuration* 1. *Same initial data as in Fig.* 1. *Self-similar Mach no. with char. lines*; 10 *contour lines*: 0.10 *to* 1.00 *step* 0.10. (b) *Configuration* 2. *Same initial data as in Fig. 2. Self-similar Mach no. with char. lines*; 10 *contour lines*: 0.10 *to* 1.00 *step* 0.10.

and

$$u_2 - u_1 = \Psi_{21}, \qquad u_3 - u_4 = \Psi_{34}, \qquad u_3 = u_2, \qquad u_4 = u_1,$$
$$v_4 - v_1 = \Psi_{41}, \qquad v_3 - v_2 = \Psi_{32}, \qquad v_2 = v_1, \qquad v_3 = v_4.$$

This gives the compatibility conditions $\Psi_{21} = \Psi_{34}$ and $\Psi_{41} = \Psi_{32}$. For polytropic gas the following equations are added:

$$\rho_i/\rho_j = \Pi_{ij} \quad \text{for} \quad (i,j) \in \{(2,1),\ (3,4),\ (3,2),\ (4,1)\}.$$

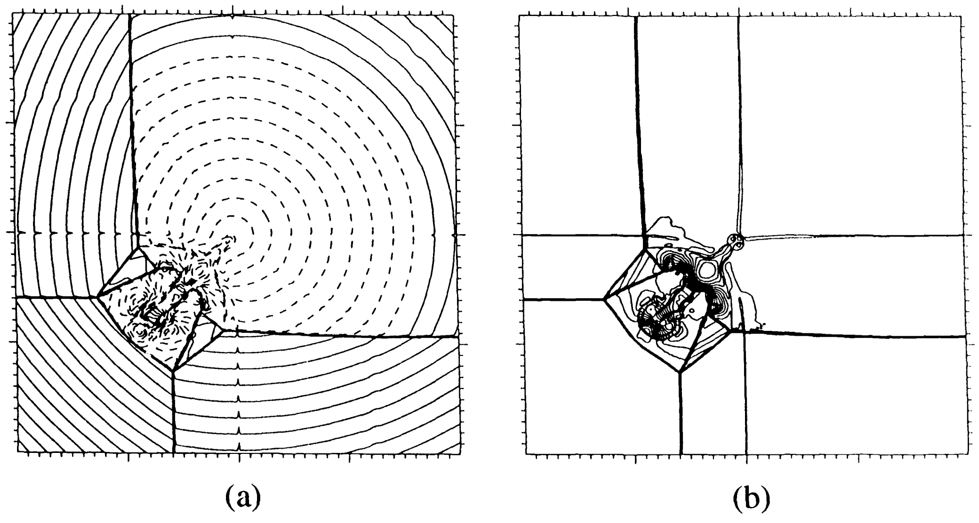

FIG. 4. *Configuration* 3. $p_1 = 1.5$, $p_2 = .3$, $\rho_1 = 1.5$, $u_1 = 0$, $v_1 = 0$. (a) *Self-similar Mach no.* (0.00 *to* 4.67); 46 *contour lines*: 0.10 *to* 4.60 *step* 0.10. (b) *Density* (0.138 *to* 1.756); 32 *contour lines*: 0.16 *to* 1.71 *step* 0.05.

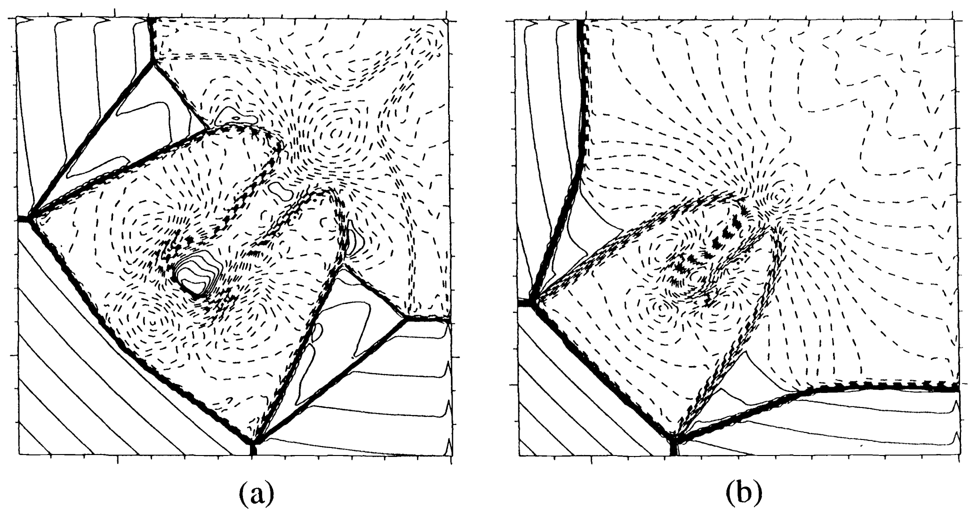

FIG. 5. *Configuration* 3. (a) $p_1 = 1.5$, $p_2 = .3$, $\rho_1 = 1.5$, $u_1 = 0, v_1 = 0$, *showing* 130 × 130 *cells of the upper-right part of the third quadrant. Self-similar Mach no.* (0.01 *to* (3.78); 47 *contour lines*: 0.04 *to* 3.72 *step* 0.08. (b) $p_1 = 1.2$, $p_2 = .35$, $\rho_1 = 1.2$, $u_1 = 0, v_1 = 0$. *showing* 120 × 120 *cells of the upper-right part of the third quadrant. Self-similar Mach no.* (0.00 *to* (3.01); 50 *contour lines*: 0.04 *to* 2.98 *step* 0.06.

It has been proved in [15] that the pressure inequalities required for this configuration and the compatibility conditions listed above can only be satisfied if $p_4 = p_2$ assuming that $1 < \gamma \leq 3$ for polytropic gas. Therefore, we must choose $p_4 = p_2$ (which implies $\rho_4 = \rho_2$), and we get $u_2 - u_1 = v_4 - v_1$. Hence the solutions are symmetric to $\eta - \xi = v_1 - u_1$, and we can concentrate on the region $\eta - \xi > v_1 - u_1$ of the domain.

For the shock speeds σ_{ij} of the shocks $\overleftarrow{S}_{ij}$, the following inequalities hold:

$$\sigma_{21} < \sigma_{34} \quad \text{and} \quad \sigma_{41} < \sigma_{32}.$$

By definition, they are equivalent to

$$u_2 - \sqrt{\frac{\rho_1}{\rho_2}\frac{(p_1 - p_2)}{(\rho_1 - \rho_2)}} < u_3 - \sqrt{\frac{\rho_4}{\rho_3}\frac{(p_4 - p_3)}{(\rho_4 - \rho_3)}}$$

and

$$v_4 - \sqrt{\frac{\rho_1}{\rho_4}\frac{(p_1 - p_4)}{(\rho_1 - \rho_4)}} < v_3 - \sqrt{\frac{\rho_2}{\rho_3}\frac{(p_2 - p_3)}{(\rho_2 - \rho_3)}}.$$

Using $u_3 = u_2$, $v_3 = v_4$, and the compatibility conditions, both inequalities become

$$\rho_1\rho_3 < \rho_2\rho_4 \quad \text{which is equivalent to} \quad p_1p_3 < p_2p_4.$$

Considering the symmetry (for a more general argument not using the assumption $p_2 = p_4$, see [20]), we set

$$p_1 = rp_3 \quad \text{and} \quad p_2 = p_4 = sp_3.$$

Then we must prove that

$$r < s^2 \quad \text{for} \quad r > s > 1$$

under the compatibility condition

$$(r - s)\left(s^{-1/\gamma} - r^{-1/\gamma}\right) = (s - 1)\left(1 - s^{-1/\gamma}\right)$$

for isentropic gas and

$$(r - s)^2 / [(\gamma + 1)r + (\gamma - 1)s] = (s - 1)^2 / [(\gamma + 1) + (\gamma - 1)s]$$

for polytropic gas. The functions

$$f_i(r) = (r - s)\left(s^{-1/\gamma} - r^{-1/\gamma}\right) - (s - 1)\left(1 - s^{-1/\gamma}\right)$$

and

$$f_p(r) = (r - s)^2 [(\gamma + 1) + (\gamma - 1)s] - (s - 1)^2 [(\gamma + 1)r + (\gamma - 1)s]$$

have the following properties:

$$\begin{aligned}
f_i(s) &= -(s - 1)\left(1 - s^{-1/\gamma}\right) < 0,\\
f_i(s^2) &= (s - 1)\left(1 - s^{-1/\gamma}\right)\left(s^{(\gamma-1)/\gamma} - 1\right) > 0,\\
f_i''(r) &= \gamma^{-2} r^{-(2\gamma+1)/\gamma}[(\gamma - 1)r + (\gamma + 1)s] > 0,\\
f_p(s) &= -2\gamma s(s - 1)^2 < 0,\\
f_p(s^2) &= (\gamma - 1)s(s - 1)^2(s^2 - 1) > 0,\\
f_p''(r) &= 2 > 0.
\end{aligned}$$

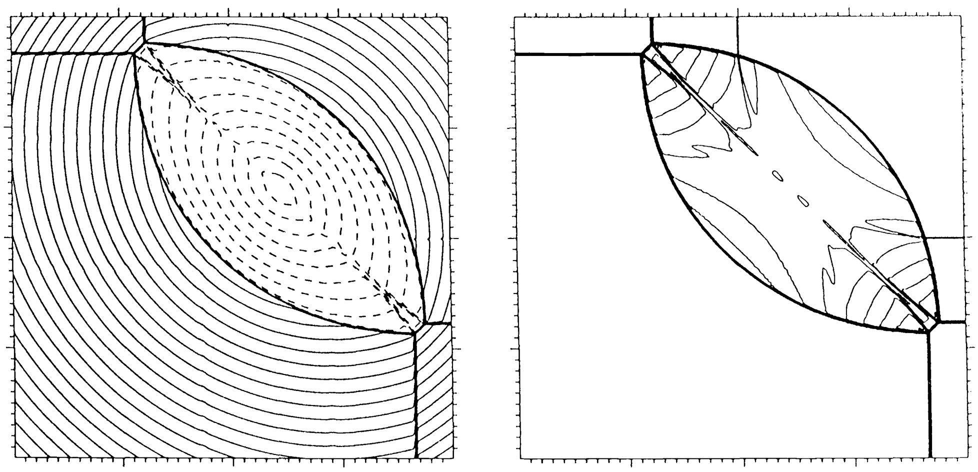
Thus the root $r > s$ of f_i or f_p, which is also the solution of the corresponding compatibility condition, satisfies $r < s^2$.

The shock $\overleftarrow{S}_{21}$ intersects the sonic circle of the constant state in the first quadrant before it meets $\overleftarrow{S}_{32}$ as expected from the shock speed inequalities. $\overleftarrow{S}_{21}$ bends toward the subsonic area. The intersection of $\overleftarrow{S}_{21}$ and $\overleftarrow{S}_{32}$ creates a three-shock configuration. The Mach shock and its symmetric counterpart join and bound the subsonic area. A slip line reaches from the branch point into the subsonic area toward the symmetry axis. Depending on the strength of the shocks we observe the different types of Mach reflections: the simple Mach reflection where the area between the reflected shock and the slip line is subsonic, the complex Mach reflection (Fig. 5(b)) where a part of that area is supersonic, and the double Mach reflection (Figs. 4, 5(a)) with another three-shock configuration. Thus far, we have not observed regular reflection and, for all cases of Mach reflection which we studied, the slip line rolls up into a vortex rather than intersecting the symmetry line at a self-similar stagnation point. The prediction of [20, Fig. 5.2] is remarkably accurate. We note that the extra slip lines at the interfaces of the quadrants in Fig. 4 are numerical artifacts that had been studied earlier [1], [6] and are due to a "starting error."

Configuration 4. $\overleftarrow{S}_{21}\overrightarrow{S}_{32}\overrightarrow{S}_{34}\overleftarrow{S}_{41}$ (Fig. 6) We have

$$p_1 > p_2,\ p_4 < p_3$$

and the same equations and compatibility conditions as in Configuration 3.



(a) (b)

FIG. 6. *Configuration* 4. $p_1 = 1.1$, $p_2 = .35$, $\rho_1 = 1.1$, $u_1 = 0$, $v_1 = 0$. (a) *Self-similar Mach no.* (0.00 *to* 3.39); 33 *contour lines*: 0.10 *to* 3.30 *step* 0.10. (b) *Density* (0.506 *to* 1.932); 29 *contour lines*: 0.52 *to* 1.92 *step* 0.05.

Necessarily, we must have $p_1 = p_3$ and $p_2 = p_4$ (which implies $\rho_1 = \rho_3$ and $\rho_2 = \rho_4$) yielding $u_2 - u_1 = v_4 - v_1$ and $u_3 - u_4 = v_3 - v_2$. Consequently, the solutions are symmetric to $\eta - \xi = v_1 - u_1$ and $\xi + \eta = u_2 + v_2$. Therefore, the description focuses on the region $\eta - \xi > v_1 - u_1$ of the domain.

It is easy to conclude from the equations that $\sigma_{21} < \sigma_{34}$ and $\sigma_{41} < \sigma_{32}$. Accordingly, the shock $\overleftrightarrow{S}_{21}$ interacts with $\overrightarrow{S}_{32}$. This interaction creates a pair of three-shock configurations. The subsonic area is bounded by the joining Mach shocks and the reflected shocks so that it has an oval shape. As in Configuration 3 we observe the different types of Mach reflections determined by the strength of the shocks. Illustrated here is a case of simple Mach reflection.

Two rarefaction and two shock waves.

Configuration 6. $\overrightarrow{R}_{21}\overrightarrow{S}_{32}\overleftarrow{R}_{34}\overleftarrow{S}_{41}$ (Fig. 7). We have

$$p_1 > p_2,\ p_4 < p_3$$

and

$$\begin{aligned} &u_2 - u_1 = \Phi_{21}, && u_4 - u_3 = \Phi_{34}, && u_3 = u_2, && u_4 = u_1, \\ &v_4 - v_1 = \Psi_{41}, && v_3 - v_2 = \Psi_{32}, && v_2 = v_1, && v_3 = v_4, \end{aligned}$$

so that the compatibility conditions are $\Phi_{21} = -\Phi_{34}$ and $\Psi_{41} = \Psi_{32}$.

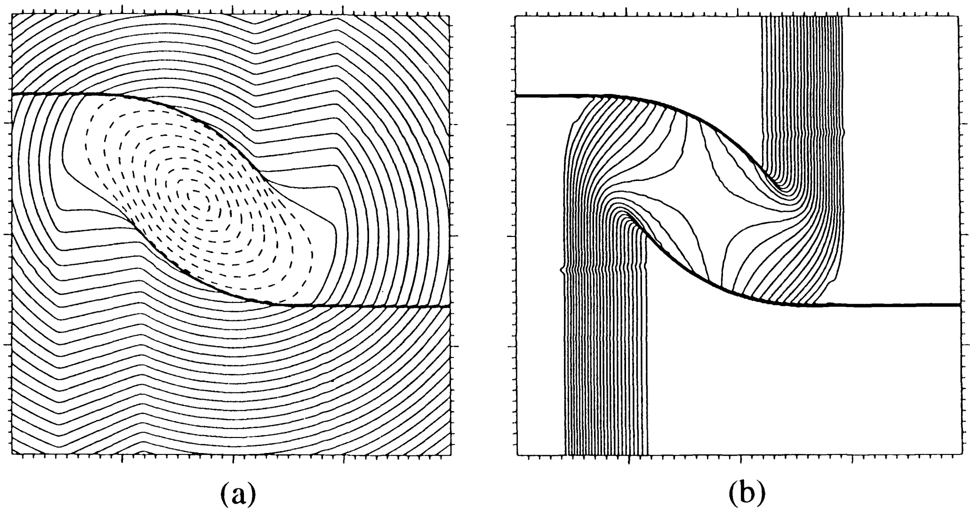


FIG. 7. *Configuration* 6. $A = 1,\ \gamma = 1.4,\ \rho_1 = 1,\ \rho_2 = .5,\ u_1 = 0,\ v_1 = 0$. (a) *Self-similar Mach no.* (0.00 *to* 4.00); 40 *contour lines*: 0.10 *to* 4.00 *step* 0.10. (b) *Density* (0.495 *to* 1.002); 25 *contour lines*: 0.51 *to* 0.99 *step* 0.02.

For polytropic gas, the equations

$$\rho_3/\rho_2 = \Pi_{32}, \quad \rho_4/\rho_1 = \Pi_{41}, \quad \rho_2/\rho_1 = (p_2/p_1)^{1/\gamma}, \quad \text{and} \quad \rho_3/\rho_4 = (p_3/p_4)^{1/\gamma}$$

must be added. As mentioned in §2, this configuration is impossible for this case [15].

For isentropic gas the pressure inequalities required for this configuration and the compatibility conditions listed above can only be satisfied if $p_3 = p_1$ and $p_4 = p_2$ [15]. Consequently, we must choose $p_3 = p_1$ and $p_4 = p_2$ (which implies $\rho_3 = \rho_1$ and $\rho_4 = \rho_2$). Thus the solutions are symmetric with respect to the point $(\xi, \eta) = (u_1, v_1)$, and we can focus the description on the upper part of the domain.

The shock $\overrightarrow{S}_{32}$ bends downward before it dissolves inside the rarefaction fan of $\overrightarrow{R}_{21}$. Thus, the predicted intersection of the shocks $\overrightarrow{S}_{32}$ and $\overleftarrow{S}_{41}$ (see [20, Fig. 6.4]) does not occur in our computations; as a consequence, the calculated results do not contain any slip surfaces in contrast to [20, Fig. 6.4]. The rarefaction wave $\overleftarrow{R}_{34}$ turns right in front of the shock $\overrightarrow{S}_{32}$. The subsonic area is centered about the point (u_1, v_1). The λ_+ characteristic lines inside $\overrightarrow{R}_{21}$ are parallel to the contour lines inside the fan and end at the sonic curve.

3.2. Cases involving slip line initial data. Now we discuss the eleven possible configurations involving slip lines. Beside the relations for the initial data listed for each configuration, we must include additional relations for polytropic gas. For a rarefaction or a shock wave between the ith and jth quadrant ($i, j \in \{1, \dots, 4\}$), we add

$$\rho_i/\rho_j = (p_i/p_j)^{1/\gamma} \quad \text{or} \quad \rho_i/\rho_j = \Pi_{ij},$$

respectively.

The predicted results of [20] are considerably more speculative for these more difficult cases. Consequently, a feature-by-feature comparison with the computed solutions will not be attempted.

Four slip lines.

Configuration A. $\overleftrightarrow{J_{21}J_{32}J_{34}J_{41}}$ (motion in opposite directions; Fig. 8). We have $p_1 = p_2 = p_3 = p_4$ and

$$u_1 = u_2 < u_3 = u_4, \qquad v_1 = v_4 < v_3 = v_2.$$

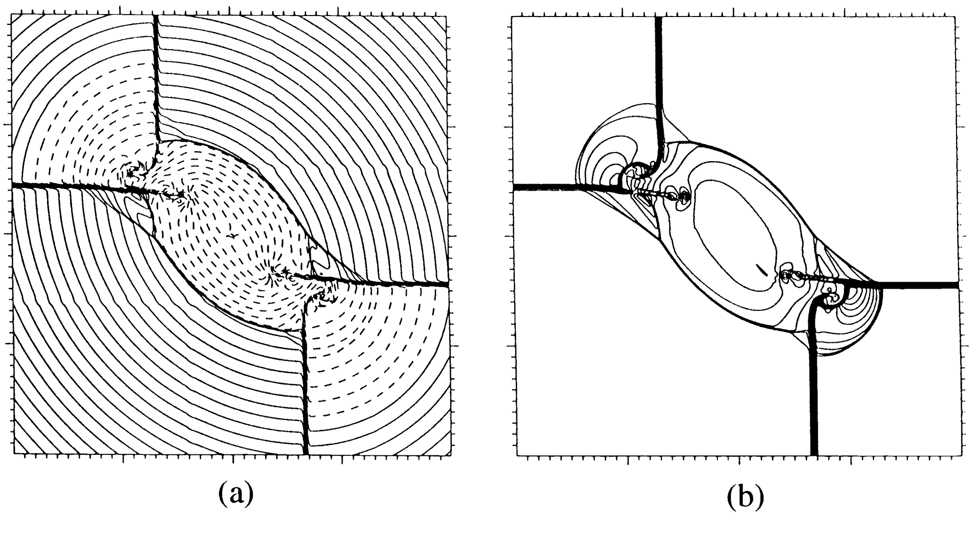

FIG. 8. *Configuration* A. $p_1 = 1$, $\rho_1 = 1$, $\rho_2 = 2$, $\rho_3 = 1$, $\rho_4 = 3$, $u_1 = -.75$, $u_3 = .75$, $v_1 = -.5$, $v_2 = .5$. (a) *Self-similar Mach no.* (0.00 *to* 3.39); 33 *contour lines*: 0.10 *to* 3.30 *step* 0.10. (b) *Density* (1.000 *to* 4.011); 30 *contour lines*: 1.05 *to* 3.95 *step* 0.10.

Only for isentropic gas are the solutions symmetric with respect to the point $(\xi, \eta) = \left(\frac{1}{2}(u_1 + u_3), \frac{1}{2}(v_1 + v_2)\right)$. The slip lines J_{21} and J_{32} meet the sonic circle of the constant state in the second quadrant and continue as almost straight lines so that a quarter of the sonic circle lies in between. The equivalent is true for the slip lines J_{34} and J_{41} in the fourth quadrant. Inside the subsonic area the slip lines bend and end in spirals. Centered about the point $\left(\frac{1}{2}(u_1 + u_3), \frac{1}{2}(v_1 + v_2)\right)$ there is an oval part of the subsonic area bounded by shocks. These shocks form simple Mach reflections near the slip lines (the contact surfaces emanating from the triple points are only barely discernible here).

Configuration B. $\overrightarrow{J_{21}J_{32}J_{34}J_{41}}$ (clockwise motion; Fig. 9). We have $p_1 = p_2 = p_3 = p_4$ and

$$u_1 = u_2 > u_3 = u_4, \quad v_1 = v_4 < v_3 = v_2.$$

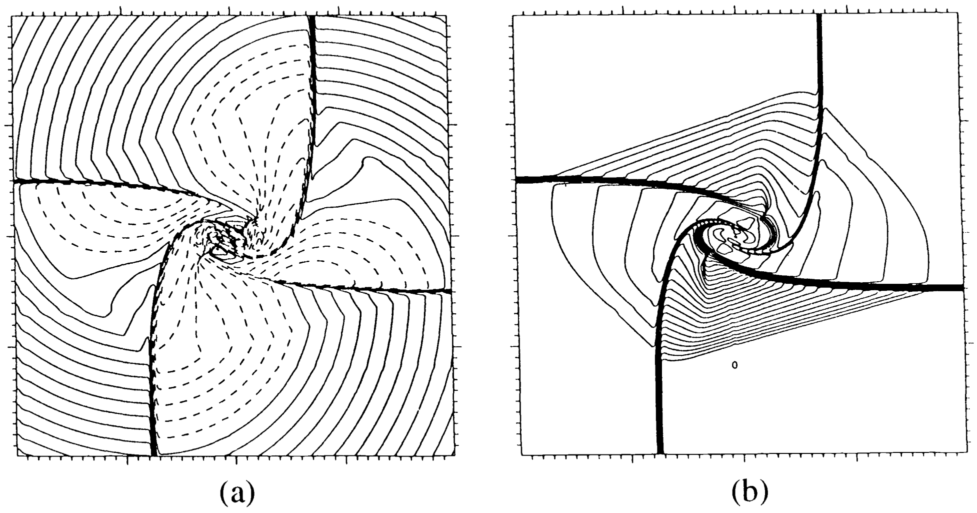

FIG. 9. *Configuration* B. $p_1 = 1$, $\rho_1 = 1$, $\rho_2 = 2$, $\rho_3 = 1$, $\rho_4 = 3$, $u_1 = .75$, ; $u_3 = -.75$, $v_1 = -.5$, $v_2 = .5$. (a) *Self-similar Mach no.* (0.04 *to* 2.35); 23 *contour lines*: 0.10 *to* 2.30 *step* 0.10. (b) *Density* (0.207 *to* 3.064); 29 *contour lines*: 0.25 *to* 3.05 *step* 0.10.

The solutions have the same symmetry properties as in Configuration A. The structure of the solutions is one of a vortex turning clockwise. The slip lines spiral around its center, and the subsonic area has the shape of a four-bladed propeller.

Two neighboring slip lines.

Configuration C. $\overrightarrow{R}_{21}J_{32}J_{34}\overrightarrow{R}_{41}$ (Fig. 10). We have $p_1 > p_2 = p_3 = p_4$ and

$$u_2 - u_1 = \Phi_{21}, \quad u_3 = u_4 = u_1, \quad v_4 - v_1 = \Phi_{41}, \quad v_3 = v_2 = v_1.$$

The solutions are symmetric to $\eta - \xi = v_1 - u_1$. In the region $\xi + \eta > u_3 + v_3$ the solution resembles that of Configuration 2. The slip lines J_{32} and J_{34} meet the sonic circle of the constant state in the third quadrant and continue as almost straight lines so that a quarter of the sonic circle lies in between.

Configuration D. $\overleftarrow{R}_{21}J_{32}J_{34}\overleftarrow{R}_{41}$ (Fig. 11). We have $p_1 < p_2 = p_3 = p_4$ and

$$u_1 - u_2 = \Phi_{21}, \quad u_3 = u_4 = u_1, \quad v_1 - v_4 = \Phi_{41}, \quad v_3 = v_2 = v_1.$$

The solutions are symmetric to $\eta - \xi = v_1 - u_1$. The slip lines J_{32} and J_{34} meet the sonic circle of the constant state in the third quadrant and continue slightly bent so that a quarter of the sonic circle lies in between. The $\lambda_{+(-)}$ characteristic lines inside $\overleftarrow{R}_{41}$ ($\overleftarrow{R}_{21}$) are almost parallel to the contour lines inside the fan and end at the sonic circle. Outside the rarefaction waves the subsonic area is bounded by a circular shock wave.

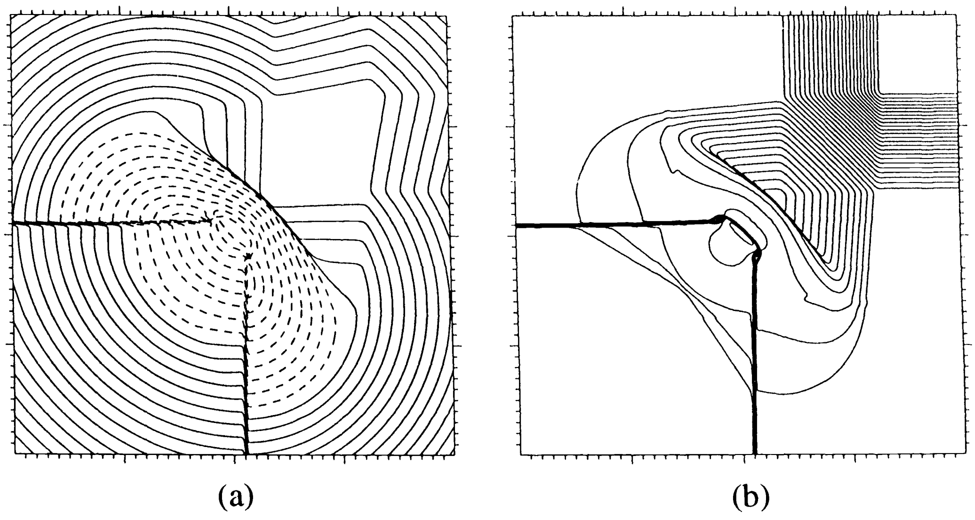

FIG. 10. *Configuration* C. $p_1 = 1,\ p_2 = .4,\ \rho_1 = 1,\ \rho_3 = .8,\ u_1 = .1,\ v_1 = .1$. (a) *Self-similar Mach no.* (0.00 *to* 2.60); 26 *contour lines*: 0.10 *to* 2.60 *step* 0.10. (b) *Density* (0.258 *to* 1.000); 37 *contour lines*: 0.27 *to* 0.99 *step* 0.02.

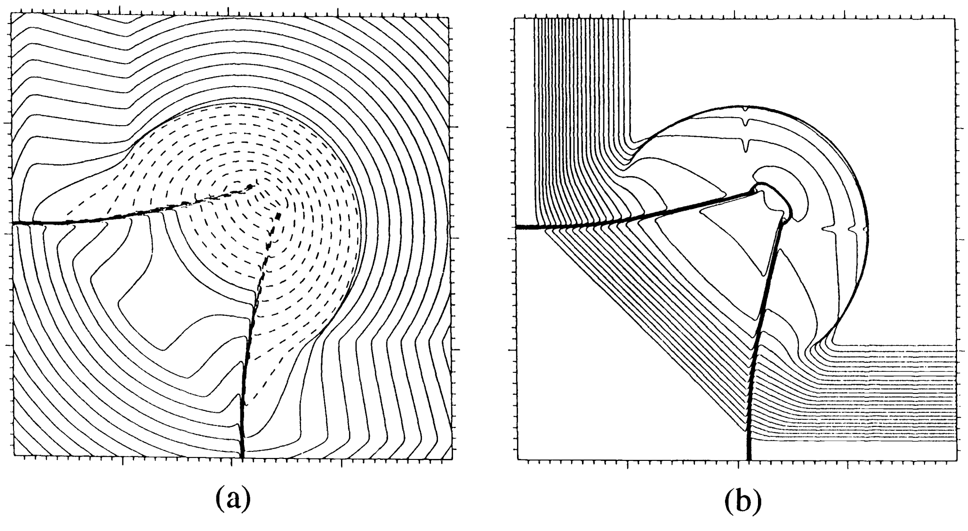

FIG. 11. *Configuration* D. $p_1 = .4,\ p_2 = 1,\ \rho_2 = 1,\ \rho_3 = .8,\ u_1 = .1,\ v_1 = .1$. (a) *Self-similar Mach no.* (0.00 *to* 2.61); 26 *contour lines*: 0.10 *to* 2.60 *step* 0.10. (b) *Density* (0.503 *to* 1.001); 25 *contour lines*: 0.51 *to* 0.99 *step* 0.02.

Configuration E. $\overleftarrow{S}_{21}J_{32}J_{34}\overleftarrow{S}_{41}$ (Fig. 12). We have $p_1 > p_2 = p_3 = p_4$ and

$$u_2 - u_1 = \Psi_{21}, \quad u_3 = u_4 = u_1, \quad v_4 - v_1 = \Psi_{41}, \quad v_3 = v_2 = v_1.$$

The solutions are symmetric to $\eta - \xi = v_1 - u_1$. The shocks $\overleftarrow{S}_{21}$ and $\overleftarrow{S}_{41}$ intersect the sonic circle of the constant state in the first quadrant and end at the slip lines. Between the slip lines J_{32} and J_{34}, which bend inside the subsonic area and end in

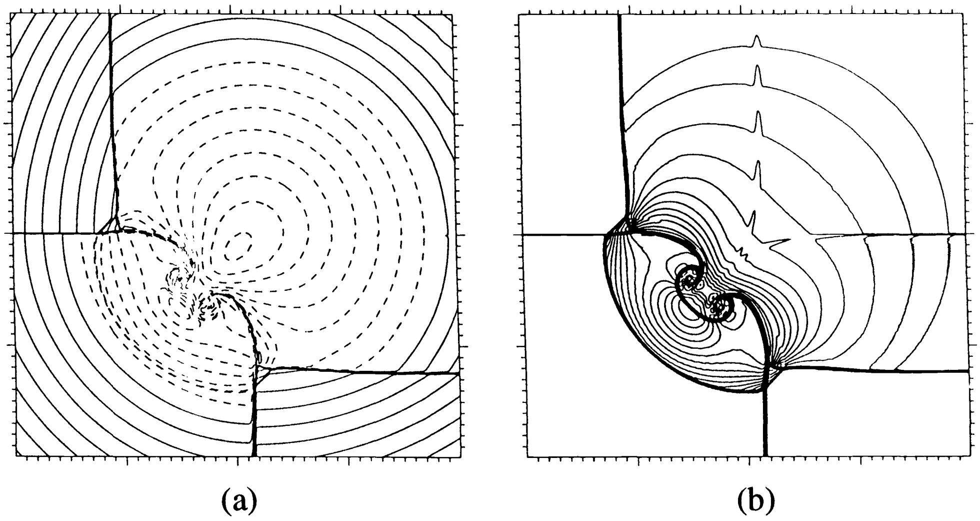

FIG. 12. *Configuration* E. $p_1 = 1,\ p_2 = .4,\ \rho_1 = 1,\ \rho_3 = .8,\ u_1 = .1,\ v_1 = 0$. (a) *Self-similar Mach no.* (0.01 *to* 2.43); 24 *contour lines*: 0.10 *to* 2.40 *step* 0.10. (b) *Density* (0.531 *to* 1.225); 34 *contour lines*: 0.55 *to* 1.21 *step* 0.02.

spirals, the subsonic area is bounded by an oval shock wave. This shock is connected to the shocks $\overleftarrow{S}_{21}$ and $\overleftarrow{S}_{41}$ by two simple Mach reflections.

Configuration F. $\overrightarrow{S}_{21}J_{32}J_{34}\overrightarrow{S}_{41}$ (Fig. 13). We have $p_1 < p_2 = p_3 = p_4$ and the same equations as in Configuration E.

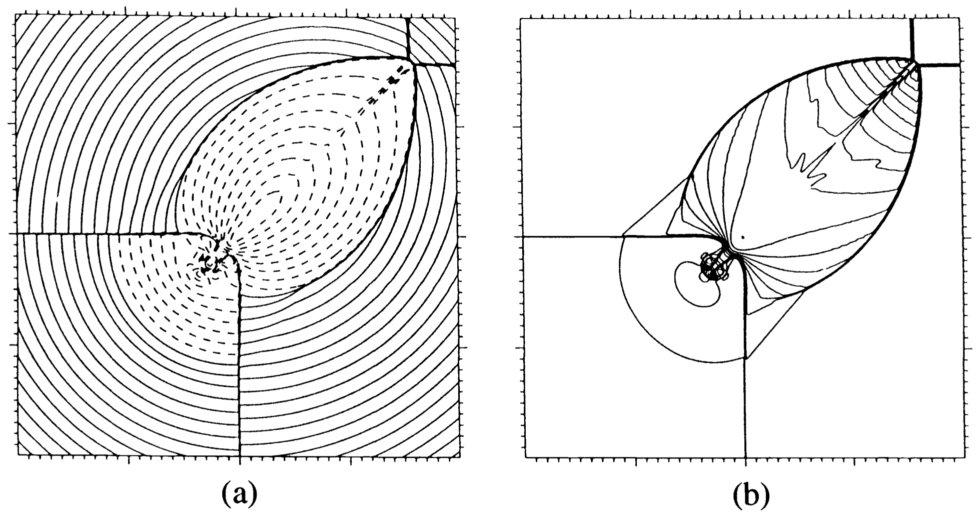

FIG. 13. *Configuration* F. $p_1 = .4,\ p_2 = 1,\ \rho_2 = 1,\ \rho_3 = .8,\ u_1 = 0,\ v_1 = 0$. (a) *Self-similar Mach no.* (0.00 *to* 2.84); 28 *contour lines*: 0.10 *to* 2.80 *step* 0.10. (b) *Density* (0.531 *to* 1.708); 30 *contour lines*: 0.54 *to* 1.70 *step* 0.04.

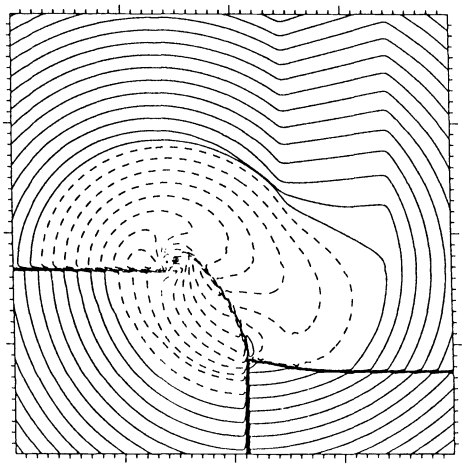
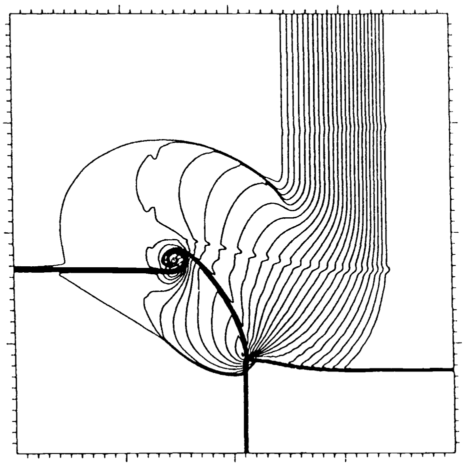
The solutions are symmetric to $\eta - \xi = v_1 - u_1$. The slip lines J_{32} and J_{34} meet the sonic circle of the constant state in the third quadrant and continue as almost straight lines so that a quarter of the sonic circle lies in between. Inside the subsonic area the slip lines bend and end in spirals. The shocks $\overrightarrow{S}_{21}$ and $\overrightarrow{S}_{41}$ interact like the pair of shocks in Configuration 4.

Configuration G. $\overrightarrow{R}_{21}J_{32}J_{34}\overleftarrow{S}_{41}$ (Fig. 14). We have $p_1 > p_2 = p_3 = p_4$ and

$$u_2 - u_1 = \Phi_{21}, \quad u_3 = u_4 = u_1, \quad v_4 - v_1 = \Psi_{41}, \quad v_3 = v_2 = v_1.$$



(a)



(b)

FIG. 14. *Configuration* G. $p_1 = 1$, $p_2 = .4$, $\rho_1 = 1$, $\rho_3 = .8$, $u_1 = .1$, $v_1 = -.3$. (a) *Self-similar Mach no.* (0.03 *to* 2.69); 26 *contour lines*: 0.10 *to* 2.60 *step* 0.10. (b) *Density* (0.429 *to* 1.004); 29 *contour lines*: 0.43 *to* 0.99 *step* 0.02.

The slip lines J_{32} and J_{34} bend after entering the subsonic area and end in a spiral. The rarefaction wave $\overrightarrow{R}_{21}$ turns backward in front of the shock $\overleftarrow{S}_{41}$ that ends at the slip line J_{34}. The λ_+ characteristic lines inside $\overrightarrow{R}_{21}$ are almost parallel to the contour lines inside the fan and end at the sonic circle.

Configuration H. $\overleftarrow{R}_{21}J_{32}J_{34}\overrightarrow{S}_{41}$ (Fig. 15). We have $p_1 < p_2 = p_3 = p_4$ and

$$u_1 - u_2 = \Phi_{21}, \quad u_3 = u_4 = u_1, \quad v_4 - v_1 = \Psi_{41}, \quad v_3 = v_2 = v_1.$$

The slip lines J_{32} and J_{34} bend after entering the subsonic area and end in a spiral. The shock $\overrightarrow{S}_{41}$ bends downward before it dissolves inside the rarefaction fan of $\overleftarrow{R}_{21}$ that turns right after crossing the slip line J_{32}. The λ_- characteristic lines inside $\overleftarrow{R}_{21}$ are almost parallel to the contour lines inside the fan and end at the sonic circle.

Two nonneighboring slip lines.

Configuration I. $J_{21}\overrightarrow{R}_{32}J_{34}\overrightarrow{R}_{41}$ (Fig. 16). We have $p_1 = p_2 > p_3 = p_4$ and

$$u_1 = u_2 = u_3 = u_4, \quad v_4 - v_1 = \Phi_{41}, \quad v_3 - v_2 = \Phi_{32}.$$

The slip lines J_{21} and J_{34}, which bend and join inside the subsonic area, divide the solution into a left and right part. In general, the rarefaction waves $\overrightarrow{R}_{32}$ and $\overrightarrow{R}_{41}$ move with different velocities so that they are shifted against each other. Below these waves the sonic curve is almost circular. Depending on the vertical velocities, weak shocks are formed below the rarefaction waves.

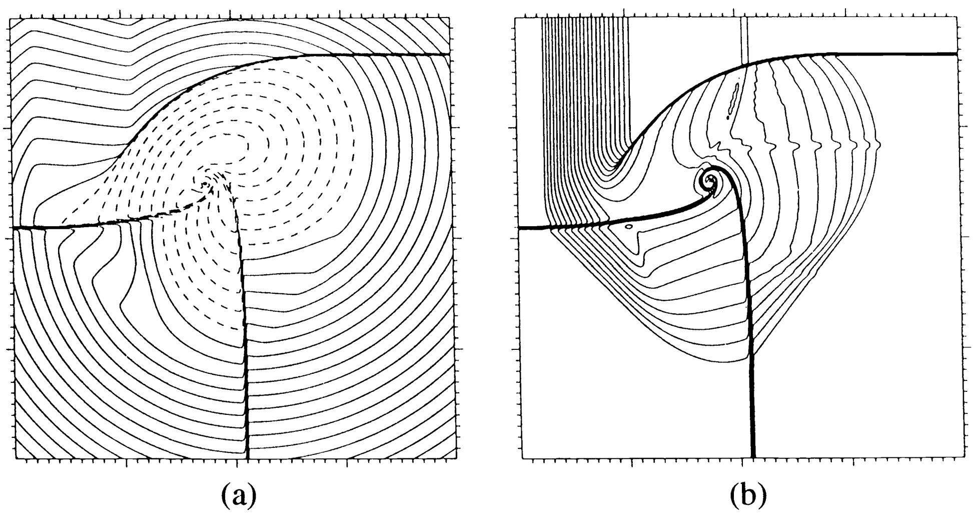


FIG. 15. *Configuration* H. $p_1 = .4$, $p_2 = 1$, $\rho_3 = .8$, $\rho_4 = 1$, $u_1 = .1$, $v_1 = .1$. (a) *Self-similar Mach no.* (0.06 *to* 2.87); 28 *contour lines*: 0.10 *to* 2.80 *step* 0.10. (b) *Density* (0.524 *to* 1.023); 24 *contour lines*: 0.53 *to* 0.99 *step* 0.02.

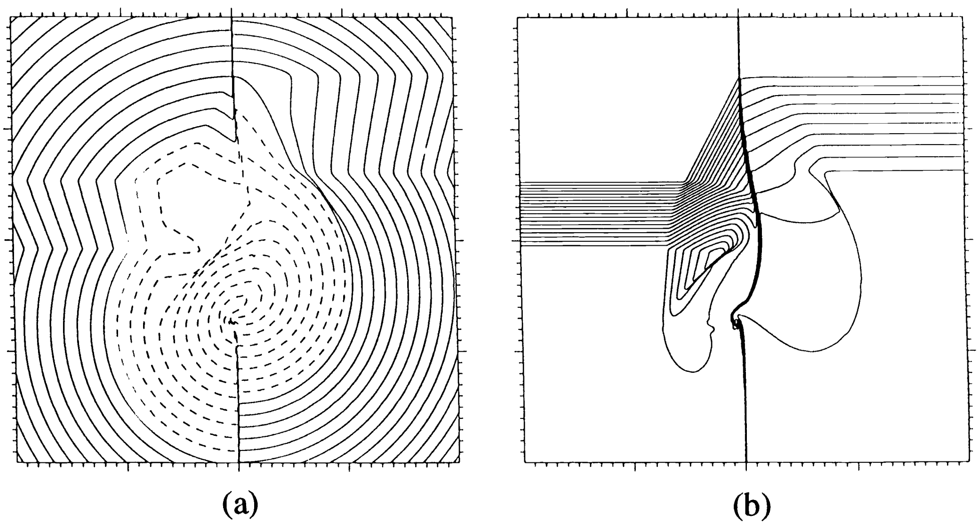

FIG. 16. *Configuration* I. $p_1 = 1$, $p_3 = .4$, $\rho_1 = 1$, $\rho_2 = 2$, $u_1 = 0$, $v_1 = .3$, $v_2 = -.3$. (a) *Self-similar Mach no.* (0.02 *to* 2.44); 24 *contour lines*: 0.10 *to* 2.40 *step* 0.10. (b) *Density* (0.515 *to* 2.000); 30 *contour lines*: 0.53 *to* 1.98 *step* 0.05.

Configuration J. $J_{21}\overleftarrow{S}_{32}J_{34}\overleftarrow{S}_{41}$ (Fig. 17). We have $p_1 = p_2 > p_3 = p_4$ and

$$u_1 = u_2 = u_3 = u_4, \quad v_4 - v_1 = \Psi_{41}, \quad v_3 - v_2 = \Psi_{32}.$$

The slip lines J_{21} and J_{34} separate the solution into a left and right section. Typically, the shocks $\overleftarrow{S}_{32}$ and $\overleftarrow{S}_{41}$ are shifted against each other. Above these shocks the sonic curve is nearly circular. $\overleftarrow{S}_{32}$ and $\overleftarrow{S}_{41}$ are connected by two simple Mach reflections. Their slip lines as well as J_{21} and J_{34}, meet in a vortex inside the subsonic area.

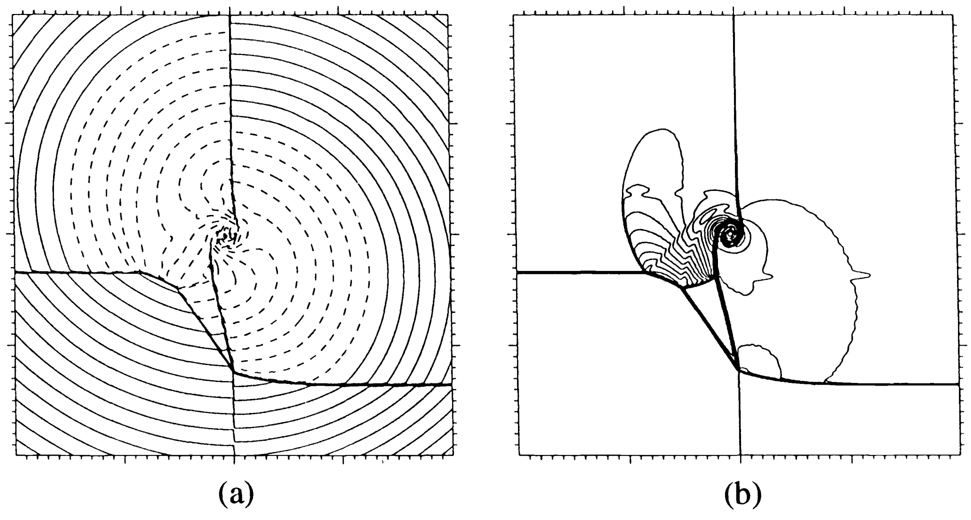

FIG. 17. *Configuration* J. $p_1 = 1$, $p_3 = .4$, $\rho_1 = 1$, $\rho_2 = 2$, $u_1 = 0$, $v_1 = -.3$, $v_2 = .3$. (a) *Self-similar Mach no.* (0.04 *to* 2.55); 25 *contour lines*: 0.10 *to* 2.50 *step* 0.10. (b) *Density* (0.531 *to* 2.407); 37 *contour lines*: 0.57 *to* 2.37 *step* 0.05.

Configuration K. $J_{21}\overleftarrow{S}_{32}J_{34}\overrightarrow{R}_{41}$ (Fig. 18). We have $p_1 = p_2 > p_3 = p_4$ and

$$u_1 = u_2 = u_3 = u_4, \quad v_4 - v_1 = \Phi_{41}, \quad v_3 - v_2 = \Psi_{32}.$$

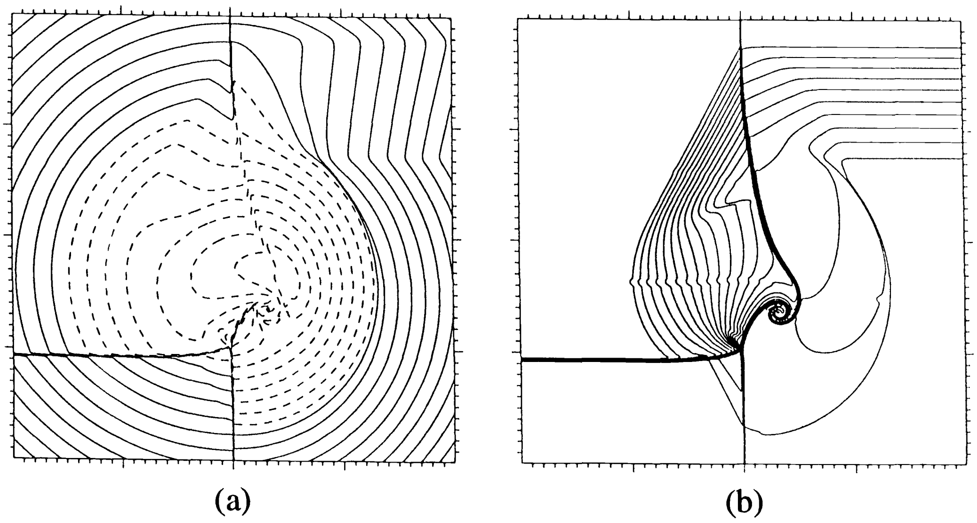

FIG. 18. *Configuration* K. $p_1 = 1$, $p_3 = .4$, $\rho_1 = 1$, $\rho_2 = 2$, $u_1 = 0$, $v_1 = .3$, $v_2 = -.3$. (a) *Self-similar Mach no.* (0.01 *to* 2.09); 20 *contour lines*: 0.10 *to* 2.00 *step* 0.10. (b) *Density* (0.512 *to* 2.003); 30 *contour lines*: 0.53 *to* 1.98 *step* 0.05.

The slip lines J_{21} and J_{34}, which bisect the solution into a left and right portion, join in a vortex inside the subsonic area. The shock $\overleftarrow{S}_{32}$ ends at J_{34}. Below $\overrightarrow{R}_{41}$ the subsonic area is partly bounded by a shock wave.

4. Conclusions. The computational results presented here demonstrate the complex phenomenology inherent in the two-dimensional gas dynamic Riemann problem, despite the limitation that each of the four jumps consists of a single elementary wave. The predictions of [20] are close to our results in most cases where this is reasonable to expect. One discrepancy is that predicted shock waves do not appear in the computations or that we have found unpredicted shock waves. Also, for Configuration 2 and Configuration C, predicted compression waves are actually computed as shock waves over a substantial range of parameter space. These changes can have further consequences for the overall solution. However, the present work has led to the discovery of many new flowfield patterns; this is especially true for cases involving slip line initial data. For such cases we remark that some of the other cases appear as part of the flowfield pattern, as might be expected.

An important result is that many of the familiar oblique shock wave reflection (OSWR) flowfields appear here. An interesting question is whether or not OSWR is a subset of the two-dimensional Riemann problem, i.e., given a wedge angle and shock wave Mach number [5], can Riemann problem initial data be found so as to construct the given OSWR case? Note that this is nontrivial only because of the restricted set of initial data allowed.

We note here that if the four initial states were separated by two lines not necessarily perpendicular, the number of allowable distinct initial configurations would increase to 77 (respectively, 75) for isentropic (respectively, polytropic) gas. Given the many other possible generalizations, including a change of equation of state, it is easy to see that the two-dimensional Riemann problem contains many possibilities.

It would appear that this is a very negative result regarding the direct use of the two-dimensional Riemann problem in constructing an unsplit RCM (for analytical or numerical purposes) or finite difference schemes. However, the set of points in physical space-time involving such complex interactions is of high codimension, and it still might be hoped that such schemes are possible. Whether or not the present calculations will prove useful in this endeavor, we can certainly expect that the results here can be used as test or reference cases in the code development process.

CONSTRUCTION OF *K*-DIMENSIONAL DELAUNAY TRIANGULATIONS USING LOCAL TRANSFORMATIONS*

BARRY JOE†

Abstract. In [SIAM J. Sci. Statist. Comput., 10 (1989), pp. 718–741] and [Comput. Aided Geom. Des., 8 (1991), pp. 123–142] the author presented algorithms that use local transformations to construct a Delaunay triangulation of a set of n three-dimensional points. This paper proves that local transformations can be used to construct a Delaunay triangulation of a set of n k-dimensional points for any $k \geq 2$, and presents algorithms using this approach. The empirical time complexities of these algorithms are discussed for sets of random points from the uniform distribution as well as worst-case time complexities. These time complexities are about the same or better than those of other algorithms for constructing k-dimensional Delaunay triangulations (when $k \geq 3$).

Key words. k-dimensional triangulation, Delaunay triangulation, Voronoi tessellation, local transformations, computational geometry, mesh generation

AMS subject classifications. 65N50, 68Q20, 68U05

1. Introduction. Given n k-dimensional (k-D) points (i.e., points in Euclidean space E^k), the k-D Delaunay triangulation problem is to connect them into nonoverlapping simplices that fill the convex hull of the points such that the empty circumhypersphere criterion is satisfied, i.e., the hypersphere passing through the $k+1$ vertices of any simplex of the triangulation contains none of the given n points in its interior. (A simplex is the convex hull of $k+1$ affinely independent points; it is a triangle in two dimensions and a tetrahedron in three dimensions.) A Delaunay triangulation is unique if no $k+2$ of the n given points are on the same hypersphere.

The Delaunay triangulation is also the dual of the Voronoi tessellation of the n given points or sites, where the Voronoi tessellation is the partitioning of E^k into n subregions such that each subregion contains the points of E^k that are closer to one site than all the other sites [22], [5]. Given the Delaunay triangulation, it is straightforward to construct the Voronoi tessellation in time proportional to the size of the triangulation (and vice versa). Two- and three-dimensional Delaunay triangulations are used for finite element mesh generation [3], [10], [11], [14], [25]. k-D Delaunay triangulations are used for surface interpolation and contouring [17], [18], [20]. Other applications of the two geometric structures are given in [2] and [29].

We are interested in algorithms that can construct k-D Delaunay triangulations (or Voronoi tessellations) for any $k \geq 2$. Some algorithms work only in two dimensions (so far), e.g., the $O(n \log n)$ divide and conquer approach [22], [19] and sweepline approach [9]. The edge swapping approach can be used for constructing two-dimensional Delaunay triangulations [17], [28]. This local transformation approach was recently extended to the three-dimensional case [12], [13], where face swaps are used instead of edge swaps. Lawson has shown that there are two different ways to triangulate some sets of $k+2$ k-D points [18]. Hence local transformations are also possible in k dimensions, $k \geq 4$. In this paper, we prove that local transformations can be used to construct k-D Delaunay triangulations using an incremental approach, and we present algorithms that are k-D versions of those in [13].

Other algorithms for constructing k-D Delaunay triangulations (or Voronoi tessellations) are given in [29], [2], [1], and [5]. Watson's algorithm [29] uses an incremental approach in which the Delaunay triangulation of the first i data points is updated from the Delaunay triangulation of the first $i-1$ data points by first deleting all simplices whose circumhypershere contains the ith data point and then adding the simplices involving the ith data point. Bowyer's algorithm [2] also uses an incremental approach, but updates the Voronoi tessellation instead of the Delaunay triangulation. The estimated time complexities of these two algorithms (for sets of random points) are $O(n^{(2k-1)/k})$ and $O(n^{1+1/k})$, respectively. The worst-case time complexities are not discussed in these two papers. We are assuming here that k is a small fixed constant; as a function of k and n, the time complexities would also include a factor involving k, e.g., k^3, which depends on implementation details.

The algorithm by Avis and Bhattacharya [1] constructs a Delaunay triangulation by finding one simplex at a time; from an unmatched facet of an existing simplex, a search is made for the vertex of the other simplex sharing this facet. For sets of random points from the uniform distribution, the empirical time complexity of this algorithm is $O(n^2)$ for any k. The worst-case time complexity is $O(n^{\lceil k/2\rceil+1})$. This is because in the worst-case, the number of simplices in a Delaunay triangulation is $O(n^{\lceil k/2\rceil})$ [5].

An algorithm for constructing k-D Delaunay triangulations based on their relationship with $(k+1)$-D convex hulls is described in [5]. This algorithm projects the n k-D data points onto a paraboloid in $k+1$ dimensions and constructs the convex hull of the $(k+1)$-D points; the k-D Delaunay triangulation is then obtained from an appropriate portion of the convex hull. The worst-case time complexity of this algorithm is $O(n \log n)$ for $k = 2$ and $O(n^{\lfloor k/2\rfloor+1})$ for $k \geq 3$; these complexities are based on the worst-case time complexities of algorithms for constructing convex hulls [21], [26]. Since $\lceil k/2\rceil = \lfloor k/2\rfloor + 1$ for odd k, the time complexity is worst-case optimal for odd k. The time complexity for sets of random points is not discussed in [5].

Of the three algorithms based on local transformations presented in this paper, the first has an empirical time complexity of $O(n(\log n)^{k-1})$ for sets of random points from the uniform distribution, and a worst-case time complexity of $O(n^{\lfloor k/2\rfloor+1})$. Thus this first algorithm is also worst-case optimal for odd k. The empirical and worst-case time complexities of the other two algorithms are theoretically not as good, but in practice they are faster than the first algorithm. Our algorithms use an incremental approach as in Watson's algorithm (i.e., the Delaunay triangulation of the first i data points is updated from the Delaunay triangulation of the first $i-1$ data points), but using local transformations, the deletion and addition of simplices are intermixed when adding the ith data point.

This paper is organized as follows. In §2, we describe local transformations in k dimensions. In §3, we describe an incremental approach for constructing k-D Delaunay triangulations using local transformations. In §4, we prove that this approach always constructs a Delaunay triangulation. In §5, we describe three algorithms and a data structure based on this approach. In §6, we discuss the time complexities of the algorithms and present experimental results from our implementation of these algorithms.

2. Local transformations. We first give some terminology before describing local transformations. In k dimensions, a (nondegenerate) *simplex* is the convex hull of $k+1$ affinely independent points, a (nondegenerate) *j-face* is the convex hull of $j+1$ affinely independent points, and a *facet* is a $(k-1)$-face. A degenerate simplex or degenerate j-face is the convex hull of $k+1$ or $j+1$ affinely dependent points, respectively. In this paper, simplices and faces are nondegenerate unless preceded by the word "degenerate."

Let $\mathcal{V}$ be a set of $n \geq k+1$ distinct k-D points, not all in the same hyperplane, and let $\mathcal{C}$ be the convex hull of $\mathcal{V}$. A *triangulation* of $\mathcal{V}$ is a set $\mathcal{S}$ of simplices satisfying the following properties:

(a) All vertices of each simplex of $\mathcal{S}$ are members of $\mathcal{V}$.

(b) Each simplex of $\mathcal{S}$ contains no points of $\mathcal{V}$ other than its vertices.

(c) The union of the simplices of $\mathcal{S}$ is $\mathcal{C}$.

(d) The interiors of the simplices of $\mathcal{S}$ are pairwise disjoint.

(e) Each facet of a simplex of $\mathcal{S}$ is either on the boundary of $\mathcal{C}$ (called a *boundary facet*) or is common to exactly two simplices of $\mathcal{S}$ (called an *interior facet*).

Let $a_1, a_2, \ldots, a_{k+2}$ be $k+2$ distinct k-D points, not all in the same hyperplane. Then there are either one or two ways to triangulate these $k+2$ points, and there are a finite number of different configurations of the $k+2$ points such that the configuration type determines how many simplices are present in the one or two possible triangulations. These results are proved in [18]. If two different triangulations are possible, then a *local transformation* is defined to be the replacement of one of these triangulations by the other.

For example, in three dimensions, the five different configurations are shown in Fig. 1. In the first two configurations, no four of the five points are coplanar; line segment a_4a_5 intersects the interior of facet $a_1a_2a_3$ in configuration 1 and a_1 is in the interior of the convex hull in configuration 2. In the last three configurations, a_1, a_2, a_4, and a_5 are coplanar and form the possible configurations of four planar points, so these can be considered to be degenerate three-dimensional configurations. Local transformations are possible only if the five points are in configuration 1 or 3; the triangulation changes from the A to the B version or vice versa. In configuration 1, the interior facet $a_1a_2a_3$ in triangulation A is swapped for the interior facets $a_1a_4a_5$, $a_2a_4a_5$, $a_3a_4a_5$ in triangulation B. In configuration 3, the edge a_1a_2 in triangulation A is swapped for the edge a_4a_5 in triangulation B (this is the diagonal edge swap used for two-dimensional triangulations).

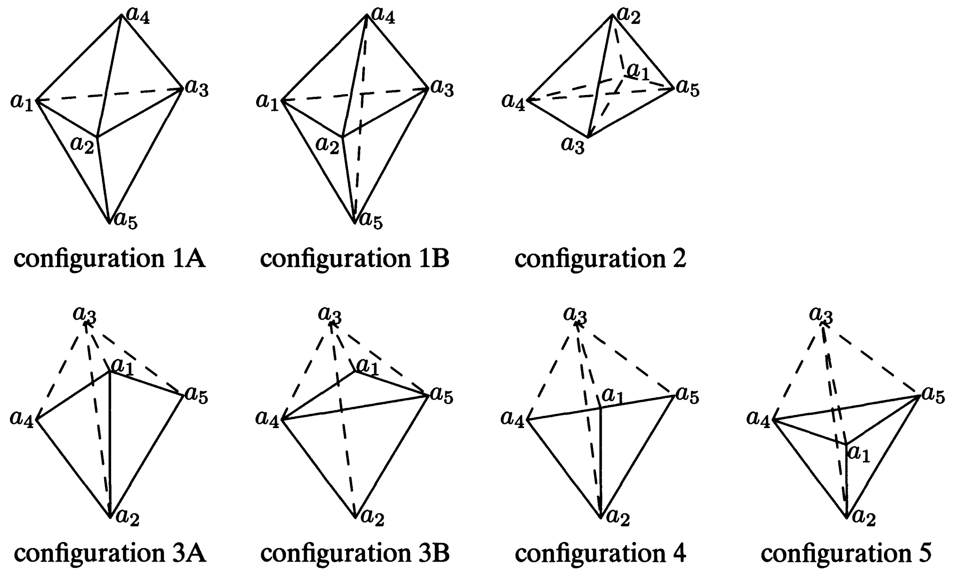

FIG. 1. *Tetrahedra are* (1A) $a_1a_2a_3a_4$, $a_1a_2a_3a_5$; (1B) $a_1a_2a_4a_5$, $a_1a_3a_4a_5$, $a_2a_3a_4a_5$; (2) $a_1a_2a_3a_4$, $a_1a_2a_3a_5$, $a_1a_2a_4a_5$, $a_1a_3a_4a_5$; (3A) $a_1a_2a_3a_4$, $a_1a_2a_3a_5$; (3B) $a_1a_3a_4a_5$, $a_2a_3a_4a_5$; (4) $a_1a_2a_3a_4$, $a_1a_2a_3a_5$; (5) $a_1a_2a_3a_4$, $a_1a_2a_3a_5$, $a_1a_3a_4a_5$.

In k dimensions, the type of configuration and the number of simplices in the one or two possible triangulations can be determined as follows [18]. From the $k+2$ vertices $a_1, \ldots, a_{k+2}$, let S_i denote the (possibly degenerate) simplex formed from $k+1$ of these vertices with a_i excluded, and let $F_{i,j}$ denote the (possibly degenerate) facet formed from k of these vertices with a_i and a_j excluded. Suppose the vertices are labeled so that S_{k+1} and S_{k+2} are nondegenerate simplices sharing common facet $F_{k+1,k+2}$ with a_{k+1} and a_{k+2} on opposite sides of the hyperplane containing $F_{k+1,k+2}$ (this labeling is always possible). Let $(\alpha_1, \alpha_2, \ldots, \alpha_{k+1})$ be the barycentric coordinates of a_{k+2} with respect to $a_1, \ldots, a_{k+1}$, i.e., $\sum_{i=1}^{k+1} \alpha_i a_i = a_{k+2}$ and $\sum_{i=1}^{k+1} \alpha_i = 1$, and let $\alpha_{k+2} = -1$. Note that the labeling of vertices implies that $\alpha_{k+1} < 0$. For $1 \le i \le k+2$, define i (a_i) to be a negative, positive, or zero index (vertex) if α_i is negative, positive, or zero, respectively. If z is a zero index, then the $k+1$ vertices a_i, $i \ne z$, lie on the same hyperplane. Let σ_N, σ_P, and σ_0 be the number of negative, positive, and zero indices, respectively. Note that $\sigma_N \ge 2$, $\sigma_P \ge 1$, and $\sigma_N + \sigma_P + \sigma_0 = k+2$.

The type of configuration determined by $a_1, \ldots, a_{k+2}$ is characterized by $\sigma = (\sigma_N, \sigma_P, \sigma_0)$. (Two sets of $k+2$ vertices have the same type of configuration if and only if their σ vectors are identical or differ only by the interchange of the σ_N and σ_P values. Any configuration with $\sigma_N \ge 2$, $\sigma_P \ge 1$, $\sigma_0 \ge 0$, and $\sigma_N + \sigma_P + \sigma_0 = k+2$ is possible.) Let $\mathcal{S}_N$ and $\mathcal{S}_P$ be the sets of simplices S_i with negative and positive indices, respectively (if i is a zero index, then S_i is degenerate). If $\sigma_P = 1$, then only one triangulation of the $k+2$ vertices is possible, and it contains the σ_N simplices of $\mathcal{S}_N$; the simplex S_j, where j is the positive index, is nondegenerate but is not a valid simplex of a triangulation because it contains the point a_j. If $\sigma_P \ge 2$, then exactly two triangulations of the $k+2$ vertices are possible; the first contains the σ_N simplices of $\mathcal{S}_N$, and the second contains the σ_P simplices of $\mathcal{S}_P$. Each simplex of $\mathcal{S}_N$ ($\mathcal{S}_P$) is adjacent to (shares an interior facet with) all the other simplices of $\mathcal{S}_N$ ($\mathcal{S}_P$ if $\sigma_P \ge 2$).

We have the $\sigma_P \ge 2$ case when a local transformation is possible. If $\sigma_0 \ge 1$, the local transformation can be considered to be applied in $k - \sigma_0$ dimensions as follows. For a negative or positive index i, let E_i be the $(k - \sigma_0)$ face consisting of the negative and positive vertices, excluding a_i. Let $\mathcal{E}_N$ ($\mathcal{E}_P$) be the set of σ_N (σ_P) faces E_i with negative (positive) index i. The local transformation swaps the faces of $\mathcal{E}_N$ for the faces of $\mathcal{E}_P$, with the σ_0 zero vertices being part of all simplices.

Since our Delaunay triangulation algorithms are based on processing and swapping facets, we now describe the facets involved in a local transformation from the simplices of triangulation $\mathcal{S}_N$ to the simplices of triangulation $\mathcal{S}_P$. Let $\mathcal{F}_N$, $\mathcal{F}_P$, $\mathcal{F}_B$, $\mathcal{F}_{BN}$, and $\mathcal{F}_{BP}$ be the sets of interior facets of $\mathcal{S}_N$, interior facets of $\mathcal{S}_P$, boundary facets common to both $\mathcal{S}_N$ and $\mathcal{S}_P$, boundary facets unique to $\mathcal{S}_N$, and boundary facets unique to $\mathcal{S}_P$, respectively. $\mathcal{F}_N$ contains the $\sigma_N(\sigma_N - 1)/2$ facets $F_{i,j}$ where i and j are negative indices. $\mathcal{F}_P$ contains the $\sigma_P(\sigma_P - 1)/2$ facets $F_{i,j}$ where i and j are positive indices. $\mathcal{F}_B$ contains the $\sigma_N \sigma_P$ facets $F_{i,j}$, where i is a negative index and j is a positive index. $\mathcal{F}_{BN}$ and $\mathcal{F}_{BP}$ are nonempty if and only if $\sigma_0 \ge 1$. $\mathcal{F}_{BN}$ contains the $\sigma_N \sigma_0$ facets $F_{i,j}$, where i is a negative index and j is a zero index. $\mathcal{F}_{BP}$ contains the $\sigma_P \sigma_0$ facets $F_{i,j}$, where i is a positive index and j is a zero index. If $\sigma_0 \ge 2$, then facet $F_{i,j}$ with zero indices i, j is degenerate.

3. Delaunay triangulations from local transformations.

3. Delaunay triangulations from local transformations. In this section, we describe an incremental approach for constructing k-D Delaunay triangulations using local transformations. Let $\mathcal{V} = \{v_1, v_2, \ldots, v_n\}$ be a set of $n \ge k+1$ distinct k-D vertices, not all in the same hyperplane. A *Delaunay triangulation* of $\mathcal{V}$ is a triangulation that satisfies the (global) empty circumhypersphere criterion, i.e., the hypersphere passing through the $k + 1$ vertices of any simplex of the triangulation contains none of the n vertices in its interior. A Delaunay triangulation also satisfies a local empty circumhypersphere criterion as indicated by the following definition and theorem from [18].

DEFINITION 1. Let $\mathbf{a} = a_1a_2 \dots a_k$ be an interior facet of a triangulation of $\mathcal{V}$, and let $\mathbf{a}b$ and $\mathbf{a}c$ be the simplices sharing facet $\mathbf{a}$ (with vertices b, c on opposite sides of the hyperplane containing $\mathbf{a}$). Then $\mathbf{a}$ is said to be *locally optimal* if and only if the circumhypersphere of $\mathbf{a}b$ does not contain c in its interior.

THEOREM 1 [18]. *A triangulation $\mathcal{T}$ is a Delaunay triangulation if and only if every interior facet of $\mathcal{T}$ is locally optimal.*

Note that Definition 1 is not affected by the labeling of b, c, and Theorem 1 provides a simple way to check whether or not a given triangulation $\mathcal{T}$ is Delaunay. This definition and theorem lead to the following corollary. A different version of part of this corollary is given and proved in [18].

COROLLARY 1. *Let $a_1, a_2, \dots, a_{k+2}$ be $k + 2$ distinct k-D vertices, not all in the same hyperplane. If $\mathcal{T}$ is the unique triangulation of these vertices, then all interior facets of $\mathcal{T}$ are locally optimal. If there are two different triangulations $\mathcal{T}$, $\mathcal{T}'$ of these vertices, then either all interior facets of $\mathcal{T}$ ($\mathcal{T}'$) are locally optimal or all interior facets of $\mathcal{T}$ ($\mathcal{T}'$) are not locally optimal, and the latter case cannot occur for both $\mathcal{T}$ and $\mathcal{T}'$.*

Proof. If $\mathcal{T}$ is the unique triangulation, then it must be a Delaunay triangulation (since this always exists), so all interior facets of $\mathcal{T}$ are locally optimal by Theorem 1. Suppose two triangulations are possible. If $a_1, a_2, \dots, a_{k+2}$ lie on the same hypersphere, then both triangulations are Delaunay, otherwise exactly one of the triangulations is Delaunay. Suppose $\mathcal{T}$ is not Delaunay. By Theorem 1, there exists an interior facet F of $\mathcal{T}$ that is not locally optimal. Suppose F does not contain the two vertices a_i, a_j. Let S be the simplex formed from F and a_i. Then the circumhypersphere of S contains a_j in its interior. This implies that all interior facets of S are not locally optimal (since a_j is always the other vertex). Since S is adjacent to all other simplices of $\mathcal{T}$, it follows that the circumhypersphere of each simplex of $\mathcal{T}$ contains the other vertex (not involved in the simplex) in its interior, and all interior facets of $\mathcal{T}$ are not locally optimal. □

Theorem 1 and Corollary 1 suggest that one approach for constructing a Delaunay triangulation of $\mathcal{V}$ is to apply local transformations to nonlocally optimal interior facets to remove them from a triangulation of $\mathcal{V}$. The following definitions suggest that removing these facets may not be straightforward.

DEFINITION 2. Let $\mathbf{a} = a_1a_2 \dots a_k$ be an interior facet of a triangulation $\mathcal{T}$ of $\mathcal{V}$, and let $\mathbf{a}a_{k+1}$ and $\mathbf{a}a_{k+2}$ be the simplices of $\mathcal{T}$ sharing facet $\mathbf{a}$. Suppose the notation of §2 is used. If $\sigma_0 = 0$, then $\mathbf{a}$ is said to be *transformable* if and only if $\sigma_P \geq 2$ and the σ_N simplices of $\mathcal{S}_N$ are all in $\mathcal{T}$. If $\sigma_0 \geq 1$, then $\mathbf{a}$ is said to be *transformable* if and only if (1) $\sigma_P \geq 2$, (2) the σ_N $(k - \sigma_0)$-faces of $\mathcal{E}_N$ are all in $\mathcal{T}$, and (3) for any two faces E_i, E_j of $\mathcal{E}_N$, $E_ib_1 \dots b_{\sigma_0}$ (the simplex containing face E_i and vertices $b_1, \dots, b_{\sigma_0}$) is a simplex of $\mathcal{T}$ if and only if $E_jb_1 \dots b_{\sigma_0}$ is a simplex of $\mathcal{T}$.

If $\mathbf{a}$ is nontransformable, then a local transformation cannot be applied to remove $\mathbf{a}$ from the triangulation. If $k = 2$, then any nonlocally optimal interior facet (edge) a_1a_2 is transformable since, by Corollary 1, $\sigma_N = \sigma_P = 2$ and $\sigma_0 = 0$ for this facet. Suppose $k \geq 3$ and $\sigma_0 \geq 1$. If interior facet $\mathbf{a}$ is transformable, then $q \geq 1$ simultaneous local transformations can be performed to remove $\mathbf{a}$, where q is the number of simplices of $\mathcal{T}$ incident on a face E_i of $\mathcal{E}_N$. Note that these local transformations must be performed simultaneously in order to guarantee that a valid triangulation is produced.

For example, suppose $k = 3$, $\sigma_0 = 1$, and the tetrahedra are $a_1a_2a_3a_4$ and $a_1a_2a_3a_5$ as in configuration 3A of Fig. 1, as well as $a_1a_2a_6a_4$ and $a_1a_2a_6a_5$ (with a_6 and a_3 on opposite sides of $a_1a_2a_4$). Then two simultaneous local transformations can be performed to produce tetrahedra $a_4a_5a_3a_1$ and $a_4a_5a_3a_2$ as in configuration 3B of Fig. 1, as well as $a_4a_5a_6a_1$ and $a_4a_5a_6a_2$.

The following examples illustrate how nontransformable facets can arise in a triangulation $\mathcal{T}$.

(a) $k = 3$, $\sigma_0 = 0$: Suppose vertices $a_1, \ldots, a_5$ are as in configuration 1B of Fig. 1 with tetrahedra $a_1a_4a_5a_2$ and $a_1a_4a_5a_3$, but tetrahedron $a_2a_3a_4a_5$ is replaced with tetrahedra $a_2a_4a_5a_6$ and $a_3a_4a_5a_6$ (where a_6 lies between a_2 and a_3 in circular order around a_4a_5). Then $a_1a_4a_5$ is nontransformable.

(b) $k = 3$, $\sigma_0 = 1$: Suppose the tetrahedra are $a_1a_2a_3a_4$ and $a_1a_2a_3a_5$ as in configuration 3A of Fig. 1, $a_1a_2a_4$ and $a_1a_2a_5$ are interior facets of $\mathcal{T}$, and the other two tetrahedra incident on these two facets are $a_1a_2a_4b$ and $a_1a_2a_5c$ with $b \neq c$. Then $a_1a_2a_3$ is nontransformable.

(c) $k = 4$, $\sigma_0 = 1$: Suppose the simplices are $a_1a_4a_5a_6a_2$ and $a_1a_4a_5a_6a_3$, where $a_1, \ldots, a_5$ are in the same hyperplane as in configuration 1B of Fig. 1. Then $a_1a_4a_5a_6$ is nontransformable if either facet $a_2a_3a_4a_5$ is not in $\mathcal{T}$ or simplex $a_2a_3a_4a_5a_6$ is not in $\mathcal{T}$ or $a_1a_2a_4a_5b$, $a_1a_3a_4a_5c$, $a_2a_3a_4a_5d$ are simplices of $\mathcal{T}$ such that b, c, and d are not all the same vertex.

(d) $k = 4$, $\sigma_0 = 2$: Suppose the simplices are $a_1a_2a_3a_6a_4$ and $a_1a_2a_3a_6a_5$ where a_1, a_2, a_4, a_5 are in the same hyperplane as in configuration 3A of Fig. 1. Let $\mathcal{E}_4$ ($\mathcal{E}_5$) be the set of edges b_1b_2 such that $a_1a_2a_4b_1b_2$ ($a_1a_2a_5b_1b_2$) is a simplex of $\mathcal{T}$. Then $a_1a_2a_3a_6$ is nontransformable if the sets $\mathcal{E}_4$ and $\mathcal{E}_5$ are not identical.

DEFINITION 3. A triangulation $\mathcal{T}$ of $\mathcal{V}$ is said to be *pseudolocally optimal* if every nonlocally optimal interior facet of $\mathcal{T}$ is nontransformable.

Any triangulation of $\mathcal{V}$ can be transformed to a pseudolocally optimal triangulation by a finite sequence of local transformations applied to nonlocally optimal transformable interior facets, i.e., the sequence of triangulations cannot cycle. This is proved in [12] for the case $k = 3$, and the proof can be easily extended to any dimension k. For $k = 2$, a pseudolocally optimal triangulation is always Delaunay since nonlocally optimal nontransformable facets (edges) cannot occur. However, for $k \geq 3$, a pseudolocally optimal triangulation may not be Delaunay. An example of a pseudolocally optimal non-Delaunay triangulation for $k = 3$ is given in [12]. By changing the three-dimensional points (x_i, y_i, z_i) in this example to k-D points $(x_i, y_i, z_i, 0, \ldots, 0)$ and adding the $k-3$ k-D points $(0,0,0,1,0,\ldots,0), \ldots, (0,0,0,0,\ldots,0,1)$ to get k-D simplices from the tetrahedra, an example of a pseudolocally optimal non-Delaunay k-D triangulation for any $k \geq 4$ is obtained.

The existence of pseudolocally optimal non-Delaunay triangulations implies that a Delaunay triangulation cannot generally be constructed by applying local transformations in any order to any triangulation. To guarantee that a Delaunay triangulation of $\mathcal{V}$ is constructed, we use the following incremental approach. Suppose the vertices of $\mathcal{V}$ are relabeled if necessary so that $v_1, \ldots, v_{i-1}$ are not in the same hyperplane and a Delaunay triangulation $\mathcal{T}_{i-1}^D$ of $v_1, \ldots, v_{i-1}$ has been constructed (when $i = k+2$, the Delaunay triangulation consists of a single simplex). If $i \leq n$, then vertex v_i is inserted into $\mathcal{T}_{i-1}^D$ and an initial triangulation $\mathcal{T}_i^{(0)}$ involving v_i is constructed as follows.

If v_i lies outside the convex hull of $v_1, \ldots, v_{i-1}$, then simplex $\mathbf{a}v_i$ is added to $\mathcal{T}_{i-1}^D$ for every boundary facet $\mathbf{a}$ of $\mathcal{T}_{i-1}^D$ that is visible from v_i ($\mathbf{a}$ is visible from v_i if v_i and any point w in the interior of the convex hull of $v_1, \ldots, v_{i-1}$ are on opposite sides of the hyperplane containing $\mathbf{a}$). If v_i lies in the interior of simplex $S = a_1a_2 \ldots a_{k+1}$ of $\mathcal{T}_{i-1}^D$, then S is deleted and replaced with the $k+1$ simplices S_j, where S_j is S with vertex a_j

replaced by v_i, $j = 1, \dots, k+1$. We have the remaining case when v_i lies in the interior of $(p-1)$-face $\mathbf{a} = a_1 a_2 \dots a_p$ of $\mathcal{T}_{i-1}^D$, where $2 \le p \le k$. In this case, any simplex $S = \mathbf{a} b_1 \dots b_{k+1-p}$ of $\mathcal{T}_{i-1}^D$ containing face $\mathbf{a}$ is deleted and replaced with the p simplices S_j, where S_j is S with vertex a_j replaced by v_i, $j = 1, \dots, p$.

In the next section, we prove that $\mathcal{T}_i^{(0)}$ can be transformed into a Delaunay triangulation $\mathcal{T}_i^D$ by a finite sequence of local transformations applied to nonlocally optimal transformable interior facets.

4. Proof of Delaunay triangulation construction. The proof that $\mathcal{T}_i^{(0)}$ can be transformed into a Delaunay triangulation $\mathcal{T}_i^D$ is just a generalization of the proof for the three-dimensional case given in [13]. To simplify the proofs of lemmas, we assume that no $k+1$ points of $\mathcal{V}$ lie on the same hyperplane and that no $k+2$ points of $\mathcal{V}$ lie on the same hypersphere. The former assumption implies that all local transformations are nondegenerate, i.e., $\sigma_0 = 0$. The latter assumption is only needed for the last lemma of this section. These assumptions apply to the proofs only; the lemmas still hold in the degenerate cases (this is indicated by parenthesized phrases). The extension of the proofs to handle the degenerate cases can be done in a way similar to that in [13] for $k = 3$, where the two assumptions are not made.

First, we give some notation. The interior of the circumhypersphere of simplex $a_1 a_2 \dots a_{k+1}$ is denoted by $\bigcirc a_1 a_2 \dots a_{k+1}$. For $r \ge 1$, let $\mathcal{T}_i^{(r)}$ be the triangulation obtained by applying a local transformation to a nonlocally optimal transformable interior facet of $\mathcal{T}_i^{(r-1)}$ (or $q \ge 1$ simultaneous local transformations if $\sigma_0 \ge 1$). For $r \ge 0$, let $\mathcal{F}_i^{(r)} = \{\text{facets } \; a_1 \dots a_k \mid a_1 \dots a_k v_i \text{ is a simplex in } \mathcal{T}_i^{(r)}\}$ and $\mathcal{G}_i^{(r)} = \{\text{facets } \; a_1 \dots a_{k-1} v_i \mid \text{there exists } a_k \text{ such that } a_1 \dots a_{k-1} a_k v_i \text{ is a simplex in } \mathcal{T}_i^{(r)}\}$. If $\mathbf{a} v_i = a_1 \dots a_{k-1} v_i$ is an interior facet of $\mathcal{G}_i^{(r)}$ incident on simplices $\mathbf{a} b v_i$ and $\mathbf{a} c v_i$, then let $\theta_i^{(r)}(\mathbf{a})$ denote the angle at $\mathbf{a}$ between (the hyperplanes containing) facets $\mathbf{a} b$ and $\mathbf{a} c$ as viewed from v_i, i.e., the angle is taken to be larger than π if and only if c and v_i are on opposite sides of the hyperplane containing $\mathbf{a} b$.

Since $\mathcal{T}_{i-1}^D$ is Delaunay, all interior facets in $\mathcal{T}_{i-1}^D$ are locally optimal by Theorem 1. This implies that in $\mathcal{T}_i^{(0)}$, all nonlocally optimal interior facets are in $\mathcal{F}_i^{(0)} \cup \mathcal{G}_i^{(0)}$ (since the two simplices incident on other interior facets are unchanged), and for all interior facets $\mathbf{a} v_i$ in $\mathcal{G}_i^{(0)}$, $\theta_i^{(0)}(\mathbf{a}) \ge \pi$ $(< \pi)$ if v_i is outside the convex hull of $v_1, \dots, v_{i-1}$ (in the interior of a simplex of $\mathcal{T}_{i-1}^D$). To show that $\mathcal{T}_i^{(m)}$ is Delaunay for some m, we first show that the local transformations applied to the $\mathcal{T}_i^{(r)}$ are type-N transformations, where a *type-N transformation* is a local transformation in which v_i is one of the $k+2$ vertices and is a negative vertex (using the notation of §2). In other words, a type-N transformation replaces σ_N simplices, exactly one of which does not have v_i as a vertex, by σ_P simplices, all having v_i as a vertex. For $k = 3$, Fig. 2 illustrates the two different kinds of nondegenerate type-N transformations.

LEMMA 1. *Suppose for all $r < m$, the local transformation applied to $\mathcal{T}_i^{(r)}$ is a type-N transformation (or simultaneous local transformations are type-N transformations). For all $r \le m$:*

(A) *all nonlocally optimal interior facets of $\mathcal{T}_i^{(r)}$ are in $\mathcal{F}_i^{(r)} \cup \mathcal{G}_i^{(r)}$, and*

(B) *if $a_1 a_2 \dots a_{k+1}$ is a simplex in $\mathcal{T}_i^{(r)}$ such that none of its vertices is v_i, then $\bigcirc a_1 a_2 \dots a_{k+1}$ does not contain any vertex except possibly vertex v_i.*

Proof (by induction). Statements (A) and (B) are clearly true for $r = 0$. Suppose they are true for $0 \le r < m$ and $\mathcal{T}_i^{(r)}$ is not pseudolocally optimal. Suppose that a

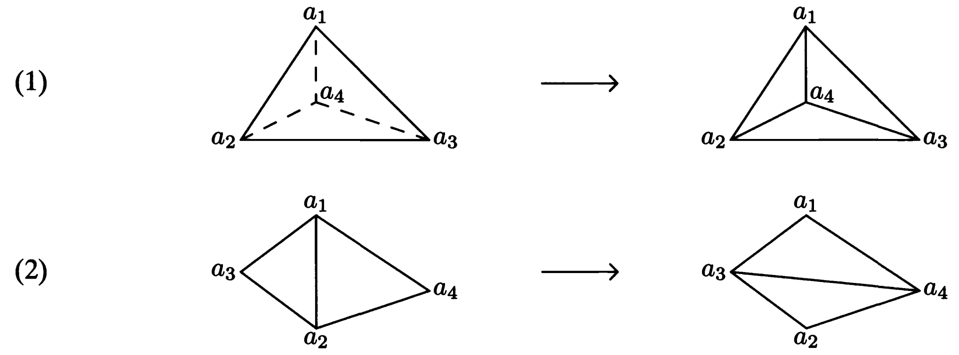

FIG. 2. *Two kinds of nondegenerate type-N transformations for* $k = 3$ (*"before" on left, "after" on right*). *Vertex* v_i *is not shown; imagine that it is above the page. Facets in* $\mathcal{F}_i^{(r)}$ *are solid lines, other edges are dashed lines.* (1) a_4 *below* $a_1a_2a_3$, a_4v_i *intersects* $a_1a_2a_3$: $a_1a_2a_3v_i$, $a_1a_2a_3a_4 \rightarrow a_1a_2a_4v_i$, $a_1a_3a_4v_i$, $a_2a_3a_4v_i$. (2) $\theta_i^{(r)}(a_1a_2) > \pi$, a_1a_2 *intersects* $a_3a_4v_i$: $a_1a_2a_3v_i$, $a_1a_2a_4v_i$, $a_1a_2a_3a_4 \rightarrow a_1a_3a_4v_i$, $a_2a_3a_4v_i$.

type-N transformation is applied to nonlocally optimal transformable facet $a_1 \ldots a_k$ of $\mathcal{T}_i^{(r)}$ to get $\mathcal{T}_i^{(r+1)}$. Let the other two vertices of the type-N transformation be a_{k+1} and $a_{k+2} = v_i$. Using the notation of §2,

$$\mathcal{F}_i^{(r+1)} = (\mathcal{F}_i^{(r)} - \{F_{j,k+2} \mid j \text{ is a negative index}\}) \cup \{F_{j,k+2} \mid j \text{ is a positive index}\},$$

$$\mathcal{G}_i^{(r+1)} = (\mathcal{G}_i^{(r)} - \{F_{j,l} \mid j,l \text{ are negative indices } < k+2\}) \cup \{F_{j,l} \mid j,l \text{ are positive indices}\}.$$

(Note that the deleted facets are in $\mathcal{F}_N$.) The new interior facets of $\mathcal{T}_i^{(r+1)}$ that may become nonlocally optimal are in

$$\mathcal{F}_B = \{F_{j,l} \mid j \text{ is a positive index and } l \text{ is a negative index}\},$$

and these facets are all in $\mathcal{F}_i^{(r+1)} \cup \mathcal{G}_i^{(r+1)}$. There are no new simplices in $\mathcal{T}_i^{(r+1)}$ not involving v_i. Hence (A) and (B) are true for $r + 1$. □

LEMMA 2. *Suppose for all* $r < m$, *the local transformation applied to* $\mathcal{T}_i^{(r)}$ *is a type-N transformation* (*or simultaneous local transformations are type-N transformations*). *For all* $r \leq m$:

(C) *for all interior facets* $a_1 \ldots a_{k-1}v_i$ *in* $\mathcal{G}_i^{(r)}$, *if* $\theta_i^{(r)}(a_1 \ldots a_{k-1}) \leq \pi$, *then facet* $a_1 \ldots a_{k-1}v_i$ *is locally optimal.*

Proof (by induction). With the assumption that no $k + 1$ points of $\mathcal{V}$ lie on the same hyperplane, an interior facet $\mathbf{a}v_i = a_1 \ldots a_{k-1}v_i$ in $\mathcal{G}_i^{(0)}$ satisfies $\theta_i^{(0)}(\mathbf{a}) > \pi$ if v_i is outside the convex hull of $v_1, \ldots, v_{i-1}$, and $\theta_i^{(0)}(\mathbf{a}) < \pi$ if v_i is in the interior of a simplex S of $\mathcal{T}_{i-1}^D$. In the latter case, $\mathbf{a}v_i$ is locally optimal by Corollary 1 since the triangulation of v_i and the vertices of S are unique. Hence statement (C) is true for $r = 0$.

Suppose (C) is true for $0 \leq r < m$. Suppose that a type-N transformation is applied to nonlocally optimal transformable facet $a_1 \ldots a_k$ of $\mathcal{T}_i^{(r)}$ to get $\mathcal{T}_i^{(r+1)}$. Let the other two vertices of the type-N transformation be a_{k+1} and $a_{k+2} = v_i$. Using the notation of §2, $\mathcal{F}_P = \{F_{j,l} \mid j,l \text{ are positive indices}\}$ contains the only facets of $\mathcal{G}_i^{(r+1)}$ not in $\mathcal{G}_i^{(r)}$. Suppose $F_{j,l} \in \mathcal{F}_P$ and $\mathbf{a}$ is the $(k-2)$-face of $F_{j,l}$ that does not contain v_i. Then $\theta_i^{(r+1)}(\mathbf{a}) < \pi$ since $\mathbf{a}a_j$ and $\mathbf{a}a_l$ are in $\mathcal{F}_B$, and $F_{j,l}$ is locally optimal by Corollary 1 since $a_1 \ldots a_k$ is nonlocally optimal.

The only facets of $\mathcal{G}_i^{(r+1)} \cap \mathcal{G}_i^{(r)}$ such that their $\theta_i^{(r)}$ and $\theta_i^{(r+1)}$ values are different (if they are interior facets) are in

$$\mathcal{G} = \{F_{j,l} \mid j \text{ is a positive index and } l \text{ is a negative index } < k+2\} \subset \mathcal{F}_B.$$

Suppose $F_{j,l} \in \mathcal{G}$ is an interior facet of $\mathcal{G}_i^{(r+1)}$, $\mathbf{a}$ is the $(k-2)$-face of $F_{j,l}$ that does not contain v_i, and $\theta_i^{(r+1)}(\mathbf{a}) < \pi$. Then $\theta_i^{(r)}(\mathbf{a}) < \theta_i^{(r+1)}(\mathbf{a})$ since $\mathbf{a}a_j \in \mathcal{F}_N \cap \mathcal{F}_i^{(r)}$ ($\mathbf{a}a_jv_i$ is a simplex of $\mathcal{T}_i^{(r)}$) and $\mathbf{a}a_l \in \mathcal{F}_B \cap \mathcal{F}_i^{(r+1)}$ ($\mathbf{a}a_lv_i$ is a simplex of $\mathcal{T}_i^{(r+1)}$). Let the other simplex of $\mathcal{T}_i^{(r)}$ and $\mathcal{T}_i^{(r+1)}$ incident on $F_{j,l}$ be $\mathbf{a}v_ib$. Then a_j and b are on the same side of (the hyperplane containing) $\mathbf{a}a_l$ as v_i. Since $\mathbf{a}a_ja_l$ is a simplex of $\mathcal{T}_i^{(r)}$, by Lemma 1, $\bigcirc\mathbf{a}a_ja_l$ does not contain b. The fact that $\mathbf{a}a_j$ is not locally optimal in $\mathcal{T}_i^{(r)}$ implies $\bigcirc\mathbf{a}a_ja_l$ contains v_i. Hence the part of $\bigcirc\mathbf{a}a_lv_i$ on the same side of $\mathbf{a}a_l$ as v_i is a subset of the corresponding part of $\bigcirc\mathbf{a}a_la_j$. This implies that $\bigcirc\mathbf{a}a_lv_i$ does not contain b, i.e., $\mathbf{a}v_i = F_{j,l}$ is locally optimal in $\mathcal{T}_i^{(r+1)}$. □

LEMMA 3. *For all* $m \geq 0$:

(D) *a type-N transformation* (*or simultaneous type-N transformations*) *is the only type of local transformation that can be applied to a nonlocally optimal transformable interior facet of* $\mathcal{T}_i^{(m)}$.

Proof (by induction). The basis and inductive steps are the same. Suppose $m = 0$ or statement (D) is true for all $r < m$. By Lemma 1, all nonlocally optimal interior facets of $\mathcal{T}_i^{(m)}$ are in $\mathcal{F}_i^{(m)} \cup \mathcal{G}_i^{(m)}$. First suppose that $\mathbf{a} = a_1 \dots a_k$ is a nonlocally optimal interior facet in $\mathcal{F}_i^{(m)}$ incident on simplices $\mathbf{a}a_{k+1}$ and $\mathbf{a}v_i$. Then a local transformation involving these two simplices must have v_i as a negative vertex, i.e., it must be a type-N transformation.

Now suppose that $\mathbf{a}v_i = a_1 \dots a_{k-1}v_i$ is a nonlocally optimal interior facet in $\mathcal{G}_i^{(m)}$ incident on simplices $\mathbf{a}v_ia_k$ and $\mathbf{a}v_ia_{k+1}$. By Lemma 2, $\theta_i^{(m)}(\mathbf{a}) > \pi$. This angle implies that $\mathbf{a}a_ka_{k+1}$ is a simplex in the triangulation of $a_1, \dots, a_{k+1}, v_i$ that includes $\mathbf{a}v_ia_k$ and $\mathbf{a}v_ia_{k+1}$. By Corollary 1, there is another triangulation of $a_1, \dots, a_{k+1}, v_i$. The local transformation that removes facet $\mathbf{a}v_i$ must be a type-N transformation since simplex $\mathbf{a}a_ka_{k+1}$ would be removed. Therefore, (D) is true for m. □

LEMMA 4. *If all interior facets of* $\mathcal{T}_i^{(r)}$ *not in* $\mathcal{G}_i^{(r)}$ *are locally optimal, then all interior facets in* $\mathcal{G}_i^{(r)}$ *are locally optimal.*

Proof. By Lemmas 1 and 3, all nonlocally optimal interior facets of $\mathcal{T}_i^{(r)}$ are in $\mathcal{F}_i^{(r)} \cup \mathcal{G}_i^{(r)}$. Suppose all interior facets in $\mathcal{F}_i^{(r)}$ are locally optimal. Suppose $\mathbf{a}v_i = a_1 \dots a_{k-1}v_i$ is a nonlocally optimal interior facet in $\mathcal{G}_i^{(r)}$. By Lemma 3, a type-N transformation is the only type of local transformation that can remove $\mathbf{a}v_i$. But a type-N transformation would also remove a nonlocally optimal interior facet from $\mathcal{F}_i^{(r)}$. This contradiction implies that $\mathbf{a}v_i$ is locally optimal. □

LEMMA 5. *Let* $\mathbf{a}a_k = a_1 \dots a_{k-1}a_k$ *be a nonlocally optimal and nontransformable interior facet in* $\mathcal{F}_i^{(r)}$ *incident on simplices* $\mathbf{a}a_ka_{k+1}$ *and* $\mathbf{a}a_kv_i$ *in* $\mathcal{T}_i^{(r)}$. *Suppose the nontransformability is due to* $(k-2)$*-face* $\mathbf{a}$, *i.e.,* $\mathbf{a}a_{k+1}v_i$ *is not a simplex of* $\mathcal{T}_i^{(r)}$, *but it is needed for the local transformation that removes* $\mathbf{a}a_k$ (*or* $\mathbf{a}$ *is in a configuration with* $\sigma_0 \geq 1$). *Then there exists another interior facet* $\mathbf{a}b$, $b \neq a_k$, *in* $\mathcal{F}_i^{(r)}$ *that is nonlocally optimal.*

Proof. Let the vertices in circular order about face $\mathbf{a}$ be $v_i, a_k, a_{k+1} = d_0, d_1, \dots, d_s = b, v_i$ where $s \geq 1$, i.e., $\mathbf{a}v_ia_k$, $\mathbf{a}a_kd_0$, $\mathbf{a}d_0d_1, \dots, \mathbf{a}d_{s-1}d_s$, $\mathbf{a}d_sv_i$ are simplices in $\mathcal{T}_i^{(r)}$. Since $\mathbf{a}d_0v_i$ is the missing simplex, $d_1, \dots, d_s$ must be on the same side of (the hyperplane containing) facet $\mathbf{a}d_0$ as v_i. By Lemmas 1 and 3, interior facets $\mathbf{a}d_0, \dots, \mathbf{a}d_{s-1}$ are locally optimal since they are not in $\mathcal{F}_i^{(r)} \cup \mathcal{G}_i^{(r)}$. The fact that $\mathbf{a}a_k$ is nonlocally optimal implies that $\bigcirc\mathbf{a}a_kd_0$ contains v_i. $\bigcirc\mathbf{a}d_0a_k$ does not contain d_1 so the part of $\bigcirc\mathbf{a}d_0d_1$ on the same side of $\mathbf{a}d_0$ as v_i contains the corresponding part of $\bigcirc\mathbf{a}d_0a_k$; in particular $\bigcirc\mathbf{a}d_0d_1$ contains v_i. This argument can be repeated to show that $\bigcirc\mathbf{a}d_1d_2, \ldots, \bigcirc\mathbf{a}d_{s-1}d_s$ all contain v_i. But the fact that $\bigcirc\mathbf{a}d_{s-1}d_s$ contains v_i implies that interior facet $\mathbf{a}d_s = \mathbf{a}b$ is nonlocally optimal, where $\mathbf{a}b$ is in $\mathcal{F}_i^{(r)}$. $\square$

To complete the proof that a Delaunay triangulation $\mathcal{T}_i^{(m)}$ is obtained for some m, we need to show that if $\mathcal{T}_i^{(r)}$ is not a Delaunay triangulation, then there exists a nonlocally optimal transformable interior facet in $\mathcal{F}_i^{(r)}$. This will be done in the next three lemmas, which use the following notations.

For a simplex $\mathbf{a}b = a_1 \ldots a_kb$, let $\mathbf{a}|b$ denote the half-space that consists of the hyperplane containing facet $\mathbf{a}$ as well as the points on the opposite side of this hyperplane from b. For two simplices $\mathbf{a}b$ and $\mathbf{a}c$ sharing common facet $\mathbf{a}$, $\mathbf{a}b$ is said to be *in front of* $\mathbf{a}c$ with respect to a viewpoint p if there exists a half-line L starting at p, such that L intersects the interior of both $\mathbf{a}b$ and $\mathbf{a}c$, and all intersections of L with the interior of $\mathbf{a}b$ are between p and any intersection of L with the interior of $\mathbf{a}c$. Note that if b and p are both in $\mathbf{a}|c$ and p does not lie on the hyperplane containing $\mathbf{a}$, then $\mathbf{a}b$ is in front of $\mathbf{a}c$ with respect to p. Also, for a point p and a simplex $a_1 \ldots a_{k+1}$, let $\phi_p(a_1 \ldots a_{k+1}) = \delta^2 - \rho^2$, where δ is the Euclidean distance between p and the centre of $\bigcirc a_1 \ldots a_{k+1}$, and ρ is the radius of $\bigcirc a_1 \ldots a_{k+1}$.

LEMMA 6. *Suppose $\mathcal{T}_i^{(r)}$ is not a Delaunay triangulation and all nonlocally optimal interior facets in $\mathcal{F}_i^{(r)}$ are nontransformable. Then there exists a cycle of simplices $a_1^0 \ldots a_{k+1}^0$, $a_1^1 \ldots a_{k+1}^1, \ldots, a_1^{t-1} \ldots a_{k+1}^{t-1}$, $a_1^t \ldots a_{k+1}^t = a_1^0 \ldots a_{k+1}^0$ in $\mathcal{T}_i^{(r)}$ such that v_i is not a vertex of any of these simplices, and for all j, $a_1^j \ldots a_{k+1}^j$ and $a_1^{j+1} \ldots a_{k+1}^{j+1}$ share common facet $a_1^j \ldots a_k^j$, $a_1^j \ldots a_k^j$ is locally optimal, and $v_i \in a_1^j \ldots a_k^j | a_{k+1}^j$.*

Proof. By Lemmas 1, 3, and 4 and Theorem 1, there exists a nonlocally optimal interior facet $\mathbf{a}a_k = a_1 \ldots a_{k-1}a_k$ in $\mathcal{F}_i^{(r)}$. By hypothesis, $\mathbf{a}a_k$ is nontransformable. Let $\mathbf{a}a_kv_i$ and $\mathbf{a}a_ka_{k+1}$ be the two simplices incident on $\mathbf{a}a_k$ in $\mathcal{T}_i^{(r)}$. Without loss of generality, suppose the nontransformability is due to $(k-2)$-face $\mathbf{a}$ as in the statement of Lemma 5. Then, by Lemma 5, $\mathbf{a}b_1 \in \mathcal{F}_i^{(r)}$ is also a nonlocally optimal interior facet where $b_1 \neq a_k$. By hypothesis, $\mathbf{a}b_1$ is also nontransformable. Suppose its nontransformability is due to $(k-2)$-face $\mathbf{b}$, where $\mathbf{b}$ consists of vertex b_1 and $k-2$ of the vertices $a_1, \ldots, a_{k-1}$ (since the angle at face $\mathbf{a}$ between facets $\mathbf{a}a_{k+1}$ and $\mathbf{a}v_i$ as viewed from b_1 is less than π, it is not possible that the nontransformability is due to face $\mathbf{a}$). Let $\mathbf{a}b_1 = \mathbf{b}b_k$, and $\mathbf{b}b_kv_i$ and $\mathbf{b}b_kb_{k+1}$ be the two simplices incident on $\mathbf{b}b_k$ in $\mathcal{T}_i^{(r)}$. There are two possible cases: either $a_{k+1} = b_{k+1}$ or $a_{k+1} \neq b_{k+1}$.

First suppose that $a_{k+1} = b_{k+1}$. Then $v_i \in \mathbf{a}a_{k+1}|a_k$ and by Lemmas 1 and 3, $\mathbf{a}a_{k+1}$ is locally optimal. Let $\mathbf{a}a_{k+1}a_k$, $\mathbf{a}a_{k+1}b_1$ be the start of a sequence of simplices. Now suppose $a_{k+1} \neq b_{k+1}$. Let the vertices in circular order about face $\mathbf{a}$ be v_i, a_k, $a_{k+1} = d_0, d_1, \ldots, d_s = b_{k+1}$, b_1, v_i where $s \geq 1$, i.e., $\mathbf{a}v_ia_k$, $\mathbf{a}a_kd_0$, $\mathbf{a}d_0d_1, \ldots, \mathbf{a}d_sb_1$, $\mathbf{a}b_1v_i$ are simplices in $\mathcal{T}_i^{(r)}$. By Lemmas 1 and 3, interior facets $\mathbf{a}d_0, \ldots, \mathbf{a}d_s$ are locally optimal. Since the nontransformability of $\mathbf{a}a_k$ is due to $\mathbf{a}$, v_i lies in the half-spaces $\mathbf{a}d_0|a_k$, $\mathbf{a}d_1|d_0, \ldots, \mathbf{a}d_s|d_{s-1}$. Let $\mathbf{a}d_0a_k$, $\mathbf{a}d_1d_0, \ldots, \mathbf{a}d_sd_{s-1}$, $\mathbf{a}d_sb_1$ be the start of a sequence of simplices.

The above argument can be repeated with $\mathbf{b}b_k$ and $\mathbf{b}$ taking on the role of $\mathbf{a}a_k$ and $\mathbf{a}$, and $\mathbf{b}c_1$ taking on the role of $\mathbf{a}b_1$, and so on, with more simplices added to the sequence of adjacent simplices. Since there are a finite number of facets in $\mathcal{F}_i^{(r)}$, there must be a cycle of adjacent nonlocally optimal nontransformable interior facets of $\mathcal{F}_i^{(r)}$. Without loss of generality, suppose this cycle of facets starts and ends at $\mathbf{a}a_k$. Then the proof of this lemma is completed by taking the sequence or cycle of adjacent simplices starting and ending at $\mathbf{a}a_{k+1}a_k$. □

To show that this cycle of simplices cannot occur, we need the following lemma from [6]. For completeness, we provide a simpler proof of this lemma here.

LEMMA 7. *Suppose* $\mathbf{a}b$ *and* $\mathbf{a}c$ *are simplices sharing common facet* $\mathbf{a} = a_1 \dots a_k$ *such that* $\mathbf{a}b$ *is in front of* $\mathbf{a}c$ *with respect to point* p*. If* c *is outside the circumhypersphere of* $\mathbf{a}b$*, then* $\phi_p(\mathbf{a}b) < \phi_p(\mathbf{a}c)$*.*

Proof. Suppose the coordinate system $(x_1, x_2, \dots, x_k)$ is first translated so that p is at the origin and then rotated so that the normal of facet $\mathbf{a}$ is $(0, \dots, 0, 1)$ and $\mathbf{a}$ lies on the hyperplane $x_k = \alpha_k$ with $\alpha_k > 0$. Note that this change to the coordinate system does not affect the value of ϕ_p. Let the radii of $\bigcirc\mathbf{a}b$ and $\bigcirc\mathbf{a}c$ be ρ_b and ρ_c, respectively, and let the centre of $\bigcirc\mathbf{a}b$ have coordinates $(\gamma_1, \dots, \gamma_{k-1}, \gamma_k)$ in the new coordinate system. Then the centre of $\bigcirc\mathbf{a}c$ has coordinates $(\gamma_1, \dots, \gamma_{k-1}, \gamma_k')$ with $\gamma_k' > \gamma_k$, since c is outside the circumhypersphere of $\mathbf{a}b$ and $\mathbf{a}b$ is in front of $\mathbf{a}c$ with respect to p. A formula for ρ_b^2 is

$$\rho_b^2 = (\alpha_1 - \gamma_1)^2 + (\alpha_2 - \gamma_2)^2 + \dots + (\alpha_k - \gamma_k)^2,$$

where $(\alpha_1, \dots, \alpha_{k-1}, \alpha_k)$ are the coordinates of a_1. A similar formula exists for ρ_c^2. By simple algebraic manipulation,

$$\phi_p(\mathbf{a}c) - \phi_p(\mathbf{a}b) = 2\alpha_k(\gamma_k' - \gamma_k) > 0. \qquad □$$

LEMMA 8. *If* $\mathcal{T}_i^{(r)}$ *is not a Delaunay triangulation, then there exists a nonlocally optimal transformable interior facet in* $\mathcal{F}_i^{(r)}$*.*

Proof. By Lemmas 1, 3, and 4 and Theorem 1, there exists a nonlocally optimal interior facet in $\mathcal{F}_i^{(r)}$. Suppose all nonlocally optimal interior facets in $\mathcal{F}_i^{(r)}$ are nontransformable. Then, by Lemma 6, there exists a cycle of simplices $a_1^0 \dots a_{k+1}^0$, $a_1^1 \dots a_{k+1}^1, \dots,$ $a_1^{t-1} \dots a_{k+1}^{t-1}$, $a_1^t \dots a_{k+1}^t = a_1^0 \dots a_{k+1}^0$ in $\mathcal{T}_i^{(r)}$ such that v_i is not a vertex of any of these simplices, and, for all j, $a_1^j \dots a_{k+1}^j$ and $a_1^{j+1} \dots a_{k+1}^{j+1}$ share common facet $a_1^j \dots a_k^j$, $a_1^j \dots a_k^j$ is locally optimal, and $v_i \in a_1^j \dots a_k^j | a_{k+1}^j$.

From the nondegeneracy assumptions made at the beginning of this section, $a_1^{j+1} \dots a_{k+1}^{j+1}$ is in front of $a_1^j \dots a_{k+1}^j$ with respect to $p = v_i$ for all j, and by Lemma 7,

$$\phi_p(a_1^0 \dots a_{k+1}^0) > \phi_p(a_1^1 \dots a_{k+1}^1) > \dots > \phi_p(a_1^t \dots a_{k+1}^t).$$

But the first and last values of this sequence of inequalities are identical. Therefore, this contradiction implies that the cycle does not exist, and there exists a nonlocally optimal transformable interior facet in $\mathcal{F}_i^{(r)}$. □

THEOREM 2. *If* $\mathcal{T}_{i-1}^D$ *is a Delaunay triangulation, then there exists a finite* $m \geq 0$ *such that* $\mathcal{T}_i^{(m)} = \mathcal{T}_i^D$ *is a Delaunay triangulation.*

Proof. By Lemma 3, the sequence of triangulations $\mathcal{T}_i^{(0)}, \mathcal{T}_i^{(1)}, \dots$ cannot cycle since each type-N transformation removes exactly one simplex that does not have v_i as a vertex and creates only simplices having v_i as a vertex. Hence there exists a finite m such that $\mathcal{T}_i^{(m)}$ is pseudolocally optimal. By Lemma 8, $\mathcal{T}_i^{(m)}$ is a Delaunay triangulation. □

5. Algorithms and data structure.

In this section, we describe three algorithms for constructing a k-D Delaunay triangulation based on the results of the previous section, as well as a data structure for representing the varying triangulations. These algorithms are k-D versions of the three-dimensional Delaunay triangulation algorithms in [13] and [15]. The first two algorithms differ in the order of adding the vertices to the triangulation. In the first, the n vertices are first sorted so that v_i is always outside the convex hull of $v_1, \ldots, v_{i-1}$. In the second, the vertices can be added in any order and a walk through adjacent simplices is used to determine the location of v_i in triangulation $\mathcal{T}_{i-1}^D$. The third algorithm does not explicitly perform the local transformations; they are made "implicit" so that nonlocally optimal nontransformable interior facets do not occur. Unlike the approaches in [29] and [28], a bounding simplex is not required in our algorithms.

The first and second algorithms are described by the following steps. By Lemmas 1, 3, and 4, only the facets of the $\mathcal{F}_i^{(r)}$ need to be tested for local optimality, so these facets are kept in a queue and the queue is updated as type-N transformations are performed.

ALGORITHM S

(1) *Initialization*: Sort $v_1, v_2, \ldots, v_n$ in lexicographic increasing order of their coordinates, and reorder the vertices slightly if necessary so that the first $k+1$ vertices are not in the same hyperplane. Form the first simplex $v_1 v_2 \ldots v_{k+1}$, and compute its centroid w. Initialize queue Q to be empty.

(2) For $i = k+2, \ldots, n$, add vertex v_i to $\mathcal{T}_{i-1}^D$, and apply local transformations to get $\mathcal{T}_i^D$ as follows:

   (a) Find a boundary facet $\mathbf{a}_0$ visible from v_i, i.e., v_i and w are on opposite sides of the hyperplane containing $\mathbf{a}_0$ (if v_{i-1} appears before v_i in lexicographic order, then there is a boundary facet containing v_{i-1} that is visible from v_i). Starting from $\mathbf{a}_0$, determine the adjacent boundary facets that are visible from v_i by checking neighbouring boundary facets of visible boundary facets. For each visible boundary facet $\mathbf{a}$, add simplex $\mathbf{a}v_i$ to the triangulation and insert $\mathbf{a}$ at end of queue Q.

   (b) While queue Q is not empty, remove the head facet $\mathbf{a}$ from Q and if $\mathbf{a}$ is still in the triangulation, do the following: Let $\mathbf{a}a_{k+1}$ and $\mathbf{a}a_{k+2}$, $a_{k+2} = v_i$, be the two simplices sharing interior facet $\mathbf{a}$. If $\bigcirc\mathbf{a}a_{k+1}$ contains v_i and $\mathbf{a}$ is transformable, then apply one or more local transformations (more than one may be needed if $\sigma_0 \geq 1$). For each local transformation, for each facet of $\mathcal{F}_B$ (as defined at the end of §2) that is an interior facet of the triangulation and does not have v_i as a vertex, add the facet to the end of Q.

ALGORITHM W

(1) *Initialization*: Reorder the vertices slightly if necessary so that the first $k+1$ vertices are not in the same hyperplane. Form the first simplex $v_1 v_2 \ldots v_{k+1}$, and compute its centroid w. Initialize queue Q to be empty.

(2) For $i = k+2, \ldots, n$, add vertex v_i to $\mathcal{T}_{i-1}^D$, and apply local transformations to get $\mathcal{T}_i^D$ as follows:

   (a) Starting from a simplex having v_{i-1} as a vertex, walk through neighbouring simplices of $\mathcal{T}_{i-1}^D$ to find a simplex or facet containing v_i (the location of v_i with respect to the facets of a simplex, as determined by barycentric coordinates, determines which adjacent simplex to visit next) or determine that v_i is outside the convex hull of $v_1, \ldots, v_{i-1}$ (the walk goes through a boundary facet $\mathbf{a}_0$). Lemma 7 guarantees that the walk does not cycle through simplices since each simplex is in front of the previous one with respect to v_i. If v_i is outside the convex hull, then create the new simplices, and add the visible boundary facets to queue Q as in Algorithm S, else delete and add the simplices described at the end of §3 and add the interior facets of $\mathcal{F}_i^{(0)}$ to Q.

   (b) This part is the same as in Algorithm S.

From §4, it can be seen that $\mathcal{T}_i^D = \mathcal{T}_i^{(m)}$ is obtained from $\mathcal{T}_{i-1}^D$ via type-N transformations that delete all simplices $a_1 \dots a_{k+1}$ in $\mathcal{T}_{i-1}^D$ whose circumhypersphere contains vertex v_i in its interior and add all simplices $a_1 \dots a_k v_i$, where $a_1 \dots a_k \in \mathcal{F}_i^{(m)} = \mathcal{F}_i^D$ (there are also some "temporary" simplices involving v_i that appear in the $\mathcal{T}_i^{(r)}$ but not in $\mathcal{T}_i^D$). Therefore, another approach is to not explicitly perform local transformations and record the temporary simplices of the form $a_1 \dots a_k v_i$, but to delete simplices $a_1 \dots a_{k+1}$ whose circumhypersphere contains v_i in its interior, record the facets that may form simplices with v_i, and create the simplices $a_1 \dots a_k v_i$ of $\mathcal{T}_i^D$ after the deletion is completed (as in Watson's algorithm [29]).

This "implicit" local transformation approach can be used in place of the explicit local transformations of Algorithm S or W. We provide the steps for Algorithm M below, where this algorithm is the "implicit" version of Algorithm W, since Algorithm W is faster than Algorithm S for sets of random points from the uniform distribution (see the next section). In Algorithm M, queue Q is used in a similar way to Algorithm W. In addition, stack S records the facets of $\mathcal{F}_i^D$. Algorithm M should be faster than Algorithm W, since local transformations are not explicitly performed and nonlocally optimal nontransformable interior facets do not occur. However, Algorithm W is more numerically robust than Algorithm M for the following reason. For sets of points on the same hypersphere, it is possible that round-off errors in determining whether a vertex is inside a hypersphere may cause an invalid triangulation with overlapping or missing simplices using the approach of Algorithm M in floating point arithmetic [29], [3], [13]. On the other hand, it is not possible for Algorithm W to produce invalid triangulations, since local transformations only change the simplices in a fixed local volume.

ALGORITHM M

(1) *Initialization*: Reorder the vertices slightly if necessary so that the first $k + 1$ vertices are not in the same hyperplane. Form the first simplex $v_1 v_2 \dots v_{k+1}$, and compute its centroid w. Initialize queue Q and stack S to be empty.

(2) For $i = k + 2, \dots, n$, add vertex v_i to $\mathcal{T}_{i-1}^D$ and delete and add simplices to get $\mathcal{T}_i^D$ as follows:

  (a) The walking phase of this part is the same as in Algorithm W. If v_i is outside the convex hull, then add the visible boundary facets to queue Q as in Algorithm S, else delete the simplices containing v_i from the triangulation and add the interior (boundary) facets of $\mathcal{F}_i^{(0)}$ to queue Q (stack S).

  (b) While queue Q is not empty, remove the head facet $\mathbf{a}$ from Q, and if $\mathbf{a}$ is still in the triangulation, do the following: Let $\mathbf{a}a_{k+1}$ be the remaining simplex incident on facet $\mathbf{a}$. If $\bigcirc\mathbf{a}a_{k+1}$ does not contain v_i, then push $\mathbf{a}$ onto S, else delete $\mathbf{a}a_{k+1}$ and $\mathbf{a}$ from the triangulation and for the other k facets of $\mathbf{a}a_{k+1}$, do the following: Let $\mathbf{b}$ be one of these other facets. If $\mathbf{b}$ is already in Q, then delete $\mathbf{b}$ from the triangulation; else if $\mathbf{b}$ is a boundary facet such that v_i lies on the hyperplane containing $\mathbf{b}$, then delete $\mathbf{b}$; else if $\mathbf{b}$ is a boundary facet, then push $\mathbf{b}$ onto S; else insert $\mathbf{b}$ at end of Q.

  (c) While stack S is not empty, pop the top facet $\mathbf{a}$ from Algorithm S, and add simplex $\mathbf{a}v_i$ to the triangulation.

As in the two-dimensional Delaunay triangulation algorithm in [28], the time in the walking phase of Algorithms W and M can be reduced by the following preprocessing bin sorting step (so that each vertex is likely to be closer to the previous one). Let $[x_{1,\min}, x_{1,\max}] \times \cdots \times [x_{k,\min}, x_{k,\max}]$ be the smallest hyperrectangle containing vertices $v_1, \dots, v_n$. This hyperrectangle is subdivided into $m^k \approx n^\alpha$ hyperrectangular bins of size $(x_{1,\max}-x_{1,\min})/m \times \cdots \times (x_{k,\max}-x_{k,\min})/m$, where α is chosen based on the distribution of points $v_1, \ldots, v_n$. (For example, for random points from the uniform distribution, $\alpha \approx 0.5$ and $\alpha \approx 0.4$ are optimal for two and three dimensions, respectively, [15].) The integers 1 to m^k are assigned to the bins such that consecutive integers correspond to adjacent bins, and the vertices are sorted based on their bin numbers, i.e., the vertices are inserted in increasing bin number order.

The data structure that we use to represent the varying triangulations in the three algorithms is the k-D version of the one for three-dimensional triangulations in [12], with the modified representation for boundary facets described in [13]. This data structure facilitates the walk through a triangulation, the determination of the neighbouring boundary facets of each boundary facet, the addition of new simplices involving v_i, the addition, deletion, and searching of facets, and the updates due to local transformations. The data structure consists of the following four arrays.

The vertex coordinates are stored in an array VC, where $VC[i].x_1$, $VC[i].x_2, \ldots$, $VC[i].x_k$ are the coordinates of the vertex v_i. The facets are stored in a hash table HT with direct chaining, where $HT[j]$ is the head pointer of the linked list of facets with hashing function value j. A new facet is added at the head of a linked list, since it is more likely to be referenced again. Let $i_1 < i_2 < \cdots < i_k$ be the k indices in VC of the k vertices of a facet. We use the hashing function $h(i_1, i_2, \ldots, i_k) = (i_1 n^{k-1} + i_2 n^{k-2} + \cdots + i_k) \bmod P$, where the hash table size P is a prime number that is approximately one-eighth of the number of facets in the final triangulation, since experimental results indicate that insertion, deletion, and searching operations take constant time, on average, with these choices.

We store the elements of the hash table linked lists in an array FC of facet records with origin index 1 (we use the array form of linked lists, which is more suitable for implementation in Fortran). The $k+4$ fields of $FC[j]$ are $i_1, i_2, \ldots, i_k, i_{k+1}, i_{k+2}|\, bfp$, $htlink$, $qlink$, where $0 < i_1 < \cdots < i_k$ are the k vertex indices of a facet; i_{k+1} and possibly i_{k+2} are the indices of the other vertex of the one or two simplices with (boundary or interior, respectively) facet $v_{i_1} \ldots v_{i_k}$; bfp is used for boundary facets only and is the negative of an index of the BF array described below (so the sign of $i_{k+2}|\, bfp$ indicates whether the facet is an interior or boundary one); $htlink$ is a pointer to the next element in the hash table linked list and is an index of FC or 0 (for end of list); $qlink$ is used by the algorithms to indicate whether or not the facet is in queue Q or some other list, and in the former case its value is a pointer to the next facet (i.e., an index of FC or 0), and in the latter case, its value is -1.

If a facet is in queue Q but is no longer in the triangulation, then the i_2 field is set to zero to indicate this and the facet record is deleted when it reaches the head of Q. We also use the i_1 field to maintain an available linked list of deleted facet records (the negative of the actual pointer value is stored to distinguish deleted facets from existing facets), so that a new facet record can be obtained from the available list if it is nonempty or the end of array otherwise.

The neighbouring boundary facets of each boundary facet are stored in an array BF of boundary records with origin index 1. The k fields of $BF[j]$ are $p_1, p_2, \ldots, p_k$, where each p_r is a pointer to a facet record (an index of FC) determined as follows. Let $i_1 i_2 \ldots i_k$ be a boundary facet stored in $FC[l]$ where the i_r are ordered vertex indices, and suppose the bfp field of $FC[l]$ is $-j$. Then the p_r field of $BF[j]$ is a pointer to the other boundary facet sharing the $(k-2)$-face $i_1 \ldots i_{r-1} i_{r+1} \ldots i_k$. As for FC, we also use the p_1 field of BF to maintain an available linked list of deleted boundary records. An example of the FC, HT, and BF arrays for a four-dimensional triangulation is given in Fig. 3.

FIG. 3. *Illustration of FC, HT, and BF arrays for the four-dimensional triangulation containing the simplices* 12345, 12356, 12456, 13456 (*a simplex is represented by its vertex indices*). *There are three facets in queue with head* = 7 (*index of FC*).

In addition to the data structure operations, the main operations required are finding the hypersphere passing through the $k+1$ vertices of a simplex, finding the barycentric coordinates of a point with respect to the $k+1$ vertices of a simplex (this is used to determine the type of configuration and the direction of walking through adjacent simplices), and finding the hyperplane passing through the k vertices of a facet. The hypersphere and barycentric coordinates can each be found by solving a k-by-k system of linear equations, and the hyperplane can be found by solving a $k-1$-by-k system of homogeneous linear equations. We use Gaussian elimination with partial pivoting to solve these systems.

The three algorithms described above have been implemented in standard Fortran 77 (including all degenerate cases such as simultaneous degenerate local transformations), and this software has been added to GEOMPACK [15]. Relative tolerances are used throughout the implementation, e.g., for determining whether a point lies on a hypersphere or a hyperplane. The time complexities of the algorithms are discussed in the next section.

6. Time complexity.

6. Time complexity. We first derive the time complexity of Algorithm S, in the worst case and for sets of random points from the uniform distribution. Then we explain how these time complexities are different for Algorithms W and M. For simplicity, we assume that k is a constant in this analysis, although we will afterwards briefly discuss the factor of the time complexity that depends on k. We also present experimental results from our implementation of the three algorithms.

First we state some results from [5] and [27] on the worst-case size of convex hulls and Delaunay triangulations of n k-D vertices. The k-D convex hull has $O(n^{\lfloor k/2 \rfloor}/\lfloor k/2 \rfloor !)$ facets in the worst case. The k-D Delaunay triangulation contains $O(n^{\lceil k/2 \rceil}/\lceil k/2 \rceil !)$ simplices in the worst case. (Any k-D triangulation also contains $O(n^{\lceil k/2 \rceil})$ simplices in the worst case, since the simplices of a k-D triangulation become facets of a $(k+1)$-D convex hull if one extra $(k+1)$-D vertex is added, and $\lfloor (k+1)/2 \rfloor = \lceil k/2 \rceil$.) This means that the worst-case time complexity of any algorithm for constructing a k-D Delaunay triangulation is at least $O(n^{\lceil k/2 \rceil})$.

We now derive the worst-case time complexity of Algorithm S; this is a generalization of the three-dimensional case in [13]. $O(n \log n)$ time is required for the initial sorting of vertices in step 1. For step 2, we use the fact that using our hash table data structure with storage proportional to the maximum number of facets in the intermediate triangulations (which is usually close to the number of facets in the final Delaunay triangulation), searching, insertion, and deletion of a facet can each be performed in constant time, on average [16]. If $2k$ extra pointer fields are added to each facet record (one pointer to each other facet of each of the two simplices incident on the facet), then hashing and searching can be avoided and data structure operations can always be performed in constant time. The time complexity for step 2 can be obtained as follows.

For i between $k+2$ and n inclusive, let the following variables denote the quantities when vertex v_i is added to the triangulation:

BF_i = number of boundary facets in $\mathcal{T}_{i-1}^D$,

DF_i = number of facets in Q that are no longer in triangulation when facet is at head of Q,

LO_i = number of facets that result in locally optimal when tested,

NTF_i = number of facets that result in nontransformable when tested,

LT_i = number of local transformations applied,

DS_i = number of deleted simplices not involving vertex v_i,

AS_i = number of added simplices involving vertex v_i in $\mathcal{T}_i^D$.

Then the time complexity for step 2 is

$$O\left(\sum_{i=k+2}^{n}[BF_i + DF_i + LO_i + NTF_i + LT_i]\right). \tag{1}$$

The variables in (1) can be bounded as follows. $DF_i \le (k-1)LT_i$ since each type-N transformation removes at most $k-1$ facets of $\mathcal{F}_i^{(r)}$. Similarly, $NTF_i \le (k-1)LT_i$ since a nonlocally optimal nontransformable facet does not get put back in queue Q, but does get swapped out later by a type-N transformation or (simultaneous type-N transformations) involving another facet of the $\mathcal{F}_i^{(r)}$. $LO_i \le AS_i$ since every tested locally optimal facet forms a simplex with vertex v_i in $\mathcal{T}_i^D$. $LT_i = DS_i$ since each type-N transformation removes exactly one simplex not involving vertex v_i. Since each deleted simplex not involving vertex v_i must have been added at the insertion of a previous vertex, $\sum_{i=k+2}^{n} DS_i \le 1 + \sum_{i=k+2}^{n-1} AS_i$. With these bounds, (1) becomes

$$O\left(\sum_{i=k+2}^{n}[BF_i + AS_i]\right). \tag{2}$$

$BF_i = O(i^{\lfloor k/2 \rfloor})$ as mentioned above for the worst-case number of facets on a k-D convex hull. Also, $AS_i = O(i^{\lfloor k/2 \rfloor})$ for the following similar reason. Since all points on all facets of $\mathcal{F}_i^D$ are "visible" from v_i, the points of the facets can be linearly projected from v_i so that the projected facets are on the boundary of the convex hull of at most $i-1$ vertices (alternatively, project the facets onto a hyperplane and use the worst-case number of simplices in a $(k-1)$-D triangulation). Hence (2) and the worst-case time complexity of Algorithm S are $O(n^{\lfloor k/2 \rfloor + 1})$. Since $\lfloor k/2 \rfloor + 1 = \lceil k/2 \rceil$ for odd k, Algorithm S has a worst-case optimal time complexity for odd k.

For sets of i random k-D points from the uniform distribution (in a hypercube), the expected number of facets in the convex hull of the i points is $O((\log i)^{k-1})$ [4]. This size complexity for BF_i also occurs empirically, as seen in the following tables. Our measurements for AS_i show that it is also empirically $O((\log i)^{k-1})$. So from (2), the empirical time complexity of Algorithm S for sets of n random points from the uniform distribution is $O(n(\log n)^{k-1})$. The expected time complexity would also be $O(n(\log n)^{k-1})$ if it could be shown that the expected size of AS_i is the same as that for BF_i.

The derivation of the worst-case time complexity for Algorithms W and M is similar to that above, except there is one extra term WS_i for the number of simplices visited during the walk through $\mathcal{T}_{i-1}^{D}$. Since WS_i may be $O(i^{\lceil k/2 \rceil})$ in the worst case which is the same or worse than the $O(i^{\lfloor k/2 \rfloor})$ bounds for BF_i and AS_i in (2), the worst-case time complexity of Algorithms W and M may be $O(n^{\lceil k/2 \rceil + 1})$, which is worse than that for Algorithm S when k is odd (see the end of this section for further remarks on this). For sets of n random points from the uniform distribution, the time complexity of Algorithms W and M is harder to analyze (but it is the same for the two algorithms). Empirically, Algorithms W and M are faster than Algorithm S (see the tables below), because the bin sorting or some other preprocessing step can be used to reduce the time spent in the walking phase and, when v_i is added to the triangulation, there are about a constant number of local transformations applied when v_i is inside the convex hull of the previous vertices compared with about $O((\log i)^{k-1})$ local transformations applied when v_i is outside the convex hull.

As a function of k and n, the time complexities have an extra factor involving k that depends on implementation details. In our implementation, Gaussian elimination is used to solve k by k linear systems for hyperspheres, hyperplanes, and barycentric coordinates in $O(k^3)$ time per system. Also, each local transformation updates $O(k^2)$ facets in the data structure, and each insertion, deletion, or search operation in the hash table takes $O(k^2)$ time to order the k vertex indices of a facet (we assume k is small and use insertion sort for this); so it takes $O(k^4)$ time to update the data structure due to a local transformation. There is also an $O(k^4)$ factor from updating the BF array when v_i is added outside the convex hull of the previous vertices (since there are $O(k^2)$ $(k-2)$-faces in a simplex). Therefore, for the three algorithms, the extra factor in the time complexity is $O(k^4)$ (ignoring the constant factor for the convex hull size which is $1/\lfloor k/2 \rfloor!$ in the worst case and unknown for random points).

We now present experimental results from our Fortran 77 implementation of Algorithms S, W, and M, first for sets of random points from the uniform distribution and then for sets of points yielding a worst-case number of simplices in the Delaunay triangulation. The results are obtained from running our routines on a Sun 4/20 workstation using the *f*77 compiler with optimizing option. For each k, problems with four or five different values of n are used. For each n, five different problems are run and the measurements are averaged. Due to the increase in the CPU times and the number of facets as k increases, smaller sizes of n are used as k increases.

In Tables 1–4, for $k = 2$ to 5, are the CPU times in seconds for Algorithms S, W, and M (denoted by STIM, WTIM, and MTIM, respectively) and number of facets (NFAC) and boundary facets (NBF) in the Delaunay triangulation for sets of random points from the uniform distribution. For the average entries in the left half of the tables, at least three significant digits are given. The number of simplices is given by the formula (2 NFAC - NBF)$/(k+1)$. For $k = 2$ and 3, the bin-sorting preprocessing step was used with about $n^{0.5}$ and $n^{0.4}$ bins, respectively, for Algorithms W and M. For $k = 4$ and 5, the bin-sorting preprocessing step was not used since the n values are too small for it to be effective. These tables show that NFAC $= O(n)$, NBF $= O((\log n)^{k-1})$, and STIM $= O(n(\log n)^{k-1})$. Although Algorithm S has the better theoretical time complexity (because of no walking phase), Algorithms W and M are faster for the random points (with Algorithm M being the fastest because it does not apply local transformations explicity and has no nonlocally optimal nontransformable facets). Using larger n values and the bin-sorting preprocessing step for $k = 4$ and 5, we expect that the empirical time complexity of Algorithms W and M for $k = 4$ and 5 would be closer to that for $k = 2$ and 3, i.e., $O(n^{1.1})$.

Tables 1–4 illustrate how the CPU times increase for the k-D Delaunay triangulation algorithms as k increases. In [15], similar timing results are given for two- and three-dimensional versions of Algorithms S and W that work for one dimension only. Since the data structure and matrix operations in these versions do not have to work for arbitrary dimensions (for $k = 2$, a much simpler data structure can be used), these special versions are faster by the following factors. For the two-dimensional version, STIM is faster by

a factor of about 4.2 and WTIM is faster by a factor of about 5.0 over the k-D version run with $k = 2$. For the three-dimensional version, STIM and WTIM are both faster by a factor of about 1.6. We expect that special two- and three-dimensional versions of Algorithm M would have improvement factors similar to those of Algorithm W.

We use the following sets of points to obtain k-D Delaunay triangulations containing the worst-case number of simplices for $k \geq 3$ (all two-dimensional triangulations have $O(n)$ triangles). In [24], it is shown that if the n k-D points lie on the moment curve $(t, t^2, \ldots, t^k)$ with parameter t, then there exists a triangulation of the n points containing $O(n^{\lceil k/2 \rceil})$ simplices. Our routines show that the Delaunay triangulation of these points contains $O(n^{\lceil k/2 \rceil})$ simplices. In Tables 5–7, for $k = 3$ to 5, are the CPU times in seconds for Algorithms S, W, and M, and number of facets and boundary facets in the Delaunay triangulation for sets of random points on the moment curve, where the first coordinate t is a random number in the interval $[0, 1]$ from the uniform distribution. For Algorithms W and M, the n points are added to the triangulation in random order. For $k = 3$, NFAC $= (n-2)^2$ and NBF $= 2(n-2)$. For $k = 4$, NFAC $= (n-3)(3n-10)/2$ and NBF $= n(n-3)/2$. For $k = 5$, NFAC $= (n-3)(n-4)^2/2$ and NBF $= (n-3)(n-4)$.

Tables 5–7 show that the time complexity of Algorithms S, W, and M for the moment curve problems are each the same as the size complexity of the Delaunay triangulation, i.e., $O(n^{\lceil k/2 \rceil})$. Algorithm S is faster than Algorithms W and M for these problems, because no local transformations are performed by Algorithm S as a result of the lexicographic increasing order of the vertices while $O(n^{\lceil k/2 \rceil})$ local transformations are performed by Algorithm W.

For $k = 4$, Algorithm S does not achieve the worst-case time complexity of $O(n^3)$ for the moment curve problems in Table 6. This is due to the ordering of the vertices. If they are added in the reverse order, or equivalently, the first coordinate t is a random number in the interval $[-1, 0]$ from the uniform distribution, then the worst-case time complexity is achieved as shown in Table 8. This is because the addition of v_i causes $(i-4)(i-5)/2$ local transformations, $i = 6, \ldots, n$, for a total of $(n-3)(n-4)(n-5)/6$ local transformations. For $k = 2$, Algorithm S also achieves the worst-case time complexity of $O(n^2)$ for moment curve (or parabola) problems generated in the same way, as shown in Table 8. In this case, the addition of v_i causes $i-3$ local transformations, $i = 4, \ldots, n$, for a total of $(n-2)(n-3)/2$ local transformations. With the vertices ordered in the same way as Algorithm S, Algorithms W and M also achieve the worst-case time complexity for $k = 2$ and 4. For $k = 3$ and 5, the reverse ordering of vertices still results in no local transformations for Algorithm S.

For $k = 3$, Algorithms W and M could achieve a time complexity of $O(n^3)$ if the Delaunay triangulation of the first $i-1$ vertices contains $O(i^2)$ tetrahedra and the walk to determine the location of vertex v_i goes through $O(i^2)$ tetrahedra for all i. Edelsbrunner [7] has constructed the following example in which there is a line going through $O(n^2)$ tetrahedra in the Delaunay triangulation. For even n, the n vertices are $v_i = (0, -1+(i-1)h, 1)$, $i = 1, 2, \ldots, n/2$, and $v_i = (-1 + (i-1-n/2)h, (-1)^i\epsilon, 0)$, $i = n/2+1, \ldots, n$, where $h = 2/(n/2-1)$ and ϵ is a small positive number. The first $n/2$ vertices are on the line $x = 0$, $z = 1$. The last $n/2$ vertices are small perturbations of points on the line $y = 0$, $z = 0$. If ϵ is sufficiently small, then the Delaunay triangulation contains (at least) the $(n/2-1)^2$ tetrahedra $v_iv_{i+1}v_jv_{j+1}$ for $i = 1, \ldots, n/2-1$ and $j = n/2+1, \ldots, n-1$. The line $y = 0$, $z = \epsilon$ goes through the interior of each of these $(n/2-1)^2$ tetrahedra. However, a walk through the Delaunay triangulation to determine the location of a point p on this line does not have to go through all of the $(n/2-1)^2$ tetrahedra since the walk does not have to proceed in a straight line. From running our routines on this example, the walk actually goes through only $O(n)$ tetrahedra.

Therefore, this example cannot be used to obtain a time complexity of $O(n^3)$ for Algorithms W and M. So far, we have not been able to construct any examples for which the time complexity of Algorithms W and M is worse than $O(n^2)$ for $k = 3$. So it is an open question whether the worst-case time complexity of Algorithms W and M is actually worse than that of Algorithm S for odd k.

7. Concluding remarks. We have presented Algorithms S, W, and M for constructing Delaunay triangulations of sets of n k-D points. We have shown that the worst-case time complexity of Algorithm S is $O(n^{\lfloor k/2 \rfloor + 1})$, which is worst-case optimal for odd k. For sets of random points from the uniform distribution, the empirical time complexity of Algorithm S is $O(n(\log n)^{k-1})$.

Algorithms S and W both use local transformations, and only differ in the order of inserting the vertices into the incremental Delaunay triangulations. By allowing vertices to be inserted in the interior of the convex hull of the previous vertices, Algorithm W is faster than Algorithm S in practice, although Algorithm S has the better theoretical time complexity. Algorithm M differs from Algorithm W in that local transformations are not explicitly performed. So Algorithm M is faster than Algorithm W in practice, but is less numerically robust since invalid triangulations may be created by Algorithm M in floating point arithmetic when there are many points on (or nearly on) the same hypersphere. Using the criteria of efficiency and robustness, the best algorithm depends on the distribution and number of points to be triangulated.

In practice, we do not expect point distributions yielding a worst-case time complexity to occur. For example, in finite element mesh generation, the empirical time complexity will depend on how the points are generated, but should be close to that for the case of random points from the uniform distribution, e.g., see [14].

Shortly after submitting this paper, the author discovered similar work in [23] and [8]. In the former paper, it is shown that the incremental approach using local transformations can construct k-D Delaunay triangulations if the local transformations at each step are applied in a special order using a priority queue (instead of a more general topological order using a queue as in this paper). In the latter paper, which was written independently at about the same time as this one, a different approach is used to prove the results of §4 for regular triangulations (which include Delaunay triangulations as a special case).

Acknowledgment. The author would like to thank the referees for their helpful comments.

A METHOD FOR DEVISING EFFICIENT MULTIGRID SMOOTHERS FOR COMPLICATED PDE SYSTEMS*

IRAD YAVNEH†

Abstract. A systematic approach is developed for gaining insight into complicated systems of partial differential equations (PDEs) in order to construct efficient smoothers for multigrid solvers. The method is derived from local mode (smoothing) analysis and employs algebraic graph theory, but it requires no knowledge of either in its implementation. It is applied to several problems, for which finding the best approach without such an analysis can be quite challenging.

Key words. multigrid, partial differential equations, systems

AMS subject classifications. 65M55, 65N55

1. Introduction. Multigrid methods are widely considered to be one of the most powerful and versatile approaches to the solution of problems with many variables, particularly discretized partial differential equations (PDEs) and systems. As more and more scientists and engineers become acquainted with these techniques, much of the mystery surrounding successful application of multigrid is lifted. And yet it is clear that the vast majority of multigrid solvers that are actually applied in scientific calculation are used for single equations or very simple systems. When multigrid methods are employed in truly complicated problems, they are usually applied only to small parts of the problem, e.g., some elliptic boundary value problem. Thus, the enormous potential of multigrid is rarely realized in practice. The main reason for this is that general tools that have been developed for dealing with complicated systems are frequently difficult to apply.

A method is introduced here for constructing the most important part of the multigrid solver, the smoother, for complicated systems. This method, which can be mastered readily by anyone capable of constructing a multigrid solver for a simple problem, frequently enables one to find a solution procedure that is as efficient as solving the equations of the system separately. Even when that is impossible, much is learned by applying this analysis, because it points out where the difficulties are.

Much of what is presented here has appeared in different form and from a different point of view in [1, §3]. When it exists, the equivalence between the two approaches will be noted.

A secondary purpose of this work is to suggest the use of graphs (via algebraic graph theory) in analyses. This may enable one, as here, to obtain tools that are far easier to utilize than the commonly used tools of linear algebra.

In §2 the analysis is presented along with examples. No mathematical justification is included in this section, but rather a heuristic motivation. In §3 the theoretical basis of the method is given, with more precise concepts. In §4 is a discussion of the main results, a comparison to present techniques and conclusions.

2. The coupling analysis. In constructing efficient relaxation schemes for multigrid solvers of discretized systems of PDEs, it is important to gain some understanding of the interrelationship between the equations. This is determined both by the differential

* Received by the editors May 18, 1992; accepted for publication (in revised form) December 14, 1992.This work was supported by the National Science Foundation through the National Center for Atmospheric Research.

† National Center for Atmospheric Research, Boulder, Colorado 80307-3000.

system and by the proposed relaxation scheme. The approach that motivates the analysis presented here is to consider the relaxation process as a feedback system. When an equation (or a block of equations) within a system is relaxed by some relaxation scheme, its residuals are decreased. But, due to the coupling between equations, the residuals of other equations in the system are perturbed. When these equations are relaxed in turn, such perturbations propagate and others are formed. Eventually, some of the perturbations caused by the relaxation of each equation may be fed back into the residuals of the equation, amplified by a certain factor that depends on the operators in the system (in particular, their orders and the size of their coefficients), on the discretization and relaxation scheme, and on the meshsize. If this factor is small enough for all the equations and all the possible routes such perturbations can follow, then the system behaves in relaxation almost as if it were decoupled. But if this is not the case, then the proposed relaxation process will generally fail.

As will be seen in §3, the same qualitative behavior is exhibited whether the equations are relaxed *simultaneously*, whereby the variables are updated only after all the equations have been relaxed, or *successively*, whereby the variables are updated as soon as each equation is relaxed.

The initial search for a useful relaxation scheme is greatly simplified by assuming a vanishingly small meshsize and finite coefficients of the operators. Then the feedback properties are determined by the orders of the operators in a straightforward manner, which is presented through the following example.

Suppose one wishes to construct an efficient, fully implicit, multigrid solver for the incompressible Euler equations in two dimensions, which can be written in terms of the vorticity $\zeta(x,y,t)$ and the streamfunction $\psi(x,y,t)$ as

$$\Delta\psi - \zeta = 0\,, \tag{1}$$

$$D_t\zeta = \zeta_t + J(\psi,\zeta) = 0\,, \tag{2}$$

where $J(\psi,\zeta) = \psi_x\zeta_y - \psi_y\zeta_x$, and Δ is the Laplace operator. Suppose that central differencing of some sort is used for the spatial discretizations, and Crank–Nicholson (or backward Euler) is used in time. Equation (1) is the Poisson equation for ψ, and it is well known (e.g., [1]) that point Gauss–Seidel (GS) relaxation, particularly in red-black (RB) ordering, provides an extremely efficient smoother. But GS relaxation for the advection operator D_t is useful only for small and moderate timesteps. When the timestep (more precisely, the Courant–Friedrichs–Lewy (CFL) number) becomes too large, point GS relaxation can no longer be used. It can be replaced by Kaczmarz relaxation (see [1, §1] and also §2.7 below), but this relaxation loses its efficiency very rapidly as the timestep is increased, and it is also more expensive. One might therefore attempt the following.

Consider the new variable $\Psi = \psi_t$. This leads to the following system, which is equivalent to (1)–(2).

$$\Delta\psi - \zeta = 0\,, \tag{3}$$

$$\zeta_t - \Delta\Psi = 0\,, \tag{4}$$

$$J(\psi,\zeta) - \Delta\Psi = 0\,. \tag{5}$$

Now, in the multigrid solution at each time-level, one can relax (3) by applying GS relaxation to ψ, relax (4) by applying GS relaxation to ζ, and (5) by similarly relaxing Ψ.

For each of these equations separately the relaxation is extremely efficient (indeed, GS relaxation applied to (4), considered as a function of ζ alone, is an exact solver). But, due to the coupling of the equations, relaxation of each equation affects the residuals of the others. Let us determine by analysis whether or not this effect of the coupling is prohibitive.

Given a system of k PDEs in k unknowns, the first step is to associate with each equation the variable for which the equation is relaxed. Thus, (3), (4), and (5) correspond to ψ, ζ, and Ψ, respectively. We shall later see what must be done if there is no such clear choice. The next step is to construct the k-by-k *order-array* Q: $q_{i,j}$, the element of Q in the ith row and jth column, is simply the order of the operator that operates on variable j in equation i. If variable j does not appear in equation i, then the null symbol N is placed in the (i,j)th position. For (3)–(5) the order-array is

$$Q = \begin{bmatrix} 2 & 0 & N \\ N & 1 & 2 \\ 1 & 1 & 2 \end{bmatrix}.$$

Note that the time-derivative is treated here similarly to the spatial derivatives. But there is an important distinction. We return to this in §2.3, §2.5, and §2.7.

From Q we next construct the k-by-k *weight-array* W: $w_{i,i}$, the diagonal elements of W, are the null symbol N; also, if $q_{i,j} = N$, then $w_{i,j} = N$; the remaining elements are given by

$$w_{i,j} = q_{j,j} - q_{i,j} ,$$

that is, the corresponding element in Q is subtracted from the diagonal Q element of the same column. For (3)–(5) W is given by

$$W = \begin{bmatrix} N & 1 & N \\ N & N & 0 \\ 1 & 0 & N \end{bmatrix}.$$

Now we plot the *coupling graph*. k nodes are plotted and numbered, each representing an equation. Then we go through the elements of W. If a null element is encountered it is skipped. But when $w_{i,j}$ is an integer, we draw a directed edge (an arrow) from node j to node i and label it with its weight $w_{i,j}$. The coupling graph for (3)–(5) is plotted in Fig. 1.

The final step in the analysis is to go over all possible simple loops (closed paths) in the coupling graph, moving only in the direction of the arrows, and sum up the weights along the loops. In Fig. 1 it is seen that only two such loops exist, (1,3,2,1) and (2,3,2), whose respective weight-sums are

$$s_{(1,3,2,1)} = w_{3,1} + w_{2,3} + w_{1,2} = 2$$

and

$$s_{(2,3,2)} = w_{3,2} + w_{2,3} = 0 .$$

DEFINITION 1. If the weight-sum of a loop is positive (nonpositive), then the equations whose nodes are included in the loop are said to be weakly (strongly) coupled.

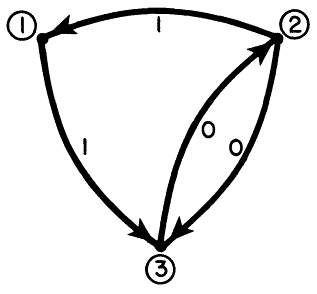

FIG. 1. *Coupling graph for* (3)–(5).

DEFINITION 2. If no loops exist, then the system is, in effect, decoupled. Otherwise, if the weight-sums of all the loops are positive, then the system is said to be weakly coupled.

Rule 1. If a system is weakly coupled, then relaxing its equations separately (successively) yields for the system a smoothing factor (i.e., the largest per-sweep amplification factor for high-frequency errors; cf. [1]) that tends to the largest (worst) of the smoothing factors of the operators on the diagonal of the system as the meshsize tends to zero.

This means that if a system is weakly coupled, then at least on fine enough grids it can be treated in relaxation as if decoupled, since the feedback is small for all the equations.

From the point of view of [1, §3], weak coupling implies that the principal part of the (linearized) matrix-operator is a diagonal matrix. Then, Brandt's principle that only the principal part of the operator needs to be relaxed (on fine enough grids) is automatically satisfied.

Rule 1 and the rules that follow are all derived from local mode (smoothing) analysis (see [1]) and hold under the same conditions as local mode analysis. But local mode analysis is well established as providing excellent prediction of smoothing performance, even when the assumptions on which it is based are not maintained exactly. In general, it can be said that the prediction holds so long as the coefficients of the (linearized) system are smooth on the scale of the mesh, i.e., their variation over a few meshsizes tends to zero with the meshsize. In practice, even if this condition is not satisfied over relatively small parts of the domain of solution, the smoothing efficiency is not affected significantly (see also [1].)

We find that (4) and (5) are strongly coupled. Therefore, these must generally be relaxed collectively, or else another formulation must be tried. Since the weight-sum of the corresponding loop is exactly zero, it is conceivable that relaxation may still be reasonably effective with this approach, depending on certain parameters. This is elaborated below. However, if the analysis had shown that the system were only weakly coupled, then the smoothing factor of the system would have been known to be the worst of the separate smoothing factors—that of the Laplace operator.

Nonlinear operators. As the first example indicates, the coupling analysis is not limited to linear systems. The order of a nonlinear operator is defined as follows.

Rule 2. The order of a nonlinear operator is determined by that of the linearized operator.

Thus, $J(\psi, \zeta)$ is a first-order operator for both ψ and ζ, and $(u_x)^3$ is a first-order operator for u, since the linearized operator is $3(u_x)^2\partial_x$. However, note that the order of a nonlinear operator is determined by the *discrete* operator, not the differential operator. Normally the orders are the same. But suppose, for example, that some nonlinear operator, say $J(\psi, \zeta)$, is discretized in conservation form,

$$J(\psi, \zeta) = \psi_x\zeta_y - \psi_y\zeta_x = (\psi_x\zeta)_y - (\psi_y\zeta)_x \, .$$

Although J is a first-order operator, this form includes second derivatives of ψ, which cancel each other in the differential operator. But they will only cancel each other in the discrete form if the discretizations of the two terms employ ψ-variables of the same meshpoints. If this is not satisfied by the discretization, then the operator is considered to be second-order in ψ for the purpose of the coupling analysis. Hence, in special cases such as will be examined later, one may choose to put off the decision of choice of discretization until after the analysis has been carried out.

2.1. Searching for weak-coupling configurations. Frequently, there is a natural and obvious correspondence between the equations in a system and the variables for which they should be relaxed. But, especially in complicated systems, there may be several plausible choices, and in other systems there may be no good choice at all. Treatment of the latter situation is examined in §2.5. Here we describe a general algorithm for finding a one-to-one correspondence between equations and variables that leads to a weakly coupled system, if it exists. Such a one-to-one correspondence is called a configuration, and a configuration that yields a weakly coupled system is called a weakly coupled configuration. Our convention is, as usual, that the the elements on the diagonal of the operator (and on the diagonal of the order-array Q) correspond to the unknowns for which the equations are relaxed.

The algorithm for searching for a weakly coupled configuration is as follows. Construct the order-array Q for some arbitrary configuration. Then find the permutation of the rows of Q that maximizes the trace (i.e., the sum of the diagonal elements), where the null symbol N is considered as $-\infty$. The following rule holds.

Rule 3. A configuration is weakly coupled if and only if the trace of its order-array Q is the unique maximum of the traces of all matrices obtainable by permutations of the rows of Q.

Hence, it suffices to find a permutation that maximizes the trace of Q, calculate the corresponding weight-array W, and construct the coupling graph. If the graph indicates that the system is weakly coupled, then it is the only weakly coupled configuration. But if the graph indicates strong coupling, then there exists no weakly coupled configuration for the formulation considered. An example of the application of this algorithm is given in §2.4.

The problem of maximizing the trace by row permutations is equivalent to the well-known *maximal* (*weighted*) *matching* problem, for which there are efficient algorithms (see, e.g., [5]). However, this problem is very easy by any means, unless the system is extremely large and complicated.

2.2. Coping with strong coupling. The following example illustrates what can be done when too strong a coupling is diagnosed. Suppose we wish to construct a smoother for the system

$$\Delta u - a^2 w = 0 \, , \tag{6}$$

$$\Delta v + \mathcal{M}(w) = 0 \, , \tag{7}$$

$$\Delta^2 u + J(u,v) + \Delta w = 0\,, \tag{8}$$

where $\mathcal{M}$ is some operator whose order q_M is yet to be determined, and a is a constant.

Let u, v, and w, respectively, correspond to (6), (7), and (8). The order-array is given by

$$Q = \begin{bmatrix} 2 & N & 0 \\ N & 2 & q_M \\ 4 & 1 & 2 \end{bmatrix},$$

and the weight-array by

$$W = \begin{bmatrix} N & N & 2 \\ N & N & 2 - q_M \\ -2 & 1 & N \end{bmatrix}.$$

The coupling graph is plotted in Fig. 2. The weight-sums of the loops are

$$s_{(1,3,1)} = w_{3,1} + w_{1,3} = 0$$

and

$$s_{(2,3,2)} = w_{3,2} + w_{2,3} = 3 - q_M\,.$$

The first and third equations are found to be strongly coupled. One way to solve this problem is to relax these equations collectively, but the resulting smoothing factor is uncertain and this form of relaxation is more expensive and complicated. It would be better if we could somehow sever the edge leading from the first equation to the third. Suppose we apply the Laplace operator to (6), subtract the resulting equation from (8) to obtain

$$J(u,v) + (1 + a^2)\Delta w = 0\,, \tag{9}$$

and use (9) instead of (8). The edge from the first equation to the third is not quite removed, but its weight increases from -2 to a very satisfactory 1, and the resulting system is weakly coupled provided that q_M is smaller than 3. A weakly coupled system has thus been obtained by *reducing the order of a crucial off-diagonal operator*, whose adverse effect was apparent in the coupling graph.

A more generally useful approach for coping with strong coupling is to transform the variables implicitly in such a way as to weaken the coupling. This is frequently the best approach, especially with staggered discretizations. It is a somewhat generalized form of Brandt's distributive relaxation (see, e.g., [3] or [1]). The generalization is that we do not necessarily require that the operator in the transformed variables form a triangular matrix. It suffices to obtain a weakly coupled system, which might ease the task of constructing the distributive scheme and lead to a less complicated smoother. This is especially important near boundaries, where ad hoc treatment of distributive relaxation is generally required (see, e.g., [4]). An example of this approach is given in §2.5.

Finally, if neither of these approaches is found to be useful, some or all of the equations might have to be relaxed collectively (once again relaxing the principal part of the operator, as suggested in [1, §3].) But even then the coupling analysis is useful in pointing out *which* equations are strongly coupled and therefore require such treatment.

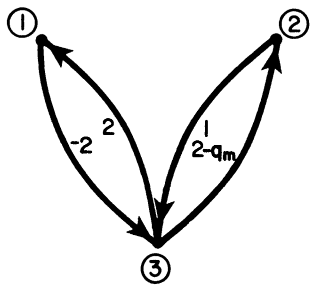

FIG. 2. *Coupling graph for* (6)–(8).

2.3. Finite meshsizes and the inclusion of coefficients. In applying the coupling analysis we have so far implicitly assumed that the coefficients in the equations were independent of the meshsize, and were therefore much larger (in absolute value) than the meshsize h and much smaller than $1/h$. This, however, need not be the case when finite meshsizes are considered, even in linear systems. A quantitative assessment of the strength of the coupling, which takes into account the meshsize and the coefficients, can be obtained just as easily. This includes, of course, the case of nonlinear systems, where the coefficients depend on the solution and its derivatives.

Rule 4. When the full coupling analysis is applied, the system must be written so that the coefficients of the operators on the diagonal (i.e., the operators of the variables that are relaxed) are $O(1)$.

If the coefficients of the operators on the diagonal are very large or very small, the equations must be divided through by these coefficients before the analysis is applied.

Consider the following linear elliptic system, whose solution is part of the explicit solution process of the shallow water balance equations [6], written in matrix form:

$$(10)\qquad \begin{pmatrix} \Delta + (R/H)\nabla\phi\cdot\nabla & 1/H & 0 \\ 0 & -\Delta & \Delta + 2R\mathcal{M} \\ R(A\Delta + \nabla\zeta\cdot\nabla) & 0 & \Delta \end{pmatrix} \begin{pmatrix} \chi \\ \Phi \\ \Psi \end{pmatrix} = \begin{pmatrix} f_1 \\ f_2 \\ f_3 \end{pmatrix},$$

where ζ and ϕ are given functions, $\mathcal{M}$ is a second-order operator, R is a constant, which may be small or moderate, and H and A, which may vary considerably in size, are given functions of the spatial coordinates. Note that the system is written with $O(1)$ coefficients on the diagonal (indeed 1, but that is not essential).

The order-array and weight-array are, respectively,

$$Q = \begin{bmatrix} 2 & 0 & N \\ N & 2 & 2 \\ 2 & N & 2 \end{bmatrix}, \qquad W = \begin{bmatrix} N & 2 & N \\ N & N & 0 \\ 0 & N & N \end{bmatrix}.$$

The coupling graph is plotted in Fig. 3, and we find that there is a single loop, (1,3,2,1), whose weight-sum is 2. Hence, the system is weakly coupled.

In order to obtain a more quantitative assessment of the strength of the coupling, we now construct the *coefficient-array* C, whose element $c_{i,j}$ is some norm of the coefficients of the highest derivatives in the operator in equation i that operates on variable j. Here it is assumed that $c_{i,j}/h$ is not small compared to the norm of the coefficients of

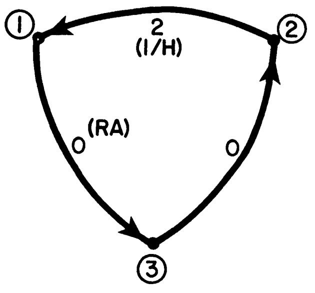

FIG. 3. *Coupling graph for* (10).

the second-highest derivatives in the corresponding operator, as may happen in singular perturbation problems. Otherwise, $c_{i,j}$, and also $q_{i,j}$, are defined as the coefficient-norm and order of the second-highest derivatives. Approximate values for $c_{i,j}$ are sufficient. For example, since R is known not to be large in (10), $c_{2,3} = 1$. The coefficient-array of (10) is

$$C = \begin{bmatrix} 1 & 1/H & N \\ N & 1 & 1 \\ RA & N & 1 \end{bmatrix} .$$

Now we return to the coupling graph and, for every element in C that is different from N (1's can also be disregarded), we write this element (in parentheses) on the edge leading from node j to node i. Finally, we go over all the loops and *multiply* the coefficients that are encountered. For (10) the coefficient-product of the only loop is

$$p_{(1,3,2,1)} = c_{1,2} \cdot c_{3,1} = RA/H .$$

In order to determine if the system is weakly coupled for a given meshsize h, we must add to the weight-sum of each loop the *log* of the loop's coefficient-product, divided by $\log h$, and still obtain a positive result. (This is due to the relative effects of coefficients and orders of the operators, and is clarified in §3). However, since now we are dealing with orders of magnitude, and with nonintegers, a more meaningful criterion is the following.

DEFINITION 3. Let s and p be the weight-sum and coefficient-product of a loop, respectively. Then the equations whose nodes are included in the loop are said to be h-weakly coupled if

$$ph^s \ll 1 .$$

DEFINITION 4. If all loops are h-weakly coupled, then the system is said to be h-weakly coupled.

Rule 5. If a system that is discretized on a grid with meshsize h is h-weakly coupled, then relaxing its equations successively yields for the system a smoothing factor

$$\bar{\mu} = \max_i \bar{\mu}_i + O(ch^\alpha) ,$$

where $\bar{\mu}_i$ are the smoothing factors of the operators on the diagonal of the system, and $c, \alpha > 0$, with c depending on the coefficients of the operators in the system.

Hence, if the meshsize is small, the equations can be treated in relaxation as if decoupled. Of course, the actual size of this positive power is of interest, and its calculation is explained in §2.6.

Sometimes (for example, in singular perturbation problems) the second-highest derivative terms may impose a greater restriction than the highest-derivative terms (because their coefficients are much larger). In such cases one can substitute some variables for the order and coefficient of the relevant operator when performing the coupling analysis and obtain conditions for weak coupling in terms of these variables.

Time derivatives. Consider once again the advection operator $D_t = \partial_t + u\partial_x + v\partial_y$. The coefficient of the spatial derivatives can be any rough estimate of the velocities u and v. In determining the coefficient of the time-derivative, however, we must multiply the actual coefficient (which is one in this case) by $h/\Delta t$, where Δt is the timestep. Thus, a good choice for the coefficient of D_t is, say, $h/\Delta t + |u| + |v|$. More generally, ∂_t^q is treated in the analysis as $(h/\Delta t)^q \partial_t^q$. Similar treatment must be used whenever spatial meshsizes differ significantly too. Returning to the first example, we find that (3)–(5) *is* h-weakly coupled only if $\Delta t(|\psi_x| + |\psi_y|)/h \ll 1$, i.e., at small CFL numbers, rather than at moderate and large ones for which the approach is required. This misfortune is not surprising, as at large CFL numbers the system loses its h-ellipticity (see [1]), and no point relaxation can be efficient. But the coupling analysis discovers this automatically, without requiring such insight.

Note the difference between time derivatives and spatial derivatives. In the solution process at each time level, the timestep Δt is fixed and only the spatial mesh is coarsened. This implies that the coupling of loops that include equations in which terms with time-derivatives are relaxed remains truly weak on coarse grids as well. The analysis predicts this phenomenon automatically. Such cases are considered in §2.5 and §2.7.

2.4. Coupling analysis of the shallow water balance equations. Let us see how the coupling analysis and the algorithm presented in §2.1 are employed to find an efficient fully implicit solver for a nonlinear, nonsymmetric coupled system—the shallow water balance equations (SWBE), which describe accurate, gravity-wave-free states on the so-called "slow manifold" of the shallow water equations. The full treatment of this problem is described in [6]. The nondimensionalized SWBE can be written for small or moderate Rossby number R and Burger number B as

$$-\nu\Delta\zeta + D_t\zeta + RA\Delta\chi = 0\,, \tag{11}$$

$$D_t\phi + H\Delta\chi = 0\,, \tag{12}$$

$$\zeta - \Delta\phi + 2RJ(\psi_x, \psi_y) = 0\,, \tag{13}$$

$$\zeta - \Delta\psi = 0\,, \tag{14}$$

where $D_t = \partial_t + J(\psi, \cdot) + R\nabla\chi \cdot \nabla$, $A = R^{-1} + \zeta$, and $H = B + R\phi$. Here, ν is a nondimensional viscosity coefficient, and in the following we consider for simplicity only the inviscid case of vanishing ν, which is the most difficult case with respect to smoothing. The system is discretized using a conservative central differencing in space and Crank–Nicholson in time.

Now we need to find a good smoother. Here it is not immediately obvious what, if any, effective correspondence between equations and variables exists. Following the algorithm of §2.1, we therefore construct the order-array for some configuration, and look for the permutation of rows that maximizes the trace. The maximal trace turns out to be seven, with (11), (12), (13), and (14) corresponding to ζ, χ, ϕ, and ψ, respectively. The order-array and weight-array are

$$(15)\qquad Q = \begin{bmatrix} 1 & 2 & N & 1 \\ N & 2 & 1 & 1 \\ 0 & N & 2 & q_M \\ 0 & N & N & 2 \end{bmatrix}, \qquad W = \begin{bmatrix} N & 0 & N & 1 \\ N & N & 1 & 1 \\ 1 & N & N & 2-q_M \\ 1 & N & N & N \end{bmatrix},$$

and the coefficient-array is

$$(16)\qquad C = \begin{bmatrix} 1 & RA\alpha & N & \alpha \\ N & 1 & 1/H\alpha & 1/H \\ 1 & N & 1 & R \\ 1 & N & N & 1 \end{bmatrix},$$

where q_M denotes the order of the discretized nonlinear operator in (13) and $\alpha = \Delta t/h$. Here, Rule 4 has been applied, and the coefficients in the advection operators were assumed to be $O(1)$. The coupling graph is plotted in Fig. 4. There are four loops, (1,3,2,1), (1,4,1), (1,4,2,1), and (1,4,3,2,1). The first three have weight-sums two, and the fourth $4 - q_M$. So the system is weakly coupled even if such a discretization is chosen that $q_M = 3$. The condition for weak h-coupling is that αh^2, $\alpha RA/Hh^2$, RAh^2/H, and $R^2 A h^{4-q_M}/H$ be much smaller than one.

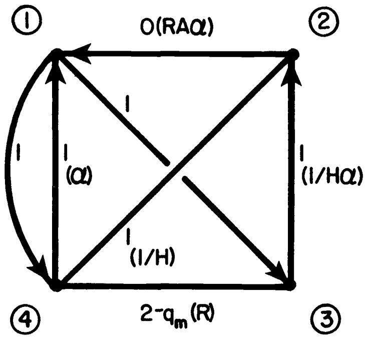

FIG. 4. *Coupling graph for* (11)–(14).

Thus it turns out that the SWBE can be smoothed efficiently simply by relaxing the equations separately.

2.5. Weakly coupled systems and distributive relaxation. As noted above, the coupling analysis requires that there be a *one-to-one* correspondence between each equation in the system and the variable for which it is relaxed. More generally, if some of the equations are relaxed collectively, then this block of equations is associated with the corresponding relaxed variables. But this is a condition that virtually *any* relaxation scheme must satisfy anyway. Sometimes there is no good choice. Consider, for example, the incompressible Euler equations in two dimensions in primitive variable form:

$$L_{IE}\begin{pmatrix} u \\ v \\ \phi \end{pmatrix} = \begin{pmatrix} D_t & 0 & \partial_x \\ 0 & D_t & \partial_y \\ \partial_x & \partial_y & 0 \end{pmatrix}\begin{pmatrix} u \\ v \\ \phi \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}, \tag{17}$$

where $D_t = \partial_t + u\partial_x + v\partial_y$. The first and second equations can be relaxed for u and v, respectively, but the third does not even include ϕ. Brandt and Dinar (in [3]) and Brandt (in [1]) propose a highly efficient approach for dealing with this problem—distributive relaxation. This is a means of obtaining a weakly coupled system by an implicit transformation of variables, defined by a *distribution matrix* M. The transformed variables never truly appear, but are used to determine how changes must be made in the actual variables so that relaxation of one equation will have a small effect (at most) on the residuals of the others (see [1], [3], or [4] for details). For (17) the suggested distribution matrix M is given by

$$\begin{pmatrix} u \\ v \\ \phi \end{pmatrix} = \begin{pmatrix} 1 & 0 & -\partial_x \\ 0 & 1 & -\partial_y \\ 0 & 0 & D_t \end{pmatrix}\begin{pmatrix} \tilde{u} \\ \tilde{v} \\ \tilde{\phi} \end{pmatrix}, \tag{18}$$

and the resulting system for the transformed variables is

$$L_{IE}M\begin{pmatrix} \tilde{u} \\ \tilde{v} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} D_t & 0 & 0 \\ 0 & D_t & 0 \\ \partial_x & \partial_y & -\Delta \end{pmatrix}\begin{pmatrix} \tilde{u} \\ \tilde{v} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}. \tag{19}$$

This system is seen to be decoupled (as triangular operators yield no loops), with a straightforward correspondence between the transformed variables and the equations in which they are relaxed. Actually, the system is decoupled in a true sense only in the case of constant coefficients and periodic boundary conditions. Otherwise, as in the actual system here, the resulting system is only weakly coupled, since terms that cancel in the constant coefficient case do not cancel when the coefficients vary.

Triangularization of the transformed system is not the true object of the transformation, but rather, the transformed system needs to be weakly coupled (i.e., its principal part must be a diagonal matrix.) This is a more general goal. Suppose, for example, that we change the order in which the equations in (17) are written by exchanging the second and third rows of the matrix operator. Now, in order to obtain the same distributive relaxation, we must similarly permute the *columns* of the distribution matrix in (18), and the resulting transformed system, though weakly coupled, is no longer triangular.

There are no general rules for determining what distribution matrix is the simplest and most efficient. But the coupling graph provides a tool that frequently points to the best approach. Consider the nondimensional shallow water equations (SWE):

$$L_{SW}\begin{pmatrix} u \\ v \\ \phi \end{pmatrix} = \begin{pmatrix} D_t & -1/R & \partial_x \\ 1/R & D_t & \partial_y \\ \tilde{H}\partial_x & \tilde{H}\partial_y & D_t \end{pmatrix}\begin{pmatrix} u \\ v \\ \phi \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}, \tag{20}$$

where $\tilde{H} = 1/F^2 + \phi$, F is the Froude number and R is the Rossby number. For this system,

$$Q = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}, \qquad W = \begin{bmatrix} N & 1 & 0 \\ 1 & N & 0 \\ 0 & 0 & N \end{bmatrix},$$

and the coupling graph (Fig. 5) shows that the first and third, as well as the second and third, equations are strongly coupled. The graph indicates that it suffices to raise the order of the diagonal operator of the third equation (without raising the order of the other operators). This can be done by applying the same distribution matrix M that is used for the incompressible Euler system. The resulting system for the transformed variables is

$$(21) \quad L_{SW}M \begin{pmatrix} \tilde{u} \\ \tilde{v} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} D_t & -1/R & \partial_y/R \\ 1/R & D_t & -\partial_x/R \\ \tilde{H}\partial_x & \tilde{H}\partial_y & (D_t)^2 - \tilde{H}\Delta \end{pmatrix} \begin{pmatrix} \tilde{u} \\ \tilde{v} \\ \tilde{\phi} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}.$$

The coefficient $\tilde{H}$ is known to be moderate or large (for physical reasons). Furthermore, assume that it is large compared to the square of the velocity, yielding an elliptic operator with a known good smoother for $\tilde{\phi}$ in the third equation (regardless of timestep size), this being the usual regime of solution. Hence, the coefficient of the operator on the diagonal of the third equation is approximately $\alpha^{-2} + \tilde{H}$, and we divide the third equation through by this coefficient. The *one-to-one* correspondence of variables and equations is now clear, and we can construct the order, weight, and coefficient arrays, obtaining

$$Q = \begin{bmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \\ 1 & 1 & 2 \end{bmatrix}, \quad W = \begin{bmatrix} N & 1 & 1 \\ 1 & N & 1 \\ 0 & 0 & N \end{bmatrix}, \quad C = \begin{bmatrix} 1 & \alpha/R & \alpha/R \\ \alpha/R & 1 & \alpha/R \\ 1 & 1 & 1 \end{bmatrix},$$

where $\alpha = \Delta t/h$, and the first two equations were multiplied by α in accordance to Rule 4. Here $c_{3,1}$ and $c_{3,2}$ are chosen to be one, rather than the more precise $\tilde{H}\alpha^2/(1+\tilde{H}\alpha^2)$, for simplicity. The latter term is bounded from above by one, and hence this choice represents the worst-case regime (since smaller off-diagonal coefficients weaken the coupling). But this is the typical case unless Δt is particularly small. The coupling graph of the transformed system is plotted in Fig. 6. The system can be seen to be h-weakly coupled under the condition

$$\Delta t/R \ll 1.$$

An efficient smoother is thus obtained that is virtually as simple as that of the incompressible Euler system.

Thus, while in (6)–(8) weak coupling was achieved by decreasing the order of an off-diagonal operator, the same end is reached here by *increasing*, in effect, the order of an operator *on* the diagonal. While here, as in (19), the principal part of the transformed system is triangular, this would not be the case if the equations were written in different order, and, as stated, it is not generally necessary.

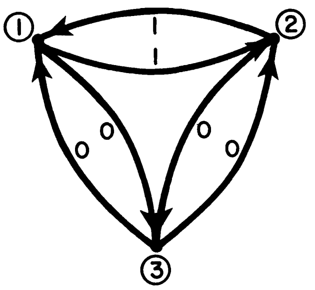

FIG. 5. *Coupling graph for* (26).

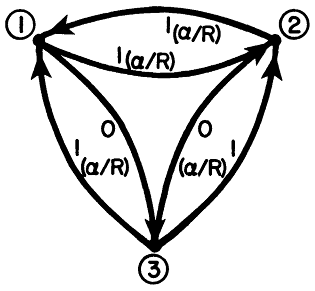

FIG. 6. *Coupling graph for* (27).

2.6. Estimating the weakness of coupling. An important notion, which is not fully addressed in Definition 4 and Rule 5, is the *degree* to which a given system is weakly coupled. This question requires a slightly more elaborate calculation.

Suppose that a given system of k partial differential equations in k unknowns is weakly coupled. Let $\bar{\mu}_i$ denote the smoothing factor corresponding to the ith equation. Then the following rule is used to calculate $\bar{\mu}$, the smoothing factor of the system.

Rule 6.

$$\bar{\mu} = \max_i \left[\bar{\mu}_i + O((ph^s)^{1/m})_i \right],$$

where

$$((ph^s)^{1/m})_i = \max_l \, (p_l h^{s_l})^{1/m_l(\bar{\mu}_i)}$$

with the maximum taken over all loops that include equations whose corresponding smoothing factor is approximately equal to $\bar{\mu}_i$ (i.e., tends to $\bar{\mu}_i$ as h tends to zero). Here, p_l is the coefficient-product of loop l, s_l is its weight-sum, and $m_l(\bar{\mu}_i)$ is the number of equations in loop l whose corresponding smoothing factors are approximately equal to $\bar{\mu}_i$.

We clarify this rule with examples. Consider the coupling graph in Fig. 3, which corresponds to system (10). There is only one loop, for which

$$ph^s = \frac{RA}{H} h^2 .$$

But in all three equations of the system the relaxed operator is the Laplacian, and all three are included in the loop. Therefore, by Rule 6, the smoothing factor of the system is

$$\bar{\mu} = \bar{\mu}_L + O\left(\left(\frac{RA}{H}h^2\right)^{1/3}\right),$$

where $\bar{\mu}_L$ is the smoothing factor for the Laplacian operator. So the smoothing factor of the system tends to that of the Laplacian only at the rate that $h^{2/3}$ tends to zero. This rate, however, can be improved (see §2.6.1 below).

Next, consider the coupling graph of (21), the shallow water system, which appears in Fig. 6. Now the relaxed operators of the first two equations are the same, but the third is different. There are three two-edge loops. Loop $(1,3,1)$ and loop $(2,3,2)$ have $ph^s = \Delta t/R$, but distinct $\bar{\mu}_i$'s. Loop $(1,2,1)$ does have two identical $\bar{\mu}_i$'s, but $ph^s = (\Delta t/R)^2$. Finally, there are two three-edge loops, $(1,2,3,1)$ and $(1,3,2,1)$, in which the advection operator again appears twice, but $ph^s = (\Delta t/R)^2$. Hence, the smoothing factor of the system differs from the worst of the smoothing factors of the individual equations ostensibly by only $O(\Delta t/R)$ on all the grids. (There is actually an $O(h)$ difference, due to the fact that the distribution matrix M yields exactly system (21) only if the coefficients are constant.)

2.6.1. Weakening weak coupling. Consider (10) once again. Suppose we multiply the first equation by RA, subtract the result from the third equation, and use this instead of the third equation (this manipulation is clearly "legal" for any finite values of R and A). For the new system

$$Q = \begin{bmatrix} 2 & 0 & N \\ N & 2 & 2 \\ 1 & 0 & 2 \end{bmatrix}, \qquad W = \begin{bmatrix} N & 2 & N \\ N & N & 0 \\ 1 & 2 & N \end{bmatrix},$$

$$C = \begin{bmatrix} 1 & 1/H & N \\ N & 1 & 1 \\ R(|\nabla\phi|RA/H + |\nabla\zeta|) & RA/H & 1 \end{bmatrix}.$$

The coupling graph is plotted in Fig. 7, ignoring coefficients for simplicity. It appears as if the strength of the coupling has not changed, since there is still a loop with weight-sum 2, but there is a subtle difference: this is a two-edge loop, and includes only two identical $\bar{\mu}_i$'s, whereas the loop of length three, which includes three identical $\bar{\mu}_i$'s, has a weight-sum of 3. So now the smoothing factor of the system tends to that of the Laplacian at the rate at which h (rather than $h^{2/3}$) tends to zero.

2.6.2. Weakening coupling by under-relaxation. When a system is h-strongly coupled, but only marginally so, a simple, yet frequently effective method for weakening the coupling is employing under-relaxation. In this well-known technique, the changes that are introduced in the relaxed variables are first multiplied by some factor $0 < \omega < 1$. This will frequently reduce the efficiency of relaxation for a single equation (though not always, e.g., Jacobi relaxation for the Poisson equation *requires* under-relaxation in order to be effective). But when the equation is part of a system, the perturbations its relaxation produces in other equations are reduced proportionally to the under-relaxation parameter.

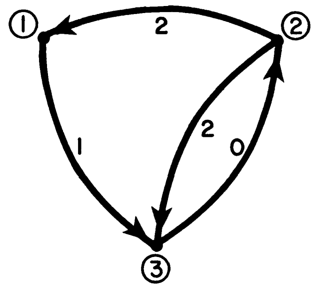

FIG. 7. *Coupling graph for modified* (10) *in* §2.6.1.

Suppose that, in a system of k equations, equation i, $i = 1, \dots, k$, is relaxed with an under-relaxation parameter ω_i. Then Rule 6 must be modified by multiplying each loop-product p by the product of the under-relaxation parameters ω_i corresponding to the equations participating in the loop. Also, $\bar{\mu}_i$ is now the smoothing factor of equation i with ω_i under-relaxation (see §3.3.1. for details.)

The under-relaxation parameters can be conveniently introduced in the coupling graphs by labeling the nodes. These results hold for over-relaxation ($\omega_i > 1$) as well, of course, but the coupling is then strengthened.

Employing under-relaxation may be useful especially on coarse grids, where h-weak coupling may be lost due to the relatively large meshsize (see [6].)

2.7. Numerical experiments. Numerical tests were performed to check various aspects of the coupling analysis. Far more extensive tests with the SWE and SWBE solvers will appear in separate reports. All experiments reported here were performed on a 2π-periodic square domain with uniform square mesh. The finest meshsize in all experiments was 128 by 128, and the coarsest 4 by 4, so that six levels were employed. The experiments were performed with the incompressible Euler equations in the formulations of (1)–(2) and (3)–(5), with system (10) (modified as suggested in §2.6.1), which appears in explicit solution of the SWBE system, with the fully implicit SWBE solver of (11)–(14), and with the SWE system (20). These are referred to as problems 1, 2, 3, and 4, respectively, below.

The multigrid cycle is defined by three parameters—the number of presweeps ν_1 (relaxation sweeps performed prior to each visit to the coarse grid), postsweeps (sweeps performed following coarse grid correction), and the cycle index, which is the number of times the next-coarser grid is visited before the correction of any intermediate grid is added to the next-finer grid solution [1]. We use the notation $\mathrm{V}(\nu_1, \nu_2)$ to denote V cycles (i.e., cycles with cycle index 1) with ν_1 presweeps and ν_2 postsweeps, and $\mathrm{W}(\nu_1, \nu_2)$ to similarly denote W cycles (whose cycle index is 2).

In all of the problems, initial conditions were prescribed on the finest grid, and a single step in time was performed, with multigrid cycles carried out until (fourteen-digit) roundoff errors were encountered. Here, problem 2 was tested within the framework of the SWBE explicit solver, but of course this has no effect on the results. The effective smoothing factor $\bar{\mu}$ was determined by calculating the asymptotic reduction factor per fine-grid relaxation sweep of the L_2 norms of the dynamic residuals averaged over all equations in the system.

In all problems, second-order Crank–Nicholson discretization was employed in time. In problems 1, 2, and 3, a conservation form was used for the spatial-derivative terms, with second-order central differencing on a nonstaggered grid (full details appear in [6]). In problem 4, nonconserving central differencing was used on a staggered grid, as in the steady-state incompressible Navier–Stokes solver described in [1], [3], and [4].

Where necessary, the average of the solution was subtracted from the solution before transferring residuals in order to maintain compatibility requirements necessary on the periodic domain (for example, existence of solution to (3) requires that the average ζ over the domain of solution be zero).

2.7.1. Incompressible Euler equations. Initial conditions for problem 1 were prescribed to be

$$\zeta(x, y, 0) = \sin(x)\ \sin(y) + rnd(-0.1, 0.1)\,,$$

where $rnd(a,b)$ denotes a uniformly distributed random number in the range (a,b). As noted in §2.3, the efficiency, indeed success or failure, of the proposed scheme (3)–(5) depends strongly on the CFL number, defined here by

$$\mathrm{CFL} = \max\ \Delta t(|\psi_x| + |\psi_y|)/h\,.$$

The numerical results confirm this. Employing V(1,1) cycles with GS relaxation in RB ordering, bicubic interpolation of corrections and full weighted residual transfers for all equations, the effective smoothing factor with CFL=1 was found to be 0.57, but already at CFL=2 there was no convergence at all. This of course is entirely unrelated to temporal stability considerations. The smoothing factors corresponding to formulation (1)–(2) with Kaczmarz relaxation in RB ordering for (2) were 0.25 in both cases since the smoothing factor of the Laplacian still dominates at CFL=2 (see problem 3 below).

2.7.2. System (10). System (10) was solved by V(1,1) cycles with GS relaxation in RB ordering and full weighted residual transfers. The effective smoothing factors were 0.25 with bicubic interpolation of errors and 0.30 with bilinear interpolation. The respective smoothing factors exhibited in the solution of the Poisson equation in seclusion were found to be 0.25 and 0.32. So the system performed as well as the Poisson equation, as predicted. (0.25 is of course the well-known smoothing factor predicted, e.g., in [1] for RB GS relaxation of the Poisson equation by precise smoothing analysis.) In these experiments the Rossby number R was 0.5, yielding RA/H in the range .37–2.2.

2.7.3. SWBE fully implicit solver. The fully implicit solver of the shallow water balance equations was tested under severe conditions by choosing the following form for the nonlinear term in (13):

$$J(\psi_x, \psi_y) = \frac{1}{2}\left[\nabla \cdot (\zeta \nabla \psi) - \frac{1}{2}\Delta(\nabla\psi \cdot \nabla\psi)\right]\,.$$

Hence q_M in (15) is three rather than two, and due to the introduction of first derivatives of ζ, $w_{3,1}$ in (15) is now zero rather than one. The main effect is that now the weight-sum of the loop (1,4,3,2,1) is one. Hence, by Rule 6, $\bar{\mu}$ of the system is given by

$$\bar{\mu} = \max\left[\bar{\mu}_L + O(h^{1/3}),\ \bar{\mu}_A + O(h)\right],$$

where $\bar{\mu}_L$ and $\bar{\mu}_A$ denote the smoothing factors of the Laplacian and the advection operator D_t, respectively.

The initial conditions for problem 3 were the same as for problem 1. A full account on how to obtain the other initial values is given in [6]. The tests were performed for the inviscid case, since the addition of viscosity leads to a smoothing factor that is at least as good. For all equations but the first, GS relaxation in RB ordering was employed. In the first equation, (11), Kaczmarz relaxation in RB ordering is used. In this relaxation the variables are scanned in the prescribed order, and the equation at each location is satisfied, in turn, by introducing to the variables changes that are proportional to the coefficients of these variables in the corresponding discretization stencil. This relaxation (unlike GS) remains stable at all CFL numbers, and is very efficient at moderate CFL numbers, provided that the viscosity coefficient is at most of the order of the meshsize. (Indeed, Kaczmarz relaxation for *steady state* (i.e., infinite CFL number) advection, discretized by first-order upstream discretization with no additional viscosity, is equivalent to GS relaxation of the Laplace operator when the streamlines are maximally nonaligned with the grid.) With greater viscosity, GS relaxation is efficient at all CFL numbers. In these equations the CFL number is defined by

$$\text{CFL} = \max\, \Delta t(|\psi_x + R\chi_y| + |\psi_y - R\chi_x|)/h\,.$$

Residuals were transferred by full-weighting, and both bilinear and bicubic interpolation of corrections were tested. R was again chosen to be 0.5, yielding a coefficient of one for the nonlinear term in (13), and B was prescribed to be one.

The results are listed in Table 1. At small CFL numbers, the 0.25 smoothing factor of the Laplacian dominates. At larger CFL numbers, relaxation of the advection operator becomes less efficient, and the corresponding performance of the advection equation in seclusion under similar conditions is included in Table 1 for V(1,1) cycles with bilinear interpolation for comparison.

TABLE 1
Effective smoothing factors exhibited by the implicit SWBE *solver, with some results of the advection-equation solver for comparison.*

CFL	Cycle	Interpolation	$\bar{\mu}_{\text{SWBE}}$	$\bar{\mu}_A$
1.0	V(1,1)	bicubic	0.26	
1.0	W(1,1)	bicubic	0.26	
1.0	V(1,1)	bilinear	0.36	0.21
1.0	W(1,1)	bilinear	0.29	
2.0	V(1,1)	bicubic	0.27	
2.0	W(1,1)	bicubic	0.25	
2.0	V(1,1)	bilinear	0.35	0.18
2.0	W(1,1)	bilinear	0.30	
3.0	V(1,1)	bicubic	0.30	
3.0	W(1,1)	bicubic	0.30	
3.0	V(1,1)	bilinear	0.33	0.31
3.0	W(1,1)	bilinear	0.30	
4.0	V(1,1)	bicubic	0.42	
4.0	W(1,1)	bicubic	0.42	
4.0	V(1,1)	bilinear	0.42	0.43
4.0	W(1,1)	bilinear	0.43	

The tests clearly indicate that the fully implicit solver of the SWBE performs as well as expected, yielding effective smoothing factors that are almost as good as that of the Laplacian at small CFL numbers and fully matching the performance of the advection-equation solver at larger CFL numbers. Indeed, given the severe conditions, the performance is somewhat better than the analysis might indicate. This is not unusual, as the analysis is based on a (quantitatively) slightly pessimistic view.

2.7.4. SWE solver. The SWE forms a system that is third-order in time, and therefore requires three initial conditions over the entire domain. In the tests these were given by

$$u(x,y,0) = \sin(x)\ \cos(y) + rnd(-0.1, 0.1)\,,$$

$$v(x,y,0) = -\cos(x)\ \sin(y) + rnd(-0.1, 0.1)\,,$$

$$\phi(x,y,0) = 0.25[\cos(2x) + \cos(2y)]\,.$$

The equations were solved with $F = 0.25$ and $R = 1$ and CFL numbers 1, 2, 3, and 4, defined here by

$$\mathrm{CFL} = \max\ \Delta t(|u| + |v|)/h\,.$$

V(1,1) cycles were employed with bilinear interpolation of corrections. The effective smoothing factors with CFL numbers 1–4 were 0.27, 0.26, 0.30, and 0.38, respectively. Comparison to Table 1 shows that the performance is as good as if the equations were decoupled.

2.7.5. Conclusions of numerical experiments. All the numerical experiments yielded results that conformed extremely well with the prediction of the coupling analysis. V cycles were found to suffice in order to obtain full efficiency. The reason for this is that, in equations with time derivatives, the CFL number is inversely proportional to the meshsize, so that the CFL number on coarse grids is much smaller than on the finest grid, leading to superior smoothing performance on the coarse grids. The steady-state type equations, on the other hand, are Poisson-like, and therefore V cycles easily suffice for these as well. Thus, in no case was any special treatment required on the coarse grids.

The smoothers for the SWE and SWBE are extremely efficient and straightforward to implement.

2.8. A systematic approach. We summarize the techniques introduced in this section by presenting a systematic approach to the development of an efficient relaxation scheme for a general system. This is done by taking the following steps.

1. Construct the order-array $\tilde{Q}$ for some arbitrary configuration.
2. Permute the rows of $\tilde{Q}$ so as to maximize the trace. Denote the resulting order-array by Q.
3. From Q construct the weight-array W and the coupling graph. Check for weak coupling.
4. If a weakly coupled system has been obtained, such that diagonal elements of Q correspond to operators that can be relaxed efficiently, then an efficient relaxation scheme for the system has been found. Check regime of weak coupling by including coefficients in the analysis (remember $O(1)$ coefficients for the diagonal operators).
5. If the resulting system is not weakly coupled, perform manipulations or implicit transformation of variables via a distributive relaxation scheme, so as to obtain a weakly coupled system. This is accomplished by raising the orders of key operators on the diagonal or lowering the orders of key off-diagonal operators. The key operators are determined from the coupling graph.
6. If a weakly coupled system cannot be obtained, relax equations that are strongly coupled collectively.

3. Theoretical development. The coupling analysis is derived from local mode analysis, which is the main tool for analyzing smoothing performance in particular, and multigrid processes in general. The full derivation is quite lengthy and will not be reported here. However, the main theorems are presented here with outlines of the proofs. Some acquaintance with smoothing analysis is presumed, but not with algebraic graph theory.

It should be noted that the full account of how to *implement* the coupling analysis is already described in §2.

3.1. Graphs and matrices. The basic concept upon which the coupling analysis is based is the following. Given a k-by-k matrix A, a directed graph G that describes A can be plotted. This is done by plotting k nodes, and for every nonvanishing element $a_{i,j}$ of A, connecting node j to node i with a directed edge (arrow), and labeling it with the "weight" $a_{i,j}$. (This convention is nonstandard with respect to the orientation, but it is convenient in the present application.) Here, j is referred to as the tail-node and i as the head-node. The diagonal terms of A correspond to edges that lead from the nodes to themselves and are treated similarly. As will be seen, certain matrix operations have useful meanings from the point of view of the corresponding graphs.

The following concepts will be used. A *path* is a concatenation of edges, such that the tail-node of each edge (except the first) coincides with the head-node of the preceding edge. A *simple loop* is a path whose every node is the tail-node of exactly one edge and the head-node of exactly one edge; this includes all single-edged loops unless noted otherwise. A *multiple loop* is a path that consists of two or more connected simple loops (i.e., simple loops with common nodes). The weight of a path is defined as the product of the weights of its edges.

LEMMA 1. *Let A be a k-by-k matrix and G its corresponding graph. Then each term in the determinant of A equals the product* (*or its negative*) *of the weight*(*s*) *of one or more disjoint simple loops in G, whose union includes every node in G exactly once. Conversely, every such product of loop-weights* (*or its negative*) *is a term in the determinant of A.*

Proof. Each term in the determinant of A is a product (or its negative) of k elements of A, no two of which share the same row or column. Hence, each node i is the tail-node of exactly one edge (corresponding to the element in the ith column) and the head-node of exactly one edge (corresponding to the element in the ith row). This proves the direct statement. Furthermore, every product of k elements from distinct rows and columns is a term (or its negative) in the determinant. This proves the converse.

3.2. Smoothing analysis. Consider a system of k linear, constant-coefficient PDEs in k unknowns,

$$Lu = \mathbf{f} \tag{22}$$

over $\mathcal{R}^n$, where $L = L(\partial_{\underline{x}})$ is a k by k matrix partial differential operator, $\mathbf{u}$ is the vector of unknowns, and $\mathbf{f}$ is the vector of forcing functions. Here, $\underline{x} = (x_1, \dots, x_n)$. All operators, variables, and functions are assumed to be in discretized form throughout the discussion.

Given some approximation $\tilde{\mathbf{u}}$ to $\mathbf{u}$, the error $\mathbf{v}$ is defined as the difference between the exact and approximate solutions,

$$\mathbf{v} = \mathbf{u} - \tilde{\mathbf{u}}\,. \tag{23}$$

Suppose that the system is discretized on a grid of meshsize h. Then $\mathbf{v}$ lends itself to the Fourier expansion

$$\mathbf{v}(\underline{x}) = \int_{-\pi}^{\pi} \hat{\mathbf{v}}(\underline{\theta}) e^{i\underline{\theta}\cdot\underline{x}/h} d\underline{\theta},$$

where $\underline{\theta} = (\theta_1, \ldots, \theta_n)$. $\mathbf{u}$ and $\tilde{\mathbf{u}}$ can be similarly expanded.

The purpose of relaxation in the multigrid process is to greatly reduce the amplitude of high-frequency components, defined as components satisfying

$$\pi/2 \leq |\underline{\theta}| \leq \pi,$$

where

$$|\underline{\theta}| = \max_{i=1}^{n} |\theta_i|.$$

If the relaxation of the equations is performed simultaneously, that is, each equation is relaxed using presweep values for all variables not corresponding to the relaxed equation, then

$$L_{new}\tilde{\mathbf{u}}_{new} + L_{old}\tilde{\mathbf{u}}_{old} = \mathbf{f}, \tag{24}$$

where

$$L_{new} + L_{old} = L.$$

Here, $\tilde{\mathbf{u}}_{new}$ and $\tilde{\mathbf{u}}_{old}$ are the approximate solutions after and before the sweep, respectively, and L_{new} and L_{old} constitute a partition of L that is determined by the particular relaxation that is applied. Equation (24) assumes that no over-relaxation or under-relaxation is used, but the generalization to such cases follows. Subtracting (24) from (22), and substituting (23), yields

$$L_{new}\mathbf{v}_{new} + L_{old}\mathbf{v}_{old} = 0,$$

and, hence,

$$\mathbf{v}_{new} = -L_{new}^{-1}L_{old}\mathbf{v}_{old}, \tag{25}$$

where $\mathbf{v}_{new}$ and $\mathbf{v}_{old}$ are the errors after and before the sweep, respectively.

In the following, it is convenient to consider the effect of relaxation in terms of reduction of the residual, $L\mathbf{v}$, rather than the error. Applying L to (25) produces

$$\begin{aligned} L\mathbf{v}_{new} &= -LL_{new}^{-1}L_{old}\mathbf{v}_{old} = -(L_{old} + L_{new})L_{new}^{-1}L_{old}\mathbf{v}_{old} \\ &= -(L_{old} + L_{old}L_{new}^{-1}L_{old})\mathbf{v}_{old} = -L_{old}L_{new}^{-1}(L_{new} + L_{old})\mathbf{v}_{old} \\ &= -L_{old}L_{new}^{-1}(L\mathbf{v}_{old}). \end{aligned} \tag{26}$$

The relaxation operator R is therefore given by

$$R = -L_{old}L_{new}^{-1}. \tag{27}$$

The smoothing analysis is mainly based on the assumption that the operators do not couple Fourier components, or couple only a small number of such components. Therefore, the components can be examined separately (or in small groups), with the difference-operators replaced by their *symbols*, defined for the operator L by

$$L(\partial_{\underline{x}})e^{i\underline{x}\cdot\underline{\theta}/h} = \hat{L}(i\underline{\theta}) \cdot e^{i\underline{x}\cdot\underline{\theta}/h}. \tag{28}$$

Here, the matrix $\hat{L}$, whose elements are generally polynomials in exponentials of $i\theta_i$, is the symbol of L. The symbol of the relaxation operator R is denoted by $\hat{R}$. If relaxation is such that there is no coupling between components, as in Jacobi relaxation, then $\hat{R}$ is a k-by-k matrix, but if several components are coupled, as in GS relaxation in RB ordering, then the dimension of R is multiplied by the number of coupled components. Such cases are not considered here.

The *smoothing factor* $\bar{\mu}$ corresponding to $\hat{R}$ is its maximal spectral radius ρ over all the high frequencies. Here, $\rho = \rho(\underline{\theta})$ is the largest of the absolute values of the eigenvalues. A successful relaxation scheme must obviously have a smoothing factor that is significantly smaller than one. Also, the spectral radii for *all* components can be assumed to be at most one (this condition can be weakened slightly, but the distinction is unimportant here).

Note that the smoothing properties in terms of the relaxation operator defined by the residual-reduction are the same as those defined by the error-reduction, since their eigenvalues are the same. (For any square matrices A and B, if $AB \cdot v = \lambda v$, multiplying by B yields $BA \cdot Bv = \lambda Bv$, proving that AB and BA have the same nonvanishing eigenvalues. For vanishing eigenvalues the result is trivial.)

3.3. Weakly coupled systems. Suppose that L is such that to each equation in system (22) there corresponds a variable for which it is relaxed, having a satisfactory smoothing factor for that equation in seclusion. The equations and their corresponding variables (and smoothing factors) will be denoted by the same subscripts. Also, let the equations be written so that the coefficients of the operators on the diagonal are all $O(1)$. There are generally two ways of relaxing the equations: simultaneously, whereby all the equations are relaxed, and only then the approximate solution is updated; and successively, whereby the equations are relaxed in some prescribed order, and the approximate solution is updated as soon as each equation is relaxed. The former is simpler to analyze and shall be considered first. Also, the discussion is simplified by only considering relaxation that does not couple components. The generalization to schemes that do couple a few components is straightforward (and all the numerical results in §2.7 were obtained with such schemes). Similarly, we do not consider here the case where some of the equations are relaxed collectively. Therefore, all the elements of $\hat{L}_{new}$ and $\hat{L}_{old}$, except elements on the respective diagonals, are either the elements of $\hat{L}$, which shall be denoted by $l_{i,j}$, or zero. The diagonal elements of $\hat{L}_{new}$ are denoted by n_i, and those of $\hat{L}_{old}$ by o_i. The elements of $\hat{R}$ are denoted by $r_{i,j}$. $q_{i,j}$ denotes the order of the operator in L in the (i, j)th position, and $c_{i,j}$ denotes some norm of the coefficients of the highest derivatives in this operator. Here it is assumed that $c_{i,j}/h$ is not small compared to the norm of the coefficients of the second-highest derivatives in the corresponding operator. Otherwise, $c_{i,j}$ and $q_{i,j}$ are defined as the coefficient-norm and order of the second-highest derivatives.

3.3.1. Simultaneous relaxation. When the relaxation is performed simultaneously, $\hat{L}_{new}$ is a diagonal matrix, since only old values are used for all the unknowns except those relaxed. Hence, by (27), $\hat{R}$ is given by

$$r_{i,j} = \begin{cases} o_j/n_j \equiv \mu_i & \text{if } i = j, \\ l_{i,j}/n_j & \text{otherwise,} \end{cases} \tag{29}$$

where $\mu_i(\underline{\theta})$ is by definition the reduction factor for an error Fourier component of frequency $\underline{\theta}$ corresponding to the ith equation in seclusion. (The smoothing factor, $\bar{\mu}_i$, is the maximal of the absolute values of μ_i over all the high frequencies.)

Now, a consistent discretization and the condition that $\bar{\mu}$ (and similarly $\bar{\mu}_i$) be smaller than one imply

$$n_i = O(h^{-q_{i,i}}). \tag{30}$$

For the off-diagonal terms in $\hat{R}$, this yields

$$r_{i,j} = O(c_{i,j}h^{q_{j,j}-q_{i,j}}), \qquad i \neq j, \tag{31}$$

since $l_{i,j}$ is at most $O(c_{i,j}h^{-q_{i,j}})$. (Indeed, it is only as large as this for high-frequency components and is only $O(c_{i,j})$ for smooth components.)

The eigenvalues of $\hat{R}$ are the roots λ_i, $i = 1, \ldots, q$, of the characteristic equation

$$|\hat{R} - \lambda I| = 0. \tag{32}$$

Rewrite (32) in the form

$$\prod_{j=1}^{k} (\mu_j - \lambda) = rhs, \tag{33}$$

where all the terms but the product of the diagonal terms of $\hat{R} - \lambda I$ have been transferred to the right-hand side. Equation (33) implies the following.

LEMMA 2. *If $rhs = O(ch^\alpha)$ for some positive c and α, then the eigenvalues of $\hat{R}$ satisfy*

$$\lambda_i = \mu_i + O((ch^\alpha)^{1/m_i}), \tag{34}$$

where m_i is the multiplicity of μ_i, defined as the number of diagonal elements of $\hat{R}$ that tend to μ_i as $h \to 0$.

Proof. By (33),

$$(\mu_i - \lambda_i)^{m_i} \leq \tilde{c}ch^\alpha$$

for some constant $\tilde{c}$, from which the proof follows.

The effect of the multiplicity is depicted in the following example. Let

$$\hat{R} = \begin{pmatrix} \mu_1 & r_{1,2} \\ r_{2,1} & \mu_2 \end{pmatrix}.$$

The characteristic equation is

$$(\mu_1 - \lambda)(\mu_2 - \lambda) - r_{1,2}r_{2,1} = 0,$$

and its roots are

$$\lambda_{1,2} = \frac{1}{2}\{\,(\mu_1+\mu_2) \pm [\,(\mu_1-\mu_2)^2 + 4r_{1,2}r_{2,1}\,]^{1/2}\,\}\,.$$

Hence, $\lambda_j = \mu_j + O(r_{1,2}r_{2,1})$ if $\mu_1 - \mu_2 = O(1)$, but $\lambda_j = \mu_j + O(\sqrt{r_{1,2}r_{2,1}})$ if $\mu_1 - \mu_2 \approx 0$.

Consider now the graph G corresponding to $\hat{R} - \lambda I$ or, equivalently, to $\hat{R}$.

LEMMA 3. *If the maximal loop-weight over all the multi-edged simple loops of G is $O(ch^\alpha)$ for some positive c and α, then the eigenvalues of $\hat{R}$ satisfy*

$$\lambda_i = \mu_i + O((ch^\alpha)^{1/m_i})\,.$$

The proof follows from Lemma 1 and Lemma 2. This is of course the h-weak coupling of the system defined in Definition 4, and Rule 5 follows. Rule 1 also follows by fixing the coefficients and sending h to zero. Rule 6, however, and indeed the concept of the strength of coupling within *subsets* of equations, requires a closer look at rhs.

THEOREM 4. *Let w_l denote the weight of simple loop l, in a system for which all loops satisfy $1 > w_l = O(ch^\alpha)$ for some positive c and α. Then the eigenvalues of $\hat{R}$ satisfy*

$$\lambda_i = \mu_i + O\left(\max_l\,(w_l)^{1/m_i^{(l)}}\right), \tag{35}$$

where the maximum is taken over all multi-edged simple loops, and $m_i^{(l)}$ is the multiplicity of μ_i in loop l, defined as the number of equations in loop l whose corresponding diagonal element in $\hat{R}$ tends to μ_i as $h \to 0$.

Sketch of Proof. Representing each group of μ_j's that tend to the same value for vanishing meshsize by $\tilde{\mu}_j$, we have from (33)

$$\prod_{\tilde{\mu}_j}(\tilde{\mu}_j - \lambda)^{m_j} = c_1\sum_j rhs_j = c_2 rhs_k\,,$$

where rhs_j are the terms of rhs, and $rhs_k = \max_j rhs_j$. Here and below c_i denote constants. Now, fix $\lambda = \lambda_i$, where λ_i is the eigenvalue of $\hat{R}$ that tends to μ_i as the meshsize tends to zero (following Lemma 3). Assume $\lambda_i = \mu_i + O(\epsilon)$. Then

$$\epsilon^{m_i} = c_3 rhs_k\,.$$

Let $\mathcal{L}_k$ denote the set of all multi-edged loops in rhs_k, and let $s_{i,k}$ denote the number of single-edged loops in rhs_k corresponding to $\tilde{\mu}_i$. Then, by Lemma 1, $rhs_k = c_4\epsilon^{s_{i,k}} \prod_{l\in\mathcal{L}_k} w_l$. Hence,

$$\epsilon^{m_i - s_{i,k}} = c_5 \prod_{l\in\mathcal{L}_k} w_l\,.$$

But $(m_i - s_{i,k}) = \sum_{l\in\mathcal{L}_k} m_j^{(l)}$ so that

$$\epsilon = c_6\left(\prod_{l\in\mathcal{L}_k} w_l\right)^{1/(m_i - s_{i,k})} \le c_6 \max_{l\in\mathcal{L}_k}(w_l)^{1/m_j^{(l)}} \le c_6 \max_l (w_l)^{1/m_j^{(l)}}\,.$$

The simple proof of the inequality used here is omitted for brevity.

Note that since, by Lemma 1, *all* products of disjoint simple loops that include all the nodes appear in rhs, one of the terms must have the loop with the maximal $w_l^{1/m_i^{(l)}}$ as its *only* multi-edged loop-weight factor; and, therefore the estimate of Theorem 4 is the best general estimate possible. Rule 6 follows directly from Theorem 4.

Under-relaxation. Let Ω be a diagonal matrix whose elements $\Omega_{i,i}$ are the respective under-relaxation (or, equivalently, over-relaxation) parameters employed. $\Omega = I$ (the identity matrix) implies that no under-relaxation is applied. When under-relaxation is employed, (27) is replaced by

$$R_\Omega = I + \Omega(R - I)\,, \tag{36}$$

where $R = R_I$ is as defined in (27). Following the proof of Theorem 4, it is now straightforward to generalize this theorem to the case where under-relaxation is employed, obtaining

$$\lambda_i = 1 - \Omega_{i,i} + \mu_i\Omega_{i,i} + O\left(\max_l \left(w_l \prod_l \Omega_{j,j}\right)^{1/m_i^{(l)}}\right), \tag{37}$$

where the product is taken over the under-relaxation parameters corresponding to the equations included in loop l.

3.3.2. Derivation of Rule 3. To outline the proof of Rule 3, let $\tilde{L}$ be a matrix whose elements are

$$\tilde{l}_{i,j} = l_{i,j}/l_{j,j}\,. \tag{38}$$

Then, by (29)–(33), the weak-coupling condition of Lemma 2, viz., $rhs = O(ch^\alpha)$, is satisfied if and only if

$$|\tilde{L}| = 1 + O(ch^\alpha)\,, \tag{39}$$

barring freak cancellations that are neglected throughout this work and are discussed in §4. But, by (38),

$$|\tilde{L}| = |\hat{L}| / \prod l_{j,j}\,, \tag{40}$$

where the product is taken over all the diagonal elements of $\hat{L}$. In orders of magnitude of h, this yields

$$|\tilde{L}| = |\hat{L}| \cdot O\left(h^{\sum_j q_{j,j}}\right). \tag{41}$$

Now $|\hat{L}|$ is invariant under row permutation, so $|\tilde{L}|$ is minimal when the sum of the orders $q_{j,j}$ of the diagonal operators of L is maximal. Furthermore, $\lim_{h\to 0} \min |\tilde{L}| \geq 1$, where the minimum is taken overall row permutations of $|\hat{L}|$, since the diagonal elements of $\tilde{L}$ are all ones. Hence, if the sum of the orders of the diagonal elements corresponding to some row permutation of L is smaller than the maximum by some positive integer m, then (41) implies $|\tilde{L}| = O(h^{-m})$, yielding a strongly coupled system. Moreover, if there is more than one permutation that maximizes the sum of the orders of the diagonal elements of L, then (39) cannot hold, since there is then at least one term in $|\tilde{L}|$ other than the product of the diagonal 1's which is $O(1)$ (the term(s) corresponding to the other permutation(s) that maximize the product of the orders of the diagonal elements of $|L|$). This implies uniqueness of the weakly coupled configuration.

3.3.3. Successive relaxation. Relaxation whereby the equations are relaxed in some prescribed order, with the variables updated immediately, yields a much more complicated relaxation operator. However, note the following.

THEOREM 5. *Theorem 4 holds for successive relaxation. Furthermore, every term in the rhs quantity for simultaneous relaxation appears in a term in the rhs quantity for successive relaxation, multiplied by one or more diagonal elements of $R - \lambda I$.*

Theorem 5 implies that, barring freak cancellation of terms which is discussed in §4, there is no qualitative difference in smoothing performance between simultaneous and successive relaxations. The sole exception is that in the (entirely moot) case where two or more μ_i's in a loop are approximately equal to zero, their multiplicity should be considered to be one. Indeed, only when *all* the smoothing factors vanish does this have any influence on the overall smoothing factor, and even then this influence is only on the rate at which the smoothing factor of the system tends to zero and not on whether or not it does.

The proof of Theorem 5 is quite lengthy and is only sketched here. In order to analyze successive relaxation, we first prescribe the order in which the equations are to be relaxed, then calculate the relaxation operator of each equation separately, and finally multiply the symbols (as is done in two-level analysis) to obtain the full successive relaxation symbol, which shall be denoted by $\hat{R}^s$ and its elements by $r^s_{i,j}$. The symbol of the relaxation operator for simultaneous relaxation analyzed above will be denoted by $\hat{R}^p$ and its elements by $r^p_{i,j}$. $\hat{R}^i$ will denote the symbol of the relaxation operator of equation i, $i = 1, \ldots k$. Its elements are given by

$$r^i_{j,m} = \begin{cases} r^p_{j,i} & \text{if } m = i, \\ 1 & \text{if } j = m \neq i, \\ 0 & \text{otherwise.} \end{cases}$$

That is, $\hat{R}^i$ acts as the identity matrix with respect to relaxation of all equations but the one relaxed, while the effect of relaxing equation i on the residuals of the other equations is the same as in simultaneous relaxation and is manifest in the corresponding column of the relaxation operator. $\hat{R}^s$ is defined by

$$\hat{R}^s = \hat{R}^k \cdot \hat{R}^{k-1}, \ldots, \hat{R}^1 . \tag{42}$$

Consider G^i, the graph corresponding to $\hat{R}^i$. It is obtained from G^p (the graph of $\hat{R}^p$) by eliminating all the edges whose tail-node is *not* node i, and adding single-edged loops of weight one at all nodes but i. By the definition of matrix multiplication it is straightforward to show that the elements of $\hat{R}^s$ are given by the following:

$r^s_{i,j} =$ the sum of the weights of all *consistently oriented* paths in G^p,

which lead from node j to node i,

where a consistently oriented path is defined as follows.

DEFINITION 5. Let $(n_0, n_1, \ldots, n_e)$ define a path of e edges from node n_0 to node n_e. Then the path is consistently oriented if for all $1 \leq j < e$, $n_{j-1} < n_j$, but $n_{e-1} \geq n_e$.

Now, since all terms in $r^s_{i,j}$ are paths from node j to node i, it follows from an analogous statement to Lemma 1 that the terms in rhs corresponding to the determinant of $\hat{R}^s$ are all products of loops (though not necessarily simple loops). Furthermore, since all simple loops can be constructed by concatenation of consistently oriented paths, all the terms in rhs of $\hat{R}^p$ must appear in rhs of $\hat{R}^s$, albeit multiplied by elements of the diagonal of $\hat{R}^s$ (which include the corresponding diagonal elements of $\hat{R}^p$ as terms). This outlines the proof of Theorem 5.

4. Discussion and conclusions. A systematic approach for developing smoothers for multigrid solvers of complicated systems of partial differential equations has been presented, and its power and straightforward implementation have been depicted by examples taken mostly from problems describing interesting physical phenomena.

The coupling analysis is derived from local mode analysis. Its main advantage is its straightforward and systematic implementation. Although general principles for relaxing systems have already been formulated by Brandt in [1], the present approach expands their scope, especially when used in conjunction with Brandt's approach. In particular, the coupling analysis offers a quantitative estimate of the strength of coupling. This, along with the structure of the coupling, which is clearly depicted by the coupling graph, suggests the methods of weakening coupling brought forth in §2.6.

The coupling analysis does not provide a precise quantitative prediction of the smoothing performance as does local mode analysis (although Rule 6 normally gives quite a narrow estimate). In particular, in some special cases for which the coupling analysis predicts strong coupling, the system may conceivably perform well under the usual simultaneous or successive relaxation of the equations, due to an "accidental" cancelling (or near-cancelling) of $O(1)$ terms in rhs of (33) (or of "perturbations" by the interpretation offered in the beginning of §2). But this may well be more of a help than a hindrance, since robustness considerations (with respect to size and variability of coefficients) will usually make such a relaxation scheme unattractive. Furthermore, once a strongly coupled loop has been diagnosed, it can be analyzed precisely by reverting to the actual symbols, rather than orders of magnitude. This reduces the problem to examining a scalar rather than a full matrix. It may then be possible to find a way to reduce the feedback sufficiently, by such means as under-relaxation or different relaxation schemes for the equations in the loop, or perhaps other means, as suggested by the feedback-system interpretation. This approach requires further research.

A potentially important notion, presented in §2.5, is the broadening of the scope of distributive relaxation to include transformed operators that are not triangular—only weakly coupled. Here and in other examples, the coupling analysis can be employed to determine the best way to use existing multigrid tools. The quick and simple application of the basic analysis, which is all that is required in the preliminary stage, allows even a trial and error search for a successful scheme, which may be useful in very complicated systems.

It is important to note that the performance predicted by the coupling analysis, as by the usual smoothing analysis, is asymptotic performance. A single cycle might exhibit reduced performance due to high-derivative off-diagonal terms in the operator. This can usually be overcome by using higher-order interpolation of the error-correction (and perhaps the solution itself in the full multigrid (FMG) algorithm) for some of the variables, or by an extra relaxation sweep for the corresponding equation(s), but, in practice, such measures are seldom necessary (see [6], for example). A discussion of required orders of interpolation appears in [1, §4.3] and [2].

Implementation of the coupling analysis can be facilitated by a small computer program that calculates the weight-array from the order-array and plots the coupling graph. Then, examination of even quite complicated systems becomes extremely fast, even on a trial and error basis. Indeed, a black-box type of search can be automatized, at least for the preliminary phase.

Acknowledgment. The author would like to thank Stephen F. McCormick for his valuable remarks.

COMPUTING THE GENERALIZED SINGULAR VALUE DECOMPOSITION*

ZHAOJUN BAI† AND JAMES W. DEMMEL‡

Abstract. A variation of Paige's algorithm is presented for computing the generalized singular value decomposition (GSVD) of two matrices A and B. There are two innovations. The first is a new preprocessing step which reduces A and B to upper triangular forms satisfying certain rank conditions. The second is a new 2×2 triangular GSVD algorithm, which constitutes the inner loop of Paige's algorithm. Proofs of stability and high accuracy of the 2×2 GSVD algorithm are presented and are demonstrated using examples on which all previous algorithms fail.

Key words. generalized singular value decomposition, CS decomposition, matrix decomposition, Jacobi algorithm, Kogbetliantz algorithm

1. Introduction. The purpose of this paper is to describe a variation of Paige's algorithm [28] for computing the following generalized singular value decomposition (GSVD) introduced by Van Loan [33] and Paige and Saunders [25]. This is also called the quotient singular value decomposition (QSVD) in [8].

THEOREM 1. *Let $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{p\times n}$ have* $\operatorname{rank}(A^T, B^T) = n$.[1] *Then there are orthogonal matrices U, V, and Q such that*

$$U^TAQ = \Sigma_1 R, \qquad V^TBQ = \Sigma_2 R, \tag{1.1}$$

where R is $n \times n$ upper triangular and nonsingular, and

$$\Sigma_1 = \begin{array}{c} \\ l \\ k \\ m-l-k \end{array} \left(\begin{array}{ccc} l & k & n-l-k \\ I_1 & & \\ & D_1 & \\ & & O_1 \end{array} \right), \tag{1.2}$$
$$\Sigma_2 = \begin{array}{c} \\ p-n+l \\ k \\ n-l-k \end{array} \left(\begin{array}{ccc} l & k & n-l-k \\ O_2 & & \\ & D_2 & \\ & & I_2 \end{array} \right),$$

$I_1 \in \mathbb{R}^{l\times l}$ and $I_2 \in \mathbb{R}^{(n-l-k)\times(n-l-k)}$ are identity matrices, $O_1 \in \mathbb{R}^{(m-l-k)\times(n-l-k)}$ and $O_2 \in \mathbb{R}^{(p-n+l)\times l}$ are zero matrices,

$$D_1 = \operatorname{diag}(\alpha_{l+1}, \ldots, \alpha_{l+k}), \qquad D_2 = \operatorname{diag}(\beta_{l+1}, \ldots, \beta_{l+k}), \tag{1.3}$$

[1]The assumption that $\operatorname{rank}(A^T, B^T) = n$ is not essential but simplifies exposition.

$$(1.4) \qquad 1 > \alpha_{l+1} \geq \cdots \geq \alpha_{l+k} > 0, \quad 0 < \beta_{l+1} \leq \cdots \leq \beta_{l+k} < 1, \quad \alpha_i^2 + \beta_i^2 = 1.$$

The GSVD is a generalization of the singular value decomposition (SVD) in the sense that if B is the identity matrix, then the GSVD of A and B is the SVD of A. Moreover, if B is nonsingular, then the GSVD of A and B reduces to the SVD of AB^{-1}. If $(A^T, B^T)^T$ has orthonormal columns, then the GSVD of A and B is the CS decomposition [31]. The pairs (α_i, β_i) defined by the diagonal elements of Σ_1 and Σ_2 are called the *generalized singular value pairs* (GSV *pairs*). The quotient $\lambda_i = \alpha_i/\beta_i$ is called a *generalized singular value* (GSV). Note that the λ_i are the square roots of the eigenvalues of the symmetric pencil $A^TA - \lambda B^TB$.

The GSVD of two matrices A and B is a tool used in many applications, such as the Kronecker canonical form of a general matrix pencil [22], the linearly constrained least-squares problem [35], [5], the general Gauss–Markov linear model [27], [3], the generalized total least squares problem [21], and real time signal processing [30]. As a further generalization of the SVD, Ewerbring and Luk [13], Zha [36] proposed a generalized SVD for matrix triplets, and De Moor, Golub, and Zha [8], [9] have generalized the SVD into a factorization of any number of matrices. For all these applications and multimatrix generalization of the SVD, the development of a stable and efficient algorithm for computing the GSVD of two matrices is a basic problem.

Stewart [31] and Van Loan [34] proposed two algorithms for computing the GSVD. Their algorithms have two phases: The first phase is to compute the QR decomposition (or the SVD if necessary) of $(A^T, B^T)^T$. The second phase is to compute the CS decomposition. Paige's algorithm is a Jacobi–Kogbetliantz approach [28], which applies orthogonal transformations to A and B separately without the CS decomposition. It also has the following two phases.

Phase 1. Reduce matrices A and B to the following forms

$$(1.5) \qquad U^TAP = \begin{array}{c} \\ r \\ q \\ m-t \end{array} \begin{pmatrix} r & q & n-t \\ A_{11} & A_{12} & A_{13} \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \qquad V^TBP = \begin{array}{c} \\ r \\ q \\ p-t \end{array} \begin{pmatrix} r & q & n-t \\ B_{11} & B_{12} & B_{13} \\ 0 & B_{22} & B_{23} \\ 0 & 0 & 0 \end{pmatrix},$$

where $m \times m$ matrix U and $p \times p$ matrix V are orthogonal, P is an $n \times n$ permutation matrix, $A_{11} \in \mathbb{R}^{r \times r}$ is nonsingular upper triangular, $B_{11} \in \mathbb{R}^{r \times r}$ is upper triangular, $t = r + q$, and if $q > 0$, $B_{22} \in \mathbb{R}^{q \times q}$ is nonsingular upper triangular.

Phase 2. Compute the GSVD of two $n \times n$ upper triangular matrices of forms (1.5) by a generalized Kogbetliantz algorithm.[2]

Phase 1 can be done first by the QR factorization with column pivoting [17] of matrix A and determine the rank r of A, meanwhile permuting the columns of matrix B in the

[2]We may need to add zero rows or columns to get square matrices. This is not essential but it simplifies the description.

same way, and then applying the QR factorization with column pivoting to the block of the last $p-r$ rows and $n-r$ columns of B and obtain the rank q of the block; this yields the forms (1.5) [4]. Phase 2 is iterative.

In this paper, we will present a variation of Paige's algorithm for computing the GSVD. There are two innovations. The first is as follows: In [28], it is assumed (without providing detail) that in (1.5) the nonzero part of V^TBP has full row rank. It is known that it is complicated to choose V to guarantee this condition and P may not be a permutation matrix. However, in the preprocessing step (1.5), we do not require this condition, and so we can simply use conventional QR factorization with column pivoting. Moreover, note that the GSVD is independent of column scaling of A and B. The forms (1.5) preserve this property.

The second innovation is a new 2×2 triangular GSVD algorithm, which constitutes the inner loop of Paige's algorithm. We will present proofs of stability and high accuracy of our method, and we will demonstrate it using examples on which all previous algorithms fail. Hereafter, we assume that A and B have been preprocessed to the upper trapezoidal forms (1.5).

The numerical technique developed in this paper can be extended to deal with the numerical computation of other closely related decompositions such as the CS decomposition and the product SVD of two matrices [20], [15]. We will not go into the details.

The rest of the paper is organized as follows. Section 2 reviews the Kogbetliantz algorithm for computing the SVD of a triangular matrix and Paige's generalization of the Kogbetliantz algorithm for computing the GSVD. Section 3 explores the inner loop of Paige's algorithm, which includes the GSVD of a 2×2 matrix in terms of exact and floating point arithmetic. In §4, we describe the overall algorithm. The last section reports the results of numerical experiments. In the Appendix, we include the 2×2 triangular SVD code of Demmel and Kahan, which has not been published in its entirety before, and which plays an important role in our algorithm.

2. Paige's GSVD algorithm.

To describe Paige's algorithm, we first review the Kogbetliantz algorithm [23] for computing the SVD of an upper triangular matrix A. Then we describe Paige's algorithm for computing the GSVD of A and B with B nonsingular. Finally, we discuss how to generalize the idea to the case where B is ill conditioned or singular.

2.1. Kogbetliantz algorithm for the SVD of a triangular matrix.

The Kogbetliantz algorithm [23] is a kind of Jacobi scheme. Assume that the kth transformation of the algorithm operates on the rows and columns i and j of A, let A_{ij} be the 2×2 submatrix subtended by rows and columns i and j of A. Let the rotation matrices $U_k = \mathrm{rot}(c_u, s_u)$ and $V_k = \mathrm{rot}(c_v, s_v)$ be chosen[3] so that

$$U_k^T A_{ij} V_k = \mathrm{diag}(\gamma_{ii}, \gamma_{jj})$$

is the SVD of A_{ij}, where $c_u = \cos\phi_k, s_u = \sin\phi_k$ and $c_v = \cos\psi_k, s_v = \sin\psi_k$. Let $\hat{U}_k$ and $\hat{V}_k$ be identity matrices with (i,i), (i,j), (j,i), and (j,j) elements replaced by the (1,1), (1,2), (2,1), and (2,2) elements of U_k and V_k, respectively. Then let

$$A_{k+1} = \hat{U}_k^T A_k \hat{V}_k,$$

where $A_0 = A$. After the first sweep through all the (i,j) in row cyclic order, an upper triangular matrix A will become lower triangular. The second sweep will restore upper

[3]Throughout this paper, we use $\mathrm{rot}(c,s)$ to denote the rotation matrix $\begin{pmatrix} c & s \\ -s & c\end{pmatrix}$.

triangular form and so on [20], [19]. There is a literature on the different sweep orders for sequential and parallel computations beside the conventional row and column order; for example [24].

Forsythe and Henrici [16] considered the convergence of the row cyclic Kogbetliantz algorithm. Fernando [14] proved a global convergence theorem under the assumption that one of the rotation angles $\{\phi_k, \psi_k\}$ at each (i,j) transformation lies in a closed interval $J \subset (-\pi/2, \pi/2)$, i.e.,

$$\phi_k \in J \quad \text{or} \quad \psi_k \in J, \qquad k = 1, 2, \ldots, . \tag{2.1}$$

This is the condition that our algorithm will satisfy. Furthermore, it has been proved that the cyclic Kogbetliantz algorithm ultimately converges quadratically [29], [2], [7].

2.2. The generalization of the Kogbetliantz algorithm for the GSVD. We begin by computing the GSVD of two upper triangular matrices A and B with B nonsingular. It is known that this is equivalent to computing the SVD of the triangular matrix $C = AB^{-1}$. Of course, it is unwise to form C explicitly. We note that a sweep of the Kogbetliantz algorithm applied to C will make it lower triangular. This means that there are orthogonal matrices U_1 and V_1 such that

$$U_1^T C V_1 = C_1, \tag{2.2}$$

where C_1 is lower triangular. Recasting (2.2) as $U_1^T A = C_1 V_1^T B$, we see that if we can determine an orthogonal matrix Q_1 satisfying

$$U_1^T A Q_1 = A_1, \qquad V_1^T B Q_1 = B_1,$$

where A_1 and B_1 are lower triangular, then $C_1 = A_1 B_1^{-1}$. This means that using a sweep of the Kogbetliantz algorithm on the upper triangular C to get the lower triangular C_1 is equivalent to the problem of finding orthogonal matrices U_1, V_1, and Q_1 so that $U_1^T A Q_1$ and $V_1^T B Q_1$ are lower triangular. Heath et al. [20], Paige [28], and Hari and Veselić [19] have shown that we may take advantage of the triangular structures of A and B and the ordering of sweeps to get the desired orthogonal transformations U_1, V_1, and Q_1 without forming AB^{-1} explicitly. Specifically, at the (i,j) transformation, the needed 2×2 submatrix C_{ij} of C is given by

$$C_{ij} = A_{ij} B_{ij}^{-1} = \begin{pmatrix} a_{ii} & a_{ij} \\ 0 & a_{jj} \end{pmatrix} \begin{pmatrix} b_{ii} & b_{ij} \\ 0 & b_{jj} \end{pmatrix}^{-1}, \tag{2.3}$$

where a_{ij} and b_{ij} are the elements subtended by the rows and columns i and j of the updated A and B, respectively. By using the SVD of C_{ij}: $U_{ij}^T C_{ij} V_{ij} = \mathrm{diag}(\tilde{c}_{ii}, \tilde{c}_{jj})$, we have

$$U_{ij}^T A_{ij} = \mathrm{diag}(\tilde{c}_{ii}, \tilde{c}_{jj}) V_{ij}^T B_{ij}.$$

This shows that the corresponding rows of $U_{ij}^T A_{ij}$ and $V_{ij}^T B_{ij}$ are parallel. Hence if we choose rotation Q_{ij} so that $V_{ij}^T B_{ij} Q_{ij}$ is lower triangular, then $U_{ij}^T A_{ij} Q_{ij}$ must also be lower triangular, which is just the GSVD of the 2×2 triangular matrices A_{ij} and B_{ij}. With this observation, we see that after completing a sweep in row order, the desired U_1, V_1, and Q_1 are the products $U_{12}U_{13} \cdots U_{n-1,n}$, $V_{12}V_{13} \cdots V_{n-1,n}$, and $Q_{12}Q_{13} \cdots Q_{n-1,n}$, respectively. By the end of the row cyclic sweep, we obtain lower triangular matrices

A_1 and B_1.[4] Then the next sweep consists of zeroing lower off-diagonal elements of $C_1 = A_1 B_1^{-1}$ in column order to return it to upper triangular form, and so on. Overall, we are actually carrying out the Kogbetliantz algorithm to diagonalize the implicitly defined matrix C. Upon convergence, this gives $U^T(AB^{-1})V = \Sigma$, a diagonal matrix. That is

$$U^T A Q = \Sigma \cdot V^T B Q,$$

i.e., the ith rows of $U^T AQ$ and $V^T BQ$ are parallel, which is the desired GSVD of A and B.

In general, if B is ill conditioned with respect to inversion or B is singular after phase 1, then using B_{ij}^{-1} is not recommended. Paige [28] suggests using

$$C_{ij} = A_{ij} \cdot \mathrm{adj}(B_{ij}) = \begin{pmatrix} a_{ii} & a_{ij} \\ 0 & a_{jj} \end{pmatrix} \begin{pmatrix} b_{jj} & -b_{ij} \\ 0 & b_{ii} \end{pmatrix} \tag{2.4}$$

instead of C_{ij} in (2.3), where $\mathrm{adj}(B_{ij})$ stands for the adjugate of B_{ij}. Since $B_{ij} \cdot \mathrm{adj}(B_{ij}) = \det(B_{ij})I$, it seems to be direct and natural to use $\mathrm{adj}(B_{ij})$ instead of B_{ij}^{-1}. The incorporation of (2.4) into the above procedure circumvents the numerical difficulties when B_{ij} is ill conditioned with respect to inversion or B_{ij} is singular. But it also introduces two questions. First, are there still rotation matrices U_{ij}, V_{ij}, and Q_{ij} such that $U_{ij}^T A_{ij} Q_{ij}$ and $V_{ij}^T B_{ij} Q_{ij}$ are the GSVD of 2×2 matrices A_{ij} and B_{ij}? Second, does the scheme converge to our required GSVD forms of A and B? The following section will address these questions.

3. The GSVD of 2×2 triangular matrices. As we see in §2, the kernel of computing the GSVD using a generalized Kogbetliantz algorithm is the computation of the GSVD of 2×2 matrices. In this section, we first discuss the computation of the 2×2 GSVD for different possible 2×2 matrices A_{ij} and B_{ij} in exact arithmetic, and then we will discuss the computation in the presence of floating point arithmetic.

3.1. The 2×2 GSVD in exact arithmetic. When A and B are processed to have upper trapezoidal forms (1.5), we see that at the (i,j) transformation, the 2×2 matrices A and B are of the forms[5]

$$A = \begin{pmatrix} a_{11} & a_{12} \\ 0 & a_{22} \end{pmatrix} \quad \text{and} \quad B = \begin{pmatrix} b_{11} & b_{12} \\ 0 & b_{22} \end{pmatrix}, \tag{3.1}$$

where $a_{11} \neq 0$, if A is nonzero. We have the following lemma.

LEMMA 1. *There exist* 2×2 *rotation matrices* U, V, *and* Q, *such that*

$$\tilde{A} = U^T AQ = \begin{pmatrix} \tilde{a}_{11} & 0 \\ \tilde{a}_{21} & \tilde{a}_{22} \end{pmatrix}, \qquad \tilde{B} = V^T BQ = \begin{pmatrix} \tilde{b}_{11} & 0 \\ \tilde{b}_{21} & \tilde{b}_{22} \end{pmatrix}$$

is the GSVD *of A and B. Moreover,*

[4]By incorporating Gentleman's suggested row and column permutations [28] after each transformation, we need only use an upper triangular array to carry out the computation. But, for clearer exposition, we will use the entire square array in this paper.

[5]For simplicity of exposition, we drop the subscript ij from the 2×2 triangular matrices A_{ij} and B_{ij}.

(a) $\tilde{a}_{11} \neq 0$ *if A is nonzero*,

(b) $\tilde{b}_{22} \neq 0$ *if both A and B are nonzero, except that*

(c) *if the first rows of A and B are parallel and the second rows are zero, then $U = V = I$, and Q can be chosen to zero the* (1,2) *entries of A and B simultaneously.*

Proof. The proof proceeds by considering all possible cases. If B is nonsingular, the lemma follows immediately by §2.2. If A or B is zero, the results are trivial. The remaining cases are for B singular but not zero. This includes the following three cases, where $C = A \cdot \mathrm{adj}(B)$:

(1) $$B = \begin{pmatrix} b_{11} & b_{12} \\ 0 & 0 \end{pmatrix} \quad \text{with} \quad b_{11} \neq 0.$$

In this case,

$$C = \begin{pmatrix} 0 & a_{12}b_{11} - a_{11}b_{12} \\ 0 & a_{22}b_{11} \end{pmatrix} \equiv \begin{pmatrix} 0 & c_{12} \\ 0 & c_{22} \end{pmatrix}.$$

If $c_{12} = 0$, i.e., the first row vectors of A and B are parallel, then if c_{22} is also equal to zero, $U = V = I$. Q_{ij} is chosen to zero (1,2) entry of A and must also zero the (1,2) entry of B, yielding the result (c). If $c_{22} \neq 0$, then both U and V are chosen as permutation matrices. Q is chosen to zero the (1,2) entry of $U^T A$.

If $c_{12} \neq 0$, then U is chosen to zero (2,2) entry of C and $V = \mathrm{rot}(0,1)$. $V^T B$ has second row nonzero. The lemma follows by choosing Q to zero (1,2) entry of $U^T A$.

(2) $$B = \begin{pmatrix} 0 & b_{12} \\ 0 & b_{22} \end{pmatrix} \quad \text{with} \quad b_{22} \neq 0.$$

Hence

$$C = a_{11} \begin{pmatrix} b_{22} & -b_{12} \\ 0 & 0 \end{pmatrix}.$$

Then $U = I$, and V is chosen to zero (1,2) entry of C, i.e., to zero the (1,2) entry of B. The lemma follows by choosing Q to zero (1,2) entry of A.

(3) $$B = \begin{pmatrix} 0 & b_{12} \\ 0 & 0 \end{pmatrix} \quad \text{with} \quad b_{12} \neq 0.$$

We see that

$$C = \begin{pmatrix} 0 & -a_{11}b_{12} \\ 0 & 0 \end{pmatrix}.$$

Then we can choose $U = I$, $V = \mathrm{rot}(0,1)$. Therefore the second row of $V^T B$ is nonzero. The lemma follows by choosing Q to zero (1,2) entry of $U^T A$. □

It has been shown by induction (see [28], [4]) that with the properties of Lemma 1, a sweep in row order with possible reordering takes the initial upper trapezoidal forms (1.5) of A and B into the forms

$$
A_1 = U_1^T A Q_1 = \begin{array}{c|cc} & r & n-r \\ \hline r & A_{11} & 0 \\ n-r & 0 & 0 \end{array},
$$

(3.2)

$$
B_1 = V_1^T B Q_1 = \begin{array}{c|cc} & r & n-r \\ \hline r & B_{11} & 0 \\ n-r & B_{21} & B_{22} \end{array},
$$

where A_{11}, B_{11}, and B_{22} are lower triangular, and A_{11}, B_{22} are nonsingular. B_{11} may be singular, but there must exist nonzero diagonal elements in the nonzero rows of B_{11}.

From (3.2), we see that at (i, j) transformation in column ordering, the 2×2 matrices A and B are lower triangular matrices, where if A is singular, then A is either the zero matrix or its second row is zero, and moreover, if $b_{22} = 0$, then $b_{21} = 0$. By a similar argument as in Lemma 1, we can show that there are 2×2 orthogonal matrices U, V, and Q such that $\tilde{A} = U^T AQ$ and $\tilde{B} = V^T BQ$ both are upper triangular and the GSVD of A and B. The proof of Lemma 1 suggests the following algorithm, where for brevity, we omit the part for lower triangular matrices.

ALGORITHM 1. (The 2×2 GSVD algorithm).
```
form $C = A \cdot \mathrm{adj}(B)$;
compute the SVD of C: $U^T CV = \mathrm{diag}(\sigma_1, \sigma_2)$;
form the products $G = U^T A$, $H = V^T B$;
if A is nonzero, then
    determine Q to zero out (1,2) entry of $G$;
else
    determine Q to zero out (1,2) entry of $H$;
end if
$\tilde{A} = GQ$;  $\tilde{B} = HQ$;  $\tilde{a}_{12} = 0$;  $\tilde{b}_{12} = 0$;
```

Again, from [28], [4], at the end of the second sweep, we have $A_2 = U_2^T A_1 Q_2$ and $B_2 = V_2^T B_1 Q_2$, such that

$$
(3.3)\quad A_2 = \begin{array}{c|ccc} & r_1 & r_2 & n-r \\ \hline r_1 & A_{11} & A_{12} & A_{13} \\ r_2 & 0 & A_{22} & A_{23} \\ n-r & 0 & 0 & 0 \end{array}, \qquad B_2 = \begin{array}{c|ccc} & r_1 & r_2 & n-r \\ \hline r_1 & 0 & 0 & 0 \\ r_2 & 0 & B_{22} & B_{23} \\ n-r & 0 & 0 & B_{33} \end{array},
$$

where A_{11}, A_{22}, B_{22}, and B_{33} are upper triangular matrices and nonsingular, $r_1 + r_2 = r$. Hence there is a unique $(n - r_1) \times (n - r_1)$ upper triangular matrix T such that

$$
\begin{pmatrix} A_{22} & A_{23} \\ 0 & 0 \end{pmatrix} = T \begin{pmatrix} B_{22} & B_{23} \\ 0 & B_{33} \end{pmatrix}.
$$

This implies that the rest of computation is essentially equivalent to computing the SVD of the implicitly defined matrix T. By the global convergence theory of the cyclic Kogbetliantz algorithm (see §2.1), we have

$$T \to \Sigma, \tag{3.4}$$

where Σ is a diagonal matrix, and the convergence is ultimately quadratic, provided the rotation angles of U and V obey (2.1). Equation (3.4) implies that there exists diagonal matrices Σ_1 and Σ_2 with $\Sigma_1^2 + \Sigma_2^2 = I$, and an upper triangular matrix R, such that

$$A_2 \to \Sigma_1 R \quad \text{and} \quad B_2 \to \Sigma_2 R,$$

which gives the desired GSVD of A and B.

3.2. The 2×2 GSVD in floating point arithmetic. In this section, we will use the usual model of floating point arithmetic: barring over/underflow, $\text{fl}(x \circ y) = (1+\delta)(x \circ y)$ where $\circ$ is one of the basic operations $\{+, -, \times, \div\}$, and $|\delta| \le \epsilon$ where ϵ is the machine round-off. This model eliminates machines like the Cray without guard digits, but with some effort all the results can be extended to these machines as well.

When using floating point arithmetic, round-off can cause the row vectors of $\tilde{A}$ and $\tilde{B}$ computed by Algorithm 1 not to be parallel. This means $\tilde{A}$ and $\tilde{B}$ are not the GSVD of the 2×2 matrices A and B, or, in short, the algorithm is not convergent. Another possibility is that the computation may not be backward stable, because the entries $\tilde{a}_{12}$ or $\tilde{b}_{12}$ ($\tilde{a}_{21}$ or $\tilde{b}_{21}$), which are explicitly set to zero by Algorithm 1, may be much larger than $O(\epsilon)\|A\|$ and $O(\epsilon)\|B\|$, respectively.[6] Thus, the algorithms in [28], [20], [4], which use the SVD of 2×2 triangular matrix to guarantee convergence, are potentially numerical unstable. On the other hand, to guarantee numerical stability, it is suggested in [18], [6] that after computing the SVD of the 2×2 triangular matrix C, one uses U (say) to form $G = U^T A$, then determines Q such that GQ is lower triangular and finally determines $\tilde{V}$ such that $\tilde{V}^T BQ$ is also lower triangular. However, in practice, $U^T C\tilde{V}$ might not be diagonal, which results in divergence. In §5, we will present numerical examples illustrating the failures of these schemes. In this section, we propose a new algorithm to overcome these shortcomings. We first discuss the two fundamental algorithmic building blocks: SLASV2 and SLARTG.

SLASV2 computes the SVD of a 2×2 upper triangular matrix

$$\begin{pmatrix} c_u & s_u \\ -s_u & c_u \end{pmatrix} \begin{pmatrix} f & g \\ 0 & h \end{pmatrix} \begin{pmatrix} c_v & -s_v \\ s_v & c_v \end{pmatrix} = \begin{pmatrix} \sigma_1 & 0 \\ 0 & \sigma_2 \end{pmatrix}.$$

Barring over/underflow, SLASV2 computes all of c_u, s_u, c_v, s_v, σ_1, and σ_2 to nearly full machine precision. This algorithm was described briefly in [10], but not published in its entirety. For completeness, we include a listing of FORTRAN code in the Appendix and a statement and proof sketch of its error analysis. As discussed in [10], the high accuracy of SLASV2 is based on the fact that the algorithm uses formulas that only contain products, quotients, square roots, sums of terms of like sign, differences of computed quantities only when cancellation is impossible, and the difference $|f| - |h|$ of the input data, which, if cancellation occurs, is exact.[7]

[6]Throughout, $\|\cdot\|$ will denote the matrix 2-norm.

[7]This exact cancellation property, which is essential for the accuracy claim of SLASV2, requires a guard digit and so fails on machines like the Cray. On a Cray we retain backward stability of SLASV2, but lose forward stability. Since the proof uses forward stability of SLASV2 in an important way, it does not apply to Cray. However, there is a more complicated proof which does work on the Cray. The reader is invited to try to find it.

SLARTG(f, g, c, s, r) generates a rotation matrix $\mathrm{rot}(c, s)$ from f and g to zero g, i.e., $c = f/r$ and $s = g/r$, $r = \sqrt{f^2 + g^2}$, but this is subject to spurious over/underflow if we directly compute them from these formulas. A more robust way to compute c, s, and r can be found in [17]:

```
(handle $f = 0$ and $g = 0$ as special cases)
if $|f| > |g|$ then
    $t = g/f$; $tt = \sqrt{1+t^2}$; $c = 1/tt$; $s = t * c$; $r = f * tt$
else
    $t = f/g$; $tt = \sqrt{1+t^2}$; $s = 1/tt$; $c = t * s$; $r = g * tt$;
endif
```

The same techniques used to analyze SLASV2 in the Appendix can be straightforwardly used to show that the relative error in the computed c and s is bounded by 6ϵ.

Using SLARTG and SLASV2, we present a high-level description of an algorithm for computing the 2×2 GSVD. Later we will show that the proposed algorithm guarantees numerical stability and convergence. We will use the notation $|X| = (|x_{ij}|)$.

ALGORITHM GSVD22. Let A and B be 2×2 upper triangular matrices. The following algorithm computes the orthogonal matrices $U = \mathrm{rot}(c_u, s_u)$, $V = \mathrm{rot}(c_v, s_v)$, and $Q = \mathrm{rot}(c_q, s_q)$, such that

$$\tilde{A} = U^T A Q = \begin{pmatrix} \tilde{a}_{11} & 0 \\ \tilde{a}_{21} & \tilde{a}_{22} \end{pmatrix}, \qquad \tilde{B} = V^T B Q = \begin{pmatrix} \tilde{b}_{11} & 0 \\ \tilde{b}_{21} & \tilde{b}_{22} \end{pmatrix}$$

are the GSVD of A and B. For brevity, we omit the part for lower triangular matrices, which can be described similarly.

```
compute $C = A \cdot \mathrm{adj}(B)$;
use SLASV2 to compute the SVD of $C : U^T C V = \Sigma$;
compute $G = U^T A$;   $H = V^T B$;
compute $\hat{G} = |U|^T |A|$;   $\hat{H} = |V|^T |B|$;
/* The angles of U and V are chosen to satisfy the convergence condition (3.4). */
if $|c_u| \geq |s_u|$ or $|c_v| \geq |s_v|$ then
        /* Choose Q to zero out (1,2) entries of $U^T A$ and $V^T B$ */
        if $\hat{g}_{12}/(|g_{11}| + |g_{12}|) \leq \hat{h}_{12}/(|h_{11}| + |h_{12}|)$ then
            call SLARTG$(-g_{11}, g_{12}, c_q, s_q, r)$      /* Compute Q from $U^T A$ */
        else
            call SLARTG$(-h_{11}, h_{12}, c_q, s_q, r)$      /* Compute Q from $V^T B$ */
        end if
        $\tilde{A} = GQ$;  $\tilde{B} = HQ$;  $\tilde{a}_{12} = 0$;  $\tilde{b}_{12} = 0$.
else
        /* Choose Q to zero out (2,2) entries of $U^T A$ and $V^T B$ and then swap rows. */
        if $\hat{g}_{22}/(|g_{21}| + |g_{22}|) \leq \hat{h}_{22}/(|h_{21}| + |h_{22}|)$ then
            call SLARTG$(-g_{21}, g_{22}, c_q, s_q, r)$      /* Compute Q from $U^T A$ */
        else
            call SLARTG$(-h_{21}, h_{22}, c_q, s_q, r)$      /* Compute Q from $V^T B$ */
        end if
        $\tilde{A} = GQ$;  $\tilde{B} = HQ$;  $\tilde{a}_{22} = 0$;  $\tilde{b}_{22} = 0$.
        /* Swap, where $P = \mathrm{rot}(0,1)$ */
        $\tilde{A} \leftarrow P\tilde{A}$; $\tilde{B} \leftarrow P\tilde{B}$;
        $U \leftarrow UP$; $V \leftarrow VP$;
    end if
```

We now present a theorem about the stability and convergence of the above algorithm. Quantities with bars (like $\bar{C}$) denote computed quantities.

THEOREM 2. *The $\tilde{A}$ and $\tilde{B}$ computed by Algorithm* GSVD22 *have the following properties*:

(a) *Both are triangular*;

(b) *$\bar{U}^T\bar{C}\bar{V}$ is within* $132\epsilon\|\bar{C}\|$ *of being diagonal*;

(c) *The rows of $\bar{\tilde{A}}$ and $\bar{\tilde{B}}$ are within* $87\epsilon\|A\|$ *and* $87\epsilon\|B\|$, *respectively, of being parallel*;

(d) *They are computed stably, i.e., there exist δA and δB, where $\|\delta A\| \leq 377\epsilon\|A\|$ and $\|\delta B\| = 377\epsilon\|B\|$, and orthogonal U, V, and Q such that*

$$\bar{\tilde{A}} = U^T(A+\delta A)Q, \qquad \bar{\tilde{B}} = V^T(B+\delta B)Q,$$

Proof. We only prove a branch of the algorithm where Q is computed from U^TA and used to zero out the (1,2) entries of U^TA and V^TB; the proof for the other cases is similar. We will also leave some of the more tedious details of error analysis to the ambitious reader.

We first note the following facts about the algorithm.

Fact 1. $\bar{C} = (A+\delta A_1)\cdot \mathrm{adj}(B+\delta B_1)$, where δA_1 and δB_1 are small componentwise relative perturbations of A and B.

$$\bar{C} = \begin{bmatrix} a_{11}b_{22}(1+\epsilon_1) & -a_{11}b_{12}(1+2\epsilon_2)+a_{12}b_{11}(1+2\epsilon_3) \\ 0 & a_{22}b_{11}(1+\epsilon_4) \end{bmatrix}$$
$$= \begin{bmatrix} a'_{11}b_{22} & -a'_{11}b'_{12}+a'_{12}b'_{11} \\ 0 & a_{22}b'_{11} \end{bmatrix},$$

where $a'_{11} = a_{11}(1+\epsilon_1)$, $b'_{11} = b_{11}(1+\epsilon_4)$, $a'_{12} = a_{12}(1+2\epsilon_3)/(1+\epsilon_4)$, and $b'_{12} = b_{12}(1+2\epsilon_2)/(1+\epsilon_1)$. (The ϵ_i are independent quantities bounded in magnitude by the machine precision ϵ.) So there is at most a 3-ulp (unit in last place) perturbation in any entry, and also $\|\delta A_1\| \leq 4\epsilon\|A\|$ and $\|\delta B_1\| \leq 4\epsilon\|B\|$.

Fact 2. The computed $\bar{U}$ and $\bar{V}$ from SLASV2 satisfy $\bar{U} = U+\delta U$, $\bar{V} = V+\delta V$, where $U^T\bar{C}V$ is the exact SVD of $\bar{C}$, and δU (δV) is a small componentwise relative perturbation of U (V), bounded by 46.5ε in each component (see the proposition in the Appendix). This also implies $\|\delta U\| \leq \sqrt{2}\cdot 46.5\epsilon < 66\epsilon$ and $\|\delta V\| < 66\epsilon$.

Fact 3. The error in the $\bar{g}_{ij}$ ($\bar{h}_{ij}$) is bounded by $48.5\epsilon\bar{g}_{ij}$ ($48.5\epsilon\hat{h}_{ij}$). In the factor 48.5, two comes from the round-off in computing $\mathrm{fl}(U^TA)$ or $\mathrm{fl}(V^TB)$, and 46.5 comes from the errors in U and V.

Fact 4. Using simple geometry, one can show that changing f to $f+\delta f$ and g to $g+\delta g$ can change $c = f/\sqrt{f^2+g^2}$ and $s = g/\sqrt{f^2+g^2}$ to $c+\delta c$ and $s+\delta s$, respectively, where $\sqrt{\delta c^2+\delta s^2} \leq 2((\delta f^2+\delta g^2)/(f^2+g^2))^{1/2}$.

Fact 5. Subroutine SLARTG computes $c = f/\sqrt{f^2+g^2}$ and $s = g/\sqrt{f^2+g^2}$ with relative errors bounded by 6ϵ. This means the 2×2 matrix $\mathrm{rot}(c,s)$ has an error bounded in norm by $\sqrt{2}\cdot 6\epsilon < 9\epsilon$.

Fact 6. If X and Y are 2×2 matrices, then $\|\mathrm{fl}(X\cdot Y) - X\cdot Y\| \leq 4\cdot\epsilon\cdot\|X\|\cdot\|Y\|$.

We note that triangularity (a) holds by construction. We prove (b) as follows. Near diagonality of $\bar{U}^T\bar{C}\bar{V}$ holds by the high accuracy of $\bar{U}$ and $\bar{V}$:

$$\bar{U}^T\bar{C}\bar{V} = (U+\delta U)^T\bar{C}(V+\delta V) = U^T\bar{C}V + F_1,$$

where Fact 2 tells us that to first order in ϵ

$$\|F_1\| \le \|\delta U^T\bar{C}V\| + \|U^T\bar{C}\delta V^T\| \le 66\epsilon\|\bar{C}\| + 66\epsilon\|\bar{C}\| = 132\epsilon\|\bar{C}\|.$$

Next we prove assertion (c). The top rows of $\bar{\tilde{A}}$ and $\bar{\tilde{B}}$ are trivially parallel by construction (their second components are zero), so we only consider the bottom rows. We know by construction that the bottom rows of $U^T(A+\delta A_1)$ and $V^T(B+\delta B_1)$ are parallel. Thus the bottom rows of

$$\bar{G} = \text{fl}(\bar{U}^TA) = \bar{U}^TA + F_2 = (U^T+\delta U^T)(A+\delta A_1-\delta A_1) + F_2 = U^T(A+\delta A_1) + F_3$$

and $\bar{H} = V^T(B+\delta B_1)+F_4$ are within $\|F_3\| \le 74\epsilon\|A\|$ and $\|F_4\| \le 74\epsilon\|B\|$, respectively, of being parallel. Here we have used Facts 1, 2, and 6.

So for *any* $\bar{Q} = Q+\delta Q$ that is within 9ϵ in norm of an orthogonal matrix Q, the bottom rows of $\bar{\tilde{A}}$ and $\bar{\tilde{B}}$ are the same as the bottom rows of

$$\text{fl}(\bar{G}\bar{Q}) = \bar{G}\bar{Q} + F_5 = (U^T(A+\delta A_1)+F_3)(Q+\delta Q) + F_5 = U^T(A+\delta A_1)Q + F_6$$

and $\text{fl}(\bar{H}\bar{Q}) = V^T(B+\delta B_1)Q+F_7$, which are within $\|F_6\| \le 87\epsilon\|A\|$ and $\|F_7\| \le 87\epsilon\|B\|$ of being parallel; we have used our bounds on $\|F_3\|$ and $\|F_4\|$, and Facts 5 and 6. This proves assertion (c).

Let $\eta_a = \bar{\hat{g}}_{12}\epsilon/(|\bar{g}_{11}| + |\bar{g}_{12}|)$, and $\eta_b = \bar{\hat{h}}_{12}\epsilon/(|\bar{h}_{11}| + |\bar{h}_{12}|)$. Then η_a (η_b) is an approximate bound on relative error of Q if it is computed from U^TA (V^TB). In the branch of the algorithm we consider, $\eta_a \le \eta_b$, and the algorithm chooses to compute Q from U^TA. The remarkable fact is that even if $\epsilon \ll \eta_a$, so that the forward error in Q is large, the backward error in B is small.

To finally prove assertion (d), we need to show the (1,2) entry of $\text{fl}(\bar{H}\bar{Q})$, which is zeroed out to get $\tilde{B}$, is at most $286\epsilon\|B\|$. (Q is chosen to accurately zero out the (1,2) entry of $\text{fl}(\bar{G}\bar{Q})$.) Earlier we showed that $\bar{h}_{11} = h_{11}+74\epsilon_8\|B\|$ and $\bar{h}_{12} = h_{12}+74\epsilon_9\|B\|$, where h_{11} and h_{12} are the exact entries of $V^T(B+\delta B_1)$. Now write $\bar{c}_q = c_q+\delta c_q$ and $\bar{s}_q = s_q+\delta s_q$, where c_q and s_q are the exact cosine and sine computed from $U^T(A+\delta A_1)$. Then

$$\begin{aligned} |\text{fl}((\bar{H}\bar{Q})_{12})| &= |(h_{11}+76\epsilon_{10}\|B\|)(s_q+\delta s_q) + (h_{12}+76\epsilon_{11}\|B\|)(c_q+\delta c_q)| \\ &= |(h_{11}s_q + h_{12}c_q) + (h_{11}\delta s_q + h_{12}\delta c_q) + \sqrt{2}\cdot 76\epsilon_{12}\|B\|\,| \\ &\le |h_{11}|\,|\delta s_q| + |h_{12}|\,|\delta c_q| + 108\epsilon\|B\|. \end{aligned} \tag{3.5}$$

There are two cases, $\eta_a < \epsilon$ and $\eta_a \ge \epsilon$. In the first case, we will show that δs_q and δc_q are both bounded by 175ϵ, and so $|\text{fl}((\bar{H}\bar{Q})_{12})| \le 286\epsilon$. To see this, use Fact 3 to write

$$(48.5\epsilon\bar{\hat{g}}_{11})^2 + (48.5\epsilon\bar{\hat{g}}_{12})^2 = (48.5\epsilon\bar{g}_{11})^2 + (48.5\epsilon\bar{\hat{g}}_{12})^2 \le (48.5\epsilon)^2(\bar{g}_{11}^2 + (|\bar{g}_{11}| + |\bar{g}_{12}|)^2),$$

so by Facts 4 and 5, $\sqrt{|\delta s_q|^2 + |\delta c_q|^2}$ can be at most

$$9\epsilon + 2\cdot 48.5\epsilon\left(\frac{\bar{g}_{11}^2 + (|\bar{g}_{11}| + |\bar{\hat{g}}_{12}|^2)}{\bar{g}_{11}^2 + \bar{g}_{12}^2}\right)^{1/2} \le 178\epsilon\,.$$

Now we use this bound in inequality (3.5) to get $|\text{fl}((\bar{H}\bar{Q})_{12})| \le 286\epsilon$ as desired.

In the second case, we bound $\sqrt{|\delta s_q|^2 + |\delta c_q|^2}$ by

$$9\epsilon + 2\left(\frac{48.5^2((\epsilon\bar{g}_{11})^2 + (\eta_a(|\bar{g}_{11}| + |\bar{g}_{12}|))^2)}{\bar{g}_{11}^2 + \bar{g}_{12}^2}\right)^{1/2} \le 178\eta_a \,.$$

Plugging in to inequality (3.5) and using

$$|\bar{h}_{11}| + |\bar{h}_{12}| = \frac{\epsilon}{\eta_b}\bar{\hat{h}}_{12} \le \frac{\epsilon\|B\|}{\eta_b},$$

yields the upper bound

$$|\text{fl}((\bar{H}\bar{Q})_{12})| \le (|\bar{h}_{11}| + |\bar{h}_{12}|)\cdot 178\eta_a + 108\epsilon\|B\| \le \frac{\epsilon\|B\|}{\eta_b}\cdot 178\eta_a + 108\epsilon\|B\| = 286\epsilon\|B\|$$

as before, since $\eta_b \ge \eta_a$.

This means that we can write the final output

$$\bar{\bar{B}} = V^T(B+\delta B_1)Q + F_7 + F_8 = V^T(B+\delta B_1 + VF_7Q^T + VF_8Q^T)Q \equiv V^T(B+\delta B)Q,$$

where F_8 zeroes out the (1,2) entry of $\bar{\bar{B}}$ and leaves the others unchanged. We just showed $\|F_8\| \le 286\epsilon\|B\|$ and combining this with our earlier bounds of $\|F_7\| \le 87\epsilon\|B\|$ and $\|\delta B_1\| \le 4\epsilon\|B\|$ yields the final result $\|\delta B\| \le 377\epsilon\|B\|$. We can similarly show that $\bar{\bar{A}} = U^T(A + \delta A)Q$ with $\|\delta A\| \le 107\epsilon\|A\|$, using the fact that Q is computed to directly zero out the (1,2) entry of $\bar{\bar{A}}$. This completes the proof of assertion (d). $\square$

The constants in these error bounds could doubtless be decreased by a more detailed analysis.

4. Summary of the complete algorithm.

In this section, we present a high-level description of our version of Paige's algorithm for computing the GSVD of two upper triangular matrices A and B of the forms (1.5). Let κ be a user-chosen parameter specifying the maximum number of cycles the algorithm may perform (say, $\kappa = 20$). Let P_{ij} be the identity matrix with rows i and j interchanged.

```
ALGORITHM GSVD
    /* Initialization */
    cycle := 0;
    $\xi := r + q + 1$; /* r and q are defined in (1.5) */
    $U := I$; $V := I$; $Q := I$ if desired;
    /* Main loop */
    if nonconvergence and cycle $\le \kappa$ do
        cycle := cycle + 1;
        do $(i, j)$-loop
            /* 2 x 2 GSVD */
            Use GSVD22 to find $U_{ij}, V_{ij}, Q_{ij}$ from $a_{ii}$, $a_{ij}$, $a_{jj}$ and $b_{ii}$, $b_{ij}$, $b_{jj}$;
            /* Updating */
            $A := U_{ij}^T A Q_{ij}$;
            $B := V_{ij}^T B Q_{ij}$;
            $U := UU_{ij}$; $V := VV_{ij}$; $Q := QQ_{ij}$ if desired;
            /* reordering */
            if the $(j,j)$ entry of $B$ is nonzero, where $j > l$, then
                $A := AP_{\xi j}$;
                $B := P_{\xi j} B P_{\xi j}$;
                $V := VV_{\xi j}$;  $Q := QP_{\xi j}$ if desired;
                $\xi := \xi + 1$;
            end if
        end of $(i,j)$-loop
        convergence test if cycle is even.
    end if
    compute $\alpha_i$ and $\beta_i$.
```

The (i,j)-loop can be simply chosen as the standard cyclic pivot sequence. It is natural to use the parallelism (linear dependency) of the corresponding row vectors of A and B at the end of an even cycle as the stopping criterion of the iteration. To measure the parallelism of two k-vectors a and b to high accuracy and despite possible over/underflow, we propose the following scheme. First, compute the QR factorization of the $k \times 2$ matrix

$$\left(\frac{a}{\|a\|}, \frac{b}{\|b\|}\right):$$

$$Q^T \left(\frac{a}{\|a\|}, \frac{b}{\|b\|}\right) = \begin{pmatrix} \mu_{11} & \mu_{12} \\ 0 & \mu_{22} \\ 0 & 0 \end{pmatrix},$$

and then compute the singular values $\gamma_1 \geq \gamma_2 \geq 0$ of the 2×2 upper triangular (μ_{ij}). It is clear that

$$\operatorname{par}\left(\frac{a}{\|a\|}, \frac{b}{\|b\|}\right) \equiv \gamma_2$$

measures the parallelism of these two vectors. Vectors a and b are exactly parallel if and only if $\gamma_2 = 0$.

Using the above described scheme as the stopping criterion in Algorithm GSVD, let a_i and b_i be the ith row vectors of A and B, respectively, at the end of an even cycle. For a given tolerance value τ, we take

$$\text{error} = \sum_{i=1}^{n} \operatorname{par}\left(\frac{a_i}{\|a_i\|}, \frac{b_i}{\|b_i\|}\right) \leq n\tau.$$

This means that there are perturbations of size at most $n\tau\|a_i\|$ in row a_i and $n\tau\|b_i\|$ in row b_i that makes them exactly parallel. This means that after making these perturbations, there would exist scalars α_i and β_i such that

$$\beta_i a_i = \alpha_i b_i, \qquad i = 1, \ldots, n, \tag{4.1}$$

where α_i and β_i can be chosen so that $\alpha_i^2 + \beta_i^2 = 1$. From (4.1), it is seen that there is an upper triangular matrix R, such that

$$U^T AQ = \operatorname{diag}(\alpha_i)R, \qquad V^T BQ = \operatorname{diag}(\beta_i)R,$$

which is the desired GSVD of matrices A and B, where α_i and β_i are the GSV pairs.

5. Numerical experiments. The numerical experiments we discuss here first compare Algorithm GSVD22 with previous algorithms developed by Paige [28], Heath et al. [20], Bai [4], Hammarling [18], and Bojanczyk et al. [6]. Then we will evaluate Algorithm GSVD for different cases of random matrices A and B, measuring the backward stability, accuracy, average total number of sweeps, rate of convergence, elapsed time when computing GSV pairs only, or both GSV pairs, and transformation matrices.

All tests were performed using FORTRAN 77 on a SUN Sparc Station 1+. The arithmetic was IEEE standard double precision [1], with a machine precision of $\epsilon = 2^{-53} \approx 10^{-16}$ and over/underflow threshold $10^{\pm 307}$. We use $\tau = 10^{-14}$ as the stopping criterion.

5.1. Backward stability and accuracy. Before we proceed, it is appropriate to state what we mean by the *backward stability* and the *accuracy* of Algorithm GSVD. The backward stability is defined as follows: Let the computed orthogonal matrices be $\bar{U}$, $\bar{V}$, and $\bar{Q}$, the diagonal matrices be $\bar{\Sigma}_1$ and $\bar{\Sigma}_2$, and the upper triangular matrix be $\bar{R}$. Then the following conditions should be satisfied:

$$\|\bar{U}^T\bar{U} - I\|_F \approx \epsilon; \quad \|\bar{V}^T\bar{V} - I\|_F \approx \epsilon; \quad \|\bar{Q}^T\bar{Q} - I\|_F \approx \epsilon; \tag{5.1}$$

$$\|\bar{U}^T A\bar{Q} - \bar{\Sigma}_1\bar{R}\|_F \approx n\epsilon\|A\|_F; \qquad \|\bar{V}^T B\bar{Q} - \bar{\Sigma}_2\bar{R}\|_F \approx n\epsilon\|B\|_F, \tag{5.2}$$

where $\|\cdot\|_F$ is Frobenius norm. These assertions say that to within round-off error, the computed matrices $\bar{U}$, $\bar{V}$, and $\bar{Q}$ are orthogonal, and the rows of $\bar{U}^T A\bar{Q}$ and $\bar{V}^T B\bar{Q}$ are parallel.

The accuracy test of computed GSV pairs by Algorithm GSVD is based on the perturbation bound of the GSV pairs of Sun and Paige [32], [26], which says that: if $\mathrm{rank}(G) = \mathrm{rank}(\tilde{G}) = n$, where $G = (A^T, B^T)^T$ and $\tilde{G} = (\tilde{A}^T, \tilde{B}^T)^T = ((A+E)^T, (B+F)^T)^T$, and the GSV pairs (α_i, β_i) of A and B and $(\tilde{\alpha}_i, \tilde{\beta}_i)$ of $\tilde{A}$ and $\tilde{B}$ are ordered as in (1.4), respectively, then we have

$$\sqrt{\sum_{i=1}^{n}[(\alpha_i - \tilde{\alpha}_i)^2 + (\beta_i - \tilde{\beta}_i)^2]} \le \sqrt{2}\min\{\|G^\dagger\|_2, \|\tilde{G}^\dagger\|_2\}\left\|\begin{pmatrix} E \\ F \end{pmatrix}\right\|_F. \tag{5.3}$$

If we generate the matrices A and B with known GSV pairs, then the above perturbation bound can be used to measure the accuracy of the computed GSV pairs.

5.2. The numerical comparison of different 2 × 2 GSVD algorithms. Several versions have been proposed for computing the 2×2 GSVD. There are essentially two kinds of schemes.

Scheme 1. First compute the SVD of $C = A \cdot \mathrm{adj}(B)$: $U^TCV = \Sigma$, then form the product of $G = U^TA$ and $H = V^TB$, and finally compute Q from G such that the (1,2) or (2,1) entry of GQ is zero. Mathematically, it is known that the (1,2) or (2,1) entry of HQ is automatically zero. The algorithms proposed by Paige [28], Heath et al. [20], and Bai [4] fall in this category.

Scheme 2. First compute the SVD of $C = A \cdot \mathrm{adj}(B)$: $U^TCV = \Sigma$, form the product of $G = U^TA$, compute Q so such the (1,2) or (2,1) entry of GQ is zero, and finally compute V to zero out the (1,2) or (2,1) entry of BQ. The algorithms proposed by Hammarling [18] and Bojanczyk et al. [6] fall in this category.

To demonstrate the failure of the first kind of scheme, the following example shows that in finite precision, the (1,2) or (2,1) entry of the final B may be much larger than

$O(\epsilon)\|B\|$:

$$A = \begin{pmatrix} 2 & 0 \\ 1 & 10^{-8} \end{pmatrix}, \quad B = \begin{pmatrix} 1 & 0 \\ 3 & 1 \end{pmatrix}.$$

With the scheme described by Paige [28], Heath et al. [20], and Bai [4], for the computed $\bar{U}$, $\bar{V}$, and $\bar{Q}$, we have

$$\bar{U}^T A \bar{Q} = \begin{pmatrix} \bar{a}_1 \\ \bar{a}_2 \end{pmatrix} = \begin{pmatrix} 0.70710677509009934E+00 & 0.21213203455917919E+01 \\ 0.00000000000000000E+00 & 0.28284271491319831E-07 \end{pmatrix},$$

$$\bar{V}^T B \bar{Q} = \begin{pmatrix} \bar{b}_1 \\ \bar{b}_2 \end{pmatrix} = \begin{pmatrix} 0.31622776518779000E+00 & 0.94868330465141837E+00 \\ -0.33959487444334968E-08 & 0.31622776582710133E+01 \end{pmatrix}.$$

If we now set the (2,1) entry of $\bar{B} = \bar{V}^T B \bar{Q}$ to zero, the backward stability condition (5.2) is violated for matrix B, even though

$$\bar{U}^T C \bar{V} = \begin{pmatrix} 0.22360679640833827E+01 & 0.00000000000000000E+00 \\ 0.17888543605335784E-16 & 0.89442719636647925E-08 \end{pmatrix}.$$

To show how Scheme 2 can fail for the same example, using Hammarling's method [18], we have

$$\bar{U}^T A \bar{Q} = \begin{pmatrix} \bar{a}_1 \\ \bar{a}_2 \end{pmatrix} = \begin{pmatrix} 0.70710677509009934E+00 & 0.21213203455917919E+01 \\ 0.00000000000000000E+00 & 0.28284271491319831E-07 \end{pmatrix},$$

$$\bar{V}^T B \bar{Q} = \begin{pmatrix} \bar{b}_1 \\ \bar{b}_2 \end{pmatrix} = \begin{pmatrix} -0.31622776518778994E+00 & -0.94868327069193081E+00 \\ 0.11102230246251565E-15 & -0.31622776684588585E+01 \end{pmatrix}.$$

Thus the stability is achieved, but for the computed $\bar{U}$ and $\bar{V}$, we have

$$\bar{U}^T C \bar{V} = \begin{pmatrix} -0.22360679640833823E+01 & -0.24012983681642603E-07 \\ 0.78163392273857838E-16 & -0.89442719636647908E-08 \end{pmatrix},$$

which is not within $O(\epsilon)\|C\|$ of diagonal form. This means that the computed $\bar{A} = \bar{U}^T A \bar{Q}$ and $\bar{B} = \bar{V}^T B \bar{Q}$ are not the GSVD of A and B. In fact, $\text{par}((\bar{a}_1/\|\bar{A}\|), (\bar{b}_1/\|\bar{B}\|)) \approx \text{par}((\bar{a}_1/\|\bar{a}_1\|), (\bar{b}_1/\|\bar{b}_1\|)) \approx 7.59 \times 10^{-9}$.

But using Algorithm GSVD22 in §3.2, we have

$$\bar{U}^T A \bar{Q} = \begin{pmatrix} \bar{a}_1 \\ \bar{a}_2 \end{pmatrix} = \begin{pmatrix} 0.70710677736817096E+00 & 0.21213203448324349E+01 \\ 0.30374288814267665E-16 & 0.28284271491319831E-07 \end{pmatrix},$$

$$\bar{V}^T B \bar{Q} = \begin{pmatrix} \bar{b}_1 \\ \bar{b}_2 \end{pmatrix} = \begin{pmatrix} 0.31622776620657461E+00 & 0.94868330431182346E+00 \\ 0.00000000000000000E+00 & 0.31622776582710133E+01 \end{pmatrix},$$

and

$$\bar{U}^T C \bar{V} = \begin{pmatrix} 0.22360679640833827E+01 & 0.00000000000000000E+00 \\ 0.17888543605335784E-16 & 0.89442719636647925E-08 \end{pmatrix}.$$

Thus both stability and convergence conditions are satisfied, where $\mathrm{par}((\bar{a}_1/\|\bar{A}\|), (\bar{b}_1/\|\bar{B}\|)) \approx \mathrm{par}((\bar{a}_1/\|\bar{a}_1\|), (\bar{b}_1/\|\bar{b}_1\|)) \approx 7.02 \times 10^{-17}$.

Recently, Bojanczyk et al. [6] proposed a variation of Scheme 2, which we refer to as the BELV scheme. The BELV scheme was originally designed for treating a matrix-triple (A_1, A_2, A_3). It is easy to see that the 2×2 GSVD of two matrices is a special case when one of the matrices (say, A_3 is the identity). The BELV scheme does significantly improve Hammarling's method, but it still suffers from possible nonconvergence. For example, using the BELV scheme, we see that for the following 2×2 matrices

$$A = \begin{pmatrix} 100000 & 10000 \\ 0 & 0.0001 \end{pmatrix}; \quad B = \begin{pmatrix} 100000 & 10000.0000000001 \\ 0 & 0.003 \end{pmatrix},$$

the computed orthogonal matrices $\bar{U}$, $\bar{V}$, and $\bar{Q}$ by BELV scheme satisfy the stability conditions (5.1) and (5.2):

$$\bar{U}^T A \bar{Q} = \begin{pmatrix} \bar{a}_1 \\ \bar{a}_2 \end{pmatrix} = \begin{pmatrix} 0.99503719020998935E-04 & -0.12189168086858831E-03 \\ 0.00000000000000000E+00 & 0.10049875621120891E+06 \end{pmatrix},$$

$$\bar{V}^T B \bar{Q} = \begin{pmatrix} \bar{b}_1 \\ \bar{b}_2 \end{pmatrix} = \begin{pmatrix} 0.29851115706299699E-02 & -0.36499576550546638E-02 \\ 0.00000000000000000E+00 & 0.10049875621120886E+06 \end{pmatrix}.$$

However, the computed $\bar{U}$ and $\bar{V}$ do not diagonalize the matrix C:

$$\bar{U}^T C \bar{V} = \begin{pmatrix} 0.99999999999999964E+01 & -0.67590597725531451E-09 \\ 0.20277179317658482E-07 & 0.30000000000000023E+03 \end{pmatrix},$$

since the off-diagonal elements are much larger[8] than $O(\epsilon)\|C\| \approx 10^{-14}$, $\mathrm{par}((\bar{a}_1/\|\bar{a}_1\|), (\bar{b}_1/\|\bar{b}_1\|)) = 6.44 \times 10^{-4}$, and even $\mathrm{par}((\bar{a}_1/\|\bar{A}\|), (\bar{b}_1/\|\bar{B}\|)) = 1.43 \times 10^{-12}$, so that the first rows of $\bar{A}$ and $\bar{B}$ are not parallel. But Algorithm GSVD22 yields

$$\bar{U}^T A \bar{Q} = \begin{pmatrix} \bar{a}_1 \\ \bar{a}_2 \end{pmatrix} = \begin{pmatrix} -0.10049875621120894E+06 & 0.00000000000000000E+00 \\ -0.12189168086858835E-03 & -0.99503719020998963E-04 \end{pmatrix},$$

$$\bar{V}^T B \bar{Q} = \begin{pmatrix} \bar{b}_1 \\ \bar{b}_2 \end{pmatrix} = \begin{pmatrix} -0.10049875621120886E+06 & -0.18189894035458565E-11 \\ -0.36567504260576521E-02 & -0.29851115706299699E-02 \end{pmatrix},$$

and

$$\bar{U}^T C \bar{V} = \begin{pmatrix} 0.30000000000000028E+03 & 0.16940658945086007E-20 \\ 0.00000000000000000E+00 & 0.99999999999999982E+01 \end{pmatrix}$$

[8]In [6] it is proven that the off diagonal elements should be $O(\epsilon)\|A\|\,\|B\| \approx 10^{-6}$, which is attained. Since $\|C\| = \|A\,\mathrm{adj}(B)\| \ll \|A\|\,\|B\|$, our bound is much tighter.

with $\mathrm{par}((\bar{a}_1/\|\bar{A}\|),(\bar{b}_1/\|\bar{B}\|)) = \mathrm{par}((\bar{a}_1/\|\bar{a}_1\|),(\bar{b}_1/\|\bar{b}_1\|)) = 0$, and $\mathrm{par}((\bar{a}_2/\|\bar{A}\|),(\bar{b}_2/\|\bar{B}\|)) < \mathrm{par}((\bar{a}_2/\|\bar{a}_2\|),(\bar{b}_2/\|\bar{b}_2\|)) = 1.72 \times 10^{-16}$.

The above examples show that Algorithm GSVD22 is superior to all previous schemes.

5.3. Test matrix generation for testing backward stability. To test the backward stability of Algorithm GSVD, we used the LAPACK test matrix generation suite [11] to generate different types of upper triangular matrices A and B. The conditioning of a generated upper triangular matrix can be controlled by the following parameters:

`dist` specifies the type of probability distribution to be used to generate the random matrices:
= U: uniform distribution on (0, 1);
= S: uniform distribution on (-1, 1);
= N: normal distribution on (0, 1).

`cond` specifies the reciprocal of the condition number of generated matrix, `cond` ≥ 1.

`mode` describes how the singular values d_i of generated matrix are to be distributed:
= 1: sets $d_1 = 1$ and $d_i = 1/\mathtt{cond}, i = 2, \ldots, n$;
= 2: sets $d_i = 1, i = 1, \ldots, n-1$ and $d_n = 1/\mathtt{cond}$;
= 3: sets $d_i = \mathtt{cond}^{-(i-1)/(n-1)}, i = 1, \ldots, n$;
= 4: sets $d_i = 1 - \frac{i-1}{n-1}(1 - 1/\mathtt{cond}), i = 1, \ldots, n$;
= 5: sets d_i to random in (1/cond , 1), their logarithms are uniformly distributed;
= 6: sets d_i to random numbers from same distribution as the rest of the matrix.

We generated 12 separate classes of upper triangular matrices A and B according to different choices of parameters `dist`, `cond`, and `mode`, since this allows us to form different types of matrices to fairly test the behavior of the algorithm. The 12 classes are listed in Table 5.1. Thus classes 1 to 6 consist of well-conditioned matrices B, and the conditioning of matrix A is changed from well to ill conditioned. Classes 7 to 10 consist of well-conditioned matrices A and the conditioning of matrix B is changed from moderate to ill conditioned. Classes 11 and 12 consist of moderately conditioned matrices A and B.

TABLE 5.1
Test matrices.

	A			B		
class	dist	cond	mode	dist	cond	mode
1	U	10	6	U	10	6
2	U	10^2	2	S	10	6
3	U	10^5	1	N	10	5
4	S	10^8	3	S	10	6
5	S	10^{12}	4	U	10	5
6	S	10^{14}	4	N	10	6
7	N	10	6	N	10^5	1
8	N	10	6	U	10^8	2
9	N	10	6	S	10^{12}	2
10	S	10	6	N	10^{14}	4
11	S	10^5	4	N	10^5	4
12	S	10^3	3	N	10^4	4

5.4. Test results. We tested the above 12 classes of matrix pairs of dimension of $n = 5, 10, 20, 50$. In each class of dimension 5 we generated 401 matrix pairs, in each class of dimension 10 we generated 301 matrix pairs, in each class of dimension 20 we generated 201 matrix pairs, and in each class of dimension 50 we generated 101 matrix pairs. This makes a total of 12,048 test matrix pairs.

Table 5.2 illustrates the average number of double sweeps required to converge with the tolerance value $\tau = 10^{-14}$, where a double sweep consists of a sweep of row ordering and a sweep of column ordering. None of 12,048 test matrix pairs failed to converge. The observed largest number of double sweeps required to converge was five. The backward stability conditions (5.1) and (5.2) held throughout the test. The following quadratic convergence rate of the algorithm is typical of what we observed:

cycle	2	4	6	8
error $= \sum_{i=1}^{n} \mathrm{par}(a_i, b_i)$	1.5094	$1.0252 \cdot 10^{-2}$	$9.4356 \cdot 10^{-9}$	$6.4874 \cdot 10^{-16}$,

where A and B are 50×50 matrices, the condition numbers for both matrices are about 10^4.

TABLE 5.2
Average number of double sweeps.

Class		1	2	3	4	5	6	7	8	9	10	11	12
n	5	2.29	2.40	2.02	2.00	2.19	2.18	2.07	2.05	2.00	2.12	2.01	1.93
	10	3.00	3.01	2.99	2.01	3.01	3.00	2.97	3.01	2.00	2.99	3.00	2.00
	20	3.26	3.50	3.07	2.19	3.53	3.30	3.05	3.21	2.98	3.23	3.21	2.20
	50	4.00	4.01	3.99	3.00	4.00	4.00	3.89	4.01	3.00	4.00	4.00	3.00

5.5. Test matrix generation for testing accuracy. To test accuracy of Algorithm GSVD, we generated random matrices A and B with known GSV pairs. Specifically, let $\Sigma_1 = \mathrm{diag}(\alpha_i)$ and $\Sigma_2 = \mathrm{diag}(\beta_i)$ be the given GSV pairs. Then we generated random orthogonal matrices U, V, and Q uniformly distributed with respect to Haar measure, and a random upper triangular matrix R with specified smallest singular value, and finally formed

$$A = U\Sigma_1 RQ^T \quad \text{and} \quad B = V\Sigma_2 RQ^T. \tag{5.4}$$

Hence the GSV pairs of A and B are known to be (α_i, β_i).

In this way we can generate random test matrices having any distribution of the GSV pairs, and

$$\|G^\dagger\|_2^{-1} = \sigma_{\min}(G) = \sigma_{\min}(R).$$

Hence $\sigma_{\min}(R)$ (the smallest singular value) gives the conditioning of the designed test matrix pair. If $\bar{\alpha}_i$ and $\bar{\beta}_i$ are computed the GSV pairs by Algorithm GSVD, then the quantity

$$\Delta_1 \equiv \left\{ \sum_{i=1}^{n} [(\alpha_i - \bar{\alpha}_i)^2 + (\beta_i - \bar{\beta}_i)^2] \right\}^{1/2} \sigma_{\min}(R) \tag{5.5}$$

should be $O(\tau)$, where $\tau = 10^{-14}$ is our stopping criterion.

We designed six different distributions of the GSV pairs as illustrated in the second column of Table 5.3, where α_i and β_i are normalized so that $\alpha_i^2+\beta_i^2 = 1$ for $i = 1, \ldots, n$ if necessary, (U(0,1),U(0,1)) means that GSV pairs (α_i, β_i) comes from the normalization of a pair of random numbers from a uniform distribution on the interval (0,1). cond is the reciprocal of the smallest singular value of the matrix R in (5.4). Note that some of the distributions of GSV are well separated, some of them are highly clustered or multiple.

TABLE 5.3
Average double sweeps and accuracy of computed GSV pairs.

Type	α_i, β_i	$\sigma_{\min}(R)$	Double sweeps for different n				Δ_1

		10^{-12}	2.00	2.00	3.00	3.20	$1.14 \cdot 10^{-15}$

5.6. Test results. We generated several categories of matrix pairs according to three parameters: the dimension n, the smallest singular value of R ($\sigma_{\min}(R)$), and the type of distribution of GSV. We first separated test matrices with three possible values of $\sigma_{\min}(R) = 1, 10^{-6}, 10^{-12}$, i.e., corresponding to well, moderately, and ill-conditioned GSVD problems. For each $\sigma_{\min}(R)$, we tested matrices of dimension $n = 5, 10, 20, 40$ with six different distributions of GSV pairs as shown in Table 5.1. This makes a total of $3 \times 4 \times 6 = 72$ different classes of matrices. In each class of dimension 5 we generated 301 matrices, in each class of dimension 10 we generated 201 matrices, in each class of dimension 20 we generated 101 matrices, and in each class of dimension 40 we generated 51 matrices, for a total of 10,772 test matrix pairs.

Table 5.3 illustrates the average number of double sweeps and accuracy of the algorithm for different size of matrices. The preprocessing orthogonal transformations of A and B to upper trapezoidal forms (1.5) are performed using LINPACK QR decomposition subroutine DQRDC [12]. In all tests, the backward stability conditions (5.1) and (5.2) are satisfied, so we do not report the details here. Given the backward stability, we can assume that the backward errors E of A and F of B satisfy $O(\|E\|, \|F\|) = O(10^{-14})$. For each type of GSV distribution, we let the conditioning (i.e., $\sigma_{\min}(R)$) of the GSVD problems vary from well to moderate to ill conditioned, as indicated in column 3 of Table 5.3. The numbers in columns 4 to 7 are the average numbers of double sweeps needed for convergence. The last column of the table is the largest value of Δ_1 computed from the formula (5.5). We see that all computed results are as accurate as predicted.

Finally, we briefly report timing results. The codes have not been polished intensively in order to reduce the execution time. Table 5.4 illustrates the required time for a 50×50 matrix pair A and B with 5 double sweeps to satisfy the stopping criterion.

Appendix. The SVD of 2×2 triangular matrix. In this Appendix, for the convenience of the reader, we include the 2×2 triangular SVD algorithm of Demmel and

TABLE 5.4
CPU timing of the GSVD *of two* 50 × 50 *matrices.*

Kahan. The algorithm was used in their high relative accuracy bidiagonal SVD algorithm [10], but the algorithm details were not presented there.

It is known that the singular values of the 2 × 2 upper triangular matrix $\left(\begin{smallmatrix} f & g \\ 0 & h \end{smallmatrix}\right)$ are the values of the unobvious expression $\frac{1}{2}|\sqrt{(f+h)^2+g^2} \pm \sqrt{(f-h)^2+g^2}|$, of which the bigger is γ_1 and the smaller is $\gamma_2 = |fh|/\gamma_1$. The right singular vector row $(-s_v, c_v)$ turns out to be parallel to $(f^2 - \gamma_1^2, fg)$. After computing a right singular vector, the corresponding left singular vector is determined by $(c_u, s_u) = (fc_v + gs_v, hs_v)/\gamma_1$. But computing the singular values/vectors directly from these expressions is unwise because round-off can destroy all relative accuracy, and they can suffer from over/underflow in the squared subexpressions even when the singular values/vectors are far from over/underflow thresholds. Demmel and Kahan have carefully reorganized the computation as described in the following so that barring over/underflow and assuming a guard digit in subtraction, all output quantities are correct to within a few ulps. In IEEE arithmetic [1], the code works correctly even if one matrix entry is infinite. Overflow is impossible unless the largest singular value itself overflows or is within a few ulps of overflow. (On machines with partial overflow, like the Cray, overflow may occur if the largest singular value is within a factor of two of overflow.) Underflow is harmless if underflow is gradual. Otherwise, results may correspond to a matrix modified by perturbations of size near the underflow threshold.

The error analysis of the main path of the code depends on the fact that all the operations except two are (i) multiplication and division, where the relative error of the result is at most 1 ulp larger than the sum of the relative errors of the inputs; (ii) addition of positive quantities, where the relative error of the result is at most 1 ulp larger than the maximum of the relative errors of the inputs; and (iii) square root, where the relative error of the result is at most 1 ulp more than half the relative error of the input.

There are also two subtractions in the main code path. The first subtracts original data D = FA-HA, and so has a 1 ulp error. In the second, T=2-L with $0 \le$ L ≤ 1, the relative error in T can only be 1 ulp larger than the relative error in L. These rules are sufficient to straightforwardly bound the error in the main code path, provided we ignore second order terms. There is another path corresponding to the case where the off-diagonal g is much larger than the other two matrix entries, which is analyzed much more easily. Summarizing all these considerations we can easily prove the following.

PROPOSITION 3. *Barring over/underflow, and assuming there is a guard digit in subtraction, the relative errors in the computed singular values are at most* 7 *ulps, and the relative errors in the computed singular vectors are at most* 46.5 *ulps in each component.*

The comments in the following code indicate the error bound in ulp of each computed quantity.

```
      SUBROUTINE SLASV2( F, G, H, SSMIN, SSMAX, SNR, CSR, SNL, CSL )
      REAL CSL, CSR, F, G, H, SNL, SNR, SSMAX, SSMIN
C
C     Computes singular value decomposition of 2 x 2 triangular matrix:
C     [ CSL SNL ] . [ F G ] . [ CSR -SNR ] = [ SSMAX 0 ]
C     [-SNL CSL ]   [ 0 H ]   [ SNR CSR ]    [ 0 SSMIN ]
C     Absolute value of SSMAX is larger singular value, Absolute value of SSMIN
C     is smaller singular value. Both CSR**2+SNR**2=1 and CSL**2+SNL**2=1.

THE USE OF THE L-CURVE IN THE REGULARIZATION OF DISCRETE ILL-POSED PROBLEMS*

PER CHRISTIAN HANSEN† AND DIANNE PROST O'LEARY‡

Abstract. Regularization algorithms are often used to produce reasonable solutions to ill-posed problems. The L-curve is a plot—for all valid regularization parameters—of the size of the regularized solution versus the size of the corresponding residual. Two main results are established. First a unifying characterization of various regularization methods is given and it is shown that the measurement of "size" is dependent on the particular regularization method chosen. For example, the 2-norm is appropriate for Tikhonov regularization, but a 1-norm in the coordinate system of the singular value decomposition (SVD) is relevant to truncated SVD regularization. Second, a new method is proposed for choosing the regularization parameter based on the L-curve, and it is shown how this method can be implemented efficiently. The method is compared to generalized cross validation and this new method is shown to be more robust in the presence of correlated errors.

Key words. ill-posed problems, regularization, L-curve, parameter choice, generalized cross validation, discrepancy principle

AMS subject classifications. 65R30, 65F20

1. Introduction. In many applications such as spectroscopy [1], seismography [13], and medical imaging [11], data are gathered by convolution of a noisy signal with a detector. A linear model of this process leads to an integral equation of the first kind:

$$\int_0^1 k(s,t)\,x(t)\,dt = y_0(s) + e(s). \tag{1}$$

Here, $y_0(s) + e(s)$ is the measured signal, $y_0(s)$ is the true signal, $e(s)$ is the unknown noise, and the *kernel function* $k(s,t)$ is the instrument response function.

Since the measured signal is usually available only at a finite number of values of s, the continuous model (1) is replaced by a discrete linear model equation

$$Kx = y_0 + e \equiv y, \tag{2}$$

where K is a matrix of dimension $m \times n$ and we assume that $m \geq n$. In all but trivial deconvolution problems, the continuous problem is *ill posed* in the sense that small changes in the data can cause arbitrarily large changes in the solution, and this is reflected in ill conditioning of the matrix K of the discrete model, increasing as the dimension of the problem increases. Thus attempts to solve (2) directly yield solution vectors that are hopelessly contaminated with noise.

Hence some sort of *regularization* of the problem is required to filter out the influence of the noise. Well-known regularization methods are Tikhonov regularization and the truncated singular value decomposition (SVD). A common feature of these regularization methods is that they depend on some regularization parameter that controls how much filtering is introduced by the regularization. Often the key issue in connection with

these methods is to find a regularization parameter that gives a good balance, filtering out enough noise without losing too much information in the computed solution.

The purpose of this paper is to propose new methods for the choice of the regularization parameter through use of the the *L-curve*. The L-curve is a plot—for all valid regularization parameters—of the size of the regularized solution versus the size of the corresponding residual. It was used by Lawson and Hanson [10] and further studied by Hansen [9]. In this work we establish two main results. First we give a unifying characterization of various regularization methods and show that the measurement of "size" is dependent on the particular regularization method chosen; for example, the 2-norm is appropriate for Tikhonov regularization, but a 1-norm in the coordinate system of the SVD is relevant to truncated SVD regularization. Second, we propose a systematic a posteriori method for choosing the regularization parameter based on this L-curve and show how this method can be implemented efficiently. We compare the method to generalized cross validation and the discrepancy principle.

Our analysis differs from the "asymptotic theory of filtering" [6] where the problem size (m and n) goes to infinity, in that we consider problems where the problem size is typically *fixed*, e.g., by the particular measurement setup. Thus we are ignoring the very important questions of convergence of the estimates as the model converges to the continuous problem or as the error converges to zero.

We give a unified survey of regularization methods in §2 and of algorithms for choosing the regularization parameter in §3. We investigate various important properties of the L-curve in §4 and demonstrate how a good regularization parameter can actually be computed from the L-curve. In §5 we discuss several important computational aspects of our method, and, finally, in §6 we illustrate the new method by numerical examples.

2. Regularization methods. Practical methods for solving the discretized problem (2) must diminish the influence of noise. They differ only in the way that they determine the filtering function for the noise. We illustrate this by discussing several of these methods in a common framework, using the SVD of the matrix K. Let

$$K = \sum_{i=1}^{n} \sigma_i \, u_i \, v_i^T . \tag{3}$$

Here, the left and right *singular vectors* u_i and v_i are orthonormal, and the *singular values* σ_i are nonnegative and nonincreasing numbers, i.e., $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n \geq 0$. Common for all discrete ill-posed problems is that the matrix K has a cluster of singular values at zero and that the size of this cluster increases when the dimension m or n is increased.

Using the SVD of K, it is straightforward to show that the ordinary least squares solution to (2), the one characterized by solving the unconstrained problem

$$\min_x \|Kx - y\|_2, \tag{4}$$

can be written as

$$x_{\mathrm{LSQ}} = \sum_{i=1}^{n} \frac{\alpha_i}{\sigma_i} \, v_i, \tag{5}$$

where $\alpha_i = u_i^T y$.

The trouble with using the least squares solution x_{LSQ} is that error in the directions corresponding to small singular values is greatly magnified and overwhelms the information contained in the directions corresponding to larger singular values. Any practical method must therefore incorporate filter factors f_i, changing the computed solution to

$$x_{\text{filtered}} = \sum_{i=1}^{n} f_i \frac{\alpha_i}{\sigma_i} v_i, \tag{6}$$

where usually we take $0 \le f_i \le 1$. If each filter factor is equal to one, we have the least squares solution x_{LSQ}. The filtered residual vector corresponding to x_{filtered} is

$$r_{\text{filtered}} = \sum_{i=1}^{n} (1 - f_i)\, \alpha_i u_i + r_\perp,$$

where $r_\perp$ is the least squares residual, i.e., the component of y orthogonal to the vectors $u_1, \ldots, u_n$. Regularization methods differ only in how they choose the filter factors.

Perhaps the best known regularization method is the one due to Tikhonov [16], which chooses the solution x_λ that solves the minimization problem

$$\min_x \{ \|Kx - y\|_2^2 + \lambda^2 \|x\|_2^2 \}. \tag{7}$$

Here, the parameter λ controls how much weight is given to minimization of $\|x\|_2$ relative to minimization of the residual norm. In some applications it is not appropriate to minimize the 2-norm of the solution, but rather a seminorm $\|L\,x\|_2$ where L typically is a discrete approximation to some derivative operator. However, Eldén [2] has shown that it is always possible to transform such problems into a form where the 2-norm is minimized.

Another regularizing method is *truncated* SVD [7], [17], where one simply truncates the summation in (5) at an upper limit $k < n$, before the small singular values start to dominate.

Certain iterative methods for solving the least squares problem (4) have minimization properties. The *conjugate gradient* family of methods minimizes the least squares function over an expanding sequence of subspaces

$$\mathcal{K}_k = \text{span}\{K^T y, (K^T K) K^T y, \ldots, (K^T K)^{k-1} K^T y\},$$

keeping $\|x\|_2$ as small as possible. One formulation particularly suited to ill-posed problems is the LSQR implementation of Paige and Saunders [12].

Another popular regularizing technique is the *maximum entropy* principle; see, for example, [15]. It is based on the idea that since y contains error, it is not reasonable to ask that x reproduce it exactly, but only that it approximate it within the expected value of the norm of the error in y. Among all of the x vectors that satisfy

$$\|Kx - y\|_2 \le \lambda,$$

the maximum entropy method chooses the vector whose entropy

$$s(x) = -\sum_{i=1}^{n} x_i \ln(x_i / x_i^0) - (x_i - x_i^0)$$

is the largest, where x^0 is a nonnegative initial approximation and the admissible points x are also nonnegative.

Like the least squares formulation (4), these regularization methods produce solutions that can be characterized as solutions to minimization problems. We can think of them as minimizing the size of the solution x subject to keeping the size of the residual $r = Kx - y$ less than some fixed value, or in a dual sense as minimizing the size of r subject to keeping the size of x less than some value $M(\lambda)$. The way that "size" is measured varies from method to method, but many of these methods are defined in terms of the norms induced by the bases of the SVD. Although the 2-norm is invariant with respect to the choice of an orthonormal basis, other norms do not share this property. We will denote the 1-norm in the SVD basis by $\|\cdot\|_{\underline{1}}$, defined by

$$\|x\|_{\underline{1}} = \|\beta\|_1 \quad \text{if} \quad x = \sum_{i=1}^{n} \beta_i v_i,$$

$$\|r\|_{\underline{1}} = \|\gamma\|_1 + \|r_\perp\|_1 \quad \text{if} \quad r = \sum_{i=1}^{n} \gamma_i u_i + r_\perp.$$

We make a similar definition for the p-norms in the SVD basis, $p = 3, \ldots, \infty$. Moreover, we denote by $M(\lambda)$ the norm of the solution vector for regularization parameter λ.

Using this notation it is easy to verify that the regularization methods mentioned above have the characterizations shown in Table 1. For instance, for the truncated SVD, we have the relations

$$\|x\|_{\underline{1}} = \sum_{i=1}^{n} f_i \left| \frac{\alpha_i}{\sigma_i} \right|,$$

$$\|r\|_{\underline{1}} = \sum_{i=1}^{n} (1 - f_i) |\alpha_i| + \|r_\perp\|_1.$$

For $M(\lambda) = 0$, $x = 0$ and all filter factors are zero. As M increases, we want to increase the size of x as little as possible for a given decrease in the size of r. When the size of r has been reduced by by δ, the size of x is

$$\sum_{i=1}^{n} \frac{|\delta_i|}{\sigma_i},$$

with

$$\sum_{i=1}^{n} |\delta_i| = \delta.$$

Thus the minimal size of x is achieved by finding the largest integer k so that

$$\sum_{i=1}^{k} |\alpha_i| \le \delta,$$

and then setting

$$\delta_i = \begin{cases} \alpha_i, & i = 1, \ldots, k, \\ (M - \sum_{i=1}^{k} |\alpha_i|)\operatorname{sgn}(\alpha_i), & i = k+1, \\ 0, & i = k+2, \ldots, n. \end{cases}$$

TABLE 1
Various regularization methods and their characterizations.

Method	Minimizes	Domain	Filter factors
Tikhonov	$\|r\|_2$	$\{x : \|x\|_2 \leq M(\lambda)\}$	$f_i = \frac{\sigma_i^2}{\lambda^2+\sigma_i^2}$
Truncated SVD	$\|r\|_{\underline{1}}$	$\{x : \|x\|_{\underline{1}} \leq M(\lambda)\}$	$f_i = 1, i = 1, \ldots, k(M)$, $f_{k(M)+1} = \frac{\sigma_{k(M)+1}}{\alpha_{k(M)+1}} \left(M - \sum_{i=1}^{k(M)} \frac{\|\alpha_i\|}{\sigma_i}\right)$ $\mathrm{f}_i = 0, i = k(M)+2, \ldots, n$
l_∞	$\|r\|_{\underline{\infty}}$	$\{x : \|x\|_{\underline{\infty}} \leq M(\lambda)\}$	$f_i = \min(1, \frac{M\sigma_i}{\|\alpha_i\|})$
LSQR	$\|r\|_2$	$\{x \in \mathcal{K}_k : \|x\|_2 \leq M(\lambda)\}$	No simple formula
Maximum entropy	$\|r\|_2$	$\{x \geq 0 : s(x) \geq M(\lambda)\}$	No simple formula

There is no *simple formula* for the filter factors for LSQR; but we will show in forthcoming work that they can be computed easily from intermediate quantities in the LSQR algorithm. For maximum entropy, we are not aware of an algorithm for computing the filter factors.

To unify notation, we will denote the regularization parameter by λ, even for methods such as truncated SVD and LSQR in which the regularization is determined by a discrete value k. We will denote the function minimized by a regularization method by $\rho(\lambda)$ and the norm or function associated with the regularized solution vector x by $\eta(\lambda)$. As an example, for Tikhonov regularization we have $\rho(\lambda) = \|K\,x - y\|_2$ and $\eta(\lambda) = \|x\|_2$.

The method l_∞ in the table is one of a family of methods, based on the l_p norms using the singular vector basis. For a comparable value of the regularization parameter, the l_∞ method produces a solution that is much "less smooth" than that of the truncated SVD or the Tikhonov method. The truncated SVD (l_1) solution has no components in directions corresponding to small singular values. The Tikhonov (l_2) solution has small components in these directions. The l_p ($p > 2$) solutions have larger components, and the l_∞ solution has components of size comparable to those in the directions corresponding to large singular values. We note that these methods can also be generalized to weighted l_p norms.

From this discussion we see that *the choice of regularization method is a choice of an appropriate pair of functions ρ and η. The proper choice of the regularization parameter is a matter of choosing the right cutoff for the filter factors f_i, i.e., the breakpoint in the singular value spectrum where one wants the damping to set in.* Algorithms for choosing the regularization parameter are still a subject of research. In the next section we survey two proposals for choosing the regularization parameter. Their shortcomings lead us to propose choosing the parameter based on the behavior of the L-curve, a plot of $\eta(\lambda)$ vs. $\rho(\lambda)$. The remainder of the paper is devoted to a discussion of the properties of the L-curve, numerical issues in using it to choose a regularization parameter, and examples of its performance compared with other methods.

3. Choosing the regularization parameter.

3. Choosing the regularization parameter. We survey the discrepancy principle and generalized cross validation, and then we propose the new method based on the L-curve.

3.1. The discrepancy principle. Perhaps the simplest rule is to choose the regularization parameter to set the residual norm equal to some upper bound for the norm $\|e\|_2$ of the errors in the right-hand side. In connection with discrete ill-posed problems this is called the *discrepancy principle* [5, §3.3]. There is also a generalized discrepancy principle that takes errors in the matrix K into account [9]. A major disadvantage of this method—apart from the fact that often a close bound on $\|e\|_2$ is not known—is the generally accepted fact that the discrepancy principle "oversmooths" the solution: i.e., it will choose the Tikhonov parameter λ too large, will drop too many singular values in the truncated SVD, or will halt LSQR at too early a stage. Thus we will not recover all the information actually present in the given right-hand side y.

3.2. Generalized cross-validation. A more promising rule is *generalized cross-validation* (GCV) [4], [18]. The basic idea in cross-validation is the following: if any data point y_i is left out and a solution $x_{\lambda,i}$ is computed to the reduced problem of dimension $(m-1)\times n$, then the estimate of y_i computed from $x_{\lambda,i}$ must be a good estimate. While ordinary cross-validation depends on the particular ordering of the data, generalized cross-validation is invariant to orthogonal transformation (including permutations) of the data vector y.

The GCV function to be minimized in this method is defined by

$$\mathcal{G}(\lambda) \equiv \frac{\|K\,x(\lambda) - y\|_2^2}{(\text{trace}(I - K\,K(\lambda)^I))^2},$$

where $K(\lambda)^I$ is any matrix that maps the right-hand side y onto the solution $x(\lambda)$, i.e., $x(\lambda) = K(\lambda)^I y$.

Although GCV works well for many problems, there are some situations in which GCV has difficulty finding a good regularization parameter. One difficulty is that the GCV function can have a very flat minimum and hence the minimum itself may be difficult to localize numerically. This is illustrated in [17].

Another difficulty is that GCV can sometimes mistake correlated noise for a signal. The underlying assumption when deriving GCV, cf. [4], [18], is that the errors in the right-hand side are normally distributed with zero mean and covariance matrix $\sigma^2 I$. We state from [18, p. 65] that GCV "is fairly robust against nonhomogenity of variance and non-Gaussian errors.... However, the method is quite likely to give unsatisfactory results if the errors are highly correlated." We illustrate this difficulty with a numerical example in §6.

3.3. The L-curve method. Another, more recent, alternative is to base the regularization parameter on the so-called *L-curve* [9]. The L-curve is a parametric plot of $(\rho(\lambda), \eta(\lambda))$, where $\eta(\lambda)$ and $\rho(\lambda)$ measure the size of the regularized solution and the corresponding residual [10]. The underlying idea is that a good method for choosing the regularization parameter for discrete ill-posed problems must incorporate information about the solution size in addition to using information about the residual size. This is indeed quite natural, because we are seeking a fair balance in keeping both of these values small. The L-curve has a distinct L-shaped corner located exactly where the solution x_λ changes in nature from being dominated by regularization errors (i.e., by oversmoothing) to being dominated by the errors in the right-hand side. Hence the corner of the L-curve corresponds to a good balance between minimization of the sizes, and the corresponding regularization parameter λ is a good one.

A feature of the L-curve that has not previously been considered is that the 2-norm is not always the appropriate measure of the size of the solution and residual vectors. The natural way to measure size is induced by the choice of the regularization method. Referring to Table 1, we conclude that the 2-norm is natural for Tikhonov regularization, for example, while the $l_{\underline{1}}$ norm should be used for the truncated SVD, since *that is the norm in which it is optimal.*

The idea of using the corner of the L-curve as a means for computing a good regularization parameter was originally proposed in [9], where it is also demonstrated that under certain assumptions that this criterion is indeed similar to both GCV and the discrepancy principle. Experiments confirm that whenever GCV finds a good regularization parameter, the corresponding solution is located at the corner of the L-curve.

The L-curve method for choosing the regularization parameter has advantages over GCV: computation of the corner is a well-defined numerical problem, and the method is rarely "fooled" by correlated errors. Even highly correlated errors will make the size of the solution grow once the regularization parameter λ becomes too small, thus producing a corner on the L-curve. We make these statements more precise in the next section.

4. Properties of the L-curve.

4.1. The shape of the curve. Many properties of the L-curve for Tikhonov regularization are investigated in [9]. In particular, it is shown that under certain assumptions the L-curve (ρ, η) for Tikhonov regularization has two characteristic parts, namely, a "flat" part where the regularized solution x_λ is dominated by regularization errors and an almost "vertical" part where x_λ is dominated by the errors. The three assumptions made in [9] are:

1. The discrete Picard condition is satisfied, i.e., the coefficients $|\alpha_i|$ on average decay to zero faster than the singular values σ_i.
2. The errors in the right-hand side are essentially "white noise."
3. The signal-to-noise ratio is reasonably large.

It was also shown in [9], under assumptions 1–3, that for any method whose filter factors behave quantitatively like those for Tikhonov regularization, its 2-norm L-curve (discrete or continuous) will be close to that of Tikhonov regularization.

It is, however, possible to show that the L-curve will *always* have an L-shaped appearance. Assume that the right-hand side has a component in each singular direction. (If not, reduce the problem dimension by dropping the corresponding component in the SVD.) The only other assumption we need to make is that the desired solution vector is bounded in size by some number $\bar{M}$ that is less than the size of the least squares solution (5). Such an assumption is realistic in all practical problems; perhaps all we know is that $\bar{M}$ is less than 10^{10}, but that is all we assume for now.

Consider first the L-curve (ρ^2, η^2) for Tikhonov regularization. We know that

$$\eta^2(\lambda) = \|x(\lambda)\|_2^2 = \sum_{i=1}^{n} \frac{\sigma_i^2 \alpha_i^2}{(\lambda^2 + \sigma_i^2)^2}$$

and

$$\rho^2(\lambda) = \|r(\lambda)\|_2^2 = \sum_{i=1}^{n} \frac{\lambda^4 \alpha_i^2}{(\lambda^2 + \sigma_i^2)^2} + \|r_\perp\|_2^2.$$

Thus

$$\frac{d(\eta^2(\lambda))}{d\lambda} = -4\lambda \sum_{i=1}^{n} \frac{\sigma_i^2 \alpha_i^2}{(\lambda^2 + \sigma_i^2)^3}, \qquad \frac{d(\rho^2(\lambda))}{d\lambda} = 4\lambda^3 \sum_{i=1}^{n} \frac{\sigma_i^2 \alpha_i^2}{(\lambda^2 + \sigma_i^2)^3}.$$

Therefore $d(\eta^2)/d(\rho^2) = -\lambda^{-2}$. Evaluation of the second derivative shows that the L-curve is convex and becomes steeper as the parameter λ approaches the smallest singular value.

The truncated SVD solutions yield a piecewise linear L-curve (ρ, η) using the l_1 norm measure of size. On the ith segment, the size of the residual changes by $|\alpha_i|$, while the size of the solution changes by $-|\alpha_i|/\sigma_i$. Thus the slope of the ith segment is $-1/\sigma_i$, and the curve becomes steeper as the size of the residual decreases.

It is easy to show that the l_∞ method has a similar property: the slope of each segment is again $-1/\sigma_i$ for some value of i.

Thus we have shown that for Tikhonov regularization, truncated SVD, and the l_∞ method, the L-curves become vertical as the size of the residual approaches its lower limit. Note that the slopes in each of these three cases are determined by K alone, independent of the right-hand side.

In forthcoming work with G. W. Stewart it is shown that the L-curve for LSQR has similar behavior if the right-hand-side coefficients decay sufficiently rapidly. The behavior of the curve for the maximum entropy criterion is a topic for future research.

Thus the L-curve basically consists of a vertical part for values of $\eta(\lambda)$ near the maximum value and an adjacent part with smaller slope. The more horizontal part corresponds to solutions where the regularization parameter is too large and the solution is dominated by regularization errors. The vertical part corresponds to solutions where the regularization parameter is too small and the solution is dominated by right-hand-side errors magnified by the division by small singular values. This behavior does not rely on any additional properties of the problem, e.g., statistical distribution of the errors, the discrete Picard condition, etc.

The idea of the L-curve criterion for choosing the regularization parameter is to choose a point on this curve that is at the "corner" of the vertical piece. Having an upper bound $\bar{M}$ on the size of x prevents us from being fooled by any other corners that the L-curve may have; in the absence of other information, we seek the leftmost corner consistent with the bound $\bar{M}$. The following are two ways of viewing the problem of corner location.

1. We could seek the point on the curve closest to the origin. The definition of "closest" can vary from method to method. For example, Tikhonov regularization measures distance as $\rho + \lambda^2\eta$.

2. We could choose the point on the L-curve where the curvature is maximum. The curvature is a purely geometrical quantity that is independent of transformations of the regularization parameter. We discuss implementation of this idea in §5.

The rationale behind using the corner to find a regularization parameter λ is that the corner corresponds to a solution in which there is a fair balance between the regularization and perturbation errors—because the corner separates the horizontal part of the curve from the more vertical part. This choice of λ may lead to a slightly underregularized solution because the influence of the perturbation errors must become apparent before the corner appears.

We stress numerically reliable methods but emphasize the fact that the L-curve picture gives a check on any method for locating the corner, as well as further insight into problem behavior, and that the user should not fail to look at it. There is good reason to use a set of routines that provide reliable numerical methods as well as good graphics, such as the Matlab-based code of Hansen [8].

4.2. Distinguishing signal from noise. In our experiments we have found that in many cases it is advantageous to consider the L-curve (ρ, η) in a log-log scale. There is strong intuitive justification for this. Since the singular values typically span several orders of magnitude, the behavior of the L-curve is more easily seen in such a log-log scale. In addition, the log-log scale emphasizes "flat" parts of the L-curve where the variation in either ρ or η is small compared to the variation in the other variable. These parts of the L-curve are often "squeezed" close to the axes in a lin-lin scale. Hence the log-log scale actually emphasizes the corner of the L-curve. One more advantage of the log-log scale is that particular scalings of the right-hand side and the solution simply shift the L-curve horizontally and vertically. Thus we do all of our computations related to curvature on $(\log\rho, \log\eta)$.

The log-log transformation has a theoretical justification as well. Consider the (ρ, η) curve for the truncated SVD algorithm. Recall that the ρ is the $l_{\underline{1}}$ norm of the residual, while η is the $l_{\underline{1}}$ norm of the solution vector, and the curve consists of the points produced by the truncated SVD algorithm for various numbers of retained singular values, $1 \leq k \leq n$. Using (5) we see that as k is increased by 1, the change in ρ is $|\alpha_k|$, while the change in η is $|\alpha_k/\sigma_k|$. Thus the slope of the kth segment of the piecewise linear interpolant is $1/\sigma_k$, independent of the right-hand side for the problem. Therefore, there is no hope of distinguishing signal from noise by examining properties of the L-curve in the lin-lin scale.

In a log-log scale, however, the slope of the kth segment is the *relative* change in η divided by the *relative* change in ρ, and these behave quite differently for signal and noise. A noiseless signal for which the discrete Picard condition is satisfied has the property that the sequences $|\alpha_k|$ and $|\alpha_k/\sigma_k|$ both approach zero. Thus the relative change in η approaches zero, while the relative change in ρ is finite and nonzero. Therefore, for a signal, the L-curve in log-log coordinates becomes flat as k is increased.

Pure noise gives a quite different L-curve in log-log scale. If we assume that the error components $|\alpha_k|$ are roughly a constant value ϵ, then $\eta_k \approx \epsilon/\sigma_k$ and the relative change in η_k is approximately σ_{k-1}/σ_k. The relative change in ρ_k is $1/(m-k)$, so the slope of the piecewise linear interpolant is $(m-k)\sigma_{k-1}/\sigma_k$. The L-curve for noise in log-log scale therefore has a steep slope as k increases, unlike the flat curve of the signal.

The same conclusion holds for the l_∞ regularization method. Suppose we increase the norm of x from γ to $\hat{\gamma}$. Then the norm of the residual changes from $\max_i |\beta_i| - |\gamma\sigma_i|$ to $\max_i |\beta_i| - |\hat{\gamma}\sigma_i|$. The slope of the L-curve in lin-lin coordinates is not strongly dependent on the right-hand-side coefficients β_i. The picture is different in log-log coordinates, though. The relative change in the norm of x is $(\hat{\gamma}-\gamma)/\gamma$, and the relative change in the norm of r is $(\hat{\gamma}-\gamma)\sigma_i/(|\beta_i| - |\gamma\sigma_i|)$ for some value of i. For pure signal, as γ increases, the value of i will be small: since $\alpha_i/\sigma_i \rightarrow 0$ by the discrete Picard condition, the components corresponding to small singular values are not changed by further increase in the norm of x. Thus the L-curve will have moderate slope. For pure noise, $i = n$, and the L-curve will be quite steep as γ increases.

The L-curves for pure signal and pure noise in Tikhonov regularization have similar characters: both curves are steep in lin-lin scale as $\lambda \rightarrow 0$, but only the noise curve is steep in log-log scale. This can be shown either by appealing to the closeness of the truncated SVD and the Tikhonov solutions and residuals when both are measured in the 2-norm, or by rather tedious computations with the 2-norm.

5. Numerical issues in locating the corner of the L-curve. Although the L-curve is easily defined and quite satisfying intuitively, computing the point of maximum curvature in a numerically reliable way is not as easy as it might seem. Below, we discuss three cases of increasing difficulty. Throughout this section we use the notation $(\hat{\rho}, \hat{\eta})$ for the chosen measures of the size of the residual vector and the size of the solution vector. In practical computation these would probably be taken to be the *log*s of the $\underline{1}$, 2, or p norms of these vectors, or some weighted versions of these norms.

5.1. The ideal situation: The L-curve defined by a smooth, computable formula. If the functions $\hat{\rho}$ and $\hat{\eta}$ are defined by some computable formulas, and if the L-curve is twice continuously differentiable, then it is straightforward to compute the curvature $\kappa(\lambda)$ of the L-curve by means of the formula

$$\kappa(\lambda) = \frac{\hat{\rho}'\hat{\eta}'' - \hat{\rho}''\hat{\eta}'}{((\hat{\rho}')^2 + (\hat{\eta}')^2)^{3/2}}. \tag{8}$$

Here, $'$ denotes differentiation with respect to the regularization parameter λ. Any one-dimensional optimization routine can be used to locate the value of λ that corresponds to maximum curvature.

This situation arises when using Tikhonov regularization on a problem for which the singular values of the matrix K are known. It is practical computationally, since the effort involved in such a minimization is much smaller than that for computing the SVD.

5.2. Lacking a smooth, computable function defining the L-curve. In many situations we are limited to knowing only a finite set of points on the L-curve. This is the case, for example, for the truncated SVD and LSQR algorithms, and in these and other cases the underlying curve is not differentiable. Thus the curvature (8) cannot be computed and in fact may fail to exist. The same may be the case for problems where the regularized solution results from some black box routine.

In a computational sense, the L-curve then consists of a number of discrete points corresponding to different values of the regularization parameter at which we have evaluated $\hat{\rho}$ and $\hat{\eta}$. In many cases, these points are clustered, giving the L-curve fine-grained details that are not relevant for our considerations. For example, if there is a cluster of small singular values σ_{i_1} through σ_{i_2} with right-hand-side coefficients even smaller, then the L-curve for the truncated SVD will have a cluster of points for values of k from i_1 to i_2. This situation does not occur for Tikhonov regularization because all the components in the solution come in gradually as the filter factors change from zero to one.

We must define a differentiable, smooth curve associated with the discrete points in such a way that fine-grained details are discarded while the overall shape of the L-curve is maintained; i.e., we want the approximating curve to achieve local averaging while retaining the overall shape of the curve. A reasonable approach is therefore to base the approximating smoothing curve on cubic splines. If we fit a pair of cubic splines to $\hat{\rho}(\lambda)$ and $\hat{\eta}(\lambda)$, or if we fit a cubic spline to $\hat{\eta}(\hat{\rho})$, then we have difficulty with approximating the corner well because dense knots are required here. This conflicts with the purpose of the fit, namely, to locate the corner.

Instead, we propose fitting a *cubic spline curve* to the discrete points of the L-curve. Such a curve has several favorable features in connection with our problem: it is twice differentiable, it can be differentiated in a numerically stable way, and it has local shape-preserving features [3]. Yet we must be careful not to approximate the fine-grained details of clusters of points too well. Since a cubic spline curve does not intrinsically have the desired local smoothing property, we propose the following two-step algorithm for computing a cubic spline-curve approximation to a discrete L-curve.

ALGORITHM FITCURVE
1. Perform a local smoothing of the L-curve points, in which each point is replaced by a new point obtained by fitting a low-degree polynomial to a few neighboring points.
2. Use the new smoothed points as control points for a cubic spline curve with knots $1, \ldots, N+4$, where N is the number of L-curve points.

Step 1 essentially controls the level of fine-grained details that are ignored. We have good experience with fitting a straight line in the least squares sense to five points centered at the point to be smoothed (a 1-norm fit may also work well, but is more difficult to compute). We illustrate the use of this algorithm in §6 .

In connection with using this algorithm as a stopping criterion for LSQR or any other iterative method, we stress that it is our belief that any sophisticated stopping rule for regularizing iterative methods (GCV, locating the point closest to the origin, finding the point of maximum curvature, etc.) must go a few iterations too far in order to determine the corner of the L-curve.

5.3. Limiting the number of L-curve points. In many cases, evaluating points on the L-curve is computationally very demanding and one would prefer to compute as few points as possible. For such problems, with differentiable as well as nondifferentiable L-curves, we need an algorithm that tries to locate the corner of the L-curve efficiently.

Assume that one knows a few points on each side of the corner. Then the ideas from the previous section can be used to derive an algorithm that seeks to compute a sequence of new regularized solutions whose associated points on the L-curve (hopefully) approach its corner. The algorithm is as follows.

```
ALGORITHM FINDCORNER
1. Start with a few points $(\hat{\rho}_i, \hat{\eta}_i)$ on each side of the corner.
2. Use the ideas in Algorithm FITCURVE to find an approximating three-
   dimensional cubic spline curve $S$ for the points $(\hat{\rho}_i, \hat{\eta}_i, \lambda_i)$, where $\lambda_i$ is the reg-
   ularization parameter that corresponds to $(\hat{\rho}_i, \hat{\eta}_i)$.
3. Let $S_2$ denote the first two coordinates of $S$, such that $S_2$ approximates the L-
   curve.
4. Compute the point on $S_2$ with maximum curvature, and find the corresponding
   $\lambda_0$ from the third coordinate of $S$.
5. Solve the regularization problem for $\lambda_0$ and add the new point $(\hat{\rho}(\lambda_0), \hat{\eta}(\lambda_0))$ to
   the L-curve.
6. Repeat from Step 2 until convergence.
```

In step 2, it is necessary to introduce λ_i as a third coordinate of S because we need to associate a regularization parameter with every point on S_2. A two-dimensional spline curve with λ_i as knots does not provide this feature. We stress again that it is not suitable to fit individual splines to $\hat{\rho}_i$ and $\hat{\eta}_i$.

Initial points for step 1 can be generated by choosing very "large" and very "small" regularization parameters, for example, λ equal to σ_1, $\frac{1}{10}\sigma_1$, $10\sigma_n$, and σ_n. Since these initial points may be far from the corner, we found it convenient to introduce an artificial temporary point $(\min_i(\hat{\rho}_i), \min_i(\hat{\eta}_i))$ between the points corresponding to "large" and "small" λ. This temporary point is *replaced* by the first L-curve point $(\hat{\rho}(\lambda_0), \hat{\eta}(\lambda_0))$ computed in the first iteration.

6. Numerical examples. In this section we illustrate the theory from the previous sections with numerical examples. We consider a first-kind Fredholm integral equation which is a one-dimensional model problem in image reconstruction from [14]. In this model, the unknown function x is the original signal, the kernel function $k(s,t)$ is the point spread function of an infinitely long slit, and the right-hand side y is the measured signal: i.e., y consists of the original signal x integrated with $k(s,t)$ plus additional noise e. The kernel is given by

$$(9)\quad k(s,t) = (\cos s + \cos t)\left(\frac{\sin u}{u}\right)^2, \quad u = \pi(\sin s + \sin t), \quad s,t \in \left[-\frac{\pi}{2}, \frac{\pi}{2}\right].$$

Discretization is performed by means of simple collocation with delta functions as basis functions. Hence the vectors x and y are simply samples of the underlying functions. Throughout, the order of the matrix K is $m = n = 64$.

We consider two different right-hand sides, both generated by multiplying the matrix K times the corresponding true solution vector x. The first right-hand side, y_1, satisfies the discrete Picard condition; i.e., the Fourier coefficients $\alpha_i = u_i^T y_1$ decay to zero faster than the singular values σ_i, so the solution coefficients α_i/σ_i also decay to zero. This right-hand side y_1 corresponds to a solution x_1 with two "humps" given by

$$(10)\qquad x_1(t) = 2\,\exp(-6\,(t-0.8)^2) + \exp(-2\,(t+0.5)^2).$$

The second right-hand side y_2 only marginally satisfies the discrete Picard condition: the right-hand-side coefficients are artificially generated so that all the solution coefficients are of approximately the same size. This problem is harder to solve numerically than the first one. The norms of the two right-hand sides are $\|y_1\|_2 = 18.6$ and $\|y_2\|_2 = 19.3$.

To each of these right-hand sides we add perturbation error consisting of normally distributed numbers with zero mean and standard deviation 10^{-2} so that $\|e\|_2 \approx 8\cdot 10^{-2}$.

The L-curves associated with truncated SVD, Tikhonov regularization, and the ℓ_∞ methods (see §2) are shown in Fig. 1. In lin-lin scale the truncated SVD and ℓ_∞ curves are piecewise linear, but these segments appear curved in the log-log scale. For both model problems and all three methods, the L-shaped appearance of the curves is very distinct. In particular, we notice the flat parts of the curves, corresponding to domination by the regularization error, and the vertical parts, corresponding to domination by perturbation errors. We also notice that even though the discrete Picard condition is barely satisfied for the second right-hand side y_2, the corresponding L-curves still have a distinct flat part.

The rounded corner on the L-curve for truncated SVD shows the need for a rigorous definition of the "corner" of the L-curve—but in fact the other L-curves also have a rounded "corner" on a finer scale.

For the first model problem and for Tikhonov regularization, let us now consider the two types of errors in the regularized solution $x(\lambda)$. To this end, let $\hat{x}(\lambda)$ denote the part of $x(\lambda)$ solely from the unperturbed part of the right-hand side, such that $x(\lambda) - \hat{x}(\lambda)$ is the perturbation component of $x(\lambda)$. We want to compare the regularization error $\|x_1 - \hat{x}(\lambda)\|_2$ with the perturbation error $\|\hat{x}(\lambda) - x(\lambda)\|_2$. This is done in the left part of Fig. 2. Obviously, the regularization error increases with λ while the perturbation error decreases. The regularization parameter λ for which the two error types are identical can be characterized as the optimal λ.

The two vertical lines in Fig. 2 represent the regularization parameters chosen by means of the L-curve criterion (dashed-dotted line) and GCV (dotted line). The right part of the figure shows the corresponding GCV function and its minimum. Two typical situations are shown. In the upper part both GCV and the L-curve criterion yield approximately the same regularization parameter. In the bottom part of the figure the GCV function is quite flat, and the regularization parameter is a factor 10 too small. Thus Fig. 2 illustrates the major difficulty with the GCV method, namely, that the minimum is not always so well-defined.

(b)

FIG. 1. *The L-curves for model problems* (a) *one and* (b) *two for the the* ℓ_∞ *method* (*dashed line*), *Tikhonov regularization* (*solid line*), *and truncated SVD* (*dotted line*).

Let us now consider the robustness of the two competing methods in more detail. To do this, we compute the relative error in the regularized solution for both model problems:

$$\frac{\|x_i - x_\lambda\|_2}{\|x_i\|_2}, \qquad i = 1, 2,$$

computing the regularization parameter λ by both the L-curve criterion and by GCV. We used a broad range of error levels: $\|e\|_2/\|y\|_2 = 10^{-j}$, $j = 1, 2, \ldots, 8$, and for each error level we generated 25 error vectors. Thus for each model problem we solved 200 regularization problems. The results are shown in Figs. 3 and 4 as histograms with a logarithmic abscissa axis. The L-curve criterion rarely fails to compute a satisfactory

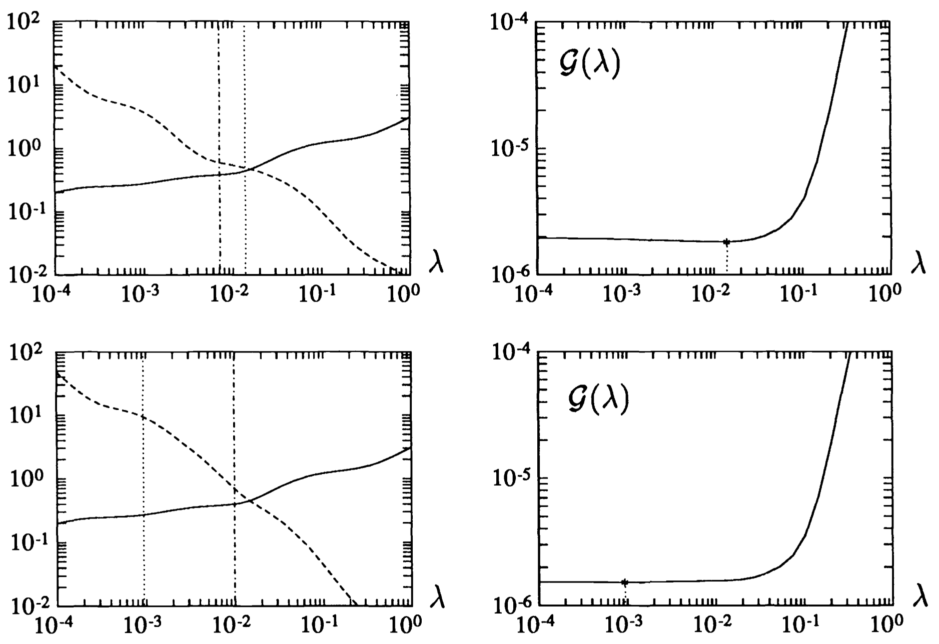

FIG. 2. *The left part shows the regularization error (solid line) and the perturbation error (dashed line) for model problem one, Tikhonov regularization, and two different random perturbations. The vertical lines represent the regularization parameters computed by means of the L-curve criterion (dashed-dotted line) and the GCV method (dotted line). The right part shows the corresponding GCV functions and their minima.*

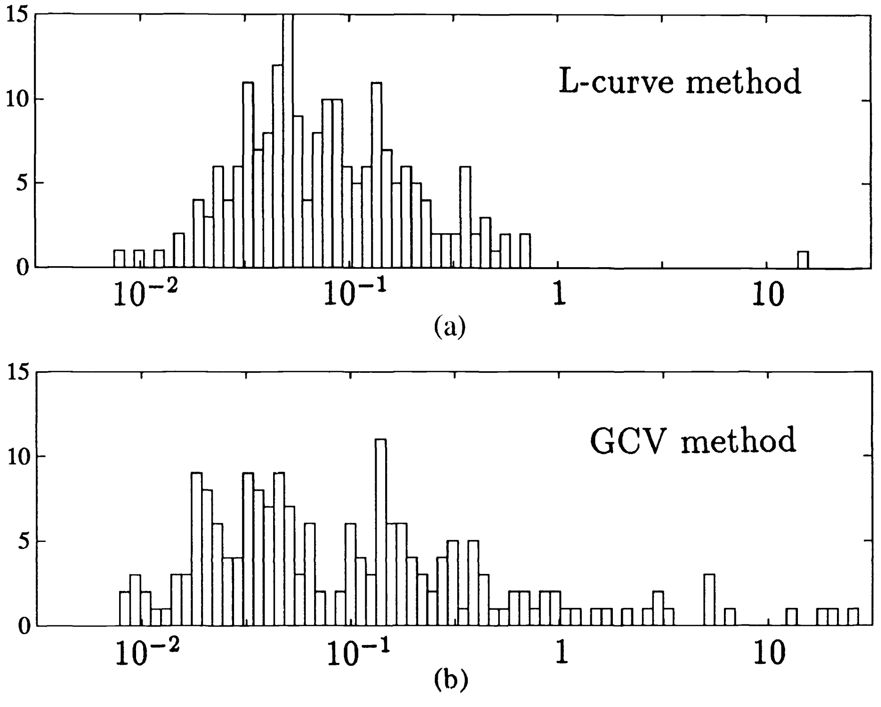

FIG. 3. *Histograms of 200 relative errors $\|x_1 - x(\lambda)\|_2/\|x_1\|_2$ for model problem one, Tikhonov regularization, and λ chosen by means of (a) the L-curve criterion and (b) the GCV. The error level $\|e\|_2/\|y\|_2$ varies between 10^{-9} and 10^{-1}.*

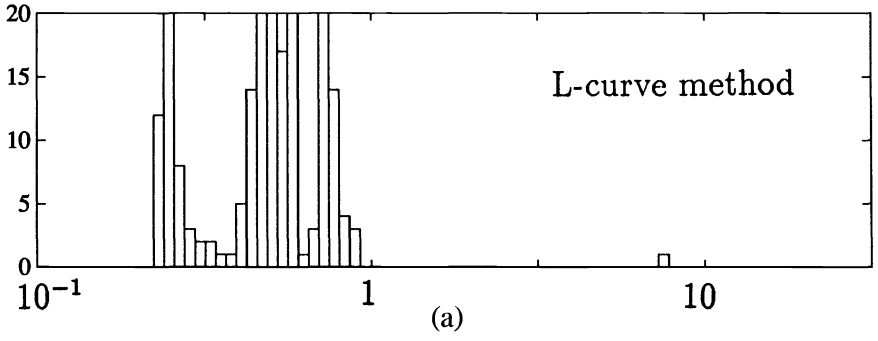
regularization parameter, while the GCV method fails quite often, due to the difficulties mentioned above. It is no surprise that the relative errors are typically smaller for the first model problem, because the satisfaction of the discrete Picard condition makes this problem somewhat easier to solve numerically than the second model problem.



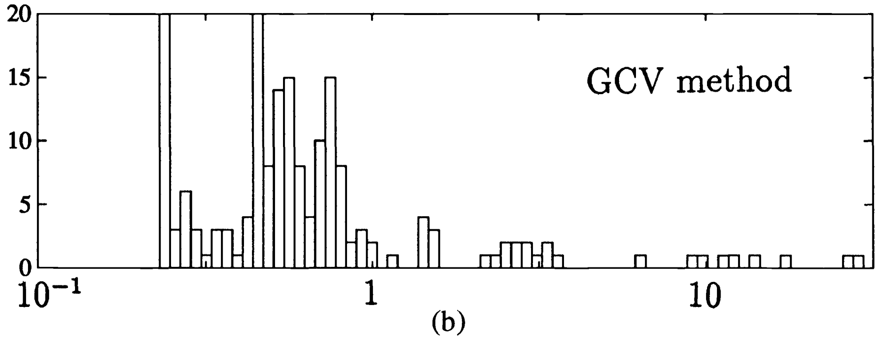


FIG. 4. *Histograms of* 200 *relative errors* $\|x_2 - x_\lambda\|_2/\|x_2\|_2$ *for model problem two, Tikhonov regularization, and* λ *chosen by means of* (a) *the L-curve criterion and* (b) *the* GCV. *The error level* $\|e\|_2/\|y\|_2$ *varies between* 10^{-9} *and* 10^{-1}.

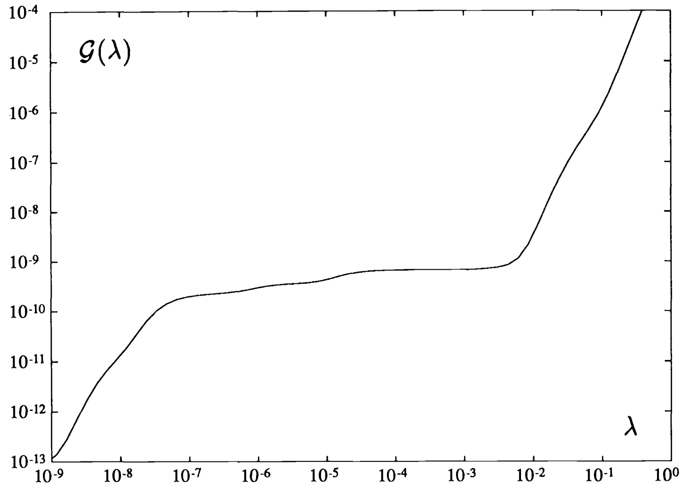
Finally, let us consider problems with highly correlated errors. For this purpose we use the first problem, but now the perturbation e is generated as follows. Once the matrix K and the right-hand-side y_1 have been computed, we smooth their elements k_{ij} and $y_{1,i}$ by the following scheme:

$$\tilde{y}_{1,i} = y_{1,i} + \mu\,(y_{1,i-1} + y_{1,i+1}), \qquad i = 2, \ldots, n-1,$$

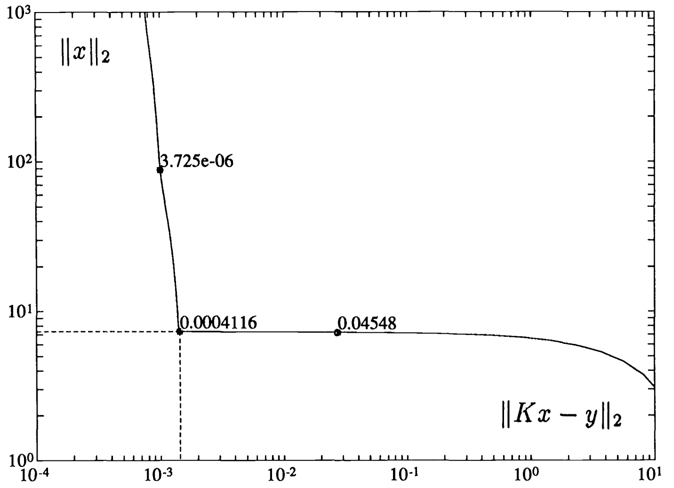
$$\tilde{k}_{ij} = k_{ij} + \mu\,(k_{i-1,j} + k_{i+1,j} + k_{i,j-1} + k_{i,j+1}), \qquad i,j = 2, \ldots, n-1.$$

Hence the right-hand-side errors are $e_i = \tilde{y}_{1,i} - y_{1,i}$, and similarly for the matrix. The parameter μ controls the amount of smoothing. These errors may, for example, represent sampling errors or the approximation errors involved in computing K and y by means of a Galerkin-type method where some "local" integration is performed. The noise is not "white" as in the first two model problems; rather, e has larger components along the singular vectors corresponding to the larger singular values.

We carried out several experiments with this third model problem for various values of μ. For all these experiments, the GCV method completely failed to compute a reasonable regularization parameter. Fig. 5 shows a typical GCV function for these experiments, for the particular choice $\mu = 0.05$. The GCV function is monotonically



(a)



(b)

FIG. 5. (a) *shows the* GCV *function for a problem with correlated errors. The* GCV *function has no minimum for any reasonable value of* λ. (b) *shows the L-curve for Tikhonov regularization for the same problem as the corner computed by our algorithm. The numbers are the regularization parameters that correspond to the dots on the L-curve.*

increasing. (In fact, there is a minimum for λ of the order of the machine precision, but this is not a useful regularization parameter.)

The L-curve, on the other hand, always has an unmistakable corner. For the same value of $\mu = 0.05$ as above, this corner occurs at $\lambda \approx 3 \cdot 10^{-4}$, and this value of the regularization parameter indeed produces a regularized solution with optimal error. There is, in fact, one more corner for λ of the order of the machine precision outside of the plot. To get the correct corner, we used $\bar{M} = 10^4$ as a huge overestimate of the solution norm. For smaller values of μ the L-curve criterion sometimes leads to an underregularized solution, essentially because, as we mentioned in §4.1, the perturbation errors must become slightly apparent in the solution to produce the corner. Nevertheless, the computed λ is still fairly close to the optimal one.

7. Conclusions. We have shown that a number of regularization methods have naturally associated L-curves defined in terms of norms that are characteristic for the particular method. We have introduced new regularization methods, based on l_p norms in the coordinate system of the singular vectors of the matrix. Moreover, we have shown that, when plotted in a log-log scale, L-curves indeed have a characteristic L-shaped appearance and that the corner corresponds to a good choice of the regularization parameter.

Based on this characterization of the L-curves, we have proposed a new a posteriori scheme for computing the regularization parameter for a given problem. This scheme uses the parameter corresponding to a corner of the L-curve, a point of maximum curvature. We have also extended this idea to discrete L-curves such as those associated with truncated SVD and iterative methods.

Our numerical examples clearly illustrate the usefulness of the L-curve criterion for choosing the regularization parameter. Although the L-curve criterion sometimes fails to compute a reasonable regularization parameter, it seems to be much more robust than its main competitor, generalized cross-validation. Of course, one can always construct problems that will also "fool" the L-curve criterion; but it is our feeling that it works so well in practice that it is indeed a useful method. Further work is needed to determine circumstances under which the regularized solution converges to the true solution as the size of the error converges to zero.
